Figure 3. Emission and absorption spectra of TTTTT*N*X*N*TTTTT. Emission spectra are shown in the left panels and absorption spectra are shown in the right panels. Spectra were measured in 50 mM sodium phosphate buffer (pH = 7.0) containing 100 mM sodium chloride at 25 °C. Black, spectra before hybridization; gray, spectra after hybridization with the corresponding cDNA. Emission spectra were recorded with excitation at 488 nm.

base pairs can be formed within two bases from **X**. When *N* is thymine, four base pairs can be drawn. When *N* is guanine, which showed a lower quenching ability, the probe can also form four base pairs. The probe with N = guanine has tight G/C base pairs on both sides of **X**, and it seems to form a more stable self-dimer than when *N* is thymine. The sequence 5′-d(TTTTTA**X**ATTTTT)-3′ can also form a self-dimer with four base pairs; thus, the slight emission observed before hybridization with the target DNA may also be explained by self-dimerization.

We prepared 30 different sequences with **X**, and measured their Φ_{ds}/Φ_{ss}. We also calculated the number of possible Watson−Crick base pairs formed within two bases from **X** (N_{bp}). These data are summarized in Figure 5, which shows the relationship between Φ_{ds}/Φ_{ss} and N_{bp}. Smaller N_{bp} produced larger Φ_{ds}/Φ_{ss}, i.e., a higher efficiency of fluorescence quenching was observed. In addition, the probes with a purine-rich sequence (sequences #8 and #13) and with a sequence that can form G/C base pairs at both sides of **X** in the formation of a self-dimer (sequences #23 and #29) exhibited low Φ_{ds}/Φ_{ss} values. The "self-dimer" formed by the probe must be thermodynamically unstable because it contains many mismatched base pairs. However, this plausible self-dimeric structure may inhibit fluorescence quenching because the formation of "primer dimer" in PCR assays is known to significantly decrease amplification efficiency. The probe #29 (5′-d(AGATCC**X**GACAGA)-3′) showed a gradual sigmoid curve in the "melting temperature" measurement without the complementary strand (λ = 260 nm, T_m = 50 °C), suggesting that the self-dimeric structure exists under the condition of fluorescence measurement. When an ordered duplex structure can be maintained around **X** of the self-dimer by Watson−Crick base pairs, the neighboring base pairs would work as the binding sites of dyes.

Mismatched Base Pairs. We next examined how much mismatched base pairs affected fluorescence emission. In this experiment, we used the hybrids with the cDNA containing one or two mismatched base pairs at and around **X**. When the base opposite **X** in 5′-d(CGCAAT**X**TAACGC)-3′ was changed to a mismatched base (i.e., 5′-d(GCGTTA*N*ATTGCG)-3′ (N = C, G, or T) as the strand to be hybridized), the quantum yields of mismatched hybrids decreased to 60−85% of that of the full-matched hybrid (Table 3). On the other hand, when both or either of the base pairs neighboring **X** of 5′-d(CGCAAT**X**-TAACGC)-3′ were mismatched (i.e., 5′-d(GCGTT*NAN*′TTGCG)-3′ as the strand to be hybridized), the unique fluorescence behavior was observed. The ratio of quantum yields of T/C mismatched hybrids to the fully matched hybrid ($\Phi_{mismatch}/\Phi_{match}$) was smaller than those observed for the mismatched base pairs at **X**. The mismatched base pair formation around **X** contributes more to the decrease in fluorescence intensity rather than the mismatched base pair at **X** because the sequence neighboring **X** works as the binding site of dyes of **X**. The CD spectra of a matched duplex 5′-d(CGCAAT**X**TAACGC)-3′/5′-d(GCGTTAAATTGCG)-3′ showed a broad negative signal and a sharp positive signal at 450−550 nm, suggesting that the dyes of **X** bind to the sequence neighboring **X** through intercalation and/or binding to the major groove (*11*). The mismatched base pair formation would lower the binding affinity of dyes to DNA and induce dissociation of dyes from the DNA structure and the formation of a nonemissive bichromophoric aggregate. The decrease in fluorescence emission by mismatched base pair formation around **X** paradoxically supports the assumption that the formation of matched base pairs around **X** in the self-dimeric mode results in low fluorescence quenching. The hybrid with the strand of $N = N'$ = T also showed a lower $\Phi_{mismatch}/\Phi_{match}$ value (0.45). On the other hand, a high $\Phi_{mismatch}/\Phi_{match}$ value was observed for the hybrid with the strand of $N = N'$ = G (0.88). This is probably because T/G wobble mismatched base pairs are relatively stable and can maintain the duplex structure (*16*−*18*); thus, they do not prevent the dyes of **X** from binding to DNA.

Label on Strand End. Hybridization with the target enhanced the fluorescence intensity even when **X** was put on the end of the probe strand. We prepared the probe 5′-d(**X**TAACGC-CAAGTG)-3′ and hybridized it with 5′-d(CACTTGGCGT-TA*N*ATTGCGGTTCAC)-3′. The fluorescence intensity was enhanced by hybridization (N = A) (Table 4). However, the fluorescence quantum yield of the hybrid was lower than that of the hybrid 5′-d(CGCAAT**X**TAACGC)-3′/5′-d(GCGTTAAAT-

TGCG)-3′. The duplex structure neighboring **X** plays an important role for fluorescence emission, and the lack of duplex structure at one side of **X**, i.e., reduction in the dye-bindable region, resulted in a decrease in the fluorescence intensity of the hybrid. When *N* was C, G, or T, the fluorescence intensity of the hybrid became approximately half of that of the hybrid with *N* = A. The decrement in the fluorescence intensity by mismatched base pair formation at **X** was larger than was the case when **X** was put on the inside of the sequence. This is probably because the structural flexibility for **X** located at the end of the probe loosened the binding of dyes to the DNA structure.

Points for Probe Design. The fluorescence behavior described above facilitates the design of probes for effective DNA detection. The keys for probe design are as follows: (i) Avoid sequences that form self-dimers to induce effective quenching of the single-stranded probe. In particular, the self-dimer capable of the formation of a G/C base pair neighboring **X** should be avoided. (ii) Mismatched base pairs of the hybrid are acceptable. However, the mismatched base pair neighboring **X** is unfavorable because the **X**-neighboring region is a dye-binding site and the mismatched base pair decreases dye-binding affinity and fluorescence intensity of the dye. (iii) The probe with **X** at a strand end may be used for detection of the difference of one base such as single nucleotide polymorphism. However, the fluorescence change is limited to approximately 50%, and the target is also confined to the sequence concerned with adenine.

The most important key is (i). Unless one takes care of this issue, the activity of a probe as a hybridization-sensitive DNA detector may be lost. A typical example is the design of a probe for detection of the 50-mer DNA strand 5′-d(ACTTGAGCGGTCCTTCGAAAGGCGAAGACCAATGAT-CAATTATGGACCTA)-3′. When we require a probe binding to a 5′-d(GGCGAAGACCAATGATCAAT)-3′ region of the 50-mer DNA strand, we can design several probes that contain **X** at different sites, such as 5′-d(ATTGATCATTGGTCT**X**CGCC)-

[a] 0.4 μM DNA, 50 mM sodium phosphate buffer (pH = 7.0), 100 mM sodium chloride. [b] Excited at 488 nm. [c] Excited at λ_{max} (longer wavelength when there are two λ_{max}). [d] The ratio of the quantum yields of mismatched and matched duplexes.

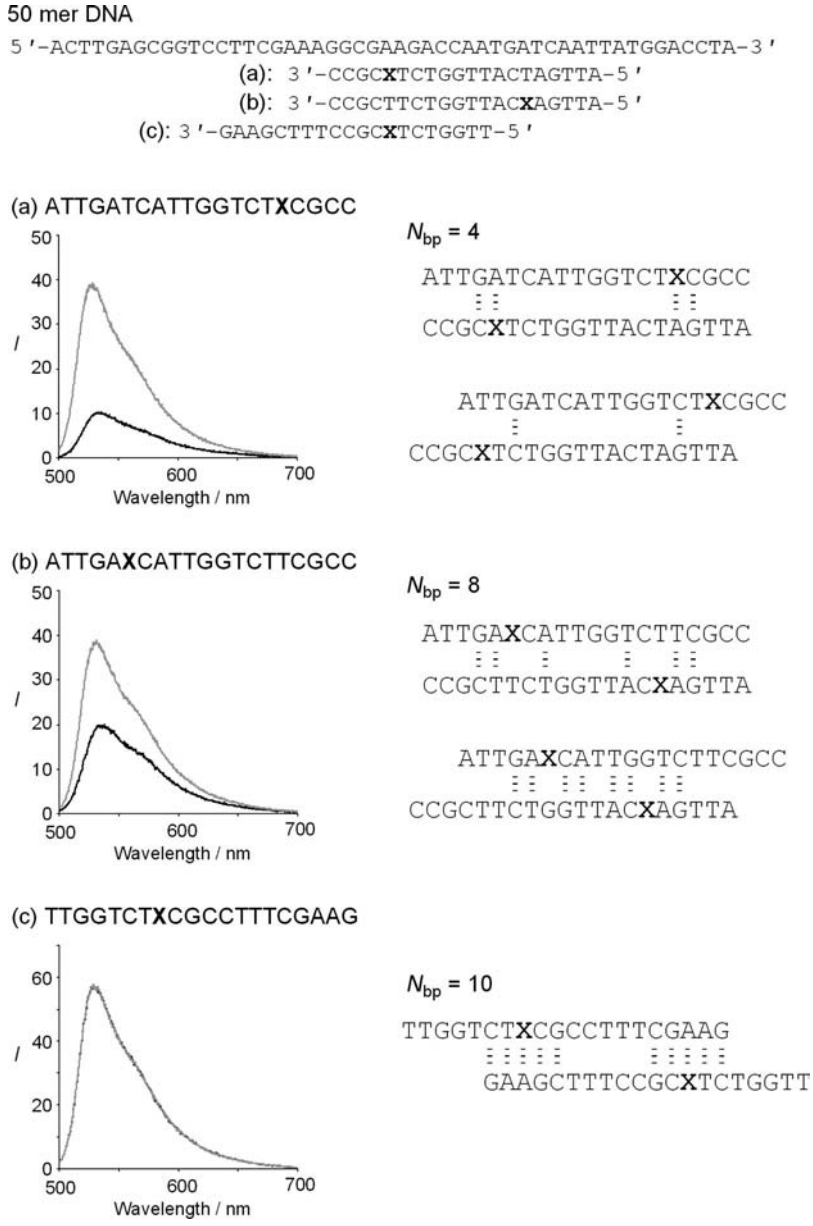

Figure 6. Probe design. Emission spectra of three designed probes were measured in 50 mM sodium phosphate buffer (pH = 7.0) containing 100 mM sodium chloride at 25 °C. Black, spectra before hybridization; gray, spectra after hybridization with the corresponding cDNA. Emission spectra were recorded with excitation at 488 nm. The two spectra in (c) almost exactly overlap each other. Watson−Crick base pairs formed within two bases from **X** are drawn by hashed lines.

3′ and 5′-d(ATTGA**X**CATTGGTCTTCGCC)-3′. The strand 5′-d(ATTGATCATTGGTCT**X**CGCC)-3′ exhibited relatively high Φ_{ds}/Φ_{ss} (Figure 6a), whereas the Φ_{ds}/Φ_{ss} value of the probe 5′-d(ATTGA**X**CATTGGTCTTCGCC)-3′ was lower (Figure 6b) because of the high fluorescence intensity of the single-stranded state. The N_{bp} values showing the possibility of self-dimer formation were 4 for the former probe and 8 for the latter probe. Therefore, N_{bp} values can inform us in advance that the former probe is a favorable sequence to be synthesized. The probe design is also similar when the site recognized by **X** is fixed and the hybridization region is selectable flexibly. For example, strands 5′-d(ATTGATCATTGGTCT**X**CGCC)-3′ and 5′-d(TTGGTCT**X**CGCCTTTCGAAG)-3′ have an **X** recognizing the same adenine base in the target DNA, and they were hybridized

with different regions of the 50-mer DNA strand. The former probe showed a high Φ_{ds}/Φ_{ss} value as describe above, whereas the fluorescence intensity observed for the latter probe before hybridization was almost the same as that of the hybrid with the target strand (Figure 6c). The N_{bp} value of the latter probe is 10, suggesting that the probe sequence is hopeless for working as a hybridization probe. Therefore, we must pay attention to the choice of the location of **X** and the recognition sequence to produce probes that are more effective.

In conclusion, the fluorescence emission and quenching of doubly thiazole orange labeled DNA probes are influenced strongly by the probe sequence. A variety of probe sequences including mismatched hybrids and end-labeled probes demonstrated how much the fluorescence emission and quenching of these probes depend on probe sequence and why such a sequence dependence is produced. The photophysical data organized in the present study make it possible to estimate the fluorescence ability of probes before synthesis and help the rational design of hybridization-sensitive probes to detect effectively the target DNA using on−off switching of fluorescence depending on hybridization.

ACKNOWLEDGMENT

We thank Dr. Takehiro Suzuki (Biomolecular Characterization Team, RIKEN) for the MALDI-TOF mass spectrometry.

Utilization of Intrachain 4′-*C*-Azidomethylthymidine for Preparation of Oligodeoxyribonucleotide Conjugates by Click Chemistry in Solution and on a Solid Support

Anu Kiviniemi,* Pasi Virta, and Harri Lönnberg

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received May 29, 2008; Revised Manuscript Received June 24, 2008

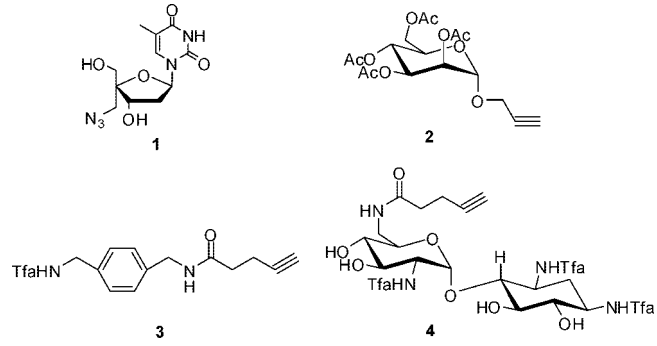
4′-*C*-Azidomethylthymidine 3′-(H-phosphonate) monomer (**10**) was synthesized in high yield and three such monomers were incorporated by the H-phosphonate coupling into a 15-mer oligodeoxyribonucleotide. The unmodified 2′-deoxynucleosides could be coupled by either the H-phosphonate or phosphoramidite chemistry, indicating that the Staudinger reaction between the azido group and the phosphoramidite reagent severely hampered the coupling only when it took place intramolecularly. After chain assembly, three alkynyl group bearing ligands, viz., propargyl 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (**2**), *N*-{4-[*N*-(trifluoroacetyl)aminomethyl]benzyl}-4-pentynamide (**3**) and N^1,N^3,$N^{2'}$-tris(trifluoroacetyl)-$N^{6'}$-(4-pentynoyl)neamine (**4**), were conjugated to the azido groups of the oligonucleotide by click chemistry both on a solid support and in solution. The products were deprotected by conventional ammonolysis and purified by HPLC chromatography. Melting temperature studies revealed that the mannose conjugated oligonucleotides formed more stable duplexes with 2′-*O*-methyl RNA than with DNA strand. With 2′-*O*-methyl RNA, a slight destabilization compared to an unmodified sequence was observed at low ionic strength, while at high salt content, the manno-conjugation was stabilizing.

INTRODUCTION

Selective inhibition of gene expression by oligonucleotides, either by single stranded antisense oligonucleotides (*1*−*4*) or by double stranded siRNAs (*5*−*7*), has become a routine technique for mechanistic studies of gene expression. Both approaches also show promise as a novel form of chemotherapy, but several thresholds must still be overcome on the way to oligonucleotide drugs (*8*−*13*). Among the existing problems, inefficient cellular uptake appears to be the most severe one. A possible way to enhance the cell penetration and to provide the oligonucleotide with cell-type or organ selectivity is to conjugate the oligonucleotide with an agent known to be actively transported into the cell (*14, 15*). Cell-penetrating peptides have been extensively used for this purpose, but the results have been somewhat disappointing (*16, 17*). These conjugates tend to remain trapped in endosomes, without any marked increase of concentration in cytoplasm or nucleus, as far as delivery of polyanionic phosphodiester-like antisense oligonucleotides is concerned. Conjugation with cholesterol (*18*) or aptamers (*19*) has, in turn, clearly increased the efficiency of siRNA-induced gene-silencing *in vivo*. Among glycoconjugates, conjugation with galactose has been shown to direct the delivery of oligonucleotides to hepatocytes, probably by recognition of a membrane bound lectin, the asialoglycoprotein receptor (*20, 21*), and lactosylated PEG-siRNA conjugates have been reported to exhibit enhanced gene silencing in hepatoma cells (*22*). High affinity binding to lectins depends on several simultaneous interactions of monomeric sugar units with the protein, a phenomenon known as a glyco-cluster effect (*23*−*25*).

A possible way to target an antisense oligonucleotide to a membrane-anchored lectin is to use a complementary sugar decorated oligonucleotide as a carrier. This carrier oligonucleotide is aimed at serving as a scaffold to which the lecting-binding sugar ligands are tethered at appropriate distances. Since the carrier is simultaneously able to hybridize with the actual antisense oligomer, the latter becomes enriched at the cell surface and, hence, internalizated by receptor-mediated endocytosis. Accordingly, the site of attachment of the sugar ligands to the carrier should be such that the duplex formation is not severely retarded.

Chart 1



Previous studies show that 4′-modified oligonucleotides, in which the 4′-branch is facing the minor groove upon hybridization, form rather stable double helices with unmodified complementary sequences and, additionally, they are less prone to enzymatic degradation than their unmodified counterparts (*26*−*33*). Accordingly, relatively straightforward synthesis of 4′-*C*-azidomethylthymidine (**1**) (Chart 1) together with the efficient postsynthetic derivatization of the azido function by the click chemistry (*34*−*40*) makes this monomer particularly appealing for the purpose. Previously, an azido group had been introduced into nucelosides by enzymatic means and used for Staudinger ligation, but all these derivatives bear the modification on the base moiety (*41*−*44*).

Unfortunately, the azido group is not compatible with standard phosphoramidite chemistry, because of the Staudinger reaction

Published on Web 08/01/2008

between azides and phosphines (*45*). This shortcoming may, however, be avoided by using H-phosphonate chemistry for the chain assembly. After the synthesis of the modified oligonucleotide, click reaction between the 4′-azidomethyl group and an alkyne functionalized conjugate group may then be performed, either on support or in solution after release and HPLC purification of the oligonucleotide. To test the applicability of the synthesis protocol and to learn more about the effects of C4′-conjugation on duplex stability, three different ligands have been used for the conjugation, viz. alkyne derivatives of mannose (**2**), *p*-aminomethylbenzene (**3**) and neamine (**4**). Mannose is a model of a neutral sugar ligand. The *p*-aminomethylbenzene-derived ligand, in turn, elucidates the effects that electrostatic interactions between the positively charged ammonium groups and negatively charged phosphate groups have on the duplex stability, and neamine serves as an example of a sugar-type ligand bearing amino groups in addition to hydroxyl functions.

EXPERIMENTAL PROCEDURES

General Remarks. The NMR spectra were recorded at 500 MHz. The chemical shifts are given in ppm from internal TMS. The mass spectra were recorded using EI, FAB, or ESI ionization methods. RP HPLC analysis of oligonucleotide conjugates were performed using Supelco Ascentis C18 (150 × 4.6 mm, 5 μm) analytical column, a gradient elution from 0.05 mol L^{-1} NH_4OAc (aq) to 30% MeCN in 0.05 mmol L^{-1} NH_4OAc (aq) buffer over 60 min, flow rate 1 mL min^{-1}, and detection at 260 nm. For semipreparative purifications, Thermo ODS Hypersil (250 × 10 mm, 5 μm) column and flow rate 3 mL min^{-1} were used. Electropherograms were obtained by capillary zone electrophoresis using a fused silica capillary (75 μm, 50 cm), inverted polarity, citrate buffer (0.2 mol L^{-1}, pH 3.1), −30 kV voltage, and detection wavelength of 254 nm.

3′-*O*-(4,4′-Dimethoxytrityl)-5′-*O*-trifluoromethylsulfonyl-4′-*C*-(trifluoromethylsulfonyl)-oxymethylthymidine (6). 3′-*O*-(4,4′-Dimethoxytrityl)-4′-*C*-hydroxymethylthymidine (2.84 g, 4.9 mmol, **5**) was dissolved in a mixture of dry CH_2Cl_2 (30 mL) and dry pyridine (10 mL). Trifluoromethanesulfonyl anhydride (2.06 mL, 12.4 mmol) was added dropwise on an ice bath. After 20 min, the ice bath was removed and the reaction mixture was stirred at rt for 1 h. The reaction mixture was then partitioned between ethyl acetate (200 mL) and water (40 mL). The organic phase was separated, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel choromatography (40−100% ethyl acetate in hexane + 0.1% triethylamine) yielding product **6** (3.63 g, 87%) as a yellowish foam. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 8.24 (br s, 1H), 7.45−7.43 (m, 2H), 7.37−7.27 (m, 7H), 6.93 (br d, 1H), 6.91−6.88 (m, 4H), 5.82 (dd, 1H, J = 8.8 Hz, 3.3 Hz), 4.79 (d, 1H, J = 10.5 Hz), 4.76 (dd, 1H, J = 7.0 Hz, 2.0 Hz), 4.53 (d, 1H, J = 11.0 Hz), 4.04 (d, 1H, J = 11.0 Hz), 3.83 (s, 3H), 3.83 (s, 3H), 3.45 (d, 1H, J = 11.5 Hz), 2.64 (m, 1H), 2.29 (ddd, 1H, J = 14.0 Hz, 9.0 Hz, 3.5 Hz), 1.91 (s, 3H); ^{13}C NMR (125 MHz, $CDCl_3$) δ_{ppm} 163.3, 159.2, 159.2, 149.4, 144.4, 138.4, 135.3, 135.0, 130.4, 130.3, 128.3, 128.0, 127.6, 113.7, 111.3, 89.4, 88.4, 85.1, 74.3, 74.2, 74.1, 55.3, 39.5, 12.2 (Tf related peaks not listed); HRMS (FAB): M^+ calcd 838.1301, obsd 838.1327.

4′-*C*-Azidomethyl-3′-*O*-(4,4′-dimethoxytrityl)-O^2,5′-anhydrothymidine (7). Compound **6** (1.26 g, 1.5 mmol) was dissolved in a mixture of dry DMF (17 mL) and dry pyridine (3 mL). Sodium hydride (63 mg of 60% dispersion, 1.6 mmol) was added and the reaction was allowed to proceed for 20 min. Sodium azide (0.14 g, 2.2 mmol) was then added and the mixture was heated to 60 °C. To ensure the completeness of the reaction, another portion of sodium azide (0.10 g, 1.5 mmol) was added after 1 h. After 5.5 h from the beginning of the reaction, the mixture was evaporated and purified by silica gel choromatography (from ethyl acetate to 5−10% MeOH in ethyl acetate + 0.1% triethylamine). The yield was 0.80 g (91%) as a yellowish oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 7.38−7.26 (m, 9H), 7.09 (br d, 1H), 6.88−6.84 (m, 4H), 5.52 (d, 1H, J = 7.5 Hz), 4.65 (dd, 1H, J = 7.3 Hz, 2.3 Hz), 4.14 (d, 1H, J = 13.0 Hz), 4.08 (d, 1H, J = 12.5 Hz), 3.93 (d, 1H, J = 13.5 Hz), 3.81 (s, 3H), 3.81 (s, 3H), 2.78 (d, 1H, J = 13.5 Hz), 2.25 (ddd, 1H, J = 15.3 Hz, 8.0 Hz, 2.5 Hz), 2.12 (m, 1H), 1.95 (br d, 3H); ^{13}C NMR (125 MHz, $CDCl_3$) δ_{ppm} 171.8, 159.1, 159.1, 156.3, 144.6, 137.3, 135.5, 135.4, 130.5, 130.5, 128.3, 128.2, 127.5, 119.8, 113.5, 113.5, 92.7, 89.4, 88.0, 77.1, 75.5, 55.3, 52.1, 44.1, 13.4; HRMS (EI): M^+ calcd 581.2274, obsd 581.2275.

4′-*C*-Azidomethyl-3′-*O*-(4,4′-dimethoxytrityl)thymidine (8). To a solution of compound **7** (1.90 g, 3.3 mmol) in 33 mL of dioxane, aqueous NaOH (10 mL, 2 mol L^{-1}, 20 mmol) was added and the mixture was stirred for 3 h. The reaction mixture was partitioned between ethyl acetate (200 mL) and water (40 mL) and the organic phase was separated, dried with Na_2SO_4, and evaporated to dryness. Compound **8** (1.87 g) was received as yellowish solid foam in 95% yield. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 8.45 (br s, 1H), 7.44−7.42 (m, 2H), 7.35−7.23 (m, 7H), 7.07 (br. d, 1H), 6.86−6.83 (m, 4H), 6.04 (dd, 1H, J = 8.0 Hz, 4.0 Hz), 4.54 (t, 1H, J = 7.8 Hz), 3.83 (d, 1H, J = 13.0 Hz), 3.79 (s, 3H), 3.79 (s, 3H), 3.60 (d, 1H, J = 11.5 Hz), 3.37 (d, 1H, J = 13.0 Hz), 3.14 (d, 1H, J = 12.0 Hz), 2.25 (m, 1H), 1.84 (br s, 3H), 1.67 (m, 1H); ^{13}C NMR (125 MHz, $CDCl_3$) δ_{ppm} 163.5, 158.9, 158.9, 150.0, 150.0, 144.9, 137.0, 136.0, 135.9, 130.4, 130.4, 128.3, 128.0, 127.3, 113.3, 110.9, 88.9, 87.5, 86.0, 72.4, 63.2, 55.3, 53.3, 39.3, 12.4; HRMS (EI): M^+ calcd 599.2380, obsd 599.2404.

4′-*C*-Azidomethyl-5′-*O*-(4,4′-dimethoxytrityl)thymidine (9). Compound **8** (0.92 g, 1.5 mmol) was dissolved in 80% aq acetic acid (100 mL) and the mixture was stirred for 1 h. After evaporation, the residue was dried over P_2O_5 in vacuum, evaporated twice from dry pyridine, and finally dissolved in dry pyridine (20 mL). 4,4′-Dimethoxytrityl chloride (0.52 g, 1.5 mmol) was added and the mixture was stirred overnight at room temperature. After evaporation, the residue was purified by silica gel chromatography (5−20% ethyl acetate in CH_2Cl_2 + 0.1% triethylamine). This afforded compound **9** (0.81 g, 88%) as a white solid foam. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 8.92 (br s, 1H), 7.40−7.38 (m, 3H), 7.31−7.23 (m, 7H), 6.86−6.82 (m, 4H), 6.41 (∼t, 1H, J = 6.8 Hz), 4.55 (m, 1H), 3.79 (s, 6H), 3.59 (d, 1H, J = 12.5 Hz), 3.55 (d, 1H, J = 12.5 Hz), 3.40 (d, 1H, J = 10.0 Hz), 3.27 (d, 1H, J = 10.0 Hz), 2.75 (d, 1H, J = 5.0 Hz), 2.49−2.38 (m, 2H), 1.52 (br d, 3H); ^{13}C NMR (125 MHz, $CDCl_3$) δ_{ppm} 163.7, 158.8, 158.8, 150.3, 144.1, 135.7, 135.2, 135.0, 130.2, 130.1, 128.1, 128.1, 127.3, 113.3, 111.4, 88.0, 87.3, 84.9, 73.6, 65.8, 55.3, 52.9, 40.9, 11.9; HRMS (EI): M^+ calcd 599.2380, obsd 599.2369.

Triethylammonium 4′-*C*-Azidomethyl-5′-*O*-(4,4′-dimethoxytrityl)thymidine 3′-(*H*-phosphonate) (10). To the solution of compound **9** (0.31 g, 0.5 mmol) in dry pyridine (2 mL), diphenyl *H*-phosphonate (0.7 mL, 3.6 mmol) was added. After 45 min, water (0.6 mL) and triethylamine (0.6 mL) were added and the mixture was stirred for additional 15 min before evaporation. The residue was dissolved in CH_2Cl_2 (20 mL) and extracted with 5% aq $NaHCO_3$ (20 mL). The organic fraction was dried with Na_2SO_4 and, after evaporation, the compound was purified by silica gel chromatography (0−20% MeOH in CH_2Cl_2 + 0.1% triethylamine). The product (**10**, 0.34 g) was isolated as with powder in 86% yield. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 7.49 (s, 0.5 H), 7.40−7.39 (m, 3H), 7.30−7.22 (m, 7H), 6.84−6.83 (m, 4H), 6.46 (t, 1H, J = 7.0 Hz), 6.25 (s,

Propargyl 2,3,4,6-Tetra-*O*-acetyl-α-D-mannopyranoside (2). α-D-Mannopyranosyl pentaacetate (**13**, 2.32 g, 5.9 mmol) was dried over P_2O_5 in vacuum overnight, dissolved in dry CH_2Cl_2 (10 mL) under N_2, and boron trifluoride etherate (0.83 mL, 6.6 mmol) was added. The mixture was stirred at room temperature for 1 h before addition of propargyl alcohol (0.52 mL, 8.9 mmol), and the reaction was then allowed to proceed overnight. The mixture was transferred onto an ice bath and aq $NaHCO_3$ was added. The mixture was extracted with diethyl ether and the organic phase was washed once with water. The diethyl ether phase was dried with Na_2SO_4 and evaporated. The residue was purified by silica gel chromatography (50% ethyl acetate in petroleum ether). The yield of white amorphous solid **2** (1.76 g) was 76%. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 5.36−5.28 (m, 3H), 5.04 (d, 1H, $J = 1.5$ Hz), 4.31−4.28 (m, 3H), 4.12 (m, 1H), 4.03 (m, 1H), 2.48 (t, 1H, $J = 2.5$ Hz), 2.17 (s, 3H), 2.11 (s, 3H), 2.05 (s, 3H), 2.00 (s, 3H); ^{13}C NMR (125 MHz, $CDCl_3$) δ_{ppm} 170.7, 170.0, 169.9, 169.7, 96.3, 77.9, 75.6, 69.4, 69.0, 68.9, 66.0, 62.3, 55.0, 20.9, 20.8, 20.7, 20.7; HRMS(ESI): $[M + Na]^+$ calcd 409.1105, obsd 409.1085.

***N*-(4-Methoxytrityl)-1,4-phenylenedimethanamine (15).** 1,4-Phenylenedimethanamine (**14**, 4.00 g, 29.4 mmol) was dissolved in dry dioxane (80 mL) and 4-methoxytrityl chloride (6.30 g, 20.4 mmol) was added within 1 h. The reaction was stirred overnight at room temperature and 10% aq NaOH was added to convert the product to a free amine. The mixture was extracted with CH_2Cl_2 and the organic phase was dried with Na_2SO_4 and evaporated. The residue was purified by silica gel chromatography (5−30% MeOH in CH_2Cl_2 + 0.1% triethylamine) yielding product **15** (2.73 g, 32%) as a white solid foam. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 7.54−7.52 (m, 4H), 7.45−7.42 (m, 2H), 7.37−7.17 (m, 10H), 6.83−6.80 (m, 2H), 3.86 (s, 2H), 3.77 (s, 3H), 3.30 (s, 2H); ^{13}C NMR (125 MHz, $CDCl_3$) δ_{ppm} 157.9, 146.2, 140.9, 138.1, 129.8, 128.5, 128.4, 128.2, 127.9, 126.3, 113.2, 70.5, 55.2, 47.5, 44.8; HRMS (EI): M^+ calcd 408.2202, obsd 408.2201.

***N*-{4-[*N*-(4-Methoxytrityl)aminomethyl]benzyl}-4-pentynamide (16).** 4-Pentynoic anhyride was prepared by dissolving 4-pentynoic acid (1.31 g, 13.4 mmol) in dry dioxane (20 mL) and adding DCC (1.37 g, 6.6 mmol) into this solution on an ice bath. After 20 min, the ice bath was removed and the reaction was allowed to proceed for 4 h. Precipitated DCU was removed by filtration and the filtrate was added to a solution of **15** (2.72 g, 6.7 mmol) in dry pyridine (20 mL). A catalytic amount of 4-dimethylaminopyridine was added and the reaction was stirred at room temperature overnight. The reaction was evaporated and purified by silica gel chromatography (3−20% MeOH in CH_2Cl_2 + 0.1% triethylamine). Yield was 2.90 g (89%) as yellowish oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 7.55−7.53 (m, 4H), 7.46−7.43 (m, 2H), 7.37−7.18 (m, 10 H), 6.84−6.81 (m, 2H), 5.90 (br s, 1H), 4.45 (d, 2H, $J = 5.5$ Hz), 3.79 (s, 3H), 3.32 (s, 2H), 2.56 (td, 2H, $J = 7.0$ Hz, 2.5 Hz), 2.43 (t, 2H, $J = 7.3$ Hz), 2.00 (t, 1H, $J = 2.5$ Hz); ^{13}C NMR (125 MHz, $CDCl_3$) δ_{ppm} 170.7, 157.9, 146.2, 140.6, 138.1, 136.6, 129.8, 128.5, 128.3, 127.9, 126.3, 113.2, 83.0, 70.5, 69.5, 55.2, 47.6, 43.5, 35.4, 14.9; HRMS (EI): M^+ calcd 488.2464, obsd 488.2468.

***N*-{4-[*N*-(Trifluoroacetyl)aminomethyl]benzyl}-4-pentynamide (3).** To the solution of **16** (2.90 g, 5.9 mmol) in CH_2Cl_2 (20 mL), trifluoroacetic acid (0.93 mL, 12.1 mmol) in MeOH was added. TLC monitoring showed that the reaction had proceeded to completion in 20 min. After evaporation, the residue was dissolved in MeOH (25 mL) and triethylamine (4.5 mL) and methyl trifluoroacetate (3.87 g, 30.2 mmol) were added. After 1 h, the reaction was evaporated and purified by silica gel chromatography (3−10% MeOH in CH_2Cl_2). The product (**3**, 1.36 g) was obtained as a white powder in 73% yield; ^{1}H NMR (500 MHz, $CDCl_3$ + drop of MeOD) δ_{ppm} 7.27−7.23 (m, 4H), 4.45−4.44 (m, 2H), 4.39 (d, 2H, $J = 5.5$ Hz), 2.54−2.51 (m, 2H), 2.44 (t, 2H, $J = 7.0$ Hz), 2.03 (t, 1H, $J = 2.8$ Hz); ^{13}C NMR (125 MHz, $CDCl_3$ + drop of MeOD) δ_{ppm} 171.9, 157.5, 137.8, 135.6, 127.9, 127.9, 117.1, 82.7, 69.3, 43.1, 35.0, 14.8; HRMS (EI): M^+ calcd 312.1086, obsd 312.1098.

***N*^{1},*N*^{3},*N*$^{2'}$-Tris(trifluoroacetyl)-*N*$^{6'}$-(4-pentynoyl)neamine (4).** Succinimidyl 4-pentynoate was obtained by dissolving 4-pentynoic acid (0.40 g, 4.1 mmol) and *N*-hydroxysuccinimide (0.48 g, 4.2 mmol) into dry dioxane (6 mL) and adding DCC (0.84 g, 4.1 mmol) on an ice bath. After 2 h stirring at room temperature, precipitated DCU was removed by filtration and the filtrate was added in portions to the solution of neamine tetrahydrochloride (**17**, 1.91 g, 4.1 mmol) in a mixture of water (4 mL), dioxane (15 mL), and triethylamine (8.6 mL) during 1 h. The mixture was stirred at room temperature overnight and evaporated. The residue was dried over P_2O_5 in vacuo and subjected without further purification to trifluoroacetylation with methyl trifluoroacetate (5.22 g, 40.8 mmol) in a mixture of triethylamine (8.5 mL) and MeOH (35 mL). After 3 h, the mixture was evaporated and the residue was partitioned between ethyl acetate and water. The organic phase was dried with Na_2SO_4 and evaporated. To facilitate purification of the *N*^{1},*N*^{3},*N*$^{2'}$-triacylated product, the major part of the crude product (75%) was subjected to acetylation with acetic anhydride (1.5 mL, 15.9 mmol) in dry pyridine (25 mL). The reaction was allowed to proceed overnight, and after evaporation, the fully protected product was purified by silica gel chromatography (50−100% ethyl acetate in petroleum ether), giving a mixture of 6,3′,4′-tri-*O*-acetylated (**18**) and 5,6,3′,4′-tetra-*O*-acetylated (**19**) products as a white solid powder. Once the chromatographic purification on a silica gel column was accomplished, the O-acetyl groups were removed with methanolic sodium methoxide (0.15 mmol NaOMe in 14 mL MeOH). After 2.5 h, the mixture was neutralized with a strong cation-exchange resin (Dowex 50WX8−200, H^+-form) and filtered. The solution was evaporated yielding pure product **4** as a white solid powder. The overall yield, when taking into account that only 75% of the crude material was subjected to acetylation and subsequent purification, was 0.43 g (20%). ^{1}H NMR (500 MHz, MeOD) δ_{ppm} 5.25 (d, 1H, $J = 3.5$ Hz), 4.09 (m, 1H), 3.98 (dd, 1H, $J = 10.8$ Hz, 3.3 Hz), 3.86 (m, 1H), 3.75−3.68 (m, 2H), 3.62−3.58 (m, 2H), 3.52 (t, 1H, $J = 9.0$ Hz), 3.45−3.37 (m, 2H), 3.29 (t, 1H, $J = 9.5$ Hz), 2.55−2.47 (m, 4H), 2.32 (br s, 1H), 1.98 (ddd, 1H, $J = 12.5$ Hz, 4.3 Hz, 4.3 Hz), 1.72 (ddd, 1H, $J = 12.7$ Hz, 12.7 Hz, 12.7 Hz); ^{13}C NMR (125 MHz, MeOD) δ_{ppm} 173.7, 98.5, 82.2, 80.9, 76.6, 74.0, 71.7, 70.9, 70.3, 69.1, 54.8, 50.1, 49.4, 39.3, 34.4, 31.7, 14.4 (Tfa related peaks not listed); HRMS(ESI): $[M + Na]^+$ calcd 713.1476, obsd 713.1469.

Synthesis of Oligodeoxyribonucleotides. The oligodeoxyribonucleotides were synthesized on an Applied Biosystems 392 DNA synthesizer in a 1.0 μmol scale using commercial 1000 Å CPG-succinyl-nucleoside supports. Two coupling chemistry methods were applied: either the oligonucleotide was assembled using solely the H-phosphonate chemistry (Method A) or the H-phosphonate chemistry was combined with the phosphoramidite chemistry so that only modified nucleotide **10** was

coupled as a H-phosphonate and commercial dA, dG, dC, and dT building blocks were used as phosphoramidites (Method B). Both approaches gave the same coupling effiency (DMTr-cation assay) and yields (RP HPLC chromatogram).

Method A. Nucleoside 3′-(H-phosphonates) (TEA salts) were dissolved in a mixture of dry MeCN and pyridine (1:1, v/v) to give a final concentration of 30 mmol L^{-1} for the commercial nucleoside phosphonates and 35 mmol L^{-1} for the 4′-modified phosphonate (**10**). Pivaloyl chloride and adamantane carbonyl chloride were tested as a condensing agent. Both of them were dissolved in a 1:1 mixture of MeCN and pyridine to obtain a concentration of 100 mmol L^{-1}. Both agents gave similar results. The H-phosphonate protocol was generated for the

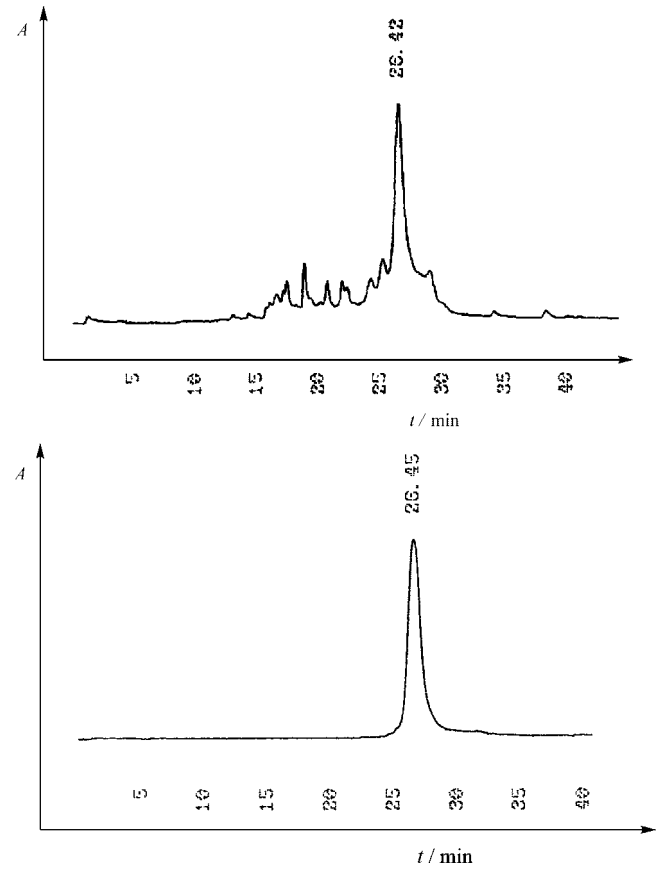

Figure 1. RP HPLC traces of the crude and purified oligonucleotide **21**.

synthesizer on the basis of previous reports (*46*, *47*). According to the DMTr-cation assay, the coupling yield for the 4′-modified H-phosphonate building block was 90% using a prolonged coupling time of 550−750 s. The coupling conditions were not optimized further. After the oligonucleotide assembly, the support-bound material was removed from the synthesizer, oxidized with iodine (0.1 mol L^{-1}) in wet pyridine (98:2, v/v) at rt for 1 h, washed with MeCN and MeOH, and dried in vacuum.

Method B. A protocol including both phosphoramidite and H-phosphonate couplings was generated for the synthesizer. No capping step was performed, but otherwise, standard phosphoramidite protocol was applied for commercial dA, dG, dC, and dT monomers and H-phosphonate protocol (as described in method A) was used for the modified monomer **10**. After completion of the chain assembly, oxidation of H-phosphonates was performed according to method A.

Oligonucleotides were released from the support with concentrated ammonia (33% aqueous NH_3) at 55 °C overnight. It should be noted that ammonolysis did not result in displacement of the azido groups. This was clearly seen by HPLC and ESI-MS characterization of the azido-functionalized oligonucleotides **20** and **21**.

Click Conjugation. Alkynyl-functionalized ligands **2**−**4** were conjugated to the azido groups of oligonucleotides **20** and **21**, containing one and three 4′-azidomethylthymidine units, respectively. The conjugation was carried out both on a solid support and in solution phase.

Conjugation on support. To the support-bound oligonucleotide, **20** or **21**, 15 or 30 equiv of the ligand in MeOH was added. With ligands **2** and **3**, the concentration was 50 mmol L^{-1}. With **4**, the concentration was 25 mmol L^{-1} and, owing to solubility problems, a mixture of MeOH, water, and DMSO

Scheme 4. Derivatization of Oligonucleotides 20 and 21 by Click Chemistry

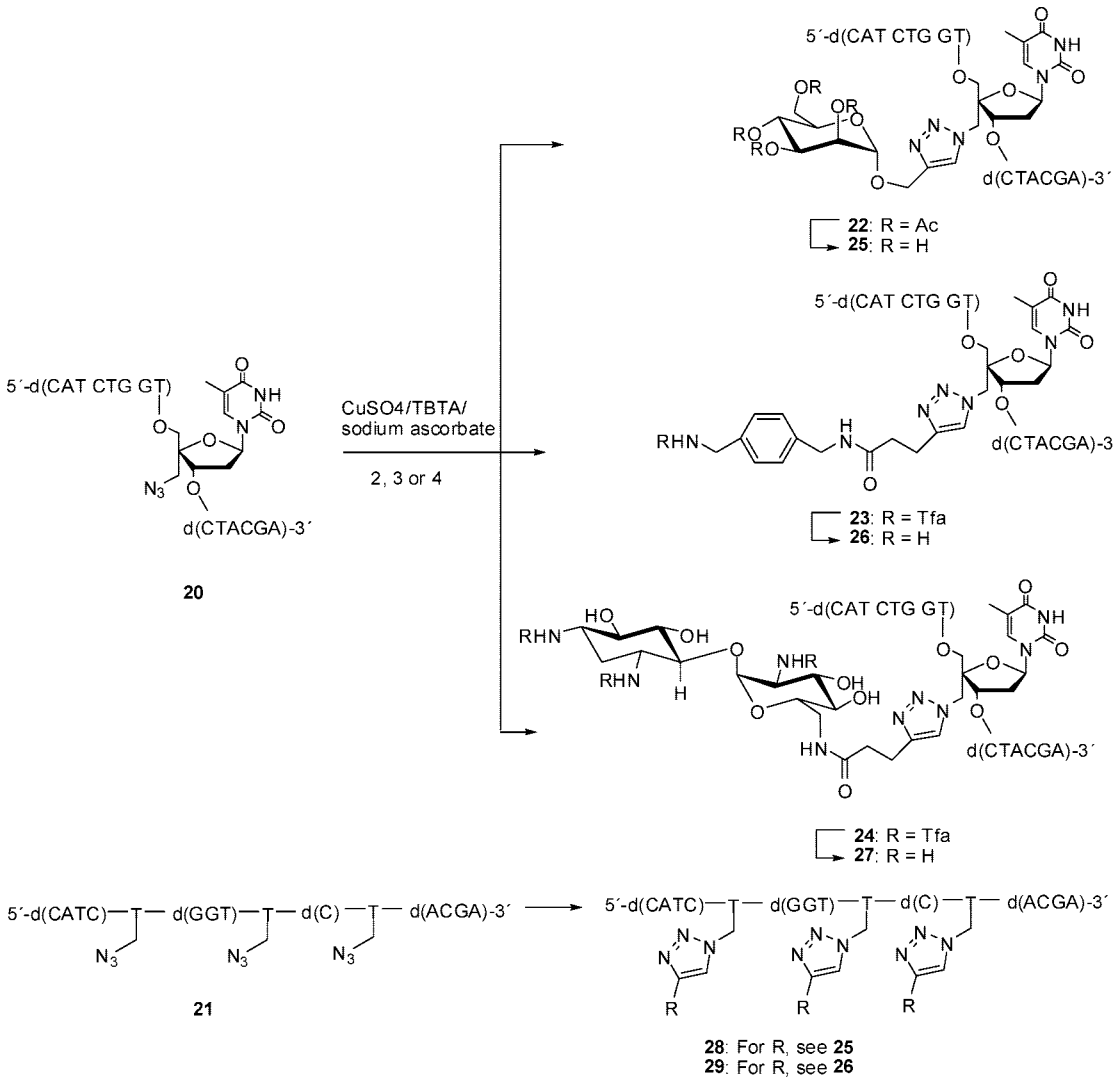

Table 1. ESI-MS Data of Oligonucleotides 20 and 21 and Their Conjugates 25−29

oligonucleotide	observed mass (g mol^{-1})	required mass (g mol^{-1})
20	4597.3	4598.1
21	4707.1	4708.1
25	4815.6	4816.3
26	4813.8	4814.3
27	4999.9	5000.5
28	5364.1	5362.7
29	5356.3	5357.0

(15:4:1 v/v/v) was used as a solvent. After that, $CuSO_4$ and tris[(1-benzyl-1,2,3-triazol-4-yl)methyl]amine (TBTA-ligand; 7.5 and 15 equiv with **20** and **21**, respectively) were added as a 25 mmol L^{-1} solution in a 12:3:1 mixture of water, DMSO, and 2-butanol. Finally, sodium ascorbate (15 and 30 equiv with **20** and **21**, respectively) as 0.1 mol L^{-1} aqueous solution was added. The mixture was efficiently stirred and allowed to stand overnight at 55 °C. The support was collected by filtration and washed with water, DMF, MeOH, aq EDTA (0.1 mol L^{-1}), water, DMF, MeOH, CH_2Cl_2, MeOH, and MeCN and finally dried in vacuum before ammonolytic release of the oligonucleotide conjugate from the support. The reason for the extensive washing was the attempt to remove as quantitatively as possible the copper salt and TBTA ligand used in the click reaction. After evaporation, the conjugate was purified by RP HPLC.

Conjugation in Solution. To an aqueous solution of the purified oligonucleotide (**20** or **21**, 0.6 mmol L^{-1}), methanolic solution of the ligand (**2** or **3**, 50 mmol L^{-1}, 50 equiv) was added. Ligand **4** was, however, added in a 15:4:1 mixture of MeOH, H_2O, and DMSO (25 mmol L^{-1}), because of its low solubility in MeOH. After that, $CuSO_4$ and TBTA-ligand (20 equiv) were added as a 25 mmol L^{-1} solution in a 12:3:1

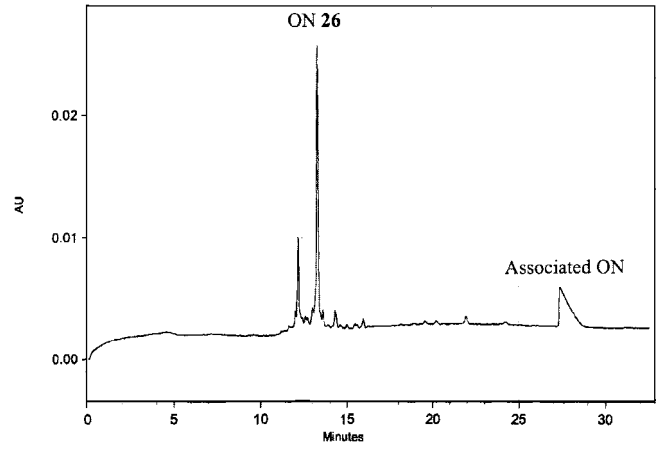

Figure 2. Electropherogram of the crude product (**26**) of the click reaction of oligonucleotide **20** with ligand **3** in solution.

[a] In 10 mmol L^{-1} potassium phosphate buffer (pH 7) containing 0.1 mol L^{-1} or 1.0 mol L^{-1} NaCl. The oligonucleotide conjugates and their cDNA or 2′-*O*-methyl RNA targets were used at a concentration of 2 μmol L^{-1}. **X** = 4′-*C*-azidomethylthymidine unit; **Y** = thymidine conjugate of deprotected **2**; **Z** = thymidine conjugate of deprotected **3**; **W** = thymidine conjugate of deprotected **4**; n.m. = not measured.

mixture of water, DMSO, and 2-butanol. Finally, aqueous sodium ascorbate (40 equiv, 0.1 mol L^{-1}) was added. The mixture was shaken overnight at room temperature. The resulting oligonucleotide conjugates were precipitated with EtOH. The precipitate was subjected to ammonolysis (overnight 55 °C) and then evaporated to dryness and purified by RP HPLC.

Melting Temperature Studies. The melting curves (absorbance versus temperature) were measured at 260 nm on a Perkin-Elmer Lambda 2 UV−vis spectrometer equipped with a Peltier Temperature contoller. The temperature was changed at a rate of 0.5 °C/min (from 20 to 90 °C). The measurements were performed in 10 mmol L^{-1} potassium phosphate buffer (pH 7) containing 0.1 or 1.0 mol L^{-1} NaCl. The oligonucleotide conjugates and their cDNA or 2′-*O*-methyl RNA targets were used at a concentration of 2 μmol L^{-1}. The T_m values were determined as the maximum of the first derivate of the melting curve.

RESULTS AND DISUCSSION

Synthesis of 4′-*C*-Azidothymidine 3′-(*H*-phosphonate) (10). 4′-*C*-Azidothymidine has been previously synthesized (*48*), but only in low yield via mesylation of 4′-*C*-hydroxymethyl-3′-*O*-TBDMS-thymidine and subsequent treatment of the mixture of the mono- and dimesylated products with LiN_3. Since this route includes tricky chromatographic separations of regioisomers, we decided to make use of O^2,5′-anhydronucleoside formation in making a difference between the two primary hydroxyl functions. Accordingly, 3′-*O*-(4,4′-dimethoxytrityl)-4′-*C*-hydroxymethylthymidine (**5**) was prepared as previously reported (*30, 49, 50*) and the primary hydroxyl groups were converted to their triflates to obtain **6** (Scheme 1). Deprotonation of the thymine base resulted in cyclization to O^2,5′-anhydro nucleoside (*51*), from which the remaining triflate group could be displaced with an azide ion, giving the desired 4′-*C*-azidomethyl group (**7**). The O^2,5′-anhydro linkage was hydrolyzed with sodium hydroxide and the resulting nucleoside 4′-*C*-azidomethyl-3′-*O*-DMTr-thymidine (**8**) was converted to its 5′-*O*-DMTr-isomer (**9**) and finally to the corresponding 3′-(H-phosphonate) (**10**). Altogether, the synthesis of building block **10** is efficient and the overall yield from compound **5** to **10** is 56%.

It should be noted that the 3′-hydroxy group must be masked before conversion of the hydroxyl function of the 4′-*C*-hydroxymethyl group to a better leaving group. The carbon atom of this group is surprisingly prone to nucleophilic attack of a neighboring hydroxyl group: a four-membered ring is easily formed by an attack of either the 5′- or 3′-OH. For example, the oxetane product **12** was the only product obtained when displacement of the tosyl group from 5′-*O*-(4,4′-dimethotrityl)-4′-*C*-tosyloxymethylthymidine (**11**) with azide ion was attempted (Scheme 2).

Synthesis of Ligands 2−4. The alkyne-derivatized ligands (**2**−**4**) used in the click conjugation were synthesized as outlined in Scheme 3. Fully acetylated propargyl α-D-mannopyranoside (**2**) was prepared from the commercially available peracetylated α-D-mannopyranose (**13**) by boron trifluoride etherate promoted glycosidation with propargyl alcohol (*52*). Trifluoroacetylated *N*-[4-(aminomethyl)benzyl]-4-pentynamide (**3**) was synthesized starting from the commercially available 1,4-phenylenedimethanamine (**14**). One of the two amino groups was protected with a 4-monomethoxytrityl group and the other one was acylated with 4-pentynoic acid by DCC activation. The acid-labile trityl protection was finally changed to a base-labile trifluoroacetyl protection, removable by the conventional ammonolysis used for release and deprotection of the oligonucleotide conjugate. Neamine tetrahydrochloride (**17**) was obtained by methanolysis of commercially available neomycin B trisulfate (*53*). The primary 6′-amino group of neamine (**17**) was selectively acylated with succinimidyl 4-pentynoate. To make this neamine derivative easier to handle and purify, the amino groups were trifluoroacetylated and the hydroxyl groups acetylated, and the product was purified at this stage. Owing to exceptionally difficult acetylation of the 5-hydroxy of neamine, a mixture of compounds **18** and **19** was obtained. Product **4** was received after removal of acetyl-protecting groups with methoxide ion catalyzed transesterification in MeOH.

Oligonucleotide Synthesis and Click Conjugation. Two 15-mer oligodeoxyribonucleotides containing either one or three 4′-*C*-azidomethylthymidine monomers were synthesized using H-phosphonate coupling chemistry: 5′-d(CAT CTG GT***T*** CTA CGA)-3′ (**20**) and 5′-d(CAT C***T***G GT***T*** C***T***A CGA)-3′ (**21**). The coupling yield for the 4′-*C*-azidomethylthymidine 3′-(H-phosphonate) monomer was 90%. The phosphoramidite coupling could not be applied, since intramolecular Staudinger reaction between the azido and phosphoramidite groups made the phosphoramidite building block highly unstable. Unmodified dA, dG, dC, and dT monomers could, however, be coupled as phosphoramidites. In other words, a mixed H-phosphonate and phosphoramidite method could be applied instead of mere H-phosphonate coupling. The yields of both approaches were comparable. This observation implies that the Staudinger reaction between the incoming phosphoramidite reagent and the support bound azide does not disturb the phosphoramidite coupling. Problems arise only when a genuine intramolecular reaction may take place. Figure 1 shows the HPLC traces of the crude oligonucleotide **21**, containing three azido-functionalized thymidine units and the product after purification.

After chain assembly, click chemistry was applied to attach alkyne-derivatized ligands **2**−**4** to the oligonucleotide backbone. To minimize radical induced modifications within the oligonucleotide chain, tris[(1-benzyl-1,2,3-triazol-4-yl)methyl]amine (TBTA) was used as a Cu(I)-stabilizing agent (*54*). Conjugation was performed either on the CPG support or in solution. Scheme 4

outlines the procedure in solution. Essentially the same chemistry was applied on a solid support. During the click reaction, the base moieties bore conventional acyl protections and the internucleosidic linkages were present as 2-cyanoethyl triesters. In both cases, the click reaction proceeded virtually quantitatively, as also reported previously for derivatization of alkyne-functionalized oligonucleotides with azides either on a solid support (*38*) or in solution (*36*). The advantage of the solid-supported synthesis is that only one HPLC purification is needed after ligation and release of the oligonucleotide from the support. By contrast, when the conjugation is carried out in solution, the oligonucleotide product must be purified both before and after conjugation. In addition, deprotection of the conjugate groups introduced requires a second ammonolysis after the click reaction. In principle, unprotected conjugate groups could have been used in the click reaction, but we felt that with amino groups containing ligands, in particular, it is safer to use protections to minimize the interactions with copper ion.

Standard ammonolysis (33% aq NH_3, 55 °C, overnight) was carried out to release oligonucleotides from the support and to remove the protections from base moieties, phosphodiester linkages, and conjugate groups. The conjugates (**25**−**29**) were then purified by RP-HPLC and their identity was verified by ESI-MS. The data are given in Table 1. The purity of the crude product mixtures were additionally checked by capillary electrophoresis. These studies quite unexpectedly revealed the existence of an additional conjugate or complex that is not seen by HPLC. In electropherograms, this species appeared as a wide peak after the signal of the oligonucleotide conjugate (Figure 2). Possibly the oligonucleotide conjugate remained partly associated with the TBTA ligand or its Cu(I) complex, albeit the solid support was thoroughly washed after the click reaction. Although this marked impurity could not be detected by HPLC, RP HPLC purification entirely removed it. After HPLC purification, no extra signals appeared any more in the electropherogram.

When the click reaction was carried out in solution, the elctropherogram of the crude product showed only the broad signal of the unidentified associate discussed above. After precipitation of the oligonucleotide conjugate from EtOH, the signals of both the desired conjugate (**26** in Figure 2) and the unidentified associate appeared, but again RP HPLC purification was needed to obtain a pure conjugate.

Capillary electrophoretic studies also revealed another peculiarity related to the click procedure. When amino group containing ligands (**3**, **4**) were conjugated on a solid support and the conjugates obtained were purified by HPLC, they still gave two peaks in electropherograms. In addition, their melting temperature curves were slightly biphasic, lending further support for the occurrence of the conjugates as two isomers that had the same molecular mass (in ESI-MS only one set of signals, *m*/*z*, was detected) and could not be separated by HPLC. When the conjugation was carried out in solution and the product was precipitated with EtOH, this anomality in behavior disappeared: the product was elecrophoretically homogeneous and exhibited normal sigmoid melting curves. Accordingly, some caution seems to be needed when applying click conjugation to ligands that offer good coordination sites, such as amino groups, for copper ions, in spite of fact that the groups are kept protected during the actual cycloaddition reaction.

Melting Temperature Studies. Melting temperatures (T_m) for the duplexes of oligonucleotides **20**, **21** and their conjugates **25**−**29** with the cDNA and 2′-*O*-methyl RNA sequences were measured at pH 7 at the ionic strength of 0.1 and 1.0 mol L^{-1} (Table 2).

When one or three 4′-*C*-azidomethylthymidine monomers were incorporated into an oligonucleotide (**20**, **21**), the melting temperature of the heteroduplexes with cDNA and 2′-*O*-methyl RNA sequences dropped, but less with 2′-*O*-methyl RNA (ΔT_m/modification ≈ −0.5 °C) than with DNA (ΔT_m/modification ≈ −1.5 °C). Conjugation of the 4′-*C*-azidomethylthymidine units with mannopyranoside (**25**, **28**) slightly increased the destabilization of the DNA-hybrid (ΔT_m/modification ≈ − 2 °C), but, interestingly, hybridization with 2′-*O*-methyl RNA was even slightly enhanced, in particular at high ionic strength.

In contrast to these results, conjugates **26**, **27**, and **29** bearing free amino group(s) formed more stable duplexes with cDNA than with 2′-*O*-methyl RNA. The difference in the behavior is, however, small. Now at low salt concentration, the modifications slightly increased the melting temperature of the hybrid complex with DNA, but at high salt concentration, T_m was decreased. This implies that the amino groups, being positively charged at neutral pH, reduce the electrostatic repulsion between negatively charged sugar−phosphate backbones, the influence playing a more important role at low ionic strength. With complementary 2′-*O*-methyl RNA strand, the melting temperatures, however, dropped more at low than at high salt concentration.

According to previous studies (*26*, *28*−*32*), oligonucleotides containing 4′-*C*-modified DNA monomers generally prefer hybridization toward cDNA over RNA. 4′-*C*-acylthymidines (*55*), for example, adopt a C(2′)-endo-like conformation found typically in B-type DNA-DNA duplex. 4′-*C*-Me, 4′-*C*-Et, and 4′-*C*-iPr groups are all, however, slightly destabilizing toward DNA (*56*). With conjugates **26**, **27**, and **29**, a similar preference for the cDNA is found. However, an opposite behavior occurs with oligonucleotides containing azido or mannose groups. The results with mannose derivatives (**25**, **28**) toward the complementary 2′-*O*-methyl RNA strand are encouraging, since they lend support for the feasibility of sugar-coated oligonucleotides as carriers of RNA-type oligonucleotides.

CONCLUSION

A novel high yielding synthesis has been developed for 4′-*C*-azidomethylthymidine 3′-(*H*-phophonate) (**10**). One or three such monomers have been incorporated into a 15-mer oligodeoxyribonucleotide using H-phosphonate coupling. Standard deoxynucleotide (dA, dG, dC, and dT) monomers have been coupled either with H-phosphonate or phosphoramidite chemistry. This suggests that the Staudinger reaction between the azido group and the phosphoramidite reagent severely hampers the coupling only when the reaction is intramolecular. Ligands bearing an alkynyl tail may be highly efficiently conjugated to the azido groups by click chemistry. This can be done both on a solid support and in solution. As far as neutral sugar ligands, such as mannose, are concerned, conjugation on support appears to be the method of choice, owing to easy removal of auxiliaries of the click reaction by washing. By contrast, for ligand containing amino groups, conjugation in solution followed by precipitation from EtOH and HPLC purification is recommended. With such ligands, washing of the solid support is not adequate to remove all impurities and these tend to comigrate with the product.

The melting temperature studies reveal that the mannose conjugates form more stable duplexes with 2′-*O*-methyl RNA than with DNA strand. With 2′-*O*-methyl RNA, a slight destabilization compared to an unmodified sequence is observed at low ionic strength, while at high salt content, the manno-conjugation is even stabilizing. With the conjugates derived from 1,4-phenylenedimethanamine or neamine, i.e., ligands containing amino groups, the situation is the opposite: compared to unmodified sequences, the 2′-*O*-methyl RNA hybrid is destabilized more markedly than the DNA hybrid, and the destabilization is more marked at high than low salt content. Evidently, the amino groups, being positively charged at neutral pH, reduce the electrostatic repulsion between negatively charged sugar−phosphate backbones, the influence playing a more important role at low ionic strength. The high stability of the duplex of 4′-mannosylated oligonucleotide with 2′-*O*-methyl RNA lends support for the feasibility of the use of such

oligonucleotide conjugates as carriers of RNA-type antisense oligonucleotides. A proper sugar coating may possibly have positive effects on the pharmacokinetics of the duplex and provide it with cell-type specificity. While coating with monosaccharide ligands may well be insufficient to warrant high affinity binding, it is worth noting that the procedure developed in the present study allows conjugation of more complicated oligosaccharide ligands, as long as they bear an alkynyl tail.

Supporting Information Available: NMR spectral data for **2**−**4**, **6**−**10**, **15**, and **16**. ESI-MS and RP HPLC chromatographic data for purified oligonucleotides **20**, **21**, and **25**−**29**. Additionally, example melting temperature curves for **20**, **21**, and **25**−**29** are presented. This material is available free of charge via the Internet at http://pubs.acs.org.

General procedures

The NMR spectra of **2-4, 6-10, 15** and **16** were recorded at 500 MHz. The chemical shifts are given in ppm from internal TMS. The mass spectra of **20, 21** and **25-29** were recorded by ESI ionization method. RP HPLC chromatographs of pure **20, 21** and **25-29** were performed using Supelco Ascentis C18 (150 × 4.6 mm, 5 μm) analytical column. The melting curves (absorbance versus temperature) were measured at 260 nm in Perkin-Elmer Lambda 2 UV-vis spectrometer equipped with Peltier Temperature contoller by using a rate of 0.5 ºC / min (from 20 to 90 ºC). The oligonucleotide conjugate and its complementary target DNA or 2´-*O*-methyl RNA were used in concentration of 2 μmol L^{-1}.

TECHNICAL NOTES

Determination of Optimal Rhodamine Fluorophore for *in Vivo* Optical Imaging

Michelle R. Longmire, Mikako Ogawa, Yukihiro Hama, Nobuyuki Kosaka, Celeste A. S. Regino, Peter L. Choyke, and Hisataka Kobayashi*

Molecular Imaging Program, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20892-1088. Received April 3, 2008; Revised Manuscript Received May 8, 2008

Optical imaging has the potential to improve the efficacy of surgical and endoscopic approaches to cancer treatment; however, the optimal type of fluorescent probe has not yet been established. It is well-known that rhodamine-core-derived fluorophores offer a combination of desirable properties such as good photostability, high extinction coefficient, and high fluorescence quantum yield. However, despite the ubiquitous use of rhodamine fluorophores for *in vivo* optical imaging, it remains to be determined if unique chemical properties among individual rhodamine core family members affect fluorophore parameters critical to *in vivo* optical imaging applications. These parameters include preserved fluorescence intensity in low pH environments, similar to that of the endolysosome; efficient fluorescence signal despite conformational changes to targeting proteins as may occur in harsh subcellular environments; persistence of fluorescence after cellular internalization; and sufficient signal-to-background ratios to permit the identification of fluorophore-targeted tumors. In the present study, we conjugated 4 common rhodamine-core based fluorescent dyes to a clinically feasible and quickly internalizing D-galactose receptor targeting reagent, galactosamine serum albumin (GmSA), and conducted a series of *in vitro* and *in vivo* experiments using a metastatic ovarian cancer mouse model to determine if differences in optical imaging properties exist among rhodamine fluorophores and if so, which rhodamine core possesses optimal characteristics for *in vivo* imaging applications. Herein, we demonstrate that the rhodamine-fluorophore, TAMRA, is the most robust of the 4 common rhodamine fluorophores for *in vivo* optical imaging of ovarian cancer metastases to the peritoneum.

INTRODUCTION

The application of targeted optical imaging probes as an aid to surgical or endoscopic procedures offers the potential for the identification and treatment of malignancies, such as ovarian and colon cancer, at subvisible volumes when the opportunity for cure is the greatest. However, maximal clinical benefit requires probes with high target-to-background ratios which are sufficient to permit identification and detection of cancer tissues in the human body. In addition, optical imaging probe selection must take into consideration imaging application-specific parameters. For example, in applications permitting access to superficial surfaces of targeted tissues, green dyes such as rhodamine core fluorophores are well-suited because of their high emission efficiency and high target-to-background ratios. In comparison, applications where greater depth of penetration is required, as occurs in submucosal lesions, near-infrared (NIR) probes are generally preferred (*1–5*). Another important consideration in the selection of an optimal fluorophore is the effect that internalization and subsequent entry into the endolysosome, with its harsh acidic microenvironment, has on the fluorescence of molecular probes (*6*).

Rhodamine core optical fluorophores are widely utilized in biomedical research, and among the green fluorescent dyes, Rhodamine Green has been shown to possess the highest emission efficiency and the longest sustained fluorescence even after cellular internalization (*6*). It remains to be determined, however, if unique chemical properties among individual rhodamine core family members affect fluorophore parameters critical to *in vivo* optical imaging. These parameters include preserved fluorescence intensity in low pH environments, similar to that of the endolysosome; efficient fluorescence signal despite possible conformational changes of targeting proteins, as may occur in harsh subcellular environments; persistence of fluorescence after cellular internalization; and sufficient target-to-background ratios of fluorophore-targeted tumors to permit identification of subvisible disease.

In the present study, we conjugated 4 common rhodamine-core based fluorescent dyes to a clinically feasible and quickly internalizing D-galactose receptor targeting reagent, galactosamine serum albumin (GmSA) (*7–9*), and conducted a series of *in vitro* and *in vivo* experiments using a mouse model of metastatic ovarian cancer to determine if differences in optical imaging properties exist among rhodamine fluorophores and if so, which rhodamine core derivative possesses optimal characteristics for *in vivo* imaging.

EXPERIMENTAL PROCEDURES

Selection of Rhodamine Fluorophores. Four fluorophores within the rhodamine fluorophore family, which differed with regard to structure of the amine side chains, were selected for this study: Rhodamine Green (RG; 9-[2-Carboxy-4(or 5)-[[(2,5-

dioxo-1-pyrrolidinyl)oxy]carbonyl]phenyl]-3,6-bisamino-xanthylium); Carboxyrhodamine 6G (CaRG; 9-[2-carboxy-4-[[(2,5-dioxo-1-pyrrolidinyl)oxy]carbonyl]phenyl]-3,6-bis(ethylamino)-2,7-dimethyl-xanthylium); Carboxytetramethylrhodamine (TAMRA; 5-[[(2,5-dioxo-1-pyrrolidinyl)oxy]carbonyl]phenyl]-3,6-bis(dimethylamino)-xanthylium); and Carboxy-X-Rhodamine (ROX; 1-[[[2′,3′,6′,7′,12′,13′,16′,17′-octahydro-3-oxospiro[isobenzofuran-1(3*H*),9′-[1*H*,5*H*,9*H*,11*H*,15*H*]xantheno[2,3,4-ij:5,6,7-i′j′]diquinolizin]-5(or 6)-yl]carbonyl]oxy]-2,5-pyrrolidinedione). Each of these 4 dyes—RG, CaRG, TAMRA, and ROX—possessed distinct side chains with primary, secondary, tertiary, or cyclic amines, respectively (Figure 1).

Synthesis of Galactosamine Serum Albumin-Rhodamine Fluorophore Conjugates. Galactosamine serum albumin (GmSA), which has approximately 23 galactosamine residues per bovine serum albumin (BSA), was purchased from Sigma Chemical (St. Louis, MO, USA) and amino-reactive RG, CaRG, TAMRA, and ROX were purchased from Molecular Probes (Eugene, OR, USA). At room temperature, 400 μg of GmSA in 196 μL Na_2HPO_4 was incubated with 4 μL of a 6 mM solution (24 nmol) of each one of 4 amino-reactive rhodamine dyes in dimethyl sulfoxide for 15 min. The mixture was then purified with a Sephadex G-50 Gel Filtration System (PD-10; GE Healthcare, Milwaukee, WI, USA). GmSA-rhodamine conjugate samples were then kept at 4 °C as stock solutions.

Comparison of Fluorescence Intensity at Various pH Values. To compare the fluorescence capability of the 4 fluorophore conjugates, fluorescence intensity and emission spectra were measured in arbitrary units using the Maestro In-Vivo Imaging System (CRi Inc., Woburn, MA, USA). 5 μg of GmSA-RG, GmSA-CaRG, GmSA-TAMRA, and GmSA-ROX were pipetted into a nonfluorescent 96-well plate and diluted in 390 μL of a buffer solution containing appropriate ratios of sodium dihydrogen phosphate and phosphate to obtain pH values of 2.3, 3.3, 5.2, 6.4, or 7.4, and spectral fluorescence imaging was performed. The ratio of RG, CaRG, TAMRA, and ROX was ~3 molecules per albumin molecule. Appropriate band-pass and long pass filter sets (445 to 490 nm/515 nm for RG; 480 to 520 nm/550 nm for CaRG; 503 to 555 nm/580 nm for both TAMRA and ROX) were used for emission and excitation light, respectively. The tunable filter was automatically stepped in 10 nm increments from 500 to 800 nm while the camera captured images at each wavelength interval with constant exposure times. Spectral unmixing algorithms that subtracted any background autoflourescence were applied to create an unmixed image for each of the 4 dye conjugates, permitting accurate evaluation of the fluorescence intensity of each conjugate. A region of interest (ROI) was drawn over the entirety of each well to determine the fluorescence intensity and emission spectra for each of the 4 GmSA-dye conjugates.

Effect of Target Protein Unfolding on Fluorescence Intensity of GmSA-Rhodamine Fluorophore Conjugates. To evaluate the effect of target protein unfolding on the fluorescence characteristics of GmSA-fluorophore conjugates, each of the 4 conjugates was incubated with 5% SDS in PBS for 10 min at room temperature. Experimental controls were established by incubating each conjugate in normal PBS without SDS. The fluorescence signal intensity of each sample and control was measured using both a fluorescence spectrometer (Perkin-Elmer LS55, Perkin-Elmer, Shelton, CT, USA) and the Maestro In-Vivo Imaging System (CRi Inc., Woburn, MA, USA). The excited wavelengths were 505, 524, 555, and 576 nm for GmSA-RG, GmSA-CaRG, GmSA-TAMRA, and GmSA-ROX, respectively. To investigate the effect of target protein unfolding on the energy absorbance of each protein-fluorophore conjugate, the number of fluorophore molecules per GmSA was calculated. The GmSA concentration was determined by Coomassie Plus protein assay kit (Pierce Biotechnology) by measuring the absorption at 595 nm using a UV−vis system (8453 Value UV−vis system, Agilent Technologies, Santa Clara, CA, USA). The fluorophore concentration was then determined by measuring the absorbance at the maximum absorption wavelength of each fluorophore to confirm the number of rhodamine fluorophore molecules conjugated to each GmSA molecule.

Cell Culture. An established ovarian cancer cell line, SHIN3, was used for *in vitro* fluorescence microscopy, flow cytometry, and intraperitoneal ovarian cancer mouse models (*10*). The cell lines were grown in RPMI 1640 medium (Gibco, Gaithersburg, MD) containing 10% fetal bovine serum (FBS) (Gibco, Gaithersburg, MD), 0.03% L-glutamine at 37 °C, 100 units/mL penicillin, and 100 μg/mL streptomycin in 5% CO_2.

Fluorescence Microscopy. SHIN3 cells (1×10^4) were plated on a cover glass bottom culture well and incubated for 16 h, after which either GmSA-RG, GmSA-CaRG, and GmSA-TAMRA or GmSA-ROX was added to the medium (3 μg/mL), and the cells were incubated with conjugates for 0, 6, or 24 h. After the respective incubation period, cells were washed five times with PBS and fluorescence microscopy was performed using an Olympus BX51 microscope (Olympus America Inc., Melville, NY) equipped with excitation filters (470−490 nm) and emission filters (515 nm long pass). Fluorescence microscopy images of cells treated with each conjugate for each incubation period were obtained.

Flow Cytometry. One-color flow cytometry was performed to evaluate the fluorescing capability of GmSA-fluorophore conjugates in SHIN3 cancer cells. SHIN3 cells (1×10^4) were plated on a 12-chamber culture well and incubated for 16 h, after which, GmSA-RG, GmSA-CaRG, GmSA-TAMRA, or GmSA-ROX was added to the medium (30 μg/mL), and the cells were incubated with fluorophore conjugates for 3 h. Cells were washed twice with PBS and incubated in RPMI 1640 medium without fluorophore conjugates for 0, 6, or 24 h. Cells were then washed once with PBS, trypsinized, and flow cytometry was performed at each incubation time point 0, 6, and 24, after transfer to conjugate-free media. The argon ion 488 nm laser was employed for excitation. Signals from cells were collected using a 530/30 nm band-pass filter. Cells were analyzed in a FACScan cytometer (Becton Dickinson, Franklin Lakes, NJ) and all data were analyzed using *CellQuest* software (Becton Dickinson, Franklin Lakes, NJ). The fluorescing capability of each fluorophore conjugate was referred to as the mean fluorescence index (MFI).

Tumor Model. All procedures were carried out in compliance with the Guide for the Care and Use of Laboratory Animal Resources (1996), National Research Council, and approved by

Table 1. Fluorescence Intensity Ratios of GmSA-Rhodamine with and without SDS Treatment

	fluorescence intensity ratio (spectrometer)	fluorescence intensity ratio (multispectral camera)
GmSA-RG	6.9	6.6
GmSA-CaRG	11.3	5.0
GmSA-TAMRA	34.3	18.1
GmSA-ROX	3.3	4.1

the local Animal Care and Use Committee. The intraperitoneal tumor implants were established by intraperitoneal (i.p.) injection of 2×10^6 cells suspended in 200 μL of PBS in female nude mice (National Cancer Institute Animal Production Facility, Frederick, MD). Experiments with tumor-bearing mice were performed at 21 days after injection of the cells.

***In Vivo* Spectral Fluorescence Imaging.** 12.5 μg each of GmSA-RhodG, GmSA-CaRG, GmSA-TAMRA, and GmSA-ROX were diluted in 300 μL PBS and injected into the peritoneal cavities of mice bearing disseminated peritoneal SHIN3 ovarian cancer implants. Three hours after injection of the fluorophore conjugate, each mouse was sacrificed individually with carbon dioxide. Immediately after sacrifice, the abdominal cavity was exposed. Mice were placed on nonfluorescent black plates and whole abdominal multispectral fluorescence images were obtained using the Maestro In-Vivo Imaging System (CRi, Inc., Woburn, MA). A band-pass filter from 445 to 490 nm and a long-pass filter over 515 nm were used for emission and excitation light, respectively. The tunable filter was automatically stepped in 10 nm increments from 500 to 800 nm, while the camera captured images at each wavelength interval with constant exposure time. The spectral fluorescence images consisting of autofluorescence spectra, and the spectra for the specific GmSA-fluorophore conjugate were obtained and then unmixed on the basis of their spectral patterns using commercial software (*Maestro* software, CRi, Inc., Woburn, MA). The experiment was repeated three times ($n = 3$ mice per fluorophore). Spectral fluorescence images were obtained for the purpose of determining the target-to-background ratios of tumor implants versus normal anatomy (see discussion below).

Determination of Target-to-Background Ratios of Tumors Compared to Normal Tissue. Spectral fluorescence images of the whole abdominal cavity were obtained as previously described. Monochromatic images corresponding to the peak emission wavelength for each fluorophore conjugate were then generated from multispectral whole abdominal images using the Maestro In-Vivo Imaging System (CRi Inc., Woburn, MA, USA) software single wavelength channel extraction function. The target-to-background ratios of tumor implants compared to surrounding normal tissue were determined by placing an ROI over tumors and ROIs over the normal tissue of the liver, intestines, and skin. Intestinal tissue without substantial fluorescence due to food was chosen for intestinal ROI placement to establish target-to-background ratios indicative of normal intestinal autofluorescence with minimal fluorescence contribution due to feed, which often varies between research centers and investigative end points. ROI average signal intensity for tumors was then compared to the versus ROI average signal intensity of the liver, intestines, and skin, respectively, were determined for each animal (Table 2). In addition, to approximate tumor-to-background ratios of tumor implants to normal tissue in general, ROI average signal intensity of tumors was compared to a calculated average ROI signal intensity that combined the signal intensity measurements of all normal anatomic features (liver, intestines, and skin combined) for each animal.

Table 2. Signal-to-Backround Ratios of GmSA-Rhodamine Congujate Targeted Tumors versus Surrounding Normal Anatomy[a]

conjugate	tumor vs normal tissue	tumor vs intestines	tumor vs liver	tumor vs skin
GmSA-RG	7.5 (2)	6.4 (1)	10.5 (2)	4.5 (4)
GmSA-CaRG	7.2 (3)	4.9 (3)	10.4 (3)	7.3 (2)
GmSA-TAMRA	11.0 (1)	6.0 (2)	15.1 (1)	9.1 (1)
GmSA-ROX	5.9 (4)	3.8 (4)	7.6 (4)	6.1 (3)

[a] Fluorophore-conjugate rank in each category is shown in parenthesis.

RESULTS AND DISCUSSION

Comparison of Fluorescence Intensity at Various pH Values. After cellular internalization, the GmSA-flourophore probe enters the highly acidic lysosomal vesicle. This isolated low pH environment may affect fluorophore chemical composition and therefore has the potential to alter fluorescence. To evaluate the effect of pH on GmSA-fluorophore probe fluorescence, fluorescence intensity and emission spectra were measured under the same conditions: total dose, concentration of solution, number of fluorophores per GmSA, and exposure time. Excitation/emission filters varied according to which filter set was optimal for each dye. The effect of pH on fluorescence intensity was determined by measuring the fluorescence intensity for each dye at pH values 2.3, 3.3, 5.2, 6.4, and 7.4 (Figure 2). Measurements of the fluorescence intensities at neutral pH (7.4) for the four conjugates, GmSA-RG, GmSA-CaRG, GmSA-TAMRA, and GmSA-ROX, demonstrated that GmSA-CaRG had the highest signal intensity while GmSA-RG had the lowest. All of the conjugates with the exception of GmSA-TAMRA demonstrated a decrease in fluorescence intensity value when comparing values obtained at pH 7.4 to pH 2.3 (Figure 2). At pH 2.3, fluorescence intensity was reduced for all dyes with the exception of GmSA-TAMRA, which demonstrated an increase in fluorescence intensity with decreasing pH (Figure 2). Both GmSA-RG and GmSA-CaRG retained nearly optimal fluorescence at pH values as low as 3.3, after which lowering pH to 2.3 resulted in an approximately 20% reduction in fluorescence intensity (Figure 2). GmSA-ROX retained near optimal fluorescence at pH 7.4 and 6.4 but reduction in pH to 5.2 resulted in decrease in fluorescence intensity. At every pH value tested, GmSA-CaRG demonstrated the highest fluorescence intensity (Figure 2).

These results demonstrate that GmSA-RG, GmSA-CaRG, and GmSA-TAMRA retain fluorescence in low pH environments. Interestingly, only GmSA-TAMRA displayed increasing fluorescence signal with decreasing pH, although none of the conjugates demonstrated substantial changes. The ability of GmSA-RG, GmSA-CaRG, and GmSA-TAMRA to retain fluorescence at low pH suggests that these agents may be preferred for *in vivo* imaging if the molecular probe is internalized within the lysosome.

Effect of Target Protein Unfolding on Fluorescence Intensity of GmSA-Rhodamine Fluorophore Conjugates. The harsh chemical environment of the endolysosomal system may potentially alter the tertiary structure of the targeting protein. To evaluate the effect of structural changes of targeting proteins on the fluorescence properties of GmSA-fluorophore conjugates, fluorescence intensity values were measured for each of the 4 conjugates in a control solution of PBS as well as after treatment with a detergent solution containing SDS, and ratios comparing fluorescence with and without SDS treatment were generated. Treatment with SDS demonstrated higher fluorescence intensity

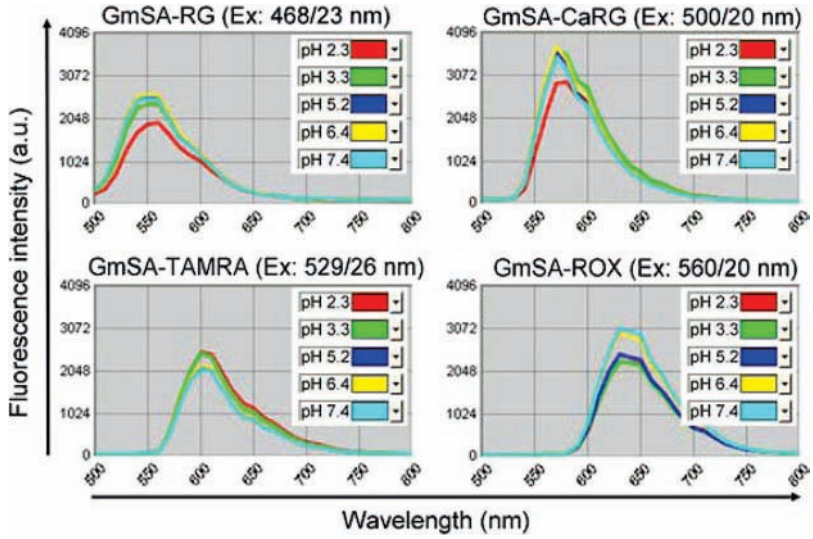

Figure 2. Fluorescence intensity of GmSA-rhodamine conjugates at neutral and acidic pH values. 5 μg of GmSA-RG, GmSA-CaRG, GmSA-TAMRA, or GmSA-ROX was placed in 390 μL PBS (pH 7.4) or in a mixture of sodium dihydrogen phosphate (pH 6.4, 5.2, 3.3, or 2.3) and then placed in a nonfluorescent 96-well plate and emission spectra and fluorescence intensity was measured. The ratio of RG, CaRG, TAMRA, and ROX molecules to GSA was approximately 3 in all cases. All four dyes possessed distinct emission peak spectra. At neutral pH (7.4), GmSA-CaRG had the highest signal intensity, whereas GmSA-RG had the lowest. With the exception of GmSA-TAMRA, all other conjugates demonstrated a decrease in fluorescence intensity value when comparing values obtained at pH 7.4 to the lowest pH value tested, pH 2.3. At pH 2.3, fluorescence intensity was substantially reduced for all GmSA-rhodamine conjugates with the exception of GmSA-TAMRA, which demonstrated an increase in fluorescence intensity with decreasing pH at all values tested.

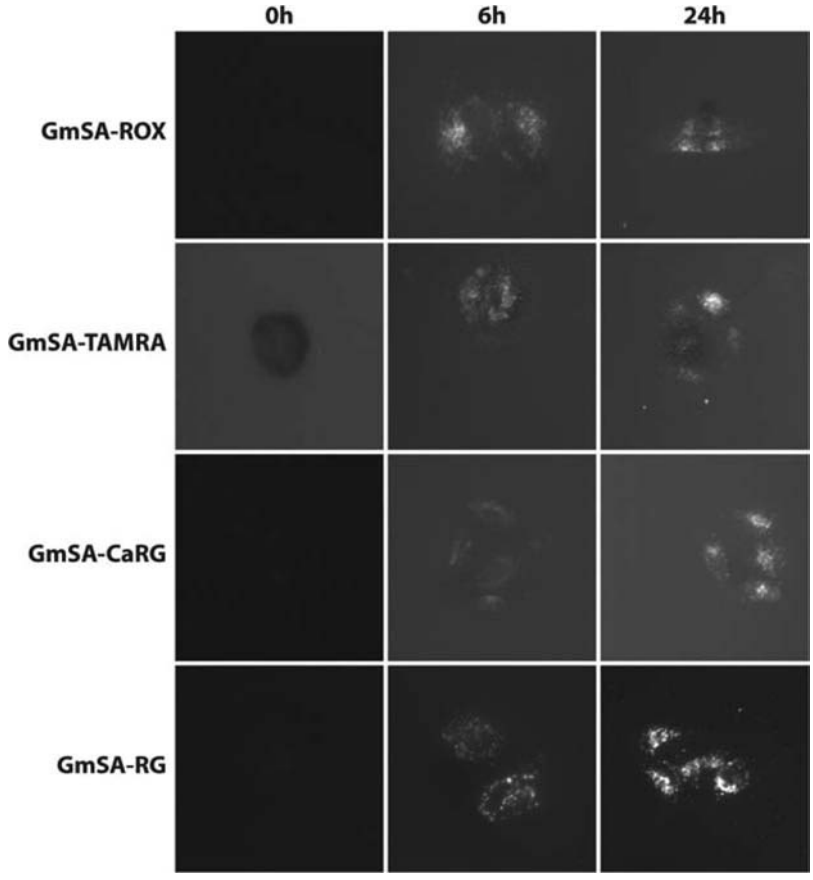

Figure 3. Serial fluorescence microscopy images of SHIN3 ovarian cancer cells treated with 3 μg/mL of GmSA-RG, GmSA-CaRG, GmSA-TAMRA, or GmSA-ROX. SHIN3 cells were incubated with each of the four GmSA-rhodamine fluorophore conjugates for 0, 6, or 24 h and fluorescence microscopy was then performed after washing with PBS. No fluorescence was detected in cells imaged immediately after treatment with GmSA-rhodamine fluorophore conjugates (at the incubation time point of 0 h) suggesting that optical probes had not yet undergone cellular internalization. Intracellular fluorescence was detected for all conjugates at the 6 h and 24 h incubation time points.

in all four GmSA-rhodamine conjugates compared to controls (Table 1). When measured using a fluorescence spectrometer (Perkin-Elmer LS55, Perkin-Elmer, Shelton, CT, USA), ratios for GmSA-RG, GmSA-CaRG, GmSA-TAMRA, and GmSA-ROX with and without SDS treatment were 6.9, 11.3, 34.3, and 3.3, respectively (Table 1). When measured with a multispectral

camera (Maestro In-Vivo Imaging System CRi Inc., Woburn, MA, USA), fluorescence intensity ratios for GmSA-RG, GmSA-CaRG, GmSA-TAMRA, and GmSA-ROX with and without SDS treatment were 6.6, 5.0, 18.1, and 4.1 (Table 1). Unfortunately, due to limitations in excitation filters available for the multispectral camera, excitation wavelengths were closer to optimal for some dyes than for others, and therefore comparison of ratios obtained with the two measurement techniques is not valid.

Although an important characteristic of xanthene ring fluorophores is their ability to undergo a synthesis reaction through the amino-reactive form by adding a succinimidyl ester, ultimately permitting conjugation with virtually any protein or peptide via the branched amine-residues on the lysine or the N-terminal anime, when the amino-reactive forms of fluorescence dyes are conjugated with proteins or peptides, it is well-known that the emission efficacy (extinction coefficient) of fluorophores is generally decreased depending on the distinct couplings of fluorescence dyes and proteins. However, our data suggest that fluorescence intensity losses due to conjugation may be minimized by exposure of conjugates to lysosomal microenvironments (*6*).

After cellular internalization, probes encounter isolated chemical environments that may alter targeting protein conformation and possibly protein−fluorophore interactions. We attempted to simulate these changes with SDS treatment. Interestingly, we have found that fluorophore-conjugated proteins can emit more light than the original conjugates after either treatment with SDS, or after lysosomal catabolism, as previously demonstrated (*6*). Among the 4 conjugates tested here, GmSA-TAMRA showed the largest increase in fluorescence after SDS-induced protein unfolding (Table 1). This feature is important for imaging applications as it enables target cells to have "activatable" potential, allowing successfully targeted probes to emit more light than the unbound agent. We have previously reported several conjugates, NuAv-BODIPY-FL and Avidin/GSA-ROX, which demonstrate such activatable characteristics and are capable of highly specific tumor targeted imaging (*9, 11*). Although we have observed this to be a general property of the rhodamine family of dyes, the data presented here suggest that the rhodamine family of dyes possess an inherent activatable characteristic. This "rhodamine effect" is most notably demonstrated by TAMRA.

Activation strategies are often independent and may have an additive effect when combined. Therefore, utilization of the rhodamine fluorescence characteristic in conjunction with other activation approaches, such as photon electron transfer, may aid in the development of fully activatable probes that exhibit fluorescence only after cellular internalization (*12*). Such probes represent an important goal in optical probe development as fluorescence due to nonspecific binding would be substantially reduced, providing maximum contrast of targeted tumors.

Intracellular Fluorescence Evaluation. To confirm fluorescence retention after cellular internalization, SHIN3 cells were incubated with each of the 4 fluorophore conjugates for 0, 6, or 24 h, and then imaged using fluorescence microscopy (Figure 3). Fluorescence microscopy revealed that all four GmSA-rhodamine conjugates demonstrated fluorescence after cellular internalization and that longer incubation resulted in increased brightness, likely due to increased intracellular accumulation of the respective fluorophore conjugate (Figure 3). However, the excitation filters were not optimized equally for all four conjugates. For instance, the excitation of ROX was not optimized in comparison to the other three conjugates.

Flow Cytometry. Not only do targeting probes need to remain fluorescent immediately after cellular internalization, but probes must also retain fluorescence for prolonged periods to be used clinically. To evaluate fluorescence longevity, one-color flow cytometry was performed using fluorophore conjugates in SHIN3 cancer cells. SHIN3 cells (1×10^4) were plated on a 12-chamber culture well and incubated for 16 h. GmSA-RG, GmSA-CaRG, GmSA-TAMRA, or GmSA-ROX was added to the medium (3 μg/mL), and the cells were incubated for 3 h to ensure dye internalization and then rinsed and placed in conjugate-free media. Flow cytometry was performed at 0, 6, and 24 h after transfer to conjugate-free media. Flow cytometry data for GmSA-RG, GmSA-CaRG, GmSA-TAMRA, and GmSA-ROX confirmed the presence of the 4 fluorophore conjugate treated cell populations (Figure 4, upper) and revealed that over time, the mean fluorescence index (MFI) decreased for each dye by 41.7%, 40.3%, 23.1%, and 5.0%, respectively, at 24 h. The rate of reduction in MFI was comparable for GmSA-RG and GmSA-CaRG (Figure 4, lower). Although the green excitation laser excited ROX less efficiently than the other 3 fluorophores, which may result in a slight underestimation of relative decrease of fluorescence intensity, GmSA-ROX dem-

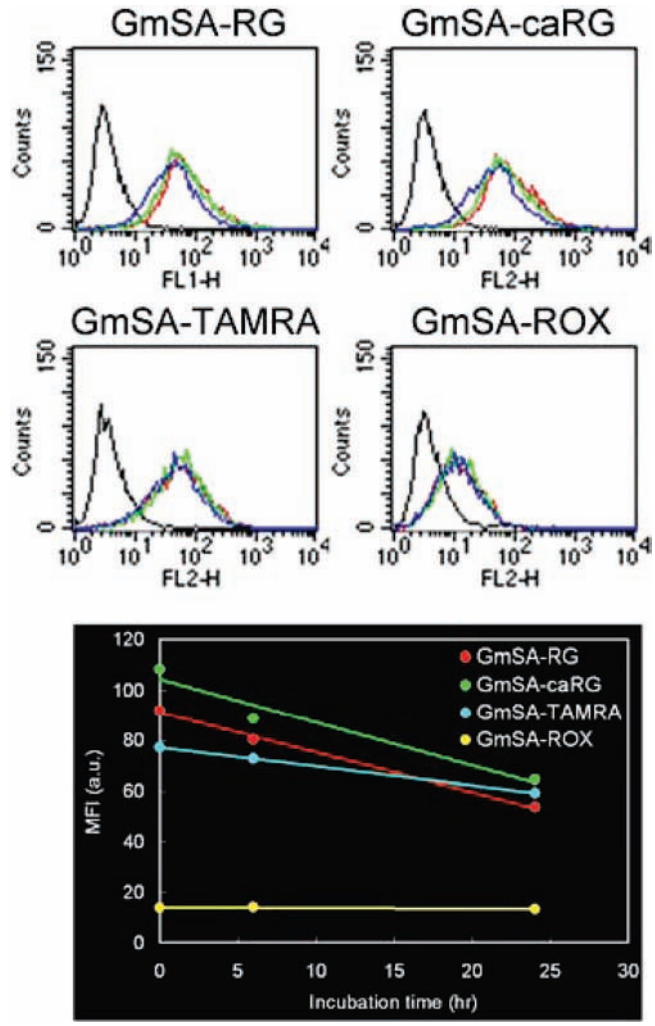

Figure 4. Change in fluorescence intensity over time. SHIN3 cancer cells treated with 30 μg/mL of GmSA-RG, GmSA-CaRG, GmSA-TAMRA, or GmSA-ROX for 3 h then rinsed and placed in dye-free media. One-color flow cytometry was performed after 0, 6, or 24 h incubation in dye-free media. (Upper) One-color flow data confirmed the presence of the 4 GmSA-rhodmamine conjugate treated cell populations. (Lower) Graphical depiction of flow data for GmSA-RG, GmSA-CaRG, GmSA-TAMRA, and GmSA-ROX. The rate of reduction in mean fluorescence index (MFI) was comparable for GmSA-RG and GmSA-CaRG, while GmSA-ROX demonstrated the lowest reduction in MFI over the 24 h time period and GmSA-TAMRA demonstrated the second lowest decrease in MFI over 24 h.

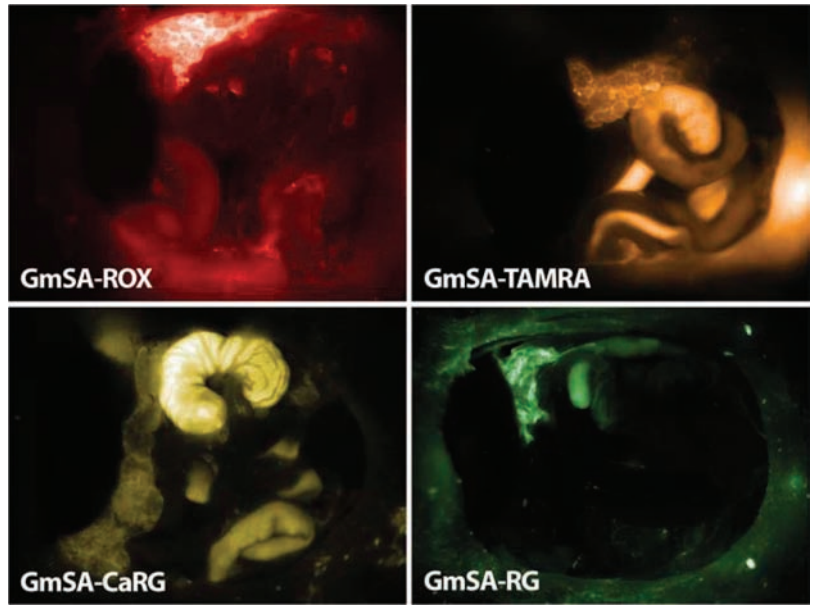

Figure 5. Representative monochromatic whole abdominal images of four mice with intraperitoneally disseminated SHIN3 ovarian cancer obtained 3 h after intraperitoneal injection of 12.5 μg of GmSA-RG, GmSA-CaRG, GmSA-TAMRA, or GmSA-ROX. Image wavelength corresponded to the peak emission-spectra wavelength for each GmSA-rhodamine conjugate. These images demonstrate that rhodamine optical probes effectively target SHIN3 cell tumors and result in tumor enhancement over background normal tissue. Images are depicted in the monochromatic color that corresponds to the fluorescence of each probe for presentation value only. Gray-scale monochromatic images similar to those shown here were used to calculate signal-to-background ratios of rhodamine fluorophore-targeted tumors.

Table 3. Summary of Fluorophore Performance in Parameters Critical to *in Vivo* Optical Imaging

in vivo imaging criteria	fluorophore performance	impact on images
fluorescence intensity at low ph	CarRhodG> TAMRA > RhodG > ROX	minor
fluorescence intensity after targeting protein unfolding	TAMRA > CarRhodG or RhodG > ROX	major
fluorescence-persistence after cellular internalization	ROX > TAMRA > CarRhodG > RhodG	minor
target-to-background ratio	TAMRA > RhodG > CarRhodG > ROX	moderate

onstrated the lowest reduction in MFI over the 24 h time period and GmSA-TAMRA demonstrated the second lowest decrease in MFI over 24 h (Figure 4).

Many *in vivo* applications of optical imaging agents involve administration of the targeted fluorophores before surgical or endoscopic procedures. It is therefore necessary for targeted imaging probes to have prolonged fluorescence half-lives to permit the completion of endoscopic or surgical procedures. Fluorescence longevity, which would derive from chemical, biological, and photophysical properties of a dye, is an important parameter to consider in probe selection. Unlike radionuclide counterparts, optical probes are prone to chemical degradation that cannot be "decay adjusted." Among the four conjugates, GmSA-ROX and GmSA-TAMRA demonstrated the lowest decrease in MFI 24 h after probe administration and therefore had the most persistent fluorescence. However, when considering multimodality and/or multiple color imaging (*13*), optical probes may not be the time-determining agent in the cocktail and therefore fluorescence longevity becomes an increasingly important parameter.

Target-to-Background Ratio of Fluorophore Targeted Tumors versus Normal Tissue. Ultimately, the goal of *in vivo* optical imaging, as applied to the detection of cancer, is to enable effective identification and removal of targeted tissues. This requires targeting probes that are easily recognized among a complex anatomic background, which often possess autofluorescent properties. To evaluate which GmSA-rhodamine probe offered the highest fluorescence signal over normal surrounding anatomic features, each of the 4 GmSA-fluorophore conjugates was injected into the peritoneal cavities of mice with disseminated peritoneal SHIN3 ovarian cancer implants ($n = 3$ for each fluorophore conjugate) and multispectral fluorescence images of the whole abdominal cavity were obtained 3 h later. Monochromatic images corresponding to the wavelength of the emission spectra peak for each fluorophore conjugate (Figure 5) were created from whole abdominal multispectral images and signal-to-background ratios of targeted tumors were determined by placing an ROI over tumors and ROIs over the surrounding normal tissues (skin, intestines, and liver) and a ratio of ROI average signal intensity value of targeted tumors versus selected anatomic features was generated. The average signal-to-background ratios of tumors targeted with GmSA-RG, GmSA-CaRG, GmSA-TAMRA, or GmSA-ROX to normal tissue was 7.5, 7.2, 11.0, and 5.9, respectively (Table 2). Thus, GmSA-TAMRA demonstrated the highest target-to-background ratio, while GmSA-ROX demonstrated the lowest ratio. In addition, when comparing target-to-background values, GmSA-TAMRA demonstrated the highest signal-to-background ratio in each case with the exception of the intestines, in which GmSA-RG was slightly better (Table 2).

The clinical application of optical imaging to surgical and endoscopic procedures requires optical probes that permit *in vivo* identification of targeted tissues. Optimal visualization of optical probes *in vivo* relies upon both probe fluorescence intensity and the level of contrast of tumor targeted fluorophores compared to the naturally occurring autofluorescence of skin and visceral organs. GmSA-TAMRA and GmSA-RG demonstrated the highest signal-to-background ratios, implying that these probes may permit the best visualization of targeted tissues *in vivo*.

Optical imaging represents a powerful technology for cancer research. Currently, *in vivo* imaging applications include: (1) the study of cancer biology *in vivo* through expression and imaging of endogenously expressed fluores-

cent proteins and (2) the development of clinical approaches for the treatment of cancer with disease-specific fluorescent probes. Early studies involving imaging of fluorescent proteins revealed the power of optical imaging in cancer biology, such as for the repeated imaging of cancer invasion and metastasis in longitudinal studies (*14–16*). One limitation to the use of fluorescence proteins for cell labeling in humans is that this process necessitates gene transfection, which is typically achieved in animal models with use of viral infection. Small fluorescent molecules such as organic fluorophores, however, may be used similarly to conventional contrast agents and are therefore more well-suited for development of optical probes for clinical applications as they do not require manipulation of the host genome. Additionally, fluorophores are small and easily conjugated to targeting proteins such as antibodies.

Rhodamine core-based fluorophores are characterized by a xanthene ring core with flanking amine residues (Figure 1). However, the structure of the amine side chains varies among core constructs (Figure 1), which results in distinct energy differences between basic and excited states and the characteristic fluorescence emission wavelengths of each dye. It is possible that variation in amine residues affects fluorescence properties of rhodamine-targeting protein conjugates *in vitro* and *in vivo*. In this study, we chose 4 well-known rhodamine fluorescent dyes with xanthene ring cores and distinct flanking amine residues: RG with primary amines, CaRG with secondary amines, and TAMRA and ROX with tertiary amines (Figure 1). In addition, variation exists within the chemical structure of the tertiary amine-containing rhodamine dyes as ROX possesses cyclic tertiary amines while TAMRA possess dimethyl amines (Figure 1). These structural differences likely affect fluorescence behavior *in vitro* and *in vivo*. For example, the bis-primary amine of RG may permit effective hydrogen bonding and the stereochemistry enables increased accessibility of the electron pair, likely enhancing basicity compared to secondary or tertiary amines. Differences in emission wavelength due to distinct side chains also affect the signal-to-background ratios of targeted tissue for *in vivo* imaging.

It is well-known that rhodamine core derived fluorophores offer a combination of desirable properties for optical imaging, including good photostability, high extinction coefficient, and high fluorescence quantum yield. Herein, we demonstrated that the rhodamine-fluorophores, CaRG and TAMRA, may represent superior probes for *in vivo* optical imaging applications (Table 3). Advantages to the use of CaRG include high fluorescence intensity at low pH and increased fluorescence intensity of fluorophore-targeting protein constructs in low pH environments. Advantages of TAMRA include superior fluorescence in low pH, persistent fluorescence after internalization and, importantly, superior *in vivo* signal-to-background ratios compared to other rhodamine core fluorophores. In addition, the data presented here suggest that rhodamine dyes possess an inherent activatable characteristic that is most markedly demonstrated by the TAMRA fluorophore. This is an important finding as creation of activatable probes would be of significant development for *in vivo* optical imaging.

Optical imaging represents an important technological advance that has the potential to improve the efficacy of surgical and endoscopic approaches to cancer treatment (*17, 18*). The physical accessibility of tumor implants has been shown to be an important criterion for optical probe selection. However, an equally important consideration is the effect of *in vivo* specific conditions on optical probe function. It was previously shown that RG possesses the highest emission efficiency after cellular internalization (*6*). With this in mind, we evaluated rhodamine core fluorophores with the following parameters critical to the *in vivo* application of optical imaging probes: probe function at low pH and protein-denaturing chemical environments, fluorescence persistence after internalization, and ultimately target-to-background ratios of fluorophore-targeted tissues. Using *in vivo* assays directly and *in vitro* assays aimed to simulate living cell conditions we demonstrated that members of the rhodamine core fluorophore family differ with regard to *in vivo* imaging functionality.

CONCLUSION

The rhodamine-core fluorophores represent a widely used group of fluorescent dyes for *in vivo* optical imaging. However, despite their ubiquitous use, a direct comparison of the performance of the rhodamine probes was previously lacking. Herein, we presented a comparison of 4 rhodamine-core fluorophores and determined that the TAMRA fluorophore represents a superior probe for *in vivo* optical imaging applications. Advantages to use of TAMRA include superior fluorescence in low pH and protein-denaturing environments, preserved fluorescence longevity postcellular internalization, and importantly, superior *in vivo* signal-to-background ratios compared to other rhodamine core fluorophores.

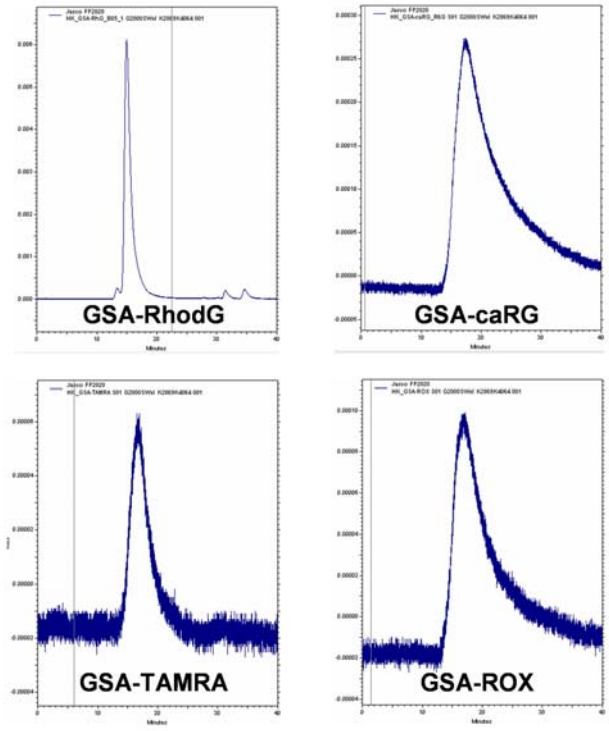
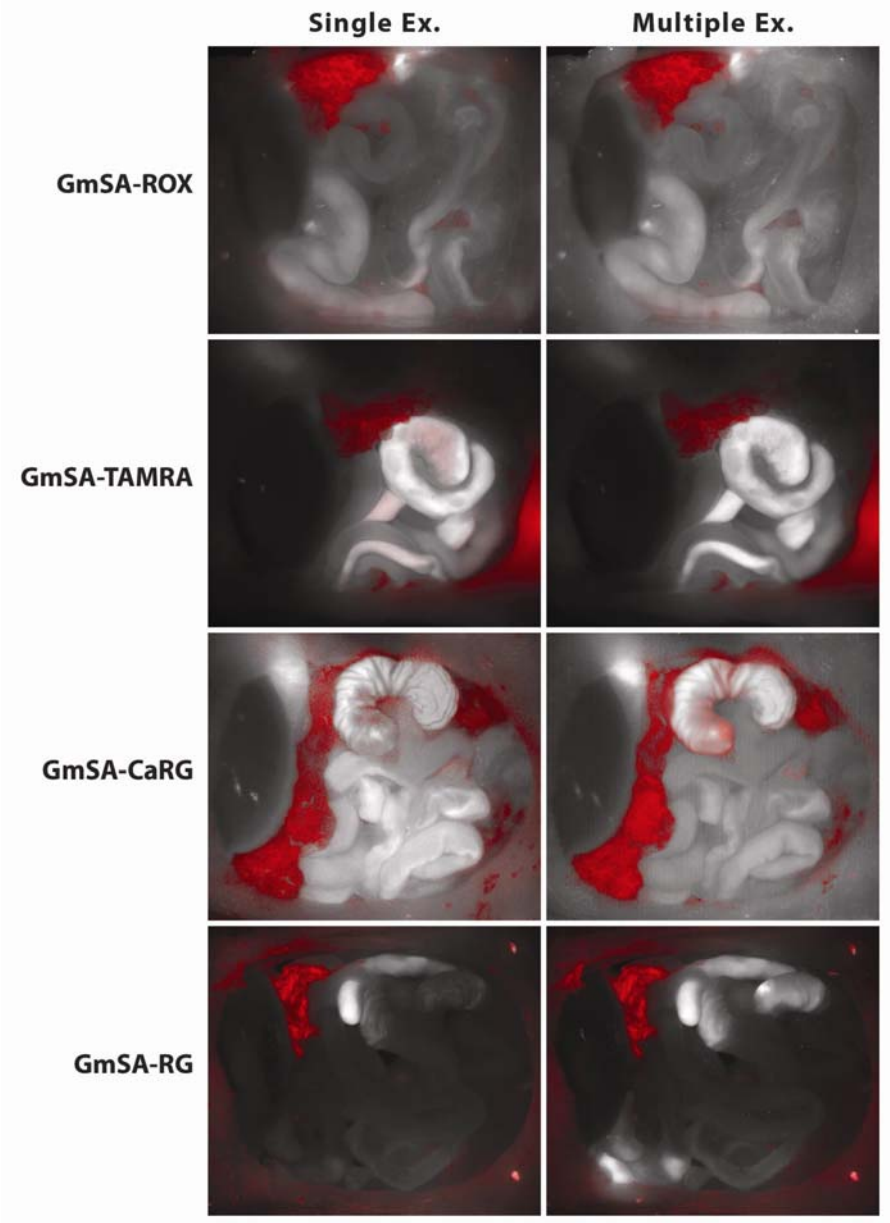
Supplemental Figures



Supplemental Figure 1. High Performance Liquid Chromatography (HPLC). HPLC was conducted to verify that each dye was conjugated to galactosamine serum albumin (GmSA). It is notable that all conjugates showed slightly different retention profiles. This is most likely due to changes of hydrophobicity and/or adherence to the column. This data verifies that all dyes (> 97%) were associated with macromolecule (GmSA) and small molecules with fluorescence are minimal after gel-filtration with PBS.



Supplemental Figure 2. Unmixed whole abdominal images of GmSA-rhodamine targeted tumor implants. Spectral fluorescence imaged of the whole abdominal cavity as well obtained. Using spectral unmixed algorithm, the fluorescence of tumors were clearly distinguished from autofluorescence of the intestines and other organs. Unmixed images of the peritoneal cavities demonstrated that GmSA-RG, GmSA-CaRG, GmSA-TAMRA, and GmSA-ROX depicted the tumor foci.

The early detection of osteoarthritis (OA) is currently a key challenge in the field of rheumatology. Biochemical studies of OA have indicated that matrix metalloproteinase-13 (MMP-13) plays a central role in cartilage degradation. In this study, we describe the potential use of a dark-quenched fluorogenic MMP-13 probe to image MMP-13 in both *in vitro* and rat models. The imaging technique involved using a MMP-13 peptide substrate, near-infrared (NIR) dye, and a NIR dark quencher. The results from this study demonstrate that the use of a dark-quenched fluorogenic probe allows for the visual detection of MMP-13 *in vitro* and in OA-induced rat models. In particular, by targeting this OA biomarker, the symptoms of the early and late stages of OA can be readily monitored, imaged, and analyzed in a rapid and efficient fashion. We anticipate that this simple and highly efficient fluorogenic probe will assist in the clinical management of patients with OA, not only for early diagnosis but also to assess individual patient responses to new drug treatments.

Degenerative joint diseases including osteoarthritis (OA) are common, particularly in the elderly. General awareness of OA is low because this condition is typically considered to be an effect of aging. The initial stages of OA are clinically silent. Therefore, people may have the disease for years with no symptoms, and when symptoms do occur, the disease has often already reached an advanced stage. However, if it was possible to monitor and assess the disease states of OA, treatment could begin before significant damage occurs. For these reasons, early detection of OA is a key challenge in the field of rheumatology. The challenges posed in identifying OA are the detection of both early and subtle changes of joint and articular cartilage. Early signs of OA are characterized by the progressive loss of proteoglycan aggrecan, which is reflected by excessive damage to type II collagen. A decrease in proteoglycan aggrecan ultimately results in the loss of articular cartilage (*1*). X-rays and computed tomography (CT) can show large changes in a joint based on bone density; however, these techniques do not reveal detailed surface information (*2*). Although magnetic resonance imaging (MRI) (*3*) and ultrasound (US) (*4*) techniques recently provided both surface and internal details of articular

cartilage, the limited resolution of these techniques prevent them from being able to detect small differences in the early stages of OA.

Recent progress in fluorescence-based optical imaging is paving the way for the development of novel methods in many biomedical areas, ranging from the detection of pathologies to biomolecular targets, i.e., biomarkers (*5, 6*). Biomarkers are molecules that reflect a specific pathological process or a response to therapeutic intervention. Biochemical studies in OA have indicated that there are various kinds of accessible biomarkers in OA, including matrix metalloproteinase (MMP), hyaluronic acid, osteocalcin, etc. (*7*). Therefore, the development of new technologies for the rapid, sensitive, and accurate optical imaging of specific biomarkers in OA would provide a method to diagnose OA early on and to assess the severity of the disease. One of the fundamental pathways in cartilage degradation is the up-regulation of expression of the MMP genes. Several lines of evidence have suggested that matrix metalloproteinase-13 (called MMP-13 or collagenase 3) promotes degradation of the cartilage extracellular matrix (*8, 9*). It was reported that MMP-13 expression occurred at very low levels in normal cartilage but was particularly upregulated in degenerating cartilage (*7*). The presence of excess MMP-13 in OA offers the possibility for successful MMP-13 targeted OA imaging and also for detecting MMP-13 inhibition (*10*) for OA treatment.

Conventional fluorogenic peptide kits for MMPs are available; however, they have had limited use *in vitro*. We have previously reported on the use of target biomolecules that are activated by fluorescence probes based on a FRET mechanism and the self-quenching properties of NIRF. However, these targets provided insufficient resolution for *in vitro* imaging (*11*−*13*). The limited resolution in this study was mainly attributed to a low signal-to-noise (S/N) ratio. Therefore, high quenching efficiency and specific recognition properties by target biomolecules that have improved S/N ratio are essential for the development of sensitive *in vitro* biomolecular probes. In this study, we describe the potential use of MMP-13 activatable near-infrared fluorescence (NIRF) dark-quenched fluorogenic probe for early OA diagnosis *in vitro* and in MMP-13 inhibitor screening.

On the basis of the known MMP-13 substrate, PLGMRG (*14*), we first designed different probes using a combination of the linker peptide and two bulky chemicals, Cy5.5 and the black hole quencher-3 (BHQ-3) (*15*). By modeling the X-ray crystal structure of hMMP-13, **1** was synthesized using standard solid-phase Fmoc peptide chemistry as an MMP-13 imaging probe (see Supporting Information, Figures 1S and 2S). As shown in Figure 1A, **1** is composed of (i) Cy5.5, which was used as the near-infrared (NIR) dye (ex/em; 675/695) and is adequate for *in vitro* imaging since it emits fluorescence above 650 nm where autofluorescence is minimal, (ii) a short peptide sequence, G*PLGMRG*LGK, which was used as the MMP-13 cleavable substrate (the recognition site indicated by italics with the cleavage site between G and L; see SI for details), and (iii) (BHQ-3), which was used as the NIR dark-quencher specific for Cy5.5 (abs. 650 nm). As a control, a probe containing a noncleavable linker **2**, which was composed of the scramble peptide sequence GRMGLPLGK was also prepared. There are two basic concepts of fluorogenic peptides when used for NIR imaging, which depends on the type of quencher used. In one case, the fluorescent pairs are composed of the dye-based donor and acceptor (fluorescence dye−dye quenching system), and in the second case, the acceptor is chemically different from the dye and does not fluoresce. Dark-quenched fluorogenic peptides have distinct advantages over conventional dye−dye quenched peptides. BHQ-3 is a dark quencher that has no native fluorescence and has maximal absorption in the 620 to 730 nm range, which can efficiently quenching fluorophores that emit in this range, i.e., Cy5.5. Therefore, Cy5.5 is spectrally matched with a BHQ-3, and FRET quenching can be maximized. The quenching properties of the probe were analyzed and visualized

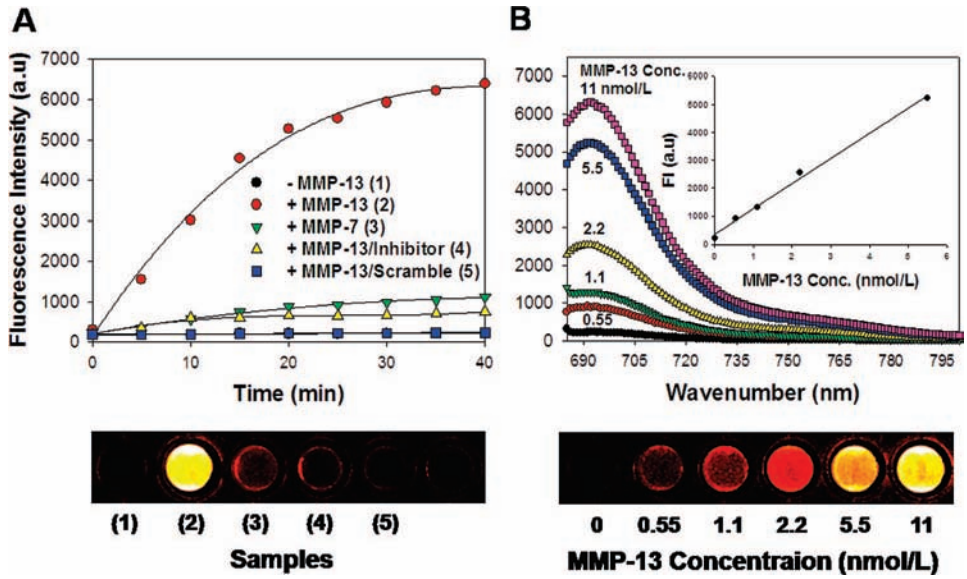

Figure 2. MMP-13 specificity of **1** in solution. (A) Fluorescence emission kinetic spectra of **1** (80 pM) in the presence of various stimuli (MMP-13 and MMP-7, 11 nmol/L; MMP-13 inhibitor) after a 40 min incubation at 37 °C. Below, fluorescence image sections of the 96-well microplate containing different combinations. (B) Fluorescence emission spectra of **1** in the presence of various concentrations of MMP-13 after a 40 min incubation at 37 °C; inset, MMP-13 standard curve; below, corresponding fluorescence image sections of a 96-well microplate.

using a spectrofluorometer with a fixed excitation wavelength of 675 nm and a Kodak Image Station 4000MM equipped with filter for Cy5.5. As shown in Figure 1B, increased concentrations of **1** in the 96-wells microplate did not affect the background NIR fluorescence signal. To determine the effect of activated MMP-13 on the NIR fluorescent signal, 11 nmol/L MMP-13 was activated by incubation with 2.5 mmol/L of *p*-aminophenyl mercuric acid in the reaction buffer (100 mM of Tris, 5 mM of calcium chloride, 200 mM of NaCl, and 0.1% of Brij) for 1 h at 37 °C. MMP-13 treatment resulted in an increased recovery of the NIR fluorescence signal, which depended on probe concentration (approximately 9, 22, 26, 37, 48-fold for 1.6, 16, 32, 80, 160 pM of the probe vs without MMP-13). The use of cleavable, dark-quenched NIR fluorescent probes resulted in significantly lower fluorescent backgrounds, which were amplified by the addition of MMP-13, thereby resulting in a highly sensitive visual detection method.

The selectivity of the MMP-13 probe was examined *in vitro* by incubating **1** (80 pM) in a cuvette containing the reaction buffer and 11 nmol/L activated MMP-13, MMP-7, MMP-13 with the MMP-13 inhibitor (pyrimidine-4,6-dicarboxylic acid, bis-(4-fluoro-3-methyl-benzylamide)) (*16*), or MMP-13 with **1**. After incubation in the reaction buffer at 37 °C for 40 min with the respective enzymes and inhibitor, the NIR fluorescence emission signals of the samples were measured using a spectrofluorometer. Simultaneously, each sample was moved into a 96-well microplate and imaged using a Kodak Image Station 4000MM. As shown in Figure 2A, the kinetics of the enzyme was evaluated and visualized through fluorescence images. The spectrofluometry plots clearly demonstrate that significant recovery of the NIR fluorescent signals only occurred in the samples containing MMP-13 (approximately 32-fold over that without MMP-13). The fluorescent signal recovery of **1** was inhibited in the presence of the MMP-13 inhibitor, thus providing clear evidence for the selectivity of **1**. Measurements were then performed under the same experimental conditions at different concentrations of activated MMP-13 (0, 0.55, 1.1, 2.2, 5.5, and 11 nmol/L; Figure 2B) in the presence of a fixed concentration of **1** (80 pM). In these experiments, there was a linear relationship between the recovered NIR fluorescent signals and MMP-13 concentrations up to 5.5 nmol/L ($r^2 = 0.995$) when **1** was used. This was further confirmed by the fluorescence images. Taken together, these results indicate that **1** could be used for quantitative and visual analysis of MMP-13 activity.

After the systematic validation of the utility of **1**, *in vitro*, its use *in vivo* was demonstrated using *in vivo* fluorescence tomography (*16*) (Kodak Image Station and eXplore Optix; see Supporting Information) in an experimental rat model of intermediate (six week OA-induced rats) and late-stage OA (eight week OA-induced rats; see Supporting Information) (*17*). Representative images are depicted in Figure 3. NIR fluorescence signals were monitored using the Kodak Image Station 1 h after intracartilage injection of **1** (10 μg/100 μL saline/cartilage, 4 nM) into OA-induced and normal cartilage rats. When **1** was injected into the normal side, NIR fluorescence signal intensity did not substantially increase. In contrast, **1** in OA-induced cartilage produced strong NIR fluorescence signals that were clearly visualized in the fluorescent images (1.3 ± 0.2, 3.3 ± 0.7, and 7.4 ± 1.4-fold vs normal side for 0, 6, and 8 weeks, respectively; $n = 3$). NIR fluorescence signals in the eight-week OA rat had a 2.2-fold increase relative to the six-week OA rat. Furthermore, the histological section of the normal cartilage showed a smooth articular surface with clear demarcation between the cartilage and subchondral bone. In contrast to the control, the images of the six and eight week OA-induced rats show a distinct erosion of the cartilage and a significant alteration in the bone−cartilage interface. These results confirm the feasibility of using **1** for the detection and visualization of upregulated MMP13 in relation to determining the stage of OA development *in vivo*.

For quantitative image analysis of the upregulation of MMP-13 in the OA rat model, similar *in vivo* imaging of OA was conducted 1 h after the injection of **1** with or without the MMP-13 inhibitor in the eight week OA rat model using a preclinical optical imaging system, eXplore Optix (ART Advanced Research Technologies Inc., Montreal, Canada) configured for NIR fluorescence detection (see Supporting Information). Figure 4A shows typical NIR fluorescence images of normal and OA cartilage obtained during the 1 h time period after the intracartilage injection of **1**. The total photon counts in normal and OA cartilage, which were quantified using Analysis Workstation Software (ART Advanced Research Technologies Inc.), were $(3.6 \pm 0.2) \times 10^6$ and $(11.5 \pm 1.73) \times 10^6$, respectively, and the NIR fluorescence intensity ratio between OA and normal

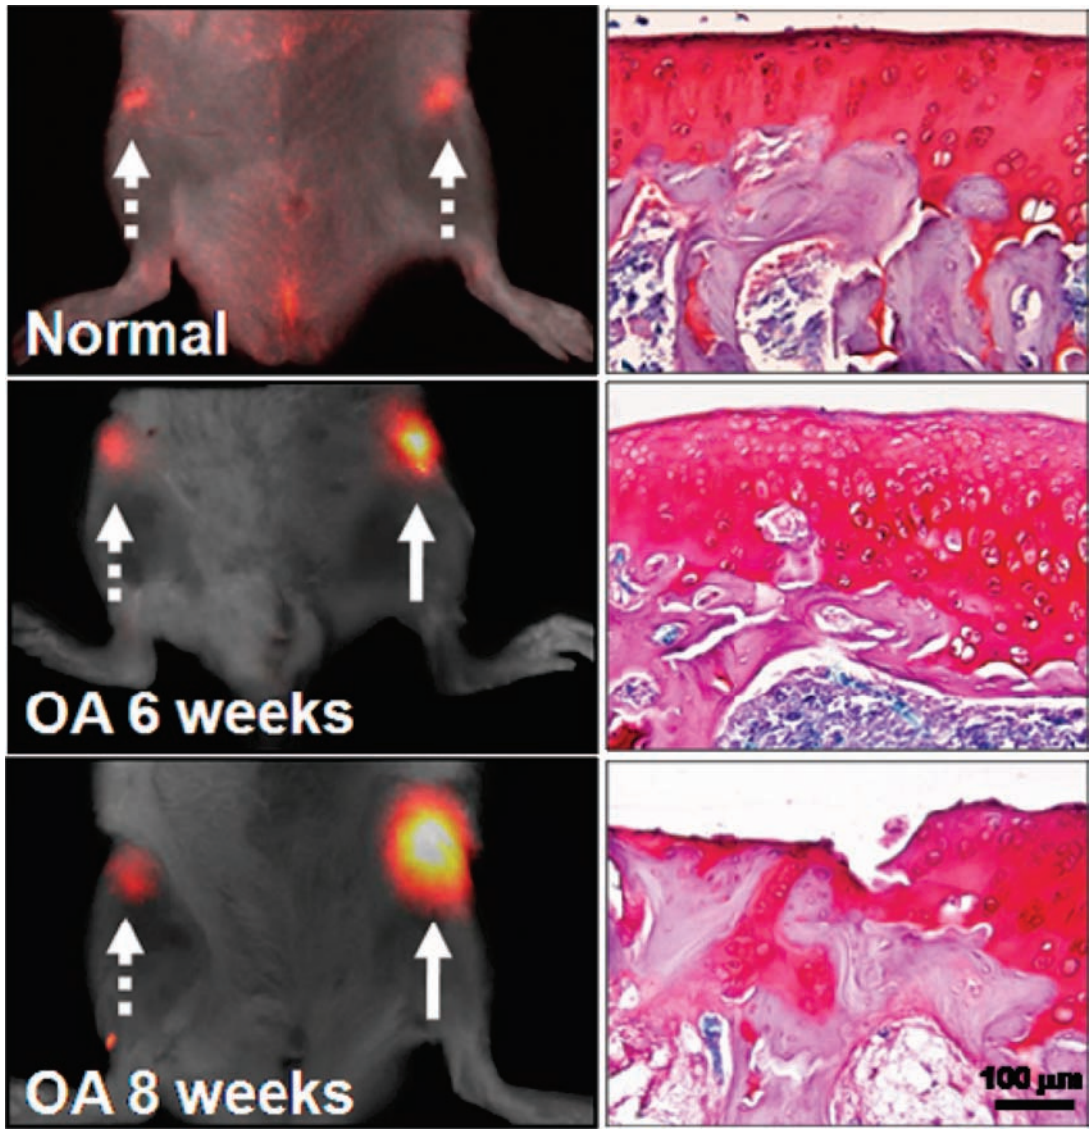

Figure 3. *In vivo* imaging of upregulated MMP-13 in normal, six, and eight week OA-induced cartilages 1 h after intracartilage-injection of **1** (4 nM). Left: NIR fluorescence reflectance imaging of normal and OA cartilage after local injection of **1**. Right: Histological evaluation of normal, six, and eight week OA joints by Safranin-O staining. Arrows: dotted line (normal) and solid line (OA).

cartilage (O/N) was approximately 3.2-fold ($p < 0.001$) (Figure 4B). However, fluorescence contrast was significantly reduced ($(4.7 \pm 0.8) \times 10^6$) when the MMP-13 inhibitor was administered 30 min before the injection of **1**. To analyze the depth profiles from the fluorescence images, the three-dimensional (3D) images were constructed by examining the intensity in slices cut along the Z-axis, which represented the two-dimensional (2D) slices, starting at $Z = 2$ to 7 mm deep (Figure 4C). The images from the OA-induced rats displayed a strong fluorescence signal between the depths of 3 to 5 mm, whereas normal and inhibitor treated cartilage displayed significantly low signals. Displaying the images in 2D allowed for the visualization of the expression and distribution of MMP-13 in OA cartilage. This may be useful for the longitudinal monitoring of the OA response in diagnosis and therapy. Overall, these data show that **1** is activated by MMP-13 and could produce strong NIR fluorescence signals, which enables OA imaging *in vivo*.

In summary, this study clearly demonstrates the potential use of the dark-quenched fluorogenic MMP-13 probe for the facile visual detection of MMP-13 *in vitro* and *in vivo*. In particular, by targeting a specific OA biomarker, the symptoms and development stages of OA can be readily and easily monitored, imaged, and analyzed in a rapid and efficient fashion. In addition, this technique can be widely applied to any target protease-based disease diagnosis and high-throughput drug screening simply by changing the specific peptide−substrate linker between the fluorophores and quenchers. Recently, the development of optical imaging instruments and sophisticated imaging probes have allowed researchers to detect and monitor molecular targets in live cells and in *in vivo* in real-time. However, because of the depth limitation of current optical imaging instruments, these techniques are only applicable to small animal models and superficial human tissues. Therefore, in order to translate dark-quenched imaging probes from preclinical studies to patients, the problems associated with interrogating fluorescence in deep tissue need to be addressed. We can envision improvements in imaging technologies that will allow optical probes to be used in larger subjects, and we anticipate that this simple and highly efficient fluorogenic probe will assist in the clinical management of patients with OA in the near future, not only for early diagnosis but also for assessing the response to treatment.

Structure-based probe design.

MMP family proteins have highly conserved sequences and these proteins share a conserved substrate binding pocket and cleavage mechanism. From the peptide-bound structures (PDB accession code: 2OY2, 1JAP), we built a model of peptide-bound MMP-13 using the program O (ref 1). Based on the known MMP-13 substrate, PLGMRG, we designed different probes by combining the linker peptide and two bulky chemicals, Cy5.5 and BHQ-3. First the shortest fluorogenic probe was prepared labeling the N-terminus and C-terminus with Cy5.5 and BHQ-3, respectively, Cy5.5-GPLGMRGK(BHQ-3)amide. Glycine and lysine were incorporated at both termini to provide the chemical conjugation sites for the Cy5.5 dyes and BHQ-3. However, the narrow binding pocket did not allow for the bulky dye and quencher, therefore, the short peptide, GPLGMRGK, failed to access the binding pocket. The short peptide inhibited accesses to the binding pocket because the bulky quencher clashed with the narrow binding pocket through steric hindrance between MMP-13 and BHQ-3 (Fig. 1SA). By considering the quenching of Cy5.5 by BHQ-3, we found that a peptide containing at least two amino acid sequences was required for effective binding to MMP-13.

Therefore, to achieve an efficient quenching and affinity to MMP-13, we chose the glycine and leucine-glycine-lysine incorporated peptide substrate, Cy5.5-GPLGMRGLGK(BHQ-3), as the fluorogenic probe for MMP-13 (Fig. S1B).

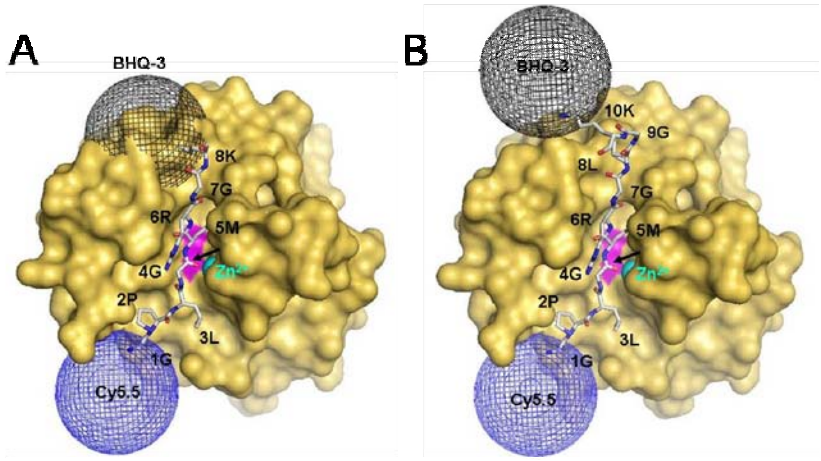

Fig. S1. Steric hindrance predicted by modeling. The molecular surface of Human MMP-13 and the peptide probes, GPLGMRGK and GPLGMRGLGK, which has Cy5.5 and BHQ-3 at both ends, are modeled in the binding pocket. Glutamic acid and Zn ion are colored by magenta and cyan. Arrow indicates the cleavage site. The short linker peptide, GPLGMRGK, results in a steric hindrance between MMP-13 and BHQ-3, thus, this substrate peptide does not have access to the binding pocket. Figures were drawn by the program Pymol (DeLano, W.L. The PyMOL Molecular Graphics System (2002) on World Wide Web [http://www.pymol.org]).

Synthesis of the probe

The peptide sequence of 1 was synthesized using standard sold-phase Fmoc peptide chemistry. For site-specific conjugation of BHQ-3 to the primary amine of the lysine adjacent to the cleavable sequence, the Dde protecting group was selectively removed by addition of 2% hydrazine in DMF. After selective lysine deprotection, BHQ-3 succinimide ester in anhydrous DMF was added and

reacted overnight followed by extensive washes of the peptide resin. Subsequently, the last Fmoc group was removed from the peptide resin and Cy5.5 succinimide ester was coupled to the N-terminal glycine. After deprotecting and cleaving the peptide from the resin using trifluoroactic acid, resulting 1 was further purified by semi-preparative reversed-phase high liquid chromatography (RP-HPLC) and characterized by analytical RP-HPLC, MALDI-TOF mass spectrometry (m/z: calculated: 2476.1).

Experimental animals and surgical procedures.

Sprague-Dawley rats (250~300g) were anesthetized with an intramuscular injection of ketamine (90mg/kg) and xylazine (10mg/kg). The right lower extremity was shaved and draped for aseptic surgery. After squeezing the leg, a sterile rubber tourniquet was applied for avascular filed during surgery. Under the operating microscope (Leica, M650, USA), the right knee joint was exposed using the anteromedial parapatellar approach. The patellar tendon was transected. Then, the anterior, posterior cruciate ligaments and the medial, lateral collateral ligaments were transected. The medial and lateral meniscuses were totally menisectomized. After copious irrigation with saline, the knee joint capsule was repaired with an absorbable suture and the skin was closed with a 4-0 monofilament nylon. The animals were allowed unrestricted activity, food, and water ad libitum.

In vivo NIRF imaging.

After intracartilage-injection of 1 (10 μg/100 μl/cartilage, 4 nM) in OA and normal cartilages, fluorescence signals in OA and normal cartilage were imaged using an in vivo fluorescence imaging systems (Kodak Image Station 4000MM Digital Imaging System and eXplore OptixTM). 1 h after MMP-13 probe injection, NIR fluorescence images of animals were obtained with a 12-bit CCD camera (Kodak Image Station 4000MM, New Haven, CT) equipped with a special C-mount lens and CY5.5 bandpass emission filter (680 nm to 720 nm; Omega Optical) to visualize and compare the expression of MMP-13 in OA and normal cartilage. The tomographic NIRF images to detect the action of MMP-13 in OA and normal cartilage, were taken by positioning the rats on an animal plate heated to 36°C in the eXplore Optix System (ART Advanced Research Technologies Inc., Montreal, Canada, ref 3). The animal was automatically moved to the imaging chamber for scanning. Laser power and count time settings were optimized 13 μW and 0.3 s per point.

Excitation and emission spots were raster-scanned in 1 mm steps over the selected region of interest to generate emission wavelength scans. A 670 nm pulsed laser diode was used to excite Cy5.5 molecules. NIR fluorescence emission at 700 nm was collected and detected with a fast photomultiplier tube (Hamamatsu, Japan) and a time-correlated single photon counting system (Becker and Hickl GmbH, Berlin, Germany). To establish the time-dependent excretion profile, the total NIR fluorescence intensity per selected region (100 mm2) in the cartilage was calculated. Quantitative data are calculated using the region of interest (ROS) function of Analysis Workstation software (ART Advanced Research Technologies Inc., Montreal, Canada), and values are presented as means ± SE for groups of three animals.

Ref 3. S. Bloch, F. Lesage, L. Mclntosh, A. Gandjbakhche, K. Liang, S. Achilefu, J. Biomed. Opt. 2005, 13, 632-641.

Histological analysis.

To compare the destruction of OA and normal cartilage, the whole knee joints were dissected, and fixed in 4% paraformaldehde buffered with PBS (pH 7.4) for 4 h at 4°C. After dehydration with an increasing concentration of ethanol and embedding in paraffin, 5 μm sagittal sections were cut from the joints. Sections were stained with Safranin-O-fast green (ref 2).

The Implications of Stochastic Synthesis for the Conjugation of Functional Groups to Nanoparticles

Stochastic synthesis of a ligand coupled to a nanoparticle results in a distribution of populations with different numbers of ligands per nanoparticle. This distribution was resolved and quantified using HPLC and is in excellent agreement with the ligand/nanoparticle average measured by ^{1}H NMR, gel permeation chromatography (GPC), and potentiometric titration, and yet significantly more disperse than commonly held perceptions of monodispersity. Two statistical models were employed to confirm that the observed heterogeneity is consistent with theoretical expectations.

Stochastic ligand conjugation is a common strategy to produce practical quantities of functionalized nanoparticles. Analytical methods used to quantify the average nanoparticle to ligand ratio, such as NMR, UV/visible spectroscopy, and elemental analysis, provide no information about the distribution of ligands bound to each particle. In this study, we quantitatively analyze the HPLC trace of the conjugated nanoparticle, including "tailing" effects, and show that the heterogeneity implied by the *entire* trace is consistent with theoretical expectations regarding the dispersity of the sample. The width of the distribution exceeds typical community expectations regarding sample homogeneity and is not well represented by a conjugated nanoparticle showing the average number of conjugated ligands. Given the importance of nanoparticle conjugates for applications such as drug delivery (*1*−*5*), biomedical diagnostics (*6*, *7*), and sensing (*8*, *9*), it is paramount that a detailed understanding of the product distribution resulting from a stochastic synthesis process be gained.

A number of groups have endeavored to characterize the distribution of ligands on nanoparticles. A variety of methods have been employed including gel electrophesis (*10*), anion-exchange HPLC (*11*), ultra performance liquid chromatography (*12*), mass spectrometry (*13*), and fluorescence quenching (*14*). In addition, synthetic efforts have focused on making particles with controlled 1:1 ligand/particle ratios (*15*−*18*). If a stochastic synthesis process is used to generate a 1:1 ratio, what percentage of the sample will be functional? In this study, we focus on the distribution that exists for ensembles with approximately one ligand per particle. This study employs partially acetylated dendrimers because these materials have been shown to be most effective for targeted drug delivery applications (*19*, *20*). The parent amine-terminated materials have been shown to nonselectively cause cell membrane permeability and are not suited for targeted drug delivery applications (*21*−*23*).

A series of reactions were conducted to conjugate varying amounts of 3-(4-(prop-2-ynyloxy)phenyl)propanoic acid to the surface primary amines of a partially acetylated generation 5 poly(amidoamine) dendrimer (G5 PAMAM; $G5(Ac)_{78}(NH_2)_{34}$) (Figure 1). Note that this ligand is suitable for "click" chemistry applications. These products were analyzed by ^{1}H NMR spectroscopy and HPLC. The ^{1}H NMR analysis, when combined with gel permeation chromatography (GPC) and potentiometic titration data, gives information about the average number of ligands bound per particle. The HPLC data, when combined with a peak fitting analysis, provide both the distribution of ligands per dendrimer and the average number of ligands per dendrimer.

The ligand−dendrimer conjugates (samples A−D) were determined to have an average of 0.20, 0.60, 1.04, and 1.47 ligands per dendrimer by comparing the integration of the methyl protons in the terminal acetyl groups to the aromatic protons on the conjugated ligand (Figure 2). The number of acetyl groups per dendrimer was independently determined by first computing the total number of end groups from the number average molecular weight (GPC) and potentiometric titration data for $G5\text{-}NH_2$(100%) as previously described (*24*). This value for the total number of end groups was applied to the ratio of primary amines to acetyl groups, obtained from the ^{1}H NMR of the partially acetylated dendrimer, to compute the average number of acetyl groups per dendrimer. This determination is sensitive to both the total number of particle functional groups and the number that have been acetylated. The excellent dispersity characteristics of PAMAM dendrimers (PDI = 1.01) greatly facilitates this analysis.

The HPLC elution profiles obtained at 210 nm for samples A−D are illustrated in Figure 3a, solid traces. The 210 nm

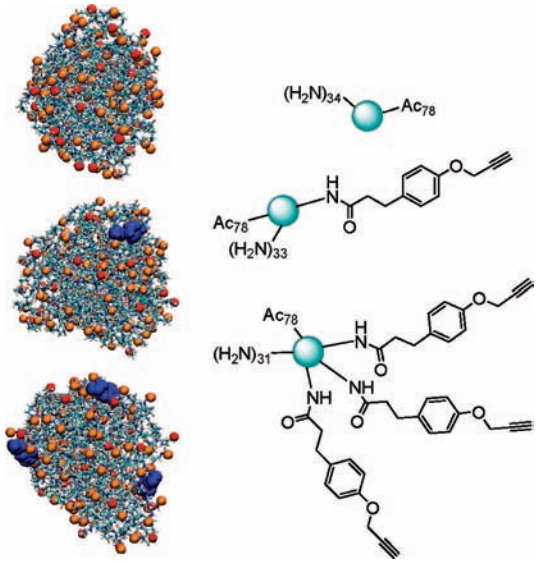

Figure 1. Equilibrated molecular dynamics models and schematics of G5 PAMAM dendrimers with different numbers of ligands. Terminal amines (red), acetyl groups (orange), and ligands (blue) are depicted in the models. Corresponding schematic representations show the dendrimer in teal with terminal groups. PAMAM dendrimers are monodisperse, highly ordered, water soluble, polymeric nanoparticles (~4.5 nm diameter). Terminal amines can be used as coupling points to attach different ligands.

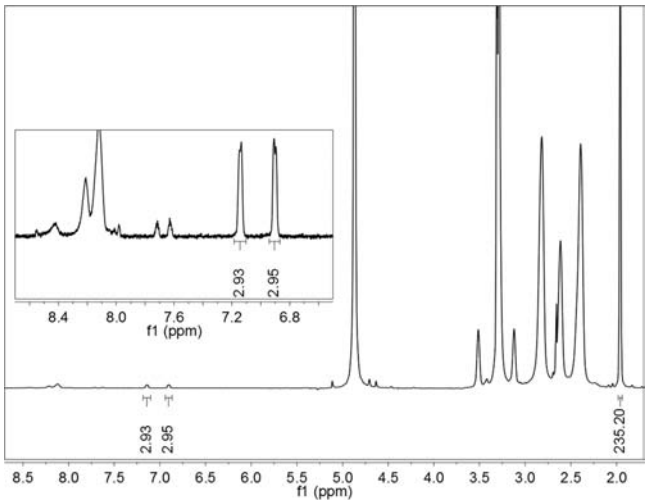

Figure 2. ^{1}H NMR spectrum for sample D. The average number of ligands per dendrimer was determined by comparison of the aromatic protons on the ligand vs the methyl protons in the acetyl group of the dendrimer. The number of acetyl groups was determined independently by GPC and potentiometric titration.

wavelength was selected because it is convenient for monitoring the PAMAM dendrimers and is not significantly affected by varying amounts of conjugated ligands (*25*). The first large peak (0) appears at an elution time consistent with unmodified $G5(Ac)_{78}(NH_2)_{34}$. The small peaks preceding peak 0 are also present in the original $G5(Ac)_{78}(NH_2)_{34}$ sample and likely result from a small amount of lower generation dendrimer (*26*). The second large peak (1) was preliminarily assigned as $G5(Ac)_{78}(NH_2)_{33}(L)_1$ (L= $NHCO(CH_2)_2C_6H_4OCH_2C_2H$) based upon elution order (Figure 3a, solid traces A−D). Additional data supporting this assignment were obtained from the elution profile monitored at 276 nm (sample D, dashed trace). At 276 nm, an absorbance maximum for the ligand with minimal contribution from the dendrimer, peak 0 ($G5(Ac)_{78}(NH_2)_{34}$), largely disappears as anticipated for dendrimer with no ligand

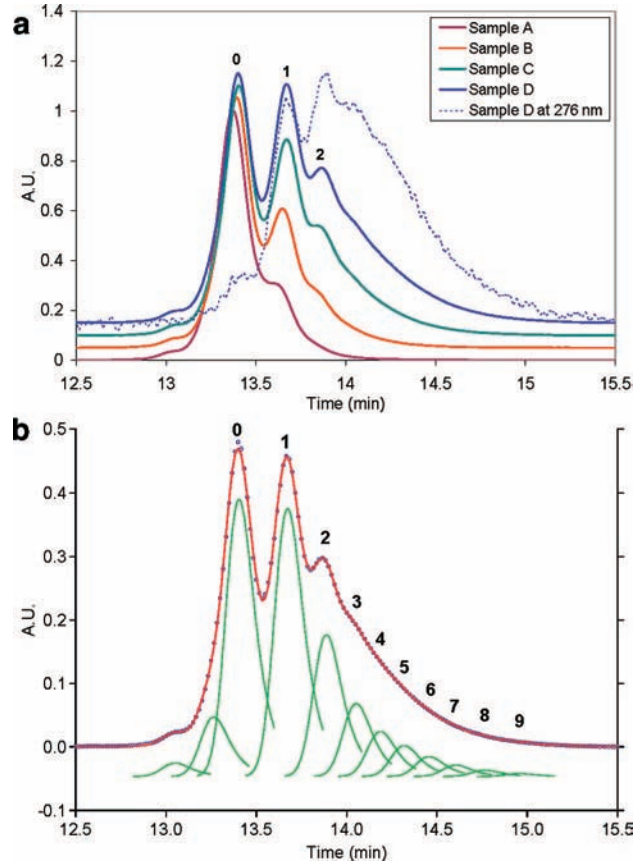

Figure 3. HPLC elution data for dendrimer−ligand conjugates. (a) Dendrimer concentration monitored at 210 nm for samples A−D are shown with solid lines. The elution profile of sample D at 276 nm, which is the maximum absorbance for the ligand, is displayed with a dashed line. Absorbance is normalized to the peak maximum. (b) The elution profile at 210 nm for sample D is shown in blue. Individual fitted peaks are presented in green, and the summation of the fitted peaks are in red.

conjugated. In this case, the first major feature observed (peak 1) was assigned as dendrimer containing one conjugated ligand ($G5(Ac)_{78}(NH_2)_{33}(L)_1$). Note that this is consistent with the assignment obtained based on monitoring dendrimer at 210 nm.

For the HPLC traces monitoring concentration of dendrimer at 210 nm, up to three distinct species are clearly resolved with a fourth apparent as an inflection point in trace D. Since the absorbance at 210 nm scales linearly with dendrimer concentration, we can use the area of each absorbance peak to obtain the relative concentration of each different dendrimer−ligand conjugate. Dilution studies of the conjugates demonstrate that Beer's law is followed and that each of the fitted peaks has the same extinction coefficient (see Supporting Information). The data taken at 276 nm are useful in helping to confirm the HPLC peak assignments but cannot be used quantitatively for concentration determinations because each dendrimer−ligand conjugate generates a dramatically different local concentration of ligand, thus causing a deviation from Beer's law.

In order to quantitatively assess the relative concentration of each dendrimer−ligand conjugate present, it was necessary to apply a peak fitting procedure to the HPLC traces. The functional form of the dendrimer peaks was determined by fitting the elution profile of acylated dendrimer ($G5(Ac)_{78}(NH_2)_{34}$) using Igor Pro 6.01. The peak shape, a Gaussian with an exponential decay tail to the right side of the elution peak, was then applied uniformly to all fitted peaks. The position and area of peaks 0−9 and the two lower generation impurity peaks at ~13 min were not constrained. The fit for sample D, which

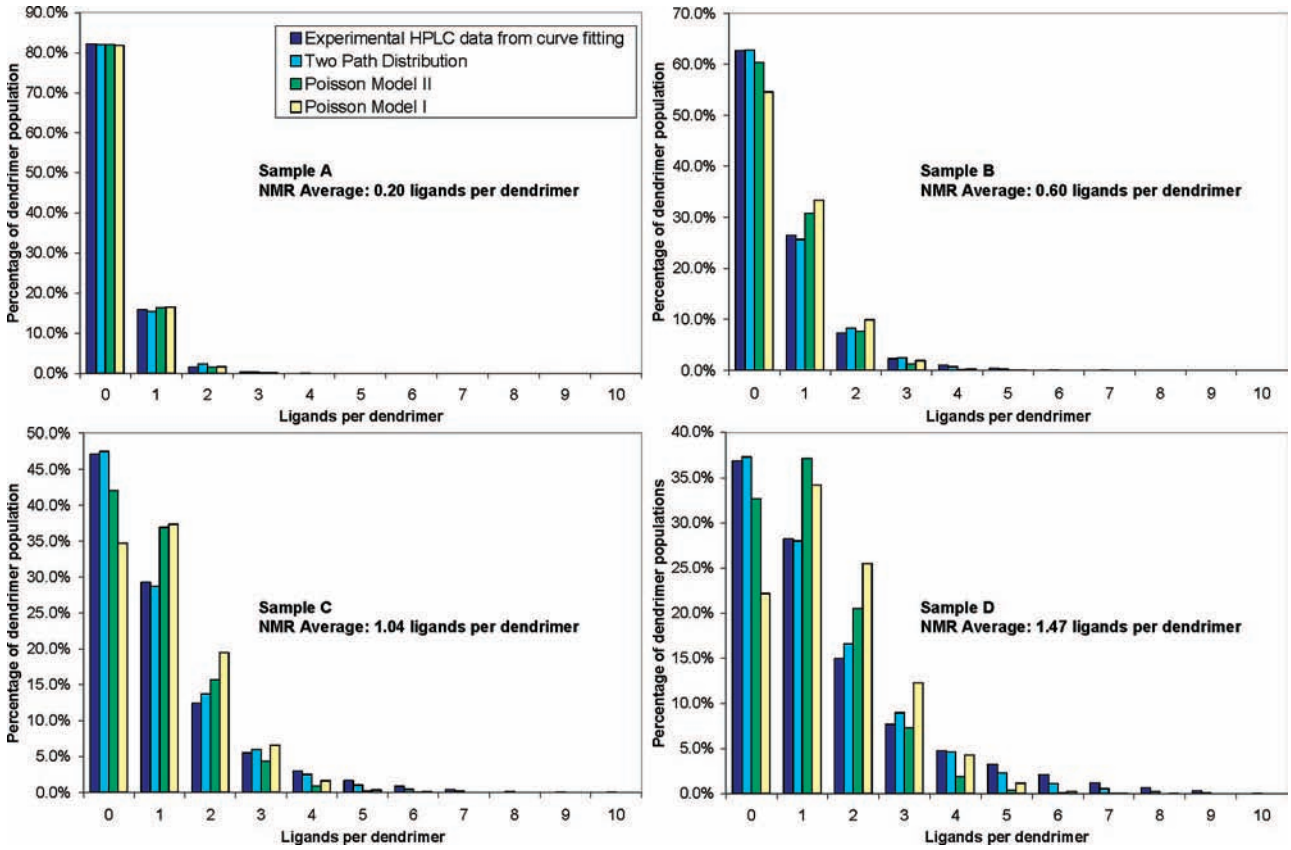

Figure 4. Experimental and statistical distributions of ligand−dendrimer conjugates A−D. Experimental distribution is calculated from fitted peaks to the HPLC elution profiles.

Table 1. Comparison of the Average Number of Ligands per Dendrimer Independently Computed by NMR and HPLC Techniques with the Three Statistical Models

	NMR average	HPLC average[a]	Poisson I ($\chi^2 = 66$)[b]	Poisson II ($\chi^2 = 47$)	two-path ($\chi^2 = 9$)
sample A	0.20 ± 0.02	0.20 ± 0.01	0.20	0.21	0.21
sample B	0.60 ± 0.06	0.54 ± 0.02	0.60	0.53	0.54
sample C	1.04 ± 0.10	0.98 ± 0.04	1.04	0.91	0.93
sample D	1.47 ± 0.15	1.45 ± 0.06	1.47	1.17	1.32

[a] Determination of HPLC error is discussed in the Experimental Methods section of the Supporting Information. [b] The Poisson I model uses the experimental NMR averages as input parameters.

has a 1.47 ligand/dendrimer ratio measured by ^{1}H NMR spectroscopy, is illustrated in Figure 3b. From these fits, the relative concentration of each dendrimer/ligand conjugate was determined (Figure 4) as well as the average ligand/dendrimer ratio (Table 1).

The relative proportions of dendrimer species, resolved by HPLC and quantified through fitted peaks, were used to calculate a weighted average number of ligands per dendrimer. Table 1 displays this for each of the dendrimer−ligand conjugates. This weighted average is in excellent agreement with the average determined independently by the combined NMR/GPC/titration analysis. Indeed, it is this comparison that gives confidence in the physical meaning of the peak fitting procedure. Significantly, the HPLC data produce additional distribution information that could not be extracted from the combined NMR/GPC/titration analysis.

The resolution of the various conjugated species by HPLC stands in stark contrast to the results obtained by NMR (Figure 2) in which no resolution of the various numbers of ligands conjugated is obtained. Gel permeation chromatography (GPC) exhibits a trend toward longer retention time but does not resolve the components (Figure 5a). Note that the longer retention time indicates that the conjugates are effectively smaller, as measured by GPC, although the light scattering and refractive index detectors verify that the mass has increased upon conjugation. MALDI-TOF MS also exhibits a trend to higher mass, but once again, the individual components are not resolved (Figure 5b).

Three statistical models were employed for comparison with the experimentally determined distributions (Figure 4, Table 1). Poisson model I assumed that ligand conjugation with the nanoparticle proceeds in a stochastic fashion. The total number of available attachment points on the dendrimer surface (34) and the average ligand/dendrimer ratio determined by NMR were used as input. This fit gave a χ^2 per degree of freedom of 66. In Poisson model II, the ligand/dendrimer ratios were allowed to vary as fitting parameters in a simultaneous χ^2 minimization using all four data sets. This fit gave a χ^2 per degree of freedom of 47. Both Poisson models match the 0.20 and 0.60 ligand/dendrimer distributions quite well but begin to deviate from the experimental data as the ligand/dendrimer ratio increases.

In order to better reproduce the experimental ligand distributions, a two-path kinetic model was used (see Supporting Information). It allowed for deviations from the Poisson distribution by varying the activation energy of the reaction as a function of n ligands on the nanoparticle (eq 1). This two-path model was also motivated by previous publications that

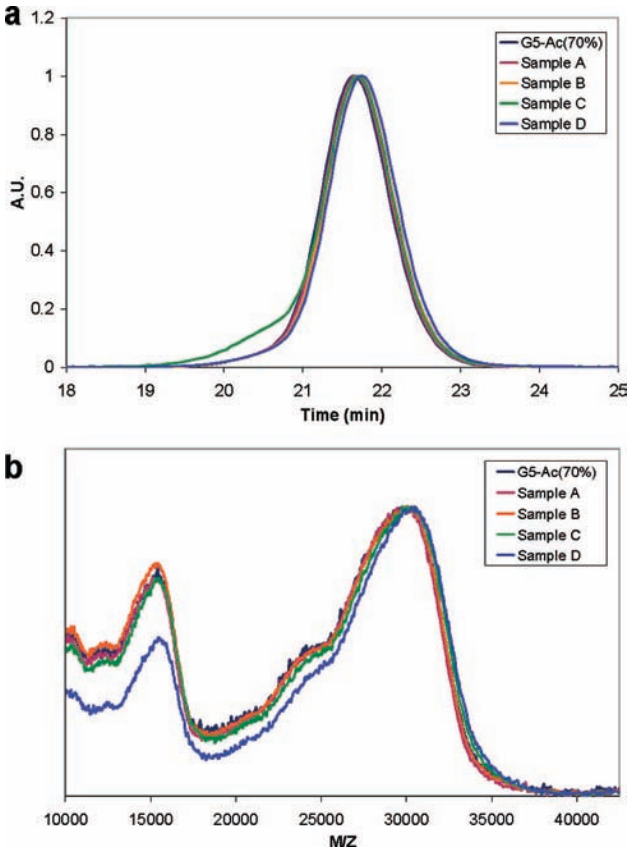

Figure 5. Standard analytical techniques that are commonly utilized to characterize nanoparticle conjugates fail to detect the different dendrimer−ligand populations. (a) The light scattering data of four dendrimer−ligand samples and partially acetylated dendrimer starting material, as separated by gel permeation chromatography (GPC), clearly demonstrate the challenges in detecting the different populations based on differences in size. The single peak resolution achieved by GPC is in stark contrast to the multiple peak resolution achieved by HPLC (see Supporting Information for GPC conditions). (b) Similarly, molecular weight analysis of the same material by matrix-assisted laser-desorption time-of-flight mass spectrometry (MALDI-TOF MS) cannot detect significant differences between the five samples (see Supporting Information for MALDI-TOF conditions).

indicate product amide autocatalysis should be expected for this reaction (*27*−*29*).

$$R_n = A_1 e^{-E_{a1}/(RT)} + nA_2 e^{-E_{a2}/(RT)} \quad (1)$$

The two paths correspond to attaching a ligand far from other ligands or near enough to previously attached ligands so that the barrier for attachment is reduced. These rates are fed into a master equation for the concentrations, c_n, of dendrimers with n ligands attached: $\dot{c}_n = R_{n-1}c_{n-1} - R_n c_n$. $A_{1,2}$ were adjusted to account for the number of available sites for the two paths. The solutions of the master equations were fit to all four data sets simultaneously using five independent parameters (E_{a1}−E_{a2}, and four independent values for the A parameters), resulting in a χ^2 per degree of freedom of 9. The best fit reproduced the experimental changes in concentration, which is a strong confirmation that the approach had physical meaning for this system. The difference in activation barrier between the two paths could be extracted from the fit and was determined to be $E_{a1} - E_{a2} = 6.2 \pm 1.5$ kJ/mol or 0.064 ± 0.016 eV.

Typically, analyses of functionalized nanoparticles only determine the average number of ligands per nanoparticle. In most cases, even HPLC does not resolve the distribution. Indeed, the "tailing" observed in the plots (Figure 3) is frequently ascribed to nonideal interaction between the analyte and the chromatography support. In this instance, we provide qualitative and quantitative data to demonstrate that tailing results from the distribution of ligands bound to dendrimers. This claim is supported by the following pieces of information: (1) no tailing is observed for the partially acetylated sample (see Figure S3); (2) the lower conversion samples (A, B) exhibit well-defined peaks; (3) dendrimers with a large number of conjugated ligands appear in "tail" region (see Figure S3); (4) the HPLC fits quantitatively agree with the NMR spectra in terms of the assessment of the average number of conjugated ligands.

The resolution of the distribution provides insight into the meaning of average ligand/dendrimer ratios. For the average of 0.20 ligands/dendrimer, the distribution comprises over 81% unmodified dendrimer, about 16% dendrimer with one ligand attached and less than 3% dendrimer with two ligands in fairly good accord with common expectations. However, the dendrimer−ligand conjugate with an average of 1.47 contains 0−9 ligands per dendrimer with the largest population of dendrimers actually containing no ligands. Note that both the random distribution and the two-path kinetic model accurately predict the breadth of the population. These experimentally measured breadths modeled herein challenge the commonly held perceptions that such a sample would comprise a narrower distribution predominantly containing dendrimers with one or two ligands attached. Furthermore, the average number misrepresents the functionally active portion of the dendrimer sample and does not make it apparent that the most common species contains no ligands and would therefore be inactive.

The deviation at larger ligand/dendrimers ratios of the experimental distribution from a Poisson analysis is quite interesting. The conjugation probability would be expected to *decrease* because of site blocking effects. Thus, the observation of an *increased* probability is particularly intriguing. A straightforward explanation of the activation energy barrier difference of ∼6 kJ/mol is product amide autocatalysis. This has the interesting implication of creating nonrandom spatial distribution of ligands on the polymer surface. These observations are of general interest, since amide/ester couplings are broadly used for conjugation reactions by the nanoparticle community.

In this paper, we have quantitatively analyzed the ligand/dendrimer distributions arising from conjugation of approximately one ligand on average to a spherical nanoparticle with excellent agreement between experimental measurements and theoretical analysis. Accurate understanding of these distributions for functional nanomaterials can lead to more informed applications and predictions of nanoparticle structure, function, and activity. It is expected that the details of the conjugation chemistry, site saturation effects, and steric blocking caused by the conjugated ligand can all affect the distributions obtained. Studies more closely examining these parameters will be the subject of future reports.

I. Experimental Methods:

Dendrimer Purification

Generation 5 PAMAM dendrimer was purchased from Dendritech Inc. To remove lower molecular weight impurities and trailing generations the dendrimer was dialysed with a 10,000 MWCO membrane against DI water for three days, exchanging washes every 4 hours. The number average molecular weight (27,336 g/mol) and PDI (1.018 +/- 0.014) was determined by GPC. Potentiometric titration was conducted to determine the average number of primary amines (112).

Partial Acetylation

Purified Generation 5 PAMAM dendrimer (133.7 mg, 4.89 μmole) was dissolved in anhydrous methanol (21 mL). Triethylamine (68.5 μL, 0.491 mmole) was added to this mixture and stirred for 30 minutes. Acetic anhydride (37.1 μL, 0.393 mmole) was added to anhydrous methanol (4 mL) and the resulting mixture was added in a dropwise manner to the dendrimer solution. The reaction was carried out in a glass flask, under nitrogen, at room temperature for 24 hours. Methanol was evaporated from the resulting solution and the product was purified using 10,000 MWCO centrifugal filtration devices. Purification consisted of five cycles (30 minutes at 5,000 rpm) using 1x PBS and five cycles using DI water. The purified dendrimer was lyophilized for three days to yield a white solid (138.4 mg, 92%). Number average molecular weight (30,660 g/mol) and PDI (1.026 +/- 0.015) were determined by GPC. ^{1}H NMR integration determined the degree of acetylation to be 70%.

Ligand Synthesis (3-(4-(prop-2-ynyloxy)phenyl)propanoic acid)

To a solution of methyl 3-(4-hydroxyphenyl)propanoate (2.18 g, 0.0121 mol) in dry acetone (56 mL) was added anhydrous K_2CO_3 (4.60 g, 0.0333 mol) followed by propargyl bromide (80% solution in toluene, 1.88 mL, 0.0126 mol). The resulting suspension was refluxed for 24 h with vigorous stirring. The reaction mixture was cooled to room temperature and the salt was removed by filtration followed by washing with portions of EtOAc. The filtrate was evaporated under vacuum to give the desired product as an oil (2.43g, 92%).

The crude product from above was dissolved in MeOH (60 mL). KOH (8 M, 5.0 mL, 0.040 mol) was added and the resulting mixture was heated at 70 °C for 1.5 h. The solution was cooled to room temperature and condensed under reduced pressure. The residue was dissolved in water (30 mL) and was acidified by addition of 1N HCl to pH 1. The white cloudy solution was diluted with EtOAc. Layers were separated and the aqueous layer was extracted with EtOAc (2 x 70 mL). The combined organic extracts were washed with a saturated NaCl solution and dried over $MgSO_4$. Solvent was evaporated under reduced pressure to give the desired product as a yellowish solid. (2.21 g, 97%).

^{1}H NMR (500 MHz, $CDCl_3$) δ 7.12, (d, 2H, J = 8.74 Hz), 6.89 (d, 2H, J = 8.71 Hz), 6.89 (d, 2H, J = 8.71 Hz), 4.65 (d, 2H, J = 2.40 Hz), 2.89 (t, 2H, J = 7.74 Hz), 2.64 (t, 2H, J = 7.75 Hz), 2.49 (t, 1H, J = 2.40 Hz)

Ligand Conjugation to Dendrimer

The ligand was conjugated to the partially acetylated dendrimer in two consecutive reactions. First, a stock solution of the ligand 3-(4-(prop-2-ynyloxy)phenyl)propanoic acid (9.4 mg, 0.046 mmole) was generated with a mixture of DMF (6.899 mL) and DMSO (2.300 mL). To this mixture was added 1-Ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDC) (123.5 mg, 0.644 mmole). The resulting solution was stirred for 4 h at room temperature to create the active ester form of the ligand.

A stock solution of partially acetylated dendrimer (77.1 mg, 2.51 μmole) was made with DI water (17.190 mL). This solution was partitioned into four aliquots, A-D (15.0 mg, 0.489 μmole each). Additional DI water (2.520 mL, 2.016 mL, 1.512 mL) was added to the first three aliquots (A-C). The active ester form of the ligand (0.504 mL, 2.521 μmole) in DMF/DMSO was added in a dropwise manner (0.1 mL/min) to the first aliquot (A) of dendrimer-water solution. Similarly, the activated ester form of the ligand was added to the second, third, and fourth aliquots (5.043 μmole, 7.565 μmole, and 10.087 μmole respectively). The resulting mixtures were stirred for 2.5 days. All reaction steps were carried out in glass flasks at room temperature under nitrogen. The four reaction mixtures were purified using 10,000 MWCO centrifugal filtration devices. Purification consisted of five cycles using 1x PBS and six cycles using DI water. All cycles were 30 minutes at 5,000 rpm. The resulting products (A-D) were lyophilized for three days to yield a white solid (14.6 mg, 16.5 mg, 15.7 mg, and 15.5 mg respectively).

HPLC Characterization

HPLC analysis was carried out on a Waters Delta 600 HPLC system equipped with a Waters 2996 photodiode array detector, a Waters 717 Plus auto sampler, and Waters Fraction collector III. The instrument was controlled by Empower 2 software. For analysis of the conjugates, a C5 silica-based RP-HPLC column (250 x 4.6 mm, 300 Å) connected to a C5 guard column (4 x 3 mm) was used. The mobile phase for elution of the conjugates was a linear gradient beginning with 90:10 (v/v) water/acetonitrile and ending with 10:90 (v/v) water/acetonitrile over 25 min at a flow rate of 1 mL/min. Trifluoroacetic acid (TFA) at 0.14 wt % concentration in water as well as in acetonitrile was used as a counter ion to make the dendrimer surfaces hydrophobic.

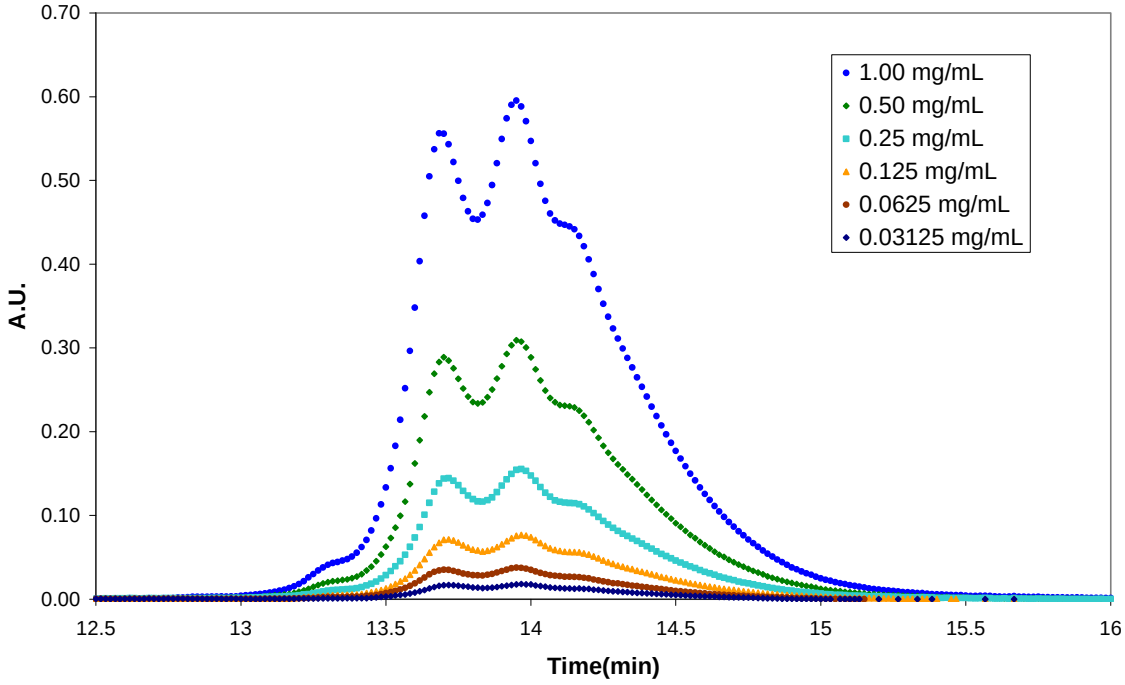
To determine the experimental error associated with the HPLC characterization, Sample D was injected five times over two days under identical conditions. The absorbance data was normalized against the major peak for each injection and standard deviations were computed at each time point. The standard deviations were normalized against absorbance and the average error in the range between 12.5 and 15.5 minutes was computed to be 4%.

II. Beer's Law: Dilution Study

A dilution study of Sample D was performed to demonstrate that the dendrimer conjugates follow Beer's Law at 210 nm. Solutions of Sample D with different concentrations were injected on the HPLC using the conditions detailed in the Methods

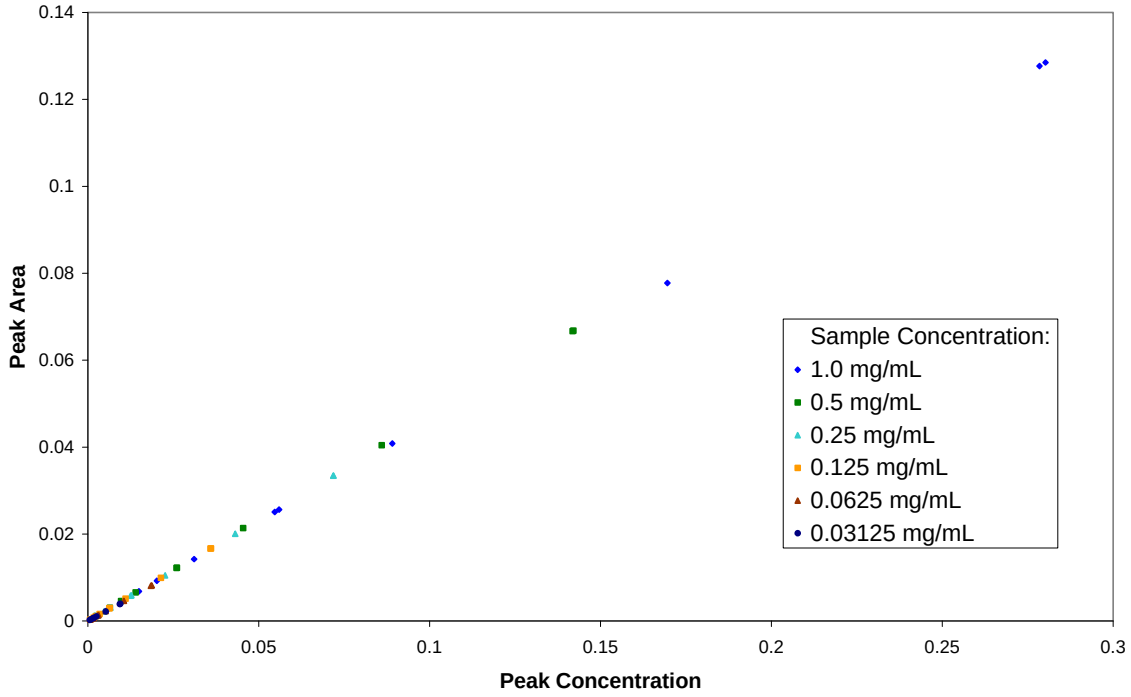
section of this publication. The elution profile at 210 nm of Sample D at varying concentrations can be found in Figure S1.

Figure S1: HPLC profile of Sample D injected at varying concentrations



Using the fitting procedure described earlier in this publication, peaks were fit to each of the elution profiles in Figure S1. Peak concentration was calculated as the product of the Peak Area Fraction and the Sample Concentration. The linear relationship found in Figure S2 between Peak Area and Peak concentration clearly demonstrates that Beer's Law is followed at 210 nm for the dendrimer conjugates in this study.

Figure S2: Peak Area vs. Peak Concentration



III. Characterization by Gel Permeation Chromatography (GPC)

GPC analysis was performed on the four dendrimer-ligand samples and the partially acetylated dendrimer using an Alliance Waters 2690/2695separations module (Waters Corp., Milford, MA) equipped with a Waters 2487 UV absorbance detector (Waters Corp.), a Wyatt Dawn DSP laser photometer (Wyatt Technology Corp., Santa Barbara, CA), an Optilab DSP interferometric refractometer (Wyatt Technology Corp.), and TosoHaas TSK-Gel Guard PHW 06762 (75 x 7.5 mm, 12 µm), G 2000 PW 05761 (300 x 7.5 mm, 10 µm), G 3000 PW 05762 (300 x 7.5 mm, 10 µm), and G 4000 PW (300 x7.5 mm, 17 µm) columns. Citric acid buffer (0.1 M concentration) with 0.025% sodium azide in water was used as a mobile phase, pH 2.74, using NaOH. Number Average Molecular Weight (Mn) and the Poly Dispersity Index (PDI) for each of the samples was calculated by using Astra software (version 4.9) (Wyatt Technology Corp.) and reported in Table S1. The general trend of increasing molecular weight is consistent with samples of increasingly higher averages of conjugated ligands.

Table S1: Number Average Molecular Weight and PDI calculated from GPC for the Dendrimer-Ligand conjugates

	Mn	PDI
G5Ac(70%)	30,660	1.026±0.015
Sample A	32,560	1.026±0.012
Sample B	33,200	1.025±0.012
Sample C	33,960	1.034±0.012
Sample D	35,080	1.024±0.012

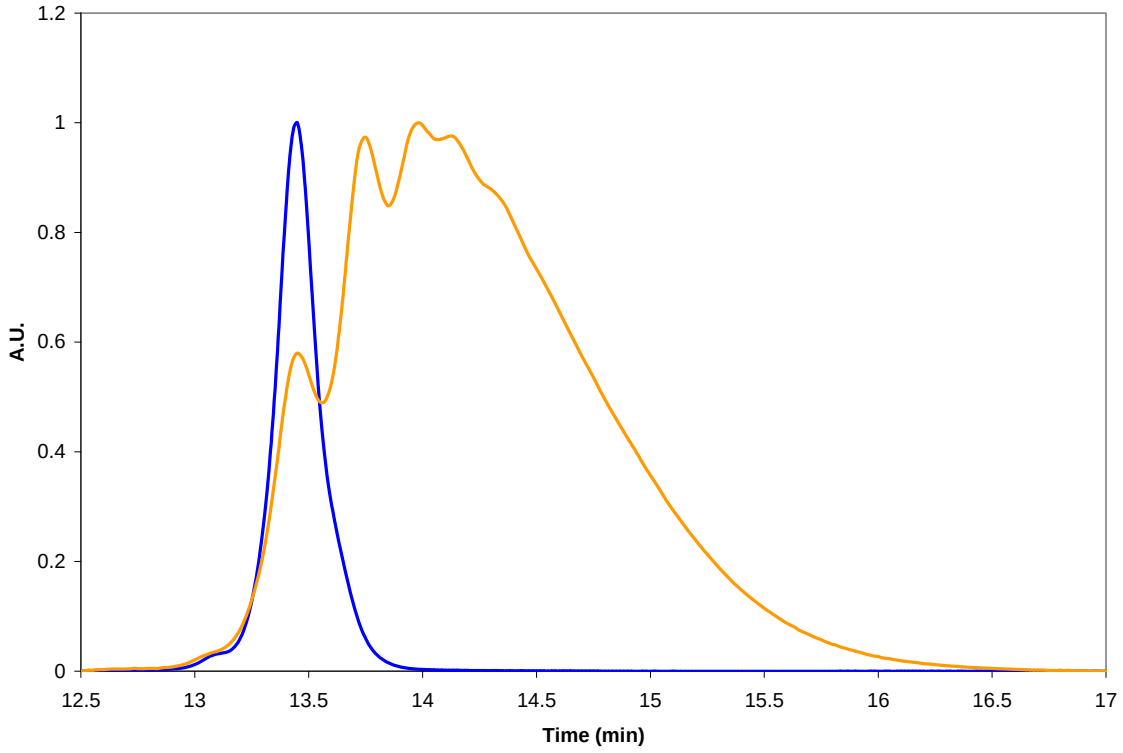
IV. Molecular Weight Characterization of the Dendrimer-Ligand Conjugates and Starting Material by MALDI-TOF

The four dendrimer-ligand samples and the partially acetylated dendrimer were characterized with a Micromass TofSpec-2E Matrix-Assisted, Laser-Desorption Time-of-Flight Mass Spectrometer. Spectra were acquired in Linear mode. The MALDI-TOF sample mixtures were prepared using 5 μL of the matrix trihydroxyacetophenone in equal amounts of water and acetonitrile (10 mg/mL), and 5 μL of the dendrimer in equal amounts of water and methanol (1 mg/mL). Each spot volume was 1 μL. Data summing and smoothing was applied post acquisition to each set of spectra. All processed spectra were normalized to the peak maximum.

V. Additional HPLC Profiles

The HPLC profiles for partially acetylated dendrimer and a dendrimer-ligand conjugate with an average of 3.1 can be found in Figure S3. Synthesis of the partially acetylated dendrimer is described in the Experimental Methods section of this paper. The dendrimer-ligand conjugate with an average of 3.1 ligands was synthesized following the procedure described for the four dendrimer-ligand samples investigated in this publication. Partially acetylated dendrimer for this dendrimer-ligand conjugate was 74% acetylated. A linear baseline subtraction was applied to both data sets and peak maxima were normalized.

Figure S3: HPLC profiles for partially acetylated dendrimer (blue) and partially acetylated dendrimer with an average of 3.1 ligands (orange).



VI. The Two Path Kinetic Model

Suppose a dendrimer has *n* ligands bound, but where *n* is small compared to the total number of dendrimer branches $M = 112$. Should another ligand encounter this dendrimer, there are two most probable avenues, that the ligand attaches to an available branch far from the influence of already-attached ligands, and that the ligand binds near a previously attached ligand. Given the low occupancy, we discount the possibility of a ligand binding near more than one other ligand.

Each avenue has an associated rate of attachment depending upon the probability of encountering such a site, the activation energy barrier, and an underlying collision frequency ω that is assumed to be the same for the two paths. The two parallel paths give two rate contributions, R_{n1} and R_{n2}, such that the total rate $R_n = R_{n1} + R_{n2}$.

The probability p_2 of a ligand binding at a site near a previously bound ligand is given by $p_2 = nze^{-E_{a2}/RT}$, where z is the effective coordination number, the number of sites

a bonded ligand influences, and E_{a2} is the activation energy barrier for this pathway, a value influenced by the proximity to the bound ligand. This leads to the rate $R_{n2} = nA_2 e^{-E_{a2}/RT}$ by multiplying with ω, giving the association of $A_2 = z\omega$.

The probability p_1 of a ligand binding to one of the other available sites is the probability of encountering an open site that doesn't belong to the other pathway. That is, $p_1 = [m - n(z+1)]e^{-E_{a1}/RT}$, where m = 34 is the number of non-acetylated sites, and E_{a1} is the activation energy barrier for this unassisted pathway. The term $n(z+1)=nz + n$ has a contribution from discounting sites under the influence of a bound ligard, nz, and the sites at which the previously bound ligands are bound, giving the n term. This leads to the rate $R_{n1} = A_1 e^{-E_{a1}/RT}$ with the association $A_1 = [m - n(z+1)]\omega$.

The effective coordination number z depends on the arrangement of the dendrimer branches and the number of those branches which are not acetylated. If we consider first nearest neighbor interactions the end of a given branch may be near a handful of others, say between four and six. We expect that m/M = 30% of these branches are ligated or open to ligation. Therefore, the effective coordination number is a number of order unity, say between one and two.

A numerical estimate of the effective coordination results in z = 0.9. This estimate was generated by randomly populating a 10x10 triangular (close-packed) lattice with 30 sites, then counting the number of neighbors each site had. This process was sampled 10 000 times, giving a low-skewed distribution of numbers of neighbors with the average being 0.9. This results in a range of values for A_2/A_1 from 0.0025 to 0.1 for n between 1 and 10, with an average value of 0.04.

Fitting the Model

The Master equation $\dot{c}_n = R_{n-1}c_{n-1} - R_n c_n$ was numerically integrated using an Euler method for 1000 steps. The time step is arbitrary, since the time derivative in the equation is only known to a constant of proportionality that is absorbed into A_1 and A_2 for each data set. Integrating for 10 000 steps instead of 1000 does not significantly change the result. A non-linear least-squares fit was conducted simultaneously for the four data sets, resulting in the following fitted values for the parameters.

	Fitted Value
$\frac{A_2}{A_1}e^{-(E_{a2}-E_{a1})/RT}$	0.58
L_1	2.0 E-5
L_2	4.7 E-5
L_3	7.4 E-5
L_4	9.8 E-5

A significant confirmation of the model is the recovery of the ligand concentration ratios. The constants L_1, L_2, L_3, L_4 are proportional to the ligand concentrations, though the constant of proportionality is not independently recoverable. Therefore, normalizing each by L_4, and normalizing the ligand concentrations by the amount used in the most concentrated data set allow comparable values.

	Fitted Values	Actual Values
L_1/L_4	0.20	0.25
L_2/L_4	0.47	0.5
L_3/L_4	0.75	0.75

The prediction for this method is a difference between the activation energy barriers of the two paths in the model. From the fit $\frac{A_2}{A_1} e^{-(E_{a2}-E_{a1})/RT} = 0.58$, we can solve for the energy difference $(E_{a1} - E_{a2}) = RT \log(0.58 \frac{A_1}{A_2})$. After finding an estimate for $A_1/A_2 = 10$, we find the energy difference E_{a1}-E_{a2} = 6.2 ± 1.5 kJ/mol.

A Designed Protein for the Specific and Covalent Heteroconjugation of Biomolecules

Christopher Chidley, Katarzyna Mosiewicz, and Kai Johnsson*

Ecole Polytechnique Fédérale de Lausanne (EPFL), Institute of Chemical Sciences and Engineering, CH-1015 Lausanne, Switzerland. Received July 1, 2008; Revised Manuscript Received August 12, 2008

Bioconjugations often rely on adaptor molecules to cross-link different biomolecules. In this work, we introduce the molecular adaptor covalin, which is a protein chimera of two self-labeling proteins with nonoverlapping substrate specificity. Covalin permits a selective and covalent heteroconjugation of biomolecules displaying appropriate functional groups. Examples for the use of covalin include the specific heteroconjugation of a reporter enzyme to an antibody and of molecular probes to the surface of living cells. The efficiency and specificity of covalin-based bioconjugations together with the availability of a large variety of substrates create immediate and ubiquitous applications for covalin in bioconjugate chemistry.

The specific heteroconjugation of two different biomolecules generally relies on cross-linkers with two independent reactive groups or binding sites. Examples of cross-linkers include bifunctional synthetic molecules, oligonucleotides, and proteins (*1*−*3*). Streptavidin is the most widely used protein in bioconjugations, as it can stably conjugate biotinylated molecules with high efficiency (*3*, *4*). However, for the specific heteroconjugation of two different molecules the streptavidin−biotin technology has the limitation that streptavidin possesses four identical binding sites and that its simultaneous incubation with two different biotinylated molecules therefore leads to a heterogeneous mixture of conjugates. Mutants of streptavidin with a reduced number of binding sites have been described (*5*), but these mutants also do not allow a specific heteroconjugation of two different biotinylated molecules. Here, we introduce a designed protein for the specific and covalent heteroconjugation of two different (bio)molecules displaying appropriate functional groups. Using an antibody or cell surface proteins as examples, we demonstrate how this protein, named covalin, can be used to specifically conjugate proteins to other proteins or to synthetic probes. The simplicity, efficiency, and general applicability of the method should allow it to become an important tool for heteroconjugations in bioconjugate chemistry.

To achieve covalent and specific bioconjugations, covalin was designed as a fusion protein of two monomeric, self-labeling proteins with nonoverlapping substrate specificity (Figure 1). The first protein is a mutant of human O^6-alkylguanine-DNA alkyltransferase (known as SNAP-tag; 182 residues) that reacts with benzylguanine (BG) derivatives (*6*). The second protein is a mutant of a bacterial dehalogenase (known as HaloTag; 293 residues) that reacts with primary chloroalkanes (*7*). The rate constants of the reactions of both proteins with their substrates are high (10^4 s^{-1} M^{-1} for SNAP-tag and 10^6 s^{-1} M^{-1} for HaloTag). This makes them well-suited for bioconjugations, especially when compared to typical bioorthogonal reactions such as copper-free click chemistry or the Staudinger ligation, which are at least 10^4-fold slower (*8*, *9*). Numerous substrates are available for SNAP-tag and HaloTag (Figure 1b) and both tags have proven their versatility in vitro and in vivo (*6*, *7*). Covalin possesses an N-terminal His-tag for purification and a human rhinovirus 3C protease (PreScission protease) cleavage site between SNAP-tag and HaloTag for an optional separation of covalently conjugated biomolecules. Its size (55 kDa) is comparable to that of streptavidin (54 kDa). Although covalin is currently not commercially available, it can be readily produced through overexpression in *E. coli* (Supporting Information).

We first characterized the reactivity of covalin toward simple SNAP-tag and HaloTag substrates. Incubation of covalin with BG-547 and Halo-DAF, substrates for the labeling of SNAP-tag and HaloTag with the fluorescent dyes DY-547 and fluorescein, respectively, resulted in the labeling of covalin with both fluorophores (Figure 1c). Digestion of the labeled protein with PreScission protease yielded DY-547-labeled SNAP-tag and fluorescein-labeled HaloTag (Figure 1c), showing that covalin has two independent self-labeling sites. Incubation of covalin with either BG-DAF or Halo-DAF, substrates for the labeling of SNAP-tag and HaloTag with fluorescein, yielded fluorescein-labeled covalins with almost identical fluorescence intensities (±5%; Figure 1c, lane 1 and 2), indicating that in covalin SNAP-tag and HaloTag are active to the same extent.

We then used covalin in a series of proof-of-principle experiments for the conjugation of an antibody to a synthetic fluorophore, a reporter enzyme and magnetic beads (Figure 2a). In a first step, this requires a chemical labeling of the antibody with one of the two covalin substrates. Subsequently, the antibody can be functionalized through simultaneous incubation with covalin and the (bio)molecule of interest displaying the other covalin substrate. The first step of the procedure is similar to a chemical biotinylation of an antibody for subsequent bioconjugations with streptavidin. However, a subsequent simultaneous incubation of a biotinylated antibody with streptavidin and other biotinylated objects would inevitably lead to a complex mixture of different products.

The commonly used monoclonal antibody 12CA5 that recognizes the HA epitope tag was chosen as the antibody for the bioconjugation experiments. 12CA5 was labeled with primary chloroalkane through incubation of the antibody with a commercially available *N*-hydroxysuccinimide (NHS) ester (Figure 1b), a labeling strategy that should result in antibodies displaying varying amounts of the HaloTag substrate (*1*). Derivatized 12CA5 was stored for weeks at 4 °C without

DY-547 and fluorescein fluorescence are shown in red and green, respectively.

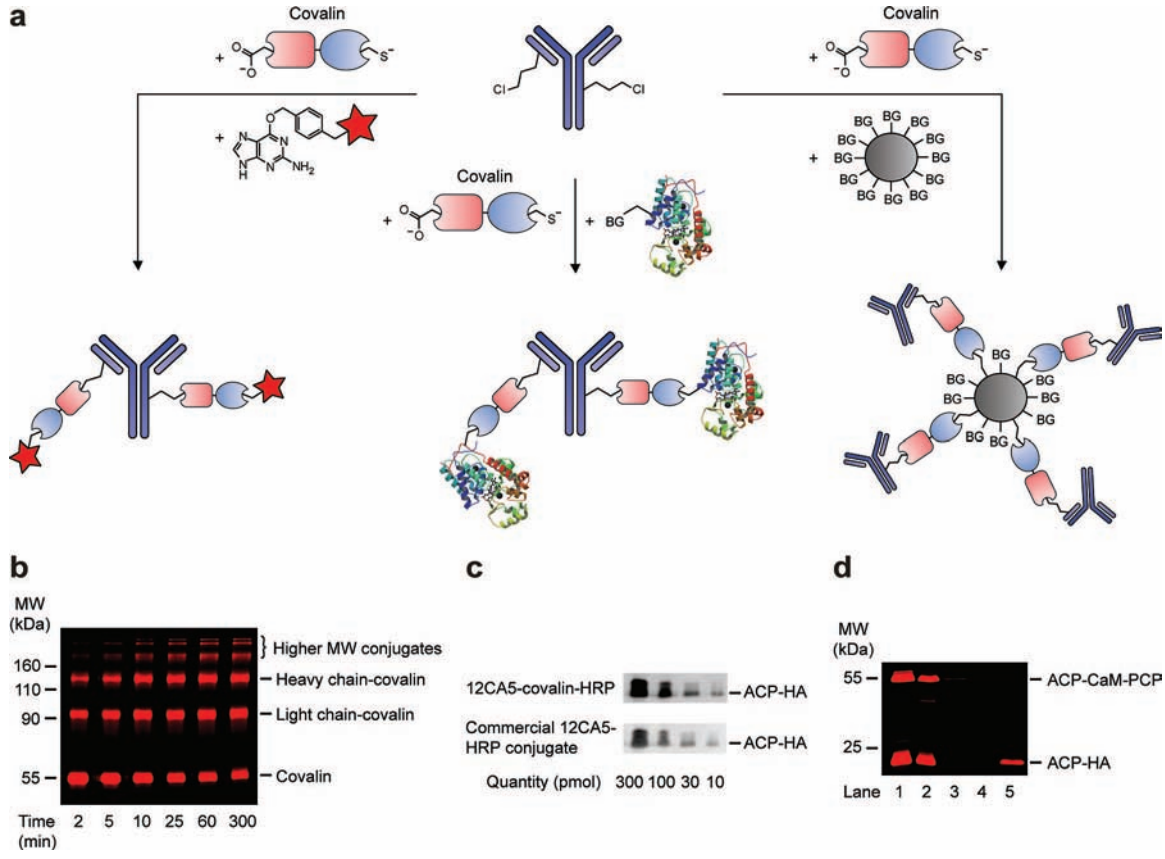

Figure 2. Covalin-dependent derivatization of an anti-HA antibody. (a) General scheme for the covalin-dependent conjugation of an antibody to a fluorophore (b), to a reporter protein (c), and to magnetic beads (d). (b) Derivatized anti-HA antibody 12CA5 (3 μM) was incubated with covalin (10 μM) and BG-547 (15 μM). Aliquots of the reaction mixture drawn at indicated time points were analyzed by SDS-PAGE and laser-based in-gel fluorescence scanning. (c) Detection of different dilutions of ACP-HA by Western blotting using 12CA5-covalin-HRP (0.17 μg/mL in 12CA5) or a commercially available 12CA5-HRP conjugate (0.15 μg/mL). (d) Analysis of the pulldown experiment using 12CA5 immobilized on magnetic beads via covalin and incubated with an equimolar mixture of Cy3-labeled ACP-HA and ACP-CaM-PCP. Samples of the pulldown were analyzed as in (b). Lane 1, sample before pulldown; lane 2, flowthrough of pulldown; lanes 3 and 4, wash fractions; lane 5, elution of captured proteins from beads.

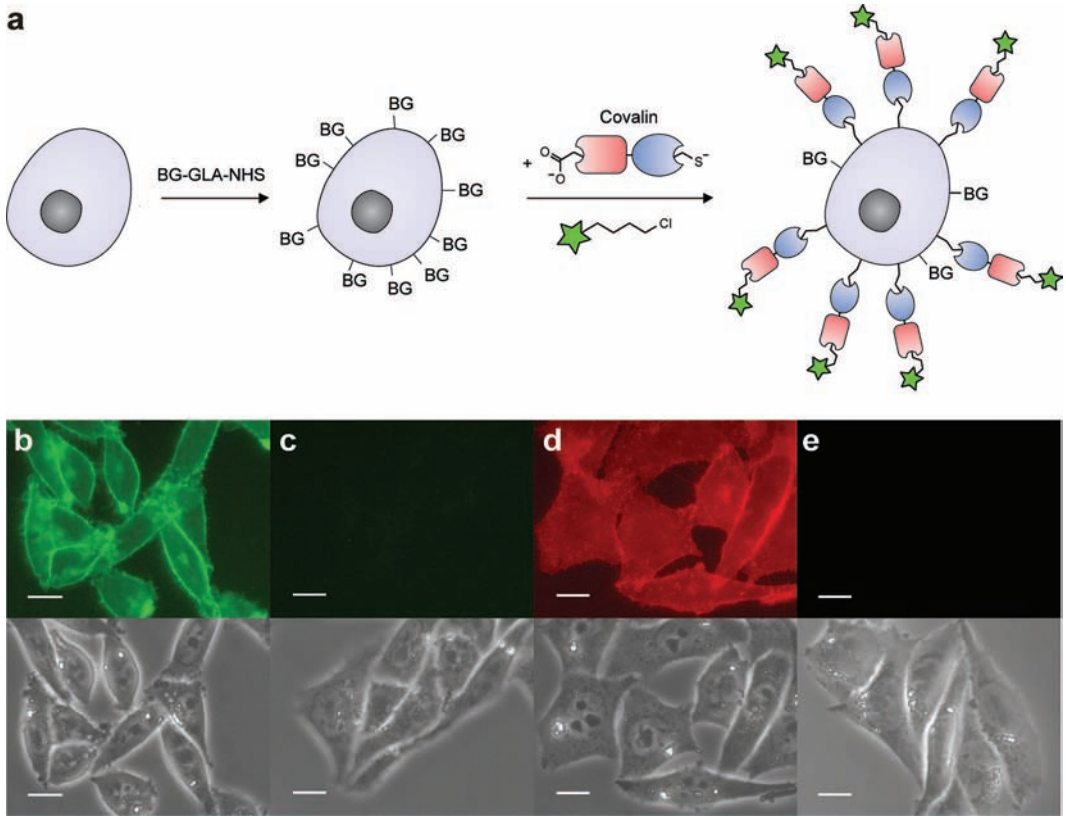

Figure 3. Use of covalin for the bioconjugation of molecular probes to cell surfaces. (a) General scheme for the bioconjugation of molecular probes via covalin to cell surfaces. In the first step, cell surfaces could either be derivatized with the SNAP-tag substrate or with the HaloTag substrate, but for reasons of clarity only one of the two orientations is shown. (b−e) Micrographs of derivatized and nonderivatized CHO cells incubated with covalin and a fluorescent covalin substrate. (b) CHO cells derivatized with BG and first incubated with covalin (10 μM) and then with Halo-DAF (2 μM). (c) CHO cells not derivatized with BG and first incubated with covalin (10 μM) and then with Halo-DAF (2 μM). (d) CHO cells derivatized with primary chloroalkane and first incubated with covalin (10 μM) and then with BG-547 (2 μM). (e) CHO cells not derivatized with primary chloroalkane and first incubated with covalin (10 μM) and then with BG-547 (2 μM). Scale bar, 10 μm.

decrease in reactivity toward covalin. To label 12CA5 with a fluorophore, the derivatized antibody (3 μM) was incubated with covalin (10 μM) and BG-547 (15 μM). Aliquots of the reaction mixture drawn at different time points were then analyzed by SDS-PAGE and in-gel fluorescence scanning (Figure 2b). Under these conditions, the fluorescence labeling of 12CA5 with covalin-DY-547 is near completion after one hour and heavy and light chains conjugated to one or multiple covalin-DY-547 could be detected. On average, approximately 2.5 covalin-DY-547 were bound per anti-HA antibody (Supporting Information; Figure S1a). This set of experiments serves as a first example to illustrate how covalin can be used for the straightforward conjugation of molecular probes to a derivatized protein. It should be noted that the covalent cross-linking of fluorescent probes to derivatized biomolecules such as 12CA5 allows the quantification of the initial derivatization step before use of the same derivatized biomolecule in further applications (vide infra).

One of the main applications that we foresee for the use of covalin is in the selective conjugation of two different proteins to each other, as it resolves the problem to derivatize one of the two proteins with a reactive group that specifically reacts only with the other protein. To demonstrate the potential of covalin for such applications, we attempted to conjugate 12CA5 via covalin to horseradish peroxidase (HRP) and to use the resulting conjugate in Western blotting. HRP is commonly used as a reporter enzyme in immunodetection experiments and HRP-antibody conjugates are therefore widely used. Toward this end, HRP was incubated with a BG-NHS ester. Derivatized HRP (3 μM) was incubated with covalin (3 μM) and Halo-DAF (4 μM) to verify that BG-labeled HRP is a substrate of covalin and to determine the degree of labeling of HRP with BG. In these experiments, 40% of HRP was derivatized with one covalin (Supporting Information; Figure S1b,c). The derivatization of HRP with NHS esters is known to be inefficient due to the low number of amino groups available (*1*), and no attempts were made to improve the labeling of HRP with BG. To conjugate HRP to the anti-HA antibody, derivatized 12CA5 (3 μM) was incubated with covalin (15 μM) and derivatized HRP (30 μM total HRP) for 5 h and then stored at 4 °C for later use. To evaluate the activity of the self-assembled 12CA5-covalin-HRP, we compared it to a commercially available 12CA5-HRP conjugate (Roche Molecular Biochemicals) optimized for applications in Western blotting. Using recombinant acyl carrier protein with a C-terminal HA tag (ACP-HA) as an arbitrary test antigen, 12CA5-covalin-HRP and the commercially available 12CA5-HRP permitted the detection of similar amounts of ACP-HA in Western blotting (Figure 2c). This demonstrates that the conjugation of HRP to 12CA5 via covalin does neither impede the antibody−antigen interaction nor the HRP activity. While the specific heteroconjugation of antibodies to HRP can be achieved via a number of different procedures using synthetic bifunctional cross-linkers (*1*), these procedures are not generally applicable to heteroconjugations of proteins, as they chemically exploit the fact that antibodies and HRP are glycosylated and/or that both proteins in their native form do not possess any free cysteines. This is in contrast to covalin-mediated heteroconjugations of proteins as the SNAP-tag and HaloTag substrates are chemically inert toward the functional groups found in proteins and other biomolecules.

Covalin should furthermore allow a selective immobilization of biomolecules on surfaces such as polymer beads as both SNAP-tag (*10*) and HaloTag (*7*) have already been successfully

used for this purpose. We therefore attempted the immobilization of the anti-HA antibody 12CA5 on magnetic beads for pulldown experiments. Primary chloroalkane-derivatized 12CA5 (6 μM) was incubated with covalin (9 μM) and magnetic beads displaying BG. For a mock pulldown experiment, derivatized beads were incubated with an equimolar mixture of ACP-HA and of a similar protein without HA-tag (a fusion protein of ACP with calmodulin and peptidyl carrier protein (ACP-CaM-PCP)) which was diluted into a crude cell lysate. For detection, ACP-HA and ACP-CaM-PCP were both labeled via ACP with Cy3 (*11*) before dilution into the cell lysate. After several washing steps, protein bound to the beads was eluted with SDS sample buffer and samples of different steps of the pulldown were analyzed (Figure 2d). The enrichment of ACP-HA over ACP-CaM-PCP in the pulldown was 80-fold and no enrichment was observed when either derivatized 12CA5 was replaced by original 12CA5 or when covalin was omitted (Supporting Information; Figure S1d). The different experiments with antibody 12CA5 show that once an antibody is derivatized with a covalin substrate it can be either conjugated to various probes or immobilized, providing the approach with a high degree of flexibility.

A further application for covalin is the conjugation of (bio)molecules to the surfaces of cells or viruses previously derivatized with appropriate substrates (Figure 3a). For a proof-of-principle experiment, we used covalin to conjugate fluorophores to the surface of CHO cells. CHO cells were first derivatized either with primary chloroalkane or with BG by a brief incubation of the cells with the corresponding NHS ester. Both NHS esters were utilized in order to test covalin in both orientations. The derivatized CHO cells were subsequently incubated first with covalin (10 μM) and then with either BG-547 or Halo-DAF (each 2 μM) for visualization. Labeling of derivatized cells with either DY-547 or fluorescein was detectable by fluorescence microscopy, whereas no labeling could be detected when nonderivatized CHO cells were incubated with covalin and either BG-547 or Halo-DAF (Figure 3b−e). The synthetic fluorophores used here could be easily exchanged for more complex (bio)molecules, thereby allowing a stepwise assembly of synthetic structures on cells and viruses.

In conclusion, covalin is a versatile and easy to use fusion protein for the specific conjugation of different molecules or objects displaying appropriate functional groups. In contrast to the popular adaptor protein streptavidin, it has two binding sites with nonoverlapping substrate specificity, ensuring the formation of complexes with defined composition and stoichiometry. Just as for streptavidin, covalin substrates are available for a large variety of applications, allowing the immediate and ubiquitous use of covalin in bioconjugate chemistry. Furthermore, the orthogonal substrate specificities of streptavidin and covalin should permit their simultaneous use in bioconjugations. Finally, the existence of other self-labeling proteins with nonoverlapping substrate specificities should allow the generation of a family of orthogonal covalins as well as covalins with different valencies (*12, 13*).

General

Substrates for the labeling of SNAP-tag were from Covalys Biosciences. Substrates for the labeling of HaloTag were from Promega.

Sequence of covalin

Covalin is composed of a fusion of HaloTag (HaloTag open reading frame from vector pHT2, Promega) (in blue) and SNAP-tag (182 amino acid mutant of the wild-type human AGT in which the last 25 amino acids were deleted and the following mutations were introduced: K32I, L33F, C62A, Q115S, Q116H, K125A, A127T, R128A, G131K, G132T, M134L, R135S, C150Q, S151G, S152D, G153L, A154D, N157G and S159E (in red).[1] The fusion has an N-terminal 6x His-tag and the linker between the two tags contains a *PreScission* protease cleavage site.

Expression of covalin

The sequence encoding covalin was inserted into pET-15b and the resulting plasmid was transformed by electroporation into the *E. coli* strain Rosetta-gami (DE3) (Novagen). A bacterial culture was grown at 37 °C in LB medium to an OD_{600nm} of 1.0 and expression of covalin was induced by the addition of 1 mM isopropyl-β-D-thiogalactopyranoside (IPTG). The bacteria were grown for an additional 21 hours at 16 °C and then were harvested by centrifugation. The bacteria were lysed by sonication and insoluble protein and cell debris were removed by centrifugation. For the purification of covalin, Ni-NTA (Qiagen) was used according to the instructions of the supplier. Eluted protein was further purified by gel filtration on a Superdex 200 column (GE Healthcare Life Sciences) using 20 mM Tris·Cl pH 8.0, 200 mM NaCl, 4 mM DTT. Glycerol was added to a final concentration of 30% (v/v) and the protein was stored at -80 °C. The concentration of the protein was determined using a Bradford assay with BSA as a standard.

Labeling of Anti-HA (12CA5) with primary alkyl chloride

HaloTag Succinimidyl ester (O4) ligand (NHS-O4-Cl; Promega) was added to a final concentration of 1 mM (from a 100 mM stock solution in anhydrous DMF) to a solution of 7 μM of 12CA5 antibody (Protein expression core facility, EPFL) in PBS pH 7.3 (137 mM NaCl, 2.7 mM KCl, 4.3 mM Na_2HPO_4, 1.4 mM KH_2PO_4). After 30 minutes at 25 °C, the excess N-hydroxysuccinimide ester was quenched for 10 minutes by adjusting the reaction mixture to 10 mM Tris·Cl pH 7.4. The labeled antibody was purified from excess HaloTag substrate by using a centrifugal filter device (Microcon YM-30, Millipore). Five washing cycles with 50 mM HEPES pH 7.4 were used to concentrate each time the sample from 500 μl to 20 μl. The derivatized antibody was stored at 4 °C until further use. The concentration of the 12CA5 antibody was determined prior to derivatization by UV spectrophotometry using an extinction coefficient for IgGs of 1.37 $ml \cdot mg^{-1} \cdot cm^{-1}$. After derivatization and purification, the concentration was set by using an estimated 90% recovery yield.

Labeling of Anti-HA (12CA5) with DY-547 via covalin

A solution of covalin and BG-547 (1.5 equivalents) was prepared and then mixed with primary alkyl chloride-derivatized 12CA5 to a final concentration of 3 μM 12CA5 and of 10 μM covalin in 50 mM HEPES pH 7.4. The kinetics of the reaction was monitored by taking samples of the reaction mixture after 2, 5, 10, 25, 60 and 300 minutes. After drawing the samples from the reaction tube, they were immediately mixed with one volume of 2x SDS sample buffer and heated to 95 °C for 5 minutes. The samples were then analyzed by SDS-PAGE and subsequent in-gel fluorescence scanning (Figure 2b).

Labeling of horseradish peroxidase with BG

Commercial horseradish peroxidase (HRP type VIA, Sigma) was dialyzed against PBS pH 7.3. BG-GLA-NHS (Covalys Biosciences) was added to a final concentration of 3 mM (from a 100 mM stock solution in anhydrous DMF) to a solution of 100 μM of HRP in PBS pH 7.3. After 90 minutes at 25 °C, the excess N-hydroxysuccinimide ester was quenched for 10 minutes by adjusting the reaction mixture to 10 mM Tris·Cl pH 7.4. The labeled HRP was purified from excess BG by using a centrifugal filter device (Microcon YM-30, Millipore). Five washing cycles with 50 mM HEPES pH 7.4 were used to concentrate each time the sample from 500 μl to 20 μl. After elution from the column, the derivatized HRP was stored at 4 °C until further use.

Labeling of horseradish peroxidase with fluorescein via covalin

A solution of covalin and Halo-DAF (HaloTag diAcFAM ligand, Promega) (1.3 equivalents) was prepared and then mixed with BG-derivatized HRP to a final concentration of 3 μM of HRP and covalin each in 50 mM HEPES pH 7.4, 1 mM PMSF and 2 μg/ml aprotinin. Kinetics of the reaction was monitored by taking samples of the reaction mixture after 5, 15, 60 and 300 minutes. After drawing the samples from the reaction tube, they were immediately mixed with 2x SDS sample buffer and heated to 95°C for 5 minutes. The samples were then analyzed by SDS-PAGE and subsequent in-gel fluorescence scanning (Figure S1b).

Procedure for Western blotting

The antibody-peroxidase conjugate was constructed with primary alkyl chloride-labeled 12CA5 and BG-labeled HRP (both prepared as described above) crosslinked via covalin. The crosslinking reaction was carried out by incubating 3 μM derivatized 12CA5, 15 μM covalin and 30 μM derivatized HRP in 50 mM HEPES pH 7.4 with 1 mM PMSF, 2 μg/ml aprotinin, 1 mM DTT and 0.1% BSA for 5 h at 25 °C. The reaction mixture was stored at 4 °C until final use. An HA-tagged recombinant acyl carrier protein (ACP-HA) was serially diluted and loaded in duplicate on a single SDS polyacrylamide gel. The proteins were then transferred to a PVDF membrane (Immobilon-P, Millipore) according to the supplier's instructions. After blocking with skim milk (3% in TBS (20 mM Tris·Cl, 500 mM NaCl) pH 7.5) for 90 minutes, the membrane was cut into two halves each composed of an identical serial dilution of ACP-HA. The first part of the membrane was incubated with 1.5 μl of the reaction mixture described above diluted in 4 ml PBS pH 7.3 + 0.05% Tween-20. This corresponds to a final concentration of 1.1 nM of 12CA5. The second part of the membrane was incubated with 6 μl of commercially available 12CA5-HRP conjugate (100 ng/μl, Roche) in 4 ml PBS pH 7.3 + 0.05% Tween-20, corresponding to a concentration of 0.15 μg/ml. Assuming a mono-derivatized antibody-HRP conjugate (MW of 12CA5-HRP: 200 kDa), the final concentration would be 0.8 nM. After 90 minutes at 25 °C, the incubation was prolonged 12 hours at 4 °C. The membranes were washed four times with PBS pH 7.3 + 0.1% Tween-20 and then detected using commercial chemiluminescent reagents (Western Lightning Chemiluminescence reagents, PerkinElmer Life Sciences) on a Kodak Image Station 440 (Eastman Kodak).

Pull-down experiments

Magnetic beads displaying BG (SNAP-capture magnetic beads, Covalys Biosciences) were washed twice with immobilization buffer (50 mM HEPES, 100 mM NaCl, 0.1% Tween-20, pH 7.4) + 1 mM DTT. In a first step, the beads were blocked with bovine serum albumin (BSA) at a final concentration of 3 μg/μl for 30 minutes at 25 °C on a tube rotator. Then, covalin was added to a final concentration of 9 μM for an additional 90 minutes. Finally, primary alkyl chloride-derivatized 12CA5 antibody was added to a final concentration of 6 μM. The reaction suspension was incubated

at 25 °C on the rotator for an additional 13 hours. The beads were then washed five times with immobilization buffer. Two recombinant proteins both containing acyl carrier protein (ACP-HA and ACP-CaM-PCP) were labeled via ACP with Cy3 according to published procedures.[2] A bacterial protein extract was prepared from *E. coli* JM83 according to standard procedures. The magnetic bead suspension in immobilization buffer was adjusted to a final concentration of 5 μM of both Cy3-ACP-HA and Cy3-ACP-CaM-PCP and to a final concentration of 10 μg/μl of bacterial protein extract. This suspension was incubated at 25 °C for 75 minutes on a tube rotator. The beads were then washed five times with immobilization buffer. Elution of the immobilized proteins was performed by adding 2x SDS loading buffer and heating the bead suspension for 5 minutes at 95 °C. In parallel to the experiment described above, two control reactions were performed. Both controls were performed in the same way as described for the experiment above except for the following: in control 1 the primary alkyl chloride derivatized antibody was replaced by original 12CA5 antibody, in control 2 covalin was replaced by a buffer load.

Labeling of CHO cells

Chinese hamster ovary cells (CHO-9-neo-C5) were grown in DMEM/F12 (Cambrex) supplemented with 10% fetal bovine serum (Cambrex) and antibiotics (Gibco, Invitrogen) (penicillin 100 U/ml and streptomycin 100 μg/ml final concentrations) in humidified atmosphere at 37 °C under 5% CO_2. Thirty-six hours before the derivatization reaction, cells were seeded on ibiTreat μ-Dishes (Ibidi) to a density of 80,000 cells per dish. Just before derivatization, the cells were washed three times with HBSS buffer (Lonza). The cells were either derivatized with BG by adjusting BG-GLA-NHS to a final concentration of 100 μM in HBSS or derivatized with primary alkyl chloride by adjusting NHS-O4-Cl to a final concentration of 500 μM in HBSS. Two control experiments were performed in which the activated ester solutions were replaced by a solvent load. The derivatization step was carried out for 30 minutes at 25 °C. The reaction was quenched for 15 minutes by adjusting to 50 mM Tris·Cl pH 7.4. The cells were washed three times with HBSS, then twice with HBSS + 0.1% BSA. Covalin was added to each plate to a final concentration of 10 μM in HBSS + 0.1% BSA and incubated at 25 °C under gentle rocking for 90 minutes. The cells were washed twice with HBSS, then once with HBSS + 0.1% BSA. The BG-

derivatized cells (and the corresponding control) were incubated with 2 μM Halo-Fl (Halo-DAF deacetylated in 25 mM K_2CO_3, 50% DMSO) in HBSS/0.1% BSA, whereas the primary alkyl chloride-derivatized cells (and the corresponding control) were incubated with 2 μM BG-547 in HBSS/0.1% BSA. After 15 minutes at 25 °C, the cells were washed three times with HBSS. The cells were then imaged in HBSS using a Zeiss Axiovert 200 inverted microscope, equipped with an LD “Plan Neofluar” 63×/0.75 corr Ph2 objective and an AxioCam MR digital camera (Zeiss). Zeiss filter sets 10 (excitation 450-490 nm; emission 515-565 nm) and 43 (excitation 545-625 nm; emission 605-670 nm) were used for fluorescence microscopy. Image analysis was performed with the AxioVision 4.0 software (Zeiss).

Figure S1

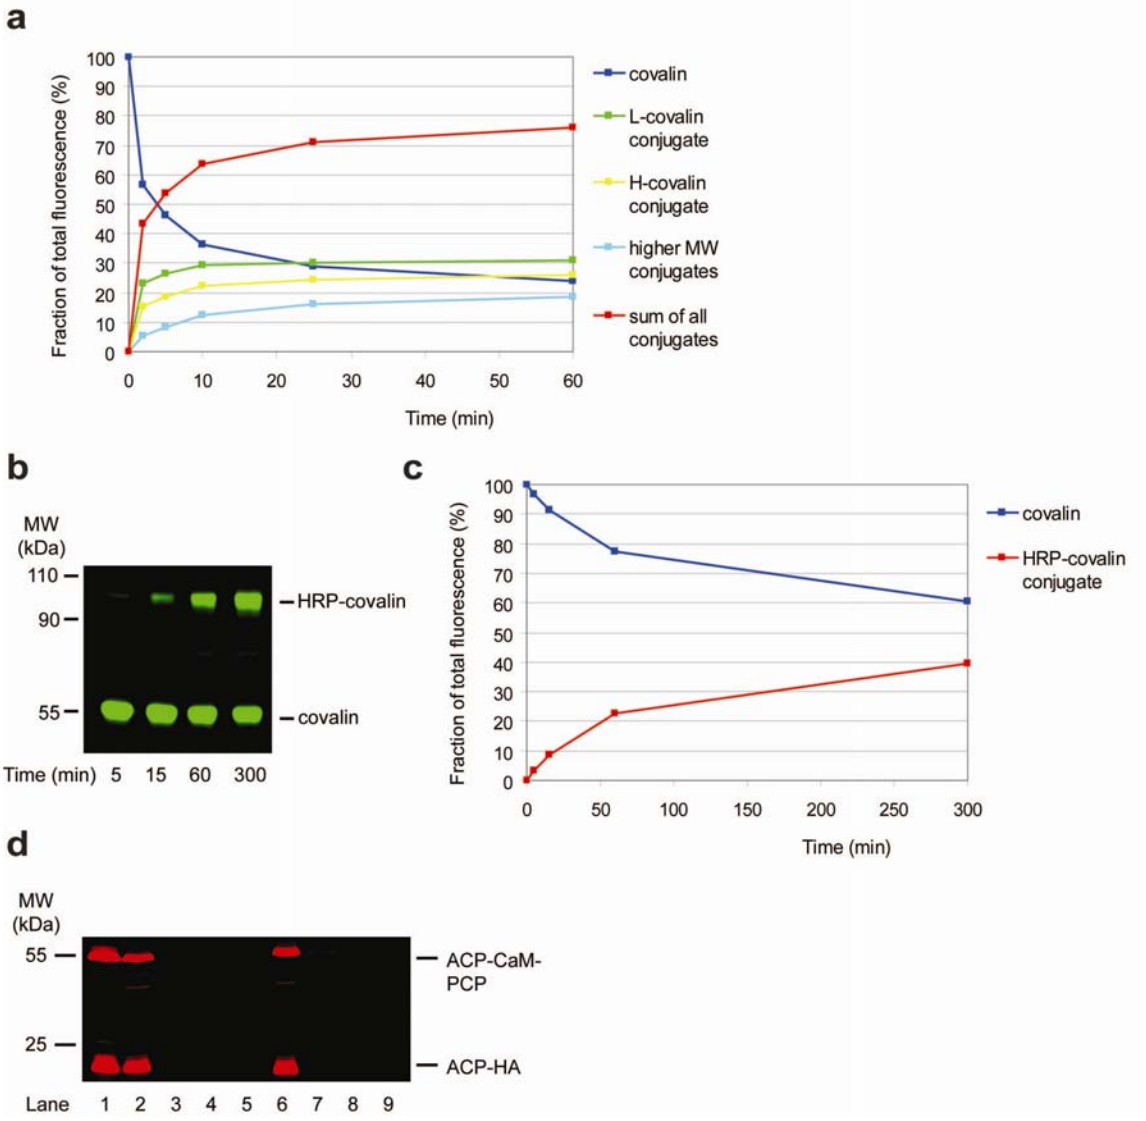

Figure S1**.** (**a**) Quantification of the fluorescence bands for Figure 2b. The four bands corresponding to covalin, Light chain-covalin conjugate, Heavy chain-covalin conjugate and higher molecular weight conjugates (Light and Heavy chains conjugated to 2 or more covalins) were quantified for each time point. Each of the four species was then represented as a percentage of the sum of the four values for each time point in the graphic representation. The sum of Light chain-covalin, Heavy chain-covalin and higher molecular weight conjugates was also represented in the graph (Sum of all conjugates). The time point 300 minutes was not included in the graph for a better visualization of the curves. The values after 300 minutes were very

close to those of the 60 minutes time point (<5% difference for the sum of all conjugates). The average number of covalin-DY-547 per anti-HA antibody was determined as follows: after 1 hour, 76% of the fluorescence signal of covalin-DY-547 is represented by antibody-covalin conjugates. This represents 7.6 μM of the initial 10 μM covalin. Using a 12CA5 concentration of 3 μM, an average number of 2.5 covalin per 12CA5 can be calculated. (**b**) Horseradish peroxidase (HRP) was derivatized with BG by incubation with the corresponding NHS ester. The derivatized HRP was then incubated with Covalin labeled with Halo-DAF. Aliquots of the reaction mixture drawn at different time points were analyzed by SDS-PAGE and in-gel fluorescence scanning. (**c**) Quantification of the fluorescence bands for Figure S1b. The two bands corresponding to covalin and HRP-covalin conjugate were quantified for each time point. Both species were represented as a percentage of the sum of the two bands in the graphic representation. (**d**) Control experiments for the pull-down experiment (Figure 2d). In control 1 (lanes 2-5) the primary alkyl chloride-derivatized 12CA5 was replaced by original 12CA5 and in control 2 (lanes 6-9) covalin was not added. Lane 1: before incubation with derivatized beads; lane 2: after incubation with derivatized beads; lanes 3 and 4: wash fractions; lane 5: elution of captured proteins from the beads; lane 6: after incubation with derivatized beads; lanes 7 and 8: wash fractions; lane 9: elution of captured proteins from the beads.

Box 32, Budapest 112 H-1518, Hungary. Received January 10, 2008; Revised Manuscript Received June 21, 2008

Cell adhesivity is a basic biological principle, which provides mechanisms for construction of multicellular organisms, tissue genesis, migration and individual cell survival. *In vivo*, the cell adhesive environment is provided by extracellular matrix molecules, neighboring cell surfaces and soluble factors delivered either by tissue cells or by blood circulation. The exact molecular composition of the microenvironment of a cell is not properly understood. The nondefined molecular composition of "native" adhesive components hinders their application when defined culture conditions are necessary, as, for an example, growing human cells for further clinical application. Applying large, substrate-coating molecules as backbones for carrying specific adhesive peptide motifs provides a relatively cheap, reproducible, and chemically defined group of synthetic adhesion molecules. Here, we report on the design, synthesis, and testing of a novel cyclic RGD-containing coating material, which promotes initial attachment, spreading, survival, and proliferation of a number of different cell types. The potent adhesive polypeptide-brush, composed of poly[Lys(DL-Ala_m)] branched chain polypeptide (AK) and multiple copies of cyclic(arginyl-glycyl-aspartyl-D-phenylalanyl-cysteine) pentapeptide prevents anoikis and supports cell attachment in the absence of serum or other biological additives. The defined conditions for cell maintenance make this material a promising candidate for coating artificial cell substrates even for therapeutic applications.

1. INTRODUCTION

Cell−extracellular matrix (ECM) interactions are pivotal for survival of adherent cells both *in vivo* and *in vitro*. Without proper attachment, cells adopt a special apoptotic fate, termed "anoikis" (homelessness in Greek) (*1*). For *in vitro* maintenance of adherent cells, artificial substrates should provide appropriate surfaces for rapid attachment.

In traditional cell culture techniques, sera of various origins, containing different attachment and spreading factors, are included in the culture medium. While serum application greatly helps cell culturing, its nondefined nature makes it ineligible when defined culture conditions are required, such as for growing human cells for clinical applications. Its high price, the risk of contamination, and the animal welfare considerations also hinder the use of sera (*2*).

Serum-free, chemically defined media are available for a wide variety of cell types (*3*), but most of them impair cell attachment. Coating the culture surfaces with native extracellular matrix molecules derived from either human/animal tissues or recombinant bacteria may overcome this difficulty but brings back the uncertainty in molecular composition and the risk of contamination. Synthetic, polycationic peptides/proteins, such as poly(L/D-lysine) (PLL, PDL) or polyornithine, are widely used for coating cell culture dishes. Such nonspecific adhesive coatings, however, promote initial cell adhesion with moderate efficiency, may cause abnormal cell-spreading, and might be cytotoxic (*4*). Applying such large, substrate-coating molecules as backbones for carrying specific adhesive peptide motifs, however, may provide a relatively cheap, reproducible, and chemically defined group of efficient synthetic adhesion molecules (*5*).

Cell−ECM adhesion is performed predominantly by integrins which serve as receptors for several ECM components (*6*). Besides anchoring the cells, signaling through the integrins can regulate the survival, proliferation, and differentiation of cells (*7*).

Various scaffold substrates had been modified with RGD motifs (*5*, *8*−*16*), a tripeptide sequence recognized by most integrins. The RGD (arginyl-glycyl-aspartic acid) sequence can be found in many extracellular matrix proteins (fibronectin, vitronectin, tenascin-C, etc.) and is responsible for the binding of these ECM proteins to their receptors (*17*) on the cell surfaces. In soluble form, RGD-containing oligopeptides can inhibit cell adhesion, by antagonizing the integrin−matrix interaction (*18*). The immobilized RGD sequence, on the other hand, is generally acknowledged as a promising biomaterial for promoting cell adhesion to artificial substrates and it is the most commonly

applied protein motif on synthetic surfaces (*5*). Because of the uncovered carboxyl terminus of the aspartate residue, the RGD tripeptide, in itself, has no biological activity. In the active RGD motif, this C-terminus should be masked by addition of another amino acid (*18*). RGD-containing cyclic pentapeptides, such as cyclo[RGDfV], were originally described as potent inhibitors of cell adhesion to vitronectin and laminin fragment P1 (*19*). Cyclic (RGDfV) (*20*), (RGDfK) (*21*), and (RGDfC) peptides have the highest affinity and selectivity toward $\alpha_v\beta_3$ and bind strongly to $\alpha_v\beta_5$, $\alpha_v\beta_6$ (*22*) integrins and with lower affinity to other integrins (such as $\alpha_{IIb}\beta_3$ and $\alpha_5\beta_1$), as well (*20*).

In order to obtain an integrin-binding macromolecule, we designed a poly[Lys(DL-Ala_m)] (AK) branched polypeptide, carrying multiple copies of cyclic(arginyl-glycyl-aspartyl-D-phenylalanyl-cysteine) pentapeptide on the N-terminal positions of the oligoalanine branches (AK-cyclo[RGDfC]). The novel synthetic polypeptide readily adsorbed to various solid substrates and provided a strongly adhesive coating for cell attachment. In order to evaluate selective versus general adhesiveness of the polymer, the attachment of a number of different anchorage-dependent cells was investigated. AK-cyclo[RGDfC]-coated surfaces promoted adhesion and spreading of almost all investigated cell types in the absence of serum or any other adhesion or spreading factors. As AK-cyclo[RGDfC]-coating supported serum-free survival of several cell types in the critical, 24−48 h initial attachment period, it has been proven to be a tool for initiating cell cultures under strictly defined conditions.

2. EXPERIMENTAL PROCEDURES

2.1. Materials. All amino acid derivatives and Rink-Amide MBHA resin were purchased from Novabiochem (Läufelfingen, Switzerland). Scavengers, coupling agents, and cleavage reagents were Fluka products (Buchs, Switzerland). Solvents for synthesis and 2-Cl-trityl chloride resin were obtained from Reanal (Budapest, Hungary). Acetonitrile for HPLC was delivered by Sigma-Aldrich (Budapest, Hungary).

Cell culture media and chemicals for cell culturing were purchased from Sigma-Aldrich (Budapest, Hungary). Fetal calf serum (FCS; Gibco) was purchased from Csertex (Budapest, Hungary). Tissue culture plates and dishes were Greiner or Falcon, purchased from Dialab (Budapest, Hungary) and Softflow (Pécs, Hungary), respectively, and the glass coverslips were obtained from Erie Scientific (Budaörs, Hungary).

2.2. Synthesis of Cyclo[Arg-X-Asp-D-Phe-Cys]. Linear side chain protected precursor peptides H-Asp(O^{t}Bu)-D-Phe-Cys(Trt)-Arg(Pbf)-X-OH (where X is Gly or Ala) were synthesized manually by solid-phase peptide synthetic method according to Fmoc/^{t}Bu strategy using 2-Cl-trityl chloride resin as a support (*23*). The attachment of the C-terminal amino acid to the resin was carried out as follows: (i) prior to use, the resin was dried overnight over solid KOH in a desiccator; (ii) swelling of the resin in dichloromethane (DCM) for half an hour, then washing with *N*,*N*-dimethylformamide (DMF); (iii) coupling of the C-terminal amino acid to the resin using 2.5 equiv of Fmoc-Gly-OH or Fmoc-Ala-OH dissolved in DMF and 2.5 equiv of *N*-ethyldiisopropylamine (DIEA) (1 + 1.5 equiv added in two portions) for 1 h, then capping with methanol (0.8 mL/g resin) for 10 min; (iv) washing with DMF (5 × 0.5 min); (v) removal of Fmoc protecting group in three steps: 5% piperidine in DMF for 10 min, 30% piperidine in DMF for 15 min, 50% piperidine in DMF for 30 min; (vi) DMF washing (6 × 1 min). The Fmoc resin loading was determined by Gude's method and resulted in 0.6 mmol/g resin capacity in both cases (*24*).

After this procedure, the further amino acid derivatives were coupled according to the following protocol: (i) coupling of Fmoc-amino acid derivative with 1-hydroxybenzotriazole (HOBt) and *N*,*N*′-diisopropylcarbodiimide (DIC) (3 equiv each) in DMF (the efficacy of the coupling reaction was monitored by ninhydrin assay (*25*)); (ii) DMF washing (5 × 0.5 min); (iii) deprotection in two steps with 30% piperidine in DMF for 3 and 17 min; (iv) DMF washing (6 × 1 min). After washing the peptide-resins with DMF, DCM, methanol, and diethyl ether, the side chain protected peptides were cleaved from the dried resins using a mixture of DCM/methanol/acetic acid = 8:1:1 (v/v/v) for 2 h at room temperature. The cleavage step was repeated, then the cleavage mixtures were combined and the solution was concentrated *in vacuo*. The intermediate crude product was precipitated with cold diethyl ether, filtered, and washed three times with ether afterward. The solid material was dissolved in 5% acetic acid prior to freeze-drying. The purification of the linear side chain protected peptides was not necessary due to their high purity determined by RP-HPLC (over 90%). To change the acetate counterion to chloride, the linear peptide derivatives were dissolved in methanol in the presence of 10 equiv of pyridinium hydrochloride and then the solvent was evaporated.

The dried linear peptides were dissolved in DMF (1 mg/mL), then 3−3 equiv of (benzotriazol-1-yloxy)tris(dimethylamino)-phosphonium hexafluorophosphate (BOP) and HOBt coupling agents in the presence of 6 equiv of DIEA were added to both peptide solutions. The pH of the reaction mixtures was slightly alkaline (pH 7.5−8). Each reaction was followed by RP-HPLC. After 24 h, the reactions were completed; then, the solvent was evaporated *in vacuo*, and the crude products were precipitated with 5% $NaHCO_3$ (aqueous solution), filtered off, and washed with d.i. water until the filtrate was neutral. The cleavage of the side chain protecting groups of the dried cyclic peptides was performed by using modified Reagent-K cleavage mixture: trifluoroacetic acid (9.75 mL), water (0.25 mL), phenol (0.75 g), thioanisole (0.25 mL), ethane-1,2-dithiol (0.25 mL), and triisopropyl silane (0.125 mL) at room temperature for 3.5 h. After cleavage, the crude products were precipitated with cold diethyl ether, washed with ether three times, filtered off, and dried *in vacuo* over P_2O_5, followed by purification using semipreparative RP-HPLC. The pure cyclic peptides were characterized by analytical RP-HPLC and ESI-MS (Table 1). The racemization of Ala-containing peptide under cyclization conditions was determined by using Marfey's reagent (*26, 27*). The D-Ala content of the cyclic peptide was less than 1%.

Table 1. Characteristics of Derivatives

peptides	R_T [min][a]	calculated mass [M]	$[M + H]^{+b}$
cyclo[Arg-Gly-Asp-D-Phe-Cys]	9.0	578.2	578.9
cyclo[Arg-Ala-Asp-D-Phe-Cys]	9.6	592.2	593.0
cyclo[Arg-Gly-Asp-D-Phe-Cys(Cmc)]	7.7	635.3	636.0
H-Arg-Gly-Asp-D-Phe-Cys-NH_2	6.5	595.3	596.2

[a] Column, Vydac 218TP C_{18} (250 × 4.6 mm, 5 μm, 300 Å); eluents, 0.045% TFA/H_2O (A) and 0.036% TFA/acetonitrile (B); gradient, 5−95% B in 30 min; flow rate, 1 mL/min; detection λ = 220 nm. [b] ESI-MS

2.3. Preparation of Cyclo[Arg-Gly-Asp-D-Phe-Cys(Cmc)]. The carboxamidation of the thiol group of the cyclic peptide was carried out as follows: 1 equiv of iodoacetamide to the cyclic peptide was dissolved in 0.1 M Tris buffer (pH 8.1) and the cyclic peptide was added to the solution at a peptide concentration of 1 mg/mL. The reaction was monitored by RP-HPLC. In half an hour, the reaction was completed, the mixture was acidified by addition of a few drops of TFA, and then it was purified by semipreparative RP-HPLC. Pooled fractions were freeze-dried and the purified product was characterized by analytical RP-HPLC and ESI-MS (Table 1).

2.4. Synthesis of H-Arg-Gly-Asp-D-Phe-Cys-OH. In the case of synthesis of the linear RGD peptide, it was cleaved from the 2-ClTrt resin directly by modified Reagent-K mixture and

Table 2. Amino Acid Composition of Conjugates

conjugate	Asp	Gly	Ala	Phe	Lys	Arg
AK-cyclo[RGDfC]	0.33	0.34	4.64	0.34	1.00	0.31
AK-cyclo[RADfC]	0.32	-	5.00	0.33	1.00	0.32
AK-RGDfC	0.34	0.35	4.62	0.33	1.00	0.32

the pure linear peptide was isolated by RP-HPLC purification followed by lyophilization. The purified product was characterized by analytical RP-HPLC and ESI-MS, similarly to the cyclic versions (Table 1).

2.5. Conjugation of Peptides to Chloroacetylated Branched Chain Polymeric Polypeptide. Branched chain polymeric polypeptide (poly[Lys(DL-Ala_m)]; AK) was prepared according to the method previously described (*28*). Chloroacetylation of AK polymer was performed as described before (*29*). Briefly, for the preparation of conjugate, AK ($DP_n = 60$, Ala/Lys= 4.6:1, $M_w = 19\,600$) was reacted with chloroacetic acid pentachlorophenyl ester in DMF/water solution (9/1, v/v): first, 20 mg AK was dissolved in 1 mL water, and then the solution was diluted with 4 mL DMF; after that, 0.5 equiv chloroacetic acid pentachlorophenyl ester (ClAc-OPcp) calculated to the branches (8.2 mg) dissolved in 5 mL DMF was added. The reaction was carried out overnight, and then the mixture was dialyzed against 1% acetic acid for two days. The precipitate (pentachlorophenol) was filtered off and the filtrate was freeze-dried. According to the organic chlorine determination, the molar ratio of chlorine and lysine in polypeptide was 0.4:1 (*30*).

The conjugation reaction of multivalent chloroacetyl-AK polymer and cyclo[RXDfC] peptides or linear H-RGDfC-NH_2 peptide resulting in a thioether linkage was carried out in 0.1 M Tris buffer, pH 8.0. To avoid significant dimerization of RGD peptide derivatives *via* disulfide bond formation, the cysteine containing peptides (2 equiv altogether to the Cl content of the polymer) were added in solid form to the solution of the chloroacetylated polypeptide (1 mg/mL) from time to time during 3 h. In all cases, the reaction was terminated after 24 h by adding an excess of cysteine to block the unreacted chloroacetyl groups. The crude products were dialyzed against d.i. water to remove the unreacted RGD peptides and cyst(e)ine, then freeze-dried. The efficacy of the conjugation was calculated from the amino acid composition of the conjugates using amino acid analysis (Table 2).

2.6. Analysis and Purification by RP-HPLC. Analytical RP-HPLC measurements for the determination of the purity of intermediate peptide derivatives (for cyclization or conjugation) were carried out on Vydac 218TP C_{18} column, 250 × 4.6 mm, particle size 5 μm, pore size 300 Å (Vydac, Hesperia, CA) using Shimadzu HPLC system (two LC-6A pump, SPD-6AV UV-detector, SIL-6B auto injector, SCL-6B system controller; (Shimadzu Corporation, Kyoto, Japan)) with eluent A: 0.045% TFA in H_2O and eluent B: 0.036% TFA in acetonitrile. Linear gradient of 5−95% eluent B was developed with 1 mL/min flow rate, during 30 min. Peaks were detected at $\lambda = 220$ nm.

Purification of peptides was performed using Phenomenex Jupiter C_{18} column (250 × 10 mm, 10 μm, 300 Å) on a Knauer laboratory assembled semipreparative HPLC system (Knauer Pump type 120, Dynamic Mixing Chamber Analytical, Spectro Photometer K-2501; (Knauer, Berlin, Germany)); with eluent A: 0.1% TFA in H_2O and eluent B: 0.1% TFA in acetonitrile−H_2O (80:20, v/v). An isocratic elution with 10% of eluent B was applied from 0 to 5 min, then 5−28 min a gradient elution of 10−33% of eluent B was used with 4 mL/min flow rate. Peaks were detected at $\lambda = 220$ nm.

2.7. ESI Mass Spectrometry Analysis. The identification of the products was achieved by mass spectrometry. Electrospray ionization mass spectrometry was performed with a Bruker Daltonics Esquire 3000 Plus (Bremen, Germany) ion trap mass spectrometer, operating in continuous sample injection at 4 μL/min flow rate. The peptides were dissolved in 50% acetonitrile−water mixture. Mass spectra were recorded in positive ion mode in the *m/z* 200−1500 range.

2.8. Amino Acid Analysis. The amino acid composition of conjugates was determined by amino acid analysis using SYKAM S-433 amino acid analyzer (SYKAM GmbH, Eresing, Germany) equipped for the determination of amino acids with postcolumn reaction with ninhydrin. Prior to analysis, the samples were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 110 °C for 24 h.

2.9. Surface Coatings. For cell-attachment analyses, polystyrene or glass surfaces were coated with the AK-cyclo[RGDfC] or with one of the control peptides (PLL, AK, AK-cyclo[RADfC], AK-RGDfC). The peptides were dissolved in distilled water in concentrations of 0.002−20 μg/mL. The solutions were left on the surfaces for 30 min, then aspirated, and the surfaces were allowed to dry at room temperature. Estimated surface densities—pretending that all molecules were deposited to the surface—were calculated between 0.00025 and 2.5 $\mu g/cm^2$. Coated surfaces could be stored for up to 4 months at 4 °C.

2.10. Atomic Force Microscopy. The morphology of the AK-cyclo[RGDfC] polypeptide layer after drying for at least 24 h was studied with an atomic force microscope (Park Syst. XE-100, South Korea). We used a cantilever NSC15 (Park Syst.) made of Si_3N_4. The tip curvature radius was less than 10 nm and the reflective side was coated with Al. The AFM scans were conducted at 0.3−0.5 Hz scanning rate taken at scan window of 2 × 2 μm. Several randomly selected locations with at least 8−10 different images were collected for each specimen. Observation was carried out at noncontact mode in air. The image analysis was performed using the XIE 1.6 progam (Park Syst.).

The morphology of the protein layers on the glass substrate was characterized by average roughness values (R_a) determined for the whole images.

2.11. Cell Cultures. Cell lines (MDCK, GENC, A431, A7r5, NE-4C, MC3T3-E1 sc4) and HUVEC cells were maintained

Table 3. Investigated Cell Types

name	cell type	origin	maintaining medium	reference
MDCK (madine darby canine kidney)	cloned kidney epithelial	canine	DMEM, 10% FCS	ATCC No.: CCL-34

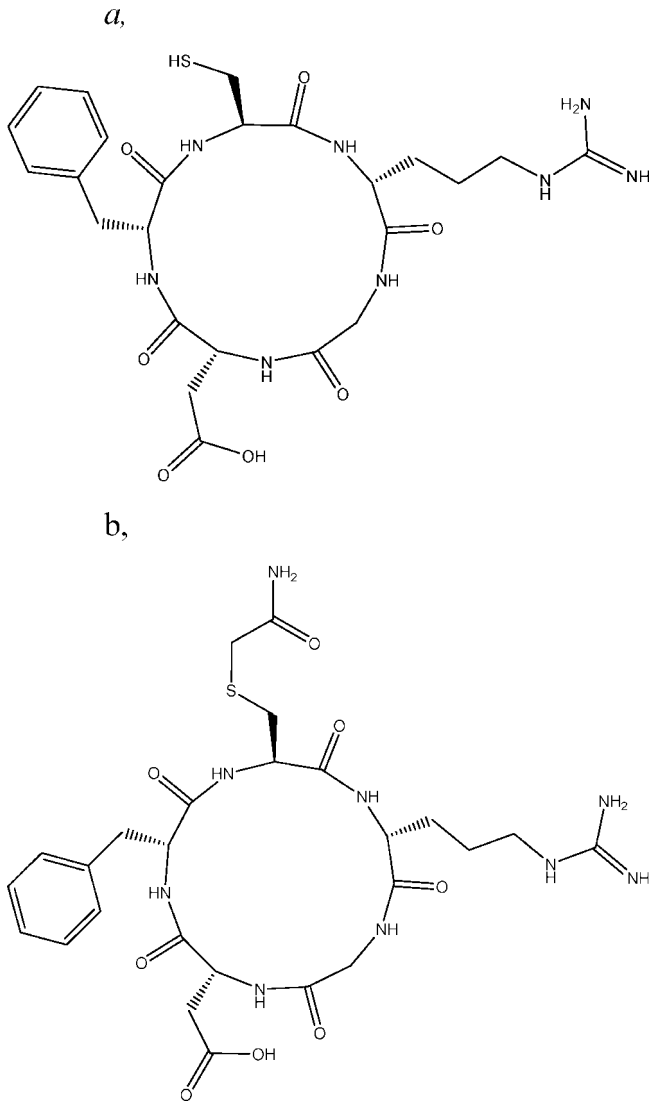

Figure 1. Structure of cyclo[RGDfC] (a) and cyclo[RGDfC(Cmc)] (b).

under standard culture conditions described for the particular cell type (Table 3). Primary cell cultures of neurons (*33*) and astrocytes (*34*) and maintained preparations of fibroblasts (*35*) and bone marrow mesenchymal cells (*36*) were established from mouse tissues and were maintained according to well established protocols, in serum-containing media (Table 3).

For cell-attachment assays, the cells were harvested by trypsinization (0.05 w/v % trypsin, in phosphate buffered saline [PBS] containing 5 mM EDTA). After inhibiting the enzyme activity and washing, the cells were collected in the maintaining media, but without serum. The cells were reseeded onto coated surfaces and were allowed to attach for no longer than 3 h (see below).

For analyzing the 48 h survival, harvested glomerular endothelial cells (GENC) were collected, seeded, and maintained in defined medium composed of DMEM/F12 3/1 (v/v) and supplemented with 1% ITS (ITS-G, GIBCO, Invitrogen) providing a final concentration of 10 μg/mL insulin, 5.5 μg/mL transferrin, and 6.7 ng/mL sodium selenite.

2.12. Microscopic Observations on Initial Cell Adhesion. 35 mm tissue culture dishes precoated with various peptides were placed into a thermo-stabilized (37 °C) chamber on the stand of a Zeiss Axiovert 200 M microscope. 1.5 mL suspensions of cells (5×10^5 cells/mL) in serum-free media were seeded and phase-contrast pictures ($10 \times$ objective) were taken at various time-points after seeding.

Time-lapse microscopic comparison of the initial attachment of MDCK cells on AK- cyclo[RGDfC] and on PLL is available in the Supporting Information. Videomicroscopic analysis was carried out similarly as described above, with a Zeiss Axiovert 200 M microscope. Photographs were taken at every 5 s.

2.13. Quantitative Cell Adhesion Assay. Cells were harvested by trypsinization, centrifuged, and washed with PBS to eliminate trypsin and EDTA and were collected in serum-free media. In some experiments (see the text), the media were supplemented with 5% (v/v) FCS. Cells were seeded into 96-well plates at densities of $(1-5) \times 10^4$ cells/well and were allowed to attach for a time-point, when the majority of cells ($\geq$75%) had adopted a spread-out, flattened shape on AK-cyclo[RGDfC] (1−3 h, depending on the cell type). Cultures were washed with PBS to eliminate nonattached cells and then fixed with 4% paraformaldehyde (w/v in PBS) for 20 min at room temperature. Attached cells were stained with 0.25% methylene blue, for 30 min (*37*). Stained cell mass was dissolved in acidic (0.05 M HCl) ethanol and light absorbance was measured at $\lambda = 650$ nm with a Bio-Rad 450 ELISA reader. For each condition, eight parallel wells were measured. Data were expressed as means and standard deviations.

2.14. Cell Viability Assay. Viability of GENC cells cultured in defined medium was determined by measuring reductive capacity according to Mosmann et al. (*38*). Briefly, cells were grown for 48 h in 96-well plates coated with different peptides and then treated with 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) for two hours at a final concentration of 250 μg/mL. After a 2 h incubation, cells and formazan crystals were dissolved in acidic (0.08 M HCl) isopropanol. Optical density was determined at a measuring wavelength of $\lambda = 570$ nm against $\lambda = 630$ nm as reference with a Bio-Rad

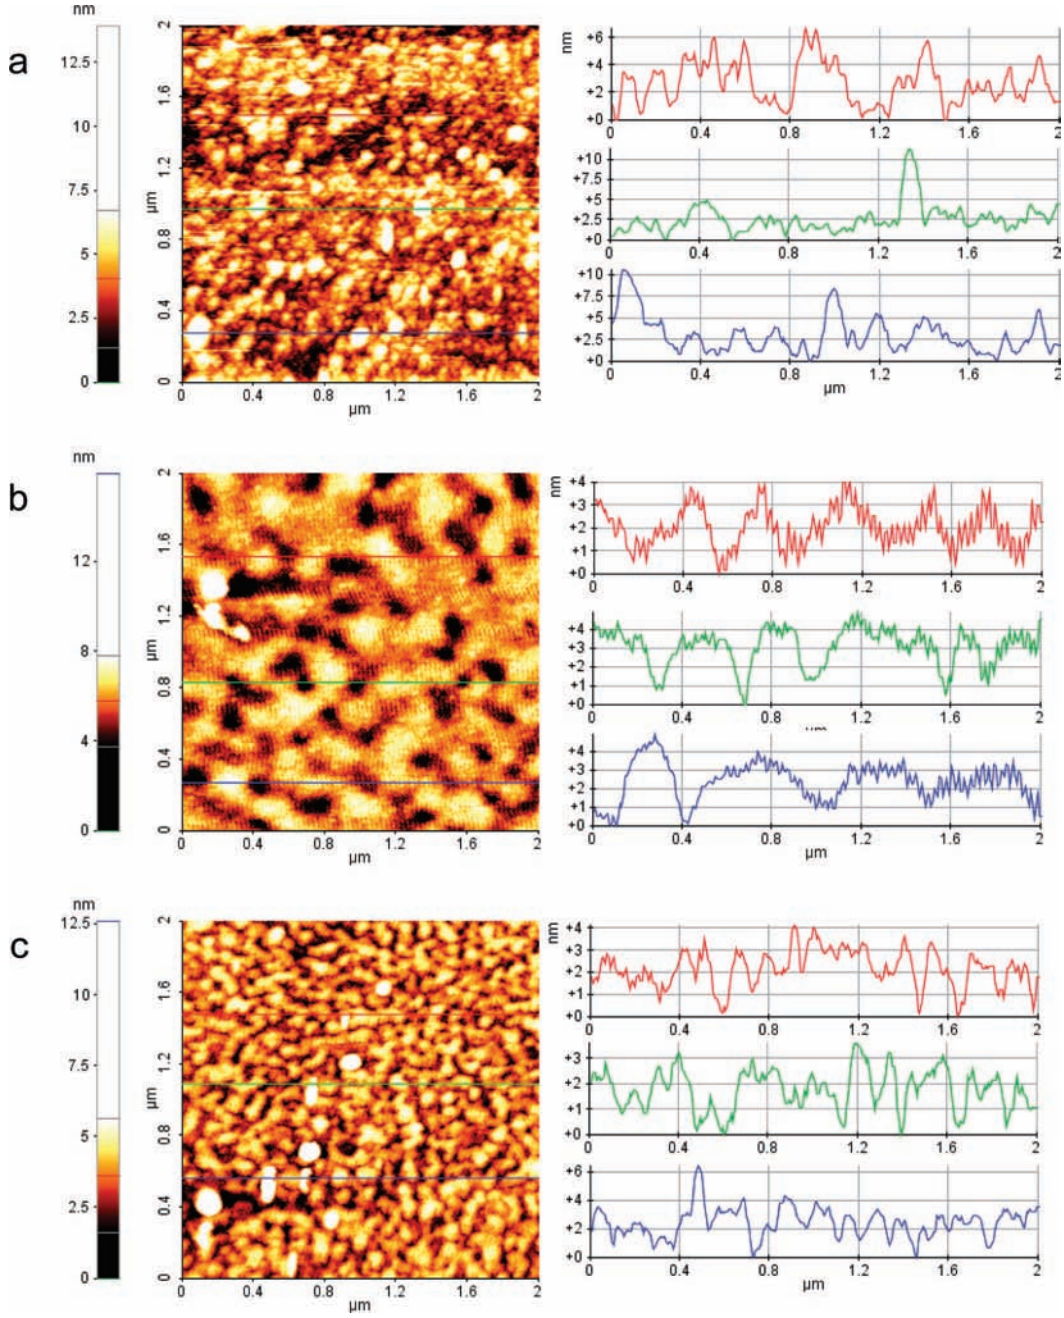

Figure 3. AFM topographic images (2 × 2 μm) of protein films formed from solution with a concentration of 2.5 (a), 0.25 (b), and 0.025 (c) μg/mL. Three selected profile lines are displayed for each image to present typical vertical cross sections of the protein films.

450 ELISA reader. Assays were carried out on 8 parallel wells. The viability data were expressed as means and standard deviations.

2.15. Visualization of Actin Cytoskeleton with Rhodamine-Conjugated Phalloidin. MDCK cells were plated onto AK-cyclo[RGDfC] coated glass coverslips in serum-free medium. They were fixed after 1.5 or 24 h with 4% paraformaldehyde for 20 min. The cell membranes were permeabilized by 5 min treatment with 0.1% Triton-X 100 (in PBS). Actin cytoskeleton was labeled with rhodamine-conjugated phalloidin according to the manufacturer's instruction (Invitrogen) and analyzed with a Zeiss Axiovert 200 M fluorescent microscope.

2.16. Statistical Analysis. All data were expressed as means and standard deviations. Statistical significance was determined by Student's *t* test. Differences were considered significant at $p < 0.05$.

3. RESULTS

3.1. Synthesis and Characterization of Cyclic RGD Conjugated AK Polymer. The aim of the present study was the development of cell adhesive conjugates carrying the biologically active integrin ligand, cyclic RGD peptide (cyclo-[RGDfC]) (Figure 1a) to provide potent adhesive surfaces for a wide range of cell types. As macromolecules with polycationic property bind readily to negatively charged tissue culture dishes and metal oxide surfaces, a polycationic branched polypeptide AK (Figure 2) with polylysine backbone was selected, in which oligo-DL-alanine moieties were introduced as branching side chains (poly[Lys(DL-Ala)$_m$]). The resulting AK (Figure 2) was used as polymeric carrier. The cyclic peptide cyclo[RGDfC] and also its cyclic and linear control derivatives (cyclo[RADfC] and H-RGDfC-NH_2)—which served as control peptides—were coupled to the AK polymer *via* thioether bonds. The thioether

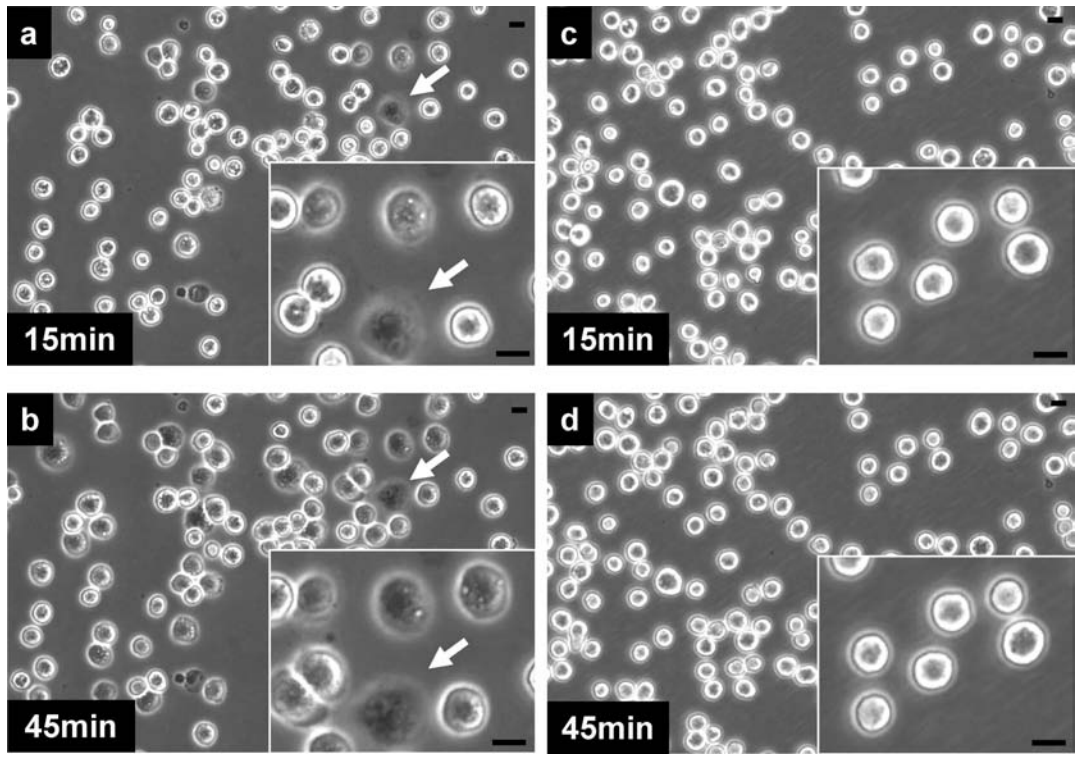

Figure 4. Initial attachment of MDCK cells on AK-cyclo[RGDfC] (a,b) and PLL (c,d) coated plastic surfaces. Pictures were taken at 15 and 45 min after plating. Note spreading cells (arrows) on the enlarged inserts on the left panels. Bars represent 10 μm.

linkage has several advantages such as easy and selective formation and high stability under the conditions of the chemical synthesis, purification, and biological measurements. For the formation of the thioether bond, the AK polymer was chloroacetylated using ClAc-OPcp, and a cysteine residue was incorporated into the sequence of the RGD peptides. To avoid the racemization during the "head-to-tail" cyclization step, glycine or alanine were the C-terminal amino acid residues. In this way, a linear, side chain protected precursor peptide with a sequence of DfCRX (X = Gly or Ala) was built up on solid phase. The peptide was prepared on 2-Cl-trityl chloride resin by Fmoc/^{t}Bu strategy. The side chain protected linear precursor peptide with free N- and C-termini (H-D(O^{t}Bu)fC(Trt)R(Pbf)X-OH) was produced by cleavage using a mixture of DCM/MeOH/AcOH = 8:1:1 (v/v/v). The purity of the crude products was over 90%; therefore, they were applied for cyclization without further purification. The "head-to-tail" cyclization was performed in a diluted DMF solution in the presence of BOP and HOBt coupling reagents and DIEA base to provide slightly alkaline conditions. The side chain protecting groups were removed from the cyclic peptides with a modified Reagent-K cleavage mixture. For a comparative study, a thiol-protected form of the cyclic peptide was also produced by carboxamidation of the Cys side chain (c[RGDfC(Cmc)]) (Figure 1b) using iodoacetamide. In order to analyze the importance of the RGD sequence and the cyclic form of the peptide, two further compounds were prepared (cyclo[RADfC] and H-RGDfC-NH_2) for conjugation. The peptides were characterized by RP-HPLC and ESI-MS (Table 1). Racemization study of cyclo[RADfC] showed no significant epimerization of Ala under cyclization conditions.

Prior to conjugation, the AK polymer was "activated" by chloroacetylation of the amino groups of the polypeptide using ClAc-OPcp at a molar ratio that resulted in about 40% substitution of the side chains of the polymer. The incorporated chlorine atoms could be exchanged for thiol-containing cyclic peptides in a nucleophile substitution reaction under slightly alkaline conditions. To avoid significant dimerization of the cysteine containing cyclic peptides by disulfide bond formation, the cyclic peptides were added in solid form to the solution of the choloracetylated polypeptide and the concentration of the peptide was kept low in the reaction mixture. After the conjugation reaction, unreacted chloroacetyl groups were blocked by the addition of an excess of cysteine to prevent alkylation during the biological experiments. The amount of the attached RGD peptides was calculated by the results of amino acid analysis (Table 2). In all three cases, 32−33% substitution of the branches of the polypeptide carrier was observed.

3.2. Coverage of the Substrate by the Deposited Peptide−Conjugates. Topographic AFM images (Figure 3) on peptide-coated glass substrates showed that the AK-cyclo[RGDfC] polypeptide conjugate formed continuous layers on the substrate. The roughness values of peptide-covered surfaces highly exceeded the values obtained for the pure glass (R_a < 0.1 nm) substrate. The surface roughness increased with the increasing peptide concentrations (0.025−2.5 μg/mL) with the average roughness values of 1.056, 0.777, and 0.729 nm for films prepared from solutions with concentrations of 2.5, 0.25, and 0.025 μg/mL, respectively. Sectional analyses on the structural details showed aggregates extending from the layer. The peak values of emerging aggregates reached about 10 nm on surfaces deposited from 2.5 μg/mL peptide solution.

3.3. Cell Adhesion. The initial attachment, spreading, and short-term (24−48 h) survival of different types of cells (Table 3) were investigated on surfaces coated with AK-[cRGDfC] polymer and were compared to the cell behavior on plastic or glass surfaces coated with control peptides. The cell types involved in the studies included cloned cell lines, long-term maintained tissue-derived cells (HUVEC, mouse bone marrow mesenchyme cells, and fibroblasts), and primary tissue cells (neurons, astrocytes) directly isolated by tissue dissociation (Table 3). The control substrates included tissue-culture treated polystyrene, poly(L-lysine) (PLL), the poly(L-lysine-alanine) (AK) carrier polypeptide, the AK-cyclo[RADfC] conjugate with

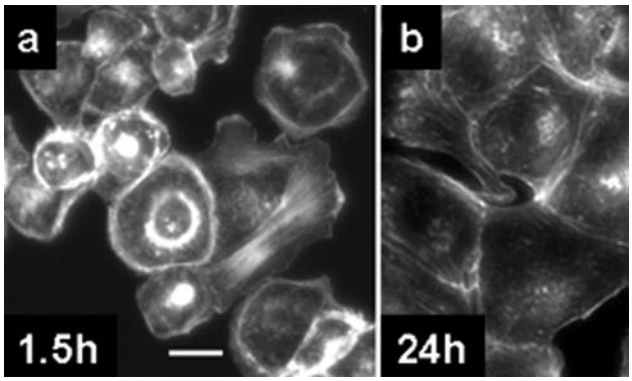

Figure 5. The rearrangement of actin fibers in MDCK cells attaching to (a) and spreading on (b) AK-cyclo[RGDfC] coated glass surfaces were visualized by rhodamine-conjugated phalloidin staining. Pictures were taken 1.5 (a) and 24 h (b) after plating. Bars represent 10 μm.

a corrupted RGD motive, and the AK-RGDfC conjugate containing the linear form of the pentapeptide. Cell attachment was assayed in serum-free environment.

The morphological observations on the cell shape during initial attachment and spreading followed with videomicroscopy (see Supporting Information) and conventional microscopy (Figure 4) indicated a rapid initial attachment to AK-cyclo-[RGDfC] coated surfaces. In the initiation of flattening, however, cell type dependent differences were observed. MDCK, GENC, or NE-4C cells were flattening against the AK-cyclo[RGDfC] coated surface within 10−15 min (Figure 4a), while spreading of MC 3T3 osteoblasts, HUVECs, or astroglial cells was observed no sooner than 40−60 min after plating. In comparison to control surfaces (bare polystyrene, PLL or AK, AK-cyclo[RADfC], AK-RGDfC), however, all cells developed filopodia and lamellipodia earlier on AK-cyclo[RGDfC] and cells flattened in a significantly shorter period (Figure 4).

The rearrangement of actin fibers during attachment to AK-cyclo[RGDfC] was visualized by rhodamine-conjugated phalloidin (Figure 5). In MDCK cells adhering to AK-cyclo[RGDfC] coated surface, spreading cells with actin stress fibers were observed within 1−1.5 h, among cells with an actin arrangement characteristic of initial attachment (*39*), namely, the inner actin ring and the outer actin zone at the actively palpating filopodia (Figure 5a). The cells kept on spreading until settling in a flattened monolayer arrangement (24 h), with stress fibers oriented toward the cell periphery and distributed almost evenly (Figure 5b). The morphological changes indicated that the contact with AK-cyclo[RGDfC] coated surface initiated a normal schedule of attachment, at least as it was judged by the rearrangement of the actin filaments.

Cell attachment was measured by colorimetric cell adhesion assay, modified after Oliver et al. (*37*). Evaluation of the attached cell mass after a period of initial attachment (see Experimental Procedures) revealed that AK-cyclo[RGDfC] promoted the initial attachment of all investigated cells, except freshly isolated neurons.

AK-cyclo[RGDfC] improved attachment if it was deposited from solutions containing 0.025−2.5 μg peptide per cm^2. The sufficient coating density, however, was cell type dependent. MDCK or NE-4C cells needed less dense (0.025 μg/cm^2 or 0.25 μg/cm^2, respectively) coating (Figure 6a), while MC 3T3 osteoblasts, astroglia, or fibroblast cells demanded higher density (2.5 μg/cm^2) for robust attachment (Figure 6b). The adhering cell mass increased with increasing AK-cyclo[RGDfC] density up to an "upper threshold". In the case of MDCK or GENC cells, adhesivity did not increase above the coating density of 0.25 μg/cm^2, while in the case of weakly adhering cells, an "upper threshold" was not reached even at the highest applied (2.5 μg/cm^2) density (Figure 6b). With changing concentration of AK-cyclo[RGDfC] solution, e.g., increasing the density of the coating molecules at the surface, the optimum coats for particular cells could be determined. Addition of fetal bovine serum (5%) to the medium could improve the attachment at low AK-cyclo[RGDfC] surface densities in the initial (1.5−3 h) period, but failed to influence cell attachment at or above the optimum coating density (Figure 7).

To test the specific adhesive effects of the cyclo[RGDfC] containing polymer, two different control motifs—a linear pentapeptide RGDfC and a cyclic pentapeptide (cyclo[RADfC])

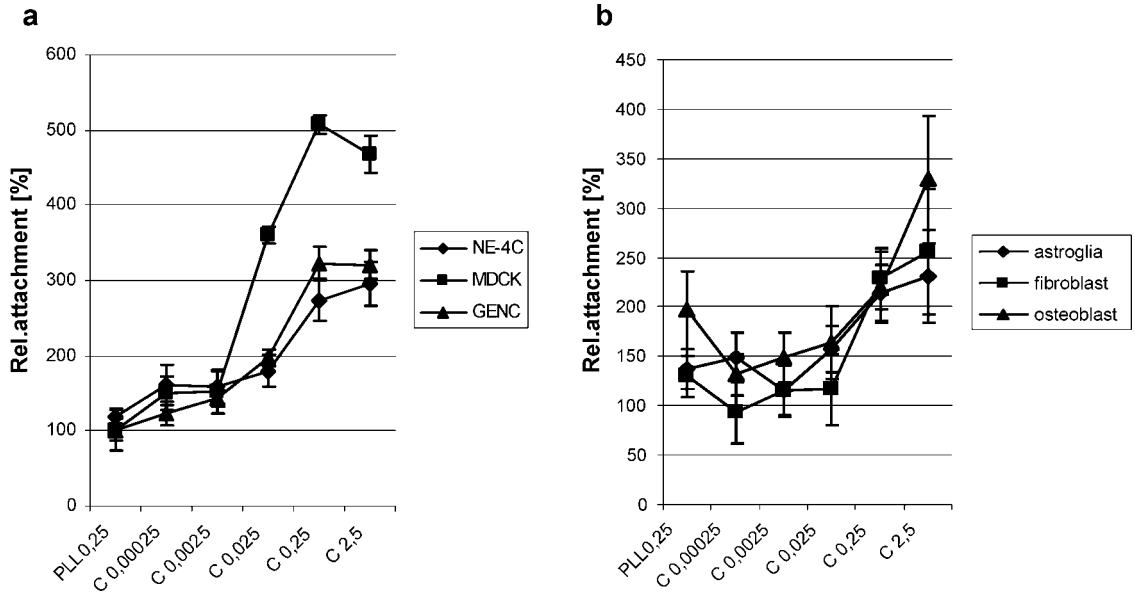

Figure 6. The attachment of different types of cells to AK-cyclo[RGDfC] deposited from coating solutions containing 0.00025−2.5 μg peptide−conjugate/cm^2. Attachment was determined by photometric evaluation of methylene-blue staining after washing off the unattached cells. The data are presented as the percentages of attachment on polystyrene (100%). Note the cell type dependent differences in the "threshold coating density" for attachment. Attachment of MDCK, GENC, and NE-4C cells (a); attachment of astrocytes, fibroblasts, and osteoblasts (b). (Abbreviations: PLL, poly(L-lysine); C, AK-cyclo[RGDfC]; the numbers indicate the peptide content [μg] in the coating solution calculated for 1 cm^2 surface area). Averages and standard deviations were calculated from 8 identical preparations.

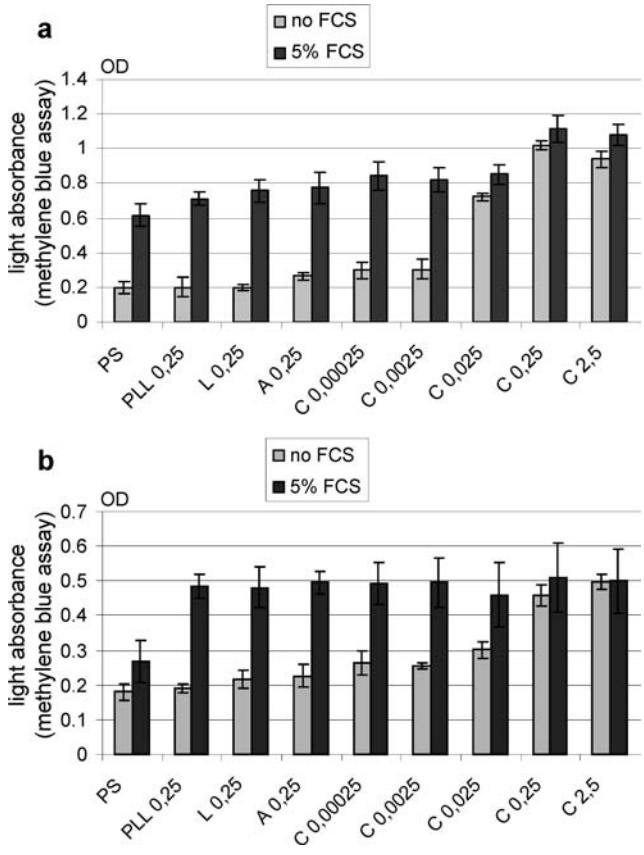

Figure 7. The effect of serum on the attachment of MDCK (a) and NE-4C (b) cells to AK-cyclo[RGDfC], AK-c[RADfC], AK-RGDfC, and poly(L-lysine) coated or bare, tissue culture treated polystyrene surfaces. Attachment was determined by photometric evaluation of methylene blue staining after washing off the unattached cells. The data are shown as averages and standard deviations of optical densities measured in 8 parallel preparations. Note that, above an "upper threshold density" of AK-cyclo[RGDfC], the presence of 5% FCS did not significantly improve the attachment. (Abbreviations: OD, optical density; PS, polystyrene; PLL, poly(L-lysine); A, AK-c[RADfC]; L, AK-RGDfC; C, AK-cyclo[RGDfC]; the numbers represent estimated surface densities of the coating peptides in $\mu g/cm^2$).

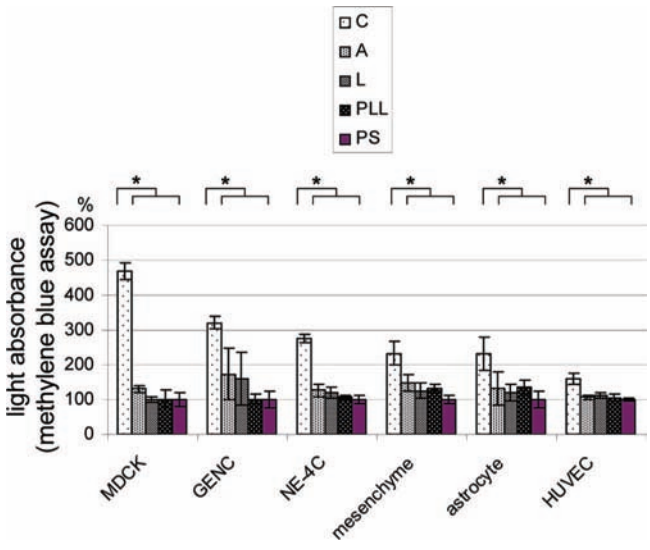

Figure 8. Comparison of initial attachment of various cell types (MDCK, GENC, NE-4C, mesenchyme, astrocyte, and HUVEC) on different substrates. The data are presented as the percentages of attachment on polystyrene (100%). (Abbreviations: PS, polystyrene; PLL, poly(L-lysine); A, AK-c[RADfC; L, AK-RGDfC; C, AK-cyclo[RGDfC]).

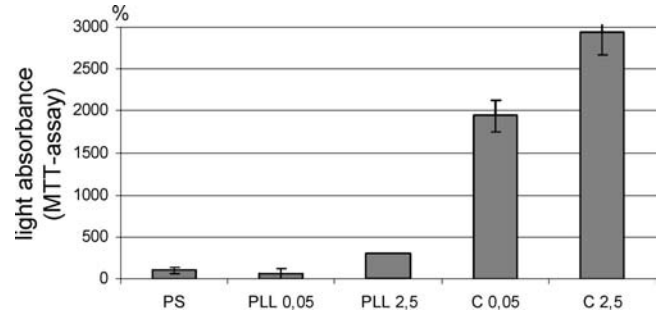

Figure 9. Serum-free survival of glomerular endothelial cells (GENC) on AK-cyclo[RGDfC] coated surfaces. MTT-assay revealed an almost 30-fold increase in viability on AK-cyclo[RGDfC] compared to polystyrene (PS) surface after 48 h. The data are presented as the percentages and standard deviations of viability on polystyrene. (Abbreviations: PS, polystyrene; PLL, poly(L-lysine); C, AK-cyclo-[RGDfC]; numbers represent the estimated surface densities of the coating peptides in $\mu g/cm^2$; 100% represents the OD value of the MTT assay on polystyrene).

with a corrupted RGD-motive—were designed and bound to the AK carrier. Neither the AK-RGDfC nor the AK-cyclo[RADfC] could support the attachment of the investigated cell types (Figure 8). On these substrates, both the morphology of the cells and the rate of attachment were indistinguishable from those observed on PLL or on the pure AK carrier peptide. The data support the importance of the stereochemical structure of the cyclo[RGDfC] motif in mediating cell adhesion.

3.4. Serum-Free Conditions for Growth of Cells. While cell type dependent growth factors have to be provided for long-term culturing of a number of cells, the application of AK-cyclo[RGDfC] surface could prevent anoikis (cell death initiated by lack of adhesion) in the case of anchorage-dependent cells. The AK-cyclo[RGDfC] surface supported a 48 h survival of several (tested for NE-4C, MDCK, GENC) types of cells in defined media (GENC; Figure 9) a "long-term" period if rapid anoikis is regarded. Moreover, serum-free cultures of selected neural stem-like cells were grown on AK-cyclo[RGDfC], in defined media supplemented with epithelial growth factor (EGF), for several weeks (personal communication; Marko et al.; manuscript in preparation). The use of the adhesive peptide conjugate provided strictly defined, serum-free conditions for initiation of cell cultures, and also for long-term growth of selected cell types.

4. DISCUSSION

In the present study, we report on the development of a novel, synthetic cell adhesion polypeptide. The conjugate contains a poly(L-lysine) backbone with oligo-DL-alanine side chains carrying biologically active cyclo[RGDfC] integrin ligand motifs at the N-termini of the oligo-alanine chains. The poly(L-lysine) backbone was chosen for promoting binding to a number of different substrates including tissue culture dishes, glass, and metal oxide surfaces. As was expected, AK-cyclo[RGDfC] bound readily to SiO_2 or metal oxide surfaces as was demonstrated by our previous studies (*40*) using the label-free OWLS technique (*41*).

To increase the accessibility of the attached cyclopeptide, a spacer was built from raceme alanine residues resulting in flexible, unstructured peptide side chains as was confirmed by previous CD analysis on AK polypeptide and related peptides (*42*, *43*). The random incorporation of 3 to 5 raceme alanine residues was shown to increase the flexibility of the spacer as well as the solubility of the carrier (*44*). The raceme oligo-alanine side chains increased the steric flexibility of the cyclo[RGDfC] end motif and improved the water solubility of the conjugate by preventing helix formation.

As a biologically active, cell-adhesive moiety, the cyclo-[RGDfC] cyclic pentapeptide was chosen due to the strong affinity of cyclic RGD pentapeptides to cell surface integrins (*19*) and the availability for conjugation through the Cys residue. The introduction of a D-enantiomer phenyalanine into the peptide ring was thought to result in a rigid RGD motif, easily recognized by integrins (*19*). The fact that AK conjugates carrying either the linear RGDfC pentapeptide or the cyclic cyclo[RADfC] peptide (with corrupted integrin binding motif) failed to support cell adhesion suggests that a precise positioning of the RGD sequence plays a crucial role in the enhanced cell-adhesive effect of the cyclo[RGDfC] conjugate. Cyclic RGD-containing peptides were reported to be potent ligands for a series of different integrin receptors, with a predominant selectivity to $\alpha_v\beta_3$, $\alpha_v\beta_5$, and $\alpha_v\beta_6$ (*22*). The specificity of the cyclic pentapeptide for integrin receptors, however, might have been modified as a consequence of coupling to the carrier polymer and also by introducing the Cys amino acid. Our previous observations demonstrated that—at least in the case of the investigated cell types—the soluble cyclo[RGDfC] and cyclo[RGDfV] pentapeptides exerted almost the same effect in cell detachment assays (Marko et al., personal observation).

While the exact amount of molecules for unit areas could not be determined, the density of the RGD-containing motifs on the surface seemed to play a crucial role in adhesivity. We think that with increasing local density of the ligand motifs, integrins displaying lower affinity to the specified ligand will also be implicated in binding, and therefore, the peptide will initiate cell adhesion above a defined "threshold density". Atomic force microscopic studies showed increasing surface roughness and aggregate formation with increasing concentration of the peptide−conjugate in the coating solution. The changing surface topography might contribute to the concentration-dependent adhesion preferences displayed by different cell types.

The AK-cyclo[RGDfC] polymer provided adequate adhesive coating for many different types of cells including cloned cells of epithelial, endothelial, or smooth muscle origin, and tissue-derived astrocytes, fibroblasts, mesenchymal, and neural stem cells.

We found that, below a "threshold" of deposited AK-cyclo[RGDfC], cell adhesion was improved by addition of serum, while at high surface densities of the conjugate, the serum did not affect adhesion. The observation indicates a synergistic action of the AK-cyclo[RGDfC] peptide with some serum components in initial cell adhesion. As fibronectin and vitronectin are the most abundant cell adhesive components in sera (*45*), the findings are in accordance with the notion that cyclic RGD pentapeptides are predominantly fibronectin- and/or vitronectin-mimetic integrin ligands.

As an exception, primary neurons could not adhere to AK-cyclo[RGDfC]. Neurons are known to adhere preferentially to the surface of glial cells or to laminin coatings *in vitro* (*46*), and—in the absence of adequate substrates—they form aggregates. As a consequence and for further application, AK-cyclo[RGDfC] may provide a "panning" surface to sort out non-attaching neurons from readily adhering non-neuronal cells.

For the anchoring of a wide variety of cells, AK-cyclo-[RGDfC] provides a chemically defined adhesive surface coating which supports serum-free cell attachment and survival in the most critical initial period of cell propagation on artificial surfaces. The defined adhesive layer, together with serum-free culture initiation, opens the way for strictly controlled cell cultivation and improves the conditions for growing human cells for therapeutic purposes. Degradation and *in vivo* stability studies should determine whether AK-cyclo[RGDfC] may serve also for coating implant surfaces, especially in cases when rapid attachment of the host cells is required.

Received February 4, 2008; Revised Manuscript Received July 14, 2008

We proposed the use of opioid drug bound covalently to hyaluronan (HA) via ester linkages as a method to prolong drug delivery and to possibly increase the quality of perioperative pain management. The *in vitro* release profile of morphine conjugated to HA (1.3 million MW) was studied. The influence of parameters such as conjugation site and steric protection of the labile ester bonds was investigated in phosphate buffered saline (PBS) medium. HA−codeine and HA−naloxone conjugates were used as structural controls. Codeine and morphine conjugated via the allylic hydroxyl group had a release half-life of 14.0 days in PBS. Naloxone conjugated via the phenolic hydroxyl group showed a half-life of 0.3 days, and all drugs admixed in HA showed half-lives of 0.1 days. Methyl, ethyl, or *n*-propyl introduced in vicinal position to the ester bond prolonged release of naloxone with half-lives of 0.5, 4.0, and 4.0 days in PBS, respectively. Incorporation of a methyl group prolonged codeine release with a half-life of 55.0 days in PBS. Drugs were released chemically unaltered from the conjugates as confirmed by LC-MS/MS. Further, morphine was conjugated to divinylsulfone cross-linked HA (Hylan B) particles and the release profiles in rat plasma were studied *in vitro* and *in vivo*. Release in rat plasma was faster than in PBS with a half-life of 2.5 days, but the release was similar (ca. 12 days) when a cocktail of protease inhibitors was added to the plasma. Sustained release of morphine was observed in a rat surgical model over 30 h. Morphine was released chemically unaltered from the conjugate and morphine intermediates were not detected in significant amounts as confirmed by LC-MS/MS. These results suggest that the morphine release profile from the HA conjugates depends on the alkyl groups vicinal to the ester and the nature of the leaving group. In rat plasma, hydrolysis seems to be controlled by esterase activity.

INTRODUCTION

Perioperative pain management has been shown to maintain the patient's functional abilities, reduce hospital costs due to faster recovery times, and improve patient well-being due to decreased incidence of adverse events (*1*−*3*). Pain control may have a further benefit of improving clinical outcome by reducing postoperative complications such as myocardial infarction or ischemia, risk of tachycardia and dysrhythmia impaired wound healing, risk of atelectasis, thromboembolic events, peripheral vasoconstriction, and metabolic acidosis (*4*−*9*).

Techniques used by anesthesiologists for perioperative pain control include epidural or intrathecal opioid analgesia, patient-controlled analgesia with systemic opioids, and regional analgesic techniques, including but not limited to intercostal blocks, plexus blocks, and local anesthetic infiltration of incisions (*10*). Many hydrophilic opioids, such as morphine, have very short half-lives in the body (i.e., 2−3 h), and therefore require frequent bolus injections or continuous pump infusion to maintain therapeutic levels in the target tissues over time (*11*). Problems, however, remain in the modalities necessary to administer them. Frequent injections are inconvenient for patients and potentially expose the patient to inconsistent drug levels and an increased risk of infections (*12*). Issues associated with in-dwelling catheters providing continuous infusion include catheter dislodgment, infections, pump failure, fibrosis, and increased costs due to physician and nursing time (*13*, *14*).

To overcome the many challenges associated with the current modes of analgesic delivery, manipulation of the pharmacokinetic properties of the drug, more specifically, the absorption of the opioid, may help to expand the management of perioperative pain. Extended-release formulations may reduce analgesic gaps associated with intermittent delivery, decrease the risk associated with repeated injections and in-dwelling catheters, as well as reduce the burden of frequent dose administration placed on health care providers. In addition, the use of extended delivery systems has demonstrated shorter lengths of hospital stay and enhanced patient functionality (*15*). Currently, there are extended-delivery systems for oral administration of the opioids morphine, oxycodone, and oxymorphone that are used for treating postoperative pain. In addition, a parenteral delivery system, DepoDur, uses a liposomal formulation of morphine that, when delivered by single epidural injection, provides superior pain control during the first 1−2 postoperative days compared with epidural or intravenous administration of unencapsulated morphine (*16*).

Hyaluronan (HA) is a naturally occurring linear polysaccharide of alternating β-1,3-D-glucuronic acid and β-1,4-*N*-acetyl-D-glucosamine units found in the extracellular matrix and synovial fluid (*17*). HA is hydrophilic and forms gels of varying viscosity depending on its molecular weight and concentration. In addition, HA can be modified using a variety of cross-linkers generating materials with a range of biophysical properties (*18*−*20*).

Prolonging morphine's effect by delivering from viscous HA formulations was observed in rabbits whereby the duration of action depended directly on the HA formulation viscosity (*21*). In other studies, HA was used to control morphine delivery by ionic complexation with multivalent cations. A morphine−HA complex was prepared using calcium as the divalent cation (*22*). This complex was injected into rats and the morphine concen-

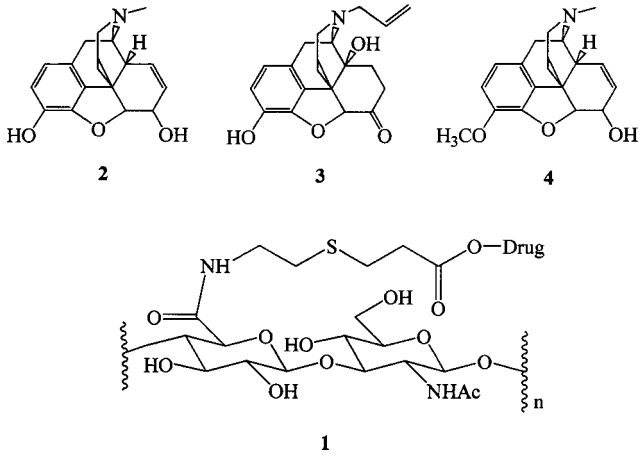
tration in blood was monitored over time. The results showed that the HA−morphine complexation decreased the peak systemic drug concentration and prolonged the time of systemic exposure when compared to aqueous morphine sulfate control. In addition, increasing the calcium content was directly related to duration of pain control as measured by paw withdrawal response time in a rat incision pain model.

We previously reported a method to prolong the release of the local anesthetic bupivacaine by conjugating to HA via a hydrolytically labile imide linkage (*23*). The aim of the current study was to investigate the release rate of morphine conjugated to insoluble cross-linked HA (hylan B gel particles) via a hydrolytically labile ester linkage. The morphine-conjugated gel particles would serve as a drug depot that could be administered to local tissues or spaces (e.g., intra-articular space (*24*)) and would release the drug slowly to provide prolonged, local analgesia. The morphine-conjugated gel particles could also be administered via intrathecal, subcutaneous, or intramuscular routes to provide prolonged exposure of morphine above its minimum effective analgesic concentration to the systemic circulation. We hypothesized that a reversible covalent bond may more effectively maintain the drug in the carrier for a longer period of time relative to a physical admixture. Thus, ester conjugates (**1**) of morphine (**2**) as well as its structural controls naloxone and codeine (**3**, **4**) with HA were prepared. The conjugates of naloxone and codeine were prepared to evaluate relative stabilities of phenolic ester and alkyl ester groups, respectively.



Our study included a divinylsulfone (DVS) cross-linked form of HA, hylan B, that shows longer residence time at the implantation site compared to non-cross-linked HA (*25*). This report describes a method to prepare morphine tethered to HA and hylan B particles. The rate of release of morphine from the conjugates was determined in phosphate buffered saline (PBS) and plasma. The rate of absorption of locally administered hylan B−morphine conjugate was compared against free morphine and morphine/hylan B particles admixture formulations by measuring morphine concentrations in plasma following subcutaneous administration in a rat model.

EXPERIMENTAL PROCEDURES

Materials and Methods. Morphine free base was a generous gift from Mallinckrodt Inc. (St. Louis, MO). Hyaluronan (1.3 MDa) was obtained by bacterial fermentation (Genzyme Corporation) and cross-linked with DVS (hylan B particles) following a previously published method (*26*). Anhydrous solvents and starting materials were purchased from Sigma-Aldrich Co. and used without further purification. Rat plasma was purchased from GeneTex, Inc. Protease inhibitor cocktail was purchased from Sigma-Aldrich Co. ^{1}H and ^{13}C NMR spectra were collected on a Varian spectrometer (400 MHz) against an internal standard of tetramethylsilane ($\delta = 0.0$ ppm). Mass spectra and high resolution mass spectrometry (HRMS) was performed on Applied Biosystems Qstar XL spectrometer with Turbolonspray source. Thin layer chromatography (TLC) was performed on Silica Gel 60 F_{254} precoated on aluminum sheets (EM Separation Technology) using CH_3OH/CH_2Cl_2 (1:4 and 1:9). Flash chromatography was carried out using silica gel (60 Å, 35−70 μ, 230−400 mesh, Teledyne Isco) using a gradient of 5% methanol in dichloromethane. Phosphate buffered saline (PBS) containing 137 mM NaCl, 2.7 mM KCl, 10 mM phosphate buffer, pH = 7.3−7.5 was purchased as a 10-fold concentrate (EMD Chemicals, Inc.) and diluted to a working concentration with deionized water. HA−drug conjugates were purified by dialysis in PBS using membrane tubing (7 kDa MWCO, Spectrum). *In vitro* release experiments in PBS were based on methodology reported in the literature (*27*, *28*) using tangential flow dialysis cassettes (Slide-A-Lyzer, 10 kDa MWCO, Pierce). UV/visible measurements were obtained using a Varian Cary 50 Probe spectrometer. The molecular weight and degree of molar modification of HA conjugates were determined using size exclusion chromatography and a multi-angle laser light scattering (SEC-MALLS) analyzer (model DAWN-EOS, Wyatt Technology). The SEC-MALLS analyzer was connected to refractive index and UV/visible (model UVIS-205, Perkin-Elmer) detectors. Separation was performed using a size exclusion column (300 Å, 7.5 × 300 mm, Macrosphere, Alltech) and a mobile phase of 0.05 M Na_2SO_4 solution. HA degree of molar modification was defined as the molar percentage of conjugated repeating dimeric units in HA. The quantitation of drug purity and release rate *in vitro* in PBS was determined by high performance liquid chromatography (HPLC model Waters 600) connected to a photodiode array detector (Waters 996 PDA) reading at 214 nm using a C18 reverse-phase column (80 Å, 4.6 × 150 mm, W Phenomenex Synergi 4 μm Max-RP) and mobile phase consisting of 90% 10 mM KH_2PO_4, 8% acetonitrile, and 2% methanol. The separation was performed at a column temperature of 25 °C ± 2 °C, flow rate of 1 mL/min, and under isocratic conditions. The quantification of morphine and morphine derivatives *in vitro* in PBS and plasma was determined by liquid chromatography tandem mass spectrometry (LC-MS/MS). The separation was performed at 25 °C ± 2 °C using a C18 reverse-phase column (80 Å, 2.0 × 50 mm, Phenomenex Synergi 4 μm Hydro RP). Mobile phases (A = 0.1% formic acid in water, B = 0.1% formic acid in acetonitrile) were delivered with a binary pump (series 1100, Agilent Technologies) using a flow rate of 0.5 mL/min. A gradient was used: 5−15% B over 1 min, 15−50% B over 1 min, 50−90% B over 0.5 min, and 90% B for 0.5 min. The effluent was monitored by tandem mass spectrometry (MS/MS) using a mass spectrometer (API4000, Applied Biosystems/MDS Sciex) with an electrospray ionization (ESI) interface in positive multiple reaction monitoring (MRM) mode.

Synthesis of Drugs Intermediates and HA Conjugates. *Synthesis of Acryl Naloxone (***5***).* Naloxone free base (800 mg, 2.44 mmol) was placed in a 250 mL round-bottom flask and anhydrous toluene (100 mL) was added under a nitrogen atmosphere. Triethylamine (408 μL, 2.93 mmol) was added and the solution was allowed to stir for 30 min at 50 °C. Acryloyl chloride (340 μL, 4.15 mmol) was added subsequently and the reaction mixture was allowed to stir at 50 °C overnight under nitrogen. Upon completion of reaction, as monitored by TLC, the mixture was cooled to room temperature and the excess reagent was quenched by the addition of MeOH (1 mL). The solvents were removed under reduced pressure and the crude product was dissolved in dichloromethane (100 mL), transferred

into a separatory funnel, and washed with water (150 mL). The organic phase was collected, dried with Na_2SO_4, hydroquinone (60 ppm) was added, and concentrated under reduced pressure. Acryl naloxone (**5**, 790 mg, 85% yield) was isolated by silica gel flash-chromatography (5% MeOH in CH_2Cl_2) to give a white solid. R_f (methanol/dichloromethane, 1/9): 0.68. mp: 85−87 °C. ^{1}H NMR (DMSO$_{d6}$): δ = 1.3 (d, 1H, J = 10.4 Hz, CH), 1.4 (dt, 1H, J = 3.3 Hz, 14.0 Hz, CH), 1.8 (d, 1H, J = 12.0 Hz, CH), 2.0 (t, 1H, J = 10.4 Hz, CH), 2.1 (td, 1H, J = 3.2, 14 Hz, CH), 2.4 (dt, 1H, J = 4.8 Hz, 12.6 Hz, CH), 2.6 (dt, 2H, J = 4.7 Hz, 16.0 Hz, CH_2), 2.9 (dt, 1H, J = 5.2 Hz, 14.4 Hz, CH), 3.0 (d, 1H, J = 4.2 Hz, CH), 3.1 (m, 1H, CH), 3.2 (s, 2H, CH_2), 4.9 (s, 1H, CH), 5.2 (d, 1H, J = 10.4 Hz, CH), 5.3 (d, 1H, J = 17.2 Hz, CH), 5.9 (m, 1H, CH), 6.2 (d, 1H, J = 10.0 Hz, CH acryl), 6.4 (m, 1H, CH acryl), 6.5 (dd, 1H, J = 1.2 Hz, 17.2 Hz, CH acryl), 6.8 (d, 1H, J = 8.4 Hz, CH aromatic), 6.9 (d, 1H, J = 8.4 Hz, CH aromatic) ppm. ^{13}C NMR (DMSO$_{d6}$): δ = 22.7, 29.8, 31.1, 35.6, 42.9, 50.2, 56.9, 61.4, 69.7, 90.2, 119.3, 122.5, 127.1, 130.3, 131.3, 131.4, 133.9, 147.2, 163.0, 207.5 ppm. HRMS calculated for $C_{22}H_{23}NO_5$ (M + H^+): 382.1649; found: 382.1584.

*Synthesis of Methacryl Naloxone (**6**).* Compound **6** was prepared as described above using naloxone free base (800 mg, 2.44 mmol), triethylamine (408 μL, 2.93 mmol), and methacryloyl chloride (405 μL, 4.15 mmol). Methacryl naloxone (**6**, 790 mg, 82% yield) was isolated by silica gel flash chromatography (5% MeOH in CH_2Cl_2) to give a white solid. R_f (methanol/dichloromethane, 1/9): 0.68. mp: 164−166 °C. ^{1}H NMR (DMSO$_{d6}$): δ = 1.3 (d, 1H, J = 11.2 Hz, CH), 1.5 (dt, 1H, J = 3.2 Hz, 14.0 Hz, CH), 1.6 (m, 1H, CH), 1.8 (d, 1H, J = 12.4 Hz, CH), 2.0 (s, 3H, CH_3), 2.1 (d, 1H, J = 14.0 Hz, CH), 2.4 (dt, 1H, J = 5.0 Hz, 13.2 Hz, CH), 2.6 (dt, 2H, J = 4.6 Hz, 16.4 Hz, CH_2), 2.9 (dt, 1H, J = 3.4 Hz, 14.2 Hz, CH), 3.0 (d, 1H, J = 4.4 Hz, CH), 3.1 (m, 1H, CH), 3.2 (s, 2H, CH_2), 4.9 (s, 1H, CH), 5.2 (d, 1H, J = 10.0 Hz, CH), 5.3 (d, 1H, J = 17.2 Hz, CH), 5.8 (m, 1H, CH), 5.9 (s, 1H, CH acryl), 6.3 (s, 1H, CH acryl), 6.8 (d, 1H, J = 8.0 Hz, CH aromatic), 6.9 (d, 1H, J = 8.4 Hz, CH aromatic) ppm. ^{13}C NMR (DMSO$_{d6}$): δ = 18.0, 22.7, 29.8, 31.1, 35.6, 42.9, 50.1, 56.9, 61.4, 69.7, 90.1, 119.3, 122.5, 125.3, 128.2, 128.9, 130.2, 131.1, 131.7, 134.8, 147.3, 164.1, 207.5 ppm. HRMS calculated for $C_{23}H_{25}NO_5$ (M + H^+): 396.1806; found: 396.1801.

*Synthesis of Ethylacryl Naloxone (**7**).* Compound **7** was prepared using the same method as compound **5** starting with naloxone free base (800 mg, 2.44 mmol), triethylamine (408 μL, 2.93 mmol), and ethylacryloyl chloride (440 μL, 4.15 mmol). Ethylacryl naloxone (**7**, 883 mg, 89% yield) was isolated by silica gel flash chromatography (5% MeOH in CH_2Cl_2) to give a white solid. R_f (methanol/dichloromethane, 1/9): 0.72. mp: 93−95 °C. ^{1}H NMR (DMSO$_{d6}$): δ = 1.1 (t, 3H, J = 7.4 Hz, CH_3), 1.3 (d, 1H, J = 12.0 Hz, CH), 1.5 (dt, 1H, J = 3.3 Hz, 14.0 Hz, CH), 1.8 (m, 1H, CH), 2.0 (m, 1H, CH), 2.1 (d, 1H, J = 14.8 Hz, CH), 2.3 (d, 1H, J = 14.4 Hz, CH), 2.4 (q, 2H, J = 7.4 Hz, CH_2), 2.6 (m, 2H, CH_2), 2.9 (dt, 1H, J = 4.9 Hz, 14.6 Hz, CH), 3.0 (s, 1H, CH), 3.1 (m, 1H, CH), 3.2 (s, 2H, CH_2), 4.9 (s, 1H, CH), 5.2 (d, 1H, J = 9.2 Hz, CH), 5.3 (d, 1H, J = 17.2 Hz, CH), 5.8 (s, 1H, CH acryl), 5.9 (m, 1H, CH), 6.3 (s, 1H, CH acryl), 6.8 (d, 1H, J = 8.0 Hz, CH aromatic), 6.9 (d, 1H, J = 8.0 Hz, CH aromatic) ppm. ^{13}C NMR (DMSO$_{d6}$): δ = 12.6, 22.7, 24.5, 29.7, 31.0, 35.6, 42.9, 50.1, 56.8, 61.4, 69.7, 90.1, 119.3, 122.5, 126.2, 128.1, 128.8, 130.2, 131.0, 131.7, 140.6, 147.4, 164.0, 207.4 ppm. HRMS calculated for $C_{24}H_{27}NO_5$ (M + H^+): 410.1962; found: 410.1935.

*Synthesis of Propylacryl Naloxone (**8**).* The preparation was identical to the method described for compound **5** using naloxone free base (800 mg, 2.44 mmol), triethylamine (408 μL, 2.93 mmol), and propylacryloyl chloride (493 μL, 3.78 mmol). Propylacryl naloxone (**8**, 876 mg, 85% yield) was isolated by silica gel flash chromatography (5% MeOH in CH_2Cl_2) to give a white solid. R_f (methanol/dichloromethane, 1/9): 0.72. mp: 89−91 °C. ^{1}H NMR (DMSO$_{d6}$): δ = 0.9 (t, 3H, CH_3), 1.3 (d, 1H, J = 10.8 Hz, CH), 1.4 (m, 1H, CH), 1.5 (sexlet, 2H, J = 7.2 Hz, CH_2), 1.8 (d, 1H, J = 8.0 Hz, CH), 2.0 (t, 1H, J = 10.8 Hz, CH), 2.1 (td, 1H, J = 2.8 Hz, 14.0 Hz, CH), 2.3 (t, 1H, J = 7.4 Hz, CH), 2.4 (dt, 1H, J = 5.0 Hz, 12.4 Hz, CH), 2.6 (dt, 2H, J = 5.0 Hz, 19.4 Hz, CH_2), 2.9 (dt, 1H, J = 5.1 Hz, 14.2 Hz, CH), 3.0 (d, 1H, J = 4.0 Hz, CH), 3.1 (m, 1H, CH), 3.2 (s, 2H, CH_2), 4.9 (s, 1H, CH), 5.2 (d, 1H, J = 10.4 Hz, CH), 5.3 (d, 1H, J = 17.2 Hz, CH), 5.8 (s, 1H, CH acryl), 5.9 (m, 1H, CH), 6.3 (s, 1H, CH acryl), 6.8 (d, 1H, J = 8.0 Hz, CH aromatic), 6.9 (d, 1H, J = 8.4 Hz, CH aromatic) ppm. ^{13}C NMR (DMSO$_{d6}$): δ = 13.5, 21.0, 22.7, 29.8, 31.1, 33.4, 35.6, 42.9, 50.1, 56.9, 61.4, 69.7, 90.2, 119.2, 122.5, 127.3, 130.3, 131.2, 131.7, 139.0, 147.3, 164.0, 207.5 ppm. HRMS calculated for $C_{25}H_{29}NO_5$ (M + H^+): 424.2119; found: 424.2089.

*Synthesis of Acryl Codeine (**9**).* Compound **9** was prepared using the method for compound **5** using codeine free base (800 mg, 2.67 mmol), triethylamine (895 μL, 6.41 mmol), dimethylaminopyridine (33 mg, 0.27 mmol), and acryloyl chloride (477 μL, 5.87 mmol). Acryl codeine (**9**, 504 mg, 54% yield) was obtained as an oily substance and used without further purification. Reversed-phase HPLC analysis: 97% AUC at t_R = 7.25 min. TLC R_f (methanol/dichloromethane, 1/9): 0.40. ^{1}H NMR (DMSO$_{d6}$): δ = 1.6 (d, 1H, J = 11.6 Hz, CH), 2.0 (dt, 1H, J = 5.1 Hz, 12.4 Hz, CH), 2.2 (m, 2H, CH_2), 2.3 (s, 3H, CH_3), 2.5 (dd, 1H, J = 4.0 Hz, 12.0 Hz, CH), 2.7 (s, 1H, CH), 2.9 (d, 1H, J = 18.8 Hz, CH), 3.3 (m, 1H, CH), 3.7 (s, 3H, -OCH_3), 5.0 (d, 1H, J = 6.8 Hz, CH), 5.2 (m, 1H, CH), 5.5 (d, 1H, J = 10.0 Hz, CH), 5.6 (d, 1H, J = 9.6 Hz, CH), 6.0 (d, 1H, J = 10.4 Hz, CH acryl), 6.2 (m, 1H, CH acryl), 6.4 (d, 1H, J = 16.4 Hz, CH acryl), 6.5 (d, 1H, J = 8.0 Hz, CH aromatic), 6.6 (d, 1H, J = 8.4 Hz, CH aromatic) ppm. ^{13}C NMR (DMSO$_{d6}$): δ = 19.9, 34.7, 42.1, 42.6, 46.0, 56.3, 58.0, 68.3, 87.6, 114.1, 119.0, 127.2, 127.9, 128.1, 130.1, 130.7, 131.9, 141.4, 146.2, 164.8 ppm. HRMS calculated for $C_{21}H_{23}NO_4$ (M + H^+): 354.1700; found: 354.1631.

*Synthesis of Methacryl Codeine (**10**).* Compound **10** was prepared as described for compound **5** using codeine free base (800 mg, 2.67 mmol), triethylamine (895 μL, 6.41 mmol), dimethylaminopyridine (33 mg, 0.27 mmol), and methacryloyl chloride (573 μL, 5.87 mmol). Methacryl codeine (**10**, 627 mg, 64% yield) was obtained as an oily substance and used without further purification. Reversed-phase HPLC analysis: 94% AUC at t_R = 7.35 min. TLC R_f (methanol/dichloromethane, 1/9): 0.40. ^{1}H NMR (DMSO$_{d6}$): δ = 1.5 (d, 1H, J = 19.2 Hz, CH), 1.9 (s, 3H, CH_3), 2.0 (dt, 1H, J = 4.8 Hz, 12.4 Hz, CH), 2.2 (m, 2H, CH_2), 2.3 (s, 3H, CH_3), 2.4 (m, 1H, CH), 2.7 (t, 1H, J = 2.4 Hz, CH), 2.9 (d, 1H, J = 18.8 Hz, CH), 3.3 (q, 1H, J = 2.9 Hz, CH), 3.7 (s, 3H, -OCH_3), 5.0 (d, 1H, J = 6.4 Hz, CH), 5.2 (m, 1H, CH), 5.5 (d, 1H, J = 9.6 Hz, CH), 5.6 (d, 1H, J = 11.6 Hz, CH), 5.7 (s, 1H, CH acryl), 6.0 (s, 1H, CH acryl), 6.5 (d, 1H, J = 8.0 Hz, CH aromatic), 6.6 (d, 1H, J = 8.4 Hz, CH aromatic) ppm. ^{13}C NMR (DMSO$_{d6}$): δ = 17.9, 20.9, 32.9, 37.7, 41.3, 43.5, 46.0, 56.4, 58.6, 67.7, 87.0, 114.6, 119.5, 124.7, 125.7, 126.1, 128.5, 128.8, 135.7, 137.1, 141.8, 146.1, 165.9 ppm. HRMS calculated for $C_{22}H_{25}NO_4$ (M + H^+): 368.1857; found: 368.1795.

*Synthesis of Mono-Acryl Morphine (**11**).* Morphine free base (100 mg, 0.35 mmol) was placed in a 50 mL round-bottom flask and anhydrous pyridine (5 mL) was added under a nitrogen atmosphere and allowed to stir for 15 min. Acrylic anhydride (85 μL, 0.74 mmol) was added and the reaction mixture was stirred at room temperature overnight under nitrogen. After completion of the reaction, as monitored by TLC, MeOH (100

μL) with hydroquinone (60 ppm) was added. The crude product was obtained by azeotropic removal of pyridine with toluene under reduced pressure. The desired product was subsequently purified by silica gel flash chromatography, using a gradient of methanol in dichloromethane (5%). Monoacryl morphine (**11**, 67 mg, 57% yield) was obtained as a white waxy solid. Reversed-phase HPLC analysis: 90% AUC at $t_R = 6.54$ min. TLC R_f (methanol/dichloromethane, 1/4): 0.56. ^{1}H NMR ($DMSO_{d6} + D_2O$): = 1.5 (d, 1H, $J = 12.0$ Hz, CH), 1.9 (dt, 1H, $J = 4.3$ Hz, 12.4 Hz, CH), 2.1 (m, 2H, CH_2), 2.2 (s, 3H, CH_3), 2.3 (s, 1H, CH), 2.5 (dd, 1H, $J = 4.2$ Hz, 12 Hz, CH), 2.8 (d, 1H, $J = 17.6$ Hz, CH), 3.3 (s, 1H, CH), 4.0 (s, 1H, CH), 4.6 (d, 1H, $J = 6.0$ Hz, CH), 5.1 (d, 1H, $J = 9.6$ Hz, CH), 5.4 (d, 1H, $J = 9.6$ Hz, CH), 5.6 (d, 1H, $J = 10.4$ Hz, CH acryl), 6.0 (m, 1H, CH acryl), 6.3 (m, 1H, CH acryl), 6.4 (d, 1H, $J = 8.4$ Hz, CH aromatic), 6.6 (d, 1H, $J = 8.0$ Hz, CH aromatic) ppm. ^{13}C NMR ($DMSO_{d6}$): = 21.2, 34.7, 42.4, 43.0, 46.0, 58.3, 66.4, 92.9, 119.4, 121.8, 127.6, 128.3, 130.9, 131.1, 132.2, 132.9, 133.8, 150.1, 163.9 ppm. HRMS calculated for $C_{20}H_{21}NO_4$ ($M + H^+$): 340.1544; found: 340.1535.

*Synthesis of Di-Acryl Morphine (***12***).* Compound **12** was prepared as described for compound **11** using morphine free base (1 g, 3.51 mmol), and acrylic anhydride (2.02 mL, 17.55 mmol). Diacryl morphine (**12**, 887 mg, 64% yield) was obtained as a white waxy solid. Reversed-phase HPLC analysis: 95% AUC at $t_R = 8.55$ min. TLC R_f (methanol/dichloromethane, 1/4): 0.73. ^{1}H NMR ($DMSO_{d6}$): $\delta = 1.6$ (d, 1H, $J = 11.6$ Hz, CH), 2.1 (dt, 1H, $J = 4.5$ Hz, 12.4 Hz, CH), 2.2 (t, 1H, $J = 12.0$ Hz, CH), 2.3 (m, 1H, CH), 2.34 (s, 3H, CH_3), 2.5 (m, 1H, CH), 2.8 (s, 1H, CH), 3.0 (d, 1H, $J = 18.8$ Hz, CH), 3.3 (s, 1H, CH), 5.1 (d, 1H, $J = 6.8$ Hz, CH), 5.2 (s, 1H, CH), 5.5 (d, 1H, $J = 10.0$ Hz, CH), 5.6 (d, 1H, $J = 10.4$ Hz, CH), 5.8 (d, 1H, $J = 9.6$ Hz, CH acryl), 6.0 (d, 1H, $J = 10.4$ Hz, CH acryl), 6.1 (m, 1H, CH acryl), 6.3 (m, 2H, CH acryl), 6.5 (d, 1H, $J = 17.2$ Hz, CH acryl), 6.6 (d, 1H, $J = 8.0$ Hz, CH aromatic), 6.8 (d, 1H, $J = 8.0$ Hz, CH aromatic) ppm. ^{13}C NMR ($DMSO_{d6}$): $\delta = 20.3$, 34.3, 42.0, 42.5, 46.0, 58.0, 67.7, 88.1, 115.6, 119.3, 121.6, 127.2, 127.9, 129.8, 130.9, 131.5, 131.8, 132.7, 133.6, 148.8, 163.1, 164.7 ppm. HRMS calculated for $C_{23}H_{23}NO_5$ ($M + H^+$): 394.1649; found: 394.1632.

*Synthesis of HA−Drug Conjugates (***14***).* The HA conjugates with naloxone, codeine, and morphine were prepared following a procedure described previously (*23*). The carboxyl group of HA (1.3 million MW) was reacted with 3-nitro-2-pyridinesulfenylethylamine (NEA) (*29, 30*) using carbodiimide-mediated coupling to provide HA−NEA with 10% degree of molar modification. To a solution of HA (1.5 g, 3.74 mmol) in water (375 mL) was added 1-hydroxybenzotriazole (1.0 g, 7.48 mmol) followed by NEA (1.5 g, 5.61 mmol). The pH of the reaction mixture was adjusted to 4.5 using 2 N HCl. Subsequently, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (2.15 g, 11.22 mmol) was added, and the reaction was allowed to stir at room temperature for 2 h. The resulting HA−NEA was purified by exhaustive dialysis using a 7 kDa MWCO membrane against PBS, followed by dialysis against water overnight. HA−NEA was recovered by lyophilization as yellow foam (95% yield). Molecular weight and degree of modification of carboxy-modified HA−NEA were determined by SEC-MALLS analysis with detection at 350 nm. HA carrying a free sulfhydryl (**13**, HA-SH) was obtained after dissolving HA−NEA (1.5 g, 3.54 mmol) in a 25 mM solution of tris-2-(carboxyethyl)phosphine hydrochloride (375 mL) followed by stirring at 4 °C for 4 h. The free sulfhydryl was purified by dialysis against succinate buffer at pH 4 followed by water. The retentate was lyophilized to give a white solid (80% yield). Each HA−drug conjugate was assembled by reacting **13** with the corresponding drug intermediate (**5**−**12**) illustrated in Figure 1. Thus, aliquots of **13** (1.0 g, 2.50 mmol) were dissolved in water (250 mL) followed by pH adjustment to 8 using triethanolamine. One molar equivalent of each intermediate **5**−**12**, per molar equivalent of free sulfhydryl (0.25 mmol), dissolved in dimethylformamide was added and the reaction solution was allowed to stir at 4 °C overnight. The consumption of the free sulfhydryl groups was monitored colorimetrically (Ellman's reagent) (*31, 32*). The HA−drug conjugates were isolated after dialysis (7 kDa MWCO membrane) against PBS followed by water, lyophilized, and recovered as white foam (95% yield). MW (1.3 million) and degree of molar modification (10%) was consistent for all conjugates. Degree of molar modification was determined by UV/visible spectroscopy with detection at 280 nm, using naloxone, codeine, and morphine, respectively, as standards.

*Synthesis of Hylan B−Morphine (***15***).* Morphine was conjugated to hylan B as described above. The synthesis was performed starting from sterile hylan B particles and conducted under aseptic conditions. hylan B particles (371 mL, 5.4 mg/mL in 0.9% NaCl solution) were functionalized with NEA, and reduced to the free sulfhydryl form. Degree of molar modification was 8% as determined colorimetrically using Ellman's reagent (*31, 32*). Hylan B particles carrying free sulfhydryl groups were reacted with a half-molar equivalent of **12** per free sulfhydryl molar equivalent. The hylan B−morphine conjugate particles (**15**) were transferred into a 7 kDa MWCO membrane and dialyzed at 4 °C against PBS overnight, followed by dialysis against water for 6 h. The retentate was lyophilized to give a white solid product (2.0 g, 98% yield). Degree of molar modification was 8% as determined by UV/visible spectroscopy with detection at 280 nm, using morphine as a standard.

In Vitro Studies, Release Rate of Drugs in PBS. The *in vitro* release rates of drugs (infinite sink) from compounds **14** and **15** incubated in PBS were compared to admixtures of free drugs in a HA and hylan B solution, respectively. To prepare the test samples, compounds **14** and **15** were dissolved at 5% w/w in distilled water. The admixed control samples were prepared by dissolving one part naloxone, codeine, and morphine, respectively, in 99 parts of a 5% aqueous solution of HA (1.3 million MW) and Hylan B. Aliquots (approximately 1 to 1.5 g) of each solution were injected in triplicate into tangential flow dialysis cassettes (10 kDa MWCO). The cassettes were placed into separate screw-cap jars containing PBS (250 mL) at 37 °C with stirring. Samples of the receptor phase (1 mL of the elution medium) were removed over time and analyzed by HPLC.

Release Rate of Morphine in Rat Plasma. The *in vitro* release rate of morphine from compound **15** incubated in rat plasma was compared to the release rate in plasma in the presence of a cocktail of protease inhibitors with broad specificity for the inhibition of serine, cysteine, aspartic proteases, and aminopeptidases. To prepare the test samples, compound **15** was dissolved at 0.024% w/w in rat plasma, together with sodium azide (0.06% w/w). Protease inhibitors were added to an aliquot of the mixture and samples were incubated at 37 °C with gentle mixing. Fifty microliter aliquots were collected over time, 200 μL of acetonitrile containing 100 ng/mL naloxone as the internal standard were added, and samples were centrifuged. The supernatant was subjected to LC-MS/MS analysis of morphine, monoacryl morphine, and diacryl morphine.

Pharmacokinetic (PK) Profile of Morphine in a Rat Surgical Model. A total of 32 male Sprague−Dawley rats weighing 250 to 300 g were acclimated with free access to food and water for a minimum of one week prior to the performance of the experimental procedures. Deionized water was available *ad libitum* throughout the study period. Rats were allocated to treatment groups (Table 1), 8 rats per group, based on body weights taken during the acclimation period. The mean weights for each group were matched to ensure that the mean values

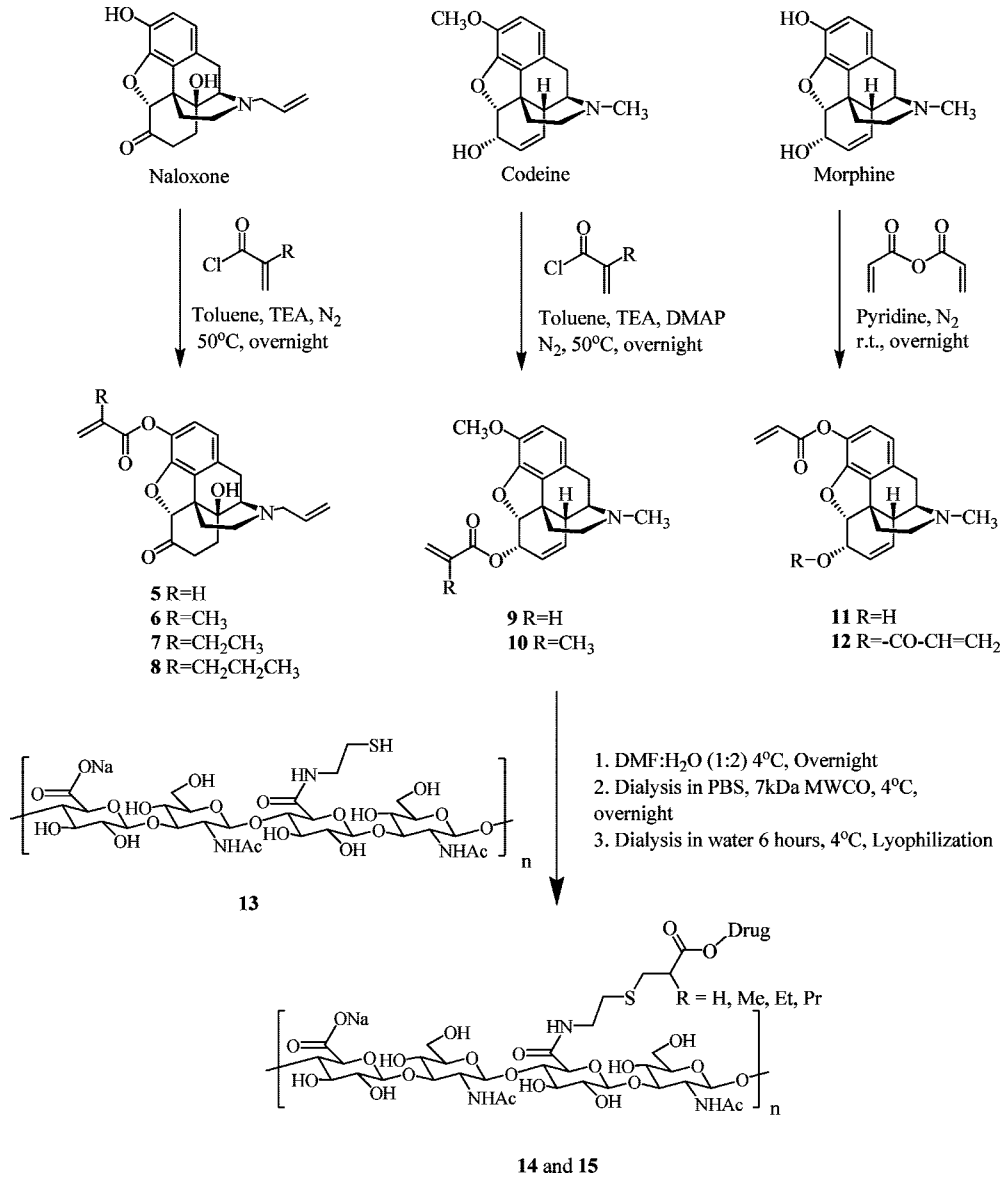


Figure 1. Synthesis of drug intermediates (**5**−**12**), HA−SH intermediate (**13**), HA−drug conjugates (**14**), and hylan B−morphine conjugate (**15**).

Table 1. Amounts of Free Morphine and Morphine from Conjugate 15 Injected Subcutaneously in Each Rat[a]

group	sample	dose	dose volume
1	morphine	5 mg/kg	5 mL
2	saline vehicle control	0 mg/kg	5 mL
3	Hylan B morphine/admix (nonconjugated)	5 mg/kg	5 mL
4	Hylan B−morphine conjugate (**15**)	146 mg/kg	5 mL

[a] $N = 8$ for each group. Morphine amounts are expressed as morphine sulfate pentahydrate (FW = 758.83).

and standard deviation satisfy the assumption of homogeneity. At time point 0, the animals were briefly sedated under inhalation anesthesia induced with 2−3% isoflurane in 100% oxygen, the dorsal area was shaved, a small skin incision was made, and blunt scissors were used to create a subcutaneous pocket. Five milliliters of either a control solution or a test formulation was injected into two sites (caudal and rostral from the incision), and the incision was closed with a wound clip. The experimenter was blinded as to which formulation was injected. At time points 1, 4, 8, 24, and 30 h, the animals were briefly anesthetized with inhalation anesthetic and approximately 250 μL of blood was collected via the retro-orbital sinus. The blood was collected into tubes containing EDTA as anticoagulant and centrifuged. Following centrifugation, the plasma was collected and transferred into separate tubes. The concentration of morphine in the plasma over time was analyzed by LC-MS/MS. Control animals were injected with 5 mg/kg morphine (i.e., morphine sulfate pentahydrate) either as a solution of free morphine or as an admixture of Hylan B gel particles and free morphine. This dose was based on previous experience that showed adequate levels of analgesia in this model without general sedation (*33*−*35*). The treatment group (Hylan B-morphine conjugate) used a ca. 30-fold higher morphine loading (146 mg/kg) compared to the controls. Samples were analyzed by LC-MS/MS as described above.

RESULTS AND DISCUSSION

Synthesis of HA−Drug Conjugates. Morphine possesses two functional groups (i.e., allylic and phenolic hydroxyl groups) that can be acrylated to form an ester. The hydrolytic cleavage of the ester bonds in the resulting HA−morphine conjugate (**14**) regenerates authentic morphine and releases it from the polymer at a slower rate compared to morphine admixed in HA. Further, it may be possible to modulate the rate of hydrolysis by

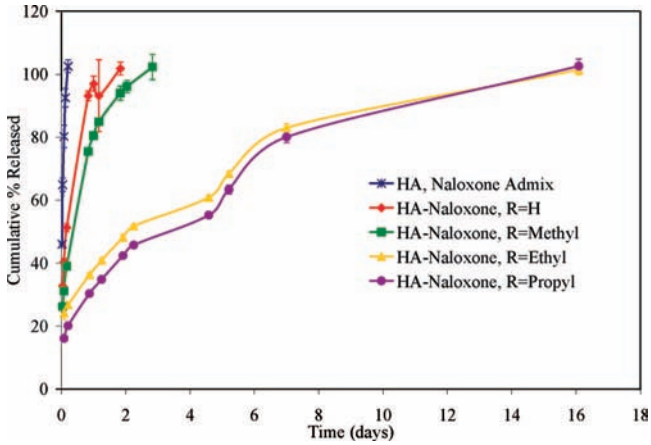

Figure 2. Release profiles of free and HA-conjugated naloxone (**14**) into receptor phase. $N = 3$, bars are SD. Receptor phase is defined as the elution medium (PBS) that is sampled to quantify the drug released. Conjugates were prepared using intermediates **5**−**8**. Increasing size of the R group (H, Me, Et, Pr) vicinal to the ester bond resulted in slower release rates.

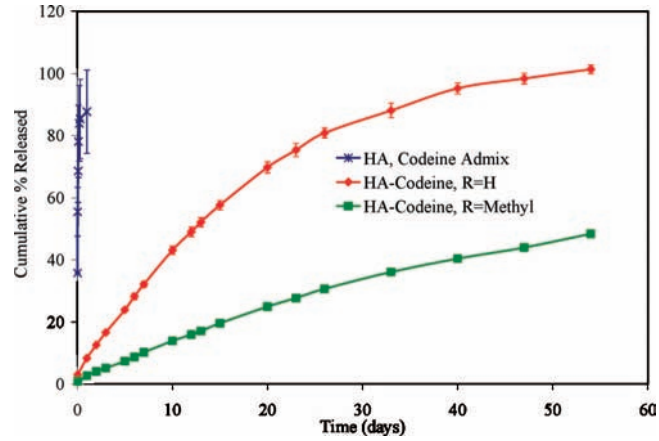

Figure 3. Release profiles of free and HA-conjugated codeine (**14**) into receptor phase. $N = 3$, bars are SD. Conjugates were prepared using intermediates **9** and **10**. Increasing size of the R group (H, Me) vicinal to the ester bond resulted in slower release rates.

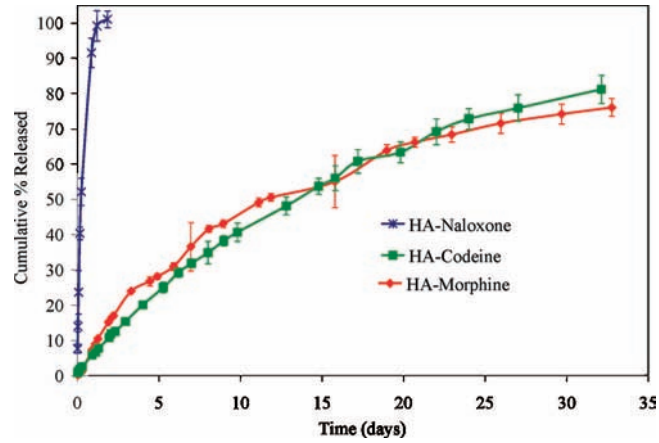

Figure 4. Release profiles of HA conjugated naloxone, codeine, and morphine (**14**) into receptor phase. $N = 3$, bars are SD. Conjugates were prepared using intermediates **5**, **9**, and **12**, respectively. Allylic leaving group (codeine and morphine) resulted in a slower release rate relative to phenolic leaving group (naloxone).

increasing the size of the alkyl functional groups (i.e., R = Me, Et, and Pr) in vicinal position to the ester bond. With these possibilities in mind, we studied the effects of acylation site and vicinal R group on the rate of hydrolysis using HA−naloxone and HA−codeine conjugates as structural controls. Using the approach described in Figure 1, naloxone, codeine, and morphine were conjugated to HA (**14**) with a 10% degree of molar modification and an overall mass recovery ranging between 80% and 90%. To avoid premature hydrolysis during workup and consequent loss of naloxone, codeine, and morphine from the conjugates, PBS and water used for dialysis were chilled to 4 °C (±2 °C).

Release Rate of Drugs in PBS. Figure 2 shows the *in vitro* release profiles obtained from the naloxone conjugates. Naloxone hydrochloride admixed in HA quickly eluted into the receptor phase, with 100% of the drug eluting within 5 h. In contrast, the HA−naloxone R = H conjugate (**14**), obtained using intermediate **5**, showed more prolonged release with 100% of the naloxone eluting within 2 days. In agreement with our expectations, delivery of naloxone was prolonged even further when R = Me, obtained using intermediate **6**, with half of the drug eluting within 12 h and 100% of the drug eluting within 3 days. For R = Et, obtained using intermediate **7**, half of the drug eluted within 3−4 days and 100% of the drug eluted within 16 days. A parallel release profile was observed for R = Pr, obtained using intermediate **8**, indicative of comparable steric protection of the ester bond by Et and Pr groups. It is known that steric hindrance of the substituents around the tetrahedral transition state influence the rate of ester hydrolysis (*36*). In particular, less sterically hindered putative tetrahedral intermediates are more stable. This greater stability leads to a higher equilibrium concentration and, in turn, a faster hydrolysis rate. The release profiles followed approximately a first-order rate consistent with the expected pseudo-first-order hydrolysis reaction.

Similar results were observed for the HA−codeine conjugates (see Figure 3). Codeine admixed in HA eluted into the receptor phase, with 100% of the drug eluting within 5 h. HA−codeine R = H conjugate, obtained using intermediate **9**, showed prolonged delivery with half the drug eluting within 14 days and 100% of the drug eluting within 55 days. Codeine delivery was significantly slower for R = Me, obtained using intermediate **10**, with only half of the drug eluted within 55 days.

Figure 4 shows a comparison of the release profiles for the HA−naloxone and codeine conjugates described above and HA−morphine conjugate obtained using intermediates **5**, **9**, and **12**, respectively. The naloxone phenolic was a much better leaving group than the codeine allylic group. HA−morphine conjugate possessed both phenolic and allylic ester groups, functioning also as HA cross-linker. However, the release profile of morphine approximately overlapped with the release profile of codeine, indicating that the rate-limiting step was the hydrolysis of the allylic ester. Half-life values in days observed for all HA conjugates are summarized in Table 2.

Table 2. Half-Lives (days) for HA−Naloxone, Codeine, and Morphine Conjugates (14) in PBS Determined by HPLC Using an Infinite Sink

sample	naloxone	codeine	morphine
HA admixture	0.1	0.1	0.1
conjugate (**14**), R = H	0.3	14.0	14.0
conjugate (**14**), R = Me	0.5	55.0	-
conjugate (**14**), R = Et	4.0	-	-
conjugate (**14**), R = Pr	4.0	-	-

PK Profile of Morphine in a Rat Surgical Model. Enzymatic and nonenzymatic release of steroid drugs conjugated through ester bonds to HA were reported in the literature (*37, 38*). Release rates *in vivo* using healthy animals, and in biological fluids obtained from healthy humans, were reported to be consistent with the release rates observed in aqueous buffered

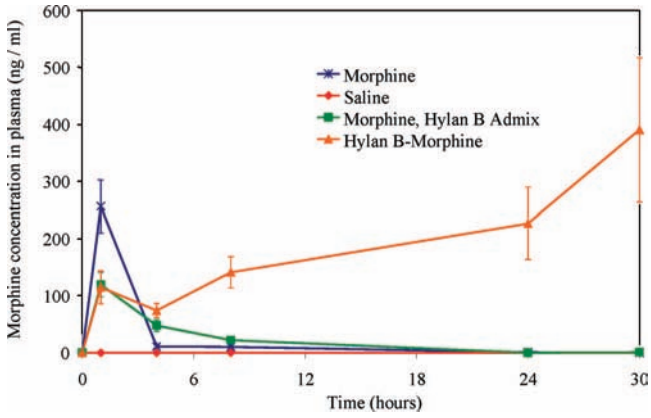

Figure 5. Pharmacokinetics in a rat surgical model. $N = 8$, bars are SD. Conjugation resulted in prolonged release relative to free morphine and morphine hylan B admix. Group 1 = free morphine (5 mg/kg), group 2 = saline, group 3 = morphine (5 mg/kg) and hylan B admix, group 4 = morphine (146 mg/kg) conjugated to hylan B (**15**).

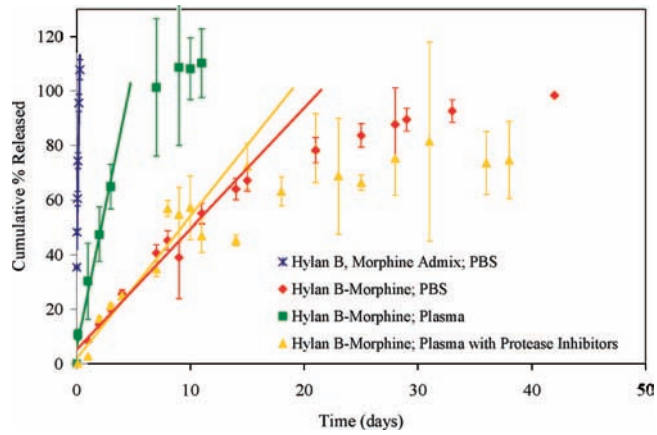

Figure 6. Comparison of release profiles of free and hylan B conjugated morphine (**15**) into receptor phase (PBS and in the presence of plasma). $N = 3$, bars are SD. Solid lines are the calculated slopes based on early data points. Conjugate was prepared using intermediate **12**. Faster release rate of morphine was observed in the presence of plasma without protease inhibitors. Release rate in plasma in the presence of protease inhibitors is similar to the release rate observed in PBS only.

solutions. With this in mind, we performed an *in vivo* study using a rat surgical model and the hylan B−morphine conjugate (**15**). Release rate of morphine from compound **15** was determined in plasma by LC-MS/MS after subcutaneous administration. The release rate was compared to a physical admixture of morphine in hylan B and bolus injection of morphine. The treatment group (compound **15**) used a ca. 30-fold higher morphine loading compared to the controls as the conjugate exhibited sustained release of morphine; a higher loading would be required to maintain the plasma morphine concentrations within the therapeutic window over time. The loading of morphine in the treatment group would also ensure that the plasma drug concentrations would be detectable by LC-MS/MS over the course of the study. Figure 5 shows the release profiles obtained from this experiment. Rapid clearance from the rats was observed for morphine sulfate admixed with hylan B and bolus injection of morphine sulfate with minimal to no detectable levels of the drug within 5 h. In agreement with our expectations, compound **15** resulted in sustained release of morphine with a significant level of morphine (ca. 400 ng/mL) detected after 30 h.

The rats were observed during the course of the PK study. Approximately 4 h post-dosing animals injected with compound **15** were hypothermic with body temperature of ca. 30 °C, and showed nonlocomotor, catatonic behavior. Heating pads were used to warm up the animals, and within one hour, their body temperature returned to normal (37.5 °C), and normal locomotor activity was observed. Twenty-four hours post-dosing, the rats performed continuous grooming activity and repetitive jaw movements. These observations were consistent with the effects of high-dose narcotic anesthesia reported in the literature (*39*−*42*).

Enzymatic and Non-Enzymatic Release Rates of Morphine. Morphine overdosing was unexpected according to our calculations based on the release profiles obtained in PBS. An additional *in vitro* study in enzymatic and non-enzymatic conditions was conducted to study the potential for nonspecific esterases to increase the release rate of morphine *in vivo* from the hylan B−morphine conjugate (**15**) obtained using intermediate **12**. Figure 6 shows a comparison of the release profiles for compound **15**, in PBS as determined by HPLC and in rat plasma as determined by LC-MS/MS. Morphine was the only species detected in the plasma samples confirming that there was no monoacryl morphine (**11**) and diacryl morphine (**12**) remaining from the conjugation reaction. Morphine admixed in hylan B eluted into the receptor phase, with 100% of the drug eluting within 5 h. hylan B−morphine conjugate eluted in PBS showed prolonged delivery with half the drug eluting within 14 days and 100% of the drug eluting within 45 days. These release profiles were consistent with those observed for compound **14**, obtained using intermediate **12**. Interestingly, the release of morphine from the same conjugate was faster in plasma than in PBS with half the drug eluting within 2.5 days and 100% of the drug eluting within 10 days. However, the release profile of morphine from the hylan B conjugate in plasma in the presence of protease inhibitors approximately overlapped with the release profile in PBS (see Figure 6), indicating that, in rat plasma samples, morphine release could be influenced by nonspecific esterase activity.

The release rates of morphine observed from hylan B conjugate in plasma *in vitro*, and during a pharmacokinetic study using rats, indicated that the system may be capable of providing sustained delivery of the drug *in vivo*. However, after observing the behavior of the animals consistent with narcotic overdosing, it will be necessary to take into account the nonspecific esterase activity of biological fluids together with the optimum dosing range to conceive of a new drug conjugate formulation. The ability to obtain sustained release of morphine *in vitro* and *in vivo* shown in this work is encouraging. This study identified a potential additional utility of HA as a drug carrier and deserves further investigation.

Identification of 14−3−3ζ by Chemical Affinity with Salicylanilide Inhibitors of Interleukin-12p40 Production

Jim P. Boyce,*,† Michael E. Brown,† Wilson Chin,‡ Jeffrey N. Fitzner,† Raymond J. Paxton,§ Min Shen,§ Tracey Stevens,‡ Martin F. Wolfson,§ and Clifford D. Wright‡

Amgen Incorporated, 1201 Amgen Court West, Seattle, Washington 98119. Received February 28, 2008; Revised Manuscript Received June 30, 2008

Salicylanilides were found as selective inhibitors of interleukin-12p40 production in stimulated dendritic cells. The conversion of one of these bioactive salicylanilides into a comparably bioactive, chemically labeled derivative was achieved using a facile and systematic functional group derivatization strategy. This resulted in a tool reagent that was then employed in an affinity chromatography approach that resulted in the identification of the protein 14−3−3ζ as having selective affinity for the chromatography matrix that was derivatized with a salicylanilide that inhibited IL-12p40 production.

INTRODUCTION

The interleukin (IL)-12 family of cytokines, including IL-12 and IL-23, play important roles in the effector functions of lymphocytes (*1*). IL-12 is involved in type 1 helper T cell (Th1) mediated inflammation in both normal host defense as well as inflammatory sequelae associated with elevated production of IL-12 such as in rheumatoid arthritis, asthma (*2*), psoriasis (*3*), and Crohn's disease (*4*, *5*). IL-23 has a divergent immunological role in regulating T cells that produce pro-inflammatory cytokines. IL-12p40 is a subunit component of both of these cytokines. Additionally, IL-12p40 may exist in monomeric or homodimeric (IL-12p80) forms that more recently have been recognized to possess their own bioactivities, independent of IL-12 and IL-23, that include chemoattraction of macrophages and stimulated dendritic cells (*6*).

As a class, salicylanilides have been reported with a wide variety of intriguing biological properties but in many cases the mechanism of action and specifically the target biomolecule(s) that these compounds interact with is not well understood. For example, niclosamide, **1**, originally discovered as a molluscicidal, is an orally administered, broad spectrum anthelmintic (*7*). Efuamide, **2a**, has been reported to be immunosuppressive in experimental allergic encephalomyelitis models in animals (*8*) and to inhibit phosphorylation and signaling of erbB-2 resulting in cell cycle arrest (*9*), and **2b** has been reported as an antimycobacterial (*10*).

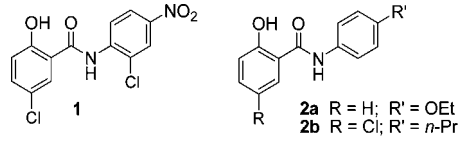

Figure 1. Examples of bioactive salicylanilides.

In the course of cell-based screening and directed analoging campaigns, we discovered certain other salicylanilides which potently and selectively inhibited IL-12p40 and IL-6 production in stimulated primary human dendritic cells. These salicylanilides were not found to be generally cytotoxic and did not show inhibition against any of the panels of recombinant proteins that we routinely screen against.

We describe here the structure−activity relationship guided conversion of these bioactive salicylanilides into a comparably bioactive derivative which was utilized as a tool for protein identification. This was accomplished using an affinity chromatography based approach to interrogate a cytosolic protein mixture which was derived from dendritic cells that were stimulated to produce IL-12p40. This approach, in conjunction with mass spectrometry, provided a method for biochemical target identification resulting in the discovery of the protein 14−3−3ζ as having selective affinity for specific salicylanilides.

EXPERIMENTAL PROCEDURES

General Synthesis Methods. Unless stated otherwise, hydrogenations were performed using a Parr 3911 hydrogenation apparatus and microwave irradiations were conducted with a CEM Explorer microwave apparatus with auto sampler. Chromatography-grade, anhydrous solvents were used without further purification. Concentration refers to distillation using a rotary evaporator (Buchi R-124). Flash chromatography was performed on E. Merck #60, 230−400 mesh silica gel. TLC analyses were performed using E. Merck glass backed silica gel #60 plates, 0.25 mm thickness, with 254 nm fluorescent indicator with visualization by UV absorption, iodine chamber, or solutions of $KMnO_4$ or other common staining technique. NMR spectra were collected with a Varian Inova AS500 equipped with a Zymark auto sampler, and spectral resonance shifts are reported after internal standardization to a characteristic resonance shift of the solvent. Coupling constants refer to apparent peak multiplicities and abbreviations used are as follows: s = singlet, d = doublet, t = triplet, q= quartet, br = broad. HPLC analyses were performed on an Agilent 1100 Series HPLC (binary pump) equipped with a reverse phase column (Zorbax Rx-C8, 9.4 mm ID × 25 cm) using an elution gradient composed of increasing ratios of 0.1% v/v TFA in CH_3CN/0.1% v/v TFA in H_2O and monitoring of analytes by UV absorption, evaporative light scattering (SEDEX ELSD), and mass spec detection (ESI/CI). Mass spectra were collected on an Agilent 1100 MSD and are reported as percent (%) relative intensity to the base peak.

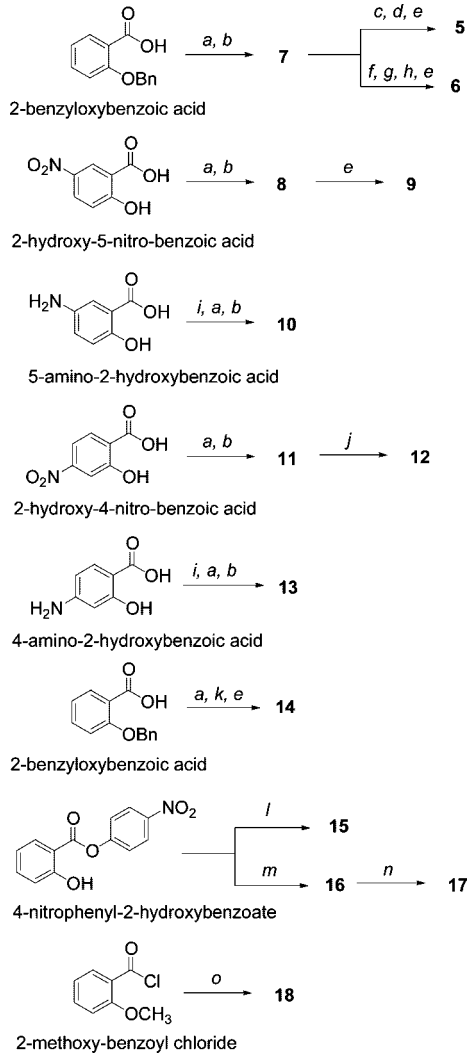
Except where otherwise stated, all reagents including compounds **25** [21615−34−9] were purchased from Sigma-Aldrich Chemical Co. Compound **21** [3107−19−5] was purchased from ChemPacific (www.chempacific.com). Compounds **3** [439145−04−7], **4** [78154−58−2], and **7** [882158−06−7] were purchased from Maybridge/Thermo Fisher Scientific Inc. Compounds **8** [439145−07−0], **16** [55411−43−3], and **22** [145881−74−9] are previously known in the chemical literature but our preparation of each is described in the following section along with new compounds **5**, **6**, **9**−**15**, **17**, **18**, **23**, and relevant nonnumbered intermediates. Compound preparation and characterization follows.

Scheme 1. Preparation of Salicylanilides Listed in Table 1[a]



[a] Reagents: (a) DCC, *N*-hydroxysuccinimide, THF; (b) 3,5-dichloroaniline; (c) NaH, THF; (d) CH_3I; (e) Pd/C, H_2; (f) NaO-*t*-Bu, 1,2-dimethoxyethane; (g) *t*-butylbromoacetate; (h) TFA, CH_2Cl_2; (i) Ac_2O; (j) $SnCl_2$, HCl, EtOH; (k) *N*-(3-amino-5-chlorophenyl)acetamide, 140 °C; (l) *N*-(4-amino-2,6-dichlorophenyl)acetamide, NMP, 225 °C; (m) 3,5-dichloro-4-methoxyaniline, NMP, reflux; (n) benzyl bromide, K_2CO_3, DMF, 150 °C; (o) 2,5-dichloro-4-methoxybenzenamine, EtN(*i*-Pr)$_2$, toluene.

N-(3,5-Dichlorophenyl)-2-hydroxy-N-methylbenzamide (**5**). A solution of 2-benzyloxybenzoic acid (2.00 g, 8.76 mmol), *N*-hydroxysuccinimide (1.21 g, 10.5 mmol), and *N*,*N*′-dicyclohexylcarbodiimide (1.99 g, 9.64 mmol) in anhydrous THF (30 mL) was stirred (rt, 4 h). The resulting precipitant was filtered and the filtrate was concentrated *in vacuo* to afford *N*-hydroxysuccinyl 2-(benzyloxy)benzoate as a crude intermediate that was used without further purification (3.39 g): ^{1}H NMR (500 MHz, d_6-DMSO) δ 7.93 (d, J = 7.5, 1H), 7.73 (m, 1H), 7.50 (d, J = 7.5 Hz, 2H), 7.38 (m, 3H), 7.32 (d, J = 7.0 Hz, 1H), 7.16 (m, 1H), 5.30 (s, 2H), 2.89 (s, 4H); ^{13}C NMR (125 MHz, d_6-DMSO) δ 170.4, 160.2, 158.8, 136.4, 136.4, 131.7, 128.4, 127.7, 127.0, 120.8, 114.5, 113.9, 69.8, 25.5. An aliquot of this crude succinate ester (1.00 g, 3.07 mmol) and 3,5-dichloroaniline (1.50 g, 9.23 mmol) was briefly warmed as a melt (10 min, 140 °C, internal). The resulting yellow solution was allowed to cool (rt). The residue was diluted with EtOAc (100 mL), and after aqueous washing (3 N HCl, brine), the organic layer was dried ($MgSO_4$) and concentrated *in vacuo* to afford a tan solid which after crystallization (EtOAc) afforded 2-(benzyloxy)-*N*-(3,5-dichlorophenyl)benzamide (**7**), CAS Registry [882158−06−7], as a white crystalline solid (0.67 g, 1.80 mmol): ^{1}H NMR (500 MHz, $CDCl_3$) δ 10.09 (br s, 1H), 8.29 (d, J = 7.5 Hz, 1H), 7.54−7.52 (m, 6H), 7.15−7.12 (m, 2H), 7.08 (s, 2H), 7.97 (s, 1H), 5.19 (s, 2H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 163.0, 156.7, 140.2, 134.9, 134.8, 133.8, 132.6, 129.8, 129.3, 129.0, 123.5, 122.0, 120.9, 117.6, 112.5, 72.0; MS (+EI) *m*/*z* 374 (MH+, 70), 372 (MH+, 100). To a cold (0 °C bath) suspension of **7** (100 mg, 0.269 mmol) and NaH (60% w/w oil disp., 16 mg, theor. 0.4 mmol) in anhydrous THF (2 mL) was added neat methyl iodide (0.2 mL, 3 mmol) and the resulting mixture was allowed to warm (rt, 30 min) with stirring. The resulting mixture was carefully quenched with methanol (0.5 mL), filtered through a plug of silica gel (hexanes/EtOAc, 5:1), and concentrated *in vacuo* to afford 2-(benzyloxy)-*N*-(3,5-dichlorophenyl)-*N*-methylbenzamide as a colorless oil (91 mg, 0.24 mmol) which was used without further purification: MS (+EI) *m*/*z* 388 (MH+, 70), 386 (MH+, 100). A suspension of 2-(benzyloxy)-*N*-(3,5-dichlorophenyl)-*N*-methylbenzamide (72 mg, 0.19 mmol) and 5% Pd/C (wet Degussa-type E101, 12 mg, theor. 0.0029 mmol Pd) in EtOAc (2 mL) was shaken under a hydrogen atmosphere (60 psi, rt, 1 h). The resulting mixture was filtered (diatomaceous earth) and the filtrate was concentrated *in vacuo* to afford a light orange oil which after flash chromatography afforded **5** (44 mg, 0.15 mmol) as a colorless oil: ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.25−7.24 (m, 2H), 7.03 (s, 2H), 6.97 (d, J = 8.5 Hz, 1H), 7.39 (d, J = 8.5 Hz, 1H), 6.54 (m, 1H), 3.46 (s, 3H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 171.5, 160.5, 147.0, 135.6, 133.5, 130.0, 127.2, 125.2, 125.2, 118.2, 115.2, 39.1; MS (+EI) *m*/*z* 298 (MH+, 70), 296 (MH+, 100).

2-(N-(3,5-Dichlorophenyl)-2-hydroxybenzamido)acetic acid (**6**). To a stirred solution of **7** (0.250 g, 0.672 mmol), prepared according to the method described in the preceding section, and sodium *tert*-butoxide (0.130 g, 1.34 mmol) in anhydrous 1,2-dimethoxyethane (7 mL) was added (rt, 5 min) neat *tert*-butylbromoacetate (0.22 mL, 1.3 mmol) and the resulting solution was stirred (rt, 90 min). After aqueous workup (EtOAc, H_2O), the organic layer was dried ($MgSO_4$) and concentrated *in vacuo* and filtered through a plug of silica gel (hexanes/EtOAc, 5:1) to afford *tert*-butyl 2-(2-(benzyloxy)-*N*-(3,5-dichlorophenyl)benzamido)acetate as a crude colorless oil (0.285 g) which was used without further purification: MS (+EI) *m*/*z* 510 (MNa+, 20), 508 (MNa+, 30), 432 ((M-56)H+, 70), 430 ((M-56)H+, 100). A suspension of this intermediate oil (0.285 g, theor. 0.586 mmol) and 5% Pd/C (wet Degussa-type E101, 22 mg, theor. 0.0053 mmol Pd) in EtOAc (3 mL) was shaken under a hydrogen atmosphere (60 psi, rt, 3 h). The resulting mixture was filtered (diatomaceous earth) and the filtrate was concentrated *in vacuo*. The crystalline solid that was obtained was triturated (hexanes) to afford *tert*-butyl 2-(*N*-(3,5-dichlorophenyl)-2-hydroxybenzamido)acetate as a white crystalline solid (0.148 g, 0.373 mmol): ^{1}H NMR (500 MHz, $CDCl_3$) δ 10.2 (br s, 1H), 7.27−7.24 (m with $CHCl_3$, ∼2H), 7.09 (s, 2H), 6.96 (d,

J = 8.0 Hz, 1H), 6.79 (d, J = 8.5 Hz, 1H), 6.55 (m, 1H), 4.41 (s, 2H), 1.50 (s, 9H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 171.3, 167.5, 160.1, 145.9, 135.5, 133.7, 129.9, 127.6, 125.6, 118.4, 118.2, 115.2, 82.9, 53.6, 28.0; MS (+EI) *m/z* 396 (MH+, 70), 394 (MH+, 100). A solution of *tert*-butyl 2-(*N*-(3,5-dichlorophenyl)-2-hydroxybenzamido)acetate (109 mg, 0.275 mmol) in CH_2Cl_2/TFA (1:1 v/v, 4 mL) was stirred (rt, 1 h) and then concentrated *in vacuo*. The resulting solid was crystallized (hexanes/EtOAc) to afford **6** as a white crystalline solid (50 mg, 0.15 mmol): ^{1}H NMR (500 MHz, d_6-DMSO) δ 12.89 (br s, 1H), 9.87 (br s, 1H), 7.39 (m, 1H), 7.25 (s, 2H), 7.13 (m, 1H), 7.06 (d, J = 7.5 Hz, 1H), 6.74−6.71 (m, 2H), 4.51 (s, 2H); ^{13}C NMR (125 MHz, d_6-DMSO) δ 170.4, 168.6, 153.5, 145.0, 133.1, 130.9, 128.4, 126.1, 125.9, 123.3, 118.8, 115.6, 50.5; MS (+EI) *m/z* 340 (MH+, 70), 338 (MH+, 100).

*5-Amino-N-(3,5-dichlorophenyl)-2-hydroxybenzamide (***9***).* A solution of 2-hydroxy-5-nitrobenzoic acid (2.02 g, 11.0 mmol), *N*-hydroxysuccinimide (1.28 g, 11.1 mmol), and *N,N′*-dicyclohexylcarbodiimide (2.30 g, 11.1 mmol) in THF (47 mL) was stirred (rt, 4 h) and the resulting precipitant filtered and the filtrate was concentrated *in vacuo* to afford a crude intermediate succinate ester which was used without further purification (3.08 g): MS (-EI) *m/z* 279 (M-, 100). An aliquot of this crude intermediate succinate (1.17 g, theor. 4.18 mmol) was dissolved in toluene (10 mL) and to this solution was added neat 3,5-dichloroaniline (0.694 g, 4.28 mmol) and diisopropylethylamine (1.8 mL, 14 mmol). This mixture was warmed to reflux and stirred for 6 h and then allowed to cool to ambient temperature. After addition of aqueous HCl (10% v/v, 10 mL), the resulting precipitate was collected, dissolved into ethyl acetate, washed (H_2O) and dried ($MgSO_4$), and concentrated *in vacuo* to afford the known compound *N*-(3,5-dichlorophenyl)-2-hydroxy-5-nitrobenzamide [439145−07−0] (0.610 g, 1.86 mmol): ^{1}H NMR (500 MHz, d_6-acetone) δ 10.42 (br s, 1H), 8.94 (d, J = 3.0 Hz, 1H), 8.39 (dd, J = 9.0, 3.0 Hz, 1H), 7.88 (d, J = 2.0 Hz, 2H), 7.34 (s, 1H), 7.23 (d, J = 9.0 Hz, 1H); MS (+EI) *m/z* 327 (MH+, 70), 325 (MH+, 100). A suspension of *N*-(3,5-dichlorophenyl)-2-hydroxy-5-nitrobenzamide (0.594 g, 1.82 mmol) and 5% Pd/C (wet Degussa-type E101, 53 mg, theor. 0.013 mmol Pd) in ethanol (20 mL) was stirred under hydrogen atmosphere (1 atm., 4 h, rt). The mixture was filtered and the filtrate was concentrated *in vacuo* to afford a crude solid of which an aliquot was purified by flash chromatography (hexanes/ethyl acetate, 4:1) to afford an analytical sample of **9** (6 mg, 0.02 mmol): ^{1}H NMR (500 MHz, d_6-acetone) δ 10.62 (br s, 1H), 10.00 (br s, 1H), 7.94 (s, 1H), 7.39 (m, 2H), 6.88 (d, J = 9.0 Hz, 2H), 6.82 (d, J = 9.0 Hz, 1H), 3.39 (br s, 2H); MS (+EI) *m/z* 297 (MH+, 70), 295 (MH+, 100).

*5-Acetamido-N-(3,5-dichlorophenyl)-2-hydroxybenzamide (***10***).* A suspension of 5-amino-2-hydroxybenzoic acid (3.45 g, 22.5 mmol) in ethanol (800 mL) and acetic anhydride (2.56 g, 25.1 mmol) was stirred with warming (50 °C, 3 h) and then allowed to cool (rt). The mixture was then concentrated *in vacuo* and crystallization was induced by the addition of water. The crystals were collected and dried *in vacuo* to afford 5-acetamido-2-hydroxybenzoic acid (1.96 g, 10.0 mmol): ^{1}H NMR (500 MHz, d_6-acetone) δ 9.22 (br. s, 1H), 8.21 (d, J = 2.5 Hz, 1H), 7.70 (app t, J = 2.5 Hz, 1H), 6.86 (d, J = 2.5 Hz, 1H), 1.95 (s, 3H); MS (+EI) *m/z* 196 (MH+, 100). A solution of 5-acetamido-2-hydroxybenzoic acid (1.85 g, 9.48 mmol), *N*-hydroxysuccinimide (1.21 g, 10.5 mmol), and *N,N′*-dicyclohexylcarbodiimide (2.20 g, 10.6 mmol) in THF (100 mL) was stirred (rt, 4 h), then filtered, and the filtrate was dried *in vacuo* to afford a crude intermediate succinate ester that was used without further purification: MS (-EI) *m/z* 291 (M-, 100). To a portion of this crude intermediate (24.3 mg, theor. 0.0832 mmol) dissolved in NMP (1.5 mL) was added 3,5-dichloroaniline (63 mg, 0.39 mmol). The resulting solution was warmed with microwave irradiation (225 °C, 10 min.) then allowed to cool (rt). After aqueous workup (EtOAc/10% aq HCl), the organic layer was dried ($MgSO_4$), filtered, and concentrated *in vacuo*. The resulting brown oil was triturated (EtOAc) and the remaining crude solid was purified by flash chromatography (hexanes/ethyl acetate, 4:1) to afford an analytical sample of **10** (14 mg, 0.041 mmol): ^{1}H NMR (500 MHz, d_6-DMSO) δ 9.82 (br s, 1H), 7.92 (br s, 1H), 7.82 (s, 2H), 7.58 (br m, 1H), 7.30 (s, 1H), 6.89 (br m, 1H), 1.99 (s, 3H); MS (-EI) *m/z* 339 ((M-, 70), 337 (M-, 100).

*N-(3,5-Dichlorophenyl)-2-hydroxy-4-nitrobenzamide (***11***).* A solution of 2-hydroxy-4-nitrobenzoic acid (2.34 g, 12.8 mmol), *N*-hydroxysuccinimide (1.48 g, 12.8 mmol), and *N,N′*-dicyclohexylcarbodiimide (2.68 g, 13.0 mmol) in THF (25 mL) was stirred (rt, 3 h), and the resulting precipitate was filtered and the filtrate concentrated *in vacuo* to afford a crude succinate ester (2.97 g) which was used without further purification: MS (-EI) *m/z* 279 (M-, 100). A portion of this material (1.52 g, theor. 6.44 mmol) and 3,5-dichloroaniline (2.06 g, 12.7 mmol) was briefly warmed (140 °C, internal, 10 min) as a melt, with stirring, then allowed to cool (rt). After aqueous workup (EtOAc/10% aq HCl), the organic layer was dried ($MgSO_4$), filtered, and concentrated *in vacuo* to afford a crude solid from which an analytical sample of **11** (130 mg, 0.397 mmol) was prepared by flash chromatography (hexanes/ethyl acetate, 17:3). ^{1}H NMR (500 MHz, d_6-DMSO) δ 11.71 (br s, 1H), 10.75 (br s, 1H), 7.89 (d, J = 10.0 Hz, 1H), 7.84 (s, 2H), 7.77 (d, J = 10.0 Hz, 2H), 7.37 (s, 1H); MS (-EI) *m/z* 327 ((M-, 70), 325 (M-, 100).

*4-Amino-N-(3,5-dichlorophenyl)-2-hydroxybenzamide (***12***).* To a suspension of **11** (0.492 g, 1.50 mmol) in ethanol (9.0 mL) and HCl (12 N aq, 1.0 mL) was added neat stannous chloride (1.72 g, 9.09 mmol). The resulting suspension was heated with microwave irradiation (120 °C internal, 10 min). The resulting brown solution was allowed cool (rt) and the solvent removed *in vacuo*. The resulting solid was dissolved in ethyl acetate, washed (10% aq NaOH; brine), dried (Na_2CO_3), and concentrated *in vacuo* to afford a yellow solid (0.414 g) from which an analytical sample of **12** (12 mg, 0.040 mmol) was prepared by flash chromatography (hexanes/ethyl acetate, 4:1) to afford a crystalline white solid. ^{1}H NMR (500 MHz, d_6-acetone) δ 12.11 (br s, 1H), 9.45 (br s, 1H), 7.85 (s, 2H), 7.68 (d, J = 8.8 Hz, 1H), 7.19 (s, 1H), 6.24 (d, J = 8.8 Hz, 1H), 6.17 (s, 1H), 5.50 (s, 2H); MS (-EI) *m/z* 297 (MH+, 70), 295 (MH+, 100).

*4-Acetamido-N-(3,5-dichlorophenyl)-2-hydroxybenzamide (***13***).* A suspension of 4-amino-2-hydroxybenzoic acid (4.65 g, 30.3 mmol) in ethanol (400 mL) and acetic anhydride (3.10 g, 30.4 mmol) was stirred with warming (40 °C, 10 min) and then allowed to cool (rt). The mixture was then concentrated *in vacuo* and crystallization was induced by the addition of water. The crystals were collected and dried *in vacuo* to afford a crude sample of 4-acetamido-2-hydroxybenzoic acid (1.78 g, theor. 9.12 mmol) which was used without further purification: MS (+EI) *m/z* 196 (MH+, 100). A solution of crude 5-acetamido-2-hydroxybenzoic acid (1.66 g, theor. 8.52 mmol), *N*-hydroxysuccinimide (1.09 g, 9.49 mmol), and *N,N′*-dicyclohexylcarbodiimide (1.99 g, 9.66 mmol) in THF (100 mL) was stirred (rt, 4 h), then filtered, and the filtrate was dried *in vacuo* to afford a crude intermediate succinate ester that was used without further purification: MS (-EI) *m/z* 291 (M-, 100). To a portion of this crude intermediate (368 mg, theor. 1.26 mmol) dissolved in NMP (4.5 mL) was added 3,5-dichloroaniline (640 mg, 3.95 mmol). The resulting solution was warmed with microwave irradiation (225 °C, 10 min), then allowed to cool (rt). The resulting crystals that formed overnight were collected by filtration, washed with ethyl acetate, and dried *in vacuo* to afford

13 (0.369 g, 1.09 mmol) as white needles: ^{1}H NMR (500 MHz, d_6-DMSO) δ 11.40 (s, 1H), 10.58 (s, 1H), 9.78 (s, 1H), 7.93 (s, 2H), 7.89 (d, J = 8.0 Hz, 1H), 7.47 (app t, J = 8.0, 1H), 7.05−6.95 (m, 2H), 2.02 (s, 3H); MS (+EI) *m*/*z* 341 (MH+, 70), 339 (MH+, 100).

*N-(3-Acetamido-5-chlorophenyl)-2-hydroxybenzamide (***14***).* To a stirred solution of 3-amino-5-chloroaniline (1.00 g, 7.01 mmol) in anhydrous THF (200 mL) at room temperature was added (rt, over 90 min) a solution of acetic anhydride (0.663 mL, 7.01 mmol) in anhydrous THF (200 mL). After stirring overnight, the resulting solution was concentrated *in vacuo* to afford a dark oil which after flash chromatography (hexanes/EtOAc, 1:2) afforded *N*-(3-amino-5-chlorophenyl)acetamide as a tan solid (0.916 g, 5.00 mmol) which was used without further purification: MS (+EI) *m*/*z* 185 (MH+, 100). A solution of 2-benzyloxybenzoic acid (2.00 g, 8.76 mmol), *N*-hydroxysuccinimide (1.21 g, 10.5 mmol), and *N*,*N*′-dicyclohexylcarbodiimide (1.99 g, 9.64 mmol) in anhydrous THF (30 mL) was stirred (rt, 4 h). The resulting precipitant was filtered and the filtrate was concentrated *in vacuo* to afford a crude intermediate succinate ester that was used without further purification (3.30 g): ^{1}H NMR (500 MHz, d_6-DMSO) δ 7.94 (d, J = 7.5, 1H), 7.73 (m, 1H), 7.50 (d, J = 7.5 Hz, 2H), 7.38 (m, 3H), 7.32 (d, J = 7.0 Hz, 1H), 7.16 (m, 1H), 5.30 (s, 2H), 2.89 (s, 4H); ^{13}C NMR (125 MHz, d_6-DMSO) δ 170.4, 160.2, 158.8, 136.4, 136.4, 131.7, 128.4, 127.7, 127.0, 120.8, 114.5, 113.9, 69.8, 25.5. An aliquot of this crude succinate ester (0.286 g, theor. 0.880 mmol) and *N*-(3-amino-5-chlorophenyl)acetamide (0.650 g, 3.52 mmol) was briefly warmed as a melt (10 min, 140 °C, internal). The resulting brown solution was allowed to cool (rt). The residue was diluted with EtOAc (30 mL), and after aqueous washes (3 N HCl, brine), the organic layer was dried ($MgSO_4$) and concentrated *in vacuo* to afford a tan solid which after flash column chromatography (hexanes/EtOAc, 1:1) afforded *N*-(3-acetamido-5-chlorophenyl)-2-(benzyloxy)benzamide as a white crystalline solid (0.211 g, 0.535 mmol): ^{1}H NMR (500 MHz, d_6-DMSO) δ 10.33 (br s, 1H), 10.16 (br s, 1H), 7.95 (s, 1H), 7.65−7.51 (m, 5H), 7.37−7.27 (m, 4H), 7.17 (s, 1H), 7.09 (app t, J = 8.0 Hz, 1H), 5.23 (s, 2H), 2.05 (s, 3H); ^{13}C NMR (125 MHz, d_6-DMSO) δ 168.9, 164.8, 155.6, 140.8, 140.4, 136.5, 132.9, 132.1, 129.7, 128.4, 128.0, 127.8, 125.1, 120.8, 113.5, 113.4, 113.3, 108.2, 70.0, 24.0; MS (+EI) *m*/*z* 397 (MH+, 70), 395 (MH+, 100). A suspension of *N*-(3-acetamido-5-chlorophenyl)-2-(benzyloxy)benzamide (146 mg, 0.370 mmol) and 5% Pd/C (wet Degussa-type E101, 50 mg, theor. 0.012 mmol Pd) in MeOH (40 mL) was shaken under a hydrogen atmosphere (60 psi, rt, 1 h). The resulting mixture was filtered (diatomaceous earth) and the filtrate was concentrated *in vacuo*. This afforded a mixture consisting of approximately equal amounts of two products (fully resolved by silica gel TLC, hexanes/EtOAc, 1:1) that were separated by flash column chromatography (hexanes/EtOAc, 1:1). One white crystalline product appears to result from reductive dehalogenation and was isolated (39 mg) and found to be identical by HPLC, MS, ^{1}H NMR, and ^{13}C NMR to a previously prepared authentic sample of *N*-(3-acetamidophenyl)-2-hydroxybenzamide (analytical data not reported here). The other component, **14**, was isolated as a white crystalline solid (25 mg, 0.082 mmol): ^{1}H NMR (500 MHz, d_6-DMSO) δ 11.55 (br s, 1H), 10.47 (br s, 1H), 10.17 (br s, 1H), 7.90 (m, 2H), 7.53 (d, J = 12.5 Hz, 2H), 7.44 (m, 1H), 6.98 (m, 2H), 2.06 (s, 3H); ^{13}C NMR (125 MHz, d_6-DMSO) δ 168.7, 166.5, 157.9, 140.8, 139.8, 133.7, 132.9, 129.3, 119.1, 118.0, 117.1, 114.7, 114.0, 109.3, 24.0; MS (-EI) *m*/*z* 305 (M-, 70), 303 (M-, 100).

*N-(4-Acetamido-3,5-dichlorophenyl)-2-hydroxybenzamide (***15***).* To a solution of 4-nitrophenyl 2-hydroxybenzoate (0.494 g, 1.91 mmol) in NMP (15 mL) was added *N*-(4-amino-2,6-dichlorophenyl)acetamide (1.26 g, 5.75 mmol). The resulting solution was briefly warmed with microwave irradiation (225 °C internal, 10 min) then allowed to cool (rt). After aqueous workup (EtOAc/10% aq HCl), the combined organic layer was dried ($MgSO_4$), and concentrated *in vacuo* to afford a crude solid from which an analytical sample of **15** (12 mg, 0.035 mmol) was prepared by flash chromatography (hexanes/ethyl acetate, 55:45): ^{1}H NMR (500 MHz, d_6-DMSO) δ 11.39 (s, 1H), 10.52 (s, 1H), 9.74 (s, 1H), 7.93 (s, 2H), 7.86 (dd, J = 7.5, 1.5 Hz, 1H), 7.44 (app t, J = 7.5, 1H), 7.00−6.96 (m, 2H), 2.05 (s, 3H); MS (-EI) *m*/*z* 339 (M-, 70), 337 (M-, 100).

*2-(Benzyloxy)-N-(3,5-dichloro-4-methoxyphenyl)benzamide (***17***).* To a solution of 4-nitrophenyl-2-hydroxybenzoate (0.717 g, 2.76 mmol) in NMP (3 mL) was added 3,5-dichloro-4-methoxyaniline (1.51 g, 7.88 mmol). The resulting solution was briefly refluxed with stirring (15 min) and then allowed to cool (rt). After aqueous workup (EtOAc/10% aq HCl), the organic layer was washed (brine), dried ($MgSO_4$), and the solvent removed *in vacuo* followed by purification of the crude solid by flash chromatography (hexanes/ethyl acetate, 4:1) to afford known compound **16** (125 mg, 0.311 mmol), [55411−43−3]: ^{1}H NMR (500 MHz, d_6-DMSO) δ 11.41 (s, 1H), 10.45 (s, 1H), 7.89 (s, 2H), 7.85 (dd, J = 8.0, 1.0 Hz, 1H), 7.43 (app t, J = 7.5, 1H), 7.00−6.94 (m, 2H), 3.81 (s, 3H); MS (-EI) *m*/*z* 312 (M-, 70), 310 (M-, 100). To a suspension of **16** (25.1 mg, 0.0804 mmol) and K_2CO_3 (26 mg, 0.19 mmol) in DMF (0.5 mL) at room temperature was added neat benzyl bromide (20 uL, 0.17 mmol). The resulting mixture was briefly warmed by microwave irradiation (150 °C internal, 10 min.) and then allowed to cool (rt). The resulting mixture was filtered. The filtrate, after aqueous workup (EtOAc/10% aq HCl) and concentration *in vacuo*, afforded an analytical sample **17** (7.6 mg, 0.019 mmol). ^{1}H NMR (500 MHz, d_6-DMSO) δ 10.35 (s, 1H), 7.67−7.65 (m, 3H), 7.54−7.52 (m, 3H), 7.38−7.36 (m, 3H), 7.28 (d, J = 8.5 Hz, 1H), 7.10 (app t, J = 8.5 Hz, 1H), 5.23 (s, 2H), 3.78 (s, 3H); MS (-EI) *m*/*z* 404 (MH+, 70), 402 (MH+, 100).

*N-(3,5-Dichloro-4-methoxyphenyl)-2-methoxybenzamide (***18***).* A mixture of 2,5-dichloro-4-nitroanisole (5.47 g, 24.6 mmol) and 5% Pd/C (wet Degussa-type E101, 175 mg, theor. 0.0422 mmol Pd) in ethanol (200 mL) and acetic acid (10 mL) was stirred under hydrogen gas (1 atm, 4 h, rt). After filtration (diatomaceous earth), the bulk of the solvent was removed *in vacuo*, the residue was partitioned (ethyl acetate/1 N NaOH), and the organic layer dried ($NaSO_4$), and concentrated *in vacuo* to afford 2,5-dichloro-4-methoxybenzenamine (824 mg, 4.29 mmol [101251−23−4]) which was used without further purification. To a solution of 2,5-dichloro-4-methoxybenzenamine (0.341 g, 1.77 mmol) and diisopropylethylamine (0.5 mL, 4 mmol) in toluene (9.0 mL) was added 2-methoxybenzoyl chloride (0.489 g, 2.87 mmol) and the resulting solution was stirred (rt, 2 h). Addition of methanol (5.0 mL) resulted in a precipitate that was removed by filtration and the filtrate was concentrated *in vacuo* to afford a crude solid from which an aliquot was purified by flash chromatography (hexanes/ethyl acetate, 9.5:1 to 4:1) to afford an analytical sample of **18** (125 mg, 0.383 mmol).^{1}H NMR (500 MHz, d_6-acetone w/∼10% d_6-DMSO) δ 10.29 (s, 1H), 7.89 (s, 2H), 7.61 (dd, J = 7.5, 2.0 Hz, 1H), 7.52 (app t, J = 8.0 Hz, 1H), 7.18 (d, J = 8.5 Hz, 1H), 7.06 (app t, J = 7.5 Hz, 1H), 3.88 (s, 3H), 3.79 (s, 3H); MS (+EI) *m*/*z* 328 (MH+, 70), 326 (MH+, 100).

*Benzyl 2-(2-(4-amino-2,6-dichlorophenoxy)ethoxy)ethylcarbamate (***23***).* To a solution of 2-(2-aminoethoxy)ethanol (6.22 g, 59.2 mmol) in aq NaOH (0.8 M, 150 mL) at 0 °C (bath) was dropwise added (over 15 min) a solution of benzoyl chloroformate (13.0 g, 76.0 mmol) in THF (16 mL). The resulting solution was stirred (0 °C, 2 h) and then aqueous HCl (1.0 N, 50 mL) was added and the resulting mixture was allowed to

warm (rt). After aqueous workup (EtOAc/H_2O), the organic layer was dried ($MgSO_4$), filtered, and concentrated *in vacuo* to afford a crude solid that was purified by flash chromatography (EtOAc/CH_2Cl_2, 1:1) to afford **22** (9.2 g, 38 mmol) [145881−74−9]): ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.35−7.30 (m, 5H), 5.25 (br s, 1H), 5.11 (s, 2H), 3.74−3.73 (m, 2H), 3.57−3.55 (m, 4H), 3.42−3.40 (m, 2H); MS (+EI) *m/z* 262 (MNa+, 20), 240 (MH+, 50), 196 (M-44/H+, 100). To a solution of **22** (9.2 g, 38 mmol) and 1,3-dichloro-2-fluoro-5-nitrobenzene, **21**, (7.33 g, 34.9 mmol) in THF (160 mL) was added sodium hydride (60% w/w disp. in mineral oil, 1.54 g, theor. 38.5 mmol) under a nitrogen atmosphere. The resulting suspension was stirred under reflux (6 h) then allowed to cool (rt) and concentrated *in vacuo*. After aqueous workup (EtOAc/H_2O), the organic layer was dried ($MgSO_4$) and concentrated *in vacuo* to afford benzyl 2-(2-(2,6-dichloro-4-nitrophenoxy)ethoxy)ethylcarbamate (13.8 g, 32.1 mmol) which was used without further purification: ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.20 (s, 2H), 7.37−7.30 (m, 5H), 5.10 (s, 2H), 5.06 (br s, 1H), 4.33 (app t, J = 4.5 Hz, 2H), 3.86 (app t, J = 4.5 Hz, 2H), 3.62 (app t, J = 5.0 Hz, 2H), 3.40 (app t, J = 5.0 Hz, 2H); MS (+EI) *m/z* 431 (MH+, 70), 429 (MH+, 100). A suspension of benzyl 2-(2-(2,6-dichloro-4-nitrophenoxy)ethoxy)ethylcarbamate (12.7 g, 29.6 mmol) and stannous chloride (41.2 g, 182 mmol) in HCl (12 N, 50 mL) and ethanol (460 mL) was stirred at reflux (2 h) and then allowed to cool (rt). The bulk of the solvent was removed *in vacuo* and the pH was adjusted (to pH 8) by cautious addition (vigorous gas evolved) of aqueous $NaHCO_3$. After aqueous workup (EtOAc/H_2O), the organic layer was dried (Na_2SO_4), and concentrated *in vacuo* to afford a crude oil from which an aliquot was removed for purification by flash chromatography (hexanes/ethyl acetate, 3:1) to afford **23** (9.89 g, 24.8 mmol) as a colorless oil: ^{1}H NMR (500 MHz, $CDCl_3$ w/ ∼5% CD_3CO_2D) δ 7.36−7.30 (m, 5H), 6.77 (s, 2H), 5.11 (s, 2H), 4.11 (app t, J = 4.5 Hz, 2H), 3.81 (app t, J = 4.5 Hz, 2H), 3.62 (app t, J = 5.0 Hz, 2H), 3.41 (app t, J = 5.0 Hz, 2H); MS (+EI) *m/z* 401 (MH+, 70), 399 (MH+, 100).

*IL-12p40 Inhibitor-Modified AffiGel-15 (***19***).* A mixture of **23** (727 mg, 1.82 mmol) and phenyl salicylate, **24**, (537 mg, 2.50 mmol) was briefly warmed (melt) by microwave irradiation (200 °C internal, 10 min) and then allowed to cool (rt) and the resulting crude oil was purified by flash chromatography (hexanes/ethyl acetate, 7:3) to afford benzyl 2-(2-(2,6-dichloro-4-(2-hydroxybenzamido)phenoxy)ethoxy)ethylcarbamate (689 mg, 1.33 mmol) as a colorless oil: ^{1}H NMR (500 MHz, d_6-DMSO) δ 11.41 (d, J = 4.5 Hz, 1H), 10.43 (d, J = 7.0 Hz, 1H), 7.87−7.84 (m, 3H), 7.43 (app t, J = 7.8 Hz, 1H), 7.35−7.28 (m, 5H), 7.00−6.94 (m, 2H), 5.00 (s, 2H), 4.09 (t, J = 5.0 Hz, 2H), 3.74 (t, J = 5.0 Hz, 2H), 3.50 (t, J = 6.0 Hz, 2H), 3.16 (t, J = 6.0 Hz, 2H); MS (-EI) *m/z* 519 (M-, 70), 517 (M-, 100). A suspension of benzyl 2-(2-(2,6-dichloro-4-(2-hydroxybenzamido)phenoxy)ethoxy)ethylcarbamate (285 mg, 0.549 mmol), 5% Pd/C (wet Degussa-type E101, 22 mg, theor. 0.0053 mmol Pd), and acetic acid (0.2 mL) in chloroform/methanol (2:1, 15 mL) was shaken under hydrogen gas (25 psi, rt, 2 h). The resulting mixture was filtered (diatomaceous earth) and the filtrate concentrated *in vacuo* to afford *N*-(4-(2-(2-aminoethoxy)ethoxy)-3,5-dichlorophenyl)-2-hydroxybenzamide as a colorless oil (0.213 g, 0.534 mmol) that was used without further purification: ^{1}H NMR (500 MHz, d_6 DMSO) δ 11.41 (s, 1H), 10.43 (s, 1H), 7.90−7.86 (m, 3H), 7.43 (app t, J = 8.5 Hz, 1H), 7.01−6.94 (m, 2H), 4.14 (t, J = 5.0 Hz, 2H), 3.82 (t, J = 5.0 Hz, 2H), 3.70 (t, J = 5.5 Hz, 2H), 3.01 (t, J = 5.5 Hz, 2H); MS (+EI) *m/z* 387 (MH+, 70), 385 (MH+, 100). A solution of *N*-(4-(2-(2-aminoethoxy)ethoxy)-3,5-dichlorophenyl)-2-hydroxybenzamide (8.4 mM in DMSO/isopropanol, 1:20 v/v, 0.40 mL per column) was then nutated (24 h, 4 °C) with a portion of Affi-Gel-15 resin (reactive load level = 1.5 umol/mL, 0.3 mL) that had been washed and swelled with isopropanol (0.5 mL resin/slurry working volume per column). The postloading filtrate was collected and determined by LC-UV absorption (254 nm) to be 11% depleted in *N*-(4-(2-(2-aminoethoxy)ethoxy)-3,5-dichlorophenyl)-2-hydroxybenzamide relative to the solution that was introduced to the Affi-Gel 15 resin. The resulting loaded resin (load ∼1.3 umol/mL) was then quenched/capped by washing with an aqueous solution of 2-aminoethanol (1.0 M, 1 mL).

*IL-12p40 Non-Inhibitor-Modified Affigel-15 (***20***).* A solution of **23** (795 mg, 1.99 mmol), 2-methoxybenzoyl chloride (623 mg, 3.65 mmol) and diisopropylethylamine (829 mg, 6.41 mmol) in toluene (10 mL) was stirred under nitrogen (rt, 1 h). After aqueous workup (EtOAc, H_2O followed by aq. $NaHCO_3$, then 5% aq. HCl and last brine), the organic layer was dried ($MgSO_4$) and concentrated *in vacuo* to afford a crude solid that after purification by flash chromatography (hexanes/ethyl acetate, 3.5:1.5) afforded benzyl-2-(2-(2,6-dichloro-4-(2-methoxybenzamido)phenoxy)ethoxy)ethylcarbamate (1.04 g, 1.95 mmol) as a colorless oil: ^{1}H NMR (500 MHz, $CDCl_3$) δ 9.78 (br s, 1H), 8.27 (d, J = 7.5 Hz, 1H), 7.53 (app t, J = 7.5 Hz, 1H), 7.36−7.27 (m, 5H), 7.15 (app t, J = 7.5 Hz, 1H), 7.05 (d, J = 7.5 Hz, 1H), 5.11 (s, 2H), 4.18 (t, J = 5.0 Hz, 2H), 4.07 (s, 3H), 3.85 (t, J = 5.0 Hz, 2H), 3.66 (t, J = 5.0 Hz, 2H), 3.44 (t, J = 5.0 Hz, 2H); MS (+EI) *m/z* 535 (MH+, 70), 533 (MH+, 100). To a stirred solution of benzyl-2-(2-(2,6-dichloro-4-(2-methoxybenzamido)phenoxy)ethoxy)ethylcarbamate (120 mg, theor. 0.230 mmol) in $CHCl_3$ (5.0 mL) under argon (rt) was added neat trimethylsilyl iodide (153 mg, 0.765 mmol) in portions over 4 h. The resulting solution was diluted with MeOH (1 mL), 10% aq HCl (5 mL), CH_2Cl_2 (50 mL), and water (50 mL) resulting in a milky white suspension which was clarified by further addition of aqueous NaOH (10% w/w, 50 mL) and CH_2Cl_2 (50 mL). The aqueous layer was washed with CH_2Cl_2, and the combined organic layer was dried (Na_2SO_4) and concentrated *in vacuo* to afford a crude solid which after purification by flash chromatography ($CHCl_3$: methanol/triethyl amine, 100:10:0.1) afforded *N*-(4-(2-(2-aminoethoxy)ethoxy)-3,5-dichlorophenyl)-2-methoxybenzamide as a colorless oil (26 mg, 0.065 mmol) that was used without further purification: ^{1}H NMR (500 MHz, d_6-DMSO) δ 10.28 (s, 1H), 7.90 (s, 2H), 7.60 (d, J = 7.5 Hz, 1H), 7.52 (app t, J = 7.5 Hz, 1H), 7.15 (d, J = 7.5 Hz, 1H), 7.05 (app t, J = 7.5 Hz, 1H), 4.14 (t, J = 5.0 Hz, 2H), 3.94 (s, 3H), 3.82 (t, J = 5.0 Hz, 2H), 3.70 (t, J = 5.5 Hz, 2H), 3.01 (t, J = 5.5 Hz, 2H); MS (+EI) *m/z* 401 (MH+, 70), 399 (MH+, 100). A solution of *N*-(4-(2-(2-aminoethoxy)ethoxy)-3,5-dichlorophenyl)-2-methoxybenzamide (8.4 mM in DMSO: isopropanol, 1:20 v/v, 0.40 mL per column) was then nutated (24 h, 4 °C) with a portion of Affi-Gel-15 resin (0.3 mL) that had been washed and swelled with isopropanol (0.5 mL resin/slurry working volume per column). The postloading filtrate was collected and determined by LC-UV absorption (254 nm) to be 10% depleted in *N*-(4-(2-(2-aminoethoxy)ethoxy)-3,5-dichlorophenyl)-2-methoxybenzamide relative to the solution that was introduced to the Affi-Gel 15 resin. The resulting loaded resin (load ∼1.3 umol/mL) was then quenched/capped by washing with an aqueous solution of 2-aminoethanol (1.0 M, 1 mL).

General Bioassay Methods. All cell culture manipulations were performed in a biological safety cabinet, unless otherwise indicated. Media and additives were prepared and maintained under aseptic conditions with storage in the refrigerator up to one month. DC-B cell growth medium was prepared by combining Hepes buffer (1 M, 10 mL, pH = 7.4), Minimum Essential Medium (MEM) 100×x with sodium pyruvate (10 mL, Gibco catalog, #11360−070), MEM Vitamin Solution

(100×) (4 mL, Gibco catalog #1120−0511), MEM Essential Amino Acids 50× without Glutamine (8 mL, Gibco catalog #11130−051), MEM 100× Non-Essential Amino Acids (4 mL, Gibco catalog #11140−050), Penicillin-Streptomycin-Glutamine (10 mL, Gibco catalog #10378−016), and 2-mercaptoethanol (1 mM, 1 mL). The resulting solution was diluted (to 1 L) with aqueous sodium bicarbonate. To this solution was added heat inactivated fetal bovine serum (FBS) and murine granulocyte-macrophage colony stimulating factor (GM-CSF) to afford a final concentration of 10% v/v FBS and 20 ng/mL for GM-CSF. Assay medium for DC-B cells was prepared by combining MEM 100× Non-Essential Amino Acids (10 mL, Gibco catalog #11140−050), sodium pyruvate (100 mM, 10 mL), Hepes buffer (10 mM, 10 mL), and 2-mercaptoethanol (1 mM, 1 mL) and diluting this to a final volume of one liter with Iscove's Modified Dulbecco's Medium (Hyclone). To this solution was added heat inactivated fetal bovine serum (FBS) and murine granulocyte-macrophage colony stimulating factor (GM-CSF) to afford a final concentration of 1% v/v FBS and 20 ng/mL for GM-CSF. ELISA antibody pairs included purified rat antimouse IL-6 monoclonal antibody (PharMingen catalog #554400), biotinylated rat antimouse IL-6 monoclonal antibody (PharMingen catalog #554402), purified rat antimouse IL-12p40/p70 monoclonal antibody (PharMingen catalog #551219), biotinylated rat antimouse IL-12p40/p70 monoclonal antibody (PharMingen catalog #554476), DELFIA Assay Buffer (Wallac catalog #1244−111), europium-labeled streptavidin, (Wallac catalog #1244−360,) and Enhancement Solution (Wallac catalog #1244−105). Assay plates were high-binding 384-well plates (Greiner Catalog #781077) and cell culture plates were black wall/clear bottom 384-well plates (Costar Catalog #3712).

Fluorescence Immunoassay Protocol. A murine dendritic cell line (DC-B cells) was cultured in growth medium (60 mL total volume) in T-175 tissue culture flasks maintained in a 37 ± 2 °C, 5 ± 1% CO_2 high humidity incubator. Nonadherent cells were collected and diluted with growth medium (1:3 v/v) every 48 h. To the test compounds (40 uM in assay media containing 0.4% v/v DMSO, 12.5 uL per well), in 384-well in cell culture plates, were added DC-B cells in DELFIA assay buffer (27.5 uL/well, cell concentration of 7.27×10^5/mL) followed by the cytokine stimulatory mixture (or assay media if a control well; 10 uL/well) in order to induce IL-12p40 and IL-6 secretion by the DC-B cells (*11, 12*). The stimulatory mixture consisted of a solution of *mu*CD40L, *mu*IL-18, and *mu*IFNgamma in assay media resulting in final concentrations of 2 ng/mL, 40 ng/mL, and 20 ng/mL, respectively. The resulting assay plates containing test compounds at a concentration of 10 uM (50 uL volume per well) were incubated (18−24 h, 37 °C incubator with 5% CO_2). After incubation, the supernatant was transferred to 384 well assay plates that were precoated at 4 °C with either anti-IL-12p40 or anti-IL-6 capture antibodies. After incubation (2 h, rt), the assay plates were washed with Tween 20 (0.05% v/v in PBS) and a solution of the secondary antibody (20 uL/well in PBS containing 10% v/v heat inactivated FBS). The secondary antibody was either biotinylated rat antimouse IL-12p40 or biotinylated rat antimouse IL-6 depending upon the assay. After incubation (1 h, rt), the plates were washed with Tween 20 (0.05% v/v in PBS) and europium-labeled streptavidin (0.60 ug/mL in Delfia Assay Buffer, 20 uL/well) was added. After incubation (0.5 h, rt), the plates were washed with Tween 20 (0.05% v/v in PBS) and then the Enhancement Solution was added (40 uL/well). After incubation (5 min, rt), the plates were analyzed using a Victor^2 plate reader (Wallac) and measuring at 615 nm. Assay experimental data points were calculated as percentage of control (POC) and plotted vs concentration. Each concentration in the dose−response plots was composed of three assay experimental data points. The concentrations tested were over a range of ten values from 0.5 nM to 10 uM (i.e., 0.0005, 0.0015, 0.0046, 0.014, 0.041, 0.12, 0.37, 1.11, 3.33, 10.0 uM). From these plots, the IC50 ± SEM is reported (Table 1) and this represents the mean of at least two (and as many as eleven) separate determinations. Assay data analysis was performed using Spotfire Decision Site 8.1 (www.Tibco.com) and Activity Base 5.0 queried with SARgen (www.idbs.com).

Cytotoxicity and Recombinant Protein Profiling Assays. Cytotoxicity was assessed in our dendritic cell line by using the Cell Titer-GLO cell viability protocol (www.promega.com). The dendritic cells, treated with test compound, were then stimulated according to the same protocol described in the preceding section for the IL-12p40 assay protocol (i.e., incubated 18 h with murine CD40L, murine IL-18, and murine IFN-gamma). The Cell Titer-GLO reagent was then added in equal volume to culture volume and incubated (i.e., 2 min with orbital shaking to induce cell lysis followed by 10 min of incubation without shaking). Luminescence was then read (Victor^2 Microplate reader, Wallac). No cytotoxicity (POC <10%) was observed over a range of nine values from 1.5 nM to 10 uM (i.e., 0.0015, 0.0046, 0.014, 0.041, 0.12, 0.37, 1.11, 3.33, 10.0 uM) for any compound with IL-12p40 activity (i.e., IC50 < 10 uM). Routine counter-screening included 75× receptor binding and 71× enzyme inhibition assays performed at Cerep (www.cerep.com).

Affinity Chromatography Columns. Two columns, containing **19** or **20**, respectively, were prepared using Affi-Gel-15 resin (Bio-Rad Laboratories, www.biorad.com) which is composed of primary/secondary amine reactive succinate ester groups on an agarose matrix (load level = 15 μmol per mL as determined by vendor). The column containing agarose labeled salicylanilide **19** we refer to as the "specific" column and the column containing agarose labeled salicylanilide **20** we refer to as the "non-specific" column.

DC-B Cell Derived Cytosolic Preparation. The same murine dendritic cell line (~100×10^6 cells) that was stimulated and used for the IL-12p40 assay (i.e., incubated 18 h with murine CD40L, murine IL-18, and murine IFNgamma) was subjected to three sequential freeze and thaw cycles (dry ice, ethanol) in order to lyse the cells. Then, buffer A (1 mL) was added. Buffer A is composed of HEPES buffer (20 mM, pH 7.1), NaCl (50 mM), β-glycerophosphate (25 mM), sodium vanidate (2.5 mM), sodium fluoride (5 mM), and Protease Inhibitor (1 tab, Sigma-Aldrich catalog #P8340). The mixture was agitated (~3× stroke cycles through a 25 gauge needle equipped with a 3 mL syringe) and centrifuged. To the DC derived cytosolic protein mixture (750 uL per column) was added quenched Affi-Gel-15 (150 uL packed) and this was nutated (overnight, 4 °C). This step was envisioned as a further control for non-specific interactions with the unmodified Affi-Gel-15 resin. The resulting material was centrifuged and the supernatant collected and introduced to each chromatography column (i.e., **19** or **20**; see preceding section) followed by nutation (2 h, 4 °C). The columns were then centrifuged, washed with buffer A (4 mL per column, pH = 7.1, see preceding description), and the supernatant layers were removed.

Competitive Elution of Affinity Columns and Postelution Analysis by SDS-PAGE. Each of the above columns, **19** or **20**, was loaded with a cytosolic protein mixture and then eluted with a solution of **16** (0.06 mM in buffer A) with ten separate fractions collected from each column. Each column fraction (200 uL) was diluted with DMSO (200 uL) and nutated (rt, 3 min) with SDS-Page Sample Prep. Kit Binding Resin (www.piercenet.com) followed by centrifugation (1400 rpm, 3 min.) using the filter cup provided with the Prep. Kit to recover supernatant fractions containing protein material. The resin was

then washed (200 uL of 50% aq DMSO) according to the general vendor protocol and then nutated (60 °C, 5 min) with SDS-Page Sample Prep. Kit Elution buffer (40 uL per column fraction) before collecting filtrate. Each filtrate (~40 uL) was diluted with a solution of 2-mercaptoethanol in SDS-Page Sample Prep. Kit Sample Buffer (15 uL, 25% v/v) and warmed (100 °C, 5 min).

In-Gel Digestion. Protein bands of interest from SDS-PAGE gels were excised and the gel pieces were processed using an automated protein digestion station (Genomic Solutions, Ann Arbor, MI) that performed the tasks of reduction and alkylation of cysteines, tryptic digestion, and extraction of the peptides.

Mass Spectrometry. According to the general method of Johnson and Davis et al. (*13*), a fully automated mass spectrometry analysis of the trypsin proteinase treated peptides was performed on a Micromass QTOF instrument (Waters Corporation, Milford, MA) and a NanoLC-2D system (Eksigent, Dublin, CA). One self-packed 75 um i.d. × 15 cm Vydac C18 columns and one 200 μm i.d. × 5 mm Monolithic trap column were attached to a 10 port switching valve (Valco Instruments Co. Inc.) which allowed sample fast loaded in the trap column to be analyzed and LC/MS/MS data to be collected through the C18 capillary column. Total run time was 65 min. Peptides were identified by searching the IPI-mouse protein sequence database (http://www.ebi.ac.uk/IPI/IPImouse.html) using the search tool MASCOT (http://www.matrixscience.com).

Molecular Docking and Minimization Methods. For compound **16** and 14−3−3ζ: Five structures of human 14−3−3ζ were downloaded from the RCSB Protein Data Bank: 1IB1, 1QJA, 1QJB, 2C1J, and 2C1N. For evaluation purposes, bound molecules, waters, and equivalent protein molecules were deleted from each structure, and the five remaining proteins were superimposed using MOE 2006.08 software (Chemical Computing Group Inc., Montreal, CN). Upon evaluation of the overlaid active sites it was found that LYS 49 was the only highly variable residue and structure 2C1J (*14*) was deemed representative of the series and thus used for the following calculations. The heavy atoms on the protein were fixed, hydrogen atoms were added, partial charges for all the atoms were calculated and the protein was minimized using Amber 99 in MOE. The small molecule was constructed and partial charges were calculated using MMFF94 in MOE. The small molecule was docked into the fixed protein's active site using MOE Dock in MOE. The top results were minimized (using Amber 99 in MOE) in a partially fixed protein (residues LYS 49, ARG 56, ARG 127, TYR 128 were free).

Calculated Physical Properties. The calculated physical properties including cLogD and pK_a were determined using ACD/LogD Suite 9.0, Advanced Chemistry Development, Inc., (ACD/Laboratories, Toronto ON, Canada, www.acdlabs.com).

RESULTS AND DISCUSSION

In the course of cell-based screening campaigns, we discovered salicylanilide **3** which inhibited IL-12p40 and IL-6 production in stimulated primary human dendritic cells as well as behaving similarly in a dendritic cell line assay (Table 1). Compounds **1** and **2a**,**b** were unfortunately not included among the original compounds that we evaluated for inhibition of IL-12p40 production. On the basis of a hypothesis that a desirable therapeutic profile is one that could block IL-12p40 but not IL-6 production, we engaged in directed analoging and developed analogue **4**, in which there is a hydrogen in place of the bromine on the salicyl-ring (i.e., ring "A"). Compound **4** was found in our assays to behave similarly to compound **3** with respect to inhibition of IL-12p40 production but to be much more selective against inhibition of IL-6 production (Table 1). The correlation between IL-6 activity and halogenation of the salicyl-ring demonstrated by these two analogues was generally observed in other analogues (*15*) and could be hypothesized to be due to some variation in interactions with different target protein(s).

We were interested in understanding the mechanism of action of these salicylanilides, and as a first step, we undertook broad counter-screening of **4** against a diverse collection of recombinantly expressed proteins but this resulted in no significant inhibition being observed versus any of more than 150 known targets (*15*). We also assessed general cytotoxicity in our dendritic cell line, and for example, **3** and **4** were each determined to have cytotoxic thresholds above 10 uM.

Focusing on **4** as an IL-12p40 inhibitor that might lend itself to chemical labeling, we chose to use affinity chromatography as a technique for protein target identification. As a preliminary step to developing chromatography matrices containing salicylanilides, we utilized a prospecting strategy in which we systematically introduced (i.e., highlighted boxes in Table 1) a limited array of functional groups around the periphery of a salicylanilide pharmacophore as a means to identify a site that might tolerate chemical labeling with agarose in a manner that would not significantly alter the bioactivity relative to the unlabeled analogue (i.e., **4**). Experience has shown us, as may be expected, that not all molecules lend themselves to chemical labeling without changes in bioactivity and this cannot be predicted *a priori* without the benefit of sufficient analogues and/or target protein structural information. For this study, we favored simple functional groups (i.e., amide, ether, alkyl) that would offer tractable syntheses and result in analogues with reasonable expectations of stability in our cellular assays, as a way to rapidly identify pharmacophore positions that might tolerate further chemical labeling.

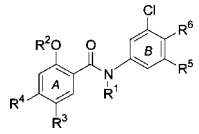
Beginning with the possibility of tethering through the central amide moiety, it was found that simple tertiary amides are not tolerated as replacements for the secondary amide group in **4** as evidenced by analogues **5** and **6**. Next, we explored the possibility of tethering through the phenol group, and various ethers such as analogue **7**, with an *O*-benzyl ether group, were prepared. However, masking the phenol group as an ether resulted in a dramatic loss of inhibition of IL-12p40 production at our highest assay concentration (i.e., 10 μM). A possible alternative strategy that may allow for tethering through the salicyl-ring (*15*) is the replacement of the phenol group on the salicyl-ring with an aryl-sulfonamide group possessing a comparable pK_a.

Continuing with positions *para* to the critical phenol group of the salicyl ring, we prepared amino- and *N*-acetyl analogues **9** and **10**, respectively. Neither of these analogues demonstrated any measurable IL-12p40 activity. Similarly, we explored the position *para* to the amide substituents on ring "A" and likewise found a dramatic loss of bioactivity in our assays with analogues **12** and **13**. Notably, synthetic intermediates **8** and **11** were identified as possessing moderate inhibition of IL-12p40 production; however, we viewed a nitro group as not being as readily useful as an amide/amine functional group for attachment to an agarose resin and thus we continued the study, orienting next on the "B" ring. We prioritized the atom positions *meta* and *para* to the critical *N*-(salicyl)-substituent of the "B" ring, since we were concerned about the stereoelectronic consequences of chemical labeling *ortho* to this critical group.

Early in our directed analoging of **3**, it was observed that the *meta*-chloro substituents as featured in **4** are important for IL-12p40 activity and neither one nor both chloro groups could be replaced with simple alkyl groups, such as isosteric methyl groups, without complete loss of inhibitory activity in the IL-12p40 assay (*15*). Thus, we looked at heteroatom replacements for the *meta*-chloro groups on ring "B" but we found that, for example, *N*-acetyl analogue **14** lacked activity in the IL-12p40

assay. However, analogue **15** with halogen substitution similar to **4** but featuring an *N*-acetyl group *para* to the *N*-(salicyl)-substituent retained some moderate activity in the IL-12p40 assay. Despite the ~50-fold lower activity of **15** relative to **4**, we were encouraged enough by this result to next examine ether functional groups at this same *para* position of ring "B". We were pleased to find that the methyl ether modification in analogue **16** resulted in comparable activity to analogue **4** with respect to inhibition of IL-12p40 production in stimulated dendritic cells.

Table 1. Salicylanilides: Survey for Tethering Site



Entry	R1	R2	R3	R4	R5	R6	IC_{50} (μM)[a] IL-12p40	IL-6

[a] Data reported here is for a murine dendritic cell line stimulated with a mixture of CD40L, IFNγ and IL-18. IL-12p40 and IL-6 detection by fluorescence immunoassay.

The affinity chromatography approach that we favored for subsequent protein target identification features two separate columns (Figure 2), each containing a differently modified agarose gel. One of these gels was derivatized using a bioactive small molecule and which we will refer to here as the "specific column" and the other, referred to as the "non-specific column", does not feature a bioactive compound attached to it (i.e., Scheme 2 describes structures **19** and **20**).

In order to make the non-specific column as similar as possible to the specific column, with respect to hydrophobicity and other bulk physical properties related to the structure of the salicylanilide-modified chromatography matrix, we required a salicylanilide analogue with no inhibitory activity toward IL-12p40 production and which would be attached in a similar manner to the agarose gel of the non-specific column. On the basis of the importance of the phenol group of salicylanilides, as seen earlier by comparing **4** with **7**, we prepared compounds **17** and **18** in which the phenol group is masked as an *O*-benzyl or *O*-methyl ether, respectively, and confirmed that these analogues had no activity in our IL-12p40 assay (Table 1). We felt that salicylanilide **16** (cLogD = 5.2, at pH 6.5 or 7.4) and its analogue **18** (cLogD = 4.3, at pH 6.5 or 7.4), which have similar structures and physical properties but very different IL-12p40 assay activities, constituted a suitable pair of candidate molecules for attachment to agarose gels for use as "specific" and "non-specific" chromatography columns, respectively.

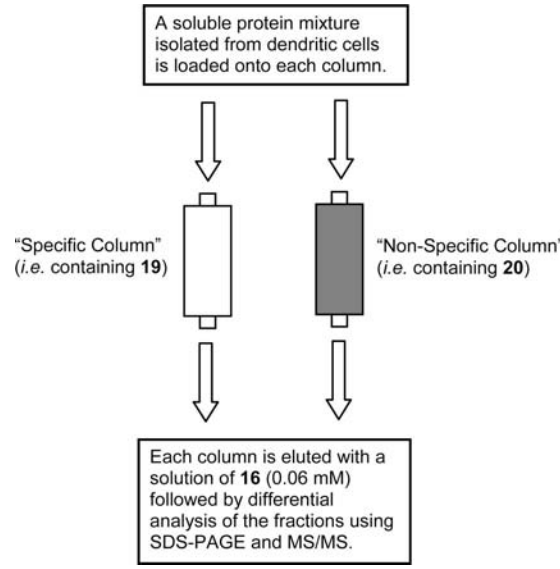

Figure 2. Chromatography: "specific" and "non-specific" agarose gels.

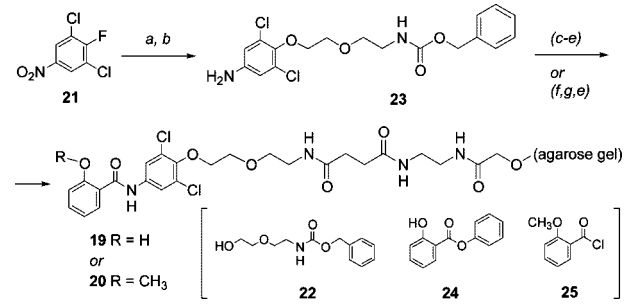
The preparation of agarose labeled salicylanilides **19** and **20** began (Scheme 2) with nucleophilic aromatic substitution of **21** with **22** followed by reduction of the product with stannous chloride to afford **23**. Acylation of **23**, using either **24** or **25** followed by removal of the CBZ-protecting group and reaction of the resulting primary amine with an *N*-(hydroxy)succinimide derivatized agarose gel, afforded **19** or **20**, respectively.

Scheme 2. Salicylanilide-Modified Agarose Gels[a]



[a] Reagents: (a) **22**, NaH, THF, reflux; (b) $SnCl_2$, HCl aq., EtOH (71% from **21**); (c) **24**, melt at 200 °C; (d) H_2, Pd/C cat. (73% from **23**); (e) *N*-(hydroxy)succinimide derivatized agarose gel, aq. buffer (load level ~1.5 umol/mL); (f) **25**, ethyl-di(isopropyl)-amine, toluene; (g) TMSI, $CHCl_3$ (28% from **23**).

Protein target identification was accomplished by loading a mixture of proteins, prepared from lysis of the stimulated dendritic cell line used in the IL-12p40 assay, onto each column. Each column, in parallel, was washed and specific vs non-specific signal detection was enhanced in this experiment by competitive elution with the solution phase inhibitor **16** (0.06 mM). The fractions from each column were compared by SDS-PAGE analysis, after elution and concentration, in order to identify any specifically absorbed proteins (i.e., from column **19** not **20**). Characterization of protein bands was accomplished by cut-out of the gels, digestion with trypsin, and identification by MS/MS analysis. Reported here is a specifically retained 28 kDa protein, 14−3−3ζ (*16*, *17*) that was eluted from the "specific" column and not detected in the analysis of fractions eluted from the "non-specific" column. Interestingly, 14−3−3

Figure 3. Consensus protein sequence of 14−3−3ζ of *Mus musculus.*

proteins have also recently been detected in immunostimulatory exosomes secreted by murine derived dendritic cells (*18*).

The 14−3−3 gene products are a large family of dimeric phosphoserine binding proteins with many reported biological functions (*19*). Of the seven isoforms known in mammals, the two peptide fragments that we found (i.e., "FLIPNASQPESK" and "DSTLIMQLLR", underlined in Figure 3) by MS/MS match only the phosphorylated and nonphosphorylated 14−3−3ζ/δ isoform of *Mus musculus* and do not match the ζ, φ/τ, ε, γ, β, or σ isoforms in *Mus musculus*. There are other human proteins that have homology with 14−3−3ζ proteins but none of these homologous proteins contain the two peptide sequences that we identified from our murine protein mixture. Murine and human 14−3−3ζ proteins share the same sequence except in one of the peptide sequences that we detected by MS/MS, PRO-112 in *Mus musculus* is an alanine in *Homo sapiens*. Serine-58, is highly conserved and, upon phosphorylation, by a number of different kinases has been shown to favor the monomeric form of the 14−3−3ζ proteins. Structurally, 14−3−3 proteins feature a bundle of nine antiparallel α-helices defining a large, concave hydrophobic pocket (*19*). Close contact amino acids are indicated (bold, Figure 3) and define a pocket where we hypothesize the small molecule (ex. "**16**") binds to 14−3−3ζ.

In a preliminary attempt to understand the binding of salicylanilides like **16** with 14−3−3ζ, we docked **16** into a solved X-ray structure (*14*) of human 14−3−3ζ in which the cocrystallized substrate peptide was first removed *in silico* and then minimization was conducted with the resulting apo-14−3−3ζ structure and **16** (Figure 4). We found that **16** prefers to bind such that its *para O*-methyl ether group accepts a hydrogen bond from ARG-56 with the methyl group (i.e., the same position that was chemically labeled to prepare target identifying gel **19**) extended away from the binding pocket. Such a binding feature would clearly be required for the affinity chromatography approach to succeed.

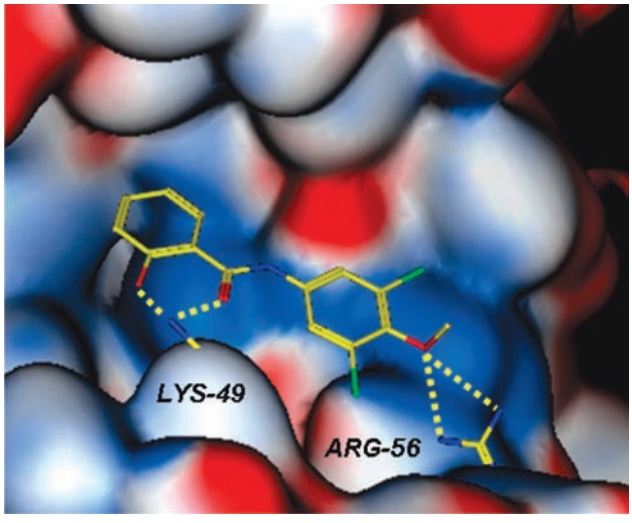

Figure 4. Molecular model of **16** docked in an apo-14−3−3, cocrystal. Surfaces are electrostatic renderings (i.e., red = positive, white = neutral, blue = negative charges).

It was also observed that the hydroxybenzamide system of **16** is preferred to be coplanar in this binding model which allows for a very favorable charge−charge interaction between the ε-amino side-chain (LYS-49) of 14−3−3ζ and both the phenolic hydroxyl group and the adjacent amide carbonyl group of **16.** This observation may explain why masking this key phenolic group as an ether, such as found in inactive analogues **7**, **17**, or **18**, and the non-specific resin **20**, would be expected to greatly diminish these salicylanilides' affinities for 14−3−3ζ. Much of the rest of the "A" ring and the N-H of the amide group are closely bound in proximity to hydrophobic residues (e.g., ILE-217, LEU-220) that define the interior of this pocket and which may explain why the chemical labeling survey (Table 1) disfavored all but certain "B" ring modifications of these salicylanilides with respect to retention of IL-12p40 activity.

In conclusion, we have demonstrated that example salicylanilides can functionally inhibit IL-12p40 production. The conversion of one of these bioactive salicylanilides into a comparably bioactive, chemically labeled derivative was achieved through a systematic synthesis strategy using readily tractable modifications around the periphery of a salicylanilide pharmacophore. This strategy provided a tool reagent for protein identification based upon selective biochemical affinity. Having demonstrated selective biochemical affinity, further experiments to address the functional role of 14−3−3ζ in IL-12p40 production, in stimulated dendritic cells, will be reported.

Intracellular Delivery of Quantum Dot−Protein Cargos Mediated by Cell Penetrating Peptides

Igor L. Medintz,*[,†] Thomas Pons,[‡,#] James B. Delehanty,[†] Kimihiro Susumu,[‡] Florence M. Brunel,[§] Philip E. Dawson,[§] and Hedi Mattoussi*[,‡]

Received March 5, 2008; Revised Manuscript Received June 19, 2008

We utilize cell penetrating peptide functionalized QDs as specific vectors for the intracellular delivery of model fluorescent protein cargos. Multiple copies of two structurally diverse fluorescent proteins, the 27 kDa monomeric yellow fluorescent protein and the 240 kDa multichromophore b-phycoerythrin complex, were attached to QDs using either metal-affinity driven self-assembly or biotin−Streptavidin binding, respectively. Cellular uptake of these complexes was found to depend on the additional presence of cell-penetrating peptides within the QD−protein conjugates. Once inside the cells, the QD conjugates were mostly distributed within endolysosomal compartments, indicating that intracellular delivery of both QD assemblies was primarily driven by endocytotic uptake. Cellular microinjection of QD-fluorescent protein assemblies was also utilized as an alternate delivery strategy that could bypass the endocytic pathway. Simultaneous signals from both the QDs and the fluorescent proteins allowed verification of their colocalization and conjugate integrity upon delivery inside live cells. Due to their intrinsic fluorescence properties, this class of proteins provides a unique tool to test the ability of QDs functionalized with cell penetrating peptides to mediate the intracellular delivery of both small and large size protein cargos. Use of QD−peptide/fluorescent protein vectors may make powerful tools for understanding the mechanisms of nanoparticle-mediated drug delivery.

INTRODUCTION

Developing nanoparticles as delivery vehicles for drugs, genes, and contrast/imaging agents to live cells, tissues, and tumors has stimulated much interest recently (*1*−*5*). Among an array of available nanoparticles, luminescent semiconductor nanocrystals or quantum dots (QDs) provide a powerful prototypical example with many demonstrated applications in biological imaging and sensing (*6*−*9*). Their utility is derived from the combination of unique photophysical characteristics and sizes comparable to that of a large protein. The hydrodynamic radius of hydrophilic CdSe-ZnS QDs varies from ∼5 nm, for nanocrystals cap exchanged with molecular ligands, to ∼20 nm for nanocrystals encapsulated within block copolymers (*10*). A single QD can be conjugated to several biomolecules (such as antibodies, peptides, DNA) to provide multifunctional QD bioconjugates with enhanced avidity. In addition, their strong resistance to chemical and photodegradation can potentially allow long-term fluorescent monitoring of specific biological processes (*6*−*9, 11*).

Several methods have been investigated to achieve the efficient intracellular delivery of various nanoparticles, including QDs. They include electroporation (*12*), lipid-based transfection reagents (*13, 14*), and microinjection (*13*), as well as receptor-mediated endocytosis (*11, 15*). Use of cell-penetrating peptides (CPP) conjugated to hydrophilic QDs as an alternate strategy to facilitate their intracellular uptake has also been reported by several groups, and results suggest that delivery was primarily driven by endocytotic uptake (*13, 16*−*23*). Although a wide range of cell penetrating peptides exist, they are most often functional analogues of the canonical HIV-derived TAT sequence and usually consist of 8−10 sequentially repeated polyarginine residues (*24*). We have recently explored the use of CPP-mediated delivery of QD−peptide conjugates to eukaryotic HEK-293 and COS-1 cells (*25*). The peptide sequence used was modular and consisted of a C-terminal 8 arginine repeat-block for mediating cellular uptake, a short linker/spacer, and a N-terminal 8 histidine tract that promoted peptide self-assembly onto CdSe-ZnS core−shell QDs (*25, 26*). Efficiency of the CPP-facilitated delivery was found to depend on both peptide-to-QD ratio and overall QD conjugate concentration. CPP-mediated uptake required short incubation times of less than 1 h compared to 2−4 h or longer incubation time for passive uptake; it was also both selective and specific even when cells were incubated with mixtures of CPP and *other* nonpeptide functionalized QDs. Nanocrystals delivered via this approach did not exhibit any discernible toxic effects to the cells, and intracellular localization was again confirmed to be primarily endosomal (*25*). The intracellular delivery and stability of nanocrystals conjugated to a mixture of His-terminated CPP and dye-labeled peptides was further verified by multiphoton fluorescence resonance energy transfer imaging (FRET between QDs and proximal dyes) of intracellular compartments several hours post-uptake (*27*).

In this report, we build upon our previous results and demonstrate that cell penetrating peptides can further promote the effective intracellular delivery of QD cargos made of

nanocrystals self-assembled with additional small or large fluorescent proteins. The QD serves as a central nanoscaffold for immobilizing proteins and peptides, while the CPPs promote conjugate internalization by eukaryotic cells. This class of proteins was specifically selected as they allow fluorescence monitoring of intracellular distribution as well as testing of the stability of QD−protein assemblies. Proteins, including yellow fluorescent protein (YFP) and the multichromophore b-phycoerythrin complex (b-PE), were conjugated to QDs, via a combination of metal-affinity interactions and biotin−avidin binding. We found that intracellular delivery of these conjugates strongly depended on CPP presence, while colocalization studies indicated that the mixed surface QD−peptide/protein assemblies were distributed within the endosomal compartments. In comparison, direct microinjection of QD−protein cargos into live cells bypassed the endolysosomal system and resulted in more homogeneous distribution of conjugates throughout the cytosol.

EXPERIMENTAL PROCEDURES

QD Synthesis. CdSe-ZnS core−shell QDs with emission maxima centered at 510 and 540 nm were synthesized using stepwise reactions of organometallic precursors in hot coordinating solvent mixtures following the procedures described in refs (*28*−*31*); absorption and emission spectra are provided in Figure 1A. The nanocrystals were made hydrophilic by exchanging the native capping shell, composed primarily of trioctyl phosphine and trioctyl phosphine oxide (TOP/TOPO), with bifunctional ligands as described in refs (*32*−*34*). We used two sets of hydrophilic QDs: (1) nanocrystals capped with only dihydrolipoic acid, and (2) nanocrystals capped with a mixture of poly(ethylene glycol)-appended dihydrolipoic acid (PEG Mw ≃ 600, DHLA-PEG) and biotin-terminated DHLA-poly(ethylene glycol) (PEG Mw ≃ 400, DHLA-PEG-biotin) with a 9:1 molar ratio of the ligands; these are referred to as DHLA-QDs and DHLA-PEG-biotin-QDs, respectively. Ligand structures are provided in Figure 1C (*32*−*34*).

Proteins and Peptides. The yellow fluorescent protein was generously provided by W. Frommer (Carnegie Institute, Stanford, CA) on plasmid pRSET B (Invitrogen, Carlsbad, CA) within a gene fusion encoding a blue fluorescent protein−glucose binding protein−yellow fluorescent protein sensor construct inserted between *Bam*HI and *Hind*III of the multiple cloning site (*35*). The blue fluorescent protein−glucose binding protein portion was excised by digestion with *Kpn*I and *Bam*HI and an insert encoding for a hexa-histidine $(His)_6$ sequence followed by a unique *Xho*I site (Asp-Gln) was ligated into the *Kpn*I and *Bam*HI restriction sites. Transformants were screened by *Xho*I digestion and confirmed with DNA sequencing. The final YFP

gene construct sequentially encodes a His_6 sequence after the start methionine, Asp-Gln, an Xpress Epitope (Asp-Leu-Tyr-Asp-Asp-Asp-Asp-Lys) and another His_6 sequence at the immediate N-terminus of the YFP coding sequence. This plasmid was introduced into BL21(DE3) *E. coli* cells (Invitrogen) and expression induced with 1 mM isopropyl-β-D-thiogalactopyranoside (IPTG, Sigma, St Louis, MO) for 3 days at 30 °C in the dark to allow for full maturation of the chromophore, before harvesting the cells by centrifugation at 4 °C. His-appended YFP was purified from soluble cell lysate using Ni-NTA Resin (Qiagen, Valencia, CA), as described in refs (*35, 36*). The absorption and emission spectra of the purified YFP are shown in Figure 1B. One-to-one b-phycoerythrin−Streptavidin conjugate solution at 1 mg/mL (referred to as b-PE) and AlexaFluor 647 dye-labeled Transferrin (AF647-TF, $\lambda_{abs\ max.} = 647$ nm, $\lambda_{em\ max.} = 670$ nm) were obtained from Invitrogen. Cell penetrating peptide (CPP) with the sequence $(His)_8$-Trp-Leu-Ala-Aib-Ser-Gly-$(Arg)_8$-amide, where Aib is α-aminoisobutyric acid and the c-terminus is blocked with an amide, was synthesized and purified as described in ref (*25*).

Self-Assembly of Quantum Dot Bioconjugates. To self-assemble QD−YFP conjugates at the desired valence, His-appended proteins at the appropriate molar ratios were added to 0.3 μM of 510-nm emitting DHLA-capped QDs in 10 mM Tris-Cl pH 8 buffer and incubated at room temp for ∼30 min. Similarly, b-PE-Streptavidin was added to 0.3 μM of 540-nm emitting QDs (capped with DHLA-PEG:DHLA-PEG-biotin 9:1 ratio) in phosphate buffered saline (137 mM NaCl, 10 mM phosphate, 2.7 mM KCl, pH 7.4, PBS) and incubated at 4 °C overnight; conjugate formation in this case is driven by Streptavidin−biotin interactions. Conjugates were characterized using gel electrophoresis, where changes in the electrophoretic mobility of QDs assembled with either His-appended YFP or Streptavidin-labeled b-PE were monitored (*10*). Samples were diluted in 1 × TBE buffer (0.09 M Tris, 0.002 M Na_2-EDTA 0.09 M Boric acid pH ∼8.3) and run on 1% or 2% agarose gels for QD−b-PE and YFP conjugates, respectively. In particular, the effects of varying the number of proteins per QD bioconjugate were monitored. Gel images were collected by exciting the QD and/or protein and capturing fluorescence images of the separated bands within the gels using a Kodak 440 Digital Image Station (Rochester, NY). Conjugate formation was also confirmed by monitoring changes in the energy transfer between the QDs and fluorescent proteins upon self-assembly. Fluorescent spectra were collected on a Tecan Safire Dual Monochromator Multifunction Microtiter Plate Reader (Tecan, Research Triangle Park, NC) using 325 nm excitation. For intracellular delivery and imaging experiments, QDs were self-assembled with a mixture of the protein and CPP at a nominal CPP:QD molar ratio of 50:1.

Intracellular Uptake of Quantum Dot−Fluorescent Protein Conjugates. HEK 293T/17 and COS-1 cell lines (ATCC, Manassas, VA) were cultured in complete growth medium (Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 4 mM L-glutamine, 1 mM sodium pyruvate, 1% (v/v) penicillin/streptomycin/actinomycin D antibiotic/antimycotic, and 10% (v/v) heat-inactivated fetal bovine serum (FBS). Cells were incubated at 37 °C under 5% CO_2 atmosphere and a subculture was performed every 3 days (*25*). Cellular internalization experiments were performed in sterile Laboratory-Tek chambered coverglass wells (Nunc, Rochester, NY). The chambers were initially coated with 50 μg/mL fibronectin (Sigma-Aldrich, St Louis, MO) in sodium bicarbonate buffer pH 8.5. Approximately 2×10^4 cells were seeded into the wells and cultured overnight. QD bioconjugates were diluted into complete culture medium and added to the cell culture and incubated at 37 °C for 1 h. AF647-TF (at 40 μg/mL) was also added to the culture to specifically colabel the endosomal vesicles as described previously (*25*). Mixed surface QD conjugates consisting of either 1:5 or 1:10 QD/YFP and QD/b-PE with assembly valence of 1:1 to 1:2.5, together with CPP at ∼50 CPPs per QD, were incubated with the cell cultures at different QD conjugate concentrations. Excess unbound QD conjugates were removed by washing the culture at least 3 times with PBS. Cells were then fixed in 3.7% paraformaldehyde for 10 min at room temperature, washed twice with PBS, and mounted in ProLong Antifade mounting media containing DAPI dye (Invitrogen) for nuclear staining. Epifluorescence image collection was carried out using an Olympus IX-71 microscope. Side-by-side split fluorescence images were collected and quantitated using a DualView system (Optical Insights, Tucson, AZ) equipped with a 565 nm dichroic filter. For 510 nm QD−YFP cellular imaging, samples were excited at 488 nm and emissions were collected/separated with the 565 nm dichroic and deconvoluted. QD fluorescence was collected at $\lambda < 565$ nm and the YFP fluorescent tail collected at $\lambda > 565$ nm. YFP leakage into the QD window was subtracted as part of the deconvolution. The 540 nm QDs and b-PE were excited at 488 nm and their respective emissions were separated with the 565 nm dichroic filter and deconvoluted. DAPI fluorescence was excited using a Xe lamp and emission collected using a DAPI cube (D350/50× for excitation, dichroic 400DCLP, D460/50m for detection). AF647-TF was excited using the Xe lamp and fluorescence detected using a Cy5 cube (excitation HQ620/60×, dichroic Q660LP, emission HQ700/75m). Both excitation/detection cubes were provided by Chroma Technology (Rockingham, VT). Differential interference contrast (DIC) images were collected using a bright light source. For microinjection, the QD−YFP and QD−b-PE conjugates described above were diluted in PBS. Conjugates were directly injected into adherent COS-1 or HEK 293T/17 cells using an InjectMan NI2 micromanipulator equipped with a FemtoJet programmable microinjector (Eppendorf, Westbury, NY). This instrumental setup allows the injection of femtoliter aliquots of conjugate solution into individual cells (*37*).

RESULTS

Fluorescent Proteins and Self-Assembly of Quantum Dot Bioconjugates. Yellow fluorescent protein (YFP) is a slightly longer wavelength emitting variant of the green fluorescent protein (GFP), and is derived from the jellyfish *Aequorea*, as described in the work of Tsien (*38*). It consists of 11 β-strands which form a hollow β-barrel or cylinder, and the chromophore, located at the center of a threaded helix, is formed by a cyclic rearrangement of three central residues (Gly_{65}, Tyr_{66}, Gly_{67}) during maturation (*38*). This relatively small protein (Mw ∼27 kDa) is easily expressed in bacteria from a plasmid, has a short maturation time, and has been used in a variety of FRET-based intracellular sensing studies (*39−41*). The second fluorescent protein we used, b-phycoerythrin (b-PE), is a member of the phycobiliprotein family of light harvesting protein complexes known as phycobilisomes found in red algae and cyanobacteria (*42, 43*). b-PE differs photophysically and structurally from YFP in many respects; see Table 1. It consists of α/β monomers associated into a symmetrical $(\alpha/\beta)_6$ hexameric structure and has ca. 34−38 covalently attached bilins (open chain tatrapyrrole chromophores) per functional moiety. It has a large molecular weight, ∼10 times that of YFP, a very large extinction coefficient, ∼100 times higher than that of YFP, and has been widely used as a highly sensitive fluorescent probe (*42, 43*).

We utilize two self-assembly approaches to form our QD bioconjugates: metal-affinity interactions and biotin−avidin binding. When used for nanoparticle conjugation, metal affinity

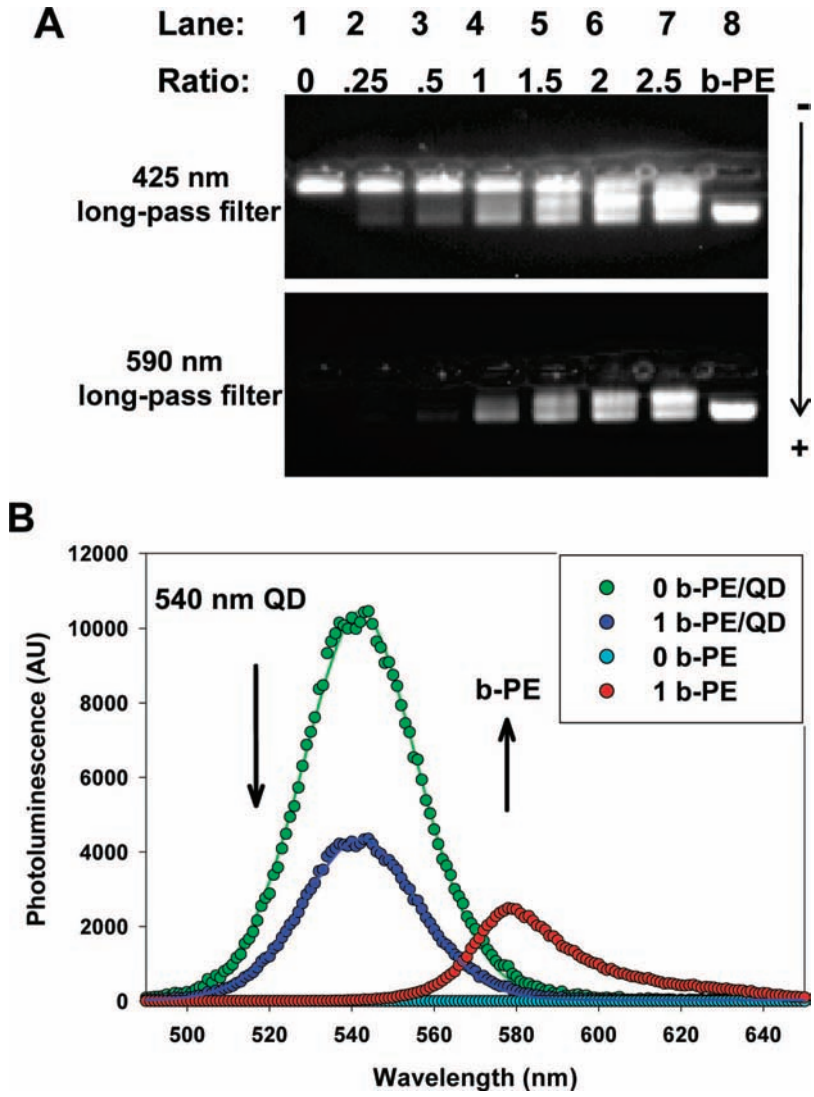

Figure 2. Agarose gel electrophoresis and FRET data. (A) Electrophoretic mobility bands captured from self-assembled QD−Streptavidin−b-PE conjugates; the corresponding average conjugate valences (ratio of b-PE per QD) are listed on top of each lane. Lane 8 has the equivalent amount of 2.5 b-PE alone. The gel was imaged with the indicated filters to isolate QD and protein emissions. QD−b-PE conjugates were separated on 1% agarose gels. (B) Deconvoluted PL spectra of 540 nm DHLA-PEG-biotin-QDs in the absence and presence of ~1 b-PE/QD along with b-PE FRET-sensitized emission. QD PL was fit to a Gaussian profile.

driven self-assembly can be versatile and easy to implement. We and other groups have shown that polyhistidine (His_n) sequences facilitate self-assembly of both proteins and peptides onto ZnS-overcoated CdSe QDs (*6*, *44*−*46*). More recently, we elucidated the kinetics of metal-His driven self-assembly between QDs and both proteins and peptides and showed that high affinity/low dissociation constants drive the interactions ($K_D \sim 10^{-9}$−10^{-8} M) (*26*). This study further showed that His interactions occur directly with the Zn-rich inorganic surface of the nanocrystals. Engineering YFP with an N-terminus bearing two-$(His)_6$ sequences separated by a small spacer and CPP having an N-terminal $(His)_8$ sequence permit the formation of tight QD−protein/peptide complexes driven by this self-assembly. Biotin−avidin binding is a ubiquitous bioconjugation strategy in biology, known for its strong interaction ($K_D \sim 10^{-15}$ M) (*47*). Using QDs surface-capped with a mixture of hydroxyl- and biotin-terminated PEG (DHLA-PEG-biotin-QDs) allowed easy conjugation to commercially available b-PE−Streptavidin.

The first characterization technique of these QD bioconjugates relied on agarose gel electrophoresis (no SDS present), where changes in the mobility shift were measured for QDs alone and QDs conjugated to increasing number of proteins. For QD−b-PE conjugates, since the emissions of the QDs and protein are spectrally distinguishable, gels were imaged with 425 and 590

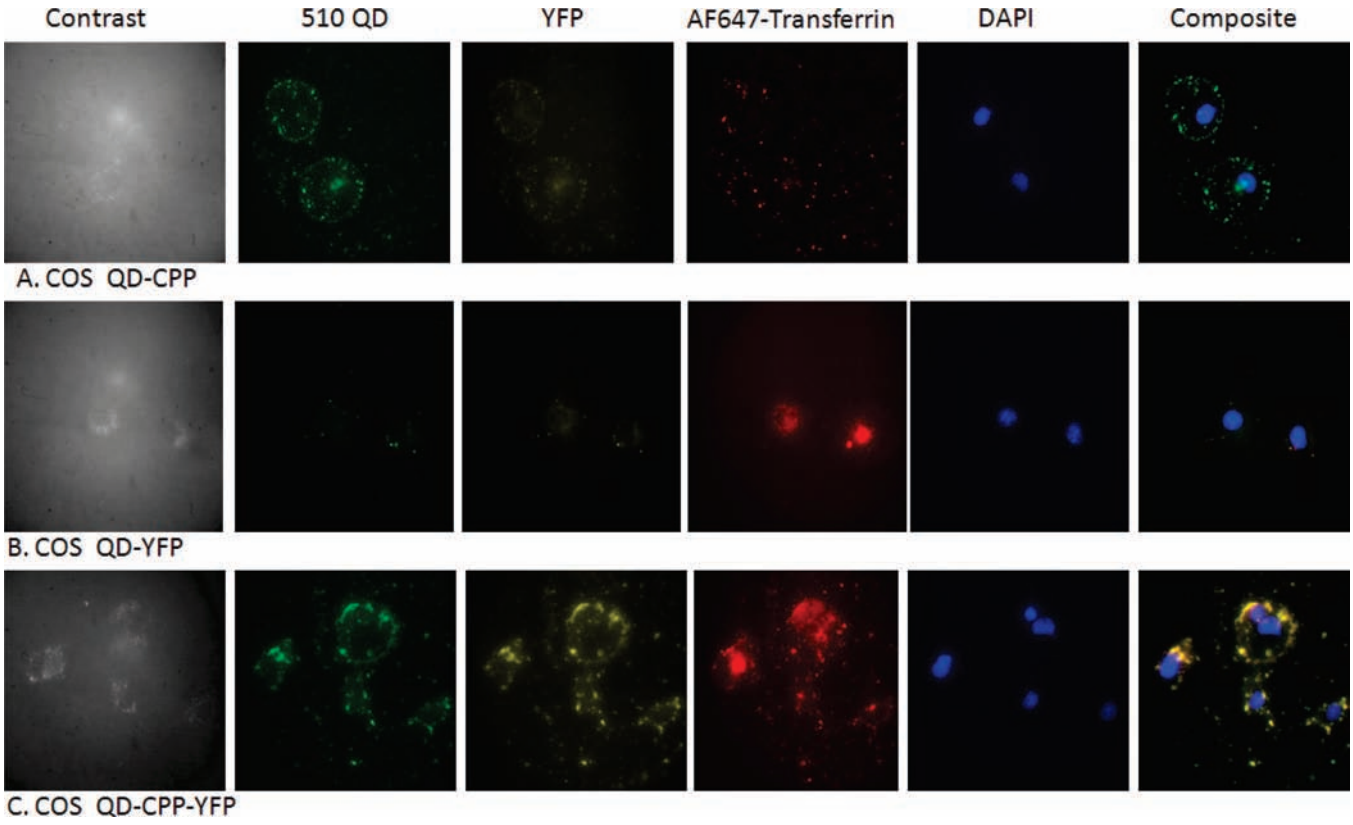

Figure 3. Cellular uptake of QD−YFP bioconjugates. Images collected from COS-1 cells incubated with (A) QD−CPP, (B) QD−YFP, and (C) QD−CPP−YFP assemblies; QD conjugate solutions at 75 nM concentration were used. For each series (left to right) the contrast, fluorescence images for 510-nm QD, YFP, AF647-Transferrin, DAPI, together with the merged fluorescence composite images are shown. Scale bar is 10 μm.

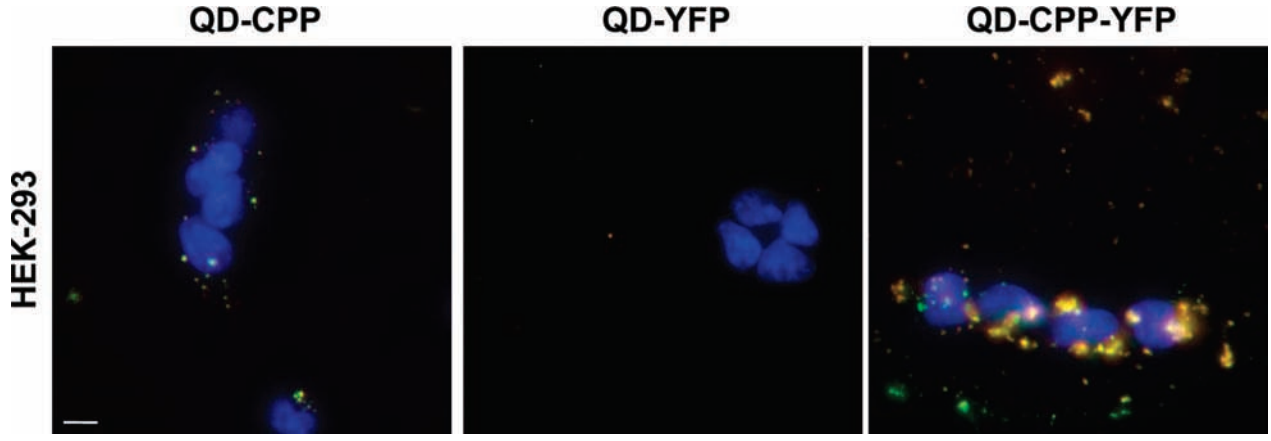

Figure 4. Cellular uptake of QD−YFP bioconjugates. HEK293/T17 cells were incubated with QD−CPP, QD−YFP, and CD−CPP−YFP assemblies as shown in Figure 2. Only merged representative fluorescent images compiled from the DAPI, QD, and YFP emissions are shown for each conjugate. Scale bar is 10 μm.

nm long-pass filters to allow visualization of either the simultaneous QD and b-PE emissions or only the emission of b-PE (see Figure 2A for representative images). The mobility of the unconjugated QDs capped with DHLA-PEG600/DHLA-PEG400-biotin mixture was essentially zero, as these ligands do not impart a net charge to the QDs. In comparison, a finite mobility shift was measured for b-PE alone. For solutions of conjugates at increasing b-PE-to-QD ratio, one can easily discern a discrete band with mobility intermediate between those of the QDs and b-PE (lanes 1 and 8, respectively). A concomitant decrease in the PL of the QD band is also noted as the ratio of b-PE and conjugate formation increases, which can be attributed to FRET interactions (see below). Furthermore, when the mobility bands corresponding to the various b-PE-to-QD ratios (lanes 2−7) and that of b-PE (control in lane 8) are compared, it appears that in addition to the main QD−b-PE conjugates, bands corresponding to the QDs and b-PE alone can also be visualized. The distribution in mobility bands for the conjugate solution is attributed to a distribution of conjugate valences varying between zero and the maximum expected, as previously observed for self-assembled bioconjugates (*10, 48*). The valence of QD conjugates is described by Poisson statistics and its effects are usually more visible at low protein-to-QD ratio as is the case in the present samples. Further, it is quite possible that not all the b-PE is conjugated to Streptavidin. Similarly, we carried out a side-by-side comparison of the mobility band shifts of solutions of QD−YFP conjugates at increasing YFP-to-QD ratios together with that of unconjugated QDs (data not shown).

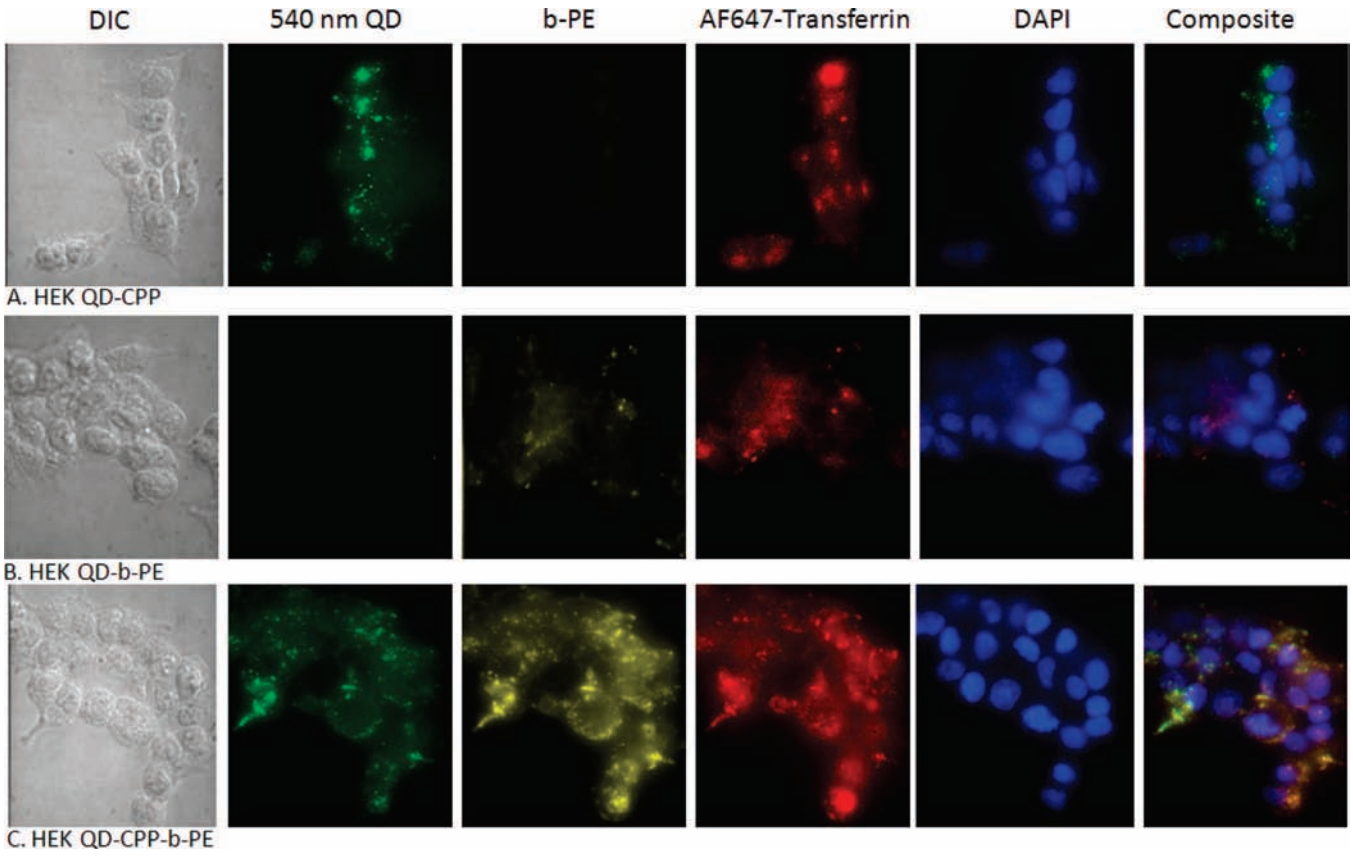

Figure 5. Cellular uptake of QD−b-phycoerythrin conjugates. Representative images of HEK293/T17 cells incubated with (A) QD−CPP, (B) QD−b-PE, (C) QD−CPP−b-PE. 540 nm emitting QD conjugates at 75 nM concentration were used. For each set of conjugates, the corresponding contrast, fluorescence images of 540-nm QD, b-PE, AF647-Transferrin, DAPI, along with the merged composite fluorescence images are shown. Due to overlap between the QD and b-PE emissions, spectral leakage between the QD and b-PE fluorescence can be seen along with some b-PE adherence to the cell membrane. Scale bar is 10 μm.

QDs exhibited the highest mobility shift due to the presence of negative surface charges (deprotonated carboxyl groups on the DHLA ligands), while a decrease in mobility shift with increasing conjugate valence was measured, which we attributed to an increase in conjugate size, i.e., YFP retards QD migration as more proteins are attached to the QD.

Assembly of both sets of QD−YFP and QD−b-PE conjugates were further confirmed by "visualizing" FRET between the central QD and proximal fluorescent proteins within the conjugates. The favorable spectral overlap between the nanocrystal emissions and either of the fluorescent proteins should result in a significant FRET interaction; see Figure 1. Representative deconvoluted spectra are shown in Figure 2B for QD−b-PE conjugates, where a loss in QD PL is measured along with a concomitant increase in acceptor PL upon conjugate, in agreement with previous results collected from solutions of QD−protein/peptide−dye conjugates (*10, 48−50*). Monitoring the relative QD donor and fluorescent protein acceptor emissions at different acceptor ratios allowed us to choose optimal assembly ratios for cellular uptake experiments. For imaging, significant emission from both the QD donor and the FRET-sensitized acceptor protein were desired. A detailed description and analysis of the FRET interactions will be presented elsewhere.

Intracellular Delivery of QD−YFP Conjugates. To verify that uptake of QDs surface functionalized with YFP cargo is mediated by the presence of CPP on the nanocrystal surface, two different cell lines, COS-1 and HEK293/T17, were separately incubated with 3 types of conjugate: QD−CPP conjugates (∼50 CPP per QD), QD−YFP conjugates (10 YFP per QD in the absence of CPP), and QDs assembled with a mixture of YFP and CPP (QD−YFP−CPP with ∼10 YFP and 50 CPP per conjugate). Cells were incubated with solutions of 510-nm emitting QD conjugates (at ∼75 nM concentration), rinsed to remove any unbound materials, and subsequently imaged using epifluorescence microscopy. Cells were also counter-stained with DAPI and AF647-transferrin to allow visualization of the nuclei and endosomes, respectively. Figure 3 shows images collected for COS-1 cells incubated with the indicated QD bioconjugates. Each row of panels shows representative DIC, 510-nm emitting QDs (green), YFP (yellow), AF647-TF (red), DAPI (blue), and the merged fluorescent composite images (right). Figure 4 shows only the merged images collected for the HEK cells similarly incubated with the three types of QD bioconjugates. The images collected for both types of cells indicate that in the absence of CPP there is essentially no intracellular uptake of QDs or QD−YFP conjugates during the incubation times used; the weak fluorescence measured in a few of the cells is attributed to nonspecific binding to the cell surfaces. When additional CPP is presented on the QD surface (mixed surface QD−protein−CPP conjugates), a substantial intracellular uptake of conjugates takes place as indicated by the pronounced fluorescence intensity measured for both sets of cells. Furthermore, images collected for both cultures showed that there is a nearly complete overlap between the fluorescence patterns of the QD and YFP; see last column of images in Figure 3 for COS-1 and merged images in Figure 4 for HEK293. Overlap between emissions of the QDs ($\lambda_{em} \sim 510$ nm) and YFP ($\lambda_{em} \sim 530$ nm) results in a small, non-negligible leakage of fluorescence signals between the respective images, as complete spectral separation is not possible with the dichroic filters used (see QD and YFP images in Figure 3). Evaluation of the staining patterns and colocalization with

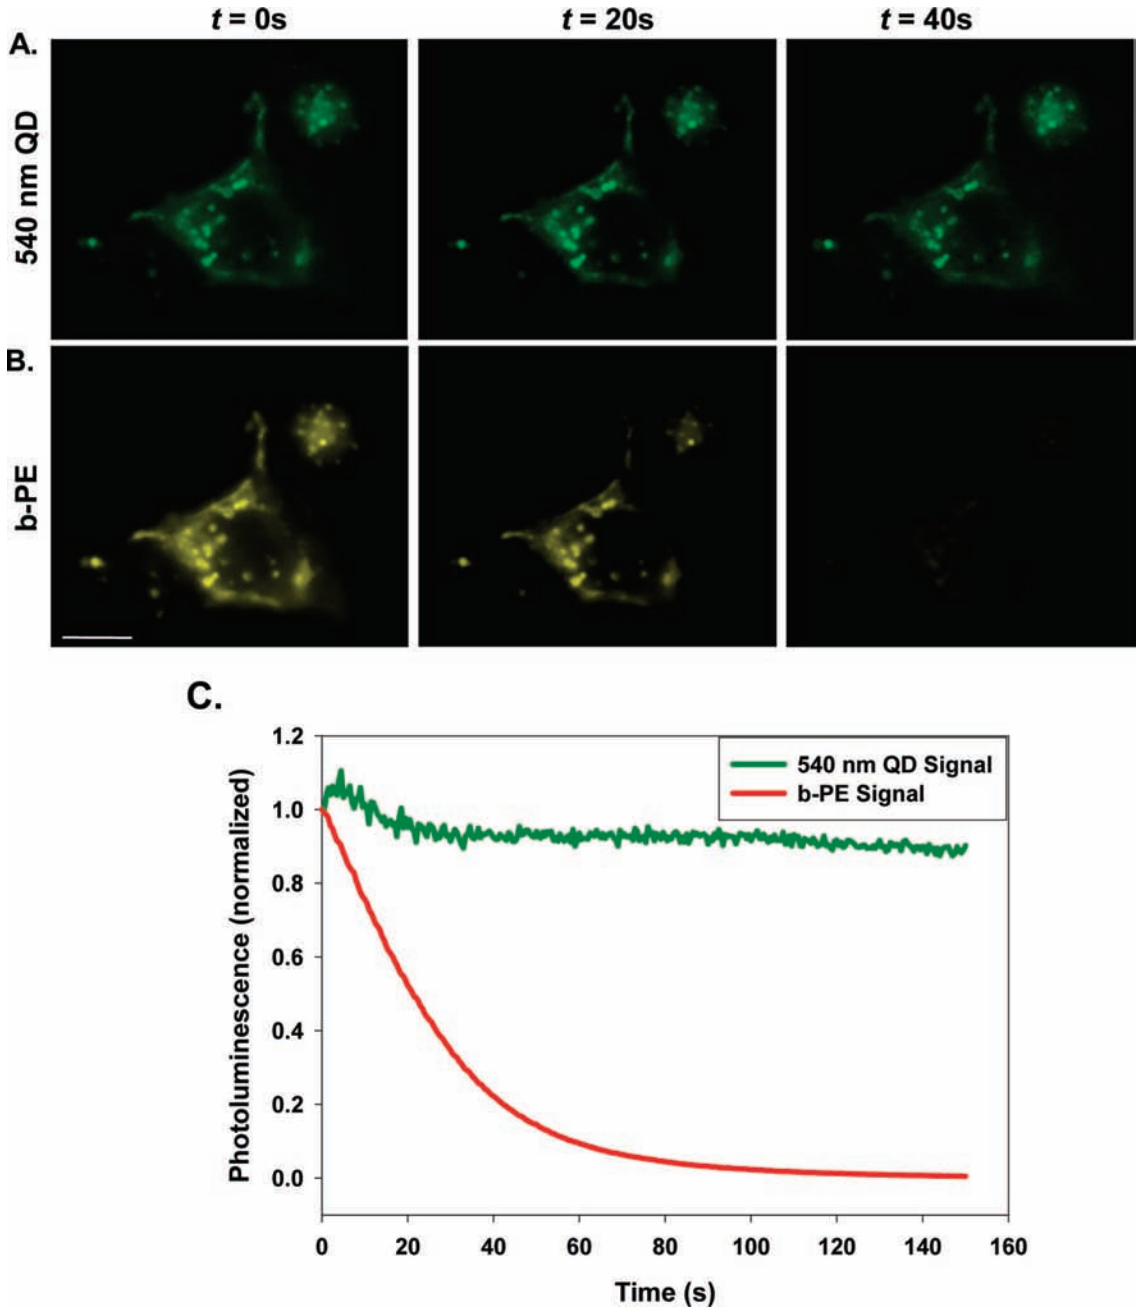

Figure 6. Photobleaching of intracellular QD−b-phycoerythrin conjugates. HEK293/T17 cells incubated with QD−CPP−b-PE conjugates and continuously illuminated with 488 nm laser excitation. (A) 540 nm QD and (B) b-PE fluorescence signals were separated using the Dualview imaging system and monitored over time; images shown were collected at the indicated time intervals. the endosome-specific AF647-TF marker indicate that QD−protein/peptide conjugates remain intact after uptake, have a perinuclear distribution, and are predominantly confined within endosomal compartments. The efficient internalization of QD conjugates by both cell lines only in the presence of CPP again demonstrates that CPP facilitates the specific intracellular uptake of QDs surface-functionalized with fluorescent protein cargos and uptake is driven mainly by endocytosis. This result complements and supports our previous findings using QD−CPP conjugates, reported in ref (*25*).

Delivery of QD−b-Phycoerthrin Conjugates. Confident in the ability of CPP to promote the cellular uptake of QD bioconjugates carrying multiple copies of a relatively small protein, we next challenged this delivery mechanism with a far larger protein complex. Streptavidin conjugated b-PE (total estimated Mw ~300 kDa) were attached to DHLA-PEG-biotin-QDs with emission centered at 540 nm and, as done above, three variations of QD conjugates were incubated with HEK293/T17 cells: QD−CPP conjugates (no b-PE), QD−b-PE conjugates (no CPP), and QD−CPP−b-PE assemblies (protein and peptide both present). Average ratios of ~1 and 2.5 b-PE per QD conjugate were used. Each row of images displayed in Figure 5A−C shows representative DIC, 540 nm QD emission (green), b-PE (yellow), AF647-TF (red), DAPI (blue), and merged composite fluorescence images (right) for each of the three QD conjugates tested. Data are shown for QD−b-PE with valence of 1, but similar results were collected for conjugates having 2.5 b-PE per QD conjugate (not shown). As found above with YFP, CPP is the key mediator of cellular uptake. The strong fluorescence of b-PE is a clear reflection of the natural brightness of these proteins. The pattern of staining from the QD, b-PE, and Transferrin-marker channels in cells exposed to the

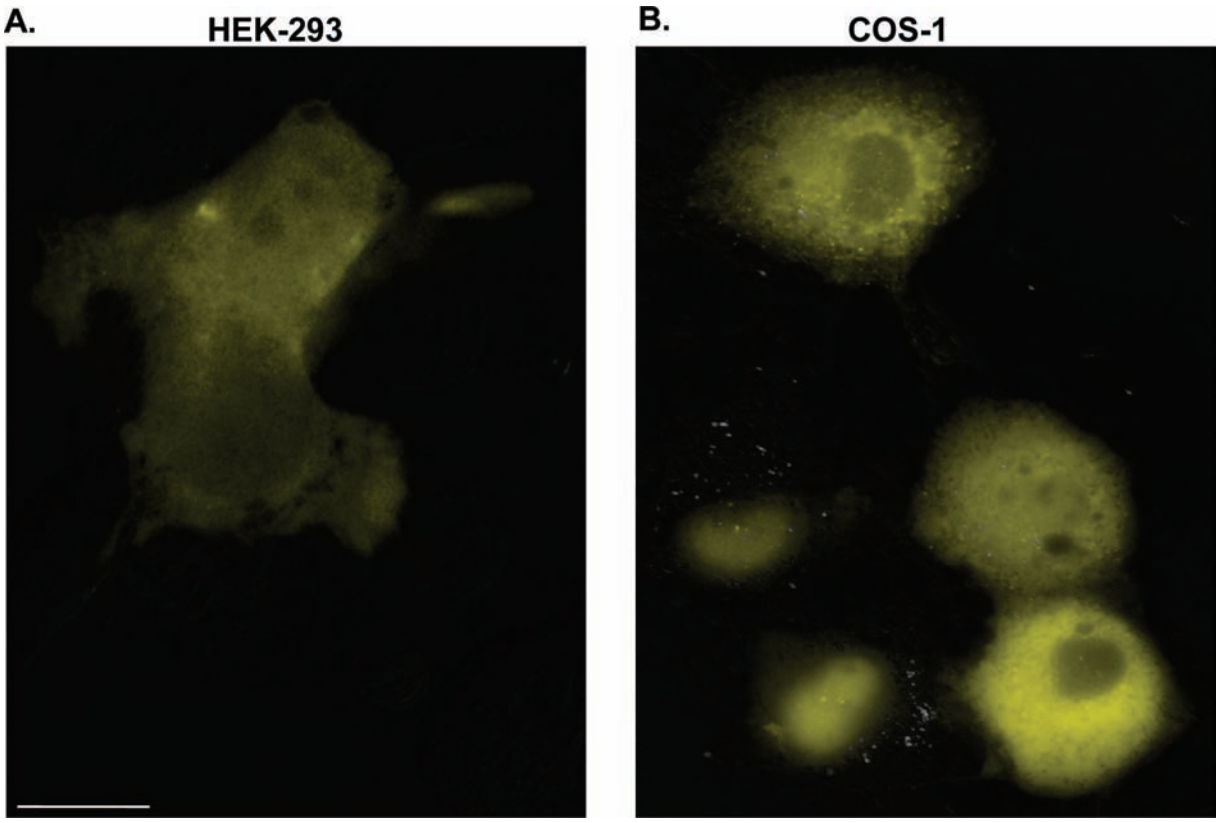

Figure 7. Cellular microinjection. 1:1 540 nm DHLA-PEG-biotin/QD−b-PE conjugates were microinjected directly into the cytosol of HEK293/T17 and COS-1 cells. Representative merged DIC and fluorescence images are shown. Note the clearly distinguishable nuclei in some of the COS-1 cells. Scale bar is 10 μm.

QD−CPP−b-PE assemblies are fully superimposable, which again strongly suggests that the b-PE remains attached to the nanocrystal and primarily localized within the endosomes. Similar results were also obtained with COS-1 cells (data not shown).

One of the unique features of luminescent QDs with direct relevance to biological imaging is their strong resistance to degradation combined with high photobleaching thresholds as compared to conventional dyes (*11, 51*). For example, Wu and co-workers compared the fluorescence decay of AlexaFluor 488 and CdSe-ZnS QDs in fixed 3T3 cells under continuous illumination and found that, while the dye fluorescence is essentially bleached after ~60 s, the QD signal persists for orders of magnitude longer exposure times (*51*). Our QD−YFP and QD−b-PE conjugates stay assembled after uptake and they thus offer an easy side-by-side comparison of QD and fluorescence protein signals for colocalization and stability studies. COS-1 cells incubated with 540 nm QD−CPP−b-PE bioconjugates were continuously excited at 488 nm for extended periods of time and the fluorescence signals of the QD and b-PE were separated using the DualView imaging system equipped with a 565 nm dichroic filter. The representative images shown in Figure 6A,B together with the plot of integrated PL intensities from each channel (Figure 6C) indicate that the b-PE signal decays to ~50% of its initial value in ca. 20 s and to less than 5% within 90 s. In comparison, the QD signal remains essentially unperturbed. The present comparison using fluorescent proteins extends and confirms prior findings on the pronounced QD resistance to photobleaching, using intracellular side-by-side comparisons between QDs and fluorescent dyes (*51*). This result also confirms the intracellular colocalization of the assembled conjugates, as the pattern of the rapidly bleached b-PE fluorescence is completely superimposed over the QD fluorescence pattern. Furthermore, by direct inference this also proves the structural and functional integrity of the QD−fluorescent protein cargos after delivery inside live cells.

DISCUSSION

Our results clearly show that cell-penetrating peptides can mediate the intracellular delivery of QDs conjugated to additional proteins of substantially larger size and molecular weight. This expands our previous results, where CPP was found to facilitate uptake of QD−CPP conjugates by eukaryotic cells (*25*). It also expands the findings by Torchilin and co-workers, where TAT peptide on the surface of liposomes allowed their intracellular delivery, even at low temperature and in the presence of metabolic inhibitors (*52*). In our case, CPP allows the QD−CPP conjugates to function as nanoscale vectors for the intracellular delivery of model fluorescent proteins cargos. Further, the conjugates essentially constitute multifunctional platforms, where the nanocrystals provide a fluorophore for visualization and scaffolds for immobilizing proteins and CPP, two biologically active "receptors" with different functions and spatial extensions. As YFP and b-PE are fluorescent, they also provide an additional means for conjugate visualization, and verification of both colocalization and delivered protein cargo integrity. The successful delivery of QD-CPP-YFP/b-PE conjugates into both HEK-293 and COS-1 cell lines proves that assembling additional larger size proteins on the nanocrystal surface does not interfere with the ability of CPP to mediate intracellular uptake of QD assemblies, a result that is *a priori* unexpected. Our results also show that multiple noncovalent conjugation schemes based on metal affinity self-assembly and biotin−avidin binding can be simultaneously applied within the same complex, without requiring further purification, to produce multifunctional QD bioconjugates that are stable even in intracellular environments. We found that the labeled cells displayed similar viability as that noted in our previous study

where little to no cytotoxicity was noted in cells exposed to QD bioconjugates for short 1 h incubations. We have also followed QD−CPP bioconjugates from 3−7 days following uptake and 1−3 days after microinjection with no apparent cytotoxicity noted (data not shown).

Although fluorescent proteins have become ubiquitous in biological research (*53*), there has not been much work aimed at exploiting hybrid dual fluorescent QD−protein conjugates beyond two preliminary studies investigating resonance energy transfer between QDs and fluorescent proteins (*54*, *55*). Our study shows the potential of such conjugates to explore specific issues such as intracellular delivery and conjugate distribution inside live cells. The ability of the relatively small cell penetrating peptide to facilitate the intracellular delivery of large protein cargos is rather remarkable. Our data suggest that by utilizing an average of ∼10 YFPs plus a nominal 50 CPP per QD, intracellular delivery of protein cargos with molecular weights of at least ∼300 kDa and a spatial extension of ∼150 Å can be achieved; the size estimate takes into account the nanocrystal and protein/peptide dimensions. The delivered cargos for QD−b-PE conjugates have much larger size and molecular weight. For instance, with an average of 2.5 Streptavidin−b-PE per conjugate, the delivered assemblies have a molecular weight that potentially exceeds $\sim 10^3$ kDa and overall dimensions approaching ∼500 Å. Molecular weight and size can increase quite substantially if conjugates with higher b-PE valences are used.

This study also provides further insight into CPP-mediated capabilities and confirms our earlier findings that nanoparticle conjugates taken up via this method are primarily distributed within endolysosomal compartments (*25*). Although CPP-mediated delivery is an efficient method of intracellular delivery and labeling of many different types of cells, a variety of cellular biosensing and translocation assays will ultimately require cytosolic distribution rather than endosomal confinement of the QD conjugates. Some techniques are available for nucleic acid transfection through endosomes; however, consistent and efficient endosomal escape methodologies, especially for functionalized nanoparticles, have yet to be developed (*56*, *57*). As such, cellular microinjection was evaluated as an alternate technique for delivering the QD−FP conjugates. Although a physical technique usually requiring manual operation, cellular microinjection is one of the few methods that can allow direct and consistent access to the cytosol of different cell types (*58*). The same 1:1 540 nm QD−b-PE bioconjugates utilized above, without additional CPP, were microinjected directly into the cytosol of both HEK293/T17 and COS-1 cells. Figure 7 show representative micrographs where the superimposed DIC and fluorescent images demonstrate a well-dispersed conjugate distribution across the entire cytoplasm, as opposed to the more localized and punctuate staining typically observed with CPP-mediated delivery. Though this delivery route is less efficient, since cells must be individually injected, it offers an alternative approach for targeted delivery of controlled cargo materials (such as drugs) directly into the cytoplasm of an array of live cells. This could potentially allow subsequent cellular effects to be intimately studied along with the tracking of other intracellular markers.

In summary, we have shown the remarkable ability of CPP to function as a simple and effective peptidic tool that can facilitate intracellular delivery of luminescent QDs decorated with both small and large protein cargos. Based on the multifunctional architecture demonstrated here, these hybrid nanostructures provide ideal tools for investigating intracellular tracking of proteins, protein−protein interactions, and potentially drug delivery (*2*, *8*, *9*, *59*, *60*). Such multifunctional QD conjugates could allow the evaluation of critical issues such as efficiency of cellular uptake, endosomal escape, intracellular conjugate stability, and intracellular fate through the simultaneous monitoring of QD and fluorescent protein emissions. Other recently described strategies aiming to address these questions necessitated multiple, complex synthetic steps to prepare the probe and rely on multiple metabolic processes and inference for results (*61*). Self-assembly of probes with control over their structures and direct monitoring of fluorescent signals potentially offers a much simpler approach. Including additional functionalities in the QD cargo such as FRET-based sensors (*50*, *62*), for example, could report on cellular physiology and responses to environmental or drug-induced challenges. Furthermore, substituting or simply adding other targeting peptides within the conjugate could also provide the means to evaluate the delivery efficacy of such cargos to particular cellular organelles. Future experiments will focus on studying QD−fluorescent protein FRET interactions intracellularly as a means of monitoring both conjugate fate and integrity over time. Lastly, it is worth noting that it is exactly these types of multifunctional nanoparticle assemblies that are projected to form the basis of next-generation nanomedicine and diagnostics (*1*−*5*, *8*, *9*, *59*, *60*, *63*) and it is clear that semiconductor quantum dots may play an important tole in their development.

closo-Borane Conjugated Regulatory Peptides Retain High Biological Affinity: Synthesis of *closo*-Borane Conjugated Tyr^3-Octreotate Derivatives for BNCT

Thomas Betzel,[§] Tobias Heß,[§] Beatrice Waser,[‡] Jean-C. Reubi,[‡] and Frank Roesch*

Institute of Nuclear Chemistry, University of Mainz, Fritz-Strassmann-Weg 2, 55128 Mainz, Germany. Received April 1, 2008; Revised Manuscript Received July 1, 2008

Despite the improvements in cancer therapy during the past years, high-grade gliomas and many other types of cancer are still extremely resistant to current forms of therapy. Boron neutron capture therapy (BNCT) provides a promising way to destroy cancer cells without damaging healthy tissue. However, BNCT in practice is still limited due to the lack of boron-containing compounds that selectively deliver boron to cancer cells. Since many neuroendocrine tumors show an overexpression of the somatostatin receptor, it was our aim to synthesize compounds that contain a large number of boron atoms and still show high affinity toward this transmembrane receptor. The synthetic peptide Tyr^3-octreotate (TATE) was chosen as a high-affinity and internalizing tumor targeting vector (TTV). Novel boron cluster compounds, containing 10 or 20 boron atoms, were coupled to the N-terminus of TATE. The obtained affinity data demonstrate that the use of a spacer between TATE and the *closo*-borane moiety is the option to avoid a loss of biological affinity of *closo*-borane conjugated TATE. For the first time, it was shown that *closo*-borane conjugated regulatory peptides retain high biological affinity and selectivity toward their transmembrane tumor receptors. The results obtained and the improvement of spacer and boron building block chemistry may stimulate new directions for BNCT.

INTRODUCTION

In 1932, Chadwick (*1*) discovered the neutron (Nobel Prize in Physics in 1935); four years later, Locher (*2*) proposed boron neutron capture therapy (BNCT) as a potential strategy to treat cancer. It is based on the high cross section of ^{10}B (3838 barn) with thermal neutrons and the resulting nuclear processes. This reaction generates two charged particles, an α-particle and a ^{7}Li nucleus, having a range of about 10 μm, which is approximately one cell diameter. If ^{10}B could be accumulated selectively in tumor tissue, which subsequently could be irradiated with thermal neutrons, the nuclear reaction products would specifically damage tumor DNA due to their high linear energy transfer and would finally destroy tumor tissue selectively (cf. Figure 1).

However, there are adequate nontoxic and high-affinity boron-containing tumor targeting vectors (TTV) required, which deliver the necessary amount of boron to tumor cells (*3*). BPA (*p*-borophenylalanine) and BSH (sodium borocaptate), the only BNCT agents approved clinically, have been shown in many cases to exhibit insufficient selectivity and efficiency for BNCT.

In order to design better boron-containing candidates for BNCT, different targeting approaches have been described utilizing various properties of proliferating tumor cells, such as boronated nucleosides and nucleotides (*4, 5*), sugars (*6*), amino acids (*7*−*10*), and cytostatic target components (*11*).

Many neuroendocrine tumors overexpress somatostatin receptors (sst) that represent the molecular basis for the use of radiolabeled somatostatin analogues as tools for diagnostic and therapeutic applications in oncology (*12*). Due to the short plasma stability of the natural peptides somatostatin 14 (SRIF-14) and somatostatin 28 (SRIF-28) of approximately three minutes (*13*), they cannot be used directly as targeting vectors for these transmembrane receptors. The syntheses of octreotides—synthetic octapeptides containing the pharmacophoric part of somatostatin and threoninol at the C-terminus—provided derivatives with extended half-lives while even further increasing the affinity toward the sst. More recently, octreotate derivatives bearing a threonine instead of a threoninol moiety at the C-terminus have been investigated, such as D-Phe^1-c[Cys^2-Tyr^3-D-Trp^4-Lys^5-Thr^6-Cys^7]-Thr^8-OH (TATE). Compared to octreotide analogues, they show higher binding affinity and internalization rate (*14*−*16*).

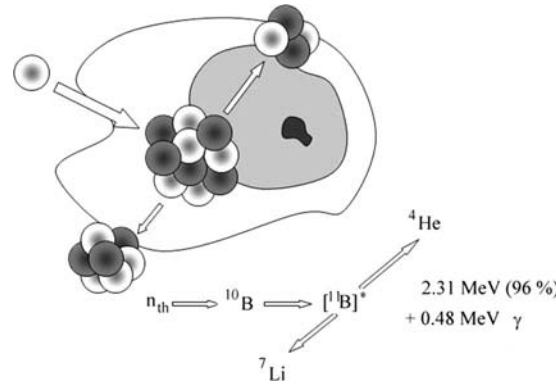

Figure 1. Simplified scheme of the BNCT reaction inside a cell.

Consequently, it was the concept of the present work to synthesize TATE based compounds that carry one, two, or more *closo*-borane units, i.e., a large number of boron atoms. Octreotate was selected as TTV instead of octreotide because its high internalization rate would allow an increased "shuttle"-type delivery of the boronated TTV. In this case, the cellular uptake is not necessarily limited by the initial number of

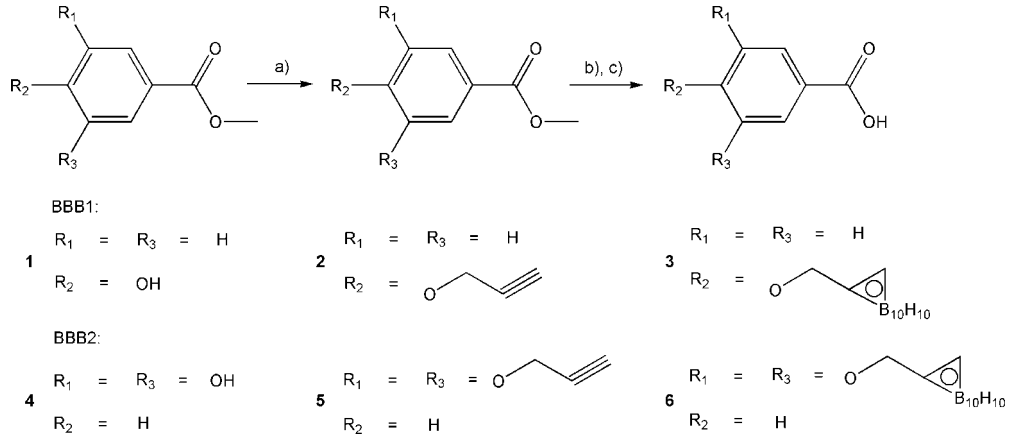
Scheme 1. Synthesis of Mono- and Di-*closo*-Borane Building Blocks BBB1 and BBB2[a]



[a] (a) 3-bromopropyne/K_2CO_3, acetone; (b) 1. decaborane, MeCN, 2. methyl prop-2-ynyloxybenzoate, toluene; (c) LiOH, THF/H_2O.

somatostatin receptors expressed at the tumor cell membrane. Syntheses of other octreotate derivatives, coupled with borane clusters, have recently been published; however, affinity studies were not performed (*17*). Prior results on our new compounds with one and two *closo*-boranes directly attached to the N-terminus of the TTV, i.e., TATE-5,6-dicarba-*closo*-dodecaboranyl hexynoic acid (*18*) and TATE-4-amino-bis-(propane-2,3-dicarba-*closo*-dodecaboranyl)-butynoic acid, showed 16 nM and >1000 nM binding affinity to sst_2, respectively. These initial results indicated for the first time that *closo*-borane conjugation to TATE may not annihilate the biological affinity of the peptide, if appropriate coupling chemistry between the borane and the peptide compartments is applied. In contrast, an inadequate design of conjugation may yield new *closo*-borane containing peptides, which are, however, not useful because of a dramatic loss of affinity. This led to the intention of inventing a conjugation chemistry that offers the possibility to obtain a variety of peptide conjugates within a modular system, useful both for octreotides or for any other peptidic TTV. We report the syntheses and characterization of a series of novel *closo*-borane conjugated octreotate derivatives as potential compounds for BNCT. We demonstrate that the introduction of spacers between *closo*-borane cluster(s) and peptide increases receptor binding affinities and leads to nanomolar IC_{50} values for the most relevant subtype sst_2.

EXPERIMENTAL PROCEDURES

Materials and Instrumentation. Wang (*p*-benzyloxybenzyl alcohol) resin, Fmoc, and other amino acids were supplied by Novabiochem (Darmstadt, Germany). All other starting materials and (dehydrated) solvents were purchased from Acros Organics (Geel, Belgium), VWR (Darmstadt, Germany), Fluka, and Sigma-Aldrich (Seelze, Germany) and were used without further purification. Decaborane was purchased from Katchem (Prague, Czech Republic). The silica gel SiO_2 (0.060−0.200 mm) used for column chromatography was purchased from Acros Organics. Thin-layer chromatography was performed using silica gel 60 F_{254} aluminum backed TLC plates, purchased from VWR.

The NMR spectra were taken on a 300 MHz FT-NMR spectrometer, AC 300 (Bruker Analytik GmbH), operating at 300 MHz for ^1H and 75.5 MHz for ^{13}C. ^{11}B-spectra were taken on a 400 MHz FT-NMR spectrometer, DIX 400 (Bruker Analytik GmbH), operating at 128.4 MHz.

The electron spray ionization mass spectra (ESI-MS) were recorded using a QTOF Ultima 3 system (Micromass/Waters). FD mass spectra were recorded using a MAT90 spectrometer (Finnigan). The matrix-assisted laser desorption-ionization time-of-flight mass spectra (MALDI-TOF-MS) were measured on an Axima-CFR (Shimadzu) spectrometer.

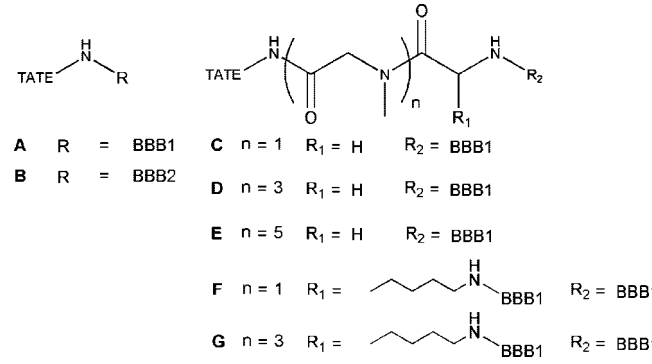


Figure 2. Overview on synthesized compounds.

Purification of the peptides was performed on a semipreparative Dionex HPLC system (P680 HPLC pump) equipped with a UV detector (UVD 170U) using a LiChroCART250 10 HPLC column LiChrosorbRP-select B (10 μ, 250 × 10 mm). The peptides were eluted applying various gradients of 0.1% TFA in 95% H_2O and 5% ACN (solvent A) and 0.1% TFA in 10% H_2O and 90% ACN (solvent B) at different flow rates. All solvent gradient programs are provided in Supporting Information. Effluent was monitored by detection of its optical absorption at 254 and 280 nm.

The synthetic chemistry was divided into three parts: the syntheses of boronated building blocks (BBB) which carry the necessary boron amount, the synthesis of the TTV using solid-phase chemistry including the conjugation with spacer units, and the coupling of various BBBs to the synthesized peptides.

***closo*-Borane Building Block Chemistry.** A hydroxybenzoate backbone was used as a linker molecule, which was conjugated with a triple bond. The introduction of a *closo*-borane cluster was achieved by coupling of decaborane to the triple bond (*19*). Due to promising experiences on the reaction of decaborane-acetonitrile adducts and triple bonds, this synthetic method was chosen for all BBBs. Two compounds, namely, *p*-(*O*-methylencarboranyl)-benzoic acid (BBB1) and 3,5-bis-(*O*-methylencarboranyl)-benzoic acid (BBB2), were synthesized starting from methyl 4-hydroxybenzoate or methyl 3,5-dihydroxybenzoate (cf. Scheme 1). The first step was the introduction of the essential triple bond via nucleophilic substitution with 3-bromopropyne, followed by the coupling with *closo*-borane cluster(s) in up to 70% yield (*20*). The use of equimolar amounts of LiOH in THF/H_2O gave the desired pure boronated benzoic

acids in yields of up to 92%. The overall yield of this three-step synthesis was up to 43%.

*Methyl-4-prop-2-ynyloxy-benzoate (***1***).* To a solution of methyl 4-hydroxybenzoate (9.12 g, 60 mmol) in acetone (100 mL), K_2CO_3 (11.58 g, 84 mmol) was added and the solution stirred for 30 min at room temperature under argon atmosphere. Propargylbromide (80% in toluene, 12.9 mL, 120 mmol) was added and the reaction mixture kept at 80 °C for 3 h. After cooling to room temperature, most of the solvent was removed in vacuo, and the residue was taken up in water (100 mL) and extracted with ethyl acetate (3 × 70 mL). The combined organic phases were successively washed with 10% NaOH, H_2O, and brine (3 × 75 mL) and dried over Na_2SO_4. The solvent was removed in vacuo and the pure product was obtained as pale yellow crystals (9.70 g, 85%). R_f = 0.75 (petrol ether/ethyl acetate, 2/1). ^{1}H NMR (300 MHz, $CDCl_3$, 298 K) δ: 7.99 (dd, ^3J(H,H) = 8.7 Hz, ^5J(H,H) = 1.2 Hz, 2 H, ArH), 6.98 (dd, ^3J(H,H) = 8.7 Hz, ^5J(H,H) = 1.2 Hz, 2 H, ArH), 4.73 (d, ^4J(H,H) = 2.4 Hz, 2 H, CH_2), 3.87 (s, 3 H, CH_3), 2.53 (tr, ^4J = 2,4 Hz, 1 H, C≡CH). ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K) δ: 165.90, 161.11, 131.25, 122.64, 114.95, 78.83, 78.75, 55.80, 51.97. MS (FD) *m/z*: calcd for $C_{11}H_{10}O_3$, 190.2; found, 190.3 $(M + H)^+$. Anal. ($C_{11}H_{10}O_3$) C, H.

*Methyl-4-(O-methylencarboranyl)-benzoate (***2***).* Decaborane (2.57 g, 23 mmol) was dissolved in dry acetonitrile (40 mL) and refluxed for 30 min. A solution of compound **1** (3.12 g, 16.5 mmol) in toluene (33 mL) was added to the yellow solution and the mixture was heated to reflux for a further 20 h. Methanol (5 mL) was added carefully, and the resulting mixture was refluxed for 30 min and afterward cooled to room temperature. The solvent was removed in vacuo, the crude product was purified by column chromatography (petrol ether/ethyl acetate, 4/1), and the pure product was obtained as a colorless solid (3.11 g, 61%). R_f = 0.33 (petrol ether/ethyl acetate, 4/1). ^{1}H NMR (300 MHz, $CDCl_3$, 298 K) δ: 7.99 (dd, ^3J(H,H) = 8.7 Hz, ^5J(H,H) = 1.2 Hz, 2 H, ArH), 6.85 (dd, ^3J(H,H) = 8.7 Hz, ^5J(H,H) = 1.2 Hz, 2 H, ArH), 4.45 (s, 2 H, CH_2), 4.05 (s, 1 H, CH), 3.88 (s, 3 H, CH_3), 1.25−3.1 (bm, 10 H, $B_{10}H_{10}$). ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K) δ: 165.78, 160.87, 131.35, 123.25, 114.98, 73.29, 68.59, 62.00, 52.01. ^{11}B-NMR (128.4 MHz, $CDCl_3$, 298 K) δ: −2.67 (bs, 1B), −4.47 (bs, 1B), −9.03 (bs, 2B), −11.59 (bs), −13.01 (bs, 6B). MS (FD) *m/z*: calcd for $C_{11}H_{20}B_{10}O_3$, 308.4; found, 308.6 $(M + H)^+$. Anal. ($C_{11}H_{20}B_{10}O_3$) C, H.

*4-(O-Methylencarboranyl)-benzoic Acid (***3** = *BBB1).* LiOH (60 mg, 2.5 mmol) was added in 4 portions to a solution of compound **2** (300 mg, 0.97 mmol) in THF/H_2O (36 mL, 2/1). The mixture was stirred for 22 h at room temperature. H_2O (25 mL) was added and most of the THF was removed in vacuo. The aqueous phase was washed with Et_2O (2 × 30 mL), adjusted to pH 2 with 1 M HCl, and extracted with ethyl acetate (3 × 30 mL), and the combined organic phases were dried over Na_2SO_4. Removal of the solvent in vacuo yielded the crude product which was purified by column chromatography (petrol ether/ethyl acetate, 2/1 + 3% formic acid). The pure product was obtained as a colorless solid (0.243 g, 82%). R_f = 0.55 (petrol ether/ethyl acetate, 2/1 + 3% formic acid). ^{1}H NMR (300 MHz, DMSO-d_6, 298 K) δ: 12.75 (s, 1 H, COOH), 7.89 (d, ^3J(H,H) = 9.0 Hz, 2 H, ArH), 7.07 (d, ^3J(H,H) = 9.0 Hz, 2 H, ArH), 5.34 (s, 1 H, CH), 4.69 (s, 2 H, CH_2), 1.25−3.1 (bm, 10 H, $B_{10}H_{10}$). ^{13}C NMR (75.5 MHz, DMSO-d_6, 298 K) δ: 166.89, 160.62, 131.47, 124.42, 114.79, 73.35, 68.60, 61.98. ^{11}B-NMR (128.4 MHz, DMSO-d_6, 298 K) δ: −2.60 (bs, 1B), −4.50 (bs, 1B), −9.12 (bs, 2B), −11.62 (bs), −13.12 (bs, 6B). MS (FD) *m/z*: calcd for $C_{10}H_{18}B_{10}O_3$, 294.4; found, 294.3 $(M + H)^+$. Anal. ($C_{10}H_{18}B_{10}O_3$) C, H.

*Methyl-3,5-bis(prop-2-ynyloxy)-benzoate (***4***).* To a solution of methyl 3,5-dihydroxybenzoate (1.68 g, 10 mmol) in acetone (15 mL), K_2CO_3 (3.86 g, 28 mmol) was added and the solution was stirred for 30 min at room temperature under argon atmosphere. Propargylbromide (80% in toluene, 4.3 mL, 40 mmol) was added and the reaction mixture kept at 80 °C for 3 h. After cooling to room temperature, most of the solvent was removed in vacuo. The residue was taken up in water (50 mL) and extracted with ethyl acetate (3 × 50 mL). The combined organic phases were successively washed with 10% NaOH, H_2O, and brine (3 × 50 mL) and dried over Na_2SO_4. The solvent was removed in vacuo and the pure product was obtained as pale yellow crystals (2.28 g, 93%). R_f = 0.51 (petrol ether/ethyl acetate, 4/1). ^{1}H NMR (300 MHz, $CDCl_3$, 298 K) δ: 7.26 (d, ^4J(H,H) = 2.7 Hz, 2 H, ArH), 6.78 (tr, ^4J(H,H) = 2.7 Hz, ArH), 4.68 (d, ^4J(H,H) = 2.1 Hz, 4 H, CH_2), 3.88 (s, 3 H, CH_3), 2.53 (tr, ^4J(H,H) = 2,1 Hz, 2 H, C≡CH). ^{13}C NMR (75.5 MHz, $CDCl_3$, 298 K) δ: 165.92, 158.82, 158.39, 131.68, 109.97, 107.12, 106.24, 73.45, 68.67, 61.95, 52.33. MS (FD) *m/z*: calcd for $C_{14}H_{12}O_4$, 244.2; found, 244.2 $(M + H)^+$. Anal. ($C_{14}H_{12}O_4$) C, H.

*Methyl-3,5-bis-(O-methylencarboranyl)-benzoate (***5***).* Decaborane (1.57 g, 14 mmol) was dissolved in dry acetonitrile (20 mL) and refluxed for 30 min. A solution of compound **4** (1.22 g, 5 mmol) in toluene (10 mL) was added to the yellow solution and the mixture was heated to reflux for a further 20 h. Methanol (2.5 mL) was added carefully and the resulting mixture was refluxed for 30 min and afterward cooled to room temperature. The solvent was removed in vacuo. The crude product was purified by column chromatography (petrol ether/ethyl acetate, 4/1) and the pure product was obtained as a colorless solid (0.957 g, 40%). R_f = 0.49 (petrol ether/ethyl acetate, 4/1). ^{1}H NMR (300 MHz, DMSO-d_6, 298 K) δ: 7.17 (d, ^4J(H,H) = 1.8 Hz, 2 H, ArH), 6.96 (d, ^4J(H,H) = 1.8 Hz, 1 H, ArH), 5.35 (s, 2 H, CH), 4.67 (s, 4 H, CH_2), 3.84 (s, 3 H, CH_3), 0.8−3.05 (bm, 20 H, $B_{10}H_{10}$). ^{13}C NMR (75.5 MHz, DMSO-d_6, 298 K) δ: 165.49, 158.31, 131.92, 109.21, 106.86, 73.29, 68.84, 61.86, 52.53. ^{11}B-NMR (128.4 MHz, $CDCl_3$, 298 K) δ: −3.47 (bs, 3 B), −9.64 (bs, 6 B), −11.31 to −15.30 (bm, 11 B). MS (FD) *m/z*: calcd for $C_{14}H_{32}B_{20}O_4$, 480.6; found, 480.7 $(M + H)^+$. Anal. ($C_{14}H_{32}B_{20}O_4$) C, H: calcd, 34.99, 6.71; found, 35.66, 6.64.

*3,5-Bis-(O-methylencarboranyl)-benzoic Acid (***6** = *BBB2).* LiOH (38.3 mg, 1.6 mmol) was added in 4 portions to a solution of compound **5** (300 mg, 0.62 mmol) in THF/H_2O (36 mL, 2/1). The mixture was stirred for 22 h at room temperature and the

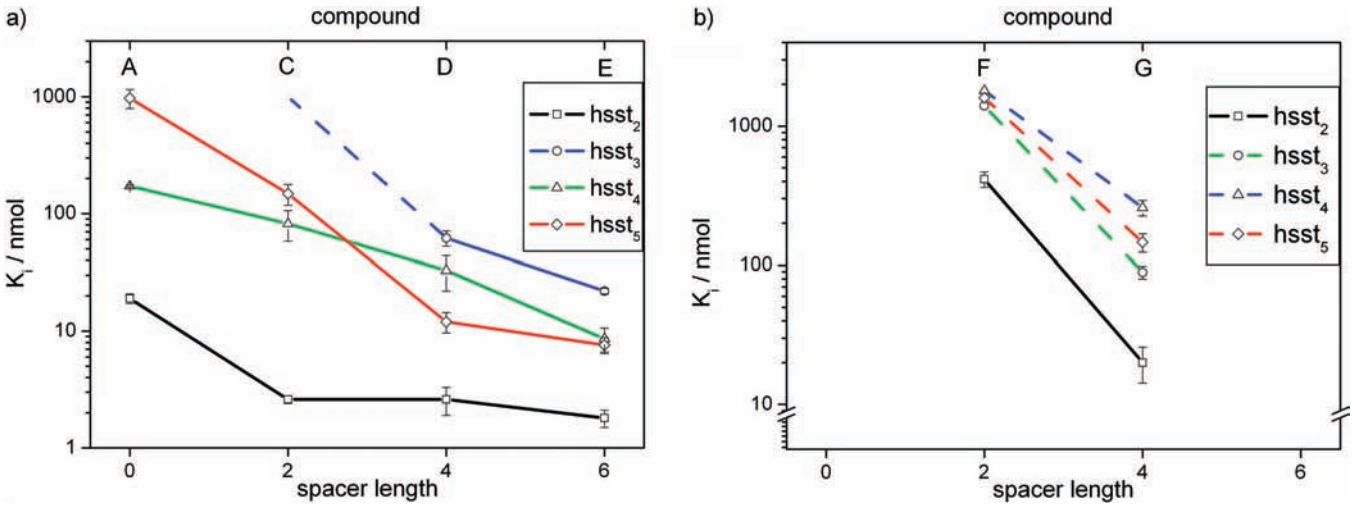

Figure 3. Structure−affinity correlation of (a) mono- and (b) di-*closo*-borane conjugated TATE-derivatives to hsst$_2$-hsst$_5$ subtypes.

solvent was removed in vacuo. Column chromatography (petrol ether/ethyl acetate, 2/1 + 3% formic acid) yielded the pure product as a colorless solid (0.215 g, 74%). R_f = 0.43 (petrol ether/ethyl acetate, 2/1 + 3% formic acid). ^{1}H NMR (300 MHz, DMSO-d_6, 298 K) δ: 7.15 (d, ^4J(H,H) = 2.1 Hz, 2 H, ArH), 6.91 (d, ^4J(H,H) = 2.1 Hz, 1 H, ArH), 5.34 (s, 2 H, CH), 4.66 (s, 4 H, CH_2), 0.8−3.05 (bm, 20 H, $B_{10}H_{10}$). ^{13}C NMR (75.5 MHz, DMSO-d_6, 298 K) δ: 166.56, 158.24, 133.22, 109.30, 106.53, 73.30, 68.81, 61.89. ^{11}B-NMR (128.4 MHz, DMSO-d_6, 298 K) δ: −3.47 (bs, 3 B), −4.47 (bs, 1B), −9.64 (bs, 6B), −11.60 (bs), −15.37 (bm, 11 B). MS (FD) *m/z*: calcd for $C_{13}H_{30}O_4$, 466.6; found, 466.5 $(M + H)^+$. Anal. ($C_{13}H_{30}O_4$) C, H: calcd, 33.46, 6.48; found, 35.25, 6.48.

Peptide Synthesis. The octapeptide TATE was synthesized manually via solid-phase reaction on a Wang resin (loading capacity 0.59 mmol/g) using standard Fmoc-strategy, HOBt/HBTU as coupling reagents, and DMF as solvent. The following N-protected and side chain protected amino acids were used: Fmoc-Thr(tBu)-OH, Fmoc-Cys(Acm)-OH, Fmoc-Lys(Boc)-OH, Fmoc-D-Trp(Boc)-OH, Fmoc-Tyr(tBu)-OH, and Fmoc-D-Phe-OH. Cyclization was achieved with Tl(III)$(CF_3COO)_3$ in DMF.

Different spacer units were coupled successively to the N-terminus of TATE on the solid phase using Fmoc-Sar-OH, Fmoc-Gly-OH, and Fmoc-Lys(Fmoc)-OH.

The following general procedures have been applied to all synthesized compounds unless otherwise noted. All methods are given for batches of 0.1 mmol. After swelling of the resin (*A1*), the Fmoc-group was removed by method *A2*. The amino acids were attached subsequently using coupling procedure *A3*. Cyclization was performed after the addition and Fmoc-deprotection of D-Phe^1 using procedure *A4*. Additional amino acids for the spacer were coupled successively to TATE on the solid phase.

Swelling of the Wang Resin (A1). The N-α-Fmoc-O-tBu-threonine Wang resin (168 mg, 0.1 mmol) was treated with DCM (2 mL) in a 5 mL syringe equipped with a frit and soaked for 3 h using a shaker and washed with DMF (6 × 1 mL).

Deprotecting Procedure (A2). The attached Fmoc-protected amino acids were treated three times successively: 1, 3, and 5 min with piperidine (20% in DMF, 1 mL). After each treatment, the resin was washed three times with DMF (1 mL).

Coupling Procedure (A3). The amino acid (4 equiv) and HOBt-hydrate (4 equiv) were dissolved in DMF (1 mL). HBTU (4 equiv) was added and the resulting solution was kept for 5 min in an ultrasonic bath. Finally, DIPEA (8 equiv) was added to the clear solution. The reaction mixture was vortexed, centrifuged, incubated for 1 min, added to the resin, and shaken for 30 min. After complete reaction, the reaction mixture was removed and the resin was washed with DMF (6 × 1 mL).

Cyclization (A4). Thallium(III)-trifluoroacetate (400 μL, 0.4 M in DMF) was added to the resin and the mixture kept for 1 h on the shaker and washed afterward successively with DMF, CCl_4, DCM, and MeOH.

Cleavage from the Resin (A5). The resin was suspended with the cleavage solution (100 μL/mg resin; 95% TFA, 2.5% H_2O, 2.5% TIS (triisopropylsilane)) and kept for 1.5 h at room temperature. Afterward the mixture was filtered over a glass frit and the remaining solid was washed with TFA (4 mL). The filtrate was evaporated in vacuo to give the crude product.

Coupling. The peptide conjugate was coupled with the boronated linker molecule (4 equiv) using HOBt/HBTU (4 equiv) in DMF as coupling reagents on the solid phase. Reaction time was extended to 4 h. After coupling, the final compounds were cleaved from the resin using TFA/H_2O/TIS (*A5*). Purification and analysis was performed on a semipreparative HPLC system to give the final products as colorless solids. All final compounds were characterized by ESI mass spectrometry. Compounds **A**, **C**, **D**, and **E** were additionally characterized by MALDI-TOF mass spectrometry.

*TATE-(BBB1)$_1$ (***A***).* 4-(*O*-Methylencarboranyl)-benzoic acid (**3**) was attached to TATE on the solid phase using *A3* with 4 h reaction time. The product was cleaved using *A5*. The pure product was obtained by HPLC purification (23.7 mg, 36%). t_R = 11.6 min. MS (MALDI-TOF) *m/z*: calcd for $C_{59}H_{80}B_{10}N_{10}O_{14}S_2$, 1325.6; found, 1326.1 $(M + H)^+$, 1348.5 $(M + Na)^+$. MS (ESI) *m/z*: found, 1326.6 $(M + H)^+$, 1348.5 $(M + Na)^+$, 1364.5 $(M + K)^+$.

*TATE-(BBB2)$_1$ (***B***).* 3,5-Bis-(*O*-methylencarboranyl)-benzoic acid (**6**) was attached to TATE on the solid phase using *A3* with 4 h reaction time. The product was cleaved using *A5*. The pure product was obtained by HPLC purification (6.9 mg, 9%). t_R = 13.2 min. MS (ESI) *m/z*: calcd for $C_{62}H_{92}B_{20}N_{10}O_{15}S_2$, 1497.8; found, 1498.9 $(M + H)^+$, 1520.9 $(M + Na)^+$, 1536.9 $(M + K)^+$.

*TATE-(sarcosine)$_n$-glycine-(BBB1)$_1$ (***C**, **D**, **E***).* The single sarcosine units (4 equiv/unit) and the glycine unit (4 equiv) were attached stepwise to TATE using *A1*−*A3*, the reaction time/unit was 30 min. After attachment of glycine, 4 equiv of compound **3** (59 mg, 0.2 mmol) were coupled to the resulting TATE derivative using *A3* with 4 h reaction time. The products were cleaved by using *A5*.

*TATE-(sarcosine)$_1$-glycine-(BBB1)$_1$ (***C***).* The pure product was obtained by HPLC purification (30.4 mg, 21%). t_R = 11.5 min. MS (MALDI-TOF) *m/z*: calcd for $C_{64}H_{88}B_{10}N_{12}O_{16}S_2$,

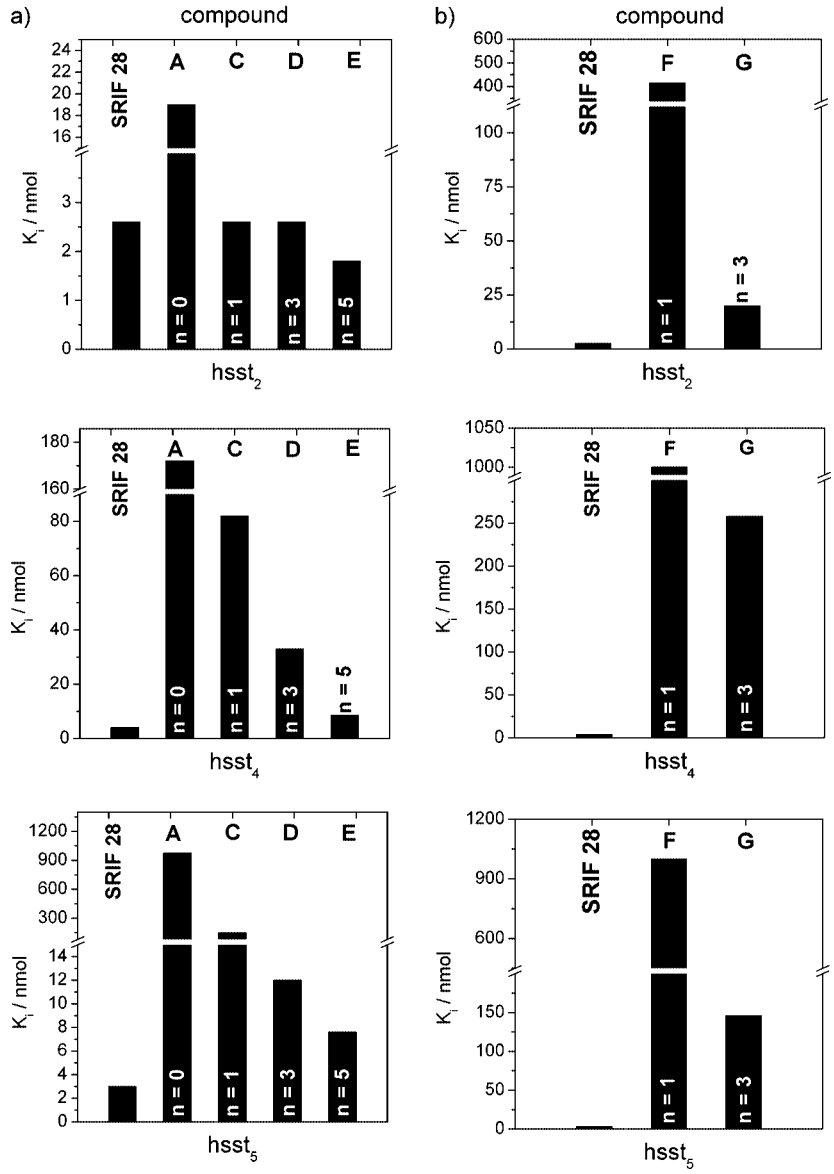

Figure 4. Structure−affinity correlation of compounds with (a) one unit of BBB1 and (b) two units of BBB1 toward $hsst_2$, $hsst_4$, and $hsst_5$.

1453.7; found, 1454.4 $(M + H)^+$, 1476.4 $(M + Na)^+$. MS (ESI) *m/z*: found, 1454.7 $(M + H)^+$, 1476.73 $(M + Na)^+$, 1492 $(M + K)^+$, 738.9 $(M + Na)^{2+}$, 746.9 $(M + K)^{2+}$.

*TATE-(sarcosine)$_3$-glycine-(BBB1)$_1$ (***D***).* The pure product was obtained by HPLC purification (17.5 mg, 22%). $t_R = 11.7$ min. MS (MALDI-TOF) *m/z*: calcd for $C_{70}H_{98}B_{10}N_{14}O_{18}S_2$, 1595.9; found, 1596.1 $(M + H)^+$, 1618.2 $(M + Na)^+$, 1634.2 $(M + K)^+$. MS (ESI) *m/z*: found, 1596.9 $(M + H)^+$, 1618.8 $(M + Na)^+$, 1634.8 $(M + K)^+$, 809.9 $(M + Na)^{2+}$, 817.9 $(M + K)^{2+}$.

*TATE-(sarcosine)$_5$-glycine-(BBB1)$_1$ (***E***).* The pure product was obtained by HPLC purification, (32.5 mg; 18%). $t_R = 11.7$ min. MS (MALDI-TOF) *m/z*: calcd for $C_{76}H_{108}B_{10}N_{16}O_{20}S_2$, 1738.0; found, 1739.4 $(M + H)^+$, 1761.4 $(M + Na)^+$, 1777.4 $(M + K)^+$. MS (ESI) *m/z*: found, 1738.9 $(M + H)^+$, 1760.9 $(M + Na)^+$, 1776.9 $(M + K)^+$, 880.4 $(M + Na)^{2+}$, 888.4 $(M + K)^{2+}$.

*TATE-(sarcosine)$_n$-lysine-(BBB1)$_2$ (***F**, **G***).* The single sarcosine units (4 equiv/unit) and the lysine unit (4 equiv) were attached stepwise to TATE using *A1*−*A3*, the reaction time/unit was 30 min. After attachment of lysine, compound **3** (4 equiv) was coupled to the resulting TATE derivative using *A3* with 4 h reaction time. The products were cleaved by using *A5*.

*TATE-(sarcosine)$_1$-lysine-(BBB1)$_2$ (***F***).* The pure product was obtained by HPLC purification (4.0 mg, 4%). $t_R = 13.6$ min. MS (ESI) *m/z*: calcd for $C_{78}H_{113}B_{20}N_{13}O_{18}S_2$, 1801.1; found, 1802.2 $(M + H)^+$, 1824.2 $(M + Na)^+$, 1840.1 $(M + K)^+$, 912.6 $(M + Na)^{2+}$.

*TATE-(sarcosine)$_3$-lysine-(BBB1)$_2$ (***G***).* The pure product was obtained by HPLC purification (2.7 mg, 3%). $t_R = 14.1$ min. MS (ESI) *m/z*: calcd for $C_{84}H_{123}B_{20}N_{15}O_{20}S_2$, 1943.3; found, 1943.2 $(M + H)^+$, 1966.2 $(M + Na)^+$, 1982.2 $(M + K)^+$, 983.6 $(M + Na)^{2+}$, 995.1 $(M + K)^{2+}$.

Binding Assay. All compounds were tested for their ability to bind to the five human sst receptor subtypes in complete displacement experiments using the universal SRIF radioligand [^{125}I]-[Leu^8, D-Trp^{22}, Tyr^{25}]-SRIF-28. CHO-K1 and CCL39 cells stably expressing the human sst_1−sst_5 receptors were grown as described previously (*14*). Cell membrane pellets were prepared and receptor autoradiography was done as described in detail previously (*14*). SRIF-28 was run in parallel as control. IC_{50} values were calculated after quantification of the data using

a computer-assisted image processing system and are given as a mean of 2 to 3 measurements.

RESULTS

***closo*-Borane Building Block Chemistry.** The first two steps of the reactions shown in Scheme 1 were accomplished in a fast and easy way and gave the desired compounds in high yields. In the final reaction, the methyl ester had to be cleaved. Here, a decomposition of the borane cluster under basic conditions was observed. Common ways of saponification of methyl esters, e.g., NaOH (0.005−5 N) as well as LiI/pyridine, were not successful. However, the use of equimolar amounts of LiOH in a mixture of THF and H_2O resulted in excellent yields. Therefore, this reaction scheme allows a practicable and sufficient synthesis of *closo*-borane conjugated linker molecules, containing 10 or 20 boron atoms.

Peptide Synthesis. The syntheses of the target compounds were performed on the solid phase, including cyclization, conjugation with spacer units, and coupling with linker molecules.

Coupling. In a first experiment, BBB1 was to be coupled to the TTV, which was conjugated with two, four, and six sarcosine units as spacer. In this trial, no coupling of the peptide conjugate and BBB1 was achieved. A possible explanation for this result is the importance of a primary amino group to couple the BBB. This led to the change of the spacer structure. Consequently, the final sarcosine unit was replaced by glycine to give conjugates with one, three, and five sarcosine units, followed by one glycine unit. The coupling of these compounds with the BBB was successful, which demonstrates the requirement of a primary amino function of the final amino acid. Alternatively, lysine was used as final amino acid to provide the possibility to connect two BBBs to one TTV by coupling a boron cluster to the N-terminus and to the ε-amino function in the side chain of lysine. Here, the final target compounds could be isolated as well. Figure 2 summarizes the derivatives synthesized.

Binding Assay. The data of the *in vitro* study prove that appropriate conjugation of TATE with a *closo*-borane compound provides derivatives still retaining biological affinity. Table 1 summarizes the results of the *in vitro* assays on the binding affinity of the derivatives to the five subtypes of the human somatostatin receptor. Furthermore, these data demonstrate a correlation between biological affinity and length of the inserted spacer.

There is almost any affinity if the boronated linker BBB1 or BBB2 is coupled to TATE directly (compound **A** and **B**). Except for sst_1 (there is no affinity toward the sst_1 subtype for almost all the octreotide and octreotate derivatives known in the literature), the affinities improve with an increase of spacer length. Similarly, the affinity increases by the use of spacer units even when two units of BBB1 are coupled to the same TATE molecule. However, a higher number of *closo*-borane clusters attached to the TTV has a negative influence on the affinity of the peptide. These findings are illustrated in Figure 3. Nevertheless, there are three compounds (**C**, **D**, **E**) that show equal or better affinity toward $hsst_2$, the most frequently overexpressed sst (*21*), than endogenous SRIF-28. Therefore, these three boronated compounds are extremely promising candidates for tumor targeting. The impact of the spacer is most obvious for $hsst_4$ for derivatives containing one or two units of BBB1.

DISCUSSION

We established a synthesis route directed to different *closo*-borane linker compounds in high yields, which contain 10 and 20 boron atoms per *closo*-borane building block. Saponification of the methyl esters could be performed by the use of LiOH in THF/water without decomposition of the borane clusters, which is essential for the synthesis of the *closo*-borane building blocks *p*-(*O*-methylencarboranyl)-benzoic acid (BBB1) and 3,5-bis-(*O*-methylencarboranyl)-benzoic acid (BBB2). These BBBs can directly be coupled to the N-terminus of TATE or to the N-terminus of other peptides. Furthermore, the BBB can be coupled to a primary amino function in the side chain of a peptide, e.g., to the ε-amino function of lysine.

Obviously, the introduction of a spacer is necessary to retain the high affinity of the peptidic targeting vector to the receptor. In the case of a directly coupled *closo*-borane building block to the TTV (e.g., compound **B**), the affinity to the somatostatin receptor may be lost completely. In contrast, various spacer units containing sarcosine, glycine, and lysine guarantee retaining affinity. This indicates a structure−affinity relation in a way that with increasing chain length of the spacer unit ($n = 1$, 3, 5 for compounds **C**, **D**, **E**) the affinities of the peptidic targeting vector to the transmembrane tumor receptor are being improved. These relationships of type affinity versus spacer length can be identified both for mono-*closo*-borane (Figure 3a) as well as di-*closo*-borane (Figure 3b) conjugated compounds for the four relevant human somatostatin receptor subtypes 2, 3, 4, and 5. In the case of the human sst_4 and sst_5 subtypes, the binding affinities of compounds **C**, **D**, and **E** successively improve by about 1 order of magnitude. This is graphically illustrated for $hsst_2$, $hsst_4$, and $hsst_5$ in Figure 4.

The affinity data demonstrate that the use of an appropriate spacer is the option to avoid a loss of biological affinity of *closo*-borane conjugated regulatory peptides. In fact, potentially useful affinities have been obtained for mono- and di-*closo*-borane linkers with 10 or 20 boron atoms per building block.

The use of amino acids with a primary amino group, such as glycine or lysine, is essential as final spacer units in the coupling step with the BBB. In the case of the N-methylated amino acid sarcosine, coupling was not successful.

The introduction of lysine as terminal spacer unit, in addition, allows the coupling of two BBBs to one TATE molecule. Even in the case of 20 boron atoms per TATE (cf. compound **G**), the binding affinities of the conjugates are still in the 20 nM range for sst_2. Continuing this concept, compounds with up to 60 boron atoms per peptide may be synthesized in the case of two tri-*closo*-borane building blocks. The approach of introducing one or two mono- or di-*closo*-borane building blocks into various candidates for BNCT by realizing the potential of appropriate spacer units may be directly converted to other relevant regulatory peptides.

There are many modified octreotide derivatives, such as ^{111}In-labeled DTPA-octreotide (OctreoScan), which is used as the gold standard for scintigraphic imaging of neuroendocrine tumors. This compound and alternative octreotide-based radioligands for PET/CT or radionuclide therapy, such as ^{68}Ga-DOTA-TOC and ^{90}Y-DOTA-TOC, show affinities to the somatostatin receptor in the ranges 2.5−22 nM for $hsst_2$ and 57−37 nM for $hsst_5$ (*14*). The best *closo*-borane conjugated TATE derivatives described in this study offer high affinities toward their transmembrane tumor receptor in the ranges 1.8−20 nM for $hsst_2$ and 7.6−146 nM for $hsst_5$. This justifies the assumption that these new *closo*-borane conjugated TATE derivatives could be potentially useful and may stimulate new directions for BNCT.

ACKNOWLEDGMENT

This work was supported by the Deutsche Forschungsgemeinschaft (RO985/22-1). We thank the group of Prof. Dr. H. Frey, especially Dr. E. Berger-Nicoletti, for measuring the MALDI-TOF spectra.

Received April 2, 2008; Revised Manuscript Received July 3, 2008

The high incidence of BB2 receptor (BB2r) expression in various cancers has prompted investigators to pursue the development of BB2r-targeted agents for diagnostic imaging, chemotherapy, and radiotherapy. Development of BB2r-targeted agents, based on the bombesin (BBN) peptide, has largely involved the use of the bifunctional chelate approach in which the linking group serves several key roles including pharmacokinetic modification. Understanding the in vivo properties of the various pharmacokinetic modifying linking groups is crucial for developing BB2r-targeted agents with improved targeting and clearance characteristics. The goal of this study was to systematically evaluate the pharmacokinetic profile of aliphatic hydrocarbon, aromatic, and poly(ethylene glycol) (ether) functional groups in order to obtain a better understanding of the in vivo properties of these pharmacokinetic modifiers. Specifically, we synthesized six radioconjugates with the structure ^{111}In-DOTA-**X**-BBN(7−14)NH_2, where **X** = 8-aminooctanoic acid (8-AOC), 5-amino-3-oxapentyl-succinamic acid (5-ADS), 8-amino-3,6-dioxaoctyl-succinamic acid (8-AOS), *p*-aminobenzoic acid (AMBA), Gly-AMBA, and Gly-*p*-aminomethylbenzoic acid (Gly-AM2BA). All of the ^{nat}In-conjugates demonstrated nanomolar binding affinities to the BB2r. In CF-1 mice, the BB2r uptake in the pancreas of radioconjugates containing aromatic linking groups was found to be significantly higher at 1 h postinjection than the radioconjugates with ether linker moieties. For PC-3 tumor-bearing SCID mice, the tumor uptake was found to be 6.66 ± 2.00, 6.21 ± 1.57, 6.36 ± 1.60, 4.46 ± 0.81, and 7.76 ± 1.19 %ID/g for the 8-AOC, 8-ADS, AMBA, Gly-AMBA, and Gly-AM2BA radioconjugates, respectively, at 15 min postinjection. By 24 h postinjection, the radioconjugates containing aromatic groups exhibited the highest percentage tumor retention with 11.4%, 19.8%, 26.6%, 25.8%, and 25.5% relative to the 15 min values remaining in the tumor tissue for the 8-AOC, 8-ADS, AMBA, Gly-AMBA, and Gly-AM2BA radioconjugates, respectively. Fused Micro-SPECT/CT imaging studies performed at 24 h postinjection revealed substantial accumulation of radioactivity in the tumor tissue for all radioconjugates. In both biodistribution and Micro-SPECT/CT imaging studies, the radioconjugates containing aromatic linking groups typically exhibited significantly higher G.I. tract retention than the hydrocarbon or ether linking moieties. In conclusion, our studies indicate that radioconjugates incorporating aromatic linking groups, of the type investigated, generally demonstrated enhanced retention in BB2r expressing tissues in comparison to either the hydrocarbon or ether linking moieties. Furthermore, this investigation clearly demonstrates the significance of the linking group upon not only the in vivo clearance of the radiopharmaceutical, but also on the in vivo uptake and retention of the BB2r-targeted agent in tumor tissue. Future designs of BB2r-targeted agents should include a careful consideration of the effect linking group functionality has upon tumor targeting and retention.

INTRODUCTION

The bombesin family of receptors currently consists of four known receptor subtypes: BB1r[1], neuromedin B receptor; BB2r, gastrin-releasing peptide receptor; BB3r, orphan receptor; and BB4r, bombesin receptor (*1*, *2*). Of these four receptors, three (BB1r, BB2r, and BB3r) have been shown to be expressed in varying degrees in a variety of human tumors and human cancer cell lines (*3*, *4*). For prostate and breast carcinomas, the BB2r subtype has received the most attention from the research community due to the high expression density of the receptor relative to the BB1r and BB3r subtypes (*4*−*6*). In normal human tissues, the pancreas has been shown to have the highest degree of BB2r gene expression with significantly lower levels in the stomach, brain, and adrenal glands (*7*). The low expression of

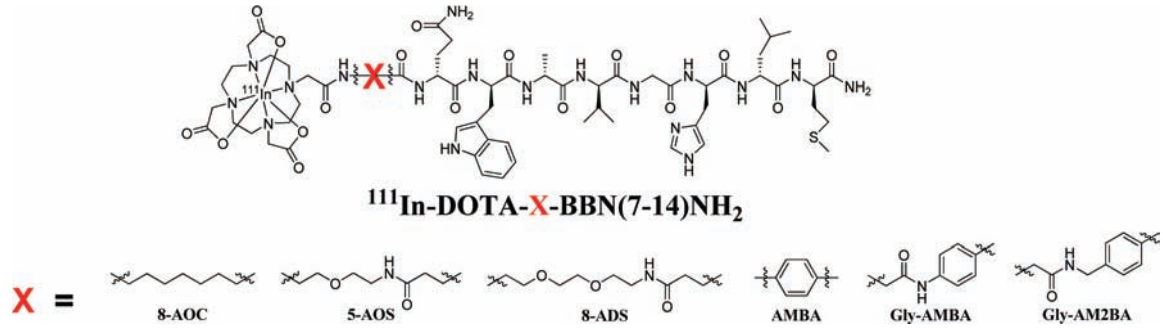

Figure 1. Structure of ^{111}In-Labeled BBN Analogues.

the BB2r in normal tissue relative to the increased expression in many cancers has validated the BB2r as a target for cancer detection and treatment. This has prompted the development of a wide variety of BB2r-targeted diagnostic imaging, chemotherapy, and radiotherapy agents. The majority of these agents have been based on bombesin, a 14 amino acid peptide. The BB2r binding region of the bombesin (BBN) peptide (Trp-Ala-Val-Gly-His-Leu-Met-NH_2, BBN(8−14)NH_2) shares a sequence homology with the gastrin-releasing peptide, the native ligand to the BB2r. Upon binding of the agonist bombesin analogue to the BB2r, the peptide and the attached chemotherapy agent and/or radionuclide are internalized and thereby retained in the cell.

The bifunctional chelate design has primarily been used in the development of BB2r-targeted BBN analogues for nuclear diagnostic imaging and radiotherapy. This approach has four distinctive components: a targeting vector, a radiometal, a chelation system, and a linking group. The choice of targeting vectors for the bombesin analogues have varied from the use of the entire 14 amino acid bombesin peptide to truncated portions of the peptide, with the latter being most prevalent in the literature. In any event, the targeting vector must employ the BBN(8−14)NH_2 or a BB2r-targeted derivative of this amino acid sequence in order to achieve uptake in BB2r expressing tissues. To date, a wide variety of radionuclides (e.g., ^{99m}Tc, ^{188}Re, ^{90}Y, ^{111}In, ^{18}F, ^{64}Cu, ^{177}Lu, ^{149}Pm, ^{68}Ga) have been used in the development of BB2-targeting peptides (*8*−*16*). The selection of the radionuclide for the BB2r-targeted BBN analogue is largely influenced by the desired function of the radiopharmaceutical. Diagnostic nuclear imaging agents employ radionuclides with gamma and positron emission properties that are appropriate for single photon emission computed tomography (SPECT) or positron emission tomography (PET), respectively. For targeted radiotherapy, radionuclides are selected to deliver a maximum radiation dose to the cancerous tissue based on tumor residence time, while at the same time attempting to ensure minimal damage to nontarget tissues (*17*). The chelation system, in general, is responsible for the binding of the radiometal and preventing transchelation throughout the in vivo lifetime of the radiopharmaceutical. The selection of the chelation system is largely dependent on the chemical nature of the radionuclide; however, an assortment of chelation systems (e.g., DOTA, TETA, DTPA) have been shown to be effective in stabilizing a variety of radionuclides in vivo (*8, 18*−*20*).

The linking group serves several crucial roles in the bifunctional chelate design of BB2r-targeted BBN analogues. The most obvious role of the linking group is to chemically connect the radiometal−chelation complex to the bombesin targeting vector. The linking group is also responsible for preventing the radiometal−chelation complex from interfering with the binding of the bombesin targeting vector to the BB2r. Our laboratory has demonstrated, using hydrocarbon-based linking groups, that the length of the linking group being employed directly impacts in vitro and in vivo BB2r targeting (*9*). These studies demonstrated that a linker length of >6 carbon atoms long, which corresponds to ∼6.5 Å, is needed to ensure optimal in vivo binding of the bombesin targeting vector to the BB2r. Finally, the linking group serves as a convenient chemical handle in which to modify the pharmacokinetics of the radiopharmaceutical. By altering the hydrophilic or hydrophobic properties of the linking group, the in vivo properties of the BB2r-targeted BBN analogue can often be tailored without altering the structure of the targeting vector and/or the radiometal−chelation complex, thereby avoiding changes that may have negative impacts on in vivo BB2r binding and/or radiometal-chelate stability.

Targeted diagnostic and radiotherapy agents based on small peptides and antibodies have employed an assortment of natural and non-natural cationic, anionic, and neutral amino acids in constructing the linker framework (*19*). Additionally, metabolically active linking groups based on esters, disulfides, protease active amino acid sequences, and other cleavable functional groups have been explored (*21, 22*). For BB2r-targeted BBN based radiopharmaceuticals, a variety of aliphatic hydrocarbons, amino acids, aromatic derivatives, and poly(ethylene glycol) units have been utilized in the design of linking groups (*1,2,14,23*−*25*). The in vivo effect of these different functional linking groups is challenging to assess because of difficulty in comparing BB2r-targeted BBN analogues that employ different components (i.e., targeting vectors, radionuclides, and chelation systems). In order to systematically determine the pharmacokinetic profile of some commonly used functional groups, we decided to synthesize and evaluate BB2r-targeted BBN analogues containing an aliphatic hydrocarbon, aromatic derivatives, and poly(ethylene glycol) derivatives. Specifically, six radioconjugates were synthesized and evaluated using the ^{111}In-DOTA-**X**-BBN(7−14)NH_2 (Figure 1) structural paradigm where **X** = 8-aminooctanoic acid (8-AOC), 5-amino-3-oxapentyl-succinamic acid (5-ADS), 8-amino-3,6-dioxaoctyl-succinamic acid (8-AOS), *p*-aminobenzoic acid (AMBA), Gly-AMBA, and Gly-*p*-aminomethylbenzoic acid (Gly-AM2BA). The synthesis and in vitro and in vivo evaluation of the radioconjugates in a PC-3 prostate cancer model is presented below.

MATERIALS AND METHODS

Unless otherwise noted, all chemicals and reagents were used as received. Indium-111 was purchased from Mallinckrodt (Maryland Heights, MO). Fmoc-protected natural amino acids, Fmoc-*p*-aminobenzoic acid, Fmoc-*p*-aminomethylbenzoic acid, and Rink Amide resins were purchased from EMD Biosciences Inc. (San Diego, CA). Tris(1,1-dimethylethyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid was purchased from Macrocyclics (Dallas, TX). *N*-(Fmoc-5-amino-3-oxapentyl)-succinamic acid and *N*-(Fmoc-8-amino-3,6-dioxaoctyl)-succinamic acid were purchased from NeoMPS (San Diegeo, CA). Fmoc-8-aminooctanoic acid was purchased from Advanced ChemTech (Louisville, KY). Naturally abundant indium chloride

was purchased from Strem Chemicals Inc. (Newburyport, MA). HPLC grade acetonitrile and trifluoroacetic acid were purchased from Fischer Scientific (Pittsburgh, PA). Deionized water used for HPLC analyses and all other chemical applications in this work was obtained from an in-house Millipore (Billerica, MA) Milli-Q Biocel water purification system. Roswell Park Memorial Institute (RPMI) 1640 media was purchased from Invitrogen/GIBCO (Carlsbad, CA). 4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) and bovine serum albumin (BSA) were purchased from Fisher Scientific (Fisher Bioreagents, Fisher Chemical, Fairlawn, NJ). [^{125}I-Tyr^4]BN (10 μCi, 370 kBq) was purchased from Perkin-Elmer (Wellesley, MA). Isoflurane was purchased from Baxter Healthcare Corp. (Deerfield, IL).

Solid-phase peptide Synthesis (SPPS) was performed using an Applied Biosystems (Foster City, CA) model 432 automated peptide synthesizer using standard Fmoc chemistry. RP-HPLC purification of the conjugates, ^{nat}In-conjugates, and ^{111}In-radioconjugates was accomplished using a Waters (Milford, MA) 600E controller equipped with an Eppendorf (Westbury, NY) TC-50 column heater. A Phenomenex (Torrance, CA) Jupiter 5u C_{18} 300 Å 250 × 10 mm semiprep column was used for the purification of bulk amounts of peptides. For the purification of conjugates, ^{nat}In-conjugates, and ^{111}In-radioconjugates used for mass spectrometric and in vitro and in vivo studies, a Phenomenex Jupiter 5u C_{18} 300 Å 250 × 4.60 mm analytical column was employed. Detection of the conjugates and ^{nat}In-conjugates during HPLC purification was accomplished using a JASCO (Easton, MD) UV 975 absorbance detector. The radioconjugates were detected during HPLC purification using a JASCO UV 1575 absorbance detector and an ORTEC (Oak Ridge, TN) NaI(Tl) scintillation detector. During the preparation of the radioconjugates, 3 M (St. Paul, MN) Empore high performance extraction disk cartridges 4215(HD) were employed. Mass spectrometric determination of the conjugates and ^{nat}In-conjugates was achieved using electrospray ionization with a Thermo-Finnigan TSQ7000 triple-quadrupole mass spectrometer equipped with an API2 source and performance pack. Gamma decay detection of ^{111}In for the in vitro binding studies was accomplished using the Packard Riastar (Downers Grove, IL) gamma counter. Pharmacokinetic gamma decay measurements were made using a well counter equipped with a NaI(Tl) scintillation detector.

Carworth Farms No. 1 (CF-1) mice were purchased from Charles Rivers Laboratories (Wilmington, MA). Four- to five-week-old Institute of Cancer Research severely combined immunodeficient (ICR SCID) mice were obtained from Taconic Farms (Germantown, NY). The mice were supplied with acidified water and irradiated rodent chow (Ralston Purina Co.) ad libitum. Five mice were housed per cage (Alternative Design) in a humidity- and temperature-controlled room with a 12 h light/dark cycle. The human prostate cancer PC-3 cell line was purchased from the American type Culture Collection (ATCC, Rockville, MD). The PC-3 cell line was grown and maintained by the University of Missouri Cell and Immunobiology Core Facility. PC-3 cells were grown in Custom RPMI Medium 1640 supplemented with 10% fetal bovine serum (FBS) (U.S. BioTechnologies Inc., Pottstown, PA) and Gentamicin (American Pharmaceutical Partners, Inc., Schaumburg, IL). To prepare the cells for inoculation, the PC-3 cells with media were centrifuged, the media decanted, and the cell pellet combined with Dulbecco's phosphate-buffered saline (Invitrogen Corporation, Carlsbad, CA) to reach a concentration of 5 million cells/100 μL. Under gas anesthesia, each SCID mouse was subcutaneously inoculated (bilateral flank) with 5 million PC-3 tumor cells in each flank. Using a nonrebreathing apparatus (Summit Medical Equipment Company, Bend, OR), gas anesthesia was administered at a vaporizer setting of ~3.5% isoflurane (Baxter Healthcare Corp., Deerfield, IL) with ~1 L/min oxygen. The flank tumors were allowed to grow for 2−3 weeks before studies were performed. All studies involving animals were conducted in accordance with protocols approved by both the Harry S. Truman Veterans' Hospital and the University of Missouri − Columbia Institutional Animal Care and Use Committees.

Solid-Phase Peptide Synthesis (SPPS). The conjugates were assembled using automated peptide synthesis. Briefly, the resin (25 μmol of the resin substituted peptide anchors) was deprotected using piperidine, resulting in the formation of a primary amine from which the C-terminus of the growing peptide was anchored. The Fmoc protected amino acids (75 μmol) with appropriate orthogonal protection were activated using HBTU and sequentially added to the resin. The resulting peptide was orthogonally deprotected and cleaved from the resin using a cocktail consisting of a 2:1:1:36 ratio of thioanisol, water, 1,2-ethanedithiol, and trifluoroacetic acid, respectively. The cleaved peptide was then precipitated and washed using cold (0 °C) methyl-*tert*-butyl ether. The crude conjugate was dried by vacuum, weighed, and analyzed by RP-HPLC. Purity of the crude peptides, as determined by RP-HPLC, varied depending on the peptide. The DOTA-8-AOC-BBN(7−14)NH_2, DOTA-8-AOC-NONSENSE, DOTA-5-AOS-BBN(7−14)NH_2, and DOTA-8-ADS-BBN(7−14)NH_2 conjugates ranged from 55% to 76% purity by RP-HPLC. The DOTA-Gly-AM2BA-BBN-(7−14)NH_2 conjugate was synthesized in a modest 47% yield. The DOTA-AMBA-BBN(7−14)NH_2 and DOTA-Gly-AMBA-BBN(7−14)NH_2 conjugates yielded crude products that were found to be 21% and 12%, respectively, by RP-HPLC. For the DOTA-AMBA-BBN(7−14)NH_2, DOTA-Gly-AMBA-BBN(7−14)NH_2, and DOTA-Gly-AM2BA-BBN(7−14)NH_2 conjugates, these peptides were purified using semipreparative RP-HPLC before studies were performed. All conjugates were peak purified to ≥93% purity and quantified by analytical RP-HPLC prior to mass spectrometric determination and in vitro cell binding assays. Confirmation of the constitution of the desired conjugates was provided by mass spectrometry.

Syntheses of ^{nat}In Conjugates. A 1 mg sample of the conjugate was dissolved in 500 μL of a 0.1 M ammonium acetate, 1.82 mM indium trichloride solution (pH = 5.5). The solution was heated at 60 °C for 30 min. In order to achieve sufficient separation (~2 min) of the ^{111}In-labeled conjugate from the unlabeled conjugate, solid $^{nat}CuSO_4 \cdot 5H_2O$ was added to the solution. The solution was heated for 5 min at 65 °C and allowed to cool to room temperature. ^{nat}In-conjugates were then peak purified and quantified by RP-HPLC. All ^{nat}In-conjugates were determined to be ≥93% pure by RP-HPLC analyses before mass spectrometric characterization and in vitro binding studies were performed.

Radiolabeling of Conjugates with $^{111}InCl_3$. A 100 μg sample of the conjugate and ~20 mg of L-ascorbic acid (radiolysis prevention reagent) was dissolved in 200 μL of a 0.4 M ammonium acetate (pH = 7.0) solution. An aliquot of $^{111}InCl_3$ (18.5−92.5 MBq) was added to the vial containing the conjugate and the solution was heated for 30−40 min at 65−75 °C. In order to achieve adequate peak separation (~2 min), solid $^{nat}CuSO_4 \cdot 5H_2O$ was added to the solution. The solution was heated for 5 min at 65 °C and allowed to cool to room temperature. The resulting ^{111}In-radioconjugate was peak purified using reverse-phase HPLC. The peak purified ^{111}In-radioconjugate was concentrated using a prepared C_{18} extraction disk and eluted with 400 μL of a 6:4 ethanol/sterile saline solution. For pharmacokinetic studies, the purified ^{111}In-radioconjugates were diluted with sterile saline to 185 kBq/100 μL. The purification of the radioconjugate and the use of carrier-free ^{111}In yielded the purified ^{111}In-radioconjugates with a specific activity on the order of the theoretical maximum

(Theo. Max: 1722 GBq/μmol). Preclinical SPECT imaging studies required 27.8−55.5 MBq/mouse necessitating the evaporation of the ethanol from the ethanic ^{111}In-radioconjugate solution under a stream of nitrogen and dilution to the appropriate volume with sterile saline solution. In all cases, the concentration of ethanol in solution was <8% by volume prior to administration. Overall radiochemical yields typically ranged from 35% to 89%. The radiochemical purity of all ^{111}In-radioconjugates for pharmacokinetic and imaging studies were reassessed prior to administration and found to be ≥93% pure.

HPLC Purification and Analyses. When necessary, bulk sample purification was performed using a semipreparative C_{18} column with a flow rate of 5.0 mL/min. Sample purification for mass spectrometric, in vitro, and in vivo studies was performed on an analytical C_{18} column with a flow rate of 1.5 mL/min. For all HPLC experiments, the mobile phase consisted of solvent A (99.9% H_2O and 0.1% TFA) and solvent B (99.9% CH_3CN and 0.1% TFA). For all conjugates, ^{nat}In-conjugates and ^{111}In-radioconjugates, the gradient was initiated at 80% A/20% B and over a period of 15 min linearly decreased to a gradient of 70% A/30% B. At the end of the 15 min run time for all HPLC experiments, the column was flushed with the gradient 5% A/95% B and re-equilibrated at the starting gradient.

In Vitro Competitive Cell Binding Studies. IC_{50} binding studies for all conjugates and ^{nat}In-conjugates were performed using PC-3 human prostate cancer cells. ^{nat}In-conjugates were used to determine the specific binding affinities for the corresponding ^{111}In-radioconjugates. Cell media consisted of Roswell Park Memorial Institute (RPMI) medium at pH 7.4, 4.8 mg/mL HEPES, and 2 mg/mL BSA. For binding assays, the cells ($\sim 3 \times 10^4$ PC-3 cells) were suspended in media and incubated at 37 °C for 40 min in the presence of radiolabeled [^{125}I-Tyr^4]BN, a known BB2r agonist, and a range of molar concentrations (10^{-6}−10^{-12} M) of the conjugate or ^{nat}In-conjugate. At the end of the incubation period, the cells were aspirated and washed 4× with media. The cell-associated activity was measured and the binding affinity determined.

In Vitro Internalization and Efflux Assays. Internalization and efflux studies were performed by incubating 3×10^4 PC-3 human cancer cells in cell media. The cell media consisted of RPMI medium with 2 mg/mL BSA and 2.8 mg/mL HEPES at a pH of 7.4. For the internalization studies, the cells were incubated at 37 °C with 20 000 cpm of the desired ^{111}In-radioconjugate in the presence of 5% CO_2 for 15, 30, 45, 60, 90, and 120 min time points. At the end of the time point, binding was halted by aspiration of the cell medium and washing of the cells (3×) with ice−cold cell culture medium. Surface-bound radioactivity was removed from the cellular membrane surface by addition of ice−cold pH 2.5 saline buffer (0.2 M acetic acid and 0.5 M NaCl). The cells were vortexed and incubated in the medium for 5 min, followed by the removal of the radioactivity in the supernatant by aspiration and washing the cells (2×) with pH 2.5 saline buffer. The radioactivity as a function of time was determined for the supernatant and the cells, which yielded the percent radioactivity surface-bound and internalized, respectively.

Efflux assays were performed by incubating the PC-3 cells with the desired ^{111}In-radioconjugate for 45 min. After this time, the cellular medium was aspirated and washed with 37 °C cell medium (3×). At 15, 30, 45, 60, and 90 min time points postincubation, samples of the incubated cellular medium were collected and the cellular media was aspirated and washed with ice−cold culture medium. This was followed by aspiration and washing of the cells with ice−cold pH 2.5 saline buffer. The radioactivity as a function of time was determined for the supernatant and the cells, which yielded the percent radioactivity effluxed from the cell and the percent remaining internalized, respectively.

Pharmacokinetic Studies of ^{111}In-Radioconjugates in normal CF-1 and PC-3 Xenograft SCID Mice. Pharmacokinetic studies were carried out using age-matched normal CF-1 and PC-3 tumor bearing SCID mice. For pharmacokinetic studies involving PC-3 xenograft SCID mice, the mice were inoculated with PC-3 cells, and the tumors, ranging from 0.1 to 1.0 g (2−3 weeks post-inoculation), were allowed to develop before the mice were utilized in pharmacokinetic studies. Each mouse (average weight, 25 g) received an intravenous bolus via the tail vein of 185 kBq of the radio-RP-HPLC peak purified ^{111}In-radioconjugate in 100 μL of saline. The mice were sacrificed and their tissues and organs excised at 0.25, 1, 4, and 24 h time points postinjection. The excised tissues were weighed, the ^{111}In activity in each tissue was measured, and the %ID and %ID/g were determined for each tissue. Whole blood %ID and %ID/g were determined under the assumption that the weight of the blood accounted for 6.5% of the body weight of the mouse.

Small Animal SPECT/CT Imaging Studies. The Micro-SPECT/CT is a combined modality unit (microCAT II, Siemens Medical Solutions) equipped with dual pixelated SPECT detectors each coupled to a square 3 × 3 array of position sensitive photomultiplier tubes. The CT component consists of a CCD X-ray detector and an 80 kVp microfocus X-ray source (40 μm focal spot). The mice were administered 27.8−55.5 MBq of the desired BB2r-targeted peptide in 150−200 μL of saline via tail vein injection. At 24 h postinjection, the mice were sacrificed and Micro-SPECT/CT imaging was performed. Micro-SPECT data were collected using a symmetrical 20% photopeak discriminating window and employing a 360° rotation, 60 step acquisition with a 2 mm pinhole collimator. Pinhole tomographic reconstruction of the generated Micro-SPECT data was performed using a 3D-OSEM algorithm with software corrections applied for pinhole misalignments. Micro-CT data acquisition proceeded immediately prior to Micro-SPECT data acquisition. Concurrent image reconstruction was achieved using a Fanbeam (Feldkamp) filtered back projection algorithm. Micro-SPECT data were fused with anatomical data from Micro-CT in order to accurately determine spatial location of radionuclide uptake within the three-dimensional volume. Whole body and axial images were normalized to the highest-intensity pixel for each image.

Statistical Analysis. A Student's *t* test was utilized to determine statistical significance. A confidence level of 95% was employed in the statistical analysis of this data and $P \leq 0.05$ was considered statistically significant.

RESULTS

Conjugate Synthesis and Radiolabeling. The conjugates were synthesized using standard solid-phase peptide synthesis techniques. Typical yields for the 8-AOC, 5-AOS, 8-ADS, and Gly-AM2BA peptide conjugates ranged from 47% to 76% as determined by RP-HPLC. Relatively poor yields (12−21%) were obtained from the AMBA and Gly-AMBA conjugates. Analysis of the crude product for the AMBA and Gly-AMBA conjugates by RP-HPLC and mass spectrometry revealed that a significant portion of the growing peptides had prematurely terminated. In the syntheses of both the AMBA and Gly-AMBA peptides, ∼45% of the crude material was attributed to the AMBA-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH_2 peptide ($[M + H]^+_{calc} = 1059.5$; $[M + H]^+_{obs} = 1059.5$). Attempts to increase the overall yield of the AMBA and Gly-AMBA conjugates by extending the coupling time and increasing the amount of the amino acids used per coupling cycle were unsuccessful. Mass spectrometric characterization of all conjugates is provided in Table 1.

Table 1. Mass Spectrometric Values, HPLC Retention Times, and IC_{50} Concentrations for the Conjugates Investigated

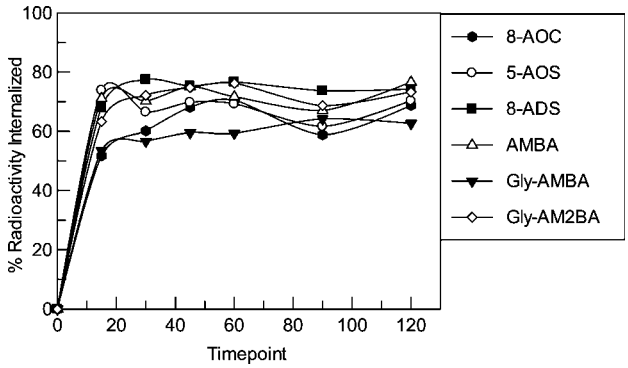

Figure 2. Internalization assays in PC-3 cells using the ^{111}In-BBN radioconjugates ($n = 4$ for each radioconjugate).

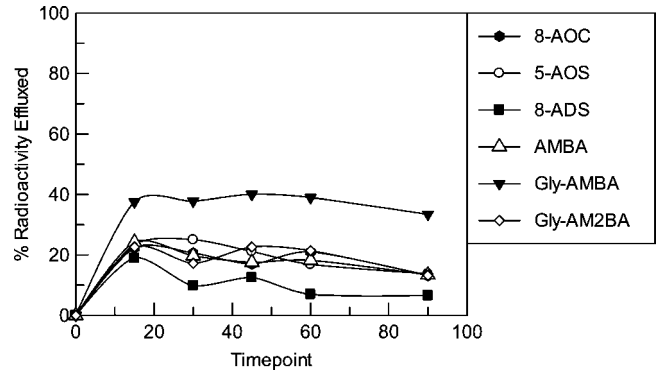

Figure 3. Efflux assays in PC-3 cells using the ^{111}In-BBN radioconjugates ($n = 4$ for each radioconjugate).

Labeling and purification of the conjugates with ^{nat}In and ^{111}In were carried out under similar conditions. Retention times for all conjugates and $^{nat/111}$In-conjugates are given in Table 1. The retention times of the unlabeled conjugates and $^{nat/111}$In-conjugates were similar (<1 min separation) and therefore were difficult to resolve due to peak overlap. Addition of excess $^{nat}CuSO_4 \cdot 5H_2O$ to the reaction vial after incubation of the peptide with $^{nat/111}$In resulted in complexation of the ^{nat}Cu with any available unlabeled conjugate. The ^{nat}Cu-conjugates typically had retention times that were ∼2 min longer relative to the $^{nat/111}$In-labeled conjugate. This allowed the $^{nat/111}$In-conjugate to be easily isolated without concern of collection overlap with the unlabeled conjugate.

In Vitro Cell Binding and Internalization Studies. The BB2r binding affinity of the conjugates and ^{nat}In-conjugates was investigated using in vitro PC-3 cell binding studies (Table 1). The scrambled peptide ^{111}In-DOTA-8-AOC-NONSENSE underwent in vitro and in vivo studies to assist in contrasting specific vs nonspecific binding. With the exception of the scrambled peptide, all of the conjugates and ^{nat}In-conjugates demonstrated nanomolar binding affinities with minimal (<10%) nonspecific binding. The ^{nat}In-labeled conjugates had IC_{50} values of 0.51 ± 0.05, 0.7 ± 0.1, 1.13 ± 0.07, 1.88 ± 0.06, 3.2 ± 0.3, and 6.2 ± 0.3 nM for the 8-AOC, Gly-AM2BA, AMBA, Gly-AMBA, 8-ADS, and 5-AOS, respectively. In general, the ^{nat}In-conjugates containing aromatic linking groups possessed higher binding affinities for the BB2r than ^{nat}In-conjugates with ether linking groups.

Internalization and efflux of the radioconjugates in PC-3 cells are depicted in Figures 2 and 3, respectively. At 15 min postincubation, the 8-AOC and Gly-AMBA radioconjugates demonstrated on average the lowest initial percent internalization. The radioconjugates demonstrated little, if any, increase in internalization after the initial 15 min incubation time point. With the exception of the Gly-AMBA radioconjugate, the radioconjugates demonstrated similar efflux of activity from the PC-3 cells. The Gly-AMBA radioconjugate exhibited an approximate 2-fold increase in efflux of the radioactivity from the cell relative to the other radioconjugates.

Biodistribution Studies. With the exception of the 8-AOC radioconjugate, the in vivo pharmacokinetic properties of the ^{111}In-radioconjugates were initially investigated in normal CF-1 mice. We have previously reported the pharmacokinetic profile of the ^{111}In-DOTA-8-AOC-BBN(7−14)NH_2 radioconjugate in normal CF-1 mice (*9*). Results from the in vivo pharmacokinetic studies in normal CF-1 mice at the 1 h p.i. time point are summarized in Table 2 (*26*). All of the investigated ^{111}In-radioconjugates demonstrated efficient blood clearance at 1 h postinjection. Biological clearance of all radioconjugates proceeded primarily through the renal/urinary system with the remaining radioactivity being secreted through the hepatobiliary pathway. At 1 h postinjection, the kidney retention of the radioconjugates was significantly higher ($P \leq 0.0003$) for the Gly-AMBA (10.60 ± 1.57%ID/g) and Gly-AM2BA (5.60 ± 2.12%ID/g) than the other derivatives (2.40 ± 0.40 to 2.51 ± 0.51). Interestingly, though, the Gly-AMBA and Gly-AM2BA radioconjugates demonstrated the highest clearance of kidney-associated activity over time with 0.70 ± 0.08 and 0.67 ± 0.08, respectively, at the 24 h p.i. time point. Even though the 5-AOS, 8-ADS, and AMBA radioconjugates had significantly less kidney-associated activity at 1 h postinjection, these radioconjugates did not clear as well with 1.29 ± 0.20, 1.30 ± 0.32, and 1.19 ± 0.18, respectively, remaining associated with the kidneys at 24 h postinjection. The rodent pancreas is known to express high densities of the BB2r and therefore provides a convenient in vivo target in which to gauge the efficacy of our

Table 2. Biodistribution Studies of ^{111}In-DOTA-5-AOS-BBN(7-14)NH_2, ^{111}In-DOTA-8-ADS-BBN(7-14)NH_2, ^{111}In-DOTA-AMBA-BBN(7-14)NH_2, ^{111}In-DOTA-Gly-AMBA-BBN(7-14)NH_2, ^{111}In-DOTA-Gly-AM2BA-BBN(7-14)NH_2, and ^{111}In-DOTA-8-AOC-NONSENSE at 1 h Postinjection in CF-1 Mice[a]

[a] Organ uptake values expressed as %ID/g and $n = 5$ unless otherwise noted. [b] Excretion values were calculated using the activity values associated with the excreted urine and bladder contents at the time of sacrifice.

radioconjugates (*27*). The pancreatic uptake of radioconjugates containing aromatic linking groups was found to be significantly higher ($P \leq 0.0002$) than the radioconjugates with ether linker moieties. The Gly-AMBA radioconjugate demonstrated significantly higher pancreatic uptake (63.35 ± 5.91) than any other radioconjugate studied in CF-1 mice ($P \leq 0.0001$). As expected, the scrambled peptide demonstrated no BB2r specific binding and cleared effectively from the mice with 94.13 ± 0.45%ID being excreted at 1 h postinjection. The clearance of the ^{111}In-radioconjugates through the G.I. tract was not surprisingly found to be dependent upon the linker functional group of the radioconjugate. Radioconjugates containing aromatic linking groups had the highest intestinal uptake at 1 h postinjection ($P \leq 0.003$). Due to the relatively low in vivo BB2r targeting properties of the ^{111}In-DOTA-5-AOS-BBN(7−14)NH_2 radioconjugate, further investigation of this radioconjugate in the PC-3 tumor mouse model was not performed.

The pharmacokinetic profiles of the 8-AOC, 8-ADS, AMBA, Gly-AMBA, and Gly-AM2BA radioconjugates were examined in the SCID mouse model bearing PC-3 tumor xenografts. In vivo nonspecific interactions were investigated in the PC-3 tumor-bearing mouse model by performing biodistribution studies using the scrambled peptide at 1 h postinjection. The 1, 4, and 24 h time points from these studies are summarized in Table 3 (*26*). At 15 min postinjection, tumor uptake was found to be 6.66 ± 2.00, 6.21 ± 1.57, 6.36 ± 1.60, 4.46 ± 0.81, and 7.76 ± 1.19 %ID/g for the 8-AOC, 8-ADS, AMBA, Gly-AMBA, and Gly-AM2BA radioconjugates, respectively. At 24 h postinjection, 11.4%, 19.8%, 26.6%, 25.8%, and 25.5% of the initial uptake was retained in the tumor tissue corresponding, respectively, to the 8-AOC, 8-ADS, AMBA, Gly-AMBA, and Gly-AM2BA radioconjugates. At 1 h postinjection, the tumor uptake of the targeted radioconjugates was a factor of 3.4−5.8 greater than the nonspecific binding of the scrambled radioconjugate (0.58 ± 0.20%ID/g). All of the radioconjugates investigated cleared efficiently from the blood. Clearance of the radioconjugates proceeded largely through the renal/urinary system. Kidney retention was found to be dependent upon the radioconjugate used. The Gly-AMBA and 8-ADS radioconjugates had the largest kidney retention values with 3.71 ± 2.37 and 2.36 ± 0.66 %ID/g, respectively, at 24 h postinjection. The hepatobiliary retention at 24 h p.i. ranged from 8% to 15% ID depending on the radioconjugate. The most striking difference in G.I. tract retention was observed with the aromatic containing radioconjugates having 2−4-fold more radioactivity than the 8-AOC and 8-ADS radioconjugates.

Small Animal SPECT/CT Imaging Studies. Micro-SPECT/CT studies were performed in SCID mice bearing bilateral flank PC-3 tumors using the ^{111}In-DOTA-8-AOC-BBN(7−14)NH_2, ^{111}In-DOTA-AMBA-BBN(7−14)NH_2, ^{111}In-DOTA-Gly-AMBA-BBN(7−14)NH_2, and ^{111}In-DOTA-Gly-AM2BA-BBN(7−14)NH_2 radioconjugates. The whole body images and the respective axial slices of the PC-3 tumors are depicted in Figure 4 and were acquired at 24 h postinjection of the radioconjugates. In the fused Micro-SPECT/CT images, visual inspection of the normalized whole body images indicates a substantially smaller tumor-to-background ratio for the AMBA radioconjugate relative to the 8-AOC, Gly-AMBA, and Gly-AM2BA images. However, axial slices of the PC-3 tumor for all the radioconjugates investigated demonstrated substantial accumulation of radioactivity in the tumor tissue with excellent tumor-to-background ratios. For the AMBA and Gly-AMBA radioconjugates, significant abdominal accumulation is observed likely, as established in the pharmacokinetic studies, due to the retention of radioactivity in the G.I. tract and pancreas. The majority of the nontarget retention for the 8-AOC and Gly-AM2BA radioconjugates was located predominantly in the kidneys.

DISCUSSION

The conjugates were synthesized in moderate yields with the exception of the AMBA (yield: 21% by RP-HPLC) and Gly-AMBA (yield: 12% by RP-HPLC) conjugates. Analysis of the AMBA and Gly-AMBA conjugates by RP-HPLC and mass spectrometry revealed that the majority of the crude material prematurely terminated. The major source of peptide termination was found to occur after the *p*-aminobenzoic acid was coupled to the growing peptide during peptide synthesis. The early termination of the peptide is likely attributed to the significantly reduced nucleophilicity of the primary amine of the *p*-aminobenzoic acid due to the lone pair of the 1° amine being tied up in resonance with the aromatic ring. Whereas the linking group of the Gly-AM2BA conjugate employs *p*-aminomethylbenzoic acid in which the capability of p-orbital conjugation between the amine and the aromatic ring is eliminated by the presence of the benzylmethyl group. Yields for the Gly-AM2BA (yield: 47% by RP-HPLC) conjugate were significantly higher than either the AMBA or Gly-AMBA conjugates.

In our experiments, the addition of $^{nat}Cu(II)SO_4 \cdot 5H_2O$ to the reaction mixture after the radioconjugates were labeled significantly aided in the separation of the ^{111}In-labeled radioconjugate from the unlabeled conjugate. Biological evaluation of the radioconjugate containing a significant amount of unlabeled BBN conjugate in solution would result in significantly reduced uptake of the ^{111}In-BBN analogue in BB2r-expressing tissues due to the blocking of available BB2rs by the unlabeled BBN analogue. However, Lantry and co-workers recently reported

Table 3. Biodistribution Studies of ^{111}In-DOTA-8-AOC-BBN(7-14)NH$_2$, ^{111}In-DOTA-8-ADS-BBN(7-14)NH$_2$, ^{111}In-DOTA-AMBA-BBN(7-14)NH$_2$, ^{111}In-DOTA-Gly-AMBA-BBN(7-14)NH$_2$, and ^{111}In-DOTA-Gly-AM2BA-BBN(7-14)NH$_2$ at 1, 4, and 24 h Postinjection in PC-3 Tumor-Bearing SCID Mice[a]

[a] The biodistribution study of ^{111}In-DOTA-8-AOC-NONSENSE was performed at 1 hr postinjection in PC-3 tumor-bearing SCID mice. Organ uptake values expressed as %ID/g and $n = 5$ unless otherwise noted. [b] Excretion values at 1, 4, and 24 h time points were calculated using the activity values associated with the excreted urine and bladder contents at the time of sacrifice; at the 24 h time point, excretion values also included the activity associated with fecal material. [c] $n = 4$.

that predose administration of a small amount (83.2 μg/m^2) of a BB2r agonist prior to administration of a radiolabeled BB2r agonist (^{177}Lu-DOTA-Gly-AMBA-BBN(7−14)NH$_2$) reduced the uptake in the BB2r-rich mouse pancreas, while maintaining the same tumor uptake and retention as studies with no predose (*23*). This study suggests that there may be a beneficial effect of having a minimal concentration of unlabeled BB2r-targeting bombesin analogues in administered doses. Further studies are required to determine if such an optimum window of concentration for nonlabeled BB2r specific peptides exists.

In vitro competitive BB2r binding assays of the ^{nat}In-BBN analogues and unlabeled BBN analogues were performed using [^{125}I-Tyr^4]BBN in PC-3 cells. All ^{nat}In-BBN conjugates demonstrated nanomolar binding affinity for the BB2r. The binding affinities followed the trend: alkyl linker > aromatic linkers > ether linkers. All radioconjugates exhibited receptor-mediated internalization and retention of the radioactivity.

In vivo biodistribution studies for each radioconjugate with exception of the 8-AOC radioconjugate were performed using healthy CF-1 mice. Of the five radioconjugates investigated, the radioconjugates containing aromatic linking groups had significantly higher pancreatic retention at 1 h postinjection ($P \leq 0.0002$). Impressively, the pancreatic retention of the Gly-AMBA radioconjugate (63.35 ± 5.91%ID/g) was nearly twice that of any of the other radioconjugates investigated. The rationale for the increased in vivo BB2r uptake of Gly-AMBA over the structurally very similar analogue Gly-AM2BA is unclear. Kidney retention is an important factor when considering the development of therapeutic radiopharmaceuticals due to potential nephrotoxicity (*28*). Even though the Gly-AMBA

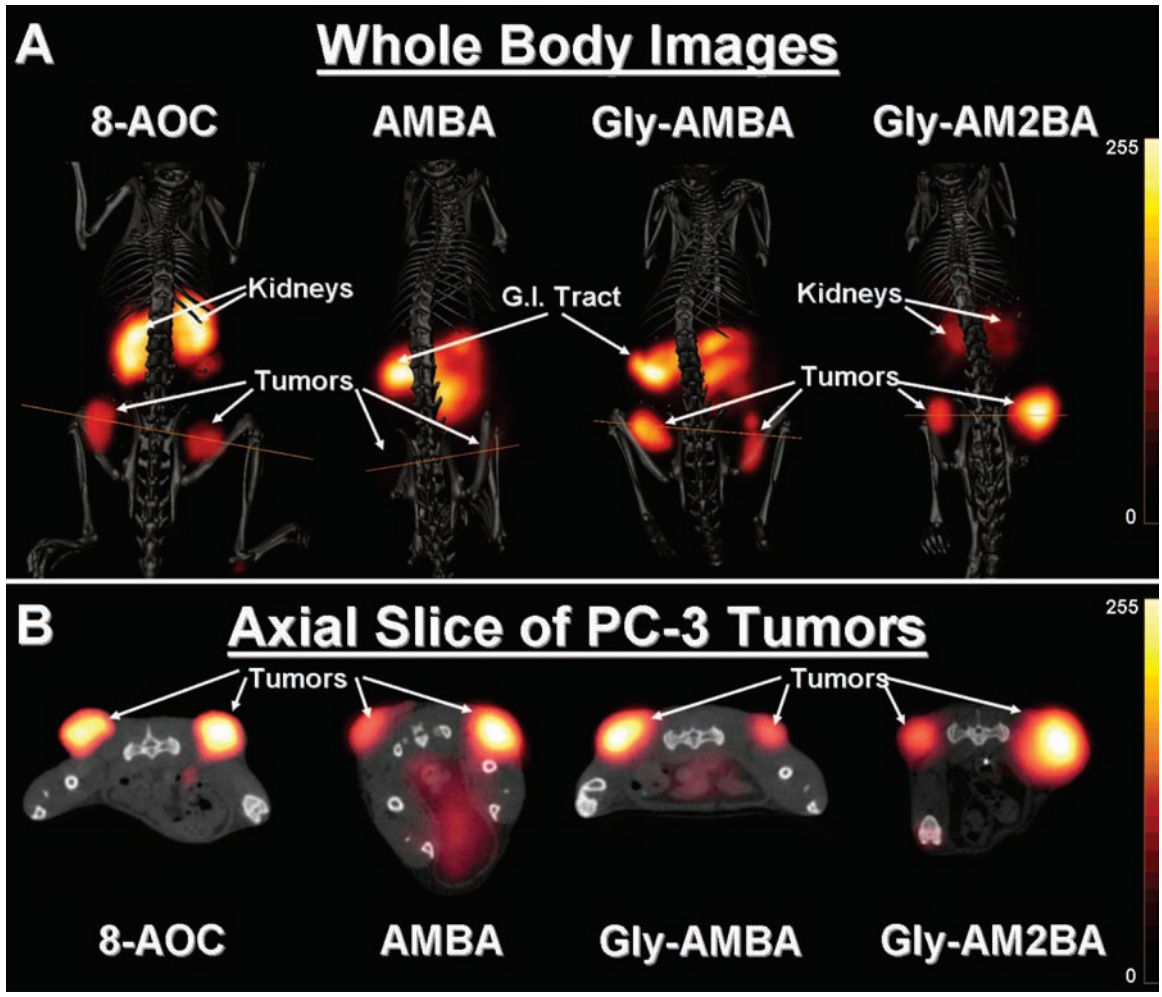

Figure 4. Small animal SPECT/CT imaging performed 24 h postinjection in PC-3 tumor-bearing SCID mice using ^{111}In-DOTA-8-AOC-BBN(7−14)NH_2, ^{111}In-DOTA-AMBA-BBN(7−14)NH_2, ^{111}In-DOTA-Gly-AMBA-BBN(7−14)NH_2, and ^{111}In-DOTA-Gly-AM2BA-BBN(7−14)NH_2. (A) Whole body images. (B) Axial slices of the PC-3 tumors corresponding to the respective transverse plane depicted in the whole body images. Each whole body and axial image was normalized to the highest-intensity pixel for each image.

and Gly-AM2BA radioconjugates initially demonstrated significantly higher kidney retention at 1 h p.i. compared to the 5-AOS, 8-ADS, and AMBA radioconjugates, all of the radioconjugates investigated demonstrated efficient clearance from the kidneys by 24 h postinjection. The hepatobiliary clearance of the radioconjugates containing ether-derived linking groups was significantly greater than radioconjugates containing aromatic linking groups ($P \leq 0.0003$). For diagnostic radiopharmaceuticals, obtaining a good target-to-nontarget ratio is crucial for the generation of easily interpretable clinical diagnostic images. The increased hepatobiliary retention of the radioconjugates with aromatic derivatives is clearly detrimental to obtaining high target-to-nontarget ratios with minimal abdominal background.

Taking the results from the CF-1 pharmacokinetic studies into account, the 8-AOC, 8-ADS, AMBA, Gly-AMBA, and Gly-AM2BA radioconjugates were further investigated in a PC-3 tumor-bearing mouse model. All of the radioconjugates cleared well from the blood, but the blood-associated activities were on average higher for the SCID mice compared to the CF-1 mice at 1 h postinjection. Like the CF-1 mice, the primary route of clearance of ^{111}In radioactivity from the SCID mice was the renal system. Renal retention of the radioconjugates at 1 h postinjection was higher in the SCID mouse model relative to what was observed with CF-1 mice. However, the overall trend in renal retention among the radioconjugates was largely unchanged. At 1 h postinjection, tumor retention followed the trend 8-AOC < 8-ADS < Gly-AM2BA < Gly-AMBA < AMBA. The AMBA radioconjugate had the highest accumulation in the tumors at the 1 h time point and was significantly greater than 8-AOC, 8-ADS, and Gly-AM2BA ($P = 0.0029$, 0.0251, and 0.0386, respectively). No statistically significant differences in tumor uptake were observed using the AMBA and Gly-AM2BA radioconjugates. The radioconjugates containing aromatic groups clearly demonstrate significantly higher retention ($P \leq 0.0213$) in the PC-3 tumor tissue at the 4 h postinjection time point when compared to the radioconjugates containing hydrocarbon or ether linking moieties. At 24 h postinjection, the trend in tumor retention was 8-AOC < Gly-AMBA < 8-ADS < AMBA < Gly-AM2BA. Statistical differences among individual radioconjugates were found, but no statistical significance was found in relating the retention of the radioconjugates in the PC-3 tumors to the linking group functionality. Comparison of the ^{111}In-labeled 8-AOC and Gly-AMBA radioconjugates with identical ^{177}Lu-labeled analogues reported by our laboratory and Lantry and co-workers revealed interesting trends in tumor retention with respect to the radionuclide employed (*23*, *29*). The ^{177}Lu-labeled 8-AOC and Gly-AMBA radioconjugates demonstrated tumor retention values at each time point that were ∼1.7−2.8 times greater relative to the ^{111}In-labeled 8-AOC and Gly-AMBA radioconjugates, suggesting that the choice of radionuclide can have a substantial impact on tumor retention. The pancreatic uptake of the ^{111}In-labeled radioconjugates was consistent in both the

CF-1 and SCID mouse models. However, it is noteworthy that the in vivo pancreatic uptake of the radioconjugates in both mouse models did not correlate strongly with the in vivo tumor uptake of the radioconjugates. The differences in pancreatic and tumor retention could possibly be accounted for by factors such as differences in the tumor vascular systems and/or differences between murine (pancreas) and human (PC-3 tumor) BB2r homology. From these studies, it appears that the methodology that employs normal mouse models (e.g., CF-1) as the sole screening tool for potential BB2r targeting radiopharmaceuticals may be inadequate in predicting the in vivo uptake in BB2r positive human tumors.

Micro-SPECT/CT imaging studies of the 8-AOC, AMBA Gly-AMBA, and Gly-AM2BA radioconjugates predominantly correlated well with the respective biodistribution studies. Visual inspection of the whole body images clearly illustrates superior tumor visualization with the Gly-AMBA and Gly-AM2BA radioconjugates. Examination of the normalized images also indicated significant abdominal accumulation for AMBA and Gly-AMBA radioconjugates, whereas the 8-AOC and Gly-AM2BA exhibited primarily renal retention as the major source of nontarget retention. Comparison of the 8-AOC and Gly-AM2BA radioconjugates reveals considerably higher tumor-to-kidney ratios for the Gly-AM2BA. The higher tumor-to-kidney ratios could be potentially significant if a radiotherapeutic derivative of the Gly-AM2BA radioconjugate were investigated. For the 8-AOC and Gly-AM2BA radioconjugates, the whole body images deviate somewhat from the corresponding biodistribution studies in which the retention of activity in both the G.I. tract and pancreas are an order of magnitude greater than the kidneys at the analogous time point. One possible explanation for the deviations between the biodistribution studies and the imaging data could be due to the fact that the preclinical SPECT/CT studies required the ^{111}In-radioconjugates to be administered in a quantity that was approximately 3 orders of magnitude greater than the biodistribution studies. The disparity in the quantity of the ^{111}In-radioconjugate employed in the studies may affect the pharmacokinetics of the radioconjugates in vivo.

In conclusion, we have systematically evaluated the pharmacokinetic profile of several diverse linking groups based upon hydrocarbon, ether, and aromatic moieties using in vitro studies and in vivo pharmacokinetic and SPECT/CT imaging studies. Our studies indicate that radioconjugates incorporating aromatic linking groups of the type investigated generally demonstrate significantly higher hepatobiliary retention when compared with either the hydrocarbon or ether linking groups. However, we found that radioconjugates containing aromatic linking groups typically exhibited higher in vivo uptake and retention in the murine pancreas, a BB2r rich tissue, than radioconjugates composed of ether linking groups. Similarly, in BB2r-positive human PC-3 tumors, the radioconjugates incorporating aromatic linking groups on average generally demonstrated higher PC-3 tumor retention. The role of linking groups in small peptide receptor-targeted radiopharmaceutical design has largely been viewed as merely a convenient way to adjust the blood retention and overall clearance of the radiopharmaceutical without making substantial alterations to the targeting vector. This study clearly demonstrates the significance of the linking group upon not only the in vivo clearance of the radiopharmaceutical, but also on the in vivo uptake and retention of the BB2r-targeted agent in tumor tissue. The design of future BB2r-targeted agents should include a careful consideration of the effect linking group functionality has upon tumor targeting and retention. Furthermore, in evaluating the uptake and retention of the radioconjugates in mouse and human BB2r expressing tissues, we find that the uptake and retention of the radioconjugates in human PC-3 tumors did not correlate strongly with the pharmacokinetic profiles obtained from the murine pancreas. This indicates that relying solely on BB2r expression in the murine pancreas to optimize or screen BB2r-targeted agents for human BB2r expressing tumors may not be appropriate. Future work will focus on evaluating and optimizing the pharmacokinetic profile of cleavable linking groups and linking groups composed of other nonstandard amino acids using the BBN paradigm.

ACKNOWLEDGMENT

The authors gratefully acknowledge the support of postdoctoral fellowship (PFTED-07-267-01-SIED) (J.C.G.) awarded by the Canary Foundation and the American Cancer Society and additional funding from the National Cancer Institute DHHS-R01-CA72942 (T.J.H.), DHHS-1P50-CA13013 (W.A.V.), the American Cancer Society RSG-99-331-04-CDD (T.J.H.) and the Department of Veterans Affairs MERIT award (T.J.H.). The authors would further like to acknowledge Dr. Nathan D. Leigh and the Mass Spectrometry Facility in the Department of Chemistry at the University of Missouri-Columbia for the collection and assistance in interpretation of the mass spectra in this manuscript. This work was supported with the resources and the use of facilities at the Harry S. Truman Memorial VA Hospital.

Supporting Information Available: Complete biodistribution data for the radioconjugates in CF-1 (1, 4, and 24 h time points) and PC-3 tumor bearing SCID mice (0.25, 1, 4, and 24 h time points) are given in tabular form. This material is available free of charge via the Internet at http://pubs.acs.org.

Peptide-Targeted Polyglutamic Acid Doxorubicin Conjugates for the Treatment of $\alpha_v\beta_6$-Positive Cancers

Huili Guan,[§] Michael J. McGuire,[§] Shunzi Li, and Kathlynn C. Brown*

Division of Translational Research, Department of Internal Medicine and The Simmons Comprehensive Cancer Center, University of Texas Southwestern Medical Center, Dallas, Texas 75390. Received April 14, 2008; Revised Manuscript Received July 8, 2008

Most chemotherapeutics exert their effects on tumor cells as well as their healthy counterparts, resulting in dose limiting side effects. Cell-specific delivery of therapeutics can increase the therapeutic window for treatment by maintaining the therapeutic efficacy while decreasing the untoward side effects. We have previously identified a peptide, named H2009.1, which binds to the integrin $\alpha_v\beta_6$. Here, we report the synthesis of a peptide targeted polyglutamic acid polymer in which the high affinity $\alpha_v\beta_6$-specific tetrameric H2009.1 peptide is incorporated via a thioether at the N-terminus of a 15 amino acid polymer of glutamic acid. Doxorubicin is incorporated into the polymer via an acid-labile hydrazone bond. Payloads of four doxorubicin molecules per targeting agent are achieved. The drug is released at pH 4.0 and 5.6 but the conjugate is stable at pH 7.0. The conjugate is selectively internalized into $\alpha_v\beta_6$ positive cells as witnessed by flow cytometric analysis and fluorescent microscopy. Cellular uptake is mediated by the H2009.1 peptide, as no internalization of the doxorubicin-PG polymer is observed when it is conjugated to a scrambled sequence control peptide. Importantly, the conjugate is more cytotoxic toward a targeted cell than a cell line that does not express the integrin.

INTRODUCTION

Most chemotherapeutics exert their effects on tumor cells as well as their healthy counterparts, resulting in dose limiting side effects. Cell-specific delivery of therapeutics can increase the efficacy of the drug while decreasing its side effects, thus opening the therapeutic window for treatment. Despite its advantages, tumor targeting of therapeutic molecules remains a major challenge in biomedicine. The challenges in developing targeted drug delivery systems can be broken into three main areas. First, cell specific binding reagents that display high affinity and specificity for the desired cell type must be identified. Additionally, if the drug mediates its cytotoxic effect by an intracellular activity, the ligand must mediate both binding and uptake by the targeted cell. Second, these targeting moieties must be incorporated into drug systems that allow delivery of molecular cargo specifically to the tumor. This takes into account factors such as size, vascular permeability, tissue retention, and stability. Third, the cargo needs to be released in an active form within the desired cellular compartment.

Toward the goal of targeted therapies for non-small cell lung carcinoma (NSCLC), we have isolated a peptide, named H2009.1, which binds to a large number of adenocarcinoma (AD) lung cancer cell lines (*1*). When placed on a tetrameric trilysine scaffold, this peptide has half-maximal binding affinity of 40−60 pM for its target cell. Additionally, the peptide can mediate cellular uptake (*2*). The cellular receptor for the H2009.1 peptide is the restrictively expressed integrin, $\alpha_v\beta_6$ (*3*). Expression of $\alpha_v\beta_6$ is widespread in early stage NSCLC, and it is associated with poor patient survival. Furthermore, this integrin is up-regulated in NSCLC tumors compared to normal lung tissue. The restricted expression suggests that it may be a good receptor for targeted therapies for lung cancer.

We have previously demonstrated that the H2009.1 peptide can be conjugated to doxorubicin to affect cell-specific death (*2*). While this experiment established proof-of-concept, only one molecule of doxorubicin was delivered per molecule of peptide. Increasing the drug load is expected to improve the efficacy. Polyglutamic acid (PG) has recently been used as a polymeric drug carrier (*4*). This water soluble biopolymer is biodegradable and is well tolerated at high doses. The pendant carboxyl groups of the glutamic acid provide a reactive moiety to which chemotherapeutics can be conjugated. As such, greater drug loads can be achieved based on a per molecule basis. This carrier has been used for doxorubicin (*5*−*7*), paclitaxel (*8*−*11*), camptothecin (*12, 13*), and retinoids (*14, 15*). In addition, MRI contrast reagents have been coupled to PG for tumor imaging (*16*−*18*). The PG-paclitaxel conjugate, XYOTAX (CT-2103, Cell Therapeutics Inc.) is in clinical trials for NSCLC and ovarian cancer (*19*−*21*).

Most of the PG-drug conjugates are large molecular weight polymers, which increase the circulation time of the drug when compared to free drug. Accumulation in the tumor is the result of passive targeting due to the enhanced permeability and retention (EPR) effect which results from the disordered, leaky vasculature of the tumor coupled with a dysfunctional lymphatic system (*22*). Active targeting of the PG-drug conjugates can be achieved by the incorporation of a targeting moiety. To date, few reports of targeted-PG conjugates have been reported, and they have relied on antibody-based targeting reagents (*5*).

Here, we report the synthesis of a peptide targeted polyglutamic acid polymer in which the high affinity $\alpha_v\beta_6$-specific tetrameric H2009.1 peptide is incorporated via a thioether at the N-terminus of a 15 amino acid polymer of glutamic acid. Doxorubicin is incorporated into the polymer via an acid-labile hydrazone bond. Payloads of four doxorubicin molecules per targeting agent are achieved and the drug is released in acidic conditions. The conjugate is selectively internalized into $\alpha_v\beta_6$ positive cells as witnessed by flow cytometric analysis and fluorescent microscopy. Cellular uptake is mediated by the

H2009.1 peptide, as minimal internalization of the doxorubicin-PG polymer is observed when it is conjugated to a scramble sequence control peptide. Importantly, the conjugate is preferentially cytotoxic toward a targeted cell when compared to a cell line that does not express the $\alpha_v\beta_6$ integrin.

EXPERIMENTAL SECTION

General Peptide Synthesis and Characterization. All peptides were synthesized on a Symphony Peptide Synthesizer (Rainin Instruments, Protein Technologies, Inc. Woburn, MA) using standard Fmoc chemistry. All Fmoc-protected amino acids, 2-(1*H*-benzotriazole-l-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), were purchased from EMD Biosciences Inc. (San Diego, CA), anhydrous 1-hydroxybenzotriazole (HOBt) was purchased from SynBioSci (Livermore, CA), *N*-methylmorpholine (NMM) was purchased from Acros Organics (Geel, Belgium), and piperidine was purchased from Sigma-Aldrich Inc. (St. Louis, MO). The crude peptides were dissolved in 20% methanol/8 M guanidinium hydrochloride and purified with RP-HPLC using eluents of H_2O/0.1% TFA (eluent A) and acetonitrile/0.1% TFA (eluent B). The programmed elution profile 0−1 min, 100% A; 1−80 min, B is increased from 0−75% at a flow rate of 10 mL/min on preparative column (Spirit Peptide C18, 5 μm column, 25 × 2.12) (referred to as method A) or 0−1 min, 100% A; 1−70 min, B is increased from 0−75% at a flow rate of 1 mL/min on analytical column (Spirit Peptide C18, 5 μm column, 15 × 0.4) (referred to as method B). Peptide purity was determined by analytical HPLC monitoring peptide elution by absorbance at 220 nm. The peptide mass was characterized by matrix assisted laser desorption/ionization (MALDI) on a Voyager DE Pro (Applied Biosystems Inc., Foster City, CA) using α-cyano-4-hydroxycinnamic acid as matrix in the reflector mode or in linear mode using sinapinic acid as matrix, respectively. N-terminal sequence analysis of peptide was carried out by Edman protein sequencers (Applied Biosystems 494) in the Protein Chemistry Technology Center of University of Texas Southwestern Medical Center.

Cell Lines. Human lung cancer cell lines were obtained from the Hamon Center for Therapeutic Oncology Research (UTSW) and were maintained according to standard protocols (*23*). RPMI1640 was purchased from Mediatech (Herndon, VA). Fetal bovine serum (FBS) was purchased from Gemini Bioproducts (Woodland, CA).

Synthesis of Tetrameric-10mer H2009.1 and a Corresponding Scrambled Sequence Peptide. The peptides were synthesized by standard Fmoc chemistry using the $Fmoc_4$-Lys_2-Lys-Cys(Acm)-β-Ala-CLEAR Acid Resin (loading 0.21 mmol/g, Peptides International, Louisville, KY). Fmoc-protected amino acids were doubly coupled at 5-fold molar excess using HBTU/HOBt/NMM (5/5/10) as an activator system. Coupling times of 40−50 min were employed. A single coupling of Fmoc-NH-$(PEG)_{11}$-COOH ($C_{42}H_{65}NO_{16}$, Polypure, Oslo, Norway) was performed overnight. The removal of the Fmoc group was carried out with 20% piperidine in DMF. The peptide was cleaved by treating the final resin with a cocktail of TFA/TIS/H_2O (95%/2.5%/2.5%) for 3 h. The cleavage solution was concentrated by passing Ar into the solution and the peptide was subsequently precipitated by addition of cold ether. The crude peptide was purified with HPLC using method A. The purified product was analyzed by method B. MALDI mass spectra were obtained in linear mode using sinapinic acid as matrix. N-terminal sequence was analyzed by Edman protein sequencer. Tetramer-10mer-H2009.1 (RGDLATLRQL; $C_{327}H_{606}N_{82}O_{114}S$): MALDI MH^+ (average mass calculated/found: 7543.86/7544.20), purity >98.4%, (RP-HPLC, retention time of 34.37 min using method B). Scramble Tetramer-10mer-H2009.1 (DALRLQGTLR; $C_{327}H_{606}N_{82}O_{114}S$): MALDI MH^+ (average mass calculated/found: 7543.86/7544.83), purity >98.1% (RP-HPLC, retention time of 34.58 min using method B).

Deprotection of the Acetamidomethyl-Cysteine To Reveal a Free Thiol on the Tetrameric Peptides. The tetrameric-10mer H2009.1 peptide with the acetamidomethyl-cysteine (22 mg, 3 μmol) was dissolved in TFA (1.5 mL) containing 1% anisole to which silver acetate (80 mg, 480 μmol) was added. The solution was stirred for 2 h at 4 °C and then concentrated under Ar to 0.5 mL. The peptide was precipitated by the addition of 5 mL of cold ether and collected by centrifugation, and then treated with dithiothreitol (1 mL, 0.2 M in 1 M acetic acid) at RT for 3 h. The solution was filtered and purified with HPLC using method A. The purified product was analyzed by method B. MALDI mass spectra were obtained in linear mode using sinapinic acid as matrix. The same reaction and characterization conditions were employed on scrambled sequence tetrameric peptide. Tetrameric-10mer-H2009.1 ($C_{324}H_{601}N_{81}O_{113}S$): MALDI MH^+ (average mass calculated/found: 7472.78/7473.99), purity >98.4% (RP-HPLC, retention time of 34.71 min using method B). Scramble tetrameric-10mer-H2009.1 ($C_{324}H_{601}N_{81}O_{113}S$): MALDI MH^+ (average mass calculated/found: 7472.78/7473.84), purity >98.1% (RP-HPLC, retention time of 33.55 min using method B).

Synthesis of Maleimido-PEG-polyGlu$_{15}$. Synthesis of maleimido-PEG-$polyGlu_{15}$ was performed by sequential coupling of Fmoc-Glu(O-*t*-Bu)-OH (5-fold molar excess) on Rink Amide AM resin (200−400 mesh, 0.43 mmol/g, EMD Biosciences Inc.). A double coupling was performed for each addition of glutamic acid to the growing peptide chain. A PEG moiety was incorporated by a single coupling of Fmoc-NH-$(PEG)_{11}$-COOH (5-fold molar excess). The peptide was capped with maleimide functionality at the amino terminus by the reaction of *N*-β-maleimidopropionic acid (BMPA, 5-fold molar excess) for 4 h. HBTU/HOBt/NMM (5/5/10) was employed as an activator system for all couplings. The removal of the Fmoc groups was performed in 20% piperidine with DMF. The linear peptide was cleaved from the final resin in a cocktail of TFA/TIS/H_2O (95%/2.5%/2.5%) for 3 h. Upon concentrating the cleavage cocktail by passing Ar into the solution, the peptide was precipitated in cold ether. The crude product was purified with HPLC using method A. The final product was analyzed by method B. The MALDI mass spectrum was obtained in reflector mode using α-cyano-4-hydroxycinnamic acid as matrix. Maleimido-PEG-$polyGlu_{15}$ (compound 1, $C_{109}H_{166}N_{18}O_{61}$): MALDI MNa^+ (monoisotopic mass calculated/found: 2726.487/2726.46), purity >98.3% (RP-HPLC, retention time of 27.95 min using method B).

Incorporation of H_2NNHBoc to Pendant Carboxyl Group of Maleimido-PEG-polyGlu$_{15}$. The hydrazide groups were conjugated to the pendant carboxyl groups of compound 1 via acid anhydride reaction. Triethylamine (TEA, 0.2 mL) was added to maliemido-PEG-$polyGlu_{15}$ (20 mg, 7.4 μmol polymer, 111 μmol COOH groups) dissolved in anhydrous DMF (1.5 mL), followed by dropwise addition of isobutyl chloroformate (0.2 mL, 1.5 mmol) under an Ar atmosphere at 4 °C. After 5 min, *tert*-butyl carbazate (H_2NNHBoc, 1.5 mmol in 0.8 mL DMF) was added. The reaction was performed for 30 min at 4 °C and then continued for 3 more hours at RT. The resultant salts were removed by filtration and low molecular weight impurities were removed by dialysis in DMF using a dialysis membrane with a molecular weight cutoff (MWCO) of 1 kDa. The final product was precipitated from cold ether and dried in vacuum. The number of carboxylate groups converted to CONHNHBoc was calculated by comparing intensity of characteristic resonance of the Boc protecting group at 1.41 ppm and maleimide resonance at 6.93 ppm (CH=CH) by ^{1}H NMR in DMSO-d_6. The results showed that 71% of the COOH groups

were converted to CONHNHBoc groups. This corresponds to an average of 10−11 hydrazide moieties per polymer molecule. MALDI mass spectrometry of the resultant maleimido-PEG-polyGlu(NHNHBoc)$_{15}$ (compound 2) showed a broad mass distribution centered around 4400 Da (α-cyano-4-hydroxycinnamic acid as matrix). This is consistent with a distribution of products due to incomplete modification of the carboxylate.

Removal of the Boc Protecting Group from Maleimido-PEG-polyGlu(NHNHBoc)$_{15}$. Compound 2 (15 mg) was treated by TFA (1 mL) to remove protective BOC groups. The resultant maleimido-PEG-polyGlu(NHNH$_2$) was purified with HPLC using method A. The removal of Boc groups is indicated by the complete disappearance of methyl proton at 1.41 ppm in ^{1}H NMR. MALDI mass spectrometry of the deprotected product maleimido-PEG-polyGlu(NHNH$_2$)$_{15}$ (compound 3) showed a broad mass distribution centered around 3288 Da (α-cyano-4-hydroxycinnamic acid as matrix). This is consistent with the removal of approximately 10−11 Boc protecting groups.

Conjugation of Peptides to Maleimido-PEG-polyGlu(NHNH$_2$)$_{15}$. A typical protocol for the reaction of thiol group of the peptide with maleimide is described below. Compound 3 (3.8 mg) was dissolved in PBS (0.5 mL, pH 7.0) containing EDTA (0.1 M) degassed by passing Ar into the solution for 5 min. The tetrameric 10mer H2009.1 peptide (9.6 mg, 1.3 μmol) was added, and the reaction was carried out at RT for 3 h. The product was isolated with HPLC using method A. The purified product was analyzed by method B and found to be a single peak with a retention time of 33.48 min for the tetrameric 10-mer H2009.1-PEG-PolyGlu(NHNH$_2$)$_{15}$ (compound 4). A retention time of 33.55 min was observed for the corresponding product coupled to the sequence scrambled version of the peptide. MALDI mass spectra were obtained in linear mode using sinapinic acid as matrix. A major product was observed with a MH$^+$ of 10 389.9 (compound 4).

Synthesis of Tetrameric 10mer H2009.1-PEG-polyGlu-(NHN=Dox). Compound 4 (5 mg, 0.48 μmol) and doxorubicin HCl (15 mg, 26 μmol, Shanco International, Inc., South Plainfield, NJ) were dissolved in anhydrous methanol (1.5 mL) with TFA as an acid catalyst. The reaction solution was stirred at RT in the dark for 48 h. After removal of the solvent, the resultant solid was dried overnight under vacuum. The crude product was purified by size exclusion chromatography (Ultrahydrogel 500, 7.8 × 300 mm) in PBS/CH$_3$CN (70/30). The proper fraction was collected and lyophilized to yield final product as wine red powder. The product was evaluated by HPLC (elution profile of 0−1 min, eluent B is increased from 0−15%; 1−40 min, B is increased from 15−80% at a flow rate of 1 mL/min using the Spirit Peptide C18 column) monitoring the presence of doxorubicin at 485 nm to confirm the absence of unbound free doxorubicin. The conjugate has a retention time of 17.8 min and is well separated from the free drug which elutes at 16.3 min. The loading percentage of doxorubicin in the conjugates was 24% as determined by comparing the concentration of Dox obtained by absorption at 481 nm (ε = 10 410 M^{-1} cm^{-1}) (*24*) and the concentration of peptide moiety obtained by Edman sequencing analysis.

Evaluation of pH Dependent Drug Release. Tetrameric 10mer H2009.1-M-PEG-polyGlu(NHN=Dox) (50 μM Dox equivalents) was dissolved in phosphate buffered saline (pH 7.0, 0.1 mL) or acetate buffer (pH 4.0, 0.1 mL and pH 5.6, 0.1 mL). The samples were incubated at 37 °C for the indicated times. The release of free doxorubicin was determined by RP-HPLC using a C18 column and monitoring doxorubicin absorbance at 485 nm.

Flow Cytometric Analysis. Integrin $\alpha_V\beta_6$-positive H2009 cells and $\alpha_V\beta_6$-negative H1299 cells (*3*) were seeded in 12 well culture plates at approximately 100 000 cells/well in a volume of 1 mL RPMI-1640 supplemented with 5% bovine serum (R5 medium) and allowed to adhere overnight. Cells were incubated for 120 min with 30 μM unconjugated doxorubicin, tetrameric scrambled peptide- or tetrameric 10mer-H2009.1-PEG-polyGlu(NHN=Dox). Cells were washed four times with PBS$^+$ containing 0.1% BSA, followed by 2 brief rinses with 20 mM HCl-glycine, pH 2.2 containing 150 mM NaCl. Following the washes, the cells were rinsed with PBS and 1 mL/well of enzyme-free cell dissociation buffer (Invitrogen, Grand Island, NY) was added. Cells were incubated for 30 min on ice in cell dissociation buffer, scraped from the plate, and prepared as a single cell suspension by passage through a 27 gauge needle. Doxorubicin uptake was assessed for 10 000 cells per treatment group by flow cytometry in a CellQuanta flow cytometer. Cells were gated by size and side scatter properties and doxorubicin assayed by fluorescence in channel 2 (excitation 488 nm, emission 550−600 nm).

Cell Viability Assay. Integrin $\alpha_v\beta_6$-positive H2009 cells and $\alpha_v\beta_6$-negative H1299 cells were seeded in 96 well culture plates at 1000 cells/well in a volume of 50 μL R5 medium and allowed to adhere overnight. Unconjugated doxorubicin or tetrameric 10mer H2009.1-M-PEG-polyGlu(NHN=Dox) was added to quadruplicate wells in 50 μL R5 media to produce the final concentrations indicated (ranging from 200 nM to 5 μM, all based on total doxorubicin concentration). Untreated control cells received 50 μL R5 only and were cultured as a set of eight replicate wells per plate. After 24 h of exposure to the drug, media was aspirated from all wells, and the wells were washed four times with 200 μL R5 before continuing culture in 100 μL R5 for 72 h. At the end of the post-treatment incubation, cell viability was assessed using CellTiter Glo reagent (Promega, Madison, WI). Luminescence was detected using a plate reader 30−60 min after the addition of the CellTiter Glo reagent.

Fluorescent Microscopy. Images of individual cells were captured from wells of 96 well plates from the viability assays detailed above. Cells were observed 2 h after removal of the drug and addition of fresh media using an inverted Leica 6500 microscope. Cell images were captured with phase contrast illumination to visualize the cells and fluorescence in the red channel to visualize doxorubicin uptake. Untreated control cells had no detectable intrinsic fluorescence under these conditions. Figures are displayed as overlays of the phase contrast and fluorescence microscopy. Images in an individual experiment were captured under the same settings (gain, time of exposure, contrast) so that fluorescence intensity is proportional to drug accumulation by the cells.

RESULTS

Synthesis of Tetrameric 10mer H2009.1-PEG-polyGlu-(NHN=Dox) (Compound 5). We sought to develop a targeted-doxorubicin conjugate that met three requirements. First, it must contain a high affinity targeting reagent that can be incorporated in a chemospecific fashion that allows for the targeting moiety to retain its activity. Second, the ratio of targeting reagent to drug must exceed the 1:1 ratio that can be achieved by direct conjugation. Third, the doxorubicin linker must be labile once the conjugate is internalized into the target cell so that doxorubicin can exert its cellular affects.

Toward these objectives, we synthesized the tetrameric 10mer H2009.1-polyGlu(NHN=Dox) (compound 5) according to Scheme 1. A defined length PG polymer serves as the drug carrier. Synthesis of the polyglutamic acid was accomplished by linear Fmoc peptide chemistry. A PEG moiety was incorporated at the amino terminus of the peptide to improve solubility and provide a flexible linker between the drug carrier and the targeting moiety. The amino terminus was capped with a maleimide so that the targeting reagent could be introduced by a chemoselective reaction with a free thiol.

While doxorubicin can be conjugated directly to the carboxylic acid of glutamic acid via an amide (*5*), we wished to incorporate the drug through an acid labile functionality. We and others have conjugated doxorubicin to a carrier by the formation of a hydrazone utilizing the ketone of 2-hydroxyacetyl group of doxorubicin (*2, 25*−*28*). To accomplish this, the carboxylic acid functionalities of the glutamic acid side chains were converted to hydrazide groups by treatment with *tert*-butyl carbazate (*25*). The number of converted carboxylate groups was determined using ^{1}H NMR by integrating the characteristic resonance of the Boc protecting group (9 protons per modification) at 1.41 ppm and maleimide resonance at 6.93 ppm (2 protons per polymer chain). Accordingly, 71% of the COOH groups were converted to CONHNHBoc groups, corresponding to 10−11 modified side chains. The Boc group was removed by treatment with trifluoroacetic acid to reveal the hydrazide.

The targeting reagent chosen was the peptide H2009.1 which binds specifically to the uniquely expressed integrin, $\alpha_v\beta_6$. This peptide was synthesized on a trilysine scaffold, as tetramerization has been demonstrated to increase affinity of this peptide for its cellular receptor (*2*). Although this peptide was originally selected as a 20 amino acid peptide, only the 10 N-terminal amino acids are necessary for binding to the integrin (S.L., M.J.M., and K.C.B., unpublished results). As such, we chose to focus on the smaller peptide to ease the difficulty of the peptide synthesis. Importantly, in this format, the peptide can mediate cellular uptake. Synthesis was performed using linear Fmoc chemistry using $Fmoc_4$-Lys_2-Lys-Cys(Acm)-β-Ala-CLEAR Acid Resin. An acetamidomethyl (Acm) protected cysteine was incorporated before the branch point. This allows for a reactive thiol to be revealed upon treatment with Ag(I). Additionally, a PEG linker was placed between the core and the peptide to improve solubility, increase flexibility between the peptide branches, and prevent peptide aggregation. As a control, a peptide that contains the same amino acid composition but a different sequence was synthesized as well. This scrambled sequence peptide has been shown to have no binding affinity for $\alpha_v\beta_6$ (data not shown). These peptides were integrated into the polyGlu($NHNH_2$) by reaction of the unique thiol of the peptide with the maleimide at the N-terminus of the polyGlu peptide.

The final step of the synthesis is the coupling of doxorubicin to the hydrazide to form the hydrazone linkage between the side chain of the glutamic acid and the ketone of doxorubicin. As the ketone functionality is chemically orthogonal to reactive groups found in naturally occurring amino acids, there was no need to protect the peptide side chains. Free drug was removed from the polymer by size exclusion chromatography under neutral pH conditions. The mole amount of doxorubicin in the conjugate was determined by UV absorbance at 481 nm. The concentration of compound 5 was determined by Edman sequencing analysis. The average drug loading is found to be 25% based on the number of glutamates or approximately 4 doxorubicin molecules per polymer unit.

Doxorubicin Is Released from the Carrier at Low pH. For the doxorubicin to be active, it must be released from the carrier so that it can exert its cellular effects within the nucleus. However, premature release of the drug will result in a decrease of the efficacy of the targeted therapeutic and will have similar side effects observed with the free drug. Internalization via a clatherin mediated endocytosis results in peptides entering the endosomal pathway with eventual localization in the lysosome (*29*−*31*). As the vesicles involved in this pathway have an acidic pH, pH sensitive linkers can be used for drug release. It is important to note that the pH drops at each sequential step of the internalization process, with early endosomes having a pH of 5.5−6.0; late endosomes exhibit a pH of approximately 5.0, whereas the lysosome's pH can drop to as low as 4.5. As such, if the drug conjugate becomes stalled at any one of these stages, drug release must occur at that pH. For this reason, the doxorubicin was coupled to the polyglutamic acid polymer via an acid labile hydrazone. To ensure that the drug conjugate is stable at the neutral pH but is released at the pH found within the lysosomal compartment of the cells, compound 5 was incubated at pH 7.0, pH 5.6, and pH 4.0 for defined times. Aliquots were removed and the release of doxorubicin was determined by HPLC. As shown in Figure 1, minimal drug was released at pH 7.0, even after 48 h. However, at pH 4.0, free doxorubicin was observed at 2 h. By 4 h, 25% of the drug has been released. This increases to 75% drug release at 51 h. As pH 4.5 is believed to be the minimum pH that would be reached in the cell, we also determined doxorubicin release at pH 5.6. The kinetics of drug release at pH 5.6 and pH 4.0 are the same (Figure 1). These results suggest that the drug will remain conjugated to the carrier in an inactive form in the serum but will be released intracellularly due to the low pH environment found in the endosome or lysosome.

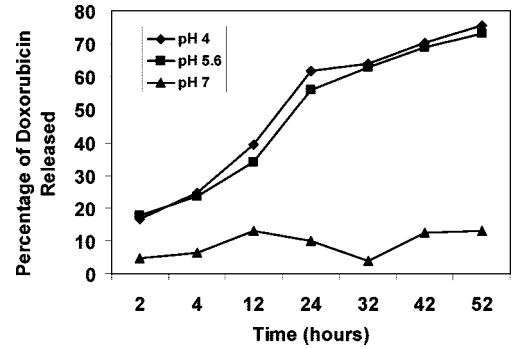

Figure 1. pH dependent release of doxorubicin from the polyglutamic acid-H2009.1 peptide conjugate. Polyglutamic acid-H2009.1-doxorubicin conjugate was dissolved in aqueous buffer at pH 7.0, pH 5.6, or pH 4.0 and incubated at 37 °C. At the indicated times, aliquots were removed and the ratio of unconjugated to conjugated doxorubicin was assessed by reverse phase HPLC on an analytical C18 column.

Tetrameric 10mer H2009.1-PEG-polyGlu(NHN=Dox) Selectivity Binds to $\alpha_v\beta_6$ Expressing Cells. Taking advantage of doxorubicin's fluorescence, the association of the conjugate with an $\alpha_v\beta_6$ expressing cell line was determined by flow cytometric analysis. Specifically, the conjugate was incubated with the human adenocarcinoma cell line H2009, which expresses $\alpha_v\beta_6$, or with H1299 cells, a human large cell lung cancer cell line which does not express the cellular receptor. As observed in Figure 2, the H2009 cells demonstrate 2-fold greater binding of targeted conjugate than the H1299 cells which do not bind the peptide. This binding is sequence specific, as the compound conjugated to the scrambled sequence peptide does not demonstrate significant binding to either cell line. Free doxorubicin internalizes into both cell lines equally. It should be noted that more doxorubicin is seen associated with the cells when they are treated with free drug versus the same concentration of targeted drug (based on total moles of doxorubicin). This phenomenon is not uncommon for drug conjugates and is most likely the result of receptor based transport of the drug versus the inherent cell permeability of the free drug (*32, 33*).

Of note, the fluorescence of doxorubicin is approximately 2-fold less when conjugated to the polymer compared to free doxorubicin (data not shown). As these studies were performed at 2 h of exposure to the polymer conjugate, in which time little doxorubicin is released from the polymer, the total uptake of the polymer conjugated drug is going to be underestimated by fluorescence experiments when compared to the free drug. However, the mean fluorescence intensity (MFI) determined by

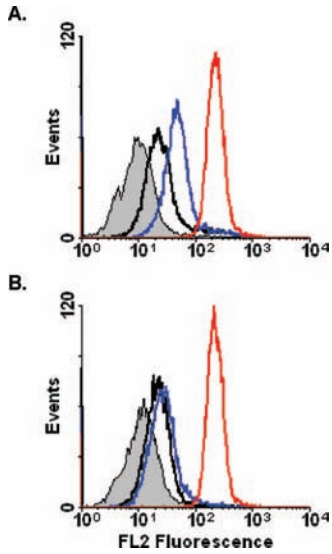

Figure 2. Cell targeted delivery of doxorubicin mediated by a cell-specific peptide. H2009 (panel A) and H1299 (panel B) cells were incubated for 2 h in the presence of 30 μM unconjugated doxorubicin (red line) or doxorubicin linked to the poly glutamic acid-H2009.1 (blue line) peptide conjugate or scrambled peptide conjugate (black line). At the end of this incubation period, the drug was removed; cells were washed with PBS^+/0.1% BSA 4 times as well as twice with 20 mM HCl-glycine, pH 2.2. Uptake of doxorubicin into cells was assessed by flow cytometry, counting 10 000 events per sample. Results obtained with untreated cells are shown in gray shaded area.

flow cytometry is greater than 4-fold higher for free doxorubicin than the conjugate on H2009 cells (Figure 2, panel A). As such, the data suggest that less drug is being delivered to the cells when conjugated to the polymer than when free doxorubicin is employed. Nonetheless, the differential binding of compound 5 to its target cell type compared to a nontargeted cell type is anticipated to reduce side effects, thus expanding the therapeutic window.

Tetrameric 10mer H2009.1-PEG-polyGlu(NHN=Dox) Is More Cytotoxic toward $\alpha_v\beta_6$ Expressing Cells. To determine if compound 5 could deliver doxorubicin selectivity to $\alpha_v\beta_6$ positive cells, H1299 and H2009 cells were incubated in the presence of varying concentrations (200 nM to 5 μM) of unconjugated doxorubicin or doxorubicin linked to the poly-glutamic acid-H2009.1 peptide conjugate. After 24 h, the drug was removed. Cells were incubated in fresh complete media for 72 h, after which the cell viability was determined. The results are shown in Figure 3. Both cell types are sensitive to free doxorubicin; pairwise comparison of cell viability after free doxorubicin treatment of both cell types did not demonstrate any statistical difference in the viability of these two cell types. However, after treatment with compound 5, more cell death was observed for the $\alpha_v\beta_6$ positive H2009 cells when compared to the $\alpha_v\beta_6$ negative H1299 cells at all concentrations ($p = 0.033$). Comparing the viability after treatment at 2 μM with the doxorubicin−peptide conjugate, the difference in viability of the two cell types is 2-fold ($p = 0.024$).

There is a significant reduction in the potency of the doxorubicin when it is conjugated to the polymer. This could be due to reduced uptake of the drug and/or inefficient release of the drug from its carrier. H1299 and H2009 cells were incubated in the presence of 5 μM unconjugated doxorubicin or doxorubicin linked to the polyglutamic acid-H2009.1 peptide conjugate. After 24 h, the drug was removed from the cells. Cells were then observed by phase contrast and fluorescence microscopy. Overlays of the resulting images are shown in Figure 4. Similar levels of unconjugated doxorubicin accumulate in the nuclei of both cell types (panel A and panel C). In

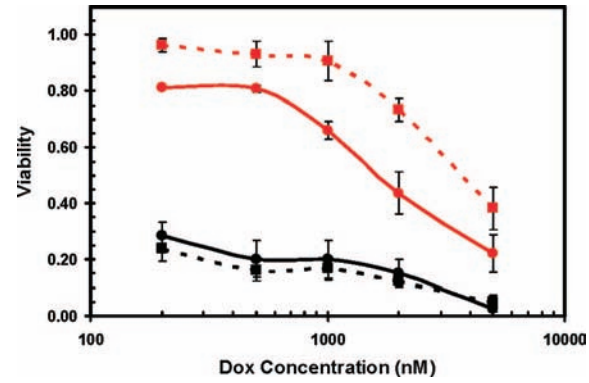

Figure 3. Cell targeted delivery of doxorubicin preferentially kills $\alpha_v\beta_6$-integrin positive tumor cells. H1299 (■ - black, red) and H2009 (● - black, red) cells were incubated in the presence of varying concentrations (200 nM to 5 μM) unconjugated doxorubicin (black lines) or doxorubicin linked to the polyglutamic acid-H2009.1 peptide conjugate (red lines). After 24 h, the drug was removed; cells were washed and incubated in fresh complete media for 72 h. Cell viability was determined using the Cell Titer-Glo assay (Promega Corp). The results shown are an average of 3 independent experiments. Pairwise comparison of cell viability after free dox treatment of both cell types did not demonstrate any statistical difference whereas the difference in the viability of these two cell types after poly-glu-dox-H2009.1 conjugate treatment was statistically significant ($p = 0.033$).

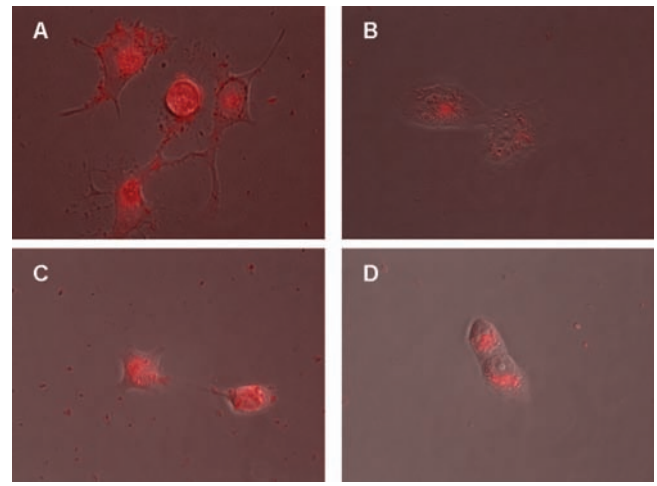

Figure 4. Cell targeted delivery of doxorubicin mediated by a cell-specific peptide. H1299 (A and B) and H2009 (C and D) cells were incubated in the presence of 5 μM unconjugated doxorubicin (A and C) or doxorubicin linked to the polyglutamic acid-H2009.1 peptide conjugate (B and D). After 24 h, the drug was removed; cells were washed and incubated in fresh complete media for 2 h. Cells were observed by phase contrast and fluorescence microscopy at 400× magnification. Overlays of the resulting images are shown.

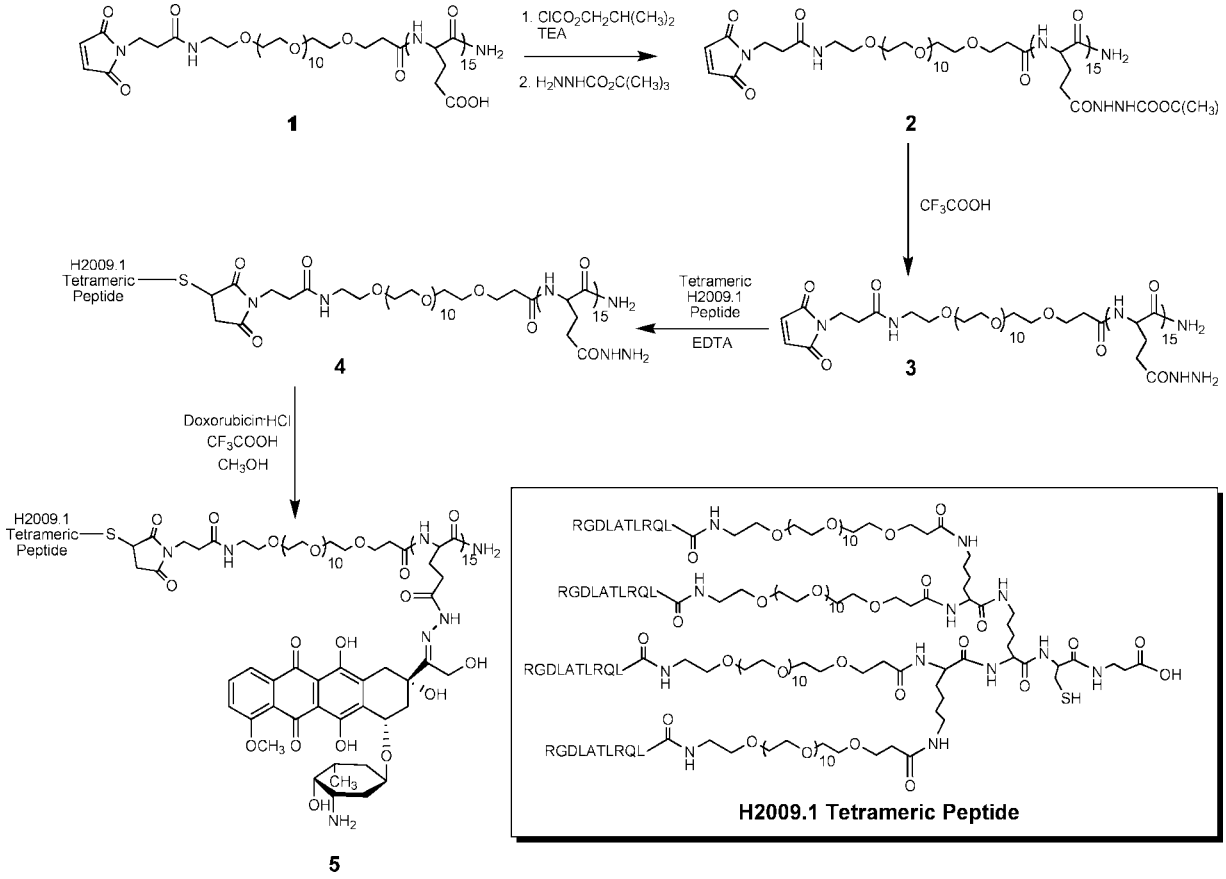
contrast, higher levels of doxorubicin accumulate in $\alpha_v\beta_6$-integrin positive H2009 cells (panel D) than in H1299 cells (panel B) when treated with compound 5. However, most of the drug appears to be perinuclear in the H2009 cells, suggesting that the release kinetics of the drug from the conjugate may be slower in living cells than expected from the *in vitro* incubation at pH 4.0 and 5.6.

DISCUSSION

Targeted therapeutic strategies for the treatment of solid tumors are dependent on the availability of high affinity and specificity ligands for cell surface cancer biomarkers as well as appropriate drug carriers which can deliver potent therapeutics in an active form. Toward this goal, we have synthesized a targeted polyglutamic acid-doxorubicin conjugate. This com-

Scheme 1. Synthesis of Targeted PG-Doxorubicin Conjugate[a]



[a] The structure of the tetrameric H2009.1 peptide is shown in the inset.

pound incorporated the high affinity $\alpha_v\beta_6$-specific tetrameric H2009.1 peptide at the N-terminus of a 15 amino acid polymer of glutamic acid. Four doxorubicin molecules per peptidic targeting reagent are attached via an acid labile hydrazone. The conjugate is preferentially internalized into $\alpha_v\beta_6$ positive cells as witnessed by flow cytometric analysis and fluorescent microscopy. Cellular uptake is mediated by the H2009.1 peptide as less internalization of the doxorubicin-PG polymer is observed when it is conjugated to a scrambled sequence control peptide. Importantly, the conjugate is 2-fold more cytotoxic toward a targeted cell than a cell line that does not express the integrin.

Water soluble polymers as drug carriers have received much attention for the treatment of solid tumors (*34, 35*). These large molecular weight polymers offer several advantages over the use of nonconjugated therapeutics. First, the polymers can overcome the poor solubility associated with hydrophobic compounds. Second, the blood half-life of the drugs is often extended from minutes to hours or days, allowing the compound time to reach its target. Last, the polymer accumulates preferentially in the tumor because of the inherent leakiness of the tumor vasculature and is retained at this site because of the lack of a functional lymphatic system within the tumor. Passive targeting as a result of EPR effect increases the drug concentration in the tumor relative to other tissues.

Several different polymers have been explored as drug carriers (*34, 35*). Most prevalent are poly(ethylene glycol) (PEG), *N*-(2-hydroxypropylmethacrylamide) (HPMA) (*36*−*38*), and polyglutamic acid (PG) (*4*). Of these, only PG is biodegradable. As such, PEG and HPMA polymers must be kept under the size required for renal clearance. A variety of polymer−drug conjugates are in different stages of clinical trials (*35*). In addition to the nature of the polymer, the linkage between the drug and polymer plays an important role in the efficacy of the treatment (*28, 37*). Typically, one of three approaches have been employed: conjugation of the drug through a peptide linkage that is cleaved by endosomal and lysosomal proteases such as cathepsin-B (*37, 39*), attachment via an acid labile hydrazone that is cleaved in the acidic environment of the endosome and lysosome (*28, 37*), or by esterification (*4*). In the case of the hydrazone or peptidyl linkers, release of the drug requires cellular uptake of the polymer. However, in the case of the ester conjugate found in XYOTAX, release of the drug occurs in the extracellular space; the antitumor efficacy is greater due to the long dwell time of the polymer within the tumor (*4*).

Toward the goal of cell-targeted therapeutics, cell-specific targeting agents have been incorporated into polymeric drug carrier compounds (*5, 33, 40*−*43*). Most have conjugated an antibody to a tumor associated biomarker into the polymer itself. Increased efficacy is observed for the targeted polymeric carrier when compared to the corresponding nontargeted polymers. In some cases, extended survival is observed in animal models, albeit with nonsolid tumor models (*37, 42*). However, conjugation of antibodies or other targeting agents such as peptides or small molecules through the side chains of the polymers can be problematic; it is difficult to control the coupling efficiency of the antibody, it reduces the total drug load by using available coupling sites, and aggregation can occur. To address these problems, Li and co-workers attached an antibody to the epidermal growth factor receptor (EGFR) to the N-terminus of a PG-doxorubicin polymer (*5*). A PEG moiety was placed between the PG and the antibody. As such, a single targeting agent was incorporated in a chemospecific fashion. Uptake of the drug carrier was observed in an EGFR positive cell line, while minimal internalization was observed in NIH3T3 fibroblasts. Importantly, the construct was able to affect cell death.

It should be noted that doxorubicin was conjugated via an amide in this PG polymer, yet nuclear localization of doxorubicin was observed. The mechanism for the nuclear accumulation is unknown, but because of the rapid time frame in which it occurs, it is unlikely to be due to hydrolysis from the polymer.

While the larger polyglutamic acid polymers are often retained in tumors due to the EPR effect and have potentially higher drug capacity, we chose to focus on a defined 15 amino acid polymer. Smaller conjugates are expected to demonstrate better tumor penetration. Additionally, the smaller peptide is easier to modify in a regiospecific fashion. However, the tradeoff is lower drug loading capacities. Additionally, the tumor accumulation due to EPR may be less. On the other hand, the ease in which a tumor targeting agent can be incorporated into the polymer is a benefit, and active targeting can potentially be enhanced by more efficient escape from the vasculature and increased diffusion into the core of the tumor. Further *in vivo* experiments will be required to address the role of passive versus active targeting and tumor penetration of the smaller polymers.

The tumor targeting agent employed in this case is the tetrameric peptide H2009.1 which displays high affinity for $\alpha_v\beta_6$ (*2, 3*). This peptide does not bind to other RGD-binding integrins and has a half-maximal cell binding affinity in the 40−60 pM range. The integrin $\alpha_v\beta_6$ is emerging as an appealing cancer biomarker for targeted therapy. Expression of the β_6 subunit is restricted to epithelial cells, and its expression is low or undetectable in most normal adult primate tissues (*44*). This integrin is up-regulated in a variety of epithelial derived malignancies, including lung, oral, colon, breast, and ovarian cancers (*3, 45*−*49*). Expression of $\alpha_v\beta_6$ correlates with features found in more aggressive tumors, such as enhanced cell migration and invasion (*50*−*53*). β_6 expression is predictive of reduced survival time for patients with nonsmall cell lung carcinoma (*3*) and colorectal cancer (*54*). Thus, this targeting peptide is anticipated to have utility in molecular guided therapies for these aggressive tumor types.

While uptake of compound 5 is greater for cell line expressing $\alpha_v\beta_6$, the difference is only 2-fold, as observed by flow cytometry. Additionally, the conjugate is only 2-fold more cytotoxic toward H2009 cells compared to H1299 cells. However, it should be noted that there is a 60 fold difference in binding of the H2009.1 peptide for H2009 cells compared to the H1299 cells, when comparing binding of the individual peptide-displayed phage clones (*1*). This suggests that the polyGlu-doxorubicin portion of the molecule may dampen the selective uptake of the peptide by contributing to non-$\alpha_v\beta_6$ dependent cellular uptake. The flow cytometry data supports this, as some uptake of the conjugate containing the scramble control peptide is observed for both H1299 and H2009 cells. However, the cellular uptake of the nontargeted conjugate is substantially less than the freely cell permeable doxorubicin, and as such, there is a widening of the therapeutic index.

The cytotoxicity of compound 5 is less than that of free doxorubicin. The reduced efficacy of the conjugate is most likely due to a combination of reduced uptake of the conjugate compared to a cell permeable small molecule and poor release of the drug from the polymer scaffold. Flow cytometry shows that uptake of the conjugate is less than that of the free drug for the targeted cells. This is not uncommon for targeted drug conjugates. This limitation can be overcome by increasing the drug loads further or by moving to more cytotoxic agents. For example, the first line treatment of NSCLC usually employs paclitaxel whose IC_{50} is 40-fold lower than that of doxorubicin for H2009 cells (personal communication, Drs. John D. Minna and Michael Peyton). However, it should also be noted that the fluorescence of doxorubicin is 2-fold less when conjugated to the polymer compared to free doxorubicin (data not shown). As these studies were performed at 2 h, in which time little doxorubicin is released from the polymer, the total uptake of the polymer conjugated drug will be underestimated by fluorescence experiments. However, the differences in MFI cannot be accounted for by this effect alone, suggesting that the targeted polymer cannot deliver as much doxorubicin to H2009 cells as when the cells are treated with free drug.

Perhaps more importantly, microscopy reveals that the drug is perinuclear. This suggests that the drug is not being efficiently released from the conjugate and moving into the nucleus where it exerts its primary effect. While others have shown that doxorubicin hydrazones are hydrolyzed within the cell (*28, 37, 55*), hydrolysis from this conjugate may not occur within the appropriate time frame. The linker type, linker length, and mechanism of cellular uptake have been shown to influence the release of the drugs from polymeric carriers (*28*). This suggests that further optimization of the drug tether is required before progressing to *in vivo* experiments.

In summary, we have completed the synthesis of an integrin targeted polyglutamic acid-doxorubicin conjugate using a peptide that is highly specific for the tumor biomarker, $\alpha_v\beta_6$. To our knowledge, this is the first targeted polyglutamic acid drug conjugate which employs a peptidic targeting agent, and the only one that utilizes an acid labile linker between the therapeutic and polymer. This compound exhibits integrin specific cytotoxicity. Future work in lowering the background uptake of the polyglutamic acid-doxorubicin conjugates and improvement of the drug release by optimizing the linker will be required to improve the therapeutic properties of this compound.

ACKNOWLEDGMENT

We thank Bethany Gray for insightful discussions and critical reading of the manuscript. This work was supported by the NIH (1RO1CA106646) and the Welch Foundation (I1622). This paper represents publication # CSCN034 from the Cell Stress and Cancer Nanomedicine Program of the Simmons Comprehensive Cancer Center.

Characterization of and Mechanism for Copper-Induced Thioureation of Serum Albumin

Yu-Wei Wu[†] and Yu-Hui Tsai*[,†,‡]

Graduate Institute of Pharmacy and Graduate Institute of Medical Sciences, Taipei Medical University, Taipei, Taiwan. Received November 10, 2007; Revised Manuscript Received July 30, 2008

Thioureas (Tus) are widely used in chemical and pharmaceutical industries. This study demonstrated that copper induced the disulfide-linkage between Tus, such as α-naphthylthiourea (ANTU) and fluorescein-5-isothiocyanate cadaverine (FTC), with albumin (Alb), a major carrier protein in plasma with multiple functions. This reaction was absolutely copper-dependent, whereas cobalt, nickel, calcium, magnesium, zinc, iron, and manganese ions could not induce the same reaction. The reaction was substrate dose-dependent, and occurred optimally at pH 6.5. The resulting conjugated product was heat-labile, but stable in pH 6.0−8.0 buffer at 25 °C. The linkage could be reduced by Cu(I) (in acidic pH) and thiol-reducing agents. The mechanism of albumin thioureation was concluded: (i) the binding of Cu(II) with albumin is not necessary for the reaction, while the formation of Tus-Cu(II) complex is essential; (ii) thioureation resulted from the attack of Tus-Cu(II) at Alb-Cys^{34}-SH to form the Alb-Cys^{34}-S-S-Tus complex accompanied by the release of Cu(I); (iii) the released Cu(I) would back inhibit the reaction because of its competition with Cu(II) for Tus binding. These phenomenons may have important implications for the pharmacokinetics of thiourea-based drugs in plasma.

INTRODUCTION

Thiourea (Tu[1]) and its derivatives are widely used in chemical, agricultural, metallurgical, and pharmaceutical industries (*1*). Exposure of human and animals to Tu-containing compounds has been considered as an environmental risk factor that may cause various illnesses such as thyroid hyperplasia, pulmonary edema, pleural effusion, tumors, and so forth (*1*−*3*). Physiologically, Tu is absorbed from the gastrointestinal tract in humans and animals and is mostly excreted unchanged in urine (*1*, *4*). The accumulation of radiolabeled Tu in rats was found mainly in thyroid tissue and to a lesser degree in the kidney, blood cells, lung, and liver (*4*, *5*). The metabolism of Tu in the thyroid gland and liver is quite different. In the thyroid gland, Tu is oxidized by thyroid peroxidase to form dithioformamidine (Tu-S-S-Tu), which is later decomposed to cyanamide, sulfur, and Tu. Both Tu and cyanamide are inhibitors of thyroid peroxidase and finally lead the dysfunction of the thyroid gland (*6*). In the liver, Tu is metabolized to formamidine sulfenate and formamidine sulfinate by microsomal flavin-containing monooxygenase (FMO)-catalyzed S-oxygenation (*7*). In addition, radiolabeled Tu was found covalently and nonenzymatically binding to thyroid and lung proteins (*8*, *9*). The binding of Tu to thyroid proteins resulted from thiol−disulfide exchange between the thiol of Tu with the intramolecular disulfide bridge of proteins to form the protein−S-S-Tu complex. The complex was finally hydrolyzed to protein−S-SH and urea (*8*).

Tu is known to interact with sulfhydryl-containing compounds such as cysteine or glutathione in vitro (*10*, *11*). The oxidation of cysteine catalyzed by Tu in the presence of hydrogen peroxide in acid solution was illustrated in reactions A and B. The formation of the Cys-S-S-Tu complex was found in the reaction of cysteine with equimolar or excess amount of dithioformamidine (Tu-S-S-Tu) (reaction C). Cys-S-S-Tu was also produced by reacting cysteine with Tu (reaction D). Finally, the Cys-S-S-Tu formed in reactions C and D was spontaneously hydrolyzed (reaction E).

$$2\text{Tu} + \text{H}_2\text{O}_2 \rightarrow \text{Tu-S-S-Tu} + 2\text{H}_2\text{O} \quad \text{(A)}$$

$$2\text{Cys-SH} + \text{Tu-S-S-Tu} \rightarrow \text{Cys-S-S-Cys} + 2\text{Tu} \quad \text{(B)}$$

$$\text{Cys-SH} + \text{Tu-S-S-Tu} \rightarrow \text{Cys-S-S-Tu} + \text{Tu} \quad (\text{Tu-S-S-Tu} \geq \text{Cys-SH}) \quad \text{(C)}$$

$$\text{Cys-S-S-Cys} + \text{Tu} \rightarrow \text{Cys-S-S-Tu} + \text{Cys-SH} \quad \text{(D)}$$

$$\text{Cys-S-S-Tu} + \text{H}_2\text{O} \rightarrow \text{Cys-SOH} + \text{Tu} \quad \text{(E)}$$

The protective role of thioureas (Tus) was found in the clearance of free radicals (*12*−*14*). In addition, Tus were known to interact with miscellaneous metal ions including copper (*15*−*17*). It was speculated that the binding of copper with Tu may protect cells from copper-induced oxidative damage (*18*). In pharmaceutical applications, Tu-containing compounds are designed as anti-HIV drugs (*19*), high-density lipoprotein (HDL)-elevating agents (*20*), appetite suppressants (*21*), and so forth. Some of these compounds were found to hydrophobically interact with albumin (*22*, *23*).

Albumin is the most abundant protein in blood plasma with miscellaneous functions. Human serum albumin (HSA) itself is a 67 KD single chain protein with 35 cysteine residues; however, it has only one free thiol group of cysteine residues at position 34 (Cys^{34}); the other 34 cysteine residues form 17 disulfide bridges for its tertiary structure. HSA with the free thiol in Cys^{34}, known as mercaptoalbumin, is capable of

participating in numerous redox reactions. Albumin is known to bind small molecules of many types. Metal ions such as copper, nickel, cobalt, zinc, and so forth are carried by albumin. Endogenous and exogenous ligands, metabolites, and drugs are generally bound to Sudlow's site-I or site-II of albumin, with some exceptions (*24*−*26*). In addition, covalent interactions with albumin including glycosylation (*27*), acylation (*28*), thiolation (*29*, *30*), S-nitrosation (*31*, *32*), and N-homocysteinylation (*33*) are also found. Thiolation of HSA (HSA-S-R) occurs at Cys^{34} with low molecular weight thiol-containing substances (e.g., cysteine, homocysteine, glutathione, and drugs such as cisplatin, D-penicillamine, and *N*-acetyl-cysteine) via disulfide bridge formation (*24*−*26*). Thiolation of albumin has not been previously reported as a copper-dependent reaction; however, a fast S-nitrosation of albumin was mediated by copper (*32*).

In our previous study, a charcoal-based fluorescence assay (CFA) was developed to rapidly analyze the incorporation of small fluorescent molecules into large protein molecules (*34*). By using the method, a copper-dependent FITC-binding protein was found in human plasma. This protein was subsequently purified and identified as albumin (*35*). The mechanism of copper-induced albumin thioureation was proposed, evaluated, and established in this study. Furthermore, the importance of this finding is discussed.

EXPERIMENTAL PROCEDURES

Materials. Essentially fatty acid free, globulin free albumin with 99% in purity from human (HSA; A3782), bovine (BSA; A0281), and porcine (PSA; A1173) sera were purchased from Sigma-Aldrich (St. Louis, MO, USA). Recombinant human serum albumin (rHSA), containing 584 amino acid residues with a single deletion at Asp^1 residue that reduces its binding affinity for copper and nickel, was from United States Biological (Swampscott, MA, USA). Fluorescein-5-isothiocyanate cadaverine (FTC) and fluorescein-5-carboxamide cadaverine (FCC) were from AnaSpec, Inc. (San Jose, CA, USA). BioMag magnetic dextran-coated charcoal (MD-Charcoal) concentrate (40 mg/mL, approximately 1.5 μm particle size) was supplied by Bangs Laboratories, Inc. (Fishers, IN, USA). Other chemicals used were of analytical grade from either Sigma-Aldrich, or Merck (Darmstadt, Germany), unless otherwise stated.

NHS-activated Sepharose 4 Fast Flow media were from Amersham Biosciences AB (Uppsala, Sweden). The ultrafiltration unit was from Millipore (Bedford, MA, USA). V96 microwell plate (#249945) was from Nalge Nunc International (Rochester, NY, USA). Slot blot manifold (Hoefer PR648) was from Hoefer, Inc. (San Francisco, CA, USA).

Stocks of 1 mM FTC, FCC, and dansylcadaverine (DC) were dissolved in 20% dimethyl sulfoxide and stored at 4 °C till use. Cuprous chloride (CuCl) of 10 mM was freshly prepared in 50 mM HCl. L-Cystine was prepared as 1 mM stock solution in 50 mM HCl. Solution of 50 mM neocuproine (NCP) was dissolved in 50% methanol. MD-Charcoal concentrate was 5-fold diluted with water and stored at 4 °C for subsequent application. The water used in this study was prepared by the Milli-Q system (Millipore, Bedford, MA, USA).

Modification of Albumin. Albumin used in this study was mercaptoalbumin (Alb-Cys^{34}-SH) unless otherwise stated. Mercaptoalbumin preparation was modified from a previous publication (*36*). Briefly, 1 mM HSA (or BSA, PSA, and rHSA) in sodium phosphate buffer (0.1 M Na_2PO_4, pH 6.86, 0.3 M NaCl, and 1 mM EDTA) was treated with 5 mM DTT at 25 °C for 45 min. The phosphate buffer of the specimen was then changed to HBS buffer (10 mM Hepes-pH 7.0, 0.15 M NaCl) by dialysis at 4 °C. One mole of albumin was confirmed to contain 1 mol of free thiol by Ellman's method (*37*).

Alkylation of albumin (Alk-HSA) was performed according to Glowacki et al. with modification (*33*). Briefly, 1 mM iodoacetamide was incubated with 0.1 mM human mercaptoalbumin containing 0.1 M Hepes-pH 7.5 and 0.2 mM EDTA at 37 °C for 2 h. The buffer of resulting products was changed to HBS buffer by dialysis at 4 °C. Free thiol content of Alk-HSA was calculated to be 0.13 (M/M).

For cysteinylation, human mercaptoalbumin (50 μM) was treated with 1 mM L-cystine in 0.1 M Hepes-pH 7.5 buffer containing 0.1 mM EDTA at 37 °C for 21 h. The mixture was subject to HBS buffer exchange by using a 30 K ultrafiltration unit (Amicon Ultra-15). This protein product (50 μM) was further treated with 1 mM IAN in 0.1 M Hepes-pH 7.5 buffer containing 0.1 mM EDTA at 37 °C for 3 h. The buffer of the protein was changed to HBS buffer as described above. This protein product was termed Cys-HSA. To determine the extent of albumin cysteinylation, Cys-HSA (165 μM) was treated with 5 mM DTT at room temperature for 45 min. The buffer of the reduced protein was changed to HBS buffer again as described above. The product from this step was termed r-Cys-HSA (thiol-reduced Cys-HSA). Free thiol content for Cys-HSA and r-Cys-HSA was calculated to be 0.08 and 0.50 (M/M), respectively. The contents of r-Cys-HSA and Cys-HSA were thus estimated as follows: r-Cys-HSA contained Alb-SH (∼50%) and Alk-HSA (∼50%); Cys-HSA contained Alb-SH (∼8%), Alb-S-S-Cys (∼42%), and Alk-HSA (∼50%).

Analysis of Ligand-Binding by CFA. A high-throughput CFA method modified from our previous publication was used to analyze the binding capacity of albumin for fluorescent dyes (see Supporting Information, Figure 1) (*34*). Typically, 30 μL per well of protein samples (2 μM HSA, unless otherwise stated) dissolved in HBS buffer (10 mM Hepes-pH 7.0, 0.15 M NaCl) were added to microplates at 4 °C. After 30 μL of freshly prepared reagent-A (100 mM Hepes-pH 7.0, 0.2 mM $CuCl_2$, and 6 μM FTC) was added into each well, the reaction was initiated by incubating the microplate in a 37 °C humidified incubator for 10 min and terminated by adding 60 μL of reagent-B (2 mM EDTA, 0.5 M Hepes-pH 8.0; 4 °C). Suspended MD-Charcoal (200 μL per well) was then added and incubated at room temperature for 5 min to remove all of the free fluorescent dyes. After precipitating MD-Charcoal by magnet for 1 min, the fluorescence intensity in each well was measured by a microplate reader (Plate Chameleon, Hidex Oy, Finland) with excitation wavelength setting at 485 nm and emission wavelength at 535 nm (Ex485/Em535); gain 35. Transfer of supernatant to a new plate for fluorescence counting is not necessary because the precipitated MD-Charcoal did not influence the fluorescence in the supernatant. Background level of fluorescence intensities were measured by replacing protein samples with HBS buffer. The binding capacity of albumin for fluorescent dye was expressed as net or relative fluorescence (fluo.) intensity per reaction. All experiments were performed in triplicate for each datum point, and the data were presented as the means ± SD.

In addition, supplementation of metal ions or small molecules such as cysteine, NCP, and so forth in the reaction mixture did not influence fluorescence counting by using our assay system (see Supporting Information Figures 2 and 3).

Beads Preparation. Tu- and Cys-beads were prepared by coupling each ligand with NHS-activated Sepharose 4 matrix. In detail, Tu (0.1 M) or cysteine (0.1 M) dissolved in PBS buffer (137 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, and 2 mM KH_2PO_4, pH 7.4) was mixed with equal volume of the drained NHS-activated Sepharose 4 Fast Flow media at 25 °C for 2 h with constant shaking. The resulting matrix was washed with basic buffer (0.5 M Tris, pH 9.0, and 0.5 M NaCl) and then with acidic buffer (0.1 M acetate and 0.5 M NaCl, pH 4.0) for 3 cycles. Finally, these beads were washed with HBS buffer

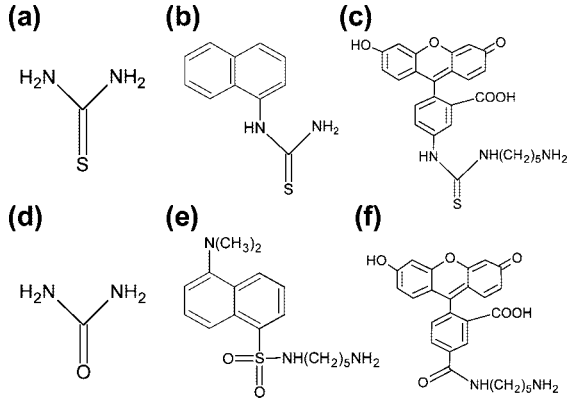

Figure 1. Chemical structures of Tu derivatives and analogues. (a) Tu; (b) ANTU; (c) FTC; (d) urea; (e) DC; (f) FCC.

and stored at 4 °C. The Cys-bead was treated with 10 mM DTT at 25 °C for 30 min before use.

Alkylation of the Cys-bead (Alk-Cys-bead) was performed by incubating the bead with an equal volume of 10 mM iodoacetamide at 37 °C for an hour with shaking. The bead was then washed with HBS buffer and stored at 4 °C.

Copper pretreated Tu- or Cys-beads were produced by mixing the Tu- or Cys-beads with an equal volume of 5 mM $CuCl_2$ at 25 °C for 15 min with constant shaking. After supplementation with 20 mM EDTA, the beads were then washed with HBS buffer and then stored at 4 °C till use.

Formation and Purification of the HSA−FTC Complex. The HSA−FTC complex was produced by reacting 2 μM human mercaptoalbumin with an equal volume of reagent-A (100 mM Hepes-pH 7.0, 0.2 mM $CuCl_2$, and 6 μM FTC) at 37 °C for an hour. After supplementation with 2 mM EDTA, the protein fraction was concentrated, and the buffer was changed to HBS buffer by ultrafiltration using a 10 kDa cutoff filter device. The resulting product (0.72 mg/mL) was stored at 4 °C till use within 24 h.

RESULTS

Copper-Induced Specific Binding of Tus to HSA. The analysis of albumin-bound fluorescent dyes was performed by CFA. As shown in Figure 2, no dyes bound to HSA unless copper was added. By comparing the structural analogues (ANTU versus DC, and FTC versus FCC), HSA-bound fluorescent dyes, either ANTU or FTC, have similar Tu functional groups (Figure 1). Thus, the Tu group is speculated to interact with albumin upon copper induction. FTC was selected for subsequent HSA binding analyses. The coupling reaction showed a positive dose-dependence on HSA, FTC, and copper contents (Figure 3).

Disulfide Bridge Formation between Tus and Cysteine. To identify the type of linkage between HSA and FTC, the purified HSA−FTC complexes were treated with/without NaCl, urea, DTT, or SDS (Figure 4a). While urea- or SDS-treatment damaged up to 40% of complexes, DTT-treatment almost eliminated the fluorescence signal of protein fractions (>90%). This indicates that the linkage between HSA and FTC is a disulfide bond. In addition, a high concentration of salt (1 M NaCl) did not significantly influence the stability of HSA−FTC complexes.

To confirm that thioureation occurred at the Cys^{34} residue of albumin, Cys^{34}-modified albumins, Cys-HSA, r-Cys-HSA, or Alk-HSA, were employed in the reaction (Figure 5). The binding capacity of FTC with Cys-HSA, r-Cys-HSA, or Alk-HSA corresponded to their free thiol content, as compared to that with HSA. In addition, the interaction of cysteine with FTC

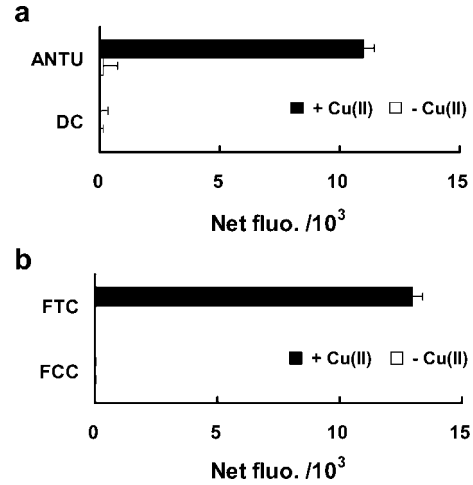

Figure 2. Analysis of copper-induced binding using the CFA method. Aliquots of 60 μL of reaction mixture containing (a) 7.52 μM HSA, 30 μM ANTU (or dansyl-cad), 50 mM Hepes-pH 7.0, with/without 0.1 mM $CuCl_2$, or (b) 1 μM HSA, 3 μM FTC (or FCC), 50 mM Hepes-pH 7.0, with/without 0.1 mM $CuCl_2$, were incubated at 37 °C for 30 or 10 min, respectively. After the addition of equal volume reagent-B (2 mM EDTA, 0.5 M Hepes-pH 8.0), unbound fluorescent dyes were removed by MD-Charcoal (0.2 mL/well). MD-Charcoal was precipitated, and the fluorescence intensities were measured at Ex340/Em460 for ANTU, Ex340/Em353 for dansyl-cad, and Ex485/Em535 for FTC and FCC. Gain value was set at 35. Data presented are the means ± SD ($n = 3$).

was also further confirmed by using the Cys-bead and Alk-Cys-bead in copper-induced reaction (Figure 4b). Similar to albumin, the Cys-bead interacts with FTC through the disulfide bond, as compared to that with Alk-Cys-bead (as control).

Furthermore, the Tu-bead was also used to confirm the participation of the Tu group of FTC in disulfide bridge formation, and the Cys-bead was used as the control (Figure 4c). In the presence of copper, HSA was also found to form a disulfide bond with the Tu-bead. The same phenomenon was also observed for Cys-beads. In the absence of copper, however, only the Cys-bead that was pretreated with copper could bind HSA. The mechanism of copper-induced cysteinylation appears different from that of copper-dependent thioureation of HSA.

The Influence of Ligand-Binding for Albumin Thioureation. Various reagents were evaluated for their effects on the formation of the HSA−FTC complex by the CFA method (Table 1). It was found that free thiol-containing molecules, such as NAC and cysteine, greatly reduced the binding of HSA with FTC, while cystine and GSSG had no significant effect. Because cysteine was also observed to interact with FTC under copper treatment (Figure 4b), the inhibitory effects of free thiol-containing molecules are speculated to compete with HSA for interacting with the Tu-Cu(II) complex. As expected, Tu and ANTU competed with FTC for HSA-binding as compared to the Tu analogue, urea. The competition of Tu was not as effective as ANTU. In addition, dansylglutamine and dansylglycine, the site I and II binding probes of albumin (*25*), respectively, did not affect the interaction of FTC with HSA.

The Effect of pH on Thioureation. Copper-induced HSA−FTC complex formation was greatly influenced by the pH of the reaction solution (Figure 6a). The optimal pH for the reaction was pH 6.5. Above pH 6.5, the reaction was gradually reduced with increasing pH and is completely abolished at pH above 8.0. The relative initial reaction rate constants of reactions at various pH values were also calculated (Figure 6b), and the kinetic data did support the observations shown in Figure 6a. In the absence of albumin, the interaction between FTC and Cu(II) was also influenced by pH (Figure 6c). Upon Cu(II) supplementation, the fluorescence intensity of FTC is severely

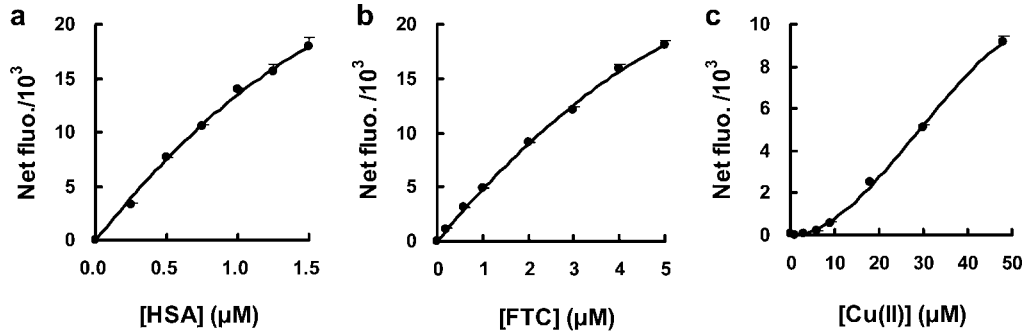

Figure 3. Dose dependence of HSA, FTC, and $CuCl_2$ for albumin thioureation. Reaction mixtures containing (a) HSA (0−1.5 μM), 3 μM FTC, 0.1 mM $CuCl_2$, and 50 mM Hepes-pH 7.0; (b) FTC (0−5.0 μM), 1 μM HSA, 0.1 mM $CuCl_2$, and 50 mM Hepes-pH 7.0; or (c) $CuCl_2$ (0−48 μM), 1 μM HSA, 3 μM FTC, and 50 mM Hepes-pH 7.0 were incubated at 37 °C for 10 min and analyzed by the CFA method as described in Experimental Procedures. Data presented are the means ± SD (n = 3).

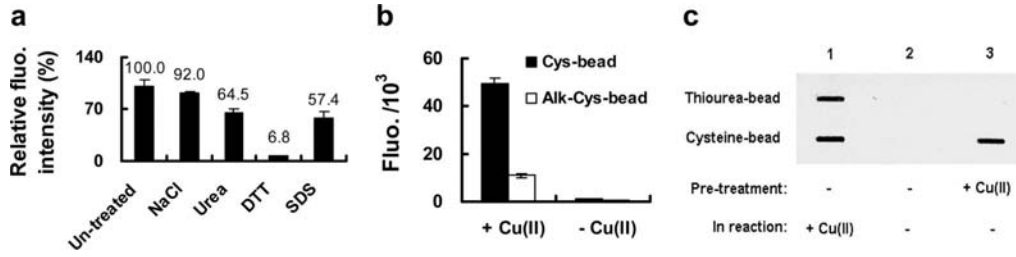

Figure 4. Disulfide bridge formation between (a) HSA and FTC; (b) cysteine and FTC; and (c) HSA and Tu. In (a), 28 μg of HSA−FTC complex in HBS buffer was treated with 1 M NaCl, 3 M urea, 5 mM DTT, or 0.1% SDS, separately, at 37 °C for 15 min. The mixtures were then ultrafiltrated using Microcon YM-30 tubes. Protein fractions were collected in microplates and adjusted to pH 8.0 for fluorescence counting. In (b), Cys-beads or Alk-Cys-beads (drained volume = 30 μL/reaction) after reaction with 3 μM FTC (in 50 mM Hepes-pH 7.0) in the presence or absence of $CuCl_2$ (0.1 mM) at 37 °C for 30 min were washed with 0.5 M NaCl (in 10 mM Hepes-pH 7.0) and then treated with 5 mM DTT at 25 °C for 15 min. The supernatants supplemented with 50 mM Hepes-pH 8.0 were measured for fluorescent intensities to assess the bound FTC molecules. In (c), reaction mixtures containing HSA (0.5 mg) and Tu- or Cys-beads (0.1 mL drain matrix) with/without 2 mM $CuCl_2$ were incubated at 25 °C for 30 min. Copper-pretreated Tu- or Cys-beads were also tested for HSA binding in the absence of copper. The copper-containing reaction was terminated by adding 2 mM EDTA. After washing with 0.5 M NaCl (in 10 mM Hepes-pH 7.0), the bead-bound proteins were eluted with DTT followed by slot blotting the eluted proteins onto nitrocellulose membranes. The existence of protein on the membrane was visualized by a MemCode reversible protein stain kit (Pierce Biotechnology, Rockford, IL, USA).

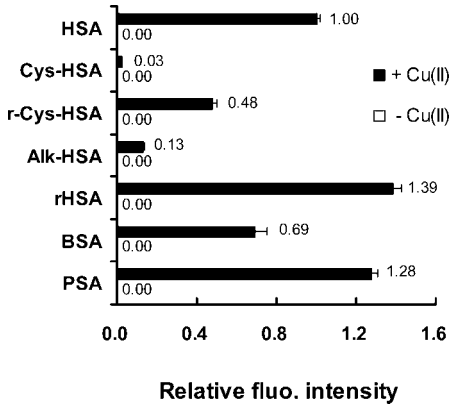

Figure 5. Evaluation of FTC binding capacity by various albumins. Various albumins (1 μM) were incubated with 3 μM FTC, 0.1 mM $CuCl_2$, and 50 mM Hepes-pH 7.0 at 37 °C for 10 min. The copper-induced coupling reactions were assessed by the CFA method as described in Experimental Procedures. The fluorescence intensity of each was calculated relative to that of HSA. Data presented are the means ± SD (n = 3). The calculated free thiol content for mercaptoalbumin (HSA, rHSA, BSA, or PSA), Cys-HSA, r-Cys-HSA (thiol-reduced Cys-HSA), and Alk-HSA were 1.00, 0.08, 0.50, and 0.13 (M/M), respectively.

Table 1. Influence of Thiol-Containing Agents, Tu Analogues, Ligands, and Cu(I) on HSA−FTC Complex Formation[a]

[a] Various reagents were included in the reaction of 1 μM HSA, 3 μM FTC, 0.1 mM $CuCl_2$, and 50 mM Hepes-pH 7.0. The complex formation of HSA−FTC was analyzed by the CFA method, and shown as relative fluorescence intensities comparing to control (no reagents added). Data represents the means ± SD (n = 3).

quenched (ΔQ). However, the fluorescence of the FTC−Cu(II) mixture is greatly enhanced (ΔH_1) with increasing pH above 7.5, as compared to that observed in the absence of copper (ΔH_2). The increased fluorescence intensity (ΔH_1) at high pH was speculated to be the result of the dissociation of FTC from Cu(II) ions.

Participation of Metal Ions in Thioureation. Various metal ions (0.1 mM in reaction), including CuCl, $CuCl_2$, $CoCl_2$, $NiCl_2$, $CaCl_2$, $MgCl_2$, $ZnCl_2$, $MnCl_2$, $FeCl_2$, and $FeCl_3$, were tested for Alb−FTC complex formation by using the CFA method. As shown in Figure 7, only Cu(II) induced the thioureation reaction among various metal ions; the small amplitude of the

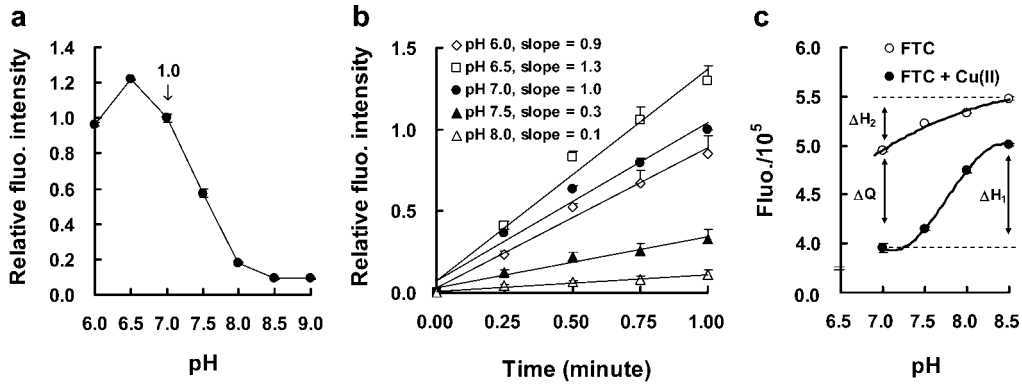

Figure 6. pH effect on Alb−FTC complex formation. (a) Reaction mixtures as described in Figure 5 were incubated at various pH values at 37 °C for 10 min to evaluate the influence of pH on the formation of the Alb−FTC complex. (b) The kinetics of the reaction at various pH values. Reactions at various pH values (pH 6.0−8.0) were performed at 37 °C for designated time intervals (0−60 s). The fluorescence intensity of the reaction at pH 7.0 for 1 min was set as 1.0, and the relative initial rate was calculated. The slopes of the trend lines of the reaction data points at various pH values correspond to the relative rate constants for the reactions. (c) The effect of pH on the interaction between Cu(II) and FTC. The fluorescence intensities of 3 μM FTC with/without 0.1 mM $CuCl_2$, in 50 mM Hepes at various pH values, were measured to assess the interaction between FTC and Cu(II). Data presented are the means ± SD ($n = 3$). ΔQ: quenched fluorescence intensity of FTC upon the addition of Cu(II). ΔH_1: increased fluorescence intensity of the FTC−$CuCl_2$ mixture with increasing pH. ΔH_2: increased fluorescence intensity of FTC with increasing pH.

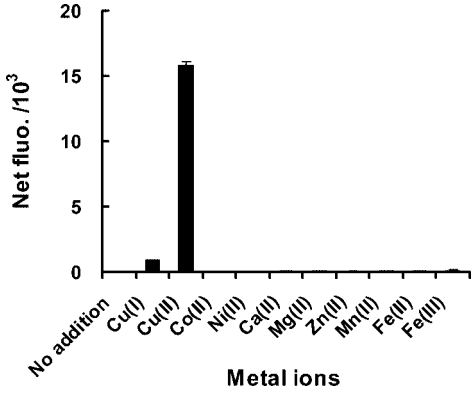

Figure 7. Necessity of metal ions for thioureation. Various metal ions (0.1 mM) incubated with 1 μM HSA, 3 μM FTC, and 50 mM Hepes-pH 7.0 at 37 °C for 10 min were analyzed by the CFA method as described in Experimental Procedures. Data presented are the means ± SD ($n = 3$).

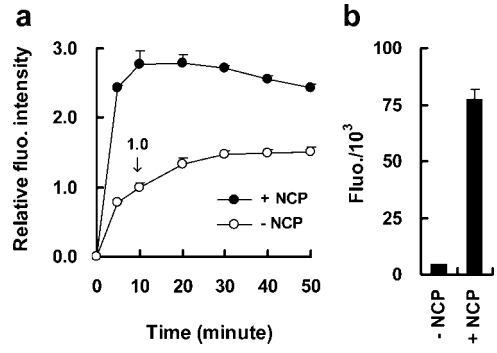

Figure 8. Effect of NCP on thioureation of HSA. (a) Reaction mixtures as described in Figure 5 were incubated at 37 °C in the presence or absence of NCP for indicated time-intervals. The relative fluorescent intensities were calculated relative to that of the 10-min reaction without NCP treatment. (b) Drained Cys-beads (30 μL) supplemented with 30 μL of HBS buffer and 30 μL of reagent-A (100 mM Hepes-pH 7.0, 0.2 mM $CuCl_2$, and 6 μM FTC), with/without 0.1 mM NCP, were incubated at 37 °C for 15 min. After the addition of 2 mM EDTA, the beads were washed with HBS buffer. Bead-bound FTC was finally eluted with 5 mM DTT (dissolved in 0.1 M Hepes-pH 8.0) and subjected to fluorescence measurement. Data presented are the means ± SD ($n = 3$).

Cu(I)-induced reaction may result from the oxidation of Cu(I) to Cu(II) during material preparation. The necessity of Cu(II) for thioureation was demonstrated by the dose-dependent reaction (Figure 3c), and the reduction of Cu(II) to Cu(I) during thioureation processes was speculated. NCP, a specific Cu(I) chelator, was used to confirm the formation of Cu(I). In the presence of NCP, the formation of HSA−FTC is greatly enhanced and reaches its plateau within 10 min as compared to that observed in the absence of NCP (Figure 8a). Similarly, the cross-linking of FTC with cysteine (which was evaluated by Cys-beads) was also elevated by NCP treatment (Figure 8b). In addition, the supplement of Cu(I) did decrease the Cu(II)-induced formation of HSA−FTC complexes (Table 1). These results implied that Cu(I) was a byproduct associated with the Cu(II)-induced thioureation of Cys^{34} of albumin and that the released Cu(I) would back inhibit thioureation.

Stability of Thioureated Products. The purified HSA−FTC complex was used for stability evaluation (Figure 9). This product appears stable at 25 °C, pH 7.0, within an hour but is unstable with increasing temperature (Figure 9a). As to the pH effect, the HSA−FTC complex was stable at pH 6−8 at 25 °C but degraded significantly in acidic (pH < 6.0) or basic (pH > 8.0) conditions (Figure 9b). In acidic conditions, Cu(I) was capable of reducing the Alb−FTC complex (Figure 9c). The presence of thiol-containing agents, including DTT, NAC, cysteine, and Tu, ANTU caused the release of FTC from the HSA−FTC complex (Figure 9d). However, cystine and GSSG did not reduce the linkage of Alb−FTC.

DISCUSSION

This study demonstrated the essential role of copper in the cross-linking of albumin with Tus, such as ANTU or FTC (Figure 2). To facilitate the assessment of the albumin−Tus interaction, FTC was chosen for subsequent analyses in this study. It was found that the level of HSA−FTC complex formation depends on the amount of HSA, FTC, and copper included in the reaction (Figure 3). As few as 6 μM Cu(II) could induce a detectable HSA−FTC complex reaction in vitro (Figure 3c). The copper concentration in blood plasma was about 15 μM (*38*); thus, the thioureation of albumin may actually occur in physiological conditions.

Our data show that the linkage between HSA and FTC is a disulfide bridge (Figure 4a). Because there is only one reactive thiol group in the Cys^{34} residue of albumin (*26*), FTC was

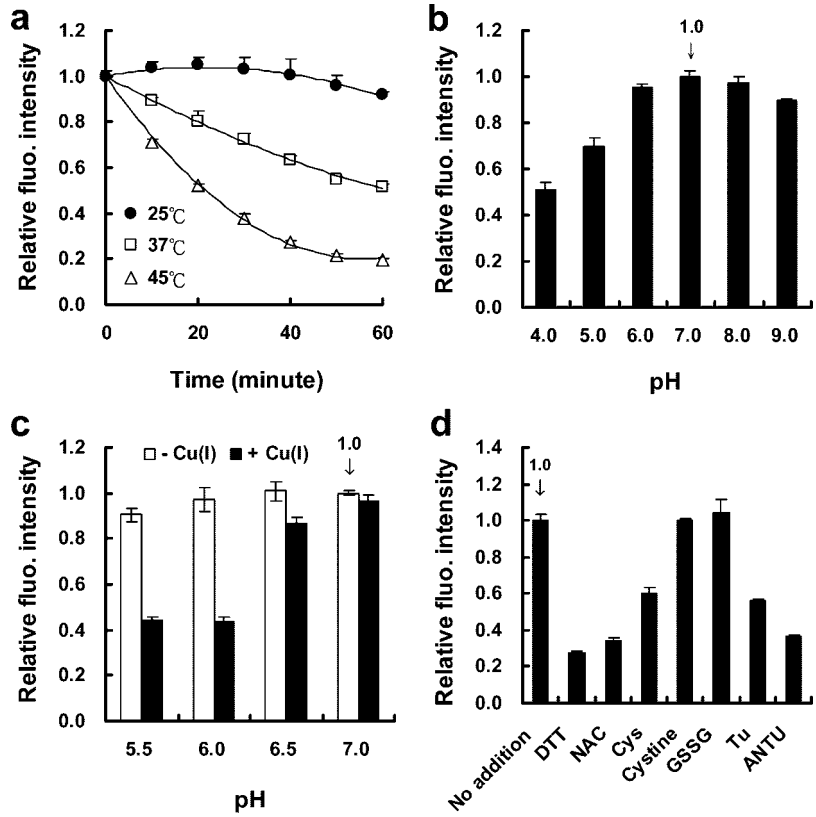

Figure 9. Stability of the thioureated complex. The influence of (a) temperature, (b) pH, (c) Cu(I), or (d) thiol-containing molecules on the stability of Alb−FTC was evaluated by using a modified CFA method (see Supporting Information, Figure 1). Aliquots of purified HSA−FTC (3 μg/well) were (a) incubated at the indicated temperature in 50 mM Hepes-pH 7.0 for designated time intervals; (b) incubated in various pH (in 50 mM sodium acetate-pH 4.0−5.0; 50 mM Hepes-pH 6.0−9.0) at 25 °C for an hour; (c) mixed with 0.1 mM Cu(I) in 50 mM Hepes-pH 5.5−7.0, at 25 °C for an hour; (d) mixed with 0.1 mM thiol-containing agents in 50 mM Hepes-pH 7.0 at 25 °C for 3 h. Reagent-B (60 μL/well) and MD-Charcoal (200 μL/well) were then added to adjust pH and remove the released FTC, respectively. After magnetic precipitation with MD-Charcoal, the fluorescent intensities were measured. Data presented are the means ± SD ($n = 3$).

speculated to cross-link with cysteine at this site. This notion was further confirmed by using Cys^{34}-modified albumin (Cys-HSA, r-Cys-HSA, and Alk-HSA) and the fact that FTC did not interact with cysteinylated or alkylated albumin (Figure 5). Furthermore, copper-induced cross-linking was also demonstrated for the interaction of FTC with cysteine (Figure 4b) and that of Tu with HSA (Figure 4c). The difference between albumin thioureation and cysteinylation could be distinguished by comparing the interaction of HSA with Tu-beads and HSA with Cys-beads. As shown in Figure 4c, both Tu- and Cys-beads were found to conjugate with HSA in the presence of copper. In the absence of copper, however, only Cys-beads that were pretreated with copper could react with HSA. As reported by other investigators (*29, 32, 39*), the binding of HSA with Cys-beads in this study is probably caused by the copper-catalyzed autoxidation of cysteine to cystine, followed by the interaction of cystine with HSA through thiol−disulfide exchange. However, copper-pretreated Tu-beads did not induce the same reaction as did Cys-beads. We speculate that the pretreatment with copper did not form dithioformamidine (Tu-S-S-Tu) in Tu-beads; instead, the Tu-Cu(II) complex was formed as described by Doona and Stanbury (*15*).

The thioureation reaction is highly sensitive to pH changes (Figure 6a and b). The decreased thioureation reaction at low pH may be due to the instability of the resulting product (Alb−FTC) in acidic conditions (Figure 9b). However, in basic conditions, the thioureation reaction is greatly reduced although the thioureated product is stable (at pH 8.0, Figure 9b). Such decreased thioureation reaction at high pH is likely due to the insolubility of copper in basic buffers, thus leading to the decomposition of the FTC-Cu(II) complex (Figure 6c). This observation implicates the importance of Tus-Cu(II) complex formation in the process of albumin thioureation.

Other metal ions tested in this study, including ferric ion, did not induce the same reaction as copper did, indicating the specific nature of copper in the reaction (Figure 7). It is difficult to clarify the role of copper in Alb-S-S-Tus complex formation since both albumin and Tus were known to interact with copper (*15, 16, 26*). The interaction site of copper with HSA was at its N-terminal copper-binding site (N-Asp-Ala-His-Lys-) and the Cys^{34} residue (*26, 40*). However, the truncated rHSA, which has a single deletion at Asp^1 and exhibits a reduced copper-binding affinity, did not reduce the binding of FTC, as compared to intact HSA (Figure 5). It appears that the binding of copper at the N-terminal copper-binding site appears unnecessary for the thioureation of HSA. Similarly, PSA, which exhibits low-affinity for copper (there is a single residue change in PSA, $His^3 \rightarrow Tyr^3$, as compared to BSA at the N-terminal Asp-Thr-His-Lys- sequence), interacted more efficiently with FTC than did BSA. We thus exclude the N-terminal copper-binding site of albumin from the reaction.

The possible interaction of Cu(II) with Cys^{34} of albumin was considered. In copper-induced S-nitrosation of albumin (*32*), it was suggested that the interaction of Cu(II) with Cys^{34} of albumin leads to the formation of a copper−thiol complex, which could further react with NO to form BSA-SNO. According to Zhang et al., Cu(II) bound with high affinity to Cys^{34} of albumin at higher pH (approximately 9) (*41*). If the formation of HSA-Cys^{34}-Cu(II) is essential for thioureation, more HSA−FTC would be formed at high pH. However, our data show that the incorporation of FTC to HSA was greatly reduced with increasing pH, and the conjugation was abolished com-

pletely above pH 8.5 (Figure 6a). Although the interaction of Cu(II) with Cys^{34} may occur, it was not essential for the incorporation of FTC into albumin. Consequently, a mechanism similar to S-nitrosation is not suitable for albumin thioureation.

Because Tus were known to form complexes with copper (*15*−*17*), we suggest that the formation of the Tus-Cu(II) complex is essential for the reaction. In copper-induced reactions, Tus including FTC, ANTU, and Tu-beads, which were in their copper-bound form would further interact with albumin (Figures 2 and 4c). There are two possible reaction mechanisms for the thioureation of cysteine or Cys^{34} of albumin: (a) Cys-SH or Alb-Cys^{34}-SH attacked by Tus-Cu(II) as shown in reactions F and G, respectively (the release of Cu(I) will be discussed later); (b) Cys-S-S-Cys or dimerized albumin (Alb-Cys^{34}-S-S-Cys^{34}-Alb) reacting with Tus by thiol−disulfide exchange as described in reaction D (see Introduction).

$$\text{Cys-SH} + \text{Tus-Cu(II)} \rightarrow \text{Cys-S-S-Tus} + \text{Cu(I)} + 2H^+ \quad \text{(F)}$$

$$\text{Alb-Cys}^{34}\text{-SH} + \text{Tus-Cu(II)} \rightarrow \text{Alb-Cys}^{34}\text{-S-S-Tus} + \text{Cu(I)} + 2H^+ \quad \text{(G)}$$

The scheme b described above was probably excluded from the copper-induced fast coupling reaction because (i) copper may not participate in the formation of dimerized albumin. In fact, the treatment of albumin with Cu(II) did not lead to the oxidation of Cys^{34} and the dimerization of BSA (*32*). (ii) Cys-HSA (Alb-Cys^{34}-S-S-Cys) could not complex with FTC in a 10-min reaction without copper (Figure 5). Therefore, it is not the major mechanism in the copper-induced reaction, although thiol−disulfide exchange described in reaction D may occur.

According to Stubauer et al., Cu(II)-induced albumin S-nitrosation accompanied the release of Cu(I) as judged by using NCP, a Cu(I) specific chelator (*32*). Similarly, by using NCP, the formation of HSA-S-S-FTC and Cys-S-S-FTC is predominantly increased (Figure 8). Thus, we speculate that the release of Cu(I) is involved in reactions F−G. There are two possible mechanisms for the Cu(I)-inhibited formation of Alb-Tus at neutral pH: (i) the Cu(I) decomposes the disulfide bridge of Alb-S-S-Tus; and (ii) the competition of Cu(I) with Cu(II) for Tus. The former is suggested by the report of Kato et al. that oxidized D-penicillamine (PSSP) and glutathione (GSSG) were reduced by Cu(I) with the release of Cu(II) (*42*). Stubauer et al. also described that the decomposition of BSA-SNO by Cu(I) reduced the S-nitrosation reaction (*32*). At neutral pH in this study, Cu(I) did decrease the formation of Alb−FTC (Table 1). However, once Alb−FTC formed, Cu(I) did not significantly decompose the complex at pH 7.0 (Figure 9c), indicating that the first scheme is not likely to occur at neutral pH. Alternatively, the second scheme that Cu(I) competes with Cu(II) for Tu is, thus, a more feasible model at neutral pH because Tu was also known to form a complex with Cu(I). It was also reported that the formation of a redox-inactive Tu-Cu(I) complex prevents copper-mediated protein oxidation (*18*). Therefore, we speculate that the Cu(II) bound Tus is active for the progression of thioureation while Cu(I)-bound Tus is inactive.

The stability of thioureated albumin, Alb−FTC, was also assessed. As shown in Figure 9a and b, Alb−FTC was unstable at high temperature (37 °C and 45 °C), under acidic (pH < 6.0) or basic conditions (pH > 8.0). Although the breakdown of the disulfide bond is considered, other possibilities may not be excluded: (i) Cys-S-S-Tu was hydrolyzed to Cys-SOH and Tu in reaction E (*10, 11*); (ii) thioureated protein (protein−S-S-Tu) in thyroid tissue was hydrolyzed to thiosulfenic acid (protein−S-SH) and urea (*8*). The latter implied that the decomposition of cross-linked product may be influenced by surrounding amino acids near the binding site. The hydrolytic products may vary among various Tu derivatives. Further experiments are required to establish the hydrolytic mechanism.

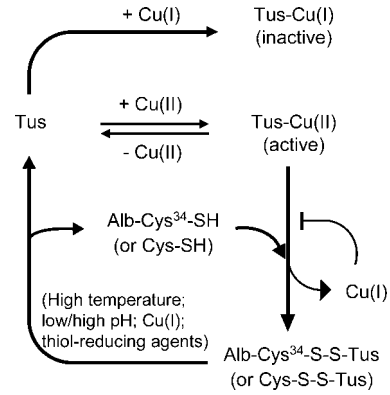

Figure 10. Schematic mechanism of copper-induced thioureation. The complex of Tus-Cu(II) is actively catalyzing the thioureation between Tus and cysteine or Cys^{34} residue of mercaptoalbumin (Alb-Cys^{34}-SH) at weak acidic or physiological pH. The resulting product is thioureated cysteine (Cys-S-S-Tus) or albumin (Alb-Cys^{34}-S-S-Tus) with the formation of a disulfide bridge and the release of Cu(I). The released Cu(I) is speculated to compete with Cu(II) for Tus, thus inhibiting the progress of thioureation. The complex, Alb-Cys^{34}-S-S-Tus, was unstable at high temperature (>25 °C) and either acidic (<pH 6.0) or basic pH (>pH 8.0). Both Cu(I) (at acidic pH only) and thiol-reducing agents degraded the Alb-Cys^{34}-S-S-Tus complex.

In addition, Cu(I) was found to reduce the linkage between albumin and FTC in acidic conditions (Figure 9c). The diminished reduction effect of Cu(I) with increasing pH may be due to the decreased solubility of Cu(I) in basic conditions (considering that CuCl must be prepared in 50 mM HCl). Finally, because of the formation of disulfide linkage between thiourea and albumin, the produced thioureated albumin could also be reduced or modified by thiol-containing compounds presented in blood plasma, such as cysteine (but not cystine) as demonstrated in Figure 9d. The mechanism of copper-induced thioureation is summarized and illustrated in Figure 10.

Tus were considered as hydroxyl radical scavengers and may help to suppress metal-induced protein damage (*12*−*14*). However, high levels of Tus are intrinsically toxic physiologically (*1*−*3*). It is noteworthy that the combination of copper with Tus (e.g., phenylthiourea, ANTU, and pyrrolidine dithiocarbamate) was much more toxic than copper or Tus alone for cultured cells (*43, 44*). The treatment of these cells with copper-binding protein such as albumin would decrease the cytotoxic effect (*44*). In our opinion, the decreased cytotoxicity in these cases may be due to the dysfunction of some important cellular proteins or enzymes that were thioureated by Tus-Cu(II) and finally resulted in cell death. Although the diminished cytotoxicity by albumin-treatment may be due to the competition of albumin with Tus for copper, the possible contribution of sacrificial albumin for Tu-binding (that forms Alb-Tus to prevent thioureation of important cellular proteins) should not be ignored. We therefore speculate that albumin may play a role in the clearance of Tus in the presence of copper. This may be important for reducing the toxicity of these compounds in circulation. In today's pharmaceutical industry, many drugs are developed in the form of Tus (*19*−*21*). Since albumin is the major thiol-containing protein in plasma, the pharmacokinetics of these Tu-based drugs may require special evaluation for patients with copper metabolism disorders such as Wilson's disease (*45*).

Supporting information

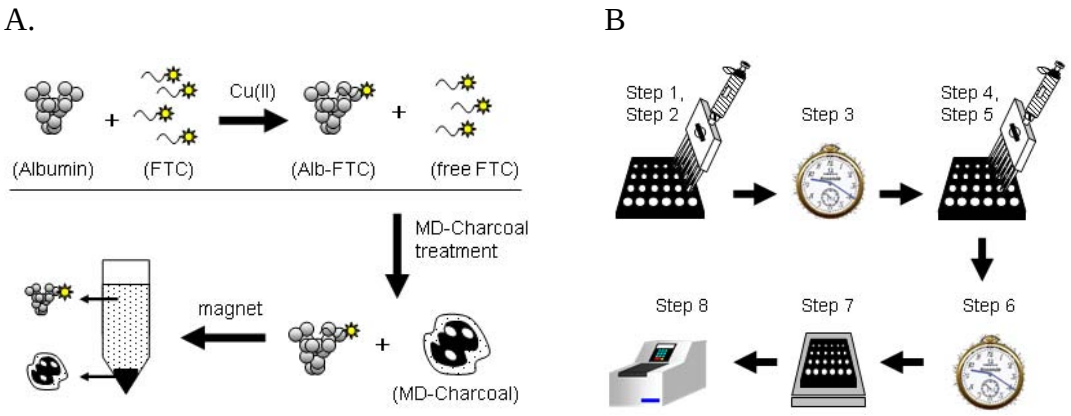

Figure 1 The schemes of CFA method. (A) The combination of albumin with FTC was initiated by the addition of copper. After reaction, the free FTC was rapidly removed from the reaction mixture by MD-Charcoal treatment. MD-Charcoal was then magnetically precipitated to separate from the Alb-FTC complex. (B) Basic protocol of CFA. To evaluate the formation of Alb-FTC complex, albumin samples (30 μl/well) are added in the wells of a microplate at 4℃ (Step 1). Upon the addition of 30 μl/well reagent-A (Step 2) (final concentration in reaction: 1 μM HSA, 3 μM FTC, 0.1 mM CuCl2, in 50 mM Hepes-pH 7.0), the reaction is immediately initiated by incubating the plate at 37℃ for 10 minutes (Step 3), and terminated by adding 60 μl reagent-B (2 mM EDTA in 0.5 M Hepes-pH 8.0) (Step 4). After addition of 200 μl MD-Charcoal (Step 5), the plate is kept at room temperature for 5 minutes to remove all of the free FTC and other small molecules (Step 6). Finally, the MD-Charcoal is precipitated by magnet (Step 7), and the fluorescence is measured by microplate reader (Step 8). Transfer of supernatant to another plate for fluorescence measurement is unnecessary due to the precipitated MD-Charcoal that had captured FTC does not exhibit fluorescent properties. In addition, a **modified CFA method** was used to evaluate the stability of Alb-FTC complex: in Step 1 & 2,

the purified Alb-FTC complex was incubated (i) at designated temperature, (ii) in various pH, (iii) with Cu(I), or (iv) with thiol-containing agents, for designated periods of time (Step 3). Reagent-B (Step 4) and MD-Charcoal (Step 5) were then added to adjust the final pH to pH 8.0 and to remove the released FTC molecules, respectively. Steps 6 ~ 8 were as described above. The measured fluorescence intensities reflect the remaining Alb-bound FTC molecules.

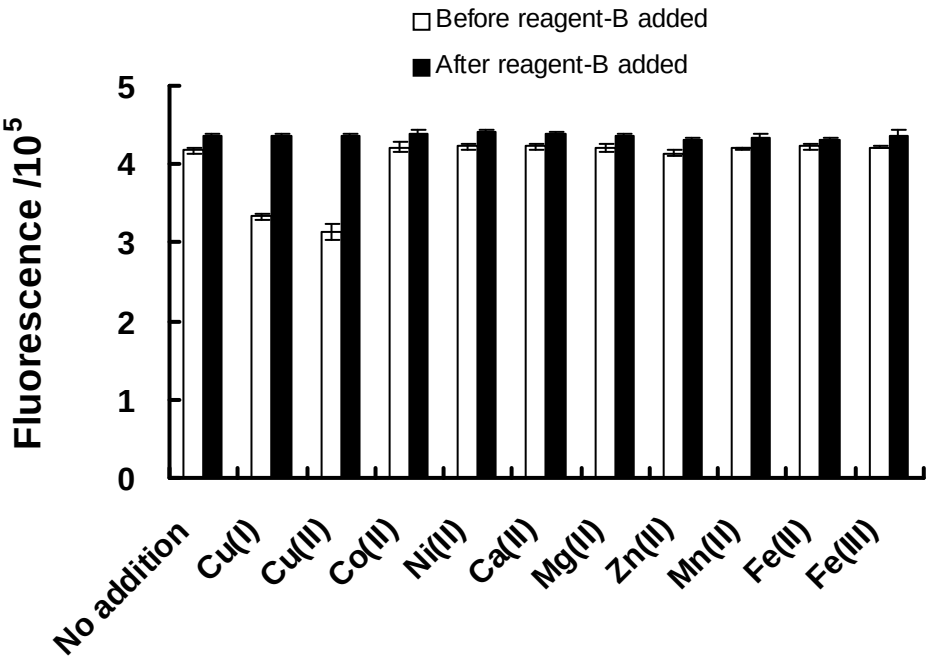

Figure 2 Metal ions did not influence the fluorescence intensity by using CFA method. The fluorescence intensities of reaction mixtures (60 μl; 50 mM Hepes-pH 7.0, 3 μM FTC, and 100 μM of various metal ions) was measured before and after reagent-B (60 μl; 2 mM EDTA, 0.5 M Hepes-pH 8.0) added. Before reagent-B added, only Cu(I) and Cu(II) found to reduce the fluorescence intensity of FTC. This effect, however, was completely eliminated after addition of reagent-B. Other metal ions did not influence the fluorescence intensity even without reagent-B added. The data presented are means ± SD (n = 3).

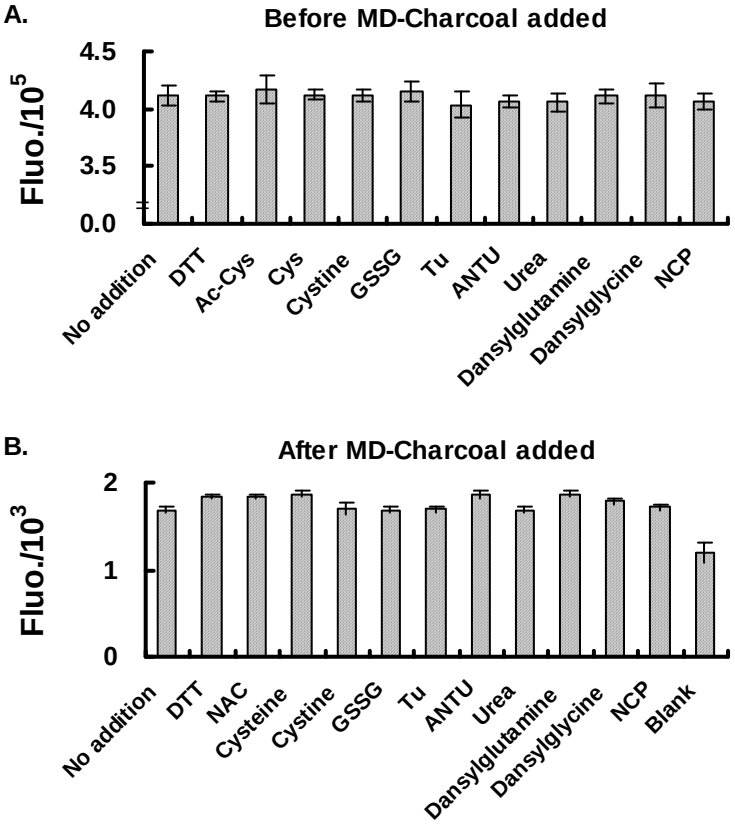

Figure 3 Small molecules analyzed by CFA did not influence the fluorescence counting. Various small molecules used in this study (Table I & Fig. 8) including thiol-containing molecules, Tu analogues, ligands, and NCP were tested for possible influence on fluorescence intensity of FTC. The reaction mixtures (60 μl; 50 mM Hepes-pH 7.0, 3 μM FTC, and 100 μM of various tested agents) was mixed with equal volume of reagent-B (2 mM EDTA, 0.5 M Hepes-pH 8.0), and the fluorescence intensities were measured before (A) or after (B) MD-Charcoal (200 μl) treatment. Before MD-Charcoal treatment (A), these molecules did not influence the fluorescence intensity of FTC. After MD-Charcoal treatment (B), the fluorescence intensities of each group were nearly the same as blank (empty well). This indicate CFA molecules were nearly completely removed by MD-Charcoal. The data presented are means ± SD (n = 3).

Nanoparticulate Glutathione Peroxidase Mimics Based on Selenocystine−Pullulan Conjugates

Mamoru Haratake,* Shinya Matsumoto, Masahiro Ono, and Morio Nakayama*

Graduate School of Biomedical Sciences, Nagasaki University, 1-14, Bunkyo-machi, Nagasaki 852-8521, Japan. Received January 4, 2008; Revised Manuscript Received June 23, 2008

We synthesized nanoparticulate glutathione peroxidase (GPx) mimics in which selenocystine (SeCyst) was conjugated to a hydrophilic linear polysaccharide, pullulan (Pul). The SeCyst ester-conjugated Pul derivatives (SeCyst-Pul) in phosphate buffer (pH 7) were treated with a sonicator to spontaneously form particulate materials. Dynamic light scattering measurements revealed that the SeCyst-Pul conjugates could form particulate materials with diameters between 100 and 300 nm. Distinctive endothermic peaks were observed for the SeCyst-Pul aggregate solutions based on a differential scanning calorimetric analysis. The tryptophan (Trp) fluorescence intensity of SeCyst benzyl ester-tryptophanyl-Pul (SeCyst-Bz-Trp-Pul) mostly decreased in comparison to those of the Trp-Pul (its precursor) and free Trp, which indicates that the Trp residues come close to each other during the aggregation of the conjugates. Formation of SeCyst-Pul aggregates could be induced by the hydrophobic interactions between the SeCyst esters and the amino acid residues on Pul. The GPx-like activity of SeCyst-Bz-Trp-Pul aggregates for the reduction of H_2O_2 was enhanced nearly 20-fold higher than that of free SeCyst. The double-reciprocal plots of the SeCyst-Bz-Trp-Pul aggregate-catalyzed reduction yielded parallel lines by varying the substrate concentrations, indicating a "ping-pong" mechanism that is similar to those of the natural GPxs. The enhanced GPx activity of the SeCyst-Bz-Trp-Pul aggregate was also supported by higher kinetic parameters, k_{cat}/K_m^{GSH} and $k_{cat}/K_m^{H_2O_2}$. Overall, the enhanced activity of the SeCyst-Bz-Trp-Pul aggregate would be attributed to a hydrophobic environment that was formed at the vicinity of the SeCyst.

INTRODUCTION

Glutathione peroxidases (GPxs) are the major antioxidant defense in living systems, which catalyze the reduction of hydrogen peroxide and phospholipid hydroperoxides using reduced glutathione (GSH) ($2GSH + R\text{-}OOH \rightarrow GSSG + R\text{-}OH + H_2O$) (*1*). Selenium-dependent GPxs (GPx-1, GPx-2, GPx-3, GPx-4, and GPx-6), except for GPx-5, contain the selenocysteine (Sec) residue in their catalytic centers (*2–4*). The Sec residue, which is called the twenty-first amino acid, is encoded by the UGA stop codon that normally functions as a stop codon. The biosynthesis of Sec incorporated in response to the UGA codon is distinctive from the twenty standard amino acids. Translation of the Sec residue is a complicated mechanism which is controlled by the specific stem-loop Sec insertion sequence (SECIS) located in the downstream of the UGA codon and four execution elements [Sec synthase (*selA*), an elongation factor (*selB*), seryl-$tRNA^{sec}$ (*selC*), and selenophosphate synthase (*selD*)] (*5–9*). As the Sec insertion into the selenoproteins occurs by such a specific translational control process, at present, it is still quite difficult to express the Sec-containing proteins by the state-of-the-art genetic engineering techniques (*10*).[1]

In the X-ray crystal structures of the GPxs, the residues that could be functionally important in the vicinity of the catalytic Sec are some aromatic amino acids [tryptophan (Trp), phenylalanine and tyrosine] and glutamine (Gln) and arginine presumably forming salt bridges and/or hydrogen bonding to the glutathione molecule (*11, 12*). A common structure around the catalytic center, i.e., the "catalytic triad", was also found in the X-ray crystal structures of the GPxs, which involves Sec and the adjacent Gln and Trp residues. The reactive selenol group of the Sec residue is thought to be stabilized by the formation of the hydrogen-bonding with the imino group of Trp and/or the carbamoyl group of Gln, and the catalytic triad of these three residues represent a catalytic center, whose integrity is essential for the full catalytic function of the GPxs (*13*).

To explore the catalytic mechanism of natural GPxs and/or apply it to medicine, low mass GPx mimics, such as Ebselen, have been synthesized (*14–21*). A report by Wilson et al. described that an improved GPx-like activity of diselenide compounds (R-Se-Se-R) resulted from intramolecular interactions of the selenium atom with the nitrogen atom that stabilizes the reaction intermediates (*18*). Some researchers also suggested that noncovalent interactions between selenium and nitrogen or oxygen atoms increase the GPx-like activity (*19, 20*). Natural GPxs, except for GPx-4, comprise four identical subunits of 21 kDa that contains one Sec residue as the active center, while most of the GPx mimics previously known was low mass compounds and not yet comparable with the natural GPxs regarding the GPx-like activity. The binding affinity of the substrates in the vicinity of the selenium atom must also be an important element for improving the GPx-like activity. Ren et al. reported that the selenocystine (SeCyst)-conjugated β-cyclodextrin provided the GPx-like activity for the organic cumene hydroperoxide that can be included in the hydrophobic cavity of β-cyclodextrin (*16*). Sun et al. developed the diselenide-linked 15-mer selenopeptide with a high GPx-like activity by incorporating a specific amino acid sequence for the binding of glutathione (*21*). However, there are only a few reports on the

GPx mimics that are designed from the viewpoint of the substrate binding.

In this study, we synthesized nanosized particulate GPx mimics based on the conjugates of which the selenocystine (SeCyst) as a functional element was attached to the hydrophilic linear polysaccharide, pullulan (Pul). The structural features of the particulate GPx mimics formed by the self-aggregation of the SeCyst-Pul conjugates were characterized by the dynamic light scattering, differential scanning calorimetric, and fluorescence spectroscopic techniques. Their GPx-like activity and steady state kinetics were further examined.

EXPERIMENTAL PROCEDURES

Materials. Pullulan (average Mw 73000, $M_w/M_n = 1.54$, Pul) used as a conjugate polymer was purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Seleno-D,L-cystine (SeCyst) was obtained from Sigma Co., Ltd. (St. Louis, MO) The amino acid derivatives were from either Merck Biosciences AG Novabiochem (Läufelfingen, Switzerland) or Kanto Chemical Co., Inc. (Tokyo, Japan). 2,3-Diaminonaphtharene (DAN) and reduced glutathione (GSH) were obtained from Tokyo Chemical Ind. Co., Ltd. (Tokyo, Japan). Nicotinamide adenine dinucleotide phosphate in the reduced form (NADPH) and glutathione reductase (GR) were from Wako Pure Chemical Ind., Ltd. (Osaka, Japan). H_2O_2, used for the substrate to determine GPx-like activity, was obtained from Nacalai Tesque, Inc. (Kyoto, Japan). An Ultrafree-MC (Millipore Corp., nominal molecular weight cutoff: 5000) was used for ultracentrifugation of the polymer solutions. Water, used for the preparations of the SeCyst-Pul aggregates and their GPx-like activity measurements, was generated by a Milli-Q Biocel system (Millipore Corp., Billerica, MA). All other chemicals were of commercial reagent grade and used as received.

Synthesis of Carboxymethylated Pullulan (CM-Pul) (*22*). Pul (1.5 g) dissolved in a 6 M sodium hydroxide aqueous solution (25 mL) and chloroacetic acid (0.375, 0.75, 1.5, 3, or 4.5 g) were combined at 70 °C, and allowed to react for 2 h with stirring. The reaction mixture was neutralized with a 1 M acetic acid aqueous solution, and then dialyzed against deionized water for 24 h. The dialysate was poured into strong cation-exchange resins (DIAION SK1B, Mitsubishi Chemical Co., Tokyo, Japan) in the free form to transform it from sodium form to free form, and then were subjected to lyophilization (CM-Pul, yield: 57.5%). CM-Pul (DS = 0.44) − IR (ATR, cm^{-1}): 3354 (O−H stretching), 1734 (C═O stretching), 1026 (C−O−C bending). ^{1}H NMR (DMSO-d_6): δ 4.42 (carboxymethyl *H*), 2.56−4.58 (glucose 2*H*, 3*H*, 4*H*, 5*H*, and 6*H*), 4.62 (glucose 1*H* (1→4)), 5.12 (glucose 1*H* (1→6)).

The degree of substitution of the carboxymethyl group in CM-Pul (DS) was estimated by pH titration; an appropriate amount of CM-Pul in free form (50−100 mg, Pul-CH_2COOH) dissolved in 10 mL of a 0.1 M sodium hydroxide aqueous solution was titrated with a 0.1 M HCl aqueous solution. The temperature of the titration vessels was maintained at 30 °C throughout each titration by a circulator RTE-111 (NESLAB Instruments, Inc., Newington, NH). The pH-metric titrations were performed on a titrator DL25 (Mettler-Toledo, Inc., Columbus, OH). The DS values were calculated from the difference between V_S and V_B using the following equation (eq 1); where F is the titer of the 0.1 M HCl, V_B is the volume of the titrant consumed for the sample-free blank (mL), V_S is the volume of the titrant consumed for the samples (mL), W is the sample weight used for the titration (mg), 162 is the molar mass of a glucose unit in Pul ($C_6H_{10}O_5$), and 59 is the molar mass of carboxymethyl group ($C_2H_3O_2$). One milliliter of 0.1 M sodium hydroxide corresponds to 0.1 mmol carboxymethyl group in this titration.

$$\mathrm{DS} = 162 \times 0.1 \times F \times (V_B - V_S)/[W - 58 \times 0.1 \times F \times (V_B - V_S)] \quad (1)$$

Synthesis of SeCyst Esters. The SeCyst esters were synthesized according to the procedures reported by Bondanszky (*23*) as follows: For the SeCyst alkyl esters, a mixture of SeCyst (30 mg) and *p*-toluenesulfonic acid (300 mg) dissolved in 10 mL of absolute methanol (ethanol or isopropanol) was refluxed for 40 h. After the removal of the alcohol, the resultant was left for 24 h in diethyl ether. The obtained solid materials were washed several times with diethyl ether, and dried *in vacuo*. For the synthesis of the SeCyst benzyl ester (SeCyst-Bz), SeCyst (30 mg), *p*-toluenesulfonic acid (300 mg) and benzyl alcohol (7.5 mL) were mixed in benzene (15 mL), and refluxed for 3 h. After removal of the benzene, the residual material was left in a 1:1 mixture of petroleum ether and diethyl ether (100 mL) for 24 h. The obtained solid material was left in diethyl ether for another 24 h (yield: 75.3%). IR (ATR, cm^{-1}): SeCyst-Me 1702 (ester C═O stretching), SeCyst-Et 1712 (ester C═O stretching), SeCyst-*i*Pro 1710 (ester C═O stretching), SeCyst-Bz 1716 (ester C═O stretching). ^{1}H NMR (CD_3OD): SeCyst-Me; δ 2.37 (s, 3H), 3.29 (s, 3H), 3.30−3.31 (m, 2H), 3.85 (s, 3H), 4.40 (m, 1H), 7.22−7.25 (d, 2H), 7.69−7.72 (d, 2H), SeCyst-Et; δ 1.30 (m, 3H), 2.37 (s, 3H), 3.40 (m, 2H), 4.29 (q, 2H), 4.32 (m, 1H), 7.25 (d, 2H), 7.70 (d, 2H), SeCyst-*i*Pro; δ 1.32 (d, 6H), 2.37 (s, 3H), 3.20−3.31 (m, 2H), 4.35 (m, 1H), 5.08−5.19 (q, 1H), 7.23 (d, 2H), 7.70 (d, 2H). SeCyst-Bz; δ 2.36 (s, 3H), 3.29 (m, 1H), 4.46 (m, 1H), 5.27 (s, 2H), 7.22 (d, 2H), 7.36 (m, 5H), 7.70 (d, 2H).

Conjugation of SeCyst Esters and Amino Acids to CM-Puls. CM-Pul (50 mg) and amino acid methyl ester (50 mg) were dissolved in 10 mL of deionized water. Triethylamine and *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ, 100 mg) dissolved in *N,N*-dimethylformamide (DMF, 10 mL) were sequentially added to the mixture, and stirred for 2 h at room temperature. After the dialysis against deionized water for 24 h, an equal volume mixture of the dialysate and a 2 M sodium hydroxide aqueous solution was stirred for another 24 h at room temperature to remove any of the unreacted amino acid esters. The resulting solution was dialyzed against deionized water, followed by lyophilization (white powder, yield: 55.1%). The degree of introduction of the Trp and Tyr residues in Pul was estimated by measuring the intrinsic absorbance at 280 nm. His residue (*24*) was also spectrophotometrically estimated by measuring the absorbance at 240 nm using diethyl bicarbonate.

CM-Pul or Trp-Pul was combined with the SeCyst esters in 10 mL deionized water in a flask, and then an appropriate amount of triethylamine and EEDQ dissolved in 10 mL DMF was added to the flask. The mixture was allowed to react for 2 h with stirring at room temperature. The resultant material was dialyzed against deionized water for 24 h, and then subjected to lyophilization (pale yellow powder, yield: 69.3%). All the SeCyst-Pul conjugates were stored in a desiccator at ambient temperature until use. SeCyst-Me-Pul (DS = 0.44) − IR (ATR, cm^{-1}): 3341 (O−H stretching), 1715 (ester C═O stretching), 1650 (amide C═O stretching), 1522 (amide N−H bending), 1038 (C−O−C bending). ^{1}H NMR (DMSO-d_6): δ 2.37−2.58, 7.30−7.72 (SeCyst-Me *H*), 2.60−4.60 (glucose 2*H*, 3*H*, 4*H*, 5*H*, and 6*H*), 4.62 (glucose 1*H* (1→4)), 5.10 (glucose 1*H* (1→6)). SeCyst-Me-Trp-Pul (DS = 0.44) − IR (ATR, cm^{-1}): 3353 (O−H stretching), 1706 (ester C═O stretching), 1642 (amide C═O stretching), 1541 (amide N−H bending), 1050 (C−O−C bending). ^{1}H NMR (DMSO-d_6): δ 2.37−2.58, 7.30−7.72 (SeCyst-Me *H*), 2.60−4.60 (glucose 2*H*, 3*H*, 4*H*, 5*H*, and 6*H*), 4.62 (glucose 1*H* (1→4)), 5.10 (glucose 1*H* (1→6)), 6.80−7.23 (tryptophan imidazole *H*). SeCyst-Bz-Trp-Pul (DS = 0.36) − IR (ATR, cm^{-1}): 3350 (O−H stretching), 1716 (ester C═O stretching), 1650 (amide C═O stretching),

1540 (amide N−H bending), 1030 (C−O−C bending), ^{1}H NMR (DMSO-d_6): δ 2.37−2.58, 7.30−7.72 (SeCyst-Bz *H*), 2.58−4.60 (glucose 2*H*, 3*H*, 4*H*, 5*H*, and 6*H*), 4.52 (glucose 1*H* (1→4)), 5.12 (glucose 1*H* (1→6)), 6.71−7.30 (tryptophan imidazole *H*).

Determination of Selenium Concentration. The selenium concentrations in the sample solutions were fluorometrically determined using DAN after digestion using a 1:4 mixture of $HClO_4$ and HNO_3 (*25*).

Dynamic Light Scattering (DLS) Measurements. The particle diameter and distribution of the SeCyst-Pul aggregates were measured by a DLS technique. The DLS measurements were carried out at 25 °C using a Zetasizer Nano ZS (Malvern Instruments, Worcs, UK) at 90° to the incident beam (a wavelength 633 nm from a 4 mW He−Ne laser tube) in a 1 cm length quartz cuvette. The SeCyst-Pul conjugates dispersed in 0.05 M phosphate buffer (pH 7) (0.2 mg/mL) were treated by a Sonifier 250D probe-type sonicator (Branson Danburg, CT) at 120 W for 5 min in an ice bath 24 h before the measurements. Data fitting was performed using a multimodal algorithm supplied by Malvern Instruments. The collected correlelograms were fitted to diffusion coefficients and converted to a hydrodynamic diameter using the Einstein-Stokes equation.

Differential Scanning Calorimetry. Differential scanning calorimetry (DSC) was performed using an MC-2 ultrasensitive scanning calorimeter (Microcal, Inc., Amherst, MA). The MC-2 contains a fixed pair of matched tantalum cells (cell volume 1.2 mL), which are separately filled with the sample and the reference solution. The SeCyst-Pul aggregate solution samples (0.01 wt %) were injected into the sample cell and the reference cell was filled with 0.05 M phosphate buffer (pH 7). A nitrogen cylinder normally set at 4 kg/cm maintained pressure in the cells to suppress the formation of air bubbles during scanning. Temperature scans were performed at the rate of 1 °C/min and in the range 30−100 °C. The baseline was drawn with the help of *ORIGIN* software supplied by Microcal, Inc. The DSC thermograms of the pullulan in 0.05 M phosphate buffer (pH 7) were subtracted from those of the SeCyst-Pul aggregates.

Determination of GPx-Like Activity (*18, 26*). The SeCyst-Pul aggregate solution (final selenium concentration: 6.25 μM) was sequentially combined with ethylenediaminetetraacetic acid (EDTA, 0.63 mM), sodium azide (0.63 mM), glutathione reductase solution (0.63 unit), reduced glutathione solution (0.63 mM), and NADPH solution (2.34 mM) in 0.05 M phosphate buffer (pH 7). The reaction was initiated by the addition of H_2O_2 solutions (3.14 mM). Absorbance at 340 nm due to the NADPH was recorded every 10 s just after mixing by inversion. The GPx-like activity was calculated using the following equation (eq 2) as μmoles NADPH oxidized per minute, where ΔA_{SMP} is the decrease in absorbance at 340 nm of sample solutions between 10 and 70 s after addition of the substrates, ΔA_{BLK} is the decrease in absorbance at 340 nm per minute of the solutions without the SeCyst-Pul conjugates, ε_{mM} is the extinction coefficient for 1 mM NADPH solution [6.22/(mM·cm)], and c is final selenium concentration (μM).

$$\text{GPx-like activity} = (\Delta A_{SMP} - \Delta A_{BLK}) \times 1000/\varepsilon_{mM}/c \quad (2)$$

Kinetic Study of SeCyst-Pul Aggregate-Catalyzed Reduction. The initial reaction rate of the SeCyst-Pul aggregates was determined by varying the H_2O_2 and GSH concentrations: at several concentrations of one substrate while the concentration of the other substrate remained the same (H_2O_2 concentrations, 0.25, 0.5, and 1.0 mM; GSH concentrations, 0.2, 0.4, 0.6, and 1.0 mM). The other reaction conditions and operating procedures were the same as those described above. By the double-reciprocal plotting (1/[GSH] versus 1/v), the kinetic parameters were calculated from the following equation (eq 3) (*27*).

$$\frac{1}{v} = \frac{1}{[GSH]}\frac{K_m^{GSH}}{V_{max}} + \frac{1}{V_{max}}\left(\frac{[H_2O_2] + K_m^{H_2O_2}}{[H_2O_2]}\right) \quad (3)$$

where $[H_2O_2]$ and [GSH] are the concentrations of hydrogen peroxide and glutathione, respectively, K_m^S is the Michaelis constant for substrate S, $V_{max} = k_{cat}[E_0]$, k_{cat}, and $[E_0]$ are a general rate constant and a total concentration of selenium, respectively.

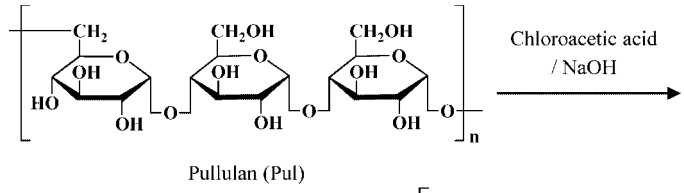
Statistical Analysis. All data were presented as mean ± standard deviation ($n = 5$ or more). Statistical analyses were performed using *PRISM 4* (GraphPad Software Inc., San Diego, CA). Multiple mean values were compared by a two-way ANOVA with a Bonferroni posthoc test with the treatment and selenium concentration in the diets as factors. Comparisons were considered statistically significant at $P < 0.05$.

RESULTS AND DISCUSSION

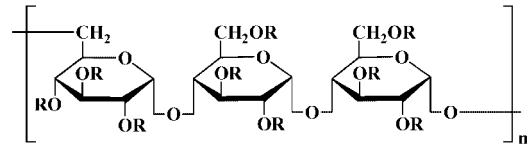
Synthesis of SeCyst-Pul Conjugates (Scheme 1). Natural GPxs have a Sec residue in their active center. The direct Sec introduction to polymers is quite difficult, because of its poor chemical stability. In this study, SeCyst (Sec-Se-Se-Sec) was used as a catalytic site to be attached to the polymers. Pullulan (Pul, average Mw 73 000) was employed as a polymer material to improve the chemical stability and the solubility of SeCyst in an aqueous medium. The Pul molecule is a hydrophilic linear polysaccharide consisting of a maltotriose repeating unit in which three glucose molecules are connected by an α-1,4 glycosidic bond. Pul molecule was first carboxymethylated in order to sequentially attach the SeCyst ester moieties through an amide linkage (CM-Pul). As the highly substituted SeCyst-Pul conjugates were thought to become water-insoluble due to the poor solubility of SeCyst, the CM-Pul derivatives with less than a 0.5 substitution degree of the carboxymethyl group per glucose unit of Pul were employed for the further chemical modifications. We tried to examine the substituent distribution of the carboxymethyl group in the CM-Pul by NMR spectroscopy, but it could not be clearly detected probably due to the low degree of substitution. It seems common knowledge that the primary alcohol at C-6 (OH-6) is the most reactive hydroxyl group of glucose in most substitution reactions. However, Glinel et al. recently reported that the reactivity order of hydroxyl groups in the carboxymethylation of Pul was found to be OH-2 > OH-4 > OH-6 > OH-3 using the hydrolyzed pullulan fragment (*28*). As the CM-Pul used in this study was also thought to be substituted by carboxymethyl groups at several positions of the hydroxyl groups, the same batches of the CM-Pul were used for the subsequent conjugation reactions.

The free SeCyst was decomposed to the red elemental selenium in both the solid and aqueous solution states. However, the conjugation of the SeCyst esters to Pul fairly improved their stability; when they were exposed to sonication and/or heating, no elemental selenium was observed throughout the experiments and during storage. The selenium contents of the SeCyst-Pul conjugates increased with an increase in the degree of substitution of the carboxymethyl group (Table 1). When the SeCyst-Pul conjugate ethanolic aqueous solutions were ultrafiltered through a 5000 molecular weight cutoff filter, the selenium amount in the filtrates was less than 1% of the total selenium amount listed in Table 1. Thus, the SeCyst esters noncovalently attached to Pul were thought to be a negligible amount in the conjugates. In addition, the residual carboxymethyl groups in the SeCyst-Pul conjugates could hardly be detected. The selenium contents of SeCyst-Me-His-Pul, SeCyst-Me-Tyr-Pul, SeCyst-Me-Trp-Pul, and SeCyst-Bz-Trp-Pul conjugates were almost consistent with those that were calculated from the contents of the amino acids in the respective precursors (97−105%), indicating that SeCyst and these amino acids were introduced into these conjugates in equal molar ratios.

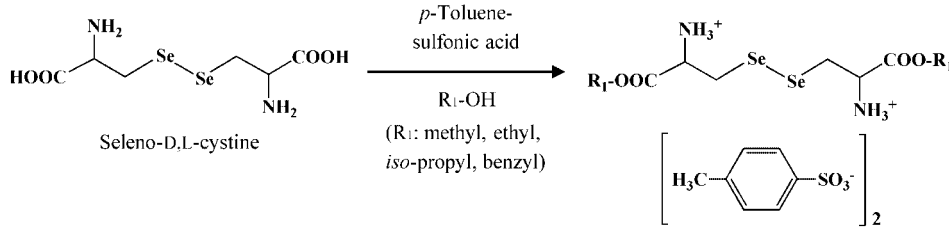
Scheme 1. Synthetic Route of SeCyst-Pul Conjugates



Pullulan (Pul)

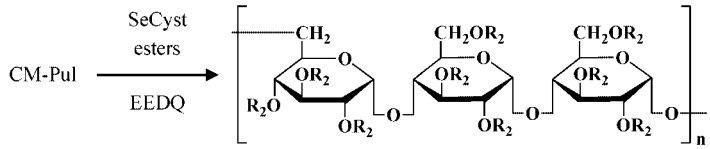


Carboxymethylated Pul (CM-Pul, R: carboxymethyl)



Seleno-D,L-cystine

SeCyst ester



- SeCyst-Me-Pul (R2: CH_2CO-SeCyst methyl ester)
- SeCyst-Et-Pul (R2: CH_2CO-SeCyst ethyl ester)
- SeCyst-*i*Pr-Pul (R2: CH_2CO-SeCyst *iso*-propyl ester)

Table 1. Degree of Substitution of Carboxymethyl Group in CM-Pul and Selenium Content of SeCyst-Pul Conjugates

Conjugate	Degree of substitution of CM group (/glucose unit of Pul)	Selenium content (mg/g conjugate)
SeCyst-Me-Pul	0.06	12.4 ± 0.3
	0.21	45.4 ± 0.7
	0.44	79.7 ± 0.5
SeCyst-Et-Pul	0.44	82.2 ± 1.8
SeCyst-*i*Pr-Pul	0.44	70.9 ± 0.9
SeCyst-Bz-Pul	0.44	79.1 ± 1.1
SeCyst-Me-His-Pul	0.44	44.1 ± 0.3
SeCyst-Me-Leu-Pul	0.44	57.9 ± 1.1
SeCyst-Me-Tyr-Pul	0.44	56.4 ± 1.9
SeCyst-Me-Trp-Pul	0.44	49.7 ± 0.7
SeCyst-Bz-Trp-Pul	0.36	56.6 ± 0.7
SeCyst-Me-His-Trp-Pul	0.36	49.9 ± 1.5
SeCyst-Me-Leu-Trp-Pul	0.36	56.2 ± 0.7
SeCyst-Me-Tyr-Trp-Pul	0.36	45.2 ± 2.7

The SeCyst esters have two chemically equivalent primary amino groups at both ends. Both amino groups could be possibly reacted intra- and/or intermolecularly with the carboxymethyl groups of the CM-Puls. To obtain structural information on the SeCyst-Pul conjugates, the particle diameters of the SeCyst-Pul conjugates were measured by the DLS technique. The mean particle diameters of SeCyst-Me-Pul (DS = 0.44), SeCyst-Me-Trp-Pul, and SeCyst-Bz-Trp-Pul conjugates were almost comparable to each other, and were close to that of Pul (Table 2 and Figure 1). The particle diameter distributions of these conjugates were also similar to that of Pul. The diselenide linkage (R-Se-Se-R) can react with free thiol compounds (R′-SH) to form selenosulfide (R-Se-S-R′). When the SeCyst-Pul conjugates are treated with an excess molar amount of glutathione (GSH), the Sec fragment (Sec-Se-SG) could be released from the SeCyst esters bound to Pul through its one end amino group. Practically, such low molecular mass selenium-containing fragments were not released from the SeCyst-Pul conjugates. Overall, the reaction of the CM-Pul with the bifunctional SeCyst esters appears to mainly result in intramolecular substitution rather than intermolecular linkage.

Aggregation of SeCyst-Pul Conjugates. The SeCyst esters have hydrophobic characteristics, and hydrophobic amino acids were also introduced to a hydrophilic Pul molecule. As the SeCyst-Pul conjugates have amphiphilic structure elements within the molecules, these conjugates could possibly form self-

Figure 1. Degree of substitution of carboxymethyl group for SeCyst-Me-Pul conjugate: 0.44.

Table 2. Particle Diameter of SeCyst-Pul Aggregates and Conjugates

Aggregate/conjugate	Degree of substitution of CM group (/glucose unit of Pul)	Particle diameter (nm)
SeCyst-Me-Pul aggregate	0.06	446.0 ± 25.6
	0.21	602.4 ± 16.8
	0.44	106.5 ± 0.9
SeCyst-Et-Pul aggregate	0.44	211.1 ± 5.7
SeCyst-*i*Pr-Pul aggregate	0.44	118.9 ± 1.2
SeCyst-Bz-Pul aggregate	0.44	175.8 ± 0.9
SeCyst-Me-His-Pul aggregate	0.44	151.1 ± 2.2
SeCyst-Me-Leu-Pul aggregate	0.44	240.9 ± 3.0
SeCyst-Me-Tyr-Pul aggregate	0.44	189.9 ± 3.5
SeCyst-Me-Trp-Pul aggregate	0.44	162.8 ± 1.3
SeCyst-Bz-Trp-Pul aggregate	0.36	253.1 ± 1.6
SeCyst-Me-His-Trp-Pul aggregate	0.36	194.2 ± 18.4
SeCyst-Me-Leu-Trp-Pul aggregate	0.36	185.7 ± 0.7
SeCyst-Me-Tyr-Trp-Pul aggregate	0.36	128.5 ± 3.6
SeCyst-Me-Pul conjugate	0.44	18.9 ± 0.8
SeCyst-Me-Trp-Pul conjugate	0.44	15.8 ± 2.8
SeCyst-Bz-Trp-Pul conjugate	0.36	15.6 ± 1.2
Pul	0.00	13.3 ± 1.0

aggregates. The aggregation behavior of the SeCyst-Pul conjugates in an aqueous medium was preliminarily checked by the static light scattering method (Supporting Information Figure S1). Scattered lights were observed from all the tested SeCyst-Pul conjugate solutions, and their intensities were apparently greater than that from the unmodified Pul solution. In comparison to the SeCyst-Me-Pul conjugates with different selenium contents, the scattered light intensity increased with the increasing selenium content (≈ degree of substitution of SeCyst ester moiety). The SeCyst-Me-Trp-Pul and SeCyst-Bz-Trp-Pul conjugates provided higher scattered light intensities than the SeCyst-Me-Pul conjugate. These facts suggest the presence of particulate materials that were formed by the self-aggregation of the SeCyst-Pul conjugates.

The SeCyst-Pul aggregates were characterized by the DLS technique (Table 2). Pul used as the starting material had a mean diameter of 13.3 nm, which indicates that Pul without any chemical modifications does not form self-aggregates. The mean particle diameters of the SeCyst-Pul aggregates were in the range from 100 to 300 nm, which were apparently greater than that of Pul. The particle diameters of the SeCyst-Me-Pul conjugates tended to decrease with an increase in the degree of substitution of the SeCyst ester moiety. The mean particle diameters of the SeCyst-Me-Pul, SeCyst-Me-Trp-Pul, and SeCyst-Bz-Trp-Pul aggregates also became greater than those of the corresponding conjugates that are dissolved in a molecularly dispersed state. The particle diameter distributions of the SeCyst-Me-Pul, SeCyst-Me-Trp-Pul, and SeCyst-Bz-Trp-Pul aggregates were evidently shifted to larger diameter ranges than those of Pul and these conjugates (Figure 1). In general, the morphology of the stable aggregate of the amphiphiles depends on their molecular orientation and freedom; the key factors are to control the hydrophile−lipophile balance, the hydrophobic interactions and dispersion of the hydrophilic moiety in the aqueous medium for formation of the structured self-aggregates (*29, 30*). The SeCyst-Me-Pul conjugates with a low DS produced larger aggregates with diameters of 400−600 nm, while the SeCyst-Bz-Pul conjugate with a high DS and benzyl group and amino acid residue produced smaller aggregate diameters (100−300 nm). Self-aggregation of the SeCyst-Pul conjugates is dependent on the degree of introduction of the SeCyst and its chemical structures, although no unambiguous relation between the hydrophobicity of the substituents and the size of the formed aggregates was found.

Since an intramolecular linkage of Pul molecules through the SeCyst esters could be cleaved by GSH treatment, the treatment of the SeCyst-Pul aggregates with GSH may give rise to

Table 3. Changes in Particle Diameter of SeCyst-Puls Aggregates after the Glutathione Treatment[a]

Aggregate	Degree of substitution of CM group (/glucose unit of Pul)	Particle diameter (nm)	
		Before	After
SeCyst-Me-Pul	0.44	106.5 ± 0.9	108.6 ± 0.4
SeCyst-Bz-Pul	0.44	175.8 ± 0.9	184.8 ± 8.8
SeCyst-Me-Trp-Pul	0.44	162.8 ± 1.3	154.2 ± 1.9
SeCyst-Bz-Trp-Pul	0.36	253.1 ± 1.6	272.1 ± 3.8

[a] Aggregate solutions were treated with 2 mM GSH at 37 °C for 30 min.

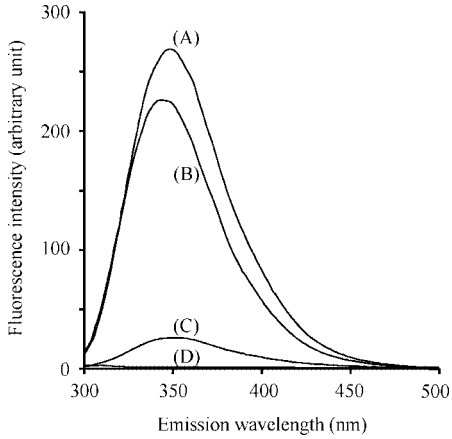

Figure 2. Tryptophan fluorescence spectra of free Trp (A), Trp-Pul (B), SeCyst-Me-Trp-Pul aggregate (C), and SeCyst-Bz-Trp-Pul aggregate (D). Trp concentration: 60 μM (*Trp concentrations were adjusted by UV absorbance at 280 nm). Excitation wavelength: 280 nm.

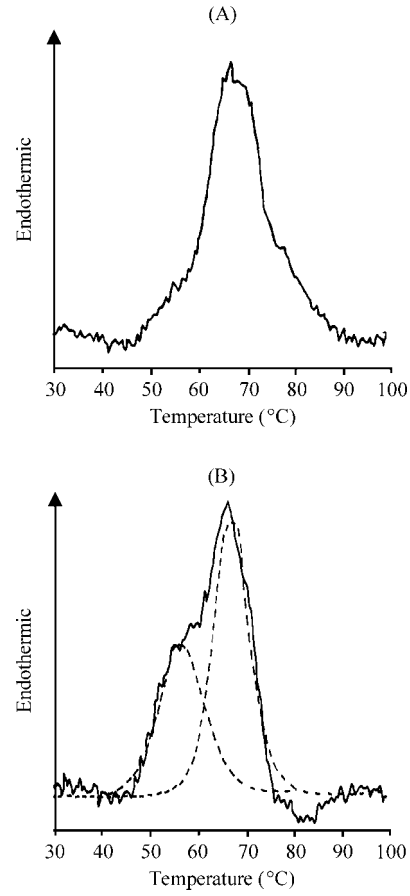

Figure 3. DSC thermograms of SeCyst-Me-Pul aggregate (A) and SeCyst-Bz-Trp-Pul aggregate (B). *Degree of substitution of carboxymethyl group for SeCyst-Me-Pul conjugate: 0.44. Heating rate: 1 °C/min. The broken lines in panel (B) were drawn by *ORIGIN* software.

structural changes in the SeCyst-Pul aggregates. The particle diameters of the SeCyst-Pul aggregates were compared before and after the treatment with an excess amount of GSH. No remarkable changes in the particle diameters were found for the SeCyst-Me-Pul, SeCyst-Bz-Pul, SeCyst-Me-Trp-Pul, and SeCyst-Bz-Trp-Pul aggregates after the GSH treatment (Table 3). Therefore, the intramolecular linkage of Pul through amino groups at both ends of the SeCyst esters does not appear to be a dominant structural element for formation of the nanosized aggregates. Consequently, the structures of the SeCyst-Pul aggregates are likely to involve noncovalent interactions such as the hydrophobic interactions between the SeCyst esters and amino acid residues rather than the diselenide linkage.

To obtain information on the structures of the SeCyst-Pul aggregates from another viewpoint, the Trp intrinsic fluorescence spectra of the SeCyst-Trp-Pul conjugates were compared to the free Trp and their precursor (Trp-Pul). Self-aggregation in aqueous medium would transfer Trp and SeCyst moieties to a hydrophobic environment. The fluorescence intensity of the SeCyst-Me-Trp-Pul aggregate mostly decreased as compared to those of the free Trp and its precursor, Trp-Pul (Figure 2). Furthermore, aggregation of SeCyst-Bz-Trp-Pul almost quenched its Trp fluorescence, demonstrating that the SeCyst-Bz-Trp moieties in Pul are associated with each other in the formed aggregates. Independently, the SeCyst-Me-Pul, SeCyst-Me-Trp-Pul, and SeCyst-Bz-Trp-Pul aggregates were prepared in the presence of a fluorescent 8-anilino-1-naphthalene sulfonic acid (ANS), and the fluorescence spectra of ANS were measured at the excitation wavelength of 380 nm. The Trp-containing SeCyst-Me-Trp-Pul and SeCyst-Bz-Trp-Pul aggregates provided a 60 nm blue shift in their fluorescence spectra (Supporting Information Figure S2). Consequently, self-aggregation of the SeCyst-Pul conjugates appears to be driven by both intramolecular chemical linking of Pul with SeCyst and the hydrophobic interactions that occur between the SeCyst side groups and amino acid residues.

The SeCyst-Pul aggregates were further characterized by a DSC analysis. When supplying heat energy to the aggregates or assemblies (e.g., lipid membranes) that are formed by noncovalent interactions, an enthalpy change due to the decomposition (disassembly) of the aggregates would be observed. Cholesterol-conjugated pullulan (CHP) can spontaneously form hydrogel aggregates in an aqueous medium with diameters ranging between 20 and 30 nm (*31–34*). The CHP self-aggregates contain hydrophobic domains that are formed by the noncovalent hydrophobic interactions among the cholesterol moieties. When the CHP aggregates were subjected to the DSC analysis, a characteristic endothermic peak was observed in the temperature range between 60 and 80 °C (Supporting Information Figure S3). This is due to the dissociation of the cholesterol hydrophobic domains in the CHP hydrogel aggregates. SeCyst-Me-Pul and SeCyst-Bz-Trp-Pul (DS of carboxymethyl group: 43.78%) also gave similar endothermic peaks at 60−80 °C (Figure 3). The observed thermal behavior resulted from the hydrophobic domains structured in the SeCyst-Pul aggregates. The Trp-containing SeCyst-Pul aggregates such as SeCyst-Me-Trp-Pul and SeCyst-Bz-Trp-Pul also produced other endothermic peaks at different temperature ranging from 50 to 70 °C. The appearance of these endothermic peaks suggests that Trp residue-associated hydrophobic interactions occur in the Trp-containing SeCyst-Pul aggregates.

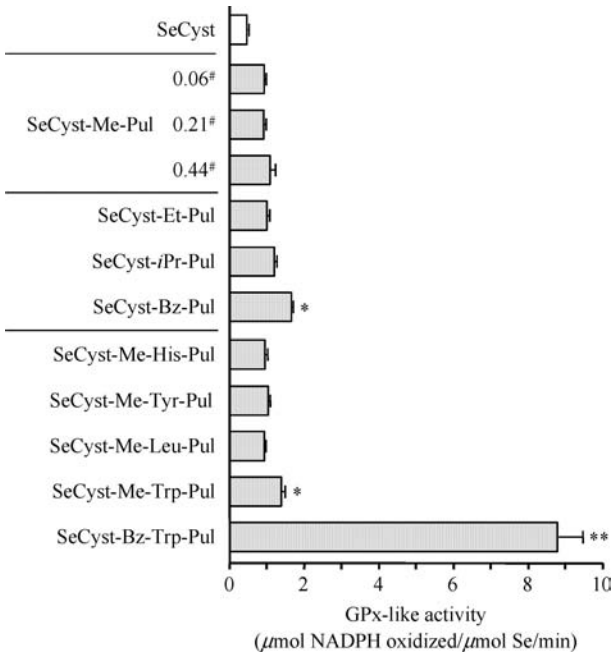

Figure 4. GPx-like activity of SeCyst-Pul aggregates for hydrogen peroxide. #: Degree of substitution of carboxymethyl group. * and **: significantly different from SeCyst at $P < 0.05$ and $P < 0.01$, respectively.

GPx-like Activity and Steady State Kinetics of SeCyst-Pul Aggregates. The GPx-like activity of the SeCyst-Pul aggregates was determined according to the conventional procedure, in which oxidation of NADPH is spectrophotometrically monitored by coupling to the reduction of the oxidized glutathione (GSSG) catalyzed by glutathione reductase. The GPx-like activity was compared among three SeCyst-Me-Pul aggregates with different degrees of SeCyst methyl ester loading. There was no significant difference in the activity among the three aggregates, and their activities were almost comparable to that of the free SeCyst (Figure 4). The SeCyst-Me-Pul, SeCyst-Et-Pul, and SeCyst-*i*Pr-Pul aggregates showed 2-fold higher activities than the free SeCyst, while the SeCyst-Bz-Pul aggregate provided 3-fold higher activity. The activities of the amino acid-inserted SeCyst-Me-His-Pul, SeCyst-Me-Tyr-Pul, and SeCyst-Me-Leu-Pul aggregates were almost twice that of the free SeCyst, whereas the Trp-containing SeCyst-Me-Trp-Pul aggregate was more effective than the other three. When SeCyst was attached to Pul through a dipeptide linkage consisting of Trp and His, Tyr, or Leu, no remarkable enhancement in the activity was also observed for SeCyst-Me-His-Trp-Pul, SeCyst-Me-Tyr-Trp-Pul, and SeCyst-Me-Leu-Trp-Pul. On the basis of these results, the benzyl side groups of the SeCyst and Trp residue appear to be good substituents for enhancing the GPx-like activity in our system. The SeCyst benzyl ester and Trp residue were, therefore, introduced to Pul. The SeCyst-Bz-Trp-Pul aggregate synergistically exhibited nearly a 20-fold higher GPx-like activity than the free SeCyst. The enhanced activity of the SeCyst-Bz-Trp-Pul aggregate was not inhibited by the radical trap 2,6-di-*tert*-butyl-4-methylphenol, which suggests that this aggregate catalyzes the reduction of H_2O_2 by the SeCyst moiety via a nonradical mechanism (*35*).

The steady state kinetics of the SeCyst-Bz-Trp-Pul aggregate-catalyzed reduction was analyzed using the double-reciprocal equation with varying concentrations of both H_2O_2 and GSH (Figure 5). The double-reciprocal plots (1/[GSH] versus 1/v) of the SeCyst-Bz-Trp-Pul aggregate-catalyzed reduction yielded parallel straight lines for three different H_2O_2 concentrations, suggesting that its reaction pathway is a "ping-pong" (double-displacement) reaction pathway analogous to those of the natural GPxs. A similar result was also obtained for the SeCyst-Me-Pul aggregate. The kinetic parameters of the two aggregates were calculated from the slope and *Y*-axis intercept of the double-reciprocal plots. The apparent reduction rate constant, k_{cat}, for the SeCyst-Bz-Trp-Pul was greater than that for SeCyst-Me-Pul (Table 4). This kinetic advantage can be supportive evidence for the enhanced GPx-like activity of the SeCyst-Bz-Trp-Pul aggregate in comparison to that of the SeCyst-Me-Pul aggregate. In addition, the SeCyst-Bz-Trp-Pul aggregate provided a higher binding affinity for GSH (K_m^{GSH}) and H_2O_2 ($K_m^{H_2O_2}$), as compared to the SeCyst-Me-Pul aggregate. Taken together with the characterization data of the SeCyst-Bz-Trp-Pul aggregate, its activity enhancement would be attributed to the hydrophobic environments that were formed together with the benzyl group and Trp residue in the vicinity of the SeCyst moiety.

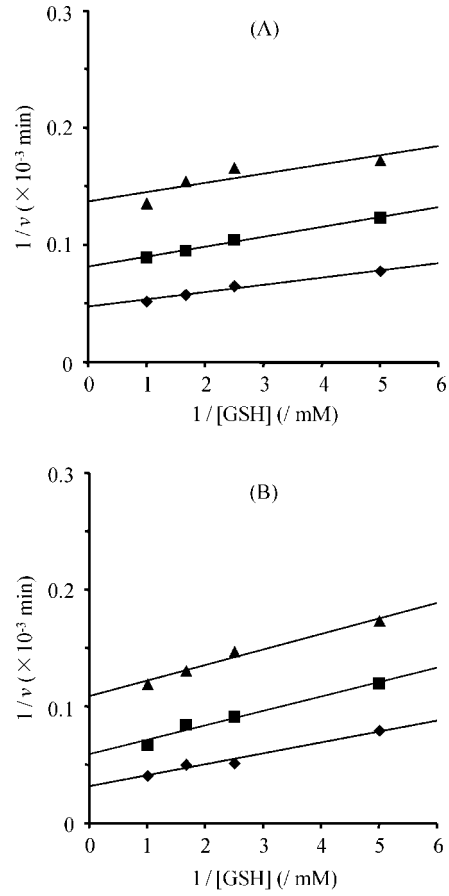

Figure 5. Double-reciprocal plots for SeCyst-Me-Pul (A) and SeCyst-Bz-Trp-Pul (B) aggregate-catalyzed H_2O_2 reduction. Selenium concentrations in SeCyst-Me-Pul and SeCyst-Bz-Trp-Pul aggregate samples: 43.6 and 2.1 μM. $[H_2O_2] = 0.25$ (▲), 0.5 (■), and 1 mM (◆).

Table 4. Kinetic Parameters of SeCyst-Me-Pul and SeCyst-Bz-Trp-Pul Aggregate-Catalyzed H_2O_2 Reduction

		K_m (mM)		k_{cat}/K_m [1/(mM·min)]	
Aggregate	k_{cat}(/min)	GSH	H_2O_2	GSH	H_2O_2
SeCyst-Me-Pul[a]	4.12	2.04	4.64	2.02	0.82
SeCyst-Bz-Trp-Pul	49.26	0.76	3.76	64.82	13.10

[a] Degree of substitution of carboxymethyl group for SeCyst-Me-Pul conjugate: 0.44.

The GPx-like activity of SeCyst-Bz-Trp-Pul aggregate for organic *tert*-butylhydroperoxide (*t*-BuOOH) as a substrate was also examined (Supporting Information Figure S4). SeCyst-Bz-Trp-Pul aggregate did not provide enhancements in the activity

for this substrate as much as that for hydrogen peroxide (nearly a 4-fold increase). A previous paper by Ren et al. (*16*) reported that SeCyst bound to the primary side of β-cyclodextrin (β-CD) via the two amino groups resulted in enhanced GPx-like activity for *t*-BuOOH and cumene hydroperoxide (CuOOH), which is ascribed to the inclusion interactions of these substrates into the hydrophobic cavity of β-CD. Although the SeCyst moieties in SeCyst-Bz-Trp-Pul aggregate exist in hydrophobic environments, *t*-BuOOH may be less accessible to the SeCyst moieties than hydrogen peroxide due to hydrophilic surrounds by Pul molecules. Consequently, the hydrophobic regions that are formed in the SeCyst-Bz-Trp-Pul aggregate do not seem to provide binding sites for such an organic substrate. Actually, selenium-dependent native GPxs possess the substrate specificity; GPx-1 is active for inorganic hydrogen peroxide, but not for organic phospholipid hydroperoxides that are substrates of GPx-4 (*36*).

In conclusion, we synthesized nanoparticulate glutathione peroxidase mimics based on the SeCyst esters-attached Pul conjugates. The chemical stability of SeCyst in an aqueous medium was somewhat improved by attachment to the Pul polymer. SeCyst-Pul conjugates were spontaneously formed into self-aggregates with diameters of several hundred nanometers. The results of the physicochemical characterization suggest the formation of hydrophobic microenvironments in the vicinity of SeCyst in the SeCyst-Pul aggregates. In comparison to the free SeCyst, improvements in the activity of the H_2O_2 reduction were observed for all the SeCyst-Pul aggregates. Even better, the most effective SeCyst-Bz-Trp-Pul aggregate produced a nearly 20-fold activity enhancement. The double-reciprocal plot analysis of the SeCyst-Bz-Trp-Pul aggregate-catalyzed reduction revealed that the catalytic mechanism of SeCyst-Bz-Trp-Pul aggregate was analogous to those of the natural GPxs (a "ping-pong" reaction pathway), and the kinetic parameters of the SeCyst-Bz-Trp-Pul aggregate were improved. Consequently, several features of our nanosized aggregate system were found to be different from the low mass GPx-mimics: (i) to improve the water solubility and stability of the liable selenium compounds in order to function as the active site; (ii) to be capable of forming a hydrophobic environment in the vicinity of the selenium compound; and (iii) to concentrate the local selenium compound in the self-aggregates. We are now designing more efficacious SeCyst-Pul aggregates with GPx-like activity. In addition, we will try to apply these aggregates to medicine as a particulate antioxidant material.

The assay was carried out at 37℃ in 0.05 M phosphate buffer (pH 7) containing 1 mM EDTA, 1 mM sodium azide, 1 mM GSH, 0.5 mM *t*-BuOOH, 0.25 mM NADPH, 1 unit of GSH reductase and 10 μmol Se/L samples.

DNA Binding and Cleaving Activity of the New Cleft Molecule *N,N′*-Bis(guanidinoethyl)-2,6-pyridinedicarboxamide in the Absence or in the Presence of Copper(II)

Ying Shao, Xin Sheng, Ying Li, Zhao-Li Jia, Jing-Jing Zhang, Fang Liu,* and Guo-Yuan Lu*

Department of Chemistry, State Key Laboratory of Coordination Chemistry, Nanjing University, Nanjing 210093, People's Republic of China. Received February 15, 2008; Revised Manuscript Received July 2, 2008

Novel cleft molecule pyridine-2,6-dicarboxamide appending two guanidinoethyl group side arms (**Gua**) was synthesized. The interactions of the cleft molecule in the absence of copper(II) (**Gua**) or in the presence of copper(II) (Cu^{2+}-**Gua**) with calf thymus DNA were studied by fluorescence and CD spectroscopy. The results indicate that the DNA binding affinity of Cu^{2+}-**Gua** is stronger than that of **Gua**, and the binding constants of Cu^{2+}-**Gua** and **Gua** are 1.61×10^6 M^{-1} and 2.86×10^5 M^{-1}, respectively. Agarose gel electrophoresis was used to assess the plasmid pUC 19 DNA cleavage activities in the presence of **Gua** and Cu^{2+}-**Gua**. Kinetic data of DNA cleavage promoted by Cu^{2+}-**Gua** under physiological conditions fit a saturation kinetic profile with k_{max} of 0.0173 ± 0.0011 h^{-1}, which gave a $\sim 10^6$-fold rate acceleration over uncatalyzed supercoiled DNA, while the catalyst concentration is lower than 0.0625 mM. The hydrolysis pathway was proposed as the possible mechanism for DNA cleavage promoted by Cu^{2+}-**Gua**. The acceleration is due to efficient cooperative catalysis of the copper cation center and the functional groups (bis(guanidinium) groups).

INTRODUCTION

Some small organic molecules and metal complexes as binding and cleaving agents for phosphodiester bonding of nucleic acids have widely been investigated due to their potential applications in the fields of molecular biological technology and drug development (*1*−*21*). However, their binding and cleaving efficiencies are still far from that of natural nuclease. In Nature, the cleavage rate of the phosphodiesters of DNA and RNA via a hydrolytic pathway is 10^{15}−10^{16}-fold accelerated by the metalloenzymes, such as staphylococcal nuclease (SNase) from *Staphylococcus aureus* (*22*−*26*). At the active site of SNase, calcium(II) ion and two guanidinium groups of arginine residues (Arg-35 and Arg-87) cooperate to activate the substrate and stabilize phosphorate-like transition states by electrostatic interaction, hydrogen bonding, and/or proton transfer (*22*−*29*). Hence, one of the basic principles of the enormous catalytic efficiency for phosphodiester cleavage of DNA and RNA by natural nucleases has been well-established as the efficient cooperation of metal ions and such functional groups at the active site.

Recently, several interesting studies (*30*−*34*) using synthetic models resembling the active site of natural nucleases, i.e., cleft molecule with amino (or ammonium) or guanidine (or guanidinium) functional groups in the presence of metal ions, have demonstrated that the reactivity toward phosphodiester cleavage can be greatly increased. The bipy unit with two ammonium groups in the presence of copper(II) designed by Krämer and Kövari (*30, 31*) can increase the hydrolytic rate of phosphodiester of bis(*p*-nitrophenyl) phosphate (BNPP). Similarly, a rigid cleft in the presence of zinc(II), reported by Anslyn and co-workers (*32*), has two guanidinium or ammonium groups proximal to the metal ion, which leads to a 3.3×10^3 enhancement of the rate of hydrolysis of the RNA dimer adenylyl phosphoadenine (ApA) compared to a corresponding complex lacking the guanidinium or ammonium group. Quite recently, Williams and co-workers (*33*) designed the Zn^{2+} complex of tetradentate tripodal ligand with aminopyridyl hydrogen bond donors that was found to be 1.5×10^3 times more reactive in promoting the cleavage of phosphodiesters of 2-hydroxypropyl 4-nitrophenyl phosphate (HPNPP) via intramolecular transesterification than the corresponding structure missing the two amino groups. These groups' outstanding work has successfully modeled the efficient catalytic cooperativity of a metal ion and functional groups and resulted in considerable increase of the cleavage rate of active phosphodiesters, e.g., BNPP, HPNPP (RNA model), and ApA. As is well known, the phosphodiester bonds of DNA are extremely stable under uncatalyzed physiological conditions and the half-life of DNA for hydrolysis is estimated to be about 200 million years (*35*−*37*). Thus, DNA cleavage via the hydrolytic pathway by artificial synthetic nuclease is a major challenge. The strategy of introduction of the functional groups proximal to the metal ion may reveal a way to cleave the DNA phosphodiester backbone effectively via a nonoxidative pathway.

Compounds with guanidium groups have attracted extensive attention due to their powerful binding ability to negative moieties as SNase (*22*−*26*) and Ptilomycalin A (*38*−*40*). With the knowledge of intermolecular recognition, the guanidium group is always used for identifying negative groups through hydrogen bonding and electrostatic interaction (*41*−*46*) in biological molecules just as the phosphate of DNA or RNA (*41, 47*−*54*). This interaction helps compounds with guanidium groups to be useful agents in phosphodiester cleaving promoters (*55*−*66*) which have been reported by several groups (e.g., Anslyn (*11, 55*−*58*), Göbel (*59*−*62*), Hamilton (*63*−*66*), and their co-workers), and a few of them were identified as powerful cleavers of RNA. Furthermore, as the guanidium group is positively charged, the corresponding compounds might also have reasonable aqueous solubility which could be used to leach toward cell wells at physiological conditions. Therefore, to mimic efficient DNA nuclease models, cleft molecule pyridine-

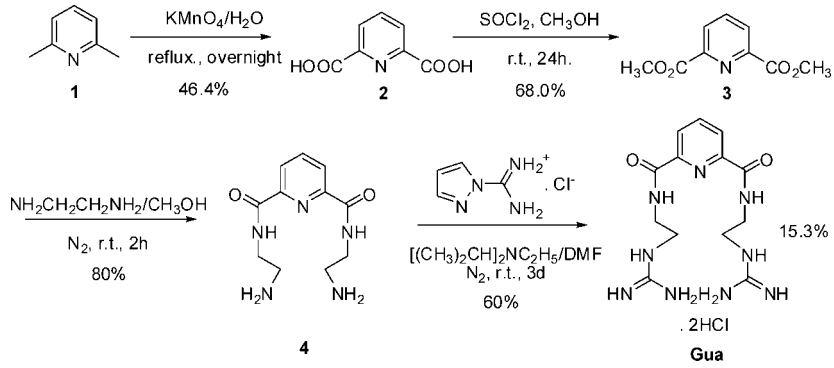
Scheme 1. Synthesis of the Compound Gua



2,6-dicarboxamide appending two guanidinoethyl group side arms (**Gua**) as hydrogen bond donors combined with strong Lewis acid copper(II) was designed as the "cooperative catalyst" promoting DNA cleavage.

In this paper, we report the synthesis (Scheme 1) of *N*,*N*′-bis(guanidinoethyl)-2,6-pyridinedicarboxamide (**Gua**), the interactions of **Gua** in the absence (**Gua**) or in the presence of copper(II) (Cu^{2+}-**Gua**) with calf thymus DNA through the spectroscopic techniques including fluorescence and circular dichroism (CD) spectroscopy, the plasmid pUC 19 DNA cleavage activities in the presence of **Gua** and Cu^{2+}-**Gua** via agarose gel electrophoresis assays, and the possible mechanism of the DNA cleavage promoted by Cu^{2+}-**Gua**.

EXPERIMENTAL PROCEDURES

Materials. All reagents, purchased from commercial sources, were of analytical grade and used without further purification. pUC 19 plasmid DNA was purchased from TaKaRa Biotechnology Co. Ltd., and the purity was checked by agarose gel electrophoresis; concentrations were determined by UV spectroscopy using the extinction coefficient appropriate for double-stranded DNA (1.0 OD_{260} = 50 μg/mL). Agarose was from Oxoid Limited (Basingstoke, UK). Ethidium bromide (EB) was from Amresco Inc. Tris(hydroxymethyl)aminomethane (Tris-Base) was from Robiot Co. Ltd. Bromophenol blue, glycerol, and ethyldiaminetetraacetic acid (EDTA) were commercially available. Deionized water was obtained from an ionized column from doubly distilled water. All solvents were purified by the standard procedure. All aqueous solutions were prepared from deionized water.

The stock solution of CT-DNA (stored at 4 °C and used for not more than 2 days) was prepared in 5 mM Tris-HCl/10 mM NaCl, pH 7.0, and the concentration of the CT-DNA was determined according to its absorption intensity at 260 nm with a molar extinction coefficient value of 6600 M^{-1} cm^{-1}, and the ratio of UV absorbance at 260 and 280 nm, A_{260}/A_{280} = 1.8−1.9, indicating that the DNA was sufficiently free of protein (*67, 68*).

Apparatus. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Brucker AM 300 spectrometer. Mass spectra were obtained on an electrospray mass spectrometer (LCQ, Finnigan or TSQ 7000, Finnigan) in positive or negative mode. IR spectra were recorded in the 4000−400 cm^{-1} region (KBr discs) on a VEVTOR 22 FT-IR spectrometer. The pH value was confirmed with an ORION868 pH meter with an Ag/AgCl electrode as the reference electrode in a saturated KCl solution at room temperature. Agarose gel electrophoresis was conducted with a DYY−5 electrophoresis apparatus. Bands were visualized by UV light and photographed using a DigiDoc-It gel imaging and documentation system (version 1.1.23, UVP, Inc., Unpland, CA). The intensity of the DNA bands was estimated by *TotalLab* image analysis software (version 2.01).

UV−vis Spectral Measurements. UV−visible spectra were measured on Perkin-Elmer Lambda 25 UV−vis Spectrometer using a 1 cm path length UV cell at room temperature. An anhydrous MeCN solution in a final volume of 3 mL consisted of 12.8 μM $CuCl_2$ and the incremental addition of **Gua** from 0 to 54.6 μM in MeCN at room temperature was prepared and subjected to spectral analysis.

Fluorescence Measurements. The fluorescent spectral studies were carried out through the detection of the emission intensity of ethidium bromide (EB) on an AMINCO Bowman Series 2 luminescence spectrometer. The experiments were carried out by adding 0 to 46 μM **Gua** or Cu^{2+}-**Gua** into the EB bound CT-DNA (0.046 mM) solution in 5 mM Tris-HCl buffer (pH 7.0), and the fluorescence was measured and normalized to 100% relative fluorescence.

Circular Dichroism Measurements. All CD spectroscopic studies were carried out with a continuous flow of nitrogen purging the polarimeter by using a Jasco J−810 automatic recording spectropolarimeter, and the measurements were performed at room temperature with 1 cm pathway cells. The CD spectra were run from 320 to 220 nm at a speed of 20 nm/min and the buffer background was automatically subtracted. Data were recorded at an interval of 0.1 nm. The CD spectrum of CT-DNA alone (116 μM) was recorded as the control experiment.

Gel Electrophoresis Assays. Cleavage reactions of supercoiled pUC 19 DNA (0.025 mM bp) were carried out at 37 °C in 50 mM Tris-HCl/10 mM NaCl buffer in a total volume of 15 μL. The results of cleavage reactions were monitored by agarose gel electrophoresis (80 V for 2 h), and the supercoiled pUC 19 DNA values were corrected by a factor of 1.3 on the basis of average literature estimates of the weakened binding of EB to this structure (*69*−*71*).

Synthesis of 2,6-Pyridinedicarboxic Acid (2). (*72*) 2,6-Dimethylpyridine (2.5 g, 23.3 mmol) was stirred with potassium permanganate (8 g, 50.6 mmol) in water (150 mL) under refluxing. When the color of the mixture turned dark without any purple for nearly 2 h, another amount of potassium permanganate (8 g, 50.6 mmol) in 30 mL of water was added dropwise. The reaction then stood overnight under reflux. The precipitate was filtered off immediately without cooling. The filtrate was condensed to about 80 mL, followed by addition of concentrated hydrochloric acid (15 mL). After cooling, acicular crystal (1.81 g, 10.8 mmol) was obtained from the solution. Yield 46.4%. m.p. 196−200 °C. ^{1}H NMR (300 MHz, D_2O) δ 8.18 (t, J = 9.0 Hz, 1H, Ar−H), 8.29 (d, J = 9.0 Hz, 2H, 2 × Ar−H).

Synthesis of 2,6-Pyridinedicarboxate Dimethyl Ester (3). (*73*) Thionyl chloride (1.9 g, 16.0 mmol) was added dropwise to a solution of 2,6-pyridinedicarboxic acid (2.5 g, 15.0 mmol) in methanol (30 mL) while stirring at room temperature. The mixture was then stirred for another 24 h.

Table 1. Selected IR Spectral Data of Gua and Cu^{2+}-Gua (cm^{-1})[a]

compound	ν_{N-H}	$\nu_{C=O}$ [amide I]	amide II	amide III	pyridine ring streching	pyridine ring C−H deformation
Gua	3302m, 3163m	1651b	1543s	1286w	(n. o.), 1446s	723m
Cu^{2+}-**Gua**	3328m, 3269m, 3203w	1651s	1548w	1288w	1624s, 1458w, 1431w	726m

[a] IR spectra of **Gua** and (b) Cu^{2+}-**Gua** (Figure S09, Supporting Information). m = medium, b = broad, s = strong, w = weak, n. o. = not observed distinctly, might have merged with the amide I band.

Filtered and washed with cold methanol, white powder (2 g, 10.2 mmol) was obtained after evaporating to dryness. Yield 68.0%. m.p. 130−132 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ 4.02 (s, 2H, 2 × CH_3), 8.04 (t, J = 7.8 Hz, 1H, Ar−H), 8.33 (d, J = 7.8 Hz, 2H, 2 × Ar−H).

Synthesis of *N,N′*-Bis(2-aminoethyl)-2,6-pyridinedicarboxamide (4). (*74*) A mixture of **3** (2 g, 0.010 mol) and 1,2-diaminoethane (4.5 g, 0.075 mol) in anhydrous methanol (150 mL) was stirred under the protection of dry nitrogen at room temperature for 2 h. The solution was filtered and evaporated under vacuum followed by azeotropy with dichloromethane (2 × 50 mL) to remove the superfluous diaminoethane. The residue was further distilled in vacuum to afford a colorless oil (2 g, 0.008 mol) at 70 °C (20 mmHg): Yield 80%. ^{1}H NMR (300 MHz, D_2O) δ 2.76 (t, J = 6.3 Hz, 4H, $2NCH_2$), 3.37 (t, J = 6.3 Hz, 4H, $2CONCH_2$), 7.86−7.94 (m, 3H, 3Ar−H). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.91 (sb, 4H, $2NH_2$), 2.98−3.07 (m, 4H, $2NCH_2$), 3.55−3.61 (m, 4H, $2CONCH_2$), 8.03 (t, J = 7.8 Hz, 2H, 2Ar−H), 8.37 (d, J = 7.8 Hz, 1H, Ar−H), 8.59 (sb, 2H, 2CONH). ESI-MS m/z $[M + H]^+$ calcd 252.1, found 252.2.

Synthesis of *N,N′*-Bis(guanidinoethyl)-2,6-pyridinedicarboxamide (Gua). (*75*). Compound **4** (550 mg, 2.2 mmol), 1*H*-pyzazole-carboxamidine hydrochloride (710 mg, 6.4 mmol), and *N,N*-diisopropyl ethylamine (DIEA, 620 mg, 4.8 mmol) were dissolved in anhydrous DMF (30 mL) and stirred under dry nitrogen at room temperature for 3 days. Then, diethyl ether (100 mL) was poured into the mixture to quench the reaction with an appearance of precipitation. Frozen in the refrigerator for 24 h, followed by filtration and washing with diethyl ether (2 × 20 mL), the solid was dried under vacuum to get a pale yellow powder (440 mg, 1.3 mmol). Yield 60%, m.p. 262−264 °C. ^{1}H NMR (300 MHz, D_2O) δ 3.41(t, J = 6.0 Hz, 4H, $2NCH_2$), 3.59 (t, J = 6.0 Hz, 4H, $2CONCH_2$), 8.01−8.16 (m, 3H, 3Ar−H). ^{13}C NMR (75 MHz, D_2O) δ 38.6 (NCH_2), 41.0 (NCH_2), 125.4 (Ar−C), 147.9 (Ar−C), 140.2 (Ar−C), 157.4 (guanidino-C), 166.2 (C=O). ESI-MS m/z $[M - 2Cl^-]^{2+}$ calcd 168.6, found 168.7; $[M - 2Cl^- - H^+]^+$ calcd 336.2, found 336.3; $[M - Cl^-]^+$ calcd 372.2, found 372.0.

Preparation of Cu^{2+}-Gua Storage Solution. A mixture of dried $CuCl_2$ (0.013 g, 0.10 mmol) and **Gua** (0.041 g, 0.10 mmol) in methanol (10 mL) was stirred for 1 h at room temperature and then evaporated to remove the solvent. The residue was dissolved in 10 mL deionized water as the Cu^{2+}-**Gua** storage solution (10 mM). ESI-MS m/z $[\mathbf{Gua} + Cu^{2+} - Cl^-]^{3+}$ calcd 145.03, found 145.00.

RESULTS AND DISCUSSION

General Aspects. The synthesis of the target compound **Gua** (Scheme 1) was achieved via a four-step reaction sequence of oxidation, esterification, nucleophilic substitution, and guanylation, starting from 2,6-dimethylpyridine **1**. Guanylation (*75*) of the primary amino group was carried out by using the guanylating reagent 1*H*-pyrazole-1-carboxamidine hydrochloride to give **Gua** in good yield. The compound **Gua** was characterized by ^{1}H NMR, ^{13}C NMR, and ESI-MS spectra (Supporting Information, S5−6). In ^{13}C NMR spectrum, the signal at δ157.4 ppm consists of the chemical shift of the guanidinium group, and in the ESI-MS spectrum, the signals at m/z 168.7, 336.2, and 372.0 correspond to $[\mathbf{Gua} - 2Cl]^{2+}$ (calcd. 168.6), $[\mathbf{Gua} - Cl^- - HCl]^+$ (calcd 336.2), and $[M - Cl^-]^+$ (calcd 372.2), respectively. The main signal at m/z 145.0 (Supporting Information, S6) in ESI-MS spectrum of Cu^{2+}-**Gua** corresponds to $[Cu^{2+} - \mathbf{Gua} - Cl^-]^{3+}$, indicating binding of **Gua** with Cu^{2+} (with an uncharged amide functional group), and the binding constants (K_{ML}) were determined to be (1.20 ± 0.09) × 10^6 M^{-1} (Figure S01, Supporting Information) by spectrophotometric titration at room temperature according to the literature (*76*−*78*). Kalagouda and co-workers reported that a pyridinedicarboxamide derivative with an uncharged amide functional group can coordinate metal ions through either the O or N and the coordination modes of several metal complexes using infrared spectrum analysis (*101*). In the IR spectra of Cu^{2+}-**Gua** (Figure S09, Supporting Information; selected data shown in Table 1), compared with that of **Gua**, the band of ν(N−H) is split into multisignals, indicating the involvement of nitrogen in coordination with either amide or guanidino, while the band of ν(C=O) (1651 cm^{-1}) does not show any considerable shift, indicating the noninvolvement of oxygen in coordination (*102*). The amide II and amide III bands show a small shift of 2−5 cm^{-1} suggesting the coordination of amide nitrogen. The pyridine band was shifted to a lower wavenumber in the Cu^{2+}-**Gua** by about 20 cm^{-1}. The band at 1446 cm^{-1} is split into two components, 1458 cm^{-1} and 1431 cm^{-1}, and indicates clearly the coordination of pyridine nitrogen to the metal. The changes in the C−H deformation mode in all of the complexes indicate the coordination of pyridine nitrogen (*102*).

DNA Binding Assays. DNA binding is the critical step for DNA cleavage in most cases. Therefore, the binding of **Gua** and Cu^{2+}-**Gua** to CT-DNA has been studied by using fluorescence and CD spectroscopy. UV−vis absorption spectroscopy is also one of the convenient tools for examining the interaction between small molecule and nucleic acids (*79*−*81*), but their UV absorbances to calf thymus (CT-DNA) were disturbed by absorbances of CT-DNA itself, and thus the DNA binding studies were not carried out by using UV−vis absorption spectroscopy.

Fluorescence Spectroscopic Studies. The binding of the compounds to CT-DNA was studied by evaluating the fluorescence emission intensity of the ethidium bromide (EB)-DNA system upon the addition of the two compounds. If these compounds added to the EB-DNA system replace the bound EB, the emission intensity will be reduced. The fluorescence quenching of EB bound to DNA by **Gua** and Cu^{2+}-**Gua** is shown in Figure S02 (Supporting Information), in which the fluorescence intensity at 600 nm (λ_{ex} = 526 nm) of EB in the bound form was plotted against the compound concentration. The relative binding propensity of the compounds to CT-DNA was determined by the classical Stern-Volmer equation I_0/I = 1 + Kr (*82*, *83*), where I_0 and I are the fluorescence intensities in the absence and the presence of the quencher, respectively. K is the linear Stern-Volmer quenching constant dependent on the ratio of r_{bE} (the ratio of the bound concentration of EB to the concentration of DNA). r is the ratio of total concentration of the quencher to that of DNA (*82*−*84*). Figure 1a is the plot of I_0/I versus [quencher]/[DNA]; the quenching constant K is given by the ratio of the slope to the intercept. The quenching constant K values obtained for **Gua** and Cu^{2+}-**Gua** are 0.045 ± 0.001 and 0.807 ± 0.020, respectively. These results demonstrate that Cu^{2+}-**Gua** has stronger affinity to DNA than **Gua**. The apparent binding constant (K_{app}) is also calculated

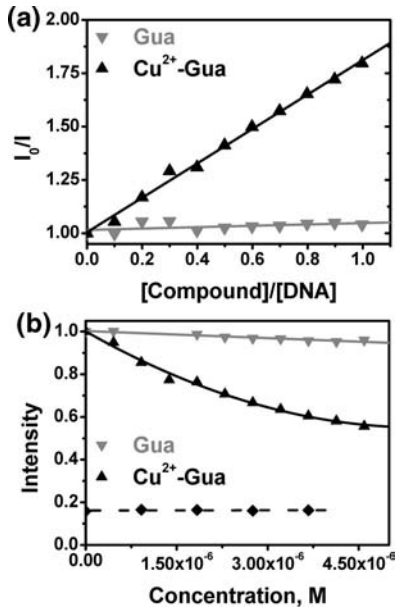


Figure 1. (a) Emission profiles of 0.046 mM CT-DNA-bound EB in a 5 mM Tris-HCl buffer (pH 7.0) upon the addition of (▼) **Gua** and (▲) Cu^{2+}-**Gua** at 25 °C. (b) The Stern-Volmer quenching plots of EB bound to DNA by (▲) **Gua** and (▼) Cu^{2+}-**Gua**, which give the quenching constants K (◆, the emission intensity of EB without CT DNA in the presence of different concentrations of Cu^{2+}-**Gua**).

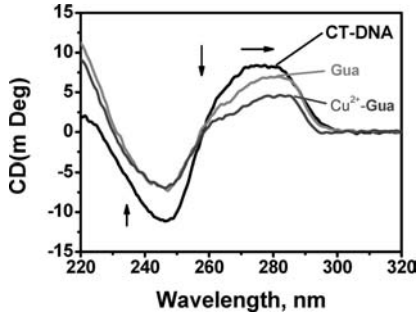

Figure 2. CD spectra of CT-DNA (0.116 mM) in black and the interaction with Cu^{2+}, **Gua**, and Cu^{2+}-**Gua** at ratio of [compound]/[DNA] = 0.4. All the spectra were recorded in Tris-HCl buffer pH 7.0.

from the equation K_{EB}[EB] = K_{app}[complex], where the complex concentration is the value at a 50% reduction of the fluorescence intensity of EB and $K_{EB} = 1.0 \times 10^7$ M^{-1} ([EB] = 1.3 μM) (*84*). The K_{app} values are $(2.86 \pm 0.29) \times 10^5$ M^{-1} for **Gua** and $(1.61 \pm 0.11) \times 10^6$ M^{-1} Cu^{2+}-**Gua** (Figure 1b). It is noticeable that the binding constant of Cu^{2+}-**Gua** is about 5-fold greater than that of **Gua**.

Circular Dichroism Studies. Circular dichroism is a powerful technique to diagnose changes in DNA morphology during drug−DNA interactions, as the band due to base stacking (275 nm) and that due to right-handed helicity (248 nm) are quite sensitive to the mode of DNA interactions with small molecules (*85*, *86*). The changes in CD signals of DNA observed on interaction with drugs may often be assigned to the corresponding changes in DNA structure (*87*). Thus, simple groove binding and electrostatic interaction of small molecules show little or no perturbation on the base-stacking and helicity bands, while intercalation enhances the intensities of both the bands stabilizing the right-handed B conformation of CT-DNA as observed for the classical intercalator methylene blue (*88*). Figure 2 displays the CD spectra of CT-DNA treated with **Gua** and Cu^{2+}-**Gua** with the ratio of 0.4 ([Compound]/[DNA]). The positive (∼275 nm) band decreased in intensity with a concomitant red shift to 280 nm (*89*) with the addition of the compound, while the negative (∼247 nm) band increased in intensity. This suggests that **Gua** and Cu^{2+}-**Gua** can unwind the DNA helix and lead to the loss of helicity (*90*, *91*). The largest decrease in the CD band intensity caused by Cu^{2+}-**Gua** larger than **Gua** at the same concentration implies that Cu^{2+}-**Gua** is more effective than **Gua** in perturbing the secondary structure of DNA.

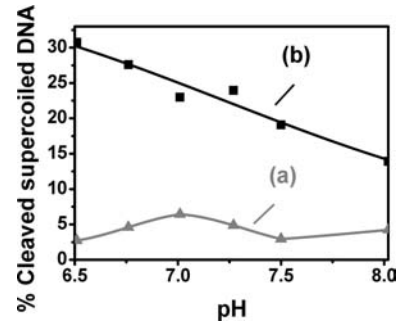

Figure 3. pH-dependent profile for pUC DNA (0.025 mM bp) cleavage promoted by 0.0375 mM (a) **Gua** and (b) Cu^{2+}-**Gua**. (The agarose gel (Figure S03, Supporting Information) of pUC 19 DNA (0.025 mM bp) incubated for 30 h in different pH buffer (50 mM Tris-HCl/10 mM NaCl) at 37 °C.)

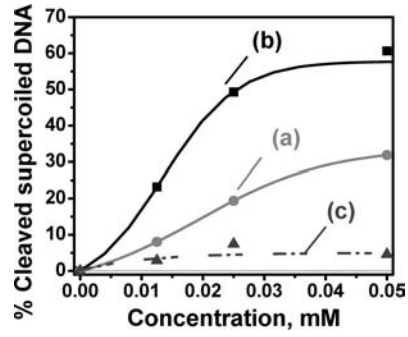

Figure 4. Plot of % cleaved DNA vs different concentrations of (a) **Gua** (b) Cu^{2+}-**Gua** and (c) Cu^{2+} control. (The agarose gel (Figure S04, Supporting Information) of pUC 19 DNA (0.025 mM bp) incubated for 48.0 h at 37 °C with different concentrations of (a) Cu^{2+}-**Gua** and (b) **Gua** in pH 7.0 buffer (50 mM Tris-HCl/10 mM NaCl).)

From the results of fluorescence and CD spectroscopic studies, it is concluded that Cu^{2+}-**Gua** binds more strongly to DNA than **Gua**.

DNA Cleavage Activity. *pH Dependence of DNA Cleavage Promoted by* **Gua** *and* Cu^{2+}-**Gua.** Figure 3 presents the pH-dependence profile which indicates that the optimal pH in physiological condition for DNA cleavage in the presence of **Gua** is pH 7.0, while the cleaving ability of Cu^{2+}-**Gua** was decreasing with the increase of pH from 6.5 to 8.0 at the same condition (the agarose gel is shown in Figure S03, Supporting Information). Therefore, pH 7.0 was chosen for the following agarose gel electrophoresis assays.

Concentration Dependence Assays of DNA Cleavage Promoted by **Gua** *and* Cu^{2+}-**Gua.** Figure 4 shows the plots of % cleaved DNA vs different concentrations of **Gua**, Cu^{2+}, and Cu^{2+}-**Gua** (the agarose gel is shown in Figure S04, Supporting Information), which represents the saturation profiles and indicates that the DNA cleavage activities of **Gua** and Cu^{2+}-**Gua** are increased with the increase of their concentrations. The further increase of concentrations of **Gua** and Cu^{2+}-**Gua** (larger than 0.05 mM) results in further fragmentation and DNA smearing on the electrophoresis gel (the agarose gel is shown in Figure S05, Supporting Information). In order to further

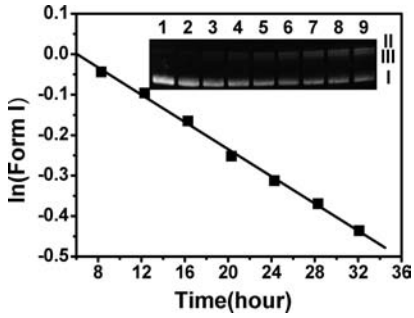

Figure 5. Time course of pUC19 DNA (0.025 mM bp) cleavage promoted by Cu^{2+}-**Gua** (0.0375 mM). Inset is agarose gel (1%) of the time-variable reaction products. Lanes 1−9: reaction times of 0, 4.27, 8.3, 12.3, 16.3, 20.3, 24.27, 28.3, and 32.10 h, respectively.

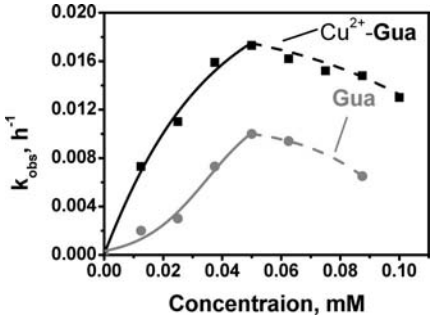

Figure 6. Kinetics plot of k_{obs} vs various concentrations of Cu^{2+}-**Gua** (■) and **Gua** (•).

understand that whether the copper ions alone are able to cleave DNA, control assays were carried out under the same conditions by the metal ions alone. Figure S04c (Supporting Information) shows the results of pUC 19 DNA cleavage in the presence of different concentrations of copper ions. Little cleavage was found and the same result was reported by Barton (*92*).

Kinetic Assays. Kinetics of pUC 19 DNA degradation has been studied. Figure 5 shows the supercoiled plasmid DNA cleavage in nicked and linear form with further reaction, promoted by Cu^{2+}-**Gua** (0.0375 mM) in Tris-HCl/NaCl buffer (pH 7.0) at 37 °C. The time course plot indicates that the extension of supercoiled DNA cleavage varies exponentially with the reaction time giving pseudo first-order kinetics with an apparent initial first-order rate constant (k_{obs}) of 0.0159 ± 0.0006 h^{-1}. Then, the apparent initial first-order rate constants of DNA cleavage reactions promoted by a series of various concentrations of **Gua** and Cu^{2+}-**Gua** under the similar conditions as described above are summarized in Table S01 (Supporting Information). Figure 6 shows the kinetics profile of the supercoiled DNA cleavage at various concentrations of **Gua** and Cu^{2+}-**Gua**. Data of Cu^{2+}-**Gua** give the first-order rate constant k_{max} of 0.0173 ± 0.0011 h^{-1} (Table S01, Supporting Information). The activity increases with the concentration of **Gua** and Cu^{2+}-**Gua** up to a maximum at approximately 0.0500 mM. When the concentration is further increased, the bands corresponding to form II and III are ill-defined due to the appearance of DNA smearing on gel, resulting in the decrease of k_{obs}, and the binding of **Gua** and Cu^{2+}-**Gua** to smaller fragments of DNA could reduce the obvious catalytic efficency for cleaving supercoiled DNA.

DNA Cleavage Mechanism. Copper(II) complexes can cleave DNA by both hydrolytic (*92*−*96*) and oxidative (*97*−*99*) pathways. In the second case, they have been shown to react with molecular oxygen or hydrogen peroxide to produce a variety of reactive oxygen species (ROS) (*100*). Normally, a reducing agent (a thiol or ascorbic acid) is required to initiate

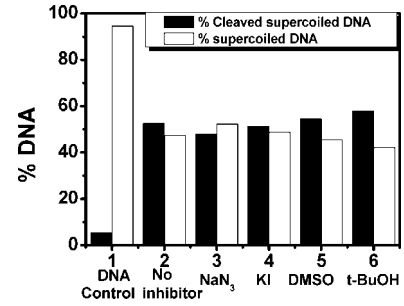

Figure 7. Histogram representing of pUC19 plasmid DNA (0.025 mM bp) cleaved by Cu^{2+}-**Gua** (0.05 mM) in the presence of standard radical scavengers incubated for 33 h at 37 °C in pH 7.0 buffer (50 mM Tris-HCl/10 mM NaCl) (the agarose gel is shown in Figure S06, Supporting Information).

and sustain the radical reaction, but particularly with the employment of DNA derived from biological sources, the presence of adventitious reducing agent is always possible (*93*). To verify whether ROS are, at least in part, responsible for the cleavage of DNA promoted by Cu^{2+}-**Gua**, reactions were carried out in the presence of typical scavengers for singlet oxygen (NaN_3, 10 mM), for superoxide (KI, 10 mM), and for hydroxyl radical (1 mM DMSO and 1 mM *t*-BuOH) (Figure 7). For Cu^{2+}-**Gua**, there is no evident inhibition effect on the DNA cleavage in the presence of all scavengers (NaN_3, DMSO, *t*-BuOH, and KI), which rules out the involvement of these reactive oxygen species, at least in a free and diffusible form, and suggests a nonoxidative pathway.

Generally, the oxidative DNA cleavage process is due to the oxidation of the ribose or base group of DNA by the reactive oxygen species (*97*−*99*). Thus, the DNA samples containing Cu^{2+}-**Gua** were incubated in the presence of nucleosides (adenosine, guanosine, and cytidine, respectively) with the ratio of [nucleoside]/[DNA bp] = 1:1, followed by electrophoresis and quantitation (Figure S07, Supporting Information). No inhibition in the amount of cleaved DNA was detected after the treatment with Cu^{2+}-**Gua** in the presence of all of the nucleosides, which proves the nonoxidative process and/or the competitive binding ability with the nucleosides (Table S03, Supporting Information). On the other hand, in the DNA cleavage reactions promoted by Cu^{2+}-**Gua**, when the active phosphates bis(2,4-dinitrophenyl) phosphate (BDNPP) or bis(*p*-nitrophenyl) phosphate (BNPP) without the pentose and the pyrimidine or purine base was added, the reactions were partially inhibited (Table S03, Supporting Information). The inhibition can be ascribed to the preferentially hydrolyzed phosphodiester of BDNPP or BNPP. It implies that the hydrolysis pathway for the DNA cleavage process is possible. All these results suggest that the DNA cleavage promoted by Cu^{2+}-**Gua** is mainly through the hydrolysis pathway.

In order to further prove the hydrolysis pathway, a small dinucleotide model system adenylyl(3′−5′)phosphoadenine (ApA) was used as the nucleic acid mimics. ApA (0.05 mM) and Cu^{2+}-**Gua** (0.0375 mM) were dissolved in deionized water (1:1), and after 8 h equilibration time at 37 °C, ESI-MS analysis was carried out. In the ESI-MS spectrum (Figure S08b, Supporting Information), the signals at *m*/*z* 267.9 and 346.2 show the ApA cleavage products $[A+H]^+$ (adenosine) (calc 268.1) and $[AMP-H]^-$ (adenosine monophosphate) (calc 346.1), and no sign of ApA was found. While at the same condition, ESI-MS spectra of ApA alone show only the signal of ApA; no sign of A and AMP (Figure S08c, Supporting Information). The generation of the A and AMP indicates that the phosphodiester bond of ApA would be cleaved by Cu^{2+}-**Gua** via the hydrolysis pathway (*47, 103*). As a comparison, ESI-MS analysis of ApA treated with **Gua** alone was also

carried out under the same conditions (Figure S08a, Supporting Information), and there were weaker signals of cleavage products A and AMP, as well as the obvious signal of ApA (Figure S08b, Supporting Information). Therefore, similar to ApA, the hydrolysis pathway should be the possible mechanism for DNA cleavage promoted by Cu^{2+}-**Gua** and the phosphodiester bond hydrolysis ability of Cu^{2+}-**Gua** is stronger than that of **Gua**.

CONCLUSION

In conclusion, novel cleft molecule, pyridine-2,6-dicarboxamide appending two guanidinoethyl group side arms (**Gua**), was synthesized. The interactions of the interactions of **Gua** in the absence or in the presence of copper(II) (Cu^{2+}-**Gua**) with calf thymus DNA were studied by spectroscopic techniques (fluorescence and CD spectroscopy). The results indicate that the DNA binding affinity of Cu^{2+}-**Gua** is stronger than that of **Gua**. Agarose gel electrophoresis was used to assess the plasmid pUC 19 DNA cleavage activities in the presence of **Gua** and Cu^{2+}-**Gua**. Kinetic data of DNA cleavage promoted by Cu^{2+}-**Gua** under the physiological conditions give the maximal initial rate constant k_{max} of 0.0173 h^{-1}, which shows about 10^6-fold rate acceleration over uncatalyzed supercoiled DNA (*35*−*37*). The acceleration is due to the efficient cooperative catalysis of the copper(II) cation center and the functional groups (bisguanidinium groups). The hydrolysis pathway should be the possible mechanism for DNA cleavage promoted by Cu^{2+}-**Gua**.

ACKNOWLEDGMENT

This work was supported by the National Basic Research (grant no. 2007CB925103) and National Science Foundation (grant no. 20774039) of China. We acknowledge gratefully Prof. Chen-Yu Zhang and Li-Qing Qiang for the assistance with the electrophoresis assays.

Supporting Information Available: Spectra for all new compounds, fluorescence and UV−vis spectroscopy, photographs of the agarose gels, and kinetic data. This material is available free of charge via the Internet at http://pubs.acs.org.

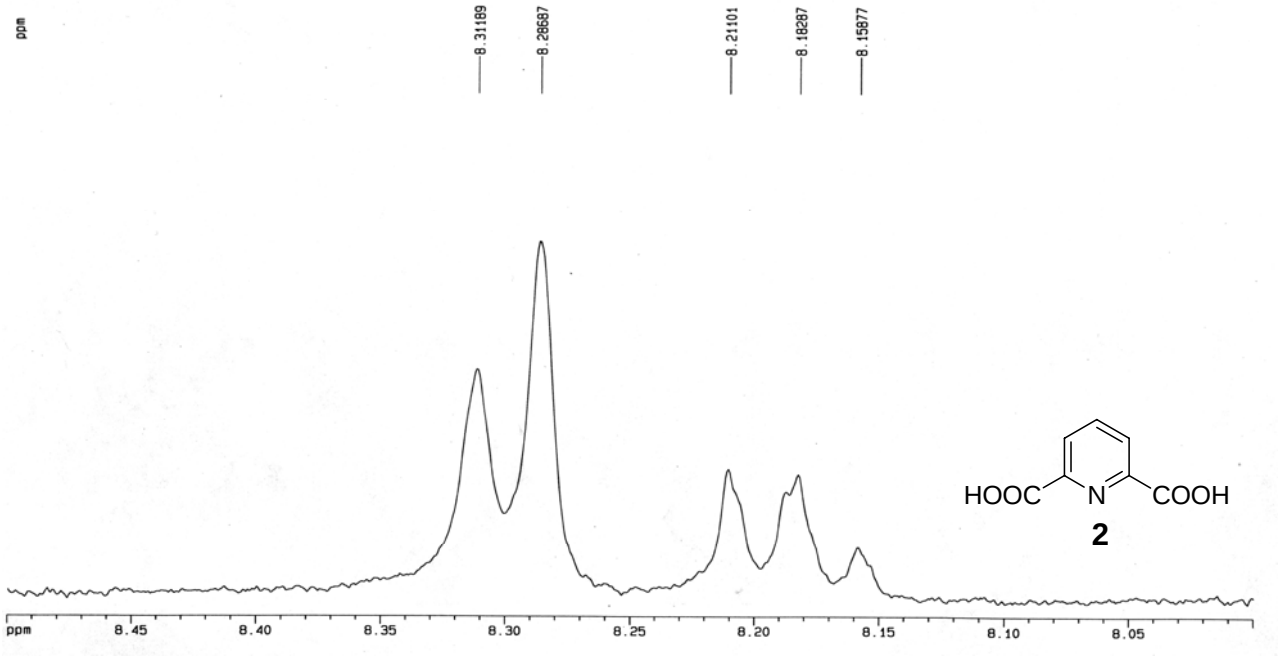
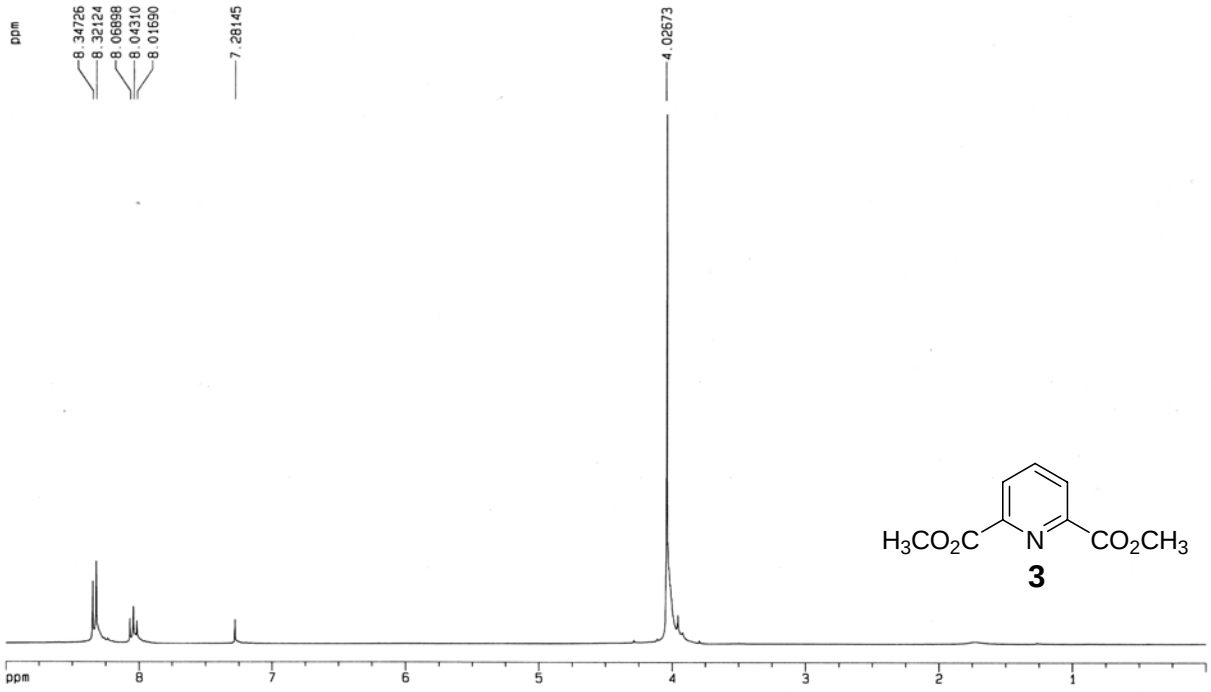
Table of content

1. NMR , ESI-MS spectra P2-P6
2. UV-Visible spectra (Figure S01) P7
3. Fluorescent spectra (Figure S02) P8-P9
4. Agarose gel of pH dependence (Figure S03) P10
5. Agarose gel of Concentration dependence (Figure S04-05) P11-12
6. Kinetic data (Table S01) P13-P27
7. Figure S06 and Table S02 P28
8. Figure S07 and Table S03 P29
9. ESI-MS spectra of ApA (Figure S08) P30-P32
10. IR spectra (Figure S09) P33-P34

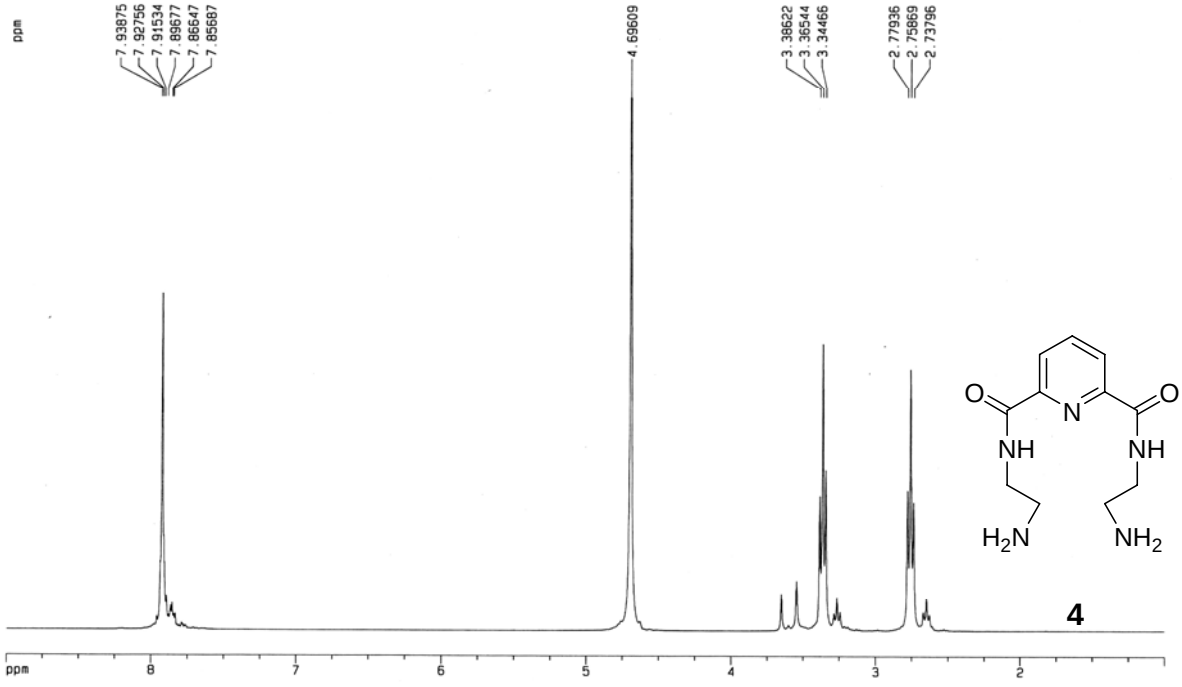
NMR and ESI-MS spectra



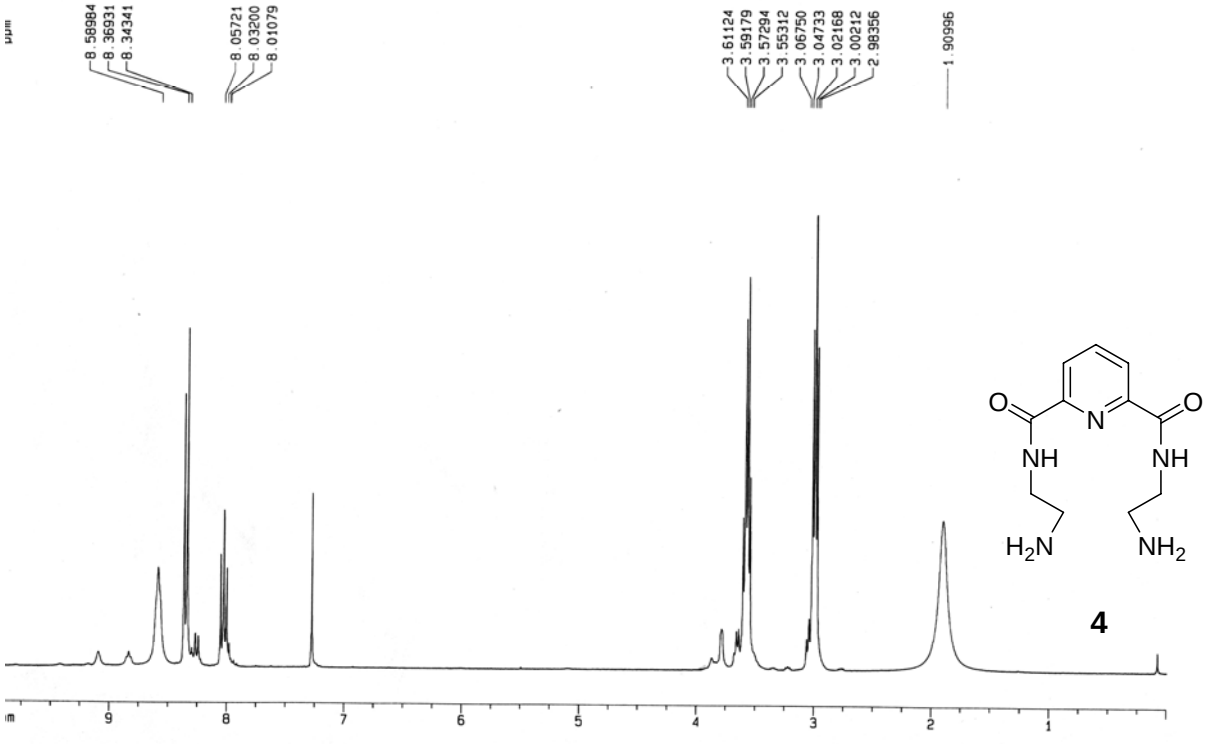
^{1}H NMR (300 MHz, D_2O) spectrum of **2**.



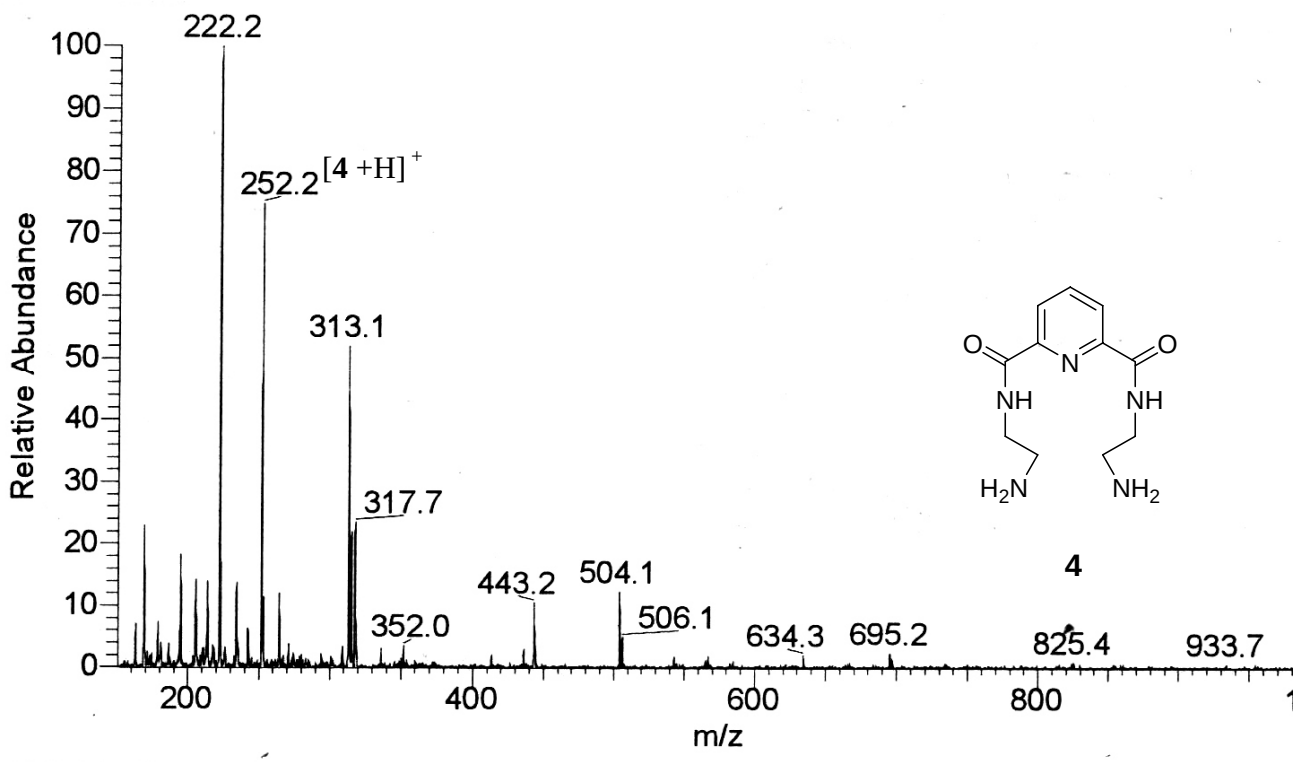
^{1}H NMR (300 MHz, $CDCl_3$) spectrum of **3**.



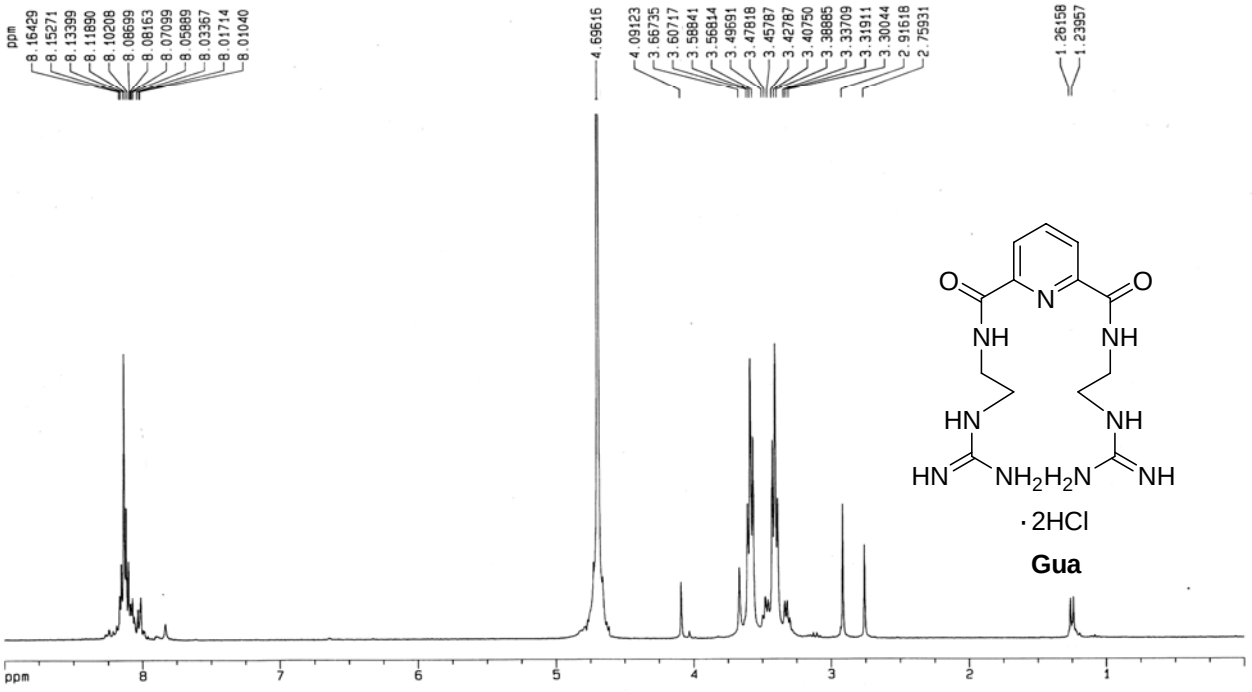
^{1}H NMR (300 MHz, D_2O) of **4**.



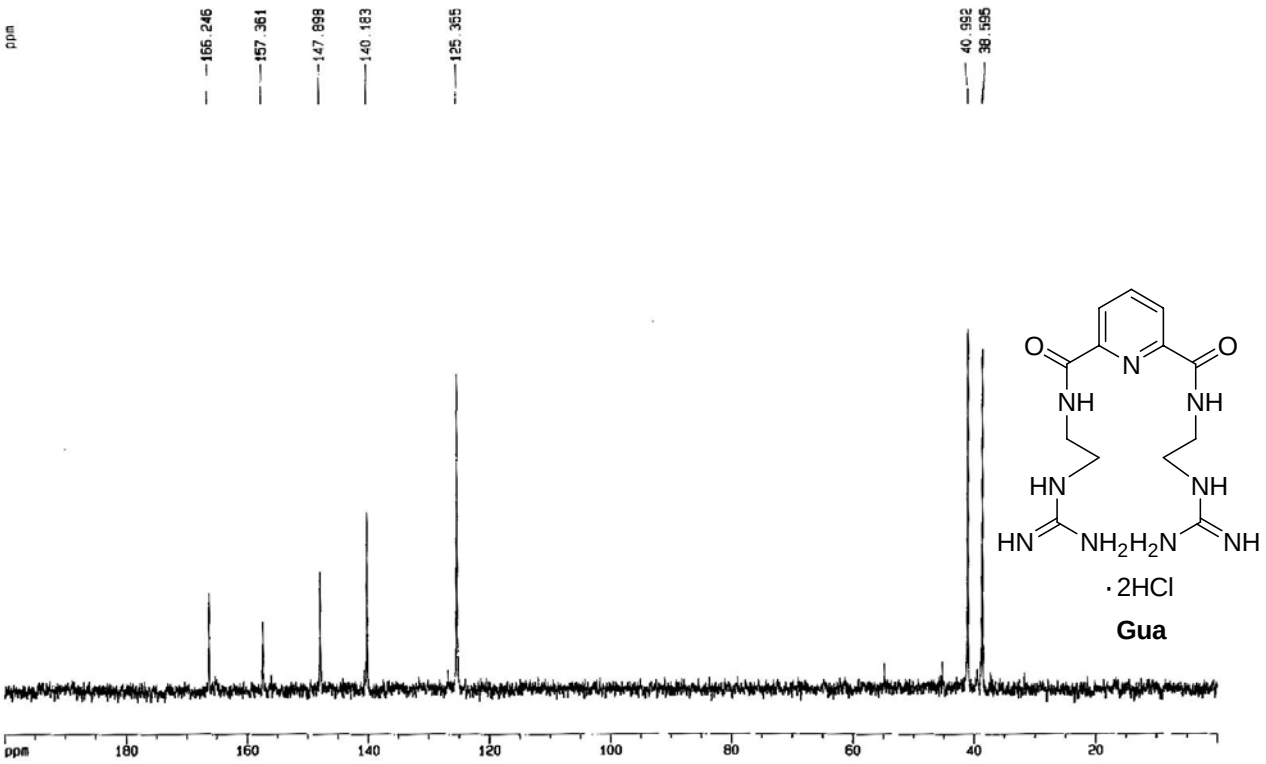
^{1}H NMR (300 MHz, $CDCl_3$) of **4**.



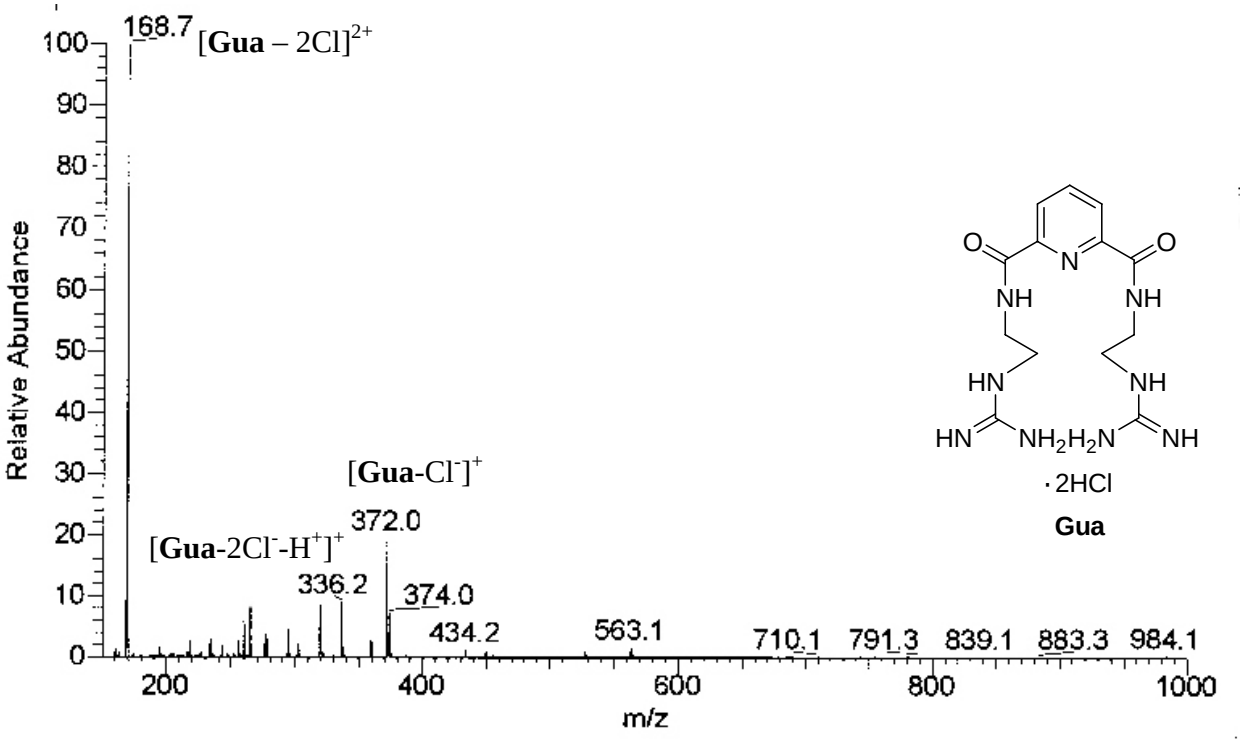
ESI–MS spectra of **4**.



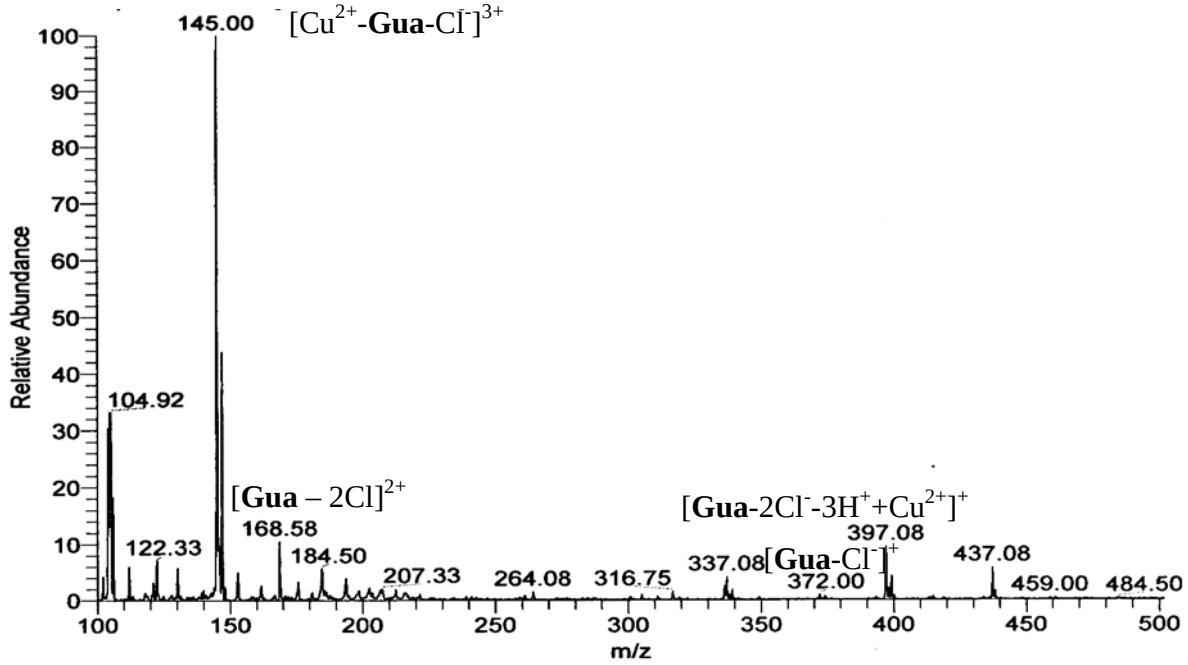
^{1}H NMR (300 MHz, D_2O) of **Gua**.



^{13}C NMR (75 MHz, D_2O) of **Gua**.



ESI–MS spectra of **Gua**.



ESI–MS spectra of Cu^{2+}-**Gua**.

UV-Visible spectra

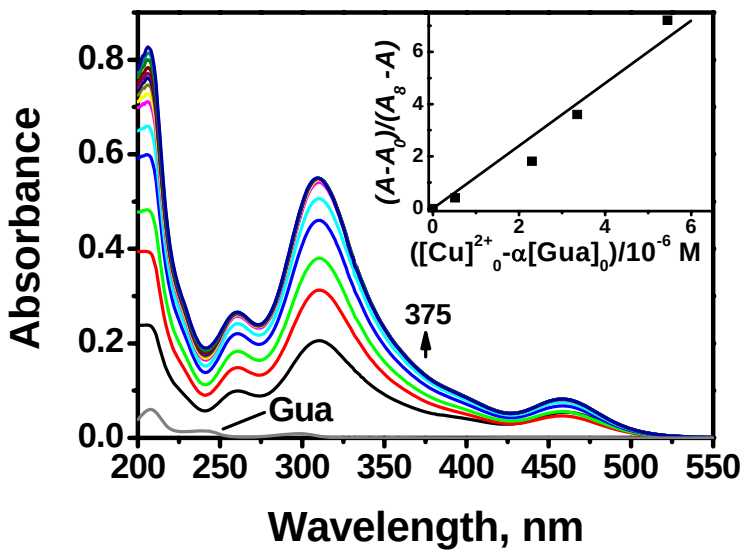


Figure S01. UV-Visible spectral changes observed upon addition of **Gua** (0 ~ 5.46×10^{-5} M) to an aqueous solution of $CuCl_2$ (1.28×10^{-5} M) at 25 °C. Insets: Plot of $(A - A_0)/(A_\infty - A)$ versus ($[Cu^{2+}]$-α[**Gua**]$_0$), $\alpha=(A - A_0)/(A_\infty - A_0)$.

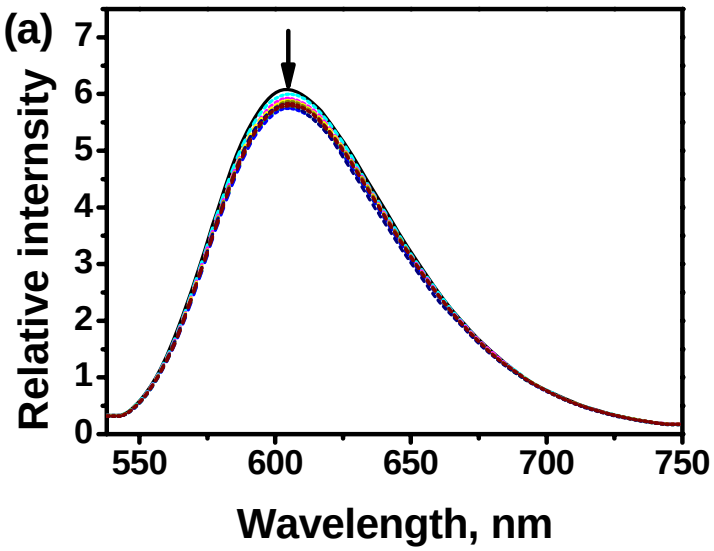
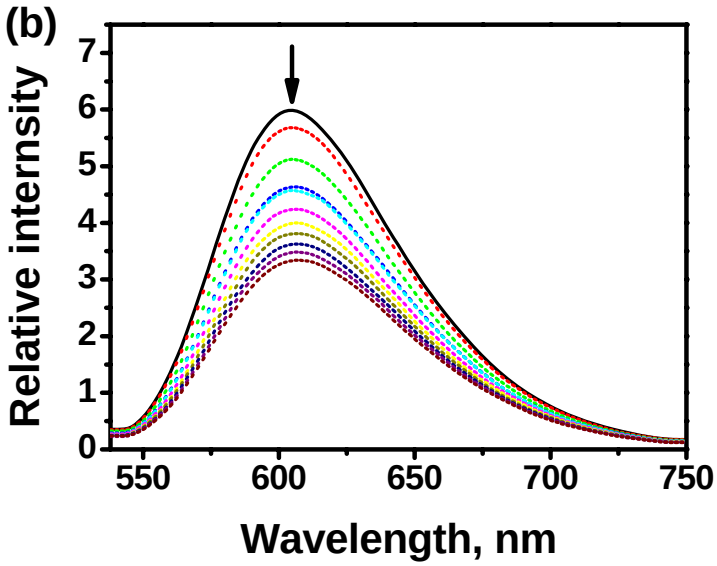
Fluorescence spectra





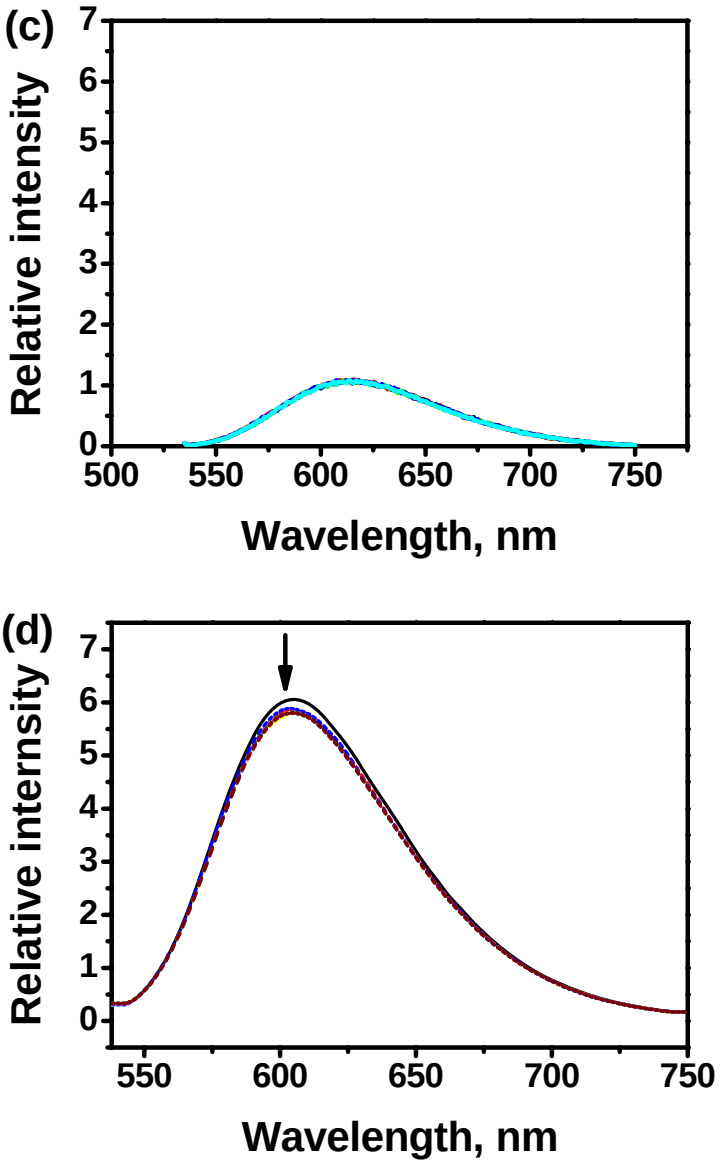


Figure S02. Emission spectra of EB bound to DNA in the absence (—) and presence (---) of (a) **Gua** (*r* = 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1) (b) Cu^{2+}-**Gua** (*r* = 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1) and (d) Zn^{2+}-**Gua** (*r* = 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1). (c) Emission spectra of EB in presence of Cu^{2+}-**Gua** (*r* = 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1). [CT–DNA] = 0.046 mM. Arrows show the intensity changes upon the addition of increasing concentration of **Gua** and Cu^{2+}-**Gua**, respectively. λ_{ex} = 526 nm.

Agarose gel

pH dependence

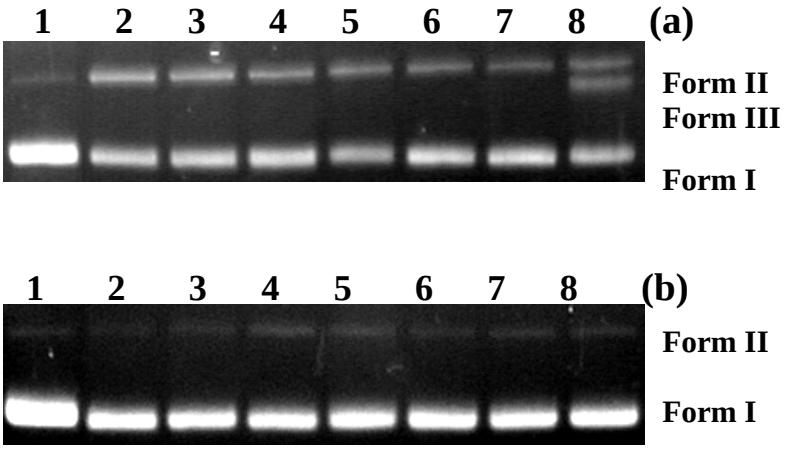

Figure S03. Agarose gel (1%) of pUC 19 DNA (0.025 mM bp) incubated for 30 h at 37°C with 0.0375 mM (a) Cu^{2+}–**Gua** and (b) **Gua** in different pH buffer (50 mM Tris–HCl / 10 mM NaCl). Lane 1, DNA control; Lanes 2–8, pH 6.51, 6.76, 7.01, 7.27, 7.50, 8.02 and 8.52, respectively.

Concentration dependence

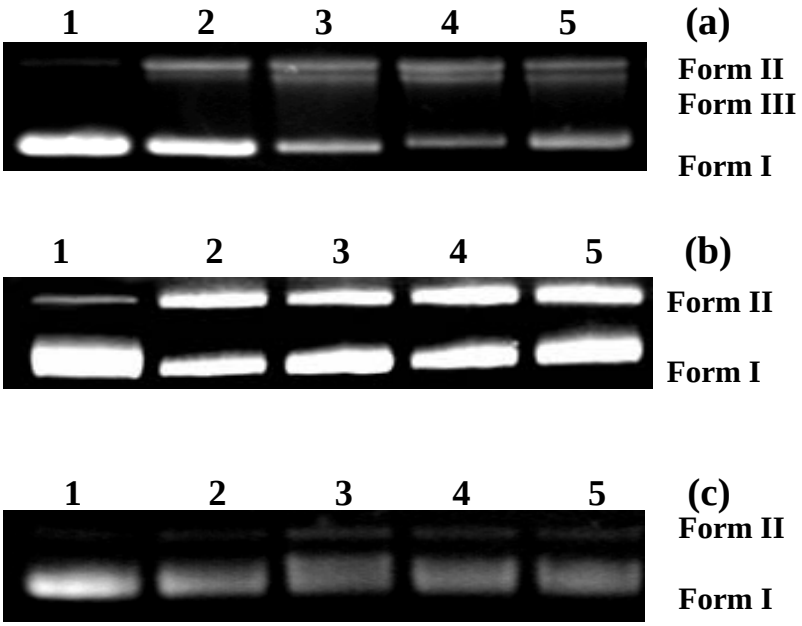

Figure S04. Agarose gel (1%) of pUC 19 DNA (0.025 mM bp) incubated for 48.0 h at 37°C with different concentrations of (a) Cu^{2+}–**Gua**, (b) **Gua** and (c) Cu^{2+} in pH 7.0 buffer (50 mM Tris–HCl / 10 mM NaCl). (a) Lanes 1-5, 0, 0.0125, 0.0250, 0.0375 and 0.0500 mM Cu^{2+}–**Gua**, respectively. (b) Lanes 1-5, 0, 0.0125, 0.0250, 0.0375 and 0.0500 mM **Gua**, respectively. (c) Lanes 1-5, 0, 0.0125, 0.0250, 0.0375 and 0.0500 mM $CuCl_2$, respectively.

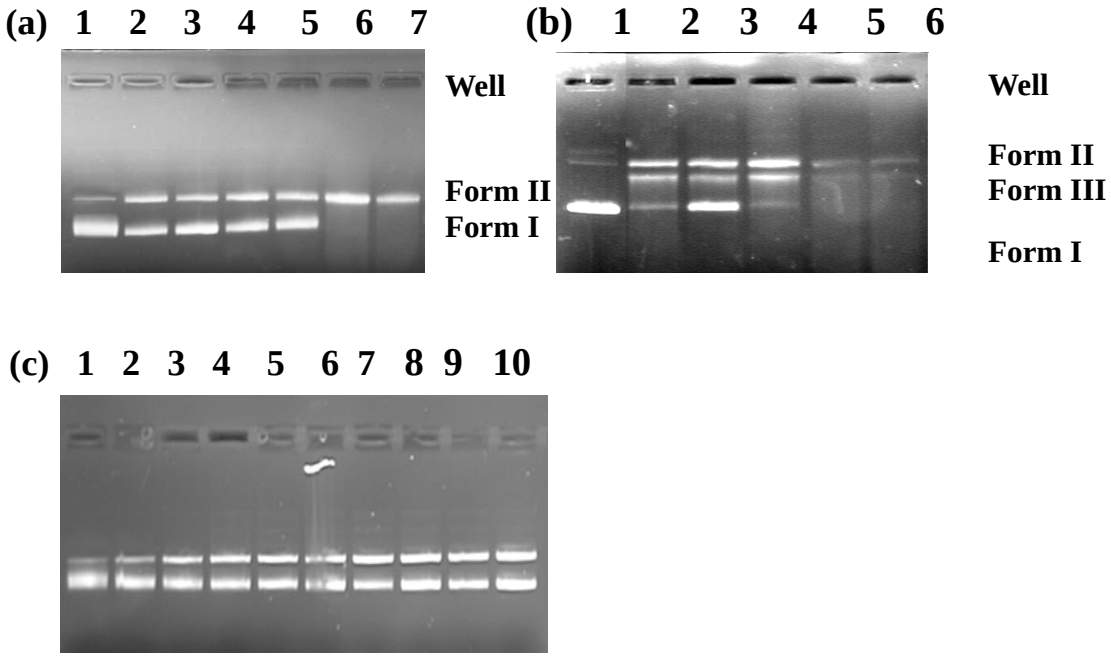

Figure S05. (a) Agarose gel (1%) of pUC 19 DNA (0.025 mM bp) incubated for 48.0 h at 37°C in pH 7.0 buffer (50 mM Tris–HCl / 10 mM NaCl) with different concentrations of **Gua**. Lanes 1-7, 0, 0.0125, 0.0250, 0.0500, 0.0625, 0.1000 and 0.1250 mM Cu^{2+}–**Gua**, respectively.

(b) Agarose gel (1%) of pUC 19 DNA (0.025 mM bp) incubated for 48.0 h at 37°C in pH 7.0 buffer (50 mM Tris–HCl / 10 mM NaCl) with different concentrations of Cu^{2+}–**Gua**. Lanes 1-6, 0, 0.0375, 0.0500, 0.0625, 0.0750 and 0.100 mM **Gua**, respectively.

(c) Agarose gel (1%) of pUC 19 DNA (0.025 mM bp) incubated for 48.0 h at 37°C in pH 7.0 buffer (50 mM Tris–HCl / 10 mM NaCl) with different concentrations of Zn^{2+}–**Gua**. Lanes 1-10, 0, 0.025, 0.050, 0.10, 0.015, 0.2, 0.25, 0.3, 0.4 and 0.5 mM **Gua**, respectively.

Kinetic Data

Table S01. Apparent initial first-order rate constants of DNA cleavage reactions at various concentrations of compound Cu^{2+}–**Gua** and **Gua**. The reactions were carried out at 37 °C in 50 mM Tris-HCl/10 mM NaCl buffer (pH 7.0).

	Cu^{2+}–**Gua**		**Gua**	
	Concentration (mM)	k_{obs} (h^{-1})	Concentration (mM)	k_{obs} (h^{-1})
1	0.0125	0.0073 ± 0.0002	0.0125	0.0020 ± 0.0002

Received February 19, 2008; Revised Manuscript Received June 16, 2008

Chitosan has been reported as a promising material for gene and drug delivery as well as for tissue engineering and regenerative medicine. We report here the conjugation of a *de novo* designed coil peptide (Kcoil) to chitosan (M_n = 200 kDa) to achieve a universal Kcoil-chitosan scaffold for subsequent immobilization of proteins tagged with the Kcoil partner, i.e., the Ecoil peptide. Kcoil-chitosan conjugate was synthesized using a tyrosinase-catalyzed protocol. Extensive UV/vis and IR characterization demonstrated that Kcoil peptide was covalently grafted to amines of chitosan. The ability of Kcoil-chitosan conjugate to recruit Ecoil tagged epidermal growth factor (EGF) was assessed by surface plasmon resonance measurements (SPR). Despite nonspecific interactions between chitosan and EGF, the specific formation of an E/K coiled coil complex was observed at slightly acidic pH and high salt concentration conditions, demonstrating that grafting to chitosan did not negatively impact binding characteristics of Kcoil peptide. Finally, the benefits of such bioconjugates for biomedical applications are discussed.

INTRODUCTION

Within the past decades, natural polysaccharides have emerged as attractive biomaterials for the development of scaffolds in the domain of tissue regeneration as well as for the production of nanoparticles to replace classical viral gene delivery vehicles (*1*). Among them, chitosan has been demonstrated to be especially promising (*2*). More specifically, its availability as a medical grade polymer combined with its gelation properties when mixed with glycerol phosphate makes it an interesting cell carrier (*3, 4*). A novel hybrid biomaterial, produced by combining chitosan with freshly drawn autologous blood, has also demonstrated beneficial wound healing properties for cartilage repair (*3–5*). The use of chitosan as a drug carrier/delivery system (*6–9*) as well as a nonviral vector for gene delivery has also led to the development of innovative therapeutic treatments (*10*).

Chitosan is a linear polysaccharide of β (1−4) linked glucosamine and N-acetyl glucosamine units obtained through N-deacetylation of chitin, which is extracted from insect and crustacean shells (*11*). The presence of primary amino groups on most of the chitosan monomeric units confers crucial chemical properties such as nucleophilicity and solubility at low pH (pH < 6.5) (*12, 13*). Several studies suggest that intrinsic properties of chitosan that are currently exploited may be further enhanced by tailored chitosan functionalization, thereby augmenting its potential applications to gene delivery and regenerative medicine. For example, the conjugation of macromolecules interacting with cell surface receptors to chitosan-based nanoparticles may enable the specific targeting of cell populations to which a gene has to be delivered. Also, specific growth factors stably immobilized onto chitosan three-dimensional scaffolds may control and modulate cell survival, growth, and differentiation. The potential advantages of immobilized growth factor versus soluble growth factor supply were recently highlighted by Fan et al. The latter demonstrated that covalent tethering of epidermal growth factor (EGF) on poly(methyl methacrylate)-based polymers and exposure to mesenchymal stem cells provided a survival advantage when compared to soluble EGF (*14*) or to adsorbed EGF (*15*).

Although unambiguous effects of tethered EGF have been reported by Fan et al., there is still a crucial need for a universal and flexible protocol that would allow any growth factor or any other desired protein to be easily and specifically captured on scaffolds. With this in view, we have developed a novel approach based on the use of *de novo* designed peptides, namely, the Ecoil and Kcoil that heterodimerize in a highly specific and stable fashion to adopt a coiled-coil structure (*16, 17*) (Figure 1). This Ecoil/Kcoil capture/delivery system has also been recently reported to be useful for adenoviral vector retargeting (*18*). Also, previous studies have demonstrated that the Ecoil/Kcoil system can be used as a versatile domain for capturing proteins onto surfaces without any loss of bioactivity (*19–21*). In the present approach, ligand tethering is achieved by incubating coil-tagged ligands with surfaces or scaffolds on which the other coil partner has been covalently attached (Figure 1).

The purpose of the present study was to examine the applicability of our coil-based approach for modification of chitosan scaffolds and nanoparticles. To achieve this, we explored the use of an enzymatic protocol (*22, 23*) in which tyrosinase-catalyzed oxidation of a tyrosine-containing Kcoil peptide is followed by its condensation onto chitosan in a nonenzymatic step (Figure 2). Peptide functionalized chitosan was then characterized by UV−vis and FT-IR spectroscopies. Additional surface plasmon resonance (SPR) assays confirmed that Kcoil-functionalized chitosan was able to recruit the Ecoil-tagged epidermal growth factor (E-EGF) *via* coiled-coil interac-

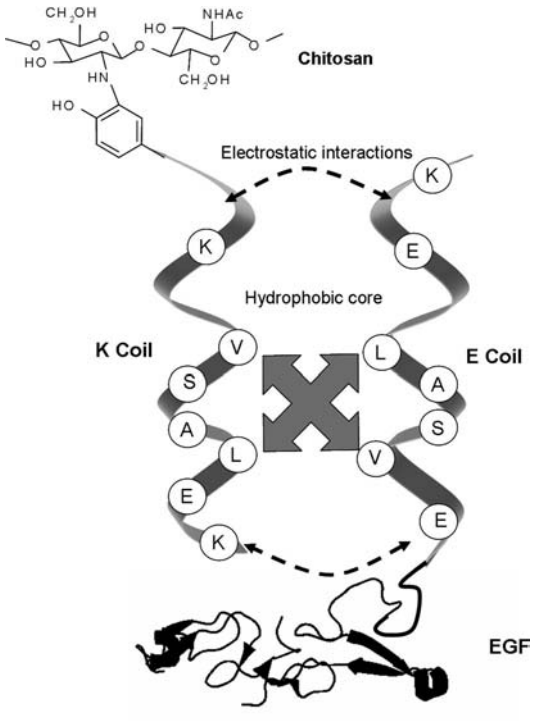

Figure 1. Schematic representation of the heterodimeric E/K coiled-coil domain and its application as a universal capture/delivery system. Each heptad, K-V-S-A-L-K-E for the Kcoil and E-V-S-A-L-E-K for the Ecoil, is repeated five times in each peptide. The stability of the coiled-coil complex is primarily due to the formation of a hydrophobic core involving leucine and valine residues of each coil, while electrostatic interactions provide additional stability as well as high specificity. This universal system enables the immobilization of coil tagged proteins (e.g., EGF as shown) on chitosan conjugated with its partner coil.

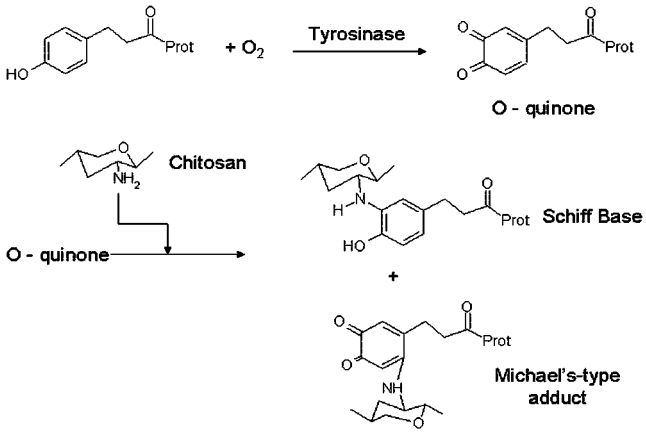

Figure 2. Chemical and tyrosinase-catalyzed reactions for the conjugation of a tyrosine-containing peptide to chitosan. Tyrosinase catalyzes the formation of an O-quinone derivative that undergoes a nonenzymatic reaction with chitosan to form two types of products, i.e., a Schiff base and a Michael's type adduct.

tions, hence validating our procedure that produces chitosan functionalized with a universal coil peptide capture/delivery system.

MATERIALS AND METHODS

High molecular weight chitosan (number average molecular mass M_n = 200 000 Da with degree of deacetylation that is % of monomers that are deacetylated called DDA = 80%) was supplied by Biosyntech (Laval, QC, Canada). 1% (w/v) chitosan solution was obtained by dissolving 500 mg of chitosan powder in 50 mL of water acidified with 20 mM HCl. After continuous overnight stirring, the pH of the solution was 4.5. Mushroom tyrosinase (EC 1.14.18.1, specific activity of 5370 U/mg according to the manufacturer) was purchased from Sigma Chemical Co. (St. Louis, MO). The enzyme was dissolved in PBS (150 mM NaCl, 50 mM potassium phosphate, pH 6.5) up to 308 U/mL, aliquoted and stored at −20 °C according to the manufacturer recommendations. Kcoil peptide (primary sequence: YGG(KVSALKE)$_5$GGC, > 80% purity) was synthesized by BioSynthesis (Lewisville, TX). 21.2 mg of Kcoil peptide was dissolved in 4 mL of distilled water, aliquoted, and stored at −20 °C before use. The K-EGF and E-EGF coding for Kcoil or Ecoil tag, (His)$_8$ tag, and EGF cDNA were produced using HEK-293 cells and purified by immobilized metal affinity chromatography (IMAC) as previously described in Boucher and al. (in press).

Synthesis of Kcoil-Chitosan Bioconjugate. Chitosan was diluted in distilled water to a final concentration of 0.1% (w/v) and 1 M NaOH was slowly added to reach a pH of 6.0, which is the highest pH that maintains solubility for this chitosan (*24, 25*). A high pH is desirable since tyrosinase only reacts with deprotonated amine groups and tyrosinase has a maximal effectiveness at pH between 6 and 7. Tyrosinase was diluted in PBS (pH 6.5) to achieve a specific activity of 120 U/mL. Equal volume of tyrosinase and chitosan solutions were then mixed and the pH was adjusted to 6.0. Kcoil peptide was then added to the mixture (4 mg of Kcoil peptide per 100 mg of chitosan, corresponding to 2 mmol of peptide per mole of chitosan glucosamine units). After overnight stirring at room temperature, the pH of the mixture was slowly increased to 11−12 by dropwise addition of NaOH, 1 M. Precipitated chitosan was separated by centrifugation (2 × 250 g for 10 min at room temperature). The pellet was extensively washed by rinsing with water and NaOH precipitation (at least twice). The washed pellet was then dissolved in water and the pH of the solution was adjusted to 5.5 for maximal product solubility. The product was aliquoted and stored at 4 °C before analysis.

UV Measurements. UV measurements (230−600 nm scans, 2 nm resolution) for pure chitosan, controls, and conjugated chitosan were carried out on a UNICO S 2100 UV spectrophotometer (UNICO, Dayton, NJ).

IR Measurements. Functionalized chitosan and control samples were first lyophilized (Benchtop 3 L freeze-Dryer, VirTis, Warminster, PA) for 24 h and used directly thereafter. Pure chitosan powder was desiccated for 24 h and used directly thereafter as control. FT-IR measurements were performed in duplicate using an FTIR 6000 StingRay instrument (Bio Rad, Hercules, CA) equipped with a photoacoustic cell (PAS) maintained in a helium atmosphere. Spectra were recorded from 500 to 4000 cm^{-1} with resolution set to 2 cm^{-1} and measurement frequency of 5 kHz. Approximately 8 mg of each sample was introduced into the PAS.

Surface Plasmon Resonance (SPR)-Based Assays. Coiled-coil mediated interactions between Kcoil conjugated chitosan and Ecoil tagged EGF were monitored using an SPR-based optical biosensor (Biacore 3000, GE Healthcare, Piscataway, NJ). HBS-EP (10 mM Hepes, pH 6.0, 150 mM NaCl, 3.0 mM EDTA, 0.05% P20 surfactant) was chosen as running buffer and for diluting all injected species. For all experiments, the flow rate was set at 10 μL.min^{-1}.

Chitosan Surface Preparation. Kcoil conjugated chitosan was adsorbed to the surface of a C1 sensorchip flowcell by manual injection of 10 mg/L Kcoil chitosan dissolved in running buffer (approximately 12 μL). Guanidium-HCl (5M) was then injected (20 μL at 100 μL.min^{-1} flow rate) to remove unbound material. After baseline stabilization, the resulting mass ac-

cumulation was of ~82 resonance units (1000 RUs corresponds to 1 ng of proteins bound to the surface). The control surface was then generated by manual injection of pure chitosan (0.1 mg.L^{-1} in running buffer) for subsequent monitoring of nonspecific protein adsorption on the chitosan-only surface without any coil. The amount of bound chitosan was adjusted to the level of the test surface. After the guanidium−HCl washing procedure (see above), chitosan mass accumulation was ~79 RUs. Control-corrected sensorgrams thus correspond to the subtraction of the chitosan-only sensorgrams from those obtained with Kcoil conjugated chitosan surface.

Monitoring of Coiled-Coil Mediated Interaction between Kcoil-Conjugated Chitosan and Ecoil Tagged EGF. Various samples (Buffer, Kcoil tagged EGF for negative control and Ecoil tagged EGF both at a concentration of 5 μg/mL) were injected for 120 s at a flow rate of 50 μL.min^{-1} over both surfaces. This was followed by buffer injection for 180 s in order to monitor complex dissociation. In between sample injections, regeneration of the surface was achieved by 5 M guanidium-HCl injection (20 μL at a flow rate of 100 μL.min^{-1}) in addition to 1 M NaCl injection (pulse of 6 s at the same flow rate). Sensorgrams were then control-corrected as described in the previous section using *Biaevaluation 3.1* software package enclosed with the Biacore 3000 instrument.

RESULTS AND DISCUSSION

Tyrosinase-Mediated Grafting of Kcoil Peptide onto Chitosan. Three different products were prepared and tested in order to provide chemical evidence for conjugation of Kcoil peptide to chitosan. The first product was generated as described in section 2.1 and corresponded to the test sample while the two others were used as controls. Specifically, the first control (referred to as Control #1 below) was prepared with tyrosinase but without Kcoil peptide added to the mixture and the second control (referred to as Control #2 below) was prepared with Kcoil peptide but without tyrosinase added to the mixture. After incubation, washing and extraction procedures were performed for each sample as described in section 2.1. Chitosan was also used as a negative control baseline in spectroscopic assays.

UV−vis Spectroscopic Characterization. Figure 3a shows UV/vis spectra (230 to 470 nm) for Control #1, pure and grafted chitosan. The spectrum of Control #2 was superimposable on that of chitosan (data not shown). Of interest, the absorbance between 230 and 350 nm was found to be considerably greater for the bioconjugate than for the other samples (Figure 3a). The conjugated chitosan showed characteristic features of proteins, i.e., a peak near 280 nm due to the presence of a tyrosine residue in the peptide chain, as well as chitosan features for wavelengths higher than 350 nm, i.e., in the region where the peptide moiety does not absorb and where all spectra superpose. When the blank chitosan spectrum was subtracted from that of modified chitosan, its high similarity with the spectrum of the pure peptide (Figure 3b) affirms that the increase in absorbance near 280 nm observed for bioconjugate was from the covalent attachment of the Kcoil peptide on chitosan. A slight shift of the peak could be observed, from 270 to 274 nm. This bathochrome effect was attributed to the disturbance of electronic distribution near the aromatic ring where glucosamine is grafted.

These UV/vis spectroscopic assays also permit an estimation of the degree of peptide grafting to chitosan. By assuming that the extinction coefficient of the conjugated peptide remained the same as that of original Kcoil peptide only (i.e., 1490 $M^{-1}.cm^{-1}$ due to the presence of one tyrosine), one can estimate the conjugation degree as follows. The absorbance at 280 nm of 0.028 A provides a peptide concentration of 0.028/1490 = 18.8 μM while the concentration of monomers (glucosamines and N-acetylated glucosamines) of chitosan in solution is 0.5 g/L ÷ 169.4 g/mol = 2.95 mM (where 169.4 g/mol is the average molecular mass of a monomer of 80% DDA chitosan (*24*)) resulting in 1 peptide conjugated per 157 monomers. A 200 kDa 80% DDA chitosan contains (200,000 ÷ 169.4 g/mol)*0.8 = 947 glucosamine monomers, thus resulting in an average of 7 peptides per chitosan chain. This level of conjugation corresponds to a modification of less than one percent of total glucosamine units and a near-complete grafting of the peptide added in the original reaction solution.

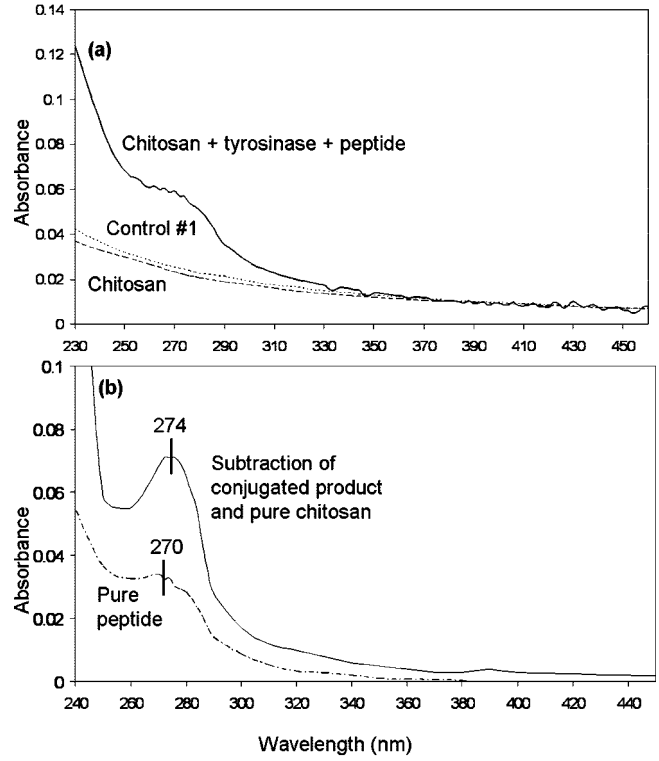

Figure 3. UV/vis spectrophotometric measurements demonstrate that both peptide and tyrosinase are necessary for bioconjugation on chitosan. (a) Each chitosan sample was incubated overnight in buffered solution with either tyrosinase (Control #1) or peptide (Control #2, not shown), or both and then washed following the procedure described in section 2.1. (b) The spectrum of the peptide-conjugated chitosan after subtraction of the chitosan-only spectrum is compared to that of the pure peptide.

Taken together, UV−vis spectroscopic results indicated that, even when working with low amounts of Kcoil peptide (4% w/w), conjugation was successfully achieved, and required the presence of both tyrosinase and peptide.

FT-IR Characterization of the Compounds. The IR spectra of blank chitosan (1), Control #1 (2), Control #2 (3), and conjugated chitosan (4) are shown in Figure 4a,b,c (corresponding to 700−1100 cm^{-1}, 1500−2000 cm^{-1}, and 3100−3650 cm^{-1} ranges, respectively). All observed spectra displayed peaks characteristic of chitosan including the imine stretch νC═N (1663 cm^{-1}, Figure 4b) and the amide II band (1559 cm^{-1}, Figure 4b), both arising from N-acetyl groups of chitosan (*26*). The intense band at 1076 cm^{-1} (Figure 4a) is likely the result of several overlapping vibrations (νCO, νCN, νCC) and has been previously reported as a spectral feature of chitosan (*22*, *27*). Of interest, its intensity was observed to increase for Kcoil conjugated chitosan (Figure 4a), which is likely due to peptidic bonds of the Kcoil peptide conjugated to chitosan.

In the case of the bioconjugate, new peaks and shifts were observed over the whole range of scanned wavenumbers. More specifically, peaks of medium intensity falling at 832 cm^{-1} (νC═C bending), 1600 cm^{-1} (νC═C stretching in aromatic

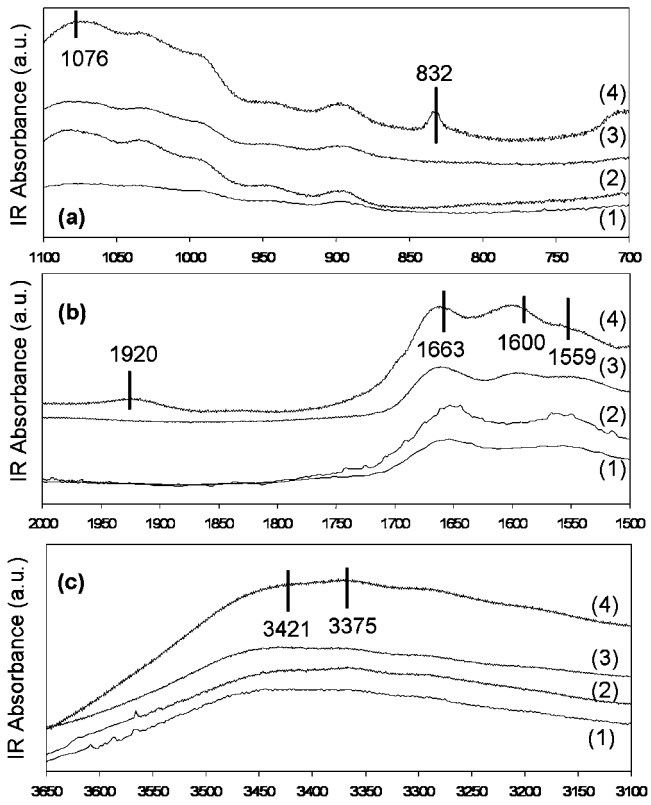

Figure 4. FT-IR characterization of the Kcoil-chitosan bioconjugate. FT-IR spectra of (1) pure chitosan, (2) Control #1 (no peptide), (3) Control #2 (no tyrosinase), and (4) Kcoil conjugated to chitosan. The products were prepared as described in section 2.1 of Materials and Methods. The resolution was set to 2 cm^{-1} and the measurement frequency was 5 kHz. The ranges of wavelengths shown are (a) 700−1100 cm^{-1}, (b) 1500−2000 cm^{-1}, and (c) 3100−3650 cm^{-1}.

rings), and 1920 cm^{-1} (νC−H out-of-plane deformation) only appeared on the spectrum of conjugated chitosan (Figure 4a,b) and are characteristic of the phenyl-group of tyrosine (*28–30*). No additional intense IR bands were observed, which can be attributed to the lack of strong IR features assigned to the aromatic ring of tyrosine (*22, 26*). Also, as can be seen in the 3100−3650 cm^{-1} range (Figure 4c) which displays the νNH bands, the primary amine band of the unmodified chitosan sample at 3421 cm^{-1} remained unchanged in both controls, whereas the bioconjugate displayed a shoulder at 3375 cm^{-1}. This additional shoulder is consistent with the modification of some primary amine groups of chitosan into secondary amino groups, as a consequence of the chemical conjugation of a peptide onto a glucosamine unit as previously observed (*23*).

Altogether, UV/vis and FT-IR measurements unambiguously demonstrated that tyrosinase was able to oxidize the tyrosyl residue of the Kcoil peptide, since subsequent covalent grafting to chitosan was achieved. Indeed, tyrosinase-modified Kcoil was shown to undergo a nonenzymatic grafting onto chitosan, whereas in the absence of tyrosinase, no grafting was observed (Figures 3 and 4). These results are in agreement with previously reported work by Lenhart and colleagues (*31*). Although quinones are able to react with several nucleophiles, the low pK_a of chitosan amino groups favored grafting as compared to lysyl or sulfydryl groups of Kcoil whose p*K*as are higher (10 for lysine, 8 for cysteine) (*22, 32*). The addition of a tyrosine at the N-terminus of the Kcoil peptide thus provided a means for controllable and oriented grafting of the Kcoil peptide.

Surface Plasmon Resonance (SPR) Characterization of Ecoil Tagged EGF Binding to Kcoil-Conjugated Chitosan. The ability of Kcoil-chitosan to recruit and bind to Ecoil tagged EGF *via* specific E/K coiled-coil interaction was tested using an SPR-based optical biosensor. Briefly, pure chitosan was immobilized on the control flowcell and grafted chitosan on the test flowcell. Buffer, Kcoil tagged EGF (negative control) and Ecoil tagged EGF were then injected over both surfaces. Preliminary experiments performed in running buffer (HBS-EP) at pH 7.4 led to high nonspecific binding of Kcoil tagged EGF to Kcoil chitosan surface (data not shown). This observation led us to hypothesize that this binding was attributable to nonspecific chitosan-protein interactions, i.e., between chitosan itself and EGF, since neither Kcoil/Kcoil nor Kcoil/chitosan interactions are likely to occur due to electrostatic repulsion between cationic chitosan and the cationic Kcoil (*19*). The pI of Ecoil tagged EGF was computed on Clone Manager (Sci-ED Software, Cary, NC) and found to be around 5.2, which indicates that the protein bears a negative charge for pH > 5.2. These nonspecific interactions are thus more likely to be due to EGF interacting with the positively charged NH_3^+ groups of chitosan (*33*). The use of HBS EP at a lower pH of 6.0 as running buffer allowed chitosan and Kcoil chitosan to remain soluble during deposition on the surface, resulting in very stable surfaces that were not modified by 5 M guanidinium-HCl injections. At this pH, chitosan and Kcoil chitosan were observed to have a high affinity for the dextran surface of the biosensor ((*34*) and results not shown). However, nonspecific interactions between injected EGF and deposited chitosan were still observed in this configuration ((*33*) and data not shown). In order to limit these nonspecific chitosan-protein interactions, NaCl pulse injections were added during the regeneration step, just after the 5 M guanidinium-HCl injection. Note that this salt injection is only required to demonstrate specific coiled-coil interactions by SPR and does not need to be applied in general to achieve coupling.

Raw data and control-corrected results corresponding to buffer, Kcoil tagged EGF (negative control) and Ecoil tagged EGF injections over Kcoil conjugated chitosan and pure chitosan surfaces, following the above-described optimized protocol, are shown in Figure 5a,b, respectively. In contrast to previous experiments performed at pH 7.4 or in the absence of NaCl pulses, Kcoil tagged EGF showed little interaction with the Kcoil chitosan surface since the raw signal monitored on test cell for Kcoil tagged EGF injection was very similar to that of buffer-only injection (only 15 RUs of accumulated material were observed, Figure 5a). In contrast, Ecoil tagged EGF injection over Kcoil chitosan surface led to approximately 75 RUs of accumulated material at the end of the injection (Figure 5a). Taken together, these results indicated that Ecoil tagged EGF capture on Kcoil-chitosan was mediated by the Ecoil moiety of Ecoil tagged EGF. However, this result did not distinguish whether the mode of interaction was between Ecoil tagged EGF and Kcoil chitosan *via* an E/K coiled-coil interaction versus Ecoil interacting directly with chitosan chains adsorbed to the test surface. To further address this issue, the sensorgrams corresponding to Kcoil tagged and Ecoil tagged EGF injections over the pure chitosan surface were subtracted from the sensorgrams obtained by injections over the surface coated with Kcoil conjugated chitosan (Figure 5b). The control-corrected sensorgram corresponding to the injection of Kcoil tagged EGF was characterized by rapid transition (less than 2 s) to equilibrium (25 RUs) during injection and by the absence of dissociation of bound material during subsequent buffer injection. In contrast, injection of Ecoil tagged EGF resulted in a kinetic profile characterized by a 5-fold higher mass accumulation during injection and dissociation of Ecoil tagged EGF/Kcoil chitosan complexes during subsequent buffer injection. Of interest, the same level of permanent accumulation of EGF after buffer injection was observed as in the case of Kcoil tagged EGF (25 RUs). These observations are thus consistent with a

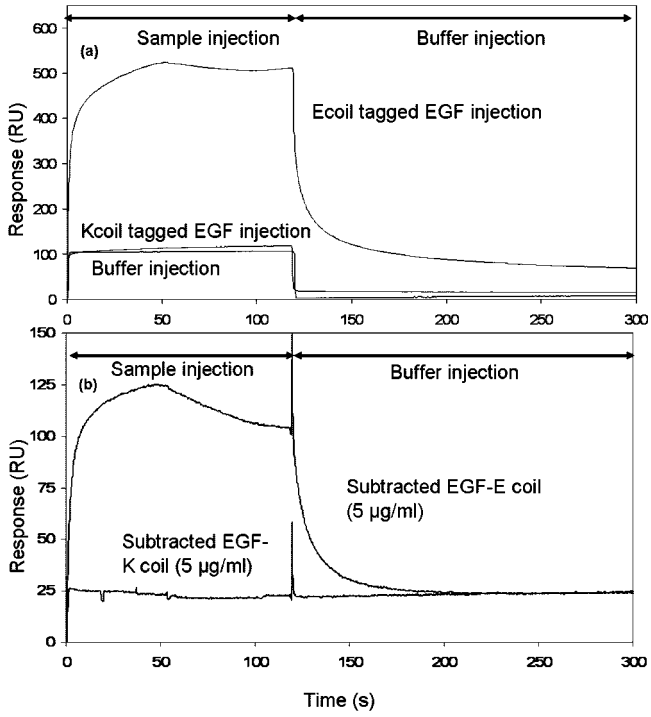

Figure 5. SPR investigation of coil tagged EGF/Kcoil chitosan interactions. (a) Raw and (b) control-corrected SPR sensorgrams corresponding to the injections of buffer, Kcoil tagged EGF (5 μg/mL) and Ecoil tagged EGF (5 μg/mL) over Kcoil chitosan bioconjugate coated surface. HBS-EP (pH 6.0) was chosen as running buffer. 1 M NaCl and 5 M guanidium-HCl injections were used to regenerate the surface.

specific E/K coiled-coil mediated interaction between Ecoil tagged EGF and Kcoil conjugated chitosan, in addition to a smaller nonspecific interaction between EGF and chitosan that is present for both E and Kcoil tagged proteins.

One limitation of the current approach and in particular of the conditions used for SPR tests is the limited stability of the coiled-coil complex composed of Ecoil tagged EGF and Kcoil chitosan that was observed to dissociate within 100 s (Figure 5b). Such instability was due to stringent experimental conditions, i.e., acidic pH in combination with injection of high concentration of salt, which we used to highlight the coiled-coil specific interactions. Indeed, maintaining chitosan solubility and simultaneously screening nonspecific interactions negatively impacted coiled-coil stability since hydrophobic cores within coiled-coil complexes are less stable at pH 6.0 than at physiological pH and since the presence of salt will mask electrostatic interactions that allow further stabilization of the complex. Thus, the hydrophobic core was formed, which created the increase of SPR signal, but the domain could not be maintained because of the lack of stabilizing electrostatic interactions consistent with previous work (*19, 20*). One remaining challenge in future work is to limit nonspecific binding of proteins to chitosan and thus achieve stable and, most of all, monitorable coiled-coil interactions at physiological pH. Indeed, the E/K coiled-coil system used in this study has already been demonstrated to be extremely stable ($k_d \sim 10^{-4}$ s^{-1}) in a physiological context (*16, 17, 19–21*), affirming the promising nature of coil-chitosan conjugates as biocompatible substrates for oriented immobilization of proteins. This may be achieved by appropriate mixing and buffer exchange systems where conditions appropriate for specificity of coiled-coil formation are followed by those required for stability of the established coiled-coil complex.

CONCLUSION

Chitosan has been reported as a promising material for gene and drug delivery as well as in tissue engineering and regenerative medicine. This report demonstrates that enzymatic covalent grafting of a *de novo* designed coil peptide to chitosan can be achieved by exploiting the high chemoselectivity of tyrosinase. A particular advantage of the current approach is the absence of tedious and time-consuming purification steps making this enzymatic process very promising to obtain easily a pure and safe product for biomedical applications. This study also demonstrates the ability of coil-chitosan conjugate to specifically capture proteins tagged with the partner coil peptide, for example, the growth factor EGF. The well-known beneficial properties of chitosan (biocompatibility, degradability, bioadhesion, antimicrobial activity) can thus be complemented with a procedure allowing flexible and oriented protein conjugation to chitosan *via* coiled-coil interactions, providing multiple additional functionalities in applications such as gene delivery and regenerative medicine.

Received March 10, 2008; Revised Manuscript Received July 2, 2008

Cell membrane lipids have been identified as key participants in cell signaling activities. One important role is their involvement as site-specific ligands in protein—membrane binding interactions, which result in the anchoring of peripheral proteins onto cellular membranes. These events generally regulate protein function and localization and have been implicated in both normal physiological processes and those pertaining to disease state onset. Thus, it is important to elucidate the details of interactions at the molecular level, such as lipid-binding specificities and affinities, the location of receptor binding domains and multivalency in binding. For this purpose, we have designed and developed azido-tagged lipid analogues as conveniently functionalizable lipid probe scaffolds. Herein, we report the design and synthesis of the initial structure of this type, diacylglycerol analogue **2**, which contains an azide tag at the *sn*-1 position of the lipid headgroup. Direct functionalization of this compound with a range of reporter groups has been performed to illustrate the facile access to probes of use for characterizing binding. Quantitative lipid-binding studies using protein kinase C, a known DAG-binding receptor, demonstrate that these probes are active mimetics of natural DAG. Thus, these DAG probes will serve as robust sensors for studies aimed at understanding binding interactions and as precursors for the development of analogous probes of more complex phospholipids and glycolipids.

INTRODUCTION

Signaling lipids present at low percentages in cellular membranes, such as diacylglycerol (DAG) (*1, 2*), phosphatidic acid (PA) (*3, 4*), and the phosphoinositides (PIP_ns) (*5*—*9*), have emerged as vital regulators in a wide array of crucial physiological and pathophysiological events. A prominent role involves the targeting and docking of peripheral proteins onto the membrane surface through site-specific lipid binding, a process that generally regulates protein function and subcellular localization (*1, 2, 10, 11*). Elucidation of the details of protein—lipid binding is necessary, as many of these interactions have been directly implicated in disease state onset. For instance, despite the simplicity of its structure, DAG has been connected to several high-profile pathophysiological events including cancer (*12, 13*) and diabetes (*14*).

The best studied DAG-responsive receptors reside in the protein kinase C (PKC) family, which consists of at least eleven known isozymes categorized into conventional (calcium, DAG, and phospholipid-dependent), novel (calcium-independent, but DAG and phospholipid-dependent), and atypical (calcium and DAG-independent) subgroups (*1, 2, 15*—*17*). PKCs have long been known to be directly involved in tumorigenesis, which is not surprising due to the various and often opposing roles of PKC isozymes in cell-cycle processes such as proliferation, differentiation, and apoptosis (*12, 13, 18*). Furthermore, compounds that compete for the DAG-binding domains of PKCs, such as the bryostatins (*19*), have shown great promise as agents for cancer therapy. However, despite a vast amount of research, the exact links between PKC activity and carcinogenesis remain unknown, primarily due to complications in elucidating the specific activities and localization of the different isozymes. Understanding the lipid-binding specificities of these isozymes is thus crucial, since these properties control both protein function and localization.

Phospholipids derived from the core diacylglycerol scaffold are also important ligands in biological processes, as evidenced by the interaction of PA with Raf-1 kinase. Binding of Raf-1 kinase to PA results in membrane association, at which point this enzyme is then activated by a protooncogene, Ras GTPase, when the two proteins are in proximity at the membrane surface (*20*—*27*). This system is crucial, as point mutations in Ras have been detected in 20% to 30% of all human tumors and carcinogenesis is known to propagate through activation of effector kinases by Ras enzymes (*28, 29*). Finally, the PIP_n family represents a highly complex series of seven phospholipids composed of phosphodiester-linked *myo*-inositol headgroups containing anywhere from one to three phosphate groups at every combination of the 3-, 4-, and 5-positions. The PIP_ns have been implicated in a litany of crucial physiological processes (*5*—*8, 30, 31*) as well as the onset of disease states including cancer, leukemia, and diabetes (*32*).

The development of lipid probes is highly beneficial for understanding the details of membrane-binding interactions at the molecular level, as these compounds can be implemented for efficient strategies aimed at the characterization of these recognition events. The synthesis of probes from scratch provides the ability to generate pure samples of a single lipid structure and the freedom to explore a wide variety of modification approaches. For instance, access to analogues through enzymatic or synthetic conversion of natural lipids limits the scope of probes that can be obtained, involves high costs, and

often precludes the production of pure samples of one specific lipid structure. Furthermore, functionalization at different positions, such as through replacement of a hydrogen at the *sn*-1 position, which has been rarely pursued due to the required synthesis (*33*), may be beneficial for presenting a reporter at the headgroup yet as far away from the *sn*-3 position, the point of lipid variation and primary recognition site, as possible.

In the end, access to an arsenal of probes with different structural modifications would be beneficial, as each compound may be particularly suited to a given study. For this purpose, a modular approach to probe development involving late-stage functionalization is beneficial to facilitate access to a range of target probe structures. Herein, we report the culmination of our initial approach to the development of diverse probes that are effective as functional derivatives of DAG as they are able to recruit DAG effector protein to lipid vesicles with similar affinities to the natural lipid. As a result, these derivatives offer a viable means of assaying complex binding mechanisms of DAG effectors *in vitro* and in cell based assays.

EXPERIMENTAL PROCEDURES

General. All reagents were purchased from Aldrich or Acros and used as received. Dry solvents were obtained from a Pure Solv solvent delivery system purchased from Innovative Technology, Inc. Column chromatography was performed using 230−400 mesh silica gel purchased from Sorbent Technologies. NMR spectra were obtained using a Bruker AC250 spectrometer updated with a TecMag data collection system, a Varian Mercury 300 spectrometer, and a Bruker Avance 400 spectrometer. Mass spectra were obtained with a JEOL DART-AccuTOF spectrometer with high resolution capabilities. Optical rotation values were obtained using a Perkin-Elmer 241 polarimeter. HPLC data was obtained using an HP series 1100 HPLC with an Alltech Lichrosphere SI 60 50U column with HPLC grade solvents purchased from Fischer. 1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoserine (POPS), and *sn*-1,2-dioleoylglycerol (DiC_{18}) were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL).

((4*S*,5*S*)-2,2-Dimethyl-1,3- dioxolane-4,5-diyl) dimethanol (5). A solution of diethyl-L-tartrate (6.76 mL, 39.5 mmol) and *p*-toluenesulfonic acid (128 mg, 0.672 mmol) in benzene (80 mL) was prepared in a flame-dried round-bottom flask. To the solution was added with stirring 2,2-dimethoxypropane (6.03 mL, 48.6 mmol). The solution was heated to 80 °C for 3 h and the azeotrope was collected in a Dean−Stark trap. The solution was allowed to cool to room temperature, at which point sodium carbonate (200 mg, 1.89 mmol) was added and stirring was continued for 2 h. The solution was filtered, concentrated on a rotary evaporator, and moved to the next step without further purification.

A solution of lithium aluminum hydride (3.0 g, 79 mmol) in anhydrous THF (70 mL) was prepared in a flame-dried, three-neck round-bottom flask. The suspension was cooled to 0 °C and kept under nitrogen. The crude mixture from above was dissolved in anhydrous THF (20 mL) and added dropwise to the reaction over 30 min. The reaction mixture was stirred at 0 °C for 1 h, then at room temperature for 1 h, and was then cooled back to 0 °C. The reaction was quenched by the dropwise addition of 3 mL water, 3 mL of 10% NaOH, and 9 mL more of water. Vigorous stirring was continued for 20 min while the mixture returned to room temperature. Anhydrous magnesium sulfate was added with stirring for 1 h to dry the reaction. The reaction was filtered and the solvent was removed by rotary evaporation. Column chromatography with silica gel and a gradient solvent system of 3% to 5% methanol/dichloromethane afforded **5** as a clear oil (4.5 g, 70% over 2 steps).

Characterizations matched previous reports (*34*). ^{1}H NMR (250 MHz, $CDCl_3$) δ 4.02−4.00 (m, 2H), 3.83−3.71 (m, 4H), 2.49−2.45 (m, 2H), 1.44 (s, 6H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 109.3, 78.3, 62.1, 27.0; HRMS $[M + H]^+$ calcd: 163.09703, found: 163.09705.

((4*S*,5*S*)-5-(Azidomethyl)-2,2-dimethyl-1,3-dioxolan-4-yl)-methanol (7). Compound **5** (990 mg, 6.10 mmol) was suspended in anhydrous dichloromethane (36 mL). With stirring was added silver (I) oxide (2.12 g, 9.15 mmol), tosyl chloride (1.28 g, 6.71 mmol), and crushed potassium iodide (203 mg, 1.22 mmol). The reaction was stirred at room temperature for 2 h at which point it was filtered through a short plug of silica using ethyl acetate as an eluent and concentrated under reduced pressure to afford crude **6**. This was passed on without further purification.

To the crude solution of **6** dissolved in anhydrous DMF (60 mL) was added sodium azide (1.19 g, 18.3 mmol). The reaction was heated to 85 °C and stirred overnight. The crude mixture was extracted with ethyl acetate, dried with magnesium sulfate, and concentrated under reduced pressure. Column chromatography with silica gel and a gradient solvent system of 20−60% ethyl acetate/hexanes afforded **7** as a colorless oil (934 mg, 82% over 2 steps).

Characterizations matched previous reports (*35*). ^{1}H NMR (300 MHz, $CDCl_3$) δ 4.12−3.97 (m, 2H), 3.84−3.78 (m, 1H), 3.69−3.55 (m, 2H), 3.37−3.31 (m, 1H), 2.39 (t, J = 6 MHz, 1H), 1.47 (s, 1H), 1.44 (s, 1H).

(2*S*,3*S*)-4-Azidobutane-1,2,3-triol (8). Alcohol **7** was dissolved in 10 mL of 90% acetic acid. The solution was heated to reflux for 10 min and then slowly cooled to room temperature. Solvent was removed under reduced pressure and column chromatography with silica gel and 10% methanol/dichloromethane afforded compound **8** as a yellow syrup (232 mg, 92%).

^{1}H NMR (300 MHz, CD_3OD) showed removal of the acetonide protecting group and, along with the R_f value by TLC analysis, matched previous characterizations (*36*). Compound **8** was thus used without any further characterization.

(2*S*,3*S*)-1-Azido-4-((4,4′-dimethoxytrityl)methoxy)butane-2,3-diol (9). Triol **8** (75.3 mg, 0.512 mmol) was dissolved in pyridine (5 mL) and a small amount of 4 Å MS was added to the reaction flask. With stirring, 4,4′-dimethoxytrityl chloride (260 mg, 0.768 mmol) was added. The reaction was placed under nitrogen and stirred at room temperature overnight. The reaction was then filtered with dichloromethane and the solvent was removed under reduced pressure at low temperature (45 °C). Column chromatography with silica gel and a gradient solvent system of 30−80% ethyl acetate/hexanes afforded **9** as a yellow oil (143 mg, 62%).

$[\alpha]_D^{296K}$ − 5.53 (c = 1.428, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.42−7.18 (m, 9H), 6.82 (d, J = 8.7 Hz, 4H), 3.82−3.64 (m, 8H ($OC\underline{H}_3$ + 2C$\underline{H}$OH)), 3.38−3.18 (m, 4H), 2.98 (d, J = 4.8 Hz, 1H), 2.82 (d, J = 6 Hz, 1H); ^{13}C NMR (100.6 MHz, $CDCl_3$) δ 158.6, 144.5, 135.7, 135.5, 130.0, 128.02, 127.97, 127.0, 113.3, 86.7, 71.3, 70.7, 65.2, 55.2, 53.6; HRMS $[M + Cl^-]^-$ calcd: 484.16392, found: 484.16204.

(2*S*,3*S*)-1-Azido-4-((4,4′-dimethoxytrityl)methoxy)butane-2,3-diyl distearate (10d). Diol **9** (289 mg, 0.643 mmol), stearic acid (549 mg, 1.93 mmol), 4-dimethylaminopyridine (79 mg, 0.643 mmol), and dicyclohexylcarbodiimide (398 mg, 1.93 mmol) were combined in dichloromethane (7 mL). The reaction was stirred at room temperature for 7 h, at which point it was filtered with ethyl acetate. Column chromatography with silica gel and 10% ethyl acetate/hexanes afforded **10d** as a white solid (546 mg, 86%).

$[\alpha]_D^{296K}$ + 3.10 (c = 0.967, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.42−7.18 (m, 9H), 6.82 (d, J = 8.7 Hz, 4H),

5.45−5.40 (m, 1H), 5.27−5.23 (m, 1H), 3.78 (s, 6H), 3.45−3.39 (m, 1H), 3.31−3.19 (m, 2H), 3.11−3.06 (m, 1H), 2.39−2.22 (m, 4H), 1.67−1.54 (m, 4H), 1.26 (bs, 56H), 0.88 (t, $J = 6.6$ Hz, 6H); ^{13}C NMR (100.6 MHz, $CDCl_3$) δ 172.8, 172.7, 158.6, 144.3, 135.6, 135.4, 129.96, 129.90, 128.0, 127.9, 126.9, 113.2, 86.3, 71.2, 70.7, 61.7, 55.2, 50.9, 34.4, 34.1, 32.0, 29.73, 29.69, 29.68, 29.67, 29.5, 29.4, 29.3, 29.28, 29.2, 25.0, 24.8, 22.7, 14.1; $[M + O_2]$[9] calcd: 1013.70683, found: 1013.71083.

(2*S*,3*S*)-1-Azido-4-hydroxybutane-2,3-diyl distearate (2). Compound **10d** (35 mg, 0.036 mmol) and *p*-aminobenzoic acid (49 mg, 0.360 mmol) were combined in 2 mL of solvent in a ratio of 1 dichloromethane/8.5 acetic acid/0.5 water. The solution was stirred at room temperature for 12.5 h. The reaction was extracted with dichloromethane (50 mL) and dried with magnesium sulfate. The solvent was removed under reduced pressure. Column chromatography was carried out on a short plug of silica gel using 30% ethyl acetate/hexanes. Because compound **2** is known to undergo acyl chain migration on silica, purification was performed rapidly. As a result of not being able to carefully purify the reaction, **2** was not obtained in pure form, but the trityl adduct impurities did not affect the next reaction and were easily removed during purification of the subsequent DAG analogues.

^{1}H NMR (300 MHz, $CDCl_3$) δ 5.33−5.30 (m, 1H), 5.12−5.07 (m, 1H), 3.68−3.61 (m, 2H), 3.49−3.46 (m, 2H), 2.44−2.33 (m, 5H, OH buried), 1.66−1.60 (m, 4H), 1.26 (b s, 56H), 0.88 (t, $J = 6.3$ Hz, 6H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 173.7, 173.2, 72.5, 70.5, 60.8, 51.1, 34.2, 32.0, 29.7, 29.5, 29.4, 29.3, 29.2, 25.0, 24.9, 22.7, 14.1; HRMS $[M - H_2O + H]^+$ calcd: 662.58358, found: 662.58257.

General Procedure for Obtaining DAG Analogues Modified by "Click" Chemistry. Compound **10d** (1 equiv) and pyrrole (2.05 equiv) or *p*-ABA (10 equiv) were dissolved in 2 mL of solvent in a ratio of 1 dichloromethane/8.5 AcOH/0.5 H_2O. The solution was stirred at room temperature for 6 h if using pyrrole or 12.5 h if using *p*-ABA. The reaction was extracted with dichloromethane (2 × 25 mL) and dried with magnesium sulfate. The solvent was removed under reduced pressure. The crude residue was then dried under high vacuum for 1−3 h and used directly in the click reactions as described below.

(2*S*,3*S*)-1-Hydroxy-4-(4-((2-(naphthalen-2-yl)acetamido)-methyl-1*H*-1,2,3-triazol-1-yl)butane-2,3-diyl distearate (11a). Alkyne **12a** (14.3 mg, 0.064 mmol) and **2** (0.064 mmol) were dissolved in dry THF (0.5 mL). Copper sulfate pentahydrate (16 mg, 0.064 mmol) and sodium ascorbate (12.7 mg, 0.064 mmol) were added along with water (0.5 mL). The reaction was stirred in the dark at room temperature overnight. The reaction was extracted with dichloromethane (2 × 50 mL) from water, and the organic phase was dried with magnesium sulfate, filtered, and the solvent removed by rotary evaporation. Column chromatography on a short plug of silica gel and a gradient solvent system of 50% to 100% ethyl acetate/hexanes afforded **11a** as a white solid (29 mg, 50% (2 steps)).

$[\alpha]_D^{296K}$ − 11.0 ($c = 0.963$, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.82−7.77 (m, 3H), 7.69 (s, 1H), 7.57 (s, 1H), 7.51−7.45 (m, 2H),7.36−7.33 (m, 1H), 6.30 (t, $J = 5.7$ Hz, 1H), 5.55−5.50 (m, 1H), 5.02−4.97 (m, 1H), 4.54 (d, $J = 6$ Hz, 2H), 4.42 (d, $J = 5.7$ Hz, 2H), 3.79−3.56 (m and s overlapped, 4H), 2.71 (b s, 1H), 2.38−2.24 (m, 4H), 1.64−1.51 (m, 4H), 1.25 (b s, 56H), 0.88 (t, $J = 6.2$ Hz, 6H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 173.4, 173.1, 171.1, 144.9, 133.5, 132.5, 131.9, 128.9, 128.3, 127.71, 127.65, 127.2, 126.4, 126.1, 123.3, 72.0, 70.0, 60.5, 50.3, 43.8, 35.0, 34.1, 33.9, 29.72, 29.68, 29.5, 29.4, 29.3, 29.2, 29.1, 24.9, 24.8, 22.7, 14.1; HRMS $[M + H]^+$ calcd: 903.69386, found: 903.68995.

(2*S*,3*S*)-1-(4-((5-(Dimethylamino)naphthalene-1-sulfonamido)methyl-1*H*-1,2,3-triazol-1-yl)-4-hydroxybutane-2,3-diyl distearate (11b). Alkyne **12b** (16.4 mg, 0.057 mmol) and **2** (0.057 mmol) were dissolved in dry THF (0.5 mL). Copper sulfate pentahydrate (14.2 mg, 0.057 mmol) and sodium ascorbate (11.3 mg, 0.057 mmol) were added along with water (0.5 mL). The reaction mixture was stirred in the dark at room temperature overnight. The reaction was extracted with dichloromethane (2 × 50 mL) from water, and the organic phase was dried with magnesium sulfate, filtered, and the solvent removed by rotary evaporation. Column chromatography on a short plug of silica gel and a gradient solvent system of 50% to 100% ethyl acetate/hexanes afforded **11b** as a greenish solid (30 mg, 55% (2 steps)).

$[\alpha]_D^{296K}$ − 12.2 ($c = 1.01$, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 8.55 (d, $J = 8.7$ Hz, 1H), 8.27−8.24 (m, 2H), 7.58−7.50 (m, 2H), 7.43 (s, 1H), 7.19 (d, $J = 7.5$ Hz, 1H), 5.51−5.44 (m, 2H, NH buried), 4.98−4.93 (m, 1H), 4.48 (d, $J = 6$ Hz, 2H), 4.18 (d, $J = 6$ Hz, 2H), 3.79−3.58 (m, 2H), 2.89 (s, 6H), 2.64 (b s, 1H), 2.39−2.27 (m, 4H), 1.66−1.53 (m, 4H), 1.25 (b s, 56H), 0.88 (t, $J = 6.5$ Hz, 6H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 173.4, 173.2, 151.9, 144.4, 134.4, 130.6, 129.8, 129.6, 129.5, 128.6, 123.3, 123.2, 118.7, 115.3, 72.0, 69.8, 60.5, 50.2, 45.4, 38.7, 34.1, 33.9, 31.9, 29.72, 29.68, 29.5, 29.4, 29.3, 29.26, 29.2, 29.1, 24.9, 24.8, 22.7, 14.1; HRMS $[M + H]^+$ calcd: 968.68739, found: 968.68743.

(2*S*,3*S*)-1-Hydroxy-4-(4-((2-oxo-2*H*-chromene-3-carboxamido)methyl)-1*H*-1,2,3-triazol-1-yl)butane-2,3-diyl distearate (11c). Alkyne **12c** (12.7 mg, 0.056 mmol) and **2** (0.056 mmol) were dissolved in dry THF (0.5 mL). Copper sulfate pentahydrate (14 mg, 0.056 mmol) and sodium ascorbate (11.1 mg, 0.056 mmol) were added along with water (0.5 mL). The reaction mixture was stirred in the dark at room temperature overnight. Solvent was removed, and column chromatography on a short plug of silica gel and a gradient solvent system of 20% to 100% acetone/chloroform afforded **11c** as a tan solid (31 mg, 60% (2 steps)).

$[\alpha]_D^{296K}$ − 14.6 ($c = 1.224$, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 9.29 (bs, 1H), 8.91 (s, 1H), 7.71−7.65 (m, 3H), 7.42−7.36 (m, 2H), 5.60−5.55 (m, 1H), 5.07−5.02 (m, 1H), 4.73 (b s, 2H), 4.61−4.60 (m, 2H), 3.80−3.59 (m, 2H), 2.64−2.62 (m, 1H), 2.39−2.28 (m, 4H), 1.65−1.53 (m, 4H), 1.25 (b s, 56H), 0.88 (t, $J = 6.6$ Hz, 6H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 173.4, 173.1, 161.8, 161.2, 154.5, 148.5, 144.8, 134.3, 129.8, 125.3, 123.3, 118.5, 118.1, 116.7, 72.1, 70.0, 60.5, 50.3, 35.4, 34.1, 33.9, 31.9. 29.72, 29.67, 29.5, 29.4, 29.3, 29.2, 29.1, 24.9, 24.8, 22.7, 14.2; HRMS $[M + H]^+$ calcd: 907.65239, found: 907.65176.

(2*S*,3*S*)-1-Hydroxy-4-(4-((5(6)-fluoresceinamido)methyl)-1*H*-1,2,3-triazol-1-yl)butane-2,3-diyl distearate (11d). Alkyne **12d** (19.8 mg, 0.048 mmol) and **2** (0.048 mmol) were dissolved in dry THF (0.5 mL). Copper sulfate pentahydrate (12 mg, 0.048 mmol) and sodium ascorbate (9.5 mg, 0.048 mmol) were added along with water (0.5 mL). The reaction was stirred in the dark at room temperature overnight. Solvent was removed and column chromatography on a short plug of silica gel and a gradient solvent system of 30% to 100% acetone/chloroform afforded **11d** as an orange solid (25 mg, 47% (2 steps)). Note: since both fluorescein isomers (5- and 6-carboxy) were present in the ^{1}H NMR spectra for compounds **12d** and **11d**, and the ratio of each isomer is unknown in the commercially available acid, integration values are not reported. ^{13}C NMR data for compounds **12d** and **11d** are not reported due to poor solubility of the compounds and the complex nature of the spectra due to the isomeric mixture.

$[\alpha]_D^{296K}$ − 8.5($c = 0.823$, 1 acetone/1 $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$/$(CD_3)_2CO$ (1:1)) δ 9.05 (b s), 8.60 (b s), 8.50 (b s), 8.33−8.30 (m), 8.24−8.21 (m), 8.04−8.01 (m) 7.91 (b s), 7.81−7.78 (m), 7.74 (s), 7.31−7.28 (m), 6.77−6.56 (m), 5.61−5.51 (m), 5.04−4.99 (m), 4.72−4.59 (m) 4.30−4.17 (m),

3.83−3.65 (m), 2. 39−2.18 (m), 1.62−1.43 (m), 1.27 (b s), 0.88 (t, $J = 6.3$ Hz); HRMS $[M + H]^+$ calcd: 1093.68408, found: 1093.68461.

(2*S*,3*S*)-1-(4-((4-Benzoylbenzamido)methyl-1*H*-1,2,3-triazol-1-yl)-4-hydroxybutane-2,3-diyl distearate (11e). Alkyne **12e** (13.6 mg, 0.052 mmol) and **2** (0.052 mmol) were dissolved in dry THF (0.5 mL). Copper sulfate pentahydrate (13 mg, 0.052 mmol) and sodium ascorbate (10 mg, 0.052 mmol) were added along with water (0.5 mL). The reaction was stirred in the dark at room temperature overnight. The reaction was extracted with dichloromethane (2 × 50 mL) from water, and the organic phase was dried with magnesium sulfate, filtered, and the solvent removed by rotary evaporation. Column chromatography on a short plug of silica gel and a gradient solvent system of 50% to 100% ethyl acetate/hexanes afforded **11e** as a white solid (34 mg, 69% (2 steps)).

$[\alpha]_D^{296K} - 11.4$ ($c = 1.127$, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.92 (d, $J = 8.1$ Hz, 2H), 7.84−7.73 (m, 5H), 7.61 (t, $J = 7.4$ Hz, 1H), 7.49 (m, 2H), 7.33 (b s, 1H), 5.61−5.57 (m, 1H), 5.06−5.01 (m, 1H), 4.77−4.71 (m, 2H), 4.62−4.59 (m, 2H), 3.81−3.75 (m, 1H), 3.67−3.60 (m, 1H), 2.39−2.27 (m, 4H), 1.64−1.49 (m, 4H), 1.25 (b s, 56H), 0.88 (t, $J = 6.6$ Hz, 6H); ^{13}C NMR (100.6 MHz, $CDCl_3$) δ 195.9, 173.3, 173.2, 166.6, 144.7, 140.2, 137.2, 137.0, 132.9, 130.1, 128.4, 127.1, 123.6, 72.1, 70.0, 60.6, 50.4, 35.4, 34.2, 34.0, 31.9, 29.7, 29.5, 29.4, 29.3, 29.2, 29.1, 24.9, 24.8, 22.1, 14.1; HRMS $[M + H]^+$ calcd: 943.68877, found: 943.68741.

Protein Binding Analysis. The DAG binding protein PKCδ was purified from Sf9 cells as previously described (*37*). Lipid vesicles were prepared as previously described (*37*) and consisted of POPC/POPS/DAG (78:20:2 where DAG is any synthetic DAG tested). POPC vesicles were prepared for the control surface. All surface plasmon resonance (SPR) experiments were performed at 25 °C using a Biacore X as described previously (*38*). Equilibrium SPR measurements were carried out at the flow rate of 5 μL/min with coating of the L1 sensor chip (GE Healthcare) done as previously reported (*38*). After injecting 85 μL of PKCδ, the protein−lipid association and dissociation were measured for 1020 and 500 s, respectively. The sensorgrams were obtained using five or more different concentrations of the protein (within a 10-fold range of K_d) for each condition tested. The sensorgrams were corrected for refractive index change by subtracting the control surface response. The maximal response (R_{eq}, saturation value) was determined from the plots and then plotted versus protein concentrations (C). The K_d value was determined by a nonlinear least-squares analysis of the binding isotherm using the equation $R_{eq} = R_{max}/(1 + K_d/C)$ (*39*).

RESULTS AND DISCUSSION

While recent advances have yielded progress in understanding protein−lipid association, these studies are complicated by the membrane environment in which they occur, and results often reveal the complex nature of these events and raise further questions for scrutiny. One of the best-studied families of peripheral proteins are the PKCs, which contain tandem C1 domains and one C2 domain, which each form specific interactions with lipids such as DAG, PS, and PA, depending on the specific domain and isoform (*1, 2*). The presence of multiple lipid-binding domains indicates multivalency in binding, a common cell-surface motif in which multiple ligands are simultaneously bound by a protein receptor (*40, 41*). Furthermore, subtle differences in lipid-binding specificities and affinities have been discerned among the eleven known PKC isoforms (*1, 2*). Differential binding properties have also been observed in the interaction of PKC isozymes with phorbol esters, which occurs at the same site as DAG recognition (*42*). In addition, variation exists in the subcellular localization of the different PKC isoforms, which often occurs in a cell-type specific manner that has represented a formidable obstacle to elucidating the roles of the different isozymes in biological processes including tumorigenesis (*12*). A current hypothesis is that the subtle differences in binding patterns between isozymes result in the variation in their distinct cellular localization, which in turn controls their involvement in specific physiological processes (*2, 11*). Due to these ramifications, it is necessary to fully characterize the multivalent lipid-binding specificities of peripheral proteins, the patterns of affinities among domains, and the role this has in controlling distribution and function.

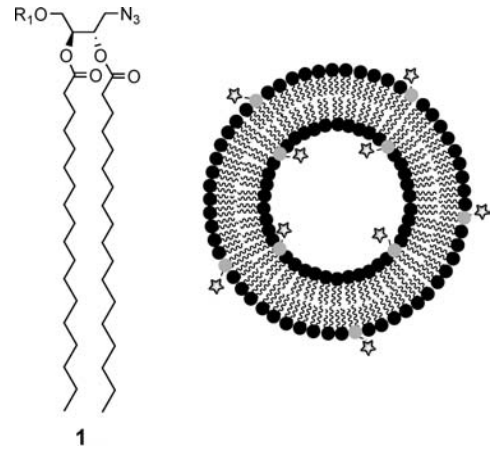

Figure 1. General design for headgroup azide-tagged lipid analogues and tag presentation in a membrane environment.

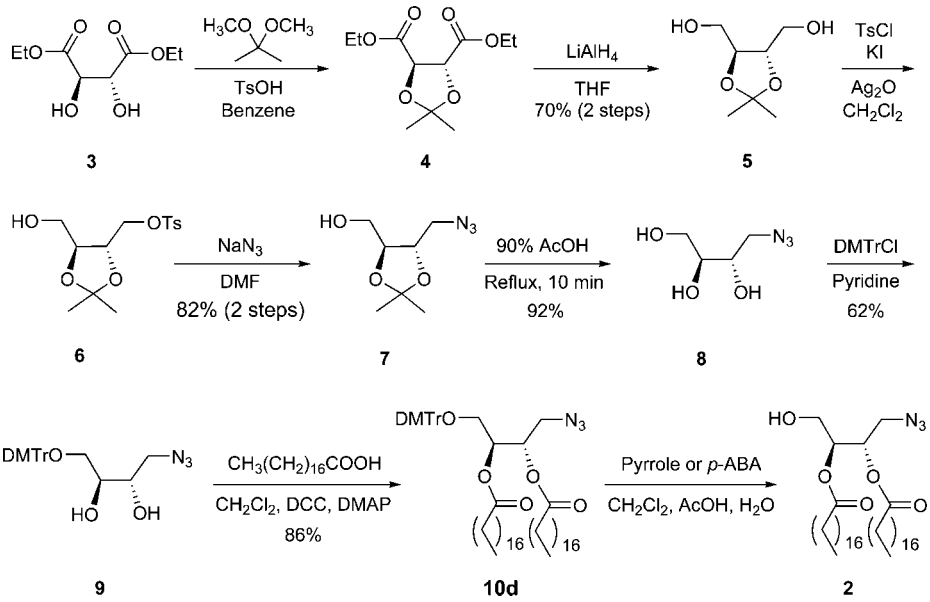
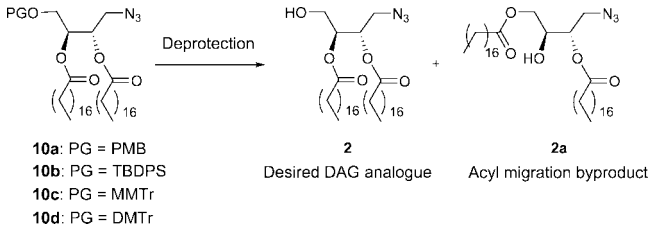
Fully synthetic lipid probes have previously proven effective for scrutinizing binding events (*7, 33, 43−49*). However, the scope of studies is often limited by the complexity of synthesis required for each distinct reporter-functionalized probe. An effective lipid probe design involves the incorporation of a versatile reactive tag into the lipid structure. This provides a common modular intermediate that can be specifically modified to introduce a variety of reporter groups or for direct functionalization within the context of a study. However, the choice of functionality for lipid derivatization is crucial, as the diversity of functional groups in these structures complicates modification. For this purpose, we have designed versatile lipid core structures, described generically by **1** (Figure 1), containing an azide-reactive tag in the form of an azidomethyl group at the *sn*-1 position. The azide group is specifically chosen due to its diminutive size, robust properties, and bio-orthogonal reactivity through the 1,3-dipolar cycloaddition (click chemistry) (*50−52*) and Staudinger ligation (*53−55*) reactions. The azide can also be reduced to an amine for functionalization (*56*). Thus, multiple pathways exist for direct modification of the tagged lipid analogue to produce a wide array of probes.

The initial modular glycerolipid probe structure of type **1** that we have developed is DAG analogue **2**. This compound can be implemented both to study the involvement of DAG in important recognition events and as the scaffold for the synthesis of probes of more complex phospholipids and glycolipids. The synthetic route that has been developed for DAG derivative **2**, indicated in Scheme 1, begins with commercially available diethyl L-tartrate (**3**). This C_2 symmetric precursor is employed to avoid mixtures of enantiomeric products during synthesis (*33*). Precursor **3** was converted to synthetic intermediate **7** via modified literature procedures (*34, 35*). Here, the diol of **3** is first protected via acetonide formation to provide fully protected tartrate analogue **4**, which is followed by ester reduction to bis-hydroxymethyl compound **5**. Next, monotosylation produces **6**,

Scheme 1. Synthetic Route to Head Group Azide-Tagged Diacylglycerol Scaffold 2



Scheme 2. Products Obtained from Deprotection and Acyl Migration of DAG analogues



which is then substituted with azide to **7**. The final synthetic route to azido-DAG analogue **2** employs a dimethoxytrityl (DMTr) group to protect the primary hydroxyl group in the corresponding product (see discussion in the following paragraphs). However, the DMTr group would not survive the subsequent acetonide deprotection under acidic conditions, which is necessary to introduce the acyl chains of the lipid. However, an advantage of the DMTr group is that it can be selectively installed onto a primary over a secondary hydroxyl group (*57*). Thus, our synthetic route employs acetonide deprotection of **7** to triol **8** in acid followed by selective DMTr introduction to **9**. Next, the acyl chains are introduced using standard coupling conditions with stearic acid to **10d**. Finally, the DMTr group is removed under mild conditions to access azido-DAG analogue **2**.

A significant issue in the synthesis of **2** involved acyl group migration upon deprotection of intermediates of type **10** (Scheme 2). Here, byproduct **2a** arose from *sn*-2 to *sn*-3 migration in amounts that were dependent upon the protecting group that was employed as well as the reaction conditions. Such migrations in acylglycerols, which can occur in both acidic and basic conditions, complicate the synthesis and biological analysis of these compounds (*58*). We pursued a range of different protecting groups and deprotection conditions to determine the most effective approach. The first attempt employed a *para*-methoxybenzyl (PMB)-protected DAG analogue (**10a**). Deprotection was performed under typical oxidative conditions using DDQ and yielded **2a** as a byproduct (Table 1). Next, we switched to the *tert*-butyldiphenylsilyl (TBDPS) group of **10b** following previous reports of this group for successfully avoiding acyl migration (*59*). Initial deprotection using just TBAF yielded quantitative migration product (**2a**). While this

Table 1. Protecting Groups and Deprotection Conditions Employed to Avoid Acyl Migration

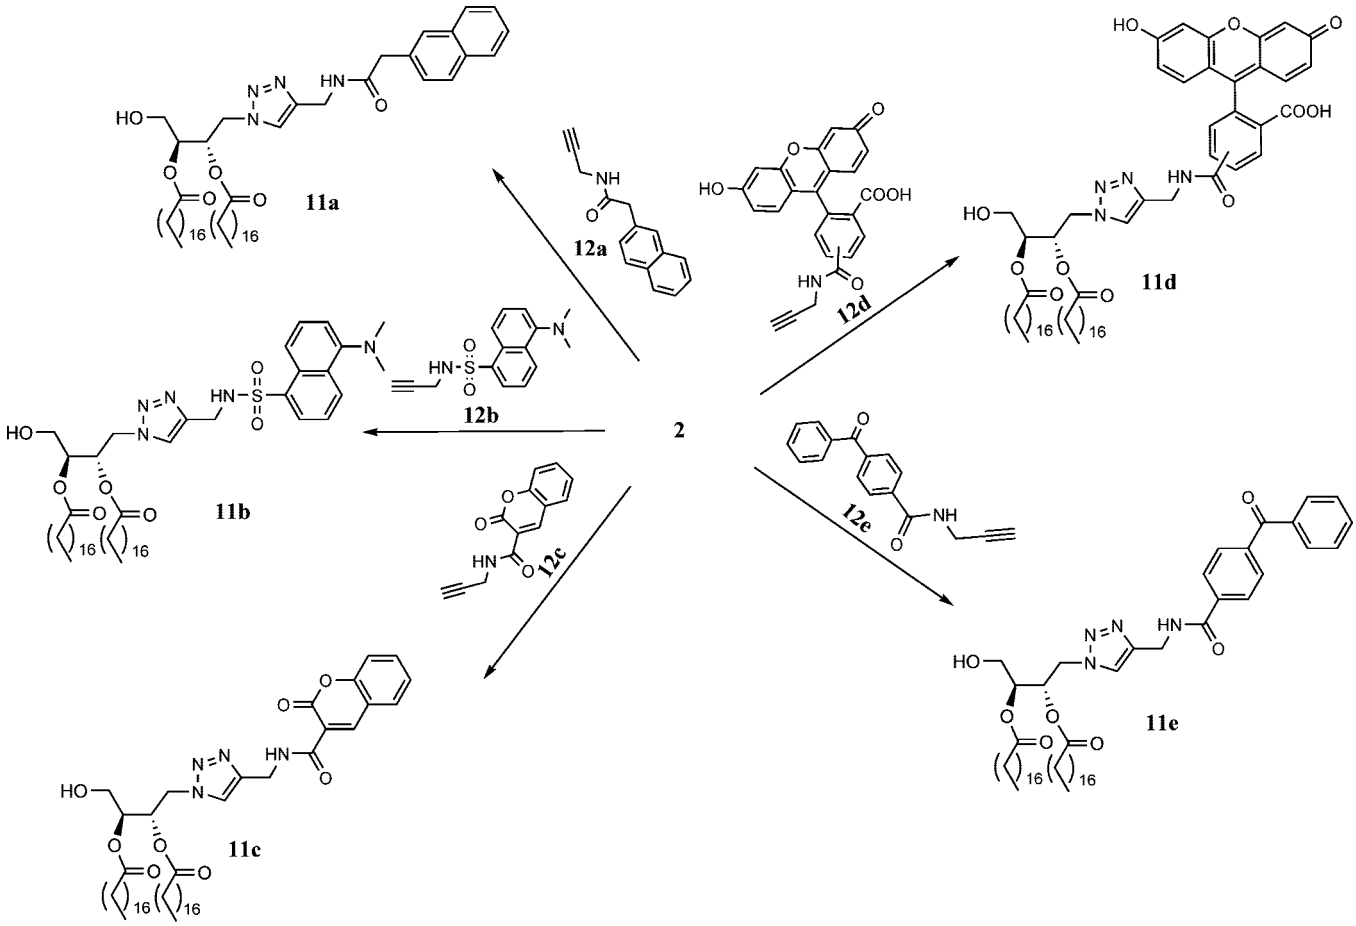
protecting group (PG)	deprotection conditions	% **2**[a]	% **2a**[a]
PMB (**10a**)	DDQ	85%	15%
TBDPS (**10b**)	TBAF	0%	100%
TBDPS (**10b**)	TBAF/AcOH	83%	17%
MMTr (**10c**)	*p*-TsOH	0%	100%
DMTr (**10d**)	$Cl_2HCCOOH$	0%	100%
DMTr (**10d**)	AcOH/*p*-ABA or pyrrole	98%	2%
DMTr (**10d**)	AcOH/pyrrole or *p*-ABA/direct click	>99.5%	<0.5%

[a] Approximate percentages of **2** and **2a** were determined by analysis of ^{1}H NMR spectra.

was minimized through TBAF deprotection in the presence of acetic acid (*59, 60*), the migration product still appeared in an amount similar to that of PMB deprotection. Modification to install the monomethoxytrityl (MMT) of **10c** unfortunately once again led to quantitvative migration product upon deprotection using acids such as *para*-toluenesulfonic acid.

Failure of each of these approaches indicated that the described system is particularly prone to undergoing migration. This is likely attributable to the increased steric bulk in the form of the added azidomethyl group, which could increase the driving force for migration of the neighboring *sn*-2 acyl chain to the less substituted *sn*-3 position. Finally, the DMTr protecting group was pursued, producing protected DAG **10d**, as it can be removed under mildly acidic conditions (*57*) and has been used in *sn*-3 hydroxyl protection (*61*). Here, deprotection using acetic acid was quite effective in reducing migration to essentially trace amounts. We initially employed traditional DMTr removal conditions, including the use of pyrrole to scavenge the intermediate dimethoxytrityl cation (*62*). However, the resulting DMTr-pyrrole adduct was found to complicate purification due to chromatographic overlap with **2**. This was especially the case because rapid chromatographic separation of all DAG analogues containing the unprotected *sn*-3 hydroxyl group was necessary to avoid on-column acyl migration, which has been previously documented (*58*). As a result, we instead employed *para*-aminobenzoic acid (*p*-ABA) for cation scavenging as the pendant carboxylic acid decreases the chromatographic mobility of the resulting DMTr-adduct. While this decreased the amount of trityl adduct impurity present following fast chromatography, it could not be completely removed. However, the trityl byproduct could be easily purified out

Scheme 3. Direct Derivatization of Azido-DAG Core 2 for Convenient Incorporation of Reporter Groups



following subsequent azido-DAG functionalization, and thus compound **2** was directly used for the next step with some trityl adduct impurity.

Following the synthesis of DAG scaffold **2**, we have extended efforts to derivatization of this core structure to showcase the ability to produce a variety of probes in a single convenient step. Here, we have utilized the 1,3-dipolar cycloaddition reaction to incorporate fluorescent (**11a**−**d**) and photoaffinity (**11e**) groups onto **2** through reaction with alkyne reagents **12a**−**e**, which were accessed in one step from propargylamine (Scheme 3). The mild conditions of the azide−alkyne cycloaddition are particularly beneficial for producing functionalized DAGs by avoiding the aforementioned acyl migration byproducts. Among the fluorophores that have been incorporated are multiple Förster resonance energy transfer (FRET) pairs. Probes labeled with FRET pairs are useful for the direct detection of changes in proximity of ligands during various processes due to the sensitivity of energy transfer to distance (*63*−*65*). Installation of a photoaffinity tag is advantageous for performing photo-cross-linking studies to characterize protein binding, such as for the mapping of the location of binding domains on receptor proteins (*66*). Functionalization at the headgroup *sn*-1 position is particularly beneficial for these studies in order to present the tag in close proximity to the bound protein and thus maximize fluorescent signal transduction or cross-linking efficiency. This strategy for probe development is beneficial, as it allows for direct access to a range of functionalized lipids in a single step. Thus, a panel of compounds can be efficiently accessed and implemented for studies to determine those that are particularly suited to a given investigation.

Having developed a series of functionalized DAG derivatives, we next sought to analyze their efficacy as probes for characterizing DAG-binding interactions. In order to demonstrate that the newly synthesized DAG probes retain the typical binding properties of DAG effectors, we monitored the binding of a well-known DAG receptor, PKCδ, to lipid vesicles containing the different analogues. To do so, we performed SPR equilibrium binding analysis using POPC vesicles as a control and POPC/POPS/DAG (78:20:2 containing varying DAG probes) as an active surface. We first performed binding experiments with DiC_{18} since the binding of PKCδ to vesicles containing this ligand has been well-documented (*47*). PKCδ bound with 24 nM affinity to these vesicles as shown in Table 2. Next, we systematically analyzed the binding efficacy of each of the described DAG reporters. As shown by the equilibrium binding constants (or K_d values) in Table 2 and binding isotherms in Figure 2, all DAG reporters displayed analogous properties to DiC_{18} for PKCδ recruitment with K_d values ranging from 16 to 28 nM.

Table 2. Binding properties of PKCδ with different DAG analogues

lipid	K_d (nM) using POPC/POPS/DAG (78:20:2)
DiC_{18}	24 ± 4
Synthetic DiC_{18}	19 ± 2
Naphthyl-DAG (11a)	16 ± 3
Dansyl-DAG (11b)	20 ± 3
Coumarin-DAG (11c)	18 ± 2
5(6)-CBF DAG (11d)	28 ± 5
Benzophenone-DAG (11e)	21 ± 3

The first quantitative analysis of these DAG derivatives illustrates their ability to mimic DAG despite the fact that each compound contains a bulky reporter appended at the headgroup. Thus, these results validate the synthetic introduction of

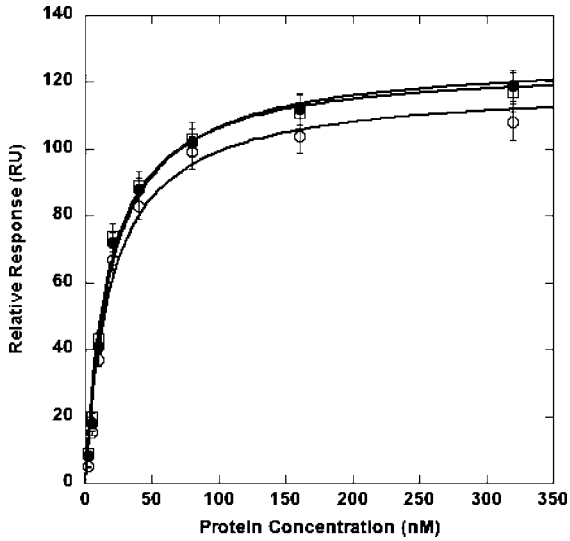


Figure 2. Affinity of PKCδ for DAG-containing membranes determined by SPR analysis. SPR measurements were used to determine K_ds of PKCδ for POPC/POPS/DAG (78:20:2) vesicles where DAG represents synthetic DAGs reported in this manuscript (see Table 2 or Scheme 3). PKCδ was injected at varying concentrations at a flow rate of 5 μL/min and the subsequent association and dissociation were monitored. From these plots, the saturation response (R_{eq}, equilibrium value) was determined. In order to calculate the K_d of PKCδ for the DAG containing vesicles, the equilibrium value (saturating response (R_{eq}) of protein bound) determined from each sensorgram was then plotted versus respective protein concentration (2, 5, 10, 20, 40, 80, 160, and 320 nM).The solid lines represent theoretical curves constructed from R_{max} and K_d values determined by nonlinear least-squares analysis of the isotherms using $R_{eq} = R_{max}/(1 + K_d/C)$. Representative curves are shown for three different DAGs tested, synthetic-DAG (•), dansyl-DAG (○), and coumarin-DAG (□).

functionality at the *sn*-1 position as an advantageous approach for obtaining effective headgroup-derivatized glycerolipid probes. These data also demonstrate the relevance of these novel probes for use as robust reporters of important biological interactions. We are currently pursuing multiple avenues for extending these investigations. First, we are implementing these compounds for the characterization of protein−membrane binding events at the molecular level. Second, we are building upon the DAG core of these structures to access probes for more structurally complex glycerolipids such as PA, PS, and the PIP_ns.

ACKNOWLEDGMENT

M.D.B. acknowledges bioorganic colleagues at UTK, Drs. David Baker, Shane Foister, and Shawn Campagna, as well as a collaborator, Dr. Wonhwa Cho, for beneficial discussions. M.D.B. also thanks the University of Tennessee for funding, and J.C.R. acknowledges a Summer Undergraduate Research Fellowship from Pfizer Global Research. Supporting Information

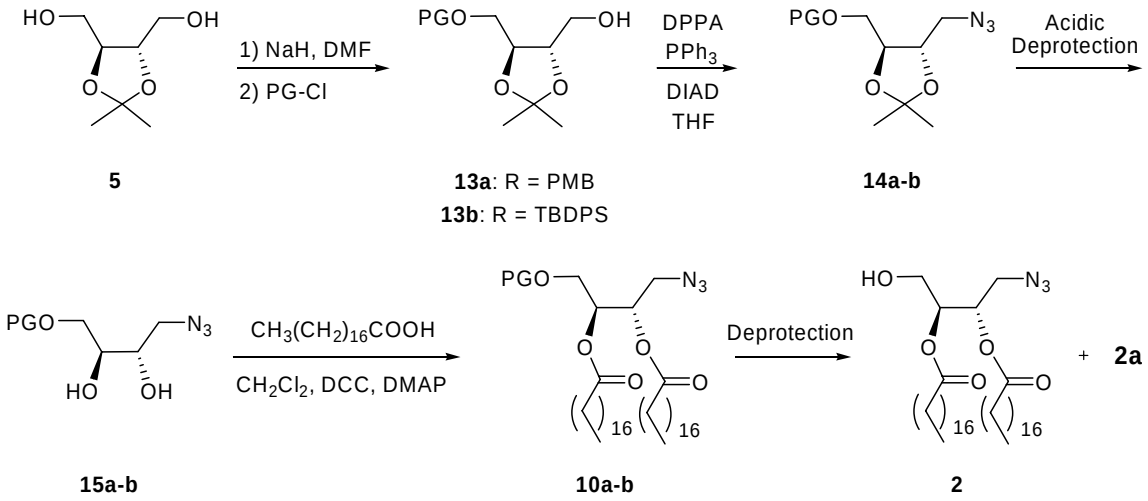
1) Original synthetic route to PMB-protected DAG analog (**10a**): Azido-DAG analog **2** was first pursued through PMB- and TBDPS-protection as shown in the scheme below. A modified literature procedure [1] was followed to convert diethyl L-tartrate (**3**) to intermediate **13a**.



1A) PMB-protection experimental procedures:

((4S,5S)-5-((4-Methoxybenzyloxy)methyl-2,2-dimethyl-1,3-dioxolan-4-yl)methanol (13a). A solution of sodium hydride (162 mg, 4.06 mmol, 60% purity) in anhydrous DMF (20 mL) was prepared in a flame-dried round-bottom flask under nitrogen and cooled to 0 °C with stirring. Diol **5** (658 mg, 4.06 mmol) was dissolved in anhydrous DMF (20 mL) and added dropwise. Stirring was continued at 0 °C for 10 min and then at room temperature for 20 min. At this point the reaction mixture was cooled to 0 °C and 4-methoxybenzyl chloride (606 µL, 4.47 mmol) was added dropwise. The mixture was then stirred at room temperature overnight. The reaction was quenched with ~50 mL water, and the mixture was extracted with dichloromethane (2 x 50 mL). The organic layer was then dried with magnesium sulfate and filtered, and the solvent was removed by rotary evaporation. Column chromatography with silica gel and a gradient solvent system of 20 to 60% ethyl acetate/hexanes afforded **13a** as a clear oil (908 mg, 79%).

^{1}H NMR (300MHz, $CDCl_3$) δ 7.24 (d, *J* = 8.7 Hz, 2H), 6.87 (d, *J* = 8.7 Hz, 2H), 4.56-4.47 (m, 2H), 4.05-3.99 (m, 1H), 3.94-3.88 (m, 1H), 3.79 (s, 3H), 3.78-3.63 (m, 3H), 3.54-3.49 (m, 1H), 2.56-2.52 (m, 1H), 1.41 (s, 6H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 159.4, 129.6, 129.5, 113.9, 109.3, 79.8, 76.5, 73.4, 70.1, 62.5, 55.2, 27.0; HRMS $[M-H]^+$ cacld: 281.13890, found: 281.13718

(4S,5S)-4-(Azidomethyl)-5-((4-methoxybenzyloxy)methyl)-2,2-dimethyl-1,3-dioxolane (14a). Alcohol **13a** (589 mg, 2.09 mmol) was dissolved in dry THF (15 mL) along with triphenylphosphine (1.096 g, 4.18 mmol). The solution was placed under nitrogen and diisopropyl azodicarboxylate (810 µL, 4.18 mmol) was added with stirring. Diphenylphosphoryl azide (901 µL, 4.18 mmol) was dissolved in dry THF (5 mL) and added to the reaction, which was then stirred overnight at room temperature. The solvent was removed with a rotary evaporator, and column chromatography with silica

gel and a gradient solvent system of 10 to 20% ethyl acetate/hexanes afforded **14** as a clear oil (507 mg, 79%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 7.23 (d, *J* = 8.6 Hz, 2H), 6.87 (d, *J* = 8.6 Hz, 2H), 4.53-4.45 (m, 2H), 4.06-3.96 (m, 2H), 3.79 (s, 3H), 3.63-3.47 (m, 3H), 3.30-3.24 (m, 1H), 1.45 (s, 3H), 1.41 (s, 3H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 159.4, 129.8, 129.3, 113.8, 109.9, 78.1, 76.5, 73.2, 69.9, 55.2, 52.0, 27.0, 26.8; HRMS $[M\text{-}N_2+H]^+$ calcd: 280.15488, found: 280.15483

(2S,3S)-1-Azido-4-(4-methoxybenzyloxy)butane-2,3-diol (15a). Compound **14a** (820 mg, 2.67 mmol) was dissolved in THF (14 mL) and 1 N HCl (14 mL) was added. The reaction was stirred at room temperature for 48 h and was then quenched with saturated sodium bicarbonate. The mixture was then diluted with water (50 mL) and extracted with dichloromethane (2 x 50 mL). The organic layer was then dried with magnesium sulfate and filtered, and the solvent was removed by rotary evaporation. Column chromatography with silica gel and a gradient solvent system of 50 to 90% ethyl acetate/hexanes afforded **15a** as a clear oil (627 mg, 88%).

^{1}H NMR (250 MHz, $CDCl_3$) δ 7.23 (d, *J* = 8.5 Hz, 2H), 6.88 (d, *J* = 8.5 Hz, 2H), 4.50-4.40 (m, 2H), 3.79 (s, 3H) 3.79-3.72 (m, 2H), 3.55-3.53 (m, 2H), 3.37-3.33 (m, 2H), 3.19 (*b* s, 1H), 3.06 (*b* s, 1H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 159.5, 129.6, 129.5, 114.0, 73.3, 71.7, 71.3, 70.2, 55.3, 53.6; HRMS $[M\text{-}N_2+H]^+$ calcd: 240.12358, found: 240.12340

(2S,3S)-1-Azido-4-(4-methoxybenzyloxy)butane-2,3-diyl distearate (10a). Diol **15a** (375.2 mg, 1.40 mmol) was dissolved in anhydrous dichloromethane (15 mL). With stirring was added stearic acid (1.194 g, 4.2 mmol), 4-dimethylaminopyridine (188 mg, 1.54 mmol), and *N,N*-dicyclohexylcarbodiimide (866 mg, 4.2 mmol). The reaction was stirred at room temperature for 3 h at which point it was filtered. Column chromatography with silica gel and a gradient solvent system of 0 to 10% ethyl acetate/hexanes afforded **10a** as a white solid (1 g, 89%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 7.22 (d, *J* = 8.7 Hz, 2H), 6.87 (d, *J* = 8.7 Hz, 2H), 5.34-5.29 (m, 1H), 5.25-5.20 (m, 1H), 4.49-4.37 (m, 2H), 3.80 (s, 3H), 3.52-3.44 (m, 3H), 3.37-3.31 (m, 1H), 2.34-2.29 (m, 4H), 1.63-1.58 (m, 4H), 1.25 (*b* s, 56H), 0.88 (t, *J* = 6.8 Hz, 6H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 172.9, 172.8, 159.4, 129.5, 129.46, 113.9, 73.0, 70.59, 70.55, 67.5, 55.2, 51.0, 34.3, 34.2, 32.0, 29.73, 29.69, 29.5, 29.4, 29.3, 29.2, 25.0, 24.9, 22.7, 14.1; HRMS $[M\text{-}N_2+H]^+$ calcd: 772.64551, found: 772.64821

(2S,3S)-1-Azido-4-hydroxybutane-2,3-diyl distearate (2). Compound **10a** (592 mg, 0.740 mmol) was dissolved in dichloromethane (7 mL) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (410 mg, 1.81 mmol) and water (700 µL, 10%) were added with stirring. Stirring was continued at room temperature for 6 h at which point the reaction was quenched with saturated sodium bicarbonate. The reaction mixture was extracted with dichloromethane (2 x 50 mL), and the organic layer was dried with magnesium sulfate and filtered. The solvent was then removed by rotary evaporation. The crude product was placed on a high vacuum line overnight to assist in the removal of volatile side products. Column chromatography with silica gel and a gradient solvent system of 0 to 20% ethyl acetate/hexanes afforded **2** as a white solid (426 mg, 85%). See paper for characterizations.

1B) TBDPS-protection experimental procedures:

((4S,5S)-5-((*tert*-butyldiphenylsilyloxy)methyl-2,2-dimethyl-1,3-dioxolan-4-yl)methanol (13b). Compound (**13b**) was prepared following published literature procedure [2] (80%).

(4S,5S)-4-(Azidomethyl)-5-((*tert*-butyldiphenylsilyloxy)methyl)-2,2-dimethyl-1,3-dioxolane (14b). To a solution of alcohol **13b** (440 mg, 1.1 mmol) in anhydrous THF (12 mL) at room temperature was added diisopropyl azodicarboxylate (426 µL, 2.2 mmol) and triphenylphosphine (577 mg, 2.2 mmol). Diphenylphosphoryl azide (474 µL, 2.2 mmol) was dissolved in dry THF (3 mL) and added to the reaction which was stirred overnight at room temperature. After the reaction was complete the mixture was concentrated under reduced pressure and column chromatography with silica gel and a gradient solvent system of 0 to 10% ethyl acetate/hexanes afforded **14b** as a pale yellow oil (380 mg, 81%).

$[\alpha]_D^{296K}$ -25.97 (c = 1.155, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.71-7.66 (m, 4H), 7.49-7.39 (m, 6H), 4.20-4.15 (m, 1H), 4.02-3.96 (m, 1H), 3.87-3.73 (m, 2H), 3.63-3.57 (m, 1H), 3.33-3.27 (m, 1H), 1.48 (s, 3H), 1.42 (s, 3H), 1.09 (s, 9H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 135.5, 132.9, 132.8, 129.9, 129.8, 127.8, 109.7, 78.0, 77.6, 64.0, 52.2, 27.0, 26.9, 26.8, 19.2; HRMS [M-N_2+H]+ calcd: 398.21514, found: 398.21530

(2S,3S)-1-Azido-4-(*tert*-butyldiphenylsilyloxy)butane-2,3-diol (15b). Azide **14b** (350 mg, 0.822 mmol) was dissolved in 8 mL 90% acetic acid and heated at reflux for 10 minutes. The reaction was then slowly cooled to room temperature and concentrated under reduced pressure and purified via column chromatography with silica gel and a gradient solvent system of 10 to 50% ethyl acetate/hexanes to afford **15b** as a pale yellow oil (235 mg, 74%).

$[\alpha]_D^{296K}$ +5.21 (c = 0.845, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.69-7.65 (m, 4H), 7.47-7.39 (m, 6H), 3.88-3.66 (m, 4H), 3.44-3.32 (m, 2H), 2.89-2.87 (m, 1H), 2.72-2.70 (m, 1H), 1.09 (s, 9H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 135.49, 135.45, 132.5, 132.4, 130.0, 127.9, 71.1, 70.9, 65.6, 53.6, 26.8, 19.1; HRMS [M+NH4]+ calcd: 403.21654, found: 403.21717

(2S,3S)-1-Azido-4-(*tert*-butyldiphenylsilyloxy)butane-2,3-diyl distearate (10b). Diol **15b** (220 mg, 0.571 mmol), stearic acid (487 mg, 1.71 mmol), 4-dimethylaminopyridine (209 mg, 1.71 mmol), and dicyclohexylcarbodiimide (353 mg, 1.71 mmol) were combined in dichloromethane (8 mL). The reaction was stirred at room temperature overnight at which point it was filtered. Column chromatography with silica gel and a gradient solvent system of 0 to 10% ethyl acetate/hexanes afforded **10b** as a white solid (524 mg, 100%).

$[\alpha]_D^{296K}$ -2.78 (c = 0.360, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.66-7.63 (m, 4H), 7.47-7.36 (m, 6H), 5.43-5.38 (m, 1H), 5.23-5.18 (m, 1H), 3.78-3.67 (m, 2H), 3.55-3.39 (m, 2H), 2.34-2.26 (m, 4H), 1.62-1.61 (m, 4H), 1.27 (bs, 56H), 1.06 (s, 9H), 0.89 (t, J = 6.0 Hz); ^{13}C NMR (75 MHz, $CDCl_3$) δ 172.8, 172.7, 135.6, 135.5, 132.8, 132.7, 129.9, 127.8, 127.7, 72.0, 70.3, 62.0, 51.0, 34.2, 34.1, 31.9, 29.7, 29.65, 29.62, 29.5, 29.35, 29.28, 29.26, 29.2, 29.1, 26.7, 24.84, 24.70, 22.7, 19.1, 14.1

(2S,3S)-1-Azido-4-hydroxybutane-2,3-diyl distearate (2). Compound **10b** (57 mg, 0.062 mmol) was dissolved in THF (2 mL). Acetic acid (3.5 µL, 0.062 mmol) and TBAF·3 H_2O were each dissolved in THF (2 mL) and added successively to the reaction. The reaction was stirred at room temperature for 80 minutes and the solvent was removed with reduced pressure. The product was extracted using a solution of 30 mL $CHCl_3$, 20 mL MeOH, and 10 mL H_20. The bottom layer was kept and concentrated. Quick chromatography with a short column of silica gel and a gradient solvent system of 10 to 100% ethyl acetate/hexanes afforded **2** as a white solid (31.3 mg, 74%, 11% TBDPS by-product that was not separable). See paper for characterizations.

2) Synthetic Procedures for Alkyne-Functionalized reagents 12a-e: Standard amide bond-forming coupling conditions were employed to obtain alkyne-functionalized fluorescent and cross-linking groups. Generally, the coupling reagent *N,N*-dicyclohexylcarbodiimide (DCC) was used to produce the highly non-polar alkyne conjugates. For the more polar alkyne conjugates, such as fluorescein, other coupling reagents, exemplified by 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC), were used to avoid problems with separating the products from the urea byproduct of DCC.

2-(Naphthalene-2-yl)-*N*-(prop-2-ynyl)acetamide (12a). 2-Naphthylacetic acid (100 mg, 0.537 mmol), *N,N*-dicyclohexylcarbodiimide (166.2 mg, 0.806 mmol), 4-dimethylaminopyridine, (32.8 mg, 0.269 mmol) and propargylamine (44 µL, 0.644 mmol) were dissolved in dichloromethane (6 mL). The reaction was stirred at room temperature in the dark overnight. The reaction was extracted with dichloromethane (2 x 50 mL) from water (50 mL) and the organic layer was dried with magnesium sulfate and filtered, and the solvent was removed by rotary evaporation. Column chromatography with silica gel and a gradient solvent system of 25 to 50% ethyl acetate/hexanes afforded **12a** as a white solid (95 mg, 79%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 7.87-7.81 (m, 3H), 7.73 (s, 1H), 7.54-7.47 (m, 2H), 7.39-7.36 (m, 1H), 5.58, (*b* s, 1H), 4.02 (dd, *J* = 5.3, 2.6 Hz, 2H), 3.77 (s, 2H), 2.16 (t, *J* = 2.6 Hz, 1H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 170.5, 133.5, 132.6, 131.9, 128.8, 128.3, 127.7, 127.7, 127.3, 126.4, 126.1, 79.4, 71.5, 43.6, 29.3; HRMS $[M+H]^+$ calcd: 224.10754, found: 224.10790

5-(Dimethylamino)-*N*-(prop-2-ynyl)naphthalene-1-sulfonamide (12b). Compound **11b** was synthesized according to a literature procedure[3] using Dansyl chloride (100 mg, 0.371 mmol), propargylamine (31 µL, 0.445 mmol), and triethylamine (62 µL, 0.445 mmol). The reaction mixture was extracted with dichloromethane (2 x 50 mL) from water (50 mL), and the organic phase was then dried with magnesium sulfate and filtered. Next, the solvent was removed by rotary evaporation. Column chromatography with silica gel and a gradient solvent system of 25 to 50% ethyl acetate/hexanes afforded **12b** as a yellow solid (97 mg, 90%). Characterization agreed with previous literature reports. HRMS $[M+H]^+$ calcd: 289.10107, found: 289.10202

2-Oxo-*N*-(prop-2-ynyl)-2*H*-chromene-3-carboxamide (12c). Coumarin-3-carboxylic acid (191 mg, 1 mmol) was dissolved in dry DMF (10 mL) and HBTU (455 mg, 1.2 mmol) and hydroxybenzotriazole (162 mg, 1.2 mmol) were added. The sides of the reaction flask were rinsed with dry DMF (1 mL), and diisopropylethylamine (198 µL, 1.2 mmol) was added and stirred for 5 min. Propargylamine (82 µL, 1.2 mmol) was dissolved in DMF (1 mL) and added to the reaction mixture, which was then allowed to stir in the dark

at room temperature overnight. After the reaction was complete, DMF was removed on a rotary evaporator and the residue was extracted with ethyl acetate (2 x 50 mL) from 10% sodium bicarbonate (50 mL). The organic phase was then dried with magnesium sulfate and filtered, and the solvent was removed by rotary evaporation. Column chromatography with silica gel and a gradient solvent system of 20 to 70% ethyl acetate/hexanes afforded **12c** as a pale yellow solid (161 mg, 71%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 9.01 (*b* s, 1H), 8.29 (s, 1H), 7.72-7.66 (m, 2H), 7.43-7.39 (m, 2H), 4.26 (dd, *J* = 5.1, 2.4 Hz, 2H), 2.28 (t, *J* = 2.4 Hz, 1H); ^{13}C NMR (69.2 MHz, $CDCl_3$) δ 161.4, 154.6, 148.8, 134.3, 129.9, 125.4, 118.6, 118.0, 116.7, 79.1, 71.6, 29.5; HRMS $[M+H]^+$ calcd: 228.06607, found: 228.06633

2-Oxo-*N*-(prop-2-ynyl)-5(6)-carboxyfluoresceinamide (12d). Propargylamine (34.3 µL, 0.5 mmol), 4-dimethylaminopyridine (61.1 mg, 0.5 mmol), *N*-methylmorpholine (82.5 µL, 0.75 mmol), and 5(6)-carboxyfluorescein (226 mg, 0.6 mmol) were dissolved in a 1:1 mixture of dry DMF and dichloromethane (4 mL) at room temperature. 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC, 115 mg, 0.6 mmol) was added. The reaction mixture was stirred at room temperature overnight in the dark. After the reaction was complete, the mixture was extracted with ethyl acetate (2 x 50 mL) from 2 N HCl (50 mL), and the organic layer was dried with magnesium sulfate and filtered. The solvent was then removed by rotary evaporation. Column chromatography with silica gel and a gradient solvent system of 5 to 15% methanol/chloroform with 0.1% acetic acid afforded **12d** as an orange solid (140 mg, 68%). Note: Since both isomers were present in the ^{1}H NMR spectra for compounds **12d** and **11d** and the ratio of each isomer is unknown in the commercially available acid, integration values are not reported. ^{13}C NMR data for compounds **12d** and **11d** are not reported due to poor solubility of the compounds and the complex nature of the spectra due to the isomeric mixture.

^{1}H NMR (300 MHz, CD_3OD), δ 8.75 (*b* s), 8.52-8.43 (m), 8.22-8.07 (m), 7.93 (*b* s), 7.62 (s), 7.32-7.30 (m), 6.69-6.52 (m), 4.21 (d, *J* = 2.4 Hz), 4.08 (d, *J* = 4.08 Hz), 2.66 (t, *J* = 2.3 Hz), 2.56 (t, J = 2.3 Hz); HRMS $[M+H]^+$ calcd: 414.09776, found: 414.09632

4-Benzoyl-*N*-(prop-2-ynyl)benzamide (12e). A solution of 4-benzoylbenzoic acid (200 mg, 0.884 mmol), *N,N'*-dicyclohexylcarbodiimide (273.5 mg, 1.33 mmol), and 4-dimethylaminopyridine (54 mg, 0.442 mmol) was prepared in dry dichloromethane and allowed to react for 30 min. Propargylamine (72.8 µL, 1.06 mmol) was added, and the reaction mixture was stirred at room temperature overnight in the dark. After the reaction was complete, the mixture was extracted with dichloromethane (2 x 50 mL) from water (50 mL), and the organic layer was dried with magnesium sulfate and filtered, followed by solvent removal. Column chromatography with silica gel and a gradient solvent system of 20 to 70% ethyl acetate/hexanes afforded **12e** as a white solid (145 mg, 62%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 7.92-7.84 (m, 4H), 7.82-7.78 (m, 2H), 7.65-7.60 (m, 1H), 7.53-7.48 (m, 2H), 6.37 (*b* s, 1H), 4.30 (dd, *J* = 2.6, 5.25 Hz, 2H), 2.32 (t, *J* = 2.6 Hz, 1H); ^{13}C NMR (62.9 MHz, $CDCl_3$) δ 196.0, 166.4, 140.3, 137.0, 136.9, 132.9, 130.1, 128.5, 127.1, 79.3, 72.0, 29.9; HRMS $[M+H]^+$ calcd: 264.10245, found: 264.10361

2) HPLC trace for functionalized DAG Probe 11b.

As discussed in the paper, the acyl chains of diacylglycerols are known to migrate in the presence of silica. NMR analysis of analogs obtained via removal of the PMB protecting group indicated that migration was occurring. Removal of the DMT group and direct modification via "click" chemistry followed by purification produced compounds with NMRs that showed virtually no migration (see subsequent NMR spectra). However, upon HPLC analysis, two peaks appeared (chromatogram for **11b** shown below), one for the migrated product and one for the unmigrated product. The same sample was reanalyzed by NMR after HPLC analysis and only trace migration was detected, leading to the conclusion that the migration observed in the HPLC occurred on the column.

V. Palladin Institute of Biochemistry, Leontovicha 9, Kiev 01030, Ukraine.
Received April 17, 2008; Revised Manuscript Received June 23, 2008

We present the design, synthesis, and functional evaluation of peptide-based fluorescent constructs for wavelength-ratiometric biosensing of a protein analyte. The concept was shown using the high-affinity model interaction between the 18 amino acid peptide pTMVP and a recombinant antibody fragment, Fab57P. pTMVP was functionalized in two different positions with 6-bromomethyl-2-(2-furanyl)-3-hydroxychromone, an environmentally sensitive fluorophore with a two-band emission. The equilibrium dissociation constant of the interaction between pTMVP and Fab57P was largely preserved upon labeling. The biosensor ability of the labeled peptide constructs was evaluated in terms of the relative intensity change of the emission bands from the normal (N*) and tautomer (T*) excited-state species of the fluorophore (I_{N*}/I_{T*}) upon binding of Fab57P. When the peptide was labeled in the C terminus, the I_{N*}/I_{T*} ratio changed by 40% upon analyte binding, while labeling close to the residues most important for binding resulted in a construct that completely lacked ratiometric biosensor ability. Integrated biosensor elements for reagentless detection, where peptides and ratiometric fluorophores are combined to ensure robustness in both recognition and signaling, are expected to become an important contribution to the design of future protein quantification assays in immobilized formats.

INTRODUCTION

The availability of sensitive, specific, and robust biomolecular quantification assays is crucial for fundamental characterization of biomolecular interactions as well as for disease diagnostics, environmental monitoring, and quality control in food production. In assay design, strategies for both biospecific recognition and detection have to be carefully considered. Proteins are attractive candidates as recognition elements, since they have evolved to specifically bind a wide variety of targets. In particular, antibodies and antibody fragments are preferred because of their target binding diversity, high affinity, and high specificity. For detection, fluorescence-based strategies are safe, inexpensive, and well-established, and offer a level of sensitivity still unrivalled by other methods. The accessibility of the technique is further expanded through a wide range of commercially available fluorophores that allow for labeling using a variety of coupling chemistries.

Today, many protein quantification systems rely on a traditional immunoassay-type of detection, involving either a multistep sandwich analysis or sample labeling. An interesting alternative is based on the design of so-called molecular (bio)sensors, where the recognition and signaling events have been molecularly integrated by the attachment of one or more fluorescent reporter probe(s) to the recognition element in a fashion that allows the probe(s) to respond to analyte binding (Figure 1) (*1*). The basis of detection is typically fluorescence resonance energy transfer (FRET) (*2*, *3*), the formation of a nonfluorescent complex (*4*), fluorescence anisotropy (*5*), or, more relevant to the present work, the change of emission intensity of a single environmentally sensitive fluorophore in the presence of the analyte. Reagentless molecular sensing methods based on singly labeled proteins or peptides and capable of direct analyte detection have mainly been demonstrated for probing of ions and small molecules (*6*–*9*), but there are also examples where fluorophores have been conjugated to streptococcal protein G (*10*), antibodies (*11*), or synthetic peptides (*12*) for the detection of protein analytes.

The construction of protein-based molecular biosensors, which requires the large-scale production and purification of recombinant proteins and their derivatization with a fluorescent dye, represents a labor-intensive task with unpredictable success. Full-length proteins are susceptible to denaturation, a problem that is especially relevant if the biosensor concept should be applied in a microarray format where the immobilization of sensor molecules would be necessary. Moreover, the only current solution to the problem of site-specific fluorophore labeling of proteins in arbitrary positions is the production of single-cysteine mutants, which is difficult to implement on a general basis, since some proteins contain crucial cysteine residues in the wild-type sequence. Also, side reactions between thiol-reactive fluorophores and lysine side chains have been observed (*13*, *14*). Synthetic binders such as peptide or nucleic acid aptamers (*15*) offer a promising alternative to recombinant proteins in molecular biosensor applications. In particular,

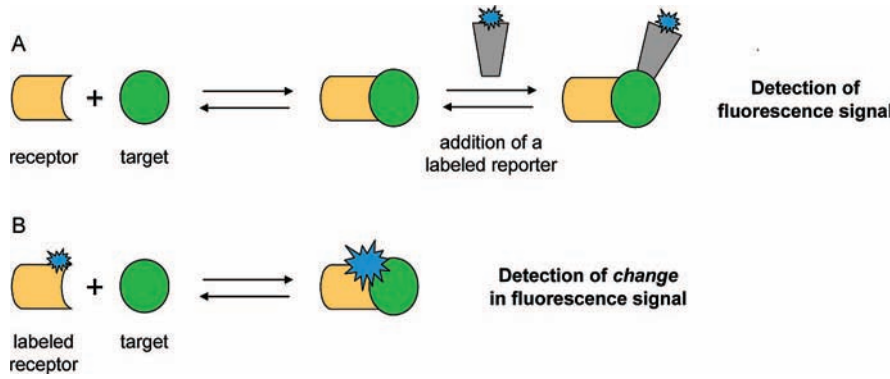

Figure 1. (a) A conventional sandwich assay for protein quantification relies on a labeled reporter molecule for detection. With this multistep approach, the target molecule must provide two distinct binding sites, and separation of free and bound molecules is required after each step. (b) If the recognition and reporting functions can be molecularly integrated, detection can be obtained in a homogeneous assay. This requires a fluorophore the emission properties of which are sensitive to changes in the local environment induced by binding to the target molecule.

synthetic peptides are ideal for molecular biosensor design since they can be straightforwardly produced at a low price, offer functional robustness superior to most proteins, and are well suited for long-term storage in dry, dissolved, and immobilized states (*16*). Also, site-specific functionalization is readily obtained.

In this work, we present the design and functional evaluation of synthetic, singly labeled peptide constructs as a promising alternative to recombinant protein-based conjugates for biosensing of a protein target. The concept was shown with an antibody fragment serving as the analyte. We further provide the first demonstration of the applicability of 3-hydroxychromone (3-HC) derivatives for wavelength-ratiometric biosensing of proteins, as an alternative to conventional dyes, which typically offer changes in absolute steady-state fluorescence intensities upon analyte binding. When relying on relative fluorescence signals for quantification, interpretation problems related to instrument parameters, photobleaching, and concentration variations of the fluorophore between samples can be avoided (*17*).

EXPERIMENTAL SECTION

Peptide Synthesis and Modification. Fluorophores 2-(2-furanyl)-3-hydroxychromone (FC) (*18*) and 6-bromomethyl-2-(2-furanyl)-3-hydroxychromone (BMFC) (*19*) were synthesized as described. The peptides pTMVP, corresponding to amino acids 134−151 of the tobacco mosaic virus coat protein (sequence: H_2N-RGTGSYNRSSFESSSGLV-$CONH_2$), C-pTMVP (H_2N-CRGTGSYNRSSFESSSGLV-$CONH_2$), R134K (H_2N-KGTGSYNRSSFESSSGLV-$CONH_2$), S146C (CH_3CO-KRGTGSYNRSSFECSSGLV-$CONH_2$), and V151C (CH_3CO-KRGTGSYNRSSFESSSGLC-$CONH_2$) were synthesized on a Pioneer automated peptide synthesizer (Applied Biosystems) using standard fluorenylmethoxycarbonyl (Fmoc) chemistry. The synthesis of each peptide was performed on a 0.1 mmol scale using an Fmoc-PAL-PEG-PS polymer (Applied Biosystems). Before each coupling, the Fmoc group was removed by treatment with 20% piperidine in *N*,*N*-dimethylformamide (DMF). Each amino acid, used at 4-fold excess, was activated with a mixture of *O*-(7-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU, 0.5 M in DMF; Alexis Biochemicals) and diisopropylethylamine (DIPEA, 1 M in DMF). Coupling times were 60−120 min. In the synthesis of pTMVP, S146C, and V151C, a pseudoproline dipeptide, Fmoc-Ser(tBu)-Ser($\Psi^{Me,Me}$pro)-OH (Calbiochem-Novabiochem AG), was used in two positions instead of the amino acid form of Ser in order to improve yields.

To allow for site-specific labeling of S146C and V151C, the side chain of Cys was protected by 4-methoxytrityl, which can be selectively removed by treatment with 1% trifluoroacetic acid (TFA). The final N termini of the peptides were capped with 0.3 M acetic anhydride in DMF. Cys was orthogonally deprotected by treatment with TFA, triisopropylsilane (TIS), and dichloromethane (DCM) (1:2:97 v/v), and the process was visually monitored by the yellow color of the detached trityl ion. For fluorophore coupling, the resins were mixed with 1.2 equiv of BMFC and 6 equiv of DIPEA in DMF (6 mL per gram of polymer) and were left at room temperature in the dark with careful swirling for 48−72 h to yield S146C-FC and V151C-FC.

Resins were rinsed in DCM and dried. Peptides were cleaved from the solid phase by treatment with 95% TFA for 2 h at room temperature (TMVP, R134K: TFA/TIS/H_2O 95:2.5:2.5 v/v; C-pTMVP, S146C, V151C: TFA/TIS/H_2O/ethanedithiol 94:2.5:2.5:1 v/v). After filtration, TFA was evaporated and peptides were precipitated by the addition of cold diethyl ether, washed, and lyophilized. They were then purified by reversed-phase HPLC on a semipreparative C-8 column with aqueous acetonitrile (ACN) containing 0.1% TFA as the mobile phase and at a flow rate of 8−10 mL/min. Elution conditions were 20−40% ACN; 40 min gradient (pTMVP), 18% ACN (C-pTMVP and R134K), and 10−50% ACN; 30 min gradient (S146C and V151C). Purified peptides were identified by MALDI-TOF mass spectrometry.

Expression and Purification of Fab57P. Cloning and expression of recombinant Fab57P in *Escherichia coli* was performed as described (*20*) with some modifications. Cells were grown in 30 × 500 mL of LB medium containing 0.3 mM ampicillin. After induction at OD_{600nm} ~0.9 with 1 mM isopropyl thiogalactoside (IPTG; final concentration), Fab57P was expressed at 30 °C for 15 h. Cells were harvested by centrifugation and treated with 0.6 M sucrose in 30 mM Tris-HCl pH 8.0 containing 1 mM ethylenediaminetetraacetic acid (EDTA) and 0.15 mg/mL lysozyme for 3.5 h on ice. The supernatant (600 mL) was dialyzed twice against HEPES-buffered saline (10 mM HEPES, 150 mM NaCl, 3 mM EDTA, pH 7.4) containing 0.2 mM phenylmethanesulfonyl fluoride. Dialyzed samples were filtered (0.22 μm) and stored at 4 °C. Presence of Fab57P was confirmed by Western blotting using a rat anti(mouse κ light chain) antibody conjugated to alkaline phosphatase for revelation.

Fab57P was affinity purified using CNBr-activated Sepharose 4B (Amersham Biosciences) and R134K as the specific capture molecule. R134K (22 mg, 12 μmoles) dissolved in 0.1 M $NaHCO_3$, 0.5 M NaCl, pH 8.3 (5 mL) was added to 4 mL washed gel and coupling was allowed for 2 h at room temperature. Blocking of unreacted CNBr groups was performed in 0.1 M Tris-HCl pH 8.0 (15 mL) for 2 h at room temperature.

The gel was then washed according to the manufacturer's instructions. The peptide coupling reaction was monitored by dot blotting of coupling and washing solutions, followed by incubation with mAb174P (*21*), which binds to TMVP and pTMVP. For revelation, a secondary goat antimouse antibody conjugated to alkaline phosphatase was used.

Filtered cell extracts containing Fab57P were applied to the gel column following equilibration at pH 7.4. The protein was eluted with 10 mM glycine pH 2.2 in 2 mL fractions. A small amount of 1 M Tris-HCl pH 8.0 was added promptly to the eluate to give a final pH of 7.2−7.5. With this protocol, 90−95% of the protein eluted within the first 8 mL. The purified protein was stored in aliquots at −20 °C until use.

Analysis of Binding Kinetics. Kinetic analysis was performed with a Biacore 2000 instrument (Biacore AB) at 25 °C using using HEPES-buffered saline (HBS-EP: 10 mM HEPES, 0.15 M NaCl, 3 mM EDTA, 0.005% polysorbate 20, pH 7.4) as the running buffer. S146C-FC and V151C-FC were immobilized in separate flow channels of a CM5 sensor chip at low (90 or 120 RU) or medium (190 or 340 RU) levels. pTMVP was immobilized to yield 10 and 20 RU. Immobilization levels were defined as the baseline difference before and promptly after the injection of the peptide. A reference flow cell without immobilized peptide was included for analysis. A detailed coupling protocol can be found in Supporting Information.

The experimental conditions were checked for mass transport limitations through variation of the analyte flow rate (30, 50, and 70 μL/min) at a constant Fab57P concentration (25 nM). For kinetic analysis, sensorgrams were collected for six analyte concentrations between 1.6 nM and 50 nM, at a flow rate of 50 μL/min. Samples were diluted in HBS-EP. One of the samples was run in duplicate to check the stability of the sensor surface. Regeneration was efficiently achieved with 50 mM HCl (30 s) after each protein injection. Reference subtraction and kinetic evaluation of the sensorgrams were performed with the *BIAevaluation 4.1* software, fitting data from the entire injection phase and the first 100 s of the postinjection (dissociation) phase in each concentration series using the Langmuir bimolecular binding model in a global fit algorithm.

Fluorescence Biosensor Experiments. Fluorescence biosensor experiments were performed in a Safire2 microplate detection system (Tecan Trading AG) using 96-well plates (Corning) at 23 °C. The sample volume in each well was 75 μL. The excitation wavelength was 365 nm and emission was monitored in the range 400−700 nm. Excitation and emission slits were 10 nm. All measurements were done in HEPES-buffered saline (10 mM HEPES, 150 mM NaCl, pH 7.4). For each peptide, three samples were measured in duplicate: 5 μM peptide, 5 μM peptide + 5 μM Fab57P, and 5 μM peptide + 2.5 μM goat antirabbit F(ab′)$_2$ (Sigma-Aldrich; product number R9130). F(ab′)$_2$ was used as a negative control. As it contains two Fab units, it was added at half the concentration relative to Fab57P. With V151C-FC, a measurement series of 10 μM peptide, 10 μM peptide + 10 μM Fab57P, and 10 μM peptide + 5 μM F(ab′)$_2$ was performed as well. At the excitation wavelength used, Fab57P and F(ab′)$_2$ did not give rise to any background fluorescence. The ratio of the maximum intensity values of the N* band (at 432 nm) and the T* band (at 520 nm), I_{N*}/I_{T*}, was calculated for each sample and the fractional signal change upon introduction of Fab57P or F(ab′)$_2$ was obtained from

$$C = \frac{|(I_{N*}/I_{T*})_{-\mathrm{Fab}} - (I_{N*}/I_{T*})_{+\mathrm{Fab}}|}{(I_{N*}/I_{T*})_{-\mathrm{Fab}}} \cdot 100\%$$

RESULTS

Design of Molecular Biosensor Constructs. A biomolecular model system with a mapped binding site and well-characterized interaction kinetics was selected to demonstrate the design of a robust molecular biosensor for ratiometric detection of a protein analyte. The 18 kDa four-helix bundle tobacco mosaic virus coat protein (TMVP) is recognized by Fab57P, a recombinant antibody fragment (*20*), and essential residues of the epitope have been mapped to positions 140−144 (*22*). In earlier studies, Fab57P has been found to bind TMVP and a synthetic peptide derivative, pTMVP, with similar affinities (*23*). pTMVP consists of eighteen amino acids, corresponding to TMVP residues 134−151, thus comprising the epitope (Figure 2a). The fact that the affinity of the protein toward Fab57P is retained in the peptide makes pTMVP an ideal recognition element for the further design into a robust molecular biosensor. In order to obtain peptide constructs for ratiometric sensing, the recently developed thiol-reactive dye 6-bromomethyl-2-(2-furanyl)-3-hydroxychromone (BMFC; Figure 2b), which has been successfully used for protein functionalization earlier (*19*), was chosen for labeling of pTMVP. BMFC is a derivative of the 3-HC fluorophore 2-(2-furanyl)-3-hydroxychromone (FC; Figure 2b) (*18*, *24*). These dyes undergo excited-state intramolecular proton transfer (ESIPT) between the normal (N*) and a phototautomer (T*) excited-state species, which are both highly emissive and give rise to a two-band fluorescence spectrum. The intensity ratio of the high energy band from the N* state and the low energy band from the T* state, I_{N*}/I_{T*}, is a very sensitive indicator of solvent polarity and hydrogen bonding ability (*25*–*27*). In aprotic solvents such as acetonitrile, FC exhibits emission predominantly from the T* state, which gives a low value of the I_{N*}/I_{T*} ratio (Figure 3). In protic media, when increasing solvent polarity in the line octanol−ethanol−methanol−water, FC exhibits a gradual increase in the I_{N*}/I_{T*} ratio until almost complete disappearance of the T* emission (Figure 3). The I_{N*}/I_{T*} ratio of an FC derivative attached to the peptide recognition element was expected to be useful as a signal for analyte binding in the molecular biosensor context explored here, where the local probe environment was expected to change upon interaction.

In a design where the biosensor response should be based on spectral changes induced by direct contact of the probe with the analyte upon binding, the position of labeling has to be

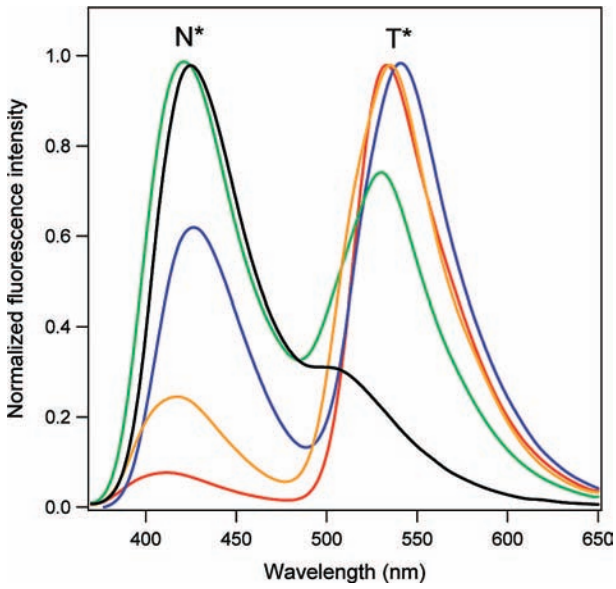

Figure 3. Normalized fluorescence spectra of FC in acetonitrile (red), octanol (orange), ethanol (blue), methanol (green), and water (black). The excitation wavelength was 350 nm. Positions of N* and T* bands are indicated.

chosen close to the binding site. However, it is important that the probe does not interfere with the interaction, thus reducing affinity. Although structural data are helpful in the selection of suitable sites, it is very difficult to rationally predict the optimal position for labeling. Here, in the absence of structural data, two positions were targeted: Ser146 in the immediate vicinity of positions mapped as essential for binding, and Val151 in the peptide C terminus. The numbering of the amino acid positions from TMVP was used also for pTMVP. Labeling in position 146 was assumed not to dramatically reduce the high affinity between Fab57P and pTMVP, as the interaction is tolerant to amino acid substitutions in this position (*22*). Both sites were assumed to allow for spectral changes of the attached probe upon peptide−protein interaction, but the local peptide flexibility was thought to be more pronounced in position 151 than in position 146.

Peptide Synthesis and Functionalization. Two variants of pTMVP were produced, where either Ser146 or Val151 was changed into a cysteine to allow for probe coupling. The peptides S146C and V151C were synthesized on the solid phase. To avoid labeling of the N terminal amine group, the peptide N termini were acetylated. BMFC was introduced after selective deprotection of the thiol at the side chain of Cys146 or Cys151 to form S146C-FC and V151C-FC. The peptides were cleaved from the resin by 95% trifluoroacetic acid to yield a C terminal amide, purified by reversed phase HPLC, and identified from their MALDI-TOF mass spectra. Yields of labeled peptides were very low, possibly due to poor accessibility of the coupling sites caused by the peptide forming secondary structure on the polymer.

Expression, Purification, and Concentration Determination of Fab57P. Fab57P was expressed in *E. coli* and identified by Western blotting. Affinity purification was performed with a lysine-containing derivative of pTMVP, R134K, as the capture molecule. The concentration of native Fab57P in cell extracts and after purification was determined in a surface plasmon resonance (SPR) assay. A pTMVP-derived peptide with an additional N terminal cysteine, C-pTMVP, was synthesized and immobilized to a Biacore CM5 sensor chip at high concentration, and Fab57P samples were introduced in solution. From the slopes of the binding curves, it was found that the production protocol resulted in approximately 0.3 mg native Fab57P per liter of culture. The purification yield was 74%. Experimental details for the concentration determination assay can be found in Supporting Information.

Kinetic Analysis. The association rate constant k_a and the dissociation rate constant k_d describing the interaction between C-pTMVP and nonpurified Fab57P have been determined by SPR (*22*). It was found that $k_a = 7.8 \times 10^5\ M^{-1}\ s^{-1}$ and $k_d = 1.4 \times 10^{-3}\ s^{-1}$, resulting in a equilibrium dissociation constant $K_d = 1.8$ nM. Here, the kinetic analysis was repeated using immobilized pTMVP and purified Fab57P. The average kinetic parameters were $k_a = 5.8 \times 10^5\ M^{-1}\ s^{-1}$ and $k_d = 0.93 \times 10^{-3}\ s^{-1}$, resulting in $K_d = 1.6$ nM (Table 1).

The kinetics of the interaction between Fab57P and the functionalized pTMVP derivatives S146C-FC and V151C-FC were analyzed in order to evaluate the effects on the interaction from labeling. The values of the kinetic parameters obtained at two different levels of peptide immobilization are summarized in Table 1. Affinities were only slightly decreased compared to that of the unlabeled peptide. In the case of S146C-FC, labeling in the immediate vicinity of residues important for binding resulted in a 2-fold decrease in the association rate and a 2-fold increase in the dissociation rate (average $K_d = 6.3$ nM). The goodness of fit was assessed by inspection of the residual plots and by relating the average squared residuals, χ^2, to the experimental value of the maximum SPR response ($R_{max,\ exp}$). The fitted curves ran closely to the experimental data and statistical parameters were good with a $\chi^2/R_{max,\ exp}$ ratio lower than 0.05.

In order to show that the equilibrium dissociation constants obtained for the labeled peptides were reasonable and that the peptide molecules were available for binding Fab57P in solution, an SPR experiment was performed where the ability of S146C-FC and V151C-FC to inhibit the interaction between Fab57P and immobilized C-pTMVP was analyzed. Fab57P was mixed with peptides at a range of concentrations and introduced to a sensor surface where C-pTMVP was immobilized at high density. The concentration of unbound Fab57P in the mixture was calculated under the assumption of K_d values obtained from the kinetic analysis and the expected slope of a binding curve from Fab57P at this concentration was compared to the experimental data. Experimental details can be found in Supporting Information. It was found that the inhibition ability of both pTMVP and the labeled peptides corresponded reasonably well with calculated values (Table S-1, Supporting Information). Consequently, the inhibition experiment showed that the kinetic data of the labeled peptides are reliable, and thus justified the conclusion that labeling did not dramatically reduce the affinity of the functionalized peptides toward Fab57P compared to that of pTMVP.

Fluorescence Biosensor Analysis. Fluorescence quantum yields Φ of 3-HC dyes are rather low in water and other polar solvents (*27*). Using quinine sulfate as a reference, it was found that Φ of S146C-FC and V151C-FC in HEPES-buffered saline pH 7.4 was 0.061 and 0.046, respectively (average of two measurements; experimental details can be found in Supporting Information). These values are in very good agreement with what could be expected, considering that Φ of FC in water is 0.05 (*27*). Moreover, they are sufficiently large to record useful fluorescence signals from the peptide constructs in a biosensor analysis.

Incorporating BMFC in a peptide or a protein can change its emission profile substantially. The I_{N*}/I_{T*} ratio of FC in water is >3.2 (Figure 3) but when attached to the αA subunit of bovine α-crystallin the ratio drops below 0.3 (*19*). Such differences could reflect a decrease in the local polarity and hydrogen-bonding ability experienced by the fluorophore due to the

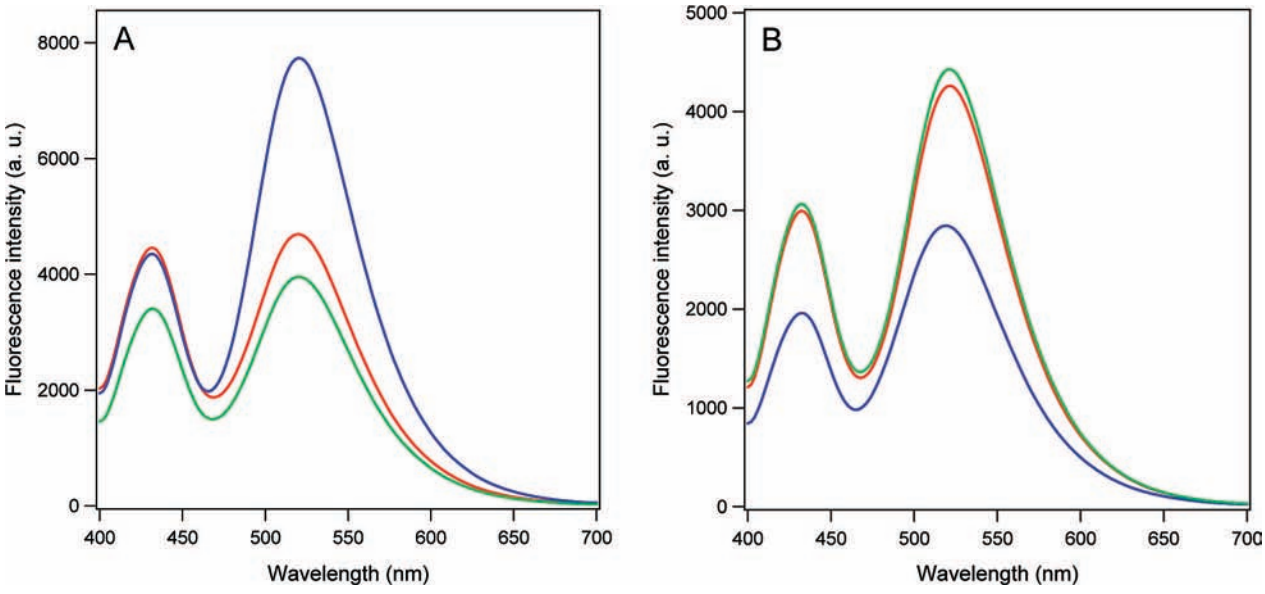

Figure 4. Fluorescence spectra of (a) V151C-FC and (b) S146C-FC in the absence (red) and presence (blue) of saturating amounts of Fab57P. A $F(ab')_2$ fragment with unrelated specificity was used as a negative control (green).

adjacent peptide chain screening it from bulk water. However, attaching BMFC to a polypeptide chain *per se* should not change the emission properties of the fluorophore, since the conjunction is realized through the formation of a thiomethylene group, which should not allow the electronic structure of FC to be modified to any significant extent.

Like in the case of labeling of α-crystallin, the I_{N*}/I_{T*} ratios of S146C-FC (I_{N*}/I_{T*} ~0.7) and V151C-FC (I_{N*}/I_{T*} ~0.9) are dramatically reduced compared to the corresponding value of FC in water (Table 2, Figure 3, Figure 4). The difference in the I_{N*}/I_{T*} value between the two constructs indicates that the choice of labeling site is important, since it can substantially influence the original signal of the molecular biosensor and thus probably the fractional change that can be obtained upon binding of the analyte. The observed spectral difference could reflect the hydrogen-bonding ability of the fluorophore being different in the two positions, as a result of screening from bulk water being less efficient in the case where the probe is attached in the peptide C terminus. However, it is also possible that specific intramolecular interactions between the probe moiety and amino acid residues are responsible for this effect. As confirmed by circular dichroism spectroscopy (data not shown), the peptide constructs do not form any well-defined secondary structure that can aid in determining which of these phenomena are primarily responsible for the spectral differences of S146C-FC and V151C-FC.

For the biosensor evaluation, the fluorescence signal from each peptide construct alone was compared to that where a fraction of >96% of the peptide molecules were bound to Fab57P, according to affinities obtained from the SPR study.

Equimolar amounts of peptide and Fab57P (5 μM or 10 μM) were used. Addition of the analyte to V151C-FC caused a pronounced change in the I_{N*}/I_{T*} ratio, from >0.9 to <0.6 (~40% decrease; Table 2, Figure 4a), without affecting the positions of the N* and T* bands (at 432 and 520 nm, respectively). The most immediate interpretation of this observation is that binding of Fab57P results in a decrease of hydrogen-bonding ability of the probe due to exclusion of water molecules from the interaction site. In contrast, the introduction of a negative control antirabbit $F(ab')_2$ did not have any significant impact on the ratiometric emission profile. V151C-FC thus demonstrates the ratiometric biosensor concept, where the two emission bands are differently affected by the binding of a protein analyte.

In contrast to V151C-FC, S146C-FC did not show any significant change in the I_{N*}/I_{T*} ratio when binding the analyte (Table 2, Figure 4b). This result was rather unexpected taking into account that the fluorophore in S146C-FC is situated very close to the residues most important for binding and should not be less shielded from buffer upon introduction of Fab57P than when attached in the C terminus. It can be speculated that if the spectral differences of the peptide constructs observed in the absence of the analyte can be attributed to specific intramolecular interactions between the peptide and the probe, upon binding of the analyte, these interactions in S146C-FC might be preserved or substituted for similar interactions with residues of Fab57P. However, without any structural data of the binding complex, it is difficult to deduce the detailed biosensor mechanism of V151C-FC and the reason for the insensitivity of S146C-FC to Fab57P binding.

DISCUSSION

Current assays for biomolecular quantification are based on a vast number of different strategies, many of them typically involving a multistep procedure where color reagents or labeled secondary antibodies are used. In contrast, we have focused on the concept of reagentless biosensing, where a single molecular construct integrates recognition specificity and reporting ability (*1*).

The key criterion for a useful fluorescent biosensor construct — attaching the fluorophore in a position where it experiences large environmental differences upon analyte binding but does not interfere with the interaction — was met in a design where the peptide recognition element was labeled seven amino acids away from the residues most important for binding. Interestingly, labeling in the immediate vicinity of the epitope core was not a sufficient condition for the realization of a ratiometric biosensor. The significance of the choice of labeling position when designing a molecular biosensor has also been thoroughly demonstrated on a larger scale by others (*28*, *11*). De Lorimier et al. attached eight environmentally sensitive fluorophores in different amino acid positions of eleven bacterial periplasmic binding proteins. The choice of positions for labeling was based on structural considerations and both allosteric and peristeric sites were addressed. A minority of the resulting 320 constructs were judged as being useful for sensing purposes and in only five protein mutants, there was a biosensor signal above the criterion level from all the analyzed fluorophores (*28*). This shows that rational prediction of a labeling site from where a probe will emit a useful signal is very difficult also when structural data is available, and that the choice of fluorophore may critically influence the biosensor performance. The studies referred to above were focused on the labeling of full-length proteins. Our results indicate that finding a suitable labeling position may require some effort also when targeting peptides. However, the number of candidate positions is more limited, which in combination with straightforward peptide synthesis procedures facilitates screening for the optimal site.

Limited reproducibility in biosensor results sometimes observed for protein constructs labeled with conventional single-band fluorophores (*11*, *29*) may very well be due to batch-to-batch variations in the degree of labeling and in the extent of photobleaching of the fluorophore. Due to the ratiometric nature of detection, the influence of such factors is minimized in the molecular biosensor design reported here. Also, ratiometric signaling will be highly interesting in future microarray applications with immobilized biosensor constructs, since the surface density of immobilized molecules is generally more difficult to control than the concentration in corresponding solution assays.

A challenging issue for the implementation of synthetic molecular biosensors on a more general level is related to binding specificity. Antibodies are highly attractive providers of specific binding, since their recognition ability is extremely versatile with respect to the nature of the analyte. In order to constitute a competitive alternative, synthetic binders displaying high-affinity, specific interactions toward virtually any target are needed. Examples of such classes of molecules are nucleic acid aptamers selected from large combinatorial libraries by selective evolution of ligands by exponential enrichment (SELEX) (*30*, *31*) and affibodies based on a robust, 58 amino acid scaffold protein derived from staphylococcal protein A (*32*–*34*). The combination of such libraries with ratiometric fluorophores attached at carefully selected positions should eventually surpass conventionally labeled protein-based biosensor molecules as components in, e.g., immobilized protein detection platforms, where robustness of the biosensor element with respect to both recognition and signaling is imperative for reliable results.

In conclusion, we have expanded the repertoire of fluorescence strategies available for protein detection assays by demonstrating the concept of wavelength-ratiometric biosensing in solution based on straightforwardly obtained steady-state emission spectra from a two-band fluorophore. Optimization of the labeling position of the recognition element will require some work in future constructs, especially in cases where the recognition site might not be as well-characterized. However, the prospect of reagentless, robust sensing should be a strong motive for investing this effort.

EXPERIMENTAL DETAILS

Determination of Fab57P Concentrations. The native concentration of Fab57P was determined with a Biacore 2000 instrument (Biacore AB) at 25°C using HEPES-buffered saline (HBS-EP: 10 mM HEPES, 0.15 M NaCl, 3 mM EDTA, 0.005% polysorbate 20, pH 7.4) as the running buffer. C-pTMVP was immobilized to the dextran hydrogel of a Biacore CM5 sensor chip at a flow rate of 10 μl/min using a modified variant of the "ligand thiol" method with 2-(2-pyridinyldithio)ethaneamine (PDEA), described in the BIAapplications Handbook (version AB 1998, Biacore AB). Conventional carbodiimide activation (with a mixture of 250 mM ethyldimethylaminopropylcarbodiimide (EDC) and 50 mM N-hydroxysuccinimide (NHS) during 10 min) was followed by derivatization with PDEA (100 mM in 100 mM sodium borate, pH 8.5, 3.5 min) and deactivation of excess active esters with ethanolamine (1 M, pH 8.5, 3.5 min). After the injection of the peptide (50 μM in 10 mM sodium formate, pH 3.0, 10 min), excess PDEA groups were eliminated by the introduction of cysteine (50 mM in 100 mM sodium formate, 1 M NaCl, pH 4.3, 3.5 min). A high surface concentration of the peptide (~1400 RU) was obtained with this protocol, which allowed for mass-transport limited binding of Fab57P independent of interaction kinetics *(1)*. Purified Fab57P was diluted in HBS-EP prior to analysis, while non-purified, dialyzed protein was introduced without dilution. Fab57P was injected over the sensor chip at a low flow rate (10 μl/min, 1 min) and for each sample the slope of the linear interaction phase was related to a standard curve of Fab57P response vs concentration. Introduction of 50 mM HCl (30 s) between Fab57P injections fully regenerated the sensor surface.

Immobilization of pTMVP, S146C-FC, and V151-FC for Analysis of Binding Kinetics. Coupling to the dextran hydrogel of a Biacore CM5 sensor chip was performed at a flow rate of 10 μl/min. Carbodiimide

activation of carboxylic acid groups with a mixture of 250 mM EDC and 50 mM NHS (4 min) was followed by the introduction of S146C-FC or V151C-FC (2-10 μM in 10 mM sodium acetate pH 4.0, diluted from a 90 μM stock in water) in several short pulses (30-60 s). Deactivation was achieved with 1 M ethanolamine, pH 8.5 (4 min). pTMVP (20 μM in 10 mM sodium acetate pH 5.5, diluted from a 90 μM stock in water) was immobilized with a similar protocol. A reference flow cell was prepared by deactivation with ethanolamine promptly after the EDC/NHS activation.

Inhibition Study. A binding inhibition study was performed with a Biacore 2000 instrument at 25°C with HBS-EP as the running buffer and at a flow rate of 10 μl/min. The sensor chip was the same as that used for the determination of Fab57P concentrations described above, with C-pTMVP immobilized to a level of 1400 RU to allow for mass-transport limited binding profiles. Fab57P was introduced to the surface (20 nM in HBS-EP; 1 min) and the slope of the linear binding curve was compared to slopes obtained when Fab57P (20 nM) was premixed with different concentrations (5, 10, 20 or 50 nM) of pTMVP, S146C-FC, or V151C-FC. Regeneration was achieved with 50 mM HCl between each analyte injection (30 s). Measurements were performed in duplicates. The concentration of unbound Fab57P, [Fab], when mixed with a peptide at total concentration $[P]_{tot}$ is given by

$$[Fab] = -\frac{[P]_{tot} - [Fab]_{tot} + [K_d]}{2} + \sqrt{\left(\frac{[P]_{tot} - [Fab]_{tot} + [K_d]}{2}\right)^2 + [Fab]_{tot} \cdot [K_d]} \qquad \text{(e1)}$$

where $[Fab]_{tot}$ is the total concentration of Fab57P and K_d is the equilibrium dissociation constant describing the interaction. As the slope of the SPR binding curve is directly proportional to the concentration of available Fab57P, expected slopes from Fab57P concentrations calculated from (e1) were obtained from the

binding curve in the case where no peptide was present in the analyte sample. These values were then compared to the experimental data.

Determination of Fluorescence Quantum Yields. Fluorescence quantum yields (Φ) of S146C-FC and V151C-FC were measured in a safire2 microplate detection system (Tecan Trading AG) according to a well-established method *(2)*. Quinine sulfate in 0.1 M H_2SO_4 was used as a reference. Each peptide and quinine sulfate were diluted in HEPES-buffered saline (10 mM HEPES, 150 mM NaCl, pH 7.4) and 0.1 M aqueous H_2SO_4, respectively, to concentrations where their absorbances (A) at 350 nm were close to 0.1. The integrated emission spectra (I) between 382 and 698 nm (λ_{exc} = 350 nm) were recorded and the quantum yield of the peptide (Φ_P) was calculated from

$$\Phi_P = \frac{A_{QS}}{A_P} \cdot \frac{I_P}{I_{QS}} \cdot \Phi_{QS} \qquad \text{(e2)}$$

where the subscripts P and QS refer to peptide and quinine sulfate, respectively. Φ_{QS} = 0.58 *(3)*.

RESULTS

Table S-1. Normalized slopes of SPR binding curves upon interaction between immobilized C-pTMVP and Fab57P mixed with peptides at different concentrations.[a]

[peptide] (nM)		pTMVP	S146C-FC	V151C-FC
5	Calc.	77	82	78
	Exp.	75	85	96
10	Calc.	56	66	58

The gastrin-releasing peptide receptor (GRPr) is overexpressed on various human tumors. The goal of our study was the synthesis of new ^{18}F-labeled bombesin analogues for the PET imaging of GRPr expression in prostate tumor using a silicon-based one-step n. c. a. radiolabeling method. The silicon-containing building blocks were efficiently coupled to the *N*-terminus of the peptides via solid-phase synthesis. Radiolabeling of the obtained peptide precursors proceeded smoothly under acidic conditions (34−85% conversion). Using the di-*tert*-butyl silyl building block as labeling moiety, products containing a hydrolytically stable ^{18}F-label were obtained. In *in vitro* receptor binding experiments 2-(4-(di-*tert*-butylfluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 (**4b**, IC_{50} = 22.9 nM) displayed a 12-fold higher binding affinity than 2-(4-(di-*tert*-butylfluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-Sta-Leu-NH_2 (**3b**, IC_{50} = 276.6 nM), and **4b** was therefore chosen for further evaluation. *In vitro* and *ex vivo* metabolite studies of **[^{18}F]4b** showed no significant degradation. In biodistribution experiments, tumor uptake of **[^{18}F]4b** was low and unspecific, whereas the GRPr-rich pancreas revealed a high and specific accumulation of the radiotracer. This study demonstrates the applicability of our silicon-based one-step n. c. a. radiolabeling method for the synthesis of new ^{18}F-labeled bombesin derivatives. This innovative approach represents a general, straightforward access to radiolabeled peptides as PET imaging probes.

INTRODUCTION

Radiolabeled peptides have been the focus of research over the past decades due to their potential as molecular imaging probes and therapeutic agents (*1, 2*). Among the peptides for tumor targeting, bombesin (BBN) and bombesin derivatives have received significant interest as they exhibit high affinity and selectivity for the gastrin-releasing peptide receptor (GRPr) (*3, 4*). The GRPr is overexpressed on various human tumors including prostate, breast, pancreatic, and small cell lung cancers (*5*). With respect to prostate cancer, a high incidence of GRP receptors was found in human normal prostate tissues, in contrast to their very low abundance in non-neoplastic prostatic tissues (*6*). Thus, radiolabeled bombesin peptides are potentially valuable tools for the discrimination of prostate cancers from prostate hyperplasia and prostatitis.

Accordingly, a lot of research has gone into the development of optimized BBN derivatives for imaging and therapy involving a wide range of peptide sequences, labeling moieties, and radionuclides. Research efforts have been devoted in particular to the optimization of peptide sequences leading to improved binding affinity and metabolic stability. The C-terminus of bombesin is required for high-affinity binding and biological potency (*7*); therefore, usually the N-terminus of bombesin is modified in order to allow labeling with radioisotopes. A number of ^{99m}Tc- and ^{111}In-labeled BBN analogues have been developed as diagnostic probes for single-photon emission computed tomography (SPECT) (*8*). For potential peptide receptor radiotherapy applications, ^{90}Y-, ^{177}Lu-, and ^{188}Re-labeled BBN conjugates have been evaluated (*9, 10*).

Despite the obvious advantage of being a more quantitative imaging method with better spatial resolution and image contrast compared to SPECT, PET imaging of GRPr expression has been less studied and labeling of bombesin conjugates has been limited to metallic PET nuclides such as ^{64}Cu, ^{68}Ga, and ^{86}Y (*11, 12*). Among the available PET nuclides, ^{18}F has ideal characteristics for peptide receptor imaging studies regarding its half-life (109.7 min) and low β^+ energy (0.64 MeV) (*13*). However, so far only one report on the ^{18}F-labeling of bombesin analogues including their *in vitro* and *in vivo* evaluation has been published (*14*). ^{18}F has been introduced into two bombesin derivates through the prosthetic labeling group *N*-succinimidyl-4-[^{18}F]fluorobenzoate (^{18}F-SFB). This approach, however, requires a multistep reaction sequence and is therefore laborious. Very recently, Schirrmacher et al. described the two-step radiolabeling of a N-amino-oxy derivatized bombesin peptide using the labeling synthon *p*-(di-*tert*-butylfluorosilyl)benzaldehyde ([^{18}F]SiFA-A) (*15*). Due to low precursor amounts, high specific activities could be obtained (225−680 GBq/μmol for [^{18}F]SiFA-A), although the ^{18}F-fluorination was achieved *via* isotopic exchange. Data from the biological evaluation of this bombesin derivative are currently not available.

We have developed new silicon-based building blocks for the one-step n. c. a. ^{18}F-labeling of biomolecules by nucleophilic displacement of an alkoxy, hydroxy, or hydride leaving group (*16, 17*). These building blocks can be efficiently coupled to the N-terminus of peptides during solid-phase synthesis.

Figure 1. Structures of bombesin derivatives.

Facile one-step radiolabeling of model compounds and tetrapeptides containing these building blocks could be demonstrated. An ^{18}F-labeled di-*tert*-butyl silyl based tetrapeptide has been shown to be stable against defluorination under physiological conditions (*17*). Here, we report on the application of this one-step labeling protocol to the radiosynthesis of a series of ^{18}F-labeled bombesin analogues (Figure 1). Moreover, we evaluated the analogue with the best *in vitro* binding affinity for its metabolic stability and *in vivo* distribution.

EXPERIMENTAL SECTION

General. All chemicals unless otherwise stated were purchased from Sigma-Aldrich or Merck and used without further purification. The syntheses of 2,5-dioxopyrrolidin-1-yl 2-(4-(hydroxydi-*iso*-propylsilyl)phenyl)acetate and 2-(4-(di-*tert*-butylsilyl)phenyl)acetic acid were previously reported (*17*). Peptide synthesis was carried out using Rink-Amide resin (0.68 mmol/g) following standard 9-fluorenylmethyloxycarbonyl (Fmoc) strategy (*18*). All amino acid residues were, if not further specified, L-amino acid residues. FA01010 is (4*R*,5*S*)-4-amino-5-methylheptanoic acid, Statine (Sta) is (3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid, and Ava is 5-aminopentanoic acid.

High-performance liquid chromatography (HPLC) analyses were performed using either a Hamilton PRP-1 (250 × 4.1 mm, 7 μm) or an ACE C18 column (50 × 4.6 mm, 3 μm) and the indicated conditions. Analytical HPLC systems used were Agilent 1100 systems with Gina or Agilent software and a Merck-Hitachi L6200A system, equipped with UV multiwavelength and Raytest Gabi Star detectors. Semipreparative HPLC purifications were carried out using a semipreparative ACE C18 column (250 × 10 mm, 5 μm) and the indicated conditions. Semipreparative HPLC systems used were an Agilent 1100 system equipped with UV multiwavelength and Raytest Gabi Star detector and a Merck-Hitachi L6200A system equipped with Knauer variable wavelength detector and Eberline radiation monitor. UV chromatograms were recorded at 218 or 230 nm. For the *ex vivo* metabolite studies, an Ultraperformance liquid chromatography (UPLC) system from Waters with a Waters

Acquity UPLC BEH C18 column (2.1 × 50 mm, 1.7 μm) and an attached Berthold coincidence detector (FlowStar LB513) was used.

All animal experiments were performed in compliance with the current version of the German law on the Protection of Animals.

Peptide Synthesis. *Fmoc-Deprotection (General Procedure).* The resin-bound Fmoc peptide was treated with 20% piperidine in DMF (v/v) for 5 min. This step was repeated with a reaction time of 20 min. The resin was washed with DMF (2×), CH_2Cl_2 (2×), and DMF (2×).

HBTU/HOBT Coupling (General Procedure). A solution of Fmoc-Xaa-OH (Xaa = amino acid, 4 equiv), HBTU (*O*-(benzotriazol-1-yl)-*N*,*N*,*N*,*N*-tetramethyluronium hexafluorophosphate, 4 equiv), HOBT (1-hydroxybenzotriazole, 4 equiv), DIPEA (*N*,*N*′-di-*iso*-propylethylamine, 4 equiv) in DMF was added to the resin-bound, free amine peptide and shaken for 90 min at room temperature. This step was repeated with a reaction time of 60 min. The resin was washed with DMF (2×), CH_2Cl_2 (2×), and DMF (2×). The peptides were typically prepared starting with 147 mg (100 μmol) of the resin. The amounts of reagents and building blocks in all subsequent reactions were calculated based on this amount.

Synthesis of 3-(3-(Di-iso-propylhydroxysilyl)phenyl)acetyl-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-FA01010-Leu-NH$_2$ (Precursor Compound **1a***).* The resin-bound, side chain protected peptide was prepared according to the general procedures described above. 2,5-Dioxopyrrolidin-1-yl 2-(4-(hydroxydi-*iso*-propylsilyl)phenyl)acetate (54.5 mg, 150 μmol) was dissolved in DMF (1 mL). The resin-bound peptide (100 μmol) was suspended in this solution and the suspension was shaken for 12 h at ambient temperature. The resin was then filtered, washed with DMF (3 × 3 mL) and CH_2Cl_2 (3 × 3 mL), and dried *in vacuo*. Subsequent treatment of the resin with 2 mL TFA/water/tri-*iso*-propylsilane/phenol (85:5:5:5) afforded the crude, fully deprotected peptide, which was precipitated and washed with cold methyl *tert*-butyl ether. The crude peptide was dried *in vacuo*, purified by preparative RP-HPLC, and lyophilized. The purified peptide (42 mg, 32%) was analyzed by HPLC-MS (*m*/*z* $[M + H]^+$ calcd.: 1311.8, found: 1311.7).

Procedure for the Syntheses of Di-tert-butylsilyl-Functionalized Peptides (Precursor Compounds **2a**−**4a***).* Representative procedure: The resin-bound, side chain protected peptide was prepared according to the general procedures described above. 2-(4-(Di-*tert*-butylsilyl)phenyl)acetic acid (55.7 mg, 200 μmol), HBTU (75.8 mg, 200 μmol), and HOBt (30.6 mg, 200 μmol) were dissolved in DMF (1.5 mL) and DIPEA (68 μL, 400 μmol) was added. The resin-bound peptide (100 μmol) was suspended in this solution and the suspension was shaken for 12 h at ambient temperature. The resin was then filtered, washed with DMF (3 × 3 mL) and CH_2Cl_2 (3 × 3 mL), and dried *in vacuo*. Subsequent treatment of the resin with 2 mL TFA/water/tri-*iso*-propylsilane/phenol (85:5:5:5) afforded the crude, fully deprotected peptide, which was precipitated and washed with cold methyl *tert*-butyl ether. The crude peptide was dried *in vacuo*, purified by preparative RP-HPLC, and lyophilized. The products were analyzed by HPLC-MS:

2-(4-(Di-*tert*-butylsilyl)phenyl)acetyl-Ava-Gln-Trp-Ala-Val-NMeGly-His(3Me)-FA01010-Cpa-NH$_2$ (**2a**, 10 mg, 7.5%): *m*/*z* $[M + H]^+$ calcd.: 1335.8 found: 1335.9.

2-(4-(Di-*tert*-butylsilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-Sta-Leu-NH$_2$ (**3a**, 18.5 mg, 12%): *m*/*z* $[(M + 2H)/2]^+$ calcd.: 748.5, found: 749.0.

2-(4-(Di-*tert*-butylsilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH$_2$ (**4a**, 33 mg, 22%): *m*/*z* $[(M + 2H)/2]^+$ calcd.: 748.5, found: 749.0.

Synthesis of Fluorinated Peptides (Reference Compounds **1b**−**4b***).* Representative procedure: The silane- or hydroxysilane-functionalized peptide (**1a**−**4a**, 3.3 μmol) was dissolved in THF (0.5 mL). This solution was added to a mixture of KF (0.8 mg, 13.1 μmol), K2.2.2. (Kryptofix 2.2.2., 4.9 mg, 13.1 μmol), and K_2CO_3 (0.9 mg, 6.6 μmol). Glacial acetic acid (2.2 μL, 39 μmol) was added and the resulting suspension was heated at 60 °C for 30 min. The crude mixture was directly subjected to preparative RP-HPLC, and the purified product was lyophilized. The products were analyzed by HPLC-MS:

3-(3-(Di-*iso*-propylfluorosilyl)phenyl)acetyl-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-FA01010-Leu-NH$_2$ (**1b**, 2 mg, 40%): *m*/*z* $[M + H]^+$ calcd.: 1313.8, found: 1313.5.

2-(4-(Di-*tert*-butylfluorosilyl)phenyl)acetyl-Ava-Gln-Trp-Ala-Val-NMeGly-His(3Me)-FA01010-Cpa-NH$_2$ (**2b**, 2.5 mg, 50%): *m*/*z* $[M + H]^+$ calcd.: 1353.8 found: 1353.8.

2-(4-(Di-*tert*-butylfluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-Sta-Leu-NH$_2$ (**3b**, 3 mg, 59%): *m*/*z* $[(M + 2H)/2]^+$ calcd.: 757.5, found: 758.0.

2-(4-(Di-*tert*-butylfluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH$_2$ (**4b**, 2 mg, 40%): *m*/*z* $[(M + 2H)/2]^+$ calcd.: 757.5, found: 758.0.

Radiolabeling and Stability Studies. No-carrier-added $[^{18}F]$fluoride was produced via the $^{18}O(p,n)^{18}F$ nuclear reaction by irradiation of enriched $[^{18}O]H_2O$. $[^{18}F]$Fluoride was trapped on an anion-exchange resin cartridge (Sep-Pak QMA light, Waters). The cartridge was eluted with a solution of Kryptofix (K2.2.2., 5 mg) and potassium carbonate (1 mg) in H_2O (0.5 mL) and CH_3CN (1.0−1.5 mL). Solvents were removed by heating at 100−140 °C for 20−30 min applying a gentle stream of nitrogen. During this time, CH_3CN (3 × 1 mL) was added and evaporated to give the dry K$[^{18}F]$F/K2.2.2. complex. The peak of the ^{18}F-labeled products was confirmed by comparison with the HPLC retention time of their nonradioactive reference molecule or by coinjection.

*3-(3-(Di-iso-propyl[^{18}F]fluorosilyl)phenyl)acetyl-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-FA01010-Leu-NH$_2$ (***[^{18}F]1b***).* A solution of **1a** (2.0 mg) and glacial acetic acid (3 μL) in anhydrous DMSO (150 μL) was added to the dry K$[^{18}F]$F/K2.2.2. complex. After heating at 90 °C for 15−30 min, an aliquot of the reaction mixture was diluted with CH_3CN (1 mL). The crude reaction mixture was analyzed using an analytical HPLC (PRP-1; isocratic 10 mM K_2HPO_4 in CH_3CN/H_2O (7:3)/10 mM K_2HPO_4 in H_2O 55:45, 1.0 mL/min). Hydrolytic stability of the ^{18}F-label was tested by addition of water (9 mL) to the CH_3CN-diluted aliquot of the reaction mixture and analysis of this mixture by HPLC at different time points.

*2-(4-(Di-tert-butyl[^{18}F]fluorosilyl)phenyl)acetyl-Ava-Gln-Trp-Ala-Val-NMeGly-His(3Me)-FA01010-Cpa-NH$_2$ (***[^{18}F]2b***).* A solution of **2a** (1.0−1.5 mg) in anhydrous DMSO (150 μL) was added to the dry K$[^{18}F]$F/K2.2.2. complex. After heating at 70 °C for 30 min or 90 °C for 15 min, an aliquot of the reaction mixture was diluted with CH_3CN (1 mL). The crude reaction mixture was analyzed using an analytical HPLC (PRP-1; isocratic 10 mM K_2HPO_4 in CH_3CN/H_2O (7:3)/10 mM K_2HPO_4 in H_2O 70:30, 0.8 mL/min). The reaction mixture was diluted with H_2O (8−9 mL) and slowly eluted through a Chromafix C18 (s) cartridge. The product was eluted with ethanol (1.5−2 mL) and analyzed by HPLC. Hydrolytic stability of **[^{18}F]2b** was tested by addition of PBS to the ethanolic solution of the product and analyses of this mixture by HPLC at different time points.

*2-(4-(Di-tert-butyl[^{18}F]fluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-Sta-Leu-NH$_2$ (***[^{18}F]3b***).* A solution of **3a** (2.0 mg) and glacial acetic acid (5 μL) in anhydrous DMSO (150 μL) was added to the dry K$[^{18}F]$F/K2.2.2. complex. After heating at 110 °C for 20 min, an aliquot of the reaction

mixture was diluted with CH_3CN (1 mL). The crude reaction mixture was analyzed using an analytical HPLC (ACE C18; gradient 10 mM K_2HPO_4 in CH_3CN/H_2O (7:3)/10 mM K_2HPO_4 in H_2O 5:95−95:5 in 7 min, 2.0 mL/min). The reaction mixture was diluted with HPLC eluent (CH_3CN/H_2O + 0.1% TFA 45:55, 4.0 mL). This solution was injected into a semipreparative HPLC (ACE C18; isocratic CH_3CN/H_2O + 0.1% TFA 45:55, 3.0 mL/min) and the product peak was collected.

2-(4-(Di-tert-butyl[^{18}F]fluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH$_2$ (**[^{18}F]4b**). A solution of **4a** (2.0 mg) and glacial acetic acid (5 μL) in anhydrous DMSO (150 μL) was added to the dry K[^{18}F]F/K2.2.2. complex and heated at 110 °C for 20 min. An aliquot of the crude reaction mixture was analyzed using an analytical HPLC (ACE C18; gradient CH_3CN/H_2O + 0.1% TFA 5:95−95:5 in 10 min, 1.0 mL/min) either before or after addition of 4.0−4.5 mL HPLC eluent (CH_3CN/H_2O + 0.1% TFA 42:58) into the reaction vial. The diluted reaction mixture was injected into a semipreparative HPLC (ACE C18; isocratic CH_3CN/H_2O + 0.1% TFA 42:58, 3.0 mL/min) and the product peak was collected. The product fraction was diluted with water (20−45 mL) and immobilized on a C18 cartridge (Sep-Pak light C18, Waters, or Chromafix C18 (s), Machery-Nagel). After washing with water (2 × 10 mL), **[^{18}F]4b** was eluted with ethanol or 5% 0.1 N HCl in ethanol (2 mL). The solvent was evaporated at 90 °C. For *in vitro* applications, **[^{18}F]4b** was reconstituted in 0.02 M phosphate buffer or phosphate buffered saline (PBS) containing max. 5% ethanol. For *ex vivo* biodistribution experiments, the radiotracer was reconstituted in 0.9% NaCl containing max 5% ethanol; for *ex vivo* metabolite studies, dried **[^{18}F]4b** was dissolved in PEG-200/H_2O (1:1).

Log *D* Measurement. The experimental determination of distribution coefficient of **[^{18}F]4b** was performed in 1-octanol and 0.06 M phosphate buffer at a pH of 7.4. The two phases were presaturated with each other. 1-Octanol (0.5 mL) and phosphate buffer (0.5 mL) were pipetted into five tubes (1.5 mL) containing of **[^{18}F]4b** (5 μL). The tubes were shaken for 15 min at room temperature and centrifuged (3 min, 5000 U/min). From each tube, 50 μL of each phase was transferred into an empty tube for counting in a γ-counter.

***In Vitro* Receptor Binding Assay.** The receptor affinity of two BBN analogues, **3b** and **4b**, was determined in quadruplicate in a scintillation proximity assay (SPA) using human bombesin 2 receptor membranes (PerkinElmer). The membranes were suspended in 20 mM HEPES, 3 mM $MgCl_2$, 1 mM EDTA, and 10% sucrose (pH 7.4) and kept on ice until use. Assay buffer was 50 mM Tris (pH 7.2, HCl, Roth), 5 mM $MgCl_2$, 1 mM EGTA, 0.3% polyethylenemine solution, protease inhibitor (Roche Diagnostics GmbH, 1 tablet/50 mL). For competition binding studies, membranes solution (106 μg/ml, 10 μL, 1.1 μg protein per well), suspended beads (agglutinin coupled SPA beads, Amersham Bioscience, 40 mg/mL, 10 μL), [^{125}I]-Tyr^4-bombesin (PerkinElmer, specific activity: 81.4 TBq/mmol, 0.50 nM, 20 μL), and increasing concentrations of test compounds (8 pM-1500 nM, 10 μL) were added to well plates to give a final volume of 50 μL. For determination of the total binding, the compound was replaced by the corresponding volume of assay buffer. Unspecific binding was measured using 1000× excess of bombesin. After incubation for 2 h at room temperature, 50 μL of assay buffer was added to the wells. The plates were centrifuged (1700 rpm) and counted in a Top-counter (PerkinElmer). IC_{50} values were calculated using GraFit 5 software (Erithacus software, version 5.0.6). K_i values were calculated using the Cheng-Prusoff equation $\{K_i = IC_{50}/(1 + [L]/K_d)\}$.

***In Vitro* Plasma Stability.** The degradation of **[^{18}F]4b** was investigated in mouse and human plasma from healthy donors. PBS was used as a control. **[^{18}F]4b** was incubated for different time periods (from 0 to 2 h) at 37 °C in PBS, and human and mouse plasma. After incubation, plasma proteins were precipitated with CH_3CN + 0.1% TFA and samples were centrifuged (10 min, 13 000 rpm) at 4 °C. The PBS controls were diluted with the same volume of CH_3CN + 0.1% TFA. The supernatants and PBS controls were analyzed by HPLC (ACE C18; gradient CH_3CN/H_2O + 0.1% TFA 5:95−95:5 in 10 min, 1.0 mL/min). The percentage of intact peptide was determined at different incubation times.

***Ex Vivo* Metabolite Studies.** Mice were injected intravenously with 120−200 MBq of **[^{18}F]4b**). Animals were sacrificed at 10 and 30 min p.i. (one animal per time point), and blood and urine were collected. An aliquot of plasma and urine was mixed with CH_3CN for protein precipitation. The samples were centrifuged (5000 rpm, Megafuge R, Heraeus) and the supernatants were analyzed by UPLC (Waters Acquity UPLC BEH C18; gradient CH_3CN/H_2O + 0.1% TFA 5:95−95:5 in 3 min, 0.8 mL/min).

Biodistribution. The biodistribution experiments were performed using nude mice bearing a human prostate tumor (PC-3). For the induction of tumor xenografts, PC-3 cells (2 × 10^6 cells/mouse) were injected subcutaneously and allowed to grow for four weeks. Animals were injected intravenously with 150 kBq of **[^{18}F]4b** (100 μL, 2.4 fmol). The animals were sacrificed at different postinjection times (from 0.5 to 4 h, $n = 3$ for each time point). Organs and tissues of interest were collected and weighed. The amount of radioactivity was determined in the γ-counter to calculate the uptake (% injected dose per g tissue). In addition, a group of 3 mice received 100 μg of GRP coinjected with the radiolabeled compound and was sacrificed at 1 h postinjection to determine unspecific uptake.

RESULTS

Peptide Synthesis. Peptide synthesis was carried out using Rink Amide resin following standard Fmoc strategy (*18*). Coupling of the resin-bound peptide with the activated ester of 2-(4-(hydroxydi-*iso*-propylsilyl)phenyl)acetic acid was achieved directly in DMF at room temperature, whereas the conjugation with 2-(4-(di-*tert*-butylsilyl)phenyl)acetic acid required the use of a coupling reagent system (HBTU/HOBt/DIPEA). The ^{19}F-reference compounds were obtained by direct fluorination of the appropriate precusors with KF in the presence of Kryptofix K2.2.2. and glacial acetic acid. Representative HPLC-MS chromatograms of a peptide precusor and reference are shown in Figure 2.

Radiolabeling and Hydrolytic Stability Studies. The direct ^{18}F-fluorination protocol developed previously in our laboratory for the radiolabeling of model compounds and tetrapeptides was tested on a series of BBN peptide precursors. To demonstrate the general applicability of the method on targeting peptides, the radiolabeling of a di-*iso*-propylsilyl building block containing a BBN derivative was investigated. A reaction time of 15 min at 90 °C led to an ^{18}F-incorporation of 4% (Table 1, entry 1). However, after heating for another 15 min at the same temperature,^{18}F-incorporation increased to 34% (entry 2). We verified the hydrolytic stability of the ^{18}F-label after the addition of water to an aliquot of the reaction mixture followed by HPLC analysis at different time points. Defluorination of the di-*iso*-propylsilyl building block was observed: the percentage of **[^{18}F]1b** in radiochromatograms decreased to 37% and 13% of the original value within 0.5 and 1 h, respectively.

Subsequently, the radiolabeling of a BBN analogue containing the most stable di-*tert*-butylsilyl building block was studied. The applied nonacidic conditions gave a rather poor ^{18}F-incorporation (entries 3 and 4, Table 1). As the radiolabel was expected to be stable under aqueous conditions, the product was

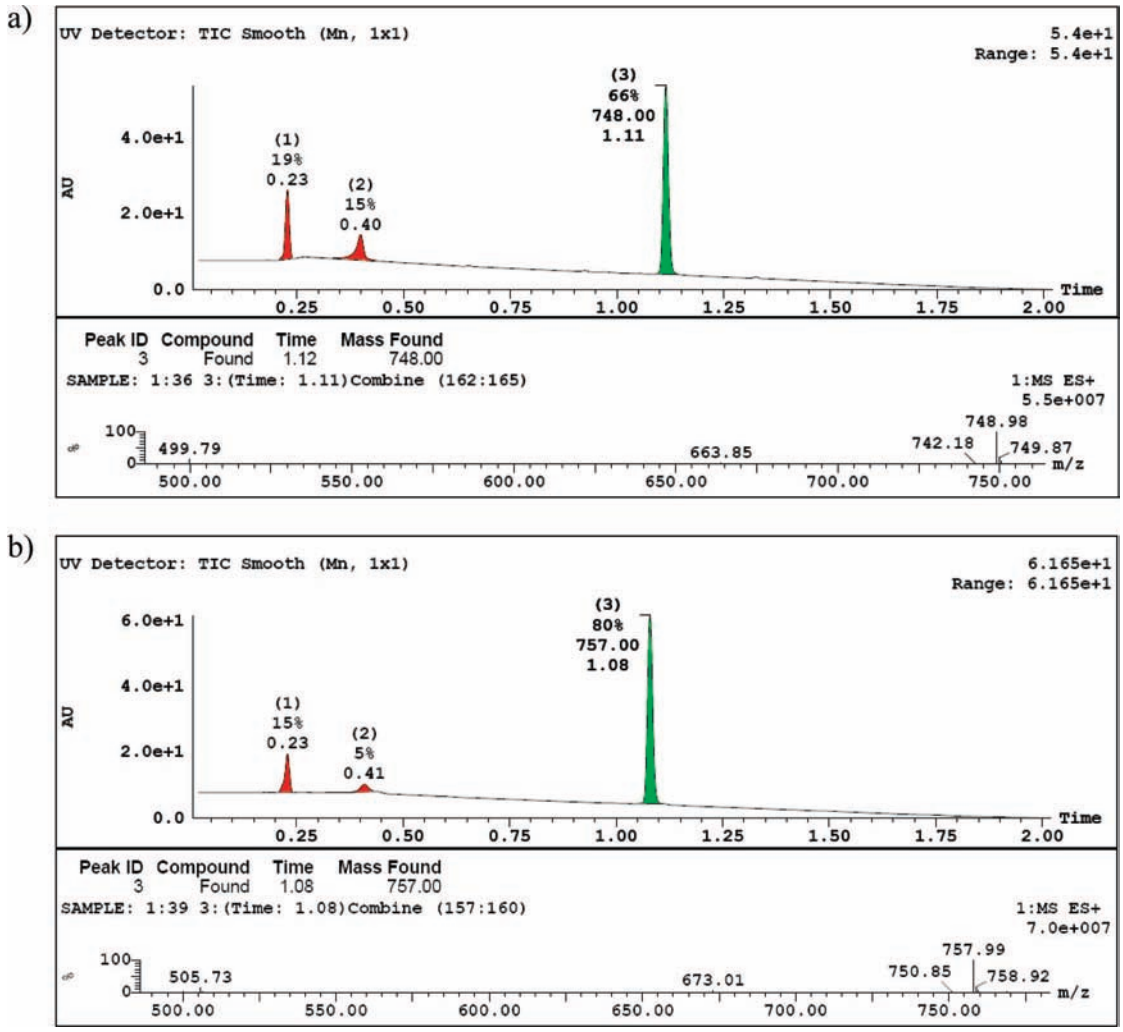

Figure 2. Representative HPLC-MS chromatograms of silyl-functionalized peptides: (a) 2-(4-(di-*tert*-butylsilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 (**4a**, peak 3 at 1.1 min; peak 1 and 2: system peaks) and (b) 2-(4-(di-*tert*-butylfluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 (**4b**, peak 3 at 1.08 min; peak 1 and 2: system peaks).

Table 1. Radiolabeling of Bombesin Derivatives

entry	precursor	precursor amount (mg)	acetic acid (μL)	T (°C)	t (min)	^{18}F-incorporation (% HPLC)
1	**1a**	2.0	3	90	15	4
2	**1a**	2.0	3	90	30	34
3	**2a**	1.0	0	70	30	15
4	**2a**	1.5	0	90	15	19
5	**3a**	2.0	5	110	20	85
6	**4a**	2.0	5	110	20	73.5 ± 1.8% [a] ($n = 2$)
7	**4a**	2.0	5	110	20	31.0 ± 2.0% [b] ($n = 2$)

[a] Aliquot directly removed from the reaction mixture. [b] Aliquot taken after dilution of the reaction mixture with HPLC eluent.

purified by solid-phase extraction (SPE) to avoid any influence of the other components in the reaction mixture during the hydrolytic stability study. **[^{18}F]2b** was obtained in 69% radiochemical purity. A minor amount of ^{18}F (6%) and side products (25%) could not be removed by this simple purification method. The stability test of **[^{18}F]2b** in PBS showed that no defluorination occurred within 2 h.

Radiolabeling of **3a** was achieved under acidic conditions (entry 5, Table 1). Starting from 257 MBq ^{18}F, 55 MBq of **[^{18}F]3b** (radiochemical purity >99%) was obtained by semi-preparative HPLC (30% d. c. RCY). **4a** was labeled under the same conditions. If an aliquot was removed from the reaction mixture directly and analyzed by HPLC, the radiochromatograms showed 73.5 ± 1.8% product (entry 6). If an aliquot of the reaction mixture was taken after dilution with HPLC eluent, the percentage of **[^{18}F]4b** measured by HPLC was 31.0 ± 2.0% (entry 7). This is probably an indication that not all of the K[^{18}F]F/K2.2.2. complex was dissolved from the vessel walls into the reaction mixture, and therefore only a certain amount of the K[^{18}F]F/K2.2.2. complex was available for the nucleophilic substitution reaction. HPLC purification and formulation gave **[^{18}F]4b** in 13.1 ± 3.3% radiochemical yield (decay-corrected, $n = 4$) and >95% radiochemical purity (Figure 4a) within 115−155 min. In a typical experiment, 2.78 GBq ^{18}F provided 191 MBq of **[^{18}F]4b** with a specific activity of 62 GBq/μmol (EOS). The distribution coefficient was determined in an equal volume mixture of 1-octanol and 0.06 M phosphate buffer (pH = 7.4). The log D value was 1.3 ± 0.1 ($n = 5$).

In Vitro Receptor Binding Assay. The IC_{50} (K_i) values determined for **3** and **4** were 267.7 (69.7) and 22.9 (5.76) nM, respectively (Figure 3). Due to the higher binding affinity, **[^{18}F]4b** was further evaluated *in vitro* and *in vivo*.

In Vitro and ex Vivo Stability Studies. Metabolite studies did not show any significant degradation of **[^{18}F]4b** in PBS or in mouse or human plasma within 2 h (Figure 4b−d). Also, after injection into mice, no degradation products of **[^{18}F]4b** were observed in blood at 10 and 30 min postinjection. (Figure 5a−c). Metabolite analyses of urine revealed intact labeled peptide and [^{18}F]-fluoride as a metabolite.

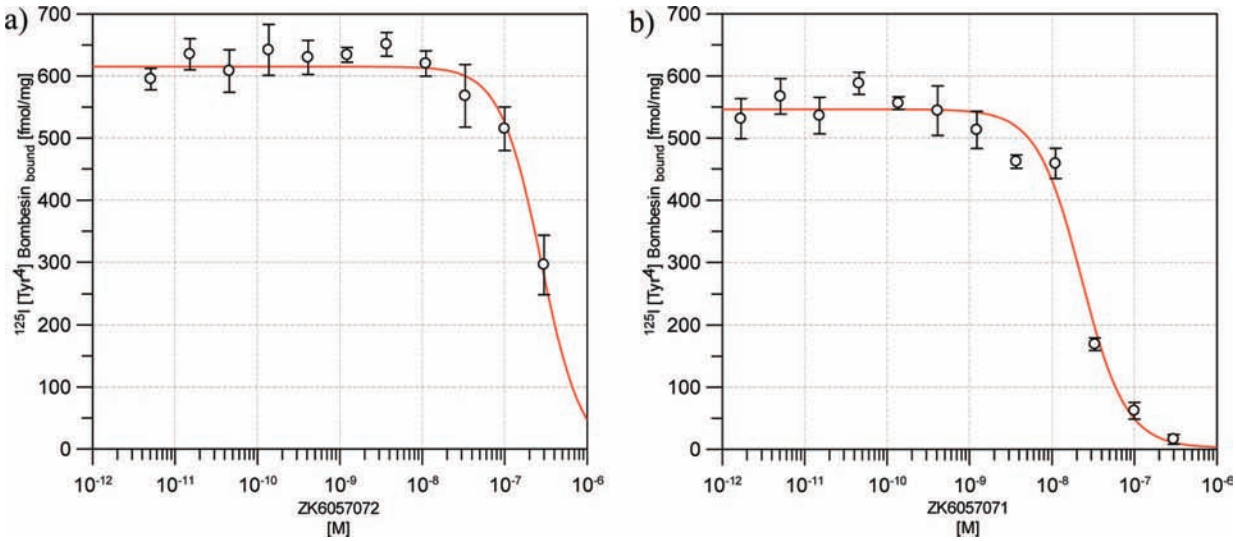

Figure 3. Competitive binding assays of (a) 2-(4-(di-*tert*-butylfluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-Sta-Leu-NH_2 (**3b**) and (b) 2-(4-(di-*tert*-butylfluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 (**4b**) versus [^{125}I]-Tyr 4-bombesin on human bombesin 2 receptor membranes in a scintillation proximity assay.

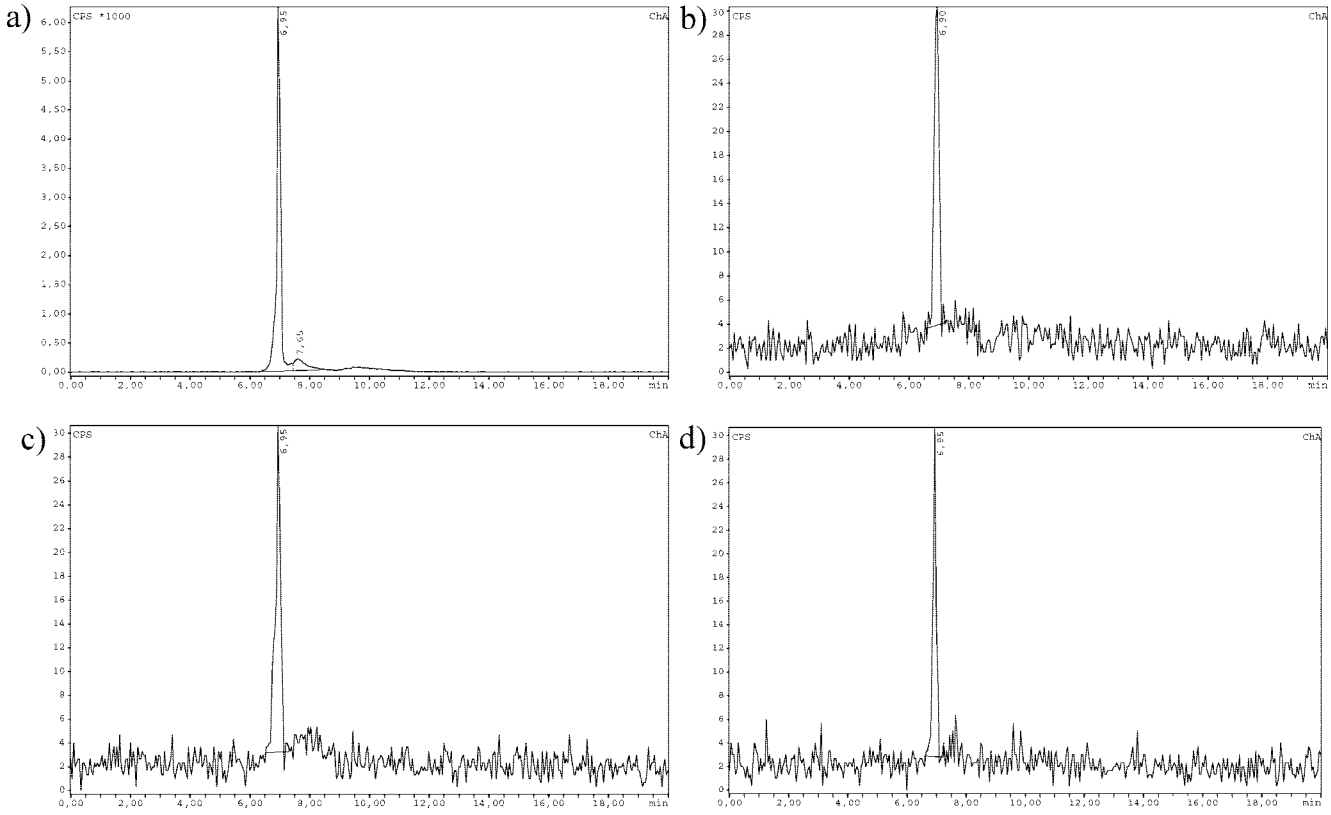

Figure 4. Radio-HPLC profiles of 2-(4-(di-*tert*-butyl[^{18}F]fluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 (**[^{18}F]4b**): (a) purified compound; (b) after 2 h in PBS; (c) after 2 h in human plasma; and (d) after 2 h in mouse plasma.

Biodistribution. The biodistribution of **[^{18}F]4b** was evaluated in nude mice bearing subcutaneous PC-3 tumors. The results are shown in Table 2. Thirty minutes after injection, tumor uptake was 0.63 ± 0.13%ID/g. It essentially remained steady over the measured period of time and was not reduced by a blocking dose of bombesin. In contrast, uptake in the GRPr-rich pancreas was high (between 5.41 ± 0.12%ID/g 0.5 h p.i. and 3.93 ± 1.11%ID/g 4 h p.i.) and specific (73% uptake reduction in the blocking group). Bone uptake increased from 1.35 ± 0.47%ID/g 0.5 h p.i. to 5.14 ± 2.71%ID/g 4 h p.i. High accumulation of the radiotracer was found in liver, gallbladder, and intestine.

DISCUSSION

Prostate tumors are characterized by low metabolic activity, which impairs the use of the most common, unspecific accumulating PET agents (e.g., FDG, ^{18}F/^{11}C-choline, ^{11}C-acetate) for the imaging of prostate cancer (*19*). A PET tracer with high sensitivity and specificity is needed for the reliable diagnosis of lymph node involvement of prostate cancer at an early stage (first diagnosis) and for the clear discrimination between local

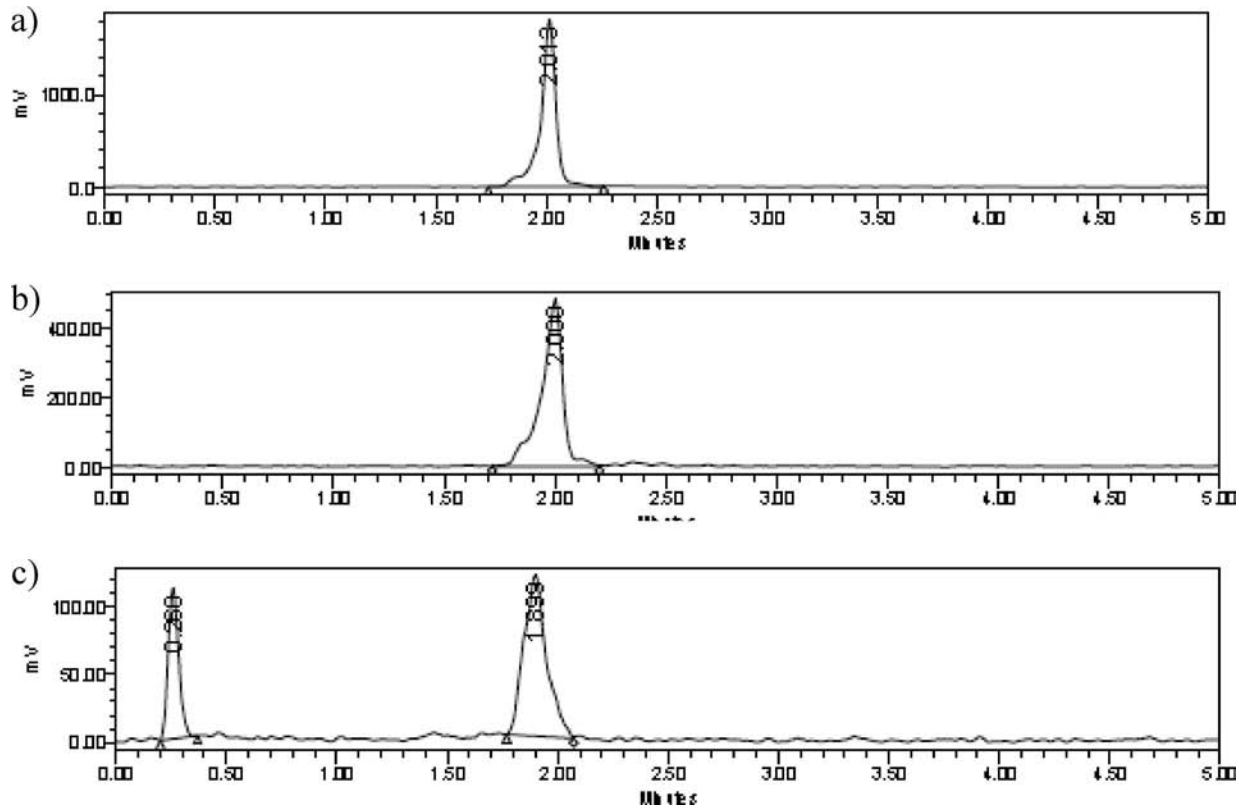

Figure 5. Radio-UPLC profiles of 2-(4-(di-*tert*-butyl[^{18}F]fluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 (**[^{18}F]4b**): (a) purified compound; (b) in blood 30 min postinjection into mouse; (c) in urine 30 min postinjection into mouse.

Table 2. Biodistribution of 2-(4-(Di-*tert*-butyl[^{18}F]fluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 ([^{18}F]4b) in Nude Mice with PC-3 Xenografts at Different Times p.i.[a]

[a] Results are expressed as %ID/g ± SD ($n = 3$). [b] Blockade study: animals received 100 μg of GRP coinjected with the radiolabeled compound.

recurrence and distant metastases in the case of prostate-specific antigen (PSA) level increase after radical prostectomy, since both cases have different therapeutic implications.

Peptides provide excellent characteristics for PET imaging, as they have fast and specific targeting features. They are rapidly cleared from the body, usually mainly via the urinary pathway (*1*). In particular, peptides targeting G-protein coupled receptors are effective in tumor accumulation because the cells internalize them. The gastrin-releasing peptide receptor (GRPr), which is overexpressed on prostatic tumors, belongs to this class of receptors.

We have synthesized new BBN analogues (Figure 1) based on the amino acid sequence 7−14 (Gln^7-Trp^8-Ala^9-Val^{10}-Gly^{11}-His^{12}-Leu^{13}-Met^{14}-NH_2). In order to increase the metabolic stability of this fragment and to allow the attachment of the labeling moiety while retaining the binding affinity, a number of changes were introduced into the molecule. Met^{14} was replaced by Leu for stabilization against aminopeptidase 3.4.11.1, and Leu^{13} was replaced by a non-natural amino acid (FA01010 or Sta) to prevent cleavage by neutral endopeptidase 3.4.24.11 (*20*). Further modifications were the introduction of the methylated versions of His^{12} and/or Gly^{11} and the insertion of a spacer, -Ava- or -Ava-Arg-, between the silicon-based building block and the binding sequence in order to avoid interference of the labeling moiety with the receptor binding C-terminus of the peptide. The new BBN analogues contained either a di-*iso*-propyl or di-*tert*-butyl silyl building block as labeling moiety.

The applicability of the direct labeling method for targeting peptides was successfully demonstrated on a di-*iso*-propyl silyl building block containing BBN derivative **1a**. As expected from previous studies (*17*), defluorination of **[^{18}F]1b** was observed under aqueous conditions. The radiolabeling of BBN analogues modified with the di-*tert*-butyl silyl building block proceeded smoothly under acidic conditions (72−85% conversion), whereas nonacidic conditions gave relatively low yields of ^{18}F-incorporation (15−19%). A preliminary study of the hydrolytic stability of one of the di-*tert*-butyl silyl substituted ^{18}F-labeled peptides showed no defluorination under aqueous conditions.

In vitro receptor binding studies verified a rather poor binding affinity for peptide **3b** (Figure 3, $IC_{50} = 276.6$ nM). Peptide **4b**, however, displayed a 12-fold higher affinity ($IC_{50} = 22.9$ nM) which is in the same range as the affinities of previously reported ^{18}F-labeled bombesin analogues ($IC_{50} = 5.3$ nM for FB-[Lys^3]BBN and $IC_{50} = 48.7$ nM for FB-Aca-BBN(7−14))

(*14*). **[^{18}F]4b** was therefore chosen for *in vitro* and *ex vivo* stability tests. No significant degradation products of **[^{18}F]4b** were detected in PBS, or mouse or human plasma within 2 h (Figure 4b−d). Compound **[^{18}F]4b** also showed high *in vivo* stability in the blood of mice (Figure 5b) demonstrating successful stabilization of the peptide sequence against degradation by endogenous enzymes.

Biodistribution experiments of **[^{18}F]4b** showed low and unspecific tumor uptake. In contrast, the GRPr-rich mouse pancreas revealed a high and specific accumulation of the radiotracer. This result may be explained by the higher receptor densities in pancreas compared to tumor and/or by the better accessibility of the GRPr-expressing pancreatic acini cells in comparison to the weakly vascularized and potentially necrotic PC-3 tumors. Bone uptake gradually increased over time, suggesting a slow defluorination (i.e., silanol formation) of the radiotracer. Due to the lipophilic character of **[^{18}F]4b**, it exhibited a mainly hepatobiliary clearance as suggested by very strong signals in the liver, gallbladder, and intestine.

Significant accumulation of radioactivity in the abdominal region can impair the effective imaging of tumors or metastatic lesions in this area of the body. Assuming that the lipophilicity of the entire molecule is decisive for its *in vivo* behavior (*21*), a reduction of the overall lipophilicity of the radiolabeled peptide may lead to new bombesin derivatives with improved pharmacokinetic profile. An indication of the superiority of less lipophilic peptides is also the prolonged retention of radiometal-labeled BBNs in PC-3 cells, which is most likely due to the lack of cell permeability of the hydrophilic macrocyclic conjugate (*9*, *22*, *23*). Furthermore, intracellular cleavage of the hydrophilic macrocycle from the peptide might lead to trapping of the radiometal inside the cells. On the opposite, ^{18}F-labeled peptides contain inherently a lipophilic labeling moiety. Consequently, ^{18}F-labeled BBNs, after GRPr-mediated internalization, are more amenable to penetration in and out of the cells due to the relatively lipophilic character of both the intact peptide and its radioactive metabolites.

Zhang et al. found in biodistribution studies that the tumor uptake of ^{18}F-FB-[Lys^3]BBN (IC_{50} = 5.3 nM) is relatively high (5.94 ± 0.78%ID/g at 60 min p.i.) compared to another derivative with lower binding affinity (^{18}F-FB-Aca-BBN(7−14), IC_{50} = 48.7 nM, 0.43 ± 0.18%ID/g at 60 min p.i.) (*14*). Hence, a high affinity may partly compensate for the comparatively high lipophilicity of ^{18}F-labeled BBNs. Besides their hydrophilicity, the subnanomolar IC_{50} values of some of the radiometal-labeled BBN derivatives known in the literature (*3*, *4*) are probably another factor for their favorable *in vivo* characteristics. Thus, our future efforts will be directed toward the synthesis of both more potent and more hydrophilic ^{18}F-silyl bombesin peptides for GRPr-targeted PET imaging.

CONCLUSION

This study demonstrates the applicability of our silicon-based one-step n. c. a. radiolabeling method for the synthesis of ^{18}F-labeled bombesin derivatives. Using the di-*tert*-butyl silyl building block as labeling moiety, products containing a hydrolytically stable ^{18}F label were obtained. Biodistribution experiments of a di-*tert*-butyl silyl substituted ^{18}F-labeled bombesin peptide revealed, besides substantial hepatobiliary clearance, low and unspecific uptake in GRPr-positive tumors. To enhance their suitability for the imaging of prostate tumors, optimization efforts toward a reduced overall lipophilicity and higher potency of our ^{18}F-silyl BBNs will be made. In conclusion, we believe that our direct labeling method is transferable to targeting peptides in general and will allow straightforward access to novel PET imaging probes.

ACKNOWLEDGMENT

We gratefully acknowledge Cindy Fischer and Claudia Keller for some experimental support, Dr. Thomas Nauser and Mathias Nobst for technical support, and Marion Kuzora, Bodo Röhr, and Frank Kuczynski for technical assistance.

Shape Effects of Nanoparticles Conjugated with Cell-Penetrating Peptides (HIV Tat PTD) on CHO Cell Uptake

Ke Zhang,[†,‡] Huafeng Fang,[†] Zhiyun Chen,[†] John-Stephen A. Taylor,[†] and Karen L. Wooley*[,†,‡]

Department of Chemistry, Washington University School of Arts and Sciences, 1 Brookings Drive, Saint Louis, Missouri 63130, and Department of Radiology, Washington University School of Medicine, 510 South Kingshighway Boulevard, Saint Louis, Missouri 63110. Received April 18, 2008; Revised Manuscript Received May 30, 2008

In order to probe the nanoparticle shape/size effect on cellular uptake, a spherical and two cylindrical nanoparticles, whose lengths were distinctively varied, were constructed by the selective cross-linking of amphiphilic block copolymer micelles. Herein, we demonstrate that, when the nanoparticles were functionalized with the protein transduction domain of human immunodeficiency virus type 1 Tat protein (HIV Tat PTD), the smaller, spherical nanoparticles had a higher rate of cell entry into Chinese hamster ovary (CHO) cells than did the larger, cylindrical nanoparticles. It was also found that nanoparticles were released after internalization and that the rate of cell exit was dependent on both the nanoparticle shape and the amount of surface-bound PTD.

INTRODUCTION

The plasma membrane of a cell serves as one of the major barriers against inward transportation of extraneous materials, such as a gene and/or a nanoscale synthetic delivery system. Modern synthetic designs have incorporated various cell-penetrating peptides (CPPs), borrowed initially from virus particles, to facilitate their uptake by cells through a receptor-independent pathway (*1*), whose mechanism is not yet completely understood. The ability of a nanostructure to translocate across the cell plasma membrane is of fundamental and practical interest, and will determine the possible outcomes of the nanomaterial in a biological context. Nanostructures of various sizes, shapes, and chemical compositions have gained access to the cell's interior with or without the assistance of CPPs, including metal nanoparticles (*2*), dendrimers (*3*), liposomes (*4*), single-walled carbon nanotubes (*5*), virus mimics (*6*), and so forth. However, the amount of assistance provided by the CPPs for the nanoparticles to be internalized by a cell may be limited (*7*); eventually, the influence of the size and geometric features of the cargo will become increasingly important. Recently, Chan et al. (*2, 8*) probed the effects of size and shape, for penetratin-coated gold nanoparticles within the 10−100 nm range, on the endo- and exocytosis by mammalian cells. A nonlinear relationship between size and uptake was found, and 50 nm spherical particles were identified as having the highest cell uptake. On the micrometer scale, Mitragotri et al. investigated the shape effect by synthesizing a variety of geometrically anisotropic polystyrene particles, whose phagocytosis rates were found to be strongly dependent on the shape of the microparticle (*9*). However, a study to compare across the 10−1000 nm region using particles of similar chemical nature is still unavailable. The mechanism of CPP-assisted cell internalization of the cylindrical structure (several μm in length), which was recently discovered to enhance *in vivo* circulation times much beyond that which can be achieved by other morphologies (*10*), remains largely unknown. It is, therefore, of interest to bridge the gap between nanoscale and microscale structures, in terms of comparing and understanding their CPP-assisted cell uptake and release.

Advances in the design and synthesis of well-controlled block copolymers have given rise to the rapid growth of a new class of complex nanostructures having various compositions, morphologies, sizes, and physical and biological properties (*11*−*13*), which can serve as the primary materials for examination of the effects of nano- to microstructure size and shape on cell internalization. For example, shell-cross-linked assemblies of amphiphilic block copolymers have in recent years attracted researchers to explore their biological and medicinal uses (*14*−*17*). These shell-cross-linked nanoparticles have enhanced stability compared to micelles and are capable of carrying biologically active molecules, which drastically change the biological behavior of the nanoparticles (*15, 18*). In this work, we take advantage of the vast array of morphologies available to polymer micelle-based nanoparticles (*19*−*23*) and their ability to allow for chemical modifications (*24, 25*) in order to study the shape and size effects of a nanoscopic particle in a cellular system.

Herein, we report a method to create spherical and cylindrical nanostructures, of different lengths, from self-assembly of block copolymers. After functionalizing the nanostructures with the protein transduction domain of human immunodeficiency virus type 1 Tat protein (HIV Tat PTD, one commonly used CPP, having the sequence GYGRKKRRQRRR), we demonstrate that the smaller spherical particles (on the 10 nm scale) are internalized by CHO cells more rapidly than are the larger cylindrical particles (20 or 30 nm diameters and larger than 200 nm in one dimension). It is also shown that, upon cellular uptake, the spherical particles are released from the cell, and the rate of release is also dependent on the amount of PTD loading.

EXPERIMENTAL PROCEDURES

Polymer Synthesis. All polymers used in this study were synthesized by atom transfer radical polymerization, according to literature procedures (*26*).

Peptide Synthesis. The ivDde-protected HIV Tat PTD peptide (sequence: GGYGRK(ivDde)K(ivDde)RRQRRR) was synthesized manually by standard Fmoc solid-phase chemistry. The two ivDde protecting groups for lysine were intentionally left on the peptide prior to and following cleavage from the

Published on Web 08/09/2008

solid support, using 95% trifluoroacetic acid/2.5% triisopropylsilane/2.5% water solution (volume fractions) for 90 min. The beads were treated with cleavage solution 3 times total, and the solutions were combined and concentrated *in vacuo*. The concentrate was precipitated into cold ether, and the precipitates were centrifuged at 3500 rpm for 10 min. The supernatant was decanted, the pellet was resuspended in cold ether, and the centrifugation process was repeated. The pellet was purified by reversed-phase HPLC. MS (MALDI-ToF): 2087.532 $[M + H]^+$ (calcd: 2087.529).

Spherical Micelle Formation. Spherical polymer micelles of narrow size distribution were obtained by dissolving the block copolymer PAA_{128}-*b*-PS_{40} (32.5 mg) in DMF (35 mL) followed by gradual addition (4 mL/h) of an equal volume of nonsolvent (H_2O) for the hydrophobic polystyrene to induce micellization. The micelles were stirred for 4 h before being transferred to presoaked and rinsed dialysis bags (MWCO 6−8 kDa) and dialyzed against nanopure water (18.0 M·cm) for 3 days to remove the organic solvent. The final volume was 115 mL of aqueous micelle solution for a final concentration of 0.28 mg/mL. TEM: 11 ± 2 nm (diameter).

Short Cylindrical Micelle Formation. PAA_{96}-*b*-PS_{48} block copolymer (10 mg) was dissolved in THF (50 mL) and was dried in a round-bottom flask *in vacuo*, leaving a thin membrane of the polymer in the flask. To the flask, nanopure water (58.8 mL) was added and then sonicated while rotating in an aqueous sonicator (VMR Aquasonic 75T) for 40 min. The resulting solution contained short cylindrical micelles, which gave a light-blue color to the solution, a characteristic of the light scattering caused by the cylindrical micelle assemblies. The final concentration was 0.17 mg/mL. TEM: 180 ± 120 nm (length) and 20 ± 2 nm (cross-sectional diameter).

Shell-Cross-Linked Spherical and Short Cylindrical Nanoparticle Formation. The aqueous solutions of spherical and short cylindrical micellar assemblies of PAA_{128}-*b*-PS_{40} and PAA_{96}-*b*-PS_{48}, respectively, were individually mixed with *O*-bis-(aminoethyl)ethylene glycol (0.15 equiv, relative to the molar number of available COOH groups) and allowed to stir at room temperature. After 30 min, an aqueous solution of 1-[3′-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDCI) (1 equiv, relative to the molar number of available COOH groups) was added. The reaction mixture was allowed to stir overnight before being transferred to presoaked and rinsed dialysis tubing (MWCO 3 kDa) and dialyzed against nanopure water (18.0 M·cm) for 3 days.

Long Cylindrical Shell-Cross-Linked Nanoparticle formation. To a solution of triblock copolymer PAA_{94}-*b*-PMA_{103}-*b*-PS_{28} (8.4 mg) in THF (8.00 mL) with stirring was added a solution of THF (2.0 mL) containing *O*-bis-(aminoethyl)ethylene glycol (0.93 mg, 0.15 equiv, relative to COOH groups). The mixture was allowed to stir overnight at room temperature, and then H_2O (40 mL) was added at a rate of 7.50 mL/h to induce micellization. To this water−THF mixture, EDCI (5.6 mg) was added to cross-link the shell domain of the micelle and to lock the morphology (*27*). The premixing of the diamine cross-linker with the triblock copolymer is essential to the formation of the desired morphology (*19*). After stirring overnight, the reaction mixture was transferred to presoaked and rinsed dialysis tubing (MWCO 6−8 kDa) and dialyzed against nanopure water (18.0 M·cm) for 3 days to remove the organic solvent. The final volume was 61.3 mL of aqueous cross-linked long, cylindrical micelle solution for a final concentration of 0.14 mg/mL. TEM: 970 ± 900 nm (length) and 30 ± 2 nm (cross-sectional diameter).

Functionalization with Fluorescent Tag. The respective shell-cross-linked nanoparticle solutions were diluted to the same molar concentration (7.5 μM polymer) and each was placed into a round-bottom flask and cooled to 0 °C using an ice bath. A mixed solution of 1:1 EDCI/*N*-hydroxysulfosuccinimide (sulfo-NHS) was added to each nanoparticle solution (1.2:1 molar ratio, relative to the available COOH groups) to activate the acrylic acid residues. After 30 min, aliquots of Alexa Fluor 594 cadaverine stock solution were added to each flask and the mixtures were allowed to react overnight. The solutions were then transferred to presoaked dialysis tubing (MWCO 6−8 kDa) and allowed to dialyze for 5 days against nanopure water.

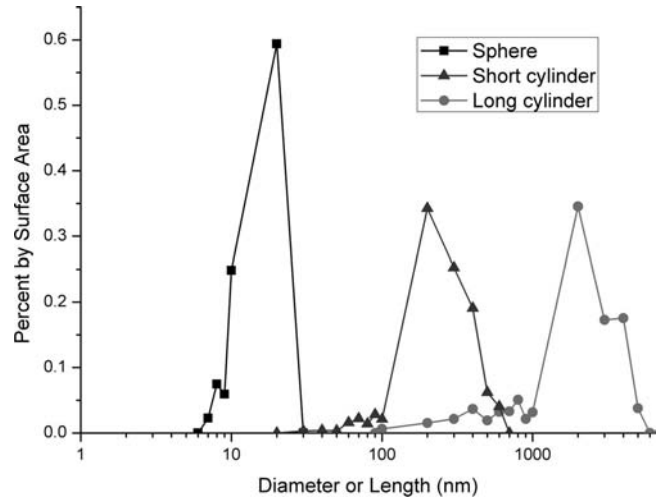

Figure 1. Size distribution by surface area. The size of the three nanostructures is each separated by an order of magnitude.

Functionalization with PTD. Shell-cross-linked nanoparticle solutions prefunctionalized with Alexa Fluor 594 were each placed into a 25 mL round-bottom flask. Sodium chloride was placed into each flask to give a concentration of 5.0 mg/mL, to minimize particle−particle aggregation. The flask was then placed in an ice bath. A mixed solution of 1:1 EDCI/sulfo-NHS was added to each nanoparticle solution (1.2:1 molar ratio, relative to the available COOH groups) to activate the acrylic acid residues. A stock solution (18.21 mg/mL) of the ivDde-protected PTD peptide was made in nanopure water, and aliquots of the solution were added to the respective flasks 30 min after the addition of EDCI/NHS. The pH of each reaction mixture was adjusted to 7.40 using pH = 8.00 sodium phosphate buffer. The mixtures were allowed to react overnight. The solutions were then transferred to presoaked dialysis tubings (MWCO 12 kDa) and allowed to dialyze for 5 days against nanopure water. At the end of dialysis, the nanoparticle solutions were treated with 2.0% hydrazine for 20 min to remove the ivDde protecting groups, and then the pH was adjusted to 6.50 using pH = 6.34 sodium phosphate buffer. The solutions were then transferred to presoaked dialysis tubings (MWCO 100 kDa) for a second-stage dialysis over a period of 15 days. UV−vis measurements confirmed coupling of the PTD peptide to the shell-cross-linked nanostructures (*18*). Removal of the ivDde protecting groups under these reaction conditions was confirmed by MALDI-ToF mass spectrometry for a model reaction performed upon nonconjugated PTD peptide (Figure 3).

Cell Line and Fluorescence Confocal Microscopy. Chinese hamster ovary cells (CHO-K1) were incubated in Ham's F-12K containing 10% FBS and 1% antibiotics (penicillin−streptomycin, 10 000 U/mL) at 37 °C in a humidified atmosphere containing 5% CO_2. 5×10^5 CHO cells were plated at 35 mm MatTek glass-bottom microwell dishes (MatTek Co.). After 24 h, the medium was replaced with 1.0 mL of fresh medium containing no FBS and combined with the respective nanoparticle solutions (100 μL each, at 7.5 μM). The plates were then returned to the incubator to incubate at 37 or 0 °C. Following desired incubation

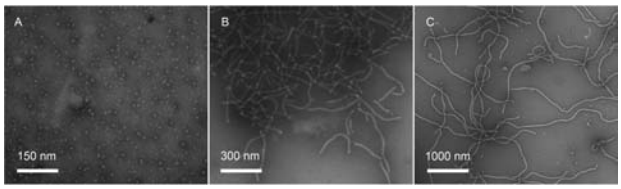

Figure 2. TEM of PAA_{128}-*b*-PS_{40} (A), PAA_{98}-*b*-PS_{48} (B), and PAA_{94}-*b*-PMA_{103}-*b*-PS_{28} (C) micelles in nanopure water.

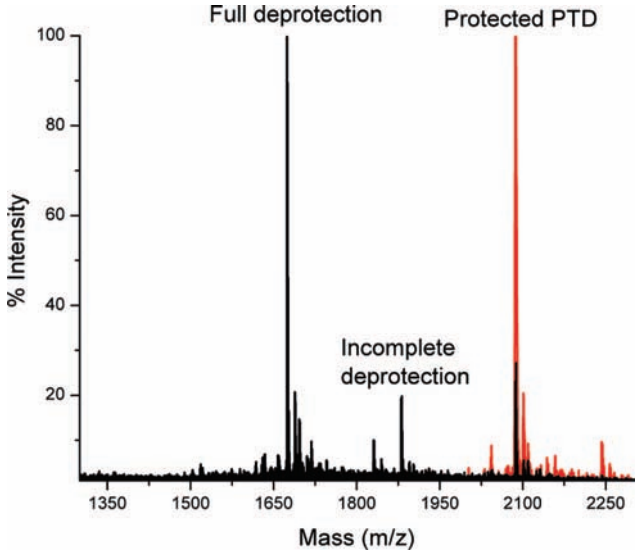

Figure 3. Overlaid MALDI-ToF spectra of ivDde-protected PTD before and after treatment with 2.0% hydrazine for 20 min in water. Adequate removal of ivDde (>70%) was achieved, despite the deprotection reaction being less efficient in water than in organic solvent.

times, the nanoparticles were removed, and each well was washed with Hanks Balanced Salt Solution (HBSS) (3 × 5.00 mL) and viewed under bright field and fluorescent conditions using a Leica TCS SP2 inverted microscope.

Quantitative Analysis of Confocal Images. The background levels of the red channel containing the signal of Alexa Fluor-labeled nanoparticles for each image were determined and subtracted from the original image. Then, individual cells in that image were manually selected and measured. A minimum of 120 cells were measured for each time point of each sample, and 10 cells with highest intensities and 10 cells with lowest intensities were removed. The mean intensity values and standard deviation values were calculated. The background levels were determined using the following method: (1) Binary masks corresponding to nanoparticles-associated fluorescence were generated ($Mask_{NP0}$). Threshold levels were determined by visual inspection. (2) $Mask_{NP0}$ was inverted by applying a NOT operation to generate a binary mask for the background ($Mask_{bg}$). (3) The inverted mask $Mask_{bg}$ was multiplied with the original red channel, Red_0, and the mean value of the resulting image, containing only the signals of the background, was determined as the background level. Cell fluorescence intensities were determined by the following method: (1) Background noise was subtracted from the original signal, Red_0, giving Red_1. (2) Binary masks were generated ($Mask_{NP1}$) for Red_1. Threshold levels were determined by visual inspection. (3) $Mask_{NP1}$ was multiplied by Red_1. (4) Over the resulting image, individual cells were manually selected as regions of interest (ROI), and mean intensities were recorded for each cell.

Cytotoxicity Assay. The cytotoxicity of PTD−nanoparticle conjugates was examined by CellTiter-GloLuminescent Cell Viability Assay (Promega Co.). The CHO-K1 (ATCC) cells were seeded in the 96-well plate at a density of 1×10^4 cells/well and cultured for 24 h in 100 μL Ham's F-12K containing 10% FBS. Thereafter, the medium was replaced with 100 μL of fresh medium containing various concentrations of nanoparticles. After 24 h incubation at 37 °C, 100 μL CellTiter-Gloreagent was added. Contents were mixed and the plate was allowed to incubate at room temperature for 10 min to stabilize luminescence signals. Luminescence intensities were recorded on a Luminoskan Ascentluminometer (Thermo Scientific) with an integration time of 1 s per well. The relative cell viability was calculated by the following equation:

$$\text{Cell viability (\%)} = (\text{luminescence}_{(\text{sample})} / \text{luminescence}_{(\text{control})}) \times 100$$

where $\text{luminescence}_{(\text{control})}$ was obtained in the absence of particles and $\text{luminescence}_{(\text{sample})}$ was obtained in the presence of particles. Polyfect dendrimer (Qiagen, Inc.), a known toxic compound, was used as a positive control. Data are shown as mean ± SD ($n = 6$).

RESULTS AND DISCUSSION

In order to validate size/shape effects of the nanoparticle carrier in their cell internalization characteristics, mediated by PTD peptide, two series of nanoparticle solutions were prepared. The first series included the same spherical structures with increasing loadings of PTD; the second series contained particles having the same amount of PTD but increasing particle length in one dimension (from 10 nm to several μm). The first series was used to probe the effectiveness of PTD on cell internalization, while the second series was used to probe the size/shape effect.

We designed and synthesized shell-cross-linked nanoparticles of different sizes and spherical or cylindrical shapes and then performed further functionalization for fluorescent labeling and PTD attachment to afford the two series of materials (Scheme 1). The spherical nanoparticle was assembled from a diblock copolymer (poly(acrylic acid)$_{128}$-*b*-polystyrene$_{40}$, PAA_{128}-*b*-PS_{40}). The short and long cylindrical nanoparticles were assembled from a diblock and a triblock copolymer, PAA_{98}-*b*-PS_{48} and poly(acrylic acid)-*b*-poly(methyl acrylate)-*b*-polystyrene (PAA_{94}-*b*-PMA_{103}-*b*-PS_{28}), respectively. All three particles were nominally 30% cross-linked in the shell domain, using standard procedures (*28*). The spherical particle had an average diameter of 11 ± 2 nm, as evidenced by transmission electron microscopy (TEM). The short cylinder had an average cross-sectional diameter of 20 ± 2 nm, and an average length of 180 ± 120 nm. The long cylinder had an average cross-sectional diameter of 30 ± 2 nm, and an average length of 970 ± 900 nm (Table 1). TEM images (Figure 1) show the morphologies of the three nanostructures.

Functionalization of the nanostructures with both the fluorescent tag (Alexa Fluor 594 cadaverine) for confocal microscopy and the Tat PTD peptide was achieved by using carbodiimide chemistry. Attachment of the Alexa Fluor 594 to the nanostructures was performed first. To ensure that all final solutions had the same amount of total fluorescence, the solution of spherical particles was then split for further labeling with different amounts of PTD (at levels of 0.5%, 1%, and 2% consumption of total COOH groups of the PAA_{128}-*b*-PS_{40}), while the solutions of cylindrical nanostructures were functionalized at a level that coincided with the 1% labeling of the spheres. Higher loadings of PTD (up to 6%, which correlates to several hundred peptides per nanoparticle) for the spherical particles were possible, although the particle dispersions appeared to become unstable, leading to aggregation observed as solution cloudiness. In addition, in our trial of 2.0% loading for the long cylindrical particles, precipitation was observed.

Scheme 1. Block Copolymers (PAA_{128}-*b*-PS_{40}, PAA_{98}-*b*-PS_{48}, and PAA_{94}-*b*-PMA_{103}-*b*-PS_{28}) Were Micellized by Different Procedures, To Afford Spherical and Cylindrical Nanoparticles of Different Cross-Sectional Diameters and Lengths

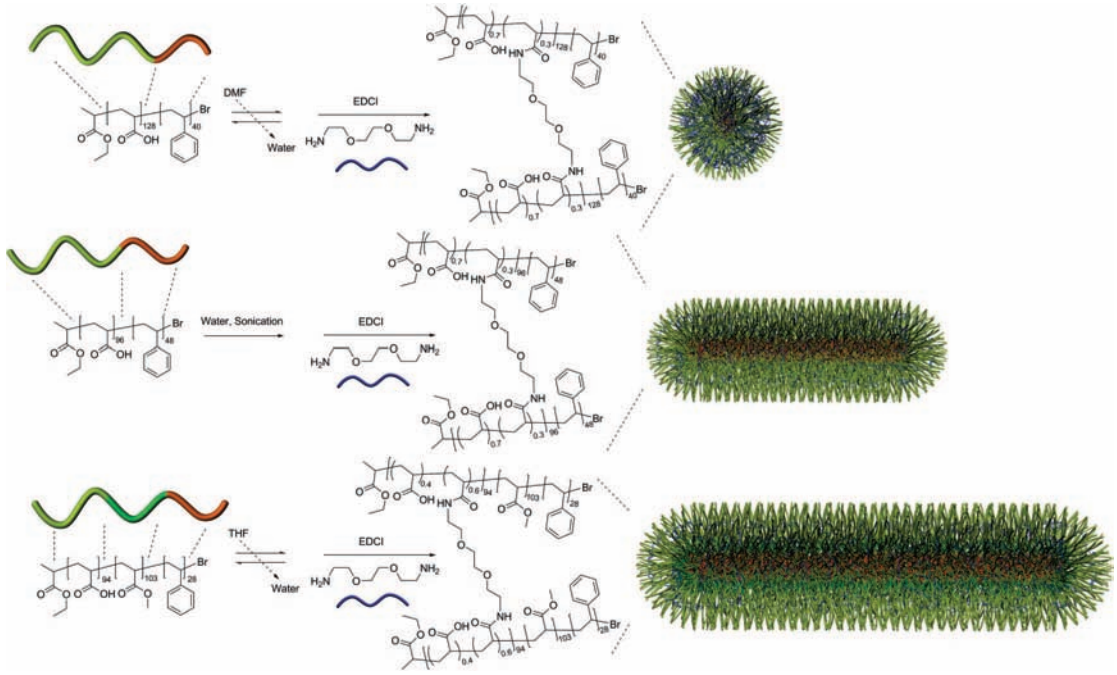

Table 1. Dimensions of the Nanostructures Evaluated

sample	cross-sectional diameter (nm)	length (nm)
sphere	11 ± 2	n. a.
short cylinder	20 ± 2	180 ± 120
long cylinder	30 ± 2	970 ± 900

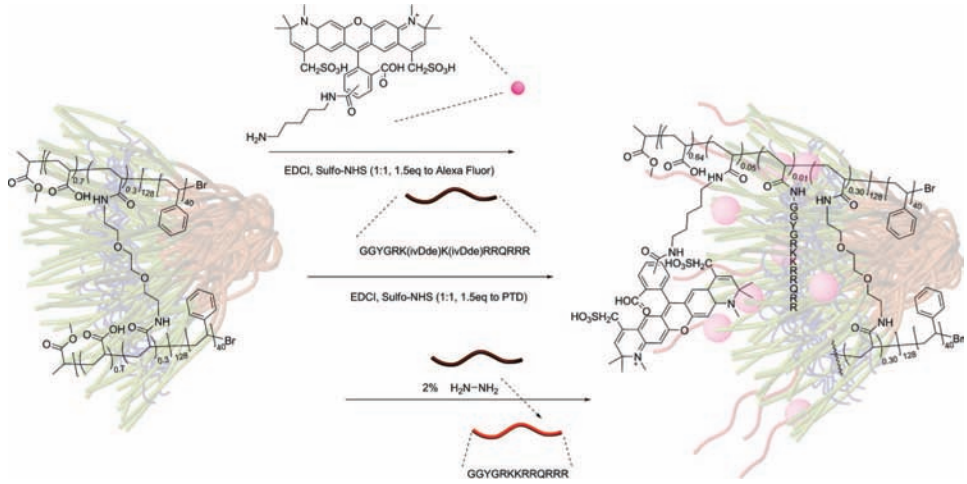
Therefore, to ensure comparison of all three sizes, 1.0% PTD loading was used for both cylindrical nanoparticles. Because the Tat PTD has two lysine residues, whose side chain amine could compete with the terminal amine for the activated carboxylic acid on the nanoparticle, ivDde protecting groups were used to cap the lysine residues and were subsequently removed, after the Tat PTD was coupled to the nanoparticle (Scheme 2). A model study on aqueous ivDde removal by matrix-assisted laser desorption ionization-time of flight (MALDI-ToF) mass spectrometry demonstrated adequate removal under reaction with 2% hydrazine in water (Figure 3). These reaction conditions were fairly mild to the nanoparticle framework, although some amount of the AlexaFluor 594 cadaverine was cleaved. Therefore, all samples, even the control particles without PTD, were treated to these deprotection reaction conditions. Extensive dialysis was used to remove unbound peptide, which previously had been reported to be effective (*18*). Both the fluorescent dye and the Tat PTD were loaded successfully within the nanoparticles, as evidenced by UV−vis spectroscopy (Figure 4), although it is not clear whether all detected peptide was covalently bound or electrostatically adsorbed onto or absorbed into the nanoparticles, due to their oppositely and highly positively charged characteristics. The UV absorbances of the nanoparticles at 263 and 300 nm correspond with the absorbances of tyrosine in the PTD peptide. Although the cylinder samples were both nominally labeled with 1% PTD, the short cylinder appeared to have slightly more than 1% PTD and the long cylinder less than 1% PTD. This result may be due to some extent of light scattering that occurred for the relatively large nanostructures (Figure 5). After functionalization, the morphologies of each nanostructure did not undergo discernible changes, as confirmed by TEM (images not shown).

Because the PTD peptides were conjugated after the micellization and cross-linking and should be present on the particles' surfaces, the surface areas of the nanostructures determine the number of peptides loaded onto each particle given the total amount of PTD peptide, assuming the particles' densities are similar (*29*). The three nanostructures each represented a unique size distribution, with the greatest percentage surface area for each morphology being separated by an order of magnitude (Figure 1).

Biocompatibility is a major concern when external substances are introduced to a living organism. In the current work, cytotoxicity is of particular importance because disruption of cellular uptake behavior due to toxicity can lead to a false understanding of the relationship between particle shape/size and cellular uptake. Low toxicity has been observed for shell-cross-linked nanoparticles comprising poly(acrylic acid) shells, even after conjugation of the PTD peptide sequence. As had been determined for spheres of similar composition to those studied here, loss in mouse myeloma B cell viability occurred only at concentrations above 500 mg/L (*30*). We considered it important to determine the cytotoxicity for the uniquely shaped structures against the CHO cells employed for the cell uptake experiments, and therefore, we further assessed the cytotoxicity of 1% PTD-functionalized spheres and cylinders. The CellTiter-Glo Luminescent cell viability assay (Promega Co.) was used to examine the cell viability of CHO-K1 cells, following exposure to PTD-shell-cross-linked nanoparticle conjugates. In the concentration range and time period over which the cell uptake experiments were performed, no adverse effects to cell viability were observed by this assay (Figure 9), thus confirming the general understanding that poly(acrylic acid)-shell particles are of low cytotoxicity, even when 1% PTD is conjugated (Figure 2).

To verify the effectiveness of CPP, spherical particles of the same size loaded with different amounts of CPP (series 1) were incubated with CHO cells at a concentration of 0.68 μM (polymer) at 37 and 0 °C for 1 h. Confocal microscopy imaging of nonfixed, live cells suggests that CPP had a pronounced enhancement in the uptake of the nanoparticles by the CHO cells (Figure 6). The highest amount of PTD loading, 2.0%,

Scheme 2[a]



[a] Functionalization of the spherical nanoparticle sample was achieved through a three-step synthesis. Alexa Fluor 594 and protected PTD were respectively coupled to the nanoparticle via carbodiimide chemistry. The ivDde protecting groups were removed by treatment with a 2.0% hydrazine solution in water.

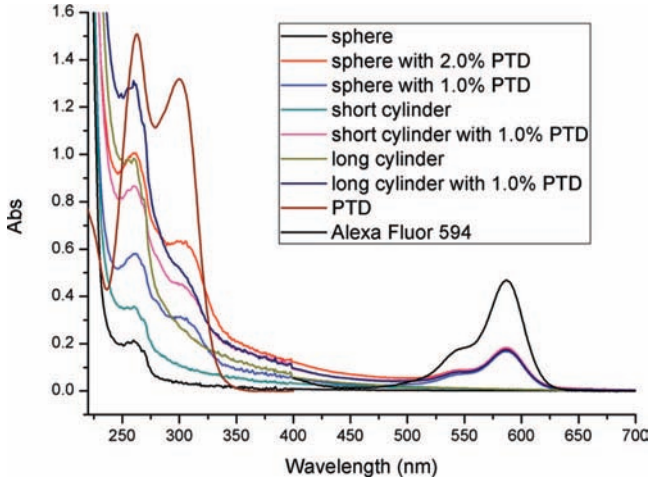


Figure 4. UV−vis spectra of spheres and cylinders labeled with Alexa Fluor 594 cadaverine and PTD peptide. The absorbances at 263 and 300 nm for the nanoparticle solutions correlate with the absorbances of the PTD peptide, and the absorption at 594 nm correlate with the absorbance of the fluorescent tag, Alexa Fluor 594.

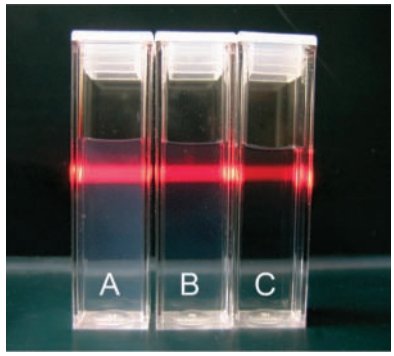

Figure 5. Light scattering of the long cylinders complicates accurate UV−vis measurement. A: Long cylinders. B: Short cylinders. C: Spheres.

gave nanoparticles that exhibited nearly a 5-fold increase in cell uptake at 37 °C than the nanoparticles without PTD. Incubation at 0 °C, under otherwise identical conditions, resulted in little cell uptake. The difference in cell uptake at different temperatures can be due to reduced membrane permeability at low temperatures, to the energy dependency of the uptake process, or to both. An interesting phenomenon we noticed is that the PTD−nanoparticle conjugates were both contained within cellular vesicles and partly spread into the cytoplasm, with exclusion from the nucleus, whereas PTD alone has been reported to accumulate selectively in the cell nucleus (*31, 32*). This observation is possibly due to the overall negatively charged nature of the PTD−particle conjugate or may be due to comparisons among different cell lines.

To probe the size/shape effect, we loaded the three differently shaped particles with a fixed amount of PTD (equivalent to 1% of the carboxylates of PAA_{128}-*b*-PS_{40}) and incubated CHO cells in their solutions (0.68 μM polymer) at 37 °C for 1 h. It was found that the smaller, spherical particle had higher cell uptake than the larger, cylindrical nanoparticles (Figure 7). In other words, a higher molar amount of polymer was internalized by the cell, through the spherical particles, relative to the cylindrical nanostructures, when both forms had the same molar concentration of polymers. On the basis of these results, we can speculate on the general mechanisms that govern the transduction of the PTD-functionalized nanomaterials. Many variables determine the uptake rate, including adhesion rate and receptor diffusion kinetics. Freund et al. (*33*) and Bao et al. (*34*) have modeled these factors and developed a hypothesis involving "wrapping time" of the membrane: the shorter the wrapping time, the faster the uptake. It has been predicted theoretically by this model that, through the competition between thermodynamic driving force and diffusion kinetics, there is an optimum radius for efficient "wrapping", which is 27−30 nm. Because the early endocytic vesicles are usually less than 100 nm in diameter (*6*), most short cylindrical particles (average length = 170 nm) would have to be curved or bent to be internalized, which requires additional energy. Therefore, although the cylindrical particles have higher surface area and hence more membrane−particle interaction (less diffusion), the system is not able to either overcome the overall lack of thermodynamic driving force caused by having to bend the cylinders to "fit" in the endosomes or create larger endocytic vesicles to contain the cylindrical nanostructures. Another factor, for the higher uptake of the small, spherical particle by the cell at a given time, is the higher particle molar concentration for the spheres, which is the result of the lower aggregation numbers of polymer chains to form the spherical particles, compared with the cylindrical particles. For example, the average long cylinder occupies ca. 1000 times as much volume as does the sphere, based on calculations from

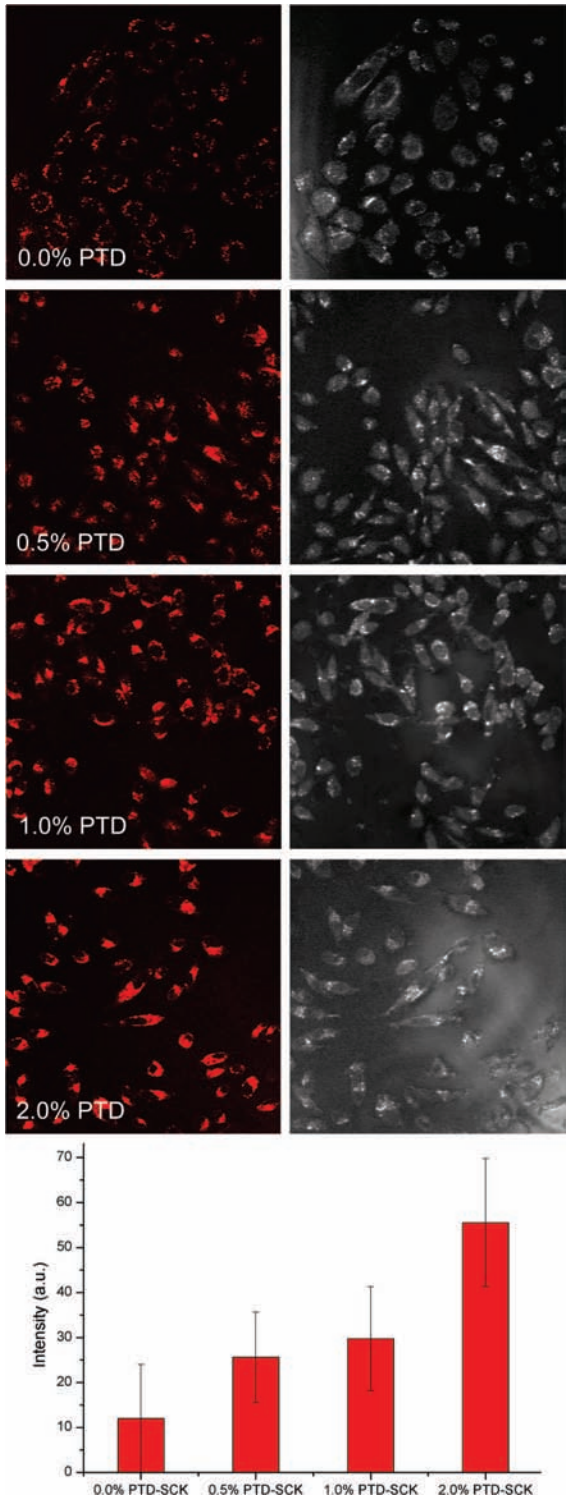

Figure 6. Confocal images of CHO cells incubated with the spherical nanoparticles having different amounts of PTD for 1 h. Cell uptake of PTD−sphere conjugates increased by the action of increasing loadings of surface-bound PTD peptide, as shown in the bar graph.

TEM cross-sectional and longitudinal measurements. It would be extremely difficult, or perhaps impossible, to investigate these materials at the same molar concentration of particles and allow for their observation in cell assays at a usable concentration range (i.e., to compare one of our micrometer-length cylinders vs one of the 10 nm particle requires a difference in material mass and number of chromophores by several orders of magnitude). Therefore, the experiments were performed at the same molar concentration of polymer (vide supra), which

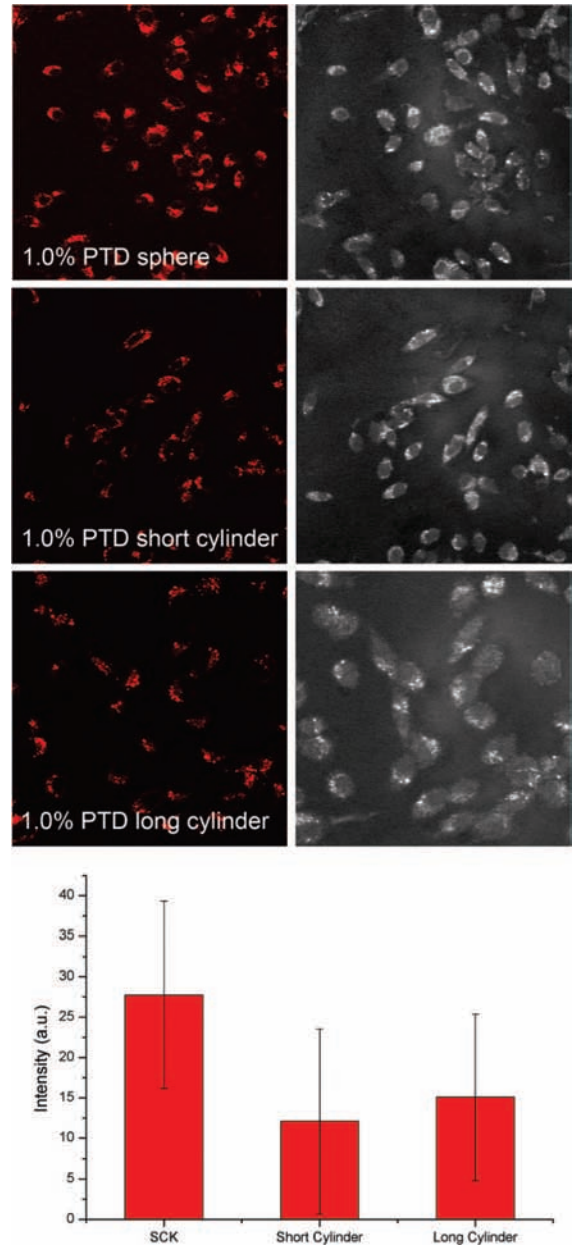

Figure 7. When conjugated with the same amount of PTD peptide, greater amounts of the smaller, spherical nanoparticles were internalized than were the larger, cylindrical nanoparticles as shown in the bar graph. Images were taken after 1 h of incubation.

corresponded to higher molar concentrations of spherical vs cylindrical nanostructures.

Last, we investigated the release of the PTD−nanoparticle conjugates from CHO cells. CHO cells were incubated with 0.68 μM particle solutions for 1 h at 37 °C. Following the incubation period, the nanoparticle-containing solutions were removed, the cells were washed with PBS, and serum-free RPMI 1640 media was introduced, followed by further incubation. Fluorescence monitoring of CHO cells immediately after buffer change and at 2, 4, and 8 h time points revealed that fluorescence intensity decreased over time for spherical nanoparticles labeled with 2%, 1%, and 0.5% PTD, suggesting particles being released from the cell (Figure 8). The rates of release of spherical particles appeared to be dependent on the amount of PTD loaded on the nanoparticle, for which the highest loading (2%) led to the fastest release. This result could suggest that PTD-assisted particle transduction works in a two-way fashion: both entry and exit seem to be facilitated by PTD (*35*). The cells that had

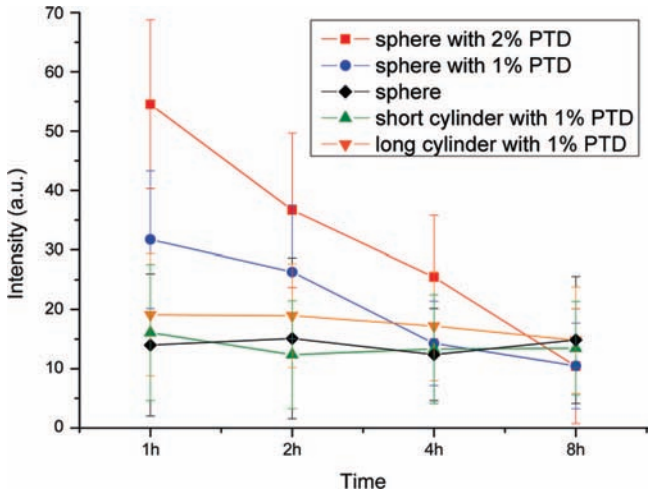

Figure 8. Release profile of series 1 nanoparticles (spherical in shape; different amounts of PTD peptide) and series 2 nanoparticles (different shapes; each with 1.0% PTD peptide conjugation).

been incubated with spheres having no PTD did not show apparent decrease of fluorescence over 8 h. Both the long and short cylinders behaved similarly to the spheres without the PTD peptide, showing little uptake and no measurable release. Other PTD-independent processes, such as peptide degradation, are possible, and thus more detailed studies on cell uptake and release of differently shaped nanostructures are needed to reveal a fuller picture of the mechanisms involved.

CONCLUSIONS

The self-assembly of block copolymers afforded spherical nanostructures and cylindrical nanostructures having distinctive lengths required to investigate the effects of different particle sizes and shapes, across a wide size range (10−1000 nm), upon cell transduction. Attachment of the Tat cell penetration peptide of HIV-1 improved cell internalization of the spheres. The amount of cell uptake was a function of PTD loading, with increasing amounts of PTD providing for increasing levels of cell internalization at a given time point. Attachment of PTD to the small cylinders (∼200 nm) and long cylinders (∼1000 nm) did not produce a detectable increase in cell uptake. Once internalized, the PTD−spherical nanoparticle conjugates escaped from the cell at a rate that was a function of PTD loading. The observation of reversible cell transduction will become important, as these nanostructures are functionalized also with ligands that are designed to probe intracellular targets, so that escape from cells lacking the target can be facilitated to allow for the nanostructures to accumulate in the designated cells.

The polymer micelle-based nanoparticles in this study have enabled comparison of size and shape on cellular uptake, for materials that have the same surface chemistry, differing only in their core composition, size, and shape. Further studies are required to understand fully the mechanisms by which the particle characteristics lead to the observed differences in cellular uptake and release. Moreover, the particles and the methodologies for functionalization described herein can be employed for fundamental studies that extend to systems involving ligand−receptor interactions to promote endocytosis, which will be important to gain new insights into the interface of biological systems with synthetic nanostructures. These results also serve as a guideline in engineering artificial nanoscale carrier particles for drug delivery, where the control of size/shape is of significance.

ACKNOWLEDGMENT

The authors gratefully acknowledge support from the National Heart Lung and Blood Institute of the National Institutes of Health as a Program of Excellence in Nanotechnology (NHLBI-PEN HL080729). The authors also thank senior microscopist G. Michael Veith of the Washington University Department of Biology Microscopy Facility for providing technical support with TEM and fluorescence confocal microscopy.

A Surface Active Benzodiazepine Receptor Ligand for Potential Probing Membrane Order of $GABA_A$-Receptor Surroundings

Anahí V. Turina,[†] Benjamín Caruso,[†] Gloria I. Yranzo,[‡] Elizabeth L. Moyano,[‡] and María A. Perillo*[,†]

Biofísica-Química, Cátedra de Química Biológica, Departamento de Química, Facultad de Ciencias Exactas, Físicas y Naturales, and INFIQC-Departamento de Química Orgánica, Facultad de Ciencias Químicas, Universidad Nacional de Córdoba. Av. Vélez Sarsfield 1611, 5016 Córdoba, Argentina. Received April 28, 2008; Revised Manuscript Received July 17, 2008

A conjugable analogue of the benzodiazepine 5-(2-hydroxiphenyl)-7-nitro-benzo[*e*][1,4]diazepin-2(3*H*)-one N_1-substituted with an aliphatic chain (CNZ acyl derivative, CAd) was synthesized. CAd inhibited FNZ binding to $GABA_A$-R with an inhibition binding constant $K_i = 176$ nM and expanded a model membrane packed up to 13 mN/m when penetrating from the aqueous phase. CAd exhibited surface activity with a collapse pressure $\pi = 18.8$ mN/m and minimal molecular area $A_{min} = 49$ Å^2/molecule at the closest molecular packing, resulting in full and nonideal mixing with a phospholipid in a monolayer up to a molar fraction $x \cong 0.1$, decreasing its surface potential and contributing with a dipole that pointed its positive end toward the air and reoriented at the interface upon compression. These findings suggested that CAd could be stabilized at the membrane−water interface with its CNZ moiety stacked at the $GABA_A$-R while its acyl chain can be inserted into the membrane depth.

1. INTRODUCTION

The 1,4-benzodiazepin-2-ones (BZDs)[1] are drugs widely used as anxiolytics, hypnotics, and anticonvulsants. They act by enhancing the activity of the neurotransmitter γ-amino butyric acid (GABA) through an allosteric binding site at the integral membrane receptor $GABA_A$ ($GABA_A$-R) (*1*). This is a pentameric protein that acts as a ligand-gated chloride channel and is the site of action of a variety of pharmacologically important drugs including benzodiazepines (BZDs) (*2*).

Several nonspecific mechanisms are known to affect the conformation and activity of membrane-bound protein receptors, such as (i) the coupling between hydrophobic mismatch and curvature stress (*3*), (ii) changes in the lateral stresses profile (the depth-dependent distribution of lateral stresses within the membrane) which affect the conformation equilibrium and the activity of intrinsic proteins, the function of which involves a structural change accompanied by a depth-dependent variation in its cross-sectional area within the transmembrane domain (*4*), and (iii) the dipolar arrangement of the membrane which was shown to affect significantly the insertion, folding, conformation, and activity of membrane proteins (*5, 6*). With GABA-R as an example, studies on natural membranes support the hypothesis that the allosteric modulation of monoterpenes (*6, 7*) and detergents (*8*) on this receptor comprise effects caused by drug insertion or other sources of mechanical tension on the supramolecular organization of the receptor environment, through the mechanisms described above. Electrophysiological (*9*) and binding (*10*) experiments showed that the cholesterol content, a known buffering mechanism of membrane microsviscosity, affected the coupling between the binding sites for BZDs and the other drugs that interact with $GABA_A$-R. Moreover, temperature-induced variations in membrane microviscosity also modulated the ligand binding to $GABA_A$-R ((*11*) and refs therein).

Membrane microviscosity is considered the main modulatory mechanism of membrane protein function. Changes in this general membrane property are accompanied by modifications in the hydrophobic thickness or in the lateral pressure profile of bilayers, which, as stated above, are indirect ways of connecting the protein structure with its function (*12*−*17*). It is known that the plasma membrane of cells is substantially ordered (e.g., RBL-2H3 cells (*18*)). It exhibits a limiting anisotropy (0.225 ± 0.005) significantly higher than that observed in the fluid phase of liposome bilayers. This indicates that, on average, a considerable amount of order exists in plasma membrane (*19*). However, far from homogeneous, many types of experiments have shown that, at the mesoscopic level, the plasma membranes of cells are patchy and locally differentiated into domains of different degrees of molecular order, some of which arise through lipid−lipid interactions (*20*). For this reason, typical evaluation of microviscosity through the analysis of general anisotropy is not enough to understand the $GABA_A$-R sensitivity to membrane mechanical properties. The latter should include a scan of $GABA_A$-R closest membrane surroundings and may be achieved by the use of molecular probes that can remain close to the protein and, at the same time, allow the scanning of the local molecular organization within the membrane depth. Hence, we propose to use a probe bearing, at one end, a $GABA_A$-R ligand that will make the whole probe capable of stacking at the receptor and, at the other end, a hydrophobic tail with a fluorescent or spin label moiety covalently attached. The latter, once inserted in the membrane, would provide spectroscopic information about the molecular order within the membrane depth where it is located. This approach is based on similar studies on the nicotinic acetylcholine receptor (*21*). In our laboratory, we have tackled this challenge in two stages.

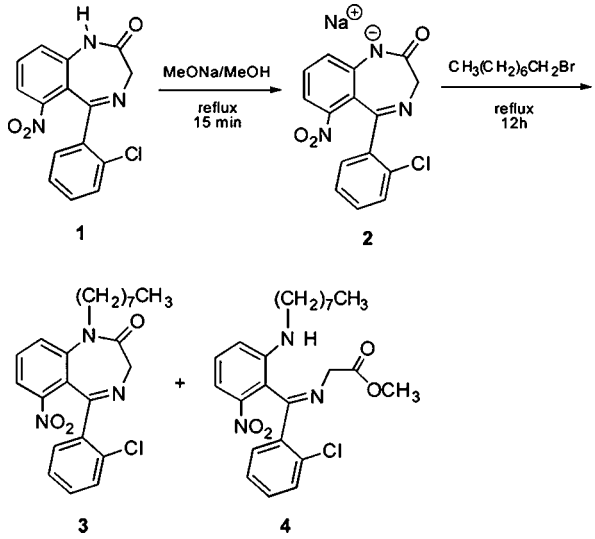
Scheme 1. Synthesis of the CNZ−Acyl Derivative (CAd)



The first stage, consisting of the synthesis of a surface active GABA$_A$-R ligand, will be followed by the addition of the sensing group in a second stage.

In the present paper, we describe the synthesis, the GABA$_A$-R binding kinetics, and the biophysical properties of a 5-(2-hydroxiphenyl)-7-nitro-benzo[*e*][1,4]diazepin-2(3*H*)-one (clonazepam, CNZ) substituted at the N_1 position with an aliphatic chain which was named CNZ acyl derivative (CAd). The ability of this compound to interact and stabilize at the membrane−water interface was studied in monomolecular layers at the air−water interface by the Wilhelmy plate method. Molecular parameters determined from surface pressure−area isotherms were used to predict not only the type of self-assembled structures that CAd would be able to form in aqueous dispersions, but also the molecular features that would contribute to enhancing the stability of this compound in the typical planar configuration that characterizes a membrane bilayer.

2. EXPERIMENTAL PROCEDURES

2.1. Materials. BZDs diazepam and clonazepam (DZ and CNZ) were kindly supplied by Products La Roche (Córdoba, Argentina). [^{3}H]-FNZ was purchased from New England Nuclear Chemistry (E.I. DuPont de Nemours & Co. Inc., Boston, MA). Dipalmitoylphosphatidylcholine was obtained from Avanti Polar Lipids (Alabaster, AL). Other drugs and solvents were of analytical grade. Merck silica gel 60 was used for filtration and Aldrich silica gel 60 F254 was used for preparative TLC.

2.2. Procedure for Preparation of CNZ Derivative. A methanolic solution of sodium methoxide (1.85 mmol/mL methanol) was added to a solution of CNZ (1.52 mmol) in 25 mL of anhydrous methanol as described in ref *22*. The mixture was refluxed for a period of 15 min. After this time, 2.26 mmol of 1-bromooctane was added and subsequently refluxed for 12 h. After cooling, methanol was evaporated and the crude was filtered using silica gel. This mixture was then purified by preparative TLC using hexane/ethyl acetate (80:20) and petroleum ether/ethyl acetate/ethanol (95:4:1) as eluents. The reaction yield was 50% compound **3** and 30% compound **4** as main products. These derivatives will be named CAd and MGd, respectively (see Scheme 1).

*5-(2-Chlorophenyl)-6-nitro-1-octyl-1,3-dihydro-2H-1,4-benzodiazepin-2-one (***3***, CAd).* ^{1}H NMR (200 MHz, CDl$_3$): δ 0.85 (t, J = 6.6 Hz, 3H), 1.24 (s, 10H), 1.60 (m, 2H), 4.31 (m, 2H), 4.37 (dd, J = 11 and 228 Hz, 2H), 7.30−7.50 (m, 4H), 7.55 (d, J = 9.1 Hz, 1H), 7.62−7.70 (m, 1H), 7.93 (d, J = 2.6 Hz, 1H), 8.35 (dd, J = 2.6 and 9.1 Hz, 1H). ^{13}C (50.33 MHz, CDCl$_3$): δ = 14.7, 23.2, 27.6, 29.1, 29.8, 29.8, 32.4, 48.2, 57.8, 123.2, 125.3, 126.6, 128.1, 131.0, 131.8, 132.4, 133.7, 137.8, 143.9, 147.8, 168.6, 169.2.

*Methyl-N-{(2-chlorophenyl)-[2-nitro-6-(octylamino)phenyl]-methylene}glycinate (***4***, MGd).* ^{1}H NMR (200 MHz, CDCl$_3$): δ 0.89 (t, J = 6.6 Hz, 3H), 1.30 (s, 10H), 1.84 (q, J = 7.3 Hz, 2H), 3.37 (m, 2H), 3.76 (s, 3H), 4.04 (q, J = 19 and 47 Hz, 2H), 6.72 (d, J = 9 Hz, 1H), 7.09−7.14 (m, 1H), 7.35−7.60 (m, 4H), 7.71 (d, J = 2.6 Hz, 1H), 8.11 (dd, J = 4 and 10 Hz), 11.08 (s, 1H). ^{13}C (50.33 MHz, CDCl$_3$): δ = 14.1, 22.6, 27.3, 29.2, 29.3, 31.8, 43.5, 51.9, 54.2, 110.4, 115.9, 127.6, 128.6, 129.8, 130.3, 131.4, 133.8, 135.1, 154.4, 170.2, 170.6.

2.3. NMR Spectroscopy. All starting materials were commercially available and solvents were distilled and dried before use. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker FT-200 (^{1}H at 200 MHz and ^{13}C at 50.33 Hz) spectrometer using CDCl$_3$. Chemical shifts are reported in parts per million (ppm) downfield from TMS.

2.4. Monolayer Studies. *2.4.1. Surface Pressure−Area and Surface Potential−Area Compression Isotherms.* Monomolecular layers were prepared and monitored essentially according to Perillo et al. (*23*). Experiments were performed at room temperature. The surface pressure (π, Wilhelmy plate method via a platinized-Pt plate), surface potential (ΔV, vibrating plate method), and the area enclosing the monolayer (A) were automatically measured with a Minitrough II (KSV, Helsinki, Finland). The Teflon trough used had 24 075 mm^2 total area. Bidistilled water (230 mL total volume) was used as subphase. Lipid monolayers were formed by spreading, on the air−water interface, between 30 and 80 μL of 1 mg/mL chloroform−methanol 2:1 of (a) the newly synthesized CNZ acyl derivative (CAd), (b) a pure saturated phospholipid (dipalmitoylphosphatidylcholine, dpPC), or (c) a binary mixture dpPC-CAd at a molar fraction (x) varying between 0 and 1. The $\pi-A$ and $\Delta V-A$ compression isotherms were recorded continuously, at a compression rate of 5 mm/min. Isotherms shown resulted from typical experiments repeated at least twice.

2.4.2. Compressional Modulus and Critical Packing Parameter Calculation. The compressional modulus (K) was calculated according to eq 1.

$$K = -(A_\pi)\left(\frac{\delta\pi}{\delta A}\right)_\pi \tag{1}$$

The critical packing parameter (P_C) was calculated according to the Israelachvili theory (*24*) by eq 2.

$$P_c = \frac{v}{a_0 \cdot l_c} \tag{2}$$

The average molecular area (a_0) was experimentally determined from $\pi-A$ isotherms, and optimal values for the hydrocarbon volume (v) and chain length (l_c) were calculated from eqs 3 and 4, according to Perillo et al. ((*23*) and refs therein):

$$v \cong (27.4 + 26.9n)n_{ch} \tag{3}$$

$$l_c \cong 1.5 + 1.265n \tag{4}$$

where n and n_{ch} are the number of methylene groups in the hydrocarbon chain and the number of chains per molecule, respectively. The molecular area (a_0) is a function of the interfacial free energy; hence, it was assigned the actual mean molecular areas (Mma) at specific values of surface pressure taken from the $\pi-A$ isotherm of each monolayer at the different compositions studied. P_c values for the binary dpPC-CAd mixtures were calculated from the weighted mean values of (v) and (l_c) of individual components.

2.4.3. Penetration of CAd in Monomolecular Layers of dpPC at the Air−Water Interface. The aim of this experiment was to determine the maximum value of π that allowed drug penetration in the monolayer (π_{cutoff}). These experiments were done in a circular Teflon trough (4.5 cm diameter and 0.5 cm depth). Between 5 and 30 μL of a chloroform−methanol 2:1 solution of phospholipid were spread on an aqueous surface (bidistilled water) and about 5 min were allowed for solvent evaporation. Monolayers were prepared at constant surface area but at different initial surface pressures (π_i). The temporal variation of π induced by the CAd penetration into the monolayer after the injection of an ethanolic solution of the derivative in the subphase was measured until reaching a plateau (π_{max}). The values of $\Delta\pi = \pi_{max} - \pi_i$ were plotted against π_i and a straight line was fitted to them. The π_{cutoff} was determined from the intersection of the regression line with the abscissa axis.

2.5. Synaptosomal Membrane Preparations. Synaptosomal membranes (SM) were obtained from bovine brain cerebral cortex. Meninges were eliminated, the cortex dissected, and the SM were purified essentially according to the method of Enna and Snyder, modified by Perillo and Arce (*25*), lyophilized and stored at −20 °C. Immediately before use, membranes were resuspended in 50 mM pH 7 Hepes buffer containing 100 mM NaCl at a final protein concentration of 0.25 mg/mL. This SM suspension was used as membrane receptor preparation and $GABA_A$-R source in the experiments that followed.

2.6. Competition Binding Experiments. The aim of this experiment was to assess the ability of the newly synthesized CAd to displace [^{3}H]-FNZ from its binding site at the $GABA_A$-R in SM.

Binding was performed essentially as described previously (*26*). The whole procedure was carried out at 4 °C. The incubation system contained, in a final volume of 230 μL, the SM suspension at a final protein concentration of 0.25 mg/mL, 3 nM (minimum specific activity 74.1 Ci/mmol) [^{3}H]-FNZ, 100 mM NaCl−50 mM Tris−HCl pH 7.4 buffer containing 9.4 μM DZ or 10 μM CAd (final concentrations). Samples were incubated at 4 °C in the dark for 1 h and then filtered through SS filters (Whatman GF/B type) with a Brandel automatic filtration apparatus (Brandel, Gaithersburg, MD). After filters were rinsed and dried in the air, they were placed in vials containing 2.5 mL of scintillation liquid (25% v/v Triton X-100, 0.3% w/v diphenyloxazole in toluene). The retained radioactivity was measured with a scintillation spectrometer Rackbeta 1214 (Pharmacia-LKB, Finland) at 60% efficiency for tritium. Specific binding (*B*) was calculated as the difference between total binding (TB) and nonspecific binding (NB) determined in the absence and in the presence of 9 nM DZ, respectively. Protein concentration was determined by the method of Lowry (*27*).

2.7. Statistical Analysis. Binding data were statistically analyzed using a two-tailed Student's *t*-test for independent samples. $p < 0.05$ was considered to be statistically significant. Regression analysis was done by the least-squares method (*28*).

3. RESULTS AND DISCUSSION

3.1. Synthesis of the Probe Precursor. The probe precursor (**3**, CAd) was synthesized from the sodium salt (**2**) of 5-(2-chlorophenyl)-7-nitro-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one (CNZ) (**1**) and 1-bromooctane (Scheme 1). The salt (**2**) was obtained by the treatment of CNZ with sodium methoxide according to the literature (*22*). The reaction of the BZD **1** and the bromoderivative was carried out *in situ* without isolation of the salt intermediate. The methyl *N*-methylene glycinate **4** (MGd) was also obtained in this reaction by the hydrolysis reaction of the benzodiazepinone ring in the presence of methanol. The formation of compound **4** could not be avoided even when the reaction times and temperatures were modified. Therefore, compound **3** was purified as described in section 2.2 (purity was higher than 95%). Detailed spectra are provided as Supporting Information.

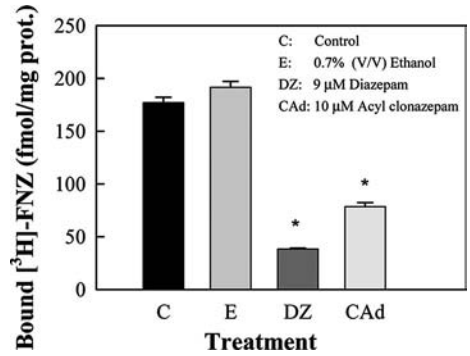


Figure 1. Displacement of the [^{3}H]-FNZ bound at synaptosomal membranes from bovine cortex induced by CAd and DZ at similar concentrations. The [^{3}H]-FNZ and protein concentration used were 3 nM and 0.25 mg prot/mL, respectively. Other details were described in the Experimental Procedures section. Data shown are the mean ± sem of triplicates. *, significantly different with respect to *E* ($p < 0.01$, Student's *t* test).

3.2. [^{3}H]-FNZ Displacement Experiments. The ability of CAd to displace [^{3}H]FNZ was evaluated by means of a radioreceptor binding assay. Results were analyzed in comparison with the well-known competitive inhibitor DZ. The results, depicted in Figure 1, show that DZ as well as CAd at similar concentrations (9 and 10 μM, respectively) were able to displace 80% and 59% of the total [^{3}H]FNZ bound to SM, respectively. According to the denifition given in the Experimental Procedures section, the 20% residual binding in the presence of 9 nM DZ corresponded to nonspecific binding. Furthermore, CAd at the concentration assayed left a 21% undisplaced binding over the nonspecific indicating a lower affinity for the $GABA_A$-R with respect to DZ.

Assuming that CAd induces a competitive inhibition of [^{3}H]FNZ binding, the inhibition binding constant (K_i) of this displacement agent can be calculated from eq 5 as follows:

$$B = \frac{B_{max} L}{K_d\left(1 + \frac{[I]}{K_i}\right) + L} \quad (5)$$

where L is the free radioligand concentration (3 nM), B and B_{max} are the specific activities of bound radioligand (expressed in moles per protein mass units) at L or at saturating radioligand concentration, respectively, and K_d is the dissociation binding constant of the radioligand−receptor interaction.

With B_{max} = 1404 fmol/mg protein and K_d = 2.28 nM for [^{3}H]FNZ binding to SM (*26*) and the experimental data shown in Figure 1, the K_i values for CAd were 176 nM. This value was similar to previously reported data (*29*) for other BZDs. This was a strong indication that the CNZ acyl derivative not only could interact with the BZD binding site at $GABA_A$-R, but also that it was bound with an affinity comparable with that of a typical BZD.

3.3. Monomolecular Layers at the Air−Water Interface. *3.3.1. Surface Pressure−Molecular Area Isotherms.* Surface pressure−area isotherms are shown in Figure 2. In Figure 2a, an isotherm of pure dpPC is shown as a reference. Dashed lines indicate the determination of the collapse pressure (π_c = 55.5 mN/m), the molecular area at the closest packing also known as minimal molecular area (A_{min} = 40 Å^2), and the transition surface pressure (π_T = 6 mN/m) corresponding to the bidimensional phase transition characteristic of dpPC.

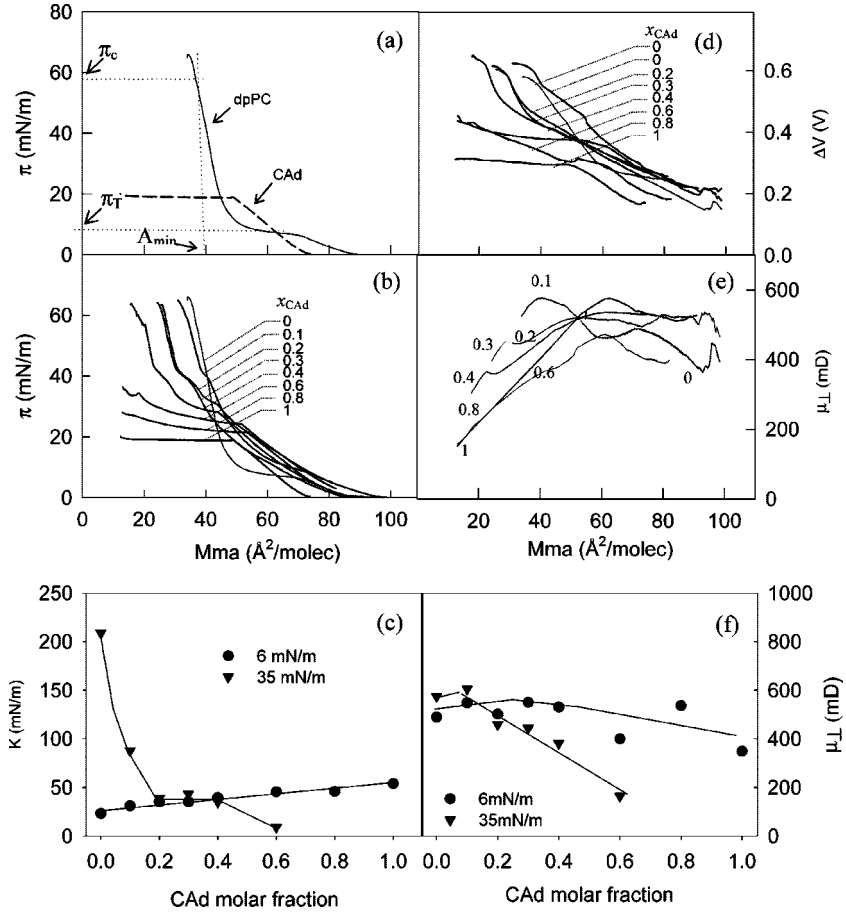

Figure 2. Behavior of dpPC/CAd binary mixtures at the air−water interface. (a) Collapse pressure (π_c), transition pressure (π_T), and minimal molecular area (A_{min}) determination exemplified over a dpPC $\pi-A$ compression isotherm. (b) Surface pressure−Mma isotherms of dpPC-CAd binary mixtures. (c) Compressional modulus at 6 and 35 mN/m, as a function of monolayer composition. (d) Surface potential−Mma and (e) $\mu_\perp$−Mma compression isotherms of dpPC-CAd binary mixtures. Dipole moments ($\mu_\perp$) calculated according to eq 6 from ΔV values taken from panel (d) depicted as a function of Mma (f) Resultant dipolar modulus at 6 and 35 mN/m, as a function of monolayer composition. Numbers in panel (e) indicate the CAd molar fraction.

CAd was able to form monomolecular layers at the air−water interface both alone (Figure 2a) as well as in mixtures with dpPC at various molar fractions (x) (Figure 2b). From the analysis of the $\pi-A$ compression isotherm of CAd (Figure 2a), a collapse pressure $\pi_c = 18.8$ mN/m and $A_{min} = 49$ Å^2 were determined and no bidimensional transitions were observed. In comparison with dpPC, CAd exhibited lower stability as reflected by its lower π_c value, which may be due to the shorter length of its hydrocarbon chain. This provides a low London dispersion energy stabilizing the aggregate, which is not enough to counterbalance the repulsive interactions between the polar head groups. This leads to an inefficient molecular packing explaining the fact that, in spite of having only one hydrocarbon chain and not two as in the case of dpPC, CAd exhibits a minimal molecular area substantially higher than that of the phospholipid.

The CAd/dpPC mixtures exhibited full miscibility up to $x_{CAd} \cong 0.1$. Above $x_{CAd} = 0.1$, mixtures showed several bidimensional reorganizations indicating the occurrence of partial collapse processes of different bidimensional phases (enriched in dpPC, within the range $0.1 < x_{CAd} < 0.4$, or in CAd, within the range $0.4 < x_{CAd} = 1$) coexisting in the monolayer. This indicated a partial miscibility of both components (Figure 2b). Further analysis was done through a phase diagram (see Figure 3 below).

The effect of the proportion of CAd in the mixtures with dpPC on the monolayer elasticity was analyzed through the compressibility modulus K (Figure 2c) in the conditions of full miscibility at all compositions (6 mN/m) or compositionally dependent miscibility (35 mN/m). At 6 mN/m, K increased continuously as a function of x_{CAd} reflecting both the higher coherence of CAd films with respect to the liquid expanded phase of dpPC (corresponding to $x_{CAd} = 0$) as well as full miscibility of both compounds at this lateral pressure. At 35 mN/m, K decreased as a function of x_{CAd} showing discontinuities that reinforced the different miscibility regimes exhibited by the phase diagram (miscibility of CAd in dpPC which is lost at $x_{CAd} \leq 0.1$) and suggested a partial miscibility of dpPC in a continuous CAd phase within the range $0.4 < x_{dpPC} < 0.6$).

3.3.2. Surface Electrostatics. The surface potential $\Delta V-$area isotherms (Figure 2d) showed that ΔV increased upon compression and decreased as a function of CAd in the mixtures. At the closest packing, $\Delta V_{dpPC} = 530$ mV and $\Delta V_{CAd} = 296$ mV, while the mixtures showed intermediate values. Surface potential is a measure of the electrostatic field gradient perpendicular to the membrane interface and thus varies considerably with the molecular surface density and with changes in orientation accompanying the monolayer compression. Taking the dielectric constant of the medium (water) as unity, the molecular dipole moment can be calculated according to eq 6

$$\Delta V = 12 \times \frac{\pi}{A} \mu_\perp + \psi_0 \qquad (6)$$

where $\pi = 3.1416$, A (molecular area), and V (surface potential) are expressed in Å^2.molecule^{-1} and mV, respectively, $\mu_\perp$ (expressed in Debye units, mD) is the apparent (resultant) perpendicular dipole moment of the molecule, and ψ_0 is the

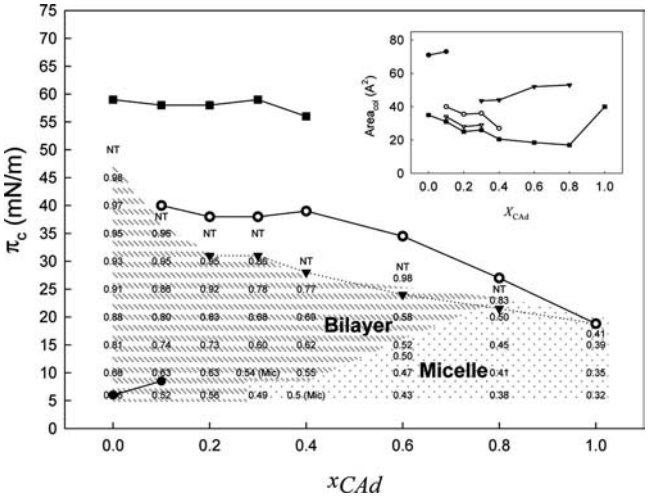

Figure 3. Surface pressure−composition phase diagram overlapped with critical packing parameter (P_c) for dpPC-CAd mixtures. Numbers on the graph refer to P_c values calculated for each mixture at the specified surface pressure. NT: no structure predicted in the theory ($P_c > 1$). The phase diagram ($\pi - x_{CAd}$) was constructed using π_c values (■), typical pure dpPC bidimensional phase transition pressure (●), and phase transitions pressures in the mixtures (▼ and ○), taken from Figure 2. The inset shows the Mma corresponding to those surface pressures at which bidimensional phase transitions and collapses occur, at each of the CAd molar fractions studied. (●) bidimensional phase transition characteristic of the pure dpPC, (○ and ▼) other bidimensional phase transitions observed in mixtures, and (■) Mma at the monolayer collapse point. Note that P_c values above the line joining the phase transition points, particularly in the range $0.2 < x_{CAd} < 0.4$, might be meaningless due to possible immiscibility.

electrostatic potential difference at the interface caused by the ionic double layer in ionized monolayers (for uncharged molecules $\psi_0 = 0$) (*23, 30*). The parameter $\mu_\perp$ contains different electrostatic contributions. In the case of uncharged molecules such as dpPC (a zwitterionic phospholipid) and CAd (uncharged at the pH assayed), main contributions arise from the resultant dipole moments of the monolayer components and those of the water hydration network (water molecules oriented at the polar headgroup). In turn, contributions from monolayer components include the polar headgroup and hydrocarbon chain contributions. An initial increase in the magnitude of $\mu_\perp$ was observed upon compression due to molecular reorientations at the surface (Figure 2e). Beyond a maximum, all $\mu_\perp$ vs Mma plots showed a decreasing trend which, in conjunction with the information taken from the π−Mma curves, can be interpreted as an indication of a monolayer compositional change due to instability occurring at high surface pressures. Figure 2f shows that, at π low enough to allow total mixing between dpPC and CAd, $\mu_\perp$ decreased upon an increase in x_{CAd}. At a high surface pressure (35 mN/m), (a) within the x_{CAd} range that allowed miscibility, $\mu_\perp$ was higher than at 6 mN/m, and (b) at $x_{CAd} > 0.1$, $\mu_\perp$ values exhibited a decreasing tendency even more noticeable than at 6 mN/m which, in this case, would be reflecting the partial collapse of the monolayer (see phase diagram in Figure 3).

3.3.3. dpPC-CAd Binary Mixtures: Phase Diagram and Prediction of Their Self-Assembling Structures in Water. From data shown in Figure 2b, the $\pi - x$ phase diagram was constructed (Figure 3). Lines in Figure 3 indicate the presence of $\pi - x$ states at which phase transitions occur and delimit regions of single bidimensional phases that may coexist with an already collapsed phase. A single monolayer phase can be found at low pressures within the whole compositional range. This monolayer shows a π_T that varies continuously with x_{CAd} (triangles joint by a dotted line). This π_T might be associated either with a bidimensional phase transition or with a partial collapse of the monolayer. The second hypothesis is supported by the shape inspection of $\pi - A$ isotherms at the high x_{CAd} (e.g., above 0.6) which suggests that after a collapse point monolayers go through overcompression states. At higher pressures, another partial collapse is observed at a π_c that remains invariant up to $x_{CAd} = 0.4$ and then, at $x_{CAd} > 0.4$, it decreases continuously with x_{CAd} (hollow circles) up to the point where π_c equaled the π_c value of pure CAd. Hence, CAd seems totally miscible in dpPC up to $x_{CAd} = 0.1$, exhibiting a bidimensional phase transition between 6 and 8 mN/m. Within the x_{CAd} range 0.1−0.2, the solubility of CAd in dpPC would be reached. This is based on the fact that, upon compression, the collapse pressure of mixtures with $0.1 < x_{CAd} < 0.2$ decreased from 39 to 37 mN/m, while at $0.1 < x_{CAd} < 0.4$, the π_c value remained constant at $\pi_c = 37$ mN/m. Within this compositional range, there was a remaining monolayer that would be composed of a dpPC excess as indicated by a third collapse point which had the typical value of 55 mN/m. The interfacial stability of mixtures with $x_{CAd} < 0.4$ decreased continuously as a function of the x_{CAd} as indicated by the decreasing π_c. Moreover, within this compositional range, after the monolayer collapsed no excess of dpPC remained stable at the air−water interface.

Critical packing parameter values (P_c) allow the prediction of the type of self-assembling structures that would be formed when an amphipathic substance is dispersed in water. P_c values for the binary dpPC-CAd mixtures were calculated by eqs 2, 3, and 4 using values of mean molecular area which were taken from the isotherms shown in Figure 2b. Those P_c values were superimposed on the phase diagram (Figure 3). $P_c < 0.5$ predicts the self-assembling into micelles, $0.5 < P_c < 1$ predicts the self-association into bilayer phases which would lead to the formation of vesicles, and $P_c > 1$ would correspond to phases with negative curvature. Although the latter are not predicted in Israelachvili's theory, those phases are compatible with inverted vesicles, as well as with hexagonal II and cubic phases (*23, 31*). According to this interpretation in Figure 3, within the region located at the bottom-left corner of the $\pi - x_{CAd}$ phase space (at low x_{CAd} and π), the resulting P_c values were compatible with the formation of bilayers. At the bottom-right corner (high x_{CAd} and low π), P_c values predicted the formation of micelles. At the top of the $\pi - x_{CAd}$ phase space, in the region located above a line crossing the plane approximately along the diagonal from 45 mN/m at $x_{CAd} = 0$ through 28 mN/m at $x_{CAd} = 0.4$ to 18.8 at $x_{CAd} = 1$, P_c values were all above 1. In conditions of total miscibility, this may be interpreted as an indication of a tendency to form negative curvature phases when the mixture is dispersed in water. However, within regions of the phase diagram where components are partially miscible with one another, these calculated P_c values become meaningless. Hence, to obtain stable planar membranes at a π compatible with the equilibrium surface pressure of biomembranes (near 30−35 mN/m) the molar faction of CAd should not be higher than 0.2.

The analysis of the variation of the Mma (mean molecular area) or the $\Delta V.A$ (surface potential per unit of molecular surface density) with the mole fraction (x_{CAd}) at constant packing conditions ($\pi = 6$, 18.5, or 35 mN/m) is shown in Figure 4. Straight dotted lines joined the values corresponding to the molecular parameters of pure dpPC and pure CAd. Experimental points lying on this line would represent either ideal mixing or immiscibility behavior of components in the monolayer. The compositional dependence or independence, respectively, of the collapse pressure might help to discriminate between both behaviors. At 6 mN/m, Mma (Figure 4a) as well as $\Delta V.A$ (Figure 4b) decreased as a function of x_{CAd}. At this lateral pressure, these parameters showed positive deviations from ideality, suggesting repulsive interactions or other steric restrictions to

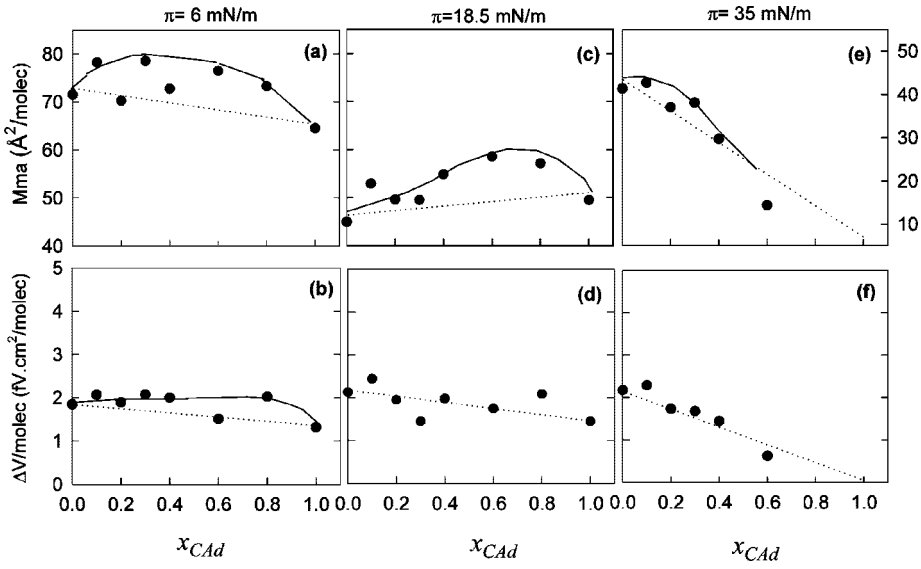

Figure 4. Mean molecular area (a, c, and e) and surface potential per unit of molecular surface density (b, d, and f) vs composition plots at constant surface pressures. $\pi = 6$ (a,b), 18.5 (c,d), or 35 mN/m (e,f). Straight lines represent the behavior expected for ideal mixing or complete segregation of the components. Deviations from this behavior, particularly at 6 mN/m, are more clearly reflected in Mma$-x$ plots.

the ideal molecular packing between the monolayer components. While the expansion observed in Mma was very important, in the case of $\Delta V.A$ the expansion was less significant. These results indicate that the permanence of CAd at high proportions in the monolayer at low π disrupts the organization of the phospholipids (Mma is highly expanded) without acquiring a coherent organization (changes in $\Delta V.A$ were small). A similar behavior was in the Mma$-x_{CAd}$ plot at 18.5 mN/m (surface pressure higher but still within the miscibility region according to the phase diagram); however, no deviation from ideality was observed in $\Delta V.A$ (Figure 4c,d). At 35 mN/m, the monolayer phase exists up to $x_{CAd} = 0.6$ and at higher proportions of CAd a discontinuity was shown in Mma (there are no data at these π and x_{CAd}, as shown in Figure 2b). Hence, at 35 mN/m, Mma and $\Delta V.A$ vs x_{CAd} plots decreased up to the ordinate axis and reach zero. Negligible x_{CAd}-dependent expansions were observed with respect to the ideality line not only in $\Delta V.A$ but also in Mma (Figure 4e,f). Either ideal mixing or total immiscibility may have exhibited this behavior. The inspection of the phase diagram suggested immiscibility within the range $0.2 < x_{CAd} < 0.4$ and partial miscibility within $0.4 < x_{CAd} < 0.6$ due to the compositional constancy and dependency of π_c, respectively. Contrary to what happened within $0 < x_{CAd} < 0.1$, where we found CAd solubility in dpPC, the latter should be ascribed to dpPC mixed within a continuous CAd phase. Beyond $x_{CAd} = 0.6$, this miscibility continued with π_c decreasing up to 18.8 mN/m at $x_{CAd} = 1$.

3.3.4. CAd Penetration in Phospholipid Monolayers. The ability of CAd to penetrate in the monomolecular layers of dpPC from the aqueous subphase was evidenced by the π increase at constant area at different initial surface pressures up to a $\pi_{cutoff} = 13.08 \pm 4.6$ mN/m. This value was determined by extrapolating the plot of $\Delta\pi$ versus π_i to $\Delta\pi = 0$ (Figure 5). On the other hand, the smooth variation of the monolayer compressibility (K) with the x_{CAd} also showed that CAd was stable in the film at low molecular packings (low π). Above 13 mN/m, not only did CAd not penetrate in the film from the subphase ($\Delta\pi = 0$), but also K at high π (Figure 2c) suffered a discontinuous variation with x_{CAd} at $x_{CAd} > 0.2$. Taken together, these results suggest that it was not possible to stabilize high amounts of CAd in highly packed monolayers independently of the direction from which the drug got access to the model membrane. However, small amounts of CAd can remain in the monolayer

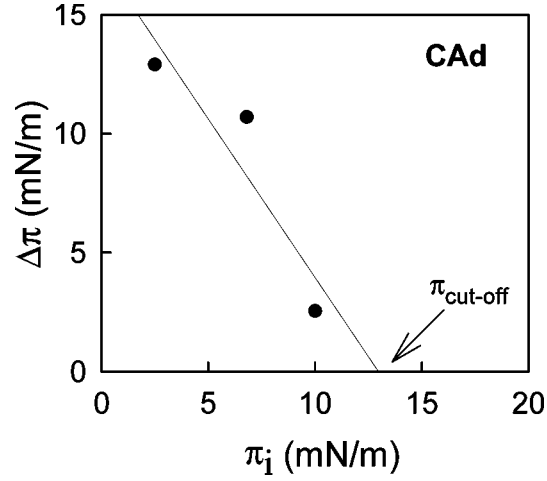

Figure 5. Penetration of CAd in monomolecular layers of dpPC at different initial molecular packings. The line represents the fitness of a straight line to the experimental points by regression analysis by the least-squares method. The π_{cutoff} value, indicated by the arrow, represents the maximum π allowing drug penetration and monolayer deformation. The regression line is defined by the equation $\Delta\pi = a + b \times \pi_i$, where a is the ordinate (17 ± 4 mN/m) and b the slope (-1.3 ± 0.6 mN/m). At $\Delta\pi = 0$, π_i equals the $\pi_{cutoff} = 13.08 \pm 4.6$ mN/m.

at lateral surface pressures compatible with the equilibrium pressure of bilayers—ca. 30−35 mN/m (*32*)—as shown in the phase diagram (Figure 3) as well as by the resultant dipolar contributions at $x_{CAd} < 0.2$ (Figure 2f).

CAd was unstable at intermediate x_{CAd} (0.2−0.4) leading to immiscibility behavior with dpPC, which at high x_{CAd} (>0.4) became a phase inversion with dpPC partially miscible in a continuous CAd phase. This interpretation was strongly suggested by the linear $A-x_{CAd}$ and $\Delta V.A-x_{CAd}$ plots (Figure 4e,f) in conjunction with π_c independence (within $0.2 < x_{CAd} < 0.4$) or dependence (within $0.4 < x_{CAd} \leq 1$) on x_{CAd}, respectively (Figure 3).

4. CONCLUSIONS

The CAd synthesized in the present work was an amphipathic CNZ derivative capable of binding at the BZD site of the GABA$_A$-R by means of its hydrophilic end and anchoring in a

biomembrane through the hydrophobic end represented by a hydrocarbon chain attached at the N_1 position. The design of the BZD derivate was supported by theoretical studies about the BZD structure−activity relationship where high-affinity analogues interacted with three $GABA_A$-R electrophilic groups located at C_7, C_2, and the iminic nitrogen N_4. It is known that the N_4 interaction is facilitated by the presence of halogens in C_2 and when the phenyl ring is rotated in the greater coplanarity direction between the phenyl and the plane $C'1 - C5 = N4$ (*33*). Consequently, some chemical alteration in the N_1 position was not expected to affect (at least chemically) the BZD capacity to interact with the receptor binding site, and our results confirmed this hypothesis.

Molecular parameters as well as conditions for self-assembly in water determined for CAd were summarized in Table 1 together with those of dpPC, which was taken as a reference.

CAd as a Precursor to Obtain a Probe to Evaluate the Molecular Organization of Synaptosomal Membranes, In the Vicinity of $GABA_A$-R. The present findings suggested that CAd could be stabilized at the membrane−water interface with its CNZ moiety stacked at the $GABA_A$-R, while its methylene end inserted within the membrane depth may be useful for sensing the molecular order in the receptor surroundings provided a hydrophobic label is attached to it. Hence, such a chemical modification would make CAd a suitable molecular probe. The longer the hydrocarbon chain attached at N_1 position of CNZ, the deeper the membrane regions that could be sensed would be. It is important to recall that a probe should provide information about the system properties without affecting them. That is why they are used at proportions sufficiently low (e.g., 0.5 mol % representing a $x_{probe} = 0.005$). Our results indicate that this condition would be satisfied with CAd in bilayers which have an equilibrium surface pressure centered at 35 mN/m (*32*).

CAd as a Precursor of an Affinity-Based Purification System for $GABA_A$-R. Both the surface activity of CAd and its ability to interact with the BZD binding site at $GABA_A$-R are equally important characteristics that would make CAd an appropriate molecule to develop an affinity-based precipitation method to purify $GABA_A$-R based on CAd coated microparticles. The latter may be proposed as a useful substitute of traditional inmunoprecipitation procedures to avoid the requirement of monoclonal antibodies against specific epitopes of $GABA_A$-R subunits (*34*).

ACKNOWLEDGMENT

The present work was partially financed by grants from CONICET, SECyT-Universidad Nacional de Córdoba and ANPCyT from Argentina. B.C. is a Ph.D. student of the Doctorado en Ciencias Biológicas of the Universidad Nacional de Córdoba. Bacterial RNase P RNA Is a Drug Target for Aminoglycoside−Arginine Conjugates

Alexander Berchanski and Aviva Lapidot*

Department of Organic Chemistry, The Weizmann Institute of Science, Rehovot 76100, Israel. Received May 14, 2008; Revised Manuscript Received July 29, 2008

The ribonuclease P (RNase P) holoenzymes are RNPs composed of RNase P RNA (PRNA) and a variable number of P protein subunits. Primary differences in structure and function between bacterial and eukaryotic RNase P and its indispensability for cell viability make the bacterial enzyme an attractive drug target. On the basis of our previous studies, aminoglycoside−arginine conjugates (AACs) bind to HIV-1 TAR and Rev responsive element (RRE) RNAs significantly more efficiently than neomycin B. Their specific inhibition of bacterial rRNA as well as the findings that the hexa-arginine neomycin derivative (NeoR6) is 500-fold more potent than neomycin B in inhibiting bacterial RNase P, led us to explore the structure−function relationships of AACs in comparison to a new set of aminoglycoside−polyarginine conjugates (APACs). We here present predicted binding modes of AACs and APACs to PRNA. We used a multistep docking approach comprising rigid docking full scans and final refinement of the obtained complexes. Our docking results suggest three possible mechanisms of RNase P inhibition by AACs and APACs: competition with the P protein and pre-tRNA on binding to P1−P4 multihelix junction and to J19/4 region (probably including displacement of Mg^{2+} ions from the P4 helix) of PRNA; competition with Mg^{2+} ions near the P15 loop; and competition with the P protein and/or pre-tRNA near the P15 helix and interfering with interactions between the P protein and pre-tRNA at this region. The APACs revealed about 10-fold lower intermolecular energy than AACs, indicating stronger interactions of APACs than AACs with PRNA.

INTRODUCTION

The complexity and diversity of RNA structures offer targets for small molecule ligands to be used as pharmacological agents (*1*). Ribonucleoprotein complexes (RNPs) are ubiquitous and essential components of all cells and appealing targets for new drugs due to their diverse functional roles in various cellular processes (*2, 3*). The ribonuclease P (RNase P) holoenzymes are RNPs composed of RNase P RNA (PRNA) and a variable number of P protein subunits: at least 1, 4, and 9 in Bacteria, Archaea and Eukarya, respectively (*4, 5*). Fundamental differences in structure and function between bacterial and eukaryotic RNase P and its indispensability for cell viability make the bacterial enzyme an attractive drug target candidate (*6*−*10*). Bacterial RNase P is composed of one RNA (∼400 nucleotides) and one small P protein (∼120 amino acids). Although the PRNA can catalyze the pre-tRNA-processing reaction *in vitro* in the absence of P protein at high salt concentrations (*11*), the P protein significantly influences multiple aspects of catalysis and is required for function *in vivo* (*12*). P protein plays a central role in RNase P function: it interacts with the 5′ leader of pre-tRNA substrates, leading to enhanced affinity for substrates (*13, 14*). In addition, P protein increases metal ion affinity (*15*) and pre-tRNA cleavage rate constants (*16*). Cross-linking studies have suggested that the central cleft of the P protein interacts with pre-tRNA 5′ leaders of at least 4 nucleotides in length, which locates the protein in close proximity to the active site (*14*). Crystal structures (*13, 17*) and the NMR structures (*18*) of P proteins reveal a remarkably similar overall topology for P proteins from different bacteria. It was suggested that three regions of the P protein interact with the RNA: the RNR motif, the central cleft, and the metal binding loop. The RNR motif is a highly basic region (K52 to R68, *Bacillus subtilis*) abundantly conserved among all bacterial P proteins, suggesting that this region is functionally important (*19*−*21*). Therefore, inhibition of bacterial RNase P activity could be accomplished with a compound that either interacts directly with the catalytic core in the PRNA or disrupts RNP interactions essential for the assembly of a functional RNase P holoenzyme.

Aminoglycosides (e.g., neomycin, neamine, paromomycin, and gentamicin) are small, polycationic molecules. These compounds are used clinically as antibacterial agents because of their ability to specifically bind prokaryotic rRNA and to inhibit bacterial protein synthesis (*22*). It has become apparent that aminoglycosides as well as their derivatives bind mRNAs (*23*), tRNAs (*24*), viral RNAs (*25*−*27*), and catalytic (*28, 29*) RNAs and that the binding of these ligands could alter the function of the RNA target. Aminoglycosides also interact with two essential elements of the human immunodeficiency virus type 1 (HIV-1) genome, Rev responsive element (RRE) and the transactivation responsive element (TAR) (*26*). Lapidot and co-workers have shown that arginine−aminoglycoside conjugates (AACs, Figure 1) are significantly more efficient anti-HIV-1 agents than aminoglycosides, as these conjugates comprise the RNA binding ability of aminoglycosides and the specific binding of arginine moieties to HIV-1 TAR and RRE RNAs (*30*−*36*). Significantly, AACs specifically inhibit bacterial rRNA (*37*). For example, the binding constants (K_D) of hexa-arginine neomycin B (NeoR6) for TAR and RRE RNAs were 5 and 23 nM, respectively (*35*). AACs (especially NeoR6) inhibit the binding of *trans*-activator protein (Tat) to various RNAs by mimicking the conserved binding arginine/lysine-rich motif of the Tat protein (*35*). Thus, we here propose that AACs, with their multiple arginine moieties, could also mimic the conserved arginine/lysine residues in the RNR motif of the bacterial RNase P protein and disrupt bacterial RNase P

holoenzyme assembly. Already in their report regarding the high potency of NeoR6 and triarginine−gentamicin C conjugate (R3G), Gopalan and Lapidot (*7*) showed that AACs act as potent and selective peptidomimetics that could prevent RNP assembly. For example, NeoR6 revealed nearly 500-fold higher potency than neomycin B in inhibiting bacterial RNase P (*7*).

Peptides carrying an arginine-rich sequence of Tat and a nona-D-arginine peptide, bind TAR RNA with high affinity and specificity (e.g. ref *38* and *39*). Arginine-rich peptides comprise a common motif of RNA recognition by proteins (*39*). Although the dominant contributions of the arginine side-chains may differ between complexes, the ability of the arginine side chains to be involved in electrostatic interactions, hydrogen bond formation, and stacking interactions makes arginine an important moiety for RNA recognition (*39*). Attempts to mimic the arginine-rich peptides led to the development of novel RNA ligands (e.g., tetra-arginine kanamycin (R4K) and R3G (*30*), and NeoR6 (*32*). Recently, we synthesized a novel set of poly arginine (hexa- and nona-arginines) aminoglycoside conjugates (APACs, Figure 1). Their anti-HIV-1 activities revealed high potency for the hexa-D-arginine-neomycin conjugate (Neo-r6), nona-D-arginine-neomycin conjugate (Neo-r9), and nona-D-arginine-neamine conjugate (Neam-r9) (*40, 41*). Thus, we anticipate that, as well as NeoR6, ParomoR5, and NeoR5, they may also bind PRNA (and other RNAs) and inhibit RNase P activity.

Westhof and co-workers (*42, 43*) succeeded in making an RNase P model with the aid of computer programs and data from physical−chemical experiments on the P protein (*44*). Their RNA model is in good agreement with most of the crystallography results (*45, 46*) including the core of the catalytic site. Thus, we, as well as Fierke and co-workers (*47*), utilize the whole modeled PRNA molecule for further investigation. This approach avoids complications introduced by unresolved regions and the effects of crystal packing contacts (*47*). These advances in our understanding of RNase P provide insight into the interface between the RNA and protein worlds. The development of many drugs (e.g., HIV-1 protease inhibitors) was heavily influenced by or based on structure-based design and screening strategies (*48*). Computational methodologies have become a crucial component of many drug discovery programs (*48*).

The main aim of our present study is predicting the binding modes of AACs and APACs to PRNA. The model presented by Westhof, Gopalan, and co-workers (*43*) was utilized in this study for docking AACs and APACs. We used a multistep docking approach (Figure 2) containing (i) geometric, geometric-electrostatic, and geometric-hydrophobic docking full scans by MolFit; (ii) intersecting of the lists of predictions from geometric-electrostatic-hydrophobic docking scans for identify-

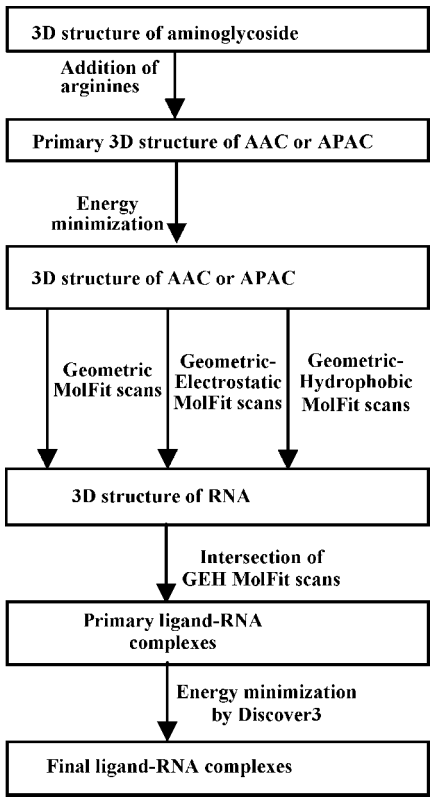

Figure 2. Schematic representation of the molecular modeling and multistep docking procedure followed in this study.

ing putative geometrically and chemically suitable binding sites; and (iii) final refinement of the obtained complexes by Discover3.

Several preferred AACs and APACs binding positions were highlighted by this approach. On the basis of these models, we here propose that AACs and APACs can inhibit RNase P activity by (i) interacting with the P protein/pre-tRNA binding site of PRNA; (ii) competing with the P protein for binding PRNA; and/or by (iii) displacing Mg^{2+} ions near the PRNA P15 loop leading to interference with RNase P catalysis. This molecular docking approach may be useful in drug design.

EXPERIMENTAL PROCEDURES

AACs and APACs. The synthesis, purification, and analysis of the following compounds NeoR6, ParomoR5, R3G, hexa-D-arginine-neomycin conjugate (Neo-r6), nona-D-arginine-neomycin conjugate (Neo-r9), and nona-D-arginine-neamine conjugate (Neam-r9) (biologically stable enantiomers) (Figure 1) were previously described (*30*−*36*, *41*).

General Procedure of Docking. We docked aminoglycosides and their arginine conjugates as well as RNase P protein to the three-dimensional (3D) model structure of the PRNA. A multistep docking procedure was used: exhaustive rotation−translation docking scans by MolFit, followed by intersecting lists of predictions and flexible ligand docking by Discover3 (Figure 2). We used the model coordinates of bacterial RNase P holoenzyme of *B. subtilis* described by Westhof and coworkers (*43*). This RNA−protein complex consists of RNA component (nucleotides 4−395), pre-tRNA molecule (includes nucleotides −9 to 72), and P protein. Molecular docking was performed with free PRNA (without P protein and pre-tRNA).

Models of NeoR6, ParomoR5, NeoR5, Neo-r9, and Neo-r6 were constructed by addition of arginines to neomycin B (its 3D coordinates were taken from PDB entry 1qd3 (*49*)) using the Biopolymer module of InsightII. We used the first NMR structure (out of 17) from 1qd3. Neam-r9 was built by trimming aminoglycoside rings III and IV of the Neo-r9 model. All these modeled structures were solvated in water and energy minimized (Figure 2). In general, all the energy minimizations in this study were performed for molecules immersed in a layer of 5 Å of water until the maximum derivative was less than 0.001 using the Discover 3 module of InsightII (Accelrys, Inc., San Diego, CA, USA) and the CVFF force field.

Full Rigid-Body Docking of Ligands to PRNA. AACs (NeoR6, NeoR5, and ParomoR5), APACs (Neo-r9, Neo-r6, and Neam-r9), neomycin B (PDB entry 1qd3 (*49*)), and P protein were docked to PRNA using the program MolFit (*50*). MolFit treats the molecules as rigid bodies. They are represented by 3D grids in which each grid point carries information concerning its position with respect to the surface/interior of the molecule. The surface grid points carry chemical information such as the electrostatic potential or the hydrophobicity of the surface. MolFit performs an exhaustive scan of the relative rotations and translations of the molecules and produces a list of models. Since PRNA consists of many negative charges, while AACs and APACs are highly positively charged compounds, at first we performed full geometric-electrostatic scans (*51*) of these ligands against PRNA. The electrostatic potential of each molecule was calculated using the program Delphi as implemented in the InsightII package. Each full docking scan tested 8760 relative orientations (angular grid interval of 12°), and for each orientation, one best scoring solution was saved. These solutions were further sorted by their geometric-electrostatic complementarity score.

Geometric, geometric-hydrophobic (*50*), and geometric-electrostatic docking scans were performed for all ligands. Geometric-electrostatic-hydrophobic (GEH) complementarity scores were obtained by intersecting the lists of predictions from geometric, geometric-electrostatic, and geometric-hydrophobic docking scans, as described previously (*50*) (Figure 2). The nearly correct solutions are likely to be included in each of the three lists, that is, in a subset of common solutions. For this subset of solutions, it is possible to combine the geometric, electrostatic, and hydrophobic scores to obtain a combined geometric-electrostatic-hydrophobic score, $S_{geo+elec+hydro} = S_{geo} + e \cdot S_{elec} + h \cdot S_{hydro}$, where S_{elec} is the difference between the geometric-electrostatic and the geometric scores, and S_{hydro} is the difference between the geometric-hydrophobic and geometric scores for a given solution. The combination of electrostatic and hydrophobic complementarity with geometric complementarity improves the docking results for complexes of proteins. This improvement is due, in some cases, to the higher combined score for the nearly correct solution. Some of the improvement in rank is also due to the elimination of false solutions, which are found in only one of the 3 lists (geometric, geometric-electrostatic, or geometric-hydrophobic) and are eliminated in the intersection process (*50*).

Flexible Docking of Ligands to PRNA. The top-ranked GEH MolFit scan solutions were used for input to the flexible ligand docking performed by the program Discover3 (Figure 2). We added the hydrogens to PRNA by using the Biopolymer module of InsightII. The PRNA was immersed in a layer of 5 Å of water and energy minimized in complex with each ligand represented by its top-ranked GEH MolFit scan solution using the Discover 3 module of InsightII. We tested several possible binding sites of each ligand to PRNA formed by GEH MolFit clusters. The intermolecular energy of the finally refined complexes was measured by the Docking module of InsightII

according to maximal radii of ligands. The best models were selected by the lowest intermolecular energy.

RESULTS

Rationale. The increased (i) affinity of AACs to HIV-1 TAR and RRE (*35*), and (ii) potency in disrupting RNP interactions and inhibiting bacterial RNase P, compared to aminoglycosides (*7*), led us to hypothesize that NeoR6 and other structurally similar AACs and APACs may inhibit RNase P activity by interacting with PRNA. Therefore, our main objective was deciphering the structure−function relationships of the two families of aminoglycoside−arginine conjugates (AACs and APACs) in the context of their interactions with PRNA, with the aim of developing effective novel antimicrobial drugs. A structural model proposed for *Bacillus subtilis* holoenzyme−substrate complex (*43*) was employed. The predicted binding sites of AACs and APACs to several regions of PRNA obtained by docking as well as their interference with the holoenzyme−pre-tRNA interaction for the cleavage process of pre-tRNA are described below.

Rigid-Body Docking of P Protein, APACs, and AACs to PRNA. We assume that AACs and APACs structurally mimic arginine/lysine-rich P protein (*19*−*21*) and may disrupt the formation of the RNase P holoenzyme complex by preventing binding of the P protein to the RNA moiety. Thus, the most potent compounds of AACs and APACs were docked to the naked PRNA molecular model. Geometric, geometric-hydrophobic, and geometric-electrostatic docking scans were performed for P protein, APACs, and AACs to PRNA using the program MolFit (see Experimental Procedures and Figure 2). Each predicted MolFit solution is a plausible position of ligand on PRNA. Since geometric-electrostatic docking does not always suggest the nearly correct solution at the first ranked position, the intersection of the lists of predictions from geometric, geometric-electrostatic, and geometric-hydrophobic docking scans was also performed according to a procedure previously described (*50*). The use of this procedure (i) improves the rank of solutions, which not only have good electrostatic contacts with macromolecule but also increase the significance of geometric and hydrophobic contacts (in case they exist); (ii) drastically reduces the number of putative solutions; and (iii) forms clusters. After intersecting GEH MolFit scans of several top-ranked solutions for each cluster, optimal matches with PRNA are obtained, which are very useful for following analysis and final refinement.

We docked the P protein to PRNA (GEH MolFit scans with intersection of the results). We obtained a cluster of putative MolFit solutions (which includes the top ranked ones) exactly at the site that was predicted by Westhof and co-workers (*43*) and confirmed by Fierke and co-workers (*47*) (Figure 3 B). Our top ranked solution was slightly rotated relative to the predicted position of the P protein within the RNase P holoenzyme structure (*43*) since the P protein consists of many arginines and lysines, not only at the RNR motif but also at other regions.

(a) Docking of APACs. The geometric-electrostatic docking scans of APACs (Neo-r9, Neam-r9, and Neo-r6) revealed two very large clusters and several smaller ones (Figure 3 C, E and G). The 60 top ranked solutions were within these two clusters. The first cluster was situated at the region of PRNA (P4, P3, P2, and J19/4, Figure 3 C); this region interacts with P protein and pre-tRNA (*43*, *47*). The second cluster was located proximal to the PRNA P15 helix. The intersection of the lists of predictions from GEH MolFit docking scans drastically reduced the number of putative solutions (from 8760 to 32 for Neo-r9 and from 8760 to 43 for Neam-r9). The first ranked solutions of Neo-r9, Neam-r9, and Neo-r6 were within cluster 1 (PRNA region of P4, P3, P2, and J19/4; Figure 3 D, F, and H). This PRNA region contacts RNR and neighboring motifs of P protein and pre-tRNA (*43*, *47*). Therefore, our suggestion, that APACs structurally mimic an RNR motif of the P protein, is supported. Cluster 2 (proximal to P15), which also consists of several high ranked docking solutions, must also be considered for a binding site.

(b) Docking of AACs. The full geometric-electrostatic docking scans of AACs (NeoR6, ParomoR5, NeoR5, and R3G) and neomycin B (Figure 4A, C, E, G, and I) revealed more disperse patterns (there are many more clusters of the putative solutions) than for APACs; however, cluster 1 at the region P4, P3, P2, J19/4, and cluster 2 near P15, which include the 10−20 high ranked solutions, are also present for NeoR6, ParomoR5, and NeoR5 (but not for neomycin B and R3G), similar to that for APACs (Figure 3). The intersection of the lists of predictions from GEH MolFit docking scans reduced the number of putative solutions, but not as markedly as for the APACs (Figure 4B, D, F, H, and J). The first ranked solution of all AACs is within cluster 1 (PRNA region P4, P3, P2, and J19/4). Cluster 2 (near P15) also consists of several high ranked solutions. In contrast to APACs, there are many additional clusters for AACs. In general, these clusters that are not situated near PRNA regions P4, P3, P2, and J19/4 or P15 helices consist of solutions with lower MolFit GEH scores. Therfore, the preference of AACs to bind PRNA at the regions P4, P3, P2, and J19/4 or P15 is significantly weaker than that of APACs. The pattern of neomycin B binding is even more disperse than for the arginine conjugates, suggesting lower binding specificity (Figure 4B). The top ranked MolFit solutions of neomycin B are not at P4, P3, P2, and J19/4 or P15 helices, and it is difficult to prefer one cluster over the others.

Refinement of APACs−PRNA Complexes. The best-scoring representatives of several predicted MolFit clusters were used for final the refinement by Discover3 (see Experimental Procedures and Figure 2). The PRNA and ligands were immersed in water, and the complex was energy minimized. Therefore, both PRNA and ligand were hydrated and flexible. The nucleotides of PRNA regions that were distant from a ligand were fixed. The ranges of intermolecular docked energies (kcal/mol) measured according to maximal radii of the ligands for Neo-r9−PRNA complexes are from −15283 to −14386 at cluster 1, from −14441 to −12645 at cluster 2, and from −13211 to −12354 at other clusters (Table 1). Similar values were found for Neam-r9−PRNA complexes from −15897 to −13988, −14331 to −12645, and −13047 to −12211, respectively. The average values of intermolecular docked energies for Neo-r9−PRNA and Neam-r9−PRNA complexes at cluster 1 are almost the same (Table 1). To determine the PRNA nucleotides that interact with the P protein and pre-tRNA, we calculated the distances between the P protein or pre-tRNA and the PRNA atoms in the RNase P holoenzyme−pre-tRNA complex (*43*). The distances between all docked ligands and PRNA were also calculated. We took into consideration intermolecular distances within 4 Å between heavy atoms. The results of comparisons between binding sites of our docked ligands and those of P protein and pre-tRNA are summarized in Tables 2 and 3. The Neo-r9−PRNA complex with the lowest energy (−15283 kcal/mol) refers to the PRNA region, which binds protein P and pre-tRNA (P2, P3, P4, J18/2, and J19/4) (Figure 5A and B, and Table 2). The best Neam-r9−PRNA complex is situated exactly at this site with some different contacts. All arginine residues of Neo-r9 and Neam-r9 have electrostatic interactions with the PRNA nucleotides. Already, the MolFit scans highlighted that rings I and II of Neo-r9 neomycin core have more contacts with PRNA in comparison to rings III and IV (Figure 1). The final refinement by Discover 3 strengthens this observation. Our results reveal similar ranges

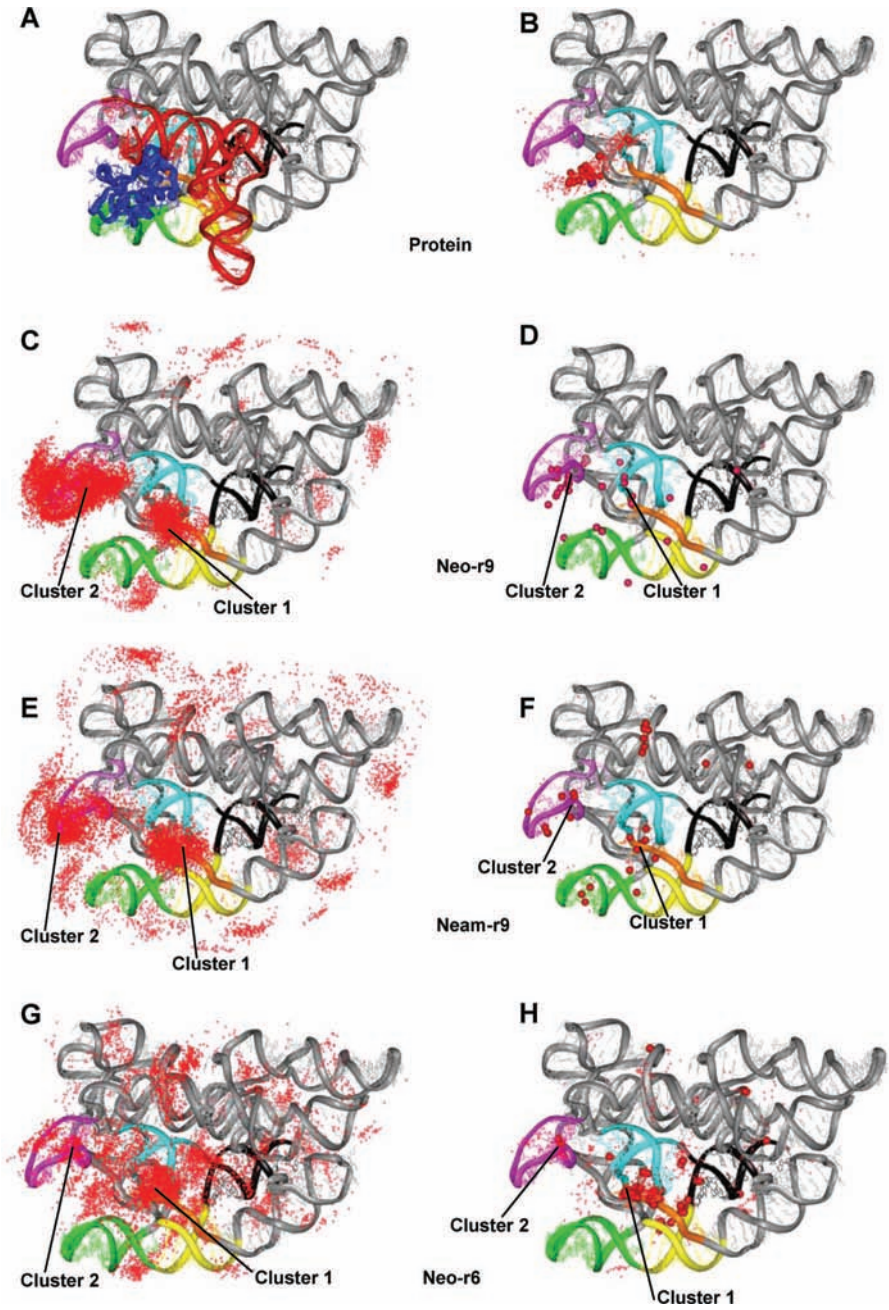

Figure 3. (A) Structural model of *B. subtilis* RNase P holoenzyme−pre-tRNA complex (*43*). The PRNA is shown as a ribbon. The important PRNA regions for interactions with pre-tRNA or P protein (according to Westhof and co-workers (*43*) and Fierke and co-workers (*47*)) are colored: P1 (black), P2 (yellow), P3 (green), P4 (cyan), and J19/4 (orange). P15 is colored magenta. P protein (dark blue) and pre-tRNA (red) are shown as ribbons. The colors and representation of PRNA, PRNA regions, pre-tRNA, and P protein are the same in Figures 4 and 5. (B) Results of P protein-PRNA GEH MolFit scans with intersection of the prediction lists. Each solution is the plausible position of ligand on PRNA, represented by the center of ligand mass (colored red). The top ranked solutions are shown in CPK representation. The colors and representation of MolFit solutions are the same for all ligands in this figure and Figure 4. (C−H) Results of MolFit geometric-electrostatic scans (C, E, and G) and GEH MolFit scans with intersection of the prediction lists (D, F, and H) for APACs (Neo-r9, Neam-r9, and Neo - r6, respectively).

of intermolecular energy for Neo-r9 and Neam-r9 (Table 1), which may be due to the fact that the number of contacts for common neomycin and neamine rings (I and II) is approximately equivalent.

The refined complexes between Neo-r9 (Figure 5D) or Neam-r9 with PRNA near the P15 region (cluster 2) reveal ranges of intermolecular energy similar to those of cluster 1 representatives. The complexes between Neo-r9 or Neam-r9 with PRNA had significantly higher interaction energy within clusters other than 1 and 2, indicating that the interactions of these ligands at other sites are less favorable than with the P2, P3, P4, J18/2, and J19/4 or P15. Therefore, all the docking results point that Neo-r9 and Neam-r9 bind PRNA preferably at the protein/pre-tRNA binding site (or at P15) than at the other possible sites.

Refinement of AACs−PRNA complexes. The ranges of intermolecular docked energies (kcal/mol) for NeoR6−PRNA complexes were from −1457 to −1403 at cluster 1, from −1427 to −1358 at cluster 2, and from −1394 to −1179 at the other clusters (Table 1). The ranges of these values for complexes of ParomoR5 and NeoR5 with PRNA were relatively similar. Figure 5C depicts the NeoR6−PRNA complex with the lowest energy (−1457 kcal/mol). For all three AACs, NeoR6, ParomoR5, and NeoR5, as well as for APACs, the complex with the lowest energy was derived from cluster 1 (P2, P3, P4, J18/

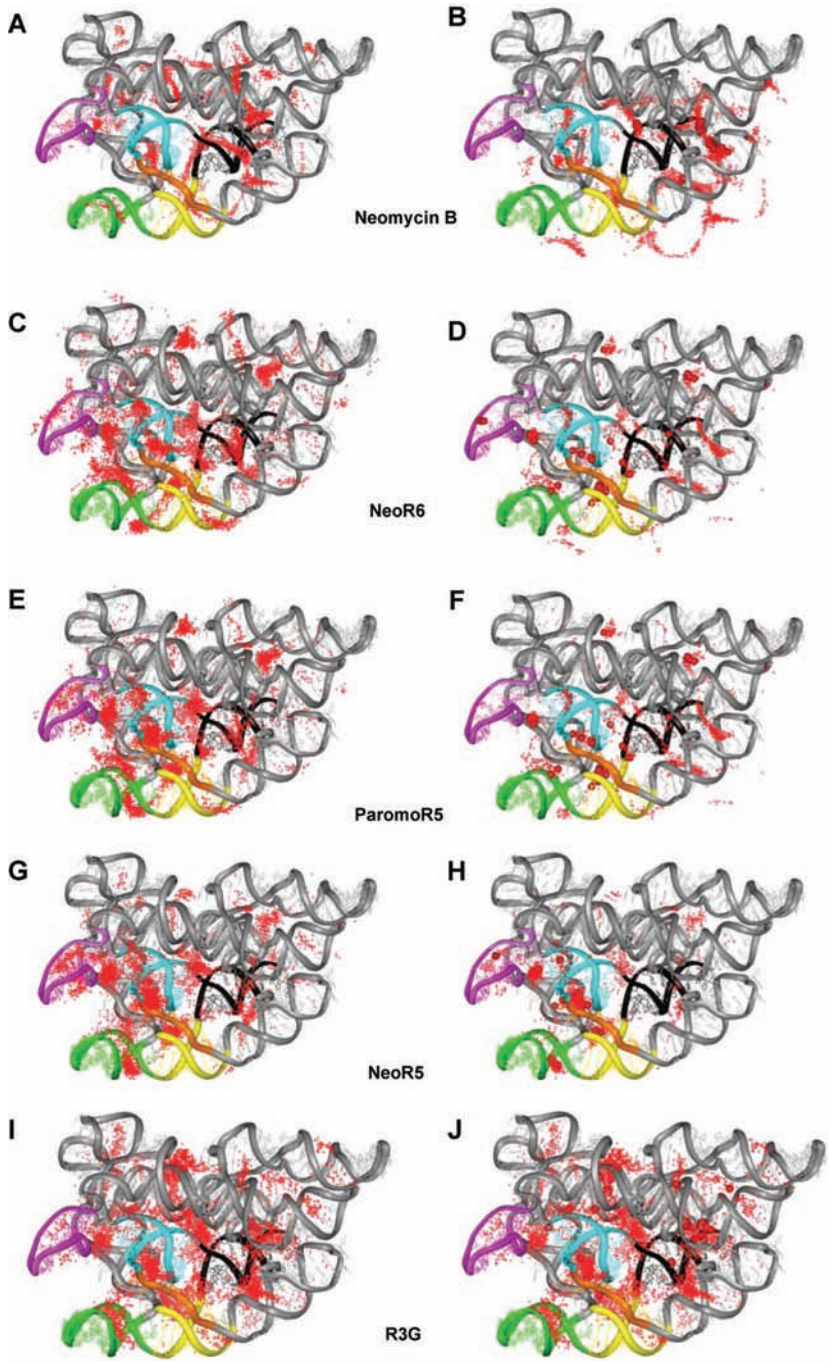

Figure 4. Results of MolFit geometric-electrostatic scans (A, C, E, and G) and GEH MolFit scans with intersection of the prediction lists (B, D, F, and H) for neomycin B and AACs (NeoR6, ParomoR5, and NeoR5, respectively). The colors and representation of PRNA and MolFit solutions are as described in Figure 3.

DISCUSSION

Validation of the RNase P Holoenzyme Model. A previously published model of the PRNA from the PRNA−protein−pre-tRNA complex, based on biochemical, phylogenetic, and biophysical studies (*43*), was employed in this study. In addition, data obtained from a recent RNase P holoenzyme model (*47*) were also considered. The constructed model of PRNA by Westhof and co-workers (*43*) from the RNase P holoenzyme−substrate complex (Figure 3A) of *B. subtilis* was significantly modified without drastically altering the overall architecture of their previous model of the PRNA (*42*), especially the positioning of various highly conserved nucleotides proximal to the cleavage site. Moreover, the resulting enzyme−substrate complex model is in excellent agreement with various biochemical and biophysical studies (*43*).

The recent findings regarding detailed distance constraints within the holoenzyme−substrate complex (*47*) are also in accordance with the complex of Westhof/Gopalan and co-workers (*43*). These groups (*43*, *47*) applied a large amount of data from previous biochemical investigations of RNase P structure in solution to construct their models. Although Fierke and co-workers (*47*) claim that the biochemical model differs in details from recently published crystal structures of PRNA, the topology and relative orientations of PRNA helices of interest for our docking study (P1−P4) are similar. Fierke and co-workers (*47*) mapped their affinity cleavage data from *B. subtilis* RNase P onto the crystal structure of PRNA from *B. stearothermophilus* (*47*) and compared the relevant parts (P1−P4, J18/2, and J19/4) of these two RNA structures. This comparison suggests that, within the resolution of their model (∼10 Å), the structural model and crystal structure yield comparable results. The final model of Fierke and co-workers (*47*) is generally in accordance with the RNase P holoenzyme−substrate complex (*43*), and it is consistent with all their cleavage results, except those observed in P19.

Interference of AACs and APACs with the Binding of P Protein and/or Pre-tRNA to the PRNA P1−P4 Region. It has been proposed that the PRNA catalytic domain recognizes the pre-tRNA acceptor stem, cleavage site, and the conserved CCA sequence on the 3 end of the pre-tRNA (*52*). Furthermore, Pan and co-workers demonstrated that the PRNA specificity domain interacts with the T-stem loop of pre-tRNA (*53*). RNase P needs Mg^{2+} ions for many functions including folding, substrate binding, and catalysis (*15*). The Mg^{2+} ions binding sites have not yet been clearly defined, although several sites,

including positions in helix P4, have been implicated in metal binding (*54*). It was suggested that Mg^{2+} ion specifically binds to a site in helix P4, at the same region of PRNA that cross-links to the P protein, and where the putative catalytic site of the enzyme is located (*47*). It was reported that the formation of the P1−P4 multihelix junction is dependent on a cluster of metal ions and that this structure contributes to catalysis (*55*). Further corroboration for metal binding in P4 comes from NMR studies that demonstrate specific Mg^{2+} binding sites in a stem-loop that serves as a model for the P4 helix (*56*). The experimental data (*47, 57*) and structural holoenzyme models placing the P protein near PRNA helix P4 suggest that the P protein could stabilize the PRNA structure to enhance the affinity of one or more metal ions binding to helix P4 and to facilitate catalysis (*47*). Therefore, the P1−P4 multihelix junction and J19/4 are the most important regions for catalytic activity of PRNA because both P protein and pre-tRNA bind to this region. Our docking studies reveal that cluster 1 of geometric-electrostatic and intersection of GEH MolFit predictions lists for all tested AACs and APACs is situated near the P1−P4 multihelix junction and J19/4 region (Figures 3−4). Cluster 1 consists of the top ranked solutions, including the first one, indicating that all tested AACs and APACs prefer binding to this region and compete with the P protein and/or pre-tRNA. Moreover, the final refined complexes with lowest energy are also derived from this cluster (Tables 1 and 2).

Interference of AACs and APACs with RNase P Activity near P15. It was reported that inhibition of *E. coli* PRNA by neomycin B was partially attributed to its capability to displace Mg^{2+} ions from P15 loop (L15); this inference was based on the moderately decreased susceptibility of P15 loop mutants to inhibition by neomycin B (*28*). P15 loop in the bacterial PRNA plays a role in substrate recognition, cleavage site selection, and metal ion binding (*58*). Biochemical data support that P15 loop is an autonomous metal (Mg^{2+}) ion-binding domain (*59*). Our results reported here suggest that AACs can inhibit RNase P primarily by binding to P4, J18/2, and J19/4 (near the protein/pre-tRNA binding); although AACs can also interfere with RNase P function by binding to P15, all our docking results (rigid body docking by MolFit and final refinement by Discover3) show consistent preference of AACs to bind P4, J18/2, and J19/4 somewhat stronger than to P15, and binding to both of these sites is much stronger than that to all other tested putative sites (other clusters). The pattern of APACs binding is generally similar to that of AACs, but with stronger preference to interact with the protein/pre-tRNA binding site (P3, P4, J18/2, P2, J19/4). Although recent findings (*10*) suggest that NeoR5 could inhibit wild-type *E. coli* RNase P holoenzyme by binding to the P15 loop, the *E. coli* RNase P ΔL15/P16/P17 mutant must offer an alternative binding site for NeoR5 that still permits its interference with RNase P function.

Our docking results suggest that AACs and APACs may also competitively interfere with the interactions between PRNA and pre-tRNA (and/or P protein) near the helix P15 (Figure 5).

The holoenzyme preference for binding pre-tRNA over mature tRNA by *B. subtilis* RNase P holoenzyme suggests the formation of a direct contact between the pre-tRNA 5′ leader and P protein in the holoenzyme (*14*). This interaction is confirmed by photo-crosslinking and affinity cleavage studies demonstrating that the 5′ leader of pre-tRNA is in close proximity to the central cleft, but not to the RNR motif or metal binding loop of the P protein (*47*). Time-resolved fluorescence resonance energy transfer studies show that the 5′ leader contacts the P protein in *B. subtilis* RNase P holoenzyme (*60*). Thus, it was suggested (*47*) that interactions between the P protein and pre-tRNAs contribute to the uniformity of the binding affinity for RNase P for pre-tRNAs. According to our docking results AACs and APACs can interact with PRNA at the region of P15 and therefore interrupt interactions between P protein and pre-tRNA at this region (Figure 5 and Table 3).

Structure−activity Relationships of AACs in Comparison to APACs. The structure−function relationship of AACs and APACs with respect to RNA binding is important for their development as possible drugs. Previously, we designed and synthesized a set of different conjugates of neomycin B, paromomycin, neamine, and gentamicin with different numbers (1−6) of arginines (*31−34*). We also reported the ability of AACs to inhibit RNA translation in direct relation to the number of arginine groups linked to the aminoglycoside backbone and on the nature of the aminoglycoside (*37*). The strong interaction between the α-amino of the arginine moiety of NeoR6 and the TAR RNA phosphate group was a modeling prediction, which was experimentally supported (*30, 31*). Indeed, the affinity of tetra-γ-guanidinobutyrate kanamycin A derivative (GB4K), lacking an α-amino acid group in the linker, to TAR RNA was very low compared to that of the tetra-arginine derivative, R4K (*30, 31*). Also, the anti-HIV activity of GB4K in cell culture (*61*) and antiequine infectious anemia virus (EIAV) activity in equine dermal fibroblasts (ED) (*31*) were very low. Thus, all of the above may explain the very low antiviral activities and affinity of GB4K and other guanidino conjugates for HIV-1 TAR RNA (*30*) and for HIV-1 RRE RNA (e.g., ref *62*). Neomycin B that binds RRE IIB with the highest affinity (K_D of 1.18 μM (*63*)) among the aminoglycosides is about 240 times weaker than NeoR6 and 6−7 times weaker than monoarginine derivative (NeoR1) (*35*). These results indicate that even one arginine conjugated to neomycin B already significantly increases its binding affinity to HIV-1 regulatory RNAs. Other aminoglycoside conjugates, e.g., guanylated aminoglycosides (e.g., ref *62*), bind TAR or RRE RNAs much weaker than AACs. Similarly, their anti-HIV-1 activities are much lower than the respective AACs (*31−34*). Thus, the recent finding (*10*) of low inhibition of RNase P catalytic activity

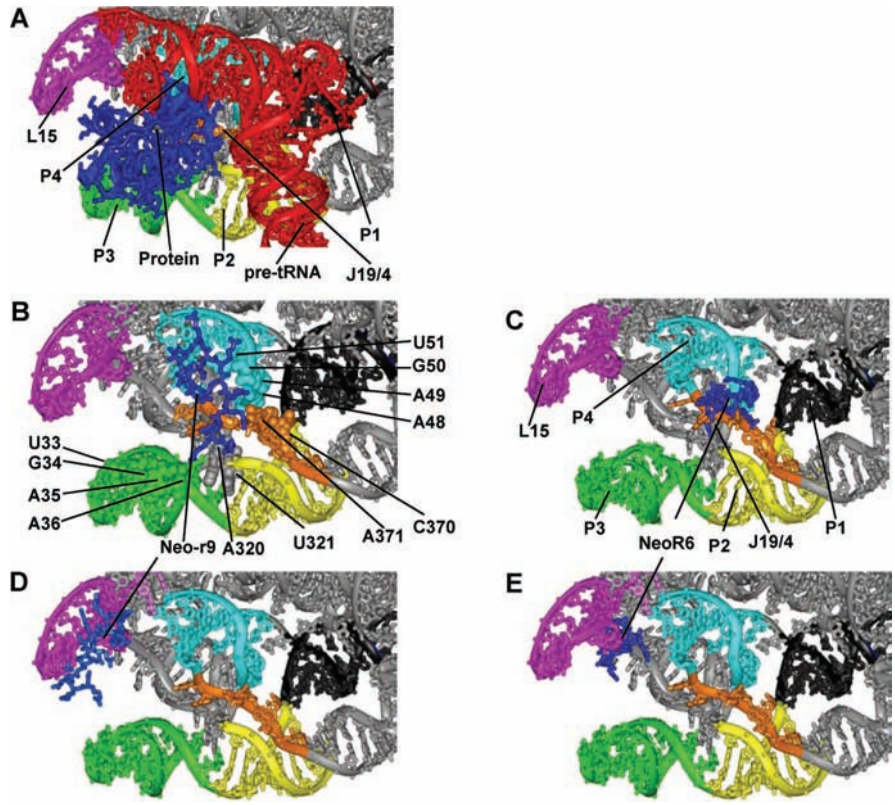

Figure 5. (A) Extended view of the catalytic domain of the structural model of *B. subtilis* RNase P holoenzyme−pre-tRNA complex (*43*). (B) Final Neo-r9−PRNA complex near the P1−P4 multihelix junction. (C) Final NeoR6−PRNA complex near the P1−P4 multihelix junction. (D) Final Neo-r9−PRNA complex near the P15 helix. by guanidino conjugates of neomycin (hexa-guanidinium−neomycin B conjugate) in comparison to that of arginines conjugated to neomycin (e.g., NeoR5 and NeoR6), supporting our previous reports, is not surprising. To determine the importance of the number of arginines conjugated to neomycin B, we compared anti-RNase P activities of NeoR1 with NeoR6 to free neomycin B. The findings that *E. coli* RNase P activity is inhibited with IC_{50} values of 60 μM (*28*), 4 μM, and 125 nM (*7*) by neomycin B, NeoR1, and NeoR6, respectively (Table 4), suggest that the number of conjugated arginine residues to neomycin B is important. Of note, using RNase P of *Neisseria gonorrheae* revealed the specifically high potency of NeoR6 (IC_{50} of 1 nM), (Table 4). The differences in IC_{50} observed for the two bacterial RNase P holoenzymes indicate the susceptibility of this inhibitor. Thus, NeoR6 is a more efficient inhibitor against RNase P of *Neisseria gonorrheae*. In accordance with our previous results, NeoR6 does not inhibit eukaryotic translation initiation, indicating its ability to discriminate between the eukaryotic and the bacterial translational machinery (*37*). Similarly, NeoR6 inhibits bacterial RNase P activity significantly (about 10-fold) more effectively than human RNase P activity (*7*). The sphere-like NeoR6−PRNA binding conformer reveals different structure in comparison to the extended structure of Neo-r9, Neam-r9, and Neo-r6 in complex with PRNA, as depicted in Figure 5. The APACs revealed about 10-fold lower intermolecular energy than AACs, indicating stronger interactions of APACs than AACs with PRNA (Table 1). Interestingly, no significant differences in intermolecular energy between Neo-r9 and Neam-r9 complexes with PRNA were found. The docking results point to the fact that only rings I and II of the neomycin core of Neo-r9 interact with PRNA, similar to neamine rings I and II of Neam-r9.

Additional studies are needed to correlate our docking results of AACs and APACs to their inhibition of bacterial RNase P activity. Our preliminary results regarding antimicrobial activity of AACs and APACs against a variety of Gram-positive and Gram-negative bacterial strains, including clinical and gentamicin-resistant isolates, indicate that most of these compounds are active, but not the free nona-D-arginine (*64*).

CONCLUSIONS

Our docking results suggest three possible mechanisms of action of AAC and APAC inhibition of RNase P: (i) the most likely mechanism of RNase P inhibition is AAC and APAC competition with the P protein and pre-tRNA on the P1−P4 multihelix junction and J19/4 region (probably including displacement of Mg^{2+} ions from P4 helix); (ii) competition with Mg^{2+} ions near the P15 loop; and (iii) competition with the P protein and/or pre-tRNA near the P15 helix and interference with interactions between the P protein and pre-tRNA at this region are also considered.

Structure−function relationships of the molecules described above with respect to PRNA binding is important for further drug design. Indeed, while the free neomycin B showed very low anti-RNase P activity (IC_{50} 60 μM (*28*)), already one arginine conjugated to neomycin B revealed much stronger activity (~15-fold) and was extremely better when 6 arginines conjugated to each amino group of neomycin−NeoR6 (~500-fold) (*7*). Notably, guanidinium or lysyl conjugates of neomycin showed significantly weaker potency against RNase P (*10*) in comparison to that of AACs (*7*). Our rigid-body docking results suggest that the binding pattern of aminoglycoside conjugates with short arginine peptide chains (APACs) to the P protein/pre-tRNA binding site (P1−P4 and J19/4) and near the P15 loop is generally similar to that of the sphere-like AACs (e.g., NeoR6). Importantly, APACs prefer to interact with the P protein/pre-tRNA binding site (Figures 3 and 4). The ranges of

intermolecular energy of APACs (after refinement) are about 10-fold lower than those of AACs, especially at the P protein/pre-tRNA binding site (Table 1), indicating stronger interactions of APACs than AACs with PRNA. Thus, the novel compounds, APACs, can be predicted as more potent RNase P inhibitors than AACs, by preventing P protein binding with PRNA (probably including displacement of Mg^{2+} ions from P4 helix). AACs interact with these two PRNA binding sites approximately with comparable potency. The competition of AACs with Mg^{2+} ions near the P15 loop is also important, almost as competition with P protein binding on PRNA. The ranges of intermolecular energy of AACs and APACs are considerably better than those of neomycin B (Table 1). Thus, arginines conjugated to aminoglycosides extremely improved their interaction with PRNA. All of the above designate that the affinity of a ligand for a target PRNA can be enhanced synergistically by fusing two different functionalities capable of RNA-binding (i.e., aminoglycosides and arginine-rich peptides). Our docking approach described in this article, in combination with RNase P holoenzyme models of Westhof and co-workers (*43*) and Fierke and co-workers (*47*), may be used for predicting the binding modes of AACs and APACs in different specific sites of PRNA and for ligand interference with RNase P activity. This approach also can be extended for the future design of new molecules.

ACKNOWLEDGMENT

We thank Dr. G. Borkow and Dr. M. Eisenstein for critical remarks and discussions. The docking program MolFit was downloaded from http://www.weizmann.ac.il/Chemical_Research_Support/molfit.

Cellular Uptake and Intracellular Pathways of PLL-g-PEG-DNA Nanoparticles

Tessa Lühmann,[†,‡] Markus Rimann,[†,‡] Anne Greet Bittermann,[§] and Heike Hall*[,‡]

Department of Materials, ETH Zurich, Zurich, Switzerland, and ZMB, Center for Microscopy and Image Analysis, University of Zurich, Switzerland. Received May 20, 2008; Revised Manuscript Received July 23, 2008

Polycationic molecules form condensates with DNA and are used for gene therapy as an alternative to viral vectors. As clinical efficacy corresponds to cellular uptake, intracellular stability of the condensates, and bioavailability of the DNA, it is crucial to analyze uptake mechanisms and trafficking pathways. Here, a detailed study of uptake, stability, and localization of PLL-g-PEG-DNA nanoparticles within COS-7 cells is presented, using FACS analysis to assess the involvement of different uptake mechanisms, colocalization studies with markers indicative for different endocytotic pathways, and immunofluorescence staining to analyze colocalization with intracellular compartments. PLL-g-PEG-DNA nanoparticles were internalized in an energy-dependent manner after 2 h and accumulated in the perinuclear region after >6 h. The nanoparticles were found to be stable within the cytoplasm for at least 24 h and did not colocalize with the endosomal pathway. Nanoparticle uptake was ~50% inhibited by genistein, an inhibitor of the caveolae-mediated pathway. However, genistein did not inhibit gene expression, and PLL-g-PEG-DNA nanoparticles were not colocalized with caveolin-1 indicating that caveolae-mediated endocytosis is not decisive for DNA delivery. Clathrin-mediated endocytosis and macropinocytosis pathways were reduced by 17 and 24%, respectively, in the presence of the respective inhibitors. When cells were transfected in the presence of double and triple inhibitors, transfection efficiencies were increasingly reduced by 40 and 70%, respectively; however, no differences were found between the different uptake mechanisms. These findings suggest that PLL-g-PEG-DNA nanoparticles enter by several pathways and might therefore be an efficient and versatile tool to deliver therapeutic DNA.

INTRODUCTION

Gene therapy has gained a lot of attention for the treatment of chronic diseases, cancer, and genetic disorders (*1*−*4*). It is also considered as a valuable alternative for conventional protein therapy since it overcomes inherent problems that are associated with the administration of protein drugs in terms of bioavailability, systemic toxicity, *in vivo* clearance rate, and manufacturing costs (*2, 4, 5*). For this reason, safe and efficient delivery systems for therapeutic DNA are developed. Polycationic substances such as poly-L-lysine (PLL), poly-L-ornithine, or polyethylenimine (PEI) alone or as graft- and copolymers with different amounts of poly(ethylene glycol) (PEG) have been shown to form complexes with DNA and are widely used as an attractive alternative to viral vectors in gene therapy (*2, 6*−*11*). However, not only the DNA-delivery vehicle itself but also cellular uptake, intracellular stability, and bioavailability of the therapeutic DNA within the cell are crucial for clinical relevance. Therefore, uptake mechanisms of DNA-containing vehicles and trafficking pathways within the cells were analyzed (*3, 12*−*14*). Unfortunately, (nano)-particle uptake and intracellular pathways seem to be dependent on the analyzed cell type (*15*) as well as on the particular size, shape, charge, and chemistry of the delivery vehicle (*16, 17*). Especially, when certain cell types or specific uptake pathways are targeted, the uptake mechanism(s) and intracellular pathways need to be analyzed carefully (*1, 3, 4, 17*). Therefore, rational design of PLL-g-PEG-DNA nanoparticles might benefit from the knowledge raised about the uptake pathways involved and the release mechanisms of therapeutic DNA in order to optimize their performance.

The analysis of gene delivery vehicles is still a complex challenge, as endocytosis may involve several pathways (*3, 18*−*21*). The first barrier is to overcome the plasma membrane, followed by cytoplasmatic pathways prior to DNA delivery into the nucleus where gene expression takes place. So far, five major uptake mechanisms are distinguished (*14, 18, 21, 22*) including phagocytosis that is performed only by specialized cells such as macrophages, neutrophils, or monocytes to eliminate debris and pathogens. In this study, four pinocytotic pathways are studied to assess cellular uptake and intracellular pathway(s) of PLL-g-PEG-DNA nanoparticles: (i) macropinocytosis that is stimulated by growth factors or phorbol esters, which cause actin-driven formation of membrane ruffles that fuse with the plasma membrane forming large endocytotic vesicles known as macropinosomes (*14, 23*). They either fuse with lysosomes or are recycled back to the cell surface. Large particles up to 1−5 μm in diameter can be internalized by macropinocytosis (*14, 22*). (ii) Clathrin-mediated endocytosis is a process involving specific receptors that recognize and internalize cargo (*24*). Ligand-bound receptors are internalized via clathrin-coated vesicles involving GTPase activity and are transformed to early endosomes. Receptor−ligand complexes are separated by low pH generated by vacuolar proton ATPases (*25*). The ligands are transferred into late endosomes for potential degradation in lysosomes, whereas the receptors are recycled and transported back to the plasma membrane (*19*). (iii) Caveolae-mediated endocytosis is characterized by the evolution of caveolae, which

are associated with caveolin-1/caveolin-2 (or caveolin-3 in the muscle) (*26*). Caveolae derive from subdomains of sphingolipid- and cholesterol-rich cell membrane fractions called lipid rafts (*27*). Caveolae are considered to be static organelles, whose internalization is induced by specific ligands such as simian virus-40 (SV40) or cholera toxin (*18, 28, 29*). After internalization, those ligands are either transferred into caveosomes having neutral pH that translocate to the endoplasmic reticulum or the Golgi complex (*30*) or they enter the endosomal pathway (*31*). (iv) This pathway is described as clathrin- and caveolae-independent, transporting cargo to the GPI-anchored protein-enriched early endosomal compartment (GEEC) and ending in the Golgi complex or in recycling endosomes (*18*). Glycosylphophatidylinositol-anchored proteins (GPI-AP) can be internalized via 40−50 nm lipid rafts (*18*). But regulatory mechanisms for this pathway are still unknown.

A recent report from our group showed evidence that PLL-g-PEG-DNA nanoparticles are a promising tool for effective transport and delivery of therapeutic DNA as they show long-term stability, a hydrodynamic diameter of 80−90 nm, and high transfection efficiency at a N/P ratio 3.125 of ∼40% combined with low cytotoxicity (>95% of cell viability) in COS-7 cells (*11*). In order to understand the uptake mechanism(s) and intracellular pathway(s) of PLL-g-PEG-DNA nanoparticles, PLL-g-PEG and plasmid DNA were differentially fluorescently labeled, and uptake into COS-7 cells was determined by uptake-inhibition analysis. Furthermore, transfected COS-7 cells were analyzed after different time points for colocalization with markers for individual uptake mechanisms, and immunofluorescence staining of cellular compartments was performed. This study may be helpful in the future design of PEGylated PLL-polymers for gene delivery approaches to identify the most efficient uptake and delivery mechanisms.

MATERIALS AND METHODS

Polymer Synthesis. The polymers were synthesized using poly-L-lysine hydrobromide with a molecular weight of 20 kDa (Sigma), referred to as PLL_{20} and an *N*-hydroxysuccinimidyl ester of methoxy-terminated poly(ethylene glycol) (Nektar, USA, MW 5 kDa) as described previously (*11, 32*). FITC-labeled PLL-g-PEG polymer was synthesized in an analogous manner, using 20% FITC-terminated poly(ethylene glycol) *N*-hydroxy succinimidyl ester (Nektar, USA, MW 5 kDa) and 80% *N*-hydroxysuccinimidyl ester of methoxy-terminated poly-(ethylene glycol). Grafting (g) was calculated using the absolute number of PEG-moieties per lysine of the PLL backbone and was about 5% for all the polymers. PLL_{20}-g_5-PEG_5 or PLL_{20}-g_5-PEG_5-FITC was used for all experiments and is referred to as PLL-g-PEG or PLL-g-PEG-FITC, respectively. Reaction rates were determined by ^{1}H NMR (D_2O) (β, γ, and δ CH_2 peaks of lysine at 1−2 ppm, CH_2CH_2O of PEG at 3.3−3.9 ppm, and the FITC-group at 6.9−7.2 ppm). The polymers were stored in PBS at −20 °C until further use.

Formulation of PLL-g-PEG-DNA Condensates. PLL-g-PEG-DNA condensates were formed using a plasmid expressing enhanced green fluorescent protein (pEGFP-N1, Clontech) at a final DNA concentration of 1 μg/150 μL (= 6.7 μg/mL) in PBS (0.01 M phosphate buffered saline, pH 7.4, Sigma) and a PLL-g-PEG concentration according to the NH_4^+/PO_4^{3-} (amino group in PLL/phosphate group in DNA; N/P) charge ratio of 3.125. For a 24-well plate, PLL-g-PEG was provided in 75 μL of PBS, and the DNA dissolved in 75 μL of PBS was added dropwise into the polymer solution. The complexes were equilibrated for 30 min at room temperature (RT) and were always freshly prepared prior to use.

Plasmid Propagation. The vector pEGFP-N1 used in this study was transformed into *E. coli* strain Top10 (Invitrogen) and grown in LB medium supplemented with 30 μg/mL kanamycin. The plasmid DNA was purified using a Maxiprep kit (Qiagen), and the concentration was determined spectrophotometrically at 260 nm.

DNA Labeling. Plasmid DNA pEGFP-N1 was covalently labeled using *Label*IT nucleic acid labeling kits (Mirus, Cat. No.: MIR3100 (CX-rhodamine) and MIR3700 (Cy5), respectively) according to the manufacturer's protocol. For colocalization studies, the DNA was labeled with CX-rhodamine (DNA-CX-rh), and for flow cytometry analysis, the plasmid was labeled with Cy5 (DNA-Cy5).

Cells and Cell Culture. COS-7 (SV 40 transformed kidney cells of African green monkey, ATCC CRL 1651, ATCC Rocksville, MA) cells were cultured as exponentially growing subconfluent monolayers at 37 °C and 5% CO_2. The cell culture was kept in 25 cm^2 culture flasks in DMEM (Cat. No.: 21885, low glucose, Glutamax I, GibcoBRL) supplemented with 10% heat inactivated FBS (Cat. No.: F7524, Sigma) and 1% ABAM (Cat. No.: 15240, GibcoBRL). For experiments, cells were used 24 h post seeding.

Temperature-Dependent Nanoparticle Uptake. In order to determine energy-dependency of nanoparticle uptake, COS-7 cells were transfected with DNA nanoparticles at either 37 or 4 °C. COS-7 cells were seeded 24 h prior to transfection in 24 well plates (10,000 cells/well). The growth medium then was replaced with 150 μL of PLL-g-PEG-DNA nanoparticles in PBS (per well: 1 μg plasmid pEGFP-N1, N/P ratio = 3.125), and the cells were incubated for 30 min, either at 37 °C or at 4 °C (here, in all the subsequent steps, the solutions were prechilled to 4 °C). Then, 400 μL of 2% serum-containing DMEM was added, and the cells were again incubated at either 37 or 4 °C for an additional 3 h. Finally, the cells were extensively washed 3× with PBS at the corresponding temperatures before DMEM supplemented with 10% FBS at 37 °C was added. After 48 h of incubation at 37 °C for both conditions, the cells were analyzed for GFP expression. To identify the total cell number, Hoechst 33342 nuclear stain (Invitrogen) was used, and ethidium bromide (AppliChem) visualized potential cytotoxicity. Briefly, the cells were incubated for 2 min in PBS containing 4 μg/mL Hoechst 33342 and 10 μg/mL ethidium bromide. After rinsing the cells three times with PBS, the transfection efficiency was analyzed by counting the GFP-expressing cells in 3 nonoverlapping areas of 500 μm^2 in relation to the total cell number as determined by the Hoechst nuclear stain. In order to analyze the data, ImageJ 1.38 was used.

In order to visualize nanoparticle uptake at 4 and 37 °C, 8000 COS-7 cells were seeded in 4 well chamber slides (Lab-Tek Chambered #1.0 Borosilicate Cover glass System, Nunc) and cultured for 16 h in DMEM containing 10% FBS. Complexes were formed by using PLL-g-PEG-FITC and DNA-CX-rh (1 μg/well) at N/P ratio 3.125 and were incubated with the cells for 3.5 h at either 4 °C or 37 °C as mentioned above. After 3× PBS washing, the cells were Hoechst-stained. Finally, cells were fixed with 1% (w/v) paraformaldehyde (PFA, Sigma) in PBS for 30 min at RT and analyzed using a high-resolution TCS-SP5 laser scanning confocal microscope (Leica Microsystems, Mannheim, Germany). To avoid cross talk, emission signals were collected independently. Image processing was performed using IMARIS software, version 6.0.0 (Bitplane AG, Zurich, Switzerland).

Colocalization Studies of Nanoparticles Formed by PLL-g-PEG-FITC Polymer and DNA-CX-rh. PLL-g-PEG-FITC was first confirmed to have transfection efficiency similar to that of nonlabeled PLL-g-PEG. Eight thousand COS-7 cells were seeded in 4 well chamber slides and cultured for 16 h in DMEM containing 10% FBS as indicated above. Complexes were formed by using PLL-g-PEG-FITC and DNA-CX-rh (1 μg/well)

at N/P ratio 3.125 as described above and were applied on the cells for 30 min and 2, 6, and 24 h. DMEM with 2% FBS was added 30 min after nanoparticle addition to guarantee cell viability. After the indicated time points, noninternalized nanoparticles were removed by rinsing the cells with PBS. Hoechst 33342 nuclear stain was performed and cells were rinsed 3× with PBS. Finally, cells were fixed with 1% (w/v) paraformaldehyde (PFA, Sigma) in PBS for 30 min at RT and analyzed by CLSM.

Optimization of Endocytosis Inhibitor Concentrations. In order to determine the most efficient concentrations of several endocytosis inhibitors without decreasing cell viability, a WST-1 proliferation assay (Roche) was performed in 48 well plates (TPP, Switzerland). The following inhibitors have been used: 150 μM−10 mM methyl-β-cyclodextrin (Sigma, Cat. No.: C4555), 200 μM genistein (Sigma Cat. No.: 91955), 2 μM−60 μM chlorpromazine (Sigma, Cat. No.: C8138), and 50 nM−20 μM wortmannin (Sigma, Cat. No.: 95455). As positive control, cells were treated with PLL-g-PEG-DNA nanoparticles in the absence of any inhibitors. Eight thousand COS-7 cells/48 well were seeded 24 h prior to the addition of inhibitors. Afterwards, the cell culture medium was replaced with 270 μL of serum free DMEM containing the different inhibitors, and the cells were incubated at 37 °C for 1 h. Then, freshly prepared 30 μL PLL-g-PEG-DNA nanoparticles in PBS (per well: 0.4 μg plasmid DNA; N/P ratio = 3.125) were added and incubated for another 3 h. Finally, the cells were washed 3× with PBS before they were incubated in 300 μL of growth medium for 48 h. Subsequently, 30 μL of WST-1 reagent was applied to each well, and the cells were incubated for another hour at 37 °C and 5% CO_2. Absorption at 440 nm was measured using a microplate reader Infinite M200 (Tecan). Each condition was performed in quadruple and repeated three times.

DNA Nanoparticle Uptake in the Presence of Endocytosis Inhibitors (FACS Analysis). Twenty-four hours prior to the experiment, 50,000 COS-7 cells were seeded into a 6 well plate and cultured as describes above. The growth medium was replaced with 1 mL of serum free medium containing the different inhibitors using the optimized concentrations. The cells were incubated for 1 h. Subsequently, the medium was replaced with 500 μL of PBS containing PLL-g-PEG-DNA-Cy5 nanoparticles (per well: 1 μg DNA-Cy5; N/P ratio = 3.125) in addition to the inhibitors as described above. The cells were incubated for 30 min, and then an additional 1.5 mL serum free DMEM medium containing the inhibitors was added. After a total inhibitor incubation time of 4 h, the cells were rinsed twice with PBS before they were detached with 500 μL of trypsin-EDTA (0.25%, GibcoBRL), resuspended, and incubated for 10 min in PBS containing 10 mg of heparin (H9399, Sigma) at RT to detach cell-surface-bound DNA-containing nanoparticles. Subsequently, the cells were washed twice with PBS before they were transferred into tubes (REF 352054, Falcon) for flow cytometry analysis. The analysis was carried out with a FACSCalibur instrument and CellGate software (BD Biosciences). Dead cells and debris were gated out by forward and side scatter spectra. The mean fluorescence intensity of 10,000 individual cells was determined. All experiments have been performed in duplicate and were repeated three times. As controls, COS-7 cells were transfected with DNA-Cy5-nanoparticles in the absence of inhibitors, and naked DNA-Cy5 was used.

Transfection Studies with Endocytosis Inhibitors. Eight thousand COS-7 cells were seeded for 24 h in 24 well plates and incubated for 1 h with inhibitors dissolved in 200 μL of serum free DMEM. The optimized inhibitor concentrations were used as follows: methyl-β-cyclodextrin (5 mM), genistein (200 μM), chlorpromazine (10 μM), and wortmannin (10 μM). Later, the inhibitor solutions were removed, and 150 μL of freshly prepared PLL-g-PEG-DNA nanoparticles in PBS (per well: 1 μg pEGFP-N1; N/P ratio = 3.125) containing the same inhibitor concentrations as those mentioned above were added and further incubated for 30 min. Then, 400 μL of serum free medium supplemented with inhibitors was added and the incubation time extended for an additional 2.5 h. Subsequently, the cells were washed 3× with PBS before 10% serum-containing medium was added to further incubate the cells for 48 h. Double and triple inhibitor transfection experiments were performed in an analogous manner. In order to determine cell viability of the multiple inhibitors used, a WST-1 proliferation assay was carried out in parallel as described above. Finally, the cells were analyzed for GFP expression by fluorescence microscopy as mentioned before. As positive control, DNA nanoparticles without inhibitors were used to transfect the cells.

Nanoparticle Distribution in the Presence of Colocalization Markers. Eight thousand COS-7 cells were seeded in 4 well chamber slides (Lab-Tek Chambered #1.0 Borosilicate Cover glass System, Nunc) and cultured as described before. After washing the cells with PBS, the condensates, consisting of 1 μg of plasmid DNA (pEGFP-N1) complexed with PLL-g-PEG-FITC at N/P ratio 3.125, were coincubated with either cholera toxin subunit B (10 μg/mL) labeled with Alexa Fluor 594 (Molecular Probes, AF-ctB) or Texas Red-labeled transferrin (50 μg/mL: Molecular Probes, TR-tf) for 30 min. DMEM supplemented with 2% FBS was added to a final volume of 500 μL per chamber slide. Additionally, cells were first incubated with FITC-labeled condensates for 1.5 h before adding AF-ctB (10 μg/mL) or TR-tf (50 μg/mL). For both experimental setups, coincubation of the nanoparticles with the colocalization markers or when colocalization markers were added after 1.5 h, the nuclei were Hoechst-stained after 2 h total incubation time. Then, cells were washed 3× with PBS and fixed in 1% (w/v) PFA in PBS for 30 min at RT. Cells were washed again with PBS and analyzed by CLSM as described above.

Immunofluorescence of TFR, Caveolin-1, GM1, and EEA-1. Eight thousand COS-7 cells were seeded into 4 well chamber slides and cultured for 16 h prior to incubation with PLL-g-PEG-DNA-CX-rh (DNA-CX-rh = 1 μg/well) condensates at N/P = 3.125. Cells were stained with antibodies against transferrin receptor (TFR), caveolin-1, and GM1 after 30 min and 45 min, and 1 and 2 h. The cultures were stained against early endosome antigen-1 (EEA-1) after 1, 2, 4, and 6 h. After the indicated time points, the cell culture medium was removed, the cells were washed 3× with PBS and fixed in 1% (w/v) PFA in PBS for 30 min at RT followed by rinsing 3× with PBS. Cells were permeabilized with 0.1% Triton X-100 in PBS for 10 min and washed with PBS. Subsequently, the cells were blocked with 5% donkey serum (Chemicon) and 2% BSA (Sigma) in PBS for at least 1 h. Polyclonal rabbit antibodies against TFR (Chemicon), caveolin-1 (Upstate), ganglioside GM1 (Calbiochem), and mouse against EEA-1 (early endosome antigen-1, BD-Transduction Laboratories) were diluted 1:100 in 1% BSA in PBS and either incubated for 1 h at RT or overnight at 4 °C. Each well was washed intensively 3× with PBS, before secondary antibodies donkey antimouse-FITC and donkey anti-rabbit-FITC (both from Chemicon) were added for 1 h (dilution 1:200 in 5% donkey serum in PBS). Cell nuclei were stained with DAPI (1 mg/mL, dilution 1:1000, Molecular Probes) for 10 min. The cells were washed 3× with PBS and analyzed by CLSM as described above.

Statistical Analysis. The mean values were compared by one-way ANOVA analysis using Origin 7.5 software. Statistical

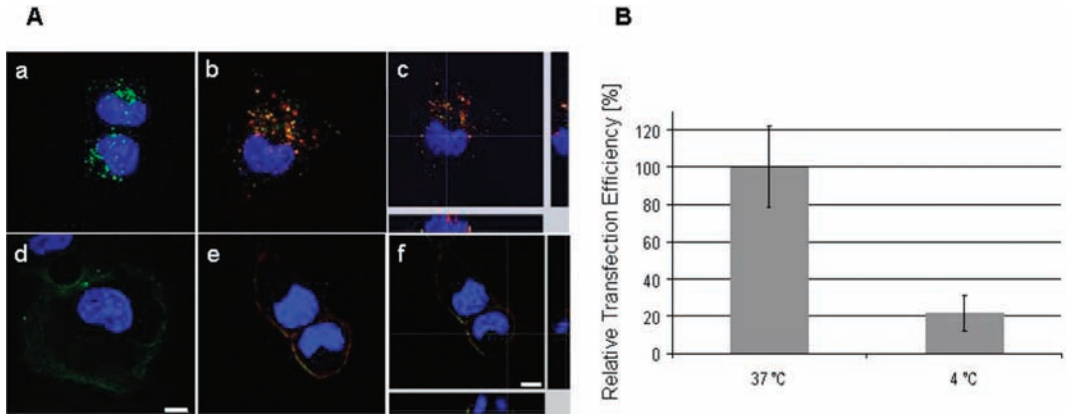

Figure 1. Temperature-dependent nanoparticle uptake into COS-7 cells. (A) Representative confocal images of COS-7 cells, which were transfected with PLL-g-PEG-FITC and CX-rhodamine-labeled pEGFP-N1 (DNA-CX-rh) nanoparticles for 3.5 h at 37 °C (a, b, and c) or 4 °C (d, e, and f). b and e display overlay images of all sections, and c and f show a section view. Uptake of PLL-g-PEG-FITC without DNA cargo at 37 and 4 °C, respectively, is demonstrated in a and d. Blue indicates Hoechst-stained nuclei, red shows CX-rhodamine-labeled DNA, and green displays PLL-g-PEG-FITC polymer. Scale bar is 10 μm. (B) PLL-g-PEG-DNA (plasmid DNA: pEGFP-N1) nanoparticles were applied on COS-7 cells and incubated for 3.5 h at either 37 or 4 °C. Transfection efficiency was analyzed after 48 h by counting transfected cells in relation to the total number of cells. The experiments indicate mean values ± standard deviation of three independent experiments carried out in triplicate. The values are normalized to particle uptake at 37 °C.

significance was accepted for $p < 0.05$ after comparing the mean values by Bonferroni test.

RESULTS

PLL-g-PEG-DNA Nanoparticles are Internalized by Endocytosis and Remain Stable within the Cytoplasm. As nonviral gene delivery systems are promising tools for gene therapy approaches, it is important to analyze nanoparticle internalization and trafficking pathways within the cell. This is especially important when comparing to viral gene delivery systems that benefit from their inherent high cell transduction efficiency. Information on particle uptake mechanisms and intracellular pathways will lead to improved design of PLL-g-PEG-DNA nanoparticles for further applications.

As PLL-g-PEG-DNA nanoparticle stability is maintained by ionic interactions between the PLL backbone of positively charged amines in PLL-g-PEG to negatively charged phosphate groups of the DNA, it is crucial to gain insight into nanoparticle uptake kinetics and intracellular stability. Therefore, PLL-g-PEG and DNA were covalently labeled with two different fluorescent labels. An FITC-labeled PEG-moiety was incorporated during PLL-g-PEG synthesis to obtain PLL-g-PEG-FITC. As determined by NMR, 1 FITC per PLL-g-PEG polymer was attached per PLL-g-PEG-FITC (data not shown). The plasmid DNA harboring the sequence of green fluorescent protein (pEGFP-N1) was covalently labeled at amino groups with CX-rhodamine to maintain condensate formation. PLL-g-PEG-FITC-DNA-CX-rh nanoparticles that were transfected into COS-7 cells showed similar transfection efficiency compared to that of the unlabeled condensates (data not shown).

Initial experiments were performed to determine the energy-dependent dependency of PLL-g-PEG-DNA nanoparticle uptake as endocytosis can be strongly inhibited by lowering the temperature (*19*). For this purpose, fluorescent PLL-g-PEG-DNA nanoparticles were prepared, and COS-7 cells were transfected at 4 and 37 °C (Figure 1). Representative confocal images taken 3.5 h after nanoparticle exposure at 4 and 37 °C show that at 37 °C nanoparticles were found in the cytoplasm of the cell (Figure 1A, b and c). In c, an optical cross section indicated that the nanoparticles were indeed found within the cytoplasm. When only fluorescently labeled PLL-g-PEG was incubated with the cells (Figure 1A, a), it was also found within the cytoplasm close to the nucleus. In contrast, lowering the temperature strongly reduced nanoparticle uptake as they remained at the cell membrane (Figure 1A, e and f). This behavior was also seen for PLL-g-PEG-FITC (Figure 1A, d). These findings were quantified; at 4 °C, transfection efficiency was found to be only 25% as compared to transfection efficiency at 37 °C. These findings suggest that PLL-g-PEG enters the cytoplasm by energy-dependent uptake processes and that it enters independent of the DNA-cargo.

Close colocalization of PLL-g-PEG-FITC and DNA-CX-rh resulted in yellow nanoparticles that could be detected. Uptake studies were performed and COS-7 cells were analyzed after 30 min and 2, 6, and 24 h of nanoparticle incubation. Figure 2A−D shows representative confocal images of fluorescent-labeled nanoparticles (DNA-CX-rh, PLL-g-PEG-FITC). After 30 min of nanoparticle incubation, the condensates were poorly incorporated into COS-7 cells as only few fluorescent particles were observed in association with the plasma membrane. After 2 and 6 h, nanoparticle uptake was enhanced indicated by the increase in the number of yellow particles. Initially, the nanoparticles were homogenously distributed within the cytoplasm (2 h), whereas after more than 6 h, nanoparticles accumulated in the perinuclear region of the cell. Optical cross-sections of transfected cells (Figure 2E and F) show that after 2 h, the nanoparticles were clearly localized within the cytoplasm and remained closely associated with the nucleus for more than 24 h. When COS-7 cells were exposed to DNA-CX-rh or PLL-g-PEG-FITC for 2 h, DNA-CX-rh did not enter the cells, whereas PLL-g-PEG-FITC was found to be distributed within the entire cytoplasm (Figure 2G and H, respectively).

Analysis of PLL-g-PEG-DNA Nanoparticle Uptake into COS-7 Cells. Uptake of PLL-g-PEG-DNA nanoparticles was studied by using different endocytosis inhibitors. Figure 3A lists endocytosis inhibitors that were used to inhibit their respective target pathways. As the effective range of inhibitors is very narrow, cell viability assays were performed 48 h after inhibitor treatment to determine efficient but not toxic inhibitor concentrations (Figure 3C). The inhibitor concentrations used here showed more than 85% cell viability compared to untreated COS-7 cells. To quantify nanoparticle uptake into COS-7 cells, FACS analysis was carried out (Figure 3B). PLL-g-PEG-DNA-Cy5 nanoparticles were individually coincubated with different substances, and inhibition of nanoparticle uptake was determined. As controls, fluorescent-labeled nanoparticles and DNA-Cy5 in the absence of inhibitors were used. Genistein, an inhibitor of caveolae-mediated endocytosis, reduced nanoparticle

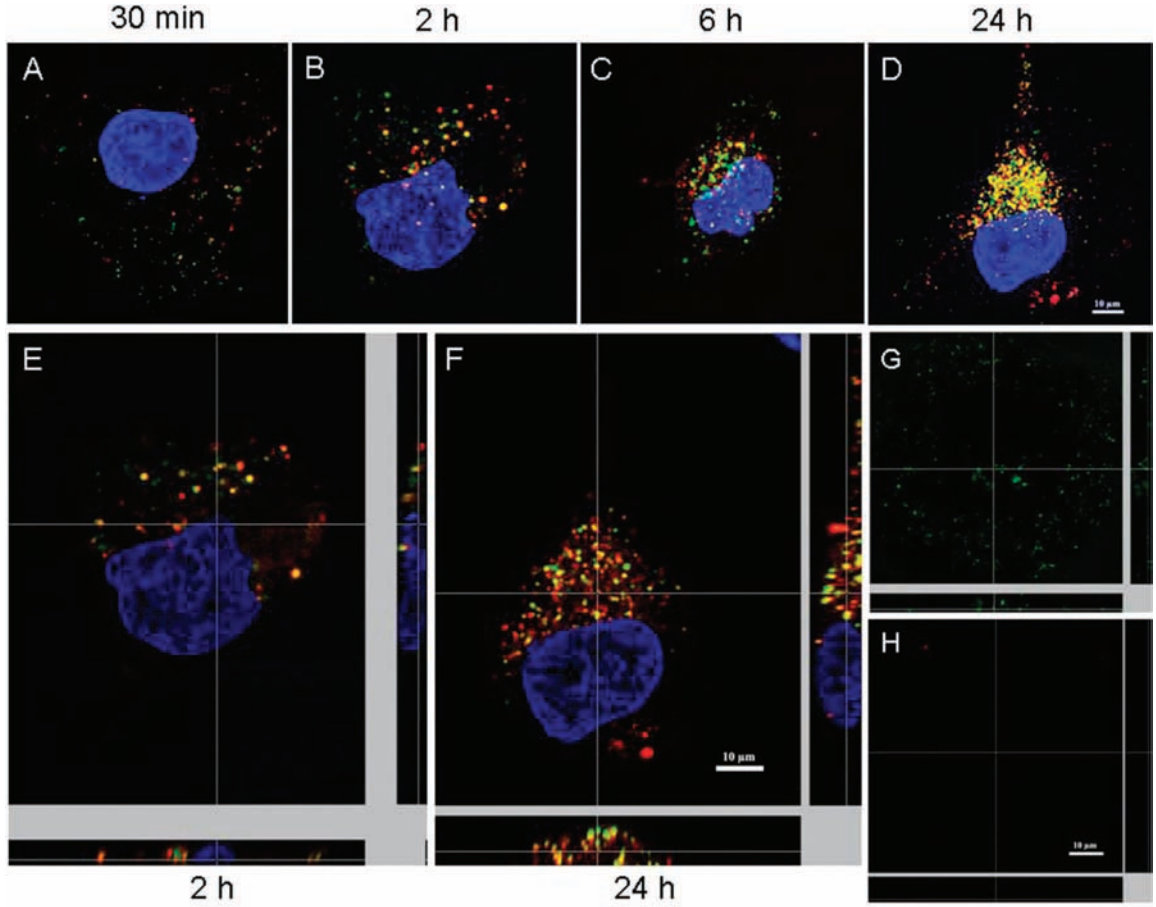

Figure 2. Colocalization of PLL-g-PEG-FITC and CX-rhodamine-labeled pEGFP-N1 (DNA-CX-rh) in COS-7 cells. Nanoparticles were prepared and applied on COS-7 cells for 30 min and 2, 6, and 24 h. After the indicated time points, cells were fixed and analyzed by confocal microscopy. Images A−D show COS-7 cells incubated with nanoparticles for the indicated times, whereas images E and F display section views of cells incubated for 2 and 24 h, respectively. G and H indicate uptake of PLL-g-PEG-FITC and DNA-CX-rh, respectively. Blue indicates Hoechst-stained nuclei, green shows PLL-g-PEG-FITC, red displays DNA-CX-rh, and yellow indicates tight association of labeled polymer and plasmid DNA. Scale bar is 10 μm.

uptake to 43 ± 5%. Whereas all other inhibitors reduced nanoparticle uptake only a little, wortmannin by 17 ± 3% and chlorpromazine by 3 ± 2%, indicating the involvement of several pathways, 74 ± 2% of the nanoparticles were internalized when methyl-β-cyclodextrin was applied.

As nanoparticle uptake is not indicative for gene expression, transfection experiments in the presence of single inhibitors were performed (Figure 3D). PLL-g-PEG-DNA nanoparticles were coincubated with the respective inhibitors, and GFP expression was analyzed. In the presence of wortmannin and methyl-β-cyclodextrin, transfection efficiency was reduced by 35 ± 18% and 30 ± 19%, respectively, whereas in the presence of genistein or chlorpromazine, transfection efficiency was not reduced significantly. In order to further analyze if multiple pathways are involved in PLL-g-PEG nanoparticle uptake, double and triple inhibitor experiments were performed. Cell viability with double inhibitors was found to be above 90% (Figure 3E), whereas triple inhibitors decreased cell viability by ∼20% (Figure 3G). Double inhibitors showed a reduction in transfection efficiency to ∼70% (Figure 3F). The transfection efficiency with triple inhibitors was reduced to ∼30% in comparison to that of control cells (Figure 3H). Interestingly, no inhibitor combination used was able to completely block nanoparticle uptake and gene expression, indicating that PLL-g-PEG-DNA nanoparticles might use several uptake mechanisms.

Analysis of PLL-g-PEG-DNA Nanoparticle Pathways within COS-7 Cells. To visualize intracellular pathways of the PLL-g-PEG-DNA nanoparticle within COS-7 cells, PLL-g-PEG-DNA nanoparticles were coincubated with known endocytosis ligands cholera toxin B and transferrin. The nontoxic subunit B of cholera toxin was used to study lipid raft-mediated endocytosis as cholera toxin B binds to membrane sphingolipid GM1 to enter a cell (*29*, *33*). Transferrin is internalized by receptor-mediated endocytosis forming clathrin-coated pits and is widely used as a tracker for clathrin-mediated endocytosis. COS-7 cells were incubated for 2 h with PLL-g-PEG-FITC-DNA nanoparticles and endocytosis markers Alexa Fluor-594-labeled cholera toxin B (AF-ctB) and Texas Red-labeled transferrin (TR-tf) were either coincubated with nanoparticles for 2 h or COS-7 cells were preincubated for 1.5 h with nanoparticles prior to the addition of transferrin or cholera toxin B for 30 min (Figure 4). When COS-7 cells were preincubated for 1.5 h with the nanoparticles prior to the addition of cholera toxin B or transferrin (Figure 4A and C), cholera toxin B was found attached to the plasma membrane, whereas transferrin was already internalized and localized close to the nucleus. PLL-g-PEG-FITC-DNA nanoparticles were internalized, but only few particles colocalized with the endocytosis markers as indicated by a few yellow particles. When COS-7 cells were coincubated with PLL-g-PEG-FITC-DNA nanoparticles and endocytosis markers for 2 h (Figure 4B and D), cholera toxin B was found in the nucleus not colocalized with PLL-g-PEG-FITC-DNA nanoparticles. Also transferrin and PLL-g-PEG-FITC-DNA nanoparticles were not colocated within COS-7 cells.

To support the findings obtained with colocalization studies, immunofluorescence stainings with endocytosis markers GM1,

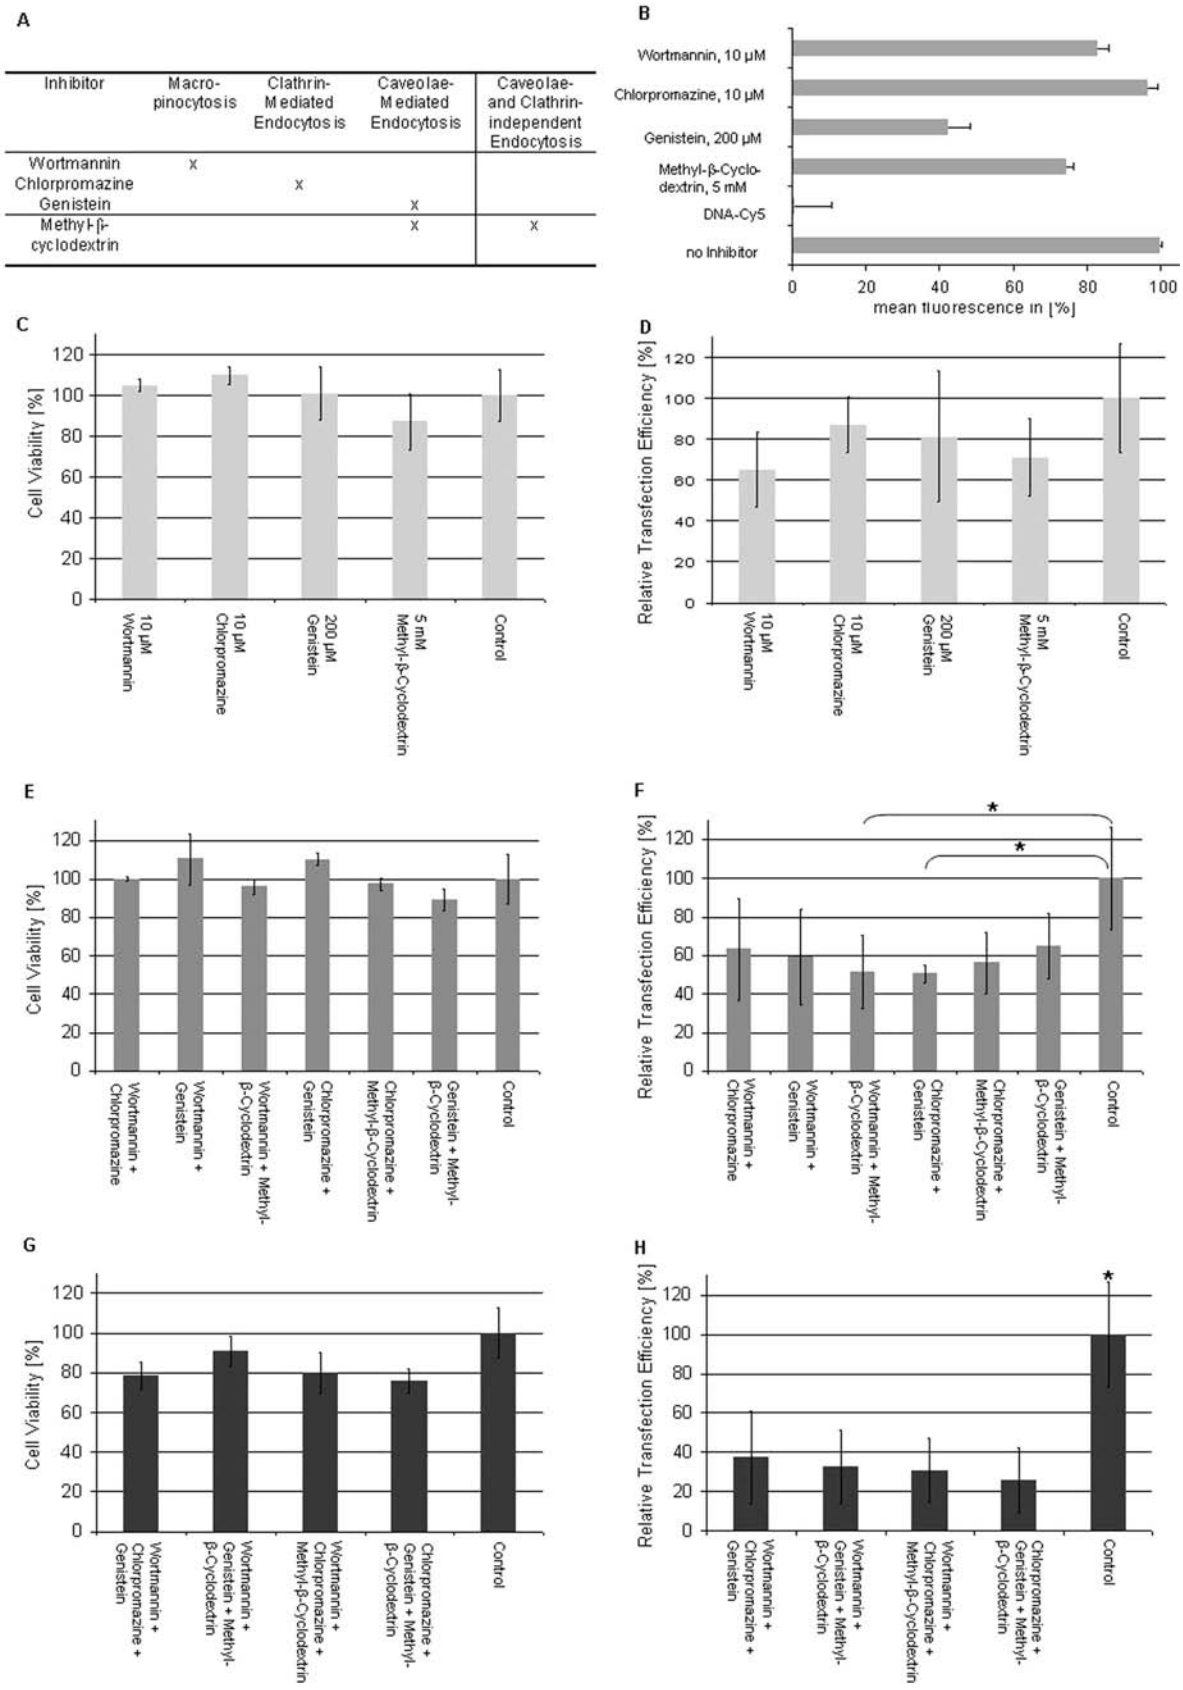

Figure 3. Inhibition of PLL-g-PEG-DNA nanoparticle uptake. (A) Endocytosis inhibitors and their targets used. (B) FACS analysis of COS-7 cells incubated with nanoparticles in the presence of four different endocytosis inhibitors. The graph displays mean fluorescence intensities of one of three independent experiments performed in duplicate. As controls, PLL-g-PEG-DNA-Cy5 without inhibitors, plasmid DNA only, and untreated COS-7 cells were used (not shown). Cell viability as determined by the WST-1 proliferation assay performed in the presence of single (C), double (E), and triple (G) endocytosis inhibitors. Transfection efficiencies after coincubation with single (D), double (F), and triple (H) endocytosis inhibitors. In D, F, and H, unlabeled pEGFP-N1 was used for nanoparticle production. The values were normalized to transfection efficiencies in the absence of any inhibitor (control). The values shown here represent mean values ± standard deviation from two to five independent experiments performed in duplicate. * refers to values that are statistically different from the control ($p < 0.05$).

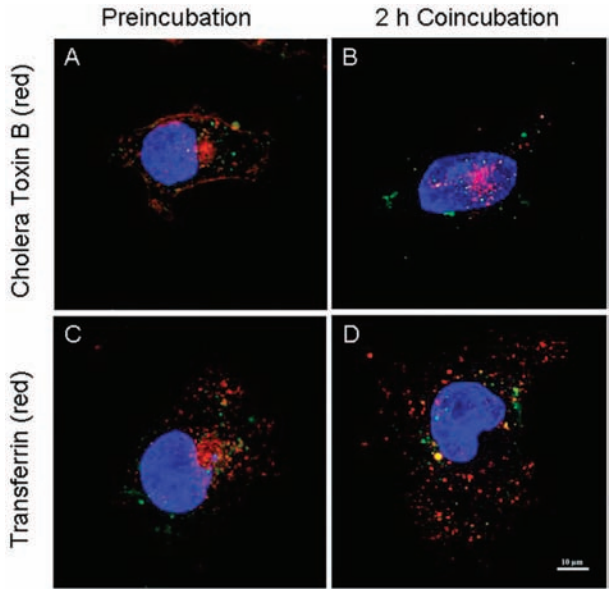

Figure 4. Colocalization studies with PLL-g-PEG-FITC-DNA nanoparticles and endocytosis markers Alexa Fluor-594-labeled cholera toxin B (AF-ctB) and Texas Red-labeled transferrin (TR-tf). In A and C, COS-7 cells were preincubated with PLL-g-PEG-FITC-DNA nanoparticles for 1.5 h, before cholera toxin B or transferrin was added for 30 min. After a total of 2 h, the cells were analyzed. In B and D, cholera toxin B and transferrin were coapplied with the nanoparticles for an entire 2 h prior to analysis. The cells were analyzed by CLSM. Blue indicates Hoechst-stained nuclei, green shows PLL-g-PEG-FITC, and red displays colocalization markers for cholera toxin B (in A and B) and transferrin (in C and D). Scale bar is 10 μm.

transferrin receptor (TFR), and caveolin-1 were performed. Ganglioside GM1, is mainly found in lipid rafts indicative for clathrin-independent pathways, TFR is involved in clathrin-mediated endocytosis, and caveolin-1 represents the main component in caveolae-mediated endocytosis. As shown in Figure 2, the majority of nanoparticles were located within the cytoplasm after 2 h; therefore, colocalization of PLL-g-PEG-DNA nanoparticles with GM1, TFR, and caveolin-1 was analyzed after 30 and 45 min, and 1 and 2 h. In addition, it was important to find out whether PLL-g-PEG-DNA nanoparticles would enter the lysosomal pathway. Therefore, colocalization with EEA-1 (early endosome antigen-1) was analyzed after 1, 2, 4, and 6 h to guarantee sufficient time for sorting into the endosomal pathway. Most PLL-g-PEG-DNA nanoparticles visualized by DNA-CX-rh did not colocalize with GM1 (Figure 5A−D). They also did not colocalize with transferrin receptors (Figure 5E−H) nor with caveolin-1 (Figure 5I−L). Moreover, PLL-g-PEG-DNA nanoparticles were not localized in early endosomal compartments (Figure 5M−P). These findings essentially confirm the inhibition of uptake and colocalization experiments in that internalized PLL-g-PEG-DNA nanoparticles do not strictly follow one of the main uptake mechanisms. Moreover, they avoid endosomal degradation within COS-7 cells that might lead to fast clearance and inefficient transfection.

DISCUSSION

Knowledge about uptake mechanisms and intracellular pathways of nonviral gene delivery vehicles is of great interest for the design of high performance delivery systems for therapeutic DNA. As PLL-g-PEG-DNA nanoparticles were previously identified as potent gene delivery vehicles in COS-7 cells that combine small size (80−90 nm), long storage stability, and low cytotoxicity with high transfection rates (*11*), this study aimed at elucidating the uptake mechanisms and intracellular pathways of these particles. Cargo uptake is usually energy-dependent and leads to the formation of membranous vesicles (*3, 4, 14, 18, 22*). PLL-g-PEG-DNA nanoparticles were shown to enter COS-7 cells by energy-dependent mechanisms as reduction of the temperature to 4 °C reduced nanoparticle uptake as shown by confocal imaging. Consequently, transfection efficiency was decreased by 75% at 4 °C. The nanoparticles were shown to enter the cytoplasm within the first 2 h of transfection; later, PLL-g-PEG-DNA nanoparticles accumulate in the perinuclear region preceding nuclear uptake. Furthermore, PLL-g-PEG-DNA nanoparticles were found within the cytoplasm at least for 24 h, and no colocalization with endosomal compartments, as indicated by fluorescence staining against early endosome antigen-1, was observed. These experiments indicate that PLL-g-PEG-DNA nanoparticles translocate efficiently to the nucleus and eventually enter the nucleus, e.g., during mitosis, to express the gene of interest. Most studies in the field of particle uptake focused on pathways via caveolin- or clathrin-coated vesicles and cholesterol- and ganglioside GM1-enriched microdomain-mediated endocytosis (*14, 34−36*). Therefore, our studies were based on such methodology to classify the intracellular fate of PLL-g-PEG-DNA nanoparticles. Inhibition of uptake experiments were performed in the presence of optimized single inhibitor concentrations of wortmannin (macropinocytosis), chlorpromazine (clathrin-mediated), genistein (caveolae-mediated), and methyl-β-cyclodextrin (caveolae-mediated and caveolae- and clathrin- independent pathways) and with double and triple inhibitor combinations. These experiments revealed that only genistein was able to substantially inhibit (∼55%) PLL-g-PEG-DNA nanoparticle uptake into COS-7 cells. However, transfection efficiency performed in the presence of genistein did not show any reduction. Also, colocalization studies with antibodies against caveolin-1 indicate no correlation between caveolin-1 and PLL-g-PEG-DNA nanoparticles. In addition, caveolae-mediated endocytosis was described to be very fast (>20 min), and the vesicles produced are usually smaller (50−80 nm diameter) (*22*) than the diameter of PLL-g-PEG-DNA nanoparticles. Therefore, all findings suggest that these nanoparticels do not follow caveolae-mediated pathways and that the inhibitory effects of genistein might be the result of genistein side reactions. It is known that genistein acts as an ATPase inhibitor (*37*) as well as a hormone analogue (*38*) that might affect nanoparticle uptake in one way or another. Similar findings with respect to genistein activity were shown when COS-7 cells were transfected with cationic polymer pDMAEMA and PEI nanoparticles (*21*).

Clathrin-mediated pathways might also be an option for PLL-g-PEG-DNA nanoparticle uptake as particles up to 120 nm in diameter can be internalized (*22*). Here, no correlation between nanoparticle uptake and markers indicative for clathrin-mediated pathways could be demonstrated. Nanoparticle uptake was not inhibited in the presence of chlorpromazine, nor was transfection efficiency in the presence of chlorpromazine impaired. Moreover, no colocalization was found for PLL-g-PEG-DNA nanoparticles with transferrin, transferrin receptors, and EEA-1.

Also macropinocytotic and caveolae- and clathrin-independent uptake mechanisms could not be assigned as primary uptake pathways for PLL-g-PEG-DNA nanoparticles. Particle uptake and transfection could be inhibited in the presence of wortmannin or methyl-β-cyclodextrin by 17 and 24%, respectively, whereas colocalization between cholera toxin subunit B and PLL-g-PEG-DNA nanoparticles as well as the membrane ganglioside GM1 with the nanoparticles failed.

The conclusion is that these PLL-g-PEG-DNA nanoparticles do not strictly follow one of the classical endocytotic pathways, although some inhibition of endocytosis can be observed for several pathways, and transfection efficiencies were reduced when combinations of inhibitors were used (Figure 6). These

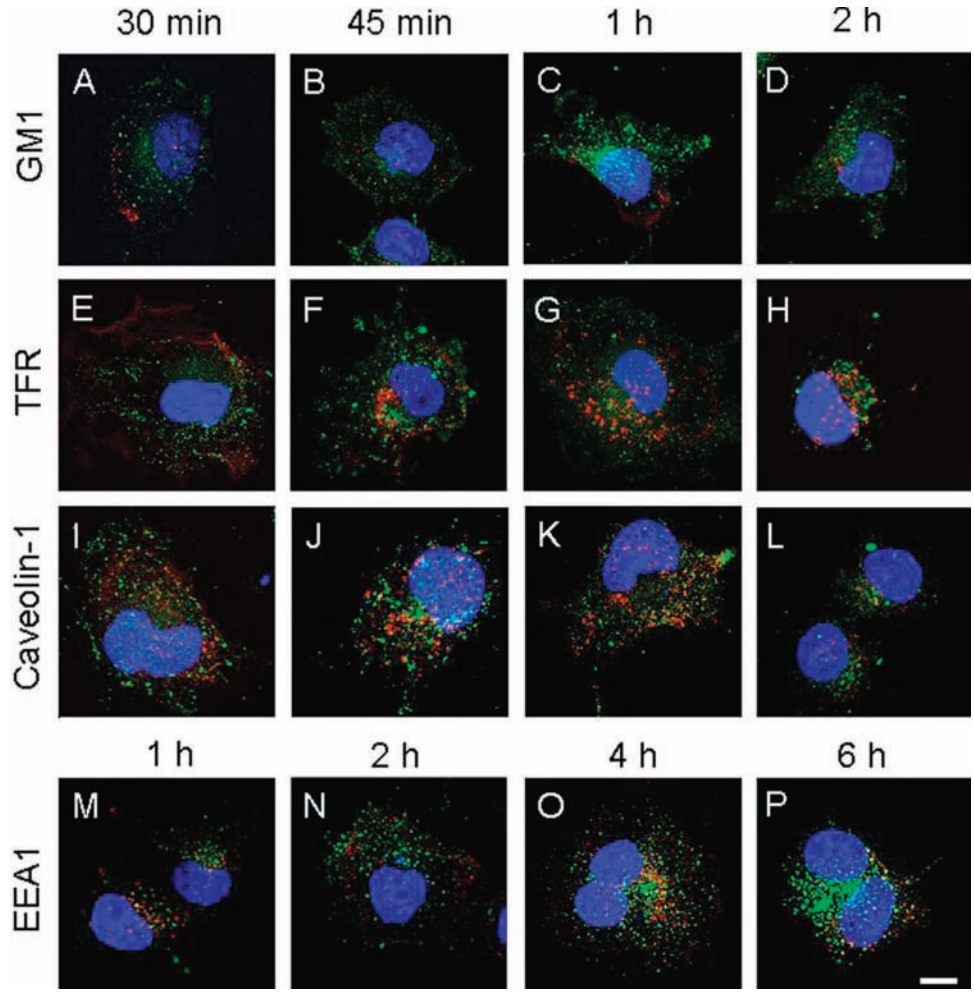

Figure 5. Colocalization studies with PLL-g-PEG-DNA-CX-rh-labeled nanoparticles and markers indicative for different endocytosis pathways. PLL-g-PEG-DNA-CX-rh nanoparticles were added to COS-7 cells, and at indicated time points, cells were fixed and immunostained against GM1 (ganglioside GM1, A-D), transferrin receptor (TFR, E-H), caveolin-1 (I-L), and early endosome antigen-1 (M-P). The cells were analyzed by CLSM. Blue indicates Hoechst-stained nuclei, red shows CX-rhodamine-labeled DNA, and green displays different endocytosis markers. Scale bar is 10 μm.

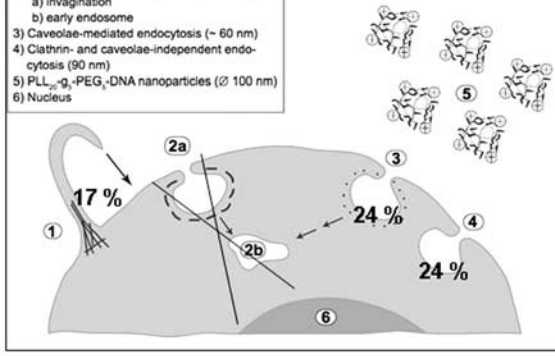
Energy-dependency	yes
Intracellular localization	< 2 h
Nuclear localization	< 24 h
Stability of nanoparticles within the cytoplasm	> 24 h
Endosomal localization	no

1) Macropinocytosis (> 1 µm)
2) Clathrin-mediated endocytosis (~ 120 nm):
a) invagination
b) early endosome
3) Caveolae-mediated endocytosis (~ 60 nm)
4) Clathrin- and caveolae-independent endocytosis (90 nm)
5) PLL_{20}-g_5-PEG_3-DNA nanoparticles (Ø 100 nm)
6) Nucleus



1) Macropinocytosis	
- uptake inhibition with wortmannin	~17 %
- colocalization with cholera toxin B	no
- colocalization with GM1 in lipid rafts	no
2) Clathrin-mediated endocytosis	
- uptake inhibition with chlorpromazine	no
- colocalization with transferrin receptor	no
- colocalization with transferrin	no
3) Caveolae-mediated endocytosis	
- uptake inhibition with genistein	~50 %
- inhibition with Methyl-β-Cyclodextrin	~24 %
- colocalization with cholera toxin B	no
- colocalization with GM1 in lipid rafts	no
4) Clathrin- and caveolae-independent endocytosis	
- inhibition with Methyl-β-Cyclodextrin	~24 %
- colocalization with cholera toxin B	no
- colocalization with GM1 in lipid rafts	no
5) Reduction in gene expression with single, double and triple inhibitor combinations	
- single inhibitors	~20 %
- double inhibitor combinations	~40 %
- triple inhibitor combinations	~70 %

Figure 6. Summary of PLL-g-PEG-DNA nanoparticle uptake mechanisms and trafficking pathways. The schematic summarizes endocytosis pathways that have been investigated. The numbers in brackets in the figure represent the diameters of particles that have been found to be internalized through that pathway.

findings might have been due to a general cellular inhibition, although overall cell viability was not impaired. Nanoparticle uptake has been described for pDMAEMA and PEI nanoparticles to follow the clathrin- and caveolae-dependent pathways

in COS-7 cells, respectively (*21*). Another study pointed out that COS-7 cells were very efficiently transfected with alginate−chitosan nanoparticles that were internalized predominantly by caveolae-mediated endocytosis (*15*). Pegylated poly-L-lysine (C_1K_{30}-PEG) compacted DNA transfected into COS-7 cells also did not show colocalization with early endosome antigen-1 (EEA-1) or transferrin receptor (TFR), indicating cytosomal stability and no involvement of clathrin-mediated uptake pathways (*3*). As C_1K_{30}-PEG-DNA condensates displayed a rod-like shape with a length of up to 300 nm, involvement of macropinocytotic uptake could clearly be identified (*3*). However, in our study the PLL-g-PEG-DNA nanoparticles display a spherical shape with homogeneous hydrodynamic diameter of 80−90 nm (*11*). One explanation for the failure to assign one prominent uptake pathway into COS-7 cells might be that PLL-g-PEG-DNA nanoparticles are formed by noncovalent bonds between the amino groups of poly-L-lysine and phosphate groups of the plasmid DNA. As the structure of such condensates is not known and might also be flexible in watery solution, it might well be that dangling ends of poly-L-lysine extend to the surface of the condensates and serve as cell-penetrating peptide sequences helping to internalize PLL-g-PEG-DNA nanoparticles (Figure 6). Cell-penetrating peptides cross biological membranes in a nondisruptive way without apparent toxicity and can therefore deliver macromolecular cargo into target cells via endocytotic-dependent and -independent ways (*14, 17, 39, 40*). They form stable complexes with proteins and nucleic acids, and the interaction is either covalent or noncovalent (*40, 41*). Cell-penetrating peptides may consist of Pep and MPG families that are short amphipathic peptides consisting of three domains: a variable N-terminal hydrophobic motif, responsible for membrane fusion; a hydrophilic lysine-rich domain, which is required for the interactions with DNA, intracellular trafficking of the cargo, and solubility of the peptide vector; and a linker domain separating the two domains (*40, 42, 43*). Structural and mechanistic investigations have revealed that the flexibility between the two domains, which is maintained by the linker sequence between the fusion and the DNA-binding motifs, is crucial for macromolecule delivery (*42*−*45*). Uptake mechanisms of condensates formed between cell penetration peptides and their cargo are usually energy-dependent, independent of the endosomal pathway, and are directly correlated to the size of particles and the nature of cargoes (*46, 47*). Here, PLL-g-PEG-DNA nanoparticles might function as cell-penetrating condensates where surface-exposed lysines in combination with flexible, noncharged PEG moieties are able to deliver plasmid DNA into the cytoplasm (*14*) and thereby circumvent the endocytotic machinery. In favor of such a hypothesis might be the fact that PLL-g-PEG enters into the cytoplasm of COS-7 cells independently of the presence of plasmid DNA (Figures 1A, a and 2G). This hypothesis might also be an explanation for the fast and efficient delivery of plasmid DNA combined with the low cytotoxicity of PLL-g-PEG-DNA nanoparticles used in this study. In future studies, this feature needs to be explored for the delivery of therapeutic DNA in the context of gene therapy.

Fluorophore Labeling Enables Imaging and Evaluation of Specific CXCR4−Ligand Interaction at the Cell Membrane for Fluorescence-Based Screening

Wataru Nomura,[†] Yasuaki Tanabe,[†] Hiroshi Tsutsumi,[†] Tomohiro Tanaka,[†] Kenji Ohba,[‡] Naoki Yamamoto,[‡] and Hirokazu Tamamura*[,†]

Institute of Biomaterials and Bioengineering, Tokyo Medical and Dental University, Chiyoda-ku, Tokyo 101-0062, Japan, and AIDS Research Center, National Institute of Infectious Diseases, Shinjuku-ku, Tokyo 162-8640, Japan. Received May 24, 2008; Revised Manuscript Received July 23, 2008

Development of CXCR4-specific ligands is an important issue in chemotherapy of HIV infection, cancer metastasis, and rheumatoid arthritis, and numerous potential ligands have been developed to date. However, it is difficult to assess their binding mode and specificity because of uncertainties in the structure of the CXCR4−ligand complexes. To address this problem, we have synthesized fluorophore labeled Ac-TZ14011, which is derived from T140, a powerful CXCR4 antagonist. Binding of Ac-TZ14011 to CXCR4 on the cell membrane was observed by fluorescence microscope, and analysis of the binding data produced IC_{50} values of several ligands comparable to those obtained in RI-based assays. This fluorescence-based assay is applicable to explore new pharmacophores of CXCR4-specific ligands with high-throughput screening and also to screening of the other GPCR binding ligands.

The interaction of CXCR4 with ligands causes diverse effects on cellular functions such as metastasis of progenitor cells (*1*−*3*), and a major role of CXCR4 is as the receptor of the chemokine, CXCL12. The interaction of CXCL12 with CXCR4 has been shown to be correlated with cancer progression (*4*) and $CD4^+$ T cell accumulation in the rheumatoid arthritis synovium (*5*). CXCR4 is also known as the second receptor of X4-type HIV-1 (*6*), and numerous ligands for CXCR4 derived from natural and synthetic compounds have been identified as inhibitors of HIV infection and cancer metastasis. [^{125}I]-CXCL12 has been utilized as a competitor in the assays to evaluate the CXCR4-binding activity of synthetic compounds such as T140 (*7*), its derivatives (*8*), KRH-1636 (*9*), and AMD3100 (*10*). Experimental methods utilizing radioisotopes (RI[1]) have advantages in the high resolution of the assays. Recently, molecular probes and fluorescent labeling, an emergent technology in chemical biology, have proved to be very useful for the evaluation in vivo of the functions of proteins and of the biological effect of changing concentrations of Ca^{2+} (*11*), Zn^{2+} (*12*), and NO (*13*), enzyme activity (*14*), and protein phosphorylation (*15*) in cells. Moreover, imaging of living cells by fluorescent probes can be utilized to estimate the accuracy of binding assays under statistically identical conditions. This article describes the synthesis and use of fluorophore labeled Ac-TZ14011 to analyze the CXCR4 binding of ligands at the cell membrane and to determine the IC_{50} values of ligands.

Ac-TZ14011, a derivative of T140 optimized for CXCR4 binding and stability in vivo by functional group substitutions, was synthesized as described previously (*16*, *17*). The D-lysine at position 8 was selectively labeled with TAMRA or fluorescein (Figure 1). A hexamethylene group was incorporated into the TAMRA or fluorescein derivative to maintain an appropriate distance between T140 residues and the fluorophore. Residues critical to the CXCR4 binding activity of TZ14011 are Arg2, Nal3, Tyr5, and Arg14, and were assessed by screening of amino acid substitution of T140 (*16*). On the basis of the previously determined interaction between Ac-TZ14011 and CXCR4 (*18*), the fluorophores labeled at D-lysine 8 were assumed not to inhibit binding of fluorescent-Ac-TZ14011 to CXCR4. To investigate if fluorescent labeled Ac-TZ14011 maintains binding activity against CXCR4, the IC_{50} values of peptides were estimated by competitive assays against [^{125}I]-CXCL12 binding. In this assay, the IC_{50} of T140 was 3.7 nM. The IC_{50} values for fluorescein- or TAMRA-labeled Ac-TZ14011 were 11 and 14 nM, respectively. These values indicated that fluorophore labeling does not inhibit binding of Ac-TZ14011 as reported elsewhere about binding of TAMRA-Ac-TZ14011 (*19*).

The binding of TAMRA-Ac-TZ14011 to a cell membrane was observed with a laser-scanning confocal microscope to determine the specific binding of Ac-TZ14011 to CXCR4. The CXCR4-GFP fusion protein was stably expressed in the NP-2 cell line (*20*), and TAMRA-Ac-TZ14011 binding to CXCR4 was clearly observed at the membrane in the absence of competitors (Figure 2A). To assess the specific binding of ligands, excess unlabeled Ac-TZ14011 was added to the medium with TAMRA-Ac-TZ14011. Upon addition of Ac-TZ14011, weak fluorescence intensity was observed on the cell membrane or cytoplasm (Figure 2B). Vesicles observed in the cytoplasm show internalization of CXCR4 receptors induced by binding of the ligands, and signals from GFP and TAMRA showed colocalization in the cytoplasm. These results indicate the specific binding of TAMRA-Ac-TZ14011 to CXCR4. To evaluate the binding specificity for CXCR4 across the different kinds of GPCRs, HeLa cells, which stably express CD4-CCR5, were utilized for microscopy assays. The binding of TAMRA-Ac-TZ14011 was observed as for the NP-2 CXCR4-GFP cell line (Figure 2C). With the addition of excess CXCL12 (Figure

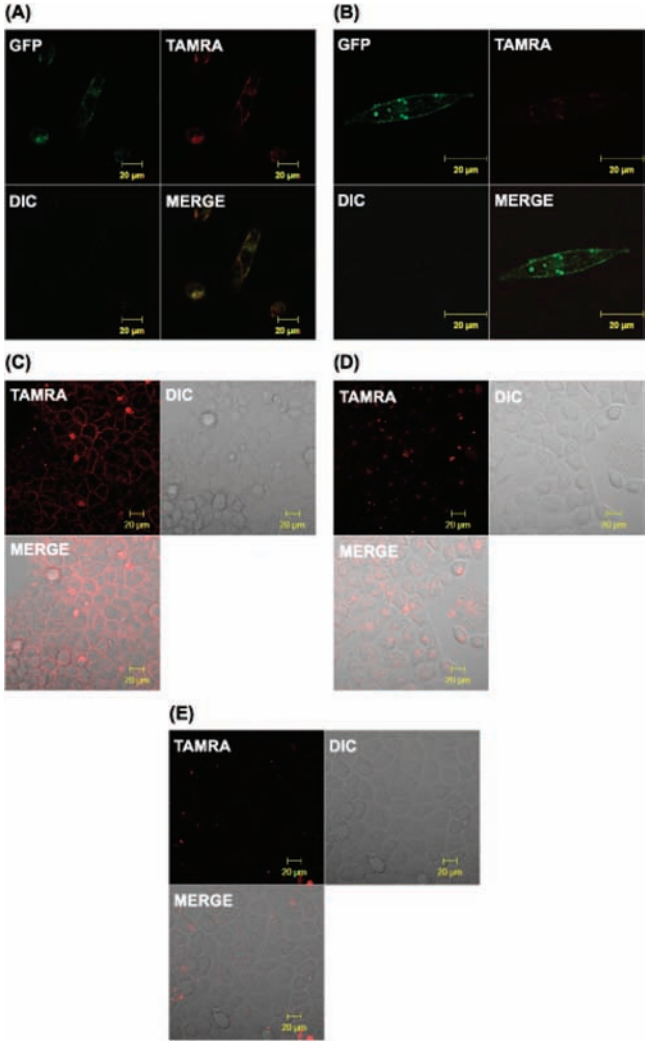

Figure 2. Confocal microscopy assays of TAMRA-Ac-TZ14011 binding to CXCR4. The signals of GFP and TAMRA are displayed in green and red, respectively. (A) Binding to NP2-GFP-CXCR4 cells. (B) Competitive binding to NP2 cells with excess amount of Ac-TZ14011. (C) Binding to HeLa-CD4-CCR5 cells. (D) Competitive binding to HeLa-CD4-CCR5 cells with excess CXCL12. (E) Competitive binding to HeLa-CD4-CCR5 cells with excess Ac-TZ14011. Descriptions of images are indicated in the pictures.

2D) or Ac-TZ14011 (Figure 2E), the fluorescence intensity on the cell membrane was decreased. These results show that TAMRA-Ac-TZ14011 binds specifically to CXCR4 but not to CCR5.

To investigate the utility of fluorescein-labeled Ac-TZ14011, cell-based binding assays were performed. In this binding assay, fluorescein-Ac-TZ14011 was utilized as a competitor to derivatives of FC131 (*8*) and the dipicolylamine-*p*-xylene Zn(II) complex [Zn^{2+}-(Dpa)-*p*-Xyl] that were developed as CXCR4 antagonists (Figure 3) (*21*). The binding constants of these compounds were previously estimated by competitive assays with [^{125}I]-CXCL12. As a result, larger values of IC_{50} than those in the previous assays were observed (Table 1). The difference of the binding constants of competitors was assumed to be a reflection of the difference of IC_{50} values in the assays. It is especially interesting that the values of IC_{50} as determined by fluorescent- and RI-competition assays are clearly correlated. It was clearly indicated that binding activity of compounds can be estimated by binding inhibition assays conducted at a constant concentration of compounds. Indeed, in the detailed binding assays, a significant correlation was observed in IC_{50} values measured by both methods for T140, TC13, and TC22.

Table 1. K_d Values Determined by RI-Competition and Fluorescent Probe Competition Assays

	IC_{50} (nM)		
	[^{125}I]-CXCL12 competition (IC_{50}C)	fluorescein-Ac-TZ14011 competition (IC_{50}F)	IC_{50}F/IC_{50}C
T140	3.93	24.7	6.3
Zn^{2+}-(Dpa)-*p*-Xyl	47[a]	291	6.2
FC131	14.6	109	7.5

[a] This value is derived from ref *18*.

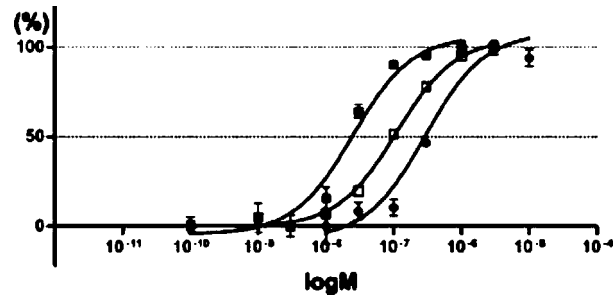

Figure 3. Curve fitting for CXCR4 binding of T140 (■), Zn^{2+}-(Dpa)-*p*-Xyl (●), and FC131 (□) in competitive assays by fluorescein-Ac-TZ14011. The *x* and *y* axes show concentrations and inhibition percentages of the binding of test compounds, respectively.

In the application of high-throughput screening for pharmacophores of CXCR4 ligands, it is important to be able to rapidly determine IC_{50} values. To test whether fluorescein-Ac-TZ14011 could be useful as a ligand in high-throughput screening, binding inhibition analyses at constant compound concentrations were performed. Twenty-four derivatives of a cyclic pentapeptide, FC131, were prepared for the analyses as described previously (Figure 4A) (*8*). The conditions used were the same as in the binding experiments shown in Figure 3 except that the compound concentration was kept constant at 2 μM. Nine compounds were found to induce >75% inhibition at this concentration (Figure 4B). The IC_{50} values of compounds that showed high inhibitory scores in the screening analyses were examined

The *x* and *y* axes show concentrations and inhibition percentages of binding of test compounds, respectively. (D) Correlation between IC_{50} values determined by RI-competition assays (*x*-axis) and fluorescein-Ac-TZ14011 competition assays (*y*-axis). The compound and IC_{50} values are shown in Tables 1 and 2. The *P* value determined from correlation analysis was 0.012.

Table 2. K_d Values Determined by RI-Competition and Fluorescent Probe Competition Assays

	IC_{50} (nM)		
	[^{125}I]-CXCL12 competition (IC_{50}C)	fluorescein-Ac-TZ14011 competition (IC_{50}F)	$IC_{50}F/IC_{50}C$
T140	3.93	24.7	6.3
TC13	27.0	143	5.3
TC22	39.4	176	4.5

further (Table 2). The IC_{50} values of TC13 and TC22 were determined to be 143 and 176 nM, respectively (Figure 4C). The IC_{50} values determined in this assay showed a clear correlation with those in RI-competition assays (Figure 4D, manuscript in preparation).

Advantages of the fluorescence-based analyses include their utility in high-throughput screening and direct observation of the binding state on cell membrane by fluorescence microscope; binding assays and confocal microscopy study were performed to evaluate these advantages. The binding of T140 was previously assessed with site-directed mutagenesis of CXCR4, which indicated that the extracellular loop 2 of the receptor is the main target for this peptide (*22*). The observation of Ac-TZ14011 binding to cell membranes provided convincing evidence of specificity for the target receptor. Competition with excess unlabeled Ac-TZ14011 and CXCL12 showed clear inhibition of TAMRA-Ac-TZ14011 binding. There has been concern that CXCR4 ligands could bind nonspecifically to other GPCRs. A binding study utilizing CCR5-CD4-HeLa cells showed evidence of a high degree of specificity of the ligands. HeLa cells naturally express CXCR4 (*23*), and in the event of overexpression of CCR5-CD4 on the membrane, the binding of TAMRA-Ac-TZ14011 was prevented by the addition of competitors. These results indicate that these peptides bind to the same target site on the cell membrane, CXCR4. Internalization of CXCR4 stimulated by binding of ligands was clearly observed, particularly in the presence of competitors indicating that ligands bound to CXCR4 are simultaneously incorporated in the cytoplasm. Interestingly, on the basis of the numbers and size of vesicles observed, CXCL12 showed stronger induction of CXCR4 internalization than Ac-TZ14011. Promotion of CXCR4 internalization is one of the important mechanisms for inhibition of HIV entry (*24*). The difference of ligand-dependent effects on CXCR4 internalization will be studied further in our laboratory.

In conclusion, the structure−activity relationships of ligands for CXCR4 have been well studied, but relatively few known ligand pharmacophores have been studied because of the difficulty associated with the analysis of receptor−ligand interactions. Our results strongly indicate that fluorescence-based ligand binding assays could be useful in the exploration of novel pharmacophores for CXCR4 ligands and that such compounds have promise as therapeutic agents for AIDS, breast cancer metastasis, and rheumatoid arthritis. Furthermore, this methodology is applicable to the design of ligands for other GPCRs.

ACKNOWLEDGMENT

We are grateful to Professor Kazunari Akiyoshi for his generous cooperation in experiments. This research was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology, Japan, and Health and Labour Sciences Research Grants.

MATERIALS AND METHODS

Reagents and chemicals

NP-2 cells with or without stable expression of CXCR4 and green fluorescent protein (GFP) fusion were kindly donated by Dr. Jun Komano. All chemicals were purchased from Wako Chemicals (Tokyo, Japan), unless otherwise indicated.

Synthesis of fluorescent Ac-TZ14011

Protected peptide resin of Ac-TZ14011 was constructed using the Fmoc-based solid-phase synthesis on Rink Amide MBHA resin, and its N-terminus was acetylated. After being treated with thioanisole/TFA in the presence of triisopropylsilane, H_2O and 1,2-ethanedithiol, the crude peptide was air-oxidized to cause disulfide bond formation and then purified by RP-HPLC. ESI-MS: calcd. for $C_{92}H_{143}N_{35}O_{19}S_2$ $[M+H^+]$; m/z 2108.47, found: m/z 2108.96.

TAMRA-Ac-TZ14011 was prepared by condensation of Ac-TZ14011 with TAMRA. N-Hydroxysuccinimide (2.22 mg, 19.3 μmol) and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (3.98 mg, 19.3 μmol) were added to a solution of 6-(TAMRA-5-(and-6)-carboxami)hexanoic acid (TAMRA-COOH, 10 mg, 18.4 μmol) in CH_3CN (500 μL) at 0°C, and the mixture was left overnight at room temperature. After cooling to 0°C again, 200 μL of the reaction mixture was added to 200 μL of Ac-TZ14011 (7.64 mg, 2.86 μmol) in a 1:1 mixture of acetonitrile and phosphate buffer (pH 7.4) and incubated overnight at room

temperature. The crude peptide was purified by RP-HPLC. ESI-MS: calcd. for $C_{123}H_{174}N_{38}O_{24}S_2$ [M+H^+]; m/z 2632.38, found: m/z 2632.49.

Fluorescein-Ac-TZ14011 was prepared by fluorescein conjugation. Ac-TZ14011 (14 mg, 3.4 μmol) in a phosphate buffer (pH 7.4) (130 μL), was added to a solution of 6-(fluorescein-5-(and-6)-carboxamido)hexanoic acid succinimidyl ester (Fluorescein-OSu) in CH_3CN (130 μL) and the mixture was allowed to stand overnight at room temperature. The crude peptide was purified by RP-HPLC. ESI-MS: calcd. for $C_{119}H_{164}N_{36}O_{26}S_2$ [M+H^+]; m/z 2577.28, found: m/z 2578.23.

Imaging analysis using a confocal microscope system

The binding of TAMRA-Ac-TZ14011 to CXCR4 on the cell surface was investigated using an LSM 510 laser-scanning confocal microscope (Zeiss GmbH, Oberkochen, Germany). NP-2 cells with or without a stable expression of CXCR4-GFP fusion [18] were seeded in a 1.4 cm diameter glass-bottom-dish containing RPMI1640 supplemented with 10% fetal bovine serum (FBS) (1×10^5 cells per dish). After 2 days incubation at 37°C under 5% CO_2, the medium was removed, and the cells were washed three times with RPMI 1640 containing 20 mM HEPES (pH 7.4). CXCR4 ligands were added to each well, and the mixture was incubated for 15 min at room temperature. The medium was then removed, and the cells were washed three times with phenol red-free RPMI 1640 medium. The concentrations of TAMRA-Ac-TZ14011

and Ac-TZ14011 that were used were 25 nM and 2.5 μM, respectively.

Cell-based binding assay

Jurkat cells were harvested and resuspended in binding buffer (RPMI 1640 medium containing 20 mM HEPES, pH 7.4). Binding experiments were performed in the presence of 10 nM Fluorescein-Ac-TZ14011 and various concentrations of test compounds. After 30 min incubation at 0°C, cells were washed with PBS, and cell-associated fluorescence intensity was counted by Wallac 1420 ARVO MX (Ex/Em = 485/535 nm). The degree of inhibition was calculated with equation (1),

$$\text{Inhibition}(\%) = (Et - Ea)/(Et - Ec) \times 100 \quad (1)$$

where Et, Ea and Ec respectively, represent the fluorescence intensity without test compounds, fluorescence intensity with addition of test compounds, and fluorescence intensity with excess amount of Ac-TZ14011 as a competitor. The inhibition values were derived by non-linear regression, and IC_{50} values were calculated by Prism 5 software.

Fluorine-18-Labeled Phospholipid Quantum Dot Micelles for *in Vivo* Multimodal Imaging from Whole Body to Cellular Scales

CEA, DSV, I^{2}BM, SHFJ, Laboratoire d'Imagerie Moléculaire Expérimentale, and Inserm U803, 4 place du général Leclerc, 91401 Orsay Cedex, France, and Laboratoire Photons et Matière, CNRS UPRA0005, ESPCI, 10 rue Vauquelin, 75005 Paris, France. Received May 6, 2008; Revised Manuscript Received June 16, 2008

We have designed new nanoprobes applicable for both positron emission tomography (PET) and optical fluorescence *in vivo* imaging. Fluorine-18, which is commonly used for clinical imaging, has been coupled to phospholipid quantum dot (QD) micelles. This probe was injected in mice and we demonstrated that its dynamic quantitative whole body biodistribution and pharmacokinetics could be monitored using PET as well as the kinetics of their cellular uptake using *in vivo* fibered confocal fluorescence imaging. Phospholipid micelle encapsulation of QDs provides a highly versatile surface chemistry to conjugate multiple chemicals and biomolecules with controlled QD:molecule valency. Here, we show that, in contrast with several previous studies using other QD polymer coatings, these phospholipid QD micelles exhibit long circulation half-time in the bloodstream (on the order of 2 h) and slow uptake by reticulo-endothelial system.

INTRODUCTION

Molecular imaging revolutionizes the way biomedical research is performed by looking at molecular events in the living organism without destroying it. Molecular meaningful images can be captured at different levels of spatial resolution and depth using different imaging modalities. For example, fluorescence imaging allows functional multiplexed imaging with submicrometer resolution, but is inherently restricted to biological objects not thicker than a few millimeters or centimeters, and does not provide quantitative concentration measurements. In contrast, nuclear imaging techniques, such as positron emission tomography (PET), allow quantitative whole body imaging, albeit with a low (a few mm) spatial resolution. Tools for combining the different levels of observation are required to reconcile molecular images into a global picture. One of nanotechnology's most promising aspects lies in the ability to design multifunctional platforms including several contrast agents for multimodal imaging. Here, we explore new multifunctional nanoparticles containing both fluorescence and nuclear contrast agents and show that they allow multimodal *in vivo* imaging from the whole body to the subcellular scale.

Semiconductor nanocrystals, or "quantum dots" (*1, 2*), are potentially excellent fluorescent probes for *in vivo* imaging due to their intrinsic optical properties, such as high quantum yields, excellent resistance to photobleaching, broad excitation spectra, and narrow emission bands tunable from the UV to the NIR regions (*3, 4*). QDs have been used in laboratory animals for optical imaging of blood vessels (*5*) and lymph nodes (*6*), for cell tracking (*7, 8*), and for specific targeting of peptides and antibodies (*9, 10*). Yet their use has been limited by concerns about their *in vivo* targeting, biocompatibility, and toxicity, which are mainly determined by nanoparticle size and surface chemistry. While fluorescence imaging offers a rapid tool to qualitatively assess the final QD biodistribution, combining optical and nuclear imaging techniques will provide a more quantitative tool to characterize the dynamics of these nanoparticle biodistribution. A recent report by Schipper et al. utilized copper-64-labeled/polymer-coated commercially available QDs to follow their biodistribution in mice using PET (*11*). Consistent with previous reports (*12, 13*), this study demonstrated QD uptake by the liver and the spleen within a few minutes, without evidence of clearance from these organs. However, the authors did not use fluorescence imaging to investigate their cellular distribution. Furthermore, even if the long half-life of ^{64}Cu is attractive for preclinical PET applications, it is not widely used in humans where ^{18}F labeling is preferred for PET radiopharmacy.

Here, we report a novel bifunctional probe for fluorescence and nuclear imaging based on QDs encapsulated in functionalized phospholipid micelles and covalently labeled with fluorine-18, the most popular positron-emitting isotope. We demonstrate that a combination of PET and fluorescence imaging can be used to monitor quantitatively and dynamically the *in vivo* distribution of these probes, from the whole body to cellular scales, and we report for the first time the major pharmacokinetics parameters of nontargeted micelle-encapsulated QDs. These probes exhibit a long circulation time in the blood, before their uptake by the reticulo-endothelial system.

EXPERIMENTAL PROCEDURES

CdSe/CdZnS Core−Shell Synthesis. CdSe nanocrystal cores were synthesized using slight variations of previously published protocols (*14, 15*). Briefly, a solution of Se in trioctylphosphine (TOP) and oleylamine was swiftly injected in a three-neck flask containing octadecene, trioctylphosphine oxide, and Cd-oleate precursors at 300 °C. The temperature was lowered to 250 °C for 10 min for nanocrystal growth. The CdSe cores were isolated by precipitation and resuspended in hexane. CdZnS shell growth was performed using dropwise injection of TOP-S solution in a three-neck flask containing CdSe cores, Cd-oleate, and Zn-

oleate precursors dissolved in trioctylamine at 300 °C under argon. Supporting Information Figure S1A shows the resulting QD absorption and emission spectra. The diameter of the obtained QDs is typically 6−8 nm, as measured by transmission electron microscopy (*15*).

QD Encapsulation and Functionalization with Thiol Groups. QDs were encapsulated in PEG-phospholipid micelles as previously described (*7, 15*). QDs were dissolved in $CHCl_3$ with a mixture of 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (DPPE-PEG2000) and DSPE-PEG2000-NH_2 (Avanti Polar Lipids) at the desired ratio. The total number of lipids per QD in the encapsulation solution was kept constant at ∼700. Distilled water was added and the solution was heated to 70−80 °C until the chloroform was evaporated. Encapsulated QDs were purified from aggregates and empty micelles by ultracentrifugation at 300 000 *g* in 30% sucrose solution, sucrose was eliminated by ultrafiltration (Vivaspin 500 10 kDa VS0102, Sartorius), and the encapsulated QDs were resuspended in PBS buffer. The resulting QD micelles have typical hydrodynamic sizes ∼20−25 nm as measured by dynamic light scattering (*15*). The amine groups at the extremity of the DSPE-PEG2000-NH_2 were converted into thiols using standard bioconjugation schemes (*16*) (Supporting Information Figure S1). Heterobifunctional linker sulfo-lc-SPDP (Pierce) was added to the QD solution with 100 sulfo-lc-SPDP per QD. The pyridine disulfide thiol group was reduced using dithiothreitol (DTT, Fluka) and the solution was purified with a desalting column (NAP-5, Amersham GE Health Care) and ultrafiltration in PBS.

Functional Group Titration. The number of functional thiol groups per QD was estimated from the absorbance of the QDs and a conjugated organic dye. Fluorescein-5-maleimide was added to the QD solution at a 40:1 fluorescein/QD ratio, and the QDs were purified with a desalting column and ultrafiltration in PBS. The absorbance of the purified QD-dye conjugates were compared to the absorbance of QD only and dye only solutions of known concentrations, and a ratio of dye per QD was calculated (Supporting Information Figure S2B). This ratio provides an estimate for the number of thiol groups per QD. As shown in Supporting Information Figure S2C, the number

Figure 1. *In vivo* imaging of [^{18}F]-QDs with PET. (A) Whole-body PET projection images acquired after intravenous injection of 200 μCi (7.4 MBq, 1 nmol) of [^{18F}]-QDs, in a nude mouse. Each image corresponds to a 10 min acquisition time interval ending at the indicated time. (B) 3D reconstruction of mouse body with the ROI of organs that were used for PET data quantification: Heart in red, lungs in gray, liver in green, spleen in pink, duodenum in black, left kidney in yellow, right kidney in blue, bladder in brown. (C) Biodistribution of [^{18F}]-QDs (%ID/g) obtained by semiautomatic quantification of PET data. Mean ± SD of three independent experiments.

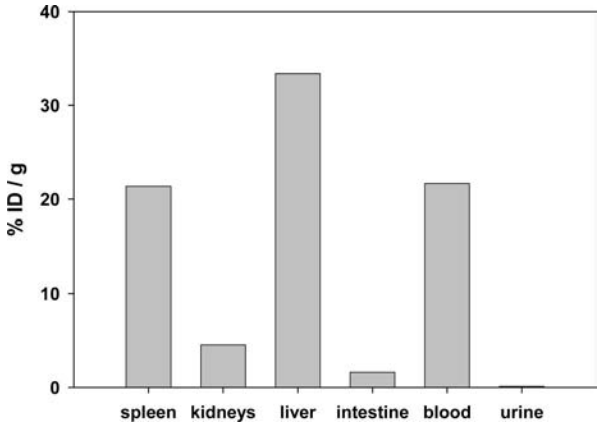

Figure 2. Elemental analysis of dissected organs. Cadmium amount measured in organs dissected 90 min postinjection. Measurements were made by inductively coupled plasma-mass spectrometry (ICP-MS).

of available thiol groups per QD is proportional to the initial percentage of DSPE-PEG2000-NH_2 phospholipids used for encapsulation. This linear dependence corresponds to ~110 phospholipids per QD micelle, consistent with a measured aggregation number of ~75 for empty DPPE-PEG2000 micelles (*17*). This allows easy control on the number of conjugated molecules per QD simply by varying the composition of the initial encapsulation solution.

Fluorine-18-Labeling of QDs. A maleimido [^{18}F]reagent, coded [^{18}F]FPyME (1-[3-(2-fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione) (*18*), was recently developed for the fluorine-18-labeling of peptides and proteins. In this reagent, the pyridinyl moiety carries the radioactive fluorine which can be efficiently incorporated *via* a nucleophilic *hetero*aromatic substitution, and the maleimido function ensures that the efficient alkylation of a sulfhydryl function borne by the macromolecules. QDs were fluorine-18-labeled using [^{18}F]FPyME, which represents the first labeling of this class of nanoobjets with such a short-lived radioactive isotope. 740−1850 MBq (20−50 mCi) of [^{18}F]-QDs (SRA: 370−740 GBq/μmol @ EOB), ready-to-use (555−1110 MBq/mL in aq. 0.9% NaCl), could be obtained starting from 37 GBq of cyclotron-produced [^{18}F]fluoride in 145 min of radiosynthesis (automation in place on a Zymate XP (Zymark) robotic system).

Step 1. Synthesis of [3-(3-*tert*-butoxycarbonylamino-propoxy)-pyridin-2-yl]-trimethyl-ammonium trifluoromethanesulfonate as precursor for fluorine-18-labeling. 3-(3-*tert*-Butoxycarbonylaminopropoxy)-pyridin-2-yl]-trimethylammonium trifluoromethanesulfonate was synthesized in two steps from commercially available (3-hydroxypropyl)-carbamic acid *tert*-butyl ester and 2-dimethylamino-3-hydroxypyridine as previously described (*18*). ^{1}H NMR (CD_2Cl_2, 298K): δ 8.10 (bd, J = 3.3 Hz, 1H); 7.66 (d, J = 8.1 Hz, 1H); 7.60 (dd, J = 6.1 and 4.2 Hz, 1H); 4.31 (t, J = 6.3 Hz, 2H); 3.71 (s, 9H); 3.31 (q, J = 6.3 Hz, 2H); 2.12 (q^5, J = 6.3 Hz, 2H); 1.38 (s, 9H).^{13}C NMR (CD_2Cl_2, 298 K): δ 156.6 [C]; 147.7 [C]; 142.6 [C]; 139.0 [CH]; 129.0 [CH]; 124.6 [CH]; 121.2 [q, J = 319 Hz, CF_3]; 79.3 [C]; 68.1 [CH_2]; 54.8 [3 × CH_3]; 37.5 [CH_2]; 30.0 [CH_2]; 28.4 [3 × CH_3].

Step 2. Radiosynthesis of 1-[3-(2-[^{18}F]fluoropyridin-3-yloxy)-propyl]pyrrole-2,5-dione as fluorine-18-labeled reagent. 1-[3-(2-[^{18}F]-Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([^{18}F]FPyME, HPLC-purified) was prepared from [3-(3-*tert*-butoxycarbonylamino-propoxy)-pyridin-2-yl]-trimethylammonium trifluoromethanesulfonate according to slightly modified published procedure (*18*) in 17−20% non-decay-corrected yield (based on starting [^{18}F]fluoride) using a three-step radiochemical pathway in 110 min.

Step 3. Conjugation of QDs with 1-[3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione. [^{18}F]-QDs were prepared as following: To 100 μL of DMSO containing HPLC-purified [^{18}F]FPyME (freed from HPLC-solvents by concentration to dryness at 65−75 °C under a gentle nitrogen stream) was added ca. 4.75−6.25 nmol of QDs dissolved in PBS (0.1 M, pH 8.0, 900 μL). The reaction mixture was gently vortexed for 15 min and then purified by gel filtration on a NAP-10 G25 Sephadex cartridge (Amersham Pharmacia Biotech). The labeled conjugated [^{18}F]-QDs was eluted in 1.5 mL of aq. 0.9% NaCl according to manufacturer's instructions.

PET Imaging. After i.v. injection of the [^{18}F]-QDs in athymic nude mice (25−30 g body weight) under isoflurane anesthesia, dynamic PET images were acquired in 3D mode in a small animal dedicated PET scanner (Siemens-Concorde Microsystems Focus 220) continuously during 90 min. The time−activity curves of [^{18}F]-QDs in the mouse organs were calculated from regions of interest placed at the center of the organs delineated by a semiautomatic segmentation method (*19*).

Metabolism Analysis. 200 μL of blood were collected from 30 g nude mice at 1 and 3 h after i.v. injection of 37 × 10^6 Bq of [^{18}F]-QDs. Blood samples were centrifuged at 3000 rpm for 5 min at 4 °C. Plasma was filtrated on a Microcon YM-10 tube (Millipore). Radioactivity from the filtrate and retentate recovery were measured by a beta counter (Cobra II Auto gamma, Packard Bioscience Company) to quantify [^{18}F]-QDs degradation. Urine was directly filtrated on a Microcon tube.

Elemental Analysis of Dissected Organs. Liver, spleen, kidneys, and intestine were dissected and blood and urine samples were taken 90 min postinjection. Samples were weighted, then diluted in 2−10 mL concentrated sulfuric acid and heated at 60 °C for 4 h for complete dissolution. Cadmium doses in each sample were then measured by ICP-MS at the Service Central d'Analyse du CNRS, Vernaison, France.

***In Vivo* Fibered Confocal Fluorescence Microscopy.** The CellVizio(R) 488, from Mauna Kea Technologies (MKT), France, consists in a flexible submillimetric probe containing *ca.* 30 000 optical fibers that carry light from a continuous laser source at 488 nm to the living tissue. Fluorescence emitted after excitation of the QDs present in the tissue is sent back to the apparatus where a dedicated set of algorithms reconstructs images in real time at a rate of acquisition of 12 frames per second. In the experiments reported here, we used a MiniO/30 probe (lateral resolution 1.8 μm, axial resolution 5 μm at 37 μm) over a field of view of 175 μm × 125 μm, corresponding in that case to 12218 fibers only. After injection of 5 nanomoles of QDs in athymic nude mice (25−30 g body weight) under isoflurane anesthesia, microsurgery in the abdominal part was performed in order to access the liver and the spleen with the probe. Both organs were scanned regularly at selected time intervals.

QD Cellular Uptake Quantification from Fibered Confocal Fluorescence. Using the data acquisition software *ICviewer* (MKT, France) and *Image J*, we constructed fluorescence intensity histograms for 30 independent pictures acquired from film scans of the liver at selected time intervals. In the first films acquired immediately after QDs administration (i.e., at a time when tissue fluorescence corresponds to the QDs present in the blood pool), values never exceeded 220 fluorescent CellVizio(R) arbitrary units (AU). Choosing this value as a threshold, we quantified the cellular uptake of QDs in the liver identifying pixels above this threshold with QDs captured by cells.

***Ex Vivo* Fluorescence Microscopy.** For microscopic analyses, tissues were recovered 90 min after QDs injection, fixed overnight in 4% paraformaldehyde, incubated overnight in 20% sucrose, snap frozen in cold isopentane, and sectioned at a thickness of 5 μm. Slides were mounted with Prolong antifade reagent with DAPI (Invitrogen). Micrographs were obtained with a wide-field fluorescence microscope (Provis AX70, Olympus) equipped with the excitation filter BP 330−385 nm, the dichroic

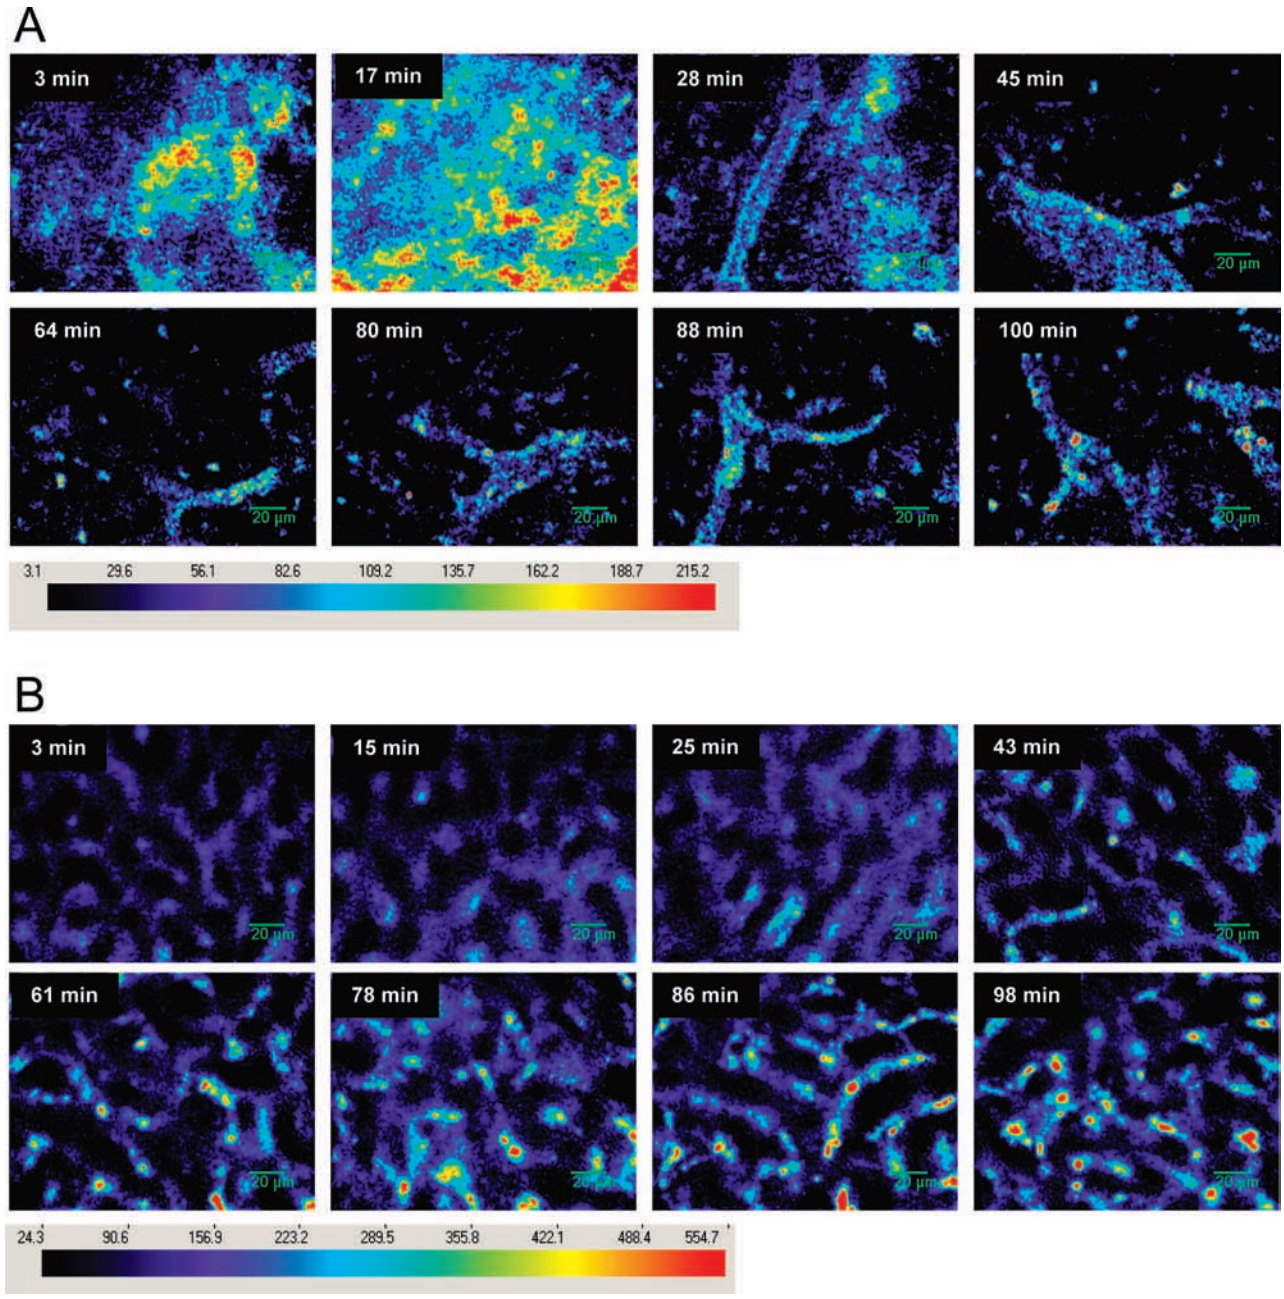

Figure 3. *In vivo* fluorescence imaging of QDs. (A) Representative *in vivo* fluorescence images of the spleen at the indicated times postinjection using the fibered confocal microscope. (B) Same as A in the liver.

mirror DM 400 nm, the barrier filter BA420 nm, and a digital color camera.

***Ex Vivo* Fluorescence Confocal Microscopy.** Tissue sections were processed as above and observed in a Leica confocal microscope SP2. 3D rendering was obtained with the *ImageJ* plugin VolumeJ from a Z-stack captured with the Leica confocal microscope SP2.

RESULTS

Core/shell CdSe/CdZnS nanocrystals were synthesized using standard organometallic procedures and encapsulated into poly(ethylene glycol) (PEG)-phospholipid micelles. The resulting nanoparticles exhibit small hydrodynamic sizes and high stability. While PEG moieties efficiently envelop the nanoparticles and limit nonspecific interactions with their environment, introduction of functionalized phospholipids bearing chemical functional groups allows fine-tuning of the QD surface chemistry and easy covalent coupling to a wide variety of molecules (*7, 15*) with a controlled molecule-per-QD ratio (see Supporting Information Figures S1−S2). Here, we conjugated PEG-phospholipid QD micelles displaying thiol groups with [^{18}F]F-PyME, a fluorine-18-containing (positron-emitter, half-life = 109.8 min) maleimide reagent (*18, 20*) (Scheme 1). Efficient coupling of [^{18}F]FPyME with the nanoparticle was confirmed by the high radioactivity observed for the purified QDs (37−75 $\times$ 10^7 Bq/QD nmol). The coupling was stable *ex vivo*, as no radioactive elements smaller than 10 kDa could be separated from the QDs by membrane separation, even six hours after coupling. The biodistribution of the [^{18}F]-QDs was then followed *in vivo* in mice using both PET and CellVizio(R) imaging, and *ex vivo* using fluorescence microscopy.

Dynamic PET imaging was recorded in a small animal dedicated PET scanner up to 90 min after i.v. injection of 1 nanomole of [^{18}F]-QDs (Figure 1). [^{18}F]-QDs were rapidly taken

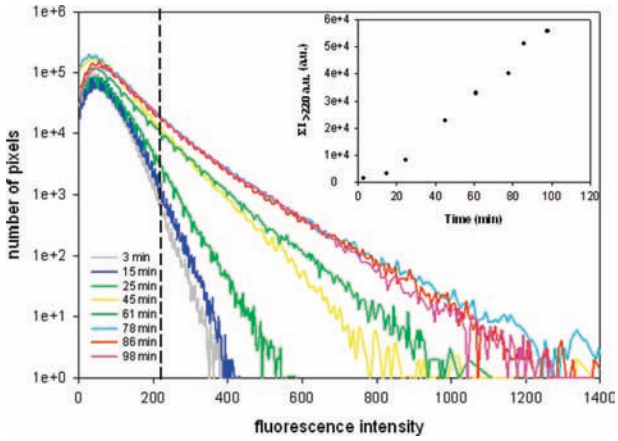

Figure 4. Quantification at the cellular scale of *in vivo* biodistribution of QDs in the liver. Distribution of the fluorescence intensities (a.u.) measured in the liver by the fibered confocal microscope in series of images corresponding to different time postinjection. QDs in the blood are predominantly detected in pixels with fluorescence intensities >220 au (dotted line). Inset: The kinetics of QD cellular uptake is estimated by plotting the sum of fluorescence intensity values above this threshold as a function of time.

up in highly vascularized organs such as the heart, the lungs, the kidneys, the liver, and the spleen. The labeled QDs were found essentially stable in plasma (less than 3% degradation three hours postinjection). The small amount of fluorine-18-labeled degradation products were readily excreted through the kidney (87% of the radioactivity recovered in urine 90 min postinjection corresponded to >10 kDa products). Taken together, these results indicate that the radioactivity concentrations measured in organs other than kidney and bladder reflect predominantly intact [^{18}F]-QDs.

Washout from the heart and lungs was slow; however, *ex vivo* fluorescence microscopy of the lungs and heart showed the absence of uptake of QDs in these organs (see Supporting Information Figure S3). This indicates that the PET signal in these two organs is essentially contributed by QDs from the blood pool. Therefore, the cardiac time−activity curve was used to calculate blood pharmacokinetics parameters of the [^{18}F]-QDs (Supporting Information Table 1). QDs exhibit a long circulation time in blood with a $T_{1/2}$ of approximately 2 h. In the liver and the spleen, radioactivity concentrations at 90 min postinjection were, respectively, 10% and 6% of the injected dose per gram tissue (Figure 1C). This major difference with polymer-coated QDs that have been shown to accumulate very rapidly at high levels in the liver (*11–13*) (ca. 30−50%ID/g, 10 min after injection), is likely a consequence of the PEG coating of our PEG phospholipid micelle QDs. Accordingly, significant amounts (ca. 10%ID/g) of QDs were detected in the blood 90 min after injection, confirming the long circulation time of PEG phospholipid micelle QDs in the bloodstream, before getting cleared from the circulation by the reticulo-endothelial system.

The biodistribution data obtained with PET were correlated by dosing cadmium using elemental analysis at 90 min postinjection. Major organs such as liver, spleen, kidney, and intestine, and blood and urine were dissolved in concentrated sulfuric acid and analyzed by ICP-MS. Concentration measurements confirmed the absence of cadmium in the bladder, urine, or intestine 90 min after injection, whereas a high concentration of cadmium could be measured in the blood, liver, and spleen (see Figure 2). These results are consistent with radioactive metabolite analysis indicating that the radioactivity detected in the urinary tract corresponded to degradation products and confirm the biodistribution of the [^{18}F]-conjugated QDs measured by PET in the other organs.

In vivo fiber confocal fluorescence imaging was used to further explore the QD biodistribution at the cellular level in the organs showing prolonged high levels of uptake, i.e., the liver and the spleen. In the spleen, QD distribution was initially very heterogeneous and particularly elevated in regions that correspond to leaky venous sinuses of the red pulp. After ~25 min, the QDs were progressively washed from these zones while uptake by macrophages sheathing small capillaries could be observed (Figure 3A). In the liver, fluorescence originated predominantly from the blood pool in agreement with PET data. A progressive uptake by cells located inside the hepatic tissue could be observed 30 min after injection (Figure 3B). These individual cells are uniformly distributed around the centrolobular vessels, a distribution suggestive of Kuppfer cells, the tissular macrophages lining the hepatic sinusoids. High resolution confocal microscopy of *ex vivo* liver sections demonstrated that QDs were internalized in these cells 90 min postinjection (Supporting Information Figures S3F and S3G). The kinetics of QD uptake by Kupffer cells was quantified and showed a constant increase between 15 and 90 min, consistent with a slow reticulo-endothelial uptake (Figure 4 and Supporting Information video).

DISCUSSION

We have designed a novel multimodal imaging probe based on a [^{18}F]-labeled QD phospholipid micelle. This QD conjugate provides a strong radioactive signal for high-sensitivity PET imaging, along with bright and stable fluorescence for *in vivo* and *ex vivo* cellular imaging. We have demonstrated the potential of this multimodal imaging probe by investigating the dynamics of the *in vivo* biodistribution of nontargeted [^{18}F]-QDs. These QD micelles do not show renal clearance, which, as suggested by the recent studies of Choi et al. (*21*), could be the result of their large diameter (>20 nm). Interestingly, these phospholipid micelle QDs exhibited prolonged circulation in the blood, with a $T_{1/2}$ on the order of 2 h. This relatively long circulation time is due to a complete coverage of the nanoparticle with PEG. In comparison, QDs coated with amphiphilic polymers containing PEG chains of similar molecular weights exhibited much faster uptake by the reticuloendothelial system, probably due to its different surface chemistry. We assume that the capacity of our QDs to evade opsonization and capture by reticuloendothelial sytem for a relatively long period of time could allow more efficient delivery to specific tissular and/or endothelial targets. On the other hand, long circulating QDs could provide higher background, and more specific studies on targeted QDs are required to optimize both delivery efficiency and signal-to-background ratios.

In vivo targeting of QDs or nanoparticles has been previously demonstrated, e.g., using peptides or antibodies (*9, 10*). In this respect, the versatility of phospholipid micelle surface chemistry is an advantage, as different functionalized phospholipids are readily commercially available. Therefore, micelles with mixed surface composition can easily be obtained without *de novo* synthesis, in contrast to polymer encapsulation. We have shown that tuning the composition of the phospholipid micelle can further provide a variety of functional end groups for easy covalent conjugation of QDs with multiple chemicals and biomolecules with controlled QD:molecule valency (*7, 15*). In that respect, it is noteworthy that our radiolabeling method does not preclude further conjugation of [^{18}F]-QDs to targeting moieties. Finally, we note that phospholipid micelle encapsulation is a general principle that has been demonstrated with various nanoparticles such as gold or iron oxide particles (see, e.g., refs *22, 23*). As a consequence, conjugation techniques using phospholipid micelles and optimization of the micelle surface chemistry for *in vivo* imaging could benefit a wide array of biomedical applications.

In conclusion, this work represents the first report of a fluorine-18-labeling and quantitative whole body imaging study of PEG-phospholipid QD micelles with PET. The results differ noticeably from previous reports on *in vivo* biodistribution using QDs (*11–13*, *24*). The results presented here show that these phospholipids QD micelles are well distributed throughout the body and exhibit long circulation times and, as expected for nanoparticles, slow uptake by the reticulo-endothelial system. These properties could stand in favor of the further development of QDs for some *in vivo* imaging applications. Furthermore, bimodal [^{18}F]-QDs are appealing nanoprobes because they make the best of two *in vivo* molecular imaging systems: PET imaging for whole body imaging and fluorescence imaging for subcellular localization, and therefore allow multiscale imaging of biomarkers of interest.

ACKNOWLEDGMENT

This work was supported by grants from the European Molecular Imaging Laboratory (EMIL) network (EU contract LSH-2004-503569), l'Agence Nationale pour la Recherche (ANR TechSan Dot-Imager and ANR Emergence ARTIC), and the Association pour la Recherche sur le Cancer (3527) and ANR-INCA programme FLUOR-C. We are grateful to Olivier Carion for discussions, Yohan Fontyn for PET experiments, Renaud Maroy for help with Semi Automatic quantification of PET data, Susanne Bolte and Marie-Noelle Soler for help in confocal microscopy at the plate-forme Imagerie et Biologie Cellulaire of Gif sur Yvette and to Arnaud Le Nevez, Tom Vercauteren and Aymeric Perchant from Mauna Kea Technologies for technical assistance with the CellVizio(R).

Rapid and Efficient Production of Radiolabeled Antibody Conjugates Using Vacuum Diafiltration Guided by Mathematical Modeling

Derek W. Bartlett, David Colcher, and Andrew A. Raubitschek*

Division of Cancer Immunotherapeutics & Tumor Immunology, Beckman Research Institute and City of Hope National Medical Center, Duarte, California 91010. Received May 30, 2008; Revised Manuscript Received July 28, 2008

Increasing interest in the use of radiolabeled antibodies for cancer imaging and therapy drives the need for more efficient production of the antibody conjugates. Here, we illustrate a method for rapid and efficient production of radiolabeled antibody conjugates using vacuum diafiltration guided by mathematical modeling. We apply this technique to the production of 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)-conjugated antibodies at the milligram and gram production scale and achieve radiolabeling efficiencies >95% using In-111. Using vacuum diafiltration, antibody−chelate conjugation and purification can be accomplished within the same vessel, and the entire process can be completed in <24 h. Vacuum diafiltration also offers safer and gentler processing conditions by eliminating the need to keep the retentate vessel under positive pressure through applied gas pressure or shear-inducing restriction points in the retentate flow path. Experimental data and mathematical model calculations suggest there exists a weak binding affinity ($\sim 10^4\ M^{-1}$) between the charged chelate molecules (e.g., DOTA) and the antibodies that slows the removal of excess chelate during purification. By analyzing the radiolabeling efficiency as a function of the number of diavolumes, we demonstrate the importance of balancing the removal of free chelate with the introduction of metal contaminants from the diafiltration buffer and also illustrate how to optimize radiolabeling of antibody conjugates under a variety of operating conditions. This methodology is applicable to the production of antibody conjugates in general.

INTRODUCTION

Radiolabeled antibodies have been used for therapy and imaging of cancer for over two decades (*1*). Radioimmunotherapy has been particularly effective in the treatment of hematologic malignancies (lymphomas), evidenced by the two FDA-approved radiolabeled anti-CD20 antibodies, Zevalin and Bexxar (*2*). The use of antibodies to achieve targeted delivery of radiation provides benefits not achievable by monoclonal antibodies or external beam radiation alone. Metal chelators, such as DOTA, can be covalently attached to antibodies and subsequently used to bind radioisotopes (*3, 4*). However, antibody-conjugated chelators can be hampered by slow radiolabeling kinetics and poor radiolabeling efficiencies (*5*). While functionalization of the chelate, as in the conjugation to lysines on a protein, has been shown to slow the metal loading rate and lower the overall thermodynamic stability of the metal complex (*4, 6, 7*), other factors such as metal contamination or unconjugated free chelate also contribute significantly to the low radiolabeling efficiencies.

Several techniques have been proposed to address the issues of metal contamination and removal of unconjugated chelate. Besides minimizing contact with metal containing materials, buffers can be processed with chelating resins such as Chelex 100 to reduce the metal burden (*8*−*12*). Care must be taken when using chelating resins, such as iminodiacetate (IDA), whose metal binding affinity may be orders of magnitude lower than chelators such as DOTA or diethylenetriaminepentaacetic acid (DTPA). If the resin is allowed to equilibrate with a solution containing the chelate (e.g., DOTA−antibody conjugate), then the metal can be thermodynamically driven to bind to DOTA instead of the chelating resin depending on the relative concentrations. Pretreatment of the buffers using a column of the chelating resin can avoid such complications, and previous reports have demonstrated >99% removal of trace metal contaminants by column operation of the Chelex 100 resin (*12*).

Dialysis is a commonly used method for purification because of its ease of scalability and gentle conditions. Each dialysis-based buffer exchange or purification step is time-intensive and can require multiple days depending on the number of buffer changes required. Furthermore, dialysis can require a large amount of buffer volume that can also increase the risk of introducing metal contaminants. Other membrane-based purification strategies, such as ultrafiltration, can offer faster processing times with reduced buffer volumes. Application of ultrafiltration requires convecting the fluid toward the membrane, and the membrane can be designed to retain larger molecules, such as antibodies, while allowing low molecular weight impurities to penetrate through the membrane. If repeated cycles of ultrafiltration are used to remove impurity-containing fluid by replacing the fluid removed with impurity-free fluid, the process is called diafiltration. Rapid changes in antibody concentration resulting from the cycles of ultrafiltration and buffer replacement can negatively impact antibody stability. This problem is avoided by using constant-volume diafiltration, where the impurity-free buffer is added to the retentate at the same rate as the fluid is removed. Previous studies have demonstrated the feasibility of constant-volume diafiltration for the preparation of radiolabeled antibody conjugates (*13, 14*).

Here, we describe the use of a constant-volume, vacuum-driven diafiltration process for the rapid buffer exchange and purification of conjugated antibodies in preparation for radiolabeling. A mathematical model of the diafiltration and radiolabeling steps is used to predict optimum operating conditions and elucidate possible mechanisms to explain experimental observations. We demonstrate the utility of this technique

through production of DOTA-conjugated monoclonal antibodies at the milligram and gram production scales. Observed radiolabeling efficiencies with In-111 exceeded 95%, and model calculations are used to specifically illustrate how metal contamination and excess chelate can both contribute to low radiolabeling efficiencies. Using vacuum diafiltration, the entire conjugation and radiolabeling procedure can be accomplished within 24 h. Besides expediting the conjugation and purification process, the use of vacuum diafiltration avoids risks associated with membrane-based processing strategies that employ positive pressure gradients as the driving force. When the retentate vessel is under positive pressure, the potential for catastrophic leakage and loss of material is greater since fluid in the retentate will be driven out under pressure through any leak in the system; such a problem is avoided under vacuum diafiltration since the retentate vessel remains near atmospheric pressure. In certain embodiments of ultrafiltration or diafiltration processes, the positive pressure gradient is created by applying a restriction in the retentate flow path. This restriction creates a region of increased shear stress that can exacerbate protein degradation. Vacuum diafiltration provides more gentle processing conditions, and the stability of the applied vacuum enables strict control of the pressure differential across the membrane for the duration of the diafiltration process. The prevalence of small vacuum pumps or house vacuum systems make vacuum diafiltration widely applicable and easily scalable from the laboratory to clinical production, and we have used this technique for the conjugation of a variety of molecules (e.g., biotin and fluorochromes) with antibodies, thereby making it generally applicable to bioconjugations.

MATERIALS AND METHODS

Proteins. Rituximab (Rituxan), a chimeric monoclonal IgG1 against the CD20 antigen, was purchased from Genentech (South San Francisco, CA). Albuminar-25, a 25% w/w human serum albumin preparation with 0.02 M sodium *N*-acetyl-DL-tryptophan and 0.02 M sodium caprylate, was purchased from Aventis Behring (King of Prussia, PA).

Radioisotope. High-purity indium-111 (indium chloride) was obtained in 0.05 M HCl from Trace LifeSciences (Denton, TX).

Buffers. Dulbecco's phosphate-buffered saline without calcium and magnesium was purchased from Mediatech (21−031-CV, Herndon, VA). Sodium bicarbonate buffer was prepared using sodium bicarbonate (7412, Mallinckrodt Baker, Phillipsburg, NJ) and plasma grade water (W9, Fisher Chemical, Fairlawn, NJ). Ammonium acetate buffer was prepared using ammonium acetate (372331, Aldrich, St. Louis, MO) and plasma grade water (W9, Fisher Chemical). Sodium acetate buffer was prepared using sodium acetate (3462-01, Mallinckrodt Baker, Phillipsburg, NJ) and plasma grade water (W9, Fisher Chemical).

Chelex 100 Trace Metal Removal. Biotechnology grade Chelex 100 chelating resin (Bio-Rad, 100−200 mesh, 143−2832) was used in column mode for trace metal removal from the ammonium acetate buffer. The Chelex 100 resin (100 g) was initially washed with ∼400 mL of 0.1 N NaOH and allowed to stand for 18 h for depyrogenation. Following depyrogenation, the liquid was removed by vacuum filtration, and the resin was rinsed with 500 mL of plasma grade water. Subsequently, the resin was washed with ∼400 mL of 0.1 N HCl followed by ∼750 mL of plasma grade water. The resin was then washed twice with 0.25 M ammonium acetate buffer (pH 7) and poured into a 5-cm diameter XK50 column (GE Healthcare, Chalfont St. Giles, United Kingdom) connected to an AKTA FPLC (GE Healthcare). In the column mode, the resin was further rinsed with ∼600 mL of 0.25 M ammonium acetate buffer (pH 7) such that the measured pH and conductivity of the effluent from the column matched that of the inlet ammonium acetate buffer. The final bed volume of the Chelex 100 resin in the ammonium form was ∼150 mL. Ammonium acetate buffer (0.25 M, pH 7) was pumped through the equilibrated Chelex 100 column at a flow rate of 5 mL/min, and the effluent was collected directly from the outlet of the column into a sterile 2-L Stedim Flexboy Bag (Stedim Biosystems, Aubagne, France).

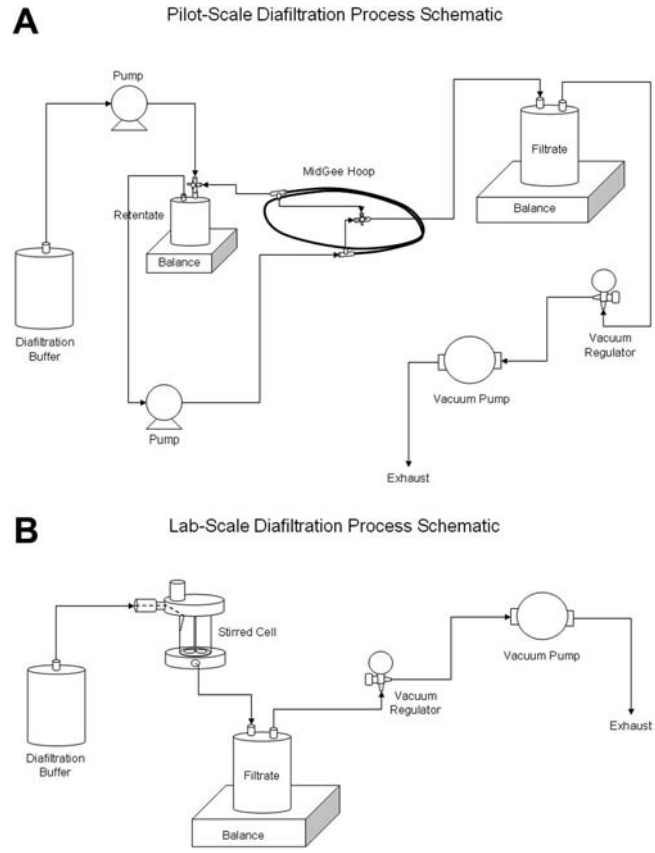

Figure 1. Schematic for vacuum diafiltration at the pilot-scale (A) and laboratory-scale (B).

Pilot-Scale Vacuum Diafiltration. A schematic of the pilot-scale vacuum diafiltration setup is shown in Figure 1A. Vacuum diafiltration was performed at room temperature using a MidGee Hoop (GE Healthcare) cross-flow hollow fiber filter with a 30 kDa MWCO polysulfone membrane, two 1-mm inner diameter fibers, and a membrane area of 73 cm^2. The retentate solution (containing the protein to be diafiltered) was circulated through the hollow fibers at a flow rate of 25−50 mL/min using a peristaltic pump. A vacuum pump was used to apply vacuum to the filtrate side of the membrane to achieve a net transmembrane pressure (TMP) of approximately 8 psi. Under these operating conditions, the flux was 20−25 L/m^2/h (LMH) during diafiltration of the antibody solutions. A weighing balance was used on both the filtrate and retentate vessels to monitor changes in mass (i.e., volume). The diafiltration buffer was pumped into the retentate vessel by a peristaltic pump at a flow rate equal to the flow rate of the filtrate to achieve constant-volume diafiltration.

Laboratory-Scale Vacuum Diafiltration. A schematic of the laboratory-scale vacuum diafiltration setup is shown in Figure 1B. By using the inlet port, normally utilized for the attachment of a gas pressure line, to introduce additional diafiltration buffer under a closed-system operation using HPLC tubing and fittings, constant-volume diafiltration could be achieved. This apparatus requires no additional equipment to achieve constant-volume diafiltration, and it can be operated under vacuum generated from a house vacuum line or a small vacuum pump. If desired, multiple diafiltration devices could

be run in parallel using a common vacuum line, offering flexibility that would facilitate screening multiple variations of an antibody conjugate during the development stage.

Laboratory-scale diafiltration experiments were performed at room temperature using an Amicon Stirred Cell Model 8010 (10-mL sample volume, 4.1 cm^2 effective membrane area) with a Biomax ultrafiltration membrane (PBQK, Millipore, Billerica, MA) with a 50 kDa MWCO. The stirring rate was adjusted such that the vortex created was approximately one-third the depth of the liquid in the stirred cell. Vacuum was applied to the filtrate side of the membrane using a vacuum pump to achieve a net TMP of approximately 8.5 psi. Under these operating conditions, the flux was typically 25−35 LMH during diafiltration of the antibody solutions. The diafiltration buffer reservoir was connected to the stirred cell using 1/16 inch i.d. HPLC tubing connected by HPLC fittings so that the outlet for the diafiltration buffer tubing dripped onto the wall of the stirred cell as shown in Figure 1B (to minimize bubble formation and to prevent contact with any other parts of the stirred cell device). Because the diafiltration setup was operated as a closed system, the diafiltration buffer was pulled into the stirred cell at the same rate as the filtrate flowed out of the stirred cell.

Removal of Acetyltryptophanate (AT) in the Presence of Human Serum Albumin (HSA) or Rituxan by Vacuum Diafiltration. The removal of AT in the presence of both HSA and Rituxan by vacuum diafiltration was studied using the pilot-scale diafiltration setup with a MidGee Hoop cross-flow hollow fiber filter and a retentate flow rate of 25 mL/min. The HSA was used at a concentration of 7 mg/mL, diluted in PBS from Albuminar-25 (which contains 0.02 M AT). Rituxan was used at a concentration of 8.3 mg/mL along with *N*-acetyl-L-tryptophan at a concentration of 4×10^{-4} M^{-1}. The HSA was initially at a concentration of 7 mg/mL in PBS, and it was diafiltered with approximately 6 diavolumes of 0.1 M bicarbonate buffer (pH 8.3). Rituxan was initially at a concentration of 8.3 mg/mL in PBS, and it was first diafiltered with 5 diavolumes of 0.1 M bicarbonate buffer (pH 8.3). Subsequently, the *N*-acetyl-L-tryptophan was added to the Rituxan solution, and the mixture was diafiltered with 7 diavolumes of 0.25 M sodium acetate buffer (pH 7.2). Samples (∼100 μL) were removed from the retentate vessel during diafiltration. The concentration of HSA/Rituxan and AT in each sample was determined by integrating the A280 peak area of the trace from a Superdex 200 column (30 cm x 10 mm i.d.; GE Healthcare) using an AKTA purifier HPLC (GE Healthcare).

Removal of DOTA or DTPA in the Presence of Rituxan by Vacuum Diafiltration. The removal of DOTA or DTPA in the presence of Rituxan by vacuum diafiltration was studied using both the pilot-scale and laboratory-scale diafiltration setup. For the pilot-scale diafiltration, Rituxan was initially at a concentration of 8.3 mg/mL in PBS, and it was buffer-exchanged by diafiltration with 5 diavolumes of 0.1 M bicarbonate buffer (pH 8.3). Subsequently, 1 mM DOTA (Parish Chemical Company, Orem, UT) was added to the Rituxan solution, and the mixture was diafiltered with 7 diavolumes of 0.25 M sodium acetate buffer (pH 7.2). For the laboratory-scale diafiltration, Rituxan was initially at a concentration of 7 mg/mL in PBS, and it was buffer-exchanged into 0.1 M bicarbonate buffer (pH 8.3). After the addition of either 1 mM DOTA or 1 mM DTPA, the mixture was diafiltered with 7 diavolumes of 0.25 M ammonium acetate buffer (pH 7). Samples (∼50−100 μL) were removed from the retentate vessel during the diafiltration. Each experiment was also repeated in the absence of Rituxan.

The concentration of DOTA or DTPA in each sample was determined by a colorimetric assay using arsenazo III. Arsenazo III exhibits a bathochromic shift from 548 to 660 nm upon binding to free gadolinium. To the DOTA- or DTPA-containing samples in microcentrifuge tubes were added 20 nmol of gadolinium chloride in 0.1 M ammonium acetate buffer (pH 6). The reaction mixture was allowed to incubate for 15 min at 75 °C to enable complex formation between the gadolinium and chelate. Using the elevated temperature also helps to minimize interference in the assay from the potential binding between IgG and arsenazo III since IgG molecules show rapid denaturation and aggregation at these temperatures (*15*). Subsequently, the reaction mixture was combined with an equal volume of 1 mM arsenazo III, and the absorbance at 655 nm was measured with a Bio-Rad 680 microplate reader (Bio-Rad, Hercules, CA) to determine the amount of free gadolinium remaining. The relative concentration of DOTA or DTPA was calculated from the change in the level of gadolinium−arsenazo III complexes formed (as indicated by absorbance at 655 nm) since the chelated gadolinium cannot interact with arsenazo III.

Pilot-Scale Production of Radiolabeled Antibodies Using Vacuum Diafiltration. Buffer exchanges and purification required in the preparation of DOTA-conjugated Rituxan were performed using the pilot-scale diafiltration setup with a MidGee Hoop cross-flow hollow fiber filter and a retentate flow rate of 50 mL/min. Rituxan was conjugated with the NHS-activated form of the macrocyclic chelator, DOTA, which reacts with exposed amine groups on the antibody. Rituxan was processed at a concentration of 7 mg/mL in a volume of 50 mL. It was initially exchanged into 0.1 M bicarbonate buffer (pH 8.3) with 1 mM DTPA (metal scavenger) for conjugation. This was achieved with 5 diavolumes and was performed in ∼2 h, after which a 19.5-molar excess of DOTA−NHS (Macrocyclics, Dallas, TX) was added and allowed to react with Rituxan for 2 h at room temperature. Dissolving the DOTA−NHS in water instead of the pH 8.3 buffer can help to reduce unwanted NHS hydrolysis prior to addition to the reaction vessel due to the low pH of the DOTA−NHS solution. Subsequently, the unreacted DOTA−NHS was removed and the conjugate exchanged into 0.25 M sodium acetate buffer (pH 7.2) with 10 diavolumes, and this diafiltration was performed in ∼4 h. Diafiltration with an additional 5 diavolumes of 0.25 M sodium acetate buffer was performed 5 days later. After each diavolume during the postconjugation diafiltration, a 100 μL sample was removed and subjected to radiolabeling with In-111. Additionally, each sample was subjected to HPLC analysis on a Superdex 200 column (30 cm x 10 mm i.d.; GE Healthcare) to analyze antibody concentration and aggregate formation by following absorbance at 280 nm.

Laboratory-Scale Production of Radiolabeled Antibodies Using Vacuum Diafiltration. For preparation of DOTA-conjugated antibodies with the laboratory-scale vacuum diafiltration setup, diafiltration was performed using an Amicon stirred cell and a Biomax ultrafiltration membrane with a 50 kDa MWCO. Rituxan was processed at a concentration of 7 mg/mL in a volume of 5 mL. The initial exchange into the 0.1 M bicarbonate buffer (pH 8.3) with 1 mM DTPA was achieved with 5 diavolumes and was performed in ∼2 h, after which a 15-molar excess of DOTA−NHS (Macrocyclics, Dallas, TX) dissolved in water was added and allowed to react with the antibody inside the stirred cell for 1 h at room temperature. Subsequently, the unreacted chelate was removed and the conjugate exchanged into 0.25 M ammonium acetate buffer (pH 7, processed with Chelex 100 as described previously) with 18 diavolumes (still using the same stirred cell device) in ∼8 h. During the postconjugation diafiltration, samples (∼75 μL each) were removed at specified diavolumes and subjected to radiolabeling with In-111. Each sample was also subjected to HPLC analysis on a Superdex 200 column (30 cm x 10 mm i.d.; GE Healthcare) to analyze antibody concentration and aggregate formation by following absorbance at 280 nm.

Radiolabeling Efficiency. Radiolabeling reactions were performed at a ratio of 5 mCi/mg antibody conjugate in acetate buffer (pH 5.5), and the reaction was allowed to proceed for 45 min at 43 °C. Radiolabeling efficiency was measured by instant thin layer chromatography (ITLC). Two equal aliquots of the reaction mixture were withdrawn, and 10 mM DTPA solution (pH 6) was added to one aliquot to give a final concentration of 1 mM DTPA. This was incubated for 10 min at room temperature. Samples from the radiolabeling reaction with and without the DTPA chase were then analyzed on 2.25 inches × 0.5 inches Tec-Control ITLC strips (Cat. # 151-020, Biodex Medical Systems, Shirley, NY) using 0.9% saline as the mobile phase. Each strip was cut into 0.5-cm segments, and each segment was counted in a Cobra Autogamma counter. The ratio of radioactivity at the origin (In-111 bound to the DOTA−antibody conjugate or free, hydrolyzed In-111) to the radioactivity near the solvent front (DOTA- or DTPA-chelated radioisotope) was calculated. An estimate of the amount of free radioisotope remaining was obtained from the difference between the fraction of the radioactivity measured at the origin (bottom half) for ITLC strips run with or without the DTPA chase.

Mathematical Model Calculations. Model calculations were performed using MATLAB 7 (The MathWorks, Inc., Natick, MA). The differential equations governing the clearance of solutes during diafiltration were solved numerically using the forward Euler method with a step size equal to 1/1000 the total number of diavolumes analyzed. Chelate−metal complex formation is assumed to reach equilibrium (both during diafiltration and during the radiolabeling reaction) to simplify calculation of metal loading and overall radiolabeling efficiency.

RESULTS

Theoretical Development. *Impurity Removal by Vacuum Diafiltration.* Removal of low molecular weight impurities during constant-volume diafiltration can be calculated from a mass balance on the impurity in the retentate. If the impurity exhibits a reversible binding affinity interaction with the retained molecule, such as an antibody, then impurity removal will proceed more slowly as a result of the binding interaction. The impact of protein binding during diafiltration has been previously analyzed using D-tryptophan and bovine serum albumin as a model system (*16*). The change in the concentration of impurity, C_i, during constant-volume diafiltration is given by the following equation:

$$V\frac{dC_i}{dt} = -f_i C_i S_i J_v A \tag{1}$$

where V is the constant retentate volume, f_i is the unbound fraction of impurity i, S_i is the sieving coefficient of impurity i, J_v is the filtrate flux through the membrane, and A is the membrane area. The binding interaction between the impurity and a retained protein can be expressed in terms of an equilibrium binding constant, K_a, which is defined as

$$K_a = \frac{[C_{i,b}]}{[C_{i,f}][C_{p,f}]} \tag{2}$$

where $C_{i,b}$ is the bound concentration of impurity i, $C_{i,f}$ is the free concentration of impurity i, and $C_{p,f}$ is the free concentration of the protein that interacts with the impurity. This expression can be used to derive an expression for f_i, the unbound fraction of impurity i, given by the following equation:

$$f_i = \frac{-nC_p + C_i - \frac{1}{K_a} + \sqrt{\left(nC_p - C_i + \frac{1}{K_a}\right)^2 + \frac{4C_i}{K_a}}}{2C_i} \tag{3}$$

where n is the number of binding sites per protein for impurity i. For an impurity that has no protein binding ($f_i = 1$), the concentration of impurity remaining after a given number of diavolumes, N_D, is equal to

$$C_i = C_{i,0}e^{-N_D S_i} \tag{4}$$

where $C_{i,0}$ is the initial impurity concentration, and the concentration of remaining impurity decays exponentially with the number of diavolumes.

Chelate−Metal Complex Formation. Chelation of metal species by compounds such as DOTA can be approximated as an association reaction between the metal species, *M*, and the chelate, *C*, to form a metal−chelate complex, *M-C*. This equilibrium binding can be described by

$$K_f = \frac{[M-C]}{[M][C]} \tag{5}$$

where K_f is the stability constant of the metal−chelate complex. This equation can be used to estimate the equilibrium metal loading into the chelate molecules given the stability constant and the initial concentrations of *M* and *C* (*17*). Metal loading is calculated for both free chelate (not protein-bound), C_f, and chelate molecules covalently coupled to the antibody molecule, *C-Ab*. For example, separate equilibrium relationships can be written for the free and conjugated chelate,

$$K_{f1} = \frac{[M-C_f]}{[M][C_f]} \tag{6}$$

$$K_{f2} = \frac{[M-C-Ab]}{[M][C-Ab]} \tag{7}$$

where K_{f1} is the free chelate−metal stability constant, and K_{f2} is the antibody−chelate−metal stability constant.

For the model calculations, any nonradioactive metal present in the buffer during diafiltration or the radiolabeling reaction is also allowed to form complexes with either free chelate or antibody−chelate according to the equilibrium relationships described by eqs 6 and 7. Chelate (remaining after diafiltration) or chelate−antibody conjugate that binds metal during the diafiltration stage is no longer available for binding to additional metal species (radioactive or nonradioactive) during the radiolabeling reaction. Since the thermodynamic stability for the DOTA−metal or DTPA−metal complexes is generally characterized by high log K_f values, a log K_f value of 23 was used for all calculations regardless of the metal species (*18*). This is justified for these calculations since the equilibrium is essentially shifted completely in favor of the complex formation for such large log K_f values. More complicated model calculations could incorporate the relative formation rate constants for DOTA or DTPA binding to the metal species, but such equations were not incorporated into the model used here. The model calculations used here also restrict nonspecific antibody binding (eq 3) to the metal-free chelate, meaning any chelate that has formed a metal complex is no longer available for antibody binding.

Since the fraction of the radiolabeled metal, *M**, that is bound to free chelate or chelate−antibody conjugates is equal to the fraction of total metal bound by each (under the assumption of equivalent chelation of all metal species), the radiolabeling efficiency is calculated as

$$RE = \frac{[M-C-Ab]}{[M]_{tot}} = \frac{[M^*-C-Ab]}{[M^*]_{tot}} \tag{8}$$

where M_{tot} is the total concentration of all metal species present, *M*-C-Ab* is the concentration of radioisotope-labeled chelate−antibody conjugates, and M^*_{tot} is the total concentration of radioisotope added to the radiolabeling reaction.

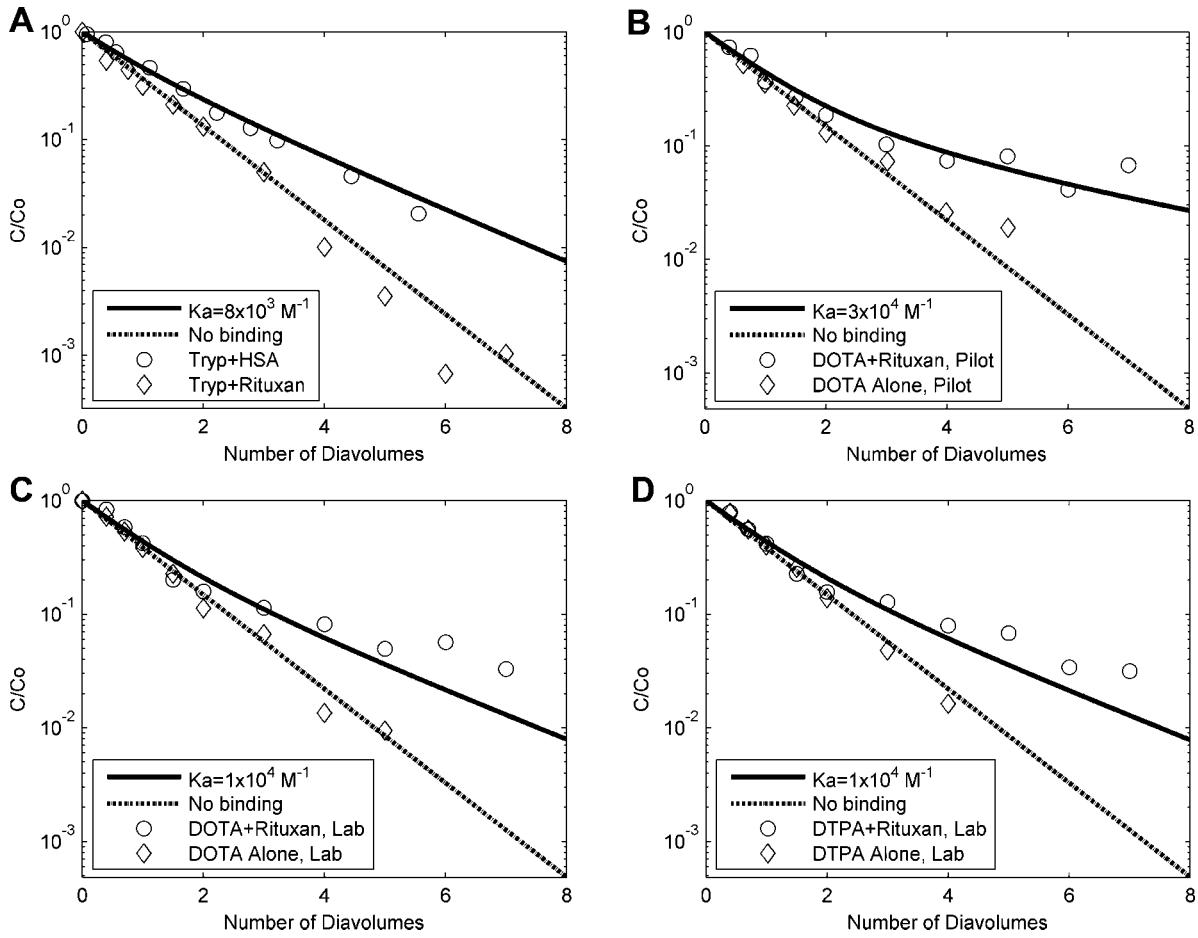

Figure 2. Effect of protein binding on the removal of acetyltryptophanate, DOTA, or DTPA by vacuum diafiltration. (A) Experimentally determined removal of acetyltryptophan by pilot-scale vacuum diafiltration in the presence of 7 mg/mL HSA (○) or 8.3 mg/mL Rituxan (◊). (B) Experimentally determined removal of DOTA by pilot-scale vacuum diafiltration in the presence of 8.3 mg/mL Rituxan (○) or no protein (◊). (C) Experimentally determined removal of DOTA by laboratory-scale vacuum diafiltration in the presence of 7 mg/mL Rituxan (○) or no protein (◊). (D) Experimentally determined removal of DTPA by laboratory-scale vacuum diafiltration in the presence of 7 mg/mL Rituxan (○) or no protein (◊). Predicted clearances are shown for protein binding (—) and no protein binding (---).

Solute Removal by Vacuum Diafiltration. It has been previously established that tryptophan and its derivative acetyltryptophan reversibly bind human serum albumin with a stoichiometry of approximately 1:1, and this interaction can be characterized by affinity constants of 10^4-10^5 M^{-1} for L-tryptophan and 10^3-10^4 M^{-1} for D-tryptophan (*19*). Furthermore, Klotz et al. estimated the binding affinity between *N*-acetyl-DL-tryptophan (acetyltryptophanate) and bovine serum albumin to be $\sim 4 \times 10^3$ M^{-1} (*20*). Using eq 1, the concentration of acetyltryptophanate (AT) can be predicted during diafiltration in the presence of human serum albumin. The predicted removal of AT was compared to experimentally determined values obtained by sampling the retentate during vacuum diafiltration. The results shown in Figure 2A reveal that the experimental data closely match the predicted removal of a solute with a sieving coefficient of 1 and an affinity constant for human serum albumin of approximately 8×10^3 M^{-1}, within the same order of magnitude as those binding constants reported previously for the interaction between tryptophan and albumin. No such binding was observed between *N*-acetyl-L-tryptophan and the monoclonal antibody, Rituxan, however (Figure 2A).

We extended this analysis to the interaction between the metal chelators, DOTA or DTPA, and the monoclonal antibody, Rituxan. Because each Rituxan molecule contains >100 negatively or positively charged amino acids, we hypothesized that it would potentially act as an ion exchanger with a weak affinity for charged molecules such as DOTA or DTPA, which contain multiple amine and carboxylate groups. Least squares regression was first used to estimate the sieving coefficient of the chelate in the absence of Rituxan from the data in Figure 2, yielding an average value of $S = 0.95$. Although the Biomax (polyethersulfone) and polysulfone membranes do exhibit a negative surface charge density at the pH values used in these studies, the negatively charged DOTA or DTPA molecules still exhibit a sieving coefficient of near unity, as indicated by the observed clearance of each chelator in the absence of Rituxan (Figure 2). Shao et al. determined that small charged impurities can be strongly rejected by charged membranes (including Biomax) at low flux or low ionic strength (*21*). Because the buffers used in our experiments had relatively high ionic strengths, these charge interactions were minimal. Subsequently, the affinity constant characterizing the binding between DOTA or DTPA and Rituxan was estimated using the data for their clearance in the presence of Rituxan (Figure 2). Assuming two binding sites per antibody ($n = 2$) on the basis of the symmetrical IgG1 structure containing two identical heavy chains and two identical light chains, the magnitude of the affinity constant, $K_a \sim 1 \times 10^4-3 \times 10^4$ M^{-1}, is similar to the weak binding observed between AT and HSA. Since the magnitude of this affinity constant will vary with the exact antibody or buffer used during diafiltration, the slightly lower affinity constant observed at the laboratory-scale relative to the pilot-scale may be the result of using ammonium acetate instead of sodium acetate buffer. The ammonium ions, more than sodium ions, may compete with the amines on the antibody for binding with the chelate carboxylates. Such a hypothesis is supported by the observation

that ammonium ions have a greater affinity toward cation exchangers than sodium ions (*22*). Future studies must be done to more precisely examine the impact that different processing conditions can have on the interaction between the chelate and antibody molecules. Comparison can also be made between the affinity constants measured using antibodies with or without prior chelate modification, as the presence of covalently conjugated chelate may impact the binding affinity toward nonspecifically bound chelate.

Production of Radiolabeled Antibodies Using Vacuum Diafiltration. During the production of radiolabeled antibodies, DOTA is first conjugated to the antibody at a molar excess of DOTA−NHS/antibody. The unreacted DOTA−NHS must be removed since it will directly compete with the conjugated DOTA−Ab for binding to the radioactive isotope during the radiolabeling reaction. The chelate−antibody nonspecific affinity constant estimated from the data in Figure 2 can be combined with eqs 1−3 to estimate the number of diavolumes needed to reduce the free chelate concentration below a desired threshold. Furthermore, the use of eqs 6−8 can allow estimation of the predicted radiolabeling efficiency, which depends on the amount of free chelate remaining as well as the total metal contaminants introduced during diafiltration. Such information allows the rational design of DOTA−Ab production to yield high radiolabeling efficiencies. To demonstrate such a procedure, a DOTA−Rituxan conjugate was synthesized and purified using both pilot-scale and laboratory-scale vacuum diafiltration and subsequently radiolabeled with In-111. The results of radiolabeling efficiency versus number of diavolumes are shown graphically in Figure 3A and provided in tabular format in the Supporting Information. Each sample was also subjected to gel filtration chromatography on a Superdex 200 column to analyze relative antibody concentration as well as the formation of any aggregates. At all diavolumes tested, there was negligible fluctuation in the measured antibody concentration (Figure 3B), and the aggregate formation remained <1.5%.

Theoretical Considerations for Maximizing Radiolabeling Efficiencies. Because variability in radiolabeling efficiencies has often plagued the production of radiolabeled antibodies, we sought to elucidate key parameters controlling the radiolabeling efficiency using a mathematical model of the vacuum diafiltration and radiolabeling processes. Additional parameters for the model calculations are given in Table 1. The solid lines in Figure 4A and B show the good fit that can be achieved between the predicted and experimentally determined radiolabeling efficiencies under the conditions used at both the pilot and laboratory scales, respectively. The dashed lines show the radiolabeling efficiency predicted if the chelate molecules exhibited no antibody binding. In the absence of antibody binding, significant radiolabeling efficiency should begin to appear as early as 4 diavolumes. Instead, measurable radiolabeling began to appear after >6 diavolumes had been processed, indicating hindered removal of the free chelate. This hindered removal can be accounted for by a weak binding affinity ($\sim 10^4$ M^{-1}) between the free chelate and the antibody molecules (Figure 2). The rapid sigmoidal rise in radiolabeling efficiency between diavolumes 6 and 10 would be expected if the free chelate (DOTA or DTPA) was able to bind the metal more readily than the DOTA−antibody conjugate. Previous studies have demonstrated that the stability constant for metals binding to monofunctionalized DOTA molecules (such as those containing amide bond linkages to the lysines on proteins) are approximately 2 orders of magnitude lower than the stability constant for metals binding to free DOTA (*7, 23*). Furthermore, there is a decreased metal loading rate when DOTA is conjugated to protein (*6*). Consistent with these observations, the model predictions closely matched the experimental data

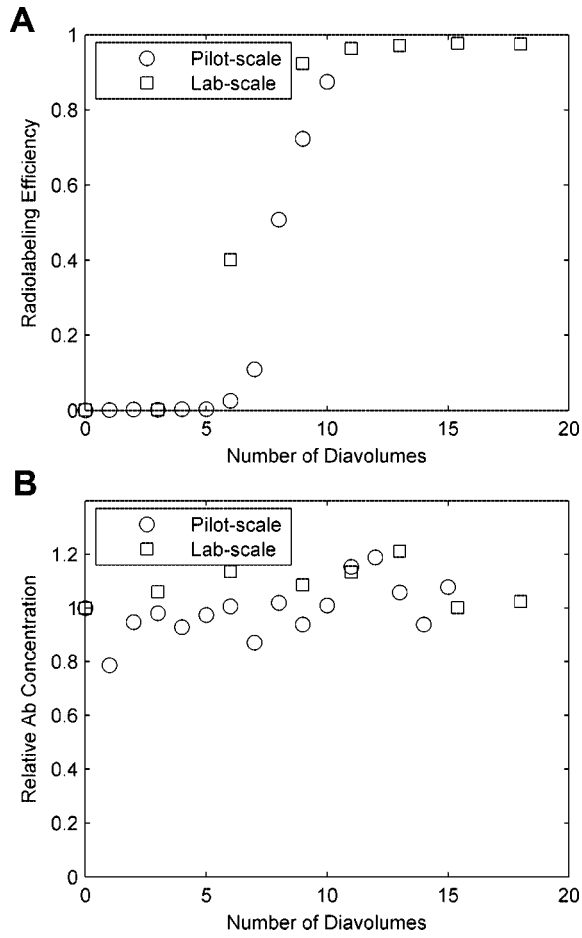

Figure 3. Production of radiolabeled Rituxan using vacuum diafiltration. (A) Experimentally determined radiolabeling efficiency as a function of the number of diavolumes by pilot-scale and laboratory-scale vacuum diafiltration. (B) Relative Rituxan concentration determined by HPLC (Superdex 200, 280 nm) as a function of the number of diavolumes during vacuum diafiltration.

observed here if the metal preferentially loaded into the free chelate relative to the DOTA−Ab conjugate. This was implemented in the model by setting the actual metal loading as a fraction of the maximum equilibrium loading value (eqs 6 and 7) depending on the relative concentrations of the two species. The preferential binding by free chelate was realized by multiplying the free chelate concentration by 100 (higher effective concentration) to enhance the relative fraction of metal bound by free chelate. Such a preferential binding by free chelate enhances the sigmoidal shape of the curve and inhibits radiolabeling at low diavolumes when there is still sufficient free chelate (DOTA or DTPA) to compete with the DOTA−Ab for metal binding. However, after approximately 6 diavolumes, the free chelate is predicted to be at a low enough concentration that it no longer can bind to all of the metal present in the radiolabeling reaction, and the radiolabeling efficiency rapidly increases with additional diavolumes. When the radiolabeling efficiency begins to plateau after ∼10 diavolumes, there is a negligible amount remaining of free chelate available for radioisotope binding (it has either been removed in the filtrate or already occupied with nonradioactive metal); therefore, all of the subsequent radioactive or nonradioactive metal in the radiolabeling reaction will bind to the DOTA−Ab conjugate. Once there is no longer any additional free chelate to be removed, then additional diavolumes will potentially add metal contaminants (depending on the metal content of the diafiltration buffer) to the DOTA−Ab conjugate until a point is reached when enough of the DOTA−Ab conjugate has been occupied

Table 1. Additional Parameters Used for Model Calculations to Predict Chelate Clearance and Radiolabeling Efficiency

parameter description	value	determination
impurity sieving coefficient (DOTA, DTPA)	0.95	least squares regression of experimental data in Figure 2
relative chelating ability (free vs conjugated chelate)	100	estimated from experimental data, supported by literature (*7*, *23*)
K_{f1}, free chelate-metal association constant (M^{-1})	1×10^{23}	literature (*17*, *18*)
K_{f2}, antibody-chelate-metal association constant (M^{-1})	1×10^{21}	calculated from K_{f1} and the relative chelating ability of free vs conjugated chelate
K_a, chelate−antibody nonspecific binding association constant (M^{-1})	3×10^4 = pilot 1×10^4 = laboratory	least squares regression of experimental data in Figure 2
n, number of nonspecific binding sites per antibody	2	estimated from experimental data and the symmetry of IgG molecules
number of conjugated DOTA per antibody	2	literature (*4*)
buffer metal concentration (M)	4×10^{-6} = pilot 2×10^{-7} = laboratory	estimated from max specifications from certificate of analysis (sodium acetate, pilot-scale) and an estimated 90−95% reduction from max specifications by Chelex 100 treatment (ammonium acetate, laboratory-scale)
radioisotope purity at calibration time and after 5-day decay	0.025 = day 0 0.008 = day 5	estimated from certificate of analysis; decayed value calculated using In-111 half-life of 67 h

by metal contaminants that it no longer can bind all of the radioactive isotope during radiolabeling, thus decreasing the radiolabeling efficiency. However, the model predicts that addition of metal can enhance radiolabeling efficiencies if there is substantial free chelate remaining in the radiolabeling reaction since the free chelate would otherwise be able to bind the majority of both the radioactive and nonradioactive metal present. Only after this extra free chelate is saturated with bound metal will the DOTA−Ab be able to bind a significant portion of the radioactive metal, meaning higher radiolabeling efficiencies can be achieved by addition of nonradioactive metal even when free chelate remains at low diavolumes.

To test this hypothesis experimentally, the same batch of In-111 that was used for the pilot-scale radiolabeling reactions shown in Figure 3 was again used to radiolabel the samples from diavolumes 8−10 of the pilot-scale diafiltration, although the In-111 had decayed for an additional 5 days before these labelings were performed. The DOTA−Ab conjugate was also subjected to an additional 5 diavolumes by pilot-scale diafiltration, and samples were removed at each diavolume for radiolabeling with this same batch of decayed In-111. The samples from diavolumes 8−10 and the new samples from diavolumes 11−15 were radiolabeled under the same reaction conditions that were used 5 days previously, and the radiolabeled samples were subjected to ITLC. The ITLC analysis was performed with and without a DTPA chase to differentiate between radioisotope that had been bound by free chelate remaining in the DOTA−Ab preparation versus free radioisotope that was still available to bind to the DTPA chase. Under the ITLC conditions without the DTPA chase, both free radioisotope and radioisotope bound to DOTA−Ab will remain at the origin, while radioisotope bound by any residual free chelate (DOTA or DTPA not removed during diafiltration) will migrate with the solvent. However, if an additional DTPA chase is included during ITLC, then any free radioisotope that would have remained at the origin will bind to DTPA and migrate with the solvent. The difference between the radioactive concentrations at the origin can thus be used to indicate the presence of free radioisotope remaining after the radiolabeling reaction. An overview of the experimental procedure is depicted in Figure 5A, while the experimental data and model calculations are summarized in Figure 5B and C, respectively. Figure 5B depicts the results of the ITLC measurements with and without a DTPA chase. The radiolabeling efficiencies are provided in tabular format in Supporting Information. Free radioisotope began to appear after 12−13 diavolumes, and the model calculations offer a possible explanation for these observations, as shown in Figure 5C. As hypothesized, the use of the decayed In-111 (which contains a higher relative amount of nonradioactive metal contaminants and thus a lower radioisotope purity) enhances the observed radiolabeling efficiency at low diavolumes because the additional nonradioactive metal saturates the remaining free chelate and thereby allows the remaining radioactive metal to be bound by the DOTA−Ab conjugate. However, at higher diavolumes, the level of free chelate has been reduced to low levels and instead of helping the radiolabeling efficiency, the additional nonradioactive metal from the diafiltration buffer (in this case, sodium acetate buffer that was not pretreated with the Chelex 100 resin) and the decayed In-111 preparation now saturates the available DOTA−Ab binding sites and prevents the conjugate from being able to bind all of the radioactive metal. This is indicated by the detection of free radioactive isotope by ITLC performed with and without the DTPA chase. However, no free radioactive isotope was detected by ITLC for samples even out to 18 diavolumes when using the Chelex 100-treated ammonium acetate buffer, which should have reduced metal contamination (Supporting Information). Previous studies have shown that the complexes formed between antibody-conjugated DOTA and metals are extremely stable, with total release of bound In-111 of ∼3% after 240 h in the presence of 1 mM DTPA (*23*). Such observations suggest that most of the bound metal is stably coordinated by the DOTA conjugates and that the contribution of metal binding to other sites on the antibody is likely to be minimal. Furthermore, this stability of the metal within the DOTA complexes enables the use of a DTPA chase to probe for the presence of free remaining radiometal after the labeling reaction is completed. The data shown in Figure 5 therefore corroborate the predictions made with the model calculations and also offer important insights into potential mechanisms for the variability in radiolabeling efficiencies.

As described earlier, the model calculations assume equilibrium binding between the chelate and metal, although the residence time during the constant diafiltration process may limit the accuracy of such an assumption. The assumption of equilibrium therefore represents a worst-case scenario for metal

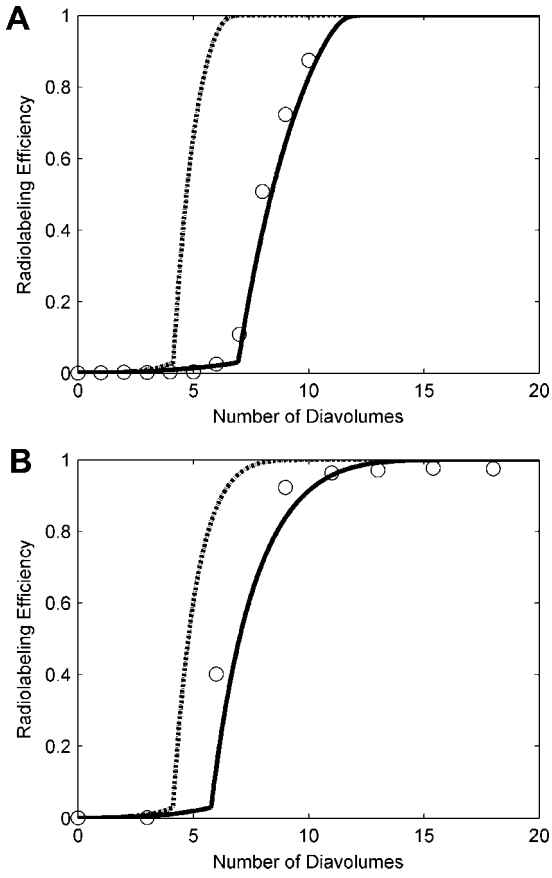

Figure 4. Comparison of predicted and experimentally determined radiolabeling efficiency as a function of the number of diavolumes. (A) Model calculations are shown for the pilot-scale diafiltration when a 19.5-molar excess of DOTA−NHS is reacted with Rituxan and the excess free chelate exhibits either a weak affinity for Rituxan of $3 \times 10^4\ M^{-1}$ (—) or no affinity for Rituxan (---). The pilot-scale diafiltration data from Figure 3A are shown for comparison (○). (B) Model calculations are shown for the laboratory-scale diafiltration when a 15-molar excess of DOTA−NHS is reacted with Rituxan and the excess free chelate exhibits either a weak affinity for Rituxan of $1 \times 10^4\ M^{-1}$ (—) or no affinity for Rituxan (---). The laboratory-scale diafiltration data from Figure 3A are shown for comparison (○). Additional model parameters are given in Table 1.

contamination from the diafiltration buffers. Notwithstanding, there is likely an optimum number of diavolumes that will achieve the highest radiolabeling efficiency, representing a balance between removal of free chelate and introduction of nonradioactive metal with the diafiltration buffer or the radioisotope preparation. The plots in Figure 6 illustrate the impact of different operating parameters (antibody concentration during diafiltration, radioisotope purity, diafiltration buffer metal concentration, and the radiolabeling reaction ratio) on the predicted radiolabeling efficiency for the pilot-scale diafiltration parameters. Similar analyses were performed for the laboratory-scale diafiltration parameters as well as for antibody conjugates containing a higher conjugation efficiency with 5 DOTA per antibody (Supporting Information). While these plots apply to the specific operating conditions used in this study, the observed trends are generally applicable for the production of radiolabeled antibodies using diafiltration.

DISCUSSION

In this article, we describe the use of constant-volume vacuum diafiltration for the production of radiolabeled antibodies. The method is a modification of standard diafiltration techniques whereby the transmembrane pressure is created by applying a vacuum to the filtrate side of the membrane as opposed to using positive pressure on the retentate side of the membrane. Vacuum diafiltration can be quickly and easily implemented with minimal equipment requirements since a house vacuum line is sufficient to generate the transmembrane pressure required for filtration. Furthermore, the use of vacuum as the driving force minimizes the risk for leakage or loss of expensive antibody materials since the membrane interface is the only region of significant pressure differential that makes contact with the antibody, thereby meaning recoverable loss into the filtrate is the most likely failure. In contrast, applying a positive pressure to the retentate (antibody) side of the membrane creates the potential for catastrophic leakage out of the retentate vessel if any of the seals were to fail under the applied pressure differential. Such safety precautions become especially important at the clinical production scale. Vacuum diafiltration is easily scalable, as we have demonstrated here on both the milligram and gram production scales, and overall processing times and buffer volumes required can be drastically reduced relative to other purification strategies such as dialysis. While we illustrate the use of the method in the production of radiolabeled antibodies, vacuum diafiltration offers an easily accessible strategy for preparing any antibody conjugate. Besides using vacuum diafiltration to achieve high radiolabeling efficiencies (>90%) for several different antibodies in addition to Rituxan, we also have used it for labeling antibodies with fluorochromes and biotin.

Through the use of mathematical modeling combined with experimental data, we also elucidate several factors that can contribute to variable radiolabeling efficiencies. Since excess free chelate can directly compete with chelate−antibody conjugates for radiolabeling, it must be stringently removed prior to radiolabeling to ensure maximum yield. The experimental data presented here suggest a weak binding affinity between DOTA or DTPA and antibodies, further complicating the removal of excess chelate. Notwithstanding, free chelate can be reduced to acceptably low levels through extensive purification, as illustrated here by the high radiolabeling efficiencies achieved at diavolumes greater than approximately 10. An interesting result of following the radiolabeling efficiency as a function of the number of diavolumes was the observation that there can be an optimum number of diavolumes for maximizing radiolabeling efficiency, beyond which point the yield will decrease if metal contaminants from the buffers outweigh the benefit derived from removing additional free chelate. Controlling the level of metal contaminants therefore emerged as one of the most important factors influencing the consistency of the radiolabeling efficiency.

The influence of metal contamination becomes most significant with respect to the purity of the radioisotope used for radiolabeling. Metal contamination during the initial conjugation and diafiltration steps can be minimized by including metal scavengers (e.g., DTPA) in the buffers used for washing or diafiltration (although one must then also ensure that sufficient diavolumes are processed during diafiltration to reduce the free DTPA concentration to levels that will not interfere with radiolabeling). Additionally, treatment of the diafiltration buffers with chelating resins, such as Chelex 100, can significantly reduce the potential burden of metal contamination (*8*−*12*). In our experience, high radiolabeling efficiencies (>95%) are achieved using Chelex 100-treated ammonium acetate buffer even out to 18 diavolumes. Removal of trace metal contaminants in the diafiltration buffer by chelating resins helps to minimize variability that could be introduced by fluctuations in buffer metal content, thereby widening the range of diavolumes that can achieve high radiolabeling efficiencies and yielding a more robust process (Figure 6 and Supporting Information).

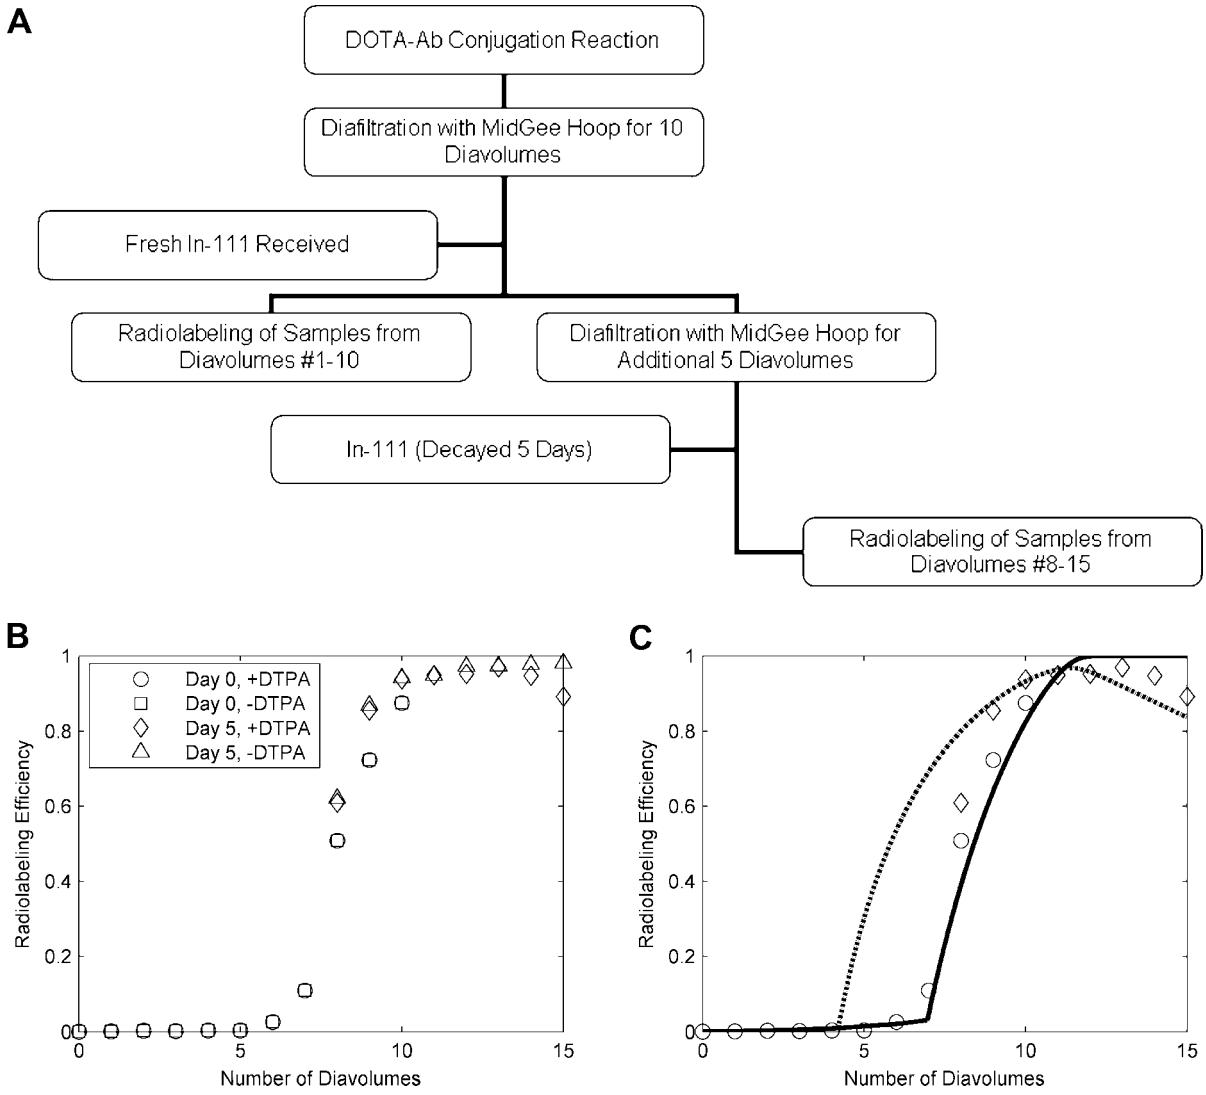

Figure 5. Effect of metal contamination on radiolabeling efficiency. (A) Flowchart depicting the experimental procedure. (B) Radiolabeling efficiency as a function of the number of diavolumes on day 0 (fresh radioisotope) and on day 5 (decayed radioisotope). ITLC was performed with or without a DTPA chase to detect the presence of free metal remaining after the radiolabeling reaction. The day 0 data points with DTPA (○) are the same data shown in Figure 3; additionally, the ITLC samples without DTPA (□) are shown for comparison, demonstrating the absence of any free metal. The day 5 data points represent samples taken from diavolumes 8−10 from the initial diafiltration and samples taken from an additional 5 diavolumes of the same DOTA−antibody conjugate preparation (diavolumes 11−15). Data are shown for ITLC samples with DTPA (◊) or without DTPA (△), demonstrating the appearance of free metal beginning at diavolumes 12−13. (C) The predicted radiolabeling efficiency as a function of the number of diavolumes was calculated for a radioisotope purity of 0.025 (day 0, solid line) and 0.008 (day 5, dashed line). Experimental data of the ITLC samples with DTPA from day 0 (○) and day 5 (◊) are shown for comparison.

Unfortunately, neither of these methods is feasible for separation of the radioactive metal from nonradioactive metal in the radioisotope preparation. Evaluation of the certificate of analysis provided by several vendors of radioisotope preparations reveals that even though the radionuclide purity may be >99.9%, there can be sufficient metal contaminants to impact radiolabeling efficiencies. For example, the specifications for In-111 (Trace LifeSciences) require the metal contaminants (including Cd, Cu, Fe, Ni, Pb, and Zn) to be at a level below 0.1 μg/mCi. Given the specific activity of In-111 (4.7×10^7 Ci/mol), then the In-111 can represent <1 mol% of the total metal contaminants and meet specifications. A typical radiolabeling reaction might be performed at a concentration of 5 mCi/mg antibody conjugate, meaning there is ∼100-fold molar excess of Ab-conjugated DOTA molecules relative to the moles of In-111 in 5 mCi. The resulting radiolabeling efficiency represents the fraction of the total In-111 atoms that will be bound by the Ab-conjugated DOTA molecules. If the In-111 represents 0.5% of the total metal atoms present in the radioisotope preparation, for example, then a 200-fold excess of available Ab-conjugated DOTA molecules would be required for all of the In-111 to be bound (assuming, for simplicity, that all of the metal atoms can bind to DOTA with equal efficiency). If the radiolabeling ratio results in only a 100-fold excess of Ab-conjugated DOTA molecules present (as described above), then the maximum theoretical radiolabeling efficiency would be 50%. These calculations illustrate the ease with which variations in radioisotope purity can alter the radiolabeling efficiencies under typical reaction conditions, even when the radioisotope is within the manufacturer's specification limits for metal contaminants.

To facilitate more consistent radiolabeling efficiencies, the metal contaminants in radioisotope preparations must be stringently controlled. The specifications for current preparations make radiolabeling reactions inherently subject to variability. Regardless of any changes made in the production of radioisotopes, several steps can be taken toward achieving more consistent radiolabeling efficiencies. First, metal contaminants must be reduced in the steps prior to the radiolabeling reaction. By minimizing the amount of metal contaminants in the buffers

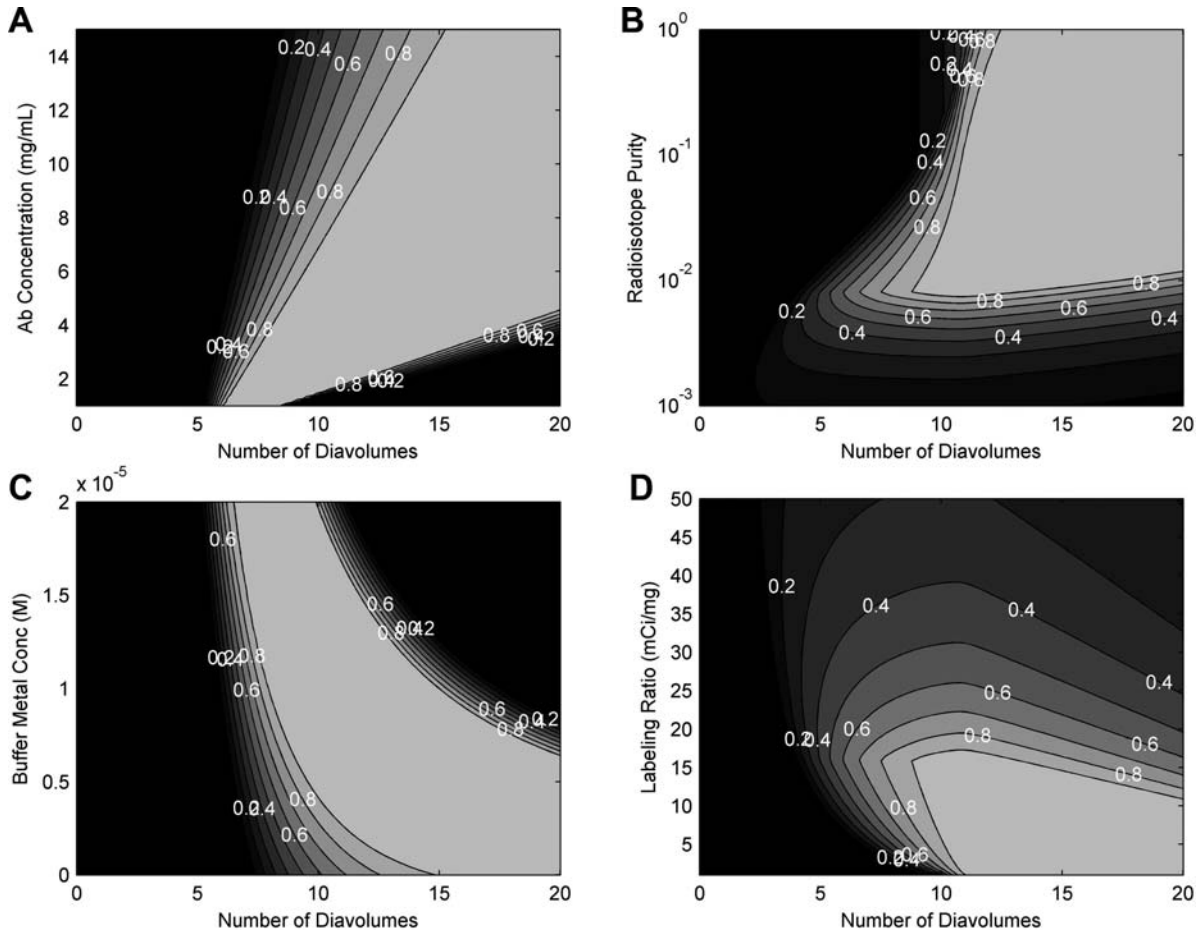

Figure 6. Contour plots showing the impact of different operating parameters on the predicted radiolabeling efficiency as a function of the number of diavolumes for pilot-scale diafiltration. Model calculations are used to estimate the predicted radiolabeling efficiency for a range of (A) antibody concentrations, (B) radioisotope purities, (C) metal concentrations in the diafiltration buffer, and (D) radiolabeling reaction ratios given as the amount of radioactivity per mass of antibody. Fixed parameter values were chosen to match those of the pilot-scale diafiltration experiment as given in Table 1. Lighter color represents higher radiolabeling efficiencies, and labels indicate the radiolabeling efficiency of a given contour line.

through the use of metal scavengers or chelating resins, it is possible to more accurately predict the ratio of available antibody-conjugated DOTA molecules to the total metal in the radiolabeling reaction. Otherwise, metal contamination prior to the radiolabeling reaction can lead to a significant fraction of the antibody-conjugated DOTA molecules already being occupied by metals, making them unavailable for radiolabeling. Second, it is important to analyze the certificate of analysis provided with the radioisotope preparation and estimate its purity (moles radioisotope relative to total moles of metal present). This purity can then be used to predict the radiolabeling reaction ratio (mCi/mg antibody conjugate) needed to ensure that there is sufficient capacity to bind all of the radioisotope during the radiolabeling reaction. Third, care must be taken to account for the decay of the radioisotope preparation, meaning the purity of the radioisotope will decrease with time as the radioisotope decays. As illustrated in Figure 5, this change in purity can either increase or decrease the radiolabeling efficiency depending on the presence of additional free chelate (which can be estimated from the number of diavolumes processed) and the ratio of radioisotope to antibody-conjugated DOTA molecules (mCi/mg antibody conjugate) used during the radiolabeling reaction.

In summary, vacuum diafiltration offers a convenient and scalable method that can be easily implemented for the production of radiolabeled antibody conjugates. Mathematical models enable a rational approach for optimizing operating conditions for the production of radiolabeled antibodies, including controlling metal contamination and free chelate removal. Several suggestions to improve overall radiolabeling efficiencies were offered according to model predictions and experimental observations. The study presented here facilitates production of radiolabeled antibodies with increased consistency and higher efficiency, offering benefits for patient safety, therapeutic efficacy, and cost minimization in the clinical application of radioimmunotherapeutics.

ACKNOWLEDGMENT

We are especially grateful to Anne-Line Anderson for performing the radiolabeling reactions, Militza Bocic for running HPLC samples, Barbara Szpikowska for preparing the Chelex 100-treated ammonium acetate buffer, Agnes Gardner for helpful discussions regarding pilot-scale diafiltration, and Nicole Skidmore for helping to assemble the laboratory-scale diafiltration apparatus. D.W.B. is a W.M. Keck Fellow. This publication was made possible in part by the W.M. Keck Foundation and program project grant P01 CA043904 and SPORE grant P50 CA107399 from the National Cancer Institute.

Many biological processes take place in close proximity to lipid membranes. For a detailed understanding of the underlying mechanisms, tools are needed for the quantitative characterization of such biomolecular interactions. In this work, we describe the development of methods addressing the dynamics and affinities of protein complexes attached to an artificial membrane system. A semisynthetic approach provides the Ras protein with palmitoyl anchors, which allow stable membrane insertion, as a paradigm for membrane associated proteins that interact with multiple effectors. An artificial membrane system is constituted by nanoparticles covered with a lipid bilayer. Such a stable suspension allows for the characterization of the interaction between membrane-bound Ras and effector proteins using conventional fluorescence-based methods.

INTRODUCTION

Many biological processes mediated by the specific interaction between proteins take place in close proximity to the plasma membrane or intracellular compartments. In particular, small GTP binding proteins such as members of the Ras, Rho, and Rab protein families are attached to membranes by insertion of hydrophobic anchor molecules covalently attached to their C-terminal region (*1*−*3*). These proteins interact with various proteins such as regulator and effector proteins, respectively, in order to further propagate the desired biological signal.

Ras is a small GTP binding protein playing a central role in cellular signal transduction. It interacts in a nucleotide dependent manner with downstream effectors such as Raf kinase (*4*), RalGDS (*5*), and Nore1A (*6*), while its activity is regulated by extra- and intracellular inputs through nucleotide exchange factors and GTPase activating proteins (*7*). In all these respects, Ras is the prototype for a large number of GTP binding proteins from various subfamilies (*8*). Crucial for function of Ras is its attachment to the inner leaflet of the plasma membrane achieved through hydrophobic anchors at its C-terminus. For example, one farnesyl group and two palmitoyl groups are linked to the isoform H-Ras by post-translational processing (*1*). The distinct roles of those modifications were investigated in great detail (*1, 9*−*11*). The farnesyl anchor alone is not able to stably attach Ras to the membrane (*1*). Therefore, H-Ras is further modified with the two palmitoyl groups. Importantly, the plasma membrane attachment of Ras correlates with its biological function. Only properly bound to the plasma membrane can H-Ras trigger cell signaling via the activation of the mitogen-activated protein kinase. The nonpalmitoylated H-Ras mislocalizes to the cytosol and fails to promote cell signaling (*10*). In contrast, constructs of H-Ras allowing for palmitoylation but not farnesylation suggested that the membrane attachment can be provided without the farnesyl group (*11*). Nevertheless, most of the biochemical studies on Ras activity and activity of many other proteins lack these modifications neglecting their potential impact and the influence of the membrane surface on interactions with effector proteins. An important issue for understanding the complex network of Ras signaling is its interaction with a defined but varying set of effector proteins depending on the particular task of Ras, such as initiating cell division, contributing to morphology changes, or leading to apoptosis (*12*). In this work, we establish a general method for analyzing protein−protein interactions at membrane surfaces using the interaction between Ras proteins and effectors as a paradigm for such processes. In order to develop a widely usable experimental setup, readily available fluorescence based methods should be used that allow the quantification of both Ras/effector affinities as well as dynamics. The artificial membrane system devised for this purpose is based on lipid coated nanoparticles with a defined size. Using a suspension of such lipidated nanoparticles allows the application of fluorescence assays previously developed in our laboratory in order to characterize Ras/effector interactions. The necessary membrane anchor is incorporated into Ras by expressed protein ligation (EPL) (*13*) where a chemically synthesized peptide carrying two palmitoyl groups is ligated to the C-terminus of Ras (*14*).

EXPERIMENTAL METHODS

Peptide Synthesis. Solid phase peptide synthesis was performed manually using Fmoc-chemistry (*15*). Cleavage of ivDde-protecting groups was achieved with 3% hydrazine in DMF. Subsequent palmitoylation was carried out with 20 equiv of palmitoylchloride, 20 equiv of *N*-hydroxybenzotriazole, and

22 equiv of triethylamine in dichlormethane/dimethylformamide (3:1) for 4 h. Cleavage was achieved by 2.5% H_2O and 5% triisopropylsilane in trifluoracetic acid (TFA). The crude product was precipitated with diethyl ether, dissolved in 50% aqueous acetonitrile (0.1% TFA), and lyophilized. Purification was carried out by RP-HPLC on C4-columns from Vydac using linear gradients of acetonitrile with 0.08% TFA in water.

Bacterial expression and purification of the effector RBDs was described earlier (*16*). Briefly, the resuspended bacterial cell pellet was sonicated, the cell lysate was cleared by centrifugation, and the GST fusion proteins were purified by glutathione sepharose affinity chromatography followed by size exclusion chromatography.

Preparation of Double Palmitoylated Ras. The DNA insert coding for C-terminally truncated H-Ras (1−180) was subcloned into the multiple cloning site of a pTXB1 vector (New England Biolabs) to express H-Ras (1−180) as fusion protein with a C-terminal intein from *M. xenopi* and the chitin binding domain from *B. circulans*. The vector was transformed into the *E. coli* BL21(DE3) strain. For protein expression, the 50 mL starting culture in LB containing 100 μg/mL Ampicillin was transferred to 10 L of the same media, and the media were incubated at 37 °C until an OD_{600} of 0.6 was reached. Expression of the fusion protein was induced by addition of 100 μM IPTG, and the culture was incubated at 37 °C overnight. The bacteria were harvested by centrifugation, and the cell pellet was resuspended in buffer A (25 mM Tris (pH 7.9), 100 mM NaCl, and 5 mM $MgCl_2$) and 1 mM PMSF. Cell lysis was achieved by 10 min of sonication (Bendelin), and the lysate was centrifuged to remove insoluble cell material. The supernatant was applied to a 40 mL chitin column (New England Biolabs) equilibrated with buffer A. The chitin material loaded with fusion protein was washed with 5 column volumes of buffer A and incubated for three days in buffer A containing 250 mM MESNA (sodium 2-mercaptoethane sulfonate) at 4 °C in order to form the H-Ras(1−180)-thioester. The cleaved protein was separated from the chitin beads, concentrated by ultrafiltration (Vivaspin) to a volume of 5 mL and further purified by size exclusion chromatography (Superdex 75 26/60, Pharmacia). The fractions containing H-Ras-thioester were pooled and concentrated using ultrafiltration (Vivaspin) to a final concentration of 70 mg/mL. The protein was shock frozen in liquid nitrogen and stored at −80 °C.

Three hundred micromolars of the protein were incubated with 5.4 molar excess of the double palmitoylated 2Palm-3PPO-peptide in the presence of 200 mM MESNA for 4 days. The ligation product was selectively precipitated from the reaction mixture by the addition of 400 mM ammonium sulfate, redissolved in buffer A, shock frozen in liquid nitrogen, and stored at −80 °C.

Peptide and protein masses were determined by electrospray ionization mass spectrometry on an LCQ Advantage Max (Finnigan) operating in positive ion mode. The molecular masses were deconvoluted from the ion spectra.

Preparation of Lipidated Nanoparticles. The amount of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC, Sigma) required in order to achieve a 40-fold excess of lipid surface over the nanoparticle surface (26 mg of DOPC) was dissolved in 2 mL of chloroform, dried under a stream of nitrogen, and subsequently dried for 2 h in vacuum. The lipid film was rehydrated in 2−4 mL of buffer A flushed with argon. The suspension was then sonicated and cooled on ice (Brenson Sonifier 250 Cup Horn) until it was clear and then ultracentrifuged (Beckman) at 100,000*g*. The clear supernatant containing small unilamellar vesicles (SUV) was used for nanoparticle preparation.

Then, 100 μL of a 50 mg/mL stock solution of silica nanoparticles (Micromod, Germany) was washed with 1 mL methanol, 1 mL 1 M KOH, and five times with buffer A, respectively. Separation of nanoparticles from supernatant was achieved by centrifugation (table top centrifuge, 5000 rpm). After washing, the nanoparticle suspension was mixed with the supernatant of the lipid preparation, flushed with argon, and incubated under gentle rotation for 2 h at room temperature. After lipidation, 1 mL of the nanoparticle suspension was washed twice to remove excess DOPC and mixed with 144 μg of the double palmitoylated H-Ras to cover (calculated) 20% of the nanoparticle surface. For this calculation, a particle radius of 130 nm, a particle concentration of 2.5 mg/mL, a particle density of 2 g/cm^3, and a footprint of Ras of 9 nm^2 were assumed. The suspension was incubated at room temperature overnight under gentle rotation, washed twice to remove the nonmembrane bound protein, and used for the GDI-assay and stopped flow experiments in concentrations of 0.05 μM and 0.25 μM, respectively. The characterization of particle size distribution was achieved by the dynamic light scattering technique. Samples of DOPC small unilamellar vesicles and lipidated nanoparticles were filtered using 0.45 μm filters, whereas blank nanoparticles were sonicated prior to addition into the cuvette. For the measurement, a He-Ne-Laser (633 nm) with a power of 35 mW was used, and the signal was collected at 90° using a four-quadrant detector (ALV 5001, Langen, Germany). The autocorrelation traces were fitted using the ALV software package, calculating the weight averaged particle size (*17*).

Measurement of Interactions. In order to detect the interaction between Ras proteins and effectors in solution, various fluorescence based methods were developed previously. The *N*-methyl-anthraniloyl (mant) group attached to the guanine nucleotide serves as a fluorescence label in these experiments. Ras, which is tightly bound to GDP after the purification, is loaded with mantGppNHp by addition of a 5-fold excess of this nucleotide and 10 mM EDTA, and overnight incubation at 4 °C. The nucleotide excess was removed by Zeba Desalt Spin Columns (Pierce) following the desalting instructions of the manufacturer. Loading was examined by C18 reversed phase HPLC. The so-called GDI-assay (*g*uanine nucleotide *d*issociation *i*nhibitor) takes advantage of a large fluorescence change upon dissociation of the mant-nucleotide after addition of a large excess (1000-fold) of nonfluorescent GppNHp. The time course of the decrease in fluorescence is measured by a Perkin-Elmer LS 55 fluorescence spectrometer with an excitation wavelength of 360 nm and an emission wavelength of 450 nm at 37 °C using buffer A. A single exponential function is fitted to the fluorescence traces yielding the observed rate constant k_{obs} representing the rate of the dissociation of mantGppNHp and Ras. Dependent on the binding of Ras effectors such as Raf, RalGDS, and Nore1A, the nucleotide dissociation rate is decreased. The observed rate constants are plotted against the concentration of the effector, and a quadratic function is fitted to the data in order to yield the K_D values of the Ras/effector interaction as described earlier (*16*, *18*).

In order to obtain, in addition to the K_D values, the individual rate constants for the Ras/effector association and dissociation, the stopped flow method was used (*19*, *20*). Again, this is a well established method for dynamic measurements of Ras/effector interactions in solution. Using a stopped flow apparatus (Biologic, Grenoble, France), Ras loaded with mantGppNHp and effector solutions were rapidly mixed and the fluorescence traces recorded. A 10-fold excess of the effector ensures pseudo-first-order conditions. To improve the fluorescence signal-to-noise ratio, fluorescence resonance energy transfer (FRET) was employed by the use of Ras·mantGppNHp and the tryptophan mutant Nore1A M305W. The largest fluorescence changes were observed at low temperatures, and therefore, kinetic measurements were performed at 10 °C in buffer A using an excitation

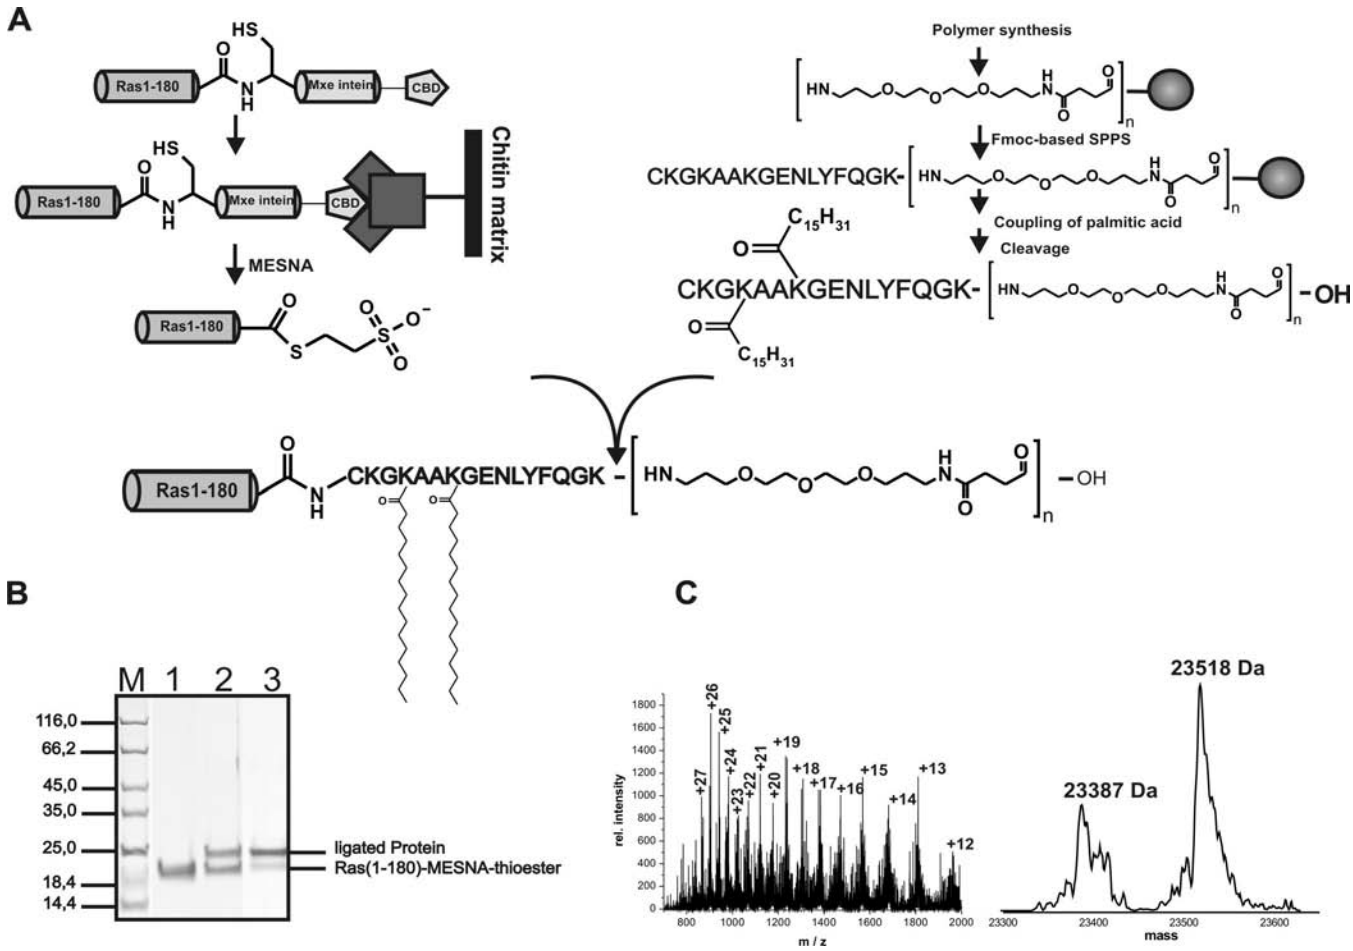

Figure 1. Synthesis of a double palmitoylated Ras variant. (A) Solid phase synthesis of a polymer-modified palmitoylated peptide (2Palm-3PPO peptide with $n = 3$; mass, 3196.1 Da) and native chemical ligation of Ras1−180 thioester with this peptide. (B) SDS−PAGE of the ligation mixture. Lane 1, Ras-MESNA thioester; lane 2, ligation mixture after one day; lane 3, ligation mixture after four days. (C) ESI-MS of the purified ligation product Ras2Palm-3PPO. The deconvoluted spectrum is shown on the right and contains 2 peaks corresponding to Ras-2Palm-3PPO with a theoretical mass of 23519.3 Da and missing its N-terminal methionine with a theoretical mass of 23388.1 Da.

wavelength of 290 nm and a fluorescence light cut off filter of 420 nm. To determine the dissociation rate constant, the double palmitoylated Ras immobilized on lipidated nanoparticles was incubated with Nore1A M305W at a concentration of 2 μM and rapidly mixed in the stopped flow apparatus with Ras loaded with the nonfluorescent GppNHp to displace the effector.

RESULTS

Palmitoylated Ras by Expressed Protein Ligation. In order to study Ras/effector interactions under conditions close to their native environment, Ras was equipped with an artificial membrane anchor. Figure 1A summarizes the strategy for the synthesis of double palmitoylated Ras. H-Ras encompassing residues 1−180 is expressed as a fusion construct with an intein and a chitin binding domain in *E. coli* and purified by affinity chromatography. By incubation with MESNA, H-Ras (1−180) is cleaved off harboring a reactive thioester at its C-terminus (*21*). In parallel, a peptide is synthesized with a cysteine at the N-terminus and two palmitoyl groups coupled to lysine side chains according to Figure 1A. In order to improve handling properties and solubility of this peptide, a polyethylene glycol polyamide oligomer (PPO) comprising three PPO subunits was introduced at the C-terminus without affecting the membrane binding properties (Figure 1A) (*22, 23*). Peptides containing shorter PPOs comprising two or only one subunit have been prepared, but these shorter PPOs do not efficiently solubilize the lipidated peptide in aqueous buffers during purification and ligation. This water-soluble 2Palm-3PPO-peptide is ligated to Ras using a large excess of MESNA as ligation mediator (Figure 1A). The ligation reaction proceeds slowly but reaches a yield of 90% after four days (Figure 1B). LC-MS analysis and deconvolution of the resulting ESI spectrum shows two mass peaks that correspond to the ligation product Ras-2Palm-3PPO (calculated mass: 23519.3 Da) with and without the N-terminal methionine (Δmass: 131.2 Da, Figure 1C). The product was precipitated by the addition of 400 mM ammonium sulfate and separated from unligated Ras protein that remained soluble. The redissolved ligation product was loaded with the fluorescent GTP analogue mantGppNHp by incubation with a 5-fold excess of this nucleotide in the presence of 10 mM EDTA.

Ras Attached to Nanoparticle Supported Lipid Bilayers. As a membrane mimic, we chose nanoparticle supported lipid bilayers that were prepared using a procedure similar to that described by Richter et al. (*24*). Small unilamellar vesicles (SUV) made of DOPC by sonication collapse onto silica beads. The size and integrity of the particles were characterized by dynamic light scattering studies and autocorrelation analysis (Figure 2A). The polydispersity index of 0.10 and 0.08, for blank and lipidated nanoparticles, respectively, indicates a narrow distribution of the particle size before and after lipidation. The hydrodynamic radius of the lipidated particles was measured to 130 nm (Figure 2B). This nanoparticle supported lipid bilayer system should be well suited for membrane anchor insertion of Ras and other proteins carrying palmitoyl groups as these

anchors are shorter than half the bilayer thickness. A high mechanical stability without loss of fluidity is provided (*25*), and these particles are easy to handle, e.g., for changing buffers or concentrating the particles by gentle centrifugation and resuspension. A large, defined surface area can be offered with varying lipid composition. Double palmitoylated Ras was inserted into this artificial membrane by the addition of the protein amount required for covering of the desired fraction of lipid surface. A reasonable upper limit of coverage seemed to be 20%, and the required protein concentration [Ras] was calculated according to eq 1

$$[\mathrm{Ras}] = \frac{[\mathrm{nanoparticle}] \cdot A_{\mathrm{nanoparticle}}}{\rho \cdot V_{\mathrm{nanoparticle}} \cdot A_{\mathrm{Ras}} \cdot N_{\mathrm{A}}} \cdot 20\% \qquad (1)$$

where A_{Ras} is the footprint of the Ras-protein estimated from its structure to be 9 nm^2 and N_{A} the Avogadro constant. [nanoparticle] is the concentration of nanoparticles in mg/mL, ρ is the density of the nanoparticles taken from the manufacturer information, which is 2 $\mathrm{g/cm}^3$. $V_{\mathrm{nanoparticle}}$ and $A_{\mathrm{nanoparticle}}$ are the volume and the surface area of the single nanoparticle, respectively, that were determined from the radius. After incubation overnight, 25% of added Ras (1 μM) was immobilized as judged by SDS−polyacrylamide electrophoresis of samples from the separated phases. This corresponds to the amount of ca. 1000 molecules of Ras per lipidated nanoparticle. Noninserted Ras was removed by two washing cycles.

Affinity of Ras/Effector Interactions at Artificial Membranes. In order to characterize the interaction of Ras immobilized on the lipidated particles with other proteins, we employed fluorescence based methods previously established for studying Ras/effector binding in solution. In order to perform the GDI assay (*16*, *18*), Ras immobilized on lipidated nanoparticles and loaded with *N*-methyl-anthraniloyl-GppNHp (mantGppNHp) is incubated with effector proteins at defined concentrations. The mant-nucleotide is excited at 360 nm, and fluorescence is detected at 450 nm. The particle suspension shows no detectable sedimentation even after 1 h, and therefore, continuous stirring is not required. Intriguingly, light scattering of the milky particle suspension only weakly interferes with fluorescence excitation and emission. Compared to fluorescence measurements in solution with approximately 50% fluorescence decrease after mantGppNHp dissociation, the scattering background in the presence of lipidated particles still gives rise to ca. 20% change of the initial signal. From this, approximately equal contributions to the signal by light scattering and fluorescence can be estimated (Figure 3A).

The affinity of three different effector proteins was titrated with help of the GDI assay. This assay relies on the inhibition of the dissociation of the guanine nucleotide by effector binding, and an increasing Ras/effector complex concentration is reported by a decreasing dissociation rate of the nucleotide (*26*). A single exponential fit (Figure 3B) yields the observed rate constant, which is plotted versus effector concentration in Figure 3C and D. From this, the K_{D} value of the Ras/effector complex is obtained by fitting a quadratic equation. An overall error on the K_{D} values of 30% is estimated from the experimental errors on the kinetic data and the measurements of the protein concentrations. The results are listed in Table 1 together with the data obtained in solution. Only an increase by a factor of 1.5 to 3 is observed for the K_{D} values of all three effectors when measuring membrane bound Ras. It should be stressed here that only the Ras binding domain of the effectors was used in these studies. Other domains of the effector adjacent to the RBD as the cysteine rich region in Raf and Nore1A may contribute to membrane interaction as well (*27*, *28*).

Dynamics of Ras/Effector Interactions at Artificial Membranes. For measuring the dynamics of the interaction between effector protein and Ras attached to an artificial membrane through its C-terminal palmitoyl anchors we used a stopped flow apparatus (biologic, France). Again, the presence of lipid bilayer covered nanoparticles does not pose any technical problems. But, as in solution, the relative change of mant-fluorescence upon formation of the Ras/effector complex is much smaller compared to the mant-nucleotide dissociation measured in the GDI-assay. It is less than 10% even in the absence of particles and decreases to 3% in the presence of our nanoparticle preparations. Therefore, we used a FRET couple based on a Trp residue introduced at position 305 of Nore1A (donor) and the mant-nucleotide (acceptor) bound to Ras in order to obtain a clear fluorescence readout for complex formation. Fluorescence was excited at 290 nm and detected through a 420 nm cutoff filter. Fluorescence changes were much larger at lower temperatures, and therefore, we measured at 10 °C. The fit to the fluorescence time course by a single exponential equation did not yield satisfying residuals. Therefore, a double exponential function was used, and the observed rate constant of the faster phase was plotted against effector concentration (Figure 4A). The linear plot of the observed rate constants versus Nore1A concentration yields a value of 1.5 $\mu\mathrm{M}^{-1}\ \mathrm{s}^{-1}$ for the apparent association rate constant k_{on} (Figure 4B), which compares to 8.9 $\mu\mathrm{M}^{-1}\ \mathrm{s}^{-1}$ for Nore1A wild type in solution in the absence of NaCl (*29*). Notably, the second phase is almost as large in amplitude as the first one, and it is 15−20-fold slower than the fast reaction. In control stopped flow experiments using the same buffer, the same Nore1A mutant and Ras loaded with mantGppNHp but without the palmitoyl modification, we observed single exponential fluorescence changes yielding a k_{on} value of 3.3 $\mu\mathrm{M}^{-1}\ \mathrm{s}^{-1}$. There is no slow phase of association of Ras/Nore1A in solution.

The dissociation rate constant k_{off} can be obtained from the intercept of the plot in Figure 4B, and it is obvious from this that the k_{off} value is close to zero and therefore not well defined

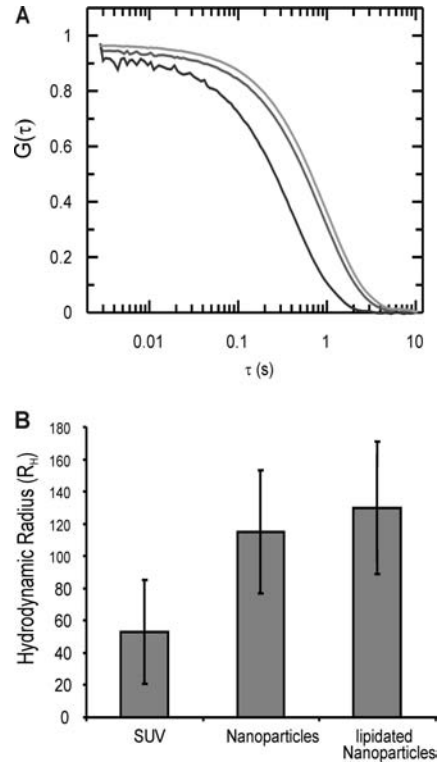

Figure 2. Dynamic light scattering and particle size distribution. (A) Autocorrelation curves of small unilamellar vesicles, naked nanoparticles, and lipidated particles (from left to right). (B) The histogram shows the hydrodynamic radii of these three species where the width of the size distribution (at half-maximum value) is indicated by the vertical lines at the top of the bars.

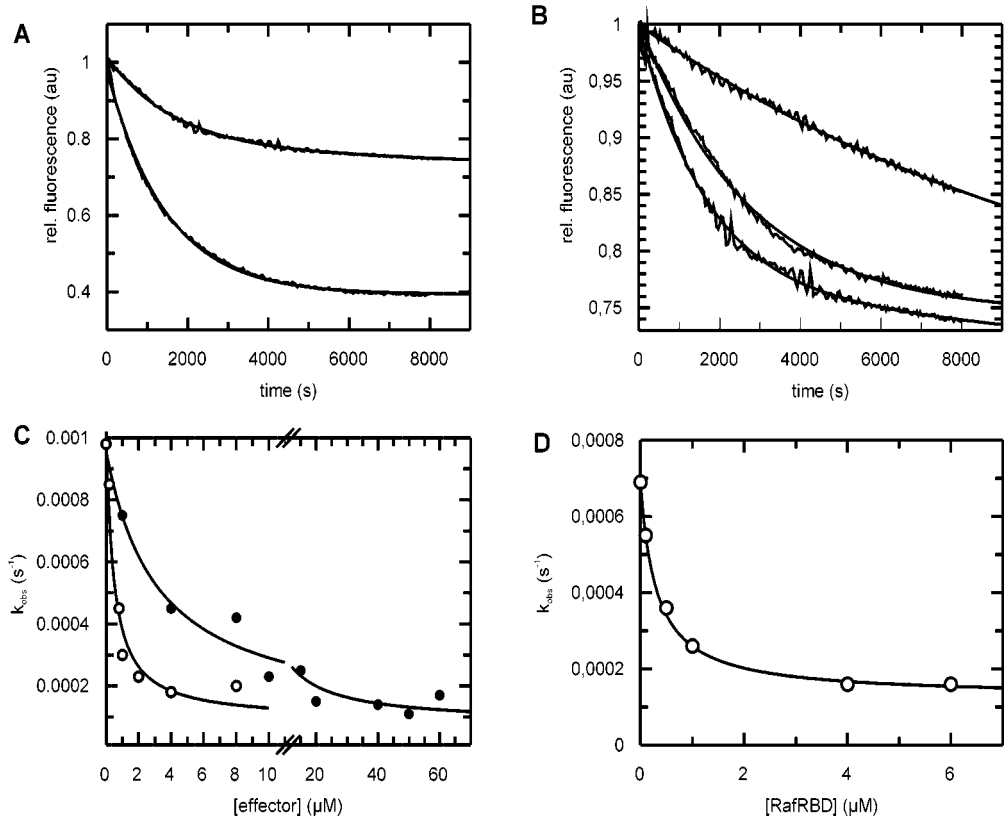

Figure 3. Ras/effector affinity measured by GDI-assay. The basis of the GDI assay is the dissociation of mantGppNHp from Ras achieved by the addition of an excess of nonfluorescent nucleotide and indicated by the strong decrease of fluorescence in buffer. (A) Ras-2Palm-3PPO bound to lipidated nanoparticles with a decay amplitude of 24% (upper curve) and in solution (lower curve) with a decay amplitude of 60%. (B) Fluorescence traces of the GDI-assay with the double palmitoylated Ras immobilized on lipidated nanoparticles in the presence of 0 μM, 0.5 μM, and 2.0 μM Raf-RBD (from bottom to top). (C) GDI plot for Ras-2Palm-3PPO with Nore1A (○) and RalGDS (●) as effectors, and (D) with Raf on lipidated nanoparticles each, fitted with a quadratic equation yielding the K_D values given in Table 1.

Table 1. Ras/Effector Affinity[a]

effector	K_D (μM) in solution	K_D (μM) on lipid. part.
Nore1A M305W	0.3	0.45
RalGDS	3.5	3.2
Raf	0.13	0.3

[a] K_D values for Ras·mantGppNHp/effector complexes in solution (*28, 30*−*32*) and on lipidated nanoparticles, respectively, obtained from GDI experiments at 37 °C, with an overall error of 30%. The solutions in all experiments contained 100 mM NaCl and were buffered with 25 mM Tris at pH 7.9 and 5 mM $MgCl_2$.

by this experiment. Nevertheless, this rate constant can be determined with high precision by a displacement experiment. The preformed complex of Ras·mantGppNHp and Nore1A-(M305W) is mixed with an excess of nonfluorescent Ras. The overall rate of the formation of the nonfluorescent complex is controlled by the dissociation of the preformed complex. In Figure 4C, the observed fluorescence time course is shown representing the dissociation of the Ras·mantGppNHp/Nore1A M305W complex. A single exponential equation plus linear slope is fitted to this curve, which yields a value of $k_{off} = 0.15$ s^{-1} (0.18 s^{-1} in solution) (*30*) for the dissociation of the complex. The slower linear decrease of fluorescence can be attributed to photo bleaching as demonstrated in control experiments. Together, from these stopped flow experiments, a K_D value of 0.10 μM is calculated that fits well to the GDI results above when taking the temperature difference into account.

DISCUSSION

Many biochemical studies report on the characterization of protein/protein interactions, but most of them ignore the membranous environment in the case when one of the partner proteins is usually bound to a membrane and neglect the possible implications for binding affinity and dynamics. With the present work, we provide a versatile method that allows one to take into account the effect of membranes on interactions between proteins of which one is attached to the membrane. We show here that conventional fluorescence techniques developed for studies in solution are also applicable for measurements of Ras/effector interactions on nanoparticle supported lipid bilayers.

An efficient synthesis of native-like small GTP binding proteins is the crucial requirement for investigations of protein interactions at membrane, if possible with the option to vary the composition of the hydrophobic anchorage. Here, expressed protein ligation was successfully employed in order to link a small synthetic peptide equipped with the desired hydrophobic anchor moieties to the Ras protein synthesized in bacteria. The Ras protein carrying two palmitoyl groups at the C-terminus was obtained in high yield, was easy to purify, and was shown to be intact in terms of nucleotide and effector binding, respectively.

As an artificial membrane system, we selected nanoparticles covered with DOPC lipids. As shown by others, such particles are straightforward to prepare, and they are covered homogenously by a lipid double layer. Incubation with palmitoylated Ras leads to attachment of the protein to the lipid surface by insertion of the hydrophobic moieties into the bilayer. Control experiments with unmodified Ras and other proteins such as the effectors clearly prove that there is no tendency of these

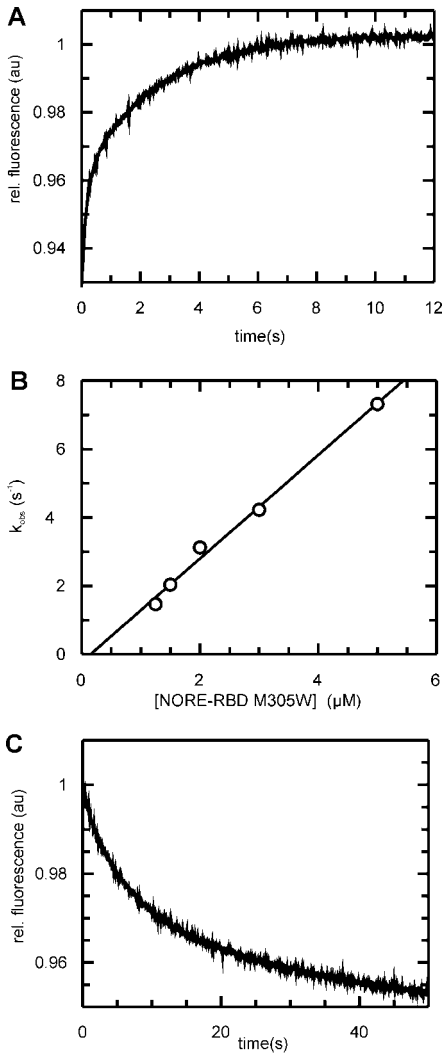

Figure 4. Interaction dynamics characterized by stopped flow. (A) Ras-2Palm-3PPO in complex with mantGppNHp and bound to lipidated nanoparticles was mixed with varying concentrations of Nore1A M305W in a stopped flow apparatus. Double exponential equations were fitted to the fluorescence traces recorded. (B) The observed rate constants of the fast phase are plotted versus the concentration. The slope of the linear fit yields the k_{on} value of 1.5 μM^{-1} s^{-1}. (C) Dissociation of the complex between double palmitoylated Ras·mantGppNHp on nanoparticles and Nore1A M305W. For displacement, an excess of GppNHp loaded Ras was mixed with the preformed complex. The exponential part of the curve yields the k_{off} value of 0.15 s^{-1}.

proteins to stick to the lipidated particles. The particles can be spun down and resuspended, which facilitates separation of bilayer-bound protein from soluble proteins as well as changing buffer conditions, e.g., during nucleotide exchange in Ras. The suspension of these particles with and without Ras attached is stable for hours as no sedimentation or coagulation is observed, and moreover, dynamic light scattering demonstrates a low degree of polydispersity and indicates an average particle radius of 130 nm. Thus, a robust and versatile protein/membrane system is provided, suitable for investigations with various biophysical techniques including spectroscopy.

We aimed at a quantitative characterization of Ras/effector interactions beyond their qualitative verification by experiments such as cosedimentation. Surprisingly, we found that conventional fluorescence spectroscopy is only perturbed a little by interference of light scattering originating from the nanoparticle suspension. Therefore, we were able to employ fluorescence assays previously established for studies on Ras/effector complexes in solution. For three different effector proteins, the GDI assay with Ras attached to lipidated particles yielded values of the equilibrium dissociation constant (K_D) that are similar to the respective values obtained in solution (Table 1). These results demonstrate on the one hand that the Ras binding domains of the effectors used in these studies do not contribute to membrane binding and on the other hand that the membrane environment does not change the ability of Ras to bind to the effector. There is no significant interference and no enhancement either. The GDI assay used in this pilot study is an indirect method as it reports the increasing saturation of Ras/effector binding through a decreased rate of nucleotide exchange. This is a big advantage here since artifacts such as unspecific effector binding to the particles can be excluded. The GDI effect most clearly indicates a specific interaction between Ras and effector protein showing the same characteristics as those in solution and emphasizing the full integrity of our Ras/membrane system.

We utilized stopped flow with fluorescence detection in order to determine the rate constants of Ras/effector interactions. After mixing Ras·mantGppNHp attached to nanoparticle supported lipid bilayers and the Trp mutant of Nore1A (M305W), the observed fluorescence traces were analyzed. There is a biphasic behavior with two rate constants, which are different by more than a factor of 10. The concentration dependence of the faster phase yields a k_{on} value comparable to Ras/Nore1A association in solution where the value for nonmodified Ras is two times larger. The slow phase of the association suggests the presence of another species of Ras immobilized on the lipidated nanoparticles, which seems to be not directly accessible for Nore1A binding. Notably, the dissociation is a single exponential and indicates a homogeneous Ras/Nore1A complex population. The k_{off} value extracted from the single exponential fit to the displacement experiment is almost identical to the value obtained for the complex in solution. Similar to the equilibrium data, we can conclude that the results on the rate constants for association and dissociation of the Ras/Nore1A complex are not significantly different when soluble and membrane bound Ras are compared apart from an unknown fraction of Ras binding Nore1A 10 times more slowly.

In summary, we demonstrated the application of readily available fluorescence techniques for the investigation of protein/protein interactions at the surface of an artificial membrane system based on nanoparticle supported lipid bilayers. Not only protein complex affinity but also binding dynamics can be quantified. The interaction of double palmitoylated, membrane bound Ras with the RBD of three different effectors does not show significant differences to the results obtained from studies in solution. In a next step, this experimental setup can be used in order to address the role of other protein domains located next to the RBD of the respective effector proteins. To this end, we provide a widely usable assay that will allow the determination of the influence of membrane composition one the one hand and lipid binding domains such as C1 and PH domains on the other hand on the overall interaction of protein complexes located at lipid membranes.

Covalent Immobilization of Proteins on Carbon Nanotubes Using the Cross-Linker 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide—a Critical Assessment

Yuan Gao* and Ilias Kyratzis

Materials Science and Engineering, Commonwealth Scientific and Industrial Research Organization (CSIRO), Bayview Ave, Clayton 3168, Australia. Received February 5, 2008; Revised Manuscript Received May 29, 2008

Functionalization of carbon nanotubes (CNTs) with proteins is often a key step in their biological applications, particularly in biosensing. One popular method has used the cross-linker 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) to covalently conjugate proteins onto carboxylated CNTs. In this article, we critically assess the evidence presented in these conjugation studies in the literature. As CNTs have a natural affinity for diverse proteins through hydrophobic and electrostatic interactions, it is therefore important to differentiate protein covalent attachment from adsorption in the immobilization mechanism. Unfortunately, many studies of conjugating proteins onto CNTs using EDC lacked essential controls to eliminate the possibility of protein adsorption. In studies where the attachment was claimed to be covalent, discrepancies existed and the observed immobilization appeared to be due to adsorption. So far, bond analysis has been lacking to ascertain the nature of the attachment using EDC. We recommend that this approach of covalent immobilization of proteins on CNTs be re-evaluated and treated with caution.

1. INTRODUCTION

The discovery and subsequent large-scale production of carbon nanotubes (CNTs) have opened a new door in nanotechnology (*1*). Due to their nanosize, exceptional physical strength, chemical stability, and conductive properties, CNTs are being explored for a wide range of applications (*2*). Among these, CNT-based biosensing has drawn particular interest with some extensive reviews published recently (*3*−*7*).

A key step in CNT-based biosensing is the immobilization of a biomolecule on the surface of the CNTs in devices such as electrodes and field effect transistors. The biomolecules are often proteins such as an antibody (*8*), antigen (*9*), or enzyme (*10*). They typically bind to, catalyze a reaction of, or are inhibited by the target molecule. The nanostructure of CNTs, together with their conducting properties, enables tiny signals to be detected and transmitted, leading to the detection of target molecules at extremely low levels. Noncovalent (e.g., adsorption) and covalent conjugation have been reported for the immobilization of various proteins. Noncovalent attachment preserves the unique properties of the CNTs, but the immobilized protein is in equilibrium in a solution and can therefore be gradually lost during the use of the CNT biosensor. On the other hand, covalent conjugation provides durable attachment, but the harsh oxidation step (e.g., with strong acids) disrupts the π-networks on the CNT surfaces and may diminish their mechanical and electronic properties (*11*). Covalent

attachment of proteins on carboxylated CNTs using the popular cross-linker 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) was first reported by Huang et al. (*12*) and Jiang et al. (*13*). Since then, it has been widely used in the covalent immobilization of proteins on carboxylated CNTs in biosensing studies (*14*−*22*).

The validity of covalent conjugation of proteins onto carboxylated CNTs using EDC appears to have been accepted without due scrutiny. In this article, we critically examine the evidence presented in the conjugation studies in the literature. We find that conclusive evidence for covalent immobilization is lacking, and that the protein immobilization in most of these studies may be largely due to adsorption.

2. ADSORPTION OF PROTEINS ONTO CNTS

Before we proceed to consider EDC-mediated covalent attachment of proteins on CNTs, it is necessary to briefly look at protein adsorption first.

Tsang and colleagues first reported that small proteins such as metallothionein, cytochrome C, and *β*-lactamase were able to adsorb on the internal as well as outer walls of CNTs after the ends were opened by treatment with concentrated nitric acid (*23, 24*). Since then, both multiwalled (MWCNT) and single-walled CNTs (SWCNT), whether dispersed or oxidized, have been demonstrated to have the ability to adsorb diverse proteins (Table 1). The adsorbed proteins form a coat on the CNT surface when visualized by atomic force microscopy (AFM) or electron microscopy (*25*−*28*). Streptavidin can almost completely cover the surface of MWCNT where it forms a highly ordered helical structure (*25, 29*). Some proteins, such as *β*-glucosidase, chymotrypsin, and soybean peroxidase (SBP), are adsorbed at very large quantities, i.e., at 630, 670, and 575 *μ*g protein per mg of CNTs, respectively (*30, 31*). Bovine serum albumin (BSA) is also adsorbed well and has been reported as an effective agent in dispersing CNTs (*9, 32, 33*).

The adsorption is spontaneous when the protein comes in contact with CNTs in a solution, and follows a pseudosaturation behavior (*30, 31, 34*). The interaction between the CNTs and the protein can be very strong. Using techniques such as FT-IR and AFM, the conformation of the adsorbed protein is observed to be distorted or partially unfolded due to the strong interaction with the CNTs (*23, 30*). As a result of such structural perturbations and other mechanisms, the activities of adsorbed enzymes are reduced by 70−99% for *β*-lactamase, *β*-glucosidase, chymotrypsin, and SBP as compared with the free enzyme in solution (*23, 30, 31*).

The interacting force between CNTs and a protein is predominantly hydrophobic interaction (*25, 29, 33*), although electrostatic interaction and hydrogen bonding can also play a role in some situations (*31, 35*). The relationship between the structure of a protein and its binding to CNTs has been further studied using peptides. Ring structures in aromatic amino acids (e.g., phenylalanine and tryptophan) are important for the interaction between the peptide and CNTs through *π*-stacking (*35*−*37*). However, due to protein folding, the binding ability of a protein to CNTs cannot be predicted by its number of hydrophobic or aromatic residues in the primary structure (*33*).

3. COVALENT IMMOBILIZATION OF PROTEINS ON CNTS USING EDC

3.1. Chemistry of EDC Conjugation. In order to better understand the studies in which EDC is used to covalently attach proteins onto CNTs, it is helpful to look at the conjugation mechanism. EDC is a zero-length cross-linker widely used in protein conjugations (*38*). The conjugation reactions occur in two sequential steps (Figure 1). EDC first reacts with a carboxyl group, forming an amine-reactive *O*-acylisourea intermediate which subsequently reacts with an amine group to produce a stable amide bond. However, the *O*-acylisourea intermediate is very unstable and susceptible to hydrolysis. Such instability results in low coupling efficiency. The addition of NHS (*N*-hydroxysuccinimide or its more water soluble analogue Sulfo-NHS) stabilizes the intermediate by converting it to a semistable amine-reactive NHS ester, thus increasing the coupling efficiency by 10−20 fold (*39, 40*).

The coupling of a protein onto carboxylated CNTs can be achieved in a single-step or a two-step procedure. In the former case, the protein, CNTs, and EDC are mixed in a single tube. The use of NHS is conceptually not essential but will greatly improve the coupling efficiency. In this single-step procedure, interprotein conjugation also takes place and can lead to protein supramolecules or even aggregates. To overcome this problem, a two-step conjugation procedure can be used. The carboxylated CNTs are first reacted with EDC in the presence of NHS (or sulfo-NHS) to yield a semistable amine-reactive NHS-ester. After excess EDC is washed off or deactivated by the addition of *β*-mercaptoethanol (*41*), the activated CNTs are then reacted with a protein. In this case, interprotein conjugation is eliminated because only the CNTs are exposed to the cross-linker. The only covalent bond formed is between the solid CNT support and the protein.

The buffer used in EDC coupling is also an important consideration. The coupling is typically performed at slightly acidic pH in MES buffer (2-morpholinoethanesulfonic acid). The use of phosphate buffer should be avoided, as phosphate reacts with EDC and reduces its stability from a $t_{1/2}$ of 20 h in MES buffer to 0.4 h at pH 6.0 (*42*). If phosphate buffer has to be used, a large excess of EDC can be used to compensate for the instability.

3.2. Conjugation of Proteins onto Carboxylated CNTs Using EDC. Due to the chemical inertness of CNTs, any covalent immobilization of molecules will require chemical modifications to create reactive groups on the surface first. Popular methods include sonicating CNTs in a mixture of sulfuric acid and nitric acid (typically 3:1 v/v) or refluxing in concentrated nitric acid. Such oxidative treatments create carboxylic groups, among others, at the ends and defect sites

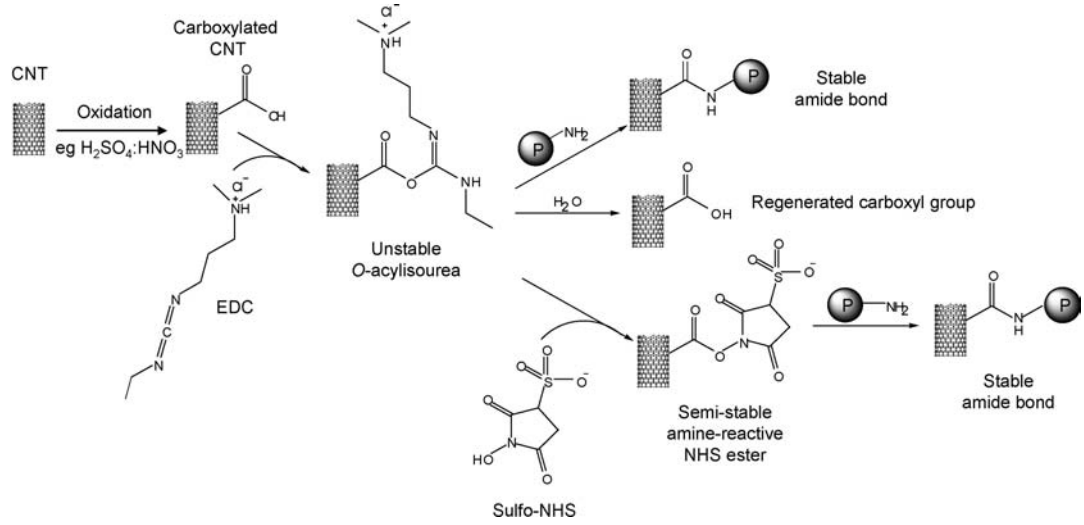

Figure 1. Theoretical conjugation of proteins to carboxylated CNTs using EDC in the presence or absence of sulfo-NHS.

on the sidewalls of the CNTs (*43*, *44*). The presence of carboxylic groups has been verified by titration experiments (*45*−*47*) and IR spectroscopy (*48*, *49*).

The carboxylic groups on the CNTs provide, in theory, ideal anchoring points for the covalent attachment of proteins using the cross-linker EDC. Indeed, this has been the method of choice by many researchers in recent years, although other cross-linkers have been occasionally used. Table 1 lists proteins that have been claimed to be covalently coupled onto CNTs using EDC. However, many of these proteins can also be adsorbed onto CNTs. This raises a question whether the observed protein immobilization in the coupling studies is actually due to covalent attachment or due to adsorption.

Huang et al. (*12*) were the first to specifically report the covalent coupling of a protein onto CNTs using EDC. In their work, acid-treated SWCNTs were sonicated for two hours in phosphate buffer containing 50 mM EDC but in the absence of NHS. BSA was then added to the solution and the coupling was allowed to proceed for 24 h at room temperature. BSA immobilization was observed by AFM to be at various points on the CNTs, which seemed to be consistent with the notion that carboxylic groups are at defect sites on the sidewall. However, the evidence presented to support the claim that BSA was covalently attached to the CNTs was inconclusive, for the following reasons. First, the comparison of CNT-conjugated BSA with free BSA on a SDS-polyacrylamide gel actually showed that the two behaved similarly (Figure 5 in (*12*)). This indicated that the CNT−BSA complex was dissociated under the denaturing electrophoretic conditions, revealing their non-covalent association nature. Second, the study lacked essential controls. As various studies have demonstrated that CNTs have great affinity for BSA, it is imperative that negative controls, i.e., reactions in the absence of the cross-linker, be incorporated to determine whether the immobilization is due to protein adsorption. Third, very unfavorable coupling conditions were used in this study. The omission of NHS in the reaction, the use of phosphate buffer, and the two hour time delay before BSA was added to the reaction would have collectively resulted in very low conjugation efficiency in a coupling reaction.

Jiang et al. (*13*) also specifically studied covalent coupling of proteins onto CNTs using EDC but using a two-step procedure. Acid-treated MWCNTs were first activated with EDC/NHS and then reacted with BSA or ferritin. Under TEM, the immobilized ferritin was observed to distribute relatively evenly on the sidewalls of the CNTs (Figure 2 in (*13*)). The authors claimed, but without presenting the data, that ferritin did not bind to the CNTs when EDC or NHS was omitted in the reactions. For BSA conjugation, the only evidence presented was two AFM images showing BSA on the CNTs. These results led to the conclusion that the attachment of ferritin and BSA onto the CNTs was mediated by EDC/NHS. This conclusion is open for further discussion. First, the uniform distribution of ferritin on the side wall may be inconsistent with carboxylic groups which are only located at the tips and defect sites on the sidewall of the oxidized CNTs. Second, it is unclear whether or not ferritin adsorbs onto CNTs. Azamian et al. and Lin et al. have shown that ferritin adsorbs efficiently to oxidized SWCNT, and that adding EDC to the binding solution does not alter the immobilization (*26*, *27*). Third, proper controls, which were not reported in the study, were needed to eliminate that the observed BSA immobilization was not due to physical adsorption.

A few other studies have used EDC to conjugate other proteins onto CNTs. Lee et al. observed that horseradish peroxidase (HRP) could be adsorbed on MWCNT and the use of EDC increased its immobilization by up to 20% (*19*). It was unknown, however, whether this small increase was significant because no statistical analysis could be performed. It is interesting to note that this increase occurred only at 10−40 mM but not at 60−100 mM of EDC. As unfavorable coupling conditions were employed in this study, (i.e., the use of phosphate buffer in the absence of NHS), one would expect that covalent conjugation should have increased with increasing EDC concentration. Asuri et al. reported that 170 μg of SBP could be coupled to 1 mg CNTs, and a control reaction in the absence of EDC/NHS showed that nonspecific binding accounted for less than 5% of total immobilized activity (*50*). Similarly, Wohlstadter et al. reported, without presenting the data, that EDC/NHS coupling tripled the amount of streptavidin immobilized on the CNTs (*14*). However, as both SBP and streptavidin can adsorb to CNTs spontaneously in large quantities resulting in complete coverage of the CNT surface, it is difficult to imagine how these proteins could still be conjugated by the much slower covalent process. More studies are needed to reconcile these studies. Some of these studies have used a two-step conjugating procedure where the only amide bonds formed would have been between the protein and the CNT surface. Functional group analysis by techniques such as FT-IR or Raman could potentially assist in determining the nature of the attachment.

EDC has been used to immobilize a number of enzymes and antibodies on CNTs using diverse conditions in biosensing studies (*15*−*18*, *20*, *21*, *51*−*53*). These studies generally did not include any necessary control reactions to differentiate adsorption from covalent conjugation and did not characterize

the immobilization. Protein immobilization on the CNTs in these studies was simply assumed to be due to the action of EDC.

Therefore, no conclusive evidence so far exists to show that proteins have been covalently conjugated onto carboxylated CNTs by the use of carbodiimide chemistry. Given the affinity of CNTs for many proteins including those used in the conjugating studies, proteins immobilization observed using EDC may be predominantly due to adsorption. If this is true, it is necessary to rethink the value of this "covalent" approach. If it does not significantly contribute to the amount of protein immobilization, the drawback would be, apart from labor and chemical cost, the likely loss of protein activity resulting from the many steps of handling in the conjugation process and the formation of cross-linked protein aggregates (if a one-step conjugation protocol is used). For many applications, it may make little difference whether the protein is adsorbed or covalently bound as long as adequate activity is maintained.

In contrast to proteins, small molecules such as short peptide nucleic acid (*54*) and amine-containing quantum dots (*55*) have been conjugated to acid-oxidized CNTs by EDC/NHS chemistry. Through the use of proper negative controls, FT-IR analysis, and localization by SEM imaging, the immobilization of these substances appears to be covalent. The difficulty with covalent protein coupling may be due to a number of factors. First, for many proteins, there is a competition between adsorption and covalent conjugation for surfaces of the CNTs. Adsorption, due to its strong affinity and spontaneity, is probably the dominating process over the much slower covalent reactions. Once occurred, the adsorbed protein may shield adjacent carboxylic groups from reacting with other protein molecules. Second, the carboxylic groups on oxidized CNTs are directly associated with the CNTs (i.e., without a spacer arm); this may lead to steric hindrance in the reactions between a soluble protein and the solid surface of CNTs, resulting in low conjugation efficiency.

4. CONCLUSIONS

Covalent conjugation of proteins on carboxylated CNTs using the coupling agent EDC has been widely used in recent years. However, many proteins used in such conjugation studies have also been shown to adsorb onto CNTs. So far, conclusive evidence is lacking to show that EDC could significantly improve protein immobilization on CNTs above the level of adsorption. It is necessary to re-evaluate this approach of protein conjugation onto CNTs. The unnecessary use of EDC chemistry will not only increase the cost of the work, but also may lead to some loss of protein activity resulting from the handling in the process and the possible formation of cross-linked protein aggregates. We recommend that this approach be treated with caution.

REVIEWS

3-D Tissue Culture Systems for the Evaluation and Optimization of Nanoparticle-Based Drug Carriers

Thomas Tyrel Goodman,† Chee Ping Ng,† and Suzie Hwang Pun*

Department of Bioengineering, University of Washington, 1705 NE Pacific Street, Seattle, Washington 98195. Received June 7, 2008; Revised Manuscript Received August 18, 2008

Nanoparticle carriers are attractive vehicles for a variety of drug delivery applications. In order to evaluate nanoparticle formulations for biological efficacy, monolayer cell cultures are typically used as *in vitro* testing platforms. However, these studies sometimes poorly predict the efficacy of the drug *in vivo*. The poor *in vitro* and *in vivo* correlation may be attributed in part to the inability of two-dimensional cultures to reproduce extracellular barriers, and may also be due to differences in cell phenotype between cells cultured as monolayers and cells in native tissue. In order to more accurately predict *in vivo* results, it is desirable to test nanoparticle therapeutics in cells cultured in three-dimensional (3-D) models that mimic *in vivo* conditions. In this review, we discuss some 3-D culture systems that have been used to assess nanoparticle delivery and highlight several implications for nanoparticle design garnered from studies using these systems. While our focus will be on nanoparticle drug formulations, many of the systems discussed here could, or have been, used for the assessment of small molecule or peptide/protein drugs. We also offer some examples of advancements in 3-D culture that could provide even more highly predictive data for designing nanoparticle therapeutics for *in vivo* applications.

INTRODUCTION

The delivery of therapeutic agents using nanoparticulate formulations offers a number of advantages over delivery of the agents alone. For this reason, both small and macromolecular drugs are often incorporated into nanoparticle vehicles. These vehicles can potentially enhance drug efficacy by incorporating adjuvants, targeting agents, and multiple therapeutics within one carrier. The nanoparticles can also offer protection against degradation of therapeutic agents as well as facilitate the delivery of otherwise insoluble agents. An additional advantage is that the pharmacokinetic profile of drugs can be favorably altered by controlling the size and surface chemistry of the nanoparticle delivery vehicles. However, the significantly increased size of nanoparticle carriers compared to their therapeutic payload generally results in reduced tissue distribution after extravasation from the circulation. There are several therapeutic applications that benefit from efficient tissue penetration of the delivery vector. For example, some vectors, such as nonviral nucleic acid delivery vehicles that assist in intracellular trafficking, would ideally remain intact until internalization by the maximum number of target cells. For such systems, a key criterion for *in vivo* efficacy is that nanoparticle carriers must be able to overcome the various extracellular barriers encountered after extravasation to reach target cells.

Currently, initial evaluations of nanoparticulate delivery formulations are usually completed in monolayer, or 2-D, cell culture systems. Oftentimes, successful nanoparticle delivery observed in 2-D cell culture studies does not translate to similar results *in vivo*. This is in part due to limitations in monolayer cultures that fail to account for extracellular barriers that are present *in vivo* (*1*−*3*) (Figure 1). While monolayer cultures produce extracellular matrix materials, they are less dense on the monolayer apical side compared to cells in a 3-D environment (*4*−*7*) and thus present a less-significant barrier for transport and cell-binding of delivered agents compared to cells in 3-D. Thus, whereas nanoparticles delivered in a bulk solution to a 2-D cell culture typically reach and bind to cells relatively unimpeded, the same nanoparticles delivered *in vivo* will be hindered by extracellular factors such as the relatively small pore sizes within the extracellular matrix (ECM) (*8*) and the tortuosity of the interstitium. The surface properties of the nanoparticles can also lead to interactions with charged ECM components, such as proteoglycans, thereby affecting the fate and stability of nanoparticles (*9, 10*). In addition, cell monolayer

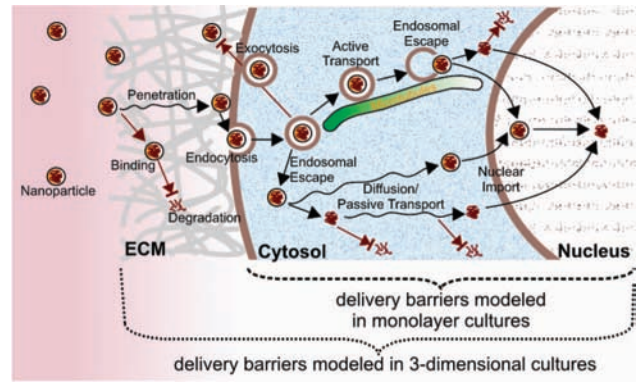

Figure 1. 3-D culture systems include additional extracellular barriers encountered by delivery vehicles that are not accounted for in 2-D monolayer cultures.

studies are typically performed under static culturing conditions, whereas living tissues are mechanically dynamic systems and are constantly subjected to mechanical forces such as tension, compression, and interstitial fluid flow. The direction and magnitude of fluid flow can alter the bioavailability of the delivery vehicle by redirecting nanoparticles in the direction of flow and potentially away from the target sites.

Cell culture conditions also affect the phenotype of cells and thereby affect the cellular response to delivered drugs. For example, hepatocytes lose some liver-specific functions, such as albumin production, when maintained under monolayer single cell-type conditions, but retain the functions when cultured in 3-D perfusion models (*11, 12*) or when co-cultured with supporting cell types such as fibroblasts (*13*−*15*) or epithelial cells (*16, 17*). These phenotypic differences may be due in part to cells residing in materials that are more compliant than on 2-D plastic substrates typically used for monolayer cultures (*18*−*21*). Cell phenotype is also determined by interactions between cells and the supporting extracellular matrix (ECM), as well as cell−cell communication that results in changes in biological activities, including gene and protein expression, proliferation, migration, remodeling, and signal transduction (*13, 22*−*25*). Cells in 2-D monolayer cultures are generally exposed to a uniform environment under culture medium, whereas cells in tissues, particularly in solid tumors, are exposed to gradients of pH, nutrients, and waste products that exert both stimulatory and inhibitory influences on proliferation and malignant properties of the cells (*26*). Furthermore, multicellular drug resistances can result from conditions in the 3-D tissue microenvironment that may not be present in monolayer cultures, such as the occurrence of hypoxic tissue regions, altered cell proliferation, and poor availability of delivered drugs in deeper tissue layers (*27*).

For these reasons, researchers are utilizing and developing 3-D culture systems with the goal of more closely mimicking the human clinical setting. Realistic and controllable *in vitro* 3-D tissue culture systems that more closely mimic *in vivo* human tissues in terms of functionality, morphological, and mechanical architecture could be applied during the development and evaluation of delivery vehicles to offer a more predictive platform for assessing *in vivo* delivery efficiencies. Such systems can serve to bridge the considerable gap between traditional 2-D monolayer experiments, animal studies, and clinical trials, since nanoparticle formulations can be more effectively optimized in these 3-D *in vitro* models (*28*).

In this review, we will summarize the evaluation of nanoparticle carriers in several prevalent 3-D cell culture models currently used in nanoparticle delivery studies. In addition, we will highlight several advanced 3-D systems designed to account for additional factors in the complex biochemical and biomechanical environment that cells experience *in vivo*. Finally, we will discuss existing challenges in the adoption of such systems and some future directions in the development of 3-D systems for the assessment of nanoparticle delivery to tissues.

3-D CULTURE SYSTEMS

Hydrogels. Acellular hydrogels have been used to study nanoparticle diffusion in a tissue-like environment. These systems offer perhaps the simplest model of a "tissue" for assessing nanoparticle behavior. Although these models lack cells and generally employ simplified ECM compositions, they offer a practical method for probing the stability, diffusion rates, and binding interactions of nanoparticle carriers in cross-linked networks. For example, investigations using iron oxide particles have shown that diffusion through isolated ECM is highly restricted even for particles as small as 130 nm in diameter (*29*). The importance of particle surface chemistry was highlighted by Valentine and co-workers who demonstrated that the addition of the hydrophilic polymer poly(ethylene glycol) (PEG) to the nanoparticle surface, an approach known as PEGylation, led to significant reductions in particle binding to fibrin networks and subsequently increased diffusion rates compared to unmodified particles (*30*). Other studies have confirmed that the PEGylation of particles can increase movement through hydrogels, but the rate of movement is still size-dependent (*29*). The effectiveness of PEGylation is highly dependent on the type of matrix and the composition of nanoparticle formulations. For example, charged matrixes can lead to the aggregation or unpackaging of polyplexes (polymer/DNA complexes) even after PEGylation (*31*). The implications of particle shape have also been probed in hydrogels with results suggesting that extending nanoparticles into a flexible wormlike structure may allow for more effective tissue penetration compared to the traditional spherical carrier (*32*). To partially alleviate the restricted movement of particles, covalent conjugation of an ECM disrupting enzyme, collagenase, to nanoparticles has been carried out, which led to significant improvements in magnetically driven nanoparticle movement through isolated ECM (*33*).

In summary, evaluations of delivery vehicles in acellular constructs have provided valuable insight into the stability of carriers in the presence of ECM components as well as the effect of size, shape, and surface chemistry on the mobility of vectors through the ECM. Still, the usefulness of such systems is limited by their inability to offer information about the interactions of carriers with cells and the efficacy of therapeutics on the target cells.

Multicellular Spheroids. Perhaps the most widely used 3-D tissue model for the assessment of nanoparticle delivery is the multicellular spheroid. Multicellular spheroids are formed by culturing cells in spinner flasks or agar-coated culture plates (*34*). Under these conditions, cells form spherical clusters that can survive for weeks and can reach sizes of up to several millimeters in diameter. Multicellular spheroids offer a simple and highly reproducible model that contains many of the features of natural tissue *in vivo* including some patterns of protein production (*35*) and the production of an ECM (*36*). In the later stages of growth, larger spheroids mimic properties of avascular regions of solid tumors including regions of differential growth such as a proliferating region, a quiescent region, and a necrotic core (*35*). As spheroids are relatively easy to handle, they are amenable to confocal analysis, cryosectioning, and commonly used fixing and tissue processing methods. They can also be dissagregated by trypsin treatment and individual cells collected for analysis by flow cytometry. Exposure of the spheroids to a cell-permeable dye prior to flow cytometry allows for determination of the original radial location of the cells within the spheroid (*37*). These properties make spheroids a very useful and widely used model for investigating nanoparticle−tissue interactions.

Multicellular spheroids have been used to probe some of the major barriers to effective drug delivery to solid tumors, including the effect of hindered vehicle diffusion in the ECM and the effect of nonspecific binding between nanoparticles and tissue components. The heterogeneous nature of the spheroids has also allowed for the study of the effect of the proliferative state of cells on delivery efficacy.

Hindered diffusion of delivery vehicles due to restrictive pore sizes and high tortuosity in the interstitial space was demonstrated in experiments that highlight the correlation between nanoparticle carrier size and tissue penetration into multicellular spheroids. Studies investigating the penetration of carboxylated polystyrene beads in spheroids showed that particles with diameters less than 100 nm can infiltrate spheroids more effectively than particles $\geq$100 nm, but that particle penetration

for all tested sizes (20−200 nm) was significantly hindered (*3*). Enger and co-workers demonstrated that adeno-associated virus (AAV), with effective diameters of ∼25 nm, can more effectively penetrate multicellular spheroids compared to adenovirus with average diameters of 100 nm (*38*). Differences in viral penetration were attributed at least in part to these differences in particle size.

In addition to size, vector surface charge affects distribution in multicellular spheroids. The penetration of liposomes with different surface charges was analyzed in this model, and liposomes with neutral or low surface charge were shown to penetrate to the central regions of the spheroids while liposomes with higher surface charge were confined to the outer cell layers of the spheroid, demonstrating an example of a binding site barrier (*39*). One approach to reduce strong binding interactions is PEGylation. Indeed, PEGylation of polyplexes results in a reduction in toxicity and improved penetration of polyplexes in multicellular spheroids (*40, 41*). Interestingly, in studies by Han et al., toxicity profiles of PEGylated polyplexes differed for spheroid cultures compared to monolayer cultures, with spheroids exhibiting an increased sensitivity to non-PEGylated polyplexes. Oishi et al. have also demonstrated that the effectiveness of siRNA delivery using lipoplexes and PEGylated polyplexes is affected by the method of cell culture, with cells in a monolayer showing increased sensitivity to therapy compared to spheroid cultures (*42*). These studies further demonstrate the importance of 3-D screening for nanoparticle carriers, as important toxicological data could be missed with only monolayer screening (Table 1).

Multicellular spheroids that reach a certain size contain different regions that are also present in solid tumors, including an outer proliferating region, an intermediate quiescent region, and a central necrotic core. For certain carriers, such as nonviral gene delivery vectors, cells must be dividing in order to observe effective therapy; therefore, quiescent regions of spheroids are not efficiently transfected even if vectors reach these target cells (*43*). The effect of cell proliferation on cell killing by antineoplastic agents has also been well-documented in the literature (*44*).

The limitations in nanoparticle penetration due to some of the aforementioned physiochemical properties of the nanoparticles can be partially overcome by modulation of the ECM. Several studies have demonstrated the potential of this approach for improving delivery efficiency. Addition of the matrix metalloproteinase (MMP), collagenase, either in solution or immobilized on the surface of nanoparticles, increases the penetration of vectors up to 100 nm in size (*3*) (Figure 2). Improved viral particle penetration has also been accomplished in spheroids through the use of the peptide hormone, relaxin (*45*). Relaxin, which can down-regulate collagen production and increase collagenase production (*46*), was engineered into an oncolytic adenovirus and delivered to multicellular spheroids. Viruses that included the relaxin gene were able to transduce almost all areas of spheroids, while control virus transduction was confined to the outer few cell layers. The ability to incorporate these penetration enhancers into nanoparticle drug carriers offers a promising method for improving treatments, such as gene therapy for solid tumors, which rely on effective access to the majority of the target tissue.

From these studies, it is clear that the 3-D tissue environment affects the mobility of nanoparticles through tissue, which in turn affects therapeutic efficacy of delivered nanoparticles. These factors also affect the sensitivity of tissues to cytotoxic therapeutics. Studies using multicellular spheroids have been used to understand key challenges for *in vivo* delivery to tissue and to demonstrate the importance of 3-D screening for nanoparticle carriers.

Table 1. Examples of Differences in Nanoparticle-Based Drug Delivery Observed in 2-D versus 3-D Cell Culture Systems

deliverable	difference between 2-D and 3-D systems	ref
cytotoxic small molecules drugs	multicellular resistance (lower cytotoxicity) observed in spheroid cultures and polystyrene scaffolds compared to monolayer cultures.	*23, 83, 84*
PEI polyplex delivery of plasmid DNA	PEI-mediated transfection was limited to cells at the spheroid periphery, even with electroporation. This spatially dependent transgene expression is not observable with monolayer cultures.	*38*
P[Asp(DET)] polyplex delivery of plasmid DNA	difference in cytotoxicity of PEGylated compared to non-PEGylated polyplexes observed in spheroids but not detected with the conventional monolayer cultures. Specifically, PEG-*b*-P[Asp(DET)] polyplex micelles did not induce the destruction of spheroids even at N/P = 40, where the MCTS structures were destroyed by the transfection with P[Asp(DET)] polyplexes. Difference in the timecourse of transgene expression observed in 3-D spheroid cultures vs monolayer cultures. Peak transgene expression occurred at 6 days after transfection in spheroids whereas difficulties were encountered in maintaining viable monolayer cultures beyond 4 days.	*36*
lipoplex delivery of siRNA	differences in growth-inhibitory effect between spheroid and monolayer cultures. OligofectAMINE-siRNA lipoplexes had no inhibitory effect on HuH-7 spheroids compared to strong effects on HuH-7 monolayer culture.	*42*
poly(glycerol-adipate) nanoparticle delivery of DNA	differences in cellular uptake of nanoparticles in cocultures. Nanoparticles were predominantly taken up by cancerous cells rather than normal cells in 3-D cocultures whereas nanoparticles were taken up more readily by normal cells in monolayer cultures.	*45*
adeno-associated vectors (AAV) and adenovirus vector (ADV)	differences in penetration efficiencies between AAV vs ADV vectors. AAV penetrated glioblastoma spheroids and xenografts more efficiently compared to ADV vectors; biodistribution not observable with monolayer cultures.	*34*
lentivirus	enhanced transduction of epithelial cells and underlying fibroblasts compared to static coculture controls in airway wall model; this transgene expression profile was not observable with monolayer cultures.	*49*

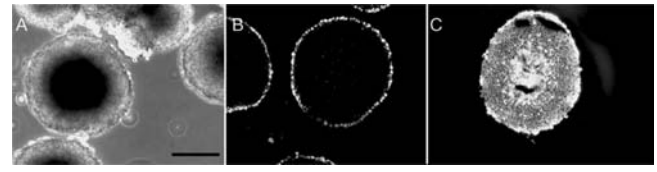

Figure 2. Penetration of model nanoparticles into multicellular spheroids. Phase contrast of multicellular spheroids shows intact spheroids prior to treatment with 40 nm fluorescent polystyrene nanoparticles (A). Cryosections of untreated spheroids (B) showed poor particle association compared to spheroids coincubated with collagenase (C). Scale bar is 200 μm.

Multilayer Cell Cultures. Multilayer cell cultures have been used for the assessment of small molecule drug delivery (*47*), and even though they have not been used extensively for nanoparticle delivery applications, they merit brief mention because they have potential use in assessing nanoparticle delivery across tissue layers. Multilayer cultures are most commonly formed by allowing monolayer cultures to continue to grow beyond confluence in Transwell cell culture dishes. The

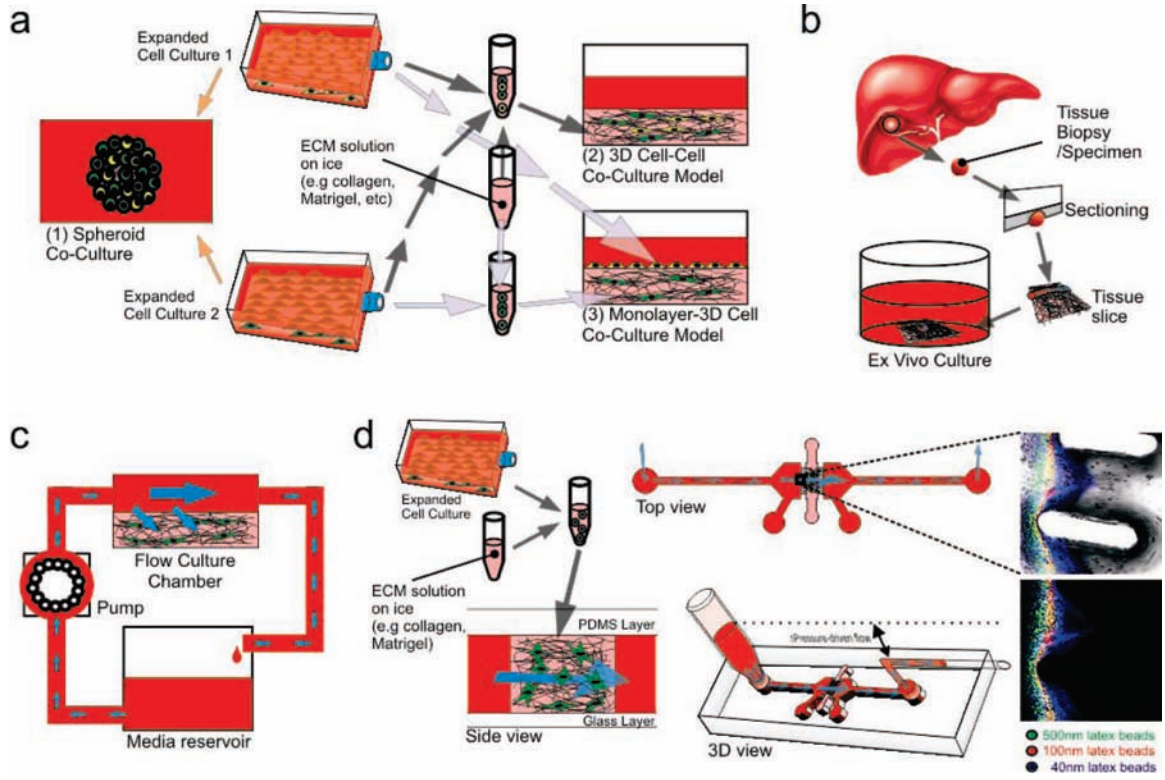

Figure 3. Examples of advanced 3-D models. (a) Some variations of co-culture models: (1) spheroid co-culture models, (2) cell−cell coculture in ECM, and (3) cell-monolayer on 3-D cell−ECM co-culture model; (b) *ex vivo* models: one version where samples of tissues such as the liver are harvested, sectioned, and cultured on 2-D substrates for screening; (c) a typical setup of 3-D perfusion cell−ECM culture models where media flow is driven over the cell−ECM by a pump from a reservoir; and (d) a short-term perfusion system developed by Ng and Pun for nanoparticle penetration studies.

Transwell dishes allow isolation between the apical and basal layer of the multilayer cell growth so that any compound delivered to one side must pass through the cell layers to reach the opposing side. This allows for easy assessment of transcellular drug delivery by incubation of drugs on one side of the growing culture followed by collection of media on the opposite side to assess the concentration of drug that has passed through the cell layer. Studies have been carried out to assess the diffusion of anticancer drugs through multilayer cultures (*47*), and could easily be extended to nanoparticulate drug carriers.

Limitations of Aforementioned Culture Systems. Despite the valuable information that can be gained from the 3-D culture systems mentioned above, deficiencies remain in the systems that limit their *in vivo* predictive power. These weaknesses include, in the case of acellular models, the inability to predict how interactions with cells affect nanoparticle distribution and therapeutic efficacy, and, in the case of the other models, an inability to recreate outside forces such as mechanical stress and convective flow. These forces could dramatically affect nanoparticle distributions. Therefore, advanced 3-D systems that incorporate mechanical forces and multiple cell types and that more closely mimic the *in vivo* architecture are desirable. In order to address the limitations of the previously described 3-D systems, more advanced 3-D models have been developed that mimic physiological conditions even more realistically. These include (a) co-culturing of 2 or more cell types in a biological matrix to mimic the complex cell−cell communications in addition to cell−ECM interactions, (b) using tissue explants, and (c) incorporating mechanical forces such as fluid flow into culture platforms to mimic the mechanical environments that cells experience *in vivo*, or combinations of these methods.

Co-Culture Models. Co-culture models, wherein two or more different cell types are grown together (Figure 3a), are useful as *in vitro* models, because tissues *in vivo* consist of more than a single cell type, and cell−cell interactions are important in determining and maintaining the normal cell function and phenotype (*14*, *16*, *17*, *48*, *49*). Applications of co-culture models are useful for investigating of the specificity of nanoparticle carriers. For example, Garnett and co-workers developed a brain tumor co-culture model consisting of cancerous cell aggregates and organotypic brain slices (*50*). Evaluation of the uptake of poly(glycerol−adipate) nanoparticles revealed that, in 3-D co-cultures, nanoparticles were predominantly taken up by cancerous cells rather than normal cells. In contrast, in monolayer cultures, nanoparticles were taken up more readily by normal cells. This conditional specificity of the nanoparticle uptake suggests that the nanoparticles may be useful for anticancer formulations with reduced toxicity to normal cells, an observation apparent only through studies with 3-D co-culture. A multicellular spheroid co-culture was also successfully used to demonstrate the specificity of a viral vector targeted toward cancer cells (*51*).

Co-culture models are particularly important when attempting to mimic a tissue containing many types of specialized cells whose function determines the tissue microenvironment. Along these lines, a 3-D co-culture that contains differentiated cells that are similar to *in vivo* lung tissue has been constructed (*52*, *53*). The co-culture of bronchial epithelial cells seeded on a human lung fibroblast-embedded collagen matrix contained a pseudostratified epithelium consisting of basal cells, mucus-secreting cells, and ciliated columnar cells with beating cilia. The cilia and mucus are important *in vivo* barriers to nanoparticle delivery to airway cells as they are specifically adapted to resist and remove foreign particles. Only in the 3-D co-cultures are well-differentiated ciliated epithelial cells observed *in vitro*; cells in monolayer culture do not express these cilia. Furthermore, the airway wall co-culture model was placed in a dynamic cyclic strain device to mimic the compressive effect observed

during bronchoconstriction in asthma in order to study the rate of viral infection of the epithelial and subepithelial cells (*54*). Previous studies with cyclic stretch in monolayer culture have suggested that intracellular processes are affected that in turn affect transfection, (*55*) and in the bronchial 3-D culture model, dynamic compression substantially increased lentiviral transduction of epithelial cells and underlying fibroblasts compared to static coculture controls (*54*). This increased transduction was attributed, in part, to enhanced transport through the matrix due to the mechanical compression. This finding, not observable in 2-D static monolayer cultures, may be useful for asthma pathophysiology as well as for designing delivery strategies of viral gene therapies to the airway.

From these studies, it can be concluded that co-culture models can promote differentiation and cell behavior of the cultured cells that resembles *in vivo* conditions more realistically than single-cell type culture models. Co-culture models thus offer a better predictive platform for nanoparticle uptake and therapeutic efficacy in complex tissue with specialized cells. An additional attribute of these models is the ability to evaluate the cell specificity of nanoparticle formulations, an important parameter for applications that must target diseased tissue while sparing surrounding healthy tissue.

***Ex Vivo* Models.** *Ex vivo* models involve harvesting tissue from human or animal sources followed by culturing on substrates such as culture wells and coverslips (*56*−*59*). Although *ex vivo* models require the use of animals, multiple data points may be obtained from a single animal source in most cases. The main advantage of *ex vivo* models is that they generally preserve the native complex and differentiated 3-D cell−matrix architecture, cell phenotype, and cell−cell interactions of the tissue of interest, thus providing a more accurate mimic of cell behavior and transport of particles to these primary cells. The *ex vivo* model also allows for direct delivery of nanoparticle formulations to target tissue along with the ability to more easily process tissues for analysis after exposure. Near real-time monitoring through confocal microscopy is also possible. *Ex vivo* models are especially beneficial if human tissue can be obtained. For example, human tissue slices have been used to screen adenoviral gene therapy agents for specificity and efficiency. In these studies, vectors were identified that effectively transduced cancerous cells while sparing normal cells (*60, 61*). For specificity studies such as this, the maintenance of cell phenotype, which is facilitated by the *ex vivo* model, is necessary for results that are likely to be predictive of *in vivo* results.

Ex vivo studies have also been used to demonstrate the possibility of gene delivery to fetal somatic cells for the treatment of monogenic disorders such as cystic fibrosis. Human fetal tracheas, maintained in *ex vivo* cultures, were shown to be highly susceptible to adeno-associated virus transduction (*62*). The high efficiency of transduction was attributed to reduced physical barriers to target cells in the prenatal tissue compared to developed tissue, which is resistant to transduction (*63, 64*). Again, preservation of the tissue in its near-native state during these studies may result in a higher probability of predicting *in vivo* efficacy and specificity.

Other *ex vivo* studies have been useful in developing methods to overcome physical barriers to therapeutic nanoparticle penetration. Quinlan et al. developed an embryonic mouse intestinal epithelium model that permits the maintenance of the gut tube and enables the introduction of exogenous genes to study the normal development of the intestinal epithelium and pathogenesis of intestinal neoplasia (*58*). These researchers found that high-efficiency adenoviral vector transduction of the intact mesenchymal and epithelial layers required the addition of an ECM modulating agent for effective adenoviral transduction.

As with other static models, results from *ex vivo* studies may not reflect the actual biodistribution of the delivery vehicles *in vivo*, because some of these studies involve incubating the explanted tissue in a bulk solution with media containing the nanoparticles of interest (Figure 3b), while *in vivo* delivery is typically administered intravenously or injected at a specific site. Furthermore, mechanical forces are typically absent during static *ex vivo* culturing, and a lack of mechanical forces, perfusion, and surrounding tissue results in remodeling and changes in cell behavior compared to the original *in vivo* environment. Long-term studies with *ex vivo* models may, therefore, be difficult, as the tissue may exhibit significant changes over the course of the experiment. Another major drawback of the *ex vivo* cultures is that they require harvesting of tissue from animal or human subjects. However, the advantage of maintaining native tissue structure makes *ex vivo* models unique.

Perfusion Models. The majority of the studies discussed to this point have been carried out under static culture conditions. As mentioned previously, cells in tissues are typically subject to fluid flow, which can be an important determinant of nanoparticle distribution in tissues as convective transport can often dominate diffusion. Nanoparticles diffuse very slowly in biological tissues and may take several months to diffuse a millimeter's distance, whereas the time to cover the same distance aided by convective transport can be much shorter. Therefore, convective transport can either greatly aid or greatly hamper the delivery of nanoparticles depending on the direction of fluid flow. In addition, it has also been shown that fluid flow can influence cellular functions. For example, under long-term culture, perfused hepatocytes maintained their liver-specific functions such as albumin secretion substantially closer to native liver compared to single monolayer or 3-D static cultures (*12, 65, 66*). Finally, static cultures can result in gradients of waste and nutrients within larger tissue constructs. Although this may be useful in studies of tissues like avascular regions of solid tumors, it can be detrimental to the preservation of larger 3-D cultures designed to model normally vascularized tissue. Thus, a model incorporating fluid flow may be beneficial for the optimization of delivery vehicles that encounter convective forces that influence their interstitial distributions.

There have been many recent advances toward the development of 3-D culture systems (Figure 3c) that allow for perfusion of tissue cultures, with particularly useful contributions from the fields of microfluidics and microfabrication (*67*−*74*). Some of these systems have the potential for higher-throughput screening due to the ability to simultaneously establish various conditions such as pH, flow rate, or drug formulation concentrations on different portions of the array. Many of the systems also allow for *in situ* visualization of the cultures and, therefore, potential real-time imaging of nanoparticle delivery. One such promising perfusion system has been developed by Griffith and co-workers, who have constructed a microfabricated multiwell chamber that allows for growth of isolated hepatocyte cultures in wells under flow conditions (*65*). A broad comparison to other standard *in vitro* models, including static ones, revealed that the perfusable system more closely mirrored *in vivo* liver function with respect to gene and protein expression as well as the ability of the cultured cells to metabolize delivered drugs (*11*). Although perfusable systems are apparently useful for nanoparticle delivery studies, there are limited examples, as many of the systems are relatively new or their development has focused primarily on cellular and tissue engineering applications rather than gene/drug delivery applications.

We have recently developed a perfusable 3-D cell-matrix gel culture model and demonstrated its applicability for *in situ* observation of nanoparticle transport in cell−gel matrixes (*75*). In this model (Figure 3d), a cell−matrix culture is loaded and

immobilized in a PDMS-glass chamber which allows for real-time imaging of particles in the 3-D structure over time. This potentially avoids any artifacts that would occur if tissue processing was necessary for visualization. Nanoparticles can be introduced laterally to media compartments situated in each side of the gel. We found size-dependent penetration of model fluorescent polystyrene nanoparticles similar to that observed in other 3-D systems such as multicellular spheroids (*3*). In addition, we observed deeper penetration of nanoparticles under interstitial flow compared to static controls using the same chamber. Currently, we are applying this simplified perfusion model to evaluate the penetration and cellular uptake of therapeutic nanoparticles, such as polyplexes, under various flow conditions. Besides the ability for real-time imaging, other advantages of this system include ease of manufacture, control over components of the initial cell−gel composition, and an ability to recover cells for flow cytometry analysis. The system can also be used for calculating the permeability of different cell−gel matrix compositions.

In summary, perfusion systems provide an additional advancement over static cultures by mimicking flow conditions in vascularized tissues. These perfusion chambers also offer the ability to recreate *in vivo* situations where convective flow is a driving force in determining nanoparticle distributions.

IMPLICATIONS FOR NANOPARTICLE CARRIER DESIGN

The results from previous studies of nanoparticle delivery to *in vitro* 3-D tissue models offer insight into a number of parameters that need to be considered during nanoparticle design. In particular, they highlight the importance of nanoparticle size, charge, surface chemistry, and stability when designing a drug delivery vehicle that can efficiently penetrate tissue. The effect of these design parameters on delivery may be understated or even ignored when nanoparticle vehicles are simply analyzed in monolayer cultures. The *in vitro* 3-D models also offer a more favorable platform for optimization compared to *in vivo* studies in terms of cost, ease of use, and time requirements.

First, and perhaps foremost, the nanoparticle carrier size must be considered. This is important for nanoparticle therapeutics that rely on transport through interstitial spaces in order to reach cells in the tissue interior. A key consideration is that particle size should be smaller than the characteristic pore size of the extracellular space. Because tissue architecture varies greatly depending on tissue type, it is impossible to determine a global cutoff diameter for tissue penetration, but the results from the studies summarized here suggest that nanoparticles with sizes less than 150 nm experience less-hindered transport.

Nanoparticle surface charge and chemistry provide an example of the balancing act that must often be played when designing a nanoparticle carrier. For charge-mediated uptake of nanoparticles, effective cell surface binding is necessary for uptake of therapeutics, but if the charge density is too high, then the carrier may experience hindered diffusion due to nonspecific interactions en route to target cells (*76*). Addition of steric shielding molecules, such as PEG, have in several instances proven to increase particle penetration in tissue (*29, 40, 41*), but can also hinder cellular uptake of particles, thus decreasing delivery efficacy (*77, 78*). The use of cleavable shielding molecules or shielding molecules with terminal targeting groups may provide a method for overcoming this reduced cell uptake (*31, 79, 80*). It is also important that targeted nanoparticles are assessed in culture models where phenotypes of cells are similar to *in vivo* situations in order to more accurately predict specificity.

Three-dimensional culture models have also helped demonstrate the usefulness of including components in nanoparticle carriers that can disrupt or digest ECM components in order to improve particle penetration. Similar to strategies employed by some pathogens to increase tissue distributions by stimulation of MMPs production to locally degrade tissue, nanoparticles that incorporate such enzymes could lead to much more favorable distributions of therapeutics in tissues (*81*).

It is important to keep in mind the high degree of variability in tissue architecture and composition. The results from studies in these 3-D tissue models offer insight into the most important parameters to consider when designing nanoparticle carriers, but specific nanoparticle behavior will vary greatly depending on the type of target tissue under consideration as well as vehicle administration method. However, 3-D models, overall, will provide a more accurate prediction of *in vivo* outcome compared to simple monolayer cultures.

CHALLENGES AND FUTURE DIRECTIONS

While researchers are increasingly turning to 3-D cell−matrix cultures for studying gene expression and other biological activities (*82*), the use of these cultures in the nanoparticle delivery field has not been widespread. This could be due, in part, to the higher degree of difficulty for setup and use compared to 2-D systems. In addition, many advanced systems are not as appealing because they are still in prototypical stages and could benefit from improvements in ease of manufacture and use. Also, the exact determinants of cell differentiation, such as cell−cell signaling, cell−ECM signaling, tissue architecture, and mechanical forces are different for each tissue and are often not well-elucidated. Therefore, accurate advanced 3-D models will have to be refined on a tissue-to-tissue basis. Despite the difficulties associated with the use of 3-D culture, many of the studies reviewed here have reinforced the need to move from 2-D to 3-D culture in order to more accurately predict the *in vivo* efficacy of drug delivery with nanoparticle formulations.

Refinement of advanced systems will most likely result through combinations of elements from many of the models discussed here. An ideal 3-D culture would allow for the introduction of multiple cell types grown in a chamber that allows for recreation of as many *in vivo* forces that act on the cells as possible, including mechanical forces that affect cell behavior. To accomplish this, current systems may need to be modified to include (i) surface modification of cell chambers to allow for long-term perfusion culture without matrix detachment due to cell contraction, (ii) more precise characterization of flow rates and profiles, (ii) the incorporation of appropriate cell types and extracellular materials to better mimic the heterotypic cell interactions, tissue architecture, and fluid flow stresses to obtain the full possible spectrum of tissue-specific functions, and, for some applications, (iv) chamber flexibility to allow for the application of mechanical forces to the tissue. With the addition of high-throughput capabilities, such systems could lead to improved screening and evaluation of nanoparticle formulations, resulting in more accurate predictions of *in vivo* outcomes and a smoother transition into clinical trials.

Novel Peptide Linkers for Highly Potent Antibody−Auristatin Conjugate

Svetlana O. Doronina,* Tim D. Bovee, David W. Meyer, Jamie B. Miyamoto, Martha E. Anderson, Carol A. Morris-Tilden, and Peter D. Senter

Seattle Genetics, Incorporated, 21823 30th Drive SE, Bothell, Washington 98021. Received July 10, 2008; Revised Manuscript Received August 18, 2008

Auristatins are highly potent antimitotic agents that have received considerable attention because of their activities when targeted to tumor cells in the form of antibody−drug conjugates (ADCs). Our lead agent, SGN-35, consists of the cAC10 antibody linked to the N-terminal amino acid of monomethylauristatin E (MMAE) via a valine-citrulline *p*-aminobenzylcarbamate (val-cit-PABC) linker that is cleaved by intracellular proteases such as cathepsin B. More recently, we developed an auristatin F (AF) derivative monomethylauristatin F (MMAF), which unlike MMAE contains the amino acid phenylalanine at the C-terminal position. Because of the negatively charged C-terminal residue, the potency of AF and MMAF is impaired. However, their ability to kill target cells is greatly enhanced through facilitated cellular uptake by internalizing mAbs. Here, we explore the effects of linker technology on AF-based ADC potency, activity, and tolerability by generating a diverse set of dipeptide linkers between the C-terminal residue and the mAb carrier. The resulting ADCs differed widely in activity, with some having significantly improved therapeutic indices compared to the original mAb-Val-Cit-PABC-MMAF conjugate. The therapeutic index was increased yet further by generating dipeptide-based ADCs utilizing new auristatins with methionine or tryptophan as the C-terminal drug residue. These results demonstrate that manipulation of the C-terminal peptide sequence used to attach auristatins to the mAb carrier can lead to highly potent and specific conjugates with greatly improved therapeutic windows.

INTRODUCTION

The use of monoclonal antibodies (mAbs) for the delivery of anticancer drugs to tumor cells has been the subject of a great deal of investigation (*1, 2*). In the past year, the field has advanced significantly, based on clinical studies with SGN-35, an anti-CD30-auristatin conjugate used to treat patients with Hodgkin's lymphoma and anaplastic large cell lymphoma, and trastuzumab-DM1, an anti-Her2/neu-maytansine conjugate for patients with breast cancer (*1, 3*−*6*). Both antibody−drug conjugates (ADCs) have led to many objective responses at well-tolerated doses.

There are several aspects of ADC design that can markedly influence activity, safety, and specificity. We and others have previously shown that highly potent drugs, stable linker technologies, carefully controlled conjugation processes, and restricted antigen expression contribute to ADC activity and tolerability (*1, 2*). Our most advanced ADC is SGN-35, which consists of the potent antimitotic agent monomethylauristatin E (MMAE), linked via the N-terminal monomethylvaline unit to the anti-CD30 AC10 mAb through a valine-citrulline (Val-Cit) dipeptide linker (*7*). ADCs containing the Val-Cit linker have been shown to be much more stable in vivo ($t_{1/2}$ for drug release ∼7 days) than previously described hydrazone and disulfide-based linkers (*7, 8*). Dipeptide linkers used for the attachment of such drugs as MMAE (*7, 9*) as well as MMAF (*10*) (Figure 1), high-potency doxorubicin derivatives (*11*), and DNA minor groove binders (*12*) to mAbs result in conjugates having pronounced and potent activities against an array of tumor types.

One of the noteworthy aspects of auristatin-based ADCs is that the drug component is synthetic, allowing for linker attachment sites to be incorporated at various positions within the molecule. This has allowed us to produce ADCs from auristatin E and MMAE involving acid-labile C-terminal hydrazones and protease-sensitive N-terminal peptides as the cleavable groups for drug release (*7*). Similarly, while MMAF was designed for linker attachment to the N-terminal monomethylvaline, the C-terminal carboxyl group could also be used as a point of linker attachment (Figure 1). Since the C-terminal residue together with the appended dipeptide would be within the binding site, it is expected that the sequence would dictate the repertoire of enzymes capable of catalyzing drug release, and would also affect the kinetics of hydrolysis. Thus, it was envisioned that dipeptide linkers attached to auristatins with various C-terminal amino acids would modulate efficacy, potency, and tolerability. In this report, we describe the design, preparation, and in vitro and in vivo properties of C-terminal linked auristatin ADCs. This work has led to the identification of new highly active conjugates with greatly improved therapeutic indices.

RESULTS AND DISCUSSION

To test the hypothesis that the dipeptide linker could influence the therapeutic window of auristatin conjugates when linked through the C-terminus, we generated a library of 29 dipeptide derivatives attached directly to the phenylalanine carboxyl group of AF (representative molecules are shown in Figure 1, Table

[a] Cells were exposed to the drugs for 96 h. The cytotoxic effects were determined using Alamar Blue dye conversion as a measure of cell viability. Concentrations are represented by the mAb component. The cell lines are CD70 antigen positive. The cytotoxicity assay used for these measurements has shown a 40% coefficient of variability in over 20 repeat measurements of h1F6-Val-Cit-PABC-MMAF. A select number of compounds in this table were assayed 4 times and gave IC_{50} values with a coefficient of variability of 13−27%; we therefore expect all compounds to show comparable variance. [b] MTD is defined as the highest dose not inducing >20% weight loss and overt toxicities. Concentrations are represented by the mAb component of the ADCs. [c] Lowest concentration tested. [d] Only concentration tested. [e] IC_{50} values are the mean and SD of 21 independent experimental titrations, each performed at least in duplicate.

1). The library was biased with D-amino acids or prolines at AA_2 in order to block potential hydrolysis between AA_1-AA_2 sequences and to increase the stringency of free drug release through proteolysis. Conjugates of these modified auristatins were generated by reacting the maleimide present on the drug linker with hinge cysteine thiol groups on the 1F6 antibody, forming ADCs that bound to the CD70 antigen on hematologic malignancies and renal cell carcinoma (*13*). After separating any unconjugated drugs (*10*), the purified ADCs contained an average of 4 drugs/mAb, according to previously published reversed-phase HPLC methods (*14*). The use of AF in this series, rather than MMAF, simplified the chemistry, as no N-terminal protecting groups were required during the synthesis, and based on previous work (*7, 10*), it was expected that there would be no loss in drug potency.

With few exceptions, the C-terminal dipeptide AF ADCs were active against the CD70 positive cell line panel (Table 1). The maximum tolerated doses (MTDs) as defined by the highest dose not inducing >20% weight loss, and overt toxicities varied from <50 mg/kg for some of the ADC constructs to 100 mg/kg for AF-Met-(D)Lys-1F6 and AF-Asn-(D)Lys-1F6. Notably, corresponding conjugates with natural L-amino acid at AA_2 position, AF-Met-Lys-1F6 and AF-Asn-Lys-1F6, were less tolerated with MTDs 50 mg/kg. These results indicated that the

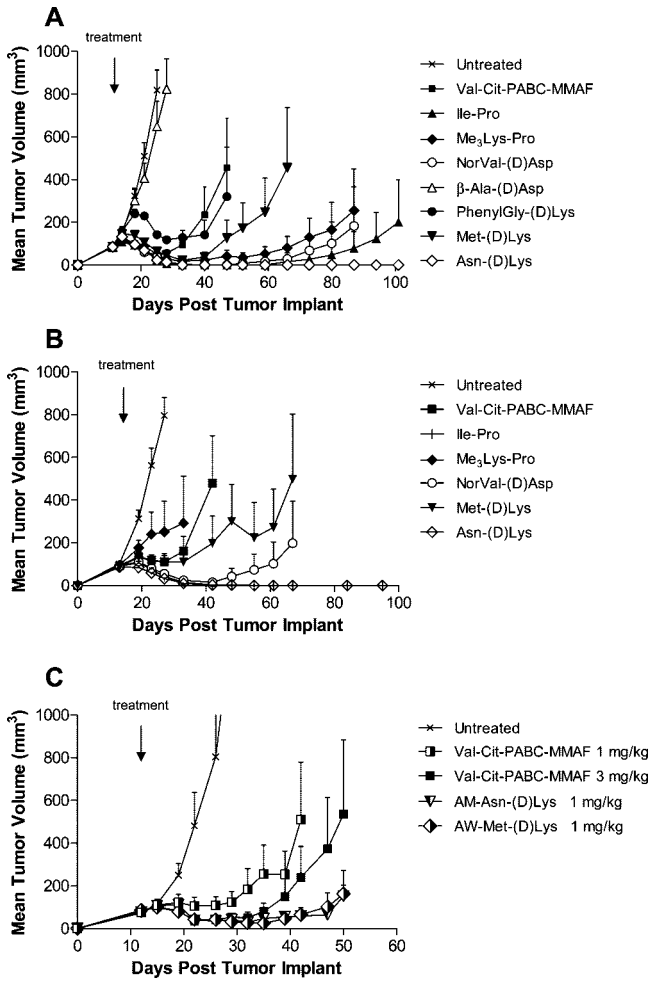

Figure 2. In vivo therapeutic efficacy of the conjugates in nude mice (5 animals/group). ADCs were delivered via intraperitoneal injections. Groups of mice with (A) subcutaneous 786-O human RCC tumors or (B) DBTRG-05MG glioblastoma tumors were treated with 1F6-Val-Cit-PABC-MMAF or AF-AA_1-AA_2-1F6 ADCs at 3 mg mAb component/kg. (C) Groups of mice with subcutaneous 786-O human RCC tumors were treated with 1F6-Val-Cit-PABC-MMAF at 1 mg or 3 mg mAb component/kg, or with AM-Asn-(D)Lys-1F6 and AW-Met-(D)Lys-1F6 at 1 mg mAb component/kg.

tolerability profiles of auristatin-based ADCs could be modulated through direct dipeptide attachment to the C-terminal residue of AF.

Several of the ADCs were tested in vivo in mice bearing subcutaneous CD70 positive 786-O RCC tumor xenografts (Figure 2A). This tumor model has been shown in previous studies to be sensitive to the 1F6-Val-Cit-PABC-MMAF (Figure 1), in which the auristatin component was linked through the N-terminal monomethylvaline residue (*13*, *15*). Treatment was initiated once the tumors were staged ($\sim$100 mm^3) and growing with a single ADC dose of 3 mg 1F6 component/kg body weight. As expected, the dose and dosing schedule of 1F6-Val-Cit-PABC-MMAF used resulted in activity against 786-O RCC tumors, but did not induce cures or durable regressions. All other C-terminal dipeptide ADCs were as potent as or more potent than 1F6-Val-Cit-PABC-MMAF, with the exception of AF-β-Ala-(D)Asp, which was inactive on cancer cell lines (Table 1). Of particular note were the activities of the most highly tolerated and active ADCs (Table 1), AF-Asn-(D)Lys-1F6 ($P = 0.0018$ by Log-rank test), which displayed greater potency than 1F6-Val-Cit-PABC-MMAF, and AF-Met-(D)Lys-1F6, which had similar potency. In addition, AF-Ile-Pro-1F6 was more potent than 1F6-Val-Cit-PABC-MMAF in this model ($P = 0.0064$), but was slightly more toxic than AF-Asn-(D)Lys-1F6 and AF-Met-(D)Lys-1F6 (Table 1).

Selected ADCs from the 786-O study were then tested for activity against subcutaneous CD70 positive DBTRG-05MG glioblastoma tumors using the previously described dosing scheme of a single treatment at 3 mg mAb component/kg (Figure 2B). The results were consistent with those obtained in the 786-O study, in that the Met-(D)Lys conjugate had comparable potency, and the Asn-(D)Lys conjugate was more potent than 1F6-Val-Cit-PABC-MMAF ($P = 0.0018$). These in vivo therapy results, taken together with the tolerability studies shown in Table 1, demonstrate that alterations in the mode of drug attachment can have a pronounced effect on ADC potency, activity, and tolerability.

We next extended the findings to include a set of auristatins in which the C-terminal phenylalanine residue was replaced with methionine or tryptophan (AM and AW, respectively; Figure 1). These molecules were identified in an independent SAR screen of auristatin analogues as drugs retaining high activity yet providing increased tolerability in mice. The new tripeptide sequences presented for protease-mediated drug release were expected to alter the spectrum of activating enzymes and potentially the therapeutic window of the ADCs as well. Mouse tolerability studies were undertaken at 150 mg/kg, since the goal of this work was to identify new ADCs that were tolerated at doses significantly higher than those reported up to this point.

In vitro cytotoxicity experiments with four of the phenylalanine replacement ADCs are shown in Table 1. Of them, AM-Asn-(D)Lys-1F6 and AW-Met-(D)Lys-1F6 were approximately as potent on all three cell lines tested as 1F6-Val-Cit-PABC-MMAF. Both AM-Asn-(D)Lys-1F6 and AW-Met-(D)Lys-1F6 were distinguished from other ADCs tested in this series, since they were tolerated at $>$150 mg/kg and had comparable in vitro potencies to 1F6-Val-Cit-PABC-MMAF. These ADCs were then tested for therapeutic efficacy in mice with 786-O RCC xenografts (Figure 2C) and were at least 3-fold more potent than 1F6-Val-Cit-PABC-MMAF. The results extend the findings with AF-dipeptide based ADCs to include new auristatin forms, providing evidence that both the peptide linker and the released drug can impact ADC therapeutic index.

CONCLUSIONS

We have demonstrated that it is possible to alter the therapeutic window of auristatin-based ADCs by changing the peptide linker between the drug and the mAb carrier protein. Attaching the dipeptide linkers directly to the C-terminal residue on the auristatin rather than to the PABC group on the amino terminus of the drug (*7*, *10*, *17*−*19*) places greater stringency on enzymatic hydrolysis. This was deemed important in the design of the drug linker, since both the site and the rate of drug release would be expected to impact ADC efficacy and tolerability. Indeed, the AF-Asn-(D)Lys and AF-Met-(D)Lys ADCs were not only more potent than 1F6-Val-Cit-PABC-MMAF (Figure 2A,B), but were also tolerated at higher doses (Table 1). This work was extended to include new auristatins (AW and AM), leading to ADCs with $>$3-fold increased potency compared to 1F6-Val-Cit-PABC-MMAF (Figure 2C), and $>$3-fold increased tolerability as determined by weight loss in mice (Table 1). Thus, the approach of optimizing both the dipeptide linker and the C-terminal residue of the auristatins leads to new generation ADCs with very promising biological properties. Currently, we are extending these findings to include mAbs with different specificities, assessing the activities of these altered auristatin linker derivatives in several in vivo models for efficacy and tolerability, and identifying the enzymes required for active drug release.

EXPERIMENTAL PROCEDURES

General. Unless otherwise noted, materials were obtained from commercial suppliers in the highest purity grade available and used without further purifications. Anhydrous DMF and CH_2Cl_2 were purchased from Aldrich. Fmoc-Dap-OH and Fmoc-MeVal-Val-Dil-OH were custom synthesized by Albany Molecular Research, Inc. (Albany, NY). 3-Maleimidopropionic acid NHS ester was obtained from Molecular Biosciences, Inc. (Boulder, CO). 1,2-Diaminoethane trityl resin was purchased from Novabiochem (substitution 0.9 mmol/gram). Solid phase synthesis was performed in plastic syringes (National Scientific Company) fitted with a filter cut out of fritware PE medium grade porous sheet (Scienceware). Burrell wrist action® shaker (Burrell Scientific, Pittsburg, PA) was used for agitation. All solid-phase yields reported are based upon the initial substitution level of the resin and constitute a mass balance of isolated pure material, unless otherwise stated.

Preparative HPLC purifications were performed on Varian instrument equipped with C12 Phenomenex Synergy MAX-RP 4μ reversed phase column, 250 × 21.2 mm, eluting with 0.1% TFA in a water-acetonitrile gradient.

Low resolution mass spectra (LCMS) were recorded on a ZMD-Micromass Single Quadrupole Mass Spectrometer equipped with an electrospray ion source (45 eV) coupled with HP1100 HPLC system (reverse phase C12 Phenomenex column, 4 μ, 100 Å, 150 × 2.0 mm. The eluent was a linear gradient of acetonitrile from 5% to 95% in water in the presence of 0.1% formic acid in 10 min, then 95% acetonitrile for 5 min, flow rate 400 μL/min).

The humanized h1F6 recognizes the CD70 antigen (*13*). Human renal cell carcinoma cell lines 786-O and Caki-1, and the glioblastoma DBTRG05-MG line were purchased from the ATCC (Manassas, Virginia). Hodgkin's disease cell line L428 was obtained from the DSMZ (Braunschweig, Germany). All cell lines were grown according to the manufacturers' recommendations and routinely checked for mycoplasma contamination.

General procedures for auristatin-AA_1-AA_2-diaminoethane-propionyl-maleimide synthesis.

Resin loading. In a 5 ml solid phase reaction vessel (plastic syringe with PET frit) was added 200 mg of 1,2-diaminoethane trityl resin (0.18 mmol based on the manufacturer's label), followed by a solution of Fmoc-AA_2-OH (0.36 mmol, 2 equiv), HATU (0.36 mmol, 2 equiv), and DIEA (0.90 mmol, 5 equiv) in 2 ml of dry DMF. The vessel was shaken for 18 h, and then the resin was washed with DMF (6 × 3 mL), CH_2Cl_2 (6 × 3 mL), ethyl ether (6 × 3 mL), and dried *in vacuo*. Complete reaction was confirmed by a negative Kaiser test.

Fmoc removal. Resin containing Fmoc-protected peptide was treated with 20% piperidine in DMF for 2 h at room temperature. Then the resin was washed with DMF (6 × 3 mL), CH_2Cl_2 (6 × 3 mL), ethyl ether (6 × 3 mL), and dried *in vacuo*.

Peptide coupling. To the resin (0.18 mmol) containing deprotected N-terminus amino acid, a solution of Fmoc-AA-OH (0.36 mmol, 2 equiv), HATU (0.36 mmol, 2 equiv), and DIEA (0.72 mmol, 4 equiv) in DMF (2 mL) was added. The reaction vessel was agitated for 2 h. Then the resin was washed with DMF (6 × 3 mL), CH_2Cl_2 (6 × 3 mL), ethyl ether (6 × 3 mL), and dried *in vacuo*.

Maleimide stretcher attachment. Penultimate diaminoethane-peptide was cleaved off the resin by treatment with 20% hexafluoroisopropanol in CH_2Cl_2 (4 mL) for 5 min, and then purified by preparative HPLC. Thus isolated diaminoethane-peptide and maleimidopropionic acid NHS ester (0.36 mmol, 2 equiv) were dissolved in CH_2Cl_2 (1 mL) with DIEA (0.72 mmol, 4 equiv) and stirred at room temp for 4 h. Solvent was removed *in vacuo.* After final deprotection with 20% TFA/CH_2Cl_2 (4 mL) for 2 h at room temperature, the product was purified by reverse phase preparative HPLC.

Preparation of Antibody-Drug Conjugates.

h1F6 antibody-drug conjugates with four drugs per antibody were prepared by partial reduction of the mAb followed by reaction with the desired drug-linker. The antibody h1F6 (23 mg/mL) was partially reduced by addition of 2.1 molar equivalents of tris(2-carboxyethyl)phosphine (TCEP) in phosphate buffered saline (PBS) pH 7.4 (Invitrogen, Carlsbad, CA) with 1 mM diethylenetriaminepentaacetic acid (DTPA), followed by incubation at 37^{o}C for ~1 h. The unpurified reaction mixture was aliquoted and frozen at -80°C for future use. The thiol content of the partially reduced h1F6 mAb was determined by alkylating a small fraction with Val-Cit-PABC-MMAF drug-linker and analyzing it by hydrophobic interaction chromatography (HIC). The average loading of Val-Cit-PABC-MMAF drug linker was determined to be 3.9 drugs/Ab. For conjugation of novel drug-linkers, a suitable quantity of partially reduced Ab was warmed to room temperature. The drug-linker was then added to a drug-linker /thiol molar ratio of ~1.5. The conjugation reaction was carried out in the presence of 10% v/v of DMSO for approximately 60 min. After conjugation, excess free N-acetyl-cysteine (4 mM final) was used to quench any unreacted, excess drug-linker. The reaction mixture was purified and buffer-exchanged into PBS using PD-10 desalting columns (GE Healthcare, Piscataway, NJ) to obtain the partially loaded h1F6-linker-drug$_4$ conjugate.

The drug/Ab ratio was estimated by HIC analysis and ranged from 3.8 – 4.2 drugs/Ab. In addition, each ADC was analyzed by size exclusion chromatography. No aggregation was observed.

In Vitro Growth Inhibition. Log phase cultures of cells were collected and cells plated at seeding densities ranging from 500 – 10,000 cells/well according to pre-determined conditions. After incubating 24 h to allow surface protein reconstitution, serial dilutions of test molecules were added and cultures incubated further for 4 days. Assessment of cellular growth and data reduction to generate IC_{50} values was done using Alamar Blue (Biosource International, Camarillo, CA) dye reduction assay. Briefly, a 40% solution (wt/vol) of Alamar Blue was freshly prepared in complete media just before cultures were added. Ninety-two hours after drug exposure, Alamar Blue solution was added to cells to constitute 10% culture volume. Cells were incubated for 4 h, and dye reduction was measured on a Fusion HT fluorescent plate reader (Packard Instruments, Meriden, CT).

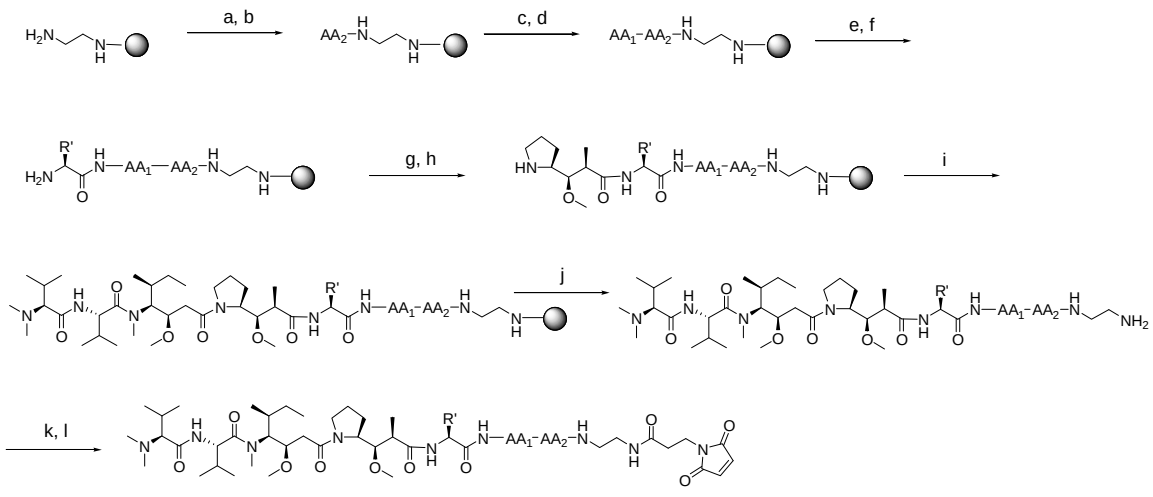
In Vivo Therapy Experiments. 786-O and DBTRG05-MG cells were obtained from American Type Culture Collection (ATCC, Manassas, VA) and propagated in culture conditions recommended by ATCC. To establish 786-O, DBTRG05-MG tumors, 5×10^6 cells were implanted into the right flank of athymic nu/nu female donor mice (Harlan, Indianapolis, IN). When donor tumors were approximately 500 mm^3, mice were euthanized and tumors were aseptically excised and ~0.5 x 0.5 mm fragments were loaded into a sterilized 13-gauge trocar for implantation into nu/nu mice. When tumors reached ~100 mm^3, mice were randomly allocated to treatment groups. Experimental groups were treated via intraperitoneal injection with compounds at the dose and

schedule indicated or alternatively left untreated. Tumors were measured periodically and volumes were calculated using the formula $V= ((L \times W^2)/2)$. Animals were euthanized when tumors reached the volume of 1000 mm^3 or at the end of the study, whichever came first.

Tumor quadrupling times were chosen as time to endpoint (TTE), which was determined by using the non-liner regression analysis for exponential growth of each individual tumor growth data sets from each experimental animal. The median tumor quadrupling time was calculated based on the tumor volume at the beginning of treatment. Animals that did not reach the endpoint were assigned a TTE value equal to the last day of the study.

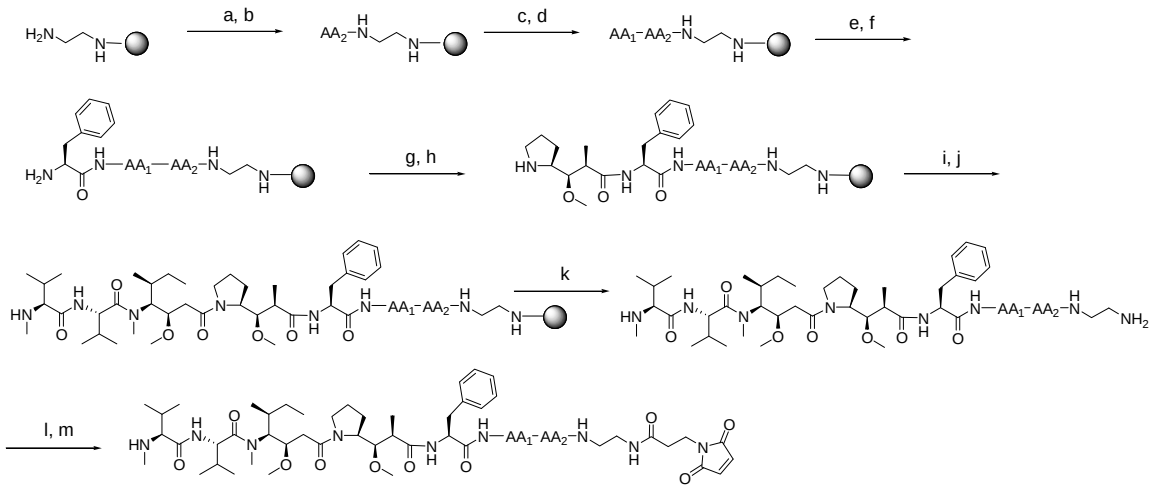
Statistical analysis was conducted using Prism (GraphPad) software for Windows. The Logrank test of the TTE was used to analyze the significance of the differences between the two groups, with differences deemed significant at $0.01 \leq P \leq 0.05$, and highly significant at $P \leq 0.01$.

Synthesis of auristatin-AA_1-AA_2-diaminoethane-propionyl-maleimide drug-linkers



Reaction conditions: (a) Fmoc-AA_2-OH (2-5 equiv), HATU (2-5 equiv), and DIEA (4-10 equiv), DMF, 18h; (b) 20% piperidine/DMF, 2h: (c) Fmoc- AA_1-OH (2 equiv), HATU (2 equiv), and DIEA (4 equiv), DMF, 2h (d) 20% piperidine/DMF, 2h; (e) Fmoc-Phe-OH, or Fmoc-Met-OH, or Fmoc-Trp(Boc)-OH (2 equiv), HATU (2 equiv), and DIEA (4 equiv), DMF, 2h: (f): 20% piperidine/DMF, 2h; (g): Fmoc-Dap-OH (2 equiv), HATU (2 equiv), and DIEA (4 equiv), DMF, 2h; (h) 20% piperidine/DMF, 2h; (i) Dov-Val-Dil-OH (2 equiv), HATU (2 equiv), and DIEA (4 equiv), DMF, 2h; (j) 20% hexafluoroisopropanol/CH_2Cl_2, 10 min; (k) 3-Maleimidopropionic acid NHS ester (2 equiv), DIEA (4 equiv), CH_2Cl_2, 1h; (l) 40% TFA/CH_2Cl_2, 1h.

Synthesis of MMAF-AA_1-AA_2-diaminoethane-propionyl-maleimide drug-linkers



Reaction conditions: (a) Fmoc-AA_2-OH (2-5 equiv), HATU (2-5 equiv), and DIEA (4-10 equiv), DMF, 18h; (b) 20% piperidine/DMF, 2h: (c) Fmoc- AA_1-OH (2 equiv), HATU (2 equiv), and DIEA (4 equiv), DMF, 2h (d) 20% piperidine/DMF, 2h; (e) Fmoc-Phe-OH (2 equiv), HATU (2 equiv), and DIEA (4 equiv), DMF, 2h: (f): 20% piperidine/DMF, 2h; (g): Fmoc-Dap-OH (2 equiv), HATU (2 equiv), and DIEA (4 equiv), DMF, 2h; (h) 20% piperidine/DMF, 2h; (i) Fmoc-MeVal-Val-Dil-OH (2 equiv), HATU (2 equiv), and DIEA (4 equiv), DMF, 2h; (j) 20% piperidine/DMF, 2h; (k) 20% hexafluoroisopropanol/CH_2Cl_2, 10 min; (l) 3-Maleimidopropionic acid NHS ester (2 equiv), DIEA (4 equiv), CH_2Cl_2, 1h; (m) 40% TFA/CH_2Cl_2, 1h.

Nitrilotriacetic Acid-Derivatized Quantum Dots for Simple Purification and Site-Selective Fluorescent Labeling of Active Proteins in a Single Step

Manish Gupta, Anne Caniard, Ángeles Touceda-Varela, Dominic J. Campopiano, and Juan C. Mareque-Rivas*

Received July 3, 2008; Revised Manuscript Received August 16, 2008

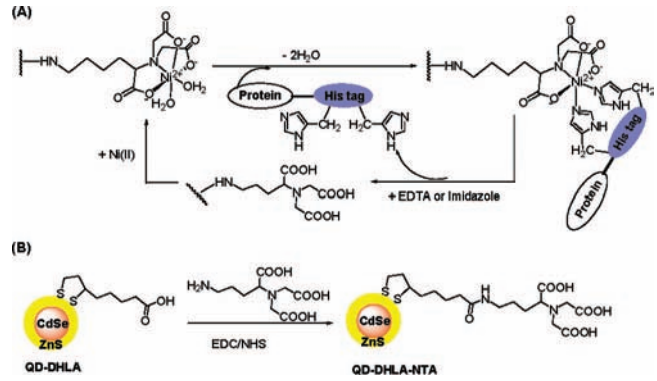
We demonstrate that QDs coated with nitrilotriacetic acid (NTA) bound to Ni^{2+} can be used to reversibly and selectively bind, purify, and fluorescently label His_6-tagged (N-terminal) glutathione S-transferase (GST) in one step with retention of enzymatic activity. We find binding to be less effective in the absence of the His_6-tag or Ni^{2+} ions.

Colloidal semiconductor nanocrystals (quantum dots, QDs) have emerged as powerful fluorescent probes for biological imaging applications (*1*−*5*). QDs have several advantages over small organic dyes and fluorescent proteins such as size-tuneable photoluminescence, wide excitation−narrow emission properties, improved brightness, and high resistance to photobleaching and degradation. To conjugate QDs to biomolecules, the QD surface is derivatized in such a way as to allow the attachment of the biomolecule through a covalent bond, electrostatic, or hydrophobic interactions. A typical biomolecule contains many residues capable of forming covalent and noncovalent linkages with the QD. The ability to control the site of attachment is important to ensure that the biomolecule bound to the QD is still active. Site-specific noncovalent binding of QDs to biomolecules has been achieved by exploiting carbohydrate−lectin and streptavidin−biotin interactions (*6, 7*).

A common approach to facilitate protein purification involves the use of genetically encoded oligohistidine (His_n) tags (*8*−*10*). Since His_n-tags are recognized by nitrilotriacetic acid (NTA) complexes of nickel(II) (Scheme 1), purification of these proteins is achieved by passing the protein mixture through chromatography columns containing Ni-NTA resins (*11*−*13*). Given the widespread use of His_n-tags and the fact that they can be introduced into regions of peptides where they do not disturb protein structure and function such as at the termini or in loops, they provide a convenient way to achieve site-specific binding for many applications (*14*−*18*). Hence, the fluorescent labeling of specific proteins by encoding His_n-tags on them coupled to the recognition of these tags by Ni-NTA has become popular. Initially, this was done using organic dye−NTA conjugates (*19, 20*), but very recently it has been extended to QDs. Thus, during the final stages of preparation of this manuscript the first study showing that Ni-NTA-containing QDs that can be applied to imaging His_6-tagged proteins in live cells has appeared (*21*). This is interesting because it has been shown that His_n-tags can also bind with very high affinity ($K_d \approx 1$ nM) to QDs with carboxylic acid functionalities requiring fewer synthetic steps and cheaper reagents (*22*). In another study, however, it was reported that QDs with carboxylic acids presented at the surface bind His-tagged proteins only in the presence of Ni^{2+} cations (*23*). Thus, it is interesting to investigate the advantages, disadvantages and applicability of each of these functionalities for the formation of QD−protein conjugates.

Here, we investigate binding of His_6-tagged and untagged GST as model protein to CdSe-ZnS core−shell nanoparticles with carboxylates, NTA, and Ni^{2+}-bound NTA at the surface.

Scheme 1[a]



[a] (A) Reversible binding between a His-tagged protein and Ni(NTA). (B) Synthesis of the QD functionalized with NTA.

QDs−GST conjugates are interesting because GSTs catalyze the nucleophilic addition of GSH to the electrophilic center of a range of nonpolar substrates as a way of detoxifying a wide range of harmful endogenous and xenobiotic compounds (*24*), and in drug resistance mechanisms (*25*). Since GST activity requires not only the formation of a dimeric structure (i.e., protein−protein interactions) but also binding of both GSH and an acceptor substrate (i.e., protein−substrate interactions), it is a good enzyme to investigate the effect of specific and nonspecific binding of QDs on enzymatic activity. We report that the combination of His_6-tagged GST with CdSe-ZnS core−shell nanoparticles coated with Ni^{2+}-bound NTA gives the best results. The resulting QD−protein conjugate is strongly fluorescent and readily purified by filtration or ultracentrifugation, which should enable widespread use of these QDs as a "two-in-one" purification−fluorescence labeling tool. Moreover, the QD binds the His_6-tagged GST with little disruption of its enzymatic activity, whereas QD binding is weaker and disrupts enzymatic activity when GST lacks a His-tag or when Ni^{2+} is unavailable. This is a significant result in that it shows that by using this simple construct protein purification, fluorescent tagging, and precise positioning of the fluorescent probe to preserve structural/functional properties are all accomplished in a single, inexpensive step. It shows also that QDs presenting Ni-NTA at the surface provide a good alternative to site-specifically binding His-tagged proteins if, like in this case, the easier-to-make QDs with carboxylic acids at the surface fail to do so (*vide infra*).

The QDs decorated with NTA were easily prepared from the reaction of CdSe-ZnS core−shell dihydrolipoic acid (DHLA)-

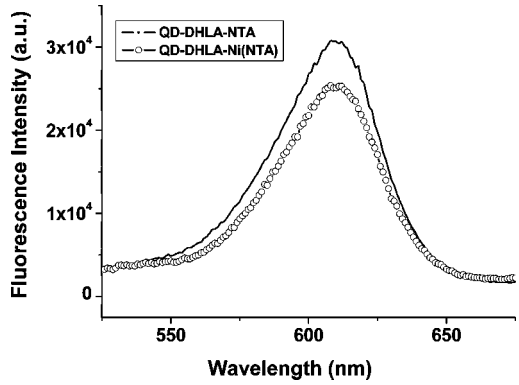

Figure 1. Photoluminescence spectra for CdSe-ZnS core−shell QDs coated with DHLA-NTA and DHLA-Ni(NTA) (spectra were acquired in 20 mM PBS pH 6.7, excitation at 350 nm; $T = 293$ K). The integrated emission decreases 15% upon Ni^{2+} addition.

capped QDs (*26*) with commercially available *N,N*-bis(carboxymethyl)-L-lysine hydrate using EDC and *N*-hydroxysuccinimide as coupling agents in phosphate buffer solution (Scheme 1). The product is purified by filtration with a Nanosep 100K centrifugal device (Pall Corporation). The composition of the QDs was examined by X-ray photoelectron spectroscopy (XPS). The XPS spectra showed the main diagnostic peaks of the product QDs: a 2s peak at 400.1 eV due to N, and 2p3 and 2p1 peaks at 857.1 and 874.1 eV, respectively, due to Ni^{2+} (Supporting Information).

The photoluminescence intensity of the Ni-NTA-capped QD is ca. 85% that of the NTA-capped QD (Figure 1). This is important because the paramagnetic Ni^{2+} was found to strongly quench the photoluminescence of some organic dyes, limiting their applications (*19*).

We selected GST from the helminth worm *Schistosoma japonica* (SjGST, 26 kDa monomer) as our target enzyme because it is amenable to recombinant overexpression in *E. coli* as a His_6-tagged construct and has been well-characterized (*9*). It is important to note that the His_6-tag was genetically fused at the N-terminus. The noncovalent attachment of His_6-tagged and untagged GST to the QD surface before and after derivatization with Ni-NTA was analyzed by SDS-PAGE. A solution of the QD or PBS (as control) was incubated with the corresponding enzyme for 2 h and passed through a Nanosep 300K centrifugal device. The retenate was redissolved in PBS buffer, and both retenate and filtrate were analyzed by SDS-PAGE. In the absence of the QD, His_6-tagged and untagged GST were found only in the filtrate. Several reports have shown that the DHLA-coated CdSe-ZnS core−shell QDs are capable of binding His-tagged proteins by coordination to Zn^{2+} ions at the nanocrystal surface (*22, 26*−*28*). Our SDS-PAGE studies, however, did not find protein in the retenate (Figure 2). Lack of binding could be due to steric hindrance at the N-terminus location of the His_6-tag preventing access to the Zn^{2+} atoms of the nanoparticle. It is also possible that the different synthetic procedures used to prepare QDs lead to subtle changes at the QD surface which affect binding of biomolecules. However, it is worth noting that it is not rare for His-tagged proteins to exhibit different properties depending on whether the His-tag is at the N- or C-terminus, and that in the studies reporting direct His-tag binding to carboxylate-coated QDs the His-tag was located at the C-terminus (*22, 26*−*28*). In contrast, using the same experimental conditions the Ni-NTA-capped QDs immobilized both enzymes. Moreover, we found more His_6-tagged than untagged GST in the retenate. Binding was also investigated in the presence of high salt concentrations. His_6-GST binding to Ni-NTA-capped QDs was not affected by 1 M NaCl. In contrast, untagged GST did not bind to the QDs under these conditions,

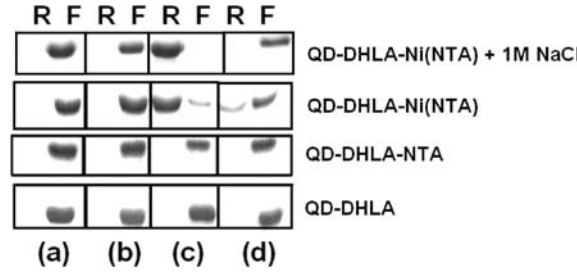

Figure 2. SDS-PAGE of the retenate (R) and filtrate (F) after ultrafiltration through a Nanosep 300K filter of His_6-GST (a), untagged GST (b), His_6-GST incubated with QD (c), and untagged GST incubated with QD (d). In each case, the enzyme and QD concentrations were 16.5 μM and 9.0 μM, respectively.

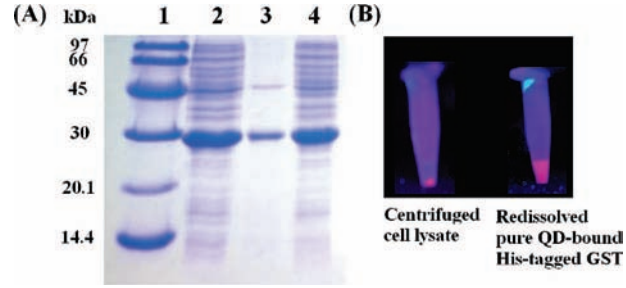

Figure 3. (A) SDS-PAGE studies of the cell lysate containing His_6-tagged GST (lane 2) and proteins released from the Ni-NTA-coated QDs treated with PBS containing 0.5 M imidazole (lane 3) and supernatant (lane 4) after ultracentrifugation. Lane 1 is the molecular weight marker. (B) Images of the cell lysate after ultracentrifugation and of the pure QD-bound His_6-tagged GST.

which suggests it is predominantly electrostatic. Thus, high salt concentrations can be used to avoid binding of untagged proteins while ensuring binding of the desired His_6-tagged target. The enzyme was easily released from the QD surface upon addition of 0.5 M imidazole, which competes for the Ni^{2+} binding sites. Thus, decorating the surface of the QD with Ni^{2+} complexes of NTA seems a good approach for noncovalent site-specific fluorescent labeling of proteins, which can be used for instance if carboxylate-functionalized QDs lacking Ni^{2+} ions fail. Potential advantages of attaching Ni-NTA units to QDs could be stronger interactions with the His-tag ($K_d \approx 10^{-13}$ M) (*18*) and less sensitivity to steric hindrance and surface properties by being further away from the nanocrystal surface.

Recently, the value of magnetic nanoparticles as affinity probes to selectively trap and separate His-tagged proteins from cell lysates has been elegantly demonstrated (*29*−*32*). The protein purification efficiency of the Ni-NTA-capped QDs was investigated by incubating cell lysates containing His_6-tagged GST for 2 h. Remarkably, pure fluorescently labeled GST was obtained simply by ultracentrifugaton of this mixture (Figure 3). Thus, by using the Ni-NTA-capped QDs it is possible to purify and fluorescently label His-tagged proteins in a single step. Current methods for efficiently purifying and fluorescently labeling His-tagged proteins need various labor-intensive and expensive steps, such as conjugation of NTA derivatives on support materials or the preparation of suitable magnetic nanoparticles for purification purposes, followed by the attachment of fluorescent tags. Another construct suitable for one-step protein purification and site-specific labeling was recently developed and involves organic fluorophore-doped Ni-NTA-modified silica nanoparticles (*33*).

In order to obtain information about the effect of QD binding on the catalytic activity of GST, we have used 1-chloro-2,4-dinitrobenzene (CDNB) as substrate. The GST-catalyzed reaction of GSH with CDNB produces a dinitrophenyl thioether

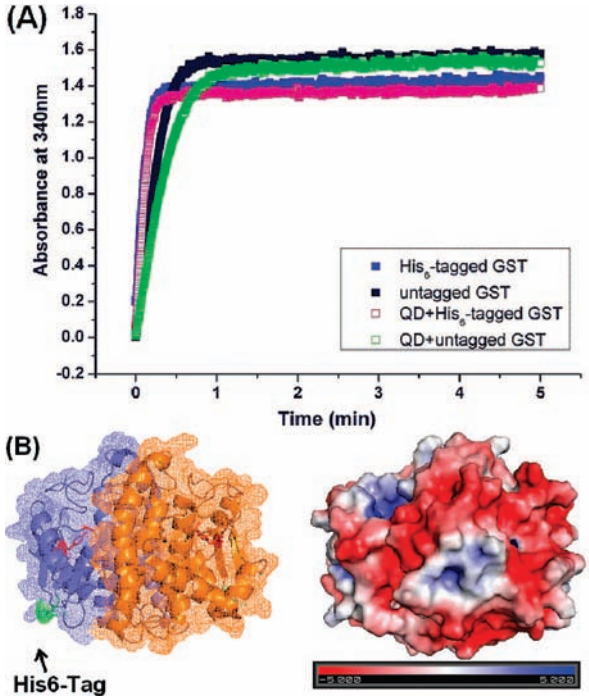

Figure 4. (A) Activity of His_6-tagged (N-terminal) and untagged GST in the presence of Ni-NTA coated QDs. Conditions: [GSH] = 8 mM, [CDNB] = 2 mM in PBS (pH 6.7), T = 298 K. The QD alone did not have any activity. (B) X-ray crystal structure of the SjGST homodimer highlighting the catalytically crucial Tyr7 residue in red, and the N-terminus site for the His_6-tag in green (left); surface charge distributions (right).

which can be conveniently detected spectrophotometrically at 340 nm (*34*). His_6-tagged GST and untagged GST were incubated with the same concentration of Ni-NTA-capped QD. We have found that His_6-tagged GST retains its activity after binding to the QD, whereas the untagged GST loses activity (Figure 4). We suggest that the ability of the His_6-tag to control the position of the Ni-NTA-capped QD relative to the GST active site is responsible for preserving the activity of the enzyme. The X-ray crystal structure of SjGST (*35*) shows that the N terminus, which is where the His_6 tag was placed, is ca. 25 Å away from the essential catalytic residue Tyr7 (Figure 4). We have examined the distribution of positively and negatively charged residues and found that there are positive and negative regions close to the active site. These are sites where in the absence of the His_6 tag nonspecific electrostatic binding could occur, disrupting the enzyme activity. By comparing the activity of the enzyme which did not bind to the QD with that of the enzyme before incubation with QD, we estimated the protein binding capacity and number of His_6-GST molecules immobilized on each QD (~16). This surface coverage correlates well with that found for QDs and proteins of similar size (*26, 27*).

In summary, we have shown that Ni-NTA-coated QDs provide a straightforward method to, in one step, purify and fluorescently reversibly label proteins. By using these QDs, we have selectively purified and labeled an N-terminal His_6-tagged GST, which was not possible using QDs with carboxylates at the surface. Moreover, we have found that Ni^{2+} provides a docking site which helps to precisely orient the fluorescent nanoparticle on the protein surface and that, as a result, GST retained its activity. The use of His-tags has been broadly adopted in the molecular biology and biochemistry communities, and therefore this specific conjugation strategy should enable widespread use of these QDs for a broad range of biological applications.

ACKNOWLEDGMENT

We are grateful to EaStCHEM for a PhD studentship to M.G. A.T.V. acknowledges the Xunta de Galicia (Spain) for a postdoctoral fellowship. A.C. is funded by a Marie Curie Fellowship. We acknowledge support from the EPSRC to purchase the XPS. We would like to thank Dr. Wuzong Zhou and Ross Blackley at EaStCHEM-St. Andrews for the HRTEM studies.

Materials and Methods. All chemicals were obtained from commercial sources and used as received. Cadmium oxide (CdO, 99.5%), tri-*n*-octylphosphine oxide (TOPO, 99%), tri-*n*-butylphosphine (TBP, 97%), hexadecylamine (HDA, 98%), diethylzinc ($ZnEt_2$,1M in hexane), hexametyldisilathiane [$(TMS)_2S$ 98%], nickel (II) chloride, *N*-hydroxysuccinimide (NHS, 98%) and *N*-*N*-bis(carboxymethyl)-L-lysine hydrate were purchased from Sigma Aldrich. 1-Ethyl-3-[3'-(dimethylamino)propyl]carbodiimide was purchased from Ademtech. Stearic acid (≥98.5) was purchased from Fluka. Selenium powder (Se, 99.999%) was obtained from Alfa Aesar.

Fluorescence studies were carried out with an Edinburgh Instruments FS900 fluorimeter. Excitation was at 350 nm with bandwidths of 2 nm for excitation (unpolarised) and emission (unpolarised). Temperature was maintained at 25 °C.

X-ray photoelectron spectra were obtained with a VG Scientific Sigma Probe (UK) XPS system. The Al Kα anode X-ray source (hυ = 1486.6 eV) was operated at 200W and the take-off angle for photoelectrons was 37º. Samples were mounted with a spring clip. In a typical experiment, a few survey scans in the -10 to 1100 eV kinetic energy range were collected at a resolution of 1 eV. Then, detailed scans of 20-60 eV over a single feature were collected at a resolution of 0.2 eV. During the measurements the pressure was 10^{-9}-10^{-10} Torr.

High-resolution transmission electron microscopy (HRTEM) studies were conducted on a JEOL JEM-2011 electron microscope operating at 200 kV. The samples were prepared by depositing a drop of a solution of nanocrystals in pyridine onto a copper specimen grid coated with a holey carbon film and allowing it to dry.

Enzyme concentrations were determined by Bradford assay on a UNICAM UV-vis spectrometer with bovine serum albumin as a standard.[1] The QD concentration was determined by the method of Peng et al.[2] Enzyme activity assays were conducted on a CARY 300 SCAN UV-vis spectrometer.

QD Synthesis. Tri-*n*-butylphosphine selenide (TBP-Se, 1M) was prepared in a N_2-filled glove box by shaking 0.08 g of selenium powder in 1 mL of TBP. A ZnS stock solution was prepared in a N_2-filled glove box by reacting $(TMS)_2S$ (0.5 ml, 2.5 mmoles) with $ZnEt_2$ (3.5 ml, 3.5 mM in hexane) in TOP (6 ml).

TOPO-coated CdSe-ZnS QDs. The TOPO-coated core-shell CdSe-ZnS QDs were synthesised and purified according to previously reported procedures.[3] In a typical synthesis, CdO (0.013 g, 0.1mmol) and stearic acid (0.254 g, 0.89 mmol) were loaded into a three-neck flask and heated to 225 °C under N_2 flow and stirring. Once the

mixture was completely dissolved, it was allowed to cool to room temperature. Then, TOPO (3 g) and HDA (1 g) were added and the mixture was heated to 225 °C under N_2 flow and vigorous stirring. At this temperature, 1 mL of freshly prepared TPB-Se solution (1 M) was quickly injected into the flask. Following injection the temperature was adjusted to ~200 °C to promote nanocrystal growth. On reaching the desired nanoparticle size, as determined by UV/vis and fluorescence spectroscopy,[2] the temperature is lowered to ca. 100 °C to stop further growth. Then, the solution is heated to 210 °C. At this temperature, 0.5 ml of the ZnS stock solution was slowly injected in. The temperature of the mixture was set to 100 °C and stirred for 2 hr. After cooling to room temperature, the nanocrystals were dispersed in chloroform and precipitated by addition of methanol. After centrifugation the supernatant liquid phase was removed. This procedure was repeated at least three times. The precipitates were combined and air-dried at room temperature. The results reported in this study are for nanocrystals which had the first absorption band at 594 nm, and a maximum emission peak at 610 nm with excitation at 350 nm, but the same results were obtained with QDs of different sizes and emission maxima.

DHLA-coated CdSe-ZnS QDs. Dihydrolipoic acid (DHLA) was prepared according to the method given by Uyeda *et al.*[4] Thiotic acid (1.22 g) was dissolved in an aqueous solution of $NaHCO_3$ (25 ml, 0.25 M) and the resultant solution was cooled to 0 °C. $NaBH_4$ (0.9 g) was added and the temperature was maintained at ca. 5 °C with continuous stirring for about 2 hr in nitrogen. The reaction mixture was acidified with HCl (3.3 M) to pH 1. The product was extracted with toluene (~30 ml) dried by adding $MgSO_4$. The final product was isolated as colourless oil.

Then, the water-soluble DHLA-coated CdSe/ZnS QDs were prepared according to the method given by Mattousi *et al.*[5] In a typical reaction, TOPO-coated CdSe-ZnS QDs (50 mg) and DHLA (50 mg) were mixed in DMF (15 ml). The solution was heated to 60-70 °C and stirred overnight. Then, potassium-*tert*-butoxide (100 mg) was slowly added to deprotonate the terminal lipoic acid groups. The nanoparticles were separated by centrifugation and the supernatant liquid was discarded. The resulting quantum dots were dried under vacuum. The QDs were further purified by redissolving them in water and passing this solution through a 100K microsep filter.

NTA-coated CdSe/ZnS QDs. *N*-*N*-bis(carboxymethyl)-L-lysine hydrate (NTA) (5 mg, 0.0132 mmoles) was dissolved in 3 ml of HEPES (20 mM, pH 7.5). Activation of

carboxylate groups of the DHLA-coated QDs was performed by mixing the QDs (9 mg) in 1 ml of EDC (3 mM in HEPES) and 1ml of NHS (3 mM in HEPES) with stirring for 30 min. Then, 1ml of NTA (4.4 mM) was added and the solution was stirred for 24 hrs. The resulting NTA-modified nanocrystals were purified using a Nanosep 100k omega membrane filter (low protein-binding, modified polyethersulfone on polyethylene substrate). The Ni-NTA coated nanocrystals were prepared in the same way using the preformed complex, which was prepared by mixing of *N*,*N*-bis(carboxymethyl)-l-lysine hydrate (NTA) (5 mg, 0.0132 mmoles) and $NiCl_2$ (5 mg, 0.021 mmoles) in 3 ml of HEPES (20 mM) with stirring for 1 hr using. Alternatively, the NTA-coated nanocrystals (18 μM) were dissolved in water and reacted with $NiCl_2$ (200 μM) for 1 hr. The excess nickel was removed by passing the solution through a 100K microsep filter.

Expression and Purification of His_6-SjGST and untagged GST

Overexpression of *Schistosoma japonicum* His_6-GST and untagged GST were achieved as we described previously[6] with the following modifications. Fresh LB broth medium (3 L) were inoculated with 100 mL of seed culture and induced with isopropyl thio-β-D-galactoside (IPTG) (0.1 mM final concentration) when OD_{600} reached 0.6. The cell debris was removed by centrifugation at 15000 g for 1 h at 4 °C. Purification of *Schistosoma japonicum* His_6-GST was achieved as described previously.[6]

Purification of untagged GST. The cell lysate was applied to a GSTPrep FF 16/10 column (20 mL, GE Healthcare Life science) pre-equilibrated with 1x PBS binding buffer (140 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 1.8 mM KH_2PO_4). The column was then washed with 5 column volumes of binding buffer (100 mL) before bound material was eluted with an elution buffer (10 mM glutathione, 50 mM Tris/HCl, pH 8.0) over 5 column volumes (100 mL). Fractions were analysed by SDS-PAGE, and those containing GST were pooled and dialyzed overnight against 4 L of a 20 mM potassium phosphate buffer (pH 7.0) at 4 °C. Liquid chromatography mass spectrometry (LCMS) analysis of the pure enzyme gave the molecular mass of the SjGST as 28059 (± 0.9 Da), in good agreement with the predicted value of 28057 Da for the monomer. The final yield of untagged GST using this method was ~ 25 mg per L of bacterial culture.

Protein Binding Studies

Protein binding studies were carried out by incubating 100 µl of the corresponding QD (1.5×10^{-5} M) with 75 µl of His-GST and Untagged-GST (1.09 mg/ml) for 2 hr at room temperature. The enzyme-QDs complexes were separated from the unbound enzyme molecules by passing this solution through a Nanosep 300k Omega membrane filter (low protein-binding, modified polyethersulfone on polyethylene substrate). The retenate containing the QD-bound enzyme was treated with 175 µl of a PBS solution of imidazole (0.5 M) to release the enzyme. Retenate and filtrate fractions were analysed by SDS-PAGE. Incubation of QDs with cell lysates was carried out at 4 ^{o}C.

GST Activity Assay

The GST activity was determined spectrophotometrically by measuring the change in absorbance at 340 nm (ε = 9600 M^{-1} cm^{-1}).[7] The solution for the blank assay was composed of potassium phosphate buffer (850 µl, 0.1 M, pH 6.5), 1-chloro-2, 4-dinitrobenzene (50µl, 40 mM) and GSH (100 µl, 80 mM). The solution for sample assay was composed of potassium phosphate buffer (800 µl, 0.1 M, pH 6.5), 1-chloro-2,4-dinitrobenzene (50 µl, 40 mM), GSH (100 µl ,80 mM) and GST (His-GST 50 µl, 2.7 mg/ml; Untagged-GST 50 µL, 1.09 mg/ml free and immobilized on QD-NTA-Ni^{+2} (9 µM)). The absorbance was measured at 340 nm for five minutes (T = 25 °C).

Received June 14, 2008; Revised Manuscript Received August 29, 2008

Prodrugs are increasingly used as delivery vehicles for pharmaceutical agents that present solubility and/or pharmacokinetic/metabolic issues. In the course of the development of prodrugs for the antitumoral agent thiocoraline, standard coupling reagents and procedures failed to provide the desired target derivatives because of the lack of reactivity of its quinolinic alcohol. In contrast, the use of *N,N,N′,N′*-tetramethylchloroformamidinium hexafluorophosphate (TCFH) resulted in good yields of ester prodrugs of thiocoraline and could be applicable to other drugs with similar limitations.

The development of numerous drugs currently in the pipeline of pharmaceutical companies is being hampered by their poor solubility and/or pharmacokinetic/metabolic properties. A way to overcome this limitation is the use of prodrugs (*1*), which are chemically modified drugs that remain inactive while being delivered, but that, having reached the target site, release the active drug in response to a change in pH or to the presence of certain enzymes (*2*). The use of prodrugs has increased enormously over recent years, which is reflected by the fact that 15% of the pharmaceutical agents approved in 2001 and 2002 were prodrugs (*3*). The design of prodrugs is limited in each case by the functional groups amenable to derivatization in the parent drug. Thus, we can find hydroxyls, carboxylic acids, amines, phosphate, and carbonyl groups susceptible to modification to esters, carbonates, carbamates, amides, phosphates, and oximes (*4*). Of these, esters are the most common type of prodrug, because their synthesis is usually straightforward, and the presence of many types of esterases in the body makes the ester bond highly labile (*5*). This linkage is used, for instance, in PGA[1]-Paclitaxel (Xyotax), currently under phase III clinical trials (*6, 7*). PEGylation (*8, 9*) has also frequently been used for drug conjugation, since it greatly enhances water solubility and decreases immunogenicity (*10*). PEGs have been introduced into many drugs, such as paclitaxel, camptothecin, doxorubicin, or interferon, among others, which have undergone clinical trials or are on the market.

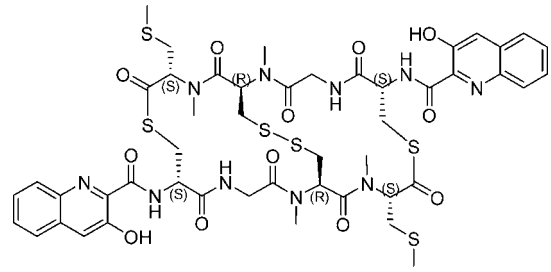

Figure 1. Structure of thiocoraline.

One drug that presents poor solubility is thiocoraline (Figure 1), a potent antitumoral agent (10^{-9} M) isolated from marine *Actynomycetes*.

Thiocoraline (*11, 12*) has a highly hydrophobic structure, where the only polar groups are the two quinolinic hydroxyls and a few amides. To develop prodrugs, we focused on anchoring solubilizing groups to the quinolinic hydroxyl group.

Nevertheless, this functionality proved to be unreactive, and esterification with common coupling reagents resulted in low yields or full recovery of starting material. To optimize conditions, we examined acetylation with several coupling systems (Table 1). For the first five entries, only the starting material was recovered. Thus, *in situ* activation of AcOH by formation of the corresponding fluoride (TFFH **1**, DAST **2**) (*13, 14*), "the mixed anhydride" (BOP-Cl, **3**) (*15*), or by using Ac_2O in the presence of pyridine (**4**), failed in rendering the desired derivative. The same results were obtained by previously activating resin-bound HOBt in polystyrene (*16, 17*) with Ac_2O and pyridine (**5**). Next, formation of the ester bond with carbodiimide/DMAP with and without activating agent (HOAt) was examined (**6**, **7**). In these conditions, some conversion was observed, although the recovery of starting material was considerable. Similar results were obtained when using a uronium salt such as TBTU (**8**) or the sulfonate MSNT (**9**) (*18*),

which is routinely used for esterification. In the latter case, the presence of several byproducts was observed, probably caused by the large excess of DIEA and NMI applied for this type of coupling. Reaction with AcCl (10 equiv), DIEA (10 equiv), and DMAP (0.1 equiv) in CH_2Cl_2 (**10**) gave good yields, thus obtaining only the bis derivative with 76% yield. In view of these results and to avoid the previous preparation of each single acid chloride, reagents that allow *in situ* formation of acid chlorides were studied. In the case of TMUC-Cl (*19*), no product was recovered. However, the use of *N*,*N*,*N*′,*N*′-tetramethylchloroformamidinium hexafluorophosphate (TCFH) resulted in high conversions to the bis and mono derivatives.

Here, we present TCFH (Figure 2) as a powerful derivatizing coupling reagent for the syntheses of ester prodrugs.

The best results for obtaining the bis derivative were achieved using AcOH/TCFH/HOAt/DIEA (10 equiv/10 equiv/10 equiv/30 equiv) in CH_2Cl_2, for 2 h at 25 °C (as the ester is not stable to basic treatment, products were directly purified by RP-HPLC). Under these conditions, a range of percentages of the mono and bis derivatives were obtained. Longer reaction times resulted in hydrolysis of the ester with more recovery of starting material.

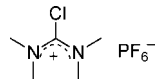

Figure 2. Structure of TCFH.

The application of microwave irradiation for this reaction was also studied in CH_2Cl_2 (MW 50) and DMF (MW 25). However, while in the first case no improvement was noticed, the use of DMF caused degradation of thiocoraline.

Another way to drive reactions to completion is the application of solid-phase synthesis, since large excesses of reagent can be used, which can later be washed away easily, thereby avoiding tedious purifications. Thus, thiocoraline was loaded on 2-CTC resin (*20*) through the quinolinic alcohol with DIEA in CH_2Cl_2 (Scheme 1). Next, the remaining free quinolinic alcohol was reacted with TCFH/HOAt/DIEA in CH_2Cl_2 for 2 h and then the resin was cleaved with TFA−CH_2Cl_2 (1:99). However, under these conditions, low yields of product were obtained. Thus, subsequent derivatizations were carried out in solution.

After optimization of the coupling conditions, a number of carboxylic acids were tested (Table 2). These included PEG acids of various sizes, protected amino acids, aliphatic acids, aliphatic acids with a protected thiol at the terminus, tertiary amine-containing acids, and diacids. For most of these, mixtures of bis and mono derivatives were obtained. The ratio of these two products depended on the acid used. Thus, in the case of octanoic acid (**11**), for instance, the bis derivative was obtained as a major product, while the mini PEG (**3**) gave mainly the mono derivative. For **14**−**16** (tertiary amines and protected Cys), thiocoraline degradation was observed, whereas for succinic acid (**17**), no reaction occurred. All products were purified by semipreparative HPLC.

Attempts to Cleave the Fmoc and Boc Groups from Protected Conjugates To improve solubility, compounds with free amino functionalities were pursued. Thus, coupling with protected amines was performed followed by deprotection of the corresponding Boc and Fmoc groups. In this regard, Boc-Lys(Boc)-OH (**8**) was coupled to thiocoraline, thus obtaining the corresponding mono and bis derivatives. Treatment of the products with 25% TFA in CH_2Cl_2 or 1 M HCl in dioxane/CH_2Cl_2 resulted in recovery of the starting thiocoraline. Under milder reaction conditions (AcCl, MeOH), monitoring of the reaction by HPLC showed the disappearance of the protected compound and appearance of plain thiocoraline. The same

results were obtained with the derivative Boc-Glu(*t*Bu)-O-thiocoraline (**9**), and Boc-Lys(Boc)-Pro-O-thiocoraline (not shown), which was synthesized with the aim of keeping the free amino groups further away from thiocoraline. Attempts were also made to remove the Fmoc group of several conjugates both in solution (from **10**) and on solid-phase, since in the latter case, cleavage of the Fmoc group is easier. As explained, thiocoraline was loaded on 2-CTC resin, and Fmoc-β-Ala-OH or Fmoc-6-aminocaproic acid was coupled. The Fmoc group was then removed with piperidine−DMF (1:4), using only two treatments of 1 min. Under these conditions, only thiocoraline was recovered. These results suggest that free amino groups attack the newly formed ester bond, even when using longer chains.

To obtain free thiols that could be conjugated to gold nanoparticles, protected thiols were used and then deprotected. However, as described above, complex mixtures were obtained when using protected Cys (**15**−**16**). In contrast, when a long-chain aliphatic carboxylic acid bearing an S-Trt protected thiol

group (**13**) was used, the reaction gave the mono derivative, and the Trt group was cleanly removed using TFA−TIS−CH_2Cl_2 (10:2.5:87.5). The final product was purified by reversed-phase HPLC, albeit purification proved difficult because of the hydrophobicity of the compound.

These results suggest that PEG and aliphatic chains can be used for thiocoraline prodrug formation, but that other functionalities such as free carboxylic acids, tertiary amines, free amines, or short thiol alkyl chains are not tolerated.

Biological Activity. The products obtained were tested in three cell lines: breast, nonsmall cell lung (NCSLC), and colon (Table 3). *In vitro* results showed that, for most of the derivatives, the activity is maintained, or decreases slightly, thereby suggesting that the ester bond is rapidly cleaved before bisintercalation to DNA. In the case of PEG 2000 and 5000, the decrease in activity can be attributed to the high increase in molecular weight of the resulting prodrug.

In conclusion, using TCFH as a coupling reagent for the esterification of thiocoraline, we prepared a number of conjugates including PEGylated compounds with higher solubility. These derivatives were assayed for biological activity in three cell lines and gave, in most cases, results comparable to the parent natural product. On the basis of our findings, we conclude that the coupling system TCFH/HOAt/DIEA could be applied

for the syntheses of ester prodrugs of molecules bearing groups of low reactivity.

Synthesis of Boc-protected 4,7,10-trioxa-1,13-tridecanediamine Succinimic Acid S7

Synthesis of Acetyl-protected 4,7,10-Trioxa-1,13-tridecanediamine Succinimic Acid S8

Cell growth inhibitory assays S8

Experimental Procedures

General

Protected and raw amino acid derivatives were obtained from Applied Biosystems (Framingham, MA), Bachem (Bubendorf, Switzerland), Albatross (Montreal, Canada), and NovaBiochem (Läufelfingen, Switzerland). DIEA, TFA, were obtained from Aldrich (Milwaukee, WI). DMF, CH_2Cl_2, TCFH was obtained from Iris Biotech GmbH (Marktredwitz, Germany). Acetonitrile (HPLC grade), methanol (HPLC grade), TBME (*t*-butyl methyl ether) and EtOAc (ethyl acetate) were obtained from SDS (Peypin, France). All commercial reagents and solvents were used as received with the exception of DMF and CH_2Cl_2 , which were bubbled with nitrogen to remove volatile contaminants (DMF) and stored over activated 4 Å molecular sieves (Merck, Darmstadt, Germany); and THF, which was distilled from sodium/benzophenone.

Solution reactions were performed in round-bottomed flasks. Organic solvent extracts were dried over anhydrous $MgSO_4$, followed by solvent removal under reduced pressure at temperatures below 40 ºC.

Solid-phase syntheses were performed in polypropylene syringes (2, 5 mL), each fitted with a polyethylene porous disc. Solvents and soluble reagents were removed by suction. The Fmoc group was removed with piperidine–DMF (1:4, v/v) (2 × 1 min, 2 × 5 min). Washings between reaction steps were carried out with DMF (5 × 1 min) and CH_2Cl_2 (5 × 1 min) using 5 mL solvent.g^{-1} resin for each wash. Peptide synthesis transformations and washes were performed at 25 ºC.

Microwave-assisted synthesis was performed on a CEM Discover® Labmate instrument equipped with an IntelliVent™ pressure control system in sealed tubes.

HPLC columns (Symmetry® C18 reversed-phase analytical column, 5.0 µm × 4.6 mm × 150 mm and Symmetry® C18 reversed-phase semi-preparative column, 5.0 µm × 7.8 mm × 100 mm) were obtained from Waters (Ireland). Analytical HPLC was performed on a Waters instrument comprising a separation module (Waters 2695), automatic injector, photodiode array detector (Waters 996), and system controller (Millenium^{32} login). UV detection was performed at 220 and 254 nm, and linear gradients of ACN (+0.036% TFA) into H_2O (+0.045% TFA) were run at 1.0 mL·min^{-1} flow rate for 15 min. Semi-preparative HPLC was carried out on a Waters instrument comprising a separation module (Waters 600), automatic injector, and a dual absorbance detector (Waters 2487). UV detection was performed at 220 and 254 nm, and linear gradients of ACN (+0.05% TFA) into H_2O (+0.1% TFA) were run under the conditions specified for each case.

MALDI-TOF and ES(+)-MS analyses of peptide samples were performed on an Applied Biosystems VoyagerDE RP, using a DHB matrix, in a Waters Micromass ZQ spectrometer and in an Agilent Ion Trap 1100 Series LC/MSDTrap.

General procedure for the synthesis of thiocoraline bioconjugates

Thio-O-Ac. Thiocoraline (10.0 mg, 0.0087 mmol) was dissolved in CH_2Cl_2. AcOH (5.0 µL, 0.087 mmol) and HOAt (10.9 mg, 0.087 mmol) were suspended in CH_2Cl_2. DIEA (44 µL, 0.26 mmol) was added, followed by TCFH (24.6 mg, 0.087 mmol), dissolved in CH_2Cl_2, and the mixture was added to the thiocoraline solution. The reaction mixture was stirred for 2 h at 25 °C, was then evaporated, and purified by RP-HPLC. Analytical HPLC (linear gradient: 50:50 to 100:0 (ACN/H_2O) in 15 min): t_R = 6.59 min (bis), t_R = 7.78 min (mono). HPLC-ESMS (mono): *m/z* calcd for $C_{50}H_{58}N_{10}O_{13}S_6$, 1198.25; found,

1199.50 $[M + H]^+$. HPLC-ESMS (bis): *m/z* calcd for $C_{52}H_{60}N_{10}O_{14}S_6$, 1240.26, found, 1241.10 $[M + H]^+$.

Thio-O-CO-CH_2-O-CH_3. Analytical HPLC (linear gradient: 50:50 to 100:0 (ACN/H_2O) in 15 min): t_R = 6.44 min (bis), t_R = 7.68 min (mono). HPLC-ESMS: *m/z* calcd for $C_{51}H_{60}N_{10}O_{14}S_6$ (mono) 1228.26; found, 1228.79 [M]•+. HPLC-ESMS: *m/z* calcd for $C_{54}H_{64}N_{10}O_{16}S_6$ (bis) 1300.28; found, 1300.84 [M]•+.

Thio-O-CO-CH_2-O-$(CH_2)_2$-O-CH_3. Analytical HPLC (linear gradient: 50:50 to 100:0 (ACN/H_2O) in 15 min): t_R = 6.32 min (bis), t_R = 7.61 min (mono). HPLC-ESMS: *m/z* calcd for $C_{53}H_{64}N_{10}O_{15}S_6$ (mono) 1272.29; found, 1272.98 [M]•+. HPLC-ESMS: *m/z* calcd for $C_{58}H_{72}N_{10}O_{18}S_6$ (bis) 1388.34; found, 1388.92 [M]•+.

Thio-O-(Boc)-Lys(Boc). Analytical HPLC (linear gradient: 50:50 to 100:0 (ACN/H_2O) in 15 min): t_R = 10.80 min (mono), t_R = 12.16 min (bis). HPLC-ESMS: *m/z* calcd for $C_{64}H_{84}N_{12}O_{17}S_6$ (mono) 1484.44; found 1485.18 $[M + H]^+$, 1508.11 $[M + Na]^+$. HPLC-ESMS: *m/z* calcd for $C_{80}H_{112}N_{14}O_{22}S_6$ (bis) 1812.64; found, 1813.44 $[M + H]^+$, 1835.45 $[M + Na]^+$.

Thio-O-(Boc)-Glu(*t*Bu). Analytical HPLC (linear gradient: 50:50 to 100:0 (ACN/H_2O) in 15 min): t_R = 11.47 min (mono), t_R = 13.19 min (bis). HPLC-ESMS: *m/z* calcd for $C_{62}H_{79}N_{11}O_{17}S_6$ (mono) 1441.40; found, 1442.21 $[M + H]^+$. HPLC-ESMS: *m/z* calcd for $C_{76}H_{102}N_{12}O_{22}S_6$ (bis) 1726.56; found, 1727.13 $[M + H]^+$.

Thio-O-(Fmoc)-6-aminocaproic. Analytical HPLC (linear gradient: 50:50 to 100:0 (ACN/H_2O) in 15 min): t_R = 11.95 min (mono), t_R = 13.88 min (bis). HPLC-ESMS: *m/z* calcd for $C_{69}H_{77}N_{11}O_{15}S_6$ (mono), 1491.39; found, 1492.04 $[M + H]^+$. HPLC-ESMS: *m/z* calcd for $C_{90}H_{98}N_{12}O_{18}S_6$ (bis), 1826.54; found, 1827.95 $[M + H]^+$.

Thio-O-(Fmoc)-β-Ala. Analytical HPLC (linear gradient: 50:50 to 100:0 (ACN/H_2O) in 15 min): t_R = 11.03 min (mono). MALDI-TOF: *m/z* calcd for $C_{66}H_{71}N_{11}O_{15}S_6$ (mono), 1449.35; found, 1472.52 $[M + Na]^+$.

Thio-O-PEG5000. Analytical HPLC (linear gradient: 50:50 to 100:0 (ACN/H_2O) in 15 min): t_R = 7.19, t_R = 7.73 min, t_R = 7.93 min, and t_R = 8.70 min. MALDI-TOF: average masses: 7582.70, 8653.57, 11043.24, 6993.97.

Thio-O-PEG2000. Analytical HPLC (linear gradient: 0:100 to 100:0 (ACN/H_2O) in 15 min): t_R = 9.25 min (mono); HPLC-ESMS: *m/z* calcd (mono) 3138.24; found, 1050.24 $[M + 3]^+/3$.

Thio-O-CO-$(CH_2)_2$-CONH-$(CH_2)_3$-O-$(CH_2)_2$-O-$(CH_2)_2$-O-$(CH_2)_3$-NHBoc. Analytical HPLC (linear gradient: 50:50 to 100:0 (ACN/H_2O) in 15 min): t_R = 7.19 (mono), t_R = 7.98 min (bis). HPLC-ESMS: *m/z* calcd for $C_{67}H_{90}N_{12}O_{19}S_6$ (mono) 1558.48; found 1559.25 $[M + H]^+$. HPLC-ESMS: *m/z* calcd for $C_{86}H_{124}N_{14}O_{26}S_6$ (bis) 1960.71; found 1961.54 $[M + H]^+$.

Thio-O-CO-$(CH_2)_2$-CONH-$(CH_2)_3$-O-$(CH_2)_2$-O-$(CH_2)_2$-O-$(CH_2)_3$-NHAc. Analytical HPLC (linear gradient: 0:100 to 100:0 (ACN/H_2O) in 15 min): t_R = 9.12 (bis), t_R = 11.21 min (mono). HPLC-ESMS: *m/z* calcd for $C_{64}H_{84}N_{12}O_{18}S_6$ (mono) 1500.44; found, 1501.38 $[M + H]^+$. HPLC-ESMS: *m/z* calcd for $C_{80}H_{112}N_{14}O_{24}S_6$ (bis) 1844.63; found, 1845.55 $[M + H]^+$.

Thio-O-octanoic. Analytical HPLC (linear gradient: 0:100 to 100:0 (ACN/H_2O) in 15 min): t_R = 16.34 min (mono), t_R = 17.63 min (bis). HPLC-ESMS: *m/z* calcd for $C_{56}H_{70}N_{10}O_{13}S_6$ (mono) 1282.34; found, 1283.00 [M]•+. HPLC-ESMS: *m/z* calcd for $C_{64}H_{84}N_{10}O_{14}S_6$ (bis) 1408.45; found, 1408.89 [M]•+.

Thio-O-palmitic. Analytical HPLC (linear gradient: 0:100 to 100:0 (ACN/H_2O) in 15 min): t_R = 20.56 min (mono), t_R = 21.15 min (bis). MALDI-TOF: *m/z* calcd for $C_{64}H_{86}N_{10}O_{13}S_6$ (mono) 1394.47; found, 1395.54 $[M + H]^+$, 1417.52 $[M + Na]^+$, 1433.50 $[M + K]^+$. MALDI-TOF: *m/z* calcd for $C_{80}H_{116}N_{10}O_{14}S_6$ (bis) 1632.70; found, 1657.83 $[M + 2H + Na]^+$, 1673.78 $[M + 2H + K]^+$.

Thio-O-CO-$(CH_2)_{10}$-SH. Analytical HPLC (linear gradient: 0:100 to 100:0 (ACN/H_2O) in 15 min): t_R = 16.75 min (mono), ESMS: *m/z* calcd for $C_{59}H_{76}N_{10}O_{13}S_7$ 1356.36; found, 1377.80 $[M + Na]^+$.

Microwave-assisted synthesis of thiocoraline conjugates: Thiocoraline (5.0 mg, 0.0043 mmol), CH_3-O-$(CH_2)_2$-O-CH_2COOH (4.9 µL, 0.043 mmol), TCFH (12.3 mg, 0.043 mmol), HOAt (5.9 mg, 0.043 mmol), and DIEA (22 µL, 0.13 mmol) were weighed in a microwave glass tube. CH_2Cl_2 or DMF (2 mL) was added, and the tube was sealed, and introduced into the microwave. Reactions with CH_2Cl_2 were performed at MW ~50, and up to 110 °C, whereas reactions with DMF were performed at MW ~25 and 100 °C.

Synthesis using PS-HOBt. PS-HOBt (100 mg, 1.05 mmol/g) was washed with CH_2Cl_2 and Ac_2O (75.5 µL, 0.8 mmol), pyridine (48.3 µL, 0.6 mmol) in CH_2Cl_2 (1 mL) was then added to the resin. After 1 h at 25 °C, the resin was washed with CH_2Cl_2. Thiocoraline (4.9 mg, 0.004 mmol) in CH_2Cl_2 was added to an aliquot of the resin (29 mg, 0.028 mmol), and the reaction was left for 3 h at 25 °C. The reaction mixture was filtered, and the filtrates were evaporated and analyzed by analytical HPLC.

Solid-phase synthesis. 2-CTC resin (10 mg, 1.5 mmol/g) was washed with DMF and CH_2Cl_2. Next, thiocoraline (11 mg, 0.01 mmol) and DIEA (11.3 μL, 0.07 mmol) in CH_2Cl_2 were added. After 5 min another portion of DIEA was added (5.6 μL, 0.03 mmol) and the resin was shaken for 45 min. After this period, MeOH (8 μL) was added to cap any unreacted site, and the resin was washed with DMF (3 × 1 min) and CH_2Cl_2 (3 × 1 min). Next, a solution of Fmoc-6-aminocaproic acid (35.4 mg, 0.10 mmol) and HOAt (13.6 mg, 0.10 mmol) in CH_2Cl_2 was added, followed by DIEA (51.0 μL, 0.30 mmol) and TCFH (28.0 mg, 0.10 mmol). The reaction was shaken for 1 h, washed with DMF and CH_2Cl_2. The Fmoc group was removed with piperidine–DMF (1:4) (2 × 1 min, 2 × 5 min). Cleavage of the resin was achieved by treatment with TFA–CH_2Cl_2 (1:99; 6 × 1 min).

Synthesis of Boc protected 4,7,10-Trioxa-1,13-tridecanediamine Succinimic Acid. 4,7,10-Trioxa-1,13-tridecanediamine (100 mg, 0.45 mmol) was dissolved in CH_3CN (10 mL) in a round-bottomed flask provided with magnetic stirring. Succinic anhydride (45.5 mg, 0.45 mmol, 1.0 equiv) was dissolved in CH_3CN (5 mL) and added dropwise over 20 min. The reaction was allowed to proceed for an additional 2 h at 25 °C. The organic solvent was decanted and discarded. The crude product (white oil) and triethylamine (94.2 μL, 0.68 mmol, 1.5 equiv) were dissolved in CH_2Cl_2 (20 mL) and placed in an ice bath for 15 min before Boc_2O (133.5 g, 0.58 mmol, 1.3 equiv) in CH_2Cl_2 (10 mL) was added dropwise over 15 min. After stirring overnight at 25 °C, the solvent was removed under vacuum. The resultant crude product (pale yellow oil) was dissolved in 5% $NaHCO_3$ (50 mL) and washed with EtOAc. The aqueous phase was then acidified with 1

N HCl to pH 4 and extracted with EtOAc (3 × 50 mL). The combined organic layers were washed with brine and dried over anhydrous $MgSO_4$. Evaporation of the organic solvent gave 128.6 mg of the desired product (68% yield). The final product was characterized by analytical RP-HPLC and HPLC-ESMS (linear gradient: 0:100 to 100:0 (ACN/H_2O) in 10 min): t_R: 5.38 min, purity: 90%, *m/z* calcd for $C_{19}H_{36}N_2O_8$ 420.25; found, 421.30 $[M + H]^+$.

Synthesis of Acetyl protected 4,7,10-Trioxa-1,13-tridecanediamine Succinimic Acid. Succinic anhydride (45.5 mg, 0.45 mmol, 1.0 equiv) dissolved in CH_3CN (5 mL) was added dropwise over 20 min to a solution of 4,7,10-Trioxa-1,13-tridecanediamine (100 mg, 0.45 mmol) in CH_3CN (10 mL). The reaction was stirred for 2 h at 25 °C. The organic solvent was decanted and discarded. The resultant product (white oil), triethylamine (94.2 L, 0.68 mmol, 1.5 equiv) and acetic anhydride (40 μL, 0.54 mmol, 1.2 equiv) were dissolved in CH_2Cl_2 (20 mL) and stirred for 3 h at at 25 °C. The mixture was evaporated under vacuum and the residue was dissolved in 5% $NaHCO_3$ (50 mL) and washed with EtOAc. The aqueous phase was then acidified with 1 N HCl to pH 2 and extracted with EtOAc (3 × 50 mL). The organic layer was washed with brine, dried over anhydrous $MgSO_4$ and evaporated to dryness to obtain 101.0 mg of the desired compound as a yellow oil (62% yield). The final product was characterized by analytical RP-HPLC and HPLC-ESMS (linear gradient: 0:100 to 100:0 (ACN/H_2O) in 10 min): t_R: 3.95 min, purity: 82%, *m/z* calcd for $C_{16}H_{30}N_2O_7$ 362.23; found, 363.50 $[M + H]^+$.

Cell growth inhibition assay

A colorimetric assay using sulforhodamine B (SRB) was adapted to perform a quantitative measurement of cell growth and viability, following a previously described method. The cells were seeded in 96-well microtiter plates at 5×10^3 cells/well in aliquots of 195 µL of RPMI medium and were left to grow in drug-free medium for 18 h to allow attachment to the plate surface. Samples were then added in aliquots of 5 µL (dissolved in DMSO–H_2O, 3:7). After 72 h of exposure, the antitumor effect was measured by the SRB methodology: cells were fixed by adding 50 µL of cold 50% (wt/vol) trichloroacetic acid (TCA) and were incubated for 60 min at 4 ˚C. Plates were washed with deionized H_2O, and dried, and 100 µL of SRB solution (0.4% wt/vol in 1% acetic acid) was added to each microtiter well and incubated for 10 min at room temperature. Unbound SRB was removed by washing with 1% acetic acid. Plates were air-dried, and the bound stain was dissolved with Tris buffer. Optical densities were read on an automated spectrophotometer plate reader at a single wavelength of 490 nm. Data analyses were automatically generated by LIMS implementation. Assays were done in a dose-response manner at 10 concentrations (from 10 µg/mL with 1:2.5 dilutions to 0.0026 µg/mL). Although concentrations were adjusted in mg/mL, GI_{50} values were calculated in molarity. All assays were run in triplicate, and the curves were automatically adjusted with 30 points by non-linear regression using "Prism 3.03" (GraphPad) software.

Received March 7, 2008; Revised Manuscript Received August 13, 2008

Modularly assembled targeting nanoparticles were synthesized through self-assembly of targeting moieties on surfaces of functional nanoparticles. Specific molecular recognition of nickel nitrilotriacetate on Fe_3O_4 nanoparticles with hexahistidine tag on RGD4C peptides results in precisely controlled orientation of the targeting peptides. Better selectivity of the self-assembled RGD4C-Fe_3O_4 nanoparticles targeting oral cancer cells than that achievable through a conventional chemical cross-link strategy was demonstrated by means of atomic absorption spectrometry (AAS). An oral cancer hamster model was applied to reveal specific in vivo targeting and MR molecular imaging contrast in cancer lesions expressing $\alpha v\beta 3$ integrin. Both AAS and MRI revealed that the self-assembled nanoparticles improved the targeting efficiency and reduced the hepatic uptake as compared with the conventional chemical cross-link particles. We investigated the biosafety, biodistribution, and kinetics of the nanoparticles and found that the nanoparticles were significantly cleared from the liver and kidneys after one week. By recombining the desired targeting moiety and various functional nanoparticles through self-assembly, this new modularly designed platform has the capability of enhancing the efficiency of targeted diagnosis and therapies for a wide spectrum of biomedical applications.

INTRODUCTION

Molecular imaging of cancers provides valuable information regarding the clinical behavior of a disease and treatment response to certain therapeutic modalities. Among various molecular imaging modalities under development, magnetic resonance imaging (MRI) provides high spatial resolution, excellent perception with tomographic capabilities, outstanding soft-tissue contrast, and good anatomical detail and orientation. Conventional MRI, however, has relatively low signal contrast because of partial volume dilution effects (*1*). Different image contrast agents have been developed for MRI by modulating proton-T1 or -T2 relaxations using contrast agents such as manganese (Mn^{2+}) (*2*), gadolinium ethoxybenzyl diethylenetriamine pentaacetic acid (Gd-EOB-DTPA) (*3*), and iron oxide nanoparticles (*4*). These contrast agents have been developed and evaluated in the past decades for their MRI applications in the laboratory and clinical use (*5*−*8*). However, in vivo molecular targeting imaging is still in the proof-of-concept stage (*9*). The major challenges for targeted MRI include effective bioconjugation and the in vivo dynamics and sensitivity of the detection. This is due to the limitations of functional groups on a given targeting antibody or peptide, which can be selected for bioconjugation without compromising binding affinity. Traditional direct chemical labeling has failed to provide homogeneous functional nanoparticles with sufficient affinity to generate high MR contrast (*10*). Recently, a study demonstrating a comprehensive artificial synthetic approach reported an optimal size (12 nm) and composition of magnetic nanoparticles ($MnFe_2O_4$) for in vivo targeting imaging of small tumors using trastuzumab (Herceptin) conjugation (*11*). However, all these efforts used to direct chemical conjugation require optimization based on each different targeting contrast agent synthesis and on the complicated combination of different targeting peptides, antibodies, and various types of functional nanoparticles, all with different surface chemistry.

Nitrilotriacetic acid (NTA) forms a stable complex with transitional metal ions such as Ni^{2+}, Zn^{2+}, and Co^{2+} (*12*). The 3D conformation of NTA enables stable and strong binding with polyhistidine sequences (*13*). Recently, NTA-modified magnetic nanoparticles attached to nickel ion (Ni^{2+}) can act as a general agent to separate, transport, and anchor a protein with an engineered arrangement of six consecutive histidine residues (*14*). This platform was capable of efficient purification of His 6-His tagged proteins that are expressed at low levels in mammalian cells (*15*). These studies revealed that Ni-NTA and 6-His have strong specific affinity to each other and potential application for self-assembling design.

Specific integrins, such as $\alpha v\beta 3$, have been highly expressed on the neoangiogenic endothelial cells of cancer lesions, for

example, glioblastoma, melanoma, breast, ovarian, and prostate tumors. Some of these cancers cells overexpress the specific integrins, while their healthy counterparts do not (*16*−*19*). Cyclic RGD4C (CDCRGDCFC) peptide is a potent but highly selective binder of $\alpha v\beta 3$ integrins and target tumors (*20, 21*). These peptides have been successfully used for tumor imaging, cancer gene therapy, and chemotherapy (*22*−*27*).

In this article, we report the concept of modularly designed nanoparticles that separate the functional part of the nanoparticle from the targeting biomolecules. Their self-assembly through molecular recognition between the Ni-NTA molecule and the 6-histidine peptide structure enabled improved in vivo targeting imaging, effective clearance from liver and kidney, and a versatible recombination of different functional nanoparticles and different targeting biomolecules in future development.

EXPERIMENTAL PROCEDURES

Preparation of Dispersed, Water-Soluble Fe_3O_4 Nanoparticles. For preparing water-soluble and dispersed Fe_3O_4 nanoparticles, two-stage additions of protective agent and chemical coprecipitation were employed in the process (*28, 29*). Briefly, 2 M Fe(II) and 1 M Fe(III) aqueous solutions were prepared by dissolving $FeCl_2$ and $FeCl_3$, respectively. To produce Fe_3O_4 nanoparticles, 1 mL of Fe(II) and 4 mL of Fe(III) aqueous solutions were mixed at room temperature, followed by the addition of 0.5 g organic acid as adherent. Subsequently, 0.5 M NaOH was dropwise added into the mixed solution to adjust the pH. The reaction was finished when the pH of the solution reached 11. The precipitates were collected by a magnet and washed with 50 mL of deionized water three times, followed by addition of another 3 g of organic acid to achieve complete coating of the particle surface that is required for their dispersion and surface functionalization with the $-NH_3^+$ group. The excess adherents were removed by centrifugation, and the precipitates were redispersed in deionized water. The amine functional group was a portion of the adherent used to coat the surface of the nanoparticles. The adherents are organic acids that have amine groups at the same time. The nanoparticle size was determined to be about 6.2 ± 2.1 nm by TEM.

Fe_3O_4 Nanoparticle Modification, Peptide Synthesis, and Conjugation to Nanoparticles. $Fe_3O_4-NH_3^+$ nanoparticles and NTA were conjugated as previously described (*30*). Briefly, 100 μL of 0.2 M Fe_3O_4 nanoparticles were added to 46 μL of 0.22 M N^{α},N^{α}-Bis(carboxymethyl)-L-lysine, 20 μL of 55% (w/w) glutaraldehyde, and 334 μL of H_2O; the mixture was then stirred at room temperature (approximately 25 °C) for 4 h. The Fe_3O_4 nanoparticle can conjugate with NTA when glutaraldehyde and $NaBH_3CN$ were added. The amine group can conjugate with the aldehyde group of glutaraldehyde to form the C═N form; then, the C═N form was reduced to the C−N form with $NaBH_3CN$. Therefore, glutaraldehyde was a linker between the nanoparticle and NTA. The resulting precipitate (Fe_3O_4−NTA) was resuspended in 1 mL of H_2O and then centrifuged at 13 000 rpm for 20 min to remove the excess NTA. After the precipitate had been washed three times with milliQ water, resuspended in 1 mL of 1.0 M $NiSO_4$, stirred at room temperature for 8 h, and then centrifuged again to obtain the $Fe_3O_4-NTA-Ni^{2+}$ complex, cyclic RGD4C with a 6-histidine peptide residue on the C-terminal (CDCRGDCFCGGGGGGH-HHHHH) was synthesized (Genesis Biotech Inc., Taipei, Taiwan) and evaluated for self-assembly on the nanoparticle surfaces. Twenty-three microliters of 8.9 mM RGD4C-6-histidine peptide was added to 1 mL of 20 μM aqueous Ni-NTA-modified Fe_3O_4 to obtain self-assembled Fe_3O_4−NTA-Ni-RGD4C nanoparticles. As a control, the original Fe_3O_4 nanoparticles, with an amine functional group on the surface, were conjugated with the same concentration of RGD4C peptide through a conventional chemical cross-linking strategy using glutaraldehyde (nanoparticles/peptides = 1:10). After the samples had been incubated at 4 °C overnight, they were centrifuged at 13 000 rpm for 10 min, and the supernatant discarded to obtain the targeting nanoparticles.

Cell Culture and Maintenance. The HCDB-1 is a hamster oral squamous cell carcinoma cell line previously isolated and characterized by Professor Lin of National Yang-Ming University, Taiwan (*31*). The NIH3T3 mouse fibroblast cell line and human oral squamous cell carcinoma line (SCC15) were purchased from the American type Culture Collection (ATCC). OEC-M1 was established by Dr. CL Meng from a Taiwanese male oral cancer patient with areca quid chewing history. HCDB-1 and OEC-M1 were maintained in RPMI 1640 medium (Invitrogen Corp., Carlsbad, CA). SCC15 cells were maintained in Dulbecco's Modified Eagle's medium (Invitrogen Corp., Carlsbad, CA). NIH3T3 cells were maintained in Dulbecco's Modified Eagle's medium (Invitrogen Corp., Carlsbad, CA). These media were supplemented with 10% fetal bovine serum (FBS; Invitrogen Corp., Carlsbad, CA) and 1% penicillin−streptomycin (Invitrogen Corp., Carlsbad, CA). Healthy oral mucosal epithelial cells were derived from excessive retromolar gingival tissue of healthy donors with consent during surgical extraction of the third molar teeth. The oral keratinocytes were purified using a previously described method (*32*). The culture was maintained in serum-free keratinocyte growth medium (Cascade Biologics, Inc., Portland, OR) with keratinocyte growth supplement. Passage-4 cultures were used in the analysis for all studies. All cell lines were incubated at 37 °C in an atmosphere with 5% CO_2.

Ligand Competition Assay. We did a ligand competition assay using free cyclic RGD4C peptide (Genesis Biotech Inc., Taipei, Taiwan) as a competitor for the RGD-4 conjugated magnetite particles. The free RGD4C (CDCRGDCFCGGGGGG) was added to the medium to a final concentration of 3 μM for 1 h to saturate the receptor molecules on the cell surface. After they had been washed with PBS, the cells were added to a different concentration of Fe_3O_4-NTA-Ni-RGD4C and analyzed using AAS.

Biocompatibility Assay for the Fe_3O_4-NTA-Ni-RGD4C. NIH3T3 and HCDB-1 cells were cultured in 96-well culture plates at a density of 5×10^3 cells/well. Fe_3O_4-NTA-Ni-RGD4C nanoparticles of different concentrations (0.003−9.4 mg/mL) were added to each culture well and incubated for 24 h. Cell viability was determined using a 5-dimethylthiazol-2-yl-2,5-diphenyl tetrazolium bromide (MTT) assay (*33*). The systemic toxicity of the Fe_3O_4-NTA-Ni-RGD4C nanoparticles were determined in vivo using 6-week-old BALB/c mice ($n = 36$) randomly assigned to three experimental groups with different dosages of nanoparticles (1, 2.5, and 5 mg/kg groups) and one PBS control group ($n = 9$ mice/group). The nanoparticles were injected into the tail vein of each mouse. The survival and pathological symptoms and signs of each mouse were monitored for a period of one month.

Animals and Tumor Model. The male Syrian gold hamsters were purchased from the National Laboratory Animal Center (Taipei, Taiwan) and BALB/c mice from the National Cheng Kung University Laboratory Animal Center (Tainan, Taiwan). All animals were given humane care in compliance with the institution's guidelines for maintenance and use of laboratory animals in research. All experimental protocols involving live animals were reviewed and approved by the Animal Experimentation Committee of Nation Cheng Kung University. HCDB1 tumor xenografts were established by injecting 10^7 tumor cells in 100 μL of normal saline into the right buccal pouch using a 27-gauge needle. Tumors were normally visible one week after the injection. For MRI experiments, the hamsters

were anesthetized with 2% isoflurane (Abbott Laboratories, Abbott Park, IL) mixed with 100% O_2 delivered using a veterinary anesthesia delivery system (ADS 1000; Engler Engineering Corp., Hialeah, FL). The animals were given an overdose of 2.5% pentothal (Abbott Laboratories, Abbott Park, IL). Their tumor and organ tissues were harvested in the following experiments.

Atomic Absorption Spectrometry Analysis. Cells (5×10^6 cells) in a 10 cm^2 culture dish were incubated with different concentrations of nanoparticles or PBS at 4 °C for 1 h. After the cells had been washed three times with cold PBS, 5 mL of nitric acid was added to dissolve the cells. The total lysate was subjected to atomic absorption spectroscopy (AAS) (Unicam Solaar M6 series) analysis. The tumor and organ tissues were surgically harvested from the hamsters, and then 1 g of the tumor and organ tissues were isolated from the harvested tissue. After they had been homogenized, they were placed into a centrifuge tube containing 30 mL of nitric acid (12 M), and incubated for 3 days to permit complete dissolution of the tissues. The obtained liquid was analyzed using AAS.

Magnetic Resonance Imaging. Sequential MRI acquisition was done in a 3T MR imager (Biospec System; Bruker BioSpin MRI GmbH, Ettlingen, Switzerland) equipped with a high-performance gradient coil (inner diameter = 12 cm; maximal gradient strength = 200 mT m^{-1}) and a quadrature coil (inner diameter = 10 cm) for RF transmission and reception. The hamsters were anesthetized using 2% isoflurane (Abbott Laboratories, Abbott Park, IL) mixed with 100% O_2 delivered using a veterinary anesthesia delivery system (ADS 1000; Engler). Fe_3O_4-NTA-Ni-RGD4C yielded signal contrast using a T2* pulse sequence (TR/TE, 743/5 ms; MTX, 256 × 256 × 25).

Measurements MR Image of Fe_3O_4 in Tumor Site with Matlab Workstation. Three sequential axial images (1.5 mm thickness, original magnification × 1.5) of each of the 75 potential implant sites were selected ($N = 225$) using *Matlab* software to analysis. The operator determined the red circle of the ROI in all sites. The spatial coordinate tool (x, y) was manually set to define a circular or oval ROI at the same anatomic location on each of the 3 axial images. The average signal intensity of each ROI relative to that of the control (fish oil capsule indicator) was calculated. The alterations in the MR signal of the tumor site in a time series (0, 24, and 48 h) were compared to that before injection. The same method was applied for the calculation of MR signal alterations in the liver.

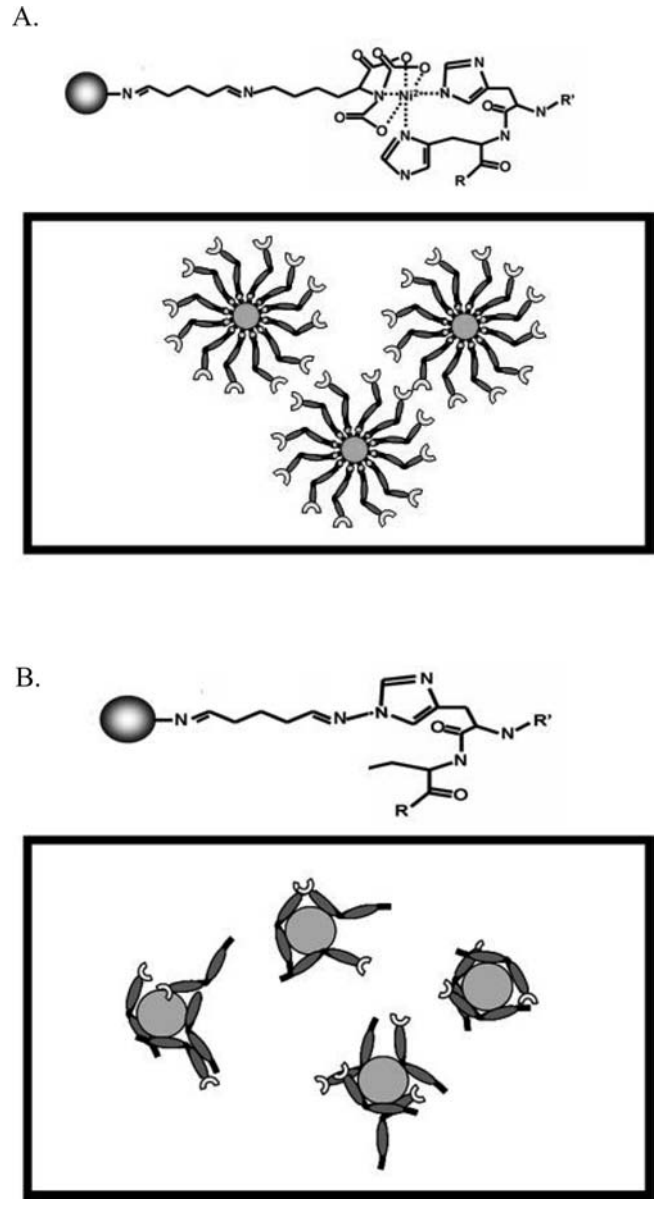
Histological Examination. For Prussian blue, hematoxylin, and eosin staining (H&E), the tumor tissue was fixed with 4% paraformaldehyde and paraffin-sectioned. Tissue samples were sliced into 5-μm-thick sections and then incubated with 2% potassium ferrocyanide in 6% hydrochloric acid for 30 min. After they had been washed, they were counterstained with Giemsa solution. The specimens were then mounted and examined under a light microscope (BH-2; Olympus, Tokyo, Japan).

Statistical Analysis. All experiments were repeated at least three times and the values are means ± standard deviation. Statistical analyses were done using Student's *t*-test. Statistical significance was set at $p < 0.05$.

RESULT AND DISCUSSION

We previously demonstrated that self-assembly of 6-His tagged RGD4C peptide to nanoparticle surface improved molecular orientation control and cancer cell targeting in vitro (*30*). In this article, the strategy was evaluated for in vivo cancer imaging. The superparamagnetic Fe_3O_4 nanoparticles (6.2 ± 2.1 nm) in aqueous solution were conjugated with RGD4C peptide through traditional chemical conjugation (Fe_3O_4-RGD4C) or the self-assembly on the particle surface method (Fe_3O_4-NTA-Ni-RGD4C) (Scheme 1).

Scheme 1. Schematic Diagram Illustrating Two Different Bioconjugation Methods[a]



[a] (A) The modular-targeting nanoparticles with orientation control made through self-assembly of the molecular key (Ni^{2+}-NTA) on the particle and the molecular lock (6-His tag) on the peptide. (B) The traditional chemical cross-linking using glutaraldehyde usually derived a peptide−nanoparticle complex with random molecular orientation because multiple sites on the peptide are available for conjugation.

Cytotoxicity of Fe_3O_4-NTA-Ni-RGD4C Nanoparticles. The cytotoxicity of the nanoparticles was evaluated using both HCDB1 (Figure 1A) and NIH3T3 cells (seeSupporting Information S1) using MTT assay. The results showed satisfactory (>80%) biocompatibility at a particle concentration below 0.376 mg/mL (Figure 1A) in both cell lines. This particle concentration was sufficient to produce a significant MR contrast effect in vivo (*28*). The inhibition in cell growth at high dosages (1.88 and 9.4 mg/mL) may attribute to the interaction of the targeting peptide with the integrin signaling pathway. The nanoparticle concentrations were referenced to iron concentration determined from AA (atomic absorption) spectrometry. Selective binding of RGD-4C peptide to $\alpha v\beta 3$ and $\alpha v\beta 5$ integrins in human

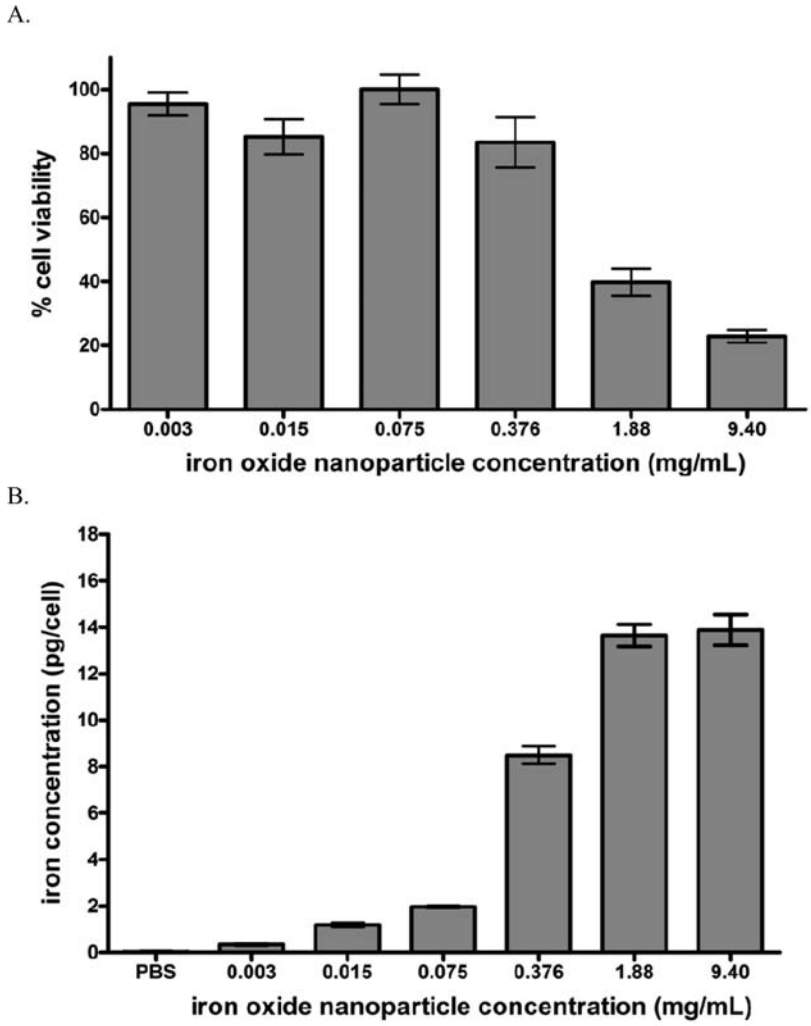


Figure 1. The biocompatibility of the nanoparticles was evaluated using MTT assay. (A) The cell viability of HCDB1 with different nanoparticle concentrations was analyzed. Biocompatibility was satisfactory at doses lower than 1.25 μM. Targeting of the self-assembled Fe_3O_4-NTA-Ni-RGD4C nanoparticles to HCDB1 cells as a function of the nanoparticle concentration was evaluated. (B) HCDB1 cells (5×10^6 cells/dish) were cultured in 10 cm^2 culture dishes and exposed to nanoparticles of different concentrations for 1 h before a quantitative atomic absorption spectroscopy analysis of the iron in the cells.

umbilical endothelial cells (HUVECs) have been reported to induce cellular detachment, caspase-8 activation, and apoptosis (*34*).

Dose-Dependent Affinity Targeting of Fe_3O_4-NTA-Ni-RGD4C Nanoparticles. The dosage-dependent affinity targeting of Fe_3O_4-NTA-Ni-RGD4C nanoparticles to HCDB1 cells that express $\alpha v\beta 3$ was analyzed in vitro by AAS quantification of total cell lysate. A dosage-dependent affinity targeting of HCDB-1 cells by the self-assembled nanoparticles was observed (Figure 1B). The targeting reached a plateau at 1.88 mg/mL concentration, while it was about 64% of the plateau at the biocompatible concentration of 0.376 mg/mL. We then evaluated the selectivity of the targeting nanoparticles toward cancerous oral epithelial cells at 0.376 mg/mL of nanoparticle concentration.

Selective Targeting of Fe_3O_4-NTA-Ni-RGD4C Nanoparticles. Three oral cancer cell lines (HCDB-1, OEC-M1, and SCC15) and one primary culture normal human oral keratinocytes (hNOK) were targeted by 0.376 mg/mL of Fe_3O_4-NTA-Ni-RGD4C or Fe_3O_4-RGD4C at 4 °C for 1 h to evaluate (1) whether Fe_3O_4-NTA-Ni-RGD4C self-assembled nanoparticles selectively bind to the selected cancer cells but not their normal counterpart healthy cells and (2) whether this modularly assembled complex exhibits at a higher targeting efficiency than that of the conventional direct chemical conjugation using the same total amount of targeting peptide for conjugation. The cells were processed for AAS analysis to calculate the total amount of the nanoparticles targeted onto the cells. The cancer cells showed a significantly ($P < 0.0001$) higher targeting efficiency than did the hNOK (range from 7.2:1 to 3.5:1). In all groups of the in vitro targeting analysis, the self-assembled Fe_3O_4-NTA-Ni- RGD4C nanoparticles outperformed the Fe_3O_4-RGD4C nanoparticles ($P < 0.001$) (Figure 2A).

To examine the specifics of the targeting, we did a ligand competition assay. The results indicated that free RGD4C peptide was highly specific and selective, as it significantly restricts the targeting efficiency in all groups with a range 23−33% for self-assembled Fe_3O_4-NTA-Ni-RGD4C nanoparticles and 40−53% for conventional Fe_3O_4-RGD4C nanoparticles (Figure 2B). It is well-known that cyclic RGD4C peptide has a specific affinity for $\alpha v\beta 3$ integrins that are selectively expressed in some tumor cells and their neoangiogenic tissue (*20, 21, 35*). An improved targeting efficiency may attribute to the increased molecular-orientation control through the on-particle self-assembly of the targeting peptide enabled by the engineered affinity peptide "lock" (6-histidine) for the Ni-NTA "key" on the nanoparticle surface (Scheme 1A).

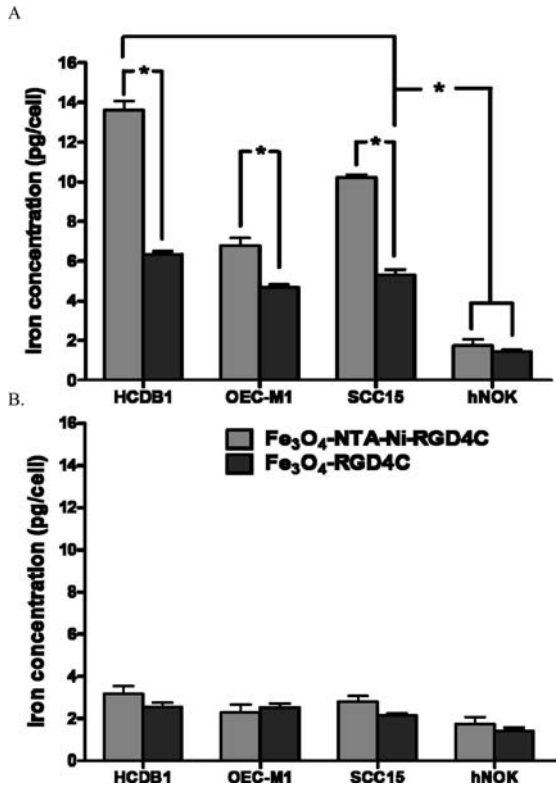

Figure 2. Atomic absorption spectroscopy analysis of the specificity and targeting efficiency for Fe_3O_4-RGD4C nanoparticles and self-assembled Fe_3O_4-NTA-Ni-RGD4C nanoparticles to oral cancer cells compared to their specificity and targeting efficiency for healthy oral keratinocytes (hNOK). (A) Both types of nanoparticles showed improved cancer cell targeting. Self-assembled targeting nanoparticles consistently outperformed the conventionally prepared nanoparticles. (B) A competition assay was done using RGD4C peptide. The affinity targeting of the nanoparticles was significantly inhibited in all groups. *, $P < 0.001$. The iron concentration for the untreated cells in all groups were between 0.06 and 0.09 pg/cell. The iron concentration of the nanoparticle treated cells presented in the chart has been subtracted from their baseline iron levels.

Biocompatibility of Fe_3O_4-NTA-Ni-RGD4C Nanoparticles in Vivo. To further explore in vivo use of the self-assembled Fe_3O_4-NTA-Ni-RGD4C nanoparticles, we analyzed their in vivo biocompatibility. The hemocompatibility of Fe_3O_4-NTA-Ni has been reported (*30*). To determine the in vivo systemic toxicity, the Fe_3O_4-NTA-Ni-RGD4C nanoparticles were injected into the tail vein of 36 6-week-old BALB/c mice with PBS as a control. We monitored the survival and pathological symptoms and signs of each mouse for one month. Only 2 mice died, 1 in the 2.5 mg/kg group on day 17, and 1 in the 5 mg/kg group on day 10. These results suggested that the RGD4C self-assembled Fe_3O_4 nanoparticles are safe for in vivo applications within the dosage range for effective MR contrast (Figure 3) (*28*).

Molecular MR Imaging of Oral Cancer Using Fe_3O_4-NTA-Ni-RGD4C Nanoparticles. We then evaluated the molecular imaging of cancer lesions for specific integrin membrane protein in orthotopic hamster buccal pouch oral cancer model. For the MRI of each tumor lesion, we injected Fe_3O_4-NTA-Ni-RGD4C or the control Fe_3O_4-Ni-NTA at a concentration of 5 mg/kg through the right jugular vein and then sequentially acquired images at 1, 6, 12, 24, and 48 h intervals in a 3T MR imager. Fe_3O_4-NTA-Ni-RGD4C yielded a specifically targeted negative contrast image of the oral cancer lesion within 24 h using a T2* pulse sequence (TR/TE, 743/5 ms; MTX, 256 × 256 × 25) (Figure 4A). The signal contrast persisted for at least 48 h after self-assembled Fe_3O_4-NTA-Ni-RGD4C nanoparticles had been intravenously injected. In order to evaluate whether the conjugation of RGD4C to iron oxide nanoparticles would affect its hepatic uptake, Fe_3O_4-NTA-Ni (5 mg/kg) with or without self-assembly with RGD4C-6-his were injected into each hamster's jugular vein, and then a series of MRI taken.

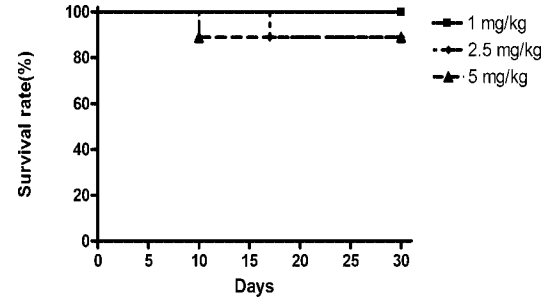

Figure 3. Survival analysis of BALB/c mice exposed to 1, 2.5, and 5 mg/kg of the self-assembled Fe_3O_4-NTA-Ni-RGD4C targeting nanoparticles ($n = 9$). In vivo biocompatibility was satisfactory.

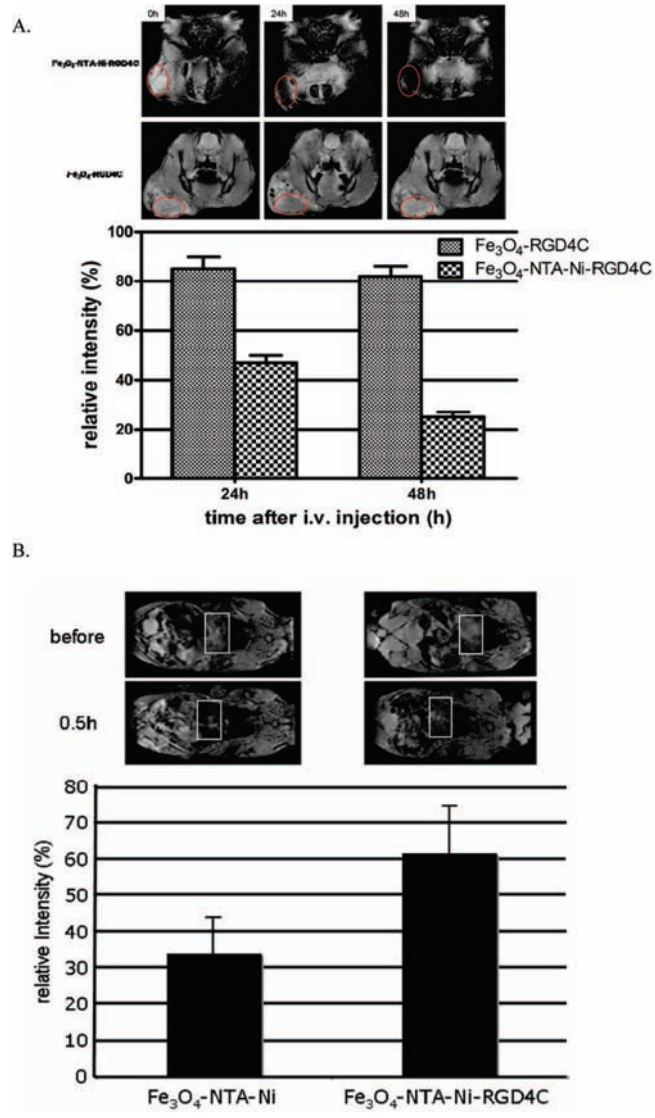

Figure 4. (A) In vivo molecular magnetic resonance imaging of oral cancer in a hamster model shows significant inverse contrast T2* images 24 and 48 h after i.v. injection of the Fe_3O_4-NTA-Ni-RGD4C and Fe_3O_4-RGD4C nanoparticles. (The red circled areas indicate the orthotopically induced tumor lesion). (B) Quantitative measurement (*Matlab* software) of tissue signal intensity showed that modifying the magnetite nanoparticles with the self-assembled targeting moiety (RGD4C) significantly decreased their absorption in the liver.

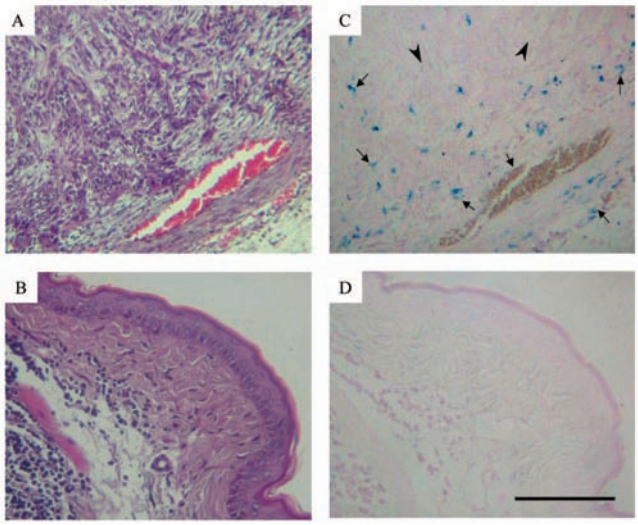

Figure 5. Oral cancer tissue and healthy oral mucosal tissue from the same hamster taken 24 h after i.v. injection of the Fe_3O_4-NTA-Ni-RGD4C nanoparticles was processed for histological and histochemical analysis. (A) Hematoxylin and eosin-stained cancer tissue showed that cancer cells had invaded through the connective tissue with numerous neoangiogenic blood vessels. (B) healthy oral mucosal tissue on the contralateral site. (C) Pearl's iron stain of the adjacent section showed a diffuse bluish-purple in the tumor tissue (arrowheads) with significant accumulation in the endothelial cells (arrows) and some macrophages. (D) Healthy oral mucosal tissue showed only pink background counterstain. (Scale bar: 100 μm.)

The signal intensity of the nanoparticles was quantified in 10 randomly selected areas of the liver. The self-assembled Fe_3O_4-NTA-Ni-RGD4C showed significantly lower hepatic uptake (39% reduction of signal intensity 30 min after i.v. injection) than the Fe_3O_4-NTA-Ni without a targeting peptide (66%) (Figure 4B).

Histological Analysis. To explore the distribution of Fe_3O_4-NTA-Ni-RGD4C nanoparticles in tumor and healthy oral mucosal tissue, a histological examination of formalin-fixed paraffin-embedded tumor and healthy tissue was performed on the surgically removed specimens 24 h after delivery of the nanoparticles. Tissue samples were analyzed for H&E (Figure 5A,B) or Pearl's iron stain (Figure 5C,D). Tumor cells (upper left region of Figure 5A) showed light bluish-purple Pearl's iron staining (Figure 5B, arrowheads) in contrast to healthy oral mucosal tissue (Figure 5C) that showed only pinkish background staining (Figure 5D). This indicates an increased uptake of the targeting iron oxide nanoparticles by the tumor cells. Some of the capillary structure of the tumor lesion and the surrounding neoangiogenic blood vessels showed a strong bluish staining (Figure 5B, arrows) from accumulated targeting nanoparticles, which was not present in healthy oral mucosal tissue (Figure 5D).

In Vivo Targeting Efficiency in the Tumor Lesions Quantified Using AAS. The in vivo targeting efficiency in the tumor lesions was quantified using AAS at a series of time points after Fe_3O_4-RGD4C nanoparticles or self-assembled Fe_3O_4-NTA-Ni-RGD4C nanoparticles had been intravenously injected. The Fe^{2+} concentration peaked 24 h after the injection for both types of nanoparticles and then decreased to the original background level after 72 h (Figure 6A). At all observation points, significantly higher Fe^{2+} concentration was detected in tumor tissue targeted by Fe_3O_4-NTA-Ni-RGD4C nanoparticles than in tumor tissue targeted by Fe_3O_4-RGD4C nanoparticles. The MR image analysis show significant decrease in the tumor signal intensity (47%) from 0 to 24 h (Figure 4A) followed by a decrease from 24 to 48 h (25%). Quantitative analysis of AA

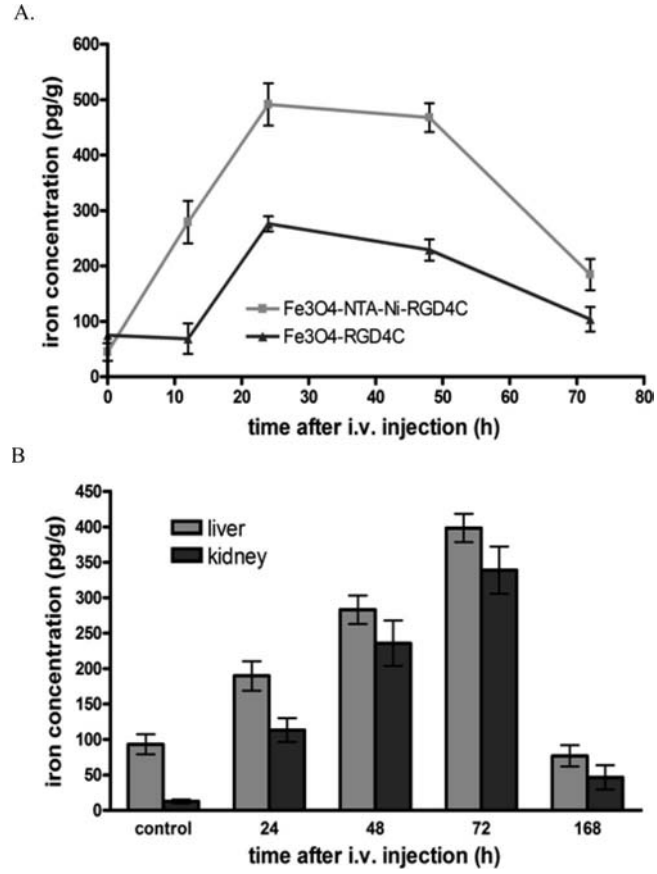

Figure 6. Hamster oral cancer lesions were surgically removed at each time point indicated and then evaluated, using atomic absorption spectroscopic quantitative analysis, for nanoparticle accumulation. (A) The accumulation of Fe_3O_4-NTA-Ni-RGD4C and Fe_3O_4-RGD4C nanoparticles (iron concentration). (B) The accumulation of Fe_3O_4-NTA-Ni-RGD4C in the liver and the kidneys was analyzed after i.v. injection of the nanoparticles.

revealed no statistical difference between iron oxide concentrations at 24 and 48 h ($p = 0.11$). The decrease in the MRI signal intensity at 48 h, while slightly decreasing the tissue iron concentration, could be explained by the aggregation of iron oxide nanoparticles in tissue or cells. A previous report demonstrated that the aggregation of magnetic particles can enhance the T2 or T2* volume in the magnetic field (*36, 37*). Nevertheless, all these data indicate that the self-assembled targeting iron oxide nanoparticles in the current report could be retained in the tumor site for at least 48 h for prolonged observation.

Biodistribution and Excretion of Iron Oxide Nanoparticles. The in vivo biodistribution of the Fe_3O_4-NTA-Ni-RGD4C nanoparticles in the liver and kidneys over time was evaluated using AAS analysis. The organs were processed for AAS analysis as described in the Experimental Procedures. The liver and kidneys were surgically removed from the hamsters at 24, 48, 72, and 168 h after injection with Fe_3O_4-NTA-Ni-RGD4C or PBS. Nanoparticles gradually accumulated in the liver and kidneys and peaked 72 h after injection (Figure 6B). The iron signal in the liver tissue returned to the normal level 168 h after i.v. injection, while decreasing to 8% of the peak level in kidney tissue at the same time point.

Using MRI to retrieve the information of molecular imaging and to track the progression of a certain disease targeting is highly valuable for disease management. A wide range of MR molecular imaging approaches for cancers have been extensively investigated (*38, 39*). However, the key has been the design of imaging probes that can sensitively relay

specific molecular recognition of certain components or pathways in cancer cells with high sensitivity. This allows for signal acquisition and image reconstruction. In vivo iron oxide-based molecular imaging modalities have also been recently reported (*40*, *41*). To the best of our knowledge, our findings here are the first to illustrate the concept of functional nanoparticles that are modularly assembled for in vivo targeted molecular imaging.

As stated above, integrin $\alpha v\beta 3$ is selectively overexpressed in the cancer and neoangiogenic blood vessels, but at a much lower level in mature quiescent cells (*42*). As a result of such expression specificity, it was chosen as the target for molecular imaging in the current study. We showed, both in vivo and in vitro, that the molecular self-assembled modular design performed better than the conventional direct chemical cross-link design in affinity targeting of cancer cells. MRI, using self-assembled nanoparticles, clearly demonstrated a cancer-specific image contrast and a relatively normal image contrast of liver tissue, superior to MRI using non-self-assembled nanoparticles. Nanoparticles are known to be easily trapped and absorbed by the RES system (*43*, *44*), especially in the liver, and normally required for special biological stealth modifications by the surface decoration of polymers such as poly(ethylene glycol) (PEG) before in vivo applications. In the present study, self-assembly of RGD4C on the nanoparticles also significantly decreased the nonspecific uptake of magnetite into the liver without additional surface modifications (Figure 4B). AAS spectroscopy also showed that nanoparticles were retained in tumor tissue for more than 48 h (Figure 6A), which allowed in vivo imaging tracking of the tumor. The results were consistent with those obtained from the iron-stained histological sections of cancer and normal mucosa tissues where only cancer tissues presented significant accumulation of the targeting nanoparticles. The nanoparticles went through metabolic clearance after about a week in the liver and the kidneys (Figure 6B), suggesting their safety as a targeting contrast agent with a traceable clearance mechanism.

CONCLUSION

The new concept of modular nanoparticle platform presented in this report enabled us to compile a library of targeting diagnostic and therapeutic agents (Supporting Information Figure S2). These agents could be sufficiently versatile for individual patient-based combinational assembly of the targeting moiety for a specific clinical need. They may meet the requirements of a variety of medial diagnostic and therapeutic purposes through selection of appropriate nanoparticle modules suitable for respective modalities, for example, magnetite nanoparticle for MRI in this report. This new concept may also fulfill the need of reduction in preparation time and transportation costs. It also allows prolonging of the half-life of the bionanoparticle-based agents, because the two modules can be stored separately in optimized environments before use. It is our goal to further enhance our current design so that it will make a significant contribution to advancement of translational applications using targeting nanoparticles in future medicine.

ACKNOWLEDGMENT

We thank the National Science Council of Taiwan for supporting this research with grants NSC95-95-2120-M-006-013, NSC-95-2120-M-006-006, NSC-95-2314-B-006-014, and NSC94-2120-M-006-004.

S2……Figure S2

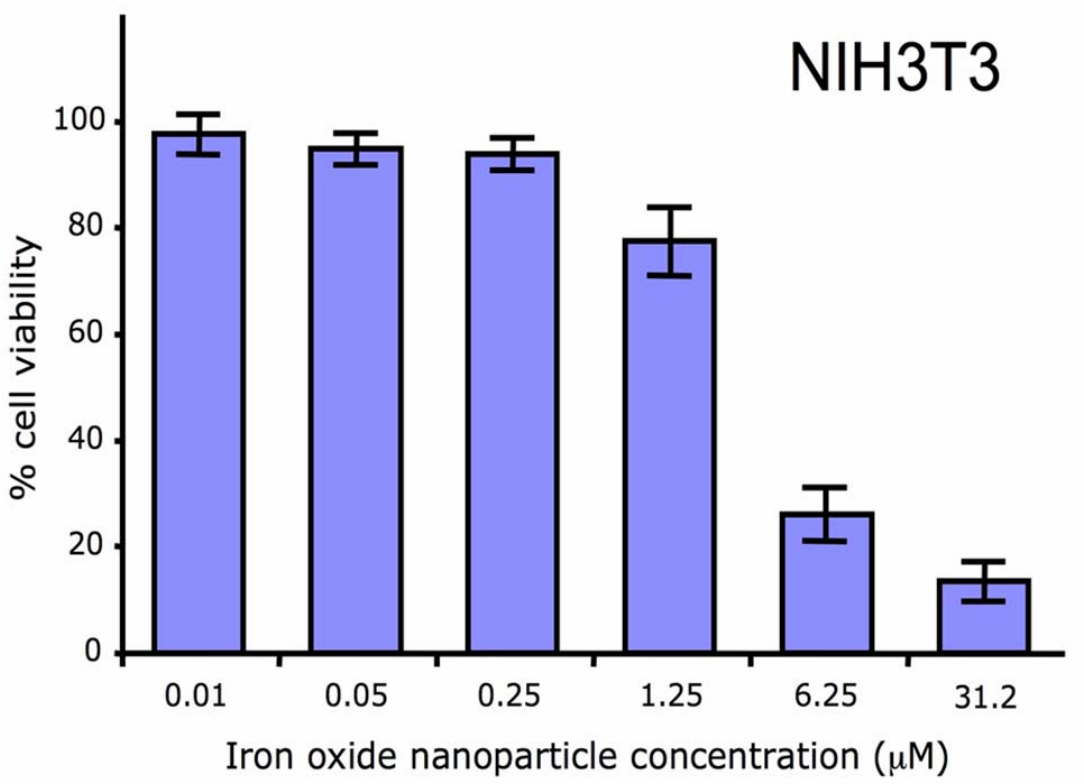

Figure S1. To evaluate the biocompatibility of the nanoparticles, NIH3T3 cells were cultured in 96-well plates. Fe_3O_4-NTA-Ni-RGD4C nanoparticles at different concentrations (range: 0.01-31 μM) were added to each culture well and incubated for an additional 24 h before the spectrophotometric quantification of cell viability using an MTT assay. Cell viability was satisfactory (> 80%) at a particle concentration below 1.25 μM.

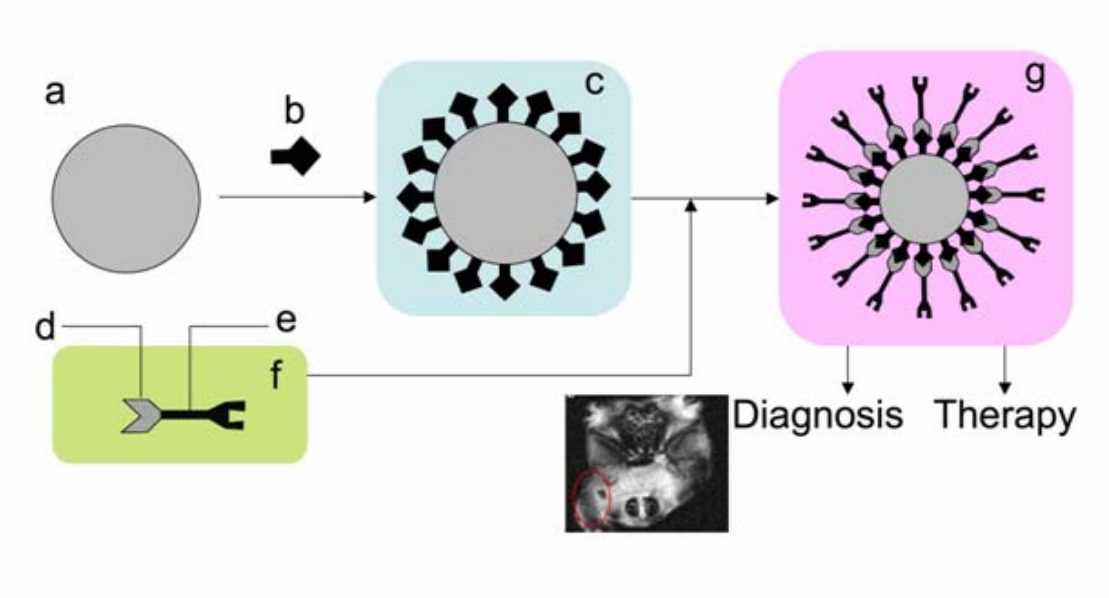

Figure S2. We developed a new concept of modular-targeting functional nanoparticles through self-assembly of the targeting moiety and the functional nanoparticles by modifying the nanoparticle surface with a small "key molecule" and the targeting peptide or recombinant antibody with an affinity peptide tag for the "lock molecule".

Schematic diagram illustrating the concept of modular-targeting functional nanoparticles for diagnostic imaging and therapeutic applications. Nanoparticle module (c) is composed of a functional nanoparticle (a) with a common surface "key molecule" (b), Ni-NTA for example, to self-assemble with targeting moieties in biomolecular module (d~f). Biomolecular module (f) is composed of a biomolecule (d) such as antibody or a peptide with a genetically engineered “lock molecule” (e) tag (6-his domain for example) for binding to "key molecules" on the nanoparticles. The two modules self-assembled to form functional targeting nanoparticles (g) that not only gives a versatile combination for biological end and the nanoparticle end based on clinical applications , but also may improve the targeting because of the orientation-control and enrichment of the effective targeting moiety through self-assembly.

An RGD-Modified Endostatin-Derived Synthetic Peptide Shows Antitumor Activity *in Vivo*

Han-Mei Xu,[†] Runting Yin,[†] Luosheng Chen,[†] Sami Siraj,[†] Xiaofeng Huang,[‡] Min Wang,[†] Huisheng Fang,[†] and Ying Wang*,[†]

It has been reported that an endostatin-derived synthetic peptide, named ES-2, that contains the amino acids 60−70 of endostatin from its N terminus, efficiently inhibits basic fibroblast growth factor-induced directional migration and tubular morphogenesis of microvascular endothelial cells. We found that the peptide had no effects on tumor growth *in vivo*. However, when the peptide Arg-Gly-Asp (RGD) was introduced into ES-2, the modified ES-2 showed significant antitumor results in animal models. Histochemical and immunohistochemical analysis showed that RGD-modified ES-2 induced large areas of continuous necrosis within tumors and significantly reduced the vessel density compared to control. Furthermore, only the peptides with RGD were able to bind tumor cells *in vitro*, suggesting that additional RGD domains may help in improving the receptor-binding ability and pharmacokinetic properties of ES-2 and preventing organic clearance, as well as enzymatic degradation of the peptide, thus enabling a greater fraction of the administered dose to be biologically available.

INTRODUCTION

Endostatin, the C-terminal fragment of collagen XVIII with a molecular weight of 20 kDa, has been approved by the State Food and Drug Administration (SFDA[1]) of China for its antitumor activity. It specifically inhibits endothelial cell proliferation and migration and reduces vascularization and blood flow in gliosarcoma (*1*). It also dramatically inhibits growth of various primary tumors in mice. Integrins could be the potential targets for endostatin (*2, 3*). Endostatin binds one atom of zinc (Zn) per monomer via the three histidines in the amino terminus of the molecule (histidines 1, 3, and 11) and aspartic acid 76 (*4*−*6*). The crystal structure of mouse endostatin reveals a compact globular fold and a basic patch of 11 arginine residues, which have been suggested to act as binding sites for heparin (*7*).

Numerous attempts have been made to produce biologically active endostatin via recombinant DNA technology (*8*). However, when expressed in *Escherichia coli*, recombinant endostatin accumulated as inclusion bodies in the cytoplasm. During the *in vitro* renaturation or refolding process, the recovery of soluble and active endostatin was very low, and most of the protein precipitated during the refolding process owing to the renaturation of proteins containing multiple disulfide bonds (*9*−*11*). Further investigations are necessary to elucidate the structure−function relationship of endostatin to meet the urgent need for new antitumor drugs. To achieve this goal, several groups have synthesized and studied the peptides that correspond to the partial sequence of endostatin (*12*−*17*). One group has reported that an 11-amino-acid peptide (ES-2: IVRRADRAAVP) derived from the amino terminus of endostatin promoted endothelial cell adhesion, migration, and tube formation (*12*). However, another group obtained data indicating that a peptide containing the 11 amino acids failed to inhibit tumor growth (*13*).

In our previous study (*18*), we found that ES-2 dramatically inhibited angiogenesis on the chorioallantoic membrane of the chick embryo *in vivo*, but had no antitumor effect in tumor-bearing mice. We speculate that this difference might be caused by a lesser distribution of the drug in the mouse model than in the chick embryo. In order to validate this hypothesis, a new strategy that increases the targeted delivery of the peptide to tumors is needed. In the past decade, many molecules with the RGD peptide have been described that efficiently deliver drugs to tumor vasculature endothelium (*19, 20*). Therefore, in the present study, we examined whether the addition of RGD will also lead to the pronounced antitumor activity of the peptide.

MATERIALS AND METHODS

Cell Lines, Animals, And Peptides. B16F10 mouse melanoma cells (provided by Nanjing University), human hepatic carcinoma Bel-7402, human gastric cancer cell line MGC-803, and human hepatic carcinoma SMMC-7721 cell line were purchased from American type Cell Culture (ATCC, Shanghai, China) and maintained in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal bovine serum and antibiotics. Human umbilical vein endothelial cells (HUVEC, provided by Nanjing Keygen Biotech Co. Ltd.) were routinely grown in DMEM, supplemented with 20% heat-inactivated fetal bovine serum (FBS) and 25 μg of endothelial cell growth factor. Mice were purchased from the Shanghai Laboratory Animal Center of the Chinese Academy of Sciences. Synthesis of the peptides was performed by GL Biochem (Shanghai) Ltd. All peptides are

very soluble in water. The purity of the products was more than 99% by analytical high-performance liquid chromatography. Amino acid analysis and mass spectroscopy were conducted to confirm their compositions.

N-terminal amino-acid sequence analysis was performed at Fudan University (Shanghai, China). Endostatin was expressed in *E. coli* and purified by our laboratory. Antibodies were purchased from Boster Biological Company (Wuhan, P. R. China).

Preparation of Conditioned Medium. Confluent cells were washed and grown in serum-free DMEM. After 20 h of incubation, conditioned medium was collected and centrifuged at 500 × *g* for 10 min and then at 800 × *g* for 20 min to remove debris. The resultant conditioned medium was immediately used for migration and tube formation assays or stored at −70 °C until use.

Cell Migration Assay. To quantify cell migration, a modified Boyden chamber assay was used as described previously (*21*). Polycarbonate filters with 8 μm pores in a 24-well Transwell chamber (Costar, Shanghai, China) were coated with 15 μL Matrigel (Becton-dickinson, Shanghai, China, 50 μg/pore) and placed at 37 °C for 1 h. Cells (0.5 mL, 8×10^4) suspended in serum-free medium were placed in the upper compartment of the chambers. Six hundred microliters of conditioned medium was added to the lower compartment. Following 48 h incubation at 37 °C, cells in the upper chamber and the remaining cells on the upper surface of filters were mechanically removed. After washing with phosphate-buffered saline (PBS), the membranes were fixed in 30% methanol for 10 min and stained with 0.1% methyl violet, and the cells that migrated to the lower surface were counted under inverted microscope at 200× magnification. Five random fields from each well were counted, and values represent five independent experiments. Migration activity was assessed by the average number of cells that migrated to the lower surface of the filter.

Tumor Implantation. B16F10 mouse melanoma, human gastric cancer cell line MGC-803, and human hepatic carcinoma SMMC-7721 cell line were grown in culture. Cell lines were washed with PBS, dispersed in a 0.05% trypsin solution, and resuspended. After centrifugation at 800 × *g* for 5 min, the cell pellets were resuspended in PBS and adjusted to a concentration of 2.5×10^6 cells/mL. BALB/c nude female mice, 5−6 weeks old, were implanted subcutaneously (s.c.) on the midright side with 5×10^6 MGC-803, SMMC-7721 cells in 0.2 mL PBS. C57BL/6 female mice (5−6 weeks old) were implanted s.c on the midright side with 1×10^6 B16F10 cells in 0.2 mL PBS.

C57BL/6 Female Mouse Treatment. After the B16F10 mouse melanoma tumor mean volume reached 100−300 mm^3, mice were separated randomly into different groups with eight mice per group. Group 1 received recombinant human endostatin at a dose of 10 mg/kg in 0.1 mL PBS, and group 2 was injected with an equal volume of PBS. The other nine groups were treated with P1, P2, or ES-2 at doses of 5, 10, or 20 mg/kg in 0.1 mL PBS. All of the groups were injected s.c., at a site distant from the tumor, once daily for 10 d. After the first round of treatment, we carried out another round of treatment with P1 alone, at doses of 6, 3, and 1.5 mg/kg.

BALB/c Nude Mouse Treatment. After the mean SMMC-7721 tumor volume reached 100−300 mm^3, mice were randomly divided into four groups with eight mice per treatment group and twelve mice in the negative control group. Group 1 received paclitaxel (Taxol, provided by Tai ji Pharmaceutical Co. Ltd., Chendu in Sichuan province of China) at a dose of 10 mg/kg, group 2 received equal volume injections of PBS alone. Another group was treated with P1 at a dose of 3 mg/kg. All the nude mouse treatment groups were injected intravenously with 0.1 mL of the drug, once a day for 10 d. Mice implanted with MGC-803 tumor cells were injected with 3 mg/kg/d of P1 peptide. The duration of this treatment was also 10 d.

Measurement of Tumor Growth. Tumors were measured individually with a vernier caliper. Volumes were determined using the formula: tumor volume = length × width^2 × 0.52. Therapeutic effects on tumor growth were expressed as mean tumor volumes versus time, calculated as $(1 - T/C) \times 100\%$, where T = treated tumor volume and C = control tumor volume. For example, if treated tumors were 40% of the volume of control tumors on a given day, tumor suppression in the treated group was 60%.

Western Blot Analysis. Cells were harvested, centrifuged, and the protein fractions separated. The protein was analyzed by 10% SDS-PAGE and further identified by Western blot analysis with PVDF Western blotting membranes (Roche, Shanghai, China) and mouse polyclonal antibody.

Flow Cytometric Analysis of Peptide Binding. Cells were grown in a 24-well plate until 80% confluency, harvested, and washed twice with ice-cold PBS. Before labeling, cells were resuspended in PBS + 1% bovine serum albumin (BSA) for 30 min, then added with 1 μL fluorescein isothiocyanate (FITC)-labeled peptides (P1, P2, RGD, and ES-2) for an additional 25 min. After labeling, cells were collected and washed again with ice-cold PBS twice, resuspended in PBS at a volume of 400 μL, and analyzed with flow cytometry (Becton Dickinson, Shanghai, China). To exclude nonviable cells, 0.5 μM of each peptide was added immediately before analysis. FITC fluorescence was measured in FL1 channel. Cells with FITC emission were gated for further analysis.

Histochemistry and Immunohistochemistry. Mice were euthanized 2 weeks post-treatment, and tumor tissue was collected, fixed with 4% formaldehyde, embedded in paraffin, and sectioned for hematoxylin and eosin (H&E) staining and immunohistochemical staining for CD31. H&E staining was performed according to standard histological procedures. Necrosis and vascularization in tumor tissue were observed under a light microscope. Vascular structures in tumors were evaluated by immunohistochemical staining of CD31 with rabbit anti-CD31 polyclonal antibody (Boster Biological Company). Briefly, staining for CD31 was performed on sections using their specific primary antibodies and biotinylated goat antirabbit secondary antibody, incubated with horseradish peroxidase-labeled streptavidin, visualized with diaminobenzidine (DAB) chromogen, counterstained with hematoxylin, and observed with a microscope.

Three-Dimensional Modeling. Modeling of the composed peptides' structure was done by using the InsightII/CHARMm module (Accelrys Inc., USA). During the simulation, residues 1 to 11 of P1 and residues 8 to 18 of P2 were combined by template which is the structure of residues 50 to 60 in human endostatin (Protein Data Base, PDB ID: 1BNL). The modified protocol was performed by 500 steps of steepest descents (convergence is 0.1 kcal/mol) and 500 steps of conjugate gradients (convergence is 0.01 kcal/mol) under the CHARMm27 force field. Then, simulation of the three-dimensional structure was performed by molecule dynamics at 300 K.

Statistical Methods. Data are expressed as mean ± SD. Statistical significance was assessed using the Student *t* test. For all statistical comparisons, treated groups were compared

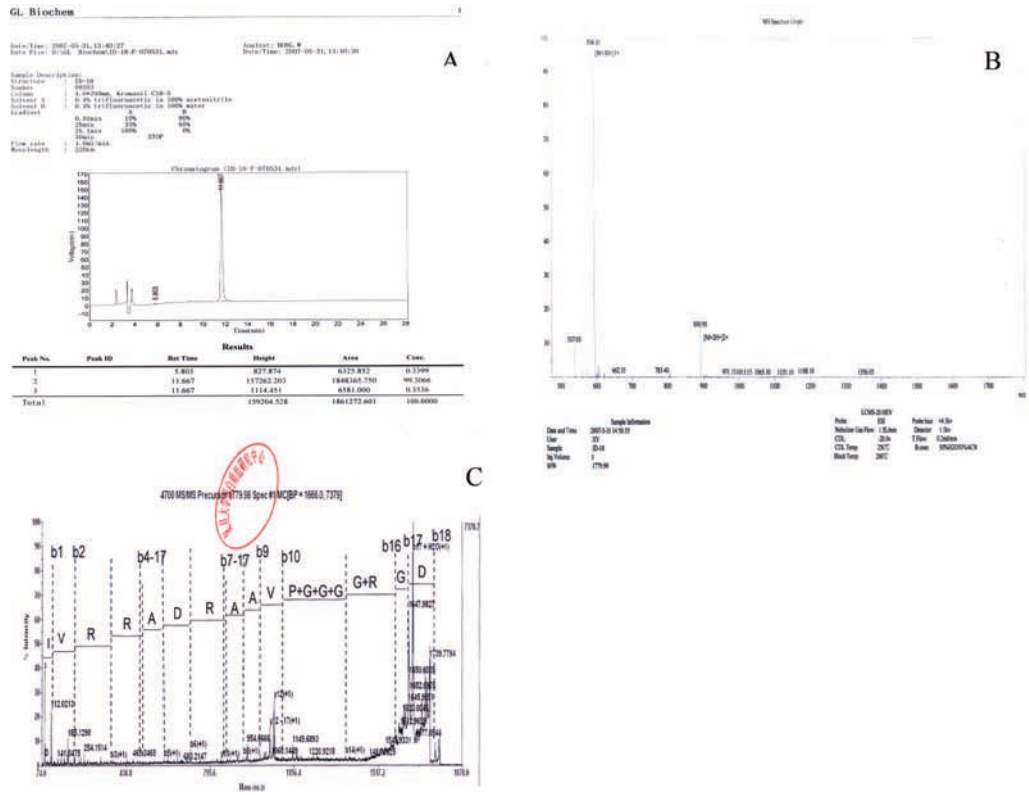

Figure 1. HPLC (A), mass spectroscopy (B), and amino acid sequencing (C) analyses of peptide P1.

with PBS-treated controls, and $P < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Endostatin, after its approval for clinical use, has given a new dimension to cancer treatment by targeting the tumor vasculature; however, the exact mechanism of endostatin remains unknown. Moreover, it is relatively expensive compared to other conventional antineoplastic drugs such as chemical antiangiogenic agents. These disadvantages limit its further use. Recently, evidence has outlined the role of integrin binding in the biological effects of endostatin in the cell (*22*−*24*). In another study, it was shown that an arginine-rich peptide, ES-2, in the soluble form inhibited basic fibroblast growth factor-induced directional migration and tubular morphogenesis of microvascular endothelial cells (*12*). The peptide induced the loss of focal adhesions and actin stress fibers in these cells. This activity was found to be lost in mutated peptides where arginine residues were substituted with alanine. This reflects some of the properties of endostatin that are associated with the heparin-binding characteristic of endostatin. However, in one study, an endostatin peptide (hP3) that contains ES-2 failed to inhibit tumor growth *in vivo* (*13*). The authors found that the entire antiangiogenic activity of endostatin was located in a 27-amino-acid peptide that binds Zn, and showed that Zn binding was required for antitumor and antimigration activities of endostatin. These results indicated that the mechanism of endostatin is complex and the unique chemical composition of each protein (or peptide) is important for its function. A change in just one amino acid can change the structure and function of a protein, so an endostatin-derived peptide could not reflect the true characteristic of endostatin.

Therefore, protein properties and activities relate to the number and type of factors. Although certain amino acid sequences can be identified as more likely to have activity *in vitro*, it is still not possible to completely predict whether the protein will be active *in vivo*. The *in vitro* antimigratory activity of ES-2 has been mapped to 60−70 amino acids of endostatin (*12*), but the *in vivo* inhibitory effect of this peptide remains poorly investigated. Peptides containing ES-2 (like hP3) cannot reflect the true characteristics of ES-2. However, ES-2 is the shortest active sequence derived from endostatin, and the results of antimigratory activity shed some light on reducing the cost of endostatin. The synthesis of a smaller peptide is much simpler and less expensive when compared to the expression and purification of endostatin, and its mechanism is clear. Still, it is necessary to identify the *in vivo* activity of ES-2.

We previously tested the antiangiogenic activity of ES-2 peptide. ES-2 at different concentrations was loaded onto chick embryos to validate the *in vivo* antiangiogenic activity, the results of which demonstrated that ES-2 dose-dependently suppressed the embryonic neovascularization and angiogenesis (*18*). Furthermore, ES-2 higher than 200 ng/mL almost completely prevented blood vessel formation and was lethal to the chicken embryo. These data indicate that the ES-2 peptide is a potent inhibitor of angiogenesis.

However, in a tumor-bearing mouse model, we found that ES-2 peptide did not show any significant antitumor activity (data not shown). We speculate that this inconsistency may be due to the lesser bioavailability and/or receptor binding by ES-2 peptide. A possible explanation could be that heparin may not be the only candidate for this peptide, which could mean it has to bind to another ligand and/or receptor *in vivo*. Additionally, direct administration of the peptide in chick embryo assay will lead to better bioavailability of the drug, but in an animal model, the drug is distributed to many compartments. Biotransformation of these drugs could lead to its inactivation because of the changes in the elimination after metabolism or the effects of other biomolecules. If ES-2 could be effectively transferred to tumor angiogenic endothelium, it may exhibit antitumor activity.

Recently, lines of evidence have shown that the addition of RGD, or RGD-4C short peptide, facilitates the molecular

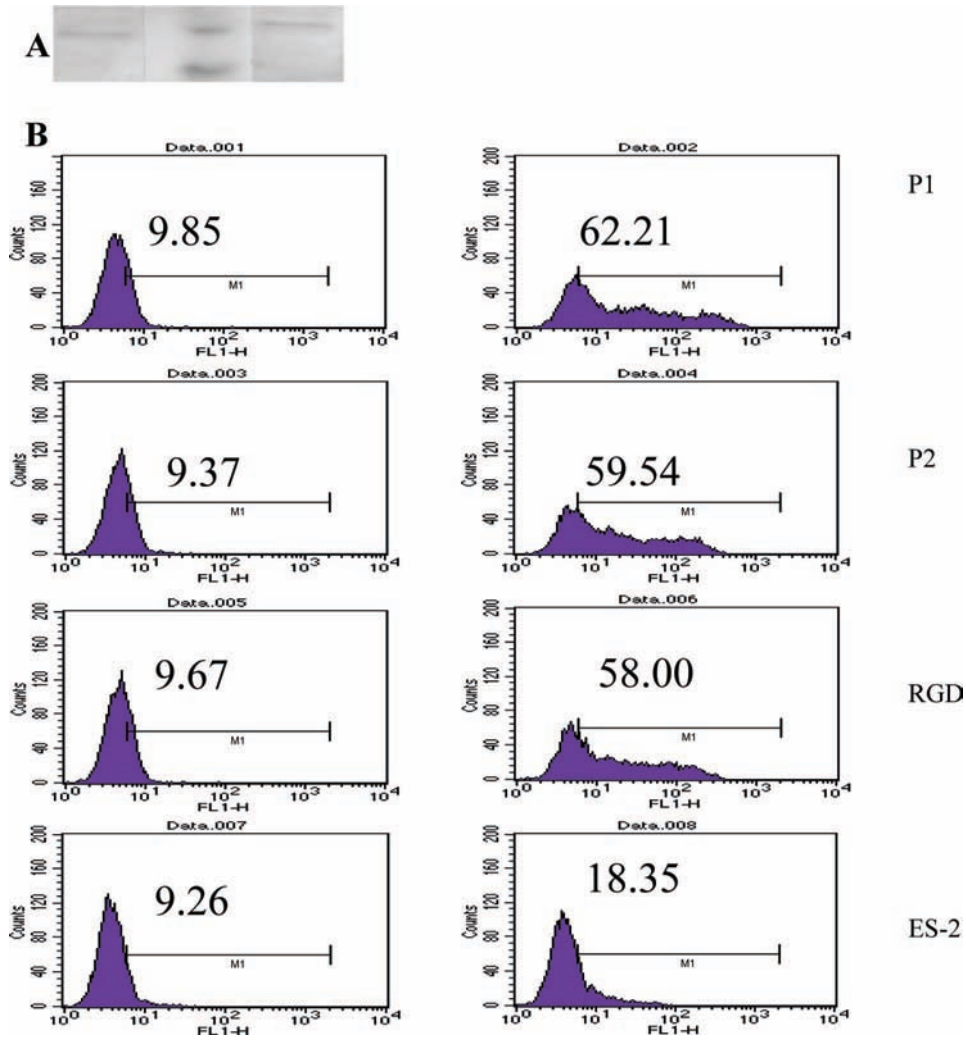

Figure 2. Western blot analysis of the expression of integrin αv and $\beta 3$ in human Bel-7402 cells using mouse antihuman integrin polyclonal antibody (A). Flow cytometry demonstrating the binding of RGD-FITC-labeled peptide to human Bel-7402 cells (B).

targeting of integrins on angiogenic endothelium, which has proven to be an effective strategy for delivering a drug to the tumor vasculature. The RGD sequence on ES-2 might have the ability to bind with the tumor endothelial cells. In view of this fact, we synthesized two peptides with RGD attached to the amino and carboxy terminals of ES-2. Four glycine residues were added between the RGD motif and ES-2 in an attempt to increase its flexibility (Table 1). The purity, molecular weight, and sequence of P1 were shown (Figure 1).

First, we wanted to know whether the modified peptides could efficiently bind integrins. Western blot analysis was performed on human hepatic carcinoma Bel-7402 whole-cell lysates using integrin αv and $\beta 3$ polyclonal antibody, and expression of both subunits was observed in Bel-7402 (Figure 2A).

A target analysis was performed on P1 and P2 coupled with FITC; RGD and ES-2 coupled with FITC were used as positive control and negative control, respectively. Bel-7402 cells were used as the target to determine the RGD-FITC-peptide binding with the cell surface receptors (integrins). Flow cytometric analysis of FITC-peptides binding to tumor cells was performed. A positive reaction was seen with P1, P2, and RGD, while ES-2 did not bind to cells (Figure 2B), which suggested that RGD-modified ES-2 could specifically bind to the receptor expressed by Bel-7402 tumor cells, resulting in efficient antitumor activity of P1 and P2 *in vivo*.

Reselection was performed with the mutant peptides. First of all, *in vitro* selection has been used to find the peptides with similar or better activity than ES-2. To investigate the role of the peptides for their antimigratory effect, transwell chamber migration assays were performed using the synthetic peptides. P1, P2, and ES-2 all displayed reduced HUVEC ability to migrate toward the basic fibroblast growth factor (bFGF) stimulus. At 1 μg/mL, P1 was most effective in inhibiting migration of HUVEC (Figure 3). Thus, P1 and P2 were used for further investigations.

For the *in vivo* assay, the mice (C57BL/6) implanted with B16F10 melanoma cells were injected s.c. with the peptides to perform the preliminary screening. According to published data, 5−20 mg/kg/d of endostatin has been reported to exert an antitumor effect; we used doses up to 20 mg/kg/d in the experiment. We assessed P1 and P2 at three doses of 20, 10, and 5 mg/kg/d and discovered that 5 mg/kg/d has the most effective cytostatic effect on the melanoma (data not shown). On the basis of this finding, we performed another experiment by testing three smaller doses, i.e., 6, 3, and 1.5 mg/kg/d, and found that 3 mg/kg/d of P1 or P2 was most effective in arresting the growth of the tumor (data not shown). Moreover, we also discovered that the administration of the drug twice a day had the most desirable effect. Adding RGD peptide sequences to any protein can cause its binding to antiangiogenic integrins. Hence, it is not clear that the biological effects are associated with ES-2 or RGD. It would be important to compare the active peptide with RGD and modified inactive endostatin sequence for reference. A mutated peptide, ES-2mut1, displayed reduced

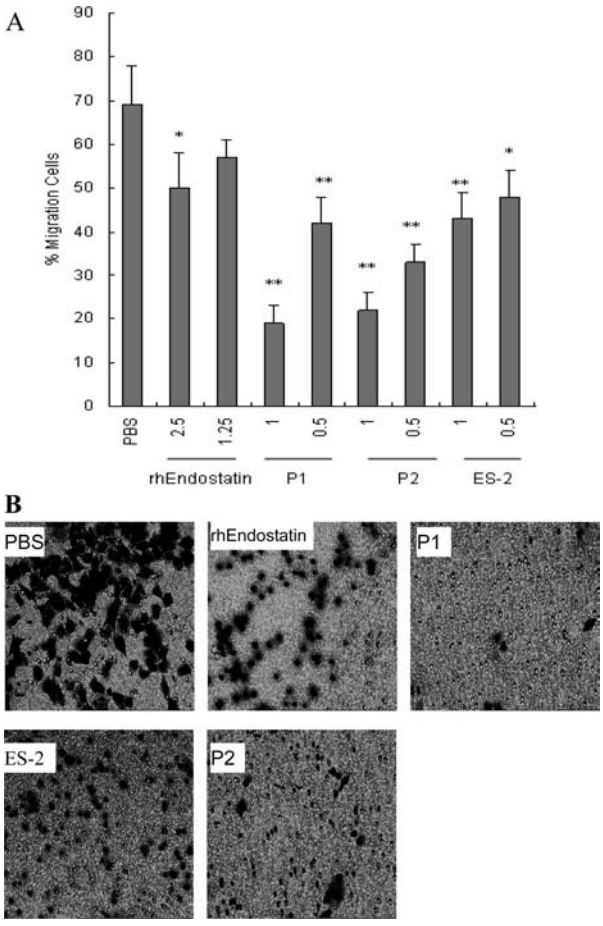

Figure 3. Inhibition of endothelial cell migration by synthetic peptides. The migration response of HUVEC was assayed by the Boyden chamber. Cells were treated with P1, P2, and ES-2. As controls, rhEndostatin and PBS were used. Columns represent mean ± SD of 5 experiments (*P < 0.05; **P < 0.01 vs control).

levels of activity compared with ES-2 (*12*). RGD was also introduced into the carboxy terminal of ES-2mut1 (i.e., P3). We found that P3 and RGD all exhibited moderate antitumor activity (compared with P1 and P2; data not shown), suggesting that the two domains were involved in the antitumor activity.

On the basis of these findings, we selected P1 to further examine their effects on tumor-bearing nude mice (P1 and P2 were all modified by RGD and P2 has antitumor effects similar to P1, so only P1 was selected). ES-2 did not show any activity *in vivo*, while endostatin expressed and purified by different laboratories had different antitumor effects because of the inclusion body's denaturation and renaturation, so for this paper, further experiments of ES-2 and endostatin were not conducted. Taxol is a standard drug for the treatment of advanced cancer, and in order to get a reliable and comparable result, we selected Taxol as a positive control. *In vivo*, the results show that intravenous injection of P1 at 3 mg/kg/d inhibited human SMMC-7721 hepatic carcinoma growth by 78% (Figure 4A). However, P1 displayed higher antitumor effects as compared to Taxol at 10 mg/kg/d, suggesting that P1 has significant antitumor effect at lower doses. We performed an additional series of experiments in a human gastric tumor model. The intravenous injection of P1 at 3 mg/kg/d inhibited human gastric cancer cell MGC-803 growth by 58% (Figure 4B).

We also examined the effect of the peptides on tumor tissue. P1 displayed more severe tissue necrosis than the control (Figure 5A,B). The control displayed necrosis interspersed with viable tumor cells, whereas P1 induced large areas of continuous necrosis within tumors. We then counted the number of visible

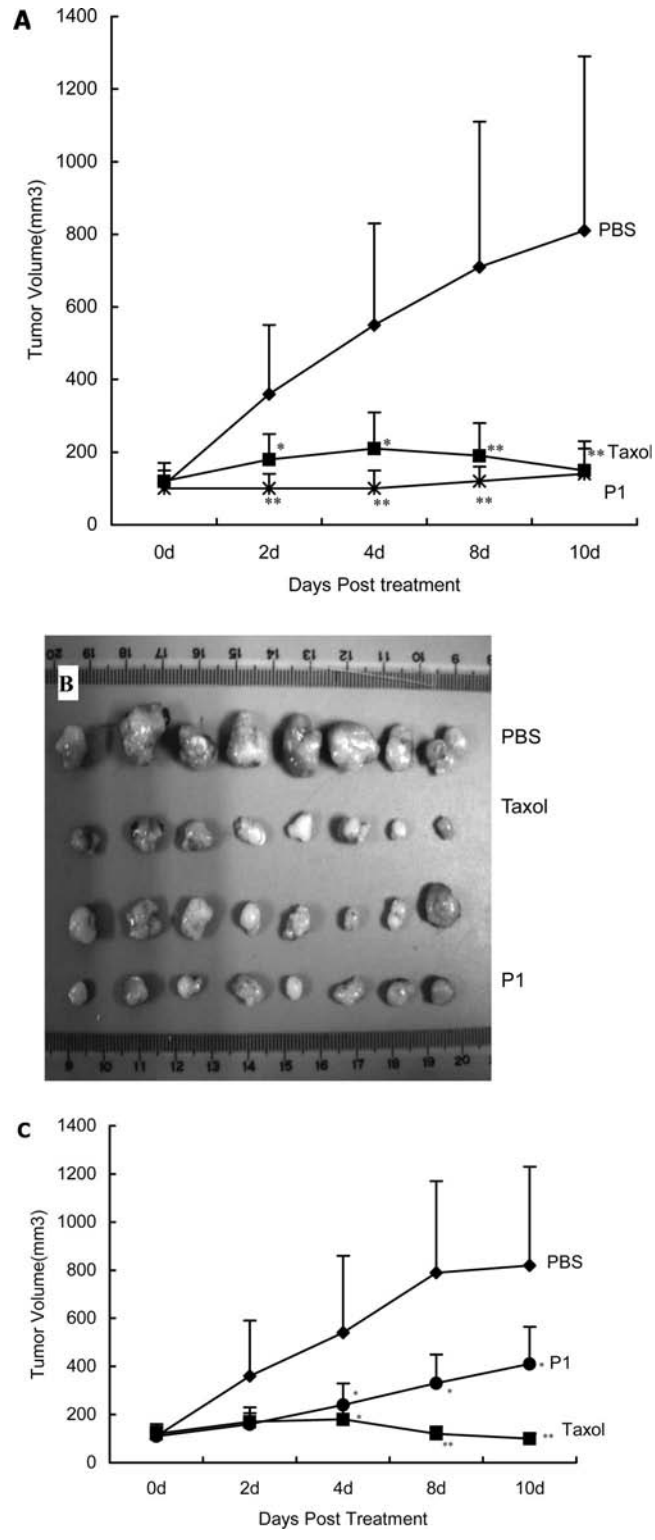

Figure 4. Therapeutic effects of peptides on the growth of tumor. (A) represents human SMMC-7721 hepatic carcinoma suppression mediated by 3 mg/kg P1 twice a day. (B) displays the tumor in different treatment groups. (C) MGC-803 human gastric cancer suppression by 3 mg/kg P1 twice a day. Each point represents mean ± SD of each group (*P < 0.05; **P < 0.01 vs control).

blood vessels in CD31 staining, and found that P1 significantly reduced the vessel density compared to control (Figure 5C,D,E) (P < 0.05).

The finding that the addition of RGD at amino and carboxy terminals has the same result calls for a justification. The peptides with an additional RGD sequence (P1, P2), regardless

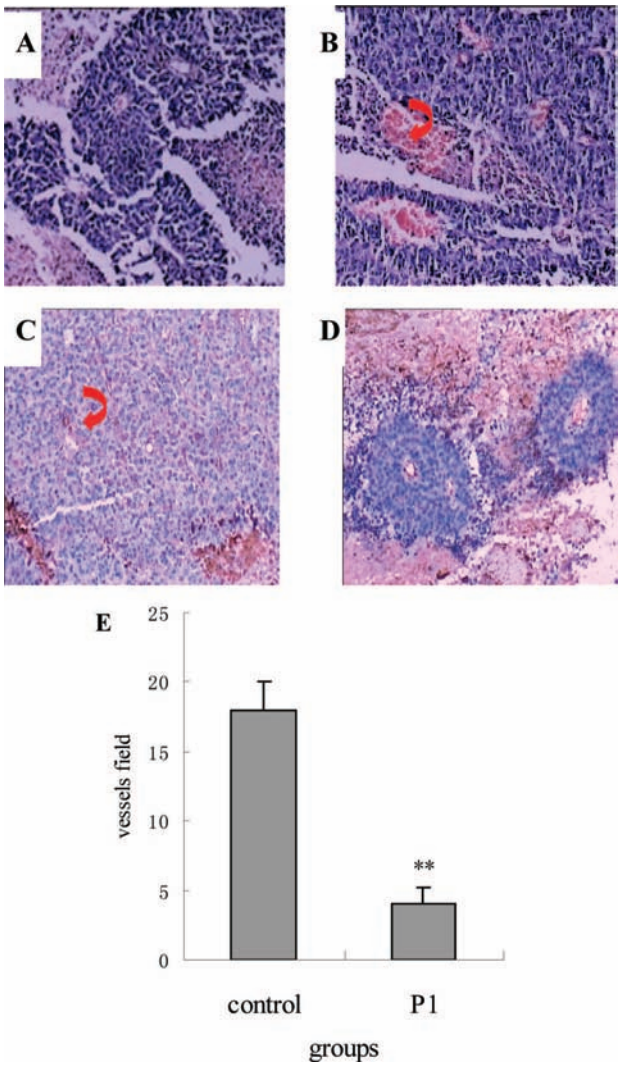

Figure 5. Necrosis areas within tumor and tumor blood vessel density. The figure shown by H&E staining observed with light microscope (40× original magnifications). PBS (A) treatment exibit incomplete tissue necrosis interspersed with viable tumor cells. (B) represents P1 treatment, showing continuously extensive necrosis area. (C, D, E) Tumor blood vessel density. (C) represents PBS, and (D) represents P1 treatment. Blood vessels in CD31 staining were indicated with arrows (40× original magnifications). Results were expressed as mean ± SD of nine regions of three sections per group (*P < 0.05; **P < 0.01 vs control).

of its location at either the amino or carboxy terminal, show an effective arrest of tumor growth. This may be due to the fact that the RGD peptide, the primary recognition sequence of some integrins, has less secondary structure (Figure 6A,B), thus P1 and P2 exhibited similar binding capability to integrins.

ES-2 is the smallest endostatin structure unit that has been discovered recently, but there is no further *in vivo* assessment to support its effectiveness. In this study, we evaluated the effectiveness of ES-2 *in vivo* for the first time, along with the determination of the most effective dosage range of modified ES-2, the most effective administration frequency, and the change in its *in vivo* activity after the addition of an RGD motif at different locations. We also performed the histochemical and immunohistochemical analysis of the tumor under investigation. Moreover, safety experiments were conducted to study the possible toxic effects of P1, and a tail vein injection of 1500 mg/kg/d P1 into Kunming strain mice revealed no evidence of toxicity in the treated animals (data not shown). These results show that P1 is an effective and safe peptide as an anticancer

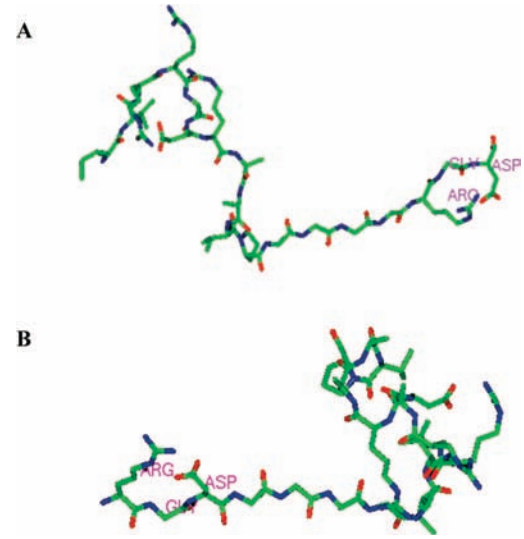

Figure 6. Modeling of the structures of the composed peptides was done by using the InsightII (Accelrys Inc.)/CHARMm module. Peptides 1 and 2 (A,B) have less secondary structure and fold in an extended manner.

drug. RGD modified ES-2 (P1 and P2) has only 18 amino acids and showed remarkable suppression of growth of human gastric and hepatic cancer at doses as small as 3 mg/kg/d. The study has proven that the addition of RGD motif to peptides is an effective strategy for the delivery of the peptide to the tumor vasculature.

During the past decade, RGD peptides have become a popular tool for the targeting of drugs and imaging agents to tumor vasculature expressing αv and β3 integrins. Some of these products show impressive results in preclinical animal models, and an RGD-targeted radiotracer has already successfully been tested in humans for the visualization of αv and β3 integrins, which demonstrates the feasibility of this approach (*25*−*27*).

The study on P1 and P2 has made it possible to develop a new drug to fight solid tumors. We are currently investigating the activity of P1 and P2 on another four types of human cancer. We also plan to study the pharmacokinetic and pharmacodynamic aspects of peptide P1, to ensure a better clinical application of it.

ACKNOWLEDGMENT

The authors are grateful to Zichun Hua (Department of Life Science, Nanjing University, 210008, P. R. China) for providing B16F10 mouse melanoma. We thank Dr. Yinwu (Department of Life Science, Nanjing University, P. R. China) for critical reading of the manuscript and Drs. Wanzhou Zhao, Yijun Sun, and Junshi Ma for assisting us to implant tumors.

Amphiphilic Block Copolymers Enhance Cellular Uptake and Nuclear Entry of Polyplex-Delivered DNA

Zhihui Yang, Gaurav Sahay, Srikanth Sriadibhatla, and Alexander V. Kabanov*

Center for Drug Delivery and Nanomedicine and Department of Pharmaceutical Sciences, College of Pharmacy, University of Nebraska Medical Center, 985830 Nebraska Medical Center, Omaha, Nebraska 68198-5830, and Faculty of Chemistry, M.V. Lomonosov Moscow State University, 119899 Moscow, Russia. Received April 4, 2008; Revised Manuscript Received July 25, 2008

This work for the first time demonstrates that synthetic polymers enhance uptake and nuclear import of plasmid DNA (pDNA) through the activation of cellular trafficking machinery. Nonionic block copolymers of poly(ethylene oxide) and poly(propylene oxide), Pluronics, are widely used as excipients in pharmaceutics. We previously demonstrated that Pluronics increase the phosphorylation of IκB and subsequent NFκB nuclear localization as well as upregulate numerous NFκB-related genes. In this study, we show that Pluronics enhance gene transfer by pDNA/polycation complexes ("polyplexes") in a promoter-dependent fashion. Addition of Pluronic P123 or P85 to polyethyleneimine-based polyplexes had little effect on polyplex particle size but significantly enhanced pDNA cellular uptake, nuclear translocation, and gene expression in several cell lines. When added to polyplex-transfected cells after transfection, Pluronics enhanced nuclear import of pDNA containing NFκB binding sites, but have no effect on import of pDNA without these sites. Altogether, our studies suggest that Pluronics rapidly activate NFκB, which binds cytosolic pDNA that possesses promoters containing NFκB binding sites and consequently increase nuclear import of pDNA through NFκB nuclear translocation.

INTRODUCTION

Nonviral gene delivery systems, such as DNA incorporated in cationic lipids, polycations, or nanoparticles, are safer, cheaper, and easier to produce in comparison to viral vectors (*1*). Unfortunately, these systems are also much less efficient in delivering DNA and initiating gene expression than the viruses. This is due to low efficacy of the nonviral vectors in overcoming numerous barriers for gene delivery into a cell. These barriers include (i) cellular uptake by endocytosis, (ii) escape from endosomes prior to delivery to lysosomes, (iii) release to the cytoplasm, and (iv) transport to the nucleus. Nuclear delivery of the DNA is believed to be among the most challenging barriers for every type of nonviral vector (*2*). Its significance is evident from numerous studies showing that microinjection of plasmid DNA (pDNA) into the cytoplasm results in negligible expression compared to expression of the same pDNA injected directly in the nucleus (*3*−*7*). It is well-known that nuclear import substrates, such as transcription factors, contain nuclear localization signals (NLSs) that are recognized by nuclear import factors (*8*). Hence, NLS-containing peptides or proteins were coupled to pDNA to facilitate its nuclear delivery (*9*−*21*). As an alternative, we posit that some safe and nontoxic pharmaceutical excipients can activate selected cell signaling pathways (*22, 23*) and harness cell trafficking machinery to enhance nuclear transport of pDNA without DNA modification. In particular, a nonionic block copolymer of poly(ethylene oxide) and poly(propylene oxide), Pluronic, can activate a transcription factor, NFκB, in cells and enhance gene expression *in vitro* and *in vivo* without inducing a cytotoxic effect (*24, 25*). It is known that NFκB can bind pDNA in cytoplasm and transport it to the nucleus through nuclear transport machinery (*26*−*28*). In this study, we demonstrate for the first time that Pluronic enhances both cellular uptake and nuclear transport of pDNA delivered into cells with DNA/polycation complexes ("polyplexes") and suggest that by combining Pluronic with existing nonviral vectors the efficiency of gene delivery can be safely increased.

MATERIALS AND METHODS

Materials. Nonionic block copolymers Pluronic P123 and Pluronic P85 were kindly provided by BASF Corp (Parsippany, NJ). SP1017, a mixture of 0.25% Pluronic L61 and 2% Pluronic F127, was kindly provided by Supratek Pharma Inc. (Montreal, Canada). Exgen 500, a 22 kD linear PEI, was purchased from MBI Fermentas Inc. (Hanover, MD). The cyanine dimmer dye, YOYO-1, was purchased from Molecular Probes (Carlsbad, CA). Plasmid gWIZLuc (encoding luciferase, under control of CMV promoter) was purchased from Gene Therapy Systems, Inc. (San Diego, CA) and plasmid pEGFP-N1 (encoding enhanced green fluorescent protein (GFP)) was purchased from Clontech (palo Alto, CA). "PathDetect c*is*-Reporting Systems" containing luciferase reporter gene with NFκB and AP-1 response elements (pNFκB-luc and pAP-1-luc) were purchased from Stratagene (La Jolla, CA). All the plasmids were expanded in DH5α *E. coli* and isolated using Qiagen endotoxin-free plasmid giga-prep kits according to the supplier's protocol. TRIzol reagent was purchased from Invitrogen (Carlsbad, CA). Oligo GEArray Mouse NFκB Signaling Pathway Microarray was purchased from SuperArray Bioscience Corporation (Frederick, MD). Methyl-β-cyclodextrin (MBCD) and sucrose were purchased from Sigma Aldrich (St Loius, MO). Bovine serum albumin was purchased from Fischer Scientific (Waltham, MA).

Synthesis of PB25080 and P85PEI Conjugates. Cationic graft or block copolymers P85PEI and PB25080 were synthesized by Dr. Vinogradov at University of Nebraska Medical Center (UNMC). Briefly, in case of P85PEI (2 kDa) 20% of free terminal hydroxyl groups of Pluronics P85 were activated by 1,1′-carbonyldiimidazole (CDI) in anhydrous acetonitrile for 4 h at 20 °C and then reacted with equimolar quantity of branched PEI (MW 2 kDa) in 20% ethanol for 48 h at 20 °C.

The conjugate was purified from free PEI by gel permeation chromatography on Sephadex G-25 using 20% ethanol as eluent (*29*). To obtain PB25080 PEG (MW 8 kDa) was modified by one terminal hydroxyl group with 4,4′-dimethoxytrityl (DMT) chloride to obtain DMT-PEG (*30*). DMT-PEG was activated with CDI in acetonitrile and reacted with ethylenediamne to obtain monoamino-PEG. Monoamino-PEG was treated with D-biotin *p*-nitrophenyl ester in 5 mL of dimethylformamide containing 1% (v/v) of triethylamine for 18 h at 40 °C to obtain biotin-PEG. Biotin-PEG was treated again with CDI and then reacted with PEI (25 kDa) to obtain PB25080 (*31*).

Labeling of Pluronic. Ahydrous Pluronic P123 (2 mg) was activated with CDI (213 mg) in 10 mL of acetonitrile for 2 h at 37 °C and reacted with ethylenediamine (313 mg) in 20 mL ethanol for 12 h at room temperature. The reaction mixture was dialyzed in a 2 kD cutoff membrane against 15% ethanol for 72 h (change ethanol twice) and lyophilized. Amino-Pluronic (0.4 mg) was dissolved in 2 mL acetonitrile, mixed with 2 mL 0.1 M NaH_2CO_3 buffer, and reacted with 25 mg of rhodamine B isothiocyanate (RITC) or fluorescein isothiocyanate (FITC) in 1 mL dimethylformamide added dropwise over 10 min with stirring. After 2 h incubation at room temperature RITC- or FITC-labeled Pluronic was dialyzed in a 2 kD cutoff membrane in 20% ethanol for 72 h at 4 °C in dark and then lyophilized. Similar procedure was used for Pluronic P85. For cell uptake studies, the labeled Pluronic 123 was mixed with the unlabeled copolymer at 1:10 ratio.

Cell Culture. Mouse fibroblasts NIH 3T3 cell line and human prostate cancer PC-3 cell line were cultured in Dulbecco's Modified Eagle's Medium **(**DMEM**)** and RPMI 1640, respectively, supplemented with 10% heat-inactivated fetal bovine serum (FBS), 100 U/mL penicillin/100 μg/mL streptomycin (complete media). All tissue material media was obtained from Gibco Life Technologies, Inc. (Grand Island, NY). Stable transfected C2C12-CMV^{luc} cells were generated as described previously (*24*). Cells were seeded at a density of 50 000 cells per well in 24 well plates and allowed to adhere for 24−48 h prior to transfection. For confocal microscopy, cells were seeded onto untreated glass coverslips at 50 000 cells per coverslip.

Formation of Polyplexes and Transfection. Transfection solutions were prepared in 1.5 mL Eppendorf tube by mixing (i) 45 μL of pDNA (0.1 mg/mL) or 90 μL of YOYO-1 labeled pDNA (0.05 mg/mL), (ii) 9 μL of Pluronic P123 solution (Pluronic P85 or SP1017 when indicated), (iii) 150 μL of DMEM, and (iv) polycations. For transfections, cell transport, and localization studies, the polycation nitrogen to pDNA phosphate ratios (N/P ratio) were kept constant N/P = 8 for PB25080 and P85PEI and N/P = 9 for Exgen 500. For physicochemical characterization, the N/P ratios were varied as indicated below. The solutions were vortexed for 30 s immediately after addition of polycation, incubated for 5 min at room temperature, and supplemented with 1270 μL of complete media. Cells were incubated with transfection solution (250 μL per well or 500 μL per coverslip) for 2 h at 37 °C (5% CO_2), rinsed with phosphate buffer saline (PBS), incubated for additional 24 h in complete media, and analyzed for luciferase or GFP expression as previously described (*24*).

Particle Size. Effective hydrodynamic diameters were measured by photon correlation spectroscopy using a ZetaPlus Zeta Potential Analyzer (Brookhaven Instrument) equipped with the Multi-Angle Option at 22 °C at an angle of 90°. Prior to particle formation, all reagents were filtered through a Whatman 200 nm polysulfone filter. Data represents average of five separate 3 min analyses. All systems exhibited stable effective diameters over the measurement time.

Transmission Electron Microscopy (TEM). Polyplexes were prepared in Eppendorf tube by first, mixing 100 μL of 0.1 M phosphate buffer (pH7.0), 120 μL of 0.1 mg/mL gWIZLuc, and 6 μL of 5% Pluronic P123, and second, adding polycation, vortexing for 30 s, and diluting with phosphate buffer to 500 μL. A drop of the sample solution was allowed to settle on a Formavar precoated grid for 1 min, the excess sample was wicked away with filter paper, and a drop of staining solution (1% uranyl acetate) was allowed to contact the sample for 1 min. The samples were analyzed using a Philips 410 TEM microscope.

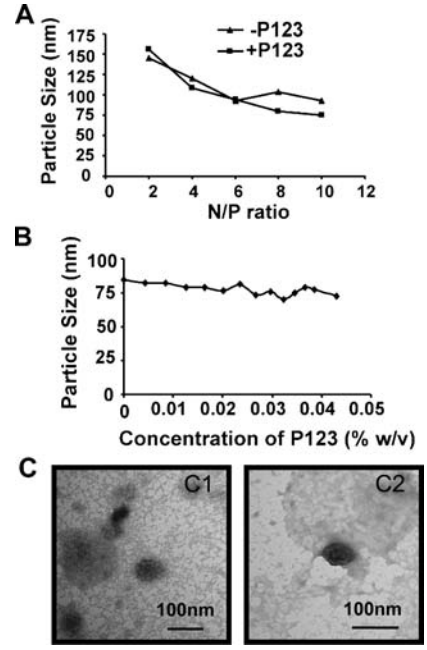

Figure 1. Effect of Pluronic P123 on the particle size and morphology of PB25080-based polyplex: (A−C) Particle effective diameters were measured at (A) various N/P ratios and (B) different Pluronic concentrations. (C) TEM images of PB25080-based polyplex without (C1) and with (C2) Pluronic P123. (B,C) Polyplexes were formed at N/P = 8. (A,C) Pluronic P123 concentration was 0.03% w/v. (A,B) All measurements were performed in phosphate buffer, pH 7.0.

Flow Cytometry Analysis. Polyplexes containing YOYO-1 labeled pDNA (*32*) with/without Pluronic were incubated with NIH 3T3 or PC-3 cells for 2 h at 37 °C (Figure 3). In select experiments, cells were pretreated for 30 min with inhibitors of endocytosis (2 mM MBCD or 0.25 M sucrose), and then, the same inhibitors were also present during subsequent incubation with the polyplex in presence or absence of the copolymer. Cells were washed by PBS, trypsinized, and suspended in 1% FBS. The mean fluorescence intensity was analyzed using Becton Dickinson FACStarPlus flow cytometer operating under Lysis II (San Jose, CA), equipped with an argon ion laser (excitation - 488 nm; emission filter - 530 ± 30 nm bandpass). Data were acquired in linear mode and visualized in logarithmic mode. Data from 10 000 events were gated using forward and side scatter parameters to exclude debris and dead cells. In a separate study, the flow cytometry analysis was performed to quantify the amount of DNA in nuclei isolated after transfection of the cells as described below.

Intracellular Trafficking. Cells were transfected with Exgen 500-based polyplex with/without RITC-labeled Pluronic P85. At the end of each time point, cells were washed, fixed (using 4% parafomaldehyde), labeled with ToPro-3 iodide, and examined under confocal microscope.

Nuclear Translocation. Cells were transfected for 2 h with YOYO labeled pAP-1-luc or pNFκB-luc using Exgen 500, washed twice with PBS, and then incubated in fresh medium with/without 0.03% Pluronic P123 for additional time points.

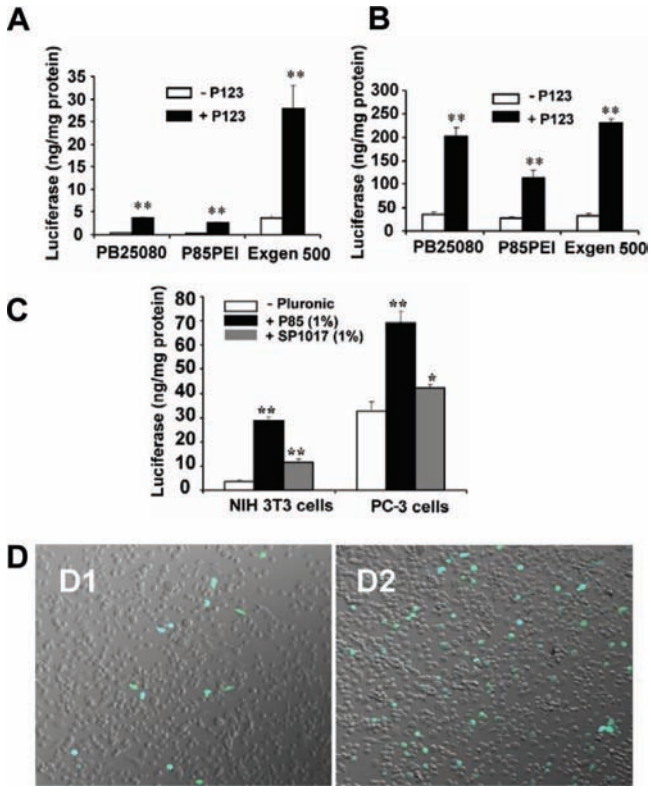

Figure 2. Enhancement of gene expression by Pluronic block copolymers in cells transfected with polyplexes. (A,B) Luciferase gene expression in NIH 3T3 (A) and PC-3 cells (B) transfected with different types of polyplexes containing gWIZLuc pDNA with/without 0.03% Pluronic P123 (** $p < 0.01$, $n = 3$). (C) Luciferase gene expression in NIH 3T3 and PC-3 cells transfected with Exgen 500-based polyplex with/without 1% Pluronic P85 or SP1017 (* $p < 0.05$, ** $p < 0.01$, $n = 3$). (D) Confocal microscopy images of GFP gene expression in PC-3 cells transfected with Exgen 500-based polyplex containing pEGFP-N1 pDNA without (D1) or with (D2) Pluronic P123.

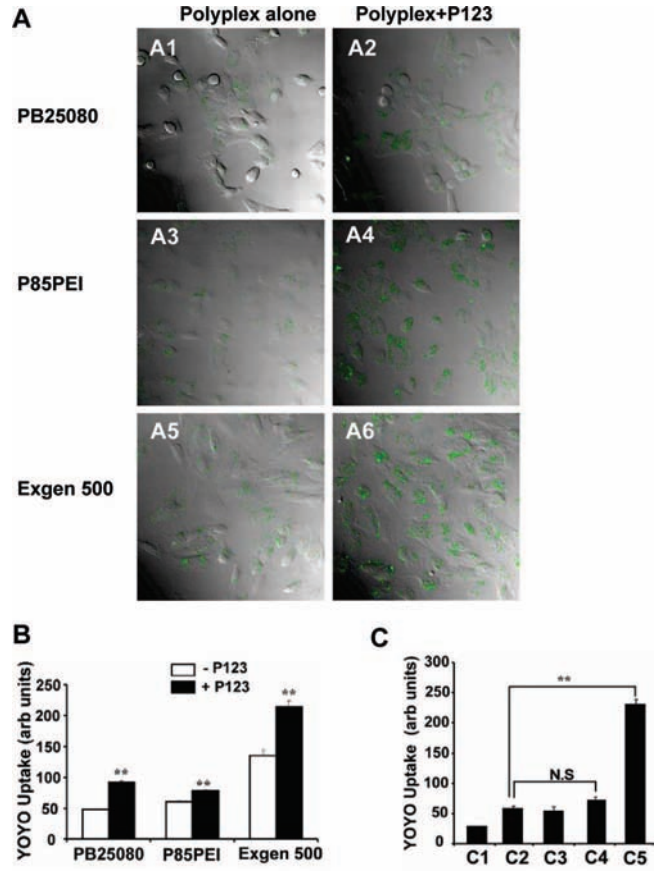

Figure 3. Effect of 0.03% w/v Pluronic P123 on uptake of the YOYO-1 labeled gWIZLuc pDNA in NIH 3T3 and PC-3 cells. (A) Confocal microscopy images of live cells 2 h after NIH 3T3 cells transfection with PB25080 (A1,A2), P85PEI (A3,A4), and Exgen 500 (A5,A6) based polyplexes without (A1,A3,A5) or with (A2,A4,A6) Pluronic P123. (B) Flow cytometry under the same transfection conditions as (A) comparing groups with/without Pluronic. (C) Flow cytometry of (C1) PC-3 cells alone and PC-3 cells transfected for 2 h with (C2) naked pDNA, (C3) naked pDNA with Pluronic P123, (C4) PB25080/pDNA polyplex, and (C5) PB25080/pDNA polyplex with Pluronic P123. (B,C) Statistical comparisons between (B) untreated and Pluronic P123 treated groups or (C) pDNA alone and polyplex-treated groups were made as follows ** $p < 0.01$, n.s., not significant ($n = 3$).

Localization of YOYO-1 labeled DNA was examined under the confocal microscope and flow cytometery was performed on nuclei isolated after transfection in these cells.

Nuclei Isolation. NIH 3T3 cells were plated in 100 × 20 mm^2 tissue culture plates (BD Biosciences, San Jose, CA) and grown overnight. Nuclei were isolated using Qproteome Nuclear Protien kit (Qiagen, Germantown, MD). Briefly, after transfection of YOYO-1 labeled DNA cells were washed twice with PBS, removed gently using a scraper, and centrifuged (12 000 rpm, 5 min, 4 °C). The pellets were lysed using the Qiagen lysis buffer supplemented with protease inhibitor solution and 0.1 M dithiothreitol, centrifuged, resuspended in the Qiagen detergent solution, centrifuged again, and then finally, the nuclei were resuspended in 1% bovine serum albumin in PBS.

Immunocytochemistry. Cells were pretreated with DMEM without FBS for 30 min and then treated with 0.03% FITC-labeled Pluronic P123 for 1 h, washed, and fixed with 4% paraformaldehyde. Rabbit anticaveolin-1-Cy3 antibody (1:100) (Sigma Aldrich, St Louis, MO) and mouse anticlathrin antibody (Affinity Bioreagents, Golden, CO) (1:10) were incubated in blocking buffer overnight at 4 °C. For detection of anticlathrin antibody specific IgG antibody conjugated to Alexa 568 (Invitrogen Inc., Carlsbad, CA) was added to cells for 1 h at 37 °C. After extensive washing, cells were labeled with ToPro-3 iodide, mounted with antifade reagent, and examined under confocal microscope.

NFκB Signaling Pathway Microarray. C2C12-CMV^{luc} cells were treated with 1% Pluronic P85 for 5 min, washed twice with PBS, and incubated for additional 3 h. Cells were collected and total RNA was isolated with TRIzol reagent, then quantified and qualified by UV spectrophotometry and gel electrophoresis, respectively. Oligo GEArray with 3 μg of total RNA of each sample was performed following the manufacture's protocol (cDNA synthesis; cRNA synthesis, labeling and amplification; cRNA cleanup; Oligo GEArray hybridization and detection). Statistical analysis was performed using the GEArray Expression Analysis Suite software.

Statistical Analysis. Unless indicated otherwise, statistical comparisons are made using Student's *t* test.

RESULTS

Polyplex Particle Size and Morphology. All polycations when mixed with the pDNA formed stable nanoparticles with effective diameters from approximately 85 nm for PB25080 to 180 nm for Exgen 500 (Table 1). Effective particle diameters were practically unchanged or changed slightly upon addition of Pluronic 123 using different orders of mixing (Table 1), N/P ratios (Figure 1A), or concentrations of the copolymer (Figure 1B). Similar results were observed with Pluronic P85 (not shown). Furthermore, the particle morphology as determined by TEM remained appear to be spherical (Figure 1C). Alto-

Table 1. Effect of Pluronic P123 on Particle Size for Different Polyplex Compositions and Component Mixing Orders

polyplex[a]	effective diameter (nm)[b]	polydispersity
DNA + P123	N/A	N/A
DNA + PB25080	85 ± 3	0.096
DNA + P123 + PB25080	76 ± 6	0.229
DNA + PB25080 + P123	72 ± 5	0.213
DNA + P85PEI	150 ± 2	0.155
DNA + P123 + P85PEI	120 ± 2	0.212
DNA + Exgen 500	180 ± 4	0.164
DNA + P123 + Exgen 500	160 ± 6	0.241

[a] Polyplexes were formed at N/P = 8 for PB25080 and P85PEI and N/P = 9 for Exgen 500. [b] Data are mean ± SEM (n = 5).

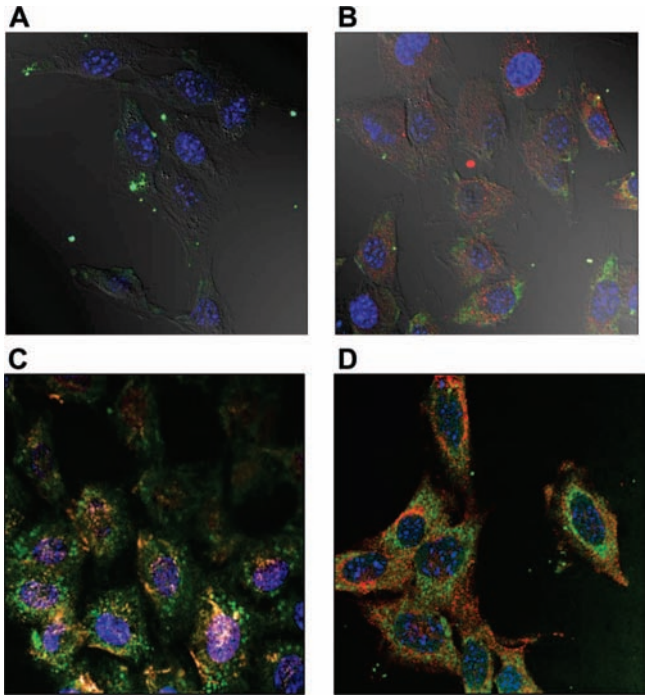

Figure 4. Cellular localization of fluorescently labeled DNA and/or Pluronic 123 examined by confocal microscopy on fixed NIH 3T3 cells. (A,B) Cells were transfected for 30 min with Exgen 500-based polyplex without (A) or with (B) 0.03% Pluronic P123. Signals correspond to YOYO-1 labeled gWIZLuc pDNA (green), RITC-labeled Pluronic P123 (red), and ToPro-3 stained nuclei (blue), respectively. (C,D) Cells were exposed to 0.03% Pluronic P123 alone for 60 min and then examined for colocalization of Pluronic P123 with caveolin-1 (C) and clathrin (D). Signals correspond to FITC-labeled Pluronic P123 (green), caveolin-1 (red), clathrin (red), and ToPro-3 stained nuclei (blue).

gether, these results demonstrate that addition of Pluronic results in little change in polyplex size or morphology.

Enhancement of Gene Expression with Pluronic. Significant enhancement of luciferase expression was observed upon addition of Pluronic P123, Pluronic P85, or SP1017 in both NIH 3T3 and PC-3 cells transfected with various polyplexes (Figure 2A−C). Overall protein levels in the cells treated with polyplexes were not affected by adding Pluronic (not shown) although the portion of cells expressing the transgene increased (Figure 2D). A similar enhancement was observed with several other polyplex types (Superfect, linear PEI) and in a different cell line (C2C12) (*24*). Thus, there is compelling evidence that Pluronic block copolymers enhance transfection by different polyplexes in numerous cell types.

Effect of Pluronic on DNA Uptake in Cells. Addition of Pluronic P123 considerably enhanced the uptake of polyplex-delivered DNA in NIH 3T3 cells (Figure 3A). The magnitude of the effect varied for each polyplex type (1.3, 1.6, and 1.9-fold for P85PEI, Exgen 500, and PB25080, respectively), but

Table 2. Effect of Endocytosis Inhibitors on Uptake of YOYO-Labeled gWIZLuc pDNA in NIH 3T3 Cells

	mean fluorescence (arb units)[a]	
polyplex	− P123	+ P123
DNA + PB25080	100 ± 3	158 ± 3
DNA + PB25080 + MBCD	75 ± 6**	111 ± 7**
DNA + PB25080 + sucrose	50 ± 1***	71 ± 1***

[a] Statistical comparisons were made for inhibitor treated and nontreated groups (** $p < 0.01$, *** $p < 0.001$, $n = 3$).

the differences in the presence of Pluronic were significant (Figure 3B). An even greater enhancement of uptake of polyplex-delivered DNA with Pluronic was observed in PC-3 cells (Figure 3C). In contrast, Pluronic did not affect uptake of the naked DNA. The effects of Pluronic on cell uptake were observed as early as 30 min after exposure (Figure 4A,B). Notably, Pluronic was internalized during the same period, but exhibited little if any colocalization with the DNA (Figure 4A,B). Interestingly, Pluronic exhibited greater colocalization with caveolin-1 compared to clathrin (Figure 4C,D). This is consistent with a recent study suggesting that caveolae-mediated endocytosis is a preferred pathway for cellular uptake of Pluronic individual molecules (*33*). At the same time, PEI-based polyplexes enter cells through both caveolae- and clathrin-mediated endocytosis (*34, 35*). Inhibitors of these pathways, MBCD for caveolae and hypertonic sucrose for clathrin, each significantly decreased uptake of pDNA delivered with polyplexes without and with Pluronic (Table 2). However, the effect of sucrose was much more pronounced than that of MBCD, suggesting clathrin-mediated endocytosis is a preferred route for the polyplex. Hence, Pluronic and polyplex are likely to have different internalization pathways, and the transport pathways of pDNA apparently did not change in the presence of Pluronic.

Enhancement of Nuclear Transport of DNA by Pluronic. Initial confocal microscopy of cellular localization of YOYO-1 labeled DNA suggested that the presence of Pluronic during transfection enhanced nuclear transport of the gWIZLuc plasmid at different time points (Figure 5). Specifically, in Pluronic treatment groups the DNA exhibited enhanced perinuclear localization 2 h after transfection and increased nuclear uptake 3 h after transfection. To exclude possible effects of the copolymer on the early stage of DNA internalization, the subsequent experiments first transfected cells with a polyplex without Pluronic (for 2 h) and then treated cells with Pluronic for different periods. In these experiments, along with the gWIZLuc plasmid we also used two other plasmids, pNFκB-luc and pAP-1-luc, containing NFκB and AP-1 response elements, respectively. Figure 6 presents the results both as quantification of the DNA in isolated nucleus as well as confocal images in live cells. The addition of Pluronic resulted in a quantitative increase in accumulation of the gWIZLuc and pNFκB-luc plasmids in isolated nuclei. The gWIZLuc is controlled by a CMV promoter, which also contains NFκB binding sites. In contrast, no increase in nuclei accumulation was observed with the pAP-1-luc, which does not contain NFκB binding sites. Altogether, these results suggest that Pluronic can enhance nuclear translocation of polyplex-delivered DNA in a promoter-dependent fashion.

Activation of NFκB Signaling Pathway by Pluronic. Pluronic was previously shown to activate the NFκB signaling pathway by inducing phosphorylation of IκB (*24*). Here, we examined the effect of Pluronic on NFκB-related genes using microarray (Figure 7). Pluronic P85 significantly upregulated

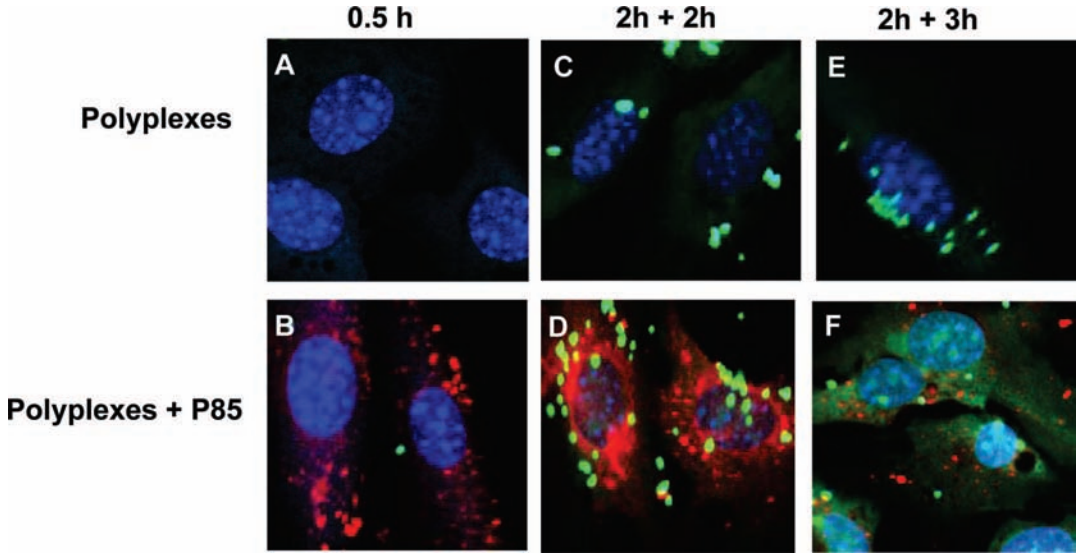

Figure 5. Effect of Pluronic on intracellular localization of DNA in NIH 3T3 cells. Confocal microscopy images of cells transfected with Exgen 500-based polyplexes with (B,D,F) or without (A,C,E) 1% Pluronic P85. Cells were exposed to polyplex for (A,B) 30 min or (C−F) 2 h and then incubated for additional 2 (C,D) or 3 h (E,F) in a fresh medium. Signals correspond to YOYO-labeled pDNA (green), RITC-labeled Pluronic P85 (red), and ToPro-3 stained nuclei (blue), respectively. This figure is representative of multiple areas in confocal images.

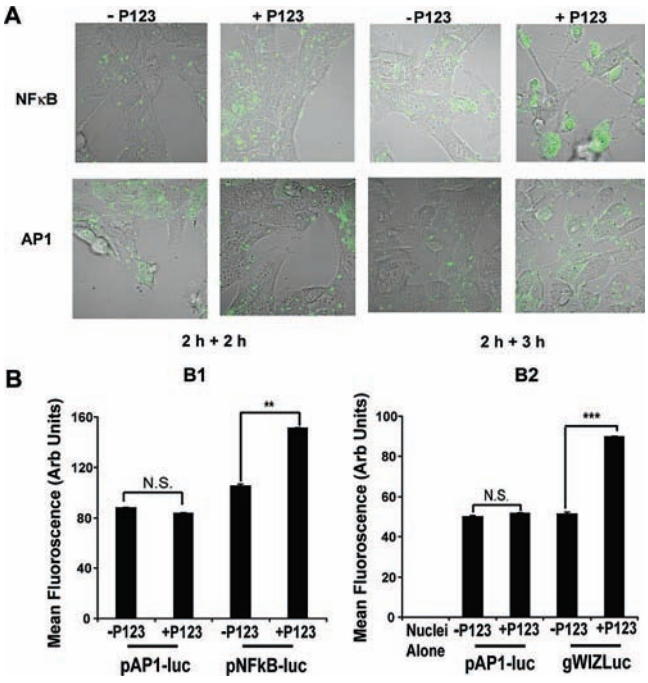

Figure 6. Promoter-dependent enhancement of nuclear transport of pDNA by Pluronic P123 in NIH 3T3 cells. (A) Confocal microscopy images of live cells transfected (2 h) with pNFκB-luc or pAP-1-luc using Exgen 500 polyplexes and then cultured for 2 or 3 h with or without 0.03% Pluronic P123. Signal corresponds to YOYO-1 labeled pDNA. (B) Flow cytometery of isolated nuclei of cells transfected with pAP-1-luc (as a control B1, B2) and either pNFκB-luc (B1) or gWIZLuc (B2). Cells were transfected using the same procedure as in (A) and then cultured for 3 h with or without 0.03% Pluronic P123. (B) ** $p < 0.01$, *** $p < 0.001$, n.s., not significant ($n = 3$).

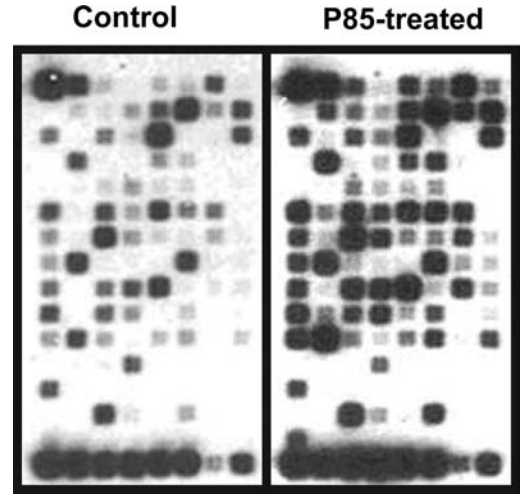

Figure 7. Effect of Pluronic on NFκB related genes expression in C2C12-CMV^{luc} cells. Cells were exposed to 1% Pluronic P85 for 5 min, washed by PBS, and incubated for additional 3 h. Total RNA was isolated and assayed using Oligo GEArray Mouse NFκB Signaling Pathway Microarray. A representative set of images is shown for control and Pluronic treated groups. The triplicate averaged data are presented in Supporting Information (Table S-1).

39 out of 113 genes related to NFκB-mediated signal transduction (Supporting Information Table S-1).

DISCUSSION

Inefficient nuclear translocation of DNA is believed to be the Achilles' heel of gene therapy (*36*). Coupling NLS peptides with pDNA to facilitate its nuclear import has been a major approach to address this problem (*9*−*21*). Our work demonstrates a simpler and potentially safer approach using a well-known pharmaceutical excipient, Pluronic block copolymer, to activate intrinsic nuclear translocation machinery and enhance nuclear gene transfer with polyplex-delivered pDNA. Pluronics are amphiphilic block copolymers that are widely used in pharmaceutical compositions and were evaluated successfully as intravenous agents in cancer therapy clinical trials (*37*). Astafieva et al. were the first to report that addition of Pluronic P85 can increase the uptake and expression of pDNA delivered by poly(*N*-ethyl-4-vinylpyridinium)-based polyplex (*38*). In this work, we demonstrate for the first time that Pluronics additionally increase nuclear transport of pDNA delivered with polyplexes in a promoter-dependent manner. To demonstrate the effects of Pluronics, we evaluated three representative polycations: (1) a linear PEI, Exgen 500; (2) biotin-modified graft copolymer of PEO and PEI, PB25080; and (3) a graft/block copolymer of Pluronic P85 and PEI, P85PEI. Among a variety

of polycations used in polyplexes, linear PEI is, perhaps, one of the most efficacious (*39, 40*). Two other PEI-based polycations evaluated in this work were developed in our laboratory to enhance polyplex stability in the body by grafting hydrophilic PEO chains to PEI (PB25080) (*30*) or enhance membrane interactions of polyplex by grafting amphiphilic Pluronic P85 to PEI (P85PEI) (*41*).

We previously suggested that Pluronic can increase gene transfer by binding with polyplexes and decreasing particle size (*32*). Since Pluronic is not charged, this interaction involves hydrophobic binding of poly(propylene oxide) chains of Pluronic with nonpolar sites in a polyplex. However, contrary to previously studied polyplex systems, which aggregated in the absence of Pluronic (*32*), the polycations used in this work each formed stable polyplexes with pDNA. Addition of Pluronic to these polyplexes resulted in little if any change in particle size. Furthermore, confocal microscopy suggested that Pluronic distribution within the cells was different from that of pDNA at each time point; i.e., Pluronic is not transported along with the DNA but may act independently, perhaps by affecting cell transport machinery, such as activating NFκB signaling pathway (as described later). Therefore, we propose that Pluronic acts as a biological response modifier, presumably by binding with cellular membranes and activating cell signaling pathways that enhance nuclear gene delivery (*22, 23*). This is supported by the observation that nuclear transport of the pDNA was enhanced when Pluronic was added to cells after polyplex transfection (Figure 6). The time course for the nuclear entry of pDNA, 4 to 5 h after beginning of transfection, is consistent with a previous report (*42*). Polyplexes formed by Exgen 500 rapidly escape the endosomes, spread into the cytoplasm, and then dissociate within 4 h, followed by the nuclear uptake of pDNA (*43, 44*). Previously, Pitard et al. reported that coinjection of pDNA and Pluronic L64 into the cytosol increased the percentage of cells expressing a reporter gene (*45*), suggesting that Pluronic may enhance transport of naked pDNA from the cytosol into the nucleus.

The involvement of the NFκB signaling pathway was directly demonstrated by the promoter dependence of Pluronic effect on pDNA nuclear uptake. The plasmids containing NFκB binding sites, gWIZLuc and pNFκB-luc, exhibited increased unclear uptake with Pluronic, while the pAP-1-luc plasmid, which lacks an NFκB binding, site did not. Evidence that supports the activation of the NFκB pathway by Pluronic was shown by phosphorylation of IκB within 5 min (*24*), increased NFκB nuclear localization (*25*), and upregulation of numerous NFκB-related genes. It has also been shown that NFκB can bind cytosolic DNA and transport it to the nucleus through nuclear import machinery (*27, 46, 47*). Furthermore, the NLS of NFκB alone can transport DNA across the plasma membrane and into the cytosol (*47*). Thus, the early stages of gene transfer may also be affected by the activation of NFκB, which would explain the increased cellular uptake of pDNA observed in this work. Altogether, we propose that Pluronics rapidly activate NFκB (*24*), and NFκB binds pDNA that contain NFκB-binding sites, then increases nuclear import of a pDNA through the NF-κB transport into the nucleus. Furthermore, following the delivery of pDNA to the nucleus, Pluronics increase transcriptional activation of genes through the NFκB signaling pathway (*24*). We present evidence here that Pluronic colocalizes in cells with caveolin-1, which regulates NFκB activation (*48*). In addition, an extensive study describing binding of Pluronic with caveolae and disruption of caveolae-mediated endocytosis has been recently published (*33*). Hence, there is a possibility that Pluronic activates NFκB through the disruption of caveolae.

The safety of Pluronic formulations may be an important advantage for their use in nonviral gene delivery. Even though NFκB was activated, inflammatory responses to Pluronics are mild and no cytotoxic effects are seen at their effective doses in many cell lines (*24*). More importantly, clinical trials in human subjects reinforce the safety of Pluronic formulations, such as SP1017 (*37*), which was also used in this study. This suggests a possibility of optimizing Pluronic formulations to safely enhance gene therapy. Pluronic may be delivered simultaneously with polyplexes or administered after polyplexes. For example, after intravenous administration Pluronic block copolymers were shown to accumulate in the tumors (data in preparation), which are same sites where polyplexes may be targeted. In addition, both polyplexes and Pluronic can be administered locally (*49*). Furthermore, the fact that the increased nuclear transfer was observed with Pluronic added after transfection introduces a possibility for consequent treatments with the polyplex and Pluronic. It is also important to note that Pluronics may not be the only polymers capable of affecting nuclear delivery of pDNA via modulation of cell signaling. Hence, it is advisable to evaluate the effects of all polymer transfection systems, especially those that produce very strong enhancements of gene expression and may have membrane-active hydrophobic moieties (*50*−*52*). It is noteworthy that most polyplex transfection systems require a considerable excess of polycation that cannot incorporate in the complex with DNA and may directly affect cell signaling machinery. Finally, this study underscores the need to match the polymeric formulation with pDNA structure to take full advantage of potential polymer effects on signal transduction.

ACKNOWLEDGMENT

This study was supported by Tobacco Settlement Funds awarded to University of Nebraska, and National Institutes of Health R01 CA116591 to A.V.K. We would like to thank Dr. Sergey Vinogradov for assistance in synthesizing PB25080 and P85PEI. We also thank UNMC Confocal and Flow Cytometery Core facilities for technical assistance. A.V.K. is a cofounder, shareholder and scientific advisor of Supratek Pharma Inc. (Montreal, Canada), which developed Pluronic-based SP1049C and SP1017 formulations for chemotherapy and gene delivery respectively.

Table S-1. Effect of Pluronic P85 on the expression of NFκB related genes in C2C12-CMV^{luc} cells. Cells were exposed to 1% Pluronic P85 for 5 min, washed by PBS and incubated for additional 3 h. Total RNA was assayed using Oligo GEArray® Mouse NFκB Signaling Pathway Microarray (see **Figure 7** for a representative gene array) and gene expression was analyzed by GEArray Expression Analysis Suite software (see http://www.superarray.com/gene_array_product/HTML/OMM-025.html for detailed list of genes and layout). Only genes exhibiting at least 2-fold increase in expression are presented. (*i*) NFκB pathway: (**3, 4, 30, 72, 77, 78, 70, 84**) transcription factors; (**6, 10, 11, 108, 110, 112, 66, 74**) other factors; (**53, 54, 56, 60, 61, 64, 87, 88, 71, 80**) kinases; (**99, 103**) ligands and receptors; (**100, 113**) inflammatory response, extracellular or membrane molecules. (*ii*) activation of NFκB pathway: (**8, 105**) ligands and receptors; (**35, 5, 22**) IκB kinase/NFkB cascade; (**37**) transcription factor; (**32**) extracellular or membrane molecules; (*iii*) NFκB responsive genes: (**42, 48**) ligands and receptors, or cytokines.

Perylene Attached to 2′-Amino-LNA: Synthesis, Incorporation into Oligonucleotides, and Remarkable Fluorescence Properties *in Vitro* and in Cell Culture

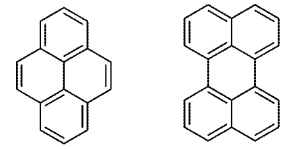
Received May 19, 2008; Revised Manuscript Received July 8, 2008

During recent years, fluorescently labeled oligonucleotides have been extensively investigated within diagnostic approaches. Among a large variety of available fluorochromes, the polyaromatic hydrocarbon perylene is an object of increasing interest due to its high fluorescence quantum yield, long-wave emission compared to widely used pyrene, and photostability. These properties make perylene an attractive label for fluorescence-based detection *in vitro* and *in vivo*. Herein, the synthesis of 2′-*N*-(perylen-3-yl)carbonyl-2′-amino-LNA monomer **X** and its incorporation into oligonucleotides is described. Modification **X** induces high thermal stability of DNA:DNA and DNA:RNA duplexes, high Watson−Crick mismatch selectivity, red-shifted fluorescence emission compared to pyrene, and high fluorescence quantum yields. The thermal denaturation temperatures of duplexes involving two modified strands are remarkably higher than those for double-stranded DNAs containing modification **X** in only one strand, suggesting interstrand communication between perylene moieties in the studied 'zipper' motifs. Fluorescence of single-stranded oligonucleotides having three monomers **X** is quenched compared to modified monomer (quantum yields $\Phi_F = 0.03-0.04$ and 0.67, respectively). However, hybridization to DNA/RNA complements leads to Φ_F increase of up to 0.20−0.25. We explain it by orientation of the fluorochrome attached to the 2′-position of 2′-amino-LNA in the minor groove of the nucleic acid duplexes, thus protecting perylene fluorescence from quenching with nucleobases or from the environment. At the same time, the presence of a single mismatch in DNA or RNA targets results in up to 8-fold decreased fluorescence intensity of the duplex. Thus, distortion of the duplex geometry caused by even one mismatched nucleotide induces remarkable quenching of fluorescence. Additionally, a perylene-LNA probe is successfully applied for detection of mRNA *in vivo* providing excitation wavelength, which completely eliminates cell autofluorescence.

INTRODUCTION

During the past decade, there has been remarkable growth in the use of synthetic oligonucleotide analogues in nucleic acid research. Thus, fluorescently labeled oligonucleotides have now been introduced into a variety of studies within molecular biology and biochemistry (*1*−*3*). The sensitivity of fluorescence detection, its simplicity, and relative cheapness stimulate continuing development of medicinal tests based on fluorescence. Detection of nucleic acid hybridization is an important task in this area, which includes diagnostics of genetic and infectious diseases, discovery of gene-targeted drugs, and other biomedicinal studies (*1*−*5*). To become an effective tool for hybridization analysis, the labeled oligonucleotide has to display considerable change of fluorescence upon formation of complexes with complementary strands. Development of such detection methods has led to several formats of homogeneous fluorescence assays (*4*). For example, fluorescence polarization detection is based on the measurement of the increase in anisotropy when labeled DNA binds to the complementary strand (*5*). Fluorescence resonance energy transfer (FRET), another useful process for the above purposes that occurs in the excited state, is determined by the distance between the donor and acceptor of fluorescence (*1*, *3*, *4*). Taqman probes (also known as 5′-nuclease probes) (*7*), sunrise primers (*8*), molecular beacons (*3*, *9*), and duplex scorpion primers (*10*) utilize a distance-dependent fluorescence quenching mechanism. Labeling of oligonucleotide with a single kind of hybridization-sensitive substance is another promising paradigm for fluorescent probe design (*11*−*22*).

Chart 1. Structures of Pyrene and Perylene Fluorochromes



Among a wide variety of fluorochromes used to covalently label DNA, fluorescent dyes based on polyaromatic hydrocarbons (PAHs) have been extensively introduced in biochemical studies. The most common PAH in this area is pyrene (Chart 1). A long lifetime of the excited state (*23*), high fluorescence quantum yield (*24*), and the possibility to form noncovalent interactions with another PAH molecule (*25*−*37*) or nucleic acids (for example, by intercalation *38*−*41*) have inspired researchers to use pyrene for the design of many different detection systems. Thus, fluorescence of a single pyrene label linked to oligonucleotides was shown to be sensitive to duplex

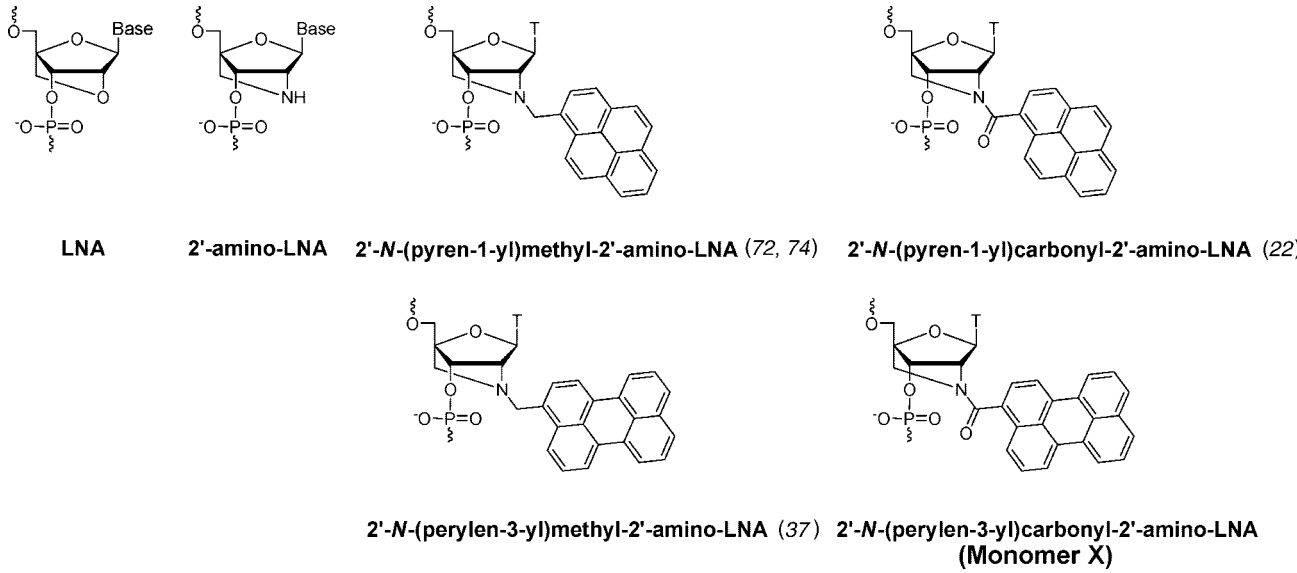
Chart 2. Chemical Structures of LNA, 2′-Amino-LNA, and Its Pyrene and Perylene Derivatives



formation (*19, 21, 42*−*46*). It has also been pointed out that changes in the pyrene excimer-to-monomer fluorescence intensity ratio can be useful for detection of nucleic acid hybridization (*27*). More recently, Hrdlicka et al. investigated multilabeled pyrene-functionalized 2′-amino-LNA probes which exhibited high-affinity hybridization to DNA/RNA complements, quenched fluorescence of single-stranded probe, and large increase of the quantum yield and fluorescence brightness after hybridization (*22*). However, pyrene and its simple derivatives absorb at relatively short wavelengths (334 nm for pyrene in ethanol), which is likely to be unsatisfactory for experiments in living cells due to irradiation of several intrinsic fluorochromes at the same wavelengths (*47*). This limitation of pyrene can be overcome by its chemical functionalization (for example, introduction of phenylethynyl substituents *47*−*49*), or by choosing another fluorochrome with a long-wave emission spectrum relative to pyrene. Among PAHs, perylene is such a fluorochrome (Chart 1), which resembles pyrene in its chemical behavior, but has essentially different photochemical properties (*23*). Fluorescence of perylene is observed at 450−500 nm; its excited lifetime is relatively short (4−5 ns), while the fluorescence quantum yield is very high (0.5−1.0). Furthermore, perylene displays a strong fluorescence anisotropy effect (*24*). Unlike pyrene, perylene is not a common fluorescent dye for modification of oligonucleotides, whereas it is widely used in the field of lipids (*50*−*55*). Mostly, perylene attached to DNA was employed as an acceptor of fluorescence energy in FRET-studies (*27, 37, 56*−*59*), and only scarcely in nucleic acid hybridization assays (*60*−*65*).

Besides insertion of fluorescent dyes, chemical modification of oligonucleotides allows improvement of their binding affinity and selective recognition of cDNA and/or RNA. These properties have in particular been reported for locked nucleic acids (LNA (*66*−*70*), 2′-amino-LNA (*71*), and its *N*-functionalized derivatives *22, 40, 72*−*74*) (Chart 2), and have stimulated intensive investigations of LNA-modified oligonucleotides as diagnostic tools and therapeutic agents (*75, 76*). Moreover, affinity enhancing LNAs are interesting monomers within nucleic acid nanotechnology, including so-called Ångström-scale chemical engineering (*32, 77*).

Stimulated by the high-affinity hybridization of LNAs (*40, 66*−*74*), sensitivity of pyrene-functionalized 2′-amino-LNA probes to hybridization (*22*), and taking into account perylene's superiority in fluorescence quantum yield and emission wavelengths relative to pyrene, we have investigated perylene-modified 2′-amino-LNA. In this paper, we describe synthesis of 2′-*N*-(perylen-3-yl)carbonyl-2′-amino-LNA monomer **X**, its incorporation into synthetic oligonucleotides, thermal denaturation studies, and spectral properties of the conjugates containing perylene residue either in one or in two complementary strands of the duplexes (Chart 3).

EXPERIMENTAL PROCEDURES

General. Reagents obtained from commercial suppliers were used as received; 3-acetylperylene (*78*), diisopropylammonium tetrazolide (*79*), and nucleoside **1** (*71, 80, 81*) were synthesized as described. Perylene and 9,10-diphenylanthracene used as standards for emission quantum yield measurements were recrystallized. HPLC grade toluene and acetone were distilled and stored over activated 4 Å molecular sieves. DCM was always used freshly distilled over CaH_2. Other solvents were used as received. Photochemical studies were performed using spectral grade cyclohexane.

NMR spectra were recorded at 303 K on Varian Gemini 2000 300 MHz and Bruker DRX 500 MHz instruments. Chemical shifts are reported in ppm, relative to solvents peaks (DMSO-d_6, 2.50 ppm for ^{1}H and 39.5 ppm for ^{13}C; 85% aq H_3PO_4, 0.00 ppm for ^{31}P). ^{1}H NMR coupling constants are reported in Hz and refer to apparent multiplicities. High resolution mass spectra were recorded in positive ion mode using IonSpec Fourier Transform ICR mass spectrometer (MALDI) or PE SCIEX QSTAR pulsar mass spectrometer (ESI). Melting points were determined using a Boetius heating table and are uncorrected. Analytical thin-layer chromatography was performed on Kieselgel 60 F_{254} precoated aluminum plates (Merck). Silica gel column chromatography was performed using Merck Kieselgel 60 0.040−0.063 mm.

Oligonucleotide synthesis was carried out on a PerSpective Biosystems Expedite 8909 instrument in a 200 nmol scale using manufacturer's standard protocols. In the case of LNA phosphoramidites (monomers T^L and $^{Me}C^L$), the coupling step time was extended to 15 min. To accomplish incorporation of monomer **X**, a double hand-coupling procedure with extended coupling time (2 × 30 min) was performed. In the case of phosphoramidite **3** pyridine hydrochloride solution in CH_3CN was used as activator. 95−99% per step coupling yields of monomer **X** were obtained based on the absorbance of the dimethoxytrityl cation released after each coupling. The coupling efficiencies of standard DNA and LNA amidites varied between

98% and 100%. Cleavage from solid support and removal of nucleobase protecting groups was effected using standard conditions (32% aqueous ammonia for 12 h at 55 °C). Unmodified DNA/RNA strands were obtained from commercial suppliers and used without further purification, while all the modified oligonucleotides were purified by DMT-ON RP-HPLC using the Waters Prep LC 4000 equipped with Xterra MS C18-column (10 μM, 300 mm × 7.8 mm). Elution was performed starting with an isocratic hold of A-buffer for 5 min followed by a linear gradient to 55% B-buffer over 75 min at a flow rate of 1.0 mL/min (A-buffer: 95% 0.1 M NH_4HCO_3, 5% CH_3CN; B-buffer: 25% 0.1 M NH_4HCO_3, 75% CH_3CN). RP-purification was followed by detritylation (80% aq AcOH, 20 min), precipitation (abs EtOH, −18 °C, 12 h) and washing with abs EtOH three times. The identity of ONs was verified by MALDI-TOF mass spectrometry (Table S1, Supporting Information). UV−visible absorption spectra and thermal denaturation experiments were performed on a Perkin-Elmer Lambda 35 UV/vis spectrometer equipped with PTP 6 (Peltier Temperature Programmer) in a medium salt buffer (100 mM NaCl, 10 mM sodium phosphate, 0.1 mM EDTA, pH 7.0). Concentrations of ONs were calculated using the following extinction coefficients (OD_{260}/μmol): G, 10.5; A, 13.9; T/U, 7.9; C, 6.6; perylene, 33.2. ONs (1.0 μM each strand) were thoroughly mixed, denaturated by heating, and subsequently cooled to the starting temperature of the experiment. Thermal denaturation temperatures (T_m values, °C) were determined as the maximum of the first derivative of the thermal denaturation curve (A_{260} vs temperature). Reported T_m values are an average of two measurements within ±1.0 °C. Fluorescence spectra were obtained in a medium salt buffer using a PerkinElmer LS 55 luminescence spectrometer equipped with a Peltier temperature controller. For recording of fluorescence spectra, 0.1 μM concentrations of the single-stranded probe or corresponding duplex were used. For weakly fluorescent samples, concentration was increased to 0.5 μM. Excitation spectrum was obtained recording emission at 510 nm. The fluorescence quantum yields (Φ_F) were measured by the relative method using standards of highly diluted solutions of perylene (Φ_F 0.93 (*82*)) and 9,10-diphenylanthracene (Φ_F 0.95 (*83*)) in cyclohexane. CD spectra were recorded on a JASCO J-815 CD Spectrometer equipped with CDF 4265/15 temperature controller. In cell studies, fluorescence was visualized with a Ziess axiovert 200m microscope using excitation wavelengths of 360 nm (DAPI), 435 nm (perylene-LNA probe), and 570 nm (mCherry protein) and emission wavelengths of 460, 480, and 630 nm for DAPI, perylene-LNA, and mCherry protein, respectively (±15 nm).

3-Perylenecarboxylic Acid. To a precooled to 0 °C solution of sodium hydroxide (600 mg, 15 mmol) in water (12 mL), bromine (205 μL, 4 mmol) and 1,4-dioxane (12 mL) were subsequently added. The resulting mixture was stirred at 0 °C for 10 min, and 3-acetylperylene (294 mg, 1 mmol) was added in 5 portions, over 10 min. The solution was stirred at 0 °C for 3 h, then left at room temperature overnight. Saturated Na_2SO_3 (2 mL) was added, and the stirring was continued for 1 h; then, the reaction mixture was acidified with 1 M aq citric acid to pH 3 and extracted with $CHCl_3$ (3 × 100 mL). The combined organic phase was dried over Na_2SO_4 and evaporated. The product was recrystallized from 5% DMF in nitromethane (v/v) to give 250 mg (84%) of the desired product as a red solid. R_f 0.45 (silica gel, 30% EtOH in $CHCl_3$, v/v). Mp 331−334 °C (5% DMF in nitromethane, v/v) (lit *78*. 333−335 °C). MALDI-HRMS: *m/z* 319.0732 ($[M + Na]^+$, $C_{21}H_{12}O_2Na^+$ calcd. 319.0730). ^{1}H NMR (300 MHz, DMSO-d_6) δ 8.70 (d, J = 8.4 Hz, 1H), 8.29−8.24 (m, 4H), 8.01 (d, J = 8.1 Hz, 1H), 7.76−7.69 (m, 2H), 7.53 (dd, J = 8.1 Hz, 1H), 7.45−7.40 (m, 2H). Carboxylate proton signal was not observed. ^{13}C NMR (75.4 MHz, DMSO-d_6) δ 171.3, 168.4, 134.5, 134.0, 132.4, 130.7, 130.5, 130.2, 129.5, 129.2, 128.3, 128.2, 128.0, 127.1, 127.0, 126.9, 125.6, 122.3, 131.5, 121.0, 119.7.

(1*R*,3*R*,4*R*,7*S*)-1-(4,4′-Dimethoxytrityloxymethyl)-7-hydroxy-5-(perylen-3-ylcarbonyl)-3-(thymin-1-yl)-2-oxa-5-azabicyclo[2.2.1]heptane (2a). To a stirred solution of the 3-perylenecarboxylic acid (116 mg, 0.39 mmol) and HBTU (136 mg, 0.36 mmol) in DMF (2 mL), diisopropylethylamine (132 μL, 0.76 mmol) was added in one portion. The mixture was stirred for 15 min at room temperature and then added dropwise to a stirred solution of nucleoside **1** (200 mg, 0.35 mmol) in DMF (2 mL). After stirring for 40 min, the reaction mixture was diluted with DCM (100 mL) and washed with water (2 × 100 mL), 5% $NaHCO_3$ (2 × 100 mL), and water (3 × 100 mL). The organic layer was dried over Na_2SO_4 and evaporated. The residue was chromatographed on silica gel using gradient elution 10→20% acetone in toluene, containing 1% NEt_3 (v/v/v) to yield nucleoside **2a** (267 mg, 90%) a as an orange foam (rotameric mixture ∼ 1:2.4:1.2 by ^{1}H NMR). R_f 0.40 (50%

(1*R*,3*R*,4*R*,7*S*)-1,7-Dihydroxy-5-(perylen-3-ylcarbonyl)-3-(thymin-1-yl)-2-oxa-5-azabicyclo[2.2.1]heptane (2b). To a stirred solution of **2a** (85 mg, 0.1 mmol) in DCM (0.5 mL), dichloroacetic acid (20% solution in DCM, 400 μL) and triethylsilane (200 μL, 1.0 mmol) were subsequently added. After 40 min at room temperature, TLC displayed the complete conversion of starting nucleoside. The reaction mixture was transferred on a column (silica gel, gradient elution 5→10% MeOH in CHCl$_3$, v/v) to give nucleoside **2b** (40 mg, 73%) as a yellow solid (rotameric mixture ~ 1:2.5 by ^{1}H NMR). R_f 0.52 (10% MeOH in CHCl$_3$, v/v). MALDI-HRMS: m/z = 570.1648 [M + Na]$^+$, calc. for $C_{32}H_{25}N_3O_6Na^+$ 570.1641. ^{1}H NMR (300 MHz, DMSO-d_6; the signals are given for the major rotamer) δ 11.03 (br s, 1H), 8.35−8.26 (m, 4H), 7.90−7.81 (m, 3H), 7.71−7.58 (m, 5H), 6.24 (br.s, 1H), 5.66 (m, 1H), 4.18 (br s, 1H), 4.00−3.43 (m, 6H, partial overlap with water), 1.45 (s, 3H). ^{13}C NMR (75.4 MHz, DMSO-d_6; the signals are given for the major rotamer) δ 169.6, 164.6, 150.7, 135.7, 135.2, 134.9, 134.2, 132.6, 132.5, 131.8, 131.6, 131.2, 130.9, 130.8, 129.5, 129.2, 128.9, 128.6, 128.4, 127.9, 127.8, 122.2, 122.0, 120.7, 109.0, 89.9, 87.2, 70.0, 66.2, 57.5, 51.8, 13.3.

(1*R*,3*R*,4*R*,7*S*)-7-(2-Cyanoethoxy(diisopropylamino)phosphinoxy)-1-(4,4′-dimethoxytrityloxymethyl)-7-hydroxy-5-(perylen-3-ylcarbonyl)-3-(thymin-1-yl)-2-oxa-5-azabicyclo[2.2.1]heptane (3). The LNA nucleoside derivative **2a** (170 mg, 0.2 mmol) was evaporated with dry DCM (2 × 30 mL), dissolved in anhydrous DCM (20 mL), diisopropylammonium tetrazolide (52 mg, 0.3 mmol), and bis(*N*,*N*-diisopropylamino)-2-cyanoethoxyphosphine (96 μL, 0.3 mmol) were added under argon, and the resulting mixture was stirred for 4 h. The mixture was diluted with DCM (100 mL) and washed with saturated solution of NaHCO$_3$ (2 × 100 mL) and brine (100 mL). The organic layer was dried over Na$_2$SO$_4$, evaporated, and the crude material purified by chromatography (silica gel, 30% acetone in toluene, containing 1% NEt$_3$, v/v/v). Yield 228 mg (95%). R_f 0.53, 0.50 (50% acetone, 1% NEt$_3$, toluene, v/v/v). ESI-HRMS: m/z = 1072.3985 [M + Na]$^+$, calc. for $C_{62}H_{60}N_5O_9PNa^+$ 1072.4020. ^{31}P NMR (121.4 MHz, DMSO-d_6) δ 149.22, 148.83 (1:1.7) (main conformer).

RESULTS AND DISCUSSION

Synthesis. Modified phosphoramidite was synthesized as shown in Scheme 1. The starting DMT-protected 2′-amino-LNA monomer **1** (*82, 83*) was coupled with 3-perylenecarboxylic acid, synthesized from 3-acetylperylene (*78*) under haloform oxidation conditions (*84, 85*). A small portion of perylene-modified 2′-amino-LNA **2a** was reacted with dichloroacetic acid in the presence of triethylsilane giving DMT-deprotected nucleoside **2b** required for spectroscopic and photophysical studies. The main portion of **2a** was converted to the phosphoramidite derivative **3** (in 86% overall yield), which was used in automated oligonucleotide synthesis to prepare a series of modified oligonucleotides (ONs). Sequences of ONs were similar to those designed for studies of pyrene-functionalized 2′-amino-LNA (*22*).

Synthesis of **X**-labeled ONs was performed following standard protocols, except for incorporation of monomer **X** for which a double coupling procedure with an extended coupling time (2 × 30 min) using pyridine hydrochloride as an activator was applied. This resulted in 95−99% stepwise coupling yields of monomer **X** based on the absorbance of the dimethoxytrityl cation released after each coupling. The coupling efficiencies of standard amidites varied between 98% and 100%. All synthesized conjugates were purified by RP-HPLC and their identity confirmed by MALDI-TOF mass spectrometry (Table S1, Supporting Information).

Spectral Properties of 2′-*N*-(Perylen-3-yl)carbonyl-2′-amino-LNA Monomer (2b). To get true solutions of nucleoside **2b** for recording of UV−vis absorption, steady-state fluorescence emission, and excitation spectra in aqueous media (Figure 1), it was dissolved in a medium salt buffer with 1% DMSO (v/v). Perylene absorbs with a maximum at 445 nm, an additional band at 419 nm, and a shoulder at 396 nm. Spectral broadening of the spectrum of **2b** compared to that of perylene (*23*) indicates increased ground-state interactions for the perylene attached to 2′-amino-LNA. These interactions are most likely caused by the nearby thymine, and less probably, by the sugar ring. Emission spectra of **2b** displays a broad, featureless peak near 480 nm corresponding to a Stokes shift of 35 nm. Compared to perylene, emission of **2b** is 30 nm red-shifted and significantly broadened.

Fluorescence emission quantum yield (Φ_F) of nucleoside **2b** was determined by the relative method using highly diluted solutions of perylene (Φ_F = 0.93 (*82*)) and 9,10-diphenylanthracene (Φ_F = 0.95 (*83*)) in cyclohexane as the reference standards. Optical densities of the solutions used for quantum yield measurements were kept between 0.1 and 0.01 to avoid

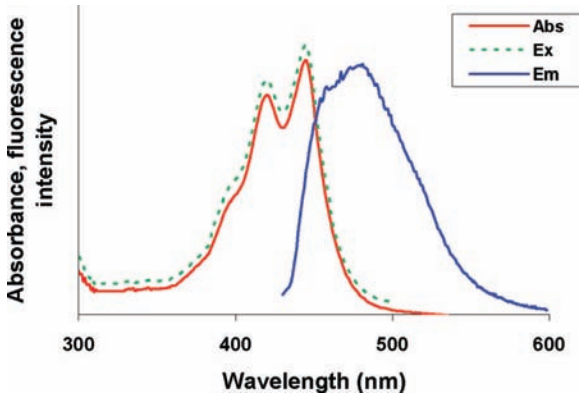

Figure 1. Normalized absorption, emission, and excitation spectra of nucleoside **2b** in a medium salt buffer containing 1% DMSO (v/v) recorded at 19 °C using an excitation wavelength of 425 nm, emission wavelength of 510 nm for excitation, 2 μM concentration of **2b** for the absorption spectrum, and 0.1 μM concentration for the excitation and emission fluorescence spectra.

Table 1. Thermal Denaturation Temperatures for Duplexes of Modified ONs and DNA/RNA Complements[a]

					duplex

[a] Thermal denaturation temperatures T_m (°C) (change in T_m per modification relative to corresponding reference duplex, ΔT_m/mod (°C)). The melting temperatures of the unmodified duplexes or LNA-modified duplex (in the case of **ON9–ON10**) used as references were as follows: 28.0 °C for **ON1–ON5**,**ON7**:DNA, 26.0 °C for **ON1**,**ON4**,**ON7**:RNA, 24.5 °C for **ON2**,**ON3**,**ON5**:RNA, 31.5 °C for **ON6**,**ON8**:DNA, 29.5 °C for **ON6**,**ON8**:RNA, 35.5 °C for **ON9–ON10**:DNA, and 34.0 °C for **ON9–ON10**:RNA. T_m values measured as the maximum of the first derivatives of the melting curves (A_{260} vs temperature). Reported expected to be hybridized to its RNA target. T_m values are averages of at least two measurements. **X** = 2′-*N*-(perylen-3-yl)carbonyl-2′-amino-LNA monomer; TL and ^{Me}CL = thymin-1-yl and 5-methylcytosin-1-yl LNA monomers, respectively. All T_m values were recorded in medium salt buffer. [b] T_m value for **ON9**:DNA measured using perylene absorbance at 425 nm.

uncertainties. The Φ_F values were corrected with the refractive index of the solvents. Quantum yield of **2b** in aerated buffer solution containing 1% DMSO measured using these conditions was $\Phi_F = 0.67$, while Φ_F for the 2′-amino-LNA nucleoside functionalized with pyrene was $\Phi_F = 0.34$ (*22*). Superiority of perylene relative to pyrene with respect to quantum yield becomes clear if fluorescence rate constants are compared ($K_f = 0.25 \cdot 10^{-7}$ s^{-1} for pyrene and $14.62 \cdot 10^{-7}$ s^{-1} for perylene in cyclohexane, respectively) (*86*).

Labeled Oligonucleotides and Duplexes Having Monomer X in One Strand. *(a) Thermal Denaturation Studies.* Thermal denaturation temperatures were determined in medium salt buffer using 1.0 μM concentration of the two complementary strands, and were compared to the denaturation temperatures of the corresponding unmodified duplexes (Table 1). The perylene-modified ONs displayed higher affinity toward complementary RNA while exhibiting lower affinity toward DNA. Previously, it had been reported that conjugates containing functionalized 2′-amino-LNA monomers form stable complexes to both DNA and RNA complements, and that N2′-acylated 2′-amino-LNA derivatives exhibit higher thermal stabilities than N2′-alkylated (*22*, *72*). In agreement with these results, the thermal stabilities of duplexes involving singly labeled **ON1**–**ON3** were much higher than those of the corresponding unmodified duplexes and of duplexes involving a recently reported perylenemethyl-2′-amino-LNA monomer (*37*), but similar to those for N2′-pyrenecarbonyl-functionalized 2′-amino-LNAs (*22*). This implies that neither a perylene nor a pyrene moiety attached to LNA essentially distorts the structure of nucleic acid helixes. Incorporation of two monomers **X** separated by one base pair induces even larger increases in thermal stabilities, especially in the case of duplex **ON4**:RNA (ΔT_m/mod = +15.5 °C). On the contrary, insertion of modifications in the neighboring positions, as well as incorporation of an additional monomer **X**, results in lower melting temperatures compared to doubly labeled conjugates **ON4**–**ON5**:DNA/RNA (Table 1, T_m values for **ON6**–**ON8**:DNA/RNA), which again parallels the behavior of pyrene attached via an amide linkage to 2′-amino-LNA (*22*).

The thermal denaturation curves of all the above-mentioned duplexes displayed S-shaped monophasic transitions similar to those of the unmodified reference duplexes. Surprisingly, 13-mer **ON9** having four perylenes showed a sigmoidal melting curve only against its RNA complement, but not its DNA complement. Therefore, a thermal denaturation experiment was performed at perylene's absorbance at 425 nm (Supporting Information, Figure S1). The resulting melting curve displayed clear S-shaped perylene hypochromism similar to that previously reported for pyrene (*19*). In the case of duplex **ON9**:RNA, the melting temperature values determined using absorbance at 260 and 425 nm coincided precisely. The observed hypochromism can be explained by the increase of the distance between perylene residues in the more rigid duplex compared to the flexible single-stranded oligonucleotide. Upon incorporation of an additional number of fluorochromes, the total absorbance of perylene residues at 260 nm may become rather significant and, therefore, may affect the 'nucleotide' melting curve.

The Watson−Crick selectivity of the perylene-functionalized conjugate **ON7** was determined also for the duplexes containing single mismatched nucleotides at positions 4−6 (Table 2). The presence of mismatches in the DNA/RNA target resulted in significantly decreased thermostability of the complexes compared to the corresponding fully matched duplexes **ON7**:DNA/RNA (data presented in Table 2 compared to T_m values of **ON7**:DNA/RNA**)**. It was previously reported that mismatches opposite of LNA monomers are generally discriminated more strongly than opposite of unmodified nucleotides (*67*). However, in the case of monomer **X**, mismatches at position 6 of target DNA resulted in more remarkable destabilization of the complexes than at position 5.

(b) Spectral Properies. The UV−visible absorption and steady-state fluorescence emission spectra were obtained in medium salt buffer using 0.1−1.0 μM concentration of the single-stranded probe or the two complementary strands. For the recording of fluorescence spectra, an excitation wavelength of 425 nm was used. Table 3 lists the resulting spectral and photophysical properties of single-stranded ONs (SS**P**) and their duplexes with DNA and RNA complements.

The UV−visible spectra recorded of all the modified ONs and duplexes, as well as the spectrum of monomer **2b**, contain two main absorption bands in the visible region with $\lambda_{max} \approx$ 448−456 nm and $\lambda_{max} \approx$ 422−429 nm. Noteworthy, perylene longwave absorption maxima of the **X**-modified ONs and duplexes are red-shifted compared to those of the nucleoside **2b**. As a result of perylene−ON interactions, the UV−visible absorption spectrum of the perylene unit has lost many of its

[a] Fluorescence brightness FB = $\varepsilon_{425} \times \Phi_F$ (*22*).

vibrational features compared to the spectra of perylene itself (*23*) and the monomer fluorochome **2b** (Supporting Information, Figure S2). The absorption maxima (λ_{max}) of the conjugates bathochromically shift 1−4 nm and absorption coefficients (ε) increase with increasing number of monomers **X** and, conversely, upon hybridization absorption maxima shift 1−8 nm to shorter wavelengths. The excitation spectra of ONs and duplexes containing one to three monomers **X** are of the same shape as the corresponding absorption spectra. The difference consists of the entire red shift 6−8 nm of the excitation spectra compared to the absorption spectra. No changes in the positioning of the excitation peaks for different emission wavelengths were observed. The peaks of the emission spectra of perylenecarbonyl-2′-amino-LNA conjugates lie within the 440−590 nm region, and none of the spectra exhibit significant vibrational features (Supporting Information, Figure S3). Singly labeled **ON1**–**ON3** revealed a broad unstructured band at fluorescence maximum $\lambda_{em} \approx 490$ nm, which is 100 nm red-shifted relative to the corresponding conjugates of pyrenecarbonyl-2′-amino-LNA (*22*). Upon duplex formation, λ_{em} slightly shifts (2−4 nm) to shorter wavelengths. No perceptible changes in the shape of the spectral curve or the fluorescence intensity were observed.

Fluorescence emission quantum yields (Φ_F) of perylene-modified ONs and the corresponding duplexes were determined by the method described in the section concerning spectral properties of fluorochrome monomer **2b**. The quantum yields of several samples were also measured in degassed buffer solutions, but no significant difference compared to nondegassed solutions was found. Thus, all Φ_F values collected in Table 3 are determined for air-saturated solutions. Fluorescence quantum yields of **ON1** and its duplexes are remarkably high (Table 3, Φ_F values for **ON1**, **ON1**:DNA/RNA). Usually, PAH molecules (for example, pyrene) incorporated into nucleic acids display low quantum yields due to interactions with the polar aqueous environment and the nucleobases (*87*). However, if the sequence can adopt a structure shielding the fluorochrome from the quenchers (i.e., nucleobases), quantum yields of ONs become very high. Direction of the fluorochrome into the groove upon hybridization can also reduce fluorescence quenching (*64*). Previously, it has been shown that the rigid bicyclic backbone of 2′-amino-LNA together with a short amide linkage direct the functionalities in the minor groove of a nucleic acid helix (*22, 40, 72*−*74, 88*). Thus, high fluorescent quantum yields of **ON1** and of its duplexes can be explained by reduced interactions of the perylene moiety with the nucleobases resulting from the above-mentioned particular features of N2′-acylated 2′-amino-LNA.

Single-stranded probe **ON4** having two incorporations of monomer **X** separated by one nucleotide exhibits significantly lower quantum yield compared to **ON1**. However, duplexes **ON4**:DNA and **ON4**:RNA display Φ_F values that are twice as high relative to **ON4** and fluorescence brightness values (FB = $\varepsilon_{425} \times \Phi_F$ (*22*)) that are almost the same as for duplexes involving **ON1**. Noteworthy, insertion of two monomers **X** in neighboring positions reduced the spectral effects observed for **ON4** (compare Φ_F and FB values for **ON4** and **ON6**). Previously, ONs with sequential incorporations of pyrene−LNA monomers exhibited very low quantum yields and FBs as well ($\Phi_F = 0.02-0.09$ (*22*)). This suggests that separation of fluorochromes by at least one base pair is an important structural requirement for this clan of probe ONs to achieve distinctly hybridization-modulated fluorescence and to generate brightly fluorescent duplexes. Thus, hybridization of **ON7** containing three separated monomers **X** results in a ∼14-fold increase of fluorescence intensity at $\lambda_{em} \approx 490$ nm (Figure 2). The quantum yield of **ON7** is $\Phi_F = 0.04$, whereas upon formation of the duplexes it increases up to $\Phi_F = 0.23-0.25$. The bright green fluorescence exhibited by the duplex **ON7**:DNA can be detected by the naked eye at concentrations less than 0.5 μM. Unlike pyrene-labeled ONs (*17, 22, 38*), perylene-functionalized **ON7** and **ON8** do not show any DNA/RNA discrimination in the fluorescence intensity response. However, in spite of this distinction, the basic spectral features (quenched fluorescence of multilabeled single-stranded probe and remarkable increase of fluorescence intensity upon hybridization) are, probably, general properties of such 2′-amino-LNA derivatives N2′-functionalized with amide-linked PAHs.

Interestingly, in contrast to pyrene-functionalized 2′-amino-LNAs, incorporation of four perylene modifications **X** into a T-rich 13-mer did not result in high values of the quantum yields for the duplexes (Table 3, Φ_F values for **ON9**:DNA/RNA compared with $\Phi_F = 0.99$ and 0.96 for pyrene-modified dsDNA and DNA:RNA, respectively) (*22*). Conjugate **ON9** does show a response in fluorescence intensity to hybridization, with ∼10×

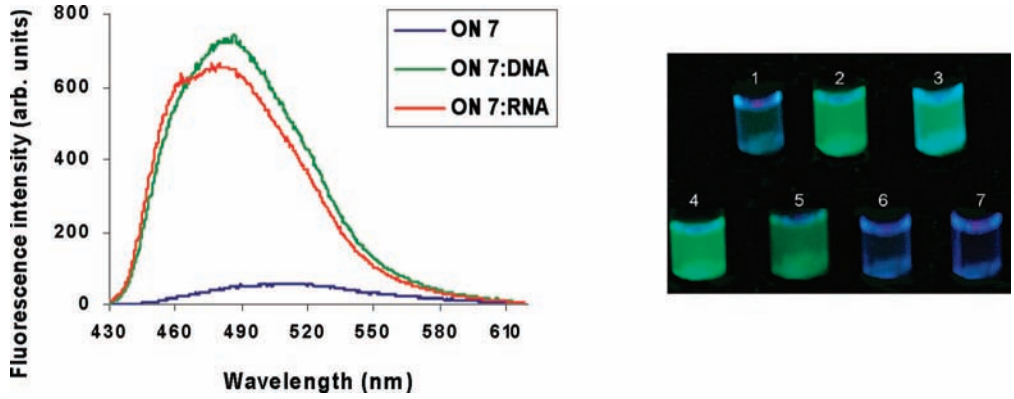

Figure 2. Left: steady-state fluorescence emission spectra of **ON7** (5′-G**X**G A**X**A **X**GC; **X** = 2′-*N*-(perylen-3-yl)carbonyl-2′-amino-LNA monomer) and the corresponding duplexes with cDNA/RNA. Spectra were obtained in a medium salt buffer at 19 °C using an excitation wavelength of 425 nm and 0.1 μM concentration of ONs. Right: photographs of the fluorescence emission in a medium salt buffer: single stranded **ON7** (vial 1, 1 μM concentration); **ON7**:DNA (vial 2, 1 μM concentration), **ON7**:RNA (vial 3, 1 μM concentration); **ON7**:DNA (vials 4−6, concentrations: 1 μM, 0.5 μM, and 0.1 μM, respectively); medium salt buffer (vial 7). Photographs were taken with a digital camera using a laboratory UV-lamp (λ_{ex} = 365 nm).

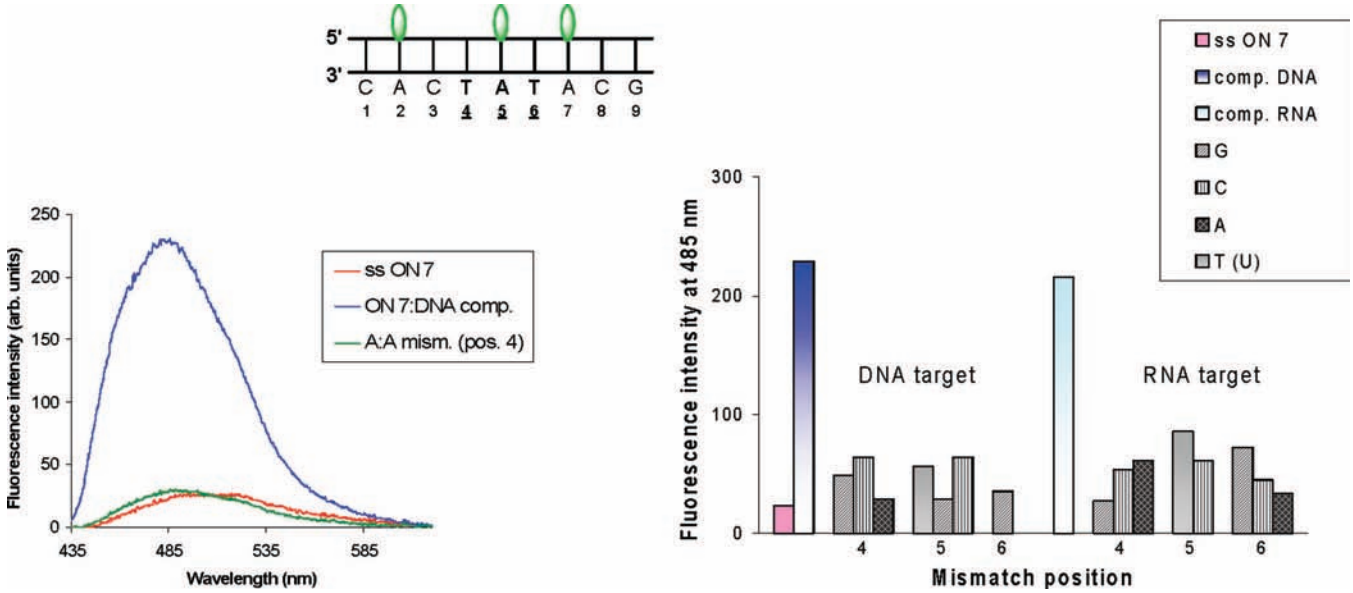

Figure 3. Left: steady-state fluorescence emission spectra of **ON7** and its duplexes with complementary and singly mismatched DNA. Right: fluorescence intensities of duplexes between **ON7** and complementary or singly mismatched DNA/RNA targets. Conditions are described in Figure 2. Green droplets indicate monomer **X**.

fluorescence intensity increase for both **ON9**:DNA and **ON9**:RNA (Supporting Information, Figure S3). However, due to decreased quantum yields the FB values of **ON9**:DNA/RNA are low (Table 3, compare FBs for **ON9**:DNA/RNA and **ON7**:DNA/RNA; also compare to FB = 51 and 52 for pyrene-modified dsDNA and DNA:RNA, respectively) (*22*).

Next, fluorescence properties of complexes formed by **ON7** and singly mismatched DNA/RNA targets were investigated. Mismatched duplexes displaying T_m values of more than 22 °C (Table 2) can be expected to be fully hybridized during steady-state fluorescence experiments performed at 19 °C. Thus, for these complexes, fluorescence emission spectra were recorded using the conditions described above. Resulting fluorescence intensities, as well as representative fluorescence spectra, are shown in Figure 3. Probe **ON7** was seen to be equally sensitive to the presence of mismatched nucleosides in DNA and RNA targets, and a decrease in fluorescence intensity of at least 60% for the all singly mismatched complexes was observed. The highest value of discrimination displayed by perylene-functionalized probe **ON7** is eight for single-base mismatches T/G, A/A, A/G in the case of the DNA target, and for A/G, A/A mismatches in the case of the RNA target. The observed significant level of discrimination is comparable with, if not better than, the discrimination previously reported for FRET-based biosensors (*89*), molecular beacons (*90*−*92*), and for other probes containing various fluorochromes (*41*, *93*−*98*). Thus, 2′-*N*-(perylen-3-yl)carbonyl-2′-amino-LNA monomer **X** may become a useful tool for homogeneous detection of genetic mutations.

To study structural features of the modified duplexes in detail, circular dichroism (CD) spectroscopy was employed (Supporting Information, Figure S4). All the modified dsDNA duplexes seem to be changed toward an intermediate A/B form, and as expected, deviations from the unmodified dsDNA clearly increase in the order **ON1** < **ON4** < **ON7** (with insertion of more RNA reminiscent monomers **X**) (*99*).

Fluorescence staining techniques and fluorescence microscopy constitute powerful tools for the biological investigations. Thus, we examined a 13-mer perylene−LNA probe for mRNA staining in cell culture, visualized by fluorescence microscopy. In doing that, a 13-mer probe **ON10** complementary to target mRNA was synthesized. For the investigation, a pCDNA5/FRT/

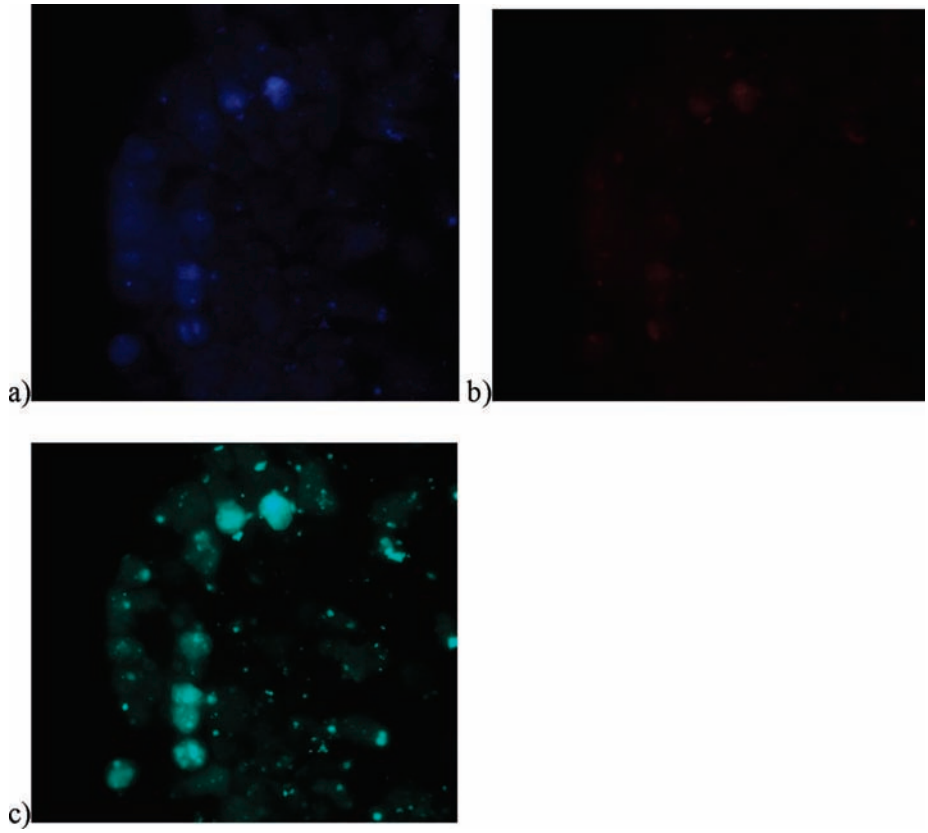

Figure 4. Images of cell culture observed using fluorescence microscopy. Cell nuclear DNA was stained with DAPI (blue signals in a, $\lambda_{em} = 460$ nm). (b) Fluorescence of mCherry protein ($\lambda_{em} = 630$ nm). (c) Fluorescence of the probe **ON10** ($\lambda_{em} = 480$ nm) expected to be hybridized to its RNA target.

Table 4. Thermal Denaturation Temperatures for Modified Duplexes Having Monomer X in Both Complementary Strands[a]

TO vector containing cloned genetic code for mCherry protein (*100*) followed by four copies of the target sequence of the probe was transfected into HEK 293 cells. The perylene−LNA probe was transfected after 40 h and cells were fixated after an additional 6 h. To identify nuclei, DAPI staining was applied ($\lambda_{ex} = 350$ nm), while red fluorescence of the mCherry protein ($\lambda_{ex} = 570$ nm) confirmed presence of the mRNA of interest in the cells (Figure 4A,B). In turn, bright cyan fluorescence of the probe **ON10** under excitation at 435 nm is seen to be colocalized with red emission of the mCherry protein and DAPI signal suggesting successful uptake of the synthesized probe into the cells (Figure 4C). Next, fluorescence of **ON10** is more intensive in well-countered zones within the cells compared to the other areas. This is most likely due to localization of the probe around the synthesized target mRNA. An important observation is that the emission signal of perylene−LNA is not obscured by cell autofluorescence—upon excitation at 435 nm in the absence of **ON10**, there is no fluorescence signal detected. Furthermore, since fluorescence of single-stranded **ON10** is quenched and its remarkable enchancement observed only upon binding to

Table 5. Spectroscopic and Photophysical Properties of the Duplexes Containing Monomers X in '+1 zipper' and '−1 zipper' Constitutions

nucleic acids, there should be little to no background signal of the probe. Thus, the results of this initial study suggest that probes containing introduced label **X** have a big potential to become useful for experiments in cell culture (e.g., mRNA-FISH analysis) with advantages of eliminated cell autofluorescence and low background signal.

Duplexes Containing Monomer X in Both Strands. *(a) Thermal Denaturation Studies.* Thermal denaturation temperatures of duplexes involving two strands each modified with a perylene-functionalized monomer **X** were determined as described before. The measured T_m values were compared to those of the corresponding unmodified dsDNA as shown in Table 4.

Positioning of two monomers **X** in a '+1 zipper' constitution does not significantly affect the thermal stability of the duplex, while two perylene−LNA residues placed in a '−1 zipper' result in remarkable stabilization (Table 4, data for **ON1**:**ON2** relative to **ON1**:**ON3**). Duplexes containing three modifications **X** in '1 + 2' and '2 + 1 zippers' exhibit higher T_m values relative to doubly modified analogues (Table 4, **ON1**:**ON5**, **ON4**:**ON2**, compared to **ON1**:**ON2**, **ON1**:**ON3**). However, incorporation of three monomers **X** in **ON4**:**ON3** decreases the thermal stability compared to other triply labeled duplexes (Table 4, T_m value for **ON4**:**ON3**, compared to **ON1**:**ON3**,**ON1**:**ON5**,**ON4**:**ON2**). Remarkably high thermal denaturation temperatures were observed for the duplexes with four insertions of the **X**-monomer (Table 4, **ON4**:**ON5**, **ON7**:**ON2**, **ON7**:**ON3**). As an illustration, **ON4**:**ON5** containing four modifications in a 'zipper' motif shows a T_m value of 69.5 °C, but incorporation of an additional fifth perylene monomer results in a T_m value of 77.5 °C, which is an extraordinary thermal stability of a 9-mer duplex containing only five modified nucleotides. Noteworthy, **X**-labeled duplexes in various 'zipper' constructions display thermal stabilities remarkably higher than those of parent dsDNAs labeled in one strand (data presented in Table 4 compared to data in Table 1). This suggests an effective and stabilizing interstrand communication between perylene functionalities in the engineered motifs.

To summarize the data listed in Table 4, the duplexes multilabeled with monomer **X** in general display remarkably high thermal stabilities, which are caused by the rigid bicyclic LNA skeleton, the short amide linkage of 2′-*N*-(perylen-3-yl)carbonyl-2′-amino-LNA monomer **X**, and consequential perylene−perylene stabilizing interactions existing in the engineered motifs.

(b) Spectral Properties. The UV−vis absorption and steady-state fluorescence emission spectra of the various interstrand 'zipper' arrangements of monomers **X** were obtained using the same conditions as described for the oligonucleotides and

duplexes containing **X**-monomer in only one strand. The spectroscopic and photophysical data evaluated for modified conjugates having monomers **X** in '+1 zipper' and '−1 zipper' constitutions are listed in Table 5. The fluorescence quantum yield for the '−1 zipper' is twice less than for the '+1 zipper', and both of them are much lower than measured for the parent duplex **ON1**:DNA (Table 3). However, the FB value for **ON1**:**ON2** is of the same magnitude as for **ON1**:DNA, as a result of an increased absorption coefficient (ε_{425}) for **ON1**:**ON2**.

All the duplexes having monomers **X** in both complementary strands displayed an unstructured emission band at $\lambda_{em} \approx 490$ nm (Figure 5) and no explicit perylene excimer signal, similar to base-coupled 1-ethynylpyrene in the RNA minor groove (*101*). The fluorescence intensity of the 'zippers' was lower than of the previously described duplexes having perylene residues in only one strand. Quenching of the fluorescence, together with increased thermal stability of these duplexes, points to electronic interstrand interaction between perylene residues taking place in the constructed duplexes and being responsible for the observed quenching effect. Alternatively, perylene↔perylene energy migration might be responsible for fluorescence quenching. In contrast, insertion of pyrene-functionalized LNAs in the 'zipper' motifs of such constitution was previously reported to result in effective excimer formation (*24*).

The CD spectra of the **ON1**:**ON2** verify the same intermediate A/B-type geometry as for duplexes involving **ON1** (Supporting Information, Figure S4). However, **ON1**:**ON3** containing perylene−LNAs in '−1 zipper' constitution exhibit significant deviation toward the A-type, which becomes apparent in disappearance of the negative bang at ~250 nm in the CD spectrum.

CONCLUSIONS

Herein, we have reported the synthesis of 2′-*N*-(perylen-3-yl)carbonyl-2′-amino-LNA monomer **X**, its incorporation into oligonucleotides, thermal denaturation studies, spectral and photophysical properties, and structural aspects for effective detection of nucleic acid hybridization. Oligonucleotides containing monomer **X** exhibit high-affinity hybridization toward complementary unmodified DNA, RNA, and monomer **X**-containing DNA, considerably quenched fluorescence of single-stranded multilabeled probes, and an evident increase of fluorescence intensity (up to 14-fold), brightness, and quantum yields upon hybridization. In the presence of single base-pair mismatches in DNA/RNA targets, perylene-functionalized probes display remarkably quenched fluorescence compared to fully matched duplexes. Thus, the executed replacement of the previously reported pyrene moiety attached via an amide group to 2′-amino-LNA (*22*) with perylene results in creation of very promising probes for homogeneous fluorescence assays. These probes display hybridization-increased fluorescence, but with an advantage of 100 nm red-shifted emission compared to pyrene and documented sensitivity of the fluorescence to single mismatches. Initial experiments in cell culture confirm that perylene-LNA ONs do provide a wavelength window which eliminates cell autofluorescence and makes them a promising tool to probe biological RNA specimens by fluorescence microscopy. Duplexes having monomer **X** in both complementary strands reveal remarkable thermal stabilities. This indicates interstrand communication between perylene functionalities, resulting in stabilizing effects and quenching of fluorescence but, however, not in the formation of perylene excimers. The attractive spectral characteristics reported herein, together with high-affinity binding to complementary targets, make probes containing 2′-*N*-(perylen-3-yl)carbonyl-2′-amino-LNA monomer potentially very useful within different fields of nucleic acid research, allowing accomplishment of experiments both *in vitro* and *in vivo*.

ACKNOWLEDGMENT

We greatly appreciate funding from The Sixth Framework Programme Marie Curie Host Fellowships for Early Stage Research Training under contract number MEST-CT-2004−504018 and The Danish National Research Foundation. I.V.A. and V.A.K. acknowledge support of RFBR grant 06−03−32426.

Supporting Information Available: MALDI-TOF MS of synthesized ODNs; fluorescence steady-state emission studies and quantum yield determination details; CD measurements; representative thermal denaturation curves, UV−visible absorption, excitation, fluorescence and CD spectra; cell transfection experiments and fluorescence microscopy details. Excitation spectra were obtained recording emission at 460 nm, 480 nm and 500 nm.

Fluorescence steady-state emission studies and quantum yield determinations

Fluorescence spectra were obtained in a medium salt buffer using a PerkinElmer LS 55 luminiscence spectrometer equipped with a Peltier temperature controller. For recording of fluorescence spectra 0.1 μM concentrations of the ss probe or corresponding duplex were used. For weakly fluorescent samples concentration was increased to 0.5 μM. Excitation spectra were obtained recording emission at 460 nm, 480 nm and 500 nm. The fluorescence quantum yields (Φ_F) were measured by the relative method using standards of highly diluted solutions of perylene (Φ_F 0.93 (*1*)) and 9,10-diphenylantracene (Φ_F 0.95 (*2*)) in cyclohexane. For fluorescence quantum yields determination concentration of 1 μM or 0.5 μM (for intensively fluorescent ONs or duplexes) of the solution was used. In all cases, absorption in the range 435-650 nm of the solutions used for quantum yield measurements did not exceed 0.1, and was not less than 0.01. Control experiments with an elimination of dissolved oxygen in the buffer solution did not show significant change of fluorescence intensity compared to non-degassed solutions. Thus, the samples used in quantum yield measurements were not degassed. Steady-state fluorescence emission spectra were obtained as an average of 5 scans using an excitation wavelength of 425 nm, excitation slit of 4.0 nm, emission slit of 2.5 nm and scan speed of 120 nm/min. The fluorescence quantum yield of perylene in cyclohexane in these experimental settings was measured to be 0.90 relative to 9,10-diphenylantracene in cyclohexane (lit. (*2*) Φ_F 0.95).

Emission quantum yields of perylene-labeled ODNs Φ_F *(ON)* were determined according to (*3*):

$$\Phi_F(ON) = \Phi_F(PerH) \times \frac{I(ON)}{I(PerH)} \times \frac{OD_{425}(PerH)}{OD_{425}(ON)} \times \frac{n^2_{buffer}}{n^2_{cyclohexane}}$$

where Φ_F (*PerH*) is the cross-calibrated (by using of 9,10-diphenylantracene in cyclohexane as a second standard) value of the fluorescence quantum yield of perylene in toluene, *I (ON)* is the area of the fluorescence emission spectra of the sample from 435 to 650 nm, *I (PerH)* is the area of the perylene's emission spectra at the same region, n_{buffer} and $n_{toluene}$ are the refractive indexes of the buffer (1.334) and cyclohexane (1.426), respectively. High quantum yields ($\Phi_F > 0.2$) were determined as the average

of two measurements within ±10%. Determinations of low quantum yields ($\Phi_F < 0.1$) may be associated with considerably larger error.

CD measurements

CD spectra were recorded on JASCO J-815 CD Spectrometer equipped with CDF 4265/15 temperature controller. Samples for CD measurements were prepared as described in the thermal denaturation studies section except that a concentration of 2.0 µM of both the complementary strands was used. Quartz optical cells with a path-length of 0.5 cm were used.

C) D)

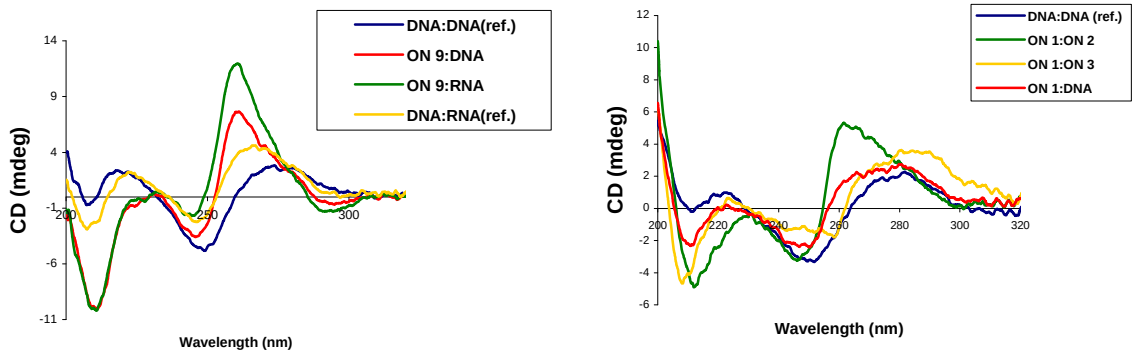

Figure S4. CD spectra of **ON1**,**ON4**, and **ON7** against A) DNA complement and B) complementary RNA; C) CD spectra of **ON9**:DNA and **ON9**:RNA. dsDNA, DNA:RNA and dsRNA. D) CD spectra of **ON1** towards **ON2** and **ON3** ("+1 zipper" and "-1 zipper" constitution, respectively) relative to **ON1**:DNA. The spectra were recorded in medium salt buffer at 19 ºC, using 2.0 µM concentration of complementary strands.

Cell transfection experiments

HEK 293 cells were grown in Gibco RPMI medium with 10% FBS. Experiments were performed on coverslips in 12 well plates coated with polyL lysine. The genetic code for mCherry protein followed by 4 x target sequence was cloned into a pCDNA5/FRT/TO vector which was transfected with Lipofectamine 2000 (LF-2000) transfection reagent using 4 µL LF-2000 and 1.6 µg DNA following the LF-2000 protocol. The medium was changed after 12 hours. The LNA probe **ON10** was transfected after 40 hours with LF-2000 using 40 pmol of the probe and 2 µL of LF-2000.

Protocol for the transfection of cloned DNA/probe **ON10**

1) Mix DNA/**ON10** with 100 µL Serum free medium. Let sit for 5 min.
2) Mix Lipofectamine-2000 transfection reagent with 100 µL Serum free medium in another tube. Let sit for 5 min.
3) Mix the contents of the two tubes and mix gently. Let it stand at room temperature for 25 min.
4) Pour the mixture over cells and rock 12-well plate gently to distribute the transfection reagent evenly.

Cells were fixated after 6 hours by washing with 2 x in PBS, incubated in 4% formaldehyde solution for 30 min, and washed with 3 x in PBS. Coverslips were mounted on objective slides with 3µL mounting media containing DAPI stain.

Visualization

Fluorescence was visualized with a Ziess axiovert 200m microscope using excitation wavelengths of 360 nm (DAPI), 435 nm (perylene-LNA probe) and 570 nm (mCherry protein) and emission wavelengths of 460 nm, 480 nm and 630 nm for DAPI, perylene-LNA and mCherry protein, respectively (±15 nm).

^{64}Cu-Labeled 2-(Diphenylphosphoryl)ethyldiphenylphosphonium Cations as Highly Selective Tumor Imaging Agents: Effects of Linkers and Chelates on Radiotracer Biodistribution Characteristics

Chang-Tong Yang,[†] Young-Seung Kim,[†] Jianjun Wang,[†] Lijun Wang,[†] Jiyun Shi,[†] Zi-Bo Li,[‡] Xiaoyuan Chen,[‡] Ming Fan,[†] Jian-Jian Li,[†] and Shuang Liu*,[†]

School of Health Sciences, Purdue University, West Lafayette, Indiana, and Molecular Imaging Program at Stanford, Department of Radiology and Bio-X, Stanford University, Stanford, California. Received May 21, 2008; Revised Manuscript Received July 28, 2008

Radiolabeled organic cations, such as triphenylphosphonium (TPP), represents a new class of radiotracers for imaging cancers and the transport function of multidrug resistance P-glycoproteins (particularly MDR1 Pgp) by single photon emission computed tomography (SPECT) or positron emission tomography (PET). This report presents the synthesis and biological evaluation of ^{64}Cu-labeled 2-(diphenylphosphoryl)ethyldiphenylphosphonium (TPEP) cations as novel PET radiotracers for tumor imaging. Biodistribution studies were performed using the athymic nude mice bearing subcutaneous U87MG human glioma xenografts to explore the impact of linkers, bifunctional chelators (BFCs), and chelates on biodistribution characteristics of the ^{64}Cu-labeled TPEP cations. Metabolism studies were carried out using normal athymic nude mice to determine the metabolic stability of four ^{64}Cu radiotracers. It was found that most ^{64}Cu radiotracers described in this study have significant advantages over ^{99m}Tc-Sestamibi for their high tumor/heart and tumor/muscle ratios. Both BFCs and linkers have significant impact on biological properties of ^{64}Cu-labeled TPEP cations. For example, ^{64}Cu(DO3A-xy-TPEP) has much lower liver uptake and better tumor/liver ratios than ^{64}Cu(DO3A-xy-TPP), suggesting that TPEP is a better mitochondrion-targeting molecule than TPP. Replacing DO3A with DO2A results in ^{64}Cu(DO2A-xy-TPEP)$^{+}$, which has a lower tumor uptake than ^{64}Cu(DO3A-xy-TPEP). Substitution of DO3A with NOTA-Bn leads to a significant decrease in tumor uptake for ^{64}Cu(NOTA-Bn-xy-TPEP). The use of DOTA-Bn to replace DO3A has little impact on the tumor uptake, but the tumor/liver ratio of ^{64}Cu(DOTA-Bn-xy-TPEP)$^{-}$ is not as good as that of ^{64}Cu(DO3A-xy-TPEP), probably due to the aromatic benzene ring in DOTA-Bn. Addition of an extra acetamido group in ^{64}Cu(DOTA-xy-TPEP) results in a lower liver uptake, but tumor/liver ratios of ^{64}Cu(DOTA-xy-TPEP) and ^{64}Cu(DO3A-xy-TPEP) are comparable due to a faster tumor washout of ^{64}Cu(DOTA-xy-TPEP). Substitution of xylene with the PEG_2 linker also leads to a significant reduction in both tumor and liver uptake. MicroPET imaging studies on ^{64}Cu(DO3A-xy-TPEP) in athymic nude mice bearing U87MG glioma xenografts showed that the tumor was clearly visualized as early as 1 h postinjection with very high T/B contrast. There was very little metabolite (<2%) detectable in the urine and feces samples for ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DOTA-Bn-xy-TPEP)$^{-}$, and ^{64}Cu(NOTA-Bn-xy-TPEP). Considering both tumor uptake and T/B ratios (particularly tumor/heart, tumor/liver, and tumor/muscle), it was concluded that ^{64}Cu(DO3A-xy-TPEP) is a promising PET radiotracer for imaging the MDR-negative tumors.

INTRODUCTION

Alteration in the mitochondrial potential ($\Delta\Psi_m$) is an important characteristic of cancer (*1*−*4*). It has been demonstrated that the mitochondrial potential in carcinoma cells is significantly higher than that in normal epithelial cells (*5*−*9*). For example, the difference in $\Delta\Psi_m$ between the colon carcinoma cell line CX-1 and the control green monkey kidney epithelial cell line CV-1 was approximately 60 mV (163 mV in tumor cells versus 104 mV in normal cells). The observation that the enhanced mitochondrial potential is prevalent in tumor cell phenotype provides the conceptual basis for development of the mitochondrion-targeting pharmaceuticals and imaging probes (*1*−*3*, *10*−*13*).

Recently, we reported several ^{64}Cu-labeled triphenylphosphonium (TPP) cations as radiotracers for tumor imaging by positron emission tomography (PET) in athymic nude mice bearing U87MG human glioma xenografts (*14*−*16*). We found that that ^{64}Cu(DO3A-xy-TPP) and ^{64}Cu(DO2A-xy-TPP)$^{+}$ have relatively high tumor uptake with long tumor retention. The most striking difference between the ^{64}Cu-labeled TPP cations and ^{99m}Tc-Sestamibi, the most successful radiopharmaceutical currently available for both tumor and myocardial perfusion imaging, is that they all have much lower heart uptake (<0.6% ID/g) than ^{99m}Tc-Sestamibi (∼18% ID/g) at >30 min postinjection (p.i.). Their tumor/heart ratios are >40× better than that of ^{99m}Tc-Sestamibi at 120 min p.i. The muscle uptake of ^{64}Cu(DO3A-xy-TPP) was undetectable at >30 min p.i. while ^{99m}Tc-Sestamibi has very high muscle uptake (∼5% ID/g) over the 2 h study period. Despite their charge difference, ^{64}Cu(DO3A-xy-TPP) and ^{64}Cu(DO2A-xy-TPP)$^{+}$ share very similar lipophilicity, tumor uptake, tumor/heart, and tumor/lung ratios. However, the positive charge in ^{64}Cu(DO2A-xy-TPP)$^{+}$ results in a dramatic reduction in its liver uptake. As a result, its tumor/liver ratio is significantly better than that of ^{64}Cu(DO3A-xy-

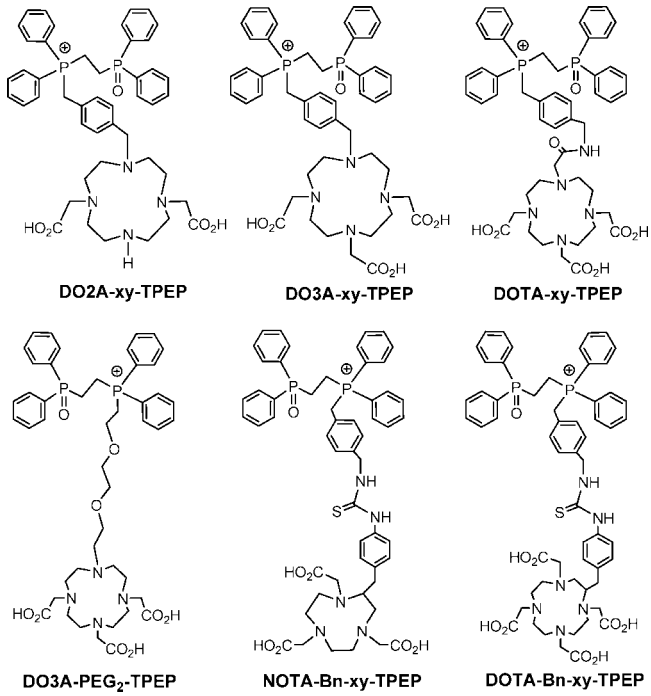

Figure 1. TPEP conjugates for preparation of the ^{64}Cu TPEP cations useful as radiotracers for imaging tumors by PET. The TPEP moiety is used as the "mitochondrion-targeting biomolecule" to carry ^{64}Cu into tumor cells that have higher mitochondrial potential than normal cells. DO3A, DO2A, DOTA, and NOTA are used as BFCs for ^{64}Cu chelation. Different linkers are used to modify pharmacokinetics and improve T/B ratios of ^{64}Cu radiotracers.

TPP) (*16*). Results from *in vitro* assays show that ^{64}Cu(DO3A-xy-TPP) is able to localize in mitochondria of glioma cells. MicroPET imaging data show that the tumor could be visualized as early as 30 min p.i. in the tumor-bearing mice administered with ^{64}Cu(DO3A-xy-TPP) (*14*). However, its high liver uptake remains a significant challenge for ^{64}Cu(DO3A-xy-TPP) to be clinically useful as a PET radiotracer.

To further improve the tumor uptake and tumor/background (T/B) ratios, we prepared several 2-(diphenylphosphoryl)ethyldiphenylphosphonium (TPEP) conjugates (Figure 1) and their ^{64}Cu complexes. We are particularly interested TPEP cation because of the phosphoryl group (P═O) that may help improve the radiotracer hydrophilicity and excretion kinetics from the liver. Biodistribution and imaging studies were performed using athymic nude mice bearing subcutaneous U87MG glioma xenografts. The U87MG glioma cell line was chosen because it has no expression of multidrug resistance P-glycoprotein (particularly MDR1 Pgp) (*17*−*20*). This tumor-bearing animal model would allow us to evaluate the intrinsic tumor-targeting capability of ^{64}Cu radiotracers and their excretion kinetics from noncancerous organs, such as heart, liver, lungs, and muscle. The main objective of this study is to explore the impact of linkers, bifunctional chelators (BFCs), and ^{64}Cu-chelates on biodistribution characteristics and excretion kinetics of the ^{64}Cu-labeled TPEP cations.

EXPERIMENTAL SECTION

Materials and Instruments. Chemicals were purchased from Sigma/Aldrich (St. Louis, MO) and used as received. DO3A(OBu-t)$_3$ (1,4,7,10-tetraazacyclododecane-4,7,10-tris(*t*-butyl acetate)), DO2A(OBu-t)$_2$ (1,4,7,10-tetraazacyclododecane-4,7-bis(*t*-butyl acetate)), DOTA(OBu-t)$_3$-NHS (1,4,7,10-tetraazacyclododecane-1-(*N*-hydroxysuccinimide acetate)-4,7,10-tris(*t*-butyl acetate)), *p*-SCN-Bn-DOTA(2-(*p*-isothiocyanobenzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid), and *p*-SCN-Bn-NOTA (2-(*p*-isothiocyanobenzyl)-1,4,7-triaazacyclononane-1,4,7-triacetic acid) were purchased from Macrocyclics Inc. (Dallas, TX). NMR (^{1}H, ^{13}C, and ^{31}P) data were obtained using a Bruker DRX 300 MHz FT NMR spectrometer. Chemical shifts are reported as δ in ppm relative to TMS. ESI mass spectral data were collected using positive mode on a Finnigan LCQ classic mass spectrometer, School of Pharmacy, Purdue University. Elemental analysis was performed by Dr. H. Daniel Lee using a Perkin-Elmer Series III analyzer, Department of Chemistry, Purdue University. ^{64}Cu was produced using a CS-15 biomedical cyclotron at Washington University School of Medicine by the ^{64}Ni(p,n)^{64}Cu nuclear reaction.

HPLC Methods. Method 1 used a LabAlliance semiprep HPLC system equipped with a UV/vis detector (λ = 254 nm) and Zorbax C_{18} semiprep column (9.4 mm × 250 mm, 100 Å pore size). The flow rate was 2.5 mL/min. The mobile phase was isocratic with 90% solvent A (0.1% acetic acid in water) and 10% solvent B (0.1% acetic acid in acetonitrile) at 0−5 min, followed by a gradient mobile phase going from 90% solvent A and 10% solvent B at 5 min to 60% solvent A and 40% solvent B at 20 min. Method 2 used the LabAlliance HPLC system equipped with a UV/vis detector (λ = 254 nm), a β-ram IN-US detector and Vydac C_{18} column (4.6 mm × 250 mm, 300 Å pore size). The flow rate was 1 mL/min with the mobile phase being isocratic with 90% solvent A (10 mM ammonium acetate) and 10% solvent B (acetonitrile) at 0−5 min, followed by a gradient mobile phase going from 10% B at 5 min to 60% B at 20 min.

(4-(Bromomethyl)benzyl)(2-(diphenylphosphoryl)ethyl)-diphenylphosphonium Bromide (TPEP-xy-Br). To a hot solution of α,α′-dibromo-*p*-xylene (528 mg, 2 mmol) in toluene (30 mL) was added slowly bis(diphenylphosphino)ethane monooxide (828 mg, 2 mmol). The mixture was heated to reflux for 20 h. The white solid was filtered, washed with toluene (20 mL) and diethyl ether (40 mL), and then dried under vacuum to give the expected intermediate product: 4-bromomethylbenzyl(diphenylphosphinoethane)phosphonium bromide (TPEP-xy-Br). The yield was 1.26 g (93%). ^{1}H NMR ($CDCl_3$, chemical shift δ in ppm relative to TMS): 2.78 (m, 2H, O═PCH_2); 3.05 (m, 2H, PCH_2); 4.23 (s, 2H, CH_2Br); 4.75 (d, 2H, PCH_2, J_{PH} = 13 Hz); 6.83 (d, 4H, C_6H_4); 7.52−7.91 (m, 20H, C_6H_5). ESI-MS: m/z = 598.5 for [M^+ + H] (calcd. 598 for $C_{34}H_{32}OP_2Br^+$). TPEP-xy-Br was isolated as the bromide salt, and was used for the next step reaction without further purification.

(2-(Diphenylphosphoryl)ethyl)diphenyl(4-((4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)methyl)benzyl)phosphonium Acetate (DO3A-xy-TPEP). To a solution of TPEP-xy-Br (67.8 mg, 0.1 mmol) and DO3A(OBu-t)$_3$ (51.5

mg, 0.1 mmol) in dry DMF (3 mL) was added triethylamine (0.07 mL, 0.5 mmol). The reaction mixture was stirred at 50 °C overnight. After complete removal of volatiles, the residue was dissolved in 12 N HCl (2 mL). The resulting solution was stirred at room temperature for 30 min. Volatiles were completely removed under vacuum. The residue was then dissolved in water (3 mL) and subjected to HPLC purification (Method 1). The fractions at ~17.3 min were collected, combined, and lyophilized to give a white powder. The yield was 30.1 mg (33%). ^{1}H NMR (D_2O, chemical shift δ in ppm relative to TMS): 1.89 (s, 3H, CH_3COO^-); 2.80−3.7 (m, 26H); 3.67 (s, 2H); 4.29 (d, 2H, PCH_2, J_{PH} = 13 Hz); 6.71 (d, 2H, C_6H_4); 7.18 (d, 2H, C_6H_4); 7.38−7.67 (m, 20H, C_6H_5). ESI-MS: m/z = 863.2 for $[M + H]^+$ (calcd. 863 for $[C_{48}H_{57}N_4O_7P_2]^+$). Anal. Calcd. for $C_{48}H_{57}N_4O_7P_2 \cdot CH_3CO_2 \cdot 5H_2O$: C, 59.28; H, 6.96; N, 5.53. Found: C, 59.48; H, 6.85; N, 5.71.

(4-((4,10-Bis(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)methyl)benzyl)(2-(diphenylphosphoryl)ethyl)diphenylphosphonium Acetate (DO2A-xy-TPEP). To a solution of TPEP-xy-Br (67.8 mg, 0.1 mmol) and DO2A(OBu-t)$_2$ (80 mg, 0.2 mmol) in dry DMF (3 mL) was added triethylamine (0.07 mL, 0.5 mmol). The mixture was stirred at room temperature overnight. After complete removal of volatiles, the residue was dissolved in 12 N HCl (3 mL). The solution was stirred at room temperature for 30 min. Volatiles were removed completely on a rotary evaporator. The residue was then dissolved in water (3 mL), and the product was separated from the mixture by HPLC purification (Method 1). The fractions at ~11.8 min were collected, combined, and lyophilized to give a white powder. The yield was 28.5 mg (33%). ^{1}H NMR (in $CDCl_3$): 1.89 (s, 3H, CH_3COO^-); 2.42 (m, 4H); 2.70−3.01 (m, 20H); 3.40 (s, NCH_2); 4.85 (d, 2H, PCH_2, J_{PH} = 13 Hz); 6.78 (d, 2H, C_6H_4); 7.30 (d, 2H, C_6H_4); 7.47−7.83 (m, 20H, C_6H_5). ESI-MS: m/z = 805.4 for $[M + H]^+$ (805 calcd. for $C_{46}H_{55}N_4O_5P_2^+$). Anal. Calcd. for $C_{46}H_{55}N_4O_5P_2 \cdot CH_3CO_2 \cdot 6.5H_2O$: C, 58.71; H, 7.29; N, 5.71. Found: C, 58.50; H, 6.89; N, 5.77.

(2-(Diphenylphosphoryl)ethyl)diphenyl(2-(2-(2-(tosyloxy)-ethoxy)ethoxy)ethyl) phosphonium Tosylate (TPEP-PEG$_2$-OTs). TsO-PEG2-OTs was prepared using the literature procedure (*16*). TPEP mono-oxide (104 mg, 0.25 mmol) and TsO-PEG$_2$-OTs (230 mg, 0.5 mmol) were suspended in dry toluene (10 mL). The mixture was heated to reflux for 20 h. Volatiles were removed under vacuum. The residue was dissolved in 50% DMF/H_2O mixture. The resulting solution was subject to HPLC purification (Method 1). The fractions at ~16.5 min were collected and lyophilized to give a white solid. The yield was 65.5 mg (30%). ^{1}H NMR (in $CDCl_3$): 2.33 (s, 3H, CH_3), 2.43 (s, 3H, CH_3), 2.75 (m, 2H, O=PCH_2), 3.17−3.71 (m, 12H), 4.09 (t, 2H, PCH_2), 7.12 (d, 2H, J = 7.8 Hz), 7.32−7.78 (m, 26H). ESI-MS: m/z = 701.17 for $[M]^+$ (calcd. 701 for $[C_{39}H_{43}O_6P_2S]^+$).

(2-(Diphenylphosphoryl)ethyl)diphenyl(2-(2-(2-(4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)ethoxy)ethoxy)ethyl)phosphonium Tosylate (DO3A-PEG2-TPEP). TPEP-PEG$_2$-OTs (24 mg, 0.027 mmol) and DO3A(t-Bu)$_3$ (14 mg, 0.027 mmol) were dissolved in dry DMF (3 mL). After addition of Et_3N (30 μL, 0.20 mmol), the solution was stirred at room temperature for 20 h. After removal of volatiles, the residue was dissolved in 12 N HCl (3 mL). The solution was stirred for 2 h. After complete removal of volatiles under vacuum, the residue was dissolved in water (3 mL). The resulting solution was subjected to HPLC purification (Method 1). The fractions at ~10 min were collected, combined, and lyophilized to give a white powder. The yield was 8.5 mg (30%). ^{1}H NMR (in $CDCl_3$): 2.21 (s, 3H, CH_3), 2.39−3.63 (m, 38H), 7.19 (d, 2H), 7.35−7.72 (m, 22 H). ^{31}P NMR: 32.41 (d, J = 54.4 Hz), 42.84 (d, J = 54.4 Hz). ESI-MS: m/z = 875.01 for $[M]^+$ (calcd. 875 for $[C_{46}H_{61}N_4O_9P_2]^+$). Anal. Calcd. for $C_{46}H_{61}N_4O_9P_2 \cdot CH_3C_6H_4SO_3 \cdot H_2O$: C, 59.76; H, 6.62; N, 5.71. (4-((1,3-Dioxoisoindolin-2-yl)methyl)benzyl)(2-(diphenylphosphoryl)ethyl)diphenyl-phosphonium Bromide (TPEP-xy-PA). TPEP-xy-Br (340 mg, 0.5 mmol) and potassium pthalimide (110 mg, 0.6 mmol) were suspended in acetonitrile (10 mL). The suspension was heated to reflux for 24 h. The solid was filtered and the filtrate was dried under vacuum to give a light-yellow solid (300 mg, 0.40 mmol, 80%). ^{1}H NMR (in $CDCl_3$): 2.83 (m, 2H), 3.14 (m, 2H), 4.66 (s, 2H, CH_2N), 5.14 (d, 2H, PCH_2, J_{PH} = 14.4 Hz), 6.80 (dd, 2H, J = 8.1, 2.7 Hz), 6.93 (d, 2H, J = 8.1 Hz), 7.45−7.90 (m, 20H), 8.05−8.18 (m, 4H). ^{31}P NMR: 28.9 (d, J = 53.1 Hz), 33.0 (d, J = 53.1 Hz). ESI-MS: m/z = 664.03 for $[M]^+$ (calcd. 664 for $[C_{42}H_{36}NO_3P_2]^+$).

(4-(Aminomethyl)benzyl)(2-(diphenylphosphoryl)ethyl)-diphenylphosphonium (TPEP-xy-NH$_2$). The TPEP-xy-PA intermediate (300 mg, 0.40 mmol) and 0.53 mL of aqueous hydrazine (55%, 88 mmol) were added into absolute ethanol (20 mL). The resulting solution was heated to reflux for 20 h. Volatiles were removed under vacuum. The light-yellow solid was dissolved in dichloromethane (20 mL). After filtration, the solvent was evaporated to get light-yellow solid. The yield was 230 mg (92%). ^{1}H NMR (in $CDCl_3$): 2.88 (m, 2H), 3.10 (m, 2H), 3.72 (s, 2H, CH_2N), 5.14 (d, 2H, PCH_2, J_{PH} = 14.4 Hz), 6.85 (m, 4H), 7.42−7.85 (m, 16H), 8.05−8.15 (m, 4H). ^{31}P NMR: 28.8 (d, J = 51.7 Hz), 33.1 (d, J = 51.7 Hz). ESI-MS: m/z = 534.11 for $[M]^+$ (calcd. 534 for $[C_{34}H_{34}NOP_2]^+$).

(2-(Diphenylphosphoryl)ethyl)diphenyl(4-((2-(4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)acetamido)methyl)benzyl)phosphonium Acetate (DOTA-xy-TPEP). TPEP-xy-NH$_2$ (10 mg, 0.01 mmol) and PF_6 salt of DOTA(t-Bu)$_3$-NHS (6.7 mg, 0.01 mmol) were dissolved in dry DMF (3 mL). Upon addition of triethylamine (44 μL, 0.32 mmol), the resulting mixture was stirred at room temperature for 20 h. After removal of volatiles, the residue was dissolved in the concentrated HCl (3 mL). The solution was then stirred at room temperature for 2 h. Volatiles were completely removed under vacuum, and the residue was dissolved in water (3 mL). The product was separated from the mixture by HPLC (Method 1). The fractions at ~18 min were collected and lyophilized to give a white powder. The yield was 5.6 mg (56%). ^{1}H NMR (in D_2O): 1.88 (s, 3H, CH_3COO^-); 2.55−3.35 (m, 26H), 3.59 (d, 2H, NCH_2), 4.12 (s, 2H, CH_2NH), 4.21 (d, 2H, PCH_2, J = 14.7 Hz), 6.60 (dd, 2H, J = 7.8 and 2.2 Hz), 6.94 (d, 2H, J = 7.8), 7.32−7.75 (m, 20H). ^{31}P NMR: 30.64 (d, J = 53.0 Hz), 43.09 (d, J = 53.0 Hz). ESI-MS: m/z = 920.1 for $[M]^+$ (calcd. 920 for $[C_{50}H_{60}N_5O_8P_2]^+$). Anal. Calcd. for $C_{50}H_{60}N_5O_8P_2 \cdot CH_3CO_2 \cdot 2H_2O$: C, 61.47; H, 6.65; N, 6.89. Found: C, 61.11; H, 6.53; N, 6.96.

(2-(Diphenylphosphoryl)ethyl)diphenyl(4-((3-(4-((1,4,7,10-tetrakis(carboxymethyl)-1,4,7,10-tetraazacyclododecan-2-yl)-methyl)phenyl)thioureido)methyl)benzyl)phosphonium Acetate (DOTA-Bn-xy-TPEP). TPEP-xy-NH$_2$ (6 mg, 0.01 mmol) and p-SCN-Bn-DOTA (6.7 mg, 0.01 mmol) were dissolved in the equal volume mixture (2 mL) of DMF and water. The pH value in the mixture was adjusted to 8.5 with 1 N NaOH. The resulting mixture was stirred at room temperature overnight and then purified by HPLC (Method 1). The fractions at ~17.8 min were collected. Lyophilization of the collected fractions gave a white powder. The yield was 6.3 mg (56%). ^{1}H NMR (in D_2O): 1.90 (s, 3H, CH_3COO^-); 2.35−3.82 (m, 29 H); 4.22 (d, 2H, PCH_2, J_{PH} = 16.2 Hz); 4.49 (s, 2H, CH_2NH); 6.55 (dd, 2H); 6.78 (m, 2H); 7.16 (m, 2H); 7.32−7.53 (m, 20H); 7.69 (m, 3 H). ^{31}P NMR: 30.62 (d, J = 52.4 Hz) and 42.84 (d, J = 52.4 Hz). ESI-MS: m/z = 1085.22 for $[M]^+$ (calcd. 1085 for

^{64}Cu-Labeling. To a 5 mL vial were added 0.5 mL 0.1 M NaOAc buffer (pH = 6.9) containing 50 μg of the TPEP conjugate and 0.12 mL of $^{64}CuCl_2$ solution (1.0−2.0 mCi) in 0.05 N HCl. The final pH was 5.0−5.5. The mixture was heated at 100 °C for 30 min. After cooling to room temperature, a sample of resulting solution was analyzed by radio-HPLC (Method 2). The radiochemical purity (RCP) was >90% for all ^{64}Cu radiotracers with specific activity being ~50 Ci/mmol. RCP data and HPLC retention times of ^{64}Cu radiotracers are listed in Table 1.

Dose Preparation. All newly synthesized ^{64}Cu radiotracers were purified by HPLC before being used for biodistribution studies. Volatiles in the HPLC mobile phases were completely removed under vacuum (<10 mmHg) at 40−50 °C. The residue was dissolved in saline to ~25 μCi/mL. The resulting solution was filtered with a 0.20 μ syringe-driven filter unit to eliminate any particles. Each animal was administered intravenously with ~0.10 mL of the dose solution. For the imaging study, ^{64}Cu(DO3A-xy-TPEP) was prepared and the resulting mixture was used without purification. The reaction mixture was diluted to ~5 mCi/mL with saline. The injected dose for each tumor-bearing mouse was about 250 μCi of ^{64}Cu(DO3A-xy-TPEP).

Solution Stability. For solution stability, ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DO2A-xy-TPEP), ^{64}Cu(NOTA-Bn-xy-TPEP), and ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ were prepared and purified by HPLC (Method 2). Volatiles in the HPLC mobile phase were removed under vacuum. The residue was dissolved in saline to ~1 mCi/mL. Samples were analyzed by HPLC (Method 2) at 0, 1, 2, 4, and 12 h post purification. In the EDTA challenge experiment, the HPLC purified ^{64}Cu radiotracers were dissolved in 25 mM phosphate buffer (pH = 7.4) containing EDTA (1 mg/mL) to 1 mCi/mL. Samples of the resulting solution were analyzed by radio-HPLC (Method 2) at 0, 1, 2, 4, and 12 h post purification.

Partition Coefficient. All new ^{64}Cu radiotracers were purified before being used for partition coefficient determination. HPLC purification is needed to eliminate potential interference from other radio-impurities. After complete removal of volatiles in the HPLC mobile phases under vacuum (<10 mmHg) at 40−50 °C, the residue was dissolved in a mixture of 3 mL 25 mM phosphate buffer (pH 7.4) and 3 mL *n*-octanol. The mixture was stirred vigorously for 20 min at room temperature, and was then transferred to an Eppendorf microcentrifuge tube. The tube was centrifuged at 12 500 rpm for 5 min. Samples in triplets from *n*-octanol, and aqueous layers were obtained and were counted a Perkin-Elmer Wizard 1480 automatic γ-counter (Shelton, CT). The log *P* value was reported as an average of the data obtained in three independent measurements.

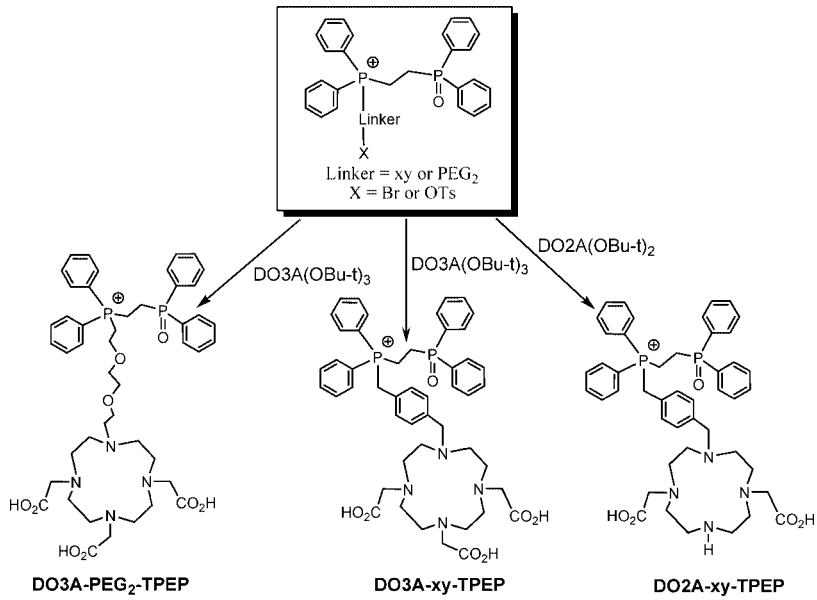
Tumor-Bearing Animal Model. The ex vivo biodistribution studies were performed using athymic nude mice bearing U87MG human glioma xenografts in compliance the NIH animal experiment guidelines (Principles of Laboratory Animal Care, NIH Publication No. 86-23, revised 1985). The animal protocol has been approved by Purdue University Animal Care and Use Committee (PACUC). Female athymic nu/nu mice (4−5 weeks of age) were purchased from Harlan (Charles River, MA). Each mouse was implanted with 5×10^6 U87MG glioma cells into the upper shoulder flank. Three to four weeks after inoculation, the tumor size was in the range 0.3−0.6 g, and animals were used for both biodistribution and imaging studies.

Biodistribution Protocol. Twelve tumor-bearing mice (20−25 g) were randomly divided into four groups. The ^{64}Cu radiotracer (~2.5 μCi dissolved in 0.1 mL saline) was administered to each animal via tail vein. Three animals were sacrificed by sodium pentobarbital overdose (100 mg/kg) at 5, 30, 60, and 120 min p.i. The blood sample was withdrawn from the heart. Organs were excised, washed with saline, dried with absorbent tissue, weighed, and counted on a Perkin-Elmer Wizard 1480 γ-counter (Shelton, CT). Organs of interest included tumor, brain, heart, spleen, lungs, liver, kidneys, muscle, and intestine. The organ uptake was calculated as a percentage of the injected dose per organ (%ID/organ) and a percentage of the injected dose per gram of organ tissue (%ID/g).

Calibration of microPET. Scanner activity calibration was performed to map between microPET image units and units of activity concentration. A preweighed 50 mL centrifuge tube was filled with solution containing $^{64}CuCl_2$ (~9.3 MBq as determined by the dose calibrator) was used to simulate whole body of the mouse. This tube was weighed, centered in the scanner aperture, and imaged for 30 min static image. From the sample weight and the density of 1 g/mL, the activity concentration was calculated as μCi/mL. Eight planes were acquired in the coronal section. A rectangular region of interest (ROI) (counts/pixel/s) was drawn on the middle of 8 coronal planes. The calibration factor was obtained by dividing the known radioactivity in the cylinder (μCi/mL) by the image ROI. This calibration factor was determined periodically and did not vary significantly with time.

MicroPET Imaging. MicroPET imaging of the tumor-bearing mice was performed using a microPET R4 rodent model scanner (Concorde Microsystems, Knoxville, TN). The tumor-bearing mice (n = 3) were imaged in the prone position in the microPET scanner. Each tumor-bearing mouse was injected with ~250 μCi of ^{64}Cu(DO3A-xy-TPEP) via the tail vein, then anesthetized with 2% isoflurane and placed near the center of the FOV where the highest resolution and sensitivity are obtained. Multiple static scans were obtained at 0.5, 1.0, 2, and 20 h p.i. The images were reconstructed by a two-dimensional ordered subsets expectation maximum (OSEM) algorithm. No correction was necessary for attenuation or scatter. At each microPET scan, the ROIs were drawn over the tumor and major organs on decay-corrected whole-body coronal images. The average radioactivity concentration within the tumor or an organ was obtained from mean pixel values within the multiple ROI volume, which were converted to counts/mL/min by using the calibration constant *C*. Assuming that the tissue density is 1

Chart 1. Synthesis of TPEP and TPPP Conjugates



g/mL, the ROIs were converted to counts/g/min, and were then divided by the total administered activity to obtain an imaging ROI-derived percentage administered activity per gram of tissue (%ID/g).

Metabolism. Metabolic stability was evaluated in normal nude mice for ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DOTA-xy-TPEP), ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$, and ^{64}Cu(NOTA-Bn-xy-TPEP). Each mouse was administered with 100 μCi of ^{64}Cu radiotracer via tail vein. Urine samples were collected at 30 and 120 min p.i. by manual void, and were mixed with equal volume of acetonitrile. The mixture was centrifuged at 8000 rpm. The supernatant was collected and filtered through a 0.20 μm Millex-LG syringe-driven filter unit to remove the precipitate and large proteins. The filtrate was analyzed by radio-HPLC (Method 2). The feces samples were collected at ~120 min p.i., and were suspended in a mixture of 50% acetonitrile aqueous solution. The mixture was vortexed for 5−10 min. After centrifuging at 8000 rpm for 5 min, the supernatant was collected and passed through a 0.20 μm Millex-LG syringe-driven filter unit to remove the precipitate or particles. The filtrate was then analyzed by radio-HPLC (Method 2).

Stability of ^{64}Cu(DO3A-xy-TPEP) in Liver. The liver tissue was harvested at 120 min p.i. from the mouse administered with ^{64}Cu(DO3A-xy-TPEP) (~100 μCi), counted in a γ-counter (Perkin-Elmer Wizard 1480, Shelton, CT) for total liver radioactivity, and homogenized. The homogenate was mixed with 2 mL of saline. After centrifuging at 8000 rpm for 5 min, the supernatant was collected and counted on a γ-counter (Perkin-Elmer Wizard 1480, Shelton, CT) to determine the percentage of radioactivity recovery. After filtration through a 0.20 μm Millex-LG filter unit to remove foreign particles, the filtrate was then analyzed by radio-HPLC (Method 2).

Data and Statistical Analysis. The biodistribution data and T/B ratios are reported as an average plus the standard variation based on results from three tumor-bearing mice at each time point. Comparison between two different radiotracers was made using the two-way ANOVA test (GraphPad Prim 5.0, San Diego, CA). The level of significance was set at $p < 0.05$.

RESULTS

Synthesis of TPEP Conjugates. DO3A-xy-TPEP, DO2A-xy-TPEP, and DO3A-PEG$_2$-TPEP were prepared according to Chart 1. They were designed to examine the impact of linkers (xy vs PEG$_2$) and molecular charge (^{64}Cu-DO3A vs ^{64}Cu-DO2A) on organ uptake and excretion kinetics of the ^{64}Cu radiotracers. DOTA-xy-TPEP, DOTA-Bn-xy-TPEP, and NOTA-Bn-xy-TPEP were designed to examine the impact of BFCs (DO3A vs DOTA, DOTA-Bn, and NOTA-Bn) on biodistribution patterns of ^{64}Cu-labeled TPEP cations. DOTA-xy-TPEP was prepared from the reaction of DOTA(OBu-t)$_3$-NHS with TPEP-xy-NH$_2$ (Chart 2), followed by hydrolysis of DOTA(OBu-t)$_3$-xy-TPEP in 12 N HCl. DOTA-Bn-xy-TPEP and NOTA-Bn-xy-TPEP were prepared by reacting TPEP-xy-NH$_2$ with *p*-SCN-Bn-DOTA and *p*-SCN-Bn-NOTA (Chart 2), respectively. All the TPEP conjugates, except DO3A-PEG$_2$-TPEP, were obtained as acetate salts after lyophilization since the HPLC mobile phases contain 0.1% acetic acid. They all have been characterized by NMR, ESI-MS, and elemental analysis. The purity values of the TPEP conjugates were >95% before being used for ^{64}Cu-labeling. Both TPEP-PEG$_2$ and DO3A-PEG$_2$-TPEP were isolated as tosylate salts, as evidenced by the proton signals of tosylate anion in their ^{1}H NMR spectra and the molecular ion at $m/z = 171$ in their negative mode ESI-mass spectra. It is not clear why TPEP-PEG$_2$ and DO3A-PEG$_2$-TPEP were obtained as tosylate salts while other TPEP conjugates were isolated as acetate salts after HPLC purification and lyophilization.

Radiochemistry. All ^{64}Cu radiotracers were prepared by reacting ^{64}CuCl$_2$ with the TPEP conjugate in 0.1 M NaOAc buffer (pH = 5.0−5.5) at 100 °C for 30 min, and were analyzed using the same reversed-phase HPLC method (Method 2). The RCP for all new ^{64}Cu radiotracers was >95% with the specific activity being >50 Ci/mmol. Their partition coefficients were determined in a 50%/50% (v/v) mixture of *n*-octanol and 25 mM phosphate buffer (pH = 7.4). Their log *P* values and HPLC retention times are listed in Table 1. All new ^{64}Cu radiotracers are very hydrophilic with their log *P* values less than −1.50. BFCs and linkers have a significant impact on lipophilicity of the ^{64}Cu radiotracer. For example, ^{64}Cu(DOTA-xy-TPEP) (log $P = -2.45 \pm 0.02$) is more hydrophilic than ^{64}Cu(DO3A-xy-TPEP) (log $P = -1.69 \pm 0.11$) due to the replacement of DO3A with DOTA. Substitution of xylene with the PEG$_2$ linker made ^{64}Cu(DO3A-PEG$_2$-TPEP) (log $P = -3.01 \pm 0.09$) more hydrophilic than ^{64}Cu(DO3A-xy-TPEP). Despite their charge difference, the lipophilicity of ^{64}Cu(DO3A-xy-TPEP) (log $P = -1.69 \pm 0.11$) was close to that of ^{64}Cu(DO2A-xy-TPEP)$^+$ (log $P = -1.90 \pm 0.10$). ^{64}Cu(NOTA-Bn-xy-TPEP) (log $P = -1.75$

Chart 2. Synthesis of TPEP Conjugates

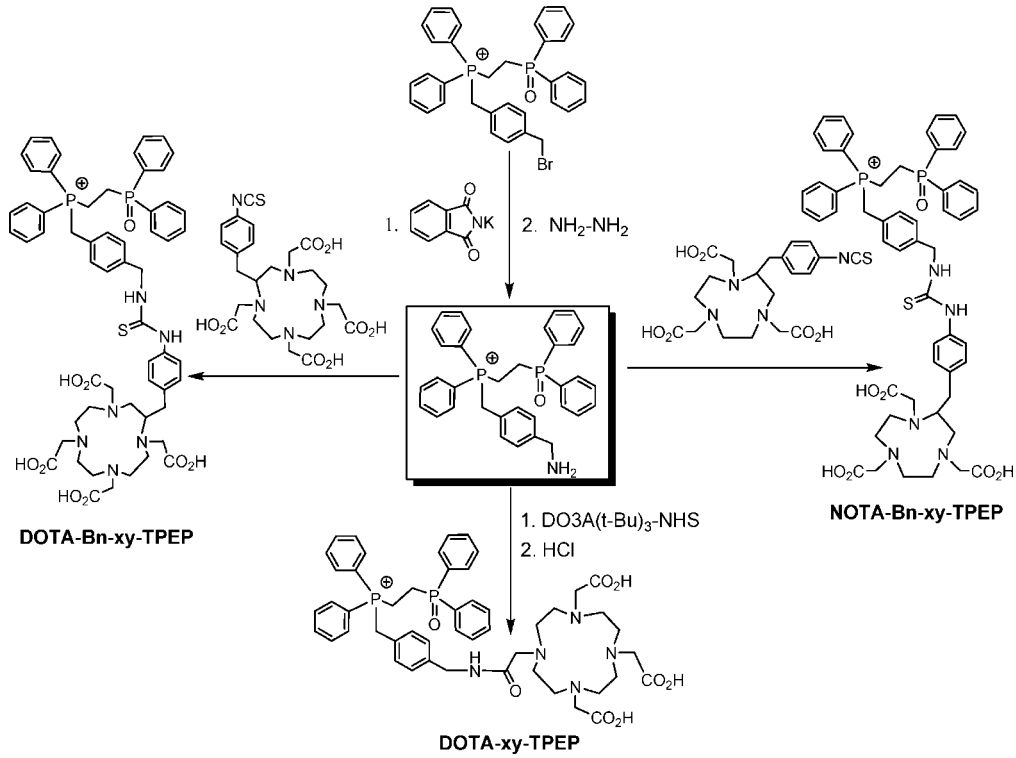


Table 2. Solution Stability Data for HPLC Purified ^{64}Cu-Labeled TPEP Cations in the Presence of Excess EDTA (1 mg/mL in 25 mM phosphate buffer, pH = 7.5)

time post-purification	0.5 h	1 h	2 h	4 h	12 h
^{64}Cu(DO3A-xy-TPEP)	99	99	98	98	97
^{64}Cu(DO2A-xy-TPEP)$^{+}$	99	98	98	97	95
^{64}Cu(DOTA-Bn-xy-TPEP)$^{-}$	99	98	99	98	97
^{64}Cu(NOTA-Bn-xy-TPEP)	99	98	99	98	97

$\pm$ 0.03) also shared similar lipophilicity with ^{64}Cu(DO3A-xy-TPEP) in spite of the extra aromatic phenyl group. Since NOTA-Bn has the same number of acetate chelating arms as DO3A, ^{64}Cu in ^{64}Cu-NOTA-Bn is most likely coordinated by six N_3O_3 donor atoms in the distorted-pseudoprismatic coordination geometry as observed in the solid-state structure of Na[Cu-(NOTA)]·0.2NaBr·0.8H_2O (*21*). Therefore, it is reasonable to believe that ^{64}Cu(NOTA-Bn-xy-TPEP) exists as its zwitterion form. In ^{64}Cu(DOTA-Bn-xy-TPEP)$^{-}$, however, ^{64}Cu is likely coordinated by only six (N_4O_2) of its eight donor atoms (N_4O_4) in the distorted octahedral coordination geometry, as observed in the solid-state structure of Cu(DOTA)$^{2-}$ with two acetate-O atoms remaining uncoordinated (*22, 23*). The extra acetate groups will results in the negative molecular charge under physiological conditions (pH = 7.4); ^{64}Cu(DOTA-Bn-xy-TPEP)$^{-}$ (log $P = -1.92 \pm 0.03$) is slightly more hydrophilic than ^{64}Cu(DO3A-xy-TPEP).

Solution Stability. The EDTA challenge experiment was used to study the solution stability of ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DO2A-xy-TPEP)$^{+}$, ^{64}Cu(DOTA-Bn-xy-TPEP)$^{-}$, and ^{64}Cu(NOTA-Bn-xy-TPEP). These four ^{64}Cu radiotracers were selected because they represent four different types of BFCs (DO3A, DO2A, DOTA-Bn, and NOTA-Bn) for ^{64}Cu chelation. The purpose of these studies was to demonstrate that the ^{64}Cu radiotracer remains intact before being injected into the tumor-bearing mice. Table 2 summarizes their solution stability data in the presence of excess EDTA (3 mM, pH = 7.4). On the basis of these data, it becomes quite clear that all four ^{64}Cu-labeled TPEP cations are stable for >12 h in the presence of 3 mM EDTA (25 mM phosphate buffer, pH = 7.4).

Biodistribution Data. Biodistribution characteristics of six new ^{64}Cu radiotracers were evaluated in athymic nude mice bearing U87MG glioma xenografts. The Western Blot data (Supporting Information Figure SI) clearly demonstrated that there is no MDR1 Pgp expression on U87MG glioma xenografts. Selected biodistribution data and T/B ratios are listed in Tables 3 and 4, respectively. Detailed biodistribution data and T/B ratios are summarized in Supporting Information Tables SI−SVI. The main objective of these studies was to explore the impact of linkers and ^{64}Cu chelates on biodistribution characteristics and excretion kinetics of ^{64}Cu-labeled TPEP cations.

Comparison with ^{99m}Tc-Sestamibi and ^{64}Cu(DO3A-xy-TPP). Figure 2 compares the selected organ uptake and T/B ratios between ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DO3A-xy-TPP), and ^{99m}Tc-Sestamibi. This comparison allows us to demonstrate advantages of the ^{64}Cu-labeled TPEP cations over ^{99m}Tc-Sestamibi with respect to tumor uptake and T/B ratios, and to assess the impact of "targeting moiety" (TPEP vs TPP) on biodistribution patterns of ^{64}Cu radiotracer. ^{99m}Tc-Sestamibi was used as the "control" since it has been clinically used for imaging tumors and monitoring the tumor MDR transport functions (*25*−*33*). Biodistribution data and T/B ratios for ^{64}Cu(DO3A-xy-TPP) and ^{99m}Tc-Sestamibi were obtained from our previous report (*14*).

The most striking differences between ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi are their uptake in the heart and muscle and their T/B (tumor/heart, tumor/liver, tumor/lung, and tumor/muscle) ratios. For example, the heart uptake of ^{64}Cu(DO3A-xy-TPEP) was <1% ID/g at >30 min p.i., while the heart uptake of ^{99m}Tc-Sestamibi was 19.22 $\pm$ 7.62 at 5 min p.i. and 19.19 $\pm$ 5.32% ID/g at 120 min p.i (*14*). The muscle uptake of ^{64}Cu(DO3A-xy-TPEP) was almost undetectable at $\geq$60 min p.i. while ^{99m}Tc-Sestamibi had a high muscle uptake (4.84 $\pm$ 1.22% and 5.45 $\pm$ 1.24% ID/g at 5 and 120 min p.i., respectively) over the 2 h period (Table 3). ^{64}Cu(DO3A-xy-TPEP) had the tumor uptake that is significantly ($p < 0.05$) higher than that of ^{99m}Tc-Sestamibi at all four time points. The tumor/heart ratio of ^{64}Cu(DO3A-xy-TPEP) at 120 min p.i. was more than 50×

[a] The organ uptake is expressed as %ID/gram. [b] $n = 6$ due to difficulty to determine the radiotracer uptake in muscle.

better than that of ^{99m}Tc-Sestamibi. Its tumor/lung and tumor/liver ratios were much better than those of ^{99m}Tc-Sestamibi (Figure 2). ^{64}Cu(DO3A-xy-TPEP) had a tumor uptake that is comparable to that of ^{64}Cu(DO3A-xy-TPP) at >30 min p.i., but its liver uptake was significantly lower ($p < 0.01$) than that of ^{64}Cu(DO3A-xy-TPP) at all four time points (Table 3). As a result, ^{64}Cu(DO3A-xy-TPEP) has tumor/liver ratios >3× better than those of ^{64}Cu(DO3A-xy-TPP). Thus, TPEP is better than TPP as a mitochondrion-targeting molecule.

Impact of BFCs. Figure 3 compares the organ uptake (heart, liver, and muscle) and T/B ratios of ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DO2A-xy-TPEP)$^+$, ^{64}Cu(DOTA-Bn-xy-TPEP)−, and ^{64}Cu-(NOTA-Bn-xy-TPEP). This comparison allows us to assess the impact of BFCs on biological properties of ^{64}Cu radiotracers. ^{64}Cu(DO3A-xy-TPEP) has the lipophilicity (log $P = -1.69 \pm 0.11$) close to that of ^{64}Cu(DO2A-xy-TPEP)$^+$ (log $p = -1.90 \pm 0.10$) despite their different charges. While the tumor uptake of ^{64}Cu(DO3A-xy-TPEP) remained unchanged between 30 and 120 min p.i., there was a significant tumor washout for ^{64}Cu(DO2A-xy-TPEP)$^+$ over the 2 h period. The liver uptake of ^{64}Cu(DO2A-xy-TPEP)$^+$ was significantly lower ($p < 0.01$) than that of ^{64}Cu(DO3A-xy-TPEP) at all four time points. Its tumor/liver ratio at 120 min p.i. was also significantly ($p < 0.05$) lower. The lipophilicity of ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ (log $p = -1.92 \pm 0.03$) is close to that of ^{64}Cu(DO3A-xy-TPEP). Even though they share a similar tumor uptake, the uptake of ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ in the heart, liver, and muscle was higher at >30 min p.i. As a result, the T/B ratios of ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ were lower than that those of ^{64}Cu(DO3A-xy-TPEP). ^{64}Cu(NOTA-Bn-xy-TPEP) has the same overall charge as ^{64}Cu(DO3A-xy-TPEP); but its tumor uptake and tumor/heart ratios were much lower than those of ^{64}Cu(DO3A-xy-TPEP). Apparently, the BFCs and their ^{64}Cu chelates have a significant impact on both tumor uptake and T/B ratios of the radiotracer.

Linker Effects. Figure 4 illustrates a comparison of the tumor uptake and tumor/heart ratios among ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DO3A-PEG$_2$-TPEP), and ^{64}Cu(DOTA-xy-TPEP). The addition of an extra acetamide group between DO3A and TPEP resulted in a significant reduction of liver uptake. However, the tumor/liver ratios (Table 4) of ^{64}Cu(DOTA-xy-TPEP) and ^{64}Cu(DO3A-xy-TPEP) were comparable within the experimental error, probably due to the faster tumor washout of ^{64}Cu(DOTA-xy-TPEP). Substitution of xylene with PEG$_2$ also leads to a significant reduction of the uptake in tumor and liver. As a result, ^{64}Cu(DO3A-PEG$_2$-TPEP) and ^{64}Cu(DO3A-xy-TPEP) shared very similar tumor/liver ratios.

PET Imaging. We performed a microPET imaging study on ^{64}Cu(DO3A-xy-TPEP) using the athymic nude mice bearing U87MG glioma xenografts. Figure 5 shows microPET images of the tumor-bearing mouse administered with ~250 μCi of ^{64}Cu(DO3A-xy-TPEP) at 1, 4, and 24 h p.i. The tumor was clearly visualized as early as 1 h p.i. with very high T/B contrast. No significant radioactivity accumulation was detected in the brain, heart, or muscle. After normalization, the tumor uptake of ^{64}Cu(DO3A-xy-TPEP) was 2.57 ± 0.41% ID/g, 3.51 ± 1.20% ID/g, and 3.11 ± 1.44% ID/g at 1, 4, and 24 h p.i., respectively. These data are completely consistent with that observed in the *ex vivo* biodistribution study (Table 3), and have clearly demonstrated that ^{64}Cu(DO3A-xy-TPEP) is useful for imaging the MDR-negative tumors.

Metabolic Properties. Metabolism studies were performed on ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DOTA-xy-TPEP), ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$, and ^{64}Cu(NOTA-Bn-xy-TPEP) using normal

[a] $n = 6$ due to difficulty determining the tumor/muscle muscle ratios.

mice. These four ^{64}Cu radiotracers were selected because of their difference in ^{64}Cu chelate. Since they were excreted from the renal and hepatobiliary routes, we tried to collect both urine and feces samples from the normal mice administered with the ^{64}Cu radiotracer. A reversed-phase HPLC method (Method 2) was used to analyze the collected urine and feces samples. Figure 6 shows representative radio-HPLC chromatograms of ^{64}Cu(DO3A-xy-TPEP) (left) and ^{64}Cu(DOTA-xy-TPEP) (right) in saline before injection, in urine at 30 and 120 min p.i., and in feces at 120 min p.i. There was very little metabolite (<2%) detectable for ^{64}Cu(DO3A-xy-TPEP) in both urine and feces samples. Similar metabolic stability was also observed for ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ and ^{64}Cu(NOTA-Bn-xy-TPEP) (Supporting Information Figure SII). ^{64}Cu(DOTA-xy-TPEP) is excreted without significant metabolism via renal route (Figure 6). However, only 15% of it remained intact in feces, and 85% of radioactivity appeared at 4 min. Thus, the extra acetamido group has a significant impact on metabolic stability of ^{64}Cu(DOTA-xy-TPEP) during its hepatobiliary excretion while it had no effect on its metabolic stability during renal excretion.

Transchelation of ^{64}Cu(DO3A-xy-TPEP) in Liver. We examined the in vivo stability of ^{64}Cu(DO3A-xy-TPEP) in the liver. About 50% of total liver activity was recovered in the liver homogenate. The liver homogenate samples were analyzed using the reversed-phase and size-exclusion radio-HPLC methods. Figure SIII shows radio-HPLC chromatograms of the supernatant from liver homogenate. Using the size-exclusion HPLC method, we were able to identify four major radiometric peaks in its HPLC chromatogram (Figure SIII: bottom). While the identity of these radiometric peaks are not known, one thing is sure that ^{64}Cu(DO3A-xy-TPEP) underwent extensive tranchelation in the liver during the 2 h study period.

DISCUSSION

For the new radiotracer to be successful as a tumor imaging agent by PET or SPECT (single photon emission computed tomography), it must show a high tumor uptake. Since most of high-incidence tumors occur in torso (namely, lung, colorectal, and breast cancers metastatic to the lymphatic system), it is highly desirable for the radiotracer to clear from the liver and lungs so that the high T/B ratios can be achieved and clinically useful tumor images can be obtained in a short period of time. Cationic radiotracers, such as ^{99m}Tc-Sestamibi and ^{99m}Tc-Tetrofosmin, have been clinically used for imaging tumors of different origin and the transport function of MDR Pgp by SPECT (*25*−*33*). However, their cancer diagnostic values are often limited due to their insufficient tumor localization and high uptake in the noncancerous organs, such as heart, liver, and muscle, which makes it difficult to detect small lesions in the chest and abdominal regions. Radiolabeled lipophilic organic cations, such as 4-(^{18}F-benzyl)triphenylphosphonium (^{18}F-BzTPP), have also been proposed as radiotracers for tumor imaging by PET (*34*−*38*). Their high uptake in the heart and liver may also impose a significant challenge for early detection of small tumors in the chest and abdominal regions. Thus, there is an unmet need for radiotracers that have high tumor selectivity (high tumor uptake with little accumulation in noncancerous organs) and are sensitive to the mitochondrial potential changes at the early stage of tumor growth.

In our previous studies, we have demonstrated that the ^{64}Cu-labeled TPP cations, such as ^{64}Cu(DO3A-xy-TPP), are able to

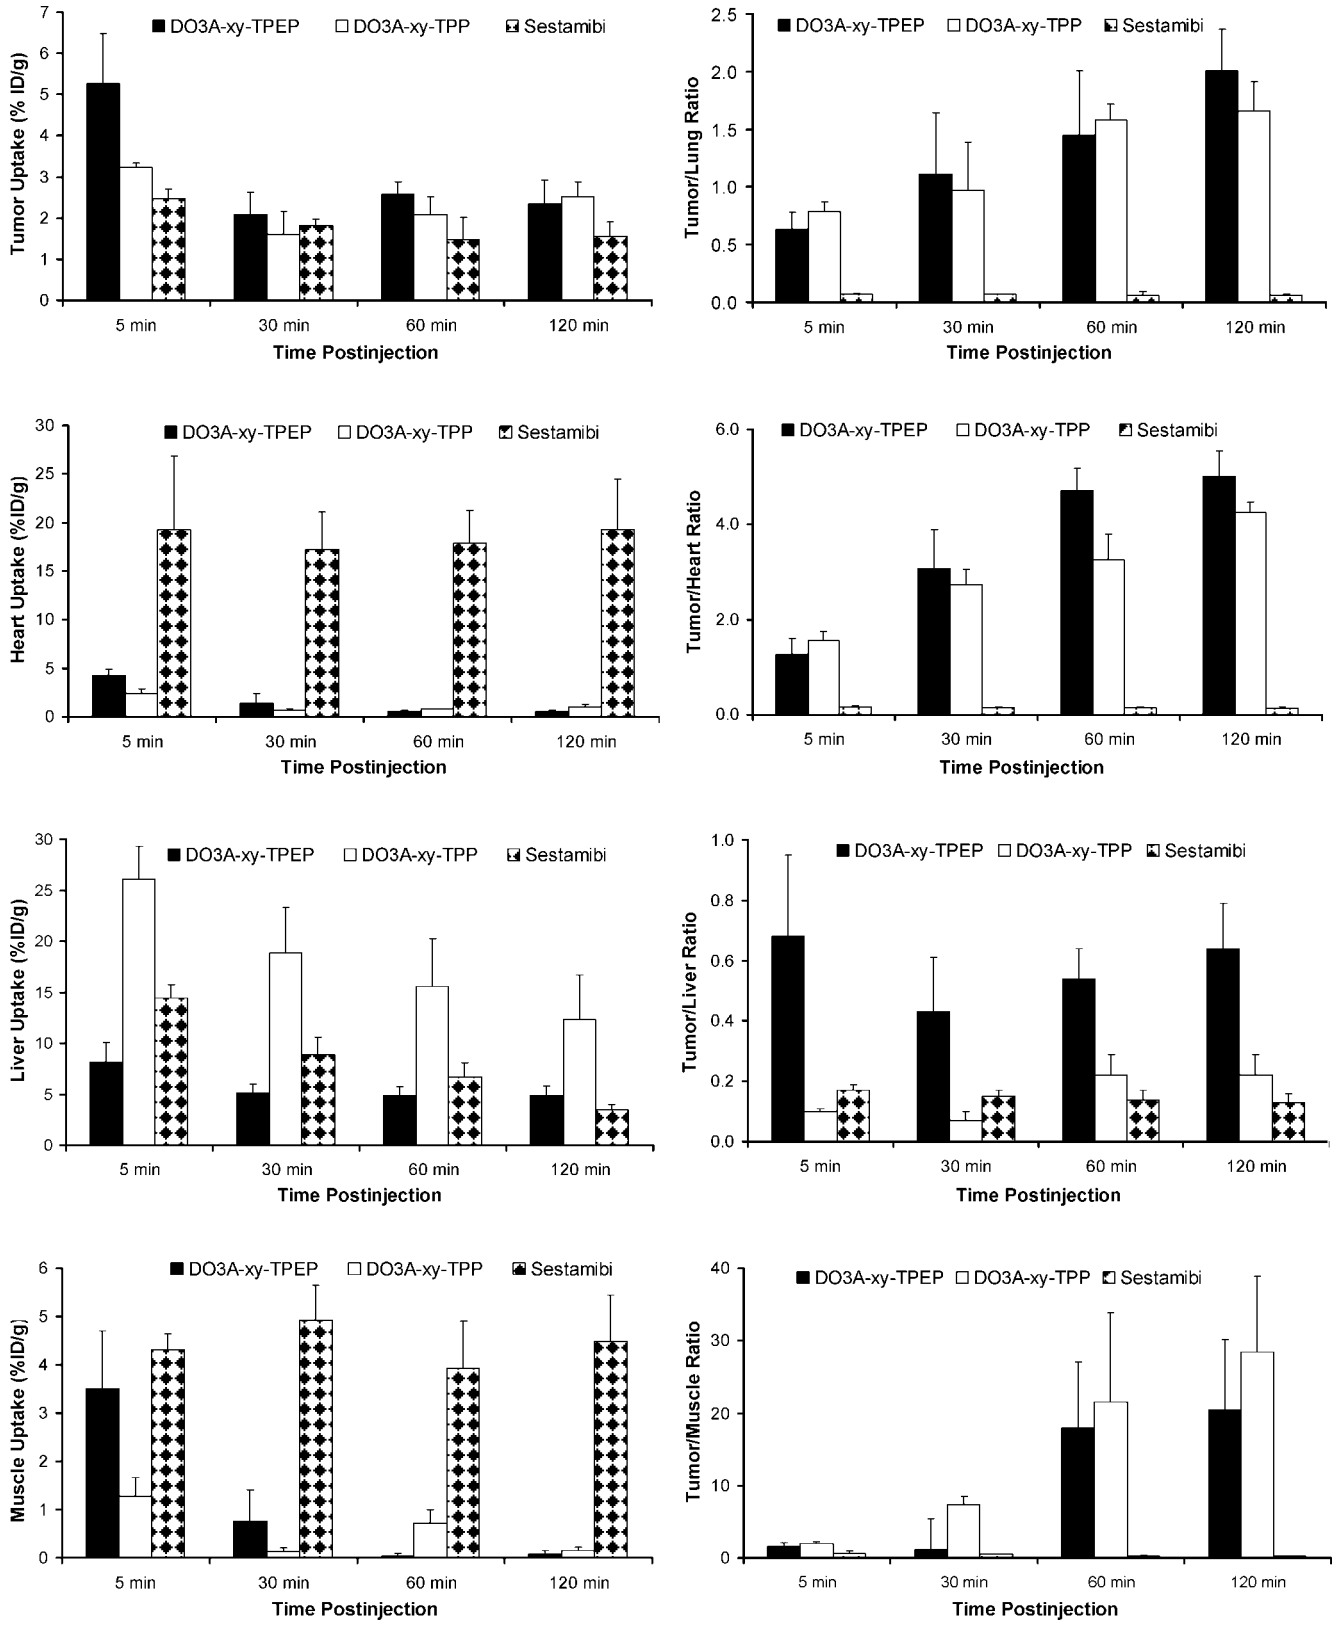

Figure 2. Direct comparison of organ uptake and T/B ratios between ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DO3A-xy-TPP), and ^{99m}Tc-Sestamibi in the athymic nude mice bearing U87MG human glioma xenografts.

localize in the mitochondria of U87MG glioma cells. MicroPET imaging data also show that the tumor could be visualized clearly as early as 30 min p.i. (*14*). Considering the tumor uptake selectivity,^{64}Cu(DO3A-xy-TPP) has a significant advantage over ^{99m}Tc-Sestamibi, the radiopharmaceutical currently available for both myocardial perfusion and tumor imaging (*24*−*33*, *39*−*45*). However, the high liver uptake of ^{64}Cu(DO3A-xy-TPP) remains a challenge for its clinical application as a new PET radiotracer for imaging tumors.

In this study, we used TPEP as the mitochondrion-targeting molecule. We are interested in TPEP cation because of the phosphoryl group that may improve radiotracer excretion kinetics from the liver. As expected, the liver uptake of ^{64}Cu(DO3A-xy-TPEP) was lower ($p < 0.01$) than that of

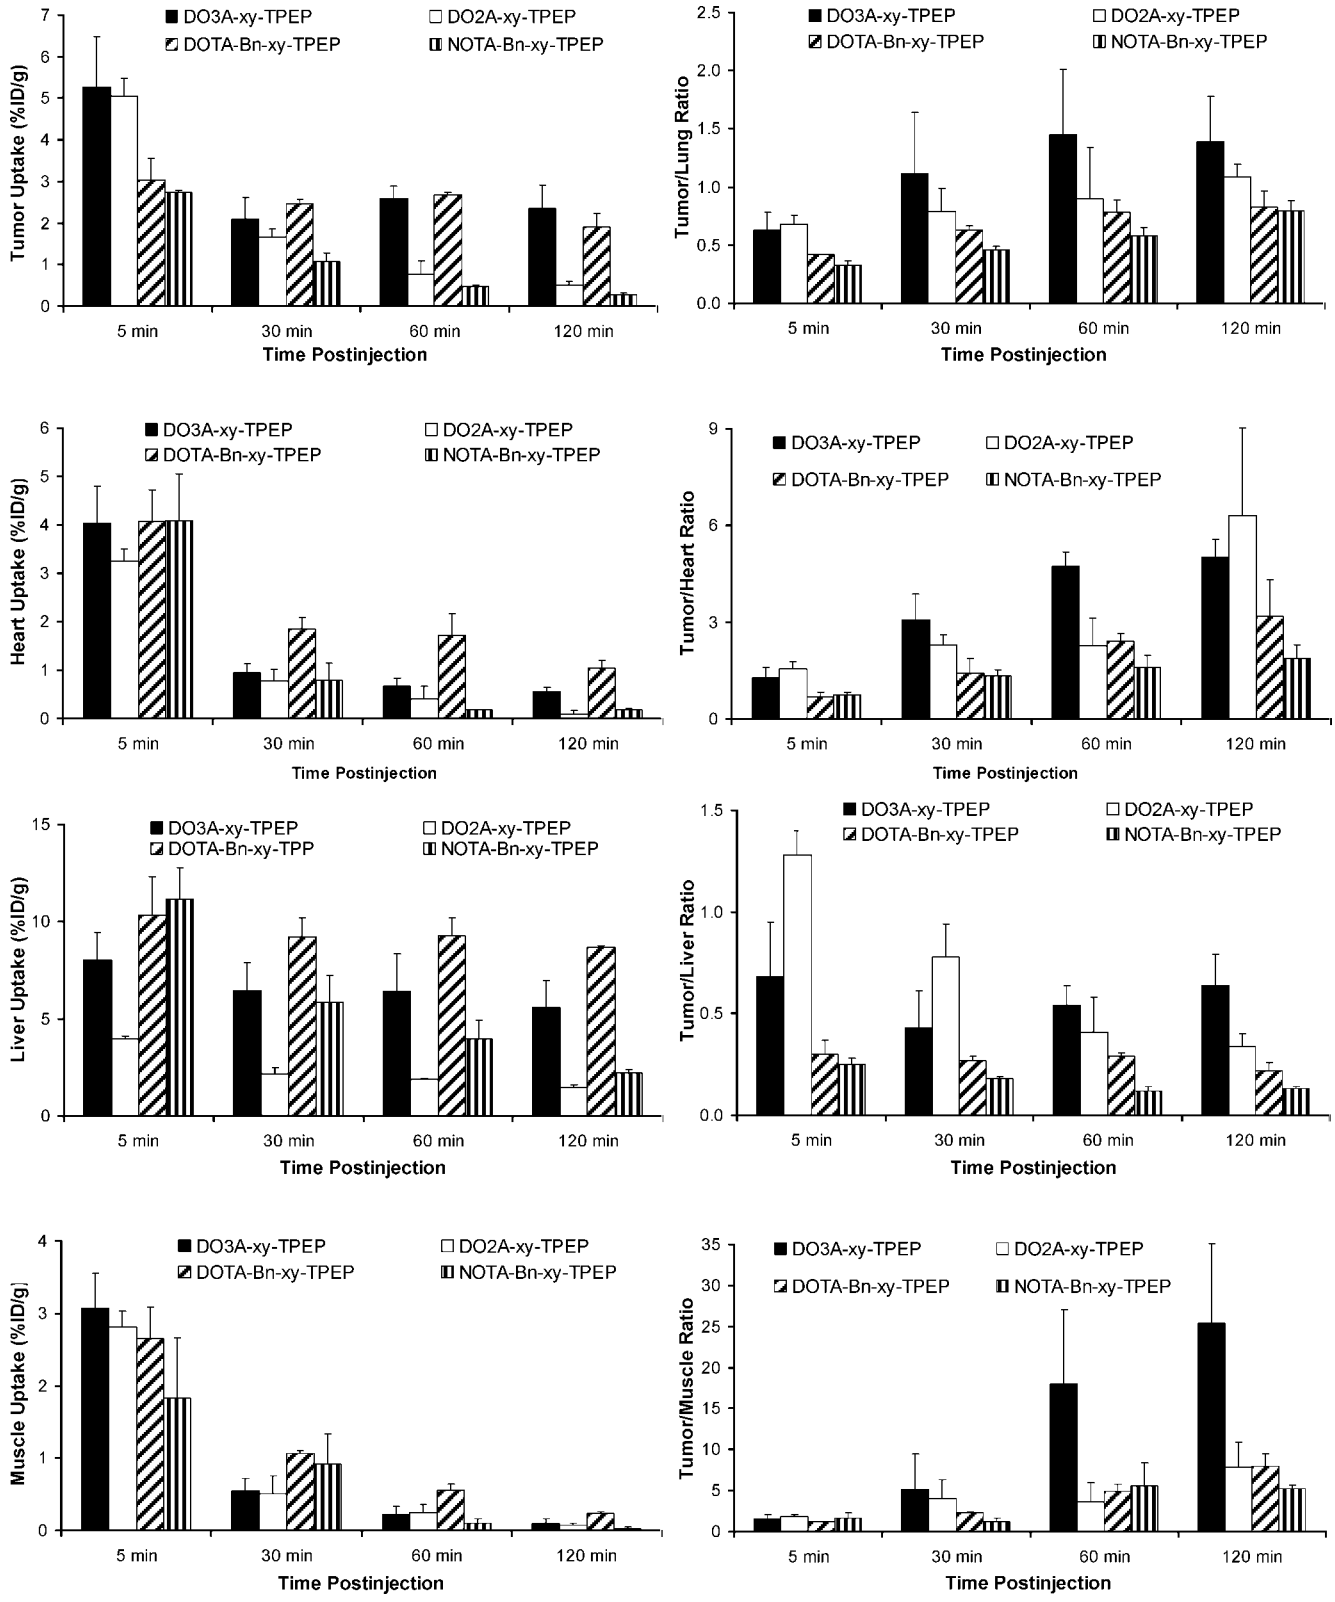

Figure 3. Impact of BFCs on organ uptake and T/B ratios of the ^{64}Cu-labeled TPEP cations.

^{64}Cu(DO3A-xy-TPP) (Figure 2), even though ^{64}Cu(DO3A-xy-TPEP) (log $P = -1.69 \pm 0.11$) is 10× more lipophilic than ^{64}Cu(DO3A-xy-TPP) (log $P = -2.67 \pm 0.21$). The tumor uptake of ^{64}Cu(DO3A-xy-TPEP) is comparable to that of ^{64}Cu(DO3A-xy-TPP) at >30 min p.i. (Figure 2). As a result, tumor/liver ratios of ^{64}Cu(DO3A-xy-TPEP) are >3× better than those of ^{64}Cu(DO3A-xy-TPP). On the basis of these results, we believe that ^{64}Cu(DO3A-xy-TPEP) is a better PET radiotracer than ^{64}Cu(DO3A-xy-TPP) for imaging the MDR-negative tumors. ^{64}Cu(DO3A-xy-TPEP) also has significant advantages over ^{99m}Tc-Sestamibi with respect to the tumor uptake and T/B (tumor/heart, tumor/liver, tumor/lung, and tumor/muscle) ratios.

The exact localization mechanism remains unknown even though the results from in vitro assays show that ^{64}Cu(DO3A-xy-TPP) is able to localize in mitochondria of glioma cells (*14*).

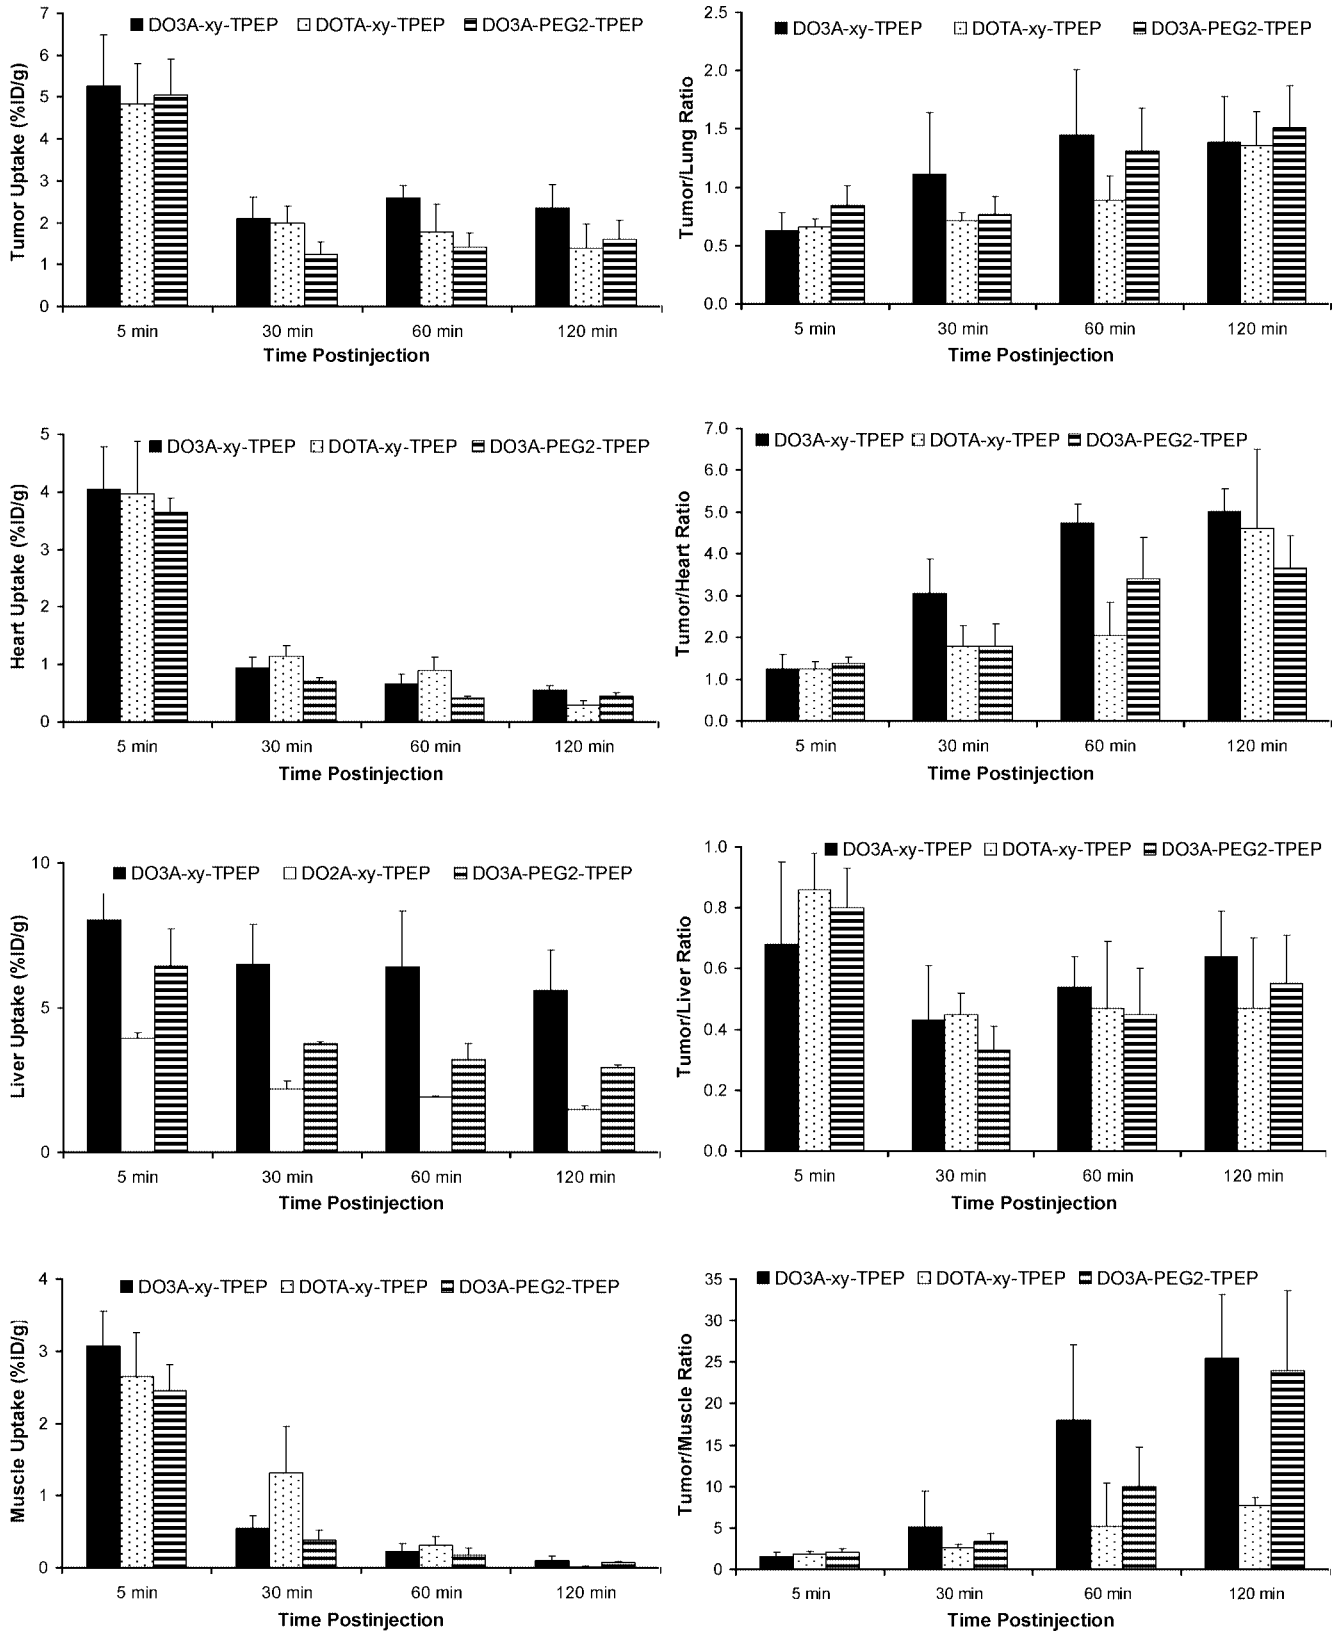

Figure 4. Impact of the linker on organ uptake and T/B ratios of the ^{64}Cu-labeled TPEP cations.

Many factors can influence biological properties of the ^{64}Cu-labeled TPEP cations. Previously, we found that replacing DO3A in ^{64}Cu(DO3A-xy-TPP) with DO2A leads to formation of ^{64}Cu(DO2A-xy-TPP)$^{+}$ and results in a dramatic reduction in liver uptake without altering its tumor uptake. In this study, a similar reduction in liver uptake was seen for ^{64}Cu(DO2A-xy-TPEP)$^{+}$ (Figure 3), but ^{64}Cu(DO2A-xy-TPEP)$^{+}$ had a rapid tumor washout over the 2 h study period. As a result, its tumor/liver ratio is significantly lower ($p < 0.01$) than that of ^{64}Cu(DO3A-xy-TPEP).

^{64}Cu(NOTA-Bn-xy-TPEP) has the same molecular charge as ^{64}Cu(DO3A-xy-TPEP). They also share almost identical lipophilicity with log P values being -1.69 ± 0.11 and -1.75 ± 0.03, respectively. However, the tumor uptake and T/B ratios

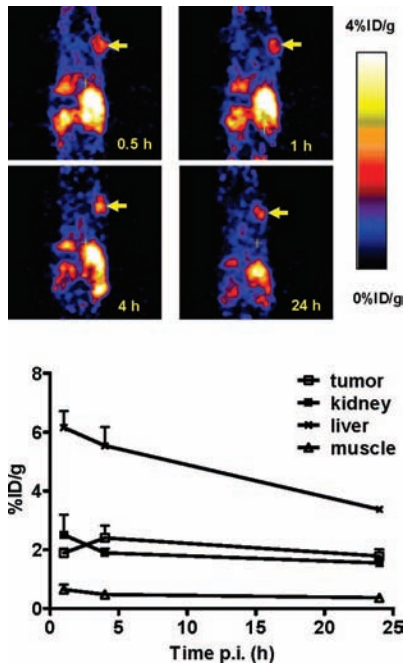

Figure 5. The decay-corrected whole-body coronal microPET images (top) and the radioactivity accumulation quantification ($n = 3$, mean ± SD) in selected organs (bottom) of athymic nude mice bearing U87MG tumor administered with ~250 μCi of ^{64}Cu(DO3A-xy-TPEP). Arrows indicate the presence of glioma tumors.

of ^{64}Cu(NOTA-Bn-xy-TPEP) are lower ($p < 0.01$) than those of ^{64}Cu(DO3A-xy-TPEP) (Figure 3). A similar adverse effect was also seen for the ^{64}Cu-labeled TPP analogues (*16*). Among six ^{64}Cu radiotracers evaluated in this study, ^{64}Cu(NOTA-Bn-xy-TPEP) has the lowest tumor uptake and poorest T/B ratios in noncancerous organs, such as the heart, liver, lungs, and muscle. Thus, it is reasonable to believe that the coordination geometry of the ^{64}Cu-DO3A chelates might play a significant role in tumor uptake and tumor retention of the ^{64}Cu-labeled TPP and TPEP cations.

The lipophilicity (log $p = -1.92 \pm 0.03$) of ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ is also close to that of ^{64}Cu(DO3A-xy-TPEP) (log $p = -1.69 \pm 0.11$) despite the difference in molecular charges. Their tumor uptake (Figure 3) is comparable within experimental error. It seems that the negative charge in ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ does not affect its capability to localize in tumor cells. However, the uptake of ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ in the heart, liver, and muscle was higher than that of ^{64}Cu(DO3A-xy-TPEP) at >30 min p.i. As a result, its T/B ratio was lower than that of ^{64}Cu(DO3A-xy-TPEP).

Linkers have a significant impact on tumor uptake and tumor/heart ratios of ^{64}Cu-labeled TPEP cations. For example, the extra acetamido group in ^{64}Cu(DOTA-xy-TPEP) results in a lower liver uptake than that of ^{64}Cu(DO3A-xy-TPEP). However, the tumor/liver ratios of ^{64}Cu(DOTA-xy-TPEP) and ^{64}Cu(DO3A-xy-TPEP) compare well within experimental error (Figure 4) due to a faster tumor washout of ^{64}Cu(DOTA-xy-TPEP). Substitution of xylene with PEG_2 leads to a significant reduction of the tumor and liver uptake. As a result, the tumor/liver ratios of ^{64}Cu(DO3A-PEG_2-TPEP) and ^{64}Cu(DO3A-xy-TPEP) are also comparable.

In addition, linkers also affect the metabolic stability of ^{64}Cu radiotracers. For example, ^{64}Cu(DO3A-xy-TPEP), ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$, and ^{64}Cu(NOTA-Bn-xy-TPEP) have no metabolism during their excretion via renal and hepatobiliary routes as evidenced by the lack of metabolite(s) in urine and feces samples. ^{64}Cu(DOTA-xy-TPEP) remains intact during excretion via the kidney, but only ~15% of it remains intact in the feces sample (Figure 6). Since the only difference between ^{64}Cu(DO3A-xy-TPEP) and ^{64}Cu(DOTA-xy-TPEP) is the extra acetamido group, the metabolic instability of ^{64}Cu(DOTA-xy-TPEP) is most likely caused by the cleavage of CO−NH bond during hepatobiliary excretion.

The radioactivity detected in urine and feces samples represents only the portion excreted from the renal and hepatobiliary routes. The remaining activity is still "trapped" in organ tissues. We examined the stability of ^{64}Cu(DO3A-xy-TPEP) in the liver, and found that there was no intact ^{64}Cu(DO3A-xy-TPEP) in the liver homogenate (Supporting Information Figure SIII: top). While the identity of these four major radiometric peaks (Supporting Information Figure SIII: bottom) remains unknown, the size-exclusion HPLC chromatographic pattern of ^{64}Cu(DO3A-xy-TPEP) is very similar to that of the ^{64}Cu-labeled TETA-Octreotide in the rat liver homogenate (*46*). On the basis of the results from stability studies of ^{64}Cu complexes with tetraazamacrocycles (*46*−*50*), we believe that these radiometric peaks are likely caused by transchelation of ^{64}Cu to the proteins, such as superoxide dismutase (SOD) abundant in the liver and kidneys (*51*).

The metabolism of the ^{64}Cu-labeled biomolecules (antibodies and peptides) and ^{64}Cu complexes of tetraazamacrocycles has been investigated extensively (*46*−*59*). These studies clearly show that kinetic inertness of the ^{64}Cu chelate is particularly important for the *in vivo* stability of ^{64}Cu radiotracers, and their instability is often caused by transchelation of ^{64}Cu from the ^{64}Cu-BFC chelate to proteins (*46, 51*). For target-specific ^{64}Cu radiotracers, the tumor uptake is predominantly determined by receptor binding of targeting biomolecules (antibodies or peptides). The BFCs for ^{64}Cu chelation should be those which form the ^{64}Cu-BFC chelates with high kinetic inertness in order to minimize the liver radioactivity. For the ^{64}Cu-labeled TPEP cations, however, the BFC contributes greatly to the radiotracer tumor uptake and excretion kinetics from noncancerous organs, such as liver and lungs. The optimal BFCs should be those which result in the ^{64}Cu radiotracer with high tumor uptake and the best T/B, particularly tumor/heart and tumor/liver, ratios. From this point view, DO3A and DOTA are suitable BFCs for ^{64}Cu-labeling of TPEP cations. It must be noted that the radioactivity "trapped" inside the liver due to transchelation of ^{64}Cu is only a small portion of the injected radioactivity. Whenever possible, one has to consider the radioactivity excreted from renal and hepatobiliary routes (urine and feces samples), as well as the radioactivity "trapped" in various organ tissues.

CONCLUSIONS

In summary, we evaluated six new ^{64}Cu-labeled TPEP cations for their biodistribution properties and excretion kinetics using the athymic nude mice bearing U87MG human glioma xenografts. It was found that most of the ^{64}Cu radiotracers described in this study have significant advantages over ^{99m}Tc-Sestamibi with respect to their tumor/heart and tumor/muscle ratios. TPEP seems to be a better mitochondrion-targeting molecule than TPP because of the lower liver uptake and better tumor/liver ratios of ^{64}Cu(DO3A-xy-TPEP) than that of ^{64}Cu(DO3A-xy-TPP). BFCs and molecular charge also have significant impact on biological properties of ^{64}Cu-labeled TPEP cations. For example, replacing DO3A with DO2A results in ^{64}Cu(DO2A-xy-TPEP)$^+$, which has a lower tumor uptake and T/B ratios than ^{64}Cu(DO3A-xy-TPEP). Substitution of DO3A with NOTA-Bn has a significant adverse effect on tumor uptake of the ^{64}Cu radiotracer. However, the use of DOTA-Bn to replace DO3A has minimal impact on the radiotracer tumor uptake; but the tumor/liver ratio of ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ is not as good as that of ^{64}Cu(DO3A-xy-TPEP),

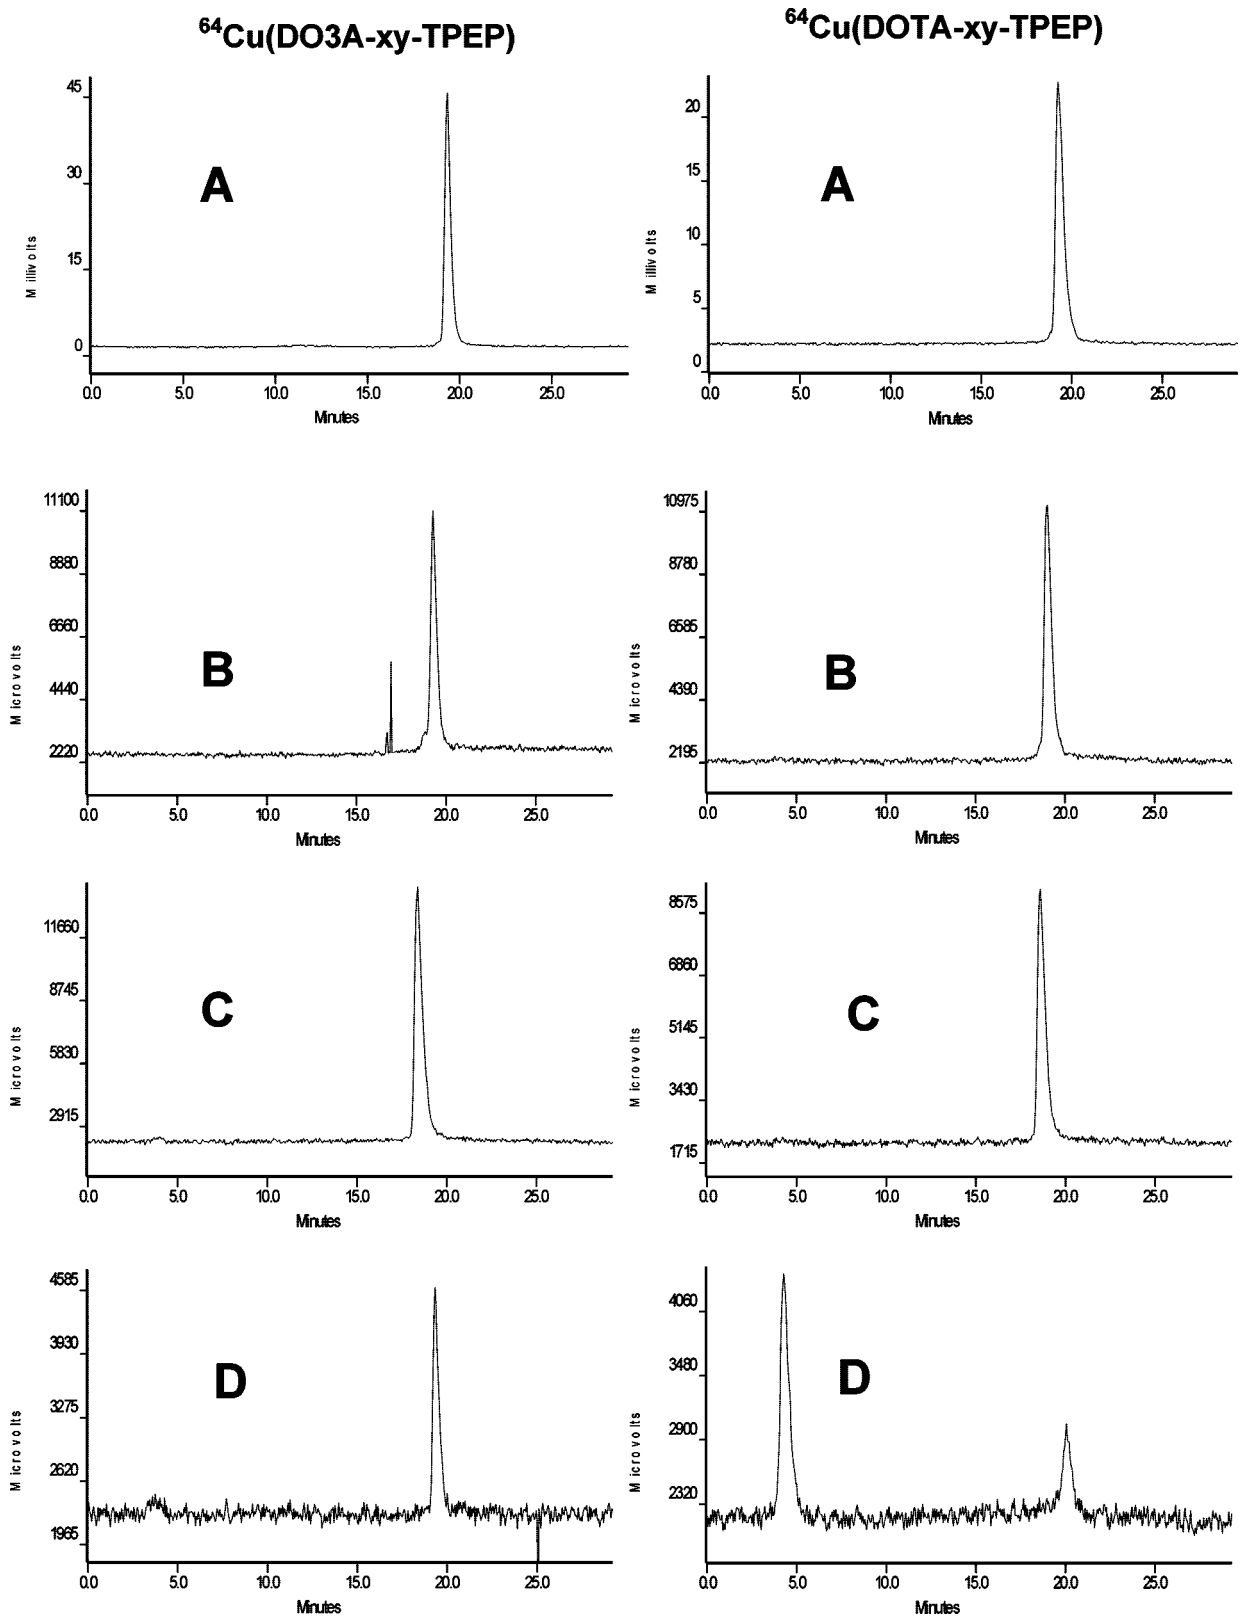

Figure 6. Typical reversed-phase radio-HPLC chromatograms (Method 3) of ^{64}Cu(DO3A-xy-TPEP) (left) and ^{64}Cu(DOTA-xy-TPEP) (right) in saline before injection (A), in the urine sample at 30 min p.i. (B), in the urine sample at 120 min p.i. (C), and in the feces sample (D) at 120 min p.i.

probably due to the aromatic benzene ring in DOTA-Bn. Addition of an extra acetamido group in ^{64}Cu(DOTA-xy-TPEP) results in a lower liver uptake, but the tumor/liver ratios of ^{64}Cu(DOTA-xy-TPEP) and ^{64}Cu(DO3A-xy-TPEP) are comparable, probably due to a faster tumor washout of ^{64}Cu(DOTA-xy-TPEP). Substitution of xylene with PEG_2 also leads to a significant reduction in both tumor and liver uptake. As a result, ^{64}Cu(DO3A-PEG_2-TPEP) and ^{64}Cu(DO3A-xy-TPEP) share very similar tumor/liver ratios. On the basis of both tumor uptake and T/B ratios of the ^{64}Cu radiotracers, we believe that both DO3A and DOTA are suitable BFCs for the ^{64}Cu-labeling of TPP cations. Among the six ^{64}Cu

radiotracers evaluated in this tumor-bearing animal model, ^{64}Cu(DO3A-xy-TPEP) is of particular interest due to its higher tumor uptake and better T/B ratios (particularly tumor/heart, tumor/liver, and tumor/muscle). ^{64}Cu(DO3A-xy-TPEP) will be further evaluated for its potential as a new PET radiotracer to monitor the MDR transport function in tumors of different origins.

ACKNOWLEDGMENT

Authors would like to thank Dr. Sulma I. Muhammed, the Director of Purdue Cancer Center Drug Discovery Shared Resource, Purdue University, for her assistance with the tumor-bearing model. This work is supported in part by research grants: R01 CA115883 A2 (S.L.) from National Cancer Institute (NCI), R21 EB003419-02 (S.L.) from National Institute of Biomedical Imaging and Bioengineering (NIBIB), and R21 HL083961-01 from National Heart, Lung, and Blood Institute (NHLBI).

Supporting Information Available: Detailed biodistribution data and T/B ratios for six ^{64}Cu-labeled TPEP cations are listed in Tables SI − SVI. Figure SI shows the Western blot data to demonstrate the absence of MDR1 expression in the U87MG human glioma xenografts. Figure SII shows radio-HPLC chromatograms of ^{64}Cu(NOTA-Bn-xy-TPEP) (left) and ^{64}Cu-(DOTA-Bn-xy-TPEP)- (right) in saline (A), in the urine at 30 min p.i. (B), in the urine at 120 min p.i. (C), and in the feces at 120 min p.i. (D). Figure SIII illustrates the radio-HPLC chromatograms of the liver homogenate at 120 min p.i. Contents of Supporting Information

Table SI. Biodistribution data and T/B ratios of ^{64}Cu(DO3A-xy-TPEP) in the athymic nude mice bearing U87MG human glioma xenografts. The organ uptake is expressed as %ID/g. Each data point represents an average of biodistribution data in three animals.

Table SII. Biodistribution data and T/B ratios of ^{64}Cu(DO3A-PEG$_2$-TPEP) in the athymic nude mice bearing U87MG human glioma xenografts. The organ uptake is expressed as %ID/g. Each data point represents an average of biodistribution data in three animals.

Table SIII. Biodistribution data and T/B ratios of ^{64}Cu(DO2A-xy-TPEP) in the athymic nude mice bearing U87MG human glioma xenografts. The organ uptake is expressed as %ID/g. Each data point represents an average of biodistribution data in three animals.

Table SIV. Biodistribution data and T/B ratios of ^{64}Cu(DOTA-xy-TPEP) in the athymic nude mice bearing U87MG human glioma xenografts. The organ uptake is expressed as %ID/g. Each data point represents an average of biodistribution data in three animals.

Table SV. Biodistribution data and T/B ratios of ^{64}Cu(DOTA-Bn-xy-TPEP) in the athymic nude mice bearing U87MG human glioma xenografts. The organ uptake is expressed as %ID/g. Each data point represents an average of biodistribution data in three animals.

Table SVI. Biodistribution data and T/B ratios of ^{64}Cu(NOTA-Bn-xy-TPEP) in the athymic nude mice bearing U87MG human glioma xenografts. The organ uptake is expressed as %ID/g. Each data point represents an average of biodistribution data in three animals.

Figure SI. Western blot experiment was performed to demonstrate the absence of MDR1 Pgp on U87MG glioma xenografts. Twenty micrograms of tissue lysate from each of the six tumor-bearing mice were analyzed by 5% SDS-PAGE and transferred to PVDF membranes, which were blocked with 5% nonfat milk in tris-buffered saline containing 0.1% Tween-20 for 1 h at 37 °C. MES-SA/Dx5 lysate (Santa Cruz, CA) was used as the positive control. Blots were immunostained with primary antibodies MDR1 (Santa Cruz, CA) at 4 °C overnight and probed with secondary antibodies conjugated to horseradish peroxidase. Specific bands were visualized by enhanced chemiluminescence kit from Pierce.

Figure SII. Typical reversed-phase radio-HPLC chromatograms of ^{64}Cu(NOTA-Bn-xy-TPEP) (left) and ^{64}Cu(DOTA-Bn-xy-TPEP)$^-$ (right) in saline before injection (A), in the urine at 30 min p.i. (B), in the urine at 120 min p.i. (C), and in the feces at 120 min p.i. (D). Each tumor-bearing mouse was administered with ~ 100 μCi of ^{64}Cu radiotracer.

Figure SIII. Radio-HPLC chromatograms of the liver homogenate at 120 min p.i. using the reversed-phase HPLC method (top) and size-exclusion HPLC method (bottom), which used the LabAlliance HPLC system equipped with a UV/vis detector (λ = 254 nm), a β-ram IN-US detector, a Superose™ 12 10/300 GL size-exclusion column, and the flow rate of 0.4 mL/min. The aqueous mobile phase was isocratic with 20 mM HEPES and 150 mM NaCl.

Table SI. Biodistribution data and T/B radios of ^{64}Cu(DO3A-xy-TPEP) in the athymic nude mice bearing U87MG human glioma xenografts. The organ uptake is expressed as %ID/g. Each data point represents an average of biodistribution data in three animals.

Lomonosov Moscow State University, 119899 Moscow, Russia. Received June 5, 2008; Revised Manuscript Received July 29, 2008

Efficient entry of synthetic polymers inside cells is a central issue in polymeric drug delivery. Though polymers are widely believed to interact nonspecifically with plasma membrane, we present unexpected evidence that amphiphilic block copolymers, depending on their aggregation state, can distinguish between caveolae- and clathrin-mediated endocytosis. A block copolymer of poly(ethylene oxide) (PEO) and poly(propylene oxide) (PPO), Pluronic P85 (P85), below critical micelle concentration (CMC) exists as single molecule coils (unimers) and above CMC forms 14.6 nm aggregated micelles with a hydrophobic PPO core and hydrophilic PEO shell. The internalization pathways of P85 in mammalian cells were elucidated using endocytosis inhibitors and colocalization with endocytosis markers (clathrin-specific antibodies and transferrin for clathrin and caveolin-1-specific antibodies and cholera toxin B for caveolae). Altogether, our results indicate that P85 unimers internalize through caveolae-mediated endocytosis, while P85 micelles internalize through clathrin-mediated endocytosis. Furthermore, at concentrations above 0.01% P85 inhibits caveolae-mediated endocytosis (cholera toxin B), while having little or no effect on the clathrin-mediated endocytosis (transferrin). Selective interaction of Pluronic with caveolae may explain its striking pharmacological activities including inhibition of drug efflux transport, activation of gene expression, and dose-dependent hyperlipidemia.

INTRODUCTION

Amphiphilic triblock copolymers of poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide) (PEO-PPO-PEO), also known as Pluronic or poloxamers, have been evaluated extensively as carriers for delivery of drugs and diagnostic imaging agents (*1, 2*). In aqueous solutions above the critical micelle concentration (CMC), the PPO chains of these block copolymers spontaneously segregate into a hydrophobic core of a micelle with the PEO chains forming a hydrophilic shell (*1*). The diameters of Pluronic micelles usually vary from ca. 10 to 100 nm. The PPO core can incorporate considerable amounts (up to 20−30 wt %) of many water-insoluble drugs (*1*). The micelles can be targeted to a specific body compartment, such as brain, by conjugating with neurospecific antibodies or insulin as targeting moieties (*3*−*5*). In addition, below the CMC Pluronic exists in the form of "unimers", which, in case of relatively hydrophobic copolymers, can bind with cell membranes and transport into cells (*3, 6*−*9*). Such block copolymers were also shown to inhibit a drug efflux pump, P-glycoprotein, Pgp, expressed in the membranes of multidrug-resistant cells (*7, 10, 11*) and induce transcriptional activation of gene expression in cells through activation of certain cell signaling pathways (*12*−*14*). Finally, Pluronic block copolymers also can serve as synthetic polymer transduction domains and carry proteins as large as horseradish peroxidase (HRP) into cells and across the blood brain barrier (BBB) (*15*).

Pluronic unimers and micelles have been known to undergo internalization in cells (*7*), which can be abolished by metabolic inhibitors (*7, 9*). On this basis, a general endocytosis mechanism was suggested for cellular entry of Pluronic, although the specific pathways remained unknown. Endocytosis can be divided into two broad categories, phagocytosis (the uptake of large particles) and pinocytosis (the uptake of fluids and solutes) (*16*). Pinocytosis can be further classified on the basis of either the membrane interaction or the type of membrane structures involved in the initial stages of internalization. The first classification includes (i) fluid-phase endocytosis (e.g., HRP uptake); (ii) receptor-mediated endocytosis (e.g., transferrin (Tf) uptake *via* Tf receptor (TfR)); or (iii) adsorptive endocytosis (e.g., albumin or wheat germ agglutinin uptake) (*17*). The second classification includes (i) clathrin-mediated endocytosis and (ii) caveolae-mediated endocytosis (*16*).

Clathrin-mediated endocytosis involves polymerization of a cytosolic protein, clathrin, which binds to the cell plasma membrane and induces formation of a coated pit (*18*). After budding, the vesicle sheds its clathrin coat and then delivers its protein cargo to endosomes. The cargo can then be recycled or transported to lysosomes via late endosomes. Tf is commonly used as a marker for this pathway. Caveolae are cholesterol-rich "flask-shaped invaginations" in the plasma membrane formed due to the presence of a dimeric protein, caveolin (*19*). These vesicles travel to caveosomes, which prevents lysosomal degradation of the cargo. Cholera toxin B (CTB) or Simian Virus 40 (SV40) typically use the caveolae-mediated mechanism for cellular entry (*18, 20, 21*). Recent studies have also indicated the existence of clathrin- and caveolae-independent endocytosis, which still remains relatively poorly explored (*22*).

In this study, we hypothesize that Pluronic block copolymers can undergo endocytosis via a clathrin- or caveolae-mediated mechanism. We further posit that Pluronic can interfere with selected membrane trafficking mechanisms. The latter is based on the knowledge that Pluronic molecules (i) incorporate into membranes by inserting their hydrophobic PPO chains into lipid bilayers (*23, 24*), (ii) decrease membrane microviscosity (*7*), and (iii) inhibit selected membranes enzymes, such as Pgp ATPase, which may be associated with cholesterol-rich membrane microdomains (*25*). To test this hypothesis, we use

Pluronic P85 (P85) as a representative copolymer of the Pluronic series, which exhibits all of the above listed activities (*1, 3, 7, 26*). Our approach involves (1) evaluation of P85 internalization in the presence of chemical inhibitors of selected endocytosis pathways; (2) colocalization of P85 unimers (below CMC) and micelles (above CMC) with clathrin- and caveolin-specific antibodies and various endocytosis markers (Tf and CTB); and (3) evaluation of the effect of P85 on the internalization of the clathrin- and caveolae-mediated and fluid-phase endocytosis markers (Tf, CTB, and HRP). The MDCK cells are used as an *in vitro* model. Altogether, our results indicate that P85 unimers at concentrations below the CMC (0.03 wt %) internalize through caveolae-mediated endocytosis, while P85 micelles at higher concentrations internalize mainly through clathrin-mediated endocytosis. Furthermore, at high concentration above 0.1 wt %, P85 inhibits caveolae-mediated endocytosis, while having little or no effect on the clathrin-mediated endocytosis. For the first time, we demonstrate that binding of the amphiphilic block copolymer with the cells may be constrained to selected membrane domains. The results are significant for understanding the mechanisms of transport of the block copolymers into cells as well as for relating the block copolymer−membrane interactions to the biological activities of the block copolymers, which may be mediated by the specific membrane microdomains affected by these interactions.

MATERIALS AND METHODS

Materials. P85, EO_{26}-PO_{40}-EO_{26} (lot # WPAU-549B) was kindly provided by BASF Corp. Synthesis of FITC labeled Pluronic block copolymers was performed by Dr. Srikanth Sriadibhatala at the University of Nebraska Medical Center (UNMC) as previously reported (*9*). Alexa 594 labeled CTB (Alexa 594-CTB), unlabeled CTB antibody, and Alexa 647 labeled Tf (Alexa 647-Tf) were purchased from Invitrogen Inc. (Carlsbad, CA). FITC labeled CTB (FITC-CTB), methyl-β-cyclodextrin (MBCD), sucrose, sodium azide, cytochalasin D, and 2-deoxyglucose (2DG) were purchased from Sigma-Aldrich (St. Louis, MO). Bovine serum albumin (BSA) (Fischer Scientific, Waltham, MA) RITC-HRP was prepared by labeling HRP (2 mg/mL) Sigma-Aldrich (St. Louis, MO) in 0.1 M bicarbonate buffer with RITC. RITC-HRP was separated from the mixture using a Sephadex G-25 column Sigma-Aldrich (St. Louis, MO).

Cell Lines. Madin-Darby Canine Kidney **(**MDCK) cells were maintained in Dulbecco's Modified Eagle's Medium (DMEM), containing 10% heat inactivated fetal bovine serum (FBS) and penicillin/streptomycin as described elsewhere (*27*). All tissue material media was obtained from Gibco Life Technologies, Inc. (Grand Island, NY). MDCK cells were used after 48 h of plating.

FACS Analysis of FITC-P85 Uptake. MDCK cells (5×10^4 cell/well in 24 well plates) were exposed to 0.001% FITC-P85 alone or to 0.001% FITC-P85 mixed with different concentrations of unlabeled P85 for 1 h at 37 °C. Cells were then washed by phosphate-buffered saline (PBS), trypsinized, and resuspended in PBS. In select experiments, cells were pretreated for 30 min with inhibitors of endocytosis (5 mM MBCD, or 0.45 M sucrose, or 0.25 mM cytochalasin D), and then the same inhibitors were also present during subsequent incubation with the copolymer. The mean fluorescence intensity was analyzed using Becton Dickinson FACStarPlus flow cytometer operating under Lysis II (San Jose, CA) equipped with an argon ion laser. Data were acquired in linear mode and visualized in logarithmic mode. Data from 10 000 events were gated using forward and side scatter parameters to exclude debris and dead cells.

FACS Analysis. MDCK cells (5×10^4 cell/well in 24 well plates) were exposed to 5 μg/mL Alexa 647-Tf or 5 μg/mL FITC-CTB with/without P85 for 1 h at 37 °C. Cells were washed, trypsinized, resuspended, and analyzed by FACS as described above. In select experiments, cells were pretreated with inhibitors of endocytosis (5 mM MBCD, or 0.45 M sucrose, or 0.25 mM cytochalasin D), and then the same inhibitors were also present during incubation with the endocytosis markers. All experiments were conducted thrice and measurements were conducted in triplicate and data presented as means ± SEM. Statistical comparisons between groups were made using the Student's *t* test.

Confocal Analysis on Live Cells. Pulse-Chase experiments were conducted for FITC-P85 uptake using live cell confocal microscope (Carl Zeiss LSM 510 Meta, Peabody, MA). MDCK cells (1×10^6) were plated in Biotech dishes (Fischer Scientific, Waltham, MA) and after two days (37 °C, 5% CO_2) were exposed for 30 min to 0.001% FITC-P85 mixed with 0.01% unlabeled P85 followed by another 30 min exposure 0.01% unlabeled P85. In select experiments, 5 μg/mL Alexa 594-CTB for 30 min, cells were washed, followed by concurrent addition of unlabeled CTB antibody with the copolymer for 30 min. The exposures to the copolymer were carried out at either 4 or 37 °C. In other experiments, 5 μg/mL Alexa 647-Tf were added to cells for 30 min and concurrently incubated with unlabeled copolymer for additional 30 min. Cells were finally washed and kept in complete media for imaging using the confocal microscope. The live cell microscopy was also used to assess effects of P85 on uptake of RITC-HRP. In this case, cells were incubated with 0.01 mg/mL RITC-HRP with/without P85 for 60 min and then analyzed by confocal microscopy.

Immunocytochemistry on Fixed Cells. Cells were pretreated with DMEM without FBS for 30 min, and then treated with 0.001% FITC-P85 in the presence of 0.01% or 0.1% unlabeled P85 for 1 h, washed, and fixed with 4% paraformaldehyde. Rabbit anticaveolin-1-Cy3 antibody (Sigma Aldrich, St Louis, MO) (1:100) and mouse anticlathrin antibody (Affinity Bioreagents, Golden, CO) (1:10) were incubated in blocking buffer overnight at 4 °C. For detection of anticlathrin antibody, specific IgG antibody (1:100) conjugated to Alexa 568 (Invitrogen Inc., Carlsbad, CA.) was added to cells for 1 h at 37 °C. Cells were examined under confocal microscope.

HRP Assay. The enzymatic activity of HRP was assessed with *o*-phenylenediamine as described earlier (*15*). Briefly, cells were treated with HRP solution (0.1 mg/mL) with/without P85. In select experiments, before adding the copolymer the cells were preincubated with 25 mM 2DG and 5 mM sodium azide, which was then added also during the exposure to the copolymer. Cells were then lysed with 0.1% Triton X-100 (Sigma-Aldrich, St. Louis, MO) and the lysate was added to a 96-well plate with the solution of *o*-phenylenediamine (5 mg/mL) in 0.1 M citrate buffer (pH 5.0) containing 1 mg/mL BSA, 0.1% Triton X-100, and 0.02% hydrogen peroxide solution. After incubating the mixture for 5 min at 37 °C, the reaction was stopped by adding 0.5% sodium sulfite in 2 M sulfuric acid (Acros Organic, Waltham, MA), and absorbance was measured at 550 nm using the microplate reader Multiskan MCC/340. The amounts of HRP in the samples were determined using a standard calibration curve. All measurements were conducted in triplicate and data presented as means ± SEM. Statistical comparisons between groups were made using Student's *t* test.

RESULTS

Internalization Pathways of P85. The confocal analysis was indicative of the vesicular uptake of FITC-P85 at 37 °C (Figure 1A). The FACS analysis further demonstrated that the uptake of the block copolymer was temperature-dependent and was considerably inhibited at 4 °C compared to 37 °C (Figure 1B). On this basis, we posit that endocytosis is a prominent pathway for internalization of P85.

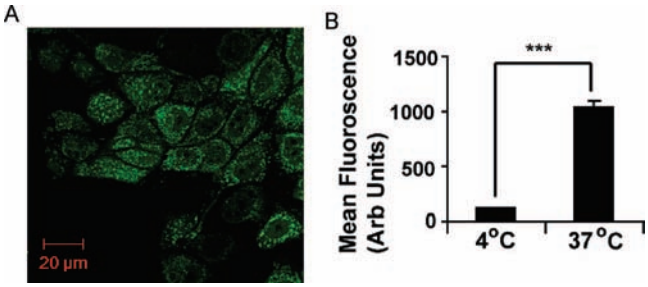

Figure 1. Uptake of FITC-P85 in MDCK cells: (A) confocal microscopy on live cells at 37 °C; (B) temperature dependence by FACS analysis. Cells were exposed to the copolymer at the corresponding temperatures for 60 min. The exposure solution contained 0.001% FITC-P85 mixed with 0.01% P85. (B) Data are means ± SEM (n = 3). Difference between 4 and 37 °C groups has a significance level of *** $p = 0.001$.

To further elucidate the specific internalization pathways of P85, we examined the effects of the endocytosis inhibitors on the uptake of this copolymer into the cells. This study used three different types of inhibitors: (1) MBCD, a cholesterol-depleting agent, for caveolae-mediated endocytosis (*28*), (2) hypertonic sucrose for clathrin-mediated endocytosis (*29, 30*), and (3) cytochalasin D, a potent inhibitor of actin polymerization, for both pathways as well as macropinocytosis (*31, 32*). To differentiate the transport of P85 unimers and micelles, the two concentrations of the copolymer were used. The first, 0.001 wt % FITC-P85, was below the CMC (~0.03% wt.) to examine the entry of the P85 unimers. The second, 0.001 wt % FITC-P85 (as a tracer) mixed with 0.1 wt % P85, was above the CMC, to characterize the entry of the micelles as well as unimers. At this high concentration, at least 70% of FITC-P85 was incorporated into the micelles, while the rest was in equilibrium in the unimer form (*33*). In each case, the FACS analysis was performed 1 h after exposure of the MDCK cells to the copolymer with or without the corresponding inhibitors. Since there is literature suggesting that various inhibitors may interfere with multiple endocytic pathways (*34*−*36*), we first demonstrated that MBCD inhibits CTB but not Tf uptake (i.e., is likely to be selective for caveolae) and sucrose inhibits Tf but not CTB uptake (i.e., is selective for clathrin) (data presented below in Figure 6).

As shown in Figure 2A, at the unimer concentration the FITC-P85 entry was blocked in the presence of MBCD but was not affected by the sucrose, suggesting that the unimers were entering cells via caveolae-mediated endocytosis. The situation was drastically changed at the higher P85 concentration (Figure 2B). In this case, the greatest inhibition of FITC-P85 entry was observed with sucrose, suggesting that the most prominent pathway for the micelle uptake was the clathrin-mediated endocytosis. Although MBCD had some effect on FITC-P85 uptake at this concentration, its effect was much less pronounced than that of the sucrose. It could be due to the presence of a smaller portion of FITC-P85 in the form of unimers, which were taken into cells by caveolae. Additionally, a minor portion of the micelles could be internalized through the caveolae-mediated pathway. Interestingly, cytochalasin D inhibited FITC-P85 uptake at both concentrations, although it was more pronounced at the unimer concentration.

To validate the conclusions of the inhibitor analysis, the cellular localization of FITC-P85 at different copolymer concentrations was examined by immunocytochemistry. In these studies following exposure to the copolymer for 60 min the cells were fixed and stained with antibodies against clathrin or caveolin-1 and examined by confocal microscope (Figure 3). Consistent with the inhibitor analysis, at the lowest concentration of the copolymer (0.001%) there was a significant colocalization of the unimers with caveolin-1, which considerably diminished as the concentration of the copolymer increased. In contrast, colocalization with clathrin was minimal if any at low concentration of the copolymer, but it greatly increased as the copolymer concentration increased. To further corroborate this result, we performed live cell microscopy on MDCK cells incubated with low concentration of labeled copolymer and either Alexa 594-CTB or Alexa 647-Tf. As shown in Figure 4, there was strong colocalization of the FITC-P85 and CTB. When the cells were exposed to the copolymer and CTB at 4 °C, the localization of both labels appeared to be mainly constrained to the plasma membrane areas. In contrast, at 37 °C the internalization and the colocalization of the labels were clearly evident. This suggests that FITC-P85 and Alexa 594-CTB are transported into cells through the same pathways. Conversely, there was little if any colocalization of FITC-P85 and Alexa 647-Tf (data not shown).

Effect of P85 on Endocytosis. To elucidate possible effects of P85 on different vesicular transport processes, we used HRP, CTB, and Tf as the markers of fluid-phase, caveolae-mediated, and clathrin-mediated endocytosis, respectively. The MDCK cells were exposed to the corresponding markers with/without P85 at different concentrations. As seen in Figure 5A, the uptake of HRP was practically unchanged at 0.001% P85, significantly decreased at 0.01% and 0.1% P85 and practically abolished at 1% P85. In the latter case, the inhibitory effect of the copolymer was practically the same as the effect of the metabolic inhibitor, 25 mM 2DG and 5 mM sodium azide. The inhibition of internalization of RITC-HRP by high concentrations of P85 was also evident in the live cell confocal microscopy experiment (Figure 5B). Altogether, these experiments demonstrate that at higher concentrations P85 inhibits nonspecific fluid-phase endocytosis of HRP.

In a separate experiment, the effects of various concentrations of P85 on the uptake of FITC-CTB and Alexa 647-Tf were evaluated using FACS analysis. At low concentrations, 0.0001% and 0.001%, the copolymer had no effect on the FITC-CTB uptake (Figure 6A). However, significant inhibition of the uptake of this marker was observed already at 0.1% P85, while at 1% and 5% P85, the uptake was completely abolished. Notably, the cytotoxicity analysis using MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay (*14*) as well as FACS analysis of the cells showed that 60 min exposure of the MDCK cells to these concentrations of P85 did not produce cytotoxicity (data not shown). Therefore, the plausible explanation of the data is that at higher concentrations P85 inhibits FITC-CTB uptake via caveolae-mediated endocytosis. This was reinforced by the effects of the endocytosis inhibitors on the FITC-CTB uptake, suggesting that cholesterol depletion by MBCD practically abolished the internalization of this marker (Figure 6A). At the same time, inhibition of clathrin-mediated endocytosis by hypertonic sucrose had no effect of the FITC-CTB uptake. Finally, using Alexa 647-Tf as a clathrin-mediated endocytosis marker we demonstrated that P85 at any concentration did not inhibit this endocytosis pathway (Figure 6B). Notably, this may explain the lack of overall toxicity of the copolymer under the conditions studied. The Alexa 647-Tf was inhibited by the hypertonic sucrose but not by the MBCD.

DISCUSSION

Nanoscale-size drug delivery systems based on synthetic polymers have attracted significant attention in pharmaceutics and medicine (*37*−*39*). An important and promising example of such systems is Pluronic block copolymers, which have been evaluated as drug and gene delivery agents in numerous studies (*3, 4, 26, 40*−*42*). A characteristic of Pluronic molecules is the ability to self-assemble into micelles in aqueous solutions

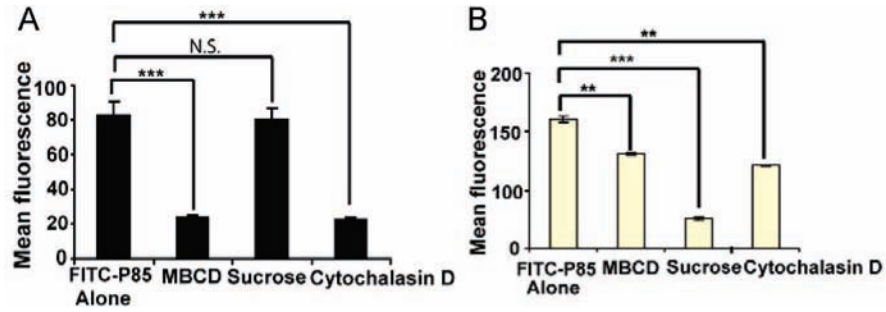

Figure 2. Effect of endocytosis inhibitors on the uptake of FITC-P85 in MDCK cells: (A) 0.001% FITC-P85 and (B) 0.001% FITC-P85 mixed with 0.1% P85. Cells were exposed to the copolymer that corresponding temperatures for 60 min at 37 °C. (A,B) Data are mean ± SEM ($n = 3$). Statistical comparisons between the control group (no inhibitor) and the corresponding inhibitor group are shown as follows: n.s. - not significant, ** $p = 0.01$ *** $p = 0.001$.

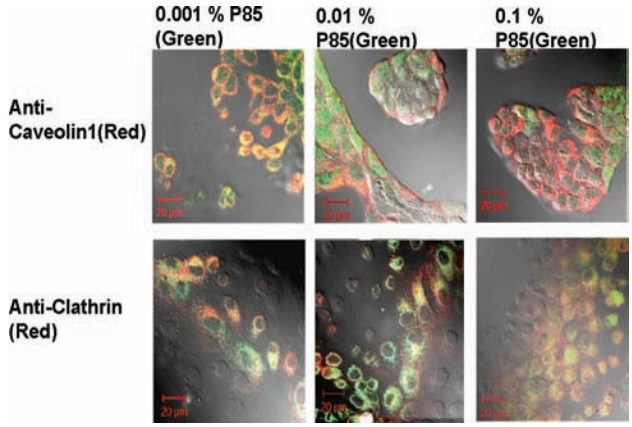

Figure 3. Colocalization of FITC-P85 with caveolin-1 and clathrin in fixed MDCK cells. Live cells were exposed for 60 min at 37 °C to 0.001% FITC-P85 alone, 0.001% FITC-P85 mixed with 0.01% P85, or 0.001% FITC-P85 mixed with 0.1% P85.

(*40*). The noncovalent incorporation of drugs into the hydrophobic PPO core of the Pluronic micelle increases (1) drug solubility, (2) drug metabolic stability, and (3) drug circulation time in the body. Furthermore, Pluronic unimers can also act as biological response modifiers: they can (1) bind with the cell membranes, (2) alter membrane microviscosity, and (3) inhibit selected membrane proteins, notably Pgp (*1, 7, 43*). This results in increased delivery of Pgp-dependent drugs in MDR tumors, as well as transport of such drugs across the BBB and intestinal epithelium, which are known to overexpress Pgp (*3, 7, 9, 10, 44*). Most recently, Pluronic block copolymers were shown to increase gene expression in stably and transiently transfected cells by activating pro-inflammatory (NFκB) cell signaling (*12, 14*) and to enhance drug-induced apoptosis in MDR cells (*45*). These multiple effects may result from interaction of block copolymers with the cellular membranes. Furthermore, the profound inhibition of Pgp in MDR cells (*10*) and, possibly, enhanced pro-apoptotic signaling in MDR cells (paper in preparation) appear to be related to the ability of Pluronic to transport inside the cells and interact with the mitochondrial membranes. Therefore, understanding of interaction of Pluronic block copolymer with cell membranes and the transport of these copolymers inside the cells is critically important for understanding their diverse biological response modifying activities. Furthermore, since Pluronic can exist in the form of (1) single chains (unimers), which exhibit the biological responses in cells, and (2) micelles, which can carry solubilized drugs inside the cells, it is essential to examine trafficking of these different aggregate forms of the copolymer. This study addresses such a need by evaluating the early stages of entry of Pluronic into cells.

Given a relative simplicity of the Pluronic block copolymer structure and apparent lack of sites for binding with specific cellular trafficking molecules, one could expect that the membrane interaction and cellular entry of this copolymer is quite unspecific. Surprisingly, to the contrary we demonstrate that Pluronic unimers appear to colocalize with markers of caveolae and enter cells rather selectively via caveolae-mediated endocytosis. Caveolae are subsets of specific cellular domains, often known as "lipid rafts", with which both the CTB and caveolin-1 are associated (*46*). Although this result appears to be paradoxical at first glance, its origin may be characteristic of interactions and self-assembly in polymeric systems. Such systems are known to exhibit highly cooperative behavior. For example, polyelectrolytes interacting with oppositely charged macromolecular species (other polyions, particles, etc.) can precisely "recognize" and "select" among different types of such species in the mixture (*47*). A recent example of this phenomenon is DNA topology recognition by synthetic polycations (*48*). This selectivity rises from small differences in the binding energy between polymers counted on a per-unit base, which is amplified on a scale of the entire polymer molecule. It is, therefore, possible that PPO blocks in Pluronic molecules may similarly recognize the cholesterol-rich microdomains in the cell membranes. To the best of our knowledge, this study is the first demonstration that amphiphilic block copolymers can interact selectively with membrane domains. One necessary factor for molecular recognition in polymeric systems is the reversibility of the binding and/or possibility of exchange between the bound polymeric species, so that the polymer can find the optimal partner by multiple trials (*13*). Such reversibility of binding with cellular membranes was previously shown for Pluronic molecules (*7*).

As the copolymer concentration in the media increases, the copolymer unimers self-assemble into polymeric micelles. In particular, P85 micelles are spherical core−shell structures of approximately 14.6 nm in diameter (*33*). They are composed of approximately 60 P85 molecules and have a PPO core of 5.4 nm in diameter surrounded by 3.7 nm PEO shell. The exterior surface of such micelles is hydrophilic and is unlikely to bind with the lipid portions of the cell membranes. For example, the lack of PEO interactions with lipid domains in cell membranes was apparent in studies using hydrophobic fluorescent probes embedded in the membranes (*9*). However, the same study also suggested that copolymers with high PEO content may adhere to the cellular surface and limit the lateral mobility of membrane lipids. It is not surprising, therefore, that micelles have different pathways of cellular uptake compared to unimers. Indeed, it was previously shown that drug solubilized in the micelles is transported into cells through a vesicular pathway rather than through trans-membrane diffusion (*49*). Furthermore, micelles can be conjugated with ligands, such as

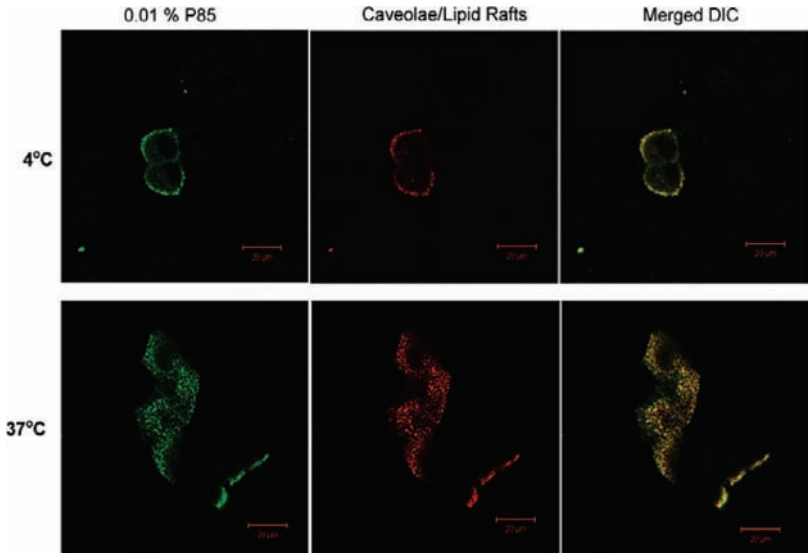

Figure 4. Colocalization of FITC-P85 and Alexa 594-CTB in live MDCK cells at 4 and 37 °C. Cells were exposed for 30 min. to 0.001% FITC-P85 mixed with 0.01% unlabeled P85 followed by another 30 min exposure 0.01% unlabeled P85 (see Materials and Methods). Some intracellular localization of the labels at 4 °C may be due to the increase of the temperature to r.t., during fluorescence observation, which could initiate endocytosis in live cells.

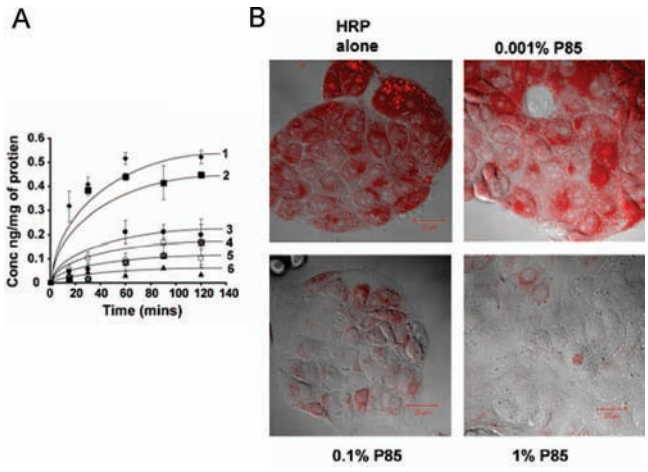

Figure 5. Effect of P85 (conc. reported as wt %) on uptake of HRP in MDCK cells: (A) cellular levels of HRP as determined by enzymatic activity in cell lyzates, cells were treated in the absence or presence of P85 and are grouped as 1, HRP alone; 2, 0.001 wt % P85; 3, 0.01% P85; 4, 0.1% P85; 5, 1% P85; 6, 2DG and sodium azide; (B) live cell confocal microscopy using RITC-HRP. (A) Data are mean ± SEM (n = 3).

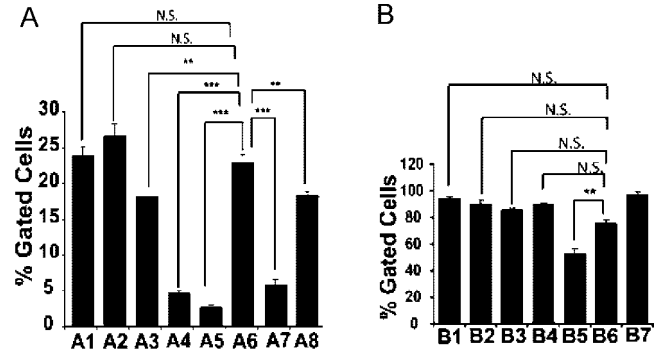

Figure 6. Effect of P85 (conc. reported as wt %) and various endocytosis inhibitors on the uptake of (A) FITC-CTB and (B) Alexa 647-Tf in MDCK cells. The experiments were grouped for (A) as A1 = 0.0001% P85, A2 = 0.001% P85, A3 = 0.1% P85, A4 = 1% P85, A5 = 5% P85, A6 = FITC-CTB, A7 = MBCD, and A8 = sucrose; and (B) as B1 = 0.0001% P85, B2 = 0.1% P85, B3 = 1% P85, B4 = 5% P85, B5 = sucrose, B6 = Alexa 647-Tf, and B7 = MBCD. (A, B) Data are mean ± SEM (n = 3). Statistical comparisons between the control group (no inhibitor) and the corresponding inhibitor group are shown as follows: n.s. - not significant, ** p = 0.05, *** p = 0.001.

insulin, and thus directed into cells via receptor-mediated endocytosis (*40, 50*). In this study, however, for the first time we can suggest with high likelihood that P85 micelles enter into cells via clathrin-mediated endocytosis.

The reasons for the apparent selectivity of the micelles with respect to the clathrin-mediated pathway as opposed to the caveolae-mediated pathway may lie in the ability of the block copolymer at relatively high concentration to inhibit caveolae-mediated endocytosis, which was also demonstrated here for the first time. The inhibition of the uptake of the fluid-phase endocytosis marker, HRP, and caveolae-mediated endocytosis marker, CTB, was already observed at 0.01% P85, which is below the CMC. (Although the mechanism of the fluid-phase endocytosis is still unclear, it was shown to be non-clathrin-mediated (*51*), and could be mediated through caveolae (manuscript in preparation)). Altogether, this indicates that the Pluronic unimers can somehow perturb the caveolae structure, with which they bind, possibly, by changing membrane micro-viscosity (*7*) or membrane curvature due to incorporation of bulky hydrophobic PPO chains in the membranes. Notably, the inhibition of caveolae cannot be linked to depletion of cellular ATP because at these concentrations no ATP depletion in MDCK cells is observed (*44*). (It is unlikely that P85 interacts directly with endocytic markers (HRP, CTB, and Tf) since, first, P85 copolymer has neutral charge and, second, all markers are hydrophilic in nature.) At higher concentrations of the copolymer, above the CMC, the unimers coexist with the micelles, and thus can inhibit the micelle transport through the caveolae pathway. Furthermore, as the concentration of P85 increases above the CMC even more copolymer can bind with membranes and further contribute to the disruption of caveolae. Under these conditions, the entry of the copolymer micelles can still proceed through the clathrin-mediated pathway, which is not inhibited. In addition, although there is no direct evidence of a specific receptor for micelles at clathrin microdomains one cannot exclude such a possibility. Moreover, nonspecific interaction of the micelle PEO corona with these domains is also possible.

As already mentioned, despite of the fact that PEO is often considered inert some surface interactions with cell membranes have been suggested (*9*). This may include one or a combination of hydrophobic and hydrogen binding interactions, for example, with membrane proteins. Interestingly, several studies suggest that either PEO alone or PEO-covered nanoparticles may induce complement activation (*52*). The structural similarity between the terminal region of the PEO chain and carbohydrates has also been noted, which may result in PEO binding with lectins (*53*) as well as carbohydrate receptors, which are endocytosed through a clathrin-mediated route (*54*).

Finally, selective interactions of P85 unimers via PPO blocks with caveolae may be also related to the copolymer's functional activities in cells. The ability of Pluronic to decrease microviscosity of some rigid membrane structures (membrane fluidization) was previously shown (*7*). It is possible that these structures are the same as or similar to the cholesterol-rich lipid rafts/caveolae. Furthermore, there are indications in literature that Pgp, also affected by Pluronic block copolymer, can colocalize with the lipid rafts/caveolae (*55*). Thus, the effects of Pluronic block copolymers on Pgp and caveolae-mediated endocytosis may be related to each other. We plan to determine this in our subsequent studies. In addition, one needs to take into account that caveolae regulate cellular signaling of cholesterol, as well as activity of various ion channels. It is known that one side effect of overexposure to Pluronic block copolymers is dose-dependent hyperlipidemia, in particular, a rise in the cholesterol and triglyceride levels in the plasma (*56*). This can be due to impairment of cholesterol trafficking and metabolism resulting from inhibition of the caveolae-mediated endocytosis. Notably, caveolae are known to cluster multiple receptors, such as EGF, CCK, Endothelin, Tyrosine Kinases, and so forth, which enable signal integration and amplification (*13*, *57*). They also host signal transducers, for example, PKC, MAPK, eNOS, and calmodulin, transporters (e.g., IP3 receptor and Porin) as well as structural molecules (e.g., actin and myosin). Therefore, detailed characterization of interactions of Pluronic block copolymers with cell membranes is likely to provide a foundation for future understanding of the diverse biological response modifying activities of these copolymers, including alteration of cell signaling, activation of transcription, and other processes.

ACKNOWLEDGMENT

This study was supported by National Institutes of Health grants RO1 NS36229, 2RO1 CA89225, and RO1 NS051334 awarded to A.V.K. We thank Dr. Srikanth Sriadibhatala for assistance in synthesizing FITC labeled P85. We would also like to thank the flow cytometery and confocal microscopy core facilities at UNMC. AVK is a cofounder, shareholder and chair of scientific advisory board of Supratek Pharma Inc. (Montreal, Canada), which developed Pluronic-based SP1049C and SP1017 formulations for chemotherapy and gene delivery, respectively.
