Synthesis of PEG-DNP. Thirty-eight milligrams of $HCl \cdot H_2N$-PEG-COOH (5000 g/mol, Nektar Therapeutics) and 1.5 equiv of triethylamine (TEA) were dissolved in 1 mL of anhydrous DMF. DNP-NHS (5.4 mg (1.8 equiv)) was dissolved in 250 μL of anhydrous DMF, added to PEG, and stirred for 48 h. Ten milliliters of dH_2O was added to the reaction mixture, which was then added to a Slide-A-Lyzer 3.5K MWCO dialysis cassette (Pierce) and dialyzed against dH_2O for 2 days to remove unreacted DNP. The reaction solution was recovered from the dialysis cassettes, passed through a glass filter with a piece of grade #50 Whatman filter paper (Fisher), and lyophilized to yield approximately 40 mg of a fluffy yellow solid. ^{1}H NMR (300 MHz Bruker Avance NMR Spectrometer using a BBI inverse probe) was performed on PEG-DNP to determine the labeling ratio of DNP by proton integration of PEG CH_2 next to the terminal carboxyl group (2.5 ppm) and of the DNP CH groups in the aromatic ring (7.1, 8.3, and 9.1 ppm). Integration revealed that 84.1% of the PEG was conjugated to DNP (Supporting Information). The remaining amine groups were reacted with Sulfo-NHS acetate (Pierce), irreversibly capping the amines with an acyl group. Amine blocking was confirmed by a 2,4,6-trinitrobenzenesulfonic acid (TNBS) assay as described in ref *43*.

Synthesis of PEI-PEG-DNP. PEG-DNP (10.5 mg) was dissolved in 400 μL of anhydrous DMF. 1,3-Dicyclohexylcarbodiimide (DCC) (2.0 mg (5 equiv)) was dissolved in 50 μL of anhydrous DMF, and 1.12 mg (5 equiv) of *N*-hydroxysuccinimide (NHS) was dissolved in 50 μL anhydrous DMF. The 50 μL of NHS was added to PEG-DNP, followed immediately by 50 μL of DCC, and the reaction was allowed to stir for 48 h to activate the carboxylic acid group on the PEG with NHS. Then, 6.08 mg of PEI (25,000 g/mol, branched) was dissolved in 608 μL of anhydrous DMF with 150 molar equiv of TEA, and the reaction was stirred for 30 min. The activated PEI solution was added to NHS-PEG-DNP for an 8:1 molar PEG/PEI ratio and allowed to stir for 24 h. Another aliquot of TEA (150 equiv), DCC (5 equiv), and NHS (5 equiv) in anhydrous DMF was added to drive the reaction to completion and stirred for another 24 h. The polymer was protonated by the addition of HCl and dialyzed in a Slide-A-Lyzer 10K MWCO Dialysis Cassette against dH_2O to remove unreacted PEG-DNP from the PEI-PEG-DNP solution. The dialyzed solution was filtered through a 0.22 μm filter and lyophilized to yield a fluffy yellow solid. ^{1}H NMR (300 MHz Bruker Avance NMR Spectrometer using a BBI inverse probe) was performed on PEI-PEG-DNP to determine the labeling ratio of PEG-DNP by proton integration of the PEI main chain CH_2 groups (2.6–3.2 ppm) (*44*) and of the DNP CH groups as described above. The integration of the DNP, the integration of the PEI, and the 0.841 DNP/PEG relationship were used to determine the labeling ratio as 6.84 mol PEG per mol PEI (Supporting Information).

Synthesis of PEI-PEG. bPEI (25,000 g/mol, 6.08 mg) was dissolved in 608 μL of anhydrous DMF with 150 molar equiv of TEA, and the reaction was stirred for 30 min. Then, 10.5 mg of mPEG-SPA (5000 g/mol, Nektar Therapeutics) was dissolved in 400 μL of anhydrous DMF, and the activated PEI solution was added to the mPEG-SPA for an 8:1 molar PEG/PEI ratio and allowed to stir for 48 h. The polymer was protonated by the addition of HCl and dialyzed in a Slide-A-Lyzer 10K MWCO Dialysis Cassette (Pierce) against dH_2O to remove unreacted PEG from the PEI-PEG solution. The dialyzed solution was filtered through a 0.22 μm filter and lyophilized to yield a fluffy white solid. ^{1}H NMR (300 MHz Bruker Avance NMR Spectrometer using a BBI inverse probe) was performed on PEI-PEG to determine the labeling ratio of PEG by proton integration of the PEI main chain CH_2 groups (2.6–3.2 ppm) and of the PEG main chain CH_2 groups (3.6 ppm) (*44*). The integration revealed a labeling ratio of 7.31 mol PEG per mol PEI (Supporting Information).

Labeling Plasmid DNA with Quantum Dots. gWiz-Luciferase plasmid (gWiz-Luc, Endotoxin-free) was purchased from Aldevron, and 1 mg of the DNA plasmid was purified by ethanol precipitation and resuspended in 1× TE buffer (10 mM Tris and 1 mM EDTA) at a concentration of 2 mg/mL. The plasmid was labeled with EZ-Link psoralen-PEO_3-biotin (Pierce) and then linked to streptavidin-conjugated quantum dots (QD-585-SA conjugate from Invitrogen/Molecular Probes) as described by the protocol of Ho et al. (*45*). Briefly, the DNA was biotinylated by photocross-linking psoralen-PEO_3-biotin onto the DNA, and then the QD-585-SA conjugates were attached to the DNA through the biotin. The degree of labeling of the DNA was determined by first creating standard curves of absorbance at 260 nm (A_{260}) versus concentration for both the DNA and the QDs and standard curves of fluorescence (ex ~350 nm, em ~585 nm) versus concentration for both the DNA and QDs. The concentration of the QDs could be determined from the fluorescence measurements, the QD concentration could be used to calculate the QDs' contribution to the A_{260} measurements, and then the corrected A_{260} signal could be used to calculate the DNA concentration. It was determined that the DNA plasmid was labeled with one QD per 2 plasmids.

Formulation of Polyplexes and Testing Salt Stability. The gWiz-Luc plasmid was diluted in water to a concentration of 0.1 μg/μL and mixed with an equal volume of polymer at the desired polymeric nitrogen to DNA phosphate (N/P) ratio. After mixing, the polyplexes were allowed to incubate for 5 min at room temperature. Ten microliters of each polyplex sample was mixed with either 90 μL of dH_2O or PBS, and the 100 μL sample was assayed for particle size by dynamic light scattering (DLS) measured on a Brookhaven Instruments Corp. ZetaPALS instrument. Particle sizing measurements were performed at a wavelength of 659.0 nm with a detection angle of 90° at RT. The samples were then diluted into 1.3 mL dH_2O, and the zeta potential was analyzed on the same ZetaPALS instrument.

Serum and ECM Components Unpackaging Assay. The gWiz-Luc plasmid was mixed with the bis-intercalating dye YOYO-1 iodide (Invitrogen/Molecular Probes) at a dye/base

pair (D:BP) ratio of 1:25 and incubated at 50 °C for 2 h to equilibrate the bis-intercalator complexes with DNA (*46*). Polyplexes were formed at N/P ratios of 0 and 3 by complexing unlabeled or YOYO-labeled DNA with either PEI or PEI-PEG. Type I collagen from rat tail (Upstate/Millipore) was prepared according to the manufacturer's instructions at pH 7.4. Fetal bovine serum (FBS, from Mediatech) was serially diluted with 1:10 dilutions into either dH_2O or OptiMEM I (Invitrogen), while heparan sulfate (HS, from Sigma), collagen, and Matrigel (BD Biosciences) were serially diluted in OptiMEM. Twenty microliters (containing 1 μg DNA) of polyplex was added to each well of a 96-well plate, followed by 80 μL of one dilution of FBS, Matrigel, collagen, or HS. The fluorescence from each well was measured on a Tecan Safire^2 plate reader with excitation at 491 nm and emission at 510–520 nm. The fluorescence signal from the N/P = 3 polyplexes was corrected by subtracting the signal from unlabeled samples and then normalizing to the N/P = 0 (DNA only) signal. For the ECM components, a concentration for 50% unpackaging was determined by fitting a trendline to the data points by linear regression and using the equation of that line to calculate the concentration at 50% unpackaging.

NBD-Oligo Internalization. Mouse fibroblast cells (NIH-3T3, passage 91, ATCC # CRL-1658) were resuspended in complete cell culture medium (DMEM + 10% FBS + 1% antibiotic/antimicrobial) to a concentration of 200,000 cells/mL. The cells were plated at 200,000 cells per well in a 12-well plate. Polyplexes at N/P = 3 with 3 μg of DNA (NBD-labeled oligonucleotide, prepared as described previously (*19*)) in 60 μL were formulated, and the polyplex samples were brought up to 600 μL with OptiMEM or with OptiMEM containing 0.01 μg/μL HS, 10% FBS, or 30% FBS. The cells were incubated with the polyplex solutions for 2 h, and then the cells were washed with 10 mM dithionite/10 mM Tris in cold PBS for 2 min at RT to quench any extracellular NBD fluorescence. The cells were washed with PBS, permeabilized with Triton X-100, and NBD uptake quantified as described previously (*19*).

***In Vitro* Transfection.** Human cervix epithelial adenocarcinoma cells (HeLa, passage 56, ATCC # CCL-2) were resuspended in complete cell culture medium (DMEM + 10% FBS + 1% antibiotic/antimicrobial) to a concentration of 2.5×10^5 cells/mL, and 5×10^5 cells were added to each well of a 6-well plate, each containing a 22 × 22 mm sterilized glass coverslip. The 6-well plates were placed in a 37 °C incubator with 5% CO_2 for 24 h to allow the HeLa cells to attach to the glass coverslips. Polyplexes were formed at an N/P of 3 using 5 μg of DNA-QD and PEI-DNP in 100 μL total volume. Controls containing polymer or DNA only were also prepared. For a polyplex + FBS sample, 300 μL of FBS was added to the 100 μL polyplex (75% v/v FBS), and for a polyplex + HS sample, 100 μL of HS at a concentration of 0.1 μg/μL was added to the 100 μL polyplex (2 μg HS/μg DNA). Each sample was brought up to 1 mL with OptiMEM. The cells were washed twice with PBS, and the transfection mixtures were added. After a 2 h incubation at 37 °C, the cells were fixed with 4% paraformaldehyde (PFA, diluted in PBS) for 7 min, followed by permeabilization with 0.1% Triton X-100 (diluted in PBS) for 7 min and blocking with 10% normal goat serum (Sigma) diluted in PBS + 1% bovine serum albumin (PBS/BSA) for 30 min. The slides were each incubated with 100 μL of a primary rat anti-DNP monoclonal antibody (Zymed) diluted 1:100 (starting concentration 1 mg/mL) in PBS/BSA for 1 h and 100 μL of a secondary antibody (Ab) solution for 30 min. The secondary Ab solution contained goat anti-rat IgG Ab that was labeled with Alexa Fluor 633 (Invitrogen/Molecular Probes) and diluted 1:100 (starting concentration is 2 mg/mL), phalloidin labeled with Alexa Fluor 488 (to stain actin, from Invitrogen/Molecular Probes) diluted 1:10 (starting concentration is 1 unit in 5 μL), and DAPI diluted 1:100 (to stain the nucleus, starting concentration is 1 mM). For the secondary Ab solution, all materials were diluted into PBS/BSA. Cells were washed twice with PBS between all steps. The slides were mounted on Gold Seal Ultra Frost glass microscope slides (Becton Dickinson) with ProLong Antifade reagent (Invitrogen/Molecular Probes) and sealed with nail polish. Cells were imaged on a Zeiss LSM 510 confocal system equipped with an inverted Axiovert 200 motorized microscope using a Zeiss plan-apochromat 63×/1.4 oil objective and taking 2 μm slices in the *z*-plane.

***In Vivo* Liver Delivery.** Polyplexes were prepared at N/P = 3 using 25 μg of DNA-QD per mouse, where both the polymer and DNA were diluted in 5% dextrose to a total volume of 200 μL (400 μL after mixing). The polyplex (PPX) sample was formed using PEI-DNP and the PEGylated polyplex (PEG-PPX) sample was formed using PEI-PEG-DNP. A DNA only sample was made with 25 μg of DNA in 400 μL of 5% dextrose, a PEI only sample was made with an amount of PEI-DNP equivalent to N/P = 3 in 400 μL of 5% dextrose, and a PEG-PEI only sample was made with an amount of PEI-PEG-DNP equivalent to N/P = 3 in 400 μL of 5% dextrose. Each sample was assayed for particle size in dH_2O and PBS before injection into animals. Female BALB/c mice (8 weeks, from Jackson Laboratories) were anesthetized with isoflurane, and the sample solutions were injected into the portal vein. After 20 min or 1 h, a Saf-T-Intima IV catheter (22 GA, 0.75 in, from BD) was inserted into the inferior vena cava, the portal vein was clipped, and the liver was perfused with 10 mL of PBS at a flow rate of 1 mL/min. During perfusion, the liver was periodically gently massaged to enhance the clearance of blood out of the vasculature in the liver. After perfusion, the liver was excised and fixed in 4% PFA for 3 h. The liver was then cut in half, with one-half remaining in 4% PFA overnight. The other half was placed in 25% sucrose (a cryoprotectant) and stored at 4 °C overnight.

Histology, Immunohistochemistry, and Imaging. The livers in PFA were embedded in paraffin, sectioned, and stained with hematoxylin and eosin. The livers in sucrose were snap-frozen in Tissue-Tek Optimal Cutting Temperature embedding medium (OCT, from Sakura Finetek) and sectioned into 8 μm thick sections on a Leica CM 1850 cryostat (Meyer Instruments). Slides were rehydrated in PBS for 10 min, nonspecific Ab binding was blocked by incubating slides in 10% normal goat serum in PBS/BSA for 1 h, and then a primary antibody solution was applied to the slides for 1 h. The primary antibody solution consisted of a 1:100 dilution of rat anti-DNP monoclonal Ab and a 1:100 dilution of rabbit anti-mouse collagen IV polyclonal Ab (Chemicon International) in PBS/BSA. The slides were washed twice with PBS, and a secondary antibody solution was applied to the slides for 30 min. The secondary antibody solution consisted of a 1:100 dilution of goat anti-rat IgG conjugated to Alexa Fluor 633, a 1:100 dilution of goat anti-rabbit IgG conjugated to Alexa Fluor 350, and 2 U per section phalloidin-Alexa488 (stock concentration is 1 Unit/5 μL) with all reagents diluted in PBS/BSA. Glass microscope coverslips were mounted on the tissue sections with ProLong Antifade reagent, then sealed with nail polish. Tissue sections were imaged on a Zeiss LSM 510 confocal system equipped with an inverted Axiovert 200 motorized microscope using either a Zeiss plan-apochromat 63×/1.4 oil objective or an F Fluar 40×/1.3 oil objective and taking 3 μm slices in the *z*-plane.

Colocalization Analysis and DNA Quantification. The 4-channel LSM image files were imported into Volocity Visualization software from Improvision, and the colocalization function was used to assess the colocalization of two channels. A threshold was set on each channel to exclude the low-signal autofluorescence associated with each channel, and then Vo-

locity was used to compute the colocalization coefficients. The calculated colocalization coefficients were M_1 and M_2 as reported by Manders et al., and these coefficients were used because they are proportional to the amount of fluorescence in the colocalizing objects and independent of the signal intensities of each channel (*47*). Volocity software was also used to quantify the amount of DNA in each tissue section. A threshold was set on the DNA channel, and then Volocity was used to calculate the number of voxels in the DNA channel above the threshold.

RESULTS

Polymer and Plasmid Labeling. PEGylated PEI was synthesized by conjugating an activated PEG (PEG-SPA, MW 5000) to PEI (MW 25,000). Graft copolymers with approximately 7 PEG polymers per PEI polymer were synthesized to allow comparisons with previous reports (*39–41*). For fluorescence microscopy studies, polymers were also labeled with 2,4-dinitrophenyl (DNP) for antibody recognition. PEI was tagged with DNP-NHS at a labeling ratio of 23.2 DNP molecules per PEI polymer. PEI-PEG-DNP was synthesized by grafting DNP-PEG-COOH to PEI by DCC/NHS coupling. Graft copolymers with approximately 7 PEG polymers and 5.75 DNP molecules per PEI polymer were synthesized.

Initial experiments were conducted with AlexaFluor568-labeled plasmid DNA. However, the fluorescence quenching observed in condensed DNA resulted in fluorescence levels that were only slightly above background levels in tissue sections. Thus, plasmids were labeled with red fluorescent quantum dots (QDs). DNA was labeled with psoralen-biotin and then reacted with streptavidin-coated QDs, resulting in the incorporation of one QD for every two DNA plasmids. The fluorescence from polyplexes formed with QD-labeled DNA (QD-DNA) at N/P = 3 was approximately 5-fold higher than that from polyplexes formulated with Alexa568-labeled DNA at 6 dye molecules per plasmid (data not shown).

Polyplex Characterization. Polyplexes were formulated at N/P = 3 on the basis of particle size, zeta potential, and gel retardation studies that showed complete DNA condensation at N/P = 3 with only small amounts of free polymer after complex formation (data not shown). The polyplexes used in this study were characterized by measuring particle size in water and physiological salt concentrations and particle surface charge (Supporting Information). Polyplex diameter was ~100–150 nm in water. The unPEGylated polyplex rapidly aggregated to sizes greater than 1 μm in phosphate-buffered saline (PBS), whereas the PEGylation of polyplex conferred improved salt stability. All polyplexes had positive surface charges.

Effect of ECM and Serum Components on Vector Unpackaging. The effect of serum on polyplex stability was assessed using a YOYO-1-based unpackaging assay (Figure 1). The unpackaging assay is based on the properties of YOYO binding to DNA. First, the fluorescence of YOYO is over 1000-fold greater when bound to DNA than when in solution, and second, when YOYO-labeled DNA is condensed with a cationic polymer such as PEI, the dye molecules become closer in proximity and begin to interact electronically, causing a dramatic decrease in fluorescence signal (i.e., YOYO dye self-quenching occurs) (*48*). Complexation of YOYO-labeled plasmid with PEI or PEI-PEG results in a ~75–90% decrease in YOYO fluorescence. Polyplexes incubated with increasing concentrations of fetal bovine serum (FBS) show corresponding increases in YOYO-1 fluorescence until, at 80% FBS, nearly all the fluorescence is recovered, indicating complete unpackaging. Interestingly, the YOYO signal of polyplexes in the absence of serum is significantly higher when diluted in OptiMEM versus water (3-fold higher for unPEGylated and 2-fold higher for PEGylated). The YOYO signal of the polyplexes in the absence of serum is also significantly higher for PEGylated polyplexes versus that for unPEGylated polyplexes (25% of the fluorescence of unpackaged DNA vs 10% for water, and 50% vs 30% for OptiMEM). These data indicate that not only does PEGylation slightly loosen the polyplexes but also the presence of counterions from the salt in OptiMEM loosens the polyplexes.

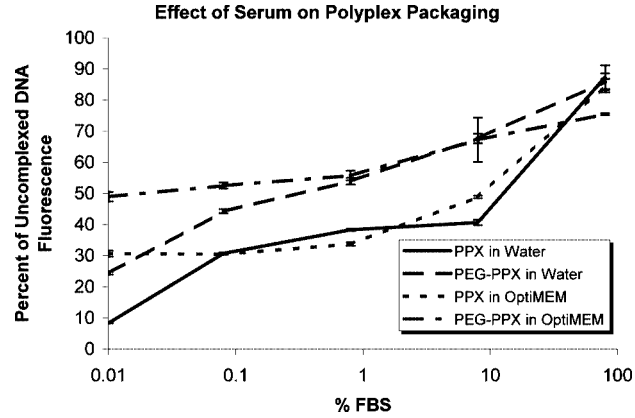

Figure 1. Polyplex (N/P = 3) unpackaging mediated by FBS diluted in water and OptiMEM. The *x*-axis shows the volume percent of FBS in solution. Eighty microliters of the indicated solution was added to 20 μL of polyplex (N/P = 3) containing 1 μg of DNA.

Table 1[a]

	PPX (μg)	PEG-PPX (μg)	fold increase
HS	0.27	0.01	26.3
Matrigel	6.30	0.57	11.0
collagen	301.03	28.50	10.6

[a] Various concentrations of extracellular matrix components (HS, Matrigel and Collagen I) were incubated with PEI and PEGylated PEI polyplex (PPX and PEG-PPX, respectively) labeled with YOYO-1. The amount of the ECM component that was required to unpackage polyplexes containing 1 μg of DNA to recover 50% of uncomplexed DNA fluorescence is reported.

The stability of polyplexes was also assessed in the presence of extracellular matrix proteins. Gene delivery vehicles entering the liver will pass out of the blood vessels and into the hepatic sinusoids that flow past rows of hepatocytes, where they will encounter an extracellular matrix (ECM) composed of both collagen and heparan sulfate proteoglycan (HSPG) (*49–55*). Thus, Matrigel (an ECM extract that contains HSPGs), heparan sulfate (HS, a negatively charged proteoglycan component), and collagen were investigated for their ability to unpackage PEI polyplexes and PEGylated PEI polyplexes (PPX and PEG-PPX, respectively). The amounts of each ECM component required to unpackage polyplexes containing 1 μg of YOYO-1abeled DNA to recover 50% of uncomplexed DNA fluorescence are reported in Table 1. HS most effectively unpackaged the polyplexes, requiring only 0.27 μg of HS and 0.01 μg of HS per μg DNA to unpackage PPX and PEG-PPX, respectively. Comparatively, approximately 25–50 times more Matrigel than HS (by weight) was required to unpackage the polyplexes, with 6.3 μg of Matrigel and 0.57 μg of Matrigel per μg DNA needed to unpackage PPX and PEG-PPX, respectively. Similarly, about 50-fold more collagen than Matrigel (by weight) was required to unpackage the polyplexes, with 301.03 μg of collagen and 28.5 μg of collagen per μg DNA needed to unpackage PPX and PEG-PPX, respectively. A general trend also appears in that approximately 10-fold more ECM component (by weight) is required to unpackage PPX compared to that required to unpackage PEG-PPX. This trend holds true for FBS unpackaging as well, with PEG-PPX unpackaging to 50% of uncomplexed DNA fluorescence around 1% FBS and PPX unpack-

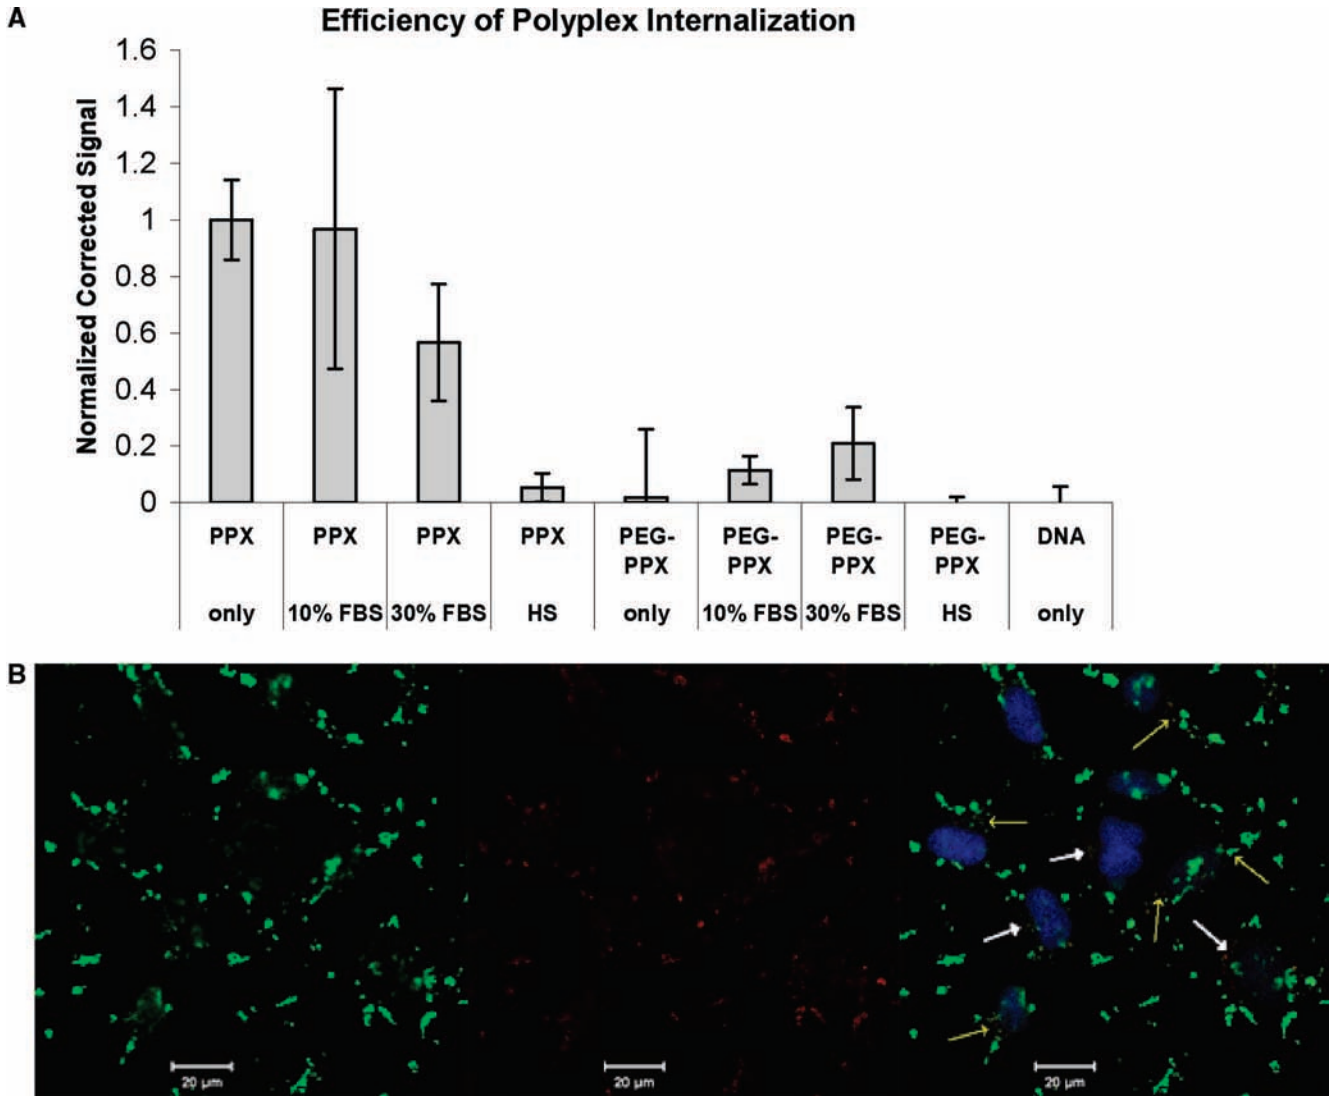

Figure 2. (A) Cellular internalization of PEI and PEGylated PEI polyplexes (PPX and PEG-PPX) incubated in the presence of heparan sulfate or FBS. The amount of internalized DNA for each formulation was normalized to that of cells incubated with PEI polyplex in OptiMEM. The internalization with PEI polyplexes in OptiMEM was statistically significantly different from PEI polyplexes in 30% FBS with $p < 0.05$ and all other samples (except the 10% FBS) with $p < 0.01$. (B) Confocal images from DNA-QD and PEI-DNP polyplex transfections. On the left is the PEI-DNP channel (green), in the middle is the DNA-QD channel (red), and on the right is an overlay of PEI-DNP, DNA-QD, and DAPI (blue). Punctate (yellow, thin arrows) and diffuse (white, thick arrows) fluorescence is observed. Some examples of free DNA are also found near the cell nuclei in the areas of diffuse fluorescence. The scale bars are 20 μm.

aging to 50% of uncomplexed DNA fluorescence around 10% FBS (Figure 1).

Polyplex Internalization. Polyplex-mediated DNA internalization in cultured mammalian cells was quantified in the presence of both FBS and HS by using an environmentally sensitive fluorophore, NBD, conjugated to DNA (Figure 2A). NBD is converted into a nonfluorescent molecule by dithionite, a membrane-impermeable reducing agent. Measurement of fluorescence from internalized NBD-labeled DNA is a facile method to quantify polyplex uptake (*19*). Exposure of cells to polyplexes in OptiMEM or OptiMEM + 10% serum resulted in efficient DNA internalization. However, significantly decreased polyplex uptake was observed in the presence of 30% serum (43% reduction in internalized DNA, $p < 0.05$). Similarly, PPX incubated with HS also led to a statistically significant decrease in the amount of DNA uptake (95% reduction in internalized DNA, $p < 0.01$). As is consistent with previous observations, PEG-PPX did not mediate much internalization of DNA.

HeLa cells were transfected with polyplexes formed with DNA-QD and PEI-DNP to verify dual fluorescence imaging of the polyplexes and to investigate intracellular distributions of polyplexes after internalization. Cells were stained with DAPI to visualize the nucleus and anti-DNP antibodies to visualize PEI and then imaged by confocal microscopy. As can be seen in Figure 2B, PPX were successfully delivered, with both cell-associated polyplexes and internalized polyplexes present. The cell-associated polyplexes are mainly visible as large aggregates attached (primarily through electrostatic interaction between the positively charged particles and the negatively charged cell surface) to the periphery of the actin network. The internalized polyplexes are present in two forms: first (and primarily) in punctate dots characteristic of vesicular localization (yellow, thin arrows) and second in diffuse fluorescence (white, thick arrows). Furthermore, it is clear that much of the PEI is colocalized with DNA, and nearly all of the DNA is colocalized with PEI. Most of the polyplex unpackaging observed occurs in and around the nucleus (in the areas of diffuse fluorescence), indicating that the majority of polyplexes remain intact until the very end stages of delivery. Low uptake of QD-DNA and significant unpackaging was observed with polyplexes incubated

with FBS or HS, consistent with the NBD internalization results (data not shown).

***In Vivo* Liver Delivery.** The intrahepatic distribution of dual-labeled PPX and PEG-PPX after portal vein delivery was next assessed. Eight-week old female BALB/c mice were injected with 400 μL of polyplexes in 5% dextrose, and liver tissue was collected either 20 min or 1 h after injection. The liver tissue was first analyzed by hematoxylin and eosin (H and E) staining for gross morphology. Tissues from a few mice had areas of sinusoidal dilation and hepatocyte death, but most of the tissue in each of the samples was normal and healthy. For fluorescent confocal imaging, tissue sections were stained with phalloidin to visualize actin and an antibody against collagen IV to represent ECM. PEI and PEG-PEI were visualized using an antibody against DNP, and the plasmid was fluorescently labeled with QD. Figure 3A shows confocal images of liver sections harvested 20 min after the portal vein injection of PPX. Both PEI and DNA can be detected in the sections. PEI is primarily colocalized with the collagen lining the sinusoidal structures and rarely colocalized with DNA. DNA was observed to be located near the cell periphery, but no cell-internalized DNA was observed. Figure 3B shows confocal images from liver that was removed 1 h postinjection, and again both PEI and DNA can be detected in the tissue. Similar to the 20 min time point, at 1 h the PEI and DNA are not colocalized with each other; interestingly, intracellular delivery of DNA was observed.

The distribution of PEG-PPX in liver 20 min after administration is shown in Figure 4. The distributions of the polymer and DNA in the tissue are very similar to that of PPX delivery. Again, both polymer and DNA can be detected in the tissue. Notably, with PEG-PPX, much less DNA is observed in the tissue compared to that in PPX (Figures 3 and 4). The relative amount of DNA in the tissues was determined using Volocity software to calculate the number of voxels containing fluorescence in the DNA channel in at least five images from each sample (Figure 5). The amount of DNA fluorescence in the liver 20 min after PPX administration is ~4-fold higher than levels from PEG-PPX or naked DNA injection ($p < 0.01$). Fluorescence from DNA in PPX samples decreases by over 50% between 20 min and 1 h ($p < 0.05$). Interestingly, PEG-PPX did not mediate a statistically significant increase in DNA in the tissue compared to that in the tissue of mice treated with DNA plasmid only, though both PPX time points showed a statistically significant increase in DNA compared to that of the DNA only sample ($p < 0.01$) (Figure 5). Unlike PPX, PEG-PPX does not appear to lead to any observable intracellular DNA delivery, even 1 h after delivery (Supporting Information). With the delivery of plasmid DNA or polymer alone (Supporting Information), it can be seen that very little DNA is present in the tissue when it is not complexed with polymer, although there is a large amount of polymer present in the tissue even when it is not complexed with DNA. No evidence of either DNA or polymer entering cells when delivered alone was found.

Colocalization Analysis. The extent of colocalization between polymer and DNA, collagen, or actin, and DNA and polymer, collagen, or actin was quantified by measuring colocalization coefficients using Volocity image analysis software. The coefficients M_1 and M_2 (as reported by Manders and Aten) are used to represent the degree to which two images overlap because they (i) do not depend on the ratio of the number of objects in both channels, (ii) do not depend on the signal intensities of the channels, and (iii) are proportional to the amount of fluorescence in the colocalizing objects (*47*). For both PPX and PEG-PPX formulations at 20 min and 1 h, DNA is most highly colocalized with actin, with colocalization coefficients ranging from 0.5 to 0.7 as shown in Figure 6. For PPX at 20 min, low colocalization of DNA with PEI or collagen is observed (colocalization coefficients of ~0.2 and ~0.15, respectively). For PPX at 1 h and both PEG-PPX at 20 min and 1 h, the colocalization coefficients of DNA with polymer and collagen are two to three times greater than the respective coefficients from PPX at 20 min. As can be seen in Figure 7, PEI is highly colocalized with collagen IV and actin (with colocalization coefficients ranging from 0.4 to 0.8), while it is only partially colocalized with the DNA (colocalization coefficients of 0.1 or less). Comparing Figures 6 and 7, it can be noted that even when DNA is highly colocalized with PEI, PEI is still not highly colocalized with the DNA, indicating that there is an abundance of free polymer in the tissue not associated with DNA. It should also be noted that the colocalization coefficients for each sample sum to greater than unity because there is colocalization among all the channels; therefore, some colocalized voxels can be counted twice.

DISCUSSION

Electrostatic condensation of polyanionic DNA and polycationic PEI into polyplexes occurs by a polyelectrolyte addition reaction driven by an increase in system entropy due to the displacement of counterions and the final formation of the polyelectrolyte complex, as described by Kabanov and co-workers (*56*). However, the addition of free polyanions can then cause dissociation of the initial complexes as a result of a polyelectrolyte exchange reaction, which is driven by a decrease in free energy due to the redistribution of interpolymeric salt bonds between the complexed polyanion and the free polyanion (*56*). Indeed, unpackaging of polyplexes delivered to cultured mammalian cells has been proposed to occur by competitive binding interactions with RNA in the cytosol or DNA in the nucleus (*30, 31, 57*). Polyplexes administered *in vivo* by systemic injection may be subject to premature unpackaging through interactions with serum proteins or ECM components, which have been shown *in vitro* to bind to and/or unpackage polyplexes (*32, 33, 58–61*).

Rice and co-workers demonstrated that plasmid is rapidly released from cationic peptide vectors in blood unless the vectors are stabilized by cross-linking (*62*). Recently, two reports investigated the biodistribution of PEI and PEGylated PEI polyplexes by radioactive labeling of both DNA and polymer, finding that polyplexes formed with PEGylated PEI or low molecular weight PEI separated in blood in a dose-dependent manner compared to polyplexes formed with high molecular weight PEI, which remained intact (*40, 41*). The studies also showed that PEGylated polyplexes were more likely to unpackage when the PEG grafting on PEI was high or when injected in small quantities but that PEI polyplexes were likely to remain intact even when injected in small quantities (*40, 41*). Additionally, both studies found that large amounts of both DNA and polymer primarily distributed to the liver, with the spleen and lung also having measurable amounts of DNA and polymer (*40, 41*). Although PEI and plasmid were shown to exhibit similar organ distributions and clearance kinetics and therefore assumed to remain packaged, the intrahepatic distributions of the polyplexes has, to date, not been investigated. In this work, the distribution of PEI polyplexes and PEGylated PEI polyplexes in the liver after intravenous delivery was investigated with dual-labeled polymer and plasmid with analysis by fluorescence confocal microscopy.

For systemic administration, the polyplexes will first encounter serum proteins in the blood. The polyplexes will then enter the liver via the portal vein and move into a parallel system of vascular channels called the hepatic sinusoids, which emanate radially from the portal triad (portal vein, hepatic artery, and bile duct) and conform to the surfaces of the hepatic epithelial cell laminae that compose the liver (*51*). The sinusoids

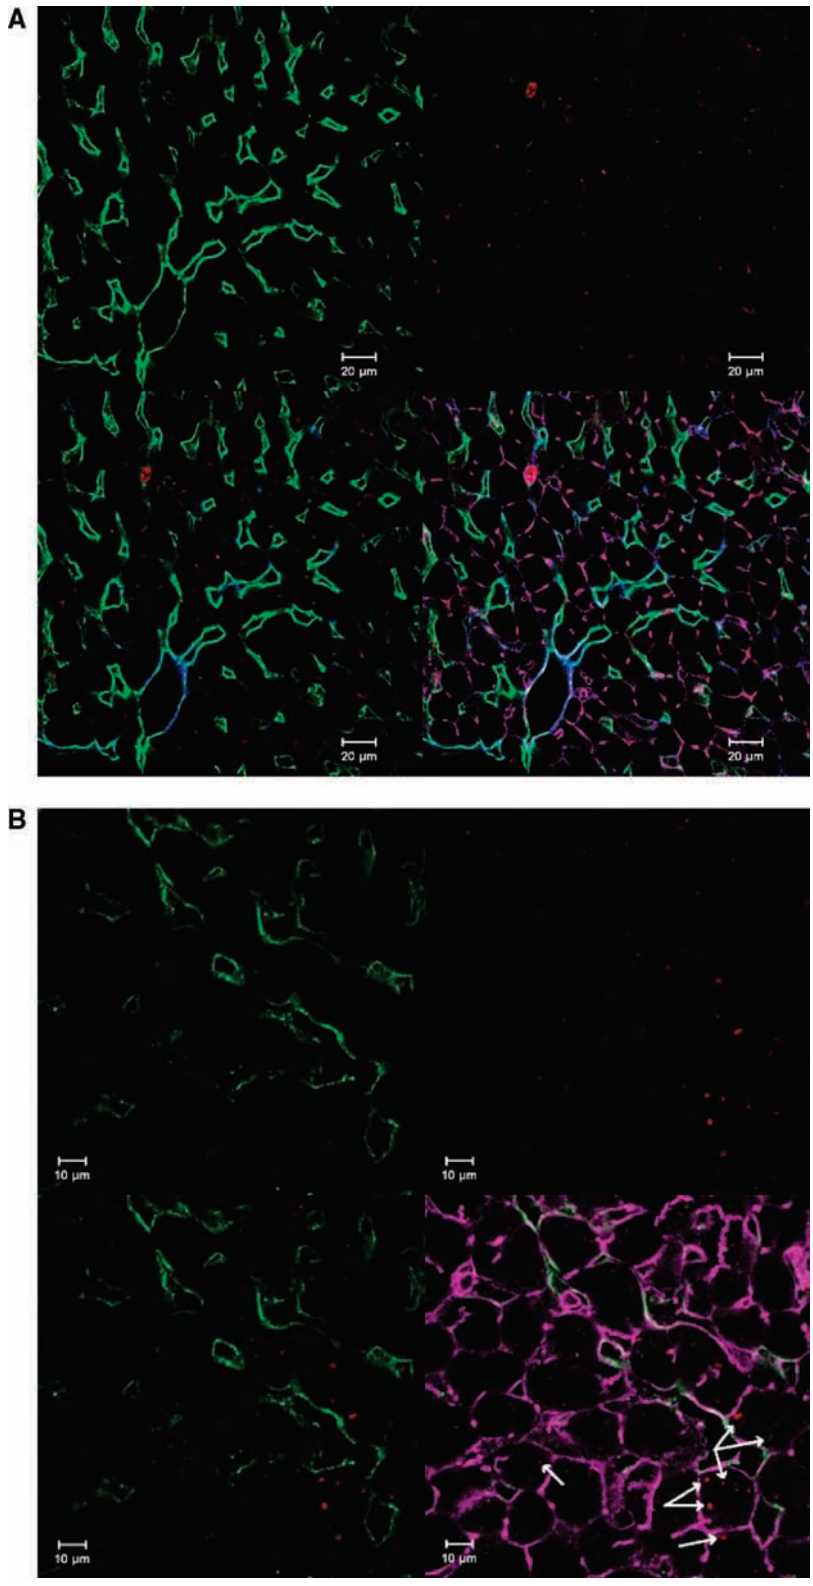

Figure 3. (A) 40× confocal images from a polyplex-injected mouse liver section from a liver that was removed after 20 min. On the top left is the PEI-DNP (green) channel; at the top right is the DNA-QD (red) channel; at the bottom left is the anti-Collagen IV Ab (blue) channel, DNA-QD, and PEI-DNP; and on the bottom right is anti-Collagen, DNA-QD, PEI-DNP, and Phalloidin (anti-actin, colored pink). The scale bars are 20 μm. (B) 63× confocal images from a polyplex-injected mouse liver section from a liver that was removed after 1 h. At the top left is the PEI-DNP (green) channel; at the top right is the DNA-QD (red) channel; on the bottom left is the anti-Collagen IV Ab (blue) channel, DNA-QD, and PEI-DNP; and on the bottom right is anti-Collagen, DNA-QD, PEI-DNP, and Phalloidin (anti-actin, colored pink). The scale bars are 10 μm; the arrows show the internalized DNA-QD.

intercommunicate through fenestrations to form an interconnected system of thin-walled vessels coupled to a large surface area of liver parenchyma to facilitate material transfer from the vessels to the cells (*51*). The hepatic sinusoids are lined with endothelial cells, and hepatic stellate cells lie in the space between the sinusoidal endothelial cells and the parenchymal

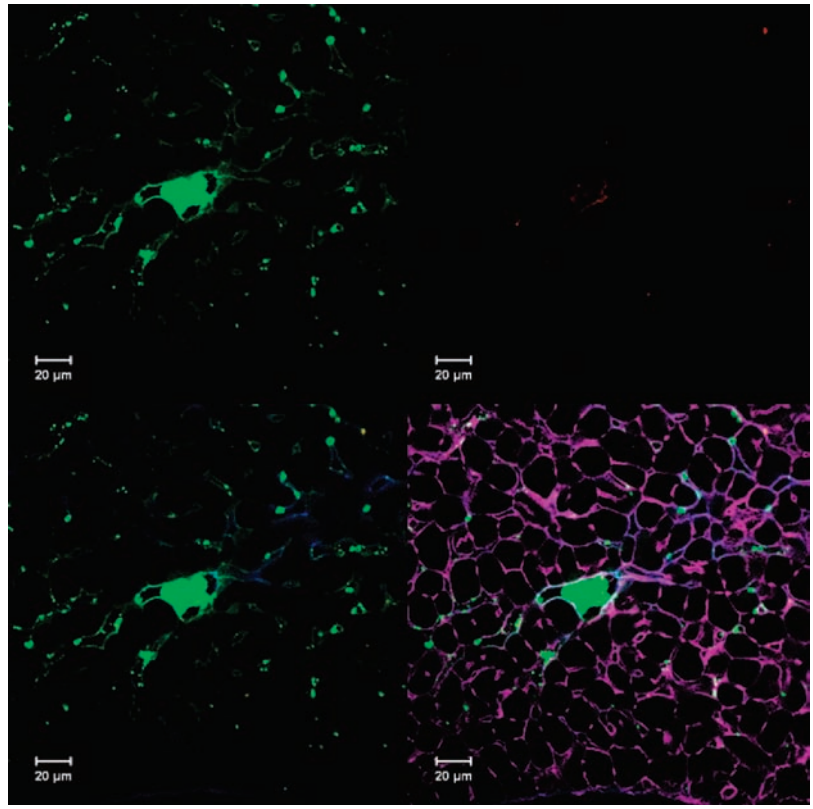

Figure 4. 40× confocal images from PEGylated polyplex-injected mouse liver section from a liver that was removed after 20 min. At the top left is the PEI-DNP (green) channel; on the top right is the DNA-QD (red) channel; on the bottom left is the anti-Collagen IV Ab (blue) channel, DNA-QD, and PEI-DNP; and on the bottom right is anti-Collagen, DNA-QD, PEI-DNP, and Phalloidin (anti-actin, colored pink). The scale bars are 20 μm.

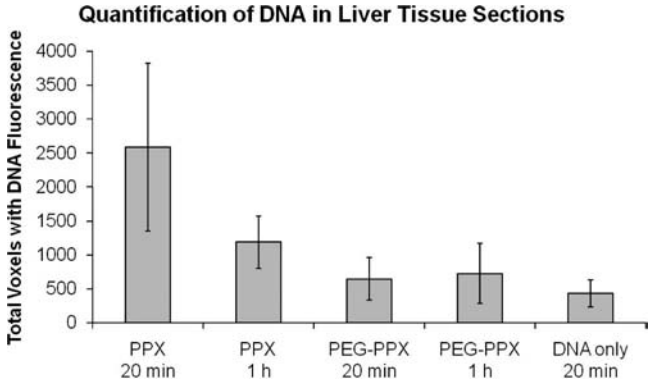

Figure 5. Quantification of DNA in liver tissue sections. Volocity image analysis software was used to quantify the total number of voxels with DNA fluorescence from tissue sections of each sample type. The amount of DNA fluorescence in the liver from PPX administration is ~4-fold higher than levels from PEG-PPX or naked DNA injection ($p < 0.01$). Fluorescence from DNA in PPX samples decreases by over 50% between 20 min and 1 h ($p < 0.05$). PEG-PPX did not mediate a statistically significant increase in DNA in the tissue compared to DNA only. Both PPX time points showed a statistically significant increase in DNA compared to the DNA only sample ($p < 0.01$).

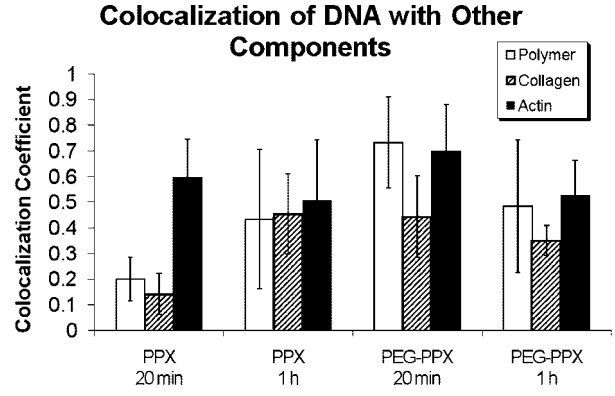

Figure 6. Colocalization coefficients (calculated from images of tissue sections taken 20 min or 1 h after injection) for DNA colocalized with polymer, collagen, or actin, as determined by Volocity. A coefficient value of 1 corresponds to perfect colocalization, while a value of 0 corresponds to no colocalization. For all groups, $n > 3$.

cells, where it has been shown that these stellate cells are mainly responsible for synthesizing the ECM surrounding the sinusoids (*51*, *55*). The ECM associated with the hepatic sinusoids is composed of collagen I, collagen IV, and heparan sulfate proteoglycan (HSPG) (*49*–*55*). Thus, both the serum and the ECM in the hepatic sinusoids present potential threats for premature polyplex unpackaging.

We first determined the ability of serum to unpackage the polyplexes *in vitro*. The assay that was employed uses the quenching of YOYO-labeled DNA fluorescence to report the compaction of DNA in polyplexes. Since YOYO intercalates into DNA before the polyplexes are formed and could potentially affect polyplex structure, it was first confirmed through a secondary approach, ethidium bromide (EtBr) exclusion, that YOYO-1 labeling does not affect polyplex packaging (Supporting Information). Figure 1 clearly shows that increasing the concentration of serum (the composition of FBS is variable, but the main protein components of FBS are albumins, globulins, and fibrinogens) in either water or OptiMEM causes the unpackaging of both PPX and PEG-PPX. The unpackaging of PEG-PPX occurs more readily at lower concentrations of FBS compared to that of PPX, indicating that PPX are more tightly complexed. Next, Table 1 shows the ability of ECM components to unpackage the polyplexes: collagen, Matrigel (the main

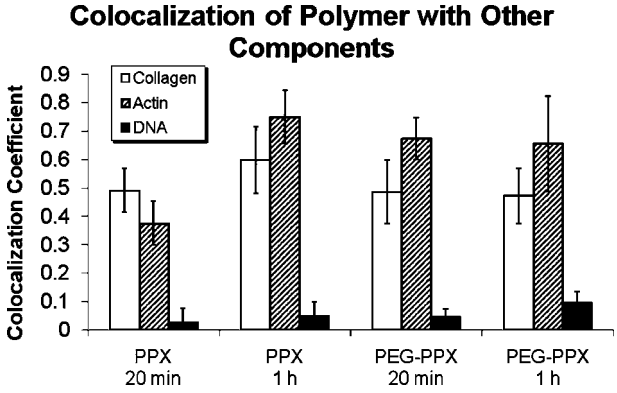

Figure 7. Colocalization coefficients (calculated from images of tissue sections taken 20 min or 1 h after injection) for polymer colocalized with collagen, actin, or DNA, as determined by Volocity. A coefficient value of 1 corresponds to perfect colocalization, while a value of 0 corresponds to no colocalization. For all groups, $n > 3$.

components of Matrigel are laminin, collagen IV, entactin, and heparan sulfate proteoglycans), and HS all effectively unpackage the polyplexes. Again, the unpackaging of PEG-PPX occurs more readily at lower concentrations of ECM components compared to that of PPX. For comparison with Table 1, the weight ratios for 50% unpackaging by FBS are approximately 500 μg FBS protein and 50 μg FBS protein per μg DNA for PPX and PEG-PPX, respectively; thus, the unpackaging mediated by FBS is comparable to that of collagen. In water, collagen I has an isoelectric point around neutral pH, but in the presence of salt, the isoelectric point can change; thus, since the collagen used in these assays was diluted in PBS, the ionic interactions could have shifted the isoelectric point, causing the collagen to be slightly charged (*63*). HS was expected to most effectively unpackage the polyplexes because of its high negative charge density. Matrigel was also expected to mediate the unpackaging of polyplexes because of the fact that it contains HSPG, but its intermediate ability to unpackage is consistent with the fact that its main component is collagen and that HSPG is only a minor component. Neither collagen nor Matrigel was allowed to gel, eliminating the possibility that the unpackaging was caused by the gelation process. Though it was determined that a large excess of FBS protein compared to DNA was required for unpackaging, the ratios necessary are within the physiological range normally found in serum. Thus, soluble GAGs, the GAGs of proteoglycans in the ECM, and serum proteins can all potentially facilitate polyplex unpackaging *in vivo*.

A series of *in vitro* transfections was performed with polyplexes formed from the DNP-labeled polymer and QD-labeled DNA, and the cells were imaged to assess uptake and intracellular distributions. The dual-labeled polyplexes were tested by the same EtBr unpackaging assay as described above, and the labeled PPX were found to be slightly more resistant to unpackaging than unlabeled PPX, while the labeled PEG-PPX were found to unpackage at levels similar to that of unlabeled PEG-PPX (Supporting Information). The dual-labeled polyplexes also exhibited slightly higher zeta potential than the unmodified polyplex, which may be responsible for the higher resistance to unpackaging seen with the labeled PPX (Supporting Information). As can be seen from Figure 2, PPX are efficiently internalized, and most of the internalized of the polymer and DNA are colocalized, while a small fraction has separated intracellularly after escape from endosomes (as evidenced by diffuse fluorescence rather than punctate). In contrast, minimal amounts of internalized DNA is observed with cells treated with plasmid only or with PPX exposed to HS or FBS before delivery, whereas levels of polymer association with cells is similar for all polyplex formulations (data not shown). These results demonstrate that (i) in the absence of serum proteins or ECM components, PPX are efficiently internalized in a packaged state and that (ii) exposure of PPX to serum or HS results in inefficient DNA delivery, likely due to premature vector unpackaging.

The intrahepatic distributions of dual-labeled polyplexes were next assessed. Initial studies used AlexaFluor-labeled plasmid, but the results reported here focus on QD-labeled plasmid because of higher fluorescence yield. However, hepatic distributions were similar for both labeling approaches. The major findings from these studies are that PEI and PEGylated PEI are not colocalized with plasmid DNA in the liver by 20 min postinjection (Figure 3A and 4). The unpackaging of PEG-PPX in the serum has been reported previously, although PEI (25 kD) has been shown to distribute in a manner similar to that of plasmid DNA in the organs (*40*, *41*). On the basis of previous biodistribution studies and these new findings, we propose that PEI polyplexes remain packaged during circulation in serum but unpackage after entering the liver because of competitive binding with ECM components, specifically HS proteoglycans. This conclusion is supported by *in vitro* unpackaging studies that show that HS efficiently unpackages PPX and PEG-PPX and by the observation that PEI is primarily localized around the hepatic sinusoids through collagen IV colocalization (Figure 3 and 4). Published images of HS proteoglycan distribution in the liver show fluorescence lining the hepatic sinusoids that bears a striking resemblance to the images in this work showing PEI lining the sinusoids (*50–53*). Collagen IV has been shown to be present in the space of Disse that lines the hepatic sinusoids, and HSPG has been shown to be present in the same areas. However, antibodies to HS also stain intracellular HS. Because colocalization of PEI with ECM components was quantified in this study by image analysis, collagen IV, which stains in a manner similar to that of extracellular HS was used as an ECM marker instead.

In contrast to PEI, DNA is visualized in intercellular spaces and is associated with the outside of the cells (Figure 3A), which is consistent with other reports (*64*). Previous results combined with the larger amount of DNA observed in the tissue in this study (compared to that in the DNA only sample; see Figure 5) and the fact that DNA disappears from serum very quickly when no PEI protects it (as it has a very short half-life due to nuclease degradation (*65*)) suggest that the polyplexes remain intact in blood. Thus, we propose that bPEI facilitates liver transfection *in vivo* primarily by protecting DNA against nuclease degradation and elimination from circulation, mediating higher levels of delivery to the liver compared with unpackaged DNA. However, because of premature unpackaging of polyplex in the liver, a significant contribution of PEI toward internalization and intracellular trafficking of plasmid DNA is unlikely. The unpackaged DNA was observed to be internalized with kinetics similar to that reported by Wolff and co-workers, who hypothesize that free plasmid DNA can be internalized in hepatocytes by a receptor-mediated process (*66*).

It is worth noting that the colocalization coefficients for DNA with polymer and collagen are higher for PPX at 1 h and PEG-PPX at 20 min and 1 h compared to those for the polyplex at 20 min because of an artifact created by a smaller amount of DNA present in the former samples (Figures 5 and 6). Liver sections acquired 20 min after PPX treatment have considerable amounts of free DNA in the tissue, but the other three samples only have small amounts of DNA remaining because of the fact that most DNA has been unpackaged from the polymeric carrier and degraded. The small amount of DNA that remains does so because it is protected by the polymer from nuclease degradation. Analysis of polymer colocalization in Figure 7 reveals that the polymer has poor colocalization with the DNA in any

sample, thus supporting the hypothesis that the high DNA−polymer colocalization at 1 h and in PEGylated formulations is simply an artifact derived from the presence of a smaller amount of DNA that has been protected by (and so is physically closer to) the PEI.

PEGylation of polyplexes was initially thought to reduce interaction with blood components, thereby increasing the stability of polyplexes in the blood. Subsequent work revealed that the PEGylated polyplexes were actually less stable in blood (*40, 41, 59, 67*). It is likely that a considerable amount of PEG is trapped within the core of the polyplexes after they form, leading to thermodynamic destabilization (*41, 59*). In line with these findings, the *in vitro* unpackaging assay that compared PPX with PEG-PPX showed that PEG-PPX unpackaged more easily. Additionally, it can be seen in Figure 5 that PEG-PPX carry much less DNA into the tissue, most likely due to early unpackaging of polyplexes in blood and DNA degradation by serum nucleases. It should be noted that in the images for PEG-PPX and PEI-PEG only, the amount of polymer seems to be lower than that seen with PPX. This observation may simply be attributed to the fact that the PEI-PEG contains less DNP (approximately 6 DNP per mol of polymer) than PEI (approximately 23 DNP per mol of polymer). However, the decreased amount of PEG-PEI may also be due to an actual change in biodistribution, similar to the report by Fischer et al. indicating that PEI preferentially accumulated in the liver and spleen, while PEG-PEI preferentially accumulated in the spleen and lung (*40*).

Also of interest is the notion that since preconjugating PEG to PEI causes PEG chains to be trapped in the core of the polyplex during formation, which destabilizes the polyplexes and leads to premature unpackaging, it would be beneficial to add PEG onto the polyplexes after they have been formed. However, this method was investigated, and it was found that coating polyplexes with a hydrophilic polymer similar to PEG generated complexes that were also less stable and unpackaged in the blood (*60*). In line with this finding, we have constructed similar postformation PEGylated polyplexes and have shown that they unpackage readily and do not aid in delivering more DNA to the tissue (data not shown). The hepatic DNA and PEG-PEI distributions observed in these studies were similar to those shown for polyplexes formed from PEG-PEI and DNA condensation.

In conclusion, we have demonstrated that both serum proteins and ECM act as extracellular barriers to polyplex-mediated gene delivery because of their ability to unpackage polyplexes. At the same time, polyplexes must unpackage once inside the cell so that transcription of the genes may occur. Thus, a double-edged sword is presented: the polyplexes must be stable enough to resist unpackaging in blood and ECM, but not too stable that they resist unpackaging once reaching their intracellular destination. Polyplexes will no doubt need to change their form in order to reach their full potential and overcome this serious flaw. One can imagine that if PEI and DNA remained associated extracellularly, PEI would be able to mediate much higher gene expression by increasing the amount of DNA taken up by the cells and aiding in DNA escape from endosomes as it does *in vitro*. A potential solution is cross-linking polyplexes with a biodegradable linker that will maintain stability in the blood and degrade in the intracellular environment, as proposed by Neu et al. and Murthy et al. (*68, 69*) or conjugating the nucleic acid cargo directly to the vector, as demonstrated by Rozema et al. (70).

ACKNOWLEDGMENT

Confocal imaging was performed at the NanoTech User Facility (NTUF) at the University of Washington, a member of National Nanotechnology Infrastructure Network supported by NSF, with special thanks to Dr. Dong Qin at NTUF for her training and support on the Zeiss confocal microscope. We also thank Dr. Matthew Yeh, from the Department of Pathology at the University of Washington, for his help with analyzing the liver tissue sections. Paraffin embedding, sectioning, and H & E staining were performed by the Pathology Core Immunocytochemistry Lab at UW. Cryosections were prepared using the cryostat at the UW Engineered Biomaterials (UWEB) histology facility. Jamie Bergen kindly donated the NBD-oligo used in the transfection studies. This work was funded by a National Science Foundation Fellowship awarded to R.S.B., an NSF CAREER Award (CBET-0448547) to S.H.P. and a Young Investigator award to S.H.P. by the National Hemophilia Foundation.

Supporting Information Available: Table S1 shows particle size and zeta potential characterization of the polyplexes. Figure S1 shows the NMR spectrum of PEG-DNP. Figure S2 shows the NMR spectrum of PEI-PEG-DNP. Figure S3 shows the NMR spectrum of unlabeled PEI-PEG. Figure S4 shows polyplex unpackaging as monitored by an EtBr exclusion assay. Figure S5 contains a 63× confocal image of PEG-PPX injected mouse liver removed after 1 h. Figure S6 contains a 40× confocal image from a PEI-only injected mouse liver removed after 20 min. Figure S7 contains a 40× confocal image from PEI-PEG-only injected mouse liver removed after 20 min. Figure S8 contains a 40× confocal image from DNA-only injected mouse liver removed after 20 min. Mitochondria Targeting by Guanidine− and Biguanidine−Porphyrin Photosensitizers

Martha Sibrian-Vazquez, Irina V. Nesterova, Timothy J. Jensen, and M. Graça H. Vicente*

Department of Chemistry, Louisiana State University, Baton Rouge, Louisiana 70803. Received October 23, 2007; Revised Manuscript Received December 3, 2007

We report the syntheses of three new amphiphilic porphyrin derivatives, containing a guanidine, a biguanidine, or an MLS peptide, that were designed to target the cell mitochondria. The guanidine− and biguanidine−porphyrins are poorly soluble in water, forming J-type aggregates in aqueous solutions. On the other hand, the porphyrin−MLS peptide conjugate bearing a low molecular weight PEG spacer is highly water-soluble and does not aggregate in aqueous media. The fluorescence quantum yields determined for all porphyrins were higher at low pH (<6) and the porphyrin−peptide conjugate had the highest quantum yields in aqueous media. All porphyrins showed low dark toxicity toward human carcinoma HEp2 cells, and the guanidine−porphyrin was the most phototoxic (IC_{50} = 4.8 μM at 1 J cm^{-2}), followed by the biguanidine−porphyrin and the porphyrin−MLS (IC_{50} = 8.2 μM and 9.8 μM at 1 J cm^{-2}, respectively). The porphyrin−MLS peptide conjugate accumulated the most within cells of all porphyrins at all times investigated and the biguanidine−porphyrin accumulated the least. Both the guanidine− and biguanidine−porphyrins localized within cell mitochondria and, in addition, were found in the lysosomes and the ER (in the case of the guanidine-porphyrin). In contrast, the porphyrin−MLS peptide conjugate localized mainly within the cell lysosomes.

INTRODUCTION

The preferential accumulation of cancer therapeutic drugs within cell mitochondria as a result of differences in the mitochondrial membrane potential between cancerous and normal cells has been an active area of research (*1*). The mitochondria are considered the "powerhouse" of the cell, playing important roles in the regulation of various biochemical processes, including the TCA and urea cycles, oxidative phosphorylation, beta oxidation of fatty cells, regulation of cell calcium, and apoptotic signaling (*2*). In particular, the role played by mitochondria in apoptosis, the process of programmed cell death, makes these cellular organelles desired targets for therapeutic drugs. The apoptotic changes in mitochondria consist of a loss of the electrochemical gradient across the inner membrane due to the opening of the permeability transition pore, followed by the release of soluble intermembrane proteins into the cytosol. These intermembrane proteins include cytochrome C, apoptosis inducing factor (AIF), and mitochondrially associated caspases that act directly as effectors of the apoptotic process (*1, 2*). Current strategies for the delivery of biologically active molecules to the mitochondria of live mammalian cells are based on (i) the high membrane potential across the inner mitochondrial membrane and the organelle's protein import machinery (*3*) or (ii) the property of certain lipophilic cations for preferential accumulation within mitochondria (*3*). The targeting of cancer cell mitochondria by porphyrin derivatives is an attractive strategy for the development of photodynamic therapy (PDT) photosensitizers with increased biological efficacy. PDT (*4, 5*) is a cancer treatment modality that involves the activation of a tumor-accumulated photosensitizer with light, which generates reactive oxygen species, mainly $^1O_2$, that cause irreversible photodamage to tumor tissues. It has been reported that the phototoxicity of Visudyne, an FDA-approved PDT photosensitizer, and that of other PDT drugs currently in clinical trials, including phthalocyanines Pc4 and ZnPcA1, is partly due to their preferential accumulation within mitochondria (*6, 7*). Previous studies have shown that some cationic porphyrin-based photosensitizers tend to accumulate within cell mitochondria (*8, 9*). Functionalities bearing delocalized positive charges (e.g., the guanidinium and biguanidinium groups) are of particular interest due to their higher lipophilicity compared with groups with localized charges. Several porphyrin derivatives containing delocalized positive charge substituents have been synthesized and some of these compounds were found to be efficient DNA intercalators (*10–15*). On the other hand, porphyrin−peptide conjugates bearing specific organelle-targeting peptide sequences have also been synthesized and investigated (*16–19*), although the use of mitochondrial localization sequences (MLS) has not yet been fully exploited as a targeting strategy for porphyrin-based sensitizers. Mitochondrial proteins bearing a MLS peptide are recognized by the mitochondrial protein import machinery and translocated into the mitochondrial matrix, where the MLS peptide is cleaved by a matrix processing protease (*20, 21*). Several MLS sequences have been identified and used for the specific delivery of drugs to the mitochondria (*22–25*). In a recent study, the sequence MLSLRQSIRFFKGC was used to deliver a cationic Mn-porphyrin to isolated rat liver mitochondria, via a mitochondrial swelling assay (*26*). In our continuing design and investigation of porphyrin-based photosensitizers with specific targeting properties, we report herein the syntheses and properties of a series of amphiphilic cationic porphyrin derivatives aimed at targeting the mitochondria of cancer cells. These compounds contain either a group with delocalized positive charge (guanidinium or biguanidinium) or a MLS peptide attached to the porphyrin via a low molecular weight PEG spacer. We report the photophysical

properties and the *in vitro* biological efficacy of this new series of porphyrins, including their ability for targeting the mitochondria of human carcinoma HEp2 cells.

EXPERIMENTAL PROCEDURES

Synthesis. Unless otherwise indicated, all commercially available starting materials were used directly without further purification. All reactions were monitored by TLC using Sorbent Technologies 0.25 mm silica gel plates with or without UV indicator (60F-254). Silica gel (Sorbent Technologies 32–63 μm) was used for flash column chromatography. ^{1}H NMR spectra were obtained on a ARX-300 Bruker spectrometer. Chemical shifts (δ) are given in ppm relative to d_6-DMSO or $CDCl_3$ (2.49 and 7.26 ppm ^{1}H, respectively,). Electronic absorption spectra were measured on a Perkin-Elmer Lambda 35 UV–vis spectrophotometer. Mass spectra were obtained on an Applied Biosystems QSTAR XL, a hybrid QqTOF mass spectrometer with a MALDI ionization source using CCA as the matrix. HPLC separation and analysis were carried out on a Dionex system including a P680 pump and a UVD340U, detector. Semipreparative HPLC was carried out using a Luna C_{18} 100 Å, 5 μm, 10 × 250 mm (Phenomenex, USA) column and a stepwise gradient; analytical HPLC was carried out using a Delta Pak C_{18} 300 Å, 5 μm, 3.9 × 150 mm (Waters, USA) column and a stepwise gradient.

Guanidinium−Porphyrin 2. To a solution of monoaminoporphyrin **1** (*27*) (0.025 g, 0.039 mmol) in DMF (0.5 mL) was added 12 M HCl (9.9 μL, 0.12 mmol) followed by methanol (0.019 g, 0.59 mmol) and cyanamide (0.0025 g, 0.059 mmol). The reaction mixture was heated at 70 °C for 24 h. The mixture was diluted with ethyl acetate (10 mL) upon which a purple precipitate formed. Complete precipitation was achieved upon addition of hexanes (5 mL). The solid residue was filtered, washed with a mixture of ethyl acetate/hexanes 1:1, and dried under vacuum. The title porphyrin was obtained as the hydrochloride in 42% yield (0.011 g). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.81–8.86 (8H, m), 8.20–8.24 (8H, m), 7.98–8.11 2H, m), 7.77 (9H, s), 7.63–7.66 (2H, d), 7.42–7.44 (1H, m), 7.02–7.05(1H, m), −2.75 (2H, s). UV–vis (CH_3OH) λ_{max} (ϵ/M^{-1} cm^{-1}) 419 (251 000), 516 (16 600), 552 (10 800), 588 (8600), 646 (7100). HRMS (MALDI) *m*/*z* 672.2920 (M + H$^+$), calculated for $C_{45}H_{33}N_7$ 672.2875.

Biguanidinium−Porphyrin 3. To a solution of monoaminoporphyrin **1** (*27*) (0.025 g, 0.039 mmol) in DMF (0.5 mL), was added 12 M HCl (9.9 mL, 0.12 mmol) followed by isopropanol (0.036 g, 0.59 mmol) and dicyanamide (0.005 g, 0.059 mmol). The reaction mixture was heated at 90 °C for 18 h. The mixture was diluted with ethyl acetate (10 mL) and hexanes (5 mL). The solid residue was filtered, washed with hexanes, and dried under vacuum. The title porphyrin was obtained as the hydrochloride in 61% yield (0.017 g). ^{1}H NMR (d_6-DMSO, 300 MHz): δ 10.31 (1H, s), 10.24 (1H, s), 8.739.07 (8H, m), 8.16–8.24 (6H, m), 7.86–7.97 (9, m), 7.52 (2H, s), 7.23–7.31 (2H. m), 6.66 (2H, s), −2.89 (2H, s). UV–vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (303 000), 516 (23 000), 553 (14 800), 590 (10 600), 647 (9100). HRMS (MALDI) *m*/*z* 714.3063 (M + H$^+$), calculated for $C_{46}H_{35}N_9$ 714.3093.

Porphyrin−MLS 4. The peptide sequence MSVLTPLLLRGLTGSARRLPVPRAKIHSL was prepared on an automated peptide synthesizer (Applied Biosystems Pioneer, Peptide Synthesis System, USA) in a 0.2 mmol scale, using the Fmoc strategy of solid-phase peptide synthesis. A 4-fold excess of the Fmoc-protected amino acids were coupled to the PAL-PEG-PS resin using TBTU/HOBt[1] as the activating agents. After the final coupling and the successive removal of the Fmoc group the resin was washed with DMF and isopropyl alcohol and then dried under vacuum. The dried resin containing the protected amino acid sequence was used in the coupling reaction to the porphyrin precursor. Peptidyl resin (0.025 mmol) was introduced into a glass synthesizer, swelled in DMF for 1 h, and then washed with DMF (2 × 5 mL). To the peptidyl resin was added 500 μL of a solution containing 0.05 mmol of pegylated porphyrin (*16*), 0.150 mmol of DIEA, 0.05 mmol of HOBt, and 0.05 mmol of TBTU. The reaction mixture was shaken overnight at room temperature and then filtered to give a dark purple resin. The resin was washed to remove unreacted porphyrin, first with DMF until the filtrate was colorless, then with dichloromethane and methanol, before being dried under vacuum. Cleavage and deprotection was carried out by treatment of the dried resin with 3 mL of a mixture of TFA/phenol/TIS/H_2O, 88/5/2/5 at room temperature for 4 h. The resin was filtered, washed with TFA (3 × 2 mL), and the filtrates combined and evaporated under vacuum to give a green residue. Addition of cold Et_2O yielded a green precipitate, which was washed repeatedly with Et_2O and dried under vacuum. The purification of the title conjugate was achieved by reverse-phase HPLC on a Luna C_{18} semipreparative column (10 × 250 mm, 5 μm) (Phenomenex, USA) using a solvent system of water/acetonitrile both containing 0.1% TFA, with a stepwise gradient from 60% to 95%. The fraction containing the conjugate was collected and lyophilized to yield pure title conjugate in 23% yield (0.024 g). The purity of the porphyrin−peptide conjugate was >98% as determined by HPLC on an analytical Delta Pak C_{18} (3.9 × 150 mm, 5 μm) column. HPLC t_r = 9.44 min. UV–vis (CH_3OH) λ_{max} (ϵ/M^{-1} cm^{-1}) 415 (295 100), 513 (16 900), 547 (10 500), 588 (8000), 645 (6700). LRMS (MALDI) *m*/*z* (M + H$^+$), 4183.55, calculated for $C_{203}H_{310}N_{51}O_{43}S$ 4182.33.

Photophysical Studies. All absorption spectra were acquired using a Perkin-Elmer Lambda 25 UV–visible Spectrophotometer with 10 mm path length quartz cuvettes. Corresponding diluents were utilized as reference solutions. Emission spectra were obtained using a Florolog 3 spectrofluorimeter. The optical density of solutions used for emission studies was below 0.05 at the excitation wavelength to eliminate inner filter effects. All the measurements were performed within 3 h of solution preparation. Stock solutions (10 mM) of porphyrins **2** and **3** were prepared in DMSO and for porphyrin−peptide conjugate **4** water was used. The aqueous solutions of porphyrins **3** and **4** were prepared by spiking 1.5–2 μL of the corresponding DMSO stock solutions into 1 mL of 100 mM phosphate buffer. The quantum yields were calculated using a secondary standard method (*28*, *29*). Methylene blue was used as a secondary standard. According to the approach, the integrated fluorescence intensity of the analyte (I) and standard (I_R), the optical density of the analyte (OD) and the standard (OD_R), and the refractive index of analyte solvent (n) and standard solvent (n_R) are related to the quantum yield of the analyte (Q) as

$$Q = Q_R \frac{I}{I_R} \frac{OD_R}{OD} \frac{n^2}{n_R^2} \quad (1)$$

where Q_R is a quantum yield of the reference standard (0.03 for Methylene Blue). To account for incomplete spectra, the bands were extrapolated using appropriate fitting models whenever necessary.

Cell Culture. All tissue culture media and reagents were obtained from Invitrogen. Human HEp2 cells were obtained from ATCC and maintained in a 50:50 mixture of DMEM: Advanced MEM containing 5% FBS. The cells were subcultured biweekly to maintain subconfluent stocks.

Time-Dependent Cellular Uptake. HEp2 cells were plated at 10 000 per well in a Costar 96 well plate and allowed to grow for 36 h. Porphyrin stocks were prepared in DMSO or water at a concentration of 10 mM and then diluted into medium to final working concentrations. The cells were exposed to 10 μM of each conjugate for 0, 1, 2, 4, 8, and 24 h. At the end of the incubation time the loading medium was removed and the cells were washed with PBS. The cells were solubilized upon addition of 100 μL of 0.25% Triton X-100 (Calbiochem) in PBS. To determine the porphyrin concentration, fluorescence emission was read at 410/650 nm (excitation/emission) using a BMG FLUOstar plate reader. The cell numbers were quantified using the CyQuant reagent (Molecular Probes).

Dark Cytotoxicity. The HEp2 cells were plated as described above and allowed 36 h to attach. The cells were exposed to increasing concentrations of porphyrin up to 100 μM and incubated overnight. The loading medium was then removed and the cells fed medium containing Cell Titer Blue (Promega) as per manufacturer's instructions. Cell toxicity was then measured by reading the fluorescence at 520/584 nm using a BMG FLUOstar plate reader. The signal was normalized to 100% viable (untreated) cells and 0% viable (treated with 0.2% saponin from Sigma) cells.

Phototoxicity. The HEp2 cells were prepared as described above for the dark cytotoxicity assay and treated with porphyrin concentrations of 0, 0.625, 1.25, 2.5, 5, and 10 μM. After compound loading, the medium was removed and replaced with medium containing 50 mM HEPES pH 7.4. The cells were then placed on ice and exposed to light from a 100 W halogen lamp filtered through a 610 nm long pass filter (Chroma) for 20 min. An inverted plate lid filled with water to a depth of 5 mm acted as an IR filter. The total light dose was approximately 1 J/cm^2. The cells were returned to the incubator for 24 h and assayed for toxicity as described above for the dark cytotoxicity experiment.

Microscopy. The HEp2 cells were plated on LabTek 2 chamber coverslips and incubated overnight, before being exposed to 10 μM of porphyrin. Since the porphyrin macrocycle fluorescences in the red region of the optical spectrum, the images were acquired using standard Texas Red filters. For the colocalization experiments, the cells were incubated for 24 h concurrently with porphyrin and one of the following organelle tracers for 30 min: MitoTracker Green (Molecular Probes) 250 nM, LysoSensor Green (Molecular Probes), BODIPY FL C_5-ceramide at 50 nM (Molecular Probes) and 50 nM, $DiOC_6$-(Molecular Probes) 5 μg/mL. The slides were washed three times with growth medium and new medium containing 50 mM HEPES pH 7.4 was added. By utilizing green fluorescing organelle tracers, it becomes possible to identify the intracellular compartments associated with the porphyrins; when the red and green images are overlaid, areas of colocalization appear as orange−yellow regions. Fluorescent microscopy was performed using a Zeiss Axiovert 200 M inverted fluorescent microscope fitted with standard FITC and Texas Red filter sets (Chroma). The images were aquired with a Zeiss Axiocam MRM CCD camera fitted to the microscope.

RESULTS

Synthesis. The new series of potentially mitochondria-targeting photosensitizers, guanidinium−porphyrin **2**, biguanidinium−porphyrin **3**, and porphyrin−MLS conjugate **4** were synthesized from monoaminoporphyrin **1**, as shown in Scheme 1. The reaction of protonated aminoporphyrin **1** with cyanamide at 70

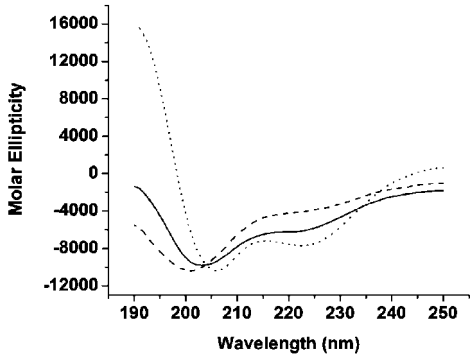

Figure 1. CD spectra in the amide region of conjugate **4** at 20 μM, (full line) TFE/H_2O, pH 7.00, (dash line) 50 mM NaH_2PO_4, pH 5.00, (dot line) 100 mM SDS/H_2O. The ellipticity is given in deg cm^2 dmol^{-1}, the cell path was 0.1 cm, and the temperature 25 °C.

°C in a mixture of DMF/methanol, gave guanidinium−porphyrin **2** in 42% yield. Using a similar procedure, although at 90 °C in a mixture of DMF/isopropanol and in the presence of dicyanamide, biguanidinium−porphyrin **3**, was obtained in 61% yield. The aminoporphyrin **1** was found to be unreactive in the presence of other guanidinylation reagents, including 1*H*-pyrazole-[*N*,*N*′-bis(*tert*-butoxycarbonyl)]-carboxamidine, *N*,*N*′-di-Boc-*N*′-triflyguanidine, and *N*,*N*′-bis(tert-butoxycarbonyl) thiourea, probably as a result of the low nucleophilicity of the amino group of **1**, as we have previously observed (*30*); the use of Mukaiyama's reagent (*31*) in conjunction with *N*,*N*′-bis(tert-butoxycarbonyl)thiourea gave the corresponding *N*-alkylated derivative rather than the targeted guanidinium-porphyrin **2**.

The porphyrin−MLS conjugate **4** was prepared using solid-phase methodology as we have previously reported (*19*). Briefly, aminoporphyrin **1** was converted to the corresponding carboxylate by reaction with diglycolic anhydride followed by pegylation, after deprotection of the terminal carboxylate and activation as the hydroxybenzotriazole ester. The activated pegylated porphyrin was conjugated to the peptidyl resin containing the sequence MSVLTPLLLRGLTGSARRLPVPRAKIHSL, and after cleavage and deprotection from the solid support, conjugate **4** was isolated in 23% yield.

All porphyrins were characterized by ^{1}H NMR, UV–vis, and MS, and in the case of conjugate **4**, also by CD (*vide infra*). Porphyrins **2**−**4** are all soluble in polar solvents, such as CH_3OH, DMSO, and DMF. However, while the porphyrin−peptide conjugate **4** was highly water-soluble, the guanidinium- and biguanidinium-substituted porphyins **2** and **3** were only partially soluble in water.

CD Studies. Conformational studies of the MLS peptide sequence in conjugate **4** were conducted in different media, including aqueous and membrane mimicking environments (in the presence of TFE or SDS). In aqueous solution at pH 5.0, the porphyrin−MLS peptide conjugate **4** shows negative Cotton effects at 198–207 nm as shown in Figure 1, which are characteristic of a random coil conformation. For example, for polylysine at pH 7, [121] = −41 900 deg cm^2 dmol^{-1} at 197 nm (*32*). In membrane mimicking environments, an α-helix structure characterized by two negative bands at 205 and 221 nm, associated with a positive band at 193 nm is induced for conjugate **4**; this conformational change is more clearly observed in the presence of SDS. For example, for polylysine at pH 7, [θ] = 76 900 deg cm^2 dmol^{-1} at 191 nm, [θ] = −32 600 deg cm^2 dmol^{-1} at 208 nm, and [θ] = −35 700 deg cm^2 dmol^{-1} at 222 nm (*32*). These results show that the MLS sequence in conjugate **4** adopts different conformations depending on the nature of the environment, as a result of the number and distribution of the hydrophobic amino acids in the MLS sequence.

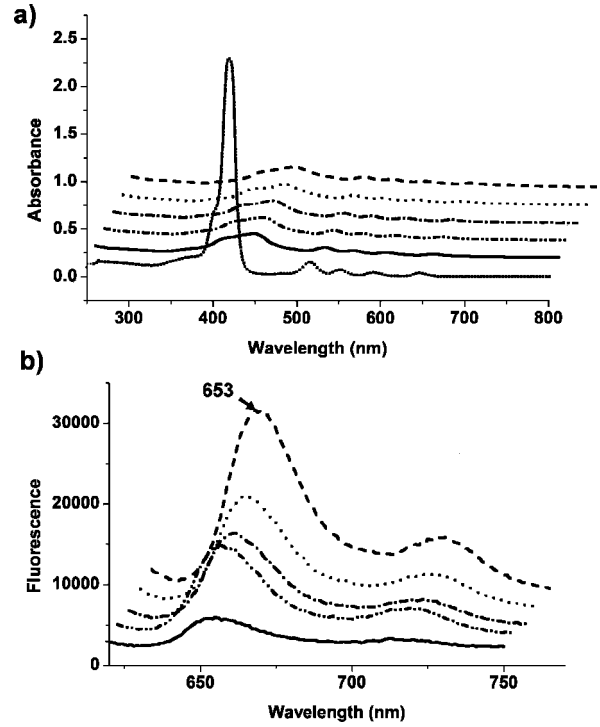

Figure 2. (a) Absorption spectra of 20 μM of porphyrin **2** in DMSO (short dot), and in aqueous solution at different pH. (b) Emission spectra of 2.8 μM porphyrin **2** at different pH (λ_{ex}= 600 nm). pH = 8.00 (full line), pH = 7.4 (dash-dot-dot), pH = 7.00 (dash-dot-dash), pH = 6.00 (large dot), pH = 5.00 (dash).

Photophysical Studies. The absorption and emission spectra in DMSO and in aqueous solutions at different pH values for porphyrins **2** and **3** and peptide conjugate **4** are shown in Figures 2, 3, and 4, respectively. The shape of the absorption spectra for porphyrins **2** and **3** (i.e., wide, poorly resolved bands in aqueous media compared with DMSO) indicate ground-state aggregation of the molecules. The slight red-shift of the Soret band on the absorption spectra (aqueous vs DMSO) and observed fluorescence suggest J-type aggregate formation (*33*). In contrast, the shape of the absorption spectra of the porphyrin−MLS conjugate **4** does not indicate any aggregation in aqueous media or in DMSO. No significant effect of pH on the position and shape of the absorption bands were observed for all porphyrins. The fluorescence quantum yields were found to be pH-dependent as shown in Figure 5. The highest quantum yield determined for porphyrins **2** and **3** and conjugate **4** were 0.0006 (pH = 5.00), 0.0012 (pH = 6.00), and 0.012 (pH = 5.00), respectively. At physiological pH (7.4), the fluorescence of all porphyrins is quenched as determined by the quantum yields determined at this pH. The reduction in quantum yields at pH 7.4 from the maxima observed for porphyrins **2** and **3** and conjugate **4** are 33%, 42%, and 66%, respectively.

Cell Studies. The time-dependent uptake of porphyrins **2** and **3** and conjugate **4** was investigated at a concentration of 10 μM in human HEp2 cells, and the results obtained are shown in Figure 6. The porphyrin−peptide conjugate **4** bearing an amphiphilic MLS sequence accumulated the most within cells at all time points studied, followed by porphyrin **2**. The biguanidinium−porphyrin **3** was the least accumulated within cells (about half as much as porphyrin **2**) of this series of compounds. All porphyrins showed similar uptake kinetics in the first 1–2 h but while porphyrin **2** and conjugate **4** continued

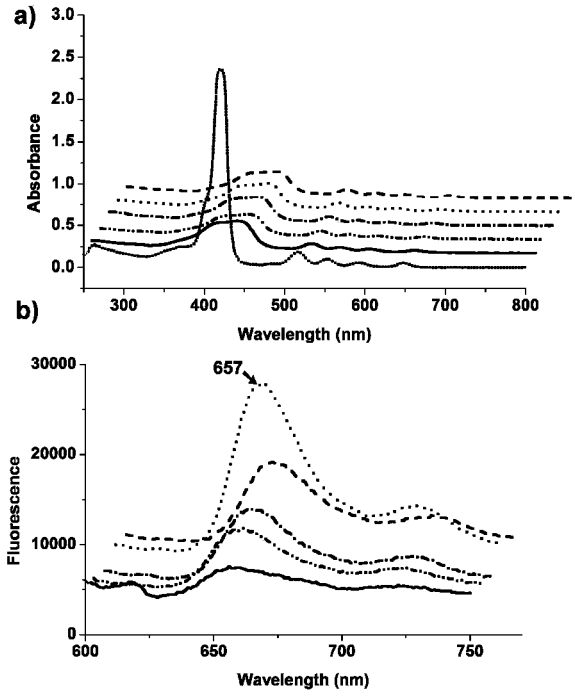

Figure 3. (a) Absorption spectra of 20 μM of porphyrin **3** in DMSO (short dot), and in aqueous solution at different pH. (b) Emission spectra of 2.8 μM porphyrin **3** at different pH (λ_{ex}= 580 nm). pH = 8.00 (full line), pH = 7.4 (dash-dot-dot), pH = 7.00 (dash-dot-dash), pH = 6.00 (large dot), pH = 5.00 (dash).

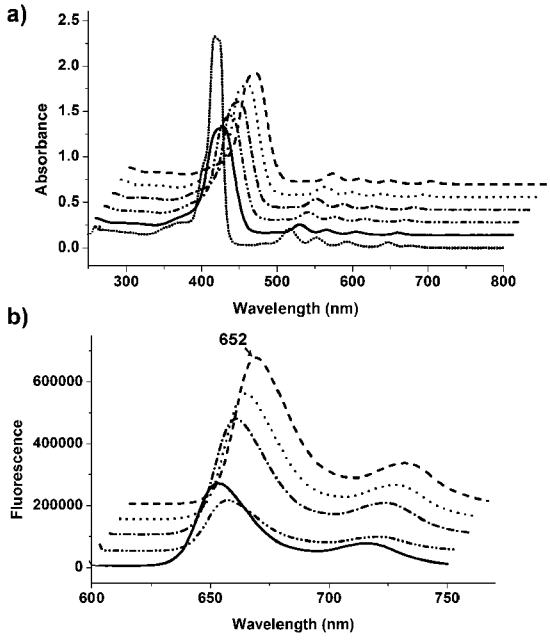

Figure 4. (a) Absorption spectra of 15 μM porphyrin conjugate **4** in DMSO (short dot), and in aqueous solution at different pH. (b) Emission spectra of 4.0 μM porphyrin conjugate **4** at different pH (λ_{ex}= 590 nm). pH = 8.00 (full line), pH = 7.4 (dash-dot-dot), pH = 7.00 (dash-dot-dash), pH = 6.00 (large dot), pH = 5.00 (dash).

to accumulate steadily over time, the biguanidinium−porphyrin **3** exhibited slower uptake.

The dark cytotoxicity and phototoxicity of the new porphyrin conjugates were evaluated upon exposure of HEp2 cells to increasing concentrations of each porphyrin for 24 h. The results obtained are shown in Figures 7 and 8, respectively. While the biguanidinium−porphyrin **3**, the least accumulated within cells, shows no toxicity at concentrations up to 100 μM in the dark,

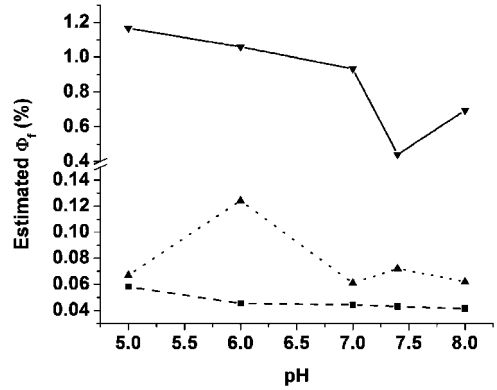

Figure 5. Estimated fluorescence quantum yields (%) at different pH. Porphyrins **2** (dash line), **3** (dot line) and **4** (full line).

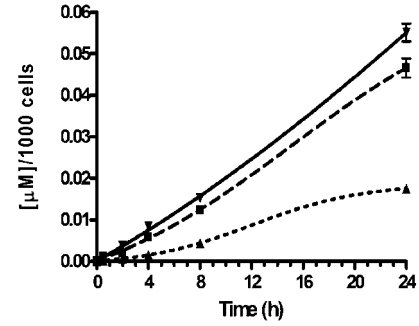

Figure 6. Time-dependent uptake of porphyrins **2** (dash line), **3** (dot line), **4** (full line), at 10 μM by HEp2 cells.

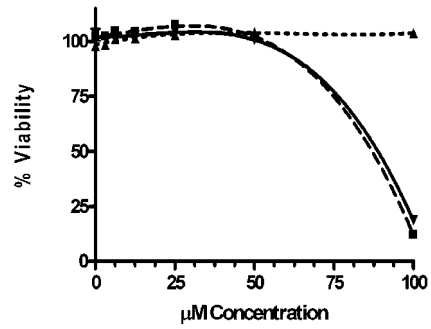

Figure 7. Dark toxicity of porphyrins **2** (dash line), **3** (dot line), and **4** (full line), toward HEp2 cells using the Cell Titer Blue assay.

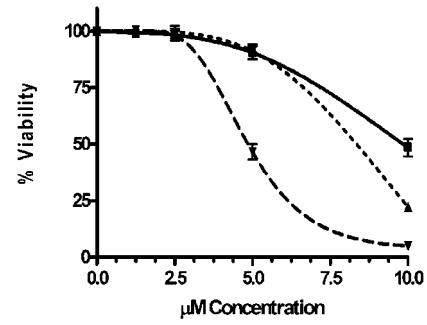

Figure 8. Phototoxicity of porphyrins **2** (dash line), **3** (dot line), **4** (full line) toward HEp2 cells using 1 J/cm^2 dose light.

the guanidinium−porphyrin **2** and conjugate **4** have estimated IC_{50} = 84 and 86 μM, respectively, in the dark (Figure 7). The most phototoxic compound with estimated IC_{50} = 4.8 μM at 1 J cm^{-2} was found to be the guanidinium−porphyrin **2**, followed

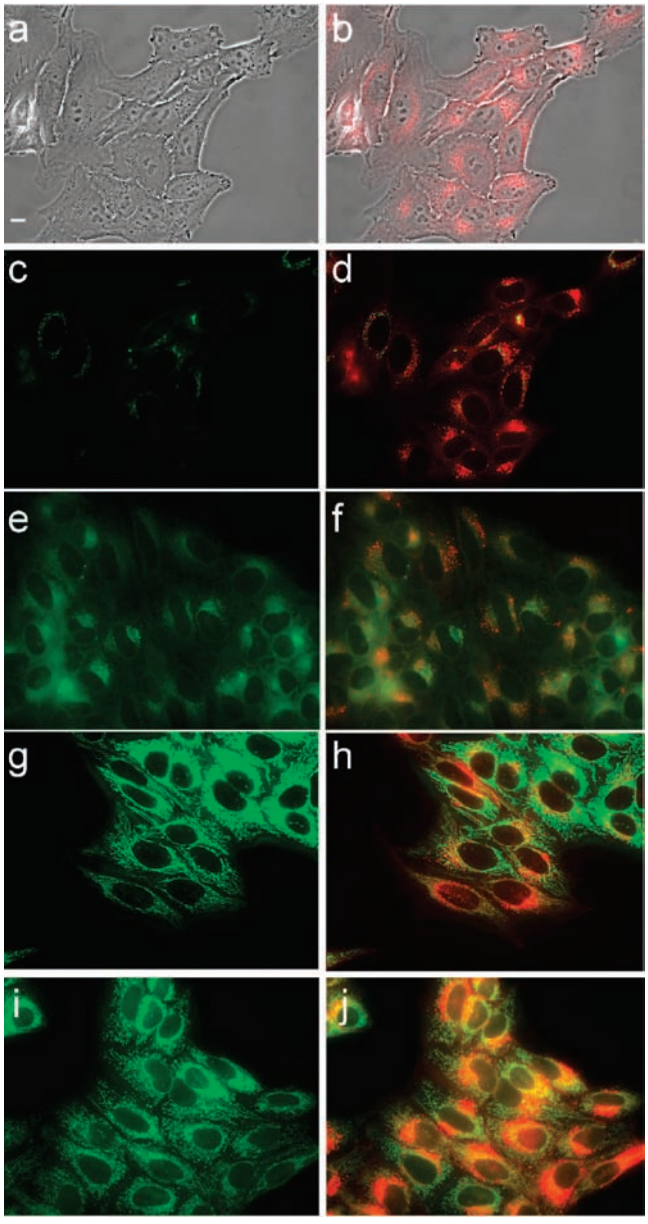

Figure 9. Subcellular localization of porphyrin **2** in HEp2 cells at 10 μM for 24 h. (a) phase contrast, (b) overlay of porphyrin **2** fluorescence and phase contrast, (c) BODIPY Ceramide fluorescence, (e) LysoSensor Green fluorescence, (g) MitoTracker Green fluorescence, (i) $DiOC_6$ fluorescence, (d), (f), (h), (j) overlays of organelle tracers with porphyrin **2** fluorescence. Scale bar: 10 μm.

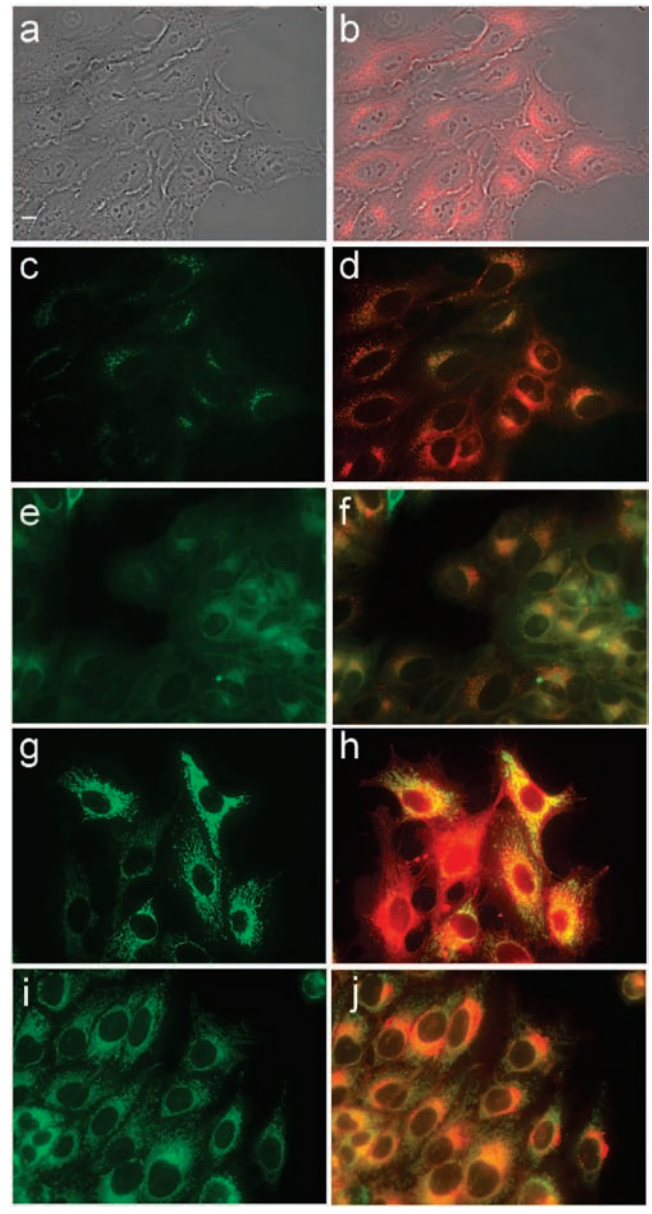

Figure 10. Subcellular localization of porphyrin **3** in HEp2 cells at 10 μM for 24 h. (a) phase contrast, (b) overlay of porphyrin **3** fluorescence and phase contrast, (c) BODIPY Ceramide fluorescence, (e) LysoSensor Green fluorescence, (g) MitoTracker Green fluorescence, (i) $DiOC_6$ fluorescence, (d), (f), (h), (j) overlays of organelle tracers with porphyrin **3** fluorescence. Scale bar: 10 μm.

by the biguanidinium−porphyrin **3** ($IC_{50} = 8.2\ \mu M$ at 1 J cm^{-2}) and conjugate **4** ($IC_{50} = 9.8\ \mu M$ at 1 J cm^{-2}), as shown in Figure 8.

The subcellular localization of the new porphyrin derivatives was investigated in HEp2 cells after 24 h, using fluorescence microscopy. Figures 9, 10, and 11 show the fluorescent patterns observed for porphyrins **2**−**4**, respectively, and their overlay with the organelle specific fluorescent probes BODIPY FL C_5-ceramide (Golgi network), LysoSensor Green (lysosomes), Mitotracker Green (mitochondria), and $DiOC_6$ (ER). The preferential sites of intracellular localization for porphyrin **2** were found to be the mitochondria and the ER (Figure 9h,j). A small amount of **2** was also found in the cell lysosomes. The biguanidinium−porphyrin **3** distributed within cell membranes with a large component in vesicles that correlated to some extent with the lysosomes and, upon longer exposures, in mitochondria and the cytosolic membrane (Figure 10f,h). On the other hand, conjugate **4** was found to localize mainly within the cell lysosomes (Figure 11f).

DISCUSSION

We used two general strategies in the design of mitochondria-targeting photosentizers. The first approach was based on the introduction of a functional group (i.e., guanidine or biguanidine) with a delocalized positive charge, in order to promote preferential accumulation via the high membrane potential across the inner mitochondrial membrane. The guanidinium and biguanidinium groups were chosen because they are strong bases ($pK_a \sim 13$) that are protonated at physiological pH (34–36), and that can form multiple hydrogen bonds and/or electrostatically interact with biological substrates. Since the positive charge is delocalized, guanidinium and biguanidinium groups attached to hydrophobic moieties (such as a porphyrin) form amphiphatic molecules with potentially enhanced affinity for crossing cellular

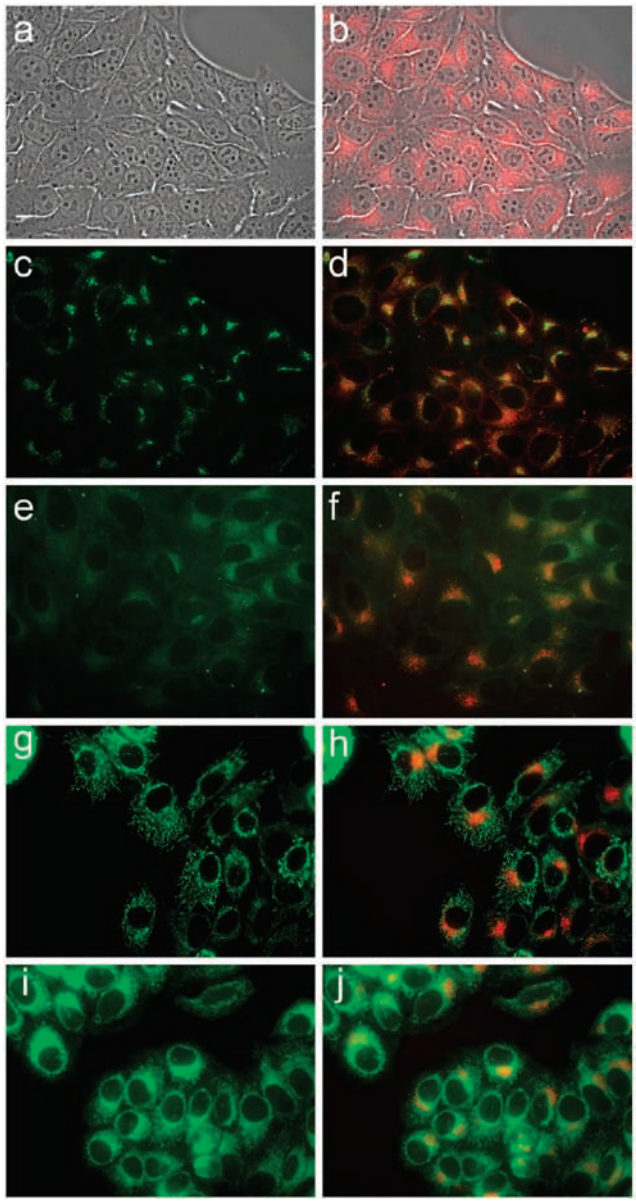

Figure 11. Subcellular localization of conjugate **4** in HEp2 cells at 10 μM for 24 h. (a) phase contrast, (b) overlay of conjugate **4** fluorescence and phase contrast, (c) BODIPY Ceramide fluorescence, (e) LysoSensor Green fluorescence, (g) MitoTracker Green fluorescence, (i) $DiOC_6$ fluorescence, (d), (f), (h), (j) overlays of organelle tracers with conjugate **4** fluorescence. Scale bar: 10 μm.

membranes, for example, via formation of bidentate hydrogen bonds with phosphate groups (*37*). Several methodologies have been developed for the preparation of guanidines in high yield, under mild conditions, typically involving the treatment of an amine with an electrophilic amidine species. The most commonly used reagents include derivatives of pyrazole-1-carboxamidine (*38*), *S*-alkylisothioureas (*39*), protected thiourea derivatives in conjunction with mercury salts or the Mukaiyama reagent (*31*), and protected triflylguanidines (*40*). However, aminoporphyrin **1** was either unreactive to the above guanidinylation reagents or afforded the corresponding *N*-alkylated derivative. We therefore prepared porphyrins **2** and **3** as shown in Scheme 1, by reaction of the anilinium salt of **1** with cyanamide or dicyanamide in DMF/alcohol, using a previously reported procedure (*34*, *41*), in 42–61% yields.

Our second approach involved the conjugation of a MLS peptide sequence to porphyrin **1** via a low molecular weight PEG spacer using a published procedure (*19*), in order to exploit the mitochondrial import machinery. We chose the peptide sequence MSVLTPLLLRGLTGSARRLPVPRAKIHSL, isolated from the subunit VII of human cytochrome c oxidase (*42*), which is encoded in a commercially available expression vector (pShooter) that targets a recombinant protein to the mitochondria of mammalian cells. The PEG spacer was used not only to improve the water solubility of the conjugate, but also to reduce aggregation (*43, 44*) and other possible interactions between the porphyrin macrocycle and the peptide sequence (*30*).

The time-dependent uptake of porphyrins **2** and **3** and conjugate **4** was found to depend significantly on the nature of the substituents at the porphyrin periphery. Conjugate **4** bearing a MLS peptide accumulated the most within cells at all time points studied, while the biguanidinium−porphyrin **3** accumulated the least. The high uptake observed for conjugate **4** is probably due to the presence of the amphiphilic peptide sequence, the low molecular weight PEG spacer, and the low tendency of this conjugate to form aggregates in aqueous media. This result is in agreement with our previous studies showing that conjugation of a peptide to a porphyrin or phthalocyanine macrocycle via a short PEG generally enhances cellular uptake and decreases both intra and intermolecular interactions (*19, 45*). Surprisingly, biguanidinium−porphyrin **3** exhibits significantly lower uptake than guanidinium−porphyrin **2**; this may be attributed to the structural differences between these two groups and their ability to interact with negatively charged groups (e.g., phosphates) on the cell membrane. While the guanidinium group exhibits a planar structure and acts as a bidentate ligand, structural studies on biguanidinium salts indicate that it adopts a nonplanar conformation in order to reduce allylic strain, while still permitting a significant degree of conjugation. Furthermore, structural analyses by X-ray diffraction indicate that arylbiguanidines and their salts can form unique networks bonded by characteristic patterns of hydrogen bonds (*34*), which might have lower affinity for membrane crossing. It is interesting to note that the guanidinium−porphyrin **2** showed similar uptake by the HEp2 cells to that of the peptide conjugate **4**.

All porphyrins showed low dark cytotoxicity, in particular the biguanidinium−porphyrin **3** which was the least taken up by the HEp2 cells. The most phototoxic compound is porphyrin **2**, followed by **3** and the porphyrin peptide conjugate **4**, as a result of both the extent of their uptake and their subcellular distribution. Whereas the preferential sites of intracellular localization of porphyrin **2** are the mitochondria and the ER, porphyrin **3** was mainly found within cellular membranes, the lysosomes, and mitochondria. In contrast, the porphyrin conjugate **4** bearing a MLS peptide sequence localized mainly in the lysosomes rather than in mitochondria, in agreement with our previous studies on porphyrin−peptide conjugates (*19, 30*). Our results show, in agreement with previous reports (*46*), that the nature of the substituents at the porphyrin periphery play an important role in determining their mechanism(s) of cellular uptake and subcellular distribution. Although SAR investigations on mitochondria-targeting molecules (*47, 48*) have indicated that (i) positively charged amphiphilic molecules are delivered into the mitochondria in response to its highly negative membrane potential, and (ii) lipophilic compounds containing delocalized positive charge(s) tend to reduce the free energy change when moving from an aqueous to an hydrophobic environment, not all cationic porphyrin-based sensitizers localize preferentially in mitochondria. We believe that the partial localization in mitochondria observed for porphyrins **2** and **3** is due to the presence of the guanidinium and biguanidinium groups, which play an important role on the lysosomal escape of these photosensitizers as a result of membrane rupture, probably by the proton sponge effect; these photosensitizers are therefore released into the cytoplasm and subsequently delivered into other

organelles, such as the ER and mitochondria (*49–52*). The porphyrin−peptide conjugate **4** containing an MLS peptide sequence was not found in mitochondria, probably as a result of its trapping within endosomes and lysosomes as a result of an endocytotic mechanism of uptake. It is possible that the MLS peptide in conjugate **4** might be cleaved off and degraded to some extent by lysosomal enzymes, as we have recently reported for other porphyrin−peptide conjugates (*53*), before the release of the conjugate from these compartments. As a result of partial mitochondria targeting, porphyrins **2** and **3** were found to be more phototoxic than the peptide conjugate **4**. The highest phototoxicity observed for the guanidinium−porphyrin **2** is probably due to its higher uptake and preferential localization in the mitochondria and ER, as photodamage to these sensitive organelles can lead to rapid cell death via apoptosis (*54–56*).

ACKNOWLEDGMENT

The authors thank Ms. Martha Juban for the MLS peptide sequence synthesis. This work was partially supported by the National Science Foundation, grant number CHE-304833.

A Doxorubicin Prodrug Activated by the Staudinger Reaction

Remco van Brakel,[‡] Roland C. M. Vulders,[‡] Rembrandt J. Bokdam, Holger Grüll, and Marc S. Robillard*

Department of Bio-Molecular Engineering, Philips Research, Eindhoven, The Netherlands. Received October 24, 2007; Revised Manuscript Received December 19, 2007

Much effort has been devoted to prodrug systems that effect drug release at the tumor through enzymatic action. To widen the scope of prodrug therapy, the use of the selective Staudinger reaction as prodrug activator, instead of relying on enzymatic action, was investigated. Doxorubicin was conjugated to a *p*-azidobenzyl trigger that is cleaved after reacting with the chemical activator, triphenylphosphine. The prodrug activation was confirmed in water, cell growth medium, and serum, using HPLC and LCMS. Next, this approach was tested in a cell proliferation assay with A431 human vulvar skin squamous carcinoma cells. The doxorubicin prodrug was shown to exhibit a 176-fold higher IC_{50} of 15.1 μM vs 0.086 μM for the parent drug, doxorubicin. Addition of triphenylphosphine (5×60 μM in 72 h) to the prodrug in cell culture effected the complete recovery of the activity of the parent drug as evidenced by an IC_{50} value of 0.074 μM. Furthermore, high levels of triphenylphosphine were tolerated well by the cells. The demonstrated usefulness of the Staudinger reaction in cell culture and its in vivo potential opens up new avenues for prodrug therapy.

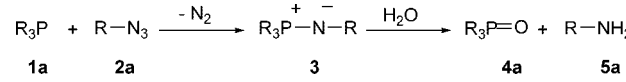
INTRODUCTION

The lack of selectivity of chemotherapeutic drugs like doxorubicin is a major problem. Dose-limiting toxic side effects can preclude the administration of effective concentrations (*1*). Therefore, much effort has been devoted to drug delivery systems that effect drug release exclusively at the tumor. One way is to activate a systemic prodrug by local or localized enzymatic activity (*2–5*). However, in many cases a target site lacks a suitable overexpressed enzyme or it is present in the cytosol, which requires the prodrug to enter the cell. Targeted enzymatic activity necessitates the use of exogenous enzymes, which are likely to be highly immunogenic, a fact that can hamper repeated administration. A promising alternative achieves tumor targeting and endocytosis of polymer−drug conjugates, followed by drug release through nonspecific (enzymatic) processes (*6*). This approach, however, could be sensitive to unpredictable, inherently slow, or reduced endocytosis. Furthermore, it in general lacks direct temporal and quantitative control over drug release.

To widen the scope of prodrug therapy, we propose here to use the selective Staudinger reaction (Scheme 1) as the prodrug activator in vivo, instead of relying on enzymatic action (*7*). This potentially bioorthogonal reaction occurs between a phosphine (**1a**) and an organic azide (**2a**) to produce an azaylide intermediate **3** that hydrolyzes spontaneously in aqueous conditions to yield the corresponding phosphine oxide (**4a**) and primary amine (**5a**). Very few reactions can be used in a biological environment, and thus far only the Staudinger ligation, a strongly related adaptation of the Staudinger reaction, has proven utility in vivo (*7, 8*). The general usefulness in biological media of the Staudinger reaction itself has remained largely unexplored.

This paper describes for the first time the design and activation of an azido-functionalized prodrug (**2b**, Scheme 2)

Scheme 1. The Staudinger Reaction



by means of the Staudinger reaction in a cell culture environment. Prodrug **2b** encompasses the anticancer drug doxorubicin **6** linked via the amino group to a *p*-azidobenzyl trigger that is cleaved after reacting with the chemical activator, triphenylphosphine **1b**. The trigger is based on *p*-aminobenzyloxycarbonyl, used in enzyme-activated prodrugs, where unmasking of the amino group leads to an elimination of imino quinone methide, spontaneous decarboxylation, and release of the active drug (*2, 9, 10*). The azide-to-amine reduction in **2b** by **1b** should initiate the same sequence of events. Analogous to the polymer-targeted prodrugs developed by Duncan (*6*) and Shabat (*9*), prodrug **2b** may in a later stage be conjugated to a polymer via the methylene group of the azidobenzyl trigger. After tumor-localization and clearance from the blood of such a polymer construct, a bolus or continuous dose of **1b** may be administered to effect local release of **6**.

EXPERIMENTAL PROCEDURES

General. All solvents and reagents were obtained from Sigma-Aldrich unless stated otherwise and were used as received. Doxorubicin was obtained from Toronto Research Chemicals. NMR spectra were measured on a Bruker Avance DPX 300 spectrometer in the given solvent. Chemical shifts are given in ppm (δ) relative to TMS as an internal standard. Thin layer chromatography (TLC) was performed using Merck ($60F_{254}$) plates. The plates were examined with UV light, iodide, or ninhydrin. Preparative TLC was carried out on Analtech plates 1500 μm (F_{254}). All experiments with the photosensitive azidobenzyl compounds were performed in the dark or in yellow light (TND77385 plastic plate from Takiron with transmittance cut off at 500 nm). HPLC was performed on a Waters system equipped with a Luna Phenyl-Hexyl column (100×4.6 mm, 3 μm). The applied eluents were A, aq NH_4OAc (20 mM, pH 4.5) + 1% AcOH; B, CH_3CN/H_2O (85/15). Flow speed: 0.80 mL/min. LC-MS was performed on an Agilent 1200 HPLC

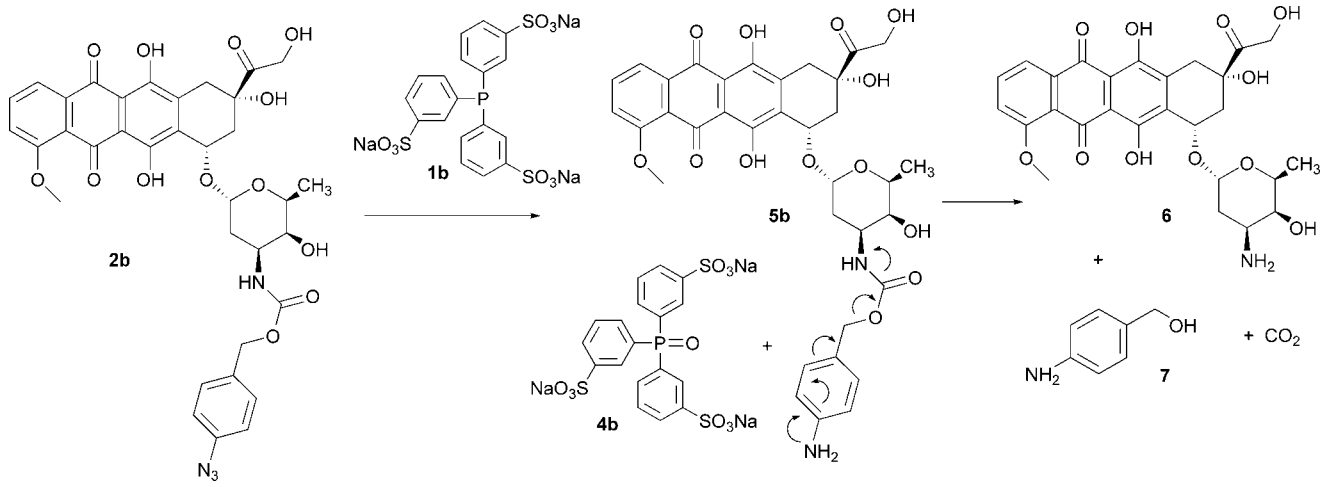
Scheme 2. Prodrug 2b and Its Activation through the Staudinger Reaction by Phosphine 1b, Affording Doxorubicin (6)



coupled to an Agilent LC MSD Trap XCT Ultra mass spectrometer. A Luna Phenyl-Hexyl column (100 × 4.6 mm, 3.08 μm) was used. The applied eluents were A, aq. NH_4OAc (20 mM, pH 4.5) + 2% CH_3CN; B, CH_3CN. Flow speed: 0.80 mL/min. MALDI TOF MS of **2b** was recorded on the Voyager-DE PRO. Mass spectra of azides **8** and **9** were taken with a Jeol SX102 mass spectrometer using field desorption (FD) (6 kV, 4 mA/min).

HPLC and LCMS Experiments. The cell growth medium used was DMEM (InVitrogen), supplemented with 10% heat-inactivated fetal bovine serum and 0.05% glutamax (InVitrogen). The serum used was 10% heat-inactivated fetal bovine serum.

Appropriate amounts of stock solutions of **2b** (10 mM in DMF) and **1b** (10 mM in DMF) were diluted to 2.5 mL with water, cell growth medium, or 10% serum, and warmed up to 37 °C. Before mixing, samples were withdrawn and analyzed separately. The solutions were mixed and stirred at 37 °C open to atmospheric oxygen. Samples were withdrawn and analyzed without any further sample preparation at the indicated times.

Cell Culture and Proliferation Assay. The A431 squamous carcinoma cells were maintained in a humidified CO_2 (5%) incubator at 37 °C in DMEM (InVitrogen), supplemented with 10% heat-inactivated fetal bovine serum and 0.05% glutamax (InVitrogen) in the presence of penicillin and streptomycin. Compounds **2b** and **6** were, prior to each experiment, freshly dissolved in DMF at 10 mM and subsequently serial-diluted in prewarmed culture medium. Triphenylphosphine-3,3′,3″-trisulfonic acid trisodium salt (**1b**) was dissolved in PBS at 10 mM and serial-diluted in prewarmed medium. Methylthiazolyldiphenyltetrazolium bromide (MTT) was used as described by the manufacturer. Cells were plated out in 96-well plates (Nunc) at a density of 7500 cells/well followed by addition of compounds the next day. Cell culture medium was replaced with 100 μL prewarmed medium containing the different concentrations of **2b** or **6**. Subsequently, 3 μL of appropriate concentrations of **1b** were added to each well twice a day. After 72 h incubation, cell proliferation was assessed by means of a MTT assay (*11*). Briefly, MTT was dissolved in prewarmed medium at 5 mg/mL, passed through a 0.22 μm filter, and 50 μL was added to each well. Following an incubation period of 120 min, the medium was gently aspirated. The formed formazan crystals were dissolved in 100 μL DMSO, and the absorbance was measured with a plate reader (BMG labtech) at 560 nm. IC_{50} values were derived from inhibition curves generated in three independent experiments.

4-Azidobenzyl Alcohol (8). A stirred solution of 4-aminobenzyl alcohol **7** (1.0 g, 8.12 mmol) in aq HCl (5 M, 5 mL) was cooled to 4 °C, and a solution of sodium nitrite (0.62 g, 8.98 mmol) in water (20 mL) was added dropwise in 30 min. Sodium azide (2.1 g, 32.3 mmol) was added in small portions over 30 min with vigorous stirring, while keeping the temperature under 5 °C. After stirring for 1.5 h at 4 °C, the reaction mixture was poured into ice–water, and the pH was adjusted to pH 8 with solid $NaHCO_3$. The water layer was extracted with ethyl acetate, which was then washed with water (2×), dried ($MgSO_4$), and evaporated. Light petroleum ether was poured on the residue, stirred for 30 min, and subsequently kept at 0 °C for 1 night. The resulting cream-colored suspension was filtered, and the residue was washed with 5 mL light petroleum ether, yielding 4-azido benzyl alcohol **8** (932 mg, 6.25 mmol, 77%) as a cream-colored powder (photosensitive). ^1H NMR ($CDCl_3$): δ = 1.89 (s, 1H; OH), 4.65 (s, 2H; CH_2), 7.01 (d, J = 8.3 Hz, 2H; aromatic), 7.34 (d, J = 8.3 Hz, 2H; aromatic). ^{13}C NMR ($CDCl_3$): δ = 64.67, 119.10, 128.51; FD MS: m/z: 149 $[M]^+$.

4-Azidobenzyl 4-Nitrophenyl Carbonate (9). A solution of 4-nitrophenyl chloroformate (204 mg, 1.01 mmol) and pyridine (160 mg, 2.02 mmol) in THF (5 mL) was stirred at 0–4 °C, and a solution of 4-azidobenzyl alcohol **8** (150 mg, 1.01 mmol) in THF (8 mL) was added dropwise in 30 min. The reaction mixture was stirred in the dark at 25 °C for 70 h. The THF solution was evaporated, and 30 mL of ethyl acetate was added. The ethyl acetate layer was washed with water (2×), dried ($MgSO_4$), and evaporated. The residue was recrystallized from light petroleum ether/ethyl acetate yielding 4-azidobenzyl 4-nitrophenyl carbonate **9** (264 mg, 0.84 mmol, 83%) as a yellow powder. IR: 2105 cm^{-1} (azide). ^1H NMR ($CDCl_3$): δ = 5.26 (s, 2H; CH_2), 7.07 (d, J = 8.7 Hz, 2H; aromatic azide), 7.38 (d, J = 9.3 Hz, 2H; aromatic nitro), 7.44 (d, J = 8.7 Hz, 2H; aromatic azide), 8.28 (d, J = 9.3 Hz, 2H; aromatic nitro). ^{13}C NMR ($CDCl_3$): δ = 70.77, 119.79, 122.17, 125.74, 130.91. FD MS: m/z: 314 $[M]^+$.

Azidobenzyl Carbamate Doxorubicin (2b). A solution of 4-azidobenzyl 4-nitrophenyl carbonate **9** (10.3 mg, 33 μmol), triethylamine (9.6 μL, 69 μmol), doxorubicin (**6**, 20.1 mg, 35 μmol) in DMF (2 mL) was stirred in the dark at rt under nitrogen gas for 24 h. After adding more triethylamine (9.6 μL, 69 μmol), the solution was stirred for another 5 days. The DMF was evaporated in vacuo (keeping temperature below 30 °C), and water (50 mL) was added and subsequently extracted with ethyl acetate (3 × 25 mL). The combined organic layers were evaporated to dryness, and the resulting red solid was purified

with preparative TLC (DCM/MeOH; 9/1). The collected fraction at R_f 0.68 was extracted with ethyl acetate/DCM (1/2) and evaporated under reduced pressure to afford **2b** as a red solid (18.3 mg, 77%). IR: 2115 cm^{-1} (azide). ^1H NMR ($CDCl_3$): δ = 1.29 (d, J = 6.6 Hz, 3H; C-CH_3) 1.80–1.90 (m, 2H; CH_2 carbohydrate), 2.17 (dd, J_A = 14.8 Hz, J_B = 4.0 Hz, 1H; CH_2), 2.33 (br dt, J_A = 14.7 Hz, J_B = 1.7 Hz, 1H; CH_2), 3.02 (d, J = 19 Hz, 1H; CH_2), 3.28 (d, J = 19 Hz, 1H; CH_2), 3.66 (br s, 1H; CH carbohydrate), 3.86 (m, 1H; CH carbohydrate), 4.09 (s, 3H; O-CH_3), 4.14 (q, J = 6.4 Hz, 1H; CH-CH_3) 4.76 (s, 2H; CH_2-OH), 4.99 (s, 2H; CH_2 linker), 5.13 (d, J = 8.6 Hz, 1H; amide NH), 5.29 (br m, 1H; CH), 5.50 (d, J = 3.5 Hz, 1H; CH carbohydrate), 6.97 (d, J = 8.3 Hz, 2H; aromatic azide), 7.29 (d, J = 8.3 Hz, 2H; aromatic azide), 7.40 (dd, J_A = 8.5 Hz, J_B = 0.75 Hz, 1H; aromatic dox), 7.80 (dd, J_A = 8.5 Hz, J_C = 7.7 Hz, 1H; aromatic dox), 8.05 (dd, J_B = 0.75 Hz, J_C = 7.7 Hz, 1H; aromatic dox). MALDI TOF MS: m/z 742 $[M + Na]^+$. LCMS: 18.6 min.

RESULTS AND DISCUSSION

Prodrug **2b** was prepared in good yield starting from 4-aminobenzyl alcohol **7** (Scheme 3). Conversion via the diazo intermediate to 4-azidobenzylalcohol **8** was followed by treatment with *p*-nitrophenylchloroformate to afford compound **9** (*12*). Substitution of the *p*-nitrophenyl moiety with doxorubicin **6** yielded prodrug **2b**.

First, the activation of **2b** was studied using HPLC and LCMS. All experiments described below were performed at 37 °C and were open to atmospheric oxygen. When **2b** and **1b** were reacted in water at 37 °C at relatively high concentrations of 100 and 200 μM, respectively, the reaction ran to completion within 20 h as evidenced by HPLC (Figure 1). In general, phosphines are prone to oxidation to phosphine oxides, which are inactive in the Staudinger reaction. Figure 1, however, shows that the phosphine is stable against oxidation in water for 20 h, since there is still a substantial amount of **1b** left after completion of the reaction, confirming stability studies of **1b** alone in water at 37 °C (Figure 2). When the same reaction was performed in cell growth

medium at 10 and 20 μM, respectively, the amount of free doxorubicin **6** reached 15% within 4 h, after which it stopped increasing as evidenced by LCMS (Figure 3). At the same time, 100% of **1b** was oxidized, demonstrating that the phosphine is rapidly inactivated via another mechanism. Subsequent stability studies in 10% serum showed that **1b** (10 μM) was stable for 16 h (Figure 4). These results indicate that a component specific for cell growth medium was causing the oxidation and that **1b** should be stable enough to be used as activator in vivo. To retain effective use of **1b** as prodrug activator in vitro, the dosing of **1b** was adjusted from single dose to multiple administrations. Additionally, this scheme may be a better mimic of a future clinical application, where clearance from the body or metabolism of the activator needs

Table 1. IC_{50} Values[a] Determined in the A431 Cell Line Using the MTT Assay (*11*)

entry	compound	IC_{50} (μM)
1	**2b** (prodrug)	15.1 ± 4.00
2	**6** (doxorubicin)	0.086 ± 0.056
3	**2b** with **1b** (5 × 10 μM)	0.320 ± 0.104
4	**2b** with **1b** (5 × 30 μM)	0.110 ± 0.027
5	**2b** with **1b** (5 × 60 μM)	0.074 ± 0.017
6	**1b** (5 × 10/30/60 μM)	[b]
7	**6** with **1b** (5 × 60 μM)	0.119 ± 0.041
8	**7** (aminobenzylalcohol)	[b]
9	**7** with **1b** (5 × 60 μM)	[b]
10	**7** with **6** (1/1)	0.082 ± 0.030

[a] Concentration that results in a reduction of cell proliferation of 50% compared to untreated controls. [b] No reduction in proliferation observed compared to untreated controls.

to be compensated by repeated infusion with fresh phosphine. Activation of prodrug **2b** at 10 μM in cell growth medium was performed by administering two larger doses (60 μM) of **1b** per day. This time, 85% of **2b** was converted to **6** after 8 h, and the reaction was nearly complete after 20 h (Figure 5).

Next, we tested this approach in a cell proliferation assay with A431 human vulvar skin squamous carcinoma cells. Cells were grown in the presence of six different concentrations of **2b** or **6**, with or without two daily doses of **1b** (5 × 10, 30 or 60 μM in 72 h). The antiproliferative effect was determined by quantifying the viable cells 72 h after the addition of **2b** or **6** by means of the MTT assay (Figure 6, Table 1) (*11*). From entries 1 and 2, it is clear that the doxorubicin motif in **2b** is indeed inactivated by the *p*-azidobenzyl trigger: **2b** is much less effective in inhibiting cell growth than **6**, exhibiting an 176-fold higher IC_{50} of 15.1 μM vs 0.086 μM for **6**. To our satisfaction, addition of **1b** (5 × 60 μM in 72 h) to **2b** in cell culture effects the recovery of the activity of the parent drug as evidenced by an IC_{50} value of 0.074 μM. Furthermore, this effect is dose-dependent: reducing the dose of **1b** to 30 or 10 μM leads to a decreased cytotoxicity of 0.110 and 0.320 μM, respectively (entries 3–5). Cells treated only with **1b** did not exhibit any inhibition in cell growth (entry 6). Accordingly, combined treatment with **6** and **1b** afforded the same cytotoxicity as **6** alone (entry 7). Aminobenzylalcohol **7**, the byproduct of prodrug activation, showed no cytotoxicity alone or in combination with **1b**, and no additional cytotoxicity in combination with **6** (entries 8–10). At present, it remains an open question whether the activation takes place extracellularly or intracellularly, or both.

CONCLUSIONS

To summarize, this paper describes the use of the Staudinger reaction in selectively addressing a prodrug in a cell culture environment. High levels of **1b** were shown to be tolerated well by cells, making this the first example of chemical prodrug activation with in vivo potential (*13*). This approach potentially allows an advanced level of temporal and quantitative control over drug release, as it does not rely on the presence of disease-specific or localized enzymes, or on general but heterogeneous mechanisms such as hydrolysis or degradation. The extension of this technology to a polymer-targeted prodrug and its in vivo application will be explored in the near future.

ACKNOWLEDGMENT

We thank Robert-Jan Lamers, Eef Dirksen, Wim Genuit (Shell), Gerard van den Heuvel, Hugo Knobel, and Jeroen Pikkemaat for assistance with HPLC, LCMS, MS, and NMR measurements; and Johan Lub, Dirk Burdinski, and Sander Langereis for useful discussions.

Received October 25, 2007; Revised Manuscript Received November 16, 2007

A new ligand derivative of 1,4,7-triazacyclononane (TACN), 2-[4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetic acid (**6**), has been synthesized and its complexation behavior toward Cu^{2+} ions investigated. The ligand **6** has been characterized by spectroscopic methods, and a molecular structure of a corresponding Cu(II) complex has been elucidated by single-crystal X-ray analysis. The suitability of **6** for conjugation to peptide substrates has been shown by amide coupling of **6** to the stabilized derivative of bombesin (BN), βAla-βAla-[Cha^{13}, Nle^{14}]BN(7–14), to give the conjugate **8**. The free ligand **6** and the bioconjugate **8** were labeled with $^{64}Cu^{2+}$, and the resulting complexes, **^{64}Cu⊂6** and **^{64}Cu⊂8**, were found to be stable in the presence of a large excess of a competing ligand (cyclam) or copper-seeking superoxide dismutase (SOD), as well as in rat plasma. Biodistribution studies of **^{64}Cu⊂8** in Wistar rats showed a high activity uptake into the pancreas (5.76 ± 0.25 SUV, 5 min p.i.; 3.93 ± 0.25 SUV, 1 h p.i.), which is the organ with high levels of gastrin-releasing peptide receptor (GRPR). This receptor is overexpressed in a large number of breast and prostate carcinomas. The novel **^{64}Cu⊂6** complex had a dominating influence on the nonspecific activity biodistribution of its BN conjugate, since the distribution data of **^{64}Cu⊂6** are similar to those of **^{64}Cu⊂8**. The ^{64}Cu complexes exhibited a low activity accumulation in the liver tissue and an extensive renal clearance, which was distinctively different to the biodistribution of $^{64}CuCl_2$, suggesting that **^{64}Cu⊂6** does not undergo significant demetalation, but rather exhibits high *in vivo* stability.

INTRODUCTION

The selection of potentially useful copper radionuclides in nuclear medicine is wide and includes ^{60}Cu, ^{61}Cu, ^{62}Cu, ^{64}Cu, and ^{67}Cu (*1–6*). However, due to their favorable decay characteristics and the ability to produce them with high specific activity on a biomedical cyclotron, ^{64}Cu ($t_{1/2}$ = 12.7 h; β^+_{max} = 0.653 MeV, 17.4%; β^-_{max} = 0.578 MeV, 39%) and ^{67}Cu ($t_{1/2}$ = 61.8 h; β^-_{max} = 0.576 MeV, 100%) are the preferred copper isotopes for radiopharmaceutical applications. Incorporation of transition metal radionuclides, such as ^{64}Cu and ^{67}Cu, into target-specific radiopharmaceuticals requires the use of chelating ligands to bind the radionuclide to the conjugate (*7–9*). An extremely important requirement is that the resulting radionuclide−ligand complex is both kinetically and thermodynamically stable *in vivo* in order to minimize release of the isotope to normal tissue, thus reducing the background for imaging and minimizing radiation exposure to normal tissue for therapy (*10*). A large variety of amine-based polydentate chelating agents have been investigated in an effort to satisfy this requirement, such as polyaminocarboxylates (*11–14*), cyclic polyamines (azamacrocycles) (*15–17*), cyclic polyaminocarboxylates (*1, 15*) and pyridine-containing polyamines (*18–22*). In general, azamacrocyclic ligands are preferred over acyclic ligands, as the structural features of the macrocyclic Cu(II) complexes render them more kinetically stable under biological conditions (*14, 16, 23–25*). Macrocyclic tetraamines such as 12-N_4 (1,4,7,10-tetraazacyclododecane, "cyclen"), 13-N_4, and 14-N_4 (1,4,8,11-tetraazacyclotetradecane, "cyclam") form very stable complexes with Cu(II) and are resistant to demetalation *in vivo* (*14, 16*). Furthermore, their carboxylate-containing analogues, 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) and 1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (TETA), can be coupled to biomolecules. Notably, a copper-based radiopharmaceutical featuring the macrocyclic ligand TETA as a chelating agent has advanced to clinical trials (*26, 27*). Unfortunately, serious problems associated with retention of radioactivity in blood, liver, and bone narrow were found for this bioconjugate (^{64}Cu-TETA-Octreotide), suggesting that dissociation of Cu^{2+} ions from the radiopharmaceutical, and subsequent binding of the ions to proteins such as superoxide dismutase (SOD) in rat livers, is a problem even for this macrocycle (*28*). ^{64}Cu complexes of macrobicyclic tetraaminocarboxylates have shown remarkably improved *in vivo* stability, but harsh labeling conditions has hampered their application (*29–32*).

Another approach to achieve highly stable Cu(II) complexes is through the use of multidentate ligands containing pyridine donor groups, such as *N*,*N*′,*N*″-tris(2-pyridylmethyl)-*cis*,*cis*-1,3,5-triaminocyclohexane (tachpyr), 3,7-diazabicyclo[3.3.1]-nonane (bispidine), and azamacrocycles with pendant pyridyl groups (*10, 18–20, 22, 33, 34*). The latter two ligand structures, in particular, allow the convenient introduction of additional carboxylic groups, enabling their coupling to appropriate biomolecules. Thus, it should be possible to develop new pyridine-containing chelating agents that are able to rapidly form stable radiocopper complexes for targeted imaging and therapeutic purposes. In an effort to address this challenge, we have

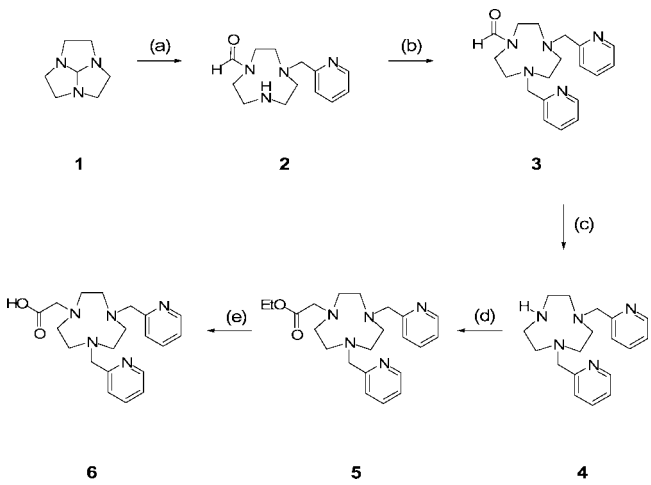
Scheme 1. Synthesis of 6[a]



[a] (a) (i) 2-Picolyl chloride, THF, r.t., o/n; (ii) H_2O, reflux, 4 h, 79%; (b) picolyl chloride hydrochloride, K_2CO_3, KI, CH_3CN, reflux, o/n, 77%; (c) 4 M $HCl_{(aq)}$, reflux, 4 h, 85%; (d) Ethylbromoacetate, K_2CO_3, KI, CH_3CN, reflux, o/n, 88%; (f) $LiOH.H_2O$, ethanol/H_2O, 70°C, o/n, 85%.

embarked on a program to develop improved copper-based radiopharmaceuticals featuring pyridyl derivatives of the tridentate macrocycle 1,4,7-triazacyclononane (TACN) as the chelating agent. Due to its small ring size, TACN coordinates facially to metal ions such as Cu^{2+}, with the metal lying out of the plane defined by the three nitrogen atoms. The donor atoms are oriented in such a way as to maximize orbital overlap and thereby produce complexes with very high thermodynamic stabilities (*35*).

Herein, we report the synthesis and copper coordination chemistry of the TACN derivative, 2-[4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetic acid (**6**) (Scheme 1), that contains two pyridyl pendant groups to increase the stability of the copper complex significantly compared to the parent TACN macrocycle and a carboxylic acid functionality that allows the covalent attachment of **6** to tumor-specific biomolecules via an amide coupling reaction. This possibility for regiospecific coupling is a convincing advantage compared to other previously described pyridine-containing polyamine ligands (*36*).

To demonstrate the utility of **6** in preparing ^{64}Cu-labeled radiotracers, we chose in the first instance to conjugate it to bombesin (BN), a tetradecapeptide that binds with high affinity to the gastrin-releasing peptide receptor (GRPR). The GRPR is overexpressed on a variety of tumors, including commonly diagnosed breast and prostate cancers, and the less common pancreatic and small-cell lung cancers (*37–39*). To date, research investigations have examined BN derivatives radiolabeled mainly with ^{99m}Tc, but also to a lesser extent with ^{64}Cu, ^{18}F, ^{68}Ga, ^{125}I, ^{111}In, ^{177}Lu, ^{188}Re, ^{86}Y, and ^{90}Y (*38–40*). ^{64}Cu conjugates with DOTA-PEG-BN(7–14) (PEG = poly(ethylene glycol)) (*41*), DOTA-[Lys^3]BN (*42, 43*), DOTA-X-BN(7–14) (X = spacer containing 4, 5, 6, 8, or 12 carbon atoms) (*43–46*), DOTA-X-BN(7–14) (X = tripeptide spacer Gly-Gly-Gly, Gly-Ser-Gly, Gly-Ser-Ser, Gly-Glu-Gly, or Gly-Glu-Glu) (*47*), and DOTA-[Pro^1, Tyr^4]BN (*40*) have been described, as well as ^{64}Cu conjugates with CB-TE2A-8-Aoc-BN(7–14) (CB-TE2A, 1,4,8,11-tetraazabicyclo[6.6.2]hexadecane-4,11-diacetic acid; 8-Aoc, 8-aminooctanoic acid) (*46*), or NOTA-X-BN(7–14) (NOTA, 1,4,7-triazacyclononane-1,4,7-triacetic acid; X = single amino acid spacer containing 3, 5, or 8 carbon atoms, Gly-Gly-Gly or Ser-Ser-Ser) (*48*).

The bombesin analogue selected in this work was βAla-βAla-[Cha^{13}, Nle^{14}]BN(7–14) (= βAla-βAla-Gln-Tpr-Ala-Val-Gly-His-Cha-Nle-NH_2), whose ^{99m}Tc-tricarbonyl conjugate (BBS-38) was investigated by García Garayoa et al. (*49, 50*). This BN analogue is characterized by the replacement of the C-terminal natural amino acids Leu^{13} and Met^{14} by Cha^{13}, Nle^{14}, and the further addition of a βAla-βAla spacer group. The Tc-tricarbonyl conjugate of this analogue exhibited an increased metabolic stability in blood plasma and tumor cells, as well as positively affecting the tumor-to-blood/kidney/liver ratio in comparison to the nonstabilized BN(7–14), without a spacer or with other spacers (*49, 50*).

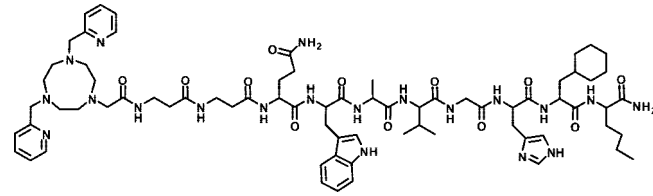


Figure 1. Structure of bioconjugate **8**.

With this in mind, we report herein the conjugation of the TACN derivative **6** to βAla-βAla-[Cha^{13}, Nle^{14}]BN(7–14), resulting in the preparation of the bioconjugate **8** (Figure 1) and present the results of subsequent ^{64}Cu labeling experiments with **6** and **8** to give **^{64}Cu⊂6** and **^{64}Cu⊂8**, respectively. *In vitro* and *in vivo* stability investigations, as well as biodistribution studies, are also presented and discussed.

EXPERIMENTAL SECTION

Materials. All solvents used were of reagent or analytical grade and used as purchased. CH_3CN was dried by standing over activated 4 Å molecular sieves overnight. Distilled water was used for all reactions in aqueous solution. CO_2-free water was prepared by boiling distilled water under nitrogen for 2 h and cooling while bubbling with nitrogen gas. High-purity nitrogen gas was used directly from a reticulated system. βAla-βAla-Gln-Trp-Ala-Val-Gly-His-Cha-Nle-NH_2 (βAla-βAla-[Cha^{13}, Nle^{14}]BN(7–14)) was obtained from Biosyntan GmbH, Germany. Rat blood plasma was prepared from Wistar rats (Harlan Winkelmann GmbH, Borchen, Germany). ^{64}Cu was produced on the PET cyclotron "Cyclone 18/9" of the FZ Dresden-Rossendorf by the ^{64}Ni(p,n) → ^{64}Cu nuclear reaction according to the procedure reported previously (*51, 52*).

Instrumentation and Methods. Infrared spectra were recorded as NaCl plates, nujol, or neat liquids as noted on a Perkin-Elmer 1600 series FTIR spectrophotometer at a resolution of 4.0 cm^{-1}. Diamond ATR spectra were recorded on a Specac "Golden Gate" apparatus. Abbreviations used to describe the peak intensities of IR and ATR spectra are as follows: vs (very strong), s (strong), m (medium), w (weak), sh (shoulder), and br (broad). Microanalytical (C, H, and N) analyses were performed by Campbell Microanalytical Service, Otago, New Zealand. ^{1}H NMR and ^{13}C NMR spectra were measured on a Bruker AC200, DPX300, or DRX400 spectrometer. Tetramethylsilane (TMS) was used as an internal calibrant for spectra recorded in $CDCl_3$ solutions. Abbreviations used to describe the resonances for ^{1}H NMR spectra are as follows: s (singlet), d (doublet), t (triplet), q (quadruplet), m (multiplet), or br (broad singlet). Low-resolution electrospray mass spectra were obtained with a Micromass Platform II Quadrupole Mass Spectrometer fitted with an electrospray source. High-resolution mass spectra were recorded on a Bruker BioApex II 47e FT-ICR MS fitted with an analytical elctrospray source. Samples were introduced by syringe pump at a flow rate of 1 μL/min. The capillary voltage was 200 V. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) was performed on an Autoflex TOF/TOF instrument from Bruker Daltonics, Germany. HPLC was performed on a Perkin-Elmer device consisting of a Turbo LC System with a quaternary pump

(series 200 LC Pump), a programmable absorbance detector model 785A (Perkin-Elmer Instruments GmbH, Germany), and a homemade γ-ray detector (well-type, NaI(T1) crystal). Eluent A, 0.1% (v/v) TFA in CH_3CN; eluent B, 0.1% (v/v) TFA in H_2O; eluent C, 0.05% (v/v) TFA in CH_3CN; eluent D, 0.04% (v/v) TFA in H_2O. HPLC system 1, Jupiter (Phenomenex) 4 μ Proteo 90Å, 250 × 4.6 mm; gradient elution, 10% to 70% of eluent A in 40 min, 1 mL/min. HPLC system 2, Jupiter (Phenomenex) 4 μ Proteo 90Å, 250 × 10 mm, gradient elution, 10% to 70% of eluent A in 40 min, 3 mL/min. HPLC system 3, Zorbax (Agilent) SB-C18, 300 Å, 5 μm, 250 × 9.4 mm; gradient elution using eluents C and D, 10% to 70% eluent C in 20 min, 3 mL/min, 28 °C. Thin layer chromatography (TLC) was performed using basic alumina (Al_2O_3) plates with detection of species present by $KMnO_4$ oxidation (eluents specified in the synthesis section). TLC of the ^{64}Cu-labeled compounds was performed using neutral alumina plates which were recorded on a Radioisotope Thin Layer Analyzer (Rita Star, Raytest Isotopenmessgerät GmbH, Straubenhardt, Germany). The eluent was a 1:1 mixture by volume methanol/ammonium acetate (5% in water) [$R_f = 0$ (Cu^{2+}); $R_f = 1$ (**^{64}Cu⊂6**)].

1,4,7-Triazacyclo[5.2.1.0^{4,10}]decane (1). 1 was synthesized following the previously reported procedure. Analytical data were in agreement with that described in the literature (*53*, *54*).

1-Formyl-4-(2-pyridylmethyl)-1,4,7-triazacyclononane (2). Picolyl chloride hydrochloride was neutralized with an excess of NaOH, and extraction with DCM yielded neutral picolyl chloride. A sample of this compound (6.02 g, 0.0472 mol) was dissolved in THF (50 mL) and then added dropwise to a solution of **1** (6.35 g, 0.050 mol) in THF (50 mL). The resulting mixture was stirred overnight at room temperature. The orange precipitate which formed was filtered off, washed with THF, and dried under reduced pressure. The solid was dissolved in water (50 mL) and the solution refluxed for 4 h. The solution was cooled to room temperature and aqueous 5 M NaOH added dropwise until a pH of 13 was reached. The compound was then extracted with $CHCl_3$, the organic phase dried with anhydrous $MgSO_4$, filtered, and the solvent removed under vacuum to give **2** as a yellow oil. Yield: 9.21 g (79%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 2.50 (s br, 1H, N*H*), 2.60–2.70 (m, 3H, CH_2TACN ring), 2.85 (m, 1H, CH_2TACN ring), 3.01 (m, 1H, CH_2TACN ring), 3.10–3.25 (m, 4H, CH_2 TACN ring), 3.40–3.50 (m, 3H, CH_2 TACN ring), 3.88 (s, 2H, N-CH_2-pyridyl), 7.18 (m, 1H, C*H* pyridyl), 7.38 (m, 1H, C*H* pyridyl), 7.68 (m, 1H, C*H* pyridyl), 8.12 (s, 1H, C*H*O), 8.54 (m, 1H, C*H* pyridyl). ^{13}C NMR (50.29 MHz, $CDCl_3$): 46.5, 46.6, 47.0, 47.6, 47.9, 49.1, 49.8, 51.7, 52.4, 53.2, 55.1, 56.5 (all *C*H$_2$ TACN ring), 62.9 (N-*C*H$_2$-pyridyl), 121.8, 121.9, 122.7, 122.8, 136.1, 136.3, 136.4, 148.8 (all *C*H pyridyl), 159.3 (*C* pyridyl), 159.4 (*C* pyridyl), 163.4 (*C*HO), 163.5 (*C*HO). IR (KBr disk, cm^{-1}): 3369w ($\nu_{N\text{-}H}$), 3049s ($\nu_{C\text{-}H(Aromatic)}$), 2923br ($\nu_{C\text{-}H}$), 1662s ($\nu_{C=O}$), 1590s ($\nu_{C=N(Pyridyl)}$), 1569s ($\nu_{C=C(Pyridyl)}$), 1435s br ($\nu_{C=C(Pyridyl)}$), 1365s br, 1273s, 1150s, 1047s, 993s, 733s, 700s. ESI-MS electrospray mass spectrum (*m*/*z*): 249.2 (100%) [M + H]$^+$, 261.2 (10%) [M + Na]$^+$. High-resolution ESI mass determination (MeOH): Found, 249.1708; calcd for $C_{13}H_{21}N_4O$, 249.1715.

1-Formyl-4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononane (3). A solution of picolyl chloride hydrochloride (6.12 g, 0.0371 mol) in CH_3CN (50 mL) was added dropwise to a mixture of **2** (9.21 g, 0.0371 mol) in CH_3CN (50 mL) containing K_2CO_3 (20.50 g, 0.1480 mol) and KI (0.10 g, 0.6020 mmol). The resulting mixture was stirred for 1 h at room temperature and then refluxed overnight. The reaction mixture was cooled to room temperature, filtered, and washed with acetonitrile. The filtrate was evaporated under reduced pressure to yield **3** as a brown oil. Yield: 9.69 g (77%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 2.59 (m, 2H, CH_2TACN ring), 2.81 (m, 2H, CH_2TACN ring), 3.03 (m, 2H, CH_2TACN ring), 3.27 (m, 4H, CH_2TACN ring), 3.42 (m, 2H, CH_2TACN ring), 3.87 (s, 2H, N-CH_2-pyridyl), 3.88 (s, 2H, N-CH_2-pyridyl), 7.14 (m, 2H, C*H* pyridyl), 7.43 (m, 2H, C*H* pyridyl), 7.66 (m, 2H, C*H* pyridyl), 8.05 (s, 1H, C*H*O), 8.53 (m, 2H, C*H* pyridyl). ^{13}C NMR (50.29 MHz, $CDCl_3$): 46.5, 47.0, 50.2, 53.0, 54.2, 57.7 (all *C*H$_2$ TACN ring), 62.9 (N-*C*H$_2$-pyridyl), 63.6 (N-*C*H$_2$-pyridyl), 120.9, 121.8, 122.5, 122.8, 135.6, 135.8, 148.8, 148.9 (all *C*H pyridyl), 159.6 (*C* pyridyl), 159.8 (*C* pyridyl), 163.5 (*C*HO). IR (KBr disk, cm^{-1}): 3052s ($\nu_{C\text{-}H(Aromatic)}$), 3008s ($\nu_{C\text{-}H}$), 2926s br($\nu_{C\text{-}H}$), 2824s br, 2250s, 1666s ($\nu_{C=O}$), 1589s ($\nu_{C=N(Pyridyl)}$), 1569s ($\nu_{C=C(Pyridyl)}$), 1473s ($\nu_{C=C(Pyridyl)}$), 1435s ($\nu_{C=C(Pyridyl)}$), 1371s br, 1314s, 1225s, 1148s, 1047s, 994s, 757s. ESI-MS electrospray mass spectrum (*m*/*z*): 340.1 (100%) [M + H]$^+$. High-resolution ESI mass determination (MeOH): Found, 340.2133; calcd for $C_{19}H_{26}N_5O$, 340.2137.

1,4-Bis(2-pyridylmethyl)-1,4,7-triazacyclononane (4). 3 (9.69 g, 0.0280 mol) was dissolved in aqueous 4 M HCl (50 mL) and the resulting solution refluxed for 4 h. The solution was then allowed to cool to room temperature, and aqueous 5 M NaOH (50 mL) was added dropwise until a pH of 13 was reached. The compound was extracted with $CHCl_3$ (3 × 50 mL), the organic phase washed with anhydrous $MgSO_4$, filtered, and the solvent removed under vacuum to yield **4** as a reddish brown oil. Yield: 7.55 g (85%). Anal. Found (%): C, 69.32; H, 7.76; N, 22.42. Calcd for $C_{18}H_{25}N_5$ (%): C, 69.48; H, 7.65; N, 22.32. ^{1}H NMR (400 MHz, $CDCl_3$): δ 2.75 (m, 4H, CH_2TACN ring), 2.95 (m, 4H, CH_2TACN ring), 3.06 (m, 4H, CH$_2$TACN ring), 3.89 (s, 4H, N-CH_2-pyridyl), 4.71 (s br, 1H, N*H*), 7.14 (m, 2H, C*H* pyridyl), 7.26 (m, 2H, C*H* pyridyl), 7.58 (m, 2H, C*H* pyridyl), 8.61 (m, 2H, C*H* pyridyl). ^{13}C NMR (75.44 MHz, $CDCl_3$): 45.4 (*C*H$_2$ TACN ring), 49.7 (*C*H$_2$ TACN ring), 52.8 (*C*H$_2$ TACN ring), 61.02 (N-*C*H$_2$-pyridyl), 121.7, 122.4, 122.7, 123.1, 136.2, 136.6, 148.8, 149.3 (all *C*H pyridyl), 158.3 (*C* pyridyl). IR (KBr disk, cm^{-1}): 3416w ($\nu_{N\text{-}H}$), 3052s ($\nu_{C\text{-}H(Aromatic)}$), 2919s br ($\nu_{C\text{-}H}$), 1590s ($\nu_{C=N(Pyridyl)}$), 1568s ($\nu_{C=C(Pyridyl)}$), 1472s ($\nu_{C=C(Pyridyl)}$), 1434s ($\nu_{C=C(Pyridyl)}$), 1362s, 1148s, 995s, 752s, 662s. ESI-MS Electrospray mass spectrum (*m*/*z*): 312.3 (100%) [M + H]$^+$.

Ethyl-2-[4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetate (5). A solution of ethyl bromoacetate (0.50 g, 2.99 mmol) in dry CH_3CN (25 mL) was added dropwise to a mixture of **4** (0.92 g, 3.0 mmol) in dry CH_3CN (25 mL) containing K_2CO_3 (1.64 g, 11.8 mmol) and KI (0.10 g, 0.60 mmol). The resulting mixture was stirred for 1 h at room temperature, and then refluxed overnight. It was subsequently cooled to room temperature, filtered, and the residue washed with dry acetonitrile. The filtrate was collected, and the solvent removed under reduced pressure to yield **5** as a brown oil. Yield: 1.18 g (88%). ^{1}H NMR (200 MHz, $CDCl_3$): δ 1.28 (t, $^3J = 7.1$ Hz, 3H, CH_3-CH$_2$O), 2.45–2.85 (m, 12H, CH_2TACN ring), 3.35 (s, 2H, N-CH_2-COO), 3.86 (s, 4H, N-CH_2-pyridyl), 4.12 (q, $^3J = 7.1$ Hz, 2H, CH$_3$-CH_2O), 7.19 (m, 2H, C*H* pyridyl), 7.46 (m, 2H, C*H* pyridyl), 7.62 (m, 2H, C*H* pyridyl), 8.54 (m, 2H, C*H* pyridyl). ^{13}C NMR (75.44 MHz, $CDCl_3$): δ 13.1 (OCH$_2$-*C*H$_3$), 53.0 (b, *C*H$_2$ TACN ring), 59.0 (N-*C*H$_2$-COO), 59.2 (O*C*H$_2$-CH$_3$), 63.5 (N-*C*H$_2$-pyridyl), 120.9 (*C*H pyridyl), 121.9 (*C*H pyridyl), 134.7 (*C*H pyridyl), 147.6 (*C*H pyridyl), 158.1 (*C* pyridyl), 170.8 (*C*OO). IR (KBr disk, cm^{-1}): 3050s ($\nu_{C\text{-}H(Aromatic)}$), 2930s br ($\nu_{C\text{-}H(TACN)}$), 1732s ($\nu_{C=O}$), 1592s ($\nu_{C=N(Pyridyl)}$), 1568s ($\nu_{C=C(Pyridyl)}$), 1472s ($\nu_{C=C(Pyridyl)}$), 1435s ($\nu_{C=C(Pyridyl)}$), 1372w, 1198w, 1049w, 994s br, 761s. ESI-MS Electrospray mass spectrum (*m*/*z*): 398.3 (100%) [M + H]$^+$.

2-[4,7-Bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetic Acid (6). To **5** (1.18 g, 3.0 mmol) dissolved in ethanol (30 mL) was added LiOH·H_2O (0.45 g, 10.7 mmol) dissolved in water (10 mL). This mixture was stirred at 70 °C overnight. It

was then cooled to room temperature, and the pH was adjusted to 7 by addition of aqueous 1 M HCl. The solvent was removed under reduced pressure and dichloromethane used to extract the solid. The solution was filtered and the filtrate dried with Na_2SO_4. After filtration, the solvent was removed under reduced pressure to yield **6** as a brown oil. Yield: 1.02 g (85%). Anal. Found (%): C, 65.18; H, 7.22; N, 18.88. Calcd for $C_{20}H_{27}N_5O_2$ (%): C, 65.09; H, 7.38; N, 18.98. ^{1}H NMR (75.44 MHz, $CDCl_3$): δ 2.40–2.80 (m, 12H, CH_2TACN ring), 3.19 (s, 2H, N-CH_2-COOH), 3.89 (d, ^2J = 15.2 Hz, 2H, N-CH_2-pyridyl), 3.98 (d, ^2J = 15.2 Hz, 2H, N-CH_2- pyridyl), 7.14 (m, 2H, C*H* pyridyl), 7.28 (m, 2H, C*H* pyridyl), 7.72 (m, 2H, C*H* pyridyl), 8.17 (m, 2H, C*H* pyridyl). ^{13}C NMR (75.44 MHz, $CDCl_3$): δ 49.9 (*C*H_2 TACN ring), 50.0 (*C*H_2 TACN ring), 50.3 (*C*H_2 TACN ring), 59.3 (N-*C*H_2-COOH), 60.5 (N-*C*H_2-pyridyl), 122.1 (*C*H pyridyl), 122.3 (*C*H pyridyl), 136.9 (*C*H pyridyl), 148.6 (*C*H pyridyl), 157.5 (*C* pyridyl), 176.1 (*C*OOH). IR (KBr disk, cm^{-1}): 3390w br ($\nu_{O\text{-}H}$), 3059w ($\nu_{C\text{-}H(Aromatic)}$), 2939m ($\nu_{C\text{-}H}$), 2867s ($\nu_{C\text{-}H}$), 2826s, 2359s, 2192s, 1667s ($\nu_{C=O}$), 1599s ($\nu_{C=N(Pyridyl)}$), 1571s ($\nu_{C=C(Pyridyl)}$), 1481s ($\nu_{C=C(Pyridyl)}$), 1456s ($\nu_{C=C(Pyridyl)}$), 1436s ($\nu_{C=C(Pyridyl)}$), 1365s ($\nu_{C\text{-}O}$), 1149s, 1119s, 1097s, 1046s, 1005s, 978s, 914m, 836s, 727m, 641s. ESI-MS Electrospray mass spectrum (*m*/*z*): 368.3 (100%) $[M - H]^-$.

Ethyl-2-{2-[4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetamido}acetate (7). 6 (0.65 g, 1.8 mmol) was suspended in acetonitrile (15 mL), and HBTU (0.67 g, 1.8 mmol), DIPEA (1.60 g, 12.4 mmol), and glycine ethyl ester hydrochloride (0.25 g, 1.78 mmol) added. The brown reaction mixture was stirred overnight at room temperature, and thereafter the solvent was removed under reduced pressure. To the residue was added dichloromethane (10 mL), and the mixture was washed with saturated $NaHCO_3$ solution (5 mL) and water (2 × 5 mL). After drying of the organic phase over Na_2SO_4 and subsequent filtration, the solvent was removed under reduced pressure. The crude product was purified by column chromatography on basic alumina with CH_2Cl_2/MeOH (98:2 by volume) as the eluent (R_f = 0.28) to yield **7** as a yellow oil. Yield: 0.32 g (40%). Anal. Found (%): C, 63.55; H, 7.46; N, 18.65. Calcd for $C_{24}H_{34}N_6O_3$ (%): C, 63.49; H, 7.55; N, 18.52. ^{1}H NMR (75.44 MHz, $CDCl_3$): δ 1.19 (t, ^3J = 7.1 Hz, 3H, CH_3-CH_2O), 2.40–2.80 (m, 12H, CH_2TACN ring), 3.40 (s, 2H, N-CH_2-CONH), 3.87 (d, ^2J = 15.3 Hz, 2H, N-CH_2-pyridyl), 3.98 (d, ^2J = 15.3 Hz, 2H, N-CH_2-pyridyl), 4.02 (d, ^3J = 5.8 Hz, 2H, CONH-CH_2-COO), 4.12 (q, ^3J = 7.1 Hz, 2H, OCH_2-CH_3), 7.02 (t, ^3J = 5.8 Hz, 1H, CON*H*), 7.19 (m, 4H, C*H* pyridyl), 7.71 (m, 2H, C*H* pyridyl), 8.07 (m, 2H, C*H* pyridyl). ^{13}C NMR (300 MHz, $CDCl_3$): δ 14.1 (OCH_2-*C*H_3), 41.6 (CONH-*C*H_2-COO), 51.1 (br, *C*H_2 TACN ring), 51.3 (*C*H_2 TACN ring), 59.6 (N-*C*H_2-CONH), 61.3 (N-*C*H_2-pyridyl), 61.7 (COO-*C*H_2-CH_3), 122.9 (*C*H pyridyl), 123.1 (*C*H pyridyl), 137.8 (*C*H pyridyl), 149.1 (*C*H pyridyl), 158.4 (*C* pyridyl), 169.3 (CH_2-*C*OO-CH2), 173.6 (*C*ONH). IR (KBr disk, cm^{-1}): 3406w ($\nu_{N\text{-}H}$), 3035w ($\nu_{C\text{-}H(Aromatic)}$), 2953s ($\nu_{C\text{-}H}$), 2867s ($\nu_{C\text{-}H}$), 2826s, 2359s, 1789s ($\nu_{C=O(ester)}$), 1658s ($\nu_{C=O(amide)}$), 1599s ($\nu_{C=N(Pyridyl)}$), 1571s ($\nu_{C=C(Pyridyl)}$), 1481s ($\nu_{C=C(Pyridyl)}$), 1456s ($\nu_{C=C(Pyridyl)}$), 1436s ($\nu_{C=C(Pyridyl)}$), 1365s ($\nu_{C\text{-}O}$), 1149s, 1097s, 1046s, 978s, 914m, 836s, 727m, 641s. ESI-MS Electrospray mass spectrum (*m*/*z*): 455.3 (100%) $[M + H]^+$.

Bioconjugate 6-βAla-βAla-[Cha^{13}, Nle^{14}]BN(7–14) (8). 6 (2.3 mg, 6.2 μmol), HBTU (4.7 mg, 12 μmol) and βAla-βAla-Gln-Trp-Ala-Val-Gly His-Cha-Nle-NH_2 (5.0 mg, 4 μmol) were dissolved in DMF (2 mL). DIPEA (5.0 μL, 29 μmol) was then added and the mixture stirred for 20 h at room temperature. The DMF was removed under high vacuum and the residual brown oil was purified HPLC (system 2) to yield **8** as a white solid after lyophilization. Yield: 3.6 mg (61%). Electrospray mass spectrum (*m*/*z*): 728 $[M + 2H]^{2+}$, 739 $[M + H + Na]^{2+}$, 1456 $[M + H]^+$, 1478 $[M + Na]^+$. MALDI-TOF MS: Found: 1457.1; calculated for $C_{73}H_{107}N_{20}O_{12}$: 1455.8. HPLC system 1: t_R = 19.2 min.

[Cu(6-H)Cu(NO$_3$)$_2$.MeOH]NO$_3$.MeOH(Cu$_2$⊂6). $Cu(NO_3)_2 \cdot 3H_2O$ (59 mg, 0.24 mmol) was dissolved in MeOH (5 mL) and added to a solution of **6** (89 mg, 0.24 mmol) in MeOH (5 mL). The color changed to dark green and a brown precipitate formed. The solution was filtered to remove the precipitate. Slow diffusion of a ether into this solution produced crystals that were suitable for X-ray crystallography. Yield: 16 mg (18%). Anal. Found (%): C, 37.60; H, 4.43; N, 15.05. Calcd for $Cu_2C_{22}H_{34}N_8O_{13}$ (%): C, 35.43; H, 4.50; N, 15.02. IR (ATR, cm^{-1}): 3049w ($\nu_{C\text{-}H(Aromatic)}$), 2932s ($\nu_{C\text{-}H}$), 2862s ($\nu_{C\text{-}H}$), 1610s ($\nu_{C=O}$), 1573s ($\nu_{C=C(Pyridyl)}$), 1440s ($\nu_{C=C(Pyridyl)}$), 1330s br ($\nu_{NO3\text{-}}$), 1021m, 976m, 826m, 777m.

X-ray Crystallography. Intensity data for a blue crystal of **Cu$_2$⊂6** (0.21 × 0.19 × 0.06 mm^3) was measured at 123 K on a Bruker Apex 2 CCD fitted with graphite-monochromated Mo Kα radiation (0.71073 Å). The data were collected to a maximum 2θ value of 60° and processed using the Bruker *Apex 2* software. Crystal parameters and details of the data collection for **Cu$_2$⊂6** are summarized and presented in the Supporting Information.

The structure was solved by direct methods and expanded using standard Fourier routines in the SHELX-97 (*55, 56*) software package. All hydrogens except for H1M and H2M, which were located on the Fourier-difference map, were placed in idealized positions, and all nonhydrogen atoms were refined anisotropically.

Preparation of ^{64}Cu⊂6 and ^{64}Cu⊂8. An aqueous solution of $^{64}CuCl_2$ (50 MBq, 100 μL, 0.1 M NH_4OAc) was added to ca. 1 mg of **6** or **8** dissolved in 100 μL MeCN/H_2O (1:1 by volume). The reaction mixtures were tempered at 40 °C for 30 min, which results in 90% labeling yield. The crude products were then purified by HPLC (system 2). This results in a radiochemical purity >97%. For *in vivo* studies, the obtained fraction was concentrated to dryness and redissolved in 0.9% aqueous saline solution; t_R = 4.4 min for **^{64}Cu⊂6**, t_R = 19.5 min for **^{64}Cu⊂8** (HPLC system 1).

Concentration Dependence. To 100 μL aqueous solution of ligand **6** (10^{-2} M, 10^{-3} M, 10^{-4} M, and 10^{-5} M in 0.1 M NH_4OAc), 200 kBq of $^{64}CuCl_2$ (100 μL in 0.1 M NH_4OAc) was added. The mixtures were shaken for 10 min and then analyzed by TLC.

Kinetic Studies. 100 μL of an aqueous solution of ligand **6** (10^{-4} M in 0.1 M NH_4OAc) was spiked with $^{64}CuCl_2$ (100 kBq) and stirred. Aliquots of the mixtures were analyzed by TLC to determine the degree of complexation. Samples were taken after 1, 5, 10, and 30 min.

Ligand "Challenge" Experiment. A solution containing 100 kBq $^{64}CuCl_2$ was added to 500 μg of **6** dissolved in 100 μL of 0.1 M NH_4OAc. After 10 min, full complexation of the ligand was checked by TLC. Cyclam (40 mg, more than 100-fold excess) dissolved in 1 mL 0.1 M NH_4OAc was then added to the complex solution, which was stirred for 24 h. Aliquots of the mixtures were assayed by TLC and HPLC (system 1) to determine the degree of decomposition.

SOD "Challenge" Experiment. A solution of 250 kBq $^{64}CuCl_2$ in 0.1 M NH_4OAc was added to 10 μg of **6** dissolved in 100 μL acetonitrile/water (1:5). The full complexation of the ligand was checked via TLC after 15 min. After the removal of acetonitrile, 1.35 mg of SOD (from bovine liver) was dissolved in 200 μL of 0.9 M NaCl solution-representing a more than 1000-fold excess-and added to the prepared complex solution, which was then stirred for 24 h. The degree of decomposition was determined by TLC using aliquots of the mixtures.

Determination of Partition Coefficient log $D_{o/w}$. Ligands **6** or **8** dissolved in 50 μL water ($c_0 = 10^{-3}$ M) were added to a mixture consisting of 390 μL HEPES/NaOH buffer (0.05 M, pH = 7.2, 7.4, 7.8), a 10 μL $^{64}CuCl_2$ solution in 0.1 M NH_4OAc, and 50 μL of a 10^{-4} M aqueous solution of $Cu(NO_3)_2$. The distribution experiments in 1-octanol/buffer system were carried out at 25 ± 1 °C in microcentrifuge tubes (2 cm^3) with mechanical shaking. The phase ratio $V_{(1\text{-octanol})}$:$V_{(aq)}$ was 1:1 (0.5 cm^3 each). The shaking time was 30 min. All samples were centrifuged and the phases separated. The copper concentration in both phases was determined radiometrically using γ-radiation [^{64}Cu, NaI(Tl) scintillation counter automatic gamma counter 1480, Wizard 3″, PerkinElmer]. The results are the average values of three independent experiments.

***In Vitro* Stability.** **^{64}Cu⊂6** or the bioconjugate **^{64}Cu⊂8** were incubated in phosphate buffer (250 μL, Sörensen, pH = 7.4) and rat plasma (250 μL) at 37 °C for 2 h and then at 25 ± 1 °C for 24 h. Cold ethanol (500 μL) was added to the mixture, and after centrifugation for 5 min, the ethanol phase was removed from the protein precipitate. This procedure was repeated another time. The ethanol solution was dried under nitrogen, and a solution of H_2O/CH_3CN (9:1 by volume) (100 μL) was added and acidified with TFA (5 μL). Samples containing **^{64}Cu⊂6** were analyzed using TLC and HPLC (system 1); **^{64}Cu⊂8** samples analyzed only by HPLC. The whole experiment was repeated two times.

***In Vivo* Stability.** The *in vivo* stability of **^{64}Cu⊂8** was analyzed using rat arterial blood samples at various time points (1, 3, 5, 10, 20, 30, and 60 min) after injection of the radiotracer. The samples were centrifuged to precipitate the blood cells. A solution consisting of 50 μL CH_3CN, 45 μL H_2O, and 5 μL TFA was added to 200 μL of the supernatant, and the mixture was then cooled to −20 °C. After centrifugation, the supernatant was analyzed by HPLC (system 3). The chromatogram of **^{64}Cu⊂8** (plasma, 0 min) was obtained by addition of **^{64}Cu⊂8** to rat blood and immediately treating the mixture as described for the *in vivo* samples. Urine and kidney homogenates were treated analogously to the arterial blood samples.

Animals, Feeding, Husbandry and Biodistribution Studies in Rats. The animal research committee of the Regierungspräsidium Dresden approved the animal facilities and the experiments according to institutional guidelines and the German animal welfare regulations. The Wistar rats (Harlan Winkelmann GmbH, Borchen, Germany) were housed under standard conditions with free access to standard food and tap water. Animals were between 7 and 9 weeks of age. The rats were housed in an Animal Biosafety Level 1 (ABSL-1) acclimatized facility with a temperature of 22 ± 2 °C and humidity of 55 ± 5%. Animals were under a 12 h light cycle in temperature (27 ± 1 °C) controlled-airflow cabinets. The animals had free access to standard pellet feed and water.

Four animals (body weight 227 ± 10 g) for each time point were intravenously injected into a tail vein with approximately 8 μCi (0.3 MBq) **^{64}Cu⊂8** conjugate in 0.5 mL electrolyte solution E-153 (Serumwerk Bernburg, Germany) with 5% Tween 80. Animals were euthanized at 5 and 60 min postinjection. Blood and the major organs were collected, weighed, and counted in a Wallac WIZARD Automatic Gamma Counter (PerkinElmer, Germany). The radioactivity of the tissue samples was decay-corrected and calibrated by comparing the counts in tissue with the counts in aliquots of the injected tracer that had been measured in the gamma counter at the same time. The activity in the selected tissues and organs was expressed as percent injected dose per organ (% ID) or as standardized uptake value (SUV). Values are quoted as means ± standard deviation (mean ± SD) for each group of four animals.

PET Imaging. General anesthesia of rats was induced with inhalation of desflurane 9% (v/v) (Suprane, Baxter, Germany) in 40% oxygen/air (gas flow 1 L/min), and was maintained with desflurane 6% (v/v). For arterial blood sampling, a 3.5 Fr umbilical vessel catheter prefilled with heparinized saline was inserted into the right carotid arteria, and 100 μL blood samples were taken at 1, 3, 5, 10, 20, 30, and 60 min after tracer application. In the PET experiments, 0.1 mCi (3.7 MBq) of the **^{64}Cu⊂8** conjugate in 0.5 mL was administered intravenously over 1 min into a tail vein. PET imaging of **^{64}Cu⊂8** in rat was performed over 60 min with a microPET P4 scanner (Siemens CTI Molecular Imaging Inc., Knoxville). Data acquisition was performed in 3D list mode. A transmission scan was carried out prior to the injection of **^{64}Cu⊂8** using a ^{137}Cs point source. Emission data were collected continuously for 60 min after injection of **^{64}Cu⊂8**. The list mode data were sorted into sinograms using a framing scheme of 12 × 10 s, 6 × 30 s, 5 × 300 s, and 5 × 600 s frames. The data were attenuation corrected, and the frames were reconstructed by Ordered Subset Expectation Maximization applied to 3D sinograms (OSEM3D) with 14 subsets, 6 OSEM3D iterations, 2 maximum a posteriori (MAP) iterations, and 0.05 beta-value for smoothing. The pixel size was 0.8 by 0.8 by 1.2 mm^3, and the resolution in the center of field of view was 1.85 mm. No correction for recovery and partial volume effects was applied. The image files were processed using the *ASIPro* software (Siemens, CTI Molecular Imaging Inc. Knoxville) and the *ROVER* software (ABX GmbH, Radeberg, Germany). Summed frames from 30 to 90 s postinjection (p.i.) and 30 to 90 min p.i. were used to define the regions of interest (ROI). The data were normalized to the injected radioactivity by using ^{18}F standards from the injection solution measured in a γ-well counter (Isomed 2000, Dresden, Germany) cross-calibrated to the PET scanner and expressed in SUV.

Statistical Analysis. The data are expressed as means ± SD. One-way analysis of variance (ANOVA) was used for statistical evaluation. Means were compared using Student's *t* test. A *P* value of <0.05 was considered significant and indicated by an asterisk symbol (*).

RESULTS AND DISCUSSION

Ligand Synthesis. The synthesis of the important synthon, 1,4-bis(2-pyridylmethyl)-1,4,7-triazacyclononane (**4**) (see Scheme 1), was reported by our group more than a decade ago (*57*). However, the method published did not afford a pure compound. Purity was not as critical in the previous work as, following complexation, purification of the metal complexes was carried out by cation exchange chromatography. For the present work, however, a pure ligand was required and therefore a new synthetic pathway (Scheme 1) was developed, starting from the known compound 1,4,7-triazatricyclo[5.2.1.0^{4,10}]decane (**1**) (*53, 54*).

Compound **2** was synthesized by first adding 1 equiv of 2-picolyl chloride dropwise to a solution of **1** in THF. The crude orange precipitate obtained was then refluxed in water to give 1-formyl-4-(2-pyridylmethyl)-1,4,7-triazacyclononane (**2**) as a yellow oil in 79% yield. ^{1}H and ^{13}C NMR spectra of compound **2** are complicated by the presence of two rotameric forms in solution due to restricted rotation around the amide bond leading to different proton environments. This phenomenon has been observed for some other TACN-based compounds which possess a formyl group (*58*). Nevertheless, the formation of **2** is confirmed by ^{1}H NMR spectroscopy, with the presence of two singlets at about 8.10 ppm (integrating as one proton in total) corresponding to the proton of the formyl group. The presence of the formyl group was also confirmed by IR spectroscopy, which revealed a strong absorption at 1662 cm^{-1}.

The second pyridyl pendant was introduced by reacting **2** with picolyl chloride hydrochloride in dry CH_3CN. The suc-

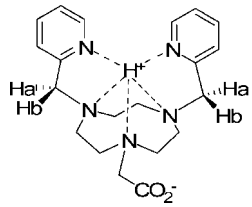

Figure 2. Proposed structure of **6** in $CDCl_3$.

cessful formation of 1-formyl-4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononane (**3**) was confirmed by ^{1}H NMR spectroscopy in $CDCl_3$, with resonances corresponding to the methylene group of the TACN ring (2.52–3.49 ppm), the methylene protons linking the pyridyl pendant groups to the macrocycle (3.95 ppm), and multiplets due to the pyridyl protons (7.15–8.50 ppm), all integrating in the expected ratio. In contrast to compound **2**, only one resonance for the formyl group was observed for compound **3** (at 8.00 ppm), indicating that the additional pyridyl pendant group restricts the molecule to one rotameric form. The disappearance in the IR spectrum of the ν(N−H) stretching frequency at 3369 cm^{-1} for **2** is a further proof of the formation of **3**.

The cleavage of the formyl group in **3** was achieved by acid hydrolysis in aqueous 4 M HCl solution to give **4** as a brown oil in 85% yield. The ^{1}H and ^{13}C NMR spectra of **4** agreed well with literature data (*57*). The introduction of an acetate pendant arm to facilitate the attachment of a biomolecule was achieved by first reacting **4** with ethyl bromoacetate in the presence of K_2CO_3 and a catalytic amount of KI to give ethyl 2-[4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetate (**5**) in 88% yield. Formation of the product was confirmed by ESI-MS, with a peak at m/z = 398.3 corresponding to [M + H]$^+$, and a distinctive IR carbonyl stretch at 1732 cm^{-1}. The ^{1}H NMR spectrum of **5** exhibited additional peaks corresponding to the ethyl acetate pendant arm; a triplet at 1.35 ppm with an integration of 3H was assigned to the terminal CH_3 group and a quartet at 4.25 ppm to the ethyl CH_2 group. A singlet at 3.42 ppm corresponding to the methylene protons of the acetate group was also observed. Base-catalyzed hydrolysis of **6** followed by a pH adjustment prior to extraction with dichloromethane yielded 2-[4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetic acid (**6**). Cleavage of the ester was confirmed by ESI-MS, with a peak at m/z = 368.3 corresponding to [M − H]$^-$. Furthermore, ^{1}H NMR spectroscopy showed the disappearance of the signals corresponding to the ethyl group. Interestingly, when the spectrum was run in $CDCl_3$, two doublets were observed at 3.89 and 3.98 ppm, which were assigned to the four protons of the pyridyl CH_2. An explanation for this observation may be that, in an aprotic solvent like $CDCl_3$, the ligand **6** exists as a zwitterion, with the H$^+$ ion interacting with the five nitrogen atoms present in the ligand (Figure 2). This interaction might cause the pyridyl pendant arms to be locked in one conformation, leading to the two protons of the pyridyl CH_2 residing in different chemical environments. The value of the observed coupling constant (15.2 Hz) is consistent with the geminal coupling that would be predicted between two such nonequivalent pyridyl CH_2 protons. Furthermore, only one signal for the two carbons bearing the four hydrogen atoms was observed in the ^{13}C NMR spectrum, indicating that the two carbons are magnetically equivalent and that only the hydrogens are not. A COSY spectrum subsequently verified that the two doublets seen in the ^{1}H NMR and $CDCl_3$ were due to the methylene protons of the pyridyl arm. The absence of a pair of similar doublets for the pyridyl CH_2 protons in the NMR spectra of the nonzwitterionic compounds **4** and **5** (all ^{1}H NMR spectra were measured in $CDCl_3$) provides evidence of the role that the H$^+$ ion plays in locking the pyridyl arms in one conformation in compound **6**.

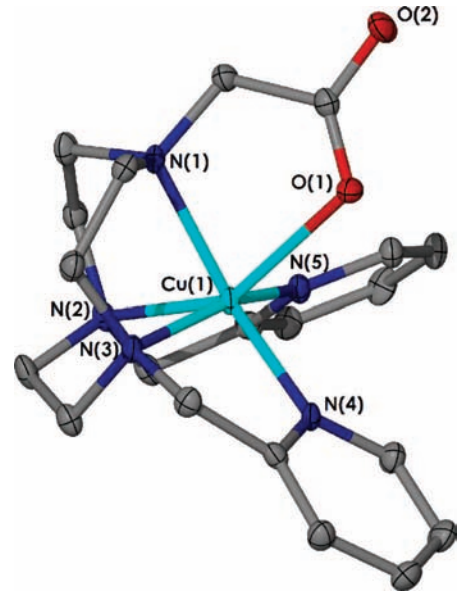

Figure 3. Thermal ellipsoid plot of the Cu(1) unit of **Cu$_2$⊂6** (thermal ellipsoids drawn at 40% probability; hydrogen atoms, nitrate counterions, and a cocrystallized methanol molecule omitted for clarity). The complete binuclear complex is shown in the Supporting Information.

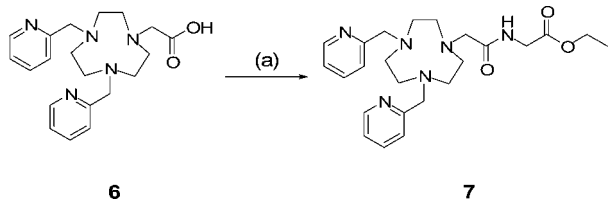
Copper(II) Complex of 6. An attempt to prepare the copper(II) complex of **6** was made by reacting the ligand with copper(II) nitrate in methanol. Instead of a mononuclear complex, dark blue crystals of a binuclear complex, [Cu(**6**-H)Cu(NO$_3$)$_2$.MeOH]NO$_3$·MeOH (**Cu$_2$⊂6**), were obtained when diethyl ether was diffused into a methanol solution of the complex. The infrared spectrum of the complex **Cu$_2$⊂6** showed bands at ca. 1610, 1573, and 1440 cm^{-1}, which can be ascribed to the ν(*C*═N) and ν(*C*═C) stretching frequencies of the 2-pyridylmethyl pendant arms. A thermal ellipsoid plot of the crystal structure of the complex is presented in Figure 3, along with the atomic numbering scheme (see Supporting Information for selected interatomic and hydrogen bonding parameters, and a further figure showing **Cu$_2$⊂6**).

The crystal structure of **Cu$_2$⊂6** reveals that the ligand accommodates two copper(II) ions at a distance of 5.404 Å. However, the formation of a similar binuclear complex is not expected under radiolabeling conditions, where extremely low concentrations of copper ions are added. Of interest to this project is the binding mode of the bioconjugate **8** to the ^{64}Cu radiolabel. Figure 3 highlights the single copper center that has its coordination sphere fully encapsulated by the TACN bioconjugate (**8**). Cu(1) is coordinated facially to three nitrogen atoms of the TACN ring [N(1), N(2), N(3)] with an average Cu−N bond distance of 2.133(4) Å. Two pyridine nitrogen atoms and one oxygen atom from the acetate pendant arm are also involved in the coordination of Cu(1). With the long equatorial bond length (2.381 Å) between the oxygen atom of the acetate and the Cu(II) center, one might consider this center to be in a pseudo-octahedral geometry. The Cu−N$_{pyridine}$ bond distances of the complex fall in the range of those reported for the Cu(II) complexes of pyridyl-containing ligands, (Cu−N$_{pyridine}$ = 2.04–2.06 Å) (*59*). The Cu−N$_{pyridine}$ distances are shorter than Cu−N$_{amine}$ distances due to the better Cu(II) coordination properties of the pyridyl nitrogens. The coordination of TACN was as expected, with, for example, the axial Cu−N$_{TACN}$ distance longer than the others (*59*), viz., the Cu(1)−N(2) distance of 2.204(4) Å is significantly longer than the remaining

Scheme 2. Preparation of 7[a]



6 **7**

[a] (a) HBTU, DIPEA, glycine ethyl ester·HCl, CH_3CN, r.t., o/n, 40%.

Cu−N interactions, which range from 2.174(4) Å [N(1)] to 2.016(4) Å [N(5)]. The two rings incorporating the pyridine rings are puckered, as seen in the values of the Cu(1)/N(2)/C(9)/C(10) and Cu(1)/N(3)/C(15)/C(16) torsion angles of −42.79 (1)° and −34.10 (1)°, respectively. The second copper(II) center, (Cu(2)), resides in a distorted octahedral geometry (see figure in Supporting Information). The coordination sites are occupied by an oxygen atom from a terminally coordinating methanol molecule, oxygen atoms from two chelating nitrates, and an oxygen from the carboxylate group of **6**. The two axial bonds Cu(2)−O(5N) and Cu(2)−O(2N) of 2.437 and 2.565 Å are very long, and the coordination interaction may be considered weak, hence resulting in a Cu-centered square-planar structure, with weak axial interactions.

Preparation of Bioconjugates 7 and 8. In order to demonstrate that ligand **6** could be coupled to a peptide, a preliminary experiment was conducted to couple **6** to a simple amino acid, glycine ethyl ester hydrochloride, applying standard peptide coupling conditions. Ethyl 2-{2-[4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetamido}acetate (**7**) was successfully isolated in 40% yield after purification by column chromatography on basic alumina (Scheme 2).

The formation of **7** was confirmed by ESI-MS, with a peak at $m/z = 455.3$ corresponding to $[M + H]^+$. ^1H NMR spectroscopy in $CDCl_3$ showed additional signals corresponding to the amino acid, a triplet at 7.02 ppm due to the amide N*H* proton, a quartet at 4.12 ppm for the protons of the ethyl CH_2 next to the terminal CH_3 group, a doublet at 4.02 ppm for the protons of the glycine CH_2 next to the amide, a singlet peak at 3.54 ppm for the protons of the CH_2 acetate, and a triplet at 1.19 ppm for the terminal CH_3. As was found for compound **6**, two doublets were observed at 3.87 and 3.98 ppm (with a geminal coupling constant of 15.3 Hz) and assigned to the methylene protons of the pyridyl pendant arm. In this case, a possible explanation for the nonequivalence of the methylene protons could be that free rotation around the pyridyl pendant arm is restricted, perhaps as a result of hydrogen-bonding interactions involving the amide-containing pendant.

The bioconjugate **8** (Figure 1) was synthesized by coupling the BN analogue βAla-βAla-Gln-Tpr-Ala-Val-Gly His-Cha-Nle-NH_2 (B1) to **6** in relatively good yield (60%). Similar experimental conditions to those used for the synthesis of **7** were employed. Compound **8** was purified by semipreparative HPLC and its purity checked by analytical HPLC. The presence of **8** was confirmed by ESI-MS, with peaks at 728, 739, 1456, and 1478 corresponding, respectively, to $[M + 2H]^{2+}$, $[M + H + Na]^{2+}$, $[M + H]^+$, and $[M + Na]^+$.

Labeling. To minimize cost, the majority of labeling studies were carried out on the copper complex of **6** rather than that of **8**. Nonetheless, the results obtained with the model compound **6** are representative of those expected for **8**. The first test performed was determination of the lowest concentration of **6** needed to obtain full complexation of $^{64}CuCl_2$ (200 kBq in 10 μL 0.1 M NH_4OAc) to form **^{64}Cu⊂6**. Following shaking of the solution obtained by mixing **6** and $^{64}CuCl_2$ for 10 min, the degree of complexation was monitored by TLC and HPLC. A ligand concentration $>10^{-4}$ M was found to be necessary to obtain complete copper complexation. At a ligand concentration of approximately 10^{-5} M, 10% of free Cu^{2+} ions were still present in solution after 10 min. The rate of copper(II) complexation with **6** was found to be very fast in ammonium acetate buffer solution (*60*) at ambient temperature, viz., the TACN derivative **6** (10^{-4} M) was successfully labeled with ^{64}Cu within 1 min in quantitative yield.

Table 1. Partition Coefficients (log $D_{o/w}$) of the ^{64}Cu Complexes of 6 and 8 at Different pHs

pH	log $D_{o/w}$ (^{64}Cu⊂6)	log $D_{o/w}$ (^{64}Cu⊂8)
7.2	−2.43	−2.39
7.4	−2.45	−2.38
7.8	−2.43	−2.36

Lipophilicity. Information about the lipophilicity of the copper complex **^{64}Cu⊂6** and the bioconjugate **^{64}Cu⊂8** was obtained by measuring their partitioning in a 1-octanol/water system. The partition coefficients (log $D_{o/w}$) were measured at different pH in buffered solution. The results are summarized in Table 1. The copper complexes of both the ligand **6** and the bioconjugate **8** are hydrophilic. This indicates that they should be predestined to show rapid blood clearance and preferential renal excretion. Interestingly, the log $D_{o/w}$ values of the **^{64}Cu⊂8** complex remain unchanged in the pH range investigated, indicating that the protonation state of the peptide does not influence the value of log $D_{o/w}$.

***In Vitro* Stability.** Competition experiments in the presence of the cyclam macrocycle, a ligand that forms one of the most stable Cu(II) complexes known (*14*), were undertaken to check the stability of the ^{64}Cu complexes. **^{64}Cu⊂6** and **^{64}Cu⊂8** were exposed to more than a 100-fold excess of cyclam. No transchelation was observed after 24 h, using HPLC as the detection system [t_R = 4.4 min (**Cu⊂6**), t_R = 5.3 min (**Cu⊂cyclam**), t_R = 19.2 min (**Cu⊂8**), HPLC system 1; see Experimental Section]. The *in vitro* stability of **^{64}Cu⊂6** and **^{64}Cu⊂8** was also assessed in a rat plasma medium after 2 and 24 h. The **^{64}Cu⊂6** complex remained unchanged. In the case of **^{64}Cu⊂8**, after 2 h, another small peak was detected. It was found that this peak was not due to free copper in solution, resulting from dissociation of copper(II) ions from the chelate complex, but instead arose from cleavage of the peptide of **^{64}Cu⊂8**, presumably brought about by the action of peptidases.

Competition experiments were also performed in the presence of SOD (Cu/Zn superoxide dismutase). SOD is a 32 kDa enzyme that is distributed in the cytosol of eukaryotic cells and is particularly abundant in liver, kidney, and red blood cells. This enzyme plays a key role as a copper-binding protein (*28, 30*). Ligand **6** was labeled with ^{64}Cu and spiked with a 1000-fold excess of SOD. After 24 h, the stability of the **^{64}Cu⊂6** complex ($R_f = 1$) was checked via TLC. We could not detect the presence of **^{64}Cu⊂SOD** ($R_f = 0$), which was synthesized for comparison as previously described (*28*). Thus, the absence of protein-bound radioactivity indicates no transchelation of copper(II). Overall, the results of the competition studies showed that both **^{64}Cu⊂6** and **^{64}Cu⊂8** are very stable. This finding is in accordance with our preliminary potentiometric measurements, which indicate that the stability constant for the copper complex is $>10^{25}$ M^{-1}.

***In Vivo* Stability.** The metabolic stability of **^{64}Cu⊂8** was determined in arterial blood samples taken at 1, 3, 5, 10, 20, 30, and 60 min after a single intravenous application of the radiotracer in a rat. The blood samples were centrifuged to obtain the plasma and then treated with acetonitrile to precipitate the proteins. The obtained supernatant was referred to as the plasma extract. The mean relative activity in the plasma was 89 ± 8% of arterial blood activity; the activity of the plasma extract samples contained 66 ± 13% of the plasma activity. The plasma extract was analyzed by RP-HPLC for radiometabolites (Figure

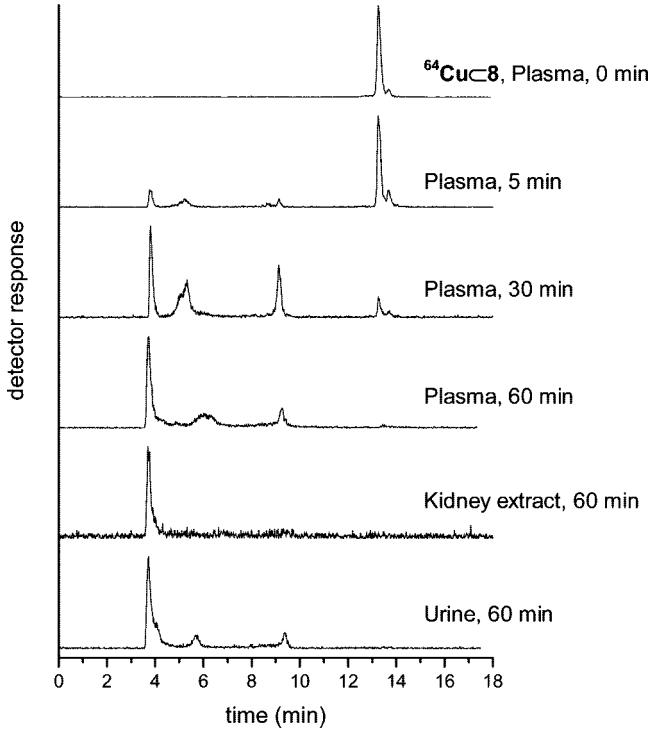


Figure 4. Examples of radiochromatograms (HPLC system 3) of **^{64}Cu⊂8** and rat plasma extract, kidney extract, and urine at various time points after single intravenous application of **^{64}Cu⊂8**.

4). The relative amount of the original compound **^{64}Cu⊂8** (t_R = 12.9 min) decreased from 93% at the time of tracer application (1 min 77%, 3 min 60%, 5 min 50%, 10 min 31%, 20 min 14%, 30 min 6%) to 3% of the total plasma extract activity after one hour (Figure 4). **^{64}Cu⊂8** was converted into three more hydrophilic radiolabeled compounds (t_R = 3.7, 5.3, 9.1 min). The peak at 3.7 min was not caused by $^{64}Cu^{2+}$ since it was eluted at 3.4 min. The residual activity in the kidney extract resulted from only one hydrophilic species (t_R = 3.7 min). The activity of the urine was caused by the same three species detected in the plasma extract. The original compound **^{64}Cu⊂8** could not be detected in the kidney extract or urine. This extensive metabolism of the compound could be species-specific for the rat.

Biodistribution Studies. A summary of the biodistribution and elimination data for the bombesin conjugate **^{64}Cu⊂8**, **^{64}Cu⊂6**, and $^{64}CuCl_2$ in rats is shown in Figures 5 and 6. The values of %ID, %ID/g, and SUV (ID = injected dose; SUV = standardized uptake value) are summarized in the Supporting Information. The SUV was used to normalize the biodistribution data and calculated as followed: SUV = tissue activity concentration (Bq/g) × body weight (g)/injected activity (Bq) (injected and tissue activity were decay-corrected). A high uptake of **^{64}Cu⊂8** was observed in the GRPR-expressing pancreas (5.8 ± 0.7 [SUV] at 5 min after injection, and 3.9 ± 0.3 [SUV] after 1 h). After one hour, the activity concentration was highest in the pancreas of all the organs examined. In contrast to these findings, the activity concentration in the pancreas after injection of **^{64}Cu⊂6** and $^{64}CuCl_2$ was very low, and roughly comparable to the blood activity uptake. The **^{64}Cu⊂8** had a rapid blood clearance, with 2.0 ± 0.3 (SUV) in the circulation at 5 min, followed by a further decrease to 0.23 ± 0.04 (SUV) at 1 h. Liver uptake reached 6.3 ± 0.7% ID at 5 min and declined to 3.7 ± 0.3% ID one hour after injection. The activity detected in the intestine attained 5.3 ± 0.4% ID at 5 min and 9.9 ± 2.4% ID after one hour. In the kidneys, the activity attained 5.3 ± 0.5% ID at 5 min and decreased to 1.6 ± 0.1% ID at one hour. Most activity was eliminated into the urine (13 ± 7% ID at 5 min and 57 ± 4% ID at 1 h). A very similar activity distribution and excretion pattern was observed

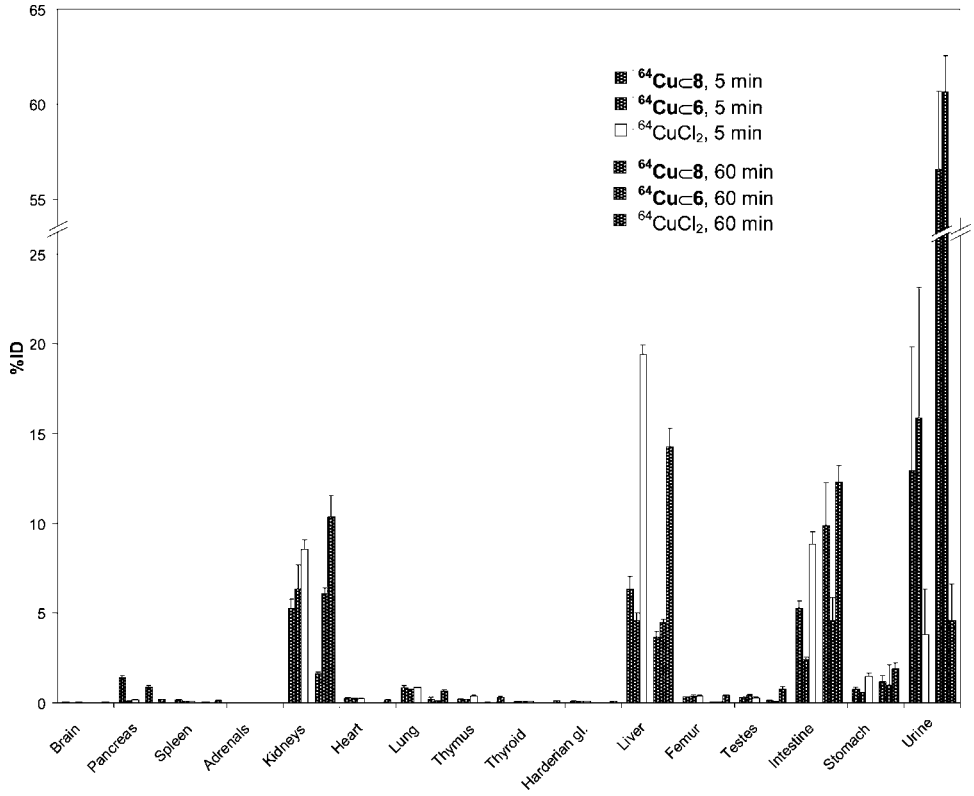

Figure 5. Biodistribution of **^{64}Cu⊂8**, **^{64}Cu⊂6**, and $^{64}CuCl_2$ in male Wistar rats 5 and 60 min after single intravenous application represented as %ID mean ± SD (4 animals per time point). (%ID, %ID/g, and SUV data are given in the Supporting Information).

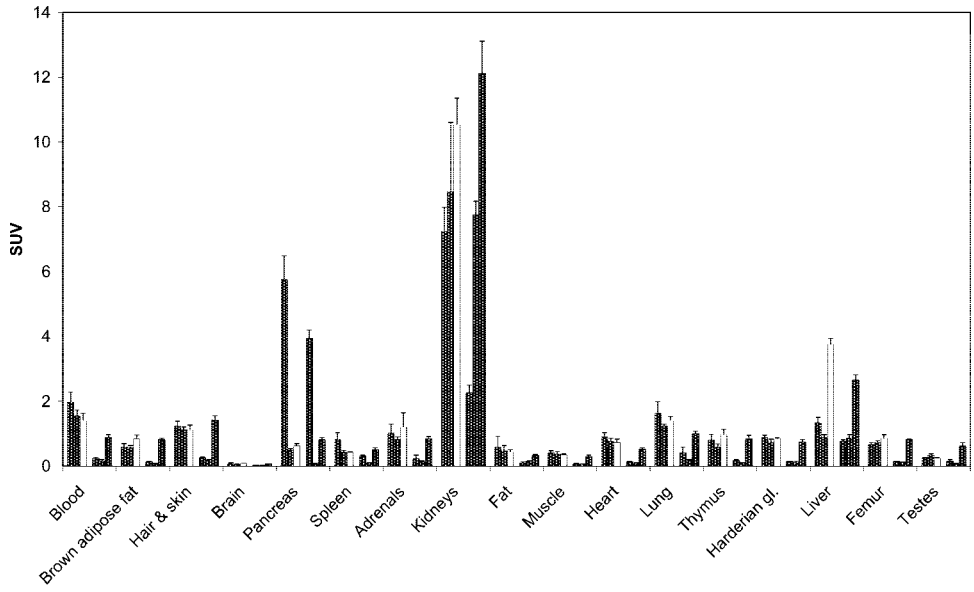

Figure 6. Biodistribution of **^{64}Cu⊂8**, **^{64}Cu⊂6**, and $^{64}CuCl_2$ in male Wistar rats 5 and 60 min after single intravenous application, represented as SUV mean ± SD (4 animals per time point). (%ID, %ID/g, and SUV data are given in the Supporting Information).

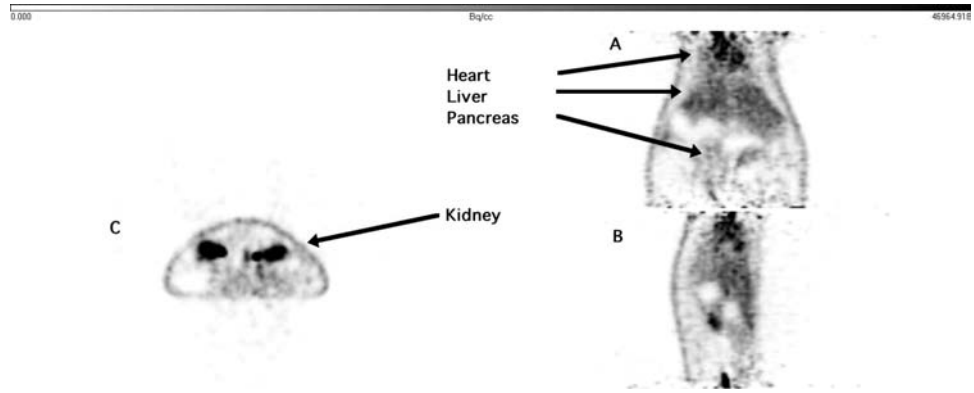

Figure 7. Small animal coronal (A), sagittal (B), and transversal (C) PET images of rat 60 min after single intravenous application of **^{64}Cu⊂8** into a rat tail vein.

after injection of **^{64}Cu⊂6**, which exemplifies the strong influence of the novel ^{64}Cu-TACN chelate to the biodistribution of its bombesin conjugate. In contrast, the activity distribution of $^{64}CuCl_2$ was distinctively different and characterized by a high liver uptake and a very low renal clearance. From the different biodistribution characteristics, it can be deduced that there was only marginal, or no, *in vivo* demetalation of the **^{64}Cu⊂6** unit.

The remarkable kidney uptake of **^{64}Cu⊂8** in comparison to the relatively low liver accumulation is also demonstrated by the small PET images (Figure 7) (note that the pancreas is hard to see due to its proximity to the duodenum of the small intestine).

A variety of radiolabeled bombesin derivatives, or analogues, containing the BN(8–14) sequence have been described in the literature, which show varying pharmacokinetic behavior depending on the radiolabeling approach taken, the spacer between the radiometal chelate, and the peptide N-terminus, and the specific modifications made to the peptide sequence. Since peptides are rapidly metabolized; bombesin derivatives with increased stability toward peptidases have been designed to tackle shortcomings, such as the intermediate or low target uptakes, and high liver and/or kidney uptakes, observed for most of the radiolabeled bombesin conjugates reported so far. Stabilized radiometal-labeled bombesin derivatives include [DPhe^6,βAla^{12},Nle^{14}]BN(6–14) (*61*),[Cha^{13}]BN(7–14) (*49,50,61*), [Nle^{14}]BN(7–14) (*49,50,61,62*),[Cha^{13},Nle^{14}]BN(7–14) (*49,50*), [Pro^1, Tyr^4]BN (*40*), [Pro^1, Tyr^4, Nle^{14}]BN (*62*), [DPhe^6, Leu-NHEt^{13}, des-Met^{14}]BN(6–14) (*63, 64*), and [DTyr^6, βAla^{11}, Thi^{13}, Nle^{14}]BN(6–14) (*64–66*), with the N-terminus conjugated to the radiometal complexes mainly via spacers. The bombesin used in the present work was selected from a study on ^{99m}Tc-tricarbonyl labeled bombesin derivatives in which the radiotracer ^{99m}Tc-BBS-38 was found to show an improved target/nontarget ratio due to the spacer βAla-βAla that stabilized BN(7–14) via Cha^{13} and Nle^{14} (*49, 50*).

The uptake level of **^{64}Cu⊂8** in the pancreas at 1 h p.i. was roughly comparable to the values for ^{99m}Tc-BBS-38 at 1.5 h p.i. The uptake of **^{64}Cu⊂8** in the kidneys and the lungs was significantly higher compared to ^{99m}Tc-BBS-38. The rapid decrease of activity accumulation in the kidneys and the increasing activity in the urine suggest a predominant renal clearance pathway for **^{64}Cu⊂8**, in contrast to the dominant hepatobiliary elimination of ^{99m}Tc-BBS-38 (*49*). The pancreatic uptake of **^{64}Cu⊂8** at 1 h p.i. was roughly in the same range as that described for ^{64}Cu-labeled DOTA bombesin conjugates studied in mice (*41, 42, 44–48*). ^{64}Cu-labeled DOTA-PEG-BN(7–14) (*41*), DOTA-X-BN(7–14) (X = spacer containing 4, 5, 6, 8, or 12 carbon atoms) (*43–46, 48*) and DOTA-X-BN(7–14) (X = Gly-Gly-Gly, Gly-Ser-Gly, or Gly-Ser-Ser) (*47*) resulted in a relatively high liver uptake, which was higher, or nearly the same, as the activity uptake into the kidneys. In contrast, **^{64}Cu⊂8** exhibited a lower uptake in the liver compared to the kidneys. ^{64}Cu-DOTA-[Lys^3]BN (*42, 43*), ^{64}Cu-DOTA-

[Pro[1], Tyr[4]]BN (*40*), ^{64}Cu-CB-TE2A-8-Aoc-BN(7–14) (*46*), and ^{64}Cu-NOTA-8-Aoc-BN(7–14) (*48*) were characterized by a predominant renal excretion pathway comparable to **^{64}Cu⊂8**, which showed an even lower liver uptake than ^{64}Cu-DOTA-[Lys[3]]BN (*42*, *43*) at 21 h p.i.

CONCLUSION

An efficient synthetic strategy has been developed for the preparation of a new TACN derivative, 2-[4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetic acid (**6**), containing two pyridine pendant arms as well as a carboxylic group for coupling to biomolecules. The X-ray structure of a copper complex of **6** confirmed that the ligand is capable of multidentate coordination to a Cu^{2+} ion. Conjugation of glycine ethyl ester and the bombesin analogue βAla-βAla-[Cha[13], Nle[14]]BN(7–14) to **6** was successfully achieved via amide coupling. Both ligand **6** and the bombesin bioconjugate **8** can readily form radiocopper complexes, **^{64}Cu⊂6** and **^{64}Cu⊂8**, with high stability. *In vitro* ligand competition experiments and stability studies in rat plasma medium gave no evidence of transchelation or demetalation. The ^{64}Cu complexes of **6** and **8** are relatively hydrophilic (log $D_{o/w} < -2.3$). Biodistribution studies of the bombesin conjugate **^{64}Cu⊂8** revealed an accumulation of the compound in the GRPR-expressing pancreas that is roughly comparable to the same bombesin analogue labeled with ^{99m}Tc (^{99m}Tc-BBS-38) (*49*). The bombesin conjugate **^{64}Cu⊂8** showed an extensive renal clearance of the activity, in contrast to ^{99m}Tc-BBS-38 or other BN(7–14) analogues labeled via ^{64}Cu-DOTA (*41*, *43–48*). The ^{64}Cu-TACN unit had a dominating influence on the nonspecific activity biodistribution, since the distribution data of **^{64}Cu⊂6** were very similar to that of **^{64}Cu⊂8**. Comparison with biodistribution data for $^{64}CuCl_2$ indicated that there was only marginal, if any, *in vivo* copper demetalation. The specificity of binding to the GRPR, as well as tumor uptake, will be evaluated in further experiments, and results will be reported in due course.

Our radiopharmacological data support the potential of **^{64}Cu⊂8** for GRPR imaging and indicate that the chelating agent **6** may be an attractive candidate for developing new copper radiopharmaceuticals because it may be efficiently labeled under mild conditions (ambient temperature, aqueous solution) and exhibits fast renal clearance.

ACKNOWLEDGMENT

This work was supported by the Swiss National Science Foundation and the Australian Research Council (ARC) through the Australian Centre for Electromaterials Science (ACES). G.G. was the recipient of a Swiss Fellowship for Prospective Researchers Grant (PBNE2-106771) and acknowledges financial support by the Forschungszentrum Dresden-Rossendorf during his stay in Germany. The authors thank Karin Landrock and Andrea Suhr for excellent technical assistance, and Christina Hultsch for MALDI-TOF measurements.

Supporting Information Available: Crystallographic data for **Cu_2⊂6** is provided in cif format. Figure S1 shows the binuclear structure of **Cu_2⊂6**. Tables of selected bond distances and angles for **Cu2⊂6**, of hydrogen bonds for **Cu2⊂6** and of biodistribution of **^{64}Cu⊂8**, **^{64}Cu⊂6**, and $^{64}CuCl_2$ in rats (mean ± SD of 4 animals per group) after single intravenous application in a tail vein (data in %ID, %ID/g, and SUV) are presented. The genetic engineering, expression, and validation of a fusion protein of avidin (AV) and a chimeric monoclonal antibody (mAb) to the human insulin receptor (HIR) is described. The 15 kDa avidin monomer was fused to the carboxyl terminus of the heavy chain of the HIRMAb. The fusion protein heavy chain reacted with antibodies specific for human IgG and avidin, and had the same affinity for binding to the HIR extracellular domain as the original chimeric HIRMAb. The fusion protein qualitatively bound biotinylated ligands, but was secreted fully saturated with biotin by COS cells, owing to the high level of biotin in tissue culture medium. Chinese hamster ovary (CHO) cells were permanently transfected with a tandem vector expressing the fusion protein genes, and high expressing cell lines were isolated by methotrexate amplification and dilutional cloning. The product expressed by CHO cells had high binding to the HIR, and migrated as a homogeneous species in size exclusion HPLC and native polyacrylamide gel electrophoresis. The CHO cells were adapted to a 4 week culture in biotin depleted medium, and the HIRMAb-AV fusion protein expressed under these conditions had 1 unoccupied biotin binding site per molecule, based on a [^{3}H]-biotin ultrafiltration assay. The HIRMAb-AV increased biotin uptake by human cells >15-fold, and mediated the endocytosis of fluorescein-biotin, as demonstrated by confocal microscopy. In summary, the HIRMAb-AV fusion protein is a new drug targeting system for humans that can be adapted to monobiotinylated drugs or nucleic acids.

INTRODUCTION

Molecular Trojan horses are genetically engineered receptor-specific monoclonal antibodies (mAb) that undergo receptor-mediated transport through biological membranes, including the blood-brain barrier (BBB) in vivo (*1*). Chimeric and humanized mAb's to the human insulin receptor (HIR) have been genetically engineered, expressed, and shown to have transport properties in vivo comparable to the original murine HIRMAb (*2*). The chimeric or humanized HIRMAb can target to brain, and other organs, recombinant proteins and monoclonal antibodies, and fusion proteins of the HIRMAb and recombinant neurotrophins, single chain Fv antibodies, and lysosomal enzymes have been produced and validated in vivo (*3–5*). However, the fusion protein technology cannot be used to deliver oligopeptides or short interfering RNA (siRNA), because fusion proteins of the HIRMAb and the oligopeptide or siRNA cannot be engineered.

Avidin–biotin technology, in conjunction with the fusion protein technology, can enable the in vivo targeting of peptides and siRNAs. In this approach, a fusion protein of the HIRMAb and avidin is genetically engineered in parallel with the production of a monobiotinylated peptide or siRNA. Recent work shows that siRNAs can be monobiotinylated on either the 5′- or 3′-terminus of the sense strand, and conjugated to streptavidin (SA)-mAb delivery systems without loss of gene siliencing biological activity (*6*). In prior work (*6*), the targeting mAb and the recombinant SA were conjugated with a thioether bond, as described previously (*7*). However, for manufacturing of human therapeutics, what is needed is a eukaryotic expression system for the production of mAb-avidin fusion proteins. Avidin is preferred over SA, because avidin is less immunogenic in humans than is SA (*8*). Previous investigations have demonstrated the feasibility of genetically engineering mAb-avidin fusion proteins, using a murine mAb to the rat transferrin receptor (TfR) (*9*). However, the HIRMAb delivery system is more active than is the TfRMAb delivery system (*1*).

The purpose of the present investigation is to examine the feasibility of the genetic engineering and eukaryotic expression of a fusion protein of avidin and the chimeric HIRMAb, which is designated HIRMAb-AV. The avidin monomer is fused to the carboxyl terminus of the HIRMAb heavy chain constant region (Figure 1). It is assumed that a HIRMAb-avidin (AV) fusion protein that is expressed in eukaryotic expression systems, such as Chinese hamster ovary (CHO) cells, would be fully saturated by the endogenous biotin present in the culture medium, and that this saturation of the fusion protein by the endogenous biotin would effectively eliminate the biotin binding activity of the fusion protein. Once biotin is bound to avidin, it does not readily dissociate off the protein. The dissociation constant (K_D) of avidin binding of biotin is 10^{-15} M, and the dissociation $t_{1/2}$ is 89 days (*10*). Therefore, the present studies examine the feasibility of production of mAb-avidin fusion proteins by CHO cells cultured in biotin-depleted medium.

MATERIALS AND METHODS

Cloning of Avidin cDNA. Avidin cDNA (GenBank X05343) corresponding to amino acids Ala^1-Glu^{128} of the mature chicken avidin protein was cloned by the polymerase chain reaction (PCR) using the oligodexoynucleotides (ODNs) described in Table 1 and an avidin plasmid DNA template. The avidin cDNA was cloned by PCR using 40 ng plasmid cDNA, 0.2 μM avidin

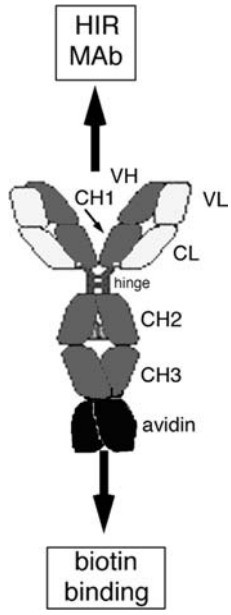

Figure 1. Structure of the fusion protein showing fusion of the amino terminus of the mature avidin monomer to the carboxyl terminus of the CH_3 region of the heavy chain of the chimeric HIRMAb. The fusion protein is a bifunctional molecule with dual functions. The fusion protein binds the HIR, at the BBB, to mediate transport into the brain, and binds biotinylated pharmaceuticals.

Table 1. Oligodeoxynucleotides Primers Used in the Cloning of Avdin cDNA

1) Avidin FWD: 5′-phosphate-CGTCTGCCAGAAAGTGCTCGCTGAC-3′
2) Avidin REV: 5′-phosphate-TCACTCCTTCTGTGTGCGCAGGCGA-3′

forward and reverse ODN primers (Table 1), 0.2 mM deoxynucleosidetriphosphates, and 2.5 U PfuUltra DNA polymerase (Stratagene, San Diego, CA) in a 50 μL Pfu buffer (Stratagene). The amplification was performed in a Mastercycler temperature cycler (Eppendorf, Hamburg, Germany) with an initial denaturing step of 95 °C for 2 min followed by 30 cycles of denaturing at 95 °C for 30 s, annealing at 55 °C for 30 s and amplification at 72 °C for 1 min; followed by a final incubation at 72 °C for 10 min. PCR products were resolved in 0.8% agarose gel electrophoresis, and the expected major single band of ~0.4 kb corresponding to the avidin cDNA was produced (Figure 2).

Engineering of HIRMAb-Avidin Expression Vectors. The ODNs used for PCR are 5′-phosphorylated for direct insertion into the *Hpa*I site of either the pHIRMAb-HC expression plasmid or the pHIRMAb tandem vector (TV) expression plasmid, respectively (Figure 3A,B), as described previously (*3*). The pHIRMAb-HC plasmid encodes the HC of the chimeric HIRMAb, and dual transfection of COS cells with this plasmid and a light chain (LC) expression plasmid, pHIRMAb-LC,

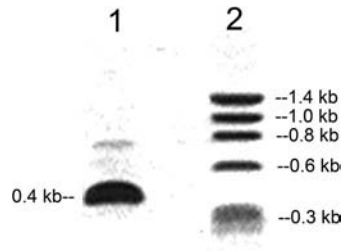

Figure 2. Ethidium bromide stain of agarose gel of avidin cDNA (lane 1), which was produced by PCR with avidin-specific ODN primers (Table 1). Lane 2: molecular weight DNA standards.

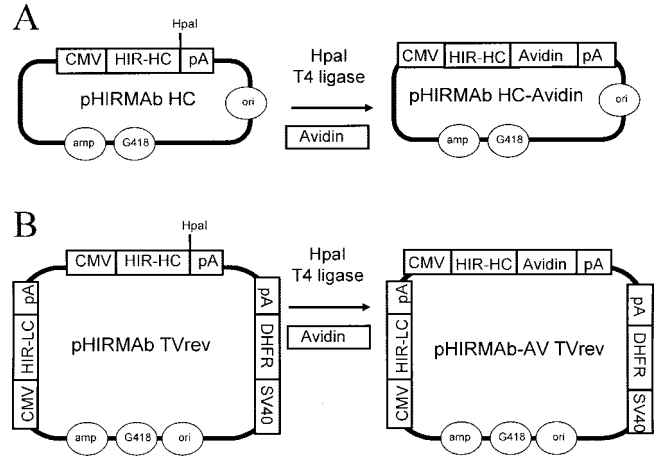

Figure 3. Engineering of the expression plasmid encoding the HIRMAb-AV fusion protein for either COS cells (A) or CHO cells (B). The PCR generated avidin cDNA was ligated into the single *Hpa*I site of either the universal pHIRMAb-HC plasmid (A) or the pHIRMAb tandem vector (B) to form the pHIRMAb-HC-Avidin vector or the pHIRMAb-AV TVrev, respectively. The pHIRMAb-HC plasmid encodes the heavy chain (HC) of the chimeric HIRMAb, and is 5′-flanked by the CMV promoter and is 3′-flanked by the BGH polyA (pA) sequence. The universal pHIRMAb-HC tandem vector (TV) contains expression cassettes, in series, for the HC and LC of the chimeric HIRMAb, and contains the expression cassette for murine DHFR in either forward (for) or reverse (rev) orientation relative to the HC and LC cassettes. In the pHIRMAb-AV TV rev, the DHFR cDNA is 5′-flanked by the hepatitis B virus pA sequence, and is 3′-flanked by the SV40 promoter.

allows for transient expression of either the chimeric HIRMAb, or a fusion protein, in COS cells. The pHIRMAb TV is a tandem vector (TV), which contains multiple genes, each within separate tandem expression cassettes, on a single piece of DNA, and includes the HC expression cassette, the LC expression cassette, and an expression cassette for the murine dihydrofolate reductase (DHFR) gene for amplification of cell lines with methotrexate (MTX). If the DHFR cassette is in the same forward (for) orientation as the HC and LC cassettes, then the TV is designated TVfor; if the DHFR cassette is in reverse (rev) orientation, then the TV is designated TVrev. The TV is engineered for permanent transfection of host cells, such as DG44 Chinese hamster ovary (CHO) cells. Placement of the HC fusion gene, the LC gene, and the genes encoding the selectable markers on a single piece of tandem vector DNA allows for isolation of a high expressing CHO line where the HC fusion gene and LC gene are equally expressed within the host cell. The selectable markers on the TV include the neomycin resistance gene (neo), for selection with G418, and the DHFR gene, for amplification of cell lines with MTX (Figure 3).

The forward avidin PCR primer introduces "CG" nucleotides to maintain the open reading frame and to introduce a Ser-Ser-Ser linker between the carboxyl terminus of the CH3 region of the HIRMAb HC and the amino terminus of the avidin, respectively. The fusion of the avidin monomer to the carboxyl terminus of each HC is depicted in Figure 1. This design sterically restricts the avidin to a dimeric configuration, which replicates the native conformation of avidin, which is a dimer of dimers (*11*). The avidin reverse PCR primer introduces a stop codon, "TGA", immediately after the terminal Glu of the mature avidin protein.

The HIRMAb HC and LC cDNA expression cassettes are driven by the cytomegalovirus (CMV) promoter and contain the bovine growth hormone (BGH) polyadenylation (pA) sequence (Figure 3). The DHFR expression cassette is under the influence of the SV40 promoter and the hepatitis B virus

pA sequence. The engineering of universal pHIRMAb-HC and the pHIRMAb TV vectors was performed by insertion of a single *Hpa*I site at the end of the HIRMAb HC CH3 open reading frame (orf) by site directed mutagenesis (SDM), as described previously (*3*).

Transient Expression of HIRMAb-Avidin Fusion Protein in COS Cells. COS cells were dual transfected with pHIRMAb-LC and pHIRMAb-HC-Avidin, or monotransfected with the pHIRMAb-AV tandem vector, using Lipofectamine 2000, with a ratio of 1:2.5, ug DNA/uL Lipofectamine. Following transfection, the cells were cultured in serum free VP-SFM (Invitrogen, Carlsbad, CA). The conditioned serum free medium was collected at 3 and 7 days. The fusion protein was purified by protein A affinity chromatography.

Permanent Expression of HIRMAb-AV Fusion Protein in Stably Transfected CHO Cells. Serum free medium (SFM) adapted DG44 CHO cells (Invitrogen) were electroporated with 5 ug pHIRMAb-AV TVfor or pHIRMAb-AV TVrev, following linearization with PvuI, using a Gene Pulser Xcell electroporator (BioRad, Hercules, CA). 5×10^6 cells were electroporated with the DNA in 200 uL of phosphate buffered saline (PBS) and 0.2 cm cuvettes using a square wave and 160 V. Cells were suspended in CHO serum free medium (SFM) (Hyclone, Logan, UT) and plated in 4 × 96-well plates. Selection of stable transfectants began 2 days following electroporation with 0.54 mg/mL G418. Aliquots of supernatant were taken for human IgG ELISA when colonies of transfectants were evident, i.e., 21 days. Positive clones were isolated and cultured individually for further characterization. DG44 cells lack endogenous DHFR, and rely on nutrients, hypoxanthine and thymidine (HT) for endogenous folate synthesis. Transfected cells carrying the TV express the exogenous DHFR. Transfected cell lines were further selected by placement in HT-deficient medium. Lines with amplification around the transgene insertion site were selected by subjecting the cells to increasing concentrations of MTX, starting at 20 nM MTX. Following stabilization of the cell line at 80 nM MTX, high producing clones were isolated by limited dilution cloning (DC) at 1 cell per well; a total of 4000 wells were plated at each round of DC, and medium IgG was measured with a human IgG ELISA using a high volume microplate dispenser and a microplate washer (Biotek, Winooski, VT).

SDS-PAGE and Western blotting. The purity of protein A purified fusion protein produced by COS or CHO cells was evaluated with a reducing 12% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Immunoreactivity was tested with a primary rabbit antibody to chicken egg white avidin (Abcam, Cambridge, MA) or a primary goat antiserum against human IgG heavy and light chains (Vector Laboratories, Burlingame, CA).

HIR Receptor Assay. The affinity of the fusion protein for the HIR extracellular domain (ECD) was determined with an ELISA using the lectin affinity purified HIR ECD. CHO cells permanently transfected with the HIR ECD were grown in serum free media (SFM), and the HIR ECD was purified with a wheat germ agglutinin affinity column, as previously described (*12*). The HIR ECD (0.2 ug/well) was plated on Nunc-Maxisorb 96 well dishes and the binding of the chimeric HIRMAb, the HIRMAb-AV fusion protein, or human IgG1 to the HIR ECD was detected with a biotinylated goat antihuman IgG (H+L) antibody (0.3 ug/well), and the ABC Elite detection system (Vector Laboratories). The concentration that caused 50% binding to the HIR ECD, the ED50, was determined by nonlinear regression analysis using the *WinNonlin* software.

Biotinylated BSA ELISA. The qualitative binding of the HIRMAb-AV fusion protein to a biotinylated ligand was assessed with an ELISA using biotinylated bovine serum albumin (BSA, Sigma Chemical Co., St. Louis, MO) as the ligand. The biotinylated BSA was plated to a 96-well ELISA plate (0.4 ug/well). Following aspiration, washing with HBS buffer with 0.05% Tween-20, where HBS = 0.01 M HEPES/0.15 M NaCl/pH = 7.4, and blocking with 2% goat serum in HBS, the HIRMAb-AV fusion protein or the chimeric HIRMAb was added in concentrations ranging from 0 to 3000 ng/mL for 90 min at room termperature. Detection of binding used a alkaline phosphatase conjugate of a goat antihuman kappa light chain antibody and *p*-nitrophenylphosphate.

Table 2. Concentration of HIRMAb-AV in Medium Following Transient Expression in COS Cells[a]

plasmid	IgG at 3 days (μg/mL)	IgG at 7 days (μg/mL)
pHIRMAb HC-avidin + pHIRMAb LC	4.7 ± 0.2	10.7 ± 2.2
pHIRMAb-AV TV-for	1.0 ± 0.2	4.7 ± 1.3
pHIRMAb-AV TV-rev	6.2 ± 0.2	7.8 ± 0.3

[a] Data are mean ± SE (n = 3).

[^{3}H]-Biotin Binding Ultrafiltration Assay. The quantitative binding of biotin to the HIRMAb-AV fusion protein was determined with an ultrafiltration assay, as described previously (*7*). The assay used [^{3}H]-biotin (Perkin-Elmer, Boston, MA), which had a specific activity of 50 uCi/nmol, and an Ultrafree-MC filter unit (Millipore, Billerica, MA), which has a low protein binding regenerated cellulose filter with a 10 kDa molecular weight cutoff. A 100 uL volume of PBS (0.01 M Na_2HPO_4/0.15 M NaCl/pH = 7.4) was added to a microfuge tube (MFT), which contained 0.1 uCi/mL of ^{3}H-biotin (2 nM), various concentrations of unlabeled biotin (25–1000 nM), and a fixed concentration of either avidin (5 ug/mL, 80 nM) or the HIRMAb-AV fusion protein (15 ug/mL, 80 nM). After a 30 min incubation at room temperature, the solution was transferred to the Ultrafree-MC ultrafiltration unit, which was placed in a 1.5 mL MFT, and the unit was centrifuged at 10 000 *g* for 5 min at room temperature. The total biotin binding was determined from the total biotin concentration and the percent binding of the [^{3}H]-biotin, which was determined by sampling the ultrafiltrate for ^{3}H radioactivity using a Perkin-Elmer liquid scintillation counter. The number of biotin binding sites per protein was determined from the ratio of the bound biotin concentration relative to the concentration of the avidin or the HIRMAb-AV fusion protein.

Equilibrium Dialysis of HIRMAb-AV Fusion Protein. The protein A affinity purified HIRMAb-AV fusion protein produced by transfected COS cells was fully saturated by the biotin in the VP-SFM tissue culture medium. The biotin concentration in this medium, 0.75 ug/mL (3100 nM), is in a 55-fold molar excess when the concentration of the HIRMAb-AV fusion protein is 10 ug/mL (Table 2). Therefore, the biotin binding sites on the expressed HIRMAb-AV fusion protein are fully saturated, which would prevent the use of the fusion protein for the drug delivery of biotinylated therapeutics. In an attempt to dissociate the biotin from the HIRMAb-AV fusion protein, the protein was subjected to extensive equilibrium dialysis, using an avidin sequestration technique. The HIRMAb-AV fusion protein was placed in a 1 mL Slide-A-Lyzer dialysis cassette with a 7 kDa molecular weight cutoff (Pierce Chemical Co., Rockford, IL), which was placed in 10 L of PBS, which contained 2 mg/L of avidin and 0.05% sodium azide, and dialysis was performed at 4 °C for 72 h, with a complete change of the 10L dialysis buffer at 36 h. The presence of high concentrations of avidin in the dialysis buffer was intended to sequester in the buffer any biotin that dissociated from the HIRMAb-AV fusion protein during the 72 h. The dialyzed HIRMAb-AV fusion protein was then recovered, and the binding of [^{3}H]-biotin was measured.

Culture of CHO Cells During Biotin Starvation. The CHO cells producing the HIRMAb-AV fusion protein were cultured in HyQ SFM4CHO-utility medium from Hyclone (Logan, UT), which contains 0.194 ug/mL (800 nM) of biotin. The medium biotin is present in a 14-fold molar ratio when the medium HIRMAb-AV fusion protein is 10 mg/L, and it would not be possible to produce fusion protein with unoccupied biotin binding sites. Therefore, the CHO cells were subjected to biotin starvation over a 27 day period. On day 1, CHO cells were centrifuged and resuspended in 25 mL fresh biotin-free serum free medium (SFM), which was supplemented with 20 nM biotin, which is a 40-fold reduction from the usual medium biotin concentration. The cells were cultured in square plastic (polyethylene terephthalate G copolyester, PETG) bottles (Nalge Nunc International, Rochester, NY), on an Innova 200 orbital shaker (New Brunswick Scientific (Edison, NJ) at 120 rpm, which was placed inside a humidified tissue culture incubator at 37 °C, and the cells continued to divide. Fresh SFM with 20 nM biotin was added on days 2 and 4 until the volume of medium was 135 mL. On day 8, fresh medium was added to a total volume of 400 mL and the biotin concentration was reduced to 10 nM. Over the next 18 days, the volume of medium was maintained at 400 mL (135 mL in each of 3 × 500 mL plastic square bottles). During this time, 1500 mL of conditioned medium was harvested from the 3 bottles, and the bottles were replenished with 1500 mL fresh biotin free SFM, so that the medium biotin concentration was successively reduced to 3 nM at day 14, to 1 nM at day 18, to 0.3 nM at day 21, and the culture was terminated at day 26.

HPLC Size Exclusion Chromatography. The presence of aggregates of the HIRMAb-AV fusion protein was evaluated with size exclusion chromatography (SEC) using a 7.8 mm × 30 cm (5 μm) G3000SW high pressure liquid chromatography (HPLC) column (Tosoh Bioscience LLC, Montgomeryville, PA), and a Perkin-Elmer Series 200 pump and UV/vis detector. The HIRMAb-AV fusion protein (100 ug), produced by CHO cells under conditions of biotin starvation, and purified by protein A affinity chromatography, was injected on to the column in a 200 uL volume of PBS, followed by elution in PBS at a flow rate of 0.5 mL/min with detection at 280 nm. The elution profile was recorded with a Servocorder model SR6253 chart recorder (Datamark Corp., Costa Mesa, CA), at 0.5 cm/min, and the chart paper was scanned with a UMAX PowerLook III scanner (Techville, Inc., Dallas, TX) into Adobe Photoshop.

Native Polyacrylamide Gel Electrophoresis. The ability of the HIRMAb-AV fusion protein to migrate into a native polyacrylamide gel was evaluated with native PAGE, using a 15% Ready Gel Tris-HCl Gel (Biorad, Richmond, CA), which was composed of a 8.6 × 6.8 cm 15% resolving gel and a 4% stacking gel. The HIRMAb-AV fusion protein, the chimeric HIRMAb, or human IgG1 was prepared in sample buffer (3 mM histidine, 3 mM MES, pH = 6.1, 30% glycerol), and 5 ug protein per lane was applied, where MES is 2-(*N*-morpholino)-ethanesulfonic acid. The electrophoresis buffer was 30 mM histidine, 30 mM MES, pH = 6.1, and electrophoresis was performed at 150 V for 4 h. Since the HIRMAb-AV fusion protein is cationic with a predicted isoelectric point (pI) of 9.02 (Results), the electrophoresis was performed with reversed electrode polarity. Following electrophoresis, the gel was stained with Coomasie blue, and photographed.

Biotin Uptake Assay. Human renal 293 epithelial cells were obtained from the American type Culture Collection (Rockville, MD), and grown on collagen coated 24-well dishes in DMEM medium with 10% fetal bovine serum. Prior to the uptake assay, the medium was discarded, and 0.4 mL/well of 0.01 M Tris/0.15 M NaCl/pH = 7.4 (TBS) was added, which contained 0.5 uCi/mL (11 nM) of [^{3}H]-biotin (Perkin-Elmer NET721) and either 0 or 5 ug/mL (26 nM) of the HIRMAb-AV fusion protein. After incubation for 2–120 min at 37 °C in a humidified chamber, the incubation was terminated by aspiration of the medium, washing of the wells with cold TBS, and the cell monolayer was solubilized in 0.5 mL/well of 1 N NaOH, followed by determination of ^{3}H radioactivity in the cell lysate and the medium. The cell protein was measured by the bicinchoninic acid (BCA) assay. The ^{3}H-biotin volume of distribution (VD) was determined from the ratio of DPM/mg protein divided by the DPM/uL medium.

Confocal Microscopy. The 293 cells were plated on collagen coated 4-well microscopy slides (Biocoat, Becton Dickinson Labware). Prior to the incubation, the medium was aspirated and replaced with 0.5 mL/well of fresh DMEM, containing 100 nM fluorescein-biotin (Invitrogen B-1370), and either 0 or 60 ug/mL of the HIRMAb-AV fusion protein. The cells were incubated at 37 °C for either 3 or 24 h. Following incubation, the medium was aspirated, the wells were washed well with cold PBS and fixed in 100% methanol for 20 min at −20 °C. The fixative was removed, the cells were washed with cold PBS, the nuclei were stained by incubation in 0.3 ug/mL propidium iodide (Sigma) for 5 min, the wells were washed with PBS, and coverslipped with Vectashield (Vector Laboratories, Burlingame, CA). Confocal microscopy was performed with a Zeiss LSM 5 PASCAL confocal microscope with dual argon and helium/neon lasers equipped with Zeiss LSM software for image reconstruction.

RESULTS

DNA sequencing of the expression cassette of the pHIRMAb-Avidin heavy chain expression plasmid (Figure 3A) encompassed 2,874 nucleotides (nt), including a 714 CMV promoter, a 9 nt Kozak sequence (GCCGCCACC), a 1782 nt coding sequence, and a 369 nt BGH transcription termination sequence. The deduced amino acid sequence showed the heavy chain fusion protein was comprised of 593 amino acids (AA), including a 19 AA signal peptide, a 443 AA chimeric HIRMAb heavy chain, a 3 AA linker (Ser-Ser-Ser), and a 128 AA avidin monomer, which was 100% identical to the AA sequence of avidin, NP_990651 (GenBank). The avidin sequence included a single N-linked glycosylation sequence, and a single internal disulfide bond. The predicted molecular weight of the fusion protein heavy chain, without glycosylation, is 63,191 Da with a pI of 9.02. The pHIRMAb-Avidin expression cassette was used for transient transfection of COS cells as described below. The fusion protein heavy chain (HC) expression cassette, the chimeric HIRMAb light chain (LC) expression cassette, and the DHFR expression cassette were all incorporated into a single tandem vector (TV), designated pHIRMAb-AV TVrev, as shown in Figure 3B; the reverse (rev) designation indicates the orientation of the DHFR cassette was in reverse direction, relative to the HC or LC expression cassettes. DNA sequence analysis showed the 3 expression cassettes were composed of 6332 nt, in the following order: a 731 nt CMV promoter, a 9 nt Kozak sequence, a 705 nt LC open reading frame (orf), a 291 nt BGH sequence, a 23 nt spacer, a 714 CMV promoter, a 9 nt Kozak sequence, a 1782 nt HC orf, a 301 nt BGH sequence, a 940 nt hepatitis B virus (HBV) transcription termination sequence, a 564 nt murine DHFR orf, a 9 nt Kozak sequence, and a 254 nt SV40 promoter. The murine DHFR sequence was 100% identical to nt 857–1510 of NM_010049. The predicted molecular weight of the LC was 23 398 Da with a pI of 5.45.

Dual transfection of COS cells with the pHIRMAb-HC-Avidin plasmid and the chimeric HIRMAb LC expression plasmid, pHIRMAb-LC, resulted in medium levels of fusion protein of the HIRMAb-AV fusion protein of 4.7 ± 0.2 μg/mL

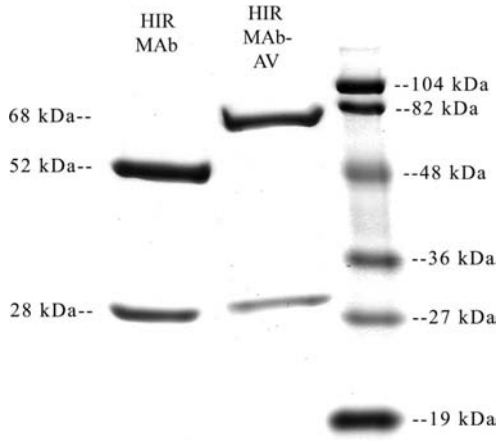

Figure 4. Reducing sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) of chimeric HIRMAb and the HIRMAb-AV fusion protein. The size of the light chain, 28 kDa, is identical for the chimeric HIRMAb and the fusion protein; the size of the heavy chain of fusion protein is about 16 kDa larger than the chimeric HIRMAb heavy chain, owing to the presence of the avidin monomer. The molecular weights shown for the standards are the actual molecular weights, whereas the molecular weights of the HIRMAb and HIRMAb-AV fusion protein are estimated.

and 10.7 ± 2.2 μg/mL at 3 and 7 days after transfection, respectively. These levels of medium IgG exceed those obtained following transient transfection of COS cells with the chimeric HIRMAb HC and LC genes. COS cells were also lipofected with the CHO cell tandem vectors, pHIRMAb-AV TVfor and pHIRMAb-AV TVrev, which are outlined in Figure 3B. The medium concentrations of the HIRMAb-AV fusion protein with the pHIRMAb-AV TV rev were comparable to that found with dual transfection with the separate HC and LC expression plasmids (Table 2). Lower levels of transient expression were observed with the pHIRMAb AV TVfor (Table 2).

The HIRMAb-AV fusion protein secreted to the serum free medium by transfected COS cells was purified with protein A affinity chromatography. The fusion protein was purified to homogeneity on reduced SDS-PAGE (Figure 4). The HIRMAb-AV fusion protein and the chimeric HIRMAb share the same light chain (LC) (Figure 4), whereas the size of the heavy chain (HC) of the HIRMAb-AV fusion protein is approximately 15 kDa larger than the size of the HC of the chimeric HIRMAb (Figure 4). Western blotting of the purified HIRMAb-AV fusion protein and chimeric HIRMAb was performed with primary antibodies to either human IgG (Figure 5A) or to avidin (Figure 5B). The antihuman IgG antibody reacts with both the HC and the LC of the HIRMAb-AV fusion protein and the chimeric HIRMAb, but not with avidin (AV), and the size of the immunoreactive HC is about 15 kDa larger for the HIRMAb-AV HC as compared to the HIRMAb HC (Figure 5A). The antiavidin antibody reacts with both avidin and the HC of the HIRMAb-AV fusion protein, but not with LC of the HIRMAb-AV fusion protein or chimeric HIRMAb, and the size of the immunoreactive HC is about 15 kDa larger for the HIRMAb-AV HC as compared to the HIRMAb HC (Figure 5B).

The affinity of the HIRMAb-AV fusion protein for the HIR ECD was determined with a binding assay, in parallel with measurements of the binding of the chimeric HIRMAb and human IgG1 (Figure 6). The concentration of chimeric HIRMAb that produced 50% saturation of binding, the ED_{50}, was 0.50 ± 0.06 nM, and the ED_{50} of the COS-cell derived HIRMAb-AV fusion protein was 1.13 ± 0.20 nM; human IgG1 did not bind to the HIR ECD (Figure 6).

An ELISA using biotinylated BSA as the ligand is outlined in Figure 7A. The HIRMAb-AV fusion protein, but not the

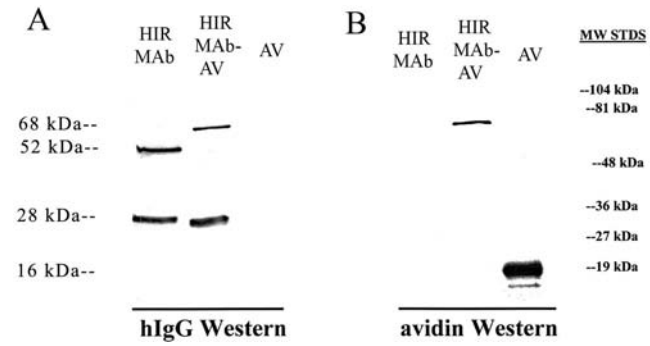

Figure 5. (A) Western blot with antihuman IgG primary antibody. The size of the heavy chain of the fusion protein and the chimeric HIRMAb is 68 kDa and 52 kDa, respectively, and the size of the light chain for either the fusion protein or the chimeric HIRMAb is 28 kDa. (B) Western blot with antiavidin antibody, which reacts with either fusion protein or avidin, but not with chimeric HIRMAb. MW standards (STDS) are shown on the right side. The molecular weights (MW) shown for the standards (STDS) are the actual molecular weights, whereas the molecular weights of the HIRMAb and HIRMAb-AV fusion protein are estimated.

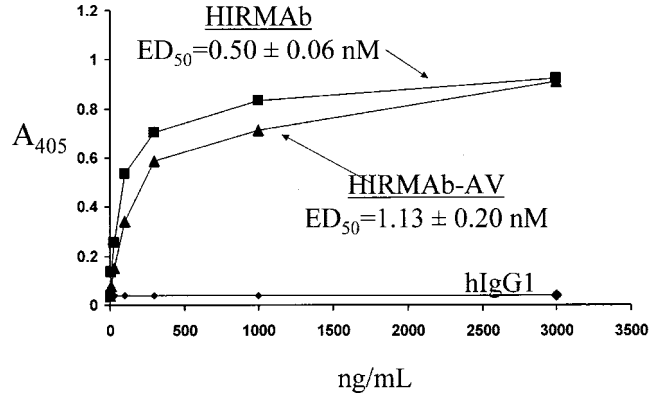

Figure 6. Saturable binding of the chimeric HIRMAb and the HIRMAb-AV fusion protein to the HIR ECD is demonstrated over a range of 0–3000 ng/mL. There is no binding to the HIR by human IgG1. The concentration that produces 50% binding, the ED50, was computed by nonlinear regression analysis with units of ng/ml, and converted to nM, based on the molecular weight of the HIRMAb, 150 000 Da, and the molecular weight of the HIRMAb-AV fusion protedin, 185 000 Da.

chimeric HIRMAb bound to the biotinylated BSA over a concentration range of 0–3000 ng/mL (Figure 7B). This ELISA provides a qualitative index of HIRMAb-AV binding to biotinylated substrate, but does not provide a measure of the number of biotin binding sites on the HIRMAb-AV fusion protein. The latter is determined with a quantitative biotin binding assay using a [^{3}H]-biotin ultrafiltration method (Methods). As shown in Figure 8, 80 nM avidin bound 250 nM biotin, which indicates there are 3 available biotin binding sites per avidin tetramer. However, in this assay, no measureable binding of [^{3}H]-biotin was observed for the COS-derived HIRMAb-AV fusion protein. This was attributed to near complete saturation of the available biotin binding sites on the HIRMAb-AV fusion protein by the endogenous biotin in the tissue culture medium. The medium biotin concentration was 3.1 uM (Methods), as opposed to the concentration of HIRMAb-AV fusion protein, which ranged from 26 nM to 59 nM (Table 2). The HIRMAb-AV fusion protein was subjected to extensive dialysis using an avidin sequestration technique (Methods). However, there were still no measureable biotin binding sites on the fusion protein, as determined with the ultrafiltration assay. These observations suggested that it would not be possible to produce the HIRMAb-AV fusion protein in eukaryotic expression

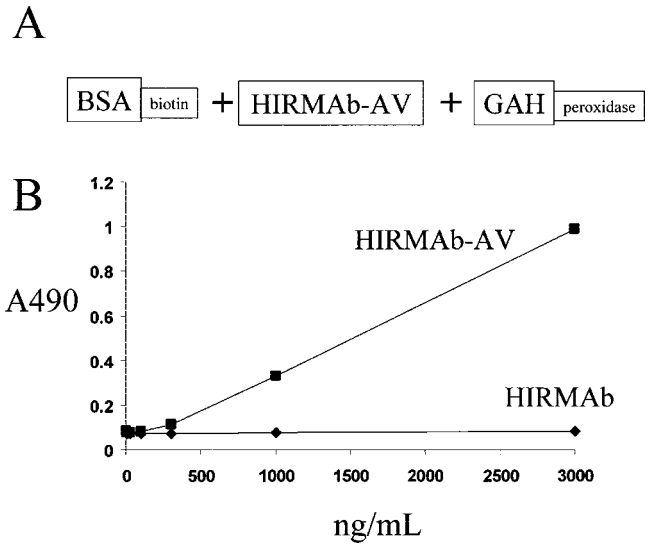

Figure 7. (A) Outline of biotinylated bovine serum albumin (BSA) ELISA. Binding of the HIRMAb-AV fusion protein to the biotinylated BSA is detected with a peroxidase conjugate of a goat antihuman (GAH) IgG. (B) Binding of the HIRMAb-AV fusion protein, but not the chimeric HIRMAb, to biotinylated BSA is demonstrated over a concentration range of 0–3000 ng/mL.

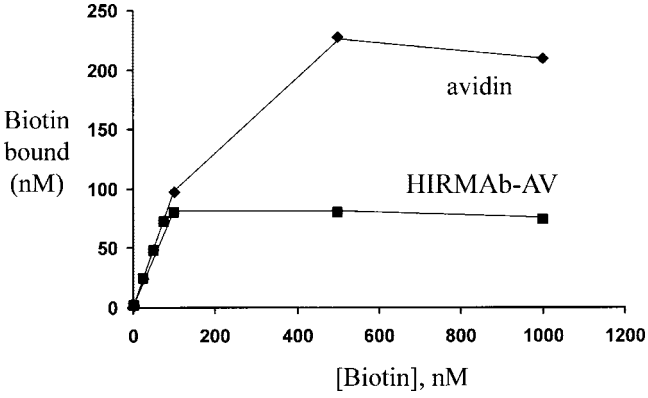

Figure 8. The binding of [^{3}H]-biotin to either avidin or the HIRMAb-AV fusion protein produced in biotin-starved CHO cells is measured with an ultrafiltration assay. The concentration of avidin or the HIRMAb-AV fusion protein in the assay is 80 nM.

systems that retained functional biotin binding sites, unless the host cell line was cultivated in biotin-depleted medium under conditions of biotin starvation over several weeks. This required the availability of a permanently transfected host cell line, such as Chinese hamster ovary (CHO) cells. Following permanent transfection of DG44 CHO cells with linearized pHIRMAb-AV TVrev (Figure 3B), a high producing CHO cell line was isolated following methotrexate amplification and dilutional cloning. The levels of human IgG in the medium of the transfected CHO line grown in serum free medium in shake flasks at a density of (1–2) $\times$ 10^6 cells/mL exceeded 40 mg/L following one round of dilutional cloning. The CHO cells were propagated in square plastic bottles on an orbital shaker, and the medium biotin concentration was reduced from 20 nM to 0.3 nM over a 27 day period (Table 3). During this time, the HIRMAb-AV fusion protein was secreted to the medium and the molar ratio of HIRMAb-AV fusion protein/biotin increased to >300 (Table 3).

The HIRMAb-AV fusion protein produced by the biotin-starved CHO cells was purified by protein A affinity chromatography. The protein eluted as a single homogeneous peak on SEC HPLC, and migrated with a molecular weight of approximately 400 kDa (Figure 9A). The fusion protein migrated as a single homogeneous product in native PAGE gels, and migrated faster than the chimeric HIRMAb or human IgG1, which is consistent with the higher cationic charge of the fusion protein as compared to the HIRMAb alone (Figure 9B).

Table 3. Expression of HIRMAb-AV by CHO Cells under Conditions of Biotin Depletion in Serum Free Medium[a]

day of culture	total cells ($\times 10^6$)	viable cells (%)	biotin (nM)	HIRMAb-Av/ biotin ratio
8	2.7	94	10	2.4
14	1.8	93	3	3.9
18	2.6	83	1	11
21	2.0	69	0.3	41
24	0.8	70	0.3	233
27	1.0	33	0.3	332

[a] Cells were grown in a shake flask on an orbital shaker in serum free medium. The medium biotin was reduced from 800 nM to 20 nM on day 1, and was reduced from 20 nM to 10 nM on day 8.

The affinity of the CHO derived HIRMAb-AV fusion protein for the HIR ECD was measured, and the ED50 of HIRMAb-AV fusion proteing binding was 0.58 $\pm$ 0.09 nM, which was not significantly different from the ED50 for the binding of the chimeric HIRMAb, 0.66 $\pm$ 0.14 nM. The HIRMAb-AV fusion protein produced by the biotin-starved CHO cells quantitatively bound [^{3}H]-biotin, and a 80 nM concentration of fusion protein bound 80 nM biotin (Figure 8), indicating 1 of the 2 biotin binding sites on the fusion protein was unoccupied.

The uptake of ^{3}H-biotin by human renal 293 cells was minimal over a 2 h incubation period at 37C (Figure 10). However, in the presence of the HIRMAb-AV fusion protein, the cell uptake of the ^{3}H-biotin increased over 15-fold, and the biotin VD exceeded 100 uL/mg protein at 120 min of incubation (Figure 10). Confocal microscopy showed no measureable uptake of fluorescein-biotin at 3 or 24 h of incubation in the absence of the HIRMAb-AV fusion protein (Figure 11A). However, in the presence of the HIRMAb-AV fusion protein, there was penetration of the fluorescein-biotin into the intracellular compartment, which was visible in intracellular endosomes, at 3 h (Figure 11B) and 24 h (Figure 11C,D) of incubation.

DISCUSSION

The results of this study are consistent with the following conclusions. First, a fusion gene has been genetically engineered, which encodes a fusion protein wherein the amino terminus of avidin is fused to the carboxyl terminus of the CH_3 region of the HC of the chimeric HIRMAb (Figure 1). Second, following expression in either COS or CHO cells, the HC of the fusion protein is 15 kDa larger than the HC of the chimeric HIRMAb (Figure 4), and the fusion protein HC reacts with antibodies to both human IgG and avidin (Figure 5). Third, the fusion protein is a bifunctional molecule, and binds both the HIR ECD (Figure 6), and binds biotinylated ligands (Figure 7). Fourth, the fusion protein can be produced in CHO cells under conditions of biotin starvation of periods of at least 27 days (Table 3), and the fusion protein retains unoccupied biotin binding sites (Figure 8). Fifth, the HIRMAb-AV fusion protein produced by CHO cells under conditions of biotin starvation is highly stable, does not form aggregates (Figure 9B), and elutes as a monomeric species on HPLC SEC (Figure 9A). Sixth, the HIRMAb-AV fusion protein enhances the cell uptake of biotin (Figure 10) or biotinylated ligands, such as fluorescein-biotin (Figure 11).

The design of the HIRMAb-AV fusion protein places the 15 kDa avidin monomer at the carboxyl terminus of the heavy chain of the chimeric HIRMAb (Figure 1). This places the avidin moiety in a configuration that favors a parallel dimer conformation, which replicates the parallel association of 2 avidin or

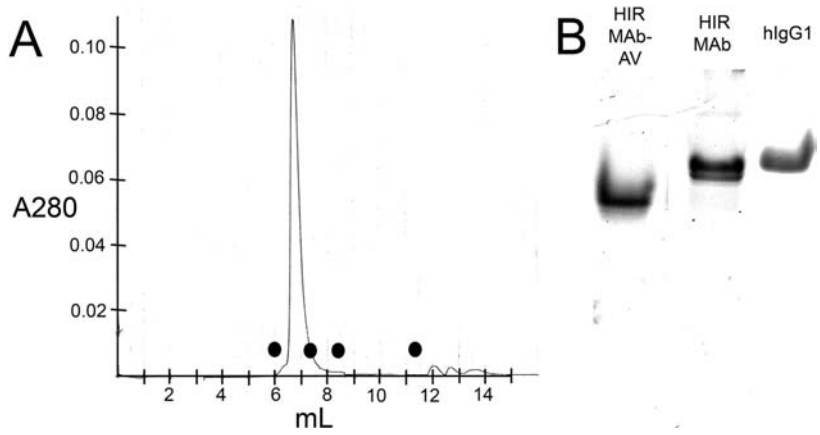

Figure 9. (A) SEC HPLC of the HIRMAb-AV fusion protein produced by biotin-starved CHO cells. The migration of 4 molecular size markers is shown by the solid circles, and in left-to-right order include, blue-dextran-2000 (2 million Da), ferritin (440 kDa), aldolase (158 kDa), and RNase A (14 kDa). (B) Native polyacrylamide gel electrophoresis (PAGE) of the HIRMAb-AV fusion protein, the chimeric HIRMAb, and human IgG1.

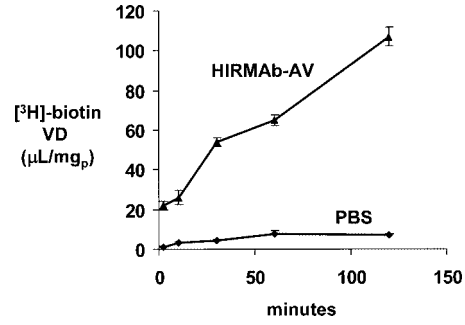

Figure 10. Volume of distribution (VD) of [^{3}H]-biotin in human 293 cells at 2 to 120 min of incubation at 37 °C after comixture of the labeled biotin with either PBS or the HIRMAb-AV fusion protein. Data points are mean ± SE (n = 4 dishes per time point).

streptavidin monomers to form a dimer (*11*). Placement of the avidin monomer at the carboxyl terminus of the heavy chain, as opposed to the amino terminus eliminates interference of antibody binding to the HIR. Avidin is a dimer of dimers (*11*), and the HIRMAb-AV fusion protein may also form a tetrameric structure formed from the association of 2 antiparallel fusion proteins. The evidence for this is the SEC HPLC, which shows the HIRMAb-AV fusion protein migrates with a molecular weight of about 400 kDa, which is twice the expected molecular weight of the glycosylated HIRMAb-AV fusion protein. Avidin has the maximal affinity for biotin when the protein is assembled in the tetrameric configuration. The fact that bound biotin could not be dissociated off the HIRMAb-AV fusion protein despite 72 h of dialysis against a 10 000-fold increase in volume with high concentrations of avidin in the dialysate (Methods) is evidence for the very high affinity of the HIRMAb-AV fusion protein for biotin.

The HIRMAb-AV fusion protein is secreted in high amounts in transfected COS cells (Table 2). The size of the heavy chain (HC) of the fusion protein is about 15 kDa larger than the HC of the chimeric HIRMAb, based on either SDS-PAGE (Figure 4) or Western blotting with an antihuman IgG antibody (Figure 5A). An antiavidin antibody reacts with the fusion protein HC, or with avidin, but not with the HC of the HIRMAb, or the light chain (LC) of either the HIRMAb or the HIRMAb-AV fusion protein (Figure 5B). The COS cell-derived HIRMAb-AV fusion protein binds with high affinity to the HIR, albeit with about 50% reduced affinity as compared to the chimeric HIRMAb (Figure 6). However, the affinity of the CHO-derived HIRMAb-AV fusion protein for the HIR is identical to that of the chimeric HIRMAb (Results), and this may be due to differential glycosylation in CHO and COS cells.

The HIRMAb-AV fusion protein produced by COS cells is fully saturated with biotin, owing to the 50-fold molar excess of biotin over the fusion protein (Results). Nevertheless, the fusion protein reacts with biotinylated BSA in an ELISA (Figure 7). This reactivity is most likely due to the presence of a minor fraction of unoccupied biotin binding sites, perhaps <5% of the total. The biotinylated BSA ELISA only is a qualitative index of biotin binding of the HIRMAb-AV fusion protein. The [^{3}H]-biotin ultrafiltration assay is a quantitative assay of biotin binding sites on the HIRMAb-AV fusion protein, and this assay shows minimal biotin binding by the fusion protein produced by COS cells. Moreover, it is not possible to displace the biotin from the HIRMAb-AV fusion protein with extensive dialysis (Results).

The HIRMAb-AV fusion protein might be produced with unoccupied binding sites if the host cell was subjected to biotin starvation. Therefore, a CHO cell line was permanently transfected with the pHIRMAb-AV TVrev (Figure 3B). Owing to the presence of the HC gene, the LC gene, and the DHFR gene all on a single piece of DNA, it was possible to isolate a high producing cell line following MTX amplification and 1 round of dilutional cloning. The CHO cell-derived fusion protein had high affinity for the HIR, did not form aggregates based on SEC HPLC or native PAGE (Figure 9), and was produced at levels >40 mg/L of human IgG in the serum free conditioned medium in shake flasks at a cell density of (1–2) × 10^6 cells/mL. The HIRMAb-AV fusion protein produced by CHO cells under conditions of biotin starvation bound ^{3}H-biotin, and accelerated biotin uptake into human epithelial cells with a >15-fold increase in VD of the biotin at 2 h of incubation (Figure 10). The HIRMAb-AV fusion protein facilitated cell uptake of fluorescein-biotin, as demonstrated by confocal microscopy (Figure 11). There was no measureable cell uptake of fluorescein-biotin alone (Figure 11A). However, following attachment of the fluorescein-biotin to the HIRMAb-AV fusion protein, there was enhanced cell uptake into the intracellular endosomal compartment at 3 and 24 h of incubation (Figure 11B,C,D).

The expression of avidin, or avidin fusion proteins, in CHO cells has not been previously described, although avidin has been expressed in baculovirus, yeast, and bacterial expression systems (*14*). In order to produce fusion protein with unoccupied biotin binding sites, it was necessary to develop a culture methodology whereby the CHO cells were grown under conditions of biotin depletion. As shown in Table 3, the cells could be maintained for 4 weeks in very low biotin medium,

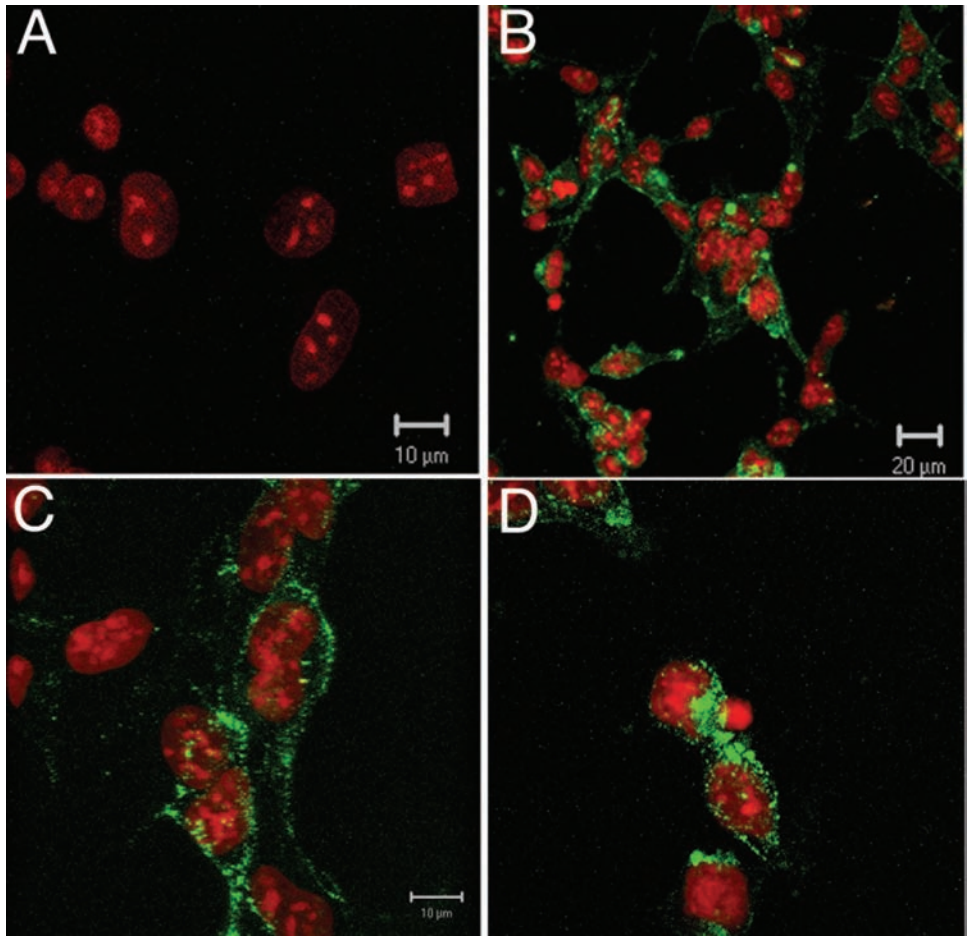

Figure 11. Confocal microscopy of human 293 cells following the addition to the medium of fluorescein-biotin comixed in either PBS (A) or the HIRMAb-AV fusion protein (B,C,D). The cells were incubated for either 3 h (B) or 24 h (A,C,D), and were photographed with either a 40× (B) or 100× (A,C,D) objective. The nuclei are stained red by propidium iodide.

and the HIRMAb-AV fusion protein was continuously produced under these conditions. The biotin ultrafiltration assay demonstrated that there was 1 biotin binding site per antibody molecule (Figure 8). There are 2 predicted biotin binding sites per fusion protein (Figure 1). Therefore, these data show that the HIRMAb-AV fusion protein can be produced in CHO cells under conditions of biotin starvation, to enable production of fusion protein with high affinity biotin binding properties.

In summary, these studies describes the genetic engineering, expression, and validation of a drug delivery system that is active in humans, and is designed to deliver monobiotinylated pharmaceuticals, including siRNA (*6*), across biological membranes via the insulin receptor. The engineering of the HIRMAb-AV fusion protein represents the merger of molecular Trojan horse technology and avidin–biotin technology in drug targeting. Owing to the extremely high affinity of avidin binding of biotin ($K_D = 10^{-15}$ M, dissociation $t_{1/2} = 89$ days), the bond between the Trojan horse HIRMAb and the biotinylated therapeutic is extremely stable in vivo. The avidin–biotin bond does not spontaneously dissociate in vivo, and is disrupted only via the action of tissue enzymatic reactions, particularly in liver and kidney (*15*). Owing to the rapid binding of biotinylated drugs to avidin, the present approach enables "2-vial pharmaceutics," where the HIRMAb-AV fusion protein is formulated in the first vial, and the monobiotinylated therapeutic is formulated in a second vial, and the 2 vials are mixed prior to systemic administration.

The concern with avidin fusion proteins is immunogenicity of the chicken avidin in humans, and a human antiavidin response (HAAR). However, avidin has been administered to humans in 5–10 mg doses intravenously without immunologic reactions (*8, 16, 17*). The human hypo-responsiveness to avidin may arise from oral antigen feeding (*18*). Avidin is abundant in egg whites, and virtually all members of Western societies have consumed dietary eggs, which is a form of oral avidin antigen feeding that could induce immune tolerance in humans to avidin. Support for this hypothesis is the finding that humans have serum antibodies to avidin, and that the titer is lower in subjects on egg-free diets (*19*). Therefore, an avidin fusion protein may be administered to humans without immunological reactions.

Received November 5, 2007; Revised Manuscript Received January 4, 2008

New surface-modified iron oxide nanoparticles were developed by precipitation of Fe(II) and Fe(III) salts with ammonium hydroxide and oxidation of the resulting magnetite with sodium hypochlorite, followed by the addition of poly(L-lysine) (PLL) solution. PLL of several molecular weights ranging from 146 (L-lysine) to 579 000 was tested as a coating to boost the intracellular uptake of the nanoparticles. The nanoparticles were characterized by TEM, dynamic light scattering, FTIR, and ultrasonic spectrometry. TEM revealed that the particles were ca. 6 nm in diameter, while FTIR showed that their surfaces were well-coated with PLL. The interaction of PLL-modified iron oxide nanoparticles with DMEM culture medium was verified by UV–vis spectroscopy. Rat bone marrow stromal cells (rMSCs) and human mesenchymal stem cells (hMSC) were labeled with PLL-modified iron oxide nanoparticles or with Endorem (control). Optical microscopy and TEM confirmed the presence of PLL-modified iron oxide nanoparticles inside the cells. Cellular uptake was very high (more than 92%) for PLL-modified nanoparticles that were coated with PLL (molecular weight 388 00) at a concentration of 0.02 mg PLL per milliliter of colloid. The cellular uptake of PLL-modified iron oxide was facilitated by its interaction with the negatively charged cell surface and subsequent endosomolytic uptake. The relaxivity of rMSCs labeled with PLL-modified iron oxide and the amount of iron in the cells were determined. PLL-modified iron oxide-labeled rMSCs were imaged *in vitro* and *in vivo* after intracerebral grafting into the contralateral hemisphere of the adult rat brain. The implanted cells were visible on magnetic resonance (MR) images as a hypointense area at the injection site and in the lesion. In comparison with Endorem, nanoparticles modified with PLL of an optimum molecular weight demonstrated a higher efficiency of intracellular uptake by MSC cells.

INTRODUCTION

Superparamagnetic iron oxide nanoparticles have been widely used for numerous *in vitro* and *in vivo* biomedical applications (*1*). Such applications exploit two major advantages of magnetic iron oxides: their low toxicity for humans (*2*) and their outstanding magnetic properties, which allow the targeting of drugs to a tumor area through external magnetic fields (*3*). Most *in vitro* applications have focused on immunoassays (*4, 5*), the detection and separation of cells, viruses (*6*), hormones (*7, 8*), oligonucleotides (*9*), DNA (*10*) and proteins (*11*). *In vivo* applications have concentrated on cell and tissue engineering, including cell tagging, tracking, and imaging (*12*) (magnetic resonance imaging, MRI); targeted drug delivery (*13, 14*); gene delivery systems and gene therapy (*15*); as well as targeted hyperthermia of cancers (*16*), tissue repair, and the detoxification of biological fluids (*17*). MRI makes use of the fact that magnetic nanoparticles generate a magnetic field and thus influence their immediate vicinity (*18*). In these applications, there is a growing need for the highly specific, efficient, and rapid internalization of nanoparticles into specific target cells, but this is severely limited by several factors (*19*): (i) nanoparticle aggregation (nanoparticles have a large surface/volume ratio and tend to agglomerate); (ii) the short half-life of the particles in blood circulation (when nanoparticles agglomerate, or adsorb plasma proteins, they are quickly eliminated from the bloodstream by macrophages of the mononuclear phagocyte system before they can reach the target cells); (iii) the low efficiency of the intracellular uptake of nanoparticles; and (iv) nonspecific targeting. Biocompatible polymers and targeting agents are therefore attached to the nanoparticle surface to prevent agglomeration, to make the nanoparticles more biocompatible, and to increase their nonspecific intracellular uptake (*20, 21*). All applications require that the nanoparticles have high magnetization values and a size smaller than 100 nm, with a narrow particle size distribution, so that the particles have uniform physical and chemical properties. Compared with paramagnetics, superparamagnetic iron oxide particles have higher molar relaxivities, and, when used as blood pool and tissue-specific agents, may offer advantages at low concentrations (*22*). The nature of the surface coating on the nanoparticles not only determines the overall size of the colloid, but also plays a significant role in the biokinetics and biodistribution of the nanoparticles in the body. Various biological molecules such as antibodies, proteins, targeting ligands, and so forth may also be bound to the nanoparticle surface to make the particles target-specific.

Since the introduction of particular contrast agents in MRI use in 1987, most superparamagnetic iron oxides (SPIO) and ultrasmall superparamegnetic iron oxides (USPIO) agents, taken up by macrophages, have been prepared using dextran or other types of polymer coatings to achieve good dispersion in water

and selectivity (*23*). Dextran-coated nanoparticles, however, do not show sufficient cellular uptake to enable cell tracking, probably because of a relatively inefficient fluid-phase endocytosis pathway. Polymer coatings significantly increase the particle size, which may affect their penetration and metabolic clearance rate in the body. A few recent papers have reported the use of nonpolymer-coated superparamagnetic nanoparticle dispersions in MR imaging (*24*). They were prepared in the water phase and stabilized, e.g., by citrate (*25*) or tetramethylammonium hydroxide (*24*), providing some advantages over those that require additional polymer protection for stabilization. Nanoparticles without a polymer coating have a much smaller size for distinct biodistribution and metabolic clearance profile than conventional polymer-coated-particles. It is, however, not clear whether these particles can be taken up by cells.

Stem cells are the body's master cells and have a unique ability to renew and give rise to other specialized cell types for the development of a tissue (*26*). Cell transplantation is a powerful treatment method for many common diseases, including brain and spinal cord injury; however, current experiments with stem cells do not give information about the behavior of the transplanted cells in the host organism *in vivo*, especially about their migration and fate within the target structures and their potential neoplastic growth. The lack of these data represents a serious obstacle for the clinical use of cell therapy. Human medicine would benefit from the labeling of implanted stem cells and the use of noninvasive methods to image the labeled cells after implantation. Superparamagnetic particles coupled to the cells could target these cells to the desired site in the body.

The preparation of stable iron oxide colloids is not easy. The first paper of this series was focused on the labeling of stem cells with iron oxide nanoparticles coated with D-mannose (*27*). The objective of the present study was to investigate the use of poly(L-lysine) (PLL), which is commonly used to enhance cell adhesion to the surface of a culture dish in *in vitro* cell cultivation, as a prospective vehicle for iron oxide nanoparticle transport into cells. The endocytosis behavior of PLL-modified particles was determined using mesenchymal stem cells (MSCs) and compared with that of control and uncoated superparamagnetic iron oxide nanoparticles.

EXPERIMENTAL SECTION

Materials. $FeCl_2 \cdot 4H_2O$ and $FeCl_3 \cdot 6H_2O$ were purchased from Fluka (Buchs, Switzerland), sodium hypochlorite solution (NaOCl) from Bochemie (Bohumín, Czech Republic), and sodium citrate dihydrate from Lachema (Brno, Czech Republic). All other reagent-grade chemicals were purchased from Aldrich (Milwaukee, WI, USA) and used as received. L-Lysine (LL) and poly(L-lysine) (PLL) hydrobromide (M_w = 9200; 58 900; 93 800; 388 100; and 579 000) and gelatin were from Sigma (St. Louis, MO, USA) and the commercial contrast agent Endorem from Guerbet (Roissy, France). Ultrapure Q water ultrafiltered on a Milli-Q Gradient A10 system (Millipore, Molsheim, France) was used for the preparation of solutions.

Preparation of Uncoated Iron Oxide Nanoparticles and their Treatment with Poly(L-lysine) or L-Lysine. In a typical experiment, 12 mL of 0.2 M $FeCl_3$ aqueous solution was mixed with 12 mL of 0.5 M NH_4OH solution (less than an equimolar amount) under sonication (Sonicator W-385; Heat Systems-Ultrasonics, Inc., Farmingdale, NY, USA) at laboratory temperature for 2 min to form colloid $Fe(OH)_3$. Then, 6 mL of aqueous 0.2 M $FeCl_2$ was added under sonication and the mixture poured into 36 mL of 0.5 M NH_4OH aqueous solution. The resulting magnetite coagulate was left to grow for 15 min, the magnetically separated and repeatedly (7–10×) washed (peptized) with Q-water to remove all impurities (including NH_4Cl) remaining after the synthesis. Finally, 1.5 mL of 0.1 M sodium citrate was added under sonication, and the magnetite was oxidized by the slow addition of 1 mL of 5% sodium hypochlorite solution to the maghemite to enhance the redox stability. The above-described washing procedure was repeated to yield the primary colloid. 0.2 mL of aqueous L-lysine (LL) or poly(L-lysine) solution (concentration 1 mg/mL) was added dropwise with stirring to 10 mL of primary iron oxide colloid, diluted to a concentration of 2.2 mg iron oxide/mL. The obtained mixture was sonicated for 5 min and used in experiments.

Particle Characterization. The morphology of the colloids was observed by transmission electron microscopy (TEM) using a JEOL JEM 200 CX. Particle size distributions were obtained using Atlas image analysis software (Tescan, Brno, Czech Republic) (*27*). For the measurements, a drop of a dilute dispersion was spread on a carbon-coated copper grid, and the grid was air-dried at room temperature before viewing under the microscope. The particle size and distribution were determined by the measurement of at least 300 particles for each sample. Two types of mean particle size were calculated: the number-average particle size (D_n) and the weight-average particle size (D_w; $D_n = \Sigma D_i/N$ and $D_w = \Sigma D_i^4/\Sigma D_i^3$, where N is the number of particles). The particle size distribution was characterized by the polydispersity index (PDI = D_w/D_n). Moreover, the hydrodynamic diameter (*z*-average), polydispersity (from 0 - monodisperse particles - to 1 - polydisperse particles) from the cumulative analysis of time correlation functions, and the surface zeta potential were determined by dynamic light scattering (DLS) using an Autosizer Lo-C (Malvern Instruments Ltd., Malvern, Great Britain).

The PLL coating on the surface of the magnetic nanoparticles was examined using a Thermo Nicolet Nexus 870 FTIR spectrometer (Madison, WI, USA) in an H_2O-purged environment with DTGS (deuterated triglycine sulfate) detector. The Golden Gate single-reflection ATR system (Specac Ltd., Orpington, Great Britain) was used to measure the ATR spectra of powdered samples over a wavenumber range 400–4000 cm^{-1}. Typical parameters were as follows: 256 sample scans, resolution 4 cm^{-1}, Happ-Genzel apodization, KBr beamsplitter. The samples for measurement were prepared by freeze−drying purified PLL-coated nanoparticles (centrifuged four times at 14 000 rpm for 1 h).

Differences in ultrasonic velocity between the reference (water) and the iron oxide colloid were monitored under the slow addition of various amounts of PLL (M_w = 388 100) using an HR-US 102 ultrasonic spectrometer (Ultrasonic Scientific, Dublin, Ireland). In a typical experiment, 1 mL of iron oxide colloid (c = 18 mg/mL) was in the first cell and 1 mL of Q-water in the second cell as a reference. PLL solution (c = 1 mg/mL) was then simultaneously added in 10 μL aliquots to both cells with a Hamilton syringe.

In protein adsorption experiments, 1 mL of the colloid solution with a concentration of 22 mg of iron oxide/mL was mixed with 1 mL of DMEM/10% FBS (fetal bovine serum) on a Vortex-T Genie-2 for 1 h; subsequently, the liquid was separated from the solid by centrifugation (14 000 rpm) for 1 h and measured on a Perkin-Elmer Lambda 20 UV/vis spectrophotometer (Norwalk, CT, USA). An aqueous solution of DMEM/10% FBS (1/1 v/v) served as a standard.

To confirm that PLL was not released from PLL-coated iron oxide nanoparticles during contact with the culture medium, both uncoated (no. 1, Table 1) and PLL-coated iron oxides (no. 4; 22 mg of γ-Fe_2O_3/0.64 mL of water) were mixed with 1 mL of DMEM/10% FBS or 1 mL of 0.15 M NaCl solution for 1 h, and after magnetic separation the supernatant was hydrolyzed in 6 M HCl for 16 h at 115 °C. The concentration of L-lysine in the supernatant was determined by the standard FMOC/*N*-

(9-fluorenylmethoxycarbonyl)/ method and reverse-phase HPLC equipped with a Flouromonitor 4100 detector (both LDC Analytical, Riviera Beach, FL, USA) using Macherey-Nagel 125/4 Nucleosil 120-3 C-8 column (Düren, Germany).

Cell Cultures. The isolation of mesenchymal stem cells (MSC) was performed as previously described (*28*). To isolate rat bone marrow mesenchymal stem cells (rMSCs), the femurs of 4-week-old Wistar rats were dissected. The ends of the bones were cut, and the marrow extruded with 5 mL of DMEM with L-glutamine (PAA, Pasching, Austria), using a syringe. Marrow cells were cultivated in DMEM/10% FBS with 100 U/mL of penicillin and 100 U/mL of streptomycin. After 24 h, the nonadherent cells were removed by replacing the medium. The medium was changed every 2–3 days as the cells grew to confluence. The cells were lifted by incubation with 0.25 wt % trypsin.

Human mesenchymal stem cells (hMSC) were obtained from the bone marrows of healthy donors. Bone marrow aspirates were diluted with phosphate-buffered saline (PBS) and centrifuged through a density gradient (Ficoll-Paque Plus, GE Healthcare Life Sciences, Vienna, Austria) for 30 min at 1000 *g* (Hettich, Germany). Nucleated cells from the interface were cultivated in Alpha-Modified Eagle Medium (α-MEM, Gibco BRL, Paisley, Scotland) containing 10% FBS, 100 units/mL penicillin, and 0.1 mg/mL streptomycin. After 48 h, the nonadherent cells were removed by replacing the medium.

Transmission Electron Microscopy of Labeled Cells. For electron microscopic examination, rMSCs were fixed at 4 °C in 2.5% buffered glutaraldehyde for 1 h, then stained with 1% osmium tetroxide for 2 h. The cells were successfully dehydrated with increasing concentrations of ethanol, immersed in propylene oxide, and embedded in Epon 812 resin (Agar Scientific Ltd., Standsted, UK). The samples were cut into ultrathin sections (~60 nm), contrasted with 4% uranyl acetate and Reynold's lead citrate, and examined using a Philips Morgagni 268 electron microscope.

Quantitative Analysis of Labeled Cells. rMSCs were cultivated in duplicate on uncoated 6-well culture plates at a density 10^5 cells/mm^2. Endorem- or poly(L-lysine)-modified nanoparticles were added to the culture medium (10 μL/mL) for 72 h. The culture medium containing excess particles was removed, and the cell were washed with PBS (three times), fixed with 4% paraformaldehyde in 0.1 M PBS, and stained to produce Fe(III) ferrocyanide (Prussian Blue). Labeled and unlabeled cells were quantified using an inverted light microscope (Axiovert 200, Zeiss, Göttingen, Germany) by counting five random fields per well and three wells per run. The cells captured on each image were manually labeled as Prussian Blue positive or negative; the labeled cells were then counted and the staining intensity of the Prussian Blue positive cells was evaluated using the image analysis toolbox in *Matlab 6.1* (The MathWorks, Natick, MA, USA). The threshold was set in the image analysis toolbox for dark blue, and all cells above this threshold were considered intensely stained. Histograms of the intensity of the cytoplasmic staining were constructed.

Comparison of Relaxivity between rMSC Labeled with Endorem or PLL-Modified Iron Oxide. The following suspensions in 4% gelatin were prepared: pure contrast agent (Endorem or PLL-modified iron oxide no. 4), unlabeled rMSC (4000, 1200, and 200 cells per μL), and cells labeled with Endorem or with PLL-modified iron oxide (4000, 2000, 1600, 1200, 800, 400, or 200 cells per μL). MR relaxation times T_1 and T_2 were measured on an 0.5 T Bruker Minispec MQ20 relaxometer (Rheinstetten, Germany). The T_1 and T_2 values were converted to relaxivities r_1 and r_2; relaxation rates $R_1 = 1/T_1$ and $R_2 = 1/T_2$ were related to the actual concentrations of iron or to the cell concentration c: $r_1 = (R_1 - R_{1G})/c$ (l s^{-1} mmol^{-1}), $r_2 = (R_2 - R_{2G})/c$ (l s^{-1} mmol^{-1}), where R_{1G} and R_{2G} are the relaxation rates of pure 4% gelatin.

Iron Analysis. The amount of iron in the cells after mineralization was determined by spectrophotometry. Cell-containing samples were mineralized by the addition of 5 mL HNO_3 and 1 mL H_2O_2 in an ETHOS 900 microwave mineralizator (Millestone, Sydney, Australia). Deionized water was added to reach a total volume of 100 mL. The iron content was determined using Spectroflame M120S apparatus (Spectro, Littleton, MA, USA) calibrated with a standard Astasol solution (Analytika, Prague, Czech Republic). The measurements were repeated four times, and the mean value was determined.

Cell Grafting. Rats were anesthesized with isoflorane and mounted in a stereotactic frame. Using aseptic technique, a hole (1 mm) was drilled in the skull to expose the dura overlying the cortex. Poly(L-lysine)-modified iron oxide-labeled cells or Endorem-labeled cells (1000, 500, or 100 cells suspended in 2 μL of PBS) were slowly injected intracerebrally into the brain over a 10 min period. Unlabeled cells (10 000 in 5 μL of PBS) were injected as a control. The opening was closed by bone wax and the skin was sutured.

MR Imaging. MR images were obtained using a 4.7 T Bruker spectrometer equipped with a homemade surface coil. The rats were anesthesized by passive inhalation of 1.5–2% isoflorane in air. Breathing was monitored during the measurements. Sagittal, coronal, and transversal images were obtained by a fast gradient echo sequence for localizing the following T_2*-weighted axial and coronal images measured by a standard gradient echo sequence. Sequence parameters were as follows: repetition time T_R = 180 ms, echo time T_E = 12 ms, number of acquisitions AC = 48, matrix size 256 × 256, field of view FOV = 3.5 × 3.5 cm (axial images) or 3 × 6 cm (coronal images), slice thickness = 0.75 mm.

Phantoms containing labeled cells were measured by the same sequence with modified geometry parameters to obtain similar spatial resolution as in the *in vivo* measurements.

RESULTS AND DISCUSSION

Chemical Coprecipitation of Fe(II) and Fe(III) Salts and Postsynthesis Iron Oxide Coating with PLL. The key step in the formation of a stable magnetite/maghemite colloid consisted of the careful removal of all the impurities remaining after the synthesis of the magnetite and its oxidation. Purification

was accomplished by magnetic separation in water. Washing with water peptized the particles. Colloidal stability was due to the charges of Fe(III) and citrate ions. Some characteristics of the prepared iron oxides are summarized in Table 1. TEM analysis indicates that dried, uncoated iron oxide particles showed a rather narrow size distribution (Figure 1a). The average size of uncoated nanoparticles no. 1 was about 6.5 nm (Table 1). The colloid showed high stability at neutral pH with no sedimentation observed even after 2 months. The stability is ascribed to the negative charges of the uncoated nanoparticles as documented by their low zeta potential (ca. −46 mV).

The surface modification of nanoparticles is a general strategy for enhancing the cells' permeability to nanoparticles. The transport of nanoparticles can be dramatically altered through the attachment of peptides (*29, 15*). It is expected that the nature of the attached poly(amino acid) strongly influences nanoparticle transport. In this report, the surface of the nanoparticles was modified by PLL (typically of M_w = 388 100) with the aim of promoting cellular uptake. Similarly as in a previous report (*27*), the postsynthesis coating of the primary iron oxide colloid with PLL changed neither the morphology nor the size of the iron oxide crystallites nos. 2–4 (Table 1, Figure 1b).

Figure 2a shows the dependence of the hydrodynamic particle diameter, measured by dynamic light scattering, on the PLL/iron oxide ratio for freshly prepared PLL-modified iron oxide nanoparticles (M_w of PLL = 388 100) and after 5 months of storage. It is normal that the hydrodynamic particle size is larger than the size obtained by TEM (*27*). The hydrodynamic size of freshly prepared particles appears to increase with the PLL/iron oxide ratio up to 0.06, probably due to a thickening of the shell. The hydrodynamic particle size is significantly larger after 5 months of storage, especially at lower PLL/iron oxide ratios,

sample	coating	medium	LL[b] (mg/mL)
1	PLL	NaCl	0.015
2		DMEM/FBS	0.419
3	PLL	DMEM/FBS	0.281
4[c]		DMEM/FBS	0.613

[a] 0.64 mL of colloid (34.7 mg γ-Fe_2O_3/ml). [b] L-Lysine after hydrolysis. [c] Control (no iron oxide particles in the medium).

because of particle aggregation. This can also be inferred from the analogous dependence of polydispersity (Figure 2b). A very high value of polydispersity was observed particularly in the absence of a PLL shell. Nevertheless, higher polydispersities were typical of all the particles after 5 months of storage (Figure 2b). Figure 3 documents an increase in zeta potential with increasing PLL/γ-Fe_2O_3 ratio, indicating that the negatively charged surface was compensated for by the positively charged PLL. This also shows that at the optimal ratio for cell labeling (0.009, see later) the zeta potential is still sufficiently low to repulse the nanoparticles.

FTIR Spectra. The structure of the surface and the efficiency of the coating of magnetic nanoparticles were analyzed by ATR FTIR spectroscopy. FTIR spectra of magnetic γ-Fe_2O_3 particles before and after surface modification with LL or PLL (M_w = 388 100) are shown in Figure 4. The spectra of pure LL and PLL are included for comparison. Two broad bands of iron oxide dominate the spectrum of the magnetic particles before modification. The spectrum of particles after modification with LL is very close to the spectrum of uncoated iron oxide (Figure 4a), confirming that LL did not coat the nanoparticles. As the molecules of LL have, at the same time, both acidic and basic character, their intermolecular interaction is stronger than the interaction with the particle surface. As a consequence, the particles are then poorly internalized by the cells (see later, Table 2).

The situation was different with PLL coating. The spectrum of particles after modification with PLL differs from the spectrum of uncoated iron oxide (Figure 4b). The main bands of PLL are clearly distinguishable in the spectrum of the modified particles. The Amide I band situated at 1648 cm^{-1} in the spectrum of pure PLL was only slightly shifted to higher wavenumbers by the coating (*30*). The Amide II band was shifted from 1539 cm^{-1} in the spectrum of pure PLL to 1502 cm^{-1} in the coating spectrum. We assume that the bands of -CH_2–NH_3^+ deformation and rocking vibrations influence the spectrum in this region. A broad, strong absorption above 1800 cm^{-1} (only the beginning is shown in Figure 4b) is observed in the spectrum, corresponding most probably to ionic interactions between PLL and the iron oxide particles. This strongly indicates that positive charges of the amine groups at the end of the PLL side chains interact with citrates complexed on the iron oxide surface as schematically illustrated in Figure 5. In contrast to the results observed with LL, the surface of γ-Fe_2O_3 nanoparticles was coated by PLL.

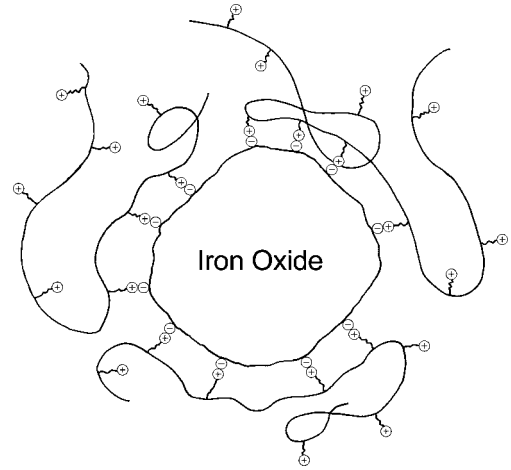

Figure 5. Schematic illustration of the interaction between PLL and a citrate-treated iron oxide nanoparticle.

High-Resolution Ultrasonic Spectroscopy. To investigate the process of PLL coating (M_w = 388 100) of the iron oxide nanoparticles in water, the colloid was monitored by high-resolution ultrasonic spectroscopy. The ultrasonic velocity increased with the addition of PLL. This is caused by an increase in the hydration layer of maghemite particles with hydrophilic PLL molecules, because water molecules are more organized in a hydration shell than in bulk (*31*). Figure 6 illustrates the

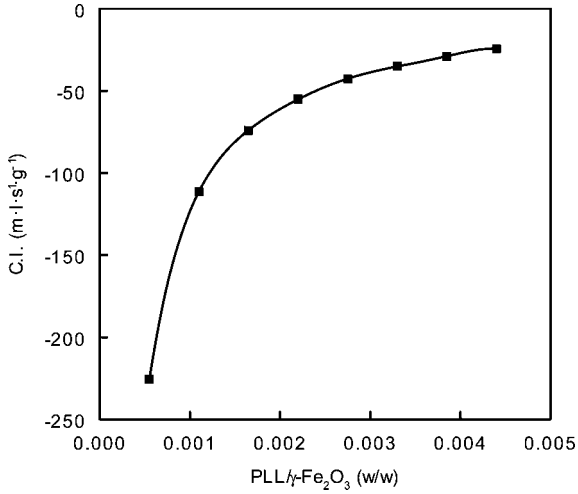

Figure 6. Dependence of the concentration increment of the ultrasonic velocity C.I. on PLL/γ-Fe_2O_3 ratio.

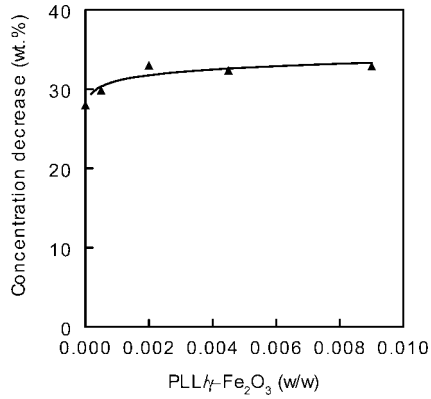

Figure 7. Effect of the PLL/iron oxide ratio on serum protein concentration in culture medium relative to a standard (DMEM/water 1/1 v/v) after adsorption by PLL-modified iron oxide nanoparticles (the concentration of serum proteins was determined by UV spectrometry at 274 nm).

concentration increment of the ultrasonic velocity depending on the amount of PLL added to the iron oxide. The largest increment in ultrasonic velocity was observed at PLL/γ-Fe_2O_3 ratios 0.0005–0.002 (w/w). The further addition of PLL solution did not significantly affect the hydration shell of the maghemite nanoparticles but resulted in a smaller increase in the increment. High-resolution ultrasonic spectroscopy thus provided another confirmation that PLL is indeed adsorbed on the particle surface. Binding is obviously achieved via the electrostatic attraction of opposite charges of PLL and iron oxide surface (Figure 5).

Protein Adsorption from Culture Medium. The adsorption of proteins from culture medium on iron oxide particles is important for elucidating both the transport of iron oxide into the cells and also nanoparticle coagulation. Iron oxide nanoparticles were mixed with serum-containing DMEM medium, the liquid was separated by centrifugation, and the UV spectra of the supernatant were measured against a standard. The relative decrease in the concentration of serum proteins was plotted against the PLL/iron oxide ratio. Figure 7 indicates that even uncoated iron oxide nanoparticles adsorbed some serum proteins from the culture medium. PLL (M_w = 388 100) modification of the iron oxide nanoparticles somewhat increased protein adsorption compared with uncoated iron oxide (Figure 7). The adsorption of serum proteins increased with increasing PLL concentration, reaching a plateau at a PLL/iron oxide ratio of 0.002. It is interesting to note that, while at higher PLL/iron oxide ratios protein adsorption did not increase, the percentage of labeled cells did (Table 1). It might be speculated that the entire PLL chain fully adheres onto the nanoparticle surface at PLL/iron oxide ratios 0.002 or less. The idea is also supported by the ultrasonic measurements. However, at higher ratios, all PLL chains remain attached to the iron oxide surface via their certain segments while their other parts move freely in the medium (Figure 5), facilitating cell labeling (see below). The free chain parts thus do not increase serum protein adsorption, but they can provide contact with the cell membrane.

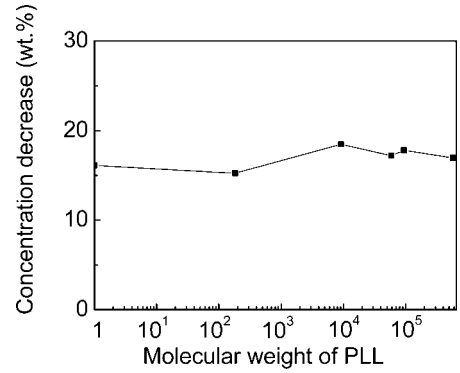

Figure 8. Effect of PLL molecular weight on serum protein concentration in culture medium relative to a standard (DMEM/water 1/1 v/v) after adsorption by PLL-modified iron oxide nanoparticles (the concentration of serum proteins was determined by UV spectrometry at 274 nm; PLL/iron oxide = 0.009 w/w—analogous to nanoparticles no. 4; Table 1).

To exclude the possibility that PLL dissociates from the iron oxide surface once mixed with serum, both uncoated (no. 1, Table 1) and PLL-coated nanoparticles (no. 4) were placed in DMEM/10% FBS medium or 0.15 M NaCl solution, magnetically separated, the supernatants hydrolyzed, and concentration of L-lysine was determined (Table 2). As expected, only traces of L-lysine were found in the supernatant from PLL-modified iron oxide during contact with the 0.15 M NaCl solution (sample 1, Table 2). This documents that PLL strongly associated with the iron oxide nanoparticles. The addition of uncoated iron oxide (sample 2) in DMEM/10% FBS induced a decrease in the amount of L-lysine in the hydrolyzed supernatant as compared with the control (sample 4), while the addition of PLL-coated iron oxide nanoparticles (sample 3) to DMEM/10% FBS led to a more pronounced decrease of L-lysine in the hydrolyzed supernatant. This is in accordance with our protein adsorption experiments (Figure 7). It should be noted that the total amount of L-lysine before hydrolysis and magnetic separation in sample 3 was higher than that in samples 2 and 4 (control), because in addition to serum L-lysine, it also contained L-lysine originating from the PLL coating. These experiments thus did not show the release of PLL from the PLL-coated iron oxide nanoparticles into the culture medium.

The effect of the molecular weight of PLL on the adsorption of FBS serum proteins from DMEM cultivation medium was also investigated by UV–vis spectrometry. The molecular weight of PLL did not significantly influence the adsorption of proteins from the DMEM medium on the surface of PLL-modified maghemite (Figure 8). It should be noted that this experiment was performed with another FBS charge than in the investigation of the effect of the PLL/iron oxide ratio on the concentration decrease in serum proteins, thus explaining the difference in the amount of adsorbed proteins (see Figures 7 and 8).

Cell Labeling. Cell labeling with Fe(III)/Fe(II)/paramagnetic substances is an increasingly common method for *in vivo* cell monitoring and separation (*32*), as the labeled cells can be detected by magnetic resonance imaging. The surface charac-

[a] Concentration 2.2 mg of PLL-modified γ-Fe_2O_3/mL. [b] Control. [c] Average of 15 measurements.

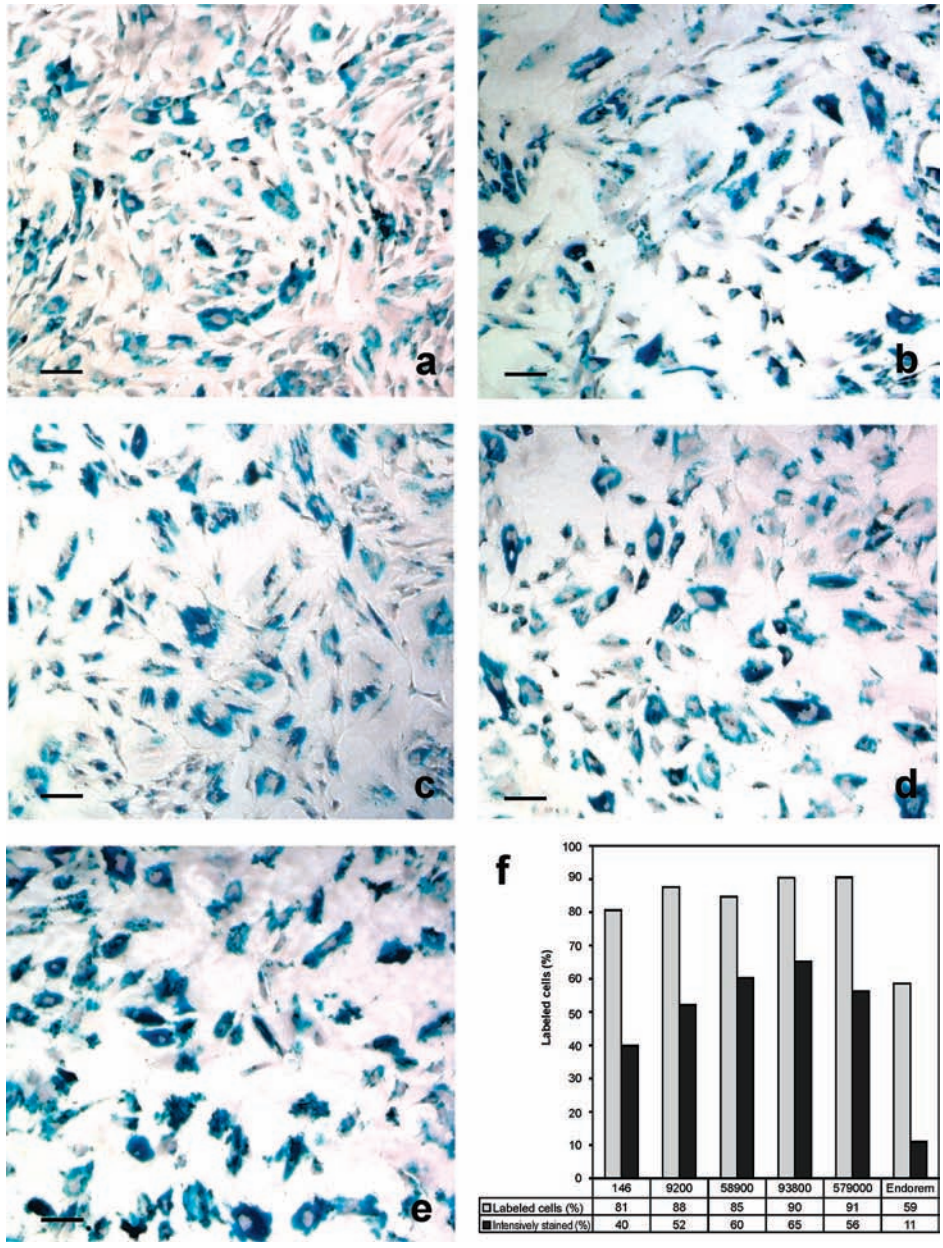

Figure 9. Microscopic observation of rMSCs labeled with PLL-modified iron oxide nanoparticles: effect of PLL molecular weight. M_w = (a) 146, (b) 9200, (c) 58 900, (d) 93 800, and (e) 579 000. Scale bar 50 μm. (f) Histograms of the percentage of the Prussian Blue stained PLL-coated iron oxide nanoparticle- and Endorem-labeled rMSC cells: effect of PLL molecular weight. Grey and black columns represent the percentage of labeled cells and strongly labeled cells, respectively, out of all the cells in the culture medium.

teristic of nanoparticles plays an important role in their internalization in cells. First, rMSCs labeled with either uncoated or surface-modified iron oxide nanoparticles were observed using an optical microscope. Cell labeling with Endorem served as a control. Endorem, however, shows a tendency to adhere on the surface of the cells, in addition to sticking to the bottom of the vessel. Using the Prussian Blue reaction, the cellular iron content was measured in MSCc exposed to the nanoparticles.

Primary Uncoated Iron Oxide. Primary uncoated iron oxide colloid no. 1 (Table 1) was tested for cell labeling to elucidate the importance of iron oxide modification/coating in subsequent experiments. Observation using an optical microscope with phase contrast revealed the iron oxide nanoparticles in rMSCs as dark dots. Cells in contact with the nanoparticles proliferated, and approximately one in every ten cells endocytosed the iron oxide. This might be explained by the formation of aggregates of sterically unstable particles due to the presence of electrolytes in the medium. As the resulting coagulates had a broad size distribution, only the small ones could penetrate into the cells, whereas the large ones were not internalized. In an attempt to increase cell labeling, the iron oxide surface was modified with PLL.

Poly(L-Lysine)-Modified Iron Oxide. PLL is a polycation due to the presence of NH_2 groups, widely used as a nonviral

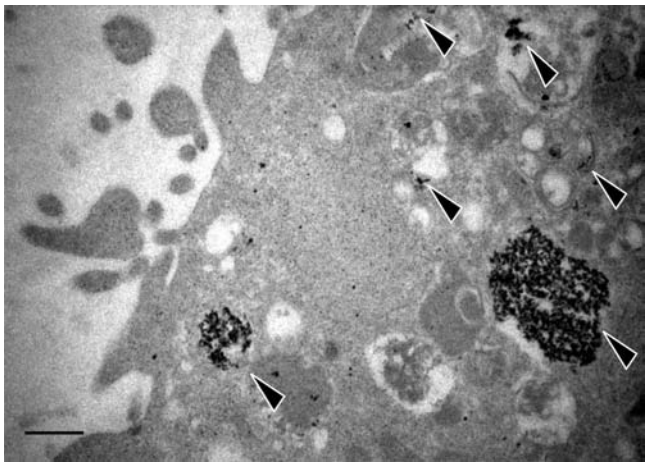

Figure 10. TEM micrographs of rMSC cells labeled with PLL-modified iron oxide nanoparticles (no. 3, Table 1). Scale bar 1 μm.

transfection agent for gene delivery and in DNA complexing thus promoting cell adhesion (*33*) through a positively charged interface clearly possessing an affinity for negatively charged cells. PLL is known to adsorb proteins not only from nutrient solutions, but also from cell membranes.

The results of both rat and human MSC cell labeling with PLL-modified maghemite nanoparticles (M_w of PLL = 388 100) are summarized in Table 1. It is clear that the degree of iron oxide internalization by the cells was PLL concentration-dependent. The higher the PLL concentration, the better the cell labeling (Table 1). The best result in terms of maximum cell labeling was achieved with 0.02 mg PLL per mL of colloid (Table 1, no. 4). The mechanism of PLL-mediated iron oxide uptake by the cells is assumed to be based on endocytosis and/or diffusion through the cell membranes (*34*). Cells took up much more PLL-modified nanoparticles than they did Endorem. Even a relatively low PLL concentration was sufficient for almost complete cell labeling. It can be thus assumed that increased endocytosis was induced by associates formed between PLL-coated nanoparticles and serum proteins. This is in accordance with both our protein adsorption experiments and also the L-lysine analysis of hydrolyzed supernatants (Table 2). The nanoparticles, however, aggregated at concentrations higher than 0.02 mg of PLL/mL. The results document a positive effect of PLL on intracellular nanoparticle uptake. This is in accordance with the published data on the cellular improved uptake of nanoparticles containing amino groups (*35*). Another approach to improve the uptake of nanoparticles into cells using PLL is based on combining a commercially available dextran-coated SPIO, such as Feridex (*36*) or Sinerem (*37*), and a commercially available transfection agent based on PLL (*38*). However, each combination of transfection agent and dextran-coated SPIO nanoparticles has to be carefully titrated and optimized for different cell cultures, since lower concentrations of transfection agent may result in insufficient cellular uptake, whereas higher concentrations may induce the precipitation of complexes or may be toxic for the cells (*39*). Also, magnetite cationic liposomes are known to promote the uptake of magnetic particles by target cells (*18*).

Table 4. Relaxivities r_1 and r_2 of Contrast Agent Suspensions and the Relaxation Rates of Suspensions of rMSCs Labeled with Contrast Agents

	relaxivities of phantoms containing suspension of pure contrast agent (s^{-1}/mmol Fe)		relaxation rates of phantoms containing labeled cells ($s^{-1}/10^6$ cells/mL)	
contrast agent	r_1	r_2	R_1	R_2
PLL-modified iron oxide no. 4	17.36	213	0.32	4.29
Endorem	19.65	126	0.18	1.24

Effect of PLL Molecular Weight. In the next series of experiments, L-lysine and PLL of several molecular weights, ranging up to 579 000, were chosen to test the cellular uptake of PLL-modified iron oxides (Table 3). Maghemite nanoparticles modified with L-lysine (M_w = 146) penetrated into the cells rather poorly, similarly to primary uncoated iron oxide particles, indicating again that LL did not coat the iron oxide (Figure 9). In contrast to LL-modified nanoparticles, the particles modified with PLL were internalized well by the cells. The efficiency of cell labeling increased with the molecular weight of PLL up to M_w = 388 100, which can be considered an optimum PLL molecular weight for γ-Fe_2O_3 nanoparticle modification. This is in accordance with earlier observations of inefficient mammalian cell labeling with low-molecular-weight PLL (*38*). On the other hand, particles coated with high-molecular-weight PLL (M_w = 579 000) showed lower cellular uptake (Table 2) and, moreover, adhered to the cell walls. This was indicated by the fact that the blue-stained areas were larger than the cells (Figure 9e). It is interesting to note that the efficiency of cell labeling with Endorem was higher in the experiments summarized in Table 1 than in those reported in Table 3, probably due to differences in the passage number of the cells used.

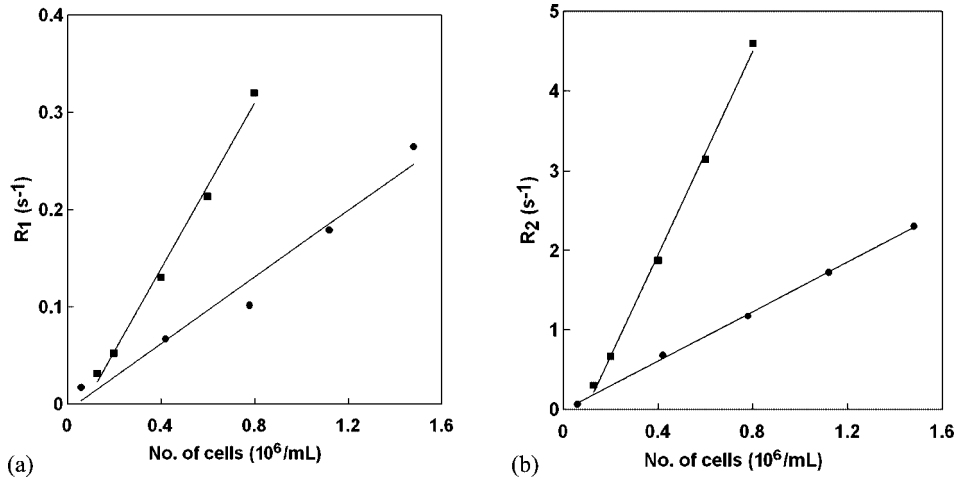

Figure 11. Proton relaxation rates (a) R_1 and (b) R_2 of rMSCs labeled with (•) Endorem and (■) PLL-modified iron oxide nanoparticles (no. 4, Table 1).

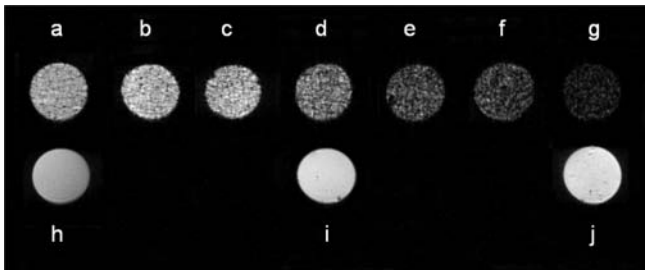

Figure 12. Gelatin phantoms containing (a) 200, (b) 400, (c) 800, (d) 1200, (e) 1600, (f) 2000, and (g) 4000 PLL-modified iron oxide (no. 4)-labeled cells per μL, and control samples with (h) 200, (i) 1200, and (j) 4000 unlabeled cells per μL.

Image analysis tools were used to evaluate not only the percentage of labeled cells, but also the intensity of Prussian Blue staining. The resulting histograms (Figure 9f) confirmed that the cells labeled with particles coated with higher-molecular-weight PLL ($M_w > 58\,900$) were stained to a darker shade of blue, because they contained a greater amount of iron per cell than those labeled with particles coated with low-molecular-weight PLL. However, the intensity of Prussian Blue staining of particles modified with PLL of $M_w = 579\,000$ was slightly decreased.

Transmission Electron Microscopy of Labeled Cells. To confirm the internalization of PLL-coated nanoparticles no. 3 by the cells rather than simply their bonding to the cell surface, and to visualize the location of the nanoparticles inside the cells after internalization, cells were examined by transmission electron microscopy (Figure 10). These observations revealed that the coated nanoparticles indeed crossed cell membranes and were internalized into the cells. They appeared as black dots evenly dispersed in the cell cytoplasm; cell membrane-bound nanoparticle clusters were not detected. The majority of the internalized PLL-coated nanoparticles were located in the lysosomes of the cells, which supports their intracellular trafficking. Nanoparticles are transported in endosomes and finally fused with lysosomes, a process during which the vesicle membranes disappear.

Comparison of Relaxivity between rMSC Labeled with Endorem and PLL-Modified Iron Oxide no. 4. MR relaxometry enables the quantification and proper comparison of relaxation times (and relaxivities), which are responsible for contrast enhancement in T_1-, T_2-, and T_2*-weighted MR images.

In Figure 11, the proton relaxation rates R_1 (a) and R_2 (b) of phantoms with labeled cells suspended in gelatin are plotted against the cell concentration. The relaxation rates of cells loaded with PLL-modified iron oxide nanoparticles were significantly higher than those of cells labeled with Endorem particles. Table 4 compares the relaxivities and relaxation rates of gelatin samples containing suspensions of the contrast agents or labeled cells relative to iron concentration or cell numbers, respectively. Relaxivity r_2 of PLL-modified iron oxide suspended in gelatin was 70% higher than that of Endorem. The difference between the relaxation rates of samples containing cells (related to the number of cells) labeled with PLL-modified nanoparticles and cells labeled with Endorem was much greater. This observation cannot be explained only by the higher relaxivity of the nanoparticles used; it is probably due to the better internalization of PLL-modified iron oxide nanoparticles in the cells. This hypothesis was confirmed by iron analysis of the cell suspensions, the average amounts of iron determined by spectrophotometry after mineralization were 41.5 pg of iron per cell for cells labeled with PLL-modified iron oxide no. 4 and 14.6 pg of iron per cell for Endorem-labeled cells.

***In Vitro* MR Imaging.** To check the sensitivity of the MRI technique and to mimic signal behavior in brain tissue, suspensions of unlabeled cells and cells labeled with PLL-modified iron oxide nanoparticles were imaged *in vitro*. Even the sample containing the lowest concentration (200 cells/μL which corresponds on average to 2 cells per image voxel) still provided visible contrast compared with a control phantom containing the same number of unlabeled cells (Figure 12). A similar set of experiments was performed in our previous work (*40*), in which MR images of gelatin phantoms showed a hypointense signal at the concentrations above 625 labeled cells per μL.

***In Vivo* MR Imaging.** Rats were examined 3 days after transplantation in an MR imager. Figure 13 shows that PLL-modified iron oxide (no. 4)-labeled cells were clearly discernible *in vivo*, even at low concentrations (1000 cells/2 μL). The iron oxide-labeled cell implants were visible as a hypointense area at the injection site. Cells labeled by PLL-modified iron oxide provide a better visible contrast than do Endorem-labeled cells. Labeling with PLL-modified iron oxide thus makes it possible to detect a lower number of cells in the tissue.

CONCLUSIONS

The preparation of new surface-modified iron oxide nanoparticles for stem labeling has been described and their

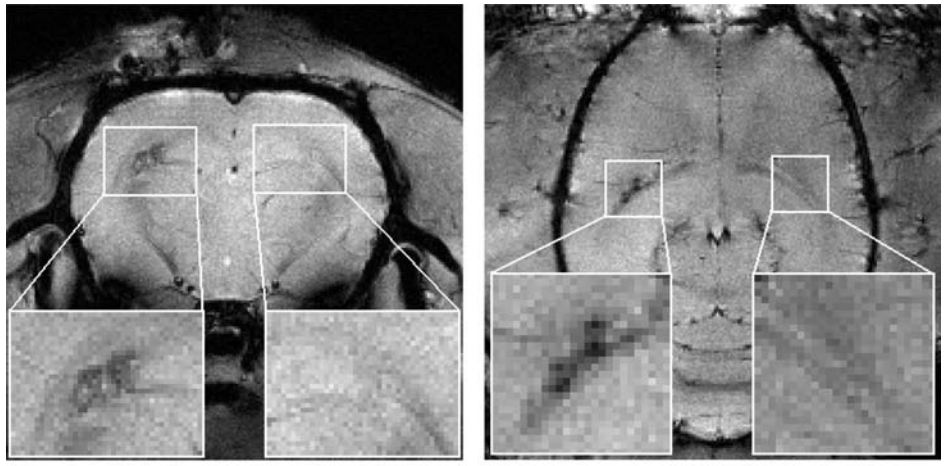

Figure 13. (a) Axial and (b) coronal MR images of a rat brain with 1000 cells labeled with PLL-modified iron oxide implanted into the left hemisphere and 1000 Endorem-labeled cells implanted into the right hemisphere. MR images were taken 3 days after implantation. Enlarged insets clearly show a hypointense signal in the left hemisphere; such a signal is not visible in the right one.

properties optimized. The structure of the polymer shell of the iron oxide core determined the efficacy of the nanoparticles' interaction with cells. A good colloidal stability has been obtained with poly(L-lysine) modifiers. Poly(L-lysine)-modified nanoparticles less than 10 nm in diameter were tested for cell labeling. PLL of high molecular weight ($M_w = 388\,100$) proved to be the most effective surface-modifier for achieving the greatest internalization by rat bone marrow stromal cells. The accumulation of the magnetic particles in the cells was obviously facilitated by PLL-induced modification of the particles' surface charge. TEM examination of PLL-coated nanoparticles showed the successful internalization of the nanoparticles into lysosomes. Nanoparticles were found inside cells, mainly in endosomes. The cellular uptake of iron oxide nanoparticles was dependent on the concentration of PLL used in the iron oxide modification. At high concentrations, the nanoparticles started to aggregate in the culture medium. The cellular iron content was also dependent on the amount of added nanoparticles. Cell labeling with newly developed PLL-modified iron oxide was more efficient than that with a conventionally used agent (Endorem). Compared to Endorem, both the higher r_2 relaxivity of PLL-modified nanoparticles and their better internalization in the cells enabled easier MRI detection and tracking of cells in the tissue after transplantation. Moreover, the viability of PLL-coated iron oxide-labeled cells determined by a colorimetric essay was much higher than in cells labeled with Endorem (*41*). The newly developed PLL-modified iron oxide nanoparticles are expected to be nontoxic, similarly as analogous iron oxide−PLL complexes (*42*), the biodegradation of which and metabolic processes in cells have been reported earlier. The iron is introduced into the normal plasma iron pool and is then incorporated into the hemoglobin of red cells or metabolized (*43*). Compared with PLL modification of dextran-coated iron oxide nanoparticles (*44*), the advantage of our new procedure is that no dextran is necessary to produce the particles, thus simplifying their preparation. The developed nanoparticles are a promising tool for the noninvasive *in vivo* tracking of transplanted cells in the host organism and for monitoring the long-term effects of such transplantation.

Calix[4]arene Decorated with Four Tn Antigen Glycomimetic Units and P_3CS Immunoadjuvant: Synthesis, Characterization, and Anticancer Immunological Evaluation

Corrada Geraci,*,† Grazia M. L. Consoli,† Eva Galante,† Ennio Bousquet,‡ Maria Pappalardo,‡ and Angelo Spadaro*,‡

Istituto di Chimica Biomolecolare, C.N.R., Via del Santuario 110, I-95028 Valverde (CT), Italy, and Dipartimento di Scienze Farmaceutiche - Università di Catania, Viale A. Doria 6, I-95125 Catania, Italy. Received November 6, 2007; Revised Manuscript Received January 10, 2008

A novel anticancer vaccine candidate built on a nonpeptidic scaffold has been synthesized. Four *S*-Tn tumor-associated glycomimetic antigens have been clustered onto a calix[4]arene scaffold bearing an immunoadjuvant moiety (P_3CS). The immunogenicity of the synthetic construct has been investigated by immunization of mice *in vivo*. ELISA assay has evidenced that the tetravalent construct stimulates a higher production of anti-Tn antigen IgG antibodies when compared to an analogous monovalent compound. This result is ascribable to an antigen cluster effect and makes the reported vaccine candidate a good mimic of the natural motifs present on the mucine surface.

INTRODUCTION

The purpose of cancer vaccination to fight tumors using the patient's own immune system continues to be very attractive and challenging, despite the successes reached during the past few years in conventional anticancer therapy (*1–4*). In fact, several metastatic tumors remain resistant to usual antitumor therapy, such as metastatic melanoma and renal and lung carcinoma. From this, numerous studies have been undertaken to exploit the immune response by successively increasing its strength and specificity in order to oppose the disease with effectiveness. On this concept are based cancer vaccines which generate antibodies capable of recognizing and eliminating circulating cancer cells and micrometastasis.

Mucine are members of a large family of glycoproteins present on the surface of many epithelial cells, where they perform physical (lubrication and moisturization) and protective (against pathogenic microorgamisms and mechanical damage) functions (*5*). The epithelial cancers such as breast, pancreatic, colorectal, ovarian, or prostate cancers are often associated with a dysregulation of the glycosylation processes and consequently with altered carbohydrate patterns expressed on the cancer cell surface (*6*). This determines alteration of the cell adhesion, migration, and communication with the immune system and produces metastatic increase and decrease of the immune response (*7*).

Specific tumor-associated carbohydrate antigens (TAs) such as Globo-H, Tn, TF, and sialyl-Tn, cryptic in normal epithelial cells, are overexpressed on the surface of tumor cells because of an incomplete glycosylation which leads to a block in carbohydrate chain elongation (*8, 9*). Due to the difficulty obtaining these antigens from natural sources, numerous chemical synthetic procedures have been developed to achieve this (*10*).

Unfortunately, TAs are autoantigens or self-antigens (*11*), and hence they are weak immunogens. To circumvent this problem, carrier proteins or macrolipid immunoadjuvants (*12–16*) have been conjugated to the antigen epitope. The elegant studies of Danishefsky et al. are milestones in this research area. Monovalent vaccine constructs composed of a single carbohydrate antigen conjugated to keyhole-limpet hemocyanin (KLH) and coadministered with QS-21 adjuvant have advanced to clinical trials (*17*).

As the carrier protein excess could cause an increased antibody response to the carrier itself and a drop in the immunogenicity of the antigen, a strategy to limit these events has provided the design of multivalent constructs in which the presence of multiple antigenic units results in a more efficient immune response (*18*). In addition, multivalent structures better mimic the mucine surface, wherein Tn antigens are exposed in clusters of 2 to 5. It has been demonstrated that at least two Tn contiguous antigen residues are crucial for the binding of the anti-Tn monoclonal antibodies 83D4 and MLS128, and that MLS128 affinity is greater on a glycopeptide with three successive Tn residues (*19–23*).

In the past ten years, great attention has been paid to the choice of scaffolds for the exposition of multiple antigenic units. Polypeptide fragments, a lysine core extended with peptidic (MAP) (*24*) or glycopeptidic (MAG) (*25*) arms, and a cyclized decapeptide have been selected as backbones to build multivalent vaccines (*26*). Some of them have presented high immunogenicity in mice and in nonhuman primates (*27*).

Following a similar approach, we decided to synthesize a novel fully synthetic cancer vaccine candidate in which a cluster of four Tn antigen glycomimetic units (*S*-Tn) is conjugated to an immunoadjuvant moiety, tripalmitoyl-*S*-glycerylcysteinyl-serine (P_3CS), through a calix[4]arene scaffold (Schemes 1−3). The presence of a rigid platform has provided a tetravalent derivative (**11**) with a definite spatial preorganization of the antigenic moieties.

Biological tests, performed *in vivo* by immunization of mice, showed that the target construct possesses higher immunostimulating activity with respect to the corresponding monovalent

analogous, emphasizing the presence of a cluster effect and the important role of the calixarene macrocycle.

EXPERIMENTAL PROCEDURES

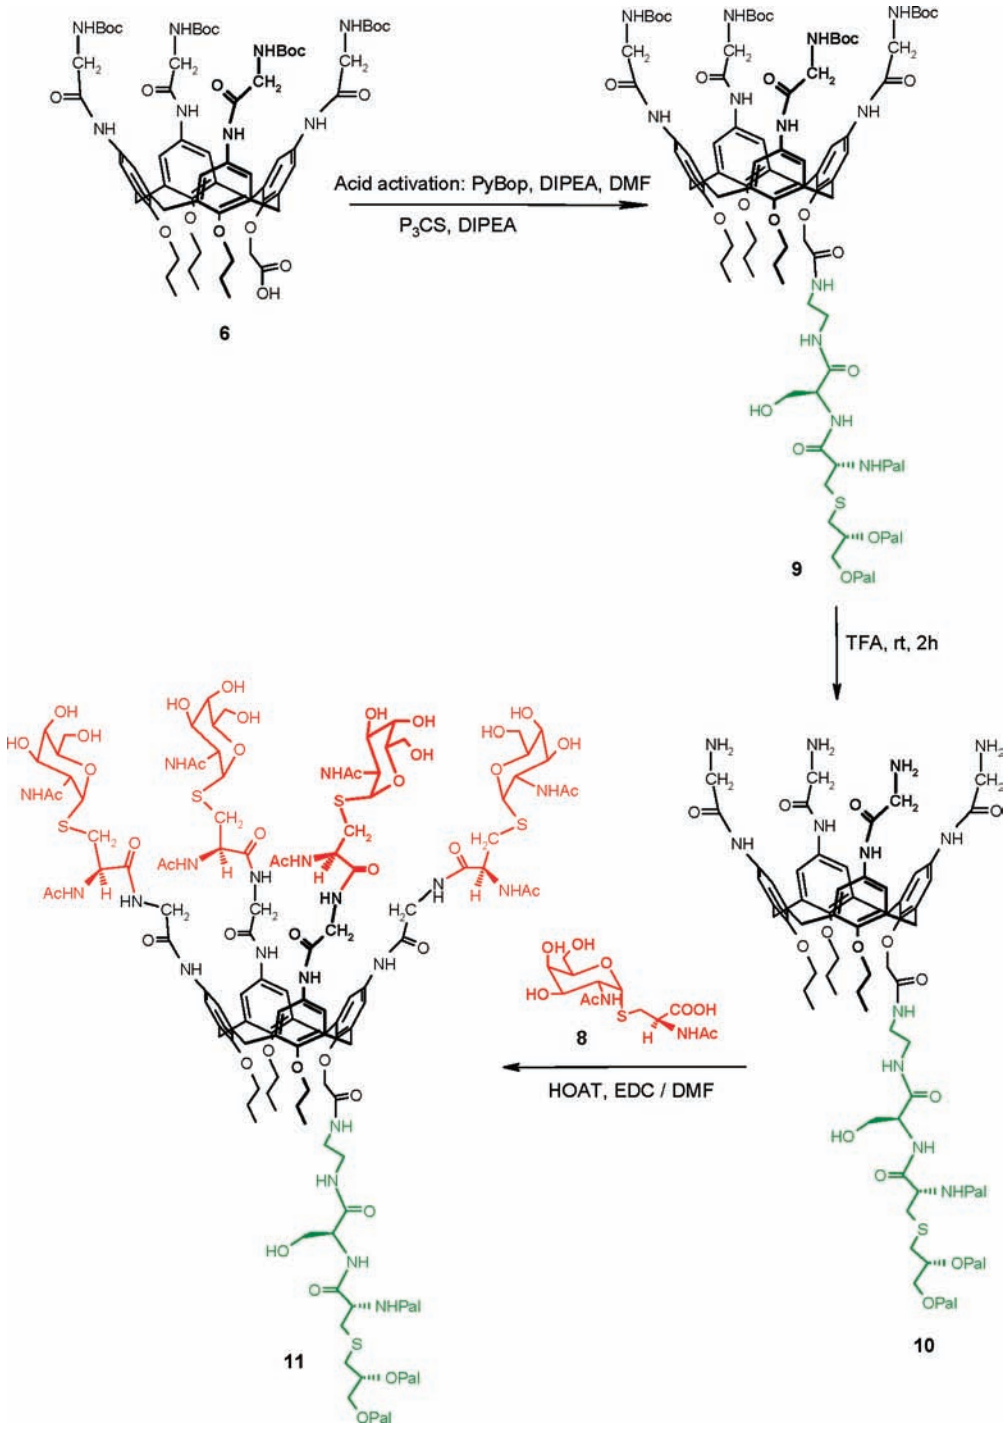
General. All chemical reagents and solvents were obtained from commercial sources and were used without purification. Analytical TLCs were performed on 0.25 mm silica gel 60 coated aluminum foils with F-254 indicator (Merck). Column chromatography was performed on silica gel 60 (230–400 mesh, E. Merck) or on silica gel 100 C18-RP (230–400 mesh, Fluka). Size exclusion column chromatography was carried out on Sephadex LH-20 (Pharmacia Biotech AB, Uppsala Sweden) or Biogel P-2 (Bio-Rad). ^{1}H NMR (400.13 MHz), ^{13}C NMR (100.61 MHz), and 2D-NMR spectra were acquired on a Bruker Avance 400 spectrometer. Chemical shifts (δ) are expressed in parts per million (ppm). Spectra were referenced to the residual proton solvent peaks; coupling constant (J) values are given in Hz. Mass spectra were recorded on a mass spectrometer Waters Micromass ZQ 2000 model ESI-MS (positive ion mode, capillary voltage 3500 V, cone voltage 60 V) or on a MALDI-STR Applied Biosystems instrument (positive ion, reflector mode, accelerating voltage 24000, 256 laser shot). In the ELISA assay, the absorbance was measured on a MDL680 microplate reader (Biorad).

Syntheses. *25,26,27-Tripropoxy-28-hydroxy-p-tert-butylcalix[4]arene (***1***).* was prepared following a literature procedure (*28*).

*25,26,27-Tripropoxy-28-[(ethoxy carbonyl)methoxy]-p-tert-butylcalix[4]arene (***2***).* Compound **1** (1.14 g, 1.5 mmol) was treated with 60% oil-dispersed NaH (62.4 mg, 2.6 mmol) in THF (70 mL)−DMF (18 mL), and then EtBrAc (332 μL, 2.99 mmol) was added. The reaction mixture was stirred for 4 h at room temperature. The mixture was concentrated under vacuum and washed with 0.1 N HCl (50 mL). The suspension obtained was filtered and the gathered white residue was purified by column chromatography (CH_2Cl_2 as eluent) to afford compound **2** (1.21 g, 95%). ^{1}H NMR ($CDCl_3$, 297 K) δ: 0.95–1.05 (overlapped, 9H, 3 × $CH_2CH_2CH_3$), 0.99, 1.16, and 1.17 (s, 18H, 9H, 9H, respectively, 4 × *t*-Bu), 1.29 (t, J = 7.1 Hz, 3H, OCH_2CH_3), 1.96 (q, J = 7.4 Hz, 4H, 2 × $CH_2CH_2CH_3$), 2.09 (q, J = 7.8 Hz, 2H, $CH_2CH_2CH_3$), 3.11 (d, J = 12.6 Hz, 2H, $ArCH_2Ar$), 3.16 (d, J = 12.6 Hz, 2H, $ArCH_2Ar$), 3.70–3.85 (m overlapped, 6H, 3 × $OCH_2CH_2CH_3$), 4.20 (q, J = 7.1 Hz, 2H, OCH_2CH_3), 4.40 (d, J = 12.6 Hz, 2H, $ArCH_2Ar$), 4.60 (d, J = 12.6 Hz, 2H, $ArCH_2Ar$), 4.81 (s, 2H, OCH_2CO), 6.65 (br d, 4H, 4 × ArH), 6.80, 6.90, (s, 2H each, 4 × ArH). ^{13}C NMR ($CDCl_3$, 297 K): 10.1, 10.4, 14.2 (q), 23.3, 23.4, 31.0 (t), 31.4, 31.5, 31.55 (q), 31.6 (t), 33.7, 33.9 (s), 53.4, 60.2, 70.9, 77.1 (t), 124.7, 124.8, 125.1, 125.4 (d), 133.0, 133.2, 134.0, 134.5 (t), 144.1, 144.5, 144.8, 153.3, 153.4, 153.9, 170.7 (s). ES-MS calcd for $C_{57}H_{81}O_6$ (861.6): m/z 861.5 $(M + H)^+$; 883.4 $(M + Na)^+$.

*5,11,17,23-Tetranitro-25,26,27-tripropoxy-28-[(ethoxy carbonyl)methoxy]-calix[4]arene (***3***).* A solution of **2** (1.21 g, 1.4 mmol) in CH_2Cl_2 (25 mL) was mixed with glacial CH_3COOH (25 mL) at room temperature. Then 100% HNO_3 (6.4 mL) was added dropwise under vigorous stirring. After 6 h, the reaction was stopped by addition of water (120 mL). The organic layer was separated and dried and the solvent evaporated in vacuum. The yellow solid was purified by crystallization (CH_2Cl_2/EtOH) to afford the white compound **3** (914 mg, 80%). ^{1}H NMR ($CDCl_3$, 297 K) δ: 0.98 (t, J = 7.4 Hz, 3H, $CH_2CH_2CH_3$), 1.05 (t, J = 7.4 Hz, 6H, 2 × $CH_2CH_2CH_3$), 1.30 (t, J = 7.2 Hz, 3H, OCH_2CH_3), 1.87–1.94 (m overlapped, 6H, 3 × $CH_2CH_2CH_3$), 3.40 (d, J = 14.1 Hz, 2H, $ArCH_2Ar$), 3.46 (d, J = 14.1 Hz, 2H, $ArCH_2Ar$), 3.80–3.97 (m overlapped, 4H, 2 × $OCH_2CH_2CH_3$), 4.00 (t, J = 7.7 Hz, 2H, $OCH_2CH_2CH_3$), 4.23 (q, J = 7.2 Hz, 2H, OCH_2CH_3), 4.53 (d, J = 14.1 Hz, 2H, $ArCH_2Ar$), 4.75 (s, 2H, OCH_2CO), 4.76 (d, J = 14.1 Hz, 2H, $ArCH_2Ar$), 7.34 (br d, 4H, 4 × ArH), 7.84 (s, 4H, 4 × ArH). ^{13}C NMR

Scheme 3. Synthesis of Tetra-*S*-TnAg-Gly-CX-P_3CS (11)



($CDCl_3$, 297 K): 10.3, 14.2 (q), 23.2, 31.1, 31.4 (t), 61.3, 70.7, 77.9 (t), 123.6, 123.7, 124.4, 124.6 (d), 134.7, 134.8, 135.8, 136.0, 143.0, 143.3, 160.9, 161.1, 162.2, 168.5 (s). ES-MS calcd for $C_{41}H_{45}N_4O_{14}$(817.3): *m*/*z* 839.6 $(M + Na)^+$.

*5,11,17,23-Tetraamino-25,26,27-tripropoxy-28-[(ethoxycarbonyl)methoxy]-calix[4]arene (***4***).* Compound **3** (440 mg, 0.54 mmol) was dissolved in AcOEt/MeOH (9:1, v/v) and hydrogenated under atmospheric pressure in the presence of Pd/C at 50 °C. After the hydrogen uptake was completed (12 h), the catalyst was filtered off and the solution was evaporated in vacuum to give pure compound **4** (338 mg, 90%). ^{1}H NMR ($CDCl_3$, 297 K) δ: 0.91 (t, $J = 7.4$ Hz, 3H, $CH_2CH_2CH_3$) 0.98 (t, $J = 7.4$ Hz, 6H, 2 × $CH_2CH_2CH_3$), 1.27 (t, $J = 7.1$ Hz, 3H, OCH_2CH_3), 1.77–1.90 (m overlapped, 6H, 3 × $CH_2CH_2CH_3$), 2.91 (d, $J = 13.3$ Hz, 2H, $ArCH_2Ar$), 2.97 (d, $J = 13.5$ Hz, 2H, $ArCH_2Ar$), 3.14 (br s, 8H, 4 × NH_2), 3.50–3.72 (m overlapped, 4H, 2 × $OCH_2CH_2CH_3$), 3.75 (t, $J = 7.7$ Hz, 2H, $OCH_2CH_2CH_3$), 4.17 (q, $J = 7.1$ Hz, 2H, OCH_2CH_3), 4.31 (d, $J = 13.3$ Hz, 2H, $ArCH_2Ar$), 4.51 (d, $J = 13.5$ Hz, 2H, $ArCH_2Ar$), 4.61 (s, 2H, OCH_2CO), 5.91, 6.22, 6.24 (s, 4H, 2H, 2H, respectively, 8 × ArH). ^{13}C NMR ($CDCl_3$, 297 K): 10.1, 10.4, 14.2 (q), 23.0, 31.1, 31.5, 60.1, 60.3, 70.4, 76.8 (t), 115.8, 115.9, 116.0 (d), 134.8, 134.9, 136.1, 136.4, 140.1, 140.7, 149.5, 149.8, 150.6, 170.6 (s). ES-MS calcd for $C_{41}H_{53}N_4O_6$ (697.4): *m*/*z* 697.3 $(M + H)^+$; 719.3 $(M + Na)^+$.

*5,11,17,23-(Boc-L-glycyl)amino-25,26,27-tripropoxy-28-[(ethoxycarbonyl)methoxy]-calix[4]arene (***5***).* To a solution of compound **4** (200 mg, 0.29 mmol) in dry DMF (15 mL), Boc-glycine

(251.3 mg, 1.43 mmol), PyBop (1.12 g, 2.15 mmol), and DIPEA (0.75 mL, 4.31 mmol) were added. The reaction mixture was stirred overnight at room temperature. The solvent was removed under vacuum; the crude product was washed with 0.1 N HCl and collected by filtration to give a white solid, which was purified by column chromatography eluting with AcOEt/cyclohexane (6:4 v/v) to afford compound **5** (285.3 mg, 75%). ^{1}H NMR ($CDCl_3$, 330 K) δ: 0.94 (t, J = 7.5 Hz, 3H, $CH_2CH_2CH_3$), 0.98 (t, J = 7.5 Hz, 6H, 2 × $CH_2CH_2CH_3$), 1.26 (t, J = 7.2 Hz, 3H, OCH_2CH_3), 1.45, 1.47 (s, 18 H each, 4 × Boc-$(CH_3)_3$), 1.75–1.90 (m overlapped, 6H, 3 × $OCH_2CH_2CH_3$), 3.06 (d, J = 13.2 Hz, 2H, $ArCH_2Ar$), 3.10 (d, J = 13.8 Hz, 2H, $ArCH_2Ar$), 3.72 (m, 2H, $OCH_2CH_2CH_3$), 3.81 (br s overlapped, 8H, 2 × $OCH_2CH_2CH_3$ and 2 × Gly CH_2), 3.89 (br s, 4H, 2 × Gly CH_2), 4.18 (q, J = 7.2 Hz, 2H, OCH_2CH_3), 4.51 (d, J = 13.2 Hz, 2H, $ArCH_2Ar$), 4.58 (d, J = 13.8 Hz, 2H, $ArCH_2Ar$), 4.62 (s, 2H, OCH_2CO), 5.61 (br s, 4H, 4 × Gly N*H*CH_2), 6.54, 6.93 (s, 4H each, 8 × ArH), 8.10 (s, 2H, 2 × Ar-NH), 8.25 (s, 2H, 2 × Ar-NH). ^{13}C NMR ($CDCl_3$, 297 K): 10.1, 10.4, 14.2 (q), 23.1 (t), 28.4 (q), 31.0, 31.3, 44.6, 60.4, 70.4, 76.8, 77.2 (t), 80.2 (s), 121.1 (d), 131.3, 131.5, 132.0, 134.3, 134.4, 135.5, 135.7, 153.0, 153.3, 154.0, 156.5, 168.0, 170.0 (s). ES-MS calcd for $C_{69}H_{97}N_8O_{18}$ (1325.7): *m/z* 1325.9 $(M + H)^+$.

*5,11,17,23-(Boc-L-glycyl)amino-25,26,27-tripropoxy-28-(carbomethoxy)-calix[4]arene (***6***).* Compound **5** (100 mg, 0.075 mmol) was suspended in THF (10 mL) in the presence of water (2 mL) and KOH (50 mg, 0.89 mmol). The resulting mixture was refluxed and stirred for 3 h. The pH was adjusted to 4 with aq 1 N HCl. The product was extracted with CH_2Cl_2, and the organic layer was dried over Na_2SO_4 and evaporated to give pure compound **6** (95.37 mg, 98%). ^{1}H NMR (MeOD, 297 K) δ: 0.95 (t, J = 7.2 Hz, 3H, $CH_2CH_2CH_3$), 1.02 (t, J = 7.5 Hz, 6H, 2 × $CH_2CH_2CH_3$), 1.39, 1.44, 1.46 (s, 9H, 9H, 18H, respectively, 4 × Boc-$(CH_3)_3$), 1.85–2.00 (m overlapped, 6H, 3 × $OCH_2CH_2CH_3$), 3.12 (d, J = 12.9 Hz, 2H, $ArCH_2Ar$), 3.18 (d, J = 13.2 Hz, 2H, $ArCH_2Ar$), 3.68 (br m, 4H, 2 × $OCH_2CH_2CH_3$), 3.81 (br s, 8H, 4 × Gly CH_2), 3.91 (t, J = 7.8 Hz, 2H, $OCH_2CH_2CH_3$), 4.46 (d, J = 12.9 Hz, 2H, $ArCH_2Ar$), 4.62 (d, J = 13.2 Hz, 2H, $ArCH_2Ar$), 4.68 (s, 2H, OCH_2CO), 6.75 (br s, 4H, 4 × ArH), 7.11, 7.13 (s, 2H each, 4 × ArH).

*N-Acetyl-3-S-(2-acetamido-2-deoxy-*α*-D-galactopyranosyl)-L-cysteine (***8***).* Compound **7** (*29*) (56 mg, 0.097 mmol) dissolved in EtOH (40 mL) was reacted with hydrazine hydrate (2.5 mL, 80 mmol) for 2 h under reflux. The mixture was evaporated in vacuum and purified by Biogel P-2 column chromatography (water). An aliquot of 18 mg (0.055 mmol) of the compound obtained was subjected to exhaustive acetylation in the presence of acetic anhydride (12.5 μL, 0.132 mmol) and MeOH as the solvent (2 mL). After 2 h at room temperature, the reaction mixture was concentrated in vacuum to give a solid which was *O*-deacetylated by dissolving in MeOH/H_2O (2:1, v/v, 4 mL) in the presence of aq 1 M NaOH (0.38 mL). After treatment with Amberlite IR-120 (H+) resin until neutralization, the mixture was filtered and the filtrate was concentrated in vacuo to give the white solid **8** (12 mg, 60%). ^{1}H NMR (D_2O, 297 K) δ: 2.02, 2.03 (s, 3H each, 2 × $NHCOCH_3$), 3.00–307 (m, 2H, CysβCHa and CysβCHb), 3.72–3.80 (m, 3H, H-5 and 2 × H-6), 3.84 (dd, $J_{4,3}$ = 3.5 Hz, 1H, H-4), 3.98 (m, 1H, H-2), 4.27 (m, 1H, CysαCH), 4.50 (m, 1H, H-3), 5.52 (d, $J_{1,2}$ = 5.5 Hz, 1H, H-1). ES-MS calcd for $C_{13}H_{23}N_2O_8S$ (367.1): *m/z* 367.2 $(M + H)^+$.

*Boc-Gly-CX-P$_3$CS (***9***).* Compound **6** (19.8 mg, 0.015 mmol) dissolved in dry DMF (2.8 mL) was reacted with PyBop (13.5 mg, 0.026 mmol) and DIPEA (9 μL, 0.05 mmol). After stirring for 4 h at room temperature, a mixture of *N*-{*N*-palmitoyl-*S*-[2,3-bis(palmitoyloxy)-(2*R*)-propyl]-(*R*)-cysteyl-(*S*)-seryl}-1,2 diaminoethane (P_3CS) (*29*) (20.6 mg, 0.019 mmol) and DIPEA (5.6 μL, 0.03 mmol) were added. The reaction mixture was stirred for 24 h at room temperature. After evaporation of the solvent, the residue was washed with water and purified by preparative TLC (MeOH/CH_2Cl_2, 1:9 v/v) to give pure compound **9** (22 mg, 63%). ^{1}H NMR (MeOD/$CDCl_3$, 297 K) δ: 0.77–0.91 (t overlapped, 12H, $CH_2CH_2CH_3$ and 3 × Palmitoyl-CH_3), 0.96 (t, J = 7.0 Hz, 6H, 2 × $CH_2CH_2CH_3$), 1.24 (br s, 60H, 30 × Palmitoyl-CH_2), 1.42, 1.46 (br s, 9H, 27H, respectively, 4 × Boc-$(CH_3)_3$), 1.60 (br m, 18H, 9 × Palmitoyl-CH_2), 1.78 (br s, 6H, 3 × $OCH_2CH_2CH_3$), 2.10–2.40 (m, 6H, 3 × Palmitoyl-CH_2CO), 2.75 (br m, 2H, SCH_2CHOCO), 2.84–3.02 (m, 1H each, Cysβ-CH_2), 3.13 (d, J = 12.8 Hz, 2H, $ArCH_2Ar$), 3.25 (d, J = 14.0 Hz, 2H, $ArCH_2Ar$), 3.49, 3.57 (m, 2H each, NCH_2CH_2N), 3.64 (s, 2H, Gly CH_2), 3.72 (m, 1H, $CHCH_2OH$), 3.84 (br s overlapped, 13H, 3 × $OCH_2CH_2CH_3$, 3 × Gly CH_2, and 1H × $CHCH_2OH$), 4.14 (m, 1H, SCH_2CHCH_2), 4.25–4.45 (overlapped, 6H, 2 × $ArCH_2Ar$, 1H × SCH_2CHCH_2, $CHCH_2OH$), 4.53 (m, 1H, Cysα-CH), 4.83 (s, 2H, OCH_2CO), 5.14 (m, 1H, SCH_2CHOCO), 6.51, 7.19 (br s, 4H each, 8 × ArH). ^{13}C NMR (MeOD/$CDCl_3$, 297 K): 9.5, 9.4, 13.3 (q), 22.3, 22.5, 24.6, 25.5 (t), 27.6 (q), 28.8, 29.0, 29.1, 29.3, 31.1, 31.5, 31.6 (t), 32.2, 33.4, 33.7, 33.9, 35.6, 38.4, 39.2, 39.5, 43.5, 43.7 (t), 52.6, 53.2, 55.2 (d), 61.4, 63.4, 63.5 (t), 70.2 (d), 73.6, 76.1, 77.5 (t), 79.5, 119.9, 120.3, 120.7, 121.2 (s), 132.0, 132.5, 132.7, 133.7, 134.3, 135.9, 151.2, 156.7, 168.0, 168.3, 169.9, 170.9, 172.0, 173.3, 173.5, 175.0 (s). ES-MS calcd for $C_{126}H_{205}N_{12}O_{25}S$ (2318.5): *m/z* 1159.8 $(M + 2H)^{2+}$.

*Gly-CX-P$_3$CS (***10***).* Compound **9** (22 mg, 0.01 mmol) was stirred with TFA (1 mL) for 2 h at rt. The mixture was dried under vacuum by washing three times with ethanol, to give de-Boc derivative **10** in quantitative yield. The CF_3COO^- counterions were replaced with Cl^- anions by repeated treatment of the sample with 0.1 N HCl and removal of the solvent under vacuum. ^{1}H NMR (MeOD, 297 K) δ: 0.88 (t overlapped, 12H, $CH_2CH_2CH_3$ and 3 × Palmitoyl-CH_3), 0.99 (t, J = 7.3 Hz, 6H, 2 × $CH_2CH_2CH_3$), 1.28 (br s, 66H, 33 × Palmitoyl-CH_2), 1.60, 1.60 (m, 6H, 3 × $OCH_2CH_2CH_3$), 1.84 (m, 12H, 6 × Palmitoyl-CH_2), 2.30 (m, 6H, 3 × Palmitoyl-CH_2CO), 2.80 (m, 2H, SCH_2CHOCO), 2.85 and 3.03 (m, 1H each, Cysβ-CH_2), 3.15 (m, 4H, $ArCH_2Ar$), 3.47, 3.56 (m, 2H each, NCH_2CH_2N), 3.68 (s, 4H, OCH_2CO and $CHCH_2OH$), 3.79 (br s, 6H, 3 × $OCH_2CH_2CH_3$), 3.87 (m, 8H, 4 × Gly CH_2), 4.15 (m, 1H, SCH_2CHCH_2), 4.31–4.53 (overlapped, 6H, 2 × $ArCH_2Ar$, 1H × SCH_2CHCH_2, $CHCH_2OH$), 4.56 (m, 1H, Cysα-CH), 5.17 (m, 1H, SCH_2CHOCO), 6.61, 6.62, (s, 2H each, 4 × ArH), 7.17 (m, 4H, 4 × ArH). ES-MS calcd for $C_{106}H_{173}N_{12}O_{17}S$ (1918.3): *m/z* 1918.7 $(M + H)^+$; 960.1 $(M + 2H)^{2+}$; 1940.7 $(M + Na)^+$; 982.6 $(M + 2Na)^{2+}$.

*Tetra-S-TnAg-Gly-CX-P$_3$CS (***11***).* *S*-Tn antigen **9** (15 mg, 41 μmol) was dissolved in dry DMF (1 mL) and reacted with HOAt (410 μL of a solution 0.5 M in DMF) and EDC (39.2 mg, 0.20 mmol). After stirring under argon for a few minutes, a solution of **10** (10.64 mg, 5.12 μmol) and DIPEA (300 μL, 1.72 mmol) in dry DMF (1 mL) was added. The mixture was kept under stirring, for 24 h at room temperature. After evaporation of the solvent (with the addition of a few mL of toluene), the residue was taken up in CH_2Cl_2 and washed with water. The organic layer was dried on Na_2SO_4 and the solvent was evaporated to give a residue that was purified by size-exclusion column chromatography (LH-20, CH_2Cl_2 as eluent). The first fraction was collected and further purified by C18-RP column chromatography (MeOH/CH_2Cl_2 gradient) to give the pure compound **11** as white powder. MALDI-TOF calcd for $C_{158}H_{252}N_{20}O_{45}S_5$ (3310.7): *m/z* 3333.4 $(M + Na)^+$.

Animal Treatment. Five- to eight-week-old female BALB/c mice (Charles River, Calco, Italy) were used in this study. Three

groups of five mice were immunized two times at one-week intervals by intraperitoneal injections of Tetra-*S*-TnAg-Gly-CX-P_3CS **11** (0.030 μM/mouse) or Mono-*S*-TnAg-P_3CS **12** (*29*) at two concentration levels (0.030 and 0.120 μM/mouse) dispersed in 300 μL of a saline solution containing 20 mg/mL of β-HP-CD and 5 mg/mL of HPMC. These additives enhance solubility and physical stability of the dispersion of the constructs tested. Two additional groups were injected with vehicle alone or not treated. After 21 days from the first immunization, sera were collected and stored at −80 °C until ELISA assay.

ELISA End-Point Titers. Total IgG antibodies specific to Tn antigen in sera were detected and quantified by end-point dilution ELISA assay on samples pooled for each group. End-point titers were defined as the highest serum dilution that resulted in an absorbance value two times greater than that of nonimmune control mouse serum with a cutoff value of 0.05 (*30*). 50 μL of 3 mM solution of *S*-Tn antigen (*29*) in water were aliquoted in Nunc CovaLink NH microtiter plate wells (VWR, Italy). An equal volume of coupling reagents NHS (12 mM) and EDC (36 mM) in water was added to each well. Blank control wells, where neither *S*-Tn antigen nor coupling reagents were added, were run in parallel. The plates were shaken at room temperature for 8 h and, after emptying, were washed with water (150 μL × 2), saturated $NaHCO_3$ (2 × 150 μL), SDS (1% in water; 3 × 150 μL), and finally water again (4 × 150 μL). Blocking was done by incubation overnight at 4 °C with bovine serum albumin (BSA, 1% w/v in phosphate-buffered saline (PBS), 200 μL). The plates were washed with PBS containing BSA (1% w/v) and Triton X-100 (0.05%) (2 × 100 μL). 2-fold dilution series of mouse sera prepared in incubation buffer (1% (w/v) BSA, 0.05% (w/v) Tween 20 in PBS) were added in duplicate (100 μL/well) and incubated overnight at 4 °C. The plates were washed with PBS containing 0.05% Tween 20 (150 μL × 3) and 100 μL per well of sheep peroxidase conjugated antimouse IgG (Sigma, Cat-Nr A 6782, 1:2000 in incubation buffer) was added and incubated for 2 h at 37 °C. After washing with PBS containing 0.05% Tween 20 (150 μL × 3), 100 μL per well of substrate TMB (Celbio, Milano, Italy) was added and incubated for 30 min at room temperature in the dark. The enzymatic reaction was stopped with 100 μL of 1 M H_2SO_4 and absorbance at 450 nm was measured in an Elisa microplate reader. Various concentrations of the *S*-Tn antigen and secondary antibody serially diluted in the plates were previously tested in order to optimize the amount of the substance used (data not shown).

Statistical Analysis. Statistical differences of in vivo data are determined using repeated measure analysis of variance (ANOVA) followed by the Bonferroni-Dunn post hoc pairwise comparison procedure. A probability, *P*, of less than 0.05 is considered significant in this study.

RESULTS AND DISCUSSION

Design of the Synthetic Vaccine Candidate. Although the glyco-amino acid GalNAc-O-Ser/Thr is considered the biochemical definition of Tn antigen, experimental evidence confirms that the antigen recognized by the immune system may be more complex. The analysis of the fine specificity of several Tn-binding antibodies demonstrated that clusters of Tn structures were a crucial part of the epitope recognized by the monoclonal antibodies MLS128 and 83D4 (*19–23*) and by the Tn-specific human macrophage C-type lectin (*31*).

In order to mimic the clustered motif of Tn antigen recognized by the immune system, we have designed a vaccine construct where four units of *S*-Tn glycomimetic are covalently linked at the wide rim of a calix[4]arene scaffold bearing, in the narrow rim, an immunoadjuvant moiety (P_3CS).

Calixarene macrocycles (*32–34*) could be suitable molecular platforms for the design of fully synthetic multivalent constructs.

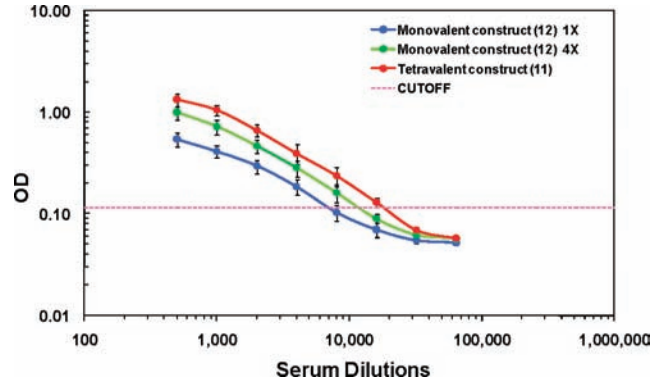


Figure 1. Reactivity of sera of mice immunized with clustered compound **11** or nonclustered monovalent construct **12**. The reference monovalent construct (**12**) was tested at two concentration levels, 1× and 4×, with respect to **11**. Results for total specific anti-Tn IgG antibodies are shown. Data points represent the mean value from group of five animals.

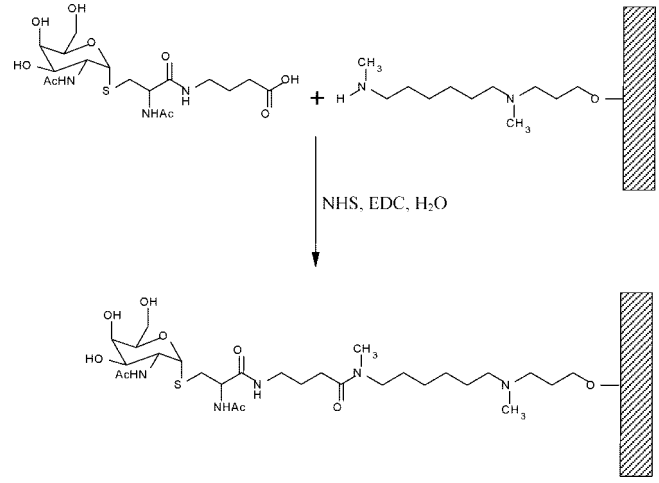
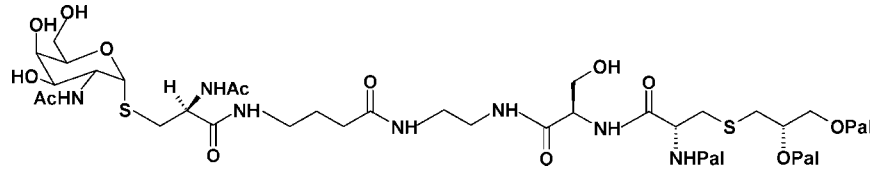
Scheme 4. Covalent Coupling of Tn Ag Glycomimetic to Covalink Plate



They are synthetically versatile compounds with various applications from inorganic to biological fields. These macrocycles are characterized by [1_n] metacyclophane units that can easily undergo the introduction of functional groups at both their narrow and wide rims (Figure 1), so as to fashion their skeleton in a rigid or mobile conformation and diversify their functional properties. Due to a low toxicity (*35–38*), calixarene derivatives have found large application in the biomedical field as enzyme inhibitors (*39–41*), and anticoagulant and antithrombotic (*42*), antiangiogenic and anticancer (*43*), antiviral (*44*), and antimicrobial and antifungal (*45*) products.

In the designed construct, the four *S*-Tn antigen units are covalently linked by glycine spacers to the calix[4]arene wide rim. Three propyloxy groups and one P_3CS unit introduced at the calixarene narrow rim block the synthetic core in a rigid cone-shaped conformation (*28*) and ensure that the antigenic units will be exposed on the same side with respect to the medium plane of the macrocycle. The all-syn orientation of Tn Ags is crucial to better mimic the cancer cell surface, whereas the presence of a glycine spacer between the calixarene backbone and the antigenic pendants should avoid steric hindrance and ensure flexibility, both advantageous in the antigen—immune system interaction (*29*). The P_3CS moiety, endowed with immunoadjuvant properties, determines the magnitude of the vaccine candidate immune response. This lipopeptide is a potent immunoadjuvant (*46*), derived from the immunologically active *N*-terminal sequence of the principal

Chart 1. Structure of Monovalent Reference Compound (12)



lipoprotein of *Escherichia coli* (*47*). It elicits its activity through the interaction with a Toll-like receptor 2 (*46*). This determines the production of cytokines and chemokines which stimulate the antigen presenting cells with the development and activation of T helper cells.

The glycomimetic *S*-Tn antigen was chosen as antigenic determinant, because of its higher metabolic stability and capability to determine the maximal immunostimulating activity of a construct at lower doses with respect to the natural *O*-Tn analogue (*29*).

Preparation of the Calix[4]arene Platform. Calixarene derivative **1** (*28*) was selected as the starting material and reacted with ethyl bromoacetate in the presence of a strong base (NaH) to obtain the 25,26,27-tripropoxy-28-[(ethoxycarbonyl)methoxy]-*p-tert*-butylcalix[4]arene (**2**) in 95% yield. This compound underwent a direct replacement of the *tert*-butyl groups via an ipso aromatic nitration to give the nitrocalixarene derivative (**3**). Subsequently, reduction of **3** in H_2 atmospheric pressure with Pd-C, as catalyst, supplied the amino derivative (**4**). Afterward, four BOC-glycine spacers were introduced into the macrocycle wide rim, via amide coupling, in the presence of PyBop and DIPEA to give compound **5**. This synthetic procedure (Scheme 1) is easier and more effective than the procedure using NHS and DCC or EDC, and it increases the yield of compound **5** by more than 30%.

TnAg-Calixarene Construct. The treatment of compound **5** with a basic solution removed the protecting ester group at the macrocycle narrow rim and liberated the COOH functionality, which activated by PyBop represents the attachment site for the P_3CS immunoadjuvant unit. The very difficult synthetic step was the simultaneous introduction of four *S*-Tn Ags at the wide rim of the calix[4]arene platform (Scheme 3).

Different synthetic procedures to couple compound **8** (Scheme 2) and **10** via amide bonds were investigated. NHS/EDC, methyl morpholine/triazine, HOBT/EDC, and HOAT/EDC were tested as coupling agents. A better yield of **11** was obtained by activation of the *S*-Tn Ag by means of HOAT/EDC in dry DMF followed by the addition of a solution of compound **10**, drop by drop under argon. MALDI-TOF mass spectrometry revealed a signal at $m/z = 3333.4$ corresponding to the $[M + Na]^+$ ion.

The complex ^1H NMR spectrum of **11** ($CDCl_3$/MeOD mixture) showed overlapping resonances which made difficult the signal assignment. However, the signals relative to the anomeric proton (4.84 ppm, 4H) and acetyl groups of the *N*-acetyl-galactosamine (1.63, 1.68, and 1.72 ppm; 12H) clearly indicated the presence of four *S*-Tn antigen units linked to the calix[4]arene macrocycle.

Biological Assay. The determination of antibodies against saccharides using standard enzyme immunoassay has been more difficult than the assays for detection of antibodies toward proteins, because sugars have very weak passive binding to plastic ELISA plate surface. To circumvent this aspect, different new polar plastic surfaces have been developed with the purpose of increasing the absorption of hydrophilic macromolecules (*48*). Nevertheless, when considering the binding efficiency of adsorbant plastic surfaces for biomacromolecules, it is important to distinguish between the total amount of molecules bonded and molecules that still remain biologically active. As an example, the binding of the carbohydrate moiety of glycopeptidic antigens on a hydrophilic surface can reduce their antibody binding activity, since the carbohydrate moiety normally is the major antigenic determinant. For the Tn antigen, it is reported that the hydrophilic *N*-acetyl-galactosamine is involved in the interaction with the immune system (*49*). To date, for Tn antigen (GalNAc-Ser) no direct absorption binding to ELISA plate has been described.

Table 1. End-Point Titers of Total Specific Anti-Tn IgG Antibodies in Mice after Immunization with Clustered (11) and Nonclustered Monovalent Constructs (12)[a]

construct	end-point titer[b,c]
11	1:16000
12 4×	1:8000
12 1×	1:4000

[a] The reference monovalent construct (**12**) was tested at 1× and 4× molar ratios with respect to **11**. [b] Data points represent the mean value from group of five animals. [c] End-point titers were defined as the highest serum dilution that resulted in an absorbance value two times greater than that of nonimmune control mouse serum.

Recently, a CovaLink NH secondary amine surface has been developed for covalent coupling of carbohydrates and nucleic acids to polystyrene (*50*). The NH functional group of the Covalink plate is spaced 2 nm via alkyl spacers from the polystyrene surface wall to minimize steric hindrance. Covalent binding through a secondary amine group has a number of advantages over passive adsorption such as high binding strength, binding of distinct functional groups, specific orientation of molecules, and improved stability (*49*, *51*). In this paper, we report for the first time the covalent binding of Tn antigen glycomimetic to CovaLink NH microtiter plates (Scheme 4). The resulting functionalized plates were used in the end-point dilution ELISA assay for the specific detection of anti-Tn IgG antibodies.

Immunological Evaluation. We evaluated the immunogenicity of the tetra-Tn mimotope target construct (**11**) using as reference compound a monovalent construct (Chart 1), previously synthesized (*29*) and bearing the same antigen. The reference construct was tested at two concentration levels, 1× and 4×, with respect to compound **11** (0.030 and 0.120 μM/mouse).

The aim was to investigate the role of the "cluster effect" in amplifying the antibody production with respect to a simple concentration increase of Tn antigen units. Sera from the groups of mice were examined for antibody production by the ELISA tests described above.

As reported in Figure 1 and Table 1, all three groups treated with the constructs under examination increased the total Tn-specific IgG antibodies with respect to control animals.

In the serum dilution range considered, mice immunized with compound **11** showed a substantial and significant ($p < 0.05$) production of antibodies. An increase of the end-point titers of 4-fold (1:16000) was measured with respect to the mice immunized using at the equimolar level (0.030 μM/mouse) the reference monovalent construct (1:4000). Even when the concentration of monovalent construct was increased 4-fold with respect to compound **11** (0.120 and 0.030 μM/mouse, respectively), so to compare solutions with the same number of Tn Ag units, the reactivity elicited by the clustered construct was

significantly higher ($p < 0.05$) in the range of serum dilution considered, with a 2-fold increase in the end point titer (1:8000 and 1:16000, respectively). Regarding the monovalent construct, when the molar concentration was quadruplicated the end-point titer increased by only 2-fold (1:4000 and 1:8000, respectively).

Taken together, these data clearly show that a cluster effect determines the higher immunostimulating activity of the tetravalent construct with respect to the monovalent analogue. A cluster effect determining specific lectin-binding ability and amplified lectin affinity has been reported for other glycocalixarene derivatives (*52*). The cluster effect is widely present in natural systems, where it increases strength and specificity in molecular recognition processes (*53–56*). In carbohydrate−protein interaction, the poor association constants for monovalent interactions ($K_a = 10^{3-4}$ M^{-1}) (*57–59*) are amplified by clustering multiple copies of carbohydrates binding multiple receptor sites. Also, the Tn antigens on mucin surface are organized in clusters which represent the preferred targets of many antitumor monoclonal antibodies (*19–23*). Therefore, the efficient antibody production elicited by tetrameric construct **11** evidences the existence of a cluster effect and that the array of Tn Ags assembled on the rigid calix[4]arene scaffold ensures a good mimicking of the natural motif encountered in vivo.

CONCLUSION

A novel, well-defined synthetic multivalent vaccine candidate has been designed. By sequential amide coupling, four *S*-Tn glycomimetic antigens and one P_3CS immunoadjuvant moiety have been anchored at the two different faces (wide and narrow rim) of a calix[4]arene macrocyle. To the best of our knowledge, this construct represents the first example of a vaccine candidate built on a nonpeptidic platform. The results presented in this study demonstrate that the target construct (**11**) induces a more effective immune response when compared to the monovalent reference compound tested both at the same and at 4-fold more concentrated level. The higher production of anti Tn IgG antibodies elicited by tetrameric construct **11** is ascribable to a cluster effect and suggests that the arrangement of Tn Ags on the rigid calix[4]arene scaffold mimics the mucine surface properly. This reveals perspectives for potential applications in cancer immunotherapy.

ACKNOWLEDGMENT

The authors thank Dr. D. Ventura of Etna Biotech (Catania, Italy) for his help in performing the biological study and for sharing his valuable experience and knowledge in working with immune system issues. Thanks are due to Professor S. Sciuto (University of Catania) for helpful discussions.

Contribution of Linker Stability to the Activities of Anticancer Immunoconjugates

Stephen C. Alley, Dennis R. Benjamin, Scott C. Jeffrey, Nicole M. Okeley, Damon L. Meyer, Russell J. Sanderson, and Peter D. Senter*

Seattle Genetics, Inc., 21823 30th Drive SE, Bothell, Washington 98021. Received November 26, 2007; Revised Manuscript Received January 10, 2008

The linker component of antibody−drug conjugates (ADC) is a key feature in developing optimized therapeutic agents that are highly active at well tolerated doses. For maximal intratumoral drug delivery, linkers are required that are highly stable in the systemic circulation, yet allow for efficient drug release at the target site. In this respect, amide bond-based technologies constitute a technological advancement, since the linker half-lives in circulation ($t_{1/2} \sim 7$ days) are much longer than earlier generation linkers that break down within 1–2 days. The amide linkers, some of which contain peptides, are appended to the mAb carriers through thioether/maleimide adducts. Here, we describe that use of a bromoacetamidecaproyl (bac) in place of the maleimidocaproyl (mc) increases the plasma stability of resulting thioether ADCs. One such ADC, 1F6-C4v2-bac-MMAF, which is directed against the CD70 antigen on lymphomas and renal cell carcinoma, was prepared containing a bac thioether spacer between the drug (MMAF) and the mAb carrier (1F6-C4v2). There was no measurable systemic drug release from this ADC for 2 weeks postadministration in mice. In order to assess the impact of improving linker stability beyond mc containing ADCs, a series of mc and bac-linked 1F6-MMAF conjugates were compared for tolerability, intratumoral drug delivery, and therapeutic efficacy in nude mice with renal cell carcinoma xenografts. There were no statistically significant efficacy differences between sets of mc and bac containing ADCs, although the bac linker technology led to 25% higher intratumoral drug exposure over a 7 day period compared to the corresponding mc linker. The mechanism of drug release from maleimide-adducts likely involves a retro-Michael reaction that takes place in plasma, based on in vitro studies demonstrating that some of the released drug-maleimide derivative became covalently bound to cysteine-34 of serum albumin. In summary, the data indicate that new linkers can be obtained with improved in vivo stability by replacing the maleimide with an acetamide, but the resulting ADCs had similar tolerability and activity profiles.

INTRODUCTION

The toxicity associated with systemically administered anticancer drugs has generated significant interest toward improving drug delivery to tumors while sparing nontarget tissues from chemotherapeutic damage. Antibody−drug conjugates (ADCs), composed of cytotoxic agents fused via conditionally labile linkers to monoclonal antibodies (mAbs) against tumor associated antigens, have figured prominently within this field, with clinically approved drug such as Mylotarg (anti-CD33-calecheamicin) for the treatment of acute myelogenous leukemia (*1–3*) and an array of newer ADCs in various stages of preclinical and clinical development (*4–14*). Studies surrounding these agents have led to the identification of several critical parameters that must be addressed in order to develop targeted drugs with broad applicability for clinical cancer medicine. These include nontarget tissue uptake of ADCs, the heterogeneity of both antigen expression and macromolecular uptake within tumor masses, inappropriate linker stability, inefficient drug release within tumors, and release of drugs with low potency (*6, 15, 16*).

Linker stability plays a central role in ADC efficacy and tolerability. Early generation ADC linkers were commonly derived from disulfides and acid-labile hydrazones, both of which were designed to be cleaved inside target cancer cells, but inevitably underwent cleavage at nontarget sites. Because of this, significant effort has been directed toward balancing the stability of these linkers in the circulation, while still allowing them to be sufficiently labile for activation at the target site. One of the first systematic studies along these lines involved conjugates of ricin A-chain attached to mAbs through differentially hindered disulfide bonds (*17, 18*). The hindered disulfide provided improved conjugate stability in vivo, together with a better therapeutic window in xenograft tumors. These findings were later extended to include ADCs composed of the potent cytotoxin maytansine. Conjugates with sterically hindered disulfides displayed potent antitumor activity and had improved biological stability compared to their less hindered counterparts (*6, 15, 16, 19*). Consistent with this trend is our earlier finding that acid-labile hydrazone linkers provided lower specificity in vitro and higher levels of toxicity in vivo compared to highly stable linkers (*20*). Such studies, together with others (*21, 22*), demonstrate how linker stability can influence ADC activity, specificity, and toxicity.

The approach we have taken toward advancing conditionally labile linker technologies involves the use of intracellular enzymes for drug release. The first example involved valine-citulline (vc) dipeptide derivatives of the potent antimitotic drug, monomethyl auristatin E (MMAE), which were designed to release MMAE upon exposure of the ADCs to lysosomal proteases such as cathepsin B (*20, 23*). While lysosomal enzymes can be detected in the blood, their activities are very low due to endogenous inhibitors and the high pH value of blood compared to lysosomes. Thus, free MMAE was released from vc-linked MMAE ADCs in plasma more slowly ($t_{1/2} > 30$ d) than corresponding acid-labile hydrazone-based ADCs ($t_{1/2} \sim 2$ d) (*20*). This trend in increased ADC stability was also observed in vivo, in that the half-life of drug release from the ADC was 6

days in mice and 10 days in Cynomolgus monkeys for the vc-linked drug (*24*), which is considerably longer than previously reported half-lives of hydrazones and disulfides (*24–26*).

The effects of extending in vivo linker half-life beyond 6–10 days are not known. To investigate this, we describe the generation of new ADCs with drug linkers that show no degradation in the circulation for up to 14 days. Interestingly, this new drug linker does not impact ADC in vivo therapeutic efficacy and tolerability when compared with ADCs that have half-lives of approximately 7 days.

EXPERIMENTAL PROCEDURES

Cell Lines and Reagents. 1F6 (chimeric anti-CD70 (*27*)), 1F6-C4v2 (humanized anti-CD70 with cys to ser heavy chain amino acid substitutions at positions 226 and 229) (*28*) and AC10 (chimeric anti-CD30 (*23*)) are IgG1 mAbs that were isolated as previously described. The human renal cell carcinoma cell lines 786-O, UMRC-3, and Caki-1 were obtained from ATCC. The human lymphoma cell line L428 was obtained from the DSMZ (Braunschweig, Germany). All cell lines were cultured according to the manufacturers suggested protocol. LC/MS and LC/MS/MS spectra were recorded on a MicroMass Q-TOF Ultima mass spectrometer equipped with a Z-spray ion source and a Waters 2795 HPLC system. mc-MMAF, mc-vc-MMAF, bac-MMAF (LC-MS *m/z* (ES^+) 965.8 (M+H)), and bac-vc-MMAF (LC-MS *m/z* (ES^+) 1370.7 (M+H)) were obtained as previously described (*29, 30*).

Preparation of Conjugates. Alkyl-maleimide linked 1F6, 1F6-C4v2, and AC10 ADCs were prepared as previous described (*28, 30*). For the bromoacetamides, the reduced antibodies (*30, 31*) were adjusted to pH 8 with sodium borate and incubated with 2 equiv of bac-vc-MMAF or bac-MMAF per antibody cysteine for 4 h at 25 °C. Subsequent purification and characterization of all ADCs were as previously described (*30*). The conjugated antibodies were unimpaired with respect to affinity for their targets (CD70 for 1F6 and CD30 for AC10) and contained <2% aggregate and <0.5% unconjugated drug.

ELISAs. The concentration of the 1F6-C4v2 component of the ADCs in plasma was measured using a previously described ELISA assay (*24*) using 96-well plates coated with an anti-idiotype-1F6 mAb at a concentration of 1 μg/mL in 100 mM sodium carbonate/bicarbonate (pH 9.6). The plasma samples were then diluted to 500 ng/mL h1F6-C4v2 mAb into PBS with 0.05% Tween 20 containing 1% BSA (PBST/BSA) and added to wells in triplicate. An hour later, the wells were washed, and anti-MMAF mAb SG3.265-biotin (1 μg/mL in PBST/BSA) was added and incubated an additional hour. The wells were washed, and streptavidin-HRP (diluted into PBST/BSA) was added and incubated for 1 h at room temperature. Detection was initiated using TMB substrate added to the washed wells. Reactions were terminated with 1 N H_2SO_4 and absorbance was measured at 450 nm against a reference wavelength of 630 nm. On the same 96-well microtiter plate, samples and standards were also subjected to total mAb ELISA analysis to ensure that the amount of mAb backbone captured to the plate were comparable. The results were compared with standards consisting of purified 1F6-C4v2-mc-$MMAF_n$ or 1F6-C4v2-bac-$MMAF_n$ ADC standards in plasma (n = 1, 2, 3, or 4 drug-linkers per mAb) that were similarly processed. Linear regression analysis of data from the standards was used to obtain an equation relating the average drug/mAb ratio of the relevant ADC to the measured OD_{450}.

Biodistribution. All animal studies were carried out in accordance with Animal Care and Use Committee guidelines. Balb/c nu/nu mice with subcutaneous 786-O tumors xenografts (in vivo passaged, 100–150 mm^3) were treated i.v. with the ADCs at 1.5 mg/kg in PBS. At the time points indicated, mice were sacrificed by CO_2 inhalation, and were then terminally bled. Serum, tumor, and liver were stored at −80 °C until all of the samples were collected. Tumor and liver samples were thawed on ice, 4 mL/gram of tissue of PBS was added, and the tissue was mechanically homogenized on ice. MMAF was extracted from 100 μL homogenate by addition of 100 μL of 0.2% formic acid in water and 400 μL of acetonitrile. After spiking with ^{13}C-MMAF internal standard (*30*), the mixture was incubated at 25 °C for 1 h with occasional vortexing. Following centrifugation to pellet cell debris and precipitated proteins, the supernatant was extracted using a Waters (Milford, MA) Oasis MCX 96-well plate that was conditioned with 0.4 mL (volumes are per well) of 2% ammonium hydroxide in dichloromethane: isopropyl alcohol (80:20), 0.4 mL of methanol, and 0.4 mL of water. The plate was washed with 0.4 mL of 0.2% aqueous formic acid and 0.4 mL of methanol. MMAF was eluted with 2 treatments of 0.4 mL of 2% ammonium hydroxide in dichloromethane/isopropyl alcohol (80:20). The elution solvent was evaporated in a vacuum concentrator and samples were reconstituted in 50 μL of 50% aqueous acetonitrile. For serum samples, serum was mixed with 1 volume of 0.2% aqueous formic acid, spiked with °C-MMAF, and extracted as described above for the tumor and liver samples.

Samples were analyzed by LC-MS/MS by injecting 20 μL of the reconstituted sample onto a 2.1 × 30 mm Agilent (Santa Clara, CA) Zorbax SB C8 column running on a Waters Acquity liquid chromatograph (flow rate 1 mL/minute; column temperature 40 °C; gradient conditions isocratic 5% B (0.1% formic acid in acetonitrile) 95% A (0.1% aqueous formic acid) for 0.5 min, 0.05 min linear gradient to 70% B, isocratic for 0.15 min, 0.05 min linear gradient to 95% B, isocratic 95% B for 0.05 min. The eluted solvent was directed into a Waters Quattro Premier triple quadrupole mass spectrometer operating in multiple reaction monitoring mode. MMAF was analyzed using its 732 *m/z* parent ion and 700 *m/z* fragment ion, while the ^{13}C-MMAF internal standard was analyzed using its 738 *m/z* parent ion and 706 *m/z* fragment ion. Standard curves were generated by spiking MMAF and ^{13}C-MMAF internal standards into tissue homogenates or serum from untreated tumor-bearing animals which were then treated as described above. All data collection and sample analyses were performed using *MassLynx* version 4.0.

Identification of mc-MMAF-Modified Peptides in Plasma. AC10-mc-MMAF was diluted with 50% citrated rat plasma to 5 mg/mL. Half of the reaction was removed and stored at −20 °C as a time zero reference, and the remaining mixture was placed at 37 °C for 5 days. The samples (50 μL) were treated with 8 M urea in 0.5 M ammonium bicarbonate (1.8 mL), dithiothreitol (45 mM, 0.36 mL) was added, and incubation was carried out at 50 °C for 20 min, followed by cooling to room temperature and treatment with iodoacetamide (2.2 mol equiv per mole dithiothreitol) in the dark for 15 min. The samples were then diluted with water to a final urea concentration of 1.9 M, and trypsin (TPCK, Pierce) was added (final concentration 13 μg/mL). After overnight incubation at 37 °C, the solutions were desalted on Pep-Clean C18 spin columns (Pierce), using seven columns for each reaction. The resins were prepared according to manufacturer's instructions and the samples were loaded in 100 μL steps with each sample being reloaded three times to ensure complete capture of peptides. The resin was washed with 5% acetonitrile 0.5% TFA (2 × 200 μL) and then eluted with 70% acetonitrile (2 × 20 μL, 1 × 50 μL). The elutions for each sample were combined and dried under centrifugal vacuum. The peptide residues were dissolved in acetonitrile (87.5 μL) and diluted with PBS (663 μL). Particulates were collected by centrifugation (16 000*g*, 5 min) and were redissolved in DMSO (20 μL) and combined with the super-

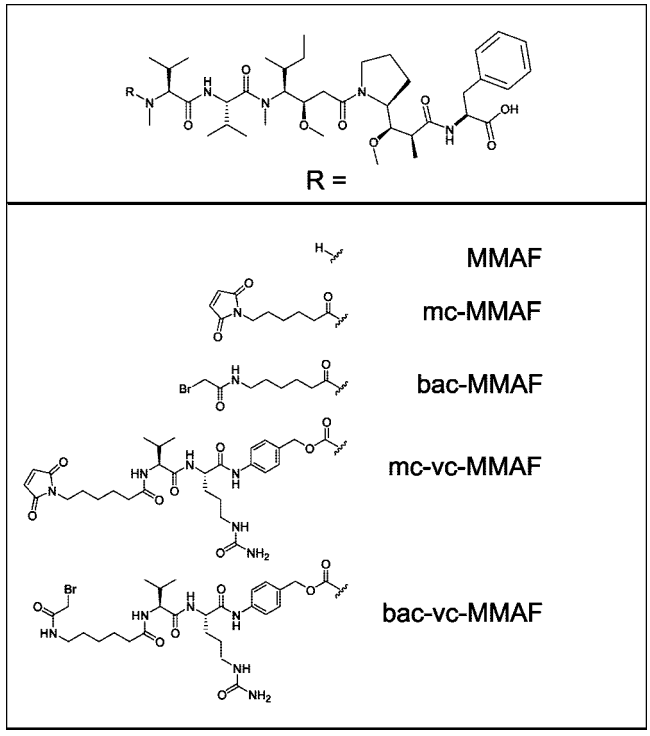

Figure 1. Structures of MMAF and linkers.

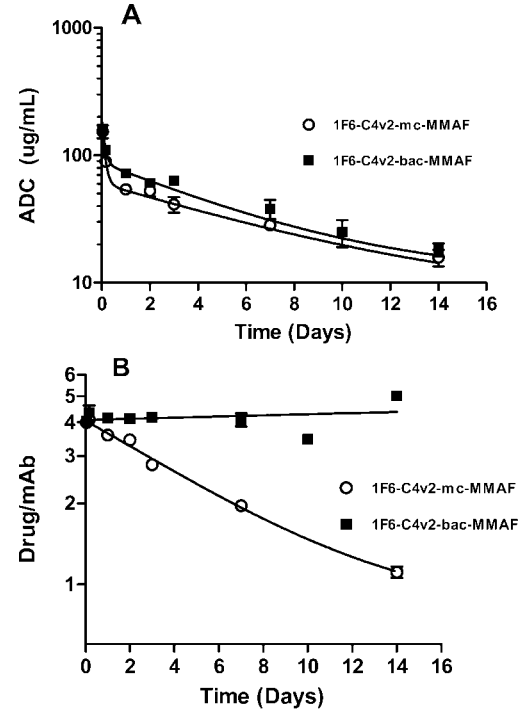

Figure 2. In vivo stability of auristatin ADCs. The mAb concentrations (A) were determined in plasma samples after a single injection of 10 mg/kg of 1F6-C4v2-mc-MMAF and 1F6-C4v2-bac-MMAF (3 animals/group). The drug/mAb ratios (B) were determined using an ELISA whose total signal is proportional to the drug loading of the ADC. The mc-MMAF conjugate shows dissociation of MMAF from the antibody with a half-life of approximately 7 days.

natant. The samples were further diluted with additional PBS to bring the organic solvent composition to 6%.

An Affigel-10 resin coupled to the anti-mc-MMAF antibody SG2.15 was used to capture mc-MMAF-containing peptides from the samples. Each sample was added to 0.9 mL of resin bed and was mixed at 4 °C for 4 h. The slurries were washed with PBS (6 × 2 mL). The bound peptides were eluted by incubation with 5.5 M guanidine hydrochloride (Pierce) in PBS at room temperature for 4 h followed by 20 min at 37 °C. A second elution with fresh guanidine hydrochloride solution was carried out at 37 °C for 30 min. The combined guanidine elutions were desalted on Pep Clean C18 spin columns as previously described using three columns per sample. The eluted peptides were dried by centrifugal vacuum and dissolved in 0.1% TFA. Drug-captured and desalted peptides were examined by LCMS using a Poroshell 300SB-C18 column (Agilent, 2.1 × 75 mm, 5 μm). The samples were separated at 0.2 mL/ minute on a gradient starting at 0% B (0.1% formic acid in acetonitrile), 100% A (0.1% formic acid) for 3 min, then ramping to 15% B over 7 min followed by 15–23% B over 30 min, 23–28% B over 1 min, 28–40% B over 10 min, and finally 40–100% B over 4 min.

In Vitro Cytotoxicity. Log phase cultures of cells were collected and cells were plated at seeding densities ranging from 500 to 10 000 cells/well according to predetermined conditions. After incubating for 24 h, serial dilutions of test molecules were added, and cultures incubated a further 4 days. Assessment of cellular growth was determined using Alamar Blue (Biosource International, Camarillo, CA) dye reduction as previously described (*30*). Briefly, a 40% solution (wt/vol) of freshly prepared Alamar Blue was added to the cells to constitute 10% culture volume. Cells were incubated for 4 h, and dye reduction was measured on a fluorescent plate reader.

In Vivo Efficacy and Tolerability. In vivo efficacy of ADCs were evaluated in female nude mice bearing 786-O xenografts. Once tumors grew to approximately 100 mm^3, test articles in PBS were injected into the tail vein at the indicated doses. Tolerability of ADCs were evaluated using BALB/c mice. The maximum tolerated dose (MTD) is defined as the highest dose that did not induce >20% weight loss, distress, or overt toxicities in any of the animals, and was generally within 20% of doses where such events took place.

Table 1. IC_{50} Values of Immunoconjugates on CD70 Expressing Cell Lines

	IC_{50} (nM)				
ADC	786-O	Caki-1	UMRC-3	L428	LP-1
1F6-C4v2-mc-MMAF	>1000	93	>1000	180	200
1F6-C4v2-bac-MMAF	450	90	490	52	88

Table 2. Percent Weight Change in Treated BALB/c Mice

ADC	day 4	day 9
1F6-C4v2-mc-MMAF 150 mg/kg	3.3	2.0
1F6-C4v2-bac-MMAF 150 mg/kg	−2.6	2.1
1F6-C4v2-mc-vc-MMAF 20 mg/kg	−5	3.0
1F6-C4v2-mc-vc-MMAF 40 mg/kg	−13	not tolerated
1F6-C4v2-mc-vc-MMAF 60 mg/kg	−19	not tolerated
1F6-C4v2-bac-vc-MMAF 20 mg/kg	−9	1.6
1F6-C4v2-bac-vc-MMAF 40 mg/kg	−19	not tolerated
1F6-C4v2-bac-vc-MMAF 60 mg/kg	−22	not tolerated

RESULTS

Auristatin Conjugates. The structures of the previously reported alkyl-maleimide containing drugs vc-MMAF and mc-MMAF (*30*), together with a set of related MMAF derivatives containing bromoacetamides in place of the alkyl-maleimide moieties, are shown in Figure 1. These MMAF-linker derivatives were designed to react with thiols, such as mAb cysteines generated after disulfide bond reduction. The antibodies used were 1F6 (chimeric IgG1 recognizing the CD70 antigen) (*27*), 1F6-C4v2 (humanized IgG1 anti-CD70 mAb with heavy chain

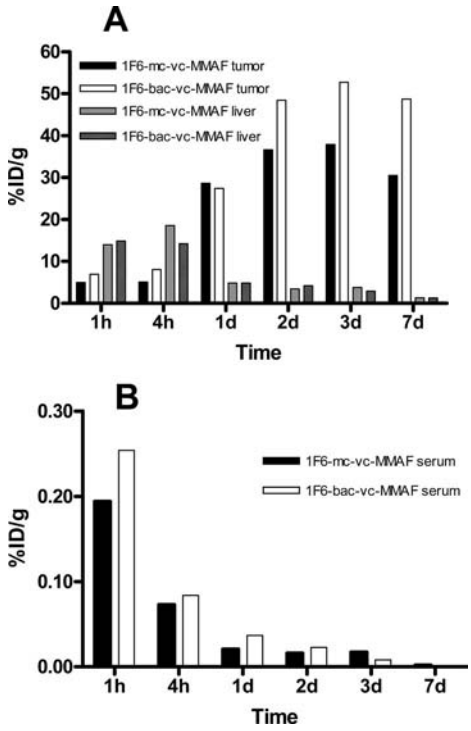

Figure 3. Concentrations of MMAF in (A) tumors and liver, and (B) serum obtained with mc-vc-MMAF and bac-vc-MMAF ADCs (2 animals/group). The results are expressed as the % of the injected dose (%ID) per gram of tissue. The initial weights of the tumors, livers, and blood were approximately 0.1, 1.0, and 1.0 g, respectively.

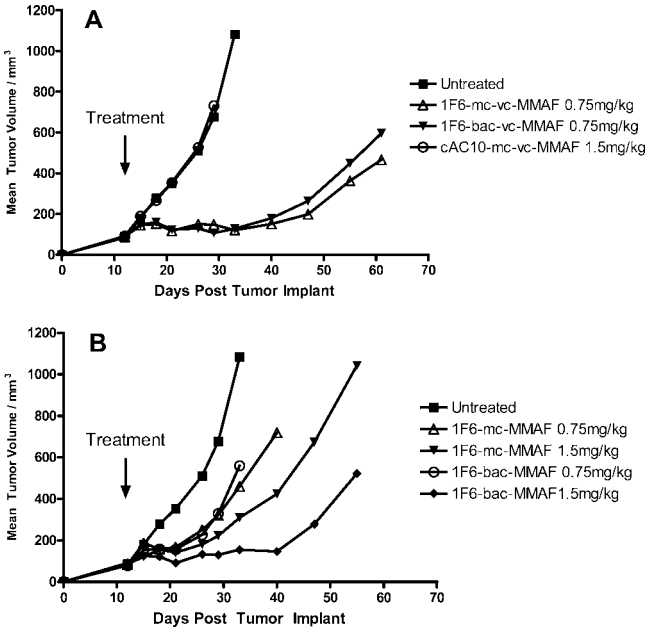

Figure 4. In vivo therapeutic efficacy of the conjugates in SCID mice. Groups of mice (five/group) with subcutaneous 786-O renal cell carcinoma xenografts were treated once (arrow) with conjugates at the doses indicated once the tumors were staged and growing. (A) Comparison of in vivo therapeutic efficacy of vc containing conjugates formed through acetamide (bac) and maleimide (mc) adducts, and (B) similar studies with directly linked ADCs lacking the vc peptide.

cysteine to serine substitutions at positions 226 and 229) (*28*), and AC10 (chimeric IgG1 recognizing the CD30 antigen) (*23*). Reduction of interchain disulfides was accomplished using the reducing agent tris(2-carboxyethyl)phosphine (TCEP), such that an average of two disulfides/mAb were reduced for the 1F6 and AC10 mAbs. Addition of the drug linker complexes led to

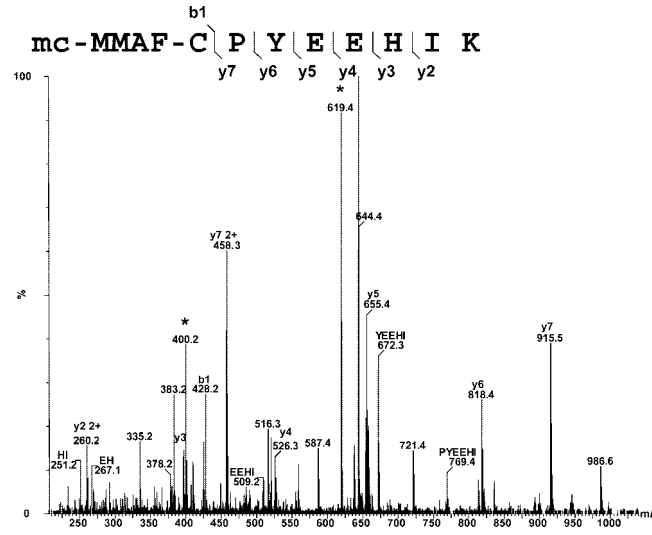

Figure 5. LC/MS/MS spectrum of the rat serum albumin (RSA) peptide-mc-MMAF adduct obtained upon incubation of AC10-mc-MMAF in rat plasma at 37 °C. The *m*/*z* of this peptide (648.4, (m+3)/3) and the MS/MS spectrum are consistent with RSA tryptic peptide T6 (residues 34–41 of the mature protein) modified with mc-MMAF at cysteine-34. Asterisks mark the a1 (400.2) ion containing mc-MMAF and the C-terminal tetrapeptide of MMAF (619.4), which is also a prominent in-source fragmentation ion.

conjugates having an average of four drugs/mAb, with a distribution centered at four drugs/mAb, but ranging between zero and eight. In contrast, the 1F6-C4v2 mAb provided ADCs that were highly homogeneous, since full reduction of the mutated mAb provided only four thiol groups for conjugation (*28*), which led to high yields of 1F6−C4v2-mc-MMAF with four drugs/mAb.

A previously described ELISA assay was used to determine drug to antibody ratios upon prolonged in vitro ADC incubation or after in vivo ADC administration (*24*). The results were compared with a 1F6-C4v2-bac-MMAF conjugate that did not contain a maleimide/thioether adduct. The recombinant mutated mAb was used for all these studies, ensuring that the administered drug was as homogeneous as possible, with initial uniform substitution of four drugs/mAb.

The first step in measuring in vivo ADC stability involved determining ADC concentrations in blood samples of treated animals. An anti-idiotype-based ELISA provided a half-life for clearance of both conjugates in nude mice of approximately 7 days (Figure 2A). Samples from this assay were then subjected to an ELISA using an anti-drug mAb that bound to conjugated drug to an extent that reflected the level of drug substitution on the 1F6 mAb. As shown in Figure 2B, 1F6-C4v2-mc-MMAF lost drug with a half-life of 7 days, which is consistent with an earlier reported half-life of 6–10 days for a maleimide containing auristatin conjugate (*24*). In contrast, the 1F6-C4v2-bac-MMAF conjugate was more stable in vivo, with no apparent drug loss throughout the 14 day assay period.

Cytotoxicity. The 1F6-C4v2 auristatin conjugates were tested on a panel of CD70 expressing renal cell carcinoma cell lines, as shown in Table 1. Cells were exposed to the ADCs continuously for 96 h, and the cytotoxic effects, compared to untreated control cells, were determined by Alamar Blue conversion. Both the dipeptide ADCs with cleavable linkers (bac-vc and mc-vc-MMAF ADCs) exhibited potent and uniform activities against all cell lines tested. The fact that the two conjugates appear to be equally potent is not surprising, given that they release the same drug (MMAF) upon linker cleavage. In contrast, drug release from the 1F6-C4v2-mc-MMAF and bac-MMAF conjugates requires antibody degradation (*30*), and

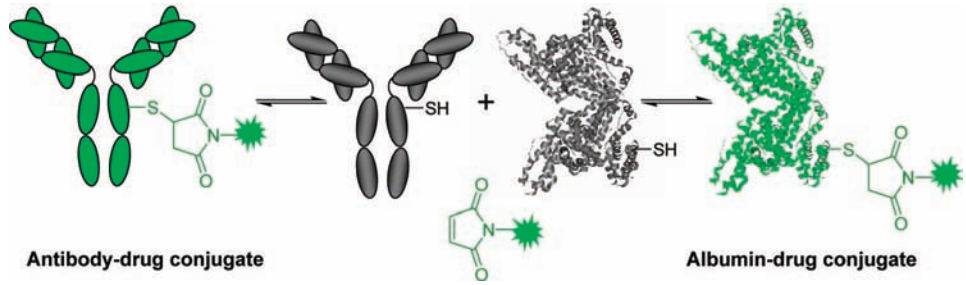

Figure 6. Proposed mechanism of drug transfer from an antibody to albumin through the thioether fragmentation reaction.

the released drugs are not chemically identical, since they contain linker and amino acids from the mAb. Based on previous studies of related ADCs (*30*), the 1F6-C4v2-mc-MMAF conjugate releases cysteine-mc-MMAF upon antibody degradation, and 1F6-C4v2-bac-MMAF should release the corresponding acetamidocysteine adduct. The data in Table 1 show that 1F6-C4v2-bac-MMAF leads to slightly greater potency than 1F6-C4v2-mc-MMAF on all but the Caki-1 cell line, and both ADCs are significantly less potent than the corresponding vc-MMAF ADCs.

Maximum Tolerated Doses. BALB/c nude mice were injected with the conjugates as indicated in Table 2, and the MTDs were determined based on body weight loss and outward signs of toxicity. Both 1F6-mc-MMAF and 1F6-bac-MMAF ADCs were nontoxic at 150 mg/kg, the highest dose tested. On the other hand, the dipeptide-containing ADCs, 1F6-mc-vc-MMAF and 1F6-bac-vc-MMAF, had MTDs of approximately 20 mg/kg. At 40 mg/kg, both ADCs were not tolerated. Therefore, tolerability was not apparently affected when comparing corresponding maleimide and acetamide derived ADCs. The differences in MTDs between the mc and vc-derived ADCs are most likely due to structural differences, as indicated above, between the released drugs.

Drug Delivery. An LC/MS/MS based assay was established to determine the amount of drug present in subcutaneous 786-O renal cell carcinoma xenografts, as well as the liver and serum of BALB/c mice treated with 1F6-mc-vc-MMAF and 1F6-bac-vc-MMAF conjugates at 1.5 mg/kg. The only identifiable drug released from these ADCs was MMAF, consistent with dipeptide cleavage followed by fragmentation of the *p*-aminobenzylcarbamate spacer (*20*). Figure 3A shows that tumor drug levels peaked at approximately 3 days, at which point 1F6-bac-vc-MMAF treated mice had higher intratumoral drug concentrations than those treated with the 1F6-mc-vc-MMAF ADC. Over the period of 7 days, the AUC difference was 25%. The liver (Figure 3A) and serum (Figure 3B) drug concentrations from the two ADCs were similar, consistent with early ADC exposure and lack of drug retention.

Efficacy. The therapeutic effects of the ADCs were determined in nude mice with subcutaneous 786-O tumor xenografts. Since the goal of these experiments was to determine if there were differences between the ADCs, each animal was injected only once at doses that were previously shown to be subcurative (*27*). As expected, 1F6-mc-vc-MMAF displayed significant antitumor activities (Figure 4A). Similar therapeutic effects were obtained with the corresponding 1F6-bac-vc-MMAF ADC, suggesting that the two agents were comparable in activity and potency. The antigen-specific nature of these activities was confirmed through the lack of activity displayed by cAC10-mc-vc-MMAF, an anti-CD30 ADC that does not bind to CD30 antigen negative 786-O cells.

A similar trend of activities was obtained with the ADCs that lacked the dipeptide spacer (Figure 4B). At 0.75 mg/kg, there was a slight delay in tumor outgrowth for both 1F6-mc-MMAF and 1F6-bac-MMAF with no apparent differences between the two groups. The effects at 1.5 mg/kg were more pronounced for both ADCs. Although 1F6-bac-mc-MMAF appears to display a higher degree of antitumor activity than 1F6-mc-MMAF, the difference is not statistically significant (*P* values of 0.10 and 0.11 for days 47 and 55, respectively). These results are consistent with the localization studies which showed comparable levels of drug accumulation for bac and vc-based ADCs (Figure 3A).

Fate of Released Drug. Having established that linker plasma stability was enhanced upon replacement of the maleimide with an acetamide functionality, in vitro experiments were undertaken to identify the fate of the released drug from AC10-mc-MMAF. The ADC was incubated in rat plasma at 37 °C for 5 days, treated with trypsin, and auristatin-conjugated peptide fragments were separated from other plasma proteins by affinity chromatography on a column with an immobilized anti-auristatin mAb. Bound material was eluted, and the resulting peptides were analyzed by LC-MS. The identity of auristatin adducts was facilitated by the prominent in-source auristatin fragmentation peak at *m/z* 619.4. Before incubation, all of the auristatin adducts were comprised of antibody peptides that contained interchain cysteines. Comparison of these traces from the samples obtained after the 5 day plasma incubation revealed a new peak, whose *m/z* and MS/MS spectrum were consistent with a rat serum albumin peptide (residues 34 to 41) modified with the mc-MMAF drug linker (Figure 5). The fragmentation pattern of this peak demonstrated that mc-MMAF was covalently bound to cysteine-34 in albumin. We have confirmed that the same transfer reaction takes place in mice treated with 1F6-C4v2-mc-MMAF (data not shown). Thus, prolonged exposure of alkyl-maleimide auristatin ADCs to plasma proteins may lead to a slow transfer of drug to albumin cysteines. We propose that the mechanism for drug transfer proceeds through the reaction scheme depicted in Figure 6. The first step involves a reversible fragmentation reaction in which the alkyl-maleimide drug product dissociates from the mAb. In buffers such as PBS, this reaction is not observed, since the conjugation reaction is favored. However, in blood or plasma the predominant thiol-containing protein is albumin, which contains a reactive cysteine residue at position 34. The reaction of the maleimide with this cysteine results in the new species observed. The bac-containing ADCs are unable to undergo an analogous fragmentation reaction, and this accounts for their increased plasma stability.

DISCUSSION

Linker stability plays an important role in both the efficacy and toxicity of ADCs. Early generation ADCs often contained unstable linkers with short half-lives (1–2 days) such as disulfides (*17, 18, 26*) and hydrazones (*19, 25, 32*). More recently, attention has turned toward linkers with improved stability characteristics while in the systemic circulation (*15, 30*). Included among them are peptides (*20, 33*), glucuronides (*34*), and nonmetabolizable spacers that remain covalently attached to the drug after the mAb carrier is hydrolyzed in lysosomes of

target cells (*15*, *30*). ADCs incorporating such linkers were formed through the reaction of thiols on one of the components with alkyl-maleimides on the other. In the examples presented here, 1F6-C4v2-mc-MMAF and 1F6−C4v2-mc-vc-MMAF were both stable in buffers, but slowly released drug with approximately 7 day half-lives upon exposure to plasma proteins in vitro and in vivo. We demonstrate that simply by replacement of the maleimide with an acetamide, ADC stability can be significantly increased. There was no apparent drug release from circulating 1F6-C4v2-mc-MMAF in vivo 14 days after administration (Figure 2B). However, in spite of the stability differences between the bromoacetamide and alkyl-maleimide based ADCs, their efficacy, potency, and toxicity characteristics were indistinguishable. This is most likely due to the very similar half-lives (approximately 7 days) of both drug dissociation from the alkyl-maleimide linked conjugates and ADC blood clearance (Figure 2). Extending linker half-life much beyond the pharmacokinetic half-life is not likely to have a pronounced effect on drug exposure, due to reduced ADC concentrations over time. We have calculated a maximum blood AUC difference between the acetamides and maleimide/thioether adducts over 7 days of only 30%, which is in agreement with the 25% difference in tumors shown in Figure 3A. The relative effects on therapeutic efficacy resulting from such small differences are likely to be quite subtle.

The results reported here provide the first direct evidence that maleimide/thioether fragmentation can lead to conjugate instability. The results are similar to a previous report in which a bis-maleimide-linked radiometal immunoconjugate was shown to be unstable in serum, with transfer of the radiometal to albumin taking place (*35*). It was not determined whether the transfer reaction involved maleimide transfer or the formation of noncovalent albumin adducts. Here, we demonstrate that alkyl-maleimides undergo slow dissociation leading to covalent drug transfer to the cysteine-34 residue on serum albumin, the same residue that is thought to be alkylated when maleimide-containing anticancer drug derivatives are systemically administered (*36*–*39*). The transfer mechanism described here most likely involves regeneration of the maleimide through thioether fragmentation, followed by alkylation of the cysteine thiol group on albumin. Experiments to confirm the proposed mechanism include the lack of transfer to S-alkylated albumin, or lack of transfer to albumin in the presence of large excesses of competing thiols (data not shown).

In conclusion, we have demonstrated that ADCs with linker half-lives in the range of 7 days in mice result in nearly optimal safety and efficacy profiles. Attachment of the drug/linker derivatives to mAb thiols through acetamides extends the half-lives significantly by circumventing maleimide transfer. We are currently engaged in studies to more fully explore the activity and toxicity profiles associated with newer generation linker technologies, such as those described here.

ACKNOWLEDGMENT

We wish to thank Drs. Paul Carter, Svetlana Doronina, and Clay Siegall for their valuable input on the studies described, and Martha Anderson, Carol Morris-Tilden, and Jamie Miyamoto for expert experimental assistance.

Synthesis of Aminoglycoside Conjugates of 2′-*O*-Methyl Oligoribonucleotides

Kaisa Ketomäki and Pasi Virta*

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received November 20, 2007; Revised Manuscript Received January 4, 2008

Aminoglycoside conjugates of 2′-*O*-methyl oligoribonucleotides have been synthesized entirely on a solid phase using conventional phosphoramidate chemistry. For this purpose, appropriately protected neamine-derived phosphoramidites, viz., 2-cyanoethyl [6,3′,4′-tri-*O*-levulinoyl-N^1,N^3,$N^{2'}$,$N^{6'}$-tetra(trifluoroacetyl)neamine-5-*O*-ethyl] *N*,*N*-diisopropylphosphoramidite, **1**, and 2-cyanoethyl [6,3′,4′,2″,3″-penta-*O*-levulinoyl-N^1,N^3,$N^{2'}$,$N^{6'}$-tetra(trifluoroacetyl) ribostamycin-5″-yl] *N*,*N*-diisopropylphosphoramidite, **2**, have been prepared and attached via phosphodiester linkage to an appropriate 2′-*O*-methyl oligoribonucleotide. Levulinoyl esters are used to cap the hydroxyl groups of the aminoglycoside moieties, since they may be selectively removed prior to ammonolysis. In this manner, the potential *O*→*N* acyl migration is excluded. Applicability of the strategy has been demonstrated by the synthesis of eight different aminoglycoside conjugates, in which **1** and **2** are attached directly to the 5′-end (**6** and **10**) or, alternatively, to an inserted non-nucleosidic hydroxyalkyl armed branching unit (**3**, **4**, or **5**), which results in intrachain conjugates (**7**–**9**, **11**–**13**). The potential of these conjugates to act as a sequence-selective artificial nuclease has been studied.

INTRODUCTION

Aminoglycosides are well-known antibiotics having affinity for structural elements of RNA in which the usual base pairing is disrupted. Their bactericidal effect is based on binding to the ribosomal decoding site (A-site), which reduces the fidelity of protein translation (*1–4*), but they additionally have comparable affinities to other structurally related RNA targets. Aminoglycosides are, e.g., able to inhibit several ribozymes (*5, 6*) and, perhaps most interesting for the general public, they bind to important HIV regions, TAR,[1]RRE (*7, 8*), and DIS (*9, 10*), resulting in inhibition of viral replication. However, the known natural aminoglycosides are very diverse RNA binders, which is mainly a consequence of their polycationic nature. To overcome this promiscuity, numerous tailored aminoglycosides have been synthesized in recent years. One approach is conjugation of aminoglycosides to nucleobases (*9, 11–14*), oligonucleotides (*15*), or PNA (*16*), in which affinity to numerous RNA targets may be whittled down by increased sequence selectivity.

In addition to the binding properties discussed above, aminoglycosides show potential for chemical cleavage of RNA. This feature is common to diamines and polyamines in general (*17, 18*), but with aminoglycosides, the more defined spatial positioning of the amino groups, their individual pK_a values, and lowered conformational freedom may further accelerate the hydrolysis. As an example, neomycin hydrolyzes simple adenylyl(3′−5′) adenosine more effectively than an unstructured diamine (*19*). This metal-ion-independent catalytic activity expectedly remains at a marginal level, but remarkable rate acceleration may be obtained by participation of metal cations. Cu^{2+}-complexes of neamine and kanamycin have been reported to be efficient cleaving agents of RNA (*20*), and even of DNA (*21*). These observations give an insight that both requirements (the RNA recognition and the cleavage) for an artificial sequence-specific nuclease may already exist in aminoglycosides (*22–25*), but conjugation to a complementary oligonucleotide or PNA may be a respectable option. A PNA−neamine conjugate has been reported not only to bind to the HIV-1 TAR region, but also to catalyze its hydrolysis (*26, 27*). The conjugate results in relatively fast metal-ion-independent cleavage, enhances cellular uptake, and inhibits viral replication.

With the above goals in mind, aminoglycoside-conjugated oligonucleotides are an attractive subject in organic chemistry, but from the synthetic point of view, they may still need some consideration. Ligation of those two classes of biomolecules in solution has advantages, such as asimple protecting group scheme, but it may be time-consuming to carry out. Fully automated synthesis may, hence, be a more attractive choice. In that case, however, several amino and hydroxyl groups of an appropriate aminoglycoside have to be masked with easily removable protecting groups, which should be compatible with the standard oligonucleotide synthesis and, preferably, be base-labile. Furthermore, the amino groups should not be exposed when the adjacent hydroxyl groups still bear acyl-type protection, since *O*→*N*-acyl migration may take place. Base-modified 2′-deoxyuridine phosphoramidites, conjugated with 2,6-diaminoglucose (*28*) and neomycine units (*29*) have been used for the synthesis of aminoglycoside-modified oligonucleotides. The aminoglycoside moieties have been capped with protecting group combinations, such as acetyl esters with trifluoroacetamides and trifluoroacetylesters with Boc-carbamates. On using the former combination (*28*), a substantial amount of acetamide byproducts have been found in the product mixture. This has been attributed to acetyl capping of the trifluoroacetamide functions upon oligonucleotide assembly, but the possibility of acyl migration has not been excluded. The latter combination (*29*) overcomes acyl migration, but the strategy suffers from potential depurination, when expanded to adenine- and guanine-containing oligonucleotides.

Published on Web 02/19/2008

In the present study, an entirely solid phase synthesis of aminoglycoside conjugates of 2′-*O*-methyl oligoribonucleotides (**6**–**13**) using standard phosphoramidate chemistry has been described. Appropriately tethered neamine-based phosphoramidites, **1** and **2**, were first synthesized using cheap neomycin trisulfate as an initial starting material. The resulted phosphoramidites **1** and **2** were then attached to resin-bound oligonucleotides via a phosphodiester linkage. Inserted non-nucleosidic branching units (**3**–**5**) were utilized to obtain intrachain conjugates (**7**–**9**, **11**–**13**), or alternatively, direct coupling to the 5′-end was performed (**6** and **10**). Prior to ammonolysis, the resins were treated with a mixture of hydrazinium acetate to orthogonally remove the levulinoyl protections. In this manner, acyl migration to the adjacent amino groups on the aminoglycoside moieties (**1** and **2**) was eliminated. Applicability of the strategy was demonstrated by the synthesis of eight different conjugates (**6**–**13**), which all were obtained with acceptable 41–65% purity. A strategy to obtain intrachain conjugates (**7**–**9**, **11**–**13**) was devised to be expanded to the library synthesis, in which various conjugates may readily be obtained by mixing different building blocks, the aminoglycosides (**1** and **2**) with the branching units (**3**–**5**), at an appropriate site in the oligonucleotide sequence. Since a neamine PNA conjugate has been reported to be an efficient artificial nuclease (*26*, *27*), a small library of aminoglycosides (**6**–**13**) bearing the native negatively charged phosphodiester backbone may advisably give further information about the general nuclease activity of these attractive biomolecules. In the present study, conjugates (**6**–**13**) were targeted to chimeric ribo/2′-*O*-methyl oligonucleotides (**14** and **15**), which upon hybridization (excluding experiments with **6** and **10**) constitute triand pentanucleotide bulges (A_3 and A_5) opposite the aminoglycosidic regions. One of the conjugates (**9**) resulted in metal-ion-independent cleavage of the targets [**14** and **15**, $k = (2.7 \pm 0.6) \times 10^{-7}$ s^{-1} and $(2.3 \pm 0.6) \times 10^{-7}$ s^{-1}, respectively], but usually the cleavage obtained by the conjugates (**6**–**8**, **10**–**13**) remained at a marginal level or the conjugates were fully inactive.

EXPERIMENTAL PROCEDURES

General Methods and Materials. The NMR spectra of **1**–**3**, **19**–**31**, and **33**–**36** were recorded at 400 and 500 MHz. The chemical shifts are given in ppm from internal TMS and coupling constants in hertz. Peak assignments were supported by appropriate 2D NMR methods, e.g., COSY, HSQC, and HMBC. The mass spectra of **1**–**3**, **6**–**13**, **20**–**31**, and **33**–**36** were recorded by EI and ESI ionization methods. The 2′-*O*-methyl oligoribonucleotide conjugates (**6**–**13**) and the chimeric target oligonucleotides (**14** and **15**) were assembled by conventional phosphoramidate strategy using a 1 μmol scale and following the standard RNA coupling protocol of Appplied Biosystems 342 DNA synthesizer. LiChroCART Hypersil ODS column (250 × 10 mm, 5 μm) at a flow rate of 3 mL min^{-1} was used for RP HPLC purifications of the 2′-*O*-methyl oligoribonucleotide conjugates (**6**–**13**). In each case, a gradient elution from 20% to 70% acetonitrile in 0.1 mol L^{-1} $Et_3N^+OAc^-$buffer over 30 min was used.

6,3′,4′-Tri-*O*-acetyl-5-*O*-allyl-1,3,2′,6′-tetraazido Neamine (20). 6,3′,4′-tri-*O*-acetyl-1,3,2′,6′-tetraazido neamine (**19**) was synthesized from neomycine trisulfate (**16**) according to the literature (*30*–*32*). Improvements to the selective acylation of **18** may be mentioned. Acetic anhydride (0.50 mL, 51 mmol) in pyridine (2.0 mL) was dropwise added to a mixture of **18** (0.68 g, 16 mmol) and a catalytic amount of DMAP in pyridine (1.0 mL). The reaction was allowed to stir overnight at ambient temperature, quenched by addition of methanol, and evaporated to dryness. The residue was purified by silica gel chromatography (40% EtOAc in petroleum ether) to yield 0.64 g (73%) of the product (**19**) as white foam. All side products, mainly 5,6,3′,4′-tetra-*O*-acetyl-1,3,2′,6′-tetraazido neamine (0.16 g, 17%), were also isolated, combined, and restored to **18** (acetyl groups were removed by 0.1 mol L^{-1} NaOMe in MeOH, 1 h at 25 °C, cf. synthesis of **26** below). The regenerated crude **18** may again be used for the selective acylation, with the same yield. **19**: ^{1}H NMR (500 MHz, $CDCl_3$) δ 5.50 (dd, 1H, J = 10.3 Hz, 9.5 Hz), 5.37 (d, 1H, J = 3.6 Hz), 5.06 (dd, 1H, J = 10.0 Hz, 9.5 Hz), 4.95 (dd, 1H, J = 10.0 Hz, 9.9 Hz), 4.35 (m, 1H), 3.70–3.66 (m, 2H), 3.62 (d, 1H, J = 3.6 Hz), 3.55 (ddd, 1H, J = 12.5 Hz, 10.1 Hz, 4.6 Hz), 3.47–3.37 (m, 3H), 3.34 (dd, 1H, J = 13.5 Hz, 5.1 Hz), 2.42 (ddd, 1H, J = 13.3 Hz, 4.5 Hz, 4.5 Hz), 2.19, 2.11, and 2.07 (each s, each 3H), 1.64 (ddd, 1H, J = 12.9 Hz, 12.9 Hz, 12.9 Hz); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 170.5, 170.2, 169.7, 98.8, 83.7, 75.0, 74.4, 71.2, 69.5, 69.3, 61.7, 58.3, 57.9, 50.8, 31.9, 20.8, 20.7, 20.6. A mixture of **19** (1.1 g, 20 mmol), $Pd(OAc)_2$ (9 mg, 0.04 mmol), Ph_3P (53 mg, 0.20 mmol), and allyl methyl carbonate (0.46 mL, 41 mmol) in THF (5.0 mL) was refluxed for 15 min and evaporated to dryness (*33*). The residue was purified by silica gel chromatography (5% EtOAc in CH_2Cl_2) to yield 0.50 g (42%) of the desired product **20** as white foam and 0.21 g (17%) of 6-*O*-allyl-1,3,2′,6′-tetraazido-5,3′,4′-tri-*O*-acetyl neamine as yellowish oil. **20**: ^{1}H NMR (500 MHz, $CDCl_3$) δ 5.88 (m, 1H), 5.61 (d, 1H, J = 3.9 Hz), 5.50 (dd, 1H, J = 10.6 Hz, 9.4 Hz), 5.26 (m, 1H), 5.17 (m, 1H), 5.04 (dd, 1H, J = 10.0 Hz, 9.5 Hz), 5.02 (dd, 1H, J = 10.0 Hz, 9.9 Hz), 4.51 (m, 1H), 4.34 (m, 1H), 4.17 (m, 1H), 3.63 (dd, 1H, J = 9.6 Hz, 9.6 Hz), 3.51 (dd, 1H, J = 9.5 Hz, 9.4 Hz), 3.50–3.45 (m, 2H), 3.41–3.36 (m, 2H), 3.31 (dd, 1H, J = 13.5 Hz, 5.1 Hz), 2.40 (ddd, 1H, J = 13.3 Hz, 4.6 Hz, 4.6 Hz), 1.63 (ddd, J = 12.7 Hz, 12.7 Hz, 12.7 Hz); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 170.1, 169.7, 169.6, 133.7, 117.0, 97.6, 82.2, 78.0, 75.5, 74.2, 70.2, 69.3, 69.3, 60.9, 58.7, 58.0, 50.8, 50.8, 31.7, 20.9, 20.7, 20.7; HRMS (ESI) $[M + Na]^+$ $C_{21}H_{28}N_{12}NaO_9$ requires 615.1994, found 615.2005. 6-*O*-allyl-1,3,2′,6′-tetraazido-5,3′,4′-tri-*O*-acetyl neamine: ^{1}H NMR (500 MHz, $CDCl_3$) δ 5.60 (m, 1H), 5.16 (dd, 1H, J = 10.8 Hz, 9.2 Hz), 5.01–4.91 (m, 2H), 4.92 (d, 1H, J = 3.9 Hz), 4.88 (dd, 1H, J = 9.7 Hz, 9.7 Hz), 4.75 (dd, 1H, J = 10.1 Hz, 9.4 Hz), 4.19 (ddd, 1H, J = 10.3 Hz, 5.0 Hz, 2.7 Hz), 4.01 (m, 1H), 3.82 (m, 1H), 3.30 (m, 1H), 3.28 (dd, 1H, J = 9.6 Hz, 4.4 Hz), 3.22 (ddd, 1H, J = 12.1 Hz, 9.9 Hz, 4.4 Hz), 3.10 (dd, 1H, J = 13.5 Hz, 2.7 Hz), 3.07 (dd, 1H, J = 10.8 Hz, 3.9 Hz), 3.02 (dd, 1H, J = 13.5 Hz, 5.0 Hz), 2.93 (dd, 1H, J = 9.8 Hz, 9.8 Hz), 2.11 (ddd, 1H, J = 13.4 Hz, 4.6 Hz, 4.6 Hz), 1.86, 1.80, 1.78 (each s, each 3H), 1.23 (ddd, 1H, J = 12.4 Hz, each); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 169.5, 169.5, 168.7, 133.3, 117.7, 98.3, 81.6, 78.3, 74.1, 74.0, 69.4, 69.2, 69.1, 60.3, 59.2, 58.3, 50.4, 31.7, 20.7, 20.4, 20.4; HRMS (ESI) $[M + Na]^+$: $C_{21}H_{28}N_{12}NaO_9$ requires 615.1994, found 615.1966.

1,3,2′,6′-Tetraazido-5-*O*-(2-hydroxyethyl)neamine (21). Osmium tetroxide (2.5 wt % solution in 2-methyl-2-propanol, 0.20 mL, 16 μmol) was added to a mixture of **20** (0.50 g, 0.84 mmol) in water−dioxane (1:4 v/v, 5.0 mL) (*34*). After 1 h stirring, the mixture was cooled to 0 °C, the solvent volume was increased to 20 mL, and $NaIO_4$ (0.36 g, 17 mmol) was slowly added. The reaction was then allowed to warm up, stirred at room temperature for 5 h, and the resulted aldehyde intermediate was then extracted with ethyl acetate (3 × 10 mL). The organic layers were combined, dried with Na_2SO_4, and evaporated to dryness. The residue was dissolved in a mixture of dichloromethane−ethanol (1:2, v/v, 15 mL), and $NaBH_4$ (64 mg, 1.7 mmol) was added. After 5 h stirring, the reaction was quenched by addition of saturated ammonium chloride, and the crude product intermediate was extracted with ethyl acetate (3 × 10 mL). The organic layers were combined, dried with Na_2SO_4, and evaporated to dryness. The residue was dissolved in 0.1

mol L^{-1} methanolic sodium methoxide (5.0 mL). The mixture was stirred at ambient temperature for 1 h, neutralized by addition of strongly acidic cation-exchange resin, and filtered. The filtrate was evaporated to dryness and purified by silica gel chromatography (40% EtOAc in CH_2Cl_2) to yield 0.21 g (53%) of the product (**21**) as a colorless oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ 5.59 (d, 1H, J = 3.7 Hz), 4.24 (m, 1H), 4.04–3.96 (m, 2H), 3.90 (dd, 1H, J = 9.9 Hz, 9.5 Hz), 3.78 (ddd, 1H, J = 11.6 Hz, 7.5 Hz, 3.1 Hz), 3.72 (ddd, 1H, J = 11.5 Hz, 3.7 Hz, 3.4 Hz), 3.55–3.33 (m, 8H), 3.16 (dd, 1H, J = 10.6 Hz, 3.8 Hz), 2.26 (ddd, 1H, J = 12.4 Hz, 4.2 Hz, 4.2 Hz), 1.42 (ddd, 1H, J = 12.2 Hz, 12.2 Hz, 12.2 Hz); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 97.9, 85.8, 77.6, 76.9, 74.4, 71.8, 71.2, 70.8, 62.9, 61.7, 60.0, 59.5, 51.2, 31.8; HRMS (ESI) $[M + Na]^+$ $C_{14}H_{22}N_{12}NaO_7$ requires 493.1627, found 493.1615.

1,3,2′,6′-Tetraazido-5-*O*-[2-(4-methoxytrityloxy)ethyl]neamine (22). Compound **21** (0.20 g, 0.43 mmol) was dissolved in pyridine (2.0 mL), and 4-methoxytrityl chloride (0.20 g, 0.64 mmol) was added to the mixture. Reaction mixture was stirred overnight at ambient temperature, quenched by addition of methanol, and evaporated to dryness. The residue was dissolved in ethyl acetate and washed with saturated $NaHCO_3$. The organic layer was separated, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (20% EtOAc in CH_2Cl_2) to yield 0.32 g (100%) of the product **22** as a white foam. ^{1}H NMR (500 MHz, $CDCl_3$): δ 7.47 (d, 4H, J = 7.6 Hz), 7.35–7.29 (m, 6H), 7.23 (dd, 2H, J = 7.4 Hz, 7.3 Hz), 6.87 (d, 2H, J = 8.9 Hz), 5.94 (d, 1H, J = 3.8 Hz), 4.25 (m, 1H), 4.15 (m, 1H), 4.02 (m, 1H), 3.91 (dd, 1H, J = 10.3 Hz, 10.1 Hz), 3.79 (s, 3H), 3.63 (dd, 1H, J = 9.6 Hz, 9.5 Hz), 3.57–3.33 (m, 9H), 3.27 (m, 1H), 2.94 (dd, 1H, J = 10.5 Hz, 3.8 Hz), 2.23 (ddd, 1H, J = 12.3 Hz, 4.3 Hz, 4.3 Hz), 1.39 (ddd, 1H, J = 12.3 Hz, each). ^{13}C NMR ($CDCl_3$, 250 MHz) δ 158.8, 144.6, 144.5, 135.5, 130.3, 128.4, 127.4, 126.6, 112.7, 97.4, 86.6, 85.2, 77.1, 76.8, 72.1, 71.8, 71.3, 70.8, 63.6, 62.9, 60.5, 60.2, 59.7, 54.3, 51.3, 31.7; HRMS (ESI) $[M + Na]^+$ $C_{34}H_{38}N_{12}NaO_8$ requires 765.2828, found 765.2804.

6,3′,4′-Tri-*O*-levulinoyl-5-*O*-[2-(4-methoxytrityloxy)ethyl]-*N*^{1},*N*^{3},*N*$^{2'}$,*N*$^{6'}$-tetra(trifluoroacetyl) Neamine (23). Trimethyl phosphine (1 mol L^{-1} Me_3P in toluene, 1.41 mL, 14 mmol) was added to a mixture of **22** (0.21 g, 0.28 mmol) in water−dioxane (1:4, v/v, 2.5 mL) under nitrogen. The reaction was stirred for 4 h at ambient temperature, and then concentrated ammonia (1.0 mL) was added. After overnight stirring, volatiles were removed, and the residue was dissolved in dry methanol (2.0 mL). Triethylamine (1.0 mL) and freshly distilled methyl trifluoroacetate (0.23 mL,) were then added to the mixture, the reaction was stirred overnight, and evaporated to dryness. The resulted crude trifluoroacetylated neamine derivative was dissolved in ethyl acetate and washed with saturated $NaHCO_3$. The organic layer was separated, dried with Na_2SO_4, and evaporated to dryness. The residue was dissolved in pyridine (2.0 mL), and then levulinic anhydride and a catalytic amount of DMAP were added to the mixture. After 2 h stirring, the reaction was quenched by addition of methanol. Ethyl acetate was added, and the crude product was washed with saturated $NaHCO_3$. The organic layer was separated, dried with Na_2SO_4, and evaporated to dryness. The crude final product was purified by silica gel chromatography (20% petroleum ether in EtOAc) to yield 0.28 g (74%) of **23** as a white foam. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.30 (t, 1H, J = 5.5 Hz), 7.75 (d, 1H, J = 9.3 Hz), 7.46 (d, 1H, J = 9.4 Hz), 7.42 (d, 4H, J = 7.5 Hz), 7.32–7.2 (m, 9H), 7.14 (d, 1H, J = 7.8 Hz), 6.85 (d, 2H, J = 9.0 Hz), 5.51 (d, 1H, J = 3.3 Hz), 5.13 (dd, 1H, J = 10.3 Hz, 9.9 Hz), 5.00 (dd, 1H, J = 10.1 Hz, 9.9 Hz), 4.98 (dd, 1H, J = 9.8 Hz, 9.8 Hz), 4.23–4.07 (m, 3H), 4.01 (ddd, 1H, J = 10.1 Hz, 4.5 Hz, 4.5 Hz), 3.91 (dd, 1H, J = 9.9 Hz, 9.6 Hz), 3.86 (m, 1H), 3.81 (s, 3H), 3.74 (dd, 1H, J = 9.2 Hz, 9.2 Hz), 3.73 (m, 1H), 3.60–3.48 (m, 2H), 3.29 (m, 2H), 2.93 (ddd, 1H, J = 18.9 Hz, 9.5 Hz, 4.2 Hz), 2.77–2.45 (m, 8H), 2.42–2.22 (m, 4H), 2.18 (s, 3H), 2.11 (s, 3H), 2.09 (s, 3H), 1.87 (ddd, 1H, J = 12.7 Hz, each); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 208.5, 206.5, 206.1, 173.7, 172.3, 172.2, 158.6, 144.3, 144.3, 135.4, 130.5, 128.5, 127.7, 126.9, 112.1, 96.5, 86.7, 81.3, 76.8, 75.1, 72.5, 70.0, 69.9, 67.9, 63.0, 55.2, 52.7, 49.4, 48.6, 41.7, 38.0, 37.8, 37.7, 31.8, 29.6, 29.5, 29.4, 28.0, 27.7, 27.6 (Tfa related peaks not listed); HRMS (ESI) $[M + Na]^+$ $C_{57}H_{60}F_{12}N_4NaO_{18}$ requires 1339.3603, found 1339.3653.

5-*O*-(2-Hydroxyethyl)-6,3′,4′-tri-*O*-levulinoyl-*N*^{1},*N*^{3},*N*$^{2'}$,*N*$^{6'}$-tetra(trifluoroacetyl)neamine (24). Compound **23** was dissolved in a mixture of dichloroacetic acid in dichloromethane (3:97, v/v, 6.0 mL). The reaction was stirred for 1 h at ambient temperature, quenched by addition of methanol, and then saturated $NaHCO_3$was added to the mixture. The resulted organic layer was separated, dried with Na_2SO_4, and evaporated to dryness. The residue was purified via silica gel chromatography (4% MeOH in CH_2Cl_2) to yield 0.21 g (97%) of the product (**24**) as white foam. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.74 (d, 1H, J = 6.6 Hz), 8.18–8.15 (b, 2H), 7.62 (d, 1H, J = 9.1 Hz), 5.38 (d, 1H, J = 3.4 Hz), 5.26 (dd, 1H, J = 10.4 Hz, 10.0 Hz), 5.20 (dd, 1H, J = 9.9 Hz, 9.8 Hz), 4.96 (dd, 1H, J = 9.9 Hz, 9.8 Hz), 4.37 (m, 1H), 4.24–4.06 (m, 5H), 3.99 (dd, 1H, J = 9.6 Hz, 9.1 Hz), 3.90 (m, 1H), 3.78–3.75 (m, 3H), 3.60 (m, 1H), 3.43 (m, 1H), 2.84–2.37 (m, 12H), 2.17 (s, 3H), 2.15 (s, 3H), 2.14 (s, 3H), 2.00 (m, 1H), 1.42 (m, 1H); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 208.9, 207.2, 207.1, 174.3, 172.9, 172.0, 97.9, 81.8, 78.9, 77.6, 74.2, 69.8, 69.2, 67.9, 62.0, 53.0, 50.7, 48.7, 47.9, 38.6, 37.7, 37.7, 37.4, 31.6, 29.6, 29.6, 29.4, 28.0, 27.9, 27.8 (Tfa related peaks not listed); HRMS (ESI) $[M + Na]^+$ $C_{37}H_{44}F_{12}N_4NaO_{17}$ requires 1067.2402, found 1067.2416.

2-Cyanoethyl [6,3′,4′-tri-*O*-levulinoyl-*N*^{1},*N*^{3},*N*$^{2'}$,*N*$^{6'}$-tetra(trifluoroacetyl)neamine-5-*O*-ethyl] *N*,*N*-diisopropylphosphoramidite (1). 2-Cyanoethyl *N*,*N*-diisopropylphosphonamidic chloride (53 μL, 0.24 mmol) was added to a mixture of **24** (0.19 g, 0.18 mmol) and triethylamine (0.13 mL, 0.90 mmol) in dichloromethane (2.5 mL) under nitrogen. The mixture was stirred for 1 h at ambient temperature and then subjected directly to a silica gel column. Elution with 2% triethylamine and 20% petroleum ether in ethyl acetate yielded 0.21 g (93%) of the product (**1**) as white foam. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.16 (t, 0.56H, J = 5.4 Hz), 8.11 (t, 0.44H, J = 5.5 Hz), 7.87 (b, 1H), 7.45 (d, 0.44H, J = 10.0 Hz), 7.42 (d, 0.56H, J = 9.6 Hz), 7.11 (b, 1H), 5.59 (d, 0.56H, J = 3.2 Hz), 5.55 (d, 0.44H, J = 3.4 Hz), 5.22 and 5.21 (both dd, sum 1H, J = 10.7 Hz, 2.5 Hz, and J = 10.5 Hz, 2.4 Hz), 5.10 (dd, 0.56H, J = 9.9 Hz, 9.8), 5.05 (dd, 0.44H, J = 9.9 Hz, 9.8 Hz), 4.99 and 4.97 (both dd, sum 1H, J = 10.1 Hz, 3.9 Hz, and J = 10.1 Hz, 4.3 Hz), 4.40–4.32 (m, 1H), 4.24–4.06 (m, 3H), 3.95–3.71 (m, 8H), 3.64–3.55 (m, 4H), 3.44–3.39 (m, 1H), 2.88 (ddd, 1H, J = 18.8 Hz, 8.9 Hz, 4.5 Hz), 2.79–2.41 (m, 14H), 2.29–2.25 (m, 1H), 2.19 and 2.18 (both s, sum 3H), 2.17 and 2.16 (both s, sum 3H), 2.13 (s, 3H), 1.94–1.86 (m, 1H), 1.20, 1.19, 1.18, 1.17, and 1.15 (each s, sum 12H); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 208.0, 207.9, 206.7, 206.7, 206.4, 206.3, 173.58, 173.56, 172.38, 172.36, 172.2, 172.1, 118.25, 118.22, 96.9, 81.38, 81.34, 75.0, 74.9, 77.4, 75.0, 74.9, 72.7, 72.7, 72.9, 72.8, 70.1, 69.7, 69.5, 68.0, 67.9, 62.6, 62.5, 62.3, 62.2, 58.5, 58.3, 58.3, 58.2, 52.8, 52.8, 49.3, 48.8, 43.0, 42.9, 41.2, 38.0, 37.9, 37.7, 31.6, 29.6, 29.5, 29.5, 28.1, 27.7, 27.6, 27.6, 24.7, 24.6, 24.6, 24.6, 24.5, 24.5, 24.5, 21.0, 20.3, 20.3 (Tfa related peaks not listed); ^{31}P NMR ($CDCl_3$, 200 MHz) δ 149.2, 148.2; HRMS (ESI) $[M + Na]^+$ $C_{46}H_{61}F_{12}N_6NaO_{18}P$ requires 1267.3481, found 1267.3432.

1,3,2′,6′-Tetraazido-5″-*O*-(4-methoxytrityl)ribostamycin (26). 6,3′,4′, 2″, 3″, 5″-Hexa-*O*-acetyl-1,3,2′,6′-tetraazidoribostamycin (**23**) (*35*) was first synthesized from the neamine derivative (**19**). **19** (0.30 g, 0.54 mmol) and 1,2,3,5-tetra-*O*-acetyl-*β*-D-ribofuranose (0.35 g, 1.1 mmol) were dissolved in dry dichloromethane (2.0 mL). The mixture was cooled to 0 °C, trimethylsilyl trifluoromethanesulfonate (0.20 mL, 1.1 mmol) was slowly added, and then the reaction was allowed to stir for 3 h under nitrogen. Saturated $NaHCO_3$ was added to the mixture, and the resulted organic phase was separated, dried with Na_2SO_2, and evaporated to dryness. The residue was purified by silica gel chromatography (from 30% to 40% EtOAc in petroleum ether) to yield 0.26 g (59%) of the product (**25**) as white foam. ^{1}H NMR (500 MHz, $CDCl_3$): δ 5.91 (d, 1H, J = 3.8 Hz), 5.46 (dd, 1H, J = 10.7 Hz, 9.3 Hz), 5.43 (d, 1H, J = 3.9 Hz), 5.20 (dd, 1H, J = 4.9 Hz, 4.8 Hz), 5.10 (dd, 1H, J = 4.9 Hz, 4.1 Hz), 5.02 (dd, 1H, J = 10.0 Hz, 9.6 Hz), 4.97 (dd, 1H, J = 9.9 Hz, 9.9 Hz), 4.49 (ddd, 1H, J = 10.1 Hz, 5.3 Hz, 2.7 Hz), 4.44 (dd, 1H, J = 12.2 Hz, 3.1 Hz), 4.26 (m, 1H), 4.16 (dd, 1H, J = 12.2 Hz, 3.6 Hz), 3.88 (dd, 1H, J = 9.3 Hz, 9.1 Hz), 3.71 (dd, 1H, J = 9.8 Hz, 9.0 Hz), 3.54 (ddd, 1H, J = 12.5 Hz, 10.0 Hz, 4.6 Hz), 3.45 (ddd, 1H, J = 12.5 Hz, 10.2 Hz, 4.4 Hz), 3.38 (dd, 1H, J = 13.5 Hz, 2.8 Hz), 3.32 (dd, 1H, J = 13.5 Hz, 5.4 Hz), 3.24 (dd, 1H, J = 10.7 Hz, 3.8 Hz), 2.40 (ddd, 1H, J = 13.3 Hz, 4.6 Hz, 4.6 Hz), 2.23, 2.12, 2.11, 2.10, 2.07, 2.07 (each s, each 3H), 1.63 (ddd, 1H, J = 13.0 Hz each); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 170.6, 170.1, 169.7, 169.6, 169.5, 169.5, 106.3, 96.4, 80.9, 79.7, 76.4, 74.7, 74.1, 70.9, 70.0, 69.2, 69.2, 63.1, 61.0, 59.1, 58.1, 51.0, 31.6, 20.9, 20.7, 20.7, 20.7, 20.5, 20.4. Compound **25** (0.98 g, 1.2 mmol) was dissolved in 0.1 mol L^{-1} methanolic sodium methoxide (10 mL). The mixture was stirred at ambient temperature for 1 h, neutralized by addition of strongly acidic cation-exchange resin, filtered, and evaporated to dryness. The residue was dissolved in pyridine (3.0 mL), and then a mixture of 4-methoxytrityl chloride (0.49 g, 1.6 mmol) in pyridine (3.0 mL) was slowly added. The reaction was allowed to stir overnight at ambient temperature, quenched by addition of methanol, and evaporated to dryness. The residue was purified by silica gel chromatography (5% MeOH in CH_2Cl_2) to yield 0.71 g (71%) of the product (**26**) as white foam. ^{1}H NMR (500 MHz, $CDCl_3$): δ 7.50 (d, 4H, J = 7.6 Hz), 7.37–7.30 (m, 6H), 7.23 (m, 1H), 6.89 (d, 2H, J = 8.9 Hz), 5.87 (d, 1H, J = 3.8 Hz), 5.35 (d, 1H, J = 1.5 Hz), 4.26–4.22 (m, 2H), 4.16 (ddd, 1H, J = 9.9 Hz, 5.7 Hz, 2.0 Hz), 4.11 (m, 1H), 3.83 (dd, 1H, J = 10.4 Hz, 9.1 Hz), 3.80 (s, 3H), 3.67–3.61 (m, 2H), 3.53–3.39 (m, 5H), 3.33–3.28 (m, 4H), 2.92 (dd, 1H, J = 10.4 Hz, 3.9 Hz, 3.8 Hz), 2.22 (m, 1H), 1.38 (ddd, 1H, J = 12.2 Hz, each); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 158.8, 144.6, 144.5, 135.3, 130.4, 128.3, 128.3, 127.5, 127.5, 126.5, 126.5, 112.8, 109.3, 96.7, 86.4, 84.3, 82.2, 76.3, 76.0, 75.3, 71.5, 71.3, 71.2, 71.0, 64.4, 63.6, 60.3, 59.7, 54.4, 51.3, 31.7; HRMS (ESI) $[M + Na]^+$ $C_{37}H_{42}N_{12}NaO_{11}$ requires 853.2988, found 853.2982.

6,3′,4′, 2″, 3″-Penta-*O*-levulinoyl-5″-*O*-(4-methoxytrityl)-*N*^{1},*N*^{3},*N*$^{2′}$,*N*$^{6′}$-tetra(trifluoroacetyl)ribostamycin (27). Compound **27** was synthesized from **26** using the three-step procedure, as described for **23**, but 10 molar equiv levulinic anhydride was used. After silica gel chromatography (2% MeOH in CH_2Cl_2), product (**27**) was obtained as white foam in a 79% yield (0.45 g). ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.98 (t, 1H, J = 5.4 Hz), 7.68 (d, 1H, J = 8.5 Hz), 7.43–7.40 (m, 5H), 7.32–7.21 (m, 9H), 6.88 (d, 2H, J = 9.0 Hz), 5.80 (b, 1H), 5.36 (d, 1H, J = 4.1 Hz), 5.37–5.32 (m, 2H), 5.12 (dd, 1H, J = 10.3 Hz, 9.9 Hz), 5.00 (dd, 1H, J = 10.2 Hz, 8.6 Hz), 4.93 (dd, 1H, J = 9.9 Hz, 9.8 Hz), 4.26–4.15 (m, 2H), 4.09 (m, 1H), 4.05–3.98 (m, 4H), 3.81 (s, 3H), 3.46–3.35 (m, 2H), 3.29 (dd, 1H, J = 10.5 Hz, 4.0 Hz), 3.24 (dd, 1H, J = 10.5 Hz, 3.1 Hz), 2.89 (ddd, 1H, J = 18.9 Hz, 9.0 Hz, 4.6 Hz), 2.83–2.30 (m, 21H), 2.21, 2.20, 2.17, 2.11, 2.09 (each s, each 3H), 1.89 (ddd, J = 12.7 Hz each); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 208.3, 206.8, 206.8, 206.6, 206.2, 174.6, 172.1, 171.8, 171.8, 171.7, 158.7, 144.1, 144.0, 134.9, 130.7, 130.6, 128.6, 127.8, 127.8, 127.0, 127.0, 113.2, 107.4, 95.5, 86.7, 80.7, 74.7, 73.5, 71.5, 70.4, 69.4, 67.7, 62.7, 55.2, 53.5, 51.9, 49.9, 48.6, 41.7, 38.2, 38.0, 37.8, 37.7, 37.6, 31.4, 29.8, 29.7, 29.7, 29.4, 29.3, 27.9, 27.8, 27.6, 27.5, 27.5 (Tfa related peaks not listed); HRMS (ESI) $[M + Na]^+$ $C_{70}H_{76}F_{12}N_4NaO_{25}$ requires 1623.4499, found 1623.4434.

After silica gel chromatography (2% Et_3N in EtOAc), product **2** was obtained as white foam in a 92% yield (0.35 g). ^{1}H NMR (500 MHz, $CDCl_3$): δ 8.49 (b, 0.54H), 8.25 (t, 0.46H, J = 5.9 Hz), 7.64 (d, 0.46H, J = 9.3 Hz), 7.53 (d, 0.54H, J = 9.3 Hz), 7.26 (d, 0.46H, J = 9.3 Hz), 7.21 (d, 0.54H, J = 9.3 Hz), 7.05 (m, 1H), 6.00 (d, 0.54H, J = 3.1), 5.90 (d, 0.46H, J = 3.5 Hz), 5.34 (d, 0.54H, J = 4.7 Hz), 5.33 (d, 0.46H, J = 4.6 Hz), 5.29–5.25 (m, 1H), 5.18–4.95 (m, 4H), 4.44 (ddd, 0.46H, J = 10.2 Hz, 10.2 Hz, 3.8 Hz), 4.38 (ddd, 0.56H, J = 10.1 Hz, 10.1 Hz, 3.9 Hz), 4.34–4.25 (m, 1H), 4.18–3.79 (m, 7H), 3.72–3.41 (m, 6H), 2.98–2.32 (m, 23H), 2.21, 2.21, 2.20, 2.19, 2.18, 2.17, 2.14, 2.14 (each s, 12H), 1.86–1.76 (m, 1H), 1.22, 1.21, 1.21, 1.20, 1.18 (each s, 12H); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 208.6, 208.2, 206.7, 206.7, 206.4, 206.4, 206.3, 206.2, 174.3, 174.2, 172.5, 172.2, 171.8, 171.7, 171.7, 171.7, 171.6, 118.8, 118.4, 106.9, 106.5, 95.5, 95.1, 81.4, 81.4, 75.5, 75.3, 74.6, 74.4, 74.1, 74.1, 71.0, 70.8, 70.8, 70.3, 69.8, 66.8, 61.8, 61.6, 58.5, 58.4, 51.9, 51.8, 49.7, 49.6, 48.0, 47.9, 43.0, 42.9, 38.2, 38.0, 38.0, 37.8, 37.7, 37.6, 31.8, 31.6, 29.8, 29.8, 29.8, 29.7, 29.7, 29.6, 29.4, 28.1, 28.0, 27.7, 27.6, 27.5, 27.3, 24.7, 24.6, 24.6, 20.4, 20.3, 20.1, 20.0 (Tfa related peaks not listed); ^{31}P NMR ($CDCl_3$,200 MHz) δ 148.9 and 148.7; HRMS (ESI) $[M + Na]^+$ $C_{59}H_{77}F_{12}N_6NaO_{25}P$ requires 1551.4377, found 1551.4329.

6,3′,4′-Tri-*O*-levulinoyl-*N*^{1},*N*^{3},*N*$^{2′}$,*N*$^{6′}$-tetra(trifluoroacetyl)-neamine (30). *N*^{1},*N*^{3},*N*$^{2′}$,*N*$^{6′}$-tetra(trifluoroacetyl)neamine (**29**) was first synthesized from neamine tetrahydrochloride (**17**) according to the literature (*28*). Levulinic anhydride (13.3 g, 62 mmol) was slowly added to a mixture of **29** (14.6 g, 21 mmol) and a catalytic amount of DMAP in pyridine (60 mL). The mixture was stirred overnight at ambient temperature and evaporated to dryness. The residue was dissolved in ethyl acetate and washed with saturated $NaHCO_3$. The organic layer was separated, dried with Na_2SO_4, and evaporated to dryness. The

crude product was purified by silica gel chromatography (50% EtOAc in CH_2Cl_2) to yield 13.8 g (67%) of **30** as white foam. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.39 (d, 1H, J = 8.3 Hz), 8.09 (b, 1H), 7.69 (d, 1H, J = 8.4 Hz), 7.65 (d, 1H, J = 7.9 Hz), 5.37 (d, 1H, J = 3.6 Hz), 5.27 (dd, 1H, J = 10.4 Hz, 9.9 Hz), 5.16 (dd, 1H, J = 10.1 Hz, 10.1 Hz), 4.95 (dd, 1H, J = 10.0 Hz, 9.9 Hz), 4.29 (m, 1H), 4.21 (dd, 1H, J = 9.7 Hz, 9.6 Hz), 4.12–4.05 (m, 2H), 3.97–3.94 (m, 2H), 3.83 (ddd, 1H, J = 9.4 Hz, 9.3 Hz, 3.2 Hz), 3.48 (m, 2H), 2.92 (ddd, 1H, J = 19.0 Hz, 9.0 Hz, 4.5 Hz), 2.87–2.40 (m, 12H), 2.34 (ddd, 1H, J = 13.0 Hz, each), 2.20 (s, 3H), 2.19 (s, 3H), 2.18 (m, 1H), 2.14 (s, 3H); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 209.2, 208.4, 206.8, 174.1, 172.7, 172.5, 98.1, 80.0, 75.4, 74.6, 70.3, 69.6, 68.4, 52.9, 49.9, 48.4, 40.4, 38.2, 38.1, 37.7, 30.3, 29.6, 29.5, 29.4, 28.5, 27.9, 27.7 (Tfa related peaks not listed); HRMS (ESI) $[M + Na]^+$ requires 512.1106, found 512.1122.

2-Cyanoethyl [6,3′,4′-tri-*O*-levulinoyl-N^1,N^3,$N^{2'}$,$N^{6'}$-tetra-(trifluoroacetyl)neamine-5-yl] *N*,*N*-diisopropylphosphoramidite (31). Compound **31** was synthesized from **30** as described for **1**, but 3.6 molar equiv 2-cyanoethyl *N*,*N*-diisopropylphosphonamidic chloride and a prolonged reaction time (3 h) were required. After silica gel chromatography (1% Et_3N and 30% petroleum ether in EtOAc), product **31** was obtained as white foam in a 90% yield (0.54 g). ^{1}H NMR (500 MHz, $CDCl_3$) δ7.81 (d, 0.55H, J = 8.8 Hz), 7.76 (d, 0.45H, J = 9.2 Hz), 7.70–7.66 (m, 1H), 7.56 (d, 0.45H, J = 9.7 Hz, 7.50–7.48 (m, 1H), 7.41 (d, 0.55H, J = 9.5 Hz), 5.81 (d, 0.55H, J = 3.7 Hz), 5.45 (b d, 0.45H, J = 2.9 Hz), 5.26 (dd, 0.45H, J = 10.4 Hz, 9.1 Hz), 5.22 (dd, 0.55H, J = 10.2 Hz, 9.4 Hz), 5.11–4.97 (m, 2H), 4.47–4.39 (m, 1H), 4.31–3.34 (m, 11H), 2.80–2.36 (m, 14H), 2.15–2.08 (m, 1H), 2.18, 2.10, 2.10 (each s, sum 9H), 1.97–1.87 (m, 1H); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 207.0, 206.9, 206.6, 206.6, 206.4, 206.3, 172.6, 172.5, 172.1, 172.0, 172.0, 171.9, 118.6, 118.3, 96.3, 94.6, 78.8, 76.5, 76.3, 75.0, 74.7, 73.5, 69.9, 69.8, 68.9, 68.7, 68.6, 68.0, 58.9, 58.8, 58.7, 58.6, 43.2, 43.1, 39.5, 39.5, 37.4, 37.3, 37.3, 31.1, 30.7, 28.8, 28.8, 28.7, 28.6, 28.6, 28.1, 28.1, 27.7, 27.6, 27.6, 23.9, 23.9, 23.8, 23.8, 23.8, 23.7, 23.6, 22.2, 22.2, 22.2, 19.8, 19.8, 19.7, 19.7 (Tfa related peaks not listed); ^{31}P NMR ($CDCl_3$, 200 MHz) δ 150.8, 150.5; HRMS (ESI) $[M + Na]^+$ $C_{44}H_{57}F_{12}N_6NaO_{17}P$ requires 1223.3218, found 1223.3191.

Ethyl 2-{(2*R*,3*S*,5*R*)-3-*tert*-butyldimethylsilyloxy-5-[(4,4′-dimethoxytrityl)oxymethyl] Tetrahydrofuran-2-yl}acetate (33). Compound **32** was synthesized as described earlier (*36*, *37*). *tert*-Butyldimethylsilyl chloride (1.43 g, 9.5 mmol) was added to a mixture of **32** (2.4 g, 4.7 mmol) and a catalytic amount of imidazole in pyridine (20 mL). The reaction was stirred overnight at 40 °C, quenched by addition of methanol, and evaporated to dryness. The residue was dissolved in dichloromethane and washed by saturated $NaHCO_3$. The organic phase was separated, dried with Na_2SO_4, and evaporated to dryness. The product was purified by silica gel chromatography (0.1% Et_3N and 3% MeOH in CH_2Cl_2) to yield 2.9 g (60%) of **33** as a colorless oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.47–7.44 (m, 2H), 7.37–7.17 (m, 7H), 6.84–6.82 (m, 4H), 4.56 (m, 1H), 4.18 (m, 1H), 4.17 (m, 2H), 3.93 (m, 1H), 3.08 (m, 2H), 2.68 (dd, 1H, J = 15.3 Hz, 7.0 Hz), 2.52 (dd, 1H, J = 15.3 Hz, 6.2 Hz), 1.96 (ddd, 1H, J = 12.6 Hz, 5.4 Hz, 2.2 Hz), 1.72 (ddd, 1H, J = 12.6 Hz, 9.8 Hz, 5.8 Hz), 1.27 (t, 3H, J = 7.3 Hz), 0.86 (s, 9H), 0.07 (s, 3H), 0.02 (s, 3H); ^{13}C NMR ($CDCl_3$,100 MHz) δ 171.2, 158.4, 144.9, 136.2, 136.2, 130.1, 128.2, 127.7, 126.6, 113.0, 86.6, 85.9, 74.6, 74.2, 64.1, 60.4, 55.2, 41.1, 40.8, 25.8, 14.2, −4.7, −4.8; MS (EI) M^+ requires 620.3, found 620.

(2*R*,3*S*,5*S*)-3-*tert*-Butyldimethylsilyloxy-2-[(4,4′-dimethoxytrityl)oxymethyl]-5-(2-hydroxyethyl)tetrahydrofuran (34). Lithium aluminum hydride (0.16 g, 4.3 mmol) was slowly added to a cooled (0 °C) mixture of **33** in diethyl ether (20 mL). The mixture was allowed to warm to room temperature, and then the stirring was continued overnight at room temperature. The excess hydride was destroyed by careful addition of water, and then the crude product was extracted with dichloromethane (3 × 20 mL). The organic layers were combined, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (0.1% Et_3N and 3% MeOH in CH_2Cl_2) to yield 1.4 g (83%) of **34** as yellowish oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.50 (d, 2H, J = 8.1 Hz), 7.40–7.24 (m, 7H), 6.88 (d, 4H, J = 8.8 Hz), 4.38 (m, 1H), 4.28 (m, 1H), 3.95 (m, 1H), 3.87 (m, 2H), 3.84 (s, 6H), 3.14 (d, 2H, J = 4.7 Hz), 2.75 (b, 1H), 1.98–1.69 (m, 4H), 0.90 (s, 9H), 0.06 (s, 3H), 0.04 (s, 3H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 158.4, 144.9, 136.1, 136.1, 130.0, 128.2, 127.7, 126.7, 113.1, 86.9, 86.0, 78.6, 74.0, 64.1, 61.6, 55.2, 41.6, 37.3, 25.8, −4.7, −4.8; MS (EI) M^+ requires 578.3, found 578.

(2*R*,3*S*,5*S*)-3-*tert*-Butyldimethylsilyloxy-2-[(4,4′-dimethoxytrityl)oxymethyl]-5-(2-levulinoyloxyethyl)tetrahydrofuran (35). Levulinic anhydride (1.5 g, 7.1 mmol) was added to a mixture of **34** (1.3 g, 2.4 mmol) in pyridine (20 mL). The mixture was stirred at ambient temperature for 3 h and evaporated to dryness. The residue was dissolved in dichloromethane and washed with saturated $NaHCO_3$. The organic phase was dried with Na_2SO_4 and evaporated to dryness. The crude product was purified by silica gel chromatography (0.1% Et_3N and 3% MeOH in CH_2Cl_2) to yield 1.5 g (86%) of **35** as colorless oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.49–7.46 (m, 2H), 7.37–7.20 (m, 7H), 6.85–6.83 (m, 4H), 4.30–4.18 (m, 4H), 3.90 (m, 1H), 3.81 (s, 6H), 3.12–3.05 (m, 2H), 2.76 (m, 2H), 2.60 (m, 2H), 2.20 (s, 3H), 1.93–1.85 (m, 3H), 1.66 (ddd, 1H, J = 12.6 Hz, 9.8 Hz, 5.8 Hz), 0.86 (s, 9H), 0.02 (s, 3H), 0.00 (s, 3H);^{13}C NMR ($CDCl_3$, 100 MHz) δ 172.7, 158.3, 144.9, 136.2, 136.1, 130.0, 128.2, 127.7, 126.6, 113.0, 86.3, 85.9, 75.2, 74.3, 64.3, 62.1, 55.2, 41.4, 37.9, 34.8, 29.9, 28.0, 25.8, −4.7, −4.8; MS (EI) M^+ requires 676.4, found 676.

(2*R*,3*S*,5*S*)-2-[(4,4′-Dimethoxytrityl)oxymethyl]-5-(2-levulinoyloxyethyl)tetrahydrofuran-3-ol (36). Tetrabutylammonium fluoride monohydrate (1.5 g, 5.7 mmol) was added to a mixture of **35** (1.2 g, 1.8 mmol) in tetrahydrofurane (15 mL). The mixture was stirred for 2 h at room temperature and then volatiles were removed. The residue was dissolved in dichloromethane and washed with water. The organic phase was dried with Na_2SO_4 and evaporated to dryness. The crude product was purified by silica gel chromatography (0.1% Et_3N and 3% MeOH in CH_2Cl_2) to yield 0.90 g (87%) of **36** as colorless oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.47–7.45 (m, 2H), 7.36–7.21 (m, 7H), 6.86–6.83 (m, 4H), 4.32 (b, 1H), 4.29–4.17 (m, 3H), 3.92 (m, 1H), 3.81 (s, 6H), 3.24 (dd, 1H, J = 9.6 Hz, 4.6 Hz), 3.10 (dd, 1H, J = 9.6 Hz, 5.9 Hz), 2.76 (m, 2H), 2.58 (m, 2H), 2.20 (s, 3H), 2.01 (b, 1H), 2.00 (ddd, 1H, J = 13.0 Hz, 7.6 Hz, 2.1 Hz), 1.96–1.89 (m, 2H), 1.79 (ddd, 1H, J = 13.0 Hz, 9.8 Hz, 6.3 Hz); ^{13}C NMR ($CDCl_3$, 250 MHz) δ 206.8, 172.7, 158.5, 144.9, 136.1, 130.1, 128.2, 127.9, 127.8, 126.8, 113.1, 86.1, 85.8, 75.3, 74.7, 64.7, 62.0, 55.3, 55.2, 40.9, 38.0, 34.7, 29.9, 28.0; MS (EI) M^+ requires 562.3, found 562.

2-Cyanoethyl {(2*R*,3*S*,5*S*)-2-[(4,4′-Dimethoxytrityl)oxymethyl]-5-(2-levulinoyloxyethyl)tetrahydrofuran-3-yl} *N*,*N*-Diisopropylphosphoramidite (3). Compound **3** was synthesized from **36** as described for **1**, above. After silica gel chromatography (2% Et_3N and 48% petroleum ether in EtOAc), product **3** was obtained as white foam in an 82% yield (0.54 g). ^{1}H NMR (500 MHz, CD_3CN) δ 7.49–7.46 (m, 2H), 7.38–7.33 (m, 4H), 7.32–7.28 (m, 2H), 7.24–7.20 (m, 1H), 6.86–6.82 (m, 4H), 4.46–4.42 (m, 1H), 4.32–4.21 (m, 3H), 4.09–4.08 (m, 1H), 3.86–3.53 (m, 4H), 3.82 (s, 3H), 3.81 (s, 3H), 3.19–3.09 (m, 2H), 2.78–2.75 (m, 2H), 2.64–2.58 (m, 3H), 2.48–2.45 (m, 1H), 2.20 (s, 3H), 2.20–2.07 (m, 1H), 1.97–1.93 (m, 2H), 1.82–1.75

(m, 1H), 1.20, 1.19, 1.17, 1.17, 1.15, 1.10, 1.08 (each s, sum 12H); ^{13}C NMR (CD_3CN, 250 MHz) δ 206.8, 206.8, 172.6, 172.6, 158.7, 145.3, 136.1, 136.1, 136.1, 136.0, 130.1, 130.0, 128.1, 128.1, 127.8, 126.8, 126.8, 118.6, 118.4, 113.1, 85.9, 85.3, 85.3, 85.0, 85.0, 75.7, 75.7, 75.6, 75.5, 75.4, 75.2, 64.4, 64.3, 61.6, 58.5, 58.4, 54.9, 43.0, 42.9, 40.0, 40.0, 40.0, 39.9, 37.5, 34.5, 34.4, 29.0, 27.8, 24.0, 24.0, 23.9, 23.9, 20.1, 20.1, 20.0, 20.0; ^{31}P NMR ($CDCl_3$, 200 MHz) δ 148.0, 147.8; HRMS (ESI) $[M + Na]^+$ $C_{42}H_{55}N_2NaO_9P$ requires 785.3537, found 785.3542.

Synthesis of the Aminoglycoside Conjugates of the 2′-*O*-Methyl Oligoribonucleotides (6–13). The 2′-*O*-methyl oligoribonucleotide conjugates (**6**–**13**) were assembled on an Applied Biosystems 392 DNA synthesizer in 1.0 μmol scale using conventional phosphoramidite chemistry and following the standard RNA coupling protocol. The coupling efficiency of the branching units **3**–**5** was equal to that of the commercially available 2′-*O*-methylribonucleoside phosphoramidites (0.1 mol L^{-1} solution of **3**, **4**, or **5** in acetonitrile, 4,5-dicyanoimidazole activation, 600 s coupling time, standard oxidation cycle: 0.02 mol L^{-1} I_2 in mixture of pyridine, H_2O, and THF, 0.4/9.1/90.5 v/v/v, 30 s) (*42*). Once the 2′-*O*-methyl oligoribonucleotide chains were assembled, the orthogonal levulinoyl protections of **40**–**42** were manually removed by conventional hydrazinium acetate treatment [i.e., resins are suspended in a mixture of $NH_2NH_2 \cdot H_2O$, pyridine, and AcOH (0.124/4/1 v/v/v, 1 h at 25 °C), washed with pyridine, MeOH, and acetonitrile, dried, and reset to the DNA synthesizer]. The aminoglycoside phosphoramidites (**1** and **2**) were then coupled to the hydroxyalkyl arms of **43**–**45** or to the exposed 5′-OH group of **37**, using two consecutive standard couplings (0.1 mol L^{-1} solution of **1** or **2** in dry acetonitrile, 4,5-dicyanoimidazole activation, 600 s coupling time, twice, followed by standard oxidation cycle, as above). In order to avoid potential acyl migration, the levulinoyl protections of the amino glycoside moieties of **38**, **39**, and **46**–**51** were selectively removed using the same hydrazinium acetate treatment, as above. Finally, the resins were subjected to concentrated ammonia (15 h at 55 °C) to release the crude 2′-*O*-methyl oligoribonucleotide conjugates (**6**–**13**). The product mixtures were filtered, the filtrates were evaporated to dryness, the residues were dissolved in water, and then the conjugates (**6**–**13**) were subjected to RP HPLC purification (Figure 1, 2, 3, 4). Purity of the crude conjugates ranged from 41% to 66%. Isolated yields of the homogenized conjugates were 15% to 26% (according to UV absorbances of dissolved **6**–**13**). The authenticity of the conjugates was verified by MS(ESI) spectroscopy (properties of the **6**–**13**; see Table 1).

Kinetic Measurements. The reactions were carried out in Eppendorf tubes immersed in a water bath, the temperature being maintained at 35.0 ± 0.1 °C. pH of the samples was adjusted to 7.3 with a HEPES buffer (0.1 mol L^{-1}) prepared in sterilized water. For the metal-ion-dependent experiments, Zn^{2+} ion was added as a nitrate salt to give the overall metal ion concentration of 90 μmol L^{-1}. The ionic strength was adjusted to 0.1 mol L^{-1} with sodium nitrate. The concentrations of the aminoglycoside conjugates (**6**–**13**) and the targets (**14** and **15**) were 18 μmol L^{-1}. 4-Nitrobenzenesulfonate ion was used as an internal standard. The total volume of the reaction mixture was 200 μL in each kinetic run. Aliquots of 20 μL were withdrawn at suitable intervals, cooled to 0 °C, and the reaction quenched by adding of 1.0 mol L^{-1} aqueous hydrogen chloride (1.0 μL). The composition of the samples was quantified by capillary zone electrophoresis (Beckman Coulter P/ACE MDQ CE System) using a fused silica capillary (50 μm, 50 cm). Inverted polarity, citrate buffer (0.2 mol L^{-1}, pH 3.1), and –30 kV voltage were used. The temperature of the capillary was kept at 25 °C. Hydrodynamic injection at 2 psi for 8 s was applied. Between each analytical run, the capillary was flushed for 3 min with water, 10 mmol L^{-1} aqueous hydrogen chloride, and the background electrolyte buffer. The quantification of the target oligonucleotides (**14** and **15**) was based on comparison of their UV absorption at 254 nm to that of internal standard. The peak area was first normalized by dividing it by the migration time and then by the similarly normalized peak area of the internal standard. First-order rate constants for the cleavage of the target oligonucleotides by the conjugates (**6**–**13**) were obtained by applying the integrated first-order rate law to the disappearance of the target oligonucleotide (**14** and **15**).

RESULTS AND DISCUSSION

Synthesis of the Aminoglycoside Phosphoramidites (1, 2, and 31). For the synthesis of aminoglycoside conjugates of 2′-*O*-methyl oligoribonucleotides, three different neamine-based phosphoramidites (**1**, **2**, and **31**) were initially synthesized (outlined in Schemes 1, 2, 3). Commercially available neamine and ribostamycin are rather expensive starting materials to be used for the multistep synthesis. Neomycin trisulfate (**16**) may readily be hydrolyzed to neamine tetrahydrochloride (**17**) (*30*), and, hence, it served as a cheap starting material for each compound. In **1** and **2**, hydroxyethyl and ribose residues were introduced between the phosphoramidite and neamine moieties. In **31**, the O^5 was directly phosphitylated. Synthesis of this reagent was straightforward, but in contrast to **1** and **2**, it turned out be incompatible with the automated RNA synthesis.

Introduction of hydroxyethyl tether to **1** involves ether bond formation, which requires complete protection of the amino functions. In contrast to carbamates or amides (*11*, *38*), azide masking of **18** meets this requirement. This was carried out according to literature by Cu^{2+}-catalyzed diazo transfer (*31*). Three of the four hydroxyl groups were then selectively acetylated with acetic anhydride in pyridine to give **19** (71%) (*31*). In this reaction, all byproducts may be combined and **18** may be regenerated by conventional sodium methoxide treatment (*39*). The reaction may be repeated with crude regenerated **16** in the same yield. The hydroxyethyl moiety was introduced to the O^5-position of neamine via an allyl ether intermediate. The free OH-group of **19** was allylated under neutral condition with allyl methylcarbonate in the presence of $Pd(OAc)_2$ and triphenylphosphine resulting in **20** in 42% yield (*33*). During this reaction, some acyl migration occurred giving 6-*O*-allyl-1,3,2′,6′-tetraazido-5,3′,4′-tri-*O*-acetyl neamine (17%) as a side product. OsO_4 hydroxylation and concomitant $NaIO_4$ oxidation converted the allyl group of **20** to an oxoethyl group, which was subsequently reduced to the hydroxyethyl group with $NaBH_4$ (*34*). Removal of the acetyl protections by sodium methoxide treatment (*39*) gave **21** in 53% overall yield. MMTr-

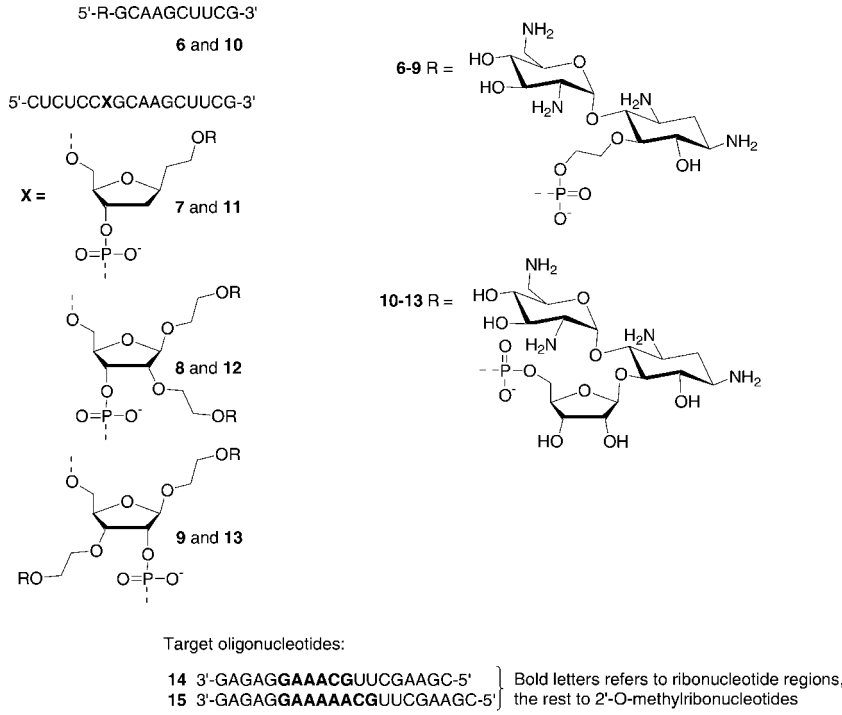

Figure 3. Synthesized neamine (**6**–**9**) and ribostamycin (**10**–**13**) conjugates of 2′-*O*-methyl oligoribonucleotides and the target oligonucleotides (**14** and **15**).

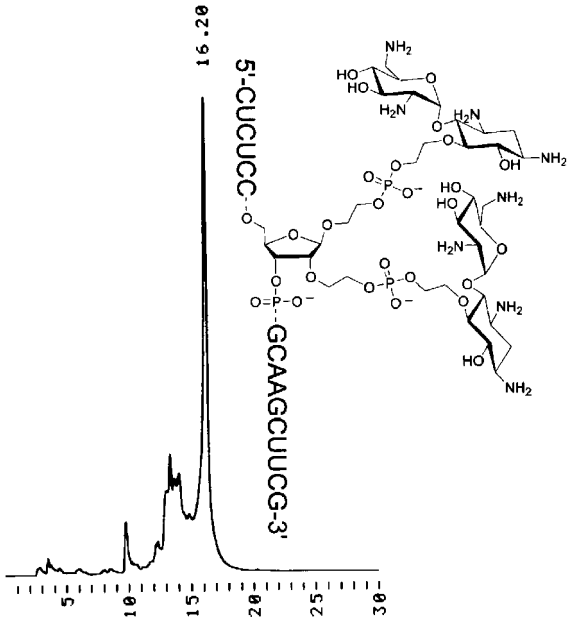

Figure 4. An example of RP HPLC chromatogram of crude product mixture (conjugate **8**).

capping of the primary OH group, in the presence of the secondary ones, gave quantitatively **22**. Staudinger reaction with Me_3P released the amino groups, which were subsequently protected by trifluoroacetyl groups. These two steps may be performed without chromatographic purification, and synthesis was directly continued to the levulinoylation resulting in **23** in 74% overall yield. Finally, the MMTr group was removed with 3% dichloroacetic acid (**24**, 97%) and the exposed primary hydroxyl group was phosphitylated (**1**, 93%).

The azide masked neamine (**19**) was a useful starting material also for the ribostamycin derived phosphoramidite (**2**). The 5-OH of protected neamines is usually only weakly reactive, like in acylations (cf. **16** and **27**), but **17** has turned out to be a good glycosyl acceptor (*35*, *40*, *41*). Analogously to the previously published furanosylation of paromamine (*40*), 1,2,3,5-tetra-*O*-acetyl-*β*-D-ribofuranose was simply used as a donor. The protected ribostamycin (**25**) was obtained in 59% yield. Per-*O*-acetylated phenylthioribofuranoside has recently been used for the same reaction to give **25** in 37% yield (*35*). After deacetylation of **25**, synthesis to obtain **2** was continued analogously to the described preparation of **1** from **21**. The primary hydroxyl group was protected with an MMTr group (**26**, 71%), the azide masks were removed, the trifluoracetyl and levulinoyl protections were introduced (**27**, 79%), the primary hydroxyl group was released (**28**, 91%) and, finally, the phosphitylation was performed to give **2** (92%).

Table 1. Properties of the Synthesized 2′-*O*-Methyl Oligoribonucleotide Conjugates (6–13)

entry	2′-*O*-methyl oligoribonucleotide conjugate	purity of the crude conjugate[a] %	observed mass[b] g mol^{-1}	required mass
1	**6**	64	3727.8	3726.8

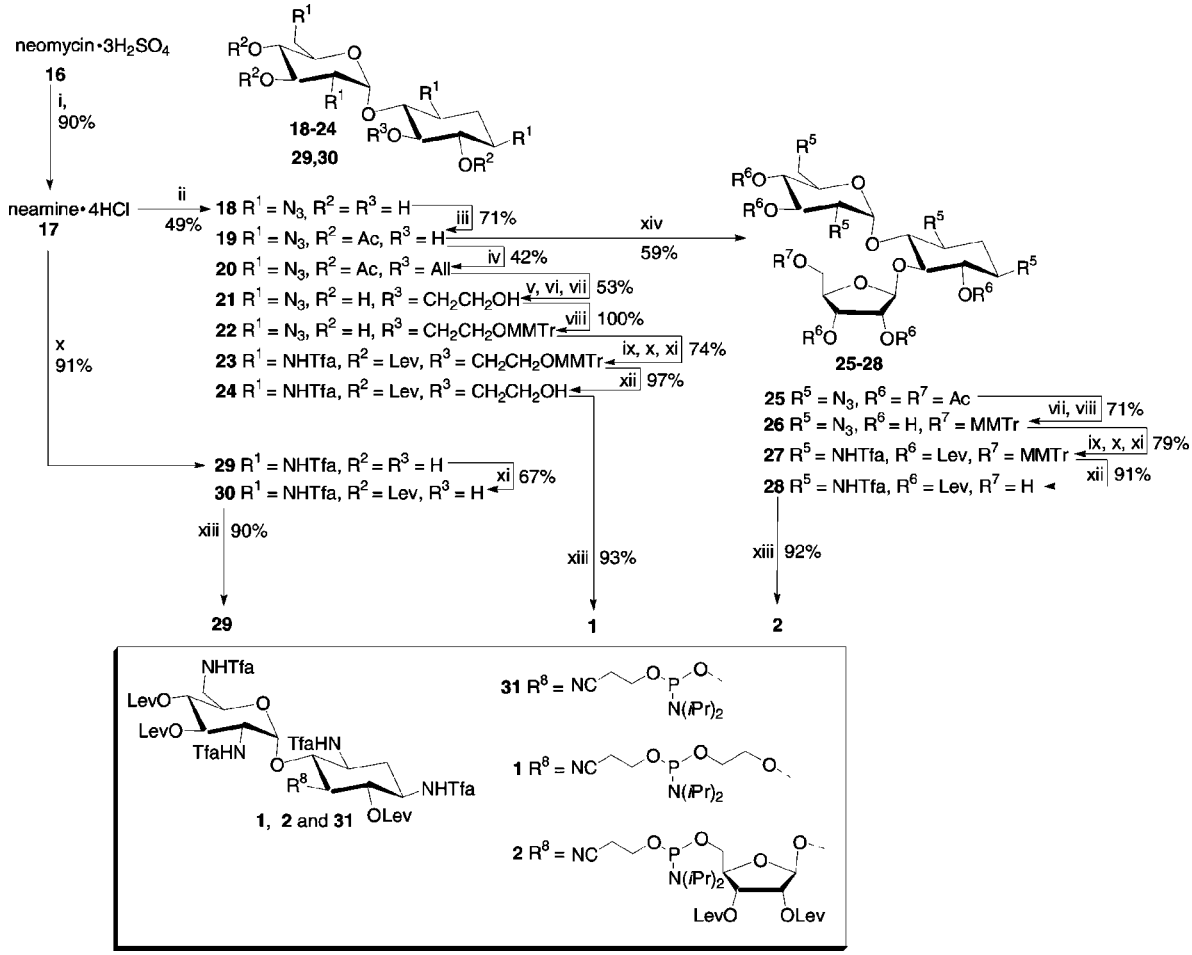
8	**13**	41	6550.2	6547.4

[a] Purities according to RP HPLC chromatograms of crude mixtures of **6**–**13**. [b] Masses calculated from $[(M - 3H)/3]^{-3}$.

The phosphoramidite **31** was synthesized from the neamine tetrahydrochloride (**17**). The amino groups were converted to the trifluoroacetamides according to the literature (**29**, 91%) (*28*). The hydroxyl groups were then selectively esterified as levulinoylates (**30**, 67%), and the remained free 5-OH was phosphitylated to give **31** (90%).

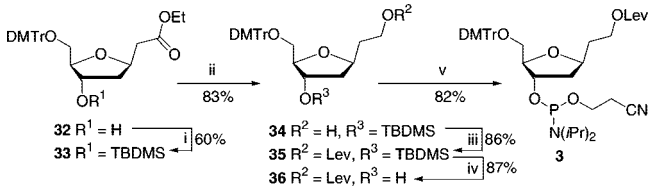
Synthesis of Branching Units 3–5. Preparation of the ribose-based branching units **4** and **5**, and their applicability to the automated RNA synthesis have recently been described (*42*). Previously prepared ethyl 2-[(2*R*,3*S*,5*R*)-5-(4,4′-dimethoxytrityloxymethyl)-3-hydroxytetrahydrofuran-2-yl] acetate (**32**) (*36*, *37*)

Scheme 1. Syntheses of the Aminoglycoside Phosphoramidites[a]



[a] Reagents and conditions: (i) aq HCl, MeOH, reflux; (ii) TfN_3, K_2CO_3, $CuSO_4$, H_2O, MeOH, CH_2Cl_2; (iii) Ac_2O, DMAP, pyridine; (iv) allyl methyl carbonate, $Pd(OAc)_2$, PPh_3, THF, reflux; (v) OsO_4, *i*PrOH, $NaIO_4$, H_2O, dioxane; (vi) $NaBH_4$, EtOH, CH_2Cl_2; (vii) NaOMe, MeOH; (viii) MMTrCl, pyridine; (ix) Me_3P, toluene, H_2O, dioxane, N_2 atm.; (x) TfaOMe, Et_3N, MeOH; (xi) levulinic anhydride, DMAP, pyridine; (xii) DCA, CH_2Cl_2; (xiii) 2-cyanoethyl *N*,*N*-diisopropylphosphonamidic chloride, Et_3N, dichloromethane; (xiv) 1,2,3,5-tetra-*O*-acetyl-*β*-ribofuranose, TMSTf, CH_2Cl_2, 0°C.

Scheme 2. Synthesis of the Branching Unit 3[a]

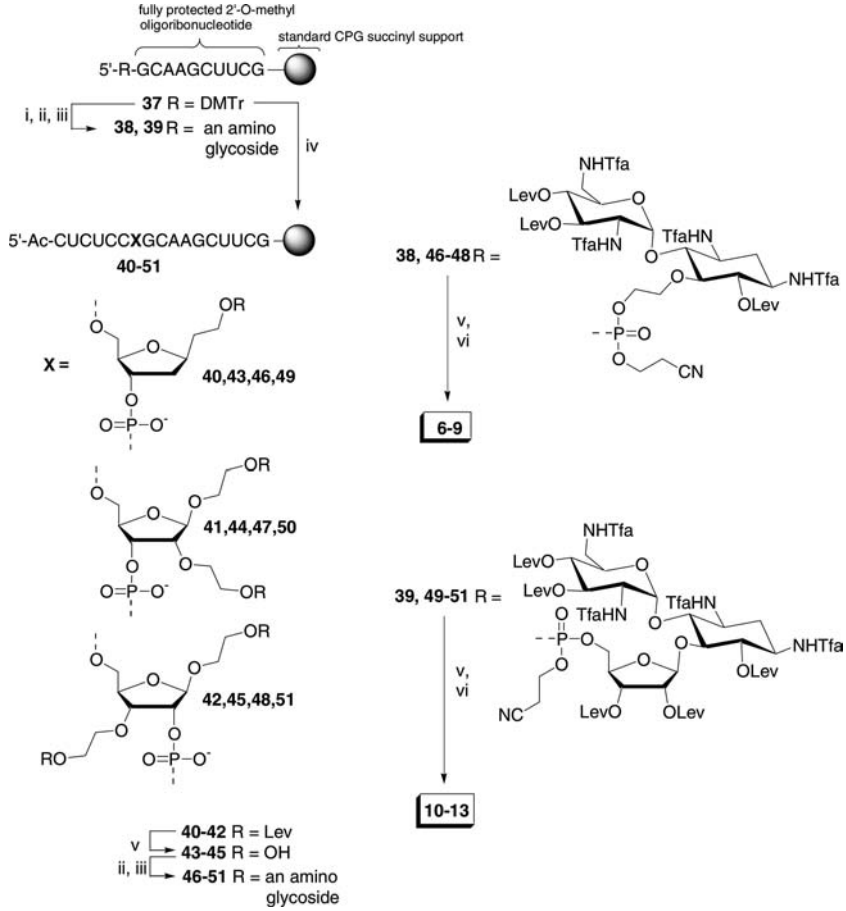


[a] Reagents and conditions: (i) TBDMSCl, imidazole, pyridine, 40 °C; (ii) $LiAlH_4$, THF; (iii) Lev_2O, pyridine; (iv) $Bu_4N^+F^-\cdot H_2O$, THF.

was used as a starting material for the branching unit **3**. The secondary hydroxyl group of **32** was *tert*-butyldimethylsilylated (**33**, 60%) and then the ethyl ester was reduced by lithium aluminum hydride to give **34** (86%). The resultant primary alcohol was capped as a levulinoyl ester (**35**, 86%), the TBDMS protection was removed (**36**, 87%), and the exposed hydroxyl group was phosphitylated to give **3** (82%).

Synthesis of the Aminoglycoside Conjugates of 2′-*O*-Methyl Oligoribonucleotides. To verify and optimize the applicability of the aminoglycoside phosphoramidites (**1**, **2**, and **31**) to the automated oligonucleotide synthesis, they were first coupled to the 5′-end of a simple solid-supported T_5 homooligodeoxyribonucleotide. Coupling efficiencies were evaluated by RP HPLC analysis of the released product mixtures. Use of standard RNA coupling protocol gave ca. 80% coupling yield for **1** and **2**. These couplings were improved to an acceptable 95% yield by using of two consecutive coupling cycles (i.e., 0.1 mol L^{-1} solution of **1** or **2** in dry acetonitrile, 4,5-dicyanoimidazole activation, 600 s coupling time, twice, followed by standard oxidation cycle: 0.02 mol L^{-1} I_2 in mixture of pyridine, H_2O, and THF, 0.4/9.1/90.5 v/v/v, 30 s). This procedure turned out to also give an acceptable yield for the conjugates bearing two aminoglycoside ligands (cf. **8**, **9**, **12**, and **13**). In contrast to **1** and **2**, coupling of **31** remained at a poor level and, hence, this building block was excluded from the synthesis of final conjugates. Coupling of the hydroxyalkyl-armed branching units (**4** and **5**) has recently been shown to be as efficient as that of the commercially available 2′-*O*-methyl-ribonucleoside building blocks; the couplings were quantitative using a standard RNA coupling protocol (*42*). The branching unit **3** behaved similarly. In order to demonstrate the importance of orthogonally removable levulinoyl protections on the aminoglycoside moieties, direct ammonolysis (15 h, 55 °C) without hydrazinium acetate treatment was used for release of the fully protected ribostamycin conjugate (**2**-T_5). In this manner, the yield of the desired conjugate decreased by 22% and *N*-acyl side products appeared (according to RP HPLC chromatograms; see Supporting Information). Thus, the *O*→*N* acylation would be a remarkable problem, especially if two aminoglycoside ligands are to be attached (cf. **8**, **9**, **12**, and **13**). One hour treatment with a mixture of hydrazinium acetate ($NH_2NH_2\cdot H_2O$,

Scheme 3. Synthesis of the Neamine (6–9) and Ribostamycin (10–13) Conjugates of the 2′-*O*-Methyl Oligoribonucleotides[a]



[a] Reagents and conditions: (i) DCA, CH_2Cl_2; (ii) **1** or **2**, 4,5-dicyanoimidazole, acetonitrile; (iii) I_2, pyridine, H_2O, THF; (iv) standard oligoribonucleotide synthesis; (v) hydrazinium acetate, AcOH, pyridine; (vi) aq NH_3, 15 h at 55 °C.

pyridine, AcOH, 0.124/4/1, v/v/v at 25 °C) eliminated acyl migrated products completely. Traces of a defective Tfa removal were found in the product mixure. This small amount of unexpectedly stable Tfa-amides may be slightly decreased (6% to 4% of total absorbance in RP HPLC) by using prolonged ammonolysis (48 h, at 55 °C). With these remarks, conjugates **6**–**13** were synthesized. The 2′-*O*-methyl oligoribonucleotide chains **37**, and **40**–**42** were assembled on a 1 μmol scale following the standard RNA coupling protocol. Levulinoyl protections of the inserted branching units (**40**−**42**) were removed by hydrazinium acetate treatment ($NH_2NH_2 \cdot H_2O$, pyridine, AcOH, 0.124/4/1, v/v/v, 1 h at 25 °C), and then the aminoglycoside phosphoramidites (**1** and **2**) were coupled to the hydroxyalkyl arms of **43**−**45** or to the exposed 5′-end of **37**. Two consecutive standard RNA couplings (0.1 mol L^{-1} solution of **1** or **2** in dry acetonitrile, 600 s coupling time, twice) were used in each case. Levulinoyl protections of the aminoglycoside moieties (**38**, **39**, **46**–**51**) were orthogonally removed by the same hydrazinium acetate treatment as used for the hydroxyalkyl arms above, and then the conjugates were released by ammonia (conc aq NH_3, 15 h at 55 °C). Purity of the conjugates (**6**, **7**, **9**, and **10**) having one aminoglycoside unit was ca. 65%. Attachment of two aminoglycosidic ligands lowered the purity (**8**, **9**, **12**, and **13**) to 41–61% (see Figure 4 and Table 1). Each conjugate was easily purified by RP HPLC (Figure 5). The isolated yield ranged from 15% to 26%. Authenticity of the conjugates **6**–**13** was verified by MS(ESI) (see Table 1). MS(ESI) also showed that the desired conjugates were free from other closely related oligonucleotide derivatives, such as *O*→*N*-acyl migrated side products.

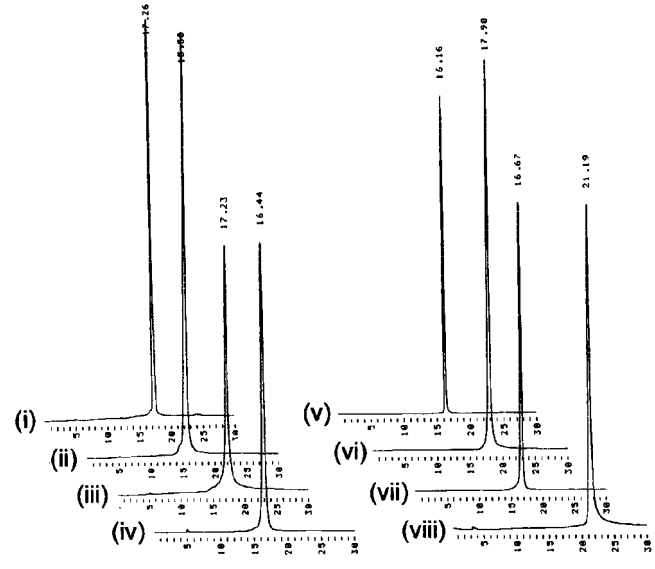


Figure 5. RP HPLC chromatograms (i−viii) of the homogenized conjugates (**6**–**13**), respectively.

RNA Cleavage by the Aminoglycoside Conjugates (6–13). Cleavage activity of the conjugates (**6**–**13**) was studied by using chimeric ribo/2′-*O*-methylribo oligonucleotides (**14** and **15**) as targets. Upon hybridization (excluding experiments with **6** and **10**), a tri- and pentanucleotide bulge (A3 and A5), serving as potential cleaving sites, is formed opposite the aminoglycoside regions. Each aminoglycoside conjugate (**6**–**13**) was

incubated with the target (**14** or **15**) at 18 μmol L^{-1} equimolar concentration (35 °C, pH = 7.3, I = 0.1 mol L^{-1}). Aliquots were withdrawn at appropriate intervals, and their composition was determined by zone capillary electrophoresis. In these metal-ion-independent cleavage studies, one of the conjugates (i.e., conjugate **9**) accelerated the hydrolysis of target oligonucleotides (**14** and **15**), the first-order rate constants being $(2.7 \pm 0.6) \times 10^{-7}$ s^{-1} and $(2.3 \pm 0.6) \times 10^{-7}$ s^{-1}, respectively, while the other conjugates turned out to be almost inactive. Cleavage of **14** by **11** [$k = (1.0 \pm 0.3) \times 10^{-7}$ s^{-1}] may still be noteworthy, but, e.g., target **14** in the presence of conjugates **6**, **7**, **10**, and **12** remained fully intact (100%, $k_{cat} = k_{uncat} = 0$, an aliquot withdrawn after three weeks incubation). Similarly, target **15** remained intact (99–100%) in the presence of **6**−**8** and **10**, and negligible cleavage (under the limits of experimental error) was observed with the other experiments (**14** in the presence of **8** and **13** and **15** in the presence of **11**, **12**, and **13**). All the conjugates contain the same active core, i.e., neamine, but site within the sequence selective motif (**6** and **10** vs **7**–**9**, **11**, **12**, and **13**), number of the cores (**6**, **7**, **10**, and **11** vs **8**, **9**, **12**, and **13**), structural orientations and lengths of the spacers are different. Comparing **9** to **8**, both conjugates have similarly orientated neamine in the 1-*O*-position (branching unit **4** vs **5**), but in contrast to **9**, conjugate **8** is inactive. Comparing **9** to **13**, both conjugates bear the same branching unit (**5**), but ribostamycine (**13**) instead of ethylene glycol derived neamine (**9**) reduces the activity. Hence, the 3-*O*-tethered orientation for the neamine (**4**) together with an appropriate spacer (ethylene glycol in **9**) probably is favorable for the cleavage. We recently described cleavage properties of di(azacrown) conjugated oligonucleotides with the same targets (**14** and **15**). Interestingly, the 3-*O* ribose (**4**) branched azacrown conjugate was even in that case superior to other closely related conjugates (*42*). Metal-ion-independent cleavage of HIV-1 TAR RNA by neamine−PNA conjugates has recently been reexamined by Chaubey et al. (*27*). Consistent with the foregoing, they noted that small structural differences perturbed the activity of the neamine−PNA conjugates; only one of the conjugates resulted in a remarkable cleavage. Chaubey et al. proposed the following mechanism for the neamine catalyzed hydrolysis of RNA (*27*). The deprotonated amino group ($pK_a = 6.9$) at the 3-position of ring I extracts a hydrogen atom from the 2′-OH group of the ribose moiety of the RNA, while the protonated amino group ($pK_a = 9.2$) at the 6′-position of ring II polarizes the phosphate group by electrostatic interaction. These two interactions, together, facilitate intramolecular nucleophilic attack of 2′-OH to the phosphorus atom, which leads to the formation of 2′,3′-cyclic phosphate and cleavage of RNA. In comparison to metal chelate-based nucleases, metal-ion-independent activity, which is based on unprotonated and protonated amino groups in a negatively charged environment, understandably may be perturbed more dramatically by structural differences. In order to study metal-ion dependence of the cleavages by **6**–**13**, each experiment was additionally performed in the presence of Zn^{2+} ion [90 μmol L^{-1} $Zn(NO_3)_2$] keeping the other conditions unchanged. Somewhat increased activities were now found. However, only in one case (conjugate **11** vs target **14**) was the first-order rate constant ($k = 9.0 \times 10^{-7}$ s^{-1}) markedly different from that of the nonspecific cleavage by Zn^{2+} complexes. Otherwise, the accelerations [$k = (1.5–7.0) \times 10^{-7}$ s^{-1}] may be considered to be more or less marginal compared to the background obtained with the targets (**14** and **15**) in 90 μmol L^{-1} Zn^{2+} concentration alone ($k < 1 \times 10^{-6}$ s^{-1}) (*42*, *43*). It is worth noting that cleavage activity of conjugate **9** was not markedly accelerated by addition of the Zn^{2+} ion. The cleavage of **14** by **9** in the presence of the Zn^{2+} ion remained unchanged [$k = (2.7 \pm 0.6) \times 10^{-7}$ s^{-1}] and slight Zn^{2+} promoted acceleration to cleavage of **15** by **9** [$k = (6.0 \pm 0.3) \times 10^{-7}$ s^{-1}] was found.

In the present study, equimolar concentrations of the conjugates (**6**–**13**) with the targets (**14** and **15**) have been used, in which the rate constants for the metal-ion-independent cleavages of **14** and **15** were as low as $k \leq 2.7 \times 10^{-7}$ s^{-1}. Real catalytic activity would require further identification (including experiments, in which a catalytic amount of the conjugate and excess of the targets are used), but as may already be noticed by these rate constants, none of the conjugates met requirements for a real catalyst. An obvious explanation to the modest cleavage activities is restricted access of the neamine cores to the phosphodiester bonds of target RNA bulges. However, this is not necessarily completely caused by structural reasons, such as an inappropriate spacer between the neamine and the 2′-*O*-methyl oligoribonucleotides or the structure of the branching units, but competitive binding of the positively charged aminoglycoside to phosphodiester groups on the same molecule (i.e., intramolecular electrostatic interaction) may also play a role. This explanation is partly consistent with findings that a polyamine−PNA conjugate provides higher catalytic activity compared to its oligonucleotide counterpart (*44*, *45*). Among the metal-ion-independent nucleases, bearing a 2′-deoxy oligoribonucleotide or 2′-*O*-methyl oligoribonucleotide as a sequence-selective motif, only a tris(2-aminobenzimidazole)-based nuclease has been reported to have marked cleaving activity so far (*46*). It should also be noted that the chimeric oligonucleotides **14** and **15** are relatively stable as targets. For example, the Zn^{2+}complexes of the di(azacrown) conjugates of 2′-*O*-methyl oligoribonucleotides, which in an optimal case have equal catalytic activity to the most efficient Zn^{2+} and Cu^{2+}-based artificial nucleases (*47*, *48*), also have moderate cleavage ability [$k = (0.9–1.7) \times 10^{-6}$ s^{-1}] to these targets (**14** and **15**) (*42*). Thus, the real cleavage potential of the aminoglycoside conjugates (**6**–**13**) may still remain obscure, and further studies with different targets are required.

CONCLUSION

In the present study, aminoglycoside conjugates of 2′-*O*-methyl oligoribonucleotides (**6**–**13**) have been successfully synthesized entirely on a solid support. The *O*-levulinoyl and *N*-trifluoroacetyl protecting group combination has been used for the aminoglycoside moieties, which enables elimination of *O*→*N*-acyl migration. The potential of these conjugates to act as a sequence-selective and metal-ion-independent artificial nuclease has been studied with chimeric ribo/2′-*O*-methyl oligonucleotides (**14** and **15**). With these experiments, one of the conjugates (**9**) resulted in metal-ion-independent cleavage of the targets [**14** and **15**, $k = (2.7 \pm 0.6) \times 10^{-7}$ s^{-1} and $(2.3 \pm 0.6) \times 10^{-7}$ s^{-1}, respectively], but usually the cleavage obtained by the conjugates (**6**–**8**, **10**–**13**) remained at a marginal level or the conjugates were fully inactive.

ACKNOWLEDGMENT

The authors thank Professor Harri Lönnberg for advice considering the cleavage studies and corrections in the preparation of the manuscript. The financial support from the Academy of Finland is gratefully acknowledged.

Supporting Information Available: NMR and MS spectral data for **1**–**3**, **6**–**13**, **20**–**31**, and **33**–**36** and RP HPLC chromatographic data as evidence for the *O*→*N*-acyl migration. This material is available free of charge via the Internet at http://pubs.acs.org.

DNA-Encoded Chemical Libraries for the Discovery of MMP-3 Inhibitors

Jörg Scheuermann, Christoph E. Dumelin,[†] Samu Melkko,[†] Yixin Zhang, Luca Mannocci, Madalina Jaggi, Jens Sobek,[‡] and Dario Neri*

Institute of Pharmaceutical Sciences, Department of Chemistry and Applied Biosciences, ETH Zürich, Wolfgang-Pauli-Strasse 10, CH-8093 Zurich, Switzerland. Received November 27, 2007; Revised Manuscript Received December 3, 2007

Encoded self-assembling chemical (ESAC) libraries are characterized by the covalent display of chemical moieties at the extremity of self-assembling oligonucleotides carrying a unique DNA sequence for the identification of the corresponding chemical moiety. We have used ESAC library technology in a two-step selection procedure for the identification of novel inhibitors of stromelysin-1 (MMP-3), a matrix metalloproteinase involved in both physiological and pathological tissue remodeling processes, yielding novel inhibitors with micromolar potency.

INTRODUCTION

Chemical compounds carrying unique DNA fragments as amplifiable identification "bar codes" may serve as building blocks for the construction and screening of chemical libraries of unprecedented size, with considerable implications for drug discovery (*1–7*). DNA-encoded chemical libraries can be classified as "single pharmacophore" chemical libraries (in which a single chemical structure is covalently attached to a DNA fragment) and as "dual pharmacophore" chemical libraries (in which each complementary DNA strand carries a chemical moiety) (Figure 1) (*6*). In the latter case, the two pharmacophores can simultaneously contact the target protein of interest, thus conferring a high binding affinity by virtue of the chelate effect (*4, 8, 9*).

Dual pharmacophore DNA-encoded chemical libraries (ESAC[1] libraries) may be used for the de novo identification of pairs of synergistic binding molecules to protein targets of interest or for the affinity maturation of known lead compounds, which can eventually be converted into small organic molecules devoid of the DNA portion. The process relies on the preferential enrichment of library compounds binding to the target protein of interest immobilized on a solid support, followed by PCR amplification of the recovered oligonucleotide−compound conjugates and by bar code identification on DNA microarrays (Figure 2) (*4, 10*).

Matrix metalloproteinases (MMPs) are zinc-dependent proteases which are involved in tissue remodeling for a variety of physiological and pathological processes (*11–14*). More than 50 MMP inhibitors have entered clinical trials, 46 of which have been discontinued while 7 are still in the evaluation process (*15*). It is generally accepted that future endeavors for the pharmaceutical targeting of MMPs should aim at the development of more selective inhibitors, and in the identification of those MMPs which play a crucial role in pathogenesis (*13, 16, 17*).

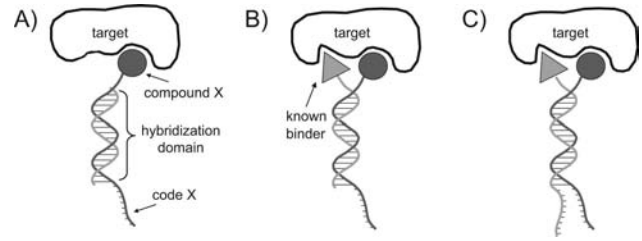

Figure 1. Schematic representation of different formats of encoded self-assembling chemical (ESAC) libraries which can be used for selections against a target antigen. Small molecules are coupled to oligonucleotides, which contain a hybridization domain and (if appropriate) a code revealing the identity of the covalently coupled molecule. After DNA−duplex formation, the oligonucleotide−compound conjugate sublibraries can be used in single pharmacophore selections (A), affinity maturation selections of known binders (B), or de novo selections of binding molecules from a combinatorial library generated by assembling two sublibraries (C).

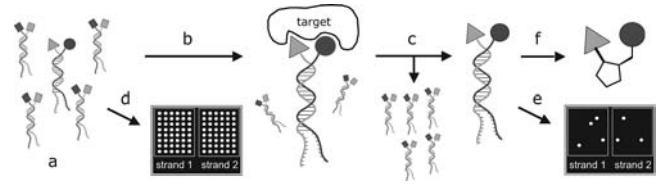

Figure 2. A typical ESAC library selection and readout procedure. The DNA−duplex library (a) is panned against the target protein of interest (b). After washing and removal of unbound molecules (c), the codes of the remaining binders are PCR amplified and compared with the unselected library on oligonucleotide microarrays (d,e). Resulting binding pairs are then validated and positive binding partners are conjugated to suitable scaffolds yielding small druglike molecules (f).

In this article, we present the use of ESAC libraries and technologies for both the identification of a novel MMP-3 inhibitory scaffold and its ESAC technology-assisted affinity maturation, yielding micromolar MMP-3 inhibitors.

EXPERIMENTAL PROCEDURES

Cloning and Expression of Human MMP-3 Catalytic Domain. The gene of human MMP-3 catalytic domain (residues 100–272) (*18*) was subcloned into a pQE12 vector (Qiagen,

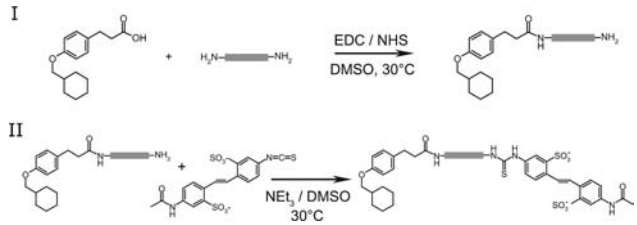
Scheme 1. Synthesis of Compounds Linking Pharmacophores I and II[a]



[a] (I) Linkage of **I** precursor carboxylic acid by carbodiimide-mediated activation with a diamino linker. (II) Coupling of **I**-amine with **II** precursor isothiocyanate to a dual pharmacophore compound.

Hombrechtikon, Switzerland) using restriction sites *Eco*RI and *Bgl*II and the primers 5′-ACT GAA TTC ATT AAA GAG GAG AAA TTA ACT ATG TTC AGA ACC TTT CCT GGC ATC-3′ and 5′-ACT AGA TCT CTA TCA GTG ATG GTG ATG GTG ATG GCC ACC GGG GGT CTC AGG GGA GTC AG-3′. The protein containing a C-terminal His_6-tag was purified with a Ni-NTA column (Qiagen) and dialyzed against 50 mM Tris−Cl, 200 mM NaCl, pH 7.3, and stored frozen at −20 °C.

Cloning and Expression of Murine MMP-3 Catalytic Domain. The murine MMP-3 catalytic domain (residues 100–273) was isolated from a murine cDNA library (eye) and cloned into a pQE12 vector (Qiagen, Hombrechtikon, Switzerland) using restriction sites *Eco*RI and *Bgl*II and the primers 5′- CCG GAA TTC ATT AAA GAG GAG AAA TTA ACT ATG TTC AGT ACC TTC CCA GG-3′ and 5′-ACT AGA TCT CTA TCA GTG ATG GTG ATG GTG ATG GCC ACC GAG GAC ATC AGG GGA TGC TGT-3′. The protein containing a C-terminal His_6-tag was purified with a Ni-NTA column (Qiagen) and dialyzed against 50 mM Tris−Cl, 200 mM NaCl, pH 7.3, and stored frozen at −20 °C.

Synthesis of Oligonucleotide Conjugates and Linked Pharmacophores. All chemicals were purchased from Sigma-Aldrich-Fluka (Buchs, Switzerland), unless otherwise denoted. The synthetic principles of the DNA-encoded chemical library of 550 compounds have been described before (*10*). A list of the 550 oligonucleotide-compound conjugates can be found in the Supporting Information (Table 1). In short, 48mer oligonucleotides (IBA GmbH, Göttingen, Germany), carrying a free amino group at the 5′ end (as ω-aminohexyl phosphate diester) were used of the general structure 5′-GGA GCT TCT GAA TTC TGT GTG CTG XXX XXX CGA GTC CCA TGG CGC AGC-3′, where the XXX XXX coding sequence unambiguously codes for the individual chemical compound displayed. The chemical compounds comprising carboxylic acid, carboxylic anhydride, N-hydroxysuccinimide ester, or isothiocyanate groups were coupled to the primary amino group of the oligonucleotides (*4, 10*).

Selection for Binding. The library containing each individual member at a concentration of 1.78 nM was dimerized at a concentration of 100 nM by heteroduplex formation with an unmodified pairing oligonucleotide (for de novo selections) or with a 3′-amino-modified oligonucleotide, which was conjugated to 3-(4-(cyclohexylmethoxy)phenyl) propanoic acid by an amide bond (for affinity maturation selections). Human MMP-3 and control resins were prepared as follows: 317 mg of dry CNBr-modified sepharose (GE Healthcare) were thoroughly washed with cold 1 mM HCl and incubated overnight at 4 °C either with 4 mL of 50 μM MMP-3 in coupling buffer (100 mM $NaHCO_3$, 100 mM NaCl, pH 8.1) or with 1 M Tris−Cl, pH 7.2 (control resin). The MMP-3 resin was washed 5 times with 550 μL of coupling buffer and excess reactive groups on the resin were quenched with 550 μL of 1 M Tris−Cl, pH 7.2, at 4 °C overnight. The resins were then washed at alternating pH with 100 mM sodium acetate, 500 mM NaCl, pH 4.7, and 100 mM Tris−Cl, 500 mM NaCl, pH 8.1 (4 times each) using SpinX columns (Corning Life Sciences, Acton, USA) and resuspended in 2 mL of selection buffer (50 mM Tris−Cl, 200 mM NaCl, 10 mM $CaCl_2$, 1 mM $MgCl_2$, 10 μM $ZnCl_2$, pH 6.7) containing 0.05 mg/mL herring sperm DNA. 10 μL of the DNA duplex library (85 nM total concentration) was then incubated with 200 μL of resin and 200 μL of selection buffer. After incubation for 1 h at 25 °C, the suspension was transferred to a SpinX column (Corning), the supernatant removed, and the resin washed 3 times with 400 μL of selection buffer. The resin was finally resuspended in 400 μL of selection buffer and stored at −20 °C.

Decoding. The codes of the oligonucleotide−compound conjugates were amplified after selection by PCR (50 μL, 25 cycles of 1 min at 94 °C, 1 min at 55 °C, 40 s at 72 °C), using 10 μL of the resuspended resin as template and primers AB_fo_short (GGA GCT TCT GAA TTC TGT GTG CTG) and Elib2_ba (GCT GCG CCA TGG GAC TCG). The product was purified with a PCR purification kit (Qiagen) and subsequently linearly amplified by PCR (as above) using 5′-Cy3-labeled Elib2_ba as primer. The product was precipitated by adding 10% v/v of 3 M sodium acetate, pH 4.7, and 250% v/v of ethanol and redissolved in 120 μL of hybridization buffer (4 × SSC (60 mM sodium citrate, 0.6 M NaCl, pH 7), 50 mM HEPES, 0.2% SDS, pH 7) and hybridized on microarray glass slides (displaying 19-mers with the structure 5′-T GTG CTG XXX XXX CGA GTC-3′) in a Tecan HS 400 instrument for 4 h at 44 °C, followed by successive washing steps with 2 × SSC/0.2% (w/v) SDS, 0.2 × SSC/0.2% (w/v) SDS, and 0.2 × SSC. After hybridization, the microarrays were analyzed by scanning with a Genepix professional 4200A scanner (Molecular Devices, Sunnyvale, CA; $\lambda_{ex} = 532$ nm, 100% laser power, photomultiplier 400). Spot intensities were quantified and evaluated using *Genespotter* software (v 2.4.3, MicroDiscovery, Berlin, Germany). After background subtraction, the mean value was used as spot signal intensity (average of all spots of the same oligonucleotide). Dividing the obtained signal intensities for the MMP-3 selection by the intensities of the control selection (no antigen resin) resulted in a fingerprint of the enrichment profile.

Affinity Chromatography of Enriched ESAC Conjugates. Oligonucleotide 5′-CAG CAC ACA GAA TTC AGA AGC TCC-3′ and the oligonucleotide conjugate 5′-CAG CAC ACA GAA TTC AGA AGC TCC-**I**-3′ were radioactively labeled at the 5′ terminus using γ^{33}P-ATP (GE Healthcare) and T4 polynucleotide kinase (USB, Cleveland, OH) and individually hybridized to enriched ESAC library compounds or controls

Table 2. Inhibition Constants of Dual Pharmacophore Conjugates Derived from MMP3 Selection

R	Linker name	Linker structure	R′	hu-MMP3 / IC_{50}	mu-MMP3 / IC_{50}	CPA / IC_{50}	uPA / IC_{50}	CAII / IC_{50}

at 200 nM final concentration. 15 μL of the hybridization was incubated with 35 μL of selection buffer and 50 μL MMP-3 resin (see above). After 45 min incubation at 25 °C, the resin was washed several times with 400 μL of selection buffer on SpinX columns (Corning). Aliquots of the remaining resin, input, flowthrough, and all washing fractions were subjected to ^{33}P radioactivity counting on a Beckman LS6500 scintillation counter (Beckman Coulter, Fullerton, CA).

Linked Pharmacophores. The synthesis of bidentate conjugates of **I** and **II** was performed according to Scheme 1: 3-(4-(cyclohexylmethoxy)phenyl) propanoic acid (20 μmol) was activated for 30 min at 25 °C with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) (50 μmol) and *N*-hydroxy succinimide (NHS) (100 μmol) in DMSO and subsequently reacted with diaminolinker (200 μmol)/TEA (144 μmol) overnight at 30 °C. The resulting linker conjugate was purified by HPLC, dried, redissolved in 200 μL of DMSO, and reacted after addition of TEA (72 μmol) with 30 μmol of 4-acetamido-4′-isothiocyanostilbene-2,2′-disulfonic acid. After quenching with a molar excess of ethanolamine, the reaction was purified by HPLC, dried, and analyzed by ESI-MS (Quattro Micro, Waters, Milford, CT). ^1H NMR spectra were measured on a Bruker 400 avance instrument (Bruker, Ettlingen, Germany) and concentrations determined using nitromethane as internal standard (compound naming **R-Linker-R′**: cf. Tables 1 and 2).

I-A-II.(*E*)-5-Acetamido-2-(4-(3-(2-(3-(4-(cyclohexylmethoxy) phenyl)propanamido)ethyl)thioureido)-2-sulfostyryl)benzenesulfonic acid. ESI-MS (*m*/*z*): 759.2 ([M + H^+], 100%), calcd: 758.21 Da. ^1H NMR (DMSO-d_6): 7.95 (d, 2.5 Hz, 2H), 7.71 (d, 2.5 Hz, 2H), 7.69 (d, 2.5 Hz, 1H), 7.57–7.47 (m, 3H), 7.09 (d, 8.5 Hz, 2H), 6.80 (d, 8.5 Hz, 2H), 3.71 (d, 6.3 Hz, 2H), 3.24 (m, 2H), 2.74 (t, 7.8 Hz, 2H), 2.40–2.32 (m, 4H), 2.04 (s, 3H), 1.82–1.60 (m, 6H), 1.35–0.96 (m, 5H).

I-B-II. (*E*)-5-(3-(4-(3-(4-(Cyclohexylmethoxy)phenyl)propanamido)butyl)thioureido)-2-(4-ethanamido-2-sulfostyryl)benzenesulfonic acid. ESI-MS (*m*/*z*): 787.2 ([M + H^+], 100%),

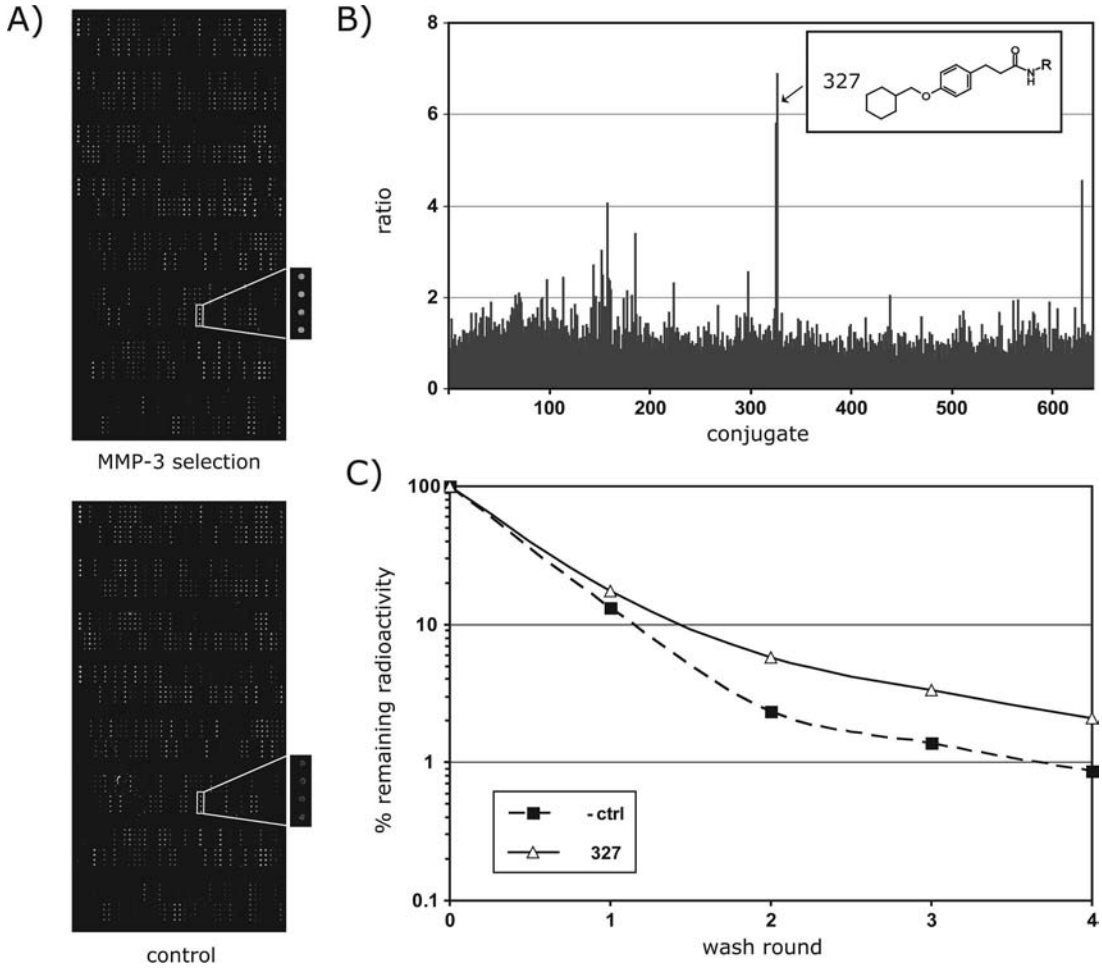

Figure 3. De novo selection of MMP-3 binders using a DNA duplex library consisting of a 3′-unmodified oligonucleotide hybridized to an ESAC library of 550 compounds. (A) Microarray readout after PCR amplification of a selection against MMP-3-displaying resin (upper panel) and control resin (no antigen, lower panel). On the microarrays, ESAC library decoding oligonucleotides are spotted in quadruplicate. The spots encoding the enriched ESAC oligonucleotide−compound conjugate 327 are shown as insets for both MMP-3 and control selection. (B) Quantitative microarray evaluation: Enrichment of ESAC library oligonucleotide−compound conjugates given as ratio of MMP-3 selection versus control selection. The enriched ESAC conjugate 327 is indicated. (C) Affinity chromatography of enriched ESAC conjugate 327 and of nonenriched ESAC conjugate 2 (- ctrl) hybridized each to a radiolabeled unmodified oligonucleotide. The retaining radioactivity was monitored for increasing washing steps.

I-K-COOH. 7-(3-(4-(Cyclohexylmethoxy)phenyl)propanamido)heptanoic acid. ESI-MS (*m*/*z*): 390.3 ([M + H^+], 100%), calcd: 389.26 Da. ^{1}H NMR (partial, DMSO-d_6): 3.71 (d, 6.4 Hz, 2H, R-OCH_2-cyclohexyl).

MMP-3 Inhibition Assay. 55 μL of MMP-3 in 7.3 mM Tris−Cl, 36.4 mM NaCl, 63.6 mM 2-(*N*-morpholino)ethane sufonate, 1.27 mM $CaCl_2$, 25.5 μM $ZnCl_2$, 0.055% Brij-35, pH 6.1 (final MMP-3 concentration: 417 nM), were incubated in a 384-well microtiter plate (Nunc, Roskilde, Denmark) with a dilution series of inhibitor in DMSO (5 μL) for 20 min at 25 °C. The reaction was started by addition of 10 μL of the fluorogenic substrate Mca-Pro-Leu-Gly-Leu-Dpa-Ala-Arg-NH_2 (OmniMMP, BIOMOL, Exeter, UK, dissolved at 50 μM in 5% DMSO) to 60 μL of MMP-3/inhibitor solution. The change of fluorescence signal (λ_{ex} 328 nm; λ_{em} 393 nm) was recorded over 5 min using a SpectraMax Gemini microplate reader (Molecular Devices). The rate of fluorescence signal increase over time (initial reaction velocity v) was plotted against the corresponding inhibitor concentration, and the IC_{50} value for the inhibitor was obtained by fitting to the equation $v = \alpha/2 \times \{-(I - E_o + IC_{50}) + \mathrm{sqrt}[(I - E_o + IC_{50})^2 + 4 \times IC_{50} \times E_o]\}$ (v = initial velocity, I_o = initial inhibitor concn, E_o = initial enzyme concn) using *SigmaPlot* software (SPSS Inc., Chicago, IL).

uPA Inhibition Assay. 58 μL of 32 nM uPA in TBS were incubated in a 384-well microtiter plate (Nunc, Roskilde, Denmark) with a dilution series of inhibitor in DMSO (5 μL) for 20 min at 25 °C. The reaction was started by addition of 7 μL of the fluorogenic substrate ZGGR-AMC (1 mM in DMSO) (Bachem, Switzerland). The change of fluorescence signal (λ_{ex} 383 nm; λ_{em} 455 nm) was recorded over 4 min using a SpectraMax Gemini microplate reader (Molecular Devices). The rate of fluorescence signal increase over time (initial reaction velocity v) was plotted against the corresponding inhibitor

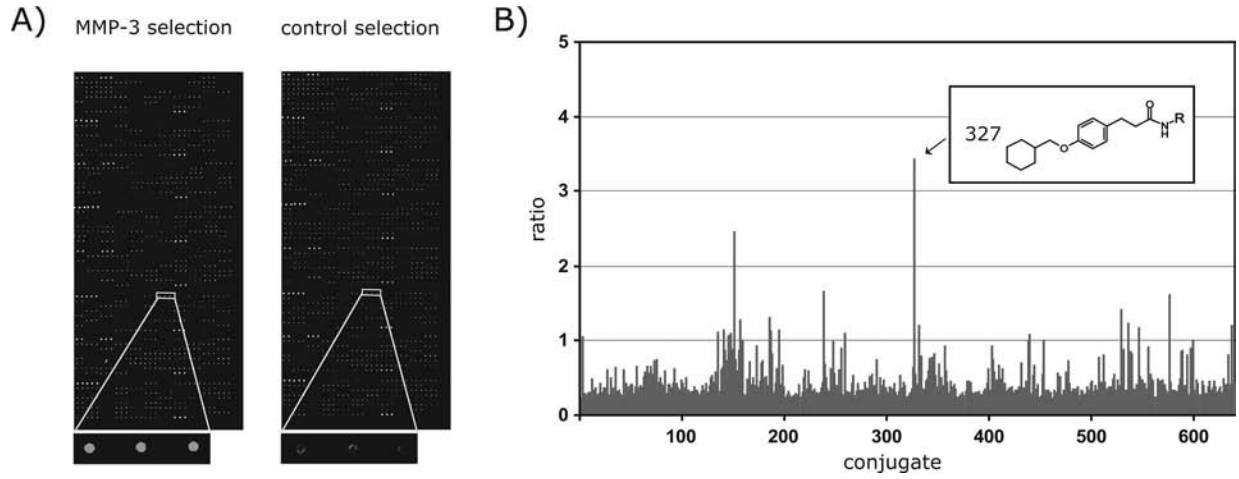

Figure 5. Verification of dual pharmacophore binding: Affinity maturation selection of ESAC conjugate 581 (**II**) using a DNA duplex library consisting of an oligonucleotide displaying **II** on its 3′ terminus hybridized to an ESAC library of 550 compounds. (A) Microarray readout after PCR amplification of an affinity maturation selection against MMP-3-displaying resin (left panel) and control resin (no antigen, right panel). On the microarrays, ESAC library decoding oligonucleotides are spotted in triplicate. The spots coding for the ESAC library conjugate 327 (**I**) are shown as insets for both MMP-3 and control selection. (B) Quantitative microarray evaluation: Enrichment of ESAC library conjugates given as ratio of MMP-3 selection versus control selection. The enriched ESAC library conjugate 327 is indicated.

concentration, and when possible, the IC_{50} value for the inhibitor was obtained by fitting to the above-mentioned equation using *SigmaPlot* software.

CPA Inhibition Assay. 85 μL of 59 nM carboxypeptidase A (cat. no. C9268, Sigma, Buchs, Switzerland) in assay buffer (50 mM Tris−Cl, 1 M NaCl, 1 mM $ZnCl_2$, pH = 7.5) were incubated in a 96-well microtiter plate (Nunclon, Nunc, Roskilde, Denmark) with a dilution series of inhibitor in DMSO (5 μL) for 20 min at 25 °C. The reaction was started by addition of 10 μL of the substrate FA-Phe-Phe-OH (10 mM in DMSO) (cat. no. M1760, Bachem, Switzerland). The change in transmission at 340 nm was recorded over 10 min using a VersaMax microplate reader (Molecular Devices). The signal increase over time (initial reaction velocity v) was plotted against the corresponding inhibitor concentration, and when possible, the IC_{50} value for the inhibitor was obtained by fitting to the above-mentioned equation using *SigmaPlot* software.

CAII Inhibition Assay. 85 μL of 1.2 μg/mL carbonic anhydrase II (cat. no. C3934, Sigma, Buchs, Switzerland) in assay buffer (50 mM Tris−sulfate, 1 mM $ZnCl_2$, pH = 8.5) were incubated in a 96-well microtiter plate (Nunclon, Nunc, Roskilde, Denmark) with a dilution series of inhibitor in DMSO (5 μL) for 20 min at 25 °C. The reaction was started by addition of 10 μL of the substrate *p*-nitrophenyl acetate (10 mM in 1% acetonitril) (cat. no. M1760, Bachem, Switzerland). The change in absorbance at 405 nm was recorded over 10 min using a VersaMax microplate reader (Molecular Devices). The net signal increase over time (initial reaction velocity v) was plotted against the corresponding inhibitor concentration, and when possible, the IC_{50} value for the inhibitor was obtained by fitting to the above-mentioned equation using *SigmaPlot* software.

RESULTS

In an attempt to find novel MMP-3 inhibitors, a library of 550 DNA-encoded chemical compounds was selected for binding to human MMP-3, encouraged by the recent observation that a precursor library of 477 oligonucleotide−compound conjugates could be successfully used in single pharmacophore selections (Figure 1A), yielding specific binders to streptavidin (*10*) and human serum albumin (*30*). Each DNA-encoded compound in the library was prepared by conjugating the chemical compound to the 5′ end of an amino-modified 48-mer oligonucleotide carrying a 6-base code for identification and regions for primer annealing and PCR amplification (*10*). Selection for MMP-3 binding was performed on human MMP-3 covalently coupled to CNBr-activated sepharose resin and on Tris-quenched CNBr-activated sepharose resin (control selection), similar to previously published procedures (*4*, *9*). After thorough washing of the resin, the enriched DNA conjugates were PCR-amplified with a Cy3-labeled primer and hybridized to decoding microarrays (Figure 3A), carrying code-complementary oligonucleotides, spotted in quadruplicate. The ratio of the average fluorescence signal intensity corresponding to each library member from MMP-3 selection and control selection on control resin was determined, giving rise to a fingerprint of enriched binding molecules (Figure 3B). One compound (ESAC library conjugate 327, structure **I** of Table 1) was strongly enriched (7-fold) compared to background.

This 327-oligonucleotide conjugate was then subjected to an affinity chromatography assay, displaying a substantial retention on MMP-3 resin compared to the control (nonenriched ESAC conjugate 2) (Figure 3C). In this assay, a ^{33}P-labeled oligonucleotide was hybridized with the individual ESAC conjugates, incubated with MMP-3 resin and subjected to consecutive washing steps. The radioactivity retained on the resin after the washing steps provided a direct estimate of the MMP-3 binding ability of the individual DNA conjugates, a process which is known to be dependent on the protein density on resin (*8*–*10*).

The newly discovered MMP-3 binder **I** was conjugated to the amino-modified 3′-extremity of a 24-mer oligonucleotide capable of pairing with the 550 member ESAC sublibrary and used as lead for affinity maturation selections (Figure 1B). After affinity capture on immobilized MMP-3, PCR amplification and microarray-based decoding (Figure 4A), enrichment of one synergistic binding moiety was observed (structure **II** of Table 1, corresponding to compound 581 in the ESAC library; Figure 4B). Preferential MMP-3 binding of the bidentate heteroduplex, displaying both compounds **I** and **II**, was confirmed in a radioactivity-based affinity chromatography assay performed as described above (Figure 4C). The bidentate binder was superior compared to DNA conjugates displaying the individual pharmacophores or no pharmacophore at all (Figure 4C).

In order to confirm the results of the ESAC selection, affinity maturation selections were performed, using the DNA conjugate 581 (**II**) as a lead, paired to the 550-member ESAC library. As expected, the corresponding pharmacophore **I** was preferentially

enriched by selections on MMP-3 resin, confirming the synergistic affinity gain offered by the combination of these two pharmacophores (Figure 5).

The newly discovered pharmacophores **I** and **II** were used for the synthesis of low-molecular weight bidentate MMP-3 inhibitors with a series of diamino linkers (A−J, Table 2), according to Scheme 1. The corresponding inhibition constants to MMP-3 were measured, revealing that only the combination of the two pharmacophores yielded compounds of micromolar potency (Table 2). The highest binding affinity was observed for compound **I-J-II**, with an IC_{50} value of 9.9 μM.

The compounds in the series were also characterized in terms of their IC_{50} values for the closely related murine MMP-3, for the Zn-dependent metalloproteinase carboxypeptidase A, for the human serine protease uPA, and for bovine carbonic anhydrase II. As expected, inhibitors of human MMP-3 were also able to inhibit the murine enzyme, but displayed only minor inhibitory activity toward both carboxypeptidase A and uPA, and no detectable activity toward carbonic anhydrase II (Table 2).

DISCUSSION

The experiments presented in this article confirm that a library of 550 compounds, individually coupled to distinct oligonucleotides carrying an identification code, could be used for the identification of novel MMP-3 binding compounds, suitable for subsequent medicinal chemistry optimization. While monodentate MMP-3 binders did not exhibit any substantial inhibitory activity, bidentate inhibitors could be isolated with inhibitory constants in the low micromolar range (*19–23*). The linker connecting the two pharmacophores appeared to play only a moderate contribution to binding affinity, with IC_{50} values for bidentate binders ranging within a factor of 10. The bidentate binders were found to display a good selectivity toward the metalloprotease CPA, the serine protease (uPA) and toward carbonic anhydrase II (Table 2). The production of good-quality catalytic domains of other MMPs, required for the reliable profiling of inhibitory activities, however, remains a major challenge in the field, due to autoproteolytic processes (*24*).

Most of the MMP-3 inhibitors reported so far in the literature featured a zinc-chelating group (e.g., hydroxamate, carboxylate, barbiturate, thiadiazole, thiadiazine, or sulfodiimine *14, 17, 25*). While monodentate zinc-binding groups usually display IC_{50} values in the millimolar range, these moieties can be fused to a peptide mimetic group, thus enhancing both binding affinity and selectivity (*26, 27*). Barbiturate, carboxylates, and thiadiazole derivatives normally display micromolar inhibitory potency to MMP-3 (*28*), but occasionally higher potencies toward gelatinases (*17*). By contrast, hydroxamate derivatives with IC_{50} values for MMP-3 are ranging between 0.27 nM and > 1 μM (*17*).

The present study confirms the potential of ESAC technology for the rapid identification of pairs of pharmacophores which, upon conjugation, display synergistic binding to the target protein of interest. Future directions of this line of research will require the construction of libraries of larger dimensions (e.g., >10 000 compounds) and the implementation of high-throughput decoding methodologies (e.g., by high-throughput sequencing *6, 29*).

ACKNOWLEDGMENT

We thank Dr. Christian Heinis and Stefanie Pfaffen for the construction of the human and murine MMP-3 expression vector, Catharine Aquino Fournier and Dr. Ralph Schlapbach from the Functional Genomics Center Zurich for help with microarray technology. Funding from ETH, SBF (EU Projects STROMA, FluorMMPI), the FP6 (EU Project Immuno-PDT), the Kommission für Technologie and Innovation, and the Swiss National Science Foundation (Project 3100A0-105919) is gratefully acknowledged.

Methods for chemical modifications of proteins have been crucial for the advancement of proteomics. In particular, site-specific covalent labeling of proteins with fluorophores and other moieties has permitted the development of a multitude of assays for proteome analysis. A common approach for such a modification is solvent-accessible cysteine labeling using thiol-reactive dyes. Cysteine is very attractive for site-specific conjugation due to its relative rarity throughout the proteome and the ease of its introduction into a specific site along the protein's amino acid chain. This is achieved by site-directed mutagenesis, most often without perturbing the protein's function. Bottlenecks in this reaction, however, include the maintenance of reactive thiol groups without oxidation before the reaction, and the effective removal of unreacted molecules prior to fluorescence studies. Here, we describe an efficient, specific, and rapid procedure for cysteine labeling starting from well-reduced proteins in the solid state. The efficacy and specificity of the improved procedure are estimated using a variety of single-cysteine proteins and thiol-reactive dyes. Based on UV/vis absorbance spectra, coupling efficiencies are typically in the range 70−90%, and specificities are better than ∼95%. The labeled proteins are evaluated using fluorescence assays, proving that the covalent modification does not alter their function. In addition to maleimide-based conjugation, this improved procedure may be used for other thiol-reactive conjugations such as haloacetyl, alkyl halide, and disulfide interchange derivatives. This facile and rapid procedure is well suited for high throughput proteome analysis.

I. INTRODUCTION

Protein molecules are often targets for chemical modification by covalent conjugation (*1, 2*). These derivatized proteins can specifically recognize and bind target molecules, providing a handle for target detection, quantification, and analysis. Specific and efficient protein labeling techniques are therefore essential for biological research, diagnostics, and therapeutics. Site-specific labeling of proteins is also needed in single molecule fluorescence experiments (*3–5*). Many labeling methods have been developed and utilized, including covalent modification of amino acid side chains (*6–8*), covalent labeling by enzymes (*9–12*), conjugation to unnatural amino acids (*13, 14*), and affinity labeling (*15, 16*).

One of the most common specific covalent coupling methods is the conjugation of a moiety bearing a thiol-reactive group to a solvent-accessible cysteine. This method affords the site-specific labeling of a protein at a unique engineered (or native) surface cysteine. This cysteine could be specifically labeled with dye derivatives of haloacetyl compounds, disulfide, or maleimides. The maleimide is by far the most prevalent functional group to be coupled to a cysteine because the coupling reaction is highly specific and efficient.

The protein must be maintained in a reduced form prior to the maleimide-cysteine coupling reaction to prevent the formation of disulfide bridges and inactivation of the cysteines. Reducing agents such as dithiothreitol (DTT) and tris[2-carboxyethyl]phosphine (TCEP) can be used for this purpose. These reducing agents must be removed before conjugation so that their thiol groups will not compete with target thiols in proteins.

The labeling reaction must be performed shortly after the elimination of reducing agents to prevent reoxidation of the target thiols, resulting in decreased labeling efficiency. In order to circumvent this problem, we developed an alternative, rapid, efficient, and specific cysteine labeling technique; this procedure does not require time-consuming and cumbersome reduction/desalting steps because the labeling reaction is directly performed on highly reduced proteins in the solid state.

We demonstrate our new labeling method, which we dub "solid state-based labeling", or SSL, on two small libraries of model proteins, all containing a single cysteine. The first library consists of mutants of the transcription initiation factor, σ^{70} subunit, of *Escherichia coli* RNA polymerase. The σ^{70} is required for promoter-specific transcription; σ^{70} binds to RNAP coenzyme, interacts with promoter DNA, plays roles in promoter unwinding, promoter escape, early elongation, and is a target for transcription regulators. The *E. coli* sigma factor has been utilized as a target protein for labeling in structural studies of

bacterial transcription on the ensemble level (*17, 18*) and more recently on the single molecule level (*19–23*). Using SSL, several maleimide-linked dyes have been incorporated specifically and efficiently into single cysteine mutants of σ^{70}, and fluorescence studies have showed that the labeled proteins are fully functional in transcription. The second library consists of a variety of proteins from the organism *Shewanella oneidensis* MR-1 (see (*24–26*) for reviews), either containing a single native surface-exposed cysteine or a single engineered cysteine added at the N-terminal region.

II. EXPERIMENTAL PROCEDURES

II.1. Materials. Alexa-maleimides and tetramethylrhodamine-maleimide were purchased from Invitrogen Corp. (Carlsbad, CA), and Cy3b-maleimide was purchased from GE Healthcare (Piscataway, NJ). *E. coli* RNA polymerase core was purchased from Epicenter Biotechnologies (Madison, WI). Size-exclusion resin HW-50F was purchased from TOSOH Bioscience LLC (Montgomeryville, PA). Disposable polypropylene columns and Nickel-nitrilotriacetic acid (Ni-NTA) Agarose were purchased from Qiagen Inc. (Germany).

II.2. Production and Purification of Proteins. Plasmid pGEMD(-Cys), encoding a σ^{70} derivative with no Cys residues, and plasmids encoding σ^{70} derivatives with single Cys residues were described in Mukhopadhyay et al. (*17*). The expression construct of the single cysteine mutant (A59C) of σ^{70} was created by site-directed mutagenesis. The σ^{70} mutants were expressed and inclusion bodies were prepared according to a published protocol (*17*). The resulting proteins were refolded from the inclusion bodies and further purified by anion exchange chromatography (MonoQ) (GE Healthcare, USA), dialyzed against TGED buffer (20 mM Tris-HCl [pH 7.9]/0.1 mM Ethylenediamine tetraacetic acid [EDTA]/1 mM DTT/5% Glycerol) plus 200 mM NaClBacterial expression constructs for MR-1 σ^{24}, σ^{32}, and the integration host factor (IHF) were provided by Dr. Jeanne Perry of the Protein Expression Laboratory at UCLA and expressed and purified in our laboratory. Single cysteine S*hewanella oneidensis* MR-1 proteins were prepared by amplification of the open reading frame from genomic DNA with KOD DNA polymerase by using conditions and reagents provided by the vendor (Novagen, Madison, WI). The genes were cloned using a modified ligation-independent cloning protocol (*27*). This process generated an expression clone producing a fusion protein with an N-terminal His-tag and a V 5 epitope tag containing a single cysteine. Proteins were purified using immobilized metal affinity chromatography (*28*).

II.3. Ammonium Sulfate Precipitation. The purified proteins in TGED buffer were reduced with 10 mM DTT at 4 °C for 2 h. The 10 mM DTT is sufficient enough to reduce up to several hundred micromolar concentration of the protein sample. Ammonium sulfate powder was added to the reduced protein samples. Final concentration of the ammonium sulfate was 70% so that most proteins were precipitated. After addition of the salt, samples were gently agitated for less than 10 min, and stored at 4 °C. This solid form of proteins in the slurry could be stably stored without losing the structural and functional integrity at 4 °C for years. To estimate the quantity of proteins in the solid state, 50 uL of ammonium sulfate slurry was centrifuged, and the pellet was dissolved in TE buffer (10 mM Tris-HCl [pH 8.0] and 1 mM EDTA). The dissolved sample was quantified by the Bradford assay.

II.4. Dye Conjugation. Four nanomoles of the sample in the slurry were taken and further reduced with 5–10 mM DTT for 2 h at 4 °C. We found that samples stored in the solid state for periods longer than 1 month at 4 °C were not in completely reduced state. Those samples were therefore treated with additional 5–10 mM DTT (at least 2 h incubation at 4 °C) before conjugation. Four nmoles of protein in the slurry were taken and centrifuged at 13 000 *g* for 2–5 min at 4 °C. After removal of the supernatant, the pellet was briefly washed with ice-cold Buffer A (100 mM Na_2PO_4[pH 7.3]/200 mM NaCl/1 mM EDTA) plus 70% $(NH_4)_2SO_4$. Washing was achieved by gently inverting the samples several times and subsequent centrifugation for 2 min. The washed pellet was dissolved in 100 μL of Buffer A containing maleimide-linked fluorophores. Several dye probes were tested: Tetramethylrhodamine (TMR)-6-maleimide (Invitrogen, Eugene); Alexa Fluor488-C5-maleimide (Invitrogen, Eugene); Alexa Fluor647-*C*2-maleimide (Invitrogen, Eugene); and Cy3B-maleimide (GE Healthcare, Piscataway). Each fluorophore was dissolved in dimethyl sulfoxide (DMSO) and mixed with Buffer A. Four nanomoles of the dissolved protein were reacted with 20 nmol of dye (1:5 ratio) for 30 min at room temperature. The conjugation reaction was quenched by adding final 0.5% (72 mM) β-mercaptoethanol to the reaction mixture and incubating for 10 min at room temperature.

To remove excess dye from labeled proteins, 2 mL of resin HW-50F were packed into a disposable column and equilibrated with Buffer B (40 mM Tris-HCl [pH 7.9]/200 mM NaCl/1 mM DTT/0.2 mM EDTA). The reaction mixture was loaded onto the column, eluted with Buffer B and collected in 0.1 mL fractions. Fractions of the labeled protein's peak were pooled together, glycerol was added to a final concentration of 50%, and the sample was stored at −20 °C. The column could be reused if it was thoroughly washed with Buffer C (20 mM Tris-HCl/6 M Guanidine HCl/pH 7.9) followed up by washing with deionized water (to get rid of the free dyes). Washed columns were equilibrated with 20% ethanol and stored at room temperature.

II.5. Determination of Labeling Efficiency and Functional Assays. Desalted proteins were quantified using Lambda 25 UV/vis spectrophotometer (PerkinElmer, Waltham). Dye coupling efficiency was calculated based on the extinction coefficient of each reagent: $\epsilon_{280}(\sigma^{70}) = 41\,370\ M^{-1}\ cm^{-1}$; ϵ_{495}(Alexa Fluor 488) = 71 000 $M^{-1}\ cm^{-1}$; ϵ_{555}(TMR) = 65 000 $M^{-1}\ cm^{-1}$; ϵ_{559}(Cy3B) = 130 000 $M^{-1}\ cm^{-1}$; ϵ_{650}(AlexaFluor 647) = 239 000 $M^{-1}\ cm^{-1}$. Absorbance at 280 nm was corrected by a correction factor (CF) defined as $CF_{280} = A_{280}$ (freedye)/A_{max} (freedye). The CF numerical values for each dye are CF_{280} (AlexaFluor 488) = 0.11; CF_{280}(TetraMethylRhodamine) = 0.03; CF_{280}(Cy3B) = 0.08; and CF_{280}(AlexaFluor 647) = 0.03.

The coupling efficiency (CE) was calculated according to eq 1 (*1*):

$$CE = \frac{\epsilon_{280}(\text{Protein}) \cdot A_{max}}{(A_{280} - CF_{280} \cdot A_{max}) \cdot \epsilon_{dye}} \quad (1)$$

Samples were run on 12% SDS-PAGE gels and visualized by Molecular ImagerFX (Bio-Rad, Hercules). A gel shift assay was carried out to confirm the complex-forming activity of derivatized σ^{70} according to a published protocol (*29*).

III. RESULTS AND DISCUSSION

III.1. Rationale of the Labeling Method. Although the maleimide reactivity toward a free thiol is robust, it is often difficult to achieve high conjugation efficiency due to a variety of issues. Labeling cysteine residues requires proteins be well-reduced by a strong reducing agent, such as dithiothreitol (DTT). However, DTT molecules need to be removed just before conjugation because their thiols are as reactive toward maleimides as cysteines' thiols. Conventional desalting methods include dialysis and size-exclusion chromatography. Dialysis is lengthy and usually results in reoxidation of the free thiols. Size-exclusion chromatography permits faster desalting and is

therefore more commonly used, but has its own drawbacks: (i) desalting is usually accompanied by a loss of proteins and undesired dilution of the sample, especially when a small quantity of proteins is labeled; (ii) desalted proteins need to be quantified before they are reacted with a stoichiometric amount of dye molecules; reoxidation cannot be avoided during this step, resulting in a lower labeling efficiency.

To increase the efficiency, methods for labeling after solid-phase reduction (*17*) and labeling in the presence of thiol-free reductant, tris(2-carboxyethyl)phosphine (TCEP) (*30*, *31*) have been devised. TCEP, a thiol-free trialkylphosphine, was believed to not react with thiol-reactive compounds, thereby obviating the troublesome desalting step. However, it has been shown that TCEP interferes with labeling of proteins with a thiol-reactive dye (*32*). The authors of this report found that the reactivity of thiol-reactive dyes is inhibited by the presence of TCEP, and that dye-TCEP adducts are found in the sample (as evident from HPLC chromatograms). The dye concentration used for the labeling reaction therefore needs to be greater than the TCEP concentration and the concentration of the target cysteine. In the solid-phase reduction protocol, proteins are reduced by immobilized reducing agents (DTT or TCEP), are directly recovered from the reductant column, and are reacted with thiol-reactive dyes after quantification. Although this scheme eliminates the reductant removal step, intrinsic problems still remain: sample loss, dilution, and exposure to reoxidation during the quantitation step.

The improved labeling protocol presented here is based on performing the labeling reaction from a precipitated form of target protein. We reasoned that thiols of protein in the solid state may not be easily oxidized and converted to disulfide forms because of their restricted movement in the state. To test this hypothesis, we chose the well-established ammonium sulfate precipitation through the salting-out effect (*33*). Ammonium sulfate is highly soluble, inexpensive, and apparently unharmful to proteins' function. Target proteins were precipitated by a final concentration of 70–75% ammonium sulfate in a highly reducing environment and stored as a slurry at 4 °C until needed. Precipitation and storage were done in the presence of 5 to 10 mM DTT in order to break any existing disulfide bonds between surface cysteines and to maintain reducing environment. The efficiency of the maleimide-dye conjugation to the protein precipitate was evaluated according to the protocol described in section II.5.

III.2. Labeling of *E. coli* σ^{70} Mutants and *Shewanella oneidensis* MR-1 Proteins. Figure 1 illustrates the labeling strategy. Prior to conjugation, the sample slurry was pelleted by centrifugation and the precipitate was briefly washed with a reductant-free wash buffer (buffer A). The washing step eliminates most of the residual DTT. The wash buffer contains 70% ammonium sulfate to prevent resolubilization of the protein. After washing, the precipitate is immediately reacted with thiol-reactive dyes. Another commonly encountered problem of protein labeling is the separation of labeled proteins from unreacted excess dyes. This step is crucial for fluorescence-based assays since free dyes contribute to a significant background signal that obscures the measurement. However, it is usually not easy to achieve a complete excess dye removal by a single desalting step. We found that the Toyopearl size-exclusion resin (consists of a modified hydrophilic methacrylate polymer) is superior to other commercially available agarose- or polyacrylamide-based resins in separating excess dyes from labeled proteins. The size exclusion separation step was performed using a 2 mL resin volume, under isocratic buffer conditions at neutral pH (pH 7–8) with a moderate ionic strength

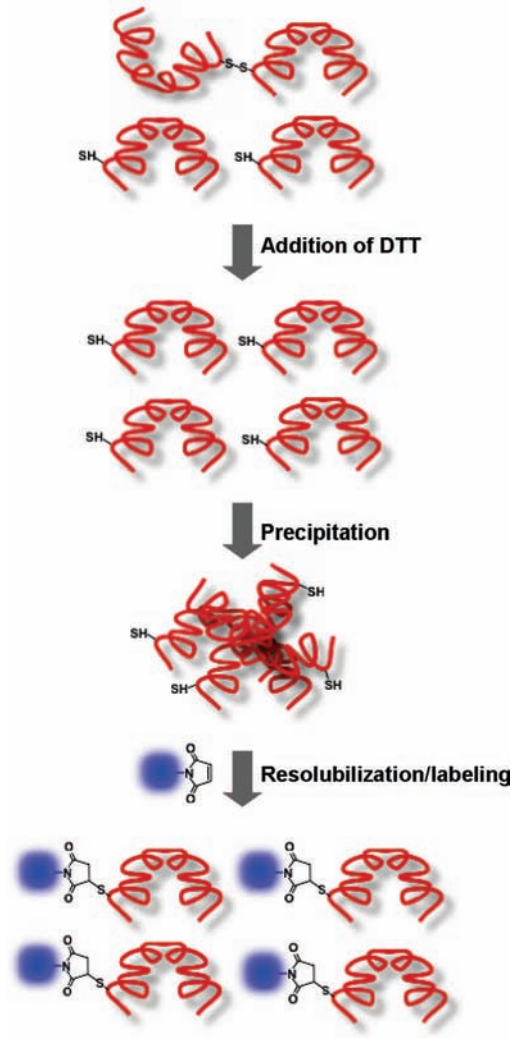

Figure 1. Strategy of solid state-based cysteine labeling. The purified protein is reduced by DTT and stored as an ammonium sulfate precipitate under reducing conditions. A brief centrifugation removes DTT in the supernatant and retrieves the protein as a pellet. Upon redissolving the proteins in a buffer containing thiol-reactive dyes, they are immediately and efficiently labeled.

(100–500 mM NaCl). This desalting step was sufficient in removing >98% of the free-dye in a single step (data not shown).

III.3. Labeling Efficiencies and Specificities. Labeling efficiencies were evaluated by measuring the UV/vis absorbance spectra of the samples (see section II.5.). In a first experiment, several dyes were conjugated to a σ^{70} mutant that has a unique cysteine at residue 596 (arginine to cysteine - R596C) (*18*). Figure 2A shows the absorbance spectra of SSL-labeled σ^{70} (R596C) with Alexa 488 (blue), Cy3b (green), and Alexa 647 (red). The corresponding calculated labeling efficiencies are 91% for Alexa 488 and 70% for Alexa 647. In the case of Cy3b, there was a significant spectral change of the dye after conjugation (appearance of an additional emission peak around 540 nm), precluding an accurate estimation of coupling efficiency to be made. We note that spectral properties of dyes could be significantly altered after conjugation due to their local environment. Nonetheless, the efficiency is likely to be high since the calculated value based on the major peak's absorption only (around 560 nm) is ~65%. SDS-PAGE of these samples analyzed by fluoroimaging and Coomassie-staining indicates the labeling is very specific (Inset of Figure 2A).

In a second experiment, conventional cysteine labeling (*1*) was compared to the SSL method. Maleimide-Cy3b and

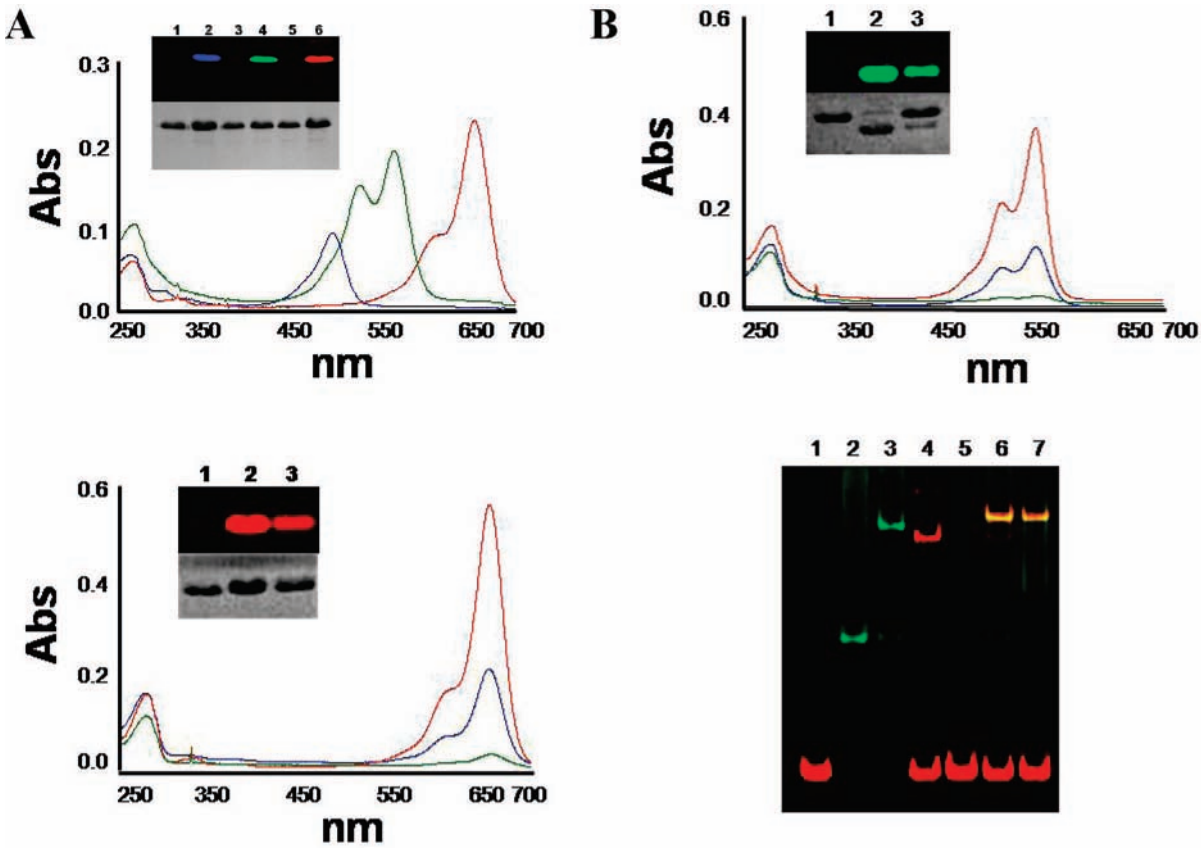

Figure 2. Efficient and specific cysteine labeling: (A) UV/vis spectra of σ^{70} (R596C) labeled with Alexa 488 (blue), Cy3b (green), and Alexa 647 (red). Inset: SDS-PAGE gel of the labeled σ^{70}: the upper panel is a gel image acquired from fluoroimager scan. Each signal, Alexa 488, Cy3b and Alexa 647, was separately imaged by Molecular Imager FX (Bio-Rad, Hercules) and the images were merged: lane 1, 3 and 5 are cysteine-free (Δcys) σ^{70} controls that were subjected to SSL procedure with Alexa 488, Cy3b and Alexa 647, respectively. The fluorescent signals of σ^{70} (R596C) labeled with Alexa 488 (lane 2), Cy3b (lane 4) and Alexa 647 (lane 6) are shown in blue, green and red, respectively. After fluoroimaging, the gel was Coomassie-stained (lower panel). (B) Comparison of SSL to conventional cysteine labeling: UV/vis spectra of Cy3b-σ^{70} (A59C) labeled by SSL (red), conventionally (blue) and a Δcys σ^{70} control (green). Inset: SDS-PAGE gel of the labeled σ^{70}: the upper panel is a gel image from fluoroimager scan: Cy3b-labeled protein bands are shown in green. After fluoroimaging, the gel was Coomassie-stained (lower panel). Lane 1 is cysteine-free (Δcys) σ^{70} control that was subjected to SSL procedure with Cy3b. Lanes 2 and 3 are Cy3b-σ^{70} labeled by SSL and conventional method, respectively. (C) Comparison of SSL to conventional cysteine labeling of Alexa 647-σ^{70} (A59C) (line colors and lane numbers are the same as in B). (D) Electrophoretic mobility shift assay of SSL-labeled Cy3b-σ^{70} (S59C). Holoenzymes were added to Alexa 647-labeled 65 base pairs long *lacCONS-11* promoter DNAs (*17*) (a derivative of the *lacUV5–11* promoter) to a final concentration of 77 nM core, 308 nM Cy3b-σ^{70}, and 77 nM DNA fragment. Following a 30 min incubation at 37 °C, the complexes were challenged with final 0.1 mg/mL heparin, the samples were then incubated for another 5 min at 37 °C before loading onto a 5% polyacrylamide gel (29:1 acrylamide/bisacrylamide; 13.5 × 16 × 0.75 cm) and electrophoresed in 0.5× TBE buffer at 150 V for 2.5 h: lane 1: Alexa 647-DNA only; lane 2: Cy3b-σ^{70} only; lane 3: RNA polymerase core (RNAPc) and Cy3b-σ^{70}; lane 4: RNAPc + Alexa 647-DNA; lane 5: RNAPc + Alexa 647-DNA + heparin; lane 6: RNAPc + Cy3b-σ^{70} + Alexa 647-DNA; lane 7: RNAPc + Cy3b-σ^{70} + Alexa 647-DNA + heparin. Each signal, Cy3b and Alexa 647, was separately imaged, and the images were merged. The yellow bands in lane 6 and 7 are comigrating signals of DNA (red) and Cy3b-σ^{70} (green), indicating that the labeled protein is fully functional for promoter binding.

maleimide-Alexa 647 were conjugated to a σ^{70} mutant that has a unique cysteine at residue 59 (alanine to cysteine - A59C). Normalized spectra of Cy3b-A59C (Figure 2B) and Alexa 647-A59C (Figure 2C) labeled by SSL (red) and conventionally (blue). A cysteine-free Δcys σ^{70} control was also subjected to the same SSL procedure (green). Labeling yields were calculated from these spectra. For SSL labeling, the calculated yields were 76% (Cy3b) and 65% (Alexa 647). For conventional labeling, the calculated yields were 33% (Cy3b) and 24% (Alexa 647).

The specificity of SSL labeling was estimated by a comparison of the UV/vis absorbance spectra of the labeled protein with a cysteine-free protein (Δcys σ^{70}). The labeling of the cysteine-free mutant was less than 5% efficient. The labeling specificity was also confirmed by a cysteine-specific cleavage assay (*29*), which did not cleave the conjugated cysteine residue. Figure S1 shows an example, Cy3b-A59C, that indicates the conjugation is specific to the cysteine residue.

The labeled proteins were also analyzed by SDS-PAGE followed by fluorescence imaging. In the case of Cy3b-maleimide labeling at residue 59, the mobility of the labeled protein was faster than the unlabeled protein (inset of Figure 2B). The reason for the difference in mobilities is unknown. We note, though, that the region containing residue 59 is highly negatively charged, and the hydrophobic Cy3B dye might change some local conformation even in the presence of SDS. Although unexplained, this mobility shift provides another assessment of the labeling efficiency via the intensity ratio of the labeled/unlabeled bands in the Coomassie-stained gel (inset of Figure 2B).

SSL-labeled σ^{70} molecules with Cy3b were analyzed for functionality by a gel-shift assay (Figure 2D). The molecules were added to core enzyme RNA polymerase (RNAP) molecules to form holoenzyme molecules. Holoenzymes were added to promoter DNAs and challenged with heparin to compete off nonspecific protein-DNA interactions (*34*). Lane 3 of Figure 2D clearly shows that the labeled σ^{70} is competent for forming holoenzyme. Lanes 6 and 7 of the same figure clearly show that holoenzyme is fully functional for binding promoter DNA.

Table 1. SSL labeling Efficiencies of Several Single-Cysteine *Shewanella oneidensis* MR-1 Proteins

protein	labeling efficiency	dye
MutT/nudix family proteina[a]	81%	TMR
Nitrogen regulatory protein P-II 1 (glnB-1)[a]	75%	Cy3B
Peptidyl-prolyl cis–trans isomerase FklB[a]	75%	TMR
dnaK, chaperone protein[a]	80%	TMR
rpoE, sigma-24 factor[a]	80%, 94%	Cy3B, Alexa488
rpoH, sigma-32 factor[b]	75%	Cy3B
Integration host factor alpha[a]	90%	Cy3B
Integration host factor beta[a]	85%	Cy3B

[a] A unique single cysteine was introduced near the N-terminus (wild type is cystene-free). [b] Contains a unique surface exposed single cysteine in the wild type.

Labeled σ^{70} proteins have been successfully applied to single molecule and ensemble biophysical assays and showed high activity (*21*). In addition, SSL method was also successfully applied to conjugation of *E. coli*catabolite activator protein (CAP) as well as σ^{70} with benzophenone-maleimide (Y. Kim, Y. Ebenstein and S. Weiss, unpublished result).

To demonstrate the general applicability of the approach, SSL was also used to label a small library of single-cysteine *Shewanella oneidensis* MR proteins with several maleimide dyes (Table 1). σ^{24}, which contained an inaccessible cysteine in the wild-type sequence, was modified such that the inaccessible cysteine was replaced with serine, and an accessible cysteine was added to the N-terminus. σ^{32} contained a unique surfaced exposed cysteine in the wild type sequence that was used for labeling. The remainder of the proteins (originally cysteine-free in the wild type) were labeled via introduction of a unique single cysteine in the N-terminal fusion tag. As shown in Table 1, the proteins were efficiently labeled, and more importantly, multiple samples at a time were labeled simultaneously with high efficiencies because the crucial steps were easily synchronized by the brief centrifugation. These results demonstrate that SSL could be implemented in a titer-plate format, allowing the site-specific and stoichiometric labeling of a large library of proteins in a high throughput fashion.

In conclusion, we developed an improved general procedure for maleimide-based labeling of cysteine containing proteins. This procedure features high labeling efficiency, specificity and simplicity. It is cost-effective and potentially could be used to label a large number of proteins in a high throughput format, offering a platform for proteome-wide analysis. Our approach could be further expanded to other types of thiol labeling such as haloacetyl, alkyl halide, and disulfide interchange derivatives. Current efforts in our laboratory include the utilization of this technique to the studies of protein–protein and protein-DNA interactions of *E. coli* and *Shewanella oneidensis* MR-1 transcription machineries by single molecule fluorescence spectroscopy (*19, 22*).

ACKNOWLEDGMENT

We thank Dr. Ekaterina Korthonjia, Mr. Yun Cheol Kim, Dr. Uljana Mayer-Cumblidge and Dr. Margie Romine for valuable discussions, and Janet Chiang and Dr. Jeanne Perry for the preparation of plasmids for this project. Light-Guided Surface Engineering for Biomedical Applications

Ashwath Jayagopal, Gregory P. Stone, and Frederick R. Haselton*

Department of Biomedical Engineering, Vanderbilt University, 5932 Stevenson Center, Nashville, Tennessee 37232. Received November 1, 2007; Revised Manuscript Received February 1, 2008

Free radical species generated through fluorescence photobleaching have been reported to effectively couple a water-soluble species to surfaces containing electron-rich sites (*1*). In this report, we expand upon this strategy to control the patterned attachment of antibodies and peptides to surfaces for biosensing and tissue engineering applications. In the first application, we compare hydrophobic attachment and photobleaching methods to immobilize FITC-labeled anti-M13K07 bacteriophage antibodies to the SiO_2 layer of a differential capacitive biosensor and to the polyester filament of a feedback-controlled filament array. On both surfaces, antibody attachment and function were superior to the previously employed hydrophobic attachment. Furthermore, a laser scanning confocal microscope could be used for automated, software-guided photoattachment chemistry. In a second application, the cell-adhesion peptide RGDS was site-specifically photocoupled to glass coated with fluorescein-conjugated poly(ethylene glycol). RGDS attachment and bioactivity were characterized by a fibroblast adhesion assay. Cell adhesion was limited to sites of RGDS photocoupling. These examples illustrate that fluorophore-based photopatterning can be achieved by both solution-phase fluorophores or surface-adhered fluorophores. The coupling preserves the bioactivity of the patterned species, is amenable to a variety of surfaces, and is readily accessible to laboratories with fluorescence imaging equipment. The flexibility offered by visible light patterning will likely have many useful applications in bioscreening and tissue engineering where the controlled placement of biomolecules and cells is critical, and should be considered as an alternative to chemical coupling methods.

1. INTRODUCTION

Strategies for the directed patterning of biomolecules at specific sites on diverse material surfaces are highly desired for multiplexed, array-based screening paradigms (*2*), as well as technologies such as tissue engineering, which rely on micro- or nanoscale cell−protein interactions (*3*). Recently, a fluorophore-based immobilization technique was described for the high-resolution, site-specific patterning of proteins such as enzymes within microfluidic channels (*1, 4*). This method utilizes photobleaching, a singlet oxygen-dependent immobilization mechanism, to couple dye-labeled proteins to glass and polydimethylsiloxane (PDMS) surfaces. Visible light patterning has two main advantages over other biomolecular patterning strategies. Nondamaging wavelengths, such as those used in aryl azide and benzophenone chemistries (*5, 6*), are avoided. Second, the reaction can be rapidly carried out in aqueous, neutral buffers preserving protein functionality.

In order to facilitate the implementation of photoattachment chemistry in the development biomolecular and/or cellular arrays, further studies are necessary to expand upon the scope of materials which can be surface engineered using this process, namely, polymer surfaces. Also, efforts to facilitate photopatterning, such as implementation with laser scanning confocal microscopes and software-driven, automated bleach parameters, are relatively unexplored. In addition, a reverse-coupling technique would be desirable. In this case, instead of labeling the soluble protein with a dye, the target surface is conjugated to a fluorophore. This has several advantages. Dye labeling of proteins is not required, and in this scenario, one photoactivable surface could be employed for the patterning of multiple biomolecules.

* Corresponding author. Frederick R. Haselton, VU Station B Box 1510, Nashville, TN 37235, ph: (615)-322-6622. FAX: (615)-343-7919. E-mail: rick.haselton@vanderbilt.edu.

In this study, we explored the utility of visible light-guided surface engineering for site-specific antibody immobilization on a differential capacitance-based viral biosensor (*7*) as well as a polyester filament-based fluorescence detection platform (*8–10*). We then extended this photopatterning technique to couple the cell-adhesion peptide RGDS (*11*) to a surface layer of poly(ethylene glycol)-fluorescein (PEG-FITC) with the intent of developing a substrate for site-specific biomolecular and cellular patterning. This latter example also features low nonspecific adsorption, a limitation not addressed in previous visible-light photopatterning techniques (*4*). In these initial studies, we observed that a variety of surfaces are amenable to photopatterning, and that the simplicity of these techniques makes automated surface patterning readily accessible to biological laboratories with access to a laser scanning confocal microscope. This method may have broad applicability in the field of biosensors which rely on an *a priori* pattern of binding partners as well as tissue engineering applications which rely on spatial control of cells in their construction. Photocoupling can also be used to functionalize nanoparticles and other bioconjugates bearing amine or PEG-FITC moieties.

2. DETAILED EXPERIMENTAL PROCEDURES

Antibodies were photocoupled onto silicon dioxide and polyester surfaces for sandwich immunoassays. In the third portion of this report, peptides were photoimmobilized on PEG-FITC-coated capture substrates in order to modulate cell attachment.

2.1. Photopatterning of Capture Antibody on Capacitive M13K07 Sensor. A previously characterized, capacitive sensor for the detection of the M13K07 bacteriophage (*7*) was prepared for use under dry argon at 25 °C with three rinses of anhydrous acetone (Sigma, St. Louis, MO). The surface was then immersed in a 4% solution of 3-aminopropyltriethoxysilane (United Chemical Technologies, Bristol, PA) in anhydrous

10.1021/bc700406w CCC: $40.75 © 2008 American Chemical Society
Published on Web 03/04/2008

acetone for 10 min, followed by 5 min immersions in anhydrous acetone and ultrapure water, and stored at 25 °C in a desiccator. Successful silanation of capacitor surfaces was verified by comparing the adsorption of fluorescein-conjugated bovine serum albumin (1 mg/mL in borate pH = 8.5) on treated and untreated chips. Immediately prior to use, the silicon dioxide surface was layered by micropipette with 100 μL of a 100 μg/mL FITC-anti-M13K07 monoclonal antibody ((mAb), 2.8 mol FITC/mol IgG) in 100 mM sodium bicarbonate buffer, pH = 8.5.

The FITC-labeled mAb (anti-M13K07 Ms IgG_1, GE Healthcare) was immobilized onto the biosensor surface using an upright laser scanning confocal microscope (LSM 510, Carl Zeiss). The timed bleach function provided in the microscope manufacturer's software package, as used for fluorescence recovery after photobleaching (FRAP) studies (*12*), was used to control the laser intensity of the 488 nm line of a 30 mW Argon laser, as well as the number of scanning iterations. A 4×, 0.1 NA objective was used to scan the 200 μm^2 capacitor surface. Two capacitors were each bleached using different bleach iterations (50 vs 10, using 100% laser intensity). Using the manufacturer's software, the laser was rastered in parallel with the plates of the capacitor, and the bleaching time was less than three minutes. The surface was rinsed three times with PBS, pH = 7.4, for 1 min each. Next, the capacitors were coated with the same amount and concentration of FITC-mouse IgG_1 isotype control mAb (3 mol FITC/mol IgG), and bleached at 100% intensity for 50 iterations.

The functionality of the photoimmobilized surface was ascertained by sandwich immunoassay. The surface was rinsed with PBS, and exposed to a solution of 100 μL of M13K07 bacteriophage (3.3×10^{11} virions/mL) for 30 min at 25 °C. The surface was rinsed with PBS and incubated with 100 μL of Cy5-conjugated anti-M13K07 mAb (1.72 mol Cy5/mol IgG, 50 μg/mL in PBS) for 30 min at 25 °C. The chip was rinsed with PBS and imaged immediately on a Nikon TE2000U inverted fluorescence microscope equipped with a Cy5 fluorescence cube, an Exfo X-Cite 120 metal halide excitation light source, and a C7780 Hamamatsu cooled CCD camera. Mean fluorescence intensities were measured by analyzing ROIs defined along capacitor boundaries using *Image Pro Plus 5.0* (Media Cybernetics), with data plotted using *SigmaPlot 9.0* (SYSTAT).

2.2. Photopatterning of Antibody on Polyester Filament-Based M13K07 Sensing Array. We investigated the utility of photoattachment chemistry in the development of high-throughput biomolecular screening. A previously described polyester monofilament-based system for viral detection based on hydrophobically immobilized capture mAb for multiplexed sandwich immunoassays (*9*) was adapted for the detection of M13K07 bacteriophage, a test virus, based on *photopatterned* mAb. All procedures were carried out at 25 °C. A 120 μm polyester monofilament (Sulky Corp.) was wrapped around a PhastGel sample applicator (GE Healthcare) and inlaid within the concave teeth as previously described (*9*). The filament/comb apparatus was rinsed in successive washes of 70% ethanol, 10% HCl, and Milli-Q water and dried overnight prior to use. A 0.75 μL solution containing 100 μg/mL of anti-M13K07 mAb or mouse IgG_1 isotype control mAb in 100 mM borate buffer, pH = 8.5, was pipetted on each loading tooth for either timed passive incubations or photobleaching sessions. The distance between neighboring teeth is 0.5 cm. For photobleaching, the comb was inverted and suspended within a humidified 60 mm Petri dish upon the Nikon TE2000U microscope stage. For photobleaching, the X-Cite 120 metal halide light source was used in conjunction with a FITC cube and 4× objective at full lamp intensity (1.4 W from microscope emission port, as determined by the manufacturer) for specific durations. Bleaching was monitored by measuring filament mean fluorescence using *Image Pro Plus 5.0*.

To test the functionality of the passively adsorbed and photopatterned surfaces, combs were rinsed three times in PBS, immersed in a multichannel pipet basin containing 3.3×10^{11} virions/mL M13K07 in PBS for 30 min, and rinsed three times with PBS. The combs were subsequently immersed in a basin containing 50 μg/mL Cy5-anti-M13K07 mAb for 30 min and rinsed in PBS.

Filaments were immediately fastened to a standard, precleaned microscope slide with tape, and the fluorescence measured using a Genepix 4000B microarray scanner (Axon Instruments) equipped with a 635 nm laser line as previously described (*9*). The mean fluorescence intensity of ROIs defined along discrete filament spots was measured by *Image Pro Plus* on grayscale 16-bit images, and plotted using *SigmaPlot*.

2.3. Photopatterning of Poly(D-lysine)-Coated Glass Substrate with PEG-RGDS. Poly(D-lysine)-coated 35 mm glass-bottom dishes with no. 1 borosilicate coverglass (MatTek Corp.) were coated with a heterobifunctional PEG spacer (MW = 3400) containing an *N*-hydroxysuccinimide ester (NHS) amine-reactive group and a fluorescein isothiocyanate moiety (NHS-PEG-FITC, Nektar Therapeutics) by incubating the surface with 0.2 mg of NHS-PEG-FITC in 100 mM borate buffer, pH = 8.5, for 1 h. followed by three rinses in borate buffer. Unreacted amine groups were quenched by 20 min incubation with 1 mg of sulfo-NHS-acetate (Pierce Chemical) in borate buffer. This acetylation reaction rendered the remaining amines unreactive. The glass dish was then incubated with with 100 μg/mL of the fibronectin-derived cell-adhesion peptide RGDS (>95% purity, Genscript Corp.) in borate buffer. Photobleaching of 1 mm rectangular areas delineated by taped foil photomasks was achieved using a 10× objective with the aforementioned inverted fluorescence microscope and light source for timed intervals, with mean fluorescence levels monitored to confirm photobleaching. Typically, the time necessary to reduce intensity levels 20% of initial fluorescence was less than 5 min. Photobleaching and RGDS passive adsorptions were followed by three rinses in borate. RGDS presence on the glass substrate was qualitatively assessed using fluorescamine.

Since RGDS has been demonstrated to promote fibroblast adhesion and spreading (*11*), we evaluated the bioactivity of the coupled RGDS using a fibroblast adhesion assay. 3T3 fibroblasts (ATCC) were cultured to 70% confluence in DMEM containing 10% bovine calf serum under incubation at 37 °C, 5% CO_2. The cells were then seeded in each dish at a concentration of 1000 cells/mL and incubated overnight under the same culture conditions. The next day, dishes were rinsed three times with PBS, and fixed for 20 min at 25 °C in 4% paraformaldehyde in PBS. Dishes were incubated with 0.5% trypan blue prior to the fixation step to ascertain cell viability via dye exclusion. The dishes were then rinsed in PBS containing 100 mM glycine and imaged by phase contrast.

2.4. Comparison of Antibody Chemical Crosslinking and Photoattachment on PEG-FITC and PEG-Maleimide-Coated Glass Substrates. Poly(D-lysine)-coated MatTek dishes were coated with 0.2 mg of NHS-PEG-FITC or thiol-reactive NHS-PEG-maleimide (NHS-PEG-MAL, MW = 3400, Nektar) and acetylated as described in section 2.3. To generate sulfhydryl groups for covalent coupling of mAb to NHS-PEG-MAL, 5 mg of anti-M13K07 mAb in 1 mL PBS-EDTA, pH = 7.4, was reacted with a 10-fold molar excess of 2-iminothiolane (Traut's reagent, Sigma) for 30 min at 25 °C. Excess Traut's reagent was removed by three centrifugation cycles of mAb/Traut's reagent on an Amicon-4 Ultra 100K MWCO spin column filtration device (Millipore) using PBS-EDTA as the rinse and

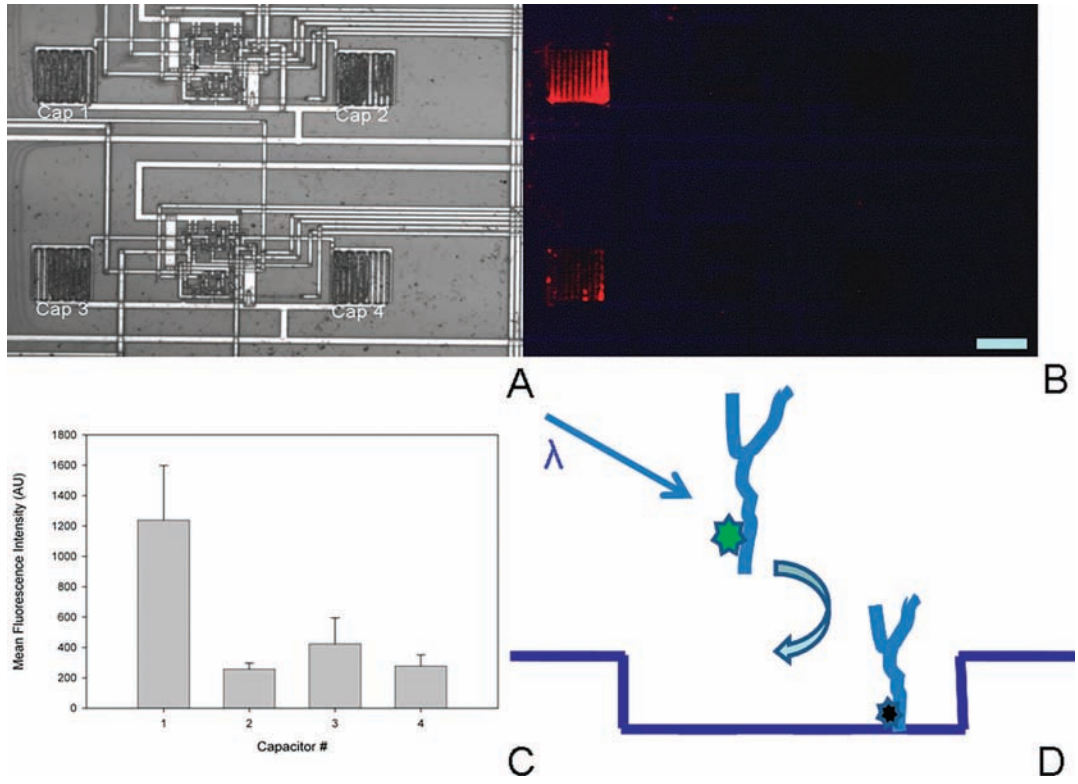

Figure 1. Light (A) and fluorescence (B) micrographs of a multiplexed capacitive biosensor photopatterned with anti-M13K07 monoclonal antibodies and isotype controls, with measured fluorescence intensities shown in (C). Parameters and reagents used for photoattachment using a confocal microscope: Cap 1, 30 mW, 50 bleach iterations, anti-M13K07 photopatterned; Cap 2, 30 mW, 50 bleach iterations, anti-Ms IgG photopatterned; Cap 3, 30 mW, 10 bleach iterations, anti-M13K07 photopatterned; Cap 4, no patterned antibody. (C) Fluorescence intensity measurements of Cy5-anti-M13K07-incubated sensors, reported as mean ± SD, $n = 3$. Bar = 10 μm.

resuspension buffer. For chemical cross-linking, 200 μg of mAb in 200 μL PBS-EDTA was pipetted onto the PEG-MAL surface and was reacted overnight at 4 °C. For photocrosslinking, 200 μg of purified mAb in a 200 μL solution of PBS-EDTA was pipetted on the PEG-FITC surface. The microwell of the dish was then photobleached using the X-Cite 120 light source (1.4 W) using a 2× objective for 10 min. Following both reactions, the dishes were rinsed 3× with PBS, saving the initial aspirate. Aspirate was collected from 20 MatTek dishes bearing either the PEG-FITC or PEG-MAL attachment linker. Protein concentration was determined using the Coomassie Plus assay (Pierce) according to manufacturer instructions.

3. RESULTS AND DISCUSSION

Our studies suggest that photobleaching can be used to pattern proteins and peptides on SiO_2, polyester, and glass surfaces. Photopatterning of anti-M13K07 mAb to capacitor surfaces was site-specific, with an achieved spatial resolution below 10 μm (Figure 1a,b). No signal was detected due to photopatterned IgG_1 control mAb capture of virus, or nonspecific binding of the virus itself, as indicated by mean fluorescence output (Figure 1c). In addition, no secondary antibody fluorescence was detected beyond the capacitor regions of the chip, indicating that diffusion of the bleached fluorophore did not interfere significantly with site-specific coupling, and that nonspecific adsorption was not significant. Specifically, the average fluorescence from 10 different noncapacitor regions of the chip was 237 ± 67, which was similar to control capacitor values (Figure 1c).

The fluorescence signal from the sandwich immunoassay generated from filament-coupled anti-M13K07 mAb using photoattachment chemistry was 2- to 3-fold higher than the signal generated by passively adsorbed antibodies (Figure 2). The enhanced signal could be due to either (a) an initially higher coupling efficiency using the photobleaching technique, and/or (b) greater preservation of bioactivity of photocoupled mAb. Although further studies would be required to differentiate between these two possibilities, we did observe that photocoupled antibodies appeared to be more tightly coupled, since successive washes of filament were associated with loss of passively adsorbed antibodies but with low loss of photocoupled antibody (data not shown).

Our studies also demonstrated that cell-adhesion peptides can be site-specifically coupled on tissue culture substratum (Figure 3). Irradiated PEG-FITC regions (Figure 3a) promoted fibroblast attachment similar in density and morphology observed on the native poly (D-lysine)-coated MatTek surface (Figure 3e). Nonirradiated PEG-FITC regions on the same were resistant to cell adhesion (Figure 3b). The lack of cell adhesion in nonirradiated regions was most likely due to the PEG coating on the surface which blocks adsorption of RGDS (Figure 3c), as well as the fibroblasts themselves (Figure 3f). The PEGylation of the surface was found to be important for controlling cell attachment, as acetylation of the surface alone was not sufficient (Figure 3d). Complete photobleaching of the entire PEG-FITC surface (from 1 to 3 h of continuous lamp illumination) did not result in cell attachment (Figure 3g,h). In a separate experiment, we demonstrated that attachment of 3T3 cells to PEG-RGDS was most likely due to specific peptide−integrin interactions, since competitive inhibition experiments (addition of 2 mM soluble RGDS peptide) reduced cell attachment by 82% (Supporting Information).

The mAb coupling efficiency of photoattachment and chemical crosslinking was compared and found to be similar. The efficiency of photocoupling was measured to be 3.3 pmol/cm^2. Thiol-maleimide crosslinking, a technique which has long been

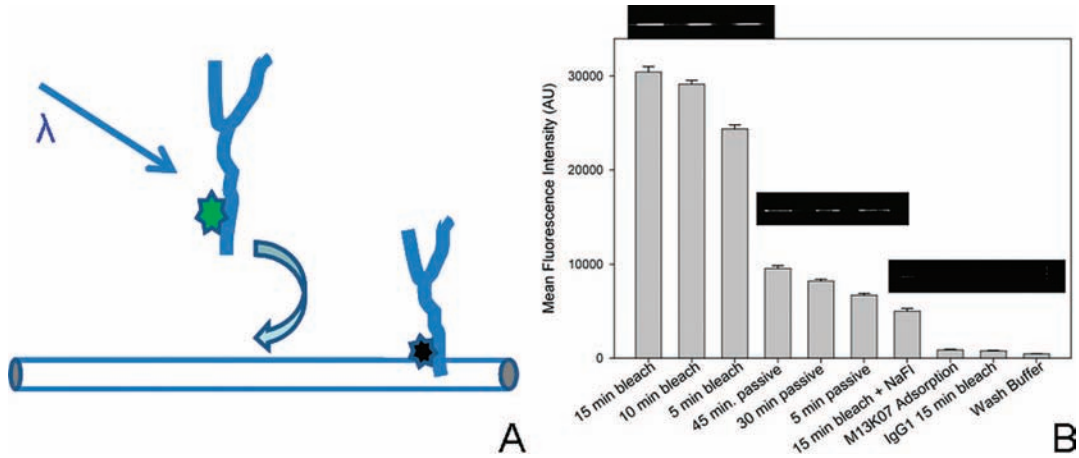

Figure 2. Schematic of a strategy for photocoupling of antibody to polyester filament (A) and resulting sandwich immunoassay Cy5-anti-M13K07 intensities (B). A representative filament is overlaid on the graph in (B).

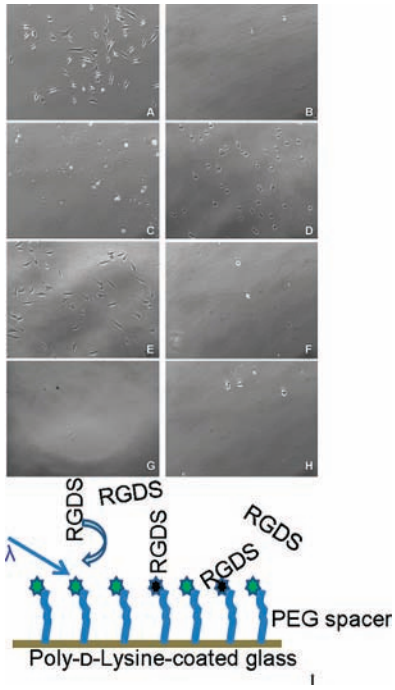

Figure 3. Representative micrographs of 3T3 fibroblast attachment on surface-engineered poly(D-lysine) MatTek dishes from three trials using PEG-FITC-based photoattachment diagrammed in (I). Experimental conditions for each substrate: (A) PEG-FITC and acetylation, RGDS photopatterned; (B) Same as in (A), but in an area where RGDS was not photopatterned; (C) PEG-FITC and acetylation, RGDS passively adsorbed; (D) No PEG-FITC, acetylation, RGDS passively adsorbed (cells are rounded); (E) No PEG-FITC, no RGDS (native surface); (F) PEG-FITC, no acetylation, no RGDS; (G) PEG-FITC and acetylation, bleached 1 h prior to cell adsorption, no RGDS; (H) PEG-FITC and acetylation, bleached 3 h. prior to cell adsorption, no RGDS. Cells in (A) and (E) showed similar viability of seeded cells as indicated by trypan blue exclusion (not shown). (50× magnification).

utilized for efficient, facile conjugation of proteins to material surfaces (*13*), resulted in a higher mAb coupling efficiency (4.2 pmol/cm^2). Although the chemical crosslinking technique was capable of immobilizing a higher quantity of mAb, further optimization of experimental conditions may produce higher yields for visible light photoconjugation, such as buffer strength, reaction volume, PEG molecular weight, and reagent concentrations. Furthermore, photopatterning offers control over site specificity of coupling, which in itself may warrant its future implementation.

The light patterning properties of the confocal microscope facilitated the efficient photoattachment of antibodies on the biosensor surface. With a fixed laser intensity (full output), the number of bleach iterations within the FRAP software module controlled the coupling efficiency of FITC-mAb. Furthermore, the ROI can be readily defined within the software to pattern microscale regions. The patterning of antibodies upon groups of four capacitors was achieved within 5 min, and real-time fluorescence intensity measurements within the software confirmed successful photobleaching. The confocal microscope should facilitate the implementation of photoattachment methods in various laboratories in biological and biomedical sciences, where they are readily available. Since these laboratories often do not have access to cleanroom facilities needed for photolithography, photoattachment chemistry may constitute a viable alternative to the in-house development of custom molecular and cellular arrays as diagnostic or biological study tools.

In addition to extending techniques related to the coupling of dye-conjugated biomolecules on surfaces, we also hypothesized that biomaterial substrates could be engineered to bear the photoreactive groups, thus obviating the need for bioconjugating proteins, a step which can often compromise native function. Poly(ethylene glycol) (PEG) has long been utilized for reducing protein adsorption to biomaterial surfaces, is biocompatible, and is amenable to the grafting of functional groups (*14*). NHS-PEG-FITC is a commercially available heterobifunctional reagent used to detect PEGylation efficiency in bioconjugate chemistry, and combines the properties of PEG with the bioconjugation moiety NHS (amine-reactive) for immobilization on a variety of substrates, as well as a FITC dye, to enable detection of the PEGylated species *in vitro* or *ex vivo*. We observed that pipetting an RGDS peptide solution over the PEG-FITC-functionalized glass substrate, followed by photobleaching of the dye groups, resulted in site-specific immobilization of the adhesion peptide, as indicated by fibroblast binding exclusively on regions of irradiation (Figure 3a). Therefore, the use of this reagent in the development of biosensor arrays affords the resistance of the coating to nonspecific adsorption of proteins.

Dye photobleaching generally involves the energy transfer from the dye in the excited state to molecular oxygen in the ground state (*15–17*). As a result of photobleaching, singlet molecular oxygen is produced, leaving the fluorophore with an unpaired electron. While the process of visible light coupling of dye-conjugated species has not been completely elucidated, it is possible that the unpaired electron on the dye serves as a binding site to an electron-rich substrate. Our data provide further evidence for the photobleached fluorophore as the

coupling moiety. When including 1 mg/mL sodium fluorescein (NaFl) as a free dye in the initial mAb coupling solution, we observed a decrease in fluorescence signal from the virus-associated Cy5 secondary antibody, indicating that the coupling technique was associated with fluorophore photobleaching (Figure 2b). In previous work, oxygen depletion in the coupling medium was associated with significantly lower photoattachment efficiency (*1*), which is consistent with our report that photobleaching chemistry is essential for the coupling reaction. Provided that photobleaching events drive the coupling of biomolecules onto the surfaces tested in this work, it is important to take necessary precautions when carrying out individual reactions. Samples were only exposed to ambient laboratory light for durations of <5 min, to minimize premature photobleaching due to the photolability of fluorescein.

This work expands upon previous approaches to achieve photopatterning of biomolecules, through adapting a confocal microscope to perform automated patterning of microscale regions, and by expanding the scope of surfaces which are candidate substrates for this technique. Future work will focus on the controlled orientation/deposition of cells on adhesion peptide-patterned surfaces. Such a feature would be useful in the development of arrays which incorporate cells as biosensors, or in the synthesis of 3-D tissue constructs, in which hierarchical organization of cells and proteins elicit specific cell functions (*18*). Our technique features the microscale resolution necessary to construct such devices, and nanoscale resolution is potentially achievable with this technique, when used in conjunction with techniques to overcome diffraction barriers, such as stimulated emission depletion fluorescence microscopy (STED) (*19, 20*). While fluorescein was used as the coupling moiety in this work, it has been demonstrated that photottachment strategies can be extended toward the patterning of multiple dye-labeled species, such as Alexa Fluor-labeled proteins (*1*).

4. CONCLUSION

Our studies have extended the utility of visible light photoattachment chemistry in creating biomolecular and/or cellular arrays in well-defined microscale regions on diverse substrates. The method is rapid and can be easily controlled on a spatial and temporal scale. Furthermore, protein activity is retained, and the high-efficiency conjugation of proteins using light patterning may facilitate the development of high-sensitivity screening platforms. Additionally, we have shown that a photoreactive substrate can be the mediator for photocoupling, eliminating the need for bioconjugation of species prior to patterning. In forthcoming applications which utilize cells as biosensors, this technique may be useful for controlling cell orientation and spreading. This rapid, flexible technique is readily accessible and can be implemented in a number of biomedical applications.

ACKNOWLEDGMENT

This work was supported in part by the National Institutes of Health (EB003516 (FRH), T32EY07135 (Jeff Schall, PI) (AJ)) and the Vanderbilt University Discovery Grant program. Confocal microscope-assisted patterning experiments were performed in part through the use of the VUMC Cell Imaging Shared Resource. We thank Ray Mernaugh for helpful discussions.

Enhanced Intracellular Delivery of Quantum Dot and Adenovirus Nanoparticles Triggered by Acidic pH via Surface Charge Reversal

Hyejung Mok, Ji Won Park, and Tae Gwan Park*

Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Daejeon, 305-701, Korea. Received December 14, 2007; Revised Manuscript Received February 14, 2008

Quantum dot (QD) and adenovirus (ADV) nanoparticles were surface-modified with graft copolymers that exhibited a charge reversal behavior under acidic condition. Poly(L-lysine) (PLL) was grafted with multiple biotin-PEG chains (biotin-PEG-PLL graft copolymer), and the remaining primary amine groups in the PLL backbone were postmodified using citraconic anhydride, a pH-sensitive primary amine blocker, to generate carboxylate groups. The surfaces of streptavidin-conjugated QDs were modified with citraconylated biotin-PEG-PLL copolymer, producing net negatively charged QD nanoparticles. Under acidic conditions, citraconylated amide linkages were cleaved, resulting in the recovery of positively charged amine groups with subsequent alteration of surface charge values. Intracellular delivery of QD nanoparticles was greatly enhanced in an acidic pH condition due to the surface charge reversal. The surface of avidin-conjugated adenovirus (ADV-Avi) encoding an exogenous green fluorescent protein (GFP) gene was also modified in the same fashion. The expression extent of GFP was significantly increased at more acidic pH than pH 7.4. This study demonstrates that various nanosized drug carriers, imaging agents, and viruses could be surface-engineered to enhance their cellular uptake specifically at a low pH microenvironment like solid tumor tissue.

For the past decade, significant endeavors have been devoted to surface modification of various nanosized drug and imaging agent carriers such as iron oxide nanoparticles, quantum dots, liposomes, polymeric micelles, polymeric nanoparticles, and viruses to target them specifically to desired cells and tissues (*1*−*7*). In particular, targeted delivery systems for tumor cells are highly desirable to enhance therapeutic and diagnostic efficacy with reducing undesirable side effects. Targeting ligands including peptides, antibodies, carbohydrates, and aptamers, which specifically bind to the receptors overexpressed only in cancer cells, have been popularly tethered on the surface of nanocarriers to deliver them to the tumor tissue in a more specific manner. As alternative approaches, minute physiological changes in the environment of tumor tissues different from that of normal tissues have been utilized as triggering signals to nanocarriers for cancer treatment and tumor imaging (*8*−*10*). It is well-known that human and rodent solid tumor tissues exhibit a more acidic microenvironment than normal tissues, and their extracellular pH ranges from 5.8 to 7.4 (*11, 12*). Thus, a variety of pH-responsive nanoparticles were widely explored to increase the extent of cellular uptake only at the acidic tumor region. A wide array of pH-sensitive moieties, such as polyhistidine, β-amino esters, and sulfonamide, and acidic-cleavable linkages such as acetal, hydrazone, and orthoester have been employed in combination to produce multifunctional nanocar-

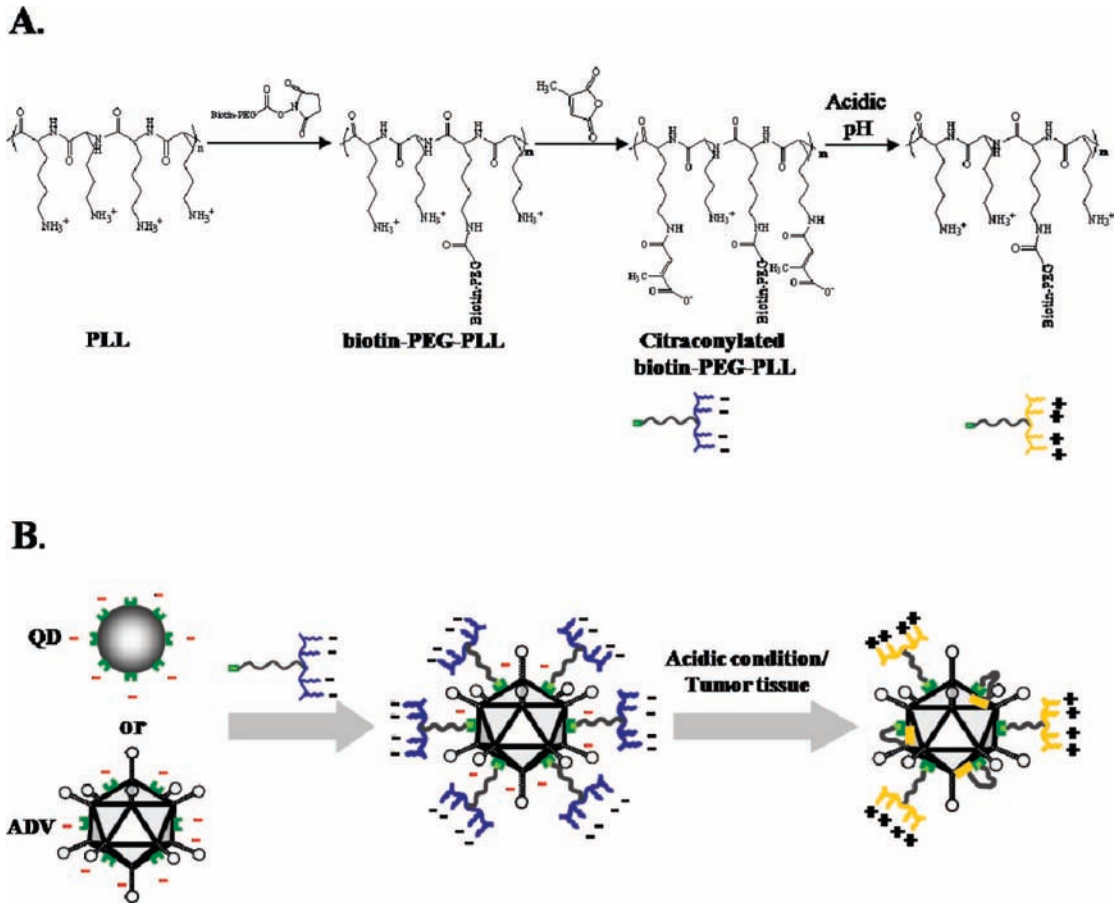
riers that enabled the release of encapsulated or conjugated chemical and biological drugs in response to acidic pH (*13*−*16*). It was recently demonstrated that cationic diblock polymers containing primary amine groups, when conjugated with citraconic anhydride, showed charge reversal from negative to positive by cleavage of citraconic amide linkage (*16*). The charge reversal diblock copolymers were used as nanocontainers for releasing cationic enzymes only in acidic pH. In this communication, we demonstrated that QD nanoparticles surface-modified with amine-blocked biotin-PEG-grafted PLL copolymer by citraconylation could be delivered efficiently into cells under acidic condition via a surface charge reversal from negative to positive. ADV was also similarly modified to selectively enhance viral gene expression under the acidic condition.

A copolymer of biotin-poly(ethylene glycol) (PEG) grafted poly(L-lysine) (PLL) (biotin-PEG-PLL) was synthesized by reacting primary amine groups of PLL (average Mw: 1100, as determined from matrix-assisted laser desorption/ionization time-of flight (MALDI-TOF) mass spectroscopy, Supporting Information Figure S1) with a biotin-PEG-*N*-hydroxysuccinimide derivative (biotin-PEG-NHS). The resultant graft copolymer had ca. 2.5 biotinylated PEG chains per PLL backbone as characterized by ^{1}H NMR (Supporting Information Figure S2). The remaining primary amine groups of the PLL in the graft copolymer were further modified with a pH-specific amine blocker, citraconic anhydride. Citraconic anhydride has been known to be able to change the net charge of cationic polymers and peptides by replacing primary amine groups with carboxylate groups (*17*). After citraconylation reaction for 2 h at various molar ratios of citraconic anhydride/amine, the amount of remaining amine group in the PLL was measured by fluorescamine assay. As shown in Figure 1A, ∼60% of total amine groups in the biotin-PEG-PLL was modified at the citraconic anhydride/amine molar ratio of 0.7, suggesting that the net charge of biotin-PEG-PLL under that condition was slightly negative. The biotin-PEG-PLL copolymer with a citraconylation substitution degree of 60% was used for further study. To show the charge regeneration of primary amine groups in the citraconylated conjugate at different pH conditions, the amount of primary amine groups was quantitatively analyzed by fluorescamine assay after incubating at different pH conditions. Previously, it was reported that the amide bond formed by citraconylation reaction with primary amine group could be specifically cleaved in acidic pH due to a neighboring carboxylic acid group (*16, 17*). When the citraconylated conjugate was incubated at pH 5.8, 6.6, and 7.4, the relative amounts of exposed amine groups were 87.1 ± 2.4%, 68.1 ± 2.3%, and 42.7 ± 5.0% after 5 h incubation, respectively. The extent of regenerated amine group was significantly increased at pH 5.8 and 6.6 in a time-dependent manner, indicating that the net charge in the conjugate was recovered from negative to positive only in the acidic conditions.

(B) Confocal microscopy images of adenoviral gene, GFP expression for HeLa cells transfected with ADV coated with citraconylated biotin-PEG-PLL (3.4×10^3 per viral particles) after incubating at pH 5.8 and 7.4, respectively. (C) The extent of relative GFP expression (%) for HeLa cells transfected with ADV coated with various amounts of citraconylated biotin-PEG-PLL copolymer after incubating at pH 5.8 and 7.4. Naked ADV was used as a control in all experiments.

Scheme 1. (A) Synthesis of Citraconylated Biotin-PEG-PLL Copolymer and Its Charge Reversal at Acidic pH; (B) Surface Coating with Citraconylated Biotin-PEG-PLL onto Streptaividin-Quantum Dot and Avidin−Adenovirus Nanoparticles



The resultant citraconylated biotin-PEG-PLL graft copolymer was immobilized onto the surface of streptavidin-conjugated QDs (QD-stp, 5−20 nm) via biotin−streptavidin interaction. Dynamic light scattering (DLS) measurement showed that QD-

stp and citraconylated biotin-PEG-PLL/QD-stp nanoparticles have hydrodynamic sizes of 12.0 ± 1.6 nm and 14.8 ± 5.8 nm, respectively. After incubating in buffer solutions of different pH values 5.8, 6.6, and 7.4 for 3 h, citraconylated biotin-PEG-PLL/QD-stp nanoparticles were treated to HeLa cells to show the intracellular uptake extent of QD. Cellular images visualized by confocal microscopy revealed that QD nanoparticles incubated at pH 5.8 and pH 6.6 were more significantly taken up by the cells than those at pH 7.4 (Figure 2). The enhanced intracellular uptake in the acidic condition was also analyzed using flow cytometry. As shown in Supporting Information Figure S3, a red fluorescent peak for QD in pH 5.8 was noticeably shifted to the right-hand side, compared to that at pH 7.4, suggesting that more efficient intracellular uptake occurred in the acidic condition. It is obvious that the net charge of the surface-anchored citraconylated conjugate was reversed from negative to positive, thereby facilitating nonspecific endocytic uptake of QD nanoparticles by increasing their charge interactions with the cell membrane. It was possible that some portion of the regenerated cationic PLL backbones was likely to be adsorbed onto the anionic surface of bare QD-stp nanoparticles via electrostatic interactions, resulting in the formation of multiple PEG loops as illustrated in Scheme 1 B.

ADV, a naturally evolved and well-defined nanoparticle, is approximately 60−90 nm in diameter. Although ADV shows high gene transfection efficiency in mammalian cells, its use as a gene carrier has been limited mainly due to nonspecific transfection and innate immune responses. To confer target-specific delivery capacity and reduced immune response, ADV was often PEGylated by tethering various targeting ligands to specific cells (*6*, *18*, *19*). In this study, surface charge reversal by citraconylated conjugate in response to acidic pH was also applied to ADV encoding for green fluorescent protein (GFP). To immobilize the citraconylated biotin-PEG-PLL copolymer onto the viral surface, avidin (avi) was preconjugated onto the ADV surface using the EDC/NHS reaction. The citraconylated biotin-PEG-PLL/ADV-avi nanoparticles were prepared via biotin−avidin interaction in a similar manner to QD-stp. Surface charge values after incubating at pH 5.8, 6.6, and 7.4 for 5 h were determined by a dynamic light scattering technique (Figure 3A). The surface charge value of naked ADV was about −20 mV at pH 7.4 due to the presence of anionic viral coat proteins (*4*). When citraconylated biotin-PEG-PLL/ADV-avi complex nanoparticles were incubated at pH 7.4, 6.6, and 5.8, the surface charge values became −12.3 ± 0.8, −4.7 ± 0.9, and −2.3 ± 1.2 mV, respectively. This suggests that the charge reversal on the surface of ADV occurred in response to acidic pH.

The GFP expression level of ADV was determined as a function of pH using confocal microscopy as shown in Figure 3B. The cells transfected with citraconylated biotin-PEG-PLL/ADV-avi nanoparticles at pH 7.4 showed significantly reduced extent of GFP gene expression, compared to those at pH 5.8. It is known that naked ADV nanoparticles were transported into cells via coxsackievirus−adenovirus receptor (CAR) mediated endocytosis (*19*, *20*). Surface-exposed fiber proteins on ADV were initially docked to the CAR on the cell membrane for cellular entry. After modifying the surface of ADV-avi with citraconylated biotin-PEG-PLL copolymers, the CAR-mediated mechanism would play a minor role in cellular uptake, because most of the fiber proteins on the surface were likely to be chemically conjugated with avidin and, more importantly, to be sterically inaccessible to the CAR by the presence of immobilized biotin-PEG-PLL copolymers. Thus, the citraconylated biotin-PEG-PLL/ADV-avi nanoparticles might be taken up by cells via a nonspecific endocytic pathway. The levels of GFP expression treated with ADV-avi coated with different amounts of citraconylated biotin-PEG-PLL were quantitatively analyzed at pH 7.4 and pH 5.8 using naked ADV as a control (GFP expression: 100%), as shown in Figure 3C. The relative extents of GFP expression for the cells transfected by ADV-avi coated with 0.9×10^3, 1.7×10^3, and 3.4×10^3 citraconylated biotin-PEG-PLL copolymers per viral particle were 122.2 ± 9.7%, 101.7 ± 2.5%, and 89.2 ± 7.8%, respectively, at pH 5.8, but they were 91.7 ± 7.2%, 72.8 ± 12.8%, and 63.8 ± 5.8% at pH 7.4 under the same condition. The results imply that the surface charge reversal of surface-engineered ADV nanoparticles, triggered by acidic pH condition, enhanced the extent of nonspecific cellular uptake and subsequently maintained the extent of viral gene expression to be similar to that of naked ADV. Since the surface charge value of fully regenerated biotin-PEG-PLL/ADV-avi nanoparticles at pH 5.8 was still negative at −2.3 ± 1.2 mV as shown in Figure 3A, it was postulated that the recovered cationic PLL chains were in part bound onto the anionic surface of ADV-avi by charge interactions, making PEG loops as shown in Scheme 1B. Although complete surface charge reversal (a net charge change from negative to positive) of citraconylated biotin-PEG-PLL/ADV-avi was not observed at acidic pH due to the rearrangement of PEG chains, a significant change in the surface charge value of ADV toward a positive direction could lead to enhanced cellular uptake and gene expression.

In conclusion, we demonstrated that QD and ADV nanoparticles immobilized by citraconylated biotin-PEG-PLL exhibited surface charge reversal at acidic pH. It was possible to deliver them into cells specifically under acidic conditions. The current targeting strategy is expected to have a wide range of applications for delivery of imaging and therapeutic agents to solid tumors that are known to have an acidic microenvironment.

Characterization of Nanogap Chemical Reactivity Using Peptide-Capped Gold Nanoparticles and Electrical Detection

Lionel Marcon,[†,‡] Didier Stiévenard,[†] and Oleg Melnyk*[,‡]

Institut d'Electronique de Microélectronique et de Nanotechnologie, UMR CNRS 8520, Dpt ISEN, 41 Bd Vauban, 59046 Lille Cedex, France, and Institut de Biologie de Lille, UMR CNRS 8161, Universités de Lille 1 et 2, Institut Pasteur de Lille, IFR 142, 1 rue du Professeur Calmette, 59021 Lille Cedex, France. Received January 9, 2008; Revised Manuscript Received February 25, 2008

Nanogaps are usually combined with synthetic or biological molecules to produce nanodevices having novel properties. This combination is better realized by controlling the chemical properties of the nanogap. We show here that the presence of a specific chemical group inside nanogaps (30–90 nm) can be probed electrically using 10 nm gold nanoparticles derivatized by complementary functional groups. $100-10^4$-fold current increases were observed following the site-specific insertion of gold nanoparticles into the nanogap.

Nanofabrication techniques in semiconductor research have accelerated the interest in nanostructure materials. In particular, creating and using nanogaps between electrodes is the subject of intense research today. Nanogaps, which allow electrical contact to structures on the nanoscale, have applications ranging from dense microprocessor chips to biosensors. The structures involve many kinds of materials, from polymer to biological molecules, through the establishment of molecular assemblies based on the nanogap surface between metallic walls. The positioning of the synthetic or biological species inside the nanogap must be controlled to reach optimal electrical or detection properties. In this context, the chemical properties of the layer between the electrodes is of prime importance, since they will impose the imbibition of the nanogap and permit the formation of chemical bonds between the molecules of interest and the substrate (*1*).

Thin films can be characterized by a variety of physical or chemical methods. However, the characterization of the chemical properties of nanogaps is complicated because of the small size of the substrate delimited by the electrodes. Currently, some powerful techniques, like scanning electron microscopy (SEM), atomic force microscopy (AFM), and chemical force microscopy (CFM), allow the study of the structure or chemical properties of nanometer-sized surfaces but provide only limited information about their chemical nature. In this context, novel experimental tools are needed for probing rapidly the chemical reactivity of nanogaps.

We show here for the first time that a specific functional group in a 30–90 nm nanogap can be detected by combining peptide-capped gold nanoparticles and electrical detection. A semicarbazide layer and semicarbazone chemoselective ligation was used in this proof-of-concept study, which thus required the preparation of stable peptide-capped gold nanoparticles modified by aldehyde groups and control GNPs derivatized by amide groups. The chemoselective insertion of gold colloids into the nanogaps led to current increases from 2 to 4 orders of magnitude, in accord with the number of gold nanoparticles in the nanogaps detected by scanning electron microscopy.

The principle of the characterization method is described in Figure 1. The chip surface is incubated with aldehyde-modified GNPs (CHO-GNPs) or amide-modified GNPs ($CONH_2$-GNPs) as a control for the site-specific GNP insertion into the nanogap. The presence of semicarbazide groups between the electrodes allows the formation of a semicarbazone bond between semicarbazide groups of the substrate and aldehyde groups on the CHO-GNPs (*2*). The chemically driven insertion of GNPs into the nanogap is detected by measuring the current changes between the electrodes.

One of the key elements of the method is the design of CHO- and $CONH_2$-GNPs. Since their development more than 10 years ago (*3*), thiol-capped GNPs have been extensively studied in a broad range of structural, electronic, optical, and chemical aspects (*3–6*). The chemical modification of GNPs can be done using thiols or disulfides (*7*). These functionalities, which are compatible with a variety of chemical groups, react with gold substrates to form dense monolayers. In particular, cysteinyl-peptides can be used for the preparation of stable peptide-capped GNPs displaying appropriate functional groups at their periphery (*3*). This strategy was chosen here to prepare CHO- and $CONH_2$-GNPs as shown in Figure 2. Peptides **1** and **2** derived from the Ac-CYKLG sequence and modified at the C-terminus by an aldehyde or amide group, respectively, were synthesized using Fmoc/*t*Bu standard solid-phase peptide synthesis protocols (*8*) and a tartaramide linker (*9*). The α-oxo carboxamide group present at the C-terminus of peptide **1** is frequently used in bioconjugation chemistry (*10*). Its reactivity with semicarbazide-functionalized soluble or solid substrates has been documented in detail elsewhere (*11–15*). The thiol moiety of cysteine was protected by a *tert*-butyl sulfenyl group. Lys residue in position 3, which can bear a positive charge due to the side-chain amino group, was expected to facilitate the MALDI-TOF analysis of the peptides and the electrostatic repulsion of the peptide-capped GNPs.

The chemisorption of disulfides on gold leads to the formation of Au(I) thiolate species which are formed by oxidative addition of the S−S bond to the gold surface (*7*). Peptides **1** or **2** were thus reacted directly with 10 nm GNPs. Ligation of peptides **1** or **2** to the GNPs was monitored in real time by collecting UV–vis absorption spectra of the peptide−GNP mixture. The plasmon band of GNPs is indeed sensitive to the nanoparticle environment, and this property was exploited in various bioassays (*16–18*). The plasmon band of bare GNPs at 516.6 nm was shifted as expected to longer wavelengths in the

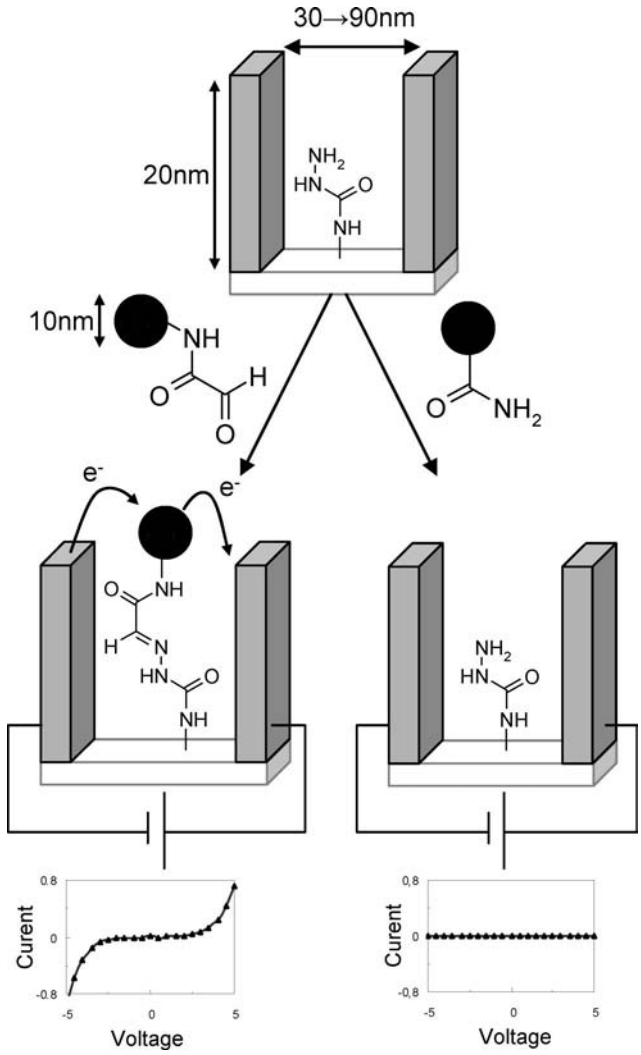

Figure 1. Principle of the characterization of the nanogap chemical reactivity using GNPs and electrical detection. The surface carrying the electrodes is modified by semicarbazide groups. The nanogap is then incubated with GNPs modified by complementary aldehyde groups (CHO-GNPs). Reaction between the GNPs and the surface between the electrodes leads to the site-specific insertion of CHO-GNPs into the nanogap, and thus to the increase of the nanogap conductance. GNPs modified by amide groups ($CONH_2$-GNPs) are used in the control experiment.

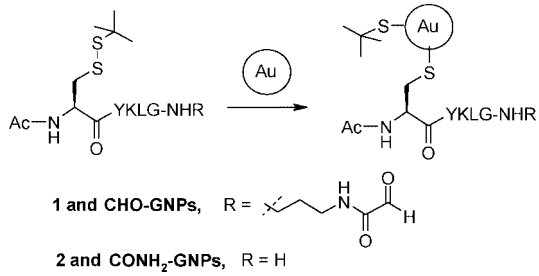

Figure 2. Synthesis of CHO- or $CONH_2$-GNPs by reaction of GNPs with peptides **1** or **2**, respectively.

presence of peptides **1** or **2** (Figure 3). The binding of both peptides to the GNPs occurred in less than 1 min at room temperature. After 3 min of reaction, bovine serum albumin (BSA) was added to the reaction medium to stabilize the suspension (*19*, *20*). The addition of BSA led to minor changes in the position of the plasmon band for both peptides and for the control experiment without peptide. The particles were finally purified by centrifugation and resuspension in PBS BSA

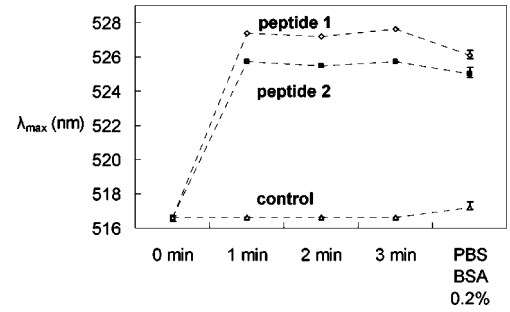

Figure 3. Wavelength of the plasmon absorption band of GNPs in the presence of CHO-peptide **1**, $CONH_2$-peptide **2**, or without peptide (control) as a function of the reaction time. First, 10 μL of 1 mg/mL peptide solution were mixed with 500 μL of the bare GNPs (5.2×10^{12} particles/mL). After 3 min, 75 μL of PBS BSA 0.2% buffer were added to stabilize the peptide-GNPs. pH of the bare GNPs was 7.9 for peptide **1** and 8.2 for peptide **2**, since aggregation of $CONH_2$-GNPs occurred at lower pH.

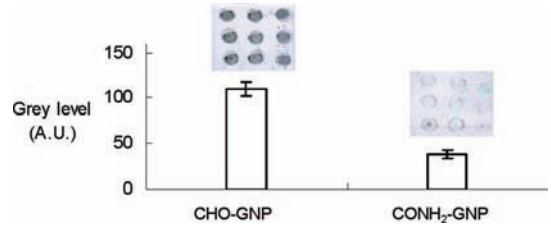

Figure 4. Grey level of the spots after incubation and enhancement of CHO- and $CONH_2$- suspensions. Inset: Gray-scale images quantified using *ImageJ* freeware (NIH, Bethesda, Maryland, USA). Drops of CHO- and $CONH_2$-GNPs suspensions (10 μL) were incubated onto semicarbazide microscope glass slides for 1 h at 37 °C. The silver enhancement with Ag^+/*p*-dihydroquinone was performed using a commercial kit (Silver Blue kit, Advanced Array Technology). Substrates were rinsed 5 min with blocking solution (block sol) and immersed 10 min at room temperature in the Ag^+/*p*-dihydroquinone solution (silver staining sol), and then washed with water, methanol, and dried. Slides were scanned with a HPScanJet 5300C scanner. Results are expressed as the mean of the gray level inside a spot minus the background around the spot ($n = 9$).

0.2% buffer. The final position of the absorption band of CHO- and $CONH_2$-GNPs after the washing steps was 526.1 and 525.0 nm, respectively. CHO- and $CONH_2$-GNPs were also analyzed by dynamic light scattering (DLS) to determine the size of the particles. The size of bare GNPs was 10.0 ± 1.4 nm, whereas the size of CHO- and $CONH_2$-GNPs was 12.4 ± 2.4 nm and 12.7 ± 2.2 nm, respectively. The DLS experiments confirmed that peptide capping of the GNPs occurred without aggregation. The CHO- and $CONH_2$-GNPs suspensions were found to be stable for at least one year when stored at +4 °C.

The reactivity of CHO-GNPs was studied by incubating a series of drops of the CHO- and $CONH_2$-GNPs suspensions with semicarbazide-functionalized microscope glass slides. Modification of microscope glass slides by a semicarbazide layer has been described in detail elsewhere (*21*). The surfaces were dried, washed, and the immobilized GNPs were detected by the immunogold silver staining enhancement technique (*22*, *23*). This method is based on the GNP-catalyzed reduction of silver ions by *p*-dihydroquinone. Precipitation of metallic silver on the GNPs leads to the formation of a silver layer whose gray level can be measured. The results of this experiment are shown in Figure 4. The signal displayed by CHO-GNPs was significantly higher (~3-fold) than those displayed by $CONH_2$-GNPs, showing a large impact of the α-oxo aldehyde group on GNP immobilization. These results, which are in accord with the GNP densities determined by SEM in the following experiment, show

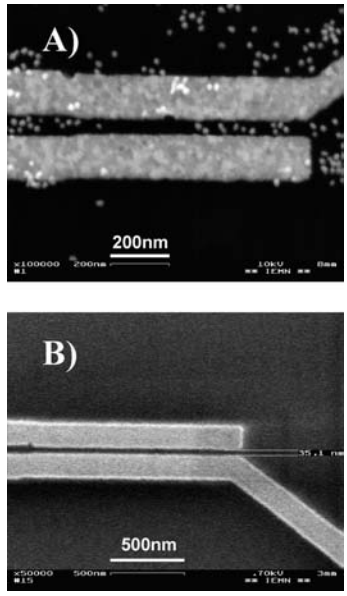

Figure 5. SEM images of the nanogaps after printing of CHO-GNPs (a) or $CONH_2$-GNPs (b). CHO-GNPs are clearly visible in the nanogap (Figure 5a). The scale of Figure 5b is larger to show the absence of $CONH_2$-GNPs on a large portion of the chip. Other images can be found in the Supporting Information. The nanoparticles were first printed and incubated on the nanoelectrodes. After washings with PBS containing 0.05% of Tween 20 (by vol), water, and ethanol, substrates were dried under a nitrogen stream and analyzed by SEM.

that CHO-GNPs were mainly immobilized through the formation of semicarbazone covalent bonds.

Next, gold nanoelectrodes were fabricated on a silicon substrate with gap dimensions varying from 30 to 90 nm and a thickness of 20 nm (15 nm Au on 5 nm Ti) as described elsewhere (*24*). The silicon chip was treated as before to coat the silicon oxide substrate by a semicarbazide layer. CHO- and $CONH_2$-GNPs were then printed onto the nanoelectrodes (19 nanoelectrodes for each GNP suspension) using a piezoelectric microarrayer (dispensed volume: 6 nL). The chips were incubated 6 h at 37 °C in a humid chamber to favor the formation of semicarbazone bonds between the CHO-GNPs and the semicarbazide surface. The chips were then washed and analyzed by SEM. The average GNP density in the area surrounding the nanoelectrodes was 150 ± 8 for CHO-GNPs and only 4 ± 2 particles/μm^2 for $CONH_2$-GNPs (images can be found in Supporting Information). The significant difference in GNP density is in agreement with the data of the silver precipitation experiment presented in Figure 4. In addition, Figure 5 shows that 120 ± 6 CHO-GNPs were present in the nanogaps, whereas no $CONH_2$-GNPs were seen between the electrodes. The chemoselective immobilization of CHO-GNPs in the nanogap shows the successful derivatization of the silicon oxide surface by a semicarbazide layer.

Moreover, we demonstrate here that the subsequent analysis of intensity–voltage $I(V)$ curves after printing of CHO- and $CONH_2$-GNPs yields valuable information regarding the presence of GNPs in the nanogap and thus its successful functionalization. Experimentally, the method is straightforward, requires no expensive techniques, and can be used for the quality control of chips. The *x, y* precision of the piezoelectric arrayer is high enough to allow the selective deposition of both GNP reagents on a subset of nanogaps whereas the other nanogaps remain unaltered and are available for other detection purposes.

The intensities measured at 5 V for CHO- and $CONH_2$-GNPs on bare or semicarbazide nanogaps were all below 10^{-13}A and exhibited a random shape associated with background noise. The printing of $CONH_2$-GNPs on semicarbazide chips led also to intensities lower than 10^{-13}A in agreement with the very low GNP densities observed by SEM. Interestingly, the printing of CHO-GNPs led to large current increments with factors between 2 and 4 orders of magnitude (Figure 6) for 10 of the 19 nanogaps. Those $I(V)$ curves are symmetric and exhibit a low conductivity gap around zero bias voltage. Such behavior suggests a Coulomb blockade, a process in which current is inhibited until electrons have enough energy to charge the GNPs. At low bias, the electrons do not have sufficient energy to overcome the Coulomb blockade. At high bias, the energy is sufficient for the electrons to tunnel from one electrode to another *via* the GNPs (*25, 26*). Independently of the exact conduction mechanism, $I(V)$ data confirm the presence of GNPs and thus the successful formation of the semicarbazide layer in the nanogap. The success of the method relies on the stability of the functional GNPs, their ability to react chemoselectively with the substrate, and importantly on the ease of removal of the GNPs that are only physisorbed on the surface during the washing steps.

In conclusion, we show for the first time the presence of a specific functional group in a nanogap by combining peptide-capped gold nanoparticles and electrical detection. Semicarbazide group was used in this proof-of-concept study, which thus required the preparation of stable peptide-capped gold nanoparticles modified by aldehyde groups and control GNPs derivatized by amide groups. The electrical measurements were in accord with SEM observations, mean GNP densities on the printed areas, and the number of GNPs trapped in the nanogaps.

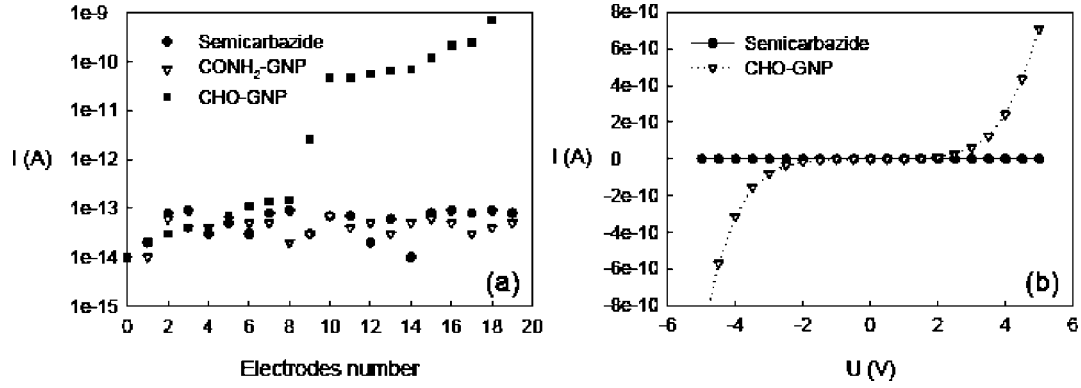

Figure 6. (a) Intensity at $V = 5$ V for 19 pairs of nanoelectrodes after semicarbazide functionalization (filled circles), incubation with $CONH_2$-GNP (open triangles), or incubation with CHO-GNP (filled squares). (b) Typical current–voltage curves before (filled circles) and after (open triangles) incubation with CHO-GNP. Measurements were performed in a nitrogen low-pressure chamber (0.2 mbar, H_2O and $O_2 < 0.1$ ppm) at room temperature with a pico-amperemeter HP4140B. The applied voltage ranged from −5 to +5 V with 500 mV steps. See also the legend of Figure 5 for other experimental details.

Interestingly, the nanoparticles could be precisely addressed on a subset of nanogaps for the quality control of the chip functionalization using a noncontact piezoelectric arrayer, whereas the other electrodes remained unchanged for other detection purposes. In principle, the method can be extended to other chemistries, since peptides are easy to synthesize and can be derivatized by various functional groups. The sequence of the peptide can also be easily adapted to match desired physicochemical properties.

ACKNOWLEDGMENT

This work was partly supported by the French Ministry of Research, grants from the EEC and from the Région Nord Pas-de-Calais. We also used the microarray platform facilities from the Institute of Biology (Lille, France).

Multivalency of Sonic Hedgehog Conjugated to Linear Polymer Chains Modulates Protein Potency

Samuel T. Wall,[†,||] Krishanu Saha,[§] Randolph S. Ashton,[§] Kimberly R. Kam,[‡] David V. Schaffer,[†,§,||] and Kevin E. Healy*[,†,‡,||]

Department of Bioengineering, Department of Materials Science and Engineering, Department of Chemical Engineering, and UCSF/UCB Joint Graduate Group in Bioengineering, University of California, Berkeley, California. Received July 15, 2007; Revised Manuscript Received February 6, 2008

A potently active multivalent form of the protein Sonic hedgehog (Shh) was produced by bioconjugation of a modified recombinant form of Shh to the linear polymers poly(acrylic acid) (pAAc) and hyaluronic acid (HyA) via a two-step reaction exploiting carboimiide and maleimide chemistry. Efficiency of the conjugation was ~75% even at stoichiometric ratios of 30 Shh molecules per linear HyA chain (i.e., 30:1 Shh/HyA). Bioactivity of the conjugates was tested via a cellular assay across a range of stoichiometric ratios of Shh molecules to HyA linear chains, which was varied from 0.6:1 Shh/HyA to 22:1 Shh/HyA. Results indicate that low conjugation ratios decrease Shh bioactivity and high ratios increase this activity beyond the potency of monomeric Shh, with approximately equal activity between monomeric soluble Shh and conjugated Shh at 7:1 Shh/HyA. In addition, high-ratio constructs increased angiogenesis determined by the in vivo chick chorioallantoic membrane (CAM) assay. These results are captured by a kinetic model of multiple interactions between the Shh/HyA conjugates and cell surface receptors resulting in higher cell signaling at lower bulk Shh concentrations.

INTRODUCTION

The use of chemical tethers to create solid-phase forms of biologically active agents is a recurring theme across a wide range of medical and biological applications. Chemical tethers can be used to attach bioactive peptide sequences or proteins to surfaces (*1*), to impart bioactivity to porous (*2*) or hydrogel implants (*3, 4*), or in a wide-ranging number of drug delivery applications (*5*−*9*). However, solid-phase presentation can potentially alter the way that such bioactive molecules work in a biological setting; cells interacting with tethered forms of ligands can have altered protein internalization for signal pathway activation (*10*), limited access of the ligands to appropriate cell surface receptors (*11*), and perturbed thermodynamics of receptor−ligand binding due to steric or avidity effects (*12*−*14*). As the dynamics of most growth factor responses are studied as single soluble molecular forms, it is important to understand how tethering molecules affects their potency and influences their use in biomedical applications, particularly for molecules whose natural forms are biologically tethered due to interactions with the extracellular matrix or cell surface lipid bilayers.

In this work, we describe a system for the attachment of recombinant proteins with added cysteine residues to long-chain linear polymers containing free carboxylate groups, specifically the synthetic polymer poly(acrylic acid) (pAAc) and the biological polymer hyaluronic acid (HyA). This method, based on carbodiimide and maleimide chemistry, allowed for control of attachment stoichiometry of the large (~20 kDa) globular protein sonic hedgehog (Shh) to a long-chain linear polymer while maintaining protein activity. Progressively higher stoichiometric ratios of Shh to the linear polymer increased the potency of the protein by a factor of 10-fold over the soluble form as assessed by a cellular differentiation assay. In addition, the constructed multivalent proteins were tested for in vivo biological significance using an angiogenic assay utilizing the chick chorioallantoic membrane (CAM). In order to examine the mechanisms of increased activity of the multivalent form of the constructs, a kinetic model of the Shh pathway was developed to determine the likely effects of multiple binding events on the observed cellular response.

METHODS

Recombinant Shh and Bioconjugation Techniques. Using the cDNA of the N-terminal signaling domain of rat Shh (*15*), base pairs coding for an additional cysteine residue and a 6× His tag were added through PCR onto the c-terminus of the protein to allow for sulfhydryl-based reactions and protein purification, respectively. This tethering site was specifically chosen on the basis of studies demonstrating that this area of the protein is distant from its active site, and inert molecules attached there do not alter activity (*16*). In addition, two hydrophobic residues were added at the N-terminus to enhance the potency of the protein (*18*). The modified Shh PCR product was inserted into a pBAD-HisA (Invitrogen, Carlsbad, CA) plasmid, the resulting plasmid was confirmed by DNA sequenc-

ing, and the protein expressed in BL21(DE3).pLys.E *E. coli* through arabinose induction . After induced protein expression, cells were lysed, and the resulting expressed Shh was purified using NiNTA (Qiagen, Valencia, CA) binding followed by imidazole elution. The purified protein was dialyzed into pH 7.4 PBS containing 10% glycerol, 2 mM EDTA, and 50 μM $ZnSO_4$.

Purified Shh was conjugated to linear polymers through a two-step reaction using carbodiimide chemistry at the carboxylate group of the polymer and a maleimide reaction at the protein C-terminal cysteine (Figure 1). The first step was the addition of [*N*-ϵ-maleimidocaproic acid] hydrazide (EMCH, Pierce Biotechnology, Rockford, IL) to the linear polymer to allow for the subsequent attachment of the protein. This nonimmunogenic hydrazide−maleimide hetereobifunctional cross-linker was added to the two linear polymers using the same general procedure, but with slightly different reaction conditions. For pAAc conjugates, 450 000 Da pAAc (Polysciences, Warrington, PA) at 2 mg/mL was reacted with 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDC) at 3.9 mg/ml, *N*-hydroxysulfosuccinimide (sulfo-NHS) at 1.1 mg/mL, and 0.5 mg/mL EMCH at room temperature for 2 h in pH 6.5 MES buffer as described for the attachment of small peptide sequences (*17*). For the activation of HyA, a method similar to that previously described for the attachment of hydrazides (*9*) was used with 10^6 Da MW HyA (Genzyme, Cambridge, MA). This was dissolved and reacted at 3 mg/mL with the same concentrations of EDC, sulfo-NHS, and EMCH used in the pAAc reaction overnight in 0.1 M MES buffer, pH 5.0. After the attachment of the EMCH, the resulting maleimide-activated linear polymers were separated from the unconjugated reagents through sequential dilution and centrifugation in 50 000 MW cutoff centrifuge filters (Pall Gellman).

The activated polymers were then reacted with the Shh in varying stoichiometric feed ratios to produce conjugates of varying molecular substitution. This reaction was performed at 4 °C overnight in 0.1 M MES buffer (pH 6.5) containing 50 μM Tris(2-carboxyethyl)phosphine hydrochloride (TCEP, Pierce Biotechnology, Rockford, IL) to keep the C-terminus Shh cysteine reduced for duration of the reaction. After the reaction, any remaining maleimide groups on the linear polymer were reduced by the addition of 0.5 mM dithiothreitol and incubation at 4 °C for 1 h.

All conjugation reactions were assayed by gel electrophoresis, comparing reaction solutions to an equal mass of unreacted Shh to visually inspect protein coupling efficiency. In addition, sets of triplicate Shh/HyA conjugation reactions at 20:1 and 10:1 molar feed ratios of Shh to HyA were dialyzed overnight in 0.1 MES buffer (pH 6.5) using Spectra/Por Float-A-Lyzer devices (Spectrum Laboratories, Rancho Dominguez, CA) to remove nonconjugated Shh. Protein concentrations in the dialyzed HyA-Shh solutions were then quantified using a microBCA assay (Pierce Biotechnology, Rockford, IL).

Bioactivity Assay. In order to test bioactivity, murine embryonic C3H10T1/2 cells (American Type Culture Collection, Manassas VA) were induced to differentiate into an osteogenic line by exposure to Shh as described elsewhere (*18, 19*). Briefly, the cells were plated at 5000 cells/well in 96 well plates in normal growth media (αMEM with 10% FBS). After 2 days, the medium was replaced with a low FBS (2%) media and supplemented with the proteins and/or conjugate reaction solutions. Test conditions included soluble Shh in the range of 1–100 nM, soluble Shh in the same range along with unconjugated HyA at 50 μ/mL, or the Shh/HyA conjugate in quantities such that the concentrations of Shh in the media solutions were also 1–100 nM. After incubation for an additional 3 days, the cells were washed and lysed, and the cell lysate was assayed for differentiation by measuring alkaline phosphatase (ALP) activity using the fluorescent probe 9-*H*-(1,3-dichloro-9,9-dimethylacridin-2-one-7-yl) phosphate (DDAO, Molecular Probes, Eugene OR). Unconjugated poly(acrylic acid) was shown to inhibit the differentiation of the cells, so bioactivity testing of these conjugates was not performed.

Angiogenesis Assay. As Shh is a known angiogenic agent (*20*), induced angiogenesis from soluble Shh and Shh/HyA conjugates was assayed using a CAM window assay. Fertile white leghorn eggs (Charles River, Franklin, CT) were incubated at 37 °C in a humidified environment until day 8, at which time 2 mL of albumin was removed from the blunt end of the egg, and a small 1 cm × 1 cm window was made in the shell on the opposite side. Sterile squares of filter paper loaded with sterile PBS, 0.1 μg of Shh, or 0.1 μg Shh of the 20:1 Shh/HyA feed ratio conjugate were placed directly on the developing CAM. This window was then sealed with parafilm and the eggs returned to the incubator. Angiogenesis around the test materials was microscopically evaluated 3 days later using an Olympus SZX7 stereoscope. High-resolution photomicrographs were taken using an attached QImaging Qfire camera. These images were analyzed using *ImageJ* software to quantify the number of blood vessels per unit length in a square perimeter surrounding the implants at distances of 0.1 and 0.25 cm away from its edge. Linear density measurements for each group were tested for statistical significance using a one-way ANOVA on both the 0.1 and 0.25 cm distance data, followed by pairwise Holm's *t* tests of the individual groups.

Molecular Modeling of Shh−HyA Conjugate Cell Signaling. We built upon binding and trafficking numerical models that describe expression of Gli transcriptional effectors in response to monomeric Shh (*21, 22*) and numerical kinetic models describing multivalent ligand–receptor binding (Figure S1, Supporting Information) (*23*). To develop the simplest model for the C3H10T1/2 bioactivity data in Figure 3, the following

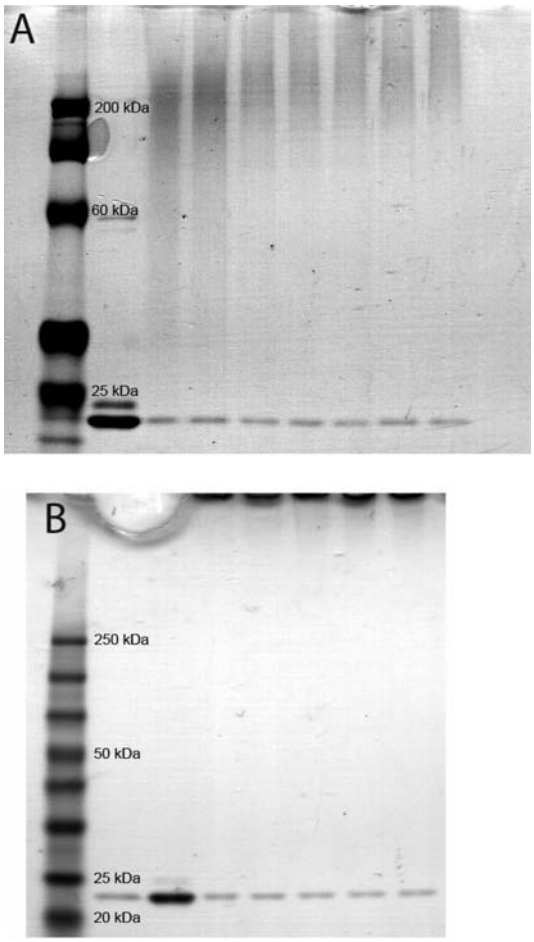

Figure 2. Gel electrophoresis of Shh and its conjugation products with pAAc (A) and HyA (B). In A, conjugates from 1:1 to 30:1 Shh/pAAc molar feed ratios appear as the loss of the Shh band and the appearance of a high molecular weight smear. In B, the large HyA conjugates are unable to enter the gel and are seen as bands residing at the top of the gel.

assumptions were invoked: Patched (Ptc) repression of Smoothened is not affected by the Ptc receptor aggregation; ligand-induced internalization rate is the same for all valencies; alkaline phosphatase activity is linearly proportional to Gli1 levels in a cell; and differentiation of a C3H10T1/2 cell does not change its responsiveness to Shh. Initial binding of the HyA−Shh conjugate was assumed to follow monomeric Shh-Ptc binding rates, but all other additional binding of Shh moieties from the conjugate to other Ptc receptors were assumed to occur at a higher rate. This assumption has been called the *equivalent site hypothesis* in that after initial binding, all subsequent sites on a multivalent conjugate for ligand binding are identical (*24*).

Model parameters were taken from literature (*21, 22*); however, a number of parameters were estimated directly from the bioactivity data in Figure 3. First, the monomeric Shh-Ptc binding constant k_{on}/k_{off} and the alkaline phosphatase activity/Gli1 expression ratio were estimated from the soluble Shh bioactivity curve. In addition, the multimeric Shh-Ptc binding constant was directly estimated from the 22:1 conjugate curve (see Table S1, Supporting Information). We also formulated an alternative model that incorporates steric hindrance of HyA chains as a simple reduction in conjugate binding affinity to Ptc. For the alternative model incorporating sterics, termed the "model with sterics", the multimeric Shh-Ptc binding constant

Table 1. Conjugation Ratios and Coupling Efficiencies Determined for Shh/HyA Reactions at 30:1 and 10:1 Molar Feed Ratios

	molar ratio of Shh/HyA		percent coupling	
feed ratio	30:1	10:1	30:1	10:1
trial 1	21.80	6.91	73.3%	69.8%
trial 2	22.58	6.65	76.0%	67.1%
trial 3	22.09	7.02	74.3%	70.8%
average	22.16	6.86	74.5%	69.2%
stdev	0.40	0.19	1.3%	1.9%

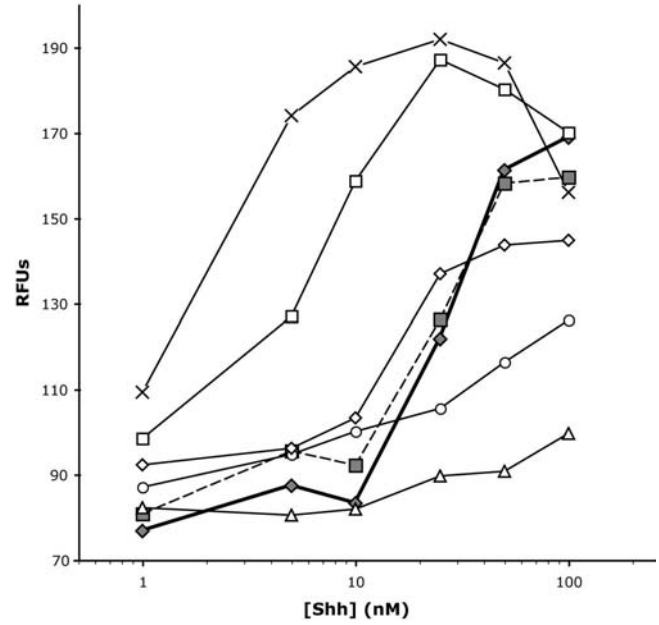

Figure 3. C3H10T1/2 bioactivity results against soluble Shh (♦, heavy line), soluble Shh with soluble HyA ■, dashed lines), and the Shh−HyA conjugates in stoichiometric ratios of 0.6:1 (△), 3.5:1 (○), 7:1 (◊), 14:1 (□), and 22:1 (×). Produced conjugates with Shh/HyA ratios of 0.6:1 and 3.5:1 have decreased efficacy on a unit basis of Shh compared to the freely soluble form, while 7:1–22:1 have increased bioactivity.

k_{on} for 0.6:1, 3.5:1, and 7:1 conjugation feed ratios was reduced 5.5-fold to match the experimental data from the 0.6:1 curve in Figure 3.

RESULTS

Chemical Conjugation. A recombinant rat Shh variant with a cysteine residue near the C-terminus was constructed, expressed, and purified via immobilized metal affinity chromatography. Conjugation of the recombinant protein was achieved on both pAAc and HyA with high efficiency. Using gel electophoresis, it was apparent that the reaction produced a decrease in the monomeric Shh band (Figure 2) and the appearance of a high molecular weight conjugate. For pAAc (Figure 2A) (MW = 450 000), this produced a smear through the gel with an increasing mass as the Shh conjugation molar feed ratio increased from 1:1 to 30:1. For HyA (MW = 10^6 Da), the high molecular weight conjugates did not penetrate deeply into the gel. By contrast, simply mixing the Shh with raw pAAc or HyA did not alter the Shh mobility in the gel (data not shown). Protein analysis of purified Shh/HyA reactions at 10:1 and 30:1 molar feed ratios performed in triplicate indicated that the reaction was reproducible with a high degree of efficiency at approximately 70−75% (Table 1). Molar feed ratios of 1:1, 5:1, 10:1, 20:1, and 30:1 produced Shh−HyA conjugates with molar substitution ratios of 0.6:1, 3.5:1, 7:1, 14:1, and 22:1, respectively.

C3H10T1/2 Cell Bioactivity Assay. Through the use of the murine embryonic cell line C3H10T1/2, conjugation of the Shh

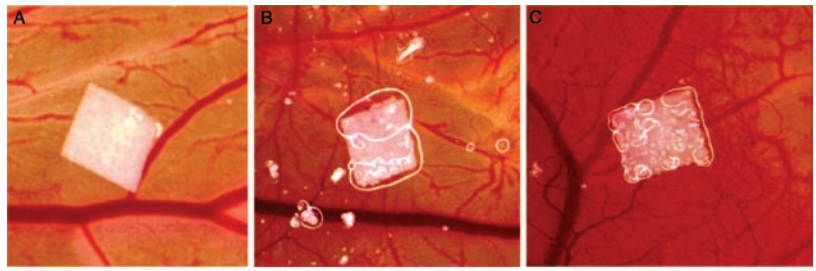

Figure 4. Panel of photomicrographs depicting CAM reactions to negative control samples (A), freely soluble Shh (B), and the 14:1 Shh/HyA multivalent form. Noted increased vessel density is apparent around the Shh sample as well as the conjugated form.

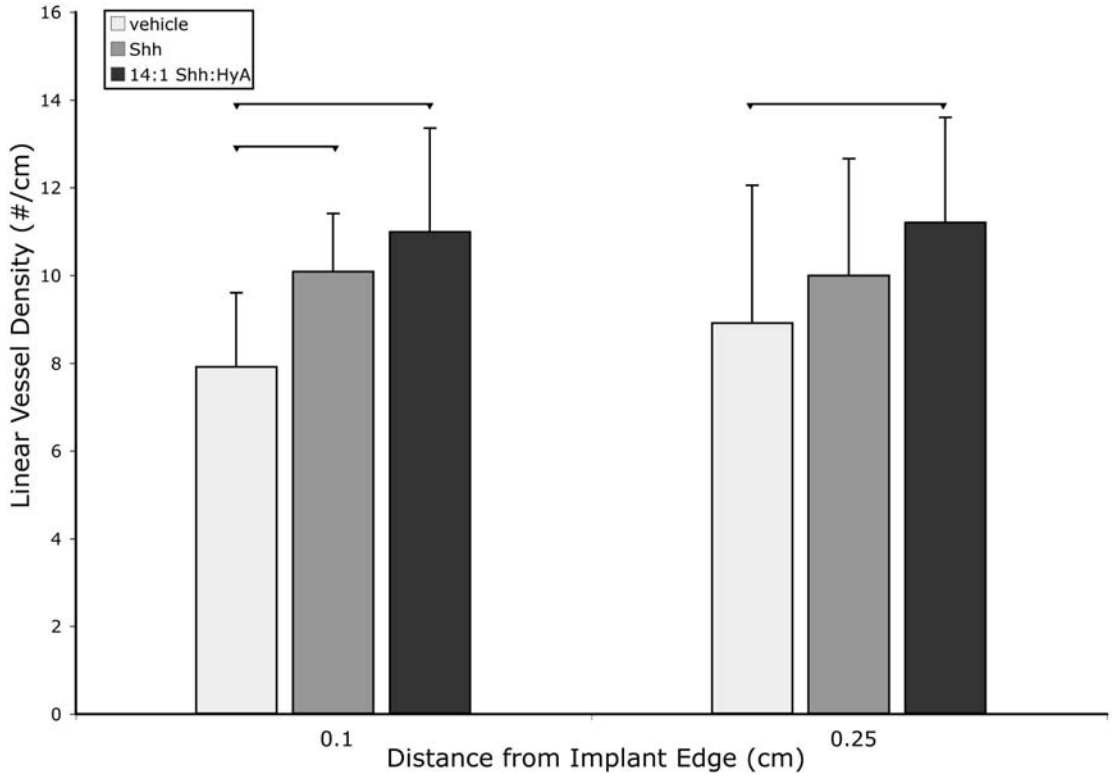

Figure 5. Quantitative results of angiogenesis in the CAM assay derived from photomicrograph image analysis. Increased vascular density is measured for both the soluble Shh and the Shh-*graft*-HyA in the 14:1 ratio. All three groups can be statistically separated at a distance of 0.1 cm from the edge of the implant, while at 0.25 cm, only the conjugated from is statistically different from the negative control.

was shown to dramatically alter the activity of the tethered protein when evaluated against actual Shh concentration in solution (Figure 3). Only HyA-conjugated Shh could be tested using this cell line, as pAAc inhibited the differentiation that soluble Shh induces in the cell line (data not shown). At low tethering (e.g., 3.5:1), the activity was decreased, with an estimated 10-fold increase in EC_{50} of the Shh in solution, presumably due to steric hindrances that the large linear polymer caused when attached. The activity increased back to normal when the conjugation ratio reached 7:1. Beyond this, activity of the tethered Shh was increased dramatically, with a 10-fold decrease in estimated EC_{50} values from the untethered Shh to the 22:1 construct.

CAM Angiogenesis Model. The CAM results indicated an increased potency for the conjugated Shh/HyA. Photographic analysis and quantification (Figures 4 and 5) revealed a statistically significant increase in vasculature around the Shh-loaded samples compared to the negative control within a close distance (0.1 cm) of the implant. While the Shh/HyA conjugated at a 14:1 ratio had an increased average vessel number over both the negative control and unconjugated Shh at 0.1 cm, it also had a longer-range persistent increase over the negative control at 0.25 cm. Although the soluble Shh also had an increased average vessel number over the negative control at this distance, this observation was not statistically significant.

Numerical Modeling of Multivalent Shh Bioactivity. We developed simple kinetic models of HyA−Shh conjugate binding, trafficking, and downstream signal activation. To focus on the effects of conjugate multivalency, a number of assumptions were invoked in the simplified models: Ptc receptor aggregation does not affect signal transduction; ligand internalization is not affected by valency; alkaline phosphatase activity is linearly proportional to Gli1 levels in a cell regardless of differentiation; and only two rates of conjugate binding occur—an initial binding of the conjugate and a higher binding rate for all additional Shh moieties from the conjugate to other Ptc receptors (see Supporting Information for model equations and parameters). With these assumptions, two types of models were developed, one incorporating steric hindrance of HyA chains as a simple reduction in conjugate binding affinity to Ptc, and one neglecting any influence of steric hindrance. These two models were termed “model with sterics” and “model without sterics”, respectively. Under these assumptions, modeling results indicated that increasing the conjugation ratio of Shh to its HyA carrier in the bioactivity assay should result in a progressive increase in cell signaling and decrease in the EC_{50}

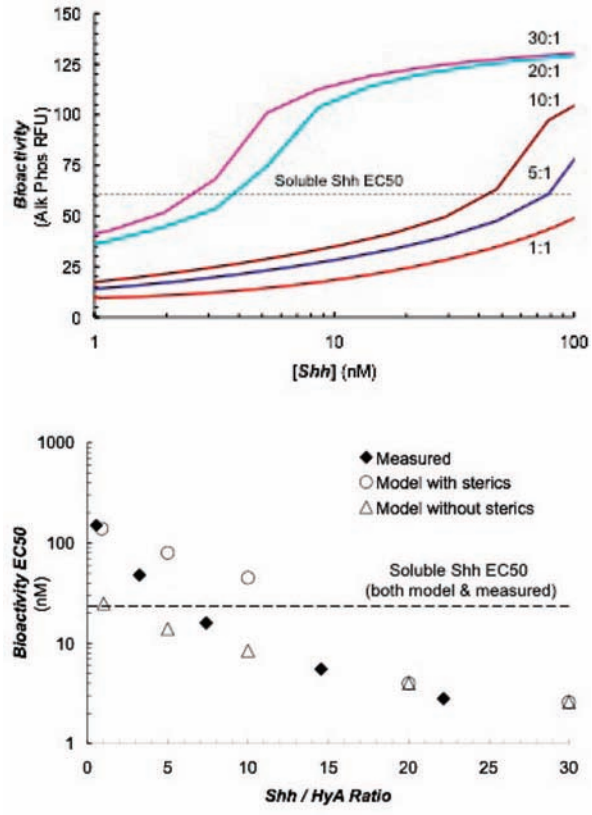

Figure 6. Numerical model results of Shh−HyA conjugate bioactivity in C3H10T1/2 cells. Activity as a function of Shh concentration for stoichiometric ratios 1:1–30:1 is shown on top for a model incorporating steric interaction (see text). A plot of EC_{50} versus substitution level for two types of models versus experimental results in Figure 3 is shown on the bottom. Both models capture the trend in EC_{50} with substitution ratio but fail to capture the increased amplitude of bioactivity for the 14:1 and 22:1 conjugates (see Figure 3).

(Figure 6). The estimated EC_{50} values from the experimental data were well-matched using both types of kinetic models at the tested conjugation ratios and with the aforementioned assumptions ($R^2 = 0.7$ for the model without sterics; $R^2 = 0.8$ for the model with sterics). For the model without sterics, EC_{50} values matched experimental results well at high conjugation ratios, but the modeling results overestimated the EC_{50} values for conjugation ratios 7:1 and lower (Figure 6). Results from the model with sterics can correct for this deviation (Figure 6); however, the fits at 3.5:1 and 7:1 conjugation ratios suggest that the exact mechanism of steric hindrance may vary from the one postulated in our model with sterics (see Discussion). Some features, such as the shape of the dose−response curve, as well as decreased peak location, were not as fit well using the developed model, as indicated by the comparison of Figures 3 and 6.

DISCUSSION

These results indicate that large proteins can be coupled to a linear polymer with high efficiency and controlled stoichiometry through the use of a heterobifunctional cross-linker under conditions that do not lead to loss of protein activity. On the contrary, coupling of a protein to a superstructure such as large linear polymer offers a method of modulating the activity of a protein by controlling its interaction with the cell. This method could be used to add multivalent protein functionality to both synthetic and biological polymers with equal efficiency. However, control of the reaction was much more difficult with the HyA than the pAAc. Conjugation to the pAAc was robust across a wide range of reaction pHs, concentrations, and times. On the other hand, adding the EMCH to the HyA required considerable optimization of the reaction conditions, as the reaction was much more sensitive to pH, concentrations, and time. High overall coupling efficiencies were observed only in the mildly acidic pH range 5.0–5.5 for the attachment of EMCH to HyA, which was consistent with the work of Pouyani et al. (*9*) and Vercruysse et al. (*25*). At neutral pH, although there are successful reports of EDC/sulfo-NHS mediated HyA bioconjugation (*26*, *27*) in these studies the overall conjugation was minimal. This may be due to hydrolysis of the maleimide rather than the lack of conjugation of the EMCH to the HyA chains, as the maleimide is susceptible to hydrolysis at pH > 6.5 and our scheme required long reaction times for the final protein attachment.

While the use of lower molecular weight HyA (∼250 kDa) in hydrazide mediated bioconjugation is observed in the literature (*28–30*), reporting better handling and more reproducible conjugation results, in our studies we chose to use high molecular weight HyA in order to maximize spacing and flexibility between conjugated protein molecules. We obtained reproducible results using this material, with repeated conjugation reactions producing nearly identical conjugation efficiencies and bioactivity curves. However, these results may be contributable to the reaction scheme used, for in our synthesis, the reaction was limited by the amount of protein added to the reaction. As only ∼1% of the available reaction sites on the HyA backbone are utilized on the highest conjugation ratio synthesized, if there is variability in the amount of EMCH substituted onto the backbone, this will be largely unnoticed as long as EMCH substitution rates exceed this small fraction of used sites.

The most striking result of our conjugation experiments was how the controlled attachment of Shh modulated protein activity as a function of valency. There are multiple possible mechanisms by which this increase in activity may result from tethering and include higher overall ligand affinity due to avidity effects, forced receptor multimerization, inhibition of receptor–ligand internalization, and changes to protein stability in solution. Such mechanisms have been previously identified and described for ligands such as DNA complexes (*6*, *7*), protein inhibitors (*8*, *12*), and growth factor pathways (*10*). We believe that similar mechanisms may be in action here, such as avidity effects from the interaction of multiple Shh molecules in the multivalent form with the Shh cell surface receptor Patched. Other mechanisms may be at play, as multimerization of Shh is known to change its short- and long-range activity in vivo (*31*), and internalization also plays a role in Shh activity (*32*, *33*).

Using novel numerical models, we attempted to elucidate the mechanism by which the bioactivity changes upon conjugation. In comparison to monomeric soluble Shh, multivalent Shh−HyA conjugates may have altered trafficking, binding, degradation, and signaling. Ordinary differential equations provide a convenient means to track the kinetics of each of these processes during Shh signal transduction. Both models—one incorporating sterics and one without sterics—can recapitulate the EC_{50} decrease with increasing valency (Figure 6). The poor fit at 3.5:1 and 7:1 conjugation ratios is likely due to the simple mechanism of steric hindrance that we incorporated into our model. In particular, steric hindrance effects on conjugate binding to Ptc is likely to change with conjugation ratio, since the average HyA chain length between Shh moieties that can shield Ptc reduces with increasing conjugation ratio. This effect has been described theoretically (*11*) and may be incorporated in future model development. A simpler model without internalization gave an even poorer fit with experiment, as did models that did not incorporate acceleration of binding after initial binding of

a multivalent conjugate, indicating the likely importance of these processes to the bioactivity of the conjugates (data not shown). Both models with and without sterics fail to describe the peak amplitude in bioactivity of the 14:1 and 22:1 conjugates (Figure 6). In our modeling results, we noticed that Ptc receptor aggregation levels have a biphasic relationship with increasing Shh concentration (data not shown): Ptc aggregation peaks at an intermediate Shh concentration much like the experimental results in Figure 3. The biphasic relationship, as described in the literature (*24*), occurs because, at high Shh concentrations, HyA−Shh conjugates compete with one another for available receptors and will be typically bound to fewer receptors, resulting in a lower avidity. Therefore, a peak in bioactivity as a function of Shh concentration could be due to Ptc receptor aggregation resulting in cooperativity in Ptc signal transduction. Future experimental work detailing Ptc cooperativity in Shh signal transduction is needed to justify future incorporation of such effects into our simple models. Also in future work, the equivalent site assumption could be relaxed to devise a binding relationship that scales with valency. Again, future experimental Ptc binding studies with conjugates of various valency may justify the incorporation of this effect into our simple models.

This work has significant implications for the fields of drug delivery and biomaterials. The surprising finding that the potency of Shh grafted onto a linear polymer is increased significantly over freely soluble Shh could be very useful in the design and administration of therapeutics as a means to increase potency. In addition, significant research effort is currently directed to impart bioactivity to materials for biological and biomedical applications, and the data and modeling presented provide insight into how the forced clustering of proteins on a surface or in a 3D matrix may alter the potency of the added protein or change the effectiveness of a peptide sequence. For example, linear polymers modified with bioactive agents have been incorporated into hydrogel networks to make bioactive semi-interpenetrating networks for tissue engineering applications (*34*, *35*). This research gives another form of modulation of added functionality in the solid state, as potency may be controllable by the both the amount of an agent added and its degree of substitution and spatial distribution.

Antibody−Dendrimer Conjugates: The Number, Not the Size of the Dendrimers, Determines the Immunoreactivity

C. Wängler, G. Moldenhauer, M. Eisenhut, U. Haberkorn, and W. Mier*

Universitaetsklinikum Heidelberg, Abteilung Nuklearmedizin, Germany. Received August 16, 2007; Revised Manuscript Received February 21, 2008

Radioimmunotherapy using antibodies with favorable tumor targeting properties and high binding affinity is increasingly applied in cancer therapy. The potential of this valuable cancer treatment modality could be further improved by increasing the specific activity of the labeled proteins. This can be done either by coupling a large number of chelators which leads to a decreased immunoreactivity or by conjugating a small number of multimeric chelators. In order to systematically investigate the influence of conjugations on immunoreactivity with respect to size and number of the conjugates, the anti-EGFR antibody hMAb425 was reacted with PAMAM dendrimers of different size containing up to 128 chelating agents per conjugation site. An improved dendrimer synthesis protocol was established to obtain compounds of high homogeneity suitable for the formation of defined protein conjugates. The quantitative derivatization of the PAMAM dendrimers with DOTA moieties and the characterization of the products by isotopic dilution titration using ^{111}In/^{nat}In are shown. The DOTA-containing dendrimers were conjugated with high efficiency to hMAb425 by applying Sulfo-SMCC as cross-linking agent and a 10- to 25-fold excess of the thiol-containing dendrimers. The determination of the immunoreactivities of the antibody−dendrimer conjugates by FACS analysis revealed a median retained immunoreactivity of 62.3% for 1.7 derivatization sites per antibody molecule, 55.4% for 2.8, 27.9% for 5.3, and 17.1% for 10.0 derivatization sites per antibody but no significant differences in immunoreactivity for different dendrimer sizes. These results show that the dendrimer size does not influence the immunoreactivity of the derivatized antibody significantly over a wide molecular weight range, whereas the number of derivatization sites has a crucial effect.

INTRODUCTION

Radioimmunotherapy is an expanding field in cancer therapy and shows very promising treatment results (*1–4*). However, the potential of this treatment modality has not yet been completely exploited. Besides heterogeneity in antigen expression, tumor load, perfusion defects, and tumor hypoxia, a further reason for this restraint resides in the low specific activity of the radiolabeled antibodies, which does not enable the delivery of optimal radioactive doses to tumor tissues and results in ineffective tumor treatment.

A solution for this problem is to introduce more than one radionuclide per protein to enhance the specific activity and by this the radioactive dose that can be applied to the tumor. However, it has been shown already that a few randomly distributed chelators or iodine atoms introduced into an IgG lead to a significant decrease of the immunoreactivity (*5, 6*). Consequently, an alternative method of introducing many chelators into an antibody molecule that does not lead to a drastic alteration of the properties of the protein is warranted. Recently, some studies about dendritic systems associated with antibodies were undertaken to solve this problem. The synthesized antibody−dendrimer conjugates showed preserved immunoreactivities of the antibodies and provided high specific activities (*7–10*).

In this study, we systematically investigated the influence of introduced dendritic structures with respect to size and the number of derivatization sites per protein. Using the anti-EGFR antibody hMAb425, we assessed the influence of DOTA-derivatized PAMAM dendrimers of various dendrimer generations and conjugation load on the immunoreactivity of antibodies. This study gives insights into a favorable derivatization pattern for antibody−PAMAM−dendrimer conjugates with a minimal loss of immunoreactivity, suited for improved radioimmunotherapy and diagnostic imaging.

EXPERIMENTAL PROCEDURES

General. All commercially available chemicals were of analytical grade and used without further purification. HPLC solvents containing TFA were prepared using 0.1% TFA (v/v).

The analytical HPLC system used was an Agilent 1100 system together with a Chromolith Performance (RP-18e, 100–4.6 mm, Merck, Germany) column. Semipreparative HPLC purifications were performed using a Gyncotech P-580 system (Germering, Germany) equipped with a variable SPD 6-A UV detector and a C-R5A integrator (both Shimadzu, Duisburg, Germany). The column applied for semipreparative purification was a Chromolith (RP-18e, 100–10 mm, Merck, Germany).

MALDI-TOF spectroscopy was performed using a Kratos Analytical Compact Maldi III system. ESI spectra were obtained using a Triple-Quadrupole-mass spectrometer TSQ 7000 (Thermo Fisher Scientific, Bremen). NMR spectra were taken using a Varian Mercury Plus 300 MHz and a Varian NMR System 500 MHz, respectively.

Thin layer chromatography was performed using Polygram SIL G/UV$_{254}$ TLC-plates (Macherey-Nagel, Düren, Germany). The PBS buffer consisted of 0.05 M phosphate, 0.15 M NaCl, at pH 7.2. Size-exclusion gel chromatography was carried out using NAP-5 columns (GE Healthcare Bio-Sciences AB, Uppsala, Sweden) and size-exclusion FPLC was performed on a Superdex 200 10/30 GL column (Amersham Biosciences AB, Uppsala, Sweden). ^{111}In was purchased from Perkin-Elmer (Rodgau, Germany).

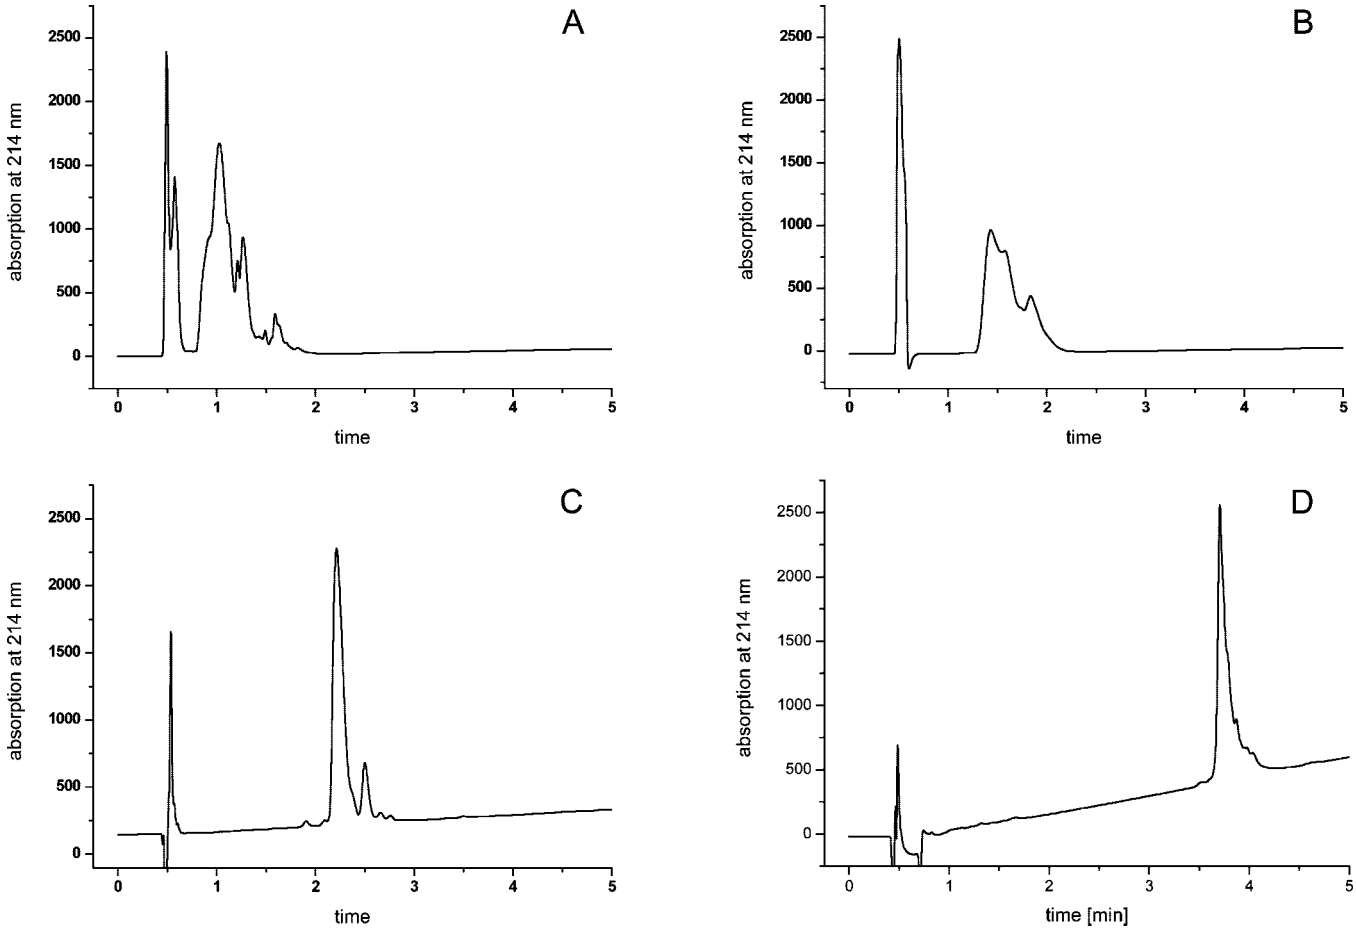

Figure 1. HPLC chromatograms of commercially available PAMAM dendrimers with 8 amino functions (A) and 16 amino functions (B). C and D show chromatograms of dendritic structures with 8 and 16 amino functions synthesized as described in the experimental procedures. Chromatograms were recorded at 214 nm and obtained using a Chromolith Performance column and a water/acetonitrile (+0.1% TFA (v/v)) gradient from 0% to 40% acetonitrile over 5 min in A and B. For C and D, a gradient from 20% to 45% acetonitrile over 5 min was used, as the compounds show a higher lipophilicity than the nonderivatized PAMAM dendrimers in A and B.

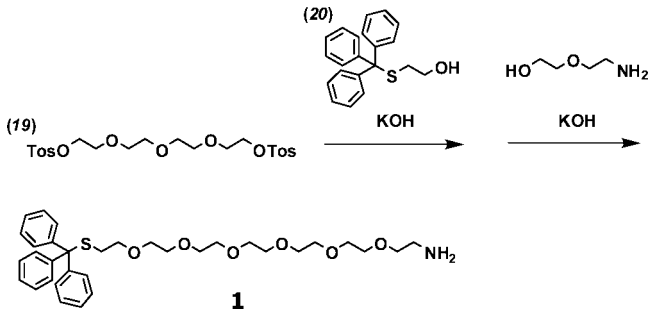

Figure 2. Synthesis scheme of the penta(ethylene glycol) linker.

Ellman′s Assay. A 2 mM solution of MESNA (sodium 2-mercaptoethanesulfonate) in PB (0.1 M, pH 8) was diluted to obtain solutions of the following concentrations: 125 μM, 64 μM, 32 μM, 16 μM, 8 μM, 4 μM, and 2 μM. To 1 mL of each of these solutions, 200 μL of a solution of Ellman′s reagent (5,5′-dithio-bis-(2-nitrobenzoic acid), 4 mg/mL in PB (0.1 M, pH 8)) was added and the absorption of the obtained mixtures was measured at 412 nm in a UV/vis spectrometer to give the calibration curve.

The thiol concentrations of the samples were determined analogously by adding 200 μL of the solution of Ellman′s reagent to 1 mL of sample in PB (0.1 M, pH 8) and by measuring the absorption at 412 nm.

The number of maleimides per dendrimer was determined by reacting it with an access of MESNA (5 equiv) and subsequent titration of free thiol with Ellman′s assay.

***S*-Trityl-mercaptoethyl-tetra(ethylene glycol)-tosylate.** To a solution of tetra(ethylene glycol)-bistosylate (22 g, 45 mmol), *S*-trityl-mercaptoethanol (10 g, 31 mmol), and TBAB (1.5 g, 4.5 mmol) in toluene (200 mL), powdered KOH (~3 g) was added. After two hours, the mixture was filtered and the resulting solution was evaporated. The remaining oil was purified via column chromatography on silica with *n*-hexane/acetone 2:1 as the eluent ($R_f = 0.4$). The product was obtained as a light yellow oil (11 g, 17 mmol, 55%).

***S*-Trityl-mercaptoethyl-penta(ethylene glycol)-ethylamine (G_0) (1).** To a solution of *S*-trityl-mercaptoethyl-tetra(ethylene glycol)-tosylate (28.5 g, 59 mmol), and 2-(2-aminoethoxy)ethanol (31 g, 296 mmol) in toluene (100 mL) and DMF (10 mL), powdered KOH (~5 g) was added. After five hours, the mixture was filtered and the resulting solution was evaporated. The remaining oil was purified via chromatography on silica with $CHCl_3$/ethanol 5:2 as the eluent ($R_f = 0.37$). The product was obtained as a yellow oil (15.5 g, 27 mmol, 45%).

Half-Generation PAMAM Dendrimers $G_{0.5}$ to $G_{6.5}$ (2, 4, 6, 8, 10, 12, and 14). A solution of the respective full-generation (G_X) dendrimer in methanol (20 mL) was added to methyl acrylate (200 equiv per amine function) and stirred for 3 to 31 days at room temperature. The volatile components were evaporated and the crude products were purified via chromatography on silica with *n*-hexane/acetone 4:5, ethanol/acetone

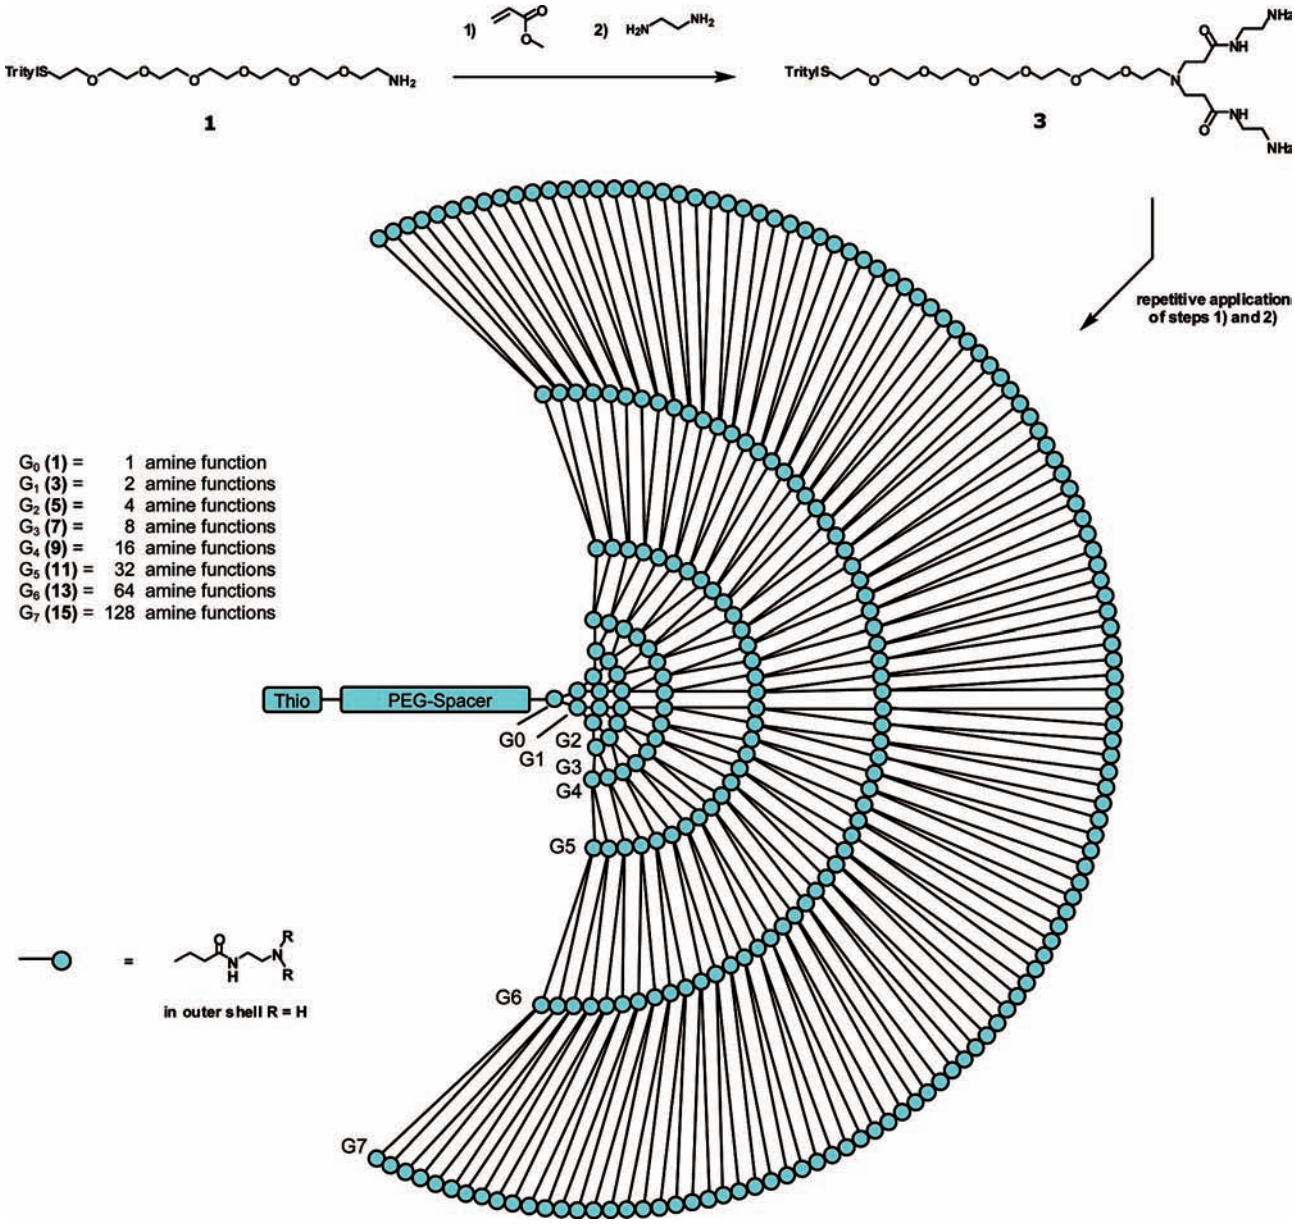

Figure 3. Synthesis scheme of the PAMAM dendrimers.

5:6, or 55% MeCN in water containing 0.1% TFA for smaller dendrimers and via semipreparative HPLC using a gradient of 0–100% MeCN + 0.1% TFA over 7 min as the eluent for larger dendrimers. The products were obtained as light yellow to orange oils in yields of 30% to 83%.

Full-Generation PAMAM Dendrimers G_1 to G_7 (3, 5, 7, 9, 11, 13, and 15). A solution of the respective half-generation dendrimer ($G_{X.5}$) in methanol (20 mL) was added dropwise to a cooled solution of ethylenediamine (400 equiv per methyl ester) over a half-hour and stirred for 5 to 41 days at 4 °C until the reaction was complete. Subsequently, the ethylenediamine was evaporated. In the case of smaller dendrimers, the products were found to be clean enough for further use. Larger dendrimers were purified using semipreparative HPLC using a gradient of 0–100% MeCN + 0.1% TFA over 7 min. The products were obtained as yellow to orange oils in yields of 70% to 99%.

G_0 to G_7 Maleimides (16, 19, 22, 25, 28, 31, 34, and 37). A solution of PyBOP (3.9 equiv per amine function of the respective dendrimer) and DIPEA (4 equiv per amine function) in DMF (300 μL) was added to maleimido caproic acid (4 equiv per amine function) and reacted for 2 min. Subsequently, this mixture was added to a solution of the respective full-generation dendrimer (G_X) (50 μmol) in DMF (200 μL). After one hour, 1 M NaOH (300 μL) and MeCN (1 mL) were added, and the volatile components were evaporated. After acidification with 1 M HCL (500 μL), the products were purified using semipreparative HPLC using a gradient of 0–100% MeCN + 0.1% TFA over 12 min. The products were isolated as colorless to brown oils in yields of 29% to 84% after lyophilization.

G_0 to G_7 *S*-trityl-Protected DOTA Dendrimers (17, 20, 23, 26, 29, 32, 35, and 38). To a solution of the respective maleimide-derivatized dendrimer (G_X maleimide) (10 μmol) in MeCN (200 μL) was added a solution of thiol-DOTA (4 equiv per maleimide) in 250 μL, and the mixture was reacted for 10 min. After acidification with 1 M HCL (200 μL), the products were purified using semipreparative HPLC using a gradient of 20–100% MeCN + 0.1% TFA over 8 min. The products were isolated as white to ocher solids in yields of 51% to 96% after lyophilization.

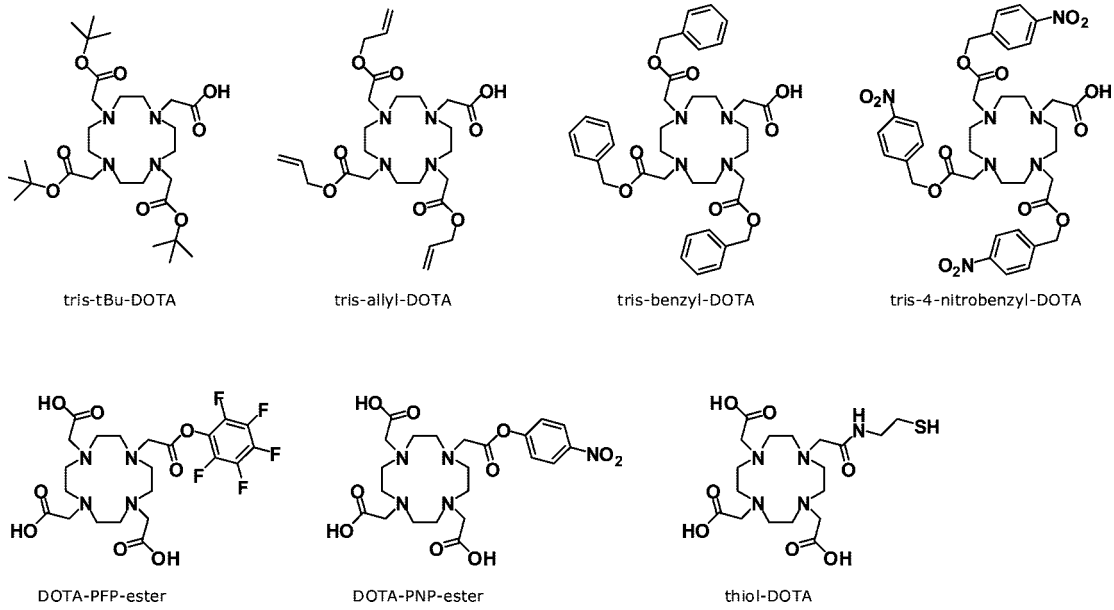

Figure 4. Structures of the studied DOTA-derivatives: tris-tBu-DOTA, tris-allyl-DOTA, tris-benzyl-DOTA, tris-4-nitrobenzyl-DOTA, DOTA−PFP−ester, DOTA–PNP−ester, and thiol-DOTA.

G_0 to G_7 Deprotected DOTA Dendrimers (18, 21, 24, 27, 30, 33, 36, and 39). The respective *S-trityl*-protected DOTA dendrimer (10 μmol) was dissolved in a mixture of TIS (200 μL) and TFA (2 mL) and reacted for 5 min. The volatile components were evaporated, and the products were purified using semipreparative HPLC using a gradient of 0–100% MeCN + 0.1% TFA over 7 min. The products were isolated as colorless oils or light ocher solids in yields of 58% to 98% after lyophilization.

Dervatization of hMAb425 with Sulfo-SMCC. A freshly prepared solution of Sulfo-SMCC (42 μg, 9.7×10^{-8} mol) in DMF/water 1:1 (10 μL) was added to a fresh solution of hMAb425 (2 mg, 1.39×10^{-8} mol) in 500 μL PBS. After one hour of incubation, the derivatized antibody was purified via size-exclusion chromatography using NAP-5 columns. The derivatized antibody was obtained in high yields (95–98%). The number of maleimide functions per antibody molecule was determined using MESNA and Ellman's assay and was found to be 1.7. The antibody derivatizations with more equivalents of Sulfo-SMCC were carried out according to this procedure.

hMAb425-DOTA$_X$-Dendrimers. To a solution of hMAb425, derivatized with Sulfo-SMCC (1.6 mg, 1.11×10^{-8} mol) in 500 μL PBS, was added a freshly prepared solution of the respective DOTA$_X$-dendrimer (25 equiv, 2.78×10^{-7} mol) in 100 μL PBS. The reaction was complete after 5 min and the products were analyzed using size-exclusion FPLC with PBS as the eluent (R_t between 13.7 and 16.1 min).

The conjugation of DOTA$_X$-dendrimers containing a lower number of equivalents of were carried out according to this procedure.

Immunoreactivities of the Antibody−Dendrimer Conjugates. *Cells.* The human colon adenocarcinoma cell line HT29 expressing considerable amounts of epidermal growth factor receptor was maintained in RPMI 1640 medium supplemented with 2 mM L-glutamine, 1 mM pyruvate, and 10% heat-inactivated fetal calf serum. Prior to use, cells were detached from the surface of the tissue culture flask by treatment with 0.25% trypsin plus 0.25% EDTA in PBS and counted.

Flow Cytometry. Serial dilutions of dendrimer-conjugated matuzumab were compared with unmodified matuzumab for binding to HT29 cells. For this, antibody dilutions ranging from 5 μg/mL to 1 ng/mL were prepared in FACS buffer (Dulbecco's PBS with 2% fetal calf serum and 0.1% sodium azide). Staining was performed in a 96-well microtiter plate (U-bottom). 100 μL/well antibody was mixed with 50 μL cell suspension containing 5×10^5 HT-29 cells and incubated for 1 h on ice. Cells were washed twice with FACS-buffer by centrifuging the plate and siphoning off the supernatant. Subsequently, 100 μL/well F(ab)′$_2$ goat-antihuman IgG (H+L)-FITC (Jackson ImmunoResearch, West Grove, PA) diluted 1:100 in FACS buffer was added as second-step reagent. The plate was incubated for 1 h on ice in the dark, and cells were washed again twice as above. Dead cells were discriminated by propidium iodide staining. Analysis was carried out on a FACScan cytometer (Becton Dickinson, Heidelberg, Germany) using the *CELLQUEST* software.

For each dendrimer conjugate as well as for unconjugated matuzumab, a binding curve was obtained by plotting the mean fluorescence intensity (MFI) versus the antibody concentration.

RESULTS AND DISCUSSION

Improvement of PAMAM Dendrimer Synthesis. Dendrimers have shown to be effective drug delivery vehicles for a variety of applications (*11–13*) and are also the basis for approved pharmaceuticals as, for example, for the diagnostic cardiac marker Stratus and the microbicide Vivagel. In general, a major advantage of dendrimers over polymers is their low dispersity. However, the homogeneity of commercially available dendrimers was found to be low (Figure 1A,B). Similar results have recently been described for commercially available PAMAM dendrimers which were analyzed with HPLC and MALDI-TOF spectrometry showing high polydispersities of the compounds (*14, 15*).

Therefore, these compounds were not chosen as building blocks for the syntheses of the DOTA-multimers. Attempts to synthesize PAMAM dendrimers according to literature methods (*16–18*) resulted in products with higher quality which, however, did not demonstrate sufficient homogeneity. Therefore, the synthesis protocols had to be improved.

The substantial modification was the strict limitation of the reaction temperatures to below 20 and 4 °C for the synthesis of half and full generations, respectively. Reactions conducted above the indicated temperatures led to highly fragmented products and a high amount of intramolecular ring formations, with the consequence of highly heterogeneous dendritic

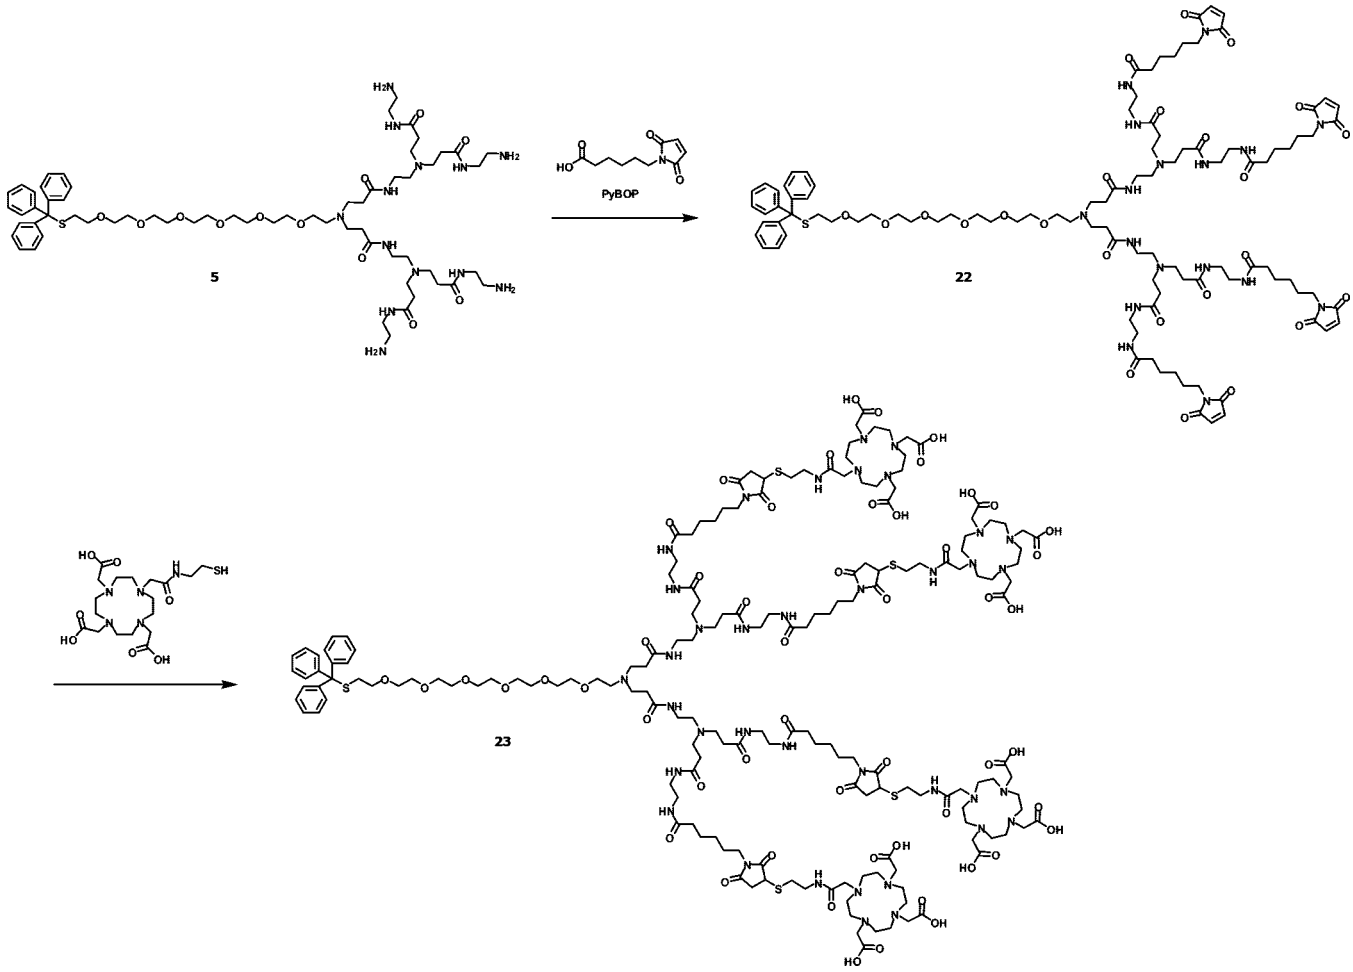

Figure 5. Synthesis scheme for the derivatization of the amino groups with maleimides and subsequently with thiol-DOTA as exemplified for the G_2 dendrimer (**5**).

Table 1. Characterization Results of the DOTA-Functionalized Dendrimers (n = 5 and 3 for the Determination of the Number of Maleimides and Functional Chelators, Respectively)

dendrimer generation (number of amino functions and chelators)/molecular weight	number of maleimides determined by mass spectrometry/ back-titration	number of functional chelators determined by mass spectrometry/ isotopic dilution titration
G_0 (1)/998 $^g/_{mol}$	1/–	1/–
G_1 (2)/1883 $^g/_{mol}$	2/–	2/–
G_2 (4)/3653 $^g/_{mol}$	4/–	4/–
G_3 (8)/7187 $^g/_{mol}$	8/–	8/9.9 ± 2.8
G_4 (16)/14261 $^g/_{mol}$	16/–	–/17.2 ± 0.4
G_5 (32)/28405 $^g/_{mol}$	–/33.1 ± 3.9	–/32.2 ± 0.3
G_6 (64)/55733 $^g/_{mol}$	–/62.9 ± 6.8	–/69.1 ± 6.7
G_7 (128)/112309 $^g/_{mol}$	–/120.2 ± 10.5	–/155.1 ± 33.7

structures and highly demanding purification steps. However, with the modifications of the synthesis protocol described, the dendrimers were obtained in good yields and purity (Figure 1C,D).

Table 2. Parameters of the Antibody−Sulfo-SMCC and −DOTA-Dendrimer Reactions

amount of Sulfo-SMCC applied relative to antibody	number of introduced maleimides per antibody	excess of $DOTA_X$-dendrimers applied relative to antibody
7 equiv	1.7	10 equiv
12 equiv	2.8	12.5 equiv
22 equiv	5.3	15 equiv
45 equiv	10.0	25 equiv

A penta(ethylene glycol) linker containing a thiol function was used as the starting structure element. This linker was introduced to enhance the accessibility of the reactive site of the dendritic system, thereby allowing the effective and selective introduction of the dendritic molecule into proteins or peptides. The linker system was synthesized starting from tetra(ethylene glycol)-bistosylate (*19*), *S*-trityl-mercaptoethanolamine (*20*) and 2-(2-amino-ethoxy)-ethanol as shown in Figure 2.

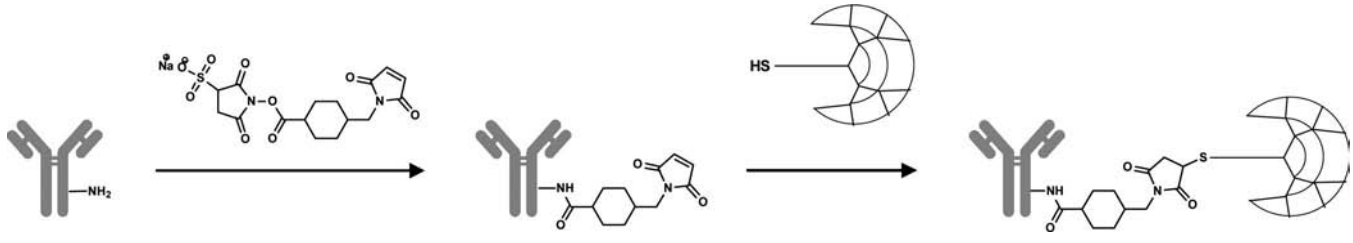

Figure 6. Schematic depiction of the conjugation of the DOTA-dendrimers to the antibody.

Table 3. Results of the Derivatization Reactions and Determination of the Immunoreactivities of the Antibody−Dendrimer Conjugates[a]

	immunoreactivity retained (number of dendrimers per antibody)			
antibody conjugate	1.7 maleimides per antibody	2.8 maleimides per antibody	5.3 maleimides per antibody	10.0 maleimides per antibody
hMAb425-DOTA$_1$	60.3% (0.4)	66.3% (0.5)	35.7% (1.0)	30.0% (1.9)
hMAb425-DOTA$_2$	68.4% (0.5)	64.3% (0.6)	31.3% (0.9)	24.4% (1.9)
hMAb425-DOTA$_4$	66.2% (0.5)	64.7% (0.6)	28.5% (1.1)	17.6% (2.1)
hMAb425-DOTA$_8$	57.8% (1.0)	55.3% (1.2)	26.7% (2.7)	13.0% (6.9)
hMAb425-DOTA$_{16}$	63.2% (0.8)	49.0% (1.5)	21.6% (2.5)	12.6% (5.8)
hMAb425-DOTA$_{32}$	60.6% (0.8)	40.8% (1.1)	27.9% (1.5)	14.2% (2.7)
hMAb425-DOTA$_{64}$	58.2% (1.7)	46.6% (2.6)	23.3% (3.6)	8.4% (7.3)
hMAb425-DOTA$_{128}$	63.9% (1.0)	56.1% (1.9)	28.5% (2.5)	16.4% (4.4)

[a] Immunoreactivities are given relative to the immunoreactivity of the underivatized antibody.

It represents the starting generation (G_0) of the dendrimer, as it shows no branching. Subsequently, the PAMAM dendrimers were grown on the terminal amino function of the linker by alternating reaction with methyl acrylate and ethylenediamine to give half ($G_{X.5}$) and full generations (G_{X+1}) of the dendrimer (Figure 3).

Using this method, we were able to synthesize PAMAM dendrimers of 1 to 128 amino functions on a penta(ethylene glycol) linker providing a thiol for selective coupling to a carrier protein. The dendrimers obtained were found to be of high homogeneity and are therefore suitable as building blocks for the synthesis of DOTA-multimers.

Formation of DOTA-Multimers. For the subsequent derivatization of the PAMAM dendrimer amino functions with DOTA, the following differently protected and activated DOTA-derivatives were studied with regard to their coupling yields and the homogeneity of the obtained products: tris-tBu-DOTA (*21*), DOTA−PFP−ester and DOTA–PNP−ester (*22*), tris-allyl-DOTA (*23*), tris-benzyl-DOTA (*24*), tris-4-nitrobenzyl-DOTA and thiol-DOTA (*25*) (Figure 4).

Tris-tBu-DOTA and tris-allyl-DOTA showed high coupling yields and very homogeneous coupling products. However, in both cases the deprotection resulted in mixtures that were difficult to purify. DOTA−PFP−ester, DOTA–PNP−ester, tris-benzyl-DOTA, and tris-4-nitrobenzyl-DOTA were found to react incompletely, thus producing inhomogeneous products even when applied in an excess of up to 5 equiv per amine function. This behavior was attributed to the relatively low reactivity of the active esters and the steric hindrance of tris-benzyl-DOTA and tris-4-nitrobenzyl-DOTA.

In contrast to the amide linked conjugates, the thiol-DOTA could be introduced quantitatively after preceding derivatization of the amino groups of the dendrimers with maleimido caproic acid (Figure 5).

Using these maleimide-bearing dendrimers, the DOTA-derivatized compounds were obtained in good yields and high purities. Furthermore, the coupling reaction was completed within a few minutes and did not require an additional deprotection step for the DOTA moieties.

The number of maleimides per dendritic structure was determined by reacting an aliquot of the maleimide-containing dendrimer with a 5-fold excess of MESNA (sodium 2-mercaptoethanesulfonate) for 5 min. The excess of thiol was subsequently quantified using the Ellman′s assay. The amount of reacted thiol corresponds to the amount of maleimides. Using this method, it could be shown that the reaction of the dendritic amines with maleimido caproic acid proceeded quantitatively (Table 1).

After the derivatization of the dendritic structures with thiol-DOTA, the number of functional chelators per dendrimer was determined by isotopic dilution titration (*22*) using a 10^{-10} mol/L solution of the respective dendrimer (relating to DOTA) and trace amounts of ^{111}In in the presence of a range of concentrations of ^{nat}In (10^{-5}, 10^{-6}, 7.5×10^{-7}, 5×10^{-7}, 2.5×10^{-7}, 10^{-7}, 7.5×10^{-8}, 5×10^{-8}, 2.5×10^{-8}, 10^{-8}, and 10^{-9} mol/mL) in sodium acetate buffer (0.4 M, pH 5). The complexation was stopped after 20 min at 60 °C by the addition of an excess of EDTA, and the amount of dendrimer-bound ^{111}In was determined by TLC. The results of the isotopic dilution titrations are shown in Table 1. Apparently, the number of functional chelators per dendrimer molecule provided a slight overestimation, which is possibly due to the formation of radiocolloids. However, the quantitative reaction of thiol-DOTA with the maleimide-containing dendrimers could be shown.

Using this technique, the amino functions of the PAMAM dendrimers were derivatized quantitatively with DOTA, yielding homogeneous products in good yields and short reaction times. Furthermore, additional deprotection steps were dispensable.

Conjugation of DOTA-Multimers to hMAb425. To determine the influence of the DOTA-containing structures on the immunoreactivity of an antibody, the dendrimers were conjugated to hMAb425. This humanized monoclonal antibody is directed against the EGF receptor and was recently investigated in clinical studies (*26–28*).

For the antibody derivatization, the protein was reacted with 7, 12, 22, or 45 equiv of the heterobifunctional cross-linker Sulfo-SMCC (sulfosuccinimidyl-4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate) for one hour and isolated using size-exclusion gel chromatography in high recovery rates of 95–98%. The antibody concentration in the obtained solution was determined using the Bradford Assay and the number of maleimides per antibody molecule was determined by back-titration with MESNA as described above and found to be 1.7, 2.8, 5.3, and 10.0 for an applied Sulfo-SMCC amount of 7, 12, 22, or 45 equiv, respectively.

The maleimide-derivatized antibodies were then reacted with the different DOTA-containing dendrimers for 5 min (Figure 6).

A summary of the reaction parameters of the antibody derivatization with Sulfo-SMCC and the following dendrimer conjugation is given in Table 2.

The number of dendritic structures per antibody was determined by ^{111}In-labeling of the DOTA-dendrimers and subsequent antibody conjugation as described above. The reaction mixtures were analyzed by size-exclusion FPLC and the amount of dendrimer conjugated was identified by determining the distribution of radioactivity between the protein and dendrimer fractions collected (results shown in Table 3).

The immunoreactivities of the antibody−dendrimer conjugates were determined by FACS analysis using HT29-cells. The immunoreactivities relative to the underivatized antibody were calculated from the corresponding IC_{50} values.

The results shown in Table 3 reveal that the dendrimer size does not influence the immunoreactivity of the derivatized antibody significantly. In contrast to this, the number of derivatization sites has a crucial effect.

These results show that the synthesis of antibody−dendrimer conjugates containing up to 128 chelating agents per binding site is feasible.

For comparison, a conjugate containing single DOTA moieties linked to the antibody hMAb425 was produced using *S*-2-(4-isothiocyanatobenzyl)-1,4,7,10-tetraazacyclododecane-tetraacetic acid (Macrocyclics Dallas, TX). This preparation contained approximately 5 DOTA molecules per antibody. The affinity measurement described in the experimental procedures showed that it retained 46.8% of its immunoreactivity.

The comprehensive study of the influence of the substitution pattern on the immunoreactivity revealed that the size of a conjugated dendritic structure does not significantly influence the immunoreactivity of antibodies over a wide molecular weight range, whereas the number of derivatization sites is the major factor that determines the binding affinity of the conjugates. Therefore, an antibody modification with dendritic structures should consist of a derivatization with few but large dendritic systems to obtain antibodies that result in a minor change of immunoreactivity. In this context, an antibody modification with less than 1.7 derivatization sites per antibody should lead to higher immunoreactivities of the conjugates than those shown above, though they would require a separation of the dendrimer-conjugated antibodies to attain high specific activities.

Additionally, a site-specific conjugation (*29*) of the dendritic structures to the constant region of the antibody might be used and allow a further improvement of the concept by less altered immunoreactivities of the antibody−dendrimer conjugates.

In these conjugates, only a minor fraction of the chelators in can be occupied by the radiometal and complexes formed with Ca(II), and other metal ions will be the predominant species in the circulation. It has to be investigated whether and to what extent large polar dendritic structures alter the pharmacokinetics and the specific accumulation of these antibody conjugates.

CONCLUSION

Several maleimide-reactive DOTA-containing PAMAM dendrimers of different sizes were synthesized for the introduction into antibodies and other macromolecules to enhance their specific activity for radioimmunotherapy and clinical diagnostics. For this purpose, the established synthesis protocols for PAMAM dendrimers were improved to obtain products of high homogeneity that are suited for further derivatization. For the subsequent coupling of DOTA moieties, a synthesis strategy was found that allows the quantitative derivatization of the PAMAM amino functions, making a deprotection of the DOTA moieties dispensable. The DOTA multimers were conjugated to the anti-EGFR-antibody hMAb425, the number of dendrimers per antibody molecule was determined, and immunoreactivity studies of the antibody−dendrimer conjugates were performed. These experiments showed that the dendrimer size over a wide range does not influence the immunoreactivity of the derivatized antibodies significantly, whereas the number of derivatization sites has a crucial effect.

Glycoside Esters of 5-Aminolevulinic Acid for Photodynamic Therapy of Cancer

Ramakrishnan Vallinayagam,[†,‡] Frédéric Schmitt,[†,§] Jérome Barge,[||] Georges Wagnieres,[||] Virginie Wenger,[‡] Reinhard Neier,[‡] and Lucienne Juillerat-Jeanneret*[,§]

Institute of Chemistry, Neuchâtel University, avenue de Bellevaux, P.O. Box 2, CH-2007 Neuchâtel, Switzerland, University Institute of Pathology, Centre Hospitalier Universitaire Vaudois (CHUV) and University of Lausanne (UNIL), Bugnon 25, CH-1011 Lausanne, Switzerland, and Swiss Federal Institute of Technology (EPFL), Laboratory of Photomedicine, EPFL, CH-1015 Lausanne, Switzerland. Received August 27, 2007; Revised Manuscript Received November 21, 2007

Aliphatic and ethylene glycol esters of 5-aminolevulinic acid (ALA) are very efficient precursors of the photosensitizer protoporphyrin IX (PpIX) for photodynamic therapy; however, they diffuse passively across the cell membrane and thus lack cell selectivity. We evaluated whether α-glucose, α-mannose, or β-galactose esters of ALA would present improved properties as precursors of PpIX. Esterification was performed either at the position O-1 or O-6 of the sugars with or without an ethylene glycol linker, and these glycoside esters of ALA were evaluated in human cells. The results demonstrated that glycoside esters of ALA are efficient precursors of PpIX in human cancer and angiogenic endothelial cells, comparable to free ALA, but not in normal human fibroblasts. PpIX production was confirmed by fluorescence microscopy and photodynamic treatment of cells. The O-1 or O-6 positions of functionalization and the nature of the sugar moiety did not influence PpIX production. The presence of the ethylene glycol linker generally resulted in decreased PpIX production. The uptake of these glycoside esters of ALA by cells was not decreased in the presence of high concentrations of the related sugars. Inhibitors of α-glucosidases or α-mannosidases did not decrease PpIX production. These results suggest the involvement of active non-glycoside-specific membrane transporter(s) for uptake and of esterases rather than glycosidases in the release of ALA from the glycoside esters of ALA.

INTRODUCTION

In recent years, fluorescent photodetection and photodynamic therapy (PDT) have received increasing attention as new approaches for the selective detection and treatment of cancer. These procedures involve the systemic or topical administration of agents leading to the accumulation of photosensitizers in the targeted tissues. Then, these photosensitizers are activated by light either to produce fluorescence, thus allowing detection of tumors, or to produce cytotoxic molecules, such as reactive oxygen species, which lead to tissue destruction by a multistep cascade. Photosensitizers can be prepared as already-light-reactive molecules, mostly as porphyrin or chlorin derivatives, or as precursor molecules able to generate the photosensitizing molecules inside the target cells using intracellular enzymatic pathways. One possibility is the production of the photosensitizer protoporphyrin IX (PpIX) from the precursor 5-aminolevulinic acid (ALA) (*1–4*). External addition of ALA, or its derivatives (*5–10*), results in enhanced synthesis of porphyrin by cells. In order to enter the cellular porphyrin biosynthetic pathways, precursor photosensitizers such as ALA must be internalized by target cells and processed to the photosensitizer PpIX. This processing depends on the presence in target cells of the necessary (1) receptor and transport systems, (2) enzymes able to release the active molecule ALA from its prodrug, and (3) enzymes able to perform the intracellular biosynthetic pathway to generate the photosensitizer PpIX (Scheme 1).

However, the selective accumulation of all photosensitizers, including ALA, in tumors is not discriminating enough, inducing damage to the surrounding tissue in PDT protocols and overall photosensitization. Thus, improvement in the selectivity of photosensitizers to tumor cells versus nontumoral cells is needed (*11, 12*). It has been previously shown in cancer that the angiogenic endothelial cells associated with cancer may also be valuable targets for photodynamic therapy, in addition to tumor cells themselves (*13–15*). Tumor-associated angiogenesis is presently under clinical evaluation also for new therapeutic approaches to cancer treatment other than PDT (*16–18*). It has also been shown that glycosylation pathways are deregulated in cancer and cancer cells, likely as a result of the increased metabolism and energy demand of actively metabolizing cells, such as cancer and proliferating endothelial cells (*19–22*). Thus, carbohydrates, including glucose, mannose, or galactose, may represent the means to selectively deliver therapeutic agents to cancer and cancer-associated cells, such as angiogenic endothelial cells, while sparing nontumoral cells such as fibroblasts.

We have previously shown that aliphatic and ethylene glycol esters of ALA increased PpIX production by cells; however, the kinetics of cell uptake suggested passive diffusion of these esters across the cell membrane and activation by cellular esterases, without cell selectivity (*8, 9*). We have also previously shown that amino acids and dipeptides coupled via a peptide bond to ALA were substrates for cellular peptidases, following their active transport across the cell membrane (*9, 10, 23*). Some selectivity for endothelial cells of peptide derivatives was obtained. To the best of our knowledge, no study has evaluated the cell uptake and efficacy of ALA conjugates of sugars, whereas in the context of photosensitizers for PDT, various

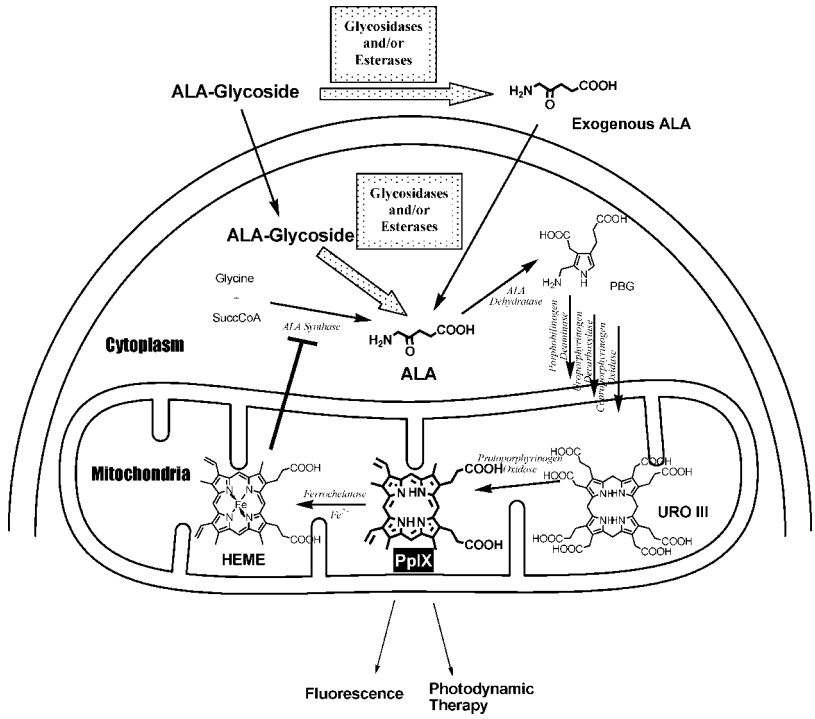
Scheme 1. Cellular Processing of the Glycoside−ALA Derivatives



glycoside derivatives of porphyrins or chlorins have been synthesized in recent years demonstrating the potential for these derivatives to improve the transport of photosensitizers into cells (*24–31*). Therefore, in the present manuscript, our objectives were to prepare and evaluate glycoside esters of ALA in order to determine (i) if these conjugates are taken up by cells and are efficient precursors of PpIX in human tumor cells, angiogenic endothelial cells, and normal fibroblasts; (ii) if cellular enzymes, such as esterases or possibly glycosidases, can release ALA from these glycoside esters of ALA; (iii) if these conjugates display improved cell selectivity among tumor cells, endothelial cells, and fibroblasts; and (iv) if they can be used as precursors of photosensitizers for efficient PDT of cancer.

EXPERIMENTAL PROCEDURES

Chemistry. *General Methods.* Chemicals and solvents were purchased from Cambridge Isotope Laboratories, Fluka, Merck, and Acros and were of the highest purity available. They were used without further purification with the exception that solvents were distilled over drying agent when requested. D-(+)-Galactose, D-(+)-glucose, and D-(+)-mannose were from Fluka, Biochemika (≥99.5% purity); levulinic acid was from Acros, and 2,3,4,6-β-D-galactopyranosyl bromide was from Fluka. Lipase from *Candida antarctica* (LCA,Novozyme 435, 10 units/mg protein), proteinase from *Bacillus subtilis* (5 units per mg of protein) and porcine liver esterase (PLE, 24 units/mg protein) were from Sigma-Aldrich, and porcine pancreas lipase (PPL, 24 units/mg protein) was from Fluka.

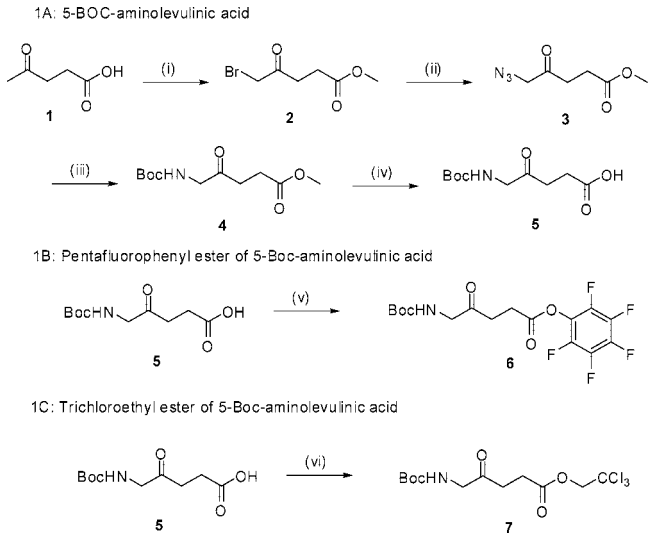
Perkin-Elmer Spectrum One version B FT-IR was used for obtaining IR spectra with the resolution of 2 cm^{-1}. The solid and thick oily substances were analyzed by preparing KBr pellets. Liquid samples were analyzed as film (sandwich) by applying between two KBr plates. The absorption bands between 4000 and 400 cm^{-1} were measured. Software used was *Spectrum* v 5.0.1. The intensity of the spectrum was divided into five equal parts for the abbreviations vs (the maximum intensity), s (intense), m (medium intensity), w (weak), br (broad), and vw (very weak).

The NMR spectra were measured using a Variant Gemini XL-200 spectrometer at 298 K (^{1}H was measured at 200 Hz and ^{13}C at 50 Hz) or using a Bruker Avance-400 spectrometer at 298 K (^{1}H was measured at 400 Hz and ^{13}C was at 100 Hz). The internal standard for the spectra of ^{1}H was TMS ($\delta = 0.00$ ppm), $CHCl_3$ ($\delta = 7.26$ ppm), CH_3OH ($\delta = 3.31$ ppm), $(CH_3)_2SO$ ($\delta = 2.50$ ppm), or D_2O ($\delta = 4.79$ ppm). The internal standard for the spectra of ^{13}C was TMS ($\delta = 0.00$ ppm), $CHCl_3$ ($\delta = 77.16$ ppm), CH_3OH ($\delta = 49.00$ ppm), or $(CH_3)_2SO$ ($\delta = 39.52$ ppm). The ^{13}C spectra were measured by decoupling from ^{1}H. The chemical shift is given in ppm in the descending order and the coupling constant J in Hz. The multiplicity of signals were given abbreviations s (singlet), d (doublet), t (triplet), q (quartet), quint (quintet), dt (doublet of triplet), br (broad), and m (multiplet). The sign $\approx$ denotes for the average value of J varying from 0.2 to 0.4 Hz. The ratio of α to β is measured by area integration in the case of ^{1}H and by the intensity (height) of peak in the case of ^{13}C. All the products were measured for HETCOR (short-range), COSY, and DEPT 135 for the accurate interpretation of signals.

The mass spectra measurements for ESI (electrospray ionization) and for APCI (atmospheric pressure chemical ionization) were performed using a ThermoFinnigan LCQ (San Jose, California, USA), using the *Tune Plus* v 1.2 software. The values given are average masses of ion with precision in the range of ±0.1 values. The nature of the ion is written in parentheses together with the intensity. The high-resolution mass spectroscopy (HR-MS) was performed at the University of Fribourg (Switzerland) by Mr. F. Nydegger. The instrument used was a Brucker BioAPEX II daltonics using electrospray ionization (ESI).

*5-Bromo-4-oxo Methyl Pentanoate (**2**).* To a solution of levulinic acid **1** (100 g, 861 mmol, 1.0 equiv) in 860 mL methanol at 0 °C, bromine (44 mL, 861 mmol, 1.0 equiv) was added dropwise over 3 h. The addition of bromine was carried out in such a way that the reaction temperature never exceeded 30 °C. At the end of the addition, the solution was dark orange. The reaction mass was brought to room temperature and was kept stirring overnight at room temperature. The resultant

Scheme 2. Synthesis of Starting Materials[a]



[a] Reagents and conditions: (i) Br_2, MeOH, reflux, 1.5 h; (ii) NaN_3, THF/H_2O, room temperature, 1 h; (iii) H_2/Pd, Boc_2O, room temperature, 12 h; (iv) porcine liver esterase (PLE), phosphate buffer pH 8.0, room temperature, 7 h; (v) C_6F_5OH, DCC, room temperature, 2 h; (vi) CCl_3CH_2OH, EDC, DMAP, room temperature, 3 h.

colorless solution was refluxed in MeOH for 1.5 h; then, solvent was evaporated. The yellow residue was dissolved in 400 mL of CH_2Cl_2 and extracted with 400 mL of H_2O. The organic phase was further extracted with 200 mL of a saturated solution of $NaHCO_3$, then with 3 × 200 mL of H_2O, dried over $MgSO_4$, filtered, and evaporated. The yellow residue (156 g) was subjected to fractional distillation by means of a Widmer column of 40 cm under reduced pressure (4×10^{-2} mbar), and fractions were collected according to changes of vapor temperature. One of the fractions contained 81 g of 5-bromo-4-oxo methyl pentanoate **2**, with 98% purity by ^{1}H NMR and with 45% yield. R_f (hexane/EtOAc 1:1): 0.50. Bp: ~80 °C at pressure = 0.045 mbar. n_D^{20}: 1.4820. IR (KBr): 3000m, 2953m, 2849w, 1734s, 1722s, 1439s, 1411s, 1359s, 1322m, 1207s, 1177s, 1079m, 1025m, 988m, 862w, 768vw, 694w, 595vw, 496vw, 464w. ^{1}H NMR (200 MHz, $CDCl_3$, 298 K): δ_H (ppm) = 3.95 (s, 2H, $H_2C(5)$); 3.67 (s, 3H, $H_3C(1^1)$; 2.95 (t, $^3J_{3-2} = 6.4$, 2H, $H_2C(3)$); 2.64 (t, $^3J_{2-3} = 6.4$, 2H, $H_2C(2)$). ^{13}C NMR (50 MHz, $CDCl_3$, 298 K): δ_C (ppm) = 201.3 (C(4)); 173.4 (C(1)); 52.6 ($C(1^1)$); 35.1 (C(3)); 34.7 (C(2)); 28.8 (C(5)). MS (ESI (+)): [M (^{79}Br) + Na]$^+$ = 231.1, [M (^{81}Br + Na]$^+$ = 233.0.

*5-Azido-4-oxo Methyl Pentanoate (**3**).* To a solution of NaN_3 (17.68 g, 272 mmol, 2 equiv) in 68 mL of deionized water at 0 °C, 70 mL of THF containing (28.43 g, 136 mmol, 1 equiv) was added dropwise. The yellow-colored reaction mass was brought to room temperature and stirred for a further 1 h. The resulting two phases were separated. The aqueous phase was extracted with 3 × 200 mL of EtOAc. The organic phases were combined and washed with 2 × 200 mL of H_2O, dried over $MgSO_4$, filtered, and evaporated. 22.05 g of 5-azido-4-oxo methyl pentanoate **3** was obtained with 95% yield as a yellow oil. R_f (hexane/EtOAc 2:1): 0.50; 0.33 (UV_{254} active, vanillin). IR (KBr): 3445w, 3366w, 3001m, 2956m, 2914m, 2850w, 2543vw, 2202m, 2106vs, 1732vs, 1619w, 1438s, 1417s, 1361s, 1280s, 1210s,1172s, 1096s, 1028m, 1008m, 988m, 921m, 885w, 843w, 799vw, 705vw, 607vw, 556m, 489vw. ^{1}H NMR (200 MHz, $CDCl_3$, 298 K): δ_H (ppm) = 4.03 (s, 2H, $H_2C(5)$); 3.69 (s, 3H, $H_3C(1^1)$; 2.76–2.72 (m, AA′ part of a system AA′BB′, 2H, $H_2C(3)$); 2.70–2.66 (m, BB′ part of a system AA′BB′, 2H, $H_2C(2)$). ^{13}C NMR (50 MHz, $CDCl_3$, 298 K): δ_C (ppm) = 202.9 (C(4)); 173.0 (C(1)); 57.3 (C(5); 51.9 ($C(1^1)$); 34.3 (C(3)); 27.4 (C(2)). MS (ESI(+)): *m*/*z* relative intensity [M + Na]$^+$ = 194.

*5-Boc-amino-4-oxo Methyl Pentanoate (**4**).* A solution of **3** (23 g, 134.37 mmol, 1 equiv) in 250 mL of EtOAc was charged in a hydrogenation autoclave reactor, followed by BOC anhydride (29.63 g, 135.76 mmol, 1.01 equiv) and by 5 g (4.7 mmol, 0.035 equiv) of 10% palladium on activated charcoal. The mass was subjected to hydrogenation in ambient temperature and to a pressure of 60 psi H_2 under mechanical agitation. After 24 h, the H_2 pressure was released and the reaction mass was filtered over celite, eluted with 3 × 25 mL of EtOAc, and the filtrate evaporated to obtain a yellow, oily mass. This yellow crude mass was purified by flash chromatography using a gradient eluent system from CH_2Cl_2/EtOAc 95:5 to CH_2Cl_2/EtOAc 85:15. A pure fraction of 5-Boc-amino-4-oxo methyl pentanoate **4** was obtained as a yellow oil (23.05 g, 70%). R_f (CH_2Cl_2/EtOAc 9:1): 0.25–0.30 (UV_{254} active, $KMnO_4$). IR (KBr): 3387s, 2979s, 2932s, 1735s, 1719s,1701s, 1697s, 1523s, 1518s, 1508s, 1500s, 1438s, 1412s, 1392s, 1252s, 1209s, 1165s, 1098m, 1060m, 1024m, 983m, 737m. ^{1}H NMR (400 MHz, $CDCl_3$, 298 K): δ_H (ppm) = 5.24 (sbr, 1H, NH); 4.03 (d, $^3J_{5\text{-}NH} = 3.6$ Hz, 2H, $H_2C(5)$); 3.64 (s, 3H, $H_3C(1^1)$; 2.71–2.68 (m, 2H, $H_2C(3)$); 2.63–2.59 (m, 2H, $H_2C(2)$); 1.40 (s, 9H, $H_3C(8^1,8^2,8^3)$. ^{13}C NMR (100 MHz, $CDCl_3$, 298 K): δ_C (ppm) = 204.5 (C(4)); 173.0 (C(1)); 155.7 (C(6)); 79.9 (C(7)); 52.0 ($C(1^1)$); 50.3 (C(5)); 34.4 (C(3)); 28.4 ($C(8^1,8^2,8^3)$); 27.6 (C(2)). MS (APCI (+)): *m*/*z* relative intensity (15, [M + Na]$^+$) = 269.1.

*5-Boc-amino-4-oxo Pentanoic Acid (**5**).* To 500 mL of phosphate buffer solution 0.1 M at pH 8, **4** (22.85 g, 93.2 mmol, 1 equiv) was added under agitation. Then, 300 mg of pig liver esterase (PLE, 24 units per mg of protein) were added under agitation. The pH of the reaction was maintained at pH 9 with 5 N NaOH. The reaction was followed by TLC (CH_2Cl_2/EtOAc 90:10) and was completed after 4 days. The reaction mixture was extracted with 3 × 200 mL of EtOAc; the aqueous phase was acidified to pH 2 with 6 N HCl, and extracted with 4 × 500 mL of EtOAc. The organic phases were combined and washed with 500 mL of saturated NaCl solution followed by 500 mL deionized water. The organic phase was dried over $MgSO_4$ and evaporated. A yellow crude solid product was obtained by trituration with ether at 0 °C. The white pure solid obtained was filtered and dried. Pure 5-Boc-amino-4-oxo pentanoic acid **5** was obtained as a white solid (13.7 g, 64%). R_f (EtOAc): 0.47 ($KMnO_4$, tailing). IR (KBr): 3379s, 2986mbr, 2919mbr, 2765w, 2692w, 2571w, 1707vs, 1686vs, 1506s, 1429s, 1407m, 1392m, 1383m, 1371m, 1363m, 1349m, 1295w, 1278m, 1240s, 1209s, 1170s, 1098w, 1065m, 1039vw, 1015m, 943m, 894m, 872m, 843vw, 803w, 787w, 759w, 741w, 653w, 575m. ^{1}H NMR (400 MHz, $CDCl_3$, 298 K): δ_H (ppm) = 11.30 (s, 1H, COOH); 5.35 (sbr, 1H, NH); 4.03 (d, $^3J_{5\text{-NH}} = 4.8$ Hz, 2H, $H_2C(5)$); 2.69–2.62 (m, 4H, $H_2C(2$ and $3)$); 1.40 (s, 9H, $H_3C(8^1,8^2,8^3)$. ^{13}C NMR (100 MHz, $CDCl_3$, 298 K): δ_C (ppm) = 204.5 (C(4)); 177.4 (C(1)); 156.0 (C(6)); 80.2 (C(7)); 50.3 (C(5)); 34.2 (C(3)); 28.4 ($C(8^1,8^2,8^3)$); 27.7 (C(2)). MS (APCI (−)): *m*/*z* relative intensity (95, [M − H]$^-$ = 230.1.

*Pentafluorophenyl Ester of 5-Boc-amino Levulinic Acid (**6**).* Under argon atmosphere, pentafluorophenol (2.7 g, 14.27 mmol, 1.1 equiv) was added to **5** (3 g, 12.97 mmol, 1 equiv) in 50 mL of CH_2Cl_2 at 0 °C, followed by 3 g of DCC (14.54 mmol, 1.12 equiv). The reaction was brought to room temperature and kept at room temperature overnight. The reaction mixture was filtered over celite and evaporated. The thick yellow, oily mass obtained was triturated with hexane to remove excess of pentafluorophenol. A white solid was obtained by filtration and dried to give 5.1 g of **6** (98%). R_f (CH_2Cl_2/EtOAc 95:5): 0.33 (UV_{254} active; $KMnO_4$). Biology. *Cell Cultures.* Human carcinoma colon (HT-29, SW480), breast (MCF-7, T47D), and lung (A549) cells were obtained from the ATCC (American Tissue type Culture Collection, Manassas, VA, USA). Human HCEC endothelial cells were a kind gift of D. Stanimirovic, Ottawa, Canada, and human VS59, SS77, GE80 and GS78 primary fibroblasts were obtained from surgical biopsies using the explant technique (*32*), according to a protocol approved by the CHUV Ethics Committee and patients. All cells were routinely grown in DMEM medium containing 4.5 g/L glucose, 10% fetal calf serum (FCS), and antibiotics (all from Gibco, Basel, Switzerland).

Evaluation of PpIX Production from Glycoside Esters of ALA. The quantification of PpIX production in living cells loaded with photosensitizers was performed as previously described (*9*, *10*). Briefly, confluent cultures of cells in 48 well plates (Costar) were exposed at 37 °C to ALA conjugates in 4.5 g/L glucose DMEM medium without FCS and without phenol red (Gibco) in a thermostatted fluorescence microplate reader (Cytofluor, PerSeptive BioSystems), Fluorescence of samples was measured kinetically at excitation and emission wavenlengths specific for PpIX ($\lambda_{ex}/\lambda_{em}$ = 409 nm/645 nm, respectively), essentially as previously described (*9*, *10*). Alamar Blue reduction was used to quantify metabolically active cells. Briefly, 24 h after the addition of glycoside-ALA, the PpIX fluorescence in the cell layer was measured, then cells were exposed at 37 °C to Alamar Blue solution (10% final concentration, Serotec, Düsseldorf, Germany) added to the cell culture medium without medium change and fluorescence increase was recorded 2 h later in a fluorescence microplate reader (Cytofluor) at $\lambda_{ex}/\lambda_{em}$ = 530 nm/580 nm, respectively.

Fluorescence Microscopy. SW480 cells were grown on histological slides in complete medium until 25% confluent, then 1-α-Glc-ALA **8h** (2 mM or 4 mM) was added for a further incubation of 24 h. Slides were washed in PBS and either directly analyzed in PBS or incubated with the nuclear stain 4′,6′-diamidino-2-phenylindolylhydrochloride (DAPI, Roche Diagnostics, Mannheim, Germany, 1 μg/mL in PBS) for 10 min at 37 °C, washed with PBS, and examined under a fluorescence microscope in PBS (Axioplan2, Carl Zeiss, Feldbach, Switzerland) and filters set at 365 nm excitation light (BP 365/12, FT 395, LP 397) for DAPI and 535 nm excitation light (BP 510–560, FT 580, LP 590) for PpIX.

Photodynamic Therapy on Cells in Cultures. Confluent SW480 cells in 96 well plates (Costar) were incubated in complete medium with 2 mM of glycoside esters of ALA for 24 h in the dark. Culture medium was replaced by DMEM containing 5% FCS without phenol red (Gibco) and cells were illuminated with a laser at λ = 635 nm (laser diode Ceralas 635, Biolitec GmbH, Jena, Germany) and with a frontal diffuser (Medlight SA, Ecublens, Switzerland), at an irradiance of 17 mW/cm^2 and light doses ranging between 1 and 10 J/cm^2. Cell survival was assessed with Alamar Blue assay 24 h after the end of the irradiation. The LD_{50} (light dose necessary to induce 50% inhibition of cell growth) were determined after linearization using a medium effect algorithm as described (*12*).

Inhibition of PpIX Production in SW480 Cells by Free or 1-Methoxy Analogues of Sugars. SW480 human colon carcinoma cells were grown in 48 well plates (Costar) until 75% confluent. Medium was replaced by 4.5 g/L glucose DMEM

medium without FCS and without phenol red (Gibco) containing the competitive agent (D-glucose, D-mannose, D-galactose, 1-MeO-galactose (Sigma), 1-MeO-glucose, or 1-MeO-mannose (Fluka), 1–1000 mM) for 1 h at 37 °C. Then, glycoside esters of ALA were added at 1 mM final concentration and PpIX fluorescence of samples was measured in a fluorescence microplate reader (Cytofluor) after 24 h. Cell viability was measured using the Alamar Blue assay.

Inhibition of PpIX Production in A549 Cells by Specific Glycosidase Inhibitors. A549 human lung carcinoma cells were grown in 48 well plates (Costar) until 75% confluent. Medium was replaced by 4.5 g/L glucose DMEM medium without FCS and without phenol red (Gibco) containing the glycosidase inhibitors 1-deoxynojirimycin, 1-deoxymannojirimycin, and castanospermine (Tocris, Ellisville, MO, USA) at 0.5–10 mM. After 1 h at 37 °C, the glycoside esters of ALA were added at 1 mM final concentration and PpIX fluorescence of samples was measured in a fluorescence microplate reader (Cytofluor) after 24 h. Cell viability was measured using the Alamar Blue assay. The inhibitory effect of the inhibitors on glucosidase and mannosidase activities was controlled with their respective 4-methylumbelliferyl-glycoside substrates in intact living cells using methods adapted from previously described protocols for α-mannosidase activity in cell extracts and for peptidases activities in intact living cells (*23, 33*) (data not shown).

Calculations of Results. Each experiment was repeated in triplicate wells at least twice. Means and standard deviation were calculated.

RESULTS

Syntheses of the Glycoside Esters of ALA. Boc-protected 5-aminolevulinic acid (5-Boc-ALA) **5** or activated esters of 5-Boc-ALA **6** and **7** were used as starting material to synthesize glycoside esters of ALA, since preliminary results have shown that these protected derivatives of ALA not only facilitate the purification by column chromatography of the final products, but also improve the yield of ALA coupling to sugars. The syntheses of 5-Boc-ALA **5** in four steps from levulinic acid **1** and of activated pentafluorophenyl and trichloroethyl esters of 5-Boc-ALA, respectively, **6** and **7**, in one step from 5-Boc-ALA **5** are described in Scheme 2.

The synthesis of 6′-*O*-ALA conjugates of sugars **8c**, **9c**, and **10c** was performed according to Scheme 3. The regioselective synthesis of **8c**, **9c**, and **10c** was carried out by enzymatic transesterification of the activated esters **6** and **7** (*34, 35*). Proper combination of enzymes and the activated esters ensured regioselective esterification of sugars on the primary hydroxyl group. Deprotection of 6′-*O*-(Boc-ALA)-glycosides **8b**, **9b**, and **10b** yielded the 6′-*O*-(ALA)-α/*β*-D-Glc **8c**, 6′-*O*-(ALA)-α-D-Man **9c**, and 6′-*O*-(ALA)-*β*-D-Gal **10c** in good overall yield (>40%) and partial selectivity at the anomeric center (Table 1).

The synthesis of 1′-*O*-ALA conjugates of sugars **8h**, **9h**, and **10i** was performed according to Scheme 4. The regioselective synthesis of **8h**, **9h**, and **10i** was carried out using Boc-ALA **5** and benzyl protection/deprotection methodology. Sugars protected by benzyl groups on all the hydroxyl groups except on the anomeric hydroxyl group (C1) were synthesized according to published procedures (*36*). Then, the free hydroxyl group at C1 was esterified with 5-Boc-ALA **5** using catalytic DMAP and DCC coupling method to obtain the α anomer and using DMAP and EDCI coupling method to obtain the *β*-anomer (*37,38*). Then, the *O*-benzyl protecting groups of the sugars were deprotected using standard catalytic hydrogenation, followed by the removal of the Boc protecting group of ALA under standard acidic conditions to obtain 1′-*O*-(ALA)-α-D-Glc **8h**, 1′-*O*-(ALA)-α-D-Man **9h**, and 1′-*O*-(ALA)-*β*-D-Gal **10i** in modest overall yield (<20%) but in good purity at the anomeric center (Table 1).

The synthesis of 1-*O*-(ALA)-2-*O*-(glycosyl) ethylene glycol **8k**, **9k**, and **10n** (where ALA is linked to the glycosides via an ethylene glycol linker) (*38*) was performed according to Scheme 5. The syntheses of 1-*O*-(α-D-Glc) ethylene glycol **8i** and 1-*O*-(α-D-Man) ethylene glycol **9i** were carried out using standard Fischer glycosidation to get predominantly the α-anomers (*40–42*). The synthesis of 1-*O*-(*β*-D-Gal) ethylene glycol **10l** was carried out using standard Koenigs−Knorr synthesis (*43*) to get predominantly the *β*-anomer. The regioselective acylation of the 1-*O*-(glycosyl)-2-*O*-ethylene glycol **8i**, **9i**, and **10l** was carried out using the enzyme *Candida antarctica* lipase which acylates mainly at the glycol moiety (*44*). Following deprotection of the Boc protecting groups of the 1-*O*-(Boc-ALA)-2-*O*-(glycosyl) ethylene glycol **8j**, **9j**, and **10m**, 1-*O*-(ALA)-2-*O*-α-D-Glc ethylene glycol **8k**, 1-*O*-(ALA)-2-*O*-α-D-Man ethylene glycol **9k**, and 1-*O*-(ALA)-2-*O*-*β*-D-Gal ethylene glycol **10n**, respectively, were obtained in modest overall yield (<20%) but in good purity at the anomeric center (Table 1).

Evaluation of the Glycoside Esters of ALA in Cells. PpIX production induced from all the synthesized glycoside esters of ALA at increasing concentrations was evaluated (Supporting Information Figures S1, S2, and S3 for the 1-*O*-(ALA)-2-*O*-(glycosyl) ethylene glycol **8k**, **9k**, and **10n**, not shown for the other analogues) in human colon (HT-29, SW480), breast (MCF-7, T47D), or lung (A549) carcinoma cell lines, human HCEC endothelial cells, as a model for angiogenic endothelium, and in human normal fibroblasts (*32*) (VS59, SS77, GE80, or GS78) as models for non-tumor-associated cells. From these experiments, a 2 mM concentration was chosen for direct comparison between cells and between the glycoside esters of ALA. The time-dependent production of the fluorescent photosensitizer PpIX induced by the glycoside esters of ALA and ALA as a reference molecule was determined for 24 h of continuous exposure to the precursor. Cytotoxicity in the dark (no exposure to laser light) was evaluated 24 h after the addition of the prodrugs, using the Alamar Blue assay which evaluates biosynthetic activity in living cells (Figure 1, human colon SW480 and lung A549 tumor cells and nontumoral HCEC endothelial cells and VS59 fibroblasts, Supporting Information Figure S4 for the human breast T47D and colon HT-29 tumor cells). All human tumor cells and the HCEC endothelial cells synthesized PpIX from all derivatives at levels comparable to ALA (See Supporting Information Table S1), whereas human fibroblasts produced only very low levels of PpIX for all precursors, including free ALA. The nature of the sugar or the position of the substitution (positions O-1 or O-6) exerted only minor influence on cellular PpIX production, whereas the intercalation of an ethylene glycol linker generally resulted in a slower or decreased synthesis of PpIX by cells.

The SW480 human colon and A549 human lung carcinoma cells were chosen as model cells for further evaluations. In order to confirm intracellular localization of PpIX production, the specific fluorescence of PpIX was visualized by fluorescence microscopy in SW480 cells grown on histological slides and exposed for 24 h to 1-α-Glc-ALA **8h** (Figure 2). When exposed to a laser light of 635 nm wavelength which corresponds to the PpIX last Q-band of absorption, all glycoside esters of ALA were effective in inducing phototoxicity in SW480 cells which produce identical amounts of PpIX from all ALA conjugates of sugars (Figure 1), with an LD_{50} (light dose necessary to induce 50% inhibition of cell growth) between 2.3 and 4 J/cm^2 (Figure 3), comparable to ALA.

In order to define which part of the bioconjugate, either the glycoside or the ALA moieties, was responsible for cell uptake, we exposed SW480 cells to high concentrations of free glucose

or 1-*O*-methoxy glucose, and measured PpIX production (Figure 4 and Supporting Information Figure S5 for mannose and galactose evaluation). The presence of the competitive sugars did not affect the induced PpIX production by cells for all the glycoside esters of ALA. In order to determine whether esterase or glycosidase activities were responsible for the release of free ALA from the sugar, we inhibited cellular glucosidases with the specific α-glucosidase inhibitors castanospermine and 1-deoxynojirimycin (Figure 5), or the specific α-mannosidase inhibitor 1-deoxymannojirimycin (Supporting Information Figure S6), and measured PpIX production. No effects of these inhibitors were observed on PpIX production. When cells were exposed to the 4-methyl-umbellifery-α-glucose and 4-methyl-umbellifery-α-mannose substrates of α-glucosidases and α-mannosidases in the presence of these inhibitors, inhibition of these enzymatic activities was observed (results not shown).

DISCUSSION

In phototodynamic therapy, photosensitizers can be added topically, not only on the skin, but also in hollow organs such as the bladder or in the kystic structures of neoplasic and inflammatory diseases, or by painting the surface of the diseased areas, under the condition that the photosensitizers can be maintained long enough in this location. Applying photosensitizers systemically results in a bodywide distribution, unless the photosensitizers can be made cell-selective by preparing analogues of photosensitizers with a targeting moiety or incorporating photosensitizers into nano/microstructures such as particles or dendrimers (*11*). However, even under these conditions, the photosensitizer will mainly encounter the cells of the blood vessels and the circulating cells. In cancer, it is accepted that tumor cells and cells of the vascular wall, in particular, proliferating endothelial cells, express more transporters for nutrients, including carbohydrates, than quiescent cells. In this project, we focused more on the possibility to use a sugar prodrug of ALA as the precursor of the photosensitizer PpIX and/or as a means to enhance cell selectivity or cell uptake than on the mode of administration of photosensitizers, either topical or systemic.

In this manuscript, we report the first synthesis and characterization of anomerically pure ALA derivatives functionalized with hexose moieties. All the human carcinoma cells tested, from colon, breast, or lung origin, and the proliferating angiogenic HCEC endothelial cells synthesized PpIX from all conjugates prepared, at levels comparable to ALA, whereas human normal fibroblasts produced only very low levels of PpIX from all precursors. Therefore, the results presented here demonstrate that ALA conjugates of sugars are effective precursors of the photosensitizer PpIX and have the potential to be used in PDT protocols to treat tumor cells and the tumor-associated angiogenic endothelial cells while sparing nontumoral cells, such as fibroblasts. The nature of the sugar or the position of the substitution by ALA (positions O-1 or O-6) exerted only a minor influence, whereas the intercalation of an ethylene glycol linker generally resulted in a slower or decreased synthesis of PpIX. Using ethylene glycol linkers in glycoconjugated porphyrins, the length and nature of the linker was found to be an important factor for cellular uptake of porphyrin analogues by retinoblastoma cells (*25*). We had previously observed that ethylene glycol esters of ALA increased PpIX production by cells; however, the kinetics of cell uptake suggested free diffusion of these organic esters across the cell membrane (*9*). This information suggests that in the glycoside−ethylene glycol esters of ALA the ethylene glycol moiety, and its position between the sugar and ALA, is not determining for cell uptake of the conjugates.

Our approach did not allow us to distinguish whether these glycoside esters of ALA are transported intact inside cells, and then ALA is released intracellularly from these prodrugs acting as substrates for cellular glycosidases or esterases, or whether they are activated extracellularly, and then free ALA is transported inside cells. Competition studies with free or 1-*O*-methoxy analogues of the sugars had no effects on PpIX production. Moreover, similar levels of PpIX production by cells was observed between free ALA and the glycoside esters of ALA irrespective of the position of functionalization and the nature of the sugar. These observations strongly suggest an uptake mechanism able to recognize the ALA moiety rather than the sugar part of the conjugates. Inhibition studies with glycosidase inhibitors suggest the involvement of esterases rather than glycosidases in the release of ALA from the glycoside esters of ALA. This hypothesis is further supported by the slower production of PpIX induced by ethylene glycol ALA conjugates of sugar esters compared to the absence of the ethylene glycol linker. As we have previously shown that ALA−ethylene glycol esters are metabolized much more rapidly than ALA to PpIX, likely as the result of an increased passive diffusion of these esters across the cell membrane, compared to an active transport of ALA (*9*), we hypothesize that the initial activation of the glycoside−ethylene glycol esters of ALA prodrugs are enzymaticaly performed at the ethylene glycol−ALA bond and not at the glycoside−ethylene glycol bond. Such a hydrolytic step at the glycoside−ethylene glycol bond would have produced ethylene glycol−ALA esters, with a concomitant increased uptake and enhanced PpIX production by cells. It has also been shown by others that cancer cells are able to cleave ethylene glycol ether of sugars at the O-1 position from glycoconjugated porphyrins (*25*) or chlorins (*24*).

In conclusion, our ALA prodrugs may be precursors of the photosensitizer PpIX, but will not enhance cell selectivity; however, they may increase the residence time of the drugs at the surface of cells. Thus, these prodrugs may be more interesting for topical administration in conjunction with painting of the surface of diseased areas than for systemic administration. Glycoside esters of ALA are more efficient precursors of intracellular PpIX production in cancer cells or cancer-associated angiogenic endothelial cells than in normal human fibroblasts. As they are able to induce phototoxicity in the target cells when exposed to light, they can be effective in PDT of cancer. These prodrugs are more likely activated by esterases rather than by glycosidases and do not seem to use glycoside cell membrane transporters for cell uptake. The advantage of glycoside esters over esters of aliphatic alcohols resides in the release of an innocuous glycoside compared to a potentially toxic aliphatic alcohol following hydrolysis by esterases.

Characterization of Multilayered Nanoparticles Encapsulated in Yeast Cell Wall Particles for DNA Delivery

Ernesto R. Soto and Gary R. Ostroff*

Program in Molecular Medicine, University of Massachusetts Medical School, 373 Plantation Street, Worcester, Massachusetts 01605. Received August 28, 2007; Revised Manuscript Received January 22, 2008

Nonviral gene delivery technologies have been developed using layer-by-layer self-assembly of nanomaterials held together by electrostatic interactions in order to provide nanoparticulate materials that protect and deliver DNA to cells. Here we report a new DNA delivery technology based on the in situ layer-by-layer synthesis of DNA nanoparticles caged within hollow yeast cell wall particles (YCWP). YCWP provide protection and facilitate oral and systemic receptor-targeted delivery of DNA payloads to phagocytic cells. The nanoparticles inside YCWP consist of a core of tRNA/polyethylenimine (PEI) followed by a DNA layer that is finally coated with a protective outer layer of PEI. Using fluorescein and rhodamine labeling of tRNA, PEI, and DNA, the layer-by-layer formation of the nanoparticles was visualized by fluorescent microscopy and quantitated by fluorescence spectroscopy and flow cytometry. Optimal conditions (tRNA:YCWP, PEI:YCWP ratios and DNA load levels) to synthesize YCWP encapsulated nanoparticles were determined from these results. The high in vitro transfection efficiency of this encapsulated DNA delivery technology was demonstrated by the transfection of NIH3T3-D1 cells with YCWP-tRNA/PEI/gWizGFP/PEI formulations containing low amounts of the plasmid gWizGFP per particle to maximally express green fluorescent protein (GFP).

INTRODUCTION

An ideal DNA delivery system needs to meet three criteria: (1) it should protect DNA against nuclease degradation, (2) it should deliver the DNA through the plasma membrane and into the nucleus of target cells, and (3) it should have minimal detrimental effects (*1, 2*). Viral vectors are able to mediate efficient gene transfer with long-term gene expression but are limited by safety concerns of an acute immune response, immunogenicity, and insertional mutagenesis. Numerous strategies have been developed to accomplish nonviral mediated DNA delivery including, naked DNA, physical methods (gene gun (*3*), electroporation (*4*), hydrodynamic delivery (*5*), ultrasound (*6*)), chemical methods (liposomes, nanoparticles and microparticles composed of cationic lipids (*7*) and polymers *8, 9*), and DNA incorporation into cell ghosts, such as bacterial cells (*10*) and erythrocytes (*11, 12*). Although significant progress has been made in the development of nonviral gene delivery systems, the majority of the nonviral approaches remain significantly less efficient than viral vectors.

The formation of stable complexes between negatively charged genetic material and cationic polymers is the most commonly studied approach to develop nonviral delivery agents. The work of several groups has focused on synthesizing and characterizing a range of cationic polymers to provide the effective DNA condensation necessary to prevent degradation of the genetic material in negatively charged nanoparticles capable of DNA delivery into cells. Once inside the cells, these nanocomplexes should be capable of releasing DNA, and the toxicity of the free cationic polymer must be minimal. Polyethylenimine (PEI) has proven to be one of the best cationic polymers for nanocomplex formation with DNA and provides good transfection efficiencies; however, PEI is toxic to cells, thus limiting the concentration range that can be used (*1, 2, 13–15*). Ongoing work by many groups is seeking to identify cationic polymers with equal or better transfection efficiency as PEI but with reduced toxicity (*15–23*).

The layer-by-layer (LbL) self-assembly of materials held together by electrostatic interactions is a facile method for the fabrication of nanomaterials with potential applications in gene therapy (*1, 13, 14, 24, 25*). This has been demonstrated by LbL deposition of DNA and cationic polymers on different templates to fabricate colloidal particles (*14, 26–31*). For example, silica, polystyrene, or gold nanoparticles and biological materials have been used as templates in combination with different synthetic polymers and biopolymers. These multilayer coated particles have been studied as multifunctional carriers of biological materials, such as DNA and enzymes, by two different methods. One approach incorporated the delivery material as part of the multilayered structure (*14, 26*). A second method used removable cores to encapsulate the material inside the remaining hollow polyelectrolyte shell (*32*). Both methods require that efficient defoliation of the polyelectrolyte layers occurs within cells. The goal of producing delivery agents that are non-toxic, capable of efficiently protecting DNA, and undergoing defoliation to release DNA inside the cells has proven challenging, and an ideal gene delivery system remains elusive.

A new gene delivery system has been developed on the basis of the use of yeast cell wall particles (YCWP) (*33, 34*). YCWP are hollow and porous 2–4 μm microspheres prepared from Baker's yeast composed primarily of β-1,3-D-glucan and chitin, and in some forms, mannoproteins. This encapsulation system incorporates polyelectrolyte−DNA nanoparticles caged within the YCWP to provide for efficient intracellular DNA delivery and release and gene expression. Formation of the YCWP encapsulated polyelectrolyte nanoparticles follows a LbL approach, with the different components assembled through electrostatic interactions.

The advantages of the YCWP DNA delivery system include high DNA capacity, multiplexable DNA, protein, and siRNA delivery, oral bioavailability, β-1,3-D-glucan receptor targeting

to macrophages and dendritic cells, and cell trafficking to the reticuloendothelial system and sites of pathology (*33–35*).

Characterization of LbL structures on planar 2D or 3D surfaces is possible by a variety of techniques (*36–39*), but most of these techniques are not amenable to characterize multilayered structures inside YCWP. The quantitative characterization of YCWP encapsulated polyelectrolyte nanoplex formation within YCWP was approached by selectively labeling each layer of the multilayered nanocomplex with fluorescent markers to optimize experimental conditions for preparation of these complexes inside YCWP. Evaluation of the different layers inside the YCWP was characterized by qualitative fluorescent microscopy and quantitative fluorescent spectroscopy and flow cytometry.

In this communication the LbL formation and characterization of nanoparticles synthesized inside YCWP is described leading to the optimization of this DNA delivery system for in vitro mammalian cell transfection.

EXPERIMENTAL PROCEDURES

Materials. Ribonucleic acid from Torula yeast, type VI, (tRNA); high molecular weight water-free branched PEI (25 kDa); DNA sodium salt from Salmon testes (DNA); and rhodamine B isothiocyanate were purchased from Sigma Aldrich (Allentown, PA) and used as received. 5-([4,6-Dichlorotriazin-2-yl]-amino)fluorescein monohydrochloride (DTAF) was purchased from Research Organics Inc. (Cleveland, OH). Solvents and buffer solutions were purchased from Sigma Aldrich or VWR and used without further purification.

Methods. *Rhodamine and Fluorescein Labeling of Nucleic Acids.* DNA or tRNA (10 mg) was dissolved in 10 mL of 5 mM EDTA. The material was sonicated until viscosity was lost, and 1.2 mL of 0.1 M carbonate buffer (pH 9.2) was added. DTAF or rhodamine at a concentration of 1 mg/mL in DMSO was added to the buffered DNA solution (10% v/v), and the solution was stirred at room temperature in the dark overnight. Tris buffer (2 mL, 1 M, pH 8.3) was added and the reaction mixture stirred for additional 15 min at room temperature to quench free fluorescent labeling reagent. Sodium chloride (1 mL of 1 M aqueous NaCl) and ethanol (30 mL) were added to the solution and incubated at −20 °C until a colored precipitate appeared. The precipitate was collected by centrifugation and washed with 70% ethanol until the supernatant was clear. The solid was dried and dissolved in water at a 10 mg/mL concentration and stored at 4 °C in the dark. The amount of fluorescent probe bound to each nucleic acid was determined spectrophotometrically by adsorption at 495 nm (DTAF) or 540 nm (rhodamine). The labeled DNA contains ∼2.3 ± 0.3% (w/w) of rhodamine and 5.9 ± 1.7% (w/w) of DTAF. tRNA was labeled with ∼0.15 ± 0.05% (w/w) of rhodamine and 0.6 ± 0.1% (w/w) of DTAF.

Rhodamine and Fluorescein Labeling of PEI. PEI was labeled following a similar procedure used for labeling of DNA and tRNA, with the following changes: PEI was dissolved in 5 mM EDTA at a concentration of 3 mg/mL. Rhodamine and DTAF were used at a concentration of 1 mg/mL in DMSO. After incubation with Tris buffer, 1 M NaCl was added (1 mL for each 10 mL of initial PEI solution). The product was purified by dialysis against water and lyophilized. Spectrophotometric characterization of the labeled PEI showed that the final product contains ∼3.1 ± 0.3% (w/w) of rhodamine and 5.7 ± 0.1% (w/w) of DTAF.

Preparation of YCWP (33). YCWP consist of two classes: glucan particles (GP) and glucan mannan particles (GMP). GP were prepared by suspending *Sacharomyces cerevisiae* (100 g of Fleishmans Bakers yeast, AB Mauri Food Inc., Chesterfield, MO) in 1 L of 1 M NaOH and heating to 80 °C for 1 h. The insoluble material containing the yeast cell walls was collected by centrifugation at 2000 × *g* for 10 min. This insoluble material was then suspended in 1 L of water, brought to pH 4–5 with HCl, and incubated at 55 °C for 1 h. The insoluble residue was again collected by centrifugation and washed once with 1 L of water, four times with 200 mL of isopropanol, and twice with 200 mL of acetone. The resulting slurry was placed in a glass tray and dried at room temperature to produce 12.4 g of a fine, slightly off-white powder.

GMP were prepared by suspending *S. cerevisiae* cell walls (75 g SAF-Mannan, SAF Agri, Milwaukee, WI) in 1 L of water, and the pH was adjusted to 12–12.5 with 1 M NaOH and heating to 60 °C for 1 h. The insoluble material containing the cell walls was recovered by centrifuging at 2000 × *g* for 10 min. This material was then suspended in 1 L of water, brought to pH 4–5 with HCl, and incubated at 55 °C for 1 h. The insoluble reside was recovered by centrifugation and washed once with 1 L of water, four times with 200 mL of dehydrated isopropanol, and twice with 200 mL of acetone. The resulting slurry was placed in a glass tray and dried at room temperature to produce 15.6 g of a fine, slightly off-white powder.

Preparation of GP and GMP Encapsulated Cationized Cores. Dry GP or GMP were mixed with a volume of the anionic core polymer tRNA (10 mg/mL in 50 mM Tris HCl pH 8, 2 mM EDTA, and 0.15 M NaCl (TEN)) to minimally hydrate the particles and incubated for 2 h to allow the particles to swell and adsorb the tRNA solution. Neutral PEI (2 mg/mL in TEN) was added in excess to form GP or GMP encapsulated tRNA polyplexes, and the particles were resuspended by homogenization or sonication. PEI adsorption and nanocomplex formation was allowed to proceed for at least 1 h. The suspension was centrifuged, and particles were resuspended in 70% ethanol to sterilize the particles and then washed three times in 0.9% saline, resuspended, counted with a hematocytomer, diluted to 1×10^8 particles/mL in 0.9% saline, and stored at −20 °C.

Preparation of GP or GMP Encapsulated Cores with DNA/PEI Coated Nanocomplexes. The binding of a DNA layer to the cationized nanoplexed cores inside GP or GMP was accomplished by preparing a suspension of GP or GMP encapsulated tRNA/PEI cores (1×10^8 particles/mL), DNA and saline solution (total volume = 75 μL). The suspension was incubated for 2 h to allow for DNA binding to the cationic nanoparticle surface, and neutral PEI (25 μL 0.01% w/v) in 0.9% saline was added to coat the DNA bound to the cationized nanoparticulate surface.

Fluorescence Assays. Fluorescence characterizations were carried out for each layer of the nanoplex delivery system by preparing YCWP samples containing one fluorescently labeled layer. The samples were prepared over a range of tRNA:YCWP and PEI:YCWP ratios and DNA concentrations to determine the optimal concentration for each layer. Fluorescence measurements were obtained with a Spectra Max Gemini XS plate reader (Molecular Devices, Union City, CA) using the SoftMax Pro v 5.0.1 software. Rhodamine fluorescence measurements were obtained at 573 nm after excitation at 540 nm, and the final fluorescence result was the average of nine measurements. The samples were mixed for 5 s before measurement. To avoid error introduced by light scattering produced by the particles, control measurements were obtained with a sample containing the same amount of particles/mL without any fluorescent compound. The final fluorescence results were corrected by subtracting the response for the control samples from the YCWP encapsulated fluorescent nanoplex samples. The amount of any particular fluorescent compound bound contained within the YCWP was determined from the fluorescence response using calibration

Table 1. Chemical Composition of YCWP (*42*)

curves obtained by measuring the fluorescence of each rhodamine labeled material in solution over a linear response range.

Fluorescence Microscopy. An Arcturus fluorescence microscope was used to acquire fluorescent photomicrographs and to score transfection results for the Green Fluorescent Protein (GFP).

Flow Cytometry (FACS). FACS measurements were obtained with a Becton Dickinson FACSCalibur instrument (BD, Franklin Lakes, NJ). Samples were prepared for FACS analysis at a concentration of 2×10^6 particles/mL in PBS. Unmodified GP and GMP particles were used as negative controls, and GP particles chemically modified with rhodamine were used as the positive control. The particles were analyzed with an FL2 laser (570–610 nm) by collecting 20000 measurements. Gating and analysis was performed using FlowJo 6.4.2 software.

Transfection Experiments. YCWP-tRNA/PEI (10 μL, 1×10^8 particles/mL) suspensions were mixed with the indicated amount of gWizGFP plasmid DNA (Genlantis, San Diego, CA) over a concentration range of 0.01 to 0.1 μg/μL, and 0.9% saline solution was added to bring the total volume to 75 μL. DNA was bound to the YCWP-tRNA/PEI cationic nanoparticle surface for 2 h at room temperature. Then, 25 μL of 0.01% neutral PEI in 0.9% saline was added to coat the DNA surface for 20 min. Dulbecco's modified Eagle's medium (DMEM medium with 10% fetal calf serum, 1% penicillin-streptomycin, and 1% glutamine) was added and the final mixture transferred to 24-well plates containing $1-5 \times 10^5$ cells/well of the murine fibroblast cell line NIH3T3-D1 (*35, 40, 41*). The plates were incubated at 37 °C under 5% CO_2 overnight, the medium was changed, and the plates were incubated for an additional 16–24 h. After 40–48 h, the medium was removed, and the cells were washed once with phosphate buffer saline (PBS), fixed with 250 μL of 0.5% formalin in PBS, and scored for GFP expression by manual counting of the proportion of fluorescent cells following visualization with a fluorescence microscope.

Evaluation of YCWP and YCWP Encapsulated DNA Formulation Toxicity. YCWP-tRNA/PEI (10 μL, 1×10^8 particles/mL) suspensions were mixed with gWizGFP plasmid DNA and PEI following the transfection loading protocol. DMEM medium was added to the mixture and transferred to 24-well plates containing $1-5 \times 10^5$ NIH3T3-D1 cells/well. The plates were incubated at 37 °C under 5% CO_2 for 40–48 h. The medium was removed, and the cells were washed once with sterile PBS and treated with 0.5% trypsin-EDTA (Invitrogen, Carlsbad, CA; 20 μL of trypsin and 200 μL of PBS were added to each well). The contents of each well were collected by centrifugation (2500 rpm for 10 min), resuspended in 100 μL of 1:1 PBS−0.4% trypan blue (Mediatech, Herndon, VA), and counted using a hematocytometer to evaluate total cell number, and the viability was assessed by trypan blue exclusion.

RESULTS

YCWP are porous hollow 2–4 μm microspheres prepared from Baker's yeast composed primarily of β-1,3-D-glucan, mannoproteins, and chitin (Table 1). YCWP consist of two classes: GP and GMP. GP are composed primarily of β-1,3-D-glucan and low levels of chitin, whereas GMP contain both β-1,3-D-glucan and mannoproteins in the outer cell wall and low levels of chitin. Nanoparticulate cores composed of anionic and cationic polymers were constructed from tRNA and PEI within YCWP as described above (Figure 1a). These YCWP encapsulated cationic nanoparticulate cores were used to absorb DNA onto the cationized nanoparticulate surface and then coated with PEI to generate the YCWP DNA transfection formulations (Figure 1b).

Rhodamine labeled tRNA, DNA, or PEI were used to optimize the formation of each layer of the encapsulated nanoparticles. A calibration curve for each labeled compound was used to quantitate binding.

Optimization of the Synthesis of YCWP Encapsulated tRNA/PEI Nanoplex Cores by Fluorescent Component Analysis. The amount of fluorescent tRNA bound within the nanoplex cores inside 10^7 YCWP was evaluated at tRNA:YCWP ratios ranging from 0 to 0.25 as indicated in Table 2. Figure 2 shows the corresponding amount of tRNA in nanoplex cores that the fluorescence signal represents for each tRNA:particle ratio. The tRNA was efficiently incorporated into YCWP

9	3.75	375

encapsulated nanoplexes over the tRNA:particle ratio tested. GP particles were capable of incorporating more tRNA in nanoplexes than GMP particles likely due to their larger hollow internal cavity.

The amount of fluorescent PEI incorporated into the tRNA nanoplex cores inside 10^7 YCWP was measured at a constant tRNA:YCWP ratio of 0.01 using the formulation ratios shown in Table 3. The results of these studies shown in Figure 3 indicate that PEI was efficiently incorporated into the tRNA nanoplex cores up to a PEI:YCWP ratio of 0.1 (w/w). More PEI was bound to GMP particles at all ratios tested, likely due to cationic PEI binding to negatively charged mannoproteins in the GMP wall.

Optimization of the Formation of DNA/PEI Complexes on YCWP Encapsulated tRNA/PEI Nanocomplex Cores by Fluorescence Analysis. Optimized YCWP formulations of YCWP-tRNA/PEI with a tRNA:YCWP ratio of 0.05 and a PEI:YP ratio of 4 were used as the starting material for the preparation of samples containing fluorescently labeled DNA. Rhodamine labeled DNA was added to this formulation over the range of 0−100 μg DNA/1 × 10^6 particles. PEI was then added at a PEI:DNA ratio of 2.5 to coat the DNA layer and prevent the DNA from washing off the tRNA/PEI cationic core surface. Figure 4 shows the amount of DNA bound for samples that were prepared with sonicated salmon sperm DNA (~5 kDa). DNA was effectively bound (80 ± 10%) over the range of DNA concentrations tested. In comparison, high molecular weight DNA (>40 kDa) was less effectively bound (40 ± 15%), suggesting that the porous YCWP hydrocolloid shell partially

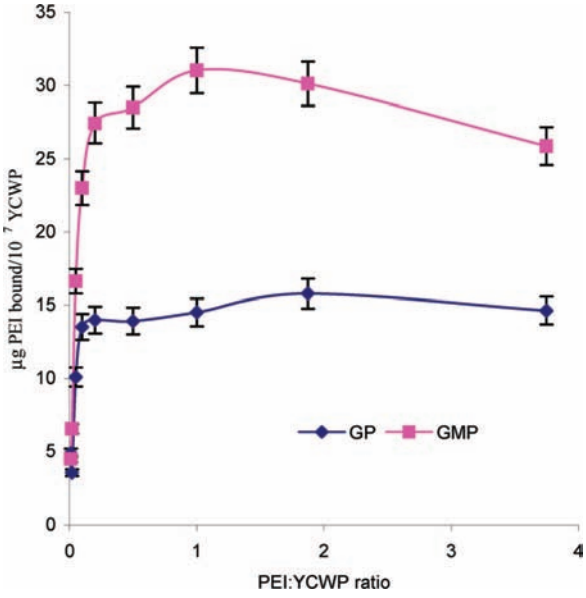

Figure 3. Fluorescent PEI (μg) bound to tRNA within YCWP to form nanoplex cores as a function of PEI loaded, at a constant tRNA:YCWP ratio of 0.01.

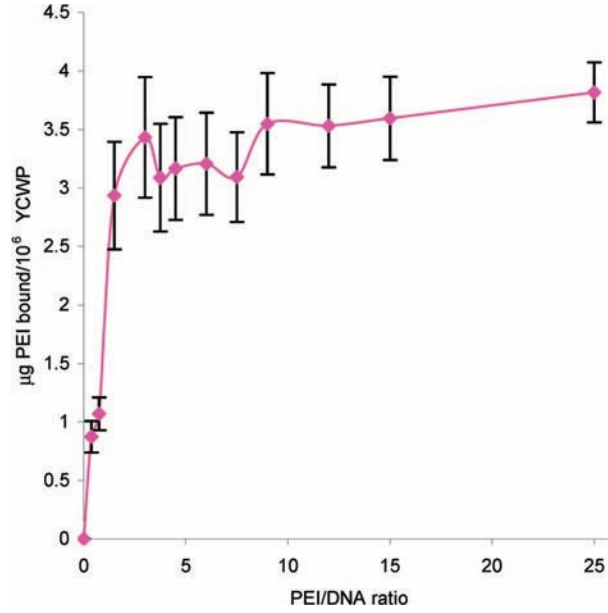

Figure 5. Amount of fluorescent PEI (μg) bound to YCWP-tRNA/PEI/DNA as a function of PEI loaded at a constant DNA load (10 μg of DNA) with a particle formulation of tRNA:YCWP ratio of 0.05 and PEI:YCWP ratio of 4 (w/w).

excludes the penetration of high molecular weight DNA molecules (data not shown). These results show the DNA binding capacity of plasmid sized DNA to be ~8 μg DNA/1 × 10^6 particles (~4 mg DNA/mg particles).

Optimization of the Final PEI Layer in the YCWP-tRNA/PEI/DNA/PEI Nanocomplex by Fluorescence Analysis. Coating of the DNA layer with a protective trapping polymer layer is important to stabilize the DNA and maximize transfection efficiency. The amount of fluorescent PEI bound to the DNA layer was measured at different DNA concentrations. It was determined that PEI adsorption reaches a maximum value at a PEI:DNA ratio higher than 3:1 (w/w) (Figure 5).

Flow Cytometry (FACS) and Fluorescence Microscopy. FACS measurements were obtained for different sets of titration experiments to quantitate tRNA, PEI, or DNA binding on a per

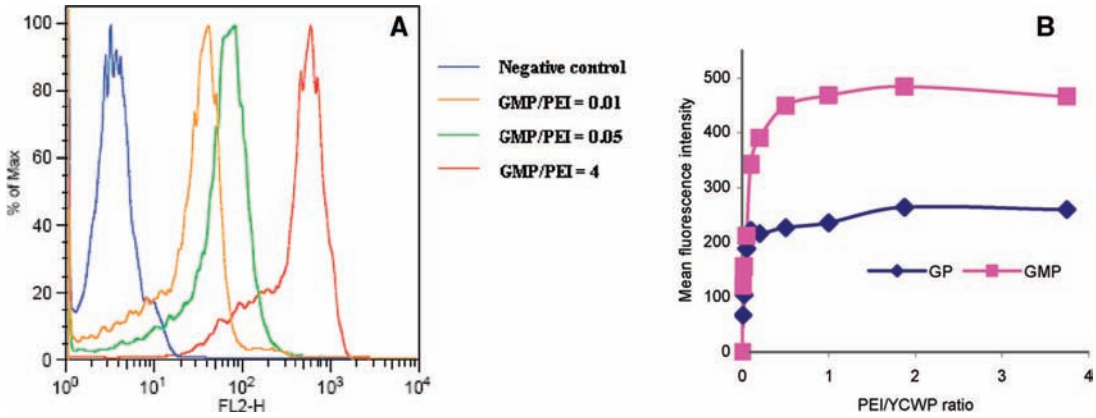

Figure 6. (A) FACS results showing the uniform increase of fluorescence from Rho-PEI bound to GMP-tRNA cores at different GMP:PEI ratios and (B) mean fluorescence intensity for Rho-PEI binding to both GP and GMP.

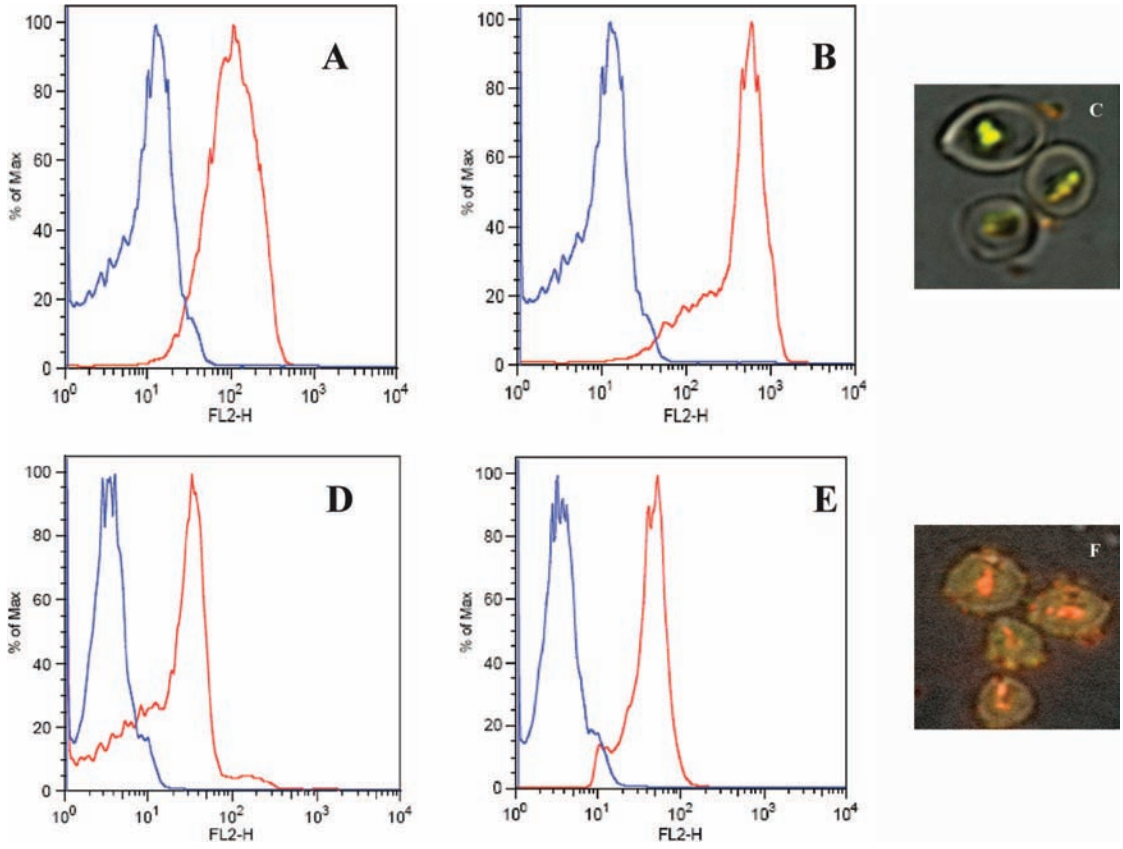

Figure 7. FACS results (blue lines indicate negative controls) and microscope images showing formation of nanoparticulate cores and adsorption of DNA/PEI complexes. (A) Rho-tRNA adsorbed into GMP at tRNA:GMP ratio of 0.1; (B) Rho-PEI bound to GMP-tRNA at a PEI:GMP ratio of 3.75; (C) overlay light/fluorescent microscopic image showing formation of nanoparticulate cores composed of DTAF-tRNA and Rho-PEI; (D) adsorption of 625 ng Rho-DNA to 10^6 GMP-tRNA/PEI particles; (E) adsorption of Rho-PEI to GMP-tRNA/PEI/DNA (25 μL of 0.01% Rho-PEI added to 500 ng of DNA); and (F) overlay light/fluorescent microscopic image of DNA/PEI nanocomplexes inside GMP showing Rho-DNA fluorescence.

particle basis and to assess the homogeneity of nanocomplex formation within YCWP. An example of this quantification is provided in Figure 6 for nanoparticle core formation. The FACS results (panel A) show that the fluorescence of Rhodamine labeled PEI bound to the GMP-tRNA core uniformly increases as the fluorescent PEI:GMP-tRNA ratio increases. In addition, a maximum fluorescence response of the same magnitude is observed for PEI:GMP or GP ratios greater than 1, confirming the bulk fluorescence measurements (panel B). Similar results were obtained for analysis of other layers (data not shown).

Figure 7 shows the maximum response for Rho-tRNA at GMP:tRNA ratio of 0.05 (panel A) and for Rho-PEI at a PEI:GMP ratio of 4 (panel B). Adsorption of both tRNA and PEI is further demonstrated by overlay fluorescent microscope images of particles containing nanoparticle cores labeled with two different fluorescent labels (Figure 7, panel C).

DNA binding to YCWP-tRNA/PEI nanocomplexes was evaluated on a per particle basis following fluorescent DNA binding by FACS. The FACS analysis (Figure 7, panel D) shows that >95% of the particles bind DNA. The formation of the final PEI layer of the YCWP-tRNA/PEI/DNA/PEI nanocomplexes was evaluated on a per particle basis following fluorescent PEI binding. The FACS analysis (Figure 7, panel E) shows that >85% of the particles bind PEI to levels detected by FACS analysis. Adsorption of both DNA and PEI on the nanoparticulate cores is shown by overlay fluorescent microscope images

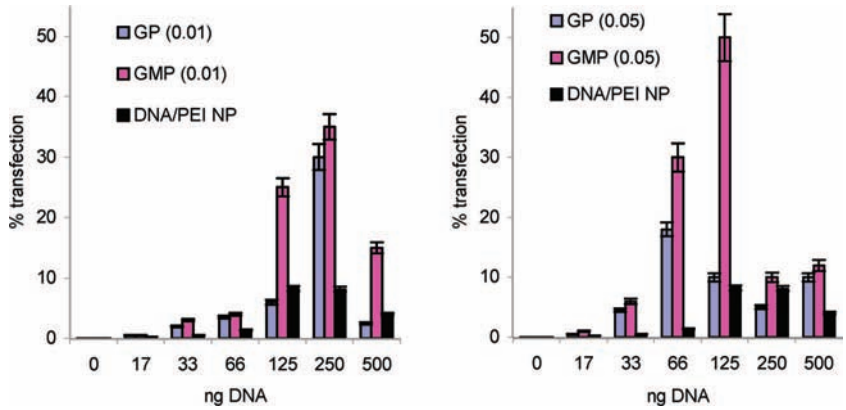

Figure 8. Transfection results for YCWP-tRNA/PEI particles with tRNA:YCWP ratios of 0.01 (left) and 0.05 (right) and a PEI:YCWP ratio of 4. Free DNA/PEI nanoparticles (NP) were used as control.

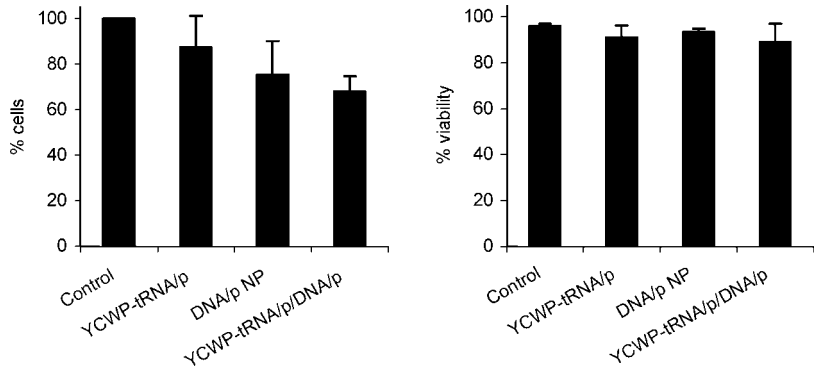

Figure 9. Toxicity of YCWP encapsulated cationic cores and YCWP encapsulated DNA formulations. Percentage of cells/well after 48 h of incubation normalized with respect to the control (left), and percentage of live cells/well after 48 h of incubation (right). Samples tested were saline control; YCWP encapsulated tRNA/PEI cationic cores; free DNA/PEI nanoparticles (NP); and YCWP-tRNA/PEI/DNA/PEI formulations used for transfection experiments.

with DNA and PEI labeled with two different colors (Figure 7, panel F), following a similar method to evaluate formation of the nanoparticulate tRNA/PEI core.

Transfection Results. Transfection experiments were carried out using NIH3T3-D1 cells. This cell line was derived from NIH3T3 by the integration of the dectin-1 gene to produce cells expressing the β-1,3-D-glucan receptor dectin-1 facilitating GP or GMP phagocytosis (*40, 41*). Several particle formulations using varied tRNA:YCWP ratios at a constant PEI:YCWP ratio of 4 were evaluated. Figure 8 shows the transfection results at different DNA loads for two formulations that consistently provided the highest transfection results.

YCWP Encapsulated Cationic Cores and YCWP Encapsulated DNA Formulation Toxicity. YCWP-tRNA/PEI cores and YCWP-tRNA/PEI/DNA/PEI formulations slow the growth rate of NIH3T3-D1 by ~20–30% compared to a saline control but have a negligible effect on cell viability (Figure 9). Free DNA/PEI nanocomplexes were evaluated as control showing an effect similar to that of the YCWP formulations. Excess PEI can be removed from YCWP-tRNA/PEI/DNA/PEI formulations by washing DNA/PEI layered preparations by centrifugation and resuspension in 0.9% saline to eliminate the growth inhibition (data not shown).

DISCUSSION

We have developed an efficient microparticle encapsulated nanoplex-based DNA delivery system through the solid-phase LbL synthesis of nanoparticles within carbohydrate microparticles YCWP. The advantages of the YCWP DNA delivery system include efficient DNA delivery, high capacity, multiplexable DNA, protein, and siRNA delivery, oral bioavailability, β-1,3-D-glucan receptor targeting to macrophages and dendritic cells, and cell trafficking to the reticuloendothelial system and sites of pathology (*33–35*).

YCWP are hollow and porous 2–4 μm microspheres prepared from Baker's yeast that have previously been demonstrated to serve as an antigen delivery system (*43*). The porous hydrocolloid shell is composed primarily of β-1,3-D-glucan, mannoproteins, and chitin and is typically <200 nm thick (Figure 1A) (*44*). YCWP consist of two classes; GP and GMP providing carbohydrate receptor-mediated targeting that facilitates oral uptake into gut associated macrophages and dendritic cells (*35*) and intracellular DNA delivery and gene expression in these cells (*34*). Formation of the polyelectrolyte nanocomplexes follows a LbL approach, with the different components assembled through electrostatic interactions (*45*).

The use of porous YCWP microcapsules as a carrier for transient gene expression therapy requires the formation of nanoparticulate cores within YCWP with the outmost layer being positively charged. This cationic layer can be used to electrostatically bind DNA to the positively charged core surface. The DNA is then coated with a second cationic polymer layer to protect the DNA.

An effective synthetic cationic polymer is PEI, a commercially available compound that has been used for gene delivery. PEI has a high positive charge that allows efficient condensation of anionic DNA. The presence of amines (only 15–20% are protonated at physiological pH) contributes to a proton−sponge mechanism, which is believed to mediate endosomal DNA release and be responsible for its high DNA transfection activity (*1, 9*). Other strategies previously reported to enhance transfection efficiency, used EndoPorter and hyalu-

ronic acid copolymers in the DNA layer to facilitate defoliation and endosomal DNA release, and Penetratin, a cationic peptide containing a nuclear localization signal to enhance DNA nuclear uptake (*34*).

To optimize the preparation of the nanocomplexes inside YCWP, we carried out a series of experiments to determine the conditions for maximal binding of each component in the encapsulated nanocomplexes. These studies used tRNA and PEI to form the nanoparticulate cores, DNA as the payload, and PEI to coat and protect the DNA payload caged inside the YCWP. Each of these polymers was fluorescently labeled with rhodamine, and fluorescence was used to quantify the binding of each layered component in the encapsulated nanocomplexes. Fluorescein labeled polymers were used to demonstrate colocalization of components in the encapsulated nanoplexes.

The first step was to characterize and optimize tRNA/PEI concentrations to maximize YCWP encapsulated nanocomplex core formation. In these experiments, YCWP encapsulated tRNA/PEI nanocomplexes were prepared at different PEI:tRNA ratios using rhodamine labeled tRNA. The fluorescence of YCWP encapsulated rhodamine labeled tRNA increased as a result of the formation of insoluble tRNA/PEI nanocomplexes within the YCWP. From these measurements it was determined that PEI:tRNA ratios of 5 or higher were necessary to optimally incorporate the tRNA into encapsulated nanocomplexes. At these ratios between 50 and 60% of the input tRNA was effectively encapsulated as nanoparticles in the YCWP. The results in Figure 2 show that it was possible to prepare YCWP encapsulated cationic nanocomplexes containing greater than 30 μg of tRNA nanoparticles per 200 μg of YCWP particles (1×10^8 particles).

To quantify PEI incorporation within the tRNA/PEI nanocomplexes inside YCWP, an optimal tRNA:YCWP ratio of 0.05 was chosen to prepare nanoplexed cores with different PEI:tRNA ratios. The results in Figure 3 show that the fluorescence of YCWP nanocomplexed cores prepared with labeled PEI reaches a saturation value at PEI:tRNA ratios as low as 5.

The use of FACS analysis allowed us to quantify tRNA and PEI binding on a per particle basis. The results for Rho-PEI incorporation in Figure 6 show a uniform increase in fluorescence with increasing Rho-PEI:YCWP-tRNA ratios demonstrating homogeneous nanocomplex formation within each YCWP. At a Rho-PEI:YCWP-tRNA ratio of 1 or higher the measured fluorescence reaches a constant value indicating the saturation value for PEI. These results support the experimental values for core formation determined from bulk fluorescence measurements (Figure 5).

The results from these studies allowed for the optimization of conditions to synthesize tRNA/PEI nanocomplex cores within YCWP to provide a sufficient cationic nanoparticle surface area for maximal DNA binding, while leaving enough space within the hollow YCWP for subsequent layers. Optimal conditions for nanoplex core formation required the use of tRNA:YCWP weight ratios between 0.01 and 0.05 and PEI:YCWP weight ratios higher than 0.5.

The next steps were to optimize DNA binding and PEI coating to form YCWP encapsulated tRNA/PEI/DNA/PEI multilayered nanocomplexes. It was observed that DNA must be used within an optimal concentration range to achieve high transfection efficiency, as high DNA levels did not necessarily translate to high transfection levels (*34*). It was also important to optimize the PEI formulation step to coat the DNA layer. PEI must completely coat the DNA layer to protect it from degradation before its release inside the cell. However, PEI is toxic, and its concentration should be minimized to reduce toxicity.

A YCWP-tRNA/PEI particle formulation with a tRNA:YCWP ratio of 0.05 and a PEI:YCWP ratio of 4 was used to quantify the amount of Rho-DNA that binds to the encapsulated nanoplex cores. It was found that Rho-DNA loosely binds to the cores and does not fully protect the DNA from enzymatic degradation as demonstrated by lower particle-associated fluorescence before PEI coating. Once PEI was used to coat the DNA layer, the percentage of DNA associated with the encapsulated cores increased to >80% (Figure 4) and the DNA was protected from enzymatic degradation ((*9,14*); data not shown). This high DNA load level of the YCWP DNA delivery system translates to the maximum delivery of $\sim 10^6$ plasmid molecules per YCWP.

A YCWP-tRNA/PEI particle formulation with a tRNA:YCWP ratio of 0.05, a PEI:YCWP ratio of 4, and a constant load of 10 μg of DNA/1×10^6 particles (DNA:YCWP ratio of 0.005**)** was used to quantify the amount of Rho-PEI coating of the encapsulated nanoplex cores loaded with a DNA payload. The results in Figure 5 show that PEI can be used at PEI:DNA ratios as low as 3:1 as the fluorescence response for Rhodamine-PEI trapped inside the particles reached a plateau at this PEI:DNA ratio. This PEI:DNA weight ratio of 3:1 is equivalent to an N/P ratio of $\sim$8. For 25 kDa branched PEI, a critical N/P ratio of 2.3:1 has been reported for formation of DNA/PEI nanoparticles (*46*), while N/P ratios of 6–8 are considered the minimum necessary for efficient DNA condensation and protection during DNA delivery to cells (*1*). Therefore, the required N/P ratio for DNA condensation within YCWP is found in the proper range reported by others for DNA/PEI nanoparticle formation.

The use of PEI as a nonviral cationic polymer is limited by its toxicity. The toxicity of PEI can be reduced by washing the PEI coated YCWP encapsulated nanoplexes to remove any unbound PEI. At a high particle:cell ratio of 10 particles:cell, unwashed YCWP encapsulated nanoplexes or DNA formulations slightly inhibit the growth rate of the cell line NIH3T3-D1 but do not induce cell death as evidenced by cell viabilities in excess of 90% (Figure 9). Several studies have identified other potentially useful cationic polymers as gene delivery vectors with the advantages of decreased toxicity and higher gene delivery efficiency than PEI. For example, toxicity of PEI can be significantly reduced by partial acetylation of amine groups (*18*) or polymers constructed from biodegradable ester units (*23*). The use of these other cationic polymers to form YCWP caged DNA nanocomplexes inside YCWP by an LbL approach is currently under investigation.

The impact of the optimization of the LbL assembly process of encapsulated DNA coated nanoplex cationic cores on transfection efficiency was assessed by YCWP mediated delivery of the plasmid gWizGFP to NIH3T3-D1 cells. The transfection results for particle formulations with two different tRNA:YP ratios and a constant PEI:YP ratio of 4 are shown in Figure 8. DNA delivered in the optimized YCWP delivery system efficiently transfects NIH3T3-D1; greater than 50% of cells are transfected by 125 ng DNA/5×10^5 cells when using a GMP formulation with a tRNA:GMP ratio of 0.05. Transfection efficiency of DNA/PEI nanocomplexes not trapped inside YCWP was negligible (<10%) at a DNA level of 125 ng/5×10^5 cells. In comparison, other groups have reported efficient in vitro transfection with unencapsulated DNA/PEI nanocomplexes using greater than 16-fold higher levels of plasmid DNA delivered/cell (*9, 47*).

The use of schizophyllan, a β-1,3-D-glucan polysaccharide to complex single stranded oligonucleotide sequences and serve as a targeting agent for DNA delivery, has been reported by Sakurai and colleagues (*48*). However, this DNA delivery strategy requires the synthesis of poly(dA) forming a hairpin

structure at both ends of the dsDNA and did not result in enhanced siRNA or DNA delivery compared to PEI polyplexes. Thus, the encapsulation of nanocomplexed DNA inside YCWP composed of β-1,3-D-glucan appears more important than β-1,3-D-glucan targeting of soluble or nanoparticulate DNA complexes to maximize DNA transfection.

CONCLUSIONS

Porous hollow YCWP have been shown to be an effective microparticulate delivery system to encapsulate DNA following LbL assembly of polymers by electrostatic interactions inside YCWP. Labeling of each layer with rhodamine allowed quantitative fluorescence analysis and optimization of LbL nanoplex synthesis within YCWP. The YCWP DNA delivery system efficiently delivered the plasmid, gWizGFP, and transfected NIH3T3-D1 cells. The advantages of the efficient YCWP DNA delivery system include high capacity, multiplexable DNA, protein, and siRNA delivery, oral bioavailability, β-1,3-D-glucan receptor targeting to macrophages and dendritic cells, and cell trafficking to the reticuloendothelial system and sites of pathology (*33–35*). Future communications will report on in vitro and in vivo YCWP-mediated DNA and siRNA delivery to macrophages, dendritic cells, tissues containing these cells.

ACKNOWLEDGMENT

The authors wish to thank Xiaoyun Huang and Marguerite Joly for technical assistance, Drs. Edward Ginns and Charles Specht (UMMS), and the UMMS FACS and Digital Imaging Core Facilities for assistance in microscopy. CPT-11, also known as irinotecan, is a prodrug that is approved for the treatment of advanced colorectal cancer. The active metabolite of CPT-11, SN38 (7-ethyl-10-hydroxy-camptothecin), has 100- to 1000-fold more potent cytotoxic activity in tissue cell culture compared with CPT-11. However, parental administration of SN38 is not possible because of its inherently poor water solubility. It is reported here that a multiarm poly(ethylene glycol) (PEG) backbone linked to four SN38 molecules (PEG-SN38) has been successfully prepared with high drug loading and significantly improved water solubility (400- to 1000-fold increase). Three different protecting strategies have been developed in order to selectively acylate the 20-OH of SN38 to preserve its E-ring in the lactone form (the active form of SN38 with cytotoxic activities) while PEG is still attached. One chemical process has been optimized to make a large quantity of the PEG-SN38 conjugate with a high yield that can be readily adapted for scale-up production. The PEG-SN38 conjugates have shown excellent in vitro anticancer activity, with potency similar to that of native SN38, in a panel of cancer cell lines. The PEG-SN38 conjugates also have demonstrated superior anticancer activity in the MX-1 xenograft mice model compared with CPT-11. Among the four conjugates, PEG-Gly-(20)-SN38 (**23**) has been selected as the lead candidate for further preclinical development.

INTRODUCTION

Camptothecin and its analogues have potent cytotoxic activity in tumor cells grown in tissue culture and moderate anticancer efficacy in animal models. The compounds selectively inhibit topoisomerase I (TOP1) by trapping the enzyme during the cleavage of DNA (*1*), thereby prohibiting faithful cell division and protein production. This ultimately leads to cell death. Early clinical development of camptothecin carboxylate in the 1970s demonstrated that the compound had antitumor activity but also substantial toxicity (*2*). It was not until the discovery of more water-soluble derivatives of camptothecin that two TOP1 inhibitors (Hycamtin [topotecan] and Camptosar [CPT-11, irinotecan]) were approved as anticancer agents by the U.S. Food and Drug Administration (FDA) in 1997.

While CPT-11 has clinical utility, there are many limitations that suggest further improvement of the compound may be possible. One major limitation is that the active ingredient, SN38 (7-ethyl-10-camptothecin), which is produced by esterase-mediated hydrolysis of the solubilizing group on CPT-11 (the bispiperidine moiety), requires carboxylesterase-2. Although carboxylesterase-2 is present in abundance within the liver, its expression is far lower in the blood (*3, 4*). As a result, only 1−9% of an injected dose of CPT-11 is converted to SN38 (*3, 5, 6*) in humans (*6*). In addition, the lactone E-ring of CPT-11 (or SN38) can be readily converted to an open carboxylate form that is inactive against TOP1 (*6–8*) and binds tightly to human serum albumin. In particular, it is known that, 24 h after CPT-11 infusion in humans, approximately 25% and 55% of CPT-11 and SN38, respectively, are in the closed lactone form (*3*) compared with the total amount of CPT-11 and SN38. Hence, inhibition of the conversion to the inactive open carboxylate form of the molecule may have therapeutic benefit. Finally, while SN38 has 100- to 1000-fold more potent in vitro cytotoxic activity compared with CPT-11 (*3*), it has poor solubility in any pharmaceutically acceptable excipient and cannot be used for systemic applications (*9*).

One solution to alleviate the above-mentioned limitations is to PEGylate SN38. PEGylation is well-known for its capability to solubilize very insoluble small molecule compounds, prolong circulation time, and alter the biodistribution of parent drugs (*10*). In fact, we previously have shown that dramatic enhancement of circulating half-life, solubility, and in vivo efficacy of the native anticancer drug camptothecin was achieved utilizing a prodrug strategy in conjunction with the nonimmunogenic 40 kDa polymeric poly(ethylene glycol) (PEG) (*11*). The active lactone form of camptothecin was largely preserved during circulation due to the acylation through the 20-hydroxyl functional group where PEG was attached (*12*). The lactone stabilization was further proven in a separate study using different acylation agents with this 20-hydroxyl group (*13*). However, the PEG used in the camptothecin delivery was the bifunctional linear PEG that had only two active sites for drug conjugation. As a result, there was about 1.7% of camptothecin (CPT) by weight per PEG-CPT conjugate. Subsequently, a large amount of the compound was given to patients during clinical trials; most of the compound was inactive PEG polymer, which could be as high as 14 g of PEG per dose. Due to the high potency of SN38 and our enhanced ability to increase the loading of the drug onto PEG, it was reasoned that PEG-SN38 would overcome the limitations of CPT-11 or PEG-CPT. We report here the description of PEGylated SN38 derivatives that have remarkable efficacy in animal tumor models and have recently entered into phase I clinical trials.

CHEMISTRY

The most commonly used PEG is a linear polymer with either one or two functional groups at the two distal ends. Simple conjugation with such linear PEG will attach up to two drug molecules per PEG conjugate. To increase the payload, we previously developed methods by branching at the ends of PEG with trifunctional moieties such as aspartic acid and have successfully increased the loading of the water-soluble antican-

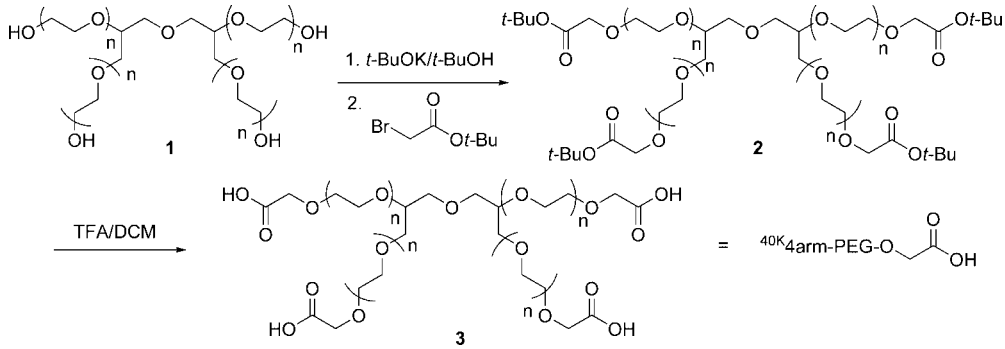
Scheme 1



cer drug cytarabine (*14*). However, this approach involved multiple steps of preparation of both the branching small molecule part as well as the PEG linkers. In addition, the sites for drug molecule attachment were too close to each other in some cases, which caused steric hindrance among the functional groups and resulted in incomplete conjugation of drug molecules. When the two aromatic drug molecules were close to each other, the stacking phenomenon became another issue that could impact the solubility of the drug molecules. This could be a bigger concern in the case of the delivery of very insoluble drug molecules. Previously, Gopin and co-workers developed dendritic prodrugs for delivery of camptothecin (*15*). To increase the loading of water-insoluble cytotoxic compounds, we sought here to use the multiarm PEG as the carrier. The active sites at the end of each "arm" of multiarm PEG are far away from each other and behave independently. This property will help to eliminate the steric hindrance and stacking phenomenon when the drug molecules are too close to each other. It also will help the completion of the loading and improve the solubility of the loaded drug molecules. It has been demonstrated conclusively that substantial increments to the area under the drug concentration−time curve or circulation time can be achieved by PEG conjugation to small molecule drugs if the molecular weight of the PEG exceeds 20 000 Da (*10*). In this study, we chose to use 40 kDa four-arm-PEG-OH (**1**), which has an active group at the distal end of each arm. Upon full loading, this PEG can conjugate up to four SN38 molecules. To do so, we first converted compound **1** to four-arm-PEG-acid (**3**) using a previously reported method (*16*). Hence, **1** was first reacted with *t*-butyl bromoacetate in the presence of potassium *t*-butoxide to form the ester **2**, which was deprotected by trifluoroacetic acetic acid (TFA) to give the desired PEG acid **3** (Scheme 1).

SN38 (**4**) has two hydroxyl groups, i.e., 10-OH and 20-OH. Since the 10-OH group is more active, in order to selectively acylate the 20-OH of SN38, the 10-OH has to be protected first. We sought to use different amino acids as the linking moiety between the PEG and SN38. During the study, alanine (Ala), methionine (Met), sarcosine (Sar), and glycine (Gly) had been chosen as the linkers based on our previous research (*17*). To find the best protecting strategy, three different approaches were tried.

The first approach was the combination of acid-labile *t*-butylcarbonyl (Boc) group and base-labile 1,1-dioxobenzo[b]-thiophen-2-ylmethyloxycarbonyl (Bsmoc) group. The Bsmoc group developed by Carpino et al. (*18*) can be removed by treatment with a secondary amine via Michael addition that is conducted under extremely mild conditions. We used this protecting group in the past to synthesize and isolate moisture- and base-sensitive compounds such as 2′-paclitaxel glycinate (*19*). Thus, SN38 was first reacted with di-*t*-butyl dicarbonate to selectively protect the 10-OH with a Boc group to give compound **5** (Scheme 2), followed by reaction with Bsmoc-Ala to acylate the 20-OH to give compound **6**. One equivalent of 4-piperidinopiperidine was used to remove the Bsmoc group, and the resulting free amine was converted to HCl salt through an acid wash (**7**). It was found that the intermediate with a free amine group was not very stable and slowly converted into byproduct. Therefore, we had to make the HCl salt of this intermediate to avoid the free amine. A similar phenomenon has been disclosed by Liu and co-workers (*20*). Compound **7** was then coupled with four-arm-PEG acid (**3**) using *N*-ethyl-*N*′-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) to give Boc-protected compound **8**. One final treatment with TFA yielded the final product PEG-Ala-(20)-SN38 (**9**). Another conjugate, PEG-Met-(20)-SN38 (**13**), was prepared in a similar fashion (Scheme 3).

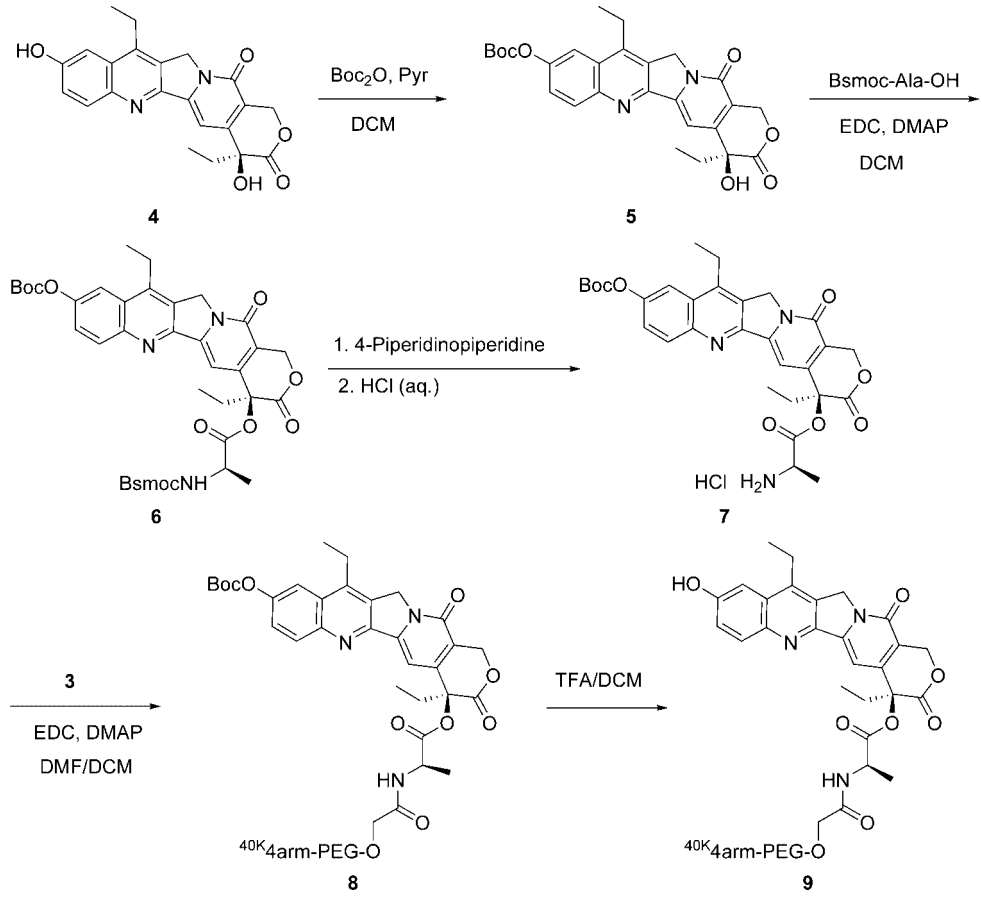
In the second approach, Boc-protected compound **5** was reacted with Boc-Sar to give compound **14** (Scheme 4). TFA treatment removed both Boc groups on 10-OH and sarcosine to give **15** as the intermediate. At this time, the 10-OH was protected again through reaction with *tert*-butyldimethylsilyl chloride (TBDMS-Cl) to prevent side reactions in the following steps. The resulting molecule **16** was directly conjugated with **3** to give **17**, and the TBDMS protecting group was removed by TFA to give the final product PEG-Sar-(20)-SN38 (**18**). The problem for this approach was that intermediate **16** was not very stable either and slowly lost the silyl protecting group TBDMS during storage in refrigerator.

To resolve this stability issue, the more hindered *t*-butyldiphenylsilyl group (TBDPS) was used to protect the 10-OH directly in the third approach (Scheme 5). Thus, *t*-butyldiphenylsilyl chloride (TBDPS-Cl) reacted with SN38 selectively to give compound **19** in the first step. Subsequent acylation of 20-OH with Boc-Gly gave compound **20**. The Boc group can be removed by HCl in dioxane without affecting the TBDPS group. The resulting intermediate **21** was a very stable molecule even under elevated temperatures. This property ensured the possibility that key intermediate **21** could be scaled up to large quantities with high purity and stored either at room temperature or in the refrigerator for a prolonged period of time. The next conjugation with PEG acid (**3**) was done by using propane phosphonic acid anhydride (PPAC) as the coupling agent. The TBDPS group was finally removed with tetra-*n*-butylammonium fluoride (TBAF) to give pure conjugate **23**. This last approach has been successfully optimized and scaled up to hundreds of grams per batch on a repetitive base.

EXPERIMENTAL PROCEDURES

General Procedures. All reactions were run under an atmosphere of dry nitrogen or argon. Commercial reagents were used without further purification. All PEG compounds were dried under vacuum or by azeotropic distillation from toluene before use. ^{1}H and ^{13}C NMR spectra were obtained using a Varian Mercury 300 NMR spectrometer and deuterated chloroform and methanol as the solvents unless otherwise specified.

Scheme 2



Chemical shifts (δ) are reported in ppm downfield from tetramethylsilane (TMS). Mass spectra (MS) were obtained by electrospray ionization (ESI).

HPLC Method. The reaction mixtures and the purity of intermediates and final products were monitored by a Beckman Coulter System Gold HPLC instrument. It employs a ZOBAX 300SB C8 reversed-phase column (150 × 4.6 mm) or a Phenomenex Jupiter 300A C18 reversed-phase column (150 × 4.6 mm) with a multiwavelength UV detector, using a gradient of 15–100% of acetonitrile in 0.05% TFA at a flow rate of 1 mL/min.

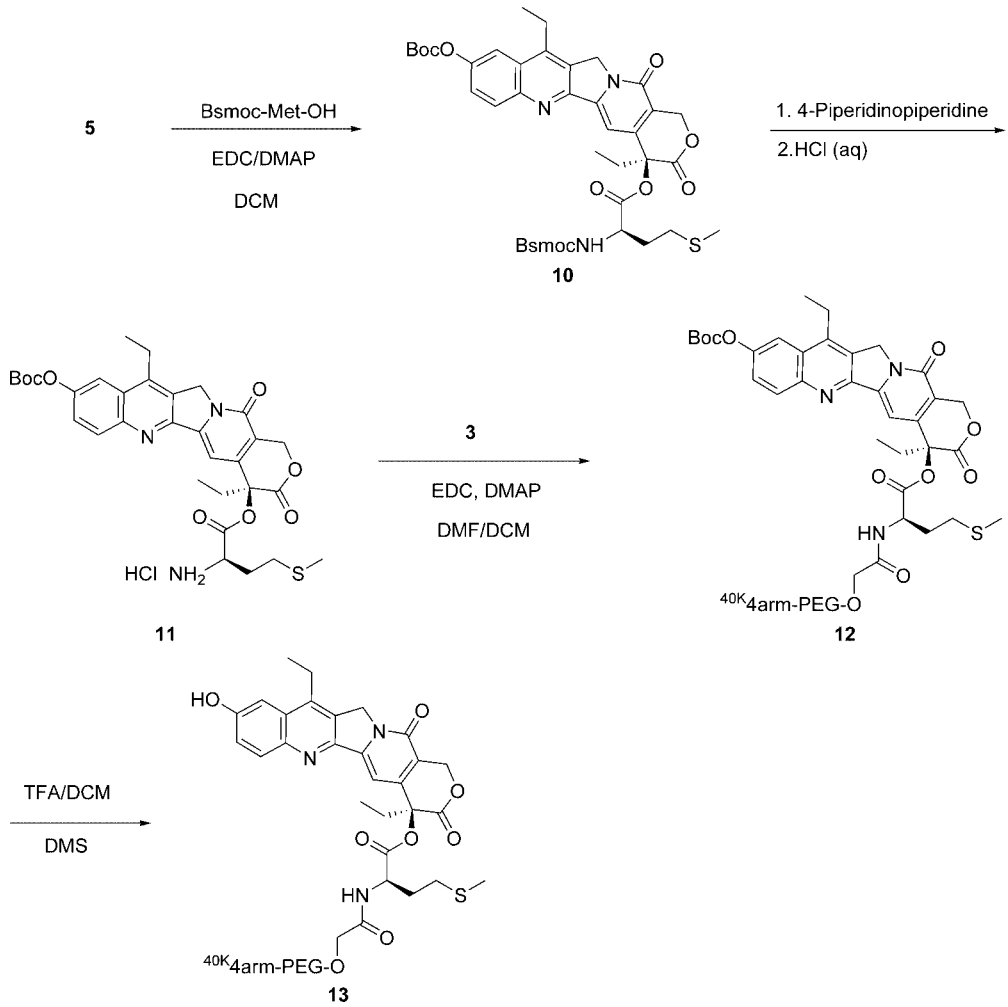
Compound 2. 40 kDa four-arm-PEG-OH (compound **1**, 12.5 g, 0.31 mmol) was azeotroped with 220 mL of toluene to remove 35 mL of toluene/water. The solution was cooled to 30 °C, and 1.0 M potassium *t*-butoxide in *t*-butanol (3.75 mL, 3.75 mmol) was added. The mixture was stirred at 30 °C for 30 min, and then *t*-butyl bromoacetate (0.975 g, 4.96 mmol) was added. The reaction was kept at 30 °C for 1 h and then was cooled to 25 °C. Ethyl ether (150 mL) was slowly added to precipitate the product. The crude product was filtered and washed with ethyl ether twice (2 × 125 mL). The resulting solids were dissolved in 50 mL of dichloromethane (DCM), precipitated with 350 mL of ethyl ether, filtered, and washed with ethyl ether (2 × 125 mL). The product was dried under vacuum at 40 °C to give compound **2** (12.25 g, 98% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 27.71, 68.48–70.71 (PEG), 80.94, 168.97.

Compound 3. Compound **2** (12 g, 0.30 mmol) was dissolved in 120 mL of DCM, and then, 60 mL of TFA was added. The mixture was stirred at room temperature for 3 h, and then the solvent was removed under vacuum at 35 °C. The resulting oil was dissolved in 37.5 mL of DCM, and the crude product was precipitated with 375 mL of ethyl ether. After filtration, the resulting solids were dissolved in 30 mL of 0.5% $NaHCO_3$. The product was extracted with DCM (2 × 150 mL), and the combined organic layers were dried over $MgSO_4$. After filtration, the solvent was removed under vacuum at room temperature. The resulting residue was dissolved in 37.5 mL of DCM, and the product was precipitated with 300 mL of ethyl ether. The resulting solids were filtered, washed with ethyl ether (2 × 125 mL), and dried under vacuum at 40 °C to give compound **3** (10.75 g, 90% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 67.93–71.6 (PEG), 170.83.

Compound 5. To a suspension of SN38 (compound **4**, 2.45 g, 6.25 mmol) in 250 mL of anhydrous DCM were added di-*tert*-butyl dicarbonate (1.764 g, 8.12 mmol) and anhydrous pyridine (15.2 mL, 185.5 mmol). The suspension was stirred overnight at room temperature. The hazy solution was filtered through celite, and the filtrate was washed with 0.5 N HCl (3 × 150 mL) and saturated $NaHCO_3$ (1 × 150 mL). The organic phase was dried over $MgSO_4$, filtered, and evaporated under vacuum at 30 °C. The resulting solids were dried under vacuum at 40 °C to give compound **5** (2.52 g, 82% yield). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.00 (3H, t, J = 7.3 Hz), 1.40 (3H, t, J = 7.7 Hz), 1.62 (9H, s), 1.81–1.97 (2H, m), 3.13 (2H, q, J = 7.7 Hz), 4.39 (1H, s, OH), 5.23 (2H, s), 5.29 (1H, d, J = 16.5 Hz), 5.73 (1H, d, J = 16.5 Hz), 7.63 (1H, dd, J = 2.6, 9.1 Hz), 7.69 (1H, s), 7.84 (1H, d, J = 2.2 Hz), 8.23 (1H, d, J = 9.1 Hz). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.90, 13.98, 23.17, 27.73, 31.62, 49.33, 66.18, 72.80, 84.26, 98.06, 113.88, 118.53, 124.98, 127.13, 127.19, 131.83, 145.15, 146.50, 147.00, 149.70, 150.02, 151.28, 151.60, 157.38, 173.53. HRMS (ESI) calcd for $C_{27}H_{28}N_2O_7$ $[M + H]^+$: 493.1975, found: 493.1969.

Compound 6. To a solution of compound **5** (0.85 g, 1.71 mmol) and Bsmoc-Ala-OH (0.68 g, 2.30 mmol) in 20 mL of anhydrous DCM at 0 °C were added EDC (0.51 g, 2.67 mmol) and 4-(dimethylamino)pyridine (DMAP, 65 mg, 0.53 mmol).

Scheme 3



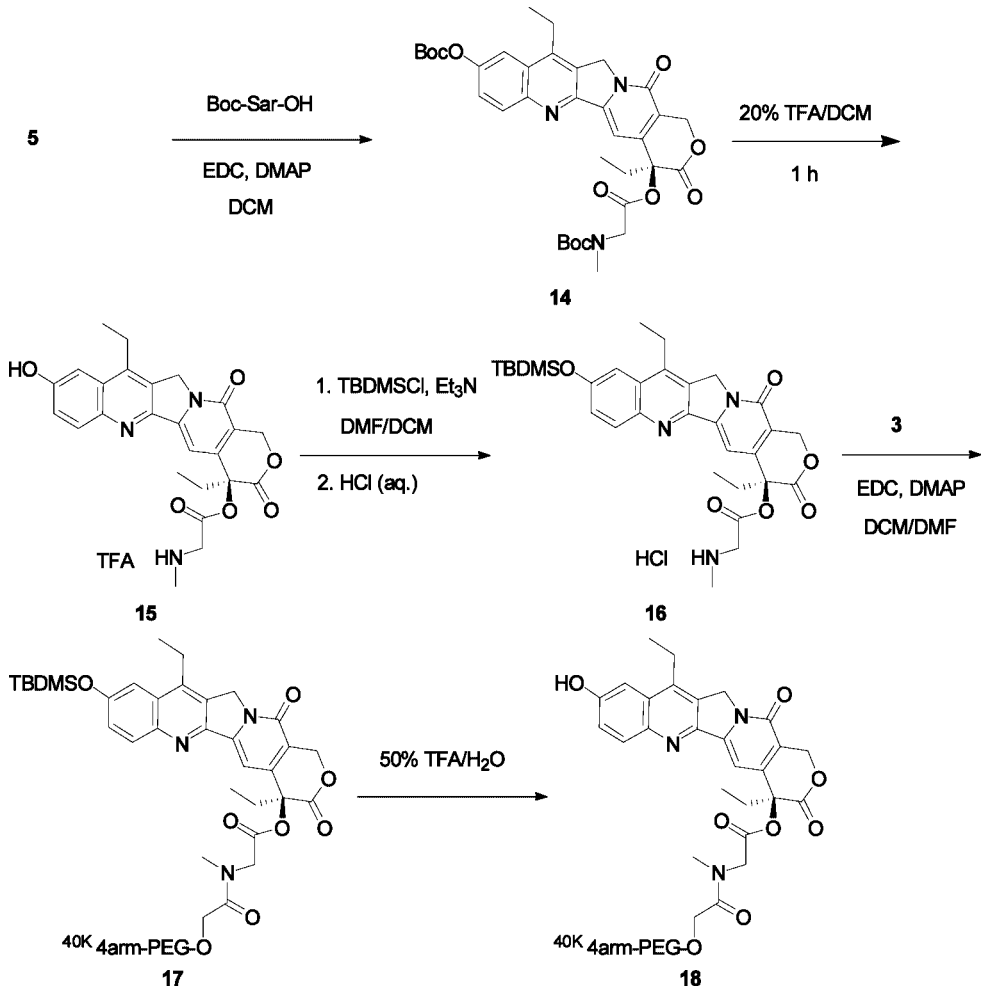
The mixture was stirred at 0 °C for 45 min and then warmed up to room temperature. When completion of the reaction was confirmed by HPLC, the reaction mixture was washed with 1% $NaHCO_3$ (2 × 50 mL), water (50 mL), and 0.1 N HCl (2 × 50 mL). The organic phase was dried over anhydrous $MgSO_4$, filtered, and evaporated under vacuum. The resulting solid was dried under vacuum at 40 °C to give compound **6** (1.28 g, 95% yield). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.90 (3H, t, J = 7.5 Hz), 1.37 (3H, t, J = 7.3 Hz), 1.56 (3H, d, J = 7.3 Hz), 1.61 (9H, s), 2.04–2.28 (2H, m), 3.13 (2H, q, J = 7.5 Hz), 4.51 (1H, quint, J = 7.2 Hz), 5.12–5.20 (2H, m), 5.23 (2H, s), 5.37 (1H, d, J = 17.0 Hz), 5.66 (1H, d, J = 17.0 Hz), 5.70 (1H, d, J = 7.0 Hz), 7.18 (1H, s), 7.21–7.78 (5H, m), 7.65 (1H, dd, J = 2.3, 9.1 Hz), 7.87 (1H, d, J = 2.3 Hz), 8.20 (1H, d, J = 9.4 Hz). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.53, 14.02, 17.94, 27.76, 31.7, 49.34, 49.96, 53.45, 56.66, 67.10, 76.64, 84.38, 95.90, 114.17, 120.01, 121.38, 125.14, 125.32, 127.08, 127.40, 130.33, 130.40, 130.45, 131.83, 133.60, 136.88, 139.08, 145.15, 145.35, 146.68, 147.17, 149.82, 151.33, 151.59, 154.78, 157.16, 166.83, 171.16. MS (ESI): 786.20 $[M + H]^+$. HRMS (ESI) calcd for $C_{40}H_{39}N_3O_{12}S$ $[M + H]^+$: 786.2333, found: 786.2321.

Compound 7. To a solution of compound **6** (4.2 g, 5.35 mmol) in 200 mL of anhydrous DCM was added 4-piperidinopiperidine (1.17 g, 6.96 mmol). The mixture was stirred at room temperature for 5 h and then washed with 0.1 N HCl (2 × 40 mL). The organic phase was dried over $MgSO_4$, filtered, and evaporated under vacuum to give compound **7** (2.8 g, 87% yield). ^{1}H NMR (300 MHz, CD_3OD): δ 1.08 (3H, t, J = 7.3 Hz), 1.37 (3H, t, J = 7.6 Hz), 1.58 (9H, s), 1.80 (3H, d, J = 7.0 Hz), 2.31 (2H, sept, J = 7.2 Hz), 3.18 (2H, q, J = 7.3 Hz), 4.41 (1H, q, J = 7.2 Hz), 5.25 (2H, s), 5.51 (1H, d, J = 17.0 Hz), 5.65 (1H, d, J = 17.0 Hz), 7.32 (1H, s), 7.65 (1H, dd, J = 2.3, 9.4 Hz), 7.95 (1H, d, J = 2.3 Hz), 8.14 (1H, d, J = 9.4 Hz). ^{13}C NMR (75.4 MHz, CD_3OD): δ 8.11, 14.27, 16.26, 23.90, 27.94, 32.12, 50.78, 67.86, 79.54, 85.11, 97.14, 115.80, 120.68, 126.66, 128.76, 129.26, 131.95, 146.74, 147.68, 147.82, 148.09, 151.37, 152.59, 152.90, 158.63, 168.30, 169.99. HRMS (ESI) calcd for $C_{30}H_{33}N_3O_8$ $[M + H]^+$: 564.2346, found: 564.2357.

Compound 8. To a solution of compound **7** (1.50 g, 2.5 mmol) and compound **3** (10.01 g, 0.25 mmol) in 100 mL of anhydrous DCM at 0 °C were added EDC (0.29 g, 1.5 mmol) and DMAP (0.30 g, 2.5 mmol). The mixture was stirred at 0 °C for 1 h and at room temperature overnight. The solvent was evaporated under vacuum. The residue was dissolved in 40 mL of DCM, and the crude product was precipitated with ethyl ether (300 mL). After filtration, the resulting solids were recrystallized with a mixture of dimethyl formamide/isopropyl alcohol (DMF/isopropyl alcohol [IPA], 60 mL /240 mL). Then, the solids were filtered, washed with ethyl ether (2 × 200 mL), and dried under vacuum at 40 °C to give compound **8** (8.5 g, 80% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 7.46, 13.87, 17.68, 23.04, 27.59, 31.53, 47.17, 49.13, 66.85, 69.67–70.88 (PEG), 84.11, 95.52, 113.83, 119.72, 124.85, 126.84, 127.14, 131.72, 145.05, 146.59, 146.97, 149.60, 151.09, 151.32, 156.92, 166.54, 169.29, 170.83.

Compound 9. Compound **8** (7.98 g, 0.19 mmol) was dissolved in 130 mL of 30% TFA in anhydrous DCM. The mixture was stirred for 3 h, and then the solvent was removed

Scheme 4



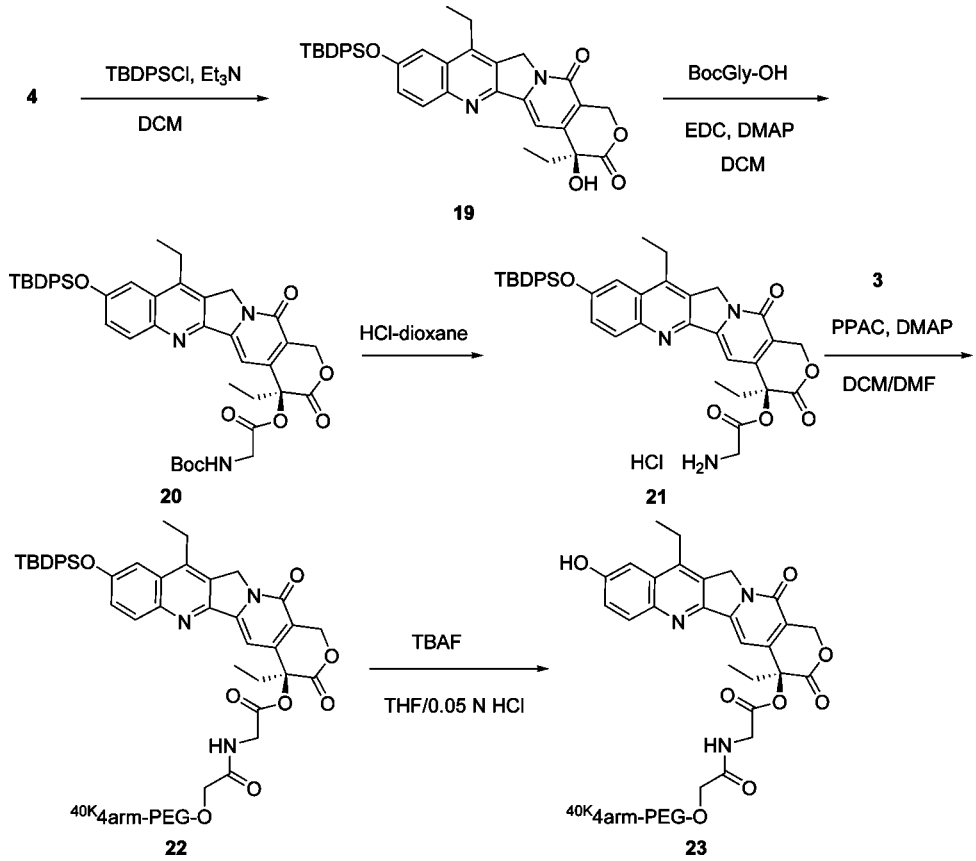
under vacuum at 35 °C. The residue was dissolved in 50 mL of DCM, and the crude product was precipitated with 350 mL of ethyl ether. After filtration, the resulting solids were recrystallized from a mixture of DMF/IPA (50 mL/200 mL). The solid was filtered, washed with ethyl ether (2 × 200 mL), and dried under vacuum to give compound **9** (6.7 g, 84% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.46, 13.52, 17.78, 22.95, 31.53, 47.14, 49.14, 66.90, 69.57–71.15 (PEG), 78.08, 94.57, 105.10, 118.79, 122.47, 126.42, 128.26, 131.49, 143.00, 144.29, 145.03, 147.19, 148.36, 156.31, 157.00, 166.65, 169.30, 170.75.

Compound 10. To a solution of compound **5** (2.73 g, 5.53 mmol) and Bsmoc-Met-OH (3.19 g, 8.59 mmol) in 50 mL of anhydrous DCM at 0 °C were added EDC (1.64 g, 8.59 mmol) and DMAP (0.21 g, 1.72 mmol). The mixture was stirred at 0 °C for 45 min and at room temperature for 1 h. The reaction mixture was washed with 1% $NaHCO_3$ (2 × 100 mL), water (100 mL), and 0.1 N HCl (2 × 100 mL). The organic phase was dried over $MgSO_4$, filtered, and evaporated under vacuum. The resulting solids were dried under vacuum to give compound **10** (4.2 g, 88% yield). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.89 (3H, t, J = 7.3 Hz), 1.39 (3H, t, J = 7.7 Hz), 1.61 (9H, s), 2.03–2.15 (2H, m), 2.10 (3H, s), 2.19–2.31 (2H, m), 2.61 (2H, t, J = 7.0 Hz), 3.15 (2H, q, J = 7.5 Hz), 4.61 (1H, dt, J_d = 5.3 Hz, J_t = 7.9 Hz), 5.11–5.28 (4H, m), 5.39 (1 H, d, J = 17.1 Hz), 5.67 (1H, d, J = 17.1 Hz), 5.70 (1H, d, J = 7.0 Hz), 7.18 (1H, s), 7.23–7.68 (5H, m), 7.65 (1H, dd, J = 2.2, 9.2 Hz), 7.89 (1H, s), 8.21 (1H, d, J = 9.2 Hz). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.45, 13.92, 15.38, 23.12, 27.68, 29.65, 30.97, 31.57, 49.32, 53.54, 56.68, 66.99, 76.58, 84.28, 96.05, 114.09, 119.75, 121.17, 125.08, 125.27, 127.05, 130.15,130.29, 130.54, 131.65, 133.52, 136.69, 138.86, 145.10, 145.29, 146.55, 146.97, 149.69, 151.25, 151.39, 155.16, 157.08, 166.78, 170.33. HRMS (ESI) calcd for $C_{42}H_{43}N_3O_{12}S_2$ $[M + H]^+$: 846.2366, found: 846.2364.

Compound 11. To a solution of compound **10** (4.1 g, 4.85 mmol) in 200 mL anhydrous DCM was added 4-piperidinopiperidine (1.06 g, 6.31 mmol). The reaction mixture was stirred at room temperature for 5 h and then washed with 0.1 N HCl (2 × 40 mL). The organic phase was dried over $MgSO_4$, filtered, and evaporated under vacuum to give compound **11** (2.8 g, 88% yield). ^{1}H NMR (300 MHz, CD_3OD): δ 1.08 (3H, t, J = 7.3 Hz), 1.37 (3H, t, J = 7.6 Hz), 1.58 (9H, s), 2.19 (3H, s), 2.26–2.37 (3H, m), 2.51–2.58 (1H, m), 2.77 (2H, t, J = 7.3 Hz), 3.17 (2H, t, J = 7.5 Hz), 4.51 (1H, t, J = 6.4 Hz), 5.25 (2H, s), 5.52 (1H, d, J = 17.0 Hz), 5.66 (1H, d, J = 17.0 Hz), 7.35 (1H, s), 7.67 (1H, dd, J = 2.3, 9.1 Hz), 7.95 (1H, d, J = 2.3 Hz), 8.17 (1H, d, J = 9.1 Hz). ^{13}C NMR (75.4 MHz, CD_3OD): δ 8.15, 14.28, 15.13, 23.90, 27.94, 30.12, 30.84, 32.07, 50.83, 52.80, 67.92, 79.95, 85.14, 97.27, 115.78, 120.68, 126.66, 128.76, 129.25, 132.04, 146.58, 147.62, 147.85, 148.12, 151.36, 152.56, 152.90, 158.65, 168.24, 169.14. MS (ESI): 624.29 $[M + H]^+$. HRMS (ESI) calcd for $C_{32}H_{37}N_3O_8S$ $[M + H]^+$: 624.2380, found: 624.2381.

Compound 12. To a solution of compound **11** (1.48 g, 2.25 mmol) and compound **3** (9.0 g, 0.22 mmol) in 80 mL of anhydrous DCM at 0 °C were added EDC (0.26 g, 1.35 mmol) and DMAP (0.27 g, 2.25 mmol). The mixture was stirred at 0 °C for 1 h and at room temperature overnight. The reaction mixture was diluted with 70 mL of DCM and then extracted with 30 mL of 0.1 N HCl. The organic phase was dried over $MgSO_4$, filtered, and evaporated under vacuum. The residue was

Scheme 5



dissolved in 40 mL of DCM, and the crude product was precipitated with 300 mL of ethyl ether. After filtration, the resulting solids were recrystallized from a mixture of DMF/IPA (60 mL /240 mL). Then, the solid was filtered, washed with ethyl ether (2 × 200 mL), and dried under vacuum at 40 °C to give compound **12** (7.0 g, 74% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.47, 13.85, 15.32, 23.06, 27.59, 29.62, 31.19, 31.53, 49.16, 50.68, 66.88, 69.93–70.97 (PEG), 78.10, 84.10, 95.53, 113.85, 119.66, 124.87, 126.81, 127.14, 131.68, 144.99, 146.62, 146.96, 149.58, 151.09, 151.24, 156.89, 166.49, 169.64, 169.82.

Compound 13. To a solution of 30% TFA in anhydrous DCM (100 mL) were added dimethyl sulfide (2.5 mL) and compound **12** (6.0 g, 0.14 mmol). The mixture was stirred for 3 h, and then the solvent was removed under vacuum at 35 °C. The residue was dissolved in 50 mL of DCM, and the crude product was precipitated with 350 mL of ether and filtered. The solids were recrystallized from a mixture of DMF/IPA (60/300 mL). Then, the solids were filtered, washed with ethyl ether (2 × 200 mL), and dried under vacuum to give compound **13** (5.1 g, 86% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.49, 13.53, 15.35, 22.96, 29.65, 31.30, 31.56, 49.19, 50.71, 66.96, 69.58–71.02 (PEG), 78.11, 94.61, 105.12, 118.72, 122.46, 126.41, 128.27, 131.54, 142.94, 144.39, 144.96, 147.31, 148.37, 156.28, 157.01, 166.63, 169.74.

Compound 14. To a solution of Boc-Sar-OH (432 mg, 2.287 mmol) and compound **5** (750 mg, 1.52 mmol) in 75 mL of DCM at 0 °C were added EDC (837 mg, 0.686 mmol) and DMAP (432 mg, 2.287 mmol). The reaction mixture was stirred at 0 °C for 30 min and at room temperature for 1 h. The mixture was then washed with 0.5% $NaHCO_3$ (2 × 75 mL), water (2 × 75 mL), and 0.1 N HCl (75 mL). The organic layer was dried over $MgSO_4$ and filtered; the solvent was evaporated under vacuum and dried to give compound **14** (0.9 g, 89% yield). ^{1}H NMR (300 MHz, $CDCl_3$, rotamers, ratio 60:40): δ 1.05 (3H, t, J = 7.5 Hz), 1.39 (3H, t, J = 7.3 Hz), 1.43 (3.6H), 1.44 (5.4H, s), 1.62 (9H, s), 2.11–2.28 (2H, m), 2.95 (3H, s), 3.13–3.19 (2H, m), 4.05 (0.4H, d, J = 17.6 Hz), 4.13 (1.2H, s), 4.28 (0.4H, d, J = 17.6 Hz), 5.23 (0.8H, s), 5.24 (1.2H, s), 5.40 (1H, d, J = 17.2 Hz), 5.70 (1H, d, J = 17.2 Hz), 7.14 (0.6H, s), 7.32 (0.4H, s), 7.66 (1H, d, J = 9.2 Hz), 7.88 (0.4H, s), 7.89 (0.6H, s), 8.17 (0.6H, d, J = 9.2 Hz), 8.24 (0.4H, d, J = 9.2 Hz). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.68, 14.04, 23.25, 27.75, 28.31, 31.84, 35.42, 49.31, 50.27, 50.67, 66.99–70.97, 80.55, 84.40, 95.50, 96.47, 114.17, 119.80, 125.12, 126.98, 127.35, 131.59, 145.26, 145.58, 146.69, 147.09, 149.75, 151.33, 155.04, 157.13, 166.82, 168.81. HRMS (ESI) calcd for $C_{35}H_{41}N_3O_{10}$ $[M + H]^+$: 664.2870, found: 664.2877.

Compound 15. To a solution of compound **14** (0.9 g, 1.36 mmol) in 16 mL of DCM was added 4 mL of TFA. The reaction mixture was stirred at room temperature for 1 h, and then the solvent was evaporated under vacuum. The residue was dissolved in 10 mL of $CHCl_3$ and then precipitated by addition of ethyl ether. The product was filtered and dried to give compound **15** (0.7 g, 78% yield). ^{1}H NMR (300 MHz, CD_3OD): δ 1.08 (3H, t, J = 7.3 Hz), 1.34 (3H, t, J = 7.6 Hz), 2.16–2.34 (2H, m), 2.77 (3H, s), 3.08 (2H, q, J = 7.6 Hz), 4.31 (1H, d, J = 17.3 Hz), 4.40 (1H, d, J = 17.3 Hz), 5.20 (2H, s), 5.48 (1H, d, J = 16.7 Hz), 5.63 (1H, d, J = 17.0 Hz), 7.30 (1H, s), 7.37–7.42 (2H, m), 7.95 (1H, d, J = 9.1 Hz). ^{13}C NMR (75.4 MHz, CD_3OD): δ 8.07, 13.86, 23.81, 31.81, 33.55, 49.46, 50.79, 67.69, 79.86, 96.72, 105.93, 119.42, 124.01, 128.80, 130.02, 131.85, 145.00, 147.23, 148.59, 149.40, 158.61, 158.79, 167.04, 168.36. HRMS (ESI) calcd for $C_{25}H_{25}N_3O_6$ $[M + H]^+$: 464.1822, found: 464.1832.

Compound 16. To a solution of compound **15** (2.17 g, 3.75 mmol) in DMF/DCM (30 /200 mL) were added triethylamine (Et_3N, 2.4 mL, 17.40 mmol) and *t*-butyldimethylchlorosilane

(TBDMSCl, 2.04 g, 13.53 mmol). The reaction mixture was stirred at room temperature for 1 h. The organic layer was washed with 0.5% $NaHCO_3$, water, and 0.1 N HCl saturated with brine, and then dried over $MgSO_4$. After filtration and evaporation of the solvent under vacuum, the resulting oil was dissolved in DCM and precipitated by the addition of ethyl ether. The resulting solids were filtered to give compound **15** (2.00 g, 87% yield). ^{1}H NMR (300 MHz, CD_3OD): δ 0.23 (6H, s), 0.96 (9H, s), 0.98 (3H, t, J = 7.3 Hz), 1.30 (3H, t, J = 7.6 Hz), 2.13–2.18 (2H, m), 2.67 (3H, s), 3.11 (2H, q, J = 7.6 Hz), 4.10 (1H, d, J = 17.6 Hz), 4.22 (1H, d, J = 17.6 Hz), 5.23 (2H, s), 5.40 (1H, d, J = 16.7 Hz), 5.55 (1H, d, J = 16.7 Hz), 7.32 (1H, s), 7.38–7.43 (2H, m), 8.00 (1H, d, J = 9.1 Hz). ^{13}C NMR (75.4 MHz, CD_3OD): δ –4.14, 8.01, 14.10, 19.30, 23.98, 26.16, 31.78, 33.52, 49.46, 50.95, 67.66, 79.80, 97.41, 111.96, 119.99, 127.75, 129.28, 129.67, 131.57, 145.24, 146.86, 147.16, 148.02, 150.34, 156.69, 158.72, 167.02, 168.27. MS (ESI): 578.35 $[M + H]^+$. HRMS (ESI) calcd for $C_{31}H_{39}N_3O_6Si$ $[M + H]^+$: 578.2686, found: 578.2694.

Compound 17. To a solution of compound **3** (10 g, 0.25 mmol) in 150 mL of anhydrous DCM was added a solution of compound **16** (1.53 g, 2.5 mmol) in 20 mL of anhydrous DMF. The mixture was cooled to 0 °C. To this solution were added EDC (767 mg, 4 mmol) and DMAP (367 mg, 3 mmol). The reaction mixture was allowed to warm to room temperature slowly and stirred at room temperature overnight. The reaction mixture was then evaporated under vacuum, and the residue was dissolved in a minimum amount of DCM. After addition of ethyl ether, solid was formed and filtered under vacuum. The residue was dissolved in 30 mL of anhydrous acetonitrile (CH_3CN) and precipitated by addition of 600 mL IPA. The solids were filtered and washed with IPA and ethyl ether to give compound **17** (9.5 g, 89% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ –4.49, 7.29, 13.44, 18.02, 22.78, 25.38, 31.36, 34.90, 48.93, 66.68, 69.98–71.15 (PEG), 94.94, 109.97, 118.64, 125.45, 126.32, 127.66, 131.55, 143.08, 144.82, 146.83, 149.08, 154.53, 156.71, 166.72, 167.70, 169.24.

Compound 18. Compound **17** (7.8 g, 0.18 mmol) was dissolved in a 50% mixture of TFA in H_2O (200 mL). The reaction mixture was stirred at room temperature for 10 h. The mixture was then diluted with 100 mL of H_2O and extracted with DCM (2 × 300 mL). The combined organic phases were washed with H_2O (2 × 100 mL), dried over $MgSO_4$, filtered, and evaporated under vacuum. The residue was recrystallized with a mixture of DMF/IPA (100/400 mL). Then, the solids were filtered, washed with ethyl ether, and dried under vacuum at 40 °C to give compound **18** (6.8 g, 89% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.51, 13.49, 22.89, 31.55, 35.18, 48.80, 49.11, 66.90, 69.57–71.13 (PEG), 78.08, 94.88, 105.00, 118.45, 122.45, 126.36, 128.14, 131.47, 142.79, 144.25, 145.09, 147.25, 148.37, 156.34, 156.96, 167.00, 167.86, 169.63.

Compound 19. To a suspension of compound **4** (2.0 g, 5.10 mmol) in 100 mL of anhydrous DCM were added Et_3N (3.2 mL, 22.93 mmol, 4.5 equiv) and *t*-butyldiphenylchlorosilane (TBDPSCl, 5.2 mL, 20.39 mmol). The reaction mixture was heated to reflux overnight and then was washed with 0.2 N HCl (2 × 50 mL), saturated $NaHCO_3$ (100 mL), and saturated NaCl (100 mL). The organic layer was dried over $MgSO_4$, filtered, and evaporated under vacuum. The residue was dissolved in DCM and precipitated by addition of hexane. The solids were filtered and dried under vacuum to give compound **19** (2.09 g, 65% yield). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.90 (3H, t, J = 7.6 Hz), 1.01 (3H, t, J = 7.3 Hz), 1.17 (9H, s), 1.83–1.92 (2H, m), 2.64 (2H, q, J = 6.9 Hz), 3.89 (1H, s), 5.11 (2H, s), 5.27 (1H, d, J = 16.1 Hz), 5.72 (1H, d, J = 16.4 Hz), 7.07 (2H, d, J = 2.63 Hz), 7.36–7.49 (7H, m), 7.58 (1H, s), 7.75–7.79 (4H, m), 8.05 (1H, d, J = 9.4 Hz). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.82, 13.28, 19.52, 22.86, 26.48, 31.52, 49.23, 66.25, 72.69, 97.25, 110.09, 117.57, 125.67, 126.57, 127.65, 127.81, 130.02, 131.69, 131.97, 135.26, 143.51, 145.05, 147.12, 149.55, 149.92, 154.73, 157.43, 173.72. HRMS (ESI) calcd for $C_{38}H_{38}N_2O_5Si$ $[M + H]^+$: 631.2628, found: 631.2622.

Compound 20. To a solution of compound **19** (3.78 g, 5.99 mmol) and Boc-Gly-OH (1.57 g, 8.99 mmol) in 100 mL of anhydrous DCM at 0 °C were added EDC (1.72 g, 8.99 mmol) and DMAP (329 mg, 2.69 mmol). The reaction mixture was stirred at 0 °C until HPLC showed complete disappearance of the starting material (approximately 2 h). The organic layer was washed with 0.5% $NaHCO_3$ (2 × 50 mL), water (1 × 50 mL), 0.1 N HCl (2 × 50 mL), and saturated NaCl (1 × 50 mL), and then dried over $MgSO_4$. After filtration, the solvent was evaporated under vacuum to give compound **20** (4.94 g, 100% yield). The solids were used in the next reaction without further purification. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.89 (3H, t, J = 7.6 Hz), 0.96 (3H, t, J = 7.5 Hz), 1.18 (9H, s), 1.40 (9H, s), 2.07–2.29 (3H, m), 2.64 (2H, q, J = 7.5 Hz), 4.01–4.22 (2H, m), 5.00 (1H, br s), 5.01 (2H, s), 5.37 (1H, d, J = 17.0 Hz), 5.66 (1H, d, J = 17.0 Hz), 7.08 (1H, d, J = 2.34 Hz), 7.16 (1H, s), 7.37–7.50 (7H, m), 7.77 (4H, d, J = 7.6 Hz), 8.05 (1H, d, J = 9.4 Hz). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.52, 13.30, 19.50, 22.86, 26.45, 28.21, 31.64, 42.28, 49.14, 67.00, 76.65, 79.96, 95.31, 110.13, 118.98, 125.75, 126.45, 127.68, 127.81, 130.03, 131.54, 131.92, 135.25, 143.65, 144.91, 145.19, 147.08, 149.27, 154.75, 155.14, 157.10, 166.98, 169.17. HRMS (ESI) calcd for $C_{45}H_{49}N_3O_8Si$ $[M + H]^+$: 788.3367, found: 788.3345.

Compound 21. To a solution of compound **20** (1 g, 1.27 mmol) in 5 mL anhydrous dioxane were added 5 mL of a 4 M solution of HCl in dioxane. The reaction mixture was stirred at room temperature until HPLC showed complete disappearance of the starting material (approximately 1 h). The reaction mixture was added to 50 mL of ethyl ether, and the resulting solid was filtered. After the solids were dissolved in 50 mL DCM and washed with brine, the pH was adjusted to 2.5 by addition of saturated $NaHCO_3$. The organic layer was dried over $MgSO_4$, filtered, and evaporated under vacuum. The residues were dissolved in 5 mL of DCM and precipitated by addition of 50 mL ethyl ether. Filtration afforded compound **21** (0.770 g, 84% yield). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.84 (3H, t, J = 7.6 Hz), 1.05 (3H, t, J = 7.3 Hz), 1.16 (9H, s), 2.15–2.30 (3H, m), 2.59 (2H, q, J = 7.6 Hz), 4.16 (1H, d, J = 17.9 Hz), 4.26 (1H, d, J = 17.9 Hz), 5.13 (2H, s), 5.46 (1H, d, J = 17.0 Hz), 5.60 (1H, d, J = 17.0 Hz), 7.11 (1H, d, J = 2.34 Hz), 7.30 (1H, s), 7.40–7.51 (6H, m), 7.56 (1H, dd, J = 2.34, 9.4 Hz), 7.77 (4H, dd, J = 7.6, 1.6 Hz), 7.98 (1H, d, J = 9.1 Hz). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 8.09, 13.72, 20.26, 23.61, 26.94, 31.83, 41.01, 50.71, 67.62, 79.51, 97.03, 111.65, 119.69, 127.13, 128.97, 128.99, 129.11, 131.43, 131.96, 133.00, 133.03,136.51, 145.62, 145.81, 147.24, 148.29, 150.58, 156.27, 158.68, 167.81, 168.34. MS (ESI): 688.40 $[M + H]^+$. HRMS (ESI) calcd for $C_{40}H_{41}N_3O_6Si$ $[M + H]^+$: 688.2843, found: 688.2844.

Compound 22. To a solution of compound **3** (1.4 g, 0.036 mmol) in 14 mL of anhydrous DCM were added compound **21** (0.207 g, 0.29 mmol), DMAP (0.175 g, 1.44 mmol), and PPAC (0.85 mL of a 50% solution in ethyl acetate, 1.44 mmol). The reaction mixture was stirred at room temperature overnight and then evaporated under vacuum. The resulting residue was dissolved in DCM, and the product was precipitated with ethyl ether and filtered. The residue was recrystallized with DMF/IPA to give compound **22** (1.25 g, 81% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.45, 13.20, 19.39, 22.73, 26.42, 31.67, 40.21, 49.01, 66.83, 69.80–71.12 (PEG), 78.08, 95.16, 110.02, 118.83, 125.58, 126.40, 127.53, 127.73, 129.96, 131.49, 131.76, 131.82, 135.12, 143.51, 144.78, 145.13, 146.95, 149.21, 154.61, 156.92, 166.70, 168.46, 170.30.

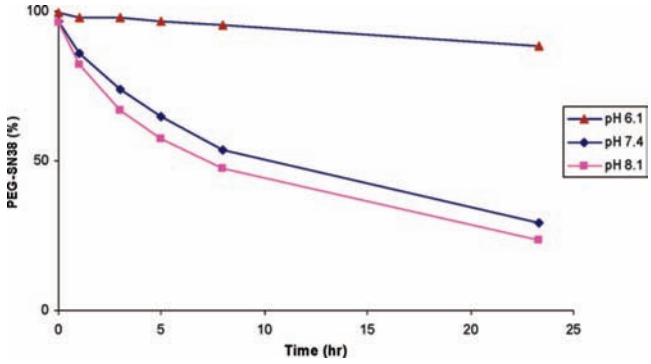


Figure 1. Stability of compound **23** in different pH conditions. Stability profile was determined using HPLC methods, by plotting the percentage of remaining compound **23** over a time course. The percentage was calculated on the basis of the ratio of the peak area of the analyte at 0, 1, 3, 5, 8, and 23 h vs the initial area peak. Each stability profile represents the average of two independent runs with the same sampling schedules. The standard deviation of each point is typically 2% or less.

Compound 23. Compound **22** (1.25 g, 0.029 mmol) was dissolved in a solution of TBAF (0.122 g, 0.46 mmol) in a 1:1 mixture of THF and 0.05 M HCl (12.5 mL). The reaction mixture was stirred at room temperature for 4 h and then extracted with DCM (2 × 30 mL). The combined organic phases were dried over $MgSO_4$, filtered, and evaporated under vacuum. The residue was dissolved in 7 mL of DMF and precipitated with 37 mL IPA. The solids were filtered and washed with IPA. Finally, the residue was dissolved in 2.5 mL of DCM and precipitated by the addition of 25 mL of ethyl ether. The solids were filtered and dried at 40 °C in vacuum oven overnight to give compound **23** (0.860 g, 71% yield). ^{13}C NMR (75.4 MHz, $CDCl_3$): δ 7.48, 13.52, 22.91, 31.67, 40.22, 49.12, 66.95, 69.70–70.87 (PEG), 78.14, 94.82, 105.03, 118.68, 122.54, 126.37, 128.20, 131.36, 142.92, 144.20, 144.98, 147.25, 148.29, 156.44, 156.98, 166.82, 168.49, 170.39.

Plasma Stability Study. PEG-SN38 conjugate (0.8 mg) was incubated with plasma (Biomeda, 1849 Bayshore Blvd., STE 200, Burlingame, CA 94010, 150 μL) at 37 °C for 0, 0.5, 2, 4, 6, 20, and 24 h. The mixtures were quenched with a 1:1 mixture of CH_3CN/MeOH (800 μL), vortexed for 1 min, and then filtered through a 0.2 μm filter membrane; 30 μL of the filtrate was analyzed by HPLC, measuring disappearance of the conjugates.

pH Stability Study. PEG-SN38 conjugate (10 mg/mL) was diluted into phosphate buffered saline adjusted to pH 6.1, 7.3, and 8.1 and incubated at 37 °C. Aliquots were removed at different time points and, after addition of an equal amount of DMSO, the samples were analyzed by HPLC, measuring disappearance of the conjugate. Stability profile graph was generated by plotting the percentage of remaining starting material over a time course (Figure 1). The percentage was calculated on the basis of the ratio of the peak area of the sample at 0, 1, 3, 5, 8, and 23 h vs the initial area peak. Each stability profile represents the average of two independent runs with the same sampling schedules. The standard deviation of each point is typically 2% or less.

In Vitro Cytotoxicity. All the cell lines were obtained from American type Culture Collection, Manassas, VA, and were grown in the listed medium: COLO 205 and OVCAR 3 (RPMI 1640 with 4.5 g/L glucose, 10 mM HEPES, 1 mM sodium pyruvate, 10% FBS); HT-29 (McCoy's 5a with 1.5 mM L-glutamine, 10% FBS) and A549 (Ham's F12K with 10% FBS). All cell lines were maintained at 37 °C (humidified, 5% CO_2). The medium was changed every 3 to 4 days and the cultures trypsinized and recultured when they reached 85% confluence. Media was obtained from Invitrogen corporation, CA. The in vitro cytotoxicity of PEG-SN38, SN38, and CPT-11 was determined using a cell proliferation (MTS) tetrazolium dye reduction assay. Briefly, adherent cells (10 000–20 000/well) were plated in 96-well plates and incubated overnight at 37 °C. The next morning, the cells were treated with serial dilutions of PEG-SN38, CPT-11, or SN38 dissolved in dimethyl sulfoxide (DMSO) and further incubated for 3–4 days at 37 °C. At the end of the incubation period, MTS dye was added, and formation of a colored product, formazan, was measured at 490 nm using a Spectramax 340PC reader (Molecular Devices, CA).

Table 1. Properties of PEG Conjugates

compound	% of loading	solubility (mg/mL)	$t_{1/2}$ (min)[b] human plasma	$t_{1/2}$ (min)[b] rat plasma
SN38		0.0072		
9	2.5	121 (3.0[a])	12.5	6.3
13	2.1	142 (2.9[a])	26.8	12.4
18	2.6	NA	19.0	10.5
23	3.7	180 (6.7[a])	12.3	3.5

[a] Equivalent to native SN38. [b] Based on the release of SN38.

In Vivo Efficacy Studies. Human mammary carcinoma (MX-1) tumor fragment were obtained from DTP, DCTD tumor repository, NCI, Bethesda, MD. Subcutaneous (s.c.) tumor xenograft models were established in the right axillary flank region of female nude mice (4–5 weeks) by injecting either human cancer cells or tumor fragments. MX-1 tumors were established by implanting a 4- to 5-mm^3 tissue fragment of MX-1 tumor collected from donor mice into the axillary flank of recipient nude mice.

RESULTS AND DISCUSSION

The objective of this study was to solubilize the insoluble anticancer molecule SN38, alter its pharmacokinetic profile, protect it in its active lactone form during transportation, and enhance its antitumor activity compared with CPT-11. To do so, we chose to use the four-arm-PEG to increase the loading of SN38 and developed highly efficient methods to make such PEG-SN38 conjugates. Three different protecting strategies had been tried, and four PEG-SN38 conjugates with different amino acid spacers were obtained successfully. The TBDPS-Boc protecting strategy (Scheme 5) had the advantage that every intermediate was stable; hence, they could be isolated, analyzed, and scaled up. The optimized method and process can be easily scaled up to multiple hundreds of grams with high quality and yield. Since the active ends of each PEG "arm" were far away from each other, they reacted independently with SN38 small molecule derivatives without steric hindrance compared with our previous branching approach. In addition, high water solubility of the PEG-SN38 conjugates was obtained by avoiding the stacking effect between lipophilic SN38 molecules. In the current approach, the loading by weight of SN38 could be as high as 3.7% compared with about 1.7% for PEG-CPT when linear bifunctional PEG was used.

As predicted, PEGylation has substantially increased the solubility of SN38, which is an insoluble molecule by itself (Table 1). The solubility of SN38 lactone in aqueous buffers published by Zhang et al. (*9*) is approximately 18 μM or 0.0072 mg/mL. All the PEG-SN38 conjugates have 120 to 180 mg/mL solubility in water, which is equivalent to as high as 6.7 mg/mL of SN38. This highly increased solubility makes it possible to systemically evaluate the therapeutic efficacy of SN38 in vivo.

The PEG conjugates were stable under neutral conditions in solution. Stability studies have demonstrated that PEG compounds release a minimum amount of free SN38 over 24 h at room temperature in clinically relevant solutions (Table 2). Since the linkage between the amino acid spacer and SN38 is an ester

Table 2. Stability at Room Temperature

compound	solution	time of detection (h)	released SN38 (%)
PEG-Ala-SN38 (**9**)	saline (0.9% NaCl)	0	0.1
		23	0.3
	water for injection	0	0.2
		24	1.6

23	0.14 ± 0.032	0.52 ± 0.066	0.16 ± 0.032	3.1 ± 0.43

bond, it will hydrolyze and release the intact SN38 under basic conditions. As predicted, when treated with buffers, the releasing rate of SN38 increased as the pH was increased above 6.0 in phosphate buffer at 37 °C (Figure 1, Table 3). In the preclinical studies, the release of SN38 could be due to several mechanisms as previously proposed (*17*). The pH-dependent study clearly showed that SN38 could be release at pH 7.4 and 37 °C with a half-life of about 14 h (Table 3). However, the half-life for the same compound in rat plasma was around 12 min (Table 1), which indicates that enzymes play a role in the release. These enzymes could be either esterases or aminopeptidases (*17*, *21*). Enzymes that catalyze the hydrolysis of tertiary esters, although rare, have been previously reported in the literature (*21*).

All the PEG-SN38 conjugates were first tested for their in vitro anticancer activities in different cancer cell lines using a cell proliferation [MTS] tetrazolium dye reduction assay. Briefly, adherent cells (10 000–20 000 /well) were plated in 96-well plates and incubated overnight at 37 °C. The next morning, the cells were treated with serial dilutions of PEG-SN38, CPT-11, or SN38 dissolved in dimethyl sulfoxide (DMSO) and further incubated for 3–4 days at 37 °C. At the end of the incubation period, MTS dye was added and formation of a colored product, formazan, was measured at 490 nm using a Spectramax 340PC reader (Molecular Devices, CA.). All conjugates were found to be very potent against a panel of cell lines (Table 4). Sensitivity of cells to PEG-SN38 is in the order COLO 205 > HT29 = OVCAR-3 > A549. PEG-SN38 conjugates were equipotent to native SN38 and about 6.5- to 666-fold more potent than CPT-11.

One unique property of camptothecin and its analogues is that the E-ring has to be in the closed lactone form in order to have any anticancer activities (*3, 5, 6*). Our previous studies (*12, 13*) had proven that acylation through the 20-OH of camptothecin and its analogues will lock the E-ring in the active lactone form. Since PEG is attached to SN38 through the acylation at 20-OH position, all the PEG-SN38 conjugates will ensure the SN38 existing in its active form during circulation without any loss of activity. In comparison, the water-solubilizing bispiperidine group is attached to the 10-OH group of SN38 in CPT-11. As a result, about 75% of CPT-11 has the potential to lose its anticancer activity due to the lactone opening even before SN38 is released. The demonstrated potent in vitro anticancer activity of all PEG-SN38 conjugates further suggests that intact SN38 in its active closed lactone form was regenerated during the incubation with tumor cells.

Table 5. Maximum Tolerated Dose Results

conjugate	dose level (mg/kg)	survival/ total	comments[a]
9	5	4/4	
	10	4/4	
	20	4/4	
	40	0/4	1 found dead, 3 sacrificed due to body weight loss
23	5	4/4	
	10	4/4	
	20	4/4	
	40	3/4	1 sacrificed due to body weight loss

[a] Total of 4 mice per study group.

In order to conduct in vivo efficacy studies, the maximum tolerable doses (MTD) were first obtained in mice. Female naive athymic nude mice were injected intravenously with a single dose of PEG-SN38 ranging from 5 to 40 mg/kg. Mice were monitored daily for visible signs of toxicity and weighed biweekly. The MTD was defined as the highest dose at which no death occurred, and body weight loss was less than 20% of pretreatment animal weight (approximately 20 g). Two PEG conjugates were selected for this study. It was found that the MTD of PEG-Ala-SN38 (**9**) or PEG-Gly-SN38 (**23**) was between 20 and 40 mg/kg when injected intravenously as a single dose in nude mice (Table 5).

For in vivo efficacy studies, MX-1 tumors were established by implanting a 4–5 mm^3 tissue fragment of MX-1 tumor collected from donor mice into the right axillary flank of recipient nude mice. When tumors reached an average volume of 100 mm^3, mice were injected with either PEG-SN38 conjugates or CPT-11 as a single dose of 20 mg/kg or multiple 5 mg/kg doses (every 2 days [q2d] × 6). Mouse weight and tumor sizes were measured at the beginning of the study and twice weekly throughout the study. Mice were euthanized when individual tumor volumes reached 1670 mm^3, and all surviving mice were euthanized at 12 weeks. Treatment with either of the four conjugates as a single dose of 20 mg/kg or multiple doses of 5 mg/kg (q2d × 6) PEG-SN38 led to >99% tumor growth inhibition (TGI) and complete cures (no evidence of tumor upon visual external examination and palpation of injection site) of the animals up to 12 weeks after which the animals were humanely sacrificed (Figure 2, Tables 6 and 7). There was only one unexplained death, which occurred in the PEG-Ala-SN38 20-mg/kg group early within the study. At equivalent dose levels, treatment with CPT-11 caused a 26% and 44% TGI when given as a single dose or multiple injections, respectively.

There was no body weight loss in all the cured mice. The mice were followed up to 100 days, and no tumor was detected after animals were sacrificed. Therefore, all PEG-SN38 conjugates demonstrated excellent anticancer activities and warrant further preclinical development. They all were superior to CPT-11 since treatment with CPT-11 resulted in either no TGI (single dose) or partial TGI sustained for a short period of time (multiple-dose regimen). The much enhanced antitumor efficacy of the high molecular weight PEG-SN38 conjugates could be partially attributed to the improved biodistribution and passive tumor targeting effect due to the enhanced permeation and retention (EPR) effect (*22*). In conclusion, treatment with PEG-SN38 conjugates was significantly more effective than treatment with CPT-11 in the MX-1 preclinical xenograft model. Due to the excellent anticancer efficacy as well as straightforward chemistry with little or no inherent impurities generated during the transformations, compound **23** was selected as the lead

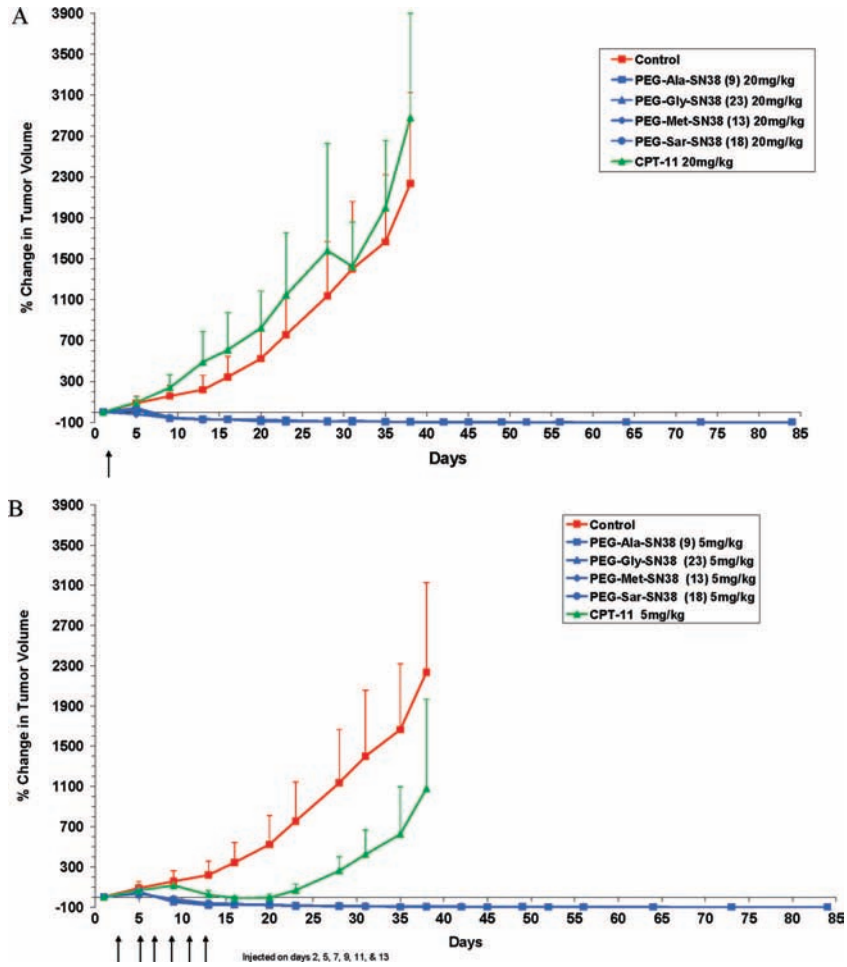

Figure 2. Therapeutic efficacy of PEG-SN38 conjugates in a xenograft model of breast cancer (MX-1). Female athymic nude mice (6 mice per group), were inoculated subcutaneously with 4- to 5-mm^3 tumor fragments of MX-1 breast tumors. When tumors reached an average volume of 100 mm^3, mice were injected with either PEG-SN38 conjugates or CPT-11 as a single dose of 20 mg/kg (panel A) or multiple 5-mg/kg doses (q2d × 6) (panel B). Data represent % change in tumor volume ± standard deviation.

candidate for further preclinical development and has entered into phase I clinical trials.

CONCLUSION

PEGylation is well-known for its ability to improve pharmaceutical properties of small molecules and to enhance the efficacy due to the EPR effect. Using multiarm PEG linkers, we successfully developed several novel PEG-SN38 conjugates that have high drug loading and high water solubility. The chemistry for the conjugation of SN38 ensures that the anticancer molecule is locked into its active closed lactone form in the body until intact SN38 is released from the PEG conjugate. Of the three different protecting strategies used to make such PEG-SN38 conjugates, one process has been optimized and scaled up with high reproducibility and yields. The improved pharmacokinetic profile of SN38, especially the possible passive accumulation of PEG-SN38 conjugates at the solid tumor sites, resulted in much enhanced anticancer activity of SN38 in the MX-1 xenograft mice model compared with CPT-11. Compound **23** was selected as the lead candidate for further preclinical development. In vitro and in vivo activities of the lead compound have been reported in another communication (*23*).

ACKNOWLEDGMENT

We wish to thank Ms. Mary Mehlig and Ms. Jennifer Malaby for their in vitro and in vivo work, Mr. Syed Ali and Mr. Nish Sanghvi for their contribution in the scale up of PEG conjugate, Mr. Honghue Hsu, Ms. Michelle Boro, and Ms. Chia Chang for their analysis of PEG compounds, and Dr. Zhihua (John) Zhang for his helpful discussion.

Received September 12, 2007; Revised Manuscript Received November 8, 2007

Fusion proteins based on the crystalline bacterial cell surface layer (S-layer) proteins SbpA from *Bacillus sphaericus* CCM 2177 and SbsB from *Geobacillus stearothermophilus* PV72/p2 and a peptide mimotope F1 that mimics an immunodominant epitope of Epstein–Barr virus (EBV) were designed and overexpressed in *Escherichia coli*. Constructs were designed such that the peptide mimotope was presented either at the C-terminus (SbpA/F1) or at the N-terminus (SbsB/F1) of the respective S-layer proteins. The resulting S-layer fusion proteins, SbpA/F1 and SbsB/F1, fully retained the intrinsic self-assembly capability of the S-layer moiety into monomolecular lattices. As determined by immunodot assays and ELISAs using monoclonal antibodies, the F1 mimotope was well-presented on the outer surface of the S-layer lattices and accessible for antibody binding. Further comparison of the two S-layer fusion proteins showed that the S-layer fusion protein SbpA/F1 had a higher antibody binding capacity than SbsB/F1 in aqueous solution and in immune sera, illustrating the importance of epitope orientation on the performance of solid-phase immunoassays. To assess the diagnostic values of S-layer mimotope fusion protein SbpA/F1, we screened a panel of 83 individual EBV IgM-positive, EBV negative, and potential cross-reactive sera for their reactivities. This resulted in 98.2% specificity and 89.3% sensitivity, and furthermore no cross-reactivity with related viral disease states including rheumatoid factor was observed. This study shows the potential of S-layer fusion proteins as a matrix for site-directed immobilization of small ligands in solid-phase immunoassays using EBV diagnostics as a model system.

INTRODUCTION

The use of peptide epitopes as diagnostic antigens in commercial diagnostics is a promising approach toward simpler and cheaper ELISA-based diagnostic assays. Diagnostic antigens may appear as complexes of more than one protein that are often highly glycosylated; therefore, it would be highly advantageous if, instead of the whole protein, one or more peptides mimicking diagnostically important epitope(s) could be used (*1*). Optimal presentation of peptide ligands is essential for the sensitivity of detection in solid-phase immuno-assays like ELISA. Peptides have to be immobilized in such a way that their three-dimensional structure, functionality, and binding sites are retained (*2*). Conventional immobilization procedures for small ligands used in ELISAs are based on covalent binding and adsorption/absorption of peptides on a solid surface. However, the accessibility of the peptide for capture of target antibodies has been recognized as the central problem of immobilized peptide ligands. For better exposition, spacer molecules, e.g., long alkyl chains, polyamino acids, or proteins, can be introduced, but common to all these spacers is nonspecific adsorption and overflexibility that may counteract the exposition of the ligands (*3, 4*). Furthermore, since the peptides are attached on the surface in random orientation, the signal-to-noise ratio can be high due to nonspecific binding (*5*).

The S-layer self-assembly systems introduce new possibilities for site-directed peptide epitope immobilization. As a novel approach, we have designed two chimeric proteins by fusing a peptide epitope to crystalline bacterial cell surface (S-layer) proteins. The suitability of S-layer protein lattices as matrices for the covalent immobilization of peptides has already been demonstrated for immunochemical-based assays such as ELISA (*6–9*). S-layers, in general, are monomolecular proteinaceous arrays that represent the outermost cell envelope component of many prokaryotic organisms (*10–14*). They are composed of identical (glycol) protein species that are aligned into 2D crystalline arrays. Isolated S-layer subunits usually have the intrinsic capability to self-assemble in suspension, on the air–liquid interface, on lipid films, or on solid supports (*12, 13, 15, 16*). By genetic engineering, discrete functions could be introduced into S-layer proteins (*17–26*). On the basis of the high density and regular display of the introduced functions, a broad spectrum of applications of S-layer fusion proteins is envisaged, particularly in the fields of biotechnology, molecular nanotechnology, and biomimetics (*14, 16, 27*). Regarding peptide epitope immobilization, the advantages offered by the S-layer self-assembly system are (i) the requirement of only a simple, one-step incubation process for site-directed immobilization without preceding surface activation of the support, (ii) the provision of a cushion to the peptide epitope through the S-layer moiety of the fusion protein preventing denaturation, and precluding a loss of detection sensitivity upon immobilization, (iii) the principle applicability of the "S-layer tag" to any peptide epitope, and (iv) the high flexibility for variation of peptide epitope groups within a single S-layer array by cocrystallization of different peptide epitope/S-layer fusion proteins.

In this study, the feasibility of fusing a peptide epitope to both the C-terminus and the N-terminus of an S-layer protein was investigated. For the setup of S-layer fusion proteins, two different types of proteins were used as S-layer protein moieties. The 200 amino acid deletion mutant of the 1268 amino acid S-layer protein SbpA of *Bacillus sphaericus* CCM 2177 (MW: 109.9 kDa) was chosen to fuse via its N-terminus toward the S-layer protein. This approach was based on previous structure–function studies revealing that the C-terminal deletion of SbpA resulted in a significant increase of the spatial accessibility of the C-terminus, while fully retaining the self-assembly capability of the proteins into a square (p4) S-layer lattice with a center-to-center spacing of the tetrameric morphological units of 13.1 nm (Figure 2A, inset) (*18*). An advantage of the SbpA system for nanobiotechnological applications is the dependence of its *in vitro* recrystallization on the presence of calcium ions, thus allowing control over lattice formation by varying the calcium ion concentration (*28*). Furthermore, the peptide epitope was attached to the N-terminus of mature full-length S-layer protein SbsB of *Geobacillus stearothermophilus* PV72/p2 (MW: 95.0 kDa). SbsB is generated from a 920 amino acid long preprotein by cleavage of a 31-aa signal sequence and assembles into an oblique (p1) lattice type with the lattice parameters $a = 10.4$ nm, $b = 7.9$ nm, and base angle $\gamma = 81°$ (Figure 2B, inset) (*29*). An understanding of the protein's structure–function relationship was gained in a preliminary study from the production and analysis of truncated forms, sequence analysis, and electron microscopy. The knowledge was used to select sequence positions for functional fusion (*24, 29, 30*).

As a peptide epitope fusion partner, we selected a 20 amino acid long peptide (F1) that mimics an immunodominant epitope of Epstein–Barr virus (EBV). In our previous study, we showed that the F1 mimotope can be used for the detection of IgM antibodies typically generated after infection with EBV. F1 was selected from a random peptide library displayed on phage by binding to the parent antibody thereby mimicking the three-dimensional conformational features of the epitope (*1*). The monoclonal antibody was generated by immunizing mice with crude EBV antigen. The exact antigen that the F1 peptide mimics is not known. In this study, we constructed S-layer/F1 peptide fusion proteins to investigate the presentation and orientation of the peptide mimotope within the S-layer lattice and have characterized the structure of the lattices. Following the successful proof of concept studies, this article deals with the investigation of the suitability of the system for diagnostic purposes. Therefore, we have also screened a panel of EBV clinical samples to evaluate the performance of the S-layer/F1 fusion proteins in diagnosis of Epstein–Barr virus infection.

EXPERIMENTAL PROCEDURES

Cloning of the Chimeric SbpA/F1 and SbsB/F1 Genes. Two constructs were synthesized with F1 peptide fused at the C-terminus (SbpA/F1) and F1 fused to the N-terminus (SbsB/F1) using pairs of complementary oligonucleotides. These were annealed to generate 10 amino acid inserts containing a $(gly)_4$ linker with the appropriate overhang for the ligation into restriction sites *Bam*HI-XhoI and NcoI-*Eco*RI (Table 1). For annealing, an equimolar mixture of one pair of phosphorylated oligonucleotides was heated to 98 °C for 2 min and cooled slowly to room temperature, allowing the complementary sequences to anneal. The two double-stranded inserts, SbpA/F1 and SbsB/F1, phosphorylated at both 5′-termini and, with the appropriate overhang at each end, were integrated into a pET28a (+) vector (Novagen), which contained the truncated S-layer protein gene $SbpA_{93–3204}$ with *Bam*HI-XhoI sites and $SbsB_{96–2760}$ with NcoI-*Eco*RI sites, respectively (*18*). Digestion of DNA with restriction endonucleases, separation of DNA fragments by agarose gel electrophoresis, ligation of DNA fragments, and transformation procedures were performed as described by Sambrook (*31*). DNA fragments were recovered from agarose gels by Qiaex II gel extraction kit (QIAgen). The constructs $SbpA_{93–3204}$/F1 and $SbsB_{96–2760}$/F1 were transformed into *E. coli* DH10b cells (Invitrogen) by electroporation.

Overexpression and Purification of SbpA/F1 and SbsB/F1 Fusion Proteins. S-layer fusion proteins were overexpressed in *E. coli* BL21(DE3)star cells (Invitrogen) in a 4-l fermenter according to the pET System Manual (Novogen) and monitored by SDS-PAGE with Coomassie staining (*32*). For isolation of SbpA/F1 and SbsB/F1 proteins, the B-PER bacterial protein extraction reagent (Pierce) was used as an efficient method of extracting proteins from bacteria following the protocol provided by the manufacturer. The S-layer fusion proteins accumulated in the insoluble fraction and were extracted with 50 mM Tris-HCl/150 mM NaCl/5 M guanidine hydrochloride (GHCl) buffer pH 7.2. The suspension was then centrifuged at 36 000*g* for 30 min at 4 °C, and the supernatant containing the S-layer fusion protein was diluted 1:2 with 50 mM Tris-HCl buffer pH 7.2. The clear solution was subjected to permeation chromatography (GPC) using a Superdex 200 column (Pharmacia) equilibrated in 2.5 M GHCl in 50 mM Tris-HCl buffer pH 7.2. Fractions belonging to the peak corresponding to the expected molecular weight were pooled and dialyzed against four changes of MilliQ water for 18 h at 4 °C. Following dialysis, the protein solution was lyophilized and stored at –20 °C.

Self-Assembly and Recrystallization Properties of the S-Layer Fusion Proteins. In order to investigate the capability of the S-layer fusion protein, SbpA/F1 and SbsB/F1, to self-assemble in solution a series of refolding steps were carried out. Purified fusion proteins (3 mg) were dissolved in 1 mL of 5 M GHCl in 0.5 mM Tris-HCl, pH 7.2, and the solution was dialyzed against 10 mM $CaCl_2$ for 18 h at 4 °C with 5 buffer changes in the first 6 h. S-layer self-assembly products were adsorbed onto EM grids coated with pioloform and carbon. Negative staining was performed with uranylacetate (2% in distilled water, pH 4.3) for 2 min. Monomeric protein solutions of SbpA/F1 and SbsB/F1 were obtained after dialysis with 3 buffer changes of the GHCl extract against distilled water for 3 h at 4 °C and centrifugation of the dialysate at 16 000*g* for 5 min at 4 °C (AvantiJ-25, Beckman Coulter). Recrystallization of SbpA/F1 and SbsB/F1 monomers on 300 mesh copper grids, coated with pioloform and carbon, was investigated by transmission electron microscopy (*33*). For recrystallization on silicon wafers with a native silicon oxide layer (p-type, 100 orientation; 7 × 7 mm; IMEC) and polystyrene slides (Bilek), wafers and slides were washed with 70% ethanol immersed with 100 μL

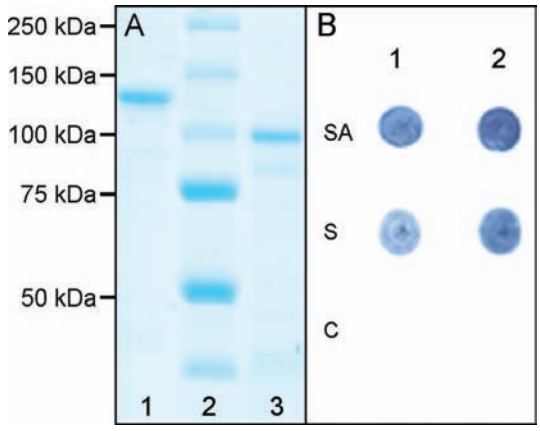

Figure 1. (A) SDS-PAGE analysis after Coomassie staining. Lane 1, purified SbpA/F1 fusion protein (MW: 112.4 kDa); lane 2, benchmark ladder (All blue, Biorad laboratories); lane 3, purified SbsB/F1 fusion protein (MW: 97.5 kDa). (B) Immunodot analysis of SbsB/F1 (1) and SbpA/F1 (2) of self-assembly products (SA), soluble S-layer fusion protein (S), and sole S-layer protein SbsB and SbpA, respectively, as control (C).

SbpA/F1 and SbsB/F1 (at 0.1 mg/mL) in 0.5 mM Tris-HCl/10 mM $CaCl_2$, pH 9.0, and incubated at 25 °C for 4 h. Atomic force microscopy (AFM) analysis was performed as described previously (*28*).

Immunodot Assays for Investigation of the Accessibility of Fused Mimotopes. To investigate the accessibility of the fused F1-domain in the water-soluble and recrystallized S-layer fusion proteins, 20 μL of SbpA/F1 and SbsB/F1 with an S-layer content of 1 mg/mL was dried onto a nitrocellulose membrane. After blocking with 2% Top Block (derivative of gelatine to block unspecific binding sites on surfaces, Fluka) in Tris-buffered saline (TBS) and incubation with 20 ng F1 monoclonal antibody (mAb) in 5 mL of TBS containing 2% Top Block with gentle agitation for 1 h at 25 °C, the membrane was washed three times with 0.5% Tween in TBS and subsequently incubated with an anti-Mouse IgG (whole molecule) alkaline phosphatase conjugate (antimouse AP, Sigma) diluted 1:5000 in blocking solution with gentle agitation for 1 h at 25 °C. After three further washing steps, detection was accomplished by treatment with 5-brom-4-chloro-3-indolyl phosphate and nitroblue tetrazolium chloride (BCIP/NBT, Roche).

Reactivity of F1 in SbpA/F1 and SbsB/F1 Fusions by ELISA. The presence of the F1 moiety in the S-layer fusion proteins was confirmed by performing ELISAs. S-layer fusion proteins (200 μL at 0.1 mg/mL) were coated onto microtiter plates (Greiner Bio-one) in 0.5 mM Tris-HCl/10 mM $CaCl_2$, pH 9.0, at 25 °C with gentle agitation for 4 h. For stabilization, the coated plates were incubated with a biomolecular stabilizator (StabilGuard, Surmodics) diluted 1:1 with phosphate buffered saline containing 0.1% Triton X-100 (PBS/Triton) for 4 h at 25 °C. Subsequently, the microtiter plates were dried overnight at 37 °C. For ELISA, the coated microtiter plates were blocked with 2% Top Block in PBS/Triton overnight at 4 °C. Subsequently, 100 μL per well of serial dilutions of anti-F1 antibody in PBS/Triton containing 2% Top Block (w/v) were added for 1 h with gentle agitation. The plates were washed three times with PBS/Triton and 110 μL per well antimouse peroxidase conjugate (Sigma) diluted 1: 2000 in PBS/Triton containing 2% Top Block was added and incubated as above. Subsequently, the plates were washed again as above, and the ELISA was developed with 3,3′,5,5′-tetramethylbenzidine substrate (TMB, Sigma). All samples were analyzed in duplicate, and wells coated with the wild-type S-layer protein SbpA without F1 peptide were used as controls.

Clinical Samples. Individual human serum samples were obtained from Queensland Medical Laboratory (Brisbane, Australia), and these had been previously tested with a commercial kit for EBV diagnosis. Samples ($n = 28$) defined as IgM positive were collected from individuals with recent or early-stage infectious mononucleosis. Negative sera ($n = 40$) were obtained from patients without EBV IgM or EBV IgG antibodies. Putative cross-reactive sera ($n = 15$) were also obtained that may cause false positive readings in EBV diagnostic tests; we analyzed 4 Parvovirus (Parvo), 2 Herpes Simplex virus (HSV), 3 cytomegalovirus (CMV), 3 Varicella Zoster (Zoster), and 2 Rheumatoid factor (RF) samples.

Screening of Clinical Samples by ELISA. Coated plates were blocked with 200 μL/well 2% BSA/PBS Tween 20 (0.1%) overnight at room temperature and washed twice with PBSTween to remove blocking agent. Serum samples were diluted 1/100 in fish gelatin diluent (PBS containing 2% fish gelatin [Sigma], 1% Tween-20, and 1% bovine serum albumin) and 100 μL applied to blocked wells in duplicate; the plate was incubated for 1 h shaking. Wells were washed 5 times with PBSTween, and 100 μL per well of sheep antihuman IgM conjugated to horse radish peroxidase (HRP, Chemicon) at 1/3500 dilution in fish gelatin diluent was added. After 1 h incubation and washing as above, bound IgM antibodies were detected with TMB substrate. All samples were analyzed in duplicate, and wells coated with the wild type S-layer protein SbpA without F1 peptide were used as controls.

RESULTS AND DISCUSSION

Cloning of the Chimeric S-Layer Fusion Proteins SbpA/F1 and SbsB/F1. Studies of the structure–function relationship of the S-layer proteins SbpA of *Bacillus sphaericus* CCM 2177 and SbsB *Geobacillus stearothermophilus* PV72/p2 were considered as presupposition for the construction of two novel S-layer fusion proteins, which retained assembly and recrystallization properties of the S-layer moiety, as well as the functionality of the fused peptide sequence (*17–26*). In attempt to optimize peptide presentation, a C-terminally truncated SbpA form and the full-length S-layer protein SbsB were selected as base forms for the construction of S-layer fusion proteins comprising the sequence of the 20-aa-long peptide F1 which mimics an immunodominant epitope of Epstein–Barr virus (EBV).

Two inserts encoding F1 peptide with overhangs of respective restriction sites were derived from alignment of two pairs of oligonucleotides. The inserts were ligated via the corresponding restriction sites into plasmid pET-28 (+)-$SbpA_{93-3204}$ and plasmid pET-28 (+)-$SbsB_{96-2760}$, containing the encoding sequence of the C-terminally truncated form of S-layer protein SbpA and the full-length S-layer protein SbsB, respectively. Sequence accuracy of the two S-layer mimotope fusion protein genes was proven by the sequencing service of Invitrogen.

Expression, Isolation, and Purification of the Chimeric S-Layer Fusion Proteins SbpA/F1 and SbsB/F1. The S-layer/F1 fusion proteins were overexpressed in *E. coli* BL21Star (DE3) cells harboring pET-28 (+)-$SbpA_{93-3204}$/F1 and pET-28 (+)-$SbsB_{96-2760}$/F1, respectively. For isolation of SbpA/F1 and SbsB/F1, the biomass harvested from a 3-l expression culture was treated with B-PER reagent. As previously observed for the sole recombinant S-layer proteins, the fusion proteins accumulated as inclusion bodies (*18*). SbpA/F1 and SbsB/F1 were extracted by treatment with 5 M GHCl (3 mL g^{-1} inclusion bodies) and finally enriched by GPC to high purity with overall yields of purified, monomeric protein chimera of 0.44 g (SbpA/F1) and 0.21 g (SbsB/F1) per liter of *E. coli* BL21Star(DE3) expression culture. The molecular masses of the purified chimeric proteins shown on SDS PAGE corresponded well to

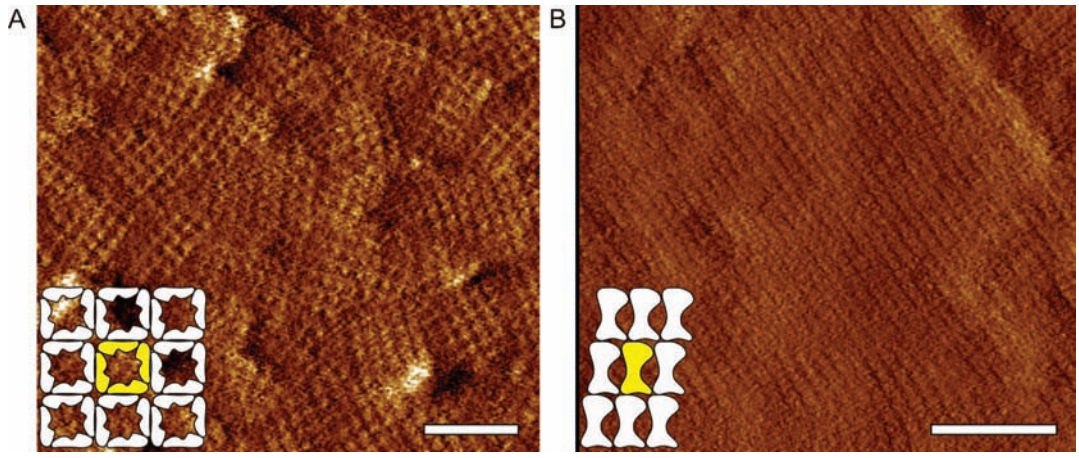

Figure 2. Atomic force microscopical images of the square lattice of SbpA/F1 (A) and the oblique lattice of SbsB/F1 (B) recrystallized on polystyrene slides. Bar, 100 nm.

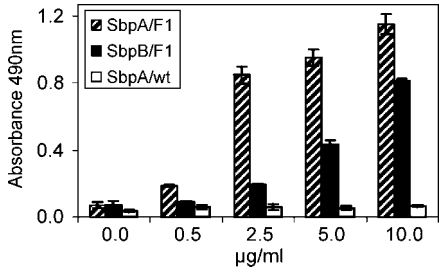

Figure 3. IgG binding capacity (F1 mAb offered: μg/mL) of S-layer mimotope fusion proteins SbpA/F1 and SbsB/F1 recrystallized on microtiter plates in comparison to wild-type S-layer protein SbpA.

the calculated molecular masses of 112.4 kDa (SbpA/F1) and 97.5 kDa (SbsB/F1) shown in Figure 2A.

Investigation of the Self-Assembly Properties of the S-Layer Fusion Proteins. Triggered by the S-layer moiety, the S-layer fusion proteins were capable of intrinsically self-assembling *in vitro* into flat sheets. The electron micrographs of negatively stained preparations clearly revealed the formation of S-layer self-assembly products of both S-layer fusion proteins in solution. The S-layer fusion protein SbpA/F1 exhibited the square lattice structure of native SbpA with a center-to-center spacing of tetrameric units of 13.1 nm (*12*). S-layer fusion protein SbsB/F1 showed the typical oblique lattice characteristic of native SbsB with the lattice parameters $a = 10.4$ nm, $b = 7.9$ nm, and base angle $\gamma = 81°$ (*13*) (electron micrographs not shown).

Investigations of Accessibility of Fused Mimotope Groups. Dot blot assays were performed to investigate the accessibility of the fused F1 for binding to IgG in monomeric and self-assembled S-layer fusion proteins. Immunodot experiments showed that the mimotope groups of the S-layer fusion proteins SbpA/F1 and SbsB/F1 were clearly accessible for IgG binding. According to the dots intensities, alignment of the mimotopes within the protein lattice resulted in better accessibility for IgG binding than when provided as monomeric S-layer fusion protein (Figure 1B).

Immobilization of the S-Layer Fusion Protein on Solid Supports. The capability of the two S-layer fusion proteins, SbpA/F1 and SbsB/F1, to recrystallize on solid supports was confirmed by AFM evidence. On silicon wafers (data not shown) as well as on polystyrene slides which present the material of ELISA wells, the S-layer fusion proteins exhibited the square (Figure 2A) and oblique (Figure 2B) lattice structures characteristic of native S-layer protein SbpA and SbsB, respectively. These microscopic analyses confirmed that the obtained S-layer fusion proteins can be considered model systems for the S-layer-based site-directed immobilization of small peptides used in diagnostics.

Investigation of the Reactivity of F1 in SbpA/F1 and SbsB/F1 Fusions by ELISA. Due to the specific physicochemical properties of the S-layer moieties (*18*), the S-layer fusion proteins were recrystallized onto microtiter wells, thereby exposing the F1 moiety at the C- or N-terminus in SbpA/F1 and SbsB/F1, respectively. The defined orientation of SbpA/F1 and SbsB/F1 was demonstrated via ELISA techniques that confirmed the ability of the F1 mimotope to bind parent F1 mAb in the formed monolayers (Figure 3). The S-layer fusion protein SbpA/F1 showed a better antibody binding capacity than S-layer fusion protein SbsB/F1 as shown by higher binding to the parent F1 mAb. The wild-type S-layer protein SbpA/wt chosen as the blank did not show any nonspecific binding of F1 mAb, giving a good signal-to-noise ratio (Figure 3).

We also compared SbpA/F1 and SbsB/F1 with a small set of EBV clinical samples. It was apparent in Figure 4A that F1 peptide when attached to SbpA was superior for recognizing IgM antibodies in the sera of patients with EBV. The better performance of the SbpA-based S-layer fusion protein was likely to be caused by the different molecular orientation of the mimotope F1 within the S-layer lattice. Fused via its N-terminus, the mimotope could fully deploy its functionality as IgM antibodies recognized this peptide conformation preferentially. The results obtained with the two different S-layer systems refer to different accessibilities of the functional groups within different S-layer lattices.

SbpA/F1 for Diagnosis of EBV. According to the data above, a more accurate assessment of the diagnostic value of the S-layer fusion protein rSbpA/F1 with a larger panel of positive, negative, and putative cross-reactive sera was performed. S-layer fusion protein SbpA/F1 was used in ELISAs as a solid phase for capture of IgM antibodies in clinical samples obtained from patients with EBV. To correct for background levels, the reactivity to SbpA/wt was also measured, and these values were subtracted from the SbpA/F1 readings. We analyzed 28 individual EBV samples and could identify IgM antibodies in 25 of these, resulting in 89.3% sensitivity (Figure 4B). Forty negative sera were analyzed and only 1 false positive was observed (98.2% specificity). In addition, very low reactivity was observed in 15 putative cross-reactive samples including rheumatoid factor, which is a common false positive in many commercial diagnostic tests (*1*).

These results were in good accordance with currently used commercially available assay systems based on the capture of IgM antibodies using complex EBV antigens (*34*). Due to the

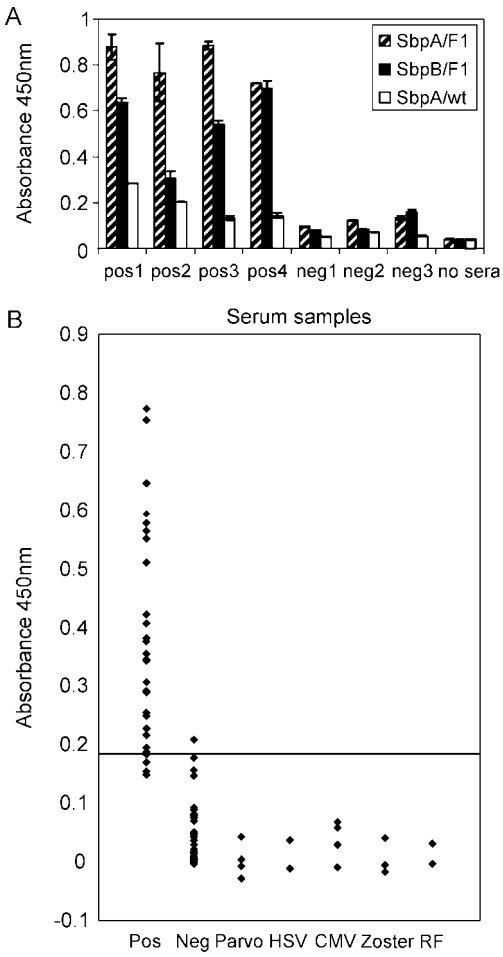

Figure 4. Screening of clinical samples using S-layer/F1 fusion proteins. (A) Detection of IgM antibodies in individual EBV-positive sera with SbpA/F1 and SbsB/F1 compared to wild-type SbpA/wt containing no F1 peptide, by ELISA. Mean values are plotted; error bars indicate the ranges of individual values. (B) ELISA showing the reactivity of SbpA/F1 fusion protein with EBV IgM positive ($n = 28$), negative ($n = 40$), and sera that could potentially be cross-reactive ($n = 15$): Parvovirus (Parvo, $n = 4$), Herpes Simplex virus (HSV, $n = 2$), cytomegalovirus (CMV, $n = 4$), Varicella Zoster (Zoster, $n = 3$), and Rheumatoid factor (RF, $n = 2$). Absorbencies for SbpA/F1 were subtracted from SbpA/wt readings and plotted. The cutoff level is defined as the mean of the negative population ($n = 40$) + 3 SD, shown as a horizontal line in the dot plot. The cutoff value for SbpA/F1 was 0.18.

high sensitivity and specificity of S-layer-based solid-phase immunoassays, S-layer proteins can be used as an immobilization matrix in ELISA-based diagnostics (*9*). Antibody capture with surface-displayed peptides is crucially affected by the accessibility of key residues of peptide ligands (*35*).The presentation of the small mimotope sequence within the S-layer lattice led to accurate accessibility and consequently reactivity of the displayed peptides. Furthermore, immobilization of peptides may cause partial denaturation at the site of adhesion to the support (*5*). It is conceivable that, with S-layer fusion proteins, the S-layer moiety acts as a cushion preventing denaturation of the mimotope upon immobilization.

CONCLUSION

The data presented here clearly demonstrate that S-layer-based self-assembly systems for functionalizing solid supports could have importance for the introduction of small peptide mimotopes in diagnostic assays. By exploiting the intrinsic self-assembly property of the S-layer protein moiety, the chimeric protein SbpA/F1 was used for spatial control over the display of the mimotope on planar surfaces. Linking the mimotope to the S-layer protein resulted in a biological function comparable to currently used commercially available assay systems using complex EBV antigens. This immobilization technology is applicable to any peptide and can be important for the development of novel diagnostic assays. Furthermore, this technology may facilitate the use of peptides as surrogate antigens in diagnostic assay.

ACKNOWLEDGMENT

We wish to thank Graham Street of Queensland Medical laboratory (Brisbane, Australia) for providing the clinical samples.

Received October 21, 2007; Revised Manuscript Received January 14, 2008

Virus-like particles composed of hepatitis B virus (HBV) or bacteriophage Qβ capsid proteins have been labeled with azide- or alkyne-containing unnatural amino acids by expression in a methionine auxotrophic strain of *E. coli*. The substitution does not affect the ability of the particles to self-assemble into icosahedral structures indistinguishable from native forms. The azide and alkyne groups were addressed by Cu(I)-catalyzed [3 + 2] cycloaddition: HBV particles were decomposed by the formation of more than 120 triazole linkages per capsid in a location-dependent manner, whereas Qβ suffered no such instability. The marriage of these well-known techniques of sense-codon reassignment and bioorthogonal chemical coupling provides the capability to construct polyvalent particles displaying a wide variety of functional groups with near-perfect control of spacing.

INTRODUCTION

A variety of strategies and expression systems have been employed to cotranslationally incorporate unnatural amino acids into proteins. The three most common approaches are the use of a nonsense or rare codon (*1–8*), the use of a larger (quadruplet) codon (*4, 9*), or the reassignment of a sense codon (*10–17*). In the last approach, codons for methionine (*11–15, 18, 19*), leucine (*20*), isoleucine (*21*), phenylalanine (*22*), tryptophan (*23, 24*), and proline (*25*) have been used for incorporation of unnatural amino acids. Here we employ this technique (*10, 16, 26*) to replace methionine with the unnatural amino acids azidohomoalanine (**1**, Figure 1) and homopropargyl glycine (**2**) for the first time in proteins that spontaneously assemble into virus-like particles in the host *E. coli* cell.

The incorporation of organic azides and terminal alkynes introduces highly energetic functional groups that are inert to biological molecules under physiological conditions. The azide group's "bio-orthogonality" has been particularly prized, due to its participation in the Staudinger reaction with phosphines (*27, 28*), cycloaddition with strained-ring alkynes (*27, 29–31*), and copper(I)-mediated cycloaddition with terminal alkynes (*32, 33*). We have developed the last of these into a robust tool for making connections with biological molecules (*34*) at reasonable concentrations (*35*). The process has been used by us and others for the selective modification of enzymes (*6, 36*), cells (*14, 15, 37*), virus particles (*7, 34, 35, 38, 39*), newly synthesized proteins (*40–43*), and tissue lysates (*44, 45*). The cotranslational incorporation of azides and alkynes into self-assembled virus-like particles enables their use in the chemoselective preparation of polyvalently labeled structures. In addition to providing near-perfect control over the positioning of desired groups on the virus surface, the genetic incorporation and subsequent chemical addressing of azides and alkynes allows the independent use of other bioconjugation techniques without protecting group manipulations or concerns about cross-reactivity.

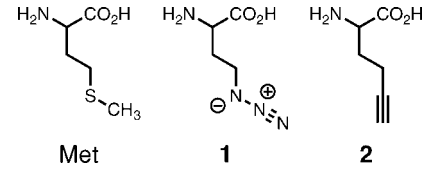

Figure 1. Methionine analogues **1** and **2** incorporated into virus-like capsids using codon reassignment.

The inner protein shell (core antigen) of hepatitis B virus is composed of either 180 (maximum diameter 318 Å) or 240 (maximum diameter 348 Å) copies of the coat protein (Figure 2) (*46, 47*). We will use the abbreviation HBV to refer to the latter structure, which is the predominant (*46*) particle used here; the designation HBcAg also appears in the literature. The native capsid protein is 183 amino acids in length; we employed the assembly domain composed of the first 149 amino acids (Cp149), which is largely α-helical and produces more than 95% of the 240-subunit particle. While a variety of recombinant protein expression systems have been used successfully to produce the HBV core antigen (*48, 49*), by far the most common has been *E. coli* (*50, 51*).

The *E. coli* bacteriophage Qβ is composed of 180 copies of the coat protein assembled into a $T = 3$ icosahedral virion (average diameter 270 Å, Figure 2) (*52, 53*), encapsidating a positive-sense RNA genome (*54*). The capsid protein is composed of 132 amino acids of mostly antiparallel β-sheet structure (*52, 55*). For a nonthermophile, the capsid is unusually stable toward extremes of pH, temperature, and chemical reagents, due to a combination of a large noncovalent contact area within capsid dimers. Furthermore, cysteine residues at positions 74 and 80, located at the five- and threefold axes of symmetry, respectively, form disulfide linkages to the corresponding residues of neighboring subunits. As a result, rings of five subunits are formed at the icosahedral fivefold symmetry axis, and rings of six protein subunits are formed around the threefold axis, with each protein dimer being linked to the capsid by four disulfide bonds. The coat protein of Qβ is tolerant of

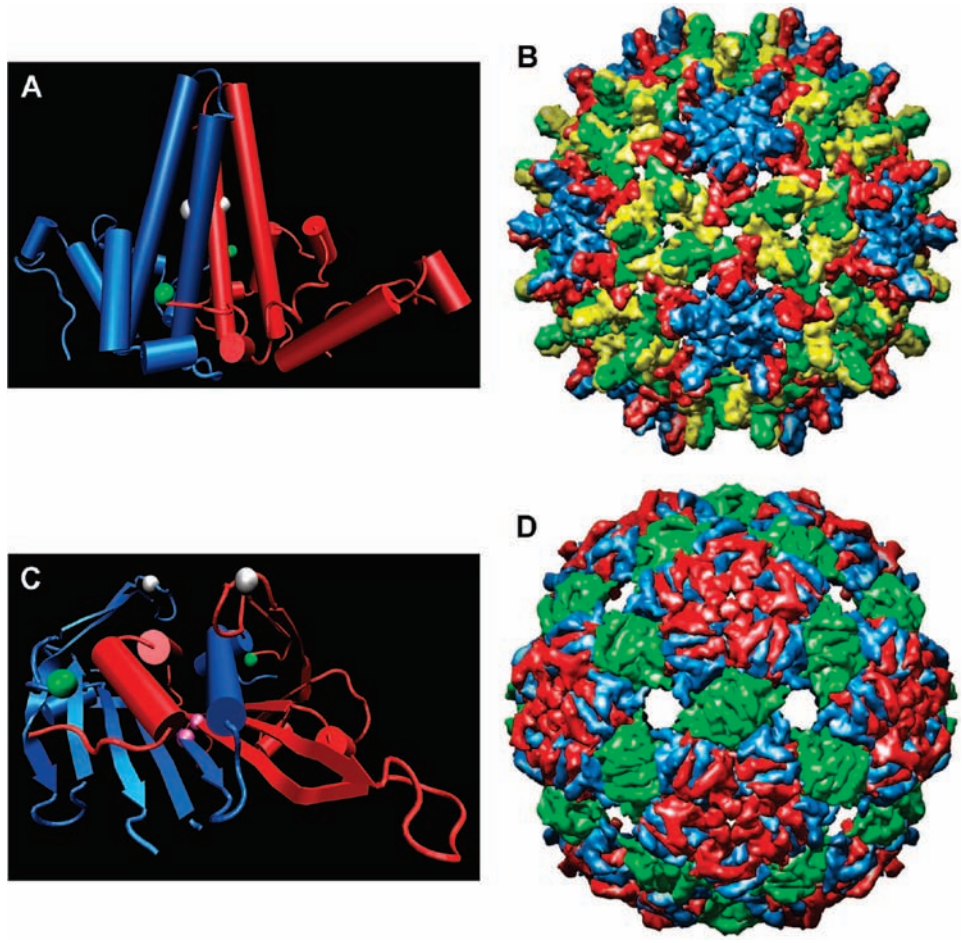

Figure 2. HBV and Qβ virus-like particles. (A) HBV dimer; (B) HBV virus-like particle; (C) Qβ dimer; (D) Qβ virus-like particle (*47*, *55*, *59*). Representations (A) and (C) look obliquely down onto the outside capsid surface, showing the 4-helix bundle for HBV and intertwined α-helix and loop segments over adjacent β-sheets for Qβ. The spheres mark the locations of methionine residues: green = *N*-termini, white = Met66 in HBV and K16 M in Qβ, purple = Qβ T93M.

genetic manipulation and can be recombinantly expressed in high yields (*56*–*58*), making it desirable for a variety of applications. All mention below of particles or virions refer to the noninfectious, self-assembled virus-like particles (VLPs) of either HBV or Qβ, encapsidating random cellular RNA.

RESULTS AND DISCUSSION

Unnatural Amino Acid Incorporation. We have incorporated the unnatural amino acids azidohomoalanine (**1**) and homopropargylglycine (**2**) into HBV and Qβ using reassignment of the methionine sense codon, which provides global replacement of all methionines with the unnatural amino acid. Thus, genetic engineering is usually required to place Met residues where the unnatural amino acids are desired. The presence of *N*-terminal methionine, required by the translational machinery, is variable for both HBV Cp149 and Qβ, as it is for many proteins expressed in *E. coli* (*60*). HBV contains one additional Met at position 66, situated halfway up the side of the four helix bundle and therefore accessible to solution-phase reactants (Figure 2A). The Qβ sequence has no other methionines, so mutants K16 M and T93 M were generated. The former places the new amino acid at the most exposed location of the capsid exterior, while the latter installs Met (or its surrogate) on the interior surface in a somewhat hindered position (Figure 2C).

For the efficient incorporation of unnatural amino acids, the protein must be expressed under tight inducible control. Native and mutant HBV and Qβ coat protein sequences were cloned into the pQE-60 plasmid (Qiagen) and the methionine auxotroph *E. coli* strain M15(pREP4)MA was used for expression. The transformed cells were grown in minimal media supplemented with all 20 naturally occurring amino acids. When the desired mass of cells was achieved, methionine was removed from the media by pelleting, washing, and resuspending the cells in minimal media containing all the natural amino acids except methionine. The cells were incubated at 37 °C for 30–60 min to allow the bacteria to deplete their intracellular stocks of methionine. Finally protein expression was initiated by distributing the cells in minimal media containing the 19 natural amino acids, 1 mM isopropyl-β-D-1-thiogalactopyranoside (IPTG), and 80 mg/L of racemic **1** or **2**.

A series of control experiments established that HBV or Qβ protein was produced only when the minimal media was supplemented by Met, **1**, or **2**, and only in the presence of IPTG. In media supplemented with **1** or **2**, the yield of isolated HBV or Qβ particles was approximately 20–60% of the amount of protein produced in normal media under the same induction by IPTG (Table 1), representing some of the highest yields of unnatural amino acid-containing proteins reported thus far (see Supporting Information).

HBV and Qβ VLPs containing **1** or **2** were indistinguishable in all physical characteristics from the analogous particles incorporating methionine (Figure 3). In each case, ultracentrifugation through sucrose gradients (not shown) and analysis on size-exclusion chromatography produced sharp virus bands at the same position as native capsids. Negative-stained transmission electron microscopy images of the particles

Table 1. Average Expression Levels of HBV and Qβ VLPs with Methionine, Azidohomoalanine (1), or Homopropargylglycine (2)

particle[a]	amino acid	yield (mg protein per g cells)	yield (mg protein per L culture)
HBV	Met	4–5 mg/g	80–100 mg/L
HBV(1M-N_3)$_{192}$(66M-N_3)$_{240}$	**1**	1–1.5 mg/g	20–30 mg/L
HBV(M66S)	Met	4–5 mg/g	80–100 mg/L
HBV(1M-N_3)$_{102}$(M66S)	**1**	2–3 mg/g	40–60 mg/L
Qβ	Met	3–4 mg/g	75–100 mg/L
Qβ(1M-N_3)$_{9-18}$	**1**	2–2.4 mg/g	50–60 mg/L
Qβ(K16M)	Met	3–4 mg/g	50–75 mg/L
Qβ(1M-N_3)$_{9-18}$(K16M-N_3)$_{180}$	**1**	1–2 mg/g	25–35 mg/L
Qβ(K16M-CCH)$_{90}$	**2**	2 mg/g	40 mg/L
Qβ(T93M)	Met	3–4 mg/g	50–75 mg/L
Qβ(1M-N_3)$_{9-18}$(T93M-N_3)$_{180}$	**1**	1–2 mg/g	25–35 mg/L

[a] Nomenclature: "HBV(1M-N_3)(66M-N_3)" denotes HBV particles with methionines at positions 1 and 66 (which happens to be the wild-type sequence) expressed in the presence of **1** to allow azide incorporation at those residues. Other particles are designated in analogous fashion, with "CCH" replacing "N_3" for those VLP's incorporating alkynyl amino acid **2**. Subscripts refer to the average number of unnatural amino acids incorporated at each position, as described in the text.

revealed homogeneous samples of icosahedral nonaggregated particles. (The HBV Cp149 particles containing **1** do not contain nucleic acid, and thus exhibit stain uptake with dark centers. Qβ particles are packed full of random cellular nucleic acid and have light centers in the negative stained images.) SDS-PAGE analyses revealed the same high purities of the capsids containing unnatural amino acids as those obtained with methionine. Last, the structures of both the HBV and Qβ virus-like particles with **1** were confirmed by cryo-electron microscopy image reconstruction. The electron density maps overlaid well with the published X-ray crystal structures for the native capsids.

The incorporation of **1** and **2** in place of methionine was confirmed by trypsin digestion and analysis of the resulting peptides using MALDI mass spectrometry, with the results summarized in Figure 4. Sequence coverage of the wild-type and **1**-labeled HBV Cp149 particle was nearly complete, with all but two residues included (Ile97, Arg98). Following normal expression in the presence of all 20 amino acids, Met was found at positions 1 and 66, the former in 70–90% of the protein, varying from batch to batch. The same result was observed when **1** was substituted for Met in the protocol described above, with **1** incorporated at the *N*-terminus in 70–90% of the protein produced, and completely (>95%) at position 66. The mutation M66S was also constructed, and found to contain the same 70–90% of **1** at the *N*-terminus when expressed with the unnatural amino acid.

Analysis of Qβ capsids required shorter trypsin digestion times to ensure limited proteolysis of the amino-terminal region. A coverage map that included all peptide fragments larger than three amino acids was obtained (Figure 4). Post-translational processing at the *N*-terminus was found to vary with the nature of the residue installed at that position. Under normal (Met-containing) expression, Met1 was never detected in either wild-type or mutant particles, showing that it was processed away during protein production (therefore, the amino acid numbering eliminates this residue). When **1** was substituted for Met in any form of the Qβ sequence, approximately 10% of the capsids were found to have the unnatural amino acid at the *N*-terminus. However, in approximately one of every five batches this level of incorporation spiked to as much as 90%. It was therefore necessary to analyze each preparation of Qβ capsids to determine the number of azide-containing residues available for conjugation. Incorporation of **1** at either of the internal positions tested (16 or 93) was uniformly excellent (>95%). The same type of analysis (not shown) revealed 50% incorporation of **2** into Qβ K16 M at position 16, with the remainder being Met. No homopropargyl glycine was detected at position 1.

Conjugation to Genetically Incorporated Azide and Alkyne Groups. Since the expression of HBV in the presence of **1** provided 70–90% incorporation at position 1 and complete incorporation at position 66, a maximum of approximately 410–460 azides per VLP should be available for conjugation. We employed these particles as reagents in the copper-catalyzed azide-alkyne cycloaddition (CuAAC) reaction, using CuOTf and accelerating ligand **4** under inert atmosphere as has been previously described (*61, 62*). The purified virus was pelleted out of solution, taken into an inert-atmosphere glovebox, and resuspended in degassed 0.1 M Tris buffer (pH 8.0) to prepare for reaction with fluorescein alkyne **3** under our standard conditions, as shown in Figure 5. After 16 h at room temperature, intact capsids could neither be detected by size-exclusion chromatography (Figure 6) nor recovered from sucrose gradients. However, gel electrophoresis (Figure 6) showed strong fluorescein labeling of the protein. Trypsin digestion and MALDI analysis in the manner described above revealed that approximately 50% of the sites at position 66 were labeled with fluorescein (equal intensities for the 56–81 fragment, m/z = 2919.3, and its labeled analogue with an increase in mass of 413 Da). Interestingly, fewer than 10% of the azide groups at position 1 were addressed.

HBV particles lacking incorporated azide groups were found to be stable toward the reaction conditions without coupling to fluorescein, ruling out nonspecific adsorption of the dye (Table 2, entry 1). All HBV particles were stable to the CuAAC reaction conditions (copper, ligand, buffer, and sample handling) and also toward extended incubation with fluorescein alkyne **3** in the absence of CuAAC catalyst. However, the particles did decompose when either ligand **4** or the previously used tris(triazolylmethyl)amine **5** was employed in the CuAAC process, showing that the nature of the ligand made no difference to particle stability. When the reaction time was varied, or the amount of catalyst was reduced, virus-like particles were recovered in yields inversely proportional to the amount of CuAAC reaction that had occurred. The use of rhodamine, biotin, or Gd(DOTA) reagents (**6**, **7**, or **8**) in place of fluorescein alkyne gave similar results. We therefore conclude that the decomposition of the particle was caused by the covalent attachment of these structures. We have previously observed other particles such as cowpea mosaic virus (CPMV) to be similarly sensitive to the covalent tethering of flat, hydrophobic species such ferrocene, tetramethylrhodamine, Fe(III) protoporphyrin IX, Ru(II) bipyridine complexes, and doxorubicin. However, the nature of the attached species varied somewhat in this case, and so it may well be that the triazole linkage, which is common to each of these examples, is responsible for the instability of the virus-like HBV particle. CPMV and Qβ have both been shown to be stable toward high levels of coverage by triazoles (*34, 35, 37, 38, 62*).

We attempted to strike a balance between covalent attachment and stability for HBV by varying the concentrations of CuOTf, ligand **4**, fluorescein-alkyne **3**, and protein. The use of 250 μM CuOTf with 500 μM ligand **4** slowed the reaction enough to allow the recovery of a maximum of 40% of the starting amount of capsids as intact icosahedra, bearing an average of 120 fluorescein molecules per capsid (Table 2, entry 2). The vast majority of these were attached to the M66 position and not to the *N*-terminal azidohomoalanine residue, as shown by trypsin digestion/MS. The loading value was determined by UV–vis absorbance spectroscopy of fluorescein (495 nm) in samples of purified labeled particles, with calibration using known samples under similar conditions (fluorescein in the presence of protein; protein concentrations determined by Lowry protein assay). It

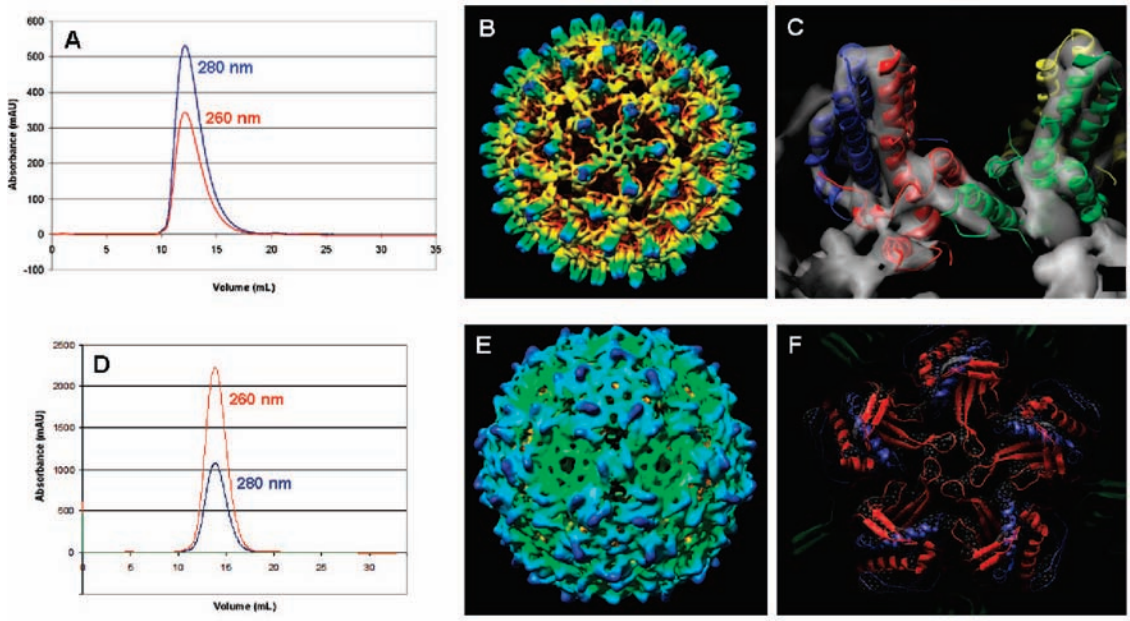

Figure 3. Characterization of the HBV (A-C) and Qβ (D-F) capsids containing **1**. (A and D) Size exclusion chromatography (Superose-6), with retention times matching those of intact native capsids. (B and E) Cryo-electron microscopy image reconstructions. (C and F) X-ray crystal structures docked into the cryo electron density maps. Characterization data for Qβ incorporating **2** may be found in Supporting Information.

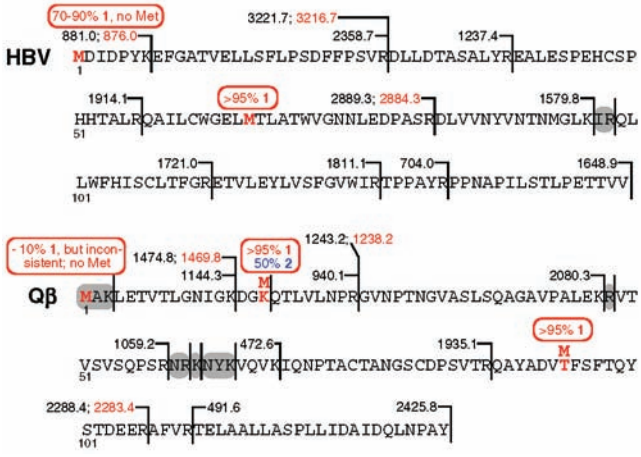

Figure 4. Summary of results from trypsin digestion and mass spectrometry of HBV and Qβ expressed with Met and **1** in locations marked in red. The detected fragments are indicated by the numerical values of *m*/*z* shown at the right of each; values in red are those with the unnatural amino acid incorporated. Many fused fragments (fragments derived from incomplete cleavage) were detected as well, giving rise to the same conclusions. The small peptides marked in gray were not detected. Conclusions about the level of incorporation of **1** at each indicated position are shown in the red ovals.

should also be noted that the attachment reaction was inhibited by the use of ligand **4** in greater than a 2:1 molar ratio with respect to Cu, consistent with previous observations (*61*), and that higher concentrations of Cu catalyst **4** gave rise to greater amounts of capsid decomposition as the number of reactions climbed above the 120-per-particle level.

The site of bioconjugation was moved from the spike to the "floor" of the HBV structure by mutation of M66 to serine. Expression of the M66S Cp149 mutant in the presence of azidohomoalanine **1** allowed the isolation of a particle having reactive azide only at the *N*-terminus (70–90% incorporation, Table 1). Reaction with fluorescein-alkyne **3** under the conditions shown in Figure 5 gave rise to the same approximate loading of 120 per particle, but isolated in significantly higher yield (60–70%, which represents the maximum possible recovery at this scale due to losses in sample handling from sucrose gradient purification; Table 2, entry 3). Since the HBV particle bearing azidohomoalanine at both positions 1 and 66 showed predominant labeling at the latter, we conclude that the more exposed position on the 4-helix bundle is both more reactive and more deleterious to capsid stability when labeled. Decomposition of the particle results in denaturation and precipitation, and thus removal of protein from the labeling reaction. The greater capsid stability in the M66S case may derive from the fact that the *N*-terminus, now the only site bearing azide groups, is relatively far from the interface between subunit dimers. Compounds attached by flexible linkers to M66, in contrast, are positioned to easily interact with the hydrophobic interior of each 4-helix bundle. The potential for small molecules to affect HBV capsid assembly and stability by binding at subunit interfaces has been previously illustrated for certain dihydropyrimidine derivatives (*63*, *64*).

Qβ proved to be much more amenable to CuAAC derivatization. Each of the few azide groups in the wild-type virus-like particle containing **1** at 5–10% of the *N*-terminal sites was addressed with alkyne reagent **4** (Table 2, entry 5). When **1** was additionally installed at each of the highly exposed K16 M positions, the particle was also completely labeled with fluorescein, causing no apparent decomposition (Table 2, entry 6). A rare sample in which azidohomoalanine was largely retained at the *N*-terminus, designated Qβ(1M-N_3)$_{160}$(K16M-N_3)$_{180}$, took on 306 $\pm$ 30 dyes under standard conditions, and 330 $\pm$ 20 dyes in the presence of higher concentrations of protein and catalyst, all with excellent particle yield and stability (Table 2, entry 7). Loading values were determined with calibrated measurements of fluorescein absorbance and protein concentration determined by a modified Lowry assay, since the Qβ VLP contains no tryptophan residues, making for poor UV–vis absorbance characteristics. The resulting particles and protein were characterized in the same manner as HBV above (see Figure 3 for size-exclusion chromatography and gel electrophoresis). Trypsin digestion and mass spectrometry confirmed the loading values by showing the expected peptide fragments (and only those fragments) to be increased by 413 Da.

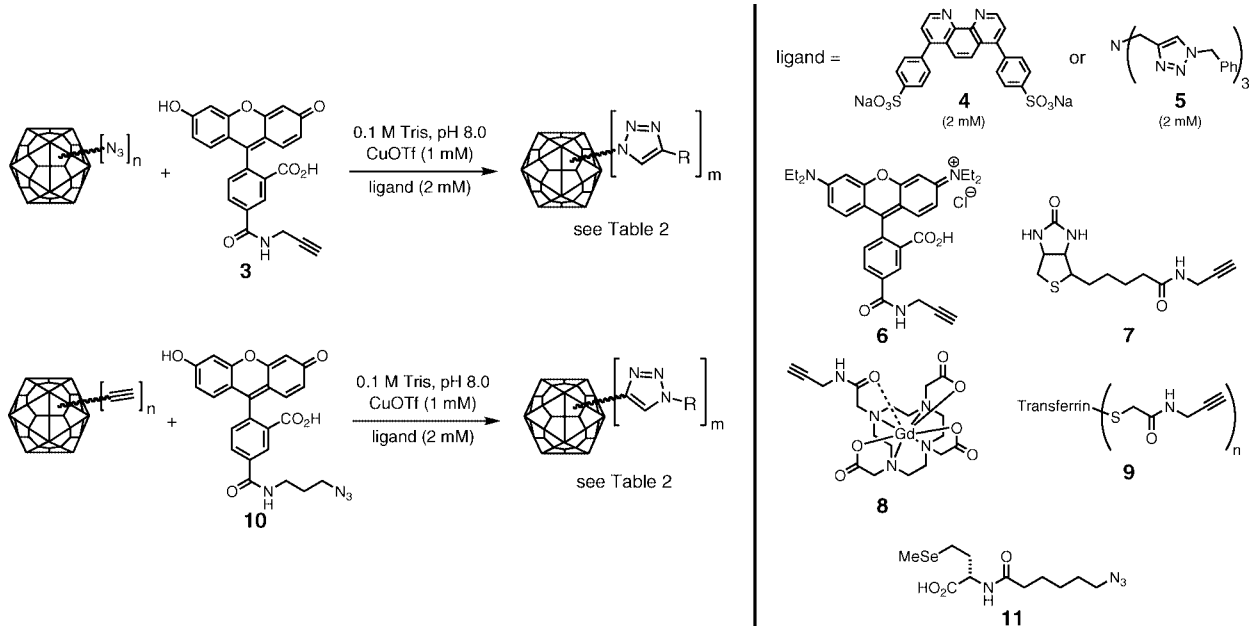

Figure 5. Copper-catalyzed azide-alkyne cycloaddition (CuAAC) reaction of virus-like particles with alkyne or azide derivatives.

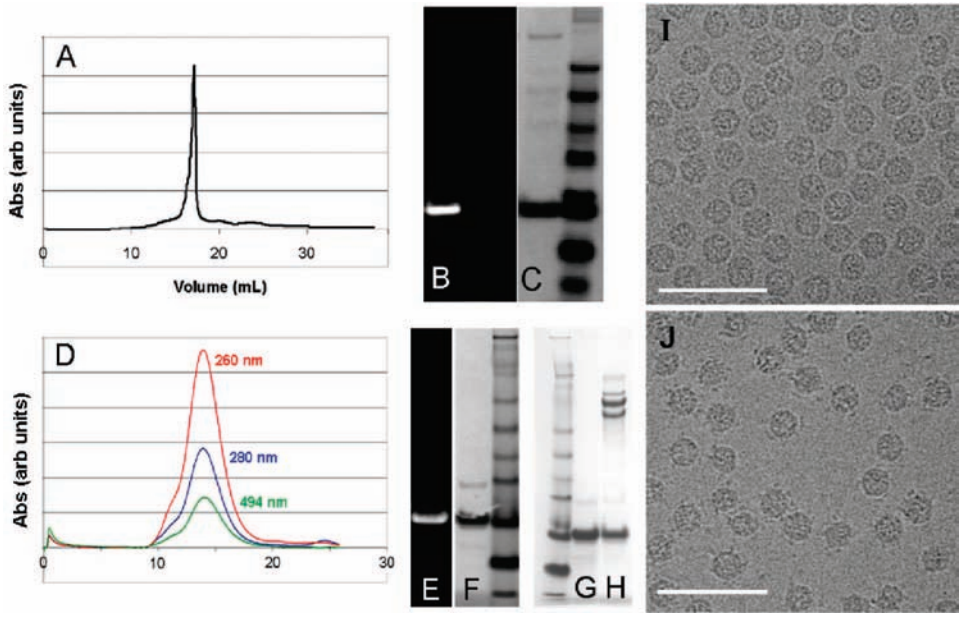

Figure 6. Characterization of virus-like capsids after CuAAC reactions: HBV = A−C; Qβ = D−H. (A) Size exclusion chromatography showing a peak with a retention volume of 18 mL corresponding to disassembled capsid. (B,C) SDS-PAGE of the Cp149 protein isolated from the reaction, visualized under ultraviolet illumination (B) and then with Coumassie staining (C). The right lane is a molecular weight ladder. (D) Size exclusion chromatography showing an elution volume of 14 mL, characteristic of intact Qβ capsids, and coelution of fluorescein with the protein showing covalent attachment. (E,F) SDS-PAGE of the Qβ protein showing fluorescein labeling as above. (G) Same as (F). (H) SDS-PAGE of purified Qβ-transferrin conjugate; the higher molecular weight bands are in the expected position for the Cp149-transferrin fusion, with multiple bands deriving from the somewhat impure nature of the starting transferrin sample. (I) Transmission electron microscopy (TEM) image of Qβ(1M-N_3)$_{9–18}$(K16M-N_3)$_{180}$. (J) TEM image of the same particle conjugated to transferrin-alkyne **9**, after purification. Note the appearance of spots surrounding most of the particles, due to the tethered 80 kD protein.

The accessibility of the K16M-N_3 insertion was further demonstrated by the chemoselective conjugation of a protein to the Qβ(1M-N_3)$_{9–18}$(K16M-N_3)$_{180}$ particle. Transferrin, an 80 kD iron transport protein, was derivatized with *N*-propargyl-bromoacetamide and purified to give **9** (Figure 5), in analogous fashion to a maleimide-alkyne derivative previously described (*35*). The CuAAC reaction of **9** with Qβ(1M-N_3)$_{9–18}$(K16M-N_3)$_{180}$ gave a particle bearing covalently attached transferrin, as shown by gel electrophoresis and TEM (Figure 6).

Qβ(1M-N_3)$_{9–18}$(T93M-N_3)$_{180}$, in which the nonterminal unnatural amino acid is on the interior surface of the capsid, was not nearly as reactive as the K16 M derivative (Table 2, entry 8). While all of the *N*-terminal residues were coupled to **3** under standard CuAAC conditions, only 30–40 dyes were attached to the particle in total, which means that only 20–30 of the 180 azide-labeled T93 M sites participated in the reaction. As before, yields of intact particles were good. The same result was observed when alkyne **8** was used. Position 93 has both a more congested protein environment than position 16, and may well be occluded by associated RNA packaged inside the particle, giving rise to sluggish reactivity.

Table 2. Results of CuAAC Reactions of VLP's Containing Unnatural Amino Acids, as Shown in Figure 5

entry	particle[a]	# incorporated per particle[b]	loading[c]	recovery[d]
1	HBV(66M)	none	0	60–70%
2	HBV(1M-N_3)$_{170–215}$(66M-N_3)$_{240}$	410–455	120 ± 15[e]	≤40%
3	HBV(1M-N_3)$_{170–215}$(M66S)	170–215	120 ± 25	60–70%
4	Qβ(K16M)	none	0	75–80%
5	Qβ(1M-N_3)$_{9–18}$	9–18	15 ± 3	80–85%
6	Qβ(1M-N_3)$_{9–18}$(K16M-N_3)$_{180}$	189–198	190 ± 20	75–80%
7	Qβ(1M-N_3)$_{160}$(K16M-N_3)$_{180}$	340	306 ± 30[f]	70–80%
8	Qβ(1M-N_3)$_{9–18}$(T93M-N_3)$_{180}$	189–198	35 ± 5	75–80%
9	Qβ(K16M-CCH)$_{90}$	90	50 ± 5	20%
10	Qβ(K16M-CCH)$_{90}$	90	85 ± 5[g]	75–80%

[a] See caption to Table 1 for nomenclature. [b] Total number of unnatural amino acids per particle, determined by trypsin digestion and mass spectrometry as described in the text. [c] The number of attached molecules (subscripts "m" in Figure 5). Unless otherwise indicated, the value was obtained from reaction with fluorescein reagents **3** or **10** and quantitation by calibrated UV–visible absorbance of the dye (average of at least three independent reactions). [d] Amount of purified intact capsids recovered from the reaction. [e] More than 90% of the attachments were made at position 66. [f] Under standard conditions; a loading of 330 ± 20 (75% recovery) was observed under the most forcing conditions tested. [g] Reaction with azide **11**, loading determined by quantitation of attached Se atoms by inductively coupled plasma optical emission spectroscopy.

Lastly, the alkyne-containing particle Qβ(K16M-CCH)$_{90}$ proved to be sensitive to the attachment of fluorescein azide **10** (Table 2, entry 9), giving rise to low recoveries of partially conjugated material. Note that azide **10**, and not alkyne **3**, induces instability in the resulting Qβ conjugate (each attached to unnatural amino acids installed at the same site). This is presumably a function of the longer tether between the reactive group and the fluorescein moiety in **10**, allowing the polycyclic aromatic structure to more easily interact with hydrophobic subunit interfaces in the particle. The use of selenomethionine derivative **11**, on the other hand, provided clean and complete triazole formation with no loss of particle integrity (Table 2, entry 10), showing again that triazole moieties are well tolerated by the Qβ capsid.

CONCLUSIONS

We describe here the first successful site-specific incorporation and subsequent reaction of unnatural amino acids into virus-like particles. The substitutions of azide- and alkyne-containing structures for methionine had no apparent effect on the ability of the resulting proteins to self-assemble into icosahedral capsids that are indistinguishable in structure from the native forms. Tight control over protein expression in methionine auxotrophic cells resulted in high yields of the assembled capsids. The degree of post-translational removal of unnatural amino acid introduced in position 1 in place of Met was variable, and was characterized by trypsin digestion and mass spectrometry analysis.

These novel capsids can be chemically addressed with perfect chemoselectivity by the CuAAC reaction. HBV was found to be sensitive to the coupling of molecules to the 4-helix-bundle spikes, while Qβ suffered from much fewer limitations in this regard. The low concentrations of azide and alkyne reagents required for coverage of most or all of the inserted azide and alkyne groups are made possible by the efficiency of the CuAAC process. Because the CuAAC reaction is insensitive to the substituents present on the azide and alkyne reactants and similarly unreactive with natural protein functional groups, the two-step process of genetically directed incorporation of azides or alkynes followed by CuAAC ligation provides a functional equivalent to the installation of almost any unnatural (triazole-linked) amino acid one can imagine.

EXPERIMENTAL PROCEDURES

CP149 HBV Plasmid Construction. A pET11c plasmid containing the Cp149 sequence was gratefully received from Prof. Adam Zlotnick of the Oklahoma University Health Sciences Center. In order to provide tight inducible control overexpression (pET11c was found to be constitutively expressed to an unacceptable degree), the HBV gene was amplified using the following primers: Cp149F 5′-AAG AAG GAG GAT ATA **GGT CTC AC** ATG GAC ATT GAC CCT-3′ and Cp149R 5′-TCG GGC TTT GTT AGC AGC CGG **AAG CTT** ATA CTA AAC AAC CGT-3′ The PCR product was sequentially digested with Hind III and Bsa I, and then ligated into pQE-60 plasmid (Qiagen) which had been sequentially digested with Hind III and Nco I. The resulting plasmid was transformed into competent M15MA cells harboring the pREP4 plasmid yielding the expression cells M15MA(pQE-60/HBV).

Site-Directed Mutagenesis of Cp149 HBV. Mutations were introduced into the coat protein of HBV by standard overlap PCR to remove the methionine at position 66 (M66S). The following general forward and reverse primers were used: Forward 5′-AGA ATT CAT TAA AGA GGA GAA ATT AAC-3′, Reverse 5′-CCA AGC TCA GCT AAT GCT TAT CCT-3′, M66SF 5′-GGA GAC TTA TCT ACT CTA GCT-3′, M66SR 5′-AGC TAG AGT AGA TAA GTC TCC-3′. The PCR products were sequentially digested with Hind III and NcoI and ligated into pQE-60 that had previously been digested with Hind III and Nco I. The resulting plasmids were transformed into competent M15MA cells yielding the following expression construct: M15MA(pQE-60/M66S HBV).

Insertion of the K16 M Qβ Coat Protein Gene into pQE-60. The coat protein gene for Qβ containing the point mutation K16 M was originally created in the pET-28b plasmid, which is not compatible with expression in M15 based Met auxotrophic *E. coli* cells. Therefore, the Qβ coat protein gene was amplified from the pET-28b plasmid using the following primers: QBF 5′-AAA GAG GAG AAA TTA AGG TCT CAC ATG GCA AAA TTA GAG ACT-3′ and QBR 5′-CCA AGC TCA GCT AAT T**AA GCT T**TA TTA ATA-3′ The PCR product was sequentially digested with Hind III and Bsa I. The digested PCR product was ligated into pQE-60 plasmid (Qiagen), which had been sequentially digested with Hind III and Nco I. The resulting plasmid was transformed into competent M15MA cells harboring the pREP4 plasmid yielding the expression cells M15MA(pQE-60/Qβ K16M).

Site-Directed Mutagenesis of K16 M Qβ. The following primers were used to introduce Met at position 93 (T93M), using standard overlap PCR as above: Forward 5′-AGA ATT CAT TAA AGA GGA GAA ATT AAC-3′, Reverse 5′-CCA AGC TCA GCT AAT GCT TAT CCT-3′, WTF 5′-GGA GAC TTA TCT ACT CTA GCT-3′, WTR 5′-AGC TAG AGT AGA TAA GTC TCC-3′. The PCR products were sequentially digested with Hind III and NcoI and ligated into pQE-60 that had previously been digested with Hind III and Nco I. The resulting plasmids were transformed into competent M15MA cells yielding the

following expression construct: M15MA(pQE-60/WT Qβ) and M15MA(pQE-60/T93 M Qβ).

Synthesis of Unnatural Amino Acids (1 and 2). Several short routes to azidohomoalanine (**1**) have been reported in the literature (*15*, *65–67*). We chose a simplified version of the method of Rappoport and co-workers (*68*), since the starting lactone is commercially available in racemic form at modest cost and an enantiospecific synthesis is not required because *E. coli* incorporates only the L-isomer during protein expression. α-Amino-γ-butyrolactone hydrobromide (5.02 g, 27.6 mmol) was refluxed in 1:1 HBr/glacial HOAc (250 mL) overnight (17–24 h). The HBr and acetic acid were then removed by rotary evaporation, yielding crude bromohomoalanine. The crude material was then dissolved in a solution of NaN_3 (9.00 g, 138 mmol) in water (125 mL) and refluxed again overnight. The solution was evaporated to dryness and the residual tan solid resuspended in a minimal volume of 0.1 M HCl. The acidic solution was passed through a column of Dowex 50WX4–100 ion-exchange resin, washing with water and eluting the product with 1 M NH_4OH. The collected fractions were evaporated to dryness, yielding an oil. Compound **1** was obtained as a tan solid (1.49 g, 10.3 mmol, 37%) upon resuspending in a minimal volume of water and lyophilizing. The purity of the solid was determined by NMR using pyridine as an internal standard and generally was >85% (overall yields 32–38%). ^{1}H NMR (D_2O, 200 MHz, $d_1 = 10$ s) δ 3.44 (t, 2H, $CHCH_2C\underline{H}_2N_3$), 3.07 (dd, 1H, $C\underline{H}CH_2CH_2N_3$), 1.58 (m, 2H, $CHC\underline{H}_2CH_2N_3$). Homopropargylglycine (**2**) was prepared as previously described (*10*).

Incorporation of 1 into HBV and Qβ. A single of colony of cells expressing the desired HBV or Qβ construct was used to inoculate 5 mL of SOB media containing carbenicillin (100 μg/mL) and kanamycin (50 μg/mL) and was grown overnight. The resulting culture was transferred into 500 mL of M9 minimal media supplemented with all 20 amino acids, carbenicillin (100 μg/mL), and kanamycin (100 μg/mL) and allowed to grow for 8 h. Aliquots (25 mL) of the resulting culture were transferred into each of 11 flasks containing 500 mL of fresh minimal media supplemented with all 20 amino acids, carbenicillin (100 μg/mL) and kanamycin (100 μg/mL) and allowed to grow overnight. In the morning the cells were pelleted and resuspended in 500 mL of fresh M9 minimal media supplemented with all of the natural amino acids minus methionine. The cells were agitated at 37 °C for 30–40 min, and then transferred into new flasks of M9 minimal media supplemented with all of the natural amino acids minus methionine, IPTG (1 mM), carbenicillin (100 μg/mL), kanamycin (100 μg/mL), and azidohomoalanine (80 mg of racemate). After 6 h at 37 °C, the cells were harvested and stored at −80 °C.

For each preparation, 30–60 g of cells were allowed to thaw at room temperature and were resuspended in 50 mL distilled water. Cold lysis buffer (200 mL, 50 mM HEPES pH 8.0, 500 mM NaCl, 0.1 mg/mL DNase1, and 0.1 mg/mL RNaseA) was added and the cells were subjected to three cycles of sonication (2 min sonication and 2 min rest per cycle). Lysozyme (1 mg per mL of lysis buffer) was added and the solution was stirred in the cold room for 1 h. Insoluble cell debris was removed by centrifugation at 10 000 rpm for 30 min in a JA-10 rotor (Beckman).

For HBV, ammonium sulfate was added to the supernatant to a final concentration of 40% of saturation, and allowed to stir at room temperature for 30 min. The precipitated HBV coat protein was separated by centrifugation (10 000 rpm, 30 min, JA-10 rotor), and then was resuspended in 0.1 M potassium phosphate buffer (50 mL, pH 7.0). Any remaining insoluble material was removed by centrifugation (10 000 rpm, 15 min, JA-17 rotor). Sodium chloride was added to a final concentration of 0.5 M and the HBV coat proteins were allowed to assemble overnight. The resulting assembled VLPs were separated from smaller proteins by ultrapelleting (42 000 rpm, 6 h, 4 °C, 50.2Ti rotor, L90K ultracentrifuge). The pelleted material was resuspended in 3–10 mL of 0.1 M potassium phosphate buffer (pH 7.0). Further purification was accomplished by the use of two successive sucrose gradient sedimentations (10–40% sucrose gradients in SW28 rotor at 28 000 rpm for 6 h at 4 °C.

For Qβ, PEG 8000 was added to the supernatant to a final concentration of 10% and the mixture was allowed to stir at room temperature for 30 min. The precipitated Qβ capsids were separated by centrifugation (10 000 rpm, 30 min, JA-10 rotor), and then resuspended in 0.1 M potassium phosphate buffer (50 mL, pH 7.0). Insoluble material was removed by centrifugation (10 000 rpm, 15 min, JA-17 rotor), and VLPs were isolated and purified as for HBV above, with final concentration by ultrapelleting.

Characterization of HBV and Qβ Particles. All protein preparations were analyzed by denaturing gel electrophoresis (4–12% NuPAGE Bis-Tris gel, Invitrogen) to estimate their purity; in all cases, the anticipated coat protein band constituted >95% of the intensity visualized by densitometry after Coomassie blue staining. HBV concentration was determined by absorbance at 280 nm, 1 mg/mL providing an absorbance value of 1.74. The concentrations of modified HBV and all Qβ particles were determined with the Modified Bradford Assay (Pierce, Inc.) and a BSA standard curve. Since HBV VLPs do not contain significant quantities of RNA, the ratio of absorbances at 260 nm vs 280 nm was 0.6–0.7. Qβ VLPs package random cellular nucleic acid, giving rise to A_{260}/A_{280} values of 1.8–1.9. The presence of individual, aggregated, and disassembled particles was determined by size-exclusion chromatography on a Superose 6 column using an Akta Explorer (GE Healthcare) fast protein liquid chromatography (FPLC) instrument. Transmission electron microscopy was performed by applying particles at a concentration of 0.2 mg/mL to a carbon-coated Formvar transmission electron grid. The grids were stained with 2% uranyl acetate, and visualized in a Phillips CM120 transmission electron microscope.

VLP samples were processed for determination of derivatization site(s) by MALDI mass spectrometry as follows. Samples (100 μL, 1–2 mg/mL protein) were mixed with 300 μL of 8 M urea and 30 μL of 1 M DTT, and incubated at 37 °C for 1 h to allow the protein to denature. Iodoacetamide (1 M, 50 μL) was added to cap any free cysteines and the sample was again incubated at 37 °C for 1 h. DTT (30 μL) was added to quench unreacted capping reagent, and the samples were diluted to a final volume of 1.9 mL using 25 mM ammonium bicarbonate (pH 8.0). Each sample was digested with 30 μg of either trypsin or Glu-C protease overnight at 37 °C. The samples were then concentrated to approximately 300 μL, and urea was removed with Zip-tips (Microcon) prior to MALDI analysis.

Cryoelectron Microscopy and Analysis. Samples were prepared for CryoEM analysis by preservation in vitreous ice via rapid-freeze plunging onto plasma cleaned Cflat carbon film grids using a Vitrobot (FEI Co). Data collection was performed on Tecnai F20 electron microscopes (FEI Co.) operating at 120 keV using a dose of $\sim 20e^-/Å^2$ and a nominal underfocus of 0.8 to 3 μm utilizing the Leginon data collection software (*69*). For the reconstructions, 735 micrographs of azidohomoalanine-incorporated HBV were collected at a nominal magnification of 80 000× at a pixel size of 0.14 nm at the specimen. 125 micrographs of azidohomoalanine-incorporated Qβ particles were collected at a nominal magnification of 50 000× at a pixel size of 0.23 nm at the specimen. All micrographs were collected on a 4000 × 4000 CCD camera (Gatan Inc.). CryoEM analysis of all other Qβ variants, including the transferrin-alkyne

conjugated particles, was performed under the same conditions as the azidohomoalanine-incorporated HBV particles.

The contrast transfer function (CTF) for each micrograph was estimated using the Automated CTF Estimation (ACE) package (*70*). 8906 HBV particles and 11 882 Qβ particles were extracted from the collected data at a box size of 304 × 304 pixels and 180 × 180 pixels, respectively. The HBV particles were binned by a factor of 2 for the reconstruction. Phase correction of the single particles and subsequent three-dimensional refinement was carried out with the EMAN software package (*71*). The amplitudes of the resulting refined structures were adjusted with the SPIDER software package (*72*). Resolution of the final HBV and Qβ densities were determined to be around 8 Å and 10 Å (respectively) according to 0.5 FSC criteria. Rigid-body docking of crystal structures into the reconstruction density and graphical representations were produced by the Chimera visualization software package (*73*, *74*).

Copper Catalyzed Azide-Alkyne Cycloaddition Reactions. Purified azide-containing HBV or Qβ particles were pelleted out of solution (42 000 rpm, 6 h), the supernatant was removed, and residual buffer was allowed to drain away from the pellet. The viral pellet was then taken into a nitrogen-filled glovebox (without exposure to vacuum) and resuspended in a minimal volume of degassed 0.1 M Tris at pH 8.0. A small aliquot of the virus solution was removed from the glovebox and used to determine virus concentration. A typical conjugation reaction employed a VLP concentration of 2 mg/mL in 0.1 M Tris (pH 8.0) in a round-bottomed 2 mL Eppendorf tube (rather than conical tubes that do not provide good mixing upon gentle agitation). Fluorescein alkyne **6** (final concentration 1 mM) was added, followed by a freshly prepared buffer solution of Cu(I) triflate and 2 equiv of ligand **4** or **5**. Final concentrations of Cu were either 100 μM or 250 μM for HBV, 500 μM or 1 mM for Qβ. The tube was sealed, placed in a secondary sealed container (usually a small round-bottomed flask), removed from the glovebox, and attached to a slow tumbler arm for agitation at room temperature for 16–18 h. After completion of the reaction, intact virus-like particles were separated from excess labeling reagent using a combination of 10–40% sucrose gradients (38 000 rpm, SW41 rotor, 4 h for HBV, 3 h for Qβ) and ultrapelleting.

ACKNOWLEDGMENT

This work was supported by the NIH (AI056013, RR021886, GM62523), the David & Lucille Packard Foundation Interdisciplinary Science Program, and the Canadian Institutes of Health Research (postdoctoral fellowship to A.K.U.).Cryo-electron microscopy was performed at the National Resource for Automated Molecular Microscopy which is supported by the NIH NCRR P41 program (RR17573).

Enhanced Cell Penetration of Acid-Degradable Particles Functionalized with Cell-Penetrating Peptides

Jessica L. Cohen,[†] Adah Almutairi,[†] Joel A. Cohen,[†] Matt Bernstein,[‡] Steven L. Brody,[‡] Daniel P. Schuster,[‡] and Jean M. J. Fréchet*,[†]

College of Chemistry, University of California, Berkeley, California 94720-1460, and Washington University in St. Louis School of Medicine, St. Louis, Missouri. Received November 11, 2007; Revised Manuscript Received December 11, 2007

Biopharmaceuticals, such as proteins and DNA, have demonstrated their potential to prevent and cure diseases. The success of such therapeutic agents hinges upon their ability to cross complex barriers in the body and reach their target intact. In order to reap the full benefits of these therapeutic agents, a delivery vehicle capable of delivering cargo to all cell types, both phagocytic and non-phagocytic, is needed. This article presents the synthesis and evaluation of a microparticle delivery vehicle capable of cell penetration and sub-cellular triggered release of an encapsulated payload. pH-sensitive polyacrylamide particles functionalized with a polyarginine cell-penetrating peptide (CPP) were synthesized. The incorporation of a CPP into the microparticles led to efficient uptake by non-phagocytic cells in culture. In addition, the CPP-modified particles showed no cytotoxic effects at concentrations used in this study. The results suggest that these particles may provide a vehicle for the successful delivery of therapeutic agents to various cell types.

INTRODUCTION

In addition to small-molecule based drugs, biopharmaceuticals, such as proteins and DNA, have tremendous potential to prevent and cure diseases (*1–3*). Currently there are over 400 biotechnology medicines in development for the treatment of over 100 diseases, including medications to treat or help prevent multiple sclerosis, hepatitis, breast cancer, and diabetes (*4*). The widespread success of such therapeutic agents hinges upon their ability to cross complex barriers in the body and to reach their target intact. Exogenous therapeutic agents are notoriously unstable in the harsh *in vivo* environment due to proteolytic degradation, sequestration, and renal clearance. These factors limit their use as therapeutic agents. However, encapsulation strategies have successfully mitigated some of these stability and delivery issues by providing protection from physical and chemical damage (*5–11*). Recent advances in polymer synthesis have allowed formulations capable of encapsulation and controlled release of macromolecular therapeutic agents, thereby increasing their stability and ultimately their bioavailability (*12–15*). In addition, by incorporating certain ligands or compounds into the polymer backbone, it is possible to enhance delivery and targeting of the vehicle (*16, 17*). A recent delivery strategy involves the use of cell-penetrating peptides to enhance cellular uptake of cargo by non-phagocytic cells (*18*). Herein, we show the integration of ligands for cell penetration and sub-cellular triggered release in a single delivery vehicle.

Biodegradable polymers have been extensively investigated as potential carriers for biopharmaceuticals (*19–21*). Delivery of a therapeutic agent via encapsulation in particles incorporating programmed release mechanisms, such as acid-degradable crosslinks, allows for their controlled release at select targets, such as inflammatory tissues, tumors, and cells of the immune system. This selective delivery through triggered release mechanisms enables enhanced therapeutic efficiency, allowing lower doses of the therapeutic agent to be used, with less toxicity (*22–27*). Recently, we described the synthesis of polyacrylamide microparticles that incorporated acid-labile crosslinks into the polymer scaffold, as well as targeting groups on the surface (*28–31*). These acid-degradable particles were capable of encapsulating and delivering a protein antigen to phagocytic cells of the immune system, specifically macrophages and dendritic cells. These cell types specialize in taking up foreign matter and trafficking it to acidic sub-cellular lysosomal compartments. After the particles are phagocytosed in this manner, they degrade rapidly in the acidic lysosome, causing the protein payload to be released into the cytoplasm (*29, 30, 32*). This is hypothesized to occur through the destabilization of the lysosomal membrane as a result of the sudden increase in osmotic pressure, due to particle swelling and degradation (*33*).

The size of these particles (ranging from 200 nm to 1 μm in diameter) makes them well-suited for uptake by phagocytic cells, such as macrophages and dendritic cells. Thus, these particles have demonstrated great success at delivering a protected payload to cells of the immune system (*31, 34*). However, the majority of cells in the human body are non-phagocytic, meaning that they are not efficient at ingesting foreign matter and particulates. As a result, access to the lysosomal delivery pathway in non-phagocytic cells is limited, making it difficult to reap the full benefits of therapeutic delivery systems, such as the hydrogel system described above. Thus, one of the most important challenges facing the use of these particles to deliver therapeutic agents is overcoming their lack of uptake by non-phagocytic cells. This problem has motivated work toward making new delivery vehicles capable of encapsulation, cell membrane penetration, and programmed release. Our aim is to design a delivery vehicle that possesses these three properties. In order to create a universal delivery vehicle which would allow for the delivery of cargo to non-phagocytic cells, we have modified our existing delivery system for phagocytic cells by incorporating a cell-penetrating peptide into our pH-sensitive particles.

Cell membranes act as protective barriers for the cell, only allowing compounds within a narrow range of molecular size, polarity, and charge to enter. Overcoming the barrier of the cell membrane to deliver membrane-impermeable cargos often requires harsh methods such as electroporation or liposomal transfection. These methods are limited to *in vitro* applications and often cause unwanted cellular effects, such as high cytotoxicity (*35*). A more recently developed delivery strategy involves the use of cell-penetrating peptides. Cell-penetrating peptides (CPPs) are peptides with up to 30 amino acids with the ability to translocate across cell membranes of various cell types (*36*). CPPs have been used to deliver a range of cargos including proteins, DNA, antisense peptide nucleic acids, small-molecule drugs, liposomes, and nanoparticles into the cell both *in vitro* and *in vivo* (*37*) without disturbing the stability of the cell membrane and with low cytotoxic effects. CPPs offer several appealing properties as delivery agents including applicability to all cell types, no apparent size constraint of the cargo, and seemingly no immunogenic or inflammatory properties (*36*). CPPs consist of a diverse group of peptides derived from such sources as HIV-Tat, the third helix of the homeodomain of Antennapedia, VP22 herpes virus protein, and other synthetic peptides (*38*), including various arginine-rich sequences (*39–44*). One common feature among these CPPs is the high number of cationic residues, such as arginine. In one study, it was found that the HIV-Tat sequence could be replaced with a simple nonamer of arginine (*45*), suggesting that the guanidinium headgroup of arginine is the essential component of this sequence's ability to transport cargos into the cell (*41, 46, 47*). In addition to the guanidine headgroup, other factors such as the number of arginine residues (*47, 48*) and the length of the side chain (*41*) were found to be important factors in the control of translocation.

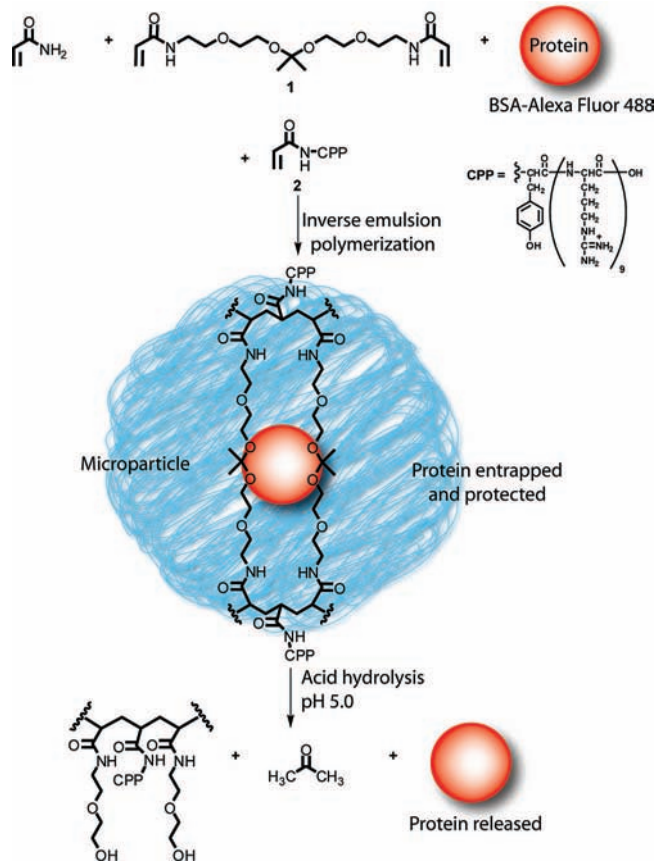
In this report, we describe the synthesis and evaluation of a new delivery vehicle for biopharmaceuticals. A cell-penetrating peptide (CPP) consisting of nine arginine residues was incorporated into acid-degradable polyacrylamide particles to enhance cellular uptake by non-phagocytic cells. Incorporation of the CPP was achieved by copolymerizing a functional monomer **2** with an acid-degradable crosslinker **1** and acrylamide (Scheme 1). The cell uptake of these modified particles in two epithelial cell lines was then investigated.

EXPERIMENTAL PROCEDURES

General Methods. All reagents were purchased from commercial sources and were used without further purification unless otherwise stated. The cell-penetrating peptide (acrylamide-Y-$(R)_9$-COOH) was purchased from Applied Peptech Suzhou. Acryloyl chloride was distilled prior to use. Triethylamine and tetrahydrofuran (THF) were dried by passing through two columns of neutral alumina within a commercial solvent purification apparatus. Combined organic layers after extractions were dried over $MgSO_4$, which was removed by filtration. Solvents were removed under reduced pressure using a rotary evaporator. Reactions requiring anhydrous conditions were performed in flame-dried vessels and under a positive pressure of dry nitrogen. ^{1}H NMR spectra were recorded at 300 or 400 MHz on a Bruker spectrometer. $CDCl_3$ was passed through a plug of basic alumina prior to recording NMR spectra of acid-sensitive samples. To prevent acid-catalyzed hydrolysis of acetal-containing compounds during chromatographic separation, 1% triethylamine was added to the solvents used for elution. Absorbance was measured using a microplate reader (Molecular Dynamics). Particles were imaged using a scanning electron microscope (S5000, Hitachi) after sputter-coating with a 35 Å platinum film.

Compound **1** was prepared following a literature procedure (*28*).

Scheme 1. Synthesis and Subsequent Degradation of CPP-Modified Microparticles



Synthesis of CPP-Modified Microparticles. Microparticles were prepared via an inverse emulsion free radical polymerization (*29, 30*). The organic phase consisted of 3% (w/v) of 3:1 (w/w) Span 80/Tween 80 in hexanes. The aqueous phase was prepared by dissolving cell-penetrating peptide monomer **2** (2.13 mg, 1.3×10^{-6} mol) in 250 μL of phosphate buffered saline (pH 8.0) containing 2 mg/mL BSA-Alexa Fluor 488 conjugate. The pH of this solution was adjusted by the addition of 0.1 M NaOH until the solution had a pH of approximately 8. Acrylamide (85 mg, 1.20 mmol) and acid-labile crosslinker **1** (37 mg, 0.10 mmol, 8 mol %) were dissolved in the aqueous phase. A 50% (w/v) ammonium persulfate solution (10 μL) was added to the aqueous phase. The aqueous phase was then combined with 2.5 mL of the organic phase. The emulsion was prepared by sonicating the solution in a water bath at rt for 30 cycles (ca. 1 s each) in rapid succession using a Branson 450 Sonifier with a ½ in flat tip, an output setting of 2, and a duty cycle of 40%. Polymerization was initiated by the addition of 20 μL of *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) and continued for 10 min at room temperature with constant stirring. The particles were recovered by centrifugation at 1380*g* (rt) for 10 min using 5 μm PVDF spin filters (Ultrafree-CL Durapore, Millipore). The particles were washed with hexanes (2×2 mL) and acetone (3×2 mL), centrifuging after each wash. After collecting the particles, residual acetone was removed by drying under high vacuum overnight.

Non-degradable CPP-Modified Particles. Non-degradable particles were prepared following the method described above using *N,N′*-methylene-bis-acrylamide as the crosslinker. The aqueous phase consisted of acrylamide (103 mg, 1.45 mmol), *N,N′*-methylene-bis-acrylamide (19.0 mg, 0.12 mmol, 8 mol %), and cell-penetrating peptide (2.62 mg, 0.1 mol %) dissolved in 250 μL of phosphate buffered saline (pH 8.0) containing 2 mg/mL BSA-Alexa Fluor 488 conjugate.

Unmodified Microparticles. Unmodified degradable and non-degradable microparticles encapsulating BSA-Alexa Fluor 488 conjugate were prepared in a similar fashion as described above omitting monomer **2**. For the degradable particles, the aqueous phase consisted of acrylamide (87 mg, 1.22 mmol) and crosslinker **1** (38 mg, 0.11 mmol, 8 mol %) dissolved in 250 μL of phosphate buffered saline (pH 8.0) containing 2 mg/mL BSA-Alexa Fluor 488 conjugate. For the non-degradable particles, the monomer composition contained acrylamide (105 mg, 1.48 mmol) and *N*,*N*′-methylene-bis-acrylamide (20 mg, 0.13 mmol, 8 mol %) dissolved in 250 μL of phosphate buffered saline (pH 8.0) containing 2 mg/mL BSA-Alexa Fluor 488 conjugate. It was unnecessary to adjust the pH of the aqueous phase in these cases.

CPP Quantification. CPP quantification was performed using a Micro BCA Protein Assay Kit (Pierce Biotechnology, Rockford, IL). The particles were dispersed in 300 mM acetic acid buffer pH 5.0 at a concentration of 5 mg/mL and incubated at 37 °C overnight to degrade the particles. The solution was then analyzed for the concentration of peptide using the kit according to the manufacturer's instructions, and the fluorescence of the resulting solution was quantified on a microplate reader. A standard curve was prepared using known concentrations of peptide in acidic buffer (pH 5.0, 300 mM acetic acid).

Cell Culture. A lung epithelial cell line derived from transformed normal human airway epithelial cells (BEAS-2B, CRL-9609, American type Tissue Culture Collection, Manassas, VA) was used for the majority of cell-based studies. Confirmatory experiments were also conducted in an alternative epithelial cell line (HeLa, obtained from ATCC, catalog no. CCL-2). With both lines, cells were grown overnight to 50% confluence on four-well LabTek plastic chamber slides using Optimem (Invitrogen) media supplemented with 5% FBS and penicillin/streptomycin (approx 50 μg/mL final). Microparticles were added to the media when the cells were 50–60% confluent.

Cell Uptake Studies. Microparticles were sonicated for two 2 s pulses just prior to incubation with cells using concentrations ranging from 15 μg/mL to 500 μg/mL in a 500 μL volume. Cells were incubated with microparticles for 2 h then washed three times in PBS and allowed to incubate an additional 24 h (HeLa cells) or simply allowed to incubate for 2 or 24 h (BEAS-2B cells). At the end of the incubation period, cells were then fixed and imaged. All studies were conducted in duplicate using 2–3 different preparations of microparticles.

Confocal Microscopy. After incubation, chamber slides were washed with PBS and fixed in 4% paraformaldehyde for 15 min at rt. Following additional PBS washes, Alexa Fluor 568 conjugated phalloidin (1:80, Molecular Probes no. A12380) was added to each well and incubated 30 min at rt to label filamentous actin. Chambers were then removed from the slides, and slides were washed again in PBS with a final rinse in water. Following shaking to remove excess water, cells were covered with mounting media (Vectashield, Vector Laboratories, Burlingame, CA) containing 4′,6-diamidino-2-phenylindole (DAPI) to stain intracellular DNA, coverslipped, and sealed with Cytoseal-60. Cells were examined by indirect fluorescent microscopy using an Olympus BX51 and/or confocal microscopy using a Zeiss 510 LSM laser scanning fluorescent confocal microscope. Cells not treated with microparticles and a well with microparticles but no cells were also prepared to measure background fluorescence.

Cytotoxicity Assay. Possible cytotoxicity associated with cell microparticle uptake was assessed by measuring the release of lactic dehydrogenase (LDH) into cell media using a commercially available kit according to the manufacturer's instructions (Roche Laboratories). BEAS-2B cells were cultured in 100 mm dishes with DMEM/10% FBS to approximately 80% confluence. Cells were washed and then incubated for 24 h in fresh media containing 500 μg/mL non-degradable microparticles, 10 mM H_2O_2 (ensuring cell death, thereby serving as a positive control), or no treatment. Testing was done in duplicate. After incubation, media was recovered, centrifuged, and LDH concentrations were measured in 1 mL of supernatant.

RESULTS AND DISCUSSION

Preparation and Characterization of Microparticles Containing a Cell-Penetrating Peptide. The pH sensitivity of our microparticulate delivery system is imparted by an acetal-containing crosslinker **1** (Scheme 1). This dimethyl acetal crosslinker is relatively stable to hydrolysis under physiological conditions (pH 7.4) but degrades rapidly under the acidic conditions typically found in lysosomes (pH 5.0–5.5) (*28*). Incorporation of oligo(ethylene glycol) substituents enhances the solubility of the crosslinker in aqueous solution, an essential characteristic for the inverse emulsion polymerization technique used to prepare the particles. The inverse emulsion process allows for the encapsulation of hydrophilic molecules such as protein and DNA in the particles. Hydrolysis of crosslinker **1** produces acetone, a relatively nontoxic metabolic intermediate of fatty acid oxidation.

Particles containing a CPP were prepared using a 10 amino acid sequence that was modified on the N-terminus with an acrylamide group, **2** (Scheme 1). This acrylamide moiety enables the direct incorporation of the peptide into the particle during its preparation. The sequence selected for use in the particles was acrylamide-Y-$(R)_9$-COOH because nona-arginine has been shown to be the most effective cell-penetrating peptide known today that is composed of natural L-amino acid residues (*41, 49*). Nona-arginine (R_9) was shown to be 20-fold more efficient than HIV-$Tat_{49–57}$ at cellular uptake (*41*). A tyrosine residue was also incorporated into the peptide sequence to allow for radiolabeling of the peptide for future *in vivo* studies.

Microparticles encapsulating bovine serum albumin-Alexa Fluor 488 (BSA-Alexa Fluor 488), a model protein conjugated with a fluorescent tracer, and including CPP were successfully prepared and characterized to investigate the possibility of enhancing cellular uptake of the particles by non-phagocytic cells. The particles were prepared using an inverse emulsion polymerization technique similar to one described previously (*30*), forming protein-loaded polymer particles incorporating CPP. In this process, CPP and BSA-Alexa Fluor 488 conjugate were dissolved in an aqueous buffer along with acrylamide, acid-sensitive crosslinker **1**, and ammonium persulfate. The aqueous phase was then dispersed as droplets in an organic phase consisting of hexanes and a mixture of two surfactants. Free-radical polymerization was initiated by the addition of ammonium persulfate and TMEDA, resulting in cross-linked polymer particles decorated with cell-penetrating peptide throughout the particles but most importantly at the surface. A schematic representation of the synthesis and subsequent degradation of these particles is depicted in Scheme 1. Exposure of the cross-linked particles to an acidic environment leads to rapid hydrolysis of the acetal linkages. Degradation of the polymer particles thus results in the release of BSA-Alexa Fluor 488, acetone, and the CPP-containing polymer backbone.

The isolated particles analyzed in the dry state using scanning electron microscopy (Figure 1) had sizes ranging from 0.2 to 1 μm. Peptide incorporation was measured by degrading a sample of particles under acidic conditions and analyzing the concentration of peptide using a bicinchoninic acid (BCA) assay (*50*). Using this method, the peptide content in the particles was found to be 0.3% by mass.

Unmodified microparticles free of CPP were also prepared using the same inverse emulsion method but omitting monomer

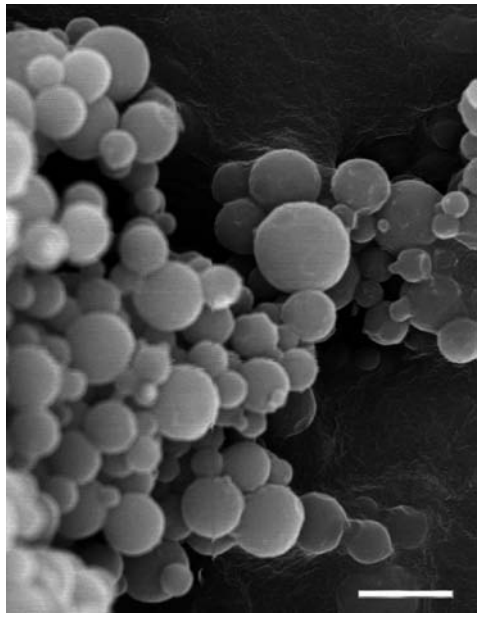


Figure 1. SEM image of CPP-modified microparticles. Scale bar = 1 μm.

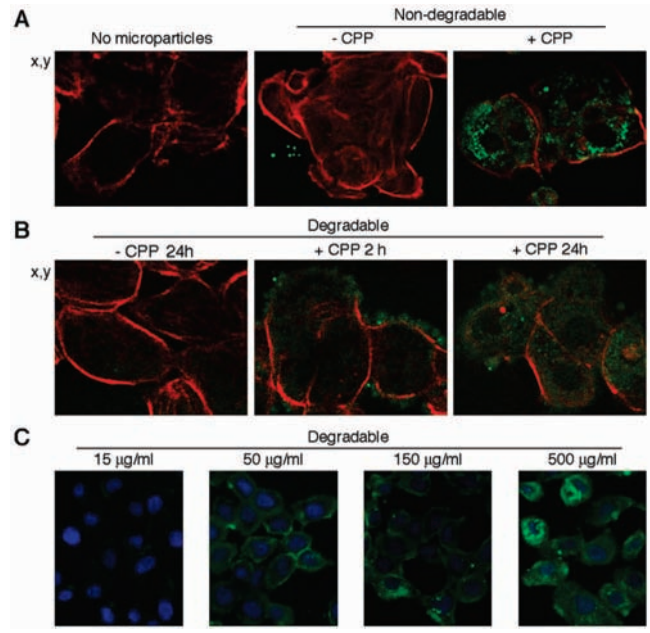

Figure 2. Representative confocal microscope images of BEAS-2B cells, taken at midcell level, 24 h after incubation with microparticles. Cell membranes and cytoskeleton are stained red by phalloidin. Panel A: The cellular accumulation of CPP-modified microparticles 500 μg/mL is markedly greater compared with cells incubated with particles without CPP modification. Panel B: A time dependency is seen when cells are incubated with microparticles at room temperature. At 2 h, most particles appear to be adherent on the cell surface. By 24 h, intracellular accumulation has increased markedly. Note also that the overall fluorescence appears to be more diffuse and less intense than with nondegradable particles. Panel C: Increasing fluorescence is seen intracellularly as microparticle concentration is increased in the medium.

2. These particles contain the same mole percent of cross-linking acetal as the functionalized particles described above. Non-degradable microparticles both with and without cell-penetrating peptide were also prepared as described above using *N*,*N*′-methylene-bis-acrylamide as the cross-linker instead of monomer **1**. SEM examination of these particles showed that they were similar in size and shape to the degradable CPP-modified particles (data not shown).

Cellular Uptake of CPP-Modified Microparticles by Non-Phagocytic Cells. The effect of the CPP modification of the microparticles on their interaction with BEAS-2B epithelial cells is shown in Figure 2. In the absence of microparticle incubation, cell membranes and elements of the intracellular Actin skeleton are clearly evident by phalloidin staining. As expected, no fluorescence from the Alexa Fluor 488 is seen, even at high magnification. When cells were incubated with unmodified non-degradable microparticles (panel A), midcell images obtained by confocal microscopy showed little fluorescence—only visible under high magnification—despite 24 h of incubation time. In contrast, the intracellular accumulation of CPP-modified non-degradable microparticles over the 24 h incubation period was readily evident.

Much research has been done to elucidate the mechanism by which cell-penetrating peptides mediate the transport of various cargoes across the cell membrane. The punctate appearance of microparticles within the cells shown in Figure 2 is consistent with endosomally mediated uptake. Studies by others suggest that uptake is facilitated by positively charged arginine residues (including those present in the CPP used in this study) forming bidentate hydrogen bonds with negatively charged phosphates, sulfates, and carboxylates on the cell surface (*49, 51*).

These results can be contrasted with those observed after cells were incubated with acid-degradable microparticles (panel B, Figure 2). In the absence of the CPP modification, only low levels of fluorescence were seen intracellularly, even after 24 h of incubation (again, most evident at high magnification). With CPP modification, however, high levels of fluorescence are obvious. After just 2 h incubation, microparticles are present both intracellularly as well as clustered on the cell surface. A similar pattern was seen when HeLa cells were incubated with acid-degradable CPP-modified microparticles (data not shown). This association with the cell membrane is probably due to the hydrogen bonding ability of the guanidine headgroup of arginine and the highly cationic nature of the cell-penetrating peptide. After 24 h incubation, the intracellular accumulation of the microparticles is even greater. Again, a similar phenomenon was observed when HeLa cells were incubated with these microparticles. Furthermore, in addition to a time dependency, the accumulation of the CPP-modified microparticles was also concentration-dependent (panel C, Figure 2).

Note, however, that the intensity of fluorescence is more diffuse and less intense than when cells were incubated with the non-degradable particles (compare panel B with panel A). We interpret this difference in appearance to be compatible with time-dependent intracellular microparticle degradation and release of the encapsulated protein. As mentioned above, acid-sensitive crosslinker **1** is chemically stable at pH 7.4, but rapidly hydrolyzes in the acidic environment (pH 5.0) of the lysosome. This hydrolysis is believed to result in an increase in osmotic pressure, leading to lysosomal disruption, thus providing delivery of the encapsulated cargo to the cytoplasm (*28–30*). These results are thus suggestive of release of the encapsulated BSA-Alexa Fluor 488 conjugate into the cytoplasm of the cell.

Importantly, there was no evidence of any cytotoxicity associated with intracellular accumulation of either degradable or non-degradable microparticles. Cells appeared viable with normal cell shape and morphology when viewed microscopically, and DAPI staining showed no evidence of nuclear fragmentation indicative of apoptosis. Furthermore, LDH concentrations in the media of cells incubated with non-degradable particles (with or without CPP modification) were $<$100 IU/mL. The LDH concentration in cells incubated without micro-

particles was also <100 IU/mL, whereas LDH levels were 4 times higher in cells treated with 10 mM H_2O_2 as a positive control.

CPP modification would be expected to be effective in any tissue. Thus, widespread intracellular accumulation of microparticles would be expected after intravenous administration *in vivo*. For some applications, this may be advantageous, but it is detrimental in others due to unwanted toxicities. It is possible that the microparticles could be further modified with highly specific tissue-targeting moieties that would result in reduced uptake in nontargeted tissues. However, with the lungs, a very attractive delivery strategy is to administer the microparticles intratracheally (e.g., as an aerosol). In this case, cellular uptake would likely remain confined to the lung epithelium, and indeed, it was for this reason that we chose a lung epithelial cell line as the primary target for these studies. Future studies will determine if CPP-modified microparticles will accumulate in lung epithelium after intratracheal delivery *in vivo*.

CONCLUSIONS

A microparticle delivery vehicle encapsulating a fluorescently labeled model protein and containing a cell-penetrating peptide was successfully prepared. *In vitro* studies demonstrated that this delivery vehicle is effective at promoting particle uptake in non-phagocytic epithelial cells. Thus, incorporation of a cell-penetrating peptide expands the potential applications of this delivery vehicle for use in non-phagocytic, as well as phagocytic, cell lines. In addition, by incorporating an acid-degradable crosslinker, the particles are capable of releasing the encapsulated payload upon uptake by these cells. Future studies will explore the feasibility of using these particles to deliver plasmid DNA, peptide nucleic acids, or small molecule therapeutic cargoes to lung epithelial cells to treat acute and chronic lung disease.

ACKNOWLEDGMENT

We thank the National Institutes of Health (PEN Grant 1 U01 HL080729-01) for funding of this research; additional NIH support (Grant RO1 EB005824) led to the development of the degradable carrier particles used in this study.

Self-Assembled Cationic Nanogels for Intracellular Protein Delivery

Hirohito Ayame, Nobuyuki Morimoto, and Kazunari Akiyoshi*

Institute of Biomaterials and Bioengineering, Tokyo Medical and Dental University, 2-3-10 Kanda-Surugadai, Chiyoda-ku, Tokyo, 101-0062, Japan. Received November 20, 2007; Revised Manuscript Received February 8, 2008

An effective intracellular protein delivery system with self-assembled cationic nanogels is reported. Interaction of proteins with self-assembled nanogels of cationic cholesteryl group-bearing pullulans ($CHPNH_2$) was investigated by dynamic light scattering (DLS), transmission electron micrograph (TEM), fluorescence resonance energy transfer (FRET), and fluorescence correlation spectroscopy (FCS). The cationic nanogels strongly interacted with bovine serum albumin (BSA) and formed monodispersed nanoparticels (<50 nm). The complex more effectively internalized into HeLa cells than cationic liposomes and a protein transduction domain (PTD) based carrier even in the presence of serum. The higher efficiency of the nanogel carrier is probably due to the formation of colloidally stable nanoparticles with the protein. The enzymatic activity of β-galactosidase (β-Gal) was retained after internalization into cells. The nanogel carrier promoted nuclear delivery of a GFP-conjugated nuclear localization signal and Tat as a PTD (Tat-NLS-GFP). A blocking experiment with chemical inhibitors revealed the possible involvement of macropinocytosis in the uptake of the nanogel complex. After cellular uptake, the complex of the nanogel−protein was dissociated and the protein was released inside the cell. Such a self-assembled cationic nanogel system should create opportunities for novel applications of protein delivery.

INTRODUCTION

Intracellular delivery of exogenous proteins is a subject of great interest in bioscience and medical science. In particular, protein transduction domain (PTD) fusion proteins have been widely used in this field (*1, 2*). However, the synthesis and purification of PTD fusion proteins from bacteria are sometimes problematic due to low expression levels and aggregation of the fusion proteins in certain cases. Protein delivery can also be performed by a noncovalent method which uses a carrier, such as cationic liposomes (*3, 4*), polymer particles (*5, 6*), or PTD-based amphiphilic peptides (*7*). In the noncovalent method, existing recombinant proteins can be easily used by simply mixing the carrier and proteins. Although such carrier methods are convenient, the efficiency is not always high. One of the problems is colloidal instability of the complex between carrier and protein. The complex sometimes forms large aggregates. The control of the size of the complex is known to be the most important factor for effective intracellular protein delivery both *in vitro* and *iv vivo* (*8*). However, it is still difficult to control the size of the complex between carriers and proteins due to multiple point electrostatic interactions and hydrophobic interactions between them.

Nanosize hydrogels (nanogels), which are composed of nanoscale gel particles, have attracted growing interest with respect to their potential application in drug delivery systems (*9–15*). We have developed self-assembly methods for preparing physically cross-linked nanogels (<50 nm) through the controlled association of hydrophobically modified polymers in water (Figure 1) (*16–22*). In particular, cholesteryl group-bearing pullulan (CHP) forms nanoparticles by self-assembly in water (Rh = ∼15 nm). These particles behave like hydrated nanogels via cholesteryl nanodomains acting as physical cross-linking points (*16, 17*). CHP nanogels with such a nanosized hydrogel matrix form complex nanoparticles with various proteins (*18*). Since the nanogel network is comparable to that of proteins, the nanogel can hold a protein molecule in a segregated nanomatrix. The characteristic that each part of the nanogel network isolates protein molecules is advantageous in stabilizing proteins, because aggregation by protein–protein interactions can be prohibited. Therefore, the nanogels act as artificial chaperones, which both protect against the aggregation of denatured proteins and assist in the refolding of proteins (*19, 20*). These features allow the CHP nanogel to function as a protein carrier (*23–25*). Although CHP nanogels are useful as nanocarriers in drug delivery systems (DDS), intracellular uptake of the nanogel was relatively low due to the nonionic character of the polysaccharide pullulan. To achieve higher cellular uptake of the nanocarrier, we designed various cationic CHP derivatives, because in general cationic nanoparticles exhibit high cellular internalization efficiency. In this study, we focus attention on simple cationic nanogels, composed of an amphiphilic polysaccharide: ethylenediamine group functionalization of cholesteryl group-bearing pullulan ($CHPNH_2$) (Figure 1). At first, the interaction of proteins with self-assembled nanogels of $CHPNH_2$ was investigated in detail by various physicochemical techniques such as dynamic light scattering (DLS), transmission electron micrograph (TEM), and fluorescence resonance energy transfer (FRET) and by fluorescence correlation spectroscopy (FCS). It was show that the advantage of using nanogels as the protein carrier is the capacity to form a colloidally stable complex with proteins at the nanometer scale (<50 nm), which is a suitable size for effective intracellular uptake.

MATERIALS AND METHODS

Materials. FITC-labeled bovine serum albumin (FITC-BSA, 66 kDa), Rhodamine B isothiocyanate, and amiloride were purchased from Sigma-Aldrich (USA). A commercial protein carrier of cationic liposome (Pro-Ject) and a peptide-based carrier (Chariot) were purchased from Pierce (USA) and Active Motif (USA), respectively. Ikarugamycin and TokyoGreen-βGal were purchased from Biomol (USA) and Daiichi Pure Chemicals (Japan). Evoblue-BSA was synthesized with a protein-labeling kit according to the manufacturer's instructions (Olympus, Japan). Cell-counting kit-8 (CCK-8) was obtained from Dojindo

Laboratories (Japan). Tat-NLS-GFP (27 kDa) was a gift from Prof. T. Tsubata and Dr. K. Watanabe (Tokyo Medical and Dental University). β-Galactosidase (β-Gal, 540 kDa (tetramer)) and other reagents were purchased from Wako Pure Chemical Industries (Japan).

Synthesis of $CHPNH_2$ (7, 11, and 17 amino groups per 100 glucose units). Dried CHP (150 mg; 0.9 mmol equivalent of anhydrous glucoside units) was dissolved in 15 mL of DMSO, and 1,1-carbonyldiimidazole (25, 38, and 75 mg; 0.15, 0.23, and 0.46 mmol) was added to the mixture under dried nitrogen. After 4 h, ethylenediamine (100, 150, and 300 mg; 1.6, 2.5, and 5.0 mmol) was added to the mixture at room temperature. After being stirred for 24 h, the reaction mixture was dialyzed with the Spectra/Pore 6 dialysis bag (molecular weight cutoff 3500; Spectrum Laboratories, USA), using distilled water for 6 days at room temperature, and lyophilized. The degrees of substitution were determined by elemental analysis (CHN CORDER MT-5; Yanako Japan) ($CHPNH_2$(7): C, 40.9%; H, 6.75%; N, 1.22%. $CHPNH_2$(11): C, 42.1%; H, 6.82%; N, 1.67%. $CHPNH_2$(17): C, 40.0%; H, 6.94%; N, 2.44%).

Synthesis of $CHPNH_2$(17)-rhodamine ($CHPNH_2$(17)-Rh; 0.5 rhodamine groups per 100 glucose units). $CHPNH_2$(17) (100 mg; 0.6 mmol equiv of anhydrous glucoside units) was dissolved in phosphate-buffered saline (PBS: pH 7.4) at 2 mg/mL. Rhodamine B isothiocyanate (1.6 mg; 3.0 μmol) was added and the mixture was heated for 8 h at room temperature. The reaction mixture was dialyzed with the Spectra/Pore 6 dialysis bag by distilled water for 6 days at room temperature. The product was purified by size-exclusion chromatography on a Sephadex G-25. The degrees of substitution were determined by UV analysis using $\epsilon = 59\,000$ at 558 nm.

Preparation of $CHPNH_2$−Protein Complexes. $CHPNH_2$ (1–5 mg/mL) was suspended in PBS. The suspension was sonicated for 15 min with a sonicator probe and filtered through a Millipore filter (pore size 0.22 μm). $CHPNH_2$ nanogel solution and protein solution were mixed and kept at room temperature. An SLS experiment showed that the nanogels of both CHP and $CHPNH_2$ were constituted by approximately four CHP or $CHPNH_2$ macromolecules (*24*).

Fluorescence Resonance Energy Transfer (FRET). The rate of the binding of FITC-BSA to the $CHPNH_2$(17) nanogel was estimated by fluorescence resonance energy transfer (FRET). FRET was estimated by $CHPNH_2$(17)-Rh nanogels (10 nM) and FITC-BSA (10 nM) using an FP-6500 fluorescence spectrometer (JASCO, Japan). FITC-BSA-$CHPNH_2$ (17)-Rh nanogel complex was excited at 495 nm and the emission intensity was measured from 500 to 600 nm.

Fluorescence Correlation Spectroscopy (FCS). The binding constants of BSA with the nanogels were estimated by fluorescence correlation spectroscopy (FCS). FCS measurements were performed using an MF10S (Olympus, Japan). Various concentrations of the nanogel solutions were mixed with Evoblue-BSA (2.5 nM) solution. After the mixture was incubated for 1 h, the data were collected. All experiments were performed with an acquisition time of 15 s per measurement, and all measurements were repeated five times per sample. FCS data were analyzed with the MF10S software package. Binding constants were calculated from triplicate measurements with an Origin 7J (OriginLab) using the best fit.

[B]: CHP or $CHPNH_2$ molar concentration of nanogel

Dynamic Light Scattering (DLS) and ζ-Potential Measurements. DLS and ζ-potential measurements were carried out with a Zetasizer Nano ZS instrument (Malvern Instruments, U.K.) equipped with a PELTIER temperature-control unit at 632.8 nm. The hydrodynamic radii of the nanogels (3 mg/mL) and nanogel (3 mg/mL)−protein (FITC-BSA, 0.52 mg/mL; FITC-β-Gal, 3.3 mg/mL) complex were determined with a Laplace inversion program (CONTIN). The ζ-potential measurements were performed using a capillary ζ-potential cell in automatic mode.

Transmission Electron Micrograph (TEM). TEM (H-600; Hitachi) observation was performed at an accelerating voltage of 100 V. Specimens were prepared by dropping 10 μL of a solution of $CHPNH_2$(17) (1 μM)−FITC-BSA (1 μM) complex on a grid and staining with 0.1% uranyl acetate.

Flow Cytometry. HeLa cells were cultured in Minimum Essential Medium (MEM) supplemented with 10% heat-inactivated fetal bovine serum (FBS). Cells were plated in a six-well culture dish at a density of 2.0×10^4 cells/well and cultured for 24 h at 37 °C in 5% CO_2. After the medium was removed, 1 mL of fresh MEM containing $CHPNH_2$ nanogel (10 nM)−FITC-BSA (10 nM) complex or $CHPNH_2$ nanogel (10 nM)−FITC-β-Gal (10 nM) was added and the cells were cultured at 37 °C in 5% CO_2. After incubation for periods of constant duration, cells were washed with medium, trypsinized, and suspended in stain buffer (BD PharMingen stain buffer, BD PharMingen USA). Flow cytometry was performed on a FACScalibur (BD Biosciences USA) with a 488 nm argon laser. The signal from the FL1 bandpass emission (530/30) was used for FITC.

The cellular uptake of $CHPNH_2$(17) nanogel (10 nM)−FITC-BSA (10 nM) complex was also examined by flow cytometry in NIH-3T3, cos-7, CHO-K1, and MC-3T3 cells. The cells were plated in a six-well culture dish at a density of 2.0×10^4 cells/well and cultured for 24 h at 37 °C in 5% humidified CO_2. After the medium was removed, 1 mL of fresh medium in the presence of serum containing $CHPNH_2$(17) nanogel (10 nM)−FITC-BSA (10 nM) complex was added. After incubation for periods of constant duration, cells were washed with medium, trypsinized, and suspended in stain buffer.

Cytotoxicity Assay. HeLa Cells were plated in a 96-well culture dish at a density of 1.0×10^3 cells/well and cultured for 24 h at 37 °C in 5% humidified CO_2. After the medium was removed, 50 μL of fresh MEM containing protein carriers ($CHPNH_2$ nanogel, peptide based carrier and cationic liposome) were added. Cells were cultured at 37 °C in 5% CO_2. After incubation for 4 h, the cells were washed with fresh medium. HeLa cells were cultured for 24 h, and cell counting kit-8 (CCK-8) solution (Dojindo Laboratories, Japan) was then added to the medium. After 2 h, the absorbance was measured at 450 nm using a microplate reader with a reference wavelength of 630 nm.

Confocal Laser Scanning Fluorescence Microscopy (CLSFM) of the Uptake of BSA into Cells. HeLa cells were plated in a glass-bottom dish (glass diameter 10 mm) at 1.0×10^4 cells/dish and cultured for 24 h at 37 °C in 5% humidified CO_2. After the culture medium was removed, 1 mL of $CHPNH_2$ nanogel (10 nM) complex solution with FITC-BSA (10 nM) was added to cells. After incubation for 4 h at 37 °C in 5% CO_2, the cells were washed with fresh medium and were observed by CLSFM (LSM510META, Carl Zeiss, German). In the case of the $CHPNH_2$(17)-Rh−FITC-BSA system, the cells were cultured for 2 or 18 h, and CLSFM observations were carried out with excitation by an argon laser (488 nm for FITC) and He−Ne laser (543 nm for rhodamine B). The emitted

fluorescence was detected through a 503–530 nm bandpass filter and a 543 nm long-pass filter, respectively.

Intracellular Delivery of Protein Using Cationic Liposome. The tube dry film of cationic liposome in Pro-Ject Protein Transfection Reagent kit (Pro-Ject, PIERCE) was dissolved with 250 μL of chloroform and vortexed for 20 s. One experiment (six-well plate; 10 μL) of the cationic liposome was dispensed to tube and the solvent evaporated by placing the tube containing the cationic liposome under a laminar flow hood for 2 h at room temperature. FITC-BSA or FITC-β-Gal (100 μL; PBS solution) was added to the tube containing the dry film of cationic liposome and vortexed for 10–20 s, then incubated at room temperature for 5 min. In the experiment of flow cytometry, HeLa cells were cultured in MEM supplemented with 10% heat-inactivated FBS. Cells were plated in a six-well culture dish at a density of 2.0×10^4 cells/well and cultured for 24 h at 37 °C in 5% CO_2. After the medium was removed, 1 mL of fresh MEM containing cationic liposome−FITC-BSA (10 nM) or cationic liposome−FITC-β-Gal (10 nM) complex was added, and the cells were cultured at 37 °C in 5% CO_2. After incubation for periods of constant duration, cells were washed with medium, trypsinized, and suspended in stain buffer. Flow cytometry was performed on a FACScalibur with a 488 nm argon laser. The signal from the FL1 bandpass emission (530/30) was used for FITC. In CLSFM, HeLa cells were plated in a glass-bottom dish at 1.0×10^4 cells/dish and cultured for 24 h at 37 °C in 5% humidified CO_2. After the medium was removed, 1 mL of fresh MEM containing liposome−FITC-BSA (10 nM) complex or cationic liposome−FITC-β-Gal (10 nM) complex was added to cells. After incubation for 4 h at 37 °C in 5% CO_2, the cells were washed with fresh medium and were observed by CLSFM.

Intracellular Delivery of Protein Using Peptide-Based Carrier. The tube of Chariot Transfection Transduction Reagent kit (Chariot, ACTIVE MOTIF) was dissolved with 150 μL of H_2O. One experiment (six-well plate; 6 μL) of the peptide-based carrier was dispensed to tube. FITC-BSA or FITC-β-Gal (100 μL; PBS solution) was added to peptide-based carrier (6 μL in 100 μL; H_2O) and then incubated for 30 min at room temperature. In the flow cytometry case, HeLa cells were cultured in MEM supplemented with 10% heat-inactivated FBS. Cells were plated in a six-well culture dish at a density of 2.0×10^4 cells/well and cultured for 24 h at 37 °C in 5% CO_2. After the medium was removed, 600 μL of fresh MEM containing peptide-based carrier−FITC-BSA (17 nM) complex or peptide-based carrier−FITC-β-Gal (17 nM) was added and the cells were cultured at 37 °C for 1 h in 5% CO_2. After incubation, the cells were added to 1 mL of fresh medium and then were cultured for 3 h. After incubation for periods of constant duration, cells were washed with medium, trypsinized, and suspended in stain buffer. Flow cytometry was performed on a FACScalibur with a 488 nm argon laser. The signal from the FL1 bandpass emission (530/30) was used for FITC. In the CLSFM case, HeLa cells were plated in a glass-bottom dish at 1.0×10^4 cells/dish and cultured for 24 h at 37 °C in 5% humidified CO_2. After the medium was removed, 600 μL of fresh MEM containing peptide-based carrier−FITC-BSA (17 nM) complex or peptide-based carrier−FITC-β-Gal (17 nM) complex was added to cells. After incubation for 1 h at 37 °C in 5% CO_2, the cells were added to 1 mL of fresh medium and then were cultured for 3 h. After incubation for periods of constant duration, the cells were washed with fresh medium and were observed by CLSFM.

Intracellular Delivery of Enzyme β-Gal. The enzyme activity of β-Gal before and after complexation with nanogel was estimated by TokyoGreen-βGal as a substrate. The initial velocities of β-Gal (10 nM) in the absence and presence of $CHPNH_2$(17) nanogel (10 nM) after the addition of 30 μM of substrate TokyoGreen-βGal were estimated using an FP-6500 fluorescence spectrometer. The fluorescence of the TokyoGreen-βGal product by enzyme reaction was measured (ex. 490 nm, em. 510 nm). Initial velocity was estimated from the slope of the change of the intensity within 15 min.

In the experiment on the enzyme activity of β-Gal inside the cell, HeLa cells were plated in a glass-bottom dish at 1.0×10^4 cells/dish and cultured for 24 h at 37 °C in 5% humidified CO_2. After the culture medium was removed, 1 mL of $CHPNH_2$ complex solution with β-Gal (10 nM) was added to cells. After

incubation for 4 h at 37 °C in 5% CO_2, the cells were washed with fresh medium and then were cultured for 12 h. Tokyo-Green-βGal (10 μM) was added to the medium. After 30 min, CLSFM was observed with excitation by an argon laser (488 nm). The emitted fluorescence was detected through a 503–530 nm bandpass filter.

Inhibition of Specific Endocytotic Pathways. HeLa cells were plated in a six-well culture dish at a density of 2.0×10^4 cells/well and cultured for 24 h at 37 °C in 5% humidified CO_2. After the medium was removed, 1 mL of fresh MEM containing $CHPNH_2$ nanogel (10 nM)−FITC-BSA complex (10 nM) was added and incubated for 4 h at 4 or 37 °C in 5% CO_2. The cells were washed with fresh medium, trypsinized, and suspended in stain buffer. Flow cytometry was performed on a FACScalibur with a 488 nm argon laser. The signal from the FL1 bandpass emission (530/30) was used for FITC.

In an experiment using an endocytosis inhibitor, HeLa cells (2.0×10^4 cells/well) were pretreated with the clathrin-mediated endocytosis inhibitor, Ikarugamycin (IKA (0–5 μM)), or the macropinocytosis inhibitor, amiloride (0–100 μM), for 30 min at 37 °C in 5% CO_2 and then cultured with fresh medium containing $CHPNH_2(17)$ (10 nM)−FITC-BSA (10 nM) complexes with one of the inhibitors for 4 h at 37 °C in 5% CO_2. The cells were washed with fresh medium, trypsinized, and suspended in stain buffer. Flow cytometry was performed on a FACScalibur with a 488 nm argon laser. The signal from the FL1 bandpass emission (530/30) was used for FITC.

CLSFM Observation of Tat-NLS-GFP. HeLa cells were plated in a glass-bottom dish at 1.0×10^4 cells/dish and cultured for 24 h at 37 °C in 5% CO_2. After the culture medium was removed, 1 mL of $CHPNH_2$ complex solution with Tat-NLS-GFP (100 nM) was added to the cells for 4 h at 37 °C in 5% CO_2. The cells were washed with fresh medium and cultured for 24 h at 37 °C in 5% CO_2. After the addition of DAPI (300 nM), CLSFM was observed with excitation by an argon laser (488 nm for GFP) and a blue diode (405 nm for DAPI). The emitted fluorescence was detected through a 503–530 nm bandpass filter and a 420 nm long-pass filter, respectively.

RESULTS AND DISCUSSION

Interaction of the Cationic Nanogel with Proteins. We synthesized amino-fucntionalized CHP ($CHPNH_2$) by reacting CHP with ethylenediamine. The designation $CHPNH_2(17)$ means that 17 amino groups per 100 glucose units were introduced to a CHP macromolecule. Cationic derivatives of CHP also formed monodispersive nanogels (Rh = 14–17 nm) by DLS, similar to CHP (Table 1). Interaction between $CHPNH_2(17)$ nanogel and BSA as a model protein was estimated by fluorescence resonance energy transfer (FRET) and by fluorescence correlation spectroscopy (FCS). After FITC-labeled BSA (FITC-BSA) (10 nM) was added to rhodamine-labeled $CHPNH_2(17)$ nanogels (10 nM), FRET was effectively observable due to the complexation (Figure 2). The binding of FITC-BSA to the cationic nanogels was quite rapid ($t_{1/2}$< 5 min).

The binding constants of BSA (Evoblue-BSA (2.5 nM)) with nanogels were estimated on the basis of a molar concentration of BSA (mol/L) and a molar concentration of the CHP or $CHPNH_2$ nanogel (mol/L) by FCS (Figure 3). Even nonionic CHP nanogels strongly bound to BSA ($K = 1.3\ (\pm 0.2) \times 10^7\ M^{-1}$). We found the CHP nanogel trapped BSA in a hydrogel matrix and formed 1:1 complex nanoparticles, mainly by hydrophobic interaction (*17*). The $CHPNH_2(11)$ and $CHPNH_2(17)$ nanogels exhibited higher binding constants than the CHP nanogel (Table 1). This is due to both hydrophobic and electrostatic interactions between the cationic nanogels and anionic BSA (pI = 4.7). The $CHPNH_2$ nanogel−BSA complexes were slightly increased in size and still monodisperse

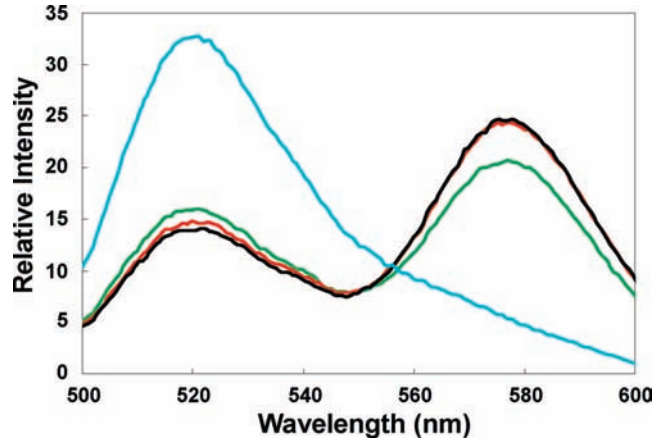

Figure 2. Emission spectra of FITC-BSA (blue line) and $CHPNH_2(17)$-Rh−FITC-BSA complex (ratio of BSA and nanogel = 1:1) after the formation of a complex at 1 (green line), 5 (red line), and 15 (black line) min, respectively. The concentrations of FITC-BSA and $CHPNH_2(17)$Rh nanogel were 10 nM.

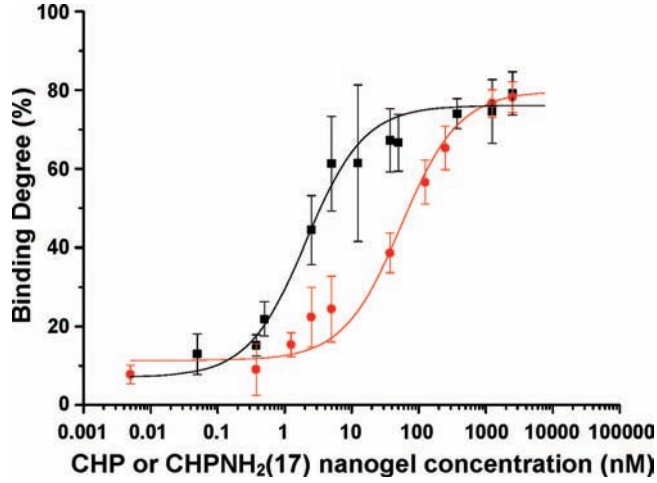

Figure 3. Binding curve between BSA and nanogels (CHP (circle) and $CHPNH_2(17)$ (square)) as estimated by FCS. Error bars represent the SD for three experiments performed in duplicate.

based on DLS (Table 1) and TEM observation (Figure 4). The zeta potentials were still positive after complexation. Colloidally stable cationic nanosized particles were formed after a simple mixing of the cationic nanogels and BSA. The self-assembled cationic nanogel is a unique macromolecular host for proteins. The nanogel structure, in which the network is comparable to the size of the protein, is suitable for effective protein trapping.

Interaction of Cationic Nanogel−Protein Complex with Cells. Protein delivery by $CHPNH_2$ nanogels to human cervical cancer (HeLa) cells was investigated. Complexes of nanogel−FITC-BSA were cultured with HeLa cells in MEM with 10% FBS. The fluorescence intensities of internalized FITC-BSA (10 nM) by $CHPNH_2$ nanogels (10 nM) were measured by flow cytometry. The time course of the cellular uptake of FITC-BSA with $CHPNH_2(17)$ nanogel was investigated. The uptake of FITC-BSA to cell increased over 6 h (Figure 5i). High cellular uptake was observed even in the case of a 1:1 molar mixture of FITC-BSA and $CHPNH_2$ nanogel (Figure 5ii). The uptake increased with an increase in the content of amino groups (Figure 5iii). The interaction of cationic nanogels with anionic domains on the cell surface due to various membrane proteoglycans may be an important factor in the cellular uptake of the nanogel complex. For example, Behr and co-workers demonstrated that, in the cellular uptake of cationic PEI/DNA complex,

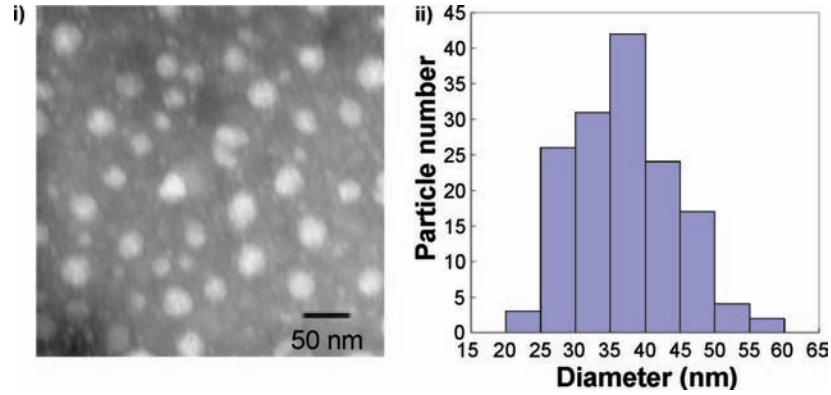

Figure 4. (i) TEM image (negative stain) of $CHPNH_2(17)$−FITC-BSA complex and (ii) particle size distribution determined from TEM images.

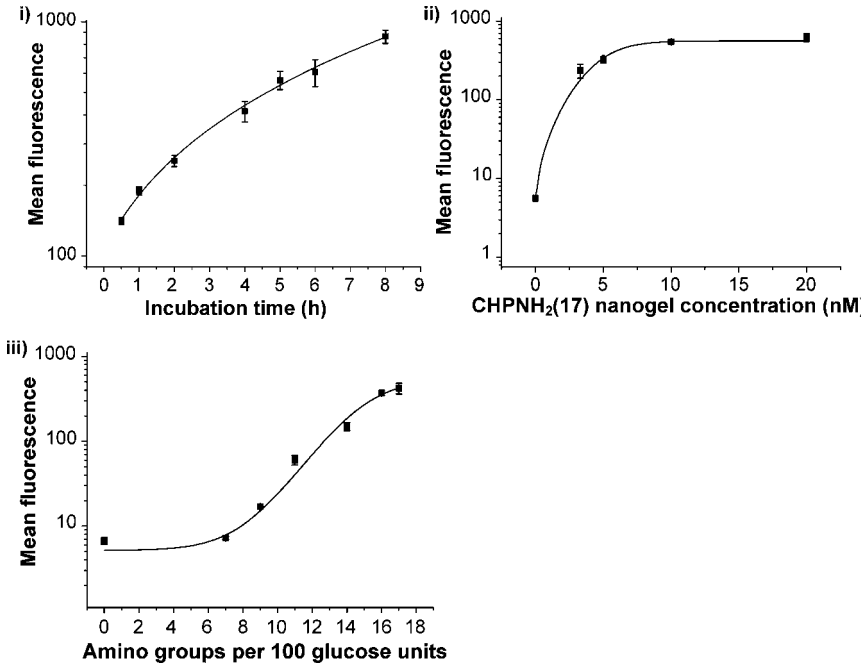

Figure 5. Cellular uptake of FITC-BSA (10 nM) by various cationic nanogels determined by flow cytometry. Error bars represent the SD for three experiments performed in duplicate. (i) Time course of the cellular uptake of FITC-BSA (10 nM) with $CHPNH_2(17)$ nanogel (10 nM) over 0.5, 1, 2, 4, and 6 h. (ii) Effect of molar complex formation $CHPNH_2$−FITC-BSA on cellular uptake. HeLa cells were cultured for 4 h in MEM containing FITC-BSA and $CHPNH_2$ nanogels (0, 3.3, 5.0, 10, and 20 nM) complexes. (iii) Effect of the degree of amino group substitution on cellular uptake. HeLa cells were cultured for 4 h in MEM containing CHP, $CHPNH_2(7)$, (9), (11), (14), (15), (16), and (17) (every nanogel concentration is 10 nM).

electrostatic interaction with anionic binding sites of syndecans (anionic heparan sulfate proteoglycans) play an important role (*27*).

We compared the efficiency of cellular uptake with those in other carrier systems such as cationic liposome and peptide-based carrier under the similar conditions. The mean fluorescence in the $CHPNH_2(17)$ nanogel system by flow cytometry was higher than that with cationic liposomes and a peptide-based carrier (Figure 6i). Images obtained by confocal laser scanning fluorescence microscopy (CLSFM) suggested that FITC-BSA was effectively internalized inside almost all of the cells by the nanogels (Figure 6ii−iv). Cell viability did not change even after incubation of the $CHPNH_2(17)$ nanogels (final concentration 10 or 100 nM) for 24 h though there was a slight toxicity in the case of both the cationic liposomes and peptide-based carrier (Supporting Information Figure S1) under the condition of cellular protein delivery.

We investigated protein delivery in various cell types such as CHO-K1 (chinese hamster ovary fibroblasts), cos-7 (african green monkey kidney fibroblasts), and NIH-3T3 (mouse embryonic fibroblasts) using three carrier systems. In all cell lines, effective cellular uptake of FITC-BSA by the nanogel $CHPNH_2(17)$ carrier was observed in comparison to the other carrier systems tested (Figure 7). This nanogel protein delivery system exhibited a general versatility for effective activity in a variety of cells.

The sizes of the cationic liposome−FITC BSA complex (Rh = 1490 nm) and peptide-based carrier (Rh = 750 nm) were larger than that of the $CHPNH_2(17)$ nanogel (Rh = 19 nm) as determined by DLS measurement. The size of the complex is an important factor in cellular uptake (*8*). A smaller carrier, comparable to the size of a virus, is effectively internalized into the cell. The higher efficiency of the nanogel carrier is probably due to the formation of nanoparticles of <50 nm in size even after complexation with proteins.

Intracellular Delivery of Enzyme β-Gal by Cationic Nanogel. The delivery and enzymaticactivity of β-Gal inside the cell were investigated. β-Gal (540 kDa (tetramer)) is a larger protein than BSA (66 kDa). The monodispersed nanoparticle was also formed after complexation of the

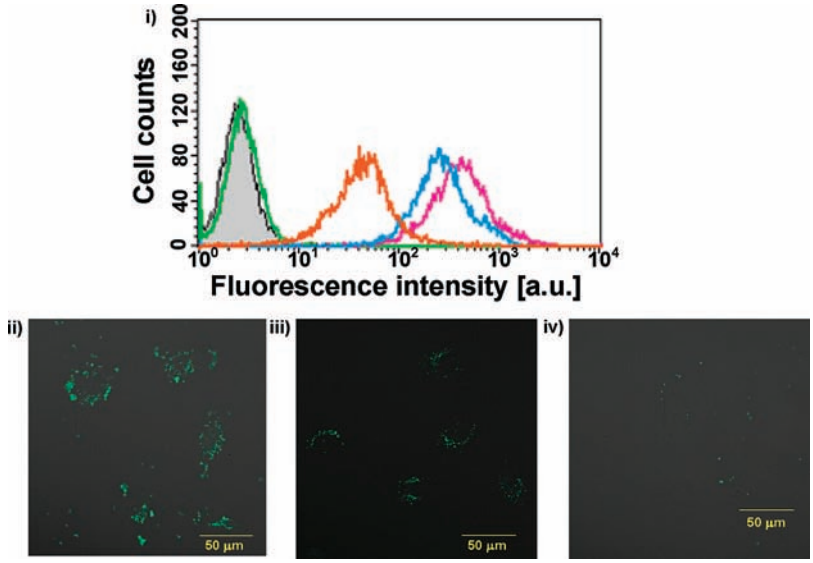

Figure 6. Uptake of FITC-BSA (10 nM) by HeLa cells after 4 h by various carriers. After being washed, HeLa cells were cultured for 4 h. (i) Flow cytometry data for cell only (black), FITC-BSA in the absence of carrier (green line), peptide-based carrier (orange line), cationic liposome (blue line), and $CHPNH_2$(17) nanogel (pink line). (ii−iv) CLSFM images of HeLa cells incubated with the carrier−protein complexes ((ii) $CHPNH_2$(17) nanogel, (iii) cationic liposome, and (iv) peptide based carrier).

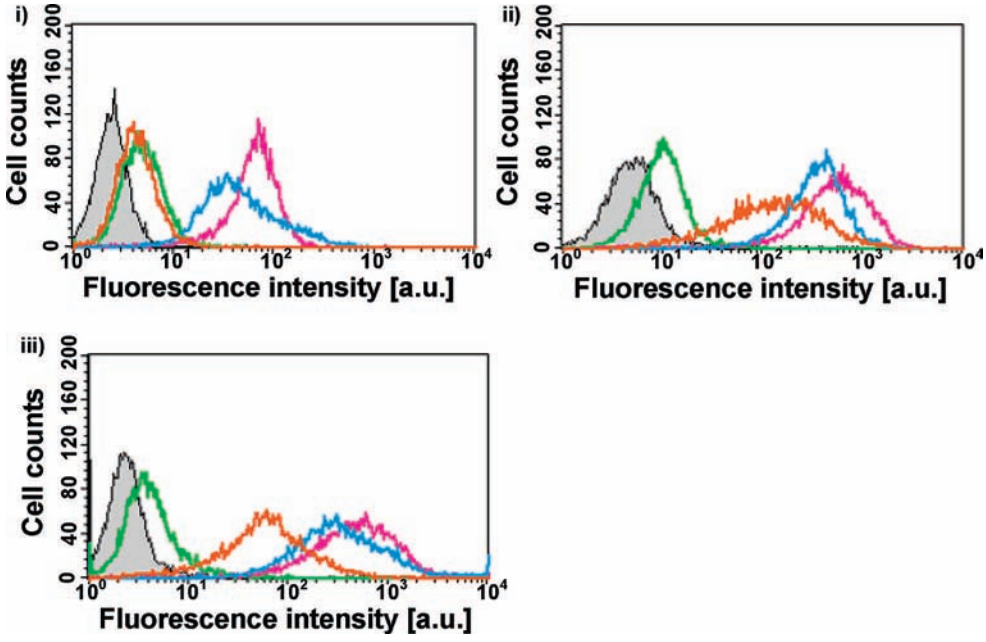

Figure 7. Flow cytometry data for uptake of FITC-BSA (10 nM) to (i) NIH-3T3, (ii) cos-7, and (iii) CHO-K1 cells after 4 h by various carriers. After being washed, HeLa cells were cultured for 4 h, cell only (black), FITC-BSA in the absence of carrier (green line), peptide-based carrier (orange line), cationic liposome (blue line), and $CHPNH_2$(17) nanogel (pink line).

$CHPNH_2$ nanogel with β-Gal (diameter 30 nm (PDI = 0.191)). The enzymatic activity *in vitro* (TokyoGreen-βGal as a substrate of β-Gal (*28*)) was retained after complexation ([initial velocity of $CHPNH_2$-β-Gal complex]/[initial velocity of β-Gal] was 0.95). The cellular uptake of FITC-β-Gal was investigated by CLSFM and flow cytometry. The nanogel carrier system was superior to the other carrier systems tested (Figure 8i). Cellular uptake was saturated at a 1:1 molar mixture of FITC-β-Gal (Figure 8ii).

The enzyme activity of β-Gal inside the cell was evaluated *in situ*on the basis of fluorescence of the reaction product of TokyoGreen-βGal (*28*). HeLa cells were incubated with nanogel−β-Gal complex for 4 h. After being washed, HeLa cells were cultured for 12 h, and the substrate was then added to the medium. The fluorescence spread uniformly throughout almost all of the cells by CLSFM (Figure 8iii). The enzyme may be delivered into the cytosol via endocytosis by nanogels. Another possibility is that the fluorescence product of TokyoGreen by enzyme reaction may escape from endosomes and spread into the cytosol. The enzyme activity of β-Gal was retained after $CHPNH_2$ nanogel-mediated intracellular delivery. The enzyme was found to be present in the native form inside the cells.

Uptake Mechanism of the Nanogel−Protein Complex. To obtain insight into the mechanism of the cellular internalization of the cationic nanogel, the following experiments were carried out. The cellular uptake of FITC-BSA by cationic nanogels decreased to 30%, based on the mean intensity of fluorescence at 4 °C compared to that at 37 °C by flow cytometry (Figure 9i). We next used chemical inhibitors to block specific endocytotic pathways,

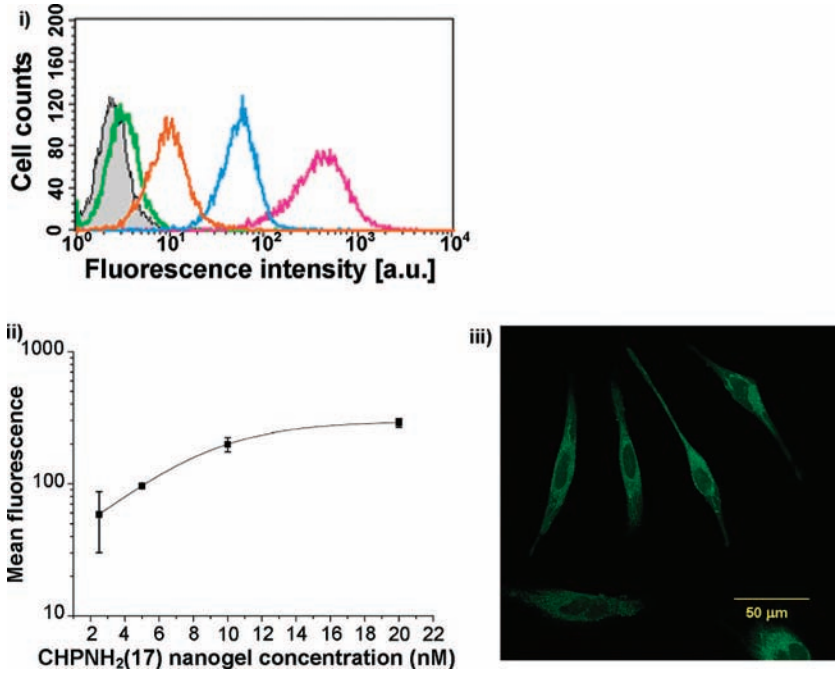

Figure 8. (i) Uptake of FITC-β-Gal (10 nM) by HeLa cells after 4 h by various carriers. After being washed, HeLa cells were cultured for 4 h. Flow cytometry data for cell only (black), FITC-BSA in the absence of carrier (green line), peptide-based carrier (orange line), cationic liposome (blue line), and $CHPNH_2$(17) nanogel (pink line). (ii) HeLa cells were cultured for 4 h in MEM containing FITC-β-Gal (10 nM) and $CHPNH_2$ nanogels (2.5, 5.0, 10, and 20 nM) complexes. Error bars represent the SD for three experiments performed in duplicate. (iii) The enzyme activity of β-Gal inside the cell was evaluated *in situ* by CLSFM. HeLa cells were incubated with $CHPNH_2$(17) nanogel (10 nM)−β-Gal (10 nM) complex for 4 h. After being washed, HeLa cells were cultured for 12 h, and the substrate was then added to the medium. The cells were observed by CLSFM.

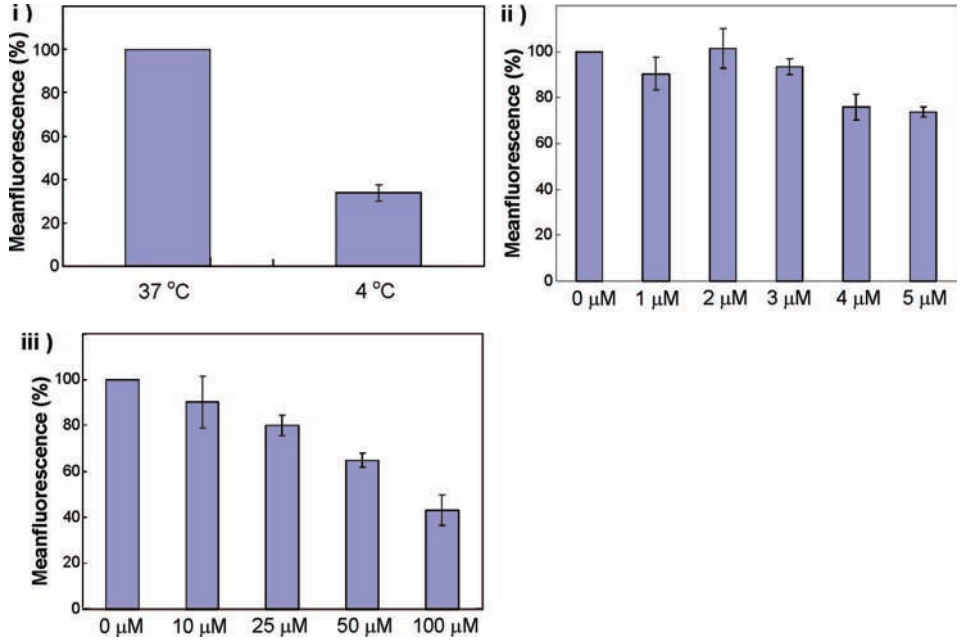

Figure 9. Inhibition of endocytosis prevents the formation of $CHPNH_2$(17) nanogel (10 nM)−FITC-BSA (10 nM) complexes. The mean fluorescence of cells was measured by flow cytometry and is represented as the percentage of that in untreated cells for 4 h at 37 °C: (i) low temperature (4 °C), (ii) clathrin-mediated endocytosis inhibitor, and (iii) macropinocytosis inhibitor. Error bars represent the SD for three experiments performed in duplicate.

such as clathrin-mediated endocytosis by Ikarugamycin (IKA) (*29*), which blocks the down-regulation of CD4 in response to phorbol myristate acetate and the macropinocytosis inhibitor amiloride, an inhibitor of the Na^+/H^+ exchange required for macropinocytosis (*30*). Cells were treated with these inhibitors before the addition of nanogel−FITC-BSA complex and then analyzed using flow cytometry. IKA inhibited the uptake of the complexes by 25% and amiloride inhibited uptake by up to 60% (Figure 9ii,iii). These results indicate the possible involvement of macropinocytosis in the uptake of the nanogel complex.

The fate of the complex of nanogel−BSA after uptake into the cell was investigated using different fluorescence probes between the nanogel (rhodamine-labeled $CHPNH_2$(17)) (red) and FITC-BSA (green) by CLSFM. After 2 h incubation, the complex had effectively internalized into the cell and most of the two fluorescences overlapped (yellow) (Figure 10i). This

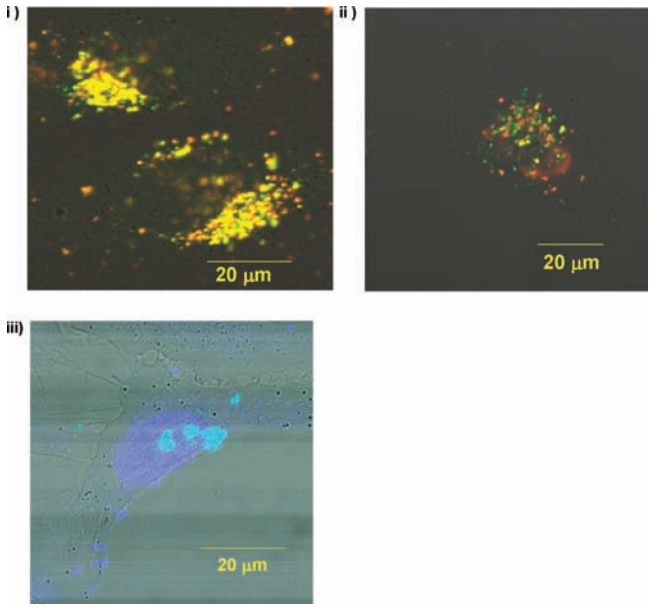

Figure 10. CLSFM images. (i,ii) HeLa cells were cultured with $CHPNH_2$Rh-FITC-BSA complexes (10 nM) (FITC-BSA (green), $CHPNH_2$(17)Rh (red), and overlay (yellow)) for 4 h. After being washed, HeLa cells were cultured for (i) 2 h and (ii) 18 h after washing. (iii) Intracellular localization of Tat-NLS-GFP (100 nM) by CHP-NH_2(17) nanogel (100 nM). The nuclei were stained with DAPI (blue).

means that FITC-BSA was internalized as a complex with the nanogel. After 18 h, however, the fluorescence of FITC-BSA (green) and rhodamine-labeled $CHPNH_2$ (red) were increased at different sites within the cell (Figure 10ii). This result suggests that the complex had become dissociated and the protein was released from the nanogels inside the cell including endosomes or cytosol. It may be possible that sorting of endosomes would give separate signals of BSA and nanogels. The ratio of BSA (green fluorecence) released from the nanogels was estimated to be approximately 20%, as shown in the Figure 10ii).

We previously reported that proteins encapsulated by CHP nanogel are released in the presence of an excess amount of other proteins without the disintegration of the nanogel. For example, chymotrypsin (Chy) entrapped in CHP nanogel was released in the presence of BSA (*31*). In an animal experiment, insulin entrapped in CHP nanogel was also released in a functional form in the bloodstream after intravenous injection (*23*). The main driving force of the binding of the protein with amphiphilic nanogel is hydrophobic interaction between the nanogel cholesterol groups and the hydrophobic domain of the protein. BSA probably expels Chy from the nanogel due to the more potent hydrophobicity property. Therefore, the encapsulated protein can be released by an exchange mechanism. The CHP nanogel is physically cross-linked with nanogels by self-assembly of the cholesterol group attached to pullulan. The dynamic property of the association of the cholesterol group enables encapsulation of the protein and also exchange of proteins.

In the intracellular uptake of the nanogel−protein complex, one of the explanations for the release of protein in the cell is the protein-exchange mechanism. The exchange reaction would effectively occur inside the cell, because the concentration of proteins in the cell is quite high. Another possibility is the disintegration of the nanogel inside the cell by cellular proteins or lipids or by enzyme degradation of polysaccharide. Finally, the cellular uptake of GFP-conjugated nuclear localization signal and Tat as a PTD (Tat-NLS-GFP) was investigated by flow cytometry and CLSFM. The results of flow cytometry showed the high cellular uptake of Tat-NLS-GFP by the nanogel delivery system, while Tat-NLSGFP was only slightly internalized into cells by itself because of the existence of PTD of Tat and an NLS amino sequence. After nanogel-mediated internalization, Tat-NLS-GFP was localized in the nuclei due to the effect of a nuclear localization signal by CLSFM (Figure 10iii). The results suggested that Tat-NLS-GFP was released from the nanogel and moved to the nucleus from the cytosol.

CONCLUSIONS

Cationic self-assembled nanogels strongly interacted with proteins such as bovine serum albumin (BSA) and β-Galactosidase (β-Gal), and formed a colloidally stable monodispersed nanoparticels (<50 nm). They have been demonstrated to be capable of effective transport of various proteins into various cells even in the presence of serum. The nanogel carrier complex was more effectively internalized into HeLa cells than cationic liposomes and protein transduction domain (PTD) based carrier system. The complex of the nanogel−protein was dissociated and the protein was released after internalization to the cell. The cationic nanogels system is useful as a carrier for intracellular protein delivery and as a tool in cell biology research.

The application of these nanogels to an antigen (oncoprotein) delivery system for high cellular and humoral immune responses is under investigation (*25*). It is possible to develop tailormade functional nanogels to create novel nanobiomaterials (nanogel engineering) through the self-assembly of functional associating polymers as the building blocks. For example, various stimuli-responsive nanogels can be obtained by the self-assembly of pH-responsive cholesteryl-bearing poly(amino acids) (*21*), thermoresponsive poly(*N*-isopropylacrylamide)-CHP (*22*), and photoresponsive spiropyrane-modified pullulan (*20*). This self-assembled nanogel should create new opportunities for protein delivery systems.

ACKNOWLEDGMENT

This work was supported by a Grant-in-Aid for Scientific Research from the Japanese government and CREST, JST. We thank Prof. T. Tsubata, Dr. K. Watanabe and Mr. Y. Kawaguchi (Tokyo Medical and Dental University) for the generous gift of Tat-NLS-GFP. We thank Prof. K. Tokunaga and Dr. H. Miyadera (Tokyo University) for using MF 10S. Pacific Edit reviewed the manuscript prior to submission.

The synthesis of an amphiphilic polymethacrylate copolymer containing cholesterol hydrophobic moieties and rhodamine as a fluorescent probe, the formation of microspheres, and the uptake of these microspheres in an invertebrate are reported. The cholesterol-derived methacryloyl monomer, which was prepared *via* a one-step synthesis, was copolymerized with methacrylic acid and methacryloxyethyl thiocarbamoyl rhodamine B in the presence of AIBN as initiator. The obtained dye-labeled copolymer was characterized by ^{1}H NMR and UV–vis spectroscopy. Fluorescence and TEM microscopies studies show that this amphiphilic copolymer aggregates to give microspheres with diameters ranging from 3 to 11 μm. The *in vivo* study in a freshwater invertebrate, a Mesostominae flatworm (Rhabdocoela, Thyphloplanidae), indicates that the microspheres enter the cells by endocytosis. The data collected demonstrate that the rhodamine B covalently attached to the amphiphilic copolymers is bioaccumulated without being translocated out of the cell by the multixenobiotic resistance (MXR) transporters. As the MXR system is similar to the multidrug resistance (MDR) first observed in tumor cell lines resistant to anticancer drugs, the present data confirm the significant role that amphiphilic copolymers can play in the ongoing development of drug delivery strategies to overcome multidrug resistance. These investigations illustrate a promising approach for the development of new medical and ecotoxicological tools that can deliver specific molecules within cells.

INTRODUCTION

Within the past four decades, there has been increased interest in the design of macromolecules for applications ranging from drug delivery (*1–3*) to biological imaging technologies (*4*). Polymer chemistry and engineering have had a direct impact on enhancing drug loading of therapeutic agents as well as creating stable biosensors for novel therapeutic (*5*) and diagnostic devices (*6*). With regard to polymeric microspheres, there are two broad categories: reservoir devices and polymer conjugates. The former involves carriers where a drug or a dye is physically incorporated into the polymeric matrix, whereas in the latter system, the drug is covalently linked to the polymer. Polymers under investigations include proteins, nucleic acids, and polysaccharides as well as synthetic polymers. Among the various options, the synthetic polymers, including polyanhydrides, polyesters, polyacrylic acids, polymethacrylates, and polyurethanes provide important avenues for research, primarily because of their ease of processing and the ability to control their chemical and physical properties. Synthetic polymers are also advantageous due to high physical stability, possibility of sustained drug release, and potential for functionalization.

In the polymer conjugates area, the bioactive molecule and/or the dye is covalently bound and transported to the tissues and cells. These macromolecular carriers should ideally be water-soluble, biocompatible, nontoxic, and nonimmunogenic (*7*), as well as degraded and/or eliminated from the organism (*8*). The biological rationale for the use of water-soluble copolymers as drug carriers is based on their unique biological behaviors in terms of pharmacokinetics properties and cellular uptake. It is well-known that high-molecular-weight polymers can accumulate in solid tumors due to the differences in the biochemical and physiological characteristics of healthy and malignant tissues (*9*). This feature termed "enhanced permeability and retention" (*10−12*) (EPR effect) was described by Maeda and his co-workers (*13*). The cellular uptake mechanism of a molecule is also known to depend on its molecular weight. Whereas most low-molecular-weight molecules penetrate into the cell *via* simple diffusion thought the cell membrane, macromolecules are taken up by the cell through endocytosis (*14*). During this step, a significant drop in the pH value takes place from the physiological values (7.2–7.4) in the extracellular space to pH 6.5–5.0 in the endosomes and finally to about pH 4.0 in primary and secondary lysosomes. Recently, Leroux and co-workers reported that synthetic polyanions derived from polycarboxylates can take advantage of this drop in pH to overcome the endosomal/lysosomal barrier and deliver macromolecular drugs (*15–17*). Moreover, it was reported that increasing the copolymer hydrophobicity by introducing hydrophobic monomers induced a destabilization of cell membranes facilitating the endosomal escape (*18*).

With the aim to further increase the hydrophobicity of polymethacrylate polyanions, an amphiphilic polymethacrylate copolymer has been synthesized. In this study, we have selected (i) the cholesterol as a highly hydrophobic species and (ii) rhodamine as a fluorescent marker as well as a substrate of the multixenobiotic resistance (MXR) pump transporter, which

removes xenobiotic molecules or drugs from the cell. These two functional monomers were prepared containing either cholesterol or rhodamine and copolymerized with methacrylate in the presence of AIBN to give the corresponding amphiphilic labeled copolymer. Based on the chemical features of this macromolecule (i) drug/dye polymer conjugate, (ii) amphipatic structure, (iii) pH-sensitive groups (carboxylates), we hypothesize that this carrier could play a significant role for drug delivery applications and/or imaging cells. A goal of this work is to investigate this new macromolecular carrier for *in vivo* delivery to a simple freshwater invertebrate: a Mesostominae flatworm (Platyhelminthes, Rhabdocoela, Thyphloplanidae) (Figure 1). Flatworms are acoelomata organisms, known as simplest triploblastic animals. They possess a simple body plan organization lacking respiratory and circulatory organs. The pharynx and epidermis are in contact with surrounding aquatic media. These flatworms also carry eggs within their body. The aquatic biota of these animals is convenient for copolymer incubation. Indeed, these organisms tolerate laboratory conditions of temperature, pH, and conductivity. Furthermore, their small size (between 2 mm to 3.5 mm long) and transparent soft body, devoid of cuticle, allows *in toto* epifluorescence microscopy observations. Aquatic invertebrates are also often used as environmental indicators for environmental risk assessment in the presence of xenobiotics such as pollutants (*19*). In general, the term xenobiotic is given to all chemicals, including drugs or pollutants that are foreign to the organism under investigation.

To study the *in vivo* uptake of the amphiphilic copolymer as well as its role in the delivery of a xenobiotic, we used the fluorescent marker, rhodamine B, covalently attached to the copolymer. Rhodamine B is a multixenobiotic resistance (MXR) pump transporter substrate; thus, animals were also incubated in a rhodamine B solution, with or without a MXR transporter inhibitor (verapamil). The MXR defense system, reported in many aquatic invertebrates, is thought to work in a similar manner to the multidrug resistance (MDR) P-glycoprotein (Pgp) observed in cancer cells (*20, 21*). It has been shown that MXR actively transports a variety of xenobiotics across the cell membrane (*22*).

In this paper, we describe a new amphiphilic copolymer labeled with rhodamine B, and report the results from *in vivo* studies in a freshwater invertebrate. The *in vivo* uptake of free rhodamine B and rhodamine B covalently attached to the amphiphilic copolymer carrier either in the presence or in the absence of the MXR inhibitor verapamil is discussed.

MATERIALS AND METHODS

Materials. *General Experiments and Analytical Conditions.* Unless noted otherwise, all starting materials were obtained from Aldrich, and were used without further purification; the solvents were redistilled on calcium chloride, calcium hydride, potassium hydroxide, or sodium according to the solvent used. All compounds were characterized using standard analytical and spectroscopic techniques such as ^{1}H spectroscopy (apparatus Bruker Avance DPX-300, ^{1}H at 300.13 MHz) and mass spectrometry (instrument JEOL SX 102, NBA matrix). The NMR chemical shifts are reported in ppm relative to tetramethylsilane using the deuterium signal of the solvent ($CDCl_3$, DMSO-d_6 or D_2O) as a heteronuclear reference for ^{1}H. The ^{1}H NMR coupling constants, *J*s, are reported in Hz. TEM microscopy experiments were performed on a Hitachi H 7650 (negative staining with ammonium molybdate 1% in water, Ni carbon-coated grids). Fluorescence microscopy experiments were realized on a Zeiss axiovert 200. UV spectroscopy measurements were carried out on a Lambda 25 (Perkin-Elmer, France) with Peltier temperature programmer PTP-6. Silica gel 60 (particle size 40–60 μm) was used for flash chromatography. Thin-layer chromatograms were performed with aluminum plates coated with silica gel 60 F_{254} (Merck). Varian silica gel reverse-phase C18 MEGA BE-C18, 2GM 12 mL, and Sephadex LH-20 (25–100 μm) were used for quantitative chromatography.

Synthesis. *N-(6-Cholesterylcarbonylaminohexyl)-2-methylacrylamide (Compound* **1***).* Triethylamine (0.6 mL, 4.03 mM, 2.1 equiv) was added under nitrogen dropwise to N-Boc-hexylammonium chloride (0.500 g, 1.94 mM, 1 equiv) in 50 mL of methylene chloride at 0 °C. Then, cholesterolchloroformiate (0.961 g, 2.14 mM, 1.1 equiv), dissolved in 20 mL of dry methylene chloride, was added to the reaction at 0 °C. The reaction mixture was stirred at 0 °C for 1 and 2 h at room temperature. The resulting mixture was washed 3 times with 20 mL of water and then dried over sodium sulfate. After removing the solvent, the crude material was dissolved in 20 mL of a 50/50 trifluoroacetic acid/dichloromethane mixture and stirred for 2 h. The solvent is removed under high vacuum. The trifloroacetate salt was suspended in DCM, and 0.5 mL of TEA was added to the reaction flask. Then, 0.1 mL of methacryloyl chloride was added to the solution at 0 °C. This solution was stirred for 1 h at 0 °C and 2 h at room temperature. Purification on a silica gel column (MeOH/DCM, 3/97) yielded 0.240 g of **1**. (Yield: 21%). ^{1}H NMR ($CDCl_3$) δ in ppm: 0.65–2.26 (m, skeleton of cholesterol, C*H*$_2$ decyl amine, C*H*$_3$ methacrylate), 3.2 (m, 4H, 2C*H*$_2$NH), 4.4 (m, 1H, *H*CO cholesterol), 4.6 (m, 1H, N*H*), 5.2 (s, 1H, C*H* methacryl), 5.3 (m, 1H, *CH* cholesterol), 5.6 (s, 1H, C*H* methacryl), 5.9 (m, 1H, N*H*). High resolution MS: $[M + H]^+$, theoritical $m/z = 597.4917$, observed $m/z = 597.5007$. Anal. Calcd. (M + 1/2 H_2O) C, 75.32%; H, 10.81%; N, 4.62%. Found C, 74.99%; H, 10.19%; N, 4.83%.

Copolymerization (Compound 2). *Copolymer* **2.** Compound **1** (0.02 g, 0.033 mM, 1 equiv), methacrylic acid (0.100 g, 1.15 mM, 35 equiv), methacryloxyethyl thiocarbamoyl rhodamine B (*N*-[9-(2-carboxy-x-methacryloxyethylthiocarbamoylphenyl)-6-diethylamino-3*H*-xanthen-3-ylidene]-*N*-ethylethanaminium chloride; PolyFluor 570) (0.005 g) and AIBN (0.005 g, 0.03 mM) were dissolved in 40 mL of dry methanol. The reaction mixture was heated under nitrogen for 24 h. Methanol was evaporated, and the resulting material was dissolved in a minimum amount of MeOH/DCM 50/50 and purified on Sephadex LH20. 43 mg of copolymer **2** was isolated. (conversion 81%). ^{1}H NMR (CD_3OD) δ in ppm (broad peaks): ^{1}H NMR ($CDCl_3$) δ in ppm: 0.65–2.26 (m, skeleton of cholesterol, C*H*$_2$ hexyl amine, C*H*$_2$ and C*H*$_3$ methacrylate, CH_2 and CH_3 of the rhodamine), 3.2 (m, C*H*$_2$NH), 4.1 (m, *H*CO cholesterol), 5.3 (m, *C*═*CH* cholesterol). Content % of each monomer was determined by measuring the integration between 0.65 and 2.26 ppm (cholesterol, CH_2 of hexyl amine, CH_2 and CH_3 of the rhodamine and polymer backbone), integration at 5.43 ppm (cholesterol *C*═CH)

Table 1. Experimental Design for *in Vivo* Uptake of the Rhodamine B (RhB) or of the Rhodamine B-Labeled Amphiphilic Copolymer (RhB-amphiphilic copolymer)

solutions of incubation	incubation period at 13 °C	incubation period at 4 °C
mineral water (control)	10 h	
RhB (5 μg.mL^{-1})	1 h 30, 4 h, 10 h	
Rh B (5 μg.mL^{-1}) + Verapamil (10 μM)	1 h 30, 4 h, 10 h

RhB-amphiphilic copolymer (5 μg.mL^{-1}) + Verapamil (10 μM)	1 h 30, 4 h, 10 h	10 h

and at 7.83 ppm (corresponding to one aromatic rhodamine H), $x = 4\%$, $y = 95.6\%$, $z = 0.4\%$.

Transmission Electronic Microscopy (TEM). The copolymer was dispersed in either methanol or distilled water for TEM experiments. Typically, 1 mg of copolymer was dispersed in 1 mL of methanol. This solution was left for 3 h at RT prior to examination.

Fluorescence Microscopy. The samples were prepared by dispersing 5 mg of copolymer in 1 L of water. The pH of the solutions was adjusted by addition of either HCl (1 M) or NaOH (1 M). Prior to examination, these solutions were heated at 70 °C for 1 min and sonicated at RT for 5 min and left for 1 h at RT.

UV–vis Spectroscopy. UV–vis spectroscopy experiments were carried out on a Lambda 25 (Perkin-Elmer, France). The absorbance of the control samples containing free rhodamine was measured at 554 nm on aqueous solutions of free rhodamine at different concentrations (5×10^{-4} to 5×10^{-3} mg/mL. The UV–vis spectrum of the polymer was recorded on aqueous suspensions containing 0.1 mg/mL of polymer in water.

Material and Methods for *in Vivo* Studies. *Collection and Conservation of Biological Material.* Flatworms were collected in a temporary pound in the south of France with a hand net (125 μm mesh). Limnological parameters were the following: water temperature 15.3 °C; conductivity (C_{20}) 252 μS/cm; pH 7.02; dissolved oxygen 3 mg/L and 31% of saturation. Animals were brought back alive to the laboratory and maintained at 13 °C in a commercial mineral water (C_{20} = 200 μS/cm, pH 7.11). Water was refreshed daily and animals were fed every day with 1 mL of Teramin (Tetra Werke, Melle, Germany) dissolved in the commercial water (4 g/L).

Protocol for in Vivo Uptake of the Amphiphilic Copolymer. Solutions were prepared with the same mineral water used for the laboratory maintenance of flatworms. Flatworms were incubated in the dark either with rhodamine B alone (5 μg/mL) or with the rhodamine B-labeled amphiphilic copolymer (5 μg/mL). These experiments have been performed in the absence or in the presence of 10 μM of verapamil, a MXR transporter inhibitor. The temperature was 4 or 13 °C and pulse period 1 h 30, 4 h, or 10 h, followed by a 1 h chase period at room temperature to allow the expulsion of nonabsorbed material from the digestive tract. For each experimental condition, 5 flatworms were used. The experimental design is summarized in Table 1. Animals were then fixed in phosphate buffer containing paraformaldehyde 1% (PB-PFA 1%). After rinsing in phosphate buffer, animals were mounted in antifading medium (Gel/Mount, BiØmeda corp., Foster city, CA, USA) and observed under an epifluorescence microscope (Leica M1560).

Evidence of MXR Membrane Proteins in Flatworms. The presence and the density of MXR membrane proteins in flatworms were evaluated using a ELISA assay. A monoclonal primary antibody (mAb_1) raised against the human Pgp (C219 clone) was produced in mouse (Interchim, Montluçon, France). The C219 probe recognizes a sequence expressed by all MXR genes whose sequence is known, from bacteria to man (*23*). Fixed flatworms in PB-PFA 1% were weighted and then homogenized in Tris-HCl 0.05 M, pH 7.4, and centrifuged 20 min at 4 °C (14 000 *g*). The supernatant was discarded and membrane pellets were resuspended in PB (0.1 M, pH 7.2). The microplate wells were coated with 200 μL of this solution overnight at 4 °C (8 mg wet weight/well). Overnight coated wells were washed five times in 0.01% Triton X100-PB, then saturation was performed 1 h at 25 °C with BSA 0.1% diluted in 0.01% Triton X100-PB. Wells were incubated (1 h at 25 °C) with mAb_1 (1:10) and rinsed three times in 0.01% Triton X100-PB. Then, the wells were incubated in alkaline phosphatase-conjugated goat antimouse IgG (Ab_2, 1:1000) (Promega, Madison, WI, USA) in 0.01% Triton X100, 0.1% BSA in PB (1 h, at 25 °C). After five washes in 0.01% Triton X100-PB, the enzymatic reaction is initiated with the addition of 100 μL of *p*-nitrophenyl phosphate (p-NPP) dissolved in diethylethanolamine (Sigma, St Quentin-Fallavier, France). The optical density (OD_{405}), that reflects the membrane density in MXR-related proteins, was measured in triplicate at 10, 20, 30, and 40 min after the initiation with a microplate reader (ELX800 with KC4 software, Biotek Instrument) at 23 °C. The negative controls were done by incubating the mAb_1 and all the components except the membrane homogenates. The other controls consisted of (i) incubating all the components without the primary antibody for background studies, (ii) incubating Ab_2 alone, and, finally, (iii) incubating Ab_2 with 0.01% Triton X100 and 0.1% BSA in PB.

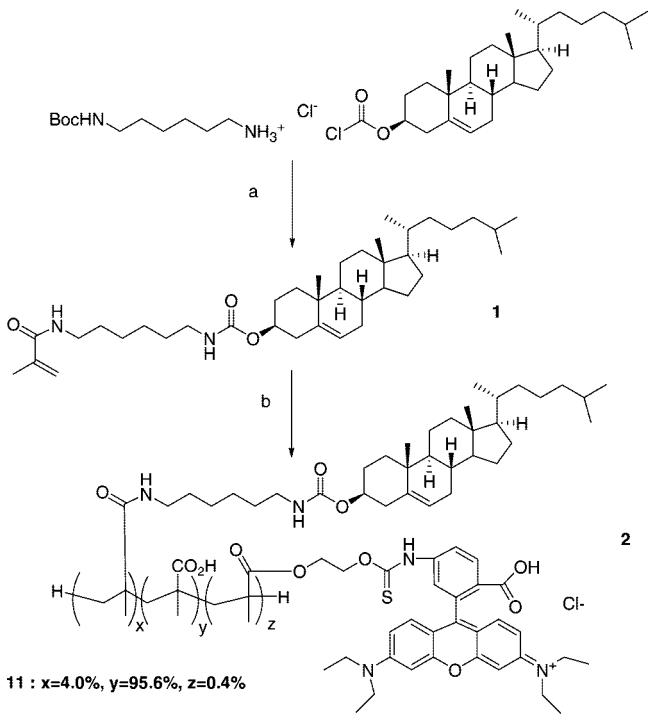
RESULTS AND DISCUSSION

The following three constituting monomeric building blocks were selected to prepare the amphiphilic copolymer: methacrylic acid (water-soluble part), methacryloyl cholesterol (hydrophobe), and methacrloyl rhodamine (fluorescent probe). Cholesterol was used as a hydrophobic moiety based on its known aggregation properties and its role in the lipid raft-mediated endocytosis (*24*). This natural lipid is also used in many cationic delivery systems including lipoplexes to both improve DNA delivery and increase the stability of formulations in the presence of serum (*25–27*). Recently, rhodamine was used as a probe to follow the release of a bioactive molecule entrapped in polymeric structures (*28*). This dye is also a known substrate of the multixenobiotic resistance (MXR) pump transporter, which removes xenobiotic molecules or drugs from the cell. Consequently, to easily follow the cellular uptake of our amphipatic copolymer structure, rhodamine was selected as a water-soluble model of a xenobiotic.

Synthesis. The amphiphilic copolymer was prepared as shown in Scheme 1. After synthesis of the cholesterol benzyloxycarbonyle (Boc) diamino derivative in basic conditions, this intermediate was treated with TFA in methylene chloride to afford the deprotected amine. A coupling reaction with methacryloyl chloride at 0 °C for 1 h and then at room temperature for 3 h yielded the expected methacryloyl cholesterol monomer **1**. The copolymerization reaction was followed by thin-layer chromatography (TLC) on silica gel (methanol/DCM 5/95). The free radical copolymerization (*29*) of the three methacryloyl monomers is facile. Specifically, the reaction mixture was heated under nitrogen for 24 h in the presence of AIBN and the resulting crude polymer purified on exclusion gel chromatography. Importantly, the synthetic strategy developed allows easy access in four steps to the cholesterol rhodamine labeled copolymer. The percentage of each monomer unit in the polymer ($x = 4.0\%$, $y = 95.6\%$, $z = 0.4\%$) was determined by measuring the integrations of CH_2 backbone and CH_2NH via ^1H NMR.

Physicochemical Studies. The UV–vis spectra of the copolymer labeled with rhodamine (Figure 2, blue) and the free rhodamine (Figure 2, red) in the region 500–600 nm are shown

Scheme 1[a]



[a] (a) (1) TEA in DCM, 1 h 0 °C, then 2 h at RT. (2) TFA/DCM 50/50, 2 h at RT. (3) Methacryloyl chloride, TEA in DCM, 1 h 0 °C then 3 h at RT (yield: 21%). (b) AIBN, MeOH, reflux, 72 h, conversion: 81%.

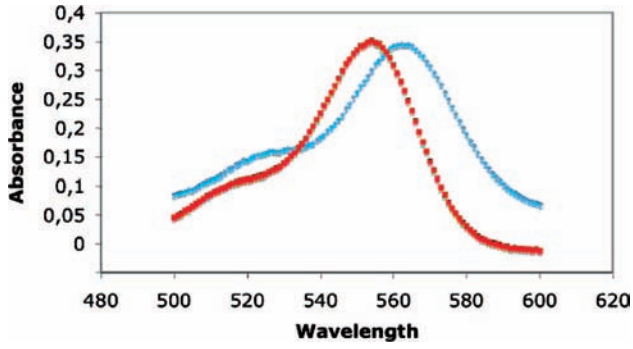


Figure 2. UV–vis spectra (absorbance vs wavelength in nm) of the copolymer labeled with rhodamine (blue) and the free rhodamine (red).

in Figure 2. The red shift observed for the labeled copolymer ($\lambda_{max} = 562$ nm) compared to free rhodamine in water ($\lambda_{max} = 554$ nm) can be attributed to the rhodamine being located in a more hydrophobic microenvironment of the copolymer structure and a resulting decrease in local polarity (*30*). The amount of rhodamine grafted to the polymeric structure was also determined by UV–vis spectroscopy. The absorbance measured at $\lambda_{max} = 562$ nm for a solution of the labeled copolymer at a concentration of 0.1 mg/mL corresponds to a concentration of rhodamine equivalent to 2×10^{-3} mg/mL (weight fraction of rhodamine = 2%). Note that a weight fraction of 2.% in rhodamine gives a mole fraction of 0.35%, similar to the value obtained from ^{1}H NMR analysis ($z = 0.4\%$).

As expected, the amphiphilic character of copolymer **2** tends to promote the formation of aggregates in both organic solutions and aqueous media. Amphiphilic copolymer (typical concentrations: 1 mg/mL) dissolved in methanol exhibits three populations of aggregates. The smallest particles are a few hundred nanometers in size, whereas the two other populations show hydrodynamic radii of a few micrometers and a few tens of micrometers, respectively.

Note that the formation of aggregates in both organic and aqueous solutions (water, methanol, DMF) prohibits the study of the isolated macromolecules. Consequently, despite numerous trials, including size exclusion chromatography (SEC) and dynamic light scattering (DLS) experiments, it was impossible to determine the average molecular weight of the copolymers, since the polymer exhibited an aggregated state even at low concentrations.

Microscopy Studies of the Aggregates. The size and morphology of the copolymer aggregates in solution were examined by fluorescence and electronic microscopies (TEM). As shown in Figure 3, the amphiphilic copolymer self-assembles in water to give large spherical aggregates with diameters of approximately 5 μm. These aggregates can be observed by using both light (Figure 3a) and fluorescence microscopies. The formation of aggregates was also confirmed by TEM (Figure 3b,c). At higher magnifications, TEM images (Figure 3c) show the presence of hollow microspheres similar to the ones reported by Caruso et al. (*31*). The folds and creases seen in the polymer microspheres are a result of evaporation of the solvent by air-drying. The size distribution of the objects obtained from TEM images reveals a relatively homogeneous population of microspheres with diameters ranging from 3 to 11 μm (Figure 4 blue). Note that the population of the microspheres observed by TEM (Figure 4 blue) is similar to the population of the same microspheres observed by *in vivo* by fluorescence microscopy (see the *in Vivo* Studies section) suggesting that the microspheres remain intact even after cellular uptake.

***In Vivo* Studies.** *Uptake of Rhodamine B.* The accumulation and efflux of model P-glycoprotein (Pgp) substrates such as fluorescent dyes (rhodamine B, rhodamine 123, etc.) is a method routinely used to follow the activity of the multixenobiotic resistance (MXR) defense mechanism in aquatic invertebrates (*32*), especially in the biomarker research field. Figure 5 presents the *in vivo* uptake of free rhodamine B by flatworms after 10 h of incubation at 13 °C either in the absence (Figure 5a) or in the presence (Figure 5b) of a MXR inhibitor, verapamil. The higher fluorescence intensity observed in the presence of verapamil indicates that, without verapamil, the molecules of rhodamine B inside the cells are actively expulsed *in vivo* by the MXR membrane efflux pump proteins.

To verify the presence of MXR transporters in these flatworms, an ELISA assay has been developed and performed. MXR transporters have been detected by the C219 antibody in membrane homogenates of flatworms. The optical density at 405 nm (OD_{405}) that reflects the membrane density in MXR-related proteins reaches 3.890 ± 0.005 for 8 mg wet weight of flatworms (Figure 6).

These results showing the absence of rhodamine B in flatworms in the absence of verapamil and presence of rhodamine B in flatworms in the presence of verapamil and the semiquantification of MXR-transporter membrane density demonstrate the presence of the MXR system in these Mesostominae flatworms. MXR genes have been highly conserved through the phylogenesis as demonstrated by their presence in microorganisms (*33*), plants (*34*), aquatic invertebrates (*35*), and vertebrates (*36*). In fact, the MXR system is similar to the multidrug resistance (MDR) first observed in tumor cell lines resistant to anticancer drugs (*20, 37–38*). One important mechanism of MDR involves the multidrug transporter, P-glycoprotein, which confers upon cells the ability to resist lethal doses of certain cytotoxic drugs by pumping them out of the cells, and thus reduce their cytotoxicity (*39–41*).

Uptake of Rhodamine B-Labeled Amphiphilic Copolymers. In light of the physicochemical properties of the copolymer and

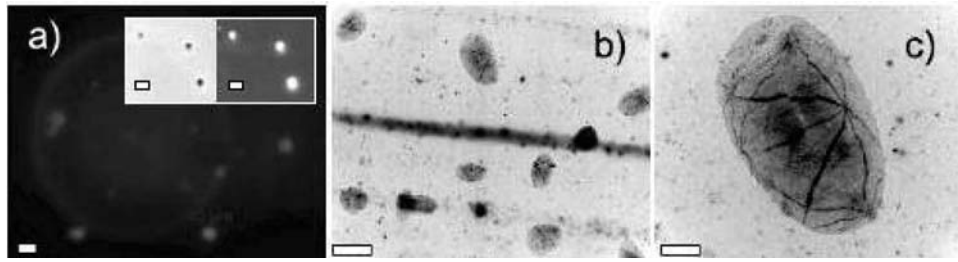

Figure 3. (a) Fluorescence microscopy image of copolymer aggregates in aqueous media at pH = 7.3 (concentrations = 5 mg/L, bar represents 10 μm). The insets left and right are light and fluorescence microscopy images of the same sample, respectively (bars represent 5 μm). (b,c) TEM images visualizing the polymer microspheres at different magnification (bars represent 10 and 2 μm for (b) and (c), respectively).

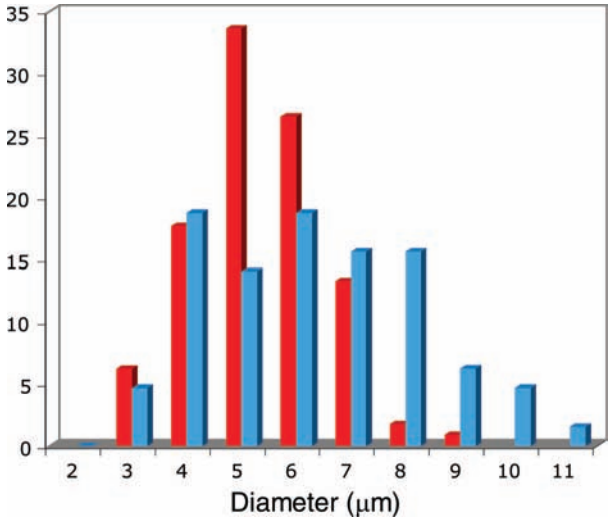

Figure 4. Size distributions of the microspheres (number of objects in percent vs size) obtained from (i) TEM images (blue) and (ii) fluorescence microscopy images (red) collected from the *in vivo* studies (copolymers in flatworm egg cells after 4 h incubation at 13 °C. See *in Vivo* Studies section for details).

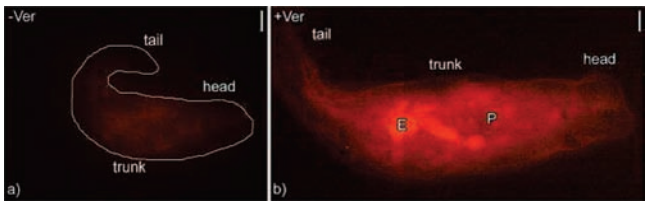

Figure 5. Uptake of rhodamine B by Mesostominae flatworms in the absence (a, −Ver) or in the presence (b, +Ver) of the MXR inhibitor verapamil after 10 h of incubation at 13 °C. Note the higher fluorescence intensity in (b) compared to (a). E: resting egg. P: pharynx. Bars = 200 μm.

the *in vivo* data collected with free rhodamine, we hypothesize that the amphiphilic macromolecule, which bears rhodamine B as a water-soluble model of xenobiotic, can be taken up by flatworms. In principle, the copolymer can be used as a carrier to improve the delivery of xenobiotics. In this context, two key issues must be addressed: (i) How is the copolymer taken up by the flatworms? (ii) Is the macromolecular carrier translocated out of the cells by the MXR system?

Endocytosis is a cellular uptake process that is coupled with temperature-dependent metabolic activities (*42*). To determine whether the rhodamine B-labeled amphiphilic copolymer is incorporated into the cells by endocytosis, the organisms were observed at two different temperatures, 13 and 4 °C, under an epifluorescence microscope. The lowest temperature corresponds to winter cold temperature tolerated by these organisms and the higher to spring water temperature of the temporary pond

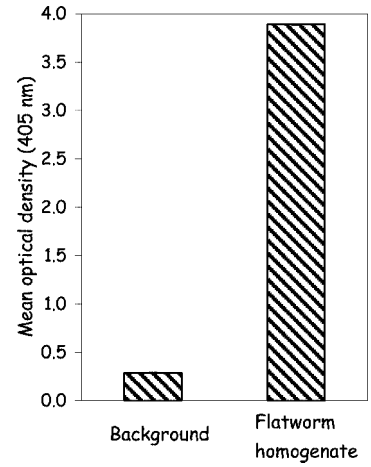

Figure 6. Optical density measured at 405 nm reflecting the density of MXR transporters in membrane homogenates of Mesostominae flatworms read at 40 min after the initiation.

where they live. A control sample showing flatworms by fluorescent microscopy is presented in Figure 7a.

For each experimental condition, rhodamine B-labeled amphiphilic copolymers are observed in flatworm cells by fluorescence microscopy. For a given incubation condition (same time and same temperature), no difference was noticed between samples treated with or without verapamil. At 13 °C, flatworms were exposed to rhodamine B-labeled amphiphilic copolymers for 1 h 30, 4 h, or 10 h. After 1 h 30 of exposure time, the labeled copolymer is observed in a few organelles, named rhabdites, which are located in some flatworm epidermal cells (Figure 7b). The rhabdite initially appears as a large Golgi saccule enclosed by an extensive system of microtubules. Golgi vesicles and vacuoles fuse with the limiting membrane of the rhabdite and contribute to enlarge this structure. Microtubules mediate movement of vesicles containing secretory material along the rhabdite length. Rhabdites are known to be acidophilic and contain predominantly proteins, which may be combined with a purine component and mucopolysaccharides (*43*, *44*). Rhabdite cells are parenchyma-derived cells that migrate into the epidermis. Once in the epidermis, the rhabdite cells become part of the epithelium. It has been proposed that most if not all of the epidermal cells originate from rhabdite cells or from other parenchyma-derived cells (*43*). After 4 h of incubation, the labeled copolymer is observed in several different cell types of the worm. For example, Figure 7c,d shows fluorescent objects within egg cells. The size distribution of the objects obtained from fluorescence microscopy images (Figure 7c,d) reveals a population of microspheres with a mean diameter of 4.25 ± 1.51 μm. Note that size distribution of the fluorescent objects observed *in vivo* (Figure 4, red graph) corresponds to the population of the microspheres obtained spontaneously with copolymer **2** (Figure 4, blue graph). Homogeneous dots in the

Bars = 50 μm.

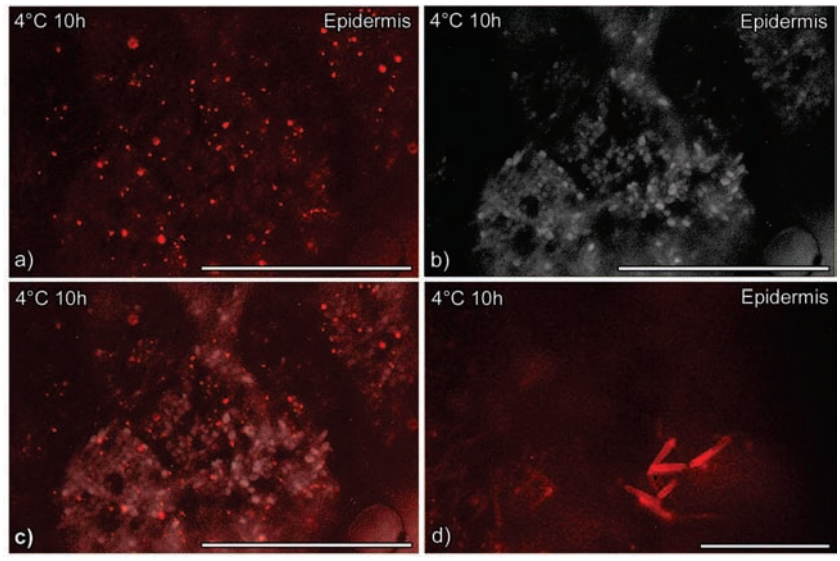

Figure 8. *In vivo* uptake of rhodamine B-labeled amphiphilic copolymers (5 μg.mL^{-1}) by Mesostominae flatworms at 4 °C. (a−c) Localization of rhodamine B-labeled amphiphilic copolymers in rhabdite cells: (a) Fluorescence view showing the localization of the labeled copolymer. (b) Autofluorescence view of (a) showing the localization of unlabeled rhabdites. (c) Merged image of (a) and (b). Note that the copolymers are located nearby the rhabdites. (d) View of a small cluster of labeled rhabdite. Note the scarcity of labeled rhabdites at 4 °C compared with their abundance at 13 °C (cf. Figure 7h). Bars = 50 μm.

pharyngeal glandular cells (Figure 7e,f) and numerous sticklike structures, which are typical mature rhabdites (Figure 7g), are also observed in the fluorescence microscopy images. After 10 h of exposure, numerous rhabdites are labeled (Figure 7h−j).

In the experiments performed at 4 °C for 10 h, labeled copolymers are observed near unlabeled rhabdites (Figure 8a−c). Some labeled rhabdites are also observed (Figure 8d). As the mean length of the rhabdites is 19.98 ± 3.52 and their mean diameter is 3.00 ± 0.80 μm, rhabdites are large enough to accumulate the amphiphilic copolymers. Furthermore, incorporation of the rhodamine B-labeled amphiphilic copolymers is time- and temperature-dependent. At 13 °C, the number of labeled rhabdites per surface unit is 1.83-fold higher at 10 h than at 4 h of incubation. For 10 h of

incubation, the number of labeled rhabdites per surface unit is 7.25-fold higher at 13 °C than at 4 °C. When flatworms were exposed to rhodamine B-labeled amphiphilic copolymers **2** for 10 h at 4 °C, the number of labeled rhabdites per surface unit represents only 13% of the maximum level measured after 10 h at 13 °C.

As has been recently reported by Suenaga et al. for a copolymer carrier featuring hydrophobic lauryloyl groups (*45*), cold temperature induces a remarkable decrease in the copolymer−rhodamine uptake, indicating that the polymer is internalized *via* an endocytosis mechanism. After a 10 h incubation at 4 °C, labeled copolymers observed near unlabeled rhabdites are probably endocytotic vesicles that are about to fuse with rhabdites (Figure 8a−c).

The following observations can be made from the above data: (i) Rhodamine B-labeled amphiphilic copolymers are *in vivo* uptaken *via* an endocytosis mechanism in the early phases of incubation in the invertebrate, and its localization is then observed in different cell types (pharyngeal glandular cells, resting egg cells, epidermis cells). (ii) After incorporation into epidermis cells, rhodamine B-labeled amphiphilic copolymers are concentrated in storage reserve structures, the rhabdites. This storage is observable after 4 h of incubation at 13 °C. The endocytotic pathways (receptors and membrane microdomains) responsible for the uptake of the amphiphilic copolymers need to be investigated further.

***In Vivo* Study Perspectives.** In an ecotoxicological study, Horvat et al. observed histological changes including a decrease in the number of rhabdites in the Platyhelminthe *Polycelis felina* (Daly.) after exposure to norflurazon herbicide (*46*). The *in vivo* uptake experiments described above show that the rhodamine B-labeled amphiphilic copolymer is taken up by the flatworm, enters the cells, and is accumulated in rhabdites. This pattern of amphiphilic copolymer uptake could be used as an ecotoxicological tool to measure cellular activity when animals are exposed to a xenobiotic(s). Moreover, the amphiphilic copolymer could be used as an *in vivo* carrier of specific molecules that could react with pollutants accumulated in cells and subsequently produce a detectable signal.

In the present study, we demonstrate that the bioaccumulation of the MXR substrate rhodamine B was dramatically increased when the rhodamine B was covalently attached to the amphiphilic copolymer and a resulting microsphere was formed. The translocation out of the cell by the MXR system is avoided in comparison to the free rhodamine. As the MXR system is similar to the MDR one, the *in vivo* uptake results strongly suggest that our amphiphilic copolymers can play a significant role in the field of carriers for drug delivery. This finding represents a potential therapeutic option that should be considered during the ongoing development of strategies to overcome multidrug resistance in cancer studies, as it was suggested for the treatment of human ovarian and endometrial cancers that express receptors for luteinizing hormone-releasing hormone with agents such as AN-152 bypassing their Pgp extrusion (*47*).

CONCLUSION

In this study, we have synthesized a new rhodamine-labeled amphiphilic copolymer featuring cholesterol moieties for *in vivo* delivery of xenobiotics and/or drugs. The amphiphilic copolymer structure was prepared from cholesterol-derived methacryloyl monomer, methacrylic acid, and methacryloxyethyl thiocarbamoyl rhodamine B. Fluorescence and TEM microscopies studies indicate that this amphiphilic copolymer aggregates to give microspheres. The *in vivo* experiments carried out on a simple triploblastic aquatic organism, a Mesostominae flatworm, clearly demonstrate that the copolymer/microsphere is bioaccumulated without being translocated out of the cell by the multixenobiotic resistance (MXR) transporters. Synthetic polyanions such as poly(methacrylic acid) are finding utility in enhancing the delivery of nucleic acids to cells, for example, as recently reported by Leroux and co-workers (*15*). Consequently, these and similar polyanionic polymers and copolymers are likely to be of further interest for the *in vitro* and *in vivo* delivery of oligonucleotides, small molecule drugs, and imaging agents. These investigations further support the synthesis and evaluation of new polyanion-based drug delivery vehicles and ecotoxicological tools.

ACKNOWLEDGMENT

The authors would like to thank Dr. Christophe Schatz and Pr. Sébastien Lecommandoux from the LCPO - ENSCPB of Bordeaux for kindly helping us with DLS and SEC experiments.

Received November 28, 2007; Revised Manuscript Received January 19, 2008

To develop artificial hemoproteins that could lead to new selective oxidation biocatalysts, a strategy based on the insertion of various iron-porphyrin cofactors into Xylanase A (Xln10A) was chosen. This protein has a globally positive charge and a wide enough active site to accommodate metalloporphyrins that possess negatively charged substituents such as microperoxidase 8 (MP8), iron(III)-tetra-α_4-*ortho*-carboxyphenylporphyrin (Fe(T*o*CPP)), and iron(III)-tetra-*para*-carboxyphenylporphyrin (Fe(T*p*CPP)). Coordination chemistry of the iron atom and molecular modeling studies showed that only Fe(T*p*CPP) was able to insert deeply into Xln10A, with a K_D value of about 0.5 μM. Accordingly, Fe(T*p*CPP)-Xln10A bound only one imidazole molecule, whereas Fe(T*p*CPP) free in solution was able to bind two, and the UV–visible spectrum of the Fe(T*p*CPP)-Xln10A-imidazole complex suggested the binding of an amino acid of the protein on the iron atom, trans to the imidazole. Fe(T*p*CPP)-Xln10A was found to have peroxidase activity, as it was able to catalyze the oxidation of typical peroxidase cosubstrates such as guaiacol and *o*-dianisidine by H_2O_2. With these two cosubstrates, the K_M value measured with the Fe(T*p*CPP)-Xln10A complex was higher than those values observed with free Fe(T*p*CPP), probably because of the steric hindrance and the increased hydrophobicity caused by the protein around the iron atom of the porphyrin. The peroxidase activity was inhibited by imidazole, and a study of the pH dependence of the oxidation of *o*-dianisidine suggested that an amino acid with a pK_A of around 7.5 was participating in the catalysis. Finally, a very interesting protective effect against oxidative degradation of the porphyrin was provided by the protein.

Hemoproteins not only play a key role in the transport (hemoglobin) and storage (myoglobin) of dioxygen, the most abundant element of our environment, but some of them are also able to catalyze its activation (cytochromes P450) or to control the level of some of its reductive metabolites such as hydrogen peroxide (peroxidases, catalases). Using, respectively, dioxygen and hydrogen peroxide as oxidant, cytochromes P450 and peroxidases are able to catalyze, under biological conditions, the oxidation of numerous endogenous substrates including steroids, fatty acids, prostaglandins, and leukotrienes, as well as exogenous substrates such as drugs, insecticides, solvents, and hydrocarbons, even the most poorly reactive ones such as *n*-alkanes. Consequently, the design of artificial metalloenzymes that are able to efficiently catalyze oxidation reactions under mild conditions and with selectivities that are comparable to those exhibited by these enzymes is of great interest for the study and prediction of the oxidative metabolism of new biologically active molecules such as drugs. In addition, it represents a promising route to catalytic systems that can be used in organic synthesis for oxidation reactions that are important in industrial and fine chemistry, such as the stereoselective oxidation of alkanes and epoxidation of alkenes (*1*).

Considering the structure–activity relationships of hemoproteins, at least three structural elements have to be mimicked to design functional biomimetic systems (Figure 1): (i) the prosthetic group, a heme or iron(III)-protoporphyrin IX, which is responsible for electron transfer (peroxidases) (*2*) or oxene transfer reactions (cytochromes P450) (*1, 3*); (ii) the apoprotein which binds and site-isolates heme, preventing its aggregation and oxidative degradation, and its active-site amino acids, which not only provide a hydrophobic environment for the substrate and control its access to the heme (cytochromes P450), but also participate in some cases in catalysis (peroxidases) (*2*); (iii) the proximal axial ligand of the iron atom (histidine in peroxidases or cysteinate in cytochromes P450) which has a role in controlling the heme redox potential and the reactivity of the high-valent iron−oxo intermediates involved in their catalytic cycle (*4*).

In the past 10 years, several strategies have been reported for the design of artificial metalloproteins, either to increase or modify the reactivity of an already existing metalloprotein or to induce a new reactivity in a nonmetal protein. They include the introduction of metal binding sites in the active site of a protein by site-directed mutagenesis (*5–7*), the design of substrate binding cavities (*8–11*), chemical modification of prosthetic groups (*12–15*), and covalent attachment of metal cofactors (*16–20*). In particular, the covalent modification of proteins through the covalent binding of a metal cofactor to a cysteine residue is a powerful tool for the generation of new

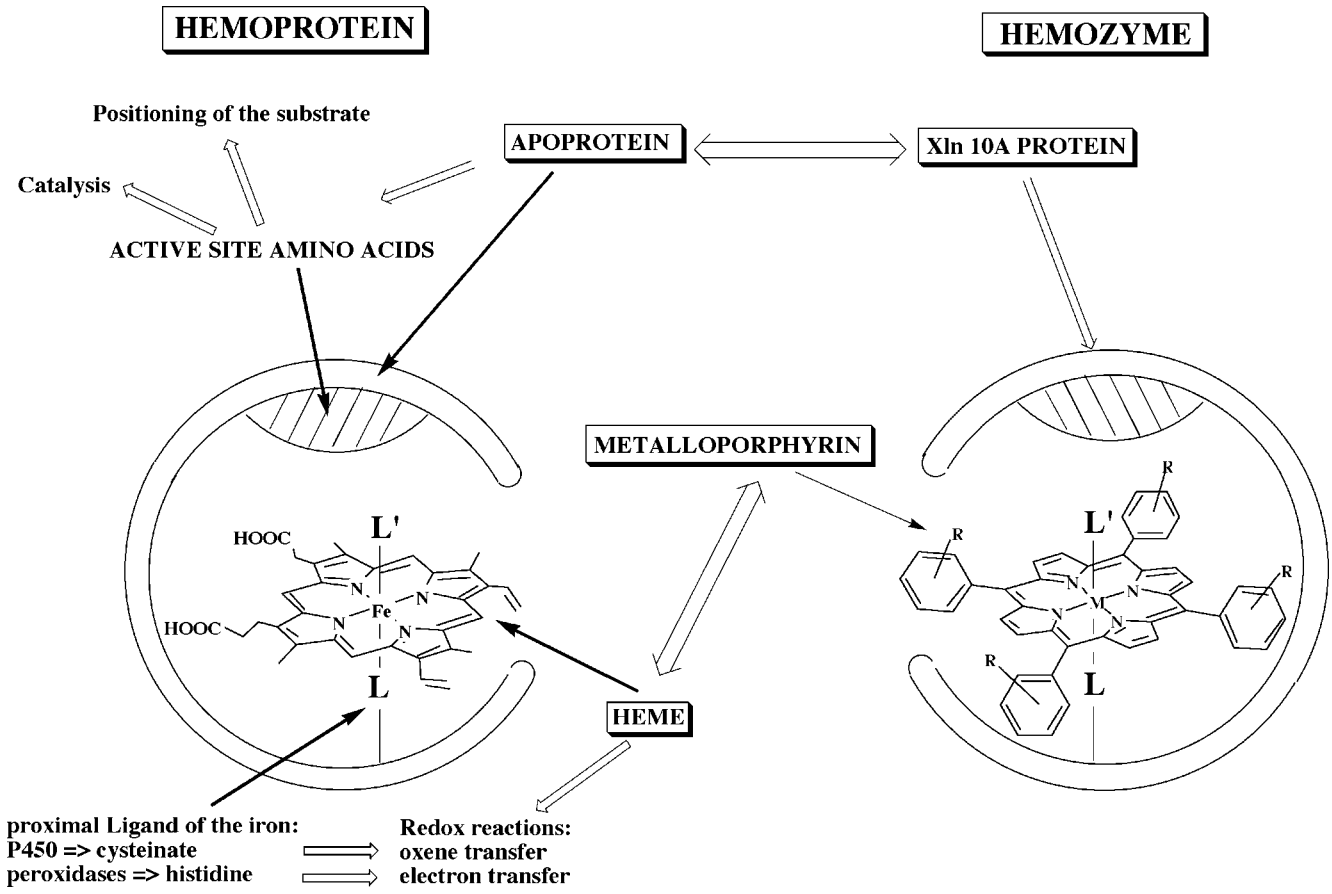

Figure 1. Schematic view of the structure of hemoproteins and their hybrid metalloporphyrin-Xln10A mimics: hemozymes.

metalloenzymes, although the efficiency of the modification is greatly dependent on the position and reactivity of the cysteinyl thiol functional group. However, on one hand, artificial hemoproteins with interesting peroxidase activities have also been obtained by the noncovalent association of a synthetic Fe(III)-$\alpha_3\beta$-tetra-*o*-carboxyphenylporphyrin (*21–25*) or microperoxidase 8 (MP8) (*26–29*) with monoclonal antibodies raised against these cofactors. The later MP8−antibody complexes were additionally shown to catalyze the stereoselective oxidation of sulfides by H_2O_2 (*29*). Furthermore, new artificial hemoproteins, also displaying interesting peroxidase activities, were obtained by insertion of modified hemes into mutated sperm whale myoglobin (*30–33*). Heat-resistant hemoproteins that are able to bind and release O_2 in an aqueous medium like hemoglobin and myoglobin were also obtained by incorporating Fe(II)-α_4-tetra-*o*-pivalamidophenylporphyrin into a thermoresistant xylanase (*34*, *35*) or into human serum albumin (HSA) (*36*). In order to generate new hemoproteins, we have thus chosen a simple strategy that involves the noncovalent incorporation of Fe(III)-α_4-tetra-*o*-carboxyphenylporphyrin (Fe(T*o*CPP)), Fe(III)-tetra-*p*-carboxyphenylporphyrin (Fe(T*p*CPP)), and MP8 (Scheme 1) into β-1,4-endoxylanase or xylanase A (Xln10A) from *Streptomyces lividans.*

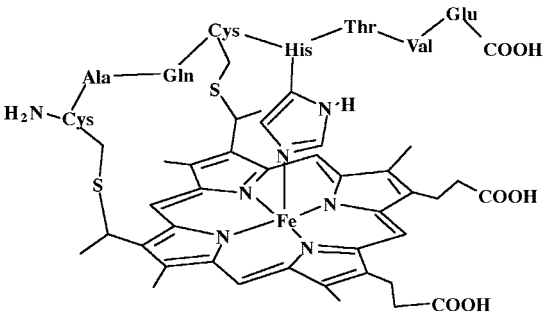
Xylanase A hydrolyzes β-1,4 bonds in the main chain of xylan, the major component of hemi cellulose in the plant cell wall. In the pulp bleaching process, the enzymatic hydrolysis of xylan at high temperature has gained importance from an environmental point of view. Consequently, growing interest in xylanases that are able to work at high temperatures under extreme pH and ionic strength conditions has led to the discovery, cloning, and characterization of numerous enzymes, such as xylanase A from *Streptomyces lividans*, which shows optimal activity at 60 °C and pH 6. This enzyme is a 47 kDa protein which contains two domains: a 14 kDa C-terminal domain, named XBD, which belongs to the CBM13 family of carbohydrate binding modules for the binding of the substrate; and a 33 kDa N-terminal catalytic domain belonging to the GH10 family of glycosyl hydrolases. The three-dimensional structure of this domain has been elucidated and refined to a resolution of 1.2 A (*37*). It presents a standard $(\beta/\alpha)_8$ TIM-barrel fold that contains the two amino acids that are essential for catalysis, Glu 128 and Glu 236. The catalytic site globally appears as a crevice that is rich in positively charged amino acids. Thus, the porphyrins Fe(T*o*CPP), Fe(T*p*CPP), and MP8 were chosen because of the negative charges of their carboxylate substituents, which should be complementary to the positive character of the active site of Xln10A. Furthermore, these groups render the porphyrins more water-soluble.

Our results show that, among the three iron-porphyrins studied, Fe(T*p*CPP) is the porphyrin which inserts the best in Xln10A with a K_D value of 0.5 μM, and the corresponding Xln10A-Fe(T*p*CPP) complex shows an interesting peroxidase-like activity characterized by a k_{cat} value of 52 min^{-1} with *o*-dianisidine as cosubstrate. In the hybrid hemoprotein obtained, the Xln10A protein brings two interesting features that would be useful in its application as catalyst for selective oxidation reactions: first, it protects the porphyrin macrocycle from oxidative degradation, and second, it confers steric hindrance around the iron atom. In addition, pH dependence studies show that an amino acid side chain characterized by a pK_A value of about 7.5 could be participating in the catalysis.

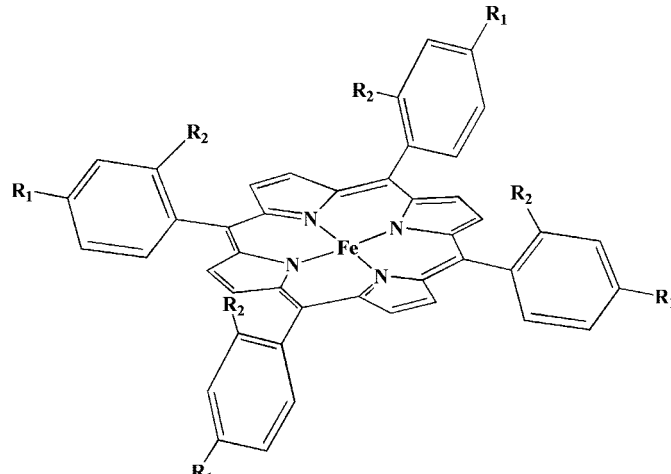
EXPERIMENTAL SECTION

Preparation of Fe(III)-Porphyrins. *Purification of Microperoxidase 8.* Microperoxidase 8 (MP8) was prepared by sequential peptic and tryptic digestion of horse-heart cytochrome

Scheme 1. Structure and Nomenclature of the Porphyrins Discussed in This Paper



Microperoxidase 8 (MP8)



R_1 = COOH, R_2 = H — iron(III)-meso-tetrakis(para-carboxyphenyl)porphyrin Fe(TpCPP)

R_1 = H, R_2 = COOH — iron(III)-meso-tetrakis-α_4(ortho-carboxyphenyl)porphyrin α_4Fe(ToCPP)

c (Sigma) as previously described (*38*). The heme content was determined by the pyridine chromogen method (*38*). The purity of the sample was over 97% based on MALDI-TOF mass spectroscopy analysis.

Preparation of Fe(III)(ToCPP) and Fe(III)(TpCPP). The synthesis of the four atropoisomers of iron(III)-*meso-tetrakis*(*ortho*-carboxy-phenyl)porphyrin Fe(T*o*CPP) as well as that of iron(III)-*meso-tetrakis*(*para*-carboxy-phenyl)porphyrin Fe(T-*p*CPP) was carried out in three steps as described in a previous paper (*40*). The *ortho*-carboxymethyl- and *para*-carboxymethyl-substituted tetraaryl porphyrins were synthetized by reaction at room temperature of *ortho*- and *para*-carbomethoxybenzaldehyde, respectively, with pyrrole in CH_2Cl_2 in the presence of BF_3-etherate as a catalyst according to an already described procedure (*39, 40*). The atropoisomers of *meso-tetrakis*(*ortho*-carboxymethyl-phenyl)porphyrin (T*o*CMePP) were then separated on a silicagel column and have been identified, as was *meso-tetrakis*(*para*-carboxymethyl-phenyl)porphyrin (TpCMe-PP), by UV–visible absorption, ^{1}H NMR, and mass spectroscopies (*40*). The iron atom was inserted by reaction of (T*p*CMePP) and the isolated α_4-(T*o*CMePP) atropoisomer with $Fe(CO)_5$ in the presence of I_2 in toluene at room temperature to avoid isomerization (*41*). Finally, the *para*- and α_4-*ortho*-carboxy-substituted tetraarylporphyrin isomers were subsequently obtained by saponification of the methyl ester substituents in 2 M KOH in 80% EtOH at room temperature (*42*).

Production and Purification of Xylanase A (Xln10A). Seven-day-old cultures of *S. lividans* from Bennett-thiostrepton plates were used as the initial inoculum. The spores were scraped from the plates and inoculated into 12.5 mL minimal M14 medium (composition per liter: glucose, 10 g; K_2HPO_4, 5.0 g; $(NH_4)_2SO_4$, 1.4 g; KH_2PO_4, 1.0 g; $CaCl_2 \cdot 2H_2O$, 300 mg; $MgSO_4 \cdot 7H_2O$, 300 mg; $FeSO_4 \cdot H_2O$, 5.0 mg; $CoCl_2 \cdot 6H_2O$, 2.0 mg; $MnSO_4 \cdot H_2O$, 1.6 mg; $ZnSO_4 \cdot 7H_2O$, 1.4 mg; Tween 80, 2.0 mL; pH 7.4) and incubated for 18 h at 34 °C with agitation. Bacteria were recovered by centrifugation, used to inoculate 500 mL of the same medium, and allowed to grow for 72 h under the same conditions. Proteins contained in the supernatant of *S. lividans* culture were first concentrated by ultrafiltration with a 3 kDa cutoff membrane (Omega). The concentrated proteins were then loaded at 4 °C on a Sephacryl S100 beaded column (2.6 × 60 cm; Pharmacia) with 100 mM sodium phosphate pH 6.0, as the eluant. Purified Xln10A containing fractions were pooled, dialyzed, and freeze−dried.

Assay of Xylanase Activity. The glycosidic activity of Xln10A and of the Xln10A-Fe(TpCPP) complex enzyme was determined using a diffusion agar assay. 100 μL of a 1 μM enzyme solution in 50 mM PBS pH 7.5 were poured into 5 mm wells coated with RBB (Remazol-Brillant-Blue)-xylan and incubated at 37 °C for 2, 6, and 24 h. At each time, the diameter of the clearing zone around the well was measured and was indicative of the glycosidic activity.

Absorption Spectroscopy Measurements. Absorption spectra were recorded at 25 ± 0.1 °C, using an UVIKON 860 XL UV–visible spectrophotometer.

For the insertion of Fe(III)-porphyrins into Xln10A, a typical procedure was followed. The Xln10A-Fe-porphyrin complexes were prepared in 50 mM PBS, pH 7.5, by incubation for 2 h at 4 °C of 1.2 μM MP8, Fe(III)(T*o*CPP), or Fe(III)(T*p*CPP) with 1.8 μM Xln10A. The UV–visible characteristics of the Xln10A-Fe-porphyrin complexes obtained were recorded at 25 ± 0.1 °C and compared to those of the MP8, Fe(III)(T*o*CPP), and Fe(III)(T*p*CPP) recorded under the same conditions. In the case of Fe(III)(T*p*CPP), a titration with Xln10A was done as follows: 0.97 μM Fe(III)(T*p*CPP) in 50 mM PBS, pH 7.5, was incubated for 20 min with Xln10A at concentrations increasing from 0.05 to 4.96 μM and visible spectra were recorded between 350 and 650 nm. The absorbance at 412 nm was plotted against the Xln10A/Fe-porphyrin ratio, which allowed the determination of the Xln10A/Fe-porphyrin stoichiometry and the value of the dissociation constant (K_D).

For the reactions with imidazole, difference spectroscopy was used. The sample cuvette contained either 1.85 μM Fe-porphyrin or 1.85 μM Fe-porphyrin preincubated for 40 min at 4 °C with 1.85 μM Xln10A in 50 mM PBS, pH 7.5. The reference cuvette contained 50 mM PBS, pH 7.5. Equal increasing amounts of imidazole (2 M in the same buffer) were then added to both cuvettes, so as to obtain a final concentration ranging between 0.33 and 25 mM, and difference spectra were recorded between 350 and 650 nm.

In most cases, the spectral evolution observed involved the formation of well-defined isobestic points indicating the presence of two absorbing species. The reaction could then be represented by

$$PFe^{III} + nL \rightleftharpoons PFe^{III}(L)_n \quad (1)$$

P = MP8, T*o*CPP, T*p*CPP, Xln10A-MP8, Xln10A-T*o*CPP, Xln10A-T*p*CPP

L = imidazole

According to Brault and Rougee (*43*), it could then be analyzed by means of the standard equation

$$1/\Delta A = 1/\Delta A_\infty + K_D/\Delta A_\infty \times 1/[L]^n \quad (2)$$

where $\Delta A = A - A_0$, $\Delta A_\infty = A - A_\infty$, and A_0, A_∞, and A are the absorbances of the initial, final, and mixed species, respectively. The linearity of the graph representing $1/\Delta A$ as a function of $1/[L]^n$ was then assayed with $n = 1$ and $n = 2$, and K_D and A_∞ could be determined graphically. It is noteworthy that, when $n = 1$, $C_{50} = K_D$, whereas when $n = 2$, $C_{50} = K_D^{1/2}$, with C_{50} representing the concentration of ligand for which half of the starting Fe-porphyrin or Fe-porphyrin-Xln10A complex has been converted into porphyrin-Fe(L)$_n$ or Xln10A-porphyrin-Fe(L)$_n$.

Assay of Peroxidase Activity. To assay the peroxidase activity of Fe(T*p*CPP) and its complex with Xln10A, the oxidation of cosubstrates, namely, guaiacol, *o*-dianisidine and 2,6-dimethoxyphenol, by H_2O_2 was performed at 19 ± 0.1 °C in 50 mM PBS, pH 7.5. The absorbance was monitored for 6 min, respectively, at 490, 450, and 469 nm using an UVIKON 860 UV–visible spectrophotometer. The initial rates of oxidation were determined from the slope at the origin of the curve representing the variations of the absorbance at 490, 450, and 469 nm as a function of time, using respective ϵ values of 5500, 7500, and 27 500 M^{-1} cm^{-1} (*26*, *44*).

The influence of the H_2O_2 concentration on the oxidation of the cosubstrates was assayed. For this, guaiacol, *o*-dianisidine, and 2,6-dimethoxyphenol (1.2 mM) were oxidized by H_2O_2 at concentrations varying between 0.080 and 8 mM, in the presence of 1.2 μM Fe(T*p*CPP) or 1.2 μM Fe(T*p*CPP) preincubated for 2 h at 4 °C with 1.8 μM Xln10A as catalyst.

In a second set of experiments, the influence of the cosubstrate concentration on the rate of oxidation was assayed. The cosubstrates, at concentrations varying between 50 and 1200 μM, were oxidized by H_2O_2 2.4 mM in the presence of 1.2 μM Fe(T*p*CPP) or 1.2 μM Fe(T*p*CPP) preincubated for 2 h at 4 °C with 1.8 μM Xln10A as catalyst.

For the pH dependence studies, solutions of 1.2 μM Fe(T-*p*CPP) or 1.2 μM Fe(T*p*CPP) preincubated for 2 h at 4 °C with 1.8 μM Xln10A were prepared in 0.1 M citrate/phosphate buffer pH 4.1, 4.6, 5.0, 5.5, 6.0, 6.5, and 7.0, and in 0.1 M Tris−HCl buffer pH 7.3, 7.6, 7.9, and 9.1. 890 μM *o*-dianisidine was first added and the reaction was initiated by the addition of 320 μM H_2O_2. The absorbance was monitored at 450 nm as a function of time for 5 min, and the initial rate of oxidation was plotted as a function of the pH value.

The influence of imidazole on the kinetic parameters of the oxidation of *o*-dianisidine by H_2O_2 in the presence of 1.2 μM Fe(T*p*CPP) or 1.2 μM Xln10A-Fe(T*p*CPP) prepared as described above was examined as follows. The catalyst was further incubated for 2 h at 4 °C with imidazole at concentrations ranging between 0 and 50 mM. 890 μM *o*-dianisidine was then added, and the reaction was started by the addition of 320 μM H_2O_2. The initial rates of oxidation were then measured as described above.

Molecular Modeling. The atomic coordinates of Xln 10A were downloaded from the Protein Data Bank (*45*) (PDB code 1V0L) (*46*). The exploration of the protein cavity volumes and shapes were performed with CASTp (*47*) and Q-sitefinder (*48*) webserver.

The structures of the different *meso*-tetraphenyl-porphyrins have been generated using the *Chem3D* package (CambridgeSoft Corporation). A short minimization was performed on each compound using the MM2 force field (*49*) implemented in *Chem3D*. For the MP8 system, the environment of the heme has been generated from one of the crystal structures available of the human cytochrome C (PDB code 1CRI (*50*)). The minimization was followed by a short molecular dynamic run to better relax the system. All the volumes of the ligands have been calculated using the Connolly solvent excluded volume package included in *Chem3D*.

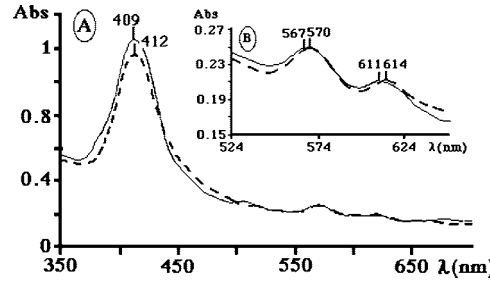


Figure 2. Incorporation of Fe(T*p*CPP) into Xln10A: (− − −) UV–visible spectrum of Fe(T*p*CPP), 1.2 μM in 50 mM PBS, pH 7.5; (—) UV–visible spectrum obtained after addition of 1.8 μM Xln10A corresponding to the Xln10A-Fe(T*p*CPP) complex. Inset: variations of the α,β bands under the same conditions.

Docking studies were performed using the GOLD v3 program (*51*) with the Chemscore (*52*) fitness function. The accessible docking space was defined as a 20 Å sphere around one of the residues at the core of the cleft. Fifty solutions were generated for each porphyrin macrocycle and ranked according to their Chemscore values. We selected this approach since it had been applied with success in predicting protein–ligand interactions for metal containing systems like cytochrome P450 (*53*). Since the ligand remains quite exposed to the solvent, a large number of low-energy solutions were analyzed in detail. Molecular graphics images were produced using the UCSF Chimera package from the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (*54*).

RESULTS

Insertion of Fe(III)-Porphyrins into Xylanase A. The insertion of three Fe-porphyrins bearing negatively charged carboxylate substituents was examined by UV–visible spectroscopy as described in the experimental section. For this, 1.5 mol equiv of Xln10A was added to solutions of either microperoxidase 8 (MP8), Fe(T*p*CPP), or Fe(T*o*CPP), 1.2 μM in 50 mM PBS pH 7.5, a concentration for which no aggregation of the porphyrin complexes was observed. In the case of microperoxidase 8 (MP8), no significant change in its UV–visible spectrum was observed, except for a decrease in intensity of its Soret band at 397 nm (data not shown). This is characteristic of a simple hydrophobic interaction between MP8 and Xln10A with no amino acid side chain of the protein binding to the iron atom of MP8, leaving a vacant coordination site on the iron available for the binding of exogenous ligands and catalysis. Similarly, the addition of Xln10A to Fe(T*o*CPP) caused only a decrease of its Soret band at 396 nm (data not shown), showing that no amino acid side chain of Xln 10A was coordinating the iron atom in this complex either, leaving two vacant axial coordination positions on the iron atom.

Finally, the addition of 1.5 equiv Xln10A to Fe(T*p*CPP) 1.2 μM in 50 mM PBS, pH 7.5, was examined by UV–visible spectroscopy. The spectrum for Fe(T*p*CPP) before the addition of Xln10A (with maxima at 409, 567, and 611 nm) was characteristic of a high-spin pentacoordinate porphyrin-iron(III) species (Figure 2). A clear change in this spectrum was observed on addition of Xln10A, with one clear isosbestic point at 445 nm and two others, less clear, at around 575 and 612 nm, leading to a final spectrum with maxima at 412, 570, and 614 nm for the corresponding Xln10A-Fe-porphyrin complex. In addition,

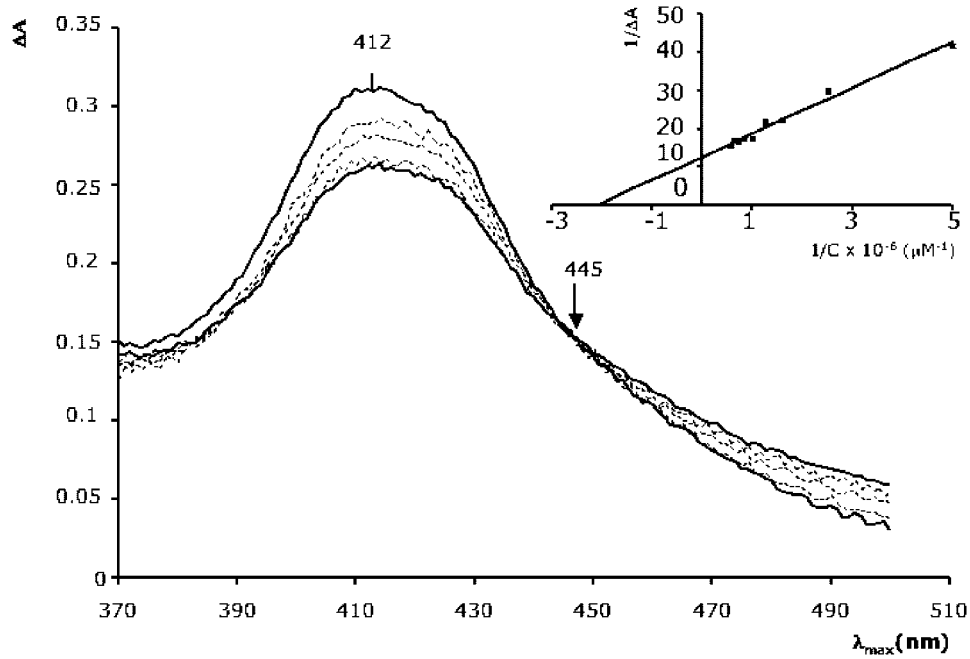

Figure 3. Titration of Fe(T*p*CPP) by Xln10A: evolution of the UV–visible spectrum of Fe(T*p*CPP), 0.97 μM in 50 mM PBS, pH 7.5, after addition of Xln10A at concentrations increasing from 0.05 μM to 4.96 μM. Inset: Double reciprocal plots of the absorbance at 412 nm versus the Xln10A/Fe-porphyrin ratio.

these changes in the UV–visible spectrum were independent of the pH, as similar variations in the spectra were recorded at pH 4.0, 5.1, 6, 6.6, 7.6, and 10.6 (data not shown). Since the final spectrum is also characteristic of a high-spin pentacoordinate iron(III)-porphyrin complex, this clearly indicates that the environment of the iron atom changes upon insertion of Fe(T*p*CPP) into Xln10A, which could be due to the binding of an amino acid side chain of Xln10A to the iron atom.

A titration of Fe(T*p*CPP), 0.97 μM in 50 mM PBS, pH 7.5, with Xln10A at concentrations increasing from 0.05 to 4.96 μM was performed (Figure 3). Double reciprocal plots of the absorbance at 412 nm versus the Xln10A/Fe-porphyrin ratio (Figure 3, inset) allowed us to determine a 1/1 Xln10A/Fe-porphyrin stoichiometry and a dissociation constant value K_D = 0.5 μM. This value was about 5-fold lower than those found for complexes of Fe(II)-2-[8-(2-methylimidazolyl)octanoyloxymethyl]-tetrakis-α_4-(*o*-pivalamidophenyl)porphyrin with xylanases from *Thermotoga maritima* (K_D = 2.2 μM) and *Dictioglomus thermophylum* (K_D = 2.9 μM) (*34, 35*) and was in agreement with a good affinity of Xln10A for Fe(T*p*CPP). This difference in affinity could be due to the rather flat shape of Fe(T*p*CPP) that better entered the cleft of Xln10A than the more bulky pivaloyl porphyrin did in the cleft of xylanases from *Thermotoga maritima* and *Dictioglomus thermophylum.*

Coordination of Imidazole on Fe(III)-Porphyrins and Their Complexes with Xylanase A. In order to evaluate the size of the cavity around the iron atom in the complexes of xylanase A with the three iron(III)-porphyrins, the coordination of imidazole on the iron atom was examined. To this effect, the progressive addition of imidazole (0–95 μM) to solutions of MP8, Fe(T*o*CPP), Fe(T*p*CPP), and the corresponding Fe-(porphyrin)-Xln 10A complexes, 1.85 μM in 50 mM PBS, pH 7.5, was analyzed by differential UV–visible spectroscopy as described in the Experimental Section. In all cases, the progressive appearance of a new spectrum, characteristic of an iron(III)-imidazole species, was observed (Table 1). The particular case of Fe(T*p*CPP) and Xln10A-Fe(T*p*CPP) is shown in Figure 4. In the case of Fe(T*p*CPP), a new spectrum with absorption maxima at 412, 545, and 581 nm and isobestic points at 402 and 439 nm is formed, whereas in the case of Xln10A-Fe(T*p*CPP), a new spectrum with absorption maxima at 415, 538, and 579 nm and isobestic points at 400 and 420 nm appears upon addition of imidazole. The inverse of the absorbance at the absorption maximum of the Fe-imidazole complex, $1/\Delta A_{\lambda max}$, was then plotted against the inverse of the concentration of imidazole added, 1/[ImH], and against the reverse of the square of the concentration of imidazole added, $1/[ImH]^2$, in order to determine whether one or two imidazoles were bound per iron atom and the corresponding K_D value, as described in the Experimental Section.

Table 1. Visible Characteristics, K_D and C_{50} Values of the Complexes of Fe(porphyrin) and Xln10A-Fe(porphyrin) with Imidazole in 50 mM PBS, pH 7.5, at 20 °C

Fe(porphyrin) or Xln10A+Fe(porphyrin)	number of imidazole ligands	λ_{max} (nm)	C_{50} (mM)	K_D
MP8	1	403	0.05	0.05 mM
Xln10A+MP8[a]	1	402	0.06	0.06 mM
Fe(T*o*CPP)	2	413	0.69	0.48 mM^2
Xln10A+Fe(T*o*CPP)[a]	2	412	0.67	0.49 mM^2
Fe(T*p*CPP)	2	415	3.4	11.6 mM^2
Xln10A-Fe(T*p*CPP)[b] complex	1	417	3.3	3.3 mM

[a] In these cases no complex coming from the insertion of MP8 or FeToCPP into the cleft of Xln10A was obtained. [b] Xln10A-Fe(T*p*CPP) was formed by insertion of FeTpCPP into the cleft of Xln10A.

With both MP8 and Xln10A-MP8, $1/\Delta A_{403}$ varied linearly as a function of 1/[ImH] and not as a function of $1/[ImH]^2$, which showed that only one imidazole was bound per iron atom in both cases. In addition, similar K_D values of 0.05 ± 0.01 and 0.06 ± 0.01 mM, respectively, were calculated for both complexes, which suggested that the xylanase protein had no effect on the binding of imidazole as a sixth ligand, trans to its histidine on the iron atom in microperoxidase 8. With both Fe(T*o*CPP) and Xln10A-Fe(T*o*CPP), $1/\Delta A_{413}$ varied linearly as a function of $1/[ImH]^2$ and not as a function of 1/[ImH], which showed that two imidazole ligands were bound per iron atom in both complexes. Here also, similar K_D values of 0.48 ± 0.01

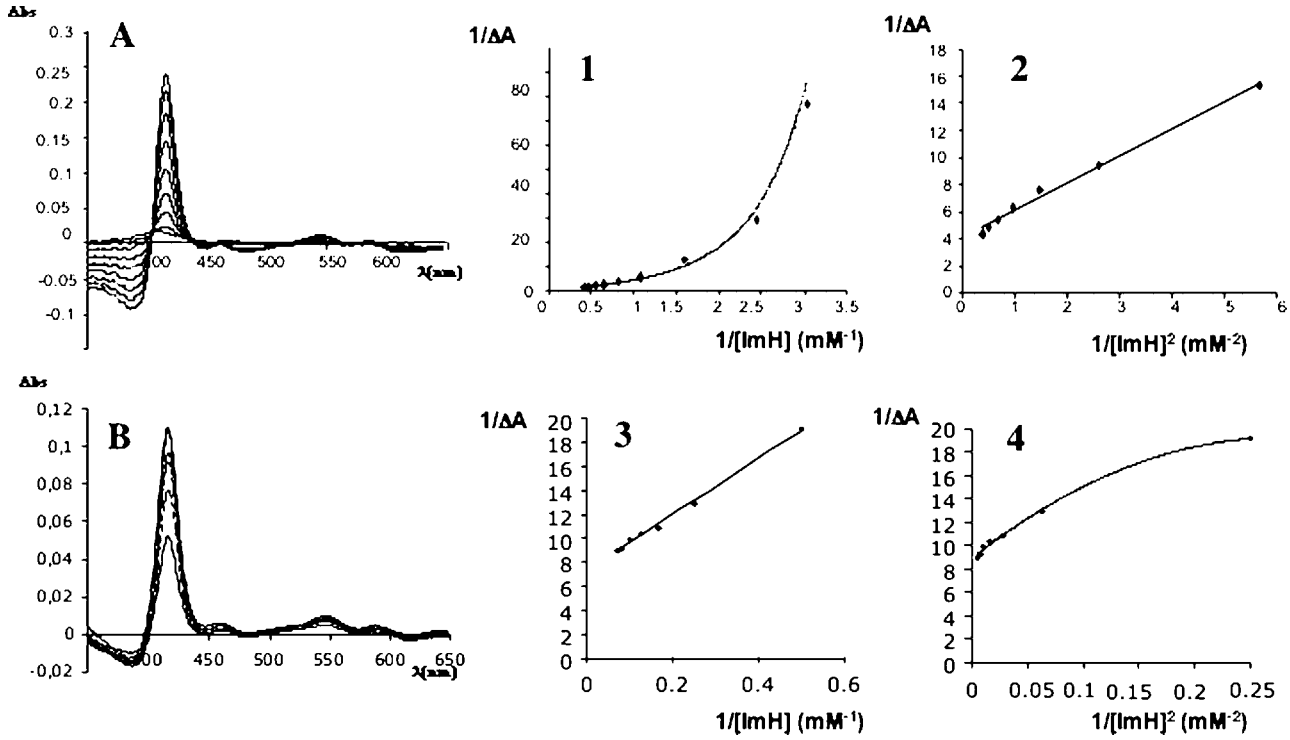

Figure 4. (A) Addition of imidazole to iron(III)-*meso*-tetrakis(*para*-carboxyphenyl)porphyrin (Fe(T*p*CPP)). Spectral evolution observed for the addition of 0 to 20 mM ImH to 1.85 μM Fe(T*p*CPP) in 50 mM PBS, pH 7.5, at 20 °C. Inset: corresponding values of $1/\Delta A_{412}$ plotted against 1/[ImH] (**1**) and 1/[ImH]^2 (**2**). (B) Addition of imidazole to the iron(III)-*meso*-tetrakis(*para*-carboxyphenyl)porphyrin Fe(T*p*CPP)-Xln10A complex. Spectral evolution observed for the addition of 0 to 20 mM ImH to 1.85 μM Fe(T*p*CPP)-Xln10A in 50 mM PBS, pH 7.5, at 20 °C. Inset: corresponding values of $1/\Delta A_{412}$ plotted against 1/[ImH] (**3**) and 1/[ImH]^2(**4**).

and 0.49 $\pm$ 0.01 mM^2, respectively, were calculated for both complexes, again suggesting that the xylanase protein had no effect on the binding of two imidazole ligands on the iron atom to give a hexacoordinate (T*o*CPP)Fe(ImH)$_2$ complex. In the case of Fe(T*p*CPP), $1/\Delta A_{413}$ varied linearly as a function of 1/[ImH]^2 (Figure 4), whereas in the case of Xln10A-Fe(T*p*CPP), $1/\Delta A_{413}$ varied linearly as a function of 1/[ImH] (Figure 4). This showed that, whereas free Fe(T*p*CPP) was able to bind two imidazole ligands as expected, Fe(T*p*CPP) incorporated into xylanase A was able to bind only one. It is thus likely that the xylanase protein brings steric hindrance around the plane of the porphyrin, leaving only one face accessible to ligands to coordinate to the iron atom.

Molecular Modeling. A series of molecular modeling studies have been carried out to address two major issues: (1) the characterization of the most probable binding site of the iron(III)-porphyrin complexes into the xylanase A structure and (2) the nature of the most stable binding modes of the Xln10A-iron(III)-porphyrin complexes when MP8, Fe(T*o*CPP), and Fe(T*p*CPP) are inserted into Xln10A.

The three iron(III)-porphyrin complexes discussed in this work have molecular structures substantially different from the natural substrate of Xln10A. Therefore, reasonable doubt exists as to whether the binding site of our porphyrin derivatives is the same as that of xylanes. We investigated this question by characterizing all possible accessible cavities of the Xln10A structure using a combination of different methods designed for this task. All the results agreed in predicting that the xylanase cleft is by far the largest accessible cavity. For example, the Q-sitefinder algorithm (*48*) showed that the cleft had a volume of 338 Å^3 (summing the volume of its different subpockets), while the three next cavities in size had volumes of 145, 100, and 98 Å^3, respectively. Since the porphyrin complexes are quite large (the approximated volume of the Fe(T*o*CPP) and Fe(T-*p*CPP) entities is around 600 Å^3), the Xln10A cleft appears as the most probable binding site for these compounds, though they are not expected to entirely fit into it.

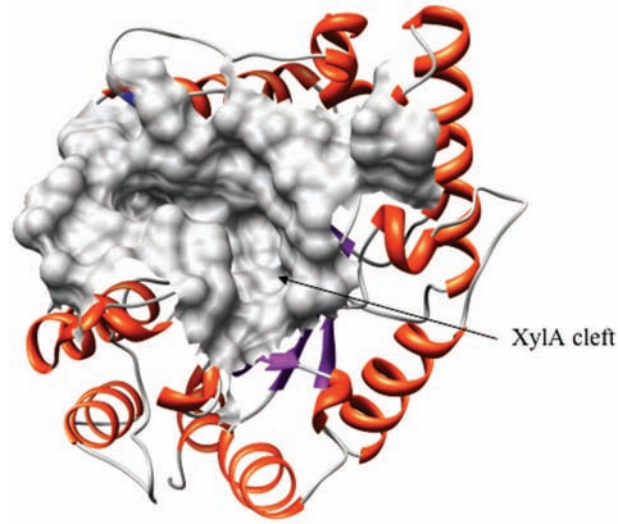

Figure 5. Upper view of the Xln10A cleft. Secondary structures of the protein are depicted in ribbon format. The solvent-accessible area of the cleft is shown in gray scale.

For MP8, not only its volume (approximately 1400 Å^3) but also its shape (mostly globular) suggests that its incorporation into this site is extremely poor. The optimized structure of the MP8 complex shows that this complex has a globular form, which suggests a very small complementarity of form with the narrow channel the cleft displays (Figure 5). This is in agreement with the experimental data that show that the activity of MP8 is not altered in solution in the presence of Xln10A.

On the contrary, the volumes of Fe(T*o*CPP) and Fe(T*p*CPP) (614 and 613 Å^3, respectively), as well as their planar shapes,

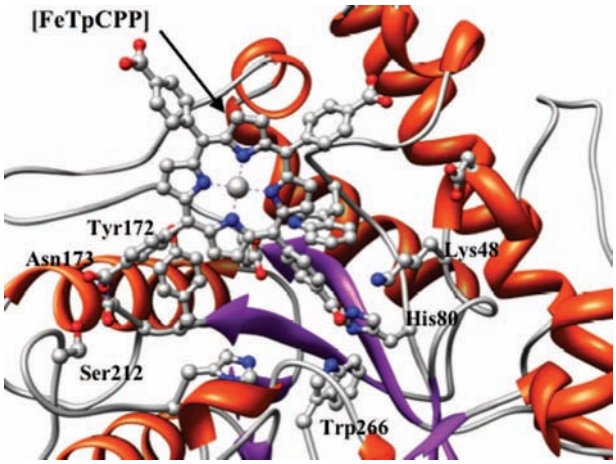

Figure 6. Best binding mode of the Fe(T*p*CPP)-Xln10A complex obtained using Gold with the Chemscore scoring function. The main interactions between the carboxylates of the Fe(T*p*CPP) and the polar patches {His80, Lys248, Trp266} (A) and {Ser212, Tyr172, Asn173} (B) are indicated.

suggest a substantial insertion of both iron(III)-porphyrin complexes into the cleft. To investigate the nature of the molecular complexes between these porphyrin derivatives and Xln10A, a series of molecular docking experiments were performed. From the 50 solutions obtained with the docking program Gold using the ChemScore scoring functions, striking differences in the structural properties of the predicted complexes were observed.

In general, all 50 solutions obtained from the docking of Fe(T*p*CPP) into Xln10A present a similar structural behavior. In low-energy solutions, two aromatic groups and part of the porphyrin ring are substantially anchored into the cleft. A strong hydrogen bonding network is observed between the carboxylates of two consecutive aromatic substituents of Fe(T*p*CPP) and the protein. One of the carboxylates interacts with a patch of three residues; two positive residues {His80, Lys48} and Trp266 and a second with another polar patch of three residues at the site opposite to the cleft {Ser212, Tyr172, Asn173} (Figure 6). It is noteworthy that a hydrogen bond is also frequently observed between a third carboxylate and Gln94: a residue that lies at the very surface of the protein (Figure 6). Finally, the general form of the Fe(T*p*CPP)-Xln10A complex shows the porphyrin tilted with respect to the average plane represented by the surface of the protein, and therefore, only one face of Fe(T*p*CPP) seems accessible to the solvent (Figure 7a).

The solutions obtained from the docking of Fe(T*o*CPP)-Xln10A complexes have a large structural variability, which depends mainly on which face of the porphyrin is occupied by the carboxylates. Although it is well-known that in *meso*-tetraphenyl-porphyrins the complete rotation of the phenyl is energetically demanding, our dockings have been performed allowing free rotation around the C_{meso}-phenyl bond in order to better explore of the conformational space. As a general feature, Fe(T*o*CPP)-Xln10A interactions are mainly based on hydrophobic contacts and have few hydrogen bond interations with the Xln10A cleft. In fact, Fe(T*o*CPP) appears to be unable to penetrate deeply into the cleft, and protein–ligand interactions mainly take place at the external part of the site (Figure 7b). At most, only one aromatic moiety fits into the cleft and most of the porphyrin remains exposed to the solvent. None of the low-energy Fe(T*o*CPP)-Xln10A complexes present an interaction of the carboxylates with the {His80, Lys48, Trp266} patch.

The comparison of calculated Fe(T*o*CPP)-Xln10A and Fe(T-*p*CPP)-Xln10A structures suggests that the carboxylates in the ortho position significantly alter the ability of the porphyrin to penetrate into the cleft, while on the contrary, the linear form of the para-substituted phenyls allows better penetration. This favors a strong polar interaction with the {His80, Lys48, Trp266} positive patch which lies slightly deeper into the cleft. This selectivity of Xln10A for the para- against the ortho-substituted porphyrin is confirmed by the computed binding energies with a significantly stronger predicted binding affinity for Fe(T*p*CPP) than Fe(T*o*CPP) (-28.8 and -24.4 kJ.mol^{-1} for best and average values of Fe(T*p*CPP) dockings and -23.8 and -18.8 kJ.mol^{-1} for best and average values of Fe(T*o*CPP) dockings, respectively).

Study of Peroxidase Activity of the Xln10A-Fe(TpCPP) Complex. *Oxidation of Various Peroxidase Cosubstrates.* Since the binding studies described above suggested that, among the assayed porphyrins, xylanase was able to influence only the accessibility of the iron of Fe(T*p*CPP), the complex associating Xln10A and Fe(T*p*CPP) appeared as the best candidate to lead to a selective catalyst for oxidation reactions. Consequently, the oxidation by H_2O_2 of several peroxidase cosubstrates, specifically two phenolic cosubstrates, guaiacol and 2,6-dimethoxyphenol, and a biaryl cosubstrate, *o*-dianisidine, was examined in the presence of Xln10A-Fe(T*p*CPP) as catalyst and compared to that catalyzed by free Fe(T*p*CPP).

The influence of the H_2O_2 concentration on the oxidation of the cosubstrates was first assayed. The rates of oxidation were measured as described in the Experimental Section, and the kinetic parameters were determined in each case from Lineweaver–Burk plots. The k_{cat} and K_M values calculated for the three substrates in the presence of Fe(T*p*CPP) and Xln10A-Fe(T*p*CPP) are reported in Table 2. The $K_M$value is higher in the case of the Xln10A-Fe(T*p*CPP) complex than for Fe(TpCPP) alone by factors of about 1.1, 1.6, and 5, respectively for guaiacol, 2,6-dimethoxypenol, and *o*-dianisidine. This showed that the affinity of H_2O_2 for the porphyrin was lower when it was incorporated into xylanase, which confirmed that access to the iron atom is restricted in the xylanase complex. With Xln10A-Fe(T*p*CPP) as catalyst, the k_{cat} value was lower for guaiacol and 2,6-dimethoxypenol, by factors of 3.1 and 1.6, respectively, whereas it was higher by a factor of 1.8 in the case of *o*-dianisidine. As a consequence, the catalytic efficiency k_{cat}/K_M was lower by a factor of 2.6, in the case of dimethoxyphenol, to 3.6, in the case of *o*-dianisidine, with Xln10A-Fe(T*p*CPP) when compared to Fe(T*p*CPP) alone as catalyst. This can probably be explained by the fact that guaiacol and 2,6-dimethoxyphenol are smaller hydrophobic substrates that can compete with H_2O_2 for the active site whereas *o*-dianisidine is a larger bicyclic compound, that hardly enters the porphyrin binding site in Xln10A.

However, the catalytic lifetime of Xln10A-Fe(TpCPP) is longer than that of Fe(T*p*CPP) alone, and when the plateau of catalytic activity is reached, more substrate has been oxidized, with all three substrates examined (data not shown). In addition, with higher concentrations of H_2O_2, the difference between the catalysts becomes more important. Typically, when *o*-dianisidine is oxidized under the conditions described above but with concentrations of H_2O_2 increasing from 80 to 640 μM, the concentration of *o*-dianisidine oxidized increases with the H_2O_2 concentration, from 18 to 37 μM with Xln10A-Fe(T*p*CPP) as catalyst (Figure 8) but decreases from 17 to 12 μM with Fe(TpCPP) as catalyst. This shows that xylanase has an important protecting effect toward oxidative degradations of the porphyrin.

The influence of the cosubstrate concentration on the rate of oxidation was then assayed in the cases of guaiacol and *o*-dianisidine. Table 3 shows the kinetic parameters that were determined in each case. In the case of *o*-dianisidine, the K_M value increases by a factor of 4 when Fe(T*p*CPP) is incorporated into xylanase, whereas at the same time, the k_{cat} value does not

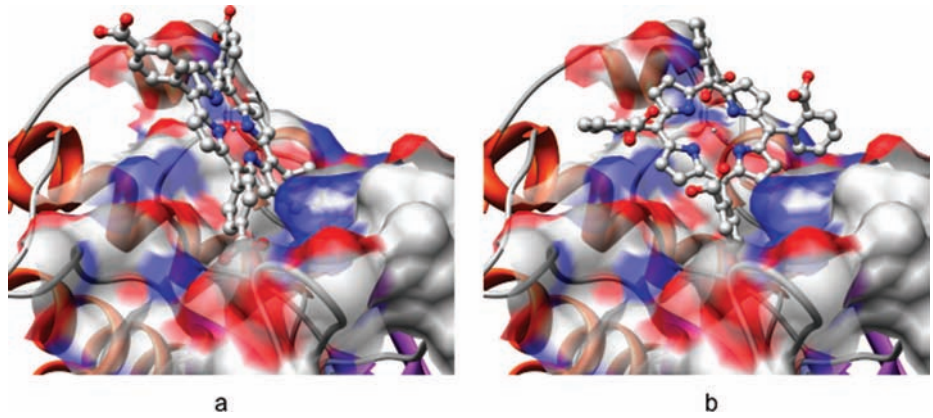

Figure 7. General view of the best binding mode predicted by Gold 3 with the Chemscore scoring function for Fe(T*p*CPP) (panel a) and Fe(T*o*CPP) (panel b).

Table 2. Comparison of Kinetic Parameters, Relative to H_2O_2, for the Oxidation of Various Reducing Cosubstrates by H_2O_2 Catalyzed by Fe(T*p*CPP) or Xln10A-Fe(T*p*CPP)

reducing cosubstrate	catalyst	K_M (mM)	k_{cat} (min^{-1})	k_{cat}/K_M (M^{-1} min^{-1})
guaiacol	Fe(T*p*CPP)	0.83	17.8	2.15×10^4
	Xln10A-Fe(T*p*CPP)	0.92	5.6	6.1×10^3
2,6-dimethoxyphenol	Fe(T*p*CPP)	0.28	9.3	3.43×10^4
	Xln10A-Fe(T*p*CPP)	0.45	6.1	2.16×10^4
o-dianisidine	Fe(T*p*CPP)	0.16	29.2	1.82×10^4
	Xln10A-Fe(T*p*CPP)	0.80	52.0	6.5×10^4

vary. Thus, the affinity for *o*-dianisidine decreases when Fe(T*p*CPP) is incorporated into xylanase, whereas the catalytic activity does not vary. In the case of guaiacol, on the contrary, the affinity increases, as shown by the K_M value which decreases from 0.44 to 0.24 mM, and the catalytic activity decreases as shown by the 11-fold decrease in the k_{cat} value, when Fe(T*p*CPP) is incorporated into xylanase. It is likely that *o*-dianisidine, which is a larger biaryl cosubstrate, does not enter easily inside the active site of xylanase, explaining the increase in K_M. However, the nature of the cosubstrate does not prevent H_2O_2 from interacting with the iron atom, leading to an unchanged catalysis. On the contrary, guaiacol, a smaller hydrophobic cosubstrate, enters the xylanase binding site more readily due to hydrophobic interactions, and K_M decreases. It also hinders the interaction of H_2O_2 with the iron atom causing a reduction in catalysis, and thus, k_{cat} decreases.

Influence of Imidazole on the Kinetic Parameters of the Oxidation of o-Dianisidine by H_2O_2. The influence of imidazole on the kinetic parameters of the oxidation of *o*-dianisidine by H_2O_2 in the presence of 1.2 μM Fe(T*p*CPP) or of 1.2 μM Xln10A-Fe(T*p*CPP) was examined. The catalyst was first incubated for 2 h at 4 °C with imidazole at concentrations ranging between 0 and 50 mM; then the *o*-dianisidine cosubstrate (890 μM) was added and the reaction was initiated by the addition of H_2O_2 (320 μM). The initial rates of oxidation were measured as described above. With both catalysts, the addition of imidazole caused an inhibition of the peroxidase activity. With Fe(T*p*CPP) as catalyst, the reaction is inhibited with an IC_{50} of about 11 mM, whereas with Xln10A-Fe(T*p*CPP), it is inhibited with an IC_{50} of about 25 mM.

pH Dependence Studies. To study the pH dependence of the peroxidase activity of Fe(T*p*CPP) and Xln10A-Fe(T*p*CPP), the oxidation of *o*-dianisidine by H_2O_2 was performed in the presence of these two catalysts at pHs ranging between 4.1 and 9.1, as described in the Experimental Section. Figure 9 shows that, in the case of Fe(T*p*CPP) alone, the rate of oxidation increases linearly with pH for pH values above 5. In the case of Xln10A-Fe(T*p*CPP), a sigmoid curve is found with an inflection point at about pH 7.5.

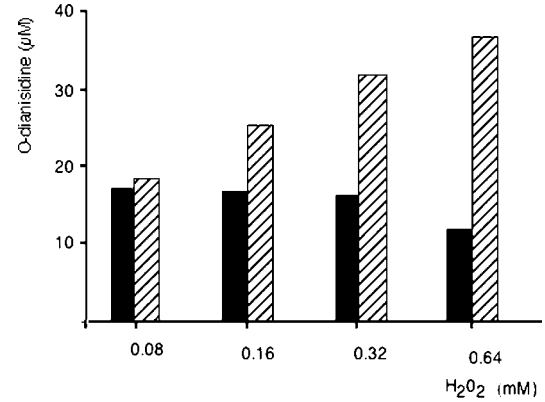

Figure 8. Variation of the concentration of *o*-dianisidine oxidized as a function of the concentration of H_2O_2. Concentration of *o*-dianisidine oxidized at the plateau, when 890 μM *o*-dianisidine is oxidized by H_2O_2 at concentrations increasing from 0.08 to 0.64 mM, with 1.2 μM Fe(T*p*CPP) or Xln10A-Fe(T*p*CPP) as catalyst, in 50 mM PBS, pH 7.5, at 20 °C.

Table 3. Comparison of Kinetic Parameters, Relative to the Reducing Cosubstrate, for the Oxidation of Guaiacol and *o*-Dianisidine by H_2O_2 Catalyzed by Fe(T*p*CPP) or Xln10A-Fe(T*p*CPP)

reducing cosubstrate	catalyst	K_M (mM)	k_{cat} (min^{-1})	k_{cat}/K_M (M^{-1} min^{-1})

DISCUSSION

The insertion into Xln10A of three Fe-porphyrins which are water-soluble and bear negatively charged carboxylate substituents, microperoxidase 8 (MP8), Fe(III)-α_4-tetra-*o*-carboxyphenyl porphyrin Fe(T*o*CPP), and Fe(III)-tetra-*p*-carboxyphenylporphyrin Fe(T*p*CPP) (Figure 1), was studied in order to define a new hybrid hemoprotein that would have interesting properties as a catalyst for selective oxidation reactions. Our results clearly show that, among the three Fe-porphyrins studied,

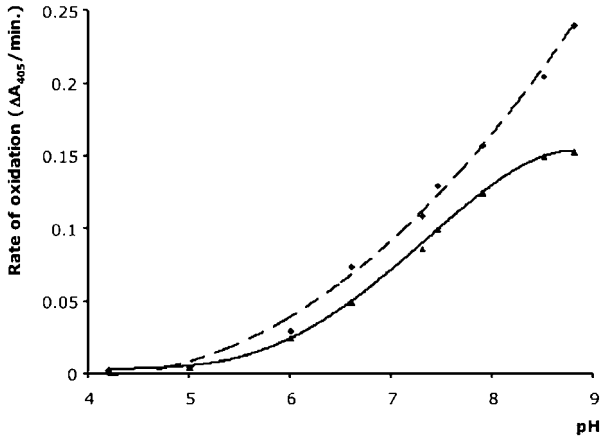

Figure 9. Influence of the pH on the peroxidase activity of Fe(T*p*CPP) and Fe(T*p*CPP)-Xln10A. Variation, as a function of the pH, of the initial rate of oxidation of 890 μM *o*-dianisidine by 320 μM H_2O_2 in the presence of 1.2 μM Fe(T*p*CPP) (- - -) or Fe(T*p*CPP)-Xln10A (—), in 0.1 M citrate/phosphate buffer pHs 4.1, 4.6, 5.0, 5.5, 6.0, 6.5, and 7.0, and in 0.1 M Tris−HCl buffer pHs 7.3, 7.6, 7.9, and 9.1.

only Fe(T*p*CPP) could lead to a new hemoprotein having such properties. First of all, UV–visible studies showed that most probably neither MP8 nor Fe(T*o*CPP) were inserted inside the cleft of Xln10A. Indeed, their titration by this protein did not lead to any significant change in their UV–visible spectrum, except a decrease in their Soret band which is characteristic of a nonspecific hydrophobic interaction between the protein and these two porphyrins, without any amino acid side chain coordinating to the iron atom. In agreement with this, similar results were observed when MP8 and Fe(T*o*CPP) were titrated by imidazole in the presence or absence of Xln10A. Both MP8 and MP8-Xln10A bound one imidazole ligand with a similar K_D value of about 0.05 mM, and both Fe(T*o*CPP) and Fe(T*o*CPP)-Xln10A bound two imidazole ligands with similar K_Ds of about 0.48 mM (Table 1). This showed that in both cases the Xln10A protein does not interact closely with the porphyrin macrocycle and does not prevent imidazole from binding on the iron atom. On the contrary, addition of Xln10A to Fe(T*p*CPP) led to a significant change in its UV–visible spectrum (Figure 2), with a 3 nm shift of its characteristic bands, which could be due to the binding of an amino acid side chain of Xln10A to the iron atom. A titration of Fe(T*p*CPP) by increasing amounts of Xln10A (Figure 3) clearly indicated a 1:1 Fe(T*p*CPP)/Xln10A stoichiometry and allowed a K_D of 0.5 μM to be measured for the obtained complex, that was close to the K_D values reported for complexes of Fe(II)-2-[8-(2-methylimidazolyl)octanoyloxymethyl]-tetrakis-α_4-(*o*-pivalamidophenyl)porphyrin with bacterial xylanases B (*34*, *35*). In addition, different results were observed when Fe(T*p*CPP) was titrated by imidazole in the presence or absence of Xln10A. Fe(T*p*CPP) bound two imidazole ligands with a K_D of 11.56 mM[2], whereas Fe(T*p*CPP)-Xln10A bound only one with a K_D of 3.3 mM (Table 1). This showed that the Xln10A protein interacted closely with the porphyrin macrocycle and brought steric hindrance around one face of the porphyrin, possibly with an amino acid side chain coordinating the iron atom, preventing imidazole from binding on this face.

Furthermore, these results were corroborated by molecular modeling studies that allowed a possible explanation of the difference in Xln10A-Fe-porphyrin interactions to be put forward. These analyses suggested that, in agreement with the UV–visible studies, both the large volume (V_{MP8} = 1400 Å^3 vs V_{cav} = 338 Å^3) and the globular shape of MP8 lead a very poor incorporation of MP8 into the quite narrow and elongated cleft of Xln10A. On the contrary, the volumes and shapes of Fe(T*o*CPP) and Fe(T*p*CPP) appeared reasonably close to those of the Xln10A cleft and suggested at least a partial insertion of both iron(III)-porphyrin complexes into it. A weak hydrophobic complementarity with the binding site of Xln10A was suggested for Fe(T*o*CPP) which bound perpendicularly to the surface of the protein with only one aromatic moiety inserted into the cleft and most of the porphyrin exposed to the solvent (Figure 7b). Therefore, both faces of Fe(T*o*CPP) seemed accessible to the solvent and could accommodate two axial imidazole ligands on its iron atom as showed by the absorption spectroscopy studies.

Finally, molecular modeling studies suggested that Fe(T*p*CPP) could be more deeply inserted into the Xln10A cleft, with two aromatic groups and part of the porphyrin ring anchored into the binding site (Figure 7a). A strong association was then observed, mainly due to a hydrogen-bonding network between the carboxylates of two consecutive aromatic substituents of Fe(T*p*CPP) and several side chains of protein residues. Indeed, from the docking experiments, it was predicted that the binding energies could be substantially stronger for Fe(T*p*CPP) than for Fe(T*o*CPP) by about 5 kJ.mol^{-1}. In the Fe(T*p*CPP)-Xln10A complex, the porphyrin is tilted with respect to the surface of the protein, and therefore, only one face of Fe(T*p*CPP) seems accessible to the solvent (Figure 7a) and this can explain why the binding of only one imidazole on the iron atom was observed in this complex.

In addition, the glycosidic activity of Xln10A and of the Xln10A-Fe(TpCPP) complex was determined using a diffusion agar assay as described in the Experimental Section. Thus, Xln10A and Xln10A-Fe(TpCPP), 1 μM in 50 mM PBS pH 7.5, were added to wells coated with RBB (Remazol-Brillant-Blue)-xylan and incubated at 37 °C for 2, 6, and 24 h. The glycosidic activity was then determined from the diameter of the clearing zone around the well that was due to the hydrolysis of xylan. Under those conditions, no clearing zones could be observed on RBB-xylan, in the presence of Xln10A-Fe(TpCPP) even after 24 h incubation, while Xln10A alone in PBS buffer showed increasing clearing zones with increasing incubation time. This clearly showed that the Xln10A-Fe(TpCPP) complex did not retain any glycosidic activity anymore. This constituted an additional strong argument proving that the Fe(TpCPP) molecule was competitively incorporated into the substrate binding cleft of the $(\beta/\alpha)_8$ TIM-barrel and affected the original enzymatic activity of the host xylanase.

The peroxidase activity of Fe(T*p*CPP)-Xln10A was then examined. This new hybrid hemoprotein was found able to catalyze the oxidation of several peroxidase cosubstrates, namely, guaiacol, 2,6-dimethoxyphenol, and *o*-dianisidine, with k_{cat} values between 3.4 and 52 min^{-1} and k_{cat}/K_M values between 6.1 × 10^3 and 6.5 × 10^4 M^{-1} min^{-1} (Table 2). These values are comparable to those already published for several Fe-porphyrin-antibody complexes (Table 3) that display k_{cat} values between 63 and 667 min^{-1} and k_{cat}/K_M between 3.7 × 10^3 and 2.9 × 10^5 M^{-1} min^{-1}, except for the 3A3-MP8 complex that displays higher k_{cat} (885 min^{-1}) and k_{cat}/K_M (2 × 10^6 M^{-1} min^{-1}) values (*26*). While the k_{cat} values remain comparable to those measured for the enzyme horseradish peroxidase (HRP) itself, the molar efficiency remains low when compared to that observed for this enzyme (k_{cat}/K_M = 6.1 × 10^8 M^{-1} min^{-1}) mainly because of the large difference in the affinity of the substrate, H_2O_2, which is much higher for HRP (K_M = 0.5 μM) (*59*) than for Fe(T*p*CPP)-Xln10A (K_M = 0.5–0.9 mM) (Table 4).

In order to examine the influence of the Xln10A protein on the catalytic activity of Fe(T*p*CPP), the kinetic parameters obtained for H_2O_2 in the presence of the three substrates with Fe(T*p*CPP)-Xln10A as catalyst have been compared with those obtained in the presence of Fe(T*p*CPP) alone as catalyst (Table 2). It appears that, in all the cases, the K_M values are higher with Fe(T*p*CPP)-Xln10A (K_M = 0.92, 0.45, and 0.80 mM) than

with Fe(TpCPP) alone (K_M = 0.83, 0.28, and 0.16 mM for guaiacol, 2,6-dimethoxyphenol, and *o*-dianisidine, respectively). It is likely that this is due both to the steric hindrance and to the increased hydrophobicity brought by the protein around the iron atom of the porphyrin. With Fe(TpCPP)-Xln10A, the k_{cat}value was lower than with Fe(TpCPP) alone in the case of guaiacol (5.6 and 17.8 min^{-1}, respectively) and 2,6-dimethoxyphenol (6.1 and 9.3 min^{-1}, respectively) but higher with *o*-dianisidine (52.0 and 29.2 min^{-1}, respectively). This could be explained by the fact that guaiacol and 2,6-dimethoxyphenol are smaller hydrophobic substrates that can compete with H_2O_2 for the active site whereas *o*-dianisidine is a larger bicyclic compound that hardly enters the porphyrin binding site in Xln10A.

The kinetic parameters for *o*-dianisidine and guaiacol have also been measured. They can be compared with the values reported for phenolic cosubstrates in the presence of myoglobin and new hemoproteins obtained by incorporation of modified hemes into recombinant myoglobin (Table 3). Both myoglobin and new myoglobin-derived hemoproteins lead to higher k_{cat} values (60–396 min^{-1}) (*32, 33*) than Xln10-Fe(TpCPP) with guaiacol (k_{cat} = 0.6 min^{-1}) and *o*-dianisidine (k_{cat} = 17.6 min^{-1}). Only one of the reported new hemoproteins, rMb(H64D)**2**, leads to a lower K_M value (K_M = 0.052 mM) (*32*) than Xln10-Fe(TpCPP) with guaiacol (K_M = 0.24 mM) and *o*-dianisidine (K_M = 0.80 mM). As a consequence, it also appears to be the more efficient catalyst, characterized by a k_{cat}/K_M value of 1.4 $\times$ 10^6 M^{-1} min^{-1} (*32*), whereas all the other myoglobin-derived hemoproteins display molar efficiencies that are in the same range as those displayed Xln10-Fe(TpCPP) (k_{cat}/K_M = 8.4 $\times$ 10^2 to 2.2 $\times$ 10^4 M^{-1} min^{-1}) (Table 3).

Oxidation of *o*-dianisidine by increasing amounts of H_2O_2, in the presence of either Xln10A-Fe(T*p*CPP) or Fe(T*p*CPP) alone as catalyst, led to a plateau value that was dependent upon the concentration of H_2O_2 that was used (Figure 8). This was due in both cases to a bleaching of the metalloporphyrin cofactor as was proven by two experimental observations: (i) UV–visible monitoring of the reaction showed a bleaching of the Soret band at, respectively, 409 nm for Fe(T*p*CPP) or 412 nm for Xln10A-Fe(T*p*CPP), (ii) further addition of the same amount of either H_2O_2 or *o*-dianisidine to the reaction mixture, once the plateau was reached, did not lead to any further oxidation of *o*-dianisidine. It is noteworthy, however, that another important advantage brought by the protein around the Fe-porphyrin cofactor could be shown: an important protecting effect toward oxidative degradation of the porphyrin. Indeed, with Xln10A-Fe(T*p*CPP) as catalyst, the reaction remains linear as a function of time for a longer time, and when the plateau is reached, more substrate is oxidized. Furthermore, as shown in the particular case of *o*-dianisidine (Figure 8), the concentration of cosubstrate oxidized increases with the H_2O_2 concentration over a wide range of concentrations (e.g., 80–640 μM), whereas under the same conditions, with Fe(T*p*CPP) as catalyst, the concentration of *o*-dianisidine oxidized significantly decreases.

When the effect of the addition of imidazole on the peroxidase activity was assayed, inhibition was observed with both Fe(T*p*CPP) and Fe(T*p*CPP)-Xln10A catalysts, with respective IC_{50} values of 11 and 25 mM. It is likely that this inhibition is due to the binding of imidazole ligands on the iron atom of Fe(T*p*CPP). With both Fe(T*p*CPP) and Xln10A-Fe(T*p*CPP), the IC_{50} value is larger than the C_{50} value for the binding of imidazole on the iron atom (C_{50} = 3.4 mM and 3.3 mM, respectively; Table 1), which could reflect competition between imidazole and the substrate to enter the active site as the basis of the inhibition.

Finally, a study of the catalytic activity as a function of pH showed that, whereas with Fe(T*p*CPP) alone the rate of oxidation of *o*-dianisidine by H_2O_2 increased linearly with pH for pH values above 5, a sigmoid curve with an inflection point at about pH 7.5 was found in the case of Xln10A-Fe(T*p*CPP). Since the solubility of Fe(TpCPP) decreases at lower pH values, and it cannot be ruled out that this could be involved in the decrease of peroxidase activity of the hemozyme at low pH. However, it is also likely that an amino acid side chain with a pK_A of about 7.5 could be participating in the catalysis. The amino acids located inside the binding pocket of Xln10A, that were both characterized by a pK_a value between 6 and 8 and close enough to the iron atom of the metalloporphyrin cofactor, were searched using molecular modeling. This allowed us to point out five amino acids that could possess those properties: Lys 48, Asp 50, His 80, Glu 128, and His 207 (Figure 10). Site-directed mutagenesis studies will be undertaken to examine which of them could be participating in catalysis.

CONCLUSION

The results described above show that the association of a synthetic iron(III)-tetra-*para*-carboxy-phenyl substituted porphyrin and a nonrelated protein xylanase A from *Streptomyces lividans*,

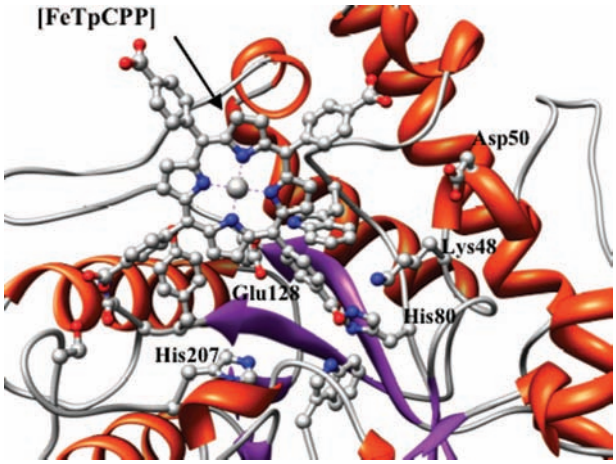

Figure 10. Amino acids located inside the binding pocket of Xln10A, that could be participating in the catalysis of the peroxidase reaction by the Xln10A-Fe(T*p*CCP) complex: Lys 48, Asp 50, His 80, Glu 128, and His 207.

leads to a new hybrid hemoprotein that displays interesting peroxidase activity. This new biocatalyst combines the advantages of both partners. First, Fe-tetraaryl-porphyrins are less sensible to oxidative degradations of meso bridges by oxidizing intermediates than natural hemes. The first positive effect of the protein is to increase this protection of the porphyrin ligand toward the highly reactive oxygenated species generated during the catalysis. Second, the protein also brings steric hindrance and an increased hydrophobic environment around the iron, two important characteristics that will be highly useful in the future for the catalysis of selective oxidation reactions. It may also be possible for the protein to bring amino acids that participate in the catalysis and in the binding of the iron. Preliminary molecular modeling experiments have already suggested a set of amino acids that could fill these functions. Further site-directed mutagenesis experiments are underway to confirm these results.

ACKNOWLEDGMENT

We thank the Ministère des Relations Internationales du Québec, the Consulat Général de France à Québec and the 61th Commission Permanente de Coopération Franco-Québecoise for a two-years collaboration grant between the team of Prof. J.-P Mahy (France) and that of Prof. C. Dupont (Quebec) that helped to develop this project.

Fully Acid-Degradable Biocompatible Polyacetal Microparticles for Drug Delivery

Sergey E. Paramonov,† Eric M. Bachelder,† Tristan T. Beaudette, Stephany M. Standley, Cameron C. Lee, Jesse Dashe, and Jean M. J. Fréchet*

Department of Chemistry, University of California, Berkeley, California 94720-1460. Received December 4, 2007; Revised Manuscript Received February 22, 2008

A library of polyurethanes and polyureas with different hydrophobicities containing the same acid-degradable dimethyl ketal moiety embedded in the polymer main chain have been prepared. All polymers were synthesized using an AA-BB type step-growth polymerization by reaction of bis(*p*-nitrophenyl carbamate/carbonate) or diisocyanate monomers with an acid-degradable, ketal-containing diamine. These polymers were designed to hydrolyze at different rates in mildly acidic conditions as a function of their hydrophobicity to afford small molecules only with no polymeric byproduct. The library of polymers was screened for the formation of microparticles using a double emulsion technique. The microparticles that were obtained degraded significantly faster at acidic pH (5.0) than at physiological pH (7.4) with degradation kinetics related to the hydrophobicity of the starting polymer. In vitro studies demonstrated the ability of the FITC-BSA loaded microparticles to be phagocytosed by macrophages resulting in a 10-fold increase in the protein uptake compared to a free protein control; in addition, the microparticles were found to be nontoxic at the concentrations tested of up to 1 mg/mL. The ease of preparation of the polymers coupled with the ability to tune their hydrophobicity and the high acid sensitivity of the microparticles identify this new class of materials as promising candidates for the delivery of bioactive materials.

INTRODUCTION

Polymer based drug or vaccine delivery systems have attracted much attention due to their ability to perform multiple critical functions. These functions include delivering therapeutic or other bioactive agents to a specific site via a targeting mechanism, increasing the circulation times of drugs in the body, protecting drugs from degradation, or increasing the bioavailability of poorly soluble drugs. We are interested in developing polymer-based delivery vehicles that utilize a change in the pH of the medium to trigger the release of a payload, yet degrade fully into small molecules without leaving a polymeric residue. Several strategies have been utilized to prepare acid-degradable carriers including the use of pH responsive micelles (*1*), microparticles (*2–5*) and liposomes (*6–8*) that encapsulate the therapeutic molecules. In addition, covalent attachment of the drug to a polymer or dendrimer carrier through an acid-sensitive linkage has also been demonstrated (*9, 10*). In this way a therapeutic payload may be released (*11*) at a site utilizing the slightly acidic conditions found in inflamed tissue and tumors or in the endosomal/lysosomal compartments of cells.

However, it is important to consider the byproducts obtained in the degradation of a polymer carrier to ensure their complete clearance from the body. Many systems reported previously including poly(beta-amino) esters (*4, 12–14*), poly(ketal)s (*15*) and poly(acetal)s (*3, 16*) degrade significantly faster at the acidic pH of 5.0–6.0 than at the physiological pH of 7.4, but their degradation into small molecule products is either incomplete or only occurs within a time frame of days to weeks, which may in some instances reduce their applicability to practical systems.

We have explored a family of novel polymers that degrade only to small molecule products when subjected to the acidic conditions found in lysosomes (Figure 1). A highly reactive pH-sensitive diamine monomer was synthesized and allowed to react with a variety of bis(*p*-nitrophenyl carbamate/carbonate)s and diisocyanates (Figure 1a,b) to afford a family of acid-degradable polyureas and polyurethanes with various degrees of hydrophobicity (**17–24**) (Figure 1c). The polymers were further tested for their ability to encapsulate a water soluble protein via a double emulsion (water/oil/water) technique to afford pH-sensitive microparticles that can degradable in aqueous medium with appreciable kinetics (Figure 1d). The hydrophobicity of the polymer is an important parameter that affects both the microparticle preparation as well as the degradation kinetics. By employing an AA-BB type step growth polymerization in which AA is the acid-degradable diamine monomer and BB represents a variety of bis-electrophilic monomers with different hydrophobicities, we synthesized a library of polymers and identified those polymers that could both form suitable microparticles and degrade sufficiently fast to be used as delivery vehicles. The potential to use any of a wide variety of commercially available or easily synthesized bifunctional monomers to readily prepare polymers with variable physical properties further highlights the versatility of our approach.

The prepared microparticles were characterized by scanning electron microscopy (SEM) and dynamic light scattering (DLS) while their cellular uptake was visualized by laser confocal microscopy and analyzed by flow cytometry. The degradation of these microparticles over time in aqueous medium was monitored at pH 5.0 and 7.4 with several microparticles demonstrating both rapid degradation under acidic conditions and relative stability at physiological pH. Complete degradation into small molecule products (Figure

1e) was confirmed and cytotoxicity studies indicated no toxicity up to the highest concentration tested of 1 mg/mL.

EXPERIMENTAL SECTION

General Procedures and Materials. Reagents and materials were purchased from commercially available sources and were used without further purification unless otherwise noted. *p*-Toluenesulfonic acid was recrystallized from toluene. ^{1}H NMR spectra were recorded at 300 or 400 MHz, while ^{13}C spectra were recorded at 100 MHz. Reported chemical shifts (ppm) are relative to tetramethylsilane and coupling constants are reported in Hz. High resolution fast bombardment mass spectrometry (FAB-HRMS) analysis was performed at the UC Berkeley mass spectrometry facility. Elemental analyses were obtained from the UC Berkeley analytical facility. Size exclusion chromatography (SEC) experiments were performed on a Waters system with simultaneous analysis of UV absorbance and refractive index using 0.1 M LiBr solution in DMF. The SEC column (75 × 300 mm PLgel, 10^3 Å, 5 μm particle size) was calibrated using poly(methyl methacrylate) standards. Fourier transform infrared spectroscopy (FT-IR) was carried out on a Varian 3100 FT-IR spectrometer.

Synthesis of Compound 9. N-(2-hydroxyethyl)-phthalimide (20.29 g, 106 mmol, 1 equiv) was dissolved in 400 mL of dry benzene, residual water was removed by azeotropic distillation in a Dean–Stark distillation setup. The solution was cooled to 0 °C using an ice bath and 2-methoxy propene (10.15 mL, 106 mmol, 1 equiv) was carefully added to the solution along with *p*-toluenesulfonic acid (190 mg, 1 mmol). The reaction mixture was then stirred for an hour while keeping the temperature at 0 °C to avoid loss of the highly volatile 2-methoxy propene (bp: 34–36 °C). After one hour, the reaction mixture was heated to evaporate the solvent while additional amounts of dry benzene were added and subsequently evaporated over the course of 3 h. Finally, the reaction mixture was cooled to room temperature and triethylamine (TEA) (24 mL) was added to quench the reaction. To facilitate further purification, acetic anhydride (6 mL) was added to convert any unreacted alcohol groups into the corresponding acetate and the reaction mixture was allowed to stir overnight. The reaction mixture was then precipitated

by dropwise addition to a large excess of hexanes. The precipitated powder was collected and recrystallized twice from ethyl acetate. Yield: 55%. Spectroscopic characterization was consistent with that reported in the literature (*17*).

Synthesis of Compound 10. Compound **9** (17.03 g, 40.3 mmol) was deprotected in 6 M NaOH (100 mL) by heating the reaction mixture at reflux overnight. The product was extracted with $CHCl_3$/iPrOH (1/1) mixture three times and the fractions were combined and dried over anhydrous $MgSO_4$. The organic layer was filtered and evaporated *in vacuo*. The excess of iPrOH was removed by repeated azeotropic distillation with hexanes. Yield: 85%. IR (cm^{-1}): 3372 (br), 1568 (s), 1480 (s), 1380 (m). ^1H NMR (300 MHz, $CDCl_3$): ∂ 1.35 (s, 6H), 1.55 (s, ~4H), 2.82 (t, 4H, $J = 5.4$ Hz), 3.44 (t, 4H, 5.4 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): ∂ 25.0, 42.1, 62.8, 99.7. Calcd: $[M + H]^+$ ($C_7H_{19}N_2O_2$) $m/z = 163.1447$. Found FAB-HRMS: $[M + H]^+ = 163.1446$. Anal. Calcd: C, 51.83; H, 11.18; N, 17.27. Found: C, 51.70; H, 11.24; N, 17.33.

Synthesis of Compounds 11–15. Compounds **11** and **12** were synthesized according to published procedures (*18*). Compounds **13**−**15** were synthesized according to the general procedure described below. Diol **3-5** (1.73 g, 19.3 mmol) was dried by azeotropic distillation with benzene and redissolved in 20 mL of dry CH_2Cl_2. Dry pyridine (9.3 mL, 115.7 mmol) was added and the reaction mixture was cooled to 0 °C. In a separate flask *p*-nitrophenolchloroformate (9.75 g, 48.4 mmol) was dissolved in dry CH_2Cl_2 (30 mL) and slowly added to the solution of diol under nitrogen atmosphere. The reaction mixture was allowed to stir overnight under N_2 while warming to room temperature. The crude reaction mixture was washed three times with NaH_2PO_4 (0.4 M, pH 4.6), the organic layer was dried over $MgSO_4$ and the solvent was removed under reduced pressure. The resulting solid was recrystallized three times from ethyl acetate.

Compound 13. Yield: 85%. IR (cm^{-1}): 1527 (s), 1594 (m), 1527 (m), 1760 (s), 2976 (w). ^1H NMR (400 MHz, $CDCl_3$): ∂ 2.23 (quintet, 2H, $J = 6$ Hz), 4.49 (t, 4H, $J = 6$ Hz), 7.39 (d, 4H, $J = 9.2$ Hz), 8.26 (d, 4H, $J = 9.2$ Hz). ^{13}C NMR (100 MHz, $CDCl_3$): ∂ 28.0, 65.7, 122.0, 125.6, 145.7, 152.6, 155.7. Calcd: $[M + Li]^+$ ($C_{17}H_{14}N_2O_{10}Li$) $m/z = 413.0808$. Found FAB-HRMS: $[M + Li]^+ = 413.0814$. Anal. Calcd: C, 50.25; H, 3.47; N, 6.89. Found: C, 50.46; H, 3.32; N, 6.77.

Compound 14. Yield: 79%. IR (cm^{-1}): 1530 (s), 1596 (m), 1618 (m), 1765 (s), 2958 (w). ^1H NMR (300 MHz, $CDCl_3$): ∂ 1.14 (d, 3H, $J = 7.2$ Hz), 2.37–2.48 (m, 1H), 4.31 (d, 4H, $J = 3$ Hz), 7.37 (d, 4H, $J = 9$ Hz), 8.25 (d, 4H, $J = 9$ Hz). ^{13}C NMR (100 MHz. $CDCl_3$) ∂ 13.4, 32.6, 70.1, 121.8, 128.4, 145.5, 152.5, 155.4. Calcd: $[M + H]^+$ ($C_{18}H_{17}N_2O_{10}$) $m/z = 421.0883$. Found FAB-HRMS: $[M + H]^+ = 421.0881$. Anal. Calcd: C, 51.43; H, 3.84; N, 6.66. Found: C, 51.22; H, 3.69; N, 6.53.

Compound 15. Yield: 82%. IR (cm^{-1}): 1529 (s), 1596 (m), 1618 (m), 1756 (s), 2979 (w). ^1H NMR (400 MHz, $CDCl_3$): ∂ 1.58 (s, 12H), 2.00 (s, 4H), 7.33 (d, 4H, $J = 9.2$ Hz), 8.20 (d, $J = 9.2$ Hz). ^{13}C NMR (100 MHz, $CDCl_3$): ∂ 25.8, 33.8, 86.0, 122.0, 125.1, 145.2, 150.4, 155.5. Calcd: $[M + Li]^+$ ($C_{22}H_{24}N_2O_{10}Li$) $m/z = 483.1591$. Found FAB-HRMS: $[M + Li]^+ = 483.1580$. Anal. Calcd: C, 55.46; H, 5.08; N, 5.88. Found: C, 55.79; H, 4.98; N, 5.77.

Synthesis of Compound 16. 2,2′-(Ethylenedioxy)bis(ethylamine) (1.00 g, 6.75 mmol) and pyridine (2.18 mL, 27.0 mmol) were dissolved in CH_2Cl_2 (250 mL); the reaction mixture was cooled to 0 °C and *p*-nitrophenyl chloroformate (5.44 g, 27.0 mmol) was added. The solution was warmed to RT while stirring for 24 h. The reaction mixture was then filtered and the solvent evaporated to afford a white solid. The crude product was dissolved in CH_2Cl_2 (150 mL) and washed with 1 M $NaHSO_4$ (3 × 30 mL). The organic layer was dried and the solvent was evaporated. The resulting solid was crystallized twice from CH_2Cl_2/hexanes providing **16** as a white solid in 68% yield. The ^1H NMR spectrum indicated that a 4:1 ratio of conformational isomers were present at RT. IR (cm^{-1}): 3329 (s), 1715 (s), 1539 (s). ^1H NMR (400 MHz, $CDCl_3$): ∂ 3.52 (dt, 3.2H, $J_1 = J_2 = 5$), 3.59 (dt, 0.8H, $J_1 = J_2 = 5$), 3.68 (t, 4H, $J = 5$), 3.71 (s, 4H), 5.68 (br, 1.6H), 5.90 (br, 0.2H), 6.35 (br, 0.2H), 7.30 (d, 4H, $J = 9$), 8.23 (d, 4H, $J = 9$). ^{13}C NMR (125 MHz, $CDCl_3$): ∂ 40.98, 69.54, 70.22, 121.88, 125.00, 144.60, 153.10, 155.77. FAB-MS *m/z*: $[M + H]^+$ 479. Anal. Calcd. for $C_{20}H_{22}N_4O_{10}$: C, 50.21; H, 4.64; N, 11.71. Found: C, 49.93; H, 4.59; N, 11.46.

Synthesis of Acid-Degradable Polyurethanes 17–21. Polymers **17**−**21** were synthesized according to the general procedure outlined below. Monomer **13** (1.962 mg, 4.68 mmol) was dissolved in dry CH_2Cl_2 (3 mL). Dry TEA (1 mL) was added to the solution. Compound **10** (759.8 mg, 4.68 mmol) dissolved in dry CH_2Cl_2 (3 mL) and dry TEA (1 mL) were mixed and the two solutions were combined and allowed to stir for 2 days while heated slightly. Over time the solutions became viscous indicating the formation of a polymer. The mixture was cooled to room temperature and the polymers were purified by dialysis against methanol containing 3% TEA using regenerated cellulose dialysis membranes with a nominal molecular weight cut off of 1500 Da.

Polymer 17. Yield: 50%. IR(cm^{-1}): 3334 (br), 1703 (s), 1536 (s), 1257 (s). ^1H NMR (400 MHz, DMSO-d_6): ∂ 1.23 (s, 6H), 3.06 (m, 4H), 3.34 (m, 4H), 3.51 (m, 8H), 4.02 (m, 4H), 7.16 (br, 2H). ^{13}C NMR (100 MHz, DMSO-d_6): ∂ 24.60, 40.55, 59.05, 63.07, 68.84, 69.65, 99.51, 156.19.

Polymer 18. Yield: 73%. IR(cm^{-1}): 3335 (br), 1707 (s), 1536 (s), 1257 (s), 1156 (s), 1057 (m). ^1H NMR (300 MHz, $CDCl_3$): ∂ 1.32 (s, 6H), 3.31 (m, 4H), 3.46 (t, 4H, $J = 5$), 3.68 (m, 8H), 5.34 (br, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): ∂ 25.01, 41.30, 60.03, 64.08, 69.71, 100.40, 156.62.

Polymer 19. Yield: 65%. IR(cm^{-1}): 3328 (br), 1707 (s), 1532 (s), 1253 (s), 1154 (s), 1060 (m). ^1H NMR (400 MHz, $CDCl_3$): ∂ 1.34 (s, 6H), 1.93 (br, 2H), 3.31 (br, 4H), 3.46 (br, 4H), 4.13 (b, 4H), 5.51 (br, ~2H). ^{13}C NMR (100 MHz, $CDCl_3$): ∂ 24.7, 28.6, 59.7, 61.3, 100.1, 156.5.

Polymer 20. Yield: 70%. IR(cm^{-1}): 3344 (br), 1709 (s), 1532 (s), 1253 (s), 1156 (s), 1064 (m). ^1H NMR (400 MHz $CDCl_3$): ∂ 0.97 (br, 3H), 1.34 (s, 6H), 2.12 (br, 1H), 3.32 (br, 4H), 3.47 (br, 4H), 4.00 (br, 4H), 5.43 (br, ~2H). ^{13}C NMR (100 MHz, $CDCl_3$): ∂ 13.7, 24.8, 33.0, 41.7, 59.8, 66.2, 100.2, 156.6.

Polymer 21. Yield: 63%. IR(cm^{-1}): 3349 (br), 1704 (s), 1520 (s), 1261 (s), 1159 (s), 1067 (m). ^1H NMR (400 MHz, $CDCl_3$): ∂ 1.34 (s, 6H), 1.42 (s, 12H), 1.79 (s, 4H), 3.27 (br, 4H), 3.46 (br, 4H), 5.11 (br, ~2H). ^{13}C NMR (100 MHz, $CDCl_3$): ∂ 24.9, 26.4, 35.1, 40.7, 60.0, 80.9, 100.2, 155.8.

Synthesis of Acid-Degradable Polyureas 22–23. Compound **10** (0.102 g, 0.63 mmol) was dissolved in CH_2Cl_2 (5 mL). Triethylamine (9 μL, 0.06 mmol) and aqueous buffer (5 mL, 30 mM phosphate, pH 8) were added and the mixture was stirred rapidly to form an emulsion. A solution of freshly distilled diisocyanate **6** or **7** (105 μL, 0.65 mmol) in CH_2Cl_2 (5 mL) was then added in one portion to the stirred emulsion, and stirring was continued at RT for 16 h. The precipitated polymer was filtered, washed with CH_2Cl_2, and dried *in vacuo*. The polymers were obtained with yields of 80–90%.

Polymer 22. $^1H-^{13}C$ HMQC NMR was utilized to distinguish between NH and Ar−H residues. IR (cm^{-1}): 3331 (br), 2934, (s), 1644 (s), 1554 (s). ^1H NMR (400 MHz, DMSO-d_6): ∂ 1.30 (s, 6H), 1.9–2.2 (s, 3H), 3.21 (br, 4H), 3.41 (br, 4H), 6.03 (br, 1H), 6.5–6.7 (br, 1H), 6.85–7.0 (br, 1H), 7.10 (br, 1H), 7.64 (br, 1H), 7.69 (br, 1H), 8.44 (br, 1H). ^{13}C NMR (125 MHz,

DMSO-d_6): ∂ 17.24, 24.76, 24.79, 39.76, 39.92, 59.98, 99.63, 110.27, 111.65, 119.43, 129.95, 138.07, 138.46, 155.22, 155.34.

Polymer 23. Polymer **23** was sparingly soluble in typical laboratory solvents, which precluded ^{13}C NMR and SEC analyses. IR (cm^{-1}): 3335 (br), 2934 (s), 1624 (s), 1585 (s). ^{1}H NMR (500 MHz, DMSO-d_6): ∂ 1.1–1.4 (br, 14H), 2.9–3.2 (br, 8H), 3.3–3.4 (overlaps with water peak), 5.8–6.0 (br, 2H), 6.0–6.2 (br, 2H).

Synthesis of Acid-Degradable Polyurea 24. Compound **10** (0.108 g, 0.67 mmol) and triethylamine (186 μL, 1.33 mmol) were dissolved in CH_2Cl_2 (1.3 mL). To this solution was added solid **16** (0.318 g, 0.67 mmol) in one portion. After stirring overnight, the viscous yellow solution was added to an excess of 1:1 isopropanol/hexanes to yield the product as a pale yellow solid in 66% yield. IR (cm^{-1}): 3346 (br), 2869 (br), 1632 (s). ^{1}H NMR (400 MHz, DMSO-d_6): ∂ 1.25 (s, 6H), 3.15–3.2 (m, 8H), 3.25–3.4 (m, 8H), 3.50 (s, 4H), 5.98 (t, 2H, $J = 5$), 6.05 (t, 2H, $J = 5$). ^{13}C NMR (100 MHz, DMSO-d_6): ∂ 25.17, 39.65, 40.09, 60.42, 70.03, 70.61, 99.85, 158.53.

Production of BSA-Loaded Microparticles. Microparticles were made using a double emulsion water/oil/water (w/o/w) evaporation method similar to that described by Bilati et al. (*19*). Briefly, 5 mg of FITC - bovine serum albumin (FITC-BSA) was dissolved in phosphate buffered saline (PBS) (50 μL). In a separate container 200 mg of polymer was dissolved in 1 mL of dichloromethane and added to the FITC-BSA solution. The solution was then sonicated for fifteen seconds on ice at 30W with a Branson Sonifier 450 resulting in the formation of the primary emulsion. This emulsion was then added into a 2 mL 3% PVA/PBS pH 8.0 aqueous solution. The w/o/w solution was sonicated again for thirty seconds on ice at 30W to form a double emulsion. This emulsion was immediately poured into a 10 mL 0.3 wt % PBS/PVA solution and vigorously stirred magnetically for 4 h allowing the organic solvent to evaporate. After evaporation, the particles were washed five times using Spectrum Laboratories, Inc. (Rancho Dominguez, CA) tangential flow filters (TFF) with a surface area of 11 cm^2 and a pore size of 0.05 μm. To stabilize the suspensions of the particles, a 10 wt % solution of glucose in water was added as a cryoprotectant. The suspension of particles was then frozen and lyophilized.

The FITC-BSA encapsulation efficiency was determined by incubating the particles in pH 5 PBS for 3 days at 50 °C and quantifying the fluorescence of the released protein.

Microparticle Characterization and Degradation Study. Microparticles were characterized by scanning electron microscopy (SEM) using a Hitachi (Tokyo, Japan) S-5000 microscope. Size distribution of the particles was determined by dynamic light scattering (DLS) using a Malvern Instruments Nano ZS (Worcestershire, United Kingdom). After lyophilization, the particles were washed five times using TFF, and then 10 μL were dripped onto a silicon wafer. After drying 15 min the particles were sputter coated with platinum.

Degradation profiles of the particles were obtained at pH 7.4 and pH 5.0 by monitoring the production of acetone in the degrading samples via ^{1}H NMR as described previously (*17*). Briefly, 25 mg of the particle suspensions were placed in an NMR tube and 0.7 mL of the corresponding deuteriated PBS buffer was added. Tubes were sealed, incubated at 37 °C and analyzed by ^{1}H NMR at different time points. The release of acetone was measured as a ratio of the acetone peak integral to the integral of the internal standard peak (3-(trimethyl silyl) propionic-2,2,3,3,d_4 sodium salt). To obtain the total release of acetone 10 μL of concentrated deuteriated HCl was added to the NMR tube and the solutions incubated overnight.

Acid-Mediated Protein Release. To study acid-mediated protein release FITC-BSA loaded particles of polymer **19** were incubated in pH 5.0 and pH 7.4 buffer. Stock solutions of microparticles were maintained at 37 °C. Aliquots of 100 μL were taken at specific time points, centrifuged and the fluorescence of the supernatant solution was measured using Fluorolog, Instruments S.A., Inc. Measurements were taken until the fluorescence reached a maximum and further incubation did not result in a fluorescence increase. Reported fluorescence data were normalized to the maximum fluorescence values.

Microparticle Uptake by Macrophages. RAW 309 cells were obtained from ATCC (Manassas, VA) and grown according to ATCC directions. Microparticle uptake was investigated by fluorescently activated cell sorting (FACS) analysis with a four color Becton Dickinson (Franklin Lakes, NJ) FACS Calibur. Particles with encapsulated FITC-BSA were incubated with 200 000 cells/mL for up to 24 h. Particle uptake was measured by the mean fluorescent intensity (MFI). For each experiment, data was normalized with respect to the 24 h particle uptake. Free protein was used as a control. Macrophages incubated with particles for 6 and 24 h were imaged using laser confocal micrscopy. Cells were seeded onto a Laboratory Tek plastic slide in a 4-well cell culture plate at initial seeding density of 10 000 cells per well. After incubation, cells were washed 3 times with PBS buffer and fixed with 4% paraformaldehyde and their cytoskeleton was stained with Alexa Fluor 546 conjugated phalloidin. Vectashield mounting medium was added and the slides were sealed with Cytoseal-60. The prepared samples were then imaged on a LSM510 Meta laser confocal microscope (Carl Zeiss MicroImaging, Inc.).

Particle Cytotoxicity Studies. Particles were incubated with 10 000 RAW macrophages for 24 h. After 24 h particles were washed away with medium and cells were incubated in medium overnight. Cell viability was measured the following day with Promega's (Madison, Wisconsin) CellTiter 96AQ_{ueous}One Solution Cell Proliferation Assay MTS per the manufacturer's instructions. Cell viability was normalized to cells that were cultured without particles.

Degradation Byproducts. In order to show full degradation of the bulk polymer, the three different polymers were incubated with a 95% CD_3OD and 5% concentrated DCl in D_2O overnight. SEC was run on the different degraded polymers (Supporting Information, Figure 1) and their traces were compared to those of nondegraded polymer **19**. After incubating under the acidic conditions the polymers fully degraded into small molecules. In addition, a similar experiment was performed using deuteriated PBS buffer (pH 5.0) in order to assess the degradation of microparticles made of polymer **19** and **20**.

Degradation Byproducts Cytotoxicity. Polymer **19** was incubated in pH 5 buffer at 37 °C for three days. The resultant degraded material was then lyophilized and the toxicity of the degraded material was tested as described above for the particles.

Degradation Product of Polymer 19 (5% HCl in methanol). ^{1}H NMR (400 MHz, CD_3OD): ∂ 1.98 (t, 2H, $J = 4$ Hz), 3.25 (t, 4H, $J = 4$ Hz), 3.63 (t, 4H, $J = 4$ Hz), 4.14 (t, 4H, $J = 4$ Hz). ^{13}C NMR (100 MHz, CD_3OD): ∂ 28.4, 42.6, 60.5, 61.7, 157.9. Calcd: $[M + H]^+$ ($C_9H_{18}N_2O_6$) $m/z = 251$. Found LRMS: $[M + H]^+ = 251$.

Degradation Product of Polymer 19 (deuteriated PBS, pH 5.0). ^{1}H NMR (400 MHz, D_2O): ∂ 1.98 (t, 2H, $J = 4$ Hz), 3.21 (t, 4H, $J = 6$ Hz), 3.58 (t, 4H, $J = 6$ Hz), 4.10 (m, 4H). Calcd: $[M + H]^+$ ($C_9H_{18}N_2O_6$) $m/z = 251$. Found LRMS: $[M + H]^+ = 251$.

Degradation Product of Polymer 20 (5% HCl in methanol). ^{1}H NMR (400 MHz, CD_3OD): ∂ 0.97 (d, 3H, $J = 8$ Hz), 2.11 (m, 1H), 3.21 (t, 4H, $J = 4$ Hz), 3.57 (t, 4H, $J = 4$ Hz), 3.98 (d, 4H, $J = 8$ Hz). ^{13}C NMR (100 MHz, CD_3OD): ∂ 12.6, 33.1, 42.8, 60.5, 66.01, 157.8. Calcd: $[M + H]^+$ ($C_{10}H_{20}N_2O_6$) $m/z = 265$. Found LRMS: $[M + H]^+ = 265$.

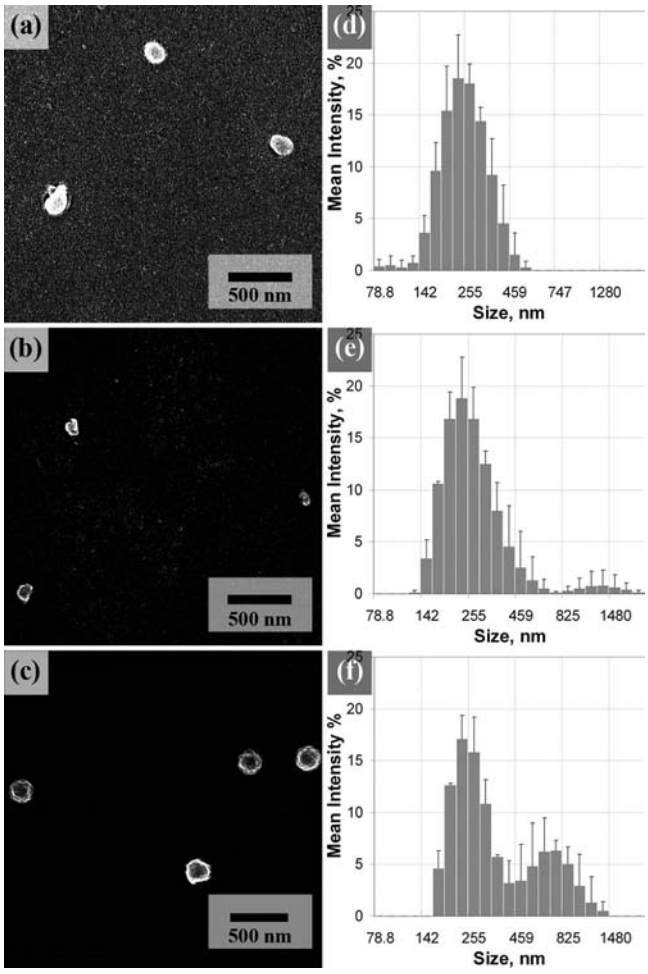

Figure 2. (a−c) SEM images of particles made from polymers **19**, **20**, and **21**; (d−f) particle size distribution as measured by dynamic light scattering (DLS). The particles obtained are individual particles several hundred nanometers in size, suitable for uptake by phagocytic cells.

Degradation Product of Polymer 20 (deuteriated PBS, pH 5.0). ^{1}H NMR (400 MHz, D_2O): ∂ 0.96 (d, 3H, $J = 7$ Hz), 2.18 (m, 1H), 3.25 (t, 4H, $J = 5$ Hz), 3.62 (t, 4H, $J = 5$ Hz), 4.03 (d, 4H, $J = 7$ Hz). Calcd: $[M + H]^+$ ($C_{10}H_{20}N_2O_6$) $m/z = 265$. Found LRMS: $[M + H]^+ = 265$.

Degradation Product of Polymer 21 (5% HCl in methanol). Spectroscopic characterization revealed a mixture of small molecule degradation products with the highest molecular mass of 339 as observed by mass spectrometric analysis.

RESULTS AND DISCUSSION

Design and Synthesis of Acid-Degradable Polymers. *Monomer Synthesis.* In order to prepare a library of acid-degradable polymers, several functional monomers were first synthesized. The key acid-degradable component was dimethyl ketal monomer **10**, which contains two amino groups for reaction with bis-electrophilic species. A similar dimethyl ketal we developed previously had a hydrolysis half-life of 6.8 h at pH 7.4, but its degradation half-life was only 1.5 min at pH 5.0, demonstrating its pH-dependent degradation kinetics (*20*).

Acid-degradable diamine **10** was synthesized in two steps (Figure 1b) following a modified literature procedure (*21*). Protected diamine **9** was prepared first by reacting N-(2-hydroxyethyl)-phthalimide with 2-methoxypropene. After 1 h of stirring at 0 °C the methanol byproduct was removed from the system by azeotropic distillation with benzene to shift the equilibrium toward product formation. Compound **9** was then deprotected under strongly basic conditions to afford acid-degradable monomer **10** in high yield.

Table 1. SEC data of Polymers 17−24[a]

	GPC			microparticle	protein loading,
polymer	M_n, kDa	M_w, kDa	PDI	size, nm	wt %
17	22	33	1.8	n/a	n/a
18	20	28	1.4	n/a	n/a
19	15	22	1.6	237±3	1.5
20	33	41	1.3	241±2	1.3
21	11	18	1.7	295±1	1.6
22	42	84	2.0	n/a	n/a
23		not soluble		n/a	n/a
24	17	40	2.4	n/a	n/a

[a] Average microparticle size is given as measured by dynamic light scattering.

Polyurethane synthesis required the activation of diols **1**−**5** using *p*-nitrophenyl chloroformate (Figure 1b) which afforded monomers **11**−**15** in good yields. Polyureas **22**, **23**, and **24** were synthesized using monomer **10** and either commercially available diisocyanates **6** and **7** or diisiocyanate derivative **16**, which was synthesized in one step as shown in Figure 1b.

Synthesis of Acid-Degradable Polymers. Five different polyurethanes **17**−**21** and one polyurea **24** were synthesized via the step-growth polymerization of acid-degradable monomer **10** and one of the six monomers **11**−**16** (Figure 1c). To prevent any deleterious acid-catalyzed hydrolysis, triethylamine was added to the polymerization reaction mixtures as well as to the methanol solution used during dialysis of the polymers (polymer **24** was isolated by precipitation from hexanes/isopropanol). To increase the molecular weight and yields of the polymers, the reaction mixtures were kept at elevated temperature, which increases the solubility of monomers and reduces the viscosity of the solution of growing polymer chains. Polyurethanes **22** and **23** were formed by interfacial polymerization of acid-degradable diamine **10** and monomers **6** and **7**, similar to a procedure reported elsewhere (*22*). The solution of diamine **10** at pH 8 was added to a rapidly stirred solution of the diisocyanate monomer **6** or **7** in dichloromethane which resulted in the precipitation of the polymers. The molecular weights and polydispersity index values (PDIs) shown in Table 1 are typical of polymers synthesized through such step-growth polymerizations (*23*).

Polymers **17**−**24** were designed with a flexible strategy whereby the key property of acid lability was provided by monomer **10** while the second monomer was tailored to control the hydrophobicity of the final polymer and hence its ability to be used in our water/oil/water double emulsion process to afford usable microparticles. Hydrophobicity is a key parameter that affects the solubility of the polymer in water, its degradation kinetics, and its ability to form stable microparticles. While more hydrophobic polymers require longer times to degrade (*24*), more hydrophilic ones may fail to form stable microparticles in aqueous solutions. Some of the polymers we prepared contained hydrophilic ethylene oxide units (**17**, **18**, **24**) whereas others contained hydrophobic aliphatic and aromatic chains of various lengths (**19**−**23**). The prepared polymers were designed to have different hydrophobicities and their ability to form acid-degradable microparticles was evaluated.

Polyureas **22**−**24** were found to be difficult to dissolve in water and were not easily dissolved in organic solvents. Unlike polyureas, polyurethanes **17**−**21** were easily dissolved in polar organic solvents such as DMSO and dichloromethane. Hydrophobic polyurethanes **19**−**21** were not soluble in water whereas more hydrophilic polymers **17** and **18** were slightly soluble. The difference in the solubility between polyurethanes and polyureas likely results from the stronger tendency of polyureas to associate via formation of interchain hydrogen bonds reducing

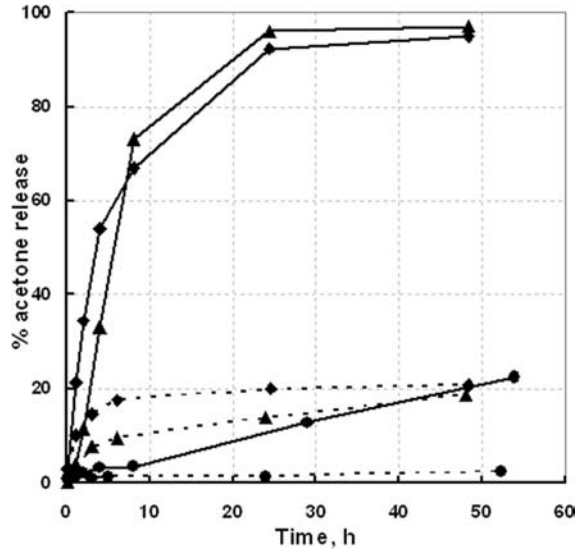

Figure 3. Degradation profiles of microparticles composed of polymers **19** (diamonds), **20** (triangles), and **21** (circles) as measured by release of acetone. Solid lines for degradation profiles at pH 5.0 and dotted lines for pH 7.4. Polymer **19** demonstrates the fastest degradation at pH 5. Polymer **21** shows the slowest degradation rate at the same pH due to its high hydrophobicity.

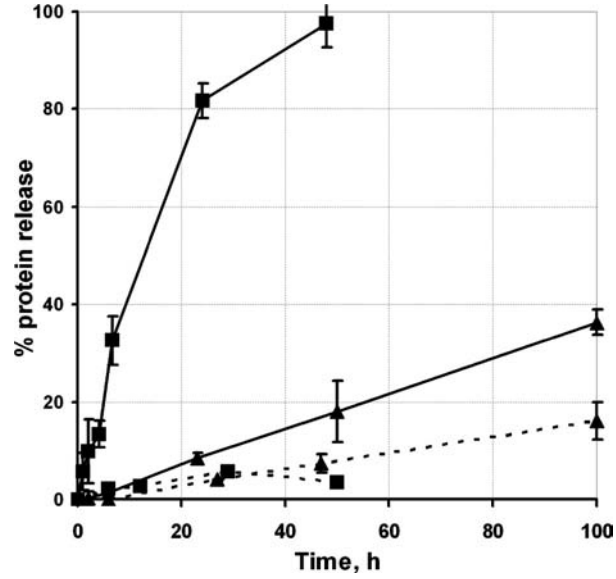

Figure 4. Acid mediated release of FITC-BSA from protein loaded microparticles of polymer **19** (squares) and**21** (triangles) at pH 5.0 (solid) and pH 7.4 (dashed). Release occurs much faster at acidic pH and the measured half-life is in good agreement with the half-life of polymer shell degradation measured in the acetone release experiment of Figure 3. Polymer **19** microparticles release the protein significantly faster than the polymer **21** microparticles.

the interactions of the polymer chains with water molecules. The solubility of the polymers in different solvents greatly affects their ability to form microparticles. For example the formation of microparticles from polyureas **22**−**24** proved to be very challenging due to their low solubility in dichloromethane. In contrast, polyurethanes **19**−**21** could be used to form stable microparticles while hydrophilic polyurethanes **17** and **18** produced unstable emulsions, most likely due to their excessive solubility in water.

Based on the ability to form microparticles, polyurethanes **19–21** were selected for further in depth studies, which included microparticle characterization by SEM and DLS, study of their pH sensitive degradation kinetics as well as model drug delivery studies *in vitro*.

Microparticle Preparation and Characterization. Microparticles were prepared using a double emulsion technique (*19*). A primary emulsion was formed by sonication of a solution of polyurethanes **19**−**21** in dichloromethane with an aqueous phase that contained FITC labeled bovine serum albumin (FITC-BSA). This emulsion was introduced into a second aqueous phase containing polyvinyl alcohol as an emulsion stabilizer. After rapidly stirring the emulsion for four hours the microparticles were isolated using tangential flow filtration (TFF) (*25*). Microparticles required the addition of a cryoprotectant to reduce their aggregation upon lyophilization and storage. It has been shown previously, that lyophilization can result in particle aggregation and that the addition of carbohydrates such as glucose, sucrose, or trehalose can help prevent this aggregation (*26*). Screening of several cryoprotectants showed that glucose was the most effective cryoprotectant to prevent aggregation of our microparticles prior to lyophilization. Particle yields after lyophilization ranged from 77 to 82% based on the polymer used, while protein loading efficiency ranged from 48 to 68% based on the starting mass of protein.

The microparticles were characterized by SEM and DLS (Figure 2a−f). In order to obtain satisfactory SEM images, microparticles were purified by removal of the cryoprotectant using TFF prior to sample preparation and were deposited onto silicon wafers at very dilute concentrations. According to SEM and DLS data, the prepared microparticles had average sizes of 230–300 nm (Figure 2, Table 1), which is a size range suitable for their uptake by phagocytic cells and for the passive targeting of macrophages and dendritic cells for *in vitro* and *in vivo* applications (*27–29*).

Acid-Mediated Microparticle Degradation. Microparticle degradation was studied at physiological pH (7.4) as well as lysosomal pH (5.0) (Figure 3). The degradation of the microparticles was monitored by ^{1}H NMR. Specifically, the appearance of acetone, the byproduct of acetal degradation, was measured over several days. All of the particles we synthesized degraded faster at pH 5.0 than at pH 7.4 while the degradation half-life of microparticles at pH 5.0 was highly dependent on the hydrophobicity of the starting polyurethane. Microparticles made from polyurethane **19**, the least hydrophobic polymer, had a degradation half-life of 3.4 h at pH 5.0 whereas microparticles made from polyurethane **20**, with an intermediate hydrophobicity, had a half-life of 5.9 h. Microparticles prepared with the most hydrophobic polyurethane **21** had the slowest rate of degradation with a half-life of more than 80 h under the conditions used for the measurement. Such a dependence of rate of degradation on the hydrophobicity of the polymer is no doubt related to the accessibility of the microparticle surface to hydronium ions. More hydrophobic surfaces are less accessible to hydronium ions and require longer times to fully degrade.

The varying degradation profiles of the prepared microparticles could be advantageous for a variety of applications in drug delivery that require different time frames for the release of a therapeutic agent. Moreover, using similar chemistry, a more extensive library of polyacetal polymers could be generated wherein the half-life of the polymer would be tuned by simply adjusting the hydrophobicity of the diol monomer or the acetal-containing monomer used in the polymerization.

As microparticles prepared from polyurethane **19** had the shortest degradation half-life, they were also characterized in terms of acid-mediated protein release with monitoring by fluorescence at both the physiological pH of 7.4 and at the lysosomal pH of 5.0 (Figure 4). As anticipated, protein release occurred much faster at acidic pH with more than 90% of the protein released after 40 h. The kinetics of protein release was similar to the kinetics of particle degradation with half-lives on

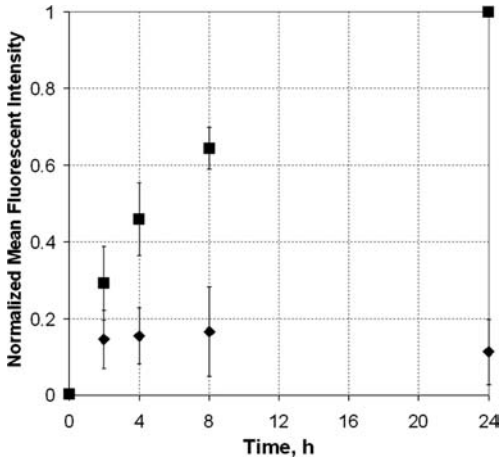

Figure 5. Normalized mean fluorescence intensity of macrophages incubated with FITC-BSA (solid diamonds) and FITC-BSA loaded microparticles (solid squares) at various time points as measured by flow cytometry. Incubation of cells with protein loaded microparticles results in a 10-fold increase in protein uptake after 24 h compared to free FITC-BSA.

the order of several hours (Figure 3). In contrast, microparticles prepared from polymer **21**, the slowest degrading polymer released the protein at a much slower rate than particles made from polymer **19** (Figure 4). Release of the protein from these microparticles occurred in an expected pH dependent manner with significantly faster release taking place at acidic pH (5.0). Due to their suitable polymer degradation profile and fast protein release kinetics polyurethane **19** microparticles were selected for use in subsequent *in vitro* experiments.

Microparticle Uptake by Macrophages. To show microparticle uptake in phagocytic cells, a murine macrophage cell line, RAW 309, was incubated with FITC-BSA containing microparticles for different time periods. Incubation with free FITC-BSA was used as a control experiment. Uptake of the protein was quantitatively measured by flow cytometry. The mean fluorescent intensity (MFI) of cells incubated for 2, 4, 8, and 24 h with microparticles is shown in Figure 5. In each experiment, the data was normalized to the fluorescence of the cell population that was incubated with microparticles for 24 h. Experimental data at each time point show that the macrophages took up statistically more FITC-BSA encapsulated in microparticles compared to free FITC-BSA only. After 24 h the microparticles encapsulating FITC-BSA showed a 10-fold higher uptake compared to the free protein control. These data are consistent with the findings of Solbrig et al. (*30*), who used double emulsion particles to increase the uptake of protein in bone marrow derived dendritic cells. More efficient uptake of the acid-degradable microparticles by phagocytic cells may lead to enhanced delivery of antigens to antigen presenting cells, such as macrophages or dendritic cells.

Uptake of the microparticles was also visualized directly by laser confocal microscopy. Macrophages were incubated with BSA loaded particles for 6 and 24 h. After the incubation period, cells were thoroughly washed with PBS buffer and their cytoskeleton was stained with Alexa Fluor 546 conjugated phalloidin. Figure 6 shows confocal microscopy images of macrophages incubated for 6 h (a−c) and 24 h (d−f). After 24 h the fluorescence in (d) appears more diffuse than observed in (a) and we speculate that this is related to the breakdown of the acid-degradable microparticles.

To study the toxicity of the particles, macrophages were incubated with varying concentrations of microparticles for 24 h. As seen in Figure 7, cell viability does not change significantly over the range of concentrations studied. Even at the highest concentration of microparticles we tested (1 mg/mL), the viability of the macrophages is similar to the untreated cells. Overall the toxicity of the microparticles appears to be comparable to that of the widely used poly(lactic-*co*-glycolic acid) (PLGA) (*32*). The negligible cytotoxicity of the particles is a favorable element when considering their further use in studies conducted both *in vitro* and *in vivo*.

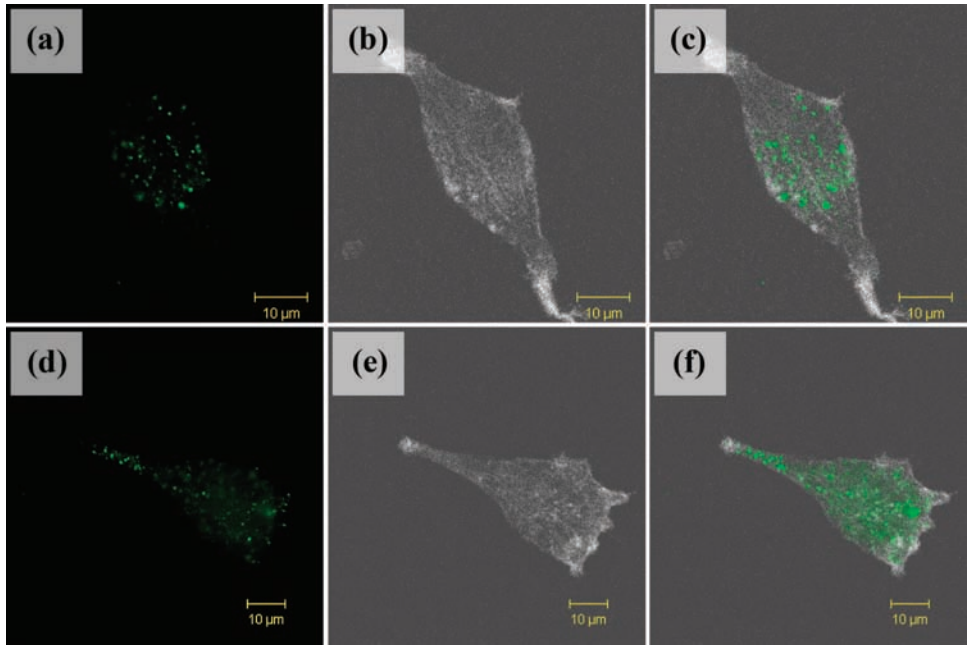

Figure 6. (a−c) Confocal microscopy image of a macrophage incubated with particles containing FITC-BSA for 6 h. (a) FITC-BSA; (b) F-Actin stained with Alexa Fluoro 546 conjugated phalloidin; (c) combined image of (a) and (b). (d−f) Confocal microscopy image of a macrophage incubated with particles containing FITC-BSA for 24 h. (d) FITC-BSA; (e) F-Actin stained with Alexa Fluoro 546 conjugated phalloidin; (f) combined image of (d) and (e). Fluorescence images (a) and (d) clearly demonstrate the uptake of the particles by microphages. FITC-induced fluorescence (d) appears to be more diffuse after 24 h likely due to the degradation of the particles in the lysosomes with concomitant release of FITC-BSA into the cytoplasm.

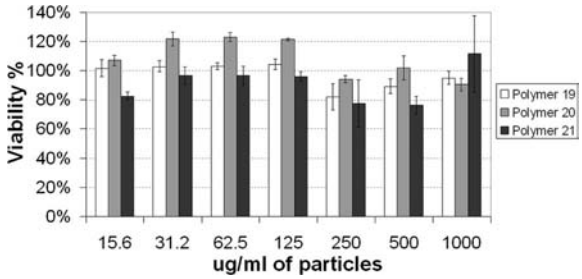

Figure 7. Toxicity of particles measured by incubation with macrophages for 24 h. The viability of cells incubated with particles was normalized to cells cultured without particles.

Degradation Products. As a preliminary step in the evaluation of the potential cytotoxicity of the newly synthesized polymers we explored whether or not large polymer fragments remain after degradation, as was the case with some of the earlier systems we have studied (*31*). Thus, the three polyurethanes **19**−**21** were degraded in the presence of deuteriated HCl and their degradation products were studied by NMR and mass spectrometry. In all cases the degradation products were low molecular weight products as expected from the acid catalyzed hydrolysis of the acetal moieties in the polymer backbone (Figure 1e). NMR spectra of the degradation products as well as mass spectrometry data and size exclusion chromatography (SEC) traces (Supporting Information, Figure 1) did not reveal the presence of residual high molecular weight polymers, which was supportive of complete degradation. Similar degradation experiments were performed for the faster degrading polymers **19** and **20** in deuteriated pH 5.0 PBS buffer to elucidate whether high molecular weight polymer fragments remained after the degradation in biologically relevant environments. NMR and mass-spectrometry data of the degradation products corresponded to expected low molecular weight byproduct confirming full degradation in the mildly acidic conditions. The absence of residual high molecular weight compounds should enable the fast elimination of byproduct from the body. In addition, we have found that the fully degraded byproducts of polymer **19** had no toxic effects on macrophages grown in culture (Supporting Information, Figure 2). These findings in which no significant toxicity is found for either the FITC-BSA loaded microparticles themselves (Figure 7) or their degradation products is encouraging as we prepare for testing of their use in formulated immunotherapeutic agents.

CONCLUSIONS

We have designed and synthesized a new class of fully acid-degradable polymers that degrade quickly in the mildly acidic environments similar to those found in endosomes and tumor tissues, but are more stable at the physiological pH of 7.4. The ease of preparation and the ability to tune polymer characteristics such as solubility and acid-sensitivity, identify this new class of polymers as promising materials for drug delivery. By screening a library of synthesized acid-degradable polymers we identified several polymers that possessed the necessary physical characteristics to form acid-degradable microparticles that can be dried to stable and redispersible powders when used with glucose as a cryoprotectant. A study of the hydrolysis of selected microparticles indicated that their degradation was complete leaving behind no high molecular weight byproduct. The particles were taken up by macrophages *in vitro* as confirmed by flow cytometry and confocal microscopy and facilitated a 10-fold increase in protein uptake compared to protein alone. The microparticles themselves were not toxic in the range of concentrations studied. In general, these acid-sensitive fully degradable polymers and corresponding microparticles may find use in the delivery of various therapeutic agent or vaccines (*11*, *33*), which makes them attractive targets for a number of medicinal targets.

Application of an HIV gp41-Derived Peptide for Enhanced Intracellular Trafficking of Synthetic Gene and siRNA Delivery Vehicles

Ester J. Kwon, Jamie M. Bergen, and Suzie H. Pun*

Department of Bioengineering, University of Washington, 1705 NE Pacific Street, Seattle, Washington 98195. Received December 5, 2007; Revised Manuscript Received January 25, 2008

Endosomal release is an efficiency-limiting step for many nonviral gene delivery vehicles. In this work, nonviral gene delivery vehicles were modified with a membrane-lytic peptide taken from the endodomain of HIV gp41. Peptide was covalently linked to polyethylenimine (PEI) and the peptide-modified polymer was complexed with DNA. The resulting nanoparticles were shown to have similar physicochemical properties as complexes formed with unmodified PEI. The gp41-derived peptide demonstrated significant lytic activity both as free peptide and when conjugated to PEI. Significant increases in transgene expression were achieved in HeLa cells when compared to unmodified polyplexes at low polymer to DNA ratios. Additionally, peptide-modified polyplexes mediated significantly enhanced siRNA delivery compared to unmodified polyplexes. Despite increases in transgene expression and siRNA knockdown, there was no increase in internalization or binding of modified carriers as determined by flow cytometry. The hypothesis that the gp41-derived peptide increases the endosomal escape of vehicles is supported by confocal microscopy imaging of DNA distributions in transfected cells. This work demonstrates the use of a lytic peptide for improved trafficking of nonviral gene delivery vehicles.

INTRODUCTION

The development of safe and efficient gene delivery vehicles is necessary for clinical gene therapy. Synthetic vehicles offer potential advantages over viral-based vectors including safety and low immunogenicity, but transfection efficiencies from many of these systems remain suboptimal (*1, 2*). An effective nucleic acid delivery vehicle must mediate either cytoplasmic or nuclear delivery, depending on its therapeutic agent. Upon internalization, the majority of carriers accumulate within endocytic vesicles (*3*). Efficient release from these vehicles before lysosomal degradation has been shown to be a major barrier for many of these systems. Thus, it would be advantageous to develop methods to improve the endosomal release of new and existing vectors for future applications of nonviral gene delivery.

Polyethylenimine (PEI) has been used widely as a nonviral vector and is among the most efficient of cationic polymer delivery vehicles (*4*). The efficacies of PEI and other protonatable cationic polymers as gene delivery agents has been attributed to their buffering properties, which have been hypothesized to mediate endosomal escape via the proton sponge mechanism (*5, 6*). In brief, pH-sensitive polymers buffer endosomes during the natural acidification process, resulting in counterion and water accumulation in the vesicles, eventually leading to osmolysis. However, the buffering capacity of PEI is correlated to the amount of PEI that is present (*6, 7*). Purification of free PEI from polyplexes after formulation results in polyplexes with only a slight charge excess of PEI. These polyplexes are much less efficient at mediating gene transfer than unpurified polyplexes (*8, 9*). This has implications for *in vivo* delivery where unassociated polymer can be separated from DNA before endocytosis occurs. The development of agents that have more potent endosomal escape properties is therefore desirable.

In an effort to develop more potent mediators of endosomal escape, research has looked to nature for inspiration. Peptides taken from the membrane-disrupting domains of proteins, such as melittin (*10*−*12*), Tat (*13*−*15*), and hemagglutinin (*16, 17*), have been incorporated into nonviral gene delivery vectors, as reviewed elsewhere (*18, 19*). In this paper, we report the application of a peptide from the endodomain of HIV gp41 envelope glycoprotein found to have lytic properties from a peptide screen recently reported in the literature (*20*). This sequence of HIV gp41, corresponding to residues 783−806 of gp160, has been shown to have high membrane association and the potential to form multimers (*21*). Peptides from this region of gp41 have been shown to adopt amphipathic α-helical structures and have the potential to form pores in membranes (*22, 23*). The goal of this work was to evaluate the lytic peptide from the endodomain of HIV gp41, HGP, as a mediator of enhanced intracellular trafficking of nonviral gene delivery vehicles. Our results demonstrate that modification of PEI with HGP increases transgene expression and siRNA knockdown, likely by increasing the efficiency of endosomal release.

METHODS

Synthesis of HGP-Modified PEI. C-terminal cysteine-terminated HGP peptide (LLGRRGWEVLKYWWNLLQY-WSQELC) was synthesized and HPLC purified by GenScript Corporation (Piscataway, NJ). Branched PEI with molecular weight 25 000 (Sigma, St. Louis, MO) was modified with succinimidyl 4-[*p*-maleimidophenyl]butyrate (SMPB) purchased from Pierce (Rockford, IL) at a molar excess of 5 according to manufacturer's protocol. SMPB-modified PEI was purified using a PD-10 column (GE Healthcare, Piscataway, NJ) and lyophilized. For peptide conjugation, SMPB-modified PEI was dissolved in DMF and reacted with 5 equiv HGP peptide in the presence of triethylamine (TEA) for 72 h. Unreacted peptide and TEA were removed by dialysis against a MWCO 10 000 membrane (Pierce) with water over 3 days. PEI concentration was determined by monitoring cuprammonium complexes formed by PEI and copper (II) acetate at 630 nm as described

10.1021/bc700448h CCC: $40.75 © 2008 American Chemical Society
Published on Web 04/01/2008

previously (*24*). HGP conjugation efficiency was determined by quantifying absorbance at 280 nm using UV/vis spectrophotometry.

Polyplex Formulation and Physicochemical Characterization. Polyplexes, complexes of polycations with nucleic acids, were formulated by adding equal volumes of polymer to nucleic acid at the desired charge ratio. The charge ratio is calculated on the basis of molar amount of polymer nitrogen to nucleic acid phosphate (N/P) ratio. Polyplexes were allowed to incubate for 10 min at room temperature to allow for complexation.

Complexation of DNA was monitored by agarose gel electrophoresis. Polyplexes were loaded on a 0.8% agarose gel containing 0.3 μg/mL ethidium bromide. Hydrodynamic size was measured in triplicate using a ZetaPALS zeta potential and particle size analyzer (Brookhaven Instruments Corp., Holtsville, NY) as described previously (*25*).

Dye Release Assay. Liposomes composed of L-α-phosphotidylcholine and cholesterol (Avanti Polar Lipids, Alabaster, AL) encapsulating 50 mM sulforhodamine B (Invitrogen, Carlsbad, CA) were prepared by extrusion through 100 nm polycarbonate membranes (Whatman, Florham Park, NJ) using the Avanti Mini-Extruder. Unencapsulated sulforhodamine B was removed by dialysis into 10 mM Tris pH 7.4, 20 mM NaCl, 0.1 mM EDTA.

Liposome lysis was monitored by dequenching of sulforhodamine B fluorescence upon release from liposomes. Fluorescence intensity was monitored using a Tecan Safire^2 microplate reader (Tecan Systems, Inc., San Jose, CA) by excitation at 565 nm and reading emission at 586 nm. Dye release was calculated as a percentage according to the equation

$$\% \text{ dye release} = \frac{F_m - F_0}{F_{100} - F_0} \times 100 \quad (1)$$

where F_m is the fluorescence value after 15 min of incubation with peptide or polyplex at 37 °C, F_0 is the fluorescence value of the initial liposome suspension, and F_{100} is the fluorescence value after incubation with a 0.05% Triton X-100 solution.

Cell Culture. HeLa cells purchased from ATCC (Manassas, VA) were cultured in complete growth medium (minimum essential medium with 10% fetal bovine serum and antibiotics). Cells were passaged every 2−3 days.

Plasmid Delivery to HeLa Cells, Evaluation of Transfection Efficiencies, and Cytotoxicity Assay. Transfection experiments were performed in triplicate. HeLa cells suspended in complete growth medium were seeded at 30 000 cells/well in 24-well plates and allowed to attach overnight. Polyplexes were formulated as described above using 1 μg of gWiz-Luciferase plasmid DNA (Aldevron, Fargo, ND) and then diluted in OptiMEM medium (Invitrogen). Cells were rinsed once with phosphate buffered saline, pH 7.4 (PBS), and incubated with polyplexes for 4 h at 37 °C in a 5% CO_2 atmosphere. Cells were rinsed with PBS and medium was replaced with fresh complete growth medium. Cells were returned to a 37 °C, 5% CO_2 atmosphere and luciferase expression was quantified after 48 h using a luciferase assay kit (Promega Corp., Madison, WI). Cells were washed with PBS, lysed with 200 μL of reagent lysis buffer (Promega Corp.), and frozen at −20 °C. 100 μL of luciferase substrate was added to 20 μL of lysate and luminescence was measured using a TECAN Safire^2 microplate reader. Luminescence was integrated for 1 s and recorded in relative light units (RLU). Luciferase activity is reported in luminescence normalized by protein content (RLU/mg), as measured by a BCA Protein Assay Kit (Pierce). Cytotoxity was measured by incubating polymer or polyplexes with HeLa cells as described above and adding the reagent 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium (MTS) (Promega Corp.) after 24 h. Cells were incubated in a 37 °C, 5% CO_2 atmosphere for 4 h and absorbance measurements of lysate at 490 nm were recorded.

siRNA Delivery to HeLa Cells and Expression Analysis by Quantitative PCR and GAPDH Activity Assay. siRNA targeting endogenous glyceraldehyde-3-phosphate dehydrogenase (siGAPDH) was purchased from Ambion (Silencer GAPDH siRNA; Austin, TX), and control siRNA targeting green fluorescent protein (siGFP) was synthesized by Dharmacon (Lafayette, CO) with the following sequence: 5′-GACGUAAACGGCCACAAGUUC-3′ (sense) and 5′-ACUUGUGGCCGUUUACGUCGC-3′ (antisense). HeLa cells were seeded on a 24-well plate as described for the plasmid transfection studies. For transfection, polyplexes were formulated by condensing either siGAPDH or siGFP with either PEI or PEI-HGP at an N/P ratio of 10 (60 pmol siRNA/well, triplicate samples). Polyplexes were diluted in 400 μL OptiMEM and incubated with cells for 5 h, after which the polyplex solution was removed and replaced with complete growth medium. 48 h after transfection, total RNA was isolated using an RNeasy Mini Kit (Qiagen, Valencia, CA). 500 ng of RNA from each sample was reverse-transcribed using Omniscript RT (Qiagen) and random hexamers as primers (Operon, Huntsville, AB). Quantitative PCR was performed using a model 7300 Real Time PCR system (Applied Biosystems, Foster City, CA) following universal thermal cycling parameters. GAPDH expression levels were determined in 20 μL reactions using TaqMan Universal PCR Master Mix (Applied Biosystems) and a TaqMan gene expression assay for human GAPDH, and were normalized by expression levels for β-actin (TaqMan gene expression assay for human ACTB). Relative GAPDH expression levels for each sample were determined on the basis of a comparison with untreated control samples, and were calculated by the $2^{-\Delta\Delta CT}$ method (*26*). To measure GAPDH activity, an identical transfection experiment was performed, and cell lysate was collected 48 h after transfection. GAPDH activity was measured in the lysate using the fluorescence-based KDalert GAPDH Assay Kit (Ambion). For each formulation, the degree of reduction in GAPDH activity mediated by siGAPDH was assessed by comparing GAPDH activity levels in siGAPDH- versus siGFP-treated samples.

Internalization and Binding Studies. Uptake and binding of PEI-HGP polyplexes relative to PEI polyplexes was investigated by flow cytometry. Nitro-2,1,3-benzoxadiazol-4-yl (NBD)-labeled oligonucleotides were prepared as described previously (*27*). HeLa cells were seeded at 300 000 cells/well in 6-well plates and allowed to attach overnight. One hour before transfection, cells were washed with PBS, supplemented with Gibco OptiMEM medium, and then equilibrated to either 37 or 4 °C. Polyplexes were formulated at an N/P ratio of 3 as described above using 4 μg of NBD-labeled oligo. Polyplex solution was added to cells and allowed to incubate for 3 h at either 37 or 4 °C. Cells were then washed twice with cold PBS, trypsinized, and resuspended in complete growth medium. Cell-associated fluorescence was quantified by flow cytometry using a BD FACScan (BD Biosciences, Franklin Lakes, NJ). Live cell populations were identified using forward and side-scattering profiles, and polyplex uptake was assessed by NBD fluorescence using *FlowJo* flow cytometry analysis software. Cell association was reported as mean fluorescence in relative fluorescence units (RFU).

Confocal Imaging. Confocal imaging was performed to determine the intracellular distribution of polyplexes. gWiz-Luciferase plasmid DNA was labeled with TOTO-3 (Invitrogen, Eugene, OR) at 1 dye per 100 base pairs and dialyzed into 10 mM Tris pH 7.4, 1 mM EDTA overnight at 4 °C. Glass coverslips were precoated with poly(L-lysine) in a 24-well plate

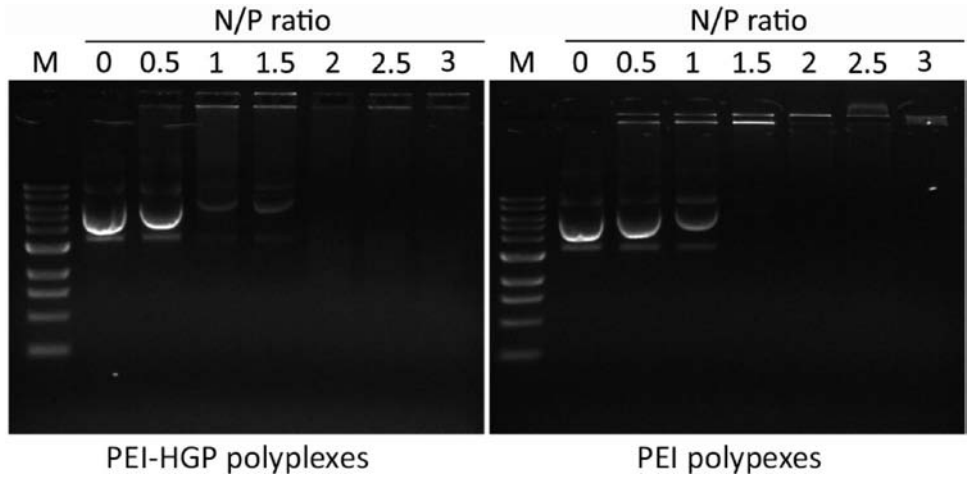

Figure 1. Gel retardation assay to monitor DNA complexation in PEI-HGP and PEI polyplexes at various N/P ratios. M: New England Biolabs 1kb ladder.

and HeLa cells were seeded at 75 000 cells/well in complete medium. 3 μg of TOTO-3 labeled DNA was complexed with PEI or PEI-HGP at N/P ratio 3 as described above and added to cells with 2 mg/mL Alexa Fluor 488-labeled dextran (MW 10 000, Invitrogen) for 1 or 3 h in a 37 °C, 5% CO_2 environment. Cells were then washed with PBS and Cell Scrub Buffer (Gene Therapy Systems, San Diego, CA), and then fixed for 7 min in 4% paraformaldehyde. Coverglasses were mounted onto a coverslip with Fluoromount-G (Southern Biotech, Birmingham, AL) and imaged with a Zeiss LSM 510 confocal microscope.

Chloroquine-Mediated Transfection Studies. HeLa cells were seeded at 120 000 cells/well in 6-well plates and allowed to attach overnight. Polyplexes were formulated at an N/P ratio of 3 as described above using 4 μg of pEGFP-C1 (Clontech Laboratories, Inc., Mountain View, CA) plasmid DNA that codes for the enhanced green fluorescent protein (EGFP) reporter. Polyplex was diluted in OptiMEM and added to cells. A 5 mM chloroquine stock solution was diluted to a final concentration of 0.1 mM and cells were allowed to incubate for 4 h in a 37 °C, 5% CO_2 atmosphere. Cells were rinsed with PBS and incubated for an additional 48 h in complete growth medium. Cells were imaged by brightfield and fluorescence microscopy. Transgene expression was quantified by EGFP fluorescence using flow cytometry as described above. EGFP expression is reported as the percent of EGFP positive cells.

Tail-Vein Injection. Female C57/Bl6 mice were purchased from Jackson Laboratory (Bar Harbor, ME). Polyplexes were formulated with 50 μg gWiz Luciferase plasmid DNA in 250 μL of 20 mM HEPES pH 7.4, 5% glucose. Polyplexes were delivered via tail-vein injections in 12−16 week old mice and lung tissue was excised 24 h after injection. Lungs were collected in reagent lysis buffer (Promega) supplemented with protease inhibitors (Roche) and underwent three freeze−thaw cycles. Tissue was mechanically homogenized using an IKA T8 Disperser (Wilmington, NC) and cell debris was spun down at 14 000 *g* for 15 min at 4 °C. Luciferase activity and protein content were measured as described above.

RESULTS

Synthesis of PEI-HGP and Polyplex Characterization. Moreno et al. recently screened 15 amino acid sequences from the HIV surface glycoprotein, gp41, in order to identify regions in the protein that interact with membranes. The sequence of HGP was chosen on the basis of its ability to mediate membrane rupture and is from the C-terminal tail region of HIV gp41 designated as the lentivirus peptide sequences (LLP-2/3) (*20*).

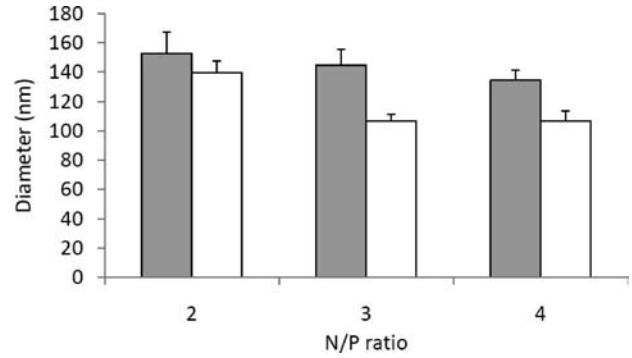

Figure 2. Hydrodynamic size of PEI-HGP (gray bars) and PEI (white bars) polyplexes were measured at N/P ratios 2, 3, and 4 using dynamic light scattering. Triplicate formulations were characterized at each charge ratio. Results are reported as mean diameter ± SD.

PEI-HGP was synthesized by conjugating a cysteine-terminated HGP to PEI with the heterobifunctional cross-linker SMPB. The concentration of peptide was determined by absorbance measurements at 280 nm and labeling efficiency was found to be 2−3 HGP per PEI on average.

Polyplexes with plasmid DNA were formed by addition of an equal volume of polymer to DNA followed by rapid mixing and incubation at room temperature for 10 min. Complex formation was examined by agarose gel electrophoresis (Figure 1). Uncomplexed DNA migrates into the gel, whereas complexed DNA is occluded and retained in the loading well. Uncomplexed gWiz-Luciferase plasmid is shown in lanes marked as N/P ratio 0. For both PEI and PEI-HGP, DNA is fully complexed at N/P ratio of 2. Therefore, HGP conjugation does not interfere with complex formation. This is expected, as the percentage of modification is low.

Hydrodynamic sizes of PEI and PEI-HGP polyplexes were measured using dynamic light scattering (DLS) in triplicate samples (Figure 2). For N/P ratios 2, 3, and 4, sizes of PEI-HGP polyplexes were 153 ± 14.7 nm, 144.8 ± 10.6 nm, and 134.4 ± 7.1 nm, respectively. Sizes of PEI polyplexes were 139.7 ± 7.7 nm, 106.7 ± 4.9 nm, and 107.0 ± 6.7 nm. PEI-HGP polyplexes are slightly larger in size.

Lytic Activity of HGP. The lytic activity of free HGP peptide and PEI-HGP polyplexes was determined by monitoring the release of sulforhodamine B dye from liposomes after incubation for 15 min at various peptide concentrations (*28*). Figure 3A shows that HGP displayed concentration-dependent lytic activity when incubated with liposomes. At a concentration of 0.63 μM,

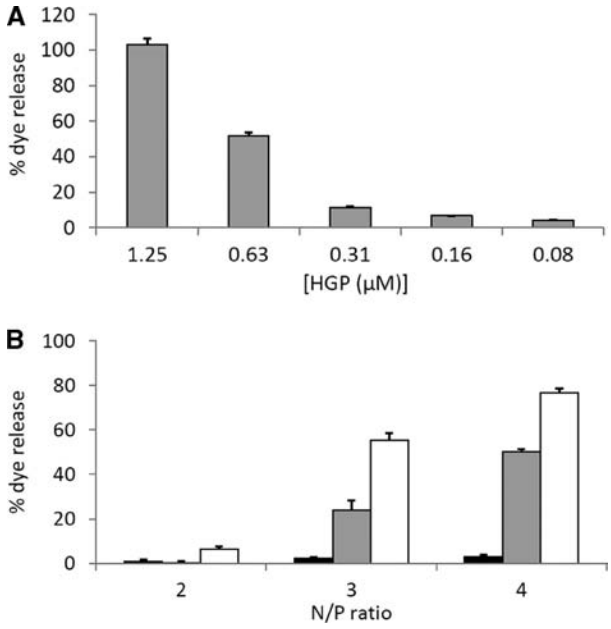

Figure 3. (A) Lytic activity of HGP was tested as free peptide using a fluorescence-based, liposomal leakage assay. (B) Lytic activities of HGP peptide (black bars), PEI polyplexes (gray bars), and PEI-HGP polyplexes (white bars) were compared. 100% dye release corresponded to fluorescence levels of liposomes treated with Triton X-100 surfactant for complete lysis. Results are reported as mean % dye release ± SD for triplicate samples.

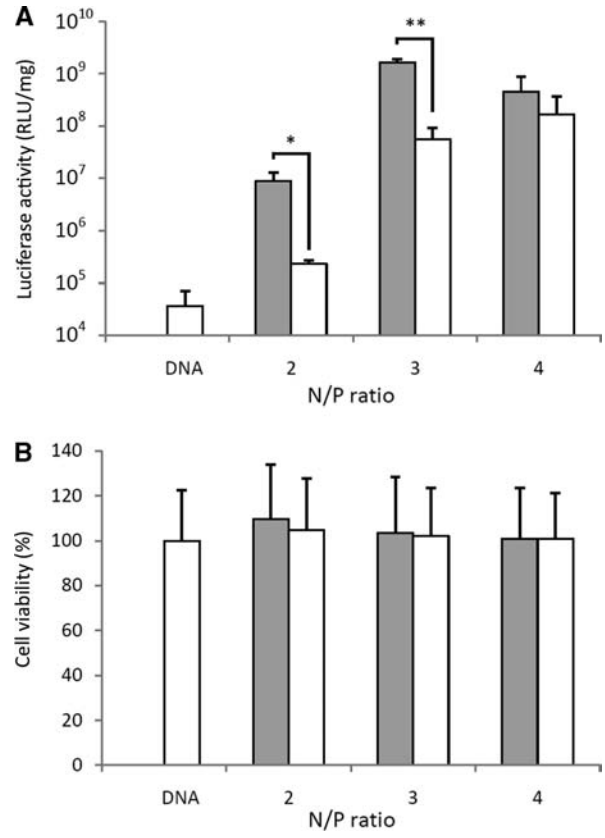

Figure 4. (A) Luciferase activity of PEI-HGP (gray bars) and PEI polyplexes (white bars) were compared in HeLa cells at N/P ratios 2, 3, and 4. (B) Cell viability of HeLa cells after transfection with PEI-HGP (gray bars) and PEI (white bars) polyplexes at N/P ratios 2, 3, and 4 as measured by MTS. Results are reported as mean RLU/mg ± SD for triplicate samples. (Student's *t*-test, $*p < 0.05$, $**p < 0.001$).

HGP was able to mediate approximately 50% dye release. The lytic activities of PEI and PEI-HGP polyplexes formulated at various N/P ratios were also evaluated (Figure 3B). The lytic activity of the equivalent amount of HGP incorporated in the PEI-HGP polyplexes was also determined for comparison. The concentrations of HGP peptide present in polyplex formulations of N/P ratios of 2, 3, and 4 were 0.13 μM, 0.19 μM, and 0.26 μM, respectively. Free peptides at these concentrations resulted in dye release percentages of 1.0%, 2.2%, and 3.0%. The dye release percentages for N/P ratios 2, 3, and 4 were 0.5%, 4.4%, and 50.3% for PEI and 6.5%, 55.3%, and 76.6% for PEI-HGP.

Evaluation of PEI-HGP for Plasmid DNA Delivery. Transfection efficiency of PEI and PEI-HGP polyplexes in HeLa cells as a function of N/P ratio was determined using the luciferase reporter gene system. PEI-HGP polyplexes showed increased expression profiles over unmodified polyplexes at N/P ratios of 2 and 3 (Figure 4A). At an N/P ratio of 2, transgene expression from PEI-HGP polyplexes ($8.9 \times 10^6 \pm 3.8 \times 10^6$ RLU/mg) was 38-fold higher than PEI polyplexes ($2.3 \times 10^5 \pm 4.0 \times 10^4$ RLU/mg) with a significance value of $p < 0.05$. At an N/P ratio of 3, transgene expression from PEI-HGP polyplexes ($1.7 \times 10^9 \pm 2.3 \times 10^8$ RLU/mg) was 30-fold higher than PEI polyplexes ($5.5 \times 10^7 \pm 3.7 \times 10^7$ RLU/mg) with a significance value of $p < 0.001$. At an N/P ratio of 4, transgene expression between PEI-HGP polyplexes ($4.5 \times 10^8 \pm 4.3 \times 10^8$ RLU/mg) was not statistically different than PEI polyplexes ($1.7 \times 10^8 \pm 2.0 \times 10^8$ RLU/mg). Increases in transfection efficiency at N/P ratios of 2 and 3 were confirmed in several separate experiments.

Cellular viability after transfection with PEI and PEI-HGP polyplexes was determined using an MTS assay and compared to untreated cells (Figure 4B). No toxicity was observed with these materials at N/P ratios 2, 3, and 4. At charge ratios greater than an N/P ratio of 15, the PEI-HGP polyplexes were more toxic than PEI polyplexes (data not shown).

Evaluation of PEI-HGP as an siRNA Carrier. The ability of HGP to enhance PEI-mediated siRNA delivery was evaluated in HeLa cells using siRNA targeting the endogenous GAPDH gene. While both PEI and PEI-HGP incorporating siGAPDH mediated significant GAPDH knockdown compared to identical polymer formulations incorporating siGFP, PEI-HGP was responsible for a significant enhancement in specific GAPDH knockdown activity compared to unmodified PEI ($53.4 \pm 2.2\%$ reduction in GAPDH expression for PEI vs $82.3 \pm 1.6\%$ reduction for PEI-HGP, $p < 0.001$) (Figure 5). In a similar experiment, cell lysates were collected and analyzed for GAPDH protein activity. Compared to the corresponding siGFP control, PEI/siGAPDH reduced GAPDH activity by $24.9 \pm 9.5\%$, while PEI-HGP/siGAPDH reduced GAPDH activity by $57.0 \pm 8.4\%$.

Binding and Internalization of PEI-HGP Polyplexes. Cellular binding and uptake of NBD-labeled PEI and PEI-HGP polyplexes was investigated using flow cytometry (Figure 6). Fluorescently labeled polyplexes were incubated with HeLa cells at 4 °C (for binding) and 37 °C (for binding and uptake) for three hours before analysis. At 4 °C, association of PEI polyplexes was greater than PEI-HGP polyplexes ($p < 0.005$). At 37 °C, there was no significant difference in total associated fluorescence between PEI and PEI-HGP polyplexes.

Confocal Imaging. In order to determine the intracellular distribution of carriers, PEI and PEI-HGP polyplexes containing TOTO-3-labeled plasmid DNA were incubated with cells for either 1 or 3 h, fixed, and imaged using confocal microscopy. Endosomes were labeled with Alexa488-dextran, a fluid-phase uptake marker. At 1 h, both PEI and PEI-hgp polyplexes exhibited punctate staining (data not shown). When PEI polyplexes were delivered for 3 h, DNA exhibited punctate intracellular staining that was colocalized with dextran (Figure

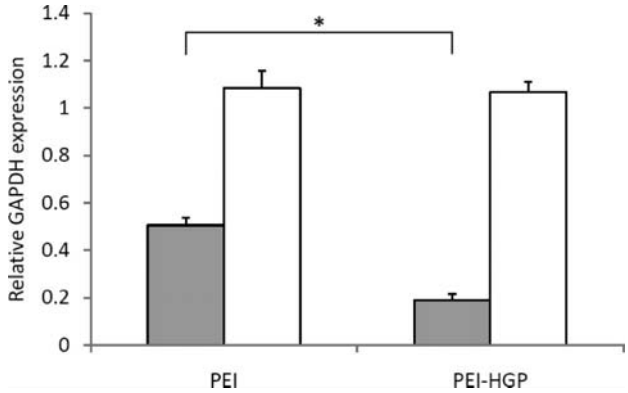

Figure 5. Quantification of GAPDH mRNA levels in HeLa cells following treatment with PEI or PEI-HGP polyplexes incorporating siRNA. Cells were transfected with polyplexes incorporating either siRNA against GAPDH (siGAPDH, gray bars) or siRNA against GFP (siGFP, white bars) as a negative control (N/P = 10). Total RNA was isolated 48 h after transfection, and relative GAPDH expression levels were measured by quantitative PCR. Values are normalized to an untreated control sample and are reported as the mean relative GAPDH expression ± SD for triplicate samples. (Student's *t* test, $*p < 0.001$).

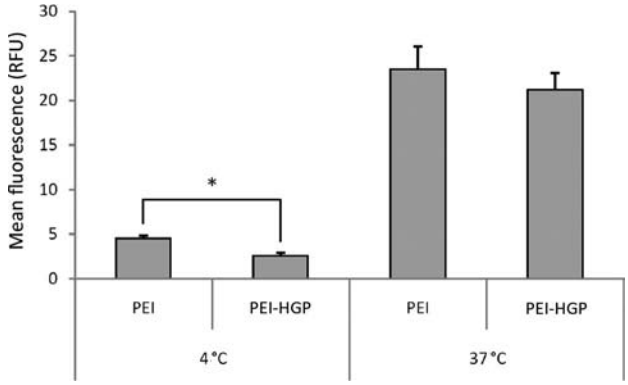

Figure 6. Binding and internalization of fluorescently labeled PEI and PEI-HGP polyplexes in HeLa cells. Cells were treated with polyplexes formulated at an N/P ratio 3 for 3 h at 4 °C (binding studies) and 37 °C (internalization studies) and analyzed by flow cytometry. Results are reported as mean fluorescence ± SD for triplicate samples. (Student's *t*-test, $*p < 0.005$).

7A). There were few examples of dextran staining that were not colocalized with DNA. When PEI-HGP polyplexes were delivered for 3 h, both punctate and diffuse DNA staining were observed (Figure 7B). Incidences of punctate DNA were colocalized with dextran, although there were examples of endocytic vesicles that were not colocalized with DNA. A substantial fraction (~30%) of cells had diffuse DNA fluorescence throughout the cells (white arrows).

Chloroquine-Mediated Transfection. In order to investigate the effects of HGP as a mediator of endosomal escape, PEI and PEI-HGP polyplex transfections were performed in the presence of chloroquine. Chloroquine is a small molecule buffering agent used to mediate endosomal escape of gene delivery vehicles (*29*−*31*). Polyplex transfections to HeLa cells were conducted in the presence of 100 μM chloroquine using an enhanced green fluorescent protein (EGFP) reporter gene. The percent of EGFP positive cells was measured by flow cytometry (Figure 8A). The percentage of EGFP positive cells after PEI-HGP transfection (20.1% ± 1.8%) was increased 16.1-fold when compared to PEI transfection (1.3% ± 0.3%, $p < 0.001$). Chloroquine increased the percentage of EGFP positive cells for both PEI and PEI-HGP; PEI transfection was increased 11.7-fold in the presence of chloroquine (14.6% ± 4.0%, $p < 0.01$), and PEI-HGP transfection was increased 3.8-fold in the presence of chloroquine (76.8% ± 3.7%, $p < 0.001$). Results from flow cytometry were verified by fluorescence microscopy (Figure 8B).

DISCUSSION

Escape from endocytic vesicles after internalization is necessary for efficient intracellular trafficking of nonviral gene therapy vehicles. For polyplex delivery, several strategies have been implemented to overcome this challenge, including pH-sensitive polymers (*32*), endosomal buffering polymers (*5*, *33*), and photosensitive systems (*34*). Membrane-interacting peptides, both natural and synthetic, have been utilized in gene delivery carriers (*15*, *35*, *36*). The use of these peptides has been shown to increase the efficiencies of delivery vehicles; however, delivery efficiencies from nonviral vectors remain suboptimal for most clinical gene therapy applications.

In this work, a lytic peptide was conjugated to a polymeric gene carrier and evaluated for its effect on gene and siRNA delivery. In a screen of HIV gp41 to identify peptides with potent lytic activity, the sequence of HGP was demonstrated to be the most lytic (*20*). Gp41, together with gp120, forms the monomer unit of the trimer HIV Env, the protein responsible for viral fusion of HIV. The sequence of HGP is from the lentiviral lytic peptide (LLP) domains 2 and 3 of the gp41 cytoplasmic tail. Another delivery system, MPG, is derived from the fusion domain of HIV gp41 and was shown to deliver oligonucleotides into the cytosol of 90% of cells in an endocytic independent pathway (*37*). However, peptides from the LLP regions of gp41 have not to our knowledge been applied in gene delivery systems.

In initial studies, the HGP peptide was compared with a recently identified peptide from adenovirus for relative lytic ability (*28*). A 10-fold higher concentration of peptide from adenovirus was needed to mediate 50% liposome disruption when compared to HGP (data not shown). Thus, we hypothesized that HGP may mediate efficient endosomal rupture at low peptide concentrations when incorporated in polycation delivery vectors.

PEI-HGP was synthesized by SMPB conjugation, and complete packaging of DNA at N/P ratio of 2 was confirmed by agarose gel electrophoresis. The same N/P ratio was needed to complex DNA with unmodified PEI (Figure 1), indicating that the ability for PEI to complex DNA is retained with peptide conjugation. This was expected, as the percentage of modified amines is very low (<0.5%). PEI-HGP polyplexes formed slightly larger polyplexes compared to PEI polyplexes (Figure 2). The difference in particle sizes of PEI-HGP polyplexes compared to PEI polyplexes is likely due to steric hindrance of peptides interfering with DNA complexation. Because polyplexes were of similar size, differences in transfection efficiencies between PEI-HGP and PEI polyplexes were most likely due to differences in the activity of HGP and not physical differences between polyplexes.

PEI and PEI-HGP polyplexes showed lytic activity that was dependent on the N/P ratio of formulation (Figure 3B). PEI-HGP polyplexes formulated at N/P ratios of 2, 3, and 4 used in the membrane lysis assay correspond to HGP concentrations of 0.13 μM, 0.19 μM, and 0.26 μM, respectively. PEI-HGP polyplexes showed increases in lytic activity over PEI polyplexes for each N/P ratio tested. The observed increase in lytic ability was much higher than what would be expected on the basis of the presence of HGP; free HGP at these low concentrations have minimal lytic activity (Figure 3A). The higher leakage values of PEI-HGP polyplexes when compared with HGP peptide at matched peptide concentrations may instead be attributed to increased local concentration of peptide tethered

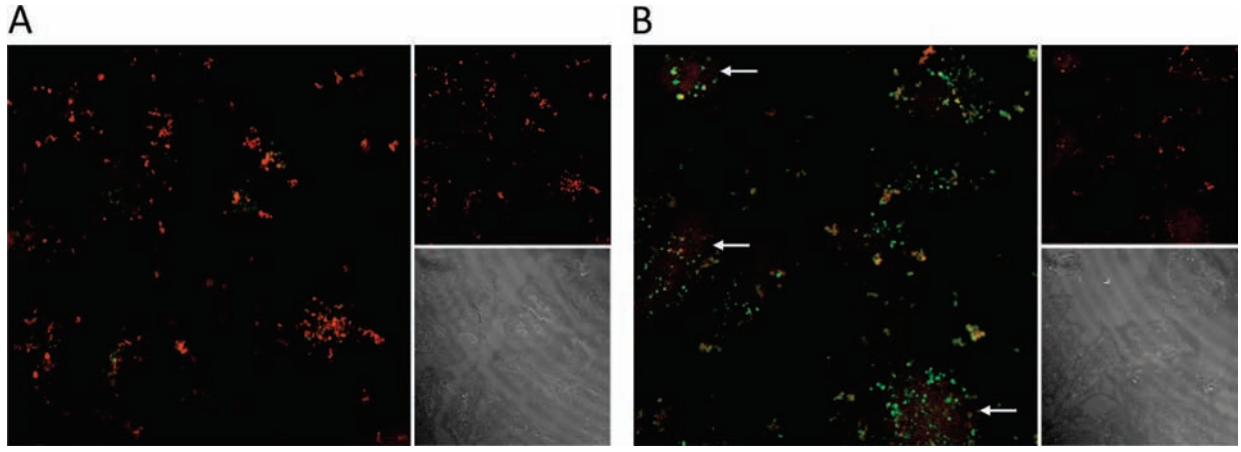

Figure 7. Confocal microscopy of HeLa cells incubated with PEI (A) and PEI-HGP (B) condensed TOTO-3 labeled gWiz-Luciferase DNA at N/P ratio 3. Vesicles are labeled with Alexa Fluor 488-labeled 10 000 Mw dextran. DNA/dextran (left panel), DNA (top right panel), and differential interference contrast (bottom right) images are shown. Arrows show cells exhibiting diffuse DNA fluorescence.

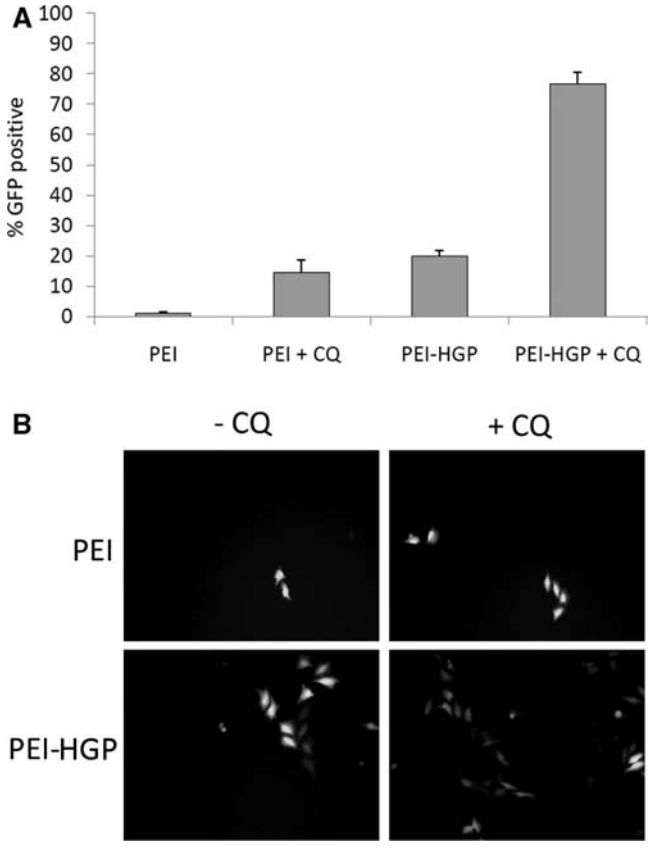

Figure 8. (A) Percentage of GFP positive HeLa cells after PEI or PEI-HGP polyplex transfection with and without chloroquine (CQ) with analysis by flow cytometry. (B) Fluorescence microscopy of representative EGFP-transfected cells.

to the polyplex surface. During membrane fusion, HIV gp41 has been shown to adopt a six-helix bundle configuration (*38*) and the endodomain of HIV gp41 has shown high potential to form multimers (*21*).

PEI-HGP was shown to be significantly more efficient than unmodified PEI for delivery of plasmids at low charge ratios (Figure 4A). Because polymer concentration (N/P ratio) also affects transfection efficiency, the polymer concentrations were carefully matched for PEI and PEI-HGP formulations by quantification of polymer concentration using copper (II) acetate and by gel retardation assay, which confirmed complete DNA condensation at similar charge ratios between the two formulations. At higher charge ratios, the difference between PEI-HGP and PEI transfection efficiency for plasmids is less significant, perhaps because the uncomplexed PEI polymer also exhibits membrane disruption ability (data not shown). Interestingly, siRNA delivery efficiency is enhanced by HGP at polymer charge ratios of 10 N/P, suggesting that the uncomplexed PEI polymer and HGP may act synergistically to increase siRNA availability in the cytoplasm (Figure 5).

In order to elucidate the mechanism for HGP-mediated increase in transfection, the efficiencies of polyplex binding, internalization, and endosomal release were investigated. The most likely route for the entry of PEI-HGP polyplexes is through endocytosis, which has been shown to be true for other endosomolytic peptide-modified delivery vehicles (*39*, *40*). Cellular internalization and binding was examined at 4 and 37 °C using flow cytometry (Figure 6). At 4 °C, a temperature at which endocytosis is inhibited (*41*), there is less cell-associated NBD fluorescence of PEI-HGP polyplexes than PEI polyplexes, indicating that there is less binding affinity of PEI-HGP polyplexes to the cellular membrane. Similar cell-associated NBD fluorescence of PEI-HGP polyplexes and PEI polyplexes at 37 °C suggests that the uptake efficiencies of PEI-HGP and PEI polyplexes are similar. Thus, the increase in transfection efficiency of PEI-HGP polyplexes is likely not due to more efficient uptake.

Confocal imaging is a technique that has been utilized to determine the intracellular distribution of nanoparticulate carriers (*3*). Cells incubated with PEI polyplexes showed punctate plasmid DNA staining that largely colocalized with endosomes, indicating that polyplexes were most likely trapped within endosomes (Figure 7A). Cells incubated with PEI-HGP polyplexes showed both punctate and diffuse plasmid DNA staining, which is markedly different than the staining observed with PEI polyplexes and indicative of endosomal release of vectors (Figure 7B). Increases in transgene expression mediated by HGP may therefore be explained by changes in intracellular trafficking, most likely escape from endocytic vesicles, since HGP modification of vehicles does not significantly alter uptake.

The HGP peptide is derived from the LLP-2 and -3 domains of gp41, which have previously been demonstrated to disrupt lipid membranes (*22*). These peptide regions have been shown to have amphipathic α-helical structure and are proposed to mediate membrane disruption by either spanning the membrane to form ion channels or by lying along the membrane surface (*22*). Formation of ion channels by viruses, called "viroporins", is a well-studied mechanism for membrane disruption based on a similar osmolytic mechanism to that proposed for PEI (*5*, *42*).

However, unlike PEI, membrane disruption by viroporins is not necessarily pH-sensitive. This raises the intriguing possibility that HGP may not only mediate enhanced endosomal release when coupled to PEI but may also change the release kinetics by relying on a critical peptide concentration in the endosomes instead of proton accumulation during endosomal maturation.

To further understand the intracellular trafficking pathway of PEI-HGP polyplexes, transfection studies were done in the presence of chloroquine. Chloroquine is a small molecule that is widely used to increase the transfection efficiency of gene delivery vehicles due to its ability to buffer endocytic compartments (*31*). In addition, chloroquine has been proposed to have auxiliary functions such as increasing the unpackaging of nucleic acids from their carriers and altering intracellular processing by changing the physical and biological characteristics of the released nucleic acids (*31*). When PEI and PEI-HGP polyplexes were coincubated with chloroquine, the transgene expression of both formulations was increased. These results indicate that HGP may be inadequate for complete release of carriers from endocytic vesicles or that the added increase in gene expression is due to the auxiliary functions of chloroquine. The observation that chloroquine increases the transgene expression of PEI-HGP polyplexes formulated at N/P ratio of 3 to greater than 75% of cells also implies that the vector can be further optimized to yield high transfection efficiencies. In addition, confocal microscopy images demonstrating the endosomal escape of PEI-HGP are supported by the observation that the effect of chloroquine on transgene expression is three times greater for PEI polyplexes over PEI-HGP polyplexes (Figure 7). Furthermore, the diffuse DNA staining observed in PEI-HGP transfected cells is also observed when PEI transfection was done in the presence of chloroquine (Supporting Information).

Pulmonary gene therapy has important applications such as cystic fibrosis and lung cancer. PEI has been one of the most effective cationic polymeric carriers used in lung gene therapy (*43*). When 50 μg of gWiz-Luciferase DNA condensed with PEI-HGP was injected into the tail vein of mice, statistically significant higher expression was found in the lung ($\sim$3-fold higher) compared to PEI (data not shown).

For the application of gene delivery *in vivo*, it is of particular importance to develop particles that can be efficient at low polymer to DNA ratios. PEI polyplex delivery has been shown to be quite efficient when there is excess PEI present; however, the removal of excess polymer results in polyplexes with N/P ratios between 2 and 3 (*8*). This has implications for *in vivo* delivery, as free polymer can be separated from complexes in the body. An additional benefit of achieving efficient transgene expression at low polymer to DNA ratios is improved cell viability, as increasing amounts of PEI can cause significant toxicity (*44*). We were therefore interested in increasing transgene expression at these low N/P ratios.

In conclusion, a lytic peptide conjugated to the cationic polymer PEI was able to significantly enhance plasmid delivery efficiency over unmodified PEI at N/P ratios of 2 and 3 in cultured cells and in the lung tissue of mice. In addition, PEI-HGP efficiently delivered siRNA to cultured cells. Investigation into the mechanism of HGP indicated that increases in delivery efficiency were not due to increases in uptake. Studies employing the small molecule chloroquine and confocal microscopy supported the hypothesis that increased transfection efficiency was most likely due to endosomal escape. The chloroquine-mediated increase of PEI-HGP polyplex transgene expression indicated that vehicle properties can be further optimized, perhaps by engineering materials that improve vector unpackaging or cytosolic trafficking. This work is applicable for the development of nonviral delivery vehicles that are biologically active for efficient nucleic acid transfer *in vivo*.

ACKNOWLEDGMENT

The authors thank Leonard Meuse for his assistance with tail-vein injections in *in vivo* transfection studies. This work was funded by the National Science Foundation (CBET 0448547), NIH/NINDS (5R21NS052030), and the National Hemophilia Foundation. Flow cytometry was conducted at the Cell Analysis Facility at the Immunology Department of the University of Washington. Confocal imaging was conducted at the Nanotech User Facility at the University of Washington. The Nanotech User Facility is a member of the National Nanotechnology Infrastructure Network (NNIN) which is supported by the National Science Foundation and the Center for Nanotechnology at the University of Washington.

Institute of Radiopharmacy, Forschungszentrum Dresden-Rossendorf, Germany, ICIS−CNR, Corso Stati Uniti, 4, Padova, Italy, and NOXXON Pharma AG, Berlin, Germany. Received December 10, 2007; Revised Manuscript Received February 7, 2008

A mirror-image oligonucleotide (L-RNA) was radiolabeled with the positron emitting radionuclide ^{86}Y ($t_{1/2}$ = 14.7 h) via the bifunctional chelator approach. DOTA-modification of the L-RNA (sequence: 5′-aminohexyl UGA CUG ACU GAC-3′; MW 3975) was performed using (*S*)-*p*-SCN-Bn-DOTA. ^{86}Y radiolabeling of the DOTA-L-RNA produced more than one species as evidenced by HPLC radiometric detection. For the identification of the ^{86}Y-labeled L-RNA, the structural analogue nonradioactive precursor [Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ was synthesized. Two coordination isomers were separated via HPLC adopting the square antiprismatic (SAP) and the twisted square antiprismatic (TSAP) geometry, respectively. Their stereochemical configuration in the solution state was assessed by NMR and circular dichroism spectroscopy. Both [Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ isomers were converted into isothiocyanate derivatives [Y((*S*)-*p*-SCN-Bn-DOTA)]$^-$ and conjugated to the L-RNA. The identity of the [^{86}Y-DOTA]-L-RNA species was finally established by comparison of the radiometric (^{86}Y) and UV–visible chromatographic profiles. Biodistribution studies in Wistar rats showed minor changes in the biodistribution profile of the [^{86}Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ complex isomers, while no significant differences were observed for the [^{86}Y-DOTA]-L-RNA isomers. High renal excretions were found for the [^{86}Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ complex isomers as well as for the L-RNA isomers.

INTRODUCTION

The radiolabeling of oligonucleotides with radiometals (e.g. ^{68}Ga, ^{111}In, ^{99m}Tc, ^{86}Y) for *in vivo* imaging studies is usually performed via the bifunctional chelator (BFC)[1] approach (*1–4*). BFCs should form highly stable complexes with the radiometal while enabling facile conjugation of the radiometal complex to the biomolecule under mild conditions. A frequently utilized chelator for trivalent metals, such as In^{3+}, Ga^{3+}, Y^{3+}, and other ions of the lanthanide and actinide series, is 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA). DOTA is known to form thermodynamically stable complexes with lanthanides and yttrium isotopes, and the corresponding radiometal complex show in many cases high kinetic inertness *in vivo* (*5*). Examples of various DOTA derivatives used as BFCs are shown in Figure 1. The reactive functionality capable of being linked to the biomolecule can be introduced into the DOTA framework either at the ethylene bridge or via a chemical activation of a free carboxylic acid sidearm of DOTA.

The positron-emitting radionuclide ^{86}Y ($t_{1/2}$ = 14.7 h, β^+ = 33%, E_{avg} = 664 keV) is an attractive isotope for molecular imaging purposes. The extensive use of the high-energy electron-emitter ^{90}Y ($t_{1/2}$ = 64.06 h, β^- = 72%, $E_{\beta-}$ = 2.288 MeV), an excellent radionuclide for endoradiotherapy, makes the positron emitter ^{86}Y an ideal radionuclide for dosimetry assessment of ^{90}Y-labeled radiotherapeutics (*6*). ^{86}Y can be prepared on a small biomedical cyclotron employing the ^{86}Sr(p,n)^{86}Y nuclear reaction (*7*). The 14.7 h half-life of ^{86}Y allows PET studies of up to two days.

In the past decade, synthetic oligonucleotides have been suggested as molecular probes for the improved targeting of cancer using pretargeting methods (*8*, *9*). In this connection, Hnatowich and co-workers have previously shown that complementary phosphorodiamidate morpholino oligomers (MORF/cMORF) are useful molecular recognition systems for targeting prostate tumor in nude mice in combination with a monoclonal antibody (*10*). Another promising class of synthetic oligonucleotides consists of mirror-image oligonucleotides (L-ON) (*11*). L-ON are constructed of an L-configured ribose or deoxyribose. As shown previously, L-ON display an extraordinary high metabolic stability in the biological environment due to the high resistance to enzymatic degradation (*12*). To explore the potential of complementary L-ON as recognition systems for pretargeting, the present work deals with basic radiopharmaceutical chemistry

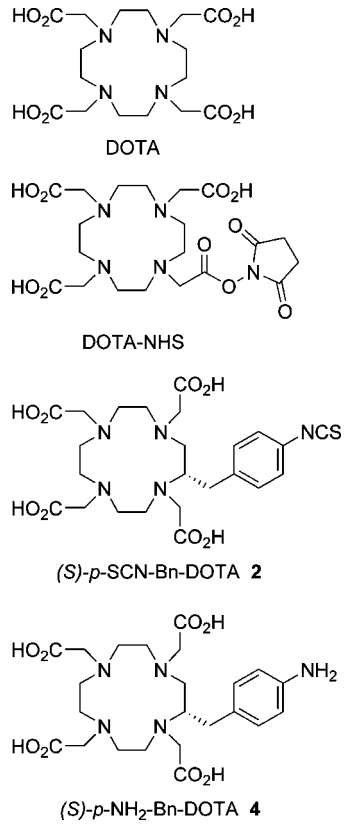

Figure 1. Bifunctional chelators based on the DOTA framework.

for labeling of an L-RNA as model system with the β^+-emitter ^{86}Y and subsequent radiopharmacological evaluation. An important criterion for the use of radiolabeled L-ON as molecular probes for *in vivo* imaging approaches is the radiochemical purity of the L-ON.

The purpose of this work was to characterize precisely different isomers formed during the complexation of a DOTA-functionalized L-RNA with Y(III). We report on the synthesis and NMR characterization of the nonradioactive [Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ precursors isolated by HPLC and further analyzed by mass spectrometry, circular dichroism spectroscopy, and polarimetric measurements. The assessment of their solution structure allows one to determine the stereochemistry adopted by the pendant benzyl residue and to establish the identity with the compounds prepared at the "carrier-free" level with ^{86}Y. The isolated [^{86}Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ isomers were further characterized by a comparative biodistribution study in Wistar rats and metabolite analysis. To draw conclusions to the observed [^{86}Y-DOTA]-L-RNA isomers, the amino groups of [Y(*p*-NH_2-Bn-DOTA)]$^-$ were transferred into isothiocyanate functionalities and the isomers were attached to the L-RNA. The coupling products were analyzed via HPLC and MALDI-TOF analysis. Finally, the biodistribution profiles of the [^{86}Y-DOTA]-L-RNA isomers were examined in rats, to characterize the influence of this chelate unit on the *in vivo* behavior of the L-RNA conjugate.

EXPERIMENTAL SECTION

Materials. L-RNA **1** [sequence: 5′-aminohexyl UGA CUG ACU GAC-3′, MW 3975] was obtained from NOXXON Pharma AG (Germany). (*S*)-*p*-SCN-Bn-DOTA **2** and (*S*)-*p*-NH_2-Bn-DOTA **4** were purchased from Macrocyclics (Dallas, TX, USA). ^{86}Y was purchased as [^{86}Y]YCl_3 in 0.04 M HCl (500 μL) from QSA Global GmbH (Germany).

Reactions and incubations were performed in 1.5 mL DNA low-binding tubes (Eppendorf, Germany) using a Thermomixer Comfort (Eppendorf, Germany). Lyophilization was carried out using an Alpha 2–4 LSC (Christ, Germany). L-RNA concentrations were determined via measurement of the UV absorbance at 260 nm using an Eppendorf (Germany) BIOPhotometer. Measurements of the pH-value in small volumes were performed using the pH sensor Biotrode (Metrohm, Germany).

Chromatographic Purifications and Analysis. HPLC purification and analysis were performed with a LaChrom Instrument (Hitachi-Merck, Germany) system, coupled with the radioisotope detector Gabi (Raytest, Germany). The used HPLC columns were as follows: (A) XTerra MS C_{18} column (Waters, USA) 3.0 × 50 mm i.d., 2.5 μm; (B) XTerra MS C_{18} column (Waters, USA) 4.6 × 50 mm i.d., 2.5 μm; (C) PLRP-S RP_{18} column (Varian Inc., USA) 4.6 × 250 mm i.d., 5 μm; (D) Aqua C_{18} column (Phenomenex, USA) 4.6 × 250 mm i.d., 5 μm; and (E) Aqua C_{18} column (Phenomenex, USA) 10 × 250 mm i.d., 5 μm. System A(I): flow 0.35 mL/min, gradient of acetonitrile (5% at 0 min, 13.5% at 18 min, 20.5% at 24 min, and 50% from 24 to 35 min) in 50 mM triethylammonium acetate (TEAA). System A(II): flow 0.35 mL/min and isocratic 5% acetonitrile in 0.1 M ammonium acetate. System A(III): flow 0.4 mL/min, gradient of acetonitrile (5% at 0 min, 7.3% at 35 min, and 50% from 36 to 40 min) in 50 mM ammonium acetate. System A(IV): flow 0.35 mL/min, linear gradient of acetonitrile (5% at 0 min, 29% at 25 min) in 50 mM NH_4OAc. System A(V): flow 0.3 mL/min and isocratic 2% acetonitrile. System B(I): flow 0.7 mL/min, gradient of acetonitrile (5% at 0 min, 7.7% from 41 to 44 min, 50% from 45 to 50 min) in 50 mM ammonium acetate. System B(II): flow 0.65 mL/min, gradient of acetonitrile (5% at 0 min, 50% from 20 to 25 min) in 0.1% TFA. System C(I): flow 1 mL/min, linear gradient of acetonitrile (5% at 0 min, 20% from 25 to 30 min) in 50 mM TEAA. System C(II): flow 1 mL/min, gradient of acetonitrile (5% at 0 min, 20% at 25 min, 40% at 30 min) in 50 mM TEAA. System C(III): flow 1 mL/min, linear gradient of acetonitrile (5% at 0 min, 11% at 25 min) in 50 mM TEAA. System D(I): flow 1 mL/min (E(I): flow 4 mL/min) and an isocratic elution with 5% acetonitrile in 50 mM triethylammonium hydrogencarbonate.

Mass Spectrometry. Mass spectra were recorded on a Quattro Ultima ESI-MS (Micromass, UK) and on a Daltonics Autoflex II TOF/TOF50 (Bruker, USA). The MALDI-TOF matrix, 3-hydroxypicolinic acid, was purchased from Aldrich (USA). The L-RNA probes were desalted for MALDI-TOF measurements using C_{18} purification tips (ZipTip, Millipore, USA) as described elsewhere (*13*).

NMR Studies. 1D and 2D spectra were recorded on an AMX300 spectrometer (Bruker, USA) equipped with direct and inverse broadband multinuclear probes and variable-temperature unit. ^{1}H and ^{13}C measurements were made at frequencies of 300.13 and 75.5 MHz, with complexes dissolved in D_2O and referenced using TSP as internal standard. The phase-sensitive COSY spectra were acquired using 2K data points in F2 and 512 increments in F1 dimensions and processed to a 2K × 1K matrix after apodalization with a QSine bell function in both dimensions. The phase-sensitive (TPPI) NOESY spectra were recorded at 25 °C using a mixing time (80 and 140 ms at 25 °C and 250 ms at 55 °C for Y**4b** and 110 ms at 25 °C for Y**4a**) measured using the standard inversion–recovery pulse sequence and processed as the COSY spectra. HMQC spectra were recorded using BIRD preparation period and 2K × 1K data points and processed using a square sine bell function in both dimensions. HMBC experiments were recorded using the pulse sequence inv4lplrnd of the Bruker software and acquired with 512 increments in the F1 dimension and 4K data points in the F2 dimension. Four dummy scans and 250 scans were used for spectral recording.

Circular Dichroism (CD) Spectroscopy and Polarimetric Measurements. CD measurements were carried out on a J-715 spectropolarimeter (Jasco GmbH, Germany) interfaced with a personal computer. The CD spectra were acquired and processed using the J-700 program for Windows. The experiments were carried out at room temperature using quartz cells (Hellma GmbH, Germany) with Suprasil windows and an optical path length of 0.02 cm. Spectra were recorded in the 190–300 nm wavelength range. The signal-to-noise ratio was improved by accumulating 8 scans. Polarimetric measurements were carried out on a 241 polarimeter (Perkin-Elmer LS, Finland) using an optical path length of 2 cm. Both CD and polarimetric measurements were performed using the deuterated aqueous solutions of Y**4a** and Y**4b** utilized for NMR studies.

[Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$. (*S*)-*p*-NH$_2$-Bn-DOTA **4** (25 mg, 40 μmol) in 1 mL ammonium acetate buffer (0.5 M, pH 6.8) was added to 87 μL of YCl_3 (0.5 M), and the mixture (pH 6.1) was incubated for 30 min at 90 °C. A solution of DTPA (300 μL, 30 mM, pH 6.0) was added, and the reaction mixture was incubated for 10 min at 40 °C to complex unreacted Y. The resulting isomers Y**4a** and Y**4b** were fractionized by HPLC system E(I), concentrated by evaporation, and lyophilized. For ESI-MS measurements, Y**4a** and Y**4b** were dissolved in acetonitrile and methanol (1:4 v/v) and the spectra were collected in the negative ion mode. ESI-MS: Y**4a**, *m/z* 594.2 $[M]^-$; Y**4b**, *m/z* 594.2 $[M]^-$. HPLC: A(V), R_T(Y**4a**) 2.1 min, R_T(Y**4b**) 2.5 min; A(II), R_T(Y**4a**) 4.4 min, R_T(Y**4b**) 6.5 min; C(III), R_T(Y**4a**), 13.7 min, R_T(Y**4b**) 15.0 min; D(I), R_T(Y**4a**) 12.9 min, R_T(Y**4b**) 20.3 min.

[Y((*S*)-*p*-SCN-Bn-DOTA)]$^-$. The [Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ isomers Y**4a** and Y**4b** (8.3 mg, 14 μmol) in 1 mL water were added separately into 10 mL glass vials (Normag, Germany) equipped with a Teflon-coated magnetic stir bar and a rubber septum. CH_2Cl_2 (0.9 mL) and Cl_2CS (0.1 mL) were added, and the mixtures were stirred vigorously at room temperature. A ninhydrine test was performed to follow the reactions as described elsewhere (*14*). After 3 h, the water layers were removed carefully and the [Y((*S*)-*p*-SCN-Bn-DOTA)]$^-$ isomers Y**2a** and Y**2b** were transferred into new glass vials and washed twice with 1 mL CH_2Cl_2. Subsequently, the isomers were lyophilized and the compounds Y**2a** and Y**2b** were obtained as a pale yellow solid. The compounds Y**2a** and Y**2b** were dissolved in acetonitrile and water (1:4 v/v) and ESI-MS spectra of both isomers were collected in the positive ion mode. ESI-MS: Y**2a**, *m/z* 638.1 $[M + 2H]^+$; Y**2b**, *m/z* 638.1 $[M + 2H]^+$. HPLC: A(I), R_T(Y**2a**) 32.7 min, R_T(Y**2b**) 31.2 min, R_T(**2**) 26.5 min; B(II): R_T(Y**2a**) 13.8 min, R_T(Y**2b**) 12.8 min, R_T(**2**) 14.4 min.

[Y-DOTA]-Hexanol. (*S*)-*p*-SCN-Bn-DOTA **4** (8.0 mg, 11.5 μmol) was conjugated to 6-amino-1-hexanol (Fluka, USA) (10.4 mg, 88.8 μmol) in water (251 μL, pH 8.4) by incubation for 4 h at 40 °C. HPLC analysis indicated the complete consumption of the DOTA precursor **4**. Subsequently, 100 μL of the reaction mixture, 9.2 μL YCl_3 (0.5 M in 0.04 M HCl), and 200 μL ammonium acetate buffer (0.5 M) were incubated for 20 min at 90 °C and pH 5.8. Additionally, the [Y((*S*)-*p*-SCN-Bn-DOTA)]$^-$ isomers Y**2a** and Y**2b** (1.1 mg, 0.6 μmol) were conjugated separately to 6-amino-1-hexanol (2.4 mg, 0.6 μmol) by incubation in water for 1 h at 25 °C and pH 8.8. Product fractions of both reaction batches were separated via HPLC analyzed via ESI-MS. ESI-MS: Y**6a**, *m/z* 755.3 $[M + 2H]^+$; Y**6b**, *m/z* 755.4 $[M + 2H]^+$. HPLC: A(IV), R_T(Y**6a**) 16.3 min, R_T(Y**6b**) 17.0 min; C(II): R_T(Y**6a**) 26.0 min, R_T(Y**6b**) 26.8 min.

DOTA-L-RNA. (*S*)-*p*-SCN-Bn-DOTA **2** (6.3 mg, 9.0 μmol) was conjugated to L-RNA **1** (2.4 mg, 0.6 μmol) in 0.7 M sodium bicarbonate buffer (121 μL, pH 9.0) by incubation for 2 h at 40 °C. For the purification of DOTA-conjugate **3**, 300 μL ethanol (abs.) and 1100 μL 70% ethanol were added, and the mixture was centrifuged for 20 min at –10 °C and 14 000 rpm. The supernatant with unreacted (*S*)-*p*-SCN-Bn-DOTA **2**, and DOTA-thiourea **5** was removed and the pellet washed twice with 70% ethanol, centrifuged, and resuspended in 0.3 M sodium acetate for an additional precipitation with ethanol as described above. Subsequently, the pellet was resuspended in 100 μL water. DOTA-L-RNA **3** was purified via size exclusion chromatography (SEC) using a 25 × 490 mm column (P4 Biogel, Medium 90–180 μm, Bio-Rad Melville, USA) with 0.1 M ammonium acetate buffer (pH 7.0) as mobile phase at a flow rate of 17.5–18.4 mL/h. The UV absorbance was monitored at 260 nm. The identity of the DOTA-conjugate **3** was verified by mass spectrometry. Maldi-TOF: **3**, *m/z* 4521.4 $[M + H]^+$.

[Y-DOTA]-L-RNA. [Y((*S*)-*p*-SCN-Bn-DOTA)]$^-$ isomers Y**2a** and Y**2b** were conjugated separately to L-RNA **1** by incubation in borate buffer (12.5 mM, pH 9.6) for 3 h at 40 °C. Product fractions of both reaction batches were separated via HPLC and lyophilized. The separated HPLC fractions were analyzed via MALDI-TOF measurements. To confirm the identity of [^{86}Y-DOTA]-L-RNA isomers Y**3a** and Y**3b**, the DOTA-modified L-RNA **3** was radiolabeled with carrier-added ^{86}Y using a molar ratio of **3** to YCl_3 of 1:1. Both ^{86}Y-complex isomers [^{86}Y]**3a** and [^{86}Y]**3b** were analyzed by HPLC and Maldi-TOF. MALDI-TOF: Y**3a**, *m/z* 4613 $[M + 2H]^+$; Y**3b**, *m/z* 4612 $[M + 2H]^+$. HPLC: A(III), R_T(Y**3a**) 26.5 min, R_T(Y**3b**) 29.4 min, R_T([^{86}Y]**3a**) 26.8 min, R_T([^{86}Y]**3b**) 29.8 min.

[^{86}Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$. (*S*)-*p*-NH$_2$-Bn-DOTA **4** (66 μg, 0.1 μmol) in 450 μL ammonium acetate buffer (0.5 M, pH 7.0) was added to 100 μL of [^{86}Y]YCl_3 (21 MBq) and the mixture was incubated for 20 min at 90 °C. A solution of DTPA (10 μL, 30 mM, pH 6.0) was added, and the reaction mixture was incubated for 5 min at 40 °C to complex unreacted [^{86}Y]Y^{3+}. The [^{86}Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ isomers [^{86}Y]**4a** and [^{86}Y]**4b** were separated by HPLC system A(II). Under these conditions, the [^{86}Y(DTPA)]$^{2-}$ complex eluted with the void volume from the column. HPLC fractions containing [^{86}Y]**4a** and [^{86}Y]**4b** were concentrated at 90 °C under a dinitrogen stream, and the residues were dissolved in saline.

HPLC fractions of the [^{86}Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ isomers [^{86}Y]**4a** and [^{86}Y]**4b**, containing TEAA as ion pair reagent, was used for estimation of the partition coefficient. A saturated *n*-octanol/water system was prepared in 1.5 mL tubes containing 400 μL buffer (25 mM disodium hydrogen phosphate and 0.09 M sodium chloride (pH 7.4)) and 400 μL *n*-octanol. The isomers [^{86}Y]**4a** and [^{86}Y]**4b** (30 μL, app. 250 kBq) were added separately, and the solutions were shaken vigorously for 5 min and incubated on a wave mixer for 30 min. The organic and aqueous phases were separated by centrifugation for 5 min at 5000 rpm. Subsequently, 300 μL of the *n*-octanol layer was transferred into a new tube, and the phase boundary was removed carefully by adding 200 μL to the waste. Afterward, the water layer (300 μL, pH 7.0) was transferred into a separate tube. The radioactivity of the organic and aqueous phases was measured on the gamma counter in five experiments, and the average was calculated. The partition coefficient log $D_{7.0}$ was defined as the ratio of the amount of the radiotracer present in the organic layer to that present in the aqueous phase. Partition coefficient: log $D_{7.0}$ ([^{86}Y]**4a**), –2.0 ± 0.029; log $D_{7.0}$ ([^{86}Y]**4b**), −2.3 ± 0.032. HPLC: A(II), R_T([^{86}Y]**4a**) 5.0 min, R_T([^{86}Y]**4b**) 7.3 min; C(III): R_T([^{86}Y]**4a**) 14.4 min, R_T([^{86}Y]**4b**) 15.7 min.

[^{86}Y-DOTA]-L-RNA. Radiolabeling of the DOTA-modified L-RNA **3** (95–160 μg, 21–36 nmol) with [^{86}Y]YCl_3 was performed in 300–350 μL ammonium acetate buffer (0.5 M, pH 7.0). After the addition of 50–100 μL of [^{86}Y]YCl_3 (13–45 MBq), the mixture was incubated for 30–60 min at 90 °C. A solution of DTPA (10 μL, 30 mM, pH 6.0) was added, and the reaction mixture was incubated for 10 min at 40 °C to complex unreacted [^{86}Y]Y^{3+}. The HPLC separation of the isomers [^{86}Y]**3a** and [^{86}Y]**3b** were performed on system B(I). Under these conditions, the [^{86}Y(DTPA)]$^{2-}$ complex eluted with the void volume from the column. HPLC fractions containing the separated isomers [^{86}Y]**3a** and [^{86}Y]**3b** were concentrated in a stream of nitrogen at 40 °C for 10 min. HPLC: B(I), R_T([^{86}Y]**3a**) 29.7 min, R_T([^{86}Y]**3b**) 32.4 min; A(III), R_T([^{86}Y]**3a**) 27.5 min, R_T([^{86}Y]**3b**) 29.8 min.

Determination of the Time-Dependent Radiochemical Yield of [^{86}Y]3. The kinetics of ^{86}Y-complexation of L-RNA **3** was followed by SDS-PAGE. In four attempts, L-RNA **3** (100 μg, 22 nmol) and [^{86}Y]YCl_3 (50 μL, 12–45 MBq) was incubated in ammonium acetate buffer (0.5 M, 300 μL, pH 7.0) at 90 °C for 60 min. At specific time points (0, 3, 9, 12, 15, 20, 25, 30, 35, 40, 45, 50, 55, and 60 min), reaction aliquots (15 μL) were mixed with a solution of DTPA (10 μL, 15 mM, pH 6.0) and heated up to 40 °C for 10 min to complex free [^{86}Y]Y^{3+} as [^{86}Y(DTPA)]$^{2-}$ complex. SDS-PAGE was performed using a Multiphor II Electrophoresis (GE Healthcare, USA) system and SDS precast gels (GE Healthcare, USA), ExcelGel Gradient 8–18. A 10 bp DNA ladder (Invitrogen, USA) was applied as a molecular weight standard. After electrophoresis, the gel was exposed to a phosphor imaging plate for 2–4 min and scanned with a Fujix BAS 5000 (Fujifilm Europe, Germany). Subsequently, the gel was stained using ethidium bromide, and the DNA ladder was visualized and photographed under UV light. Radiochemical yields were calculated from the radioactivity area of the product peak related to the total radioactivity area using *Tina 2.09* software (Raytest, Germany).

Biodistribution. All animal experiments were performed in accordance with the German laws for the protection of animals and were approved by the regional council. The biodistribution profiles of the radiolabeled L-RNA isomers [^{86}Y]**3a** and [^{86}Y]**3b** and the [^{86}Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ isomers [^{86}Y]**4a** and [^{86}Y]**4b** were studied in male Wistar rats (150 g body weight). For the time points 5 and 60 min, approximately 120 kBq aliquots of each compound were administered in 300 μL saline into the tail vein. For the longer examination period of 18 h, approximately 250 kBq aliquots of the L-RNA isomers [^{86}Y]**3a** and [^{86}Y]**3b** were administered. After the radiotracer application, four rats were anaesthetized for each radiotracer with ether at 5 min, 60 min, and 18 h, respectively. Blood was withdrawn by heart puncture, and the animals were euthanized. Organs and tissues were removed and weighed, and the radioactivity was measured in a calibrated well counter. The data were normalized to the amount of injected radioactivity and expressed as standardized uptake values (SUV). The SUV was calculated with following equation:

SUV = (organ activity/organ weight)/(total given activity/rat body weight)

The amount of radioactivity in urine was calculated as the total radioactivity of the injected dose subtracted by the values of all individual organs.

Metabolite Analysis. The *in vitro* stability analysis of the radiolabeled L-RNA [^{86}Y]**3b** was performed via HPLC as described in detail in the Supporting Information. The *ex vivo* autoradiography of the kidney sections containing the L-RNA [^{86}Y]**3b** was detailed in the Supporting Information.

[^{86}Y((S)-p-NH_2-Bn-DOTA)]$^-$. The [^{86}Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ somers [^{86}Y]**4a** and [^{86}Y]**4b** (2.3 MBq) were injected separately and intravenously into male Wistar rats. After sacrificing the rats 60 min p.i., the bladders were removed. Urine samples were collected by puncture of the bladders and methanol was added to the sample in a ratio of 1:2. The mixtures were shaken vigorously and centrifuged for 10 min at 13 000 rpm. The supernatants were transferred into a new vial, and the solutions were concentrated at 65 °C in a stream of nitrogen. TLC analyses were performed on Merck (Germany) RP_{18} plates with system (I): 0.1 M ammonium acetate in 5% acetonitrile (pH 7.0) and with system (II): methanol and 10% ammonium acetate (9:1 v/v) as the running buffer. The dried TLC plates were exposed to phosphor imaging plates for 10 min. The plates were scanned and the rates of radioactivity were calculated as described above. HPLC analyses of the prepared urine samples ([^{86}Y]**4a**, 50 μL, 17 kBq; [^{86}Y]**4b**, 100 μL, 90 kBq) were performed on system C(II).

[^{86}Y-DOTA]-L-RNA. The radiolabeled L-RNA [^{86}Y]**3** (2.3 MBq) isomers was injected intravenously into a male Wistar rat. Arterial blood samples of the rat were collected after injection of the radiolabeled compounds after 1, 3, 5, and 10 min p.i. The plasma of the blood samples was separated by centrifugation for 10 min at 13 500 rpm and 23 °C. Subsequently, the plasma samples were diluted in buffer (25 mM disodium hydrogen phosphate and 0.09 M sodium chloride (pH 7.4)) in a ratio of 1:1 and applied on a 20% PAGE. The plasma fraction of the blood probes obtained after 20 min p.i. contained insufficient radioactivity (<10 cps) for a subsequent PAGE analysis.

After sacrificing the rat 60 min p.i., the bladder and the kidneys were removed. A urine sample was collected by puncture of the bladder. A volume of 500 μL of the urine sample was applied onto Microcon YM-10 centrifugal filter units (10 kDa MWCO, Millipore, USA) and centrifuged for 60 min at 13 500 rpm at RT to separate low molecular weight metabolites. The protein pellet in the sample reservoir was transferred into a new vial by an invert spin mode. The pellet was enzymatic digested with a solution A (10 mM Tris-HCl (pH 8.0), 100 mM NaCl, 25 mM EDTA, and 2.0 mg/mL Proteinase K (Serva, Germany)) at 65 °C for 20 min. Subsequently, the probe was mixed with phenol/chloroform (1:1 v/v) and centrifuged at 13 500 rpm for 10 min. The water phase was extracted with chloroform (1:1 v/v) and centrifuged as described above. The water phase and the YM-10 filtrate fraction were analyzed on HPLC system C(I) and via PAGE.

The rat kidneys were homogenized in solution A and digested at 65 °C for 20 min. The homogenates were extracted with phenol/chloroform (1:1 v/v) as described above and analyzed via PAGE with a native 20% polyacrylamide gel. A 10 bp DNA ladder (Fermentas, USA) was applied as a molecular weight marker. After electrophoresis, the gel was exposed to a phosphor imaging plate for 60 min and scanned with a Fujix BAS 5000 (Fuji Photo Film, Japan). Subsequently, the DNA ladder was stained using ethidium bromide, visualized, and photographed under UV light.

RESULTS AND DISCUSSION

DOTA-Modification of the 12mer L-RNA. The primary amine group of the 5′-hexylamine containing 12mer L-RNA **1** was used for modifications of **1** with a BFC. The coupling reaction between the L-RNA **1** and the DOTA derivative (*S*)-*p*-SCN-Bn-DOTA **2** accomplished in the formation of a selective thiourea bond **3** (see Figure 2). A 50-fold excess of **2** was required for quantitative reactions, since L-RNA **1** cannot be separated from DOTA-L-RNA **3** via size-exclusion chromatography (SEC).

It must be noted that isothiocyanates are easily hydrolyzed in aqueous alkaline solutions (*15*). As outlined in Figure 3,

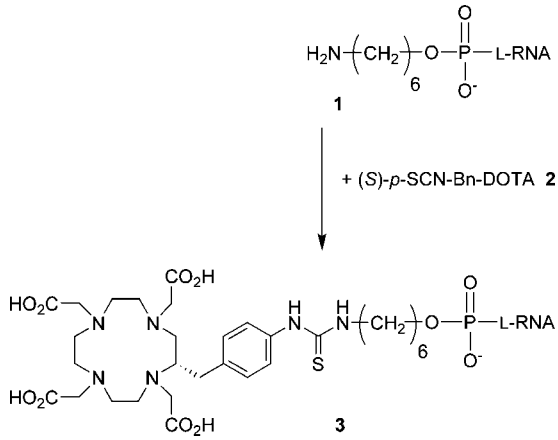

Figure 2. DOTA modification of the L-RNA **1** with (*S*)-*p*-SCN-Bn-DOTA **2** to DOTA-L-RNA **3**.

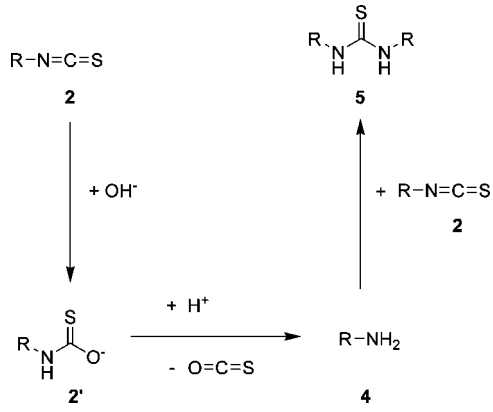

Figure 3. Hydrolysis of isothiocyanate **2** and proposed formation of symmetric thiourea **5**.

isothiocyanate **2** is hydrolyzed into primary amine **4** via the thiocarbamate **2′**, which subsequently reacts with an additional isothiocyanate **2** to afford symmetric thiourea **5**. The formation of symmetric DOTA-thiourea **5** was confirmed by ESI-MS analysis of SEC fractions containing **5**. SEC profiles of the reaction mixture and an ESI-MS spectrum of the DOTA-thiourea **5** are shown in the Supporting Information.

Complete separation of (*S*)-*p*-SCN-Bn-DOTA **2** and DOTA-thiourea **5** from the reaction batch was achieved through ethanol precipitation of DOTA-L-RNA **3** followed by SEC. Chemical purities of >95% for DOTA-L-RNA **3** were achieved as confirmed by HPLC chromatography. Only L-RNA **1** was detected as a minor (<5%) impurity.

Radiolabeling. DOTA-L-RNA **3** was used for radiolabeling with [^{86}Y]YCl_3. ^{86}Y-complexation kinetics of DOTA-conjugate **3** at 90 °C was monitored via PAGE as described in detail in the Supporting Information. The time-dependent radiochemical yields of [^{86}Y]**3** are shown in Figure 4. Compound [^{86}Y]**3** was obtained with the maximum radiochemical yield of 85 ± 2% already after 9 min. Less then 4% radioactivity was characterized as $[^{86}Y(DTPA)]^{2-}$ complex at the same time.

An important observation was made by analyzing the radiolabeled L-RNA [^{86}Y]**3** via ion-pair chromatography with a very shallow solvent gradient. Two isomers, [^{86}Y]**3a** and [^{86}Y]**3b**, could be observed in the radiometric profile with a difference in the retention times of 3 min. To verify the isomerization of the ^{86}Y-labeled L-RNA, the DOTA-conjugate **3** was radiolabeled with carrier added ^{86}Y, and the mixture was analyzed via HPLC. The ratio of the isomers [^{86}Y]**3a** and [^{86}Y]**3b** was found to be 1:2 in both the UV profile (Figure 5A) and the radiometric profile (Figure 5C).

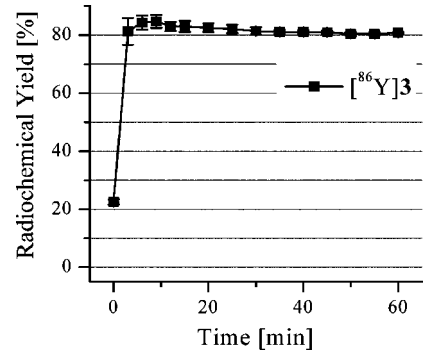

Figure 4. Kinetics of ^{86}Y-complexation of DOTA-L-RNA **3** expressed as % radiochemical yield as a function of time.

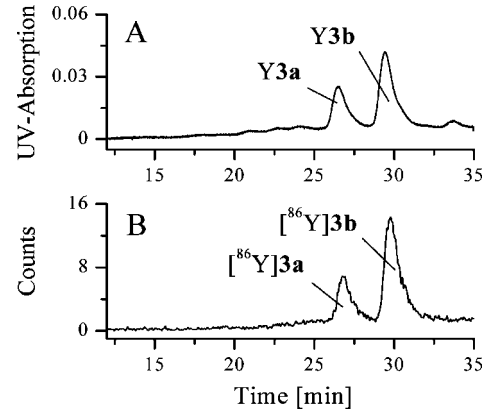

Figure 5. HPLC profiles of the L-RNA isomers: Analysis of the crude reaction mixture of [^{86}Y]**3** gave the same ratio of the isomers [^{86}Y]**3a** and [^{86}Y]**3b** (1:2) in both the UV profile (A) and the radiometric profile (B).

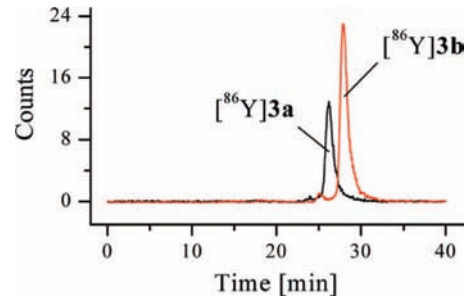

Figure 6. Overlay of the radiometric profiles of the separated HPLC fractions containing [^{86}Y]**3a** and [^{86}Y]**3b**.

The cumulative radiochemical yield of the isomer mixture [^{86}Y]**3** was determined separately by HPLC and PAGE analysis giving values of 73% and 85%, respectively. Conversely, thin layer chromatography did not give reproducible results. HPLC purification of the radiolabeled L-RNA [^{86}Y]**3** gave radiochemical purities of up to 98%. Effective specific activities of up to 0.15 MBq/μg were achieved as determined by HPLC. Hence, in a typical experiment starting from 24.1 MBq of [^{86}Y]YCl_3, 6 MBq of [^{86}Y-DOTA]-L-RNA [^{86}Y]**3** was obtained within 90 min. Additionally, the isomers [^{86}Y]**3a** and [^{86}Y]**3b** were separated via HPLC, and the obtained fractions were used for biodistribution studies in rats (see Figure 6).

Structure of LnDOTA$^-$ Complexes. The structure of $[Ln(DOTA)]^-$ complexes in solution have been examined extensively by NMR studies and are well-understood, as reviewed in ref (*16*). Briefly, the four nitrogen atoms of the azamacrocycle coordinate the metal from the upper side, while the four oxygen atoms of the pendant carboxylic acid arms coordinate the opposite bottom

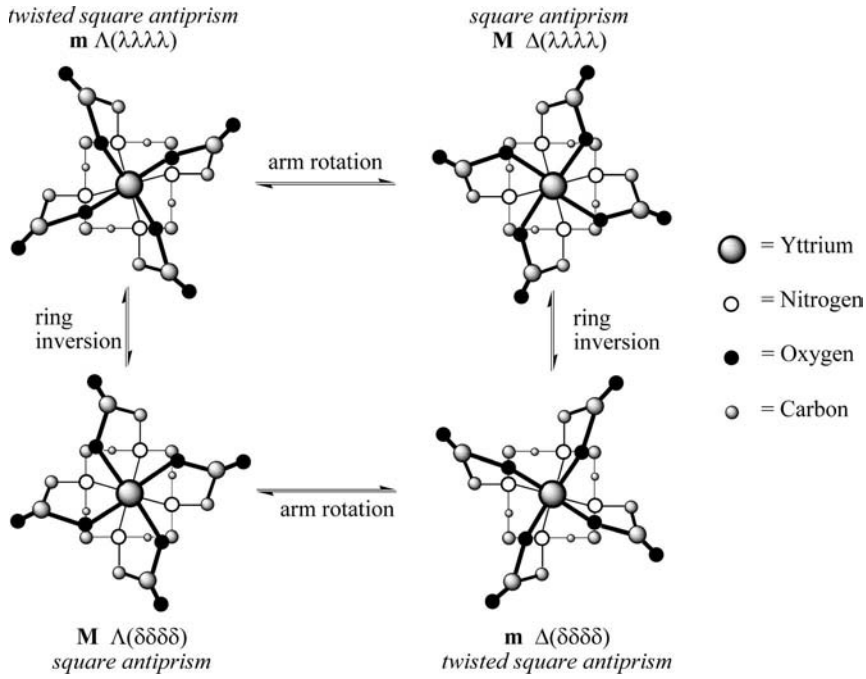

Figure 7. Interconversion pathways of the four possible stereoisomers of the [Y(DOTA)]$^-$ complex. The figure has been adapted from ref (*17*).

side. The coordination is usually completed by a capping water molecule inserted on the carboxylate face. These species adopt two coordination geometries: capped square antiprism (SAP or M; torsion angle ~39°) and capped twisted square antiprism (TSAP or m; torsion angle ~25°), which are related by elements of helicity of the carboxylate side arms (Δ or Λ) and flipping of the azamacrocycle (defined as either *δδδδ* or *λλλλ*), eventually resulting in formation of four stereoisomers related as two pairs of enantiomers designated as Δ(*λλλλ*) or Λ(*δδδδ*) (SAP type) and Δ(*δδδδ*) or Λ(*λλλλ*) (TSAP type) (see Figure 7). The SAP/TSAP ratio depends on the ionic radius of the lanthanide ion; the SAP geometry is preferred with larger ions (*17*). The trivalent yttrium ion has a large ionic radius (r_i = 1.075 Å for coordination number 9), thereby producing preferentially SAP isomers. The insertion of a substituent onto the carbon framework of the tetra-azamacrocycle introduces a new chiral center leading to the formation of additional stereoisomers. For steric reasons, such a side chain should adopt a pseudo equatorial conformation to avoid interactions with the macrocycle, thus "freezing-out" ring flip motion and locking the macrocycle ring into a (*δδδδ*) conformation (see Figure 8) (*18*).

Isomer Formation of the [Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ Complex. After complexation of Y^{3+} with the (*S*)-*p*-NH$_2$-Bn-DOTA **4** chelator, two conformers could separated by ion pair chromatography (see Figure 10). HPLC analysis of the [Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ isomers Y**4a** and Y**4b** was performed using ion pairing agents such as triethylammonium acetate (TEAA) or ammonium acetate. By analysis of the isomers Y**4a** and Y**4b** with HPLC system D(I), the retention times differ by 7.4 min. Without an ion pairing agent in the eluent, the retention times of the isomers Y**4a** and Y**4b** differ only by 0.44 min (system A(V)).

For both isomers Y**4a** and Y**4b**, the ratio of square antiprism (SAP) to twisted square antiprism (TSAP) was found to be 3:1. The thermal stability of the [Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ isomers Y**4a** and Y**4b** were determined by separate incubation of Y**4a** and Y**4b** in water for seven days at 90 °C. No interconversions of the two isomers Y**4a** and Y**4b** were observed for this period by HPLC and NMR analysis.

NMR Spectra. The stereochemistry of the [Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ isomer Y**4b** (peak 2 in Figure 10) was assessed through a battery of monodimensional and two-dimensional NMR spectra, taking into account that SAP geometry is usually adopted in DOTA-substituted metal complexes (*18, 19*). The diamagnetic nature of the Y(III) ion confines the proton signals of Y**4b** in a relatively narrow region compared to the usually large ppm window accessible in the case of paramagnetic lanthanide ions. In detail, Y**4b** dissolved in deuterated water exhibits four aromatic protons of the 4-amine-substituted benzyl residue (A_2B_2 system) at ca. 7.00 ppm and 25 aliphatic protons spread over the 3.70–2.10 ppm region as a series of overlapped multiplets. The unique methyne carbon C(4) (see Figure 11) is

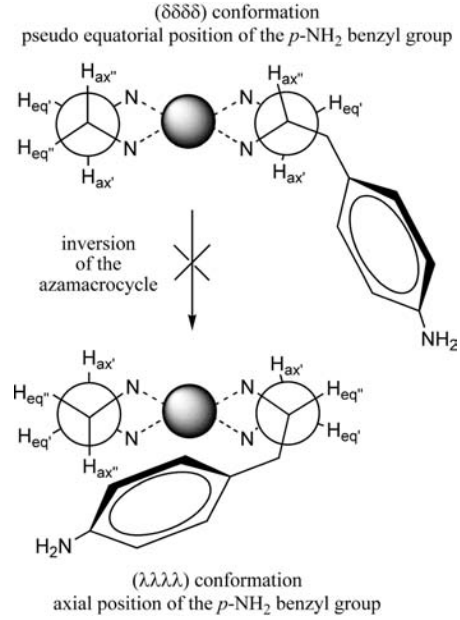

Figure 8. Newman projection of the [Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ complex Y**4**. The figure has been adapted from ref (*18*). For steric reasons, the bulky *p*-NH$_2$ benzyl substituent looks the complex into a (*δδδδ*) conformation and inhibits the ring flip motion to the (*λλλλ*) conformation. As a result, only the Λ(*δδδδ*) SAP (M) and the Δ(*δδδδ*) TSAP (m) species are observed in solution as a pair of conformational isomers.

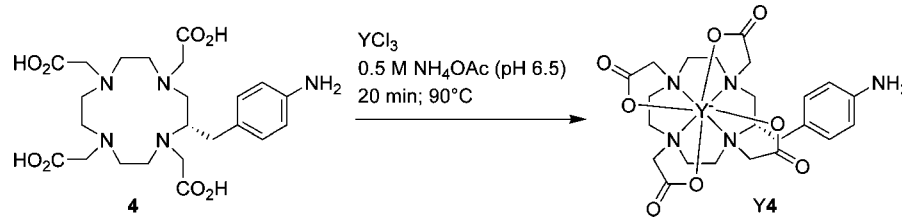

Figure 9. Complexation of Y^{3+} with the (*S*)-*p*-NH_2-Bn-DOTA **4** chelator.

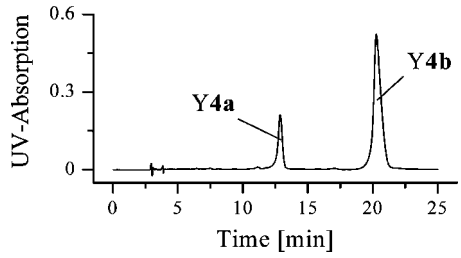

Figure 10. HPLC separation of the TSAP isomer Y**4a** and the SAP isomer Y**4b** of the [Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ complex.

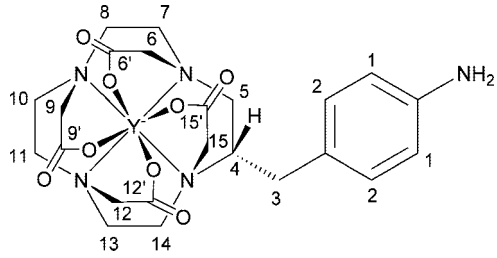

Figure 11. Proposed structure of the [Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ isomer Y**4b**.

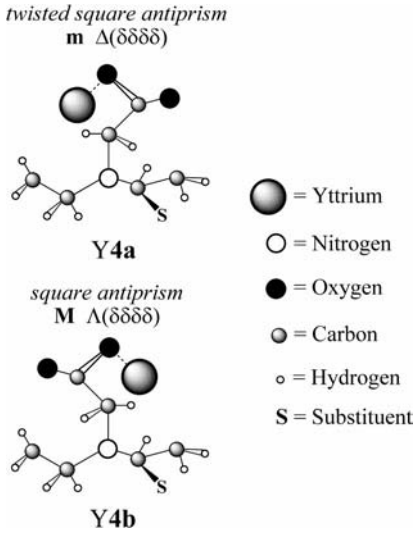

Figure 12. Structures of the [Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ isomers Y**4a** and Y**4b** are represented schematically. The figure has been adapted from ref (*17*). Only the geometry around the N-CH_2-COO group next to the (*S*)-configured carbon atom bearing the *p*-NH_2 benzyl group **S** is given.

assigned by means of the $^{13}C\{^1H\}$ DEPT experiment at δ 66.68 ppm, and the corresponding methyne proton H(4) is found at δ 3.11 ppm according to the $^1H-^{13}C$ HMQC map correlation (Figure 13A). The $^1H-^1H$ COSY map indicates that H(4) is scalarly coupled with diastereotopic H(3) and H(5) methylene protons. The $^1H-^{13}C$ HMBC map shows the ^2J correlation of C(4) with H(3) and H(5) and the ^3J correlation with H(15) protons (Figure 13A). This acetate methylene is also correlated with the unique carbonyl (C(15′) at δ 180.41 ppm) slightly upfield shifted compared to the other three carbonyls (C(6′), C(9′), and C(12′), which fall at δ 180.59 ppm).

Moreover, the $^1H-^1H$ NOESY map shows the additional dipolar couplings of $H(5)_{eq}$ with aromatic H(2) and of H(4) with the unique acetate methylene group identified as H(15) (Figure 13B). The occurrence of the latter interaction establishes that methyne H(4) is axially positioned toward the N_4O_4-DOTA "sandwich" and that the bulkier benzyl residue is equatorially positioned away from the "sandwich". The pseudo equatorial position of the pendant group is in agreement with previous observations on similar DOTA-substituted Eu complexes (*18*). In addition, the aromatic H(2) protons display a distinctive coupling with $H(5)_{eq}$ (Figure 13B) along with the expected couplings with H(3) and H(4). According to these data, Y**4b** is assigned to be the SAP isomer $\Lambda(\delta\delta\delta\delta)\Lambda$ (see Figure 12).

The minor isomer Y**4a** (see Figure 12) shows broader ^1H and ^{13}C profiles which do not sharpen in the range 5−90 °C and, therefore, do not allow complete NMR characterization. The difficulty to obtain well-resolved spectra and the observation in the phase-sensitive $^1H-^1H$ NOESY map of wide areas of positive cross peaks in the methylene region suggest the occurrence of exchange processes in the NMR time scale. However, the retention of the pseudo equatorial conformation of the benzyl side chain allows the assignment of the minor isomer as the TSAP isomer $\Delta(\delta\delta\delta\delta)$.

In accordance with this assignment, both isomers rotate plane-polarized light to the identical direction (α(Y**4a**), +0.008; α(Y**4b**), +0.018) indicating the presence of the same chiral carbon in the tetra-aza backbone. On the contrary, circular dichroism spectroscopy shows absorptions in opposite directions in the far-UV region indicating change of helicity of the carboxylate groups (see Figure 14).

Radiolabeling and Estimation of the Partition Coefficient. The radiolabeling of (*S*)-*p*-NH_2-Bn-DOTA **2** with [^{86}Y]YCl_3 yielded two [^{86}Y((*S*)-*p*-NH_2-Bn-DOTA)] isomers [^{86}Y]**4a** and [^{86}Y]**4b** with a cumulative radiochemical yield of 99% as determined by HPLC. The complex isomers [^{86}Y]**4a** and [^{86}Y]**4b** were separated via HPLC, and the obtained fractions were used for biodistribution studies and metabolite analyses and for the estimation of the partition coefficient. The partition coefficient log $D_{7.0}$ was defined as the ratio of the amount of radiotracer present in the organic layer (*n*-octanol) to that present in the aqueous phase. The log $D_{7.0}$ values were determined in the presence of the ion pair reagent TEAA (log $D_{7.0}$ ([^{86}Y]**4a**) −2.0 ± 0.029; log $D_{7.0}$ ([^{86}Y]**4b**), −2.3 ± 0.032).

Isomerism of the [Y-DOTA]-L-RNA. To draw additional information from the isomeric forms of the chelate unit [Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ Y**4**, both Y**4a** and Y**4b** isomers were attached separately to the L-RNA **1**. Thus, the amino group of the benzylamine residue in Y**4a** and Y**4b** was transferred into an isothiocyanate moiety by reaction of Y**4a** and Y**4b** with thiophosgene. The resulting [Y((*S*)-*p*-SCN-Bn-DOTA)]$^-$ complexes Y**2a** and Y**2b** were obtained quantitatively after 3 h, as confirmed by the ninhydrine test. After HPLC separation, both Y**2a** and Y**2b** were attached to the L-RNA **1** by incubation in

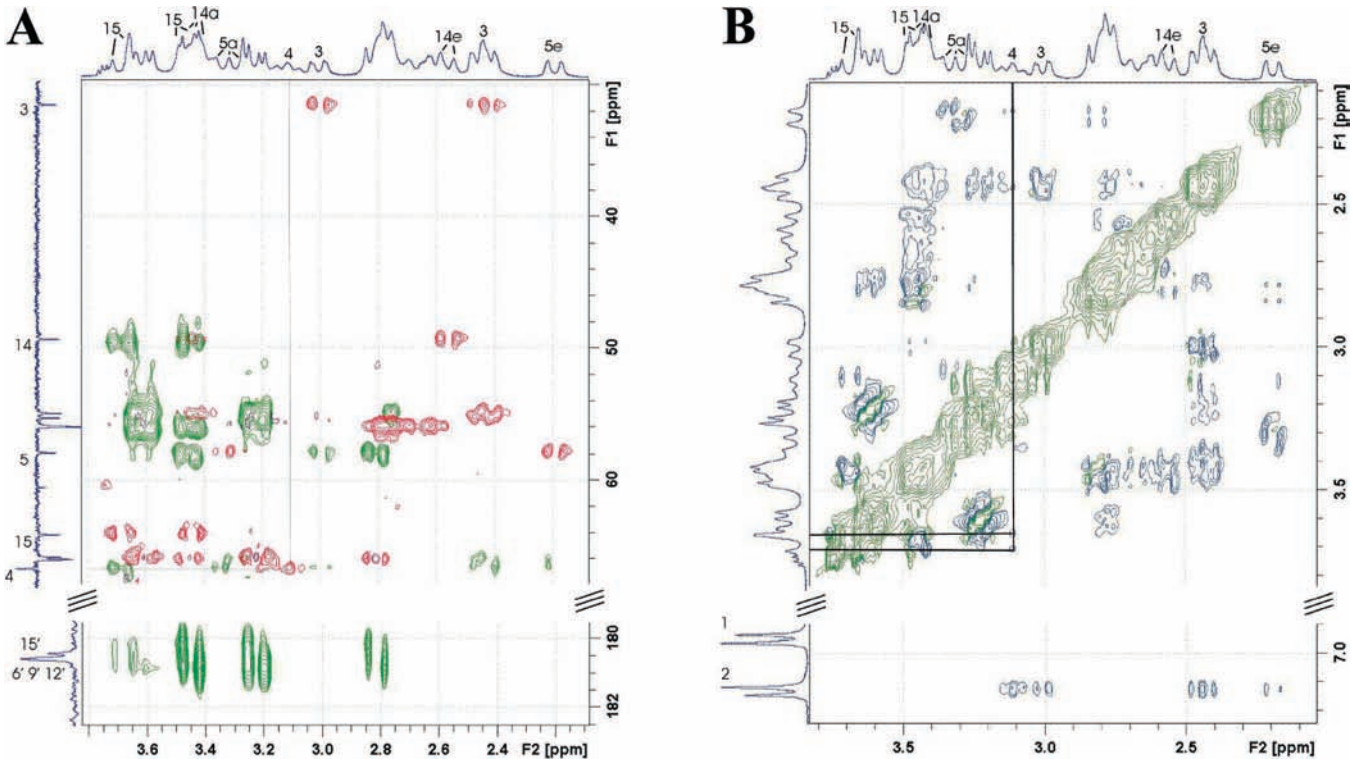

Figure 13. (A) Heterodinuclear $^{1}H-^{13}C$ HMQC (red) and HMBC (green) NMR maps of the Y**4b** isomer at 25 °C in D_2O (30–70 ppm of F1 projection: ^{13}C DEPT 135 spectrum). (B) NMR 2D NOESY map of the Y**4b** isomer at 25 °C in D_2O.

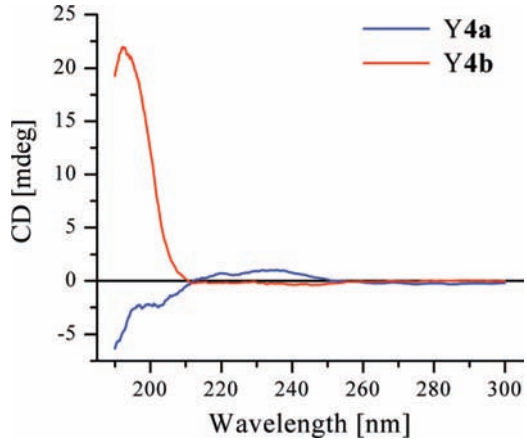

Figure 14. CD spectra of the [Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ isomers Y**4a** and Y**4b**.

borate buffer (12.5 mM, pH 9.6) for 3 h at 40 °C. Product fractions of both reaction mixtures were separated via HPLC and lyophilized. The separated HPLC fractions containing the isomers Y**3a** and Y**3b** were analyzed via MALDI-TOF mass spectrometry and found the same mass (see Supporting Information). The identity of the [^{86}Y-DOTA]-L-RNA species was finally established by comparison of the radiometric (^{86}Y) and the UV–visible chromatographic profiles of the references Y**3a** and Y**3b**.

Biodistribution Studies. After HPLC separation (see Figure 6) the [^{86}Y-DOTA]-L-RNA isomers [^{86}Y]**3a**, [^{86}Y]**3b**, and the [^{86}Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ isomers [^{86}Y]**4a**, [^{86}Y]**4b** were administered separately and intravenously to male Wistar rats. The biodistribution of the chelate units [^{86}Y]**4a** and [^{86}Y]**4b** were determined after 5 and 60 min. The biodistribution of the radiolabeled L-RNA isomers [^{86}Y]**3a** and [^{86}Y]**3b** were determined after 5 min, 60 min, and 18 h. The normalized concentrations of radioactivity expressed as SUV (standardized uptake values) in several organs are presented in Table 1.

Minor changes in the biodistribution profile of the complex isomers [^{86}Y]**4a** and [^{86}Y]**4b** were determined in the liver. The TSAP isomer [^{86}Y]**4a** indicate a higher liphophilicity (log $D_{7.0}$, -2.0 ± 0.03) and, as a result, a higher liver uptake after 5 min (1.7 ± 0.5) and 60 min (0.4 ± 0.1). In contrast, the SAP isomer showed a lower liphophilicity (log $D_{7.0}$, -2.3 ± 0.03) and a lower liver uptake after 5 min (0.5 ± 0.04) and 60 min (0.1 ± 0.04). The highest levels of radioactivity were determined after 60 min in the adrenals with SUV values of 4.1 ± 2.4 for the isomer [^{86}Y]**4a** and 2.6 ± 0.6 for the isomer [^{86}Y]**4b**. The SUV of the isomer [^{86}Y]**4a** in the kidneys reached 5.3 ± 1.3 after 5 min and decreased to 1.8 ± 0.19 after 60 min. For isomer [^{86}Y]**4b**, lower SUVs were observed in the kidneys with 4.4 ± 1.3 after 5 min and 1.1 ± 0.19 after 60 min. The SUVs in other organs were below 1.0 after 60 min for [^{86}Y]**4a** and [^{86}Y]**4b** in this study. A rapid clearance of the radioactivity was observed from blood, lungs, and liver for both compounds [^{86}Y]**4a** and [^{86}Y]**4b**. Very low SUVs were found in the brain for both compounds [^{86}Y]**4a** and [^{86}Y]**4b** after 60 min (0.09 ± 0.02 and 0.07 ± 0.02) suggesting that the negatively charged complexes are unable to cross the blood−brain barrier. The low uptake of radioactivity in the femur after 60 min (0.45 ± 0.28 and 0.32 ± 0.07) confirms the *in vivo* stability of the [^{86}Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ isomers [^{86}Y]**4a** and [^{86}Y]**4b**, since free ^{86}Y accumulates in the bone (*20*).

No significant differences in the biodistribution were observed after 18 h for the radiolabeled L-RNA isomers [^{86}Y]**3a** and [^{86}Y]**3b**. The highest levels of radioactivity were measured in the kidneys and the adrenals. For both compounds, the SUVs of the kidneys slightly increased from 7.8 ± 1.0 ([^{86}Y]**3a**) and 8.8 ± 1.4 ([^{86}Y]**3b**), respectively, at 5 min to 9.8 ± 0.6 ([^{86}Y]**3a**) and 11 ± 2.0 ([^{86}Y]**3b**), respectively, at 18 h. Remarkably high SUVs (2.5 ± 0.4 and 2.0 ± 0.2) were also observed in the adrenal glands 18 h p.i. of the radiolabeled L-RNAs [^{86}Y]**3a** and [^{86}Y]**3b**. A rapid clearance of the radioactivity was observed

Applied samples in the lane: aliquot of the reaction mixture (1); HPLC fractions containing [^{86}Y]**4a** (2) and [^{86}Y]**4b** (3) as references; rat urine samples containing [^{86}Y]**4a** (4) and [^{86}Y]**4b** (5).

for [^{86}Y]**3a** and [^{86}Y]**3b** in the other organs with SUVs below 1.0 after 60 min and 18 h, respectively.

Metabolite Analysis. *[^{86}Y((S)-p-NH$_2$-Bn-DOTA)]$^-$ Isomers.* Metabolite analyses of urine samples containing the [^{86}Y((*S*)-*p*-NH$_2$-Bn-DOTA)]$^-$ isomers [^{86}Y]**4a** and [^{86}Y]**4b** were performed via radio-HPLC and radio-TLC. The results (see Figure 15) indicate that the isomers did not metabolize during the renal extraction in the urine. Due to the low resolution of TLC, equal R_f values were observed for the isomers [^{86}Y]**4a** and [^{86}Y]**4b** in both TLC systems (R_f, 0.23 (I); R_f, 0.71 (II)). The urine samples from Wistar rats containing [^{86}Y]**4a** and [^{86}Y]**4b** showed only minor changes of the R_f values ((I) R_f ([^{86}Y]**4a**), 0.26; R_f ([^{86}Y]**4b**), 0.27; (II) R_f ([^{86}Y]**4a**), 0.61; R_f ([^{86}Y]**4b**), 0.67). The observed differences could be explained by the inhomogeneous sample matrix, which might influence the chromatographic separation.

[^{86}Y-DOTA]-L-RNA Isomers. The *in vitro* stability of the radiolabeled L-RNA [^{86}Y]**3** isomer mixture was determined by incubation of [^{86}Y]**3** in whole rat blood for 12 h at 37 °C as described in the Supporting Information. No decomposition of [^{86}Y]**3** was observed for this period by analyzing via HPLC.

The high *in vivo* stability of the L-configured oligonucleotides (L-ON) was additionally confirmed by metabolite studies with the radiolabeled L-RNA [^{86}Y]**3b** isomer in Wistar rats. PAGE analysis of urine samples and kidney homogenates, obtained 60 min after administration of [^{86}Y]**3b**, showed no decomposition of the radiotracer for this period (see Figure 16).

The urine samples for the HPLC analysis were prepared via ultrafiltration with YM-10 filter units (10 kDa cutoff). Potential low molecular weight metabolites were separated by this method from the protein matrix. The remaining protein residue in the filter unit was enzymatically digested and the L-RNA fraction was extracted with phenol/chloroform. HPLC analysis of the YM-10 filtrate fraction (see Figure 17C) showed two metabolites M1 and M2 beside the intact compound [^{86}Y]**3b** in the radiometric profile. A comparison of the retention time of M2 and that of the potential metabolite [Y-DOTA]-hexanol Y**6b** of the L-RNA Y**3b** indicate that [^{86}Y]**3b** was cleaved at the phosphorus ester of the 5′-hexyl spacer with the subsequently release of [^{86}Y-DOTA]-hexanol [^{86}Y]**6b**. By analysis of the protein pellet fraction only, metabolite M1 was visible in HPLC (see Figure 17D). In all, over 85% of the radioactivity was eluted as intact [^{86}Y]**3b**.

***Ex Vivo* Autoradiography.** Recently, it has been shown that the kidneys are the primary site for the excretion of L-ON (*21*). As outlined in this report, the radioactivity of a radiolabeled [^{125}I]-L-RNA 25mer was found exclusively in the tubular structures of the renal cortex. In agreement with this observation, the autoradiogram obtained from kidney sections 60 min after injection of the radiolabeled L-RNA [^{86}Y]**3b** indicated the

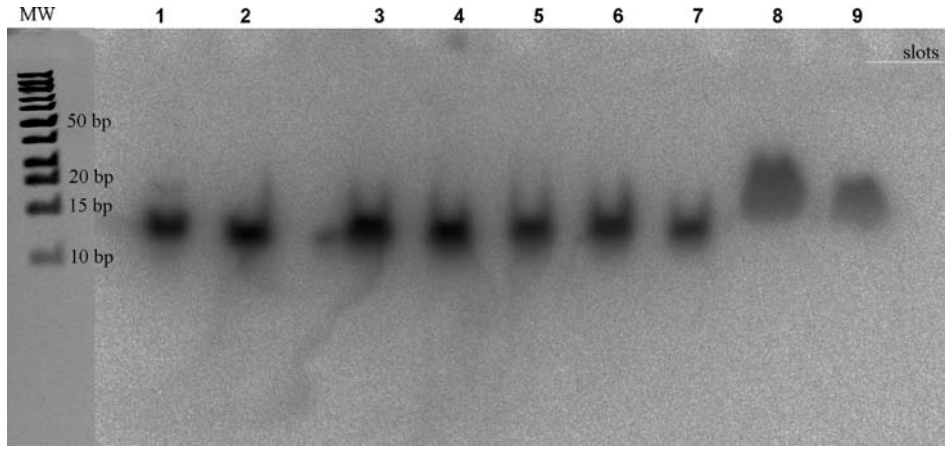

Figure 16. Image fusion of the autoradiogram of the exposed 20% polyacrylamide gel and the photographed 10 bp DNA ladder (MW) after staining with ethidium bromide. Applied samples in the lane: [^{86}Y]**3b** as reference (2); rat urine sample (5); YM-10 filtrate of rat urine sample (7); and rat kidney homogenate containing [^{86}Y]**3b** (9). The samples were obtained 60 min p.i. In the other lanes (1, 3, 4, 6, 8), the *in vivo* stability of a further ^{86}Y-labeled DOTA-12mer (lanes 1–4) was analyzed, which was published elsewhere (*4*). Variances in the running distance of the kidney homogenate samples could be explained by the inhomogeneous sample matrix, which might influence the electrophoretic separation.

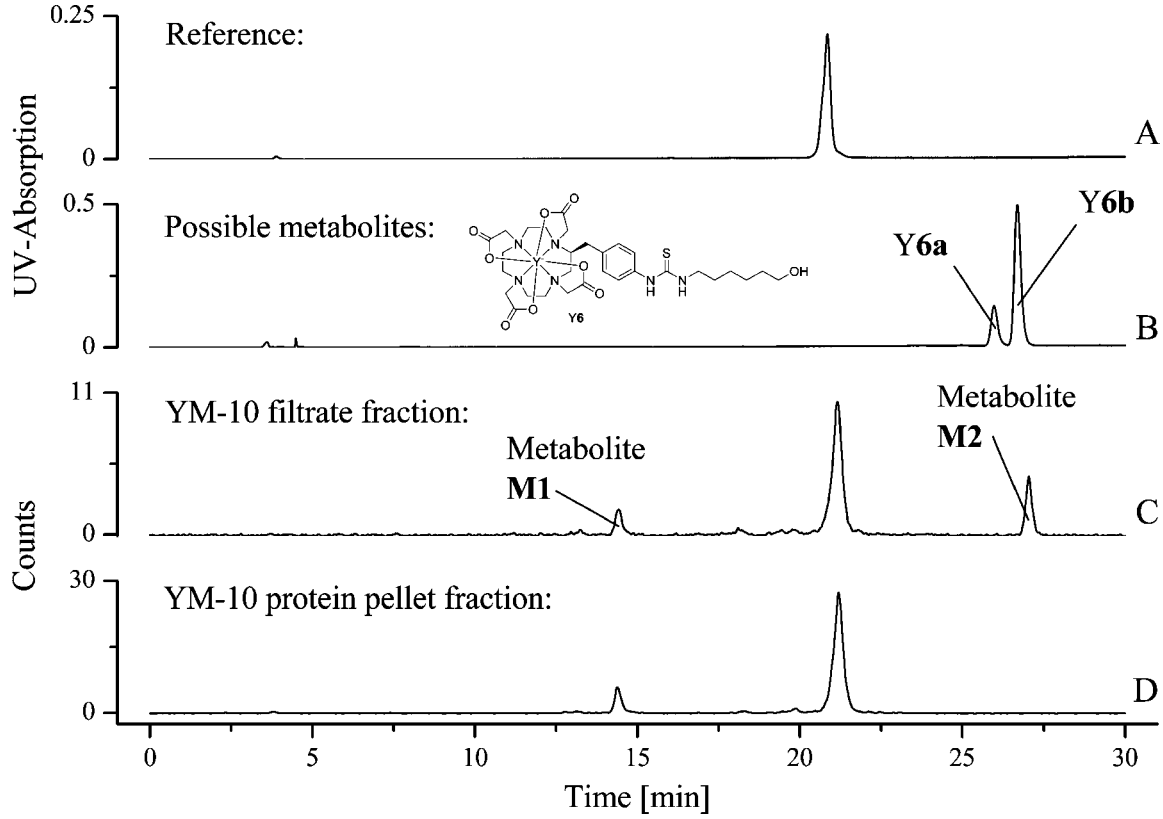

Figure 17. HPLC profiles of [Y-DOTA]-L-RNA Y**3b** as reference (A) and the [Y-DOTA]-hexanol isomers Y**6a** and Y**6b** as possible metabolites (B). Radio-HPLC profiles from rat urine samples collected 60 min p.i. of [^{86}Y]**3b**. (C) YM-10 filtrate fraction containing the low molecular weight metabolites M1 and M2. accumulation of the radioactivity in the renal cortex of the rats (see Figure 18). PAGE analysis of the kidney homogenates from these animals showed no decomposition of [^{86}Y]**3b** (see Figure 16).

CONCLUSIONS

In this study, we modified a mirror-image oligonucleotide (L-RNA **1**) via the bifunctional chelator approach with (*S*)-*p*-SCN-Bn-DOTA **2**. The ^{86}Y-labeling of the DOTA-conjugate **3** produced two isomer species [^{86}Y]**3a** and [^{86}Y]**3b** as evidenced by ion-pair chromatography with a very shallow solvent gradient. The isomerization of the conjugate [^{86}Y-DOTA]-L-RNA [^{86}Y]**3** was affected by different isomer structures of the ^{86}Y-DOTA complex. HPLC and NMR studies with the structural analogue nonradioactive precursor [Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ Y**4** revealed that the complex Y**4** exists as two conformers, adopting the $\Lambda(\delta\delta\delta\delta)$ (SAP) (Y**4b**) and $\Delta(\delta\delta\delta\delta)$ (TSAP) (Y**4a**) configurations. The differences in the helicity of the carboxylate side arms (Λ or Δ) affected the lipophilicity of the conformers Y**4a** and Y**4b**. As a result, both isomers Y**4a** and Y**4b** differ not only in the retention time. At the tracer level, both ^{86}Y complex isomers [^{86}Y]**4a** and [^{86}Y]**4b** evidenced differences in the liver uptake in Wistar rats after 5 and 60 min. The TSAP isomer [^{86}Y]**4a** indicates a higher liphophilicity and

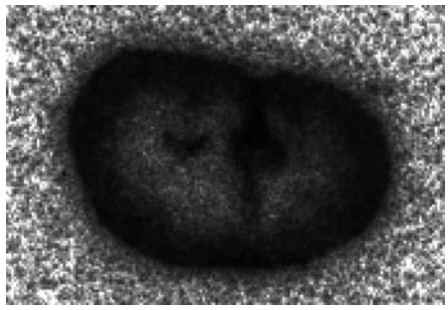

Figure 18. Autoradiogram obtained from a rat kidney sections 60 min after injection of [^{86}Y]**3b**.

a higher liver uptake. For this reason, it is important to characterize the influence of this chelate unit [^{86}Y]**4** on the *in vivo* behavior of the molecule to be labeled. Due to the high metabolic stability of the L-ON, the 12mer L-RNA **1** was a useful model for this investigation. Biodistribution studies with the L-RNA isomers [^{86}Y]**3a** and [^{86}Y]**3b** indicate no significant differences in the tissue and organ uptake of the rat up to 18 h. In conclusion, the 12mer L-RNA leveling the minor changes in the biodistribution profile of the [^{86}Y((*S*)-*p*-NH_2-Bn-DOTA)]$^-$ complex isomers [^{86}Y]**4a** and [^{86}Y]**4b** in rats. To confer this observation on other substances, like peptides or small organic molecules, further investigation are required.

HPLC analysis of rat urine samples containing [^{86}Y]**3b** suggested that the phosphorus ester of the 5′-hexyl spacer is a cleavage site in the radiolabeled L-RNA [^{86}Y]**3**. Besides that, more than 85% of [^{86}Y]**3b** was found intact in rat urine 60 min after injection. An additional metabolic stabilization of the L-RNA **1** can be achieved by a chemical modification of the linkage between the aminohexyl spacer and the L-ON. In conclusion, the high metabolic stability of the L-ON suggests the potential of this class of compounds as molecular probes for *in vivo* imaging applications.

ACKNOWLEDGMENT

This work was supported by the EU-FP6 integrated project BioCare contract no.: 505785. The authors thank Regina Herrlich for the performing the biodistribution and Mareike Barth for preparing the rat kidney autoradiograms. Furthermore, the authors thank Peggy Jaehrig for synthesis of several Y-DOTA chelates.

Preparation and in Vitro Evaluation of Novel Lipopeptide Transfection Agents for Efficient Gene Delivery

Tarwadi,[†] Jalal A. Jazayeri,[†] Richard J. Prankerd,[‡] and Colin W. Pouton*[,†]

Department of Pharmaceutical Biology and Department of Pharmaceutics, Victorian College of Pharmacy, Monash University, 381 Royal Parade, Parkville, Victoria 3052, Australia. Received December 14, 2007; Revised Manuscript Received February 1, 2008

Gene therapy by delivery of nonviral expression vectors is highly desirable, due to their safety, stability, and suitability for production as bulk pharmaceuticals. However, low transfection efficiency remains a limiting factor in application on nonviral gene delivery. Despite recent advances in the field, there are still major obstacles to overcome. In an attempt to construct more efficient nonviral gene delivery vectors, we have designed a series of novel lipopeptide transfection agents, consisting of an alkyl chain, one cysteine, 1 to 4 histidine and 1 to 3 lysine residues. The lipopeptides were designed to facilitate dimerization (by way of the cysteine residues), DNA binding at neutral pH (making use of charged lysine residues), and endosomal escape (by way of weakly basic histidine residues). DNA/lipopeptide complexes were evaluated for their biophysical properties and transfection efficiencies. The number and identity of amino acids incorporated in the lipopeptide construct affected their DNA/lipopeptide complex forming capacity. As the number of lysine residues in the lipopeptide increased, the DNA complexes formed became more stable, had higher zeta potential (particle surface charge), and produced smaller mean particle sizes (typically 110 nm at a charge ratio of 5.0 and 240 nm at a charge ratio of 1.0). The effect of inclusion of histidines in the lipopeptide moiety had the opposite effect on complex formation to lysine, but was necessary for high transfection efficiency. In vitro transfection studies in COS-7 cells revealed that the efficiency of gene delivery of the luciferase encoding plasmid, pCMV-Luc, mediated by all the lipopeptides, was much higher than poly(L-lysine) (PLL), which has no endosomal escape system, and in two cases was slightly higher than that of branched polyethylenimine (PEI). Lipopeptides with at least two lysine residues and at least one histidine residue produced spontaneous transfection complexes with plasmid DNA, indicating that endosomal escape was achieved by incorporation of histidine residues. These low molecular weight peptides can be readily synthesized and purified and offer new insights into the mechanism of action of transfection complexes.

INTRODUCTION

There are several strategies for mediating gene delivery to the nucleus of eukaryotic cells. One approach has been direct injection of naked DNA into a tissue. This has been attractive due to simplicity and lack of toxicity. However, the size and hydrophilic nature of DNA prevents it from being taken up by cells efficiently. Approximately 10^6 plasmid DNA are needed for a single cell transfection in vitro with less than 100 reaching the nucleus (*1*). This is due to several physical, chemical, and metabolic barriers in the cell interior, with the final obstacle being the nuclear membrane which, in the absence of cell division, is a major impediment to gene delivery. The DNA delivery system needs to prevent degradation and facilitate intracellular transport on its journey to the nucleus.

To achieve this target, several strategies are being exploited by researchers in the field of gene therapy. These include (i) physical methods, using mechanical or electrical forces, such as particle bombardment, gene guns, electroporation, microinjection, ultrasound, and hydrodynamic; (ii) chemical means (condensing DNA using cationic lipids or cationic polymers); and (iii) viral vectors (e.g., using adenoviruses). Viral vectors, although comparatively efficient, are considered to have safety problems associated with recombination events. Nonviral delivery vectors, on the other hand, are relatively inefficient in their current form and have not been successful for in vivo gene therapy. Nevertheless, they are attractive alternatives to viral and physical methods, because of their relative safety (for recent reviews, see refs *2*–*6*). Systematic efforts will be required to improve the efficiency of nonviral delivery before they can be used clinically.

Among the nonviral vehicles, cationic lipids have been explored most extensively, and many have been commercialized as in vitro transfection agents (*7*–*10*). Felgner and co-workers were the first to report a highly efficient lipid-mediated DNA-transfection agent using a synthetic cationic lipid, *N*-(1-(2,3-dioleyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride (DOTMA) (*11*). They found that small unilamellar liposomes containing DOTMA interacted spontaneously with DNA to form lipid−DNA complexes. They also reported that, depending on the cell line used, DOTMA was 5- to 100-fold more efficient, compared to either the calcium phosphate or DEAE dextran transfection methods. In designing a cationic lipid as a transfection agent, they showed that the alkyl chain length and the number of double bonds could either increase or decrease the transfection efficiency (C14:0 > C18:1 > C16:0 > C18:0) (*7*).

Using a different set of cationic lipids, Wheeler et al. formulated a liposome composing of GAP-DLRIE; (±)-*N*-(3-aminopropyl)-*N*,*N*-dimethyl-2,3-bis-(dodecyloxy)-1-propanaminium bromide, and DOPE (dioleoylphosphatidyl-ethanolamine). This formulation enhanced chloramphenicol acetyl-transferase (CAT) expression in vivo by more than 100-fold (observed in mouse lung) (*12*). Recently, Slimani and co-workers reported

a ligand-bearing lipopeptide specifically targeting neurophilia fen-1 (NRPAL1) receptor, which is overexpressed by human breast cell lines (*13*). The lipopeptide was based on a palmitoyl fatty chain (C_{16}) linked to a sequence of seven amino acids (ATWLPPR). Upon transfection, they showed that the lipopeptide delivery of either a β-galactosidase reporter gene or a green fluorescence protein was selectively enhanced in NRPAL1 positive cells as compared to NRPAL1 negative cells.

The synthetic polycation polyethylenimine (PEI) has also been used widely in transfection studies, either alone (*14*) or by bonding to adenovirus particles (*15*) or to other viral protein and targeting devices (*16, 17*). However, although PEI and its derivatives have a prominent position in gene delivery research, due to their ability to facilitate endosomal escape which results in high transfection efficiency in vitro, the toxicity of PEI remains the drawback, especially for in vivo gene delivery applications (*14, 18*).

Low-molecular-weight cationic peptide-based nonviral vectors have considerable potential but are probably the least explored, whereas cationic polymers such as polyethylenimine (PEI) or poly(L-lysine) (PLL) have been investigated regularly (*19–25*). Recently, there have been several publications on peptide-based structures for delivery of DNA to mammalian cells (*8, 26–29*). Chen et al. reported that, in combination with cationic liposomes such as DOTAP, Lipofectin, Lipofectamine, and DOSPER branched copolymers of histidine and lysine were able to condense and enhance transfection efficiency in MDA-MB-435 cells (*30*). In addition, histidine-rich amphiphatic peptides were reported to transfect several cell lines with efficiencies comparable to those of DOTAP and PEI (*28*). Meanwhile, Lentz and co-workers reported the use of highly branched histidine−lysine peptides as carriers for small interfering RNA molecules (*29*). Arginine-rich peptides have also been exploited in nonviral gene transfer (*31, 32*). Arginine-rich peptides can facilitate the cellular uptake of macromolecules such as proteins, liposomes, and iron nanoparticles. They have also been shown to enhance DNA delivery by making use of protein transduction sequences, including hepta-arginine and $TAT_{47–57}$ (*31*).

A group led by Rice has been exploring the application of copolymers incorporating peptide sequences of cysteine, lysine, histidine, and tryptophan residues to mediate nonviral gene delivery (*33–35*). McKenzie et al. reported that a minimal repeating lysine chain of 18 residues, followed by tryptophan and an alkylated cysteine residue (AlKCMK$_{18}$, MW 2672 Da), formed small particles with DNA (~80 nm) and mediated efficient in vitro gene transfer to a level higher than that of PLL (MW of 1–4 kDa) (*34*). This group developed peptide-mediated gene delivery agents by inserting multiple cysteine residues into a short (dp 20) synthetic peptide (*33*). They found that the stability of cross-linked peptide DNA condensates increased in proportion to the number of cysteines incorporated into the peptide. They suggested that disulfide bond formation led to a decrease in particle size, relative to control peptide DNA condensates, and prevented dissociation of peptide DNA condensates (*33*). In addition, they demonstrated that substitution of His for Lys resulted in an optimal peptide of Cys-His-$(Lys)_6$-His-Cys, which provided a buffering condition capable of enhancing in vitro gene expression in the absence of chloroquine (*33*).

Despite recent advances in the design of nonviral gene delivery systems, transfection agents based on nonviral reagents are still very inefficient, particularly for in vivo gene delivery applications, where typically a very small proportion of cells are transfected. In this study, a series of lipopeptide transfection agents were designed and constructed. In addition to an investigation of transfection efficiency, these complexes were also evaluated in terms of their physical properties, since complex size and charge are known to influence processes involved in gene delivery. A better understanding of the physical properties of DNA complexes, in particular, the factors which promote DNA condensation, cellular uptake, and endosomal escape, will help design more efficient gene delivery vectors.

[a] Lau: Lauryl; Pal: Palmitoyl. [b] Determined by mass spectrometry. [c] Determined as per number of protons. [d] The purity of the compounds was measured by HPLC using 218 nm UV absorption; SH was detected by Ellman's test.

EXPERIMENTAL PROCEDURES

Materials. The lipopeptides (Table 1) were synthesized by Auspep Pty. Ltd. (Parkville, Victoria, Australia). The purities of the compounds were examined by HPLC (Waters, USA) with nonspecific short-wavelength UV detection and found to be >95%. Their molecular weights were confirmed by mass spectrometry. The plasmid pCMV-Luc was a gift from Dr. David Melroy (University of Bath, UK) and the plasmid pCMV-β-gal stock solution (1 mg/mL in water) was obtained from Clontech (NSW, Australia). Lipofectamine was from Invitrogen (Melbourne, VIC, Australia); PLL (average M_w 15–30 kDa), branched PEI (average M_w 750 kDa), decamethonium (dication C_{10}), dodecyltrimethylammonium bromide (DDTAB), and hexadecyltrimethylammonium bromide (HDTAB) were from Sigma-Aldrich (Sydney, Australia). Dulbecco's Modified Eagle's Medium (DMEM) was from Invitrogen (Melbourne, VIC, Australia). All tissue culture flasks, including black polystyrene 96-well plates, were obtained from Corning Costar (Melbourne, VIC, Australia). All other chemicals were commercially obtained and were of analytical grade.

Design and Construction of Lipopeptides. The basic structure comprises an N-terminal alkylamide, one cysteine, 1 to 4 histidine and 1 to 3 lysine residues. The addition of each lysine provided a unit positive charge on the lipopeptide at neutral pH, which was able to interact with the negatively charged sugar–phosphate backbone of the DNA molecule. Histidine was included because its side hain is weakly basic and predominantly un-ionized at neutral pH, but is more highly protonated in the weakly acidic environment of the endosome. It was hypothesized that this phenomenon would facilitate release of the DNA−lipopeptide complex from the endosome. The number of lysine and histidine residues included in the lipopeptide was varied to explore the effect on transfection efficiency.

The inclusion of an alkyl amide chain, either lauryl (C_{12}) or palmitoyl (C_{16}), in the lipopeptide was intended to promote hydrophobic interactions to stabilize the lipopeptide−plasmid complex, subsequent to an initial ion interaction between primary amine and phosphate groups. To inform the choice of alkyl chain length, a range of dicationic molecules were investigated using the ethidium bromide exclusion assay (Table 2). The thiol-bearing cysteine residue was included with the intention of facilitating dimerization by disulfide formation on the DNA molecular template.

Plasmid DNA Isolation. The plasmid pCMV-Luc, a luciferase mammalian expression vector, was cultivated in *E. coli*,

Table 2. Structure of Molecules Used in DNA Condensation assays

	Structure of the molecules used in DNA condensation assays and their state of ionisation at pH 7.4	Ref
1	Decamethonium (dication C_{10}), molecular weight = 418.3, 2 N^+/molecule 	(*9, 50*)
2	Dodecyltrimethylammonium bromide (DDTAB), molecular weight = 308, 1 N^+/molecule 	(*51*)
3	Hexadecyltrimethylammonium bromide (HDTAB), molecular weight = 364, 1 N^+/molecule 	(*52*)
4	Poly-L-lysine (PLL), molecular weight of 1 L-lysine unit = 128 (1 N^+/unit) 	(*53-55*)

strain DH5-α, and isolated using a Qiagen Maxiprep kit (Qiagen Pty. Ltd., Clifton Hill, Victoria, Australia). The purity of each plasmid was checked electrophoretically on a 1% agarose gel. Their concentrations were determined from UV absorbance at 260 and 280 nm. Purified plasmids were resuspended in Milli-Q water (MQW) and frozen (−20 °C) until use.

Determination of Charge and N/P Ratios. The charge ratio (+/−) of DNA complexes refers to the number of positively charged (protonated) nitrogens provided by the transfection agent per negatively charged nucleotide unit. An average mass of 330 Da per nucleotide was used for the calculations. For example, to obtain a theoretical charge ratio of 1:1 between $PalCK_2H_2$ (889 Da, $2NH^+$/molecule) and DNA, 1 μg of DNA (3 nmol of nucleotide) was mixed with 1.3 μg of $PalCK_2H_2$ (1.5 nmol), since every molecule of $PalCK_2H_2$ generates 2 NH^+ groups. For the cationic polymer PEI, rather than using charge ratio, complexes were described in terms of the total nitrogen/phosphate (N/P) ratio.

DNA Condensation Assay. The ability of the lipopeptide constructs to condense DNA was evaluated using the ethidium bromide (EtBr) exclusion assay, as described by Murphy et al. (*36*). This assay was carried out in 96-well black plates; the fluorescence intensities were measured using a FluoStar OPTIMA plate reader (FluoStar OPTIMA, BMG Laboratory Technology, Sydney, NSW, Australia). A sample containing 5 μg plasmid DNA and an excess of EtBr (20 μL; 100 μg/mL) was used to calibrate the spectrofluorometer to 100% fluorescence intensity (λ_{ex} = 520 nm; λ_{em} = 610 nm). For the assays; 50 μL of 60 mM Tris HCl buffer (pH 7.4) was added to each well containing plasmid DNA. A series of charge ratios from 0 to 10 (or N/P ratios for PEI) of the DNA complexes were prepared. Milli-Q water was added to a total volume of 230 μL per well. The samples were left to stabilize at ambient temperature for 3 min after which 20 μL of EtBr solution was added. The 96-well plate was shaken orbitally for 30 s and the fluorescence intensity measured.

Gel Mobility Shift Assay. The formation of the DNA-transfection agent complex was studied using a gel mobility shift assay. A series of charge ratios from 0 to 5 (or N/P ratios for PEI) of the complexes were prepared in HEPES glucose buffer pH 7.4 (15 mM HEPES and 5.13% w/v glucose). Complexes of DNA (20 μg/mL) and transfection agent were incubated for 30 min at 37 °C. Subsequently, the samples (15 μL) were mixed with 3 μL of loading buffer and analyzed by 1% agarose gel electrophoresis. DNA bands were visualized by UV transillumination.

DNA−Lipopeptide Stability Assay. The susceptibility of the condensed DNA to enzymatic degradation was assessed by exposing the complex to nucleases (Turbo DNase, Ambion, Scoresby, VIC, Australia). The plasmid DNA sample (20 μg/mL) and the appropriate lipopeptide were diluted separately in HGB[1]pH 7.4 in a series of charge ratios from 0 to 5. The samples were then mixed and incubated in the presence of DNaseI (2U/μg DNA) on ice (4 °C) for 15 min prior to 1% agarose gel electrophoresis. DNA bands were visualized by UV transillumination.

[1]Abbreviations: HGB, HEPES glucose buffer; PBS, phosphate buffered saline, PEI, polyethylenimine; PLL, poly(L-lysine); EtBr, ethidium bromide; DOPE, (dioleoyl phosphatidyl-ethanolamine); DOTMA, *N*-[1-(2,3-dioleyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride; DOTAP, *N*-[1-(2,3-dioleoyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride.

Particle Sizing and Zeta Potential. The mean particle size and zeta potential (ζ) of each DNA−lipopeptide complex was determined with a Zetasizer Nano Series instrument (Malvern Instruments, Worcestershire, UK). Calibration of particle sizes was carried out with 60 nm ± 2.7 nm NIST/Nanosphere (Duke Scientific Corp. Palo Alto, CA, USA) standard polystyrene spheres. For calibration of zeta potential, the −50 mV ± 5 mV zeta potential standard was used. DNA−lipopeptide complexes were prepared in HEPES glucose buffer pH 7.4. The mean particle sizes were measured at 25 °C using 1.5 mL disposable cuvettes. Zeta potentials were determined at 25 °C using the folded capillary (Smoluchowski) cell (Malvern Instruments, Worcestershire, UK).

To study the physical stability of each DNA−lipopeptide complex, 40 μg of DNA (pCMV-Luc) was combined in a cuvette with each of $PalCK_2H_2$, $PalCK_2H_3$, $PalCK_3H_2$, or $PalCK_3H_3$ (at a charge ratio of 1.5), in a total of 500 μL of HEPES glucose buffer, pH 7.4. The mean particle size distributions were measured at 0.05, 0.5, 1, 2, 8, 30, 60, and 120 h after complex formation. The effect of DNA concentration on particle aggregation was studied at a fixed charge ratio of 1.5; DNA (2.5, 5, 10, 15, 20, or 40 μg) was diluted with 250 μL HGB pH 7.4 and then added dropwise into 250 μL HGB pH 7.4 containing the appropriate mass of $PalCK_3H_2$, $PalCK_3H_3$, PEI, or Lipofectamine to obtain DNA at a final concentration of 7.6, 15.2, 30.4, 45.6, 60.8, or 121.6 nM, respectively. The effect of increasing charge ratio on particle size and zeta potential was also studied. This was achieved by diluting 5 μg DNA in 250 μL of HGB pH 7.4 dropwise into 250 μL HGB pH 7.4 in a microtube containing the appropriate mass of $PalCK_2H$, $PalCK_2H_2$, $PalCK_3H_2$, or $PalCK_3H_3$ to obtain charge ratios of 0.5, 0.75, 1.0, 2.0, 3.0, 4.0, or 5.0, respectively.

Preparation of Lipopeptide/Plasmid DNA Complexes for Transfection. The plasmid pCMV-Luc (2 μg) was diluted in 12.5 μL HGB pH 7.4 and added to the lipopeptide solution (diluted in the 12.5 μL of the same buffer) in dropwise manner. Lipofectamine, PLL (MW 70–150 kDa) and branched PEI (MW 750 kDa) were used as positive controls.

In Vitro Transfection. COS-7 cells were cultured in DMEM media supplemented with 10% FCS, 100 units/mL penicillin, and 100 μg/mL streptomycin in a humidified incubator with 5% CO_2 at 37 °C. The day before transfection, cells were seeded at 5×10^4 cells/well in the 24-well plates. After reaching a confluency of ~60–70%, the cells were washed twice with PBS, and the medium replaced with Opti-MEM prior to addition of the DNA/lipopeptide complexes. After 24 h of incubation in Opti-MEM, cells were washed twice with PBS, then harvested by adding 115 μL/well of Reporter Lysis Buffer (Promega, NSW, Australia) and incubated for 15 min at room temperature. The cells were then scraped, collected, and centrifuged, and the supernatants were used for protein and luciferase assays.

Luciferase and Protein assays. After harvest, cells were centrifuged at 13 000 g for 2 min at 4 °C. The supernatant (50 μL) was used to measure luciferase activity using a luciferase detection kit (Promega, Annandale, NSW, Australia). Quantilum Recombinant Luciferase (QRL) (Promega, Annandale, NSW, Australia) was used as a standard for luciferase assays. Total protein concentrations were measured using the Bradford protein assay (Sigma Aldrich, Sydney, NSW, Australia). Bovine serum albumin (BSA; Sigma-Aldrich Sydney, NSW, Australia) was used as a standard for protein assays.

RESULTS

DNA Condensation Studies. The results of DNA condensation experiments showed that the alkyltrimethylammonium bromide with a C_{16} alkyl chain (HDTAB) condensed DNA as efficiently as PLL (Figures 1, 2A), whereas the C_{12} compound

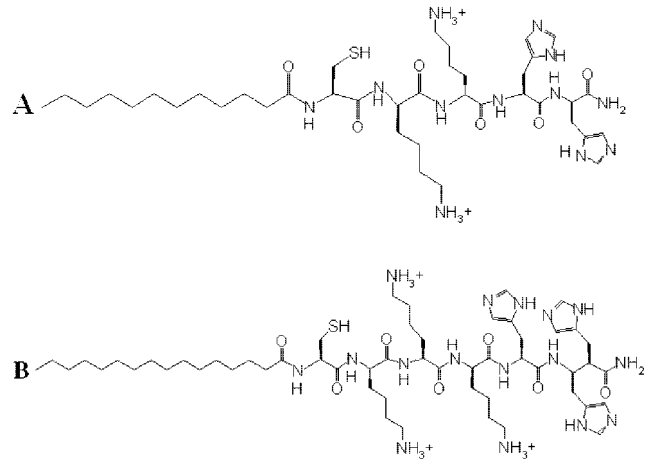

Figure 1. Representative structures of the lipopeptide-based transfection agents and their protonation at physiological pH 7.4: (A) Lauryl (C-12)-CK_2H_2 and (B) Palmitoyl (C-16)-CK_3H_3.

(DDTAB) and the decamethonium dication did not. Similarly, a lipopeptide bearing a palmitoyl (C_{16}) alkyl chain condensed DNA more efficiently than the corresponding lauryl (C_{12}) equivalent (Figure 2B). Lipopeptides with a single lysine residue, such as $PalCKH_2$, were weak condensers of DNA when compared to lipopeptides with two or three lysine residues (Figure 2C). The extent of DNA condensation by palmitoylated compounds with two lysine residues was a function of the number of histidine residues. At each charge ratio, the extent of ethidium exclusion decreased with increasing histidinyl chain length over the range 2–5 (Figure 2D).

Gel Mobility Shift Assay. Condensation of DNA with $PalCK_2H_2$ and $PalCK_2H_5$ caused retardation of DNA migration at charge ratios above 1 (Figure 3A,B). At a charge ratio of 0.5, migration was substantially retarded, though some DNA appeared to migrate into the gel from the $PalCK_2H_5$ complex, indicating less efficient condensation. Figure 3C shows that an N/P ratio of at least 1.5 was required to effect gel retardation by PEI. At charge ratios of 5.0 or above, the DNA-$PalCK_2H_2$ and DNA-$PalCK_2H_5$ complexes could not be detected on the agarose gel (Figure 3A,B). Similarly, DNA−PEI complexes, at an N/P ratio of 5 or above, were not identified on the gel (Figure 3C). This can be explained by the previous observation that more complete condensation at higher charge ratio prevents the binding of ethidium to the complex, as exemplified by the results of the ethidium exclusion experiments (Figure 2). The results of the gel-shift experiments suggest that immobilization of the complex occurred before the DNA was fully condensed.

Complex Stability in the Presence of DNase. The stability of lipopeptide−DNA complexes was evaluated in the presence of DNase to model the protection to enzymatic degradation resulting from condensation. Figure 4 shows a representative experiment using $PalCK_2H_2$ complexes. The results show that the majority of the mass of DNA in free solution was degraded after 30 min of incubation in the presence of DNase. At charge ratios greater than 1.0, the lipopeptide $PalCK_2H_2$ fully protected DNA from DNase degradation. The protection from nuclease degradation at this low charge ratio was superior to the protection given by cationic polymers and liposomes. This level of DNA protection by $PalCK_2H_2$ was also more pronounced than that offered by the cationic amphiphile guanidinocysteine *N*-decylamide (C_{10}-C^{G+}). The latter compound has been reported to protect DNA from serum degradation at a charge ratio of 3.0 (*37*), but as indicated by our ethidium exclusion studies (Figure 2), DNA condensation was less efficient than that achieved with $PalCK_2H_2$.

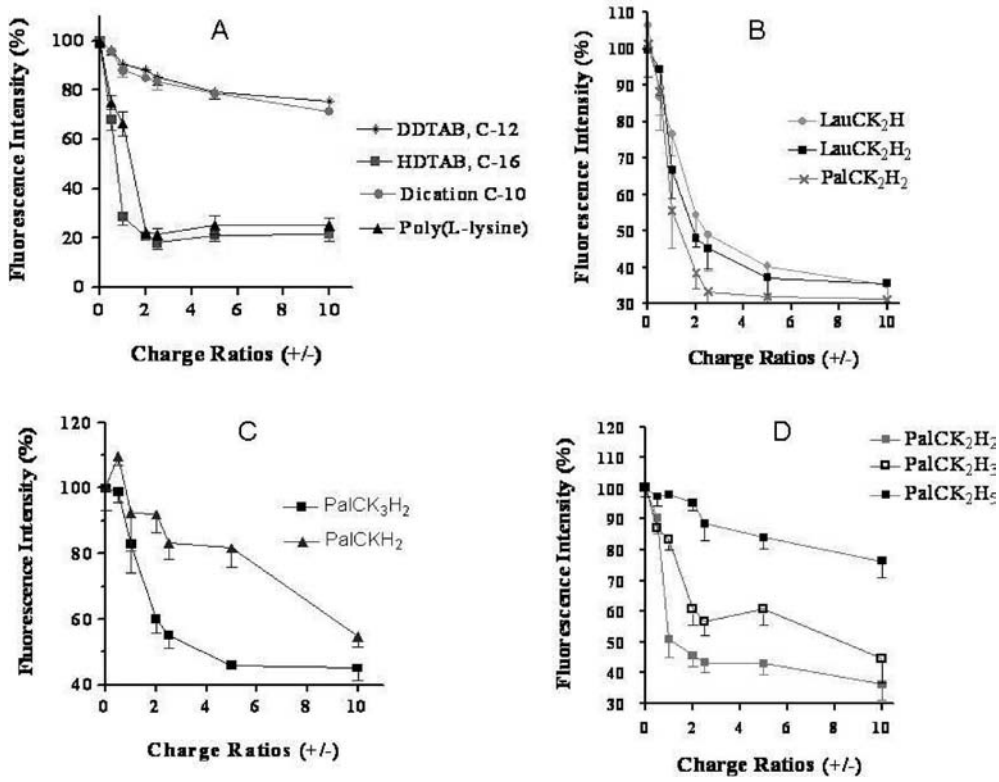

Figure 2. Condensation studies of DNA-transfection agents using ethidium bromide exclusion assay (measured at $\lambda_{ex} = 520$ nm and $\lambda_{em} = 610$ nm; FluoSTAR plate reader). Data are presented as mean ± SD ($n = 3$). (A) Comparison of alkyl chains, as the hydrophobic anchors, on ethidium exclusion during DNA condensation. (B) Effect of lauryl (C-12) and palmitoyl (C-16) chains on ethidium exclusion. (C) Effect of the number of lysine residues on ethidium exclusion by lipopeptides containing two histidine residues. (D) Effect of the number of histidine residues on the ability of lipopeptides with two lysine residues to condense DNA molecules.

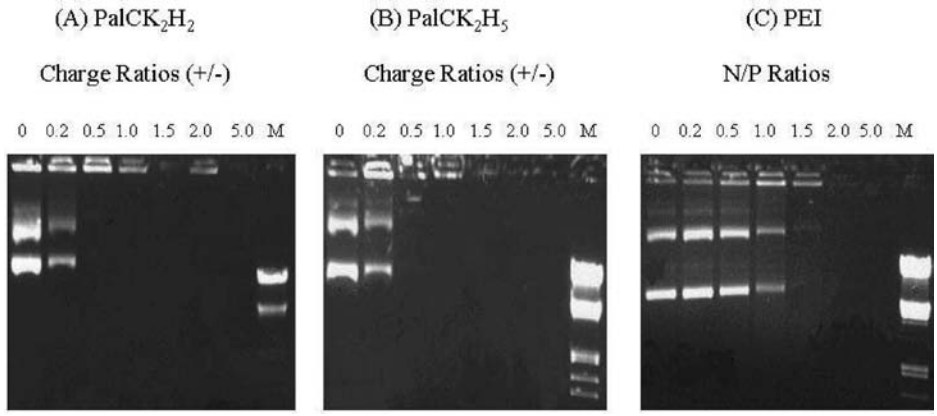

Figure 3. Gel mobility shift assays of DNA complexes formed by (A) $PalCK_2H_2$, (B) $PalCK_2H_5$, and (C) PEI. At a charge ratio of 1.0 or 1.5, both $PalCK_2H_2$ and $PalCK_2H_5$ effectively condensed the plasmid DNA to an extent analogous with condensation by PEI.

Physical stability of DNA−Lipopeptide Complexes. Particle size was determined over a 120 h period after formation of the complexes in HGB pH 7.4. This was of practical significance, particularly with regard to transfection studies, to ensure that the complexes did not aggregate during the period between formation and use, a common problem with polyelectrolyte complexes. Complexes formed at a charge ratio of 1.5, using 40 μg of DNA (243 nM) and the lipopeptides $PalCK_2H_2$, $PalCK_2H_3$, $PalCK_3H_2$, and $PalCK_3H_3$ in 500 μL HGB pH 7.4. These were completely stable for 1 h and had particle diameters in the range 250–300 nm. After longer time periods, some aggregation was evident with $PalCK_3H_2$ complexes (forming aggregates approximately twice the original diameter), but the other complexes remained unchanged for 60 h (Figure 5A). More aggregation was observed after 120 h, but $PalCK_3H_3$ complexes remained unchanged. A major advantage of the lipopeptides introduced in this study is their ability to form 200–300 nm complexes at relatively high DNA concentrations. Unlike complexes formed by Lipofectamine or PEI, the diameter of complexes of DNA with $PalCK_3H_2$ or $PalCK_3H_3$ was independent of DNA concentration over the range 10–120 μm (Figure 5B).

Mean Particle Size, Polydispersity Index, and Zeta Potential of Complexes. The mean particle size and zeta potential of complexes formed by DNA (15.2 nM) and lipopeptides (in 500 μL HGB pH 7.4) were examined as a function of increasing charge ratio (Figure 6A,B). As the charge ratios increased from 0.5 to 5.0, the mean particle sizes of the complexes formed with $PalCK_2H_2$, $PalCK_3H_2$, and $PalCK_3H_3$ decreased slightly (Figure 6A), from 230−260 nm down to

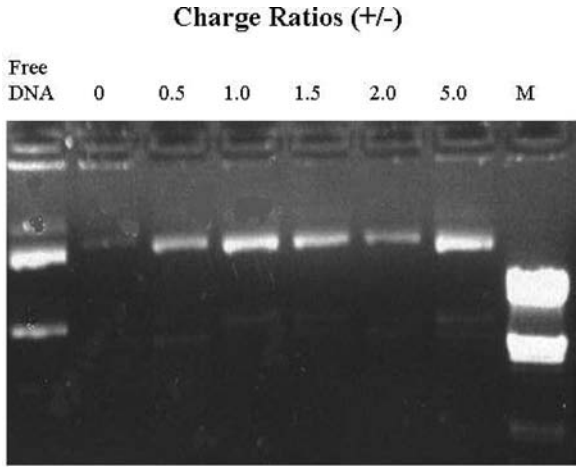

Figure 4. Stability of DNA-PalCK_2H_2 complexes against enzymatic degradation by DNase (Turbo DNase). In the absence of PalCK_2H_2 (a charge ratio = 0), the plasmid DNA was almost completely degraded. At a charge ratio of >1.0, the majority of the plasmid DNA remained intact after 30 min incubation with DNase at 4 °C.

110–150 nm at a charge ratio of 5.0 (Table 3). Complexes formed by PalCKH_2 were larger (Figure 2C), which may reflect a lower degree of DNA condensation by this lipopeptide, a hypothesis which is supported by the ethidium exclusion data. When PalCKH_2 was used to condense DNA the extent of ethidium exclusion was considerably lower than exclusion caused by K_2 or K_3 lipopeptides at the same charge ratio.

The zeta potential of complexes was a function of charge ratio and was similar for complexes formed by all lipopeptides. The zeta potential was negative at charge ratios below 1.0 and approached zero at a charge ratio of unity. When the charge ratio was increased above 1.0, the zeta potential became positive, reaching a maximum value of approximately +20 mV for charge ratios between 2.0 and 5.0 (Figure 6B).

Figure 7 shows typical values of the PDI, mean particle size, and zeta potential for 40 μg DNA complexed with (A) lipopeptide PalCK_2H_2, (B) PEI, and (C) Lipofectamine in HGB pH 7.4, at a charge ratio of 1.5 (N/P of 9.0 for PEI). For complexes of DNA−transfection agents shown, the PDI for the DNA−Lipofectamine complex was the highest (PDI = 1.0), indicating a wide size distribution. The Nanosizer data suggested that PEI and Lipofectamine complexes may have been multiphasic as well as polydisperse. DNA complexes formed by PalCK_2H_2 and other lipopeptides typically had more consistent particle size, narrower size distributions, and more precise zeta potentials than complexes formed with PEI or Lipofectamine.

For lipopeptides with the same number of histidine residues (2 or 3 histidines), we observed that, as the number of lysine residues in the lipopeptide increased, their mean particle sizes and polydispersities decreased (Tables 4 and 5). However, zeta potential was increased as the number of lysines was increased.

In Vitro Transfection Studies. The transfection efficiency of PalCK_2H_2 in Cos7 cells was found to be 80-fold greater than LauCK_2H_2 ($p < 0.001$) (Figure 8A), which correlated with its superior properties with respect to DNA condensation, complex stability, and resistance to nuclease digestion. PalCK_3H_2 was twice as effective as PalCK_3H_3 (Figure 8B). When the lipopeptides containing two histidine residues were compared, there were clear differences. The compound with one lysine residue was significantly less active than those with two or three lysine residues, which had similar activity (Figure 8C). For lipopeptides with three histidine residues, the K_3 lipopeptide was over twice as active as the K_2 lipopeptide (Figure 8D). When the best lipopeptides were compared with PEI and Lipofectamine,

Table 3. Effect of Charge Ratio on Mean Particle Size of DNA−Lipopeptide Complexes

	charge ratio	
	particle size	
lipopeptide	0.5	5
$PalCK_2H_2$	229 ± 23 nm	112 ± 5 nm
$PalCK_3H_2$	256 ± 22 nm	146 ± 50 nm
$PalCK_3H_3$	240 ± 27 nm	117 ± 3 nm

activity was comparable, although generally Lipofectamine was a marginally better transfection agent in vitro (Figure 8E).

DISCUSSION

This project investigated the effect of lipopeptide composition (alkyl chain length, number of lysines, and histidines) on DNA complex formation and transfection efficiency, and compared these novel lipopeptides with PEI and Lipofectamine. DNA condensation studies indicated that the addition of an alkyl chain to the lipopeptide molecule promoted complexation, and that the palmitoyl peptides were more effective than the corresponding lauryl lipopeptides. We hypothesize that the presence of the alkyl chain promotes complex formation resulting from the increased entropy derived by loss of water structure around the alkyl chain, commonly called the hydrophobic effect. The longer hydrophobic palmitoyl (C_{16}) chain would be expected to promote a stronger hydrophobic interaction, and this results in more compact and stable particles that have improved transfection efficiency.

The lysine residues on the lipopeptides were included to provide a protonated amine group at neutral pH that effected condensation of plasmid DNA. The amino acid side chain of lysine has a $pK_a = 10.80$, and is therefore 99.96% ionized at pH 7.4, enabling ionic interaction with the negatively charged sugar–phosphate backbone of DNA. DNA condensation with lipopeptides such as $PalCK_2H_2$ took place efficiently, and zeta potential data suggested that the complex formed included all lysine residues in a one-to-one stoichiometric relationship with the nucleotides. At least two lysine residues were required for efficient condensation and good transfection efficiency. The advantage of including a third lysine residue was limited.

Histidine residues were included to provide a source of weakly basic groups. It was hypothesized that these residues would become protonated in the endosome, thereby promoting endosomal escape in a manner analogous to the mechanism by which PEI is thought to achieve transfection. This approach led to efficient DNA condensation and transfection by the compound $PalCK_2H_2$. Additional histidine residues might be expected to improve the efficiency of endosomal escape, but this strategy resulted in less efficient condensation, when compared to $PalCK_2H_2$ (Figure 2D). There was a clear rank order, $H_5 < H_4 < H_3 < H_2$, in condensation efficiency as determined by ethidium exclusion, for palmitoylated lipopeptides containing two lysine residues. The lipopeptide $PalCK_2H_4$, for example, with four histidine residues per lipopeptide, resulted in only 10% ethidium exclusion at a charge ratio of 2.0. In contrast the DNA−ethidium fluorescence intensities for $PalCK_2H_3$ and $PalCK_2H_2$ complexes, at the same charge ratio, were reduced to 40% and 55% of the initial value, respectively. We suggest that the reduction in efficiency of DNA condensation with increase in histidine chain length may be explained by steric hindrance or a decrease in the entropic driving force for complexation.

Cysteine was included in the design if the lipopeptides to promote complexation by formation of disulfide bonds in a manner analogous to the compounds described previously by Behr and colleagues (*36*). We hypothesized that, in the presence of the DNA template, the Cys-lipopeptide is likely to dimerize, leading to in situ formation of a transfection agent with a double alkyl chain. This is the main advantage of including cysteine in the lipopeptide structure, since most single alkyl chain

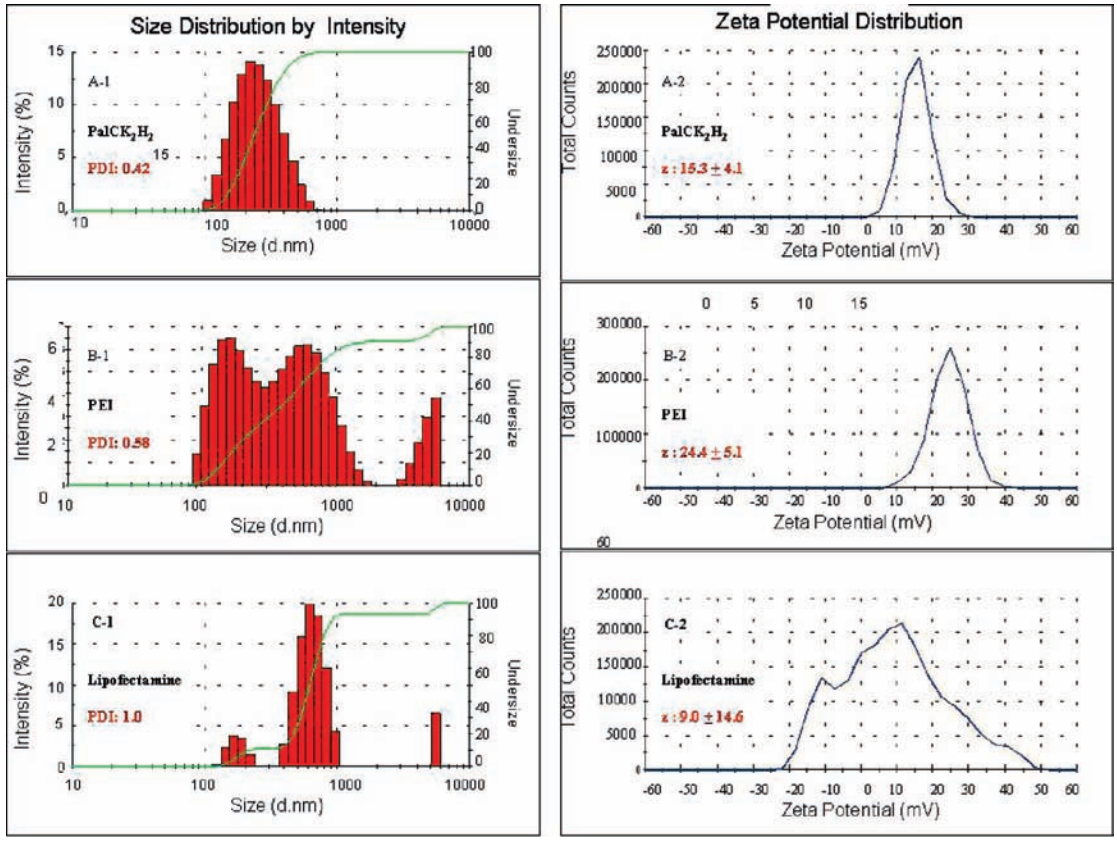

Figure 7. Typical size distributions and zeta potentials of DNA complexes formed at a charge ratio of 1.5 in HGB pH 7.4: with $PalCK_2H_2$ (A-1 and A-2), PEI (B-1 and B-2), and Lipofectamine (C-1 and C-2). The particle size data are expressed as a histogram showing the size distribution and as the cumulative % undersize, shown as the solid line plotted against particle size.

Table 4. Effect of Lipopeptide Structure on Mean Particle Sizes, Zeta Potential, and Polydispersity of DNA−Lipopeptide Complexes at a Charge Ratio of 1.5 in HGB pH 7.4[a]

lipopeptide	particle size (nm) (mean ± SD)	PDI (mean ± SD)	zeta potential (mV) (mean ± SD)
$PalCKH_2$	688 ± 28	0.77 ± 0.05	3.6 ± 1.7
$PalCK_2H_2$	240 ± 4.1	0.31 ± 0.03	13.2 ± 0.7
$PalCK_2H_3$	254 ± 6.2	0.35 ± 0.04	5.4 ± 0.3
$PalCK_3H_3$	247 ± 3.3	0.27 ± 0.001	6.3 ± 0.5

[a] Complexes were formed by diluting 40 μg DNA (~243 nM); data are represented as mean ± SD of triplicate measurements ($n = 3$).

Table 5. Effect of Coupling Histidine to $PalCK_2$ Lipopeptides on Mean Particle Size, Zeta Potential, and Polydispersity of DNA−Lipopeptide Complexes at a Charge Ratio of 1.5 in HGB pH 7.4[a]

lipopeptide	particle size (nm) mean ± SD	PDI mean ± SD	zeta potential (mV) mean ± SD
$PalCK_2H_2$	240 ± 4.1	0.31 ± 0.03	13.17 ± 0.74
$PalCK_2H_3$	254 ± 6.2	0.35 ± 0.04	5.44 ± 0.28
$PalCK_2H_4$	724 ± 317.0	0.67 ± 0.18	1.53 ± 0. 25
$PalCK_2H_5$	Sedimentation[b]	-	-

[a] Complexes were formed by diluting 40 μg DNA (~243 nM); data are presented as mean ± SD of triplicate measurements ($n = 3$). [b] The complex formed large aggregates that sedimented rapidly, therefore their mean particle sizes and other particle properties could not be determined with the Zetasizer Nano ZS.

transfection agents are (a) less efficient at condensing DNA and (b) generally regarded as toxic to cells (*38*). We have not established yet whether dimerization is indeed occurring after complexation, and this is the subject of further investigation in our laboratories.

In our studies, the mean diameters of the DNA−lipopeptide complexes were between 180 and 275 nm and 250–400 nm for DNA-$PalCK_3H_3$ and DNA-$PalCK_3H_2$, respectively. Particle mean size was approximately independent of DNA concentration, up to 120 nM. Typically, DNA complexes aggregate at high concentration. For example, Duguid et al. have reported that the diameter of DNA complexes formed at a charge ratio of 3.0 with synthetic cationic peptide analogues ($YKAK_nWK$) and the amphipathic peptide (GLFEALLELLESLWELLLEA) increased as DNA concentration increased (*39*). The lipopeptides described here are unlikely to bind more than one primary condensed DNA particle at once. This reduces the opportunity for particle cross-linking, which we suggest may explain the particle growth at high concentrations observed in this study with DNA−PEI or DNA−Lipofectamine complexes. The mean particle sizes of the DNA−PEI complexes were <500 nm at DNA concentrations of <10 nM, but complexes were 5–10 μm in diameter at concentrations of 60–120 nM. Similarly complexes of DNA−Lipofectamine resulted in a substantial particle aggregation (~8 μm) at high DNA concentration (~120 nM) (Figure 5B). Many DNA complexes are unstable over short periods of time. For example, Park et al. observed that complexes formed by 2 μg of DNA with linear or branched PEI (N/P = 10 in 1.2 mL PBS pH 7.2) increased in particle size when the complexes were incubated for longer than 10 min (*40*). The lipopeptides described here appear to form stable complexes even at high DNA concentrations, which we believe will be important for gene delivery in vivo.

The mean particle size and zeta potential of complexes were examined as a function of increasing charge ratio. In general terms, mean particle diameter decreased as charge ratio increased. In the case of complexes formed by the compound $PalCKH_2$, which only has one lysine residue, the mean particle

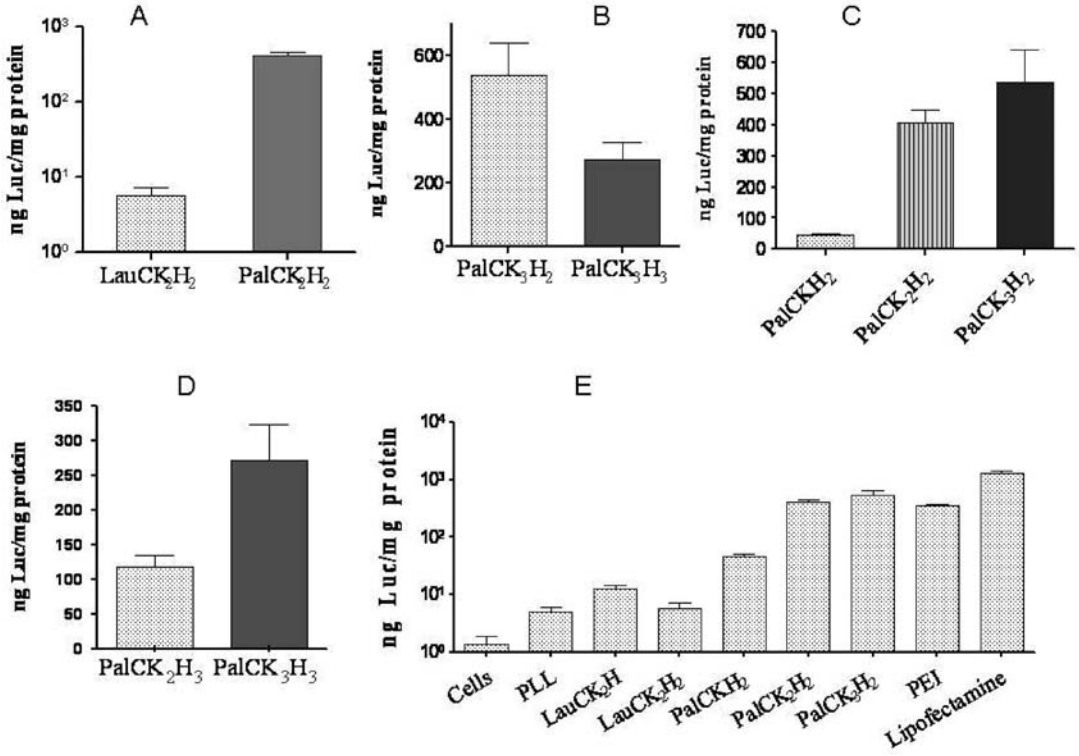

Figure 8. Transfection studies of DNA−lipopeptide complexes and DNA−Lipofectamine complexes at charge ratio of 1.5 in COS7 cells.The PEI complexes were formed at an N/P ratio of 9. Data are presented as mean ± SD for triplicate determinations ($n = 3$). Effect of (A) alkyl chains, lauryl, and palmitoyl on transfection efficiency; (B) the number of lysine residues in lipopeptides with two histidine residues; (C) the number of lysine residues in lipopeptides with three histidine residues; (D) the number of histidine residues in lipopeptides with three lysine residues. (E) The transfection efficiency of selected lipopeptide constructs compared to commercially available transfection agents (PLL, PEI, and Lipofectamine).

size decreased markedly from 1186 ± 375 nm at a charge ratio of 1.0 to 423 ± 5 nm at a charge ratio of 5.0. Particle sizes were smaller for complexes formed by $PalCK_2H_n$ lipopeptides, but they still decreased as charge ratio increased. These data were consistent with previous publications (*33, 41*). As the charge ratio increased from 0.5 to 5.0, the zeta potential of the complexes changed from a negative value (−16 ± 5 mV) to a positive value (approximately 20 ± 3 mV) (Figure 6B). No further increase in the zeta potentials of the complexes were observed when the charge ratio was increased above 2.5. This may indicate that much of the additional lipopeptide was in a free state when charge ratio exceeded this value. At a charge ratio of 1.0, the zeta potential was close to zero, which indicated that all or most of the lipopeptide was engaged in binding DNA. These observations were in agreement with another report which noted that the zeta potential of DNA complexes became positive at a charge ratio of >1.5 (*13*).

It is generally accepted that complexes of DNA and transfection agents are heterogeneous in particle size. As shown in Figure 7, at a charge ratio of 1.5 (N/P of 9.0 for PEI), the zeta potentials of $PalCK_2H_2$, PEI, and Lipofectamine complexes were positive: 15.3 ± 4.1 mV, 24.4 ± 5.1 mV, and 9.0 ± 14.6 mV, respectively. It was interesting to note that complexes which had a high polydispersity, such as Lipofectamine complexes, typically had a higher standard deviation for the estimated zeta potential, a further reflection of increased heterogeneity. We also observed that, at a charge ratio of 1.5, the zeta potential for some DNA−Lipofectamine complexes were negative, indicating that some of the transfection agent was not involved in binding DNA. This is in agreement with Slimani et al., who reported that the zeta potentials for complexes of DNA with liposomes (DMHAPC-Chol/DOPE (1:1) changed from negative to positive at a charge ratio of 1.5–2.0 (*13*). Gilot et al. also reported that the zeta potentials of complexes of DNA-cationic lipid GB12 (glycine betaine 12) were still negative at a charge ratio of 1.45 (*42*). These data show that the complexes produced with $PalCK_2H_2$ were less heterogeneous than complexes formed with two standard transfection agents, PEI and Lipofectamine. This is an important result in the search for better transfection agents.

The effect of extra lysine residues on the mean particle sizes, zeta potentials, and polydispersities of DNA complexes was to induce formation of more condensed DNA−lipopeptide complexes, though the $PalCK_2$ series compounds compared well with $PalCK_3$ series compounds. Increasing the number of histidine residues led to an increase in the mean particle size of DNA complexes and corresponding increases in polydispersity. Thus, although longer histidine chain length may have been advantageous for endosomal escape, any advantage was abrogated by less efficient DNA condensation, or additional aggregation of primary complexes. The compound $PalCK_2H_5$ resulted in substantial aggregation and sedimentation of DNA complexes. This may have been due to the hydrophobic nature of the imidazole side chain, rendering it less water-soluble compared to the effects of the lysine side chain. These observations were supported by the data obtained using the EtBr exclusion assay, when addition of more lysine in the lipopeptide constructs resulted in lower fluorescence intensity (more condensed particles), while addition of histidine residues had the opposite effect (Figure 2).

Experiments were conducted in order to determine the relative transfection efficiencies of the constructs. Several groups have reported that histidine-rich peptides have enhanced transgene expression (*43–46*), and it was our intention to exploit this property. However, our results suggest that there is an optimum histidine chain length for $PalCK_nH_m$ compounds, for efficient DNA condensation while retaining disruptive activity to the endosome. The sequence order of histidine residues in the

lipopeptide may also affect transfection efficiency, and this merits further study. We used linear clusters of K and H, i.e., K−K−K−H−H−H rather than alternating lysyl-histidinyl chains (H−K−H−K−H−K). Chen et al. reported that an alternating copolymer of histidine and lysine (with several variations of H−K, such as the (13mer)-[K−H−K−H−K−H−K−G−K−H−K−H−K−H−K], significantly enhanced the transfection efficiency of cationic liposomes up to 10-fold (*30*). The copolymer of H−K alone did not facilitate gene expression, suggesting that complexation may not have been efficient in the absence of the liposomes.

Midoux and co-workers reported that the transfection efficiency of a histidine-substituted (PLL) was much greater than unmodified PLL (*47*). This transfection efficiency was even higher than unmodified PLL complexes used in conjunction with chloroquine treatment. In the case of these graft copolymer DNA condensing agents, gene expression improved markedly at a low level of histidine substitution and only improved slightly with additional histidine substitution. It can therefore be concluded that those histidine residues whose side chains become protonated at pH ∼6.0 (endosome vesicle) contribute favorably to transfection by endosomal disruption, but that DNA condensation must also be efficient to gain maximum benefit. For this reason, addition of histidine residues does not always enhance overall transfection efficiency (*25, 47–49*).

The data presented in this study provide insights into new synthetic transfection agents that have several advantages for nonviral gene delivery. They are chromatographically purifiable, relatively low molecular weight compounds, which lack the inevitable heterogeneity of polymeric transfection agents, and therefore have advantages in terms of pharmaceutical analysis and characterization. Complexes formed with DNA are less sensitive to DNA concentration because they are unlikely to cross-link two or more primary particles. Although the in vitro transfection efficiencies of the lipopeptides reported here were lower than Lipofectamine, the transfection efficiencies of two of the lipopeptide constructs ($PalCK_2H_2$ and $PalCK_3H_2$) were much higher than PLL and somewhat higher than PEI (Figure 8E). It is likely that, by varying the ratio of histidine (H) and lysine (K) residues, as well as optimizing the sequence order and position of H−K, the transfection efficiency of the lipopeptide constructs might be significantly improved further. However, it should also be recognized that in vitro transfection is a poor indicator of activity in vivo, and high in vitro activity is often explained by sedimentation of large DNA complexes onto the cell surface during the transfection period (typically 4 h). In contrast, in vivo applications require complexes to be small and stable to promote improved biodistribution. The lipopeptides introduced here have the potential to improve gene delivery in vivo by producing stable complexes with DNA, and further investigation of their properties is warranted.

ACKNOWLEDGMENT

We wish to thank Dr. Ben Boyd for his assistance with the use of the Zetasizer Nano ZS. A scholarship for Tarwadi was provided by the Australian Government overseas aid program (AusAID).

Achieving high-yielding, robust, and reproducible chemistry is a prerequisite for the ^{18}F-labeling of peptides for quantitative receptor imaging using positron emission tomography (PET). In this study, we extend the toolbox of oxime chemistry to include the novel prosthetic groups [^{18}F]-(2-{2-[2-(2-fluoroethoxy)ethoxy]ethoxy}ethoxy)-acetaldehyde, [^{18}F]**5**, and [^{18}F]-4-(3-fluoropropoxy)benzaldehyde, [^{18}F]**9**, in addition to the widely used 4-[^{18}F]fluorobenzaldehyde, [^{18}F]**12**. The three ^{18}F-aldehydes were conjugated to the same aminooxy-bearing RGD peptide and the effect of the prosthetic group on biodistribution and tumor uptake studied in mice. The peptide conjugate [^{18}F]**7** was found to possess superior *in vivo* pharmacokinetics with higher tumor to blood, tumor to liver, tumor to muscle, and tumor to lung ratios than either [^{18}F]**10** or [^{18}F]**13**. The radioactivity from the [^{18}F]**7** conjugate excreted more extensively through the kidney route with 79%id passing through the urine and bladder at the 2 h time point compared to around 55%id for the more hydrophobic conjugates [^{18}F]**10** and [^{18}F]**13**. The chemical nature of a prosthetic group can be employed to tailor the overall biodistribution profile of the radiotracer. In this example, the hydrophilic nature of the ethylene glycol containing prosthetic group [^{18}F]**5** clearly influences the overall excretion pattern for the RGD peptide conjugate.

INRODUCTION

Integrins are heterodimeric glycoproteins involved in cell−cell and cell−matrix interactions (*1*). One of the most important members of this receptor class is the $\alpha_v\beta_3$ integrin, which is involved in the process of tumor-induced angiogenesis (*2*). We have previously reported on [^{99m}Tc]-NC100692, an RGD-containing peptide which has demonstrated clinical utility for imaging of breast cancer (*3*). The peptide pharmacophore binds strongly to the integrin receptors expressed on proliferating endothelial cells, and the structure allows for attachment of a variety of imaging reporter groups with no significant loss in binding affinity (*4*). These peptides therefore represent a new class of RGD-containing probes for the imaging of angiogenesis (*5–8*).

Although there are many examples of molecular imaging agents based on single photon emission computed tomography (SPECT), positron emission tomography (PET) represents a superior modality with respect to resolution, sensitivity, and the ability to acquire quantitative information from the imaging data (*9*). In addition, the widespread availability of [^{18}F]fluoride, optimal half-life (110 min), and low positron energy (0.64 MeV) makes this isotope the first choice for PET imaging (*10–13*). Significant challenges, however, still need to be overcome before ^{18}F-labeled peptides can be routinely manufactured for broad clinical application. Generic radiolabeling strategies using prosthetic groups offer the advantage that a significant part of the radiochemical process can be standardized and applied to multiple products. The prosthetic group must be unreactive toward the various functional groups found in peptides, forming instead a stable bond in a site-specific manner. The aforementioned criteria are met by utilizing oxime bond formation between an ^{18}F-aldehyde and an aminooxy-modified peptide. This type of chemoselective ligation chemistry has been employed in the past by ourselves and others using 4-[^{18}F]fluorobenzaldehyde with acceptable yields being reported for a range of peptides (*14–18*). We have previously observed, however, that the hydrophobic nature of this prosthetic group has an effect on *in vivo* pharmacokinetics, often increasing excretion of the tracer through the hepatobiliary system. The aim of this work was to further extend the toolbox of available ^{18}F-aldehydes with the principle goal of improving the pharmacokinetic profile of our RGD tracer. To this end, we considered a design strategy utilizing a short poly(ethylene glycol) (PEG) spacer as an integral component of the prosthetic group. Short PEG spacers are known to increase hydrophilicity and have been shown to improve the biodistribution profile of tracers *in vivo* (*19, 20*). As predicted, the PEG-containing conjugate [^{18}F]**7** demonstrated superior *in vivo* performance as compared to the more hydrophobic tracers [^{18}F]**10** and [^{18}F]**13** in the Lewis Lung Carcinoma mouse model (LLC). Micro-PET imaging studies were performed to examine the potential of this novel conjugate for the imaging of angiogenesis in vivo.

MATERIALS AND METHODS/EXPERIMENTAL PROCEDURES

Chemicals and solvents used were all reagent grade and used without further purification. The RGD core peptide **6** was synthesized as previously described in the literature from key intermediate NC100717 (*4*). ^{1}H NMR spectra were run at 25 °C on a Varian Unity Inova 500 MHz spectrometer equipped with a 5 mm ^{1}H-broadband PFG indirect detection probe. Mass analyses were recorded on a LCQ quadrupole ion-trap mass spectrometer (Thermo Finnigan). All chemicals used in radiolabeling were anhydrous solvents purchased from Sigma-Aldrich (Gillingham, UK). HPLC solvents were obtained from Fisher

Scientific (Loughborough, UK). Fluorine-18 was produced by a Scanditronix MC 40 cyclotron using the $^{18}O(p,n)^{18}F$ reaction. Enriched [^{18}O]H_2O (10–30% ^{18}O) was irradiated by protons (19 MeV) with an integrated beam current of 5–10 μAh. The microwave oven was made in-house and consisted of a brass cavity [coaxial resonance system with apperture (1.3 cm) for microreaction vessels] and an external magnetron (Microtron 200, Electro-Medical Supplies Ltd., Wantage, England). The temperature was measured using an internal fiber-optic probe (FTP3–003H, system FT1310 by Takaoka Electric Ltd., Japan). The HPLC system was a Beckman System Gold instrument equipped with a gamma detector (Bioscan Flow-count). A Phenomenex Luna C18(2) column (50 × 4.6 mm, 3 μm; flow rate 1 mL/min) was used for analytical HPLC. The preparative HPLC system utilized the semipreparative column Phenomenex Luna C18(2), 250 × 10 mm, 5 μm, at a flow rate of 4 mL/min unless otherwise stated. The following mobile phase/gradient systems were used. Gradient 1: solvent A, water (0.1%) TFA; solvent B, acetonitrile (0.1% TFA); 1 min 10% B, 10–50% B in 20 min. Gradient 2: solvent A, water (0.5%) TFA; solvent B, acetonitrile (0.5% TFA); 1 min 10% B, 10–50% B over 20 min.

Synthesis of Compound 1 (Scheme 1). To a stirring suspension of sodium hydride (248 mg, 5.15 mmol in mineral oil) in THF (5 mL) was added through a syringe a solution of 2-{2-[2-(2-hydroxyethoxy)ethoxy]ethoxy}ethanol (1.00 g, 5.15 mmol) in THF (5 mL) at ambient temperature. After gas evolution had ceased, the mixture was stirred for 45 min giving a clear slightly yellow solution. Bromoacetaldehyde dimethyl acetal (8.70 g, 51.5 mmol) was then added with stirring for 24 h followed by 3 mL of ethyl acetate for a further 2 h. The mixture was poured into ether (100 mL) and extracted with 10% aqueous K_2CO_3 (30 mL) and brine (30 mL). The organic phase was dried over Na_2SO_4, filtered, and evaporated. Excess bromoacetaldehyde dimethyl acetal was removed from the mixture by distillation and the residual oil purified by flash chromatography using 100% ethyl acetate to afford the pure product (355 mg, 21%). ^{1}H NMR ($CDCl_3$): δ 4.52 (t, 1H, $^3J_{HH}$ = 5.2 Hz, OCH_2CH), 4.20–4.24 (m, 2H, $CH_3CO_2CH_2CH_2O$), 3.69–3.72 (m, 2H, $CH_3CO_2CH_2CH_2O$), 3.63–3.69 (m, 12H, OCH_2CH_2O), 3.54 (d, 2H, $^3J_{HH}$ = 5.2 Hz, OCH_2CH), 3.39 (s, 6H, CH_3O), 2.08 (s, 3H, CH_3CO_2).

Synthesis of Compound 2. A solution of 1 N NaOH in methanol (1 mL) was added to a stirring solution of acetic acid 2-(2-{2-[2-(2,2-dimethoxyethoxy)ethoxy]ethoxy}ethoxy)ethyl ester (110 mg, 0.34 mmol) in methanol (3 mL) at ambient temperature. The reaction was monitored by TLC ($CHCl_3$/MeOH, 9:1) and was found to be complete within 30 min. The solvent was evaporated and the residue purified by flash chromatography (silica, $CHCl_3$/MeOH, 9:1) to afford the product (73 mg, 76%) as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 4.52 (t, 1H, $^3J_{HH}$ = 5.2 Hz, OCH_2CH), 3.71–3.75 (m, 2H, $HOCH_2CH_2O$), 3.63–3.70 (m, 12H, OCH_2CH_2O), 3.59–3.63 (m, 2H, $HOCH_2CH_2O$), 3.55 (d, 2H, $^3J_{HH}$ = 5.2 Hz, OCH_2CH), 3.40 (s, 6H, CH_3O), 2.94 (broad s, 1H, $HOCH_2CH_2O$).

Synthesis of Compound 3. To a solution of alcohol **2** (60 mg, 0.21 mmol) in THF (1 mL), triethylamine (59 μL, 0.42 mmol), and methanesulfonyl chloride (24 μL, 0.30 mmol) were added with stirring. The reaction was monitored by TLC (silica, $CHCl_3$/MeOH, 9:1). After 2 h, the precipitated triethylamine hydrochloride salt was filtered off. The solvent was evaporated and the product obtained as an oil (75 mg, 99%) following flash chromatography (silica, chloroform/methanol (9:1). ^{1}H NMR ($CDCl_3$): δ 4.52 (t, 1H, $^3J_{HH}$ = 5.2 Hz, OCH_2CH), 4.37–4.40 (m, 2H, $CH_3SO_3CH_2CH_2O$), 3.75–3.78 (m, 2H, $CH_3SO_3CH_2CH_2O$), 3.62–3.69 (m, 12H, OCH_2CH_2O), 3.54 (d, 2H, $^3J_{HH}$ = 5.2 Hz, OCH_2CH), 3.40 (s, 6H, CH_3O), 3.08 (s, 3H, $CH_3SO_3CH_2CH_2O$).

Synthesis of Protected Aldehyde [^{18}F]4. To a Wheaton vial (2 mL) charged with Kryptofix-222 (10 mg), potassium carbonate (1 mg dissolved in 50 μL water), and acetonitrile (0.8 mL), the fluorine-18 containing water (1 mL) was added. The solvent was removed by heating at 110 °C for 1 h under a stream of nitrogen. A 0.5 mL portion of anhydrous acetonitrile was added and immediately removed by evaporation. This step was repeated an additional two times, followed by addition of mesylate **3** (1.0 mg, 2.7 μmol) in anhydrous DMSO (0.2 mL). After heating by microwave (5 min, 160 °C, 150 → 50 W) the reaction mixture was analyzed by HPLC (gradient 1, t_R = 7.8 min). After diluting with water (0.4 mL), the solution was applied to a SepPak ^{t}C18-plus cartridge preconditioned with acetonitrile (5 mL) and water (20 mL). The cartridge was flushed with water (10 mL) and [^{18}F]**4** eluted using acetonitrile (0.5 mL). The solvent was evaporated under a stream of nitrogen at 80 °C.

Synthesis of Aldehyde [^{18}F]5. To the above product was added a mixture of 12 M HCl (34 μL, 0.41 mmol) and acetonitrile (34 μL) and the vial left at room temperature for 15 min. Complete deprotection of starting material was observed as evidenced by HPLC analysis.

Synthesis of Aminooxy−Peptide Precursor 6. To peptide precursor NC100717 (detailed synthesis described in ref (*4*)) (150 mg, 0.12 mmol) in DMF (5 mL) was added a solution of Boc-aminooxyacetic acid (34 mg, 0.18 mmol), 7-azabenzotriazol-1-yloxy-tris-(pyrrolidino)phosphonium hexafluorophosphate (PyAOP) (94 mg, 0.18 mmol), and *N*-methylmorpholine (NMM) (40 μL, 0.36 mmol) in DMF (3 mL) and the mixture left stirring for 12 h. Excess solvent was evaporated in vacuo and the crude product purified by preparative HPLC chromatography (Phenomenex Luna C18 column, 00G-4253-V0; solvents A = water/0.1% TFA and B = CH_3CN/0.1% TFA; gradient 10–50% B over 60 min; flow 50 mL/ min; detection at 254 nm), affording 97 mg (57%) of pure compound (analytical HPLC: Phenomenex Luna C18 column, 00G-4252-E0; solvents: A = water + 0.1% TFA and B = CH_3CN + 0.1% TFA, gradient 10–50% B over 20 min; flow 1.0 mL/min; t_R 19.4 min, detected at 214 and 254 nm). Further characterization was carried out by mass spectrometry, giving an *m*/*z* value for the desired product at [M − H^+] 1431.2.

Synthesis of Peptide Conjugate [^{18}F]7. To a small centrifuge vial (PP with screw cap, 1.5 mL) was added Boc-aminooxy RGD peptide precursor **6** (1 mg, 0.7 μmol) and 0.2 mL of a 95% TFA solution containing 5% water. After standing for 5 min at room temperature, the solvent was removed under a flow of nitrogen. To the vial containing [^{18}F]**5** were added 28% ammonium hydroxide (48 μL, 0.71 mmol) and 0.5 M sodium acetate buffer pH 4.0 (50 μL). This mixture was transferred into the vial containing the peptide and the solution incubated at 75 °C for 7 min. The reaction mixture was cooled in an ice bath, quenched with 0.2 mL HPLC mobile phase (20% acetonitrile/ water), characterized by analytical HPLC (gradient 2, t_R = 11.8 and 12.0 min), and isolated by preparative HPLC (gradient 2, t_R = 13.0 min). The peptide conjugate [^{18}F]**7** was formulated, following evaporation in vacuo of excess solvent at 40–50 °C, by addition of PBS buffer containing 10% ethanol.

Synthesis of Compound 8 (Scheme 2). To a solution of 4-(3-hydroxypropoxy)benzaldehyde (1.4 g, 8.0 mmol) in dichloromethane (10 mL) was added triethylamine (1.2 mL, 8.5 mmol) and mesyl chloride (0.62 mL, 8.0 mmol). After stirring for 1.5 h at room temperature, the reaction mixture was washed with water and dried over Na_2SO_4 to give 1.8 g of crude material (yellow oil). An aliquot of 290 mg was purified by reverse-phase chromatography (column Phenomenex Luna C18(2) 5 μm

21.2 × 250 mm, solvents: A = water/0.1% TFA and B = acetonitrile/0.1% TFA; gradient 20–40% B over 60 min; flow 10.0 mL/ min). The structure was confirmed by NMR analysis. ^{1}H NMR [$CDCl_3$]: δ 2.279 (q, 2H, $MsOCH_2CH_2CH_2CH_2$, J = 6.0 Hz), 3.012 (s, 3H, CH_3); 4.190 (t, 2H, $MsOCH_2CH_2CH_2CH_2$, J = 5.9 Hz), 4.462 (t, 2H, $MsOCH_2CH_2CH_2CH_2$, J = 6.1 Hz), 7.010 (pd, 2H, aromatic, J = 8.8 Hz), 7.845 (pd, 2H, aromatic, J = 8.8 Hz); 9.895 (s, 1H, CHO).

Synthesis of Aldehyde [18F]9. A Wheaton vial (2 mL) was charged with tetrabutylammonium hydroxide solution (1.0 M in MeOH, 13.5 μL) and water (0.1 mL). After saturation with gaseous CO_2, acetonitrile (0.4 mL) and ^{18}F-containing water (178–485 MBq) were added. The water was removed azeotropically as described above, followed by addition of mesylate **8** (0.5 mg, 1.9 μmol) in anhydrous DMSO (0.2 mL). The mixture was heated in the microwave oven for 2 min at 110 °C. The product was identified by HPLC analysis (gradient 1, t_R = 16.1 min).

Synthesis of Peptide Conjugate [18F]10. Peptide **6** (4.0 mg, 2.8 μmol) was Boc-deprotected as described above and dissolved in 0.5 M ammonium acetate buffer pH 4.0 (0.1 mL). The reaction mixture containing [18F]**7** was added and the vial heated for 20 min at 70 °C. The coupling reaction was quenched by adding HPLC mobile phase (0.2 mL, 20% B). The labeled peptide [18F]**10** was identified by HPLC (gradient 1, t_R = 14.4 min), isolated by preparative HPLC (gradient 1, t_R = 15.4 min), and formulated by adding water (4 mL) followed by extraction using a SepPak C18-plus cartridge. The labeled peptide was eluted with ethanol (0.5 mL). After partial evaporation under a flow of nitrogen, the mixture was reconstituted with PBS.

Synthesis of Aldehyde [18F]12 (Scheme 3). To a Wheaton vial (2.0 mL) was added Kryptofix−222 (5 mg), potassium carbonate (1 mg in 50 μL water), acetonitrile (0.8 mL), and water containing [18F]fluoride. The water was removed azeotropically as described above. After addition of triflate **11** (0.5 mg, 1.6 μmol) in anhydrous DMSO, the vessel was heated for 15 min at 80 °C.

Synthesis of Peptide Conjugate [18F]13. Peptide **6** (2.3 mg, 1.6 μmol) was Boc-deprotected as described above, dissolved in 0.5 M ammonium acetate buffer pH 4.0 (0.2 mL), mixed with the solution containing [18F]**10**, and then heated to 70 °C for 10 min. [18F]**13** was identified by analytical HPLC (gradient

1, t_R = 13.7 min). After quenching with 0.1 mL HPLC mobile phase (20% acetonitrile/water), the product [^{18}F]**13** was isolated by preparative HPLC (gradient 1, t_R = 14.5 min) and formulated by SPE as described above.

The identities of all three ^{18}F-labeled peptide conjugates were confirmed by HPLC analysis in coelution experiments using authentic nonradioactive standards.

***In Vitro* Binding Assay.** Membranes from the human endothelial adenocarcinoma cell line EA-Hy926 were prepared and the K_d calculated for the purified membrane fraction. A competitive binding assay was then established to measure inhibition constants for each test substance without the need for labeling of the substance itself (*4*). ^{125}I-Echistatin was used as the labeled ligand and nonradioactive echistatin as a reference standard. A total of sixteen dilutions of test compound (either echistatin or test substance) were prepared and mixed with a combination of the radioactive tracer and membrane prior to incubation for 1 h at 37 °C. Following washing, the bound material was harvested on a filter using a Skatron microharvester. The filter spots were finally excised and counted in a Packard γ-counter. K_i values were calculated from the binding curves using *Prism* software.

[a] Summarized data at 5 and 120 min p.i. Average data (n > 3) of 2 independent experiments, presented as mean (SD).

Biodistribution Studies (LLC model). Lewis Lung carcinoma cells (LLC) (0.1 mL, 1 × 10^7 cells/ mL in medium) were injected subcutaneously into the right inner thigh of C57/BL6 mice (*ca.* 20 g; Charles River UK Ltd.). At 15 days following inoculation of the tumor cells, animals were divided into 3 groups (3 mice per group). Each mouse received 1.0 MBq of [^{18}F]**7**, [^{18}F]**10**, or [^{18}F]**13** as an intravenous bolus *via* the tail vein. Mice were sacrificed by cervical dislocation at 5, 60, and 120 min postinjection. Blood, tumor, and major organs were collected, weighed, and counted in a γ-counter (Wallac Wizard, Perkin-Elmer LAS (UK) Ltd.). The percentage of injected dose per gram (%id/g) or percentage of injected dose (%id) was determined for each sample.

The specificity of tumor uptake was determined by coinjecting an excess dose of nonradiolabeled RGD peptide with the [^{18}F]RGD peptide. Six LLC tumor-bearing mice were coinjected with 0.4 mg RGD peptide per kilogram of bodyweight, and the uptake of [^{18}F]RGD at 120 min postinjection in the blood, muscle, and tumor in these animals compared with that in control animals.

All animal experiments were approved by and carried out in compliance with the UK Home Office guidelines.

Imaging Studies. PET imaging was performed on a Micro-PET-P4 system (Siemens Inc., Knoxville, USA). Images were generated from three-dimensional sinogram data, rebinned to two-dimensional format by the FORE algorithm followed by

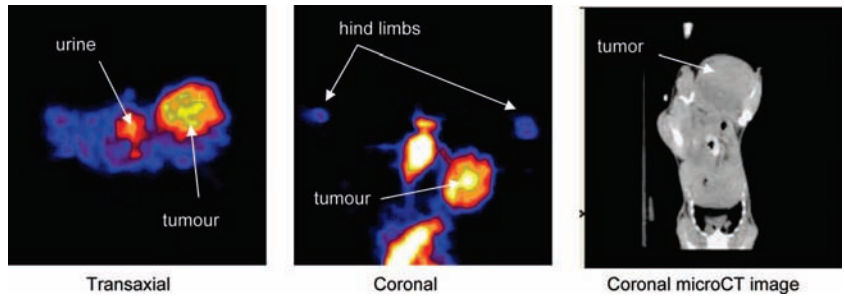

Figure 4. Transaxial and coronal MicroPET images of a mouse bearing a LLC tumor 2 h after tail vein injection of 8 MBq [18F]**7**. The animal was anaesthetized in the prone position using isoflurane.

two-dimensional filtered back-projection. For imaging studies, the animal model described above was used, followed by injection of 8.0 MBq of [18F]**7** as an intravenous bolus *via* the tail vein. Imaging was performed dynamically up to 120 min postinjection, with the animal anaesthetized in the prone position by inhaled isoflurane. Ten minutes prior to the beginning of the CT image, each mouse received an intravenous bolus of 0.1 mL Omnipaque (GE Healthcare, UK) in order to give improved tumor contrast. MicroCT imaging was performed using the microCAT II system (Siemens Inc., Knoxville, USA) with manufacturer recommended settings. MicroPET data were analyzed by using Amide software (http://amide.sourceforge.net).

RESULTS AND DISCUSSION

Radiosynthesis and Conjugation. Scheme 1 outlines the steps involved in the radiosynthesis of [18F]**5** and subsequent conjugation to the aminooxy-RGD precursor peptide **6**. Initial experiments to prepare the diacetal [18F]**4** using Kryptofix resulted in low labeling yields and so attempts were made to evaluate the effect of solvent and temperature on incorporation of [18F]fluoride. Changing the solvent from acetonitrile to dimethylsulfoxide did not significantly increase the yield at a reaction temperature of 80 °C (Table 1, entries 1 and 3). In addition, only modest improvement was observed with 30 min heating compared to 15 min (Table 1, entries 2 and 4) due to the rapid degradation of mesylate **3**. Although attempts at using the milder base [18F]TBAF (*21, 22*) gave no further improvement (Table 1, entry 5), increasing the temperature further to 160 °C for 5 min did favor the fluoridation reaction giving 60% radiochemical yield as evidenced by HPLC analysis (Table 1, entry 6). Optimal conditions were, however, established using microwave heating with near-quantitative incorporation of [18F]fluoride observed using an open vessel at 160 °C for 5 min (Table 1, entry 7). Figure 1 shows a typical HPLC analysis of the reaction mixture. Internal heating using microwaves gave better control of the [18F]fluoridation step and appeared to prevent side reactions. This result supports the growing evidence that microwave activation is often beneficial in PET radiochemistry (*23*).

The intermediate [18F]**4** was isolated by solid-phase extraction and following facile removal of the acetal groups aldehyde [18F]**5** was ready for conjugation with the aminooxy RGD peptide. Starting with 2 mg of peptide precursor, the desired compound [18F]**7** was obtained following preparative HPLC with a decay-corrected radiochemical conjugation yield of 24 ± 6% ($n = 10$) and a total radiochemical yield (decay-corrected referring to starting activity of [18F]fluoride) of 14 ± 6% ($n = 10$). Doubling the amount of precursor, however, to 4 mg increased the conjugation yield further to 51% with a total isolated yield of 38%. The analytical HPLC profile of the [18F]**7** revealed two peaks with identical retention times to the nonradioactive standard (Figure 2) formed by the isomerism of the oxime bond. The final product was formulated in PBS on a rotary evaporator with a recovery of 93 ± 7% ($n = 5$) in a total synthesis time of 3 h.

The radiosynthesis of aldehyde [18F]**9** was first attempted using the standard Kryptofix protocol in acetonitrile for 30 min at 80 °C as shown in Scheme 2. Surprisingly, only two byproducts with longer retention times were generated during the reaction as evidenced by HPLC analysis. In this case, the less basic [18F]TBAF system produced the desired aldehyde [18F]**9** in acceptable yields. Radiochemical yields could again be enhanced by microwave heating, the aldehyde [18F]**9** obtained in 57% yield after 5 min at 110 °C in DMSO, while with conventional heating, only 36% yield was obtained. In both experiments, the thermal lability of the mesylate **8** was found to be a limiting factor with complete decomposition occurring after 5 min. The Kryptofix/oxalate method, an alternative mild fluoridation approach, was tested under microwave conditions in DMSO (*24*). Although the mesylate precursor **8** appeared to have better stability, [18F]**9** was produced with a radiochemical yield of only 14% after 5 min heating at 110 °C. Optimal conditions were achieved with a combination of [18F]TBAF and microwave activation. [18F]**9** was isolated from the reaction mixture by solid-phase extraction with a radiochemical yield of 38% (decay corrected) and a radiochemical purity of 70%. Figure 3 shows the radio-HPLC of the conjugation step demonstrating that the aldehyde [18F]**9** was near-quantitatively consumed to give product [18F]**10**. Using the one-pot conjugation method, [18F]**10** was isolated following HPLC with an overall radiochemical yield of 14 ± 7% (decay-corrected, $n = 4$) and a radiochemical purity of 94%. The tracer was formulated by C18 SepPak extraction with a total synthesis time of 170 min.

[18F]**12** was obtained from 4-*N*,*N*,*N*-trimethylammonium benzaldehyde trifluoromethanesulfonate **11** following a literature method (*25*). On the basis of the labeling results for the fluoroaldehydes [18F]**5** and [18F]**9**, [18F]**12** was used in the conjugation step without isolation as shown in Scheme 3. The corresponding product [18F]**13** was obtained with a decay-corrected radiochemical yield of 23 ± 5% ($n = 3$) and a radiochemical purity of 96%. The radio-HPLC analysis of the reaction mixture after 10 min incubation indicated an almost quantitative coupling efficiency with only a trace of [18F]**12** remaining (5%).

***In Vitro* Affinity.** The competition binding assay (*4*) was established to measure the binding affinity for the integrin $\alpha_v\beta_3$ of the three conjugates. The nonradioactive compounds [19F]**7**, [19F]**10**, and [19F]**13** were found to compete with 125I-echistatin with K_i values calculated to be 2.3, 1.1, and 13.3 nM, respectively. In comparison, the α_v selective inhibitor cyclo(-Arg-Gly Asp-D-Phe-Lys-), a widely used RGD pharmacophore (*26*), had a K_i value in this assay of 27.8 nM. We would therefore suggest that differences observed in the biodistribution profiles

of the three conjugates could not be explained on the grounds of differences in the binding affinity for the integrin receptors *in vivo*.

Biodistribution and Imaging Studies. The conjugate [^{18}F]**7** demonstrated favorable biodistribution profile with good tumor uptake and retention at 120 min postinjection (1.64%id/g and 53%, respectively) as shown in Table 2. Additionally, due to the reduced background tissue uptake (e.g., in lung and liver) the ratios against tumor were improved with a tumor to blood ratio of ~6 and tumor to muscle ratio of ~7 at 120 min postinjection. The majority of the radioactivity was excreted via the urine, with 79%id in the urine and bladder 120 min postinjection. The localization of [^{18}F]**7** in LLC tumors as determined by MicroPET imaging is shown in Figure 4 alongside a microCT slice for anatomical reference. Representative transaxial and coronal images are shown from one mouse. There is clear visualization of the LLC tumor in the animal, along with clearance of [^{18}F]**7** through the bladder and gastrointestinal tract, which was consistent with the biodistribution data.

Although the blood kinetic profiles for [^{18}F]**13** and [^{18}F]**7** are similar, as summarized in Table 2, the increased lipophilicity of [^{18}F]**13** results in higher liver uptake compared to that of [^{18}F]**7** (data shown 120 min postinjection). Consequently, the amount of activity excreted via the liver into the gastrointestinal tract was around 21%id for [^{18}F]**13** compared to only 5%id for [^{18}F]**7**. Similarly, [^{18}F]**10** had significant gastrointestinal tract excretion (23%id) and lower urinary excretion (53%id).

Perhaps the most striking observation of the effect of the prosthetic group on biodistribution was seen on kidney excretion rates. In all, 79%id of [^{18}F]**7** activity passed into the urine and bladder and 5.4%id into the gastrointestinal (g.i.) tract at 2 h postinjection. This was compared to >20% g.i. excretion for both [^{18}F]**10** and [^{18}F]**13**.

In order to look at specificity, an *in vivo* blocking study with 10 μg excess unlabeled RGD peptide per animal resulted in a significantly reduced [^{18}F]**7** uptake in the tumor at 120 min postinjection. Tumor uptake was decreased from 1.48 ± 0.3%id/g to 0.76 ± 0.2%id/g ($p < 0.01$). Although this represents a 49% reduction of tumor uptake, further studies are needed with higher doses of nonradioactive peptide in order to achieve full blocking.

In summary, this work demonstrates that a rational approach to prosthetic group design can be successfully employed to optimize key *in vivo* characteristics of peptide-based tracers. Although localization of all three conjugates to the tumor was observed, [^{18}F]**7** possessed superior tumor to blood, lung, liver, and muscle ratios compared to the more hydrophobic conjugates [^{18}F]**10** and [^{18}F]**13**.

ACKNOWLEDGMENT

We would like to thank Colin Steel and the cyclotron operators of Hammersmith Imanet Ltd for providing us with fluorine-18.

Preparation of Rh[16aneS$_4$-diol]^{211}At and Ir[16aneS$_4$-diol]^{211}At Complexes as Potential Precursors for Astatine Radiopharmaceuticals. Part I: Synthesis

Marek Pruszyński,*,† Aleksander Bilewicz,† and Michael R. Zalutsky‡

Department of Radiochemistry, Institute of Nuclear Chemistry and Technology, Dorodna 16, 03–195 Warszawa, Poland, and Department of Radiology, Duke University Medical Center, Durham, North Carolina 27710. Received November 8, 2007; Revised Manuscript Received February 1, 2008

The goal of this study was to evaluate a new approach that can be applied for labeling biomolecules with ^{211}At. Many astatine compounds that have been synthesized are unstable *in vivo*, providing motivation for seeking different ^{211}At labeling strategies. The approach evaluated in this study was to attach astatide anions to soft metal cations, which are also complexed by a bifunctional ligand. Ultimately, this complex could in principle be subsequently conjugated to a biomolecule with the proper selection of ligand functionality. We report here the attachment of ^{211}At$^-$ and *I$^-$ (*I = ^{131}I or ^{125}I) anions to the soft metal cations Rh(III) and Ir(III), which are complexed by the 1,5,9,13-tetrathiacyclohexadecane-3,11-diol (16aneS$_4$-diol) ligand. Radioactive *I$^-$ anions were used for preliminary studies directed at the optimization of reaction conditions and to provide a baseline for comparison of results with ^{211}At. Four complexes Rh[16aneS$_4$-diol]*I/^{211}At and Ir[16aneS$_4$-diol]*I/^{211}At were synthesized in high yield in a one-step procedure, and the products were characterized mainly by paper electrophoresis and reversed-phase HPLC. The influences of time and temperature of heating and concentrations of metal cations and sulfur ligand 16aneS$_4$-diol, as well as pH on the reaction yields were determined. Yields of about 80% were obtained when the quantities of Rh(III) or Ir(III) cations and 16aneS$_4$-diol ligand in the solutions were 62.5 nmol and 250 nmol, respectively, and the pH ranged 3.0–4.0. Syntheses required heating for 1–1.5 h at 75–80 °C. The influence of microwave heating on the time and completeness of the complexation reaction was evaluated and compared with the conventional method of heating in an oil bath. Microwave synthesis accelerates reactions significantly. With microwave heating, yields of about 75% for Rh[16aneS$_4$-diol]^{131}I and Ir[16aneS$_4$-diol]^{131}I complexes were obtained after only 20 min exposure of the reaction mixtures to microwave radiation. In conclusion, this study has shown that it is possible to attach an astatide anion to soft metal cations in a simple and fast one-step procedure, with high yields. These complexes will be evaluated as reagents for labeling biomolecules.

INTRODUCTION

In the field of targeted radiotherapy, the selection of radionuclide is related to the type of treated disease. Currently, many radionuclides are under intensive investigation for therapeutic applications, particularly the Auger emitter ^{67}Ga ($t_{1/2}$ = 3.3 d), ^{111}In ($t_{1/2}$ = 2.8 d), α-particle emitters ^{211}At ($t_{1/2}$ = 7.2 h), ^{212}Bi ($t_{1/2}$ = 1 h), ^{213}Bi ($t_{1/2}$ = 45.6 m), and β^--particle emitters ^{90}Y ($t_{1/2}$ = 64 h), ^{188}Re ($t_{1/2}$ = 16.7 h), and ^{177}Lu ($t_{1/2}$ = 6.7 d) (*1*). An important factor is the nature of the cytotoxic radionuclide, mainly its physical parameters such as half-life and the nature of its associated emissions. Solid tumors generally have been pursued with β^- emitters including ^{90}Y and ^{131}I, because their β^- particles have a tissue range of several millimeters. The effective tissue range of β^- particles is not optimal for treatment of tumors as small clusters of cells or single cells, and micrometastases, because much of the decay energy is deposited outside the boundary of the tumor. Treatment of these diseases might be more effective with α-emitters, which combine short-range and high linear energy transfer, a combination that results in the high relative biological effect and cytotoxicity (*2*). Thus, α particles are able to make double-strand breaks in DNA, lesions that have a relatively high probability of leading to a "kill effect" on tumor cells (*3*). The shorter path length (40–100 μm) of α particles also should help limit radiotoxicity to neighboring normal tissue. For these reasons; considerable effort has been placed recently on the development of the α-emitters ^{223}Ra ($t_{1/2}$ = 11.4 d), ^{225}Ac ($t_{1/2}$ = 10 d), generator-obtained ^{212}Bi, ^{213}Bi, as well as the cyclotron-produced ^{211}At. The latter may perhaps be the most promising candidate for targeted radiotherapy, because its 7.2 h half-life allows sufficient time for performing its transportation, synthetic chemistry and multistep labeling, quality control, and clinical application without the problematic characteristic of having relatively long-lived α-particle-emitting daughters. Besides, each event of astatine decay is accompanied by emission of high-energy α particles with average energy of 6.4 MeV, corresponding to a mean range in human tissue of 65 μm (*4*). Therefore, the ionization occurs within a small volume, and when astatine is localized within a tumor, the surrounding tissue will not suffer from its radiation. Additionally, its electron capture decay branch gives rise to Po K X-rays making ^{211}At easy to follow with standard nuclear detection devices including γ cameras for imaging (*5*). Dosimetry calculation and preclinical testing of compounds labeled with ^{211}At have indicated a significant therapeutic potential, at least in certain settings, relative to the use of radionuclides that emit particles with low linear energy transfer (*6–12*).

Because astatine is the heaviest member of the halogen group, it has generally been recognized as a nonmetal. It is also similar

to iodine with regard to its biochemical properties. Thus, standard radioiodination protocols had been commonly adapted for preliminary ^{211}At labeling of biomolecules. Unfortunately, proteins labeled by direct electrophilic astatination were unstable due to rapid loss of ^{211}At in both *in vitro* and *in vivo* conditions (*13*). The reason was probably the unspecific binding of astatine to sulfur atoms in peptides instead of attaching to tyrosine residue, like in the case of radioiodine (*14*). This problem was circumvented later by using two-step procedures, where ^{211}At first was electrophilically incorporated into an aryl compound (e.g., benzoates) and, in the second step, coupled to a protein (*15–19*). Unfortunately, biomolecules labeled by this method have been found to not always be stable to *in vivo* deastatination (*20*). One of the reasons can be the nature of labeled carrier molecule, especially its rate and mode of metabolism (*21*), but this behavior also probably reflects the weaker aryl carbon−halogen bond for astatine when compared to that with iodine (bond strength for astatine is ∼49 kcal/mol and for iodine is ∼62 kcal/mol) (*22, 23*). This fact prompted investigations directed at identifying other labeling approaches that can yield rapid astatination and high stability. For example, the boron−astatine bond should be stronger than the carbon−astatine bond based on the general trend for boron−halogen bond energies (*24*). Therefore, boron cage moieties have been studied as pendant groups for radiolabeling proteins and peptides with radioiodine (*25, 26*) and with ^{211}At (*27, 28*). Studies with *nido*-carborane derivatives did not provide adequate stability of astatination of these compounds (*21*), whereas anionic monocarboranes were not reactive enough to be useful for radiohalogenation (*29*). However, recent experiments with *closo*-decaborate(2-) derivatives showed good stability and fast labeling of biomolecules with high yield (*30*), and studies on the optimization of the *closo*-decaborate(2-) conjugates for protein labeling are underway.

Herein, we have proposed an alternative method of labeling molecules with ^{211}At to solve stability problems of formed conjugates. Instead of using an electrophilic reaction, we decided to attach astatide anions to soft metal cations, which are also complexed by a bifunctional ligand. Ultimately, this complex could in principle be subsequently conjugated to a biomolecule with proper selection of ligand functionality. It can be expected that ^{211}At$^-$, similar to I$^-$ anions, should demonstrate soft ligand properties and form strong complexes with soft metal cations, like Hg(II), Pt(II), Rh(III), and Ir(III), according to the hard and soft acids and bases theory (HSAB) (*31*). On the basis of the generally observed trend that stability constant values for soft metal cation−halogen anion complexes increase in the halogen group, we can expect that a complex with astatide should be stronger than one with iodide. Previously, we reported that ^{211}At$^-$ formed strong complexes with Hg(II) cations, much stronger than I$^-$ (*32*). In the present paper, we describe the results of our studies on attaching ^{211}At$^-$ to complexes of Rh(III) or Ir(III) with the thioether ligand 1,5,9,13-tetrathiacyclohexadecane-3,11-diol (16aneS$_4$-diol). Rh(III) and Ir(III) cations were chosen because they are moderately soft metal cations, and we hypothesize that they will form strong bonds with the soft astatide anion. In addition, the very high kinetic inertness of low-spin Rh(III) and Ir(III) d^6 complexes is particularly well-suited to the formation of a stable conjugate. The 16aneS$_4$-diol ligand was selected for these initial model compound studies based on literature reports that it forms stable complexes with Rh(III) (*33*). Additionally, this macrocyclic tetra-thioether with diol functionality can be easily modified to create a bifunctional chelate ligand (*34*).

EXPERIMENTAL PROCEDURES

Reagents and Radioactivity. The macrocyclic crown thioether 1,5,9,13-tetrathiacyclohexadecane-3,11-diol (16aneS$_4$-diol) cis/trans mixture (Figure 1, panel A) was purchased from Aldrich Chemical Co. and used without further purification. Rhodium(III) nitrate hydrate $Rh(NO_3)_3 \cdot 3H_2O$ and iridium(III) chloride hydrate $IrCl_3 \cdot 3H_2O$ were obtained from Alfa Aesar, a Johnson Matthey Company. Solvents for HPLC analysis were obtained as HPLC grade and degassed before use by ultrasonification for 15–20 min. All other chemicals were of pure reagent grade and used as received unless otherwise specified. The ion exchange resins Dowex 1 × 8 and Dowex 50W × 8 of different mesh sizes were purchased at Sigma-Aldrich Company. The ^{131}I and ^{125}I in the form of Na*I (*I = ^{131}I or ^{125}I) in 0.1 M NaOH solution were supplied from Perkin-Elmer Life and Analytical Sciences (formerly NEN/Dupont, Billerica, MA) and from the Isotope Production Centre Polatom in Swierk (Poland) as high concentration/high specific activity radioiodide. ^{211}At was produced on the CS-30 cyclotron at the Duke University Medical Center. The targets were prepared from pure metallic bismuth and were irradiated with 28 MeV α particles using the ^{209}Bi(α,2n)^{211}At reaction. Separation of ^{211}At from the bismuth target was performed with a dry distillation method described in ref (*35*). Finally, the ^{211}At activity was washed out from the cooled trap by MeOH with Na_2SO_3 (10^{-4} M) addition to obtain ^{211}At in astatide form. All radioactive materials were handled according to approved protocols at the Institute of Nuclear Chemistry and Technology and at Duke University.

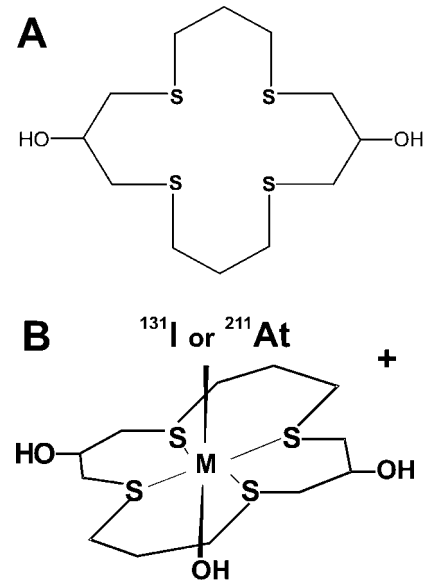

Figure 1. Structure of (A) macrocyclic thioether ligand 1,5,9,13-tetrathiacyclohexadecane-3,11-diol (16aneS$_4$-diol) and (B) cationic complexes *trans*-M[16aneS$_4$-diol]*I/^{211}At (M = Rh(III) or Ir(III)).

Measurements of ^{131}I, ^{125}I, and ^{211}At at Duke University were accomplished in a dose calibrator on a Capintec CRC-7 Radioisotope (Ramsey, NJ). The ^{133}Xe setting was used with a multiplication factor of 2.3, to count ^{211}At on that instrument. The ^{131}I radioactivity at the Institute of Nuclear Chemistry and Technology was measured in a NaI(Tl) well counter (Polon Alfa, Warszawa).

Preparation of Rh[16aneS$_4$-diol]*I/^{211}At and Ir[16aneS$_4$-diol]*I/^{211}At Complexes and Optimization of the Reaction Conditions. Rh[16aneS$_4$-diol]*I/^{211}At and Ir[16aneS$_4$-diol]*I/^{211}At complexes were prepared by addition 20 μL of *I$^-$ or ^{211}At$^-$ activity (6.5–70 MBq for *I and 4.5–30 MBq for ^{211}At) to the mixture of 125 μL Rh(III) or Ir(III) and 25 μL 16aneS$_4$-diol in water−ethanol solution. The quantities of metal cations and sulfur ligand were varied during the optimization reactions over the ranges 0.125–125 nmol and 18.75–250 nmol, respectively. After adjusting the pH to 4.0, by dropwise addition of

0.001–0.1 M HNO_3 or NaOH, the solutions were heated in sealed Eppendorf tubes or glass vials capped with Teflon-coated septa for about 2 h at 80 °C in an oil bath. Control experiments were also performed in which 125 μL of aqueous Rh(III) or Ir(III) solution was mixed with 25 μL of ethanol without sulfur ligand, and 20 μL of $*I^-$ or $^{211}At^-$ solution was added (blank 1). Blank 2 was prepared by mixing 125 μL of water without metal cation and 25 μL of 16aneS_4-diol ligand in ethanol and 20 μL of $*I^-$ or $^{211}At^-$. All control experiments were adjusted to pH 4.0 and heated under the same conditions as the main samples for the complexes. Solutions were analyzed mainly by paper electrophoresis and HPLC methods, but also by sorption on ion exchange resins.

The optimization of reaction conditions was focused on increasing the yield of synthesis, ideally, in a reaction time suitable for use with 7.2 h half-life ^{211}At. The influences of time and temperature of heating, concentrations of metal cations, sulfur ligand 16aneS_4-diol, and pH of the solutions on the reaction yields were determined. Optimization of each parameter was repeated 2 times for astatine complexes and 3 times for *I complexes in separate experiments. Each set of conditions during 1 experiment was replicated 2–3 times. First, optimization of reaction conditions was performed with *I radionuclides and later repeated with ^{211}At. The reaction volume in all cases was kept at 170 μL.

The formation of complexes was studied by heating solutions for different time periods (30–120 min) and over a wide range of temperatures (40–90 °C). For this experiment, the reaction mixtures contained 125 nmol of metal cation and 250 nmol of sulfur ligand, and the reaction was performed at pH 4.0.

The effect of metal cation concentration on complex formation yield was measured in solutions at pH 4.0 containing 250 nmol of sulfur ligand with the quantity of metal cation being varied from 0.125 to 125 nmol. Solutions were heated for 1–1.5 h at 75–80 °C. The influence of 16aneS_4-diol concentrations on reaction yield was evaluated by keeping the quantity of metal cation at 62.5 nmol, while varying the quantity of sulfur ligand in the range 18.75–250 nmol. The reactions were carried out at 75–80 °C for 1–1.5 h and at pH 4.0.

The effect of pH on the yield of the radiohalogenation reactions was also determined. For these studies, the reaction mixtures contained 62.5 nmol of metal cation and 250 nmol of 16aneS_4-diol. The pH was varied from 2 to 8.5 by addition of 0.001–0.1 M HNO_3 or NaOH, and the reaction mixtures were heated for 1–1.5 h at 75–80 °C. Buffers were not used to stabilize the pH, because studies in the literature indicating that several buffers (e.g., phosphate, carbonate) interfered with rhodium complexation (*33, 36*).

The influence of microwave heating on the yield of Rh[16aneS_4-diol]^{131}I and Ir[16aneS_4-diol]^{131}I complexes was determined under the best conditions found during the optimization experiments. The quantities of Rh(III) or Ir(III) cations and sulfur ligand in the solutions were kept at 125 nmol and 250 nmol, respectively, and the pH of the reaction mixture was between 3.0 and 4.0. A UniClever II microwave unit (Plazmatronika, Poland) was used for these studies. This device provides control of the processing time, radiation power, temperature, and pressure in a hermetically sealed autoclave. Prepared samples in glass vials were put into the UniClever apparatus, and microwave heating was performed for 5–35 min at 50% of power mode (corresponds to the 300 W absolute power). During this time, the temperature of the samples was maintained between 75 and 80 °C.

Radiochemical Analyses of Synthesized Complexes. The charge of the radioactive products was determined using paper electrophoresis and ion exchange methods. Electromigration was measured utilizing Sigma-Aldrich and Bio-Rad units on glass fiber Whatman Paper Chromedia GF83 (W. & R. Balston, Ltd., England) and cellulose fiber Whatman 3MM (Whatman International Ltd., England) at the potential gradient equal to 10 V/cm for 25–60 min. The electrolyte was 0.02 M phosphate buffer at pH 4.0 and 7.4. An aliquot of the radioactive reaction mixture was spotted on the center of paper strip, and the power supply was switched on. The distribution of radioactivity on the paper strips was measured by cutting the paper into 1 cm pieces and counting them in a NaI(Tl) well counter. Alternatively, a radiochromatographic strip scanner (BioScan System 200 Imaging Scanner) was utilized.

Dowex 1 × 8 and Dowex 50W × 8 ion exchange resins were rinsed with 250–500 mL 1 M $NaNO_3$ and then washed with deionized water. The resins were dried at 60–70 °C and stored in a desiccator. The distribution of radioactive compounds between the aqueous phase, and the ion exchange resin was analyzed by the batch method. Between 50 and 150 mg of ion exchange resin was added to Eppendorf tubes (two replicates for each sample during one experiment) containing 1.5 mL of 0.05 M $NaNO_3$ at pH 4.0 to which 5–20 μL of the radioactive compound was added. Tubes were shaken for 15–20 min, centrifuged, phases separated, and the radioactivity in the resin and solution counted on either a NaI(Tl) well-type counter or an automated gamma counter (1282 LKB Pharmacia, Turku, Finland).

Additionally, radiochemical identification of the reaction products was accomplished using reversed-phase HPLC with a Waters XTerra C18 column (5 μm, 250 × 4.5 mm) on a Beckman System Gold device equipped with both UV and radiometric (Gamma Detector 170) detectors. The gradient elution system utilized mobile phase A (deionized H_2O) and mobile phase B (100% acetonitrile) and flow rate of 1 mL/min, starting with 95% A/5% B for 5 min; then, the gradient was increased to 100% B over the next 30 min and then held at 100% B for 5 min, after which gradient parameters returned to the initial conditions during the next 5 min. The HPLC analysis took about 45 min. Both mobile phases contained 0.1% TFA.

RESULTS AND DISCUSSION

Astatine-211 is one of only a few α-emitters that have properties suitable for application to targeted radiotherapy of cancer, especially of micrometastatic disease, cancer resistant to other forms of radiation (e.g., melanoma), and ovarian carcinoma (*12, 37*). Although a large number of cancer cell selective monoclonal antibodies (mAbs) and other cancer cell targeting agents suitable for targeted radiotherapy have been developed, using them in the treatment of cancer is only possible when the radionuclide is stably coupled with the carrier molecule. In the case of highly toxic α-emitters, only conjugates that are stable toward *in vivo* release of the α-particle-emitting radionuclide can be used in targeted radiotherapy.

The stability of astatinated biomolecules has been a major impediment to the development of ^{211}At-labeled radiotherapeutics. Direct electrophilic astatination of proteins and peptides was unsuccessful. The yield of the reaction was low, and the labeled molecules were unstable to *in vivo* deastatination (*13*). More stable astatinated proteins have been prepared by acylation with a variety of astatobenzoic acid derivatives prepared from trialkylstannyl precursors (*15, 16*), but the problem with stability appeared when smaller, more rapidly metabolized molecules and mAb fragments (Fab′) were used (*20, 38*). The conjugates undergo rapidly deastatination, even with molecules for which *in vitro* studies indicated quite good stability in serum (*20*). Therefore, without a good chemical method of attaching ^{211}At to these potential cancer targeting agents that will provide high *in vivo* stability of formed conjugate, the application of this radionuclide in targeted radiotherapy will be limited.

The aim of this work was focused on finding a new stable labeled precursor for use in labeling of biomolecules with ^{211}At. The original idea is to attach astatide anions to soft metal cations, which are complexed by bifunctional ligand bearing a functionality that would facilitate attaching this complex to a biomolecule. We believe that the proposed combination of high kinetic inertness of Rh(III) and Ir(III) compounds with the formation of strong complexes between soft metal cations and soft anions will result in high stability of formed metal−astatide bond.

Results from literature studies show that the 16aneS$_4$-diol ligand reacts with $RhCl_3$ to form a cationic Rh[16aneS$_4$-diol]Cl$_2$ complex with a *trans*-Rh(III)Cl$_2$ core. In this complex, the sulfur donor atoms of the macrocyclic ligand occupy four equatorial positions, whereas the Cl^- anions are in the axial positions (*33*). Therefore, we hypothesized that analogous complexes could be formed in which one axial position is occupied by either the $*I^-$ or $^{211}At^-$ anion. It should be noted that in our studies we used $Rh(NO_3)_3$ for synthesis instead of $RhCl_3$, as was used previously (*33*). Therefore, due to the weak complexing properties of NO_3^- anions, we believe that the second axial position will be occupied by a OH^- group (Figure 1, panel B). We prepared the well-defined macroscopic nonradioactive Rh[16aneS$_4$-diol]Cl$_2$ complex according to a literature procedure (*33*). Following the same scheme, the Rh[16aneS$_4$-diol]I complex with cold iodine was prepared. The electrophoretic migration of the yellow Rh[16aneS$_4$-diol]Cl$_2$ complex was compared with the orange Rh[16aneS$_4$-diol]I complex and radioactive Rh[16aneS$_4$-diol]^{131}I. In all cases, the migration toward cathode was identical. Also, cospotting Rh[16aneS$_4$-diol]^{131}I with nonradioactive Rh[16aneS$_4$-diol]Cl$_2$ and Rh[16aneS$_4$-diol]I gave identical electrophoretic behavior. The properties of three complexes were also studied by reverse-phase HPLC using the gradient conditions mentioned above. The UV detection was performed at 275 nm for nonradioactive Rh[16aneS$_4$-diol]Cl$_2$ and Rh[16aneS$_4$-diol]I complexes, and the radioactive Rh[16aneS$_4$-diol]^{131}I complex was detected by the radiometric detector. The retention times for both nonradioactive Rh[16aneS$_4$-diol]Cl$_2$ and Rh[16aneS$_4$-diol]I complexes were identical and comparable to the radioactive Rh[16aneS$_4$-diol]^{131}I, with peaks appearing between 15 and 17 min. From these results, we assumed that the structures of cold Rh[16aneS$_4$-diol]I and radioactive Rh[16aneS$_4$-diol]^{131}I were identical to the structure of Rh[16aneS$_4$-diol]Cl$_2$ presented in ref (*33*).

Paper electrophoresis and ion exchange studies confirmed the predicted cationic character of the synthesized complexes. For example, the distribution of *I radioactivity on the paper strip for Rh[16aneS$_4$-diol]*I complex and control samples is presented in Figure 2. It is shown that, in the heated solution contained Rh(III) cations, sulfur ligand 16aneS$_4$-diol and $*I^-$, a cationic complex was formed, because most of the radioactivity (80–85%) migrated toward the cathode. During the electrophoretic studies, we also noticed that the percentage of radioactivity distributed on both fiber strips was similar; however, the migration of the complex on cellulose fiber was slower than on the glass one at the same applied voltage. In the case of Whatman GF83, migration of the cationic complex was 4.5–5.0 cm toward the cathode during 25 min, whereas for Whatman 3MM, fiber migration was 3.7–4.0 cm toward the cathode during 1 h. The last result is comparable to the migration reported for the cationic ^{105}Rh[16aneS$_4$-diol]Cl complex also on the cellulose fiber (Whatman #1) (*34*). The differences in migration range and time are probably due to different components and structures of both fibers. Nevertheless, the migration time did not influence the final results of the overall percentage distribution of radioactivity on the fibers, but for the electrophoretic studies, glass fiber was mainly used, because of the shorter analysis time, an advantage that was of particular importance for the characterization of the astatine complexes. The pH of the sodium phosphate buffer (4.0 or 7.4) used as the electrolyte did not influence the migration range and time for all four complexes, which were found to remain positively charged at the higher pH.

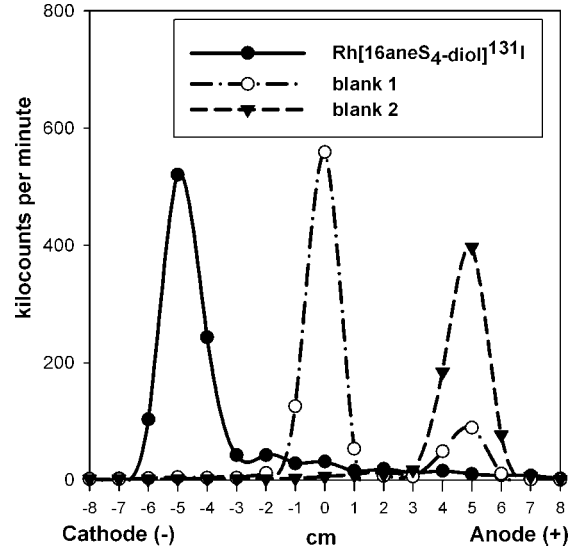

Figure 2. Electrophoretic analysis of heated mixtures: (Rh[16aneS$_4$-diol]*I) contained Rh(III) cations, 16aneS$_4$-diol ligand, and $*I^-$; blank 1 contained Rh(III) and $*I^-$ without sulfur ligand; blank 2 contained sulfur ligand and $*I^-$ without metal cations. Paper electrophoresis was performed on glass fiber Whatman Paper Chromedia GF83 using phosphate buffer (pH 4.0 or 7.4) at 10 V/cm for 25 min.

Confirmation that the synthesized complex Rh[16aneS$_4$-diol]*I has cationic character was also obtained from an experiment determining its adsorption on a cation exchange resin. In the case of the complex, most of the *I radioactivity was adsorbed on the cationic resin, with only 15–20% remaining in solution; this was nearly completely adsorbed on the anion exchange resin. This suggests that 15–20% of free iodide remains uncomplexed in solution at the end of the synthesis reaction.

Studies on control samples indicated that, in the heated solution of 16aneS$_4$-diol with $*I^-$ but without the metal cation (blank 2), all the radioactivity migrated toward the anode, consistent with uncomplexed iodide (Figure 2). This indicates that there are no interactions of the halogen anion with 16aneS$_4$-diol ligand in the absence of the metal. In the case of blank 1, where iodide was heated with Rh(III) cations in the absence of the 16aneS$_4$-diol ligand, most of the radioactivity stayed at the origin and only 10–35% moved toward the anode like iodide (Figure 2). Radioactivity from this compound also was not adsorbed on Dowex 50W × 8, but stayed in solution, even after a few hours of shaking. Only 10–35% was adsorbed on Dowex 1 × 8, suggesting the presence of uncomplexed iodide. We speculate that, in blank 1, the neutral species Rh(OH)$_2$*I was formed.

The results mentioned above were confirmed by reversed-phase HPLC as shown in Figure 3. If iodide was heated with the macrocyclic thioether ligand without metal cations (blank 2), only one peak was visible on the radiochromatogram (Figure 3, panel A) with a retention time of around 3.9 min. corresponding to an uncomplexed iodide standard. In the case of blank 1, where iodide was heated with Rh(III) cations in the absence of 16aneS$_4$-diol, two peaks were found with the retention times 3.9 and 5.4 min, corresponding to free iodide and probably neutral Rh(OH)$_2$*I, respectively (Figure 3, panel B). The synthesized cationic complex Rh[16aneS$_4$-diol]*I ap-

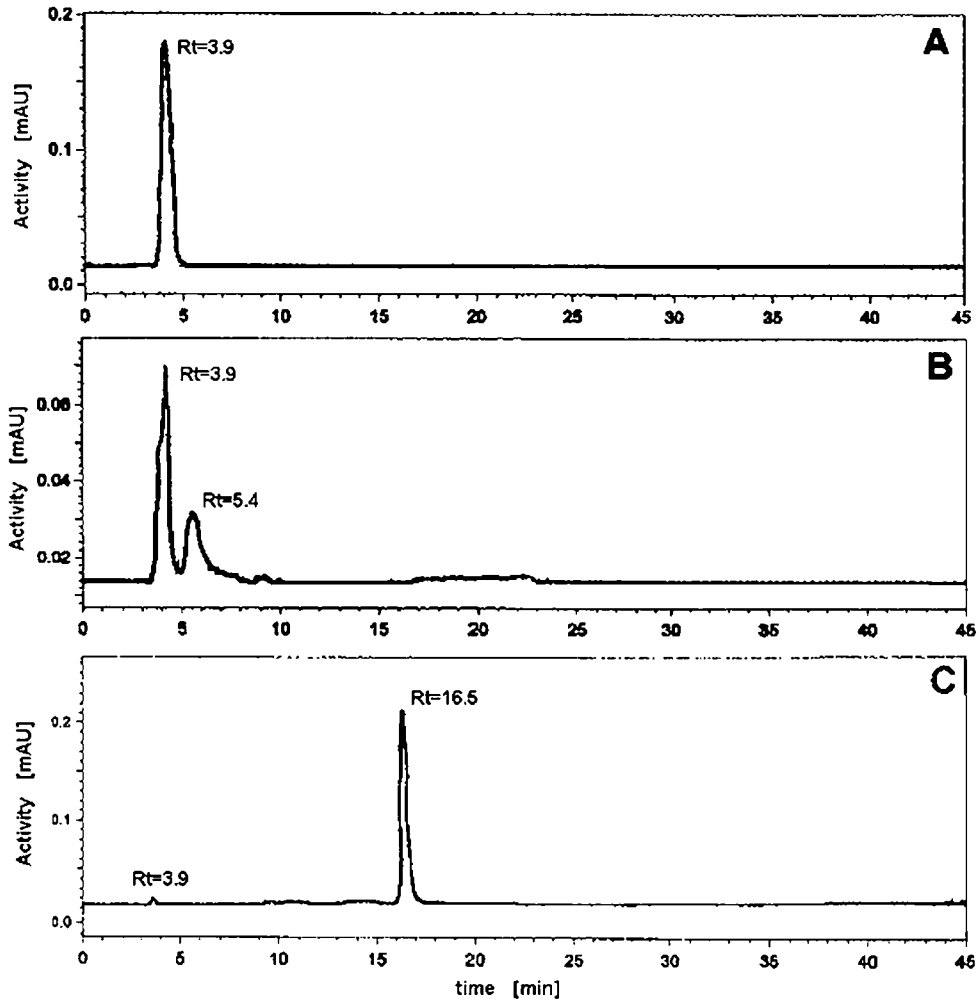

Figure 3. HPLC radiochromatograms of (A) control sample "blank 2"; (B) control sample "blank 1"; (C) sample containing cationic complex Rh[16aneS$_4$-diol]*I.

peared at 15–17 min when using the previously described gradient (Figure 3, panel C).

Although not shown, the results obtained by paper electrophoresis and reversed-phase HPLC methods for the other cationic complexes that were synthesized, Rh[16aneS$_4$-diol]^{211}At and Ir[16aneS$_4$-diol]*I/^{211}At, were quite similar to those described above for Rh[16aneS$_4$-diol]*I. Therefore, only the results for Rh[16aneS$_4$-diol]*I are shown as examples.

The synthesis of inert low-spin d^6 metal complexes often requires heating at high temperature and sometimes for extended time periods (*39*). Our studies also showed that temperature and time of heating are important parameters for high-yield synthesis of the desired complexes. The yield of Rh[16aneS$_4$-diol]*I synthesis was below 20% at 40 °C, even after 2 h of heating (Figure 4, panel A). Raising the temperature from 40 to 90 °C resulted in a sharply increased rate of reaction. The yield of Rh[16aneS$_4$-diol]*I complex formation was around 55–60% after 30 min of heating at 80–90 °C, and it was still increasing during the next 1.5 h, approaching a maximum value of about 90% at 2 h. The temperature-dependence studies for the Ir[16aneS$_4$-diol]*I complex were performed at 40, 60, and 80 °C (Figure 4, panel B). Generally, the obtained results were very similar to those for the Rh[16aneS$_4$-diol]*I complex. The yield of reaction was low at 40 °C and increased up to 87% after heating for 2 h at 80 °C. In the case of Rh[16aneS$_4$-diol]^{211}At and Ir[16aneS$_4$-diol]^{211}At, the effect of heating time on yield was evaluated only at 75–80 °C (Figure 4, panel C). The maximum reaction yield for both astatine complexes was about 80%, and could almost be achieved after 1.5 h of heating.

Microwave-assisted synthesis is commonly used in organic chemistry because it enhances chemical yields by reducing reaction times without causing major degradation or introducing undesired reactions. There are also few articles about preparation of transition metals coordination complexes using microwave techniques (*40*, *41*), including studies on Rh(III) complexes with bipyridine, cyclopentadiene, and pyridylazoresorcinol group ligands (*39*, *42*). This technique has been also applied to labeling biomolecules with short-lived radionuclides, which require procedures that afford the labeled product in a short reaction time. Therefore, it is used in the synthesis with ^{18}F (*43*, *44*), but also with other radiohalogens such as ^{123}I (*45*). Microwave heating may significantly accelerate the synthesis, especially of substitutionally inert second- and third-row transition metal coordination compounds (*40*). For example, the microwave synthesis of *cis*-[Rh(bpy)$_2$I$_2$][PF$_6$] (bpy = bipyridine) from RhCl$_3$ reduced the reaction time from 65 min to 12 min (*39*). In our studies, after 10 min of microwave heating, the yields for Rh[16aneS$_4$-diol]^{131}I and Ir[16aneS$_4$-diol]^{131}I complexes were 51% and 38%, respectively (Figure 5). During the next 10 min, the yields increased up to 75% and 73%, the level which was almost reached in conventional heating in the oil bath for 1.0 h at 75–80 °C. Finally, the yields obtained for Rh[16aneS$_4$-diol]^{131}I and Ir[16aneS$_4$-diol]^{131}I after 35 min of microwave heating were 90% and 83%, respectively. The temperatures of all samples exposed to microwave radiation were kept in the

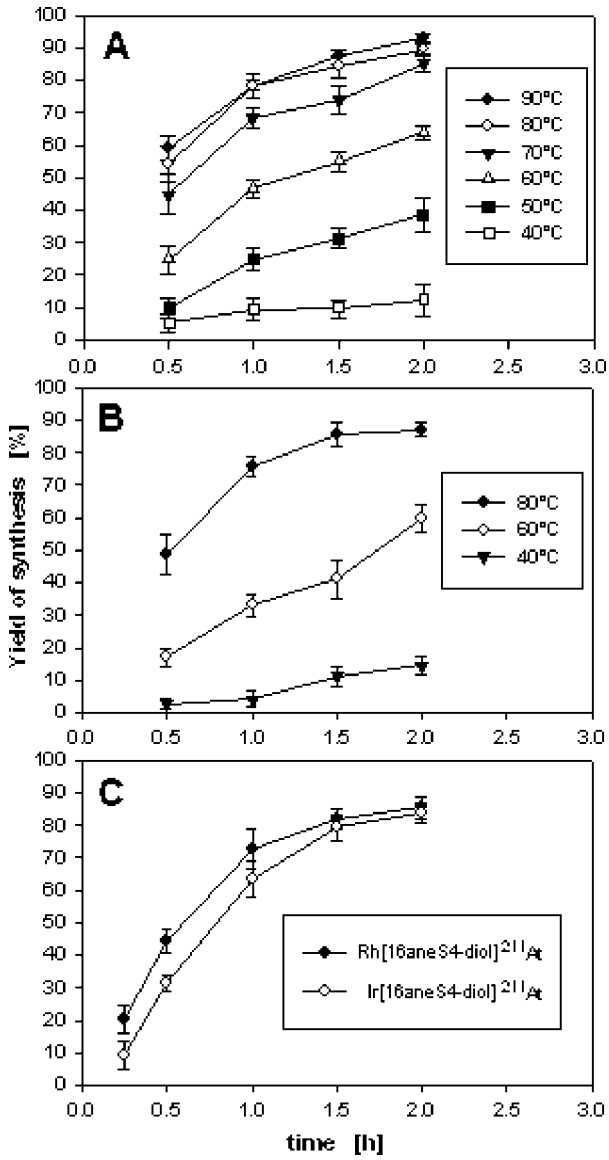

Figure 4. Influence of temperature and time of heating on the synthesis yield of complexes: (A) Rh[16aneS$_4$-diol]*I; (B) Ir[16aneS$_4$-diol]*I; (C) M[16aneS$_4$-diol]^{211}At (M = Rh(III) or Ir(III)).

range 75–80 °C by using only 50% of maximum during microwave irradiation.

Good synthesis yields of about 80% were obtained for Rh[16aneS$_4$-diol]*I/^{211}At and Ir[16aneS$_4$-diol]*I/^{211}At complexes from solutions containing 62.5 nmol of Rh(III) or Ir(III) cations, 250 nmol of 16aneS$_4$-diol ligand, and carrier-free radiohalogen. Decreasing the amount of metals cation in the reaction mixture resulted in a significant decrease in yield for all four complexes (Table 1). High complex formation yields were obtained even when the complexation reaction was performed under a 1:1 stoichiometry ratio of 16aneS$_4$-diol to Rh(III) or Ir(III) at pH 4.0 (n_M = 62.5 nmol). The yield was reduced when the ratio was less than 1:1 (Table 2).

The pH was an important parameter, which influenced the formation of all four complexes. The Rh[16aneS$_4$-diol]*I/^{211}At and Ir[16aneS$_4$-diol]*I/^{211}At yields were the highest in the range 3.0–4.0 and dramatically decreased with pH higher than 5.0, declining to 4.5 ± 0.4% and 12.4 ± 6.7% for *I and ^{211}At, respectively at pH 8.5 (Table 3). The reduction in complex formation probably was due to hydrolysis of the metal cations. During pH studies, we noticed that the decrease in yield for Rh[16aneS$_4$-diol]*I/^{211}At was greater than for Ir[16aneS$_4$-diol]*I/^{211}At. This is consistent with the hypothesis that this behavior reflects hydrolysis of the metal cation, because Ir(III) as a larger cation, which is below Rh(III) in the Periodic Table, should have a smaller affinity to hydrolysis reaction than Rh(III).

CONCLUSIONS

Our results demonstrate the feasibility of attaching ^{211}At$^-$ anions under mild conditions to moderately soft Rh(III) or Ir(III)

cations complexed by 16aneS$_4$-diol to form kinetically inert positively charged Rh[16aneS$_4$-diol]^{211}At and Ir[16aneS$_4$-diol]^{211}At complexes. The macrocyclic ligand 16aneS$_4$-diol with diol functionality was chosen for model studies, because it forms stable complex with Rh(III) and can be easily modified to provide a bifunctional chelate ligand. For further labeling studies with biomolecules, we will use a bifunctional sulfur ligand. A macrocyclic sulfur ligand with an additional carboxylic group as a functionality for attachment will probably be the best for conjugation with biomolecules. This type of ligand has been described previously. Li et al. (*34*) and Goswami et al. (*36*, *46*) utilized rhodium complexes with different bifunctional sulfur ligands and reported that the carboxylic group did not coordinate with the rhodium core in their complexes, even after heating at high temperatures for a long time. Therefore, we also do not expect the competition reaction and replacement of astatide or iodide in our complexes by the carboxylic group. However, this must be verified experimentally. The complexes labeled with ^{211}At, after appropriate purification, could be used in the future as the precursors for labeling of biomolecules such as monoclonal antibodies. Because the formation of Rh[16aneS$_4$-diol]^{211}At and Ir[16aneS$_4$-diol]^{211}At or complexes with similar bifunctional sulfur ligands requires heating at high temperatures, we anticipate the need for a two-step procedure for labeling biomolecules. First, the appropriate astatine complex should be synthesized and, after purification, conjugated at room temperature with the biomolecule via an appropriate functional group (e.g., carboxylic group mentioned above).

Studies with *I$^-$ anions were performed mainly for optimization of reaction conditions. In addition, results obtained during synthesis of Rh[16aneS$_4$-diol]*I and Ir[16aneS$_4$-diol]*I complexes, enable us to compare them with the results for ^{211}At complexes and make final conclusions. Generally, results obtained during optimization processes for all four complexes were comparable. However, we noticed that complexes with the Rh(III) cation core were formed with a few percent higher yield in comparison to complexes with the Ir(III) cation core. This situation was changed only when the effects of reaction pH were evaluated. Also, the yield for complexation with *I radionuclides was a few percent higher than for ^{211}At. Finally, we showed that microwave heating could significantly accelerate the reactions. Using microwaves, instead of conventional heating, reduced the time of reaction from 1−1.5 h to about 20–35 min with the approximate yield of 80%.

Preliminary stability studies of Rh[16aneS$_4$-diol]*I and Ir[16aneS$_4$-diol]*I complexes in PBS and human serum have been performed and gave promising results. Both iodine complexes were stable in PBS and human serum over 51 h incubation at 37 °C. The stability of Rh[16aneS$_4$-diol]^{211}At and Ir[16aneS$_4$-diol]^{211}At complexes was checked only in PBS solution. We did not observe any loss of astatine from the complexes after 6 h (almost one-half-life) incubation at 37 °C. Extended studies on the evaluation of the *in vitro* and *in vivo* stability of Rh[16aneS$_4$-diol]*I/^{211}At and Ir[16aneS$_4$-diol]*I/^{211}At complexes will be described in a subsequent publication.

ACKNOWLEDGMENT

This work was done under the N204 081 31/1939 and N204 143 32/3547 grants of Polish Ministry of Science and Higher Education. Part of the work was carried out in the frame of Marie Curie Action for the Transfer of Knowledge, contract no. MTKD-CT-2004-509224 with the European Commission and part was funded by Grant CA42324 from the National Institutes of Health of the United States. We gratefully acknowledge the Polish-US Fulbright Commission for enabling Marek Pruszyński to spend 5 months working at Duke University Medical Center, Durham, NC.

Magnetic Proteinase K Reactor as a New Tool for Reproducible Limited Protein Digestion

Marcela Slováková,* Jean-Michel Peyrin,† Zuzana Bílková, Martina Juklíčková, Lenka Hernychová, and Jean-Louis Viovy

Laboratoire Physicochimie-Curie, Institut Curie, Paris Cedex 5, France, Unité de Virologie Immunologie Moléculaires, INRA, 78350 Jouy-en-Josas, France, Department of Biological and Biochemical Sciences, University of Pardubice, 53210 Pardubice, Czech Republic, and Institute of Molecular Pathology, University of Defence, Hradec Králové, Czech Republic. Received December 3, 2007; Revised Manuscript Received January 31, 2008

As an aid to differentiating between the prion proteins Prp^c and PrP^{Sc}, the preparation and use of immobilized Proteinase K (PK) is described. An accumulation of PrP^{Sc} in the central nervous system is the one of the causes of neurodegenerative disease. Current routine diagnosis is based on the postmortem detection of the distinct neuropathological lesion profiles of CNS and by the presence of the PK-resistant core of the prion protein isolated from brain lysates. An assay with PK immobilized to magnetic −COOH micro- and nanoparticles can offer a convenient as well as economic method. The individual immobilization steps were verified by measuring the ζ potential of the particles. The stability of the newly developed PK magnetic reactor, observed during kinetics measurements, was highly satisfactory. The calculated values of the apparent Michaelis constant (4.25 mM for native enzyme and 1.28 mM for immobilized enzyme) were determined from Lineweaver–Burk plots. Human growth hormone was digested using the newly prepared magnetic PK reactor and MALDI-TOF-MS analysis of the digests showed satisfactory efficiency. Controlled digestion of PrP^c from the Mov mouse cell line was demonstrated with Western blot detection.

INTRODUCTION

In general, proteolytic enzymes covalently bonded on solid carriers have a wide range of practical applications. Although their hydrolytic activity usually decreases slightly upon immobilization, they possess important advantages over dissolved enzymes, e.g., the possibility of recovery and reuse, simple operation, enhanced stability, and limited protease autolysis. The activity and stability of such biocatalysts after their immobilization depends on the type of carrier (biopolymer or synthetic, magnetic, size, porosity, etc.), the enzyme, and the immobilization method (*1*, *2*). The choice of matrix is a key factor in the operating range of the final application and degree of process automation (*3*, *4*).

The magnetic form of the particles provide the best simple, reproducible, and economic approaches, which enable a highly efficient and gentle separation, during either an immobilization procedure or biochemical applications (*2*), e.g., on-chip technology (*3*, *4*). Due to their small size (up to 1 μm in mean diameter), they offer a very large specific surface area. The specific surface area and size of the polymeric particles used in this research work (Ademtech, France) were within narrowly defined ranges. The composition of the particles is stable in solutions of widely ranging pH and at moderate salt concentrations. The surface charge density is negative at slightly basic pH, according to the manufacturer.

Proteinase K (PK) is a subtilisin family serine protease isolated from *Tritirachium album* Limber. This highly active extracellular alkaline serine endopeptidase was so named in the past because of its ability to digest native keratin (*5*–*7*). PK has an immense range of applications in pure and applied research. One of the fundamental fields of application of PK is its use together with a prion protein immunoblot for the detection of the pathological form of prion protein in various fluids and tissues. Other important applications of PK are in the scientific and biomedical fields: the removal of biomolecules, e.g., inhibitors, DNA molecules, highly resistant proteins, and glycoproteins, and so forth, from biological materials (*8*–*10*).

The main characteristics of PK have already been determined: molecular mass 28 930 (*11*), isoelectric point 8.9, optimal pH range for enzyme activity from 7.5 to 12 (*5*). Calcium ions are involved in this enzyme's activity, and additional calcium ions in solution are also required for the stability of the enzyme (*11*). This proteinase has unusual stability at low concentrations of SDS and urea. PK is primarily specific against aromatic or hydrophobic amino acid residues on the carboxyl side of the splitting point (*12*).

In this paper, we tested new magnetic carriers for utilization in a proteinase K reactor: 500A5 and 145TTa magnetic beads (styrenic copolymer with hydrophilic monomer, Ademtech, France), A120 magnetic alginate microparticles (Academy of Sciences, Czech Republic), Estapor magnetic latex microparticles (Merck, France). Along with optimizations of the grafting conditions, i.e., temperature, time, type and strength of buffer, the characterization of the enzyme reactor was a further aim of this work. The stability of the PK reactor was investigated in terms of multiple uses. The ζ potential and apparent Michaelis–Menten constant of the magnetic PK reactor were determined.

The newly prepared enzyme reactor was used for the proteolytic digestion of human growth hormone (HGH) (22 kDa) and PrP^c from the Mov mouse cell line. Mass spectrometry and

Western blotting analysis were used to confirm digestion by the newly prepared enzyme reactor.

EXPERIMENTAL PROCEDURES

Chemicals. Proteinase K (E.C.3.4.21.64, lot 104K8622, 33 U/mg of solid protein), succinyl-Ala-Ala-Ala-*p*-nitroanilide (EC 257-823-5; substrate for PK), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDAC), sodium azide, and the surfactants polyoxyethylsorbitane monolaurate (Tween 20), Triton X-405, and Triton X-100 were purchased from Sigma-Aldrich. The surfactant Pluronics F127 NF (PF 127) was purchased from the BASF Corporation (New Jersey, USA). The sodium salt of *N*-hydroxysulfosuccinimide and trifluoric acid were obtained from Fluka (Buchs, Switzerland). A Micro BCA Protein Assay Kit (Perbio Science, Pierce France) was used for complete protein determination. All other reagents, of analytical or electrophoresis quality, were obtained from international suppliers (Merck, Darmstadt, Germany; Bio/Rad, Hercules, CA, USA; Sigma, St. Louis, MO, USA). The mouse overexpressed PrP^c cells (Mov cell line) were lysated in a lysis buffer (0.5% sodium deoxycholate, 0.5% Triton X100, 50 mM Tris-HCl pH 7.4). The PK immobilized to Eupergit C was purchased from Sigma-Aldrich (USA).

Magnetic Carriers. The 500A5 (626 nm mean diameter) and 145TTa (980 nm mean diameter) magnetic latex beads used in this study were donated by Ademtech SA (Pessac, France), both functionalized with −COOH groups. The A120 magnetic alginate microparticles (−COOH) were donated by the Academy of Sciences (Czech Republic) (2–5 μm diameter). Magnetic latex microparticles (−COOH) were purchased from Estapor (Merck, France) (160 nm mean diameter). All stock solutions were stored in an aqueous suspension containing 0.09% NaN_3. Carriers were washed extensively with the enzyme buffer (10 mM phosphate buffer pH 7.3) before each use.

Equipment. A magnetic separator (Dynal, USA) was used for manipulations with the magnetic carriers. All microscopic observations were made using an inverted microscope (Zeiss Axiovert 100) with 10×, 5× (Zeiss), and 100× oil immersion (Olympus) objectives, and an intensified CCD camera (Lhesa, Cergy Pontoise, France). Spectrophotometers (Shimadzu Corporation, Japan, and NanoDrop, Nyxor Biotech, France) were used for measuring the optical density for catalytic activity quantification. A Voyager-DE STR MALDI-TOF spectrophotometer (Applied Biosystems, Germany) was utilized for mass spectrometry analysis.

Immobilization of PK (PK) on Magnetic Particles. Generally, 1 mg of magnetic particles (functionalized by –COOH) was washed with 10 mM of phosphate buffer (pH 7.3). Carboxyl groups were activated via the method developed by Staros et al. (*13*) using water-soluble carbodiimide EDAC [1-ethyl-3(3-dimethylaminopropyl) carbodiimide] at a concentration of 79 mM. Addition of *N*-hydroxysulfosuccinimide [sulfo-NHS], at a concentration of 12 mM, enhances the yield of amide bond formation (*14*). The chosen amount (from 1 to 4 mg) of PK was dissolved in 10 mM phosphate buffer (pH 7.3) with 5 mM $CaCl_2$; the total concentration of Ca^{2+} ions in the mixture was 1 mM according to (*11*). The immobilization time depends on the chosen temperature: at room temperature, the grafting reaction was maintained for 6 h; at 4 °C the reaction was maintained overnight. Blocking the unreacted activated sites on the particle surface was done with 100 mM Tris, 100 mM MES, and 52 mM EDAC at room temperature for 2 h. The PK reactor was washed and stored in 50 mM Tris/HCl buffer (pH 7.8) with 5 mM $CaCl_2$ and the addition of 0.02% sodium azide.

Immobilized PK Activity Assay. The specific enzyme activity was assayed using succinyl-Ala_3-*p*-nitroanilide as a substrate (*11, 15*). 1 I.U. of the activity is expressed as the amount of enzyme which can hydrolyze casein to produce the color equivalent to 1.0 μmol of tyrosine per minute at pH 7.5 and 37 °C (colored by the Folin-Cocteau reagent). The assays were routinely carried out at a substrate concentration of 1.05 mM and in 50 mM Tris/HCl buffer (pH 7.8) with 5 mM $CaCl_2$ (total volume 1 mL). Assay mixtures were composed of 50 mM Tris/HCl buffer (pH 8.0) $CaCl_2$ (5 mM), *N*-succinyl-Ala_3-*p*-nitroanilide (1.1 mM), and PK (immobilized or 2–10 μg/mL). The mixture was incubated for 15 min at room temperature. The reaction was terminated by adding 0.2 mL glacial acetic acid for the native enzyme or by the separation of the PK particles with a magnetic separator (Dynal, USA), and the optical density at 405 nm of free pNA was measured against the substrate solution as a reference. The final PK activity was estimated from the linear increase in optical density. Except for steps investigating thermal stability, all experiments were carried out at 25 °C.

Measurement of ζ Potential. A Zetasizer (Malvern Instrument, U.K.) was used in the ζ measurememt protocols. The ζ potential of the beads was measured in a phosphate buffer of strengths 10 and 100 mM and with pHs ranging from 3 to 11; the pH was adjusted with HCl and NaOH. The total volume for measurements was 1 mL, and the concentration of the beads was 3×10^{-3}%.

Determination of Apparent K_M and V_{max} for PK. The Michaelis–Menten kinetic parameters K_M and V_{max} for the hydrolytic reactions between succinyl-Ala-Ala-Ala-*p*-nitroanilide and PK were determined from Lineweaver–Burk (L-B) plots. All kinetic experiments were carried out in 50 mM Tris/HCl buffer (pH 7.8) at 25 °C (tempered solution). The concentration range of the substrate *N*-succinyl-Ala_3-*p*-nitroanilide was $(0.275-4.8) \times 10^{-3}$ mol/L.

Proteolysis of Proteins by Immobilized PK. The protein (human growth hormone, molecular size 22 kDa) was dissolved in 50 mM ammonium acetate (pH 7.8) and digested with soluble PK or an immobilized PK reactor in a microtube. Procedure: 100 μL of protein (1 mg/mL) was added to the appropriate amount of PK reactor (E:S 1:16), and digested over 4 h at room temperature with slow rotation.

Mass Spectrometry Analysis of Digested Protein by MALDI-TOF-MS. The digest of HGH was desalted using RP $ZipTip_{C18}$ (Millipore). 1 μL of each sample was applied to a MALDI plate and covered with 1 μL of 2,5-dihydroxybenzoic acid (DHB) (LaserBio Laboratories) as the matrix. For the matrix solution, DHB was dissolved in a solution containing 50% ACN and 0.3% trifluoracetic acid (Fluka Biochemika) to a DHB concentration of 50 mg/mL. The Voyager-DE STR MALDI-TOF mass spectrometer (Applied Biosystems) was used in all experiments. The MALDI-TOF measurements were carried out in positive ion reflectron mode with a mass range of m/z 110−2500. The list of detected monoisotopic masses (m/z) was used for protein identification with the PeptideMass tool of the ExPASy proteomic server (http://www.expasy.org/).

Digestion of Cell Lysate Overexpressing PrP^c. Mov cells are immortalized neuroglial cells isolated from mice expressing the ovine gene for PrP^c. Cells were grown as in (*16*). Once confluency was reached, cells were lysed in buffer (0.1% Triton X100, 0.1% sodium deoxycholate, 50 mM Tris, pH 7.2). Cell lysates were centrifuged for 2 min at 1000 *g* to remove cell debris, and stored at −20 °C until used. Cell lysates were then incubated with the proteinase K reactor for 2, 5, 10, 30, and 60 min at RT (0.7 μg of PK reactor for 100 μL of protein). Pefabloc SC (0.4 mM) was then added to stop the reaction, and proteins were precipitated with 4 volumes of cold methanol.

Western Blotting. Pellets were resuspended in sample buffer (50 mM Tris/HCl pH 7.8), boiled, subjected to 10% SDS/PAGE

Table 1. Influence of Temperature on Soluble PK assay with the Substrate *N*-Succinyl-Ala-Ala-Ala-p-NA (1.05 mM in volume 1 mL), Measured in 50 mM Tris/HCl, pH 7.8

cross-linker	buffer, pH	conditions	amount of PK [μg/mg carrier]
EDAC, S-NHS	10 mM phosphate, pH 7.3	p6h,RT	9.92
EDAC, S-NHS	50 mM MES, pH 6	6 h,RT	4.81
EDAC, S-NHS	100 mM TRIS/HCl, pH 7.8	6 h,RT	3.29

[a] 10 mM sodium phosphate buffer at pH 7.3, 50 mM MES solution at pH 6.0, and 100 mM TRIS/HCl at pH 7.8, in the presence of 1 mM $CaCl_2$, 6 h at RT, slow rotation.

electrophoresis, and electrotransferred (1 h) onto nitrocellulose membranes. PrP^c was visualized with either ICSM18 or SAF 84.3 mAb overnight at 4 °C; both directed to the C-terminal half-of PrP^c. Western blots were developed by $AgNO_3$ (Amersham Pharmacia) in a darkroom.

RESULTS

Proteinase K Activity Assay. With regard to the proteinase K activity assay, we focused on common conditions for assays of the soluble enzyme to verify that these conditions are usable for the immobilized enzyme. Further, we wanted to verify that there is no change in the basic kinetic parameters of the enzyme assay.

To find the optimal conditions for the immobilized PK activity assay, various pH levels, buffering systems, and temperatures were examined for the soluble enzyme (Tables 1 and 2). The synthetic substrate *N*-succinyl-Ala-Ala-Ala-p-NA was used (*11*, *15*). The temperatures for both the soluble and immobilized enzyme were compared, and the results showed identical courses (data not shown). The activity was determined in three buffering solutions with differing pH levels (*5*, *11*).

Optimizations of PK Immobilization. Though commercial kits for binding proteins or enzymes to various carriers are now readily available, extensive optimizations are essential in testing newly developed carriers. Optimizations are needed to improve enzyme performance, for example, activity and stability.

Appropriate conditions for PK immobilization to 500A5 magnetic microparticles (Ademtech, France) were first proposed and subsequently optimized. The following paragraphs describe the experiments in which the composition of the immobilization mixture, addition of calcium ions, ionic strength in the mixture, temperature, and duration were examined.

Three buffers were tested for the immobilization procedure: 10 mM sodium phosphate buffer at pH 7.3, 50 mM MES at pH 6.0, and 50 mM MES at pH 7.3, all with 1 mM $CaCl_2$. The resulting enzyme activities suggested differences between the individual buffers during the grafting procedure (Table 3). The 10 mM phosphate buffer at pH 7.3 was determined to be the most suitable, then came 50 mM MES at pH 6.0 and pH 7.3.

Table 4. Monitoring Effects of Temperature and Reaction Time on Grafting Efficiency of PK to 500A5 (Ademtech)[a]

temperature	reaction time	amount of PK [μg/mg carrier]
4 °C	overnight	14.8
	6 h	5.5
RT	overnight	1.1
	6 h	10.1

[a] Immobilization occurred in 10 mM sodium phosphate buffer, pH 7.3, 6 h at RT, slow rotation.

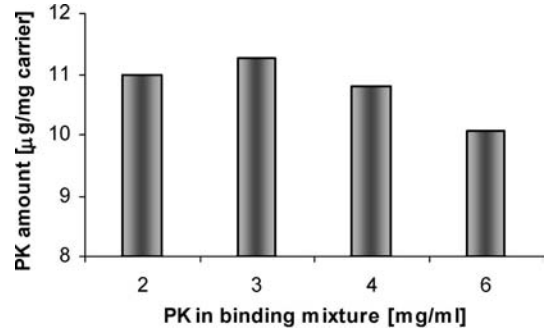

Figure 1. Binding efficiency of PK to 500A5 microparticles (Ademtech). Composition of the reaction mixture: 1 mg of magnetic particles, specified amount of PK, 79 mM EDAC, 12 mM S-NHS per 1 mg of the carrier, 6 h at RT, slow rotation.

One or two-step carbodiimide activations of −COOH particles using EDAC and/or S-NHS are known from the literature (*14*). In order to ensure the highest levels of PK reactor activity, both methods were tested (at pH 6.0). An immobilization protocol using only EDAC leads to a 24% lower enzyme activity (data not shown). It was proven that the combined use of EDAC and S-NHS activation is required for high PK reactor performance with 500A5 microparticles (Ademtech).

It was previously shown that the ratio of the protein and EDAC/S-NHS concentrations plays a role in the grafting efficiency and also in unwanted particle agglomeration (*17*). Increasing the concentration of EDAC/S-NHS produces a significant change in the charge of the beads, which then causes their repulsion or agglomeration. For these reasons, we looked for a compromise level of EDAC/S-NHS with a proven optimal ratio. A decrease in EDAC/S-NHS concentrations by half in the subsequent experiments using PK reactor prepared with 500A5 microparticles led to 30% lower levels of catalytic activity. The stability of the enzyme reactor was also dramatically lower.

In the next experiments, temperature and reaction time were altered; results of PK activity after immobilization are shown in Table 4.

The effect of the amount of PK per mg of particles added to the reaction volume was studied. Increasing quantities of PK added to 1 mg of 500A5 microparticles were incubated under fixed binding conditions: 6 h at room temperature. The enzyme activity was determined with the substrate succinyl-Ala_3-*p*-nitroanilide in 50 mM Tris/HCl at pH 7.8 with 5 mM $CaCl_2$. The highest activity was obtained using 3 mg of PK per mg of the carrier. Additional increases in initial PK concentration led to a decrease in final proteolytic activity (Figure 1).

Since calcium ions are involved in enzyme activity and are needed for enzyme stability (*11*), we studied the effect of Ca^{2+} on the covalent bond (Figure 2).

Zeta Potential Measurement. Zeta potential is a measure of the magnitude of the repulsion or attraction between particles. Its measurement provides detailed insight into the dispersion mechanism and is the key to electrostatic dispersion control. The most important factors that affects zeta potential are the pH and molar strength of the buffering solution used. Particles

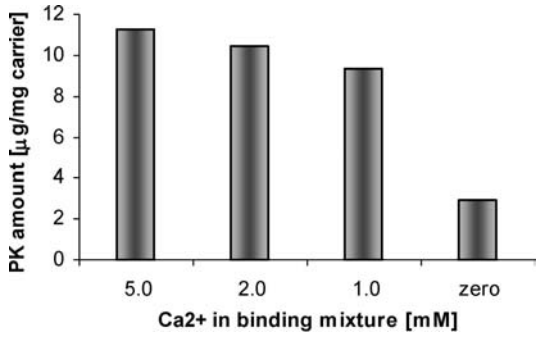

Figure 2. Effect of Ca^{2+} in binding solution on binding efficiency of PK reactor (500A5 microparticles).

Table 5. Zeta Potential Measurement for 500A5 particles (2%) in 10 mM and 100 mM Phosphate Buffer at pH 7.3 and Addition of 0.3% PF127 Surfactant

buffering	10 mM phosphate buffer pH 7.3	10 mM phosphate buffer pH 7.3 with 0.3% PF127	100 mM phosphate buffer pH 7.3
zeta potential value (mV)	−37.12	−23.1	−16.68

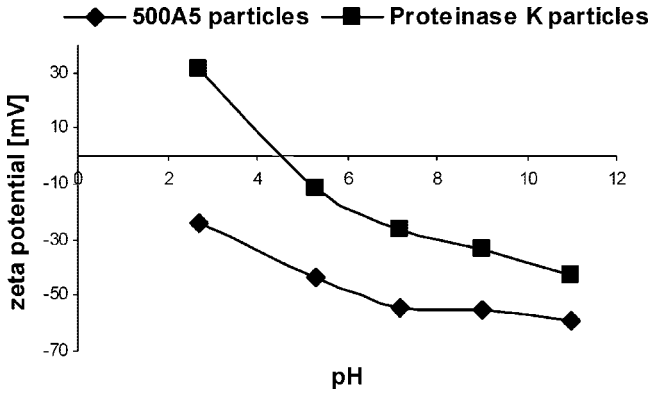

Figure 3. Zeta potential curves of magnetic 500A5 particles and of magnetic PK reactor (prepared with 500A5 particles) in 10 mM phosphate buffer at pH 7.3.

are considered to have a lower stability in the range −30 to 30 mV (*18*). By measuring the zeta potential (Table 5, Figure 3) of the 500A5 microparticles and preparing the PK reactor using the same particles, the optimal conditions were found to be as follows: 10 mM phosphate buffer at pH 7.3 with the addition of 0.3% PF127 surfactant. Under these conditions, the particles showed only a slight agglomeration, which affected neither the binding nor digestion processes.

The optimal conditions for the PK assay and for preparation of the PK reactor with 500A5 microparticles were used for other types of magnetic carriers and commercially available carriers in order to find the best working system.

In general, 1 mg of magnetic particles was activated by the above EDAC and S-NHS cross-linking two-step method at pH 7.3 and the immobilization procedure occurred at 4 °C overnight. Due to the different sizes and material compositions of the chosen microparticles, the obtained enzyme activities varied significantly (Table 6). The achieved activities of the PK reactors were also compared to a commercially available nonmagnetic PK reactor, consisting of PK bonded to Eupergit C macroporous acrylic beads (Sigma, USA). In comparison, the activity of the commercial nonmagnetic PK reactor only reached 6% of that of 500A5 particles (Ademtech).

Characteristics of PK Reactor. *Stability of PK Reactor.* Its storage and operational stabilities were analyzed. The activity remained the same as the initiatial value after 10 weeks. The catalytic activity per mg of carrier temporarily increased at the beginning of the observation period. One possible explanation is the conformation of the enzyme molecule was restored after the immobilization procedure (*3, 19*).

Operational Stability. By repeated use of the same aliquot at 25 °C with 1.05 mM substrate, up to 50% of the activity of the immobilized PK was maintained after 8 batches. In comparison, the reusability of the nonmagnetic commercially available PK reactor maintained 68% of its original activity after 8 repeats (data not shown).

Kinetic Constants. Enzyme reactor was characterized by measurement of Michaelis constant (K_M) which reflects the affinity between enzyme and substrate. The method used here was based on the frontal analysis of enzymatic reaction products, which was performed by the monitoring of the absorption at 405 nm of *p*-nitroaniline from the hydrolysis of succinyl-Ala-Ala-Ala-p-nitroanilide (*20*).

Our experimentally obtained data were processed in terms of Michaelis–Menten kinetics by the Lineweaver–Burk plots of v versus [S] as shown in Figure 4, where [S] is concentration and v the velocity of enzymatic reaction (*21*). Initial conditions of the reaction (ratio E:S, reaction volume) were chosen in agreement with Michelis−Menten kinetics. The apparent K_M of the PK reactor observed was 1.29 mM, and that of native PK 4.23 mM. The obtained K_M is influenced by the chemical composition of the carrier and by the microenvironment of the enzyme reactor from the bonded enzyme molecules, and is called apparent K_M (Figure 4). Maximum velocity V_i of the reaction catalyzed by the PK reactor was 0.36, which is 57% in comparison to native PK catalysis (value 0.63).

Application of Magnetic PK Reactor. *Digestion of Model Protein: Human Growth Hormone.* The efficiency of digestion was confirmed using a model protein human growth hormone (HGH) with a MW of 22 kDa by peptide mass fingerprinting. Proteolytic digestion was carried out in batch mode at room temperature for 15, 60, and 180 min and 24 h in 50 mM ammonium acetate (pH 7.8). The HGH was subsequently analyzed by Tricine/SDS PAGE (Figure 5) and Voyager-DE STR MALDI-TOF (Figure 6). The sequence coverage for the 15 min digestion of HGH, calculated from the list of obtained peptides, was 75%. It was proven that the proteolytic activity and specificity of PK were maintained after its immobilization to magnetic particles.

SDS PAGE and Western Blot of Digested PrP^c Peptides. Having shown that the PK reactor reproducibly digests a model protein, we thought to test its efficiency on a more complex medium such as a cell extract. We next digested proteins extracted from the immortalized Mov cell line overexpressing prion protein with the appropriate amount of the immobilized PK reactor (Figure 7). Our results showed a visible decay of the proteolysis-sensitive cellular prion protein with digestion time.

DISCUSSION

PK from *Tritirachium album* Limber (3.4.21.64) is reported as one of the most active serine proteases with a strong proteolytic activity on denatured proteins. The most interesting property of the enzyme is its capacity to degrade native proteins (*5*), which is commonly employed for differentiating between the physiological and pathological forms of prion protein (*22*).

This study reports the immobilization of PK on newly developed magnetic latex microparticles (Ademtech, France) and other chemically and structurally similar types of magnetic carriers. 500A5 microparticles were developed to have a reduced tendency to agglomerate and low levels of nonspecific sorption. Various conditions for coupling were utilized with the aim of

preparing a magnetic enzyme reactor with sufficient enzyme activity and stability.

From the surface chemistry, it is known that a pH slightly below the isoelectric point of the protein positively influences the grafting efficiency. The experimentally determined isoelectric point of PK was at the value 8.4 (data not shown), which is in general agreement with the value 8.9 in (*5*) and the theoretical value 8.25 from (*23*). At pH 7.3, the positively charged enzyme and negatively charged magnetic particles lead first to adsorption of the enzyme to the particle surface based on ionic forces and second to covalent linkage after carbodiimide activation in the immobilization procedure. By selecting a specific binding buffer, the subsequent adsorption of the enzyme molecules onto the particle surface potentiates a local amount of molecules in the immediate vicinity of the functional groups of the carrier, which enhances binding efficiency.

In the coupling reaction, N-substituted carbodiimide EDAC reacted with a carboxylic group of the 500A5 microparticles to form a highly reactive and short-lived acylisourea derivative. The activated species then reacted with the primary amines of the ligands to form a stable peptide bond. The binding efficiency was substantially increased by the presence of S-NHS as described in the paper by Staros (*24*). The two-step protocol at pH 7.3 in 10 mM phosphate buffer exhibited the highest binding yields and was chosen as optimal for further immobilizations (*25, 26*).

Temperature and reaction time have a considerable influence on the resulting enzyme reactor activity, especially with enzymes that have proteolytic and autolytic activities. Experiments with various immobilization procedures showed that using a low temperature of 4 °C with prolonged incubation overnight ensured a high binding efficiency of the enzyme reactor. The most possible explanation for the activity decrease after prolonged incubation overnight was autolytic activity (Table 4). If the immobilization was truncated from 6 to 2 h at room temperature, the resulting PK activity was very low and not sufficient for further applications.

To find a compromise between immobilization yield and catalytic activity, we optimized the amount of protein to 3 mg per mg of activated beads (500A5), corresponding to a reactor with high catalytic activity.

The X-ray structure study showed that two bound Ca^{2+} ions were required for the catalytic activity of PK (*11*). In the absence of Ca^{2+} ions, the catalytic activity of PK dropped to 20%, while the presence of Ca^{2+} slows down PK autolysis and also enhances thermal stability. In our experiments, increasing Ca^{2+} concentrations from 1 mM to 2.5 mM and 5 mM (the recommended concentration) only slightly increased the activity of the PK reactor (Figure 2). A Ca^{2+} increase to 5 mM negatively influenced the colloidal stability of the 500A5 microparticles. A total concentration of Ca^{2+} of 1 mM during the immobilization was considered to be sufficient.

Under all the studied and optimized conditions, this newly developed magnetic PK reactor prepared with 500A5 microparticles exhibited a more than sufficient storage and operational stability. These parameters are usually important for using an enzyme in routine laboratory work.

The "apparent" K_M of immobilized PK compared to the soluble enzyme exhibited a threeford higher affinity to the substrate. Such a decrease in the K_M values of immobilized enzymes has been recognized previously (*20, 27*), and has been ascribed to the presence of areas of increased substrate concentration around the particle due to electrostatic attraction or hydrophobic adsorption of the substrate to the solid. From a reaction rate point of view, the maximal velocity of substrate change was calculated as a change in optical density (formation of product) units per time unit. The lower rate of enzyme reaction with immobilized PK, shown by its maximum velocity V_i, can possibly be explained as due to limited diffusion of the substrate molecules to the surface of the particles and to the active sites of the immobilized enzyme.

The 500A5 microparticles exhibited slight bead agglomeration during manipulations, which may complicate reactor application and efficiency. The zeta potential measurement confirmed the necessity of adding the surfactant. The surfactant PF127 at concentration of 0.3% was considered optimal.

The magnetic PK reactor was applied in the proteolytic cleavage of high-molecular-weight substrates, the model substrate human growth hormone, and the cellular prion protein. Both HGH and PrP^c were digested by limited proteolysis, and

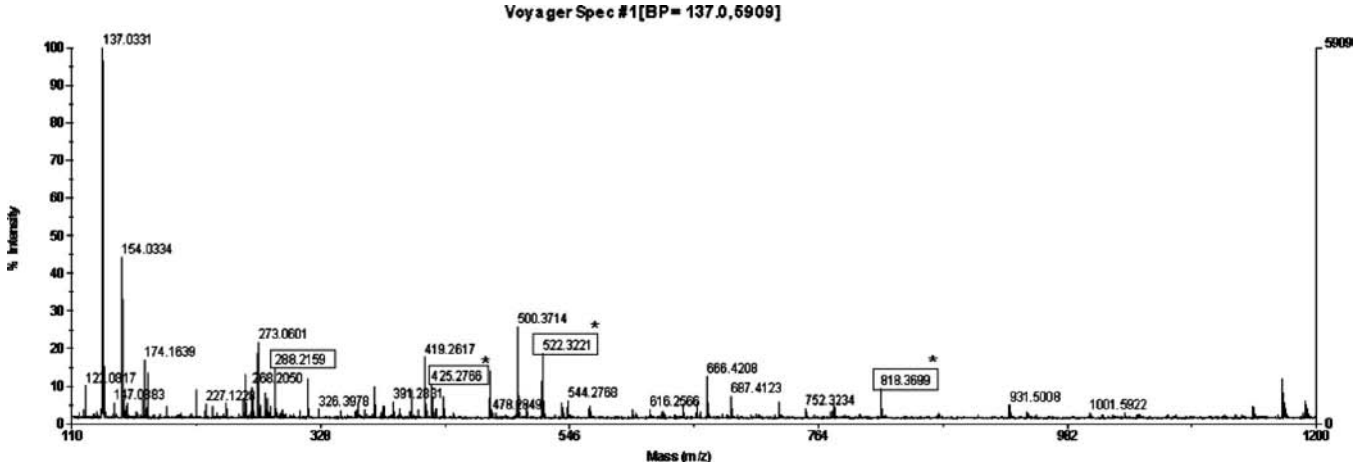

Figure 6. MALDI mass spectra of 15 min digested HGH by PK reactor (prepared with magnetic latex microparticles, Estapor). The framed masses correspond to identified peptides by the Expasy software (PeptideMass) with 0 or 1 (*) miscleavages. The nonframed masses arise from further miscleavages and contamination. Conditions of MS analysis: 1 μL of every digested sample was dried on MALDI-target before covering with 1 μL of DHB in ACN (50%) and TFA (0.3%) as the matrix ("dried droplet" technique). Calibration was performed with a standard peptide mixture with an *m*/*z* range of 800 to 3500 Da (LaserBio Laboratories, FR).

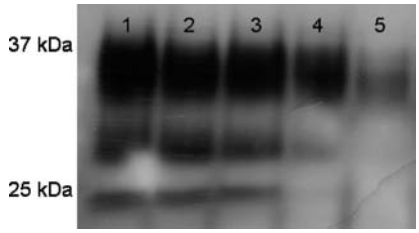

Figure 7. Western blotting of limited proteolysis of digested cellular prion protein (Mov cell line overexpressing ovine PrP^c). Samples were digested with PK reactor (0.7 μg, prepared with 500A5 microparticles, Ademtech) in 100 μL volume of cell lysate, precipitated with methanol, separated on 10% Tris/HCl gel, and blotted to nitrocellulose membrane with specific ICSM18 or SAF 84.3 mAb. Positions: 1, PrP^c digested for 2 min; 2, PrP^c digested for 5 min; 3, PrP^c digested for 10 min; 4, PrP^c digested for 30 min; and 5, PrP^c digested for 60 min.

mass spectrophotograms, electrophoreograms, and blots confirmed that the proteolysis system was working well. Through these experiments, we confirmed the PK magnetic reactor to be a useful tool for PrP digestion, with the use of a magnetic carrier being published for the first time.

CONCLUSION

This study describes (1) the methods used to optimize the PK grafting procedure, (2) the characterization and validation of the newly prepared magnetic enzyme reactor, and (3) the benefits of using immobilized PK in bioanalytical applications, and examples of those applications. We optimized a method for covalently bonding PK to a magnetic carrier with polymer coating and carboxylic derivatization. The carbodiimide chemistry used here to bind the enzyme to the new carrier gave the amide bonds excellent stability. The newly developed carrier prepared by the manufacturer Ademtech served as a good example of magnetic particles with a large range of possible uses. Furthermore, these optimized conditions, when applied to other magnetic nano and microparticles, showed high applicability and reusability. The results of this study also demonstrated that the storage conditions of the PK enzyme reactor are highly compatible with a laboratory routine. As examples of the simple handling of the magnetic PK reactor, the human growth hormone and mouse overexpressed PrP^c were digested and verified by the analytical methods MALDI-TOF-MS, PAGE, and Western Blot. This magnetic PK reactor can possibly be used for the digestion other resistant proteins with all features of covalently bonded enzymes.

ACKNOWLEDGMENT

We gratefully acknowledge the Ademtech Company, France, and Academy of Sciences, Czech Republic, for their donations of magnetic particle batches. This work was supported in part by Czech funding grant MSMT0021627502, the EU project "Neurotas" (contract no. 037953) and Czech Science Foundation 203/05/0241.

TECHNICAL NOTES

Long Functionalized Poly(ethylene glycol)s of Defined Molecular Weight: Synthesis and Application in Solid-Phase Synthesis of Conjugates

Dan Niculescu-Duvaz, Jayne Getaz, and Caroline J. Springer*

Cancer Research UK Centre for Cancer Therapeutics, The Institute of Cancer Research, 15 Cotswold Road, Sutton, Surrey SM2 5NG, U.K. Received August 3, 2006; Revised Manuscript Received January 28, 2008

A concise synthesis of long-chain poly(ethylene glycol) (PEG) of defined molecular weight up to 29 ethyleneoxy units is described. These PEG diols were converted in a two-step synthesis into Fmoc-protected PEG amino acids, suitable as long linkers and compatible with solid-phase peptide synthesis. Long PEG chains (MW > 1000) can be readily synthesized with this method, which has the advantage of defined single molecular weight products over the comparable commercial polymers. The application of these PEG linkers to the synthesis of peptide−PEG−folate conjugates on a solid support was investigated. A method for the solid support synthesis of the targeting component of the conjugate, folic acid−cysteine, was developed, resulting in improved yields with respect to literature methods. The assembly of the peptide, PEG linker, and targeting group on solid support resulted in the synthesis of a conjugate of defined molecular weight and structure.

INTRODUCTION

Poly(ethylene glycol) is a biologically inert polymer that has been used extensively to alter the physiological properties of drugs, therapeutic proteins, liposomes, and polyplexes. Conjugation with PEG has been reported to confer a number of beneficial properties including increased solubility, reduced interaction with serum and complement proteins and a significantly increased half-life *in vivo* (*1*).

PEGylation can improve the performance and dosing frequency of peptides, proteins, antibodies, oligonucleotides and many small molecules by optimizing pharmacokinetics (PK), increasing bioavailability and decreasing immunogenicity. PEGylated therapeutic agents with clinical approval include liposomes, proteins, and aptamers (*2*, *3*).

In addition, PEG chains can act as spacers. In bioconjugation, the separation between components is often necessary to preserve the affinity and activity of each component of the conjugate. For example, polyplexes containing targeting ligands for specific tissues have been shown to retain better ligand–receptor binding affinity when separated by a PEG spacer (*4–6*). Labeling of peptides with fluorophores and biotin often includes a PEG chain to improve the activity/affinity of the reporter group (*7*).

The biological effects of PEG modification have been related to the molecular weight of the polyether used. In general, longer PEG chains are more efficient in improving the PK of conjugates and preserving the affinity of the targeting ligand for its receptor (*8*, *9*). PEG of higher molecular weight is obtained by relatively uncontrolled polymerization techniques, leading to polydispersity in the molecular weight of the product. Advances in anionic polymerization techniques have led to the synthesis of relatively well-defined monobenzylated PEG (*10*) and heterofunctional PEG (*11*) with polydispersity indexes equal or below 1.09. However, the products of polymerization show a range in molecular weights, even at low polydispersity indexes. An example of the MALDI mass spectrometry analysis of commercially available PEG is shown in Figure 1.

This heterogeneity in PEG molecular weight has an effect on the biological activity of the conjugates and compromises their characterization and quality control, which is important for clinical applications. Batch-to-batch variability could obscure the results and complicate investigations into the structure–activity relationship of these heterogeneous conjugates. The availability of intermediate and high molecular weight PEG of defined molecular weight (MW) is therefore highly desirable.

One method for obtaining longer PEG chains of defined MW is to synthesize them starting from commercially available shorter chains of defined length. A few reports have described synthetic routes to PEG of intermediate length (up to 24 units). Here, we describe a simple route to PEG up to 29 units, with potential to be extended to higher MW.

Another requirement for bioconjugation is that PEG chains need to be modified with functional groups that allow chemical coupling to biomolecules. The most common coupling strategies involve the formation of amide bonds (usually via activated esters of carboxylic acids) and thiol bonds (thioether or disulfide). One convenient functionalization of PEG is with an amino acid, which can be used in peptide synthesis on solid support, or it could be deprotected and coupled further to convert to a heterobifunctional linker. Here, we report a simple strategy for bifunctionalization of PEG diol to Fmoc-protected PEG amino acid.

The utility of these linkers is exemplified by the synthesis of a folate−PEG−amphipathic peptide conjugate on solid support. Amphipathic peptides have been used in nonviral gene therapy approaches with some success *in vitro* (*12*, *13*). These peptides are able to facilitate endosomal escape by destabilizing the endosomal membrane directly as a result of a change in

conformation at the lower pH conditions within the endosomal compartment. Incorporation of such a peptide in a modular conjugate containing a PEG and a targeting ligand could lead to an effective nonviral gene vector for systemic application.

Folic acid is the small molecule ligand for the α-folate receptor, and is overexpressed in pituitary adenomas (*14*) and ovarian (*15*) cancers. Folic acid has been conjugated to drugs (*16*), macromolecules (*17*), liposomes (*5*) and polyplexes (*18*), in order to achieve specific targeting and enhanced uptake of conjugates in α-folate-expressing tumor cells. We have attached the folic acid to the amphiphatic peptide−PEG on solid support, and demonstrated the synthesis of a complex conjugate of defined structure on solid support. This conjugate is the prototype for potential modular nonviral vectors for gene delivery.

EXPERIMENTAL PROCEDURES

All starting materials, reagents, and solvents for reactions were reagent grade and used as purchased. Chromatography solvents were HPLC grade and were used without further purification. Reactions were monitored by thin layer chromatography (TLC) analysis using Merck silica gel 60 F-254 thin layer plates. LCMS analyses were performed on a Micromass LCT/Water's Alliance 2795 HPLC system with a Discovery 5 μm, C18, 50 mm × 4.6 mm i.d. column from Supelco at a temperature of 22 °C using the following solvent systems: solvent A, methanol; solvent B, 0.1% formic acid in water at a flow rate of 1 mL/min. Gradient starting with 10% A/90% B from 0 to 0.5 min, then 10% A/90% B to 90% A/10% B from 0.5 to 6.5 min and continuing at 90% A/10% B up to 10 min. From 10 to 10.5 min, the gradient reverted back to 10% A/90% B where the concentrations remained until 12 min. UV detection was at 254 nm and ionization was positive or negative ion electrospray. Molecular weight scan range is 50–1000. Samples were supplied as 1 mg/mL in DMSO or methanol with 3 μL injected on a partial loop fill. Preparative HPLC was carried out on an Agilent 1100 series system (Agilent Technologies, Wokingham, UK) using a Gemini C18 column (250 × 30.0 mm, 10 μm). Gradient (15 mL/min): 10% MeCN to 95% MeCN over 25 min, 5 min at 95% MeCN, 95% MeCN to 10% MeCN over 10 min. NMR spectra were recorded in DMSO-d_6 on a Bruker DPX 250 instrument operating at 250.13 MHz or on a Bruker Advance instrument 500 operating at 500.26 MHz. The signal of the deuterated solvent was used as internal reference; the chemical shifts are expressed in ppm (δ). MALDI analysis was carried out using either a Lasermat (Finnigan Mat, Hemel Hampstead, UK) or Dynamo system (Thermo Bioanalysis Ltd., Hemel Hampstead, UK). The samples were analyzed using a 0.4 μL matrix (5.1 mg α-cyano-4-hydroxy cinnamic acid in 100 μL TFA, 500 μL H_2O, and 500 μL MeCN).

1. Synthesis of Diols. *Preparation of BnO-PEG$_6$-OH (2). a. Using NaH.* A solution of hexa(ethylene glycol) (4.5 mL, 17.73 mmol) and NaH (60% in mineral oil) (0.85 g, 21.28 mmol) in dry THF (60 mL) was stirred under argon for 90 min. Benzyl bromide (2.1 mL, 17.73 mmol) was added dropwise, and the reaction was stirred at room temperature for 20 h. The reaction was quenched with H_2O, evaporated, extracted with EtOAc, and dried over $MgSO_4$. The residue was purified by column chromatography on silica (eluent EtOAc/hexane 5:1, then EtOAc) to afford the required product (2.37 g, 35%).

b. Using Ag$_2$O. Ag_2O (6.16 g, 26.60 mmol) and KI (1.18 g, 7.10 mmol) were suspended in dry DCM (150 mL) under argon. Hexa(ethylene glycol) (4.5 mL, 17.73 mmol) was added dropwise, followed by benzyl bromide (2.3 mL, 19.50 mmol) after 5 min. The reaction was stirred at room temperature for 2 h, then filtered through Celite. The filtrate was evaporated, extracted with AcOEt, and dried over $MgSO_4$. The residue was purified by column chromatography on silica (eluent EtOAc/acetone 4:1) to afford the required product (3.49 g, 53%). LC-MS (ES): 372 $[M + H]^+$, 395 $[M + Na]^+$. HPLC retention time (discovery column of LCMS): 5.59 min; the unsubstituted hexa(ethylene glycol) and disubstituted BnO-PEG$_6$-OBn have retention times of 3.10 and 7.05 min, and are present only in traces in the purified BnO-PEG$_6$-OH (**2**). ^{1}H NMR ($CDCl_3$): 7.35–7.34 (m, 5H, H_{arom}), 4.58 (s, 2H, PhCH_2), 3.73–3.60 (m, 25H, C$H_{2,PEG,}$ O*H*). ^{13}C NMR ($CDCl_3$): 138.32 (C_{arom}), 128.33 (CH_{arom}), 127.72 (CH_{arom}), 127.55 (CH_{arom}), 73.23 (PhCH_2), 72.58 (OCH_2CH_2OH), 70.64 ($CH_{2,PEG}$), 70.62 ($CH_{2,PEG}$), 70.60 ($CH_{2,PEG}$), 70.57 ($CH_{2,PEG}$), 70.54 ($CH_{2,PEG}$), 70.33 ($CH_{2,PEG}$), 69.47 ($CH_{2,PEG}$), 61.73 (CH_2OH).

Preparation of BnO-PEG$_{17}$-OBn (4). In a solution of BnO-PEG$_6$-OH (**2**) (2.97 g, 7.97 mmol) in dry THF (50 mL) under

argon, NaH (60% in mineral oil, 0.43 g, 10.63 mmol) was added and stirred at room temperature for 2 h. Penta(ethylene glycol) di(*p*-toluenesulfonate) (**3**) (0.9 mL, 1.99 mmol) was added and the reaction was refluxed for 20 h. A second portion of NaH (0.43 g, 10.63 mmol) was added and the reaction mixture was stirred for 1 h. A second portion of penta(ethylene glycol) di(*p*-toluenesulfonate) (0.9 mL, 1.99 mmol) was then added and the reaction was refluxed for a further 20 h. The reaction was quenched with H_2O, evaporated, extracted with EtOAc, and dried ($MgSO_4$). The residue was purified by precipitation from DCM with cold diethyl ether, to afford the required product (3.16 g, 84%). LC-MS (ES): 948 $[M + H]^+$, 474 $[M + 2H]^{2+}$. MALDI +ve ion mode: 968 $[M + Na]^+$, 984 $[M + K]^+$. ^{1}H NMR ($CDCl_3$): 7.35–7.34 (m, 10H, H_{arom}), 4.57 (s, 4H, PhCH_2), 3.66–3.64 (m, 68 H, C$H_{2,PEG}$). ^{13}C NMR ($CDCl_3$) 125 MHz: δ 128.30 (CH_{arom}), 127.67 (CH_{arom}), 127.52 (CH_{arom}), 73.17 (PhCH_2), 70.58 (C$H_{2,PEG}$), 70.54 (C$H_{2,PEG}$), 70.51 (C$H_{2,PEG}$).

*Preparation of PEG$_{17}$ Diol (**5**).* A solution of BnO-PEG$_{17}$-OBn (**4**) (3.16 g, 3.34 mmol) containing 10% Pd/C (0.07 g) in EtOH (60 mL) was stirred under hydrogen for 4 days. The reaction was filtered through Celite and the filtrate evaporated. The residue was purified by precipitation from DCM with cold diethyl ether, to afford the required product (2.48 g, 97%). LC-MS (ES): 767 $[M + H]^+$, 334 $[M + 2H]^{2+}$. ^{1}H NMR ($CDCl_3$) 500 MHz: δ 3.66–3.61 (m, 70 H, C$H_{2,PEG}$, O*H*). ^{13}C NMR ($CDCl_3$) 125 MHz: δ 72.46 (HOCH$_2$*C*H$_2$O), 70.43 (*C*H$_{2,PEG}$), 70.40 (*C*H$_{2,PEG}$), 70.19 (*C*H$_{2,PEG}$), 61.38 (HO*C*H$_2$CH$_2$O). Elemental analysis: ($C_{34}H_{70}O_{18}\cdot 0.5H_2O$): required C 52.63, H 9.22; found C 52.81, H 9.20.

*Preparation of BnO-PEG$_6$-OTos (**6**).* In a solution of BnO-PEG$_6$-OH (**2**) (2.00 g, 5.37 mmol) in dry DCM (100 mL), under argon, *p*-toluenesulfonyl chloride (1.54 g, 8.05 mmol), KI (0.36 g, 2.15 mmol), and Ag_2O (1.87 g, 8.05 mmol) were added. The reaction was stirred at reflux for 20 h under argon and protected from light. The mixture was filtered through Celite and the filtrate evaporated. The residue was purified by column chromatography on silica (eluent EtOAc) to afford the required product (2.60 g, 92%). LC-MS (ES): 526 $[M+H]^+$. ^{1}H NMR ($CDCl_3$): 7.81 (d, J = 8.50, 2H, CH_{arom}), 7.35–7.28 (m, 7H, CH_{arom}), 4.57 (s, 2H, PhCH_2), 3.70–3.58 (m, 24H, C$H_{2,PEG}$), 2.45 (s, 3H, CH_3). ^{13}C NMR ($CDCl_3$): 144.74 (C$_{arom}$), 138.33 (C$_{arom}$), 133.11 (C$_{arom}$), 129.80 (CH_{arom}), 128.32 (CH_{arom}), 127.94 (CH_{arom}), 127.69 (CH_{arom}), 127.54 (CH_{arom}), 73.20 (PhCH_2), 70.72 (C$H_{2,PEG}$), 70.64 (C$H_{2,PEG}$), 70.59 (C$H_{2,PEG}$), 70.55 (C$H_{2,PEG}$), 70.51 (CH_{2PEG}), 69.47 (OCH_2CH$_2$OTos), 68.65 (CH_2-OTos), 21.59 (CH_3).

*Preparation of BnO-PEG$_{29}$-OBn (**7**).* To a solution of PEG$_{17}$ diol (**5**) (0.50 g, 0.65 mmol) in dry THF (50 mL) under argon, NaH (0.52 g, 13.04 mmol) was added. The reaction was stirred under argon for 2 h at room temperature before a solution of BnO-PEG$_6$-OTos (**5**) (0.69 g, 1.3 mmol) in dry THF (5 mL) was added. The reaction was refluxed for 20 h. The reaction was quenched with H_2O, evaporated, extracted with EtOAc, and dried ($MgSO_4$). The residue was purified by precipitation from DCM with cold diethyl ether, to afford the required product (0.80 g, 83%). LC-MS (ES): 1476 $[M + H]^+$, 738 $[M + 2H]^{2+}$, 493 $[M + 3H]^{3+}$, MALDI +ve ion mode: 1495 $[M + Na]^+$. ^{1}H NMR ($CDCl_3$): δ 7.35–7.34 (m, 10H, H_{arom}), 4.57 (s, 4H, PhCH_2), 3.66–3.64 (m, 116 H, C$H_{2,PEG}$). ^{13}C NMR ($CDCl_3$): δ 128.28 (CH_{arom}), 127.64 (CH_{arom}), 127.50 (CH_{arom}), 73.16 (PhCH_2), 70.61 (C$H_{2,PEG}$), 70.56 (C$H_{2,PEG}$), 70.54 (C$H_{2,PEG}$).

*Preparation of PEG$_{29}$ Diol (**8**).* A solution of BnO-PEG$_{29}$-OBn (**7**) (0.60 g, 0.41 mmol) containing 10% Pd/C (0.01 g) in EtOH (10 mL) was stirred under hydrogen for 3 days. The reaction was filtered and the filtrate was evaporated. The residue was purified by precipitation from DCM with cold diethyl ether, to afford the required product (0.49 g, 93%). LC-MS (ES): 1296 $[M + H]^+$, 648 $[M + 2H]^{2+}$, 432 $[M + 3H]^{3+}$. MALDI +ve ion mode: 1318 $[M + Na]^+$. ^{1}H NMR ($CDCl_3$): δ 3.66–3.61 (m, 118 H, C$H_{2,PEG,}$ O*H*). ^{13}C NMR ($CDCl_3$): 72.52 (HOCH$_2$-*C*H$_2$O), 70.61 (*C*H$_{2,PEG}$), 70.57 (*C*H$_{2,PEG}$), 70.36 (*C*H$_{2,PEG}$), 61.71 (HO*C*H$_2$CH$_2$O). Elemental analysis ($C_{58}H_{118}O_{30}\cdot 0.5H_2O$): required C 53.40, H 9.19; found C 53.28, H 9.17.

2. Functionalization to Fmoc-Protected Amino Acid. *Preparation of PEG$_{17}$ Diacid (**9**).* Potassium *tert*-butoxide (2.93 g, 26.08 mmol) was added to a solution of PEG$_{17}$ diol (**5**) (1.00 g, 1.30 mmol) in *tert*-butanol (46 mL). The mixture was stirred at 50 °C under argon for 8 h, protected from light. Ethyl bromoacetate (2.9 mL, 26.08 mmol) was then added and a precipitate formed. The reaction was stirred for 24 h before being filtered and the filtrate evaporated. The residue was taken in 30 mL 1.0 M NaOH and stirred at room temperature for 8 h. The reaction was adjusted to pH 3 with 1.0 M HCl and extracted with chloroform. The organic layer was collected and dried with $MgSO_4$. The residue was purified by precipitation from DCM with cold diethyl ether, to afford the required product (0.91 g, 79%). LC-MS (ES): 883 $[M + H]^+$, 442 $[M + 2H]^{2+}$, 295 $[M + 3H]^{3+}$. MALDI +ve ion mode: 903 $[M + Na]^+$, 919 ($[M + K]^+$. ^{1}H NMR ($CDCl_3$): δ 4.08 (s, 4H, OCH_2COOH), 3.66–3.58 (m, 68 H, C$H_{2,PEG}$). ^{13}C NMR ($CDCl_3$): δ 172.00 (*C*O), 71.20 (*C*H$_{2,PEG}$), 70.64 (*C*H$_{2,PEG}$), 70.61 (*C*H$_{2,PEG}$), 70.54 (*C*H$_{2,PEG}$), 70.50 (*C*H$_{2,PEG}$), 70.46 (*C*H$_{2,PEG}$), 70.39 (*C*H$_{2,PEG}$), 68.81 (CO*C*H$_2$O).

*Preparation of PEG$_{29}$ Diacid (**10**).* The title compound was prepared starting from PEG$_{29}$ diol (**8**) (0.4 g, 0.31 mmol) using the same method as described for compound **9** (0.39 g, 88%). LC-MS (ES): 1412 $[M + H]^+$, 706 $[M + 2H]^{2+}$, 471 $[M + 3H]^{3+}$. MALDI +ve ion mode: 1433 $[M+Na]^+$. ^{1}H NMR ($CDCl_3$): δ 4.09 (s, 4H, OCH_2COOH), 3.60–3.58 (m, 116 H, C$H_{2,PEG}$). ^{13}C NMR ($CDCl_3$): δ 71.08 (C$H_{2,PEG}$), 70.61 (C$H_{2,PEG}$), 70.59 (C$H_{2,PEG}$), 70.54 (C$H_{2,PEG}$), 70.47 (C$H_{2,PEG}$), 70.44 (C$H_{2,PEG}$), 70.36 (C$H_{2,PEG}$), 68.86 (CO*C*H$_2$O).

*Preparation of Fmoc-PEG$_{17}$-COOH (**11**).* *N*-Hydroxysuccinimide (0.05 g, 0.45 mmol) was added to a solution of PEG$_{17}$ diacid (**9**) (0.40 g, 0.45 mmol) in dry DCM (40 mL) under argon. The reaction mixture was cooled in an ice bath, and a solution of DCC (0.09 g, 0.45 mmol) in dry DCM (5 mL) was added dropwise. The reaction was allowed to warm to room temperature and stirred for 4 h. A solution containing 1.0 equivalent of mono-Fmoc 1,3 diaminopropane hydrochloride (0.15 g, 0.45 mmol) in dry NMP (1 mL) was then added, followed by 4.0 equiv of triethylamine (0.3 mL, 1.81 mmol). The reaction was stirred at room temperature for 20 h before being evaporated. The residue was purified by preparative HPLC to afford the required product (0.12 g, 23%). LC-MS (ES): 1162 $[M + H]^+$, 581 $[M + 2H]^{2+}$. MALDI +ve ion mode: 1183 $[M + Na]^+$. HPLC retention time (min): 12.95. Purity by HPLC: 99%. ^{1}H NMR ($CDCl_3$): δ 7.75 (d, 2H, CH_{arom}, J = 7.45 Hz), 7.61 (d, 2H, CH_{arom}, J = 7.35 Hz), 7.39 (t, 2H, CH_{arom}, J = 7.45 Hz), 7.31 (t, 2H, CH_{arom}, J = 7.45 Hz), 5.79 (t, 2H, J = 6.35 Hz), 4.40 (d, 2H, FmocCH_2O, J = 7.25 Hz), 4.20 (t, 1H, FmocC*H*, J = 6.90 Hz), 4.14 (s, 2H, CH_2COOH), 4.00 (s, 2H, COCH_2O), 3.73–3.58 (m, 68H, C$H_{2,\ PEG}$), 3.35 (d, J = 6.20, 2H, CH_2NHCO), 3.21 (d, 2H, OCONHCH_2, J = 6.20), 1.69 (t, 2H, NHCH$_2$CH_2, J = 6.30 Hz). ^{13}C NMR ($CDCl_3$): δ 144.05 (C$_{arom}$), 141.29 (C$_{arom}$), 127.63 (CH_{arom}), 127.05 (CH_{arom}), 125.10 (CH_{arom}), 119.91 (CH_{arom}), 71.01 (C$H_{2,PEG}$), 70.93 (C$H_{2,PEG}$), 70.53 (C$H_{2,PEG}$), 70.46 (C$H_{2,PEG}$), 70.40 (C$H_{2,PEG}$), 70.29 (C$H_{2,PEG}$), 70.24 (C$H_{2,PEG}$), 70.13 (C$H_{2,PEG}$), 68.99 (CH_2CO), 66.35 (C$H_{2,Fmoc}$), 47.28 (CH_{Fmoc}), 37.72 (CH_2), 35.70 (CH_2), 29.71 (CH_2). Elemental analysis ($C_{52}H_{92}N_2O_{23}\cdot 2H_2O$): required C 56.17, H 8.08, N 2.34; found C 56.25, H 8.01, N 2.11.

*Preparation of Fmoc-PEG$_{29}$-COOH (**12**).* The title compound was prepared starting from PEG$_{29}$ diacid (**10**) (0.30 g, 0.21

mmol) using the same method as described for compound **11** (0.39 g, 88%). 0.13 g of required product was obtained. Yield: 35%. LC-MS (ES):1690 $[M + H]^+$, 845 $[M + 2H]^{2+}$, 564 $[M + 3H]^{3+}$. MALDI +ve ion mode: 1712 $[M + Na]^+$. HPLC retention time (min): 12.56. Purity by HPLC: 99%. ^{1}H NMR ($CDCl_3$): δ 7.84 (d, 2H, CH_{arom}, $J = 7.60$ Hz), 7.68 (d, 2H, CH_{arom}, $J = 7.25$ Hz), 7.51 (m, 1H, OCON*H*), 7.40 (t, 2H, CH_{arom}, $J = 7.40$ Hz), 7.32 (t, 2H, CH_{arom}, $J = 7.25$ Hz), 6.53 (m, 1 H, CH_2N*H*CO), 4.36 (d, 2H, FmocCH_2O, $J = 7.25$ Hz), 4.22 (t, 1H, FmocC*H*, $J = 6.77$ Hz), 4.10 (s, 2H, CH_2COOH), 3.92 (s, 2H, COCH_2O), 3.72–3.52 (m, 116H, C$H_{2,\ PEG}$), 3.32–3.28 (m, 2H, CH_2NHCO), 3.20–3.17 (m, 2H, OCONHCH_2), 1.70–1.67 (m, 2H, NHCH$_2$CH_2). ^{13}C NMR ($CDCl_3$): δ 170.68 (*C*$_{arom}$), 157.21 (*C*$_{arom}$), 145.07 (*C*H$_{arom}$), 142.00 (*C*H$_{arom}$), 128.38 (*C*H$_{arom}$), 127.82 (*C*H$_{arom}$), 125.94 (*C*H$_{arom}$), 120.68 (*C*H$_{arom}$), 71.66 (*C*H$_{2,PEG}$), 71.30 (*C*H$_{2,PEG}$), 71.13 (*C*H$_{2,PEG}$), 71.00 (*C*H$_{2,PEG}$), 70.94 (*C*H$_{2,PEG}$), 68.77 (*C*H$_2$CO), 66.62 (*C*H$_{2,Fmoc}$), 48.06 (*C*H$_{Fmoc}$), 38.64 (*C*H$_2$), 36.38 (*C*H$_2$), 29.71 (*C*H$_2$). Elemental analysis ($C_{80}H_{140}N_2O_{35}\cdot H_2O$): required C 56.26, H 8.38, N 1.64; found C 55.97, H 8.35, N 1.42.

3. Synthesis of the Peptide−PEG−Folate Conjugate. *Synthesis of Folic Acid-Cysteine Targeting Ligand (**13**).* A Glu(tBu)-Cys(Trt) dipeptide was synthesized on 0.65 g of Fmoc-Cys(Trt) HMP resin (loading capacity 0.58 mmol/g) using automated peptide synthesis. 4.0 equiv of Fmoc-Glu-O^{t}Bu (Bachem, UK) was utilized in each coupling step. The peptideo-resin was washed in DCM and MeOH and dried in a desiccator. Pteroic acid (0.10 g, 0.32 mmol) was taken up in dry DMF (3 mL) and dry DMSO (1.3 mL) and added to 0.19 g of peptideo-resin under argon. A 0.5 mM HOBt/HBTU solution in DMF (0.6 mL, 0.32 mmol) was added, followed by a 2.0 mM DIPEA solution in NMP (0.3 mL, 0.64 mmol). The reaction mixture was protected from light and shaken at room temperature for 24 h. The peptido-resin was filtered and washed in DMSO (4 mL) four times, DMSO/DMF 1:1 (4 mL) once, DMF (4 mL) once, and two alternating washes of DCM and MeOH (4 mL). The resin was then dried in a desiccator. 0.10 g of peptido-resin was cleaved using 3.0 mL cleavage mixture (0.75 g phenol, 0.5 mL thioanisole, 0.5 mL H_2O, 0.3 mL EDT, 10.0 mL TFA). The reaction was shaken at room temperature for 3 h. The filtrate was precipitated in cold diethyl ether and centrifuged to pellet. The pellet was washed in diethyl ether four times before drying in a desiccator 0.02 g of required product was obtained. Yield: 62% LC-MS (ES): 544 $[M + H]^+$. HPLC retention (min): 7.38. Purity by HPLC: 70%. ^{1}H NMR $(CD_3)_2SO$ 500 MHz: δ 8.66 (s, 1H, AromH$_1$), 8.21–8.17 (m, 2H, NH amide), 7.66 (d, 2H, $J = 8.50$, AromH$_4$), 7.33–7.23 (m, 3H, PhN*H*, N*H*$_2$), 6.64 (d, 2H, $J = 8.85$, AromH$_3$), 4.50 (s, 2H, H$_2$), 4.42–4.37 (m, 1H, H$_5$), 4.31–4.28 (m, 1H, H$_8$), 2.85–2.68 (2m, 2H, H$_9$), 2.31–2.19 (m, 2H, H$_7$), 2.09–1.86 (2m, 2H, H$_6$).

*Preparation of Amphipathic Peptide KKALLALALHHLAH-LALHLALALKKA (**14**) (**19**).* The peptide was synthesized using an ABI 433A peptide synthesizer (Applied Biosystems, California, USA) equipped with conductivity monitoring. The activation solution used in each coupling step contained HOBt/HBTU in DMF (0.5 mM) and DIPEA in NMP (2 mM). Each coupling step was carried out over approximately 4.5 min and was followed by a wash in NMP. Fmoc deprotection was carried out using 22% piperidine in DMF over 2 min and was followed by conductivity monitoring. This step was repeated up to 6 times. The peptide was synthesized on 149 mg of Fmoc-Ala HMP resin (loading capacity 0.7 mmol/g) using 10.0 equiv of amino acid in each coupling step. 462 mg of peptido-resin was obtained from the synthesis. Theoretical yield: 88%.

The peptide from 100 mg peptido-resin was cleaved using a cleavage mixture: 0.75 g crystalline phenol, 0.25 mL EDT, 0.50 mL thioanisole, 0.50 mL H_2O, and 10.00 mL TFA. Cleavage was carried out in an Isolute SPE single fritted reservoir (Argonaut Technologies Inc., Mid Glamorgan UK). The resin was filtered and the filtrate was collected and precipitated by adding cold diethyl ether. The precipitate was collected by centrifugation and washed with diethyl ether. The precipitate was dried in a desiccator.

The peptide was purified by semipreparative HPLC on a Jupiter C18 column (250 × 10 mm, 5 μm). A gradient was run at 3 mL/min from 95% H_2O (0.1% TFA), 5% MeCN (0.1% TFA) to 5% H_2O (0.1% TFA), 95% MeCN (0.1% TFA) over four column volumes. 38 mg of required product was obtained. Yield of purified peptide: 54%. MALDI +ve ion mode: 2779 $[M + H]^+$, 2801 $[M + Na]^+$. HPLC retention (min): 12.84. Purity by HPLC: 98%.

*Preparation of Amphipathic Peptide-PEG$_{17}$-NH-Fmoc (**15**).* 1.5 equiv each of FmocNHPEG$_{17}$-COOH (7 mg, 6.24 μmol) and HCTU (3 mg, 6.24 μmol) were taken up in dry NMP/DCM 9:1 (1 mL) and added to 25 mg amphipathic peptido-resin under argon. 3.0 equiv of DIPEA in NMP (2 mM) (0.01 mL, 12.0 μmol) were added and the reaction was shaken for 72 h. The reaction was filtered, rinsed in DMF, DCM, and MeOH, and dried in a desiccator. Cleavage was carried out as previously described. MALDI, +ve ion mode: 3923 $[M + H]^+$,3944 $[M + Na]^+$. HPLC retention (min): 13.47. Product in crude by HPLC: 66%.

*Preparation of Amphipathic Peptide-PEG$_{17}$-NH$_2$ (**16**).* 65 mg of amphipathic peptide-PEG$_{17}$-NHFmoc peptido-resin was taken up in 1.5 mL of 20% piperidine in DMF and shaken for 3 h. The reaction was filtered, rinsed in DMF, DCM, and MeOH, and dried in a desiccator. Cleavage was carried out as previously described. MALDI, +ve ion mode: 3700 $[M + H]^+$, 3722 $[M + Na]^+$. HPLC retention (min): 12.37.

*Preparation of Amphipathic Peptide-PEG$_{17}$-NH-Maleimide (**17**).* 10.0 equiv of 6-maleimidohexanoic acid *N*-hydroxysuccinimide ester (26 mg, 83.00 μmol) was taken up in dry DMF (2 mL) and added to 54 mg amphipathic peptide-PEG$_{17}$-NH$_2$ peptido-resin. The reaction was shaken for 72 h. The reaction was filtered, rinsed in DMF, DCM, and MeOH, and dried in a desiccator. Cleavage was carried out as previously described. MALDI, +ve ion mode: 3891 $[M + H]^+$, 3913 $[M + Na]^+$. HPLC retention (min): 12.62.

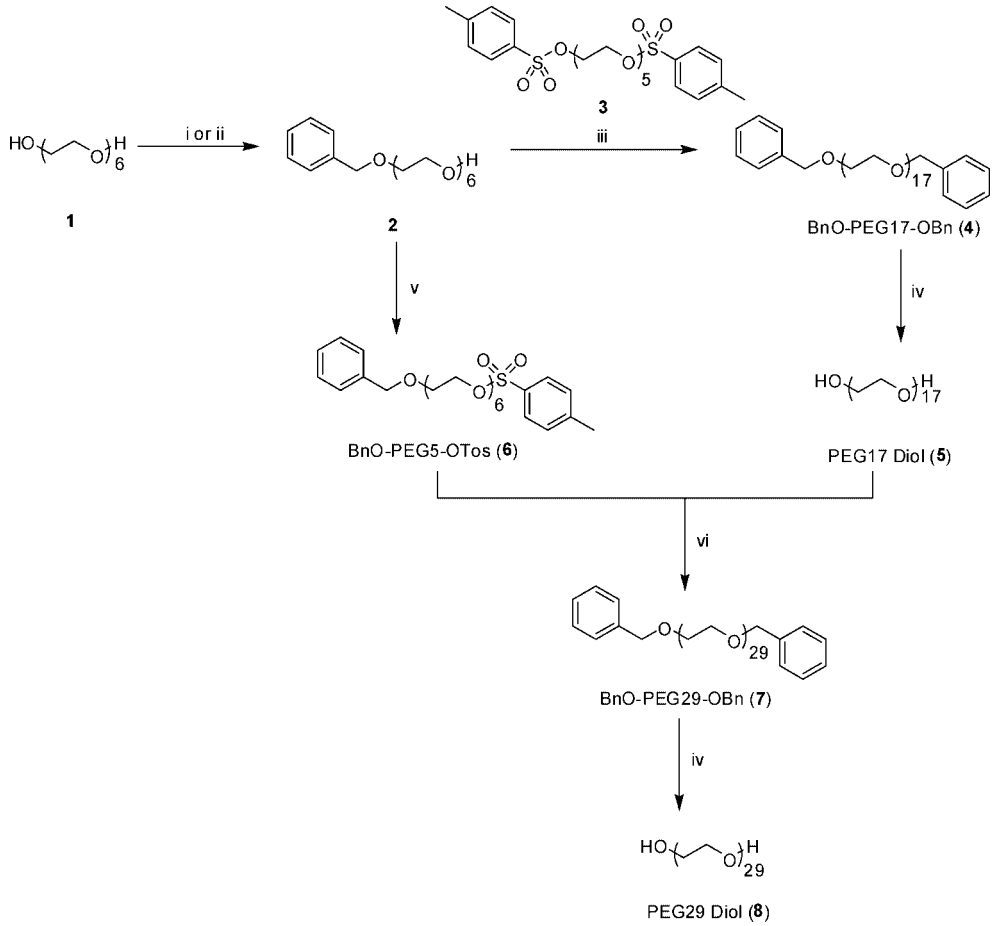
Preparation of Amphipathic Peptide-PEG$_{17}$-Folate Cysteine (*18*). 9 mg folate cysteine was taken up in dry DMF (1 mL) and added to 35 mg amphipathic peptide-PEG$_{17}$-maleimide peptido-resin under argon. The reaction was protected from light and shaken at room temperature for 72 h. The reaction was filtered, rinsed in DMSO, DMF, DCM, and MeOH, and dried in a desiccator. Cleavage was carried out as previously described. The crude product was purified by semipreparative HPLC on a Jupiter C18 column, followed by repeat purification on a Luna CN (250 × 6.4 mm, 5 μm) column. 1.2 mg of required product was obtained. Yield: 7% over four synthetic steps and two purification steps. HPLC retention time (standard conditions) (min): 10.90. HPLC retention time (Luna CN column, 250 × 4.60 mm, 5 μm, Phenomenex Ltd.) (min): 10.86. Purity by HPLC (standard conditions): 92%. MALDI: 4438 $[M + H]^+$.

RESULTS AND DISCUSSION

1. Synthesis of PEG17 and PEG29. The controlled synthesis of PEG is achieved by the Williamson ether formation; a suitably activated PEG chain is attacked by another PEG chain with a nucleophilic alkoxide ion. The use of protecting groups enables the controlled synthesis of extended PEG chains of defined MW.

Orthogonal protection with two different protecting groups has been used in the synthesis of smaller PEG oligomers (up to

Scheme 1. Synthesis of PEG_{17} and PEG_{29}



24 glycol units) (*20*, *21*). Our strategy is a quicker, more efficient route to PEG oligomers of defined MW, achieved through the simultaneous extension of both terminal hydroxyls of a PEG diol, using a single protecting group (Scheme 1). Similar approaches were investigated previously using monotritylated and ditosylated PEG oligomers (*22*, *23*). The oligomers synthesized were 12 and 16 units and synthesis was initiated with monoprotected ethylene and diethylene glycol.

Hexa(ethylene glycol) (**1**) and penta(ethylene glycol) ditosylate (**3**) were used as starting materials for the synthesis of PEG oligomers of 17 glycol units. Benzyl ether was chosen as the protecting group due to its stability under the basic conditions required to generate the alkoxide ion and ease of removal by hydrogenation.

The first step in this synthetic route required the generation of a monoprotected hexa(ethylene glycol) (**2**). The initial approach utilized sodium hydride to generate the alkoxide ion, followed by reaction with benzyl bromide. Monoprotection was achieved by carrying out the reaction in diluted solution. Yields from this approach were modest: at or below 35%.

An alternative approach to the monoprotection of diols involves the use of silver oxide. This method is milder, since there is no need for excess base to deprotonate the hydroxyl group, and it has been reported to result in monoprotection (*24*). The silver atom is hypothesized to act as a Lewis acid and complex with one hydroxyl group and the other terminal oxygen atom within a single PEG chain, which may make the proton that is not involved in the intramolecular bond more labile (*25*). Yields using this approach were improved to 52%.

The monoprotected hexa(ethylene glycol) (**2**) was reacted with ditosylated penta(ethylene glycol) (**3**) to afford **4**. An excess of sodium hydride was used to generate the monoprotected hexa(ethylene glycol) alkoxide, which was refluxed in dry THF in the presence of 2 equiv of penta(ethylene glycol) ditosylate. The reaction proceeded in good yield at 83%, with no contaminating monoprotected hexa(ethylene glycol) (**2**) as detected by HPLC. The product (**4**) was isolated by extraction and precipitation in cold ether and did not require purification by column chromatography, in contrast to the orthogonal protection approach (*21*). Hydrogenation of the product obtained proceeded quantitatively to yield the PEG_{17} diol (**5**) (Scheme 1).

The next step in PEG extension was the synthesis of PEG_{29} utilizing the PEG_{17} diol (**5**) and monoprotected hexa(ethylene glycol) tosylate (**6**). The monoprotected hexa(ethylene glycol) tosylate **6** was prepared from monobenzyl ether hexa(ethylene glycol) (**2**) using Ag_2O and tosyl chloride (*21*). The tosylate (**6**) (2 equiv) was reacted with the dialkoxide of PEG_{17} (**5**), to afford the dibenzylated PEG_{29} (**7**). Hydrogenation over palladium catalyst produced the PEG_{29} diol (**8**) (Scheme 1). The reaction proceeded in 70% yield over three steps from **5** to **8**. The product was isolated by precipitation from diethyl ether and did not require further purification. This novel approach has demonstrated a controlled, straightforward, and high-yielding synthesis of PEG chains of higher molecular weight in relatively few synthetic steps.

The MALDI analysis of the product showed a single peak (Figure 2A), unlike the distribution of molecular weights in commercial products (compare to Figure 1).

2. Functionalization of PEG17 and PEG29 as Fmoc-Protected Amino Acids. Methods to convert PEG diols to amino acids have been described (*26*, *27*). Here, we describe a short (two-step) synthetic approach to obtain a PEG amino acid directly in the Fmoc-protected form. This method generates the

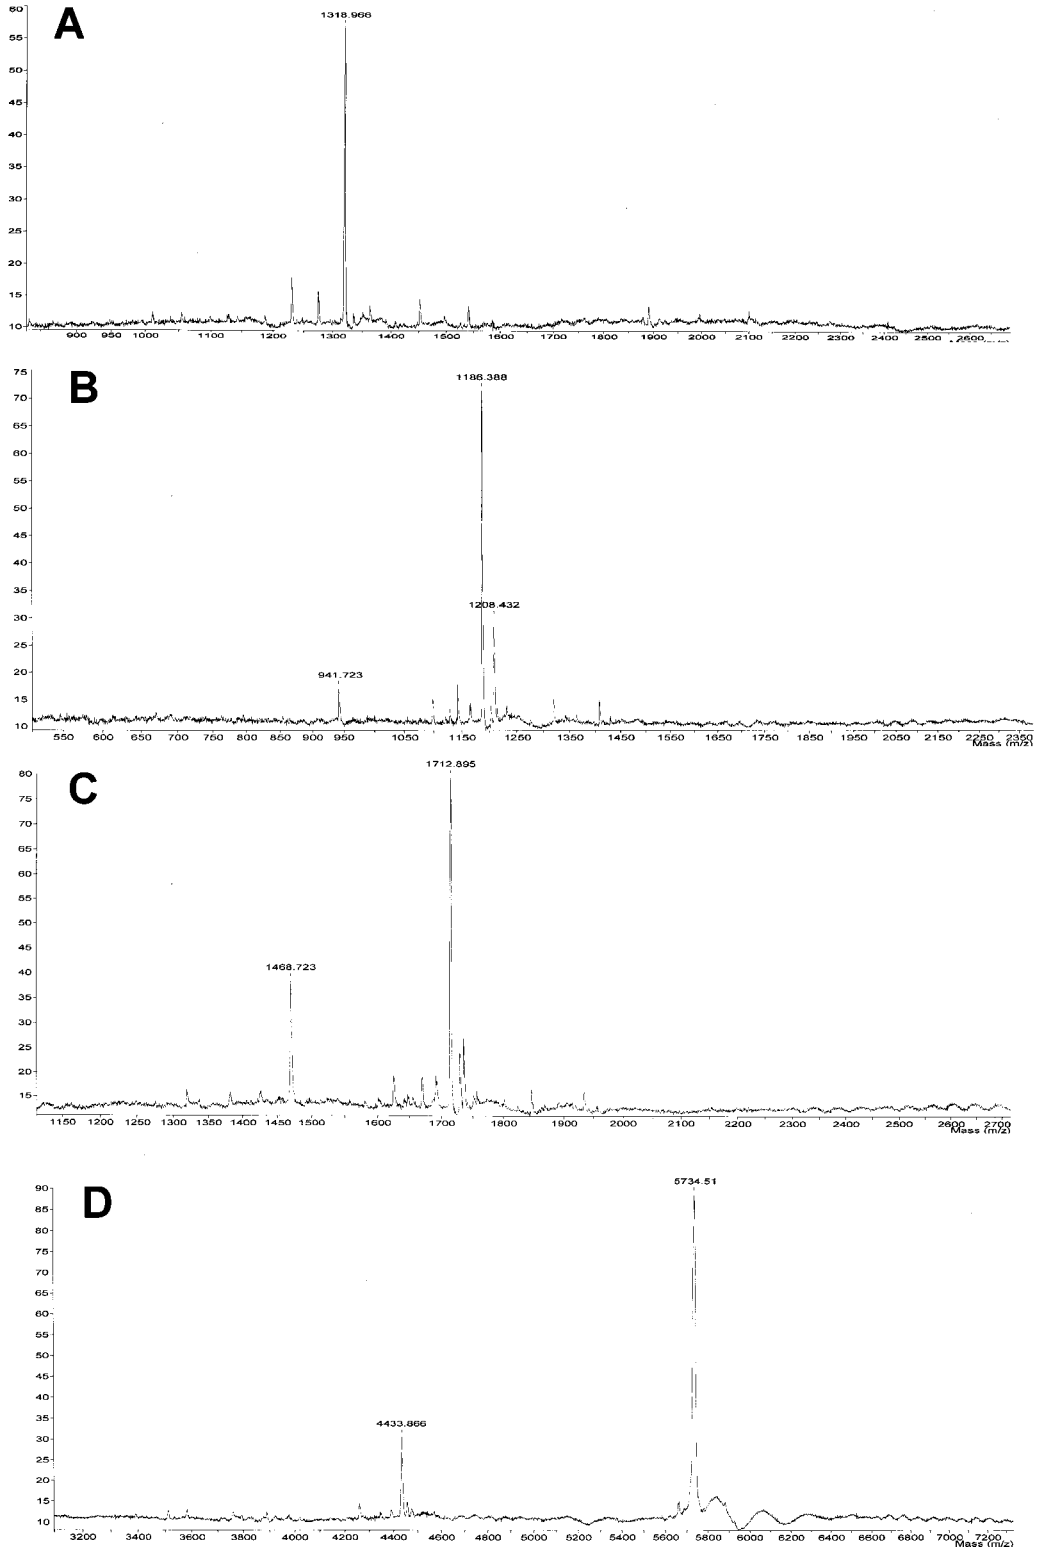


Figure 2. MALDI analysis. (A) PEG_{29} diol (**8**); (B) Fmoc-PEG_{17}-COOH (**11**); (C) Fmoc-PEG_{29}-COOH (**12**); (D) peptide-PEG_{17}-folate conjugate (**18**).

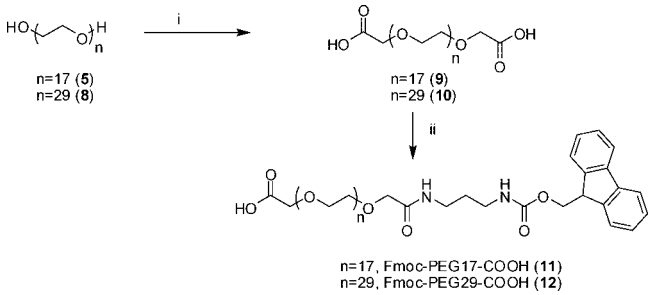
dicarboxylic acids of PEG (**9**) and (**10**), followed by the conversion of a single carboxyl group to mono-Fmoc 1,3 diamino propane to obtain the required mono-Fmoc PEG amino acids **11** and **12** (Scheme 2).

Veronese et al. synthesized a PEG carboxylic acid using ethyl bromoacetate and potassium *tert*-butoxide in *tert*-butanol, followed by the hydrolysis of the ethyl ester (*28*). This approach was successfully incorporated into the synthesis of the PEG diacids. The diacids were precipitation from DCM with diethyl ether, without need for further purification. Yields of up to 79% and 88% were obtained for PEG_{17} diacid (**9**) and PEG_{29} diacid (**10**), respectively.

The PEG diacids were coupled with 1 equiv of mono-Fmoc 1,3 diamino propane to obtain the required mono-Fmoc PEG amino acids **11** and **12** alongside the corresponding di-Fmoc amino modified PEG. Purification of this mixture was carried out using preparative HPLC on reverse-phase silica. Yields of the products were 23% and 35% for PEG_{17} amino acid (**11**)

Scheme 2. Synthesis of Fmoc-Protected PEG Amino Acids



Scheme 3. Solid-Phase Synthesis of Folate−Cysteine Ligand

and PEG_{29} amino acid (**12**), respectively. The MALDI analysis of **11** and **12** is shown in Figure 2B,C, respectively. The main peaks correspond to the product; the extra peaks at 942 (Figure 2B) and 1469 (Figure 2C) are due to the loss of Fmoc under the MALDI conditions.

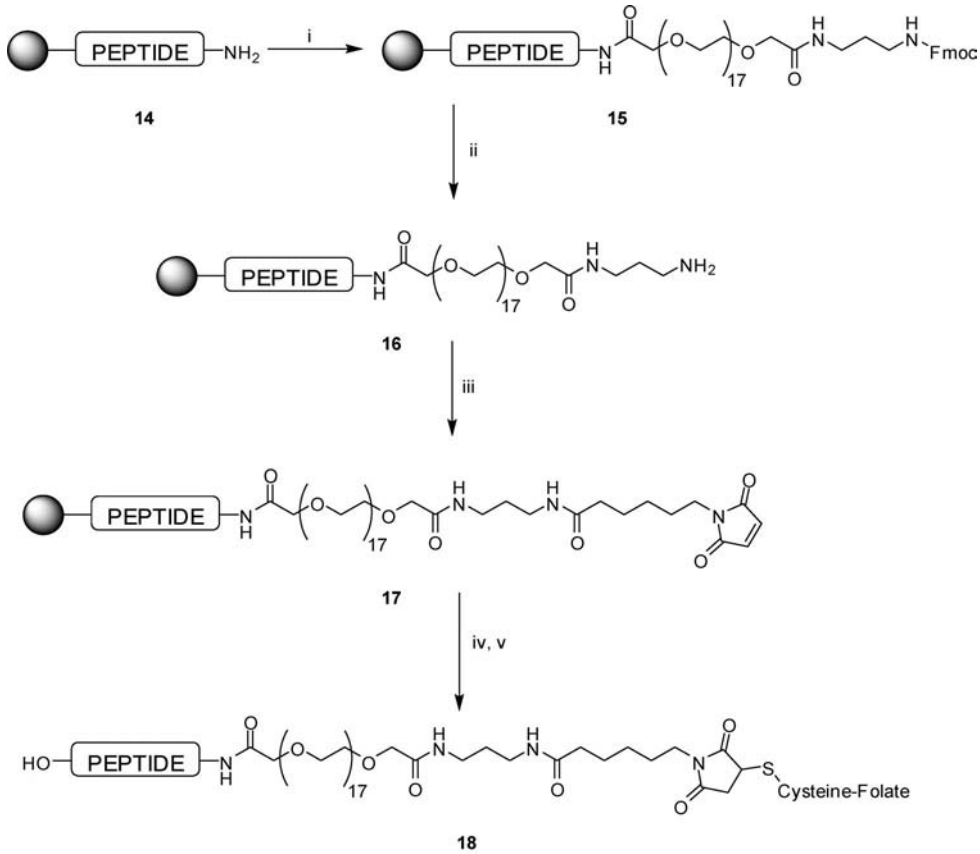
3. Synthesis of the Peptide−PEG−folate Conjugate. The PEG_{17} amino acid (**11**) was used in the solid-phase synthesis of a conjugate comprising an amphiphatic peptide and a targeting moiety (folate) separated by the PEG_{17} linker. This conjugate is the prototype of a potential nonviral gene delivery vector, where the peptide achieves DNA condensation and endosomal escape, the folate is specifically targeting tumors overexpressing the α-folate receptor and contributes to conjugate internalization, and the PEG chain improves the PK properties of the conjugate and contributes to the DNA protection.

An amphiphatic histidine-rich peptide (KKALLALAL-HHLAHLALHLALALKKA) (**14**), reported to have high transfection efficiency (*19*), was chosen for the conjugate. The peptide was synthesized on solid support using Fmoc chemistry. A portion of the peptide was cleaved, purified, and analyzed; the bulk of the peptide was left on the resin and used for conjugate synthesis.

The folate−cysteine targeting ligand (**13**) was synthesized on a solid support. Advantages of this approach include higher purity of the final product and conjugation at only the preferred γ-carboxyl of the glutamic moiety, since suitable protected components such as Fmoc-Glu-O^{t}Bu are commercially available. Previous work by Zhang et al. described the synthesis of the folate−cysteine conjugate on a solid support utilizing the expensive N^{10}-trifluoroacetyl pteroic acid group, which improves the solubility of pteroic acid, but affords low yields due to its incomplete deprotection with base (*29*).

We carried out the solid-phase synthesis of folate−cysteine using the less expensive pteroic acid rather than its N^{10}-

Scheme 4. Synthesis of Peptide−PEG_{17}−Folate Conjugate



i. **11** (1.5 eq.), HCTU (1.5 eq.), DIPEA (3 eq.), DMF, 72 hours; ii. piperidine; iii. 6-maleimidohexanoic acid NHS ester, dry DMF, 24 hours; iv. **13**, DMF, 72 hours; v. TFA, phenol, thioanisole, H_2O, EDT.

trifluoroacetyl protected form. Synthesis of the Glu-Cys dipeptide was carried out using automated peptide synthesis. The final coupling of pteroic acid onto the dipeptide resin was carried out manually due to the low solubility of pteroic acid in NMP, which blocked the peptide synthesizer filters and prevented delivery to the reaction vessel. The manual coupling of pteroic acid utilized 3.0 equiv of pteroic acid in a mixture of DMF and DMSO and was carried out over 24 h. Despite the low solubility of pteroic acid, coupling to the dipeptide sequence proceeded efficiently and cleanly.

No coupling of the unprotected N^{10} amine of pteroic acid, leading to large multipteroate conjugates, was detected by MALDI analysis. This indicated that unprotected pteroic acid could be utilized in a viable route to the synthesis of folate−cysteine conjugates. This synthetic route is shown below in Scheme 3.

The yield obtained by using pteroic acid in the synthesis of the folate−cysteine conjugate was 64%, in comparison with yields of 38% obtained using the N^{10}-trifluoroacetyl pteroic acid as reported by Zhang et al. (*29*). Therefore, this approach was been shown to be a more efficient, less expensive synthesis of folate cysteine on a solid support.

The first step in the multicomponent vector assembly was the coupling of the FmocNH-PEG_{17}-COOH chain to the N-terminus of the resin-bound peptide. The coupling was carried out using the aminium-based coupling reagent HCTU. Optimization of the reaction conditions was required. The best conditions for coupling were found to be 1.5 equiv FmocNH-PEG_{17}-COOH, 1.5 equiv of HCTU, 3.0 equiv of DIPEA, dry DMF, 72 h. The conversion to the required product was 66%, as determined by HPLC analysis. Standard Fmoc deprotection conditions using 20% piperidine in DMF was quantitative and was followed by coupling to a commercially available NHS-activated ester of maleimide.

The success of this series of reactions validated the functionalization of PEG on solid support as an achievable step in the synthesis of multicomponent vectors. This approach is versatile and can be used to incorporate alternative coupling reagents. This could be of interest, as it has been reported that certain linkers such as maleimide can initiate linker-specific immune responses (*30*), and therefore, the ability to change the conjugation chemistry could be of benefit.

The maleimide functionalized peptide−PEG conjugate was coupled to the targeting ligand folate−cysteine. Folate−cysteine was dissolved in dry DMF, added to the peptido-resin and shaken for 72 h. The synthetic scheme demonstrating PEG and ligand coupling on solid support is shown in Scheme 4.

Coupling of folate−cysteine proceeded in good yield. Following cleavage from the resin, the multicomponent vector, amphipathic peptide-PEG_{17}-folate-cysteine, was purified twice by semipreparative HPLC. The first purification used a Jupiter C18 column; however, the required product was contaminated by a side product, amphipathic peptide−folate−cysteine, obtained due to the incomplete coupling of FmocNH-PEG_{17}-COOH. Therefore, the mixture obtained was further purified on a Luna CN column, which was able to separate the two products. The global yield of the complete vector was calculated from the amphipathic peptide resin over the four modification steps including FmocNH-PEG_{17}-COOH coupling, deprotection, 6-maleimidohexanoic acid NHS ester coupling, and folate−cysteine coupling and two purification steps. The yield of purified amphipathic peptide-PEG_{17}-folate-cysteine vector was 7%. This calculation is based on a theoretical amount of resin-bound peptide. The yield could be improved by acetylation of the unreacted resin-bound amphipathic peptide prior to Fmoc deprotection of the PEG oligomer. This would prevent the formation of the contaminating side product and reduce the number of purification steps required.

The MALDI analysis of the conjugate confirms the single molecular weight of the product (Figure 2D; the large peak at 5734 is the calibration standard).

SUMMARY AND CONCLUSION

An efficient synthetic route to long PEG oligomers was designed. This utilized only a benzyl ether protecting group which avoided the tedious purification and low overall yields of methods reported previously (*20*, *21*). The availability of starting materials longer than hexa(ethylene glycol) would make this route a practical method to obtain PEG of comparable length to polymeric commercial products, but with the added advantage of a single MW composition.

The functionalization as PEG amino acids suitable for solid-phase synthesis and heterobifunctional linkers was accomplished through the corresponding diacids and the coupling of a single equivalent of a monoprotected diamine. The preparation of two mono-Fmoc PEG amino acids of 17 and 29 units was achieved. This simple method also allows the rapid synthesis of a variety of PEG linkers. Using diamines with one amino group modified with other moieties instead of Fmoc (for example, biotin, maleimide, targeting ligands), the range of bifunctional PEG linkers can be greatly extended.

The application of these linkers was demonstrated by the synthesis of a complex conjugate on a solid support. An advantageous method for the solid support synthesis of the targeting component of the conjugate, folic acid−cysteine, was found, resulting in improved yields with respect to literature methods. The assembly of the peptide, PEG linker, and targeting group on a solid support was successful, resulting in a conjugate of defined molecular weight and structure. The successful synthesis of a complex multicomponent conjugate on a solid support demonstrates the power and versatility of this approach, and opens the way to the generation of a combinatorial library of peptide-PEG-targeting ligands with defined structure and molecular weight as potential nonviral vectors and conjugates for biological applications.

A Novel Near-Infrared Indocyanine Dye−Polyethylenimine Conjugate Allows DNA Delivery Imaging *in Vivo*

Andrea Masotti,*[,†,‡] Paola Vicennati,[†,‡] Federico Boschi,[§] Laura Calderan,[§] Andrea Sbarbati,[§] and Giancarlo Ortaggi[‡]

Chemistry Department, SAPIENZA Università di Roma, P.le Aldo Moro 5, 00185 Rome, Italy, and Department of Morphological-Biomedical Sciences, Section of Anatomy and Histology, University of Verona, Strada Le Grazie 8, 37134 Verona, Italy. Received September 14, 2007; Revised Manuscript Received February 27, 2008

Near-infrared (NIR) fluorescence light has been applied to monitor several biological events *in vivo* since it penetrates tissues more efficiently than visible light. Dyes exhibiting NIR fluorescence and having large Stokes shift are key elements for this promising optical imaging technology. Here, we report the synthesis of a novel conjugate between a near-infrared indocyanine dye and an organic polyamine polymer (polyethylenimine, PEI) (**IR820-PEI**) with high chemical stability and good optical properties. **IR820-PEI** absorbs at 665 nm, emits at 780 nm, and displays a large Stokes shift (115 nm). Moreover, the reported conjugate is able to bind DNA, and the delivery process can be monitored *in vivo* with noninvasive optical imaging techniques. These characteristics make **IR820-PEI** one of the most effective and versatile indocyanine dye polymeric-conjugate reported so far.

Near-infrared (NIR)-absorbing dyes represent an intriguing avenue for extracting biological information from living subjects since they can be monitored with safe, noninvasive optical imaging/contrasting techniques (*1–7*). Optical imaging represents a rapidly expanding field, with direct applications in pharmacology, molecular and cellular biology, and diagnostics. More sensitive optical sensors and new, powerful probes such as semiconductor nanocrystals (*8–11*), fluorescent proteins (*12, 13*), or NIR fluorescent molecules (*14–16*) have been synthesized and studied in the past few years.

While light in the visible range is routinely used for intravital microscopy, imaging of deeper tissues (>500 μm to cm) requires the use of near-infrared light, as hemoglobin and water, the major absorbers of visible and infrared light, respectively, have their lowest absorption coefficient in the NIR region (650−900 nm). The advantages of imaging in the NIR region (700−1100 nm) are numerous: the absence or significant reduction of background absorption, fluorescence, and light scattering along with high sensitivity, the availability of low-cost sources of irradiation (but no radiation is necessary for acquisition), and the versatility of different reporter probes. Numerous long-wavelength fluorophores belonging to the BODIPY (*17*), rhodamine (*18, 19*), and oxazine (*20*) have been used, but only cyanine dyes (*21–23*) have been reported to display large molar extinction coefficients, moderate-to-high fluorescence quantum yields, and a broad wavelength tunability (*24–26*).

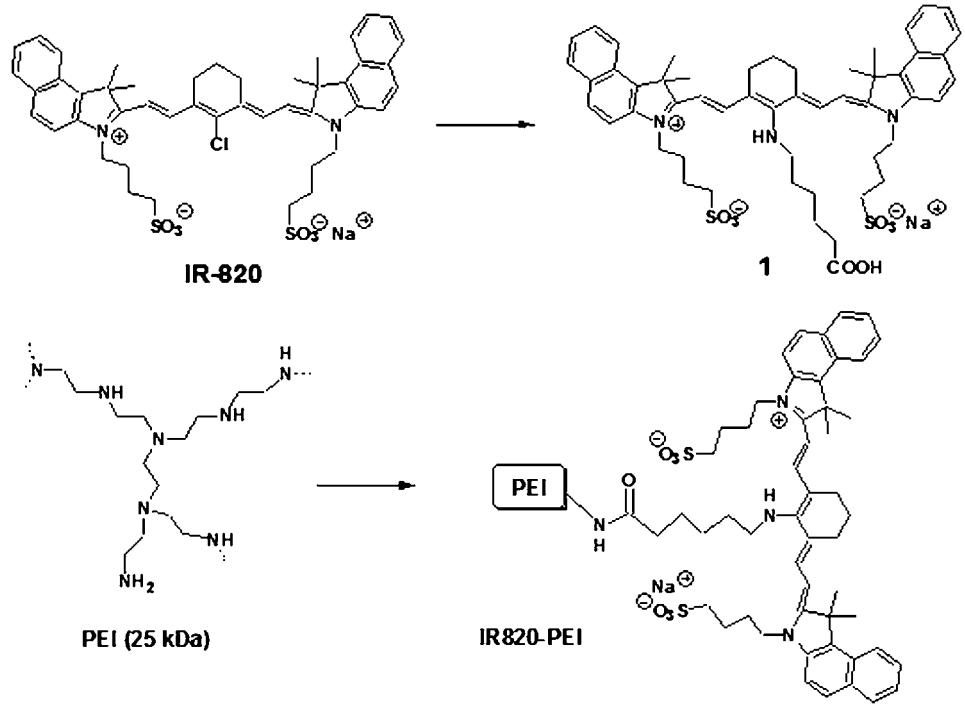
Scheme 1[a]



[a] Synthesis of **1**: DMF, TEA, $H_2N(CH_2)_5COOH$, 85 °C 3 h. Synthesis of **IR820-PEI**: DMF, EDC·HCl, **1**, rt 18 h.

Heptamethine dyes with a rigid chloro-cyclohexenyl ring in their moiety have increased photostability and a better fluorescence quantum yield, and also provide a useful reactive site for further chemical substitution (*27*, *28*). However, reactions replacing the central chlorine atom, with phenol (*26*) or thiophenol (*29*) have led to chemically unstable probes (*30*). Only heptamethine cyanine dyes containing C−N bonds were reported to display large Stokes shifts (around 100−140 nm) and considerably stronger fluorescence that might be attributed to an excited-state intramolecular charge transfer (ICT) between the donor and acceptor in the same dyes (*31*).

Recently, we reported an *in vitro* study focusing on polyethylenimine (PEI) and PEI derivatives able to form complexes (polyplexes) with DNA and to deliver (or transfect) it to cells (*32*). This polyamine polymer having a high cationic charge-density potential is able to establish electrostatic interactions with DNA and compact it efficiently and has been employed as a versatile vector for several biomedical applications (i.e., gene therapy) (*33*). Once penetrated into cells, PEI destabilizes the endosomal membrane due to the protonation of its numerous amino groups ("proton sponge" effect). The influx of protons and counterions into endosomes leads to membrane lysis and to the release of their internal contents (DNA). The conjugation of PEI with an NIR dye is aimed at obtaining a multifunctional delivery vector whose localization can be monitored *in vivo* with noninvasive techniques and that may serve to identify potential transfection sites and assess its efficiency to deliver DNA.

To obtain an NIR−PEI conjugate, we chose the recently reported indocyanine **IR-820** (See Scheme 1) among the heptametine NIR dyes, since its heterocyclic nitrogen atoms bear two alkyl-sulfonate groups that improve photostability and provide a sphere of solvation in water preventing this dye from aggregation.

Attempts to directly replace the *meso*-chlorine atom of **IR-820** with an amino group of PEI were unsuccessful. We hypothesized that the close proximity between the dye and the hindered polymeric structure could prevent this substitution. Thus, we replaced the *meso*-chlorine atom with a less-hindered carboxy-terminal amino linker (6-aminohexanoic acid), obtaining an intermediate (**1**) suitable for further conjugations (Scheme 1).

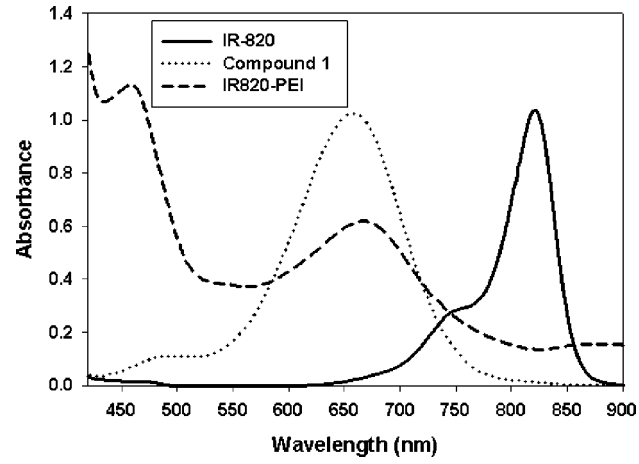


Figure 1. Visible/NIR absorption spectra of **IR-820** (solid line), **1** (dotted line), and **IR820-PEI** dyes (dashed line) in MeOH (0.1 mM, 25 °C).

The successful conjugation of **1** with PEI allowed us to obtain a near-infrared dye−polymer conjugate (**IR820-PEI**) highly soluble in water.

IR820-PEI absorbs at 665 nm (Figure 1) and emits at 780 nm displaying a large Stokes shift (115 nm) (Figure 2). These characteristics make this system more suitable for use as fluorescence probes than do common cyanine dyes.

To investigate the feasibility of employing **IR820-PEI** as a vector able to bind and deliver DNA, agarose gel retardation assays (Figure 3) were performed. **IR820-PEI** is able to bind DNA similarly to PEI itself, while intermediate **1**, being negatively charged, has no effect, as expected. These results confirm that, when PEI is derivatized at a small percentage of substitution, it substantially retains all the physicochemical and acid−base properties of the starting polymer (*32*).

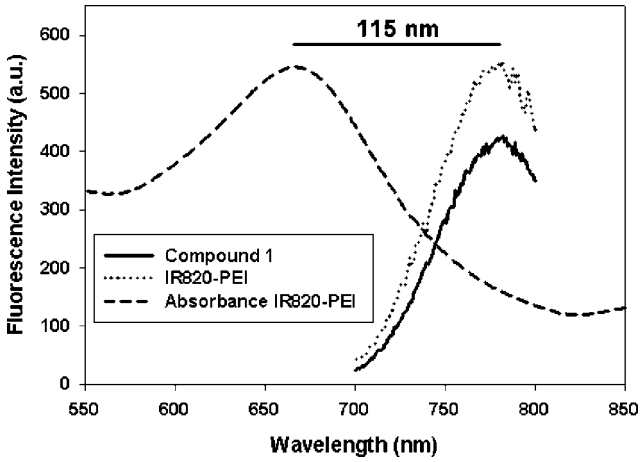

Figure 2. Emission spectra of **1** (solid line) and **IR820-PEI** (dotted line) dyes in MeOH (0.1 mM, 25 °C). The absorption spectrum (arbitrary unit) of **IR820-PEI** is also reported for comparison.

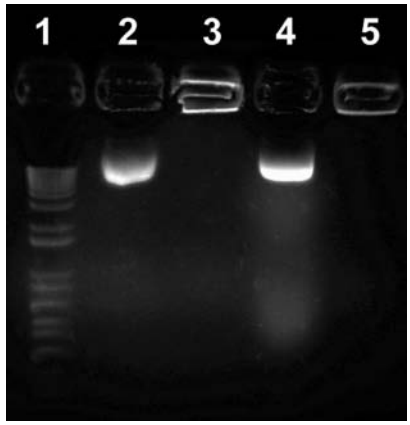

Figure 3. Gel retardation assay (agarose 1%) of **IR820-PEI**/DNA (lane 5) compared to **PEI**/DNA (lane 3) and **1**/DNA (lane 4). DNA ladder (lane 1) and reference β-Gal pDNA (lane 2) are also reported.

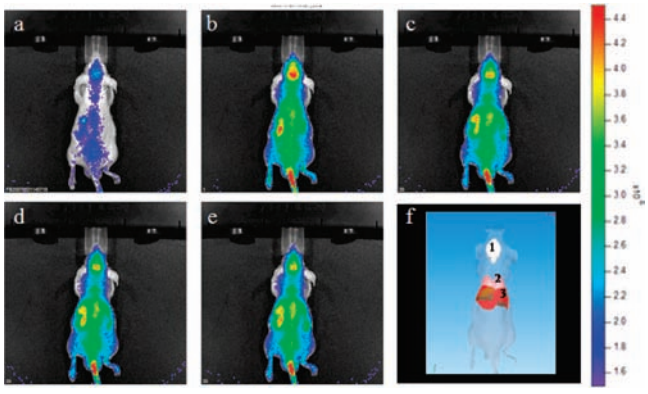

Figure 4. Optical images of a nude mouse with 2 mg/mL tail vein injection of **IR820-PEI**: preinjection (a), and after 1 min (b), 1 h (c), 2 h (d), and 3 h (e) from the injection. 3D reconstruction of mouse body and the organs of interest (f): 1, brain; 2, lungs; and 3, liver. Color bar on the right side indicates the signal efficiency of the fluorescence emission coming out from the animal.

The properties of the novel NIR system **IR820-PEI** and its ability to deliver DNA *in vivo* (**IR820-PEI**/DNA) were assessed using a VivoVision Systems, IVIS 200 Series Imaging System (Xenogen Corporation, Alameda, CA, USA). Figure 4 shows the optical images of a nude mouse before (Figure 4a) and after 1 min (Figure 4b), 1 h (Figure 4c), 2 h (Figure 4d), and 3 h from the injection of **IR820-PEI** (Figure 4e). Figure 4f shows

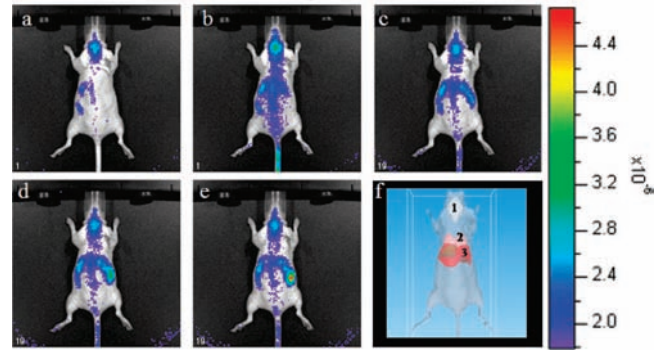

Figure 5. Optical images of a nude mouse with 2 mg/mL tail vein injection of **IR820-PEI-DNA**: preinjection (a), and after 1 min (b), 1 h (c), 2 h (d), and 3 h (e) from the injection. 3D reconstruction of mouse body and the organs of interest (f): 1, brain; 2, lungs; and 3, liver. Color bar on the right side indicates the signal efficiency of the fluorescence emission coming out from the animal.

the 3D reconstruction of the mouse body and the organs of interest (1, brain; 2, lungs; 3, liver). After i.v. injection of **IR820-PEI**, a signal enhancement localized in the regions corresponding to the brain and liver was observed. CCD camera collects light coming out from the skin of the animal without any *a priori* information regarding the deepness of the sources. However, excitation and emission photons employed in our experimental sessions have a mean path before absorption of 1−2 cm, and this property depends on the optical characteristic of tissues themselves. Thus, since the light can pass up to 2 cm through the animal body, sources located up to 2 cm below the skin can be visualized. However, in order to unambiguously localize the fluorescent dye accumulated in specific anatomical districts, a much more detailed study should be taken into account.

Figure 5 shows the optical images of a nude mouse before (Figure 5a) and after 1 min (Figure 5b), 1 h (Figure 5c), 2 h (Figure 5d), and 3 h from the injection of **IR820-PEI**/DNA (Figure 5e). Figure 5f shows the 3D reconstruction of the mouse body and the organs of interest (1, brain; 2, lungs; 3, liver). Also, in this case, after the i.v. injection of the **IR820-PEI**/DNA, optical images shown signal enhancement, in the region corresponding to the brain, lungs, and liver.

Optical imaging data suggest that, after intravenous tail vein injection of **IR820-PEI** or **IR820-PEI**/DNA, a predominant hepatic accumulation occurs. This effect is most likely due to a nonspecific electrostatic interaction between **IR820-PEI** (or **IR820-PEI**/DNA) conjugate and the negatively charged plasmatic membranes of capillary endothelial cells (i.e., sulfated proteoglycans, glycosylaminoglycans, etc.) that may explain the initial NIR dye biodistribution thought brain and lungs (the first highly vascularized organ encountered by NIR dyes after intravenous tail vein injection and in which blood flow is slower due to the capillary circulation). After 1 h, the two NIR systems began to accumulate in the liver, a typical store organ, and after 3 h, the signal intensity increased. The signal is clearly visible even after 24 h from the injection (see Figure 1S in Supporting Information). The reported distribution observed for **IR820-PEI** and **IR820-PEI**/DNA is in good agreement with published works on other systems like NIR-nanoparticles (*34*–*36*) and NIR-nanoprobes (*37*).

However, the fluorescence signal acquired by the optical imaging device might be due both to **IR820-PEI**/DNA complex and to unbound **IR820-PEI**. So, to discriminate between the contributions of these two species, we assessed the ability of **IR820-PEI** to bind a fluorescent oligonucleotide (randomized sequence) 5′-labeled with a Cy5.5 fluorochrome (**Cy5.5-ODN**) (Figure 6). This modified oligonucleotide emits in the red region

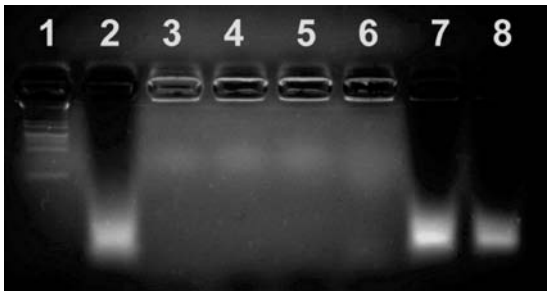

Figure 6. Gel retardation assay (agarose 4%) of **IR820-PEI** complexed with 0.3 (lane 3), 0.6 (lane 4), 1 (lane 5), 1.5 (lane 6), 2.5 (lane 7), and 3 nmol (lane 8) of **Cy5.5-ODN**. DNA ladder (lane 1) and reference **Cy5.5-ODN** (1 nmol) are also reported.

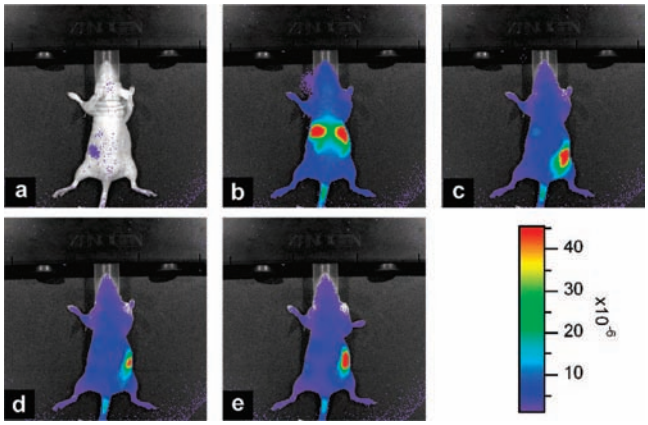

Figure 7. Optical images of a nude mouse with 2 mg/mL tail vein injection of **PEI/IR820-DNA**: pre injection (a), and after 4 min (b), 1 h (c), 2 h (d), and 3 h (e) from the injection. Color bar on the right side indicates the signal efficiency of the fluorescence emission coming out from the animal.

and not in the near-infrared region (like **IR820-PEI)**. For this reason, a differential localization of the cDNA and the delivery vector is possible through a sequential acquisition of the fluorescence emission first in the red then in the NIR region. Unfortunately, even if a partial accumulation of **IR820-PEI/Cy5.5-ODN** was observed in the liver, a spurious fluorescence emission coming out from the food ingested by the animal before the experiment was observed (see Figure 2S in Supporting Information). However, even if this experiment is neither significant nor conclusive, DNA accumulation in the liver is reported, and the region concerned is the same as that involved when using the **PEI-IR820**/(unlabeled)DNA complex.

Therefore, in order to overcome this problem and clearly see the localization of DNA (and not that of the delivery vector), we repeated the acquisition injecting a calf thymus DNA labeled with the same NIR dye used for **IR820-PEI** (indicated as **IR820-DNA**) (see Supporting Information) complexed with a solution of unlabeled **PEI**. In this way, it was possible to follow the fluorescence in the NIR region of the **PEI/IR820-DNA** complex and to obtain indications, at least in the initial stages, on DNA localization. DNA accumulated in the liver analogously to **IR820-PEI**/DNA (Figure 7). These results indicate, at least in a first approximation, that DNA is transported and/or delivered *in vivo* in the same regions, but additional assays are required to investigate the effective transfection *in vivo* of this novel synthesized system.

Liver uptake or nonselective accumulation into undesired organs is an obvious problem that should be taken into account, in the near future, for the development of efficient tumor-targeting therapies.

In conclusion, **IR820-PEI** is one of the most attractive near-infrared indocyanine dye−polymer conjugate molecules that should be further investigated for its potential use as a multifunctional system for targeted gene delivery by conjugation with selected molecules (i.e., folic acid, folate−PEG, etc.) or specific antibodies.

MBC94, a Conjugable Ligand for Cannabinoid CB_2 Receptor Imaging

Mingfeng Bai,[†] Michelle Sexton,[‡] Nephi Stella,[‡] and Darryl J. Bornhop*,[†]

Department of Chemistry, Vanderbilt University, VU Station B 351822, Nashville, Tennessee 37235-1822, and Department of Pharmacology, Psychiatry and Behavioral Sciences, Health Sciences Center, BB-1538c, University of Washington, Seattle, Washington 98195-7280. Received November 15, 2007; Revised Manuscript Received March 7, 2008

Cannabinoid CB_2 receptor is a particularly attractive target for noninvasive imaging of neuroinflammation and monitoring of therapeutic efficacy. Its expression is low to undetectable in healthy brain and induced in resident microglial cells (the macrophage of the brain) after cerebral ischemia, injury, and in neuroinflammatory disease. Additionally, immune cells migrating across the blood−brain barrier typically express CB_2 receptors, which adds to the expression pool of this target and provides a reliable indicator of inflammation in the brain. Here, we synthesized a novel conjugable CB_2 receptor ligand, mbc94, which has a terminal amino group that allows for facile conjugation to imaging moieties. A near-infrared (NIR) dye labeled mbc94, NIRmbc94, was developed for CB_2 targeted imaging. Preliminary evidence, including *in vitro* fluorescence imaging and a competition study, showed that NIRmbc94 specifically labeled CB_2-expressing cells.

Two cannabinoid receptors, CB_1 and CB_2, have been identified at the molecular level (*1*, *2*). They are G protein-coupled receptors that share an overall 44% amino acid homology and a 68% amino acid homology within their transmembrane domains (*1*). CB_1 receptors are abundantly expressed by neurons, whereas CB_2 receptors are abundantly expressed by immune cells (*3*, *4*).

The high level of CB_2 receptor expression in immune cells and much lower expression in other cell types, particularly in the CNS, makes this receptor an attractive target for imaging and monitoring of therapy (*3*, *4*) for neurological diseases. Specifically, CB_2 receptor expression is high in spleen, tonsils, and thymus and low—or even undetectable—in brain, thyroid, retina, placenta, skeletal muscle, kidney, liver, adrenal gland, heart, prostate, and ovary (*4*). This expression profile provides great opportunities for imaging with low background. Furthermore, CB_2 receptor expression is highly plastic and may be induced under specific disease conditions, for example, in tumor cells (*5*) and CNS-resident microglia. Accordingly, CB_2 receptor has become a predominant target for drug development aimed at treating pain (*6*, *7*), chronic inflammation (*8*), osteoporosis (*9*), malignant gliomas (*10*), tumors of immune origin (*11*), and immunological disorders (*12*,*13*), and thus developing a tool that allows for its precise mapping in tissue is essential.

Together with the characterization of the CB_2 receptor, a considerable effort has been made to develop CB_2 receptor−ligands. The term cannabinoid was first used to describe terpenophenolic compounds in *Cannabis sativa* L., among which (-)-trans-Δ^9-tetrahydrocanabinol (Δ^9-THC) is the main bioactive constituent (*14*). Many anti-inflammatory effects of Δ^9-THC have been described, including inhibition of tumor necrosis factor-α, interleukin-2, nitric oxide, and arachidonic acid production from macrophages and T cells (*8*, *15*).

CB_2 receptor ligands can be divided into three main groups: plant-derived, endogenous, and synthetic. The best-known plant-derived cannabinoid is Δ^9- THC, but cannabinol and cannabidiol also induce profound biological effects (*16*). Two endocannabinoids, arachidonoylethanolamide (anandamide) and 2-arachidonoyl glycerol (2-AG), have been identified (Figure 1) (*17*). Both molecules have greater affinity at CB_1 than CB_2 receptors (*18*). 2-AG acts as a full agonist at CB_1 and CB_2 receptor, and anandamide acts as a partial agonist (showing mixed agonist−antagonist properties) toward these receptors (*19*). Many synthetic cannabinoid receptor ligands have been developed, including HU-210, CP55940, WIN55212−2, SR141617A, AM630, and SR144528 (Figure 2). HU-210, CP55940, and WIN55212−2 are cannabinoid receptor agonists with no or marginal CB_1/CB_2 selectivity (*18*). AM630 and SR144528 are both selective CB_2 receptor ligands and behave as inverse agonists rather than "silent" or "neutral" antagonists. The CB_2/CB_1 affinity ratio is less for AM630 (CB_2/CB_1 affinity = 165) than for SR144528 (CB_2/CB_1 affinity > 700) (*18*). Accordingly, SR144528 has been widely used as a pharmacological tool to determine CB_2 receptor-mediated effects (*18*). However, the use of SR144528 for CB_2 receptor-targeted imaging has never been tested directly, since SR144528 is not conjugable. In other words, signaling moieties, such as fluorescent dyes, lanthanide chelates, and nanoparticles, cannot be easily coupled to SR144528. Thus, to further study CB_2 receptor and diseases associated with an increase in the expression of this receptor, development of a conjugable SR144528 analogue constitutes an essential step. Here, we synthesized such a conjugable SR144528

analogue, mbc94. To our knowledge, this is the only fully conjugable CB_2 receptor ligand in existence. It has a terminal amino group allowing easy conjugation to other molecules, including imaging moieties that can provide opportunities for CB_2 receptor-targeted imaging. A near-infrared (NIR) dye, IRDye 800CW NHS ester, was selected to label mbc94 for optical imaging. The resulting imaging agent, NIRmbc94, was used to label CB_2-expressing cells. Preliminary fluorescence imaging of live cells and competition study showed that indeed NIRmbc94 specifically labeled CB_2-expressing cells.

The synthetic pathway of the conjugable SR 144528 analogue, mbc94, is shown in Scheme 1. Compound **3** was prepared from 4′-chloro-3′methylacetophenone and diethyl oxalate as previously described (*20*). Formation of pyrazoles **4** and **5** was achieved by following literature procedures (*21*). Fenchylamine **8** was prepared by converting fenchone to a formamide **7**, followed by hydrolysis of the amide bond as previously described (*22*). Compound **9** was prepared using thionyl chloride before, but the yield was relatively low (70%) (*21*). We synthesized **9** by regular peptide coupling using 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyl uronium hexafluorophosphate (HBTU), and the yield was improved to 84%. The following N-alkylation with α,α-dibromo-*p*-xylene produced **10**, and another N-alkylation with 1,6-hexane diamine yielded the conjugable CB_2 receptor ligand, mbc94.

The use of NIR (650−900 nm) light has gained increasingly wide acceptance in molecular imaging during recent years (*23*)

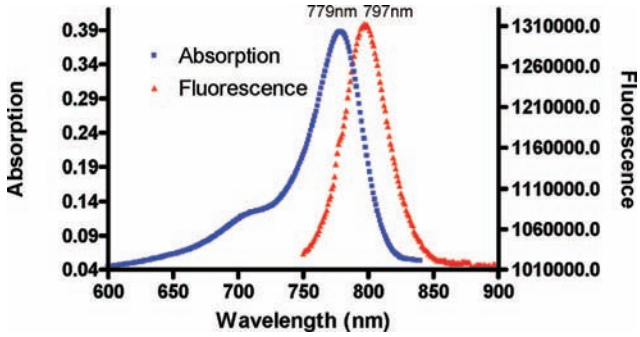

Figure 3. NIRmbc94 absorption and fluorescence in water.

in part because tissues are relatively transparent in this region of the electromagnetic spectrum, with hemoglobin, water, and lipids exhibiting low absorption coefficients (*24*). Therefore, we labeled mbc94 with a NIR dye, IRDye 800CW NHS ester, for NIR optical imaging. The reaction was monitored by analytical HPLC at 780 nm and the product, IRDye 800CW-mbc94 (NIRmbc94), was purified using a semipreparative HPLC and characterized by NMR and mass spectrometry. The absorption and emission spectra were then taken (Figure 3). NIRmbc94 has maximum absorption at 779 nm and emission at 797 nm (water), allowing deep tissue emission for enhanced *in vivo* imaging.

To test whether NIRmbc94 reliably binds to the CB_2 receptor, we already had in place a system wherein the receptor was both absent and present. Specifically, the highly malignant mouse astrocytoma cell line, DBT, lacks the targeted receptor (wild-type), and we generated a clone that stably expresses our target, 2D4DBT. First, we demonstrated that NIRmbc94 gave a significant signal ($S/N = 1.6$), whereas the "free" dye (IRDye 800CW acid) does not produce significant fluorescence, as illustrated by microscopy in the NIR (thus indicating a lack of nonspecific binding due to the dye: Figure 4). Next, as a preliminary indicator of specific targeting of our receptor, both wild-type cells and 2D4 clones were incubated 5 μM concentration of NIRmbc94. Figure 5B,E shows that the fluorescence signal is relatively low in wild-type DBT cells compared to the clone (A,D).

A competition study gave further evidence for specific binding of NIRmbc94 to CB_2 receptors. Specifically, in a preliminary competitive binding experiment, the fluorescence signal was significantly reduced when 100 nM SR144528 was added to compete with 5 μM NIRmbc94 at the receptor site. The lack of fluorescence is due to the higher-affinity unlabeled ligand, SR144528 (*25*), occupying the receptor site and thus inhibiting binding by NIRmbc94. This preliminary pharmacological characterization is typical, and the data indicate that we have indeed labeled our target of interest. More detailed pharmacological and biological characterization, including binding affinity (K_d) and reliable measurement of receptor expression (B_{max}) are in order and forthcoming.

In conclusion, we developed a conjugable CB_2 receptor ligand, mbc94, which has a terminal amino group, making it universally conjugable. An NIR dye-labeled mbc94, NIRmbc94, specifically labeled CB_2-expressing DBT cells, whereas the same cells incubated with same concentration of free NIR dye did not show any significant signal. In addition, the reduced fluorescence signal was observed from non-CB_2expressing wild-type DBT cells incubated with NIRmbc94 compared to CB_2-expressing DBT cells incubated with the same concentration of NIRmbc94. Finally, the specific binding of NIRmbc94 to CB_2 receptors was confirmed by *in vitro* competition study. A preliminary competition study in which cells were coincubated with NIRmbc94 and SR144528 showed signal reduction compared to cells incubated with NIRmbc94 only. Overall, mbc94 constitutes a promising conjugable CB_2 receptor ligand. NIRmbc94 specifically binds to CB_2 receptors and can potentially be used to image CB_2-expressing cells *in vivo*, including immune and cancer cells.

The use of phage display peptide libraries allows rapid isolation of peptide ligands for any target selector molecule. However, due to differences in peptide expression and the heterogeneity of the phage preparations, there is no easy way to compare the binding properties of the selected clones, which operates as a major "bottleneck" of the technology. Here, we present the development of a new type of library that allows rapid comparison of the relative affinity of the selected peptides in a high-throughput screening format. As a model system, a phage display peptide library constructed on a phagemid vector that contains the bacterial alkaline phosphatase gene (BAP) was selected with an antiherbicide antibody. Due to the intrinsic switching capacity of the library, the selected peptides were transferred "en masse" from the phage coat protein to BAP. This was coupled to an optimized affinity ELISA where normalized amounts of the peptide−BAP fusion allow direct comparison of the binding properties of hundreds of peptide ligands. The system was validated by plasmon surface resonance experiments using synthetic peptides, showing that the method discriminates among the affinities of the peptides within 3 orders of magnitude. In addition, the peptide−BAP protein can find direct application as a tracer reagent.

INTRODUCTION

The development of phage-displayed peptide libraries (*1*) allows millions of peptides to be screened, simultaneously, for binding to a target of interest. In these libraries, any one bacteriophage displays a distinctive peptide sequence typically fused to either the pIII or pVIII viral coat protein. The peptide sequence can be encoded in the phage DNA, or most commonly in a phagemid system, consisting of a vector that codes for the peptide−viral coat protein fusion, and utilizes a "helper phage" to allow recombinant phage production. Since even a single peptide−target binding event can be detected and amplified, the technique has the potential to discover peptides that specifically bind to almost any target. For this reason, the technology has been applied in many fields (*2*–*5*).

Typically, the outcome of the selection procedure (panning) is analyzed by the so-called phage ELISA, but this test does not provide any information other than a negative/positive binding result. Further evaluation of positive clones requires DNA sequencing of the encoded peptide and the preparation of the encoded sequences as synthetic peptides, which must then be individually analyzed by competitive ELISA or surface plasmon resonance experiments in order to identify the peptide sequences that bind with the highest affinities. For most purposes, not only the specificity, but very importantly, the affinity of the selected peptides is a major issue. This approach is a time-consuming and costly step that constitutes a major bottleneck for the technique, because it restricts the number of clones that can be assayed, and thereby contributes to the loss of low-abundancy but valuable clones.

In order to overcome these limitations, several works have been published in which model peptides selected from a phage library are transferred by different strategies to a partner molecule (i.e., maltose binding protein, bacterial alkaline phosphatase, etc.) to analyze the reactivity of the peptide out of the context of the phage particle (*6*−*9*). Due to its enzymatic activity and good expression in bacteria, BAP has been one of the most studied scaffolds. In this regard, Han et al. (*9*) devised a convenient method for the transference of the selected peptides to a highly active form of BAP using a ligation-independent cloning protocol, but the information provided by their procedure was only in terms of positive or negative binding. Other authors worked to obtain additional information on the peptide reactivity, particularly with regard to their relative affinity for the selector molecule (*6*, *8*), but their approaches required one by one processing of the peptide−BAP candidates. Indeed, these methods require the purification of the peptide−BAP protein for each individual clone, followed by adjustment of the BAP activity of each clone in order to assay comparative amounts of individual peptides, which greatly restricts the number of clones that can be examined.

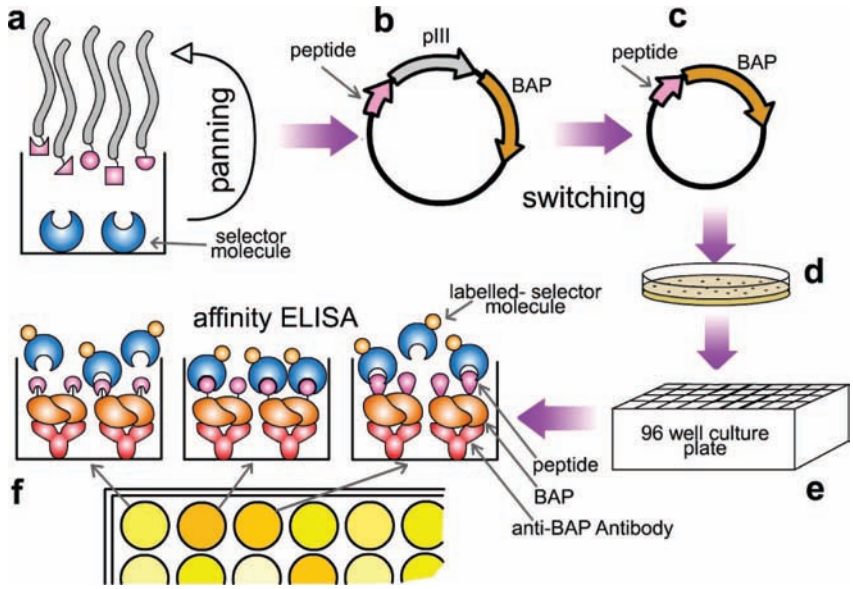

Figure 1. Schematic representation of the use of phage/mBAP switch libraries for the selection and high-throughput affinity evaluation of peptides. (a) The phage display paptide library containing the pAFF/mBAP vector is panned using standard protocols. (b) After 3–4 rounds of panning, the final phage output is amplified in *E. coli,* and the phagemid DNA is purified and digested with SpeI to delete pIII gene. (c) The digested pooled vectors are religated and used to transform *E. coli* to create a sublibrary of peptide−BAP fusion proteins. (d) The cells are plated and blue colonies (indicating BAP activity on the BCIP substrate) are individually transferred to 96-well block culture. (e) After overnight growth, the plates are centrifuged, the cell pellets are lysed with B-PER (Pierce), and the supernatants are analyzed by affinity ELISA. (f) Equal amounts of each peptide−mBAP protein are retained in the wells of a microtiter plate by capturing saturating concentrations of the cell lysates on wells coated with an anti-BAP antibody, and the fusion peptides are probed with the same concentration of the selector molecule (optionally labeled with biotin or a fluorescent tracer). Under these conditions, the readout of each well (amount of bound detector molecule) correlates with the affinity of the peptide under study.

To date, no practical procedure for high-throughput assessment of the relative affinities of the peptides selected from phage display libraries has been reported. Here, we present a novel method devised to solve the critical steps that limit this analysis. For this, we constructed a new type of phage display library with the intrinsic capacity of being easily "switched" into peptide−mBAP expression libraries. In this way, after initial selection of the phage library (usually three to four rounds of panning) the pool of selected phagemids is digested to remove the gene encoding the viral coat protein pIII, which allows fusion of the encoded peptides to the N-terminus of a highly active mutant bacterial alkaline phosphatase (mBAP). This switching process is coupled to a fast normalized selection procedure that does not require purification of the recombinant peptide−BAP fusions, and allows simultaneous direct investigation of hundreds of peptide candidates in terms of relative affinities and binding characteristics to the selector molecule. By this means, even if they are underrepresented, the most valuable peptide ligands can be rapidly identified. The method was developed and validated using a monoclonal antibody against the herbicide molinate as a model-selector molecule. In addition to providing information about the relative binding strengths of the peptides, the method yields ligand−enzyme recombinant proteins that can be used as tracer bioconjugates in different applications.

EXPERIMENTAL PROCEDURES

Cells and Plasmids. Vector pAFF2 (*10*) and *E. coli* cell strains ARI292 and ARI236 were kindly provided by Dr Peter Schatz; Affymax Research Institute, Palo Alto, CA. Vector pUY10 was a gift from Dr. Magela Laviña, Facultad de Ciencias, Montevideo, Uruguay. *E. coli* strain LMG194 (*11*), a strain derived from *E. coli* KS272 (*12*), a negative mutant for alkaline phosphatase, was a gift from Dr. Carina Gaggero, IIBCE, Montevideo, Uruguay.

Construction of pAFF/mBAP Phagemid Vector. Plasmid pUY10 encoding wild type BAP was used as template for PCR amplification using primers (5′-TC*AGTCGAC*ACTAGTGCT-GCTCAGGGCGATAT TACT-3′) and (5′-CAG*AAGCTT*T-TATTAGTGATGGTGATGGTGATGTTTCAGCC CCAGA-GCGGCTTTCATGGTGT- 3′). *Sal*I and *Hin*dIII restriction sites (italics) were introduced for cloning, as well as a SpeI site (underlined) at the 5′ end of the BAP gene to allow later elimination of pIII phage coat protein gene. After PCR amplification using *pfu* DNA polymerase (Stratagene), the BAP product was digested with *Sal*I and *Hin*dIII (New England Biolabs), and cloned into the arabinose regulatable phagemid vector pAFF2. Quickchange Site-Directed Mutagenesis Kit (Stratagene) was used both for removing a BstXI restriction site within BAP, as well as for introduction of a Asp101→Ser mutation in the BAP gene cloned in pAFF2. This amino acid change has been reported to possess enhanced BAP catalytic activity (mBAP) (*13*). The obtained phagemid was named pAFF/mBAP (Figure 2).

Cloning of a Model Peptide on pAFF/mBAP and Transference of the Peptide from pIII to mBAP. pAFF/mBAP vector was digested with BstXI restriction enzyme (New England Biolabs). The digested vector was mixed with two "half sites" adaptor oligonucleotides, ON-28 and ON-29, and the long DNA oligo coding for the cyclic peptide CAREGYPARYC, which binds to EB7 mAb (*14*) followed by a SpeI site (Figure **2**). The three oligonucleotides and the vector were annealed and later ligated with T4 DNA ligase (Invitrogen) using standard DNA procedures. ARI 236 competent cells were transformed with the ligation mix. Transformed cells were plated on LB agar ampicillin plates. DNA sequencing of clones confirmed the correct cloning of the model peptide fused to pIII phage coat protein. One of these clones was grown and a miniprep DNA extraction (Qiagen) was performed. Phagemid DNA was then digested with SpeI (New England Biolabs) restriction enzyme, removing pIII gene. Digestion was run on an agarose gel, and the band corresponding to the phagemid without the pIII gene was purified using QIAGEN Quiaquick gel extraction

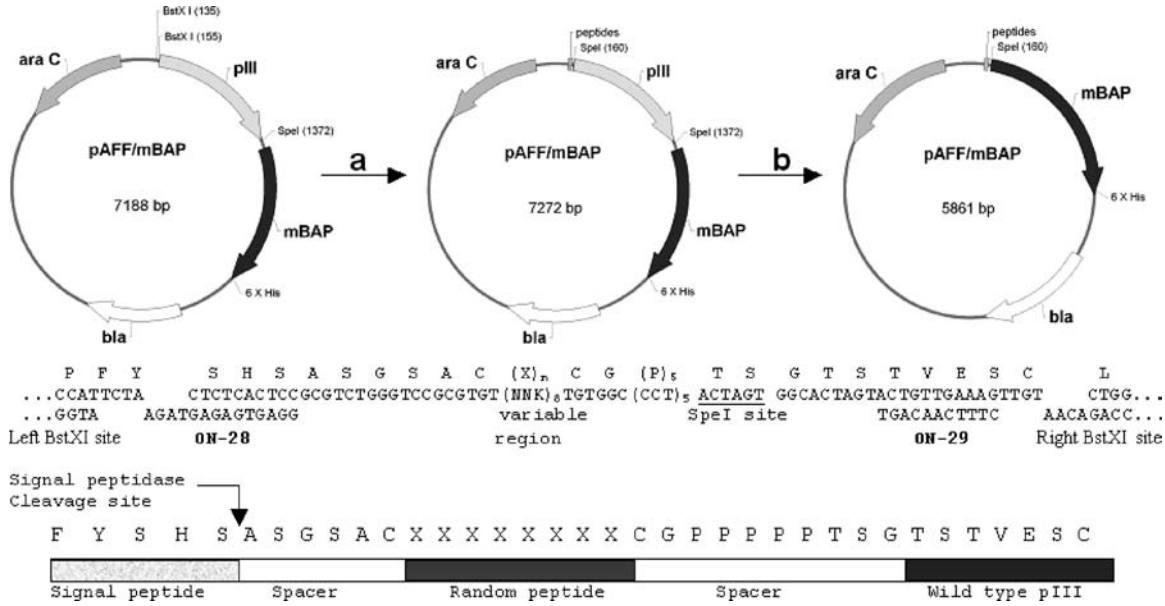

Figure 2. Representation of pAFF/mBAP vector, cloning of oligonucleotides in frame with pIII gene, and transfer of peptides from pIII to mBAP. pAFF/mBAP vector map: araC, arabinose represor gene; pIII, pIII phage coat protein gene; mBAP, mutated form of BAP gene with increased k_{cat}; bla, β-lactamase gene. (a) Library construction; the two BstXI restriction sites are used for cloning of the oligonucleotides encoding the peptides, as shown at the bottom. ON-28 and ON-29 adaptor oligonucleotides are used to form the cohesive termini required for ligation (bottom). The amino acid sequence of the assembled library is also shown at the bottom. (b) Library switching; SpeI digestion and ligation is used to switch from peptide−pIII to peptide−BAP expression. The SpeI restriction site required for this "switch" is shown underlined in the oligonucleotide sequence.

kit and ligated as described above. ARI 236 competent cells were transformed with the ligation mix. A direct screening for successful fusion of peptides−mBAP was performed by plating the transformed cells in LB plates with ampicillin (100 μg/mL), 0.2% arabinose, and BCIP (5-bromo, 4-chloro, 3-indolylphosphate (Pierce) at 40 μg/mL). After overnight incubation of the plates at 37 °C, bacterial colonies expressing peptide−BAP fusions could be clearly distinguished from colonies that were BAP by simply checking for blue colonies.

Capture of CAREGYPARYC-mBAP in ELISA Plate Wells. ARI 236 cells expressing the model fusion CAREGYPARYC-mBAP were cultured for 6 h at 37 °C after inducing with 0.2% arabinose. Cells were then pelleted by centrifugation (in aliquots of 1 mL) and the pellets were frozen at –80 °C. The cell pellet was lysed with 300 μL of B-PER reagent (Pierce) plus 1/25 volume of Complete EDTA-FREE Protease Inhibitor Cocktail (Roche Diagnostics, GmbH). Cell lysates were centrifuged and the supernatants were transferred to low-binding, nontreated, polystyrene plates (100 μL lysate + 100 uL AP wash buffer (50 mM Tris−Hcl pH = 8; 150 mM NaCl; 0.05% Tween-20)) and serial dilutions (twofold) were then performed in AP wash buffer. Dilutions were transferred to a 96-well microtiter plate (Nunc-Immuno Plate Maxi-Sorp) precoated with anti-BAP monoclonal antibody (mAb) (Sigma) at 1.25 μg/mL of IgG1 in 1× PBS (phosphate-buffered saline), polyclonal anti-BAP antibody (Polysciences, Inc.) at 2.5 μg/mL of total IgG in PBS 1×, both of them preblocked with BSA 1%. These serial dilutions were also transferred to a microtiter plate coated with Ni-NTA (Qiagen) and blocked with 1% bovine serum albumin (Sigma) in PBS buffer. Wells were washed 5 times with AP wash buffer and mBAP activity was detected by adding PNPP (*p*-nitrophenyl phosphate at 1 mg/mL) substrate (Pierce) in 50 mM Tris pH = 10, 200 mM NaCl, 1 mM $MgCl_2$. Plates were read at 405 nm in a microtiter plate reader (Multiskan MS, Labsystems).

Peptide Library Construction on pAFF-mBAP and Panning Procedure. A peptide phage library was constructed on pAFF/mBAP vector and harvested as described by Cwirla et al. (*15*). Library diversity was estimated to be around 2×10^8 independent clones. This library was panned against an antimolinate (herbicide) (*16*) mAb 14D7. Microtiter plates (Nunc-Immuno Plate Maxi-Sorp) were coated with mAb 14D7 at 5 μg/mL in PBS by incubating overnight at 4 °C (100 μL per well). Blocking was performed by completely filling the wells with 1% BSA in PBS and incubating at 37 °C for 1 h. After blocking, each well was washed 5 times with PBS−0.5% Tween-20 (PBST) and peptide library in PBS 1×−BSA1% was added to 6 precoated wells (approximately a total of 10^{11} phage particles). The plate was incubated for 2 h at 4 °C; wells were washed 10 times with cold PBST to remove unbound phages. Bound phages were eluted by adding 100 μL per well of elution buffer (0.1 N glycine, pH = 2.2 adjusted with HCl) and incubating at room temperature for 10 min. Neutralization of pH was done by adding 35 μL of 2 M Tris (pH unadjusted). The eluted phage (300 μL) were added to 10 mL of log-phase *E. coli* ARI 292 cells and amplified in LB media containing 0.25% K_2HPO_4, 0.1% $MgSO_4$, 0.1% glucose, and 100 μg/mL ampicillin to an OD_{600} = 0.4. Helper phage M13KO7 at a multiplicity of infection 10:1 was added. After a period of 30 min at 37 °C without shaking, arabinose and kanamycin were added at a final concentration of 0.02% and 40 μg/mL, respectively, and the cultures incubated overnight at 37 °C with vigorous shaking. This panning protocol was then repeated twice, and after three rounds of panning, individual amplified

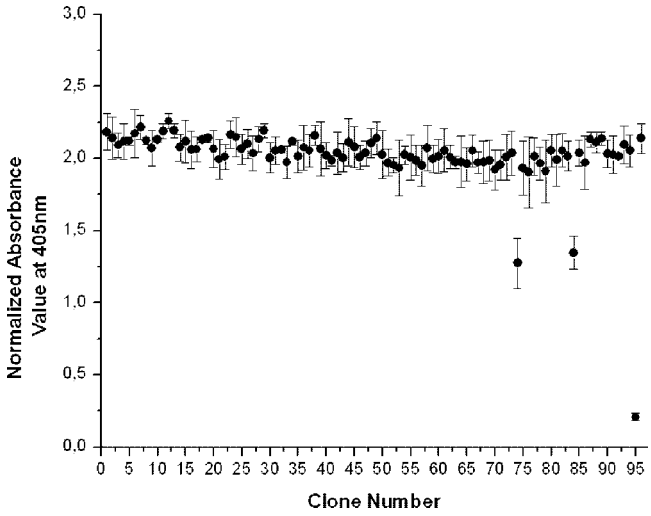

Figure 3. Comparative captured BAP activity of different peptide−mBAP fusion clones. Cell lysates from peptide−mBAP fusion expressing clones were used to saturate the binding capacity of microtiter plate wells coated with anti-BAP polyclonal antibodies. The retained BAP activity was detected with PNPP substrate, under conditions of initial velocity. Each value represents the average of three independent experiments (starting from the culture). The readout of replicates was normalized as described in the Methods section. Clone 95 corresponds to a negative control clone (LMG194 cells transformed with pAFF2 vector).

phage clones were tested for their ability to bind 14D7 coated wells. Phage ELISAs were performed as reported before (*5*).

High-Throughput Screening of the Peptide-mBAP Sublibrary Enriched in Clones Specific for mAb 14D7. ARI 292 cells were infected with approximately 5×10^7 phage particles from the third output of panning and grown in LB−ampicillin as described. Phagemid DNA was obtained using the Qiagen miniprep kit (Qiagen). The encoded peptides were fused to mBAP by switching with SpeI as described above. Competent LMG194 was transformed with the ligation mix and plated as described above. Blue colonies were individually inoculated in 0.5 mL of LB−ampicillin with 0.1% glucose in wells of a 2 mL 96-well block (Qiagen). The plate was sealed with airpore tapesheets (Qiagen) and grown with shaking at 37 °C. The next day, 80 μL of glycerol were added, and the block was frozen at –80 °C (master plate).

Replicates of this plate were established by touching the surface of the master plate frozen cultures with a multichannel micropipette using sterile tips. The tips were then used to inoculate 1 mL cultures of LB−ampicillin, 0.1% glucose, that were grown at 37 °C in a 96-well block. The next day, 5 μL was used to inoculate wells of a fresh block containing 1 mL of LB−ampicillin and 0.2% arabinose. The block plate was incubated for 6 h at 37 °C with vigorous shaking and was then centrifuged for 30 min at 1200 $\times$ *g* at 4 °C. The supernatant was discarded, and the pelleted cells were frozen at –80 °C. Each cell pellet was lysed with 300 μl of B-PER reagent (Pierce) plus 1/25 volume of Complete EDTA-FREE Protease Inhibitor Cocktail (Roche Diagnostics, GmbH) by gently pipetting up and down and using a multichannel micropipette. Cell lysates were centrifuged as previously, and 100 μL of each clone supernatant were transferred with a multichannel micropipette to each of two ELISA plates precoated with polyclonal anti-BAP antibody, and preblocked with 1% BSA. After 1 h incubation, one of the plates was washed 10 times with AP wash buffer, followed by addition of 100 μL of PNPP in substrate buffer (50 mM Tris, 200 mM NaCl, 1 mM $MgCl_2$, pH 10), and the reaction was incubated at 37 °C. The plate was read at 405 nm in a microtiter plate reader (Multiskan MS, Labsystems). The second plate was washed with PBS, 0.05% Tween 20 (PBST), and probed with 100 μL of biotinylated mAb 14D7 (0.6 μg/mL) in PBST for 1 h at room temperature. After washing, streptavidin−peroxidase (Roche Diagnostics) conjugate was added (1:1000 dilution) and incubation was continued for 30 min at room temperature. The plate was washed with PBST, and 100 μL of the peroxidase substrate (0.4 mL of a 6 mg/mL DMSO solution of 3,3′,5,5′-tetramethylbenzidine (TMB) and 0.1 mL of 1% H_20_2 in water in a total of 25 mL of 0.1 M citrate acetate buffer, pH 5.5) was dispensed into each well. The enzymatic reaction was stopped by the addition of 50 μL of 2 M H_2SO_4, and the absorbance was read at 450 nm. Three replicates were prepared in this way to perform three independent experiments for plates A and B. Values obtained for clone number 1 were used as an internal control for normalization of the ELISA values.

Affinity Measurement by Surface Plasmon Resonance. Interaction analyses were performed using a Biacore 3000 optical biosensor equipped with research-grade CM5 sensor chips (Biacore AB, Uppsala, Sweden). Data were collected at the highest collection rate, with the biosensor instrument thermostatted to 25 °C. HBS-P (10 mM Hepes, 0.15 M NaCl, 0.005% P20 surfactant, pH 7.4) running buffer, amine coupling reagents (*N*-ethyl-(3- dimethylaminopropyl) carbodiimide (EDC), *N*-hydroxysuccinimide (NHS), and ethanolamine HCl) were purchased from Biacore AB. mAb14D7 was immobilized on a CM5 sensor chip using standard amine-coupling chemistry. The carboxymethyl dextran surface was activated with a 7 min injection of a 1:1 ratio of 0.4 M EDC/0.1 M NHS. The antibody was coupled to the surface with a 7 min injection of 14D7 mAb diluted in 10 mM sodium acetate (pH = 5.0). Remaining activated groups were blocked with a 7 min injection of 1 M ethanolamine (pH = 8.5). The immobilization procedure was performed at 25 °C and a 14D7 surface density of approximately 12 000 RU was obtained. Peptides were assayed on the sensor chip in the 20 nM to 100 μM range.

Purification of Peptide−mBAP. Selected clones expressing different fusions were grown expressing the recombinant protein. Recombinant proteins were purified by standard Ni-NTA agarose (Qiagen) following manufacturers' instructions. An aliquot of the purified proteins was run on a 12% SDS-PAGE and stained with Coomasie blue.

Competitive Molinate Standard Curves Performed with Peptide−mBAP as Tracers. Nunc Maxisorp ELISA plates were coated with 0.6 ug/mL of 14D7 mAb and blocked as described above. After that, a fixed amount of peptide−mBAP previously assessed by checkerboard titration was mixed with different amounts of molinate and transferred to the 14D7 mAb coated wells, to allow competition for binding to the antibody. After 1 h incubation, plates were washed with AP Wash buffer and PNPP substrate was added. Plates were read as described above.

RESULTS

Overall View of the Concept of Phage/mBAP Switch Libraries and Vector Construction. The basic principles underlying the use of phage/mBAP switch libraries for the selection and evaluation of peptides are schematized in Figure 1. As shown in the figure, the system relies on two critical steps: first, it must allow massive transfer of the individual peptides selected on the phages to create a large peptide−mBAP library. Second, the peptide−mBAP expression library must be easily examined for the desired binding properties of the peptides. The developments required to accomplish these two aims are described in the following sections.

Vector Construction. Vector pAFF/mBAP (Figure 2), which contains a truncated version of the mutated *E. coli* BAP, was

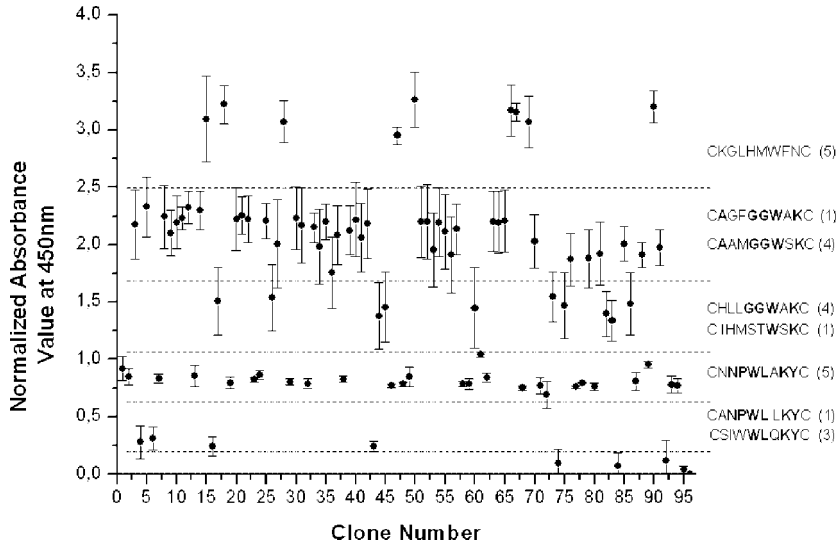

Figure 4. Affinity ELISA performed on the peptide−BAP fusion proteins probed with mAb 14D7. Saturating amounts of peptide−BAP fusion proteins captured on anti-BAP polyclonal antibody-coated wells were reacted with the same low amount of biotinylated mAb 14D7, and developed with streptavidin−horseradish peroxidase conjugate. According to the readouts, the peptides were divided into five groups (dotted lines). The sequences of five representative clones of each group are shown on the right side (consensus residues in bold), with their frequency indicated in parentheses. Each value represents the average of three independent experiments, each of them starting from a new culture from the "master plate". The readout of replicates was normalized as described in the Methods section. Clone 95 corresponds to a negative control clone (LMG194 cells transformed with pAFF2 vector).

Table 2. Kinetic Parameters of the Peptide−Antibody Interaction Measured by Surface Plasmon Resonance

peptide sequence	k_{on} (M^{-1} s^{-1})	k_{off} (s^{-1})	K_d (M)
CKGLHMWFNC	$3.1 \pm 0.1 \times 10^5$	$1.6 \pm 0.1 \times 10^{-2}$	$5.1 \pm 0.1 \times 10^{-8}$
CAAMGGWSKC	$8.3 \pm 0.1 \times 10^3$	$7.3 \pm 0.1 \times 10^{-3}$	$8.8 \pm 0.2 \times 10^{-7}$
CHLLGGWAKC	$2.8 \pm 0.1 \times 10^4$	$6.4 \pm 0.1 \times 10^{-2}$	$2.3 \pm 0.1 \times 10^{-6}$
CNNPWLAKYC	–	–	1×10^{-4} [a]

[a] No binding was observed for this peptide at the highest concentration (100 μM) assayed, indicating that its K_d is higher than 10^{-4} M, the detection limit of the Biacore 3000 instrument.

constructed as described in the Methods section. A shortened version of BAP (lacking residues 1–10) was used because it has been reported to be more resistant to proteolysis (*17*) with no loss of catalytic activity (*18*). A 6 × His tag was appended to its C-terminus to facilitate the purification of the recombinant protein. The vector contains two noncomplementary BstXI sites that are used to insert the random oligonucleotide sequences encoding the peptides. Oligonucleotide cloning introduces an additional SpeI site that allows later switching of peptide fusions from pIII to BAP.

Switch from pIII to m-BAP Using a Model Peptide. The system was initially explored using the model cyclic peptide CAREGYPARYC, which binds to mAb EB7 (*14*). The DNA sequence encoding for the peptide was cloned in frame with pIII in the pAFF-mBAP vector. Later, this construct was digested with SpeI (Figure 2), then ligated and used for transformation of *E. coli* ARI236. Peptides correctly fused to mBAP could be identified as blue colonies on LB ampicillin agar plates after addition of arabinose and the chromogenic substrate for alkaline phosphatase, BCIP (Figure 1d). Although the cells used for transformation (ARI236) have the wild-type alkaline phosphatase gene in their chromosome, streaking of this strain in control plates produced white colonies suggesting that endogenous expression of alkaline phosphatase is negligible. Fusion of peptides to mBAP through SpeI switching proved to be highly efficient, as nearly 99% of the colonies were positive by the BCIP assay.

Analysis of Peptide−mBAP Expression and Immobilization in ELISA Plate Wells. The expression of the peptide−mBAP fusion was studied using cell cultures of ARI 236 expressing the CAREGYPARYC−mBAP protein. After 6 h induction with arabinose, the expression of the recombinant peptide−BAP protein was analyzed by Western blot. The immunoreactivity of the peptide was easily detectable with mAb EB7 (*14*) and comparable to that of BAP with the anti-BAP antibody (Supporting Information, Figure A). Since BAP spontaneously forms dimers by self-association, two copies of the peptide are expected to be displayed when the enzyme is used as scaffold. Further analysis of the CAREGYPARYC−mBAP expression was tested by growing the clone in 1 mL cultures in 96-well culture blocks (supplementary methods). The cell pellet was lysed with B-PER reagent, and the supernatant was incubated into microtiter wells precoated with different antibodies or Ni-NTA. Saturation was directly examined by measuring BAP activity (Supporting Information, Figure B). The best capture efficiency was obtained with polyclonal anti-BAP antibodies. The supernatant could be diluted over 100 times without significant change in signal, showing that the amount of recombinant CAREGYPARYC−mBAP obtained from 1 mL culture was in large excess of the amount required to saturate the wells. This result proved to be valid for other peptide sequences as shown in the following section. The endogenous alkaline phosphatase activity, although detectable, was negligible and about 500-fold less than that of the recombinant protein. Nevertheless, to rule out any possible interference of this activity, we adopted the strain LMG194 for all of the following expression experiments. This strain is mutant for alkaline phosphatase, and also for the catabolic arabinose genes, and hence induction of gene expression can be done without arabinose being consumed by *E. coli*.

Panning a Library Constructed in pAFF-mBAP, Output Diversity and Switch of Selected Peptides from pIII to mBAP. A library coding for 8-mer cyclic peptides with an estimated diversity of 2×10^8 independent clones was constructed on phagemid pAFF-mBAP. As model selector molecule we used mAb 14D7 (Figure 1a), which is specific for the herbicide molinate, and is the basis for a competitive assay for this herbicide (*16*). Since competitive elution with the analyte would not warrant elution of the highest-affinity clones, we used acid conditions in order to ensure that all low- and high-affinity

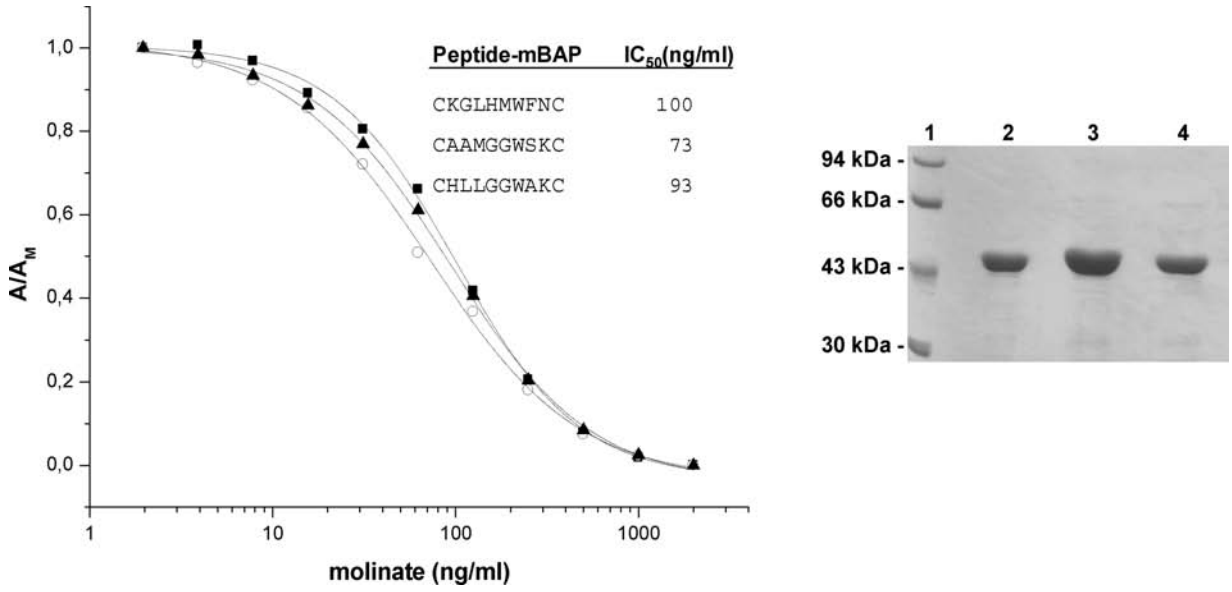

Figure 5. Purified peptide−mBAPs used as tracers in molinate competitive standard curves. Left panel: Peptides belonging to three groups with different affinities for mAb 14D7 (used for coating in the ELISA wells) were used as tracers to obtain competitive molinate standard curves. The peptide sequences and the corresponding amounts of molinate necessary to produce a 50% loss in signal (IC_{50}) are shown in the insert. Right panel: SDS-PAGE Coomassie blue stained: lane (1) molecular weight marker, (2) commercial affinity purified native BAP (Sigma), (3) Ni-NTA-agarose purified CAAMGGWSKC-mBAP, (4) Ni-NTA-agarose purified CHLLGGWAKC-mBAP.

clones were selected. After three rounds of panning, individual phage clones were tested for binding to the antibody by ELISA on plates coated with either mAb 14D7 or BSA (negative control). Ten out of ten clones examined were specific for the antibody, and six different sequences were identified (Table 1). Thus, at this point of the selection process most clones were specific and diverse, which was very convenient for the purpose of developing a method for ranking the affinities of a high number of clones. DNA from this pool of phage was "switched" with SpeI as described in the methods section (Figure 1b,c) and electroporated into LMG194. Blue colonies were picked from an arabinose-BCIP plate (Figure 1d) and were used to inoculate the "master plate" described in the Methods section.

High-Throughput Screening of the Relative Affinities of mAb 14D7 Specific Peptides. As mentioned before, the intrinsic affinity of the peptides for the selector molecule can not be estimated by phage ELISA (*6*). To overcome this limitation, we devised a method that rapidly normalizes the amount of peptide ligand to be tested by capturing saturating amounts of peptide−mBAP fusion on each of the microtiter wells to be analyzed. The method was applied to screen the third output of the panning experiment. Individual clones expressing peptide−mBAP fusions were picked from the "master plate", grown, and later lysed in 96-well square culture plates as described in the Methods section. Cell lysates were transferred to two identical plates coated with polyclonal anti-BAP antibody. One of the plates was used to verify that the same molar amount of each peptide−mBAP fusion (same BAP activity under conditions of initial velocity) was retained in each well, Figure 3. This was valid for all but two of the clones examined, clones 74 and 84. Once it was verified that the same amount of the peptides were retained in each well, mAb 14D7 (0.6 μg/mL) was used to examine the reactivity of the peptides. Under these conditions, the signal of each well is expected to be proportional to the affinity of the peptide for the antibody (Figure 1f). On the basis of the ELISA signal, the clones were grouped in five categories (Figure 4). Excellent reproducibility was attained for individual clones analyzed in three independent experiments. Sequence analysis of five clones from each category revealed peptide sequences characteristic of each group, supporting the assumption that the method sorts the peptides according to their reactivity with the antibody. Notice that, in none of the cases, was a peptide sequence belonging to a particular affinity group found in another group. To confirm this, four representative peptides belonging to each of the different affinity groups were synthesized (including disulfide formation). Binding of the soluble peptides to mAb 14D7 was studied using surface plasmon resonance. The results confirmed that the method properly sorts the peptides in a range of up to 3 orders of magnitude as shown in Table 2. Peptide CNNPW-LAKYC, which was the most abundant after selection, exhibited immeasurable interaction on the Biacore chip, showing that the avidity effect due to the two peptide copies expressed in the peptide−mBAP protein may be the cause of the moderate binding observed in the affinity ELISA. In spite of its low affinity for the antibody, this peptide was most probably preferentially selected due to a favorable expression in *E. coli*, which resulted in an over-representation of this phage clone in the amplified phage stock. This may also promote a multivalent display of the peptide in the phage particle reinforcing the avidity of the interaction with the antibody. Supporting that, experimental evidence of the preferential expression of this peptide was obtained during the preparation of the recombinant peptide−mBAP fusion proteins (not shown).

Finally, notice that, in addition to favor the selection of the desired peptides, the method produces peptide−mBAP fusions that have the potential of being used directly as probe or tracer reagents in different applications. Supporting that, the peptide−mBAP fusions of three of the peptides selected here could be used to set up sensitive competitive assays for molinate as shown in Figure 5. Similar IC_{50} values were obtained with the three peptide−mBAP tracers, and these values were similar to that obtained for the competitive assay set up using the chemically synthesized hapten (*16*) (69 ng/mL).

DISCUSSION

In the past decades, phage display has been consolidated as a reliable and rapid technology for the identification of bioactive peptides and antibody fragments selected from high-diversity libraries. For most purposes, not only the specificity, but very importantly, the affinity of the selected peptides is a major issue.

This is particularly true for bioactive peptides that must show agonist or antagonist activity at the low concentration reached at the place of action. For this reason, the affinity of the peptides obtained after the initial selection from fully random peptide libraries is often improved through the construction of a secondary phage display library (mutagenesis library). In the mutagenesis libraries, the consensus residues of the initial phage pool are over-represented to favor the optimization of their flanking residues along the selection process (*10, 19*). In both cases (random and mutagenesis libraries), the outcome of the panning experiments should be easily examined to identify the higher-affinity clones. However, the identification of high-affinity binders among the pool of selected phage-borne peptides is not an easy task, and there is currently no systematic, yet practical, method to do this.

To deal with this problem, several alternative methods have been developed to facilitate the evaluation of the specificity and relative affinity of the isolated peptides; some of these methods use BAP as a partner fusion protein to study the peptide out of the context of the phage (*69*), but they are not compatible with high-throughput analysis. Here, we present a simpler method for the generation of large collections of clones expressing peptide−BAP fusions, coupled with a new method for rapid and simultaneous evaluation of the relative affinity of a large numbers of clones. In this method (affinity ELISA), the BAP activity works as an internal control to verify that equal amounts of peptides are assayed in each well of the affinity ELISA. Notice that the use of a much simpler affinity ELISA based on the capture of the phage particle bearing the peptide with an antiphage antibody would not produce reliable results due to the differential expression of individual peptides, which, as discussed above, would affect the average copy number of the displayed peptides.

The method showed excellent reproducibility and allowed us to sort the peptides within a wide range of affinities (up to 3 orders of magnitude) as shown by surface plasmon resonance analysis. Although we cannot rule out that, depending on their sequences, the peptides may show occasional interactions with the fusion partner that affect their binding to the target, in the four cases examined here there was a complete agreement between the affinity ELISA and the surface plasmon resonance analysis. By modification of the affinity ELISA conditions, it may be possible to shift this range to the target affinity (i.e., using stringent washing, lower amount of selector molecule, lowering the incubation time with the substrate, etc.). Interestingly, the highest-affinity clone (CKGLHMWFNC) which happened to be a low-abundance clone (about one in ten in the third output) could be easily spotted. This shows the potential of the method as a tool to identify valuable clones that are underrepresented in the selected phage pool. These "rare" nonconsensus fitting and low-frequency clones would be probably lost by the standard procedure of DNA sequencing and chemical peptide synthesis based on consensus or single sequences.

An additional benefit of the method is that the selected peptides can be directly produced as recombinant peptide–protein fusions. In our model, the recombinant peptide is linked to a high-turnover mutated form of BAP, in a fixed stoichiometric relationship, constituting a highly defined bioconjugate reagent that can be promptly used, for instance, as an immunoassay reagent. The applications of the concept of switch phage libraries can be extended to fusion partners others than BAP. In principle, any gene that is properly expressed in the periplasmic compartment of *E. coli* could be used to substitute the BAP gene in the pAFF/mBAP-PhoA vector, allowing the creation of sublibraries carrying the desired gene. This may include a different tracer activity such as firefly luciferase or green fluorescent protein to monitor intracellular binding of the peptides, or intein genes, that may help to produce the free recombinant peptide.

The measurement of matrix metalloproteinase (MMP) activity in diseases like inflammation, oncogenesis, or atherosclerosis in vivo is highly desirable. Fine-tuned pyrimidine-2,4,6-triones (barbiturates) offer nonpeptidyl lead structures for developing imaging agents for specifically visualization of activated MMPs in vivo. The aim of this study was to modify a C-5-disubstituted barbiturate and thus design a highly affine, nonpeptidic, optical MMP inhibitor (MMPI)-ligand for imaging of activated MMPs in vivo. A convergent 10 step synthesis was developed, starting with a malonic ester and (4-bromophenoxy)benzene to generate 5-bromo-pyrimidine-2,4,6-trione as the key intermediate. To minimize the interactions between activated MMPs and the dye of the conjugate **6**, a PEGylated piperazine derivative was used as a spacer and an azide as a protected amino function. After linking both building blocks, reducing the azide (*Staudinger* reaction) and labeling with Cy 5.5, we obtained the nonhydroxamate MMP inhibitor **6** with high affinity (IC_{50}-value: 48 nM for MMP-2) measured in a fluorogenic assay using commercially available MMP-substrates and the purified enzyme. Zymography revealed an efficient blocking of enzyme activity of purified MMP-2 and MMP-9 and of MMP-containing cell supernatants (HT-1080), (A-673) using the PEGylated barbiturate **5**. Fluorescence microscopy studies using a highly (A-673) and a moderate (HT-1080) MMP-2 secreting cell line showed efficient binding of the Cy 5.5 labeled tracer **6** to the MMP-2 positive cells while MMP-2 negative cells (MCF-7) did not bind. Therefore, this new barbiturate-based MMP-probe has a high affinity and specificity toward MMP-2 and -9 and is thus a promising candidate for sensitive MMP detection in vivo.

INTRODUCTION

Molecular imaging of locally upregulated and activated matrix metalloproteinases (MMPs) in vivo is a clinical challenge. MMPs are zinc- and calcium-dependent endopeptidases and represent a subfamily of the metzincin superfamily. They are able to degrade all protein components of the extracellular matrix (ECM) with overlapping substrate specificities (*1–3*).

To date more than 20 human MMPs have been characterized. Based on their specificity the MMPs are classified into collagenases, gelatinases, stromelysins, and matrilysins. Another subclass of the MMPs is represented by the membrane-type MMPs (MT-MMPs) (*4, 5*). An increased MMP expression is associated with pathophysiological processes including the progression of cancer, cardiovascular diseases such as atherosclerosis, and inflammation (*6–13*).

Recently, the pyrimidine-2,4,6-triones (or barbiturates) were identified as nonhydroxamate MMP inhibitors that exhibit specific activities for a subgroup of secreted MMPs comprising the gelatinases A (MMP-2) and B (MMP-9), neutrophil collagenase (MMP-8), the membrane bound MMPs, MT-1-MMP (MMP-14), and MT-3-MMP (MMP-16) (*14*). Barbiturates are, therefore, promising candidates for molecular imaging of MMP activity. The enolic tautomer of the pyrimidine-2,4,6-triones binds to the zinc active site (*15, 16*). Recently, C-5-disubstituted pyrimidine-2,4,6-triones were exploited as a new class of potential MMP inhibiting radiotracers with improved MMP binding potency (*17, 18*).

Fluorochrome-based molecular tracers have been shown to allow highly sensitive visualization of molecular targets. Moreover, optical technologies are inexpensive and free of ionizing radiation and isotope decay as well as applicable to tomographic (e.g., fluorescence mediated tomography, FMT) and surface-weighted (e.g., fluorescence reflectance imaging, FRI) imaging techniques.

In this study the synthesis of a barbiturate-based MMP-2 and MMP-9 ligand is described. A poly(ethylene glycol) (PEG) spacer group containing the amino functionality was inserted to enable labeling with fluorescent dyes without changing the MMP binding pharmacophor. The conjugation of the fluorescent dye Cy 5.5 was accomplished by forming an amide bond under standard conditions. Enzyme activity assays and cell binding studies in vitro confirmed a high binding affinity of the probe to the target.

EXPERIMENTAL PROCEDURES

Materials and Methods. All chemicals, reagents, and solvents for the synthesis of the compounds were analytical grade and purchased from commercial sources. For the labeling procedure DNA-grade dimethylformamide was used. Melting points (uncorrected) were determined on a Stuart Scientific SMP3 capillary melting point apparatus. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker ARX 300 (Bruker BioSpin GmbH, Rheinstetten, Germany). Mass spectrometry was per-

formed using a QUATTRO LCZ (Waters Micromass, Manchester, U.K.) spectrometer with a nanospray capillary inlet.

Synthetic Organic Chemistry. *N-Boc-Piperazine.* A solution of piperazine (27.60 g, 320 mmol) in 450 mL of dichloromethane was cooled to 0 °C. Di-*tert*-butyl dicarbonate (34.96 g, 160 mmol) in 150 mL of dichloromethane was added dropwise. The resulting mixture was stirred for 2 h at 0 °C and then at ambient temperature for 22 h. The precipitate was filtered off, and the filtrate was concentrated in vacuo. The crude product was dissolved in water (300 mL) and extracted with diethyl ether (3 × 200 mL). The organic layer was dried over magnesium sulfate and concentrated to give a colorless solid. Yield: 20.27 g (109 mmol, 68%). Mp: 72–73 °C. ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 1.46 (s, 9H, C(CH_3)$_3$), 1.85 (s, 1H, N*H*), 2.79–2.83 (m, 4H, NH(CH_2)$_2$), 3.37–3.41 (m, 4H, (CO)N(CH_2)$_2$). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 28.3 (C(*C*H$_3$)$_3$), 45.8 (NHCH$_2$), 51.1 (CO)N(*C*H$_2$)$_2$), 79.4 (*C*(CH$_3$)$_3$), 154.7 (N(*C*O)O). MS (ES+) *m*/*e* = 209.1 (M + Na)$^+$, 187.1 (M + H)$^+$.

Tetraethyleneglycol Dimethanesulfonate. Methanesulfonyl chloride (317 mL, 470 g, 4.1 mol) was added dropwise over a period of 4 h to a solution of tetraethylene glycol (347 mL, 388 g, 2 mol) in dichloromethane (1.8 L) and triethyl amine (570 mL, 415 g, 4.1 mol) at 0 °C. The mixture was stirred at ambient temperature for an additional 16 h, and the resulting precipitate was filtered off. Concentration of the filtrate yielded an orange oil, which was used without further purification. Yield: 596 g (1.7 mol, 85%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 3.08 (s, 6H, SO$_3$C*H*$_3$), 3.65–3.68 (m, 8H, OC*H*$_2$C*H*$_2$O), 3.76–3.78 (m, 4H, SO$_3$CH$_2$C*H*$_2$), 4.37–4.40 (m, 4H, SO$_3$C*H*$_2$CH$_2$). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 37.6 (SO$_3$*C*H$_3$), 68.9 (SO$_3$*C*H$_2$CH$_2$), 69.2 (SO$_3$CH$_2$*C*H$_2$), 70.4, 70.5 (OCH$_2$*C*H$_2$O). MS (ES+) *m*/*e* = 373.1 (M + Na)$^+$, 351.1 (M + H)$^+$.

*2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethyl Methanesulfonate (**1**).* To a solution of tetraethyleneglycol dimethanesulfonate (83.4 g, 272 mmol) in dimethyl formamide (600 mL) was added sodium azide (10.6 g, 163 mmol), and the reaction mixture was stirred at 120 °C for 5 h. Most of the dimethyl formamide was removed in vacuo. The crude product was dissolved in ethyl acetate (400 mL) and washed with water (5 × 200 mL) and brine (200 mL) and dried over magnesium sulfate. After removing the solvent the resulting oil was chromatographed on a silica gel column (cyclohexane/EtOAc 2/1 to 1/1) to give a pale yellow oil. Yield: 17.2 g (58 mmol, 36%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 3.08 (s, 3H, SO$_3$C*H*$_3$), 3.64–3.69 and 3.76–3.79 (m, 14H, OC*H*$_2$C*H*$_2$O and OC*H*$_2$C*H*$_2$N$_3$), 4.37–4.40 (m, 2H, SO$_3$C*H*$_2$CH$_2$). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 37.6 (SO$_3$*C*H$_3$), 51.0 (*C*H$_2$N$_3$), 68.8 (SO$_3$*C*H$_2$CH$_2$), 69.3 (SO$_3$CH$_2$*C*H$_2$), 69.9, 70.4, 70.5 (OCH$_2$*C*H$_2$O). MS (ES+) *m*/*e* = 319.1 (M + Na)$^+$, 297.1 (M + H)$^+$.

tert-Butyl-4-(2-(2-(2-(2-azidoethoxy)ethoxy)ethoxy)ethyl)piperazine-1-carboxylate. A solution of **1** (12.44 g, 41.8 mmol), *N*-Boc-piperazine (9.34 g, 50.2 mmol), and triethyl amine (8.3 g, 11.5 mL, 82 mmol) in acetonitrile (150 mL) was heated to reflux for 24 h. After removing the solvent the crude product was purified by column chromatography on silica gel (cyclohexane/EtOAc 1:2) to give a pale yellow oil. Yield: 9.76 g (25.2 mmol, 60%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 1.45 (s, 9H, C(CH_3)$_3$), 2.44 (t, 4H, (CO)NCH$_2$C*H*$_2$N, ^3J = 5.1 Hz), 2.59 (t, 2H, NCH$_2$CH$_2$NC*H*$_2$, ^3J = 6 Hz), 3.38 (t, 2H, C*H*$_2$N$_3$, ^3J = 5.4 Hz), 3.43 (t, 4H, (CO)NC*H*$_2$, ^3J = 5.1 Hz), 3.60–3.69 (m, 12H, OC*H*$_2$C*H*$_2$O). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 28.3 (*C*(CH$_3$)$_3$), 43.7 ((CO)N*C*H$_2$), 50.6 (*C*H$_2$N$_3$), 53.2 (NCH$_2$CH$_2$NCH$_2$), 57.7 (NCH$_2$*C*H$_2$NCH$_2$), 68.8, 69.9, 70.3, 70.5 (OCH$_2$*C*H$_2$O). MS (ES+) *m*/*e* = 388.3 (M + H)$^+$.

*1-(2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethyl)piperazine TFA Salt (**2**).* Trifluoroacetic acid (12 mL) was added to a solution of the Boc-protected PEGylated piperazine (3.64 g, 9.4 mmol) in dichloromethane (12 mL) and stirred for 2 h. The solvent was removed and the crude product chromatographed on a silica gel column (EtOAc/MeOH 9/1 to 4/1) to give a yellow sticky oil. Yield: 2.6 g (6.7 mmol, 71%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 3.38 (t, 2H, C*H*$_2$N$_3$, ^3J = 5.4 Hz), 3.62–3.91 (m, 22H, piperazine-C*H*$_2$ and OC*H*$_2$C*H*$_2$O), 9.81 (bs, 2H, $^+$NH$_2$). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 42.3 (NH$_2$*C*H$_2$), 50.4 (*C*H$_2$N$_3$), 52.3 (NCH$_2$CH$_2$NCH$_2$), 58.5 (NCH$_2$*C*H$_2$NCH$_2$), 65.7, 69.9, 70.3, 70.4, 70.6 (OCH$_2$*C*H$_2$O). MS (ES+) *m*/*e* = 288.2 (M + H)$^+$.

*5-(4-Phenoxyphenyl)pyrimidine-2,4,6-trione (**3**).* A mixture of palladium acetate (135 mg, 0.6 mmol), copper difluoride (60 mg, 0.6 mmol), tri-*tert*-butyl phosphine (90% grade, 220 μL, 0.8 mmol), sodium *tert*-butoxide (6.98 g, 73 mmol), and tetrahydrofurane (30 mL) was prepared. 4-Bromophenyl phenylether (10.5 mL, 60 mmol) and diisopropyl malonate (14.4 mL, 76 mmol) were added consecutively. The clear solution was heated to reflux for 15 h. The resultant suspension was diluted with cyclohexane (30 mL), and 3 M HCl (7.5 mL, 22.5 mmol) was added. The mixture was filtered through Celite, and the filter pad was washed with cyclohexane/THF (1/1, 100 mL). After removing the solvent, the residue was dissolved in diethyl ether, washed with 3 M HCl (3 × 25 mL), 1 M NaHCO$_3$ (2 × 25 mL), and brine, dried over magnesium sulfate, and concentrated under reduced pressure yielding a yellow oil. Urea (6.41 g, 107 mmol) and isopropanol (130 mL) were added. The mixture was heated to 80 °C, and a 1 M solution of potassium *tert*-butoxide in THF (152 mL, 152 mmol) was added slowly over 3 h while distilling off approximately 70 mL of solvent and maintaining a reflux temperature between 75 and 85 °C. After the addition was complete the mixture was heated to reflux for an additional 16 h. Following cooling to ambient temperature concentrated HCl (15 mL) and water (35 mL) were slowly added and the mixture was stirred for 10 min. The solution was concentrated under reduced pressure to remove the organic solvents. The resulting aqueous mixture was diluted with water (100 mL), and the precipitate was filtered off. The off-white solid was dissolved in ethyl acetate (70 mL), heated to reflux for a few minutes, and after cooling to ambient temperature cyclohexane (35 mL) was slowly added. The precipitate was filtered off, washed with cyclohexane/EtOAc (1/1, 100 mL), and dried in vacuo to give an off-white solid. Yield: 4.2 g (12.3 mmol, 21%). ^{1}H NMR (DMSO-d_6, 300 MHz): δ (ppm) = 4.87 (s, 1H, C*H*), 6.91–7.49 (m, 9H, Ph*H*), 11.41 (bs, 2H, (CO)N*H*). ^{13}C NMR (d_6-DMSO, 75 MHz): δ (ppm) = 60.6 (barbituric-*C*H), 118.9, 123.6, 123.7, 130.4, 131.0 (Ph*C*H), 131.3 (q-Ph*C*CH), 157.1, 157.3 (q-Ph*C*O), 155.4 (NH*C*ONH), 172.8 (NH*C*OCH). MS (ES+) *m*/*e* = 319.1 (M + Na)$^+$.

*5-(4-(2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethyl)piperazin-1-yl)-5-(4-phenoxyphenyl)-pyrimidine-2,4,6-trione (**4**).* A solution of **3** (3.9 g, 11.5 mmol) in dimethyl formamide (15 mL) was cooled to 0 °C, and a solution of *N*-bromosuccinimide (2.1 g, 11.5 mmol) in 10 mL of dimethyl formamide was added over 20 min while maintaining the temperature of the reaction mixture below 10 °C. After stirring for 20 min, **2** (4.6 g, 11.5 mmol) and potassium carbonate (3.22 g, 23 mmol) were added, and the mixture was stirred for 1 h at 0 °C followed by stirring for 20 h at ambient temperature. After removing the solvent, the crude product was dissolved in toluene (25 mL) and heated to reflux for a few minutes. After cooling to ambient temperature, diethyl ether (10 mL) was added dropwise and the resulting suspension was stored overnight at –20 °C. The precipitate was filtered off, washed with diethyl ether, and dried in vacuo giving a white powder. Yield: 2.9 g (4.9 mmol, 43%).

Table 1. MMP Inhibition Potencies of the Barbiturates for MMP-2 and -9 Expressed in IC_{50} Values

	IC_{50}[a] [nM]			
compound	MMP-2	MMP-9	$_c\log D$[b]	$_c\log P$[b]
4	24 ± 8	68 ± 10	1,84	2.15 ± 0.85
5	27 ± 3	138 ± 19	−0.34	1.29 ± 0.85

*5-(4-(2-(2-(2-(2-Aminoethoxy)ethoxy)ethoxy)ethyl)piperazin-1-yl)-5-(4-phenoxyphenyl)-pyrimidine-2,4,6-trione (**5**).* Triphenylphosphine (560 mg, 2.5 mmol) was added to a solution of **4** (1.16 g, 2 mmol) in tetrahydrofurane (50 mL), and the reaction mixture was stirred for 16 h at ambient temperature. Then water (0.1 mL) was added, and the mixture was stirred for 3 h. The solvent was removed under reduced pressure, and the residue was chromatographed on a silia gel column (EtOAc/MeOH 2/1 + 2% TEA) to give a colorless foam (R_f = 0.2). Yield: 785 mg (1.41 mmol, 71%). Mp: 50 °C. ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 2.57–2.81 (m, 10H, piperazine-*H*,$(CH_2)_2NCH_2$), 3.33 (bs, 2H, CH_2NH_2), 3.59–4.04 (m, 16H, OCH_2CH_2O, NH_2), 6.90–7.35 (m, 9H, Ph-*H*). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 40.5 (CH_2NH_2), 45.6 (q-$CNCH_2$), 46.9 ($CH_2CH_2NCH_2$), 58.8 ($CH_2CH_2NCH_2$), 66.4, 69.4, 70.3, 70.9 (OCH_2CH_2O), 72.1 ($CH_2CH_2NH_2$), 74.0 (q-*C*$(CO)_2$), 118.5, 119.1 (Ph*C*H), 123.6 (q-Ph*C*), 129.7, 130.3, 131.2 (Ph*C*H), 149.7 (NH*C*ONH), 156.8, 157.3 (q-Ph*C*O), 170.3 (*C*ONH). Fluorochrome Conjugation. The amino-functionalized derivative **5** (1.0 mg, 1.7 μmol) was dissolved in 400 μL dry dimethylformamide including 10 μL triethylamine. To this solution was added Cy 5.5 NHS ester (Amersham Bioscience; 1 mg, 0.9 μmol). The reaction mixture was vortexed for 2 h at room temperature in the dark. Purification of the Cy 5.5-labeled derivative **6** was performed by gradient HPLC using a Knauer system with two K-1800 pumps, an S-2500 UV detector, and a RP-HPLC Nucleosil 100-5 C18 column (250 mm × 4.6 mm). Eluent A: water (0.1% TFA). Eluent B: acetonitrile (0.1% TFA). Gradient from 99% A to 40% A over 23 min at a flow rate of 5 mL/min, detection at λ = 254 nm. The appropriate fractions (t_R = 16.5 min) were collected, lyophilized, redissolved in PBS, and finally stored at –20 °C. The average content of **6** was 0.8 ± 0.2 μmol/mL (≈ 65%) as determined by fluorometer measurements with λ_{abs} = 678 nm and ε_{678} = 250 000 M^{-1} cm^{-1}. MS (ES−): *m*/*e* = 483.6 (100%), 484.0, 484.3, 484.6, 485.0 $[M]^{3-}$; 725.8, 726.3, 726.7, 727.4 $[M + H]^{2-}$.

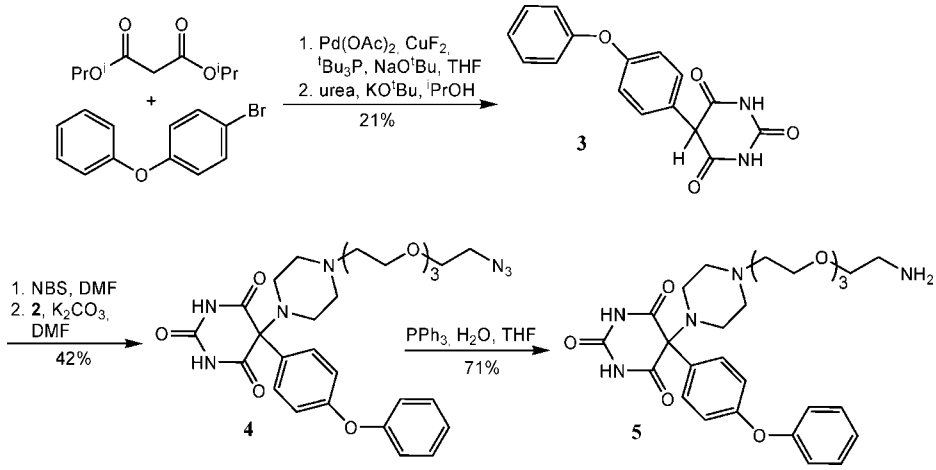
In Vitro Enzyme Inhibition Assays. The synthetic broad-spectrum fluorogenic substrate (7-methoxycoumarin-4-yl) acetyl pro-Leu-Gly-Leu-(3-(2,4-dinitrophenyl)-L-2,3-diamino-propionyl)-Ala-Arg-NH_2 (R & D Systems, Minneapolis, U.S.A.) was used to measure MMP-2 and MMP-9 activities as described previously (*19*). The inhibition of human active MMP-2 and MMP-9 by the barbiturates **4** and **5** and the conjugate **6** was measured by preincubating MMP-2 (2 nM) or MMP-9 (2 nM) and inhibitor compounds at varying concentrations (10 pM –1 mM) in 50 mM Tris·HCl, pH 7.5, containing 0.2 M NaCl, 5 mM $CaCl_2$, 20 μM $ZnSO_4$, and 0.05% Brij 35 at 37 °C for 30 min. An aliquot of substrate (10 μL of a 50 μM solution) was then added to 90 μL of the preincubated MMP/inhibitor mixture, and the activity was determined at 37 °C by following product release per time. The fluorescence changes were monitored using a Fusion Universal Microplate Analyzer (Packard Bioscience, Massachusetts, U.S.A.) with excitation and emission wavelengths set to 330 and 390 nm, respectively. Reaction rates were measured from the initial 10 min of the reaction profile where product release was linear with time and plotted as a function of inhibitor dose. From the resulting inhibition curves, the IC_{50} value for each inhibitor was calculated by nonlinear regression analysis, performed using the Grace 5.1.8 software (Linux).

Cell Cultures. Three human carcinoma cell lines, purchased from ATCC (Manassas, VA, U.S.A.), were cultivated in the following media: fibrosarcoma HT-1080 (CCL-121) and adenocarcinoma MCF-7 (HTB-22) in RPMI-1640, and rhabdomyosarcoma A-673 (CRL-1598) in DMEM. Media (Invitrogen Corporation, San Diego, CA) were supplemented with 10% fetal calf serum (FCS), 1% penicillin and streptomycin (Biochrom AG, Berlin, Germany), 2 mM L-glutamine (Gibco BRL), and 13.5 mM sodiumbicarbonate when using A-673 cells. Cells were grown routinely in T75 flasks, incubated at 37 °C in a 5% CO_2 humidified air atmosphere until the cultures were confluent (80–100%); medium was changed every 3−4 days. The amount of vital cells was determined by trypan blue staining (Sigma-Aldrich Chemie GmbH, Munich, Germany). A total of 10^7 cells were washed three times in serum-free medium and incubated in freshly FCS-free medium for a further 24 h. For gelatine zymography and Western blotting the supernatant was collected and stored at –20 °C. For RNA isolation, adherent cells were washed with phosphate-buffered saline (PBS), treated with 0.5% trypsin, and harvested by centrifugation (5 min, 1400 × *g*).

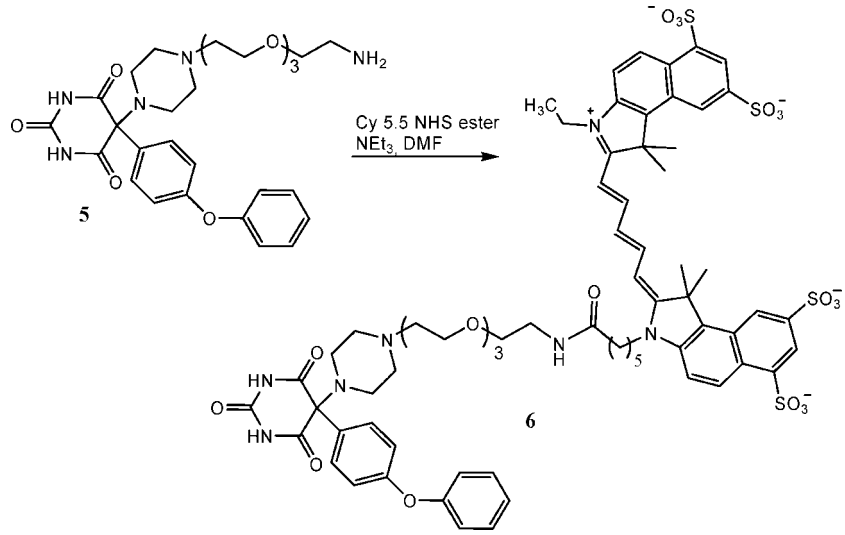
RNA Isolation and cDNA Synthesis. Total RNA was isolated from harvested cells (see above) using the peqGOLD Total RNA Kit (PeqLab Biotechnology GmbH, Erlangen, Germany) according to the manufacture's instructions. To remove possible genomic DNA contaminations a DNase I digestion reaction mix, consisting of OBI DNase I Digestion Buffer and RNase-free DNase I (20 units/μL), was added directly to the surface of the HiBind spin column. Total RNA was eluted with RNase-free water and stored at –86 °C until use.

RNA concentrations and its purity were measured with the Quant-iT RNA Assay Kit (Invitrogen, Karlsruhe, Germany).

Scheme 2. Synthesis of the Barbiturate Precursor 5



Scheme 3. Labeling of the Precursor 5 with the Cyanine Dye Cy5.5



Prior to the reverse transcription reaction, total RNA was denatured at 65 °C for 10 min and subsequently placed on ice. Reverse transcription of RNA was performed using the RevertAid First Strand cDNA Synthesis Kit (MBI Fermentas, St. Leon-Roth) in a 20 μL reaction volume, consisting of 1 μg of total RNA, 5× reaction buffer, 1 mM of each nucleotide triphosphate, 20 units of RiboLock Ribonuclease Inhibitor, and 1 μL of random Hexamer (0.2 μg/μL). After incubation at 25 °C for 5 min, 200 units of RevertAid M-MuLV Reverse Transcriptase were added, and the reaction mixture was incubated according to the supplier's instructions. Synthesized cDNA was stored at –20 °C until use.

PCR Conditions. Polymerase chain reaction (PCR) reactions were performed in a total volume of 25 μL, containing 0.2 mM of each nucleotide triphosphate, 1× PCR-buffer, 50 μM of each primer (see Table 2), 1 mM $MgCl_2$, 1 unit of Taq DNA polymerase (PeqLab Biotechnologie GmbH, Erlangen, Germany), and 1 μL of synthesized cDNA. Thermal cycling conditions comprised an initial degradation step (94 °C, 3 min) and 35 cycles at 94 °C for 30 s, 60 °C for 20 s, and 72 °C for 30 s, followed by a final elongation step (72 °C, 1 min) in an Eppendorf Mastercycler EP Gradient (Eppendorf AG, Hamburg, Germany). PCR products were separated by agarose gel electrophoresis (2%) (Biozym Diagnostik GmbH, Oldendorf,

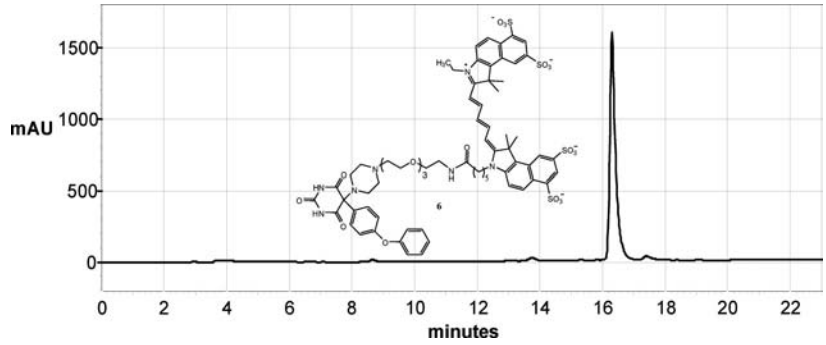


Figure 1. HPLC chromatogram of the purified conjugate **6** (UV-trace).

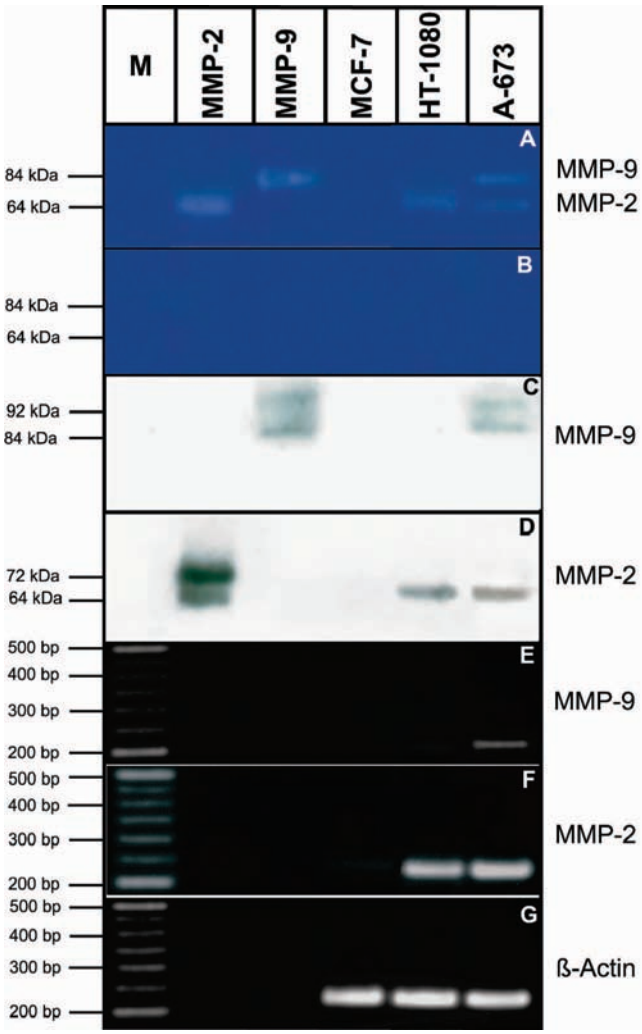

Figure 2. MMP-2 and -9 expression, secretion, and activity tests. Gelatinolytic activity of cell extracts was determined by zymography (A). Inhibition of the gelatinolytic activity with **5** (B). Western blot analysis of cell supernatants to detect pro-MMP-2, MMP-2 (C), pro-MMP-9, and MMP-9 (D). Semiquantitative PCR analysis was performed with the primer pairs listed in Table 2, specific for MMP-9 (E), MMP-2 (F), or β-Actin (G).

Germany). Fragment sizes were determined using the 50-bp DNA ladder standard (MBI Ferments, St. Leon-Rot, Germany).

Gelatine Zymography. Gelatine zymography was performed as described previously with minor modifications (*20*). Twenty microliters of FCS-free cell supernatant from 1×10^7 cells were mixed with (4×) SDS sample buffer without reducing agent and separated in a sodium dodecyl sulfate (SDS)−polyacrylamide electrophoretic gel (PAGE) (0.75 mm comb, 4 °C, 150 V). The 7% separating SDS gel contained 0.6 g/L gelatine to detect latent and activated forms of gelatinases. Following electrophoresis, the gel was washed twice in 2.5% Triton X-100 for 30 min at room temperature with shaking to remove residual SDS. Subsequently, zymograms were developed by incubation overnight at 37 °C with gentle shaking in collagenases buffer (50 mM Tris-HCl pH 7.8, 10 mM $CaCl_2$) and afterward stained/destained with 1% Coomassie Brillant Blue G-250 dissolved in 10% ethanol and 5% acetic acid at room temperature for 120 min. Active MMP-2 from human fibroblasts and MMP-9 from human recombinant NSO cells (Sigma-Aldrich Chemie GmbH, Munich, Germany) were used as a gelatinase control. Gelatinolytic/proteolytic activity was visible as clear bands (zones of gelatine degradation) against a dark blue background of stained gelatine.

Western Blot Analysis. Total protein was separated in nonreducing SDS-PAGE electrophoresis using separating gels with 10% and stacking gels with 4.5% polyacrylamide. Lanes were loaded with 20 μL of FCS-free cell supernatant and mixed with (6×) SDS buffer. After electrophoresis (4 °C, 100 V), proteins were transferred to PVDF membranes (Millipore Corporation, Bedford, MA) via electroblotting (4 °C, 60 V). Blots were blocked in tris-buffered saline-NaCl, pH 7.4, containing 1% bovine serum albumin, 0.5% milk powder (Carl Roth GmbH & Co KG, Karlsruhe, Germany), and 0.1% Tween 20, washed, and incubated at 37 °C for 120 min with 1:500 diluted primary polyclonal antibody against MMP-2 (Cell Signaling, New England Biolabs GmbH, Frankfurt a. M., Germany), which detects full length proenzyme (72 kDa) and cleaved active enzyme (64 kDa). Subsequently, blots were washed three times in tris-buffered saline, pH 7.4, containing 0.5% milk powder and 0.1% Tween 20 and incubated with 1:1000 diluted peroxidase-conjugated goat antirabbit IgG antibody (Vector, Burlingame, U.S.A.). Following three washing steps, peroxidase activity was revealed using ECL chemiluminescence (Amersham, Buckinghamshire, U.K.) according to the manufacturer's instructions to visualize signals. MMP-2 from human fibroblasts (Sigma-Aldrich Chemie GmbH, Munich, Germany) was used as a positive control.

In Vitro Cell Assays. The cell-based binding assay was performed in U-shaped polypropylene 24-well plates (Nunc); each well was seeded with 2.5×10^4 cells and grown in 1 mL of medium to confluence. Briefly, after washing the wells with PBS, 150 μL of preincubation buffer (50 mM Tris-HCl, 10 mM $CaCl_2$, 62 mM $ZnSO_4$, pH 7.4), with or without predosing using 50 μM **5**, was added to each well and incubated for 30 min at 37 °C. Following incubation, the preincubation buffer was replaced by binding buffer (50 mM Tris-HCl, 10 mM $CaCl_2$, 30 mM $ZnSO_4$, pH 7.4) containing 2 nmol of **6**. After an incubation time of 120 min at 37 °C, cells were washed with PBS, and subsequently 300 μL of medium/trypan blue solution (2:1 (v/v); Sigma-Aldrich Chemie GmbH, Munich, Germany) was added. Cells could be directly visualized by fluorescence microscopy (Nikon TE 2000-S, Tokyo, Japan) which was equipped with a mercury vapor lamp, 620/775 nm (excitation/emission) filters (AHF Analysentechnik AG, Tübingen, Germany), and a Nikon DXM1200F camera using the NIS-Elements BR 2.30 sofware (Nikon, Tokyo, Japan).

RESULTS AND DISCUSSION

As MMPs are involved in the regulation of the tumor microenvironment and expressed and activated in many types of human cancers, this distinct enzyme class appears to be a molecular target for imaging of cancer in vivo (*8*). The selective targeting of MMP-2, -9, and -14 may help to visualize tumor angiogenesis. These three MMPs are most consistently detected in malignant tissues in which they are associated with tumor aggressiveness, metastatic potential, and poor prognosis (*9*, *21*). Increased levels of activated MMPs in inflammatory, malignant, and degenerative diseases have been attributed to increased cytokine and growth-factor-stimulated gene transcription, enhanced zymogen activation, and an imbalance in the MMP: TIMP ratio, which can be used as a "noninvasive" diagnostic test for bilharzial bladder cancer (*22*, *23*).

The objective of this work was the modification of an existing lead structure (barbiturate) with a fluorescent dye, to allow near-infrared detection of the target enzymes. Taking into account the size of the dye molecule compared to that of the parent inhibitor, we have chosen a short PEG spacer to distance the dye from the MMP-binding site and preserve the desired binding affinity for gelatinases as outlined in Table 1. Furthermore, optical imaging techniques allow the detection of molecules in

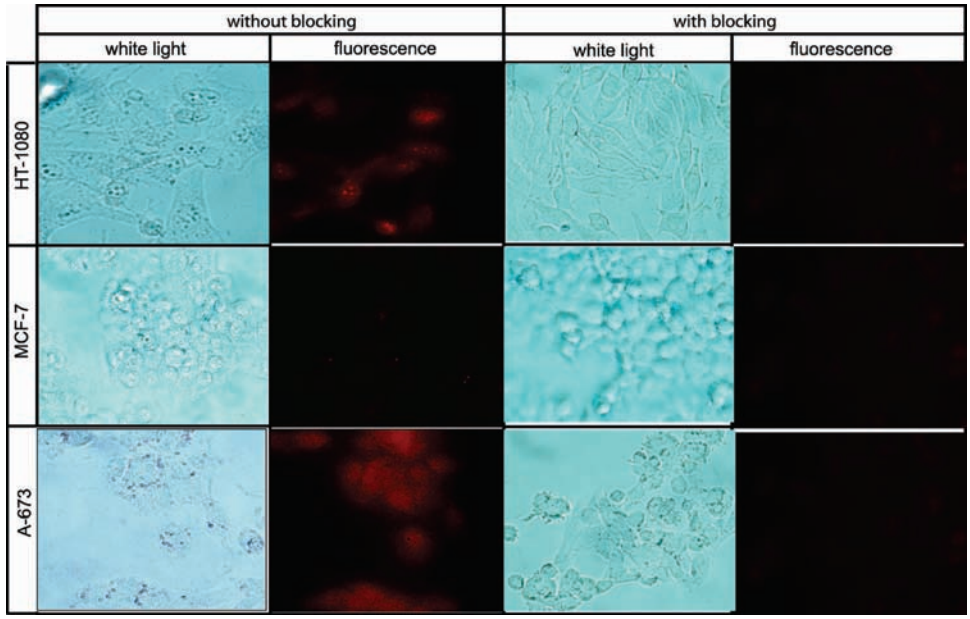

Figure 3. Fluorescence microscopy of the in vitro cellular assay of HT-1080, MCF-7, and A-673 cells, in the presence or absence of protease inhibitor **5** (50 μM) incubated with the Cy 5.5 labeled ligand **6** (2 nmol).

picomolar (10^{-12} M) concentrations, which is comparable to conventional scintigraphic imaging techniques. As well as high signal-to-noise ratios (SNRs), imaging in the near-infrared spectrum (λ = 650−950 nm) shows very efficient tissue penetration as the absorption by water and hemoglobin is relatively low ("diagnostic window") (*24*, *25*).

Chemistry. The PEGylated piperazine derivative **2** was prepared as illustrated in Scheme 1. Mesylation of tetraethylene glycol and subsequent mono-substitution with sodium azide on a large scale gave the PEGylated azide derivative **1** in a satisfactory yield. Nucleophilic substitution of the mesyl moiety with Boc-protected piperazine and subsequent deprotection with trifluoroacetic acid yielded the desired piperazine derivative **2** (*26*). To synthesize the barbiturate **3** (Scheme 2), in the first steps a Pd-catalyzed C−C bond formation followed by a condensation with urea was used (*27*). After bromination with *N*-bromo succinimide in DMF we linked the barbiturate with the PEGylated piperazine derivative **2** to get the PEGylated barbiturate **4**. For labeling with the NHS-ester of the commercially available cyanine dye Cy 5.5 it was necessary to reduce the azide function by a *Staudinger* reaction to get the precursor **5** in good yields.

Fluorochrome Conjugation. The amino functionalized compound **5** was used for the conjugation of Cy 5.5. The reaction was carried out in dry DMF with triethyl amine as the base (Scheme 3). The conjugate **6** was purified by reversed phase HPLC on an analytical column by collection of the appropriate fractions. After lyophilization and redissolving in PBS the sample showed a purity of >98% (HPLC) (Figure 1). The labeled ligand was verified by mass spectrometry with a triple negative charged ion emerging at 100% intensity. With a molecular mass of 1.45 kD the resulting probe belongs to the small molecule tracers. Moreover, the tracer's excitation and emission spectra were identical to that of the Cy 5.5 dye (Ex, 678 nm; Em, 692 nm).

In Vitro Enzyme Studies. The inhibition potencies of the barbiturates **4** and **5** and the conjugate **6** were measured for MMP-2 and MMP-9 using fluorogenic in vitro assays. The resulting MMP inhibitions were determined as IC_{50} values and calculated from a nonlinear regression fit of the concentration-dependent reaction rates. Both PEGylated barbiturates (MMP-2 and -9) and the conjugate **6** (MMP-2) show binding in the nanomolar range (Table 1), and these results were confirmed by zymography assays showing the potency of the labeled barbiturate **6** (Figure 2).

MMP-2 and -9 Transcription, Translation, and Activity Tests. For the biological characterization of **6** in vitro experiments on different cell lines were performed with respect to target expression on the genomic, proteomic, and functional level. To determine whether the chosen cell lines express and synthesize functional MMP-2 and -9, a semi-quantitative PCR analysis, Western blots, and zymography were performed. In the PCR analysis, MMP-2 and MMP-9 mRNA expression of the three human carcinoma cell lines were normalized by using the house keeping gene β-Actin. Whereas the rhabdomyosarcoma cell line A-673 expressed both MMPs, the fibrosarcoma cell line (HT-1080) only transcribed MMP-2 and the MCF-7 produced neither MMP-2 nor MMP-9 mRNA at detectable levels (Figure 2 E−G). The expression of both enzymes on the protein level was assessed by Western blotting with polyclonal antibodies against MMP-2 and MMP-9. These antibodies recognize the latent and active MMP forms and, therefore, reflect the cell lines via de novo synthesis levels of both enzymes (Figure 2 C,D). Similarly to the PCR results, Western blot analysis demonstrated that the human carcinoma cell line MCF-7 did not secrete MMP-2 and MMP-9 at detectable levels. However, activated MMP-2 (64 kDa) was secreted by HT-1080 and A-673 cells, respectively. Furthermore, in the A-673 supernatant pro-MMP-9 (92 kDa) and the active MMP-9 form (84 kDa) could be detected. Positive controls, that is, purified enzymes, give also clear signals as shown in Figure 2 C,D. The zymography perfectly corresponds to the results obtained by semiquantitative PCR and Western blot analysis. Gelatinolytic bands were visible for the cell lines HT-1080 and A-673, which secret active MMP-2 (62 kDa) with nearly similar levels. In addition to MMP-2 activity, MMP-9 (72 kDa) gelatinase activity was only detectable in the rhabdomyosarcoma cell line A-673. No gelatinase activity could be shown for the cell line MCF-7 (Figure 2 A). Incubation of the zymogram with the nonlabeled barbiturate **5** (100 μM) inhibited the MMP-2 and MMP-9 gelatinolytic activity,

completely confirming efficient binding of the probe precursor **5** (Figure 2 B). Zymographical analysis corroborated the former analysis and revealed the barbiturate **6** as a potential MMP-2 and -9 inhibitor. Therefore we used the Cy 5.5-labeled barbiturate in an in vitro cell binding assay in order to support these findings.

In Vitro Cellular Assay. Functionally active MMP-2 and MMP-9 ligands should bind to secreted MMP-2 and/or MMP-9 of monolayer cells. Indeed, a strong fluorescence signal was obtained from the surface of A-673 cells, which were shown to secret both MMP-2 and MMP-9 (Figure 3). The HT-1080 monolayer fluorescence was less powerful compared to that of A-673, and MCF-7 cells again failed to show the corresponding MMP activities. Predosing experiments using 50 μM of the unlabeled barbiturate **5** successfully blocked the binding of the Cy 5.5-labeled ligand **6** (Figure 3). In every case the cell integrity and viability were confirmed by a trypan blue test.

The aim of this work was to develop a nonpeptide MMPI with high MMP binding potency which is applicable for optical imaging of MMP-2 and -9. We have chosen a barbiturate as the lead structure and developed a route for the synthesis of an amino-PEG-derivatized compound which can be used for the conjugation of common amino-reactive fluorescent markers such as Cy 5.5. Thus, we obtained a near-infrared fluorescent photoprobe for the imaging of MMP-2 and -9. Applying semiquantitative PCR, Western blot analysis, and zymograms we checked not only the cells' transcriptional and translational levels but also their secretion levels and the functionality of the secreted MMPs. Taking this into account, the unlabeled barbiturate **5** blocked both MMP-2 and MMP-9 activities. Additional binding studies in vitro proved the inhibition capacities of the precursor **5** and revealed the specific binding capacities of the Cy 5.5-labeled ligand **6**. Thus, MMP-2 and -9 imaging with the fluorescent labeled probe **6** is feasible and should be applicable to imaging modalities to monitor activiated MMP-2 and -9 associated disease processes such as invasion, metastasis, and angiogenesis in cancer in vivo.

Factors Determining the Efficacy of Nuclear Delivery of Antisense Oligonucleotides by Gold Nanoparticles

Yanli Liu and Stefan Franzen*

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695. Received November 16, 2007; Revised Manuscript Received February 19, 2008

The present study investigates the applicability of nanoparticle delivery vectors for two-stage targeting that involves both cell entry by endocytosis and nuclear targeting using viral peptide signals. A nanoparticle vector consists of four components: a carrier nanoparticle, a stabilizer, targeting peptides, and a therapeutic cargo. Extensive study of bovine serum albumin (BSA)-peptide stabilized nanoparticle conjugates demonstrated limitations of these systems due to colloidal instability when oligonucleotides and multiple peptides were attached to the BSA protein. We found that the widely used protein streptavidin (SA) was an appropriate alternative to BSA for cell-targeting experiments. Targeting peptides and gene splicing oligonucleotides were attached to SA-nanoparticles using biotin labels. The present study uses a gene-splicing assay as a test for oligonucleotide delivery to the cell nucleus. Successful modification of gene splicing by an antisense oligonucleotide indicates that the latter must have crossed the plasma membrane, entered the nucleus, found the target sequence in the newly transcribed pre-mRNA, and hybridized to it in the spliceosome strongly enough to displace the splicing factors designed to interact with the target sequence. Targeting nanoparticles that carry gene-splicing oligonucleotides were compared with a control experiment that used lipofectamine (LF). While enhanced activity was observed in the control experiment, in the presence of LF, no gene splicing was observed for the nanoparticle targeting vectors without LF. We conclude that sequestration of cargo from the harsh conditions of the endosome is a desirable strategy for cell-targeting nanoparticles.

INTRODUCTION

A variety of approaches are available that aim to improve the efficacy of oligonucleotide delivery. One of the most common strategies for delivery of oligonucleotides to cells is to complex the nucleic acid with cationic polymers (*1, 2*) and lipids (*3*). Because of the cytotoxicity and associated problems, strategies based on complexation with cationic polymers and lipids have been primarily used for *in vitro* studies. Another approach for nucleic acid delivery is the use of viral vectors, which are adept in cell entry and cell targeting (*4, 5*). Viral vectors are widely used in gene therapies, and there has been limited application to the delivery of short oligonucleotides for antisense therapy. Moreover, viral vectors have the drawback of potential infectivity and immunogenicity. The use of a nanoparticle-based delivery vector for nuclear targeting is inspired by the cell-targeting experiments that demonstrate the use of viral targeting peptides to facilitate internalization of nanoparticles in cells and including transport into cell nuclei. In theory, such targeting vectors have the advantage of safety and simplicity.

This study investigates the applicability of nanoparticle delivery vectors for two-stage targeting that involves both entry by endocytosis and nuclear targeting using viral peptide signals. A nanoparticle vector consists of four components: a carrier nanoparticle, a stabilizer, targeting peptides, and a therapeutic cargo. Figure 1 illustrates the construction of a nanoparticle-based delivery vector that has a stabilizer and carrier protein, targeting peptide, and oligonucleotide payload. Combining both targeting and functional modification of gene expression into one targeting nanoparticle is challenging. The first challenge is to prepare and characterize the nanoparticle-based delivery vectors, which requires the assembly of the various components onto a single nanoparticle without compromising functionality of any component in the system. A second challenge is to maintain the colloidal stability of nanoparticle.

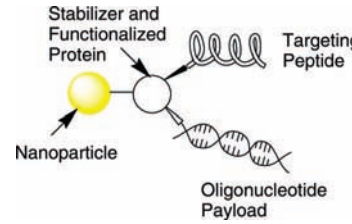

Figure 1. Illustration of a nanoparticle-based delivery vector.

The ease of synthesis and functionalization, unique optical properties, and biocompatibility of gold nanoparticles (Au-NPs) are advantages in intracellular diagnostic applications (*6–8*). These properties have recently sparked great interest in gold nanoparticles as a scaffold for cell-targeting studies (*9–12*). However, the large polarizability of Au-NPs decreases their colloidal stability (*13, 14*). Direct functionalization of stable Au-NPs by nucleic acids has provided stable formulations (*8, 15–17*), but functionalization by peptides has only been successful for a few sequences (*18*). For many years, protein stabilizers such as bovine serum albumin (BSA) have been used to improve the stability of citrate-stabilized Au-NPs as well as providing a protein layer that can be used to attach targeting peptides to the surface (*13, 19, 20*). The steric stabilization of proteins such as BSA is a key aspect of their application. Citrate-coated Au-NPs rapidly aggregate and precipitate at their isoelectric point. However, using ζ-potential measurements we have determined that BSA-stabilized Au-NPs are stable at their isoelectric point

and the pI of both Au-NPs and BSA is nearly the same, pI ~ 4.6 (*14*). Both BSA and Au-NPs are negatively charged at neutral pH, which provides electrostatic stabilization in addition to the steric stabilization. However, BSA-coated nanoparticles will aggregate when the BSA is cross-linked to basic peptides that increase the pI of the bioconjugate to a range that was not stable under physiological conditions (pH 7.4). The combination of peptides and oligonucleotides presents a further problem for colloidal stability BSA conjugates with nanoparticles. Streptavidin (SA) was identified as an appropriate alternative bioconjugation protein for cell-targeting experiments. SA is a tetrameric protein from *Streptomyces avidinii* that has strong biological and noncovalent affinity with the vitamin biotin ($K_d = 10^{-15}$ M) (*21*). SA can be easily attached to colloidal gold and streptavidin-conjugated Au-NPs of different sizes are readily available. Using this approach, we tested whether Au-NPs can both target a cell using peptide signals and carry an antisense cargo to the nucleus.

Virus-mimetic targeting peptides provide one method of cellular and nuclear targeting that can be applied to Au-NP conjugates. For example, the combination of two short peptides adapted from adenoviruses can promote receptor-mediated endocytosis (RME) via the coxsackie-adenoviral receptor (CAR) or the CD46 receptor and nuclear targeting via a nuclear localization signal (NLS) peptide that interacts with importin α/β and promotes transit through the nuclear pore complex (*19*). The sequences were derived from the full-length adenoviral fiber peptide, which has the ability to target CAR, CD46, and the importins (*22, 23*). Nanoparticles solubilized by BSA conjugates carrying peptides singly and in combination were used to show that a full-length peptide containing both CAR and CD46 was less effective for nuclear targeting than two shorter peptides that contained the same sequence information (*19*). The Arg-Gly-Asp (RGD) motif, naturally found in a number of proteins including laminin and fibronectin, has been used to target several cell lines (*24, 25*). RGD interacts with several surface receptors, most prominently the CD51 family. HeLa cells strongly express the CD51 receptor at a level of ~200 000 antibody binding receptors per cell (*26*). The most commonly used NLS peptide, the SV40 large T-antigen-derived NLS (PKKKRKV), can facilitate nuclear uptake of non-nuclear proteins with a molecular weight up to 465 kDa (*27*). Peptides can have more than one function, permitting cargo such as DNA (*28*) or Au-NPs (*20*) to be transported to the nucleus. While these methods have application for large cargo such as genes or nanoparticles, the use of targeting methods to transport smaller antisense oligonucleotides has been less well explored.

Antisense oligonucleotides have attracted attention as promising therapeutic agents (*29–31*). Applications of antisense oligonucleotides include both down-regulation of gene expression (*32–35*) and modulation of gene splicing (*29–31*). Antisense oligonucleotides are short sequence of nucleotides (DNA, RNA, or a chemical anologue) typically with 25 or fewer bases, which are designed to be complementary to a specific type of mRNA or precursor mRNAs (pre-mRNAs). The use of native RNA oligonucleotides in therapy has been limited because they are easily degraded by nucleases. Modified oligonucleotides such as 2′-*O*-methylphosphonate, phosphorothioate, morpholino (*36*), and peptide nucleic acid (PNA) (*37*) have shown resistance to nuclease degradation (*29, 38*). Antisense therapy is limited by the low intrinsic ability of oligonucleotides to target cells.

The present study uses a gene splicing assay (*39*) as a test for oligonucleotide delivery to the cell nucleus. Successful modification of gene splicing by an antisense oligonucleotide indicates that the latter must have crossed the plasma membrane, entered the nucleus, found the target sequence in the newly transcribed pre-mRNA, and hybridized to it in the spliceosome strongly enough to displace the splicing factors designed to interact with the target sequence. Moreover, a new product alternatively spliced mRNA is generated, which can be easily detected on a low background. Thus, apart from potential clinical applications, modification of splicing can be used as a positive readout assay to determine whether functional oligonucleotides have been delivered to the splicing machinery within the cell nucleus. In this model system, HeLa cells are stably transfected with a recombinant plasmid (pLuc/705) carrying the luciferase gene interrupted by a mutated human β-globin intron 2 (IVS2–705). The mutation in the intron causes aberrant splicing of luciferase pre-mRNA, preventing translation of luciferase (Luc), unless corrected by the presence of an antisense oligonucleotide targeted to the splice site. The splice correction assay therefore measures the ability of antisense oligonucleotides to correct splicing of an aberrant intron inserted into the Luciferase gene.

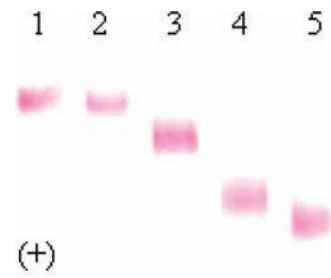

Figure 2. 1% Agarose gel electrophoresis of ON705-SA-Au-NPs. Lane 1: SA-Au-NPs with added ratio of SA/Au-NP of 500:1. Lanes 2–5: ON705-SA-Au-NPs with increasing ratios of ON705 to Au-NP of 100, 200, 300, and 500, respectively.

By using this positive readout assay, we have examined whether the presence of the nanoparticles (Au-NPs and quantum dots) and peptides affect the ability of oligonucleotides to interact with their nucleic acid target. These studies provide new insights into the possibilities and limitations of the biological applications of multifunctional nanoparticles.

RESULTS

Assembly and Characterization of the Particles Containing Peptides and/or Oligonucleotides. Agarose gel electrophoresis (1%) was used to confirm the binding of SA to Au-NPs and the binding of peptides and RNA oligonucleotides (ON705) to SA-Au-NPs. Citrate-coated Au-NPs tend to aggregate in the running condition of gel electrophoresis due to the high ionic concentration of the running buffer. The migration of the Au-NPs as shown in lane 1 of Figure 2 indicated that SA stabilized the particles and the charge/mass ratio of the particles was changed. Thus, it was confirmed that SA was bound to the Au-NPs. The gel shifts between lane 1 and lanes 2–5, respectively, confirmed the binding of biotin-labeled ON705 to SA-coated Au-NPs. The charge/mass ratio of the particles increased as more biotin-labeled ON705 was attached to particles. Saturation of biotin-labeled ON705 on SA-Au-NP occurred at a molar ratio of biotin-labeled ON705 to gold of roughly 500:1. Similarly, the distance difference of band migrations revealed in Figure 2 confirmed the binding of peptide large T to Au-NPs as well as the formation of mixed monolayer of peptides and oligonucleotides on SA-Au-NPs with different molar ratio of peptide to oligonucleotides.

Dynamic light scattering (DLS) also qualitatively confirmed the binding of SA and ON705 to Au-NPs. These data showed an increase in the hydrodynamic diameter (nm), which is expected following the binding of SA/oligonucleotides/(SA + peptide)-SA to citrate-coated Au-NPs (Table 3). These results also confirmed that the size of the nanoparticle conjugates was

compatible with the nuclear pore complex (<40 nm) (*40*). Fluorescence spectroscopy was employed to determine the surface coverage of SA and thiolated-oligonucleotides on Au-NP (*15*), and it was found that the surface coverage for SA was 14 ± 2 pmol/cm^2 and for thiolated-oligonucleotides was 26 ± 3 pmol/cm^2.

Once the ON705-SA-Au-NPs were prepared and characterized by UV–vis spectroscopy, gel electrophoresis, DLS, and fluorescence microscopy, they were tested in cell growth medium. One concern with the present formulation is that ON705 could dissociate from Au-NP surfaces once the ON705-SA-gold vectors were incubated with LF in a cell medium, which contains various proteins and high concentrations of salts. In order to test whether such dissociation occurs, gel electrophoresis was performed on two samples: the ON705-SA-Au-NPs and the incubation mixture of LF and ON705-SA-Au-NPs with Opti-MEM supplemented with 10% FBS. The band shift was observed for both samples (data not shown), confirming that ON705 was bound to the Au-NPs and did not dissociate from the nanoparticle surfaces.

Colloidal Stability of Nanoparticle Formulations. The colloidal stability of Au-NP formulations is sensitive to the ionic strength of the solution. An increase in ionic strength compresses the ionic double layer and thereby reduces the electrostatic repulsion between particles. When van der Waals attraction due to Au-NP polarizability outweighs electrostatic and steric repulsion, the Au-NPs aggregate. To determine the stability of the Au-NPs afforded by the combination of the stabilizer protein (SA), targeting peptides and oligonucleotides, a critical coagulation concentration (CCC) assay was conducted at various stages of the formulation of the targeting nanoparticles. In this assay, concentrated NaCl was added to a given Au-NP preparation in aliquots until precipitation was observed. Citrate-stabilized Au-NPs have a CCC of 50 mM NaCl. Cell media contains approximately 150 mM NaCl. Consequently, citrate-stabilized Au-NPs form a precipitate immediately upon the addition of Au-NPs into cell media. This can be easily observed in a phenol-free DMEM medium by a color change from red to blue. On the other hand, the formulations using SA as a stabilizer and for conjugation were all observed to be stable in cell media. It was found that SA-Au-NPs were stable in solutions containing up to 800 mM NaCl. ON705-SA-Au-NPs were stable in solutions up to 1 M NaCl. On the other hand, thiolated ON705-Au-NPs were stable in solutions up to 500 mM NaCl. The stability of (ON705 + peptide)-Au-NPs varied as different types of peptides were used. All the formulations of (ON705 + peptides)-Au-NPs that were studied in cell culture were stable in up to 300 nM NaCl solution.

Antisense Activity of Au-NP Conjugates Examined by the Luciferase Assay System. The antisense activity of Au-NPs loaded with ON705 oligonucleotides was studied using pLuc 705 HeLa cells. The Luc expression assay provides a means to quantitatively study the delivery of antisense agents for the alteration of gene splicing (*18*). By performing a Luc assay with Au-NPs carrying only ON705 oligonucleotides, which were transfected with LF, it was found that the oligonucleotides were able to reach the nucleus and interact with mRNA in the splicesome to correct the splice defect.

The expression of Luc was measured for increasing concentrations of ON705 both conjugated to Au-NPs and as a free oligonucleotide at a constant LF concentration (8 μg/200 μL). LF concentration is reported as it is measured in terms of the mass per well. Figure 3 shows that the Luc level reached a maximum at 0.3 μM of ON705 and then decreased to near-background levels at 1.0 μM in agreement with a previous report (*18*). This phenomenon has been explained as the dependence of the charge ratio of oligonucleotide to cationic lipid. At 8 μg of LF, the optimum value was 0.3 μM. Excess oligonucleotide results in a decrease in Luc expression because the LF complex is not able to neutralize the negative charge as effectively (*39*).

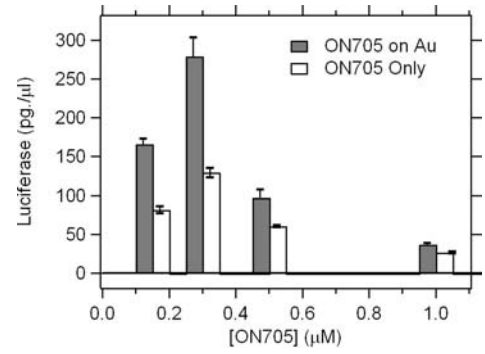

Figure 3. Relative antisense as a function of the concentration of ON705-gold and ON705 only with 8 μg of LF/ 200 μL solution in pLuc 705 HeLa cells. The maximum in activity reproduces previous studies of the concentration dependence of ON705 activity.

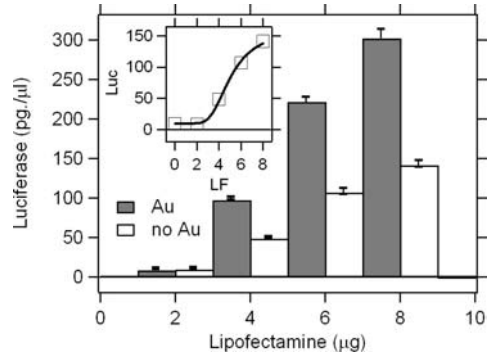

Figure 4. Relative antisense activity of ON705-Au-NPs and ON705 RNA only with a fixed concentration of ON705 (0.3 μM) in pLuc 705 HeLa cells as a function of the LF concentration. Comparisons were using 2, 4, 5, and 8 μg of LF per well volume of 200 μL. The inset shows the ON705 only data fit to a sigmoidal function.

Fixed concentrations of both ON705 and nanoparticles with increasing concentrations of LF were tested to study the dependence of antisense activity on LF concentration. The antisense activity increased in proportion to the LF concentration from 2 μg to 8 μg LF per well volume of 200 μL. In the experiment shown in Figure 4, the presence of Au-NPs was also compared without the addition of targeting peptides. In this experiment, it was found that Luc expression increased as LF concentration increased in an approximately sigmoidal fashion that can be modeled in terms of the equilibrium interaction between LF and ON705. Both Figures 3 and 4 show that Au-NPs facilitate the uptake of ON705 by a factor of 2 under all conditions where Luc protein is measured above the background level.

Relative Antisense Activity of Au-NPs Modified with Both Peptides and Oligonucleotides. Six formulations of targeting peptides using single- and double-labeled Au-NPs with virus peptides were prepared using the conjugation chemistry described above. The peptide sequences are given in Table 1 and the formulations are illustrated in Figure 5. The formulations were tested using the Luc expression assay. The data showed that, under the current experimental conditions, peptides did not enhance the nuclear targeting of oligonucleotides modified with Au-NPs in the absence of LF (Figure 6). Formulation 1 was the positive control consisting of 0.3 μM ON705 with LF. Control experiments performed with SA-modified ON705 and peptide at the same concentration (0.3 μM ON705) did not show any difference in the level of Luc expression compared to free

[a] All peptides have a fluorescence label at N-terminal and biotin nova tag at C-terminal.

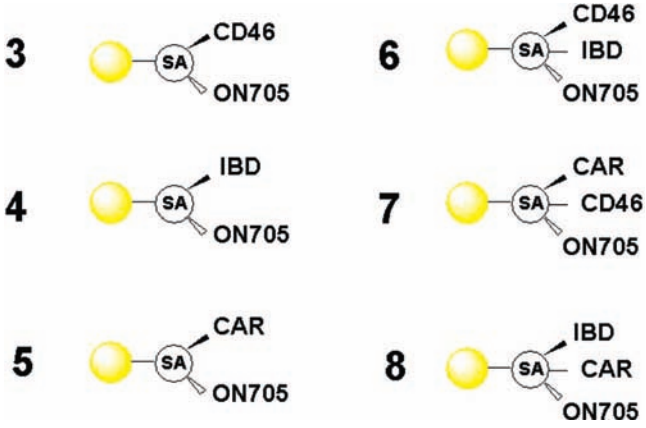

Figure 5. Representative nanoparticle formulations including one targeting peptide and an oligonucleotide payload. The stabilizer protein is streptavidin. The numbers correspond to the formulations in Figures 5 and 6.

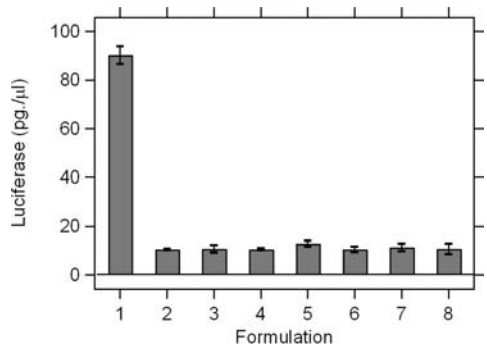

Figure 6. Relative antisense activity of Au-NPs modified with peptide and ON705 in the absence of LF detected as Luc expression. Formulation 1 was the positive control, consisting of free ON705 + LF. Formulation 2 was a negative control consisting of ON705 without LF. Formulations 3–8 are described in Figure 4. Concentrations of ON705, peptides, SA, and Au-NPs were 0.3 μM, 0.3 μM, 0.15 μM, and 6 nM, respectively.

ON705 (data not shown). Figure 6 shows that Luc was produced at the level of 90 pg/μL. Formulation 2 consisted of the same 0.3 μM ON705, but without any LF. The Luc produced in these cells was decreased 9-fold to 10 pg/μL. None of the preparations 3–8 using Au-NPs with targeting peptides and same total concentration of ON705 produced any Luc above the background level.

However, the same formulations of Au-NPs did target the nucleus of cells in the presence of LF as shown in Figure 7. Formulation 1 was the same positive control used in Figure 6 (also Formulation 1). Formulation 2 consisted of an LF-only experiment. The level of Luc expression in this experiment was 10 pg/μL, which is the same level of expression observed in the ON705-only experiment (formulation 2 in Figure 6). Formulations 3–8 showed an increase in Luc expression by a factor of 2, which is also the level of increase seen in the ON705-Au-NP experiments shown in Figures 3 and 4.

Relative Antisense Activity of QD Formulations. SA-modified QDs were coupled with peptides and ON705 to target

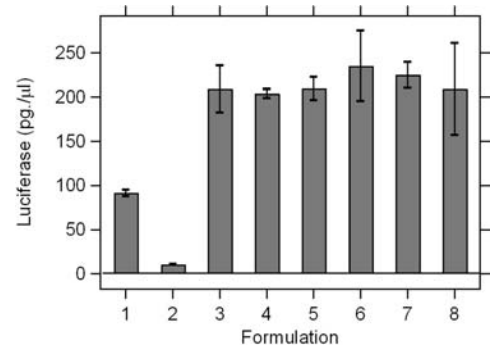

Figure 7. Relative antisense activity of Au-NPs modified with peptide and ON705 in the presence of LF detected as Luc expression. Formulation 1 was positive control, free ON705+ LF. Formulation 2 was a negative control consisting of LF without ON705. Formulations 3–8 are described in Figure 4 except that they each were combined with LF. Concentrations of ON705, peptides, SA, and Au-NPs were 0.3 μM, 0.3 μM, 0.15 μM, and 6 nM, respectively.

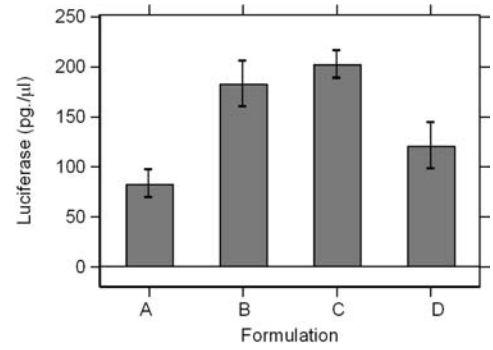

Figure 8. Comparison of relative antisense activity of Au-NPs with two different linkers and QDs in the presence of LF. Formulations correspond to the designations in Table 4.

D	biotin	QD	ON705-SA-QD

nucleus of the cells and correct aberrant pre-mRNA splicing. Similar results were obtained as those reported above using Au-NPs. The comparison given in Figure 8 shows that, although the QD (shown as formulation D in Figure 8 and Table 4) shows uptake in the presence of LF, it does not give greater uptake than Au-NPs. QDs did boost the Luc expression level in the presence of LF relative to ON705 alone. However, in the case

of QDs, the increase was approximately 50% rather than a factor of 2 (formulations A and D in Figure 8). Finally, as observed with Au-NPs, none of the 5 peptides tested enhanced the nuclear uptake of the Au-NPs in the absence of LF (data not shown).

Comparison of Bioavailability of Thiolated ON705 with Biotinylated ON705. A study of the relationships between the bioavailability of ON705 on two types of Au-NPs was made. The comparison in Figure 8 is shown in formulations B (biotinylated) and C (thiolated) as given in Table 4. Although the ON705 only Au-NP was taken up in the presence of LF, extensive experimentation using thiolated targeting peptides resulted in failure to create a stable formulation that combined targeting peptides and ON705.

DISCUSSION

In this study, we have employed a splice variant of the β-thalessemia intron as an assay for evaluating functional cellular uptake and nuclear targeting of the oligonucleotides conjugated to an Au-NP and QDs. The splice variant assay is specific for quantifying the uptake of multifunctional nanoparticles into the nucleus and for functional interaction with the spliceosome. A positive readout in the Luc assay provides information on the expression of Luc in an assay that involves tens of thousands of cells ($\sim 10^5$ cells per well of a 24-well plate). The results of this study indicate that the pLuc 705 reporter gene-splicing assay is an excellent method for a comparative study of antisense applications specific to nuclear targeting.

The Luc assay revealed that the antisense oligonucleotide ON705 was available to hybridize with pre-mRNA and functioned as a gene-splicing modifier according to its design. The studies showed that the availability of ON705 for gene splicing was not strongly dependent on the kind of chemical linker used or the presence of targeting peptides. Moreover, it was found that ON705 had a 2-fold increase in gene splicing efficiency when tethered to a Au-NP in the presence of LF. In the absence of LF, there was no increase in gene splicing above background. One possible explanation for the increased gene splicing efficiency is that the local density of ON705 attached to Au-NPs was significantly increased compared to free oligonucleotides in the cell media. The experiments were carried out at the ON705 concentration of maximum effective action (Figure 3) so that it is not possible for a minority population of free ON705 to give a signal that would compete with the population bound to nanoparticles (*39*). The fact that the assays showed enhanced expression of Luc in the presence of LF demonstrates that neither the preparation nor the colloidal stability of the nanoparticles is responsible for the lack of Luc expression.

The role of LF is well-known for transfection of genes, antisense oligonucleotides, and RNA interference applications. Commercially available Lipofectamine 2000 (LF) is a proprietary cationic lipid basically consisting of a positively charged headgroup and hydrocarbon chains. The positive charge interacts with the phosphate backbone of the nucleic acid and the negatively charged cell membrane, allowing the fusion of the liposome/nucleic acid with the cell membrane, forming a membrane-bound vesicle. After endocytosis, the complex escapes the endosomal/lysosome pathway, diffuses through the cytoplasm, and enters the nucleus of the cell. The use of gold nanoparticles as an aid to LF was not contemplated in this study, but was observed in the control experiments.

The results obtained here can be compared to cell-targeting studies for gene therapy and delivery of proteins. Nuclear targeting has been demonstrated using SA functionalized with targeting peptides attached to biotinylated DNA. Addition of the NLS peptide increased both nuclear uptake and expression of DNA after microinjection into the cytosol of HeLa cells (*41*). A 21-residue peptide carrier, Pep-1, has been used for protein (*42*) and quantum dot (*43*) internationalization. The peptide consists of a hydrophobic tryptophan-rich domain for efficient cell membrane translocation and the hydrophilic lysine-rich domain derived from the SV-40-T antigen NLS to facilitate solubility and nuclear targeting. The Pep-1 has been shown to be extremely efficient in the targeting of proteins into cells independent of endocytosis (*42*). Pep-1 is an example of a peptide transduction domain (PTD), which is sequence of cationic amino acids that interact with the cell membrane to facilitate entry via a route that is not believed to involve RME. Cationic peptides also have a known function in a manner that may have similarity to LF. However, PTDs in combination with Au-NPs have not yielded promising results. One reason for the lack of success with PTDs may be that cationic peptides tend to increase the pI of carrier proteins such as BSA and thereby reduce the colloidal stability of the nanoparticle.

The observations reported here indicate that nanoparticle integrity is compromised at some point during uptake in the cell. In the absence of LF, this could occur during receptor binding, endocytosis, escape from endosome/lysosome, cytosolic trafficking, or nuclear localization of nanoparticle vectors. Given that cellular internalization and nuclear targeting have been observed in independent experiments (*19*, *20*), it is unlikely that there is a problem with interaction with cell receptors. On the other hand, the nanoparticles could be endocytosed and then trapped in endosomes/lysosomes. The results here suggest multiple pathways could be involved in the process of cellular internalization and targeting (*44*, *45*). The degree to which each pathway contributes to the overall uptake and intracellular distribution depends on a variety of factors, including the structure of the peptide itself, peptide exposure, the loading density of peptide signal on the particle surface (*46*, *47*), the structure of the chemical linkage between the peptides, oligonucleotides, and nanoparticles, as well as the cell type.

CONCLUSION

The results obtained indicate that antisense oligonucleotides bound to nanoparticles are bioavailable to interact with pre-mRNA in the nucleus of the cells only under certain conditions. In the presence of LF, Au-NPs enhance the delivery efficiency of the antisense oligonucleotide ON705 compared to the control. However, the intrinsic targeting ability of the oligonucleotides attached to Au-NPs was not improved by the conjugation of targeting peptides that facilitate endocytosis or uptake. The results indicate that a strategy based on surface attachment of oligonucleotides or other therapeutic cargo has the potential for loss or degradation of the of the oligonucleotide cargo in cell-targeting experiments. Transit through endosomes results in the exposure of surface-attached molecules to harsh conditions that may compromise their efficacy in cell-targeting experiments. For this reason, sequestration of cargo inside a cage (*48–50*) may provide a mode-effective method for delivering cargo to cells.

MATERIALS AND METHODS

Nanoparticles and Targeting Peptide Preparations. Citrate-coated Au-NPs (10 and 20 nm in diameter) were purchased from Ted Pella. Streptavidin (SA) coated nanocrystals (CdSe/ZnS), QD605, were purchased from Quantum Dot Corporation. Streptavidin (SA) was purchased from Pierce. Texas Red-labeled streptavidin was purchased from Biomeda Corporation. Tris−HCl prepacked PAGE gels, native sample buffer, and biosafe Coomassie G250 stain were purchased from Bio-Rad. Agarose DNA grade, tris-boric acid-EDTA (TBE) 5× buffer, tris−glycine 10× buffer, and 20× saline−sodium citrate solution were purchased from Fisher Scientific. Dulbecco's modified Eagle's medium

(DMEM), fetal bovine serum (FBS), and Dulbecco's phosphate-buffered saline (DPBS) were purchased from BioWhittaker. Opti-MEM reduced serum medium and Lipofectamine (LF) were purchased from Invitrogen. pLuc 705 HeLa cells were a gift from R Kole at Lingberger Comprehensive Cancer Center at University of North Carolina at Chapel Hill. The Luciferase Reporter Assay kit was purchased from Applied Biosystem International (ABI, Foster City, CA).

The peptide sequences investigated in this work (Table 1) were synthesized by The University of North Carolina Peptide Synthesis Facility, purified by HPLC, and supplied in lyophilized form. The oligonucleotides were custom-ordered from MWG-Biotech (Ebersberg, Germany) or Integrated DNA Technologies (IDT, Coralville IA). The ON705 sequence was ordered as a free 18-mer RNA, a 5′-thiolated RNA, or a biotinylated and pegylated RNA (Table 2).

All UV–vis absorption measurements were acquired on a Hewlett-Packard 8453 Chemstation Photo Diode Array Spectrophotometer with attached Chemstation software.

Fluorescence intensity data were obtained using a Perkin-Elmer luminescence spectrometer LS50B or a BioTek FL-600 plate reader. Dynamic light scattering (DLS) measurements were obtained on a Malvern Zetasizer 1000.

Preparation of Streptavidin (SA) Coated Au-NPs. One milligram SA was dissolved in 1 mL of 10 mM phosphate-buffered saline (PBS) to produce a 16.7 μM SA stock solution. 140 μL of the above solution was added into 500 μL of 9.5 nM citrate-capped Au-NPs (10 nm in diameter), producing a molar ratio of SA to Au-NP of 500:1. The mixture was vortexed and then incubated at room temperature for at least half an hour. The excess SA was removed by centrifugation at 13 000 rpm for 20 min. The pellet was resuspended in 500 μL of PBS buffer.

Determination of Surface Coverage of Streptavidin (SA) on Au-NPs. In order to obtain the binding isotherm of Texas Red labeled streptavidin (TR-SA) on Au-NP surfaces, different surface coverages of SA on Au-NPs were prepared. For example, 10 nm Au-NPs (500 μL of 9.5 nM) were mixed with 63 μL of TR-SA solution (18.9 μM in PBS), producing a molar ratio Au/TR-SA of 1:250. After stirring for 30 min, those sols were centrifuged at 13 000 rpm for 15 min. Supernatants containing unbound proteins were carefully removed from the pellets, followed by washing the sediments with 200 μL of phosphate buffer two more times. All the supernatants for each sample were collected and then diluted to 1 mL. A standard curve was created by measuring the fluorescence intensities of TR-SA solutions ranging from 0.078 μM to 10 μM in 10 mM phosphate buffer (pH 7.4) and was used to determine the concentration of unbound TR-SA in the supernatant solution. The amount of TR-SA molecules bound on the nanoparticle surface was calculated by subtracting free TR-SA from the total amount of TR-SA added initially. The ratio TR-SA/AuNP was determined by measurement of the Au-NP concentration using the extinction coefficient of $\epsilon = 5 \times 10^8\ M^{-1}\ cm^{-1}$ to calculate the concentration.

Preparation of Peptide-Modified QDs. The peptides were incubated with SA-modified QDs (~10–15 nm in diameter) at a molar ratio of 10:1 to 20:1 in phosphate buffer saline (PBS) with 20 min of reaction time. The incorporation of biotinylated peptides onto the SA-QD conjugates under these conditions is best probed by gel electrophoresis, where the ratio of peptide/QDs spans from 1:1 to 50:1.

Preparation of ON705-SA-Au-NPs. The oligonucleotide ON705 was incubated with 1 mL of SA-coated Au-NPs (10 nm in diameter) at molar ratio of 75:1 in PBS. After 45 min, the mixture was centrifuged at 13 000 rpm for 20 min, and the pellet was washed 2 more times with PBS. The resulting nanoparticles were resuspended in 1 mL of PBS.

Preparation of (ON705 + peptides)-SA-Au-NPs. The peptides were mixed with ON705 in either a 1:1 or 2:1 molar ratio before mixing with 1 mL of Au-NPs (10 nm in diameter). The mixtures were incubated at room temperature for 1 h and purified by centrifugation (2×, 13 000 rpm for 20 min). The modified nanoparticles were resuspended in 1 mL of PBS buffer.

Preparation of ON705-Thiol (S)-Au-NPs. Oligonucleotide-modified Au-NP conjugates were prepared as previously described with a few modifications (*8*, *15*). Briefly, 50 μL of a 47.5 μM of oligonucleotide solution was added to 500 μL of 10 nm diameter Au-NPs (9.5 nM). The molar ratio of the final concentration of oligonucleotides to colloid was 400:1. The samples were placed into a water bath at 37 °C for 8 h, after which the solution was gradually brought to 0.1 M NaCl/10 mM Na phosphate pH 7.4. The samples were left in the solution for an additional 16 h at 37 °C. Then, samples were centrifuged at 13 500 rpm for 15 min three times, with 2× wash using 500 μL of 0.1 M NaCl/10 mM Na phosphate pH 7.4 in between to remove excess oligonucleotides. The final pellet was resuspended in 500 μL of 10 mM Na phosphate. Since a small amount of Au-NPs was discarded with the supernatant in the washing procedure, the corresponding nanoparticle concentration was determined by UV–visible absorption spectroscopy.

Determination of Surface Coverage of Oligonucleotides on Particle Surface. The quantification method to determine the surface coverage of oligonucleotides on the nanoparticle surface was mainly based on the literature procedure (*15*). Briefly, mercaptoethanol (ME) was added (final concentration 14 mM) to Au-NPs (20 nm in diameter) modified with fluorescein-labeled oligonucleotides in 10 mM phosphate, 0.1 M NaCl, pH 7.4. After 15 h incubation at room temperature with intermittent shaking, the solutions containing displaced oligonucleotides were separated from the gold by centrifugation at 10 500 rpm for 15 min three times, with 2× wash using 200 μL of 10 mM Na phosphate pH 7.4 in between in order to collect all free fluorescein−oligonucleotides. Standard linear calibration curves were prepared with known concentrations of fluorescein−oligonucleotides using identical buffer and ME concentrations. The fluorescence intensities were converted to molar concentrations of fluorescein−oligonucleotides by interpolation from a standard curve.

Determination of Critical Coagulation Concentrations (CCC). To determine the critical coagulation concentration (CCC) of SA, peptides, and oligonucleotides modified Au-NPs, a series of Eppendorf centrifuge tubes containing 500 μL of identical concentrations of Au-NPs (1.16 nM for 20 nm diameter and 9.4 nM for 10 nM) were prepared. Increasing volumes of a 1.7 M NaCl stock solution were added to each sample with the final salt concentration ranging from 20 mM to 1 M. The tubes were vortexed and then allowed to incubate for at least 3 h. Aggregation was assessed by monitoring changes in the characteristic Au-NP plasmon frequency. The threshold NaCl salt concentration in the gold sol, which caused the rapid aggregation of the particles, is determined as the CCC.

Nanoparticle Transfection with pLuc HeLa Cells. The experimental protocols were similar to those previously described (*18*). Briefly, The pLuc HeLa cells were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS) at 37 °C in a humidified atmosphere with 5% CO_2. HeLa 705 cells were grown in 24-well flasks to 95% confluency. The cells were washed twice with Dulbecco's phosphate-buffered saline (DPBS). The control experiments were performed with (1) mock transfected pLuc 705 cells, i.e., cells were incubated with media only or media containing LF; (2) free oligonucleotides in the absence of LF; (3) free oligonucleotides in the presence of LF. Au-NPs modified with ON705 were purified in order to remove excess ON705.

The nanoparticles incubated with cells were tested in two conditions as well: with or without the presence of LF.

The samples were mixed in Opti-MEM reduced serum media. For example, a 0.1 mL aliquot of an oligonucleotide at a given concentration (0.3 μM) in Opti-MEM was mixed with 8 μg of Lipofectamine to make a total volume of 200 μL. After being mixed, the preparation was left at room temperature for 15 min, followed by dilution to 1.0 mL with Opti-MEM. The cells were incubated at 37 °C for 4 or 5 h. The final concentrations for all oligonucleotides with or without nanoparticles were 0.15 μM. Subsequently, the media was replaced with DMEM containing 10% FBS. After an additional 18 h, the Luc reporter assay was performed following manufacturer's protocol (ABI). All experiments were done in triplicate.

ACKNOWLEDGMENT

We thank R. Kole for the gift of the Luc HeLa cell line that contains the Luc gene with a β-thalessemia intron. We acknowledge support from NIH grant CA098194.

Cellular siRNA Delivery Mediated by a Cell-Permeant RNA-Binding Protein and Photoinduced RNA Interference

Tamaki Endoh, Masahiko Sisido, and Takashi Ohtsuki*

Department of Bioscience and Biotechnology, Okayama University, 3-1-1 Tsushimanaka, Okayama 700-8530, Japan. Received January 14, 2008; Revised Manuscript Received March 21, 2008

HIV-1 TAT peptide, which is a cell-penetrating peptide (CPP), was fused to the U1A RNA-binding domain (TatU1A) to generate a sequence-specific siRNA delivery system for mammalian cells. The siRNA contained a short 5′-extension that is specifically recognized by the U1A RNA-binding domain (*U1A*siRNA). Specific binding of TatU1A to the *U1A*siRNA was confirmed using a gel mobility shift assay. The *U1A*siRNA was internalized by cells only when it was preincubated with TatU1A before addition to the cells. Although most of the internalized siRNA seemed to be entrapped in endocytic compartments, efficient redistribution of the entrapped siRNAs was achieved by photostimulation of a fluorophore attached to TatU1A. Once in the cytoplasm, the siRNA induced RNAi-mediated gene silencing. We refer to this delivery strategy as CLIP-RNAi. CLIP-RNAi is a promising strategy for RNAi experiments and for pinpoint RNAi therapy.

INTRODUCTION

RNA interference (RNAi), discovered in *Caenorhabditis elegans*, is a phenomenon in which gene expression is down-regulated by a double-stranded RNA containing a sequence homologous to a specific gene (*1*). In mammals, the introduction of short double-stranded RNAs, termed small interfering RNAs (siRNAs) or short hairpin RNAs (shRNAs), into the cytoplasm can silence genes (*2–4*). RNAi-mediated gene silencing is now an essential method for analyzing protein function and an attractive therapeutic tool for interfering with the expression of undesirable genes such as oncogenes and viral genes. Experimental techniques to introduce siRNAs or shRNAs into mammalian cells usually involve either direct delivery of RNA or introduction of a gene encoding an shRNA (*5*). In therapeutic use, the latter strategy could cause undesirable gene recombination. Thus, an efficient and safe method for direct RNA delivery is essential for RNAi therapy.

Recently, cell-penetrating peptides (CPPs), such as partial sequences of the HIV-1 TAT protein and the *Drosophila* Antennapedia homeodomain, have been used to deliver fused or conjugated macromolecules into cells (*6–9*). CPPs enable the delivery of biologically active molecules into mammalian cells with high efficiency and low toxicity (*10, 11*).

To deliver siRNAs, several groups have covalently linked CPPs to siRNAs by introducing an amino or thiol group at one terminus of the siRNA (*12–14*). However, siRNAs can be introduced into mammalian cells by noncovalent, electrostatic conjugation to CPPs (*15–17*), a method which is much easier than covalent linking. One possible drawback of the noncovalent conjugation strategy is that the carrier molecule has no sequence specificity for the RNA. A nonspecific carrier could internalize naturally occurring extracellular RNAs (*18*, *19*) into cells, which may cause unexpected results. Thus, a cell-penetrating peptide or protein that noncovalently binds a specific RNA sequence is needed.

The U1 small nuclear ribonucleoprotein A (U1A) has a relatively small RNA binding domain (RBD) of 98 amino acids at its N-terminus. The U1A RBD recognizes a short RNA sequence with high specificity and affinity (*20, 21*). In this study, we genetically fused the U1A RBD to the HIV-1 TAT peptide (-YGRKKRRQRRR-), a well-characterized CPP. As a cargo partner, we prepared siRNAs bearing a short sequence that binds to the U1A RBD (*U1A* RNA sequence) and examined the specific binding of the fused protein (TatU1A) to the cargo RNA and internalization of the complex. We also examined the photoinduced release of RNA from endosomes, since internalized TatU1A/RNA complexes were entrapped in the endosomes. We refer to this delivery system as CLIP-RNAi (CPP-linked RBP-mediated RNA internalization and photo-induced RNAi).

EXPERIMENTAL SECTION

Plasmid Construction. Coding sequences for the TAT peptide and U1A RBD (amino acids 2 to 98) (*22*) (TatU1A) fusion construct were prepared by PCR ligation using two-step PCR. For the first PCR, the U1A RBD was amplified from human cDNA (Ambion Inc.) using the following primers: 5′-GGCAGTTCCCGAGACCC-3′ and 5′-GCGCTCGAGT-TATTTCATCTTGGCAATGATA-3′ (3XhoU1A). Double-stranded DNA encoding the Tat peptide was prepared by primer extension using the following primers: 5′-CATCATCACAG-CAGCGGCTACGGCCGCAAGAAACGCCGCCAGCGCCG-TCGCGGCTACCCA-3′ and 5′-CGGGTCTCGGGAACTGCG-CCGCTAGCGTAATCCGGAACATCGTATGGGTAGCCGCG-ACGGC-3′. For the second PCR, the first PCR product and primer extension product were ligated by PCR using 5′-GGCGCCATGGGCAGCCATCATCATCATCATCACAGCA-GCGGCTACGGC-3′ and 3XhoU1A as primers. The coding sequence of TatU1A was cloned into the *Nco* I−*Xho* I site of pET-28b to construct the expression vector pET-TatU1A.

Expression vectors for U1A RBD only [U1A(-Tat)] and TatU1A bearing a C-terminal Cys (TatU1A-C) were constructed from pET-TatU1A using the QuickChange Site-Directed Mutagenesis Kit (Stratagene). Mutagenesis was performed using two sets of primers: 5′-CACAGCAGCGGCTACGGCTAC-CCATACGATGTTCC-3′ and 5′-GGAACATCGTATGGG-TAGCCGTAGCCGCTGCTGTG-3′ for preparation of the U1A(-Tat) expression vector, and 5′-CAGATATCATTGCC-AAGATGAAAGGATCCTGCTAACTCGAGCACCACC-3′ and 5′-GGTGGTGCTCGAGTTAGCAGGATCCTTTCATCTTGG-

CAATGATATCTG-3′ for preparation of the TatU1A-C expression vector. Underlined regions are inserted sequences encoding Gly-Ser-Cys residues just upstream of the stop codon.

The coding sequence for destabilized EGFP (dEGFP) (*23*) was prepared by PCR ligation. For the first PCR, EGFP was amplified from pEGFP-N3 (Clontech) using the following primers: 5′-CGCGCTAGCACCATGGTGAGCAAGGGCGAG-3′ (5pcDNAeGFP) and 5′-CTTGTACAGCTCGTCCATG-3′. Double-stranded DNA encoding the mutated degradation domain of mouse ornithine decarboxylase was prepared by primer extension using the following primers: 5′-CATGGACGAGCTGTACAAGAAGCTTAGCCATGGCTTCCCGCCGGCGGTGGCGGCGCAGGATGATGGCACGCTGCCCATGTC-3′ and 5′-CACATTGATCCTAGCAGAAGCACAGGCTGCAGGGTGACGGTCCATCCCGCTCTCCTGGGCACAAGACATGGGCAGCGTGCC-3′. For the second PCR, the first PCR product and primer extension product were ligated by PCR using the 5pcDNAeGFP and 5′-CGCCTCGAGTTACACATTGATCCTAGCAGAAG-3′ primers. The coding sequence of dEGFP was cloned into the *Nhe* I−*Xho* I site of pcDNA5/FRT (Invitrogen) to construct the expression vector pcDNA/FRT-dEGFP.

All coding sequences were confirmed by sequencing analysis using an ABI PRISM 310 genetic analyzer.

Preparation and Fluorescent Labeling of Proteins. *E. coli* strain BL21 (DE3) was transformed with pET-28b-derived expression vectors harboring TatU1A, U1A(-Tat), and TatU1A-C with N-terminal His-tags. The transformed cells were cultured, harvested by centrifugation, and then lysed by sonication and fractionated as described (24) with slight modifications. Buffer A [50 mM HEPES-KOH (pH 7.5), 150 mM $(NH_4)_2SO_4$, 7 mM $MgCl_2$, 20% glycerol, 7 mM β-mercaptoethanol, and 100 μM phenylmethylsulfonyl fluoride] was used to resuspend the cells, Buffer B [50 mM HEPES-KOH (pH 7.5), 1 M NH_4Cl, 40 mM imidazole, 20% glycerol, and 5 mM β-mercaptoethanol] was used to wash the Ni-NTA column, and Buffer C [50 mM HEPES-KOH (pH 7.5), 100 mM $(NH_4)_2SO_4$, 150 mM imidazole, 20% glycerol, and 5 mM β-mercaptoethanol] was used to elute the His-tagged protein. Purified proteins were then dialyzed against T buffer [20 mM HEPES-KOH (pH 7.4), 115 mM NaCl, 5.4 mM KCl, 1.8 mM $CaCl_2$, 0.8 mM $MgCl_2$, and 13.8 mM glucose] using Slide-A-Lyzer (Pierce).

To label TatU1A-C with Alexa Fluor 546, we mixed eluted TatU1A-C with 100 μM Alexa Fluor 546 C5 maleimide (Molecular Probes) in Buffer C and incubated the mixture at room temperature for 2 h. The Alexa-modified TatU1A-C (TatU1A-Alexa) was purified in a Centri-Sep spin column (Princeton Separations) equilibrated with T buffer.

Concentrations of all recombinant proteins were quantified using a Protein Assay Kit (Bio-Rad).

Preparation and Fluorescent Labeling of RNAs. All RNAs used in this study were purchased from Japan Bio Services Co., Ltd. In order to construct an siRNA-type cargo RNA, antisense and *U1A*-fused sense strands were dissolved in distilled water at final concentrations of 20 μM, and were then annealed by incubation at 90 °C for 1 min followed by a 60 min incubation at 37 °C. Hybridization was confirmed by polyacrylamide gel mobility shift assays. shRNA-type cargo RNA was annealed by incubation at 90 °C for 1 min followed by slow cooling (1 °C/min) to 30 °C to enhance intramolecular annealing. RNAs that targeted dEGFP mRNA (the coding region 274−292 relative to the first nucleotide of the start codon), luciferase mRNA (1188−1206), and epidermal growth factor receptor (EGFR) mRNA (2121−2139) are referred to as siGFP (or shGFP), siLuc (or shLuc), and shEGFR, respectively.

RNA was labeled with Cy3 or fluorescein using a LabelIT siRNA Tracker Intracellular Localization Kit (Mirus). To adjust

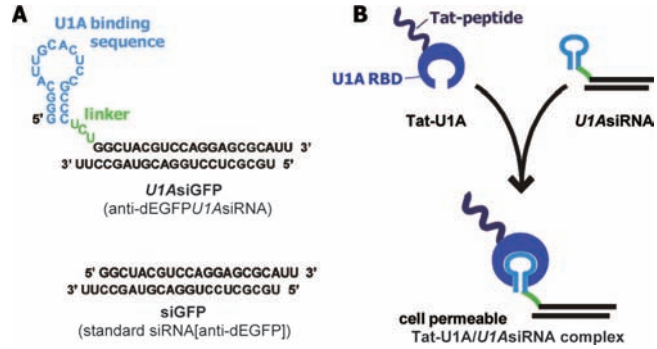

Figure 1. Construction of cell-permeable TatU1A/*U1A*siRNA complexes. (A) Sequences of the 5′-extended *U1A*siRNA and standard siRNA. The U1A-binding sequence and following UCU linker sequence were added to the 5′ end of the sense strand (upper). (B) TatU1A specifically bound to the 5′-extended U1A binding sequence, forming the cell permeable TatU1A/*U1A*siRNA complex.

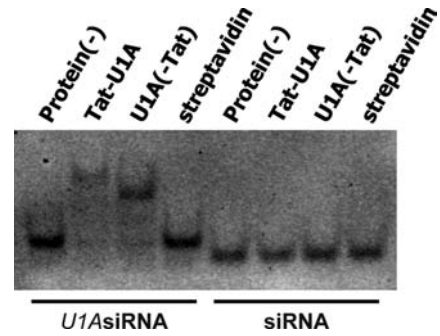

Figure 2. Specific interaction between TatU1A and *U1A*siRNA detected by gel mobility shift assays. Complex formation was initiated by mixing 500 nM siRNA with 1 μM of the indicated proteins, and 20 μL of the mixtures were loaded on the gel.

the RNA/fluorophore molar ratio of labeled siRNA and *U1A*-fused siRNA, only the antisense strand was labeled and the labeled antisense strand was mixed with the sense strand or the *U1A*-fused sense strand before the annealing procedure. Annealing using the labeled strand was performed by incubation of 20 μM each of the sense and antisense RNAs at 65 °C for 3 min followed by a 60 min incubation at 37 °C.

Gel Mobility Shift Assay. Purified proteins (1 μM) were mixed with 500 nM *U1A*siRNA or standard siRNA in T buffer. Streptavidin was purchased from Amresco (US) and used as a negative control protein. After a 10 min incubation at 37 °C, protein−RNA mixtures were analyzed in 6% native polyacrylamide gels with Gel-Shift buffer (50 mM Tris-HCl [pH 6.8], 10 mM $Mg(OAc)_2$, 65 mM NH_4OAc, 1 mM EDTA) at 4 °C. The gel was stained with ethidium bromide to detect RNAs.

Cell Culture and Construction of a Cell Line Expressing Destabilized EGFP. Chinese hamster ovary (CHO) cells (Invitrogen Flp-In-CHO cell line) were cultured at 37 °C under 5% CO_2 in Ham's F-12 medium supplemented with 10% fetal bovine serum (FBS). The human epidermoid carcinoma cell line A431 was kindly provided by Professor Seno (Okayama University) and cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% FBS. Both media contained 100 units/mL penicillin and 100 μg/mL streptomycin. pcDNA/FRT-dEGFP was cotransfected with pOG-44 (Invitrogen) into Flp-In-CHO cells using the Effectene Transfection Reagent (Qiagen) and cultured in medium containing 500 μg/mL hygromycin B in order to construct a cell line stably expressing dEGFP (dEGFP-CHO).

RNA Delivery and Photoaccelerated Endosomal Escape. For RNA delivery experiments, a carrier protein (TatU1A or TatU1A-Alexa) and cargo RNA were mixed in 50 μL of

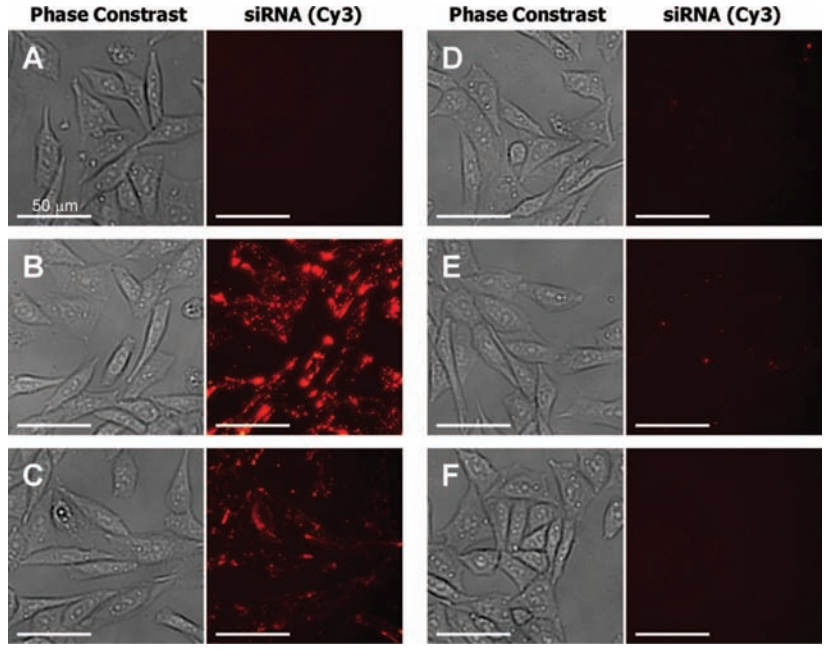

Figure 3. Cy3-*U1A*siRNA internalization into CHO cells mediated by TatU1A. Cellular images were obtained after incubation in the presence of TatU1A only (A), TatU1A and Cy3-*U1A*siRNA (B), TatU1A and Cy3-siRNA (C), Cy3-*U1A*siRNA only (D), U1A(-Tat) and Cy3-*U1A*siRNA (E), or T-buffer (F). Concentrations of RNA and protein were 200 nM and 1 μM, respectively. The cells were treated with RNase A to remove extracellularly bound RNAs before imaging. Scale bars = 50 μm. Fluorescence images were obtained with an excitation wavelength of 530−550 nm.

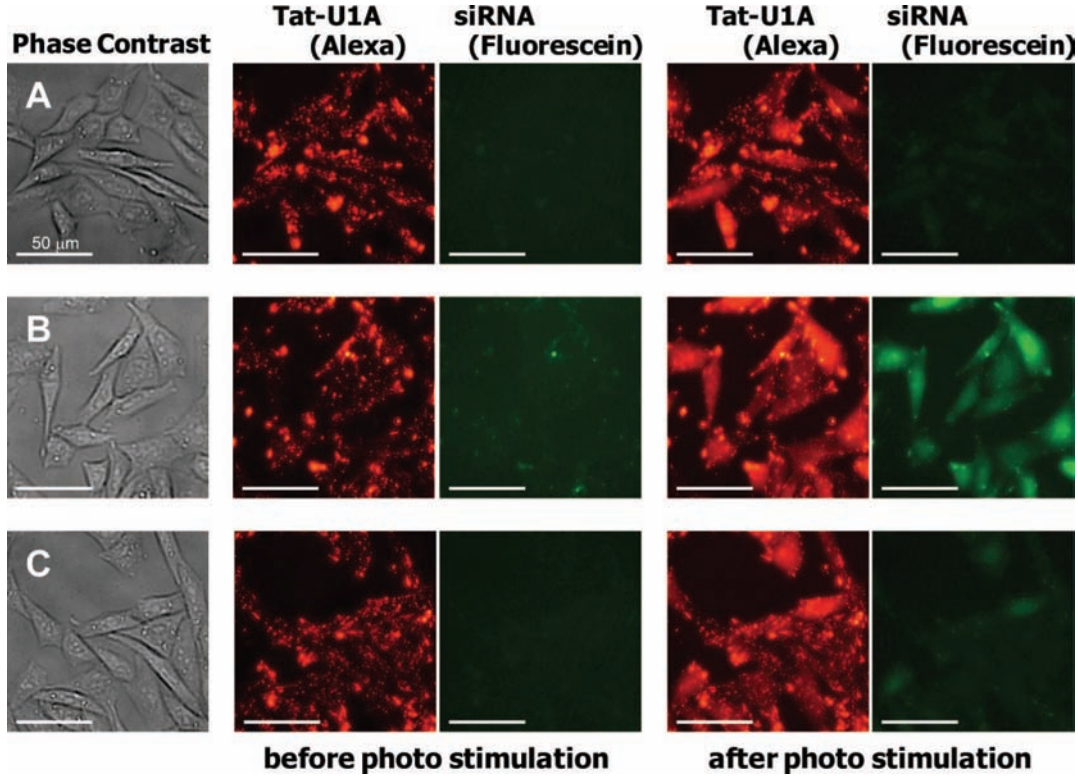

Figure 4. Photoinduced release of TatU1A-Alexa/Flc-*U1A*siRNA from endocytic compartments. TatU1A-Alexa only (A), TatU1A-Alexa and Flc-*U1A*siRNA (B), or TatU1A-Alexa and Flc-siRNA (C) were mixed to induce complex formation, added to CHO cells, and then incubated as described in the Materials and Methods section. Images were obtained before a 10 s light stimulation at 540 ± 10 nm and at 2 min after photostimulation. The excitation wavelengths were 530−550 nm for Alexa Fluor 546 and 460−495 nm for fluorescein.

T buffer at the indicated concentrations, and incubated at 37 °C for 10 min. Cells grown to 70% confluence in 96-well culture plates were then overlaid with the mixture. After a 3 h incubation at 37 °C in T buffer, cells were treated twice with culture medium containing 34 μg/mL RNase A for a total of 1 h at 37 °C to remove RNAs adhering to the extracellular surface of the cells. Cells were then washed with T buffer, and fluorescence images were obtained using a fluorescence microscope (IX51/IX2-FL-1/MP5Mc/OL-2, Olympus, Japan). In order to induce photoaccelerated endosomal escape of the internalized complex, cells were irradiated at 540 ± 10 nm for the indicated lengths of time with a 100 W halogen lamp (Olympus USH-1030L) passed through the 40× or 4× objective lens.

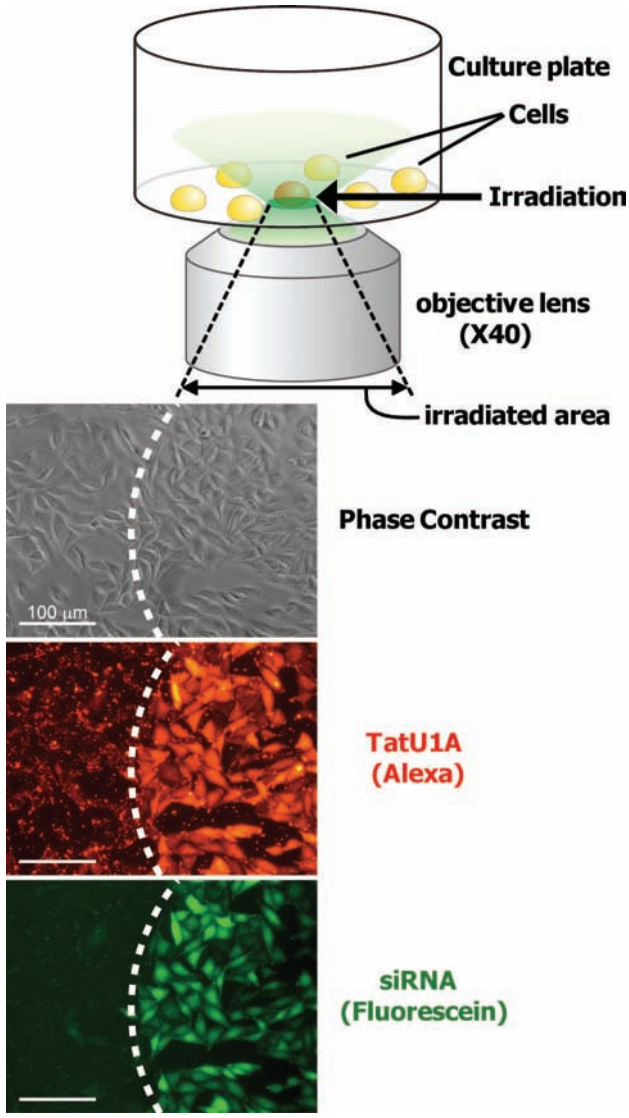

Figure 5. Region-specific photostimulation of cells. TatU1A-Alexa and Flc-*U1A*siRNA were mixed for complex formation, added to CHO cells, and incubated, as described in the Materials and Methods section. Images were obtained at 2 min after a 10 s light stimulation at 540 ± 10 nm. The excitation wavelengths were 530−550 nm for Alexa Fluor 546 and 460−495 nm for fluorescein. The irradiated area is to the right of the dotted line.

Induction of RNAi-Mediated EGFP Silencing. One day prior to RNA delivery, dEGFP-CHO cells were plated in a 96-well culture plate at a density of 2×10^4 cells per well. *U1A*-fused siRNA or shRNA was delivered into the cells using TatU1A-Alexa, and photoaccelerated endosomal escape was induced as described above. The cells were cultured at 37 °C. At 24 h after light stimulation, the culture medium was replaced with T buffer followed by two washes. The fluorescence intensity of adhering dEGFP-CHO cells was directly quantified by FLUOstar OPTIMA (BMG Labtech, Germany) using a 480 nm excitation and 540 nm emission filter set. The fluorescence intensity values were normalized by subtracting the values of the wells containing no cells. Cellular fluorescence images were subsequently obtained using a fluorescence microscope.

Induction of RNAi-Mediated Epidermal Growth Factor Receptor (EGFR) Silencing. One day prior to RNA delivery, A431 cells were plated in a 96-well culture plate at a density of 1×10^4 cells per well. *U1A*-fused shRNA was delivered to the cells using TatU1A-Alexa and photoaccelerated endosomal escape was induced as described above. The cells were cultured at 37 °C. At 72 h after light stimulation, cells were incubated with the Alexa488/EGF complex (Molecular Probes) (5 μg/mL) in medium for 30 min at 37 °C. The cells were then washed with T buffer, and fluorescence images were obtained.

Cell Viability Assay. In order to determine the effect of RNA delivery and light stimulation on cell viability, cell proliferation and cytotoxicity were evaluated using the Cell Counting Kit-8 (Dojindo, Japan) and a Cytotoxicity Detection Kit (LDH) (Roche, Switzerland), respectively. At 22 h after light stimulation, as described above, the culture medium was replaced with a medium containing 10 μL/well of cell counting kit substrate. The absorbance at 450 nm of each well was measured after a 2 h incubation at 37 °C. Simultaneously, an aliquot of medium was removed and mixed with the cytotoxicity detection substrate according to the manufacturer's protocol, and the absorbance at 490 nm was measured. The absorbances at 450 and 490 nm were measured using a FLUOstar OPTIMA instrument, and the values were normalized by subtracting the values measured in wells containing no cells. In the case of the cell proliferation assay, the values for cells incubated with T buffer without carrier protein and cargo RNA were considered to represent 100% proliferation. In the case of the cytotoxicity assay, the values for cells that were incubated with medium containing 0.2% NP-40 were considered to represent 100% cytotoxicity.

RESULTS AND DISCUSSION

Specific Interaction Between TatU1A and *U1A*siGFP. We hypothesized that TatU1A binding to a *U1A*-fused cargo RNA (Figure 1) would generate a cell-permeable complex that delivers the RNA to cells. We confirmed the specific interaction between TatU1A and *U1A*siGFP (Figure 1A) using a gel mobility shift assay (Figure 2). Shifted bands were present in the *U1A*siGFP and TatU1A or U1A(-Tat) preparations, but not in the control mixture of *U1A*siGFP and streptavidin. An siGFP lacking the *U1A* sequence did not exhibit a mobility shift in the presence of the U1A protein (Figure 2). These results demonstrate a specific interaction between the U1A RBD and *U1A* RNA and the formation of a TatU1A/*U1A*siGFP complex. When an excess of TatU1A was incubated with the *U1A*siGFP (2.5 μM TatU1A and 500 nM *U1A*siGFP), the U1A(-Tat)/*U1A*siGFP complex was observed as a very broad, faint band and no free *U1A*siRNA was detected (Supporting Information Figure 1). Furthermore, the siGFP band was also faint in the presence of excess TatU1A, but not in the presence of excess U1A(-Tat) (Supporting Information Figure 1). These results indicate that TatU1A selectively bound to *U1A*siGFP, but that nonspecific RNA binding also occurred, most likely due to electrostatic interactions between the polycationic Tat-peptide and polyanionic RNA.

siRNA Delivery into Mammalian Cells Using TatU1A as Carrier. Cy3-labeled *U1A*siGFP (Cy3-*U1A*siGFP) was prepared to examine whether siRNAs can be delivered to cells after forming a specific complex with TatU1A. Using a gel mobility shift assay, we confirmed that the Cy3 label does not affect *U1A*siGFP binding to TatU1A (data not shown). No Cy3 fluorescence was observed in CHO cells treated with *U1A*siGFP/TatU1A obtained by incubating 200 nM Cy3-*U1A*siGFP with 200 nM or 400 nM TatU1A (Supporting Information Figure 2). A 5× molar excess of TatU1A (1 μM) in complex formation was required to generate detectable fluorescence in cells. As shown in Figure 3, strong fluorescence was observed in cells treated with TatU1A/Cy3-*U1A*siGFP (Figure 3B), but no fluorescence was observed in cells treated with U1A(-Tat)/Cy3-*U1A*siGFP or Cy3-*U1A*siGFP alone (Figure 3D,E). Since both TatU1A and U1A(-Tat) form a protein−*U1A*siGFP complex, as shown in Figure 2, the results of Figure 3B,E indicate that cellular internalization of *U1A*siGFP was mediated by the

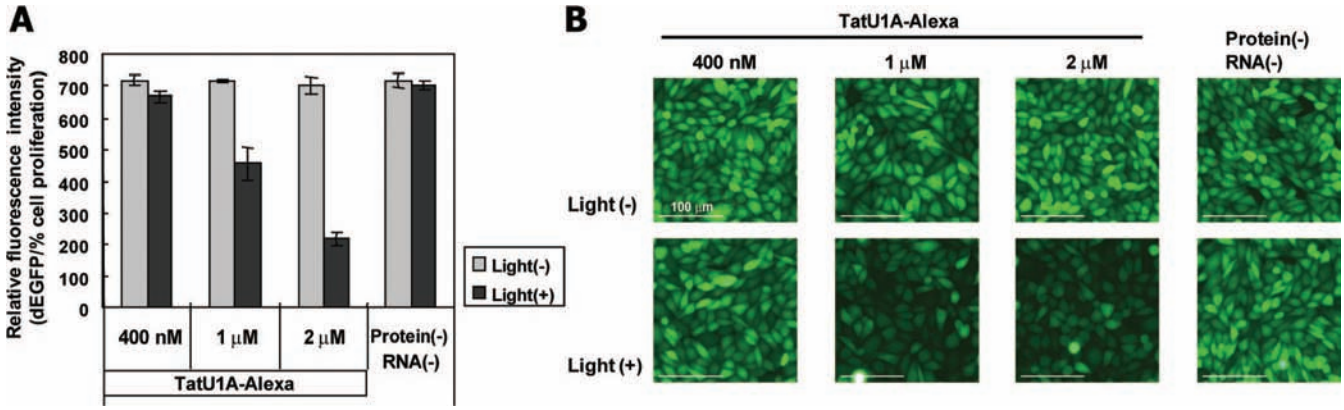

Figure 6. dEGFP silencing after siRNA redistribution mediated by light stimulation. *U1A*siGFP (200 nM) was mixed with TatU1A-Alexa for complex formation, added to dEGFP-CHO cells, and incubated as described in the Materials and Methods section. The relative fluorescence intensity (A) and fluorescent images (B) were evaluated after a 24 h incubation following a 60 s light stimulation or no stimulation. Irradiation was performed at 540 ± 10 nm for 60 s through a 4x objective lens. In (A), the fluorescence intensity was normalized by cell proliferation, estimated using a Cell Counting Kit-8. The dEGFP intensity in (A) is the mean ± standard deviation of three independent measurements.

Tat−peptide. Unexpectedly, weak fluorescent signals were also observed in cells treated with TatU1A/Cy3-siGFP (Figure 3C), indicating that a small amount of Cy3-siGFP entered the cells, potentially as a result of nonspecific interactions between Cy3-siGFP and TatU1A, as shown in Supporting Information Figure 1. Thus, *U1A*siGFP was selectively delivered to cells by TatU1A, probably because of the synergistic effect of two types of RNA−protein interactions: specific interactions between the *U1A* sequence and the U1A RBD and nonspecific interactions between the Tat−peptide and RNAs.

Release of siRNA from Endocytic Compartments by Photostimulation of TatU1A-Alexa. The internalized Cy3-*U1A*siGFP exhibited a punctuate cytoplasmic distribution (Figure 3B). This distribution indicated that Cy3-*U1A*siGFP was localized in endocytic compartments, as demonstrated by colocalization with LysoTracker Green (Molecular Probe), which labels lysosomes and other types of acidic compartments (Supporting Information Figure 3). Several groups have previously reported that Tat-peptide-mediated cellular internalization occurs through an endocytotic pathway by macropinocytosis (*25*). The transfer of Tat-peptide-conjugated macromolecular cargos from endocytic compartments to the cytosol is thus a critical step in activating the cargo's function in cells. Chloroquine and influenza-virus-derived hemagglutinin peptide (HA2) have been used to destabilize the endosomal membrane and enhance delivery of entrapped Tat-peptide-conjugated macromolecules to the cytosol (*25–27*). Recently, as an alternative strategy, two groups reported the efficient release of fluorescently labeled CPP or CPP-fused proteins from the endosome using photostimulation of the fluorophores (*28, 29*). This is a very attractive strategy because controlled light stimulation would enable region-specific delivery of cargo molecules.

We prepared TatU1A-Alexa bearing an Alexa Fluor 546 fluorophore to confirm whether the release of TatU1A-Alexa from endosomes could be induced by light stimulation. Since TatU1A-C contains a Cys residue only at the C-terminus, Alexa Fluor 546 C_5 maleimide reacts specifically with the C terminus. We confirmed that TatU1A-Alexa binds to *U1A*-fused cargo RNA using a gel mobility shift assay (data not shown). We also prepared fluorescein-modified siRNAs (Flc-*U1A*siGFP and Flc-siGFP) to examine whether the entrapped siRNA could be released into the cytoplasm following TatU1A-Alexa-mediated internalization. Fluorescent signals were monitored after incubation of CHO cells with TatU1A-Alexa/Flc-*U1A*siGFP complexes, TatU1A-Alexa/Flc-siGFP complexes, or TatU1A-Alexa alone (Figure 4). Prior to light stimulation, TatU1A-Alexa (red images) exhibited a punctuate distribution (Figures 4A−C) similar to that of Cy3-*U1A*siGFP (Figure 3B). The Flc-*U1A*siGFP signal (green) was very weak compared to the Cy3-*U1A*siGFP signal. The low pH in the endosomes diminishes the fluorescence, because fluorescein is pH-sensitive (*30*).

Next, we irradiated the cells at 540 ± 10 nm for 10 s using a 40× objective lens. In this procedure, the light from a 100 W halogen lamp was reduced to 12% of the total output using a neutral-density filter (Olympus 32-ND12) to avoid damaging the fluorophores and cells. Following this photostimulation, TatU1A-Alexa was widespread throughout the cytosol (Figures 4A−C). A widespread fluorescein signal was also observed in cells which were incubated with TatU1A-Alexa/Flc-*U1A*siGFP complexes (Figure 4B). The RNA released from endosomes by light stimulation was localized to the cytosol and nucleus as shown in Supporting Information Figure 4. The green fluorescence signal indicates that Flc-*U1A*siGFP but not TatU1A-Alexa is released from the endosome, because green fluorescence was not observed in cells treated only with TatU1A-Alexa (Figure 4A). The fluorescein signal from the Flc-*U1A*siGFP intensified after photostimulation (Figure 4B), reflecting the higher pH of the cytoplasm relative to the endosomes. In cells treated with TatU1A-Alexa/Flc-siGFP, the dispersed fluorescein signal was much weaker than in those treated with TatU1A-Alexa/Flc-*U1A*siGFP (Figure 4C), indicating that complex formation and uptake was enhanced in the latter. Figure 5 shows the region-specific redistribution of Flc-*U1A*siGFP. Green fluorescence in the cytoplasm was observed only in the irradiated area. These results indicate that *U1A*siGFP was delivered to CHO cells by the TatU1A protein and released into the cytoplasm by photostimulation of the Alexa 546 fluorophore. Although the mechanism of the cytosolic redistribution of TatU1A-Alexa is not well understood, reactive oxygen species generated by photostimulation may damage the membranes of endosomal compartments (*28, 29*). Several groups have used photostimulation of photosensitizers to produce reactive singlet oxygen and to induce the cytosolic redistribution of macro-biomolecules entrapped in the endocytic compartment (*31, 32*).

dEGFP Silencing Mediated by *U1A*-Fused Interfering RNA. In order to examine whether the redistributed cargo RNA can induce RNAi-mediated gene silencing, dEGFP-CHO cells were treated with complexes generated using 200 nM *U1A*siGFP and various concentrations of TatU1A-Alexa (Figure 6). Cells in the wells of a 96-well plate were then irradiated at 540 ± 10 nm for 60 s through a 4× objective lens. For irradiation through the 4× objective lens, we removed the neutral-density filter and extended the irradiation time because the light intensity is considerably weaker than that transmitted through the 40×

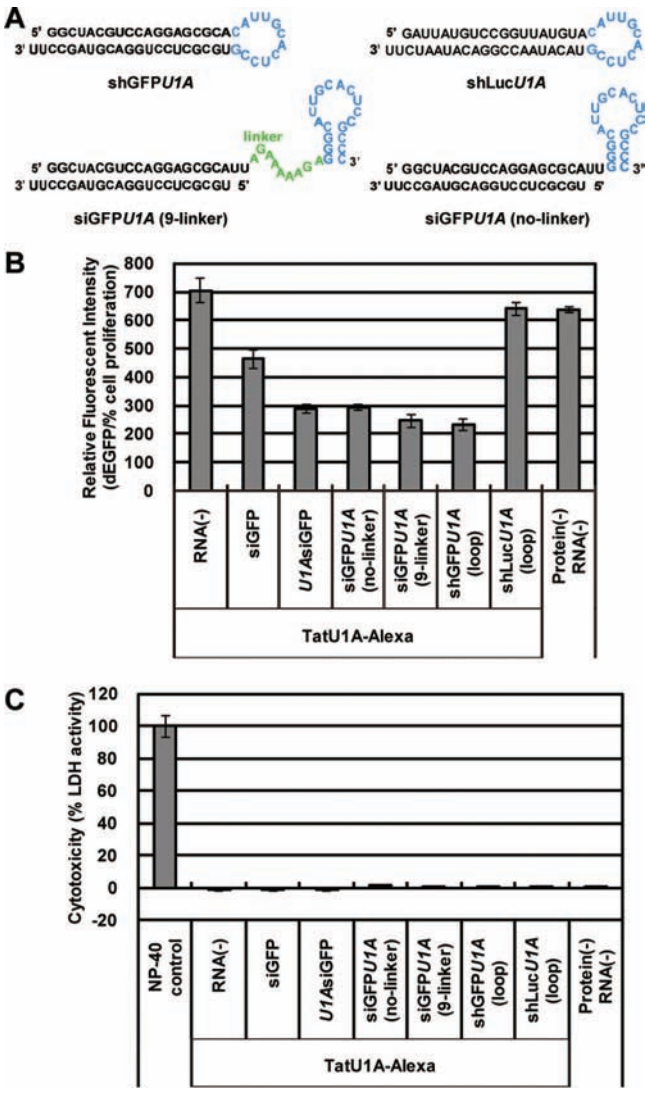

Figure 7. dEGFP silencing using *U1A*-fused RNAs. (A) Sequences of *U1A*-fused cargo RNA variants. RNA delivery to dEGFP-CHO cells was performed using complexes formed from incubating 2 μM TatU1A-Alexa and 200 nM cargo RNA. Cargo RNAs internalized with TatU1A-Alexa were redistributed into the cytosol using an 80 s photostimulation at 540 $\pm$ 10 nm through a 4$\times$ objective lens. Fluorescence intensity (B) and cytotoxicity (C) were evaluated at 24 h post-photostimulation. In (B), fluorescence intensity was normalized by cell proliferation, estimated using a Cell Counting Kit-8. The values in B and C are the mean $\pm$ standard deviation of three independent measurements.

objective lens. The dEGFP intensity was unchanged in cells treated with the TatU1A-Alexa/*U1A*siGFP complex, compared to cells treated with T buffer only, but decreased following irradiation of TatU1A-Alexa/*U1A*siGFP treated cells (Figure 6). We also confirmed the reduction in the mRNA level by RT-PCR (data not shown). These results indicate that the photostimulation-induced redistribution of *U1A*siGFP resulted in RNAi-mediated dEGFP silencing, and that the *U1A*-fused siGFP retains silencing activity. These results suggest that the internalized TatU1A-Alexa/*U1A*siGFP complex could not mediate gene silencing without light stimulation due to endosome trapping. In the subsequent RNAi experiments, we used a TatU1A-Alexa concentration of 2 μM, to increase the level of gene silencing (Figure 6).

We prepared various cargo RNA constructs (Figure 7A) in order to improve the RNAi efficiency. For siRNA type variants, the *U1A* sequence was linked to the 3′ terminus of the sense strand directly [siGFP*U1A*(no-linker)] or through a 9-mer linker [siGFP*U1A*(9-linker)]. For the shRNA-type variant, a minimum

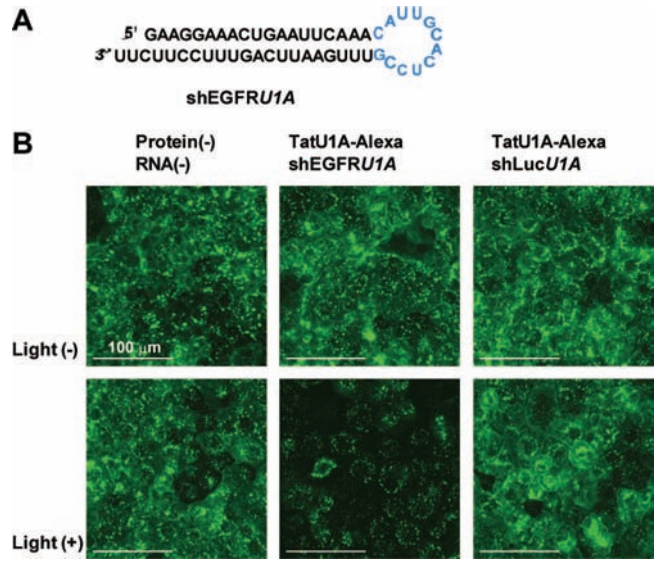

Figure 8. EGFR silencing in A431 cells. (A) Sequence of shRNA-type cargo RNA targeted EGFR. (B) A431 cells were incubated with a mixture of 2 μM TatU1A-Alexa and 200 nM cargo RNA. Cells were stained with an Alexa488/EGF complex (Molecular Probes) after 72 h of culture after a 60 s light stimulation through a 4$\times$ objective lens. Fluorescence images were obtained at an excitation wavelength of 460 to 495 nm.

U1A sequence was inserted in the loop region, which connects the sense and antisense strands (shGFP*U1A*). All the variants and standard siRNA (siGFP) were incubated with 2 μM TatU1A-Alexa for complex formation. Cells were treated with the complexes and siRNAs were redistributed using an 80 s light stimulation through a 4$\times$ objective lens. All the variants containing the *U1A* sequence induced dEGFP silencing, with the highest RNAi efficiency being induced by shGFP*U1A* (Figure 7B). The efficiency of dEGFP silencing by the standard siGFP was considerably weaker than the other variants, indicating that TatU1A-Alexa selectively delivers the *U1A* containing cargo RNAs. The shLuc*U1A*, an shRNA-type cargo RNA targeted to the luciferase gene, did not change the dEGFP intensity in cells, suggesting that there were no nonspecific effects resulting from treatment with the RNA (Figure 7B).

In order to compare the RNAi efficiency of this method with common transfection, cells were transfected with siGFP and siLuc using the TransIT-TKO transfection reagent (Mirus) according to the manufacturer's protocol (Supporting Information Figure 5). Our method, using 200 nM *U1A*siGFP, induced dEGFP silencing as effectively as TransIT-TKO mediated transfection with 10 nM siGFP (a concentration of approximately 10 nM is recommended in the manufacturer's protocol) (Figure 7B and Supporting Information Figure 5A), and the cytotoxicity associated with our method was considerably lower than that observed with transfection (Figure 7C and Supporting Information Figure 5B).

We estimated the effects of RNA concentration and photoirradiation time on dEGFP silencing (Supporting Information Figure 6). First, 2 μM TatU1A-Alexa was used to complex with various concentrations of shGFP*U1A*, and the cells were then incubated with the complexes and a 60 s light stimulation was then used to redistribute the RNA to the cytoplasm. On the basis of the results of this experiment, we used 200 nM RNA in the subsequent RNAi experiments. Cells were treated with complexes formed from 200 nM shGFP*U1A* and 2 μM TatU1A-Alexa and the length of photostimulation was varied. Longer irradiation times induced more efficient dEGFP silencing, and the effect was saturated at irradiation times longer than 60 s (Supporting Information Figure 6B). When cells were irradiated

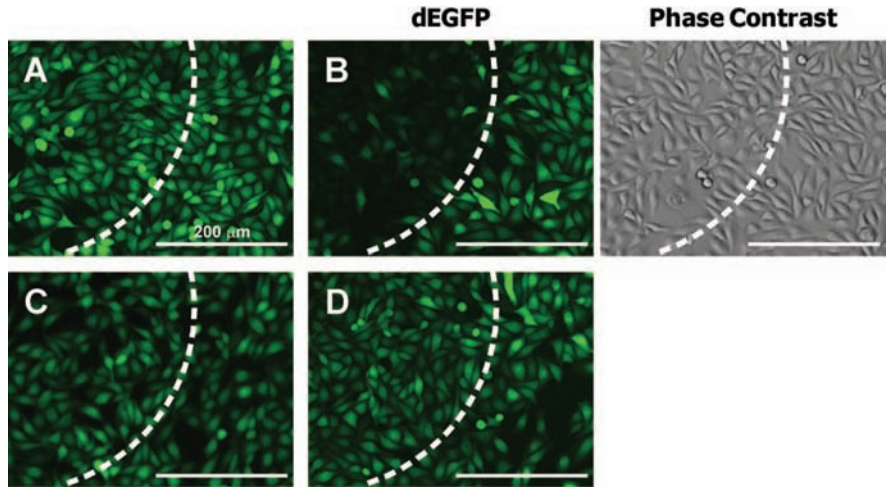

Figure 9. Region-specific silencing of the dEGFP gene. CHO cells expressing dEGFP were incubated with TatU1A-Alexa only (A), TatU1A-Alexa and shGFP*U1A* (B), TatU1A-Alexa and shLuc*U1A* (C), or TatU1A-Alexa and siGFP (D), and stimulated with light at 540 ± 10 nm as described in the Materials and Methods section. dEGFP fluorescence images of the photoirradiated area were obtained 20 h after photostimulation. In panel (B), a phase contrast image is shown below the fluorescence image. The irradiated area is to the left side of the dotted line.

for 120 s, cell proliferation was reduced to less than 80% (Supporting Information Figure 6C). Although prolonged irradiation damaged the cells, cellular damage was minimal with irradiation times of 60 s or less (Supporting Information Figure 6C), indicating that the silencing activity could be efficiently and safely regulated by photostimulation.

EGFR Silencing Mediated by shEGFR*U1A*. We prepared an shRNA-type *U1A*-fused cargo RNA, shEGFR*U1A* (Figure 8A), to reduce endogenous EGFR expression. EGFR is overexpressed in many tumors, and is a convenient target for cancer therapy. We selected the A431 cell line as a model of EGFR-overexpressing carcinoma cells. A431 cells were treated with complexes formed from 2 μM TatU1A-Alexa and 200 nM shEGFR*U1A*, and then irradiated with light at 540 ± 10 nm for 60 s through a 4× objective lens. Photostimulation of the cells reduced the Alexa488 fluorescence, which is proportional to the amount of EGF bound to EGFR (Figure 8B). Neither the cells without light stimulation nor the cells incubated with TatU1A-Alexa and shLuc*U1A* (nonspecific cargo RNA) reduced the fluorescent signal compared to control cells incubated with T buffer only. These results indicate that TatU1A-mediated RNA delivery and photoaccelerated endosomal escape was correlated with silencing of the endogeneous EGFR gene.

Region-Specific Gene Silencing Mediated by CLIP-RNAi. shGFP*U1A* and control RNAs (shLuc*U1A* and standard siGFP) were delivered to dEGFP-CHO cells using 2 μM TatU1A-Alexa for complex formation. TatU1A-Alexa only was used as a negative control. After a 4 h incubation, the cells were photostimulated for 5 s through the 40× objective lens, using a neutral-density filter to reduced the light intensity to 12%. Figure 9 shows the dEGFP fluorescence in the irradiated area at 20 h after photostimulation. The cells treated with TatU1A-Alexa and shGFP*U1A* exhibited a decrease in dEGFP only within the irradiated area (Figure 9B). In contrast, control cells treated with TatU1A-Alexa alone (Figure 9A), TatU1A-Alexa and shLuc*U1A* (Figure 9C), or TatU1A-Alexa and siGFP (Figure 9D) did not induce a decrease in dEGFP irrespective of photostimulation. These results indicate that RNA is only released from endosomes in areas of photostimulation and that RNAi is thus restricted to the irradiated areas.

CONCLUSIONS

We have demonstrated the efficient and selective delivery of an siRNA into mammalian cells mediated by TatU1A. Although several studies have induced RNAi in mammalian cells using CPPs, the release of siRNAs from the endosome is a rate-limiting step in activating RNAi. We achieved the cytosolic redistribution of cargo RNA using TatU1A-Alexa and controlled light stimulation. The method demonstrated here is a simple strategy to deliver any shRNA or siRNA bearing a short extension with a specific recognition sequence. In addition, the light stimulation strategy (CLIP-RNAi) enables the implementation of regionally and temporally controlled RNAi.

ACKNOWLEDGMENT

We thank H. Sakakoshi (Okayama Univ.) for his help with RNA purification, K. Kishimoto (Okayama Univ.) for his help with plasmid construction, Prof. M. Seno (Okayama Univ.) for the material, and Dr. J. Futami for Hoechst33342. Biocompatible and Biodegradable Polymersome Encapsulated Hemoglobin: A Potential Oxygen Carrier

Shahid Rameez, Houssam Alosta, and Andre F. Palmer*

Department of Chemical and Biomolecular Engineering, The Ohio State University 231A Koffolt Laboratories, 140 West 19th Avenue, Columbus, Ohio 43210. Received December 14, 2007; Revised Manuscript Received March 18, 2008

This work describes the development of polymersome-encapsulated hemoglobin (PEH) self-assembled from biodegradable and biocompatible amphiphilic diblock copolymers composed of poly(ethylene oxide) (PEO), poly(caprolactone) (PCL), and poly(lactide) (PLA). In the amphiphilic diblock, PEO functions as the hydrophilic block, while either PCL or PLA can function as the hydrophobic block. PEO, PCL, and PLA are biocompatible polymers, while the last two polymers are biodegradable. PEH dispersions were prepared by extrusion through 100 nm pore radii polycarbonate membranes. In this work, the encapsulation efficiency of human and bovine hemoglobin (hHb and bHb) in polymersomes was adjusted by varying the initial concentration of Hb. This approach yielded Hb loading capacities that were comparable to values in the literature that supported the successful resuscitation of hamsters experiencing hemorrhagic shock (*1*). Moreover, the Hb loading capacities of PEHs in this study can also be tailored simply by controlling the diblock copolymer concentration. In this study, typical Hb/diblock copolymer weight ratios ranged 1.2−1.5, with initial Hb concentrations less than 100 mg/mL. The size distribution, Hb encapsulation efficiency, oxygen affinity (P_{50}), cooperativity coefficient (n), and methemoglobin (metHb) level of these novel PEH dispersions were consistent with values required for efficient oxygen delivery in the systemic circulation (*2*−*5*). Taken together, our results demonstrate the development of novel PEH dispersions that are both biocompatible and biodegradable. These novel dispersions show very good promise as therapeutic oxygen carriers.

INTRODUCTION

Liposome-encapsulated hemoglobin (LEHb) comprises one subset of cellular Hb-based O_2 carriers (HBOCs). The architecture of these particles consists of a purified and concentrated Hb solution that is encapsulated inside the aqueous core of the liposome. Lipids are for the most part biocompatible. This property has motivated the development of liposomes as drug and protein carriers (*3*, *5*, *6*). Liposomes lack controlled release mechanisms and have several other pharmacokinetic limitations (e.g., limited half-life in the circulation) which minimize the effective delivery of therapeutic molecules (*7*). In order to mimic the carbohydrate coat on cell membranes and thus prolong the circulatory half-life of liposomes, biocompatible poly(ethylene glycol) (PEG) was attached to a small fraction (5−10 mol %) of the lipid headgroups on LEHb particles. This resulted in increased circulatory half-life of LEHb particles, due to decreased recognition by the reticuloendothelial system (RES). However, the beneficial effects gained by the prolonged circulation time of PEGylated LEHb is attenuated by significant particle accumulation in the liver and spleen. Splenic sequestration of LEHb particles saturates the RES, thereby limiting the effectiveness of the body's natural defense system against foreign bodies . To counteract these effects, we propose to use vesicles composed of amphiphilic diblock copolymers, instead of lipids, that have the ability to degrade once sequestered in the spleen. Biocompatible diblock copolymers that consist of a PEO block plus a degradable block, such as PEO-poly(lactic acid) (PEO-PLA) or PEO-poly(caprolactone) (PEO-PCL), are promising candidates for the preparation of polymer vesicles that have the native ability to evade the RES and degrade once sequestered in the spleen or liver (*8*−*10*).

Self-assembled polymer vesicles composed of diblock copolymer amphiphiles where one block is hydrophilic and the other block is hydrophobic are called polymersomes (*4*). These vesicles are synthetic in nature. The amphiphilic diblocks are similar in structure to lipids, but possess much larger molecular weights (*4*). In aqueous solution, the diblocks form an arrangement where the hydrophobic blocks tend to associate with each other to minimize direct exposure to water, whereas the more hydrophilic blocks face inner and outer hydrating solutions and thereby form the two interfaces of a typical bilayer membrane (*11*). Polymersomes are composed of synthetic polymers of molecular weights more typical of polypeptides (order of 10 kDa), whereas lipids possess molecular weights less than 1 kDa (*4*). Lipid membranes appear conducive to various cellular processes (endocytosis, cell division, receptor clustering, etc.) because of the flexibility afforded by the low molecular weight lipids, which made them an attractive candidate for an oxygen carrier over the last few decades. Polymersomes can be prepared from diblock copolymers by the same techniques used to prepare liposomes such as rehydration, sonication, and extrusion, which can generate unilamellar micrometer-sized vesicles as well as monodisperse submicrometer-sized vesicles (*12*).

Diblock copolymers consisting of poly(ethylene glycol-*b*-lactide) (PEG-PLA) or poly(ethylene glycol-*b*-caprolactone) (PEG-PCL) have been used to prepare controlled release polymer vesicles (*13*). One study (*13*) demonstrated the encapsulation of anticancer agents in polymersomes and their ability to release drug to cancer cells. Another study demonstrated degradable polymersomes being used in the growth arrest and shrinkage of rapidly growing tumors (*14*). In addition, polymersome-encapsulated paclitaxel has exhibited slow, steady release of the anticancer drug paclitaxel in human breast cancer cells. Paclitaxel−polymersomes have exhibited desirable restrained release profile and long-term stability.The formulations

also showed comparable activity to the drug alone in inhibiting the growth of MCF-7 human breast cancer cells (*15*).

Polymersomes made from either PEG-PLA or PEG-PCL form stable vesicles (*16*). Dynamic light scattering provides an accurate measurement of the vesicle size distribution. Periodic measurements over a period of time has shown that PEO-PBD polymersomes are stable whereas vesicles made with degradable copolymer PEO-PLA disassemble over a period of days at room temperature (*16*).

By changing the copolymer composition, especially the molecular weight and type of hydrophobic block, the release of encapsulated material from polymersomes can be adjusted accordingly (*17*). Biodegradable polymersomes also have the potential to be targeted to specific sites in the body, as has been shown by the specific interaction of antihuman serum albumin conjugated polymersomes with a human serum albumin coated sensor surface (*17*).

In this work, we prepare biodegradable and biocompatible polymersomes encapsulating Hb and show that they are promising candidates for hemoglobin-based oxygen carriers (HBOCs). To our knowledge, this is the first study that explores the possibility of employing biodegradable and biocompatible polymersomes to be used as HBOCs.

EXPERIMENTAL PROCEDURES

Materials. Four biodegradable and biocompatible diblock copolymers composed of poly(ethylene oxide-*b*-ϵ-caprolactone) and poly(ethylene oxide-*b*-lactide) (both DL and L forms) were used in this study. Two of these diblocks were composed of poly(ethylene oxide-*b*-caprolactone), and two were composed of poly(ethylene oxide-*b*-lactide). The diblock copolymers were purchased from Polymer Source Inc. (Dorval QC, Canada). For convenience, PEH composed of poly(ethylene oxide-*b*-ϵ-caprolactone) and poly(ethylene oxide-*b*-lactic acid) will be referred to as PEO-b-PCL-1, PEO-b-PCL-2, PEO-b-PLA-1, and PEO-b-PLA-2 (Table 1). Likewise, their corresponding controls (i.e., empty polymersomes) will be referred to as PEO-b-PCL-1 (control), PEO-b-PCL 2 (control), PEO-b-PLA-1 (control), and PEO-b-PLA-2 (control) (Table 1).

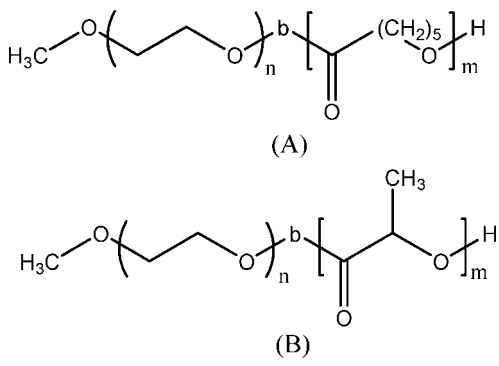

Figure 1. Chemical structure of (A) poly(ethylene oxide-*b*-ϵ-caprolactone) and (B) poly(ethylene oxide-*b*-lactide). The block inside the parentheses is hydrophilic (PEO), while the block inside the square bracket is hydrophobic (PCL or PLA).

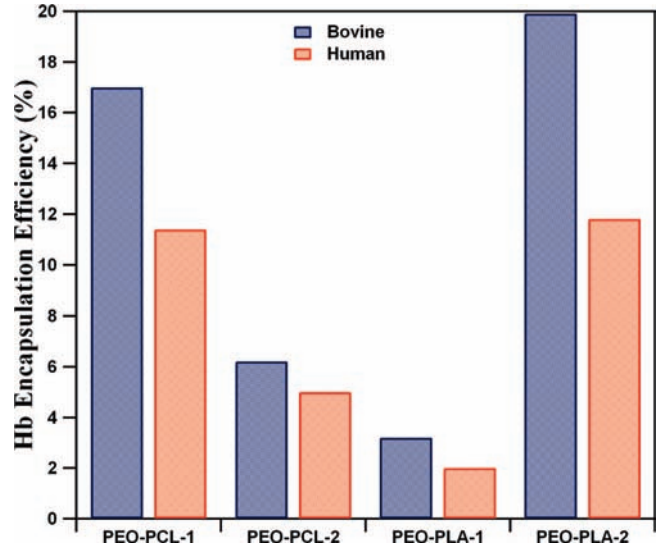

Figure 2. Comparison of Hb encapsulation efficiency in PEH dispersions extruded through 200 nm diameter polycarbonate membranes using different sources of Hb.

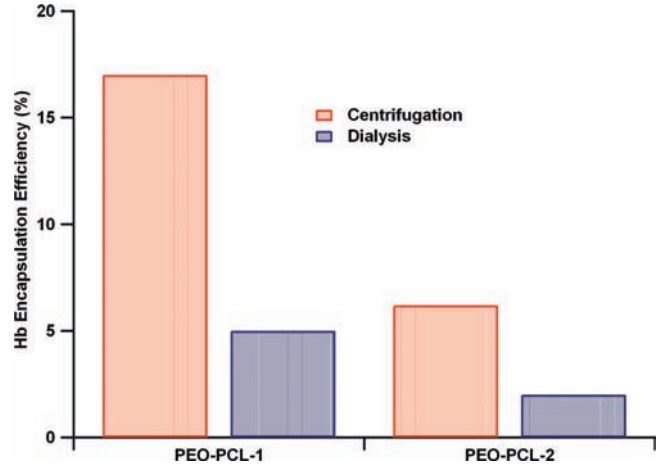

Figure 3. Comparison of bHb encapsulation efficiency in PEH dispersions extruded through 200 nm diameter polycarbonate membranes determined via the centrifugation and dialysis methods.

The chemical structures of PEO-b-PCL and PEO-b-PLA are shown in Figure 1, and the structural properties of the four diblock copolymers are summarized in Table 1.

Extraction and Purification of bHb and hHb from RBCs. Sterile bovine red blood cells (bRBCs) were purchased from QUAD 5 (Ryegate, MT), while human red blood cells (hRBCs) were obtained from the American Red Cross (Columbus, OH). Both bRBCs and hRBCs were initially prepared in the same manner for filtration. RBCs were harvested by centrifugation for 15 min at 4500 rpm and 4 °C. Collected cells were washed three times with a 0.9% (w/v) saline solution. The washed cells were then lysed on ice with 15 mOsM phosphate buffer solution (pH 7.2) for 1 h. The lysate was passed through a glass wool filter three times, then filtered through a paper filter to remove the majority of cell debris.

The filtrate was then passed through a four stage hollow fiber setup ranging from 0.2 μm to 50 kDa in molecular weight cutoff (MWCO). The Hb retentate from the 50 kDa MWCO filter was used for the experiments in this study. This method was used to both purify and concentrate the Hb used in this study.

Assay of Hb Solution. SDS-PAGE was used to determine the purity of fractionated Hb. The purity of Hb bands in each lane of the SDS-PAGE gel was assessed from the relative band

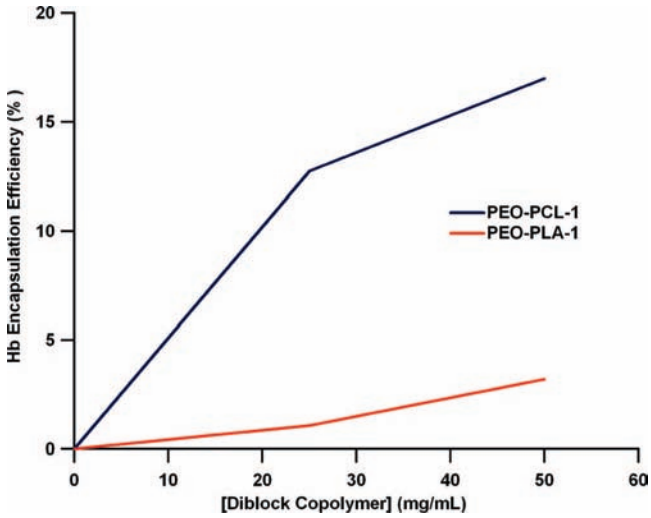

Figure 4. Effect of diblock copolymer concentration on bHb encapsulation efficiency in PEH dispersions extruded through 200 nm diameter polycarbonate membranes.

intensities using the *Quantity One 1-D* analysis software (Bio-Rad Laboratories, Hercules CA).

bHb with 97% purity and hHb with 96% purity were used to prepare PEHs. The freshly prepared Hb was buffer-exchanged with phosphate buffered saline (PBS) (pH 7.3). The metHb levels of the Hb solutions used in this study were always less than 3%.

PEH Preparation. 50 mg of diblock copolymer dried into a thin film was mixed with 1 mL of purified Hb in PBS at pH 7.3 as the extrusion buffer, in order to mimic the salinity and pH of blood plasma. The mixture was hydrated for at least 1 h.

To increase the efficiency of Hb entrapment in higher molecular weight copolymers, the copolymer/Hb mixture was subjected to 3 to 5 freeze/thaw cycles by alternatively placing the vials in a dry ice bath and warm water bath. After full hydration, the sample was extruded 20 times through 200 nm diameter polycarbonate membranes (Avanti Polar Lipids Alabaster, AL). Empty polymersomes were prepared in the same manner and used in the study as controls. Instead of hydrating with Hb solution, PBS was used as the hydration buffer. Both PEH and controls were used in the study immediately after preparation.

Dialysis and centrifugation methods were used to separate unencapsulated Hb from PEH particles. In the dialysis method, extruded PEH samples were dialyzed overnight using 300 kDa MWCO dialysis bags (Spectrum Laboratories Inc. Fort Lauderdale, FL) in PBS at 2−3 °C at a 1:1000 v/v dialyzed sample/PBS ratio in order to remove unencapsulated Hb. In the centrifugation method, extruded PEH samples were centrifuged at 14 000 rpm for 60 min. The supernatant containing unencapsulated Hb was discarded, while the PEH pellet was resuspended in PBS. This process was repeated 3 times until a clear supernatant was obtained.

PEH Size Distribution. An Eclipse asymmetric flow field flow fractionator (AFFFF) (Wyatt Technology Corp., Santa Barbara, CA) coupled in series to an 18-angle Dawn Heleos multiangle static light scattering (MASLS) photometer (Wyatt Technology Corp., Santa Barbara, CA) was used to measure the size distribution of PEHs and controls. The MASLS photometer was equipped with a 50 mW GaAs linearly polarized laser operating at a laser wavelength of 658 nm. *ASTRA* software (Wyatt Technology Corp., Santa Barbara, CA) was used to analyze the light scattering spectra and calculate the particle size distribution of the particle dispersions.

Hb Encapsulation Efficiency and Methemoglobin Level. In order to measure the Hb encapsulation efficiency and encapsulated methemoglobin (metHb) level, centrifuged PEHs were first lysed using 0.2% Triton X-100 (Sigma-Aldrich, St. Louis, MO) in PBS. The encapsulation efficiency was calculated using the following equation:

$$\text{Hb Encapsulating Efficiency (\%)} = \left[1 - \frac{V_1C_1 - V_2C_2}{V_1C_1}\right] \times 100 \quad (1)$$

where V_1 = Initial volume of unencapsulated Hb and PEH particles (mL);

C_1 = Initial concentration of Hb (mg/mL);

V_2 = Volume of PEH particles obtained after centrifugation (mL);

C_2 = Concentration of encapsulated Hb obtained after lysing PEHs (mg/mL).

The metHb levels of Hb encapsulated inside PEH particles were assayed via UV−vis spectroscopy (Thermo Electron Corp. Madison, USA) using the cyanomethemoglobin method detailed elsewhere (*2*−*5*, *7*, *18*). The absorbance of Hb extracted from lysed PEH dispersions was measured at 630 nm (L_1) against a blank reference (deionized water). Three drops of a 1:1 potassium cyanide solution made from equal parts of 10% KCN and 50 mM phosphate buffer were added to the lysed PEH samples. This converted methemoglobin to cyanomethemoglobin, which does not absorb at 630 nm. After 2 min, the

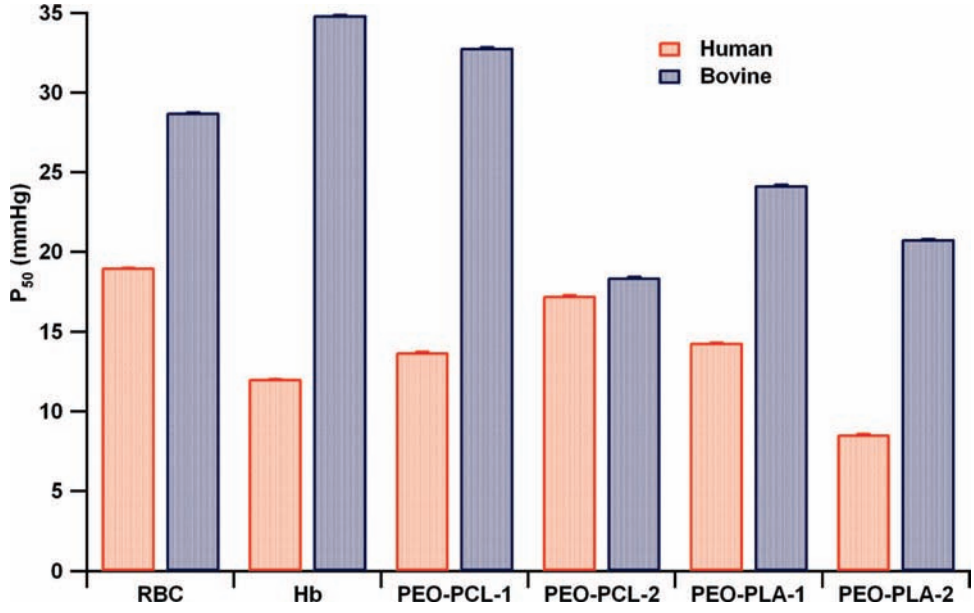

Figure 6. Oxygen affinity (P_{50}) of PEHs extruded through 200 nm diameter polycarbonate membranes.

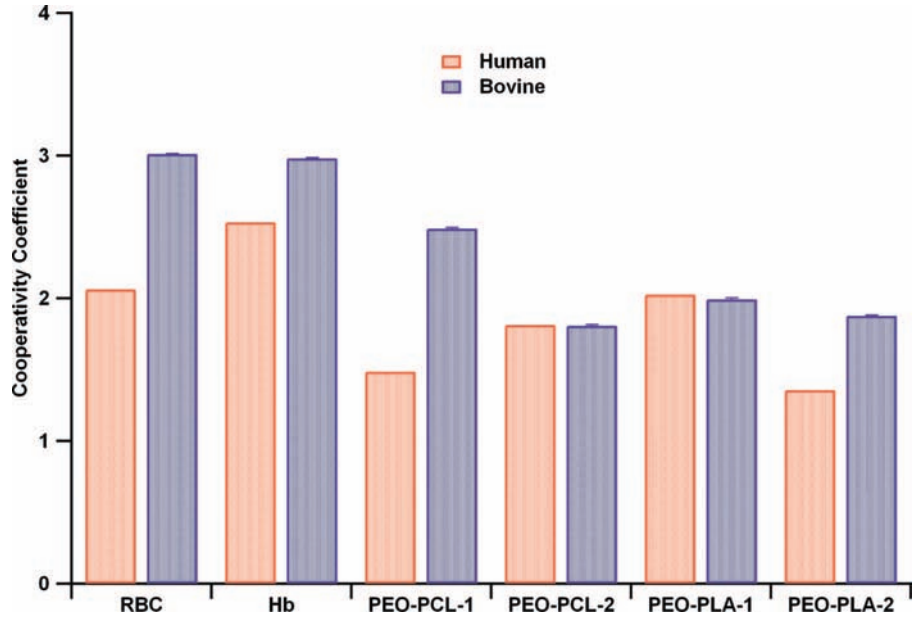

Figure 7. Cooperativity coefficient of PEHs extruded through 200 nm diameter polycarbonate membranes.

absorbance was read at 630 nm (L_2) against a blank reference. The concentration of metHb was determined as follows:

$$[\text{MetHb}]_{\text{mM}} = \frac{L_1 - L_2}{E} D_1 \qquad (2)$$

where $E = 3.7$ (cm $\times$ mM)$^{-1}$ is the extinction coefficient of metHb at 630 nm. The metHb level (%) is then expressed as follows:

$$[\text{MetHb}](\%) = \frac{[\text{MetHb}]_{\text{mM}}}{[\text{MetHb}]_{\text{mM}} + [\text{tHb}]_{\text{mM}}} \times 100 \qquad (3)$$

To determine the concentration of Hb, 3 drops of 20% potassium ferricyanide $K_3(Fe(CN)_6)$ was added to 3 mL samples diluted appropriately (D_2). The solution was allowed to react for 2 min before 3 drops of 10% KCN was added. The absorbance was then measured at 540 nm (L_3). The concentration of Hb was determined as follows:

$$[\text{tHb}]_{\text{mM}} = \frac{L_3}{E} D_2 \qquad (4)$$

where $E = 11.0$ (cm $\times$ mM)$^{-1}$ is the extinction coefficient for metHb at 540 nm.

Oxygen Equilibrium Binding Properties. The oxygen equilibrium binding curves of PEH dispersions were measured using a Hemox-Analyzer (TCS Scientific Corp. New Hope, PA) at physiological temperature (37 °C) (*4*, *7*, *18*) Briefly, 1 mL of PEH dispersion was added to a mixture containing 4 mL Hemox buffer, 20 μL of Additive-A, and 10 μL of antifoaming agent (TCS Scientific Corporation). The PEH dispersion was allowed to saturate to a pO_2 of 145 $\pm$ 2 mmHg using compressed air. The PEH dispersion was given extra time to saturate since oxygen takes a longer time to diffuse across the PEH membrane. After that, the gas stream was switched to pure N_2 to deoxygenate the PEH dispersion. The absorbances of oxy- and deoxy-Hb in solution were recorded as a function of pO_2 via dual wavelength spectroscopy. A six-parameter (A_0, A_∞, A_1, A_2, A_3, A_4) Adair model (5) and a four-parameter (A_0, A_∞, P_{50}, n) Hill model (6) were used to fit the oxygen equilibrium curves of PEH dispersions in order to regress the Adair parameters, as

RESULTS AND DISCUSSION

Hb Encapsulation Efficiency. Figure 2 shows the encapsulation efficiency of PEHs extruded in PBS (pH 7.3). The Hb encapsulation efficiency was calculated using the centrifugation method. PBS was chosen as the extrusion buffer, since it produces monodisperse suspensions (*6*). Figure 2 shows that, as the molecular weight of the PEO block of the copolymer increases, the Hb encapsulation efficiency decreases. This observation is expected, since as the PEO chain lengths of the outer leaflets of polymersomes become larger, less volume in the core will be available for Hb encapsulation. We did not observe any effect on Hb encapsulation efficiency with a change in the chemical nature of the hydrophobic block (PLA or PCL). However, in all cases, the percentage of Hb encapsulation was generally low.

Moreover, Figure 2 shows that Hb encapsulation was more efficient with copolymers possessing lower molecular weight hydrophobic blocks. This is probably due to the relatively thin membrane of these polymersomes, which results in the availability of more internal core volume for Hb encapsulation. However, the use of PEH with higher molecular weight PEO does offer advantages in suppressing nonspecific protein interactions with the polymersome surface (*8*). This, in turn, influences the release properties of the polymersomes and will lead to more efficient removal of these particles from the body by the mononuclear phagocytic system.

Figure 3 compares the Hb encapsulation efficiency measured via centrifugation and dialysis methods. The PEHs used for the comparison were composed of different chain lengths of the same type of hydrophobic blocks (PEO-b-PCL-1 and PEO-b-PCL-2). The calculated Hb encapsulation efficiencies from the centrifugation method were higher than those of the dialysis method for both types of PEH dispersions. This may be due to the effect of dialysis on the hydrophilic outer and inner shell of PEHs, which swells during the dialysis process. This in turn results in the release of Hb, and hence reduces the observed Hb encapsulation efficiency. This observation is corroborated by the fact that the volume of packed PEH particles after dialysis was always greater than the initial packed volume of PEH particles before dialysis.

Figure 4 shows the effect of total polymer concentration on encapsulation of Hb in PEHs composed of two different types of hydrophobic blocks (PCL and PLA). The results show that encapsulation of Hb increased with increasing total polymer concentration. Therefore, by adjusting the diblock copolymer concentration, more or less polymersomes will be formed, and hence Hb encapsulation can be tailored accordingly.

It has been shown that the circulation half-life and *in vivo* stability of polymersomes surpass those of liposomes (*10*). The circulation half-lives of 100 nm diameter polymersomes with PEG brushes ranging from 1200 to 3680 Da and hydrophobic core thickness ranging from 9.6 to 14.8 nm were shown to be 10−20 h longer compared to PEG-liposomes with similar sizes (*10*). The hydrated PEO blocks obscures the hydrophobic core from the RES, which leads to the dependence of circulatory half-life of polymersomes on the molecular weight of PEO rather on the hydrophobic core thickness. Previous studies have also shown that the *in vivo* clearance mechanism of polymersomes appears to be similar to that of PEG-liposomes (*10*). This is achieved through opsonizing plasma protein deposition onto the membrane, which mediates clearance by the phagocytes of the liver and spleen (*10*).

In these experiments, the Hb/polymer weight ratio ranged between 1.2 to 1.5. These results are in the same range as those found in the literature. For example, Sakai et al. (*19*) obtained Hb/lipid weight ratios of ∼1.61, while that Takeoka et al. (*20*) obtained ratios near 1.7. However, our initial Hb concentration (70−80 mg/mL) was always less than the initial Hb concentrations used in their studies (>100 mg/mL) (*19*). Hence, it is possible for us to realize higher weight ratios.

The appropriate Hb concentration that is required for effective physiological oxygen delivery to tissues has recently been debated (*21*). For example, an Hb vesicle suspension containing 16 g/dL of Hb suspended to a volume fraction of 40% (v/v) yields an oxygen-carrying capacity that is comparable to that of blood (*21*). Therefore, our results suggest that the Hb/polymer weight ratio can be modified by simply varying the molecular weight of the diblock copolymer used in the formulation.

Oxygen Binding Properties. Equilibrium oxygen binding curves of PEH dispersions extruded through 200 nm pore diameter membranes are shown in Figure 5. All measured oxygen dissociation curves showed full saturation with O_2 at high pO_2s. While saturating the samples, it was observed that PEH dispersions took longer to saturate versus bovine and human RBCs. The membrane thickness of PEHs is greater than that of human and bovine RBCs. The increased membrane thickness results in the reduced permeability of oxygen across the PEH membrane. The oxygen binding properties of Hb were not compromised by encapsulation as is evident from the sigmoidal shape of the oxygen binding curves exhibited by all PEH dispersions. A decrease in the rate of PEH oxygen unloading or uptake is expected, because oxygen will take a longer time to diffuse across the PEH membrane.

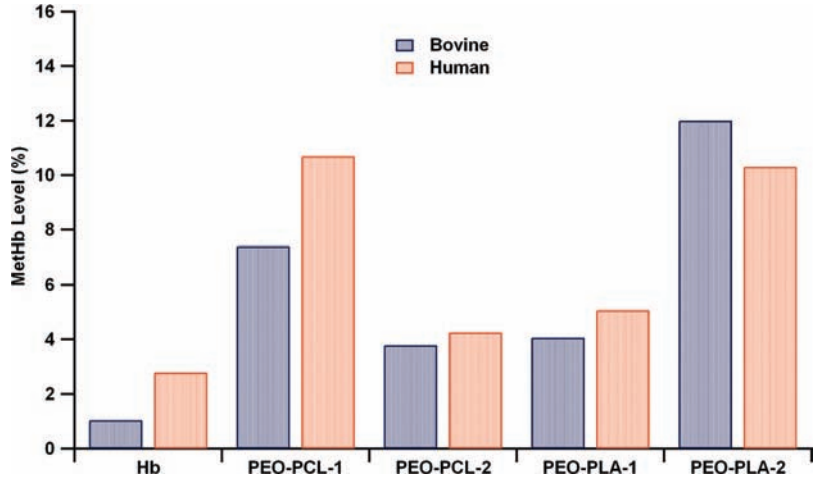

Figure 8. MetHb level of PEHs extruded through 200 nm diameter polycarbonate membranes.

Table 3. Phase Transition Temperatures Where T_m (°C) Is Melting Temperature and T_c (°C) is Crystallization Temperature

sample	T_m (°C)	T_c (°C)
PEO-PCL	52.4	18
PEO-PLA	48.1	-

The oxygen affinity (P_{50}) and cooperativity coefficient (n) of PEH dispersions are shown in Figures 6 and 7, respectively. The P_{50} and cooperativity coefficient were regressed from the oxygen equilibrium data using the Hill equation (eq 6). The P_{50} and n of all PEH dispersions vary depending upon the number-averaged molecular weight of the diblock copolymer. The variation in P_{50} for bHb was more significant than that of hHb. The P_{50} values for PEHs encapsulating hHb were generally low, in the range 8−18 mmHg, which makes them suitable for the oxygenation of ischemic tissues (*1*).

The cooperativity coefficient of Hb is a gauge of the ability of Hb to change from a low-affinity to a high-affinity state depending on the surrounding oxygen concentration. All PEH dispersions exhibited $n \approx 2$ for hHb and $n > 2$ for bHb, suggesting that all PEH dispersions display reasonable cooperativity with respect to oxygen binding and release. Table 2 compares the oxygen binding properties for select PEH dispersions and other encapsulated Hb dispersions. These results clearly show that oxygen binding properties of PEH dispersions are comparable to those of other Hb encapsulated systems (*3*−*5*).

Encapsulated MetHb Level. The metHb levels of PEH dispersions are shown in Figure 8. The metHb levels of the stock bHb solution and hHb were 1−1.5% and 2.5−3%, respectively. The metHb level of PEHs composed of lower molecular weight copolymers (PEO-b-PCL-1 and PEO-b-PLA-2) was higher than that of PEHs composed of higher molecular weight copolymers (PEO-b-PCL-2 and PEO-b-PLA-1).The increase in metHb level is primarily attributed to the rigorous preparation procedure of the PEHs and their high phase transition temperatures (Table 3), which are in the range 30−55 °C. However, the effect of higher phase transition temperatures decreased with increase in the molecular weight of the copolymer. This may be attributed to the fact that higher molecular weight copolymers produced polymersomes with thicker membranes, which maintained the oxidation state of the heme. Due to this, the increase in metHb level of Hb in higher molecular weight polymers was less significant than that of low molecular weight polymersomes.

In addition, the presence of chloride ions in the extrusion buffer was found to enhance Hb oxidation (*7*). However, the effect of Cl^- ions in this study was less significant that the effect

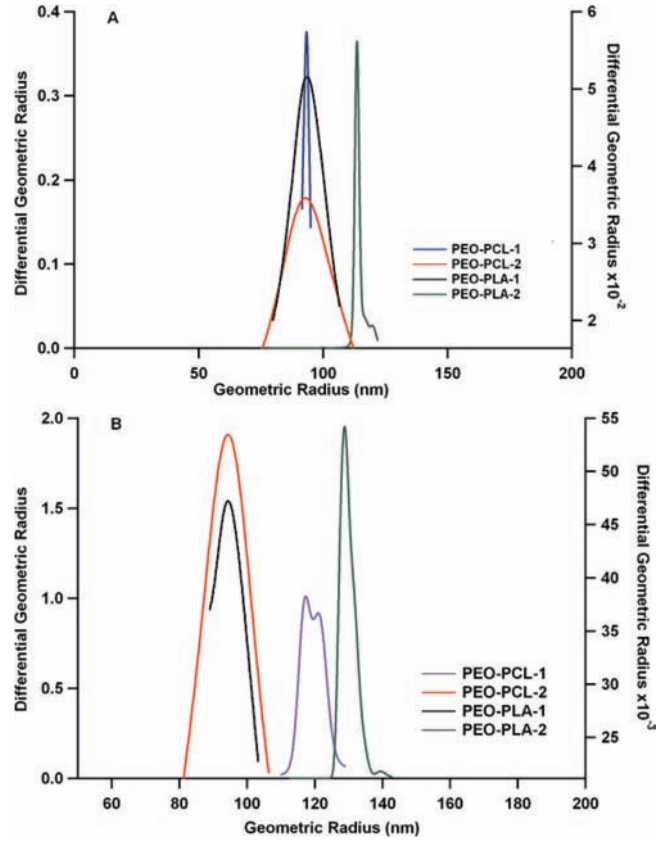

Figure 9. Size distribution of (A) empty polymersomes and (B) PEHs extruded through 200 nm diameter polycarbonate membranes.

of the vigorous preparation conditions, since the metHb levels of PEHs like PEO-b-PCL-2 and PEO-b-PLA-1 were comparable to the metHb levels of stock bHb and hHb solutions (<5%).

Also, unlike others (*22*), no reductants and catalases were used in this study to suppress Hb oxidation. However, the coencapsulation of low concentrations of reductants and catalases can be easily incorporated in order to further suppress Hb oxidation if desired. Unlike liposomes (*7*), the bilayer of polymersomes did not enhance Hb oxidation. Hb oxidation in LEAcHbs and nonmodified LEHs is mainly due to phospholipid peroxidation, which is not the case with polymersomes. Thus, encapsulation of Hb into polymersomes did not induce metHb formation. This is one important aspect that favors PEH as a potential cellular HBOC, since Hb oxidation reduces the amount of oxygen that is available for oxygen transport.

Size Distribution and Average Radii. The differential size distributions of empty polymersomes and PEHs extruded through 200 nm pore diameter membranes are shown in Figure 9, panels A and B, respectively. All polymersomes have monodisperse size distributions with an approximate distribution width of 20 nm and are generally Gaussian in shape . The average size of PEHs is greater than that of empty polymersomes, which may be due to swelling of polymersomes on encapsulating Hb.

According to previous studies (*16*, *23*), the average molecular shape is most simply a reflection of the hydrophilic fraction, *f*. To generate polymersomes in water, the value of *f* should be $\sim 35 \pm 10\%$; values of $f < 50\%$ presumably reflects the ability of hydration to balance a disproportionately large hydrophobic fraction (*16*, *23*). Hydrophilic fractions greater than 45% can be expected to form micelles (*16*), whereas molecules with $f <$ 25% can be expected to form inverted microstructures (*16*). Copolymers with molecular weight ranging 2000−20 000 Da have been observed to follow these packing rules and yield polymersomes when the *f* requirement is satisfied (*8*). The scaling of copolymer membrane thickness with copolymer molecular weight has been experimentally verified and confirmed by a novel coarse-grained molecular dynamics simulation that yielded the following expression:

$$d \approx \mathrm{MW}_\mathrm{h}^b \quad (b \cong 0.55) \tag{7}$$

where d = thickness of polymersome membrane;

$\mathrm{MW_h}$ = molecular weight of hydrophobic block.

This property of polymersome membranes thus presents a novel opportunity to study membrane properties as a function of membrane thickness *d* (*8*, *9*). The mean diameter of PEHs used in this study was calculated with eq 7 and shown in Table 2.

CONCLUSIONS

This study investigated the use of biodegradable and biocompatible diblock copolymers for the preparation of Hb-encapsulated polymersomes. Our results showed that the Hb encapsulation efficiency decreased with an increase in the molecular weight of the PEO block of the copolymer. However, changing the chemical nature of the hydrophobic block (PLA or PCL) did not result in any observable effect on Hb encapsulation efficiency. In addition, our results showed that Hb encapsulation increased with increasing total copolymer concentration. Thus, by adjusting the diblock copolymer concentration, Hb encapsulation can be tailored accordingly. The Hb/polymer weight ratio can also be modified in order to make the oxygen carrying capacity of PEHs comparable to that of blood.

Hb encapsulation did not affect oxygen binding properties of Hb, as is evident from the sigmoidal shape of the oxygen binding curves. In addition, the P_{50}s for PEHs encapsulating hHb were low, which makes them suitable for oxygenating ischemic tissues. All PEH dispersions showed reasonable cooperativity with respect to oxygen binding and release. Moreover, encapsulation of Hb inside polymersomes did not induce metHb formation. All polymersome dispersions exhibited monodisperse size distributions with an approximate distribution width of 20 nm. Taken together, all of our observations favor the use of PEHs as potential cellular HBOCs.

Zinc(II)-Coordinated Oligotyrosine: A New Class of Cell Penetrating Peptide

James R. Johnson, Hua Jiang, and Bradley D. Smith*

Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, Indiana 46556 USA. Received December 16, 2007; Revised Manuscript Received January 20, 2008

A new series of cell penetrating peptides (CPPs) are described. The peptides are oligomers of Tyr-ZnDPA, a tyrosine derivative with an appended 2,2′-dipicolylamine unit that forms a very stable coordination complex with a zinc (II) cation. This in turn allows reversible association with a chelating oxyanion such as a carboxylate or phosphate derivative. The peptide oligomers $(Tyr\text{-}ZnDPA)_n$ where $n = 1, 2, 4, 8$, are highly water soluble, but upon association with fatty acids or phospholipids they partition into an organic octanol phase. Furthermore, a fluorescent, fluorescein-labeled version of the octamer, $(Tyr\text{-}ZnDPA)_8$-Fl, can enter living mammalian cells via endocytosis and a biotin derivative can deliver fluorescein-labeled streptavidin. Fluorescence microscopy and flow cytometry experiments show that cell uptake is diminished by conditions that inhibit endocytosis. Additionally, uptake of $(Tyr\text{-}ZnDPA)_8$-Fl is greater than fluorescein labeled octaarginine (Arg_8-Fl) in all cell lines tested (CHO, COS-7, HeLa). Another difference with Arg_8-Fl is that cell uptake of $(Tyr\text{-}ZnDPA)_8$-Fl does not require the presence of heparan sulfate proteoglycans on the cell surface. This difference may eventually be of practical value because drug delivery systems that employ alternative endocytic mechanisms may be optimal for different cell lines or they may deliver selectively to different organelles within a cell.

INTRODUCTION

Spontaneous diffusion of charged or high molecular weight compounds across the cell plasma membrane is kinetically unfavored which means that many potential drugs and diagnostic reagents are ineffective because they cannot reach their intracellular targets. To overcome this transport barrier, a range of cell delivery systems have been proposed and investigated, including cell surface receptors, synthetic transporters, nanotubes, and nanoparticles (*1–4*). In the mid 1960s Ryser and Hancock discovered that cationic peptides can promote the entry of macromolecules into living cells (*5–7*), and peptide mediated delivery has subsequently been applied to a wide variety of molecular cargo (*8*). Most designs of cell penetrating peptides (CPPs) are based on a membrane translocation sequence (sometimes referred to as a protein transduction sequence) that is within the larger structure of a larger transport-active protein like HIV-Tat or the *Drosophila antennapedia* homeodomain (*9, 10*). In other cases, the peptide designs are *de novo* (*11*). Usually, CPPs enter living cells via endocytosis; however, some appear to directly translocate across the plasma membrane in an energy-independent manner (*12*). The transported cargo includes biologically active proteins, DNA, liposomes, fluorescent dyes, and nanoparticles (*13–17*), and delivery success has even been achieved in vivo (*18, 19*). Often the peptide is covalently linked to the cargo (*20*), and in some cases the linker is cleavable (*21*). There are CPPs that associate noncovalently with the cargo (*22, 23*), and also CCPs that are activated by protease cleavage of an inhibitory segment (*24*).

We have designed a novel oligomeric CPP that requires metal cations for cell delivery activity. The peptide monomer is $(Tyr\text{-}ZnDPA)_1$ a tyrosine derivative with an appended 2,2′-dipicolylamine unit that forms a stable coordination complex with a zinc (II) cation (Scheme 1) (*25*). Previously, we have shown that this water soluble, zinc-coordinated monomer can associate with a chelating oxyanion such as a carboxylate or phosphate derivative. The resulting ternary complex is net neutral and if the oxyanion is sufficiently lipophilic, it can partition from water into vesicles. Here, we describe the anion binding and membrane partitioning properties of a various oligomers of $(Tyr\text{-}ZnDPA)_n$, where $n = 1, 2, 4, 8$ (Scheme 2). These peptide oligomers are also highly water soluble, but upon association with fatty acids or phospholipids they migrate into an organic octanol phase. Furthermore, we find that fluorescently labeled versions of these peptides can enter cells via endocytosis and that a biotin derivative of these peptides can deliver fluorescently labeled streptavidin. The results of this work raise the idea of a cell delivery system that is activated by increased local concentrations of zinc (*26*), and thus may be useful for selective delivery to zinc-rich tissues or to tissues upon stimulated zinc efflux from cells (*27, 28*).

EXPERIMENTAL PROCEDURES

Synthesis. See Supporting Information.

Water/Organic Partitioning. (*1*) $(Tyr\text{-}ZnDPA)_n$ and sodium hydroxide were dissolved in water to give a 10 mM stock solution in each case. Lauric acid was dissolved in octanol to give 10 mM stock solution (*2*). To a 2 mL glass vial was added water (0.5 mL), octanol (0.5 mL), and an aqueous solution of $(Tyr\text{-}ZnDPA)_n$ (5 μL). For experiments with lauric acid, a solution of lauric acid (6 μL, 1.2 molar equiv per Zn) was added

n=2, (Tyr-ZnDPA)$_2$
n=4, (Tyr-ZnDPA)$_4$
n=8, (Tyr-ZnDPA)$_8$

followed by a solution of sodium hydroxide (6 μL, 1.2 molar equiv). The mixed solution was shaken for 30 s and centrifuged. Spectrometric measurements were made with 100 μL aliquots from each layer. The aqueous phase was diluted with 0.1 mL octanol and 0.6 mL methanol. The octanol phase was diluted with 0.1 mL water and 0.6 mL methanol (*3*). The partitioning protocol for (Tyr-ZnDPA)$_n$-Fl is similar to above procedure. Since (Tyr-ZnDPA)$_1$-Fl is soluble in octanol rather than in water, no partition experiment was done in this case. The stock solution of (Tyr-ZnDPA)$_2$-Fl was 0.5 mM in a mixture of water and methanol (9:1). The stock solutions of (Tyr-ZnDPA)$_4$-Fl and (Tyr-ZnDPA)$_8$-Fl were 1 mM in water.

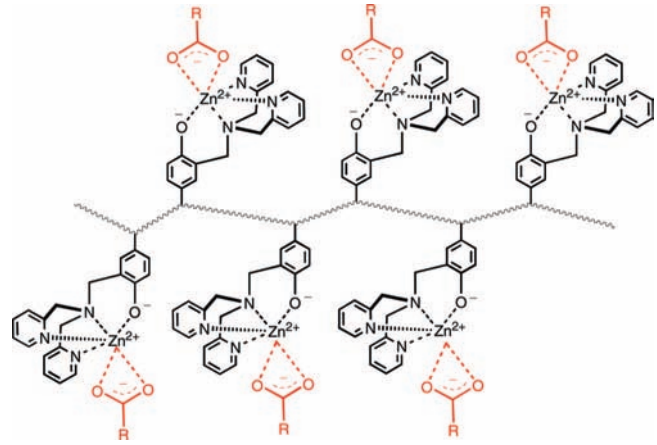
Eukaryotic Cell Culture. CHO, PGSA, PGSD, COS-7, and HeLa cells were cultured according to ATCC protocols. All cell lines were cultured in T75 cell culture flasks with vented caps and incubated at 37 °C in a humidified 5% CO_2 atmosphere. For fluorescence microscopy, cells were plated out on 8-well microscope chambered slides and allowed to grow to approximately 80% confluence. Upon treatment and incubation with CPPs, cells were rinsed 3 times with phenol free Dublecco's Minimum Essential Medium (DMEM) containing 2 mM L-glutamine, glucose, and supplemented with 10% fetal bovine serum. For flow cytometry all cell cultures were grown in 6-well cell culture plates to approximately 80% confluence. In preparation for flow cytometry cells were rinsed with phosphate buffered saline solution and then trypsinized for 10 min to remove externally bound peptide and to detach cells from the surface of well plates. Upon trypsinization, cells were resuspended in phenol-free DMEM. For both flow cytometry and fluorescence microscopy cells were analyzed in phenol-free DMEM.

Cell Toxicity. Cell toxicity was assessed via MTT assay using the Vybrant MTT Cell Proliferation Assay Kit (Invitrogen, V-13154). A 200 μL mixture of cells (approximately 5×10^4 cells/mL) in growth media were dispensed into each well of a 96-well plate and allowed to grow to 80% confluence. An aliquot of 1 mM (Tyr-ZnDPA)$_8$ in 50:50 water/methanol was administered to the first well in each treatment and subsequent wells were given a serial 2-fold dilution. The cells were allowed to incubate for 6 h at 37 °C, then the growth medium was removed and replaced with 100 μL of growth media supplemented with [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] (MTT) at a concentration of 1.2 mM. The cells were incubated at 37 °C for 4 h then treated with 100 μL of an SDS-HCl solution to kill the cells, and dissolve the formazan product. The SDS-HCl solution was prepared by adding 10 mL of 0.01 M HCl to 1 g of SDS. The SDS-HCl/cell solution was then incubated for 12 h at 37 °C, after which the absorbance of each well was read at 570 nm. In order to determine the viability in each sample the following equation was used:

$$\text{Cell Viability} = (\text{Abs} - \text{Abs}_{\text{Neg}})/(\text{Abs}_{\text{Con}} - \text{Abs}_{\text{Neg}})$$

where Abs is the absorbance of the test well, Abs_{Neg} is the absorbance of the negative control (no cells added to the well)

Scheme 2. Schematic View of (Tyr-ZnDPA)$_n$ and Association with Carboxylates



and Abs_{Con} is the absorbance of wells in which cells were not treated with (Tyr-ZnDPA)$_8$.

Fluorescence Microscopy. Fluorescence microscopy was conducted on a Nikon Eclipse TE-2000 U epifluorescence microscope equipped with blue field (Exciter: D360/40×, Dichroic: 400DCLP, Emitter: 460/50m), green field (Exciter: D360/40×, Dichroic: 400DCLP, Emitter: HQ535/50m), red field (Exciter: HQ545/30×, Dichroic: Q570LP, Emitter: HQ610/75m) filters, and far red (Exciter: HQ620/60X, Dichroic: 660LP, Emitter: HQ700/75m) filters. Images were acquired using a Photometrics 512-B black and white digital camera and appropriate field colors were added using Metamorph Software V6.2.

Flow Cytometry. Flow cytometry was conducted on a Beckman Coulter MPL 500 flow cytometer, and data was manipulated using the instrument's MPL and CXP software packages. After incubation, the cell cultures were prepared for flow cytometry analysis by removing the cell growth media, rinsing with PBS buffer, and treating with trypsin. This served to detach the cells from the culture wells and to degrade any remaining fluorescent peptide on the outside of the cells. Cell populations that were not pretreated in this manner exhibited greater fluorescence intensity due to externally bound peptide. Analysis was conducted for a minimum of 10 000 counting events.

Endocytosis Inhibition. For inhibition of endocytosis, cells were incubated at 4 °C for 15 min, treated with 10 μM (Tyr-ZnDPA)$_8$-Fl in growth media, and incubated for another 3 h at 4 °C. Cells were then prepared for analysis as previously described. For ATP depletion, cells were preincubated in growth media supplemented with 0.1% NaN_3 and 50 mM deoxyglucose for 1 h, then treated with 10 μM (Tyr-ZnDPA)$_8$-Fl and incubated for 3 h. For specific endocytosis mechanisms, cells were treated with chlorpromazine (30 μM), 400 mM sucrose, nystatin (25 μg/mL), amiloride (3 mM), or wortmannin (10 μM) for 1 h prior to administration of (Tyr-ZnDPA)$_8$-Fl in growth media. After a 3 h incubation, cells were prepared for flow cytometry analysis.

RESULTS

Synthesis. The doubly protected amino acid (Tyr-DPA)$_1$ was prepared in one step and large scale using cheap starting materials. The oligomeric series (Tyr-DPA)$_n$, where $n = 1$, 2, 4, 8 was subsequently constructed in high yields (≥80% for each step) using solution-state amide coupling chemistry with EDC/HOBt as the activating agent. Chromatographic purification was greatly facilitated by using silica gel and an admixture of acetonitrile/ammonium hydroxide as the eluent. The pure

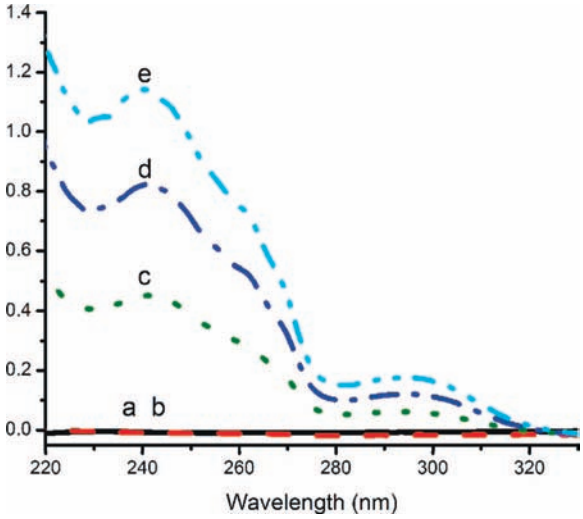


Figure 1. Absorption spectra of octanol phase after partitioning of (Tyr-ZnDPA)$_8$ (10 μM) between water and octanol with various molar equivalents of sodium laurate per Zn(II); (a) 0 equiv, (b) 0.5 equiv, (c) 0.75 equiv, (d) 1 equiv, (e) 1.5 equiv.

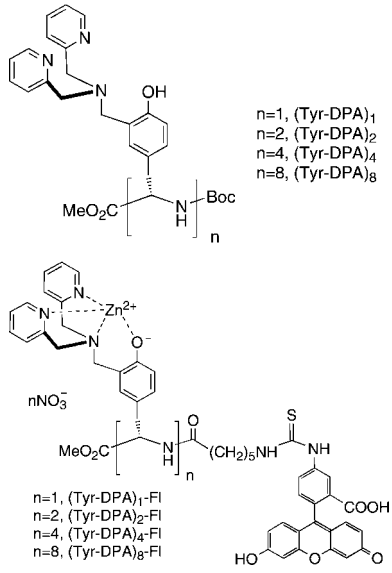
(Tyr-DPA)$_n$ peptides were converted into zinc(II) complexes, (Tyr-ZnDPA)$_n$, by simply stirring with a stoichiometric amount of $Zn(NO_3)_2$. To make the fluorescent conjugates, (Tyr-ZnDPA)$_n$-Fl, the amine versions of (Tyr-DPA)$_n$ were linked to FITC via an aminohexanioic acid chain, and the pure peptides converted into zinc(II) complexes. Fluorescein labeled octa(arginine), (Arg_8-Fl) was prepared by reported methods (*29*).



Liquid Water/Organic Partitioning Studies. The partitioning of unlabeled peptides (Tyr-ZnDPA)$_n$ between water and octanol is easily monitored by the UV absorption of the aromatic groups at 240 and 300 nm. In all cases, the zinc-coordinated oligomers are highly water-soluble and they reside completely in the aqueous phase. However, the presence of sodium laurate ($\geq$1.5 mol equiv per zinc cation) induces complete migration of each oligomer into the octanol phase. As shown in Figure 1, the presence of 0.5 mol equiv of sodium laurate is able to move significant amounts of the longest oligomer, (Tyr-ZnDPA)$_8$ into the octanol, but complete partitioning requires 1.5 mol equiv of laurate.

Similar phase transfer results were obtained with the fluorescein conjugated oligomers (Tyr-ZnDPA)$_n$-Fl. In this case, the yellow color of fluorescein tag can be monitored by the naked eye, and as shown in Figure 2, the sodium laurate promotes complete partitioning of (Tyr-ZnDPA)$_8$-Fl into the octanol layer. In Figure 3 is a comparison of the (Tyr-ZnDPA)$_8$-Fl partitioning induced by sodium laurate and the anionic phospholipid 1-palmitoyl-2-oleoylphosphatidylglycerol (POPG). In both cases, there is extensive peptide migration into the organic phase but the process is achieved more slightly readily with the POPG, reflecting its comparatively greater lipophilicity and higher affinity for the zinc cations in the peptide. The same (Tyr-ZnDPA)$_8$-Fl partitioning results were obtained with the anionic phospholipids 1-palmitoyl-2-oleoylphosphatidic acid (POPA) and 1-palmitoyl-2-oleoylphosphatidylserine (POPS), whereas no partitioning into the organic layer was induced by the presence of POPC (see Supporting Information).

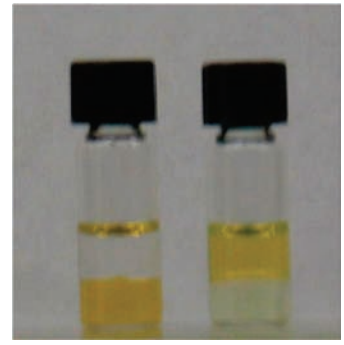


Figure 2. Partitioning of (Tyr-ZnDPA)$_8$-Fl (1 μM) between water and octanol: (left) with no sodium laurate present the peptide is completely in the lower aqueous phase. (right) the presence of 1.5 mol equiv of sodium laurate per Zn(II) induces complete migration into the upper octanol phase.

Octanol partitioning was also used to evaluate the affinity of (Tyr-ZnDPA)$_8$-Fl for the multianionic polysaccharide heparin (sodium salt from porcine intestinal mucosa, average molecular weight 3000 g/mol). In this case, the heparin was used as a water-soluble inhibitor of laurate induced transfer of (Tyr-ZnDPA)$_8$-Fl into the organic phase. As shown in Figure 4, peptide partitioning into octanol was prevented when the level of heparin in the aqueous phase was above 60 μg/mL. We infer that the multianionic heparin has a strong affinity for (Tyr-ZnDPA)$_8$-Fl and the ternary complex is not lipophilic.

Penetration of Fluorescent (Tyr-ZnDPA)$_n$ into Living Cells. The fluorescent peptides (Tyr-ZnDPA)$_n$-Fl were administered to a variety of eukaryotic mammalian cell lines (CHO, COS-7, HeLa) and examined for cellular uptake using fluorescence microscopy. Figure 5 shows fluorescent micrographs of CHO and COS-7 cells that have been incubated with (Tyr-ZnDPA)$_8$-Fl (10 μM) in serum supplemented growth media for 3 h at 37 °C. Binding of the (Tyr-ZnDPA)$_8$-Fl to the exterior of the cell was observed as early as 15 min after treatment and likely occurs immediately after administration of the compound to the cell culture. Within 1 h the fluorescence was confined to punctuate compartments within the cell. The presence of serum or growth media did not appear to inhibit uptake; however, administration of these peptides to cells in phosphate buffered saline caused precipitation, and diminished cell uptake as judged by fewer fluorescent endosomal compartments.

The amount of cell uptake of (Tyr-ZnDPA)$_n$-Fl was quantified by flow cytometry. The flow cytometry histograms in Figure 6 show that the order of uptake in HeLa cells is (Tyr-ZnDPA)$_8$-Fl > (Tyr-ZnDPA)$_4$-Fl > (Tyr-ZnDPA)$_2$-Fl. No uptake or cell surface binding was observed with (Tyr-ZnDPA)$_1$-Fl. Thus, cell adhesion and uptake increases substantially with the length and multivalency of the peptide. The uptake of (Tyr-ZnDPA)$_8$-Fl and Arg_8-Fl in different cell lines was compared by flow cytometry (see Supporting Information). With HeLa cells the

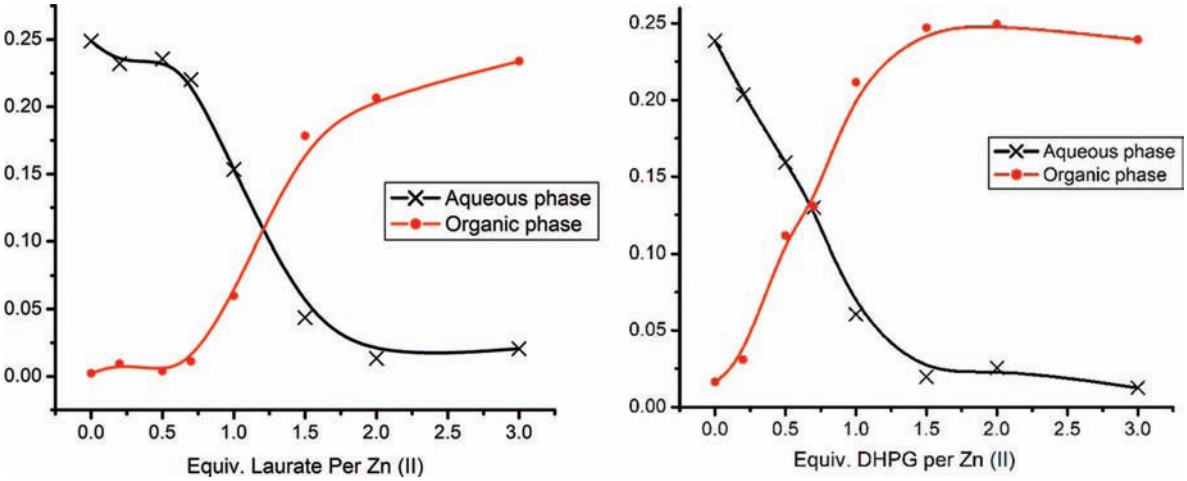

Figure 3. Amount of (Tyr-ZnDPA)$_8$-Fl (1 μM) (reflected by absorbance at 500 nm) in aqueous and organic phase after partitioning between water and octanol in the presence of: (left) various molar equivalents of sodium laurate per Zn(II); (right) various molar equivalents of POPG per Zn(II).

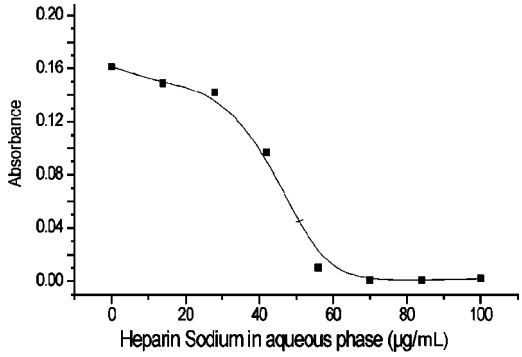

Figure 4. Amount of (Tyr-ZnDPA)$_8$-Fl (1 μM) in the organic phase (reflected by absorbance at 500 nm) for a two phase aqueous/octanol mixture that also contains sodium laurate (two molar equivalents of per Zn(II)) and various amounts of heparin sodium in the aqueous phase.

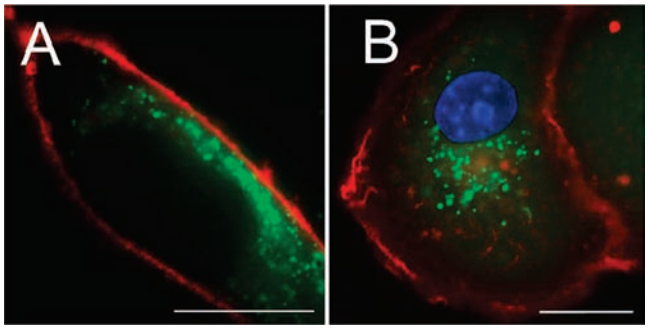

Figure 5. Panel A, a single CHO cell showing uptake of (Tyr-ZnDPA)$_8$-Fl (green). The plasma membrane is costained with FM 4–64 (1 μM) (red). Panel B, a single COS-7 cell showing uptake of (Tyr-ZnDPA)$_8$-Fl (10 μM) (green). The cellular membranes are costained with FM 4–64 (1 μM) (red) and the nucleus is costained with Hochest 33342 (1 μM) (blue). The bars denote a distance of 20 μm.

uptake of (Tyr-ZnDPA)$_8$-Fl was slightly greater, but with CHO and COS-7 cells the uptake was quite superior.

The toxicity of (Tyr-ZnDPA)$_8$ was determined by measuring cell viability using a standard MTT assay. The viability of CHO cells was unaffected by (Tyr-ZnDPA)$_8$ concentrations up to 40 μM, whereas the COS-7 cells were slightly effected with an approximate LD_{50} of 60 μM. With both cell lines there was little, if any measurable toxicity at the concentrations used in this study (10 μM).

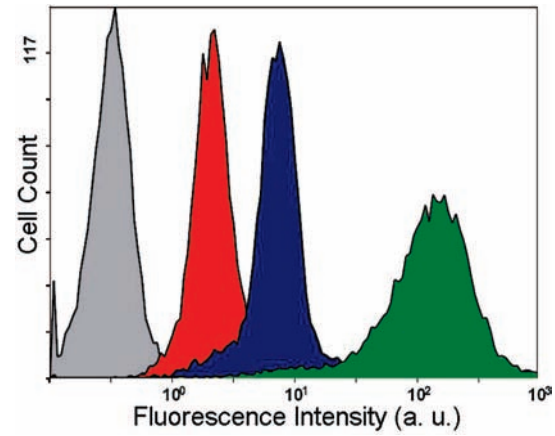

Figure 6. Overlay of flow cytometry histograms showing cellular uptake of the zinc tyrosine oligomers (10 μM) in HeLa cells. Histograms are as follows: gray, untreated cells; red, cells treated with of (Tyr-ZnDPA)$_2$-Fl; blue, cells treated with (Tyr-ZnDPA)$_4$-Fl; green, cells treated with (Tyr-ZnDPA)$_8$-Fl.

Table 1. Percent Cellular Uptake of (Tyr-ZnDPA)$_8$-Fl in the Presence of a Given Inhibitor As Quantified by Flow Cytometry[a]

		cell line		
compound	inhibits	COS-7	CHO	HeLa
4 °C incubation	endocytosis	0	0	0
NaN_3/DOG	endocytosis	0	0	0
Chlorpromazine	endocytosis[b]	6	13	50
Sucrose	endocytosis[b]	6	13	2
Nystatin	endocytosis[c]	60	40	80
Amiloride	pinocytosis	100	100	100
Wortmannin	pinocytosis	100	100	100

[a] Values are compared to uptake in the absence of inhibitor. [b] Clathrin-mediated endocytosis. [c] Caveolin-mediated endocytosis.

To determine how much of the cell uptake was due to endocytosis, the cell incubations were repeated under various conditions that inhibit endocytic processes (Table 1). The first method involved incubation of cell cultures at low temperature. Fluorescence microscopy and flow cytometry showed that incubation at 4 °C greatly inhibited the uptake of (Tyr-ZnDPA)$_8$-Fl. In addition, there was no entry into cells whose ATP levels were depleted of by preincubation with growth media supplemented with 0.1% NaN_3 and 50 mM deoxyglucose (DOG). These results indicate that cellular uptake occurs via one or more endocytosis mechanisms.

Table 2. Percent Uptake of Arg_8-Fl and $(Tyr\text{-}ZnDPA)_8$-Fl into PGSA and PGSD Cells Compared to Uptake into CHO Cells

peptide (10 μM)	PGSA	PGSD	CHO
Arg_8-Fl	<5	90	100
$(Tyr\text{-}ZnDPA)_8$-Fl	100	160	100

Additional mechanistic insight was gained by treating the cells with compounds that inhibit specific endocytosis processes. Separate samples of cells were each pretreated with an inhibitor prior to addition of $(Tyr\text{-}ZnDPA)_8$-Fl. Chlorpromazine and sucrose are known to be inhibitors of clathrin-mediated endocytosis while nystatin inhibits caveolin-mediated mechanisms (*30*). Cells were also treated with amiloride and wortmannin which inhibit pinocytosis. The amount of cell uptake was determined using flow cytometry and as summarized in Table 1, the inhibition varied with cell-type. The most effective inhibitors were chloropromazine and sucrose; whereas, amiloride and wortmannin were ineffective. Taken together the data in Table 1 indicates that $(Tyr\text{-}ZnDPA)_8$-Fl enters cells primarily by clathrin-mediated endocytosis.

There is strong evidence that oligo(arginine) internalization requires the presence of cell surface heparan sulfate proteoglycans (*30*). Since the phase transfer studies demonstrated that $(Tyr\text{-}ZnDPA)_8$-Fl also associates with the heavily sulfonated, heparin, we investigated if cell internalization was mediated by heparan sulfate proteoglycans. Our study compared the uptake into native CHO cells with entry into cells that were deficient in certain types of proteoglycans; that is, the PGSA 745 and PGSD 677 strains of CHO cells. PGSA cells do not have glycosaminoglycans because they are deficient in xylosyltransferase, which catalyzes attachment of the first sugar in glycosaminoglycan synthesis. Similarly, PGSD cells are deficient in both N-acetylglucosaminyltransferase and glucuronyltransferase activities and do not produce heparan sulfate, but they do produce chondroitin sulfate (*31, 32*). Separate samples of each cell type were treated with Arg_8-Fl and $(Tyr\text{-}ZnDPA)_8$-Fl (10 μM) and analyzed by both fluorescence microscopy and flow cytometry (Table 2). The decreased uptake of Arg_8-Fl was consistent with literature expectations. In contrast, the uptake of $(Tyr\text{-}ZnDPA)_8$-Fl into PGSA and PGSD cells was the same as native CHO cells (see Supporting Information). It appears that the presence of heparan sulfate proteoglycans on the cell surface is not necessary for uptake of $(Tyr\text{-}ZnDPA)_8$-Fl.

Streptavidin Delivery into Living Cells. Delivery of the versatile and multivalent protein, streptavidin into living cells is an important technical goal because it can be used to cotransport biotinylated cargo or target biotinylated intracellular targets. Previous studies have used Tat-streptavidin fusion protein (*33*), biotinylated antibody (*34*), biotinylated steroid (*35*), and biotinylated carbon nanotube (*36*). We prepared some zinc tyrosine-biotin conjugates and evaluate their abilities to noncovalently bind and transport the tetrameric streptavidin (molecular weight 64 kD) into living cells. Two groups of peptide-biotin conjugates were prepared. Direct attachment of the biotin to the N-terminal of the zinc tyrosine oligomers gave the series $(Tyr\text{-}ZnDPA)_n$-Biotin, whereas a longer spacer was attached to the C-terminal to make the series, $(Tyr\text{-}ZnDPA)_n$-TEO-Biotin.

These biotin conjugates were mixed separately with FITC labeled streptavidin and administered to living cells. There was no uptake of FITC-streptavidin when it was mixed with the $(Tyr\text{-}ZnDPA)_n$-Biotin, but cell delivery was achieved when the FITC-streptavidin was mixed with $(Tyr\text{-}ZnDPA)_n$-TEO-Biotin. Typical results with $(Tyr\text{-}ZnDPA)_8$-TEO-Biotin are shown in Figure 7. The fluorescence emission of the transported FITC-streptavidin appeared in the same types of endosomal compartments as the $(Tyr\text{-}ZnDPA)_n$-Fl series. A stoichiometry study indicated that FITC-streptavidin uptake increased until the $(Tyr\text{-}ZnDPA)_8$-TEO-Biotin: FITC-streptavidin ratio reached 4:1 and then remained constant for higher values.

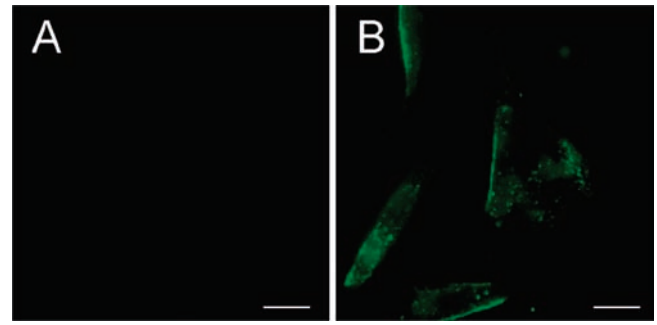

Figure 7. Fluorescence microscopy images of COS-7 cells treated with FITC-streptavidin (panel A) or $(Tyr\text{-}ZnDPA)_8$-TEO-Biotin complexed with FITC-streptavidin (panel B). The complexes were formed prior to cell treatment and complexes were administered at a concentration of 250 nM streptavidin.

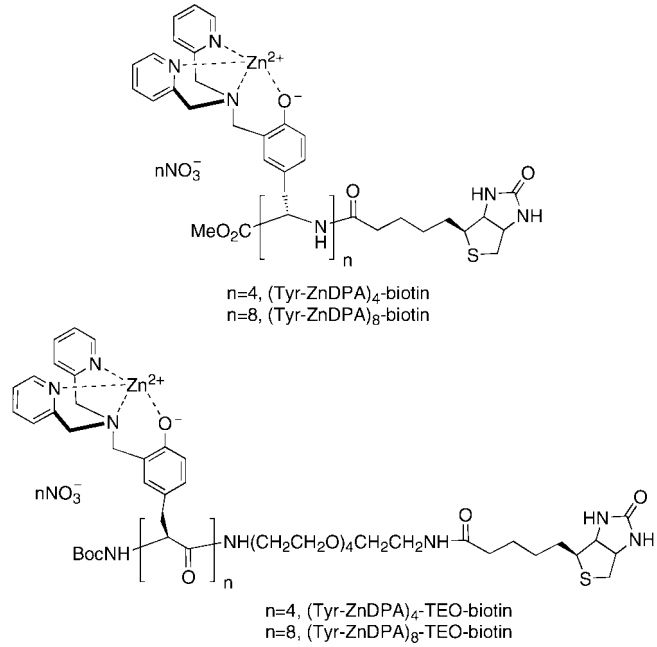

DISCUSSION

Cellular uptake of the $(Tyr\text{-}ZnDPA)_n$ peptides into living cells increases with peptide length and higher order multivalency. The biotin conjugate $(Tyr\text{-}ZnDPA)_8$-TEO-Biotin is able to promote internalization of the fluorescently labeled protein, streptavdin. In contrast, the biotin conjugate $(Tyr\text{-}ZnDPA)_8$-Biotin with a shorter linker is ineffective. The shorter linker may not allow the biotin group to reach the binding pocket of the streptavidin, or alternatively, the large streptavidin protein may prevent the peptide from achieving favorable interactions with the cell surface target (*37*). In any case, linker length is important for effective streptavidin delivery.

Uptake of the fluorescent octamer $(Tyr\text{-}ZnDPA)_8$-Fl is greater than the analogous Arg_8-Fl in all cell lines tested. Another striking difference with Arg_8-Fl is that cell uptake of $(Tyr\text{-}ZnDPA)_8$-Fl does not require the presence of heparan sulfate proteoglycans on the cell surface. It appears that the $(Tyr\text{-}ZnDPA)_n$ peptides target other markers on the cell surface, perhaps anionic phospholipids, negatively charged proteins (*38*), or cell surface carbohydrates (*39*). Our water/organic partitioning studies show that the $(Tyr\text{-}ZnDPA)_n$ peptides associate with anionic phospholipids and fatty acids to form lipophilic complexes that partition into organic phases. However, the cell entry

mechanism is primarily clathrin-mediated endocytosis and not passive diffusion through the plasma membrane. It appears that the $(Tyr\text{-}ZnDPA)_n$ peptides bind to the membrane surface and trigger an endocytosis event (*40*), or they may internalized by the routine membrane recycling mechanisms of the cell (*41–43*). While further studies are needed to fully elucidate the uptake mechanism(s) used by the $(Tyr\text{-}ZnDPA)_n$ peptides, the data in hand suggest that it differs to oligo(arginine) internalization. The distinction may eventually be of practical value because drug delivery systems that employ alternative endocytic mechanisms may be optimal for different cell lines or they may deliver selectively to different organelles within a cell (*44–46*).

The fluorescence microscopy data indicate that the transported peptides (or cotransported streptavidin) remain localized within endosomal compartments of the living cells. Therefore to effectively reach the cell cytosol it will be necessary to trigger endosomal release using an adjuvant (*47*, *48*). We plan to determine if these multivalent $(Tyr\text{-}ZnDPA)_n$ peptides can form noncovalent complexes with anionic cargo such as oligonucleotides and deliver them into cells. Another idea is to conjugate a $(Tyr\text{-}ZnDPA)_n$ peptide to a hydrophobic tryptophan-rich sequence and produce a zinc-dependent mimic of the noncovalent protein carrier Pep-1 (*49*). It may even be possible to create triggered cell delivery devices that can be activated by increases in local concentrations of zinc (II) cation.

Preparation of pH-Sensitive Poly(glycidol) Derivatives with Varying Hydrophobicities: Their Ability to Sensitize Stable Liposomes to pH

Naoki Sakaguchi, Chie Kojima, Atsushi Harada, and Kenji Kono*

Department of Applied Chemistry, Graduate School of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, Osaka 599-8531, Japan. Received December 19, 2007; Revised Manuscript Received February 16, 2008

We have previously shown that modification with succinylated poly(glycidol) (SucPG) provides stable egg yolk phosphatidylcholine (EYPC) liposomes with pH-sensitive fusogenic property. Toward production of efficient pH-sensitive liposomes, in this study, we newly prepared three carboxylated poly(glycidol) derivatives with varying hydrophobicities by reacting poly(glycidol) with glutaric anhydride, 3-methylglutaric anhydride, and 1,2-cyclohexanedicarboxylic anhydride, respectively, designated as GluPG, MGluPG, and CHexPG. Correlation between side-chain structures of these polymers and their respective abilities to sensitize stable liposomes to pH was investigated. These polymers are soluble in water at neutral pH but became water-insoluble in weakly acidic conditions. The pH at which the polymer precipitated was higher in the order SucPG < GluPG < MGluPG < CHexPG, which is consistent with the number of carbon atoms of these polymers' side chains. Although CHexPG destabilized EYPC liposomes even at neutral pH, attachment of other polymers provided pH-sensitive properties to the liposomes. The liposomes bearing polymers with higher hydrophobicity exhibited more intense responses, such as content release and membrane fusion, at mildly acidic pH and achieved more efficient cytoplasmic delivery of membrane-impermeable dye molecules. As a result, modification with appropriate hydrophobicity, MGluPG, produced highly potent pH-sensitive liposomes, which might be useful for efficient cytoplasmic delivery of bioactive molecules, such as proteins and genes.

INTRODUCTION

Recent advances in protein and nucleic acid based therapies, such as immunotherapy and gene therapy, require efficient delivery systems of such labile bioactive molecules into the cytoplasm of target cells. In general, these molecules are not able to permeate a cellular membrane, although their site for action exists inside a cell, such as the nucleus. Therefore, it is necessary to use carrier systems that deliver these molecules into the cytoplasmic space of the target cell. Although various systems have been attempted for application to cytoplasmic delivery, pH-sensitive liposomes are a promising system. pH-sensitive liposomes are stable at physiological pH, but become destabilized and/or fusogenic under mildly acidic conditions. In general, a main pathway for cellular internalization of liposomes is shown to be endocytosis. Therefore, after being taken up by a cell, liposomes are trapped in endosomes and are eventually degraded in lysosome. Because the endosome has a weakly acidic environment, pH-sensitive liposomes induce destabilization of endosomes and/or fusion with endosomes, resulting in the release of encapsulated materials into the cytosol.

To date, various approaches to the production of pH-sensitive liposomes have been attempted. For example, pH-sensitive amphiphiles, such as oleic acid (*1*) and cholesteryl hemisuccinate (*2*), have been mixed with non-bilayer-forming phospholipid dioleoylphosphatidylethanolamine to yield pH-sensitive liposomes. In this case, pH-sensitive amphiphiles act as a pH-sensitive stabilizer, which stabilizes unstable liposomes only when they are negatively charged. However, the lipid molecules used for this type of pH-sensitive liposome have a strong tendency to form a hexagonal II structure; consequently, these liposomes are readily destabilized (*3*).

Another efficient method for pH-sensitization of liposomes is modification of stable liposomes with pH-sensitive membrane-active molecules. Various kinds of fusion peptides derived from viral fusogenic proteins and their analogues have been used as liposomal membranes. Synthetic polymers with carboxyl groups have also been used to sensitize liposomes to pH (*4, 5*). In comparison to peptide-based pH-sensitizers, synthetic polymers might be advantageous because of their simplicity of preparation and low immunogenicity.

Tirrell and co-workers have demonstrated that some poly(alkylacrylic acid)s interact with phospholipid membranes in a pH-dependent manner (*4, 6*). In particular, poly(2-ethylacrylic acid) exhibits a strong interaction with phospholipid membranes at mildly acidic pH: it permeabilizes and, at sufficiently high concentration, solubilizes them by micelle formation (*7*−*9*). In addition, they showed that attachment of this polymer onto the liposome surface gave pH-sensitive content release properties (*10*). Hoffman et al. further derivatized poly(2-ethacrylic acid) and obtained poly(2-propylacrylic acid), which exhibited even higher membranelytic activity than poly(2-ethylacrylic acid) (*11*−*13*).

In a previous study, we developed succinylated poly(glycidol), named SucPG, for sensitization of liposomes (Figure 1) (*13, 14*). This polymer has a backbone that resembles that of poly(ethylene glycol) (PEG) and carboxyl groups on the side chains, which control interaction of the polymer backbone with lipid membranes in a pH-dependent manner. We have shown that modification with SucPG gave stable phosphatidylcholine liposome pH-sensitive properties. The SucPG-modified liposomes are stable at neutral pH but exhibit considerable destabilization under mildly acidic conditions. In contrast to poly(2-ethacrylic acid), which induced destabilization by solubilizing liposomal lipid molecules upon protonation of its pendant carboxyl groups, SucPG caused fusion of liposomes

in the same situation (*8*, *13*). Because the fusion ability of liposomes is useful for cytoplasmic delivery of membrane-impermeable molecules, such as proteins and oligonucleotides, the fusogenic properties of the SucPG are of great importance. In fact, SucPG-modified liposomes were shown to deliver calcein into the cytosol through fusion with endosome/lysosome membranes (*14*). Fusion capabilities of SucPG-modified liposomes were used to increase the transfection activities of various lipoplexes: complexation of the SucPG-modified liposomes with lipoplexes generates efficient gene vectors (*15*, *16*).

Although the mechanism of destabilization of liposome membranes mediated by SucPG has not been clarified, it might be assumed that hydrophobic interaction of its backbone with the lipid membrane and hydrogen bond formation between the polymer carboxyl groups and phosphate groups of the phospholipid membrane are responsible for inducing fusion (*13*). Therefore, one strategy for production of polymers with high fusogenic activity might be synthesis of poly(glycidol) with carboxyl groups and enhanced hydrophobic characteristics. For this study, we prepared poly(glycidol) derivatives with various side chains having carboxyl groups with different chemical structures (Scheme 1). Correlation between hydrophobicity of the side chains of poly(glycidol) derivatives and their membrane active properties was investigated. The ability of these poly(glycidol) derivatives to provide pH-sensitive properties to stable liposomes has been described.

MATERIALS AND METHODS

Materials. Egg yolk phosphatidylcholine (EYPC) were kindly donated by Nippon Oil and Fats Co. (Tokyo, Japan). Pyrene, pyranine, and Triton X-100 was obtained from Tokyo Kasei Kogyo (Tokyo, Japan). *p*-Xylene-bis-pyridinium bromide (DPX) was from Molecular Probes (Oregon, USA).

N-(7-Nitrobenz-2-oxa-1,3-diazol-4-yl)dioleoylphosphatidylethanolamine (NBD-PE) and Lissamine rhodamine B-sulfonyl phosphatidylethanolamine (Rh-PE) were purchased from Avanti Polar Lipids (Birmingham, AL, USA). 1-Aminodecane was purchased from Nakalai Tesque (Kyoto, Japan). Glutaric anhydride and 1,2-cyclohexanedicarboxylic anhydride were from Tokyo Kasei Kogyo (Tokyo, Japan). 3-Methylglutaric anhydride was from Aldrich (Milwaukee, WI). 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) was from Dojindo (Kumamoto, Japan).Triton X-100 was obtained from Tokyo Kasei Kogyo (Tokyo, Japan). Two kinds of poly(glycidol) [PG-1: number average molecular weight (Mn) 82 000, weight average molecular weight (Mw) 13 000; PG-2: Mn 8700, Mw 16 100] were prepared as previously reported (*13*, *14*). Succinylated poly(glycidol) (SucPG) was prepared using PG-1 as previously reported (*13*).

Synthesis of Poly(glycidol) Derivatives. Glutarylated poly(glycidol) (GluPG) was prepared by reaction of poly(glycidol) with glutaryl anhydride. Poly(glycidol) (PG-1) (2.0 g) was dissolved in *N*,*N*-dimethylformamide (19 mL) and 3.0 equiv of glutaryl anhydride (9.2 g) was added to the solution. The mixed solution was kept at 80 °C for 6 h with stirring. Then, the reaction mixture was evaporated and dialyzed against water for 7 days. The product was recovered by freeze−drying. 3-Methylglutarylated poly(glycidol) (MGluPG) and 2-carboxy-cyclohexanoylated poly(glycidol) (CHexPG) were prepared by the same procedure by the reaction of poly(glycidol) (PG-2) with 3-methylglutaric anhydride and 1,2-cyclohexanedicarboxylic anhydride, respectively. As anchor moieties for fixation of poly(glycidol) derivatives onto liposome membranes, 1-aminodecane was combined with carboxyl groups of these poly(glycidol) derivatives. Each polymer was dissolved in water around pH 5, and 1-aminodecane (0.15 equiv to carboxyl group of polymer) was reacted to carboxyl groups of the polymer using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (0.2 equiv to carboxyl group of polymers) at 4 °C for two days with stirring. The resultant polymers were purified by washing with chloroform and subsequent dialysis in water.

Precipitation pH. Precipitation pHs of polymers were determined by measuring the optical density of aqueous polymer solutions (0.25 mg/mL) at various pH. Polymers were dissolved in 2.0 mL of acetate buffer (30 mM sodium acetate, 120 mM NaCl) adjusted to various pH. After 5 min incubation at 25 °C, optical densities (OD) of the polymer solutions at 500 nm were measured by using a spectrophotometer (Jasco V-520). Precipitation pH were determined by optical density−pH profile as the pH at which OD drastically rose.

Preparation of Pyranine-Loaded Liposomes. To a dry, thin membrane of EYPC (7 mg) was added 500 μL of pyranine solution containing 35 mM pyranine, 50 mM DPX, and 25 mM MES of pH 7.4, and the mixture was sonicated for 2 min using a bath-type sonicator. The liposome suspension was further hydrated by freeze and thaw, and extruded through a polycarbonate membrane with a pore size of 50 nm. The liposome suspension was applied to a G75 column to remove free pyranine from the pyranine-loaded liposomes.

Modification of Liposomes with Polymers. Liposome suspensions were obtained by the above procedure. To a liposome suspension (lipid concentration 17.5 mM) in the 25 mM MES and 125 mM NaCl buffer was added polymer solution (final concentration 10 mg/mL), and the mixture was incubated 60 min at room temperature. Liposomes were purified by gel filtering with a G75 column to separate excess polymer and nonencapsulated pyranine in the case of pyranine containing polymer-modified liposome.

Release of Pyranine from Liposome. Release of pyranine from liposome was measured as previously reported (*17*). Pyranine fluorescence was quenched by DPX inside of the liposomes, but this molecule exhibits intense fluorescence when released from the liposome (*17*). To a suspension of pyranine-loaded liposomes (lipid concentration 2.0×10^{-5} M) in the 25 mM MES and 125 mM NaCl buffer of varying pHs was added varying amounts of the polymer dissolved in the same buffer. Pyranine fluorescence at 512 nm with excitation at 416 nm was monitored by using a spectrofluorometer (Jasco FP-6500). 100% release was achieved by adding Triton X-100 (final concentration 0.1%) to the liposome suspension.

Fusion Assay. Fusion between bare EYPC liposomes and polymer-modified liposomes was detected by measuring reso-

[a] EDC represents 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide.

nance energy transfer between NBD-PE and Rh-PE (*15*, *19*). Polymer-modified liposomes containing NBD-PE and Rh-PE were prepared via the above method using the membrane composed of EYPC, NBD-PE, Rh-PE (98.8:0.6:0.6, mol/mol/mol), and varying amounts of the polymers. The labeled liposomes (final concentration of lipid 0.125 M) were mixed with fluorescent probe-free EYPC liposomes (final concentration of lipid 0.25 M) in 25 mM MES, and 125 mM NaCl solution of varying pHs and fluorescence intensities NBD-PE and Rh-PE followed. Their fusion was followed by monitoring the fluorescence intensity ratio of NBD-PE to Rh-PE (*R*). The excitation wavelength of NBD-PE was 450 nm, and monitoring wavelengths for NBD-PE and Rh-PE were 520 and 580 nm, respectively. Percentage increase in *R* was defined as

Percentage increase in

$$R = (R_t - R_0)/(R_{100} - R_0) \times 100 \quad (1)$$

where R_0 and R_t represent the initial and intermediary *R* values. R_{100} is the *R* of the labeled liposomes when the liposomes fused completely. The fluorescent lipid-labeled liposomes and the unlabeled liposomes were dissolved in methanol, dried by evaporation, and resuspended in MES buffer. The *R* value of the suspension was taken as R_{100} (*15*).

Pyrene Fluorescence. A known amount of pyrene in acetone solution was added to an empty flask, and acetone was removed under vacuum. Polymer (0.2 mg/mL) in the 25 mM MES and 125 mM NaCl buffer solutions of varying pHs were added the flask, yielding 1 μM concentration of pyrene. The sample solution was stirred overnight at room temperature, and emission spectra with excitation at 337 nm were recorded. The fluorescence intensity ratio of the first band at 373 nm to the third band at 384 nm (I_1/I_3) was analyzed as a function of pH of the solution.

Interaction of Liposomes with Cells. Polymer-modified liposomes containing calcein were prepared via the above procedure using an aqueous calcein solution (63 mM, pH 7.4) instead of an aqueous pyranine solution. HeLa cells (1.0×10^5) were seeded on glass-bottomed culture dishes and incubated in 10% FCS/DMEM overnight. The cells were washed with PBS and reincubated with fresh medium with 10% FCS (0.5 mL). Then, liposomes in the 20 mM Hepes and 130 mM NaCl suspension (0.5 mL) were added to the dishes (final concentration of liposomal lipid: 0.5 mM), and the cells were incubated for 4 h. For the incubation in the presence of NH_4Cl, cells were preincubated in 10% FCS/DMEM containing NH_4Cl (20 mM) for 1 h before the addition of liposome suspension. After the incubation with the liposomes, the cells were washed with PBS and were observed using a fluorescence microscope (BX51WI Olympus). In addition, cells were incubated for another 2 h in 10% FCS/DMEM with or without NH_4Cl (20 mM) and were observed using a fluorescence microscope.

RESULT AND DISCUSSION

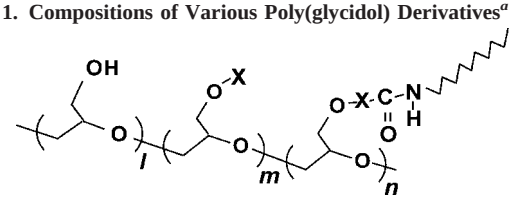
Properties of Poly(glycidol) Derivatives. For a previous study, we developed SucPG, which generates fusogenic activity under weakly acidic conditions and is useful to produce pH-sensitive liposomes that destabilize at mildly acidic pH (*13*). In fact, we observed that SucPG-modified liposomes delivered membrane-impermeable fluorescent dye calcein efficiently into the cytosol through fusion with endosomal/lysosomal membranes (*14*). For the present study, we attempted to develop new polymers with even higher pH-responsive properties than SucPG. We postulated that both a PEG-like structure of the backbone and carboxyl groups on the side chains are important for their pH-dependent fusogenic activity (*13*). Therefore, an increase in the side chains hydrophobicity is expected to strengthen their interaction with the lipid membranes, thereby producing polymers with a high ability to destabilize lipid membranes in a pH-dependent manner.

Three kinds of polyglycidol derivatives with more hydrophobic side chains than those of SucPG were designed (Scheme 1). We synthesized them using the reaction of poly(glycidol) with various acid anhydrides according to Scheme 1. Compositions of these polymers were estimated using ^{1}H NMR and are listed in Table 1. For all polymers, only a small percentage of unreacted glycidol units around 2.0−3.8% remained on the polymer backbone after the reaction of poly(glycidol) with acid anhydrides, indicating that these reactions were very efficient; fundamentally, every repeating unit possesses a carboxyl group in the resultant polymers. We observed that ester bonds of these polymers were essentially not hydrolyzed during dialysis against distilled water for several days, indicating their high stability in water.

Many studies have shown that hydrophobic moieties, such as stearyl groups and cholesteryl groups, were incorporated into polymer chains to act as an anchor for their fixation to liposome membranes (*22*−*24*). We showed that attachment of 1-aminodecane to about 8 unit % of a SucPG chain is sufficient to fix the polymer chain onto an EYPC liposome membrane (*13*). On the basis of a previous study (*13*), we combined decylamine to about 10 unit % of the polymer chains in the present study using a condensing agent, EDC (Scheme 1). As shown in Table 1, decyl chains were attached to around 10 unit % of the polymer chains for all poly(glycidol) derivatives.

We first investigated the pH sensitivity of the poly(glycidol) derivatives because these polymers contain many carboxyl groups. Acid−base titration of these polymers was performed to estimate the pK_a values. As presented in Table 2, SucPG, GluPG, and MGluPG had almost equal pK_a values around 6.2−6.4, although CHexPG showed a somewhat higher pK_a

Table 1. Compositions of Various Poly(glycidol) Derivatives[a]



polymer	*l* (mol %)	*m* (mol %)	*n* (mol %)
SucPG	2.4	97.6	–
GluPG	2.0	98.0	–
MGluPG	3.8	96.2	–
CHexPG	2.3	97.7	–
SucPG-C_{10}	3.0	85.7	11.3
GluPG-C_{10}	3.7	83.8	12.5
MGluPG-C_{10}	5.6	86.6	7.8
CHexPG-C_{10}	3.2	85.7	11.1

[a] Estimated by ^{1}H NMR. SucPG-C_{10}, GluPG-C_{10}, MGluPG-C_{10}, and CHexPG-C_{10} are anchor-carrying types of corresponding poly(glycidol) derivatives.

Table 2. pK_a and Precipitation pH of Various Poly(glycidol) Derivatives

polymer	pK_a	precipitation pH	α at precipitation pH
SucPG	6.2	4.0	0.93
GluPG	6.4	4.7	0.95
MGluPG	6.3	5.0	0.93
CHexPG	7.0	5.4	0.99
