Bioconjugate Chemistry

Editorial: The Twentieth Year of *Bioconjugate Chemistry*

As we complete the second decade of the journal during this milestone year, we will occasionally look back to see how the subject has advanced. The science and technology of bioconjugate chemistry concern the joining of two or more molecular functions, using chemistry, biology, or combinations of the two, to make products with useful biological properties. While today the molecules involved may be almost anything, twenty years ago this was most highly developed with proteins. Appropriately, the first article in the first issue of *Bioconjugate Chemistry* was a review of protein chemistry by Means and Feeney (*1*), which begins, "With roots in ancient formulations, methods for the chemical derivatization of proteins continue to expand and develop. The creation of this new journal dealing exclusively with bioconjugate chemistry was barely conceivable just a few years ago. An explosion of interest in the subject during the last decade is, however, easily seen". The authors go on to explain that those ancient formulations were based on empirical observations, without any real understanding of the underlying chemistry. One of the cardinal reasons for the American Chemical Society to found the journal was to help bring order to this sometimes-unruly subject. However, the empirical roots are still very much the basis for progress; without that "What will happen if I do this?" curiosity, bioconjugate chemistry would lose its essential spirit. Over the years, innovations such as intein-mediated labeling, native ligation, enzyme-catalyzed conjugation, and the ubiquitous click reaction have added surprising new dimensions to the preparation of proteins tagged with synthetic molecules. This suggests that even more unexpected developments lie ahead. As someone remarked at a recent meeting, the best of today's bioconjugate chemistry is so remarkable, it is as if the dreams of a science fiction writer have become reality. Let us see what the new year brings.

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 2008 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the nineteenth volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are listed on the following pages.

Claude F. Meares
Editor-in-Chief

REVIEWS

siRNA Conjugate Delivery Systems

Ji Hoon Jeong,[†] Hyejung Mok,[‡] Yu-Kyoung Oh,[§] and Tae Gwan Park*[,‡]

College of Pharmacy, Sungkyunkwan University, Suwon 440-746, South Korea, Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Daejeon 305-701, South Korea, and School of Life Sciences and Biotechnology, Korea University, Anam-dong, Seungbuk-gu, Seoul, South Korea. Received July 4, 2008; Revised Manuscript Received August 18, 2008

Small interfering RNA (siRNA) has been chemically conjugated to a variety of bioactive molecules, lipids, polymers, peptides, and inorganic nanostructured materials to enhance their pharmacokinetic behavior, cellular uptake, target specificity, and safety. To efficiently deliver siRNAs to the target cells and tissues, many different siRNA bioconjugates were synthesized and characterized, and their gene silencing efficiencies were tested in vitro and in vivo. In this review, recent developments of siRNA bioconjugates are summarized.

I. INTRODUCTION

Synthetic siRNAs have been considered a new class of nucleic acid therapeutics for treatment of various infectious and genetic diseases including cancer (*1*). RNA interference (RNAi), a cellular post-transcriptional gene silencing mechanism, can be induced by double-stranded siRNA consisting of 21−25 nucleotides that degrades a target mRNA in a highly sequence specific manner (*2*–*4*). Despite the high therapeutic potential of siRNA, its application in clinical settings is still limited mainly due to the lack of efficient delivery systems (*5*). Clinically acceptable siRNA delivery systems should be carefully designed to improve the stability of siRNA after administration into the body, to deliver siRNA specifically to the desired tissue site, and to facilitate the cellular uptake of siRNA within target cells (*6*)

A number of nonviral delivery carriers, including liposomes (*7, 8*), lipids (*9, 10*), polymers (*11, 12*), peptides (*13*), virus-based vectors (*14*), and pressurized hydrodynamic injection (*15*), have been suggested for improved intracellular delivery of siRNA. Various kinds of cationic species can form nanosized polyelectrolyte complexes with negatively charged siRNA by ionic interactions. The resulting complexes can provide excellent protection of siRNA from attack by extracellular nucleases and allow facile cellular uptake via an endocytic pathway. Among the carriers, a wide array of cationic polymers with different architectures and functionalities can also be molecularly engineered for further modifications to provide the carriers with targeted delivery, biodegradability, and prolonged circulation properties (*16*). However, many cationic agents used for condensing siRNAs have often exhibited severe cytotoxicity, limiting clinical applications.

Recently, it has been reported that direct conjugation of small drug molecules, aptamers, lipids, peptides, proteins, or polymers to siRNA could improve in vivo pharmacokinetic behavior of siRNA (*17*). Such siRNA bioconjugates, either with or without forming nanocomplexes with cationic carriers, could significantly enhance biological half-life with a concomitant increase of delivery efficiency to the target tissue while maintaining sufficient gene silencing activity. This short review focuses on the recent development of various siRNA conjugate delivery systems for in vitro and in vivo applications.

II. PREPARATION OF siRNA CONJUGATES

A. Site of Conjugation and Chemical Modification. Since siRNA is a hybridized product of two complementary strands (sense and antisense), there are four terminal ends for potential conjugation sites. After cellular uptake, an antisense strand of siRNA, a strand having a complementary sequence to a target mRNA, is incorporated into the RISC to initiate the RNAi mechanism. This characteristic strand bias could be greatly influenced by chemical modification or conjugation of siRNA. Previous observations showed that the integrity of the 5′-terminus of the antisense strand, rather than that of the 3′-terminus, is important for the initiation of an RNAi mechanism (*18*–*20*). Therefore, the 3′- and 5′-terminus of the sense strand and the 3′-terminus of the antisense strand are primarily considered as potential sites for conjugation with minimal influence on RNAi activity. Conjugation strategies of several siRNA conjugates in the literature are summarized in Table 1. Either the 3′- or 5′-terminus of the sense strand is generally used for conjugation. Also, most of the conjugates employ cleavable linkages including acid-labile and reducible bonds between siRNA and the conjugation partner for facilitating the release of intact siRNA inside cells. The acid-labile and disulfide linkages are expected to be cleaved in the acidic endosome compartments and the reductive cytosolic space, respectively. Some siRNA conjugates use the action of the endogenous Dicer, which can process a premature double-stranded RNA to generate an active siRNA (*17, 21*)

To improve the nuclease resistance of siRNA and enhance its stability in biological fluids, siRNA itself is chemically modified. Chemical modification of the phosphorothioate linkage (backbone phosphate group O → S) or the boranophosphate linkage (backbone phosphate group O → BH_3) has been popularly used, since it is considered a simple and effective

Table 1. Strategies for Synthesis of siRNA Conjugates

siRNA conjugate	site of conjugation (I)	site of conjugation (II)	linkage	conjugate chemistry	target siRNA
Cholesterol-siRNA	3′-end of sense strand (*33*)[a]	Cholesterol-aminocaproic acid-pyrrolidine linker	Noncleavable (pyrrolidone)	Solid-phase synthesis (phosphoramidite)	Apo-B-1 siRNA
	5′-end of sense strand (*49*)	Cholesterol phosphoramidite coupled to (CH2)−S-S-(CH2)6 linker	Reducible (disulfide)	Solid-phase synthesis (phosphoramidite)	p38 MAP kinase siRNA
α-tocopherol-siRNA	5′-end of antisense strand (*17*)[a]	α-tocopherol phosphoramidite	Cleavable (phosphodiester, cleavage site of Dicer)	Solid-phase synthesis (phosphoramidite)	Apo-B-1 siRNA
Lipid-siRNA	3′-end of sense strand (*34*)[a]	Hydroyprolinol-lipophile moiety	Noncleavable (trans-4-hydroxyprolinol)	Solid-phase synthesis (phosphoramidite)	Apo-B-1 siRNA
TAT-siRNA	3′-end amine of antisense strand (*46*)[b]	N-terminal Cys containing TAT	Noncleavable (amide bond)	Cross-linker (sulfo-succimidyl 4-(*p*-maleimidophenyl)-butyrate)	GFP siRNA/CDK9 siRNA
	5′-end thiol of sense strand (*49*)	C-terminal Cys containing TAT	Reducible (disulfide)	Disulfide exchange	p38 MAP kinase siRNA
Penetratin-siRNA	5′-end thiol of sense strand (*47*)[b]	N-terminal Cys containing penetratin	Cleavable (disulfide)	Oxidation	Luciferase siRNA
	5′-end thiol of sense strand (*49*)	C-terminal Cys containing penetratin	Cleavable (disulfide)	Disulfide exchange	p38 MAP kinase siRNA
Transportan-siRNA	5′-end thiol of sense strand (*47*)[b]	N-terminal Cys containing transportan	Cleavable (disulfide)	Oxidation	Luciferase siRNA
PEG-siRNA	3′-end amine of sense strand (*50, 55, 56, 81*)[b]	Thiol modified PEG	Cleavable (disulfide)	Disulfide exchange (SPDP)	VEGF siRNA
	5′-end thiol of sense strand (*65, 66*)	Acrylate modified PEG	Cleavable (*β*-thiopropionate)	Michael addition	Luciferase siRNA/RecQL1 siRNA
Peptide analogue of insulin-like growth factor 1-siRNA	5′-end amine of sense strand (*60*)	C-terminal carboxyl group of IGF1 analogue	Noncleavable (amide bond)	Carbodiimide chemistry (DCC/NHS)	Insulin receptor substrate 1 siRNA
Antibody-siRNA	3′-end biotin of sense strand (*63*)	Streptavidin-conjugated antibody	Noncleavable (tetra-ethyleneglycol)	Biotin-streptavidin	Luciferase siRNA
Aptamer-siRNA	5′-end of sense strand (*64*)	In vitro transcription	Cleavable (disulfide) or noncleavable	Biotin-streptavidin	Lamini A/C siRNA
	5′-end of sense strand (*21*)		Cleavable (phosphodiester)	RNA aptamer-siRNA chimera	Bcl-2 siRNA/PLK1 siRNA
Quantum dot-siRNA	5′-end thiol of sense strand (*69*)	Amine-modified quantum dot nanoparticle	Cleavable (disulfide) or noncleavable (thioether)	Disulfide exchange (SPDP) or Micheal addition	GFP siRNA
Iron oxide nanoparticle-siRNA	5′-end thiol of antisense strand (*70*)	MBS-activated iron oxide nanoparticle	Noncleavable (thioether)	Michael addition	GFP siRNA/survivin siRNA
Carbon nanotube-siRNA	5′-end thiol of sense strand (*71*)	Amine modified carbon nanotube	Cleavable (disulfide)	Disulfide exchange (SPDP)	Luciferase siRNA

[a] Chemical modification of backbone nucleotide: partial 2′-*O*-methyl sugar modification, phosphorothioate linkage. [b] Reaction with duplex siRNA -Cys: cysteine; rxn: reaction.

method to increase the nuclease resistance of siRNA (*22*–*25*). Modification of the 2′-hydroxyl group of the pentone sugar, such as 2′-*O*-methyl (*22*, *26*), 2′-*O*-(2-methoxyethyl) (*26*), 2′-deoxy-2′floro (*27*), 2′-deoxy-2′floro-*β*-D-arabinonucleic acid (FANA) (*28*), and a methylene linkage between the 2′ and 4′ positions of the ribose (locked nucleic acid, LNA) (*29*), has also been employed for the enhanced nuclease resistance of siRNA, since the 2′ modifications apparently did not interfere with the action of the intracellular RNAi machinery (*18*). The replacement of oxygen linked to the 4′ carbon of the ribose with sulfur and the modification of terminal nucleotides of siRNA have also been attempted to enhance resistance to enzymatic degradation (*30*, *31*). However, it should be noted that, in order to fully maintain its silencing activity of siRNA, extensive chemical modifications of siRNA are not desirable (*32*)

B. Lipophile−siRNA Conjugates. Cholesterol was covalently conjugated to siRNA for systemic delivery (*33*). Cholesterol was conjugated to the 3′-terminus of the sense strand of siRNA via a pyrrolidone linkage. The cholesterol−siRNA conjugate (chol-siRNA) could induce intracellular RNAi without the significant loss of gene silencing activity. In addition, the conjugate exhibited significantly higher cellular transfer efficiency in cultured cells without the aid of transfection agents. In animal experiments, the significant silencing of apoliporotein B (apoB) gene, which encodes a protein essential for cholesterol metabolism, was observed in the liver and the jejunum after intravenous administration of the chol-siRNA conjugate. The silencing of the apoB gene resulted in a decreased plasma apoB protein level and consequently a reduction in the total levels of cholesterol. The conjugation of cholesterol to siRNA improved in vivo pharmacokinetic behaviors of siRNA as well. Intravenously administered chol-siRNA was distributed to various tissues including the liver, heart, lungs, kidneys, and fat tissues and was detected in the tissues even 24 h after injection (*33*). In contrast, no detectable naked siRNA could be observed in the tissues 24 h after intravenous injection. In addition to the chol-siRNA conjugate, a series of lipophilic siRNA conjugates, including siRNA conjugates with bile acids and lipids, were synthesized (Figure 1) (*34*, *35*). They interacted with lipoproteins in the blood serum, such as high-density lipoprotein (HDL) and low-density lipoprotein (LDL), lipoprotein receptors, and transmembrane proteins, influencing tissue distribution and uptake behaviors of the siRNA conjugates (*34*). The degree of hydrophobicity, which directly relates to the length of the alkyl chain, seemed to be a major determinant for the affinity of siRNA−fatty acid conjugates to lipoproteins. The siRNA conjugates with higher affinity to lipoproteins, i.e., the ones with longer fatty acid chains, showed enhanced gene silencing capabilities, suggesting that lipoproteins may facilitate the cellular uptake of the conjugates. When systemically administered, chol-siRNA bound to HDL demonstrated ca. five times higher cleavage of the target RNA transcript (apoB) in mouse, compared to unbound chol-siRNA at the same concentration. This suggests that the association of lipoproteins may further improve the pharmacokinetic properties of lipophilic siRNA conjugates. The association of lipoprotein also changed tissue distribution profiles of the conjugates. The lipophilic siRNA conjugates bound to LDL were mainly distributed to the liver by the action of LDL receptors, while the conjugates bound to HDL were taken up by various tissues, including the liver, gut, kidneys, and steroidogenic organs. The high affinity of HDL to the scavenger receptor SR-BI plays an important role in the uptake of HDL-bound siRNA conjugates. Further optimization may be possible by modifying strategies for the formation of preassembly between the lipophilic siRNA conjugates and lipoproteins or by identifying new lipophilic conjugate partners that lead to more favorable interaction with serum lipoproteins.

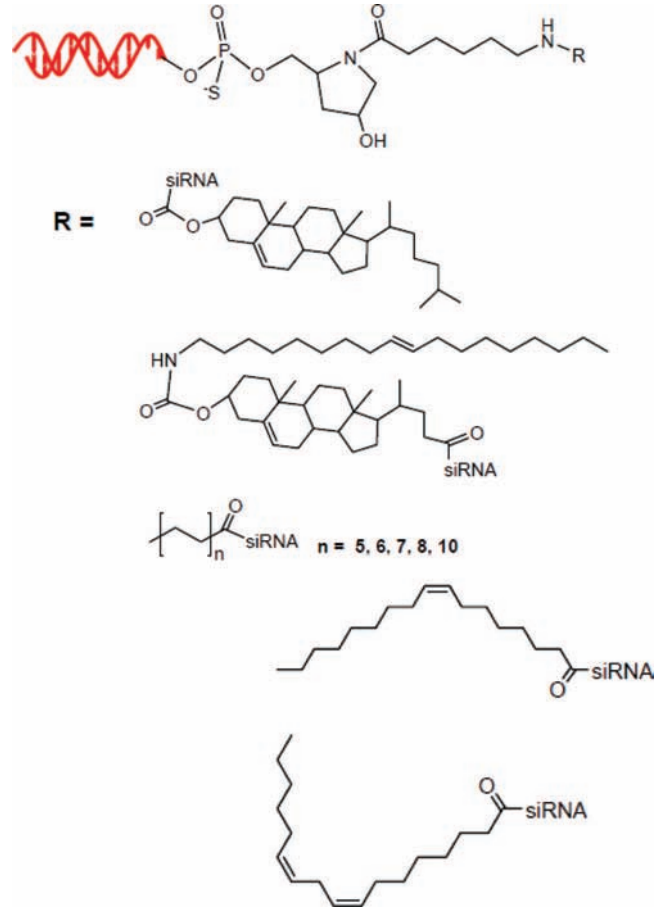

Figure 1. Structure of lipophile−siRNA conjugates. Various lipophiles (R), including cholesterol, bile acid, and a series of lipids with different chain lengths, were covalently conjugated to siRNA.

Although the animal results are encouraging, since the study showed the feasibility of using siRNAs as therapeutics, the requirement of a relatively high siRNA dose (50 mg/kg) remains to be solved for clinical applications.

Another lipophile−siRNA conjugate, α-tocopherol (vitamin E)-siRNA, was introduced for systemic siRNA delivery to the liver (*17*). Lipophilic vitamin E was covalently conjugated to the 5′-terminus of the antisense strand of 27/29-mer siRNA, which was partially modified with 2′-*O*-methylated ribose and phosphorothioate linkage. After intracellular delivery, the 27/29-mer siRNA was to be processed by the action of Dicer (*36*) to generate 21/21-mer siRNA, which caused the simultaneous release of the vitamin E moiety. The intravenous administration of the conjugate achieved a significant reduction of the target protein (apoB) in the liver without any induction of inflammatory interferons, such as interferon-α and interferon-*β* (*17*).

C. Peptide−siRNA Conjugates. A wide range of cell-penetrating peptides (CPPs), also called protein transduction domain (PTD), have been identified and employed as a vehicle for intracellular delivery of macromolecules such as proteins (*37*, *38*). Well-known examples of CPPs are TAT trans-activator protein (48−60) from human immunodeficiency virus type-1 (HIV-1) (*39*), Penetratin from the homeodomain protein of *Antennapaedia* (*40*), and Transportan, a hybrid amino acid sequence from glanin and mastoparan (*41*). The intracellular delivery efficiency of antisense oligonucleotides (*42*, *43*) and peptide nucleic acid (PNA) (*44*, *45*) could be improved by direct conjugation of CPPs. The same strategies were applied for the enhanced intracellular delivery of siRNA (Figure 2). TAT (47−57) was conjugated to the 3′-terminus of the antisense strand of an siRNA using a heterobifunctional cross-linker (HBFC), sulfo-

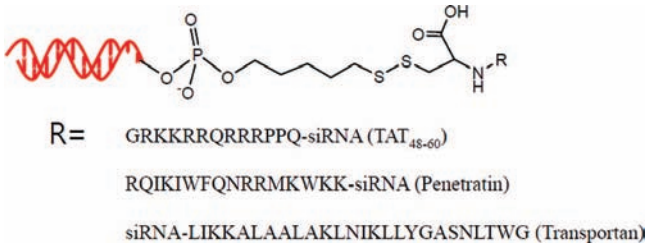

Figure 2. Structure of peptide−siRNA conjugates. Cell-penetrating peptides (TAT_{48-60}, penetratin, and transportan) were conjugated to siRNA through a terminal cysteine residue derivatized at either the N- or C-terminus of each peptide.

succinimidyl 4-(*p*-maleimidophenyl)butyrate (*46*). The TAT−siRNA conjugate demonstrated a dramatic improvement in the intracellular delivery of siRNA. The extent of cellular uptake showed a direct relationship with the amount of conjugate used for the transfection and the time elapsed after transfection. Cellular uptake of siRNA by the conjugate was as highly efficient as the commercial Lipofectamine formulation. The TAT−siRNA conjugate also successfully elicited the effective silencing of the target gene. Although TAT was conjugated to the antisense strand of siRNA via a noncleavable thioether linkage, the presence of the peptide did not seem to seriously interfere with the downstream process for the induction of RNAi, including the incorporation of TAT−siRNA into the RNA-induced silencing complex (RISC). The 5′-terminus of the antisense strand of siRNA was considered crucial for induction of the RNAi mechanism (*19, 20*). Many research groups used a cleavable linkage, such as the disulfide linkage, between CPP and siRNA to minimize potential reduction of RNAi activity by the presence of highly charged peptides. The disulfide linkage was employed for the conjugation of CPPs, including Penetratin and Transportan, to the 5′-terminus of the sense strand of siRNA. This delivery system was designed to improve the intracellular delivery of siRNA by the action of CPP and to release intact siRNA by reductive cleavage of the disulfide linkage between the CPP and the siRNA in the reductive cytoplasmic environment. The reductive release of intact siRNA from the conjugate may further facilitate the incorporation of siRNA into RISC by eliminating the potential interference of CPP. The CPP−siRNA conjugates, in which the disulfide linkage between the CPP and siRNA was formed by oxidation of thiol groups in the presence of oxidant, diamide, exhibited efficient suppression of the target reporter gene expression, such as luciferase or green fluorescence protein (GFP), in a variety of cell lines (*47*). The gene silencing efficacy of the conjugates was comparable to those of a cationic lipid-based formulation. Similar conjugates of Penetratin 1 peptide to siRNA, which also contain a disulfide linkage between the two components, were used for the delivery of siRNA to primary mammalian neuronal cells (*48*). The conjugate showed efficient down-regulation of the target genes, including superoxide dismutase (SOD) variants and caspases, in the neuronal cells without apparent cytotoxicity. However, the conjugation of CPP to siRNA did not appear to improve siRNA stability. The conjugates of CPP and siRNA showed similar degradation profiles to those of naked siRNA after exposure to mouse bronchoalveolar lavage (BAL) fluid (*49*). Besides, some peptide−siRNA conjugates elicited undesirable immune responses. Although intratracheal delivery of siRNA using CPP−siRNA conjugates successfully suppressed the expression of a target gene, p38 MAP kinase, the siRNA conjugate of Penetratin but not TAT(48−60) caused elevated secretion of inflammatory cytokines, such as interferon-α, tumor necrosis factor-α, and interleukin-12, after intratracheal distillation, suggesting the induction of innate immunity (*49*)

D. PEG−siRNA Conjugates. Poly(ethylene glycol) (PEG), a biocompatible, hydrophilic, and nonionic polymer, was conjugated to siRNA via a reducible disulfide linkage (Figure 3A) (*50*). The PEG−siRNA conjugate could be further complexed with cationic polymers or peptides as core condensing agents to form colloidal nanoparticles, so-called polyelectrolyte complex micelles (PEC micelles) (Figure 3B). The formation of PEC micelles and their use as a delivery vehicle for oligonucleic acid therapeutics has also been studied using PEG conjugated antisense oligonucleotides and siRNA in our previous studies (*50–54*). The negatively charged siRNA part was completely buried inside the polyelectrolyte core by the addition of the core-forming polycation due to charge neutralization, while the hydrophilic PEG segment surrounded the charge-neutralized core, improving the solubility of the insoluble polyelectrolyte core in an aqueous environment. The micelle-like core−shell structure, which is thermodynamically favored, provides additional stability to the PEC micelles when they are administered into the bloodstream, leading to prolonged circulation. The surrounding PEG shell also effectively prevented interparticular aggregation and shielded the surface charges of the core to make the PEC micelles neutral nanoparticles with a hydrophilic surface, resulting in acceptable blood compatibility. The PEG−siRNA conjugate itself showed much higher levels of siRNA stability than the naked siRNA in the presence of 50% serum. The conjugate lasted up to 16 h without a significant loss of integrity (*50*). The integrity of siRNA was fully maintained even after 48 h in 50% serum, when the PEG−siRNA formed PEC micelles via interactions with polyethylenimine (PEI). The PEC micelles achieved significantly enhanced transfection efficiency. A fusogenic cationic peptide, KALA, which is known to destabilize the endosomal membrane, was also used as a core forming agent to facilitate the endosomal escape process (*55*). The PEG−siRNA/PEI PEC micelles were used for local and systemic treatments for tumors in an animal model (*56*). An siRNA targeting vascular endothelial growth factor (VEGF) was chosen for antiangiogenic cancer therapy. The local and intravenous administration of the PEC micelles achieved significant retardation of tumor growth in tumor-bearing mice. In situ fluorescence imaging directly showed enhanced accumulation of the PEC micelles in a solid tumor region after intravenous injection through a mouse tail vein, suggesting the possibility of passive tumor targeting of siRNA therapeutics using the PEC micelles. This property of PEC micelles may be due to the passive diffusion of nanoparticles through the loosened endothelial vascular structure in the vicinity of highly proliferative tumors, which is called the enhanced permeation and retention (EPR) effect (*57*)

III. siRNA CONJUGATES FOR TARGETED DELIVERY

The lack of tissue- or cell-type specificity of siRNA is one of the most challenging problems in the development of therapeutic siRNAs. Targeted delivery of siRNA to the desired cells and tissues has been considered as an attractive way to bring siRNA drugs to clinical settings. The targeted siRNA delivery strategy not only minimizes the chance of potential adverse effects, but also reduces the amount of dose required to achieve a desired therapeutic effect. Cell-specific ligands, including aptamers, antibodies, sugar molecules, vitamins, and hormones, have been popularly employed to confer cell specificity on siRNA delivery systems (*58, 59*). Specific interaction between a specific ligand and its cellular membrane receptor generally enhances the cellular uptake by the aid of a mechanism called receptor-mediated endocytosis. Therefore,

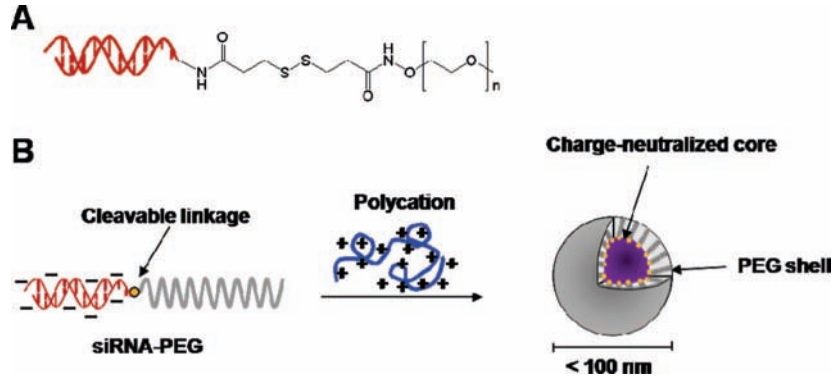

Figure 3. (A) Structure of PEG−siRNA conjugate. (B) Formation of PEC micelles from the interactions between PEG−siRNA conjugate and a polycation.

increasing specific cellular uptake by targeted delivery can significantly improve therapeutic efficacy with a much lower dose.

A. Ligand Peptide−siRNA Conjugates. For the receptor−ligand mediated delivery of siRNA, a ligand peptide for the targeted receptor was conjugated to siRNA. A carboxylic acid group of peptide mimetic of IGF1, D-(Cys-Ser-Lys-Cys) was activated and conjugated to an amine group of the 5′-sense strand of siRNA (*60*). After the annealing reaction, the gene silencing effect by an IGF1−siRNA conjugate was analyzed without the use of a transfection reagent. About 60% of the target IRS1 (insulin receptor substrate 1) gene expression was inhibited by the IGF1−siRNA conjugate, which was similar to that from the chol−siRNA conjugate.

B. Antibody−siRNA Conjugates. Antibody-mediated targeted drug delivery systems have attracted much attention due to their superior stability during systemic circulation and high selectiveness toward a target protein on the cell surface. A PEGylated immunoliposome-based brain targeting system was previously introduced, in which two antibodies were immobilized on the surface of liposomes (*61*). One monoclonal antibody was to target a transferring receptor expressed in the blood brain barrier (BBB), and the other antibody was to target insulin receptors expressed in brain cancer. The binding of transferrin receptor antibody may induce the transcytosis of the immunoliposome across the BBB. Similarly, the monoclonal antibody targeting the transferrin receptor at the BBB was directly conjugated to siRNA via a biotin−streptavidin linkage (*62*). The siRNA biotinylated at either terminus (3′ or 5′) of the sense strand was coupled to the streptavidin-conjugated antibody (Figure 5). The intravenous administration of the antibody−siRNA conjugate led to the efficient suppression of a reporter gene expression in a rat model bearing intracranially transplanted brain tumor.

C. Aptamer−siRNA Conjugates. Aptamers, modified oligonucleotides having selective affinities toward target proteins, are characterized by their globular structure, like the shape of tRNA. Generally, aptamers have intermediate molecular weights between small peptides (∼1 kDa) and single chain antibody fragments (∼25 kDa) (*63*). An aptamer targeting prostate-specific membrane antigen (PSMA), a cellular receptor abundantly expressed in prostate cancer cells, was directly conjugated to siRNA for prostate cell-specific delivery. Chu et al. used the biotin−streptavidin interaction for the conjugation of siRNA to the aptamer (Figure 4A) (*64*). Biotinylated siRNA and aptamer were joined together by using streptavidin via streptavidin−biotin interactions. The resulting conjugate was readily taken up by PSMA overexpressing cells without using transfection agents and successfully mediated specific RNAi, comparable to silencing activities by conventional lipoplexes. Another group proposed similar but more sophisticated targeting

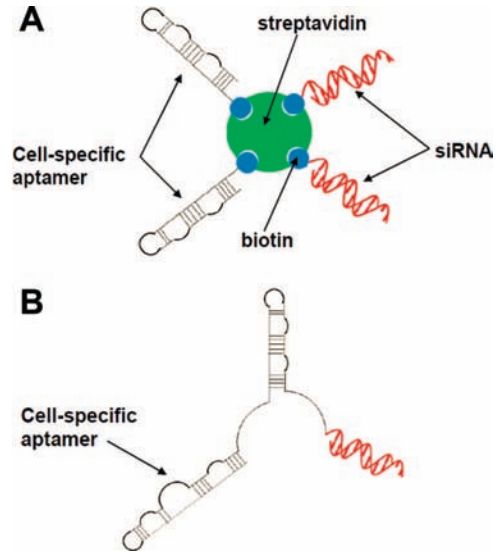

Figure 4. Schematic diagrams of aptamer−siRNA conjugates. (A) Conjugation of siRNA to a PSMA-targeting aptamer. The end group of the aptamer and siRNA was derivatized with biotin. Streptavidin was used as a core for the association of the biotinylated aptamer and siRNA. (B) Structure of chimeric conjugate of RNA aptamer and double-stranded siRNA. After intracellular delivery, the conjugate can be further processed by Dicer to induce RNAi.

system using a chimeric double-stranded RNA−aptamer hybrid (Figure 4B) (*21*). The chimera was synthesized by the in vitro runoff transcription method from a double-stranded DNA template containing a T7 RNA polymerase promoter. The dsRNA−aptamer hybrid was selectively bound to the cells overexpressing the target receptor, PSMA, and was taken up by the cells via receptor-mediated endocytosis. After the cellular uptake, the hybrid molecule could be further processed by endogenous Dicer, producing siRNA which target survival genes, such as polo-like kinase 1 (PLK1) and Bcl-2. Cell-type specific inhibition of tumor growth and tumor regression were achieved in a mouse tumor xenograft model by intratumoral administration of the chimeric siRNA delivery system. Although both proof-of-concept studies suggested the potential use of aptamers for the targeted delivery of siRNA drugs, nuclease susceptibility of aptamer ligands may limit their application in systemic treatments and the possibility of premature degradation of siRNA in the endolysosomal compartment due to the lack of endosomal escape machinery may require additional functionality.

D. Targetable Polyelectrolyte Complex Micelles. Polyelectrolyte complex (PEC) micelles consisting of PEG-conjugated siRNA and a polycation as a core forming agent can be formed by electrostatic interactions between negatively

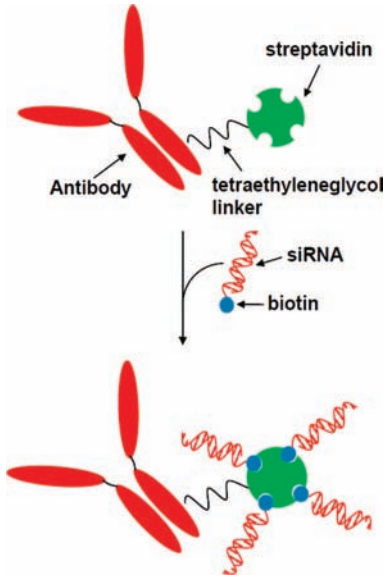

Figure 5. A schematic representation of antibody−siRNA conjugate. Biotinylated siRNA was coupled to streptavidin-conjugated antibody.

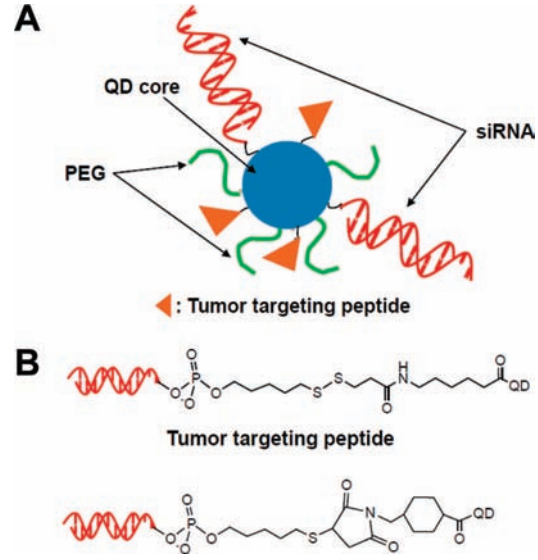

Figure 6. Quantum dot (QD)−siRNA conjugate. (A) A schematic diagram of a targetable QD−siRNA conjugate. Quantum dot modified with PEG and primary amine was used for further conjugation of siRNA and tumor targeting peptide. (B) The conjugate of QD−siRNA was synthesized through a reducible disulfide linkage or a nondegradable thioether linkage.

charged siRNA and polycation. The PEG segment acts as a hydrophilic shell protecting the charge-neutralized PEC core. In previous studies, PEC micelles could be passively targeted to a solid tumor region through the loosened endothelial junctions via the EPR effect (*56*). Because of the lack of cell specificity of the PEC micelles, the main route of cellular entry is expected to be adsorptive endocytosis. However, the cellular contact of PEC micelles may be hampered by the PEG shell that prevents nonspecific adsorption of blood components owing to the steric-hindrance effect of flexible PEG chains. Therefore, decoration of cell-specific ligands on the micelle surface would not only facilitate the cellular uptake via receptor-mediated endocytosis, but also reduce it by nontargeted cells. The lactose moiety was coupled to the distal end of the PEG−siRNA conjugate and used as a targeting ligand for the asialoglycoprotein receptors on hepatoma cells (*65, 66*). An siRNA was conjugated to the PEG segment via an acid-cleavable β-thiopropionate linkage and expected to be cleaved in the acidic environment of the endosomal compartment. The lactosylated-PEG−siRNA conjugate was used for the formation of PEC micelles by interacting with poly(L-lysine). The ligand installed PEC micelles containing siRNA targeting RecQL5 helicase demonstrated significant growth inhibition of the spheroids formed from human hepatocarcinoma cells (*66*). In our recent study, a luteinizing hormone-releasing hormone (LHRH) peptide analogue was attached to the end of PEG segment of the PEG−siRNA conjugate for the targeted siRNA delivery to ovarian cancer cells (Figure 7A) The system was designed to release siRNA in the cytoplasm by the reductive cleavage of the disulfide linkage between PEG and siRNA. The PEC micelles formed from the interaction between LHRH-PEG-siRNA and PEI (Figure 7B) showed selectiveness toward the ovarian cancer cells expressing LHRH receptors, leading to enhanced cellular uptake and suppression of the target gene expression. Surface installment of cell-specific targeting moieties onto the carriers gives selectivity toward target cells, which may increase the therapeutic effect in a target tissue with minimal risk of potential adverse effect by reducing the amount of the dose.

IV. siRNA−NANOPARTICLE CONJUGATES

Recently, various nanosized imaging agents (quantum dot nanoparticles, iron oxide nanoparticles, gold nanoparticles, carbon nanotubes, etc.) have been utilized for the development of multifunctional nanoparticles for dual therapeutic and diagnostic purposes (*67, 68*). QDs are fluorescent semiconductor nanocrystals with tunable emission properties in a wide range of colors (*69*). PEGylated QDs with surface amine groups were used for the conjugation of a tumor targeting peptide (F3), which binds to cell-surface nucleolin, and siRNA targeting a reporter gene encoding green fluorescence protein (GFP) (Figure 6) (*67*). The peptide and siRNA was attached to the QD using sulfo-LC-SPDP (sulfosuccinimidyl 6-(3′-[2-pyridyldithio]-propionamido) hexanoate) and sulfo-SMCC (sulfosuccinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate) as heterofunctional cross-linkers. Sulfo-LC-SPDP generates a disulfide linkage that can be cleaved in the reductive cytoplasm, while sulfo-SMCC generates a stable thioether linkage. The QD−siRNA/F3 conjugate successfully delivered to HeLa cells without transfection agents presumably by receptor-mediated endocytosis. However, the gene silencing effect could not be observed due to the lack of an endosomal escape function (*67*). The addition of cationic liposomes after transfection of the QD conjugate led to significant reduction of the target gene expression in HeLa cells. Significantly higher silencing efficiency was observed with the conjugate containing a disulfide linkage between QD and siRNA, suggesting that the release of siRNA is required for the induction of RNAi due to the potential hindrance of large QD in the incorporation of siRNA into RISC.

Magnetic nanoparticles have been intensively investigated for their potential biomedical applications, such as magnetic resonance imaging (MRI), hyperthermia, magnetofection, and drug delivery (*70*). For siRNA delivery with concomitant visualization of its localization in vivo, siRNA was immobilized onto the surface of magnetic nanoparticles (*68*). Primary amine groups on the iron oxide nanoparticles were activated with a heterofunctional cross-linker, *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS), and then conjugated to the thiol group of the antisense strand of siRNA. Near-infrared Cy5.5 dye (NIRF) and membrane translocation peptides were also coated onto magnetic nanoparticles. Tumor tissues were successfully visualized by MRI and NIRF image due to the accumulation of the resultant magnetic nanoparticle−siRNA conjugate at the tumor tissue after intravenous injection. The

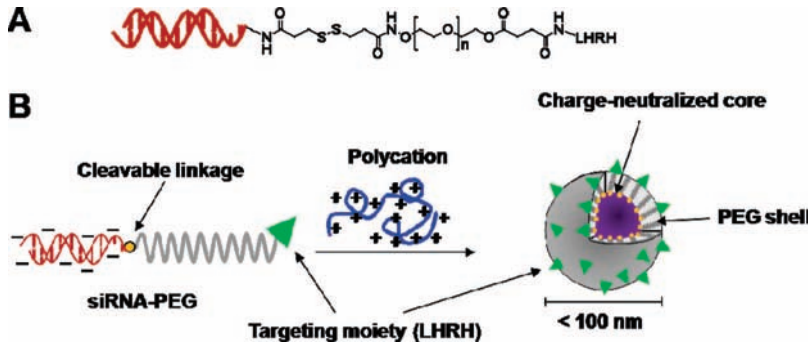

Figure 7. (A) Structure of an LHRH-tethered PEG−siRNA for targeting ovarian cancer cells. (B) The formation of PEC micelles from the interaction between LHRH-PEG-siRNA conjugate and a polycation (*81*).

mRNA level of target genes (green fluorescence protein and human survivin) was suppressed to below 15% by systemic injection of the magnetic nanoparticle−siRNA conjugate, compared to saline-treated controls. Although siRNA was conjugated onto magnetic nanoparticles via a noncleavable bond (thioether) in this experiment, surprisingly significant RNAi activity was achieved in vivo. The carbon nanotube−siRNA conjugates was also reported (*71*). The gene silencing effect by cleavable nanotube−siRNA conjugates was more enhanced about 20%, compared to that by lipofectamine/siRNA complexes and noncleavable nanotube−siRNA conjugates in vitro.

V. REDUCING OFF-TARGET EFFECTS BY siRNA CONJUGATES

Several recent papers have suggested that false-positive gene silencing could also be generated by siRNA due to its unexpected off-target effects. Recent evidence demonstrated that the off-target effects are mainly mediated by host innate immune response against the administered double-stranded RNA (siRNA) and the hybridization of siRNA-loaded RISC to undesirable mRNAs.

Synthetic siRNA can be recognized by cytoplasmic proteins, including RNA-dependent protein kinase, retinoid-acid-inducible gene 1 (RIG-1), and melanoma differentiation-associated gene 5 (MDA-5), to trigger downstream signal transduction required to elicit inflammatory responses (*72*, *73*). In addition, a series of transmembrane toll-like receptors (TLRs) are also known to play a crucial role in the recognition of synthetic siRNAs, which trigger innate immune responses (*74*). The siRNA-directed immune responses may be modulated by varying the sequence and backbone chemistry of siRNA and the type of delivery vehicle (*74*, *75*) The siRNA-dependent immune stimulation could be reduced by a certain degree of chemical modification in the backbone, including 2′-fluoro, 2′-*O*-methyl substitution and *N*-benzyl-2′-deoxyguanosine modification (*76*, *77*). However, the effect of siRNA conjugates on the inflammatory responses remains to be investigated. Previous reports suggest that the inflammatory responses can be induced depending on the property of a conjugation partner of siRNA. Intratracheal administration of Penetratin−siRNA conjugate could induce the expression of IFN-α and TNF-α, while TAT−siRNA and cholesterol−siRNA conjugate did not show any detectable immune responses (*49*). In the case of PEG−siRNA conjugate, the conjugation of PEG to siRNA seems not to further induce the expression of an inflammatory cytokine, interferon alpha (IFN-α) both in vitro and in vivo (*56*). It may be possible to reduce immune responses by conjugating appropriate materials to siRNA, which can hinder the interaction of siRNA with cellular proteins involved in the inflammatory signaling process.

Sometimes, silencing of unwanted genes by siRNA can occur. These false positive hits can be frequently observed in transcripts with ∼7 nucleotides of sequence complementarity at the 5′ end of the siRNA antisense strand (*78*, *79*). In addition, due to structural symmetry of siRNA strands, the incorporation of siRNA sense strand to RISC could lead to the off-target silencing of genes with sequence complementarity of the siRNA sense strand (*78*). Although improved selection of siRNA sequence may reduce the chance of off-target silencing, such a method cannot completely remove the off-target phenomenon, due to the lack of an efficient algorithm for the selection process (*79*). Recent study demonstrated that 5′-*O*-methylation at 5′ end of the siRNA sense strand could enhance biased incorporation of siRNA antisense into RISC, leading to reduction of the sense strand-directed off-target effect (*80*). This result suggests that the conjugation of proper materials to the 5′ terminus of the siRNA sense strand may further facilitate the biased strand selection process to reduce undesirable off-target effects. Reducing the off-target effect of siRNA is one of the challenging barriers that should be addressed before clinical applications of siRNA therapeutics. The conjugation of foreign materials to siRNA may be a double-edged sword, the benefit and risk, in terms of off-target effect. However, it is worth further investigation to determine whether the critical problem of siRNA can be avoided with siRNA bioconjugates.

VI. CONCLUSIONS

Therapeutic use of RNAi has gained a lot of attention because of its high specificity and broad therapeutic potential to target proteins that are not easily accessed and modulated by conventional small molecular weight or protein drugs. Synthetic siRNA is considered a major player in the induction of RNAi. Development of an efficient delivery system is one of the most challenging hurdles to turn siRNAs into clinically acceptable therapeutic drugs. A wide variety of siRNA conjugate delivery systems have been proposed, and some of them have demonstrated very promising preclinical results. Direct cleavable and noncleavable conjugation of various functional and nonfunctional molecules to siRNAs could not only improve their pharmacokinetic behaviors and cellular uptake efficiencies, but also promote cell specificities. To maximize delivery efficiency of siRNA bioconjugates, several crucial conjugation parameters, such as the conjugation site of siRNA, cleavability, the length of spacer, and the nature of molecules to be conjugated (charge, molecular weight, and hydrophobicity), should be carefully considered. A new class of siRNA bioconjugates integrating multiple functions in a single conjugate delivery system would be further required to solve various challenging barriers such as stability, prolonged circulation, target-specific cellular uptake, endosomal escape, and off-target property of siRNA.

Materials and Methods.

Reagents: The plasmid containing the gene for Rluc (phRl-CMV) was purchased from Promega (Madison, WI). Chemically synthesized oligonucleotide probes (Probe 1, 5'-Thiol-TAGCTTATCAGACTGATGTTGA-3', Probe 2, 5'-TCAACATCAGTCTGATAAGCTA-Thiol-3', and free Probe 1, 5'-TAGCTTATCAGACTGATGTTGA-3') were obtained from Operon Biotechnologies (Huntsville, AL). Luria Bertani (LB) broth and agar were purchased from DIFCO Laboratories (Detroit, MI). The Hi-Trap copper chelating columns (1 mL) were purchased from GE Healthcare (Piscataway, NJ). Ampicillin, bovine serum albumin (BSA), and Coomasie Brilliant Blue R250 stain were obtained from Sigma Laboratories (St. Louis, MO). Protein molecular weight marker was purchased from Fisher Scientific. Coelenterazine (ctz) was purchased from Prolume (Pinetop, AZ). 96-well Neutravidin coated white microtiter plates and 1,8-bis-Maleimidotriethylene glycol ($BM(PEO)_2$) were purchased from Pierce Technology (Rockford, IL).

Apparatus

Bacterial cell cultures were grown in a Fisher Scientific orbital shaker, and centrifuged using a Beckman J2-MI centrifuge (Palo Alto, CA). Luminescence emission scans were obtained using the Varian Cary Eclipse Fluorescence Spectrophotometer (Palo Alto, CA). Luminescence intensity measurements were recorded using a Genios workstation luminometer (Tecan, NC). All luminescence intensities reported are the average of three replicates, and have been background corrected.

Construction of Rluc split fragments. The gene for *Rluc* from the plasmid phRl-CMV was employed as the initial template. Before constructing fragments of Rluc, we introduced a non-cleavable N-terminal 6x histidine tag on the Rluc gene to aid in protein purification, as well as a recognition site for *EcoRI* restriction enzyme cleavage. The 6-His tag and *EcoRI* site were introduced using site-directed mutagenesis with the following primers: RlucHisTagFor-5'CTAGCCACCATGCATCACCATCACCATCAC*GAATTC*GCTTCCAAGGTGTAC-3' and RlucHisTagRev-5'GTACACCTTGGAAGC*GAATTC*GTGATGGTGATGGTGATGCATGGTGGCTAG-3'. The bases coding for the histidine tag are underlined and the *EcoRI* site are italicized. In order to perform site-directed mutagenesis, primers were added to the template phRL-CMV, along with DNA polymerase and deoxynucleotide triphosphates (dNTPs). Next, polymerase chain reaction (PCR) was performed for 25 cycles to copy the new plasmid. Following PCR, the sample was digested with DpnI enzyme to digest plasmids that did not contain the added DNA. The mutated plasmid (pRluc-HisTag) was transformed into *E. coli* cells strain ER 2566, plated on LB agar supplemented with 100 μg/mL ampicillin, and DNA was isolated from the colonies via mini-preparation to perform gene sequencing and restriction analysis.

In order to genetically engineer the plasmid to code for the N-terminal Rluc fragment (amino acids 1-229), two stop codons were added between the codons for amino acids Gly229 and Lys230, using the plasmid pRluc-HisTag as the template DNA. Along with the stop codons, the DNA coding for a flexible linker (Ser Gly Gly Gly Gly Ser) and for a cysteine residue was added via site-directed mutagenesis as described above (Figure S1a). The primers which coded for the stop codons, flexible linker, and cysteine to construct the N-terminal fragment are the following:

BigLuxFor-

5'GTTAAGGGAGGC*AGTGGAGGTGGAGGTAGTTGT*TAGTAAAAGCCCGACGTC3' and

BigLuxRev-

5'GACGTCGGGCTTTTACTA*ACAACTACCTCCACCTCCACT*GCCTCCCTTAAC-3'. The bases coding for the stop codons are underlined, and the flexible linker and cysteine codons are italicized. After site-directed mutagenesis, the mutated plasmid (pSKD3) was transformed into ER 2566 competent cells, followed by minipreparation, restriction analysis, and gene sequencing to confirm the presence of the stop codons, flexible linker, and cysteine codons. The purpose of the flexible linker was to allow the oligo-Rluc fragments to come into close proximity, while decreasing the amount of strain on the Rluc fragments caused by the oligonucleotide hybridization. The cysteine residue is present to provide an accessible thiol moiety through which conjugation to thiol-modified oligonucleotide probes can occur.

In order to genetically engineer the plasmid coding for the C-terminal fragment (amino acids 230-311), a recognition site for *EcoRI* cleavage was added via site-directed mutagenesis between the codons coding for amino acids Gly229 and Lys230, using plasmid pRlucHisTag as the template. Also, a flexible linker and cysteine residue were added adjacent to the *EcoRI* cleavage site, on the N-terminal side of the C-terminal fragment (Figure S1b). The following primers were used for the addition of the *EcoRI* cleavage site, linker, and cysteine: SmallLuxFor-

5'GTTAAGGGAGGCGAATTC*TGTAGTGGAGGTGGAGGTAGT*AAGCCCGACGTC-3'

SmallLuxRev-

5'GACGTCGGGCTT*ACTACCTCCACCTCCACTACA*GAATTCGCCTCCCTTAAC-3'. The bases coding for the *EcoRI* site are underlined, and the linker and cysteine-coding DNA is

italicized. After site-directed mutagenesis was performed, followed by Dpn1 digestion, the new plasmid was transformed into ER 2566 cells. Minipreparation was performed to isolate the plasmid, followed by restriction analysis with *EcoRI*, and gene sequencing in order to confirm the addition of the *EcoRI* site, the linker, and the cysteine residue. Upon verification of the mutated plasmid, digestion with *EcoRI* was performed to cut the plasmid, resulting in two DNA fragments, one fragment representing the N-terminal fragment, and the other representing the linker, cysteine, and C-terminal fragment. After gel extraction, the C-terminal fragment was ligated to form the plasmid pSKD4 (Figure S1b). Gene sequencing and restriction analysis with *EcoRI* were performed again to verify that the C-terminal fragment plasmid did not contain the N-terminal fragment gene. Once verified, the plasmid pSKD4 was transformed into ER 2566 competent cells for protein expression.

Expression of Rluc Fragments.

Cells containing plasmids pSKD3 and pSKD4 coding for the Rluc N-and C-terminal fragments, respectively, were grown in Luria Bertani (LB)-broth containing ampicillin (100 μg/mL) at 37 °C to an optical density of 0.5 measured at 600 nm. Protein expression was induced using IPTG (1 mM final concentration) and the cells were grown for 24 h at room temperature. The cells were harvested by centrifugation at 16 °C, 8600 x g for 15 min, resuspended in PBS buffer (50 mM sodium phosphate buffer, pH 8.0 containing 300 mM NaCl), and were sonicated for 3 min with a 20 s on and 15 s off cycle. The crude protein was obtained by centrifugation at room temperature, 3000 x g, for 15 min.

Purification of Rluc Fragments.

The Hi-Trap copper chelating column precharged with $CuSO_4$ was prepared by washing with 5 mL of distilled water to remove the 20% ethanol storage solution. The column was equilibrated with 5 mL of binding buffer (50 mM sodium phosphate, pH 8.0 buffer containing 300 mM NaCl) before adding the samples of crude Rluc fragments. The column was then washed with 20 mL of binding buffer followed by a 10 mL of wash buffer (50 mM sodium phosphate, pH 8.0 containing 300 mM NaCl and 5 mM imidazole). The purified Rluc fragments were eluted with 2 mL of elution buffer (50 mM sodium phosphate, pH 8.0 containing 300 mM NaCl and 100 mM imidazole). The purity of eluted fractions was determined by SDS-PAGE. Protein concentration was determined via Bradford assay.

Control Study:

A 1 nanomole of Rluc N-terminal fragment and Rluc-C-terminal fragments were prepared in PBS buffer (100 mM sodium phosphate buffer containing 250 mM NaCl, 1 mM EDTA, and 0.1 % BSA, pH 7.4). To 1 nanomole of both fragments in a white, flat-bottom microtiter plate, 0.5 μL of coelenterazine (ctz) (1 mg/mL)was added and luminescence measurement was performed with a 100 ms integration time. Next, 1 nanomole of both fragments were mixed together and incubated at 37 °C for 30 min. At the end of 30 min, 0.5 μL of ctz was added to the plate and luminescence measurement was performed with a 100 ms integration time.

Labeling of Rluc fragments

The conjugations for both the C-terminal fragment and N-terminal fragment consisted of a two step process. First, the crosslinker $BM(PEO)_2$ and the Rluc fragments were linked through the cysteine thiol moiety which is adjacent to the SGGGGS flexible linker present on the fragments, followed by addition of the thiol-modified oligonucleotide probes (Figure S2). In order to

conjugate the Rluc fragments to $BM(PEO)_2$, the fragments' disulfide bonds formed from the exposed cysteine residues were reduced by adding 10-fold mole excess of TCEP to the Rluc fragments, while stirring for 30 min at room temperature. Next, the $BM(PEO)_2$ was added to the Rluc fragments in a two-fold mole excess, while stirring for 2 h at room temp. Before adding the thiol-modified oligonucleotide probes, the disulfide bonds between the probes were reduced with 40 mM TCEP for 30 min at 37°C. After reducing, the oligonucleotide probes were added dropwise to the stirring Rluc fragment-$BM(PEO)_2$ solution. The final mole ratio of Rluc fragment: crosslinker: oligonucleotide probe was 1:2:5. Upon linking the oligonucleotide probe to the Rluc fragment, extensive dialysis against PBS buffer (50 mM $NaHPO_4$, 300 mM NaCl, pH 7.2) was performed to remove unconjugated linker and probe. Unreacted Rluc fragments were not separated from labeled fragment since removal using dialysis will be a challenging task due to large size of Rluc fragments. However, the fragments are inactive in isolation and cannot form functional Rluc by self-reassembly therefore non-conjugated Rluc fragments would not cause any interference or yield any background signal. Further the complete conjugation of Rluc fragments with probes was verified by running an SDS-PAGE gel.

Hybridization Study:

A 5×10^{-6} M concentration of Rluc N-terminal fragment probe 2 conjugate and Rluc C-terminal fragment probe 1 conjugate was prepared in PBS buffer (100 mM sodium phosphate buffer containing 250 mM NaCl, 1 mM EDTA, and 0.1 % BSA, pH 7.4). A volume of 100 μL of both fragment probe conjugates were mixed together and incubated at 37 °C for 30 min. At the end of 30 min, the probe mixture was placed in a white, flat-bottom microtiter plate and 0.5 μL of coelenterazine (ctz) was added to the plate and luminescence measurement was performed with a

100 ms integration time. Control studies were performed using (1) buffer + ctz, (2) buffer + Rluc-N terminal fragment probe 1 conjugate + ctz, (3) buffer + Rluc-C terminal fragment probe 2 conjugate + ctz. Next, different concentrations of two Rluc fragment probe conjugates were mixed together in equimole amounts and incubated at 37 °C for 30 min. Coelenterazine was added at the end of the incubation period and the luminescence intensity was measured.

Effect of free probe 1:

A mixture of Rluc-N-terminal fragment probe 2 conjugate (50 μL, 1 x 10^{-6} M) and Rluc-C-terminal fragment probe 1 conjugate (50 μL, 1 x 10^{-6} M) was incubated at 37 °C for 30 min followed by the addition of 100 μL of two different concentrations (17 μM, 66 μM) of free probe and further incubation at 37 °C for 30 min in a microtiter plate. Next, 0.5 μL of ctz was added to the wells and luminescence measurement was performed. A one nucleotide mismatched probe (5'-TAGCTTATCCGACTGATGTTGA-3') was similarly added to hybridized probe-fragment complex and was followed by luminescence measurement.

Reassembly in cellular extract

The ER2566 cell extract was prepared by growing the strain in LB media up to an optical density of 0.9 measured at 600 nm. The cells were sonicated with a 20 s on and 20 s off cycle for 5 min in 50 mM sodium phosphate buffer, pH 7.4, containing 150 mM NaCl. The resulting mixture was directly used as an extract. Nanomole amounts of probe2-N-terimnal Rluc fragment and Probe1-C-terminal Rluc fragment were mixed with the cell extract and hybridized at 37 °C for 30 min. A luminescence measurement was performed after the addition of ctz.

Reassembly of a Bioluminescent Protein *Renilla* Luciferase Directed through DNA Hybridization

Kyle A. Cissell, Yasmeen Rahimi, Suresh Shrestha, and Sapna K. Deo*

Department of Chemistry and Chemical Biology, Indiana University−Purdue University Indianapolis, Indiana 46202. Received July 18, 2008; Revised Manuscript Received November 10, 2008

Reassembly of split reporter proteins, also referred to as protein complementation, is utilized in the detection of protein−protein or protein−nucleic acid interactions. In this strategy, a reporter protein is fragmented into two inactive polypeptides to which interacting/binding partners are fused. The interaction between fused partners leads to the formation of a reassembled, active reporter. In this Communication, we have presented a proof-of-concept for the detection of a target nucleic acid sequence based on the reassembly of the bioluminescent reporter *Renilla* luciferase (Rluc), which is driven by DNA hybridization. Although, reassembly of Rluc though protein interactions has been demonstrated by others, the Rluc reassembly through DNA hybridization has not been shown yet, which is the novelty of this work. It is well established that bioluminescence detection offers significant advantages due to the absence of any background signal. In our study, two rationally designed fragments of Rluc were conjugated to complementary oligonucleotide probes. Hybridization of the two probes with fused Rluc fragments resulted in the reassembly of the fragments, generating active Rluc, measurable by the intensity of light given off upon addition of coelenterazine. Our study also shows that the reassembly of Rluc can be inhibited by an oligonucleotide probe that competes to bind to the hybridized probe−Rluc fragment complex, indicating a potential strategy for the quantitative detection of target nucleic acid. We were able to achieve the reassembly of Rluc fused to oligonucleotide probes using femtomole amounts of the probe−fragment protein conjugate. This concentration is approximately 4 orders of magnitude less than that reported using green fluorescent protein (GFP) as the reporter. A DNA-driven Rluc reassembly study performed in a cellular matrix did not show any interference from the matrix.

The split protein reassembly method has found applications as a biochemical tool to detect specific protein−protein and protein−nucleic acid interactions (*1*−*8*). In this method, two rationally designed fragments of a reporter protein are fused to proteins that are capable of interacting when close to one another. The fragments in isolation are inactive; however, biomolecular interactions between fused proteins leads to the formation of an active reporter, allowing for the detection of protein−protein interactions. This strategy has been successfully used in the reassembly of reporter proteins, specifically, dihydrofolate reductase, β-lactamase, ubiquitin, aminoglycoside kinase, *Renilla* luciferase, firefly luciferase, red fluorescent protein, and green fluorescent protein (GFP) driven by interacting proteins (*4, 5, 9*−*11*). There is only one report on reporter protein reassembly achieved through nucleic acid hybridization using split GFP as the reporter (*12*). In this study, the reassembly of split GFP upon formation of a hybrid between two complementary oligonucleotides at a 200 nM concentration was accomplished. Design and development of fluorescent proteins such as GFP have revolutionized the biochemical field. However, these proteins have some limitations because of the requirement of high energy excitation and high background signal, reducing the sensitivity of the signal measurement. In that respect, bioluminescent proteins that emit light by a biochemical reaction do not require a high energy excitation source and do not suffer from background noise in signal measurement (*13*−*17*). In a recent paper by Porter et al., these advantages of the bioluminescent enzyme firefly luciferase (Fluc) were utilized to detect proteins, small molecules, RNA, and double stranded DNA, both methylated and nonmethylated (*18*). This was accomplished through the expression of the Fluc fragments flanked by expressed protein domains, which bound to the specific target, bringing split Fluc fragments within close proximity. This allows for protein reassembly to occur, resulting in a luminescent signal upon the addition of luciferin, the substrate for Fluc. However, this method is not a hybridization-based assay that works for any target nucleic acid. This method will work only for targets for which peptide domains that bind to the target can be engineered. Taking this into consideration, here we evaluated in a proof-of-concept study of whether a bioluminescent protein, specifically *Renilla* luciferase (Rluc), is amenable to protein reassembly driven by DNA hybridization (Figure 1) similar to reassembly that can be achieved through protein complementation. We have also demonstrated the usefulness of this method in the detection of target nucleic acid. The reporter, Rluc, is a monomeric ∼38 kDa protein that catalyzes the oxidative decarboxylation of coelenterazine, the substrate that binds to Rluc, to coelenteramide, resulting in the production of light (*19*−*21*). One of the rationales for using Rluc in this study is that it is a small monomeric bioluminescent enzyme that is amenable to cellular imaging (*16, 22*−*26*). It

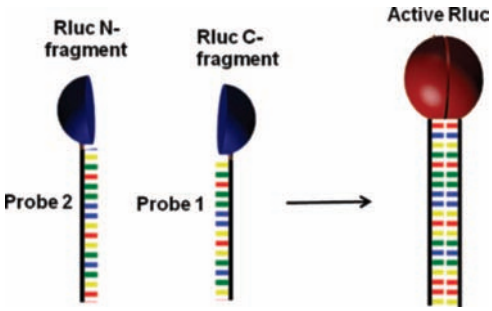

Figure 1. Schematic representation of the Rluc fragment reassembly driven through oligonucleotide probe hybridization.

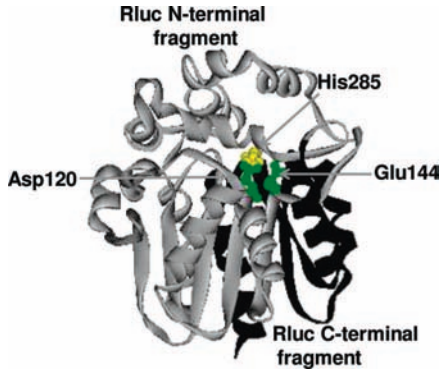

Figure 2. X-ray crystal structure of Rluc8, a mutant of Rluc showing the catalytic triad. The N-terminal Rluc fragment region is shown in gray, and the C-terminal Rluc fragment region is shown in black.

can be detected at very low levels over a broad dynamic range using inexpensive luminometers. Rluc also does not require post-translational modification for its activity. Several analogues of its substrate coelenterazine have been synthesized with different properties in terms of emission wavelength, quantum efficiency, and cell permeability, thus enhancing the applications of Rluc. Unlike fluorescence, there is no need for external excitation, and thus, problems with light scattering and source instability are avoided.

The most critical issue in the success of protein reassembly from its split fragments is the selection of a cleavage site in the protein. Availability of the three-dimensional structure can aid in the design of the protein fragments. Other considerations in the design of successful protein reassembly include small protein size, monomeric structure, and simplicity of the assay system. Reassembly of split *Renilla* luciferase from its fragments, driven by the interactions between the proteins myoD and Id in vivo, has been demonstrated (*27*), although the fragments were not isolated or purified. On the basis of this work a cleavage site of Gly229-Lys230 (Figure 2) was chosen to dissect Rluc in our study. The X-ray crystal structure of a mutant of Rluc (RL8) was solved recently (Figure 2) (*28*); however, we decided to select the cleavage site on the basis of prior complementation work performed in detecting protein−protein interactions using the native Rluc. The X-ray crystal structure of RL8 mutant shows that it has a classic α/β-hydrolase fold at its core and contains a catalytic triad made from Asp120-Glu144-His285. The cleavage site selected in our study, Gly229-Lys230, would be such that the residue Asp120 and Glu144 of the catalytic triad will be in the N-terminal fragment, whereas His285 will be in the C-terminal fragment. This suggests that although the substrate binding may occur in the N-terminal fragment, the catalytic triad is not completed until the two fragments come close for the generation of the bioluminescence signal. In the future, other cleavage sites will be evaluated on the basis of the X-ray crystal structure of the Rluc mutant. It would be

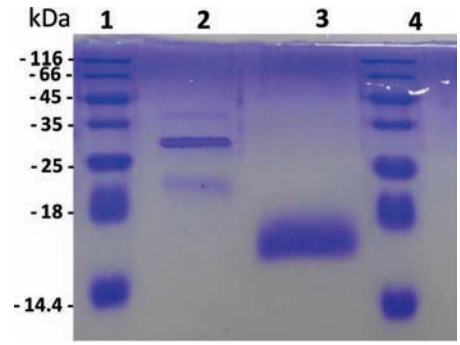

Figure 3. Picture of 12.5% SDS−PAGE gel of purified Rluc fragments stained with Coomassie Blue. Lane 1: molecular weight protein marker. Lane 2: purified N-terminal Rluc fragment. Lane 3: purified C-terminal Rluc fragment. Lane 4: molecular weight protein marker.

interesting to cleave Rluc such that the triad is kept intact in one of the fragments while the substrate binding is disturbed in the absence of assembly of the two fragments. This type of fragmentation where the active site is maintained may reduce the overall time needed for the reassembly of protein as observed in the case of split GFP work (*12*).

Using the gene for native *Rluc* from the plasmid phRL-CMV as the template, primers were designed to introduce a noncleavable 6-histidine tag to allow purification of the Rluc fragments as well as codons for a flexible amino acid linker and a cysteine residue for oligonucleotide probe conjugation (Supporting Information). The Rluc N-terminal fragment was constructed by introducing two stop codons after the amino acid Gly229 using site-directed mutagenesis (Supporting Information). Similarly, primers were designed to obtain the gene sequence of the C-terminal fragment of Rluc (amino acid 230−311) with a unique cysteine near its N-terminus (Supporting Information). Rluc fragments were expressed in *E. coli* cells and purified using a copper-immobilized Hi-Trap column (Supporting Information). The purity of the two fragments was verified using SDS−PAGE and Coomassie staining (Figure 3). The SDS−PAGE shows that the two fragments, the N-terminal fragment (∼30 kDa) and the C-terminal fragment (∼16 kDa), were purified efficiently. The concentrations of purified Rluc fragments were determined using a Bradford assay. The luminescence activity of the individual Rluc fragments (1 nmol) was monitored by adding the substrate coelenterazine (0.5 μL, 1 mg/mL). As expected, no luminescence signal was observed in the presence of substrate, indicating the inability of fragments to process the substrate (Figure 4). Next, the two fragments (1 nmol each) without the probe attached were mixed together followed by the addition of coelenterazine to check for any nonspecific binding between the fragments in the absence of oligonucleotide probes. The mixing of the two fragments did not result in the generation of any bioluminescence signal indicating that spontaneous reassembly between Rluc fragments does not occur (Figure 4).

Thiol-modified oligonucleotide probes were conjugated to the split Rluc fragments using maleimide-sulfhydryl chemistry through the homobifunctional cross-linker $BM(PEO)_2$ (1,8-bis-maleimidotriethylene glycol). The Rluc N-terminal fragment contains three cysteine residues buried within the protein structure. Therefore, we hypothesize that a cysteine introduced at the C-terminus during the construction of the fragment will be the major target site for oligonucleotide conjuation through the thiol moiety. The Rluc C-terminal fragment does not contain a cysteine residue; therefore, the cysteine introduced near the N-terminus of the C-terminal fragment via site-directed mutagenesis was targeted for the oligonucleotide conjugation. In order to perform the conjugation, Rluc fragments were first reduced using tricholroethyl phospine (TCEP). Rluc fragments

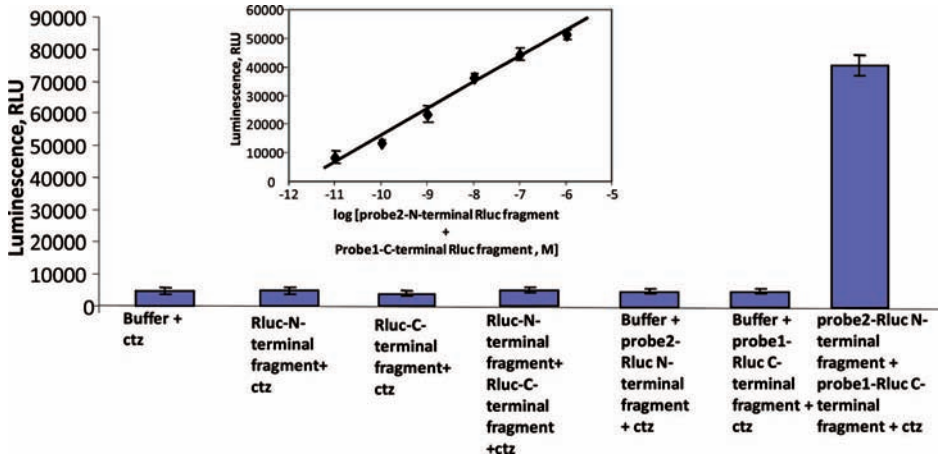

Figure 4. Bar graph showing the luminescence activity obtained in control and samples. The data are based on an average response of three samples ± the standard deviation. The inset shows a plot of luminescence activity obtained after mixing different moles of the probe1−Rluc N-terminal fragment conjugate and probe2−Rluc C-terminal fragment conjugates and adding coelenterazine. The data are based on an average response of three samples ± the standard deviation.

were then reacted with $BM(PEO)_2$ using the manufacturer's protocol in a 1:2 ratio of fragments to linker (Supporting Information). Both oligonucleotide probes (probe 2, 5′TCA-ACATCAGTCTGATAAGCTA3′-thiol and probe 1, thiol-5′TAGCTTATCAGACTGATGTTGA3′) were reduced using 40 mM TCEP at 37 °C and were added at a 5 times mole excess to the Rluc-$BM(PEO)_2$ conjugate. Probe 2 was conjugated to the N-terminal fragment, and probe 1 was fused to the C-terminal fragment. Since there is a unique cysteine introduced via site-directed mutagenesis in the C-terminal fragment, only one probe is conjugated to each fragment. Even though the N-terminal fragment contains three cysteine residues, the cysteine introduced via site-directed mutagenesis is more accessible for conjugation than the other three cysteine thiols. Unreacted probes and cross-linker were then separated using dialysis in sodium phosphate buffer (50 mM sodium phosphate, pH 7.2, containing 300 mM NaCl). In general, chemical conjugation techniques are not highly reproducible. However, in our studies we found about 70−80% conjugation efficiency monitored using SDS−PAGE analysis. This conjugation efficiency was found to be independent of the amount of mole excess of oligonucleotide probes used in the conjugation reaction. Furthermore, these conjugates were observed to be either mono-or bioligonucleotide conjugated as monitored using SDS−PAGE. Unreacted split fragments were not separated from the fragment−probe conjugates since the fragments alone are not active and thus will not contribute to any background signal.

Initially, a control study was performed to determine any background signal from fragment−probe conjugates. The bioluminescence measurements were performed by adding coelenterazine to Rluc-N-terminal fragment−probe 2 and to Rluc-C-terminal fragment−probe 1 separately. The luminescence signal obtained using probe−fragment conjugates was comparable to that obtained using buffer mixed with coelenterazine. Next, 5 nmol of each of the two probe−fragment conjugates were mixed together at 37 °C for 30 min, and bioluminescence intensity was measured after the addition of coelenterazine. Figure 4 depicts a bar graph of luminescence intensity obtained upon mixing the two complementary probe−fragments and the intensity obtained in the control study. The control resulted in a minimal background luminescence representative of the luminescence of coelenterazine alone. In comparison, a strong bioluminescence signal was observed upon the reassembly of Rluc fragments driven through probe hybridization. In another study, we mixed various concentrations of probe−Rluc fragment conjugates and measured bioluminescence signal after incubation (Figure 4 inset). A linear increase in luminescence with increasing concentrations of the two probe−fragment conjugates was obtained. We were able to detect Rluc with a detection limit of 5 fmoles (2.5×10^{-11} M) of probe−Rluc fragment conjugates. This detection limit was calculated corresponding to the signal obtained using the formula signal of the blank + 3 standard deviation of the blank. In a study performed using GFP as the reporter for fragment reassembly driven through DNA hybridization, the concentrations of probe−GFP fragment conjugates employed were 200 nM (*12*). Our results indicate that we were able to detect oligonucleotide probe hybridization using Rluc reassembly approximately 4 orders of magnitude lower than that with split GFP. A bioluminescence emission profile of the reassembled Rluc compared to the native Rluc (Figure 5) was obtained using a cuvette on a Cary Eclipse spectrophotometer (Varian, CA). The reassembled protein showed an emission maximum of 495 nm, while the native Rluc showed a 485 nm emission peak. This red shift of reassembled protein versus native protein has been observed previously with GFP (*12*). It is thought that the shift in emission wavelength may be explained by the change in proximity of the amino acids around the chromophore compared to the native Rluc, as well as the presence of the negatively charged DNA molecules driving the reassembly.

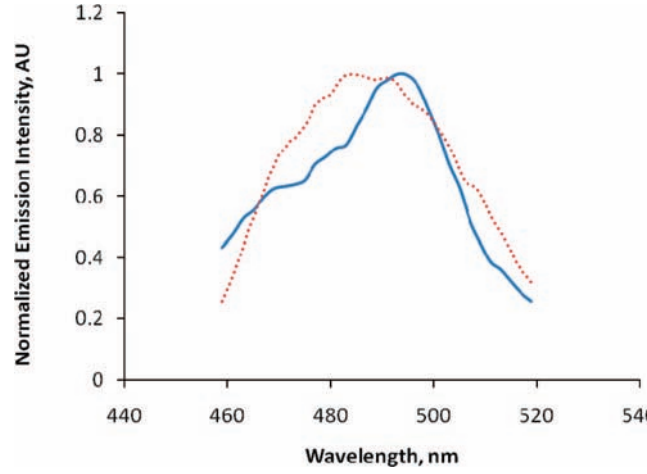

Figure 5. Luminescence emission profile obtained using a Cary Eclipse fluorometer of reassembled Rluc (solid line) and intact Rluc (dotted line) after adding coelenterazine.

Next, we studied the possibility of the potential application of reassembly of Rluc for the target nucleic acid detection. This was evaluated by examining whether the fragment reassembly driven through oligonucleotide hybridization can be competitively inhibited by a free complementary probe. When a 13.2 nmol of free oligonucleotide probe (5′-TAGCTTATCAGACTGATGTTGA-3′) was added to the reassembled Rluc fragment−probe complex (1 nmol each), we observed a reduction in the bioluminescence signal. Approximately 45% reduction in bioluminescence intensity in the presence of free probe compared to that in the control without the free probe was observed. Although we have used excess free probe, complete quenching of the bioluminescence was not observed. We believe that the possible reason for this is when the free probe is added to the fragment−probe hybridized complex, a higher temperature than 37 °C may be needed to separate hybridized strands, which may be due to a tight assembly between the probe−fragment hybridized complex. A similar phenomenon was observed in the study performed using GFP split fragments in oligonucleotide hybridization (*12*). To further validate this result, when we added 3.4 nmol of the free probe to the probe-directed reassembled Rluc (1 nmol each), a 25% reduction in the bioluminescence intensity was observed. This result indicates that the free probe can prevent DNA-directed reassembly of Rluc in a concentration-dependent manner. Ideally, a competitive assay can be performed such that the free probe is allowed to hybridize with the complementary probe−Rluc fragment followed by the addition of the second probe−Rluc fragment. An alternative method would be to simultaneously mix probe−fragment conjugates and the free probe. Another strategy to perform target nucleic acid quantitation can be based on designing the probes such that they bind adjacently to the target. Here, the Rluc fragments can be conjugated to the probes and directly added to the target to be detected. This would allow reassembly of fragments and the generation of active Rluc in the presence of the target, yielding an increase in the signal rather than a decrease and hence a higher sensitivity of detection. All of these strategies and application of Rluc reassembly in nucleic acid quantitation are under evaluation in our laboratory.

Finally, we performed the reassembly of probe−Rluc fragments in a cellular extract. This study was performed to evaluate whether the Rluc reassembly strategy will work in a more complex matrix. Another objective that was fulfilled by this experiment was to evaluate whether any nonspecific nucleic acid present in the sample will interfere with the hybridization of probes and hence the subsequent reassembly of Rluc fragments. For this study, we used the extract of *E. coli* strain ER 2566. We employed the sonication method to obtain the extract, which is also a method to get the genomic DNA (*29*). After sonicating *E.coli* strain ER 2566 cells in 50 mM sodium phosphate buffer, pH 7.2, containing 300 mM NaCl, 1 nmol of the probe 2-N-terminal Rluc fragment and probe 1-C-terminal Rluc fragment were mixed with the cell extract and hybridized. Bioluminescence emission intensity was measured after adding coelenterazine. The luminescence intensity obtained was comparable to that obtained in the in vitro study (Figure 6). A comparison of the light intensity in the buffer matrix and in the *E. coli* cell matrix showed an approximately 4.1% decrease from buffer matrix to cell matrix, which is within the allowed 10% limit. Therefore, reassembly of Rluc driven through DNA hybridization is not significantly affected by the sample matrix.

In summary, our work demonstrates that Rluc reassembly can be performed in vitro driven through oligonucleotide hybridization. The detection limit for Rluc reassembly was 5 fmoles (2.5×10^{-11} M) of probe−Rluc fragment conjugates, which is approximately 4 orders of magnitude lower than that reported using probe−GFP fragment conjugates. Our study also shows that the reassembly can be inhibited in the presence of a complementary oligonucleotide indicating that this strategy can be useful in the quantitative detection of target nucleic acid. The bioluminescence emission, small size, and monomeric structure make Rluc an efficient label for the development of complementation assays. Furthermore, the method developed offers the advantage of parallel analysis in a 96-well microtiter plate and makes it suitable for high throughput nucleic acid quantitation applications.

The controlled introduction of azides in proteins provides targetable handles for selective protein manipulation. We present here an efficient diazo transfer protocol that can be applied in an aqueous solution, leading to the facile introduction of azides in the side chains of lysine residues and at the *N*-terminus of enzymes, e.g. horseradish peroxidase (HRP) and the red fluorescent protein DsRed. The effective introduction of azides was verified by mass spectrometry, after which the azido-proteins were used in Cu(I)-catalyzed [3 + 2] cycloaddition reactions. Azido-HRP retained its catalytic activity after conjugation of a small molecule. This modified protein could also be successfully immobilized on the surface of an acetylene-covered polymersome. Azido-DsRed was coupled to an acetylene-bearing protein allowing it to act as a fluorescent label, demonstrating the wide applicability of the diazo transfer procedure.

In recent years, with the advent of chemical biology the need to manipulate and modify proteins has increased considerably. One of the important limitations in selective chemical modification of proteins is the overabundance of functional groups present in these biomacromolecules. In order to introduce, site specifically, bioorthogonal reactive groups, multiple strategies have been developed. In many cases, the free thiol groups of cysteine residues are specifically targeted for conjugation because these functionalities are reactive and relatively rarely present in proteins (*1*−*4*). Unfortunately, electrophiles that readily react with thiols are, to a lesser extent, also susceptible to attack by amines or even alcohols, leading to loss of specificity. Furthermore, cysteines are often essential for the structural integrity and function of proteins and therefore cannot always be modified.

To overcome these shortcomings, some strategies make use of functional groups that do not naturally occur and are deliberately introduced, enabling individual targeting of these groups without inadvertent cross-linking or other reactions (*5*−*8*). An example of this approach is the [3 + 2] transition metal-catalyzed Huisgen cycloaddition between an azide and an acetylene function (*1, 9*−*11*). Since "click" chemistry has been shown to work well for protein modification, efficient methods for the controlled introduction of azides or acetylenes into biomolecules have become of great interest (*12*−*14*).

Although azido-modified amino acids can be introduced by single-site or multisite protein engineering replacement strategies (*7, 13, 15*), the degree of site specificity provided by these laborious methods is not always needed. This led us to investigate the possibility of applying the relatively mild and facile diazo transfer reaction to amines, in order to directly introduce azides at the lysine positions of proteins. Traditionally, however, the diazo transfer reaction is carried out on small organic molecules in organic solvents such as CH_2Cl_2, with trifluoromethanesulfonyl azide (TfN_3) as reagent and catalyzed by Cu(II) (*16*−*18*). These conditions make this type of reaction unsuitable for protein modification. Recently, this method was improved by Goddard-Borger and Stick (*19*), who introduced imidazole-1-sulfonyl azide hydrochloride (**1**, see Figure 1) as a nonexplosive and shelf-stable alternative to TfN_3. Particularly interesting is the fact that **1** can be applied in protic solvents. We therefore envisaged the use of compound **1** to perform the diazo transfer reaction on proteins and enzymes in aqueous solutions, residue-specifically introducing azido-moieties at their lysine residues or *N*-terminus.

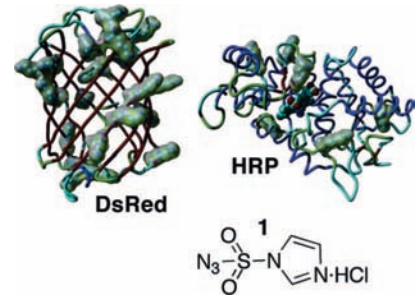

Figure 1. Structures of DsRed, horseradish peroxidase (HRP), and imidazole-1-sulfonyl azide hydrochloride (*1*). The molecular surfaces of all lysine residues in the proteins are shown. The structure of DsRed was derived from the PDB file 2VAD and contains 22 lysine residues. The structure of HRP was derived from PDB file 7ATJ and contains 6 lysine residues.

To study the applicability of this relatively simple method, we initially used the enzyme horseradish peroxidase (HRP, see Figure 1) as a model protein (*20, 21*). To functionalize HRP, it was dissolved in milliQ (MQ) pure water (200 μL, 2.5 mg/mL) and an aqueous solution of K_2CO_3 (100 μL, 2 mg/mL) was added, along with 25 μL of Cu(II)$SO_4 \cdot 5H_2O$ in MQ (1 mg/mL). After mixing, transfer agent **1** in MQ was added (1.75 equiv relative to the amines in HRP) and the reaction was left stirring overnight, after which the enzyme was purified using centrifugal filter devices. ESI-TOF analysis of the thus treated enzyme showed that, under the applied experimental conditions, an average of four amines were transformed into azides (see Figure 2). A small amount of HRP possessed three or five azides (out of a total of seven), which implies a statistical mixture of functionalized compounds.

The influence of the diazo transfer treatment and subsequent conjugation of a small molecule (butynol; see Supporting

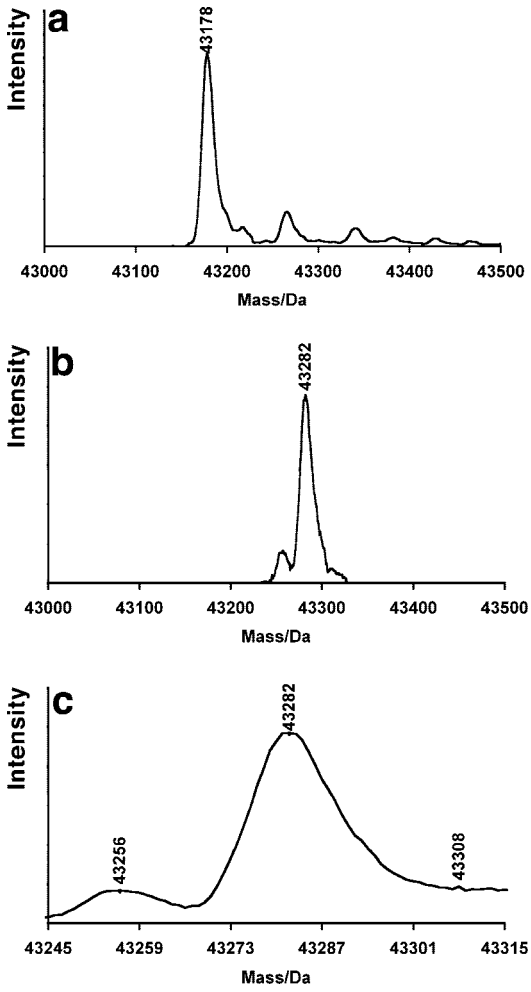

Figure 2. Mass spectrometry results (ESI-TOF): (a) unreacted HRP; (b) azido-HRP; (c) enlargement of (b). The mass difference between (a) and (b) is four times 26, corresponding to four diazo transfers. A closer inspection of (b), as shown in (c), reveals that tri- and penta-azido-substituted HRP molecules are also present, indicating that azido-HRP is a statistical mixture of transfer products.

Information) on the catalytic activity of HRP was assayed using 2,2′-azinobis(3-ethyl-benzothiazoline-6-sulfonic acid) (ABTS) as substrate, which is converted by HRP into the strongly absorbing product $ABTS^{\cdot+}$ using H_2O_2. A comparison was made with the catalytic activity of the untreated enzyme. The results are shown in Figure 3. It can be concluded that the activity of the enzyme is only slightly reduced by the introduction of the azido functions and the subsequent conjugation.

To test whether azido-HRP can be used for bioconjugation studies, experiments were performed to link this modified enzyme to the surface of polymersomes (*22*−*24*). Polymersomes are robust spherical vesicles with an average diameter of ca. 200 nm, created via the self-assembly of amphiphilic block copolymers (*25*, *26*). For our experiments, polymersomes derived from polystyrene$_{40}$-*b*-poly(L-isocyanoalanine(2-thiophen-3-yl-ethyl)amide)$_{50}$ (PS-PIAT) admixed with 10 wt % PS$_{40}$-poly(ethylene glycol)$_{67}$-acetylene were used (*24*), designed for exterior modification via the acetylene moieties presented on their surfaces. The compounds were incubated in a phosphate buffer (20 mM, pH 7.4) with azido-HRP for 60 h in the presence of a Cu(I) catalyst. Hereafter, they were washed using centrifugal filter devices until no residual HRP activity could be detected in the flowthrough. To test the resulting aggregates for HRP activity, they were incubated with ABTS in the presence of H_2O_2. The progress curves shown in Figure 4 indicate that azido-HRP can be successfully immobilized on the polymeric surfaces

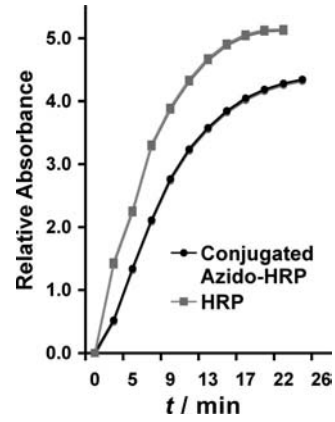

Figure 3. Catalytic activities of HRP and butynol-conjugated azido-HRP. Equal amounts of both enzymes were incubated with ABTS and H_2O_2, and the formation of $ABTS^{\cdot+}$ was measured over time. Comparison of the initial slopes suggests that the "clicked" HRP has retained 75% of its catalytic activity (see Supporting Information).

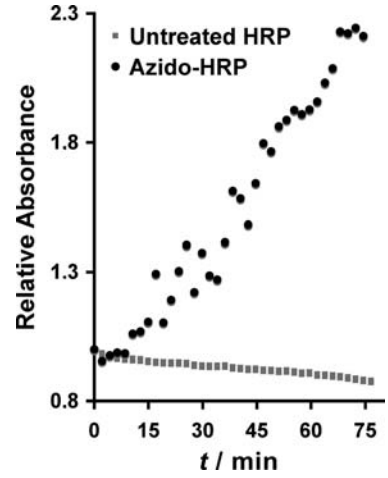

Figure 4. Progress curve for polymersomes with and without surface-conjugated HRP. The polymersomes were incubated with ABTS in the presence of H_2O_2, and the formation of $ABTS^{\cdot+}$ was measured as a function of time. After a short initial incubation period (i.e., 8 min), azido-HRP-conjugated polymersomes produced increasing amounts of $ABTS^{\cdot+}$ (black dots). Polymersomes that were incubated with untreated HRP did not show any activity (gray dots).

using "click" chemistry. Electron micrographs of the (clicked) polymersomes are shown in Figure 5.

To further evaluate the scope of our method, we also investigated the diazo transfer reaction on DsRed (see Figure 1), an engineered red fluorescent protein from *Discosoma striata* (*27*). To this end, DsRed was treated with transfer agent **1** in the presence of K_2CO_3 and $Cu(II)SO_4 \cdot 5H_2O$ in MQ (0.5 equiv of **1** was used relative to the amines in DsRed). Analysis by ESI-TOF revealed that under these experimental conditions an average of 4 amines were converted to the corresponding azides, as shown in Figure 6. The fluorescent azido-DsRed was subsequently reacted with a biochemically engineered elastin-like protein (ELP, MW 39.8 kDa) fitted with an acetylene moiety at its *N*-terminus. The Cu(I)-catalyzed conjugation successfully labeled the ELP with the fluorescent protein marker, as was demonstrated by SDS-PAGE analysis (Figure 7). As an additional demonstration, azido-DsRed was "clicked" to propargylic poly(ethylene glycol)$_{45}$ and analyzed in the same fashion (Figure 7) (*28*).

In summary, we may conclude that the diazo-compound **1** is a robust and facile transfer reagent for the introduction of azides in proteins. It was demonstrated that the catalytic activity of

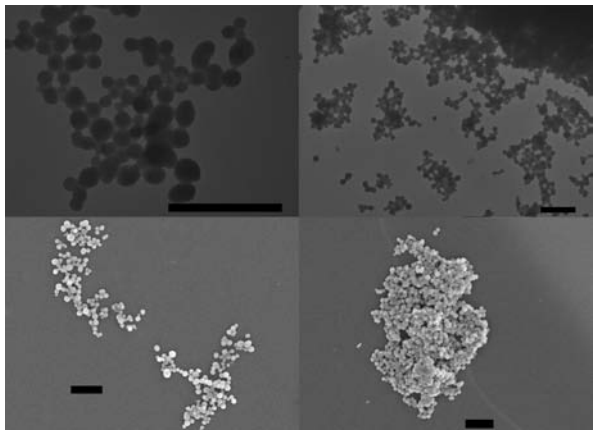

Figure 5. TEM and SEM images of polymersomes containing GOx (top row) and of vesicles containing GOx that have azido-HRP immobilized on their surfaces (bottom row). The black scale bars represent 1 μm.

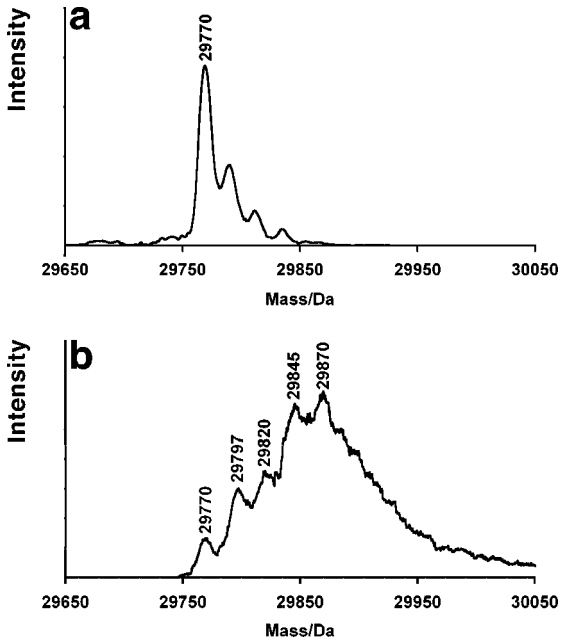

Figure 6. Mass spectrometry results (ESI-TOF) for (un)functionalized DsRed: (a) unreacted DsRed; (b) azido-DsRed. The broad signal shown in b contains approximate masses for mono-, di-, tri-, and tetra-azido-DsRed, along with a small signal for the unfunctionalised protein. This statistical mixture of transfer products, caused by the 22 lysine residues present in DsRed, slightly compromises the accuracy of the deconvolution results. The symmetry of the signal suggests that penta and higher degrees of azido-DsRed are also present.

enzymes, such as HRP, after the diazo transfer reaction and subsequent coupling to a small molecule was not substantially reduced. This was further verified by the immobilization of the azido-HRP on the surface of a polymersome, after which the catalytic activity of the enzyme was also retained. To further demonstrate the versatility of the diazo transfer reaction, the fluorescent protein DsRed was equipped with azides and subsequently conjugated to an acetylene-bearing elastin-like protein via Cu(I)-catalyzed triazole formation. These examples show that the diazo-transfer reaction is a suitable technique for the selective modification of proteins under ambient conditions. It should be noted, however, that the present method may not be suitable for proteins containing lysines that are essential to their biological activity.

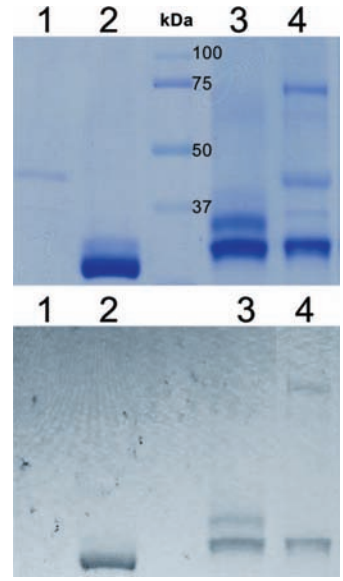

Figure 7. SDS-PAGE analysis of DsRed conjugation reactions. Proteins were visualized with Coomassie staining (top) or *via* fluorescence of DsRed (bottom): (1) acetylene-ELP; (2) azido-DsRed; (3) PEGylation of azido-DsRed. A signal with an increase in mass of ~2 kDa can be seen, corresponding to one PEG addition; (4) reaction of azido-DsRed with acetylene-ELP. A signal with a mass difference of ~40 kDa can be seen, corresponding to ELP-conjugated DsRed.

ACKNOWLEDGMENT

This work was funded in part by the Dutch National Research School Combination - Catalysis (NRSC-C) and NWO-ACTS. We thank RJRW Peters for the synthesis of α-Me, ω-dipropargylic poly(ethylene glycol)$_{45}$.

(28) The small mass difference between lanes for DsRed is presumably caused by the influence of either Cu(II) or the introduced diazo-moieties; further investigations did not satisfactorily elucidate this. The fluorescent image still indicates that both bands are indeed DsRed signals.

Reagents

Heavy water (D_2O, 99.9%) was purchased from Aldrich. $CuSO_4$ (Merck), sodium ascorbate (Fluka, >99%), 4,7-diphenyl-1,10-bathophenanthroline disulfonic acid disodium salt (ligand) (Sigma-Aldrich), anhydrous sodium sulphate (Fluka, 99%), K_2CO_3 (Fisher), magnesium sulfate dihydrate (Fluka, 99%), NaN_3 (Acros, 99%), acetonitrile (MeCN)(Baker), Na_2CO_3 and Na_2HPO_4 (Merck) imidazole (99%, Fluka), sulfonyl chloride (Acros, 98.5%), 3-butyn-1-ol (Aldrich, 99%) and 2,2'-azinobis(3-ethyl-benzothiazoline-6-sulfonic acid) diammonium salt (ABTS) (Fluka, 99%) and all other chemicals were all used as received. Ultrapure water was purified using a WaterPro PS polisher (Labconco, Kansas City, MO) set to 18.2 MΩ/cm.

Horseradish peroxidase (E.C. 1.11.1.7) type VI and glucose oxidase (E.C. 1.1.3.4) type X-S from *Aspergillus niger* were purchased from Sigma (BioChemika). PS_{40}-$PIAT_{50}$ was purchased from Encapson B.V. (Nijmegen, The Netherlands). PS_{40}-PEG_{65}-acetylene was prepared as previously described (*1*). Ligand **3** was prepared as described elsewhere (*2*).

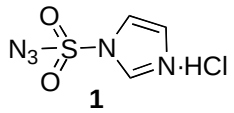
DsRed was prepared according to standard microbiological procedures. Elastin-like protein (ELP) was prepared under auxotrophic conditions where methionine was replaced by homopropargylglycine for acetylene incorporation, in analogy to previous work (*3*). The ELP construct can be described using the notation ELP$[V_5L_2G_3\text{-}90]^5$, where the capitals between the brackets represent the single letter amino acid code replacing guest residue Xaa in the pentapeptide ValProGyXaaGly. The subscript stands for the number of guest residues in the monomer gene, and the ELP consists of 90 pentapeptide repeats. (MALDI-TOF analysis of ELP calc. 39758; found 39551).

Instrumentation

^{1}H NMR spectra were recorded on a Varian Inova 400 MHz instrument at 25°C. Infrared spectra were measured on an ATI Matson Genesis Series FTIR spectrophotometer fitted with an ATR cell. Transmission electron microscopy (TEM) images were obtained using a JEOL JEM 1010

microscope (60 kV) equipped with a CCD camera. Scanning electron microscopy (SEM) images were obtained using a JEOL JSM T300 Scanning microscope (30kv). Samples were prepared by placing 10 µL of a solution on a carbon-coated copper grid for 15 min., after which the liquid was removed. The grid was washed by placing 10 µL MQ on it, which was subsequently removed, after which the grid was dried in vacuo. For SEM, grids were coated in 1.5 nm Pt/Au using a BALZERS sputter machine. UV absorption was measured using a Wallac Multilabel Counter 1420 (Victor Wallac). ESI-TOF measurements were performed using an AccuTOF-CS (JEOL) with samples dialized towards MQ containing 0.5% formic acid. LCQ spectra were obtained using an LCQ advantage max (Thermo Finnigan, Thermo scientific). SDS-PAGE analysis was performed using standard methodology for 10% crosslinked gels.

Synthesis of Imidazole-1-sulfonyl azide hydrochloride (1).



1

As described by Goddard-Borger *et al.*,(*4*) NaN_3, 3.26 g (50 mmol), was suspended in ice-cooled MeCN (50 mL) and 4.1 mL sulfuryl chloride (50 mmol, 1 eq.) was added dropwise, after which the mixture was stirred vigorously overnight allowing it to warm up to room temperature. The mixture was recooled to 0 °C, and 6.50 g imidazole (95 mmol, 1.9 eq.) was added in small portions, after which the reaction mixture was stirred over a period of 2.5 h allowing the temperature to rise to room temperature. The mixture was diluted with 100 mL EtOAc, washed twice with MilliQ water (MQ) and twice with a saturated $NaHCO_3$ solution, and dried over $MgSO_4$. Subsequently, 40 mL of HCl in EtOAc (4M) was added to the ice-cooled mixture, which was left to stand for 15 min. The resulting precipitate was isolated through filtration and washed with EtOAc (3 · 50mL). This produced 7.05 g (67.3%) of colorless (white) needles. LCQ: (Mass - Cl) calc. 174.01, found 173.93. FTIR: $\nu_{max.}$ 2362, 2169, 1436, 1196. ^{1}H NMR (D_2O): ∂ 7.44 (dd, 1H, *C*^{4}*H*), 7.85 (dd, 1H, *C*^{5}*H*), 9.17 (dd, 1H, *C*^{2}*H*).

Diazo-transfer to HRP. To a solution of HRP in MQ (200 µL, 2.5 mg/mL) an aqueous solution of K_2CO_3 (100 µL, 2 mg/mL) was added, along with 25 µL of a Cu(II)SO_4·5H_2O solution in MQ (1 mg/mL). After mixing, a solution of **1** in MQ was added (15 µL, 2 mg/mL, 1.75 equiv. relative to amines in HRP) and the reaction was left agitated overnight. The mixture was transferred to an Amicon UltraFree-MC centrifugal filter with a 3 kDa cutoff and centrifuged to dryness. The supernatant was redissolved in 600 µL MQ and centrifuged again. This procedure was repeated for a total of five washings. Finally, the product was redissolved in 200 µL MQ and analyzed by ESI-TOF (calc. for four transfers (based on 43178.00 found for unreacted HRP): 43281.96; found: 43282.00).

Diazo-transfer to DsRed. To 0.5 mL DsRed (2.6 mg/mL, 87 µM) was added 70 ⌈L K_2CO_3 (0.1 M in MilliQ water), 1 ⌈L $CuSO_4$ (40 mM in MilliQ water), ending with 20 ⌈L diazotransfer agent (24 mM in MilliQ water, 0.5 equiv. relative to amines in DsRed). The solution was incubated at room temperature overnight, and purified over a 5 mL Sephadex-G50 (Amersham Biosciences)

column equilibrated with MilliQ water. The solution was concentrated on a lyophilizer, yielding 2.5 mg/mL. The product was analyzed by ESI-TOF (calc. for three transfers + Na (based on 29768.95 found for unreacted DsRed): 29869.93; found: 29870.11).

3

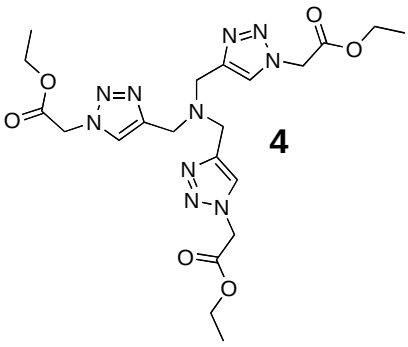
Preparation of polymersomes.

A solution of 0.5 mg PS-PIAT (**2**) in 0.5 mL tetrahydrofuran (THF) containing 10 wt.-% of anchor **3** was gently dripped into 2.25 mL of a phosphate buffer (20 mM, pH 7.4) with 250 µL of a GOx stock solution in the same buffer (2.5 mg/mL, 15.6 µM). and left to equilibrate for 30 min. The suspension was transferred to an Amicon Ultra Free-MC centrifugal filter with a 100 kDa cutoff and centrifuged to dryness. The polymersomes were redispersed in 600 µL of a phosphate buffer (20mM, pH 7.4) and centrifuged again. This step was repeated six times. The resulting vesicles were redispersed in 1mL phosphate buffer (20 mM, pH 7.4). Figure 5 (main text) gives representative electron micrographs of these polymersomes.

Conjugation of 3-butyn-1-ol to azido-HRP. 3-Butyn-1-ol (2.5 µL, $3.3 \cdot 10^{-2}$ mmol) was added to a solution of azido-HRP in MQ (100 µL, 2.5 mg/mL). Aqueous solutions of $Cu(II)SO_4 \cdot 5H_2O$ with sodium ascorbate (10 mM each, 10 µL) and 4,7-diphenyl-1,10-bathophenanthroline disulfonic acid disodium salt (ligand, 10 mM, 10 µL) were premixed, added to the enzyme solution and left for 14 hrs at room temperature. The mixture was then transferred to an Amicon UltraFree-MC centrifugal filter with a 3 kDa cutoff and centrifuged to dryness. The supernatant was redissolved in 600 µL MQ and centrifuged again. This procedure was repeated for a total of five washings. Finally, the product was redissolved in 100 µL MQ. The product was analyzed by ESI-TOF (calc. for one addition (based on 43178.00 for unreacted HRP): 43352.00; found: 43352.00), the result of which is shown in figure S3.

Conjugation of azido-HRP to polymersome surfaces. To a dispersion of GOx-containing polymersomes in 200 µL phosphate buffer (20 mM, pH 7.4) an aqueous solution of azido-functionalized HRP (33 µL, 75 µM, 2 equiv. relative to **3**) was added. Aqueous solutions of $Cu(II)SO_4 \cdot 5H_2O$ containing sodium ascorbate (10 mM each, 33 µL) and bathophenanthroline ligand (10 mM, 33 µL) were pre-mixed and then added to the dispersion, which was left at 4 °C for 60 hrs. The mixture was transferred to an Amicon UltraFree-MC centrifugal filter with a 100 kDa cutoff and centrifuged to dryness. The polymersomes were redispersed in 600 µL phosphate buffer (20 mM, pH 7.4) and centrifuged again. This step was repeated until no enzyme activity could be detected in the filtrate. The resulting biohybrid was redispersed in 200 µL phosphate buffer (20 mM, pH 7.4).

Conjugation of azido-DsRed to ELP.



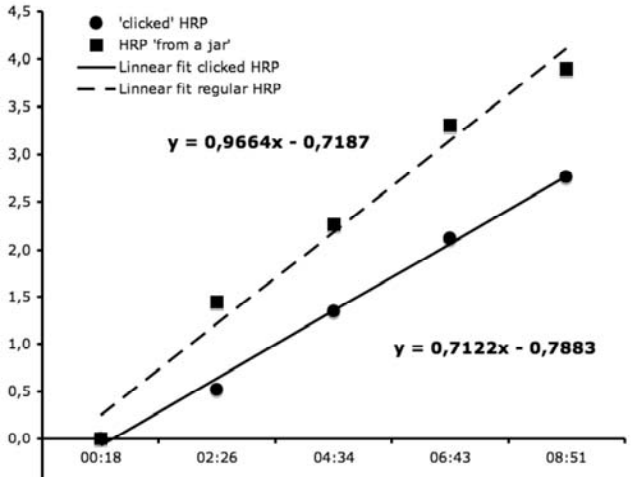
4

To a mixture of ELP (16 µL, 0.587 mg/mL in PBS buffer pH 6.5, MW 39.8 kDa) and azido-DsRed (2 µL, 3.3 mg/mL in MQ) was added 2 µL of CuBr/ligand mixture. The CuBr/Ligand mixture contained CuBr in MeCN (40 mM) and ligand **4** (80 mM) in a 1:1 v/v ratio. The reaction mixture was gently shaken at r.t. for 18 hours and used for gel electrophoresis without further purification.

Conjugation of α-Me, ω-propargylic PEG_{45} to azido-DsRed. To a mixture of PEG (5 µL, 2.3 mg/mL in MQ) and azido-DsRed (5 µL, 3.3 mg/mL in MQ) was added 2 µL of CuBr/ligand and 8 ⌈L MQ giving a total volume of 20 ⌈L. The CuBr/Ligand mixture contained CuBr in MeCN (40 mM) and ligand **4** (80 mM) in a 1:1 v/v ratio. The reaction mixture was gently shaken at r.t. for 18 hours and used for gel electrophoresis without further purification.

Activity assay for (azido-)HRP. An ABTS/H_2O_2 stock solution (4 mM in 20 mM phosphate buffer, pH 7.4, with 0.22% H_2O_2) was freshly prepared before each series of measurements. In a single well of a 96-well micro titer plate a solution of HRP or azido-HRP (2.5 µg/mL in 20 mM

phosphate buffer, pH 7.4, 100 µL) or an aliquot of control buffer (100 µL) was placed, followed by the ABTS/H_2O_2 stock solution (5 µL.) The monitoring of the formation of the radical cation of



ABTS via its absorption at 405 nm was started immediately after mixing. A comparison of initial reaction rates is shown in figure S2.

Figure S2. Comparison of the linear parts of the progress curves for HRP and azido-HRP as shown in figure 3. The initial rates were compared *via* a linear fit on the first five data points, suggesting that azido-HRP retains 74% of untreated HRP's activity under these conditions. The inhibiting effect of azide moieties on HRP activity,could contribute to this result.

Activity assay for biohybrid polymersomes. A stock solution of glucose (1 M in 20 mM phosphate buffer, pH 7.4) was freshly prepared before each series of measurements, as was an ABTS stock solution (4 mM in 20 mM phosphate buffer, pH 7.4). In a single well of a 96-well micro titer plate a dispersion of polymersomes (100 µL) or an aliquot of control solution (100 µL) was placed, followed by the glucose (40 µL) and the ABTS (20 µL) stock solutions. The monitoring of the formation of the radical cation of ABTS via its absorption at 405 nm was started immediately after mixing.

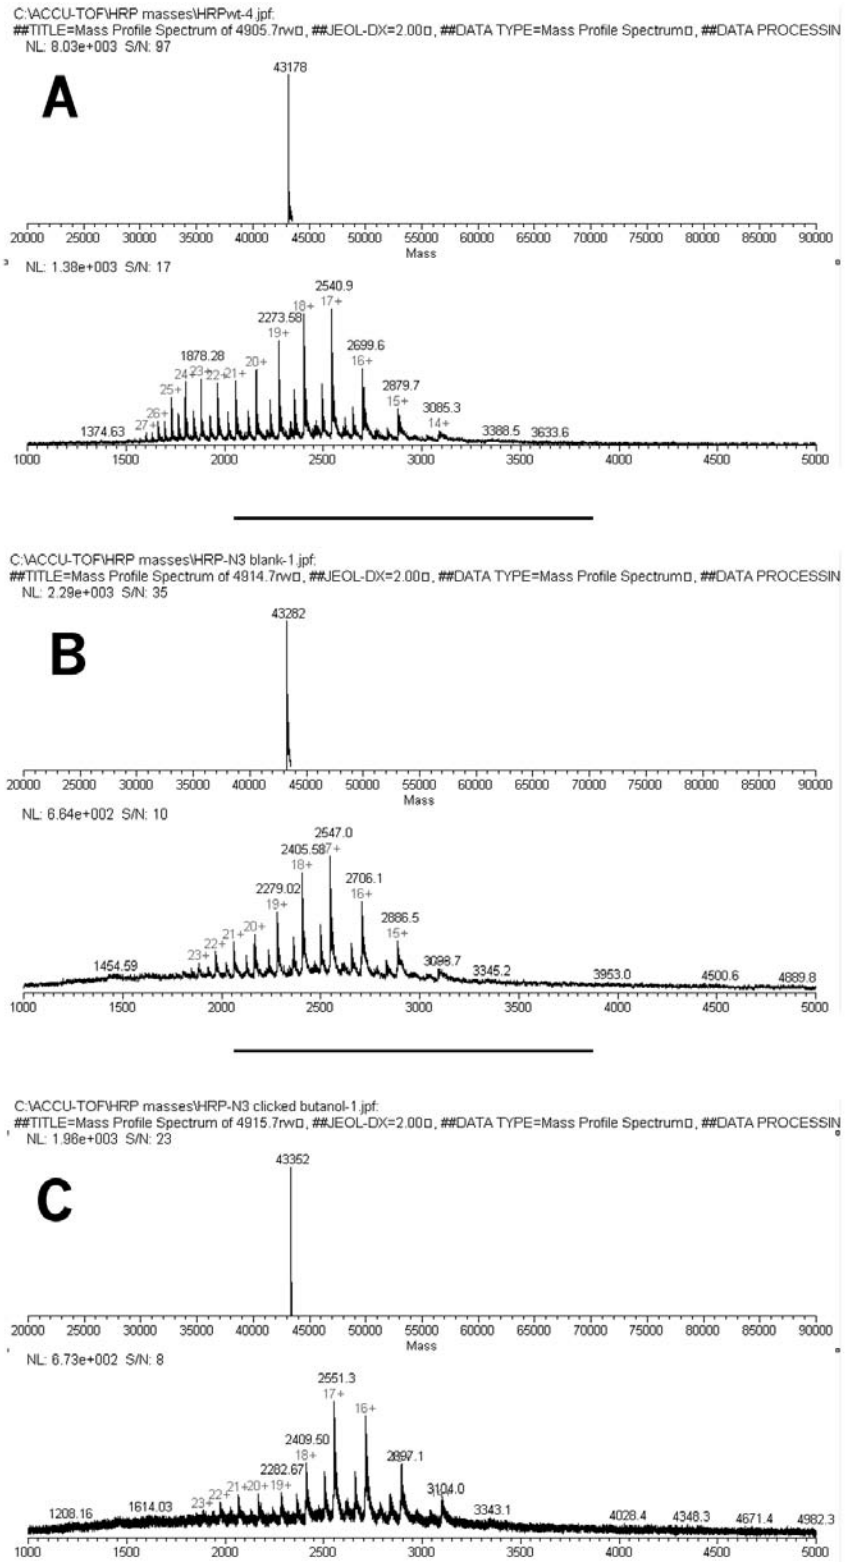


Figure S3. Mass spectra for HRP, azido-HRP and butynol-conjugated azido-HRP. Each panel shows both the experimental results and the deconvoluted peaks; **A.** Unreacted HRP; **B.** Azido-HRP; **C.** Azido-HRP reacted with 3-butyn-1-ol.

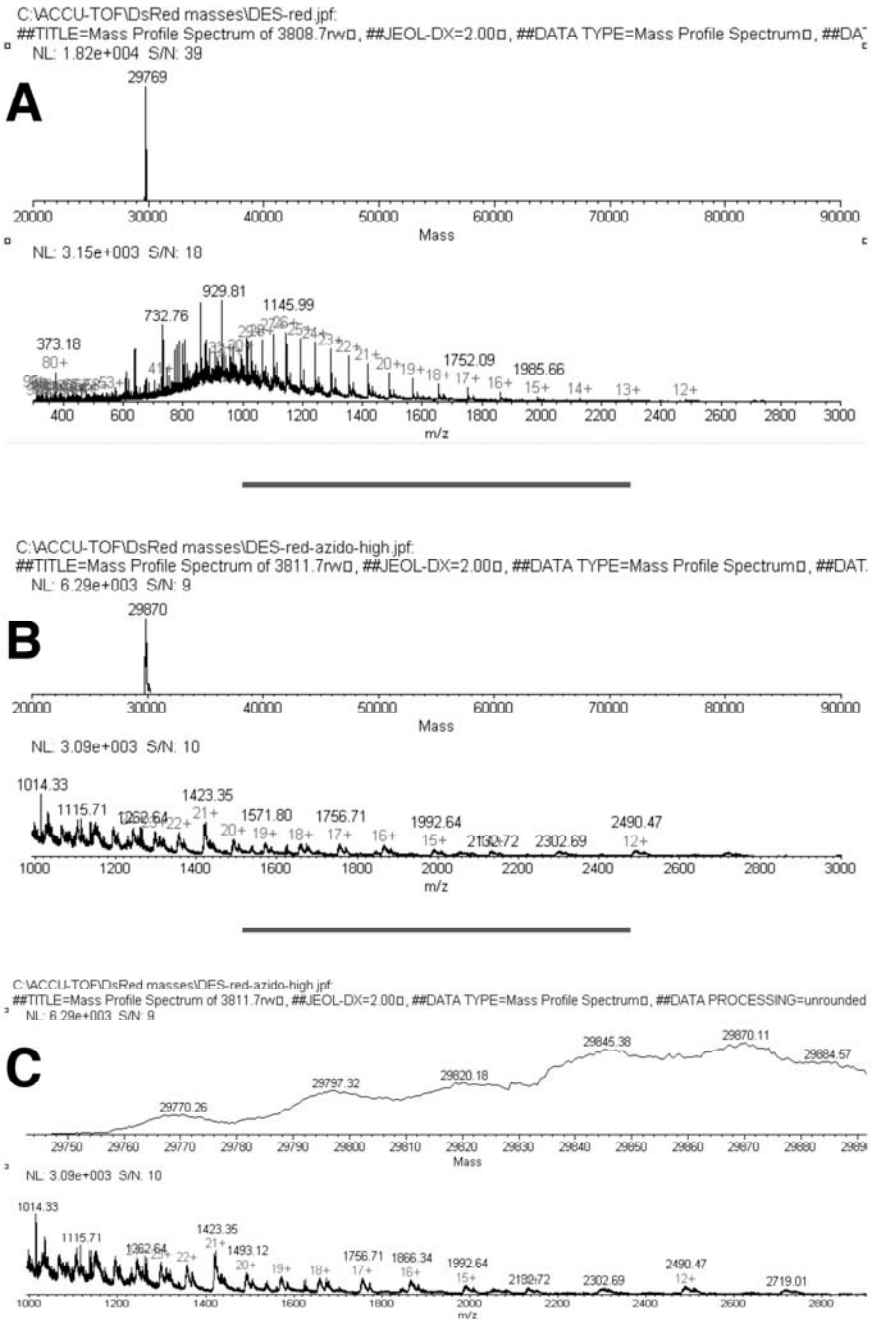

Figure S4. Mass spectra for DsRed and azido-DsRed. Each panel shows both the experimental results and the deconvoluted peaks; **A.** Unreacted DsRed; **B.** Azido-DsRed; **C.** Zoomed view of azido-DsRed.

Received April 22, 2008; Revised Manuscript Received November 3, 2008

Nasopharyngeal carcinoma is a neoplasm with a high incidence in Southeast Asia, and it is strongly associated with Epstein−Barr virus (EBV) activation involving the expression of a weakly immunogenic protein, namely, latent membrane protein (LMP)-2. Previous immunological studies already identified the human leukocyte antigen (HLA)-A11 restricted peptide epitope (SSCSSCPLSK) in the LMP-2 antigen. In this work, we prepared gold nanoparticle (AuNP)−peptide conjugate **1** by treating the nanoparticles with the *N*-cysteinated LMP-2 epitope. The AuNP−peptide conjugates have been characterized by TEM (15−24 nm in diameter) and UV−vis spectroscopy (surface plasmon resonance absorption band at $\lambda_{max} = 520$ nm). In the presence of a CALNN capping peptide, the AuNP−peptide conjugates are stable in solution without aggregation at room temperature for at least 48 h. By ELIspot studies, AuNP−peptide conjugate **1** was found to elicit a significantly stronger INF-γ response [number of spot forming cells (SPC) = 727 ± 198] from peripheral blood mononuclear cells of healthy HLA-A11 donors when compared to that induced by the unconjugated LMP-2 peptides (SFC = 73 ± 28). Further studies showed that dendritic cells treated with conjugate **1** can effect CD8+ T-cell activation leading to epitope-specific cytotoxic T lymphocyte killing responses in vitro.

INTRODUCTION

Nasopharyngeal carcinoma (NPC) is a prevalent malignancy in Southeast Asia. Conventional treatment is ineffective for advanced NPC patients and is often accompanied with severe long-term side-effects. In this regard, immunotherapy is now attracting current interest in developing more effective cancer treatment. Epstein−Barr virus (EBV) is a γ-herpesvirus that resides in over 95% of the general population as a life-long asymptomatic harmless infection (*1*, *2*). However, poorly differentiated and undifferentiated NPC is strongly associated with EBV activation. The EBV latent membrane proteins (LMP-1 and -2) expressed in the tumor tissues have become the target antigens for cancer immunotherapy. A recent clinical study by Straathof and co-workers showed that the adoptive transfer of LMP- and LMP-2 specific cytotoxic T-lymphocytes (CTLs), which were generated by stimulating the peripheral blood mononuclear cells (PBMCs) with autologous EBV-transformed lymphoma cell lines (LCL), could induce antiviral response in vivo and conferred tumor regression in some advanced NPC patients (*3*). Apart from the LMP proteins, the LCLs are also known to produce six other nuclear antigens (EBNAs 1, 2, 3A, 3B and 3C, and EBNA-LP) (*4*) and some of which are oncogenic (*5*−*7*). Despite the encouraging clinical results, the use of EBV-transformed LCLs for CTL priming may jeopardize the safety of patients. Apparently, the development of synthetic peptide antigens that can induce EBV-specific CTL activation is clearly advantageous over whole-protein antigen mixtures in terms of safety and ease for production.

Dendritic cells (DC) are professional antigen-presenting cells for activation of antigen-specific CTL, which underlies effective cancer immunotherapy. Dendritic cells are responsible for processing and presenting human leukocyte antigen (HLA)-restricted peptide epitopes to CD8+ T cells through the major histocompatibility complex (MHC)-I pathway (*8*−*11*). Recently, one of us reported that intranodal injection of dendritic cells ex vivo pulsed with a HLA-A11 restricted LMP-2 epitope (SSC-

SSCPLSK) induced EBV specific CTL in vivo, and regression of metastatic tumor in selected NPC patients has been observed (*12*). Yet, the antitumor effect of this DC-based immunotherapy for NPC was not seen in all tested individuals, and the poor immunogenicity of the LMP-2 epitope is probably one of the reasons. Conventionally, keyhole limpet heamocycnin (KLH) and bovine serum albumin (BSA) have been used as carriers to conjugate with peptides for inducing antibody responses. Recently, KLH has been shown to have an adjuvant effect that primes dendritic cells for enhancing peptide specific CD8+ T cell responses (*13*−*15*); however, the potential side effects (*16*) from the use of this potent adjuvant have been a cause for concern in human settings. As a result, several alternative approaches have been exploited to enhance the immunogenicity of peptide antigens for human uses. A notable example is the multiple antigenic peptide (MAP) system based on the conjugation of multiple peptide epitopes onto a benign carrier such as liposomes and branched/dendrimeric poly lysine core (*17*−*22*). While arduous synthetic processes are often required, the purification and characterization of the MAP peptides are also technically demanding. In addition, the number of different epitopes incorporated into the construct is also limited, rendering development of a broad scope peptide vaccine difficult.

The use of nanoparticles as delivery vehicles for therapeutic agents is receiving current attention (*23*−*27*). For example, nanoparticle based biodegradable polymers such as poly(γ-glutamic acid) and poly(DL-lactic-coglycolic acid) have been used to deliver peptide/protein antigens to murine and human dendritic cells for effective induction of antigen-specific CTL responses (*28*). However, the nanoparticles were prepared by self-assembly of their polymers, and this process often operates in a small scale and at high dilution. By virtue of high surface area and chemical stability, biomolecule functionalized gold nanoparticles (AuNP) have found important applications in many areas, including catalysis, biosensing, and diagnostics (*29*−*36*). In search of highly immunogenic peptides for potential application to NPC immunotherapy, here we describe that bioconjugation of the LMP-2 epitope (SSCSSCPLSK) to gold nanoparticle (AuNP) is a simple and effective approach for assembling solution-stable immunogenic multivalent peptides. Immunoassay studies showed that the AuNP−peptide conjugate is a potent immunogen in inducing interferon (IFN)-γ production by peripheral blood mononuclear cells. Also, treatment of human dendritic cells with the nanoparticle−peptide conjugate resulted in EBV-specific CTL priming in vitro.

MATERIALS AND METHODS

The Fmoc-protected amino acids and the Wang resins were purchased from EMD Biosciences, Inc. (Novabiochem, 10394 Pacific Center Court, San Diego, CA 92121); the Wang resins precoated with amino acids were purchased from Advanced ChemTech Inc. (Louisville, KY), and the other chemicals were purchased from Aldrich Chemical Co. (P.O. Box 206, Milwaukee, WI 53201). All of the solvents were of HPLC or peptide synthetic grade and were used as received. The nanopure water was collected from a Barnsted water purification system (nanopure diamond).

Buffy coats were obtained from the Hong Kong Red Cross for research purposes; anti-HLA antibodies were purchased from US Biology Corp. (USA); antihuman CD8 and the isotype control antibodies were obtained from PharMingen (USA). The cytokines, GM-CSF (granulocyte macrophage colony stimulating factor) and Interleukin (IL)-4, were obtained from Peprotech Inc. (USA). MultiScreenHTS-IP PVDF filter Elispot plates (MSIPS4510) were purchased from Millipore Corp (USA); the ELIspot kit (SEL285) and ELIspot Blue Color Module (SEL002) were purchased from R&D System (USA). The ^{51}Cr-sodium chromate isotope for the chromium release assays was purchased from GE Healthcare Medical Co. Ltd., (CJS1−1mCi, USA). The peptides were prepared by a Chemspeed 500 parallel synthesizer. All of the samples were lyophilized by a Savant system (SC250DDA speedvac Plus). The peptides were analyzed and purified on a Waters HPLC system (Waters Alliance 2690 equipped with a 996 PDA UV−vis detector or Waters delta 500 preparative HPLC). The masses of the samples were determined by either matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF, Amersham Biosciences, Voyager DE-STR MALDI TOF Mass spectrometry) or fast atom bombardment ionization (FAB, Finnigan MAT 95). The gold nanoparticles (AuNP) were analyzed by a transmission electron microscope [TEM, Philips (Techian 20)]. For the uptake of the AuNP−peptide conjugates by dendritic cells, a transmission electron microscope of Philips EM208s model was employed.

Solid Phase Peptide Synthesis. All of the peptides including the multiple antigenic peptides (MAP) were synthesized by solid phase peptide synthesis using the Fmoc-protected amino acid strategy (*37*). The crude peptides were purified by preparative HPLC, and >95% purity of the peptides were confirmed by analytical HPLC equipped with a UV−vis detector (monitoring wavelength $\lambda = 214$ nm). The purified peptides were lyophilized to give an amorphous white solid. The peptides were dissolved in 10 μL of DMSO and diluted with sterile phosphate buffered saline (PBS) to 2 mM. The solutions were kept at −70 °C for long-term storage (6 months) and −20 °C for temporary storage (2 weeks). The mass spectrometry data of the synthetic peptides are available in Supporting Information. The multiple antigenic peptide (MAP) **7** was synthesized from the Wang resin precoated with ([Fmoc-Lys(Fmoc)]$_2$-Lys-Cys(Acm)-β-Ala-resin (SM5105, Advanced ChemTech, Inc., Louisville, KY) using the Fmoc protected amino acid strategy as described earlier. The crude products were dialyzed with a dialysis tubing (1200 dalton cutoff; Sigma, D7884−10FT) in nanopure water containing urea (10%) and acetic acid (10%) for 48 h at room temperature. The purified products were lyophilized and analyzed by ESI-MS. The animo acid sequence of **7** was confirmed by the amino acid sequencing technique (Department of Zoology, The University of Hong Kong). MAP **8** was synthesized in a similar manner using the precoated Wang resin ([Fmoc-Lys(Fmoc)]$_4$-Lys$_2$-Lys-Cys(Acm)-β-Ala-Wang resin, SM5102).

Synthesis of Gold Nanoparticles (AuNPs) (*38*). A sodium citrate solution (0.5 g in 10 mL of water) was added to a boiling $KAuCl_4$ solution (36 mg in 90 mL of water). The color of the reaction mixture changed gradually from pale yellow to wine red over 30 min. The gold nanoparticles obtained in this manner were found to have particle sizes of 15−24 nm based on transmission electron microscopic analysis. The gold nanoparticle solution was used for the subsequent peptide conjugation without purification.

Synthesis of AuNP−Peptide Conjugate 1. To the gold nanoparticle solution prepared above (9 mL) was added the LMP-2′ peptide (C-SSCSSCPLSK; 0.1 mL of 2 mM in water) and the capping peptide CALNN (Cys-Ala-Leu-Asn-Asn) (0.9 mL of 2 mM in water). The reaction solution was stirred overnight at room temperature to afford AuNP−peptide conjugate **1** as a wine red solution. On the basis of HPLC analysis of the reaction mixture, unreacted/unbound LMP-2′ and CALNN peptides were not detected. The conjugate was purified by Sephadex column chromatography and lyophilized to obtain a red powder (3.0 mg). The red powder was resuspended in PBS for TEM, UV−vis spectroscopic analysis.

For the preparation of AuNP−peptide conjugates **2**−**6**, a similar protocol was employed by using different ratios of LMP-2′ and CALNN peptides (see Supporting Information).

HPLC Analysis of Peptides. Ten microliters of a sample was injected to a reverse phase column (Waters, Xterra column, 4.6 × 150 mm) using a gradient of solvent mixtures [solvent A (H_2O with 0.1% trifluoroacetic acid) and solvent B (acetonitrile with 0.1% trifluoroacetic acid); gradient program: 0−3 min A (100%), 20 min A (50%), 25 min A (100%), 25−30 min A (100%)] using an Alliance 2690 HPLC system with a photo diode array PDA (996) detector (monitoring wavelength λ = 214 nm). The % amount of the peptides was determined by comparing the authentic samples.

Peripheral Blood Mononuclear Cells (PBMCs) (*39*). The PBMCs were harvested from the buffy coats (Red Cross Hong Kong) by Ficoll-Hypaque (Pharmacia Biotech, Uppsala, Sweden) density gradient centrifugation. The PBMCs were washed with PBS three times and resuspended in culture medium for immediate use or frozen for later experiments by keeping in liquid nitrogen.

Human Leucocyte Antigen (HLA) Typing. The buffy coat (1 mL) was diluted with PBS (1 mL) and incubated with ACK buffer (2 mL; 150 mmol/L NH_4Cl, 61mmol/L $KHCO_3$, and 1 mmol/L Na_2EDTA; pH 7.4) for 5 min to lyse the red blood cells. The white blood cells were washed with PBS three times and resuspended in PBS (1 million cells/mL; 50 μL). To identify the HLA types of each PBMC, HLA-A2, HLA-A11, HLA-A2/A24, and HLA-A11/A24 antibodies (US Biology, H6098−28A and H6098−07A) were employed for immunostaining (at 4 °C for 20 min), followed by incubation with FITC-conjugated secondary antibody and subsequent flow cytometric analysis (BD, FACS Calibur). In this work, only the HLA-A11+/A2+ donors were used for the experiments. The HLA A2/A24 and HLA A11/A24 antibodies (US Biology, H6098−31, H6098−11) were also employed to discriminate any HLA A24+ donors.

ELIspot Assay. The ELIspot assay was performed using the ELIspot kit (SEL285) and ELIspot Blue Color Module (SEL002) by following the manufacturer's instruction. Briefly, 2 μL of the AuNP−peptides as prepared above was added to 1 mL of PBMCs (4×10^6 cell number) in complete medium (10 unit/mL of penicillin, 10 μg/mL of Streptomycin, and 10% fetal bovine serum in RPMI1640) and IL-2 (10 unit/mL) at 37 °C with 5% CO_2 for 18 h. The treated PBMCs were placed in triplicate onto the microtiter plate (96 wells) precoated with capture antibody. The ELIspot plate was kept at 37 °C with 5% CO_2 overnight and then washed with washing buffer (PBS with 0.05% of tween) three times. A detection antibody was added to the microtiter plate, and the mixture was kept at 2−8 °C for 16 h. The microtiter plate was then washed with washing buffer (three times) and the INFγ-releasing cells were revealed as color spots by adding a color developing agent. The blue spots were counted with a dissection microscope.

Generation of Dendritic Cells (*40*). PBMCs ($1 - 2 \times 10^7$ cells/well) were plated on a 6-well plate at 37 °C with humidified 5% CO_2 for 2 h in complete medium. The nonadherent cells were then removed, and fresh complete medium with GM-SCF (100 ng/mL) and IL-4 (100 ng/mL) was added to the semiadherent monocytes. The medium and the cytokines were changed every two to three days. On day 7, the immature dendritic cells were harvested. The purity of the harvested dendritic cells was about 80% as determined by immunostaining with antihuman CD11c antibody, followed by flow cytometry analysis.

Uptake of AuNP−Peptide Conjugate by Dendritic Cells (*31*). Briefly, 2 μL of **1** was added to 5×10^5 immature dendritic cells in 1 mL medium at 37 °C in humidified 5% CO_2 for 24 h. The treated cells were washed twice and fixed with 2.5% glutaraldehyde in cacodylate buffer at 4 °C for 16 h. Afterward, the dendritic cells were then washed and supported in agar gel. The agar gel was further dehydrated by shaking with stepwise increase in ethanol concentration from 50% to 100%. The dehydrated agar was embedded with epoxy resin by polymerization overnight at 60 °C. The resin was sliced for electron microscopic analysis. The dendritic cells were examined by a Philips EM208s transmission electron microscope (Electron Microscope Unit, Department of Pathology, Queen Mary Hospital).

Generation of Peptide-Specific Cytotoxic T-lymphocytes. The HLA A11+ CD8+ T cells were isolated from HLA-typed PBMCs by negative depletion (Dynal Biotech ASA, Dynabeads Goat antimouse IgG, 110.33) according to the manufacturer's instructions. The CD8+ T cells were obtained with about 80% purity based on flow cytometry analysis.

On day 7 (see Scheme 1), **1** (2 μL) was added to the immature dendritic cells (iDCs, 2×10^5 cells irradiated with 3000 rad) in 0.1 mL medium generated earlier, and the mixture was incubated for 1 h. The iDCs were then washed and mixed with CD8+ T cells (1×10^6 cells) in 1 mL of complete medium with β-mercapthanol (55 μM) and IL-2 (50 unit/mL). On day 10, 50 unit/mL of IL-2 was added to the medium. On day 14, CD8+ T cells were restimulated with the autologous dendritic cells pulsed with the peptide−AuNP conjugate as described above, and the restimulation procedure was repeated on day 21. The CD8+ T cells were harvested on day 28, and the specific killing efficiency of CTL was assessed by the chromium (^{51}Cr) release assay. In addition to **1**, MAP **7** (4 μL of 2 mM in water) and LMP-2 (native epitope = SSCSSCPLSK, 50 μL of 2 mM in water), **6** (2 μL of working solution), MAP-A24 (4 μL of 2 mM in water; see Figure 3 for structure) and HLA mismatched peptide (TYGPVFMSL, 50 μL of 2 mM in water) were used for comparison and as irrelevant controls.

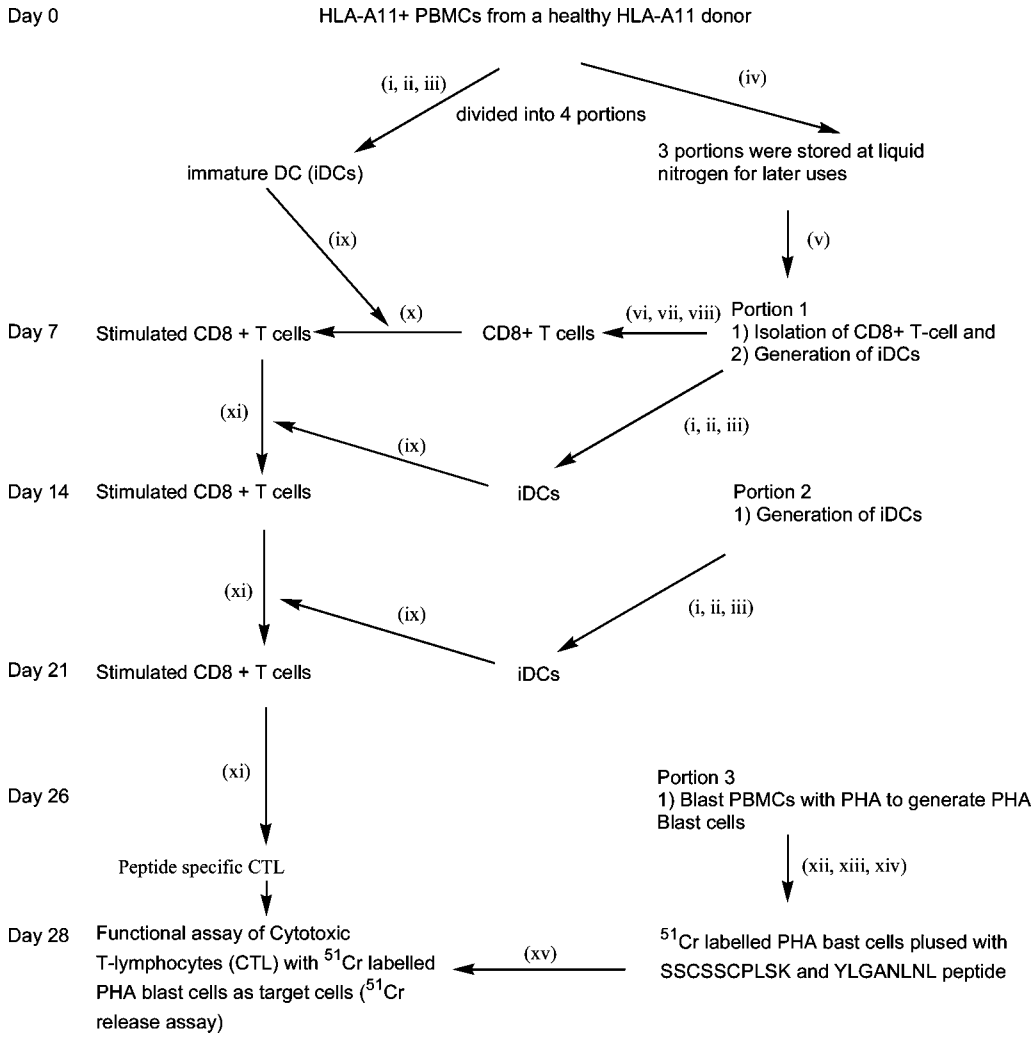
Chromium (^{51}Cr) Release Assay (*41*). To prepare the target cells, autologous or HLA-matched PBMCs (4×10^6 cells) were cultured with phytohemagglutinin (PHA, 0.2 mg/mL) and IL-2 (400 unit/mL) in complete medium for 2 days to obtain PHA blast cells (*42*). The blast cells (*43*) (2×10^6) were washed three times and treated with 100 μL (0.1 mCi) of Na_2CrO_4 (1 mCi, Amersham, CJS1−1mci) for 1 h at 37 °C with 5% CO_2 to obtain chromium labeled target cells. The targets were split into two equal portions and pulsed with LMP-2 peptide (SSCSSCPLSK, 100 μM) and irrelevant peptide (YLSGANLNL, 100 μM) for 1 h. The peptide-pulsed PHA blasts were resuspended to 10^5 cell/mL and aliquot (100 μL, 10^4 cells/well) into the U-bottom 96-well plate in triplicate.

The specific CTLs (which were stimulated with **1**, **6**, **7**, MAP-A24, and HLA mismatched peptide) were harvested and used as effector cells for the cytotoxicity assay. Effector cells in triplicate (6.0×10^5, 2.0×10^5, 6×10^4, and 2×10^4 cells per well; cell number would vary according to donors) were placed on a 96 U bottom plate and cocultured with target cells (1×10^4 cells per well) for 4 h. The maximum release was obtained by lysing the target cells with 5% Triton X-100 in PBS. The spontaneous release was obtained from the supernatant of the target cells in medium only. The released chromium was counted by a scintillation counter (LKB Wallac, 1470 Wizard). % Cell lysis = (experimental release − spontaneous release)/(maximum release − spontaneous release) × 100%.

RESULTS AND DISCUSSION

Gold nanoparticles (AuNP) were prepared by reduction of $KAuCl_4$ (1 mmol) with sodium citrate according to a reported method (*38*). The nanoparticles showed a characteristic surface plasmon resonance absorption band at λ = 520 nm, and a TEM study revealed a size distribution of 15−24 nm (Figure 1). By standard solid phase peptide synthesis, the LMP-2 epitope (SSCSSCPLSK) (*44*, *45*) was prepared with purity >95% as confirmed by HPLC analysis. In this work, a cysteine residue

Scheme 1. Flow Chart Showing the Processes of the Cytotoxic T-Lymphocyte Generation and the ^{51}Cr Release Assay[a]



[a] Reagents and conditions: (i) PBMC (2×10^7 /well, 6 well), 37 °C, 5% CO_2, 2 h in complete medium (10 unit/mL of penicillin, 10 mg/mL of Streptomycin, 10% fetal bovine serum in RPMI 1640); (ii) removed non-adherent cells and washed semi-adherent monocytes by complete medium; (iii) replenished monocytes with complete medium containing GMCSF (100 ng/mL) and IL-4 (100 ng/mL) and changed medium every 3 days; (iv) 10% DMSO, 50% fetal bovine serum in RPMI 1640, in liquid nitrogen; (v) replenished with completed medium, 37 °C, 5% CO_2; (vi) mouse anti-human CD4, CD14, CD16, and CD56 (10 μg/mL/10^6 cell), 4 °C, 20 min, washed 3 times; (vii) Dynabeads (goat anti-mouse, IgG 110.33, 100 μL/mL), 4 °C, 30 min; (viii) magnetic beads depletion; (ix) immature DC (0.2×10^6, irradiated with 3000 rad), **1** (2 μL), 1 h; (x) CD8+ T (1×10^6, 1 mL) in complete medium with β-mercapthanol (55 μM) and IL-2 (50 unit/mL); (xi) replenish fresh medium with β-mercapthanol (55 μM) and IL-2 (50 unit/mL) every 3 days; (xii) PBMC (4×10^6), Phytohemagglutinin (PHA, 0.2 mg/mL) and IL-2 (400 unit/mL) in complete medium, in 2 days to become blast cells; (xiii) blast cells (2×10^6), Na_2CrO_4 (100 μL of 1 mCi/mL), 1 h, 37 °C, 5% CO_2, washed 3 times; (xiv) divided PHA blast cells into 2 equal parts and pulsed with LMP-2 peptide (SSCSSCPLSK, 50 μL of 2 mM) and irrelevant (YLSGANLNL, 50 μL of 2 mM), 37 °C, 5% CO_2, 1 h, washed 3 times; (xv) co-cultivated different E:T ratio of CTLs (100 μL) to PHA blast cells 10^4 cell/100 uL/well, 37 °C, 5% CO_2, 4 h. (Note: E:T ratio varied from donor to donor and depended on CTL harvested.)

was appended to the *N*-terminus of the LMP-2 epitope (i.e., C-SSCSSCPLSK = LMP-2′) to enable peptide ligation to the Au surface.

Conjugation of LMP-2 Peptide Epitope to Gold Nanoparticles. To the AuNP solutions was added the LMP-2′ peptide and the CALNN (Cys-Ala-Leu-Asn-Asn) peptide (mole ratio of LMP-2′/CALNN = 1:9), and a red solution of AuNP−peptide conjugate **1** was obtained. HPLC analysis of the red solution revealed that all of the LMP-2′ and the CALNN peptides were completely consumed for ligation to the nanoparticles. Conjugate **1** can be purified by Sephadex G-10 column chromatography and lyophilized to afford a red powder (3.0 mg). It is noteworthy that any species corresponding to the inter/intramolecular disulphide bond formation were not observed by LC-MS analysis (*46*). By employing different quantities of the LMP-2′ and CALNN peptides for the bioconjugation, AuNP−peptide conjugates **2**−**6** were prepared (see Supporting Information for details). In all cases, the LMP-2′ peptides were completely consumed for the bioconjugation, and thus, the equivalent peptide concentrations for the AuNP−peptide conjugates in solution should be 20 (**1**), 40 (**2**), 60 (**3**), 140 (**4**), and 200 μM (**5**). These solutions will be utilized as the working solutions for the biological assays. Treating the AuNPs with CALNN peptide alone (i.e., without LMP-2′ peptide) gave conjugate **6**, which will be used as the negative control in the immunoassays.

As noted earlier, conjugate **1** can be isolated as a red powder after Sephadex column purification followed by lyophilization. Conjugate **1** can be dissolved readily in PBS, and the UV−vis spectrum is characterized by a distinct UV−vis absorption band at λ_{max} = 520 nm. Similar spectral features were observed for **2**−**6** as well as the peptide-free gold nanoparticles (Figure 1b). For all of the AuNP−peptide conjugates, no significant changes in the particle diameters were observed after peptide conjugation according to TEM analyses.

As reported by Levy and co-workers (*47*), the CALNN sequence is important for maintaining solution stability of the

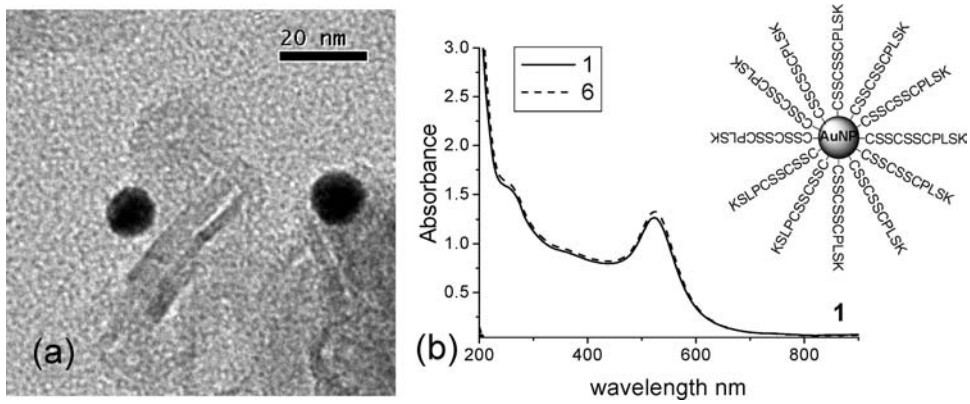


Figure 1. (a) TEM image of AuNP−peptide conjugate **1** (diameter = 15−24 nm) against PBS (shaded area); (b) UV−vis spectra of **1** (solid line) and **6** (dotted line) in PBS showing a characteristic surface plasmon band at 520 nm. Inset: schematic depiction of the AuNP−peptide conjugates.

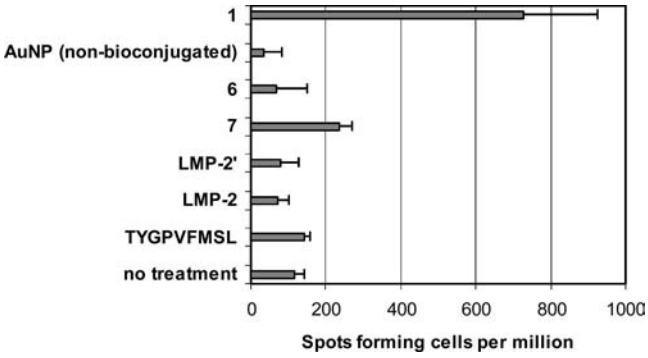

Figure 2. ELIspot results depicting the INF-γ release from the PBMCs of a HLA-A11 donor 1 upon stimulation by the peptides/conjugates; HLA mismatched A24 peptide = TYGPVFMSL.

AuNP−peptide conjugate without aggregation. By monitoring the surface plasmon resonance band (520 nm) of AuNP−peptide conjugates **1**−**4** (in PBS buffer) containing the CALNN sequence, no significant spectral changes were observed for those samples. The solutions of **1**−**4** were found to be stable at room temperature for at least 48 h without apparent precipitation. However, for the PBS solution of **5** that lacks the CALNN sequence, significant precipitation occurred over 48 h at room temperature. As expected, **6** containing only the CALNN peptide alone was stable in PBS solution under identical conditions.

INF-γ ELIspot Assay for the Peptide-Conjugated Gold Nanoparticles. Gamma interferon (INF-γ) is an important cytokine in provoking antiviral immunity (*48*). The immunogenicity of the AuNP−peptide conjugates **1**−**6** was evaluated by their activity to activate INF-γ producing cells in peripheral blood mononuclear cells (PBMCs) using the enzyme linked immunospot (ELIspot) assay. PBMCs from four healthy HLA-A11 donors were employed for this study. Briefly, PBMCs were treated with the AuNP−peptide conjugate **1** (equivalent epitope concentration in culture medium = 0.04 μM) in a 24-well plate for 16 h at 37 °C. The peptide-treated PBMCs (2×10^5 cells) were then incubated in triplicate wells for 24 h with INF-γ capture antibody precoated on a PVDF membrane. After washing, a color developing agent was added to the plate, and the INF-γ-releasing cells were identified as colored spots. The number of spot-forming cells (SFC) was counted with a dissection microscope.

Figure 2 shows the ELIspot results from donor 1. As expected, stimulation with nonpeptide conjugated AuNPs, conjugate **6** with CALNN peptide-alone, and the HLA-mismatched (TYGPVFMSL) peptides could not induce any significant IFN-γ response in the PBMCs. Interestingly, the unconjugated LMP-2 and LMP-2′ peptides (10 μM) also failed to induce a significant IFN-γ response [spot-forming cells (SFC) = 73 ± 28 vs 117 ± 24 of no peptide control) suggesting that this peptide per se was a poor immunogen and was unable to stimulate significant cytokine response from the PBMCs of healthy individuals by a simple single stimulation procedure. These results were in agreement with previous findings that this HLA-A11 restricted LMP-2 epitope (SSCSSCPLSK) is weakly immunogenic and that the CTL precursor frequency for this epitope in healthy individuals is very low (e.g., < 1/100,000 PBMCs) (*49*). However, when this weakly immunogenic epitope was administered in the form of gold nanoparticles, i.e., conjugate **1**, a strong and significant INFγ response was observed (SFC = 727 ± 198 vs 117 ± 24 in no peptide control, $P = 0.007$). It is noteworthy that in these experiments, the equivalent epitope concentration of conjugate **1** (0.04 μM) was much less than that of the unconjugated peptide (10 μM) under our experimental conditions, and yet, the observed INFγ response with conjugate **1** was 10-fold stronger than of the native peptide.

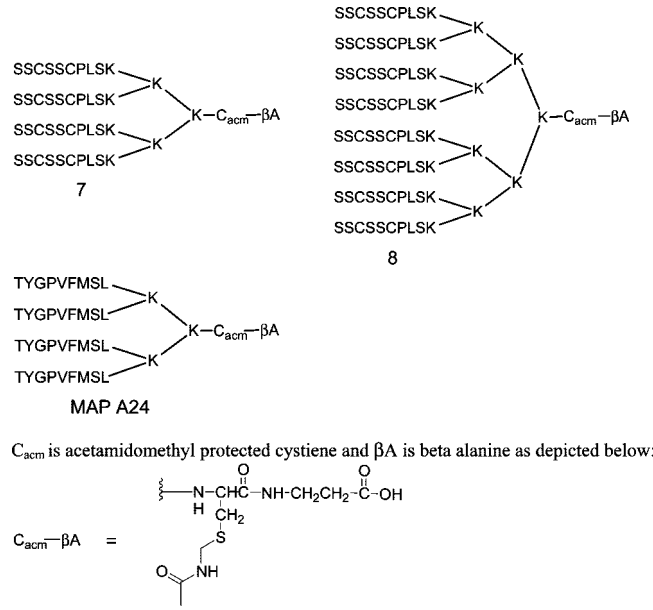

Figure 3. Schematic depiction of the multiple antigenic peptides 7, 8, and MAP A24.

Apart from the AuNP−peptide conjugates, the immunogenicity of the multiple antigenic peptides (MAP) derived from a branched lysine core was also examined in parallel by the ELIspot assays. In this work, antigen **7** conjugated with four LMP-2 epitopes (Figure 3) was also prepared by conventional

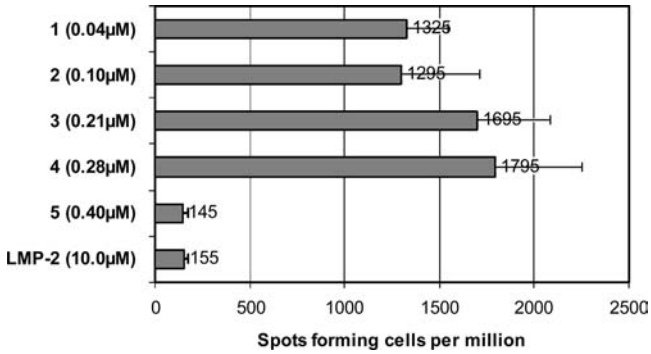

Figure 4. ELIspot results depicting the INF-γ release from the PBMCs of a HLA-A11 donor 4 upon stimulation by AuNP−peptide conjugates. Conjugates **1** with SFC of 1325 ± 218 ($P < 0.001$) when compared with the untreated group.

solid phase peptide synthesis. We found that stimulating the PBMCs of donor 1 by antigen **7** (8 μM) produced a sizable INF-γ response (SFC = 237 ± 33, $P = 0.008$ when compared with that of the no peptide control). Yet, this response was only about one-third of that induced by the AuNP−peptide **1** (SFC = 727 ± 198). However, an octavalent derivative **8** (i.e., eight LMP-2 epitopes covalently linked to a lysine core) failed to elicit a comparable INFγ response (SFC = 88 ± 4; data not shown).

The ELIspot results for two other HLA-A11 healthy donors-2 and -3 are given in Supporting Information. Irrespective of the variation among the donors, **1** induced the strongest INF-γ responses in the PBMCs of all the individuals versus other peptides tested herein.

Other AuNP−peptide conjugates with different LMP-2′ content were also tested for the INFγ release; the ELIspot assay was performed by employing a fixed quantity (2 μL) of the working solutions of **1**−**5**. As shown in Figure 4, stimulation of the PBMCs from a healthy A11 donor-4 with **1** (equivalent epitope concentration = 0.04 μM) induced a strong INFγ response (SFC = 1325 ± 218; $P = 0.0005$ compared with that of the no peptide control). Comparable responses were obtained for **2** (0.08 μM), **3** (0.12 μM), and **4** (0.28 μM; equivalent epitope concentrations in the culture medium given in brackets). However, conjugate **5** (equivalent epitope concentration = 0.4 μM *without the CALNN capping peptide*) induced a minimal INFγ response (SFC = 145 ± 27). It is noteworthy that this observed induction is only comparable to that induced by unconjugated LMP-2 peptide (10 μM; SFC = 155 ± 19). These results indicate that the stabilization effect offered by the CALNN capping peptide is essential for the optimal induction of immune response by these AuNP−peptide conjugates.

Dendritic cells (DC) are important for the efficient activation of antigen-specific CTL response, and we therefore examined the uptake of the AuNP−peptide conjugate by human dendritic cells. Immature DCs from a healthy HLA-A11 donor-5 were cocultured with **1** for 24 h. After washing, the stimulated DCs were processed for transmission electron microscopy (TEM) analysis. As shown in Figure 5, the gold nanoparticles can be identified as dark spots in the cell cytoplasm, suggesting that internalization of the antigen into the DCs may enable antigen processing by the MHC class I pathway for CD8+ T lymphocyte priming.

Next, we turned to test the ability of the AuNP−peptide conjugates to induce antigen specific CTL response. The immature dendritic cells derived from the PBMCs of three healthy HLA A11+ donor-6, -7, and -8 were stimulated with either conjugate **1** or other control peptides for 1 h, and were subsequently cocultured with autologous CD8+ T cells (80% purity) and restimulated weekly over 21 days (Scheme 1). The

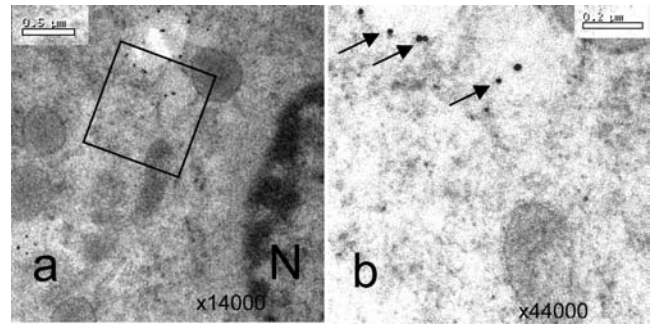

Figure 5. (a) TEM image of a dendritic cell showing the uptake of **1** into the cell (N denotes the nucleus); (b) magnification of the marked area shows **1** indicated by arrows.

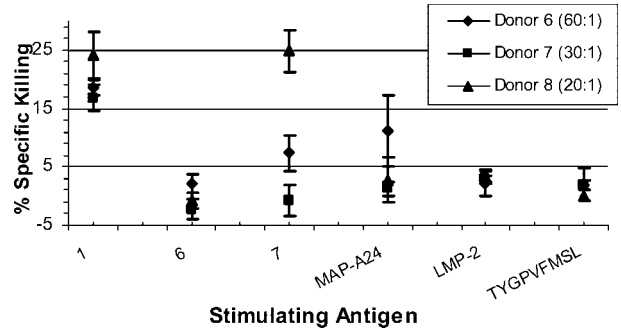

Figure 6. Results of % specific killings by CTLs reactivated from three HLA A11+ donors 6, 7, and 8 with various antigens, in response to autologous PHA blast cells pulsed with LMP-2 (SSCSSCPLSK). HLA mismatched peptide YLSGANLNL as irrelevant peptide. Inset indicates the effector-to-target (E:T) ratio.

cytotoxic CD8+ T-cells were subsequently harvested and tested for their ability to lyse autologous PHA blast cells presenting the EBV LMP-2 epitope SSCSSCPLSK by ^{51}Cr release assay (*41*). PHA blasts pulsed with an irrelevant peptide YLSGANLNL was also included as a nonspecific target for determining antigen-specific CTL killing. The antigen specific CTL killing was determined by the percent cell lysis observed with the LMP-2 target versus the one observed with an irrelevant target.

As depicted in Figure 6, stimulation of the DCs with **1** produced effective CTL responses for all three donor-6, -7, and -8 as manifested by the significant lysis of peptide-specific target cells of 15−25%. In contrast, <5% specific lysis was observed when **6** (the CALNN only-AuNP conjugate) was used as the DC stimulant.

The cytotoxic T-lymphocytes activated with the DCs that had been pulsed with the LMP-2 epitope alone and the HLA-mismatched A24 peptides induced only 2−4% CTL-mediated cell lysis. As noted earlier in the ELIspot assay, MAP **7** could induce some noticeable INFγ response. However, we found that significant CTL-mediated epitope specific cell lysis of 24% was only observed in donor-8; poor lysis results (0−7%) were found for donors-6 and -7.

To conclude, highly immunogenic multivalent EBV antigens can be prepared by conjugation of an EBV LMP-2 epitope onto Au nanoparticles. The AuNP−peptide conjugate is stable in solution and can elicit effective anti-LMP-2 immune response, at least in vitro. AuNP-LMP-2 peptide conjugate, therefore, may play a promising role in the future design of immunotherapy against NPC.

Targeting specific receptors is attracting growing interest in the fields of drug delivery and gene therapy for cancer treatment. The urokinase plasminogen activator receptor (uPAR) is overexpressed on many tumors, particularly that of prostate and breast cancers. The aim of this study is to design, prepare, and characterize a synthetic self-assembled nanoparticle that presents targeting ligands at a certain conformation and molar ratio on the surface of the particles. Here, we describe the synthesis of a novel uPAR targeting ligand consisting of an 11-amino-acid sequence named U11 peptide modified with an alkyl chain to form an U11 peptide−lipid amphiphile. This peptide−lipid is inserted into the outer layer of a parent stealth liposome by post-modification to derive a U11 peptide-targeted nanoparticle. We demonstrate that the peptide moieties become separated into more singular conformations as they are inserted into a liposome membrane, rendering them to be sufficiently biologically active to observe specific receptor-mediated endocytosis (RME) and delivery of plasmid DNA to uPAR positive cells (DU145 cells). The U11 peptide targeted nanoparticle transfection of DU145 cells is essentially 10-fold higher compared to transfection achieved by nanoparticles having a scrambled peptide sequence on their surface. U11 peptide targeted nanoparticles also proved to be uPAR-specific, as they did not improve transfection levels on the uPAR-negative cell line, HEK293.

INTRODUCTION

The urokinase plasminogen activator receptor (uPAR) is overexpressed on a variety of cancer cells, such as those of the prostate and the breast (*1*−*3*). As it is the receptor's natural ligand, the urokinase plasminogen activator (uPA) interacts with the cognate receptor, uPAR, to form a uPAR-uPA conjugate that enters cells by clathrin-coated, receptor-mediated endocytosis (*4*). The uPAR-uPA conjugate is subsequently involved in stimulating various cellular activities such as extracellular matrix invasion (*5*, *6*), plasminogen activation (*7*), cell adhesion, and metastasis (*8*, *9*). The uPA ligand is known to be a composite structure of three independent regions: an amino-terminal growth factor domain (termed ATF or GFD; growth factor domain), a kringle domain, and a carboxy-terminal domain, the region in which uPA exhibits catalytic properties (*10*, *11*). Crystallographic studies of the uPAR-uPA conjugate have revealed that the binding region of uPA for uPAR is localized at the tip of a β-hairpin loop within the GFD (*12*), representing amino acid residues 12−32 (*10*, *13*). Within this tip are two looped structures, one comprising seven amino acid residues (U7) and one of eleven amino acid residues (U11) (Table 1). The second loop, U11, appears to be the primary uPAR binding motif within the uPA binding tip (*14*, *15*). Previous studies from our laboratory have determined that the interaction of U11 peptide with uPAR is characterized by an equilibrium dissociation constant, K_d, of 1.3−1.4 μM (*16*).

Table 1. Amino Acid Sequences of Binding Epitopes within uPA with Specificity for uPAR[a]

	peptide sequence
residue 11−32 in EGF domain	CDCLNGGTC-VSNKYFSNIHWCNC
U7	DCLNGGT
U11	VSNKYFSNIHW
scrambled	ISKSVYNFWNH

[a] U7 and U11 indicate specific fragments within the binding region that exhibit high receptor affinity as synthetic peptides (*15*).

Considering the binding affinity along with and the RME properties of the uPAR-uPA complex, our expectation has been that the uPAR-uPA receptor−ligand system could hold potential for the targeting of synthetic nanoparticles, bearing therapeutic nucleic acids to either prostate or breast cancer.

Previously, uPAR-targeting has been used in gene delivery experiments making use of whole GDF fragments (*17*). In comparison with the use of antibodies, proteins, or protein fragments as receptor-targeting moieties, peptide-based ligands hold several advantages for receptor-mediated targeting such as increased organizational control plus the opportunity to exclude undesirable natural biological activities (*18*). A number of peptide-based ligands for targeted delivery are already described in the literature, the most prominent examples being the use of $\alpha_v\beta_{3/5}$ integrin receptor-targeting RGD family peptides (*19*, *20*). Other examples include $\alpha_9\beta_1$ integrin receptor-targeting peptide sequences (*21*) and the ApoE peptide that targets the LDL receptor (*22*). uPAR-specific peptides have also been used for viral vector retargeting and site-specific molecular imaging (*23*, *24*).

Here, we describe the synthesis of a simple U11 peptide−lipid amphiphile and the formulation of that peptide−lipid into nanoparticles using our laboratory's nomenclature and coding of each functional component. The "ABCD nanoparticle"

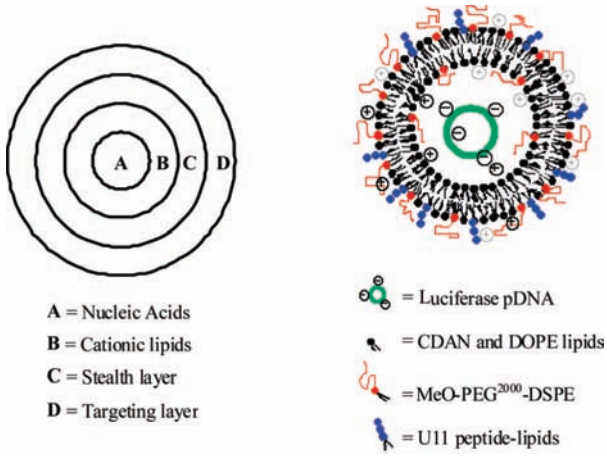

Figure 1. Structure of the synthetic self-assembly ABCD-type nanoparticle paradigm for nonviral vector mediated nucleic acid delivery. (Left) ABCD nanoparticles are assembled from tool kits of purpose-designed chemical components. They comprise the following concentric layers: A, nucleic acids (siRNA, miRNA, pDNA); B, lipid envelope layer; C, stealth/biocompatibility polymer layer; and D, biological recognition ligand layer. (Right) Representation of the actual pDNA-ABCD nanoparticle system formulated as part of the reported investigations here.

paradigm has been used to define multicomponent nanoparticles designed to substantially mediate nucleic acid delivery (Figure 1) (*25*). ABCD nanoparticles comprise a therapeutic nucleic acid such as pDNA (A-component) condensed into AB core particles by means of cationic and fusogenic lipids (B-component), which are then coated by post-modification or postcoupling procedures with variable amounts of a stealth polymer (such as poly-(ethylene glycol), lipid−PEG amphiphiles) (C-component) to provide stability in biological fluids. Ligands (D-component) may be similarly introduced sequentially for receptor targeting. Here, we prepare a number of nanoparticles based on ABCD systems, to identify and promote the targeting potential of such nanoparticles when decorated with U11 peptide−lipid amphiphile. The molar ratio of peptide−lipid in the nanoparticle is investigated with respect to their size and transfection efficiency. Nanoparticles are tested on uPAR overexpressing DU145 prostate cancer cells and on negative uPAR HEK293 (embryonic kidney) cell line as control.

MATERIAL AND METHODS

Chemical. 1,2-Dioleoyl-3-*sn*-phosphatidylethanolamine (DOPE), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(Lissamine Rhodamine B sulfonyl) (DOPE-Rho) and *N*-[methoxy(poly-(ethylene glycol)-2000)]-1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine (MeO-PEG^{2000}-DSPE), and *N*-cholesteryloxycarbonyl-3,7-diazanonane-1,9-diamine (CDAN) were purchased from Avanti Polar Lipids (Alabaster, AL). 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC), and cholesterol lipids were obtained from Sigma and Aldrich (UK). 4-(4-Formyl-3-methoxyphenoxy)butyryl AM (FMPB AM) resin, *O*-(benzotriazol-1-yl)-*N*,*N*,*N*',*N*'-tetramethyluronium (HBTU), hydroxybenzotriazole (HOBt), and all *N*-protected fluorenyl methyloxycarbonyl (Fmoc)-amino acids were purchased from Novabiochem (Nottingham, UK). *N*,*N*-Diisopropylethylamine (DIPEA), trifluoroacetic acid (TFA), triisopropylsilane (TIPS), and piperidine were obtained from Sigma-Aldrich (Poole, UK). Dimethylformamide (DMF) and acetonitrile were purchased from Rathburn (Walker-Burn, Scotland). Centrifugal filter device was obtained from Millipore UK.

Biological. DU145 and HEK293 cell lines were obtained from the ECACC (European Collection of Cell Culture, Wiltshire, UK). Dulbecco's Modified Eagle Media (DMEM), Optimem, fetal calf serum (FCS), penicillin and streptomycin, phosphate-buffered saline (PBS) and trypsin−EDTA were purchased from Gibco (Invitrogen, Netherlands). Luciferase reporter gene assay kit and reporter lysis buffer 5× were obtained from Promega (Southampton, UK), and BCA total protein content assay was purchased from Pierce (Rockford, USA). Urokinase plasminogen activator (uPA) was obtained from American Diagnostica (CT, USA). All plasticware, including falcon tubes and tissue culture flasks, was obtained from Falcon (Becton Dickinson, UK). 4′,6′-Diamidino-2-phenyindole, dilactate (DAPI) nuclear staining was purchased from Sigma-Aldrich (Poole, UK).

Synthesis of U11 Peptide−Lipids. FMPB AM resin (250 mg, 0.74 mmol/g loading) was combined with hexadecylamine (447 mg, 1.85 mmol, 10 equiv) and dissolved in DMF (50 mL). Acetic acid (105 μL, 1.85 mmol, 10 equiv) was then added to the flask followed by $NaCNBH_3$ (116 mg, 1.85 mmol, 10 equiv), and the reaction was stirred at 80 °C for 3 h under reflux. The resin was then transferred into a filtered reaction vessel and washed with CH_2Cl_2, MeOH, CH_2Cl_2, DMF, and CH_2Cl_2 three times in the respective order. Using a few beads from the reaction, the presence of a secondary amine was confirmed by the chloranil test (*26*). The U11 peptide sequence was extended by standard Fmoc-coupling strategy. All Fmoc-amino acids were activated with HOBt and HBTU (3 equiv) for 45 min per coupling and the Fmoc group removed at each step using 20% piperidine in DMF. The terminal amine was capped with Ac_2O and DIPEA (3 equiv) for 45 min before cleavage off the resin using 10 mL of 95:2.5:2.5 TFA/TIS/H_2O cocktail for 5 h. The solution was filtered, and the TFA mixture was precipitated in cold ether. The precipitate was collected by filtration, followed by resolvation in H_2O, and lyophilized overnight. Purification of peptide−lipids was carried out on a Gilson semipreparative HPLC system at a flow rate of 10 mL/min, using a Vydac C_4 protein column, with a gradient of 10% to 90% acetonitrile (20 min). ES mass spectroscopy of purified peptide−lipids was $[M + H]^+$, 1774.

Formulations of Nanoparticles. The following lipids CDAN, DOPE, and MeO-PEG^{2000}-DSPE were dissolved in chloroform at 5 mg mL^{-1}, 5 mg mL^{-1}, and 1 mg mL^{-1}, respectively. Appropriate aliquots were combined in a round-bottom flask (5 mL) and the solvent evaporated to dryness in vacuo to form a thin lipid film on the walls of the flask. For nonstealth, core AB nanoparticles, CDAN and DOPE lipids were combined in a 1:1 (m/m) ratio. For PEGylated nanoparticles (ABC), CDAN, DOPE, and MeO-PEG^{2000}-DSPE lipids were combined in a $(50 - x/50 - x/2x$ m/m/m ratio where x was between 0.25 and 2.5, as required). The flask was further purged with argon gas to remove final traces of organic solvent, then hydrated with double-distilled H_2O (ddH_2O) to give a lipid dispersion, which was then subjected to sonication for 30 min at 40 °C (final total lipid concentration, 1 mg mL^{-1}). After sonication, resulting cationic liposome solutions were further diluted to 0.5 mg mL^{-1} and pDNA (0.1 mg mL^{-1} in ddH_2O) was then added slowly by pipet under heavy vortex mixing conditions (final lipid/pDNA ratio, 12:1 w/w). To prepare targeted nanoparticles (ABCD), U11 peptide−lipid (or scrambled peptide−lipid) was dissolved (1 mg mL^{-1} in 20% EtOH in H_2O) and an appropriate aliquot (containing 1−5 mol % of peptide−lipid as required) was added to formulations of PEGylated (ABC) or non-PEGylated (AB) nanoparticle suspension (with different mol % of MeO-PEG^{2000}-DSPE), and the mixture was then incubated for 1 h at 37 °C. Excess peptide−lipids left uninserted into nanoparticles were removed by a centrifugal filtration (MWCO = 30 kDa) and centrifuged at 8000 *g* for 6 min before the redilution of the filtrate (containing nanoparticles) with ddH_2O, and the supernatant was analyzed. The amount of uninserted peptide−lipid

in the supernatant was determined by measuring the intrinsic amino acid fluorescence (excitation wavelength: I_{ex} 298 nm; emission maximum: I_{max} 349nm) and extrapolated against a concentration-dependent calibration curve. Components of all purified nanoparticles were characterized by the following methods: Analytical HPLC (0% to 100% acetonitrile in 20 mins, flow rate 1 mL/min) was used to determine the amount of CDAN lipids within the purified formulation, the Stewart assay for the determination of the amount of DOPE lipids (*27*) and UV−visible spectroscopy for the analysis of encapsulated DNA, using an $A^{0.1}{}_{260}$ value of 30.

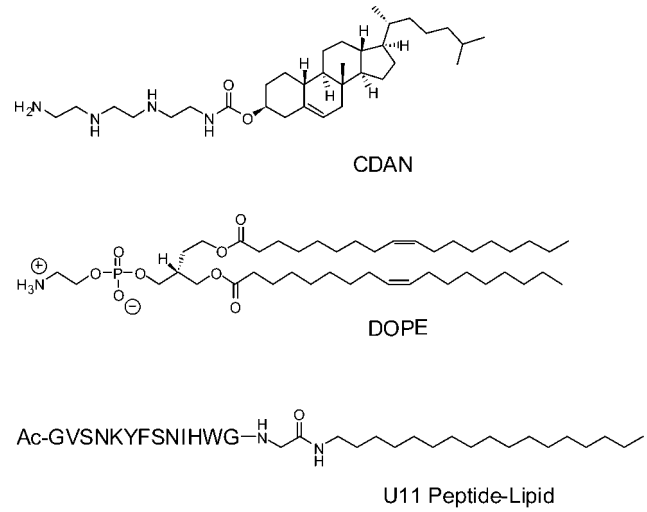
Growth and Maintenance of Cells. DU145 and HEK293 cells were maintained in DMEM supplemented with 10% FCS (v/v) and 1% penicillin and streptomycin (DMEM +/+) in T-25 tissue culture flasks. On confluency, media was removed by aspiration and washed with 5 mL PBS. Cells were then detached from the flask by addition of 1.5 mL of trypsin−EDTA and incubated for 10 min at 37 °C and 10% CO_2. After detachment, cells were diluted with 5 mL DMEM +/+ and centrifuged to removed trypsin solution. Cells were resuspended in 5 mL DMEM +/+, diluted 1:10 with more DMEM +/+, of which 5 mL of diluted cells were placed in a new T-25 culture flask. DU145 cells were used up to a passage number of 30, after which they were discarded and a new batch defrosted.

In Vitro Transfections. uPAR-overexpressing human prostate cancer cell line (DU145) was cultured with DMEM +/+ at 37 °C and 5% CO_2. Cells were seeded at 4×10^4 cells/well in 24 well plates (0.5 mL volume per well) and incubated for 80 h (70% confluency) before experiments. For transfections, growth media was removed from wells by aspiration and replaced with 0.5 mL of Optimem-containing delivery systems that allowed 1 μg pDNA per well. Transfections were carried out for 3 h before transfection media was removed by aspiration and replaced with DMEM +/+ for further cell growth. After further incubation at 37 °C for 48 h, cells were lysed with 80 μL of 1× reporter lysis buffer per well. One cycle of freeze−thaw was carried out before cells were scraped from wells and centrifuged at 8000 *g* for 2 min to separate cellular debris. Supernatants were analyzed for luciferase transgene expression and normalized with the BCA total protein content kit.

Characterization of Nanoparticles. Nanoparticle sizes were measured by photon light scattering on a Coulter Delta N4 PCS plus 440SX photon correlation spectrometer (PCS). After assembly, all nanoparticles were diluted to 0.1 mg mL^{-1} in ddH_2O, a concentration allowing the count rate to stabilize between 4 and 6×10^4 counts per second. The calculated unimodal distribution was used as the determinant for average diameter size. For aggregation studies, the nanoparticles were diluted in the same volume of Optimem used in preparation of transfection cocktail. The diluted nanoparticles were then incubated at 37 °C and average particle diameter analyzed at the time points of 0, 30, 60, 90, and 120 min post-formulation. For aggregation studies in serum, nanoparticle solutions were diluted in fetal calf serum instead of Optimem. The diameter errors were taken as the standard deviations calculated by dynamic light scattering.

Secondary Structure Determination. Circular dichroism experiments were conducted using the Jasco J-715 spectropolarimeter equipped with Jasco PCT-348WI thermostat device. Targeted nanoparticles were prepared as before, by incubation of either 1 or 5 mol % U11 peptide−lipids with naked nanoparticles formulated with 0.5 mol % of MeO-PEG^{2000}-DSPE, at a lipid concentration of 1 mg/mL. A 0.1 mm path length cell was used to record spectra, values of ΔA were collected from 250 to 190 nm at an elevated temperature of 37 °C. A scan rate of 10 nm/min and a step resolution of 0.2 nm were used throughout.

Scheme 1. Structures of Main Lipids Used in Formulation: Cationic Lipid CDAN, Fusogenic Lipid DOPE, and Targeting Lipid U11 Peptide−Lipid



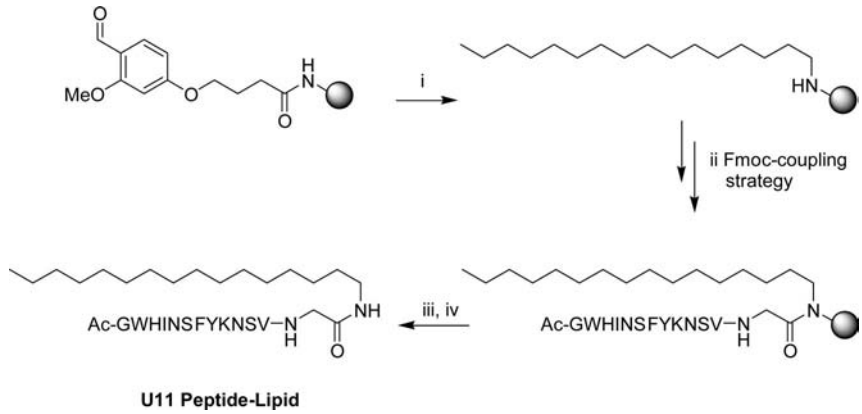
Fluorescence Imaging. Six-well plates were loaded with presterilized circular coverslips (thickness 1 mm) and cells seeded on top at a density of 6×10^4 cells/well. After incubation at 37 °C and 5% CO_2 for 80 h (70% confluency), growth media was removed from wells and replaced with an aliquot of nanoparticles (50 μg) in Optimem. Nanoparticles were incubated with cells for 1 or 2 h, before removal by aspiration; thereafter, coverslips were washed twice with PBS. Coverslips were then treated with paraformaldehyde per well (1 mL, 4%v/v) and incubated at 37 °C for 20 min, followed by another PBS wash (×2) and further incubation with 1 mL glycine solution (20 mg mL^{-1}). Cells were stained with 1 mL DAPI solution (100 nM) for 5 min at 37 °C, and after one last PBS wash, mounted face-down onto a microscopy slide with 1 drop of PBS/glycerol (1:1, v/v). Images were taken on an Olympus 251 scope.

Competitive Binding of Targeted Nanoparticles in the Presence of uPA. DU145 cells were seeded in 6-well plates and incubated for 80 h before 70% confluency was achieved. Cells were washed twice with cold PBS followed by incubation at 4 °C with glycine/NaCl (0.05 M/0.1 M, pH 3) for 5 min. After incubation, HEPES/NaCl (0.5 M/0.1 M, pH 7.5) was added to the wells before removal of all solution and washing with PBS. Optimem-containing 0 or 40 nM uPA was applied to the cells and incubated at 4 °C for 30 min. Rhodamine-labeled pDNA-encapsulated nanoparticles (ABCD; with U11- or scramble peptide) were then spiked into the cell medium to form concentrations of 25 μg lipids/well. The cells were then incubated for a further 30 min at 4 °C before removal of media and washing with PBS twice. After final washing, 1 mL of PBS (2% FCS) was added to each well, and the cells were detached from the wells. The cell-associated fluorescence per well was then analyzed by flow cytometry using a Becton Dickinson FACS 4 Color Caliber.

RESULTS

Synthesis of U11 and Control Peptide−Lipids. After synthesis on solid phase, the crude U11 peptide−lipid was then purified to homogeneity (>95%) by high-performance liquid chromatography (HPLC). The identity of the U11 peptide−lipid (Scheme 2, Table 1) was confirmed by electrospray mass spectrometry ($[M + H]^+$, 1774.0). The scrambled (control, Table 1) peptide-lipid was prepared in an equivalent manner, retaining the U11 amino acid residue composition, but with a reordered sequence.

Scheme 2. - Synthesis of U11 Peptide−Lipid on Solid Phase[a]



[a] (i) $C_{16}H_{33}-NH_2$, HOAc, $NaCNBH_3$, 80 °C, 3 h. (ii) (a) Extension of peptide chain using standard Fmoc-protocol with 3 equiv Fmoc-amino acid, HBTU (3 equiv), HOBt (3 equiv) in DMF, 1 h RT per coupling. (iii) Ac_2O, DiPEA in DMF, 1 h. (iv) 95/2.5/2.5 TFA/TIS/H_2O, 5 h RT.

Formulation of Nanoparticles. Nontargeted and targeted nanoparticles were prepared using the pDNA construct pEGFP-Luc (SV40 promoter) expressing the luciferase gene (*luc*). Cationic lipid (CDAN), neutral fusogenic lipid (DOPE), MeO-PEG^{2000}-DSPE, and synthetic U11 peptide−lipid (or control peptide−lipid) were added.

The CDAN/DOPE (1:1, m/m) cationic liposomes (Scheme 1) were chosen for their capacity to mediate high levels of transfections without cellular toxicity (*28*). Targeted, non-PEGylated nanoparticles were prepared by the method of post-modification, involving the incubation (at 37 °C, 1 h) of standard nanoparticles with an appropriate mol % (typically 1 or 5 mol %) of synthetic U11 peptide−lipid (or scrambled peptide−lipid as required). This procedure allowed the insertion of the lipid moieties of peptide−lipids into the outer leaflet membrane of the AB core nanoparticles in order to create targeted nanoparticles (*29*). Removal of excess, noninserted peptide−lipids was carried out by centrifugal filtration (MWCO = 30 kDa, Microcon Millipore), and gratifyingly, a very high level of peptide−lipid insertion (>90%) was observed using fluorescence analysis of the filtrate. Accordingly, no further nanoparticle purification steps were considered necessary. These purified particles were characterized by HPLC and Stewart assay to verify that CDAN and DOPE compositions, respectively, were unaltered (comparable to initial molar ratios) by the centrifugation process. Peptide−lipid content was confirmed by fluorescence spectroscopy (excitation wavelength, I_{ex} 298 nm; emission maximum, I_{max} 349 nm) and pDNA content was quantified by UV−visible spectroscopy (using $A^{0.1}{}_{260}$ value of 30).

PEGylated nanoparticles (ABC) were formulated along similar lines by the addition of pDNA to CDAN/DOPE/MeO-PEG^{2000}-DSPE ($50 - x/50 - x/2x$, m/m/m; x is 0.25 to 2.5) cationic liposomes (prepared as before) with rapid vortex mixing (final lipid/pDNA ratio 12:1, w/w, final pDNA concentration 0.1 mg mL^{-1}). Selected stealth nanoparticle systems were then incubated (at 37 °C, 1 h) with the appropriate mol % (typically 1 or 5 mol %) of synthetic U11 peptide−lipid (or scramble control peptide−lipid as required). Once again, this procedure allowed for the post-modification of these nanoparticle systems with peptide−lipids and the formation of ABCD-type nanoparticles (*25, 29*). Excess peptide−lipid was removed once again by centrifugal filtration and the composition of purified nanoparticles confirmed as described above.

Secondary Structure of U11 in Nanoparticles. Circular dichroism (CD) spectroscopy has been used widely to characterize protein or peptide secondary structures and their conformational changes (*30*). Ligand conformation on the surface of the nanoparticle is important as this affects the binding interactions.

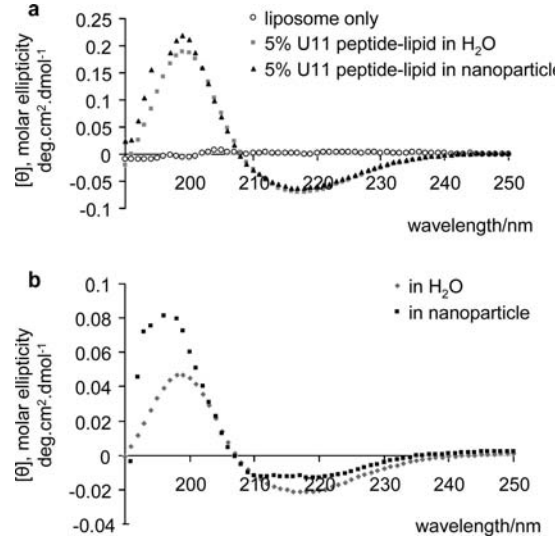


Figure 2. Circular dichroism spectra of U11 peptide−lipids alone and when incorporated on the surface of optimized nanoparticles (CDAN/DOPE/MeO-PEG^{2000}-DSPE 49.75:49.75:0.5, m/m/m) (BC system). (a) Peptide−lipids incorporated at 5 mol % on nanoparticles (▲) and in H_2O at equivalent concentration (grayscale ■); the spectra of liposomes without peptide−lipids are shown for comparison (○). (b) Peptide−lipids incorporated at 1 mol % on nanoparticles (■) and in H_2O at equivalent concentrations (♦). Negative maximum at ΔA_{216} indicates the presence of β-sheet aggregates.

Using CD spectroscopy, we report the change in organization of U11 peptide−lipids as they are inserted into CDAN/DOPE/MeO-PEG^{2000}-DSPE (49.75/49.75/0.5, m/m/m) PEGylated cationic liposomes (Figure 2a,b). CD spectra of the U11 peptide−lipids (1 or 5 mol %) were recorded before and immediately after incubation with nanoparticles (without pDNA) and compared with that recorded for U11 peptide−lipids incubated in H_2O only. Incubation of 1 and 5 mol % peptide−lipids in H_2O alone gave rise to spectra with significant negative maxima at ΔA_{216}, indicating the formation of β-sheet aggregates between the peptide bonds of the peptide−lipid molecules. The same spectral pattern was observed on the insertion of 5 mol % peptide−lipids into liposomal solutions, suggesting that incorporation of high concentrations of peptide−lipids into liposomes still results in β-sheet aggregation, this time most likely on the liposome surface (Figure 2a). Insertion of U11 peptide−lipid at a lower percentage, however, generated a spectrum with fewer characteristics of β-sheet formation, indicating the disruption of the β-sheet aggregates as the peptide−lipids are inserted into the liposomal layer (Figure 2b).

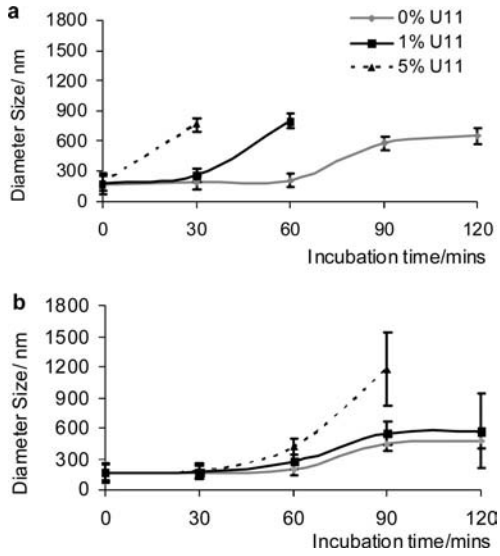

Figure 3. Effect of insertion of 0%, 1%, or 5% U11 peptide−lipid on the sizes of non-PEGylated nanoparticles (comprising CDAN/DOPE 1:1, m/m, and pDNA, lipid/pDNA ratio 12:1, w/w) incubated in (a) Optimem and in (b) 50% FCS over 120 min at 37 °C, as measured by PCS. Non-PEGylated nanoparticles with indicated mol % of U11 peptide−lipid have greater inclination for aggregation in transfection media, especially systems with high peptide−lipid loading. Diameter errors are plotted as the standard deviation calculated by PCS.

The reduction of β-sheet character on liposomal insertion could indicate the reorganization of the peptide−lipid aggregates into more separated chains when incorporated into the surface of the targeted nanoparticles.

Optimizing Mol % of U11 Peptide−Lipid. Core AB nanoparticles (non-PEGylated) and two targeted nanoparticle systems (comprising 1 or 5 mol % of U11 peptide−lipid) were incubated in transfection media or in 50% fetal calf serum (to mimic in vivo circulation conditions), and particle size was observed as a function of time. Nanoparticles with surface-inserted peptide−lipids were clearly less resistant to aggregation, although higher mole percentages of peptide−lipids lead to greater tendencies toward aggregation (Figure 3a,b). These data are consistent with a mechanism of aggregation promoted by hydrophobic and β-sheet-forming interactions between surface peptide ligands of U11-decorated nanoparticles. It appeared that colloidal stability of such systems was also poor for transfection and uPAR-mediated targeting studies. Using a plasmid-based reporter gene assay, transfection studies were performed with targeted nanoparticles, where U11-decorated nanoparticle transfections were found to be much less effective than corresponding lipid/pDNA nanoparticle transfections, thereby linking the detrimental effects of nanoparticle overaggregation with poor transfection efficiency (data not shown). Accordingly, we decided that non-PEGylated nanoparticles were not suitable for further transfection and that only stable nanoparticles should be used for uPAR-mediated targeting studies.

Optimizing Mol % of MeO-PEG^{2000}-DSPE in ABCD Nanoparticles. A general method for alleviating propensity toward aggregation of nanoparticles is by introducing poly(ethylene glycol) (PEG) units onto the surface of such nanoparticles. Nanoparticles were prepared with 1 mol % of U11 peptide−lipid in each case, plus 1−5 mol % of MeO-PEG^{2000}-DSPE. By increasing the percentage of MeO-PEG^{2000}-DSPE from 1 mol % to 5 mol %, nanoparticle stability was indeed observed in transfection media over time. However, transfection experiments on the DU145 cell (uPAR positive cell line) indicated no substantial difference in transfection levels achieved by PEGylated-targeted nanoparticles and corresponding nontargeted

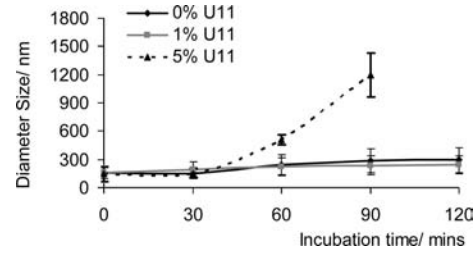

Figure 4. Effect of inclusion of U11 peptide−lipid (mol % as indicated) on PEGylated nanoparticle size with time. PEGylated, nontargeted nanoparticle (comprising CDAN/DOPE 1:1, m/m, and pDNA, lipid/pDNA ratio 12:1, w/w, MeO-PEG^{2000}-DSPE, 0.5 mol %; ABC) or targeted nanoparticles (1 or 5 mol % U11 peptide−lipid, ABCD). Nanoparticles were incubated in Optimem over 120 min at 37 °C, as measured by PCS. Both nontargeted and targeted (with 1 mol % U11 peptide−lipid) nanoparticles were both stable in transfection media, where the diameter was maintained under 250 nm throughout incubation time. However, higher loading with 5 mol % peptide−lipid was still prone to aggregation. Diameter errors are plotted as the standard deviation calculated by PCS.

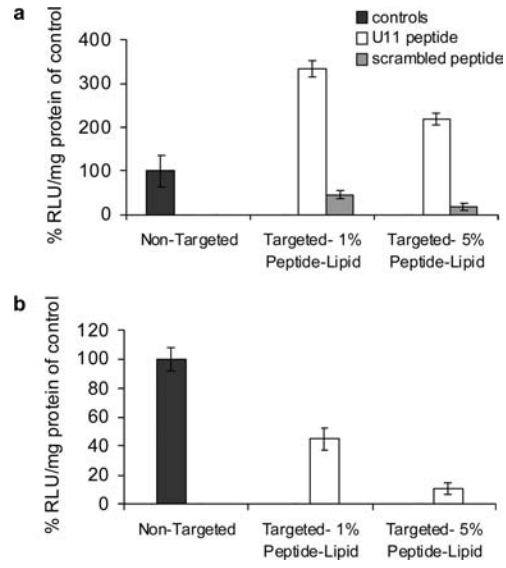

Figure 5. Luciferase transfection on uPAR-positive DU145 (a) and uPAR-negative HEK293 cell lines (b) with nanoparticles (nontargeted, comprising CDAN/DOPE 1:1, m/m, and pDNA, lipid/pDNA ratio 12:1, w/w, MeO-PEG^{2000}-DSPE, 0.5 mol %; ABC) or targeted nanoparticles (with 1 or 5 mol % of U11 peptide−lipid or nonspecific scrambled peptide−lipid; ABCD). Transfection data normalized on the value of nontargeted nanoparticle transfections. Transfection times for cells were 3 h in Optimem after which cells were incubated for 48 h before lysis and analysis for luciferase activity.

nanoparticles (data not shown). The inclusion of even only 1 mol % of MeO-PEG^{2000}-DSPE appeared to render nonfunctionality of targeted nanoparticles, presumably due to steric blocking of surface-attached U11 peptide−lipids by neighboring PEG chains. Nanoparticles stabilized with 0.5 mol % of MeO-PEG^{2000}-DSPE (ABCD), however, were shown to resist aggregation in transfection media (Figure 4), and their transfections were clearly enhanced over corresponding nontargeted nanoparticle-mediated transfections (Figure 5a) on DU145 cells.

U11 Peptide Enhanced Transfection. U11 decorated ABCD nanoparticles were formulated with 0.5 mol % of MeO-PEG^{2000}-DSPE and either 1 or 5 mol % of peptide−lipid (U11 sequence or scrambled control). uPAR is a common trait found in all cancers, where levels of its expression depend on the cell type (*31*). Transfections were performed in two cell lines, namely, uPAR positive cells (DU145) and uPAR negative cells (noncancerous HEK293 human embryonic kidney cell line) (*32*).

ABCD nanoparticles presenting 1 mol % U11 peptide ligand mediated the highest levels of DU145 transfection, nearly 3.5-fold higher than that by nontargeted nanoparticles (Figure 5a). Nanoparticles presenting 5 mol % U11 peptide−ligand mediated approximately half the levels of DU145 transfection compared to 1 mol % nanoparticles. In comparison, the highest level of HEK293 cell transfection was mediated by nontargeted nanoparticles. On these uPAR-negative cells, ABCD targeted nanoparticles presenting 1 mol % U11 peptide ligand mediated transfection levels that were about 50% of the control nanoparticle transfection level, while targeted nanoparticles presenting 5 mol % of U11 peptide−ligand mediated very poor transfection (Figure 5b). On uPAR-negative cell lines, the U11 peptide sequence becomes nonspecific for membrane receptors, hence functioning instead as a steric shield of the surface positive charges. In addition, as with the use of PEGylated lipids, inclusion of nonspecific polymer chains into the surface of nanoparticles results in their impaired cell uptake and transfection efficiency (*33*). There is a clear impression with reference to the nontargeted nanoparticle transfections that DU145 transfection mediated by nanoparticles presenting 1 mol % of U11 scrambled peptide is on par with HEK293 transfection mediated by nanoparticles presenting 1 mol % of U11 peptide ligand. Therefore, there appears to be a clear U11 peptide ligand mediated enhancement of approximately one log in ABCD-type nanoparticle transfection of uPAR positive cells (DU145) compared with key controls, namely, the transfection of uPAR positive cells by nanoparticles presenting 1 mol % of U11 scramble peptide, and the transfection of uPAR negative cells (HEK293) using nanoparticles presenting 1 mol % of U11 ligand.

For fluorescence microscopy, 1 mol % of the fluorescent probe lipid DOPE-Rhodamine (DOPE-Rho) was included into the optimized targeted and nontargeted nanoparticles. After introduction to DU145 cells, cell-associated rhodamine fluorescence was examined at 1 and 2 h post-administration (Figure 6). We observed that fluorescence intensity was much greater in cells treated with ABCD targeted nanoparticles as compared with control ABC nanoparticles, again another indication of receptor-targeted delivery by uPAR-U11 recognition. Although the images obtained do not allow us to attribute the increased fluorescence intensity solely to cell internalization, we can confidently conclude that the targeted ABCD nanoparticles are nevertheless binding more efficiently to the cell membrane than the nontargeted nanoparticles.

Competitive Binding of Targeted Nanoparticles in the Presence of uPA. Following analysis by fluorescence microscopy, flow cytometery was used to assess the uptake of rhodamine-labeled targeted nanoparticles by DU145 cells (Figure 6e). Cell-associated fluorescence generated by binding of scramble peptide−nanoparticles was 15% lower than that of U11-nanoparticles, indicating a decreased amount of binding due to the nonspecificity of the scrambled peptide sequence. The binding of such targeted nanoparticles was challenged by preincubation of the DU145 cells with a high concentration of uPA, to competitively block the uPAR receptors before administration of the nanoparticles. The binding study was performed at 4 °C to minimize receptor-mediated endocytosis. Using free uPA to block uPAR, the receptor to which U11 peptides are specific, binding of U11-nanoparticles was inhibited by 15%, whereas the binding by scramble peptide−nanoparticles was not affected. These data again emphasize the selectivity of U11-nanoparticles for uPAR, but also indicate the high level of background or nonspecific interactions between the nanoparticles and cell membranes.

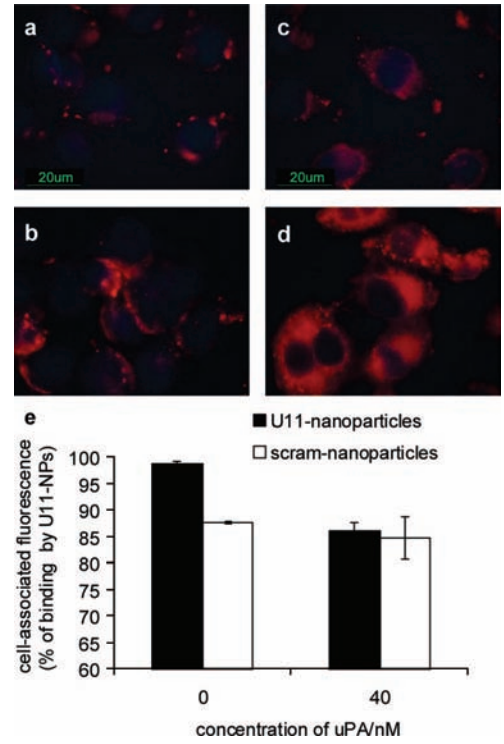

Figure 6. Uptake and binding of rhodamine-labeled optimized nanoparticles. For fluorescence microscopy, DU145 cells were incubated with nontargeted, ABC (a,b) and targeted ABCD nanoparticles (1 mol % U11) for 1 h (a,c) and 2 h (b,d) before fixing and visualizing. Images were overlaid with DAPI-nuclear staining. At 1 h, the cell-associated fluorescence appears similar in cells treated with targeted (c) and nontargeted nanoparticles (a). The difference in fluorescence is more apparent at 2 h, where cells treated with uPAR-targeted nanoparticles (d) show increased internal rhodamine intensity, compared to corresponding control nontargeted nanoparticles (b), an indication of either increased membrane binding or cellular internalization. Competitive binding of rhodamine-labeled nanoparticles with free uPA, assessed by flow cytometry (e), shows the lower cell binding by scramble peptide decorated nanoparticles, and demonstrates U11 specificity for uPAR by reduced cell binding of U11 nanoparticles after blocking of uPAR receptors with 40uM uPA.

DISCUSSION

The main objective of this study was to identify the potential of U11 grafting on the surface of nanoparticles for optimum uPAR binding and cell targeting. Here, the method of post-modification was chosen for the incorporation of peptide−lipids onto the surfaces of nanoparticles (*29*, *34*). In order to implement this strategy, a U11 peptide−lipid was prepared using an aldehyde-modified resin (FMPB resin) for the attachment of a hexadecylamine chain to the U11 peptide moiety by a reductive amination procedure (Scheme 2) (*35*, *36*). Initially, 1 or 5 mol % of the U11 peptide−lipid was inserted into nanoparticles lacking a stealth/biocompatibility polymer. The most striking aspect of the physicochemical behavior of these nanoparticles was their propensity to aggregate through nonspecific peptide−peptide interactions. (Figure 3a,b). Nanoparticles without PEGylation exhibited immediate aggregation in transfection media, where diameters of over >500 nm were recorded after 30−60 min incubation at 37 °C, a more than adequate demonstration of the need for a stealth polymer such as PEG. However, the overloading of such a sterically hindering polymer−lipid can have deleterious effects on the targeting ability of the nanoparticle, caused by shielding of the targeting peptides by the

polymer chains. The difficulty therefore lies within striking a balance between the molar percentages of the stealth lipid and the targeting peptide−lipid.

In this study, we also investigated the properties of the assembled nanoparticles and the organization of peptide targeting ligands on their surface. This poses as the first stage of development of nanoparticles for uPAR targeting and prostate cancer drug/gene therapies. For cancer targeting, nanoparticles require a diameter less than 200 nm to bypass the fenestration found in leaky tumor vasculature and between the tumor endothelium (*37, 38*). Accordingly, in the preparation of ABCD-type nanoparticles, the amount of stealth/biocompatible polymer (C-component) attached to the surface of AB core particles should be sufficient to prevent particle aggregation in all relevant biological fluids, but not so overburdening as to obscure the benefits of including a biological targeting ligand. Long chains of linear PEG units are intended to create a spherical, steric barrier around pDNA/lipid core nanoparticles, reducing the tendency for particle aggregation through the generation of steric repulsion (*39*). The steric effect provided by PEGylation also masks the lipophilic nature of the core AB nanoparticle and provides stealth properties against immune surveillance and serum aggregation, essential for in vivo applications. However, PEG at higher surface densities (>1 mol %) may interfere with the presentation of the ligand, reducing molecular recognition by the cognate receptor. This is in agreement with our transfection results using ABCD nanoparticles formulated with increasing percentages of MeO-PEG^{2000}-DSPE (data not shown). Much of our nanoparticle study described here was designed to find the most appropriate balance between incorporated components for the optimization of both stability and functional delivery of nucleic acids. In this event, this was achieved by including 0.5 mol % of MeO-PEG^{2000}-DSPE and 1 mol % of U11 peptide−lipid (Figures 4 and 5).

Nanoparticle integrity also depends on the balance of surface ligands. Similarly, as we observed, the inclusion of biological targeting ligands at higher surface densities (>1 mol %) can induce nanoparticle aggregation and interligand β-sheet aggregation (Figure 2a), without furnishing any benefits for transfection (Figure 3). Indeed, other reported studies on ligand loading have shown that lower loading rates of RGD peptide−lipid (<1 mol %) on DSPC vesicles did not reduce the binding effects of the ligand, nor was there reduction in the ability of RGD moieties to induce cell adhesions on HUVEC (human umbilicord endothelial) cells (*40*). Concurring with our data, it is believed that the physicochemical properties of the peptide (size, hydrophilicity) lead to particle aggregation on excessive loading.

The incorporation of peptide−lipids into lipid membranes for presentation of peptide ligands has been used widely in the literature (*41*−*45*), although few studies consider the effect of the anchoring procedure on the secondary structure of the ligand (*36, 46*). In our case, we investigated the effect of introducing peptide−lipids at high and lower molar percentages into the outer leaflet membrane of PEGylated cationic liposomes (Figure 2). The CD data clearly indicate that β-sheet, secondary structures are forming when the peptide−lipids are dissolved in aqueous solution (*47, 48*). However, when they are inserted at low concentrations (1 mol %), the same peptide−lipids appear to rearrange into more separated structures, as indicated by the reduction in ΔA_{216} in the CD spectrum. A targeted nanoparticle with surface ligands that are more separated into individual strands is more favorable for receptor binding. This phenomenon is only observed with peptide−lipids at low molar percentages, as the introduction of peptide−lipids into liposomes at 5 mol % showed β-sheet aggregation to the same extent as that observed in aqueous solution alone. This again highlights the advantages of incorporation of peptide−lipids at lower concentrations, where interparticle and intermolecular aggregation is prevented. Nanoparticle transfections using this formulation were clearly superior to all control transfections (including transfections with nanoparticles prepared from scramble control peptide−lipid) (Figure 5a), thereby suggesting that the U11 peptide−lipids were adopting appropriately active conformations to enable functional receptor mediated uptake of nanoparticles where uPAR were presented. Further evidence for receptor-mediated uptake in uPAR positive cells DU145 was obtained by fluorescence microscopy (Figure 6).

Previous work on ABCD nanoparticles in our laboratory had focused on the development of a $\alpha_9\beta_1$-integrin-targeting peptide−lipid for incorporation into nanoparticles in order to induce receptor-mediated uptake into appropriate cell lines followed by efficient transfection (*21*). Inclusion of the peptide−lipid into nanoparticles did indeed result in one log increase in nanoparticle-mediated transfection of a $\alpha_9\beta_1$-overexpressing cell line (in comparison with nanoparticle transfection without peptide−lipid). However, this enhanced transfection was found to be the result of nonspecific enhanced cellular uptake processes, as inclusion of the same ABCD nanoparticles gave the same increase in transfection of a cell line without $\alpha_9\beta_1$-integrin expression (in comparison with nontargeted nanoparticle transfection). Gratifyingly, the studies with U11-nanoparticle-mediated transfection and fluorescence microscopy data (Figures 5 and 6) do indicate the active involvement of receptor-mediated cell uptake processes and U11 ligand specificity for uPAR receptor. Uptake studies in DU145 cells further demonstrate the receptor specificity of the U11 peptide, where the binding of U11-targeted nanoparticles was shown to be reduced when the uPAR receptors are preblocked with high concentrations of free uPA ligand (Figure 6e). Flow cytometry showed that the binding of nanoparticles decorated with scramble peptides was 15% lower than that by U11-targeted nanoparticles, plus its uptake in uPAR-overexpressed cells was not affected by uPAR blocking. However, the maximum reduction in U11-nanoparticle binding by uPAR blocking was 15%, indicating the presence of strong nonspecific interactions that cause the binding of the nanoparticles to the cell membranes.

The challenge of nonspecific cell interactions is also emphasized by the relatively low transfection enhancement (3.5-fold) between transfections mediated by our leading U11-targeted ABCD nanoparticles and the corresponding control nanoparticles (Figure 5a). The reason for this may well lie in the high overall cationic charge of the nanoparticle systems. Zeta potentials were found to be on the order of +112 mV, a consequence of the high lipid/pDNA ratio of 12:1 (w/w) that corresponds to an N/P ratio of 4.25, assuming that each cytofectin CDAN presents a net charge of +1.7 at neutral pH (*49*). Cell membranes are typically anionic, owing in part to negatively charged cell surface proteoglycans, with which cationic nanoparticles may interact in a nonspecific manner to trigger cellular uptake by endocytosis without the requirement for receptor mediation (*50*). Therefore, the discrimination between ABCD and ABC-type nanoparticle mediated transfections should be improved by reducing the overall cationic charge of both nanoparticles. This could be feasible by engineering the lipid scaffold of these nanoparticles using alternative neutral lipids or cytofectins in order to reduce the lipid/pDNA ratio and overall mol % of cytofectin without impairing transfection efficiency and nanoparticle stability with respect to aggregation.

The design of therapeutic nanoparticles must consider both colloidal stability in biological fluids plus the ability to be tissue-specific. The targeting of such nanoparticles to tumor cells involves the use of surface ligands that are recognized and further internalized by the cancer-related receptors. The primary

sequence should already have intrinsic selectivity for its targeted receptor, but also important is the secondary conformation of the ligand, for maximizing receptor affinity. Here, in this study we show that, by tuning the mol % of each lipid component within the nanoparticle system, we can optimize the delivery efficacy of tumor-targeted nanoparticles.

CONCLUSION

In this study, we present for the first time uPAR-targeted nanoparticles for prostate cancer cells and we propose the example of tailormade solutions for different biological challenges. U11 is a peptide derived from the GFD in domain 1 of uPA and is responsible for binding to the receptor due to its epitopal folding. On the basis of this observation, we prepared U11 peptide−lipids that were inserted on the surface of the nanoparticles. It was shown that insertion of 0.5 mol % of PEG lipids induced particle stability and promoted receptor specificity for improved cell uptake and transfection. The U11-targeting strategy proved efficient and specific, where the U11 ABCD-type nanoparticles increased cell uptake and transfection levels in uPAR-expressing cell lines. It is expected that optimized U11-nanoparticles for in vivo administration will show the same specificity to uPAR expressing prostate cancers.

Received May 20, 2008; Revised Manuscript Received November 11, 2008

The conformational dynamics of proteins plays a key role in their complex physiological functions. Fluorescence resonance energy transfer (FRET) is a particular powerful tool for studying protein conformational dynamics, but requires efficient site-specific labeling with fluorescent reporter probes. We have employed different tris-NTA/fluorophore conjugates, which bind histidine-tagged proteins with high affinity, for site-specific incorporation of FRET acceptors into proteins, which were covalently labeled with a donor fluorophore. We demonstrate versatile application of this approach for exploring the conformation of the type I interferon receptor ectodomains ifnar1-EC and ifnar2-EC. Substantial ligand-induced conformational changes of ifnar1-EC, but not ifnar2-EC, were observed by monitoring the fluorescence intensity and the fluorescence lifetime of the FRET donor. Time-resolved fluorescence correlation spectroscopy revealed a substantial conformational flexibility of ifnar1-EC and a ligand-induced tightening. Our results demonstrate that protein labeling with tris-NTA/fluorophores enables for efficient quantitative intramolecular FRET analysis.

INTRODUCTION

Protein−protein recognition frequently imposes conformational changes on the interaction partners. These conformational changes can modulate protein function, which plays a key role in many biological processes, in particular, in biological signaling cascades. Dissecting the conformational dynamics on the level of individual proteins proved particular promising for understanding the molecular basis of binding-induced structural changes (*1*−*4*). Single molecule fluorescence techniques are particularly capable of monitoring conformational dynamics in real time (*5*−*9*). One of the main challenges in this approach, however, is the need to incorporate appropriate fluorescence probes as reporter for conformational changes into the protein. For monitoring distance changes within macromolecules, typically fluorescence resonance energy transfer (FRET) is employed, which requires site-specific dual-color labeling. Covalent coupling of thiol-reactive fluorescence dyes to free cysteines is the most common approach toward site-specific labeling of proteins. For dual-color labeling, however, this approach is not suitable, requiring the separation of different species (*10*). Thus, alternative strategies for site-specific incorporation of a second fluorescence dye into proteins are required. Fusion with fluorescent proteins (*11, 12*) or with other proteins or peptide tags, which can be post-translationally labeled in a selective manner based on biomolecular recognition, is a powerful tool for labeling proteins (*13*−*17*). The size of the proteins involved in labeling and their flexible attachment to the target proteins, however, heavily reduce the distance resolution, which can be probed by intramolecular FRET. Thus, approaches for site-specific fluorescence with small recognition units are particularly promising for studying protein conformations (*17*−*21*).

Recently, we have described multivalent chelator heads (MCH) that recognize oligohistidines with subnanomolar affinity and high specificity (*22*). These chelators have been used for site-specific, quantitative labeling of His-tagged proteins in solution with several different fluorescence probes (*23*). Here, we have employed MCH conjugates (Figure 1a−c) for studying the conformational organization of the extracellular domain of a cytokine receptor and its changes upon ligand binding. The principle is depicted in Figure 1d,e: the proteins were site-specifically labeled with a fluorescence donor through covalent attachment through a free cysteine residue. Using MCH conjugates, a fluorescence acceptor is site-specifically incorporated in situ through a C-terminal decahistidine tag and the conformations can be probed by FRET (Figure 1d). The extracellular domains of the type I interferon receptor (*24*) subunits carrying a C-terminal decahistidine tag (ifnar1-H10 and ifnar2-H10) were employed as model systems for conformational analysis. While the high-affinity subunit ifnar2-H10 does not change its structure upon interferon binding (*25*), we have recently observed complex ligand-induced conformational changes of ifnar1-H10 (*26*). Ifnar1-H10 and ifnar2-H10 were site-specifically labeled through additional cysteines. For ifnar1-H10, the mutation N23C on the N-terminal Ig-like domain was incorporated by site-directed mutagenesis. The protein was labeled with the maleimide-functionalized green fluorescent dyes Oregon Green 488 (OG488) or Alexa Fluor 488 (AF488). In order to ensure quantitative ligand binding to ifnar1-H10, we used the interferon triple mutant H57A, E58A, and Q61A (IFNα2-HEQ), which binds ifnar1-H10 with ∼40-fold higher affinity (∼150 nM) than the wild-type (*27*). Ifnar2-EC, which binds both IFNα2 wt and HEQ with high affinity (∼5 nM), was employed as a reference protein, and three mutants with single cysteines in different positions were prepared for

experimentally calibrating the FRET efficiencies (indicated in Figure 1e).

EXPERIMENTAL PROCEDURES

Synthesis, Protein Expression, and Labeling. The tris-NTA/fluorophore conjugates with ATTO 565 (^{AT565}tris-NTA) and FEW Chemicals S0387 (^{FEW646}tris-NTA) were synthesized and loaded with Ni(II) ions as described previously (*23*, *28*). Ifnar1-EC with a C-terminal decahistidine-tag (ifnar1-H10) was expressed and purified as described before (*29*). Ifnar1 without His-tag (ifnar1-tl) was prepared from an ifnar1-H10 containing a factor Xa cleavage site upstream of the His-tag by proteolytic cleavage. Ifnar2-H10 was cloned into the same expression vector as ifnar1-H10 (pAcGP67B) and expressed in *Sf*9 insect cells as described for ifnar1-H10 (*29*). Single cysteine mutants of ifnar1-H10 (N23C) and ifnar2-H10 (S35C, S131C, and T169C, respectively) were generated by ligase chain reaction. The proteins were expressed and purified as wild-type ifnar1-H10. Thiol-specific labeling of these cysteine mutants required reduction of these additional cysteine residues without reducing the disulfide bonds in the proteins. Different conditions were found to be suitable for the different proteins: ifnar1 N23C was reduced by incubation with 3 mM tricarboxyethylphospine and 1 mM EDTA for 1 h; ifnar2-H10 mutants S35C, S131C, and T169C were reduced using 300 μM dithiothreitol for 1 h. After removing the reducing agent by SEC (Superdex 200 in 20 mM Tris pH 7.5, 50 mM sodium chloride), a 3-fold molar excess of the maleimide-functionalized fluorescence dye (OG488 and AF488 maleimide from Molecular Probes) was added and incubated overnight. The labeled proteins were further purified by ion exchange chromatography to separate unlabeled and multiply labeled species, followed by a final polish by SEC in 20 mM Hepes pH 7.5 and 150 mM NaCl (HBS).

Cuvette Fluorescence Assays. Fluorescence quenching experiments were carried out in HBS complemented with 1 mg/mL BSA. Fluorescence spectra were recorded with a Cary Eclipse (Varian, Germany) and fluorescence lifetime measurements were carried out in a FluoTime 200 instrument (Picoquant GmbH, Germany) using a 120 μL cuvette. A solution of 100 nM covalently labeled protein was filled into the cuvette, and the fluorescence measurement was carried out. Subsequently, 250 nM of ^{FEW646}tris-NTA, ^{AT565}tris-NTA, or ^{BT}tris-NTA was added to the protein solution in the cuvette, incubated for 15 min, and then the fluorescence spectra or fluorescence lifetime was recorded. Subsequently, 1 μM IFNα2-HEQ was added, and fluorescence spectra or fluorescence lifetime was recorded after 5 min. The stock solutions of the tris-NTA conjugates and IFNα2-HEQ were so concentrated that the change of volume was negligible. Fluorescence spectra were acquired with an excitation of OG488 and AF488 at 470 nm (5 nm slit-width). For ensemble fluorescence lifetime measurements, OG488 was excited at 493 nm by a pulsed LED (PLS500, Picoquant GmbH, Germany) with 500 ps pulse width and 20 MHz repetition rate. Fluorescence lifetimes were fitted by a double-

exponential decay. For evaluation of the FRET efficiency and the donor−acceptor distance, we treated each component independently.

Time-Resolved Fluorescence Correlation Spectroscopy. Time-resolved fluorescence correlation spectroscopy was carried out in a home-built confocal microscope that was described previously (*30*). The excitation laser used was a pulsed diode laser at 470 nm wavelength (PDL 470, PicoQuant GmbH, Germany) generating pulses with ca. 50 ps pulse width and 40 MHz repetition rate. Fast electronics (PicoHarp 300, PicoQuant GmbH, Germany) was used for recording the detected photons in time-correlated time-tagged recording mode. From these raw data, the autocorrelation curves $G(\tau)$ were calculated by cross-correlating photons from two different single-photon avalanche photodiodes. Binding experiments were carried out with 1 nM ^{OG488}ifnar1-H10 or ^{AF488}ifnar1-H10 mixed with 100 nM unlabeled ifnar1-H10 in HBS complemented with 1 mg/mL BSA. The mixture was incubated with 250 nM ^{AT565}tris-NTA for 15 min prior to the measurements, and with 1 μM IFNα2-HEQ for 5 min. For measurements with no addition of the tris-NTA conjugates, 1 mM EDTA was added in order to remove contaminating transition metal ions. Data were acquired over 30 min. The fitting of the normalized autocorrelation function data was done using the standard model introduced by Rigler et al. (*31*). To account for the complex photophysical processes, this model was extended using three exponential decay terms. Hence, the following model function was used to describe the data:

$$G(\tau) = G_D(\tau)G_F(\tau) + 1$$

with

$$G_D(\tau) = \frac{1}{N}\frac{1}{(1+\tau/\tau_{diff})\sqrt{1+\tau/(\gamma\tau_{diff})}}$$

and

$$G_F(\tau) = \frac{1}{1-\sum_3 A_j}\left[1-\sum_{j=1}^{3} A_j\left[1-\exp\left(\tau/\tau_j\right)\right]\right]$$

where τ is the lag time, τ_{diff} the diffusion time, τ_j the time constants of photophysical processes, and γ the aspect ratio of the confocal volume.

RESULTS AND DISCUSSION

Fluorescence quenching in solution was explored by using either ^{AT565}tris-NTA or ^{FEW646}tris-NTA binding to the decahistidine-tag of ^{OG488}ifnar1-H10. Typical assays using spectral fluorescence detection are shown in Figure 2. Upon addition of ^{AT565}tris-NTA, the fluorescence of ^{OG488}ifnar1-H10 was quenched by more than 50% (Figure 2a). The same fluorescence quenching was observed in the presence of a 10-fold excess of unlabeled, tagless ifnar1-EC (ifnar1-tl), confirming specific and exclusive binding of ^{AT565}tris-NTA to the His-tag of ifnar1-H10 (data not shown). Moreover, no change in fluorescence was observed after scavenging excess ^{AT565}tris-NTA by adding 200 nM His-tagged maltose binding protein (MBP-H10) to the ^{AT565}tris-NTA/^{OG488}ifnar1-H10 complex, excluding nonspecific interaction of excess ^{AT565}tris-NTA with other regions of ifnar1-H10. On the basis of the calculated Förster radius for this pair of fluorescence dyes (~58 Å), this extent of fluorescence quenching suggests a distance of less than 6 nm between dye attached to N23 and the C-terminal His-tag. Strikingly, a substantial increase in fluorescence was observed upon binding of the ligand IFNα2-HEQ (~70% of the signal before adding the quencher), suggesting a substantial spatial rearrangement of the Ig-like domains. Fluorescence dequenching by the ligand binding was fully reversed upon adding unlabeled, tagless ifnar1-EC (ifnar1-tl), corroborating that indeed ligand binding was responsible for this effect. No change in fluorescence intensity was observed upon ligand binding to ^{OG488}ifnar1-H10 without ^{AT565}tris-NTA (Figure 2c), confirming that fluorescence dequenching was not caused by interaction of the ligand with the fluorophore. Also, changes in the signal of the acceptor fluorescence were observed upon addition of the ligand. However, owing to the rather high excess of ^{AT565}tris-NTA (250 nM) compared to the fluorescence donor (100 nM), the background signal from direct excitation of AT565 was already rather high. Furthermore, the quantum yield of ^{AT565}tris-NTA is rather low due to strong quenching (by ~80%) of the fluorophore by the chelated Ni(II) ions (*23*).

Similar experiments were carried out with ^{FEW646}tris-NTA as a quencher (Figure 2b). As expected, substantially lower decrease of the fluorescence signal was observed upon binding of ^{FEW646}tris-NTA to ^{OG488}ifnar1-H10 (~25%, Figure 2b). Taking the theoretical Förster radius for this pair of dyes (~47 Å) into account, this effect confirmed an effective distance of less than 6 nm between N23 and the N-terminus. Again, the fluorescence recovered substantially upon addition of IFNα2-HEQ (~90% of the signal before adding the quencher), corroborating the spatial arrangement and the distance between the N-terminal Ig-like domain and the C-terminus. Dissociation of the ^{FEW646}tris-NTA from the His-tag by addition of 50 mM imidazole resulted into a full recovery of the fluorescence signal, confirming that the changes in fluorescence were due to interactions between ^{FEW646}tris-NTA and the His-tag.

The role of Ni(II) ions for the quenching of the covalently attached dye was explored by complex formation with ^{BT}tris-NTA instead of the fluorescent tris-NTA conjugates. Strikingly, no change in fluorescence of ^{OG488}ifnar1-H10 was observed upon complex formation (Figure 2d). Stable binding of ^{BT}tris-NTA and thus incorporation of Ni(II) ions was confirmed by subsequent addition of 250 nM ^{AT565}tris-NTA, which did not quench the fluorescence under these conditions, because the decahistidine tag was already blocked by ^{BT}tris-NTA. These experiments furthermore corroborated the high specificity of the fluorescence quenching by site-specific incorporation through the His-tag.

Ifnar1-H10 labeled with AF488 instead of OG488 as a fluorescence donor yielded similar results (Supporting Information), in agreement with the highly similar photophysical properties of AF488 and OG488. As a further control, as well as for calibrating the quenching signals, similar experiments were carried out with several single cysteine mutants of ifnar2-H10, which were used for site-specific labeling at different positions within the molecule (cf. Figure 1e). Upon addition of ^{FEW646}tris-NTA, the fluorescence decreased by ~20% (Figure 2). Importantly, however, no recovery of the fluorescence was observed after ligand binding. This is in line with the rigid structure of the protein observed in NMR, which remained essentially unchanged upon ligand binding (*32*). These results corroborate that the fluorescence changes observed for ifnar1-H10 were indeed due to conformational changes. Again, stronger quenching by ~35% was observed for binding of ^{AT565}tris-NTA (spectra not shown). On the basis of the distances between the C-terminus of ifnar2-EC and the mutated residue as determined from the NMR structure of ifnar2-EC, the quenching amplitudes obtained for different mutants were used for a distance calibration. The relative quenching amplitudes obtained for ^{FEW646}tris-NTA and ^{AT565}tris-NTA for different distances are compared in Figure 2f and fitted by the Förster function. From these calibration curves, Förster radii of 48 Å and 59 Å were estimated for ^{FEW646}tris-NTA and ^{AT565}tris-NTA, respectively, which were in excellent agreement with the Förster radii calculated from

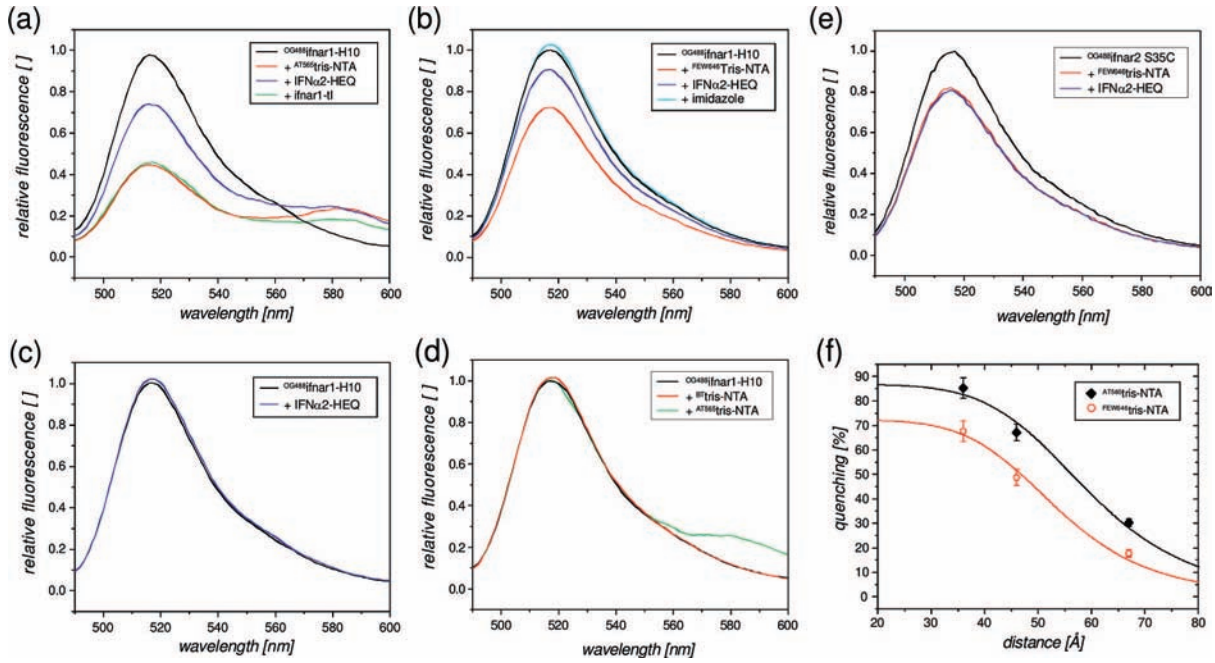

Figure 2. FRET experiments in solution. (a,b) Fluorescence spectrum of 100 nM ^{OG488}ifnar1-H10 before and after adding 250 nM ^{AT565}tris-NTA (a) or ^{FEW646}tris-NTA (b), and upon addition of the ligand IFNα2-HEQ (1 μM). In (a), IFNα2 HEQ was competed out of the complex by addition of 5 μM ifnar1-tl; in (b), ^{FEW646}tris-NTA was competed out of the complex by addition of 50 mM imidazole. (c) Fluorescence of 100 nM ^{OG488}ifnar1-H10 without tris-NTA conjugate before and after addition of 1 μM IFNα2-HEQ. (d) Fluorescence of 100 nM ^{OG488}ifnar1-H10 before and after addition of 250 nM ^{BT}tris-NTA, followed by the addition of 250 nM ^{AT565}tris-NTA. (e) Fluorescence spectrum of 100 nM ^{OG488}ifnar2-H10 S35C before and after adding 250 nM ^{FEW646}tris-NTA, and upon addition of the ligand (1 μM). (f) Comparison of relative quenching with ^{FEW646}tris-NTA and ^{AT565}tris-NTA for ifnar2-H10 labeled at three different positions and fit of the Förster equation.

Table 1. Relative Quenching and Estimated Mean Intramolecular Distances in ^{OG488}ifnar1-H10

	^{OG488}ifnar1-H10		^{OG488}ifnar1-H10/IFNα2-HEQ	
	Q [%][a]	r [Å][b]	Q [%][a]	r [Å][b]
^{AT565}tris-NTA	55 ± 2	56 ± 1	30 ± 2	67 ± 1
^{FEW646}tris-NTA	25 ± 2	56 ± 1	10 ± 2	68 ± 1

[a] Relative loss in fluorescence compared to ^{OG488}ifnar1-H10. [b] Distance between donor and quencher as estimated from the Förster radii (47 Å for ^{FEW646}tris-NTA and 58 Å for ^{AT565}tris-NTA).

absorbance and emission spectra assuming a quantum yield of 50% for the protein-bound OG488 (47 Å and 58 Å, respectively). On the basis of these Förster radii, the distances between N23 from the C-terminus before and after ligand binding were estimated (Table 1). Distances of ∼56 Å before and ∼67 Å (^{AT565}tris-NTA) as well as ∼68 Å (^{FEW646}tris-NTA) after ligand binding were obtained, highly consistent for both quencher. Thus, the N-terminal domain moves away from the C-terminal domain by ∼11−12 Å.

The multidomain architecture and the ligand-induced conformational change suggested that a flexible organization of the Ig-like domains of ifnar1 may contribute to the intramolecular FRET. We, therefore, further explored fluorescence quenching and ligand-induced dequenching by fluorescence lifetime measurements (Figure 3a,b). An overall decrease of the fluorescence lifetime was observed upon binding of ^{AT565}tris-NTA (Figure 3a) as well as ^{FEW646}tris-NTA (Figure 3b), which was followed by a recovery upon ligand binding. The differences in the decrease and recovery of the fluorescence lifetimes qualitatively matched well with the spectral data. The fluorescence lifetime curves obtained with ^{AT565}tris-NTA yielded substantially stronger changes in the fluorescence lifetime compared to ^{FEW646}tris-NTA and were therefore analyzed in more detail. All samples showed a biexponential decay indicating a rather complex scenario. We interpreted this as a two-state environment of the attached label, which might be either due to linker flexibility that allows the label to find two possible positions on the protein surface or due to conformational dynamics of the protein (see below). For ^{OG488}ifnar1-H10 alone, we observed two lifetimes of ∼2.5 ns and ∼4.4 ns (cf. Supporting Information). After binding of ^{AT565}tris-NTA, both lifetimes decreased (1.5 and 3.9 ns, respectively), but the effect was much more prominent in the case of the short-lifetime component. Upon addition of the ligand, both lifetimes increased (2.0 and 4.0 ns, respectively), and again the change in the short lifetime component was more pronounced. Using the previously estimated Förster radii, we could conclude that upon ligand binding the C-terminal His-tag moves by ∼12−14 Å away from the labeled position near the N-terminus (detailed in the Supporting Information), consistent with the conformational changes estimated from intensity changes.

We further explored the conformational dynamics of ifnar1-H10 by means of fluorescence correlation spectroscopy. FRET introduces an additional channel that de-excites the fluorescence of the fluorophore. For fluctuations of FRET efficiencies due to conformational dynamics, one expects to observe an additional decay term in the autocorrelation function. For this purpose, 1 nM ^{AF488}ifnar1-H10 mixed with 100 nM unlabeled ifnar1-H10 was incubated with 250 nM ^{AT565}tris-NTA, and fluorescence fluctuations in the confocal volume were followed by time-correlated single photon counting (TCSPC). Under these conditions, a similar excess of ^{AT565}tris-NTA was maintained as in the cuvette experiments, thus ensuring the same specificity and complete complex formation. Typical autocorrelation functions obtained for ^{AF488}ifnar1-H10 in different states are compared in Figure 3c and d. Normalization of the autocorrelation curves to individual fluorophores (data not shown) confirmed the intramolecular FRET signals obtained by ensemble measurements. A clear change in the shape of the correlation curve was observed upon binding of ^{AT565}tris-NTA (Figure 3c). Upon ligand binding, the autocorrelation curves

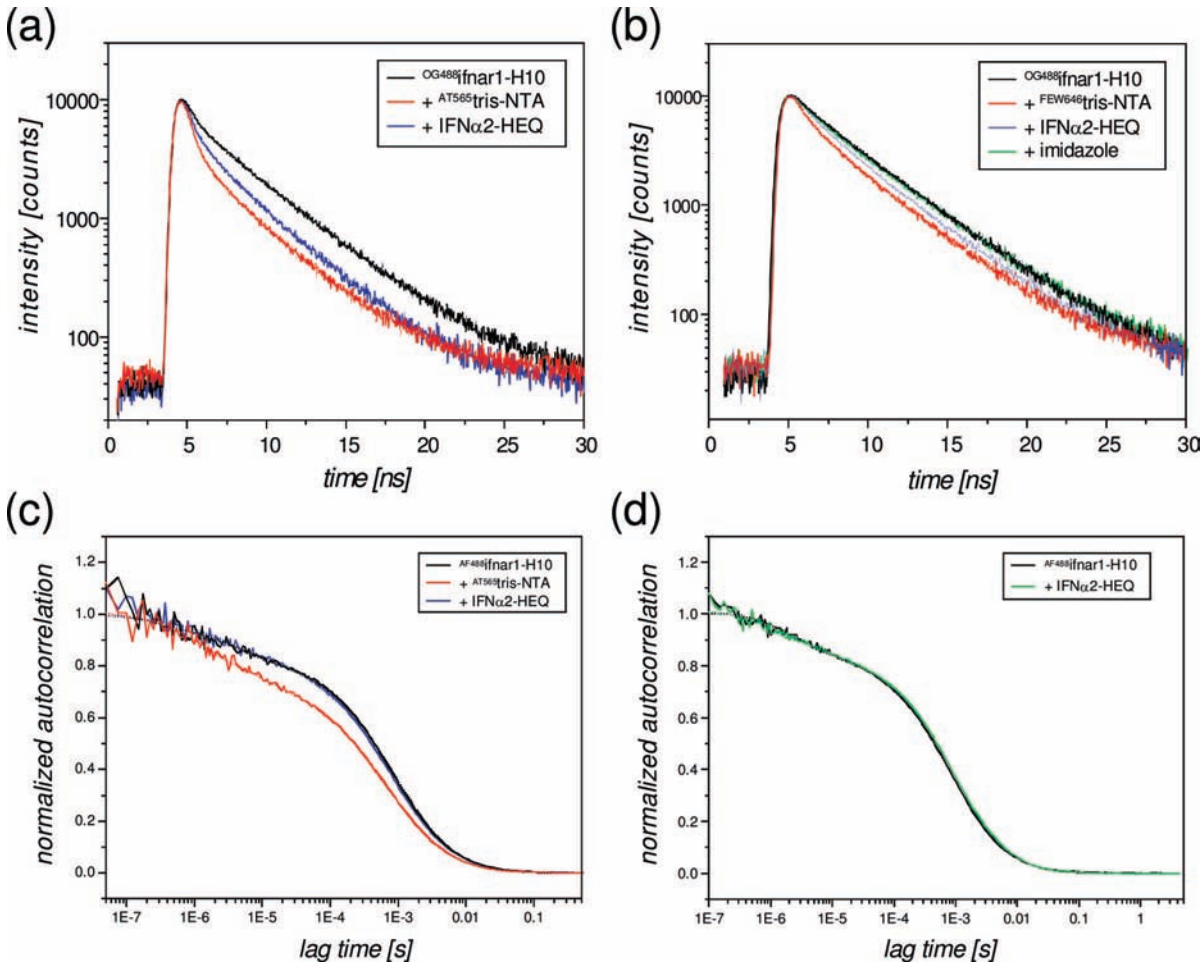

Figure 3. Probing conformational dynamics by time-resolved fluorescence experiments. (a) Fluorescence lifetime of ^{OG488}ifnar1-H10 before and after adding ^{AT565}tris-NTA, and upon addition of the ligand IFNα2-HEQ. (b) Fluorescence lifetime of ^{OG488}ifnar1-H10 before and after adding ^{FEW646}tris-NTA, after addition of the ligand IFNα2-HEQ, and after treatment with imidazole. (c) Autocorrelation curves for ^{AF488}ifnar1-H10, after binding of ^{AT565}tris-NTA, and after ligand binding (IFNα2-HEQ) to the ^{AF488}ifnar1-H10/^{AT565}tris-NTA complex. The fits of the curves are shown as dotted lines. (d) Autocorrelation curves for ^{AF488}ifnar1-H10 without ^{AT565}tris-NTA before and after ligand binding (IFNα2-HEQ). The fit of the curves are shown as dotted lines.

recovered to a very similar behavior as observed prior to the binding of ^{AT565}tris-NTA. These observations suggest that an additional mode of dynamic quenching takes place in the ^{AF488}ifnar1-H10/^{AT565}tris-NTA complex, which is lost upon complex formation with the ligand. In contrast, no changes in the shape of the autocorrelation curves were observed without ^{AT565}tris-NTA (Figure 3d). Fitting of the autocorrelation curves revealed a transition time of ∼200 μs, which we ascribe to conformational dynamics of ifnar1-H10 in the unliganded state. The amplitude of this photophysical decay term was 25% of the diffusional autocorrelation amplitude (Supporting Information Table 2). Very similar autocorrelation curves were obtained when the same experiments were carried out with ^{OG488}ifnar1-H10 (data not shown). These results clearly corroborate a conformational flexibility of ifnar1-H10, which is largely lost upon ligand binding. This observation is in line with the fact that the three N-terminal domains simultaneously interact with the ligand, thus reducing the potential flexibility of the molecule in the linker between SD2 and SD3.

CONCLUSIONS

These results demonstrate that noncovalent labeling by multivalent chelator heads efficiently complements cysteine-specific labeling for probing protein conformations. The key advantage of this approach is that an acceptor dye can be rapidly incorporated into the protein in situ in a quantitative fashion without the addition of other reagents being required. Thus, the fluorescence of the covalently attached fluorescence donor can be readily quantified before and after attachment of the acceptor dye, and the FRET efficiencies can be quantified reliably from the donor quenching even if the donor dye is coupled at a low degree of labeling. Compared to other noncovalent labeling techniques, the localization of the fluorophore is very well defined, though not as well as for a dye chemically coupled to a cysteine residue. The method is therefore particularly suited to explore the domain organization of multidomain proteins, which was applied to the ectodomain of ifnar1 (*26*). Binding of tris-NTA/fluorophore conjugates to the His-tag is fast, quantitative, and reversible under mild conditions, and suitable for labeling in live cells (*23, 33*). Our studies demonstrate the elegance and versatility of labeling through tris-NTA/fluorophore conjugates and its compatibility with different fluorescence detection techniques including TCSPC-based FCS.

ACKNOWLEDGMENT

We thank Thomas Gensch for help with the fluorescence lifetime instrument. This project was supported by grants to J.P. from the DFG (Emmy-Noether Program PI 405/1 and SFB 628), and from the Human Frontier Science Program (RGP60/2002). J.P. is a Heisenberg Professor funded by the DFG (PI 405/3) and was supported by the Cluster of Excellence "Macromo-

lecular Complexes" at the Goethe University Frankfurt (DFG Project EXC 115).

By fitting the fluorescence decay curves we obtained the decay times and thus the quantum yields of the samples. A bi-exponential decay was fitted for all samples. We interpreted this as a two state environment of the attached label. This might be due to linker flexibility that allows the label to find two possible positions on the protein surface. For evaluation of the FRET efficiency and the donor-acceptor distance, we treated each component independently. The distance between fluorescence donor and acceptor (r_{DA}) were estimated separately for each of the two decay time constants according to:

$$\frac{R_0}{r_{DA}} = \frac{1}{k_{fl}}\left[\frac{1}{t_{fl}} - \frac{1}{t_{fl,0}}\right]$$

Where R_0 is the Förster radius of the FRET pair, k_{fl} is the fluorescence rate constant, t_{fl} and $t_{fl,0}$ are the fluorescence lifetimes with and without FRET, respectively. The fluorescence rate constant k_{fl} was estimated to be 0.218 ns^{-1} (assuming a quantum yield of 0.9 and a fluorescence lifetime of 4.1 ns). The r_{DA} obtained for different FRET pairs and the different fluorescence lifetimes are summarized in Supplementary Table 1. With the estimated values R_0 of 5.8 nm for ^{AT565}tris-NTA and of 4.7 nm for ^{FEW646}tris-NTA, a change in distance of 1.2 - 1.4 nm was obtained from the fluorescence lifetimes t_2.

Cytoplasmic Delivery of Liposomal Contents Mediated by an Acid-Labile Cholesterol-Vinyl Ether-PEG Conjugate

Jeremy A. Boomer,[†] Marquita M. Qualls,[‡] H. Dorota Inerowicz, Robert H. Haynes, V. Srilakshmi Patri, Jong-Mok Kim, and David H. Thompson*

Department of Chemistry, Purdue University, 560 Oval Drive, West Lafayette, Indiana 47907-1393. Received June 13, 2008; Revised Manuscript Received October 30, 2008

An acid-cleavable PEG lipid, 1′-(4′-cholesteryloxy-3′-butenyl)-ω-methoxy-polyethylene[112] glycolate (CVEP), has been developed that produces stable liposomes when dispersed as a minor component (0.5−5 mol %) in 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE). Cleavage of CVEP at mildly acidic pHs results in dePEGylation of the latently fusogenic DOPE liposomes, thereby triggering the onset of content release. This paper describes the synthesis of CVEP via a six-step sequence starting from the readily available precursors 1,4-butanediol, cholesterol, and mPEG acid. The hydrolysis rates and release kinetics from CVEP/DOPE liposome dispersions as a function of CVEP loading, as well as the cryogenic transmission electron microscopy and pH-dependent monolayer properties of 9:91 CVEP/DOPE mixtures, also are reported. When folate receptor-positive KB cells were exposed to calcein-loaded 5:95 CVEP/DOPE liposomes containing 0.1 mol % folate-modified 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-polyethylene[76] glycolamide (folate-PEG-DSPE), delivery of the calcein cargo to the cytoplasm of the cells was observed as determined by fluorescence microscopy and flow cytometry. Fluorescence resonance energy transfer analysis of lipid mixing in these cells was consistent with membrane−membrane fusion between the liposome and endosomal membranes.

INTRODUCTION

Liposomes are clinically important drug delivery vehicles that can encapsulate a wide variety of low molecular weight drugs (*1*) as well as biopharmaceutical agents such as peptides, oligonucleotides, and plasmids (*2*−*5*). Major advantages are often provided by this class of drug carrier system due to their ability to encapsulate cargo by exploiting transmembrane chemical gradients, so-called "remote loading" (*6, 7*), and passivate it toward biodegradation in vivo during its transport to the target tissue. The performance of these carriers in vivo can be further enhanced by passive targeting (*8, 9*) via the enhanced permeability and retention effect (*10*), typically achieved in liposome systems by incorporation of poly(ethylene glycol)−lipid conjugates (e.g., mPEG-DSPE)[1] within the bilayer membrane. The primary effect of the PEG layer is to reduce and/or mask opsinization (*11*), thereby improving blood circulation lifetimes by sterically stabilizing the liposomes against clearance by the reticuloendothelial system and promoting their deposition at sites of porous and poorly formed vasculature such as those found in tumor tissues and sites of inflammation (*12*−*14*). Once deposited at these sites, however, drug retention by PEGylated liposomes can limit the bioavailability of the active agent, even when they have been internalized via receptor-mediated endocytosis pathways using actively targeted liposomal constructs (*15*). These observations suggest that the development of triggerable liposome formulations bearing site-specific targeting ligands could produce greatly increased drug efficacy when exposed to the appropriate stimulus (*16*−*22*). Previous work from this laboratory (*23, 24*) suggests that this is indeed the case; however, the slow release kinetics in these systems provided the impetus to develop improved triggerable liposome systems.

Several groups have developed lipid-based carrier systems that employ triggering mechanisms activated by pH (*25*−*35*), disulfide exchange (*36*−*43*), enzymes (*44*−*46*), heat (*47*−*49*), and photochemical reactions (*50, 51*) for deploying the encapsulated contents in a site- and/or time-specific manner. The presence of low pH environments within ischemic tissues and endosomal compartments during receptor-mediated endocytosis and vesicle trafficking (Figure 1) suggests that acid-triggering approaches should be a widely applicable activation strategy, since they would not require an external stimulus to initiate liposomal content release. This has motivated the development of triggering strategies in which the latent fusogenicity of DOPE liposome formulations containing cleavable PEG−lipids is restored upon removal of the PEG corona via dePEGylation (Figure 2). Several fusogenic and/or targeted liposome constructs

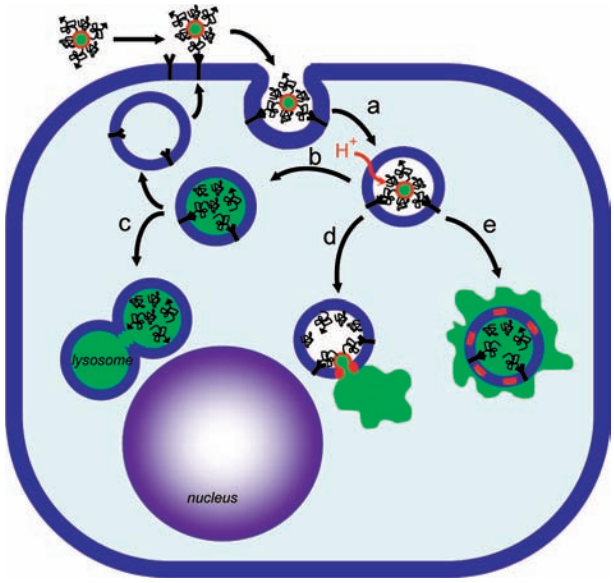

Figure 1. Conceptual diagram of receptor-mediated endocytosis pathway. Step a: Endosome formation. Step b: Endosome acidification and liposome degradation with endosomal trapping. Step c: Endosome−lysosome fusion. Step d: Liposome−endosome fusion. Step e: Lipid-mediated endosomolysis.

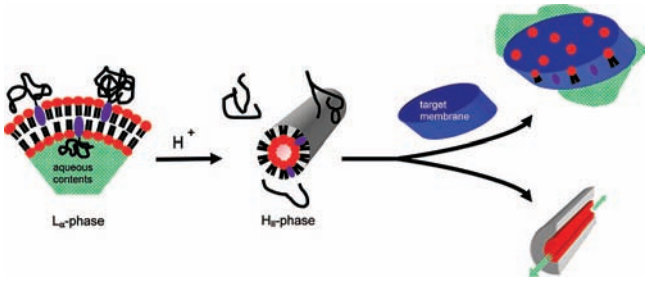

Figure 2. Schematic of lamellar → hexagonal II (L_α−H_{II}) phase transition driven by dePEGylation of cleavable PEG/DOPE liposomes (left and center). Detachment of PEG induces a change in the local membrane curvature leading to the formation of H_{II} domains within the bilayer. Contact of these sites with other lamellar phases can promote membrane−membrane fusion and transmembrane content transport (top right). Absence of membrane contact due to low membrane concentrations or steric repulsion results in L_α phase collapse and content release into the surrounding solution (bottom right).

stabilized by cleavable (*25*, *27*, *28*, *33*, *36*, *37*, *41*), exchangeable (*52*−*58*), or polymerizable (*59*) PEG conjugates have been designed and investigated; however, a broadly applicable system for in vivo application has yet to emerge.

Our laboratory previously reported a novel acid-labile PEG-lipid conjugate, (*R*)-1,2-di-*O*-(1′*Z*,9′*Z*-octadecadienyl)-glyceryl-3-(ω-methoxy-poly(ethylene glycol[112])ate (BVEP, Figure 3) that displays pH-dependent content release properties when dispersed as a minor component (i.e., 1−10 mol %) in BVEP/DOPE liposome formulations (*27*). The content release and membrane fusion kinetics of this system, however, are too slow for many envisioned in vivo applications. We anticipated that there were three possible reasons the observed release kinetics are slow: (1) the acid-labile vinyl ether linkages are buried too

[2]Since PEG is known to osmotically deplete waters of hydration at membrane and protein surfaces (*61*−*66*), it is also reasonable to expect that the local proton activity will be lower at this water-depleted interface—an effect that could impact either the first or second steps (or both) in the hydrolysis pathway (Figure 3). This would be especially problematic for BVEP since complete separation of PEG from the lipid anchor requires two sequential hydrolysis events.

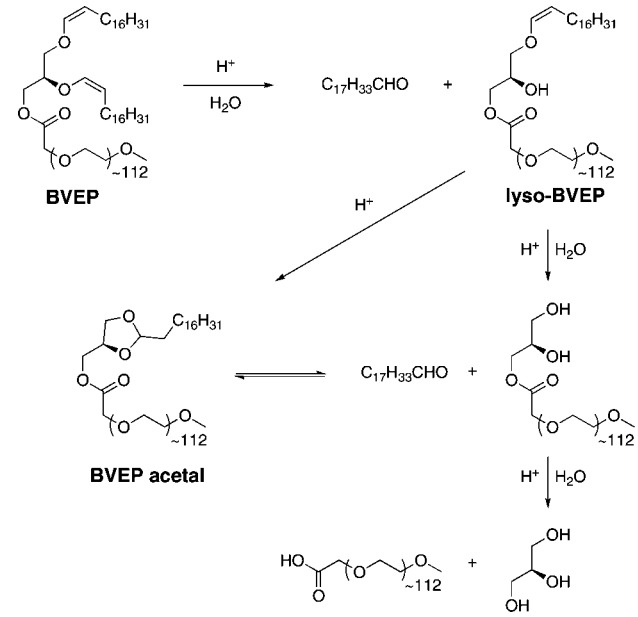

Figure 3. Acid-catalyzed hydrolysis pathway for BVEP. Mechanistic details of the rate-determining β-carbon protonation, oxonium ion hydration, and hemiacetal cleavage steps are not shown. The protonated intermediate of lyso-BVEP has two possible fates—trapping by water to give the desired products (bottom right) or intramolecular trapping to give the L_α-phase stabilizing species, BVEP acetal (bottom left).

deep in the membrane to permit rapid protonation of the vinyl ether β-carbon, the rate determining step in vinyl ether hydrolysis (*60*)[2]; (2) a side reaction of partially hydrolyzed BVEP produces BVEP acetal, a dioxolane-based PEG−lipid conjugate that could stabilize the DOPE membrane via binding of the single aliphatic chain; or (3) the PEG remains weakly adsorbed to the membrane even after it is fully hydrolyzed, thereby preventing the expected lamellar (L_α) to hexagonal (H_{II}) phase transition.

We have developed a cleavable PEG lipid, 1′-(4′-cholesteryloxy-3′-butenyl)-ω-methoxy-polyethylene[112] glycolate (CVEP, Figure 4), to circumvent these limitations. This lipopolymer target was designed because a single hydrolysis event would cleave the PEG headgroup from CVEP, thereby accelerating the rate of dePEGylation and the subsequent content release and/or fusion processes. Another integral part of this design was the relocation of the vinyl ether linkage closer to the aqueous region where the rate of hydrolysis could be enhanced by placing the acid-sensitive linkage within a region of higher proton activity. This paper describes the synthesis of CVEP, the physical characterization of CVEP/DOPE liposomes, and their performance with respect to intracellular delivery of liposomal cargo in folate receptor-positive KB cell culture using folate-targeted CVEP/DOPE formulations.

EXPERIMENTAL METHODS

Synthesis of CVEP. 2,2′-Dipyridylcarbonate was purchased from TCI-America. MPEG-acid was purchased from Shearwater Polymers. All other compounds were purchased from Aldrich and used without further purification unless otherwise stated. Triethylamine and diisopropylamine were distilled from CaH_2. All solvents used were spectrophotometric grade, dried over an appropriate desiccant, and distilled. Reactions were performed under an argon atmosphere. $Pd(PPh_3)_4$ was obtained from Strem. Column chromatography was typically performed with 230−400 mesh silica gel using high-grade solvents to elute the compounds. Thin layer chromatography was performed using Baker-flex IB-F plates and visualized using UV, I_2 adsorption, $KMnO_4$/

heat, and/or molybdic acid/heat. ^{1}H NMR and ^{13}C NMR spectra were recorded on a 4.7 T spectrometer. Chemical shifts are reported in ppm relative to the residual solvent peaks as the internal standard. Attached proton test (APT) results are reported as odd (O, one or three protons attached) or even (E, zero or two protons attached) after the corresponding ^{13}C chemical shifts.

*4-t-Butyldimethylsilyloxybutan-1-ol (**1**) (67).* *t*-Butyldimethylsilyl chloride (8.65 g, 57.4 mmol) in dry THF (25 mL) was added dropwise to a solution of 1,4-butanediol (22.0 g, 244 mmol; dried 2 h in vacuo) and imidazole (5.1 g, 70.5 mmol) in THF (100 mL) at 0 °C over a ~20 min period. The reaction, which turned cloudy after 10 min, was stirred for 1 h, warmed to room temperature, and ether (300 mL) added. The solution was then washed with saturated NH_4Cl (2 × 200 mL) and saturated NaCl (1 × 200 mL). The ether layer was dried over $MgSO_4$, filtered, evaporated, and dried in vacuo yielding a pale yellow oil (11.4 g, 97% yield). NMR analysis indicated that the product was sufficiently pure to utilize in the ensuing step without additional purification. TLC (4:1 hexane/ether, $KMnO_4$): $R_f = 0.35$. ^{1}H NMR ($CDCl_3$): 0.05 (s, 6H), 0.85 (s, 9H), 1.60 (m, 4H), 2.60 (bs, 1H), 3.65 (q, 4H). ^{13}C NMR/APT ($CDCl_3$): −5.54 (O), 18.15 (E), 25.76 (O), 29.60 (E), 29.79 (E), 62.33 (E), 63.18 (E).

*4-t-Butyldimethylsilyloxybutanoic acid (**2**) (68).* $KMnO_4$ (3.2 g, 20.2 mmol) was dissolved in water (50 mL), stirred vigorously for 10 min, then cooled to 0 °C. A solution of 4-*t*-butyldimethylsilyloxybutan-1-ol (**1**, 1.98 g, 9.7 mmol) and tetraoctylammonium bromide (TOAB, 812 mg, 1.5 mmol) in benzene (40 mL) was added dropwise via addition funnel over a ~20 min period. The solution was then warmed to room temperature and stirred for 3 h. The remaining $KMnO_4$ was quenched with $NaHSO_3$, producing a two-phase mixture with a colorless organic layer. Benzene (20 mL) and 50% CH_3CO_2H (50 mL) were added and the mixture extracted. The benzene layer was then washed with saturated NaCl (50 mL), dried over $MgSO_4$, filtered, evaporated, and dried in vacuo. The remaining TOAB was removed via elution through a small silica plug with 2:1 hexane/ether mobile phase. The solvent was evaporated and the sample dried in vacuo giving a colorless oil (1.65 g, 78% yield). TLC (1:1 hexane/ether, Bromphenol blue): $R_f = 0.65$. ^{1}H NMR ($CDCl_3$): 0.05 (s, 6H), 0.85 (s, 9H), 1.83 (p, $J = 7$ Hz, 2H), 2.44 (t, $J = 7$ Hz, 2H), 3.65 (t, $J = 7$ Hz, 2H), 11.09 (bs, 1H). ^{13}C NMR/APT ($CDCl_3$): −5.47 (O), 18.24 (E), 25.85 (O), 27.57 (E), 30.71 (E), 61.95 (E), 179.96 (E).

*Cholesteroyl-4-t-butyldimethylsilyloxybutanoate (**3**).* Cholesterol (609 mg, 1.58 mmol), 4-*t*-butyldimethylsilyloxy butanoic acid (**2**, 325 mg, 1.49 mmol), and DMAP (20 mg, 0.14 mmol) were dissolved in CH_2Cl_2 (15 mL) and the solution cooled to 0 °C. EDCI (284 mg, 1.49 mmol) was added, and the mixture was warmed to room temperature with stirring for 10 d. The reaction mixture was poured into H_2O (75 mL) and extracted with CH_2Cl_2 (3 × 75 mL). The combined CH_2Cl_2 layers were dried over $MgSO_4$, filtered, evaporated, dried in vacuo, and the crude product purified via chromatography (230−400 mesh silica, 9:1 hexane/ether, 1.5 cm diameter × 5 cm height) to give a white solid (780 mg, 90% yield). TLC (2:1 hexane/ether, acid char): $R_f = 0.52$. MP: 133−135 °C. ^{1}H NMR ($CDCl_3$): 0.05 (s, 6H), 0.65 (s, 3H), 0.8−2.05 (m, 49H), 2.25−2.4 (m, 4H), 3.65 (t, $J = 7$ Hz, 2H), 4.6 (m, 1H), 5.35 (d, $J = 5$ Hz, 1H). ^{13}C NMR ($CDCl_3$): −4.8, 12.4, 18.8, 19.1, 19.3, 19.7, 19.9, 21.5, 23.0, 23.1, 23.2, 23.3, 24.3, 24.8, 26.4, 26.5, 28.3, 28.5, 28.7, 31.5, 32.4, 36.3, 36.7, 37.1, 37.5, 38.6, 40.0, 40.2, 40.3, 42.8, 50.5, 56.6, 57.2, 62.5, 123.1, 140.2, 173.5. MS (CI): $m/z = 587$ (M + H).

*4-t-Butyldimethylsilyloxy-1-cholesteryloxy-1-diethylphosphoryloxy-1-butene (**4**).* *n*-Butyl lithium (795 μL, 1.94 mmol, 2.4 M in hexane) was added dropwise, via syringe, to diisopropylamine (453 μL, 3.23 mmol) in THF (250 μL) at −78 °C and the solution stirred for 30 min. Cholesteroyl-4-*t*-butyldimethylsilyloxy butanoate (**3**, 758 mg, 1.29 mmol) in THF (3 mL) was then slowly added dropwise, via syringe. The solution was stirred for an additional hour, followed by the addition of diethylchlorophosphate (373 μL, 2.58 mmol) in HMPA (4.9 mL) in three aliquots. The solution turned orange/brown and gelled. It was thawed enough to resume stirring, then returned to −78 °C for 10 min. The reaction was then warmed to room temperature and stirred for an additional hour. Ether (50 mL) was added and the reaction mixture filtered through a small silica plug. The solvent was evaporated, the oil redissolved in ether (75 mL), and the organic layer washed with 5% $NaHCO_3$ (3 × 75 mL). The ether layer was dried over $MgSO_4$, filtered, evaporated, and dried briefly in vacuo. The crude product was purified via flash chromatography (230−400 mesh silica, 6:1 hexane/ether, 2 cm diameter × 16 cm height) to give a white solid (750 mg, 81% yield). The product was used immediately without additional characterization. TLC (2:1 hexane: ether, I_2): $R_f = 0.35$.

*4-t-Butyldimethylsilyloxy-1-cholesteryloxy-1-butene (**5**).* Tetrakis(triphenylphosphine) palladium (15 mg, 12.4 μmol) and 4-*t*-butyldimethylsilyloxy-1-cholesteryloxy-1-diethylphosphoryloxy-1-butene (**4**, 270 mg, 373 μmol) were added to CH_2Cl_2 (8 mL) and cooled to 0 °C. Triethyl aluminum (653 μL, 653 μmol; 1.0 M in hexane) was then added dropwise via syringe. The solution was stirred at 0 °C for 1 h before warming to 23 °C and stirring for an additional 3 h. The crude mixture was purified via flash chromatography (230−400 mesh silica, 16:1 hexane/ether, 1.5 cm diameter × 20 cm height) to give a 90:10 cis/trans mixture as a white solid (66 mg, 31% yield). TLC (16:1 hexane/ether, *p*-anisaldehyde): $R_f = 0.75$ (cis), 0.71 (trans). ^{1}H NMR (C_6D_6, 90:10 cis/trans mixture): 0.13 (s, 6H), 0.68 (s, 3H), 0.8−2.75 (m, 51H), 3.4 (m, 1H), 3.75 (t, $J = 12$ Hz, 2H), 4.6 (dt, $J_1 = 8$ Hz, $J_2 = 7$ Hz, 0.9H), 5.15 (dt, $J_1 = 13$ Hz, $J_2 = 7$ Hz, 0.1H), 5.35 (m, 1H), 6.04 (dt, $J_1 = 7$ Hz, $J_2 = 2$ Hz, 0.9H), 6.15 (dt, $J_1 = 13$ Hz, $J_2 = 2$ Hz, 0.1H). ^{13}C NMR/APT (C_6D_6,

90:10 cis/trans mixture): −4.8 (O), 12.2 (O), 19.1 (O), 19.5 (O), 19.6 (O), 21.5 (E), 22.8 (O), 23.1 (O), 24.3 (E), 24.6 (E), 26.2 (O), 28.5 (O), 28.8 (E), 28.9 (E), 29.2 (E), 29.6 (E), 29.7 (E), 30.3 (E), 30.6 (E), 32.2 (O), 32.4 (E), 36.2 (O), 36.8 (E), 37.0 (E), 37.3 (E), 37.6 (E), 39.9 (E), 40.0 (E), 40.2 (E), 40.3 (E), 42.6 (E), 51.5 (O), 56.8 (O), 57.0 (O), 63.8 (E), 81.3 (O), 103.0 (O), 106.5 (O), 122.1 (O), 140.5 (E), 141 (O), 145.2 (O).

*4-Cholesteryloxy-3-buten-1-ol (**6**).* TBAF (210 μL, 210 μmol, 1.0 M in THF) and 1.0 mL 40% TBAH were added via syringe to 4-*t*-butyldimethylsilyloxy-1-cholesteryloxy-1-butene (**5**, 40 mg, 70 μmol) in THF (3 mL). The reaction was run for 12 h at 23 °C, then filtered through a small silica plug with ether and the solvent evaporated. The mixture was purified via flash chromatography (230−400 mesh silica, 8:1 hexane/ether, 1.5 cm diameter × 15 cm height) to give *cis*-4-cholesteryloxy-3-buten-1-ol (29 mg, 91% yield) and *trans*-4-cholesteryloxy-3-buten-1-ol (1.5 mg, 4% yield) as white solids (95% combined yield). TLC (2:1 hexane/ether, acid char): $R_f = 0.18$ (cis), 0.14 (trans). ^{1}H NMR (C_6D_6, cis): 0.65 (s, 3H), 0.8−2.05 (m, 39H), 2.3−2.53 (m, 4H), 3.35 (m, 1H), 3.58 (t, $J = 6$ Hz, 2H), 4.4 (dt, $J_1 = 7$ Hz, $J_2 = 7$ Hz, 1H), 5.35 (m, 1H), 5.98 (dt, $J_1 = 6$ Hz, $J_2 = 1$ Hz, 1H). ^{1}H NMR (C_6D_6, trans): 0.65 (s, 3H), 0.8−2.05 (m, 41H), 2.4−2.5 (m, 2H), 3.35 (t, $J = 7$ Hz, 2H), 3.5 (m, 1H), 4.95 (dt, $J_1 = 13$ Hz, $J_2 = 6$ Hz, 1H), 5.35 (m, 1H), 6.15 (dt, $J_1 = 12$ Hz, $J_2 = 1$ Hz, 1H). ^{13}C NMR/APT (C_6D_6, 70:30 cis/trans): 12.06 (O), 12.40 (O), 14.40 (O), 19.04 (O), 19.4 (O), 19.5 (O), 21.0 (E), 21.4 (E), 22.8 (O), 23.0 (O), 24.4 (E), 24.6 (E), 25.5 (E), 28.4 (O), 28.6 (E), 28.7 (E), 29.1 (E), 29.5 (E), 30.0 (E), 32.1 (O), 32.3 (E), 36.2 (O), 36.7 (E), 36.9 (E), 37.3 (E), 37.5 (E), 39.8 (E), 39.9 (E), 40.2 (E), 42.6 (E), 50.5 (O), 50.6 (O), 54.3 (E), 56.6 (O), 57.0 (O), 62.7 (E), 63.0 (E), 75.9 (O), 79.8 (O), 81.2 (O), 102.0 (O), 102.9 (O), 106.2 (O), 122.1 (O), 122.3 (O), 140.4 (E), 140.8 (E), 145.6 (O). MS (CI): $m/z = 457$ (M + H).

*1′-(4′-Cholesteryloxy-3′-butenyl)-ω-methoxy-poly(ethylene-[112]glycol)ate (CVEP, **7**).* 4-Cholesteryloxy-3-buten-1-ol (**6**, 44 mg, 96 μmol), mPEG5000-acid (435 mg, 87.0 μmol), DCC (21.6 mg, 104 μmol), and DMAP (10 mg, 81 μmol) were added to CH_2Cl_2 (7 mL) and stirred for 4 d. The reaction mixture was then cooled to 0 °C and the DCU removed via filtration (21 mg). The solvent was concentrated to 2 mL, dripped into cold ether (20 mL), and the ether solution centrifuged at 4000 rpm for 10 min. The ether was carefully decanted and the pellet triturated with fresh ether (20 mL). This process was repeated 5 times. The pellet was then dissolved in CH_2Cl_2, evaporated to a dry film, dissolved in 2 mL 18 MΩ Millipore H_2O, and lyophilized to give 420 mg PEG-containing product (86% yield based on recovered DCU). TLC (90:10:1 $CHCl_3$/MeOH/H_2O, I_2): $R_f = 0.75$. ^{1}H NMR ($CDCl_3$, cis): 0.65 (m, 3H), 0.75−2.5 (m, 50H + H_2O), 3.2−4.5 (m, >120H), 5.35 (m, 1H), 6.1 (m, 1H). ^{1}H NMR ($CDCl_3$, 65:35 cis/trans): 0.65 (m, 3H), 0.75−2.5 (m, 50H + H_2O), 3.2−4.5 (m, >120H), 5.35 (m, 1H), 6.08 (m, 0.65H), 6.15 (m, 0.35H).

Hydrolysis Kinetics. HPLC solvents were spectrophotometric grade and filtered through a 450 nm FP Vericel membrane (Gelman Sciences, Ann Arbor, MI) immediately prior to use. Reverse-phase HPLC analysis was performed with a Spherisorb C_{18} column (4.6 × 150 mm, 5 μm particles; Waters Corp., Milford, MA) protected with a C_{18} Guard-Pak prefilter (Waters). Peak detection was achieved with a Sedex 55 evaporative light scattering detector (Sedere, France). Pump control and data analysis were performed using *EZChrom* v. 6.8 (Scientific Software, Pleasanton, CA). The following gradient elution was performed with a flow rate of 1.5 mL/min: 0−29 min, 6:4 MeOH/H_2O; 30−50 min, MeOH; 51−65 min, 6:4 MeOH/H_2O. Chromatographic peaks assigned to mPEG-aldehyde ($R_T = 14$ min) and mPEG-acid ($R_T = 10$−11 min) were verified by comparison with retention times determined for standard samples. The identities of the peaks assigned to CVEP ($R_T = 35.2 \pm 0.2$ min) and cholesterol ($R_T = 36.3$ min) were confirmed by comparing the NMR and mass spectra of lyophilized HPLC fractions with reference spectra.

Preparation of Liposomes. DOPE and EPC were purchased from Avanti Polar Lipids (Alabaster, AL) as either lyophilized powders or chloroform stock solutions. Calcein was purchased from Sigma (St Louis, MO). A 50 mM calcein stock solution was prepared in 20 mM HEPES buffered saline (HBS, 150 mM NaCl, pH 8.0) or 20 mM TRIS (150 mM NaCl, pH 7.4). Low pH hydrolysis was performed in 20 mM citrate buffered saline (CBS, 150 mM NaCl, pH 4.5) or 20 mM oxalate buffered saline (OBS, 150 mM NaCl, pH 2.0).

Liposomes were prepared by the thin film method. A chloroform solution of the desired lipids (5 μmol) was carefully evaporated under nitrogen flow, producing an even, thin film. The film was placed under a 50 μm Hg vacuum for at least 3 h to remove trace solvent impurities. This film was then hydrated in 1 mL 50 mM calcein buffer stock buffer solution via 10 freeze−thaw−vortex cycles. The resulting multilamellar liposome solution was then extruded ten times through two stacked 100 nm polycarbonate filters at 50−60 °C with ∼200−300 psi nitrogen. After extrusion, the extraliposomal calcein buffer was exchanged with either 150 mM NaCl or 20 mM HBS buffer via a 0.5 × 25 cm Sephadex G-50 column. This exchange process typically resulted in a 2- to 2.5-fold dilution of the liposome solution. The liposomes were always used immediately, but appeared stable for ∼1 week when stored at 4 °C (as monitored by calcein leakage and light scattering).

EPC sink liposomes were prepared in the same manner as other liposomes at a 10-fold higher concentration (100 mg/mL) in 0.9% NaCl. These liposomes appeared to be stable for at least 3 weeks when stored at 4 °C.

Calcein Release Assay. All solutions were equilibrated at 37 °C for 10 min prior to mixing. An aliquot of liposome stock solution (100 μL) was added to 1.3 mL of HBS, CBS, OBS, TRIS, or 20 mM FD-DMEM containing 10% heat-inactivated fetal calf serum and 0.5% penicillin/streptomycin. Then, 100 μL 150 mM NaCl or 100 μL of EPC stock liposomes (sink experiments) were added. This solution was maintained at 37 °C for the duration of the experiment. At each time point, 100 μL aliquots were removed and diluted with 2 mL HBS. The fluorescence ($\lambda_{ex} = 490$ nm, $\lambda_{em} = 518$ nm) was then measured before and after the addition of two drops of 10% Triton X-100 (solution gently shaken to ensure complete liposome disruption). The percent release was then quantified using the ratio method: % release $= 100 \times [(T - T_o)/(1 - T_o)]$, where T = Triton ratio = (fluorescence before Trition/fluorescence after Triton) at time T and T_o = Triton ratio at $T = 0$ min (*26*).

Cytoplasmic Delivery of Calcein. Folate-deficient KB cells were plated at 100 000 cells/well in 33 mm dishes with 2.0 mL of FD-DMEM. Two hundred microliters of 5:95:0.5 CVEP/DOPE/folate-PEG-DSPE (targeted) or 5:95 CVEP/DOPE (non-targeted) liposomes (5 μM total lipid containing 50 mM entrapped calcein) were incubated at 37 °C for 2 h, followed by three thorough washes with PBS buffer (-Mg^{2+}, -Ca^{2+}) to remove any unbound liposomes. Fresh FD-DMEM (2 mL) was added and the cells incubated for an additional 2 h before qualitative fluorescence microscopy analysis of localization and total cellular fluorescence intensity. Fluorescence micrographs were taken approximately 6 h after introduction of liposomes. Endosomal pH inhibition was achieved by preincubating the cells in FD-DMEM containing 50 mM chloroquine 30 min prior to addition of liposomes.

Quantitative evaluation of endosomal release of calcein was determined by flow cytometry. Media from the cell culture

dishes was removed and collected in 1.5 mL centrifuge tubes to ensure inclusion of all cells. Cell dissociation solution (100 μL) was added to the wells and incubated for 20 min. This fraction was then added to the collected media and centrifuged. An average of 5000 cells were then analyzed on a Coulter Epics XL flow cytometer using 488 nm excitation and 525 nm/620 nm emission filters.

Lipid Mixing Assay (*69*). NBD-PE (1%), Rh-PE (1%), and folate-PEG3350-DSPE (0.5%) were added to a benzene/methanol (95:5) solution of the CVEP/DOPE dispersion to be studied (5 μmol total lipid). The solution was vortexed thoroughly, frozen in liquid nitrogen, and then lyophilized overnight. The resulting lipid powder was hydrated with HEPES buffer, pH 7.4, and extruded as described above.

Cells were plated at 100 000 cells/well in Labtek 4-chambered coverslips that had been previously treated with fibronectin (4 μg/mL). KB cells were incubated for 2 h with 100 μL of the dual-labeled NBD-Rh liposome solution. Cells were then washed three times with liposome-free media, replenished with fresh media, and imaged at various intervals using a BioRad MRC 1024 laser confocal microscope (488 nm excitation). A 585 nm LP filter was used to collect the rhodamine fluorescence and a 535 nm filter was used to collect the NBD fluorescence.

Light Scattering. Liposome size was determined by quasi-elastic light scattering on a Coulter N4-Plus instrument and distributions calculated using the manufacturer's supplied software (version 1.1). Samples were prepared by diluting 25 μL liposome stock with 2 mL HBS. Experiments were run in triplicate and the size distributions averaged for these runs.

Transmission Electron Microscopy. Negatively stained EM samples were prepared with 1% $UO_2(OAc)_2$ using the post-staining method on Formvar-coated copper grids and analyzed using a Phillips TEM operating at 40 kV.

RESULTS AND DISCUSSION

Synthesis of CVEP (7). Initial attempts at the synthesis of CVEP via transformation of a cholesterol ester linkage to a vinyl ether linkage (*70*−*72*) in the presence of the PEG functionality proved unsuccessful. This outcome is likely due to the presence of water that is tightly bound by PEG (even after vacuum drying at 50 μm Hg in the presence of P_2O_5 for two days), which rapidly quenches the LDA reagent during the vinyl phosphate transformation. This approach was abandoned when it became clear that the same interference would occur during the subsequent $Et_3Al/Pd(PPh_3)_4$ reduction steps. Compounding this problem is the fact that the resulting product mixture would be too difficult to purify on a large scale because of the presence of the PEG moiety.

These problems prompted the development of a new synthetic route to CVEP (Figure 5) wherein the water-soluble polymer could be attached to the cholesterol membrane anchoring group during the final step, after installation of the vinyl ether functionality. In this strategy, the PEG headgroup and cholesterol lipid anchor are conjugated via a four-carbon, vinyl ether containing linker derived from 4-hydroxybutanoic acid. The three key advantages provided by this approach are as follows: (1) the PEG headgroup is added in the final step; (2) the Z-vinyl ether transformation step is easily accommodated; and (3) the route allows facile incorporation of a wide variety of alcohol-bearing lipid anchor substituents.

The CVEP synthesis sequence begins with the production of cholesteryl 4-*t*-butyldimethylsilyloxybutanate (*3*) from 1,4-butanediol in a three-step process. Monoprotection of 1,4-butanediol with *t*-butyldimethylsilyl chloride in THF afforded 4-*t*-butyldimethylsilyloxybutane-1-ol (*1*) in 97% yield after extraction of the excess 1,4-butanediol. The presence of the TBDMS ether necessitated the use of neutral oxidation conditions in the subsequent step. Initial attempts using pyridinium dichromate under neutral conditions were successful; however, yields were typically low and the purification difficult. Alternatively, alcohol **1** was readily converted in 78% yield to the corresponding carboxylic acid **2** via a two-phase potassium permanganate oxidation, mediated by tetraoctylammonium bromide as phase transfer catalyst. EDCI/DMAP-mediated coupling of acid **2** and cholesterol afforded **3** in 90% yield.[3]

The vinyl ether bond was then installed via a two-step ester reduction procedure. The kinetic enolate of ester **3** was *O*-trapped with diethylchlorophosphate in the presence of HMPA to afford a vinyl phosphate intermediate (*4*) in 81% yield after chromatographic purification. The normally facile $Et_3Al/Pd(PPh_3)_4$-mediated reduction of vinyl phosphates in hexane, however, failed to produce 4-*t*-butyldimethylsilyloxy-1-cholesteryloxy-1-butene (*5*); instead, a mixture of ester **3** and vinyl phosphate **4** was recovered. The use of CH_2Cl_2 as solvent provided vinyl ether **5** in 31% isolated yield, well below the 70+% yields typically observed for this transformation. Un-

[3]DCC/DMAP conditions were also employed to afford ester **3**; however, the use of EDCI is preferred since product isolation is easier when this dehydrating agent is employed.

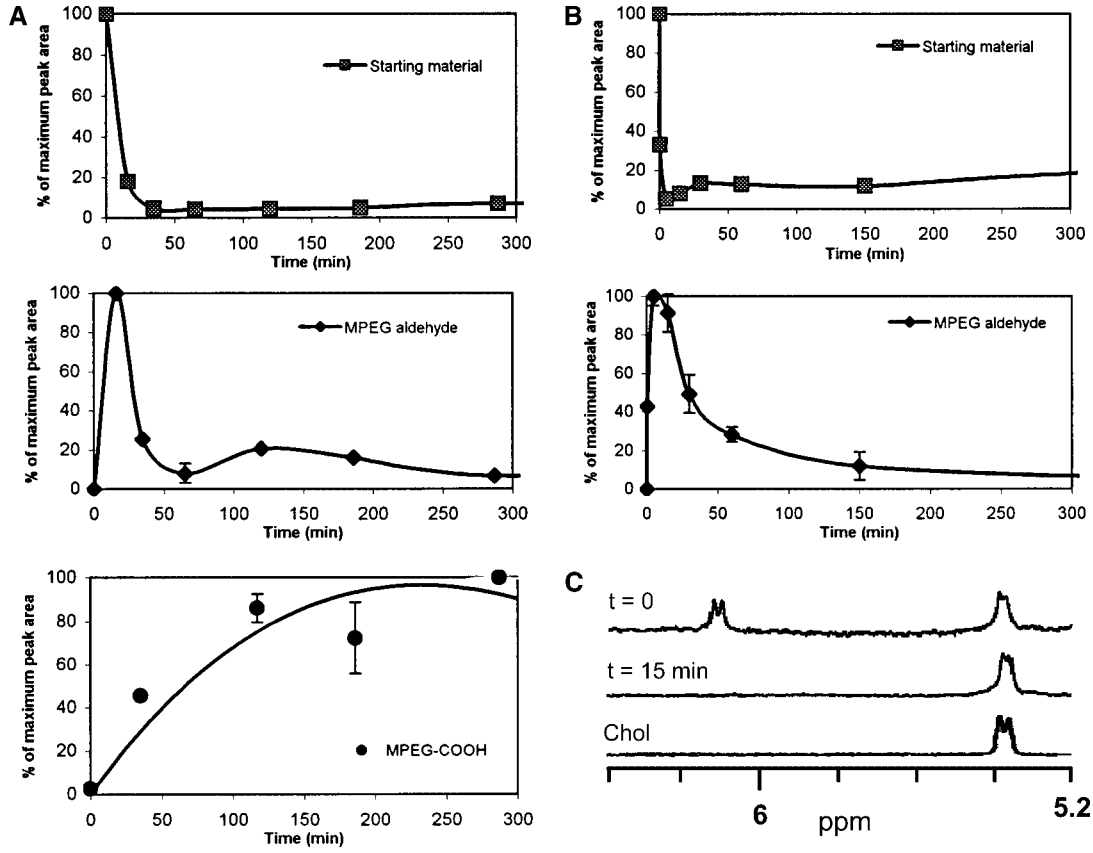

Figure 6. CVEP hydrolysis at 25 °C in acidic aqueous solution as detected by HPLC-ELSD (A,B) and ^{1}H NMR (C). A: CVEP hydrolysis kinetics at pH 1.0. Top: CVEP disappearance rate. Middle: mPEG-aldehyde appearance/disappearance rate. Bottom: mPEG-acid formation rate. B: CVEP hydrolysis kinetics at pH 3.0. Top: CVEP disappearance rate. Bottom: mPEG-aldehyde appearance/disappearance rate. C: NMR characterization of CVEP hydrolysis at pH 1.0. HPLC fractions eluting at $R_T = 32-37$ min were collected and lyophilized before NMR analysis. Top: CVEP before acid treatment, showing α-H vinyl ether signal (6.12 ppm) and cholesterol vinyl protons (5.38 ppm). Middle: Same CVEP sample after 15 min at pH 1.0. Bottom: Cholesterol standard.

fortunately, use of this more polar solvent produced scrambled vinyl ether stereochemistry (9:1 Z/E). Two other reduction methodologies, Li/NH_3/*t*-butanol and Bu_3SnH, were also attempted; however, these transformations either failed or regenerated ester **3**.

The final stages of CVEP synthesis involved deprotection of vinyl ether **5**, followed by esterification with ω-methoxy-poly(ethylene [112]glycol)-carboxymethyl (mPEG-acid). Desilylation of **5** with tetrabutylammonium fluoride afforded alcohol **6** in 95% overall yield. Addition of small amounts of tetrabutylammonium hydroxide (TBAH, 30% in water) significantly increased the reaction rate and ensured a basic solution, thereby preventing hydrolytic decomposition of the vinyl ether species (occasionally observed in its absence). Careful chromatographic separation of the E and Z stereoisomers of **6**, followed by a DCC/DMAP-mediated coupling reaction with mPEG-acid produced CVEP (*7*) in 86% yield.[4] The seven-step sequence in Figure 5 afforded the pure cis form of CVEP in 20% overall yield. All subsequent experiments utilized the pure Z CVEP isomer; however, no significant differences in release or hydrolysis rates were observed when 2:1 Z/E mixtures of CVEP were used.

CVEP Hydrolysis Kinetics. CVEP hydrolysis kinetics at 25 °C were determined via HPLC-ELSD by monitoring both the time-dependent disappearance of the CVEP peak ($R_T = 34-35$ min) at different pHs, as well as the appearance times of the degradation products mPEG-aldehyde, mPEG-acid, and cholesterol. Chromatographic peaks for CVEP and its hydrolysis products—cholesterol, mPEG-alcohol, and mPEG-acid—were verified by injection of known standards as well as by NMR and MS characterization of all collected fractions, except for mPEG-aldehyde (which used mPEG-alcohol as a retention time standard due to the rapid oxidation of this material to mPEG-acid). Under all conditions studied, decreasing CVEP peak areas were accompanied by proportional increases in the peak areas corresponding to mPEG-aldehyde, an intermediate product in the hydrolysis of CVEP (Figure 4). CVEP hydrolysis rates were very fast at pH 1 (Figure 6A), with less than 20% of CVEP remaining and maximal levels of mPEG-aldehyde and cholesterol existing after 15 min exposure. The disappearance rate for CVEP and the appearance rate for mPEG aldehyde were identical. As the reaction time increased, mPEG-acid slowly increased at the expense of both CVEP and mPEG-aldehyde, consistent with the reaction pathway shown in Figure 4. After 15 h reaction time, only two HPLC peaks were observed. ^{1}H NMR analysis of the material eluting between 32 and 37 min corresponded to cholesterol, whereas the lower R_T species ($R_T = 10-11$ min) was identified as mPEG-acid.

At pH 3 (Figure 6B), the rates for CVEP disappearance and mPEG-aldehyde appearance also occurred on similar time scales. Unlike the pH 1 experiments, however, the CVEP peak stopped decreasing in relative area after ~35 min and began to increase slightly with time. The peak for cholesterol also began decreasing at the same time as this apparent increase in CVEP concentration. We infer from these observations that a cholesterol−mPEG complex is formed at pH 3.0 (possibly the cholesterol−mPEG hemiacetal), which displays a similar reten-

[4]EDCI/DMAP coupling also provided CVEP, although the urea side product proved difficult to remove via the ether precipitation method.

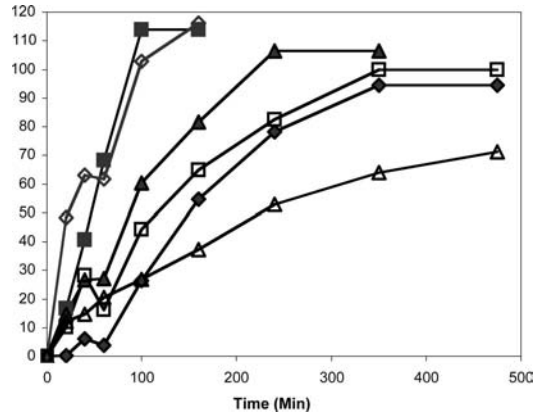

Figure 7. Calcein release kinetics at pH 2.0 as a function of CVEP molar ratio in extruded DOPE liposomes. CVEP/DOPE ratios: ■, 0.5:99.5; ◇, 1:99; ▲, 2:98; □, 3:97; ◆, 4:96; △, 5:95.

tion time to the CVEP starting material at 35.5 min. Physical mixtures of unmodified cholesterol and mPEG5000 at either pH 1 or 3 (control experiments) showed that only the CVEP sample treated at pH 3.0 produced a HPLC peak at this retention time. These observations support the hypothesis that mPEG−cholesterol complexation accounts for the peculiar increase in CVEP peak area at long reaction times at pH 3.0. The data in Figure 6C, showing loss of the vinyl ether α-proton resonance upon exposure to pH 1.0, provides further support of the reaction pathway proposed in Figure 4.

Acid-Triggered Content Release From CVEP/DOPE Liposomes. Liposomes were prepared via the thin film/extrusion method at CVEP/DOPE ratios ranging from 0.5:99.5 to 5:95. These liposomes were stable for approximately one week, except for the 0.5:99.5 dispersions where lipid aggregation was observed within 2 days. Liposomes prepared in this manner had diameters ranging between 150 and 220 nm as observed via light scattering analysis and electron microscopy.

Cargo release from CVEP/DOPE liposomes was examined using the calcein fluorescence dequenching assay. Calcein, encapsulated at self-quenching concentrations (50 mM), undergoes fluorescence dequenching as it leaks into the extraliposomal solution, producing an increase in calcein fluorescence at 520 nm. The calcein release percentage at each time point was then calculated using the ratio method (*26*). Figure 7 shows the calcein release rates from liposomes composed of different CVEP/DOPE ratios that were incubated at pH 2.0 and 37 °C. These data show that increased CVEP molar ratios in the CVEP/DOPE liposomal membrane caused a reduction in the observed acid-triggered calcein release rate. We conclude from these results that a critical concentration of CVEP is required to maintain a lamellar phase of DOPE, such that release rates are governed by the extent of displacement from that concentration. In other words, since the rate of CVEP hydrolysis is constant at a given temperature and pH, the rate of content release is controlled by the amount of CVEP present in the DOPE membrane above the minimal amount required to form a stable lamellar phase. Consequently, when the CVEP content is low, acid-catalyzed degradation of CVEP quickly reaches this critical concentration to produce a rapid release rate. As the CVEP concentration increases, however, more time is required for CVEP hydrolysis to reach this critical point such that slower content release rates are observed. Comparison of the $t_{50\%\ release}$ values for the 0.5−5% loadings revealed an approximately 15-fold decrease in leakage rates as the CVEP ratio increased, suggesting that content release rates scale in a roughly linear fashion with PEG loadings over this range. The small observed differences in release rates observed for 0.5:99.5 and 1:99 CVEP/DOPE formulations suggest that liposome formulations containing such low molar ratios may already be near the critical lamellar−hexagonal II ($L_\alpha-H_{II}$) phase boundary.

Content release rates from CVEP/DOPE liposomes were also examined at pH 4.5, a value that has been reported for late endosomal compartments within KB cells (*73*). The observed rates for 1%, 3%, and 5% CVEP loadings are shown in Figure 8A, B,C, respectively. The content release rates of pure CVEP/DOPE dispersions at pH 4.5 were surprisingly slow, typically only ∼5−10% higher than that observed at pH 7.4 and reaching a maximum of ≤25% after 24 h, regardless of the CVEP loading. We attempted to improve the acid-triggered release rates of these CVEP/DOPE dispersions by adding a second population of "sink" egg phosphatidylcholine (EPC) liposomes at a 25-fold molar excess, since Holland et al. have previously demonstrated that DOPE liposome dePEGylation could be enhanced by addition of a sink EPC liposome population into which their PEG−lipid conjugates could exchange from the host DOPE membrane (*53, 54*). Inclusion of sink liposomes in our CVEP/DOPE system was expected to increase the rate of content release at both pH 4.5 and 7.4 due to a similar PEG−lipid exchange process[5], however, substantial increases in release rate were only observed at pH 4.5 (i.e., sink liposome-induced increases were modest at pH 7.4—typically only 5−10% over a 24 h period). In the 1:99 CVEP/DOPE case (Figure 8A), the combination of pH 4.5 and sink liposomes produced 100% content release within 550 min, an ∼80% increase over the pH 4.5 alone and pH 7.4 + sink liposome cases. The overall magnitude of the sink liposome effect, however, was much less pronounced at the 3% and 5% loading levels, yet ≥70% release occurred over a 24 h period. Taken together, the pH 4.5 results are generally consistent with the observations made at pH 2.0—i.e., that increased CVEP loading leads to slower release kinetics from CVEP/DOPE dispersions. We can further infer from these results that contact between the CVEP/DOPE and sink EPC liposomal membranes promotes PEG adsorption to the polymer-free surface. If this occurs with EPC and hydrolyzed CVEP/DOPE liposomes, a net exchange of PEG onto the sink liposome surface can result, giving rise to an accelerated $L_\alpha-H_{II}$ transition and content leakage response. An alternative explanation is that PEG adsorption onto sink EPC during EPC-CVEP/DOPE contact simply improves the proton accessibility to the CVEP vinyl ether linkage, either by rehydrating the interface (due to a net reduction in the local oxoethylene monomer concentration at the CVEP/DOPE surface) or by physically displacing the cleavable site toward the bulk aqueous environment. Although additional experiments are necessary to clarify this issue, we favor the PEG desorption interpretation as the most likely pathway in this system.

Electron Microscopy of CVEP/DOPE Liposomes Before and After Acidification. Negatively stained electron microscopy images collected before and after treatment of a 8:92 CVEP/DOPE dispersion at pH 4.5 for 24 h revealed a transformation from vesicular structures with average diameters of ∼150 nm (Figure 9A) to electron-dense lipidic material indicative of hexagonal II phase lipid with periodic features of 3.6 nm repeat distances (Figure 9B). Transformation of vesicular structures at pH 8 into aggregated and electron opaque objects after acidification to pH 4 was observed for 8:92 CVEP/DOPE dispersions. The collapsed vesicle structures were similar to the

[5]DePEGylation induced by sink liposomes is believed to proceed via collision-mediated surfactant exchange of PEG−lipid conjugate from the host DOPE liposome membrane to the sink membrane pool. PEG−lipid exchange via the bulk aqueous phase, however, may also occur when the PEG substituents are large such that they tip the hydrophilic−lipophilic balance toward increased water solubility.

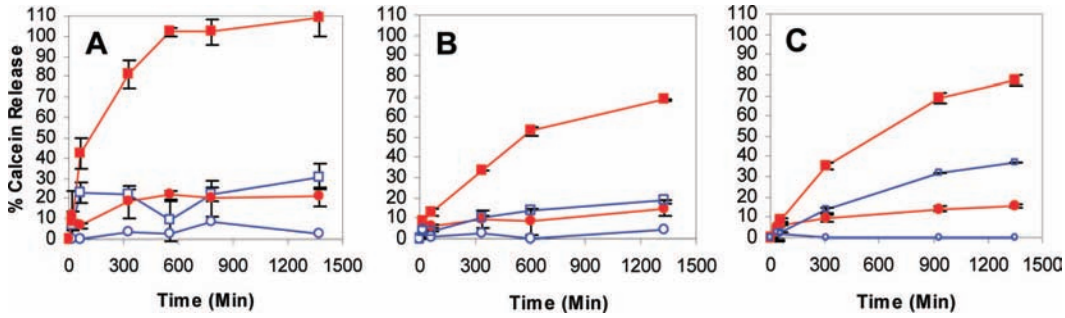

Figure 8. Calcein release kinetics at pH 4.5 as a function of CVEP loading and sink EPC liposomes. red ●, pH 4.5; red ■, pH 4.5 with sink EPC; ○, pH 7.4; □, with sink EPC. A, 1:99 CVEP/DOPE; B, 3:97 CVEP/DOPE; C, 5:95 CVEP/DOPE.

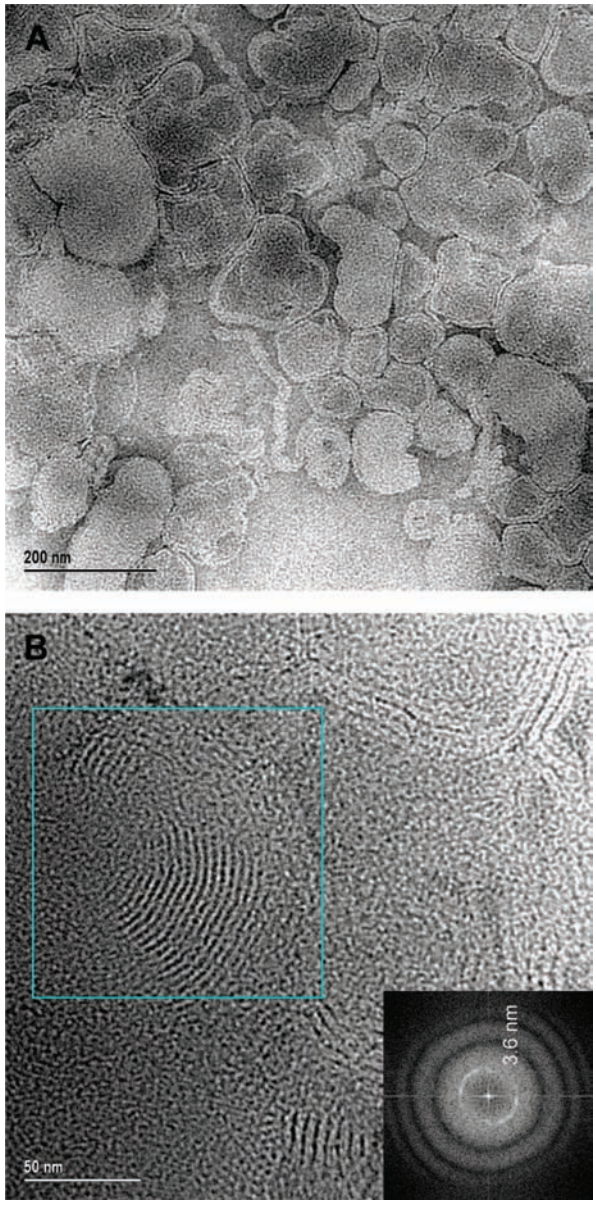

Figure 9. Negatively stained electron micrographs of CVEP/DOPE dispersions before (left) and after (right) 12 h exposure at pH 4.5. Samples were imaged with a FEI Tecnai F20 TEM operating at 4.5 kV using energy filtered detection for bright-field and selected area diffraction analysis.

hexagonal-phase structures previously observed in acidified BVEP/DOPE (*27*) and DHCVEP/DOPE (*28*) phases. These observations support the involvement of the acid-triggered $L_\alpha-H_{II}$ phase transition in this system.

Behavior of 1:9 CVEP/DOPE Monolayers Before and After Acidification. Langmuir monolayer hysteresis experiments were performed at pH 7 and 3.5 on 1:9 CVEP/DOPE monolayers to gain further insight into the adsorption behavior of PEG onto DOPE interfaces. As the pH 7 data in Figure 10A show, the presence of PEG introduces a weakly positive surface pressure at large molecular areas relative to 1:9 chol/DOPE (used as a model of a fully hydrolyzed 1:9 CVEP/DOPE monolayer) as has been shown for PEG adsorbed to DPPC monolayers (*74*). Upon further compression of the monolayers, the CVEP/DOPE isotherm is displaced by the same increment in molecular area at any given surface pressure due to the presence of the PEG headgroups at the interface. When the surface pressure is relaxed, the monolayer films re-expand with no apparent hysteresis. We infer from these findings that the neighboring PEG units in CVEP/DOPE monolayers interact with one another in the so-called mushroom regime (*75*) to produce a modest increase in surface pressure. The absence of hysteresis during surface pressure relaxation suggests, however, that there is little interaction between the PEG chains at low areal densities and the DOPE monolayer under these conditions.

CVEP/DOPE monolayers display substantially different behavior at pH 3.7 (Figure 10B). At large molecular areas, the CVEP/DOPE monolayers display low surface pressure as they did at pH 7, but unlike the pH 7 case, the isotherm is gradually displaced toward the chol/DOPE isotherm at small molecular areas. Most significantly, however, is the hysteretic behavior of the film upon re-expansion—essentially retracing the chol/DOPE film out to large molecular areas. Furthermore, the initially low surface pressure upon re-expansion to 150 $Å^2$/molecule was found to gradually increase to ~10 mN/m over a 10 min period. Since PEG hydrolysis occurs rapidly at this pH, we conclude from these observations that the hydrolyzed PEG remains adsorbed to the chol/DOPE surface until high surface pressures are applied (Figure 10C), when it is then "squeezed" out of the interface as has been reported for Poloxamers in DPPC and DPPG monolayers (*76*). Although the surface pressure in CVEP/DOPE liposomes is not known, the implications of these observations are that PEG adsorption to the hydrolyzed CVEP/DOPE liposome interface is the primary inhibition toward rapid cargo release and membrane fusion via inhibition of membrane−membrane contact. It also suggests a reason that sink liposomes are needed to exchange the adsorbed PEG from the hydrolyzed CVEP/DOPE liposome surface to another (sink) membrane surface so that $L_\alpha-H_{II}$ phase transition and membrane−membrane contact can occur for content leakage and membrane fusion, respectively.

Cytoplasmic Delivery of Calcein to Folate-Deficient KB Cells. We next explored whether KB cells produced endosomes that were sufficiently acidic for triggering the $L_\alpha-H_{II}$ phase transition of internalized CVEP/DOPE liposomes. Our hypothesis was that folate-targeted CVEP/DOPE liposomes could exploit the receptor-mediated endocytosis pathway to deliver

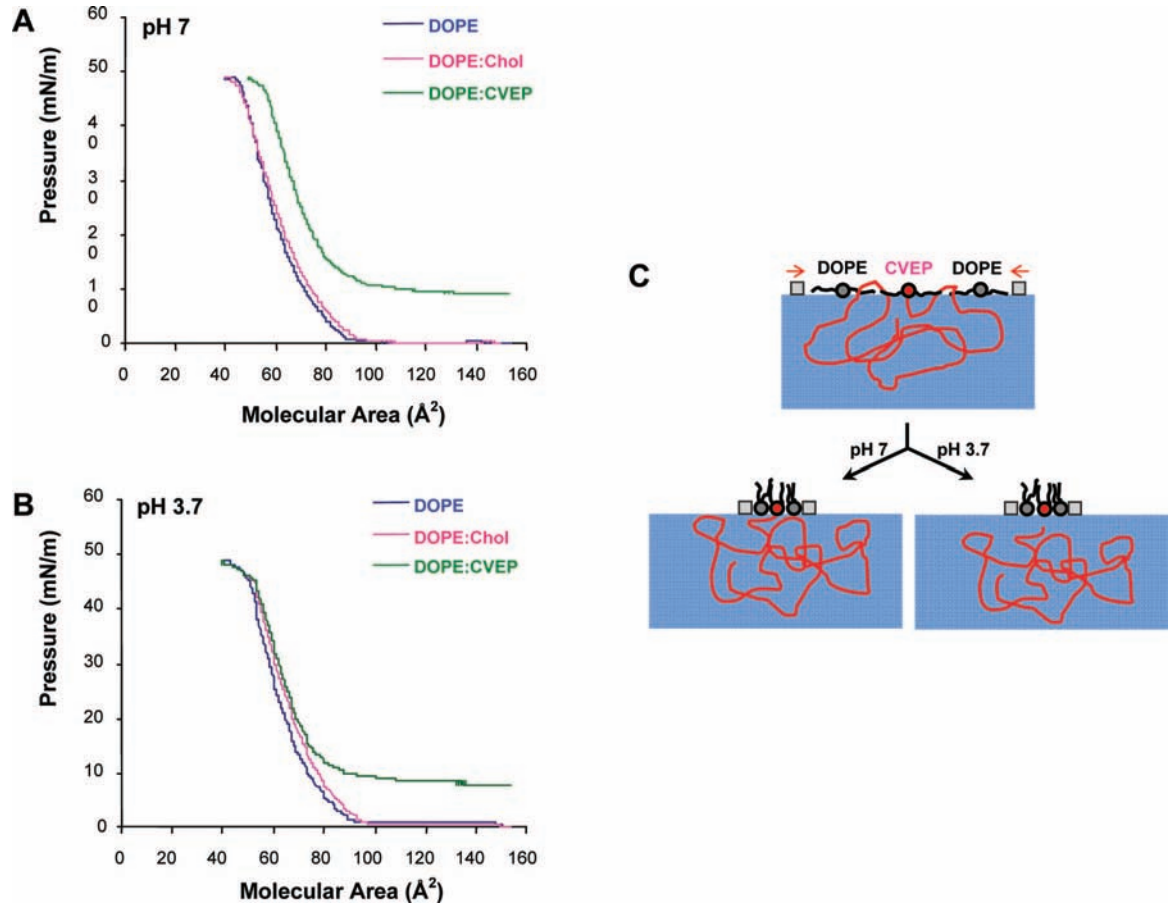

Figure 10. Compression cycles of DOPE, 1:9 chol/DOPE, and 1:9 CVEP/DOPE monolayers. A, pH 7.0; B, pH 3.7; C, Conceptual model showing that PEG is displaced from the chol/DOPE surface at high surface pressure in pH 3.7 solution (where CVEP is rapidly hydrolyzed), but remains adsorbed at low surface pressure and/or when CVEP is intact (pH 7.0). See text for experimental details.

their cargo directly to the cytoplasm via acid-triggered dePEGylation and liposome−endosomal membrane fusion (i.e., Figure 1, steps a, d, and e). It was first necessary to probe the stability of CVEP/DOPE liposomes in KB cell growth media by incubating them at 37 °C in either FD-DMEM (folate-deficient Dublecco's modified Eagle media) or pH 7.4 TRIS buffer (control). Even though the release kinetics of 0.5:99.5 CVEP/DOPE formulations were the most favorable in cell free suspensions, these low CVEP loadings produced liposomes that were too unstable in serum for in vitro experimentation. We found that 5:95 CVEP/DOPE liposomes were stable in serum, releasing less than 20% of their calcein payload over 24 h, most of which occurred within the first hour. This formulation was used for all subsequent cell culture experiments.

The cytoplasmic distribution of calcein within KB cells under various conditions is shown in Figure 11. In these experiments, the cells were incubated for 2 h with media containing liposomes, washed thoroughly to remove all extracellular liposomes, then incubated for an additional 2 h in liposome free media prior to examination via fluorescence microscopy. Bright field images are shown on the left and the corresponding fluorescence images on the right. Without folate targeting (Figure 11A,D), very low levels of fluorescence were visible. Since KB cells are known to accumulate materials via nonspecific pathways, the low levels of fluorescence observed in these experiments were likely the result of either autofluorescence or nonselective uptake of calcein-loaded liposomes from the media. Incorporation of 0.5 mol % folate−PEG−DSPE conjugate as a targeting agent within the 5:95 CVEP/DOPE formulation, however, produced a large increase in cellular fluorescence that appeared diffuse, indicative of cytoplasmic calcein delivery of calcein (Figure 11B,E). KB cells pretreated for 30 min with chloroquine, an inhibitor of endosomal acidification, exhibited strong punctate fluorescence and significantly reduced cytoplasmic staining, indicative of endosomal trapping (Figure 11C,F). This suggests that inhibition of acidification reduces the capacity for endosomal escape by blocking the acid-catalyzed dePEGylation reaction. Flow cytometric analysis of these cultures showed a nearly 40-fold increase in average calcein fluorescence when KB cells were incubated with 0.5:5:95 folate−PEG−DSPE/CVEP/DOPE//calcein compared to 5:95 CVEP/DOPE//calcein (nontargeted) controls, indicating that the calcein cargo is efficiently released from CVEP/DOPE liposomes that have been targeted to acidic endosomes (Supporting Information). Coincubation of KB cells with 0.5:5:95 folate−PEG−DSPE/CVEP/DOPE//calcein and excess folic acid (i.e., folate blockade with 2 μM folic acid) reduced the cell-associated calcein fluorescence by more than an order of magnitude. These observations are generally consistent with the findings of Baba et al. (*77*) who have reported that clathrin-dependent and clathrin-independent endocytosis are not appreciably affected by the presence of $<10\%$ surface coverage of nondegradable cholesterol-PEG2200, although internalization is affected at higher ($>20\%$) chol-PEG concentrations in the plasma membrane.

Attempts to identify the mechanism of cytoplasmic delivery via FRET dequenching experiments were inconclusive. Incubation of KB cells with folate-targeted 5:95 CVEP/DOPE liposomes containing 1% each Rh-PE and NBD-PE produced cells that exhibited signs of both Rh and NBD fluorescence, suggesting that some liposomes had undergone significant

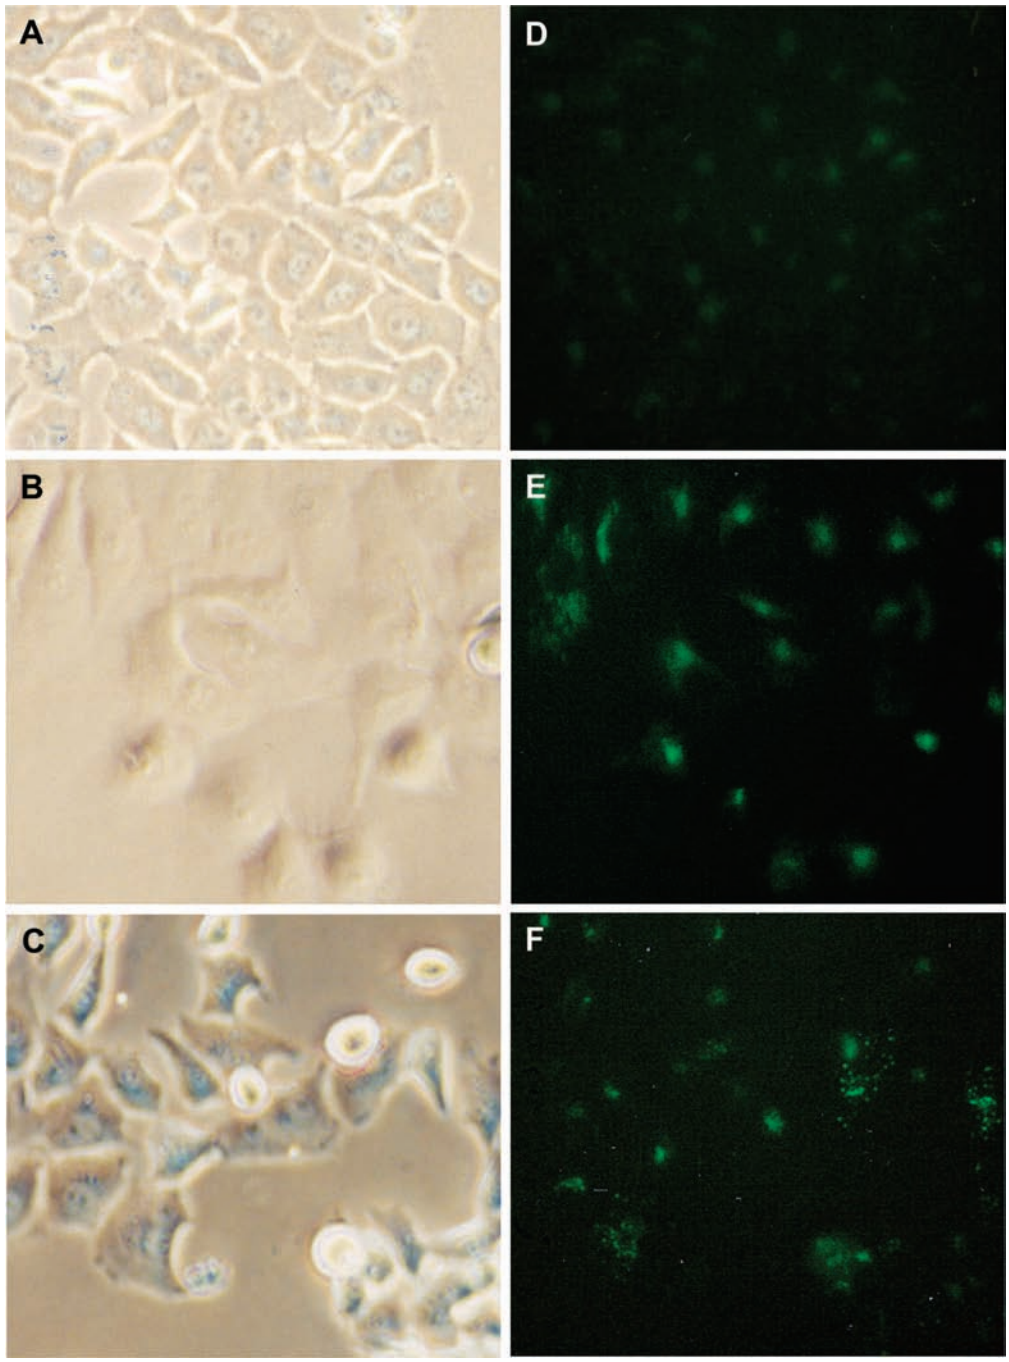

Figure 11. Phase contrast (A,B,C) and fluorescence (D,E,F) micrographs of KB cells treated for 2 h at 37 °C with 5:95 CVEP/DOPE (A,D), 0.5:5:95 folate−PEG−DSPE/CVEP/DOPE (B,E), and 0.5:5:95 folate−PEG−DSPE/CVEP/DOPE with chloroquine inhibition (C,F), rinsed, and incubated with liposome-free media for 2 h prior to imaging. The fluorescence apparent in panel D is due to nonselective uptake of calcein-loaded liposomes from the media.

demixing of the FRET probes, presumably via liposome−endosome membrane fusion, while Rh fluorescence was still observed in other regions, suggesting that the probes were still intimately mixed and engaged in FRET. Whether the latter case is the result of fusion inhibition by adsorbed PEG on hydrolyzed CVEP/DOPE liposomes or their incomplete hydrolysis/dePEGylation due to the presence of modestly acidic and/or early endosomes is not clear at this time. No obvious signs of cellular toxicity were observed in these experiments. Taken together, these results suggest that the combination of endosomal-targeting and acid-triggered content release represents a viable route for the cytoplasmic delivery of liposomal contents to KB cells, with the possible involvement of liposome−endosome membrane fusion as the mode of delivery to the cytosol.

CONCLUSIONS

An acid-labile lipid for triggering fusogenic liposome deP-EGylation has been synthesized and tested in solution and cell culture assays. The synthetic route developed for CVEP is readily amenable to a wide variety of alcohol-containing lipid anchor modifications as well as to varied PEG chain lengths and architectures. This cleavable PEG lipid was designed to increase the rate of contents release by requiring only a single vinyl ether cleavage event. The observed release kinetics in solution-phase experiments, however, were significantly slower

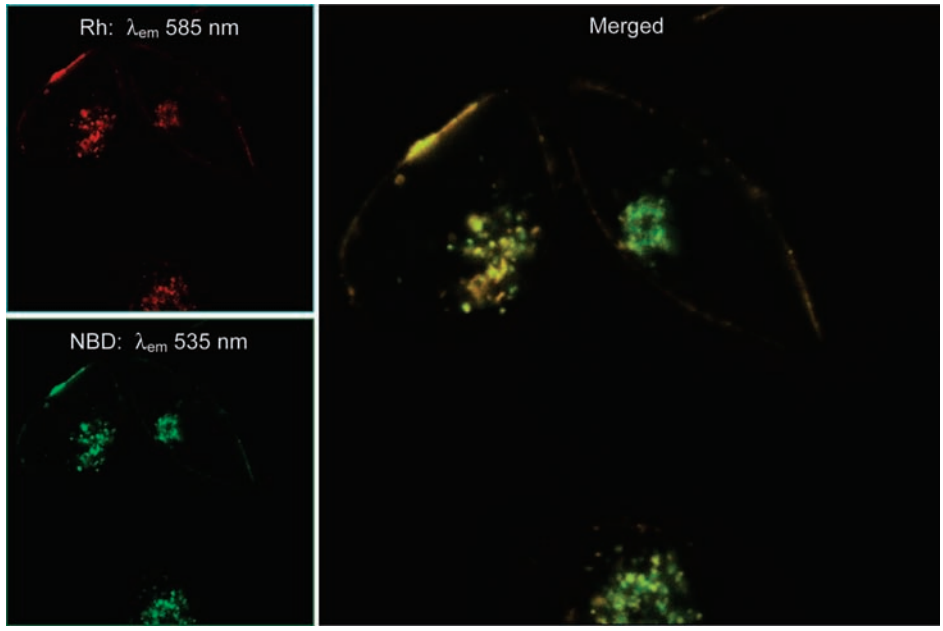

Figure 12. Confocal microscope images of KB cells treated as in Figure 11 with 0.5:5:95 folate−PEG−DSPE/CVEP/DOPE liposomes containing 1% Rh-PE and 1% NBD-PE. λ_{ex} = 488 nm; λ_{em}(Rh) = 585 nm; λ_{em}(NBD) = 535 nm. The areas of yellow fluorescence in the merged image to the right indicate cellular regions where both Rh and NBD fluorescence are apparent.

than those of the previously reported PEG lipid, BVEP. This suggests the possibility that the liposome structure and interactions between DOPE and CVEP (or its hydrolysis products) are such that the lamellar phase of DOPE is stabilized relative to BVEP/DOPE.

The inclusion of a second population of "sink" liposomes was found to substantially increase release from CVEP/DOPE liposomes at pH 4.5 without inducing significant leakage at pH 7.4. On the basis of monolayer experiments, we propose that the role of the sink liposomes is to provide a polymer-free interface which facilitates PEG desorption from the DOPE liposome surface via exchange. Since the endosomal membrane may be conceptually viewed as a large sink liposome, the necessity for sink liposomes in vitro was not expected to diminish the ability of these liposomes to elicit cytoplasmic delivery. In fact, CVEP/DOPE liposomes targeted to KB cells exhibited significant cytoplasmic delivery of calcein as evidenced by diffuse cellular fluorescence. Neutralization of the endosomal pH with chloroquine also produced strong, punctate fluorescence, indicative of endosomal trapping of the calcein that is retained by unhydrolyzed CVEP/DOPE liposomes. This result also suggests that exchange of unhydrolyzed CVEP into endosomal membranes must be kinetically slower than the rate of CVEP hydrolysis and PEG desorption. Without targeting, only small amounts of diffuse cellular fluorescence were observed due to nonspecific cellular uptake processes. In summary, the dePEGylative triggering strategy appears to be a promising route for the site-specific cytoplasmic delivery of liposomal contents.

ACKNOWLEDGMENT

J. A. Boomer synthesized CVEP and characterized the release properties of CVEP/DOPE liposomes. R. H. Haynes assisted with the CVEP synthesis and release experiments. M. M. Qualls characterized the CVEP/DOPE release properties in cell culture and performed the lipid mixing experiments. D. H. Inerowicz monitored the CVEP hydrolysis kinetics by HPLC, NMR, and MS. V. Srilakshmi Patri performed the flow cytometry experiments. J.-M. Kim performed the negative stain electron microscopy and the monolayer film balance experiments. The authors wish to acknowledge Dr. Oleg Gerasimov for his scientific contributions to the design of this system. The authors also thank Prof. J. Paul Robinson for his guidance with the confocal microscopy and flow cytometry experiments and the Purdue Cancer Center Analytical Cytology, NMR and MS Core Facilities for their support. This work was supported by NIH GM55266.

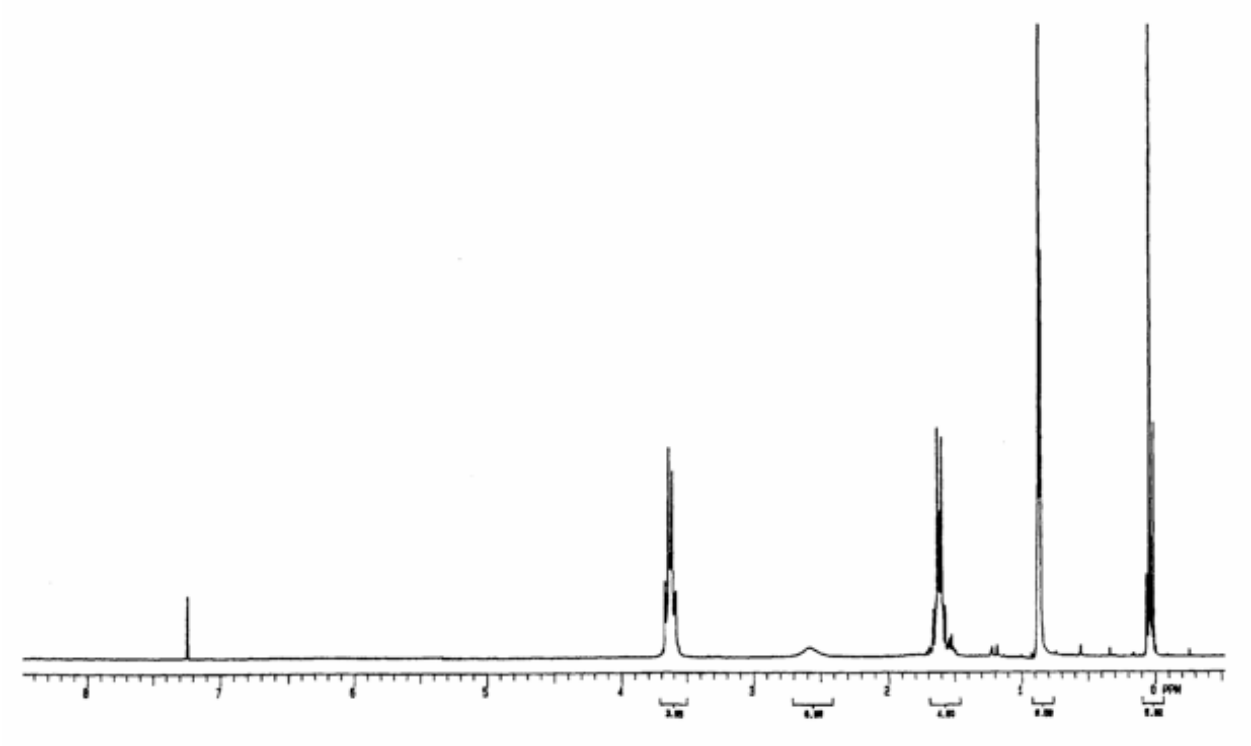
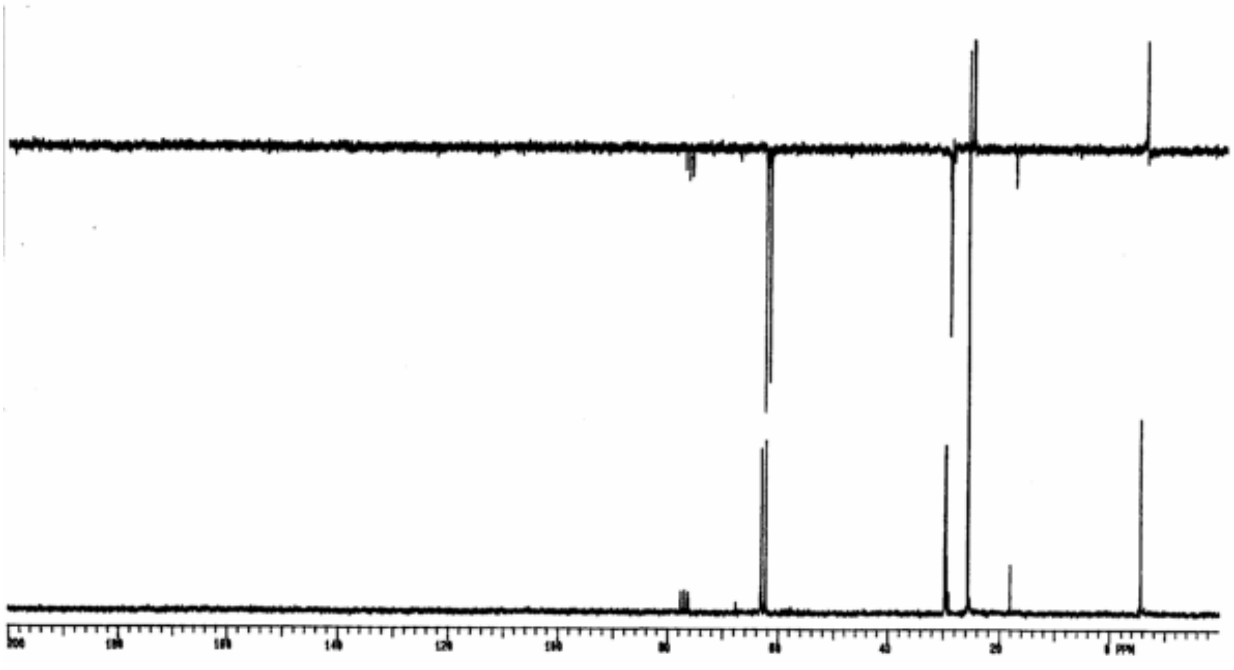
SYNTHESIS OFCVEP (7).

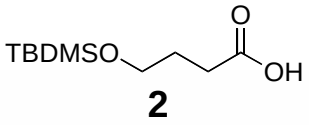
4-*t*-BUTYLDIMETHYLSILYLOXYBUTAN-1-OL (1). *t*-Butyldimethylsilyl chloride (8.65 g, 57.4 mmol) in dry THF (25 mL) was added dropwise to a solution of 1, 4-butanediol (22.0 g, 244 mmol; dried 2 h *in vacuo*) and imidazole (5.1 g, 70.5 mmol) in THF (100 mL) at 0 °C over a ~20 min period (turned cloudy after 10 min). The reaction was stirred for 1 h, warmed to room temperature, and ether (300 mL) added. The solution was then washed with saturated NH_4Cl (2 x 200 mL) and saturated NaCl (1 x 200 mL). The ether layer was dried over $MgSO_4$, filtered, evaporated and dried *in vacuo* yielding a pale yellow oil (11.4 g, 97% yield). NMR analysis indicated that the product was sufficiently pure to utilize in the ensuing step without additional purification. TLC (4:1 hexane:ether, $KMnO_4$): R_f = 0.35. ^{1}H-NMR ($CDCl_3$): 0.05 (s, 6H), 0.85 (s, 9H), 1.60 (m, 4H), 2.60 (bs, 1H), 3.65 (q, 4H). ^{13}C-NMR/APT ($CDCl_3$): -5.54 (O), 18.15 (E), 25.76 (O), 29.60 (E), 29.79 (E), 62.33 (E), 63.18 (E).

1

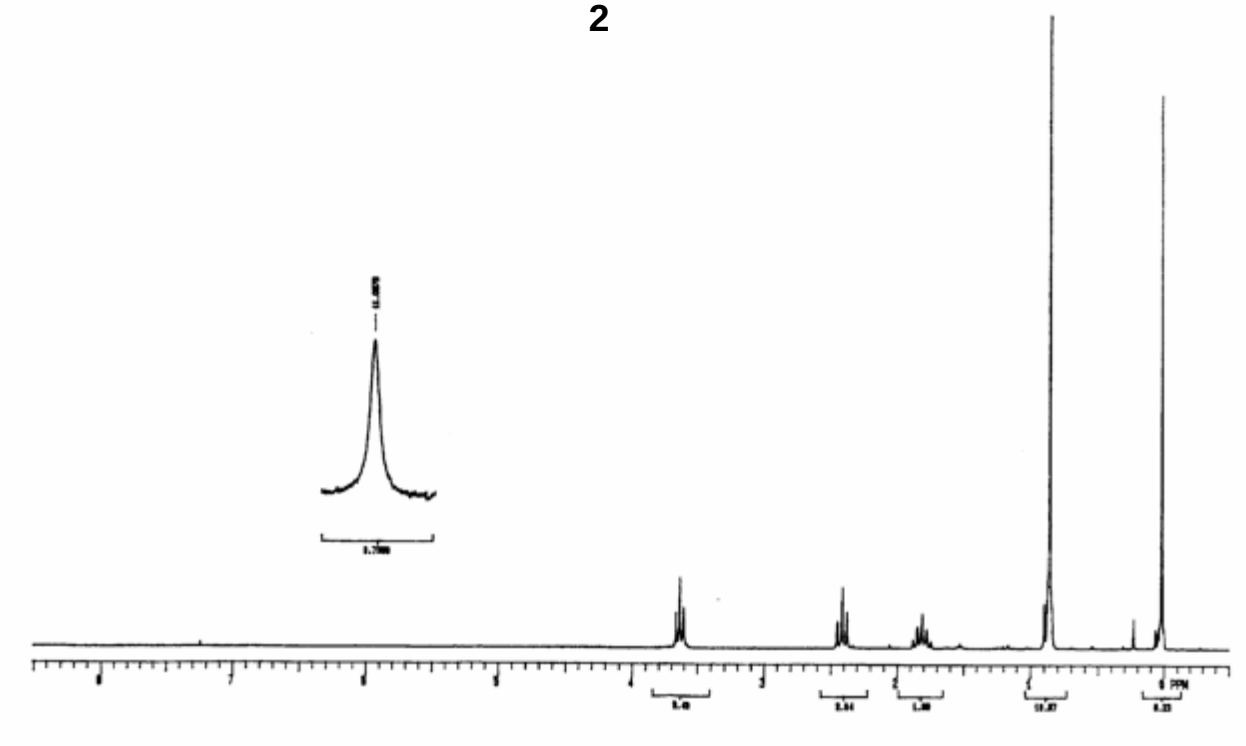


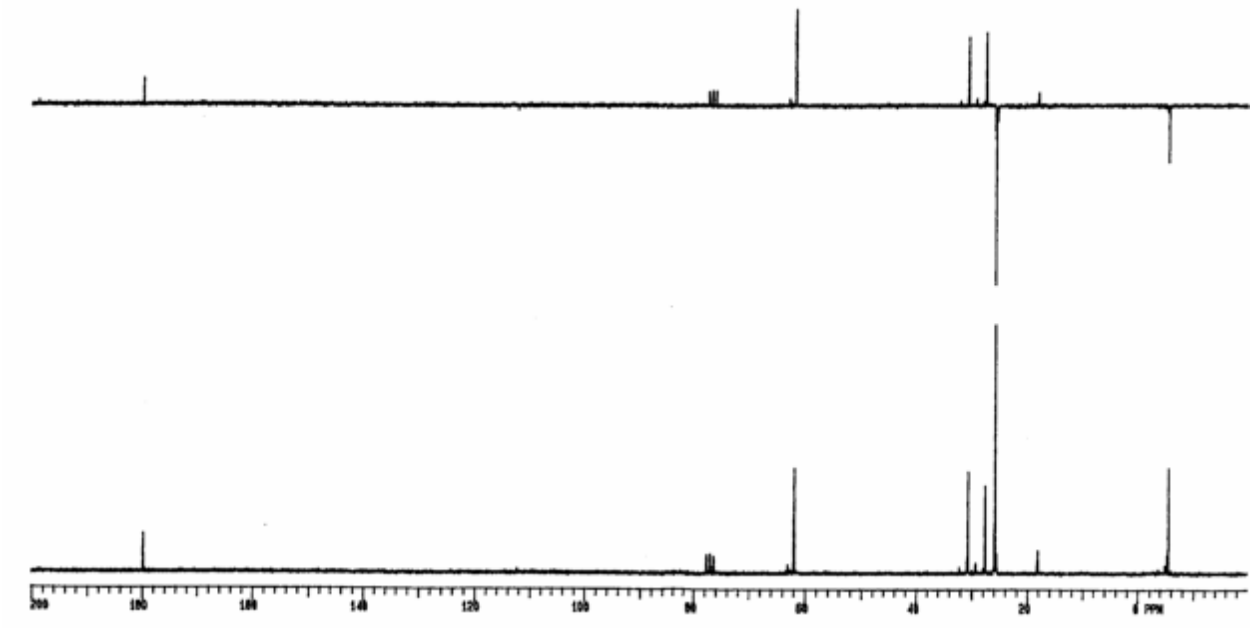


4-*t*-BUTYLDIMETHYLSILYLOXYBUTANOIC ACID (2). $KMnO_4$ (3.2 g, 20.0 mmol) was dissolved in water (50 mL), stirred vigorously for 10 min, then cooled to 0 °C. A solution of 4-*t*-butyldimethylsilyloxybutan-1-ol (**1**, 1.98 g, 9.7 mmol) and tetraoctylammonium bromide (TOAB, 812 mg, 1.5 mmol) in benzene (40 mL) was added dropwise via addition funnel over a ~20 min period. The solution was then warmed to room temperature and stirred for 3 h. The remaining $KMnO_4$ was quenched with $NaHSO_3$, producing a two-phase mixture with a colorless organic layer. Benzene (20 mL) and 50% CH_3CO_2H (50 mL) were added and the mixture extracted. The benzene layer was then washed with saturated NaCl (50 mL), dried over $MgSO_4$, filtered, evaporated, and dried *in vacuo*. The remaining TOAB was removed via elution through a small silica plug using 2:1 hexane:ether as the mobile phase. The solvent was evaporated and the sample dried *in vacuo* giving a colorless oil (1.65 g, 78% yield). TLC (1:1 hexane:ether, Bromphenol blue): R_f = 0.65. ^{1}H-NMR ($CDCl_3$): 0.05 (s, 6H), 0.85 (s, 9H), 1.83 (p, *J* = 7 Hz, 2H), 2.44 (t, *J* = 7 Hz, 2H), 3.65 (t, *J* = 7 Hz, 2H), 11.09 (bs, 1H). ^{13}C-NMR/APT ($CDCl_3$): -5.47 (O), 18.24 (E), 25.85 (O), 27.57 (E), 30.71 (E), 61.95 (E), 179.96 (E).

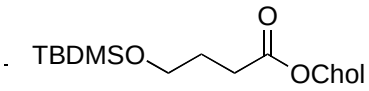


2

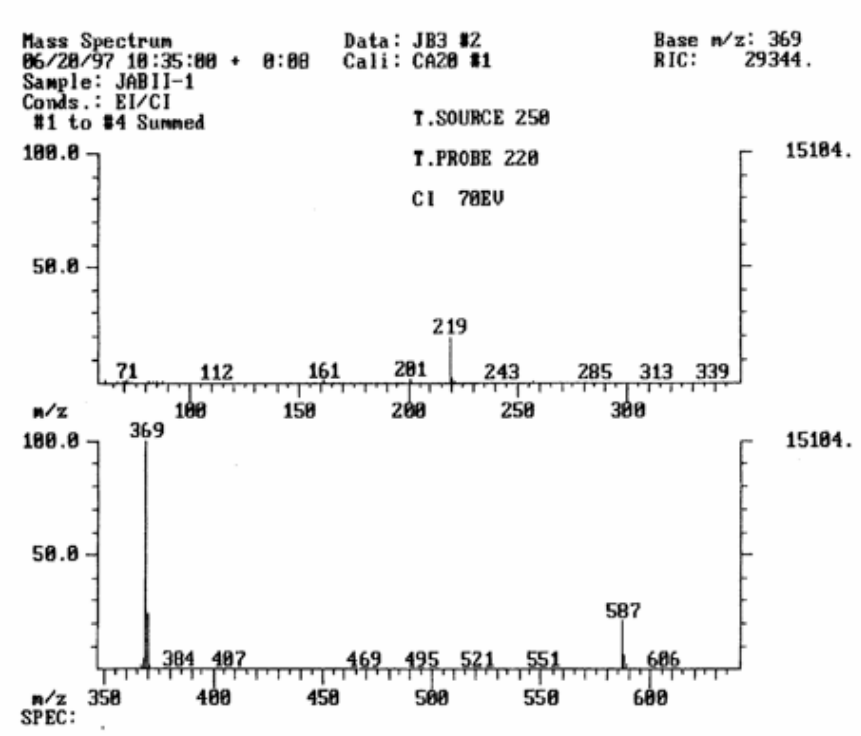


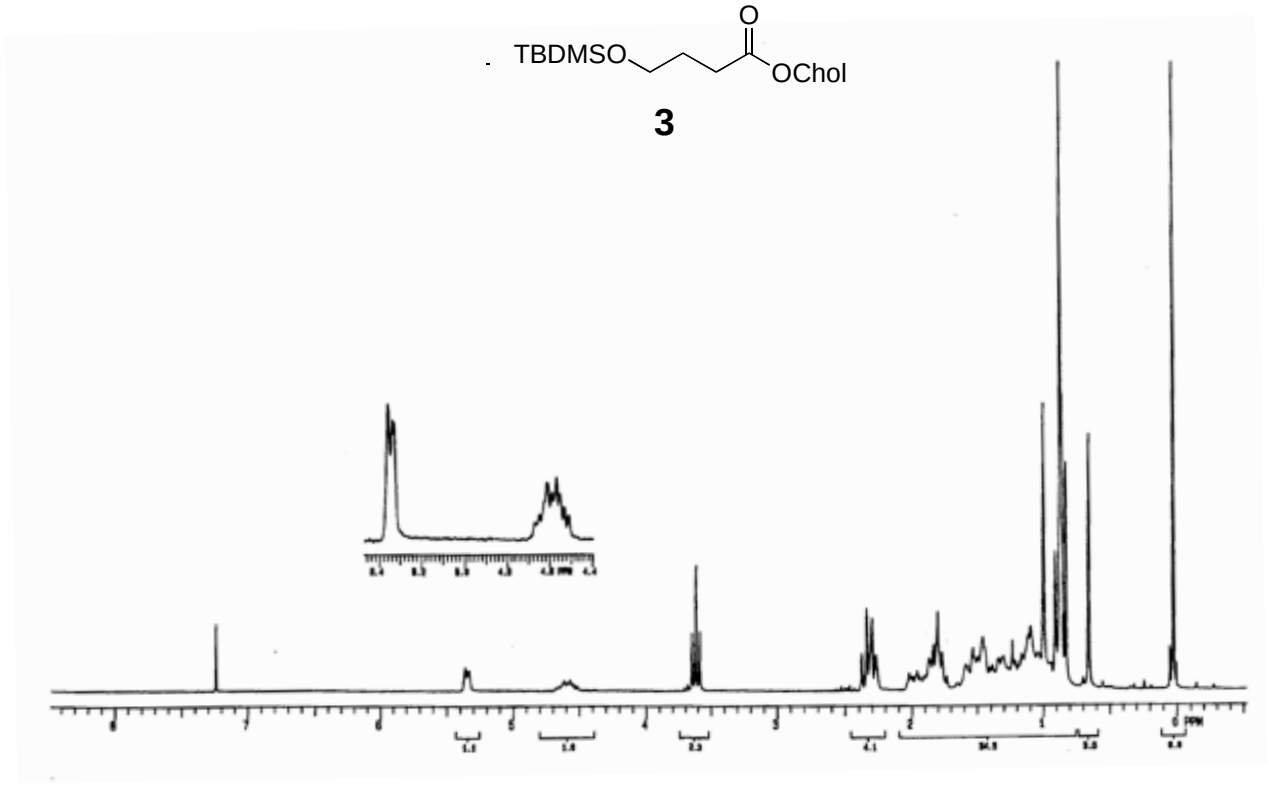


CHOLESTEROL 4-*t*-BUTYLDIMETHYLSILYLOXYBUTANOATE (3). Cholesterol (609 mg, 1.58 mmol), 4-*t*-butyldimethylsilyloxy butanoic acid (**2**, 325 mg, 1.49 mmol), and DMAP (20 mg, 0.14 mmol) were dissolved in CH_2Cl_2 (15 mL) and the solution cooled to 0 °C. Ethyldimethylaminopropylcarbodiimide (EDCI, 284 mg, 1.49 mmol) was added, the mixture warmed to room temperature, and stirred for 10 d. The reaction mixture was poured into H_2O (75 mL) and extracted with CH_2Cl_2 (3 x 75 mL). The combined CH_2Cl_2 layers were dried over $MgSO_4$, filtered, evaporated, and dried *in vacuo.* The crude product was purified via chromatography (230-400 mesh silica, 9:1 hexane:ether, 1.5 cm diameter x 5 cm height). A white solid (780 mg, 90% yield) was recovered. TLC (2:1 hexane:ether, acid char): R_f = 0.52. MP: 133-135 °C. ^{1}H-NMR ($CDCl_3$): 0.05 (s, 6H), 0.65 (s, 3H), 0.8-2.05 (m, 49H), 2.25-2.4 (m, 4H), 3.65 (t, *J* = 7 Hz, 2H), 4.6 (m, 1H), 5.35 (d, *J* = 5 Hz, 1H). ^{13}C-NMR ($CDCl_3$): -4.8, 12.4, 18.8, 19.1, 19.3, 19.7, 19.9, 21.5, 23.0, 23.1, 23.2, 23.3, 24.3, 24.8, 26.4, 26.5, 28.3, 28.5, 28.7, 31.5, 32.4, 36.3, 36.7, 37.1, 37.5, 38.6, 40.0, 40.2, 40.3, 42.8, 50.5, 56.6, 57.2, 62.5, 123.1, 140.2, 173.5. MS (CI): m/z = 587 (M+H).

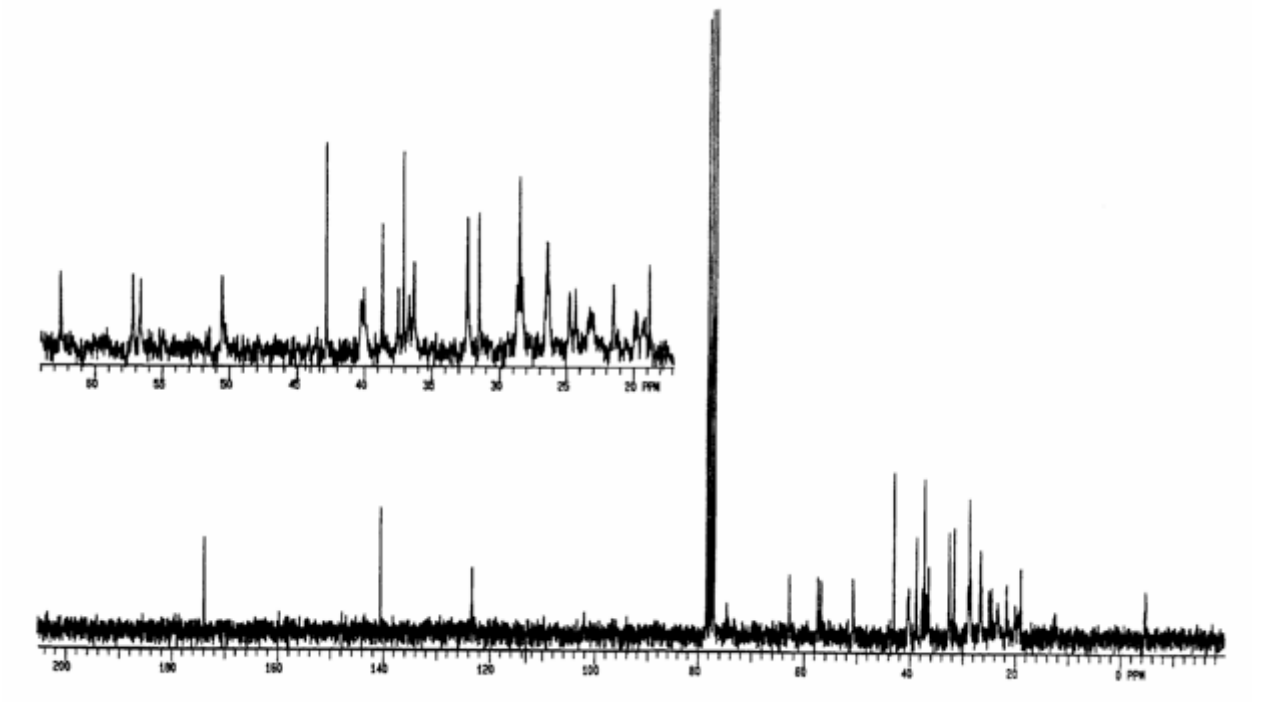


3





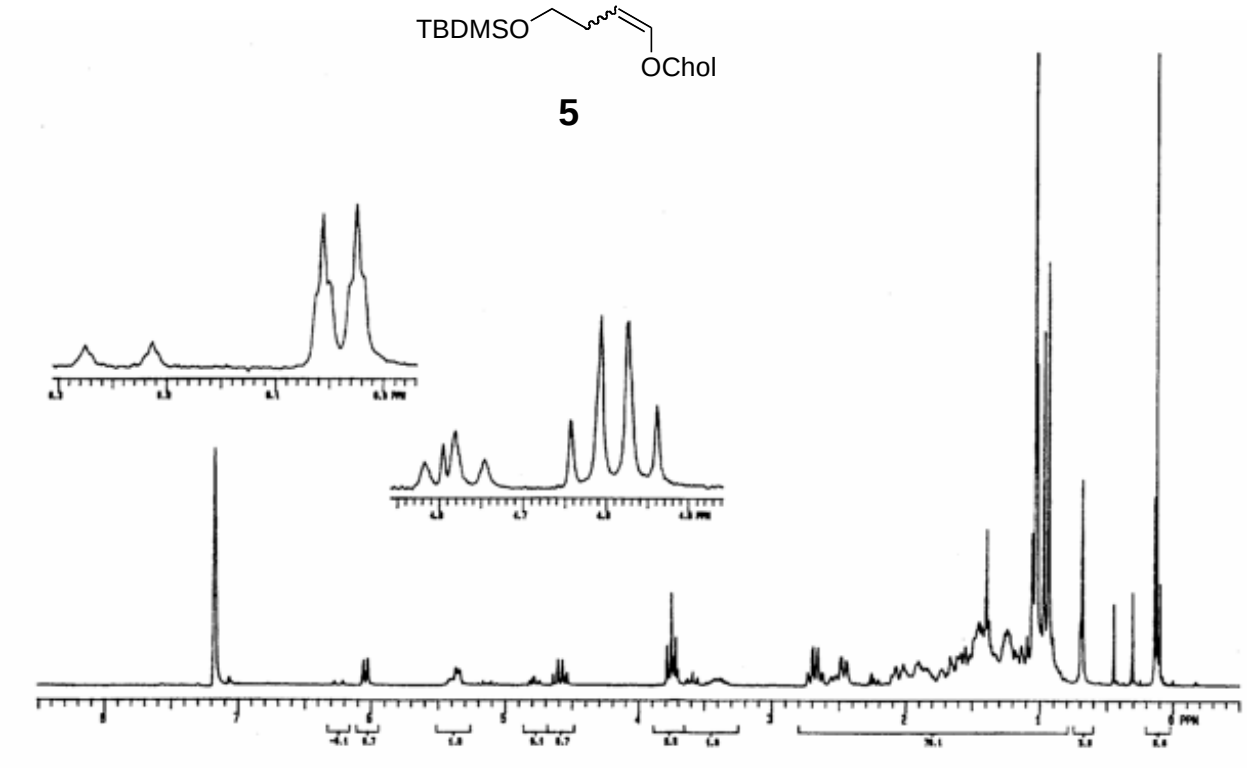
3



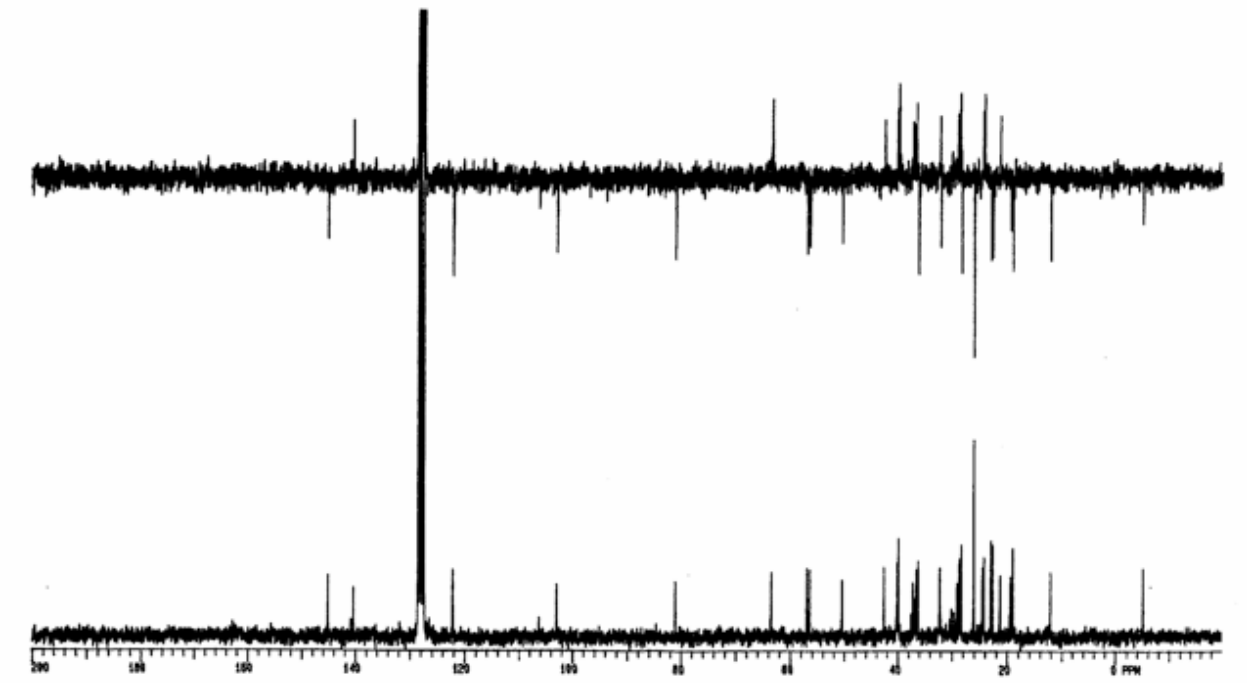
4-*t*-BUTYLDIMETHYLSILYLOXY-1-CHOLESTERYLOXY-1-DIETHYLPHOSPHORYLOXY-1-BUTENE (4). n-Butyl lithium (795 µL, 1.94 mmol, 2.4M in hexane) was added dropwise, via syringe, to diisopropylamine (453 µL, 3.23 mmol) in THF (250 µL) at -78 °C and the solution stirred for 30 min. Cholesteroyl-4-*t*-butyldimethylsilyloxy butanoate (**3**, 758 mg, 1.29 mmol) in THF (3mL) was then slowly added dropwise, via syringe. The solution was stirred for an additional hour, followed by the addition of diethylchlorophosphate (373 µL, 2.58 mmol) in HMPA (4.9 mL) in 3 aliquots. The solution turned orange/brown and gellated. It was thawed enough to stir, then returned to -78 °C for 10 min. The reaction was then warmed to room temperature and stirred for an additional hour. Ether (50 mL) was added and the reaction mixture filtered through a small silica plug. The solvent was evaporated, the oil redissolved in ether (75 mL), and the organic layer washed with 5% $NaHCO_3$ (3 x 75 mL). The ether layer was dried over $MgSO_4$, filtered, evaporated, and dried briefly *in vacuo*. The crude product was purified via flash chromatography (230-400 mesh silica, 6:1 hexane:ether, 2 cm diameter x 16 cm height). A white solid (750 mg, 81% yield) was recovered after evaporation. The product was used immediately without additional characterization. TLC (2:1 hexane:ether, I_2): R_f = 0.35.

4-*t*-BUTYLDIMETHYLSILYLOXY-1-CHOLESTERYLOXY-1-BUTENE (5).

Tetrakis(triphenylphosphine) palladium (15 mg, 12.4 µmol) and 4-*t*-butyldimethylsilyloxy-1-cholesteryloxy-1-diethylphosphoryloxy-1-butene (**4**, 270 mg, 373 µmol) were added to CH_2Cl_2 (8 mL) and cooled to 0 °C. Triethyl aluminum (653 µL 653 µmol; 1.0 M in hexane) was then added dropwise via syringe. The solution was stirred at 0 °C for 1 h before warming to room temperature and stirring for an additional 3 h. The crude mixture was purified via flash chromatography (230-400 mesh silica, 16:1 hexane:ether, 1.5 cm diameter x 20 cm height). A white solid (66 mg, 31% yield) was recovered as a 90:10 cis:trans mixture. TLC (16:1 hexane:ether, p-anisaldehyde): R_f = 0.75 (cis), 0.71 (trans). ^{1}H-NMR (C_6D_6, 90:10 cis:trans mixture): 0.13 (s, 6H), 0.68 (s, 3H), 0.8-2.75 (m, 51H), 3.4 (m, 1H), 3.75 (t, J = 12 Hz, 2H), 4.6 (dt, J_1 = 8 Hz, J_2 = 7 Hz, 0.9H), 5.15 (dt, J_1 = 13 Hz, J_2 = 7 Hz, 0.1H), 5.35 (m, 1H), 6.04 (dt, J_1 = 7 Hz, J_2 = 2 Hz, 0.9H), 6.15 (dt, J_1 = 13 Hz, J_2 = 2 Hz, 0.1H). ^{13}C-NMR/APT (C_6D_6, 90:10 cis:trans mixture): -4.8 (O), 12.2 (O), 19.1 (O), 19.5 (O), 19.6 (O), 21.5 (E), 22.8 (O), 23.1 (O), 24.3 (E), 24.6 (E), 26.2 (O), 28.5 (O), 28.8 (E), 28.9 (E), 29.2 (E), 29.6 (E), 29.7 (E), 30.3 (E), 30.6 (E), 32.2 (O), 32.4 (E), 36.2 (O), 36.8 (E), 37.0 (E), 37.3 (E), 37.6 (E), 39.9 (E), 40.0 (E), 40.2 (E), 40.3 (E), 42.6 (E), 51.5 (O), 56.8 (O), 57.0 (O), 63.8 (E), 81.3 (O), 103.0 (O), 106.5 (O), 122.1 (O), 140.5 (E), 141 (O), 145.2 (O).



5



4-CHOLESTERYLOXY-3-BUTEN-1-OL (6). Tetrabutylammonium fluoride (TBAF, 210 µl, 210 µmol, 1.0 M in THF) and 1.0 mL 40% tetrabutylammonium hydroxide were added via syringe to 4-*t*-butyldimethylsilyloxy-1-cholesteryloxy-1-butene (**5**, 40 mg, 70 µmol) in THF (3 mL). The reaction was run for 12 h, then filtered through a small silica plug with ether and the solvent evaporated. The mixture was purified via flash chromatography (230-400 mesh silica, 8:1 hexane:ether, 1.5 cm diameter x 15 cm height) to give *cis*-4-cholesteryloxy-3-buten-1-ol (29 mg, 91% yield) and *trans*-4-cholesteryloxy-3-buten-1-ol (1.5 mg, 4% yield) as white solids (95% combined yield). TLC (2:1 hexane:ether, acid char): R_f = 0.18 (cis), 0.14 (trans). ^{1}H-NMR (C_6D_6, cis): 0.65 (s, 3H), 0.8-2.05 (m, 39H), 2.3-2.53 (m, 4H), 3.35 (m, 1H), 3.58 (t, J = 6 Hx, 2H), 4.4 (dt, J_1 = 7 Hz, J_2 = 7 Hz, 1H), 5.35 (m, 1H), 5.98 (dt, J_1 = 6 Hz, J_2 = 1 Hz, 1H). ^{1}H-NMR (C_6D_6, trans): 0.65 (s, 3H), 0.8-2.05 (m, 41H), 2.4-2.5 (m, 2H), 3.35 (t, J = 7 Hz, 2H), 3.5 (m, 1H), 4.95 (dt, J_1 = 13 Hz, J_2 = 6 Hz, 1H), 5.35 (m, 1H), 6.15 (dt, J_1 = 12 Hz), J_2 = 1 Hz, 1H). ^{13}C-NMR/APT (C_6D_6, 70:30 cis:trans): 12.06 (O), 12.40 (O), 14.40 (O), 19.04 (O), 19.4 (O), 19.5 (O), 21.0 (E), 21.4 (E), 22.8 (O), 23.0 (O), 24.4 (E), 24.6 (E), 25.5 (E), 28.4 (O), 28.6 (E), 28.7 (E), 29.1 (E), 29.5 (E), 30.0 (E), 32.1 (O), 32.3 (E), 36.2 (O), 36.7 (E), 36.9 (E), 37.3 (E), 37.5 (E), 39.8 (E), 39.9 (E), 40. 2 (E), 42.6 (E), 50.5 (O), 50.6 (O) 54.3 (E), 56.6 (O), 57.0 (O), 62.7 (E), 63.0 (E), 75.9 (O), 79.8 (O), 81.2 (O), 102.0 (O), 102.9 (O), 106.2 (O), 122.1 (O), 122.3 (O), 140.4 (E), 140.8 (E), 145.6 (O). 1´(4´-CHOLESTERYLOXY-3´-BUTENYL)-ω-METHOXY-POLYETHYLENE[112] GLYCOLATE (CVEP, 7). 4-Cholesteryloxy-3-buten-1-ol (**6**, 44 mg, 96 µmol), methoxy-poly(ethylene glycol)-carboxymethyl, MW 5000 (435 mg, 87.0 µmol), dicyclohexylcarbodiimide (DCC, 21.6 mg, 104 µmol), and 4-*N,N*-dimethylaminopyridine (DMAP, 10 mg, 81 µmol) were added to CH_2Cl_2 (7 mL) and stirred for 4 d. The reaction mixture was then cooled to 0 °C and the dicyclohexylurea crystals removed via filtration (21 mg). The solvent was concentrated to 2 mL, dripped into cold ether (20 mL), and the ether solution centrifuged at 4000 rpm for 10 min. The ether was carefully decanted and the pellet triturated with fresh ether (20 mL). This process was repeated 5 times. The pellet was then dissolved in CH_2Cl_2, evaporated to a dry film, dissolved in 2 mL 18 MΩ Millipore H_2O, and lyophilized to give 420 mg PEG containing product (86% yield based on recovered dicyclohexylurea). TLC (90:10:1 $CHCl_3$:MeOH:H_2O, I_2): R_f = 0.75. ^{1}H-NMR ($CDCl_3$, cis): 0.65 (m, 3H), 0.75-2.5 (m, 50H + H_2O), 3.2-4.5 (m, >120H), 5.35 (m, 1H), 6.1 (m, 1H). ^{1}H-NMR ($CDCl_3$, 65:35 cis:trans): 0.65 (m, 3H), 0.75-2.5 (m, 50H + H_2O), 3.2-4.5 (m, >120H), 5.35 (m, 1H), 6.08 M, 0.65H), 6.15 (m, 0.35H).

Ltd., Kasai R&D Center, Kita-Kasai 1-16-13, Edogawa-Ku, Tokyo 134-8630, Japan and Department of Drug Delivery Research, Graduate School of Pharmaceutical Sciences, Kyoto University, Kyoto 606-8501, Japan. Received June 13, 2008; Revised Manuscript Received October 9, 2008

The primary purpose of this study was to comprehensively delineate specificity of the peptide spacer sequence to tumor-expressed proteases for the design of macromolecular carrier−peptide spacer−drug conjugate system. 225 conjugates of carboxymethyldextran polyalcohol (CM-Dex-PA) as water-soluble carrier and a dansyl derivative (*N*-(4-aminobutyl)-5-(dimethylamino)-1-naphthalenesulfonamide, DNS) as the model drug linked with different tetrapeptide spacers (Gly-Gly-P_2−P_1, P_2, P_1: Ala, Asn, Gly, Cit, Gln, Ile, Leu, Met, Phe, Pro, Ser, Thr, Trp, Tyr, and Val) were combinatorially synthesized. First, the drug release assay of all of the fluorogenic model conjugates was performed in murine Meth A solid tumor homogenates. The drug release rate was higher with conjugates having hydrophobic amino acids at P_2. It was also found that conjugates with Asn release the drug rapidly and, in contrast, those with Pro does not. Second, we selected three peptide spacers (Gly-Gly-Phe-Gly, Gly-Gly-Ile-Gly, Gly-Gly-Pro-Leu), which release only DNS at different rates, and applied them to doxorubicin (DXR) conjugates. These three DXR conjugates were used for investigating relationships with drug release, pharmacokinetics, and antitumor activity against Meth A bearing mice of these conjugates. The release of DXR from the conjugates corresponded well with that of DNS conjugates in tumor homogenates. CM-Dex-PA-Gly-Gly-Phe-Gly-DXR and CM-Dex-PA-Gly-Gly-Ile-Gly-DXR indicated strong antitumor activity, with the comparable pharmacokinetic profile of released DXR in tumor. Taken with the fact that the drug release rate in tumor homogenates was ∼10-fold different between these two DXR conjugates, it is likely that cellular uptake of the conjugate would be rate-limiting, rather than the drug release process under the in vivo situation. However, much weaker antitumor activity was observed with CM-Dex-PA-Gly-Gly-Pro-Leu-DXR, of which the drug release was extremely slow.

INTRODUCTION

Development of macromolecular prodrugs, which alter the pharmacokinetic profile of an aimed drug through conjugation with macromolecules, is a promising approach to increasing therapeutic efficacy and reducing adverse effect of the drug. Coupling of low-molecular-weight drugs to water-soluble macromolecular carrier can involve the following: (1) the improvement of drug movement in the body, prolonging its residence time in the blood circulation; (2) sustained release of the drug from the carrier by chemical or enzymatic hydrolysis; (3) site-specific delivery of drug due to moieties recognizing target cells (*1*). In solid tumors, macromolecules are known to accumulate preferentially, due to the "enhanced permeability and retention (EPR)" effect, i.e., leakiness of tumor angiogenic blood vessels and lack of effective lymphatic drainage (*2*). Exploitation of such mechanisms for tumor targeting has been successfully proven with various anticancer drugs, including doxorubicin, paclitaxel, camptothecin, and their analogues (*3*−*6*).

In addition to the efficiency of delivery to target tissue, the stability of the drug−polymer linkage is an important factor in determining therapeutic potentials. Prodrugs intended for tumorotropic delivery are required to release the drug using proteolytic cleavage of the polymer−drug linker by overexpressed enzymes in the tumor tissue, including thiol protease cathepsin B, metalloproteases such as collagenases and stromelysins, and serine proteases like plasminogen activator and plasmin. Acid-activated cleavage of the polymer−drug bond can also be used since the polymeric drug encounters endosomal/lysosomal acidification in tumor cells. The works of Duncan et al. on poly-*N*-(2-hydroxypropyl)methacrylamide (HPMA)-*p*-nitroaniline conjugates linked with peptidyl spacers have suggested that of all the lysosomal proteases the thiol protease cathepsin B was primarily responsible for the cleavage of the drug−polymer linkage (*7*−*9*). In addition, the rate of release of the *p*-nitroaniline was found to be dependent on the specificity of the peptide spacer sequence to cathepsin B, with the fastest rates of hydrolysis being observed for Gly-Phe-Leu-Gly among nine tetrapeptide spacers tested (*10*).

Being aware that there have been a limited number of studies (*10*−*13*) on sequence specificity of peptide spacers in tumorotropic macromolecular prodrugs, we initiated this study to comprehensively delineate specificity of the peptide spacer sequence to tumor-expressed proteases in a similar manner to that reported by Schmid et al. (*14*). 225 conjugates of carboxylmethyl dextran polyalcohol (CM-Dex-PA) and a dansyl derivative (*N*-(4-aminobutyl)-5-(dimethylamino)-1-naphthalenesulfona-

mide, DNS) linked with different tetrapeptide spacers were combinatorially synthesized, and the rate of release of DNS from the conjugates was measured using murine Meth A solid tumor homogenates. Effectiveness of CM-Dex-PA as a backbone of tumorotropic macromolecular prodrugs has been demonstrated in our previous studies (*6*). On the basis of the in vitro studies, conjugates of CM-Dex-PA and DXR[1]linked with different peptide spacers (Gly-Gly-Phe-Gly, Gly-Gly-Ile-Gly, and Gly-Gly-Pro-Leu) were designed. The in vitro drug release, pharmacokinetics, and in vivo antitumor activity of the carboxymethyldextran polyalcohol−doxorubicin conjugates were investigated to demonstrate the importance of peptide spacers in the design of macromolecular prodrugs.

EXPERIMENTAL PROCEDURES

Reagents. Fifteen fluoren-9-ylmethyloxycarbonyl (Fmoc)-protected amino acids were purchased from Bachem America Inc. (Torrance, CA). Doxorubicin (DXR) was obtained from Kyowa Hakko Co., Ltd. (Tokyo, Japan). Other chemicals were of reagent grade and used without further purification.

Synthesis of *N*-(4-Aminobutyl)-5-(dimethylamino)-1-naphthalenesulfonamide (DNS). After 1,4-butanediamine (33.0 g, 371 mmol) was dissolved in dichloromethane (100 mL), dansyl chloride (5.0 g, 18.5 mmol) in dichloromethane (100 mL) was added dropwise to the solution for 30 min on ice. The reaction mixture was stirred at room temperature for 20 h. After the solvent was evaporated, the residue was dissolved in ethyl acetate, washed with saturated sodium bicarbonate and NaCl, and then dried with sodium sulfate. After the solvent was evaporated, DNS (5.99 g) was yielded as oil. ^{1}H NMR ($CDCl_3$) δ: 1.28−1.37 (m, 2 H, CH_2), 1.43−1.49 (m, 2 H, CH_2), 2.57 (t, 2 H, J = 6.4 Hz, CH_2), 2.84−2.89 (m, 8 H, Me_2, CH_2), 7.18 (d, 1 H, J = 7.6 Hz, H-6 of Dansyl), 7.51, 7.55 (2d, 2 H, J = 8.3 Hz, 8.8 Hz, H-3, H-7 of Dansyl), 8.25 (d, 1 H, J = 7.0 Hz, H-2 of Dansyl), 8.33 (d, 1 H, J = 8.8 Hz, H-8 of Dansyl), 8.53 (d, 1 H, J = 8.3 Hz, H-6 of Dansyl).

Succinic acid (66 mg) was added to the solution of DNS (90 mg) in methanol (20 mL). The solvent was evaporated, and diethyl ether was added to the residue for solidification. The residue was washed with diethylether and dried to yield 130 mg of DNS salt (0.5 succinic acid 0.7 hydrate). Anal. Calcd for $C_{16}H_{23}N_3O_2S \cdot 0.5$ succinic acid $\cdot 0.7$ H_2O: C, 55.00; H, 7.03; N, 10.69; S, 8.16. Found: C, 55.10; H, 6.80; N, 10.46; S, 8.16. DNS was dissolved in 50% acetonitrile solution and prepared to 3.57 mg/mL. Furthermore, the solution was diluted to adequate concentration as HPLC standard sample.

Combinatorial Synthesis of CM-Dex-PA-Tetrapeptide-DNS Conjugates (Scheme 1). *a. Transduction to MB-CHO Resin of DNS.* DNS succinic salt (5.96 g, 18.54 mmol) in *N*,*N*-dimethylformamide (DMF, 30 mL) was added to trimethyl ester (30 mL) suspended with ArgoGelTM-MB CHO resin (6.9 g, 0.40 mmol/g). After shaking for 16 h, the solvent was removed, and the resin was washed with methanol and dried. To the resin, 1% acetic acid in methanol (100 mL) and 1 N $NaBH_3CN$ in tetrahydrofuran (THF, 20 mL) were added, and the solution was shaken for 2 days. The resin was isolated, washed with methanol and chloroform, and dried overnight to yield DNS-resin (19.7 g).

b. Synthesis of H-Gly-Gly-P_2-P_1-DNS by ACT496. Using DNS-resin (25 mg, 0.01 mmol), 225 kinds of crude H-Gly-Gly-P_2-P_1-DNS (15 × 15 amino acids) were synthesized by

[1]Abbreviations: Ala, L-alanine; Asn, L-asparagine; Cit, L-citrulline; DCC, *N*,*N*′-dicyclohexylcarbodiimide; DIPEA, diisopropylethylamine; DMF, *N*,*N*-dimethylformamide; DNS, *N*-(4-aminobutyl)-5-(dimethylamino)-1-naphthalenesulfonamide; DXR, Doxorubicin; EDC, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide; EDTA, ethylenediaminetetraacetic acid; Fmoc, fluoren-9-ylmethyloxycarbonyl; Gln, L-glutamine; Gly, L-glycine; GPC, gel permeation chromatography; HBTU, 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate; HOBt, 1-hydroxybenzotriazole; HPLC, high-performance liquid chromatography; Ile, L-isoleucine; LC/MS, liquid chromatography−mass spectrometry; Leu, L-leucine; MMPs, matrix metalloproteases; MES, 2-(*N*-morpholino)ethanesulfonic acid; Met, L-methionine; Phe, L-phenylalanine; Pro, L-Proline; Ser, L-serine; THF, tetrahydrofuran; Thr, L-Threonine; Tos, toluenesulfonyl; Trp, L-tryptophan; Trt, triphenylmethyl; Tyr, L-Tyrosine; Val, L-valine.

ACT496 (Advanced Chem. Tech., KY). P_2 and P_1 amino acids were Ala, Asn, Cit, Gln, Gly, Ile, Leu, Met, Phe, Pro, Ser, Thr, Trp, Tyr, and Val. The DNS resin was placed in the reaction vessel of the synthesizer and washed with DMF. The DMF was removed by filtration. To bond P_1 amino acid to DNS, a 0.1 M solution of Fmoc-protected amino acids in DMF (0.5 mL) was added, followed by 1-hydroxybenzotriazole (HOBt, 0.1 mL of 0.5 M solution in DMF), diisopropylethylamine (DIPEA, 0.2 mL of 0.5 M solution in DMF), and 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU, 0.2 mL of 0.25 M solution in DMF). The mixture was shaken for 2 h at room temperature. Then, DMF was removed by filtration. The procedure was performed once again. The resin was washed three times with 1 mL DMF. To remove the Fmoc group, piperidine in DMF was added and the mixture shaken for 1 min. The resin was washed with DMF (3 times). The bonding of P_2 amino acid to P_1-DNS, the removal of Fmoc, and the bonding of Boc-Gly-Gly to P_2-P_1-DNS were performed following the same protocol as that for P_1 amino acid. After the reaction was completed, the resin was washed twice with 1 mL DMF, twice with 1 mL THF, once with 1 mL MeOH, and three times with 1 mL CH_2Cl_2. To remove the Boc group and isolate H-Gly-Gly-P_2-P_1-DNS from the resin, CH_2Cl_2 solution including 50% trifluoroacetic acid (1 mL) was added and incubated for 2 h. The crude H-Gly-Gly-P_2-P_1-DNS was collected by filtration and dried.

c. HPLC Purification of Crude H-Gly-Gly-P_2-P_1-DNS. The crude H-Gly-Gly-P_2-P_1-DNS, which was synthesized by the solid phase method, was dissolved in methanol (500 μL), transferred to Eppendorf tube, and evaporated. Then, these were dissolved in 10% methanol (100−200 μL) and purified by HPLC. The HPLC separation was performed on a 15 × 250 mm reversed-phase column packed with Capcell Pak C18 UG 120 (Shiseido, Tokyo, Japan) with 8 mL/min flow rate. The detector was set at 260 nm (UV-8020, Tosoh, Tokyo, Japan). The mobile phase consisted of methanol/acetonitrile (1:2) and 0.1 M trifluoroacetic acid, of which the proportion ranged from 20% to 45% according to the elution property of H-Gly-Gly-P_2-P_1-DNS. All samples were confirmed by LC/MS and HPLC purity (260 nm) >95%.

d. Synthesis of CM-Dex-PA. Carboxymethyl dextran polyalcohol (CM-Dex-PA) was synthesized from dextran (molecular weight 500 kDa, Pharmacia). Dextran (50 g) was dissolved in 0.1 M acetic acid buffer (pH 5.5, 5 L). A sodium periodic acid (165.0 g) was dissolved in distilled water (5 L) and added to the solution of dextran. The mixture was stirred under shade at 4 °C for ten days. Then, ethylene glycol (35 mL) was added and the mixture stirred overnight. The reaction mixture was adjusted to pH 7.5 using 8 M sodium hydroxide solution. Then, sodium borohydride (70 g) was added, and the mixture was stirred overnight. The solution was adjusted to pH 5.5 with acetic acid on ice, and ultrafiltration was performed using a Biomax 50 (size exclusion 50 kDa, Millipore). The filtration was freeze−dried to yield dextran polyalcohol (Dex-PA, 27.1 g). Dex-PA was dissolved in 14% sodium hydroxide solution (150 mL), and monochloroacetic acid (30 g) was added under cooling with ice and stirred at room temperature overnight. The reaction mixture was treated by ultrafiltration using Biomax 50 after having adjusted to pH 8 with acetic acid. A macromolecular fraction was freeze−dried, and Na salt (5.6 g) of CM-Dex-PA was obtained. The molecular weight of CM-Dex-PA was approximately 263 000 using pullulan standard by GPC and has a polydispersity index of 1.6 (M_w/M_n). The decrease in molecular weight of dextran following periodic acid oxidation has also been observed by Ahmad et al. (*15*), presumably due to structural changes associated with C2−C3 bond cleavage and increased molecular flexibility. The carrier was shelf-stable for over three months. On the other hand, the degrees of substitution of the CM groups in the carrier were determined by titration (ca. 0.0027 mol CM equiv per gram of CM-Dex-PA).

e. Synthesis of CM-Dex-PA-Gly-Gly-P_2-P_1-DNS. CM-Dex-PA was dissolved in collidine buffer (pH 7.0) containing 50% methanol to yield a concentration of 15 mg/mL. A 36 μL aliquot of 10 mg/mL 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) and 10 μL of 10 mg/mL HOBt in methanol was added to 200 μL of the CM-Dex-PA solution. H-Gly-Gly-P_2-P_1-DNS was dissolved in 42 μL of methanol, added to the reaction mixture, and then stirred for 3 h. 36 μL of the 10 mg/mL EDC solution was added and the mixture stirred for another 3 h, to yield CM-Dex-PA-Gly-Gly-P_2-P_1-DNS.

f. Purification of CM-Dex-PA-Gly-Gly-P_2-P_1-DNS. The reaction mixture of CM-Dex-PA-Gly-Gly-P_2-P_1-DNS was diluted with 600 μL of distilled water and subjected to GPC for purification. The conjugates were eluted with 0.1 M sodium acetate buffer (pH 5.0) containing 20% of acetonitrile using TSK GEL PW-6000XL column (Tosoh, Tokyo, Japan). The flow rate was 1 mL/min and detected at 254 nm (SPD-10A, Shimazu, Tokyo, Japan). The fraction eluting between 8.5 and 11.5 min, which corresponded to the molecular weight of 100 to 400 kDa, was collected.

g. Determination of DNS Contents in CM-Dex-PA-Gly-Gly-P_2-P_1-DNS. The eluate fraction was diluted 10 times with distilled water. The content of DNS associated with CM-Dex-PA-Gly-Gly-P_2-P_1-DNS was determined by the GPC system equipped with a fluorescence detector (RF-10A, Shimazu, Tokyo, Japan) set at excitation and emission wavelength of 335 and 530 nm, respectively. Other conditions were the same as mentioned above. The DNS content was calculated by the calibration curve of DNS. The DNS content of the conjugates ranged from 3% to 6% (w/w).

Synthesis of CM-Dex-PA-tetrapeptide-DXR Conjugates. CM-Dex-PA-Gly-Gly-Phe-Gly-DXR, CM-Dex-PA-Gly-Gly-Ile-Gly-DXR, and CM-Dex-PA-Gly-Gly-Pro-Leu-DXR were synthesized by Research Laboratory of Daiichi Pharmaceutical Co., Ltd. (Tokyo, Japan).

a. Synthesis of H-Gly-Gly-Phe-Gly-DXR. A mixture of H-Phe-Gly-OH (10 g, 44.0 mmol) and toluenesulfonyl (Tos) OH (8.36 g, 44.0 mmol) and benzylalcohol (10 mL) was suspended and refluxed through a Dean−Stark system for 16 h. A reaction mixture was concentrated, and ether was added to give Tos OH·H-Phe-Gly-OBzl (20 g, 94%). Triphenylmethyl (Trt) -Gly-Gly-OH·Et_3N (1.40 g, 3.0 mmol) and TosOH·H-Phe-Gly-OBzl (1.46 g, 3.0 mmol) and HOBT (490 mg, 3.6 mmol) and (*N*,*N*′-dicyclohexylcarbodiimide DCC, 740 mg, 3.6 mmol) were dissolved in DMF (10 mL) and the mixture stirred overnight. The mixture was concentrated, diluted with ethyl acetate, and washed with 5% aqueous citric acid, a saturated sodium bicarbonate solution, saturation solution of salt, and distilled water in this order. Then, it was dried with $MgSO_4$ and filtered, and the filtrate was concentrated. Trt-Gly-Gly-Phe-Gly-OBzl was obtained by column chromatography (CH_2Cl_2/MeOH = 50:1) to yield 1.5 g. Trt-Gly-Gly-Phe-Gly-OBzl (500 mg) and $HCOONH_4$ (150 mg) were dissolved in DMF (5 mL), followed by the addition of 5% Pd−C (500 mg) and agitation for 2 h. Pd−C was removed by filtration, and the filtrate was purified by column chromatography (CH_2Cl_2/MeOH = 50:1) to give Trt-Gly-Gly-Phe-Gly-OH (330 mg, 78%). ^{1}H NMR (CD_3OD): δ 7.18−7.45 (m, 20H), 4.64 (dd, 1H, J = 8.8, 5.6 Hz), 3.94 (d, 1H, J = 16.5 Hz), 3.80 (d, 1H, J = 16.5 Hz), 3.78 (d, 1H, J = 17.5 Hz), 3.64 (d, 1H, J = 17.5 Hz), 3.23 (dd, 1H, J = 14.2, 5.6 Hz), 2.90 (dd, 1H, J = 14.2, 8.8 Hz), 2.90 (s, 1H).

Trt-Gly-Gly-Phe-Gly-OH (330 mg, 0.57 mmol), DCC (141 mg, 0.68 mmol), and HOBt (92 mg, 0.68 mmol) were dissolved in DMF (120 mL), and DMF solution containing of HCl/DXR

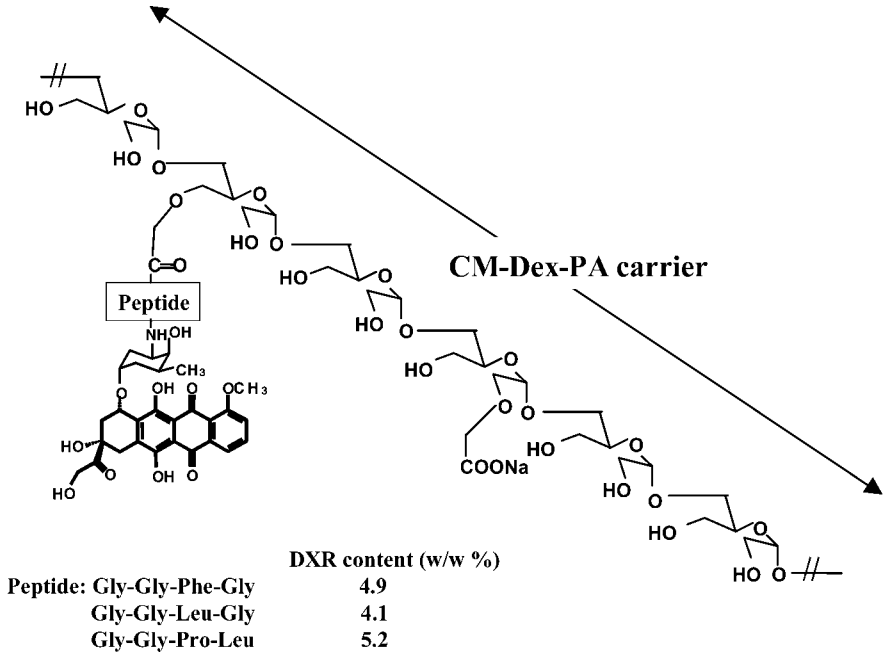

Figure 1. Partial structure of DXR conjugates.

(331 mg, 0.57 mmol) and triethylamine (0.063 mL, 0.57 mmol) were added and the mixture stirred for 16 h. Then, Trt-Gly-Gly-Phe-Gly-DXR was purified by column chromatogrphy (CH_2Cl_2/MeOH = 10/1) to yield 400 mg. ^{1}H NMR (CD_3OD): δ 7.91 (d, 1H, J = 7.6 Hz), 7.80 (t, 1H), 7.54 (d, 1H, J = 8.3 Hz), 7.16−7.26 (m, 5H), 5.43 (d, 1H, J = 3.9 Hz), 5.13 (br, 1H), 4.73 (s, 2H), 4.43 (dd, 1H, J = 8.4, 6.6 Hz), 4.30 (q, 1H, J = 6.6 Hz), 4.16 (m, 1H), 4.03 (d, 1H, J = 17.0 Hz), 4.02 (s, 3H), 3.86 (d, 1H, J = 16.9 Hz), 3.83 (d, 1H, J = 17.0 Hz), 3.77 (d, 1H, J = 15.9 Hz), 3.73 (d, 1H, J = 15.9 Hz), 3.62 (d, 1H, J = 1.5 Hz), 3.59 (d, 1H, J = 16.9 Hz), 3.13 (dd, 1H, J = 13.9, 6.6 Hz), 3.10 (d, 1H, J = 18.6 Hz), 3.00 (d, 1H, J = 18.6 Hz), 2.94 (dd, 1H, J = 13.9, 8.4 Hz), 2.38 (d, 1H, J = 14.7 Hz), 2.19 (dd, 1H, J = 14.7, 5.1 Hz), 1.98 (ddd, 1H, J = 12.7, 12.7, 3.9 Hz), 1.71 (dd, 1H, J = 12.7, 4.6 Hz), 1.28 (d, 3H, J = 6.6 Hz).

Trt-Gly-Gly-Phe-Gly-DXR (350 mg, 0.32 mmol) was dissolved in 75% AcOH (2 mL) and stirred for 1 h. Distilled water (10 mL) was added, and the solution was filtered and dried in vacuo. The resulting red solid product was collected by treatment of Dowex 1 × 8 ion-exchange resin (CL-form) and dried in vacuo to give HCl·H-Gly-Gly-Phe-Gly-DXR (180 mg).

b. Synthesis of CM-Dex-PA-Gly-Gly-Phe-Gly-DXR. CM-Dex-PA (750 mg) was dissolved in 50% MeOH/0.02 M Tris-maleate buffer (pH 7.0) (50 mL). HCl·H-Gly-Gly-Phe-Gly-DXR (100 mg) in MeOH (10 mL) and EDC·HCl (80 mg) in MeOH (4 mL) were added and the mixture stirred for 4.5 h. A solution of EDC·HCl (40 mg) in MeOH (4 mL) was added twice at 1.5 and 3 h. To stop the reaction, 3 M NaCl (50 mL) was added, and the mixture was filtered using a MW 50 kDa cutoff membrane. The product was dried in vacuo, redissolved in 3 M NaCl, and precipitated by dropping into EtOH (40 mL). The precipitate was collected, treated by ultrafiltration, and purified through a 0.22 μM filter, to give the product (740 mg). CM-Dex-PA-Gly-Gly-Ile-Gly-DXR and CM-Dex-PA-Gly-Gly-Pro-Leu-DXR were synthesized by the same method. The contents of DXR in the DXR conjugates ranged from 4% to 6% w/w, and contamination of free DXR was less than 0.01% DXR equiv. The partial structure of these conjugates was indicated in Figure 1.

Inoculation of Tumor Cells. Meth A (murine fibrosarcoma) was kindly obtained from Dr. Ichiro Azuma (Institute of Immunological Science, School of Medicine, Hokkaido University, Japan). Meth A tumors were propagated in vivo by subcutaneous inoculation of cells (1×10^6 cells/0.1 mL) into the left flank of syngenic male BALB/c mice (6 weeks of age). Murine histiocytoma M5076 cells were obtained from Japanese Foundation for Cancer Research (Tokyo, Japan). The cells were cultured in RPMI 1640 medium supplemented with 17% horse serum (Hyclone Laboratories, Logan, UT). M5076 solid tumors were propagated in vivo by subcutaneous inoculation of cells (1×10^6 cells/0.1 mL) into the left flank of syngenic male C57BL/6 mice (6 weeks of age).

Preparation of Tumor Homogenate from Meth A Solid Tumor in Mice. Meth A solid tumor homogenates were prepared according to the method of Rozhin et al. (*16*). On 21 days post-subcutaneous inoculation of Meth A tumor cells, the mice were sacrificed under anesthesia to excise the tumor tissue. A pool of the tumor tissues with a total weight of 27 g was washed three times with 20 mL of ice−cold MES buffer (250 mM sucrose, 25 mM MES, 1 mM EDTA, pH 6.5), and then placed in 35 mL of the fresh MES buffer. The tumor homogenization was performed at 4 °C for 5 min. The homogenate was centrifuged at 500 × g for 11 min, and the supernatant was collected and centrifuged again at the same condition. Furthermore, the supernatant was centrifuged at 15 000 × g for 19 min to yield a mitochondrial lysosomal pellet. The pellet was resuspended in citrate buffer (pH 5.5), quickly frozen, and stored at −80 °C. M5076 tumor homogenates were prepared by the same method.

Drug Release Assay of DNS Conjugates and DXR Conjugates in Tumor Homogenate. The enzyme reaction mixture consisted of 80 μL of Britton Robinson buffer (pH 4.5), 5 μL of 200 mM cysteine, 5 μL of 0.1% Brij 35, and 5 μL of the tumor homogenate. Five microliter of the DNS conjugate or DXR conjugate solution was added to the mixture and incubated at 40 °C for given time period (DNS conjugates, 2 or 20 h; DXR conjugates, 4, 8, 24 h). Then, acetonitrile (100 μL) was added to stop the reaction. Following centrifugation of the solution at 15 000 × g for 10 min, the amount of the liberated drug contained in the supernatant was determined by HPLC.

Release of DXR from the Conjugates in M5076 Cell Culture. Two milliliters of M5076 cell suspension (5×10^6 cells/mL) was seeded onto a 60 mm dish, and cultured in RPMI 1640 medium supplemented with 17% horse serum medium for 2 h. 100 μL of DXR conjugate solution (2 mg DXR equiv/mL) was added to the cell culture dish, and incubated at 37 °C in a humidified atmosphere of 5% CO_2 (v/v) in air. 24 h later, 1 M HCl containing 90% acetonitrile (2 mL) was added, and the lysate was taken and centrifuged for 10 min at 10 000 $\times$ *g*. The amount of DXR released from the conjugates was determined by HPLC.

Antitumor Activity of DXR Conjugates against Meth A Bearing Mice. After inoculation of Meth A cells (day 0), DXR conjugate (5, 20, or 40 mg DXR equiv/kg) or DXR (5, 10, or 20 mg/kg) were intravenously administered on day 9. On day 14, mice were sacrificed to excise and weigh tumor masses. The growth inhibition rate (IR) on the basis of tumor weight was calculated using the following formula: IR = (1 − TWt/TWc) × 100 (%), where TWt and TWc represent the mean tumor weight for treated and nontreated groups, respectively. The statistical significance of differences between the nontreated and treated groups was evaluated using Dunnett's test. The body weight of mice (BWt) was measured every day and compared to that on day 0 (BWc). The rate of body weight loss (BWL) was calculated on the basis of the following formula: BWL (%) = (1 − BWt/BWc) × 100. BWLmax indicates the maximum value of BWL.

Distribution of DXR in Tumor, Liver, and Serum after Administration of DXR Conjugates. Meth A bearing mice were intravenously administered with DXR conjugates or DXR at 20 mg DXR equiv/kg. In order to examine the release of DXR from macromolecular conjugates in detail, distribution of DXR following injection of the conjugates was measured on the same time scale as the case of DXR, which is rapidly distributed to and eliminated from tissues. That is, at 2, 4, 8, 24, and 48 h after injection, mice were anesthetized with dimethyl ether, and blood, liver, and tumor were collected. The blood were left to clot for 10 min and then centrifuged (10 000 $\times$ *g*, 10 min at 4 °C) to collect serum. The samples (serum, liver, and tumor) were stored at −30 °C until analysis. 100 μL of the serum was mixed with 100 μL of 1 M HCl containing 90% acetonitrile (v/v) and then centrifuged at 10 000 $\times$ *g* for 10 min at 4 °C. The supernatant was injected into the HPLC system. To liver and tumor 0.5 M HCl containing 50% acetonitrile (v/v) were added (1 mL solvent per 0.25 g tissue), homogenized on ice by the handy micro-homogenizer NS-310F (Microtec Co., LTD, Chiba, Japan), and centrifuged at 10 000 $\times$ *g* for 10 min at 4 °C. The supernatant was injected into the HPLC system. A preliminary experiment indicated that the procedure provided more than 95% recovery of DXR from tissues.

HPLC Condition. LC/MS was performed with an HP 1100 HPLC system with API 150Ex mass spectrometer on a Develosil Combi-RP-5 column (4.6 × 50 mm, Nomura Chemical Co., Ltd. Aichi, Japan). The mobile phase consisted of A, 0.1% HCOOH/H_2O (v/v), and B, 0.1% HCOOH/acetonitrile (v/v), with a linear gradient from 0% to 100% of B for 3.6 min (flow rate 2.5 mL/min). Determination of DNS and its peptide conjugates released was performed with a HPLC system on a Symmetry Shield RP18 column (4.6 × 100 mm, Waters Co., Milford, MA) and a fluorimetric detector (excitation 335 nm, emission 530 nm); the mobile phase consisted of acetonitrile and methanol (2:1) and 0.1 M sodium acetic acid, with a linear gradient from 30% to 90% for 15 min (flow rate 1 mL/min). Determination of DXR was performed on a Symmetry Shield RP18 column (4.6 × 100 mm) and a fluorimetric detector (excitation 480 nm, emission 590 nm); the mobile phase consisted of acetonitrile, methanol, and 0.1 M sodium acetic acid buffer (23.4/11.6/65.0, v/v/v, flow rate 1 mL/min).

RESULTS

Drug Release Assay of DNS Conjugates by Meth A Homogenate. Considering the pH dependence on the cathepsin activities associated with Meth A tumor homogenate (*17*), the drug release assay of the conjugates was performed at pH 4.5. When CM-Dex-PA-Gly-Gly-P_2-P_1-DNS was incubated, not only DNS but its peptide conjugate (P_1-DNS and P_2-P_1-DNS) were detected by HPLC. Figure 2 is a $P_2 \times P_1$ combination of pie charts, of which the diameter represents the total release rate. The red, blue, and yellow colors indicate DNS, P_1-DNS, and P_2-P_1-DNS. In the case of Pro at P_1, the release of DNS and its peptide conjugates was very slow (small chart) for any amino acids at P_2, while in the case of Asn at P_1, DNS (red color) was rapidly released. On the other hand, when P_2 was Val, Tyr, Trp, Phe, Met, Leu, or Ile, DNS was rapidly released. By contrast, Thr, Ser, Pro, Gly, Gln, Cit, and Ala at P_2 retarded the release of DNS and its peptide conjugates. Interestingly, when Asn was at P_2, P_1-DNS (blue color) was largely released. Taken together with the result of Asn at P_1, peptidases associated with Meth A tumor homogenates preferentially cleaved the carboxy side of Asn. In the case of Pro at P_1 and P_2, P_2-P_1-DNS (yellow color) and DNS tended to be mainly released, respectively, indicating that both the amino and carboxy sides of Pro are extremely resistant against the peptidases.

With regard to the conjugates which released DNS completely within 20 h, drug release for the shorter time (2 h) was also measured (Figure 3). When P_2 was Tyr, Phe, or Leu, and P_1 was Met, Leu, Gln, or Cit, the release of DNS were extremely high.

As well as Meth A homogenates, M5076 tumor homogenates were subjected to DNS release assays of the conjugates. When drug release in M5076 tumor homogenate was investigated with nine voluntarily selected conjugates (peptide: Gly-Gly-Leu-Met, Gly-Gly-Met-Asn, Gly-Gly-Gly-Asn, Gly-Gly-Phe-Gly, Gly-Gly-Ile-Cit, Gly-Gly-Ile-Leu, Gly-Gly-Pro-Gln, Gly-Gly-Pro-Ala, Gly-Gly-Met-Pro), it was highly correlated with that of Meth A tumor homogenate (Figure 4).

Comparison of Drug Release between DNS Conjugates and DXR Conjugates in Meth A Homogenates. As well as the DNS-bearing model conjugates, the release of DXR from DXR conjugates was investigated in Meth A homogenates. The conjugates, which have three typical peptide spacers (i.e., Gly-Gly-Phe-Gly, Gly-Gly-Ile-Gly, or Gly-Gly-Pro-Leu), were selected. Although the amount of DXR released within 20 h was less than that of DNS, the rank order of three types of conjugates was the same in both DXR- and DNS conjugates: that is, the release of the drugs was highest with conjugates having Gly-Gly-Phe-Gly, followed by Gly-Gly-Ile-Gly and Gly-Gly-Pro-Leu (Table 1).

Drug Release Assay of DXR Conjugates in M5076 Tumor Homogenates and in Vitro Cultured M5076 Cells. As well as Meth A homogenates, the M5076 tumor homogenates were subjected to drug release assays of DXR conjugates. DXR conjugates, for which the spacer varied in the rate of hydrolysis (Gly-Gly-Phe-Gly, Gly-Gly-Ile-Gly, Gly-Gly-Pro-Leu), were selected. The release rate constants of DXR from CM-Dex-PA-Gly-Gly-Phe-Gly-DXR, CM-Dex-PA-Gly-Gly-Ile-Gly-DXR, and CM-Dex-PA-Gly-Gly-Pro-Leu-DXR were 0.064 h^{-1}, 0.0066 h^{-1}, and 0.00013 h^{-1}, respectively (see Supporting Information). It indicated that, as well as in the case of DNS conjugates, the rank order of the DXR conjugates was the same in both Meth A and M5076 tumor homogenates.

In addition, the release of DXR from the conjugates was also evaluated in the in vitro cultured M5076 cells. Figure 5

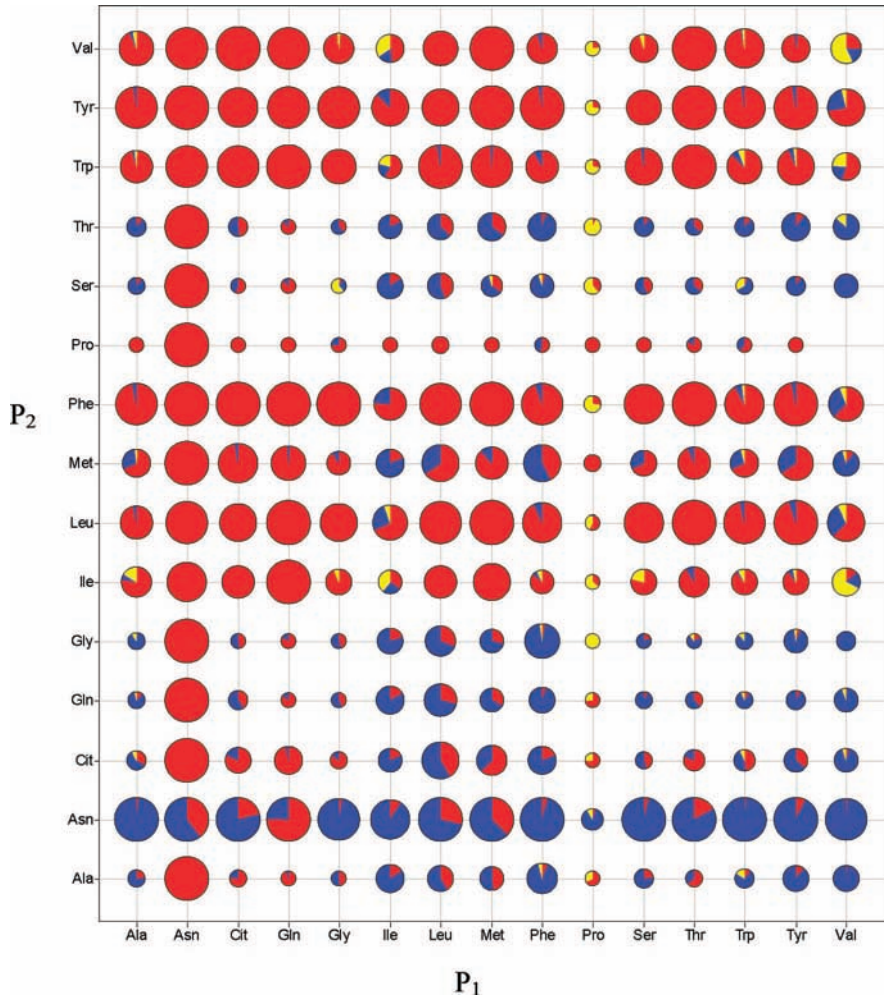

Figure 2. Characterization of DNS and its derivatives released from DNS conjugates in Meth A homogenate at 37 °C for 20 h. The vertical axis indicates the P_2 residure, and the horizontal axis indicates the P_1 residure. The total amounts of drug release are indicated by the size of circle, and the ratio of DNS, P_1-DNS, and P_2-P_1-DNS are indicated as red, blue, and yellow, respectively.

represents a plot of the amount released within 24 h in the cultured M5076 cells against the release rate constant evaluated in the homogenates. Although the rank order of drug release was the same in both cultured cells and tumor homogenates, the difference between CM-Dex-PA-Gly-Gly-Phe-Gly-DXR and CM-Dex-PA-Gly-Gly-Ile-Gly-DXR was not so remarkable in the cultured cells (ca. 1% for both) as expected from the tumor homogenates (~10-fold difference). It is likely that cellular uptake of the DXR conjugates is the rate-limiting step, and therefore the difference in the intracellular hydrolysis rate minimally affects the appearance of DXR from the conjugates.

Antitumor Activity of DXR Conjugates against Meth A Bearing Mice. Antitumor activity of CM-Dex-PA-Gly-Gly-Phe-Gly-DXR, CM-Dex-PA-Gly-Gly-Ile-Gly-DXR, and CM-Dex-PA-Gly-Gly-Pro-Leu-DXR was investigated in Meth A bearing mice. As shown in Table 2, intravenous injection of 5−40 mg/kg CM-Dex-PA-Gly-Gly-Phe-Gly-DXR remarkably decreased the tumor weight, although the loss of body weight (>20%) was observed at the highest dose. CM-Dex-PA-Gly-Gly-Ile-Gly-DXR, in spite of giving slower in vitro drug release than CM-Dex-PA-Gly-Gly-Phe-Gly-DXR, exhibited comparable antitumor activity to CM-Dex-PA-Gly-Gly-Phe-Gly-DXR, although two mice died at 40 mg/kg. On the other hand, antitumor effect of CM-Dex-PA-Gly-Gly-Pro-Leu-DXR was much less than the other two DXR conjugates. It clearly indicated that the rate of drug release is important in the antitumor activity. When DXR itself was administered at 20 mg/kg, four of six mice died, and antitumor activity was moderate. At 10 mg/kg, on the other hand, the antitumor activity and body weight loss were not observed. Thus, macromolecular prodrugs exhibiting a fast drug release due to tumor proteases, e.g., CM-Dex-PA-Gly-Gly-Phe-Gly-DXR and CM-Dex-PA-Gly-Gly-Ile-Gly-DXR, greatly improved therapeutic potential of DXR.

Distribution of DXR in Tumor and Liver after Administration of DXR Conjugates. The serum, hepatic, and tumoral levels of free DXR after intravenous injection of DXR conjugates were determined. When DXR was administered, the serum level of DXR was decreased rapidly in the early phase and gradually in the late phase. When the conjugates were injected intravenously, the serum level of free DXR was extremely low (Figure 6A).

As for administration of DXR, its tumoral level reached a maximum at 4 h and gradually decayed thereafter. In contrast, when CM-Dex-PA-Gly-Gly-Phe-Gly-DXR or CM-Dex-PA-Gly-Gly-Ile-Gly-DXR was administered, the tumoral level of free DXR released from the conjugates was gradually increased and remained high for a long time. The tumoral level of free DXR from the conjugates at 48 h was about 3-fold higher than the level following administration of DXR itself. In the case of CM-Dex-PA-Gly-Gly-Pro-Leu-DXR, the level of free DXR was minimally detected (Figure 6B).

DXR was highly distributed into the liver immediately after intravenous injection. In the case of CM-Dex-PA-Gly-Gly-Phe-Gly-DXR or CM-Dex-PA-Gly-Gly-Ile-Gly-DXR, the hepatic level of free DXR was kept low. The Cmax values for the conjugates were 5-fold lower than that for DXR. In the case of

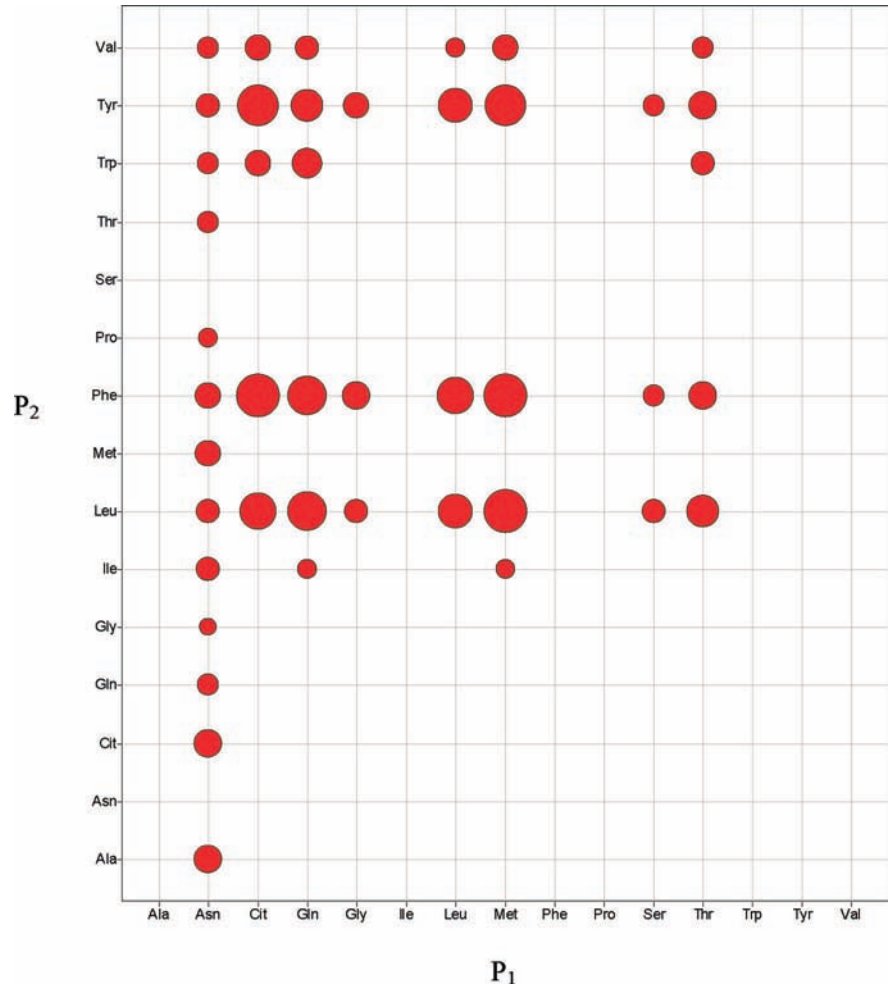

Figure 3. Released DNS for 2 h from DNS conjugates, which released DNS to 70% for 20 h. The vertical axis indicates the P_2 residure, and the horizontal axis indicates the P_1 residure. The amounts of drug released are indicated by the size of circle.

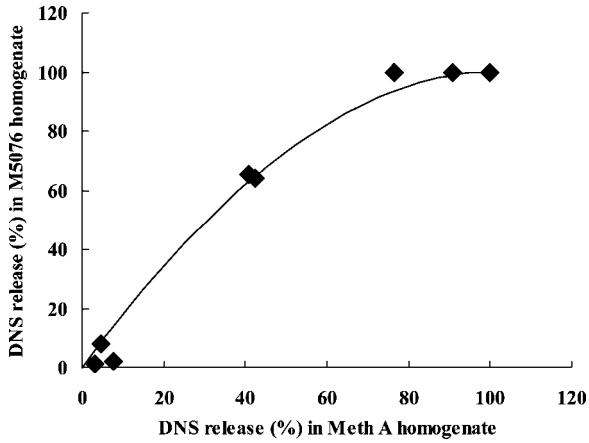

Figure 4. The relationship of released DNS from DNS conjugates between Meth A and M5076 homogenate. Several kinds of DNS conjugates were incubated in Meth A or M5076 homogenate for 20 h, and released DNS were determined by HPLC.

CM-Dex-PA-Gly-Gly-Pro-Leu-DXR, DXR was hardly detected in the liver as well as the tumor (Figure 6C).

DISCUSSION

Tumorotropic macromolecular prodrugs with peptide spacers promise to improve the efficacy and reduce the toxicity of the cancer chemotherapy. It is generally believed that the prodrugs

Table 1. Drug Release from DNS Conjugates and DXR Conjugates in 20 h Incubation with Meth A Homogenates

	drug release (%)	
peptide	DNS conjugate	DXR conjugate
Gly-Gly-Phe-Gly	100	100
Gly-Gly-Ile-Gly	41	8
Gly-Gly-Pro-Leu	15	0.3

that reached tumor tissues are taken up by tumor cells and release drug by lysosomal cysteine protease, cathepsins (*9*, *10*, *18*). Substrate specificity of cathepsins has been investigated over a few decades (*19*−*21*), including high-throughput profiling of serine and cysteine proteases using a microarray technique (*22*−*24*). However, taking into account that a polymer backbone sterically limits acceess of proteases to the peptide bond (*11*, *25*−*27*), systematic studies specialized to macromolecular prodrugs have been required. In this context, we combinatorially synthesized 225 fluorogenic macromolecular prodrugs with a CM-Dex-PA backbone and evaluated sequence dependence of amino acid spacers on the rate of drug release by tumor-associated proteases. We intended to evaluate structure−activity relationship of drug release under rather physiologically relevant conditions (i.e., tumor cell homogenates) than by individual cathepsins, since it was obvious that multiple proteases including cathepsins B and L are responsible for hydrolysis of the same type of macromolecular prodrugs (*17*).

Several investigations have already found that dipeptide having hydrophobic amino acid at P_2, such as Phe, Val, Leu, Ile, and Trp, and basic amino acid as Lys, or hydrogen bond

[a] Meth A cells were inoculated s.c. into BALB/c mice (Day 0). After 9 days, mice received a single (qd×1) administration of DXR conjugates and DXR (Day 9). Tumor weight was assessed on day 21. Asterisks indicate significant differences from the untreated control by Dunnett*s test. [b] Dose levels of compounds were expressed as those of DXR. [c] Maximum rate (%) of body weight loss, with numbers in parentheses denoting the day. <0 indicates no body weight loss. [d] Number of mice that died of toxicity/number of mice used. Death days were as follows. CM-Dex-PA-GGIG-DXR 40 mg/kg: day 16 and 17. DXR 20 mg/kg: days 17, 20, 20, and 20. *** $P < 0.001$. ** $P < 0.01$. * $P < 0.05$.

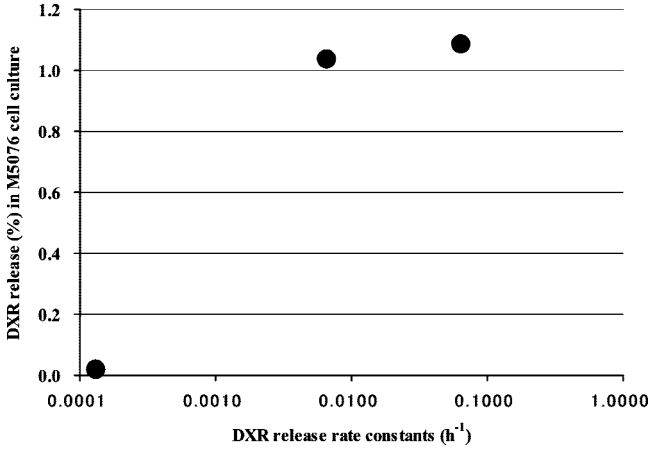

Figure 5. Relationship of released DXR from DXR conjugates between tumor homogenate and M5076 cell culture. CM-Dex-PA-Gly-Gly-Phe-Gly-DXR, CM-Dex-PA-Gly-Gly-Ile-Gly-DXR, and CM-Dex-PA-Gly-Gly-Pro-Leu-DXR were incubated with M5076 homogenate or M5076 cells for 24 h; released DXR were determined by HPLC (see Supporting Information).

amino acid as Cit at P_1, is able to be the substrate to cathepsin B (*28*). As shown in Figure 2, the release of DNS from prodrugs was rapid in the case of Val, Tyr, Trp, Phe, Met, Leu, and Ile at the P_2 position but slow in the case of Thr, Ser, Pro, Gly, Gln, Cit, and Ala. Thus, hydrophobicity of amino acids at P_2 would undoubtedly be important. When the P_1 position was a hydrophobic amino acid (Ile, Leu, Met, Phe, Tyr, Val), the cleavage appeared to occur even for spacers showing some resistance due to hydrophilic characters at P_2. It suggests that the proteases might simply recognize hydrophobic moieties and have a moderate sequence specificity. In addition, it should be noted that the P_1-DNS form tended to be released. From the viewpoint of molecular design, such hydrophobic amino acids should not be selected for P_1 to avoid the undesirable release of amino acid-conjugated drug.

In addition, when Asn was at P_1 or P_2, DNS and P_1-DNS, respectively, was released. It suggested that proteases associated with Meth A homogenate preferentially cleave the peptide bond at the C-terminal of Asn. On the other hand, the drug release rate became extremely low, when Pro was at P_1 or P_2. Pro, due to its distinctive cyclic structure in the side chain, exhibits steric hindrance and electrostatic repulsion and protects biologically active peptides against enzymatic degradation (*29*). Proteases associated with tumor cells would not be exceptional.

As mentioned above, it is desirable to design a macromolecular conjugate that does not release any conjugates with amino acids or peptides but only a native drug. On the basis of the examinations using fluorogenic macromolecular prodrugs, we selected three peptide spacers (Gly-Gly-Phe-Gly, Gly-Gly-Ile-Gly, Gly-Gly-Pro-Leu) that release only DNS at different rates and applied the spacers to the design of DXR conjugates. The rank order of the release of DXR from the conjugates was the same as that of DNS conjugates in both Meth A and M5076 tumor homogenates. Thus, examinations using fluorogenic macromolecular prodrugs undoubtedly gave useful information on the design of DXR conjugates. When CM-Dex-PA-Gly-Gly-Pro-Leu-DXR was administered to Meth A tumor-bearing mice, the tissue concentration of free DXR and antitumor activity was observed only minimally. This was quite reasonable, since the release of DXR from CM-Dex-PA-Gly-Gly-Pro-Leu-DXR was extremely slow in tumor homogenates. On the other hand, CM-Dex-PA-Gly-Gly-Phe-Gly-DXR and CM-Dex-PA-Gly-Gly-Ile-Gly-DXR, in spite of the fact that the release rate was ~10-fold different in tumor homogenates, exhibited similar pharmacokinetics and antitumor activity. The release of DXR from the conjugates would be determined not only by enzymatic activity but also by cellular uptake. It should be reiterated that water-soluble macromolecules hardly permeate plasma membranes. In the in vitro experiments using M5076 cells, the release of DXR was similar between CM-Dex-PA-Gly-Gly-Phe-Gly-DXR and CM-Dex-PA-Gly-Gly-Ile-Gly-DXR, being as slow as 1% of DXR per 24 h. Along with the fact that more than 15% of DXR could be released from these conjugates within 24 h, it is most likely that cellular uptake of the DXR conjugates is the rate-limiting step in vitro. As for DXR conjugates with the carboxymethyl−pullulan (CMPul) backbone (*12, 30, 31*), it has been reported that CMPul-Gly-Gly-Phe-Gly-DXR, which releases DXR rapidly in tumor homogenates, showed the highest antitumor activity, while CMPul-Gly-Gly-Gly-Gly-DXR, which releases DXR slowly, showed weaker activity than DXR in walker-256 and Yoshida sarcoma-bearing rat models. Our present investigation also revealed that the Gly-Gly-Gly-Gly spacer gave much slower release of DXR as compared to Gly-Gly-Phe-Gly and Gly-Gly-Ile-Gly spacers. Although the past (*12, 30, 31*) and present studies were different in terms of tumor models and polymer backbones, they presented an

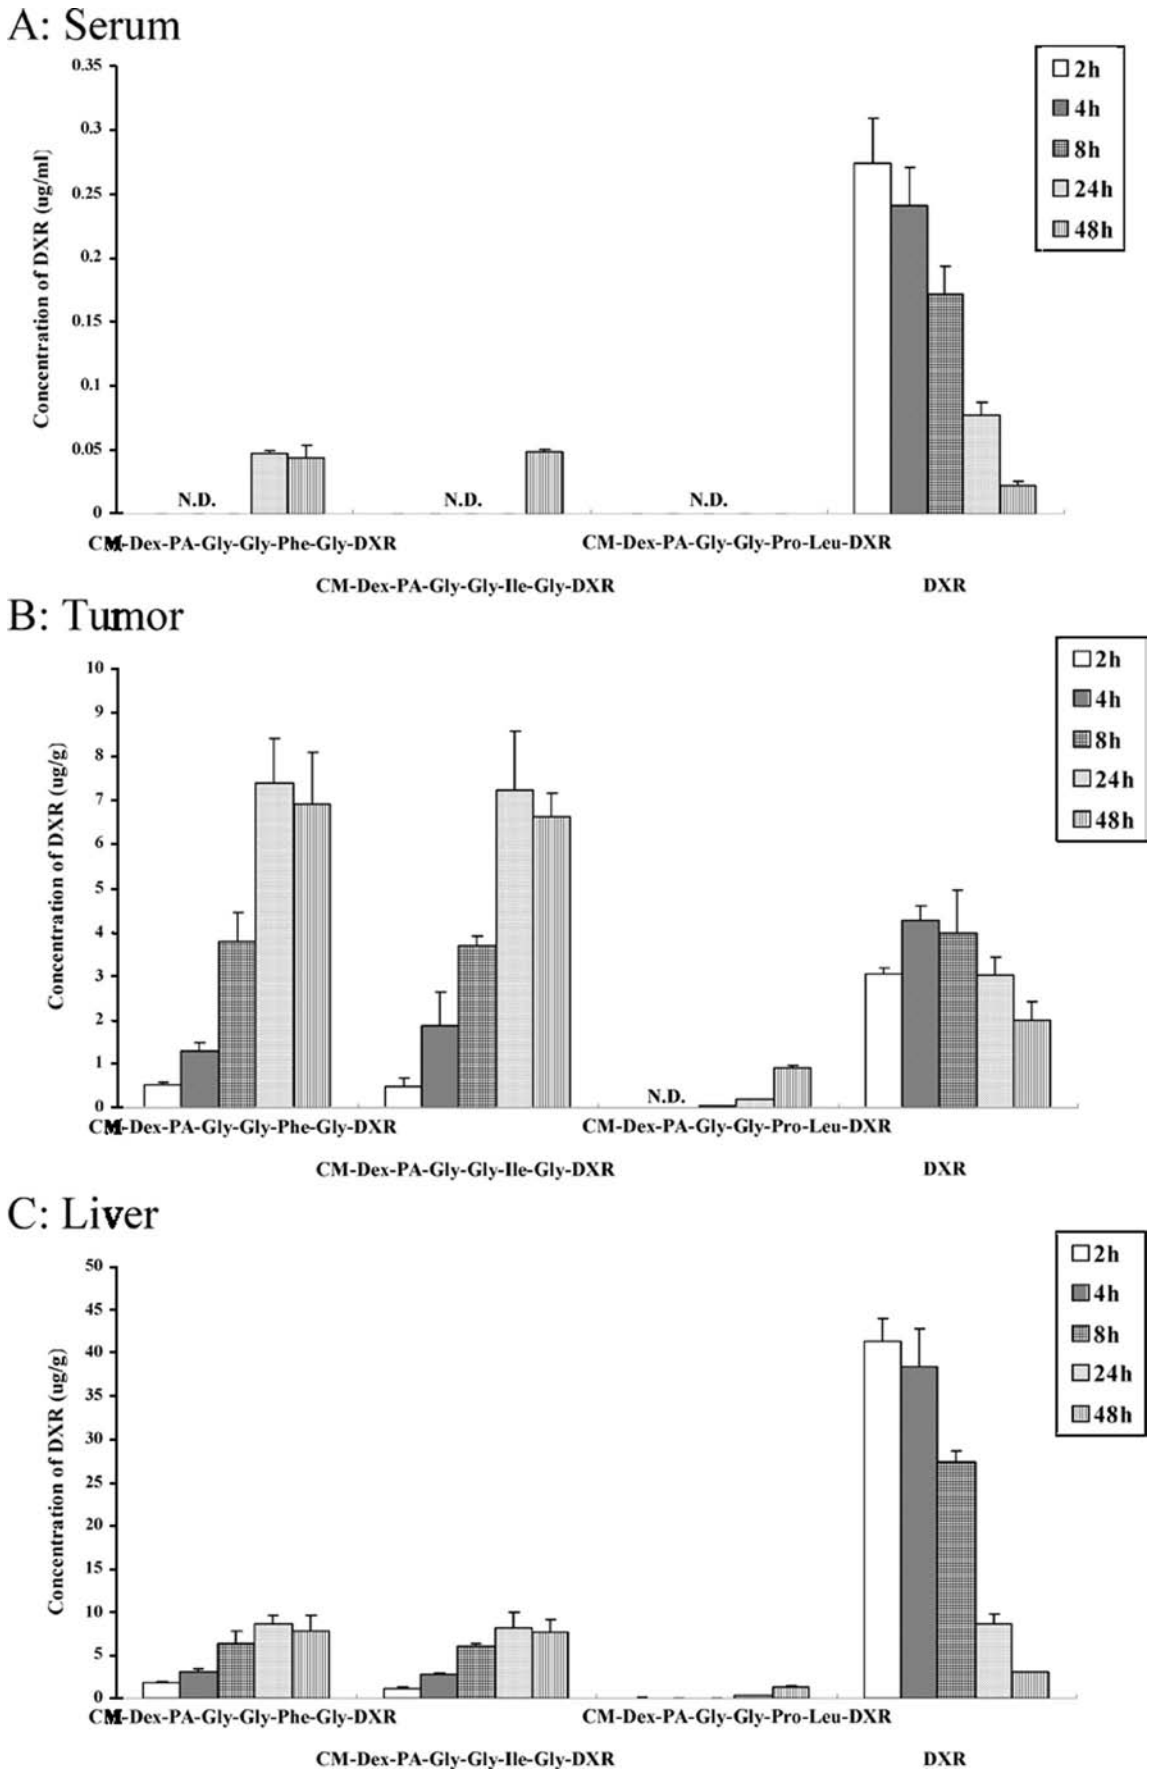

Figure 6. Pharmacokinetic profiles of free DXR after i.v. administration of DXR-conjugates or DXR to Meth A bearing mice at a dose equivalent to 20 mg/kg. Each point represents the mean for three mice; bars, SD. Parts A, B, and C indicate DXR concentration of serum, tumor, and liver, respectively. N.D.: Not detected.

essentially similar tendency. It might be concluded that the faster release of DXR provides greater antitumor activity, but the trend is saturated since cellular uptake of conjugates is smaller than the release of DXR based on the in vitro observations.

It is well-known that matrix metalloproteases (MMPs) are highly expressed in the tumor tissues. Macromolecular drug conjugates releasing active ingredients with MMPs have also been developed (*32*, *33*). These conjugates were designed on the basis of earlier studies on substrate specificity of MMPs demonstrating a consensus motif of Pro-X-X-X_{Hy} where X_{Hy} is a hydrophobic amino acid residue (*34*−*36*). It is also known that peptides having Leu and Ile instead of Pro in the sequence can be substrates for MMP-2 (*34*). Since our macromolecular prodrugs have quite different amino acid sequences, i.e., Gly-Gly-X-X, from MMP substrates and showed a fairly good in vitro/in vivo correlation of drug release, it is unlikely that MMPs are responsible for the release of DXR from the conjugates. At this moment, however, involvement of MMPs has yet to be ruled out.

In summary, we systematically investigated the properties of peptide spacers controlling the drug release from conjugates and found representative peptide spacers, which release only parent drug with different rates. With regard to DXR conjugates, the conjugates showing a faster drug release rate provided greater antitumor activity in tumor-bearing mice. Considering that antitumor drugs are classified into time−concentration product (AUC)-dependent and time-dependent drugs (*37*, *38*), however, the release rate of drugs needed to be controlled properly. We believe the present study provides useful information on the design of macromolecular prodrugs intended for antitumor chemotherapy.

ACKNOWLEDGMENT

The support of Dr. Kazuhiro Inoue is gratefully acknowledged. We thank Satoru Ohsuki for supporting the synthesis of the conjugates, and Setsuko Fukutake for carrying out the antitumor activity experiments.

Received July 7, 2008; Revised Manuscript Received November 20, 2008

Surface-initiated atom transfer radical polymerization (ATRP) has been used to prepare antifouling copolymer brushes based on 2-(2-methoxyethoxy)ethyl methacrylate (MEO_2MA) and hydroxyl-terminated oligo(ethylene glycol) methacrylate (HOEGMA). The amount of hydroxyl reactive groups incorporated into the brushes was varied by changing the composition of the monomer mixture. These coatings were subsequently functionalized by a natural antibacterial peptide, magainin I, via an oriented chemical grafting on hydroxyl groups, which maintains the activity of the peptide. The antibacterial activity of the functionalized brushes was successfully tested against two different strains of gram-positive bacteria.

INTRODUCTION

The adhesion of bacteria on the surfaces of materials is of crucial importance in diverse fields such as ship hull fouling, contamination of medical devices, industrial cooling water systems, and food processing equipment (*1*−*3*). Once adhered on a solid surface, bacteria form colonies and subsequently biofilms that serve as reservoirs for the development of pathogenic infections (*4*−*6*). In this context, many studies were performed to generate thin coatings that reduce bacterial adhesion onto solid surfaces. The developed methods are mainly based on two different strategies: (i) the immobilization of biocidal substances and (ii) the deposition of an antifouling coating that prevents proteins and subsequently cell adhesion on the surface. The techniques employed to immobilize antibacterial substances onto solid surfaces involve chemical grafting, surface impregnation, or physical entrapment (*7*−*11*). As for the nonadhesive coatings, they are mainly self-assembled monolayers (SAMs) (*12*−*24*) or polymer brushes based on poly(ethylene glycol) (PEG) or its derivatives (*15*−*17*). However, even though the antifouling properties of PEG-based layers have been widely reported in the literature, these layers do not completely prevent the adhesion of bacteria (*18*−*21*). Therefore, it is desirable to combine both approaches in effective antibacterial coatings: nonadhesive properties to reduce initial cell adhesion and the simultaneous presence of a biocidal substance to kill bacteria adhering onto the surface.

Recently, polymer brushes have attracted considerable attention as a way to engineer the surface properties of materials (*22*). By comparison with other surface modification methods (e.g., SAMs), they offer a higher mechanical and chemical robustness, which results in a higher long-term stability. A broad range of chemical functionalities can be obtained from an adequate choice of the monomers, as we demonstrated by testing the antibacterial properties of sulfonate brushes loaded with silver ions (*23*). Among techniques used to prepare polymer brushes, the "grafting from" approach based on surface-initiated atom transfer radical polymerization (ATRP) offers an experimentally straightforward route to dense brushes with a narrow polydispersity, a controlled architecture, and a well-defined thickness and composition (*24*). We have reported previously on the preparation of copolymer brushes based on 2-(2-methoxyethoxy)ethyl methacrylate (MEO_2MA) and oligo(ethylene glycol) methacrylate (OEGMA) (*25*−*27*). These PEG-based brushes are expected to be nontoxic, non-immunogenic, non-antigenic, and nonadhesive toward cells (*28, 29*). Here, similar copolymer brushes incorporating a hydroxyl-terminated oligo(ethylene glycol) methacrylate (HOEGMA) monomer were used as a platform to immobilize a natural antimicrobial peptide.

Among the substances used to inhibit the growth of bacteria, the natural defense peptides that are secreted by living organisms such as plants, microorganisms, and various mammalians, insects, and amphibians have recently emerged as a particularly promising class of biocidal drugs (*30*−*32*). Indeed, compared to conventional antibacterial substances such as antibiotics, quaternary ammonium compounds, or heavy metal derivatives, defense peptides have been shown to act at a much lower concentration, which considerably limits the potential problems related to toxicity (*33*−*35*). Moreover, these natural peptides have a broad spectrum of antimicrobial or even antifungal activity, and they rarely promote bacterial resistance. Recently, a few studies have reported on the immobilization of antibacterial peptides coupled to SAMs (*7*) or polyelectrolyte multilayers (*10, 11*) to prepare antibacterial thin films.

In this paper, we describe the oriented end-grafting of an antimicrobial peptide on poly(MEO_2MA-*co*-HOEGMA) brushes. Beside their nonadhesive behavior, these copolymer brushes offer reactive hydroxyl groups which allow controlled loading of the brushes with antimicrobial peptide grafted on the brushes and consequently the activity of the resulting coatings. Magainin

I, a 23-residue defense peptide initially isolated from the skin of the African clawed frog *Xenopus laevis* (*36, 37*), was selected for its broad biocidal activity against Gram-positive and Gram-negative bacteria and its non-hemolytic properties at its effective antimicrobial concentration. Magainin-functionalized copolymer brushes of various compositions were tested against two different gram-positive bacteria.

EXPERIMENTAL SECTION

Materials. Di(ethylene glycol) methyl ether methacrylate (MEO_2MA) (95%), and hydroxyl-terminated oligo(ethylene glycol) ether methacrylate (HOEGMA) of molar mass ~360 g/mol were obtained from Aldrich and were used without purification. FITC-labeled streptavidin (streptavidin^{FITC}) and *N*-(*p*-maleimidophenyl)isocyanate (PMPI) were purchased from AbD Serotec and Appolo Scientific, respectively. Copper(I) chloride (99.995+%) (Cu^ICl), copper(II) chloride (99.999+%) ($Cu^{II}Cl_2$), and 2,2′-dipyridyl (99+%) (bipy), tris(hydroxymethyl)aminomethane (tris) were from Aldrich. All solvents were distilled before use except methanol, which was analytical reagent grade. Milli-Q water (resistivity higher than 18.2 MΩ.cm) was obtained from a Millipore Simplicity 185 system. Silicon wafers (⟨100⟩ orientation) were obtained from Compact Technology Ltd.; they were cleaned for 10 min in an air plasma asher (100 W, Emitech K1050X) before use. Magainin I derivatives with an additional C-terminal cysteine residue and tagged with an N-terminal biotin moiety (Biotinyl-MAG-Cys) or untagged (MAG-Cys) were synthesized by the solid-phase methodology on Fmoc-Cys(Trt)-HMP resin by using a 433A Applied Biosystems peptide synthesizer and the standard Fmoc manufacturer's procedure. The synthetic peptides were purified by reversed-phase preparative HPLC on a Vydac 218TP1022 C_{18} column by using a linear gradient (10−60% over 60 min) of acetonitrile/trifluoroacetic acid (99.9:0.1; v/v) at a flow rate of 10 mL.min^{-1}. Analytical HPLC, performed on a Vydac 218TP54 C_{18} column, showed that the purity of the peptides was higher than 99.8%. The purified peptides were characterized by MALDI-ToF mass spectroscopy on a Voyager DEPRO in the reflecton mode with α-cyano-4-hydroxycinnamic acid as a matrix. LIVE/DEAD BacLight Bacterial Viability Kit L7007 containing SYTO 9 and propidium iodide dyes was purchased from Molecular Probes.

Preparation of the Antibacterial Brushes. *Initiator-Grafted Silicon Wafers.* The synthesis of the 2-bromo-2-methyl propionic acid 3-trichlorosilanylpropyl ester was adapted from a previously published procedures (*38*), and the formation of the initiator monolayer was performed as described previously (*39*). An ellipsometric thickness of 0.6−0.9 nm was found for the initiator monolayer (*25*).

Copolymer Brushes. The synthesis of the copolymer brushes by surface-initiated ATRP was adapted from a procedure recently published (*25*). Briefly, the monomers (95 mmol) were dissolved in a mixture of water (30 mL) and methanol (15 mL) (e.g., for a MEO_2MA/HOEGMA molar ratio of 67:33, 12 g of MEO_2MA (63.7 mmol) and 11.3 g of HOEGMA (31.3 mmol) were used) in a round-bottom flask sealed with a rubber septum. Bipy (5 mmol, 782 mg) and $Cu^{II}Cl_2$ (0.16 mmol, 21.5 mg) were added to this solution, which was stirred and degassed with a stream of nitrogen for 1 h. Cu^ICl (1.6 mmol, 158.5 mg) was then added quickly to the solution. The solution was stirred and degassed for 45 further min. Meanwhile, the initiator-grafted Si wafers (1 × 1 cm^2) were sealed into Schlenk tubes and were degassed (4 vacuum/nitrogen filling cycles). The polymerization solution was then syringed and quickly transferred to the Schlenk tubes. The Schlenk tubes containing the samples were kept at room temperature under an overpressure of nitrogen in the absence of stirring, for a given polymerization time that depends on the monomer ratio (from 3 h to 9 h). Then, the samples were removed, washed with water then methanol, dried with a stream of nitrogen, and stored under nitrogen before use. The polymerization times used for each monomer ratio were adapted to get copolymer brushes with an average thickness of about 110 nm (Table 1). Four different MEO_2MA/HOEGMA monomer ratios were tested to prepare the copolymer brushes: 100:0; 83:17, 67:33, and 33:67.

Table 1. Characteristics of the Poly(MOE_2MA-*co*-HOEGMA) Brushes

composition of the monomer mixture [MOE_2MA/HOEGMA]	reaction time (min)	brush thickness[a] (nm)
100:0	150	106
83:17	210	110
67:33	245	110
33:67	527	111

[a] Measured by ellipsometry.

Oriented Grafting of Magainin I Derivatives on Copolymer Brushes. Two milliliters of 6 mM PMPI solution prepared in distilled dry THF were transferred to a Schlenk tube containing the silicon wafer functionalized by the poly(MEO_2MA-*co*-HOEGMA) brush in a nitrogen-purged glovebox. After a reaction time of 6 h at room temperature, the silicon wafer was sonicated in distilled THF for 5 min, and the surface was thoroughly washed 3 times with distilled THF before finally being dried in a stream of nitrogen. Next, the PMPI-grafted brush was reacted with MAG-Cys or biotinyl-MAG-Cys derivative. For this, the silicon wafer was treated with a 280 μM solution of the peptide prepared in 100 mM tris buffer (pH 7.04). After a reaction time of 2 h 30 min at room temperature, the silicon wafer was sonicated 5 min in Tris buffer, thoroughly washed 3 times with Milli-Q water, and finally dried in a stream of nitrogen before use in bacterial assays.

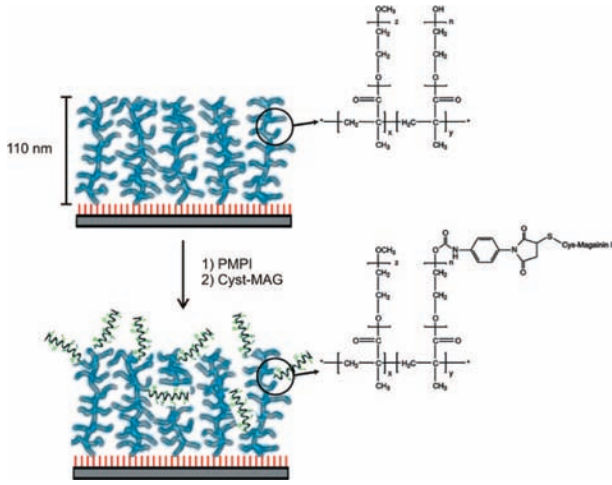
Analytical Techniques. *Ellipsometry.* Ellipsometric measurements were carried out with a spectroscopic ellipsometer (α-SE from J. A. Woollam Co., Inc.). The data were fit using a Cauchy model for the index of refraction of the organic layer, using tabulated values for the index of refraction of silicon. The 1.5-nm-thick layer of native silicon oxide was included in the organic layer, since they have close indices of refraction. Five measurements were taken and averaged for each sample. In most cases, the standard deviation of the thickness about its average value was lower than 3 nm.

Optical Microscopy. Optical and fluorescence images were taken with a Nikon Eclipse ME600L microscope equipped with a FITC filter set and an Epi-Fluorescence module, and connected to a DN100 image-capture system. Images were processed using *IGOR Pro* software (Wavemetrics, Inc.).

Confocal Laser Scanning Fluorescence Microscopy (CLSM). CLSM imaging was carried out with a Leica SP2 upright confocal laser scanning microscope (DM RXA2) equipped with an Acousto-Optical Beam Splitter (AOBS) system and using a 63× oil immersion objective with numerical aperture 1.32 (Leica Microsystems, Rueil-Malmaison, France). SYTO 9 was excited at 476 nm and observed from 485 to 540 nm, and propidium iodide was excited at 514 nm and observed from 580 to 670 nm. The laser power, the gain, and the offset for each photomultiplier have been adjusted to optimize the bacteria detection.

Images of the CLSM observations (1024 × 1024 pixels) have been acquired through the sequential mode to avoid fluorescence emission spectrum overlap, and the signal/noise ratio has been increased through line (×2) and frame (×4) averaging. Overlay images have been built with post-acquisition Leica Confocal software (LCS).

Scheme 1. Oriented Grafting of MAG-Cys Derivative on Poly(MOE_2MA-*co*-HOEGMA) Brushes via a PMPI Heterolinker



Fourier Transform Infrared Spectroscopy (FTIR). FTIR spectra were acquired between 1000 and 4000 cm^{-1} with a BioRad FTS-6000 spectrometer. The measurement were performed in transmission through the silicon wafers. The sample compartment was thoroughly purged with dry nitrogen before measurement.

X-ray Photoelectron Spectroscopy (XPS). XPS measurements were performed using a Kratos Axis Ultra spectrometer (Kratos Analytical) with a monochromatic Al Kα X-ray source ($h\nu$ 1486.6 eV). The pass energy was set at 40 eV for the detailed scans. In these conditions, the energy resolution gives a full width at half-maximum of the Ag $3d_{5/2}$ peak of about 0.1 eV. All binding energies were referenced to the *C*-(C,H) component of the C 1s peak fixed at 284.8 eV. The base pressure in the spectrometer was in the low 10^{-8} Torr range. Quantitative information was obtained by the photoemission peak areas of each element normalized according to acquisition parameters and sensitivity factors provided by the manufacturer. Peak decomposition was achieved with the Casa *XPS* software (Casa Software Ltd., UK), after subtraction of a linear baseline.

Bacterial Inhibition Assays. Magainin-functionalized brushes were tested against two Gram-positive bacteria: *Listeria ivanovii* (strain kindly provided by the UMR CNRS 6008 of University of Poitiers, France) and *Bacillus cereus* (strain kindly provided by the UMR CNRS 6143 of University of Rouen, France). Both bacteria strains were precultured in Mueller-Hinton broth for 18 h, then harvested by centrifugation (2000 × *g* for 15 min) and resuspended in distilled water. A functionalized silicon wafer was immersed in 10 mL of diluted bacteria suspension freshly prepared in distilled water (10^7 colony forming units (CFU).mL^{-1}). After 3 h incubation at room temperature, the silicon wafer was taken out and briefly rinsed with distilled water. To test the viability of bacteria adhering on the functionalized copolymer brush, the cells were immediately stained with the LIVE/DEAD BacLight Bacterial Viability Kit. For this, the wet silicon wafer was immersed in 2 mL of diluted viability kit solution. After an incubation time of 30 min, the silicon wafer was briefly rinsed with distilled water, and the surface was visualized by microscopy. The viability of the cells suspended in the distilled water was also controlled by counting the number of bacteria colonies grown on a seeded Mueller-Hinton agar medium (Difco). This control experiment confirmed that the viability of the bacteria was absolutely not affected after an incubation time of 3 h in water.

Culturability of sessile *L. ivanovvi* cells was also investigated. 1 × 1 cm^2 functionalized silicon wafers were deposited on 15 g/L κ-carrageenan plates (on which no bacterial growth occurs) and covered with a bacterial suspension (10^7 CFU.mL^{-1}). After incubation for 3 h at room temperature, wafers were picked up and rinsed with sterile distilled water. Adherent cells were recovered by sonication (two steps of 1 min at 50 W) of the material in 5 mL of sterile distilled water (Deltasonic bath, Meaux, France). The resulting cell population was enumerated by plating out decimal dilutions of the suspension on Plate Count Agar. After incubation for 24 h at 37 °C, the number of bacteria was expressed as CFU.cm^{-2} material.

RESULTS AND DISCUSSION

To prepare antibacterial coatings combining both biocidal and nonadhesive properties, we explored the tethering of a natural defense peptide, magainin I, on poly(MEO_2MA-*co*-HOEGMA) brush platforms. Because magainin I exerts its toxicity against bacteria by permeabilizing the cell membranes through pore forming or structural defects in membranes (*40*, *41*), it is important to maintain its mobility and its accessibility after attachment on the copolymer brushes (*7*). To maintain the solution properties of magainin I upon attachment to the brushes, the peptide derivatives were tethered on the hydroxyl extremities of the relatively long water-soluble and flexible oligo(ethylene glycol) side chains of the poly(MOE_2MA-*co*-HOEGMA) brushes (Scheme 1). Furthermore, to orient the peptide on the surface and allow it to easily access bacterial membranes, a cysteine residue was attached to the C-terminal side of magainin I. Because magainin I does not contain cysteine residue, the magainin I derivative MAG-Cys could be exclusively attached to the brushes by its C-terminal part, via a PMPI heterolinker (Scheme 1): the isocyanate moiety of the linker reacts with the hydroxyl group of the copolymer brushes; the maleimide reacts with the thiol function of the MAG-Cys or Biotinyl-MAG-Cys derivative (*42*, *43*). An interesting feature of the poly(MOE_2MA-*co*-HOEGMA) brushes is the possibility to vary their functionality in hydroxyl-reactive groups and subsequently the amount of immobilized magainin I, simply by changing the composition of the monomer mixture used. Various copolymer brushes of increasing content in reactive HOEGMA were thus prepared and subsequently functionalized by magainin I derivatives (Table 1). The reaction times used for the surface-initiated ATRP were adjusted to get ∼110-nm-thick brushes. The grafting of the MAG-Cys peptide on the copolymer brushes was confirmed by FTIR, which showed the occurrence of a new amide I absorption band centered at 1661 cm^{-1} after grafting (Figure 1). However, the poor signal/noise ratio obtained from these measurements does not allow us to quantify the real amount of peptide grafted

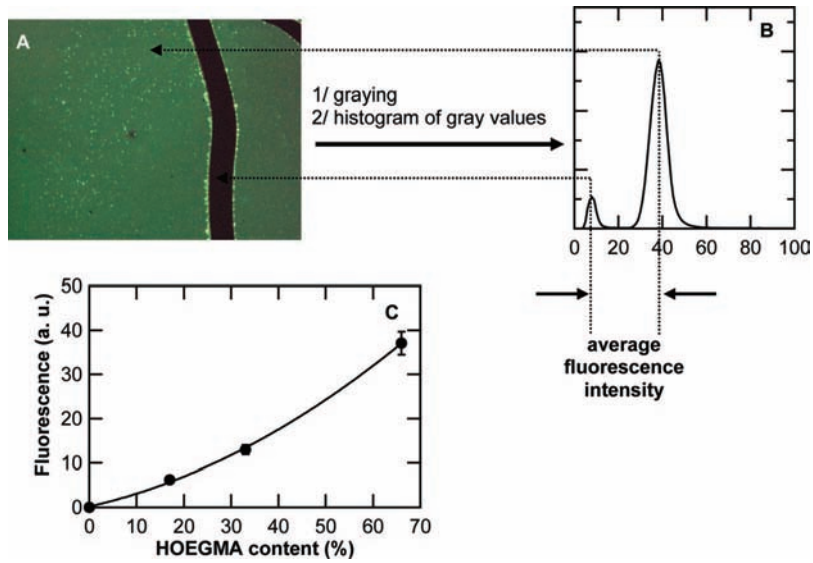

Figure 2. Image analysis of Biotinyl-MAG-Cys-grafted poly(MEO_2MA-*co*-HOEGMA) brushes incubated in a streptavidin^{FITC} solution: (A) Fluorescence image of a Biotinyl-MAG-Cys-grafted poly(MEO_2MA-*co*-HOEGMA) [33:67] brush; a deliberate scratch was made on the sample surface to determine the fluorescence background; (B) fluorescence intensity histogram computed from image (A) after graying; (C) fluorescence intensity of Biotinyl-MAG-Cys-grafted poly(MEO_2MA-*co*-HOEGMA) brushes vs their composition.

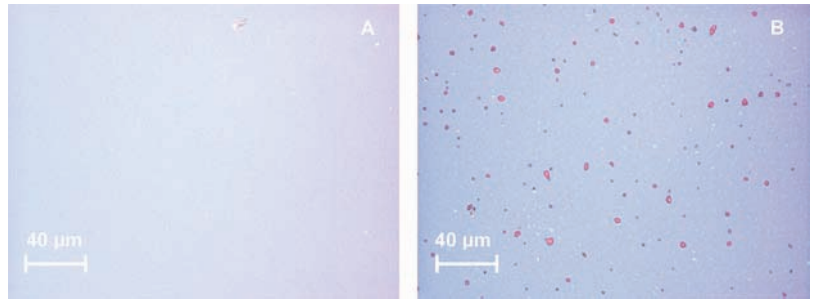

Figure 3. Optical micrographs of the brush surface after 3 h incubation in *L. ivanovii* suspension: (A) nonfunctionalized and (B) MAG-Cys-functionalized poly(MEO_2MA-*co*-HOEGMA) [33:67] brushes.

on the copolymer brushes. The percentage of monomer unit grafted by magainin was quantitatively estimated by XPS to be about 5% for a poly(MOE_2MA-*co*-HOEGMA) brush [67:33]. This percentage is significantly lower than the content of the brush in hydroxyl grafting moieties, which strongly supports the notion that the grafting reaction essentially occurs on the brush surface. To estimate qualitatively the influence of the composition of the copolymer brush on the amount of magainin I grafted on the brush surface, the brushes were functionalized with a biotin-tagged derivative (Biotinyl-MAG-Cys) and were subsequently incubated with streptavidin^{FITC}. Then, the surface-immobilized streptavidin^{FITC} was detected by fluorescence microscopy. For all Biotinyl-MAG-Cys-functionalized brushes tested, the surfaces were uniformly fluorescent on a micrometer scale, which indicates the uniform immobilization of the biotin-tagged magainin I molecules on the surface (Figure 2). In contrast, the absence of fluorescence of brushes not functionalized by magainin I (result not shown) testified to their inertness toward protein adsorption. Therefore, the fluorescence detected on functional brushes arises from the streptavidin binding to the biotin-tagged brushes, not from unspecific adsorption. The amount of grafted peptide was indirectly estimated as a function of the composition of the copolymer brush (e.g., HOEGMA content) by extracting the average fluorescence intensity by image analysis (Figure 2). For this, a deliberate scratch was made on the sample surface to determine the fluorescence signal-to-background (Figure 2). After graying the recorded image and computing the histogram of gray values, the fluorescence intensity was extracted as shown in Figure 2. The results displayed in Figure 2 show that the amount of streptavidin^{FITC} bound to the Biotinyl-MAG-Cys-functionalized brushes increases with the amount of HOEGMA in copolymer brush. As a consequence, the higher the content in hydroxyl reactive group in the brush, the higher the amount of magainin derivative grafted. This result confirms that the amount of tethered magainin I can be tuned by simply varying the composition of the copolymer brush used as a platform. Such a design is of a particular interest to optimize the biocidal properties of the surface.

The antibacterial properties of the MAG-Cys-modified brushes were tested toward two strains of Gram-positive bacteria: *L. ivanovii*, which causes serious food intoxications (*44*), and *B. cereus*, which is also involved in food-borne diseases and exhibits a high ability to adhere and to form biofilms on stainless steel (*45*) and glass (*46*). Experimentally, the functionalized silicon substrates were incubated for 3 h in bacteria suspension and immediately observed by optical microscopy. For the sake of comparison, a control adhesion test with unmodified copolymer brushes was also performed. The inspection of recorded micrographs (Figure 3) revealed the absence of bacteria on the unmodified poly(MOE_2MA-*co*-HOEGMA) [33:67] brush for both strains tested (results shown only for *L. ivanii*), which testifies to the inertness of this brush platform. A similar result was obtained for unmodified copolymer brushes of varying composition. In contrast, some bacteria were observed on magainin-functionalized brushes, but the cell coverage did not exceed 1% of the surface, independent of the copolymer brush composition. This result indicates that the bacterial attachment

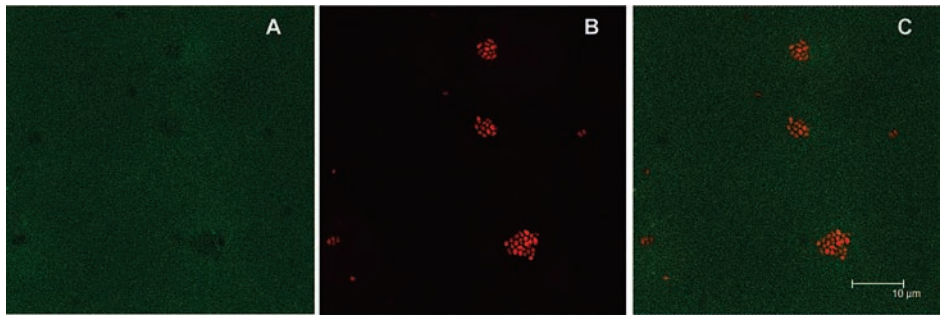

Figure 4. CLSM images of MAG-Cys-functionalized poly(MEO_2MA-*co*-HOEGMA) [33:67] brush incubated in the presence of *L. ivanovii* and subsequently stained with the LIVE/DEAD viability kit: (A) green channel image corresponding to alive stained bacteria; (B) red channel image corresponding to dead bacteria; (C) overlay image built from (A) and (B).

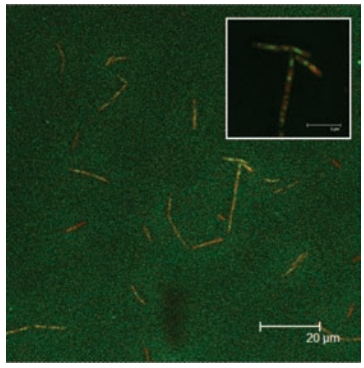

Figure 5. CLSM overlay image of MAG-Cys-functionalized poly(MEO_2MA-*co*-HOEGMA) [33:67] brush incubated in presence of *B. cereus* and subsequently stained with the LIVE/DEAD viability kit. The overlay image was built from both red channel and green channel images. Inset: An enlarged image of stained bacterial cells.

onto the brushes is exclusively due to the presence of the magainin I peptide, which interacts with cell membranes. To check the viability of the bacteria observed on the magainin-functionalized brushes, the adhering cells were stained with the fluorescent LIVE/DEAD viability kit before CLSM observation (*47*). The inspection of the green and red channels of the CLSM images obtained on magainin-functionalized brushes exposed to *L. ivanovii* (Figure 4) revealed only the presence of red-stained cells corresponding to dead bacteria. This observation was made even for the sample of lower grafting ratio (results not shown). Similar assays were performed on *B. cereus*. CLSM observations showed that every single *B. cereus* cell adhering to the surface of the functionalized brushes is partially red-stained (Figure 5), which testifies to the presence of damages to its membrane. The fact that *B. cereus* cells were not seen to be completely red-stained is most probably due to the staining process, which depends on the conditions and on the bacteria used, as was previously noted (*48, 49*). Bacterial cell counts performed with *L. ivanovii* after 3 h of contact, confirmed the antimicrobial properties of the magainin-grafted brushes. Indeed, a colonization of 700−800 $CFU.cm^{-2}$ was measured, independent of the composition of the copolymer brush. Sessile bacteria represents less than 0.0001% of the planktonic population, a ratio close to those reported by Kebir et al. (*50*) with *Pseudomonas aeruginosa* on antibacterial cross ionic copolyurethanes, and much lower than those generally obtained in same experimental conditions with raw materials (*50, 51*). Thus, the assays performed on both tested bacterial species demonstrate the high efficiency of the magainin-functionalized copolymer brushes to kill all the bacterial cells adhering on their surface. The biocidal activity was detected even for the lower grafting ratio in magainin I peptide tested.

One might wonder about how the grafted peptide molecules exert their antimicrobial effect. The detailed mode of antibacterial action of magainin is still unclear. However, it seems obvious that the membrane barrier properties are reduced by the presence of magainin molecules in the membrane, even though experimental data do not support the formation by magainin of well-defined membrane channels (*52*). As a consequence, the accumulation of magainin at the surface of the brushes combined with the flexibility of the HOEGMA side chains is probably sufficient to allow an antimicrobial effect, which is compatible with current models of magainin action, such as transmembrane helical bundles, toroidal model, carpet model, and the detergent-like peptide model (*52*). It has to be noted that biocidal activity of an antimicrobial peptide immobilized onto a solid surface via an oriented chemical grafting was also previously reported (*7*). Therefore, the magainin-functionalized brushes provide an efficient protection against bacterial spreading by killing cells in contact with them. The presence of the antimicrobial peptide combined with the intrinsic antifouling properties of the brushes should result in a strong delay of Biofilm formation, which is of interest for many applications in the medicine and food industries.

CONCLUSION

Bacterial biofilms cause infections as well as bacterial and chemical contaminations in many domains, from food and water industries to the biomedical field. On biomaterials, in particular, they often lead to removal of infected implants, because biofilms protect bacteria against antibacterial treatments and store bacteria for further infections. Among the possible methods of action against Biofilm formation, prevention by the control of the first stage of its formation (primary colonization of bacterial adhesion) is considered to be the most efficient strategy. Here, we described an original approach combining the antiadhesive property of poly(MEO2MA-*co*-HOEGMA) brushes and the antibacterial activity of an immobilized natural peptide to prepare efficient antibacterial coatings. Surface-initiated ATRP was used to synthesize nonadhesive poly(MEO2MA-*co*-HOEGMA) brushes that were subsequently used as platforms to covalently immobilize a natural antibacterial peptide. We demonstrated that the peptide can be tethered in various densities by changing the composition of the copolymer brushes, which allows variation of the biocidal activity of the coatings. The highly biocidal activity of the peptide-functionalized brushes was in evidence even for low levels of grafted peptide. The strategy developed here should be easily adaptable to coat various materials or items used in the medicine and food industries. Moreover, this approach could be generalized to other natural peptides to prepare thin coatings with a broad spectrum of activity against bacteria, fungi, and protozoa.

ACKNOWLEDGMENT

Dr. J. Gautrot (Melville Laboratory, Cambridge) and X. Laloyaux (CeRMiN, UCL, Louvain-la-Neuve) are thanked for FTIR and XPS measurements, respectively. The authors are thankful to the CIFA laboratory (UCL) for providing access to the XPS apparatus. This research was financially supported by the French National Research Agency (ANR) (project ANR-06-BLAN-0196-01).

Androgen receptors are overexpressed in most primary and metastatic prostate cancers. A series of single photon emission computed tomography imaging agents (SPECT) utilizing the organometallic radioactive imaging species, *fac*-^{99m}Tc$(OH_2)_3(CO)_3^+$, were prepared on the basis of the structure of Flutamide, a potent nonsteroidal antiandrogen prostate cancer drug. Novel bifunctional chelate-linked Flutamide analogues were prepared using a newly developed universal alkylating reagent, 2-bromo-*N*-[4-nitro-3-(trifluoromethyl)phenyl]-acetamide, **1**. From compound **1**, several ligands (i.e., cysteine **2**, histidine **5**, imidazole **3**) were conjugated to the flutamide derivative to yield targeting ligands capable of either tridentate or monodentate coordination in a "2 + 1" complex. *fac*-$Re(CO)_3^+$ complexes were prepared and characterized with the functionalized conjugates to yield *fac*-$Re(CO)_3$(2-amino-3-(1-(2-(4-nitro-3-(trifluoromethyl)phenylamino)-2-oxoethyl)-1*H*-imidazol-4-yl) propanoate), **4**, *fac*-Re $(CO)_3$(2-(*S*-cysteinyl)-*N*-[4-nitro-3-(trifluoromethyl) phenyl]-acetamide), **6**, and *fac*-$Re(CO)_3$(picolinate)(2-(1*H*-imidazol-1-yl)-*N*-[4-nitro-3-(trifluoromethyl)phenyl]-acetamide), **7**. The corresponding radioactive ^{99m}Tc analogues were prepared and stability studies of the radioactive compounds were also conducted.

INTRODUCTION

Prostate cancer is the second leading cancer affecting men in the United States (*1*). Current screening methods utilized in medicine for prostate cancer involve a digital rectal exam, prostate specific antigen (PSA), and/or prostate core biopsies (*2, 3*). Each of these methods has their own limitations in specificity and accuracy in diagnosing prostate cancer. Major limitations of current diagnostic methods are caused by the inability to noninvasively image and spatially resolve cancerous tissues amidst normal prostate tissue without perturbation of the organ. Prostate cancer cells have been found to overexpress the androgen receptor (AR) during the cancer development (*4*). The AR provides an excellent biological target for discriminating from normal prostate cells due to the increased up-regulation of the AR. The overexpression of AR is most likely due to the increased transportation of testosterone into the cancerous cells, which has been attributed to a role in DNA transcription and cell proliferation (*5*).

Current treatment of prostate cancer involves single or combination treatment strategies from hormone treatment, radiation implants, surgical removal of the prostate, and/or chemical castration for eliminating testosterone production. Major side effects of the treatment methods involve decrease or elimination of normal sexual function and loss of urinary function. Hormone therapy, targeting the androgen receptor, is typically regarded as the first round of treatment for prostate cancer to control the prostate size and tumor growth. Several nonsteroidal antiandrogens, such as nilutamide, bicalutamide, flutamide, and the corresponding metabolite hydroxyflutamide, have been utilized as hormonal therapeutic agents in a clinic setting for a number of years (Figure 1) (*6*−*11*). Although hormone therapy may have some initial success, recurrent or hormone refractory prostate cancers may occur 1−3 years after hormone treatment as an advanced form of metastatic cancer that is resistant to chemotherapy and is believed to be androgen-independent due to a mutation of the AR (*12*).

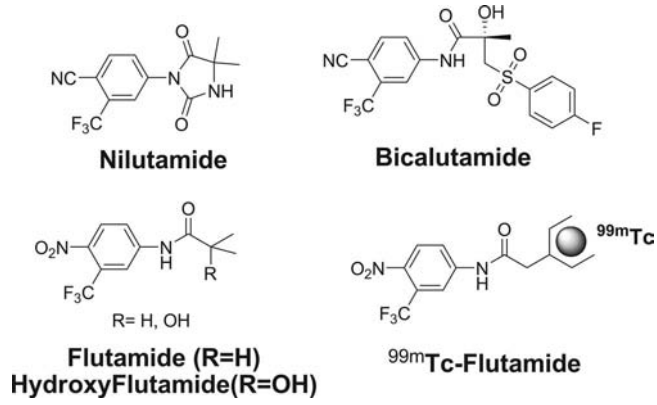

Figure 1. Examples of nonsteriodal antiandrogens clinically utilized in hormone therapy for prostate cancer and the ^{99m}Tc complex-linked flutamide reported within.

The presence or absence of AR in prostate cancer could be identified by a noninvasive imaging probe and would provide a key indicator in early screening as well as disease progression. Several positron emission tomography (PET) AR targeting analogues (i.e., flutamide, testosterone, dihydrotestosterone) have been previously reported for imaging. However, limitations in the half-life of positron (β^+) emitting isotopes, production, and PET imaging instrumentation required may have restricted clinical applications (*13*−*17*). Albeit with decreased resolution compared to PET, the development of a clinically routine single photon emission computed tomography (SPECT) imaging agent

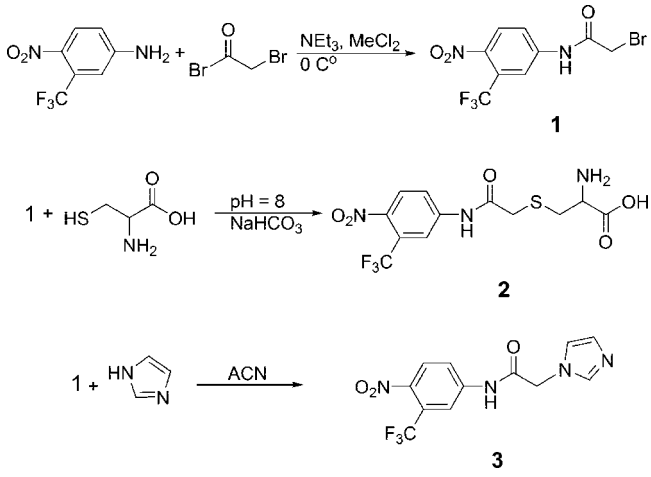
Scheme 1. Preparation of 2-Bromo-*N*-[4-nitro-3-(trifluoromethyl)phenyl]acetamide, 1, and the Corresponding Ligand-Linked Flutamide Compounds by Conjugation of 1 with Cysteine and Imidazole to Generate the Respective Compounds 2 and 3



utilizing ^{99m}Tc (E_γ = 140 keV, I_γ = 89%, $t_{1/2}$ = 6.02 h) would provide an alternative for hospitals already equipped with a SPECT camera. A number of small-molecule-linked ^{99m}Tc(V) oxo complexes with steroids, such as testosterone, have been reported in the literature for prostate imaging (*18, 19*). The recent development of the organometallic precursor, *fac*-^{99m}Tc-$(OH_2)_3(CO)_3^+$, has several important advantages over Tc(V) oxo complexes for biological targeting of prostate cancer (*20*−*24*). The *fac*-^{99m}Tc$(OH_2)_3(CO)_3^+$ species can be conveniently prepared in aqueous conditions from pertechnetate isolated from a ^{99}Mo/^{99m}Tc generator with an Isolink kit produced by Tyco (*25*). The ^{99m}Tc organometallic complexes have a reduced molecular weight, molecular volume, polarity, and ligand size compared the ^{99m}Tc(V) oxo complexes. The stable CO ligands also help increase the lipophilicity of the compounds, which may assist in hepatic clearance rather than renal clearance. The chemical and structural differences of the two types of Tc compounds can have important implications in biological interactions of complexes. This is of particular importance, as bladder collection of more polar ^{99m}Tc agents would significantly impact the clarity of the images by increasing the background or completely obstructing the prostate.

Our investigation reported herein was designed to develop a model system to explore the feasibility of ^{99m}Tc-linked flutamide derivatives that utilized the *fac*-^{99m}Tc$(OH_2)_3(CO)_3^+$ precursor. We developed a central strategy that would generate a library of flutamide analogues capable of complexing the technetium species. The universal flutamide derivative was prepared and conditions determined to use general alkylation methods to covalently link a number of ligand systems to the flutamide derivative (Scheme 1). The flutamide-linked ligands were examined with both the nonradioactive rhenium for chemical and structural characterization followed by the radioactive ^{99m}Tc analogues to determine labeling effectiveness and radiochemical stability.

EXPERIMENTAL SECTION

All reagents and organic solvents were purchased from Aldrich, Acros, or Fluka in reagent grade or better and were used without further purification. Rhenium starting materials $Re(CO)_5OTf$, and *fac*-$[Re(CO)_3(H_2O)_3]OTf$, were prepared by literature methods from $Re_2(CO)_{10}$ purchased from Strem (*24, 26*). Rhenium complexes *fac*-$Re(CO)_3$(Histidine) and *fac*-$Re(OH_2)(CO)_3$(picolinate) were prepared by reacting the rhenium starting materials with the appropriate ligand according to reported methods (*27, 28*). Normal mouse serum (L10410) with 0.1% sodium azide was purchased from Caltag Laboratories and was centrifuged to remove particulate matter prior to use. Elemental analyses were performed by Quantitative Technologies, Inc., New Jersey. Separation and identification of compounds were conducted on a Perkin-Elmer Series 200 high pressure liquid chromatograph (HPLC) equipped with a UV/vis series 200 detector and a Perkin-Elmer Radiomatic 610TR detector utilizing a 30 cm 5 μm Agilent Zorbex SB-C18 column. The compounds were separated with a reverse-phase gradient system beginning with 0.1% trifluoroacetic acid (TFA) aqueous eluent gradually shifting to methanol according to the following method, 0−3.0 min (100% TFA), 3.0−9.0 min (75% TFA, 25% MeOH), 9.0−20.0 min (25% to 100% MeOH linear gradient), 20.0−25.0 min (100% MeOH) at a flow rate of 1.0 mL/min or 5.0 mL/min for separation. ^{1}H NMR spectra were recorded on a Varian 300 MHz spectrometer, and chemical shifts were referenced to the internal standard sodium 3-(trimethylsilyl) propionate-d_4 (TSP, 0.00 ppm) in D_2O or the residual solvent signal and/or tetramethylsilane (TMS) in organic solvents. Spectra were processed using Varian VNWR 6.1 software. IR spectra were collected with a Thermo Nicolet 6700 FT-IR with an ATR cell and analyzed with OMNIC 7.1a software. Mass measurements were performed as Q3 scans on an API4000 triple quadrupole (Applied Biosystems). Sample concentrations of ~0.1 μg/μL in methanol were infused at 10 μL/min, with orifice heating on, declustering potential 20 V, and entrance potential 10 V.

2-Bromo-*N*-[4-nitro-3-(trifluoromethyl)phenyl]acetamide, 1. Et_3N (5.9 mL, 42 mmol) was added slowly to a solution of bromoacetyl bromide (8.1 g, 40 mmol) and 5-amino-2-nitrobenzotrifluroride (7.0 g, 34 mmol) in CH_2Cl_2 (200 mL) at 0 °C. The solution was stirred for 2 h at 0 °C, which resulted in a clear solution. The solution was continuously stirred and allowed to reach rt overnight. The solution was washed with 0.6 M of HCl three times (200 mL × 3), followed by water. The organic phase was dried over Na_2SO_4, filtered, and evaporated to dryness to give a pure slight yellow product (9.9 g, 89%). Anal. Calcd for $C_9H_6BrF_3N_2O_3$: C, 33.05; H, 1.85; N, 8.57. Found: C, 33.00; H, 1.62; N, 8.33. ^{1}H NMR [δ (ppm), $CDCl_3$] 8.53 (s, 1H), 8.02 (m, 3H), 4.08 (s, 2H). ^{13}C NMR [δ (ppm), $CDCl_3$] 164.5, 141.3, 127.4, 125.6 (q), 123.6, 122.7, 120.0, 118.7 (q), 29.1. MS [$M^+ - Na^+$] 349.0, 351.1.

2-(*S*-Cysteinyl)-*N*-[4-nitro-3-(trifluoromethyl)phenyl]acetamide, 2. To a solution of excess cysteine (1.21 g, 10 mmol) in water (50 mL) was added $NaHCO_3$ (10 mL, 1 M), followed by **1** (1.0 g, 3.0 mmol) in CH_2Cl_2 (50 mL). The biphasic mixture was vigorously stirred overnight at rt. A small amount off-white solid product was observed in the reaction mixture and additional material was formed after selective evaporation of CH_2Cl_2 from the mixture. The off-white solid was filtered and dried under vacuum (0.75 g, 67%). Anal. Calcd for $C_{12}H_{12}F_3N_2O_5S \cdot 0.6H_2O$: C, 38.12; H, 3.52; N, 11.11. Found: C, 37.89; H, 3.28; N, 11.38. ^{1}H NMR [δ (ppm), DCl/D_2O, 0.25 M] 7.98 (d, J = 2.1 hz, 1H), 7.95 (d, J = 9.0 hz, 1H), 7.82 (dd, J = 2.1 and 9.0 hz, 1H), 4.48 (dd, J = 4 and 8 hz, 1H), 3.70 (s, 2H), 3.46 (dd, J = 4 and 15 hz, 1H), 3.29 (dd, J = 8 and 15 hz, 1H). ^{13}C NMR [δ (ppm), DCl/D_2O, 0.25 M] 173.4, 173.1, 145.2, 145.0, 130.3, 126.6, 125.9, 121.6, 55.4, 39.2, 35.0, 29.1. MS [M^+] 367.9, [$M^+ - Na^+$] 389.9.

2-(1*H*-Imidazol-1-yl)-*N*-[4-nitro-3-(trifluoromethyl)phenyl]acetamide, 3. To an acetonitrile solution (10 mL) containing imidazole (1.57 g, 5 mmol) was added **1** (0.33 g, 1 mmol). The solution was stirred overnight at rt, then evaporated to dryness under vacuum to yield a faint yellow solid. Water (10 mL) was added to the solid and the solution filtered. HCl (0.5 M, 10

mL) was added to the collected solid, and the corresponding mixture was centrifugated, and the solution collected, and the solid discarded. The slow addition of $NaHCO_3$ (1 M, 4 mL) to the centrifuged solution caused the formation of a yellow precipitate, which was filtered and dried to yield the desired faint yellow product **3** (0.26 g, 82%). Anal. Calcd for $C_{12}H_9F_3N_4O_3$: C, 45.87; H, 2.89; F, 18.14; N, 17.83; O, 15.28. Found: C, 44.60; H, 2.84; N, 17.07. ^{1}HNMR [δ (ppm), methanol-d_4] 9.04 (t, 1H), 8.23 (d, 1H), 8.03 (m, 2H), 7.69 (t, 1H), 7.27 (t, 1H), 5.36 (s, 2H). ^{13}CNMR [δ (ppm), methanol-d_4] 166.8, 142.9, 138.3, 127.0, 126.9, 124.5, 124.0, 122.5, 121.1, 117.9, 117.8, 49.5. X-ray Crystallography. Crystals of compound **7** were removed from the flask; a suitable crystal was selected, attached to a glass fiber, and data were collected at 90(2) K using a Bruker/Siemens SMART APEX instrument (Mo Kα radiation, λ = 0.71073 Å) equipped with a Cryocool NeverIce low-temperature device. Data were measured using omega scans 0.3° per frame for 5 s, and a full sphere of data were collected. A total of 2400 frames were collected with a final resolution of 0.77 Å. Cell parameters were retrieved using SMART software (*29*) and refined using SAINTPlus (*30*) on all observed reflections. Data reduction and correction for Lp and decay were performed using the SAINTPlus software. Absorption corrections were applied using SADABS (*31*). The structure was solved by direct methods and refined by least-squares method on F^2 using the SHELXTL program package (*32*). The structure was solved in the space group *C*2/*c* by analysis of systematic absences. No decomposition was observed during data collection. Details of the data collection and refinement are given in Table 1. Further details are provided in the Supporting Information.

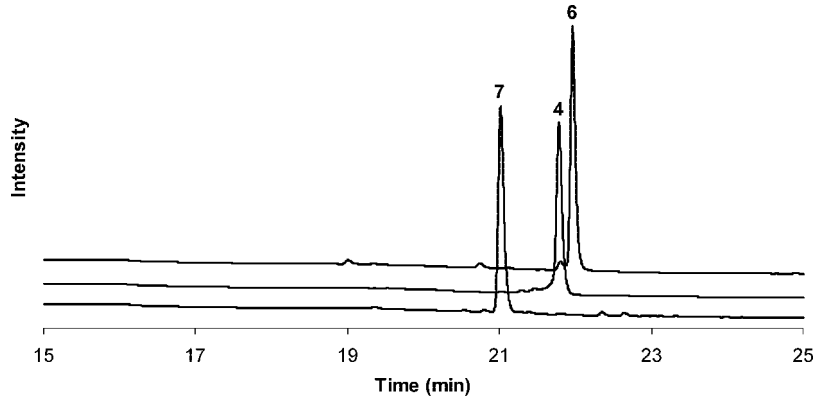

Figure 2. UV/vis HPLC (220 nm) chromatograph of Flutamide-linked rhenium tricarbonyl complexes of **4**, **6**, and **7**.

Radiochemistry. ^{99m}Tc-pertechnetate ($^{99m}TcO_4^-$) was purchased from Cardinal Health in Spokane, WA. IsoLink kits to prepare the $^{99m}Tc(H_2O)_3(CO)_3^+$ precursor were obtained as a gift from Tyco, Inc. The radiolabeled products were characterized by Perkin-Elmer Series 200 HPLC under the same mobile-phase conditions previously mentioned, except the γ emissions were detected with a Perkin-Elmer Radiomatic 610TR detector equipped with a Gamma B cell (80 μL loop). The *fac*-$^{99m}Tc(H_2O)_3(CO)_3^+$ precursor was prepared according to the manufacture's procedure, the addition via syringe of 10−20 mCi of $Na^{99m}TcO_4$ in 1 mL saline to the Isolink kit followed by heating at 95 °C for 20 min. The resulting solution was cooled in an ice bath, neutralized with HCl (∼100 μL, 1 M) and checked on the γ-HPLC system to ensure complete formation of the precursor.

General $^{99m}Tc(H_2O)_3(CO)_3^+$ Radiolabeling Procedure. The ligand **2** or **5** (100 μL, 10^{-4} or 10^{-5} M) and phosphate buffer (800 μL, 0.1 M) at pH 7.4 was added to a sealable labeling vial (5.0 mL). The vial was sealed and degassed with nitrogen for ∼10 min. The $^{99m}Tc(H_2O)_3(CO)_3^+$ precursor solution (100 μL) was added to the degassed vial and the vial heated for 30 min at 70 °C. The reaction mixture was then allowed to cool on an ice bath prior to injection and analysis by radio-HPLC.

2 + 1 Radiolabeling Procedure. *Method 1: One-Pot Preparation.* Ligand **3** (100 μL, 10^{-2} M), picolinic acid (100 μL, 10^{-4} M), and phosphate buffer (700 μL, 0.1 M) at pH 7.4 were added in order to a sealable labeling vial (5.0 mL). The vial was sealed and degassed with N_2 for ∼10 min. The $^{99m}Tc(H_2O)_3(CO)_3^+$ precursor solution (100 μL) was added to the degassed vial and heated for 30 min at 80 °C. The reaction mixture was allowed to cool on an ice bath prior to analysis by radio-HPLC.

Method 2: Stepwise Formation. Picolinic acid (100 μL, 10^{-4} M) and phosphate buffer (700 μL, 0.1 M) at pH 7.4 were added to a sealable vial (5.0 mL). The vial was purged with nitrogen for ∼10 min. The $^{99m}Tc(H_2O)_3(CO)_3^+$ precursor solution (100 μL) was added to the degassed vial and heated for 30 min at 80 °C. After the formation of *fac*-$^{99m}Tc(H_2O)(CO)_3$(picolinate) was confirmed by radio-HPLC, ligand **3** (100 μL, 10^{-2} M) was added to the vial and the sample heated for an additional 30 min at 80 °C.

Biological pH Stability Studies. The respective ^{99m}Tc labeled compound (100 μL) prepared with ligands **2**, **3**, or **5** as directed above was added to phosphate buffer (900 μL, 0.1 M) at pH 7.4. The vial was sealed and incubated at 37.0 °C for the duration of the study. The solution was examined by radio-HPLC at 1, 2, and 4 h during the incubation to determine the effective stability of the compounds.

Mouse Serum Stability Studies. The respective ^{99m}Tc complexes (100 μL) prepared from ligands **2**, **3**, or **5** as directed above was added to an Eppendorf 1.5 mL flextube containing 400 μL of normal mouse serum with 0.1% sodium azide that had been previously clarified by centrifugation. The tube was sealed and constantly heated at 37.0 °C for the duration of the study. The serum was examined by radio-HPLC at 1, 2, and 4 h of incubation to observe decomposition or loss of the radiolabeled complex due to a shift in the retention time or decrease in the product peak intensity.

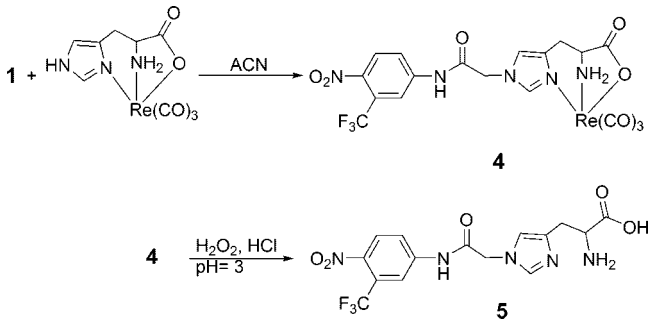
Cell Studies. *In vitro* analysis of the ^{99m}Tc complexes were conducted with DU-145 according to established methods prepared from ligand **2** or **5** as directed above was added. Aliquots of compounds (4, 6, 8 μL of a 0.1 mCi/100 μL) were incubated in triplicate with androgen receptor positive DU-145 prostate cancer cell line for 2 h in a CO_2 incubator at 37 °C. The cells were washed twice with cold PBS to remove nonspecific bound ^{99m}Tc complex; the cells were collected and counted with a Cobra II γ counter for 1 min.

RESULTS AND DISCUSSION

Nonsteroidal antiandrogen drugs, i.e., flutamide, bicalutamide, nilutamide, have been found to effectively mitigate early-stage prostate cancer growth (Figure 1) (*10*). We report within this paper the first analogues of flutamide that incorporate technetium-99m complexes into the structure. Flutamide was modified to incorporate a number of ligand systems capable of coordinating the ^{99m}Tc species, *fac*-$^{99m}Tc(OH_2)_3(CO)_3^+$ (Figure 2). We report within the synthetic methods used to prepare the bifunctional flutamide compounds, characterization of rhenium complexes formed, and radiochemical preparation and stability studies of the technetium-99m complexes formed.

The focus of this work was to develop a flutamide analogue that could be conveniently functionalized with a variety of ligand systems quite readily. The designs of such analogues were restricted to modifications along the carbonyl axis of flutamide's amide bond as the dominent binding motif for the compound to the androgen receptor is understood to be the functionalized aromatic ring (*6, 7, 10, 34, 35*). Transforming the alkyl backbone into an alkyl halide provided an accessible group that could function as a synthetic handle for nucleophilic substitution by a number of reactive species (i.e., amines, thiols, alcohols) (*13,15,36,37*). The brominated flutamide compound, 2-bromo-*N*-[4-nitro-3-(trifluoromethyl)phenyl]-acetamide, **1**, was chosen as the congener of fluatamide in order for later incorporation of chelators. Compound **1** was prepared in high yield by the reaction of bromoacetyl bromide and 5-amino-2-nitrobenzotrifluroride in CH_2Cl_2 in the presence of triethylamine (Scheme 1). The crude product **1** isolated from the reaction mixture after acid washing the reaction mixture was clean enough to use for the subsequent experiments without further purification based on ^{1}H and ^{13}C NMR spectroscopy. Compound **1** could also be further purified by silica gel chromatography (ethyl acetate/hexane 1:5) or

Scheme 2. Preparation of Histidine-Linked Flutamide Ligand (5) by Alkylation with 1 of the Rhenium Histidine to Yield the Rhenium Histidine-Linked Flutamide Complex (4) and Followed by Demetallation to Generate the Free Ligand (5)



recrystallized from ethyl acetate. Compound **1** was found to be a strong irritant as a dry powder, and care was utilized when handling the material.

The reactivity of the acetyl bromide in compound **1** provided an excellent synthetic handle to functionalize with corresponding ligand systems. Introduction of compound **1** afforded a series of molecules **2**, **3**, and **5** that incorporate flutamide and ligands (cysteine, imidazole, histidine, respectively). These ligands had been previously identified for coordination with a $M(CO)_3$ ($M = Re$, ^{99m}Tc) species due to high-efficiency labeling methods (*27, 28, 38*). The synthetic routes to **2**, **3**, and **5** are divided into two categories, direct organic synthesis and metal-coordinated synthesis. Direct synthesis involved a standard alkylation synthesis route to couple **1** with the ligand. The ligands cysteine and imidizole were attached to **1** via the direct synthesis route in a one-step substitution reaction to yield the flutamide-coupled ligands, compounds **2** and **3**, respectively (Scheme 1). The metal-coordinated synthesis of compound **5** involves the use of a rhenium as a protecting group on the histidine (Scheme 2).

Direct synthetic methods allowed the preparation of the compounds directly from compound **1** (Scheme 1). The cysteine-linked flutamide analogue, **2**, was successfully prepared in high yield after a number of synthetic attempts. The reported method has an important synthetic advantage by utilizing the reactive differences between thiol and amine groups to yield the desired product without the use of protecting groups. Early attempts utilizing protecting groups on cysteine on the amine and the carboxylic acid with Boc-Cys-OMe did yield the corresponding alkylation product with **1**. However, deprotection with base of the methyl ester was found to also cleave the amide bond as indicated by the presence of 5-amino-2-nitrobenzotrifluroride in the reaction mixture. Potential amide cleavage was anticipated at high pH due to the strong electron-withdrawing groups (NO_2, CF_3) on the aromatic ring weakening the amide bond. By treatment of **1** with excess cysteine in aqueous conditions at slightly basic pH, alkylation selectivity of the thiol over the amine in cysteine and the avoidance of protecting groups that require basic deprotection methods yielded the desired product, **2**. Initially, the reaction was conducted in aqueous solution only, but it proceeded slowly with low yields (<25%) due to the limited solubility of compound **1**. Attempts to improve reactivity and solubility with increased base and/or heat yielded undesired cleavage products. It is noteworthy to mention that, when the reaction was carried out in biphasic reaction conditions (aqueous/methylene chloride), compound **1** readily dissolved in the methylene chloride and the reaction proceed smoothly without the need of a phase transfer catalyst at room temperature with a significant improvement in yield. Careful control of the solution pH in the reaction was critical to yield the desired product, **2**. The cystine dimer was observed as the major product instead of **2** when the reaction was carried out in acidic conditions (pH < 5). Other water-miscible solvents (i.e., DMF, methanol) did dissolve **1**; however, the reaction did not afford compound **2** in any appreciable yield. The conditions reported here are mild for alkylation of a thiol compared to refluxing 1 M NaOH that can lead to racemic mixtures or utilizing carcinogenic solvents. Ligand **2** was characterized by elemental analysis and ^1H and ^{13}C NMR spectroscopy.

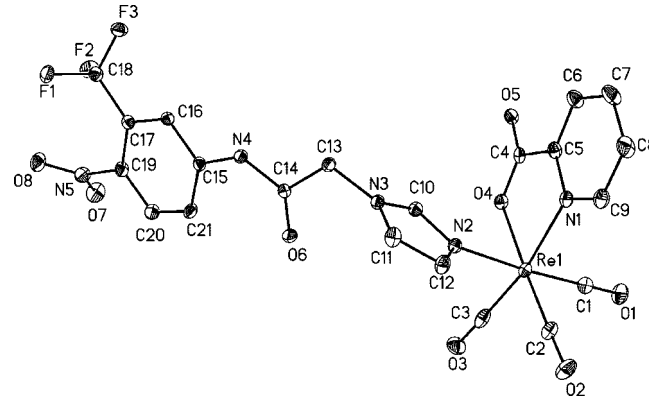


Figure 3. A modeled X-ray structure of *fac*-$Re(CO)_3$(Picolinate)(**3**), **7**, with 30% thermal ellipsoids. Hydrogen atoms are excluded for clarity.

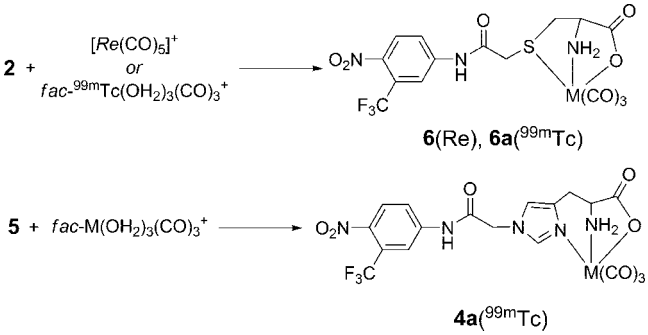
An imidazole-linked flutamide analogue was prepared by treatment of **1** with excess imidazole in acetontrile gave **3** in high yield (Scheme 1). Under the reported reaction conditions, only the monosubstituted product was isolated, where the imidazole ligand was functioning as both the reactant and the proton scavenger. However, when the imidazole was added in stoichiometric concentrations and in the presence of an additional base (i.e., Cs_2CO_3) in acetonitrile, a mixture of the mono- and disubstituted products were observed. The mixed species were also observed when the reaction was conducted in a biphasic solvent system ($H_2O/MeCl_2$) similar to compound **2**. ^1H and ^{13}C NMR reported for **3** were consistent with the proposed compound.

Preparation of a N^{ϵ} histidine-linked flutamide compound ligand with **1** was originally attempted utilizing protecting groups similarly to previous reports (*28*, *39*, *40*). However, deprotection methods yielded cleavage products at the amide bond as noted previously in the synthesis of **2**. Therefore, utilizing a metal-coordinated synthetic route for the preparation of the ligand was a more appropriate method. In this procedure, $Re(CO)_3$ was coordinated in a tridentate fashion to the histidine ligand in place of more traditional organic protecting group (*28*). Alkylation of $Re(CO)_3$(histidine) with compound **1** in the presence of solid Cs_2CO_3 in an acetonitrile solution yielded compound **4** in near quantitative yields (Scheme 2). The reaction proceeds smoothly with no unwanted side products as indicated by HPLC, as the metal coordination bonds sufficiently protect the bound amine, carboxylate, and imidizole functional groups from substitution reactions (Figure 3). The coordinated imidazolyl ligand was of particular importance to maintain the coordination mode and strength for the subsequent ^{99m}Tc labeling. Dissociation of the nitrogen ligands from the rhenium center could lead to substitution at the NH_2 terminus or N^{τ} or disubstitution of the ring, similar to what was observed as a side product in the formation of compound **3**. The complexes were characterized by NMR, and comparison of **4** to the $Re(CO)_3$(Histidine) starting material illustrated similar splitting and slight downfield shifts for the protons associated with the coordinated histidine, indicating no change in the coordination mode of the ligand on the metal center. ^1H NMR of **4** in acetone showed two peaks associated with the imidazolyl group at 8.26

Scheme 3. Complexation of Flutamide-Linked Ligand Analogues with *fac*-M(CO)$_3$ (M = Re, ^{99m}Tc (a)) with Tridentate Ligands 2 and 5 to Generate *fac*-M(CO)$_3$(2) (6, 6a) and *fac*-M(CO)$_3$(5) (4, 4a) Complexes



and 7.18 ppm, slightly shifted downfield from the Re(CO)$_3$(Histidine) starting material at 7.06 and 8.08 ppm. The aromatic protons of the molecule were overlapped in the spectrum to yield a multiplet at 8.12 ppm of 3H. The metal coordinated amine protons are observed as diastereotopic protons of equal integration of one proton as a doublet at 5.4 and mulitplet at 5.75 ppm. The chiral Hα was also observed as a multiplet at 4.35 ppm, and the beta protons Hβ were also diastereotopic, exhibiting a dd pattern at 3.51 and 3.37 ppm.

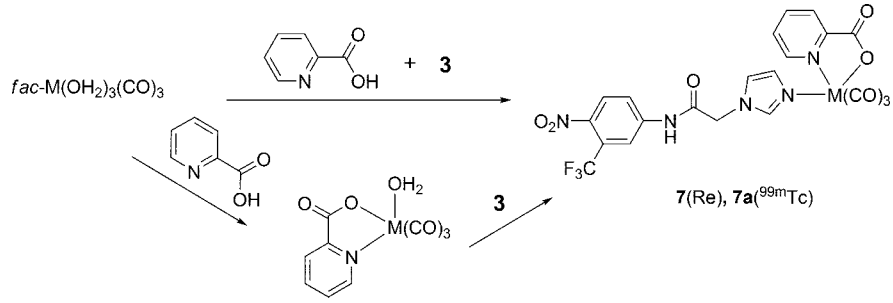
Removal of the coordinated rhenium tricarbonyl complex in **4** to generate the free ligand compound **5** was achieved under acidic oxidative conditions (Scheme 2). The selective oxidation and decomplexation of the rhenium center of **4** occurs by the addition of a 10-fold quantity of H_2O_2 under acidic conditions at room temperature. The reaction was monitored by HPLC and was completed after 3 days. Although a lower pH and increased H_2O_2 concentration would potentially decrease the reaction time, minimal amide cleavage products of the ligand were observed under the conditions reported. The free ligand **5** was isolated by preparatory HPLC from the reaction mixture in reasonable yields. Characterization of **5** by ^{1}H and ^{13}C NMR was consistent with the proposed structure and simplified in comparison to the corresponding rhenium complex, **4**.

Complexes were prepared from the ligands prepared above with rhenium and technetium-99m carbonyl precursors to yield M(CO)$_3$(Ligand/s) complexes. The preparation and characterization of the rhenium complexes provides a stable compound for characterization by standard methods and a reference for comparison to the radioactive ^{99m}Tc complexes in HPLC (Figure 2). The rhenium complexes of the flutamide-linked ligands were prepared by reacting the ligand with a rhenium carbonyl starting material as indicated in Scheme 3, except for complex **4a**, which was prepared directly from the Re(CO)$_3$(Histidine) complex as mentioned above. Ligands **2** and **3** utilized slightly different Re starting materials according to the solubility of the ligand system. Ligand **2** was reacted with the organic soluble [Re(CO)$_5$OTf] in methanol, due to the limited solubility of macroscopic amounts of **2** in water. The reaction involves the displacement of two CO molecules from the rhenium center upon complexation of **2** to generate the neutral complex Re(CO)$_3$(**2**), **6**, in high yield and isolated as a pale yellow solid. HPLC analysis of the product showed a single sharp peak with retention time of 22.1 min (Figure 2). Elemental analysis of **6** confirmed the existence of 1:1 ratio of rhenium to ligand. ^{13}C NMR profile of **6** is in consistent with the proposed structure. Relatively broad signals were observed in the ^{1}H NMR spectrum of **6** in CD_3OD at room temperature. At low temperature (−14 °C), sharp signals were observed, showing two sets of signals indicative of two coordination isomers in solution. The coordinated ligand **2** has a chiral carbon and prochiral sulfur resulting in the formation of diastereoisomers upon metal coordination. Two isomers can equilibrate fast by inversion of the sulfur configuration at room temperature. However, the minor species was observed at approximately 10% in the solution, indicating a preference for one coordination species with the Re(CO)$_3$ most likely due to interactions of functionalized thioether moiety driven by steric factors. Similar observations were reported for other thioether derivatives of cysteine Re(CO)$_3$ complexes (*26*, *38*).

Mundwiler et al. (*41*) reported a "2 + 1" mixed-ligand complex approach consisting of a bidentate and a monodentate ligand coordinated to the M(CO)$_3$ (M = Re, ^{99m}Tc) core provides an alternative method to single ligand coordination. This methodology was adopted to prepare a "2 + 1" flutamide derivative with the M(CO)$_3$ M = Re, ^{99m}Tc core. The rhenium complex, Re(CO)$_3$(pic)(**3**), **7**, prepared within this paper consisted of a bidentate picolinate and a monodentate flutamide fuctionalized imidazole, **3**. Two synthetic approaches, one-pot and stepwise synthesis, were attempted to prepare complex **7** (Scheme 4). The one-pot reaction yielded some of the product **7**; however, several other species were observed in the reaction mixture attributing multiple coordinating ligands of **3**. The stepwise synthesis provided a more clearly defined product in high yields. The compound *fac*-Re(OH$_2$)(CO)$_3$(picolinate) was prepared and isolated according to previous methods (*27*) and reacted with **3** in methanol to yield compound **7** as the only product in the HPLC chromatogram (Figure 2). Elemental analysis, ^{1}H and ^{13}C NMR as well as X-ray crystallography confirm the formation of complex **7**. ^{1}H NMR spectrum of **7** had increased overlapping signals at ∼8 ppm of the aromatic protons from the four protons of the coordinated picolinate and the three protons **3**. The methylene protons of **3** displayed a singlet signal, in contrast to doublet signals observed in **4**, suggesting that the monodentate ligand **3** is more flexible than the analogous tridentate ligand **5** in rhenium complexes. Crystals suitable for X-ray crystallography were obtained by diffusion of hexane into acetone solution of **7** (Figure 3). The structural parameters are listed in Table 1 and selected bond angles (°) and distances (Å) in Table 2. The rhenium center in complex **7** is a distorted octahedron with three CO ligands occupying the facial geometric sites in near-equivalent Re−C distances (1.89−1.92 Å) and C−Re−C angles (88.4−90.2°) with respect to each other. The other coordination sites are occupied by the coordinated "2 + 1" ligands, picolinate (pic) and **3**. Pic functions as a planar bidentate ligand (N, O) with distances and angles comparable to other reported structures (*27*, *41*, *42*). The monodentate ligand **3** is coordinated to the rhenium center through an imidazole nitrogen at N(2)−Re(1) 2.186 Å. The imidazole ligand itself is slightly tilted toward the plane of the pic ligand (∼83°) yielding an acutely distorted octahedron along the pic and **3** coordination sites. Compound **7** also exhibits interesting intermolecular NH−O (2.79 Å) hydrogen bonding between two molecules through the amide proton donor and the noncoordinated oxygen of the picolinate as a proton acceptor, yielding two hydrogen bond interactions per set of molecules in the unit cell.

Investigation of the radioactive ^{99m}Tc complexes were conducted by reacting ligands (**2**, **3**, and **5**) with the *fac*-[^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ generated from a Tyco Isolink kit in aqueous conditions. The general labeling procedure for tridentate ligands **2** and **5** involved mixing the ligand with the *fac*-[^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ at pH 7.4 and heating at 70 °C for 30 min (Scheme 3). Concentrations (10^{-4}, 10^{-5}, 10^{-6} M) were investigated at these conditions to determine effective labeling of the ligand. Both ligands **2** and **5** demonstrated good labeling of >90% at 10^{-4} and 10^{-5} M to yield *fac*-[^{99m}Tc(CO)$_3$(**2**)] **4a** and *fac*-[^{99m}Tc(CO)$_3$(**5**)] **6a** complexes (Figure 4). Labeling yields for both ligands **2** and **5** at 10^{-6} M were slightly diminished, 28% and 20% respectively, compared to the

Scheme 4. 2 + 1 Labeling Strategy for Reacting Ligand 3 with *fac*-M(OH$_2$)$_3$(CO)$_3$ (M = Re, ^{99m}Tc (a)) to Yield Complexes *fac*-M(CO)$_3$(pic)(3), (7, 7a)[a]



[a] Two strategies are reported: (1) single pot reaction; (2) stepwise addition of ligands.

previously reported ^{99m}Tc labeling with similar ligands at higher temperatures (95 °C) (*28*, *38*, *43*). When the reaction of *fac*-[^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ with **2** or **5** was carried out at 95 °C, decreased labeling yields of **4a** and **6a** and the corresponding amide cleavage product as a ^{99m}Tc(CO)$_3$ free carboxylate ligand complex were observed in the radiochromatograms. The pH of

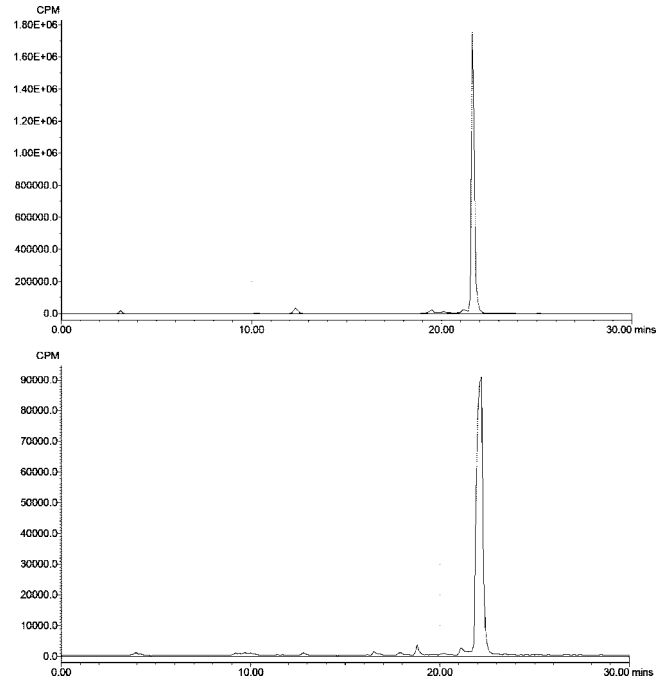

Figure 4. Radio HPLC of the ^{99m}Tc(CO)$_3$ complexes **4a** (top) and **6a** (bottom) formed with ligands **5** and **3**, respectively.

the labeling solution was also found to significantly impact the labeling yields observed. Reactions conducted in slightly acidic conditions between pH 6.5 and 7.4 would yield the desired product, **4a** and **6a**, without the appearance of cleavage products. Attempts to prepare **4a** and **6a** by direct addition of Isolink kit to the reaction mixture in 0.1 M phosphate buffer partially yielded the products and cleavage products. However, neutralization of the Isolink kit with hydrochloric acid to pH ~7.0 prior to addition to the ligand solution was found to be the imperative step in the labeling procedure as the kit solution is quite basic (pH ~11) during the production of *fac*-[^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$. Despite the combination of heating and pH effects impacting the labeling yields, carefully control of the reaction conditions afforded the desired compounds in good yield. The complexes **4a** and **6a** were further studied to determine the stability of the compound in solution at 37 °C in phosphate buffer (pH 7.4) and in mouse serum at 1, 2, and 4 h (Table 4). Both compounds, **4a** and **6a**, were found to be stable for up to four hours in the pH stability and the serum studies with minimal decomposition of complex or cleavage products observed in the radio-HPLC.

The "2 + 1" ^{99m}Tc complex, **7a**, with ligand **3** was prepared by similar methods to the rhenium analogues: one-pot and stepwise (Scheme 4). The preparation of **7a** by either method at 70 °C and pH 7.4 yielded a peak with a similar retention

time to the analogous rhenium complex (Table 3). Each of these methods had comparable labeling results of ~70%. The formation of the "2 + 1" complex **7a** required much higher concentrations (10^{-2} M) of **3** compared to the tridentate ligands **2** and **5**. HPLC purified complex **7a** was incubated in phosphate buffer (0.1 M, pH 7.4) and 37 °C to determine stability of the complex at 1, 2, and 4 h (Table 4). During this study, ligand **3** was observed to partially dissociate during incubation from complex **7a** to yield the intermediate species *fac*-^{99m}Tc(CO)$_3$(H$_2$O)(pic) as identified by retention time. Mouse serum studies further confirmed the instability of the "2 + 1" complex as multiple species in addition to the dissociation of **3** were observed in the radio-HPLC. Despite the previously reported and successful synthesis with the rhenium analogue (*41*), the "2 + 1" complex **7a** containing functionalized imidazole **3** may have limited application due to stability of the complex.

In vitro analysis were conducted with the ^{99m}Tc complexes (**4a**, **6a**) to determine cellular uptake with an androgen-positive DU-145 prostate cancer cell line. Incubation of the ^{99m}Tc complexes with the prostate cancer cells displayed a modest ~2% binding relative to control experiments. Although the uptake was much lower than expected, the decrease binding of these particular model compounds was anticipated. The changes in the chemical nature (i.e., polarity, steric bulk) of the native flutamide compound by introduction of the ^{99m}Tc complexes may have impacted the internalization of the modified compounds. Additionally, the functionalized flutamide complexes may also have decreased AR affinity due to poor metabolic conversion. The native flutamide compound is metabolized to the more potent α-hydroxyl antagonist, hydroxyflutamide, by the AR. Although it is uncertain the potential affect of the ^{99m}Tc complexes will have on the AR with limited internalization of the compounds, additional studies will be required.

CONCLUSION

The study presented here demonstrates the first $M(CO)_3$-linked flutamide compounds (M = Re, ^{99m}Tc) prepared for prostate cancer imaging. Although the amide bond of the flutamide was considered to be unstable due to hydrolytic cleavage, conditions were found to prepare the compounds in high yield. Reactions involving *fac*-^{99m}Tc(CO)$_3$(H$_2$O)$_3$ with tridentate ligands, cysteine and histidine, offered higher labeling yields and greater stability than the "2 + 1" approach utilizing a functionalized imidazole analogue. The tridentate ligands exhibited excellent radiochemical stability at 37 °C at physiological pH and in mouse serum. *In vitro* assays did show limited uptake in DU-145 prostate cancer cells. However, further investigations are required to conclusively determine internalization mechanism and androgen inhibition. Further studies involving metabolic activation of ^{99m}Tc(CO)$_3$ linked flutamide complexes to the hydroxyflutamide analogue and *in vivo* tumor model experiments are currently underway.

Click Chemistry Functionalized Polymeric Nanoparticles Target Corneal Epithelial Cells through RGD-Cell Surface Receptors

Jiao Lu,[†] Meng Shi,[‡,§] and Molly S. Shoichet*[,†,‡,§]

Department of Chemistry, Department of Chemical Engineering and Applied Chemistry, and Institute for Biomaterials and Biomedical Engineering, Terrence Donnelly Center for Cellular and Biomolecular Research, University of Toronto, 160 College Street, Room 514, Toronto, Ontario M5S 3E1. Received July 24, 2008; Revised Manuscript Received November 17, 2008

Self-assembled polymeric nanoparticles modified with targeting ligands on the surface provide a means for localized cell delivery. To gain greater insight into the possibility of derivatizing poly(2-methyl-2-carboxytrimethylene carbonate-*co*-D,L-lactide) (poly(TMCC-*co*-LA)) nanoparticles using the Huisgen's 1,3 dipolar cycloaddition reaction, we synthesized amphiphilic copolymers comprising a hydrophobic poly(TMCC-*co*-LA) backbone and a hydrophilic poly(ethylene glycol) (PEG) pendant chain. By coupling amine-terminated PEG-azide to the carboxylic acid group of the poly(TMCC-*co*-LA) via EDC chemistry, an amphiphilic copolymer was formed. The poly(TMCC-*co*-LA)-*g*-PEG-N_3 self-assembled in aqueous solution and presented azide groups on the surface of the nanoparticles. Alkyne-modified KGRGDS peptides were synthesized and coupled to the azide-functionalized nanoparticles via Huisgen's 1,3 dipolar cycloaddition, which was catalyzed by copper sulfate and sodium ascorbate in aqueous solution. Using coumarin-modified lysine (K) of the KGRGDS peptide, fluorescence was used to determine that there were approximately 400 peptides bound to each nanoparticle. The bioactivity of the GRGDS nanoparticle was confirmed with a competitive cell attachment assay using rabbit corneal epithelial cells. This GRGDS-nanoparticle system may be suitable for targeted drug delivery.

INTRODUCTION

Peptides have attracted significant attention because of their diverse biological functionalities. For example, the Arg-Gly-Asp (RGD) containing motif is known to be vital for integrin-receptor mediated cell attachment, which influences cell migration, growth, and differentiation (*1*). The specific binding between RGD-containing peptides and their integrin receptors also plays an important role in cell targeting. The application of RGD-modified nanoparticles (NP) for endothelium targeting has been broadly studied (*2, 3*), specifically in the context of tumor vasculature, which undergoes continuous angiogenesis. RGD peptides can be used to prevent integrins from binding to their respective ligands, thereby causing apoptosis of endothelial cells of newly formed blood vessels (*4*).

Few studies have explored the use of RGD-containing nanoparticles for targeted delivery to the eye, yet fibronectin accumulates in the corneal epithelium after injury (*5*). In wound healing, the binding between RGD motifs on fibronectin and the $\alpha_v\beta_1$ integrin on the surface of corneal epithelial cells plays an important role in cell spreading and migration upon stimulation by epidermal growth factor (EGF) (*6*). Several features of the cornea profoundly reduce the efficiency of gene transfer or drug absorbance (*7, 8*) including the low permeability of the intact epithelial layer and the rapid secretion of tears. However, the delivery of ophthalmic drugs using polymeric nanoparticles engineered with targeting molecules, such as RGD-containing peptides, is promising for the treatment of a wide range of corneal epithelial defects such as corneal neovascularization, dystrophies, neurotrophic keratopathy, recurrent erosion, and dry eye syndrome, among others (*9*). Thus, coupling RGD-containing peptides to nanoparticles may provide a method for targeted drug delivery to the eye after injury.

Building on our previous experience with self-assembling polymers (*10*), we investigated the use of "click chemistry" to surface-functionalize novel nanoparticles with RGD peptides. The term "click chemistry" was first introduced by Sharpless et al. in 2001 to included those reactions that are broad in scope, have high yields, and are simple in product isolation, stereospecific, and compatible with both organic and aqueous reaction conditions (*11*). While "click chemistry" has come to include Diels−Alder among other coupling chemistries, Sharpless defined it as two small units being joined together with heteroatom links and fulfilling the above requirements. Among all the carbon−heteroatom bond formation reactions, the copper-catalyzed Huisgen 1,3-dipolar cycloaddition is the premier example of click chemistry and is known for its high degree of selectivity and stability (*11*). Moreover, the resulting triazole ring itself has been shown to possess a variety of biological functions including anti-HIV, antibacterial, and potent antihistamine activity (*12*−*14*). To take advantage of this click chemistry, we synthesized alkyne-KGRGDS and azide polymeric nanoparticles and reacted them together.

On the basis of the previous development of a novel copolymer backbone of poly(2-methyl-2-carboxytrimethylene carbonate-*co*-D,L-lactide) (poly(TMCC-*co*-LA)) (*15*), we coupled amine-terminated PEG-azide via EDC chemistry to the carboxylic acid groups of TMCC. The known properties of PEG, including water solubility, hydophilicity, and resistance to protein adsorption, make the polymer-*graft*-PEG structure highly desirable for biomaterial and drug delivery applications (*16*). This poly(TMCC-*co*-LA)-*g*-PEG-N_3 copolymer self-assembled to nanoparticles in aqueous solution and presented azide groups on the surface for further modification with alkyne-KGRGDS peptides by click chemistry (Scheme 1). The bioactivity of the peptide-modified nanoparticles was tested with rabbit corneal

epithelial cells using a competitive cell attachment assay. To the best of our understanding, this is the first time that peptide-modified nanoparticles have been designed for targeted delivery to corneal epithelial cells.

EXPERIMENTAL PROCEDURES

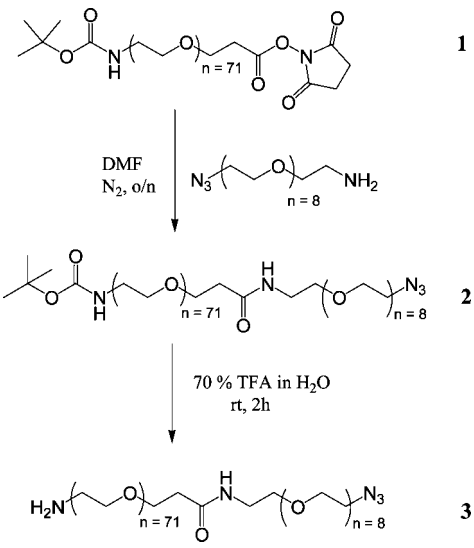
Materials and Methods. The ^{1}H NMR spectra were recorded at 400 MHz at room temperature using a Varian Auto X8308−400 spectrometer. All the chemical shifts are in ppm. Molecular weights and polydispersity indices were measured by gel permeation chromatography (GPC) in THF relative to polystyrene standards on a system equipped with two-column sets (Viscotck GMHHR-M and Viscoteck GMHHR-H) and a triple detector array (TDA302) at room temperature with a flow rate of 0.6 mL/min THF eluent. Dynamic light scattering (DLS) measurements were performed using the Brookhaven 90Plus Particle Size Analyzer (Brookhaven Instruments, USA), which was operated at 647 nm at a scattering angle of 90°. Nanoparticle samples were suspended at 0.5 mg/mL in distilled water before the measurement. Cumulant analysis of light scattering data was used to estimate the hydrodynamic diameter and polydispersity of the nanoparticles. When the polydispersity equals zero, the sample is monodisperse, and as polydispersity increases so does the width of the distribution. As a general rule, nanoparticles are considered to have narrow size distributions when polydispersity is less than 0.025, and cumulant analysis works best when polydispersity is $\leq$0.3. (Additional information is available from Brookhaven.) The dry nanoparticle size was estimated by measuring the average diameter of 50 nanoparticles from images taken in the scanning transmission electron microscope (STEM) mode of the Hitachi S-5200 scanning electron microscope system operating at 30 kV. Samples were prepared by placing one drop of self-assembled nanoparticle solution (0.5 mg/mL in distilled water) on a carbon support film (Electron Microscopy Sciences, PA, USA). Excess solution was drained, and the sample was allowed to air-dry. The presence of an azide functional group was characterized by Nicolet Avatar 370 FTIR (Thermo Instruments Canada Inc.). The RGD-containing peptides were synthesized by solid-phase synthesis using a Pioneer Peptide Synthesis System (Foster City, CA, USA) using standard Fmoc/ HATU chemistry. The synthesized peptides were purified by HPLC (Jupiter 5 μ, C 18, 300 Å, 250 × 21.2 mm) using a gradient mixture of acetonitrile with 0.1% TFA and water. The gradient of acetonitrile with 0.1% TFA increased from 10% (10 min) to 30% (30 min) and finally to 90% (10 min). The Sephadex G-25 column was prepared according to the following procedures: Sephadex G-25 beads was soaked in 0.01 M PBS buffer at pH 7.4 overnight prior to packing the column (2.5 × 10 cm). The column was washed with the same PBS buffer for 1 h before use. The flow rate is determined by gravity. The Sepharose C4B column (5 × 15 cm) was prepared in the same manner as Sephades G-25 column, except distilled water was used instead of PBS buffer. Fluorescence intensity of coumarin was measured by a fluorescent microplate reader (SpectraMax GeminiEM, Molecular Device, USA) at excitation and emission wavelengths of 340 and 405 nm, respectively. The concentration of nanoparticles was measured by their absorbance in Bradford reagent (*10*) at 595 nm using a microplate reader (VersaMax, Molecular Devices, USA). Triplicate samples of equal volumes of NP solution and Bradford reagent were mixed in a clear 96-well plate at room temperature. After incubating for 30 s, a reading was taken.

All solvents and reagents were purchased from Sigma-Aldrich and were used as received, unless otherwise noted. Amino acids including Fmoc-Lys(MCA)-OH were purchased from Novabiochem (CA, USA). Activators and resins were obtained from Applied Biosystems (CA, USA). The peptides for cell attachment assays, GRGDS (97.8% pure, 490.48 g/mol), were acquired from Genscript Corp (New Jersey, USA). The SIRC-rabbit corneal epithelial cell line, CCL-60, was obtained from American type Culture Collection (ATCC, USA). Difunctional *tert*-butoxycarbonyl-protected amine-PEG-activated acid was purchased from Nektar Theraputics (Birmingham, AL, USA). All regenerated cellulose (RC) membranes were purchased from Spectrum Laboratories Rancho Dominguex (CA, USA). All the dialysis procedures used 4 L of distilled water as the exchange solvent. The water was replaced every 2 h for the first 8 h. 96-well reacti-bind amine-binding, maleic anhydride activated plates and the blocking buffer were purchased from Pierce. The Quant iT Picogreen dsDNA assay kit and the protocol are available from Invitrogen (Burlington, ON). The protocol document number is MP 07581, revised December 20th, 2005.

Synthesis of PEG-Azide (PEG-N_3). As shown in Scheme 2, difunctional *tert*-butoxycarbonyl-protected amine-PEG-activated acid (BocNH-PEG-NHS; **1**; 3446 Da, 1.00 g) and azido-octaethyleneglycol-amine (438.52 Da, 0.50 g) were dissolved in 10 mL of DMF and stirred for 24 h at room temperature. The reaction mixture was purified by dialysis against distilled water at room temperature for 24 h using a regenerated cellulose (RC) membrane with a molecular weight cutoff (MWCO) of 1 kDa. The dialyzed solution was freeze−dried to yield BocNH-PEG-N_3 **2** (0.92 g, 82% yield) as a white solid, which was then deprotected in 6 mL of 70% TFA aqueous solution. After 2 h, the reaction mixture was diluted with 18 mL of water and purified again by dialysis, as described above. After freeze−drying, a white solid product **3** (0.59 g, 64%) was recovered. The presence of the terminal azide group and the C−O bond were characterized by a stretching frequencies at 2103 cm^{-1} and 1012 cm^{-1}, respectively, in the FTIR spectrum. MALDI-TOF-MS: 3727.2 (calc. 3727.52). ^{1}H NMR (D_2O): δ 3.68 (s). For ^{1}H NMR and FTIR spectra, see Supporting Information Figure S1 for compound **2** and Figures S2 and S11 for compound **3**.

Synthesis of Poly(TMCC-*co*-LA)-*g*-PEG-N_3. The synthesis of PEG-grafted copolymer was carried out as illustrated in Scheme 3. The poly(TMCC-*co*-LA) **4** was synthesized by bulk copolymerization as previously reported (*10*). Copolymer **4** (100 mg) was dissolved in DMF (5 mL) and 10 mM MES buffer

Scheme 2. Synthesis of H_2N-PEG-N_3 by Reacting NHS-Activated PEG Chains with Amine-Terminated Octaethylene Glycol-Azide Followed by BOC Deprotection



(0.5 mL, pH 5.5). *N*-ethyl-*N*′-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC, 10 wt %) and *N*-hydroxysulfosuccinimide (sulfo-NHS, 10 wt%) were then added, and the reaction solution was stirred at room temperature for 30 min. The PEG azide **3** (50 mg), dissolved in 0.5 M borate buffer (1 mL, pH 9.0), was slowly added to the activated copolymer solution under stirring. The reaction mixture was incubated at room temperature for 24 h, after which it was dialyzed against distilled water using an RC membrane at a MWCO of 12−14 kDa. The excess PEG was removed using a Sepharose C4B column equilibrated with distilled water. The collected fractions containing polymers were freeze−dried to give a white solid (55 mg, 50% yield). ^{1}H NMR (DMSO): δ 0.99 (br s, CH_3 from TMCC), 1.42−1.46 (m, CH_3 from LA), 3.49 (s, PEG), 4.19 (br s, methylene from TMCC), and 5.17−5.19 (m, CH from LA). ^{1}H NMR spectra of poly(TMCC-*co*-LA) **4** and poly(TMCC-*co*-LA)-*g*-PEG-azide **5** are shown in Supporting Information Figures S3 and S4.

Self-Assembly of Polymers to Nanoparticles by Dialysis. The nanoparticles **6** were prepared by self-assembly of poly(TMCC-*co*-LA)-*g*-PEG-azide by memberane dialysis, as previously reported (*15*). Briefly, copolymer **5** (15 mg) was dissolved in 1.5 mL of DMF/borate buffer (0.5 M, pH 9.0) at a volume ratio of 1.425 to 0.075. The solution was dialyzed against distilled water using a dialysis membrane with a MWCO of 12−14 kDa at room temperature for 8 h.

Synthesis of Alkyne-Modified KGRGDS. The synthesis of alkyne-modified KGRGDS peptide is shown in Scheme 4. The alkyne-modified KGRGDS was synthesized by solid-phase synthesis 4-pentynoic acid (0.20 g, 2 mmol) was activated by *N*,*N*′-diisopropyl carbodiimide (DIC, 1.24 mL, 8 mmol) in 10 mL of CH_2Cl_2 under N_2 for 30 min. Alkyne-KGRGDS was added, and the mixture was stirred at room temperature for another 2 h. The resin was filtered and washed with 20 mL each of dichloromethane, methanol, and isopropyl alcohol (IPA).

The resin recovered from the previous step was dissolved in TFA/water (9.5 mL/0.5 mL, v/v) and stirred for 2 h. The peptide dissolved in solution was separated from the resin by vacuum filtration and concentrated by rotary evaporation. The crude oily product was precipitated in 100 mL of cold ether and stored in a −80 °C freezer overnight. The precipitated white peptide (65 mg, 65% yield) was recovered by centrifugation and dried under N_2.

The product was further purified by HPLC to yield 50 mg of the final product as a white solid (yield 76%). The final product was confirmed by ^{1}H NMR and mass spectrometry (MS). ^{1}H NMR (D_2O, 400 MHz): δ 1.28−1.83 (m, 10H), 2.31 (s, 1H), 2.44 (m, 4H), 2.77−2.95 (m, 2H), 3.10−3.16 (t, 2H, J = 6 Hz), 3.18−3.22 (t, 2H, J = 6 Hz), 3.82−3.97 (m, 11H), 4.10−4.16 (dd, 1H, J_1 = 5 Hz, J_2 = 8 Hz), 4.26−4.32 (dd, 1H, J_1 = 5 Hz, J_2 = 8 Hz), 4.48−4.51 (dd, 1H, J_1 = 4 Hz, J_2 = 5 Hz), 4.79−4.81 (m, 1H) 6.30 (s, 1H), 6.99−7.02 (m, 2H), 7.62−7.64 (m, 1H). ESI-MS (MNa^+): 936.4 (calc. 937.38). (The same syntheses and characterization methods were used for the following additional peptides studied and are described in the Supporting InformationFigures S1−S8: alkyne-KGRGDS, scrambled alkyne-KGRDGS, alkyne-GRGDS, and scrambled alkyne-GRDGS.)

Immobilization of KGRGDS on Nanoparticles by Click Chemistry. Alkyne-modified KGRGDS, at concentrations of 25, 50, and 100 μg/mL, was reacted with poly(TMCC-*co*-LA)-*g*-PEG-azide nanoparticles (1.875 mg/mL) at room temperature in distilled water under catalysis with copper sulfate (0.6 μmol/mL) and sodium ascorbate (3.0 μmol/mL). The reaction mixture was stirred at room temperature for 1, 3, and 5 h (see Results and Discussion). It was then purified through a Sephadex G-25 column equilibrated with 0.01 M PBS buffer at pH 7.4.

Cell Attachment Assay. *GRGDS-Modified Cell Culture Plates.* The peptide sequence GRGDS in borate buffer (pH 9.0, 0.5 M) was placed in a 96-well reacti-bind amine-binding, maleic anhydride activated plates (100 μL/well) at a concentration of 100 μg/mL. The plate was incubated on a shaker at room temperature overnight, and the peptide solution was then removed. Protein blocking buffer (200 μL/well) was added and incubated for 1 h at room temperature to quench any remaining reactive maleic anhydride groups and block remaining open sites on the plate surface.

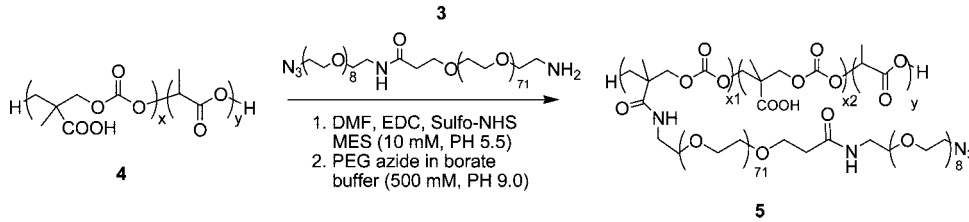
Preparation of Cells. SIRC-rabbit corneal epithelial cells were cultured in tissue culture plates with minimum essential medium α (α-MEM) containing 10% FBS, 1% penicillin/streptomycin, and 1% glutamine in an incubator (37 °C, 5% CO_2, 100% humidity). Before harvesting, cells were incubated with fresh cell culture medium containing with 10 ng/mL of epidermal growth factor (EGF) overnight.

Competitive Cell Attachment Assay. To test the binding affinity of the GRGDS-modified nanoparticles, the attachment of cells to GRGDS-modified cell culture wells was tested after preincubation with either GRGDS-nanoparticles or scrambled GRDGS-nanoparticles and compared to the cell attachment observed when cells were preincubated in soluble GRGDS. Specifically, a cell suspension of cultured rabbit corneal epithelial cells with an equal volume of 1 or 10 μg/mL of GRGDS or 2.0 mg/mL of peptide-modified nanoparticles with peptide concentration of 5.5 μg/mL in PBS buffer (0.01 M, pH 7.4) was preincubated at 37 °C for 30 min before plating into wells (1×10^4 cells/well, 100 μL). The cells were incubated at 37 °C for another 4 h after plating. The wells were then washed three times with fresh cell culture medium before quantifying the number of attached cells using the PicoGreen assay. It was assumed that every cell contained 7.7 pg of DNA.

RESULTS AND DISCUSSION

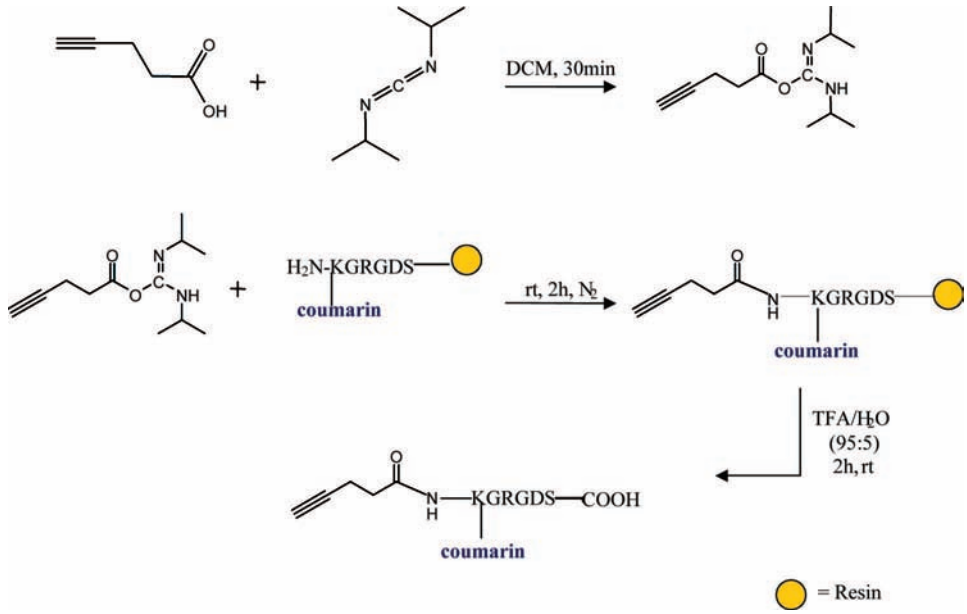
Synthesis of Poly(TMCC-*co*-LA)-*g*-PEG. The amphiphilic copolymer, poly(TMCC-*co*-LA)-*g*-PEG-azide, was designed specifically for the creation of RGD-nanoparticles by combining strategies of polymeric self-assembly and click chemistry of bioconjugation in one process. The copolymer is biodegradable and biocompatible for in vivo applications, amphiphilic with the ability to self-assemble into ordered structures, and capable

Scheme 3. Synthesis of Poly(TMCC-*co*-LA)-*g*-PEG-Azide[a]



[a] The carboxylic acid groups on the copolymer backbone were first activated with *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC) and *N*-hydroxysulfosuccinimide (Sulfo-NHS) for 30 min. Then, amine-terminated PEG azide was covalently bound under basic conditions overnight.

Scheme 4. Synthesis of the Alkyne-Modified KGRGDS Peptides[a]



[a] 4-Pentynoic acid was activated by *N*,*N*′-diisopropylcarbodiimide (DIC) for 30 min and reacted with amine-terminated peptides. The peptide was cleaved from the resin using a 95% TFA aqueous solution for 2 h at room temperature.

of click chemistry chemistry due to the presence of azide groups at the PEG terminus.

The number average molecular weight and polydispersity of poly(TMCC-*co*-LA) were determined by GPC (see Supporting Information Figure S10), relative to polystyrene standards in THF, to be 30.4 kDa and 2.7, respectively. The molar percentage of TMCC in the copolymer was determined from ^{1}H NMR data to be 9.3% by comparing the integrated peak of TMCC methylene (4.18 ppm) with that of the LA methine (5.13−5.19 ppm). This number is slightly lower than the feed ratio (TMCC/D,L-lactide 10/45), where each D,L-lactide monomer contains two repeat units. This is probably because LA is more reactive than TMCC in the copolymerization, leading to an enrichment of LA in the copolymer (*17*). The random copolymer composition was estimated from ^{1}H NMR and GPC data to be poly(TMCC)$_{32}$-*co*-(LA)$_{310}$.

After copolymerization, the carboxylic acid groups along the copolymer chain were deprotected, allowing for further functionalization with PEG-N_3 using EDC chemistry. This resulted in amphiphilic copolymers of poly(TMCC-*co*-LA)-*g*-PEG-azide with well-defined hydrophobic and hydrophilic segments. The ratio of PEG grafted to poly(TMCC)$_{32}$-*co*-(LA)$_{310}$ was estimated by comparing the integrated peak areas from the ^{1}H NMR spectrum of PEG methylene (3.49 ppm) to that of the TMCC methylene (4.18 ppm). On average, there was approximately one PEG chain grafted to every poly(TMCC)$_{32}$-*co*-(LA)$_{310}$ backbone. The number average molar mass of poly(TMCC)$_{32}$-*co*-(LA)$_{310}$-*g*-PEG was calculated according to

$$M_{\text{n (poly(TMCC}-co-\text{LA)}-g-\text{PEG)}} = M_{\text{n (backbone)}} + (M_{\text{n (PEG)}} \times \#\text{ of PEG per copolymer backbone}) \quad (1)$$

Given that $M_{\text{n(backbone)}}$ is 30.4 kDa, $M_{\text{n(PEG)}}$ is 3.40 kDa and there is one PEG chain per copolymer backbone; the $M_{\text{n (poly(TMCC-}co\text{-LA)-}g\text{-PEG)}}$ is estimated at 33.8 kDa.

Estimation of the Molecular Weight of Nanoparticles (M_{NP}) and the Number of Chains Aggregated in a Nanoparticle (N_{agg}). When poly(TMCC-*co*-LA)-*g*-PEG was dissolved in DMF with 5% borate buffer and dialyzed against water (see Experimental Procedures), the hydrophobic poly(TMCC-*co*-LA) backbone self-assembled to form the nanoparticle core, while the hydrophilic PEG chains interacted with the surrounding water to form the nanoparticle shell. As observed by dynamic light scattering (DLS), the resulting self-assembled nanoparticles had an average diameter of 130.8 nm and a polydispersity index (PDI) of 0.2897, which indicates that the nanoparticles are polydisperse. By scanning transmission electron microscopy, the average diameter of the nanoparticles was 87.4 ± 12.5 nm (n = 50 nanoparticles, mean ± s.d.). The STEM image has been previously reported (*10*). The diameter measured by STEM is smaller than that measured by DLS, because STEM imaged the dry nanoparticles, whereas DLS detected the hydrated nanoparticles in aqueous solution. While the DLS data

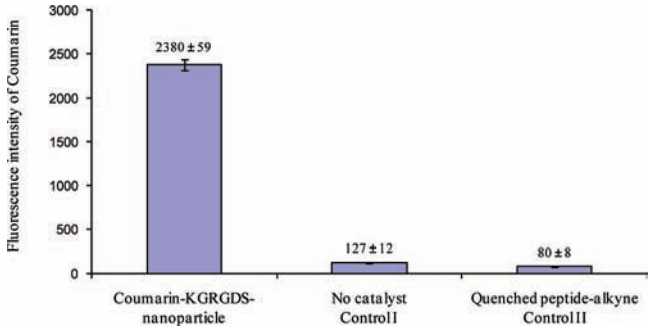


Figure 1. The fluorescence intensity of coumarin was readily detected on azide-functionalized nanoparticles that had reacted with alkyne-peptide in the presence of copper sulfate and sodium ascorbate. In control I, the identical incubation between peptides and nanoparticles was repeated in the absence of copper sulfate and sodium ascorbate, demonstrating the importance of the catalyst for successful peptide modification. In control II, peptides were preincubated with 4-azidoaniline for 3 h before incubating with nanoparticles and catalyst, demonstrating that alkyne groups were quenched and unavailable for reaction with nanoparticle-azide.

are a better measure of the hydrated nanoparticle diameter, the standard deviation of the mean calculated from the STEM data is likely a better indication of the polydispersity of the nanoparticles (*10*). Assuming that the dried nanoparticle is a hard sphere with negligible porosity, the molar mass of the nanoparticle M_{NP} can be calculated from

$$M_{NP} = \frac{4\pi R^2 N_A}{3\upsilon_2} \quad (2)$$

where R is the radius of the nanoparticle (43.7 ± 6.3 nm from STEM); υ_2 is the partial specific volume of the polymer, which is estimated at 0.95 mL/g, and N_A is Avogadro's constant (6.02×10^{23}) (*18*). The average nanoparticle aggregation number, N_{aggs}, can be estimated as

$$N_{agg} = M_{NP}/M_{n(\text{poly(TMCC-}co\text{-LA)-}g\text{-PEG})} \quad (3)$$

using the value of M_{NP} calculated from eq 2.

Thus, one nanoparticle comprises approximately (6.5 ± 0.4) $\times 10^3$ polymer chains.

Immobilization of Alkyne-KGRGDS on Azido-Nanoparticles by Click Chemistry. In the self-assembled nanoparticle system, the azide-alkyne Huisgen's cycloaddition reaction was designed to occur at the interface between the azide-PEG corona of the nanoparticles and the aqueous phase in which alkyne-peptides were dissolved. After the amphiphilic copolymer self-assembled into nanoparticles, the hydrophilic segments oriented outward to the water phase. The terminal azide groups are accessible to alkyne-functionalized molecules in the aqueous solution, enabling click chemistry at the PEG terminus of the self-assembled nanoparticles. Coumarin-modified alkyne-KGRGDS was reacted with azide-nanoparticles at room temperature for 5 h in the presence of copper sulfate and sodium ascorbate. To confirm the Huisgen's 1,3 dipolar cycloaddition reaction, two controls were carried out: (1) the reaction was carried out in the absence of catalyst; and (2) the reaction was carried out after quenching the alkyne groups on KGRGDS with a large excess of 4-azidoaniline.

The fluorescence of the coumarin-modified alkyne-KGRGDS was used to measure the success of the reaction between peptide-alkyne and azido-nanoparticle. As shown in Figure 1, nanoparticles incubated with an excess of alkyne-KGRGDS showed a strong fluorescent signal at (2380 ± 59) indicating that the fluorescent peptide was coupled to the nanoparticles. Neither the control group lacking the copper sulfate/ascorbic acid (127 ± 12) nor that with quenched peptide-alkyne (80 ± 8) showed significant fluorescence. Together, these data confirmed the successful Huisgen's 1,3 dipolar cycloaddition reaction between peptide-alkyne and azido-nanoparticle. The hydrodynamic diameter of the nanoparticles (130.8 nm), determined by DLS, did not change significantly after peptide modification (126.2 nm) where the PDI was 0.2879. This suggests that the nanoparticles do not aggregate as a result of peptide modification.

Estimation of the Amount of Peptides Per Nanoparticle. To estimate the amount of peptide coupled per nanoparticle, the concentrations of both peptide and nanoparticle were independently determined, relative to standard curves with known concentrations of peptides and nanoparticles. The concentration of peptide was measured by the fluorescence intensity associated with coumarin. The concentration of nanoparticles was measured by their absorbance in Bradford reagent (*10*) at 595 nm using a microplate reader. The number of peptides per nanoparticle (n) was estimated according to eq 4

$$n = \frac{\text{peptide[M]}}{\text{nanoparticle[M]}} \quad (4)$$

To determine the optimum reaction time and the maximum number of peptides that can be conjugated per nanoparticle, both the click chemistry reaction time and the alkyne-KGRGDS concentration were varied. In Figure 2a, azido-nanoparticles reacted with 7-fold molar excess of alkyne-KGRGDS catalyzed by copper sulfate and sodium ascorbate at room temperature for 1, 3, and 5 h. The amount of peptide per nanoparticle increased between 1 and 3 h, after which a plateau of 439 ± 11 (mean ± standard deviation) peptides per nanoparticle was achieved, demonstrating that the reaction was complete after 3 h. In Figure 2b, azido-nanoparticles reacted for 5 h with various concentrations of alkyne-KGRGDS, where the peptide to copolymer molar ratio increased from 2:1 to 7:1. As the peptide to polymer ratio increased, the amount of peptide bound per nanoparticle increased from 229 ± 2 to 406 ± 21. According to our calculation, each NP has approximately 6500 PEG groups, but only ~440 peptides immobilized. This low reaction yield may be explained by not all PEG chains having azido groups and some of the azido groups not being available for reaction due to steric interactions. For example, some of the azido groups may have been buried within the PEG corona. Although the yield for azide-alkyne Huisgen's cycloaddition reaction of small molecules is normally above 80% (*19*−*21*), the kinetics of this reaction are very different between small molecules and polymers. As reported, the yield of this reaction dropped below 50% when the cycloaddition reaction was performed between two polymers (*22*). The yield is expected to drop further with polymeric nanoparticles, where accessibility of the azido groups is limited by entangled polymer chains and steric hindrance associated with solid particles. The number of immobilized peptides per nanoparticle is comparable to literature values (*23*). While many of the PEG-azido groups are left unreacted, they are largely inert in cell culture, as has been previously shown with azido-sugars on the cell surface that were used for bioorthogonal chemistry (*28*). However, the click chemistry in this nanoparticle system is advantageous over other coupling methods described in the literature because of the specificity, speed, and relative ease of the reaction. While the Huisgen 1,3 dipolar cycloaddition reaction requires the introduction of alkyne and azide groups, the common thiol-maleimide Michael-type addition chemistry also requires the introduction of free thiol and maleimide groups. However, the ligation reaction of the thiol-maleimide occurs in the narrow pH range 6.5−7.5. If the pH is too high, hydrolysis of the maleimide will occur; if the pH is too low, the reaction will occur very slowly or not at all. Thiol groups are very reactive toward various electrophiles and rapidly deteriorate when in solution. A protecting group is usually introduced, followed by a deprotection step (*24*−*26*).

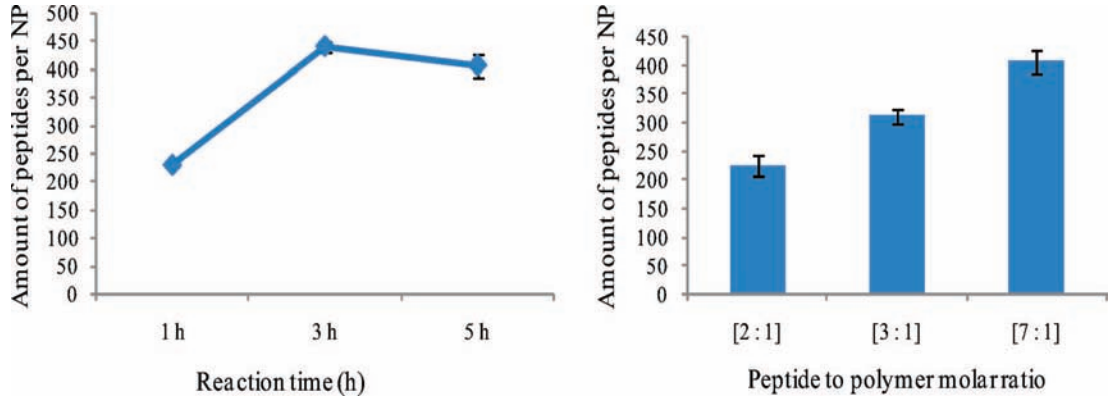

Figure 2. (a) Nanoparticles reacted with 7-fold molar excess of alkyne-KGRGDS catalyzed by copper sulfate and sodium ascorbate at room temperature for 1 h (229 ± 2), 3 h (439 ± 11), and 5 h (406 ± 21). (b) Nanoparticles reacted for 5 h with various concentrations of alkyne-KGRGDS where the peptide to copolymer molar ratio increased from 2:1 (224 ± 18) to 3:1 (311 ± 13) to 7:1 (406 ± 21). The numbers in parentheses are the means ± standard deviations for the number of peptides per nanoparticle.

Unlike the 3 h required for the click chemistry described herein, alternative coupling mechanisms, such as amine−aldehyde conjugation in the presence of the reducing agent, $NaBH_3CN$, has the disadvantage of requiring four days of reaction time (*27*) and the use of the highly toxic $NaBH_3CN$ reducing agent. Short reaction time, broad pH range, mild reaction conditions, and a simple purification process demonstrate the broad utility of click chemistry. Importantly, the click chemistry also allows us to couple the bioactive molecules (in this case, GRGDS peptides) in water after nanoparticle formation, thereby avoiding exposure of peptides (or proteins) to potentially denaturing organic solvents.

A clinically useful nanoparticle carrier for drug delivery, in addition to allowing surface modification, also has to be nontoxic, amenable to sterile filtration, and stable over a long period of time (*15*). Our nanoparticle system fulfills these criteria.

Cell Attachment Assay. Maleic anhydride functionalized 96-well plates were coated with amine-terminated GRGDS-containing peptides, and then, any unreacted sites were blocked with blocking buffer to ensure that GRGDS peptides were the only binding sites for corneal epithelial cells. To test the bioactivity of immobilized NP-GRGDS and the binding affinity between NP-GRGDS and corneal epithelial cells, a competitive cell attachment assay was performed, as shown quantitatively in Figure 3 and qualitatively in Supporting Information Figure S9. The number of corneal epithelial cells that adhered to the GRGDS-modified culture wells was quantified, comprising the positive control, as shown in Figure 3. The negative control, where the 96-well plate lacked the GRGDS peptide, showed very little cell adhesion. To better understand the binding affinity of this interaction, the epithelial cells were preincubated with soluble GRGDS peptides prior to plating on GRGDS-modified surfaces. As shown, cell attachment reduced from 70% to 40% compared to the positive control as the concentration of soluble GRGDS increased from 1 μg/mL to 10 μg/mL, indicating that the RGD integrin receptors on the cells were at least partially responsible for cell attachment. To determine the binding affinity of GRGDS bound to the nanoparticles, we repeated the preincubation study, replacing soluble GRGDS with NP-GRGDS.

When preincubated with NP-GRGDS prior to plating, fewer cells attached to the GRGDS-modified plate, similar to that observed when cells were preincubated with soluble GRGDS. The cell attachment was both significantly less than the positive control and similar to the negative control (where the cell plates lacked GRGDS). Importantly, the cell surface integrin−RGD interaction was confirmed with two controls: scrambled NP-GRDGS and NPs with blocked azido groups (i.e., no peptides). When the epithelial cells were preincubated with either scrambled NP-GRDGS or blocked NP-azido groups, the NPs did not sufficiently block the epithelial cell-surface integrin receptors, and thus, there were significantly more cells attached to the GRGDS-modified cell culture surfaces than had been observed when cells were preincubated with NP-GRGDS samples. However, there were fewer adherent cells after preincubation with either scrambled NP-GRDGS (1446 ± 377) or NP-blocked azido groups (1305 ± 215) relative to the positive control (1958 ± 214), which suggests some nonspecific binding of nanoparticles to cells.

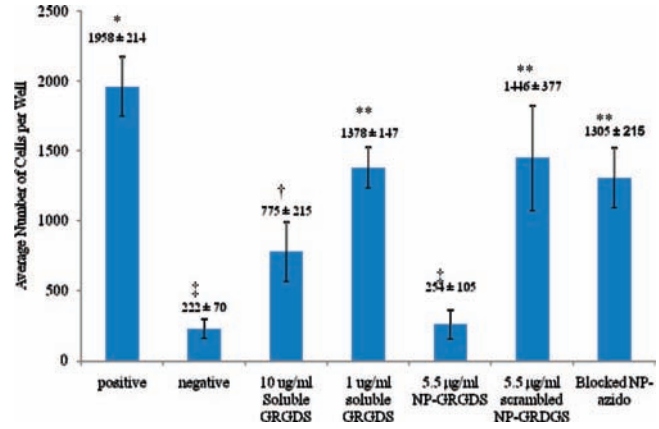

Figure 3. Competitive assay of rabbit corneal epithelial cell surface receptors to RGD. The positive control demonstrates a large number of cells bind to GRGDS-coated well-plate surfaces after a 4 h incubation. The negative control shows that few epithelial cells bind to unmodified well surfaces, demonstrating an RGD-mediated cell attachment. Competitive inhibition of cell attachment was demonstrated with soluble GRGDS (at concentrations of 10 and 1 μg/mL) where the number of adherent cells to the well plates decreased with increased GRGDS concentration. The bioactivity of the click chemistry bound NP-GRGDS (5.4 μg/mL) was confirmed by the similar competitive inhibition of cell attachment. The binding affinity of this interaction was verified with the scrambled NP-GRDGS (5.4 μg/mL) and nanoparticles with blocked azido groups where cell attachment was not inhibited. Shown are the mean ± standard deviation for $n = 3$ independent tests of triplicate assays; ANOVA was used for statistical analysis. The Posthoc analysis showed that there is a statistical difference ($p < 0.05$) between the different symbols.

Interestingly, NP-GRGDS samples seemed to be more effective at inhibiting epithelial attachment to the GRGDS-modified plates than soluble GRGDS, as demonstrated in Figure 3. While there is some nonspecific cell adhesion to the nanoparticles, as was observed with the NP controls, the NP-

GRGDS sample significantly reduced cell adhesion relative to the NP controls and the soluble GRGDS, indicating that additional mechanisms are required to explain the results. It is unlikely that there was any cytotoxicity associated with the remaining copper sulfate due to the small amount used, with our thorough purification methodology and literature demonstrating cell viability at 100−1000× greater copper concentrations (*29*). Thus, there are at least two possible explanations. The presence of multiple peptides on a given nanoparticle suggests multivalent interactions with the cells or avidity, as has been suggested by others (*23*). Alternatively, some of the soluble GRGDS peptides may have been internalized by the cells via an integrin-independent pathway, or even if by an integrin-dependent pathway, the integrin may have been recycled on the cell surface and available to interact with substrate-bound GRGDS-cell culture plates. A similar mechanism was observed by Castel et al. who showed that, at a concentration of 10 μg/mL, the RGD peptide targeted for $\alpha_v\beta_3$ was internalized in both α_v-integrin expressing and nonexpressing melanoma cells by an integrin-independent fluid-phase endocytosis pathway that did not alter the number of functional integrin receptors at the cell surface (*30*). This internalization occurred within 30 min at 37 °C. In our studies, relative to the soluble GRGDS, the NP-GRGDS effectively limited cell adhesion to the GRGDS coated well plates likely because it could not be internalized in the time frame studied due to the large particle size. Using confocal microscopy and fluorescent GRGDS-nanoparticles, we had no evidence for internalization (data not shown).

In order to improve the specificity and binding affinity of these GRGDS- nanopaticles, the synergistic proline-histidine-serine-arginine-asparagine (PHSRN) sequence can be similarly coupled to our nanoparticles, with the appropriate spacer between the two peptides (*31*)for optimal specificity with $\alpha_v\beta_1$ intergrins (*32*). Importantly, the platform conjugation technology described is applicable to a variety of peptides.

CONCLUSIONS

GRGDS peptides were successfully immobilized on self-assembled, polymeric nanoparticles using the azide-alkyne Huisgen 1,3 cycloaddition reaction. This chemistry is efficient and broadly applicable to a diversity of molecules. The azide-alkyne reaction was complete within 3 h and resulted in approximately 400 conjugated peptides per nanoparticle, allowing for interactions with cells that have $\alpha_v\beta_1$-integrin receptors up-regulated. The size of the nanoparticles detected by DLS was unchanged after peptide modification. The covalently bound NP-GRGDS peptides maintained their bioactivity and binding affinity with rabbit corneal epithelial cells relative to scrambled NP-GRDGS controls. These NP-GRGDS samples are small enough for sterile filtration and may be useful for targeted delivery to the injured eye.

ACKNOWLEDGMENT

We thank Professor Mitchell Winnik and Daniel Majonis for the use of their GPC, Dr. Neil Coombs for STEM imaging, and Ryan Wylie for helpful discussions. We are grateful to NSERC and CIHR for funding through the Collaborative Health Research Program.

Received July 29, 2008; Revised Manuscript Received November 10, 2008

We report a novel series of radioiodinated aurone derivatives as probes for imaging Aβ plaques in the brains of patients with Alzheimer's disease (AD) using single photon emission computed tomography (SPECT). In binding experiments in vitro, aurone derivatives showed very good affinity for Aβ aggregates (K_i = 1.1 to 3.4 nM). No-carrier-added radioiodinated aurones were successfully prepared through an iododestannylation reaction from the corresponding tributyltin derivatives. In biodistribution experiments using normal mice, aurone derivatives displayed high brain uptake (1.7−4.5% ID/g at 2 min) and rapid clearance from the brain (0.1−0.4% ID/g at 30 min), especially [^{125}I]**15**. Furthermore, a specific plaque labeling signal was observed in in vitro autoradiography of postmortem AD brain sections using [^{125}I]**15**. [^{125}I]**15** may be a useful SPECT imaging agent for detecting Aβ plaques in the brain of AD.

INTRODUCTION

Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by cognitive decline, irreversible memory loss, disorientation, and language impairment. Senile plaques containing β-amyloid (Aβ) peptides and neurofibrillary tangles in the postmortem brain are two pathological hallmarks of AD (*1, 2*). Excessive production of Aβ via various normal or abnormal mechanisms is considered to be the initial neurodegenerative event in AD. Currently, it is difficult for clinicians to differentiate between the cognitive decline associated with normal aging and the cognitive decline associated with AD. There is no simple and definitive diagnostic method to detect Aβ plaques in the brain without postmortem pathological staining of brain tissue. Thus, the development of imaging agents for positron emission tomography (PET) or single photon emission computed tomography (SPECT), which can detect Aβ plaques in vivo, may assist with the early diagnosis of AD (*3*−*5*).

In the past few years, several groups have reported potential amyloid-imaging probes for the detection of Aβ plaques in vivo. Tracers such as [^{11}C]PIB (*6, 7*), [^{11}C]SB-13 (*8, 9*), [^{18}F]BAY94-9172 (*10*), [^{11}C]BF-227 (*11*), [^{18}F]FDDNP (*12*−*14*), and [^{123}I]IMPY (*15*−*18*) have been tested clinically and demonstrated utility (Figure 1). [^{123}I]IMPY is the only tracer for SPECT; the other five tracers are amyloid imaging probes for PET. Since SPECT is more valuable than PET in terms of routine diagnostic use, the development of more useful β-amyloid-imaging agents for SPECT has been a critical issue.

Recently, we have reported that radioiodinated aurones possessing a nucleophilic group (NH_2, NHMe, and NMe_2) function as a new backbone structure in the development of amyloid-imaging probes for SPECT (*19*). These compounds showed strong binding to Aβ aggregates (K_i = 1.2−6.8 nM), good penetration of the brain (1.9−4.6% ID/g at 2 min), and a fast washout from the brain (0.3−0.5% ID/g at 30 min). However, the aurone derivatives appeared inferior to IMPY in pharmacokinetics, although their high affinity for β-amyloid plaques is sufficient for imaging in vivo. Therefore, additional structural changes are essential to further improve the properties of aurone derivatives to make them suitable for the imaging of β-amyloid plaques in the brain.

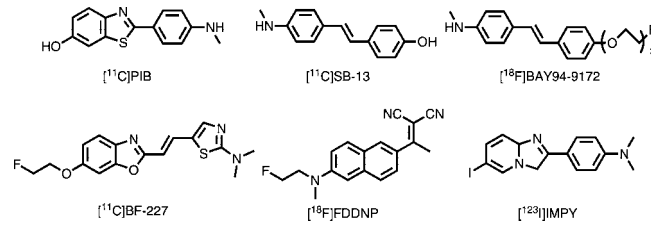

Figure 1. Chemical structure of Aβ imaging probes clinically tested.

To develop more promising aurones for SPECT-based imaging of β-amyloid plaques, we designed a novel series of radioiodinated derivatives with poly(ethylene glycol) (PEG). PEG is nontoxic, nonimmunogenic, highly soluble in water, and FDA-approved, and PEGylation has been used to change the pharmacokinetics of various biologically interesting proteins or peptides, leading to better therapeutics (*20, 21*). Therefore, PEGylated aurone derivatives are worthy of further evaluation as novel β-amyloid-imaging probes for SPECT.

In the present study, we designed and synthesized a novel series of radioiodinated aurone derivatives with not only 1 to 3 units of ethylene glycol at the 4′ position, but also other nucleophilic groups (-OCH_3 and -OH), and evaluated their biological potential as probes for imaging β-amyloid by testing their affinity for Aβ aggregates in vitro and their uptake by and

clearance from the brain in biodistribution experiments using normal mice.

MATERIALS AND METHODS

All reagents were commercial products and used without further purification unless otherwise indicated. ^{1}H NMR spectra were obtained on a Varian Gemini 300 spectrometer with TMS as an internal standard. Coupling constants are reported in hertz. Multiplicity was defined by s (singlet), d (doublet), t (triplet), and m (multiplet). Mass spectra were obtained on a JEOL IMS-DX instrument.

Chemistry. *Methyl 2-((Ethoxycarbonyl)methoxy)-5-bromobenzoate (**1**).* To a solution of 2-hydroxy-5-bromobenzoic acid methyl ester (1.5 g, 6.49 mmol) in acetone (10 mL) was added K_2CO_3 (2.7 g, 19.5 mmol) and ethylbromoacetate (1.3 mL, 7.78 mmol). The mixture was stirred for 3 h under reflux. After the solvent was evaporated, the residue was dissolved in water (100 mL) and extracted with ethyl acetate (100 mL). The organic layer was dried over Na_2SO_4, and evaporation of the solvent gave 1.60 g of **1** (77.7%). ^{1}H NMR NMR (300 MHz, $CDCl_3$) δ 1.29 (t, J = 7.2 Hz, 3H), 3.91 (s, 3H), 4.24 (q, J = 7.2 Hz, 2H), 4.69 (s, 2H), 6.78 (d, J = 9.0 Hz, 1H), 7.54 (d, J = 6.3 Hz, 1H), 7.96 (s, 1H).

*2-(Carboxymethoxy)-5-bromobenzoic Acid (**2**).* To a solution of **1** (1.6 g, 5.04 mmol) in methanol (10 mL) was added 10% aqueous KOH (3.0 mL). The mixture was stirred for 2 h at room temperature. The product formed by adding 1 N HCl was filtered to give 1.10 g of **2** (79.4%). ^{1}H NMR (300 MHz, CD_3OD) δ 4.81 (s, 2H), 7.02 (d, J = 8.7 Hz, 1H), 7.63 (dd, J = 2.4, 2.7 Hz, 1H), 7.93 (d, J = 2.4 Hz, 1H).

*5-Bromo-3-acetoxybenzofuran (**3**).* A mixture of acetic anhydride (20 mL), acetic acid (4 mL), anhydrous sodium acetate (1.0 g, 12.0 mmol), and **2** (100 mg, 0.36 mmol) was heated to reflux for 5 h. Water (100 mL) was then added, and the mixture was extracted with chloroform (100 mL). After drying of the organic layer on Na_2SO_4, evaporation gave 78 mg of **3** (86.5%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.37 (s, 3H), 7.33 (d, J = 9.0 Hz, 1H), 7.43 (dd, J = 3.6, 2.1 Hz, 1H), 7.71 (s, 1H), 8.02 (s, 1H).

*5-Bromobenzofuran-3(2H)-one (**4**).* A mixture of **3** (78 mg, 0.31 mmol), methanol (3 mL), water (1 mL), and 1 N HCl (2 mL) was heated to reflux for 3 h. The precipitate formed was collected by filtration, washed with water, and dried under vacuum to obtain 15 mg of **4** (22.5%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 4.67 (s, 2H), 7.06 (d, J = 9.0 Hz, 1H), 7.69 (dd, J = 2.1, 2.1 Hz, 1H), 7.79 (d, J = 2.1 Hz, 1H).

*(Z)-2-(4-Methoxybenzylidene)-5-bromobenzofuran-3(2H)-one (**5**).* To a solution of **4** (300 mg, 1.41 mmol) and 4-methoxybenzaldehyde (192 mg, 1.41 mmol) in chloroform (5 mL) was added Al_2O_3 (2.7 g, 26.0 mmol). The mixture was stirred for 20 min at room temperature. After filtration of the reaction mixture, the solvent of the filtrate was removed, and drying under vacuum yielded 410 mg of **5** (85.7%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 3.88 (s, 3H), 6.91 (s, 1H), 6.99 (d, J = 9.0 Hz, 2H), 7.24 (d, J = 8.4 Hz, 1H), 7.73 (dd, J = 2.1, 2.1 Hz, 1H), 7.88 (d, J = 8.7 Hz, 2H), 7.92 (d, J = 1.8 Hz, 1H).

*(Z)-2-(4-Hydroxybenzylidene)-5-bromobenzofuran-3(2H)-one (**6**).* BBr_3 (3 mL, 1 M solution in CH_2Cl_2) was added to a solution of **5** (300 mg, 0.91 mmol) in CH_2Cl_2 (25 mL) dropwise in an ice bath. The mixture was allowed to warm to room temperature and stirred for 15 h. Water (50 mL) was added while the reaction mixture was cooled in an ice bath. The mixture was extracted with chloroform (2 × 30 mL), and the organic phase was dried over Na_2SO_4 and filtered. The filtrate was concentrated and the residue was purified by silica gel chromatography (hexane/ethyl acetate = 2:3) to give 15 mg of **6** (5.2%). ^{1}H NMR (300 MHz, DMSO-d_6) δ 1.23 (s, 1H), 6.92 (d, J = 8.4 Hz, 2H), 6.96 (s, 1H), 7.56 (d, J = 9.3 Hz, 1H), 7.88−7.92 (m, 3H), 7.95 (s, 1H). MS (EI) m/z 316 [M^+].

*(Z)-2-(4-Methoxybenzylidene)-5-(tributylstannyl)benzofuran-3(2H)-one (**7**).* A mixture of **5** (200 mg, 0.60 mmol), $(Bu_3Sn)_2$ (0.4 mL), and $(Ph_3P)_4Pd$ (50 mg, 0.043 mmol) in a mixed solvent (15 mL, 1:1 dioxane/Et_3N) was stirred under reflux for 24 h. The solvent was removed, and the resulting residue was purified by silica gel chromatography using chloroform to give 50 mg of **7** (15.3%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.89−1.64 (m, 27H), 3.87 (s, 3H), 6.89 (s, 1H), 6.99 (d, J = 8.7 Hz, 2H), 7.31 (d, J = 8.1 Hz, 1H), 7.71 (dd, J = 0.9, 0.9 Hz, 1H), 7.86 (d, J = 9.0 Hz, 2H), 7.90 (d, J = 8.7 Hz 1H). MS (EI) m/z 528 [M^+].

*(Z)-2-(4-Hydroxybenzylidene)-5-(tributylstannyl)benzofuran-3(2H)-one (**8**).* The same reaction as described above to prepare **7** was used, and 10 mg of **8** was obtained in a 12.0% yield from **6**. ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.86−1.60 (m, 27H), 6.74 (d, J = 9.0 Hz, 2H), 6.90 (s, 1H), 7.30 (d, J = 8.1 Hz, 1H), 7.69 (d, J = 8.1 Hz, 1H), 7.80 (d, J = 8.4 Hz, 2H), 7.89 (s, 1H). MS (EI) m/z 542 [M^+].

*(Z)-2-(4-Methoxybenzylidene)-5-iodobenzofuran-3(2H)-one (**9**).* To a solution of **7** (10 mg, 0.03 mmol) in $CHCl_3$ (3 mL) was added a solution of iodine in $CHCl_3$ (1 mL, 0.25 M) at room temperature. The mixture was stirred at room temperature for 5 min, and saturated $NaHSO_3$ solution (15 mL) was added. The organic phase was separated, dried over Na_2SO_4, and filtered. The solvent was removed, and the residue was purified by preparative TLC (2:3 hexane/ethyl acetate) to give 6 mg of **9** (84.0%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 3.88 (s, 3H), 6.91 (s, 1H), 6.98 (d, J = 6.9 Hz, 2H), 7.14 (d, J = 8.4 Hz, 1H), 7.87−7.91 (m, 3H), 8.12 (d, J = 2.1 Hz, 1H). HRMS (EI) m/z calcd for $C_{16}H_{11}O_3I$ (M^+) 377.9753, found 377.9753.

*Methyl 2-((Ethoxycarbonyl)methoxy)-5-iodobenzoate (**10**).* The same reaction as described above to prepare **1** was used, and 2.62 g of **10** was obtained in a 99.0% yield from 2-hydroxy-5-iodobenzoic acid methyl ester. ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.29 (t, J = 7.2 Hz, 3H), 3.90 (s, 3H), 4.25 (q, J = 6.0 Hz, 2H), 4.69 (s, 2H), 6.66 (d, J = 8.7 Hz, 1H), 7.71 (dd, J = 2.4, 2.4 Hz, 1H), 8.12 (d, J = 2.1 Hz, 1H).

*2-(Carboxymethoxy)-5-iodobenzoic Acid (**11**).* The same reaction as described above to prepare **2** was used, and 2.02 g of **11** was obtained in a 87.2% yield from **10**. ^{1}H NMR (300 MHz, CD_3OD) δ 4.81 (s, 2H), 6.89 (d, J = 9.0 Hz, 1H), 7.80 (dd, J = 2.7, 2.4 Hz, 1H), 8.10 (d, J = 2.4 Hz, 1H).

*5-Iodo-3-acetoxybenzofuran (**12**).* The same reaction as described above to prepare **3** was used, and 1.45 g of **12** was obtained in a 76.6% yield from **11**. ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.37 (s, 3H), 7.23 (d, J = 8.1 Hz, 1H), 7.59 (dd, J = 1.5, 1.8 Hz, 1H), 7.90 (d, J = 1.5 Hz, 1H), 7.98 (s, 1H).

*5-Iodobenzofuran-3(2H)-one (**13**).* The same reaction as described above to prepare **4** was used, and 1.17 g of **13** was obtained in a 93.8% yield from **12**. ^{1}H NMR (300 MHz, $CDCl_3$) δ 4.65 (s, 2H), 6.96 (d, J = 9.0 Hz, 1H), 7.85 (dd, J = 1.8, 1.8 Hz, 1H), 7.99 (d, J = 1.8 Hz, 1H).

*(Z)-2-(4-Hydroxybenzylidene)-5-iodobenzofuran-3(2H)-one (**14**).* The same reaction as described above to prepare **5** was used, and 78 mg of **14** was obtained in a 87.0% yield from **13** and 4-hydroxybenzaldehyde. ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.28 (s, 1H), 6.87 (s, 1H), 6.91 (d, J = 5.4 Hz, 2H), 7.29 (d, J = 8.7 Hz, 1H), 7.85 (d, J = 6.9 Hz, 2H), 8.12 (d, J = 6.9 Hz, 1H), 8.08 (d, J = 1.8 Hz, 1H). HRMS (EI) m/z calcd for $C_{15}H_9O_3I$ (M^+) 363.9596, found 363.9571.

*(Z)-2-(4-(2-Hydroxyethoxy)benzylidene)-5-iodobenzofuran-3(2H)-one (**15**).* A mixture of potassium carbonate (3.7 g, 26.8 mmol), **14** (194 mg, 0.53 mmol), and ethylene chlorohydrin (0.1 mL, 1.43 mmol) in anhydrous DMF (7 mL) was heated at 120 °C for 15 h. After cooling to room temperature, water was added,

and the reaction mixture was extracted with ethyl acetate. The organic layer was separated, dried over Na_2SO_4, and evaporated. The resulting residue was purified by silica gel chromatography using ethyl acetate to give 123 mg of **15** (56.5%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.01 (s, 1H), 4.02 (s, 2H), 4.18 (t, J = 3.9 Hz, 2H), 6.89 (s, 1H), 7.00 (d, J = 7.5 Hz, 2H), 7.14 (d, J = 8.4 Hz, 1H), 7.80−7.92 (m, 3H), 8.12 (d, J = 1.8 Hz, 1H). HRMS (EI) *m*/*z* calcd for $C_{17}H_{13}O_4I$ (M^+) 407.9859, found 407.9879.

*(Z)-2-(4-(2-(2-Hydroxyethoxy)ethoxy)benzylidene)-5-iodobenzofuran-3(2H)-one (***16***).* The same reaction as described above to prepare **15** was used, and 56 mg of **16** was obtained in a 30.2% yield from **14** and ethylene glycol mono-2-chloroethyl ether. ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.17 (s, 1H), 3.70 (d, J = 4.8 Hz, 2H), 3.78 (d, J = 4.8 Hz, 2H), 3.92 (t, J = 4.8 Hz, 2H), 4.21 (t, J = 4.5 Hz, 2H), 6.89 (s, 1H), 7.00 (d, J = 11.4 Hz, 2H), 7.13 (d, J = 8.7 Hz, 1H), 7.84−7.91 (m, 3H), 8.11 (d, J = 2.1 Hz, 1H). HRMS (EI) *m*/*z* calcd for $C_{19}H_{17}O_5I$ (M^+) 452.0121, found 452.0131.

*(Z)-2-(4-(2-(2-(2-Hydroxyethoxy)ethoxy)ethoxy)benzylidene)-5-iodobenzofuran-3(2H)-one (***17***).* The same reaction as described above to prepare **15** was used, and 140 mg of **17** was obtained in a 67.9% yield from **14** and 2-[2-(2-chloroethoxy)ethoxy] ethanol. ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.96 (s, 1H), 3.74−3.80 (m, 6H), 3.92 (t, J = 4.8 Hz, 2H), 4.24 (t, J = 4.8 Hz, 2H), 4.45 (t, J = 4.5 Hz, 1H), 4.65 (t, J = 4.5 Hz, 1H), 6.91 (s, 1H), 6.98 (d, J = 9.0 Hz, 2H), 7.15 (d, J = 8.7 Hz, 1H), 7.85−7.92 (m, 3H), 8.15 (d, J = 2.1 Hz, 1H). Iododestannylation Reaction. The radioiodinated forms of compounds **9**, **14**, **15**, **16**, and **17** were prepared from the corresponding tributyltin derivatives by iododestannylation. Briefly, to initiate the reaction, the tributyltin derivative (50 μg/50 μL EtOH) was added to a mixture of a [^{125}I]NaI (3.7−7.4 MBq, specific activity 2200 Ci/mmol), 50 μL of H_2O_2 (3%), and 50 μL of 1 N HCl in a sealed vial. The reaction was allowed to proceed at room temperature for 2 min and was terminated by addition of $NaHSO_3$. The reaction, after neutralization with sodium bicarbonate, was extracted with ethyl acetate. The extract was dried by passing through an anhydrous Na_2SO_4 column and was then blown dry with a stream of nitrogen gas. The radioiodinated ligand was purified by HPLC on a Cosmosil C_{18} column with an isocratic solvent of H_2O/acetonitrile (3:7) at a flow rate of 1.0 mL/min.

Binding Assays Using the Aggregated Aβ Peptide in Solution. A solid form of Aβ(1−42) was purchased from Peptide Institute (Osaka, Japan). Aggregation was carried out by gently dissolving the peptide (0.25 mg/mL) in a buffer solution (pH 7.4) containing 10 mM sodium phosphate and 1 mM EDTA. The solution was incubated at 37 °C for 42 h with gentle and constant shaking. (*Z*)-2-(4-Aminobenzylidene)-5-iodobenzofuran-3(2*H*)-one ([^{125}I]AAU) was synthesized and used as the radioligand for the competition binding experiments (K_d value of [^{125}I]AAU is 4.2 nM) (*19*). The binding experiments were carried out in 12 × 75 mm borosilicate glass tubes according to a procedure described previously (*19*). A mixture containing 50 μL of test compound (0.8 nM−12.5 μM in 10% ethanol), 50 μL of 0.02 nM [^{125}I]AAU, 50 μL of Aβ(1−42) aggregate, and 850 μL of 10% ethanol was incubated at room temperature for 3 h. The mixture was then filtered through Whatman GF/B filters using a Brandel M-24 cell harvester, and the filters containing the bound ^{125}I ligand were placed in a gamma counter. Values for the half-maximal inhibitory concentration (IC_{50}) were determined from displacement curves of three independent experiments using GraphPad *Prism* 4.0, and those for the inhibition constant (K_i) were calculated using the Cheng-Prusoff equation (*22*): $K_i = IC_{50}/(1 + [L]/K_d)$, where [L] is the concentration of [^{125}I]AAU used in the assay, and K_d is the dissociation constant of AAU (4.2 nM) (*19*).

Staining of Amyloid Plaques in Transgenic Mouse Brain Sections. Tg2576 transgenic mice (20 month of age) were used as an Alzheimer's model. The brain was removed and sliced into serial sections 10 μm thick. Each slide was incubated with a 50% ethanol solution of compound **9**, **14**, **15**, **16**, and **17** (100 μM). Finally, the sections were washed in 50% EtOH for 3 min two times. Fluorescent observation was performed with the Nikon system (Excitation filter, 450−490 nm; Dichroic mirror, DM505; Barrier filter, BA520). Thereafter, the serial sections were also stained with thioflavin S, a pathological dye commonly used for staining Aβ plaques in the brain.

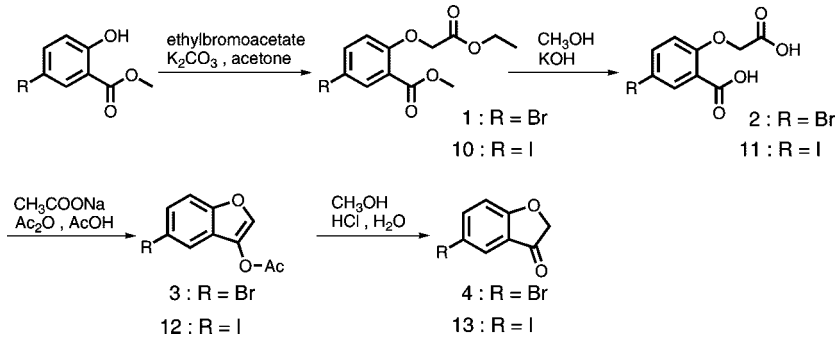
In Vivo Biodistribution in Normal Mice. Animal studies were conducted in accordance with our institutional guidelines and were approved by Nagasaki University Animal Care Committee. A saline solution (100 μL) containing radiolabeled agents (4.2−6.3 kBq) and 10% ethanol was intravenously injected directly into the tail vein of ddY mice (5 weeks old, average weight 20−25 g). The mice were sacrificed at various time points postinjection. The organs of interest were removed and weighed, and the radioactivity was measured with an automatic gamma counter (Aloka, ARC-380). Percent dose per gram of samples was calculated by comparing the sample counts with the counts of the initial dose.

In Vitro Autoradiography. Postmortem brain tissues from an autopsy-confirmed case of AD (73-year-old male) and a control subject (36-year-old male) were obtained from BioChain Institute Inc. The presence and localization of plaques on the sections were confirmed with immunohistochemical staining using a monoclonal Aβ antibody BC05 (Wako) as reported (*23*). The sections were incubated with [^{125}I]**15** (120000 cpm/100 μL) for 1 h at room temperature. They were then dipped in saturated lithium carbonate in 40% EtOH (two 2-min washes) and washed with 40% EtOH (one 2-min wash), before being rinsed with water for 30 s. After drying, the ^{125}I-labeled sections were exposed to a Fuji Film imaging plate overnight.

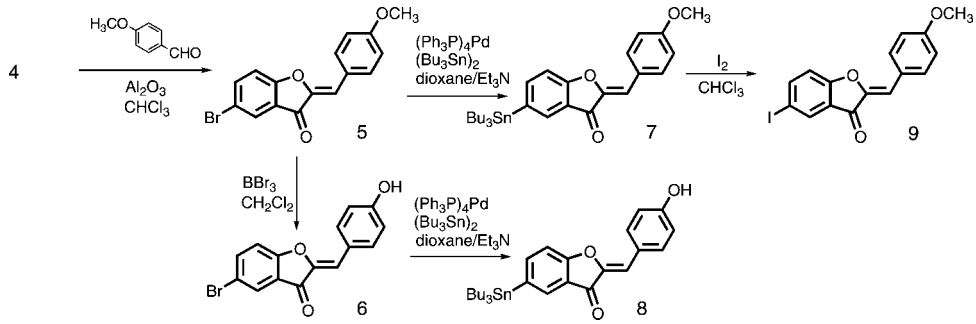
RESULTS AND DISCUSSION

Chemistry. The target aurone derivatives (**9**, **14**, **15**, **16**, and **17**) were prepared as shown in Schemes 1−3. The synthesis of

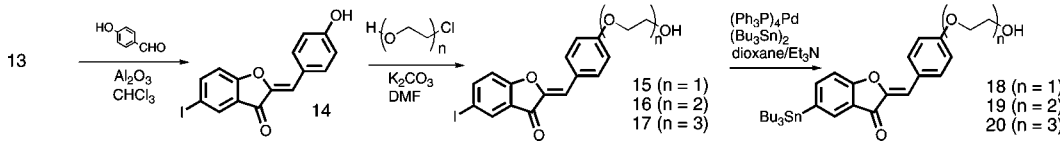
Scheme 1



Scheme 2



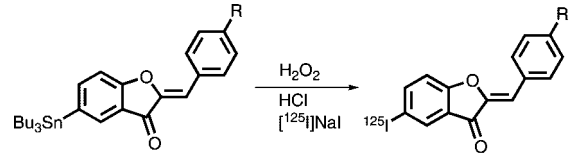
Scheme 3



the aurone backbone was achieved by an Aldol reaction of benzofuranones with benzaldehydes using Al_2O_3 (*23*). In this process, benzofuranones were reacted with methoxy benzaldehyde or hydroxy benzaldehyde in the presence of Al_2O_3 in chloroform at room temperature to form compounds **5** and **14** in yields of 85.7% and 87.0%, respectively. Compound **5** was converted to **6** by demethylation with BBr_3 in CH_2Cl_2 (5.2% yields). Direct alkylation of **14** with ethylene chlorohydrin, ethylene glycol mono-2-chloroethyl ether, or 2-[2-(2-chloroethoxy)ethoxy]ethanol with potassium carbonate in DMF resulted in **15**, **16**, and **17**, respectively. The tributyltin derivatives (**7**, **8**, **18**, **19**, and **20**) were prepared from the corresponding compounds (**5**, **6**, **15**, **16**, and **17**) using a halogen to tributyltin exchange reaction catalyzed by Pd(0) for yields of 15.3%, 12.0%, 25.0%, 31.4%, and 30.3%, respectively. The tributyltin derivatives were used as the starting materials for radioiodination in the preparation of [^{125}I]**9**, [^{125}I]**14**, [^{125}I]**15**, [^{125}I]**16**, and [^{125}I]**17**. Novel radioiodinated aurones were achieved by an iododestannylation reaction using hydrogen peroxide as the oxidant, which produced the desired radioiodinated ligands (Scheme 4). It was anticipated that the no-carrier-added preparation would result in a final product bearing a theoretical specific activity similar to that of ^{125}I (2200 Ci/mmol). The radiochemical identities of the radioiodinated ligands were verified by coinjection with nonradioactive compounds by their HPLC profiles (Supporting Information). Five radioiodinated products were obtained in 25−57% radiochemical yields with radiochemical purities of >95% after purification by HPLC.

Binding Experiments Using Aβ Aggregates in Vitro. Our initial screening of the affinity of aurone derivatives (**9**, **14**, **15**, **16**, and **17**) was carried out with Aβ(1−42) aggregates, using

Scheme 4



[^{125}I]AAU as the competing radioligand (Table 1). The K_i values estimated for **9**, **14**, **15**, **16**, and **17** were 2.9, 1.3, 1.1, 3.4, and 2.6 nM, respectively. These values suggested that the new series of aurone derivatives had binding affinity for Aβ(1−42) aggregates despite their substituted groups. The binding affinity is in the same range as that of aurone derivatives possessing a nucleophilic group (NH_2, NHMe, NMe_2), reported previously

Table 1. Inhibition Constants (K_i) of Newly Synthesized Aurone Derivatives for the Binding of Ligands to Aβ (1−42) Aggregates

compound	K_i (nM)[a]
9	2.89 ± 0.42
14	1.28 ± 0.29
15	1.05 ± 0.06
16	3.36 ± 0.29
17	2.56 ± 0.31

[a] Data are the mean ± SEM for two independent measurements done in triplicate.

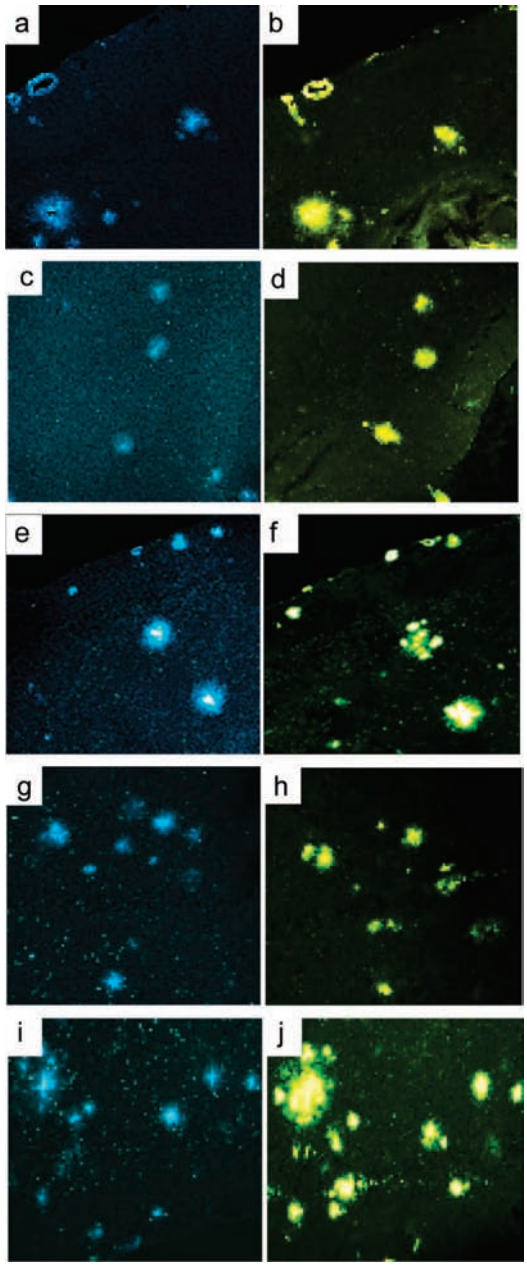


Figure 2. Neuropathological staining of **9**, **14**, **15**, **16**, and **17** (a, c, e, g, and i) in 10 μm sections from a mouse model of AD. Labeled plaques were confirmed by staining of the adjacent sections with thioflavin S (b, d, f, h, and j).

(*19*). These results clearly indicated that there exists considerable tolerance for structural modifications of aurone derivatives. The binding affinity of aurone derivatives is very close to that of known β-amyloid-imaging agents such as SB-13 ($K_i = 1.2$ nM) (*24*), PIB ($K_i = 2.8$ nM) (*25*), and IMPY ($K_i = 1.4$ nM) (*24*), indicating that they have strong enough affinity to test clinically.

Neuropathological Staining of Mouse Brain Sections. To confirm the affinity of aurone derivatives for β-amyloid plaques in the mouse brain, neuropathological fluorescent staining with **9**, **14**, **15**, **16**, and **17** was carried out using double transgenic Alzheimer's mouse brain sections (Figure 2). Many amyloid plaques were clearly stained with the derivatives, as reflected by the high binding affinity for Aβ aggregates in in vitro competition assays. The labeling pattern was consistent with that observed with thioflavin S. These results suggest that novel aurone derivatives show affinity for β-amyloid plaques in the mouse brain in addition to having binding affinity for synthetic Aβ42 aggregates.

[a] Expressed as % injected dose per gram. Each value represents the mean (SD) for 4−5 animals. [b] Expressed as % injected dose per organ.

Biodistribution Experiments. To evaluate brain uptake of the aurone derivatives, biodistribution experiments were performed in normal mice with five radioiodinated aurones ([^{125}I]**9**, [^{125}I]**14**, [^{125}I]**15**, [^{125}I]**16**, and [^{125}I]**17**) (Table 2). Radioactivity after injection of the aurone derivatives penetrated the blood−brain barrier showing excellent uptake ranging from 1.7% to 4.5% ID/g brain at 2 min postinjection, a level sufficient for imaging β-amyloid plaques in the brain. In addition, it displayed good clearance from the normal brain with 0.1−0.4% ID/g at 30 min postinjection. Since normal mice were used for the biodistribution experiments, no Aβ plaques were expected in the young mice; therefore, the washout of probes from the brain should be rapid to obtain a higher signal-to-noise ratio earlier in the AD brain. One way to select a ligand with

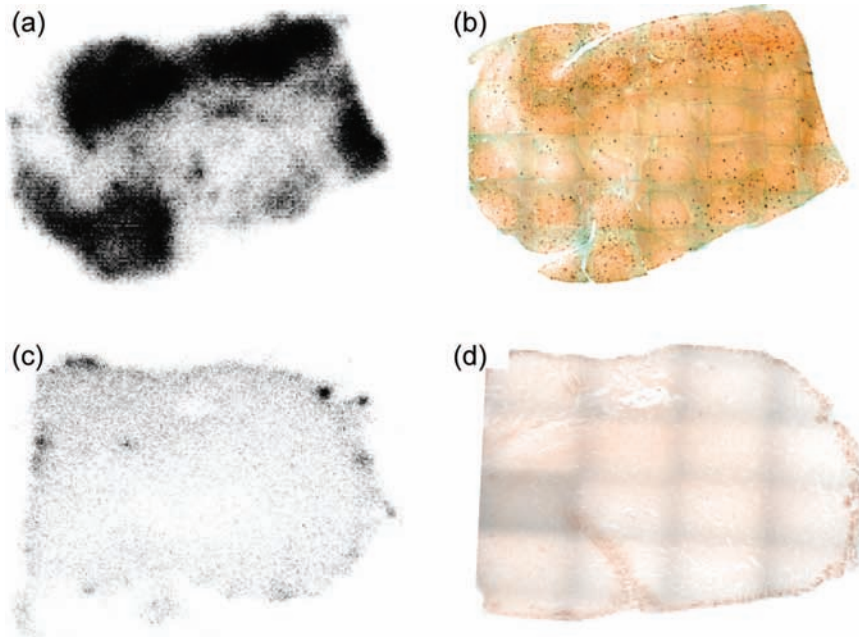

Figure 3. In vitro ARG of [^{125}I]**15** reveals a distinct labeling of amyloid plaques in AD brain sections (a). Under similar conditions, there is very little labeling of [^{125}I]**15** in control brain section (c). The presence and localization of plaques in the sections were confirmed with immunohistochemical staining using a monoclonal Aβ antibody (b, d).

appropriate in vivo kinetics is to use brain$_{2min}$/brain$_{30min}$ as an index to compare the washout rate. The five radioiodinated aurone derivatives [^{125}I]**9**, [^{125}I]**14**, [^{125}I]**15**, [^{125}I]**16**, and [^{125}I]**17** showed brain$_{2min}$/brain$_{30min}$ ratios of 15.4, 8.3, 18.8, 9.7, and 15.6, respectively. [^{125}I]**15** had the best washout index. Previously reported radioiodinated aurones showed high uptake (1.9−4.6% ID/g at 2 min postinjection) and good clearance from the brain (0.3−0.5% ID/g at 30 min postinjection) (*19*). However, the brain$_{2min}$/brain$_{30min}$ ratios of these compounds were 7.3−9.9, lower than that of [^{125}I]**15**, indicating that [^{125}I]**15** could clear more rapidly from the normal mouse brain than aurones with amino groups. It has been reported that [^{123}I]IMPY entered the brain rapidly (2.88% ID at 2 min postinjection) and was cleared from normal brain (0.26% ID at 30 min postinjection), indicating the brain$_{2min}$/brain$_{30min}$ ratio to be 11.1 (*16*). The aurone derivatives reported in this study appear superior to IMPY in pharmacokinetics, in addition to showing similar binding affinities sufficient for the imaging of β-amyloid plaques in vivo. The pharmacokinetics demonstrated by [^{125}I]**15** is critical to the detection of β-amyloid plaques in the AD brain.

In Vitro Autoradiography. Next, [^{125}I]**15** was investigated for its binding affinity for β-amyloid plaques by in vitro autoradiography in human AD brain sections as shown in Figure 3. Autoradiographic images of [^{125}I]**15** showed high levels of radioactivity in the brain sections (Figure 3a). Furthermore, we confirmed that the hot spots of [^{125}I]**15** corresponded with those of in vitro immunohistochemical staining in the same brain sections (Figure 3b). In contrast, normal human brain displayed no remarkable accumulation of [^{125}I]**15** (Figure 3c), correlating well with the absence of β-amyloid plaques (Figure 3d). These results demonstrate the feasibility of using [^{125}I]**15** as a probe for detecting β-amyloid plaques in the brains of AD patients with SPECT.

CONCLUSION

In conclusion, we successfully designed and synthesized a new series of aurone derivatives as amyloid-imaging agents with high affinity for Aβ(1−42) aggregates in vitro. The derivatives clearly stained amyloid plaques in an animal model of AD, reflecting strong binding to Aβ aggregates in vitro. In biodistribution experiments using normal mice, they displayed good penetration of and fast washout from the brain, especially [^{125}I]**15**. A specific plaque-labeling signal was clearly depicted by [^{125}I]**15** in postmortem AD brain sections. Taken together, the present results suggest [^{125}I]**15** to be a potentially useful probe for the SPECT-based imaging of β-amyloid plaques.

Surface-Anchoring of Spontaneously Dimerized Epidermal Growth Factor for Highly Selective Expansion of Neural Stem Cells

Tadashi Nakaji-Hirabayashi, Koichi Kato, and Hiroo Iwata*

Institute for Frontier Medical Sciences, Kyoto University, 53 Kawahara-cho, Shogoin, Sakyo-ku, Kyoto 606-8507, Japan.
Received July 31, 2008; Revised Manuscript Received November 21, 2008

To develop culture substrates for use in selective expansion of neural stem cells (NSCs), epidermal growth factor (EGF)-containing chimeric proteins were designed and synthesized by means of recombinant DNA technology. The chimeric proteins consisted of three components including an EGF domain, an α-helical oligopeptide, and a hexahistidine sequence. Two different α-helical oligopeptides were separately incorporated into chimeric proteins. Structural analyses by native gel electrophoresis and circular dichroism spectroscopy revealed that the heterodimer of these proteins was spontaneously formed through coiled-coil association of the α-helical oligopeptides. The monomeric and dimeric forms of these chimeric proteins were immobilized to the glass-based substrate via coordinate bonding between the hexahistidine and Ni(II) ions fixed on a substrate. The results of cell culture assays with NSCs showed that cells proliferated most rapidly and selectively on a substrate with the surface-anchored EGF dimer. The rate of cell proliferation on the surface with dimeric EGF was 1.3−2.0 times higher on the surfaces with monomeric EGF. In addition, the content of stem cells, determined 96 h after cell seeding, was highest on the surface with dimeric EGF (98%) among the surfaces studied (90−97% on surfaces with monomeric EGF). The observed growth rate and the stem cell content on the surface with EGF dimer were far beyond those in the standard neurosphere culture. The effect of surface-anchored dimeric EGF may be attributed to the enhanced dimerization of EGF-EGF receptor complexes leading to efficient signaling for mitogenic activity. We conclude that surface-anchoring of the EGF dimer provides an excellent substrate that allows the highly efficient expansion of NSCs.

INTRODUCTION

Large-scale production of neural stem cells (NSCs) with high purity is crucial for their clinical application in cell transplantation therapy for neurodegenerative diseases such as Parkinson's disease (*1, 2*). The culture substrate previously developed by our group (*3*) has the potential to provide the culture method that allows to selective expansion of NSCs from heterogeneous cell populations. The substrate was designed to display epidermal growth factor (EGF), a strong activator for the proliferation of NSCs (*4*), on the surface of a glass-based substrate. The key feature of substrate preparation was to terminally anchor EGF molecules to the surface through the hexahistidine sequence that was fused with EGF via recombinant DNA technology (*5*). The surface-anchoring of engineered growth factors was also reported by Ogiwara et al. (*6, 7*) and Nagaoka et al. (*8*).

The EGF-anchored substrate facilitates production of a cell population rich in NSCs (purity >92%). The selectivity of stem cell expansion is much higher than the neurosphere culture (*9, 10*) that has been used as the most standard method to obtain NSCs. However, a population expanded by our culture method still contains approximately 7% differentiated cells. For this reason, the present study was undertaken to improve much more the efficiency of NSC production. Our strategy adopted here was to promote the interaction of surface-anchored EGF with EGF receptors (EGFR) by designing spontaneously dimerizing EGF.

Numerous studies have shown that EGF binding to EGFR triggers receptor dimerization that is considered to be a critical step for the subsequent transduction of intracellular signaling (*11*). Inspired by this mechanism, we designed EGF-containing chimeric proteins that spontaneously form a dimerized form of EGF. The dimer was terminally anchored onto the substrate. Our expectation is that the preformed dimeric structure of EGF facilitates the formation of EGF-EGFR dimer complexes more efficiently than the monomeric form of EGF as presented on our previous substrate.

Our strategy for the spontaneous dimerization of EGF is to incorporate an α-helical oligopeptide that has the ability to participate in the formation of a coiled-coil structure. To avoid aggregation of proteins in expression host cells due to spontaneous homodimerization, we implemented here a heterodimerization system in which $(EKLASVK)_5$ (K5) and $(KELASVE)_5$ (E5) peptides form a stable coiled-coil structure. These peptides were designed according to previous reports (*12, 13*). The coiled-coil structure formed by the intermolecular association of α-helical peptides is an abundant motif found in various proteins (*14*) and has also been utilized for creating engineered biomaterials such as hydrogels (*15*−*17*), nanostructured molecular machines (*18*), and scaffolds for tissue engineering (*19*).

In this study, we synthesized two chimeric proteins containing an EGF domain and the K5 or E5 oligopeptide. As we previously reported, a hexahistidine sequence was further added to the C-terminus of both chimeric proteins, so as to anchor the chimeric proteins through coordination to the substrate on which Ni(II) ions were fixed. The heterodimerization of chimeric proteins was examined by native polyacrylamide gel electrophoresis (native PAGE) and circular dichroism (CD) spectroscopy. The effect of surface-anchored EGF dimer was studied by analyzing the adhesion and proliferation of cultured NSCs and the phosphorylation of EGFR. These assays revealed that NSCs proliferate much

rapidly on the substrate with dimeric EGF than that with the monomeric one.

EXPERIMENTAL PROCEDURES

Plasmids. Synthetic DNA fragments (ca. 50 mer) corresponding to 5′-terminal, middle, and 3′-terminal parts of DNA encoding $(EKLASVK)_5$ (K5) and $(KELASVE)_5$ (E5) were purchased from Invitrogen (Carlsbad, CA). The 5′-terminal fragment contained 21-mer oligonucleotides for heptapeptides (PGGGGGP) to be inserted between EGF and the K5 or E5 sequence as a flexible linker (*20*, *21*) (Figure 1A). These fragments were ligated with each other in a proper order using the method by Pachuk et al. (*22*) to obtain DNAs encoding full-length K5 or E5 flanked with PGGGGGP at the N-terminus. The sequence of all oligonucleotides was shown in Table 1. All steps for ligation are schematically represented in Figure 1B. The 5′-end of the DNA fragments including sense 2 and 3 and antisense 2 and 3 were phosphorylated using T4 polynucleotide kinase. Then, the phosphorylated oligonucleotides were mixed with sense 1 and antisense 1 (each 1 μM) in a 50 μL reaction buffer (20 mM Tris-HCl, 25 mM KCl, 10 mM magnesium chloride, 0.5 mM NAD, and 0.01% Triton X-100, pH 8.3) containing 0.3 U/μL thermostable DNA ligase (Ampligase, Epicenter Technologies, Madison, WI) and 1 μM bridge oligonucleotides (Table 1). Chain reaction cloning was allowed to proceed by thermal cycling using GeneAmp 9600 (Applied Biosystems, Foster City, CA) under the following conditions: 50 cycles, denaturation at 94 °C for 30 s, annealing at 58 °C for 30 s, and ligation at 66 °C for 1 min. Finally, the ligated DNA was amplified by polymerase chain reaction (PCR) using outer primers (Table 1). The forward primers contained 20-mer oligonucleotides that overlapped with the 3′-region of EGF gene. Reverse primers contained an Xho I restriction site. On the other hand, the EGF gene was amplified by PCR from pET-22b-EGF (*4*) using specific primers (Table 1). The forward primers contained an Nde I site at the 5′-end. The reverse primers were flanked with 20-mer oligonucleotides that overlapped with the 5′-region of DNA for PGGGGGP-K5 or PGGGGGP-E5. The DNAs for EGF and PGGGGGP-K5 or PGGGGGP-E5 were annealed, extended by overlap extension (*23*), and amplified by PCR to obtain EGF-PGGGGGP-K5 and EGF-PGGGGGP-E5 chimeric genes. The chimeric genes were digested with Nde I and Xho I and inserted into the Nde I-Xho I site of pET-22b (Novagen, Darmstadt, Germany). The plasmids (pET-22b-EGF-K5, pET-22b-EGF-E5) were cloned in *Escherichia coli* (*E. coli*) DH5α. The correctness of the plasmids was confirmed by sequencing.

Protein Expression, Purification, and Refolding. The EGF chimeric proteins, EGF-K5-His and EGF-E5-His, were expressed in *E. coli* strain BL21-codonplus (Stratagene, La Jolla, CA) using overnight express autoinduction system (Novagen). The preparation of a control protein, EGF-His, was reported previously (*4*). These proteins obtained as inclusion bodies were extracted with 8 M urea solution containing 5 mM 2-mercaptoethanol and then purified using a Prime AKTA chromatography system (GE Healthcare Bio-Science Corp., Piscataway, NJ) equipped with a His Trap HP column (GE Healthcare). These proteins were refolded by dialyzing against a solution of reduced and oxidized forms of glutathione. The detailed conditions of the refolding procedure were provided in Supporting Information Table S3. Protein concentration was determined using a microBCA kit (Pierce Biotechnology, Rockford, IL). The yields of EGF-K5-His and EGF-E5-His were determined to be, respectively, 210 mg and 275 mg per liter of medium. The purity and molecular size of proteins were analyzed by sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE). The biological activity of EGF contained in these proteins was assessed from the mitogenic activity in neurosphere culture (*9*).

Heterodimerization. EGF-K5-His and EGF-E5-His were mixed in PBS at various compositions, and the coiled-coil association between E5 and K5 peptide segments was allowed to proceed at room temperature for 30 min to obtain their heterodimer (dEGF-His). Heterodimerization was assessed by native PAGE in which 3 μg of total proteins were electrophoresced in 16% polyacrylamide gel with 50 mM Tris-HCl running buffer (pH 8.3) containing 192 mM glycine followed by staining with Coomassie brilliant blue.

CD Spectroscopy. Chimeric proteins were dissolved in PBS (pH 7.4) to a mean residue concentration of 4.2 mM (EGF-His) or 4.4 mM (EGF-K5-His, EGF-E5-His, and dEGF-His). dEGF-His solution was prepared by mixing 0.5 mg/mL EGF-E5-His (250 μL) with 0.5 mg/mL EGF-K5-His (250 μL). CD spectra were recorded with JASCO J-805 spectropolarimeter and a 1-mm path length cell at a response time of 0.5 s, a bandwidth of 1 nm, a scan speed of 100 nm/min, and 20 °C with an accumulation of 8 scans.

Substrate Preparation. As reported previously (*3*), EGF-containing chimeric proteins were anchored through the His sequence onto a glass-based substrate bearing a thin gold layer and a carboxylic acid-terminated alkanethiol monolayer on the surface. In brief, the mixed self-assembled monolayer consisting of 10% 16-mercapto-1-hexadecanoic acid (Aldrich, Munich, Germany) and 90% (1-mercaptoundec-11-yl)triethylene glycol

(TEG-thiol, SensoPath Technologies, Bozeman, MT) was formed on a gold-evaporated surface. The triethylene glycol-terminated alkanethiol was used to prevent nonspecific protein adsorption and to control the surface density of EGF chimeric proteins (*3*). Then, the terminal carboxylic acid of 16-mercapto-1-hexadecanoic acid was activated by immersing the plate in an aqueous solution containing 50 mM *N*,*N*′-dicyclohexyl carbodiimide and 25 mM *N*-hydroxysuccinimide at room temperature for 30 min. Then, the plate was exposed to an aqueous solution containing 10 mM *N*-(5-amino-1-carboxypentyl) iminodiacetic acid (NTA; Dojindo Laboratories, Kumamoto, Japan) to couple with the activated carboxylic acid followed by exposure to 40 mM $NiSO_4$ solution to chelate Ni(II) ions. The His sequence in the chimeric proteins was coordinated to the fixed Ni(II) ions to anchor the proteins onto the surface. For the immobilization of dEGF-His, a solution containing 0.5 mg/mL EGF-E5-His and 0.5 mg/mL EGF-K5-His was prepared, and then the Ni(II)-chelated surface was exposed to the mixted solution. Prior to cell culture assays, the glass plates were washed with PBS and culture medium to remove weakly adsorbed chimeric proteins.

Surface Plasmon Resonance (SPR) Analysis. SPR analysis was carried out as before (*3*, *24*) using an in-house SPR apparatus. The light reflectance was continuously monitored at an incident angle 0.5° smaller than the resonance angle during the following procedures: After equilibrating with PBS, the surface of a Ni(II)-chelated gold plate was exposed to 20 mM sodium phosphate buffer (pH 7.4) containing 20 mM imidazole (binding buffer) in a flow cell for 5 min followed by circulation of binding buffer containing 50 μg/mL chimeric protein for 65 min. Subsequently, pure binding buffer was circulated for 50 min. The reflectance was converted to the resonance angular shift. The angular shift observed before and after the binding of chimeric protein was converted to the amount of EGF chimeric protein, assuming that unit angular shift corresponds to a protein density of 0.5 μg/cm^2 (*25*).

Cell Isolation and Culture. Cell isolation from the striatum of rat fetus (E16) and neurosphere culture were performed as reported previously (*3*−*5*). All the procedures were conducted according to the guidelines of the Animal Welfare Committee of the institute. Neurosphere forming cells at passage 2 were dissociated into single cells by treatment with 0.05% trypsin-EDTA solution. The single cells were suspended in a base medium [DMEM/F12 (1:1), 3 mM glutaMAX, 100 units/mL penicillin, 100 μg/mL streptomycin, and 5 μg/mL heparin] supplemented with 2% B27, and then seeded at 3×10^4 cells/cm^2 onto the substrates prepared as described earlier. Cells were cultured for 4 days at 37 °C under 5% CO_2 atmosphere. Finally, cells were washed gently with base medium to remove weakly adhering cells and observed with a phase-contrast optical microscope (BX51 TRF, Olympus Optical Co., Ltd., Tokyo, Japan).

Cell Proliferation Assay. Cell proliferation assays were carried out with neurosphere-forming cells cultured in suspension under base medium supplemented with 2% B27 containing 20 ng/mL EGF-His, EGF chimeric proteins, or recombinant human EGF (rhEGF, Invitogen Corp., Carlsbad, CA). Cells were cultured for 4 days, and then cell number was determined by the modified MTT assay (*3*). Cells were incubated in the base medium containing 10% cell counting reagent SF (Nacali Tesque, Kyoto, Japan) for 3 h, and then absorbance at 450 nm was determined for the medium using a microplate reader (model 5500, Bio-Rad, Hercules, CA). The number of cells proliferated on the substrates was also determined by the modified MTT assay. After the substrate was washed with DMEM/F12 (1:1) to remove nonadhering cells, cell number was determined as described above. The absorbance was converted to cell number using a calibration curve. The assays were carried out at 24, 36, 48, 60, 72, and 96 h after cell seeding.

Immunocytochemistry. After fixation and permeabilization, cells were immunofluorescently stained using antibodies against a neural stem cell marker (nestin, 1:200, mouse monoclonal Rat 401, BD pharmingen, Franklin Lakes, NJ) and a neuronal marker (class III β-tubulin; βIII, 1:600, rabbit polyclonal, Covance, Princeton, NJ), as reported previously (*3*, *5*, *23*). The localization of fluorescently labeled secondary antibodies was analyzed with an epifluorescent microscope (DP70, Olympus). Cells expressing these markers were counted on microphotographs for the area of 340×460 μm^2, which contained at most approximately 800 total cells, using *Image J* software (National Institutes of Health, Bethesda, MD). Cell numbers were determined on five different microphotographs for each sample, and the data are shown as the mean plus/minus standard deviation for five independent samples. In addition, neurosphere cells were dissociated and immunocytochemically stained. The conditions for fixation, permeabilization, blocking, reaction with antibodies, and counterstaining were the same as described above, but these procedures were performed in suspension by separating cells from each solution by centrifugation. The total cells and nestin- and βIII-positive cells were counted in the same manner as described above.

Western Blotting. Cells cultured for 2 days on the substrate were harvested using a cell scraper and dissolved in a lysis buffer (20 mM Tris-HCl, 150 mM NaCl, 1 mM EDTA, 1 mM EGTA, 1% Triton X-100, 1 mM Na_3VO_4, 10 mM $Na_4P_2O_7$, and 25 mM β-glycerolphosphate; pH 7.5) containing a cocktail of protease inhibitors (Complete Mini, Roche Diagnostics, Mannheim, Germany). The lysate was separated by SDS-PAGE and electrically blotted to a poly(vinylidene fluoride) membrane. After blocking with Blocking One-P (Nacalai Tesque, Kyoto, Japan), the membrane was immersed in a solution containing antibody against the phosphorylated form of EGFR (1:1000, #2236, Cell Signaling Technology, Danvers, MA) or total EGFR (1:1000, #2232, Cell Signaling Technology). The antibodies bound to the membrane were reacted with HRP-linked secondary antibody (1:5000, GE Healthcare) and visualized by the chemiluminescence reagent

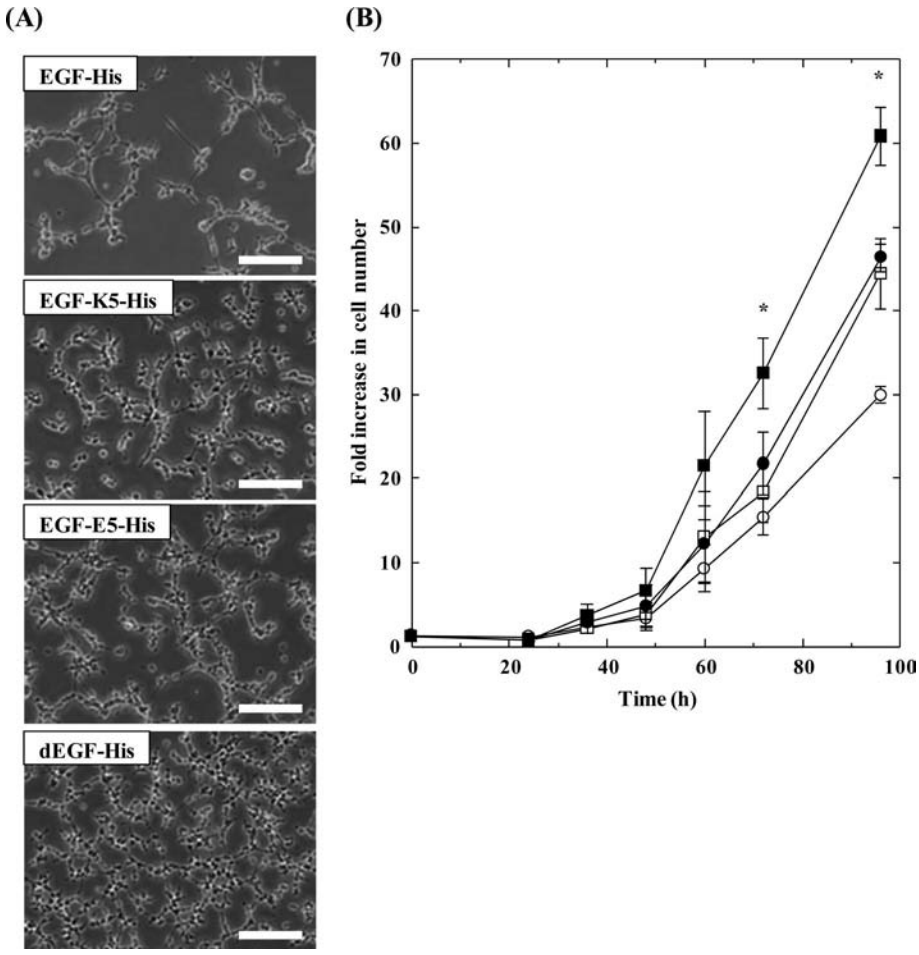

Figure 5. (A) Phase-contrast images of cells cultured for 48 h on the substrates with surface-anchored chimeric proteins. The identity of surface-anchored chimeric proteins is shown in the images. Bars: 100 μm. (B) Growth curves of cells cultured on the substrate with surface-anchored (○) EGF-His, (●) EGF-E5-His, (□) EGF-K5-His, and (■) dEGF-His. Data are expressed as mean ± standard deviation ($n = 3$). Cell seeding density: 3.0×10^4 cells/cm^2. *Cell growth on the substrates with dEGF-His was significantly large compared with that on each of the other substrates (Tukey's HSD test, $p < 0.05$). Apparent doubling time was 14.6 ± 2.3 h (EGF-His), 10.0 ± 1.0 h (EGF-K5-His), 8.7 ± 1.2 (EGF-E5-His), and 7.1 ± 1.3 h (dEGF-His), when determined from growth curves for 24−60 h.

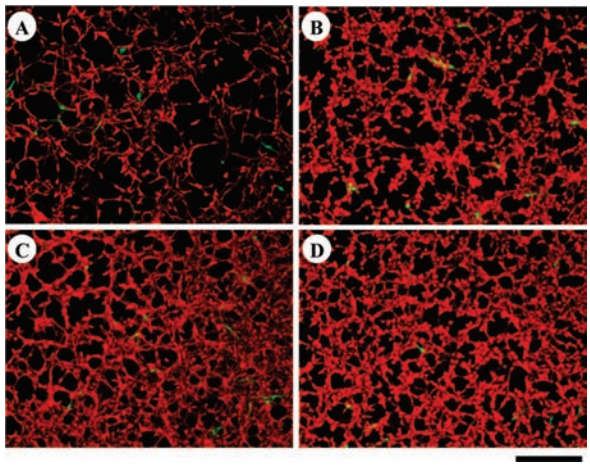

Figure 6. Immunofluorescent staining of nestin (red) and βIII (green) expressed in cells cultured for 4 days on the substrate with surface-anchored (A) EGF-His, (B) EGF-E5-His, (C) EGF-K5-His, and (D) dEGF-His. Bars: 100 μm.

(ECL plus, GE Healthcare). The intensity of protein bands was determined using *Image J* software. The data are shown as mean plus/minus standard deviation for three independent experiments.

Statistical Analysis. The results of cell proliferation, immunostaining of nestin and βIII, and Western blotting were statistically analyzed using software (JMP5.0.1a, SAS Institute Inc., Cary, NC). One-way analysis of variance (ANOVA) was performed for assessing significant differences. Tukey's honestly significant difference (HSD) test was performed for multiple comparisons at a significance level set of $p < 0.05$.

RESULTS

Characterization of Chimeric Proteins. As shown in Figure 2A, purified EGF-K5-His, EGF-E5-His, and EGF-His gave single bands in SDS-PAGE analysis. The molecular weights estimated from the mobility of protein bands are 7.1 kDa for EGF-His, 14.8 kDa for EGF-K5-His, and 15.6 kDa for EGF-E5-His. These molecular weights are nearly in agreement with those estimated from their amino acid compositions. However, a slight difference is seen between EGF-E5-His and EGF-K5-His, though these proteins are expected to have similar molecular weights. This is probably due to the acidic nature of EGF-E5-His that has the low capacity of SDS binding and hence exhibits reduced mobility in SDS-PAGE.

Figure 2B shows the result of native PAGE analysis carried out for the mixture of EGF-K5-His and EGF-E5-His at various compositions. Lanes 1 and 7 represent results for pure EGF-K5-His and EGF-E5-His, respectively. When the mixtures of these proteins were analyzed (Figure 2B, lanes 2−6), new bands appeared at the position between the bands of EGF-K5-His and EGF-E5-His, associated with a decrease in band intensity for both EGF-K5-His and EGF-E5-His. This result suggests the

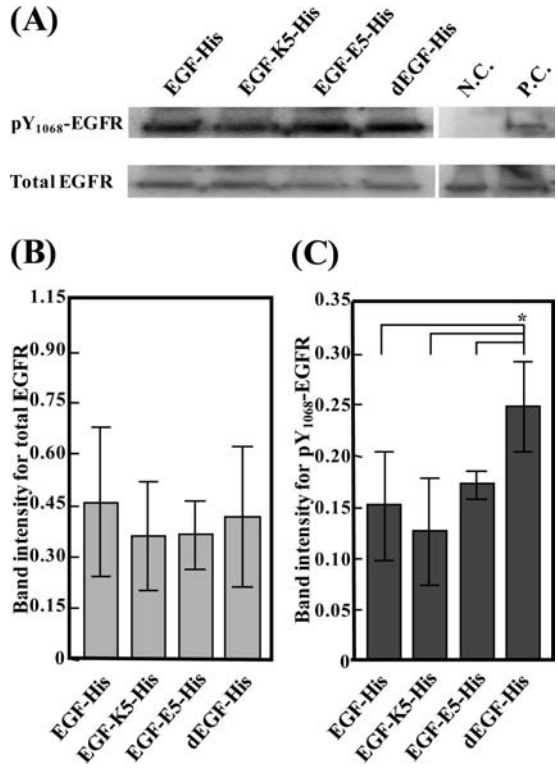

Figure 7. (A) The result of Western blot analysis for the phosphorylated EGFR and total EGFR. Lysates were prepared from cells cultured for 2 days on the substrate with surface-anchored chimeric proteins. N.C.: Negative control. Cells were cultured for 1 day in serum-free base medium without EGF-His. P.C.: Positive control. Cells were cultured for 1 day in serum-free base medium in the absence of EGF-His and then stimulated for 15 min with 1 μg/mL EGF-His. Data shown are representative of three independent experiments. (B,C) Quantative evaluation for the band intensity of (B) total EGFR and (C) pY_{1068}-EGFR. The data are expressed as mean $\pm$ standard deviation ($n = 3$). The asterisk indicated the statistical significance (Tukey's HSD test, $p < 0.05$) compared to other EGF-containing chimeric proteins.

formation of heterodimer, dEGF-His. A single, most intense band was visualized in lane 5 where the equimolar mixture of these proteins was electrophoresced. This result indicates the spontaneous and stoichiometric heterodimerization of EGF-K5-His and EGF-E5-His. However, the intensity of the dEGF-His bands appear to be higher than that expected from the mixing ratios and the band intensities of single components, EGF-K5-His and EGF-E5-His. This is probably due to enhancement of band intensity by dimer formation as shown in Supporting Information Figures S1 and S2.

Dimerization of Chimeric Proteins. Figure 2C shows the CD spectra recorded for EGF-containing chimeric proteins. The CD spectrum of EGF-His exhibited a small negative cotton effect around 216 nm, indicating the existence of β-strands (*26*). This is explained well from the fact that native EGF consists of 41% β-strands other than loops and random coils (no α-helical segments) (*27*). The spectrum of EGF-His is similar to that of native EGF (Supporting Information Figure S4) (*27*). In the spectrum of EGF-E5-His, a negative Cotton effect is additionally observed at 198 nm. This is indicative of random coil structure present in EGF-E5-His. Our observation that, as described earlier, this protein exhibited EGF bioactivity (Figure 3) suggested the proper secondary structure of the EGF domain. Thus, the random coil structure is presumably attributed to the E5 peptide. On the other hand, EGF-K5-His obviously exhibited a negative Cotton effect at 222 nm, representing α-helical structure due to the K5 peptide. The mixture of EGF-E5-His with EGF-K5-His displayed stronger dichroism at 208 and 222 nm and reduced absorption at 198 nm. This result suggests that heterodimerization, as detected by native PAGE (Figure 2B), is ascribed to the coiled-coil association between E5 and K5 peptides.

CD analysis was additionally carried out for α-helical segments alone and in a mixture with wild-type EGF, EGF-E5-His, or EGF-K5-His. These analyses were carried out with the tandem form of E5 [$(KELASVE)_{10}$, E10], because we failed to prepare E5 and K5 peptides in sufficient quantities for CD analysis, probably due to degradation of the short peptides during their expression in and purification from *E. coli*. The tandem form of K5 [$(EKLASVK)_{10}$] was also prepared but could not be used because of its poor solubility. As shown in Supporting Information Figures S4−S7, no detectable intermolecular and intramolecular interactions of the helical peptide operated with the EGF and His segments. The data further suggested self-associations of the helical peptides, associated with strong negative Cotton effect at 222 nm.

Biological Activity of Chimeric Proteins. Figure 3 shows the results of proliferation assays for the chimeric proteins. Cells proliferated approximately 5-fold during 96 h in the presence of chimeric proteins with no significant differences between conditions. The observed growth rates were similar to that for neurosphere-forming cells cultured in base medium containing rhEGF. This result suggests that the EGF domain contained in chimeric proteins holds biological activity without any perturbation of the His peptide. As shown in Table 2, when chimeric proteins were dissolved in a medium, their molecular architectures had minor effects on the differentiation of neurosphere-forming cells.

Surface Immobilization of Chimeric Proteins. The monomeric and dimeric forms of the chimeric proteins were coordinated to the Ni(II)-fixed surfaces. These processes were monitored by surface plasmon resonance analysis (*3*). As shown in Figure 4, all the chimeric proteins gave a similar angular sift corresponding to the surface density of ca. 0.32−0.35 μg/cm^2. This result implies that, on a molar basis, the surface density of an EGF domain on the EGF-His-immobilized substrate is approximately 1.5-fold higher than that on the substrates with immobilized EGF-K5-His, EGF-E5-His, and dEGF-His.

Adhesion, Extension, and Proliferation of NSCs. Supporting Information Figure S8 shows the phase-contrast microphotographs of cells cultured on the substrates with different chimeric proteins. The morphology of cells on the surface with EGF-His is similar to that observed in our previous studies (*3*−*5*). On this surface, cells proliferated and extended neurites. In comparison with the substrate with EGF-His, a slightly increased number of cells initially adhered on the substrates with EGF-K5-His and EGF-E5-His, and the larger number of cells are seen at the same time points. These trends are much more notable on the substrate with surface-anchored dEGF-His. In particular, cell confluency on the substrate with dEGF-His at 48 h (Figure 5A) is similar to that on the EGF-His-anchored substrate at 96 h.

Figure 5B shows the growth curves for cells cultured on the substrates with different chimeric proteins. The cell number increased 30-fold on the substrate with EGF-His during the initial 96 h, being in good accordance with our previous results (*4*). On the other hand, cells on the substrates with EGF-K5-His, EGF-E5-His, and dEGF-His were expanded, respectively, 42-, 45-, and 60-fold for 96 h. As shown in Figure 5B, the apparent doubling time is shorter in the case of EGF-E5-His and EGF-K5-His than EGF-His, and much more shortened in the case of dEGF-His (approximately half of the case with EGF-His).

Selective Expansion of NSCs. Figure 6 shows the result of immunofluorescent staining of cells cultured for 4 days on the substrates with surface-anchored chimeric proteins.

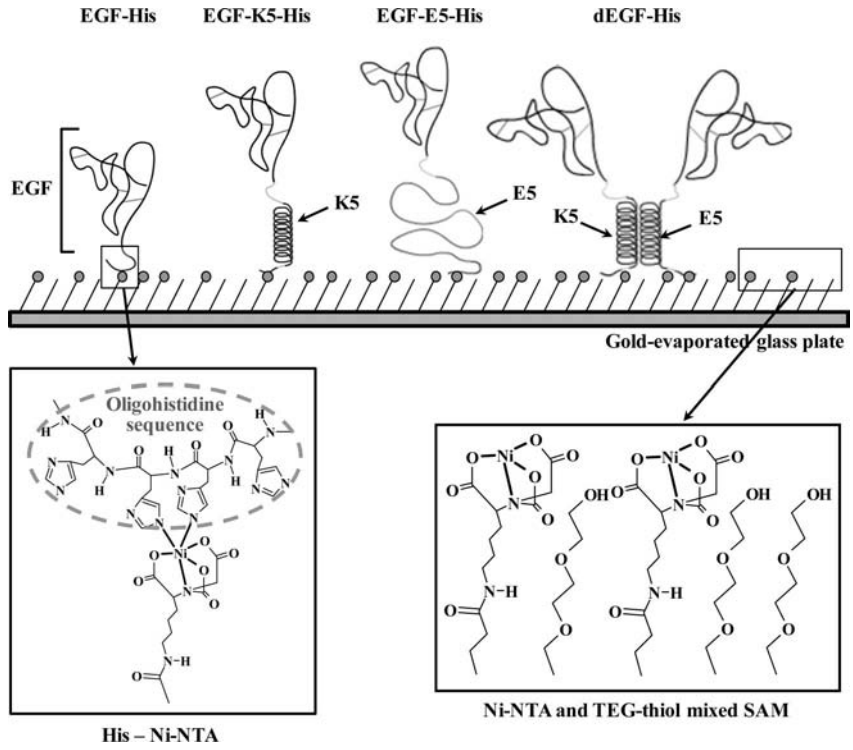

Figure 8. Schematic representation for EGF-containing chimeric proteins anchored to the Ni-chelated surface through coordination. Bold lines in the molecular formula represent chelate bonding. TEG-thiol: triethylene glycol-containing alkanethiol.

On all of the substrates studied here, the majority of cells expressed a neural stem cell marker, nestin (visualized in red), while few cells expressed a neuronal marker, βIII (visualized in green). These results indicate that neural stem cells were selectively proliferated on the substrates with surface-anchored chimeric proteins. However, as shown in Table 2, the fraction of nestin-expressing stem cells is varied depending on the type of chimeric proteins: The fraction of stem cells is significantly higher on the substrate with EGF-E5-His and EGF-K5-His than EGF-His. The highest fraction is seen on the substrate with dEGF-His among the substrates studied, although there was no statistical difference between the substrates with dEGF-His and EGF-E5-His.

EGFR Signaling. EGFR is a member of tyrosine kinase receptors and phosphorylated upon ligand binding to activate an intracellular signaling cascade (*11*). To analyze the phosphorylation of EGFR by Western blotting, we used antibodies against the phosphorylated form of EGFR (specific for pY_{1068}-EGFR) and total EGFR (specific for both phosphorylated and nonphosphorylated forms). The results are shown in Figure 7A. Neurosphere-forming cells were starved for 24 h in growth factor free base medium and then treated with 1 μg/mL EGF for 15 min before lysis as a positive control. Cells just starved in the absence of EGF were used as a negative control. Total EGFR was detected to a similar extent in negative and positive control cells, whereas pY_{1068}-EGFR was detected exclusively for the cells treated with EGF. In the case of cells cultured for 2 days on the substrates with surface-anchored chimeric proteins, strong bands of pY_{1068}-EGFR are seen for all of the substrates, indicating the occurrence of receptor phosphorylation. The band intensities determined for total EGFR and pY_{1068}-EGFR are shown in Figure 7B and C. As can be seen in Figure 7B, the level of EGFR expression was almost similar between substrates. In contrast, EGFR was most efficiently phosphorylated on the substrate with anchored dEGF-His (Figure 7C). The differences in the level of phosphorylation are statistically insignificant among the substrates with EGF-His, EGF-E5-His, and EGF-K5-His.

DISCUSSION

The E5 and K5 peptides were designed to create an α-helical coiled-coil structure stable under the physiological conditions. The coiled-coil structure is stabilized by hydrophobic effects operated between L and V at the core region of the associating chains (*12, 13*). We incorporated these peptides separately into EGF-His. Analyses by native PAGE (Figure 2B) and CD spectroscopy (Figure 2C) revealed that spontaneous coiled-coil association takes place to form a heterodimer consisting of EGF-E5-His and EGF-K5-His. In CD spectroscopic analysis (Figure 2C), disordered structure was suggested for the E5 peptide contained in monomeric EGF-His. α-Helical structure is induced in the E5 peptide when associated with EGF-K5-His (Figure 2C). According to these findings, the structure of the chimeric proteins at the surface may be schematically represented as in Figure 8.

On the surface with fixed Ni(II) ions, the His-containing EGF chimeric proteins are expected to be anchored through coordinate bonding, exposing the EGF domain toward outer environment. Our previous study using the monomeric form of EGF-His (*3*−*5*) demonstrated the structural integrity of surface-anchored EGF-His. In addition, it was shown that stable anchoring is necessary to establish adherent culture of NSCs (*5*). These effects are important for both the selective capture of EGFR-expressing NSCs on the surface and the efficient EGFR signaling leading to the active proliferation of captured cells (*6*−*8*).

In spite of the lower surface density of an EGF domain with dEGF-His, EGF-K5-His, and EGF-E5-His compared with EGF-His, the adhesion and proliferation of cells were most prominent on the surface with anchored dEGF-His. It is likely that, on the substrate with dEGF-His, the dimerized form of EGF efficiently facilitates dimerization of EGFR, transducing intracellular

signaling for mitogenic activity (Figure 7), associated with reduced doubling time (Figure 5B). Therefore, it appears that the highest purity of NSCs obtained on the substrate with surface-anchored dEGF-His is attributed to both efficient signaling in and rapid growth of NSCs. Moreover, the adhesion and proliferation of cells were also promoted on the surfaces with anchored EGF-K5-His and EGF-E5-His (Figure 5A,B) compared to the surface with EGF-His. These results suggest that the E5 and K5 peptides inserted between the EGF domain and the His sequence function as a flexible linker. Interestingly, the molecular architecture of chimeric proteins has an effect on the proliferation and differentiation of neurosphere-forming cells only when the chimeric proteins are anchored at the surface, but not when dissolved in solution (Figures 3 and 5B, and Table 2).

It is considered that EGFR signaling is activated by dimerization of EGF-EGFR complexes (*11*). In the case of surface-anchored monomeric EGF-His, the probability of receptor dimerization seems to be limited because of the reduced mobility of surface-anchored EGF. In the case of EGF anchored to the surface as a dimer, such a constraint may not affect receptor dimerization because two EGF domains are always located in close proximity to each other. Conceivably, this is the reason for the most efficient proliferation of NSCs observed on the surface with dEGF-His (Figure 6). Our estimation suggests that the distance between two EGF domains in the dimer form is approximately comparable to the span of two binding sites in dimerized EGFR (*28*). The results in which both EGF-E5-His and EGF-K5-His were surface-anchored as a single component also provided more efficient substrates than EGF-His does (Figures 5A,B and 6). This can also be explained from the mobility of the EGF domain enhanced by E5 and K5 peptides inserted between the EGF domain and the His sequence. Interestingly, the effects of these peptides are not noticeable when chimeric proteins are used as diffusible factors (Figures 3 and 5B).

Accordingly, the selective expansion of NSCs can be most efficiently achieved on the substrate with surface-anchored dEGF-His. On this substrate, cells are expanded 60-fold during 96 h of culture. It is important to note that more than 98% of the expanded cells express a stem cell marker, nestin, with no expression of a neuronal marker, βIII. These specifications are in large contrast to those with the standard neurosphere culture by which cells proliferate 6-fold for 96 h (Figure 3) to produce a heterogeneous population containing 60% of nestin-expressing cells (*3*).

CONCLUSION

By means of recombinant DNA technology, EGF was engineered to carry an α-helical peptide and a hexahistidine sequence. The chimeric proteins, EGF-E5-His and EGF-K5-His, spontaneously form a heterodimer, dEGF-His. NSCs proliferate most rapidly and selectively on the substrate with surface-anchored dEGF-His, compared to the other substrates with monomeric EGF. This effect may be attributed to the enhanced dimerization of EGF-EGFR complexes at the cell−substrate interface. The rate of cell proliferation on this surface is far beyond those on our conventional substrate with monomeric EGF-His, as well as those in the standard neurosphere culture. In conjunction with the capability of highly selective expansion of NSCs, it follows that the dEGF-His-immobilized substrate allows the most efficient preparation of NSCs. For the clinical application of our technology, further feasibility study is needed with human NSCs.

2. Native PAGE analysis

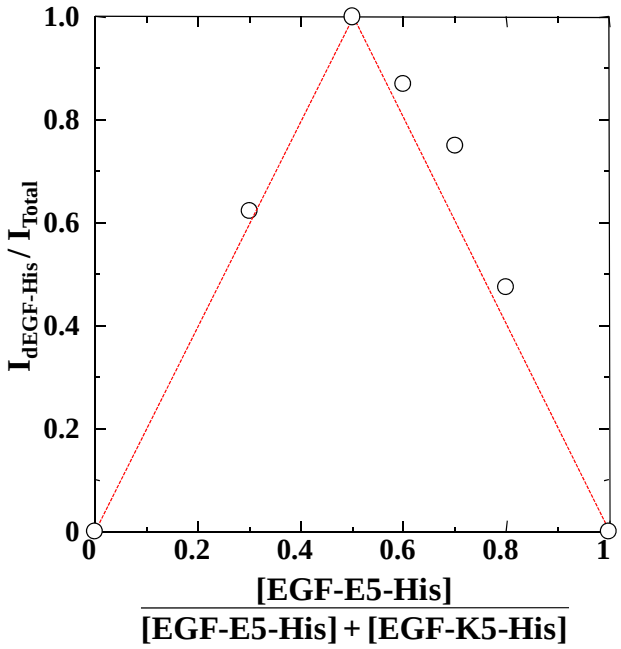

Figure S1. Band intensity ratio determined from the result of native PAGE shown in Figure 2B (see the main body of the article) using an Image J software. Data are plotted as a function of the molar fraction of EGF-E5-His in the mixed solution. Open circle: experimental results, red broken line: a curve predicted by assuming the stoichiometric interaction between EGF-E5-His and EGF-K5-His. $I_{dEGF-His}$: the band intensity for dEGF-His, I_{Total}: a sum of the band intensity for dEGF-His, EGF-E5-His, and EGF-K5-His. Note that the $I_{dEGF-His}$ / I_{Total} for the mixing ratio of 0.6, 0.7, and 0.8 is higher than the prediction.

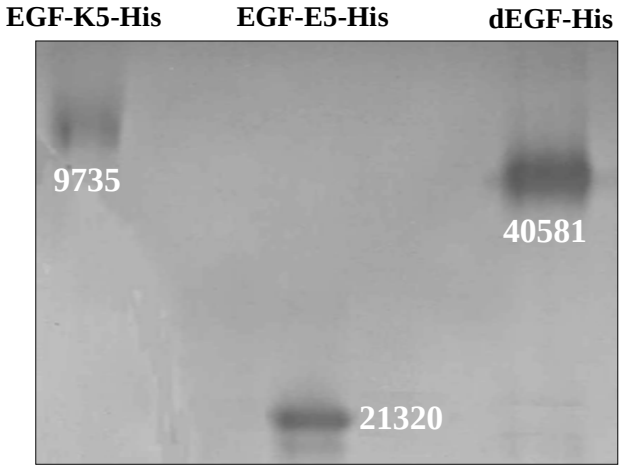

Figure S2. The result of native PAGE analysis performed for EGF-K5-His (0.2 mM), EGF-E5-His (0.2 mM), and dEGF-His (a mixture of 0.2 mM EGF-K5-His and 0.2 mM EGF-E5-His). Band intensities determined using an Image J software were shown in the image. Note that the band intensity for dEGF-His (ca. 40000) is enhanced compared with the sum of the band intensity for EGF-K5-EGF and EGF-E5-His (ca. 31000). At this moment, we have no clear explanation for the enhanced staining, but this is probably related to the alteration of ionic and hydrophobic nature of the monomers upon dimerization (*1*).

3. Interactions of α-helical peptide

CD spectroscopic analyses were performed for investigating the intramolecular and intermolecular interactions of an α-helical peptide with an EGF domain and the self-assembly of the peptides. First, we prepared the tandem forms of K5 [$(EKLASVK)_{10}$, K10] and E5 [$(KELASVE)_{10}$, E10] using recombinant DNA technology. This is because we failed to prepare E5 and K5 peptides in sufficient quantities for CD analysis, probably due to degradation of the short peptides during their expression in and purification from *E. coli*. The K10, however, had strong propensity to form insoluble substances probably because of coiled-coil formation and therefore could not be subjected to CD analysis. In contrast, E10 was successfully obtained in the soluble form and used for CD analysis alone or together with His-deficient EGF, EGF-E5-His, or EGF-K5-His.

Preparation of E10 peptide. cDNA encoding E10 (70 amino acids) was synthesized using chain reaction cloning method (*2)*. Synthetic DNA fragments (ca. 70 mer) corresponding to 5'-terminal, first middle, second middle, 3'-terminal parts of DNA encoding E10 were purchased from Invitrogen (Table S2). The 5'-terminal fragment contained 24-mer oligonucleotide for octapeptides (HHHHHHGG) to fuse His to the N-terminus. Four synthetic DNA fragments were ligated each other using three bridge primers (Table S2) to obtain DNA encoding full length E10 fused with HHHHHHGG at the N-terminus. All steps for ligation of DNA fragments were carried out at the same procedure in previous report (*2*). The ligated DNA was amplified by PCR using outer primers (Table S2). Forward primer contained an Nde I restriction site. Reverse primer contained an Xho I restriction site. The His-E10 gene was digested with Nde I and Xho I and inserted into the pET-22b (Novagen, Darmstadt, Germany) previously digested by the same restriction enzymes. This plasmid was cloned in *Escherichia coli* (*E. coli*) stain, DH5α, to obtain pET22–His-E10. The correctness of the plasmids, pET22–His-E10, was confirmed by sequencing.

E10 (Figure S3A) was expressed in *E. coli* stain, BL21-codonplus (Stratagene, La Jolla, CA) using Overnight Express Autoinduction System (Novagen). E10 obtained as inclusion bodies were extracted with phosphate buffer saline containing 8 M urea, and then purified using a Prime ÄKTA chromatography system (GE Healthcare Bio-Science Corp., Piscataway, NJ) equipped with a His Trap HP column (GE Healthcare). These proteins were refolded by step-wise dialyzing against the series of buffers (Table S3). The yields of E10 were determined to be 37 mg per liter of medium. The purity and molecular size of proteins were analyzed by sodium dodecylsulfate–polyacrylamide gel electrophoresis (SDS–PAGE) (Figure S3B). The result of SDS–PAGE analysis for E10 shows a single bund at 11 kDa, suggesting the dimerized form of the peptide even under the denatured condition with SDS.

CD spectroscopy. Sample proteins were dissolved in PBS (pH 7.4) to a mean residue concentration of 0.855 mM (rhEGF) or 2.75 mM (E10, EGF-His, EGF-K5-His, and EGF-E5-His). In addition, the solution of E10 was mixed with a solution containing an equimolar concentration of EGF-His, EGF-K5-His, or EGF-E5-His to a total protein concentration of 5.50 mM.

As shown in Figure S4, CD spectrum for EGF-His was in good agreement with that for rhEGF, indicating that EGF-His had secondary structure to a similar extent to rhEGF. This result demonstrates that EGF-His is correctly refolded and that the His sequence has insignificant effect on the structure of the EGF domain.

Figure S5 shows the CD spectra for EGF-His, E10, and the their equimolar mixture. The spectrum for E10 exhibits a negative cotton effect at 222 nm, indicating the presence of α-helical structure. The spectrum for the mixture of EGF-His and E10 has similar shape and intensity to the theoretical spectrum obtained by numerical summation of the individual spectra. This provides the evidence for the undetectable interactions between E10 and EGF-His. Similar results were obtained from the CD spectroscopic analysis for the mixture of E10 with EGF-E5-His (Figure S6), indicating the undetectable interactions of E10 with any regions of EGF-E5-His polypeptide. Accordingly, the data presented in Figures S4–S6 demonstrate that no detectable intermolecular and intramolecular interactions of the model helical peptide (E10) are operated with EGF, E5, and His sequences.

In contrast to the results described above, the mixiging of E10 with EGF-K5-His gave rise to peculiar alterations in CD spectrum (Figure S7). Negative cotton effects were considerably intensified at 208 and 222 nm, making the spectrum quite different from the theoretical curve. This is plausibly due to the heterodimer formation between E10 and the K5 segment in EGF-K5-His through coiled-coil association. Although E10 spontaneously dimerizes by self-association (see also Figure S3), mixing of E10 with a K5 containing

protein might induce the formation of E10–K5 heterodimer with higher stability than the E10 homodimer. As we used E10 as a model peptide of E5, the results shown in Figure S5 support the coiled-coil association between E5 and K5 segments in EGF-E5-His and EGF-K5-His to form dEGF-His.

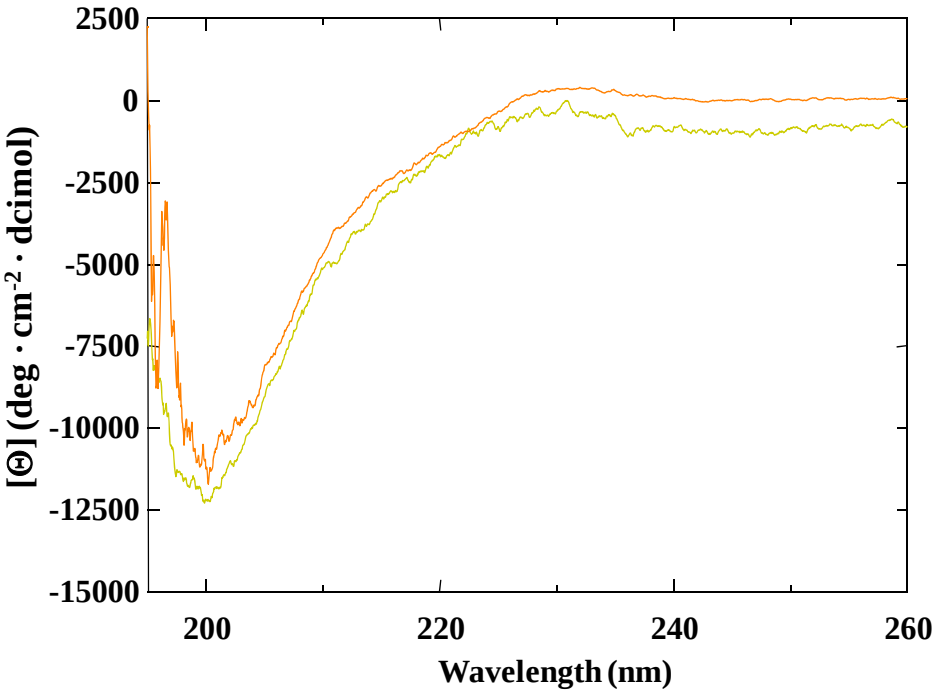

Figure S4. CD spectra for EGF-His (orange) and rhEGF (yellow). The spectrum for EGF-His is also presented in the main body of this paper (Figure 2C).

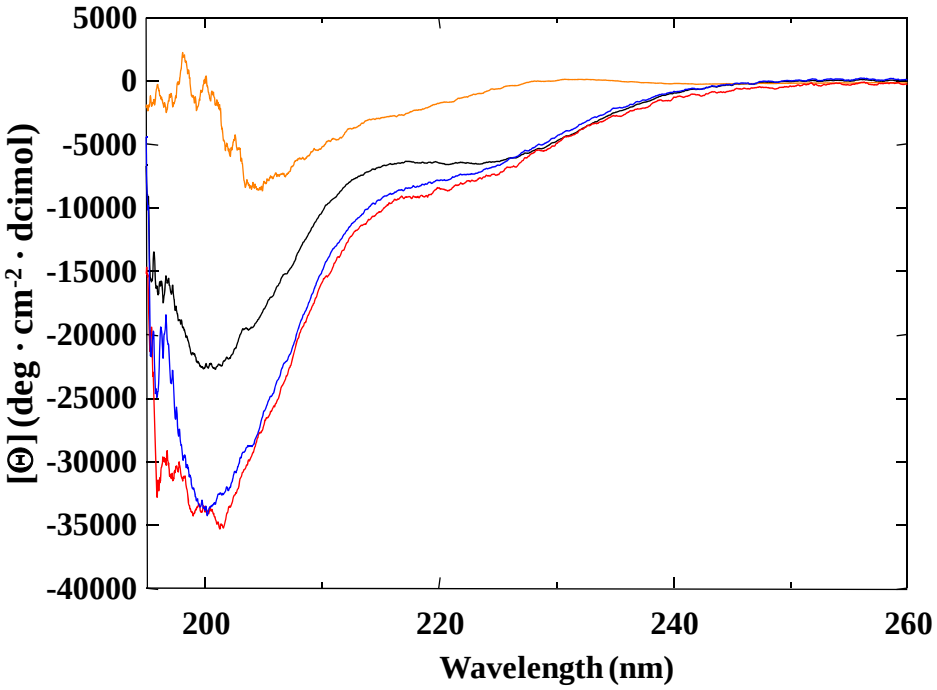

Figure S5. CD spectra for EGF-His (orange), E10 (black), and the equimolar mixture of EGF-His and E10 (red). The spectrum in blue represents the theoretical curve obtained by numerical summation of individual spectra (orange + black). The spectrum for EGF-His is also presented in the main body of this paper (Figure 2C).

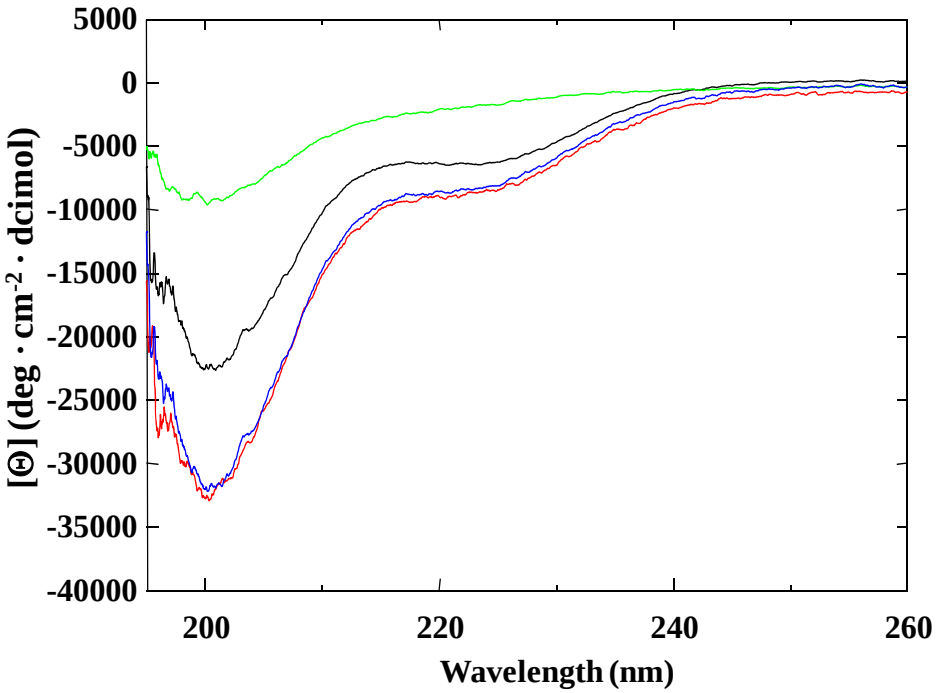

Figure S6. CD spectra for EGF-E5-His (right green), E10 (black), and the equimolar mixture of EGF-E5-His and E10 (red). The spectrum in blue represents the theoretical curve obtained by numerical summation of individual spectra (right green + black). The spectrum for EGF-E5-His is also presented in the main body of this paper (Figure 2C).

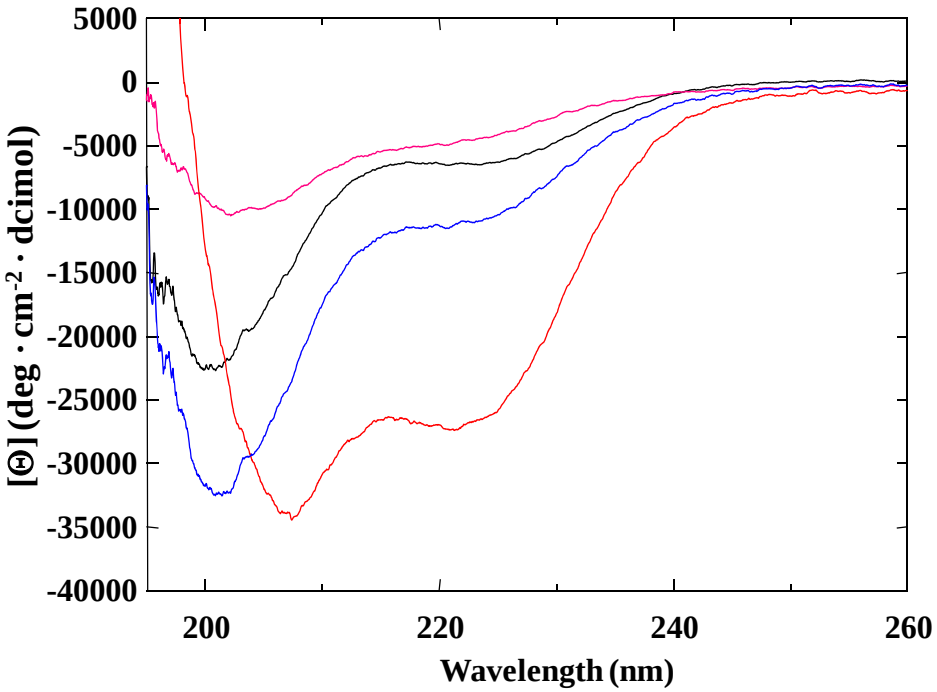

Figure S7. CD spectra for EGF-K5-His (pink), E10 (black), and the equimolar mixture of EGF-K5-His and E10 (red). The spectrum in blue represents the theoretical curve obtained by numerical summation of individual spectra (pink + black). The spectrum for EGF-K5-His is also presented in the main body of this paper (Figure 2C).

4. Cell growth on the substrate with surface-anchored EGF chimeric proteins

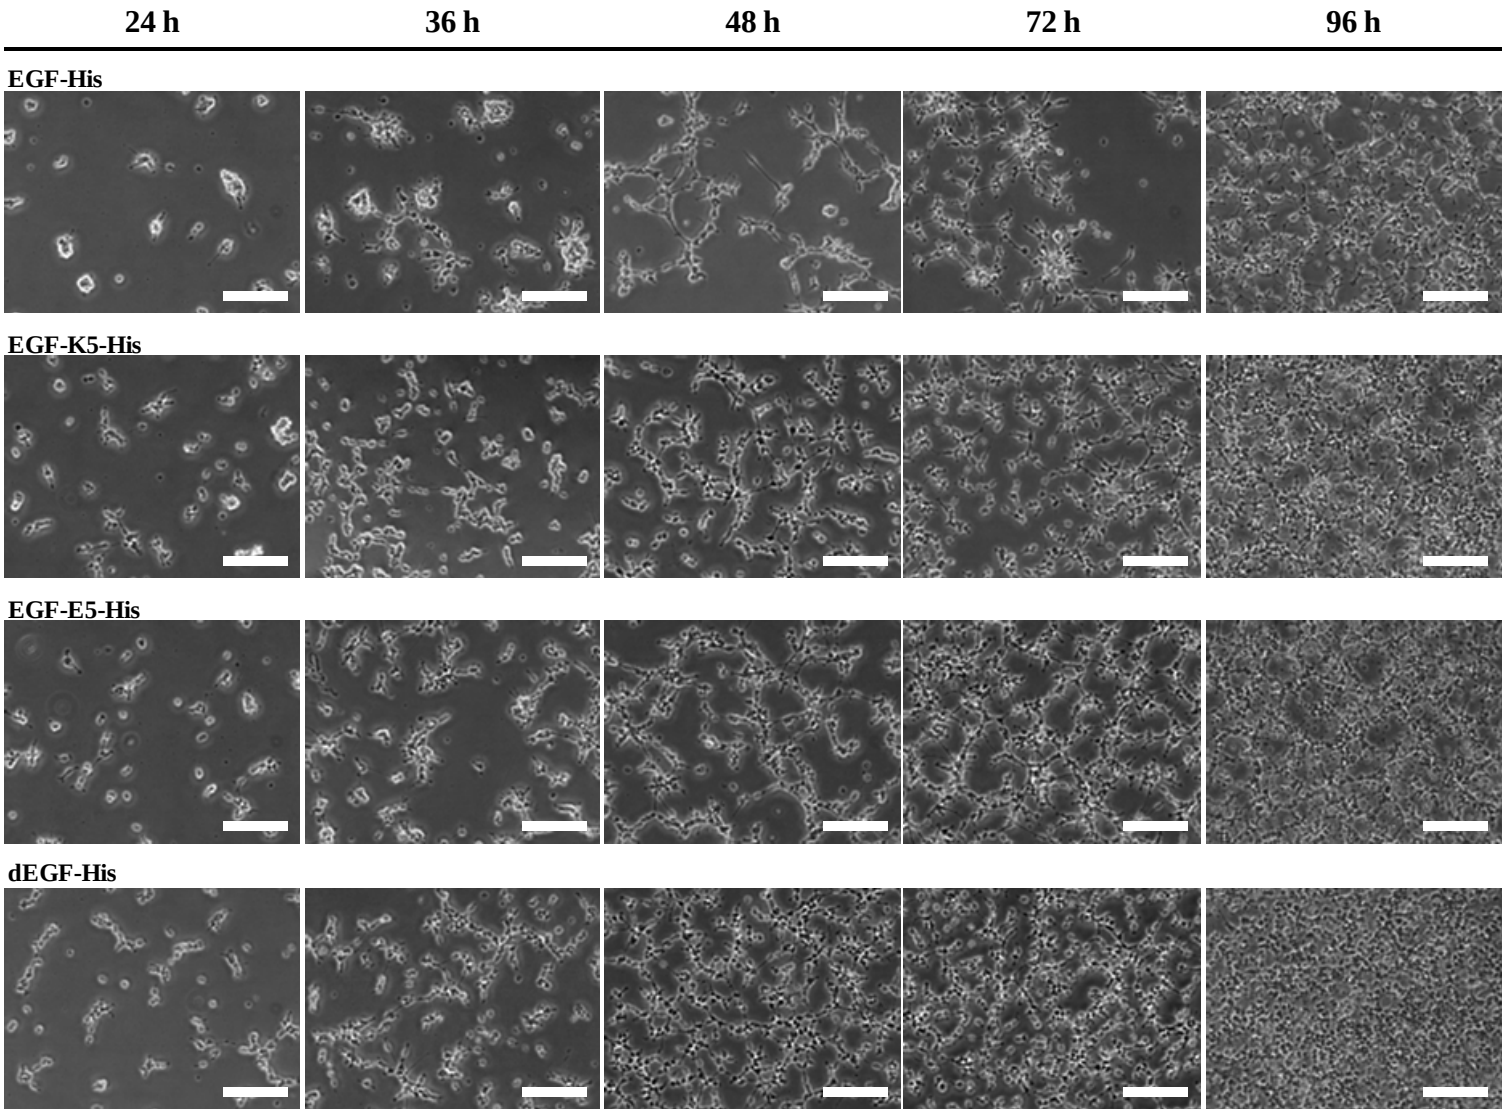

Figure S8. Phase-contrast images of cells cultured on the substrates with surface-anchored chimeric proteins. Images were acquired at 24, 36, 48, 72, and 96 h after seeding. The identity of surface-anchored chimeric proteins is shown on the left side of the images. Images for 48 h culture are the same as those in Figure 5A in the main body of this paper. Bars: 100 μm.

T-Cell Activation by Antigen-Loaded pH-Sensitive Hydrogel Particles *in Vivo*: The Effect of Particle Size

Joel A. Cohen,[†] Tristan T. Beaudette,[†] William W. Tseng,[‡] Eric M. Bachelder,[†] Ines Mende,[‡] Edgar G. Engleman,[‡] and Jean M. J. Fréchet[†,*]

College of Chemistry, University of California, Berkeley, California, 94720-1460, and Department of Pathology, Stanford University School of Medicine, Palo Alto, California. Received August 6, 2008; Revised Manuscript Received October 9, 2008

Polymeric carriers designed to encapsulate protein antigens have great potential for improving the efficacy of vaccines and immunotherapeutics for diseases such as cancer. We recently developed a carrier system based on polyacrylamide hydrogel microparticles cross-linked with acid-labile moieties. After being phagocytosed by antigen-presenting cells, the protein encapsulated within the carrier is released and processed for subsequent presentation of antigenic epitopes. To understand the impact of particle size on the activation of T-cells following uptake by antigen-presenting cells, particles with mean diameters of 3.5 μm and 35 nm encapsulating a model protein antigen were synthesized by emulsion and microemulsion based polymerization techniques, respectively. *In vivo* tests demonstrated that both sizes of particles were effective at stimulating the proliferation of T-cells and were capable of generating an antigen-specific cytotoxic T-cell response when coadministered with immunostimulatory DNA. Contrary to previous reports in the literature, our results suggest that there is no significant difference in the magnitude of T-cell activation for the two sizes of particles used in these experiments. This disparity in findings may be related to fundamental differences in material properties of the carriers used in these studies, such as the hydrophilicity of the polyacrylamide particles described here versus the hydrophobic nature of carriers investigated by other groups.

INTRODUCTION

The physical dimensions of a biomaterial are key parameters that may dictate the interaction of the material with its surrounding biological environment, particularly when those dimensions are on the micro- or the nanoscale. For example, while many cell types are capable of ingesting small-sized particulate matter (typically <200 nm in diameter) by mechanisms such as pinocytosis, and receptor- and clathrin-mediated endocytosis (*1*), the uptake of particles with diameters up to several micrometers is generally restricted to the phagocytic antigen-presenting cells of the immune system such as macrophages and dendritic cells. This difference in uptake has been exploited in the development of protein antigen carrier systems, which often increase the efficacy of protein-based vaccines (*2*−*4*). Tuning the size of particulate antigen delivery systems can enable passive targeting of exogenous proteins to antigen-presenting cells for presentation of derived peptide fragments on major histocompatibility class I (MHC I) molecules, which can subsequently enhance the activation of cytotoxic T-lymphocyte (CTL) immune responses (*5*).

Several reports have highlighted the impact that particle size may have on interactions with antigen-presenting cells and the immune system in general. For example, while dendritic cells are capable of ingesting polystyrene particles ranging in size from tens of nanometers to micrometers in diameter, it appears that these cells may demonstrate preferential uptake for particles with diameters less than 300 nm *in vitro* (*6*). Early studies on the functional application of particulate antigen carriers indicated that, for proteins bound to the surface of polystyrene beads with diameters between 500 nm and 10 μm, carriers with diameters between 2 and 3 μm were most effective at inducing cross-presentation of antigenic peptides in macrophages in an ovalbumin-based model system *in vitro* (*7*). However, *in vivo* studies using a similar polystyrene-based system with diameters ranging from 20 nm to 2 μm suggested that particles less than 200 nm (*8*) or 100 nm (*9*) in diameter were most effective at generating CTL responses. Additional work showed that, among those particles with diameters less than 100 nm, 40−50 nm particles were potentially more effective at biasing the activation of the adaptive immune system toward a CTL-dominated response (*10*).

Carrier size has also been shown to influence *in vivo* behavior at the systemic level. Poly(propylene sulfide) particles with 20 and 45 nm diameters were shown to traffic to draining lymph nodes via convective transport through the lymphatic capillaries after subcutaneous injection, with the potential for targeting lymph-node-resident dendritic cells. In contrast, 100 nm particles were not observed to drain to the lymph nodes to any significant extent (*11, 12*). These observations are in agreement with an earlier report demonstrating that 0.5−1 μm polystyrene particles were generally found to reside at the site of injection after several days where they were capable of targeting peripheral antigen-presenting cells (*13*).

With these studies in mind, we aimed to investigate the effect of particle size on T-cell activation in a microparticulate carrier system we recently developed based on polyacrylamide networks containing pH-sensitive cross-links. This system has been shown to be effective at delivering protein antigens to cells of the immune system both *in vitro* and *in vivo* using particles typically greater than 1 μm in diameter (*14*−*17*). Compared to the particles used in the studies described above, which primarily utilized polystyrene or other hydrophobic-core carriers, this polyacrylamide-based system is inherently hydrophilic and mechanically compliant, and the protein payload is physically encapsulated, which should offer protection from proteolytic

degradation prior to reaching the target antigen-presenting cells. The particles are relatively stable at physiological pH but degrade rapidly when they encounter the lower pH environment present in the lysosomes of cells. When ingested by antigen-presenting cells, the particles rapidly break down into smaller fragments, releasing their contents in a manner that enhances MHC I presentation of antigen-derived peptides (*14, 15, 17*).

To investigate the effect of particle size on T-cell activation using our polyacrylamide-based system, we first had to synthesize submicrometer-sized particles. To this end, we optimized the inverse emulsion conditions of free-radical polymerization to generate acid-labile polyacrylamide nanogels. After characterizing these nanoparticles, we investigated their ability to induce T-cell proliferation and an antigen-specific cytotoxic T-cell response *in vivo* in a direct comparison with the performance of analogous but larger acid-degradable particles.

EXPERIMENTAL PROCEDURES

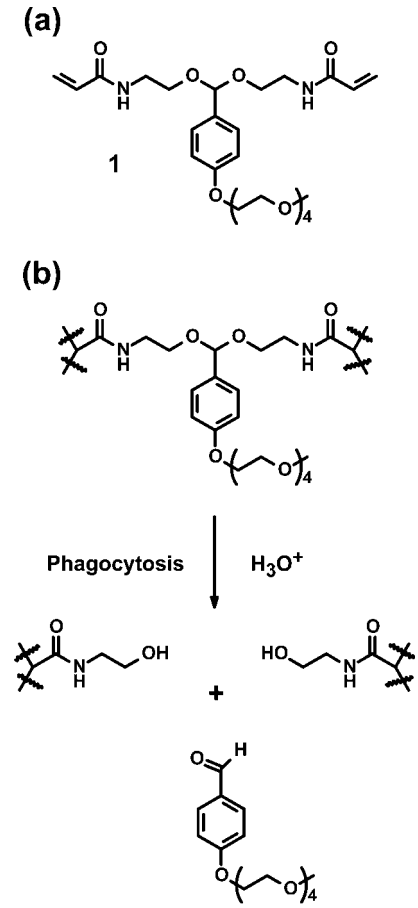
General Procedures and Materials. Unless otherwise noted, all chemicals were purchased from Sigma-Aldrich (St. Louis, MO) and used without additional purification. Acrylamide, *N*,*N*′-methylene-bis-acrylamide, ammonium persulfate, and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) were purchased from Bio-Rad (Hercules, CA). Hexane (OmniSolv grade) was purchased from EMD (Gibbstown, NJ). UltraPure 0.1 μm filtered water and phosphate buffered saline (pH 7.4, PBS) were purchased from Invitrogen-Gibco (Carlsbad, CA). The pH of PBS solutions was adjusted using either HCl or NaOH. Unless otherwise noted, dried particles were suspended in buffer by alternately vortexing the solution and sonicating in a VWR model 75 water bath for 1−3 min until particle aggregates were no longer visible.

Cross-Linker Synthesis. Synthesis of the benzylidene acetal cross-linker **1** (Scheme 1) was performed as previously reported (*17*).

Preparation of 35 nm Diameter Particles. To prepare the organic continuous phase, AOT (sodium bis(2-ethylhexyl) sulfosuccinate) (178 mg, 0.40 mmol) and Brij 30 (poly(ethylene glycol) dodecyl ether with $M_n \sim 362$) (344 mg, 0.95 mmol) were added to a 20 mL borosilicate glass vial to which a stir bar was added. The vial was sealed with a Teflon-lined septum cap and purged with dry nitrogen for 10 min. Hexane (5 mL) was deoxygenated by bubbling dry nitrogen through the solvent for 10 min and was added to the vial. The vial was placed in an oil bath with the temperature set to 23.5 °C, and stirring was started at 600 rpm to dissolve the surfactants. For the aqueous phase, ovalbumin (7.0 mg) was dissolved in PBS (pH 9, 203 μL), to which acrylamide (48.0 mg, 0.68 mmol) and cross-linker **1** (39.0 mg, 0.07 mmol) were added and dissolved. A 20% (w/v) solution of ammonium persulfate in PBS (pH 9, 30 μL) was added to the monomer/protein solution. The mixture was sonicated for 30 s in a Branson 1210 water bath and added to the organic continuous phase dropwise via syringe over approximately 3 min. After 10 min, polymerization was initiated by the addition of TMEDA (20 μL) via syringe over the course of 2 min, and the mixture was stirred for 2 h. Solvent was removed by rotary evaporation, and absolute ethanol (5 mL) was added, resulting in a milky-white suspension. The particles were isolated by centrifugation for 10 min at 4000 × *g* at rt, and washed with absolute ethanol (4 × 5 mL), centrifuging as before. The particles were suspended with absolute ethanol (2 mL) and sonicated for 30 s in a Branson 1210 water bath. The ethanol was removed under vacuum and the particles dried overnight to yield a fine white powder (54.0 mg).

Nondegradable 35 nm Diameter Particles. Nondegradable particles used in light scattering studies were prepared as described above with the exception that *N*,*N*′-methylene-bis-acrylamide (10.8 mg, 0.07 mmol) was substituted for cross-linker **1** in the monomer mixture.

Scheme 1[a]



[a] (a) Acid-labile benzylidene acetal cross-linking monomer (**1**) used to prepare nanoparticles. (b) Hydrolysis of cross-linker in polymerized particles generates linear polyacrylamide chains with pendant alcohols along with the release of the corresponding benzaldehyde.

Fluorescently Labeled 35 nm Diameter Particles. Particles encapsulating an ovalbumin−AlexaFluor 488 conjugate (OVA-AF488, Invitrogen-Molecular Probes, Carlsbad, CA) were prepared as described above with the exception that the monomers were dissolved in a PBS solution containing 2 mg/mL of OVA-AF488 in lieu of using unlabeled ovalbumin.

Preparation of 3.5 μm Diameter Particles. The 3.5 μm diameter particles were synthesized according to a previously reported procedure (*16*). Briefly, ovalbumin (7.0 mg) was dissolved in 300 mM phosphate buffer (pH 8, 250 μL), to which acrylamide (63.0 mg, 0.89 mmol) and cross-linker **1** (63.0 mg, 0.12 mmol) were then added and dissolved. Ammonium persulfate (7.0 mg, 0.03 mmol) was added to the monomer/protein solution, and the mixture was added to the organic continuous phase (2.5 mL), consisting of a 3 wt % surfactant solution in hexane, using a 3:1 weight ratio of Span 80 (sorbitan monooleate) to Tween 80 (poly(ethylene glycol)−sorbitan monooleate). The two phases were emulsified by sonicating for 30 s using a Branson Sonifier 450 with a 0.5 in flat tip, an output setting of 2, and a duty cycle of 40%. Polymerization was initiated by the addition of TMEDA (25 μL), and the mixture was stirred at rt for 10 min. The particles were isolated by centrifugation for 10 min at 1380 × *g* at rt, and washed with hexanes (3 × 2 mL) and acetone (4 × 2 mL), centrifuging as before. The solvent was decanted and the particles dried overnight under vacuum to yield a fine white powder (53.7 mg).

Fluorescently Labeled 3.5 μm Diameter Particles. Particles encapsulating OVA-AF488 were prepared as described above with the exception that the monomers were dissolved in a PBS solution containing 10 mg/mL of OVA-AF488 in lieu of using unlabeled ovalbumin.

Ovalbumin-Free Particles. As background controls for determining protein loading, particles of each size were prepared as described above with the exception that no ovalbumin was included in the aqueous phase.

Scanning Electron Microscopy (SEM). A sample of 35 nm particles was suspended at 20 mg/mL in 1 mM NH_4OH (in UltraPure water) and deposited onto a silicon wafer. After 5 min, the residual solution was wicked away using filter paper, and the residue was dried overnight under vacuum. The sample was sputter-coated with a 1 nm film of gold/palladium and visualized using a Hitachi S-5000 SEM at 10 kV.

Particle Size Measurements. The size distribution of the 35 nm particles was determined by dynamic light scattering using a Zetasizer Nano-ZS instrument (Malvern Instruments, Malvern, UK) after suspending the particles at 2 mg/mL in PBS (pH 10). Particle samples were maintained at 25 °C and the instrument settings were determined automatically. The reported results represent the average particle size ± half-peak width at half-maximal height of 15 sequential measurements (to ensure measurement stability) from a multimodal data fit using the manufacturer's software package.

The size distribution of the 3.5 μm particles was determined using a Horiba Partica LA-950 laser scattering particle size distribution analyzer after suspending the particles at 5 mg/mL in PBS. The reported results represent the geometric mean ± standard deviation of the size distribution.

The refractive indices of PBS and polyacrylamide used in the size distribution calculations were 1.33 and 1.47, respectively (*18*), and the viscosity of PBS used was 0.888 cP. Particle size distributions for both measurement techniques were volume-weighted.

Determination of Particle Loading. Particles containing ovalbumin were suspended at a concentration of 5 mg/mL in PBS (pH 5). The solutions were incubated overnight at room temperature while vortexing at 1000 rpm to completely degrade the particles. The amount of protein released from the particles was quantified using a bicinchoninic acid (BCA) assay kit according to the manufacturer's instructions (Micro BCA Protein Assay Kit, Pierce, Rockford, IL). Dilutions of free ovalbumin were used as a standard. Absorbances were recorded using a SpectraMax 190 microplate reader (Molecular Devices, Sunnyvale, CA). Particle loading was corrected for background absorbance from ovalbumin-free particles degraded in the same manner.

^{1}H NMR. NMR samples were prepared in deuterated phosphate-buffered saline consisting of potassium phosphate monobasic (0.144 mg/mL), sodium phosphate dibasic heptahydrate (0.795 mg/mL), and sodium chloride (9 mg/mL) in D_2O. As necessary, this buffer was adjusted to pH 5 using 0.5 M DCl in D_2O. Particles were suspended at 3 mg/mL. Spectra were acquired using a 400 MHz Bruker spectrometer. Chemical shifts are reported relative to 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid (sodium salt) as a standard.

To monitor cross-link hydrolysis at pH 7.4, a 35 nm particle sample was maintained at 37 °C and spectra were acquired at the indicated time points. To monitor cross-link hydrolysis at pH 5, a particle suspension was maintained at 37 °C; and at the indicated time points, 0.6 mL aliquots were removed, hydrolysis was quenched by adding 2.4 μL of 1 M NaOD in D_2O, and the samples were transferred to sealed NMR tubes. Spectra were acquired within 1 h after samples were quenched.

To determine the cross-linker hydrolysis rate, the ratio of the integration of the benzaldehyde proton signal (δ 9.8 ppm) to the integration of the standard signal was calculated. The ratios were normalized to the ratio obtained from a completely hydrolyzed particle spectrum. To obtain the half-life with respect to hydrolysis, the normalized ratio was plotted versus time and initial data points were fit with an exponential function. All peak areas were determined by numerical integration after background subtraction using *Mathematica 5.0* (Wolfram Research).

Particle Degradation Measurements. To monitor degradation of the 35 nm particles by light scattering (*19*), samples were suspended at a concentration of 2 mg/mL in PBS at the indicated pH values. Samples (1 mL) were added to a cuvette sealed with parafilm to prevent evaporation and vortexed at 600 rpm at 37 °C between readings. Scattering intensity was measured using a Zetasizer Nano-ZS instrument with the temperature set to 37 °C, with the instrument settings held constant from run to run. Reported values represent the mean unadjusted scattering count rate.

Cell Lines and Culture. RAW 309 Cr.1 macrophages (#TIB-69) and HeLa cells (CCL-2), were purchased from ATCC (Manassas, VA) and were cultured in Dulbecco's Modified Eagle Medium containing 4.5 g/L D-glucose and supplemented with 10% fetal bovine serum, 100 units/mL of penicillin, 100 μg/mL streptomycin, and 2 mM GlutaMAX (DMEM). All culture media components were from Invitrogen-Gibco with the exception of the serum, which was from Hyclone (Logan, UT). Cell incubations were performed in a water-jacketed 37 °C/5% CO_2 incubator.

Nanoparticle Cytotoxicity. RAW 309 and HeLa cells were added to the wells of a 96-well tissue culture plate at 5×10^3 cells/well (100 μL/well in DMEM). After overnight incubation, the medium was exchanged for dilutions of ovalbumin-loaded 35 nm particles prepared in DMEM at the indicated concentrations in triplicate (100 μL/well). After 7 h, the wells were washed 3 × 150 μL with DMEM, and 100 μL of DMEM was added to each well. After 24 h, the medium was exchanged for 120 μL of a 0.83 mg/mL solution of MTT (3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide) in DMEM. After 3 h, the medium was exchanged for 200 μL of DMSO, and the plates were vortexed to dissolve the purple formazan crystals present. On a separate plate, 100 μL from each well was mixed with 100 μL of DMSO and 25 μL of a glycine buffer (0.1 M glycine, 0.1 M NaCl, pH 10.5), and the absorbance of each well was read at 570 nm using a SpectraMax 190 microplate reader. After background subtraction, each well was normalized to the average absorbance of wells containing cells not treated with particles.

Particle Uptake. RAW 309 and HeLa cells were added to the wells of a 12-well tissue culture plate at 1.5×10^5 cells/well (2 mL/well in DMEM). After overnight incubation, the medium was exchanged for particles encapsulating OVA-AF488 suspended at 0.25 mg/mL in DMEM (1 mL/well). At the indicated time points, cells were washed 3 × 1 mL with PBS, harvested by trypsinization, and centrifuged for 10 s at 13 000 × *g* at rt. The cells were then washed with 1 mL of PBS and centrifuged as before. The cell pellet was resuspended in 300 μL of a 4% paraformaldehyde solution (Electron Microscopy Sciences, Hatfield, PA) in PBS. Cells were analyzed for particle uptake using a Becton-Dickinson Biosciences FACSCalibur flow cytometer (San Jose, CA) with 488 nm excitation.

Confocal Microscopy. RAW 309 cells were seeded in the wells of a four-chambered glass Lab-Tek chamber slide (Nunc, Rochester, NY) at 2×10^4 cells/well (0.75 mL/well) in DMEM. After overnight incubation, the medium was aspirated from each well and 35 nm particles (suspended at 0.25 mg/mL in DMEM) encapsulating OVA-AF488 were added to the wells (0.5 mL/well). After 8 h, the wells were washed 3 × 0.75 mL with

DMEM, and 0.5 mL of DMEM was added to each well. After 16 h, the wells were washed 3 × 0.75 mL with PBS and incubated in a 4% paraformaldehyde solution in PBS for 15 min at rt. The cells were then washed 3 × 0.75 mL with PBS and incubated with 410 μL of a 1:40 dilution of phalloidin−AlexaFluor 546 (Invitrogen-Molecular Probes) in PBS for 30 min in the dark. After washing 3 × 0.75 mL with PBS and 1 × 0.75 mL with distilled water, mounting medium containing DAPI (4′,6 diamidino-2-phenylindole) (Vectashield, Vector Laboratories, Burlingame, CA) was added, and the slide was coverslipped and sealed with Cytoseal 60 (Richard-Allan Scientific, Kalamazoo, MI). Imaging was performed using a Zeiss LSM 510 Meta confocal microscope with a 63× objective (Carl Zeiss, Germany) using excitation wavelengths of 361 nm for DAPI, 488 nm for OVA-AF488, and 543 nm for phalloidin−AlexaFluor 546.

Animals. Male C57BL/6 mice and CD45.1 congenic C57BL/6 mice, 6 to 8 weeks of age, were purchased from the Jackson Laboratory (Bar Harbor, ME). The 1100Mjb mice (OT-I mice) express an H-2K^b restricted T-cell receptor specific for the octapeptide SIINFEKL ($OVA_{258-265}$) (*20*). All mice were housed in the Stanford Animal Facility in accordance with NIH guidelines, and all procedures were approved by the Stanford Institution for Animal Care and Use (IACUC).

***In Vivo* T-Cell Proliferation Assay.** Vaccinations with each particle type were normalized to 5 μg of ovalbumin per mouse. C57BL/6 mice ($n = 3$) received subcutaneous flank injections of particles in 200 μL of PBS, followed by intravenous adoptive transfer of 7.5 × 10^6 congenic OT-I T-cells 24 h later. The OT-I T-cells were labeled with 10 μM 5-(and-6)-carboxyfluorescein diacetate succinimidyl ester (CFSE, Invitrogen) prior to adoptive transfer in order to follow their proliferation by CFSE dilution. Mice vaccinated with 5 μg of free ovalbumin or PBS alone served as controls. Three days after adoptive transfer, draining inguinal lymph nodes were harvested from vaccinated mice, and single cell suspensions were stained with fluorochrome-conjugated antibodies against CD3 (BD Biosciences, San Jose, CA) and CD8 (BioLegend, San Diego, CA). The CFSE proliferation profile of gated CD3+ CD8+ T-cells was determined by flow cytometry.

***In Vivo* Cytotoxicity Assay.** C57BL/6 mice ($n = 4$, minimum) were vaccinated with each particle type normalized to 50 μg ovalbumin, with or without 10 μg CpG ssDNA (TCCATGACGTTCCTGACGTT, phosphorothioate backbone, Oligos, Etc., Wilsonville, OR), in a final volume of 200 μL PBS. At day 7 after vaccination, mice were injected intravenously with 1 × 10^7 CFSE-labeled target cells consisting of 50% SIINFEKL-pulsed splenocytes labeled with 5 μM CFSE and 50% unpulsed splenocytes labeled with 0.5 μM CFSE. Mice were tail-vein bled 18 h after adoptive transfer, and the CFSE profile of transferred cells was determined by flow cytometry for analysis of ovalbumin-specific cytotoxicity.

Endotoxin Testing. Particles were suspended at 5 mg/mL in PBS (pH 5) and degraded overnight at 37 °C while vortexing at 1200 rpm. The degraded samples were diluted to 1 mg/mL and 0.5 mg/mL in PBS (pH 7.4). The presence of endotoxin was quantified using an FDA-licensed colorimetric limulus amebocyte lysate assay cartridge with an Endosafe-PTS test system (Charles River Laboratories, Charleston, SC) with a detection range of 0.05−5 endotoxin units per mL (EU/mL). Endotoxin levels were measured at 0.14 EU/mg and less than 0.05 EU/mg (below the detection range of the assay) for the 3.5 μm and 35 nm particles, respectively. The presence of these levels of endotoxin has been found to result in minimal stimulation of immune cells (*21, 22*).

Statistical Data Analysis. In experiments where replicate samples were analyzed, the results are presented as the mean ± standard deviation unless otherwise noted. Comparisons of statistical significance were made using one-way analysis of variance combined with paired Student's *t* tests at a significance level of $p < 0.05$ after confirming equal variances with the Bartlett test.

RESULTS AND DISCUSSION

Nanoparticle Synthesis and Characterization. Reports in the literature have suggested that the size of particulate antigen carriers may influence vaccine efficacy *in vivo*; however, to the best of our knowledge there are no studies investigating this phenomenon in hydrogel systems. To this end, we sought to produce acid-labile polyacrylamide particles with diameters smaller than 100 nm. To achieve this goal, we investigated the possibility of polymerizing aqueous monomer-containing droplets formed in inverse microemulsions. The stable droplets formed under these conditions are typically less than 50 nm in diameter and upon polymerization yield swollen hydrogels less than 100 nm in diameter with relatively narrow size distributions. The synthesis of cross-linked polyacrylamide and polyacrylate hydrogel particles in this size range utilizing inverse microemulsions has been reported in the literature (*23, 24*), and the encapsulation of enzymes (*25*−*27*) in particles prepared by this technique has been demonstrated. However, in most cases the encapsulated species was intended to be retained within the particle structure, thus nondegradable cross-linking monomers such as *N*,*N*′-methylene-bis-acrylamide were generally used. In this report, we synthesized particles incorporating an acid-labile acetal cross-linker (**1**, Scheme 1) to afford release of the encapsulated protein at pH values encountered in the endolysosomal vesicles of antigen-presenting cells (∼pH 5) (*17*).

In the present study, we utilized this polymerization method to afford a good yield (ca. 60%) of particles approximately 20 nm in diameter in the dry state (Figure 1) and showing a size distribution of 32.6 ± 6.8 nm as measured by dynamic light scattering when suspended in PBS. Throughout the remainder of this report, these will be referred to as 35 nm particles. A small population of particles (approximately 10%) was also observed with a size centered around 310 nm, likely due to the formation of aggregates. To determine the amount of the model protein (ovalbumin) loaded in the particles, samples were

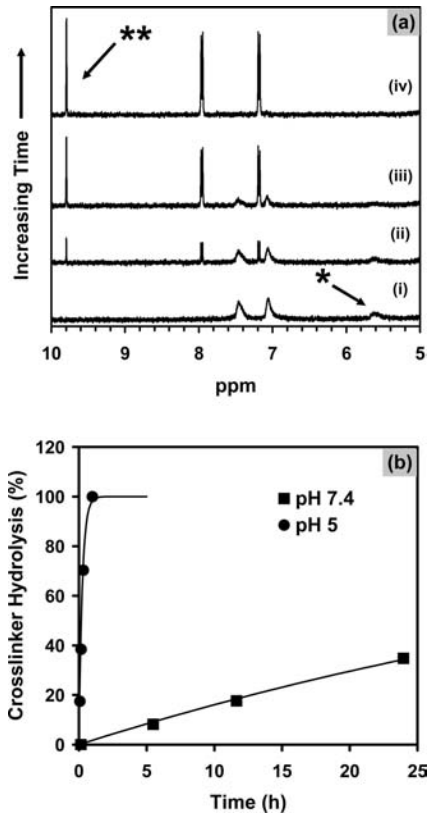

Figure 2. (a) ^{1}H NMR spectra demonstrating the time-dependent hydrolysis of benzylidene acetal cross-linker (*) and release of the resultant aldehyde (**) from ovalbumin-loaded nanoparticles at pH 5 at (i) 0, (ii) 5, (iii) 20, and (iv) 60 min. (b) Cross-linker hydrolysis kinetics for particles hydrolyzed at pH 7.4 and pH 5. Solid lines represent pseudo-first-order hydrolysis models fit using the initial data points at each pH value.

degraded in PBS (pH 5) overnight, and the released protein was quantified using a bicinchoninic acid assay (*28*). The particles were found to contain 5.4 ± 0.1% of ovalbumin by weight.

Cross-Linker Hydrolysis and Particle Degradation. To characterize the rate of cross-linker hydrolysis in the carrier particles, samples of 35 nm particles were suspended in deuterated phosphate buffers at pH 7.4 and pH 5, and ^{1}H NMR spectra were acquired after various times. Figure 2a illustrates the general behavior of the particles upon exposure to acidic conditions. The resonance attributed to the benzylidene acetal proton of the cross-linker within the particles appeared as a broad peak at 5.6 ppm. As the incubation time increased, the intensity of this peak diminished along with the concomitant appearance of a sharp peak at 9.8 ppm corresponding to the proton of the benzaldehyde liberated during hydrolysis. The growth rate of the latter peak can be modeled using pseudo-first-order kinetics with respect to the cross-linker concentration (*29*) to yield a half-life of particle cross-link hydrolysis of 40 h at pH 7.4, compared to 10 min at pH 5 (Figure 2b). These values are roughly equivalent to hydrolysis rates reported for a similar cross-linker in monomeric form (*30*). Within 1 h, hydrolysis was essentially complete at pH 5, while at pH 7.4, hydrolysis progressed slowly over the course of 10 days (data not shown).

A complementary view of particle stability as a function of pH was obtained using measurements of light scattering intensity for suspensions of the particles (Figure 3). The time required for the particles to fragment into linear polyacrylamide chains following cross-linker hydrolysis at pH 5 was approximately 3 h, as determined by a 90% decrease in scattering intensity. On the other hand, over the course of 8 h, no observable decrease in scattering intensity occurred at pH 7.4, and it took

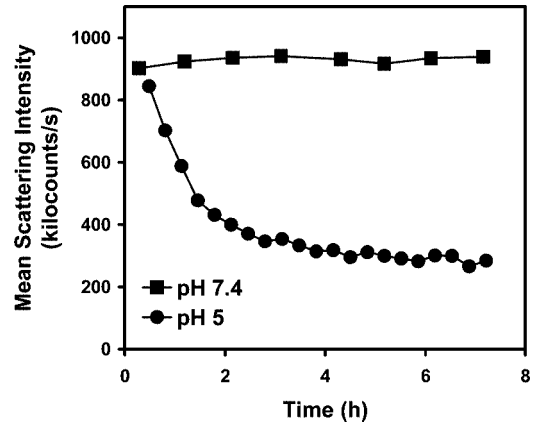

Figure 3. Fragmentation of ovalbumin-loaded nanoparticles as a function of time at pH 7.4 and pH 5 as observed by scattered light intensity measurements.

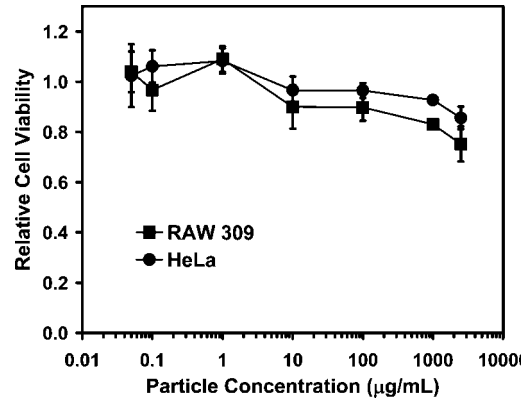

Figure 4. Evaluation of the cytotoxicity of ovalbumin-loaded 35 nm particles in phagocytic RAW 309 macrophages and non-phagocytic HeLa cells using an MTT-based assay.

over 9 days for the scattering intensity to decrease 90% from its original value (data not shown). We confirmed that the decrease in scattering intensity observed in the protein-loaded particles at acidic pH was dependent on the presence of acid-labile cross-links, as the scattering intensity of particles cross-linked with *N,N′*-methylene-bis-acrylamide showed no change in intensity at pH 5 over the same length of time (data not shown). Together, the NMR and light scattering data suggest that, while the particle cross-links hydrolyze relatively rapidly, overall particle degradation appears to be limited by disentanglement of the linear polymers that are formed as the result of cross-linker hydrolysis.

***In Vitro* Cytotoxicity and Uptake of 35 nm Diameter Particles.** In order to assess the cellular toxicity of the 35 nm particles, MTT-based assays were performed using cell lines with both phagocytic (RAW 309 macrophages) and non-phagocytic (HeLa) phenotypes. Cells incubated with 35 nm particles demonstrated very low particle-associated toxicity (Figure 4), with approximately 75% and 85% viability retained at doses up to 2.5 mg/mL in RAW 309 and HeLa cells, respectively.

As many non-antigen-presenting cells are capable of ingesting particulate material less than 200 nm in diameter, we compared the relative uptake of the 35 nm particles for both phagocytic (i.e., antigen-presenting cells) and non-phagocytic cells. The kinetics of particle uptake in RAW 309 macrophages was monitored *in vitro* by flow cytometry using acid-labile, fluorescently labeled 35 nm particles. A rapid increase in fluorescence intensity was initially observed indicating cellular uptake

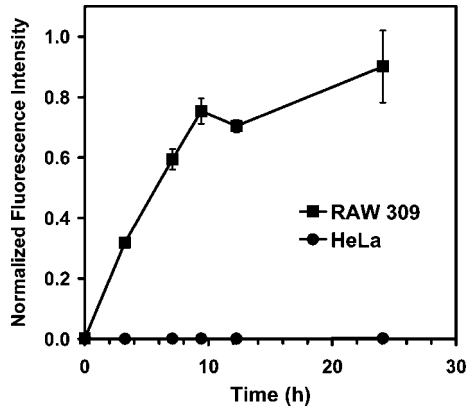

Figure 5. Comparison of the time-dependent *in vitro* cellular uptake of 35 nm particles encapsulating OVA-AF488 by phagocytic RAW 309 macrophages and non-phagocytic HeLa cells as measured by flow cytometry. Mean fluorescence channel values were averaged and normalized to the maximum observed value.

of nanoparticles, with a plateau occurring at approximately 9 h (Figure 5). In contrast, non-phagocytic HeLa cells showed minimal uptake of the 35 nm particles during the same time frame with a 200-fold difference observed between the maximum uptake values for each cell type. The neutral, hydrophilic nature of the polyacrylamide-based particles may limit uptake of the particles by non-phagocytic mechanisms.

Particle uptake was also confirmed by confocal microscopy. After 8 h of incubation with 35 nm particles containing fluorescently labeled ovalbumin, RAW 309 macrophages were fixed, stained, and imaged. As shown in Figure 6, fluorescence was observed throughout their cytoplasm. To ensure that the fluorescence was coming from within the cells, the focal plane was varied throughout the thickness of the cells. Fluorescence was observed as both punctate and diffuse signal. Although a definitive conclusion regarding protein release could not be reached from these data alone, the images may provide an indication that the diffuse signal may result from protein released from particles, while the punctate signal may result from protein entrapped in particles in the early stages of endocytosis prior to degradation (*31*). No fluorescence from within HeLa cells was observed when using the same microscope settings (data not shown), which is complementary to the minimal uptake observed by flow cytometry.

Effect of Particle Size on T-Cell Proliferation and Generation of Antigen-Specific Effector T-Cells. To assess the effect of particle size on the activation of T-cells *in vivo*, we prepared larger analogous acid-labile hydrogel particles by an inverse suspension polymerization method (*14*−*17*). Particles synthesized in this manner had a mean diameter of 3.67 ± 1.18 μm when suspended in PBS and are referred to as 3.5 μm particles in this report. These particles incorporated approximately the same mole percent of cross-linker (10%) and loading of ovalbumin (7.3 +/− 0.2% by weight) and were produced in ca. 40% yield. The 3.5 μm particles were comparable to the 35 nm particles in terms of their morphology as seen by SEM (Supporting Information Figure S1), their degradation characteristics, and their *in vitro* cytotoxicity (*14*). Additional experiments performed using particles containing fluorescently labeled ovalbumin showed similar *in vitro* uptake of both sizes of particles in RAW 309 macrophages as confirmed by flow cytometry (Supporting Information Figure S2). Using confocal microscopy, we found that the intracellular appearance and distribution of both types of particles in macrophages were also similar (Supporting Information Figure S3). We therefore expected that differences in T-cell activation induced by these

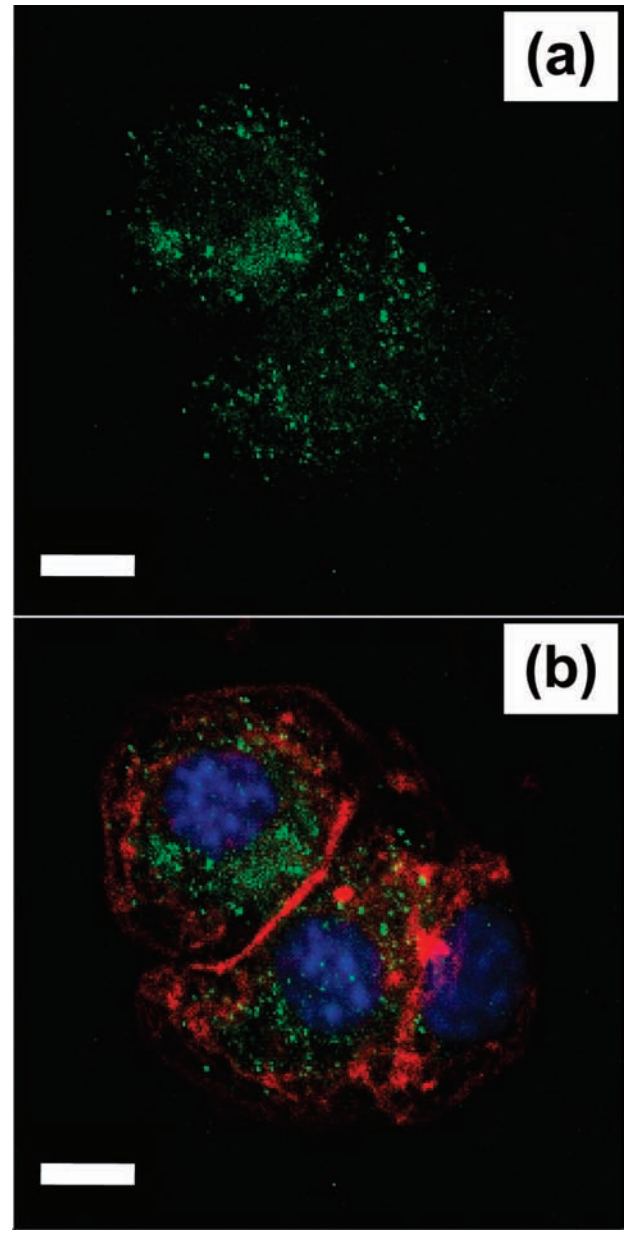

Figure 6. Confocal microscopy images of RAW 309 macrophages incubated with OVA-AF488-loaded 35 nm particles for 8 h followed by fresh medium for 16 h. two types of particles would primarily be due to the effect of particle size.

The purpose of encapsulating ovalbumin within the particles was to exploit existing *in vivo* experimental models that rely on the presentation of the immunodominant, ovalbumin-derived, SIINFEKL peptide ($OVAC_{258-265}$) in the context of MHC I molecules ($H\text{-}2K^b$) on the surface of antigen-presenting cells. The first experiment we used to assess the activation of T-cells by the two sizes of particles examined the ability of each type of particle to induce T-cell proliferation. We have previously shown that ovalbumin-loaded pH-sensitive particles are capable of stimulating the proliferation of T-cells *in vivo*, even at relatively low ovalbumin concentrations (*16*). In the present study, C57BL/6 mice were injected with either 3.5 μm or 35 nm particles in quantities normalized to deliver 5 μg of ovalbumin. After 24 h, CFSE-labeled naïve OT-I T-cells, capable of specifically recognizing SIINFEKL/MHC I com-

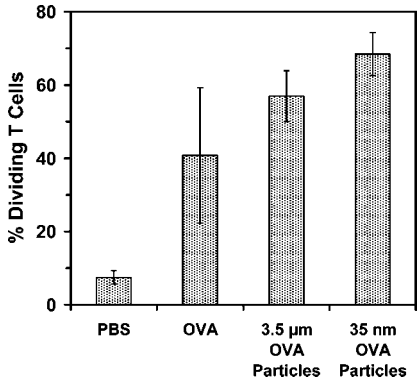

Figure 7. *In vivo* proliferation of SIINFEKL ($OVA_{258-265}$)/H-$2K^b$ specific CD8 T-cells in mice immunized with 3.5 μm and 35 nm ovalbumin-loaded particles. Data derived from CFSE profiles of gated CD3+ CD8+ T-cells isolated from lymph nodes of vaccinated mice 3 d after adoptive transfer.

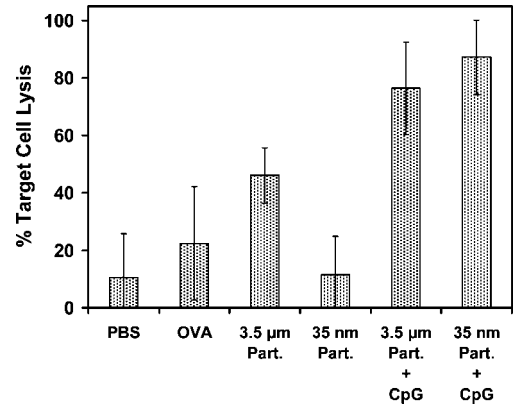

Figure 8. *In vivo* induction of T-cells capable of specific lysis of adoptively transferred SIINFEKL-pulsed splenocytes by 3.5 μm and 35 nm ovalbumin-loaded particles, both without and with coadministration of CpG oligonucleotide. The percentage of specific target cell lysis was determined by comparing remaining numbers of CFSE-labeled splenocytes pulsed with either SIINFEKL peptide or no peptide after adoptive transfer. Average and standard deviation of replicates ($n = 4$ for PBS, $n = 5$ for all others) is presented.

plexes, were adoptively transferred to each mouse. Three days later, draining lymph nodes were assessed for the fraction of OT-I cells that had undergone division in the interim as seen by a dilution of the CFSE signal present in the initially labeled OT-I cells. Figure 7 shows that both the 3.5 μm and the 35 nm particles were capable of stimulating OT-I cell proliferation with 57% and 68% of T-cells undergoing division, respectively, compared to mice injected with free ovalbumin, where only 41% of T-cells were found to be dividing. The level of T-cell division stimulated by 35 nm particles was greater than that of ovalbumin ($p < 0.018$), while 3.5 μm particles were not found to be more stimulatory than ovalbumin alone ($p < 0.12$). While the 35 nm particles appeared to be slightly more stimulatory than the 3.5 μm particles, the difference was not found to be statistically significant.

The proliferation of T-cells stimulated by these acid-labile carriers, however, only provides a general perspective on the activation capacity of this particle system. More importantly, we wanted to determine if antigen-specific effector T-cells were being generated *in vivo*, as this would indicate whether or not the particle formulations would be capable of stimulating an effective CTL response necessary for vaccine-related applications. For this experiment, C57BL/6 mice were injected with either 3.5 μm or 35 nm particles in quantities normalized to deliver 50 μg of ovalbumin. After 7 days, a population of cells consisting of equal amounts of C57BL/6 mouse splenocytes either pulsed or not pulsed with SIINFEKL were injected into the mice. Prior to injection, the two cell types were labeled with either high (SIINFEKL-pulsed) or low (non-SIINFEKL-pulsed) concentrations of CFSE to enable tracking of each set of cells. After 18 h, the quantities of circulating CFSE-labeled cells were analyzed by flow cytometry (Figure 8). A decrease in the fraction of SIINFEKL-pulsed cells relative to the fraction of nonpulsed cells was taken to indicate the presence of antigen-specific effector T-cell cytotoxicity. Without coadministration of additional immunostimulatory compounds, mice injected with 3.5 μm particles alone were found to generate a greater cytotoxic response (46% specific target cell lysis) than ovalbumin alone (22% specific target cell lysis). On the other hand, the 35 nm particles alone did not seem to generate a significant cytotoxic response, with specific cell lysis roughly equivalent to both ovalbumin and PBS controls. It may be possible that the decreased response generated by the 35 nm particles relative to that of the 3.5 μm particles may be associated with a dilution of the injected dose that could occur if the 35 nm particles are indeed small enough to be convectively transported through the lymphatic capillaries draining the injection site. In contrast, due to their larger size, the 3.5 μm particles likely reside at relatively high concentration at the injection site. Elucidating the actual reason for this disparity between the cytotoxicity stimulated by the 3.5 μm and 35 nm particles requires additional study.

We have previously demonstrated that incorporating short, single-stranded oligonucleotide sequences containing unmethylated CpG dinucleotides into the structure of our polyacrylamide-based hydrogel system greatly enhances the activation of antigen-presenting cells and improves the overall immune response (*16*). In addition, it was demonstrated that a similar effect could be observed if the CpG-containing oligonucleotide was simply coadministered along with ovalbumin-loaded particles. As a result, these types of particle formulations represent a more relevant context for antigen delivery than using particles that encapsulate antigen alone. Thus, we sought to investigate the impact of particle size on T-cell activation in formulations where particles were combined with immunostimulatory DNA. For ease of manipulating the experimental conditions such that particle size was the only factor varied, this latter method of coadministering the CpG oligonucleotide was chosen, and additional mice were administered with 10 μg of CpG DNA along with the 50 μg ovalbumin-equivalent of particles. Under these conditions, we found that both 3.5 μm and 35 nm particles were significantly more effective at generating antigen-specific cytotoxic T-cells compared to 3.5 μm particles administered without CpG ($p < 0.0036$ and $p < 0.0002$, respectively), with 76% and 87% specific target cell lysis, respectively (Figure 8). The small difference in target cell lysis between these two treatments was not found to be statistically significant.

Overall, the results of the *in vivo* tests of T-cell activation suggest that, for our acid-labile polyacrylamide-based hydrogel carrier system, particle size does not appear to play a significant role in the generation of CTL responses. Both sizes of particles tested in this study demonstrated a high capacity for stimulating populations of antigen-specific cytotoxic T-cells. Why the behavior we observed differs from reports in the literature for hydrophobic carriers suggesting that smaller particles are more effective in this application requires additional study. In all of the experiments described in this study, we were unable to ascribe the immunostimulatory activity observed using either of the particle types to the presence of particle-associated endotoxin. It is possible that these differences in behavior compared to previously studied polystyrene and poly(propylene sulfide) systems may be related to the overall hydrophilicity of the carrier system or the site of immobilization of the protein antigen being delivered (i.e., encapsulated within the bulk of

the carrier, or bound to the carrier surface), which may influence interactions of the particle system with phagosomal receptors in antigen-presenting cells. To this end, we plan to compare our polyacrylamide-based particle system side-by-side with polystyrene-based carriers to determine their relative stimulatory capacities.

CONCLUSION

In this study, we successfully synthesized and characterized acid-labile and protein-loaded polyacrylamide particles with sub-100 nm diameters by utilizing a microemulsion-based polymerization technique. These nanoparticles were analyzed to determine their degradation characteristics and were found to be readily taken up by antigen-presenting cells of the immune system. We were able to investigate the effect of particle size on T-cell activation *in vivo* using this hydrogel system in comparison to larger analogous particles. In comparison to 3.5 μm diameter particles, 35 nm particles were found to be equivalent at inducing T-cell proliferation and antigen-specific cytotoxicity *in vivo* when coadministered with immunostimulatory DNA. These results suggest that, for hydrophilic carrier systems, size may not be as critical of a factor in stimulatory capacity as in hydrophobic, surface-conjugated systems currently under evaluation. While the present work focused on the use of microemulsion-based hydrogels in immunological applications, we anticipate that these pH-sensitive particles with diameters less than 100 nm may also find use in other *in vivo* applications where their small size and inherently hydrophilic character could be advantageous. For example, we are currently evaluating these nanoparticles as targeted carriers of imaging and therapeutic agents for intravenous or pulmonary administration.

ACKNOWLEDGMENT

We thank the National Institutes of Health (R01 EB005824) for funding of this research; additional NIH support (PEN grant 1 U01 HL080729-01) led to the development of the 35 nm particles used in this study. We thank Ann Fischer and Michelle Yasukawa for help with cell culture studies and Paul Hudson for assistance with analysis of NMR spectra.

General Procedures and Materials S1
Experimental Methods S2

General Procedures and Materials

RAW 309 Cr.1 macrophages (#TIB-69) were purchased from ATCC (Manassas, VA) and were cultured in Dulbecco's Modified Eagle Medium containing 4.5 g/L D-glucose, and supplemented with 10% fetal bovine serum, 100 units/mL of penicillin, 100 μg/mL streptomycin, and 2 mM GlutaMAX (DMEM). All culture media components were from Invitrogen-Gibco with the exception of the serum, which was from Hyclone (Logan, UT). Cell incubations were performed in a water-jacketed 37 ºC/5% CO_2 incubator.

Experimental Methods

Scanning electron microscopy (SEM). A sample of the dried 3.5 μm particle powder was sputter coated with a 20 nm film of gold and visualized using a Hitachi S-4300SE/N SEM at 5 kV.

A sample of the dried 35 nm particle powder was sputter coated with 1 nm film of gold/palladium and visualized using a Hitachi S-5000 SEM at 10 kV.

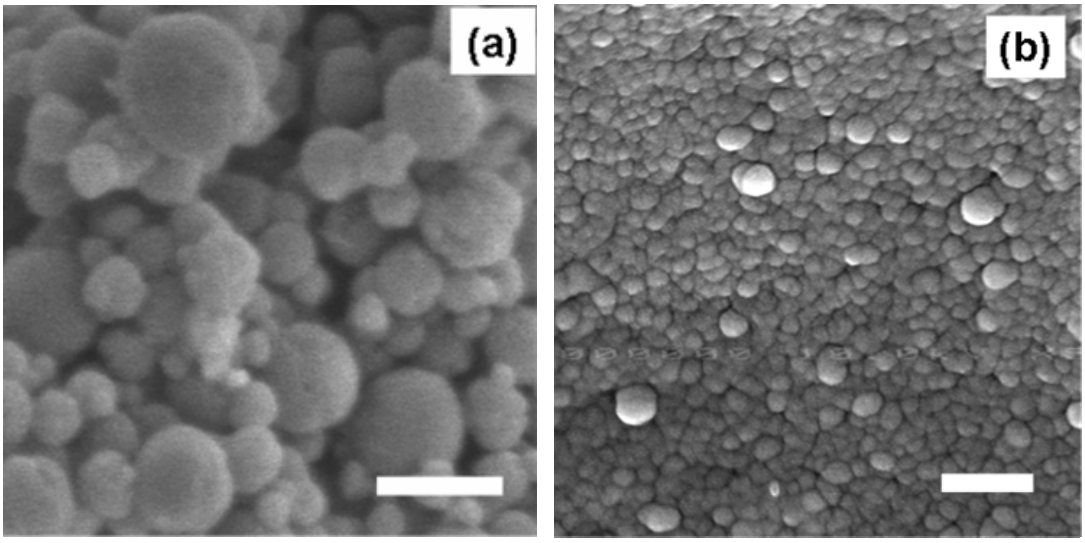

Figure S1. Representative SEM images of dry (unswollen) (a) 3.5 μm particles (scale bar equal to 1 μm), and (b) 35 nm particles (scale bar equal to 100 nm).

Particle Uptake. RAW 309 cells were added to the wells of a 12-well tissue culture plate at 1.5 x 10^5 cells/well (2 mL/well in DMEM). After overnight incubation, the medium was exchanged for a suspension of 3.5 μm particles or 35 nm particles (0.25 mg/mL in DMEM, 1 mL/well) encapsulating OVA-AF488. At the indicated time points cells were washed 3 x 1 mL with PBS, harvested by trypsinization, and centrifuged for 10 seconds at 13,000 x *g* at rt. The cells were then washed with 1 mL of PBS and centrifuged as before. The cell pellet was resuspended in 300 μL of a 4% paraformaldehyde solution (Electron Microscopy Sciences, Hatfield, PA) in PBS. Cells

were analyzed for particle uptake using a Becton-Dickinson Biosciences FACSCalibur flow cytometer (San Jose, CA) with 488 nm excitation.

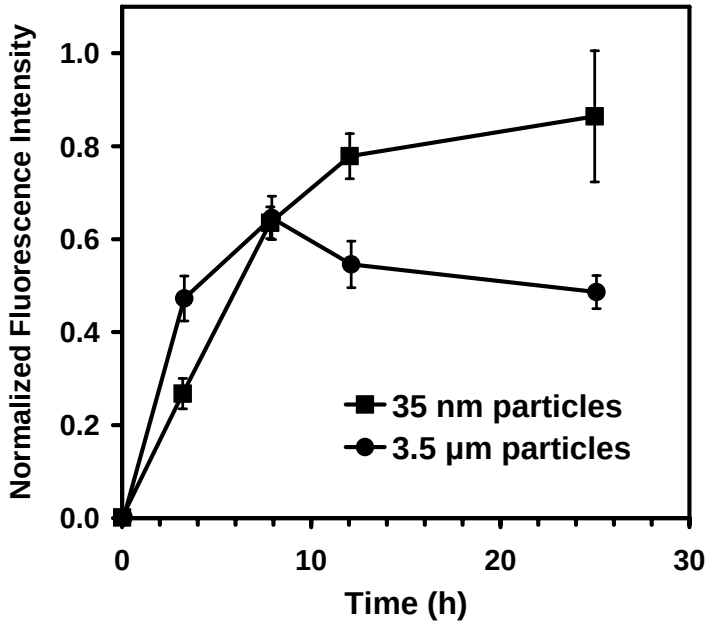

Figure S2. Comparison of the time-dependent *in vitro* cellular uptake of 35 nm particles (■) and 3.5 μm particles (●) encapsulating OVA-AF488 by phagocytic RAW 309 macrophages as measured by flow cytometry. Mean fluorescence channel values were averaged and normalized to the maximum observed value.

Confocal Microscopy. RAW 309 cells were seeded in the wells of a four-chamber Permanox Lab-Tek chamber slide (Nunc, Rochester, NY) at 2 x 10^4 cells/well (0.75 mL/well) in DMEM. After overnight incubation, the medium was aspirated from each well and either 3.5 μm particles or 35 nm particles (suspended at 0.25 mg/mL in DMEM) encapsulating OVA-AF488 were added to the wells (0.5 mL/well). After 8 h, the wells were washed 3 x 0.75 mL with DMEM, and 0.5 mL of DMEM was added to each well. After 19 h, the wells were washed 3 x 0.75 mL with PBS, and incubated in a 4% paraformaldehyde solution in PBS for 15 min at rt. The cells were then washed 3 x 0.75 mL with PBS, and incubated with 410 μL of a 1:40 dilution of phalloidin – AlexaFluor

546 (Invitrogen-Molecular Probes, Carlsbad, CA) in PBS for 30 min in the dark. After washing 3 x 0.75 mL with PBS and 1 x 0.75 mL with distilled water, mounting medium containing DAPI (4',6 diamidino-2-phenylindole) (Vectashield, Vector Labs, Burlingame, CA) was added and the slide was coverslipped and sealed with Cytoseal 60 (Richard-Allan Scientific, Kalamazoo, MI). Imaging was performed using a Zeiss LSM 510 Meta confocal microscope with a 40x objective (Carl Zeiss, Germany) using excitation wavelengths of 361 nm for DAPI, 488 nm for OVA-AF488, and 543 nm for phalloidin – AlexaFluor 546.

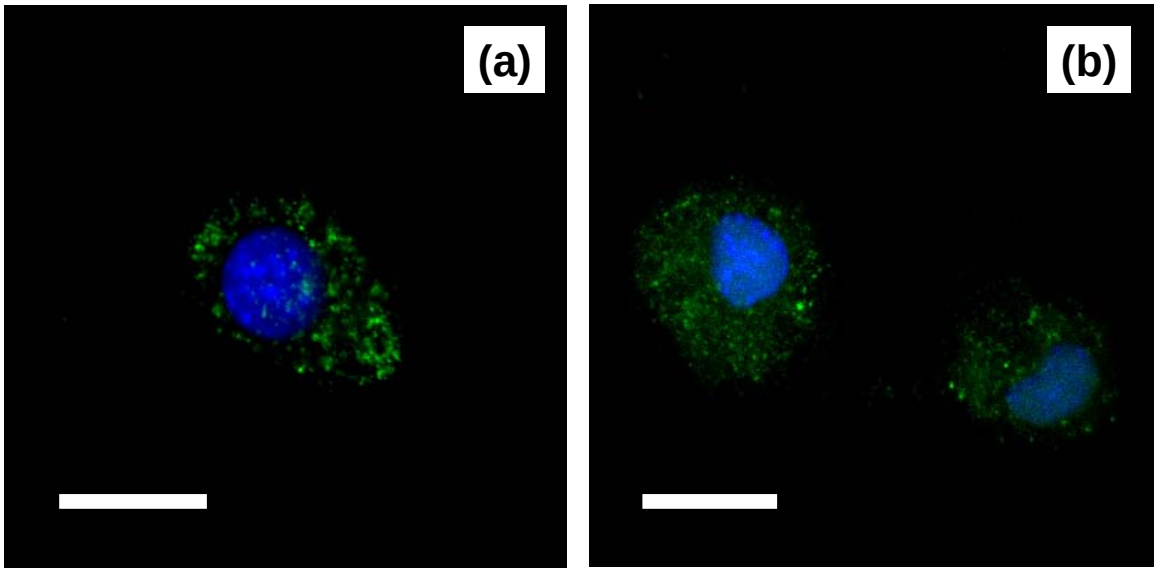

Figure S3. Representative confocal microscopy images of RAW 309 macrophages incubated with OVA-AF488-loaded 35 nm particles (a), or 3.5 μm particles (b), for 8 h followed by fresh medium for 19 h. OVA-AF488 emission (green) and merged with nuclear DNA stained with DAPI (blue). The scale bar is equal to 20 μm. Phalloidin stain omitted for clarity. The focal plane was varied throughout the thickness of the cells to ensure that the fluorescence was coming from within the cells.

Efficient Transfection of Blood−Brain Barrier Endothelial Cells by Lipoplexes and Polyplexes in the Presence of Nuclear Targeting NLS-PEG-Acridine Conjugates

Hongwei Zhang, Anton Mitin, and Serguei V. Vinogradov*

Department of Pharmaceutical Sciences and Center for Drug Delivery and Nanomedicine, College of Pharmacy, University of Nebraska Medical Center, Omaha, Nebraska. Received August 7, 2008; Revised Manuscript Received November 13, 2008

Brain capillary endothelial cells of the blood−brain barrier (BBB) are difficult targets for nonviral transfection even for the most potent transfection agents. Efficient protection and nuclear delivery of plasmid DNA are the key requirements for enhancing the transfection. We designed novel DNA intercalating conjugates of PEG−tris(acridine) with a short nuclear localization signal (NLS) peptide and investigated the effect of their complexes with luciferase-encoded plasmid DNA on lipoplex- and polyplex-mediated transfection of murine brain capillary endothelial bEnd.3 cells. These intercalation complexes protected DNA from nucleolytic degradation forming a protective PEG layer around plasmid DNA and could be efficiently condensed by Lipofectamine2000 or Exgen500 into nanosized particles. Complexation of plasmid DNA with a PEG-acridine/NLS-PEG-acridine mixture (9:1 w/w), taken in an amount equal to 5−6 NLS peptides per DNA molecule, significantly enhanced both lipo- and polyplex transfection efficacies and increased the number of transfected bEnd.3 endothelial cells in the presence of serum. Comparative transgene expression efficiency was significantly higher at longer PEG linker and optimal conjugate-to-DNA weight ratio, especially, at lower N/P ratio for both transfection agents, reaching 15−16-fold for lipoplexes and 10−11-fold for polyplexes. In addition, the NLS-PEG-acridine conjugates did not increase cytotoxicity of lipoplexes and polyplexes to bEnd.3 cells. These conjugates can serve as promising components for development of systemic nonviral transfecting approach to the transfection of the BBB and temporary modulation of its drug permeability.

INTRODUCTION

Many chemotherapeutic agents have limited penetration into the brain through the BBB because brain capillary endothelial cells (BCEC), forming the BBB, express various drug efflux transporter (DET) membrane proteins that actively remove drugs from the brain (*1*). Transient inhibition of the selective DET expression using RNA interference or other therapeutic approaches can potentially increase drug efficacy in the treatment of CNS-related diseases (*2*). It is known that successful application of nonviral vectors is largely limited by their relatively low transfection efficiency in spite of some attractive features like safety and low cost. Even more challenges remain for systemic nonviral gene delivery to the BCEC that have a high intrinsic resistance to the transfection compared to other cell lines (*3*). Nuclear accumulation of plasmid DNA is among the major barriers of nonviral gene delivery, especially in postmitotic, slow-dividing, and quiescent cells (*4, 5*). Actively dividing cells display a regular nuclear envelope disassembly and offer more opportunity for DNA to reach the nuclei. In addition, DNA is sensitive to degradation by nucleases in the cytoplasm.

Nuclear proteins are transferred from the cytoplasm into the nuclei through active transport across nuclear pores mediated by importins recognizing a nuclear localization signal (NLS) sequence (*6*). Various applications of short NLS peptides to increase the nuclear entry of plasmid DNA have been investigated, including covalent or non-covalent attachment of NLS peptides to DNA (*7*−*10*). Zanta et al. demonstrated that only one NLS peptide covalently linked to DNA could increase the transfection efficacy following an intracellular injection of the plasmid (*11*). Jeon et al. conjugated an NLS peptide to PLGA copolymer and demonstrated that slowly degradable PLGA nanospheres could increase the nuclear localization and transfection efficiency of foreign DNA (*12*). Covalent conjugation of NLS peptides to DNA appeared to be a straightforward method, but the modification could result in the loss of biological activity (*13*). Peptide nucleic acids (PNA) were also employed to attach NLS peptide to DNA via sequence-specific noncovalent binding in order to avoid a decrease in transcription activity (*14*). However, this method required individual PNA synthesis for each targeted DNA.

A nonspecific intercalation strategy is looking promising for application to the nonviral transfection. Acridine is a well-known molecule with high affinity to the DNA duplex. However, previous attempts to apply acridine conjugates of NLS peptide resulted in controversial data about their structural requirements for efficient transfection (*15, 16*). In the present study, we investigated effects of direct modification of plasmid DNA with NLS-PEG-acridine conjugates having various PEG linker lengths on the transfection of murine brain capillary endothelial bEnd.3 cells, an in vitro model of the BBB (*17*), by lipoplexes and polyplexes.

EXPERIMENTAL PROCEDURES

Materials. All solvents and reagents, except specially mentioned, were purchased from Sigma-Aldrich (St. Louis, MO) at the highest available quality grade and used without purification. Maleimide (MAL)-PEG_{5000}-*N*-hydroxysuccinimide (NHS), MAL-PEG_{3400}-NHS, and PEG_{5000}-NHS linkers were from JenKem Technology USA (Allen, TX) and MAL-PEG_{900}-NHS linker from Pierce (Rockford, IL). The cystein-containing NLS pep-

tides CAPKKKRKVA-$CONH_2$ and mutant peptide CAPKT-KRKVA-$CONH_2$ were synthesized by Biomer Technology (Pleasanton, CA) and purified by reverse-phase HPLC. Acridine 9-isothiocyanate was purchased from Acros Organic and purified by chromatography on silicagel before use.

Both gWIZ-Luc (6.7 kb) and gWIZ-GFP (5.7 kb) plasmids were originally purchased from Gene Therapy System (San Diego, CA), propagated in *E. coli* (DH5-α), and isolated using a Qiagen Giga plasmid purification kit (Valencia, CA). The plasmid DNA integrity and topology was analyzed by agarose gel electrophoresis.

Synthesis and Characterization of NLS-PEG-Acridine Conjugates. *Modification of the G1.0 PA-Dendrimer with PEG-Linkers.* MAL-PEG_{5000} (PEG_{3400} or PEG_{900})-NHS linkers or PEG_{5000}-NHS linker (10 μmol) were dissolved in 0.5 mL of water and slowly added to G1.0 PA-dendrimer (9 mg) dissolved in 0.5 mL of water and adjusted to pH 8.0 by 1 N HCl. The reaction continued under stirring for 30 min at 20 °C. The high-MW fraction of the PEGylated products was isolated by gel filtration on the Sephadex G-25 column (G-10 for the PEG_{900} derivative), concentrated in vacuo, and immediately used in the next step.

Reaction with Acridine 9-Isothiocyanate. Acridine 9-isothiocyanate (13 mg) was dissolved in 3 mL of methanol containing 4 μL of triethylamine and mixed with the previously obtained aqueous solution of a PEG−dendrimer conjugate. The reaction mixture was stirred for 1 h at 20 °C, and methanol was removed in vacuo.

The high-MW yellow fraction of the MAL-PEG-acridine product was isolated by gel filtration as previously described, concentrated in vacuo, and immediately used in the last step.

Reaction with Cystein-Containing NLS Peptides. A purified NLS peptide (9 mg) was dissolved in 0.5 mL of DMF and mixed with degassed aqueous solution of the MAL-PEG-acridine conjugate obtained in the previous step. The reaction mixture was left overnight at 4 °C. The final product was concentrated in vacuo, isolated by gel filtration as previously described, purified on the semipreparative reverse-phase HPLC column (C18, 5 μm, 1 × 25 cm), using gradient elution by acetonitrile in 0.1% trifluoroacetic acid (v/v), and lyophilized.

Analysis of NLS−Conjugates. Isolated compounds were analyzed by analytical reverse-phase HPLC. UV absorbance of these conjugates at 420 nm was measured to calculate the acridine content (ε_{420} 5500). MALDI-TOF mass spectrometry in positive mode and sinapinic acid as a matrix were used to determine an average MW of these conjugates. Amino acid analysis was conducted on the ABI Protein Analyzer following acid hydrolysis (UNMC Protein Structure Core Facility).

Preparation of Lipoplexes and Polyplexes Containing NLS−Conjugates. 7.5 μg of pDNA was initially incubated with different amounts of NLS-PEG-acridine conjugates or PEG−acridine conjugate (10 mg/mL) in 1 mL of 5% dextran (w/v) for 30 min. To prepare lipoplexes, 15 or 10 μL of Lipofectamine2000 in 5% dextran (w/v) was added to these complexes or pDNA. To prepare polyplexes, 20 or 14 μL of Exgen500 in 5% dextran (w/v) was added to these complexes or pDNA. Final formulations were incubated for 30 min at 20 °C with continuous shaking.

Particle Size and Surface Charge. The particle size and ζ-potential of the transfection complexes were measured using Zetasizer Nano ZS equipped with 50 mV laser (Malvern Instruments, Worcestershire, UK) in PBS at 25 °C (in triplicate).

Agarose Gel Mobility Shift Assay. Samples were loaded on 0.8% (w/v) UltraPure agarose (Invitrogen, Carlsbad, CA) and analyzed by electrophoresis at 120 V for 35 min in 1× TAE buffer. After electrophoresis, the gel was stained by ethidium bromide and subjected to image analysis.

Cell Line Culture. Murine brain capillary endothelial cell line bEnd.3 was purchased from American type Culture Collection (ATCC, Manassas, VA) and cultivated in Dulbecco's Modified Eagle's Medium (DMEM, Invitrogen, Carlsbad, CA) supplemented with 10% fetal bovine serum (FBS) and 2% penicillin−streptomycin in a humidified incubator containing 5% CO_2 at 37 °C.

In Vitro Transfection. All transfection studies were performed in the presence of 10% FBS. Unless specific indicated, bEnd.3 cells were seeded in 96-well plate with an initial density of 7×10^3 cells per well 24 h prior to transfection. The transfection complexes containing 0.5 μg of pDNA were added to each well and incubated for 4 h at 37 °C. The medium was then replaced by fresh medium, and cells were incubated for additional 40 h. Luciferase expression level was determined in the Bio-Tek FLx800 microplate fluorescence reader using a firefly luciferase assay kit (Biotium, Hayward, CA). Protein content was measured by the BCA assay (Pierce Biotechnology, Rockford, IL). All experiments were performed in 5 parallels, and the results were expressed as nanograms of luciferase per milligram of protein.

DNA Resistance to Degradation by DNase I. Both NLS−lipoplexes and NLS−polyplexes (pDNA/NLS-conjugate = 4:1, w/w) were incubated at 37 °C with DNase I (1 U/μg pDNA) in DNase reaction buffer (Promega/Fisher Scientific, Pittsburgh, PA). After incubation, the samples were placed on ice and treated with 10 μL of stop buffer (Promega) and 30 μL of heparin sodium (5000 USP U/mL, American Pharmaceutics Partners, Schaumburg, IL). The samples were then analyzed by 0.8% agarose gel electrophoresis as described above.

In the functional test of DNA protection, 4.5 μg of pDNA was incubated with 1.1 μg of PEG_{5000}-acridine for 30 min at room temperature. This complex was incubated with DNase I (0.005 U/μg DNA) at 37 °C for 15, 30, or 60 min. The reaction was stopped by adding 1 μL of stop buffer and cooling on ice. The solution was then incubated with 12 μL of Exgen500 for 15 min at 25 °C. Naked pDNA was used as control and treated by DNase I under identical conditions. The bEnd.3 cells were transfected by these complexes in the presence of serum as indicated above.

Evaluation of Gene Expression by Flow Cytometry. bEnd.3 cells were seeded in 6-well plates with an initial density of 4×10^5 cells per well 24 h prior to transfection. Three micrograms of the green fluorescent protein (GFP)-encoded pDNA was pretreated with NLS-PEG_{5000}-acridine, encapsulated in lipo- or polyplexes, and added to the cells in the medium containing 10% FBS. Following incubation for 4 h at 37 °C, the medium was replaced by a fresh one, and cells were incubated for additional 40 h. The transfected cells were rinsed with PBS, trypsinized with 0.3 mL trypsin-EDTA solution, and resuspended in 0.5 mL PBS with 0.1% FBS. The percentage of cells displaying GFP-associated fluorescence was quantified by flow cytometry (FACSCalibur, BD Biosciences, San Jose, CA). The experiments were performed in triplicate.

Confocal Microscopy Analysis. pDNA was labeled with CX-Rhodamine by the Label IT Tracker intracellular nucleic acid localization kit (Mirus Bio Corporation, Madison, WI) according to the manufacturer's instructions. bEnd.3 cells were seeded in 8-chamber culture slides (BD Biosciences, Bedford, MA) with an initial cell density of 1.5×10^4 per chamber 24 h prior to transfection. The transfection complexes containing 0.7 μg of the rhodamine-labeled pDNA were added to the cells as described above. After transfection, cells were washed by PBS and fixed by 4% (w/v) paraformaldehyde for 15 min on ice. Then, the SlowFade gold with DAPI solution (Invitrogen) was applied to the cells. The

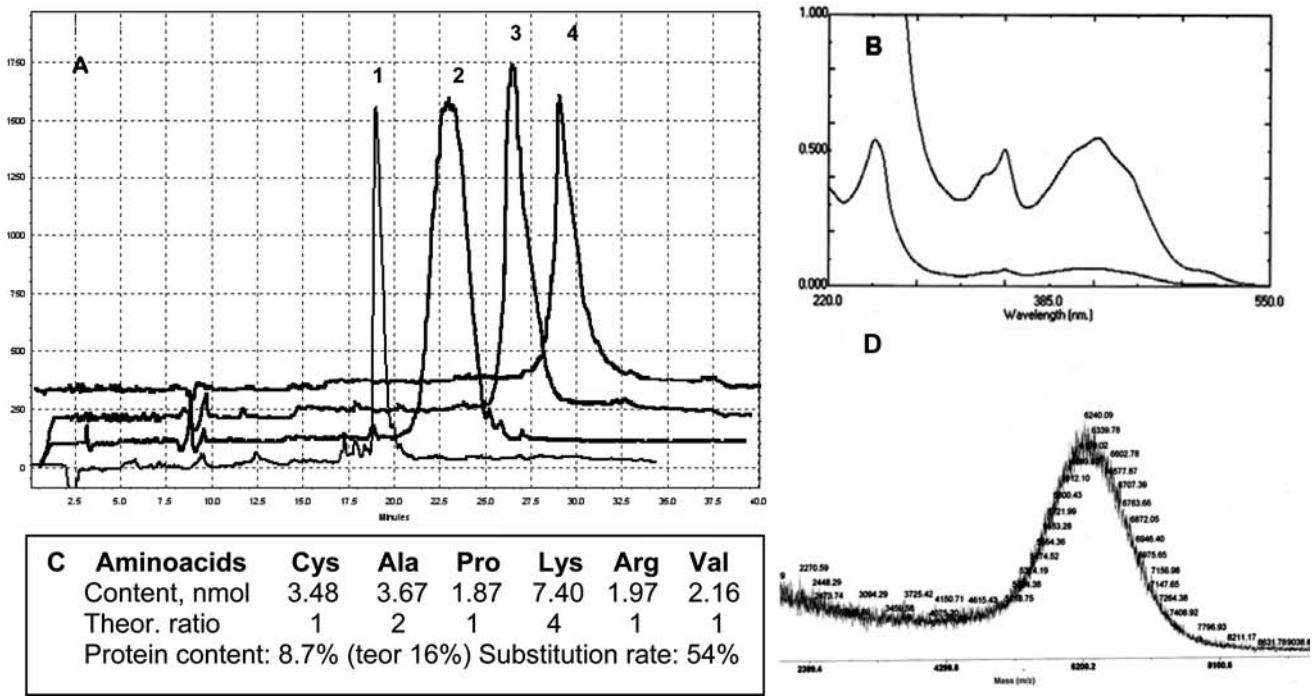

Figure 1. (A) Analytical reverse-phase HPLC (UV detector: 220 nm) of isolated NLS peptide (*1*) and NLS-PEG-acridine conjugates (**2**, PEG_{900}; **3**, PEG_{3400}; **4**, PEG_{5000}). (B) UV spectrum of the NLS-PEG_{5000}-acridine. Acridine absorbance: 420 nm (50% acetonitrile−water, ε 5500). (C) Amino acid analysis of the NLS-PEG_{5000}-acridine conjugate. Expected amino acid ratio in the NLS peptide is shown in the third row. (D) MALDI-TOF spectrum of the NLS-PEG_{5000}-acridine. The average Mw of 5900 belongs to PEG_{5000}−tris(acridine) conjugate, and the average Mw of 7000 corresponds to NLS-PEG_{5000}-tris(acridine) conjugate; superposition of two nearly equal fractions of both conjugates results in the observed average Mw of 6300.

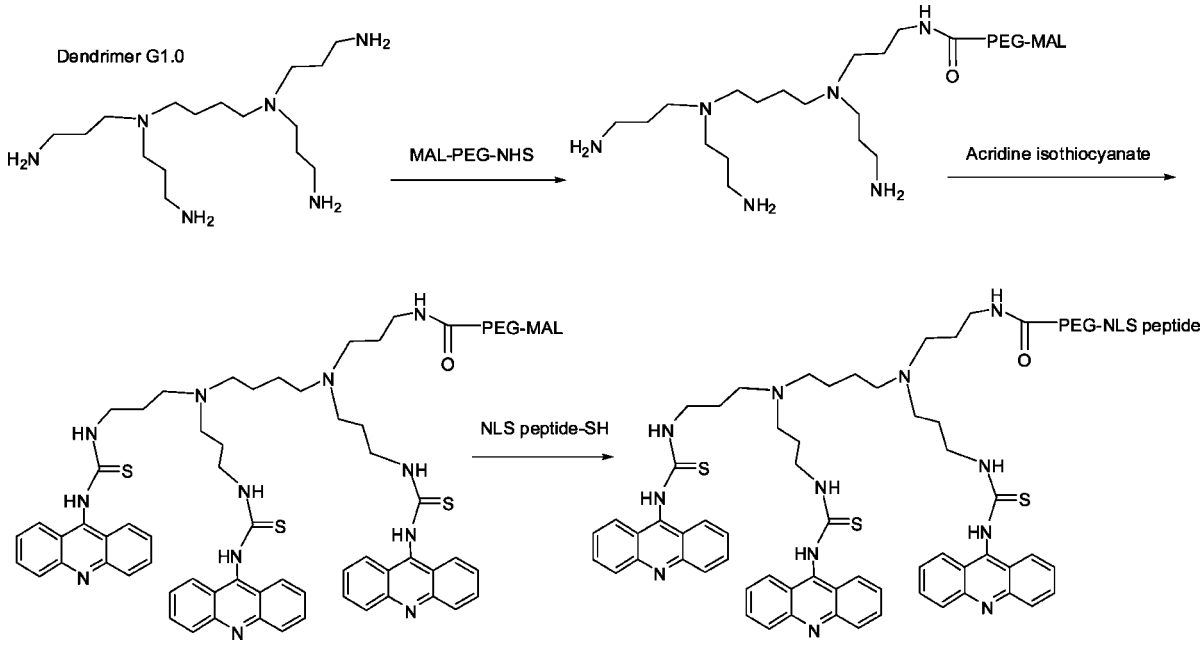
Scheme 1. Synthesis of NLS-PEG-Acridine Conjugates MAL-PEG-NHS: Bifunctional Maleimide-PEG-*N*-Hydroxysuccinimide Derivatives



slides were carefully sealed and observed under an LSM 510 confocal laser scanning microscope (Carl Zeiss, Germany).

Nuclear Accumulation of pDNA. To directly measure nuclear accumulation of fluorescent DNA, bEnd.3 cells were seeded in 6-well plates with an initial density of 2×10^5 cells per well 24 h prior to transfection. CX-Rhodamine labeled pDNA was used to prepare NLS-polyplexes at 4:1 (w/w) ratio as mentioned above. Cells were transfected for 4 h in the presence of 10% FBS at 37 °C, then washed by PBS 3 times, and allowed to grow in complete medium for 24 h. The transfected cells were rinsed with PBS, trypsinized with 0.3 mL trypsin−EDTA solution, and resuspended in 0.5 mL PBS/0.1% FBS. For each sample, cells were counted and 4×10^5 cells were collected by centrifugation at 600 *g* for 5 min at 4 °C. The genomic DNA was extracted from nuclei using the Genomic DNA Isolation Kit (Biovision Inc.,

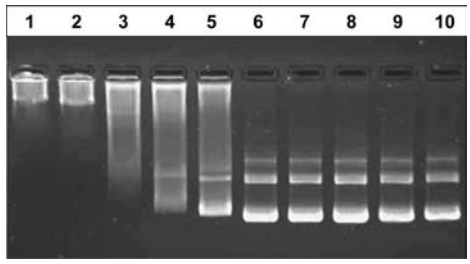


Figure 2. Agarose electrophoresis mobility assay following the pDNA binding with NLS-PEG_{5000}-acridine. 0.5 μg of pDNA was incubated with the NLS conjugate for 30 min at 25 °C at different weight ratios and analyzed by 0.8% (w/v) agarose gel electrophoresis. Lanes 1−5, pDNA with NLS-PEG_{5000}-acridine at weight ratios of 1:6, 1:4, 1:2, 1:1, and 2:1; lane 6, pDNA with NLS−peptide alone; lane 7, pDNA with PEG_{5000} alone; lane 8, pDNA with acridine alone; lane 9, pDNA with the mixture of NLS peptide, PEG_{5000}, and acridine; lane 10, pDNA alone as control.

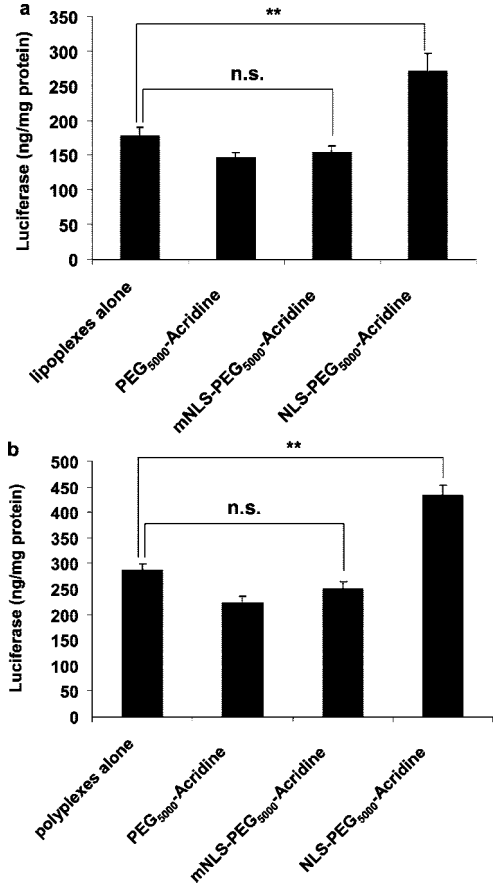

Figure 3. Sequence-specific enhancement of luciferase expression levels in bEnd.3 cells transfected by NLS−lipo- and polyplexes. bEnd.3 cells were transfected with different complexes containing 0.5 μg pDNA/well at pDNA/conjugate ratio 6:1 for 4 h at 37 °C in the presence of 10% FBS. The luciferase expression level and protein content were determined 40 h post-transfection. Results are presented as mean ± SEM ($n = 5$). **, $P < 0.01$; n.s., no significant difference.

Mountain View, CA) (*18*). Extracted DNA was resuspended in 1 mL of TE buffer and analyzed by fluorescence at λ_{ex} 576 nm/λ_{em} 597 nm. The experiment was performed in triplicate.

Cytotoxicity Assay. Cytotoxicity of NLS−conjugates and transfection complexes in bEnd.3 cell culture was evaluated by the thiazolyl blue tetrazolium bromide (MTT) assay as described previously (*19*). Briefly, bEnd.3 cells were seeded in a 96-well plate at initial density of 7×10^3 per well 24 h prior the assay. NLS−conjugates and transfection complexes were incubated with cells using transfection conditions. Then, 20 μL of the MTT solution (5 mg/mL) was added to each well, and formazan crystals were allowed to form for 4 h. The medium was carefully removed, and 200 μL of dimethylsulfoxide (DMSO) was added to each well. The plate was then incubated for 15 min at 37 °C, and the absorbance of formazan was measured at 570 nm using a model 680 microplate reader (Bio-Rad Laboratories, Hercules, CA). The experiments were performed in 5 parallels, and cell viability was calculated relative to that of untreated cells.

Table 1. Properties of NLS−Lipo- and Polyplexes

RESULTS

Synthesis and Characterization of NLS−Conjugates. Preliminary molecular modeling showed that conjugates of acridine 9-isothiocyanate with the generation 1.0 PA-dendrimer have proper dimensions and good fitting for intercalation in the double helix of DNA. To prepare NLS-PEG-acridine conjugates, we used heterofunctional maleimide-PEG-*N*-hydroxysuccinimide linkers of MW 900, 3400, and 5000 Da (Scheme 1). Initially, these linkers were modified with a large excess of generation 1.0 PA dendrimer. For fast product isolation, we used a significant difference between PEGylated products and reactants. All MAL-PEG-dendrimer conjugates were isolated by gel filtration, and then all three remaining primary amino groups were immediately modified with acridine 9-isothiocyanate. The MAL-PEG-acridine product was also purified by gel filtration and immediately introduced into reaction with the thiolated NLS peptide. Final NLS-PEG-acridine conjugates were isolated by reverse-phase HPLC using a C18 semipreparative column and extended gradient of the acetonitrile concentration. However, it was difficult to completely separate the NLS-PEG-acridine conjugates from corresponding PEG−acridine conjugates. On the basis of the amino acid analysis, an average yield at the last step was ca. 50%. The NLS-PEG-acridine and PEG−acridine conjugates eluted in one peak by analytical HPLC and could be easily separated from the free NLS peptide (peak 1, Figure 1A). A stronger retention of NLS−PEG conjugates of higher Mw was also observed. The characteristic mass distribution in the MALDI-TOF mass spectra confirmed the presence of overlapping PEG-acridine and NLS-PEG-acridine molecules in near-equimolar ratio. As an example, NLS-PEG_{5000}-acridine sample showed overlaying of two PEG-containing peaks with

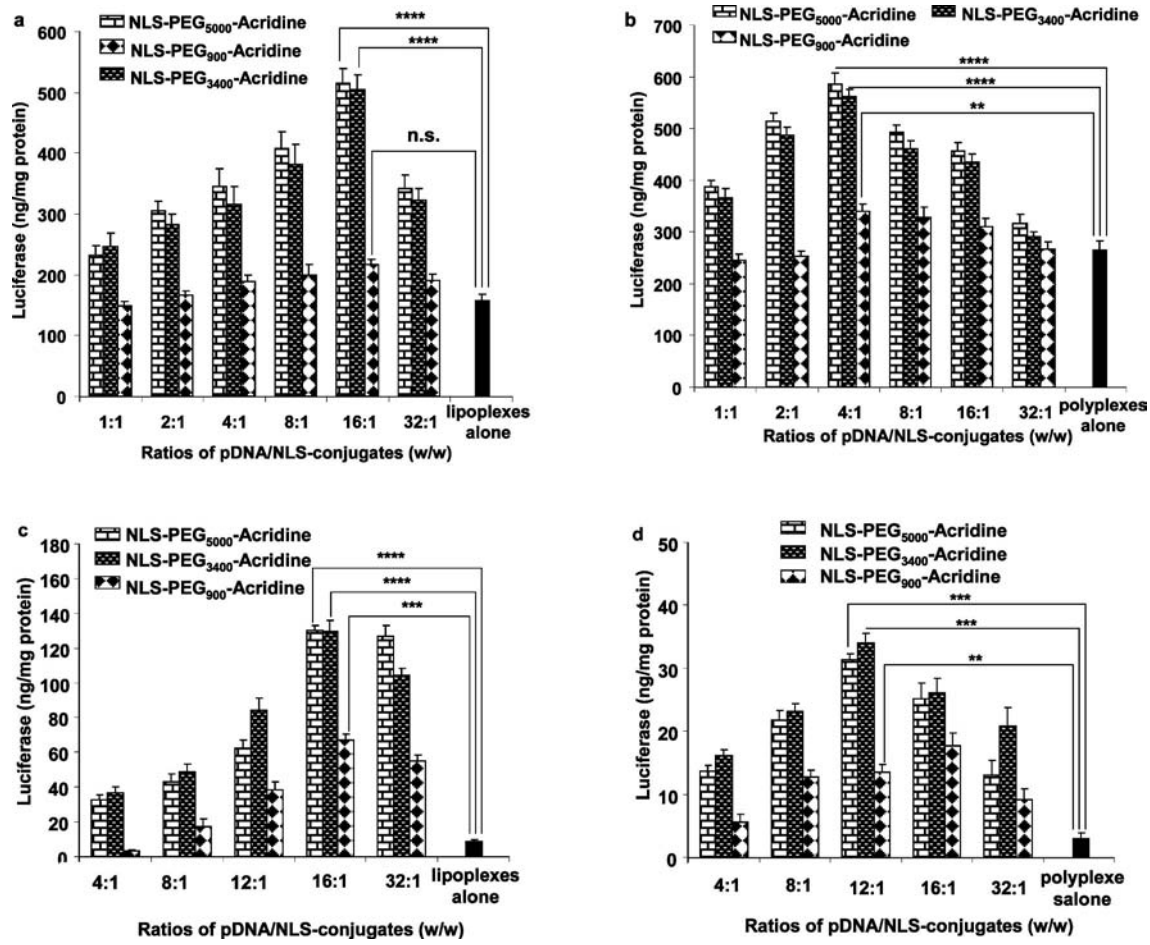

Figure 4. Optimization of the effect of NLS−conjugates on the luciferase expression in bEnd.3 cells transfected by lipo- and polyplexes. NLS−lipo- and polyplexes were prepared at optimized (a and b) and 1/3 lower (c and d) ratios of transfection reagents to pDNA. bEnd.3 cells were incubated with complexes containing 0.5 μg pDNA/well for 4 h at 37 °C in the presence of 10% FBS. The luciferase expression level and protein content were determined 40 h post-transfection. Results are presented as mean ± SEM ($n = 5$). **, $P < 0.01$; ***, $P < 0.005$; ****, $P < 0.0001$.

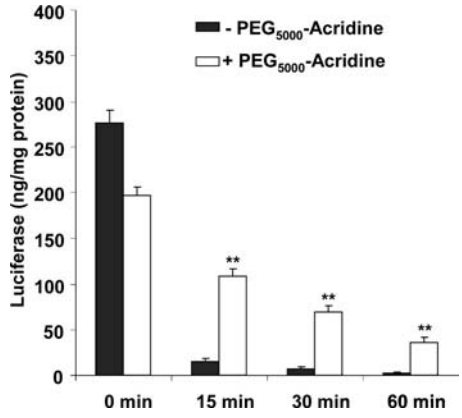

Figure 5. Protective effect of PEG molecules on the luciferase pDNA activity. Naked pDNA or pDNA complexed with PEG_{5000}−acridine conjugate at the ratio 6:1 was treated by DNase I (0.005 U/μg DNA) at 37 °C for different time periods. Exgen500 was then added to both mixtures, and they were used to transfect bEnd.3 cells for 4 h at 37 °C in the presence of 10% FBS. Results are presented as mean ± SEM ($n = 5$). (**, $P < 0.01$).

an average MW between 5900 and 7000 Da, corresponding to PEG_{5000}-acridine and NLS-PEG_{5000}-acridine conjugates, respectively, presented in the final product in nearly equal amounts (Figure 1D). By UV-spectrophotometric data, NLS-PEG-acridine conjugates contained the molar amounts of acridine that were close to values calculated for the corresponding tris(acridine) conjugates (Figure 1B). Finally, amino acid microanalysis after the total acidic hydrolysis of NLS-PEG-acridine conjugates demonstrated the presence of peptide with the correct amino acid content and provided the protein content that was used to calculate the NLS peptide derivatization degree. On the basis of these data, the total peptide content in the obtained NLS−conjugates was equal to 8−13% and equivalent to the NLS peptide derivatization degree of 40−54% (Figure 1C).

Binding of NLS−Conjugates to pDNA. The binding of NLS−conjugates with plasmid DNA was analyzed by the band shift assay using agarose electrophoresis. As shown in Figure 2, pDNA showed the first signs of retardation at pDNA to NLS-PEG_{5000}-acridine ratio 2:1 (wt) and, then, was efficiently retained in the wells at lower ratios. By contrast, individual NLS peptide, PEG, or acridine showed no influence on the pDNA mobility. These results suggest that only the binding of NLS-PEG_{5000}-acridine conjugate with pDNA resulted in the increase of total MW and steric hindrance of the intercalation complex and was observed as band retardation during electrophoresis. Similar results were obtained with NLS-PEG_{3400}-acridine and NLS-PEG_{900}-acridine, although at various weight ratios for all conjugates (data not shown).

Properties of NLS−Lipoplexes and NLS−Polyplexes. Intercalation complexes have been prepared by premixing of NLS−conjugates with pDNA, and following the short incubation, these complexes were mixed with Lipofectamine2000 or Exgen500 at optimized ratios recommended by manufacturers. Compared to plain lipo- and polyplexes, NLS−lipo- and NLS−polyplexes demonstrated slightly increased particle size and decreased surface charge (Table 1). Introduction of

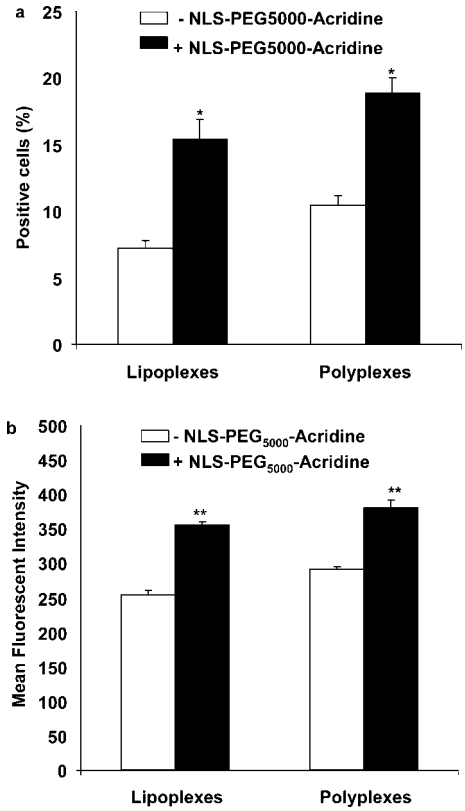

Figure 6. Enhancement of transfection efficiency and GFP expression levels in bEnd.3 cells in the presence of NLS-PEG_{5000}-acridine conjugate. Cells were treated in 6-well plates with NLS−lipo- and polyplexes containing 3 μg of the green fluorescent protein pDNA for 4 h at 37 °C. 40 h later, cells were trypsinized and analyzed by flow cytometry. Results are presented as mean ± SEM ($n = 3$). *, $P < 0.05$; **, $P < 0.01$.

NLS−conjugates in lipo- and polyplexes practically did not affect protection of encapsulated pDNA against enzymatic degradation at conditions when free pDNA was completely digested (Figure S1, Supporting Information).

The intrinsic cytotoxicity of NLS−conjugates was very low ($IC_{50} = 5-7$ mg/mL at 24 h incubation) and did not enhance the cytotoxicity of lipoplexes and polyplexes incubated with bEnd.3 cells. As shown in Figure S2 (Supporting Information), the cytotoxicity of plain lipoplexes at the optimized ratio of transfection reagent to DNA was generally higher than that of polyplexes; NLS−lipoplexes and polyplexes followed the same trend.

In Vitro Transfection. bEnd.3 cells were transfected by lipoplexes or polyplexes in the presence of 10% serum. First, the capability of NLS−conjugate to improve the transgene expression was investigated. NLS-PEG_{5000}-acridine significantly enhanced luciferase expression by lipoplex (Figure 3a) and polyplex transfection (Figure 3b) ($P < 0.01$). On the contrary, no or a slight decrease in transfection was observed when pDNA was coupled with PEG_{5000}−acridine or mNLS-PEG_{5000}-acridine before complexation with transfection reagents. The influence of various NLS−conjugates and different pDNA/conjugate ratios on lipoplex and polyplex-mediated luciferase transgene expression is illustrated in Figure 4. At the optimized ratio of Lipofectamine2000 to pDNA, the highest luciferase expression level was observed at the ratio of pDNA to NLS-PEG_{5000}-acridine of 16:1 (w/w) (Figure 4a). The NLS-PEG_{3400}-acridine conjugate showed a very similar enhancing effect. However, further reduction of the PEG length resulted in lower or no enhancement as indicated for NLS-PEG_{900}-acridine conjugate. At a 33% lower ratio of Lipofectamine2000 to pDNA, the observed comparative transfection increase for NLS−lipoplexes over plain lipoplexes was even more significant ($P < 0.0001$) (Figure 4c). The addition of NLS-PEG_{5000}-acridine, NLS-PEG_{3400}-acridine, and NLS-PEG_{900}-acridine to lipoplexes resulted in 15-, 15-, and 8-fold increases of the luciferase expression, respectively. In terms of polyplexes, NLS−conjugates also displayed a very strong effect on transfection (Figure 4b,d). At the optimized ratio of Exgen500 to pDNA, the highest luciferase expression level was observed at the pDNA to NLS-PEG_{5000}-acridine ratio 4:1 (w/w) (Figure 4b). At the 33% lower ratio, the improving effect of NLS-PEG-acridine conjugates also becomes more evident (Figure 4d). Application of NLS-PEG_{5000}-acridine, NLS-PEG_{3400}-acridine, and NLS-PEG_{900}-acridine resulted in 11-, 11-, and 6- fold increase of the luciferase expression, respectively. The pDNA dose dependence was determined at fixed optimal ratios for both NLS−lipoplexes and polyplexes (Figure S3, Supporting Information). Our results demonstrated that the highest transfection level could be achieved at pDNA doses used in the study, and the transgene expression began to drop at higher doses, evidently, because of the toxicity of transfection agents.

The protective role of bulk PEG chains on the resistance of the pDNA/PEG_{5000}−acridine complex to enzymatic hydrolysis was illustrated by the luciferase expression functional test. The complexed luciferase-encoded pDNA was primarily treated with DNase I and then mixed with Exgen500. Comparative results of the bEnd.3 cell transfection by the protected and naked DNA treated with DNase I are shown in Figure 5. Tremendous loss of transfection activity of the naked pDNA was observed after the enzymatic digestion, resulting in the complete disappearance 30 min post-treatment. By contrast, the pDNA/PEG−acridine complex was much more stable, and 20% luciferase activity still remained after 60 min of incubation.

Flow Cytometry Assay. Since NLS-PEG_{5000}-acridine demonstrated the strongest enhancing effect, we quantitatively studied transfection efficiency and GFP expression levels for NLS−lipoplexes and polyplexes by flow cytometry. Our flow cytometry results showed that NLS-PEG_{5000}-acridine could enhance both GFP transfection efficiency and GFP expression. Specifically, we observed a stronger effect on transfection efficiency (2.13- and 1.81-fold enhancement) than on the GFP expression level (1.40- and 1.31-fold enhancement) for lipoplexes and polyplexes, respectively ($P < 0.01$; Figure 6a,b).

Subcellular Localization of pDNA. Effect of NLS-PEG_{5000}-acridine on the nuclear accumulation of rhodamine-labeled pDNA in bEnd.3 cells was studied 24 h post-transfection (Figure 7). Using confocal microscopy, we observed only a limited amount of rhodamine-labeled pDNA in the nuclei and perinuclear area following the transfection by lipoplexes or polyplexes (Figure 7A,D). In contrast, cells transfected by NLS−lipoplexes or polyplexes showed much more pDNA delivered inside the nuclei and in the perinuclear area (Figure 7B,E). Similar results were obtained with NLS-PEG_{3400}-acridine and NLS-PEG_{900}-acridine conjugates for both types of transfection complexes (data not shown). The lateral confocal images clearly demonstrate efficient penetration of the rhodamine-labeled DNA into the nuclei (Figure 7C,F).

For direct evaluation of nuclear accumulation of rhodamine-labeled pDNA following the polyfection, total nuclear DNA was extracted from the isolated nuclei of transfected cells and its fluorescence intensity was determined. As shown in Figure 7G, NLS-PEG_{5000}-acridine polyplex enhanced nuclear accumulation of pDNA by almost 2-fold compared with plain

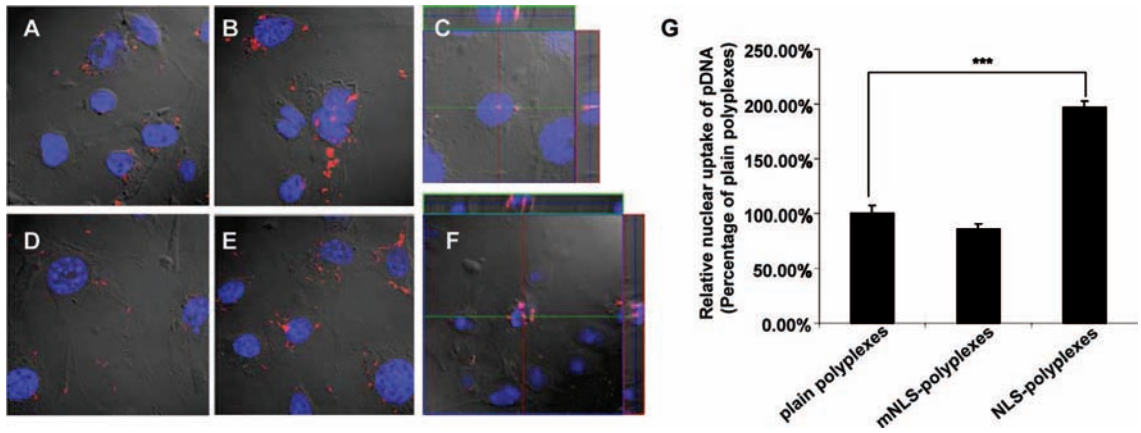

Figure 7. Enhanced intracellular and nuclear accumulation of rhodamine-labeled pDNA following the transfection of bEnd.3 cells with NLS−lipo- and polyplexes. Confocal microscopy images of bEnd.3 cells 24 h post-transfection by pDNA complexed with NLS-PEG_{5000}-acridine conjugate (6:1) at optimal transfection agent ratios in the presence of 10% FBS. After fixation, the cells were imaged using laser scanning confocal microscope. Panes A,D show lipo- and polyplexes without NLS−conjugates, respectively. NLS−poly- and lipoplexes are shown in panes B,E in regular mode, respectively, and in lateral mode in panes C,F, respectively. (G) Accumulation of rhodamine-labeled pDNA in nuclei 24 h following transfection of bEnd.3 cells by plain or NLS−polyplexes. The fluorescence of isolated nuclear DNA following transfection with plain polyplex was taken for 100%. ***, $P < 0.005$.

polyplexes ($P < 0.05$), while the corresponding mutant mNLS−polyplex showed no enhancement effect.

DISCUSSION

Efficient nuclear delivery of plasmid DNA is one of major requirements for successful nonviral transfection. Different approaches have been explored to increase nuclear accumulation including association of DNA with hydrophobic molecules (*20*), engineered histone H2B (*21*), and adenovirus hexon protein (*22*), but without a notable success. Application of NLS peptides and cellular machinery for transporting nuclear proteins was shown to be a very promising approach, although many experiments resulted in only limited success. The major problem is the size of the nuclear pores, which is restrictive to molecules larger than 23 nm in diameter. Only direct attachment of NLS peptide to pDNA, not affecting its expression activity, demonstrated positive effects, while condensing the DNA with NLS-modified carriers usually had no effect on transfection (*11*). The second decisive factor is stability of pDNA in cytoplasm. Fast degradation of pDNA by cytosolic nucleases, following its release from lipo- or polyplex, and lower mobility of free pDNA in cytoplasm can be additional reasons for the rapid loss of transfection activity. In addition, finally, in slowly dividing cells pDNA has a lower chance to internalize in the nuclei during mitosis, which is probably the major way for the carrier-associated DNA to efficiently penetrate nuclei.

In this study, we demonstrated that noncovalent modification of pDNA by PEG−tris(acridine) conjugates of NLS peptide could significantly enhance nuclear accumulation and transgene expression in slowly dividing cells following the lipoplex or polyplex-mediated transfection. Acridine-based intercalating agents tightly bind double-stranded DNA ($K_d < 10^{-9}$ M), and no sequence specificity is required for this process (*23, 24*). Previously, we demonstrated that modification of oligonucleotides with acridine 9-isothiocyanate strongly enhanced their antisense activity (*25*). Recent data on NLS-polypeptide-acridine constructs confirmed that acridines as anchor molecules for noncovalent, strong, and reversible binding of NLS peptide to pDNA could be an inexpensive alternative to PNA clamps (*16*). Here, we constructed novel intercalating conjugates based on the generation 1.0 PA dendrimer linked to three acridine molecules and one NLS peptide via a PEG linker. This scheme allowed us to find an appropriate distance between the peptide and tris(acridine) anchor to achieve an efficient pDNA protection and in vitro transfection by lipo- and polyplexes. Previously, Boulanger et al. reported that, when the distance between NLS peptide and anchor molecule was shorter than 20 methylene groups, NLS−conjugates showed no enhancing effect on transfection ability of lipo- and polyplexes in vitro (*15*). Our results demonstrated that the NLS-PEG-acridine conjugates with longer PEG linkers (PEG_{5000} and PEG_{3400}) showed rather similar high transfection enhancement, while the effect of shorter PEG linker with 40 methylene groups was much lower. Our data showed that the optimal MW requirement for the PEG linker is close to 3000 Da. Evidently, a sufficiently long PEG linker can facilitate the NLS peptide recognition by nuclear transport proteins, such as importins.

Since high PEG density may potentially affect the cellular binding of transfection complexes, reducing transfection efficiency, the amount of NLS conjugates used in transfection was optimized at two constant weight ratios of transfection agent to pDNA. A significant increase was observed at the higher optimized weight ratios recommended for both agents by manufacturers (Figure 4a,b), although the highest differences could be observed at the 33% lower weight ratios ($P < 0.0001$, Figure 4c,d). The strong positive charge of transfection complexes is the major factor that determines cellular uptake and endosomal escape of pDNA in vitro. In our conditions, at the optimized ratios of transfection agents to pDNA, cellular capacity to internalize and express large amounts of exogenous DNA can already be at saturation. The effect of nuclear targeting on the transgene expression may be hidden in these conditions. This conclusion is partially confirmed by the transfection dose dependence results, where both lipoplexes and polyplexes at fixed ratios of NLS−conjugate to pDNA and transfection agents to pDNA demonstrated a bell-shaped dependence on the pDNA dose, and maximum luciferase expression was observed at the dose 0.5 μg per well used in transfection experiments (Supporting Information Figure S3). Thus, our results at the higher ratio are obtained at nearly maximum transfection level for the used number of bEnd.3 cells. By contrast, at the 33% lower weight ratio, the number of internalized pDNA molecules was reduced and the effect of NLS-promoted nuclear accumulation became more evident. Very low amounts of NLS conjugates were required to obtain a significant accumulation of pDNA, 1/16 and 1/4 of the pDNA weight for lipoplexes and polyplexes, respectively. Calculations of the optimal number of peptide molecules per pDNA molecule give us 4−5 NLS peptides for

lipoplexes and 16−20 NLS peptides for polyplexes. It is interesting to note that, at the lower amount of Exgen500 in polyplexes, optimal pDNA to NLS conjugates weight ratio also dropped to 12:1, corresponding to 5−7 NLS peptides per pDNA. Evidently, an average minimal amount of 5−6 NLS peptides is generally sufficient for efficient delivery of pDNA molecule into the nuclei. On the contrary, equal amounts of the PEG_{5000}−acridine conjugate did not result in any enhancement and even suppressed the transfection. In control experiments with the PEG_{5000}−acridine conjugate, containing a mutant NLS peptide with point mutation (Lys→Thr), the luciferase expression level was even slightly lower compared to plain polyplexes (Figure 3). These results indicated that observed improvements of transgene expression were caused by sequence-specific active nuclear transport rather than by beneficial effect of the cationic peptide sequence.

Under transfection efficiency is usually mentioned the ability to transfect a certain number of cells, while transgene expression level typically shows how efficient the pDNA expression is within the cell. Successful nuclear entry and subsequent expression of only one copy of pDNA may result in the GFP-derived fluorescence and change the cell count from negative to positive. Efficient degradation of internalized exogenous pDNA can be a cause of the observed differences. At equally effective cellular uptake of transfection complexes, pDNA protected by the PEG coating has a better chance to remain intact in the cytoplasm and eventually be delivered to the nuclei. Previously, nucleolytic degradation of pDNA in the cytoplasm was recognized as another barrier to efficient nonviral transfection (*26*). PEGylation is one of the successful approaches to protect protein therapeutics from enzymatic degradation and hydrolysis (*27*). Here, we investigated the protective effect of PEG coating of pDNA against DNase digestion. Evidently, a sufficient amount of attached PEG molecules along with the optimal number of NLS peptide-modified PEG molecules via intercalation strategy can form a protective PEG layer that should considerably shield pDNA from interaction with cytosolic nucleases following its release from lipo- and polyplexes. Our results demonstrated a longer persistence of functional pDNA following the treatment with DNase I for NLS-PEG-acridine conjugate-modified pDNA vs naked pDNA (Figure 5).

Our confocal microscopy results qualitatively demonstrated better cellular persistence and nuclear incorporation of NLS-PEG-acridine conjugate-modified fluorescent pDNA; a significant pDNA accumulation was observed also in perinuclear regions after lipo- or polyplex-mediated transfection (Figure 7B,E). In the nuclear incorporation studies, fluorescent pDNA was observed in the form of red dots rather than in the form of diffuse staining. This is consistent with previous reports, which showed the similar punctuated signals for nuclear-imported pDNA (*28, 29*). The diffuse fluorescent signals observed in earlier experiments could be caused by degraded DNA (*30*). However, the confocal pictures are insufficient for quantitative evaluation of nuclear accumulation of pDNA and explanation of all these observed improvements in the expression of luciferase-encoded pDNA. The direct isolation and quantitation of fluorescent pDNA from the nuclei of transfected cells strongly suggested that NLS−conjugate could significantly ($P < 0.005$) improve nuclear transport of exogenous pDNA in comparative polyplex transfection experiments, while mutant NLS-modified and nonmodified conjugates did not affect the nuclear accumulation compared to naked DNA (Figure 7G).

Safety is another important issue in the development of gene delivery systems. The NLS-PEG-acridine conjugates showed very low cytotoxicity and at the concentrations used had no effect on the summary cytotoxicity of lipoplexes and polyplexes (Supporting Information Figure S3). Additionally, application of the lower amount of transfection agent together with enhancing NLS−conjugates potentially can significantly reduce toxicity of lipo- and polyplexes without compromising high levels of the achieved nonviral transfection.

In conclusion, the present study demonstrated that the novel NLS-PEG-acridine conjugates could effectively increase nuclear accumulation of pDNA and transgene expression levels at the lipoplex- or polyplex-mediated transfection of slowly dividing cells such as BCEC in the presence of serum. Therefore, these conjugates can be used as potential components for development of nonviral gene delivery systems for systemic applications. This general approach can also be applied to the attachment of other modifying or targeting peptides to further enhance gene delivery to specific cells in vivo and penetration across cellular barriers hampering application of nonviral transfection strategies.

Synthesis and Evaluation of Multivalent Branched HPMA Copolymer−Fab′ Conjugates Targeted to the B-Cell Antigen CD20

Russell N. Johnson,[†] Pavla Kopečková,[‡] and Jindřich Kopeček*[,†,‡]

Departments of Bioengineering, and Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84112. Received August 15, 2008; Revised Manuscript Received September 26, 2008

Several drug delivery designs combine synthetic drug carriers with covalently conjugated targeting moieties. Such modifications of monoclonal antibodies (mAb), or their Fab′ fragments, inevitably result in diminished affinity for their targeted tissue. In an attempt to overcome this limitation, high molecular weight, branched *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymers were synthesized and conjugated with Fab′ fragments of the anti-CD20 antibody, 1F5. This produced multivalent conjugates with varying valency (amount of Fab′ per macromolecule) targeted to the B-cell antigen CD20. Evaluation of a multivalent effect was done by determining the apparent K_D at low concentrations of conjugates, the Sips heterogeneity factor, *a*, and the binding enhancement factors of each construct. The results clearly indicated that multivalency could improve the affinity of the HPMA copolymer−Fab′ conjugates to that of unconjugated mAb.

INTRODUCTION

A central tenet of modern drug delivery is to increase the concentration of drug in diseased tissues, while limiting its systemic exposure (*1, 2*). This translates to increased therapeutic efficiency and reduced side effects. Increasing concentrations in diseased tissues can be challenging and has been addressed through both synthetic (*3*−*5*) and biological approaches (*6, 7*). Several studies have combined high-affinity targeting moieties and high molecular weight drug carriers to confer tissue specificity and enhanced bioactivity to polymer−drug conjugates (*8*−*12*). However, covalent modification of targeting moieties resulted in diminished affinity (*13*). Multivalent conjugate designs were one approach that improved the specificity of the construct (*14*). Successful studies have demonstrated that multivalent carbohydrates (*15*), peptides (*16*), or other small molecules (*17*) can enhance binding affinity to targeted tissue. Other larger and more specific molecules such as monoclonal antibodies and Fab′ have only been rarely used in such approaches. In this study, we synthesized a high molecular weight soluble polymer that is able to accommodate multiple Fab′ fragments to produce a multivalent drug carrier. Furthermore, we demonstrated the effects of multivalent and multimeric binding of our constructs to the B-cell antigen CD20 in experiments using whole cells.

The soluble polymer poly[*N*-(2-hydroxypropyl)methacrylamide] (pHPMA) is inert and biocompatible (*18, 19*). It has been used extensively as an anticancer drug delivery platform that is able to improve the physicochemical and pharmacokinetic properties of the polymer−drug conjugates by increasing circulating half-life, increasing the solubility of hydrophobic drugs, affecting passive accumulation in solid tumors, and providing the potential to evade multidrug resistance mediated by efflux pumps (*18, 20*). A number of studies have developed methods of HPMA copolymer synthesis that create high molecular weight, branched copolymers that are soluble in water (*21, 22*). Similar HPMA copolymers were used to create multivalent conjugates using anti-CD20 Fab′ antibody fragments.

As with any well-designed drug delivery system, the biological target is of critical importance. CD20 is a reliable B-cell marker that is highly expressed on normal and malignant B-cell populations (*23, 24*) and has been successfully used as a target with the first FDA-approved monoclonal antibody, Rituximab (*25, 26*). CD20 is a 33−37 kDa, integral membrane receptor that forms dimers and tetramers in the cell membrane (*27, 28*). In the absence of a known ligand, there is remarkable diversity of epitopes among anti-CD20 mAb clones. The most studied and best characterized clones include Rituximab, B1, 2H7, and 1F5 (*29*). Our study utilized 1F5, which has a dissociation constant (K_D) between 20 and 30 nM (*30*), while the K_D for Rituximab is around 4 nM (*31*). Rituximab and 1F5 bind distinct epitopes on CD20 (*32, 33*). Notably, cross-linking certain CD20-ligated mAb, including 1F5, with secondary antibodies (generally goat-antimouse Ab) can induce apoptosis (*34, 35*). This fact has clinical relevance for Rituximab. Its activity is partially attributed to ligated Rituximab becoming cross-linked by effector cells. Cross-linking, in turn, induces antibody-dependent cell-mediated cytotoxicity (ADCC). However, a full response to Rituximab requires a high-affinity allele of an Fc receptor on effector cells (FcγRIIIa). Patients that are not homozygous for the allele have diminished responses (*36*). Recent studies have shown that multivalent Rituximab constructs are able to effectively induce apoptosis independent of effector cells (*37, 38*).

A construct that is able to elicit apoptosis without the need to be internalized by a cell has clinical relevance. Such a construct could be used in a therapeutic regimen such as those used in either Bexxar (*39*) or Zevalin (*40*), where anti-CD20 constructs and radioimmunotherapeutics could be given in combination to treat refractory disease. The multivalent construct would induce apoptosis independent of effector cells, and the radioimmunotherapeutic could synergistically eliminate neighboring malignant cell populations which may not express CD20 via a bystander effect.

In this study, several multivalent HPMA copolymer−(anti-CD20) Fab′ conjugates were designed and synthesized. The conjugates varied in the amount of Fab′ per polymer chain to allow studies that could determine the effect of a conjugate's

valence on binding to B-cell antigen CD20. The apparent K_D at low concentrations of conjugates, the Sips heterogeneity factor, and the affinity enhancement factors of each construct were determined.

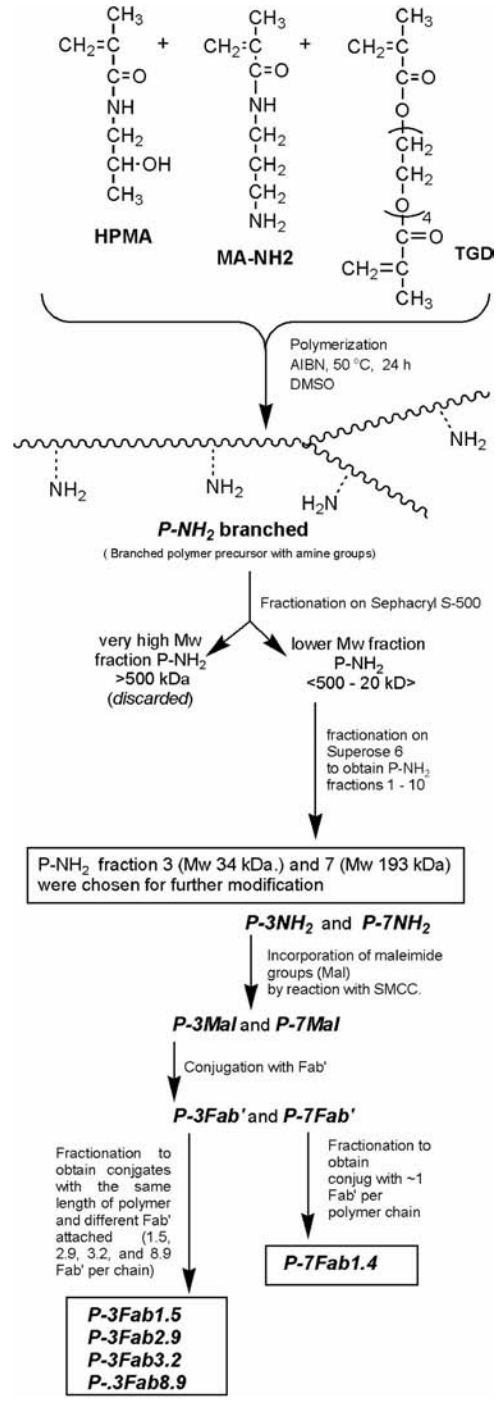
EXPERIMENTAL PROCEDURES

Materials. Chemicals and solvents used were of reagent grade or better unless otherwise stated. *N*-(2-Hydroxypropyl)methacrylamide (HPMA) was prepared as previously described (*41*). *N*-(3-Aminopropyl)methacrylamide hydrochloride (AMA) was purchased from Polysciences (Warrington, PA). Succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC) was purchased from Soltec Ventures (Beverly, MA). Tris(2-carboxyethyl) phosphine hydrochloride (TCEP) and Iodogen tubes were purchased form Thermo Scientific (Waltham, MA). Tetraethylene glycol dimethacrylate (TGD), phthalic dicarboxaldehyde (OPA), and 3-mercaptopropionic acid (MPA) were purchased from Sigma Aldrich (St. Louis, MO). Carrier free radionuclide sodium iodide-125 was purchased from Perkin-Elmer (Waltham, MA).

Cell Lines, Hybridomas, Fab′ Fragment Preparation. Human Burkitt's B-cell non-Hodgkin's lymphoma Raji cells (ATCC, Bethesda, MD) were cultured in RPMI-1640 medium (Sigma, St. Louis, MO) supplemented with 10% fetal bovine serum (Hyclone, Logan, UT). Cells were grown at 37 °C in a humidified atmosphere of 5% CO_2 (v/v). All experiments were performed using cells in exponential growth. The anti-CD20 hybridoma clone 1F5 (ATCC, Bethesda, MD) was initially cultured and recloned through limiting dilution in RPMI 1640 supplemented with 10% FBS in a humidified environment with 5% CO_2 in air (*42*). The selected clone was adapted to chemically defined, serum-free media (Invitrogen, Carlsbad, CA). Adapted cells were used to seed a CellMax bioreactor (Spectrum Laboratories, Rancho Dominguez, CA) according to the manufacturer's instructions. Anti-CD20 mAb was purified on a Protein G Sepharose 4 Fast Flow column (GE Healthcare, Piscataway, NJ) from bioreactor harvest supernatant. Whole IgG_{2a} was digested into $F(ab')_2$ with lysyl endopeptidase (Wako Chemicals USA, Richmond, VA) following the protocol of Fowers et al. (*43*). Purity of harvested IgG_{2a} and digested $F(ab')_2$ were shown to be >95% by SDS-PAGE and SEC (size exclusion chromatography). Immediately prior to using, 5 mg/mL of $F(ab')_2$ was reduced to Fab′ with 4 mM TCEP in 0.1 M phosphate buffer (pH 6.5) at room temperature for 30 min.

Preparation of Multivalent Conjugates. The synthesis of copolymers, their fractionation, polymeranalogous modification with SMCC, Fab′ binding, and fractionation of the conjugates are depicted in Scheme 1. The HPMA copolymer containing side chains terminated in NH_2 groups (*P-NH₂*) was prepared by radical polymerization using AIBN as the initiator. Briefly, HPMA (658.7 mg, 93 mol %), AMA (53.6 mg, 6 mol %), TGD (16.5 mg, 1 mol %), and AIBN (3.4 mg) were dissolved in 2.9 g of DMSO. After mixing, the polymerization solution was bubbled with argon, sealed in a glass ampule, and then incubated at 50 °C for 24 h. After polymerization, the HPMA copolymer was precipitated and washed in acetone, and then washed with diethyl ether. The precipitate was dried, dissolved in H_2O, and dialyzed against distilled water using dialysis tubing with a molecular weight cutoff of 12−14 kDa (Spectrum Laboratories, Rancho Dominguez, CA) to remove any unreacted monomers. The polymer was then lyophilized, dissolved in PBS, and fractionated on a Sephacryl S-500 preparative column (GE Healthcare, Piscataway, NJ) to produce two fractions. The fraction with the very high molecular weight was discarded; the fraction with an upper limit of Mw ∼500 kDa was fractionated a second time on a Superose 6 HR16/60 preparative column (GE Healthcare, Piscataway, NJ) to produce a molecular weight "ladder" of ten fractions. Two fractions (*P-7NH₂*: 34 kDa, 5.5 mol % NH_2, yield 2.7 wt %; and *P-3NH₂*: 193 kDa, 5.5 mol % NH_2, yield 18 wt %) were selected for the synthesis of conjugates. The fractions *P-3NH₂* and *P-7NH₂* were dialyzed against water and then lyophilized. The molecular weight averages were estimated using size-exclusion chromatography on an analytical Superose 6 column (GE Healthcare, Piscataway, NJ). All SEC was done using an ÄKTA FPLC system (GE Healthcare, Piscataway, NJ).

Scheme 1. Synthesis of Multivalent HPMA Copolymer−Fab′ Conjugates Targeted to the B-Cell Antigen CD20



Polymeranalogous Conversion of Pendant Amine Groups into Maleimide Groups. The fractions *P-3NH₂* and *P-7NH₂* (*P-3NH₂*: 37 mg, 22.5 μmol $-NH_2$; *P-7NH₂*: 6 mg, 3.6 μmol $-NH_2$) were reacted with excess SMCC (14.4 mg, 45.6 μmol; 2.4 mg, 7.2 μmol, respectively) in dry DMF under basic

conditions (DIPEA: 26 μL, 72 μmol; 2.1 μL, 12 μmol, respectively) to generate pendant maleimide groups. The activated precursor was precipitated into an excess of acetone, filtered, and washed with ether to remove free SMCC. The conversion of amine groups into maleimide on the polymer proceeded with ~72% to 75% conversion, as determined by modified Ellman's assay. The products *P-3Mal* and *P-7Mal* were then conjugated with reduced 1F5 Fab′ fragments as previously described (*13*). Briefly, approximately 5 mg of either *P-3Mal* or *P-7Mal* (~2.3 μmol maleimide) was dissolved in 50 μL of DMF. Then, 10 mg of Fab′ (0.2 μmol) in 2 mL of PBS (pH 6.5) was added to the reaction, and the solution was mixed overnight at room temperature. The products were fractionated (and unbound Fab′ removed) on a size-exclusion S6 preparative column HR 16/60. HPMA copolymer−Fab′ conjugates containing different amounts of Fab′ per macromolecule, *P-3Fab1.5*, *P-3Fab2.9*, *P-3Fab3.2*, *P-3Fab8.9*, and *P-7Fab1.4*, were isolated and characterized. In these abbreviations, the number following Fab′ indicated the amount of Fab′ fragments per macromolecule.

Effective Diameter of HPMA Copolymer−Fab′ Conjugates. The effective diameter for fractions of HPMA copolymer−Fab′ conjugates was evaluated by dynamic light scattering (Brookhaven Scientific Instruments, Holtsville) in PBS at a concentration of at least 1 mg/mL. Prior to analysis, the solution containing conjugates were filtered through a 0.45 μm filter. In addition to the effective diameter, dynamic light scattering (DLS) also calculated the distribution of size, referred to as the polydispersity index (PDI), which differs from molecular weight polydispersity (M_w/M_n). DLS PDI values greater than 0.2 are considered to be heterogeneous, and those below 0.2 are considered homogeneous. The effective diameter of whole Ab served as a positive control with both effective diameters (measured 13.6 nM, literature 14.3) and PDI values (0.06 measured, literature 0.05) compared well with published values (*44*).

Determination of Fab′ Content per Polymer Chain. The composition of the conjugates, the ratio of protein to polymer, was determined in one step by amino acid analysis. This method enabled measurement of, after acid hydrolysis, both individual amino acids from Fab′ as well as 1-amino-2-propanol released from HPMA monomer units. Calibration was done using free 1F5 Fab′ and HPMA homopolymer. A small amount (>3 mg) of Fab′, homopolymer, or conjugate was dissolved in 6 N HCl in a small ampule, bubbled with nitrogen for 5 min, and then the ampule was sealed. The solution was incubated at 125 °C for 24 h, the ampule was opened, and the hydrolyzed product was dried in vacuo. Hydrolyzed products were dissolved in dH_2O, and then derivatized with OPA and MPA prior to being analyzed on a HPLC with an eclipse XDB-C8 column (Agilent, Santa Clara, CA). Fab′ concentration was calibrated with a peak produced by hydrolyzed glutamate, which had an elution time of 9.4 min. Poly(HPMA) concentration was calibrated with a peak produced by 1-amino-2-propanol, which had a retention time of 23.9 min.

Iodination of Fab′ and Multivalent Fab′ Constructs. Reduced anti-CD20 Fab′, anti-CD20 HPMA copolymer−Fab′ conjugates, and whole antiCD20 IgG molecules were labeled with $Na^{125}I$ using Iodo-Gen tubes as previously described (*13*). Approximately 300 μg of Fab′ or IgG in 0.3 mL PBS was added to a glass vial coated with 4 μg of Iodo-Gen, followed by 0.5 mCi of $Na^{125}I$. After the solution was incubated (and shaken) at room temperature for 7 min, ^{125}I-labeled protein was separated from free ^{125}I by passing the reaction mixture over a PD-10 desalting column (GE Healthcare, Piscataway, NJ). The labeled molecules were stored at 4 °C in PBS. The specific radioactivity of each conjugate was between 0.7 and 1.5 μCi/μg.

Binding Experiments. Raji cells grown in RPMI containing 10% FBS were washed twice with HBSS. The cells were adjusted to 4×10^6 cells/mL and split into two volumes. To one of the volumes of Raji cells, unlabeled anti-CD20 IgG was added to a final concentration of 500 nM to block CD20 for a negative control. Serial dilutions of ^{125}I-labeled anti-CD20 IgG, Fab′, and multivalent Fab′ conjugates were made from 2000 nM to 1 nM of Fab′ fragment concentration. Millipore 96-well filter plates, coated with a 1% solution of nonfat dry milk in distilled water and incubated at 4 °C overnight, were washed with HBSS. For each of the serial dilutions, 25 μL of negative control cells were added to a single well, and 25 μL of unblocked cells were added to three different wells; then, 25 μL of the respective dilutions were added to each well. The filter-well plates were incubated for 90 min at 120 rpm on a shaker at 25 °C. Following incubation, the Raji cells were washed twice with 200 μL of cold HBSS with 10% FBS, and then collected on filters. The filters were allowed to air-dry, removed from the plate, and counted. Negative control wells were used to correct for nonspecific binding.

The equilibrium binding was evaluated using either single-site binding parameters (eq 1) or the Sips equation (eq 2) using *Sigma Plot* (Systat Software, San Jose, CA). Data was also drafted in Scatchard plots.

$$B = \frac{B_{max} F}{K_D + F} \tag{1}$$

$$B = \frac{B_{max}\left(\frac{1}{K_D} F\right)^a}{1 + \left(\frac{1}{K_D} F\right)^a} \tag{2}$$

where B is the concentration of bound ligand, F is the concentration of free ligand, B_{max} is the theoretical limit of bound ligand, K_D is the dissociation constant, and a is the Sips heterogeneity factor. When a is equal to 1, the Sips equation simplifies to the single-site binding equation.

RESULTS

Synthesis of Multivalent Conjugates. Copolymerization of HPMA with a small amount of the cross-linker TGD, at conditions below the gel point, yielded an HPMA copolymer with broadly distributed molecular weight that ranged from 20 kDa to greater than 1000 kDa (Scheme 1). The yield of this polymerization reaction was 69%, with a reproducible molecular weight profile after three separate polymerization experiments. Macromolecules with a molecular weight higher than 500 kDa were removed by fractionation on a SEC column. The fraction containing macromolecules with M < 500 kDa (45% by weight of original copolymer) was used to build a molecular weight "ladder" with narrowly disperse molecular weights by a second fractionation. The amine content of these fractions was 5.5 mol %. Two of the fractions, *P-3NH*$_2$ (Mw =193 kDa) and *P-7NH*$_2$ (Mw = 34 kDa), were selected for the use in conjugate synthesis and were activated by a reaction with SMCC. The maleimide content in polymer precursors *P-3Mal* and *P-7Mal* was 4.1 mol %.

Reduced Fab′ fragments of the anti-CD20 mAb were conjugated to polymer precursors *P-3Mal* and *P-7Mal* via thioether bonds in an overnight reaction. The *P-3Fab′* conjugate was fractionated on a SEC column to provide fractions with different amounts of bound Fab′ fragments per macromolecule. The free (unbound) Fab′ could be easily separated from the conjugate fractions (Figure 1). However, only a single fraction was isolated from the *P-7Fab′* conjugate (data not shown). The fractions are referred to by the fraction number (e.g. *P-3* or *P-7*) and by the

number of Fab′ fragments per polymer chain as determined by modified amino acid analysis (e.g., *P-3Fab′8.9*).

Determination of Valence. A modified amino acid analysis protocol was used to determine the Fab′ per polymer chain or valence of each fraction. The method cleaved 1-amino-2-propanol from the HPMA monomer units. Following derivatization with OPA and MPA, the 1-amino-2-propanol related peak was well-separated from Fab′-associated amino acid peaks. It is important to note that the analysis determined the average valence, which is dependent on the polydispersity of the conjugate fraction. The polydispersity within each conjugate fraction was not determined in this study, but the elution volumes for each fraction were sufficiently small to guarantee a low polydispersity (1.2−1.3).

Amino acid analysis demonstrated that Fab′ "loading" was responsible for the broadened FPLC profile of the conjugates as seen in Figure 1. The fractions of *P-3* conjugate with the highest valence of 8.9 Fab′/chain eluted first. The *P-3* fraction with the lowest valence *P-3Fab1.5* eluted last. Determination of valence also confirmed that Fab′ loading was directly related to the size of the polymeric precursor. After conjugation, the larger polymer fraction *P-3* had a broad distribution of Fab′ per chain with a median valence of ∼3 Fab′/chain, while the fraction *P*-7 (Mw 34 kDa) had an average valence of 1.4 Fab′ per polymer chain (Table 1).

Analysis of the effective diameters of HPMA copolymer−Fab′ conjugates by DLS demonstrated that Fab′ loading directly corresponded with the size of the conjugate. Loading of Fab′ extended HPMA copolymers from their native random coil structure. As the valence of the polymeric precursor increased, the effective diameter also increased (Figure 2). In the case of *P-3* fractions, the fraction with the most Fab′ per chain, *P-3fab8.9*, had an effective diameter of 38.7 nm, while the

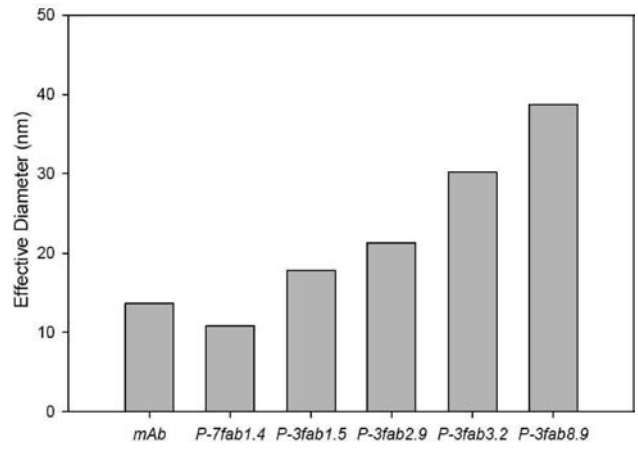

Figure 2. Effective diameters of the multivalent HPMA copolymer−Fab′ conjugates as determined by dynamic light scattering (DLS). The effective diameter corresponded to the valence of each conjugate.

fraction with the least Fab′ per chain, *P-3fab1.5*, had an effective diameter of 17.8 nm. Also, fractionation of the conjugate produced low polydispersity index values near or below 0.2 as shown in Table 1. To ensure that the fractions were not aggregates, a Zimm plot was also used to calculate the molecular weight of the conjugate *P-3fab′8.9*. The calculated molecular weight was 611 ± 43 kDa, a value that corresponded well with the molecular weight estimates made by adding the molecular weight of polymer and the total molecular mass of Fab′ attached to the conjugate.

Binding Isotherms and Scatchard Plots. The single-site binding equation produced a good fit to experimental data for the analysis of CD20 binding with whole Ab or with Fab′. The binding constants (K_D) were 19 nM and 58 nM, respectively. The average number of CD20 receptors per cells was 217 000 ± 27 000 and 217 000 ± 39 000 as calculated from binding experiments with whole Ab and Fab′ fragments, respectively. Both K_D and receptors/cell were close to other published values (*30, 31*). However, the single-site binding equation failed to adequately model the binding of multivalent conjugates to the CD20 receptor, with the most significant deviation occurring at low concentrations of Fab′. A better fit was produced by the Sips equation; typical data for conjugate *P-3Fab′3.2* are shown on Figure 3c,d. The Sips equation uses the same K_D and B_{max} fitting parameters as the single-site binding equation and adds a heterogeneity constant, *a*, as a fitting parameter (eq 1) (*45*). If the heterogeneity constant is set to 1, the Sips equation simplifies to the single-site binding equation. For that reason, K_D and B_{max} values listed in Table 1 for mAb and Fab′ are listed as $K_{D,Sips}$ and $B_{max,Sips}$. Figure 3 provides a representative example of how the Sips equation was used to fit the binding isotherm data and of the curved Scatchard plot. For the conjugates evaluated, the Sips heterogeneity constant was within the interval ⟨0.78; 0.99⟩ (Table 2). The isotherms for conjugates *P-3Fab′1.5, P-3Fab′2.9, P-3Fab′8.9,* and *P-7Fab′1.4* are presented in Supporting Information.

The Scatchard plots of the multivalent conjugates were concave curves, whereas the Scatchard plots for whole Ab and Fab′ were linear. The curvature of the Scatchard plots was relevant in describing the multimeric nature of binding; the latter was also described by the heterogeneity constant, *a*, of the Sips equation. Curvature of Scatchard plots may suggest a number of phenomena, including heterogeneity of binding sites, and nonspecific binding. In the analysis of experimental data, nonspecific binding was subtracted from total binding. Also, the heterogeneity of binding sites was considered to be minimal, since the thioether bond would be distant from the binding site

[e] Theoretical limit of bound ligand determined by graphical extrapolation of Scatchard plots to the *x*-axis. [f] Heterogeneity factor determined by the Sips equation. [g] Valence of conjugates determined with modified amino acid analysis. [h] Valence of conjugates determined by the ratio of B_{max} of the conjugate over B_{max} of the Fab′

of the Fab′ (*13*). In this instance, a concave Scatchard plot suggests negative cooperativity. Consequently, the strongest binding will occur at the lowest concentration of multivalent conjugate. At low concentrations, a multivalent conjugate can bind multiple receptors. As the concentration of the conjugate increases, the probability of a single multivalent conjugate binding multiple receptors is reduced to the point that each multivalent molecule only binds a single receptor (all of the receptors are occupied by different molecules). As a result, the ratio of the conjugate's B_{max} divided by the B_{max} of the Fab′ is indicative of the total valence of the conjugate or Fab′ per polymer chain. The valence of conjugates (Fab′ per macromolecule) determined with binding isotherms was in good agreement with the values determined by chemical analysis (Table 2).

The multivalent or multimeric binding effect may be quantified by the enhancement factor, the ratio of the apparent binding constant, $K_{D,Sat[Fab']}$, at saturating concentrations of Fab′ and the apparent binding constant, $K_{D,low[Fab']}$, at low concentrations of Fab′ (*46*). The apparent binding constants were extrapolated from relevant sections of Scatchard plots. The $K_{D,low[Fab']}$ are shown in Figure 4, and the enhancement factors in Figure 5. The largest enhancement factor, 17.7, of the investigated conjugates was found for *P-3Fab′8.9*. The $K_{D,low[Fab']}$ for

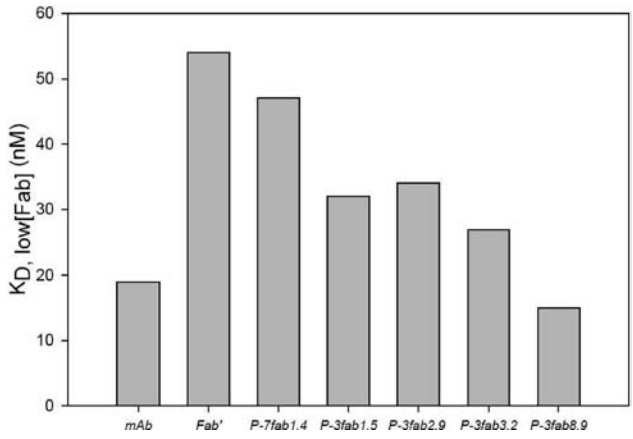

Figure 4. Apparent binding constants, $K_{D,low[Fab']}$, for anti-CD20 Ab, Fab′ fragment, and HPMA copolymer−Fab′ conjugates. The $K_{D,low[Fab']}$ is indicative of the slope of the Scatchard plot at low concentrations of Fab′ (see Figure 3d). Generally, the $K_{D,low[Fab']}$ decreased (affinity increased) as the valence of the construct increased.

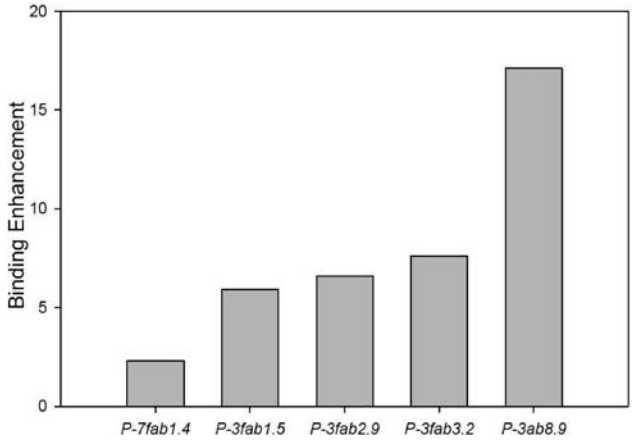

Figure 5. Binding enhancement for anti-CD20 Ab, Fab′ fragment, and HPMA copolymer−Fab′ conjugates. Enhancement is derived from increase in affinity due to multiple binding sites per construct. It was calculated by dividing the $K_{D,sat[Fab']}$ by $K_{D,low[Fab']}$.

P-3Fab′8.9 was 15 nM; the $K_{D,Sat[Fab']}$ was 256.5 nM. The smallest enhancement factor was for conjugate *P-7Fab′1.4*, which had a $K_{D,low[Fab']}$ of 47 nM, a $K_{D,Sat[Fab']}$ of 108.1 nM, and an enhancement factor of 2.3.

The $K_{D,low[Fab']}$ values provide good evidence of a multivalent, multimeric binding enhancement as shown in Figure 4. The value observed for *P-3Fab′8.9* (15 nM) was better than those for free Ab (19 nM) and free Fab′ (58nM).

DISCUSSION

The aim of this study was to demonstrate that water-soluble polymers have potential as multivalent drug carriers. To this end, high molecular weight branched HPMA copolymers were prepared by copolymerization of HPMA with a cross-linking agent (TGD) at conditions below the gel point. Fractions of different molecular weight were used in the synthesis of multivalent HPMA copolymer−Fab′ conjugates. The Fab′ fragment (of anti-CD20 1F5 antibodies) was attached to the copolymers via a thioether bond. The maximum enhancement of binding affinity for the target Raji cells achieved here (17.7 times) bodes well for the development of novel, more effective long-circulating polymer−drug conjugates. To ensure biocompatibility, degradable sequences have to be incorporated into the HPMA copolymer carrier structure, using primary chains with molecular weight below the renal threshold. This can be achieved by connecting primary HPMA copolymer chains via enzymatically degradable cross-links (bridges). Previously, two approaches have been used for the synthesis of degradable, water-soluble, cross-linked (branched) copolymers short of gel point. The first approach consisted of cross-linking reactive HPMA copolymer precursors, containing side chains terminated in reactive ester groups, with degradable α,ω-diaminooligopeptides (*47*−*49*). The second approach was to use biodegradable cross-linkers and prepare the conjugates by copolymerization. One cross-linker, N^2,N^5-bis(*N*-methacryloylglycylphenylanaylleucylglycyl)ornithine methyl ester, has been used to reproducibly synthesize high molecular weight branched HPMA copolymers that can be lysosomally degraded to primary chains to facilitate elimination from the organism by renal filtration (*21*). It is interesting to note that the efficacy of doxorubicin conjugates with branched HPMA copolymers, in an ovarian carcinoma xenograft model, increased with increasing molecular weight of the conjugate (*22*).

The enlargement of the effective diameter of HPMA copolymer with conjugation Fab′ was demonstrated qualitatively by SEC and quantitatively with DLS. This result is not unexpected. HPMA copolymers, in an aqueous environment, have a dynamic, random coil conformation. Dispersive forces would exist between intrachain Fab′ that would result in stretching out the polymer chain. This report demonstrated that enlargement of the HPMA copolymer was directly related to the amount of Fab′ that had been loaded onto the polymer. Due to the nature of HPMA copolymers, the conjugates would maintain a dynamic and flexible structure, a property that may increase the effective valence of the conjugates, and the ability of intrachain Fab′ to gain access and bind to CD20.

The valence of the conjugates was analyzed chemically with a modified amino acid analysis method (*50*). The valence was confirmed by comparing the B_{max} of each conjugate with the B_{max} of unconjugated Fab′ (Table 2). The two determinations corresponded well and infer that the polydispersity among the fractions was narrow (1.2−1.3). However, the effective valence, or the maximum amount of Fab′ per conjugate that could bind CD20, was not determined. It can be hypothesized that most intrachain Fab′ could bind with CD20 simultaneously at low concentrations of conjugate. The formation of dynamic oligomers of CD20 in lipid rafts (*29, 51*) would create several local binding sites for the targeted conjugate. After the first Fab′ of a conjugate bound to a CD20 molecule, the dynamic and flexible nature of the HPMA copolymer backbone (*52*) would allow a conformational response within the polymer, so that intrachain Fab′ could bind proximal CD20 molecules. Also, the size of the conjugates appears to favor multivalent interactions, since conjugates with higher orders of valency had effective diameters in a saline solution greater than whole mAb, 14.3 nm (*44*), and in the theoretical range of cross-linked Abs.

Multivalency is important for the clinical efficacy of Rituximab. Ghetie and co-workers demonstrated enhanced efficacy of tetravalent homodimers prepared by cross-linking of Rituximab with heterobifunctional reagents (*37*). Homodimers and trimers possessed similar binding affinity to lymphoma B cells in vitro but a slower rate of dissociation when compared to the monomer. Zhang et al. (*38*) cross-linked Rituximab with oxidized dextran (M_w = 6000) into high molecular weight conjugates (no data on molecular weight provided) possessing similar binding avidity as Rituximab monomer. In both cases (*37, 38*), multivalent conjugates induced apoptosis in CD20(+) cells.

It is notable that the single-site binding equation accurately modeled isotherms for both mAb and unconjugated Fab′ bound to CD20, but failed with multivalent constructs. In this case, the Sips equation provided a good model. This is likely due to

the thermodynamic assumptions of the single-site binding equation. It assumes that there is a single energy of adsorption, regardless of ligand concentration (*53, 54*). This assumption is not valid for a multivalent conjugate that can bind multimerically to a cell surface (*55*). In the case of a multivalent Fab′ conjugate such as *P-3Fab′8.9*, a single conjugate molecule could bind multiple CD20 receptors at low concentrations. As the concentration of *P-3Fab′8.9* is increased, it would become less likely that the conjugate could bind multiple receptors to the point that each multivalent conjugate could only bind to a single receptor (*56*). Just as the probability of a conjugate binding multiple receptors is reduced, so is the energy of adsorption reduced with an increase of conjugate concentration. This is reflected in a concave Scatchard plot and a heterogeneity factor, *a*, that is less than 1. In this context, the factor, *a*, represents the distribution of adsorption energies at all concentrations of conjugate and the binding constant K_D represents the average affinity of binding (*45, 57*). However, in an in vivo setting, the concentration of the conjugate at the target site is expected to be low. Consequently, the binding enhancement for the multivalent conjugates (Figure 5) should be fully operative.

Evidence of multivalent interactions involving the conjugates and CD20 include a general increase of affinity of the conjugates toward CD20 (Figure 4) and an increase of the enhancement factor (Figure 5) with increase of a conjugate's valence. The theoretical basis of a multivalent interaction is that the first univalent interaction creates a complex in which the remaining free binding sites on both species are at greatly enhanced local concentrations. Such "cooperative" interactions are also responsible for two strands of DNA annealing, viruses binding to cells, and the folding of proteins into stable structures. Several studies have demonstrated that multivalent enhancement can improve the binding affinity of low-affinity targeting moieties, such as saccharides binding to concavanalin A, by several orders of magnitude (*58−60*). Depending on the adsorption kinetics, these studies have displayed similar binding isotherms (*61*). However, the multivalent effect dramatically increased the average binding constant K_D of the multivalent ligand, rather then merely recovering the binding constant associated with the monomeric ligand, as we were able to demonstrate. The best explanation for this is the increased effective diameter of the construct, which would not be observed in studies that involve small, low-affinity multivalent molecules. The increased diameter of the multivalent construct directly impacts the K_{on} rate of the construct by limiting the construct diffusivity (*62*).

Several studies have evaluated the stability of the thioether bond made by maleimide and cysteine under saline and serum conditions. Studies of HPMA copolymer−Fab′ conjugates have demonstrated stability under saline conditions (*13*). In another study that measured the half-life of antibody−drug conjugates, it was shown that the thioether bond has a half-life of seven days in serum (*63*). Interestingly, this did not affect the overall effectivity of drug, and the half-life could be extend by substituting the thioether bond with a bromoacetamide linker, a strategy that could also be utilized in a future design. Other HPMA copolymer constructs conjugated to Fab′ fragments by thioether bonds have shown stability in vivo (*64*).

In summary, methods to produce multivalent HPMA copolymer−anti-CD20 Fab′ conjugates and to analyze their multivalent binding to the B-cell antigen CD20 were examined. Binding of the multivalent constructs was characterized by the binding constant, K_D, the Sips heterogeneity factor, *a*, and the binding enhancement factor. The multivalent constructs bound the B-cell antigen CD20 in a manner that was consistent with negative cooperative models. It was revealed that using Fab′ conjugated to soluble branched HPMA copolymer can result in binding enhancement that can surpass binding affinities of whole mAb. Furthermore, the multivalent binding of these conjugates may be useful in exploring cell-surface dynamics involved with induction of apoptosis, initiated by cross-linking the B-cell antigen CD20.

ACKNOWLEDGMENT

BC800351M

Synthesis and evaluation of multivalent branched HPMA copolymer-Fab' conjugates targeted to the B-cell antigen CD20

R. Johnson, P. Kopečková, and J. Kopeček

Supporting Information

Binding analysis of each multivalent conjugate was performed as described in the Experimental Procedures section. Briefly, Raji cells grown in RPMI medium containing 10% fetal bovine serum (FBS) were washed twice with Hank's balanced salt solution (HBSS). The cells were adjusted to $4x10^6$ cells/ml and split into two volumes. To one of the volumes of Raji cells, unlabeled anti-CD20 IgG was added to a final concentration of 500 nM to block CD20 for a negative control. Serial dilutions of ^{125}I-labeled anti-CD20 IgG, Fab', and multivalent Fab' conjugates were made from 2000 nM to 1 nM of Fab' fragment concentration. Millipore 96-well filter plates, coated with a 1% solution of nonfat dry milk in distilled water and incubated at 4 °C overnight, were washed with HBSS. For each of the serial dilutions, 25 µL of negative control cells were added to a single well, and 25 µL of unblocked cells were added to 3 different wells; then 25 µL of the respective dilutions were added to each well. The filter-well plates were incubated for 90 min at 120 rpm on a shaker at 25 °C. Following incubation, the Raji cells were washed twice with 200 µL of cold HBSS with 10% FBS, and then collected on filters. The filters were allowed to air-dry, removed from the plate and counted. Negative control wells were used to correct for non-specific binding. Isotherms were evaluated with the Sips equation using SigmaPlot software (Systat Software, San Jose, CA).

Two Cys-containing analogues of the anticancer drug Kahalalide F are synthesized and conjugated to 20 and 40 nm gold nanoparticles (GNPs). The resulting complexes are characterized by different analytical techniques to confirm the attachment of peptide to the GNPs. The self-assembly capacity of a peptide dramatically influences the final ratio number of molecules per nanoparticle, saturating the nanoparticle surface and prompting multilayered capping on the surface. In such way, the nanoparticle could act as a concentrator for the delivery of drugs, thereby increasing bioactivity. The GNP sizes and the conjugation have influence on the biological activities. Kahalalide F analogues conjugated with GNPs are located subcellularly at lysosome-like bodies, which may be related to the action mechanism of Kahalalide F. The results suggest that the selective delivery and activity of Kahalalide F analogues can be improved by conjugating the peptides to GNPs.

INTRODUCTION

Nanotechnology offers tremendous potential for medical diagnosis and therapy. Various types of nanoparticles have been explored for biomedical applications (*1*−*3*), having been widely employed in biological systems (*4*−*6*). Nanoparticles have been suggested for imaging (*7*−*13*), screening (*14*), and biosensing (*15*−*17*), not using only gold nanoparticle optical properties but also electrical (*18*−*23*), and furthermore are known to carry higher payloads of drugs than other vehicles and are currently used in gene and drug delivery (*24*−*26*), as well as in cancer diagnostics and therapeutic applications (*27*−*29*). Gold NPs (GNPs) display several features that make them well-suited for biomedical applications, including straightforward synthesis, stability (*30*), and the facile ability to incorporate secondary tags such as peptides targeted to specific cell types to afford selectivity (*31, 32*). On the other hand, GNPs have been used in photothermal therapy for the destruction of cancer cells or tumors. When irradiated with a focused laser in the near-infrared region (NIR) of suitable wavelength, targeted aggregates of GNPs, nanorods, or nanoshells can kill bacteria (*33*) and cancer cells (*34*).

The conjugation of GNPs to an antitumoral drug could play two parallel roles: to enhance the delivery of a drug to the cell by presenting numerous peptide copies anchored to the nanoparticle surface and to help in the delivery of the nanoparticle to the pathological cell favoring the local aggregation of nanoparticles in tumor cells by increasing absorption in the NIR where tissues present low NIR region radiation absorption, after irradiation.

Nanobiotechnology is expected to widen the therapeutic index of current cancer therapies. For example, tumor-targeting drug delivery vectors are now approaching "true" nanometer size, which allows them to arrive in close proximity to several biological targets (*35*). Cellular delivery involving the transfer of various drugs and bioactive molecules (e.g., peptides, proteins, and DNA) through the cell membrane into the cytoplasm has generated great interest because the general administration of drugs and biomolecules suffers from inefficiency and enzymatic degradation, among other problems. Hence, there is a pressing need to develop safe and efficient transport vehicles to deliver drugs into cells (*36*). Taking into account the advantages of GNPs for drug delivery, in this work we have conjugated a Kahalalide F analogue, an antitumoral drug candidate, with GNPs to enhance the delivery of Kahalalide F to tumoral cells by increasing its cytotoxic effect. Kahalalide F is a marine cyclodepsipeptide isolated from a mollusk, *Elysia rubefescens*, with antitumoral activity (*37*). Two synthetic diasteromeric analogues of the Kahalalide F (Figure 1) were synthesized and conjugated with GNPs. Kahalalide F is the most bioactive member of the Kahalalide family of peptides. The presence of the compound appears to cause alterations in cell lysosomes, meaning that lysosomes become a target for Kahalalide F action (*38, 39*). Kahalalide F exerts a potent in vitro cytotoxic activity toward several tumor cell lines and specimens derived from various human solid tumors. In contrast, nontumor cell lines are 5 to 40 times less sensitive to Kahalalide F (*40*).

Figure 1. Structures of Kahalalide F, **P1**, and **P2**; amino acid sequences and linear cyclopeptides are represented in a one-line text formula using the protocol of Spengler et al. (*43*).

Kahalalide F shows in vitro activity against prostate and colon cancer cells, and to a lesser extent, antiviral, antifungal, and bactericide activity (*41*). Two clinical phase I trials in adult patients with advanced prostate cancer and pretreated solid tumors have established the recommended dose for two distinct treatment regimes (once a week and five consecutive days every 3 weeks) (*40, 42*). Kahalalide F phase II clinical trials in hepatocellular carcinoma, non-small cell lung cancer (NSCLC), and melanoma finished in 2006. Moreover, Kahalalide F is being tested in phase II clinical trials in patients with severe psoriasis.

Herein, we report on the ability of Kahalalide F analogue−GNP complexes to enter HeLa cells. The penetration, localization, and in vitro cytotoxicity of the conjugates in HeLa cells were evaluated.

MATERIALS AND METHODS

Materials. Cl-TrtCl-resin (100 mg, 1.56 mmol/g), protected Fmoc-L-amino acids and Fmoc-D-amino acids derivatives, were purchased from Iris Biotech GmbH (Marktredwitz, Germany), Luxembourg Industries (Tel-Aviv, Israel), Neosystem (Strasbourg, France), Calbiochem-Novabiochem AG (Laüfelfingen, Switzerland), and Bachem AG (Bubendorf, Switzerland). Diisopropylcarbodiimide (DIC) was obtained from Fluka Chemika (Buchs, Switzerland); HOAt, from GL Biochem (Shanghai, China); PyBOP, from Calbiochem−Novabiochem AG; and *N*,*N*-diisopropylethylamine (DIEA), from Merck (Darmstadt, Germany). Solvents for peptide synthesis and RP-HPLC were obtained from Scharlau (Barcelona, Spain). Trifluoroacetic (TFA) acid was supplied by KaliChemie (Bad Wimpfen, Germany). Other chemicals used were obtained from Aldrich (Milwaukee, WI) and were of the highest purity commercially available.

Peptide Synthesis and Purification. Both peptides were synthesized on solid phase using a method previously reported by our group (*44*). HPLC was performed using a Waters Alliance 2695 (Waters, MA) chromatography system with a PDA 995 detector, a reverse-phase Symmetry C_{18} (4.6 × 150 mm) 5 μm column, and a linear gradient of MeCN with 0.036% TFA into H_2O with 0.045% TFA. The system was run at a flow rate of 1.0 mL/min. HPLC-MS was performed using a Waters Alliance 2796 with a UV/vis detector 2487, ESI-MS Micromass ZQ (Waters) chromatography system, a reverse-phase Symmetry 300 C_{18} (3.9 × 150 mm) 5 μm column, and H_2O with 0.1% formic acid, and MeCN with 0.07% formic acid, as mobile phases. Mass spectra were recorded on a MALDI Voyager DE RP time-of-flight (TOF) spectrometer (PE Biosystems, Foster City, CA).

Synthesis of GNPs. GNPs were produced by reduction of hydrogen tetrachloroaurate ($HAuCl_4 \times H_20$) obtained from Aldrich (Milwaukee, WI).

20 nm Nanoparticles. $HAuCl_4 \times H_2O$ (8.7 mg) was added to a sodium citrate solution (100 mL, 2.2 mM) at 150 °C reflux. The reducing agent was added rapidly, and the reaction was allowed to continue under uniform and vigorous stirring until a red wine color was observed (*45*).

40 nm Nanoparticles. Same procedure as above except that a lower concentration of reducing agent was used (100 mL of a 1.22 mM solution of sodium citrate).

Conjugation of Peptides with GNPs. An excess of peptide was used for the conjugation (*6*). Peptide solutions (1 mg/mL in MilliQ water) were added dropwise to 10 mL of GNPs solution at room temperature with magnetic stirring, and agitation was then maintained for 15 min. The conjugates were then purified by dialysis over three days in a Spectra/Por MWCO membrane: 6−8000 against 2.2 mM sodium citrate. The solution was refreshed six times to eliminate the excess peptide (**P1** or **P2**).

UV−visible. UV−vis absorption spectra were recorded at room temperature with a 2501PC UV−vis recording spectrophotometer (Shimadzu Corporation, Kyoto, Japan).

High-Resolution Transmission Electron Microscopy (HR-TEM). Drops of GNPs conjugated to both Kahalalide F analogues under uranyl acetate staining were deposited over carbon-coated Formvar films on copper grids. To obtain the transmission electron microscopy (HRTEM) results, a field emission gun microscope JEOL 2010F was used, working at 200 kV and with a point-to-point resolution of 0.19 nm.

Electron Energy Loss Spectroscopy (EELS). Electron energy loss spectra (EELS) were obtained in a Gatan Image

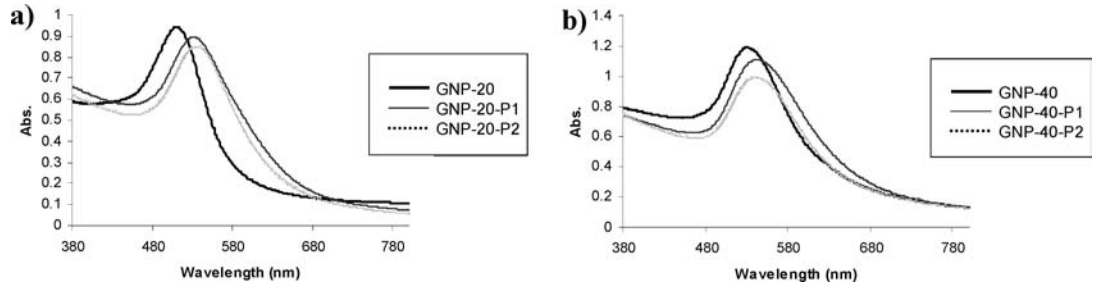

Figure 2. UV−vis spectra of GNPs and their respective conjugates; a shift in the maximum is representative of the conjugation. (a) GNP-20, GNP-20-P1, and GNP-20-P2; and (b) GNP-40, GNP-40-P1, and GNP-40-P2.

Filter (GIF 2000) coupled to the JEOL 2010F microscope, with an energy resolution of 1.2 eV.

X-ray Photoelectron Spectroscopy (XPS). Gold surfaces were purchased from Arrandee (Germany), and PMMA surfaces, from GoodFellow (Huntingdon, United Kingdom). XPS studies were performed by depositing a drop of GNPs or the conjugates over PMMA surfaces, and then drying the samples under reduced pressure before analysis. Gold surfaces functionalized with **P1** were obtained by immersion of **P1** (0.1 mg) in a $CHCl_3$ (1 mL) solution for 24 h.

Cell Culture and Incubation with the Conjugates. HeLa cell line was obtained from ATTC no CCL-2 (Manasas, VA) and maintained in DMEM low-glucose medium (Biological Industries) containing 10% fetal calf serum (FCS), 2 mM glutamine, 50 U/mL penicillin, and 0.05 g/mL streptomycin. For experiments, exponentially growing HeLa cells were detached from the culture flasks using a trypsin−0.25% ethylenediaminetetraacetic acid (EDTA) solution, and the cell suspension was seeded at a concentration of 3.5×10^3 cells/cm^2 onto glass coverslips (Nalge Nunc International, Rochester, NY). Experiments were carried out 24 h later, when the confluence was approximately 70−80%. Non-adherent cells were washed away and attached cells were incubated at 37 °C in 5% CO_2 in DMEM with a known concentration of GNPs.

WST-1 Assay. HeLa viability in the presence of unconjugated or conjugated nanoparticles was tested using a WST-1 assay, including a control with no nanoparticles added. For each assay, 3.5×10^3 cells/cm^2 were seeded onto a 96 well plate (Nalge Nunc) and cultured for 24 h. The conjugates were added in a 1:4 (conjugate/DMEM) ratio. Cells were incubated for 24 h at 37 °C under a 5% CO_2 atmosphere. After 20 h, 10 μL of WST 1 were added. The cells with the conjugate solutions were incubated for another 4 h. Cell viability is expressed as a percentage ratio of cells treated with the different compounds against untreated cells.

Confocal Laser Scanning Microscopy (CLSM). For the cellular localization of GNP conjugates, HeLa cells were plated on glass coverslips, grown to 60% confluence, and then incubated (at 37 °C under a 5% CO_2 atmosphere) with either **P1**− and **P2**−nanoparticle conjugates for 24 h. At indicated time points, the coverslips were rinsed extensively with phosphate-buffered saline (PBS), and the cells were fixed with 4% paraformaldehyde in PBS for 20 min at room temperature and then rehydrated in PBS.

Once the cells were fixed, the coverslips with cells were mounted onto glass slides with Mowiol mounting media (Calbiochem, CA), and then allowed to dry overnight prior to microscopy analysis. The samples were examined using an Olympus Fluoview 500 confocal microscope with a 60×/1.4 NA objective.

Nanoparticle Localization by Transmission Electron Microscopy (TEM). HeLa cells were incubated with conjugated or unconjugated gold nanoparticles for 24 h. Cells were fixed with 2.5% glutaraldehyde in phosphate buffer, and then kept in the fixative at 4 °C for 24 h. The cells were then washed with the same buffer, and postfixed with 1% osmium tetraoxide in the same buffer containing 0.8% potassium ferricyanide at 4 °C. The samples were then dehydrated in acetone, infiltrated with Epon resin for 2 days, embedded in the resin, and polymerized at 60 °C for 48 h. Ultrathin sections were obtained using a Leica Ultracut UCT ultramicrotome, and then mounted on Formvar-coated copper grids. The sections were stained with 2% uranyl acetate in water and lead citrate, and then observed under a JEM-1010 electron microscope (Jeol, Japan).

RESULTS AND DISCUSSION

Modification of Kahalalide F for Conjugation with GNPs. Two Kahalalide F analogues **P1** and **P2** (Figure 1) were synthesized and conjugated to NPs. For conjugation with GNPs, a free thiol containing Cys that facilitates the attachment to the gold surface was introduced in the peptide sequence. In **P1**, the D-^{13}Val was replaced by a D-Cys residue that does not seem to be crucial for biological activity. To determine whether the Cys configuration affects toxicity, **P2** was obtained from where the D-Val had been replaced by a L-Cys instead a D-Cys, as in **P1**.The change of chirality from D-Cys (**P1**) to L-Cys (**P2**) should induce a decrease in antitumoral activity from **P1** to **P2**. These results are in agreement with Jimenez et al., who reported that when the chirality of a residue of the Kahalalide F tail changes, the activity decreases (*46*).

P1 and **P2** were synthesized using a Fmoc/tBu solid-phase synthesis strategy (Supporting Information) (*44*).

Conjugation of P1 and P2 with GNPs. GNP cellular uptake is heavily dependent on nanoparticle size (*47*). In this work, **P1** and **P2** were conjugated to two different GNP sizes, i.e., 20 and 40 nm (GNP-20 and GNP-40, respectively) obtaining conjugates GNP-20-P1, GNP-20-P2, GNP-40-P1, and GNP-40-P2 in order to determine the influence of nanoparticle size on the penetration and cytotoxicity of the conjugates.

GNPs were obtained via the sodium citrate reduction method (*48*−*52*), which allows the synthesis of clusters between 6 and 60 nm by adding varying amounts of the reducing agent. The GNPs were characterized by UV−vis and TEM (Supporting Information). The peptide-capped GNPs were prepared by mixing a colloidal gold solution with an excess of peptide to obtain functionalized gold surfaces. The conjugates were exhaustively characterized by using UV−vis spectroscopy, amino acid analysis (AAA), transmission electron microscopy (TEM), electron energy loss spectroscopy (EELS), and X-ray spectroscopy (XPS).

Characterization of Conjugates. *UV*−*visible Spectroscopy.* UV−vis spectra of GNPs were taken (Figure 2). The characteristic correlation between surface plasmon resonance band and nanoparticle size (*53*) (520 nm for the 20 nm size, and 530 nm for the 40 nm size) was observed. In peptide−GNP conjugates, the wavelength of maximum absorption was shifted to longer

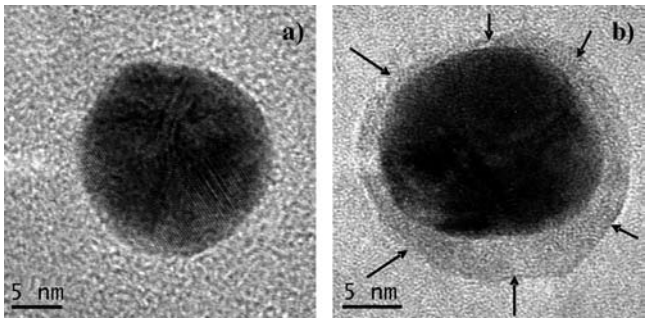

Figure 3. (a) bare GNP-20 and (b) GNP-20-P1.

wavelengths (Figure 2), which could be explained by the capping of the nanoparticle surface with the peptide molecules.

High-Resolution Transmission Electron Microscopy (HR-TEM). Figure 3 shows high-resolution TEM micrographs (HRTEM) of GNP-20 (Figure 3a) and GNP-20-P1 (Figure 3b). The presence of a layer around the nanoparticle core (Figure 3b) corresponding to the peptide was observed following uranyl acetate staining. As observed, the peptide covered the whole surface of the nanoparticle and increased the hydrodynamic size of the peptide-capped nanoparticle by 6 nm (the GNP metallic core as 20 nm in diameter, while the GNP-20-P1 was approximately 25 nm). The capping of GNPs by the adsorption of proteins was observed by TEM by other authors (*54*). However, in our case, although the nanoparticle was capped with a short peptide (approximately 1 nm long in an extended form), the formation of a wide layer (5 nm) was observed. This result led us to conclude that the nanoparticle was capped by a peptide multilayer.

Further characterization of the conjugates was carried out as described next. EELS (electron energy loss spectroscopy) and XPS (X-ray photoelectron spectroscopy) were used to confirm the presence of S−Au bonds on the surface, and amino acid analysis was performed to determine the number of peptide molecules that were conjugated to the GNPs.

Electron Energy Loss Spectroscopy (EELS). An accurate analysis of the electron energy loss near edge spectra (ELNES) at the Au $O_{2,3}$ edge (54 eV), showed that the shape of the edge changed slightly when the spectrum was obtained on the unconjugated GNPs with regard to the **P1**-conjugates (Figure 4b,e, respectively). The change of the ELNES shape at the Au $O_{2,3}$ edge can be directly attributed to a bonding variation on some of the Au surface atoms. To determine the cause of this bonding variation, we also analyzed the S $L_{2,3}$ edge placed at around 165 eV. In this case, energy-filtered spectra obtained on the Au conjugated nanoparticle surfaces showed a clear signal around 165 eV (Figure 4f), indicating the presence of S atoms on the Au nanoparticle surface as detailed by Olmedo et al. (*55*).

The same energy region analyzed on the unconjugated nanoparticle surfaces showed a noise signal only, as indicated in Figure 4c. Given that the unconjugated sample was assumed to have a low quantity of S atoms, it was used to evaluate the signal-to-noise ratio at the S $L_{2,3}$ energy region. The average ratio between the maximum on the Au $O_{2,3}$ peak and the maximum noise signal after background subtraction found at the S $L_{2,3}$ energy region was 4×10^{-3} for the unconjugated nanoparticles. However, values of up to 8×10^{-3} were found for the functionalized nanoparticles, indicating that the increase in the signal-to-noise ratio may be due to bound S atoms. This last result corroborates the presence of S atoms on the Au surface, which would be responsible for the slight change in the Au $O_{2,3}$ ELNES spectra due to their bonding. Consequently, the presence of bound S atoms would indicate the functionalization of the GNPs with P1.

X-ray Photoelectron Spectroscopy (XPS). The gold colloids were further characterized by X-ray photoelectron spectroscopy (XPS). XPS studies were carried out on **P1**-conjugate and unconjugated gold nanoparticles deposited on polymethylmethacrylate surfaces (PMMA). This polymeric surface was used to minimize interference coming from the substrate, a problem commonly observed when sulfur-containing compounds are analyzed on silicon surfaces (*56*).

The S_{2p} spectrum gave a weak signal due to the presence of only one sulfur atom per attached peptide (Figure 5). The signal consists of a broad band with a maximum at 163.2 eV that corresponds to sulfur grafted onto gold, indicating the presence

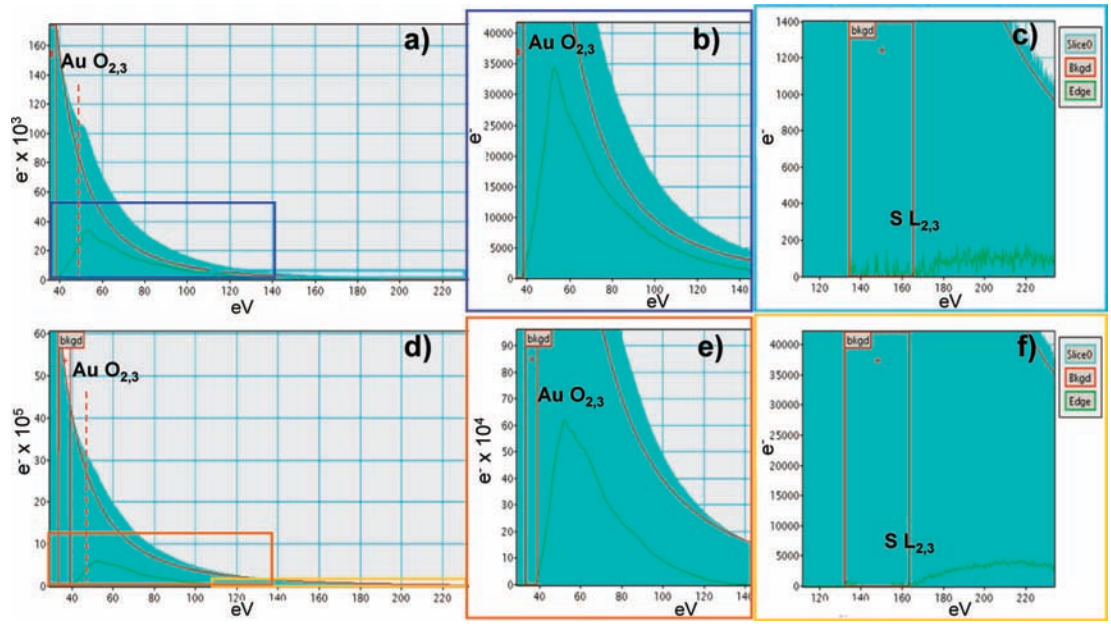

Figure 4. (a) EELS spectrum obtained on the surface of a non-functionalized GNP-20. (b) Detail of the Au $O_{2,3}$ ELNES spectrum bound by the blue rectangle in (a). (c) Detail of the S $L_{2,3}$ edge bound by the cyan rectangle in (a). (d) EELS spectrum obtained on the surface of GNP-20-P1. Figure 6. Representation of the functionalization of GNPs with the Kahalalide F analogues and the formation of adlayers. The peptide chain is depicted in green; the thiols belonging to the cysteins are depicted in orange.

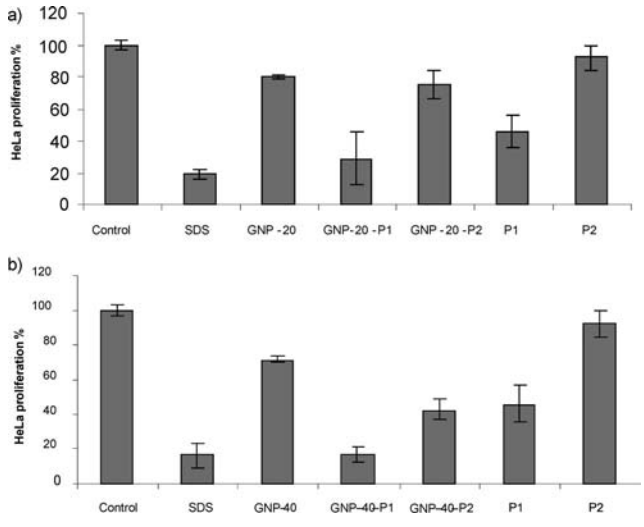

Figure 7. Antiproliferation results of the incubation of **P1**- and **P2**-conjugated 20 nm (a) and 40 nm (b) gold nanoparticles with HeLa cells for 24 h. Cell culture media and SDS were used as negative and positive controls, respectively. The conjugated and nonconjugated peptides were screened against the HeLa cells at a concentration of 1×10^{-5} M. The GNP concentration is the same in all samples.

of Au−S bonds. Although $S_{2p3/2}$ and $S_{2p1/2}$ signals can usually be observed separately, we observed a single broad band, presumably due to shielding of the electron emission by the large peptide. A similar S_{2p} signal was obtained when the peptide was on a non-functionalized gold surface (*57*).

Determination of the Number of Peptide Molecules per GNP. To determine the number of peptide molecules per nanoparticle, nondialyzed aliquots of the conjugated solutions (2.5 mL) were centrifuged at 13 500 rpm for 30 min. The supernatant was lyophilized and then analyzed by HPLC to determine the amount of unconjugated peptide. Approximately 85% of the peptide used in the conjugation was attached to the GNPs. The number of peptides per particle was calculated by dividing the concentration of grafted peptide by the amount of GNPs in solution, which was determined spectrophotometrically considering the molar extinction coefficients detailed in ref *58*. Despite the GNP's size (GPN-20 or GPN-40), the conjugates showed ratios of 60 000 ± 5000 peptide molecules per nanoparticle. However, assuming that the surface of a GNP-20 is 1256 nm^2 or 5024 nm^2 for a GNP-40 and that the surface of a single peptide molecule in an extended conformation is 0.6 nm^2 (data obtained from molecular modeling calculation using the *Insight II* software package), the theoretical number of molecules that would completely cover a GNP-20 surface is only 2090 and 8373 for a GNP-40. This indicated to us that not all peptide molecules were chemisorbed to the nanoparticle surface through the sulfur bond, with the excess of peptide being attached to the nanoparticle by another sort of interaction (Figure 6). One option is the formation of peptide adlayers due to the hydrophobic character of KF, which prompts the assembly of the peptide on the GNP surface in aquous media. Kahalalide F spontaneously self-assembles in aqueous solution, forming spherical supramolecular structures as has been observed by TEM (Supporting Information). This formation of peptide adlayers is a relevant issue to consider when the conjugation of a peptide to a GNP is considered and dramatically influences the final ratio of molecules per nanoparticle, saturating the nanoparticle surface and prompting multilayered capping on the surface. In such a way, the nanoparticles are acting as a concentrator for the delivery of drugs, thereby increasing bioactivity. The influence of the conjugation of **P1** and **P2** on cytotoxic activity was examined as follows.

Cytotoxicity Studies. The degree of cytotoxicity of single peptides (**P1** and **P2**), single GNP solutions (GNP-20 and GNP-40), and their respective conjugates was determined by the WST-1 assay in HeLa tumor cells following 24 h of incubation.

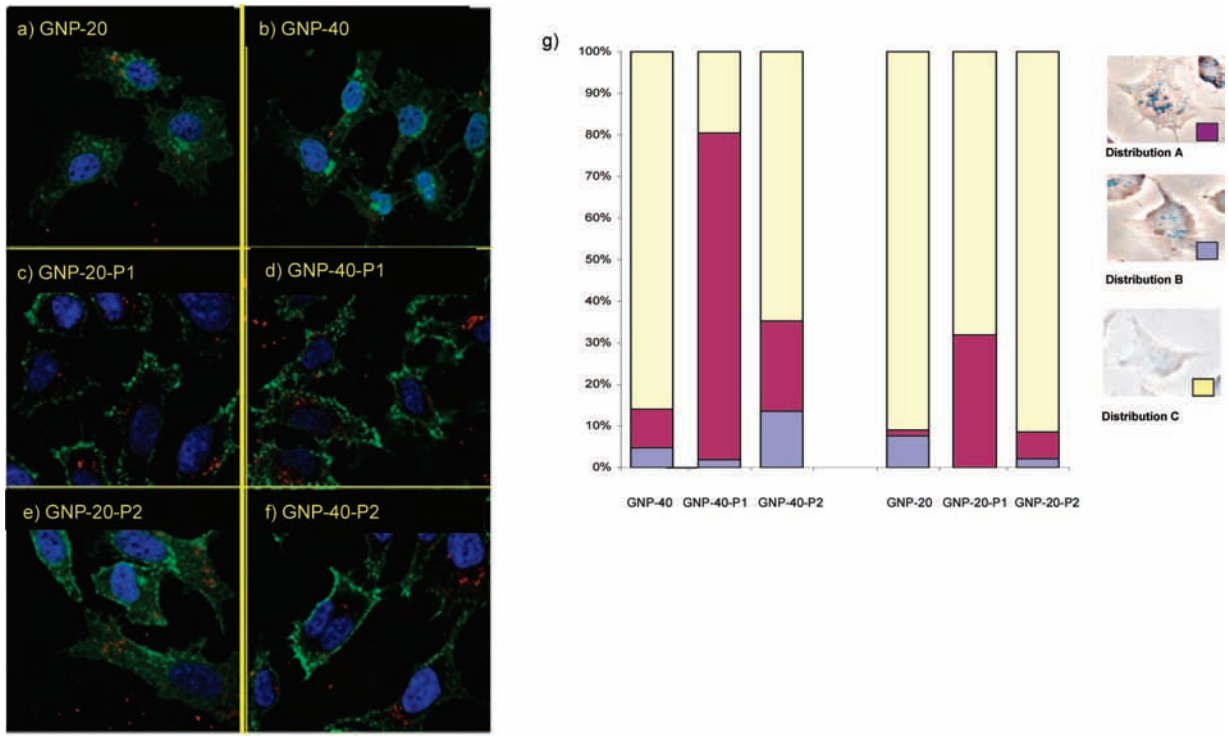

Figure 8. Localization of GNPs and their conjugates in HeLa cells incubated for 24 h (a−f); the red dots represent reflections of groups of nanoparticles. Membranes (green) were stained with a fluorescence marker (WGA), and nuclei (blue) by a DNA marker (Hoechst). Left column: GNP-20. Right column: GNP-40. (g) Percentage of accumulation of GNPs in HeLa cells. The proportion of cells that contain 10 or more reflecting spots (nanoparticules) is represented in burgundy (distribution A). The proportion of cells that contain more than 3 and less than 10 reflecting spots is represented in blue (distribution B). The proportion of cells that contain less than 3 reflecting spots is depicted in yellow (distribution C). The total number of cells taken into account was 100 for each nanoparticle sample.

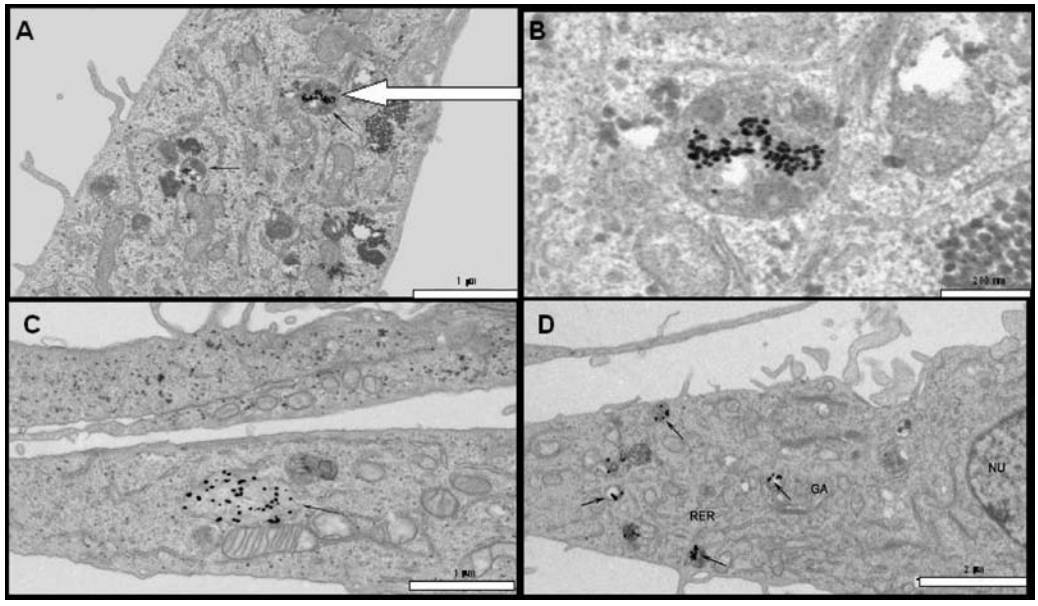

Figure 9. TEM images of HeLa cells incubated with (A) GNP-20-P1. The arrows indicate the presence of the GNPs inside lysosome-like structures. (B) Higher magnification of the accumulated GNP-20-**P1** inside lysosome-like structures. (C) GNP-40-**P1** and (D) bare GNP-20. NU (nucleus), RER (rough endoplasmic reticulum), GA (Golgi apparatus).

Cell culture medium and SDS were considered as negative and positive controls (0% and 80% of inhibition, respectively). The results showed that GNPs displayed residual cytotoxicity against HeLa cells, determined in approximately 22% inhibition for GNP-20 and GNP-40 (Figure 7 and Supporting Information). Regarding the cytotoxicity of single peptides, **P2** was found to be less cytotoxic than **P1** (10% vs 50% inhibition, respectively). The cytotoxicity of conjugates **P1** and **P2** with GNP-20 did not change with respect to the free peptides (Figure 7 and Supporting Information). In contrast, for **P1** and **P2** conjugated with GNP-40 the cytotoxicity is higher with respect to the free peptides (Figure 7). This enhancement could be the result of better cell uptake of the former conjugate, which would be consistent with the findings of Chithrani et al. (*47*). The authors reported that, among nanoparticles of different sizes, those of 50 nm demonstrated the highest level of uptake by HeLa cells. In agreement with these results, Osaki et al. (*59*) qualitatively showed that 50 nm nanoparticles entered the cells via receptor-mediated

endocytosis more efficiently than smaller ones. We attributed the enhanced toxicity of GNP-40-P1 and GNP-40-P2 with respect to **P1** and **P2** to a synergic effect between the peptide and the GNP-40 that favored the penetration and targeting to the lysosome (the putative target of Kahalalide F) (*38*). Confocal and TEM observations to evaluate the accumulation and localization of the conjugates in the cells were carried out.

Cellular Localization of Conjugates. *Accumulation of the Peptide−GNP Conjugates by Confocal Laser Scanning Microscopy (CLSM).* To study the influence of the peptide conjugation on the penetration and distribution of GNPs in cells, both conjugated and unconjugated nanoparticles were observed under confocal microscopy for detection of their reflections. It is important to mention that, in this technique, single GNPs could not be observed; however, if the nanoparticles had been localized together in a cell region, then their detection would have been possible. The cells were fixed with paraformaldehyde and the membranes and nuclei stained. Figure 8 shows how GNPs and peptide−GNP accumulate in cells. Bare GNPs accumulate in cells in low proportion with respect to the conjugates. As expected, the accumulation of GNP-40 is higher than GNP-20, which is in accordance with the results Chitriani et al. (*47*), who hypothesized that GNP uptake is mediated by nonspecific adsorption of serum proteins onto the gold surface; these proteins induce the nanoparticles to enter into cells via the mechanism of receptor-mediated endocytosis. On the other hand, functionalized nanoparticles with peptides presented a higher degree of accumulation in HeLa cells with respect to bare GNPs, with the GNP-40-P1 conjugate showing the highest accumulation. The functionalization of GNPs with **P1** and **P2** introduces a positive charge into the nanoparticle. This charge is achieved by Orn (see Figure 1), which is charged positively at pH = 7.4. This positive charge favors interaction with the membrane (charged negatively) and consequently enhances penetration into the cell. There are several examples in the literature describing the addition of Lys or Arg residues for transfecting molecules into cells (*60*, *61*). The lower accumulation of GNPs that are capped with citrate ions in comparison to functionalized nanoparticles could be explained by the fact that the charge of the GNPs is negative (due to the citrate stabilizing ligand). Anionic molecules and structures bind less efficiently to cell surfaces than neutral or cationic molecules, since electrostatic repulsion between the negatively charged surface membrane and cellular environment will repel nanoparticles. Thus, to gain entry, these GNPs must be capped with serum proteins.

Localization of the Conjugates by Transmission Electron Microscopy (TEM). Localization of the peptide−GNP conjugates in the cells was investigated with by TEM. HeLa cells were incubated for 24 h with either conjugated or unconjugated GNPs. TEM images (Figure 9) showed that the penetration of GNP was lower than that of peptide−GNP. Both GNPs and peptide−GNPs were localized in lysosome-like structures. This behavior was not surprising due to lysosomal compartmentalization and was certainly the expected result in most cell uptake processes.

CONCLUSIONS

In summary, conjugating Kahalalide F analogues to GNPs improves the ability of the peptide to target tumoral cell lysosomes (the putative target for Kahalalide F) by using GNPs with high capacity to enter into the cell, thus allowing higher concentrations of peptide molecules which in turn enhances cytotoxicity, as observed for peptides conjugated to GNP-40. The conjugation of bioactive peptides such as Kahalalide F to GNP could be used to direct the drug to the desired pharmacological target, thereby widening the therapeutic index of current cancer therapies. In addition, the peptides conjugated to GNP-40 could find application in treatments based on the destruction of tumoral cells by applying NIR radiation to cells that contain accumulated nanoparticles.

(56) Usually XPS characterizations are performed on silicon oxide surfaces. Silicon surfaces present two signals corresponding to Si2s and Si2p at 165 and 167 eV, respectively. The Si2s and S2 signals overlapped. The use of PMMA instead of a silicon surface is proposed in the present work in order to avoid interference. XPS characterization of the polymer was performed to discard sulphur impurities.

Solid-Phase Synthesis

Two epimer peptides were synthesized using the Fmoc solid-phase strategy in polypropylene syringes fitted with polyethylene porous disks. Side chains of Fmoc aminoacids were protected as follows: Thr was protected with the *tert*-butyl group (tBu) and Cys with the trityl group (Trt). Solvents and soluble reagents were removed by suction. Washings between deprotection, couplings and subsequent deprotection steps were carried out with DMF and DCM using 10 mL of solvent/g of resin each time. The Fmoc group was removed by treatment with piperidine: DMF (1:4) for 20 min. All syntheses were performed on Cl-TrtCl resin (100 mg each peptide). Couplings of all Fmoc-aa-OH (4 equiv) except with the dipeptide Alloc-Phe-(Z)Dhb-OH were performed with DIC (4 equiv) and HOAt (4 equiv) in DMF for 1.5 h at room temperature. Recouplings were done with PyBOP (4 equiv), HOAt (4 equiv) and DIEA (12 equiv) for 1.5 h at room temperature. The coupling of dipeptide Alloc-Phe-(Z)Dhb-OH (1 equiv) was performed with DIEA (1 equiv) for 5 min , DIEA (2 equiv) for 1 h. The resin was washed with DMF and DCM after each coupling. After each coupling, the capping steps were performed with Ac_2O: DIEA: DMF (4:2:94) but with the dipeptide Alloc-Phe-(Z)Dhb-OH the capping step was done with Methanol (300 μL).

Alloc group was removed with $Pd(PPh_3)_4$ (0.1 equiv) in the presence of $PhSiH_3$ (10 equiv) during 15 min and it was repeated three times.

To cleave the peptide from the solid support, the resin was washed with DCM (3 x 1 min), dried, and then washed again with a mixture TFA: DCM (1:99) (6 x 1 min) and washed with DCM and the filtered was collected in a round-bottom flask which contained 100 μL H_2O and 50 μL DIEA. TFA was then removed by evaporation under reduced pressure, and peptides were precipitated with cold anhydrous TBME, dissolved in H_2O: MeCN (1:1) and then lyophilized. The two peptides were cycled upon dissolution in a PyAOP (4 equiv) and DIEA (8 equiv) solution. It was then stirred at room temperature for 24 h. Cyclization was monitored RP-HPLC. The solution was then evaporated with N_2 , dissolved in

H_2O: MeCN(1:1) and then lyophilized. The crude peptides were purified by semi-preparative HPLC.

TEM of unconjugated gold nanoparticles

Drops of bare gold nanoparticles were deposited over carbon-coated Formvar films on copper grids. The samples were viewed with a transmission electron microscope (JEOL JEM 1010 (Japan)) at an accelerating voltage of 80 kV. The images were obtained with a CCD Megaview III (SIS) camera (Münster, Germany).

The gold nanoparticles were free from aggregation, and had a size variation of either 7% (for the 20 nm nanoparticles) or 10% (for the 40 nm nanoparticles).

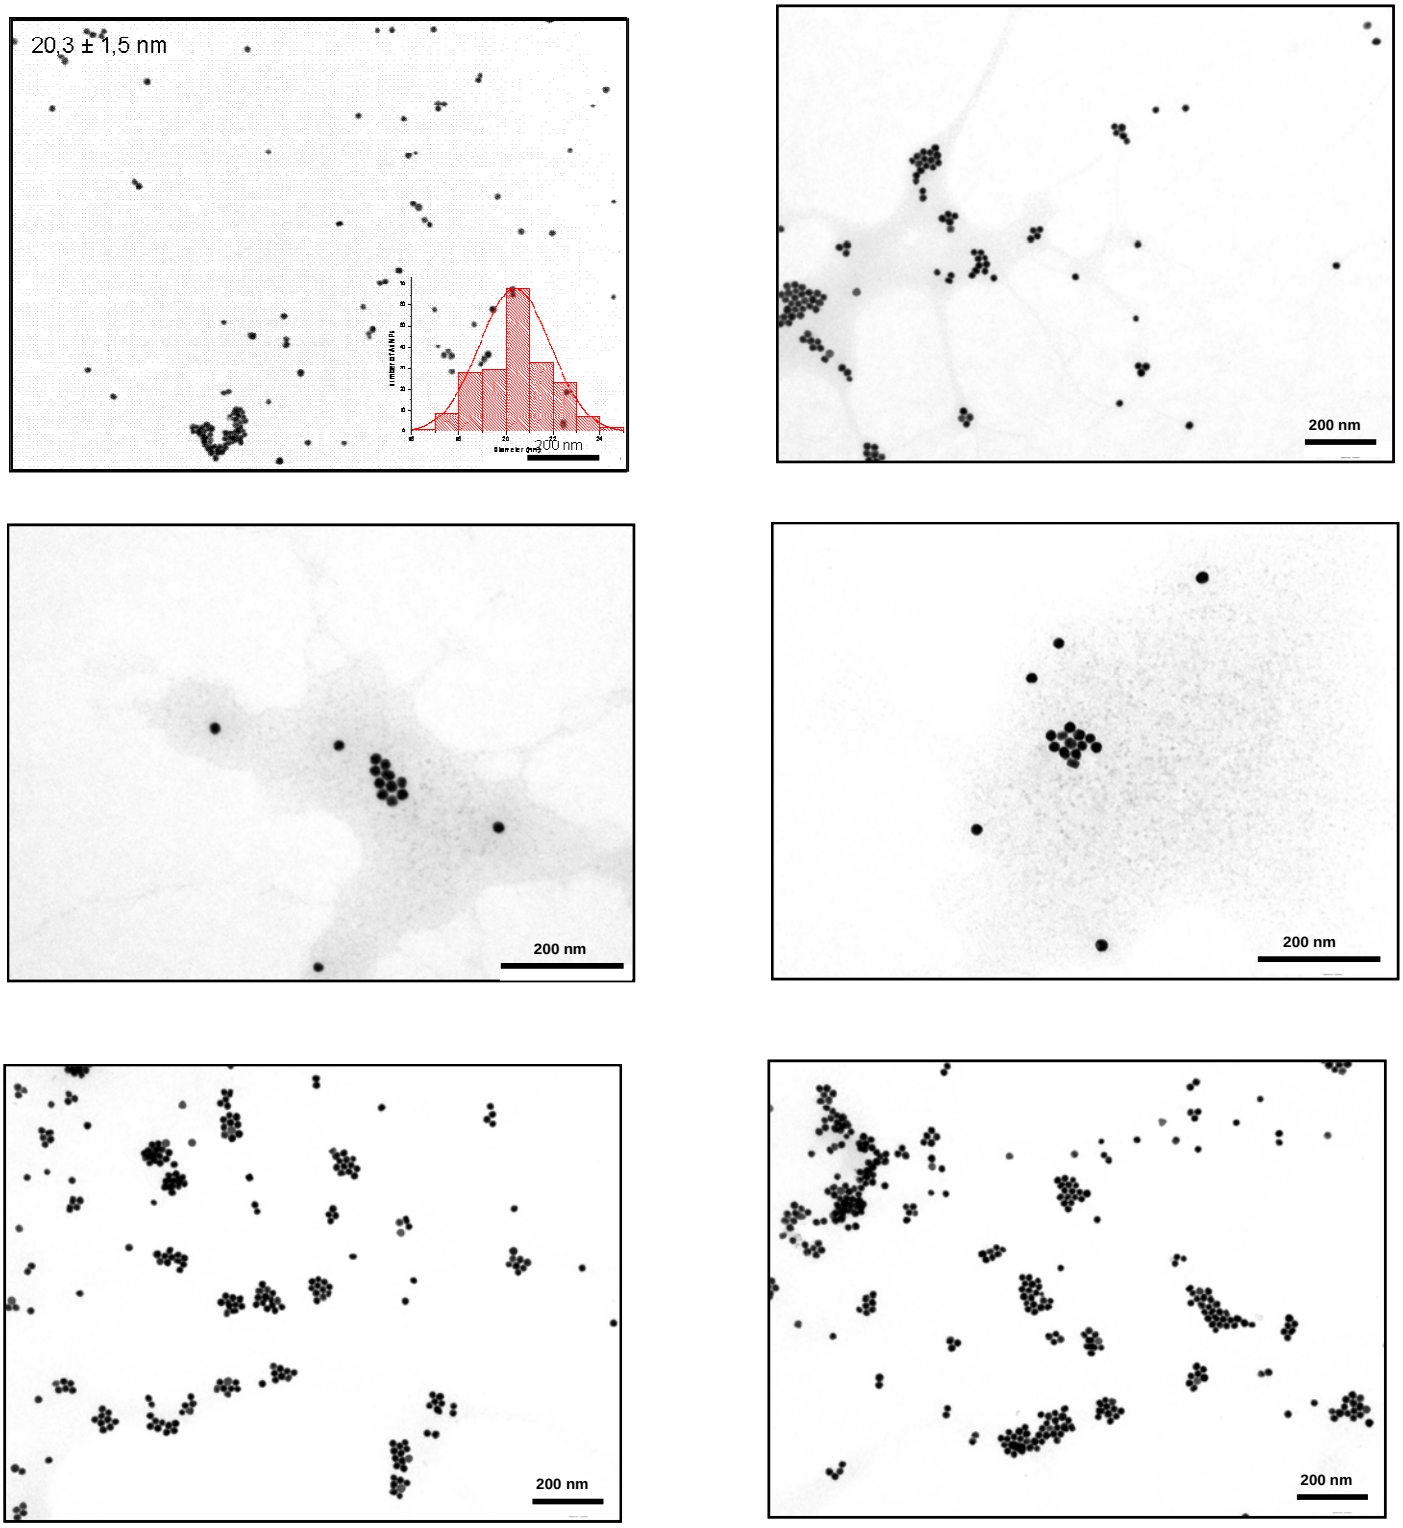

Figure S1. TEM images of 20 nm gold nanoparticle solution.

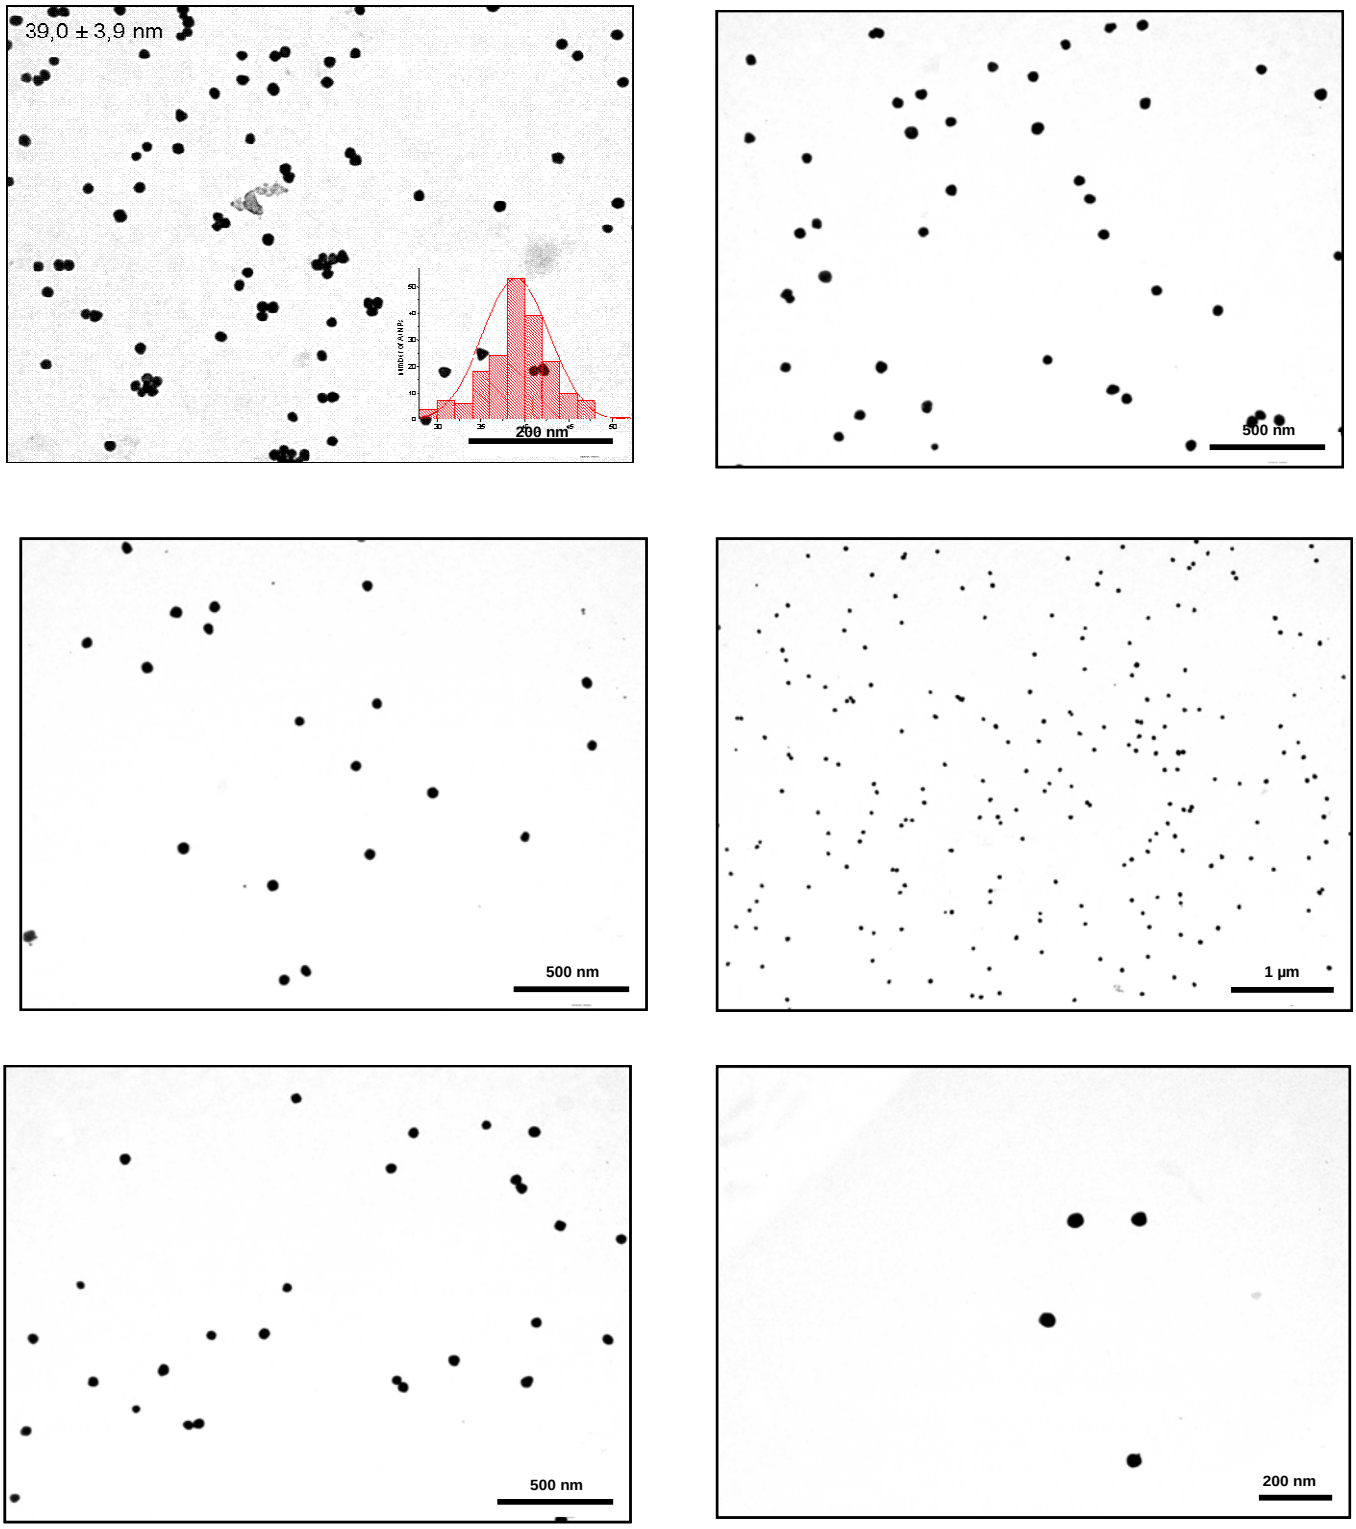

Figure S2. TEM images of 40 nm gold nanoparticle solution

XPS

The XPS spectra were centred at 163.2 eV. Based on the various chemical environments of the sulphur atom, two different groups of chemical states can be differentiated. One group corresponds to the sulphur present in the unreacted peptide and the second group corresponds to the chemisorbed sulphur. Subgroups, such as the difference in chemical shift induced by various metal absorbing sites[1], can be identified.

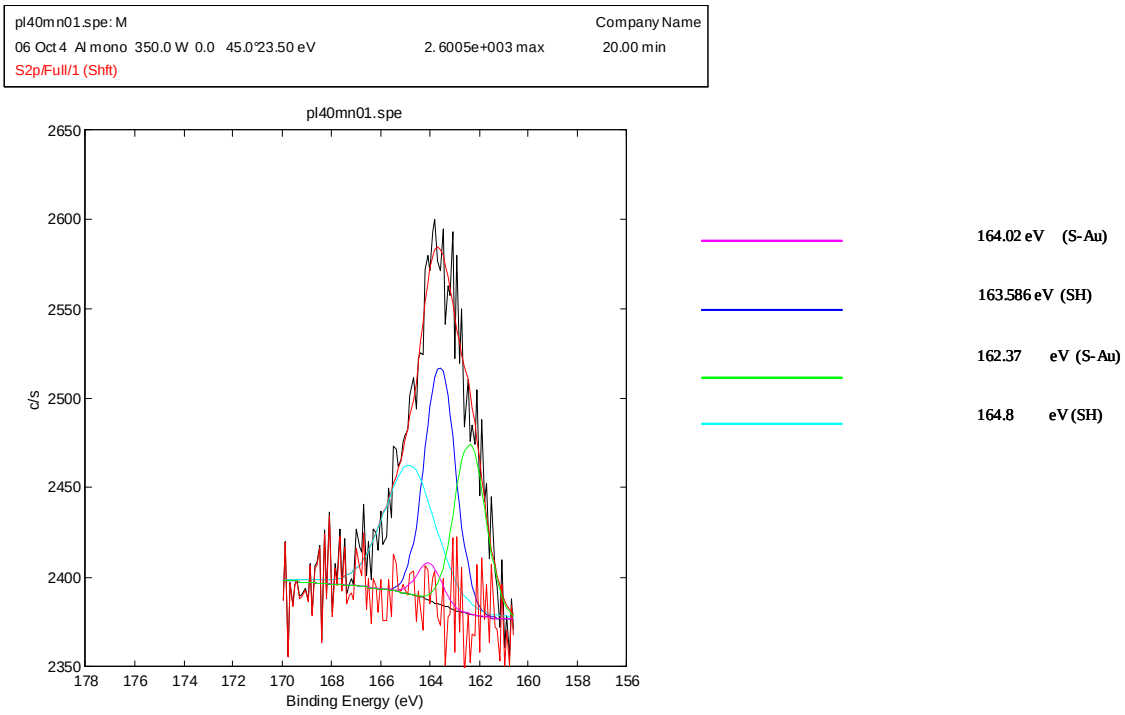

Figure S3. High-resolution XPS spectra of S 2p photoelectrons of P1-20 nm gold conjugates.

Quantification of gold nanoparticle loading

Aliquots (3 mL) of both conjugated solutions were centrifuged at 13,500 rpm for 30 min (AuNP-peptide sediments). The supernatant was lyophilised, and then analysed by HPLC. The resulting chromatogram was interpolated into the calibration curve. The percentage of unconjugated peptide was thus determined to be ca. 15 %.

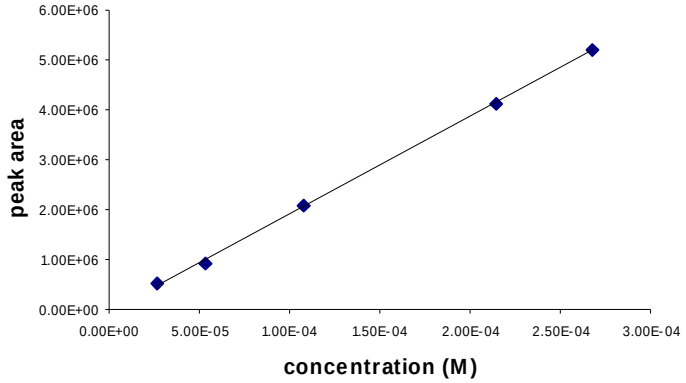

Figure S4. Calibration curve of P1: concentration of P1 is plotted against the area of the HPLC peak.

HRTEM

P1-20-GNP

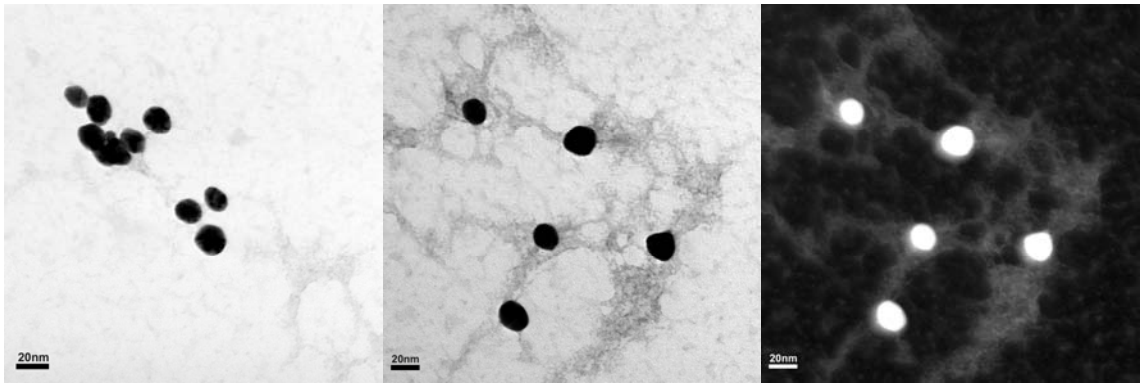

Figure S4. **HRTEM image of** P1-20-GNP.

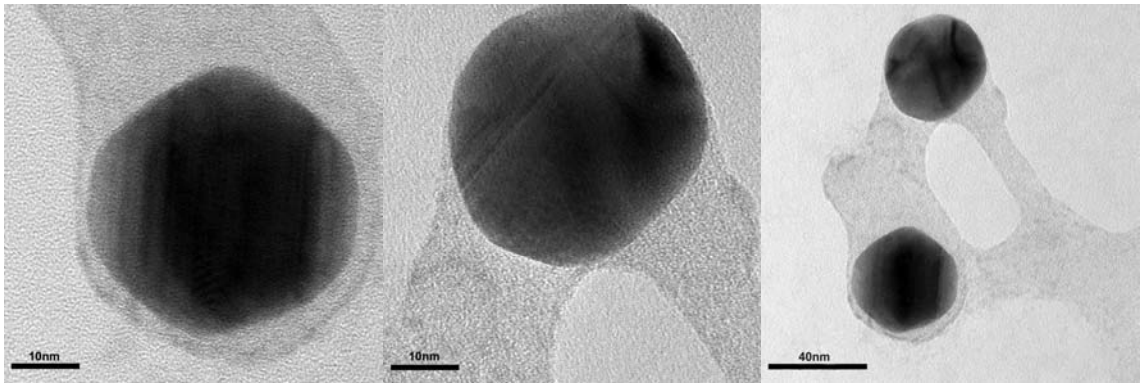

Figure S5. **HRTEM image of** P1-40-GNP.

Amino acid analysis

The relationship among the concentrations of the amino acids valine, isoleucine and proline is 4: 2: 1 in P1 and P2. The same relationship was observed on the gold conjugates by means of amino acid analysis, showing that no disruption of the peptides occurs, proving that the peptides maintain their integrity during the conjugation and dialysis process.

Amino acid analysis was carried out by the AccQ.Tag method after acid hydrolysis with HCl (6N) for 24 hours at 110°C. The analysis was performed in a Waters Delta 600 RP-LC system with UV detection at 254 nm. Each peptide was thus determined to contain four Val, two Ile and one Pro.

	Val (mM) (4)	Ile (mM) (2)	Pro (mM) (1)
P1 20 nm gold nanoparticle	0.2486	0.1279	0.0663
P2 20 nm gold nanoparticle	0.9465	0.4717	0.2925
P1 40 nm gold nanoparticle	0.4512	0.2299	0.1326
P2 40 nm gold nanoparticle	1.1504	0.7323	0.4902

Anti-proliferation assay

HeLa viability in the presence of unconjugated or conjugated nanoparticles was tested using a WST 1 assay, including a control with no nanoparticles added. For each assay 3.5 x 10^3 cells/cm^2 were seeded on a 96-well plate (Nalge Nunc) and cultured for 24 h. The conjugates were added in a 1:4 (conjugate/DMEM) ratio. Cells were incubated for 24 h at 37º C under a 5% CO_2 atmosphere. After 20 h, WST 1 was added. The cells with the conjugate solutions were incubated for a further 4 h. Cell viability is expressed as a percentage ratio of cells treated with the different compounds against untreated cells. All determinations were carried out in sextuplicate and Tukey's multiple comparison test after one-way ANOVA statistics was also performed.

Tukey's Multiple Comparison Test	**P value**
control vs SDS	P < 0.001

In vivo molecular cancer imaging with monoclonal antibodies has great potential not only for cancer detection, but also for cancer characterization. However, the prolonged retention of intravenously injected antibody in the blood causes low target tumor-to-background ratio (TBR). Avidin has been used as a "chase" to clear the unbound, circulating biotinylated antibody and decrease the background signal. Here, we utilize a combined approach of a fluorescence resonance energy transfer (FRET) quenched antibody with an "avidin chase" to increase TBR. Trastuzumab, a humanized monoclonal antibody against human epidermal growth factor receptor type 2 (HER2), was biotinylated and conjugated with the near-infrared (NIR) fluorophore Alexa680 to synthesize Tra-Alexa680-biotin. Next, the FRET quencher, QSY-21, was conjugated to avidin, neutravidin (nAv), or streptavidin (sAv), thus creating Av-QSY21, nAv-QSY21, or sAv-QSY21 as "chasers". The fluorescence was quenched in vitro by binding Tra-Alexa680-biotin to Av-QSY21, nAv-QSY21, or sAv-QSY21. To evaluate if the injection of quencher-conjugated avidin derivatives can improve target TBR by using a dual "quench and chase" strategy, both target (3T3/HER2+) and nontarget (Balb3T3/ZsGreen) tumor-bearing mice were employed. The "FRET quench" effect induced by all the QSY21 avidin-based conjugates reduced but did not totally eliminate background signal from the blood pool. The addition of nAv-QSY21 administration increased target TBR mainly because of the "chase" effect where unbound conjugated antibody was preferentially cleared to the liver. The relatively slow clearance of unbound nAv-QSY21 leads to further reductions in background signal by leaking out of the vascular space and binding to unbound antibodies in the extravascular space of tumors, resulting in decreased nontarget tumor-to-background ratios but increased target TBR due to the "FRET quench" effect, because target-bound antibodies were internalized and could not bind to nAv-QSY21. In conclusion, the proposed "quench-and-chase" system combines two strategies, fluorescent quenching and avidin chasing, to improve target TBR and reduce nontarget TBR, which should result in both improved tumor sensitivity and improved specificity.

INTRODUCTION

In vivo molecular cancer imaging with monoclonal antibodies has great potential for cancer detection and characterization. However, a high target tumor signal is required to overcome the high background signal arising from the slow blood clearance of antibodies. "Avidin chase" is a classic method to increase TBR in immunoscintigraphy by reducing background signal arising from circulating unbound antibodies by accelerating hepatic clearance (*1*−*5*). In this method, radiolabeled biotinylated antibodies circulating in the blood are "chased" from the circulation after avidin injection, since the avidin−biotin antibody complex is rapidly removed from circulation in the liver. This "chase" paradigm has recently been applied to dendrimer- and albumin-based MRI contrast agents and optical imaging agents (*6*−*8*).

Activation of optical probes at the target can further increase TBR. The fluorescence signal from optical imaging probes can be deactivated and activated (or "quenched and dequenched") by changing the surrounding environment. FRET is one mechanism of quenching whereby fluorescence energy is transferred from an electronically excited donor molecule to a ground-state acceptor molecule (*9*). Activation can also be achieved with other modalities. For instance, MRI signal from contrast agents can be deactivated and activated (*10,11*). However, the percentage change in signal between the activated and deactivated state is substantially higher for optical imaging. If the acceptor molecule is a quencher, which does not emit light when it returns to the ground state, the fluorescence from the donor molecule is absorbed and the molecular probe is quenched. FRET is observed only when the distance between the donor and the acceptor is less than 100 Å, the so-called Förster radius (*9*). The avidin−biotin linkage allows a FRET interaction to occur between the fluorophore and its quencher, a phenomenon that has been exploited in in vitro assays for many years (*12*−*14*). Thus, when the appropriate pair of fluorophore-quencher molecules is linked via avidin−biotin binding to a carrier molecule, such as an antibody, the fluorescent signal from the donor fluorophore is quenched by the acceptor quencher molecule.

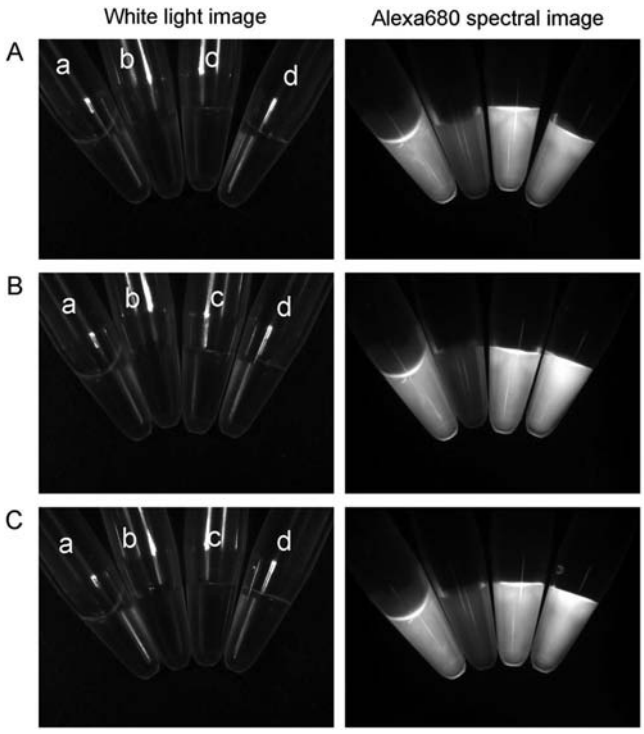

Figure 1. FRET quench by forming Tra-Alexa680-biotin and Av-QSY21 (A), nAv-QSY21 (B), or sAv- QSY21 (C) complexes in vitro. a, Tra-Alexa680-biotin + PBS; b, Tra-Alexa680-biotin + QSY21 conjugated avidin or derivatives; c, Tra-Alexa680 + PBS; d, Tra-Alexa680 + QSY21 conjugated avidin or derivatives. The fluorescence was quenched by forming Tra-Alexa680-biotin and Av- QSY21, nAv-QSY21, or sAv-QSY21 complexes.

In this study, we combined two strategies to improve target TBR: "FRET quenching" and an avidin "chase". Trastuzumab, a humanized monoclonal IgG_1 antibody to human epidermal growth factor receptor type 2 (HER2), was biotinylated and conjugated with a near-infrared (NIR) fluorophore, AlexaFluor680 (Alexa680). To implement this dual "quench and chase" strategy, QSY-21 (quencher) was conjugated to avidin or to one its derivatives, neutravidin or streptavidin, resulting in simultaneous tumor-specific activation (or dequenching) and improved background clearance. This "quench-and-chase" system was evaluated in vivo, using both HER2 positive and negative tumor bearing mice to demonstrate improved target TBR and reduced nontarget TBR.

EXPERIMENTAL PROCEDURES

Reagents. Trastuzumab (Tra), an FDA-approved humanized anti-HER-2 antibody, was purchased from Genentech Inc. (South San Francisco, CA). Alexa680-NHS ester and QSY21-NHS ester were purchased from Invitrogen Corporation (Carlsbad, CA). Amine-reactive biotin, sulfosuccinimidyl-6-(biotin-amido)hexanoate (Sulfo-NHS-LC-Biotin) was purchased from Pierce Chemical Co. (Rockford, IL). ZsGreen plasmid was purchased from Clontech Laboratories, Inc. (Mountain View, CA). All other chemicals used were of reagent grade.

Synthesis of Alexa680 Conjugated Biotinylated Antibody (Tra-Alexa680-biotin). Trastuzumab (6.8 nmol) was incubated with Alexa680-NHS (55 nmol, 5 mM in DMSO) in 0.1 M Na_2HPO_4 (pH 8.5) at room temperature for 30 min. The mixture was purified with a Sephadex G50 column (PD-10; GE Healthcare, Piscataway, NJ). The protein concentration was determined with the Coomassie Plus protein assay kit (Pierce Biotechnology, Rockford, IL) by measuring the absorption at 595 nm with a UV−vis system (8453 Value UV−visible Value System; Agilent Technologies, Santa Clara, CA). The concentration of Alexa680 was measured by absorption with the UV−vis system to confirm the number of fluorophore molecules conjugated to each trastuzumab molecule. The number of Alexa680 per antibody was ∼4−5. The resulting conjugate (Tra-Alexa680) was concentrated using a centrifugal filter device (Centricon YM-30, Millipore, Bedford, MA) to 37 μM. Then, NHS-LC-biotin (195 nmol, 5 mM in DMSO) was added to this solution and reacted in 0.1 M Na_2HPO_4 (pH 8.5) at room temperature for 30 min. Unreacted biotin was separated from antibody by Sephadex G50 column and the Tra-Alexa680-biotin was purified. The biotin labeling ratio was determined by the HABA method (*15*). The number of biotin molecules conjugated to trastuzumab was ∼11.

Synthesis of QSY21 Conjugated Avidin, Neutravidin, and Streptavidin (Av-QSY21, nAv-QSY21, sAv-QSY21). Avidin, neutravidin, or streptavidin (14 nmol) were incubated with

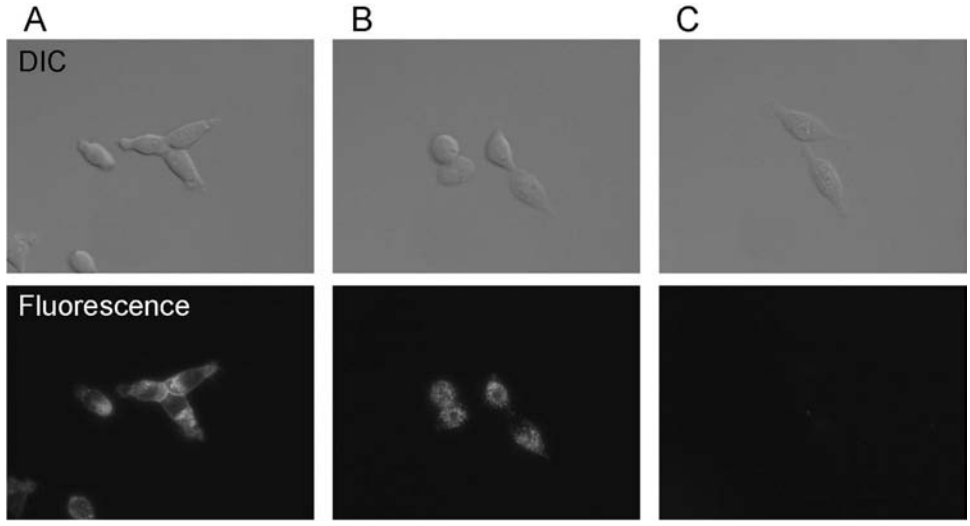

Figure 2. 3T3/HER2+ cell images of (A) 6.5 h after incubation with Tra-Alexa680-biotin, (B) 6 h after incubation with Tra-Alexa680-biotin then added nAv-QSY21 30 min before observation, and (C) 6.5 h after incubation with both Tra-Alexa680-biotin and nAv-QSY21. The bright fluorescence signal was detected on the surface as well as inside the cells with Tra-Alexa680-biotin incubation (A). In contrast, nAv-QSY21 only quenched the fluorescence on the cell surface (B) but not the fluorescence yielded from the internalized antibodies.

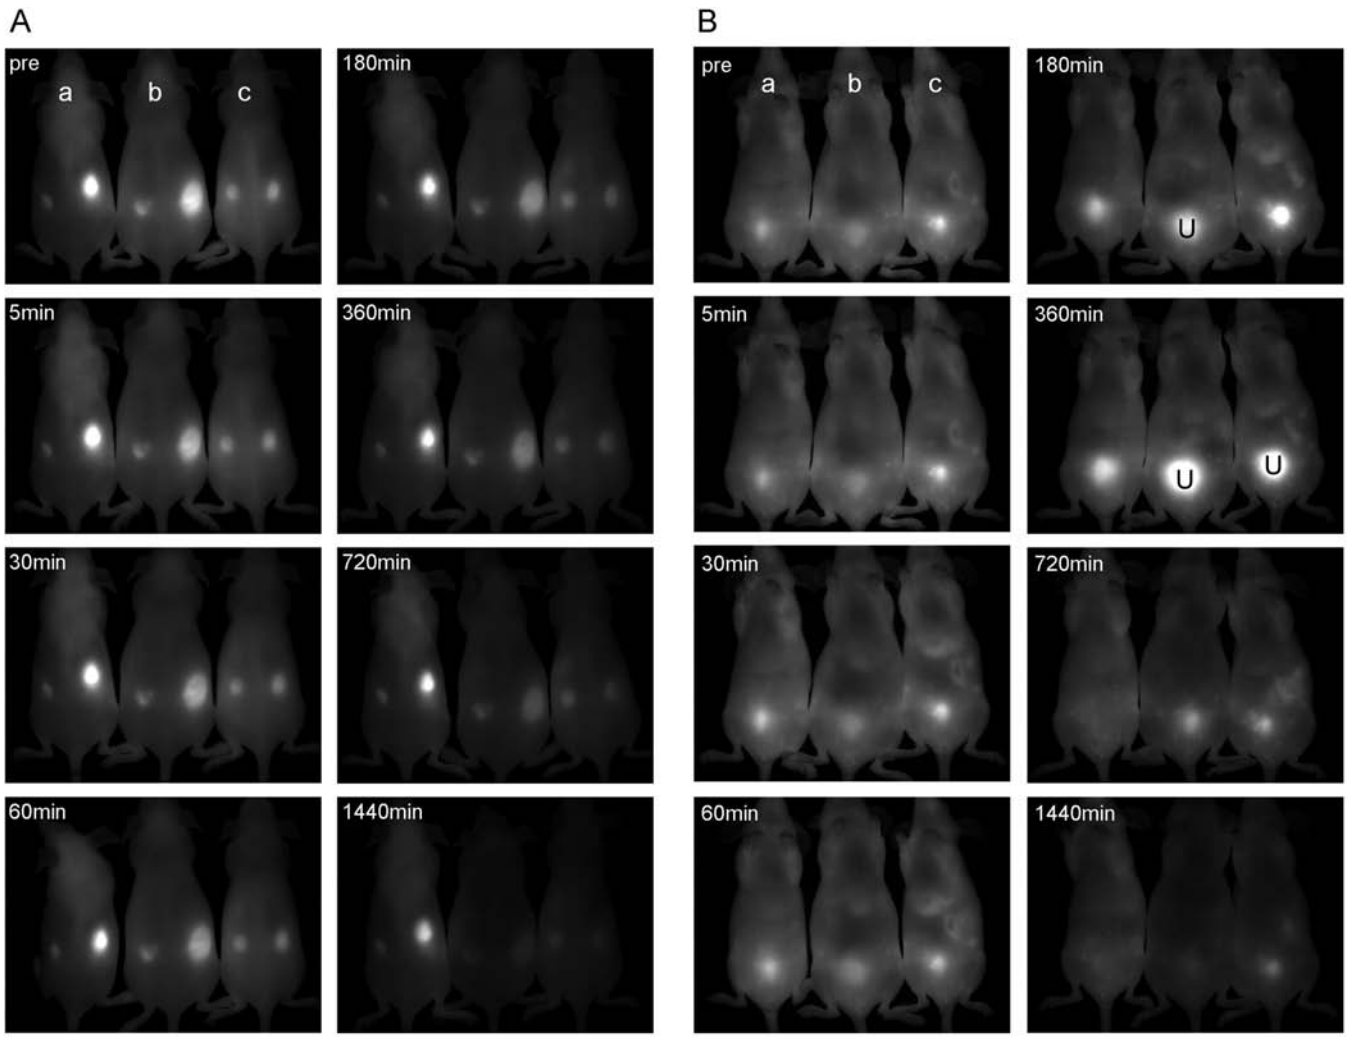

Figure 3. Comparison of Alexa680 spectral images after (b) Av-QSY21 (250 μg, iv) or (c) avidin (250 μg, iv) injection into Tra-Alexa680-biotin treated mice at each time point. (a) nontreated control. A, prone; and B, supine images. Tra-Alexa680-biotin (50 μg, iv) was injected into tumor-bearing mice (left dorsal, 3T3/HER2+; right dorsal, Balb/3T3/ZsGreen HER2− shown in A) one day before avidin treatments. The accumulation in the lower abdomen shown in B is the urine (U) in the bladder.

QSY21-NHS (42 nmol, 12 mM in DMSO) in 0.1 M Na_2HPO_4 (pH 8.5) at room temperature for 30 min. Each mixture was purified with a Sephadex G50 column. The concentrations of protein and QSY21 were measured as described above. The number of QSY21 per avidin or avidin derivative was approximately 1.

Determination of FRET Quench Effect with Complexes of Tra-Alexa680-biotin and Av-QSY21, nAv-QSY21, or sAv-QSY21 in Vitro. Tra-Alexa680-biotin (0.034 nmol in 100 μL PBS) was mixed with Av-QSY21, nAv-QSY21, or sAv-QSY21 (0.171 nmol in 100 μL PBS). For control, Av-QSY21, nAv-QSY21, or sAv-QSY21 was mixed with Tra-Alexa680. The change in fluorescence intensity was investigated with the Maestro In Vivo Imaging System (CRi Inc., Woburn, MA) using 671 to 705 nm excitation and 750 nm long-pass emission filters.

Determination of FRET Quench Effect before and after Cell Binding of Tra-Alexa680-biotin. 3T3/HER2+ (1×10^4) were plated on a cover glass-bottomed culture well and incubated for 16 h. Then, Tra-Alexa680-biotin was added to the medium (10 μg/mL), and the cells were incubated for 6 h. Then, to check the quench effect, nAv-QSY21 was added to the medium (50 μg/mL) and the cells were incubated for an additional 30 min. As a control, the cells were incubated with Tra-Alexa680-biotin for 6.5 h without nAv-QSY21 or incubated for 6.5 h with both Tra-Alexa680-biotin and nAv-QSY21. Cells were washed once with PBS, and fluorescence microscopy was performed using an Olympus BX51 microscope (Olympus America, Inc., Melville, NY) equipped with the following filters: excitation wavelength 590 to 650nm, emission wavelength 662.5 to 747.5 nm. Transmitted light differential interference contrast (DIC) images were also acquired.

Mouse Tumor Model. All procedures were carried out in compliance with the Guide for the Care and Use of Laboratory Animal Resources (1996), National Research Council, and approved by the local Animal Care and Use Committee.

The *HER2* gene transfected NIH3T3 (3T3/HER2+) cell line was the positive control, and green fluorescence protein transfected Balb/3T3 cell line (Balb/3T3/ZsGreen) was used as a negative control, since the Balb/3T3/ZsGreen cell line does not express HER2 receptor. The cell lines were grown in RPMI 1640 (Life Technologies, Gaithersburg, MD) containing 10% fetal bovine serum (Life Technologies), 0.03% L-glutamine, 100 units/mL penicillin, and 100 μg/mL streptomycin in 5% CO_2 at 37 °C.

Both receptor-positive and -negative tumor cell lines were implanted in the same mice. 3T3/HER2+ cells (2×10^6 cells in PBS) were injected subcutaneously in the left dorsum, and Balb/3T3/ZsGreen cells (2×10^6 cells in PBS) were injected

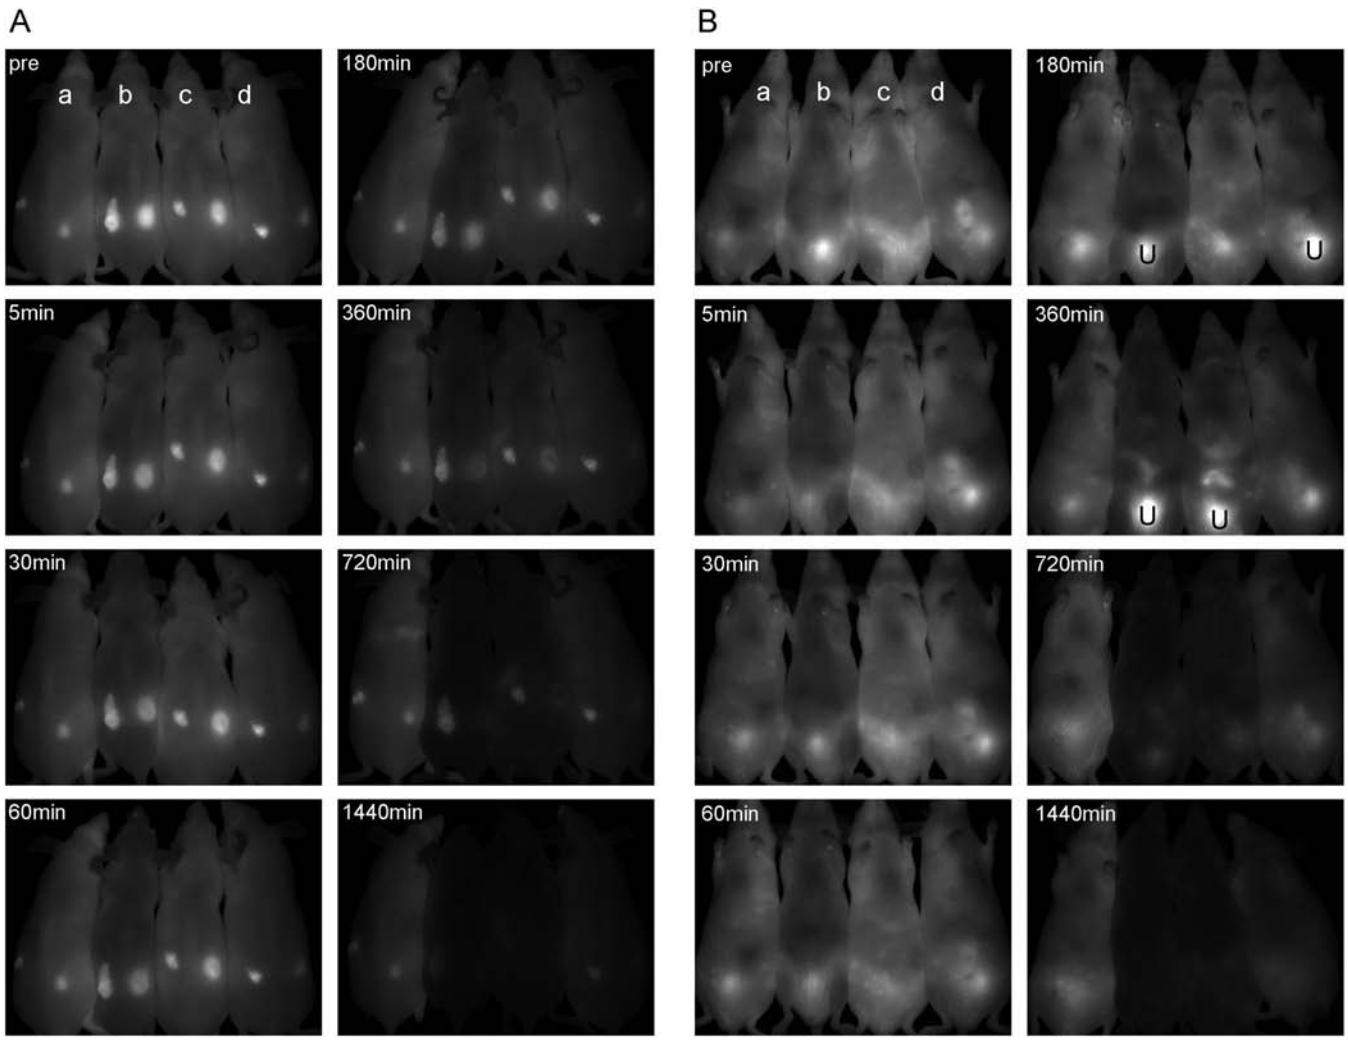

Figure 4. Comparison of Alexa680 spectral images after (b) nAv-QSY21 (250 μg, iv), (c) neutravidin (250 μg, iv), or (d) Av-QSY21 (250 μg, iv) injection into Tra-Alexa680-biotin treated mice at each time point. (a) nontreated control. A, prone; and B, supine images. Tra-Alexa680-biotin (50 μg, iv) was injected into tumor-bearing mice (left dorsal, 3T3/HER2+; right dorsal, Balb/3T3/ZsGreen HER2− shown in A) one day before neutravidin treatments. The accumulation in the lower abdomen shown in B is the urine (U) in the bladder.

subcutaneously into the right dorsum. The experiments were performed at 5−8 days after cell injection.

In Vivo Spectral Imaging Studies. Tra-Alexa680-biotin (50 μg) was injected via the tail vein into tumor-bearing (3T3/HER2+ and Balb/3T3/ZsGreen HER2-) mice ($n = 4$ in each group). One day after the Tra-Alexa680-biotin injection, the mice were anesthetized with intraperitoneally administered 10% sodium pentobarbital with 0.1% scopolamine butyl bromide, then spectral fluorescence images were obtained using the Maestro In Vivo Imaging System (CRi Inc., Woburn, MA) using two filter sets. The deep red filter sets were used to image Alexa680 fluorescence, and the blue filter sets were used for ZsGreen fluorescence. The deep red filter sets use a band-pass filter from 642 to 680 nm (excitation) and a long-pass filter over 702 nm (emission); the blue filter sets use a band-pass filter from 437 to 476 nm (excitation) and a long-pass filter over 493 nm (emission). The tunable emission filter was automatically stepped in 10 nm increments from 650 to 950 nm for the deep red filter sets and from 500 to 800 nm for the blue filter sets, while the camera captured images at each wavelength interval with constant exposure.

After taking the images, Av-QSY21, nAv-QSY21, or sAv-QSY21 (250 μg) were injected via tail vein into mice already injected with Tra-Alexa680-biotin. Then, fluorescence images were obtained in the same manner as described above at 5, 30, 60, 180, 360, 720, and 1440 min after the Av-QSY21, nAv-QSY21, or sAv-QSY21 injection. The spectral fluorescence images were then unmixed on the basis of their spectral patterns using commercial software (*Nuance* software, CRi, Inc., Woburn, MA). Prone images were used for fluorescence intensity measurement. Regions of interest measurements were placed on the Alexa680 spectrum images with reference to the white light and ZsGreen spectrum images to measure the fluorescence intensities of the 3T3/HER2+ and Balb/3T3/ZsGreen HER2- tumor. For the background signal, regions of interest were placed between the tumors. Data are presented as the mean ± SD. Statistical analysis was carried out using the Mann−Whitney *U*-test.

RESULTS

Complexes of Tra-Alexa680-biotin and Av-QSY21, nAv-QSY21, or sAv-QSY21 Are Quenched. As shown in Figure 1, the fluorescence was quenched by adding Av-QSY21, nAv-QSY21, or sAv-QSY21 to the Tra-Alexa680-biotin solution. The quenching capacities were 2.4-, 4.4-, and 3.2-fold for Av-QSY21, nAv-QSY21, or sAv-QSY21, respectively. On the other hand, there was no effect on non-biotinylated probe, Tra-Alexa680.

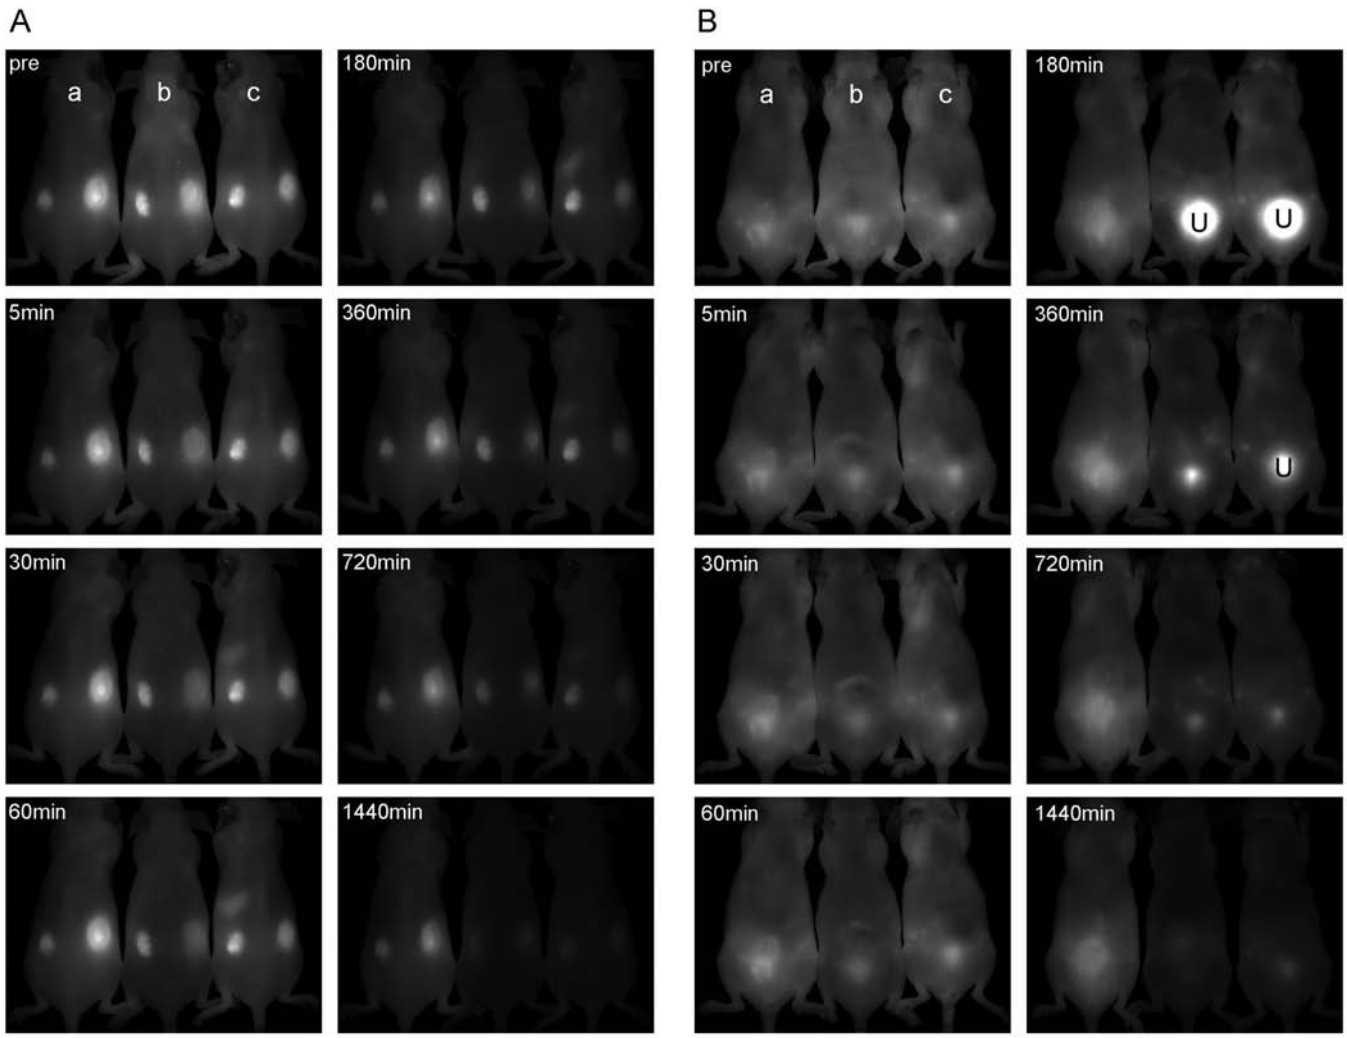

Figure 5. Comparison of Alexa680 spectral images after (b) sAv-QSY21 (250 μg, iv) or (c) streptavidin (250 μg, iv) injection into Tra-Alexa680-biotin treated mice at each time point. (a) nontreated control. A, prone; and B, supine images. Tra-Alexa680-biotin (50 μg, iv) was injected into tumor-bearing mice (left dorsal, 3T3/HER2+; right dorsal, Balb/3T3/ZsGreen HER2− shown in A) one day before streptavidin treatments. The accumulation in the lower abdomen shown in B is the urine (U) in the bladder.

nAv-QSY21 Quenched Tra-Alexa680-biotin on the Cell Surface but Not Internalized Conjugates. To investigate FRET quenching effects in vitro, fluorescence microscopy studies were carried out. High fluorescence signal was detected on the surface as well as inside of the cells with Tra-Alexa680-biotin incubation alone (Figure 2A). In contrast, after nAv-QSY21 was added quenching was observed at the cell surface (Figure 2B) but not from previously internalized Tra-Alexa680-biotin. When both Tra-Alexa680biotin and nAv-QSY21 were added at the same time, fluorescence signal could not be detected either on the surface or inside the cells even 6.5 h after incubation (Figure 2C).

Pharmacokinetic Effect of Adding Av-QSY21, nAv-QSY21, or sAv-QSY21 to Tra-Alexa680-biotin in Vivo. Figures 3 to 6 show the prone and supine images of tumor-bearing mice with time, respectively. The measured fluorescence values are represented by changes in TBR (=(TBR at each time point)/(TBR at 0 min)) and summarized in Figure 7. The changes in background fluorescence intensity from the body are shown in Figure 8.

The background fluorescence was immediately decreased by all QSY21 conjugated molecules, Av-QSY21, nAv-QSY21, and sAv-QSY21. The largest decrease was observed for nAv-QSY21 treatment. The background fluorescence was decreased only at 180 min postinjection of non-QSY21 conjugated neutravidin or later time points. The decreased level was not significant for avidin-treated mice compared to nontreated controls except for the 1440 min time point. For streptavidin-treated mice, the background level was even higher than the control group at 30 min after the injection, and it was decreased at 180 min and later time points.

After nAv-QSY21 injection, fluorescence from the HER2 negative tumor decreased while the TBR in HER2 positive tumor increased with time. As a result, at 720+ min after injection of the nAv-QSY21 only the HER2 positive tumor was visualized. The unconjugated neutravidin resulted in decreased nontarget tumor-to-background ratio; however, the effect was much weaker than with QSY21-conjugated neutravidin, indicating the combined effects of the "quench and chase" strategy. The sAv-QSY21 complex resulted in decreased fluorescence in the HER2 negative tumor, but the tumor was still barely visible. In addition, since streptavidin does not have a substantial "chase effect", the TBR for HER2 positive tumors did not increase with streptavidin without QSY21 conjugation. The Av-QSY21 and avidin treatment did not result in a difference between targeted and nontargeted tumors, indicating that the avidin or Av-QSY21 primarily affected the unbound antibodies in the circulation.

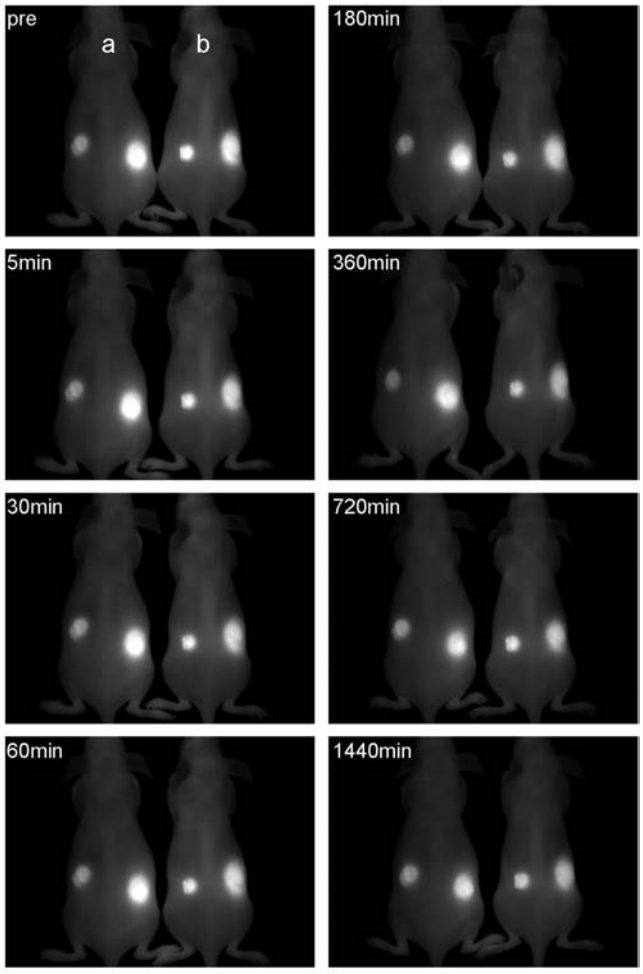

Figure 6. Alexa680 spectral images of non-biotinylated antibody, Tra-Alexa680 treated mice. a, nontreated control; b, nAv-QSY21 (250 μg, iv). No effect was observed by nAv-QSY21 treatment.

The liver fluorescence due to the chase effect was observed at 30 min+ postinjection with avidin and 360 min+ postinjection of neutravidin, but this liver signal was not observed for QSY21-conjugated avidin or neutravidin due to FRET quench effects.

DISCUSSION

To achieve target specific imaging with high tumor TBR, we combined "avidin chase" and "FRET quenching" methods, which reduce background signal by a combination of rapidly clearing unbound conjugate through the liver as well as photochemically quenching non-internalized labeled and biotinylated antibody. As expected, the FRET quencher, QSY21 conjugated to avidin, and its derivatives quenched the fluorescence of extracellular Tra-Alexa680-biotin in vitro (Figure 1). Among the three avidin derivatives, the quenching efficiency was strongest for nAv-QSY21, although the number of biotin binding sites and affinities for biotin are the same for avidin, neutravidin, and streptavidin. Some structural differences including isoelectric points or hydrophilicity in each derivative might affect the steric distance between Alexa680 and QSY21 leading to differences in quenching efficiency. Quenching was only observed when the QSY21−avidin (or derivative) complex was mixed with biotinylated antibody, but not with non-biotinylated antibody. Therefore, quenching is due to the FRET effect between Alexa680 and QSY21 after forming the avidin−biotin bond.

To investigate this phenomenon in vivo, both targeted (3T3/HER2+) and nontargeted (Balb3T3/ZsGreen) tumor-bearing mice were employed. The "FRET quench" effect induced by all QSY21−avidin (and derivatives) reduced background signal from the blood pool just after the injection (Figures 3, 4, 5, and 8). This rapid decline in signal represents the "FRET quench" effect in vivo; non-QSY21 conjugated avidin derivatives, with the exception of avidin, did not decrease background at the initial time point. The injected QSY21−avidin (and derivatives) conjugates rapidly distributed in the circulation and bound to circulating Tra-Alexa680-biotin in the blood forming an avidin−biotin bond, leading to "FRET quenching". The background signal quenching effect was stronger for nAv-QSY21 and sAv-QSY21 than for Av-QSY21. This is likely because the blood clearance of avidin is much faster than for streptavidin (*16, 17*) or neutravidin, which are deglycosylated and neutralized avidins (*18, 19*). The prolonged relative retention of nAv-QSY21 and sAv-QSY21 in circulation increased the likelihood of binding with Tra-Alexa680-biotin, which was distributed in both the vascular and extravascular spaces.

In contrast, unconjugated avidin reduced the background signal as a result of the "chase" effect. The "chase" effect of avidin is quicker than the other avidin derivatives (*20*). A consequence of this faster clearance was that avidin was less effective in "chasing" Tra-Alexa680-biotin that had entered the extravascular space due to the EPR effect, leading to a reduced target-to-nontarget tumor ratio.

In comparison to avidin complexes, the complexes formed by neutravidin and streptavidin and the biotinylated antibody in circulation are more slowly formed and cleared (*20*).

At the initial points, the background signal was increased by nonconjugated streptavidin compared to controls as shown in Figures 4 and 7. We hypothesize that streptavidin, which has minimal "chase" effects, leads to retention of the biotinylated antibody in the circulation by forming streptavidin−biotin antibody complex that leads to a redistribution of Tra-Alexa680-biotin from the extravascular space to the circulation, thus increasing the fluorescence signal of the background. This increase was not observed with sAv-QSY21, because the fluorescence from the circulating streptavidin−biotin antibody complex was quenched by the "FRET effect".

With nAv-QSY21, the slower clearance of neutravidin compared to avidin and the faster clearance of neutravidin−biotin antibody complex compared to streptavidin−biotin antibody complex increased the target TBR because of the "chase" effect, where unbound conjugate was preferentially cleared by the liver. Relatively slow clearance of nAv-QSY21 allows leaking out and binding to the unbound antibodies in the extravascular space, resulting in decreased nontarget TBR but increased target TBR due to the "FRET quench" effect, because target-bound antibodies were internalized and could not bind to nAv-QSY21. In this model, nAv-QSY21 remained in the circulation long enough to leak out and bind nonspecifically to Tra-Alexa680-biotin, which had nonspecifically entered the extravascular space of the nontarget Balb3T3 (HER2−) tumor due to the enhanced permeability and retention (EPR) effect. These nAv-QSY21-biotin antibody complexes were quenched and gradually cleared to the liver. Therefore, the background level was continuously decreased after nAv-QSY21 administration due to the combined effects of "FRET quenching" and background "chasing". On the other hand, neither "quench" nor "chase" effects were observed when non-biotinylated Tra-Alexa680 was used (Figure 6). These results support the dual functionality of nAv-QSY21 as both a "quencher" and a "chaser".

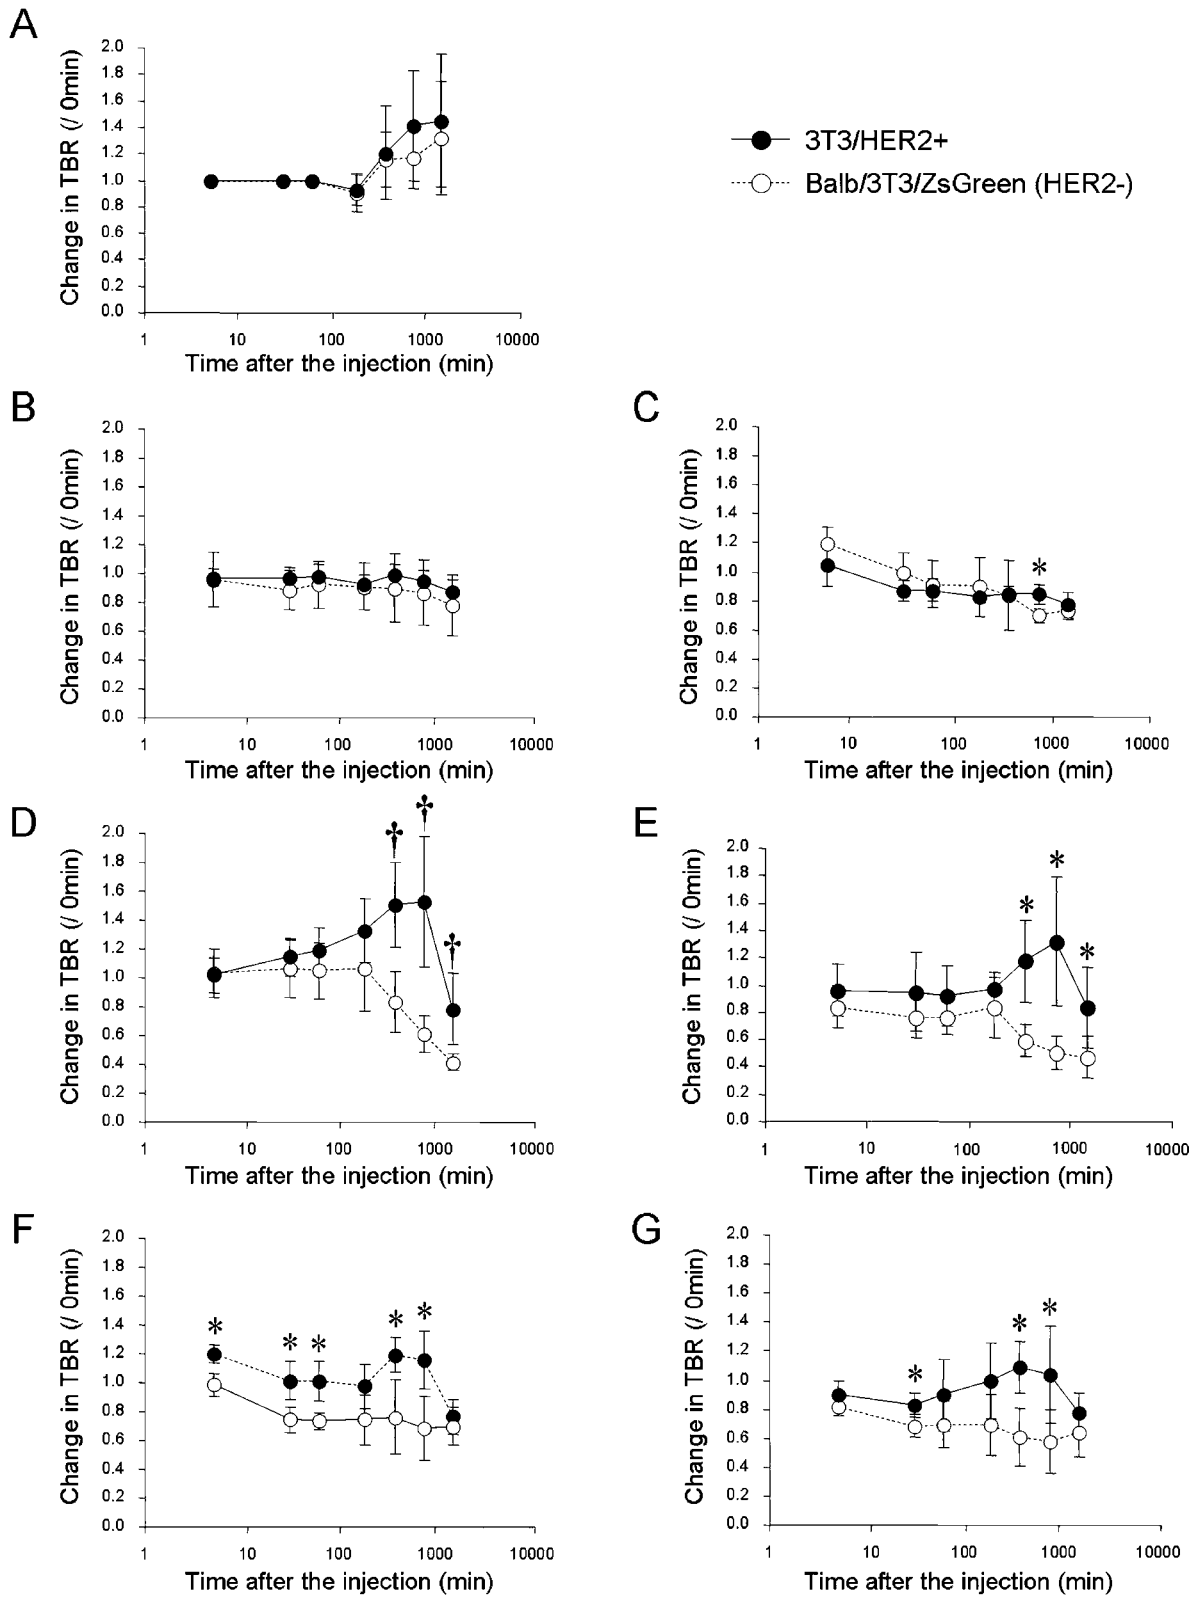

Figure 7. Time courses of changes in fluorescence TBR (TBR in each time point/TBR at 0 min) in HER2 positive and HER2 negative tumors. A, nontreatment; B, Av-QSY21; C, avidin; D, nAv-QSY21; E, neutravidin; F, sAv-QSY21; G, streptavidin. *$P < 0.05$, †$P < 0.005$ (Mann−Whitney U-test) vs HER2 negative tumor in each treated condition.

In conclusion, the proposed "quench and chase" strategy using nAv-QSY21 allowed high TBR in target tumor and reduced TBR in the nontarget tumor, resulting in successful imaging with a fluorescently labeled antibody. This "quench and chase" system can distinguish the tumor-specific targeted antibody fraction from the nonspecific accumulation of the antibody in the tumor due to EPR effects. Recently, multiple pairs of fluorophore−quencher have been developed, and these pairs could be readily adapted for the "quench and chase" strategy. Furthermore, the principle of "quench and chase" can be applied to other carrier molecules, such as peptides, dendrimers, and liposomes, to achieve high TBR during in vivo molecular imaging. Thus, "quench and chase" is a

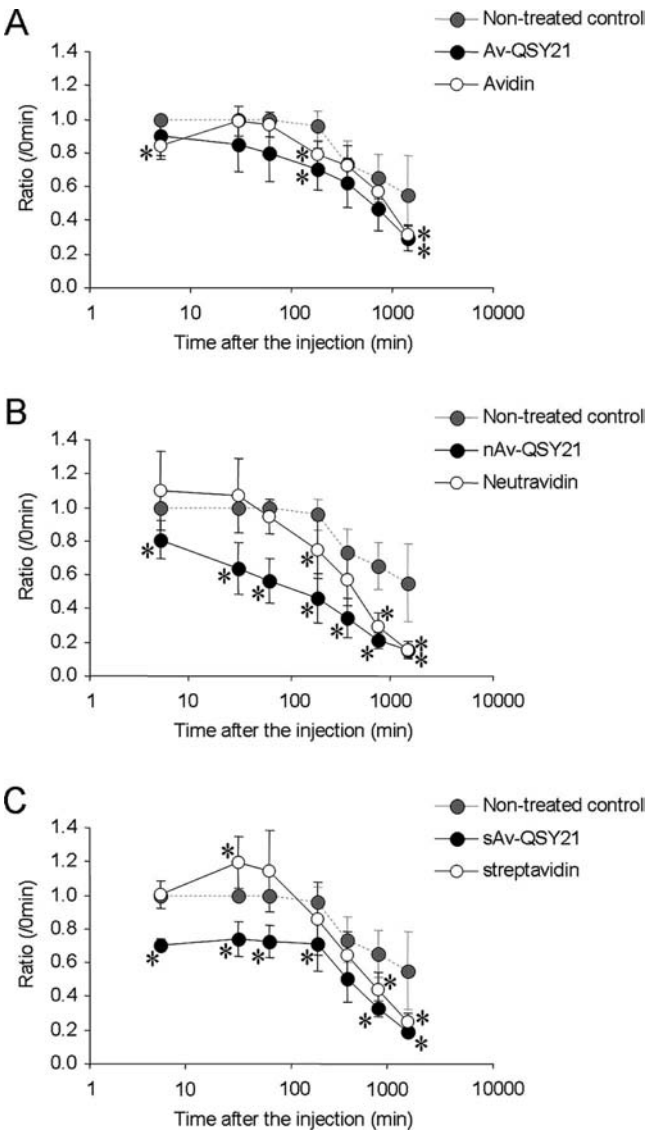

Figure 8. Change in background fluorescence intensities after (A) avidin or Av-QSY21, (B) neutravidin or nAv-QSY21, or (C) streptavidin or sAv-QSY21 treatments. *P < 0.05 (Mann−Whitney U-test) vs non-treated control.

generalizable dual strategy to improve the target TBR of molecular optical probes.

Supplemental figure 1.

Change in fluorescence signal in HER2 positive and HER2 negative tumors. One day after the Tra-Alexa680-biotin (50 μg, iv) injection, avidin (250 μg, iv) was injected to each mouse. Fluorescence images were obtained in the same manner as described above at 5, 30, 60, 180, 360, 720 and 1440 min after the avidin injection (A). The additional nAv-QSY21 injection (250 μg, iv) was performed 30min after the avidin injection to investigate the quenching effect, and images were obtained in the same manner at 5, 30, 60, 180, 360, 720 and 1440 min after the nAv-QSY21 injection (B). The additionally injected nAv-QSY21 decreased the fluorescence only from HER2 negative tumor. Because the chase effect is mostly performed by previous avidin treatment, these results show the quenching effect of nAv-QSY21.

Construction of Carbohydrate Microarrays by Using One-Step, Direct Immobilizations of Diverse Unmodified Glycans on Solid Surfaces

Sungjin Park, Myung-Ryul Lee, and Injae Shin*

Department of Chemistry, Yonsei University, Seoul 120-749, Korea. Received October 15, 2008; Revised Manuscript Received December 3, 2008

Carbohydrate microarrays have received great attention as high-throughput analytic tools in studies of carbohydrate-mediated biological processes. Most of the methods employed to fabricate glycan microarrays rely on the immobilization of modified glycans on the properly derivatized surfaces. This immobilization strategy requires the availability of modified glycans whose syntheses in many cases are time-consuming and difficult. We have developed a simple and direct immobilization technique that involves a one-step, site-specific attachment of diverse unmodified glycans to the hydrazide-derivatized glass surface. To demonstrate the generality of this direct immobilization method, we examined its use for the construction of carbohydrate microarrays containing a variety of glycans. The results of protein and cell-binding experiments indicate that the glycan microarrays, prepared by using this methodology, are applicable to the rapid evaluation of glycan-mediated biomolecular interactions and the determination of quantitative binding affinities between carbohydrates and proteins.

INTRODUCTION

Carbohydrates are vital components of living systems and a large group of biomolecules that are present mainly in the form of glycoconjugates inside or on the surfaces of cells. Through their interactions with proteins, the glycoconjugates are involved in a wide variety of important biological processes, such as cell differentiation, cell adhesion, signaling, trafficking, and immune response (for some recent reviews, see *refs 1*−*3*). Carbohydrate−protein recognition events also play key roles in many pathological processes, including infection by pathogens, cancer cell metastasis, and inflammation processes (*4, 5*). Consequently, the understanding of glycan−protein interactions at the molecular level provides deep insight into glycan-mediated biological processes and enables the development of more effective therapeutic agents and diagnostic tools in the postgenomics era.

Since 2002, carbohydrate microarrays, which are composed of diverse glycans orderly and densely attached to a single chip substrate, have been extensively developed as reliable and efficient tools for the rapid analysis of carbohydrate-based biomolecular interactions (*6*−*9*). The microarray technology has notable advantages over the use of conventional methods, such as the hemagglutination inhibition assay, enzyme-linked lectin assay, surface plasmon resonance (SPR), and isothermal titration calorimetry (ITC). The most significant advantage is that glycan microarrays enable fast, quantitative, and simultaneous analyses of a number of glycan−protein interactions with small amounts of carbohydrate samples. Another notable feature is that glycans immobilized on microarrays strongly interact with proteins, even in cases where the proteins have low binding affinities to the monovalent carbohydrates in solution. This is due to the fact that immobilized glycans display multivalent binding to proteins caused by a cluster effect. Owing to these advantageous characteristics, carbohydrate microarray-based technologies are applicable to high-throughput analyses of glycan−protein interactions.

A variety of carbohydrate microarray formats that use different surfaces and immobilization methods have emerged over the past few years (for some reviews, see *refs 10*−*16*). The most general method for construction of these microarrays involves site-specific and covalent immobilization of chemically modified carbohydrates to properly derivatized surfaces. For example, we have shown that carbohydrate microarrays can be fabricated by attaching maleimide- or hydrazide-conjugated glycans on respective thiol- or epoxide-coated glass surfaces (*6, 17*−*20*). This immobilization strategy requires the use of properly functionalized sugars, which are typically prepared by multistep synthetic sequences. To circumvent the need for synthetically intensive methods, one-step procedures for the preparation of functionally conjugated sugars have been developed and used for the fabrication of glycan microarrays. For example, amine appended sugars have been prepared by reacting free carbohydrates with 2,6-diaminopyridine in the presence of sodium cyanoborohydride or with *N*-methylaminooxy-containing bifunctional linkers (*21, 22*). The modified sugars, generated in these ways, are then covalently immobilized on the NHS ester-coated surfaces.

However, the requirement for derivatization of glycans by either one-step or multistep sequences remains a significant hurdle for the construction of microarrays containing diverse sugars. In order to avoid the need for functionalized glycans, immobilization strategies that employ unmodified sugars have been developed. One approach involves the attachment of ploysaccharides to the nitrocellulose-coated or the black polystyrene-coated surfaces (*8, 9*). This immobilization strategy is limited by a size dependence and nonspecific adsorption of glycans. An alternative approach that does not require modified sugars involves photoinduced covalent attachment of unmodified sugars to surfaces that are coated with photolabile groups (*23*). A major drawback of this technique is associated with nonspecific attachment of glycans to the surfaces.

An ideal method for the construction of carbohydrate microarrays would rely on site-specific, size-independent covalent attachment of unmodified sugars to proper surfaces. In recent investigations directed at this goal, we have developed a novel, direct, site-specific technique for immobilization of unmodified carbohydrates, including simple carbohydrates, oligosaccharides and polysaccharides, on hydrazide- and aminooxy-derivatized

surfaces (*24*). This method eliminates the need for laborious and tedious glycan derivatization. To demonstrate the scope and applicability of this approach, carbohydrate microarrays containing a variety of glycans (58 glycans) have been constructed by using one-step, direct attachment of free carbohydrates to a hydrazide-coated surface. These microarrays have been employed for analysis of sugar binding specifities of lectins, antibodies, and bacterial cells. In addition, this microarray format has been applied to the determininations of binding affinities between proteins and glycans. The results of these studies, which have led to the development of facile methods to prepare carbohydrate microarrays and their application to investigations of glycan-mediated biomolecular interactions, are described below.

MATERIALS AND METHODS

General. All chemical and biochemical products were of analytical grade and purchased from commercial suppliers: lectins from Vector Laboratories (Peterborough, UK) and Sigma-Aldrich (St. Louis, MO, USA); Cy3 and Cy5 *N*-hydroxysuccinimide from Amersham Pharmacia biotech (Piscataway, NJ, USA); carbohydrates from Sigma-Aldrich, Calbiochem (Gibbstown, NJ, USA), TCI Corporation (Tokyo, Japan), Acros (Morris Plains, NJ, USA), Senn Chemicals (Dielsdorf, Switzerland), Carbohydrate Synthesis (Oxford, UK), Dextra Laboratories (Reading, UK), and GlycoTech Corporation (Gaithersburg, MD, USA); antidextran antibody from Stemcell Technologies Inc. (Vancouver, BC, Canada) and monoclonal antichondroitin 6-sulfate antibody from MP Biochemicals Inc. (Solon, OH, USA); amine-coated glass slide from Nuricell (Seoul, Korea); SYTO 83 from Molecular Probes (Carlsbad, CA, USA). The solutions of carbohydrates were printed on the surface with a MicroSys 5100 from Cartesian Technologies Inc. (Irvine, CA, USA). Carbohydrate microarrays probed with fluorescent dye labeled-lectins were scanned with an ArrayWoRx Biochip Reader from Applied Precision (Northwest Issaquah, WA, USA).

Preparation of Aminooxy- And Hydrazide-Functionalized Glass Slides Tethered by Oligo(ethylene glycol). Commercially available amine-coated glass slides were kept in a staining jar containing a solution of succinic anhydride (3%) in DMF with gentle shaking for 3 h. The slides were washed with DMF and a solution of diisopropylcarbodiimide (DIC, 3%) and *N*-hydroxysuccinimide (NHS, 3%) in DMF was poured into a staining jar. After gentle shaking for 3 h, the slides were washed with DMF. The slides were immersed into a solution of 4,7,10-trioxa-1,13-tridecanediamine (3%) in DMF with gentle shaking for 3 h. After washing with DMF, the slides were dried by purging with argon gas.

To prepare hydrazide-coated slides, a solution of succinic anhydride (3%) in DMF was poured into a staining jar that contained the slides treated with 4,7,10-trioxa-1,13-tridecanediamine. After gentle shaking for 3 h, the slides were washed with DMF. A solution of DIC (3%) and NHS (3%) in DMF was poured into a staining jar and the slides were gently shaken for 3 h. After washing with DMF, the slides were immersed into a solution of hydrazine monohydrate (3%) in DMF with gentle shaking for 3 h. After washing with DMF, the slides were dried by purging with argon gas. The derivatized slides can be stored at room temperature in a desiccator for several weeks.

To prepare aminooxy-coated slides, a solution of *N*-(2-bromoethoxy)phthalimide (3%) and TEA (3%) in DMF was poured into a staining jar that contained the slides treated with 4,7,10-trioxa-1,13-tridecanediamine. After gentle shaking for 6 h, the slides were washed with DMF. The slides were immersed into a solution of hydrazine monohydrate (3%) in DMF with gentle shaking for 3 h. After washing with DMF, the slides were dried by purging with argon gas. The derivatized slides can be stored at room temperature in a desiccator for several weeks.

Preparation of Hydrazide-Functionalized Glass Slides Tethered by Poly(ethylene glycol). Commercially available amine-coated glass slides were kept in a staining jar containing a solution of poly(ethylene glycol) diglycidyl ether (3%, average $M_n \sim 526$) in 10 mM $NaHCO_3$ with gentle shaking for 1 h. After washing with water, the slides were immersed into a solution of 4,7,10-trioxa-1,13-tridecanediamine (3%) in 10 mM $NaHCO_3$ with gentle shaking for 1 h. They were washed with water and soaked into a solution of succinic anhydride (3%) in DMF with gentle shaking for 3 h. After washing with DMF, the slides were treated with a solution of DIC (3%) and NHS (3%) in DMF with gentle shaking for 3 h. They were washed with DMF and immersed into a solution of hydrazine monohydrate (3%) in DMF with gentle shaking for 3 h. The slides were washed with water and dried by purging with argon gas. The derivatized slides can be stored at room temperature in a desiccator for several weeks.

Printing of Carbohydrates on the Surface. Carbohydrates were dissolved in sodium phosphate buffer (pH 5.0) containing 30% glycerol. A solution of carbohydrates (1 nL, 30 mM) from a 384-well plate was printed in predetermined places on a hydrazide or aminooxy-coated glass slide with a distance of 250 μm between the centers of adjacent spots. After completion of printing, the slide was placed into a humidity chamber at 50 °C for 12 h, and then, a compartmentalized plastic film that was coated by adhesive on one side (thickness: 0.1−0.2 mm) was attached to the glass slide (*17*). The slide was washed with PBS (pH 7.4) containing 0.1% Tween 20 and a solution of 0.1% Tween 20 possessing 1% BSA was dropped in the blocks. After incubation for 0.5 h, the slide was washed with the same buffer without BSA.

Detection of Carbohydrate−Protein Interactions. The printed slides were probed with fluorescent dye-labeled lectins (1−10 μg/mL) or unlabeled antibodies in PBS (pH 7.4) containing 0.1% Tween 20 for 1 h at room temperature. For ConA binding, $MnCl_2$ and $CaCl_2$ were added at final concentrations of 1 mM. The unbound lectins or antibodies were then removed by washing with the same buffer and rinsed with water. After drying by purging with argon gas, the slide treated with fluorescent dye-labeled lectins was scanned by using an ArrayWoRx scanner. The slide probed with unlabeled antibodies was further treated with FITC-secondary IgG antibody and then scanned by using a microarray scanner. Fluorescence intensity was analyzed using *ImaGene 6.1* software from BioDiscovery.

Detection of Glycan−Pathogen Interactions. *E. coli* ORN 178 and 208 strains were grown in LB media at 37 °C for 12 h and then harvested by centrifugation. The collected cells were suspended with PBS buffer containing $CaCl_2$ (1 mM) and $MnCl_2$ (1 mM). SYTO 83 (50 μM) was added to the suspension of bacterial cells, and then, the mixture was poured onto the carbohydrate microarray. After 30 min, unbound cells were removed by gentle washing with PBS buffer and water. The slide was scanned by using a microarray scanner. Fluorescence intensity was analyzed using *ImaGene 6.1* software from BioDiscovery.

Determination of Dissociation Constants for Protein−Glycan Interactions Using Carbohydrate Microarrays. The carbohydrate microarray containing fucose, Fucα1,2Gal, Fucα1,3GlcNAc, Fucα1,4GlcNAc, and GalNAcα1,3(Fucα1,2)Gal was treated with a solution of 0.1% Tween 20 possessing 1% BSA at room temperature for 30 min. The microarray was washed with PBS (pH 7.4) containing 0.1% Tween 20 and then probed with various concentrations (0.1 nM−4 μM)

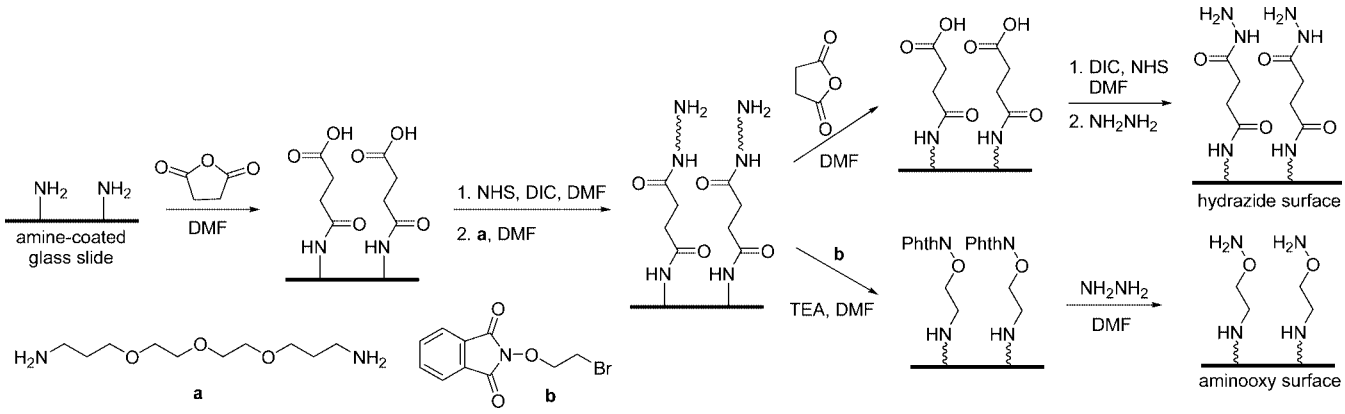

Figure 1. Preparation of hydrazide- and aminooxy-derivatized glass slides from amine-coated glass slides.

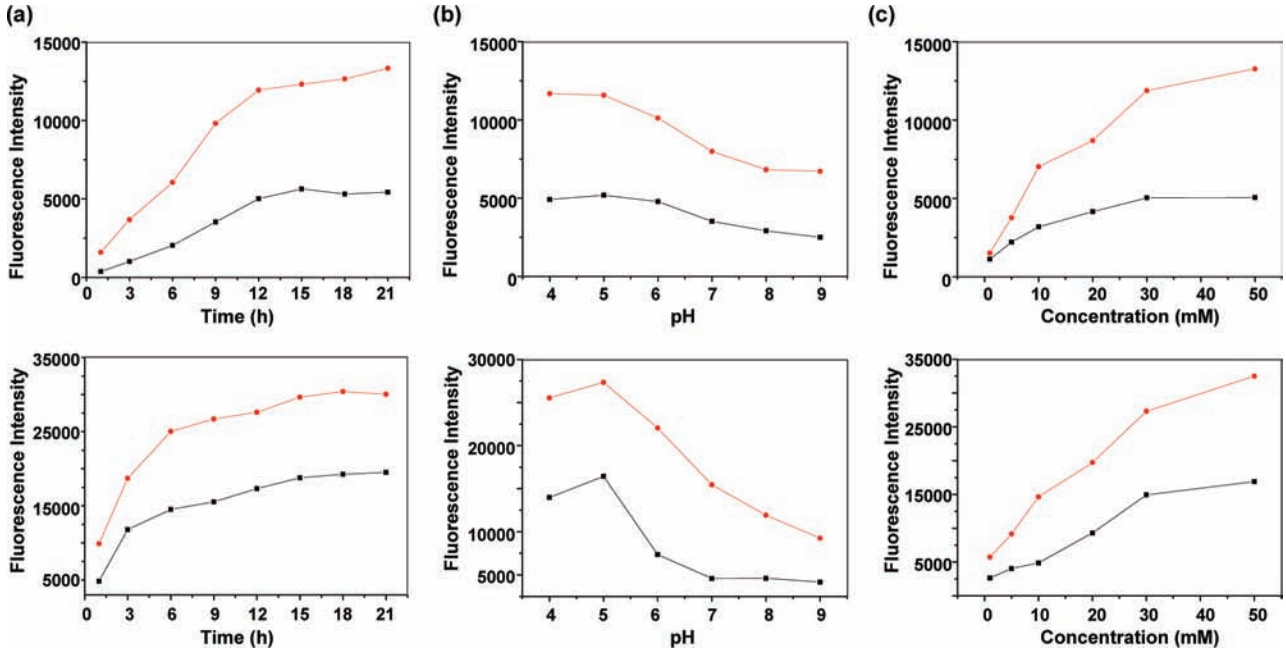

Figure 2. Immobilization of fucose (top) and *N,N′*-diacetylchitobiose (bottom) on the hydrazide (red line) and aminooxy (black line) functionalized glass surfaces as a function of (a) incubation time, (b) pH, and (c) concentration. Fluorescence intensities were measured after probing immobilized sugars with Cy5-AA and Cy3-WGA, respectively.

of Cy5-AA in PBS buffer containing 0.1% Tween 20 for 1 h at room temperature. The unbound proteins were removed by washing with PBS containing 0.1% Tween 20 by gentle shaking. After drying by purging with argon gas, the slide was scanned by using a microarray scanner. The fluorescence intensity of spots was measured and used for data processing. The means for replicate spots for each glycan was calculated, and then the mean and standard deviations for the three replicate experiments were determined and used for subsequent K_d measurement.

Apparent dissociation constants were obtained by the commercial nonlinear regression program *Origin 8.0*. Fluorescence intensity of replicate spots was plotted as a function of AA concentration. Nonlinear line-fitting to the equation was carried out,

$$Fl = Fl_{max}[P]_o/(K_d+[P]_o)$$

where Fl is the fluorescence intensity of spots for AA binding at a given concentration, Fl_{max} is the maximum fluorescence intensity, $[P]_o$ is the initial concentrations of the lectin, and K_d is the equilibrium dissociation constant for AA-surface-linked glycan interactions (*20*).

RESULTS AND DISCUSSION

The identification of suitable functional groups that efficiently react with free glycans is a prerequisite for the development of direct immobilization processes for the construction of carbohydrate microarrays. Reactions of aminooxy or hydrazide groups with unmodified carbohydrates, known to take place chemoselectively, have been widely employed for the synthesis of various glycoconjugates (*25*, *26*). We have used this technique, involving covalent immobilization of unmodified glycans on the aminooxy- or hydrazide-derivatized surfaces, for the facile fabrication of carbohydrate microarrays.

Glass slides, functionalized by aminooxy and hydrazide groups, are prepared from the commercially available amine-modified glass slides by the route shown in Figure 1. The surface amino groups are reacted with succinic anhydride in order to produce carboxylic acid groups, which are then reacted with *N*-hydroxysuccinimide (NHS) and diisopropylcarbodiimide (DIC) to generate activated NHS ester. Reaction with 4,7,10-trioxa-1,13-tridecanediamine (**a**) results in insertion of oligo-

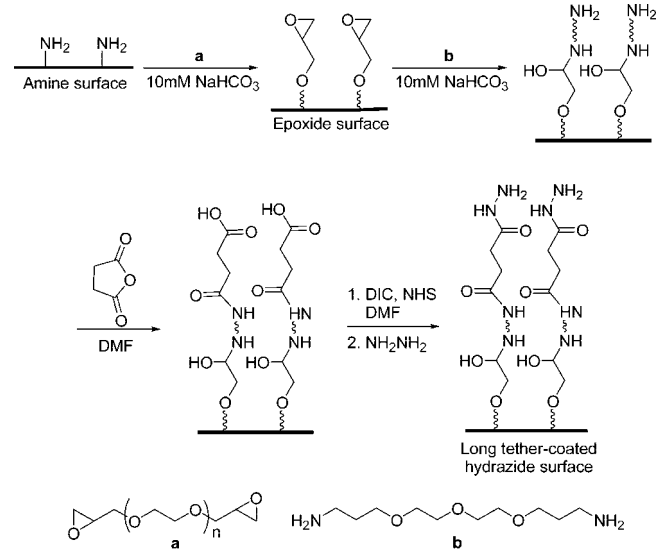

Figure 5. Preparation of hydrazide-coated glass slides containing a PEG linker.

(ethylene glycol) tether, which will serve to increase the accessibility of proteins to glycan ligands and to reduce nonspecific adsorption of proteins to the substrate during protein binding. The resulting amine-derivatized surfaces are sequentially treated with succinic anhydride, DIC-NHS, and hydrazine to prepare the target hydrazide-coated glass slide. The aminooxy-coated slide is obtained by treatment of the amine-derivatized slide with *N*-(2-bromoethoxy)phthalimide (**b**) followed by hydrazine-induced removal of phthaloyl group. Although the surface modification processes described above require synthetic procedures, they simply and reproducibly generate derivatized glass slides that can be stored in a desiccator for months.

Optimized conditions (temperature, time, pH, and concentration) have been probed for glycan immobilization on the hydrazide- and aminooxy-derivatized glass slides. To determine the optimized immobilization temperature and time, fucose and *N,N′*-diacetylchitobiose (30 mM in sodium phosphate buffer containing 30% glycerol, pH 5.0) were printed on both derivatized substrates by using a robotic pin-type microarrayer. Since ligation reactions are generally performed at relatively high temperature (*25*), the resulting slides were kept in a humid chamber for 1−21 h at temperatures of 22, 37, or 50 °C. To measure the extent of glycan immobilization, the slides were incubated with Cy5-*Aleuria aurantia* (Cy5-AA) and Cy3-wheat germ agglutinin (Cy3-WGA) for 0.5−1 h. The carbohydrate microarrays prepared at 50 °C show the highest fluorescence intensities after probing with proteins (data not shown). It has been reported previously that unmodified glycans are immobilized on a hydrazide-coated gold surface and an aminooxy-acetyl-coated glass surface at 18 °C and room temperature, respectively (*27, 28*). However, our results show that the glycans are not efficiently attached to hydrazide- and aminooxy-coated glass surfaces at low temperature. Finally, microarrays obtained using incubation time greater than 12 h incubation at 50 °C display similarly high fluorescence intensities (Figure 2a). The results of these experiments indicate that unmodified glycans

are efficiently immobilized after 12 h incubation at 50 °C. It is important to note that extensive washing of the slides with PBS buffer after immobilization of the carbohydrates does not affect lectin binding, demonstrating that the covalent linkages between carbohydrates and aminooxy or hydrazide groups on the surface are stable.

To investigate the effects of pH and concentration on immobilization efficiencies, fucose and *N,N′*-diacetylchitobiose were immobilized on both substrates at pHs between 4 and 9 and concentrations in the range 1−50 mM for a the fixed incubation time (12 h) and temperature (50 °C). Probing of the slides with proteins reveals that 20−30 mM concentration of carbohydrates and pH 4−5 are ideal for efficient immobilization (Figure 2b,c). Although glycans immobilized at lower concentrations (1−5 mM) can interact with proteins, higher concentrations (20−30 mM) of glycans are desired in order to obtain reproducible and reliable binding results, especially in the case of glycans that are only weakly bound to proteins. It is worthwhile mentioning that the immobilization concentrations used in this procedure are relatively high in comparison with those used in other methods. However, this immobilization technique leads to efficient construction of microarrays, since a little of underivatized glycans (spotting volume: 1 nL) are required.

An interesting observation made in these experiments is that carbohydrates immobilized on hydrazide-coated glass slides exhibit more intense fluorescence signals after lectin binding than those immobilized on aminooxy-coated slides. There are two possible explanations that account for this result. The first is that hydrazide groups on the surface react with free glycans more efficiently than do aminooxy groups. To examine this possibility, galactose (Gal) and glucuronic acid (GlcA), linked to a fluorescence probe (Cy3) at their C-6 positions, were immobilized on both types of substrate under the same conditions (0.1−500 μM concentrations for 12 h at 50 °C). As shown in Figure 3, the two glycans were attached to both substrates with similar efficiencies, indicating that two functional groups on the surface have a similar reactivity with glycans.

A second possible explanation focuses on differences in the nature of anomeric linkage involved in sugar attachment to the surfaces. It is known that reactions of unmodified glycans with aminooxy group-possessing substances produce acyclic adducts preferentially (Figure 4a) (*26*, *29*). However, it has been reported that cyclic products with β-configuration at the anomeric centers are produced predominantly in reactions of carbohydrates with substances containing hydrazide groups (Figure 4b) (*25*, *30*, *31*). Consequently, the nature of the linkage present in products obtained from reactions of carbohydrates with hydrazide groups was investigated. For this study, four carbohydrates (glucose, mannose, fucose, and maltose) were reacted with hydrazide derivatives in solution and on a solid support (pH 5, 50 °C, 12 h). NMR analyses of mixtures obtained from these reactions show that β-anomeric adducts are produced predominantly (more than 90%) in both cases (*24*). Therefore, it is likely that the stronger binding of proteins to carbohydrates attached to hydrazide-modified surface rather than aminooxy-coated sur-

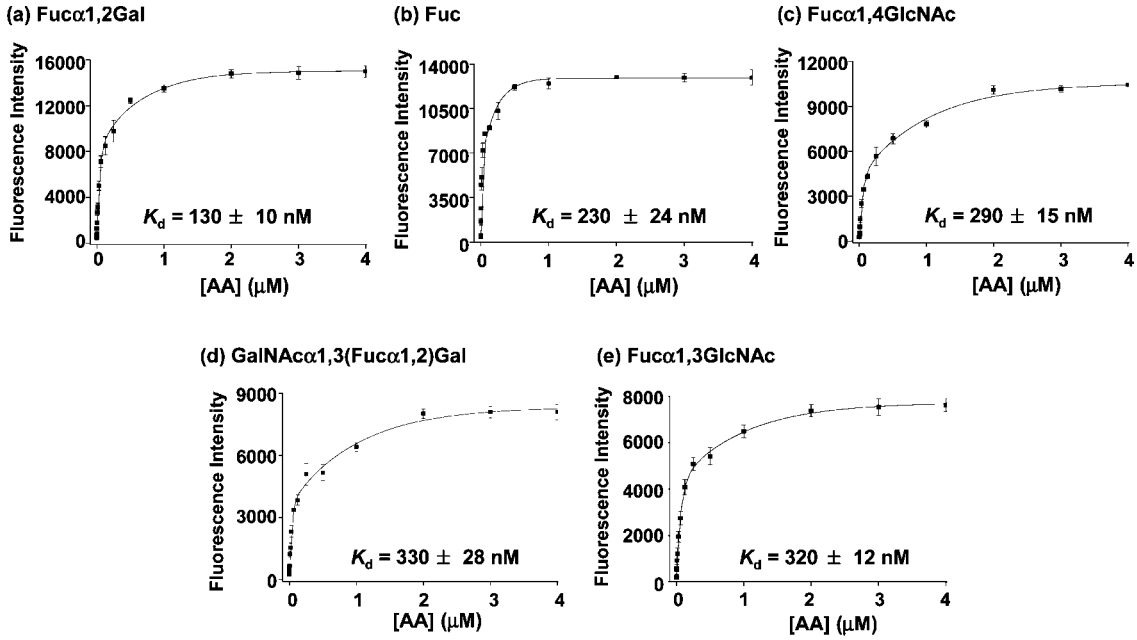

Figure 7. Determination of dissociation constants (K_d) for (a) AA-Fucα1,2Gal, (b) AA-fucose, (c) AA-Fucα1,4GlcNAc, (d) AA-GalNAcα1,3(Fucα1,2)Gal, and (e) AA-Fucα1,3GlcNAc interactions using carbohydrate microarrays.

faces results from a higher ratio of cyclic to acyclic linkages present in the former system.

The effect of insertion of a tether between hydrazide groups and the surface on protein binding was examined. For this purpose, hydrazide-coated glass slides containing poly(ethylene glycol) (PEG) were prepared by the procedure shown in Figure 5. A commercially available amine-coated glass slide is first treated with poly(ethylene glycol) diglycidyl ether (**a**) to place epoxide groups on the surface. The resulting substrate is then reacted with diamine **b** to introduce amino groups. The PEG-containing hydrazide-functionalized substrates are obtained by sequential reactions with succinic anhydride, DIC-NHS, and hydrazide. The results of protein binding experiments show that hydrazide substrates containing a long spacer arm give higher S/N ratios (around 1.5 times) than those arising from hydrazide substrates containing a shorter linkage. As a consequence, hydrazide-coated glass slides tethered by the long spacer arm were used throughout the remainder of this study. To our knowledge, these hydrazide-modified surfaces containing PEG were prepared for the first time for the construction of microarrays.

Prior to applications of carbohydrate microarrays, we measured the number of carbohydrates immobilized on the surface. To this end, various concentrations (500 μM−0.5 μM) of Cy3-Gal were printed on the hydrazide-coated slide, and the fluorescence intensity of the printed spots was measured before and after immobilization. The density of maximum carbohydrate immobilized on the surface was measured to be $10^{14}-10^{15}$ molecules/cm^2, a similar value to carbohydrates attached to the glass surface by other methods (see Supporting Information) (*32*).

To demonstrate the utility of this immobilization method and the application of the arrayed glycans to the rapid analysis of glycan−protein recognition events, 58 glycans (1 nL, 30 mM) shown in Figure 6 were printed in duplicate on a hydrazide-derivatized glass slide in a microarray format. The glycans comprise simple carbohydrates, oligosaccharides, and polysaccharides. The microspotted slide was kept at 50 °C for 12 h, washed with water, and dried. Since lectins serve as important models for studying glycan−protein interactions at the molecular level, the glycan microarrays were probed with the four fluorescent dye-labeled lectins, Cy5-AA, FITC-ConA, Cy3-*Bandeiraea simplicifolia* I (Cy3-BS-I), and Cy3-*Ricinus communis* agglutinin 120 (Cy3-RCA$_{120}$). Fluorescence data of carbohydrate microarrays obtained after probing with lectins are shown in Figure 6. The data demonstrate clearly that Cy5-AA interacts selectively with its cognate fucose-containing ligands and that it does not bind to the other sugars on the microarrays (Figure 6a). The carbohydrate microarrays treated with FITC-ConA exhibits binding to α-mannose and α-glucose containing ligands, a result that is consistent with the established specificity of this lectin (Figure 6b). However, this lectin does not recognize monomeric mannose and glucose that are attached to the surface with β-configurations.

Binding specificities of two galactose/*N*-acetylgalactosamine binding proteins, Cy3-labeled BS-I and RCA$_{120}$, were determined by using these microarrays. The results of microarray experiments indicate that BS-I recognizes terminal α-galactose and α-*N*-acetylgalactosamine residues preferentially. In contrast, BS-I rarely interacts with monomeric galactose and *N*-acetylgalactosamine owing to the fact that these glycans are immobilized to the surface with β-configuration (Figure 6c). However, RCA$_{120}$ was shown to bind to a broader range of galactose/*N*-acetylgalactosamine containing glycans than does BS-1 (Figure 6d). RCA$_{120}$ recognizes terminal galactose and *N*-acetylgalactosamine residues as well as galactan, but it rarely binds to Le^a (*33*). Subsequently, binding specificities of antibodies were analyzed by using carbohydrate microarrays. The results of experiments, in which carbohydrate microarrays were probed with antidextran and antichondroitin 6-sulfate antibodies followed by treatment with FITC-secondary IgG antibody, show that each antibody interacts with the corresponding antigen selectively (i.e., antidextran antibody binds to dextran and antichondroitin 6-sulfate antibody binds to chondroitin sulfate C) (Figure 6e,f). The observations made in this effort demonstrate that carbohydrate microarrays prepared by a direct immobilization method can be effectively employed to assess carbohydrate-binding properties of proteins.

Many bacteria, including pathogens, express specific lectins on pili. Pathogenic properties are caused by the initial binding of pathogens to host cells through specific glycan−protein interactions. In order to demonstrate that the fabricated glycan microarrays can be used to detect pathogens, microarrays containing 58 glycans were incubated with *E. coli* ORN178

strain, which was pretreated with SYTO 83. In accord with the fact that the ORN178 strain expresses a mannose-binding protein, a gene product of *fimH*, on pili, the microspots containing mannose epitopes were found to display fluorescence (Figure 6g) (*34*, *35*). In contrast, glycan microarrays treated with the ORN208 strain which lacks the *fimH* gene do not show fluorescence signals in the regions containing these glycans (data not shown).

Recently, we developed a procedure in which carbohydrate microarrays are used to determine binding affinities of glycans for protein (*20*). The microarrays, prepared through the one-step, direct immobilization method described above, were applied to measuring dissociation constants (K_d) associated with lectin surface-linked glycan interactions. For this study, the five fucose-containing glycans, fucose, Fucα1,2Gal, Fucα1,3GlcNAc, Fucα1,4GlcNAc, and GalNAcα1,3(Fucα1,2)Gal, were printed in replicates of five on a hydrazide-derivatized surface. The resulting microarrays were incubated with various concentrations (0.1 nM-4 μM) of Cy5-AA. After 1 h incubation, the microarrays were thoroughly washed with PBS buffer to remove unbound lectin. Fluorescence intensities of microspots were quantitated by using a microarray scanner. The K_d values of Fucα1,2Gal, fucose, Fucα1,4GlcNAc, GalNAcα1,3(Fucα1,2)Gal, and Fucα1,3GlcNAc are determined to be 1.3×10^{-7} M, 2.3×10^{-7} M, 2.9×10^{-7} M, 3.3×10^{-7} M, and 3.2×10^{-7} M, respectively (Figure 7). These studies demonstrate clearly that this immobilization technique is suitable for measuring quantitative binding affinities of glycans for protein.

CONCLUSIONS

The investigation described above has led to the development of a simple and efficient method for the construction of carbohydrate microarrays that relies on site-specific and covalent immobilization of unmodified carbohydrates on a hydrazide-coated surface. The insertion of a hydrophilic poly(ethylene glycol) linker between hydrazide groups and the surface leads to the desired orientational flexibility and increased accessibility of binding partners to the glycan ligands. Protein and cell-binding experiments show that, irrespective of their size, all types of carbohydrates undergo efficient covalent bonding to the hydrazide-coated surface. The glycan microarrays, generated in this way, are applicable to the rapid analysis of carbohydrate−protein recognition events, the detection of pathogens, and measurements of quantitative binding affinities of glycans for protein. This immobilization method can be readily modified to enable the identification and quantification of binding patterns of biologically relevant materials. As such, the technique should open new avenues for elucidating glycan−protein interactions. Of great significance is the fact that this free glycan based immobilization procedure can be used by scientists who lack organic synthesis experience.

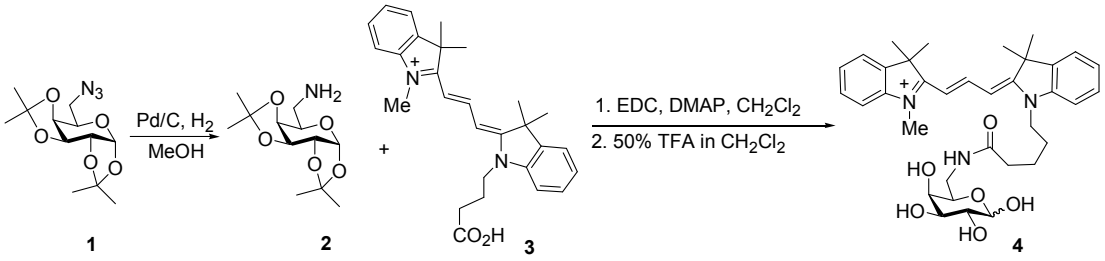
SUPPORTING INFORMATION

Construction of Carbohydrate Microarrays by Using One-step, Direct Immobilizations of Diverse Unmodified Glycans on Solid Surfaces

Sungjin Park, Myung-Ryul Lee, and Injae Shin*

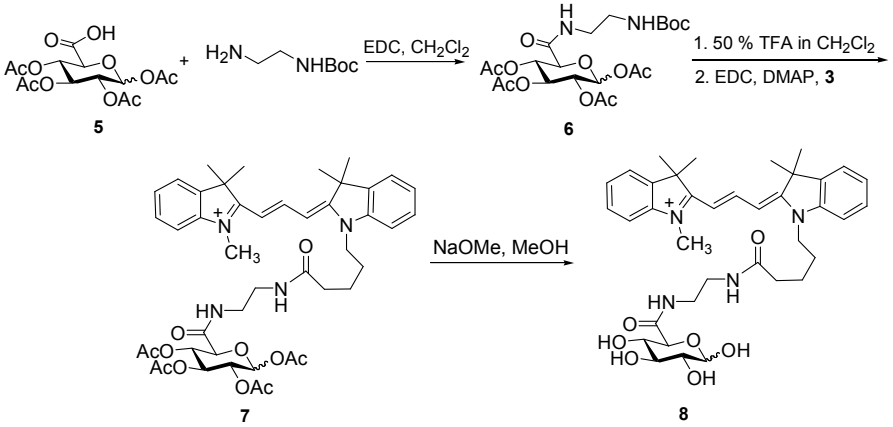
Synthesis of Cy3-Gal conjugate 4



Compound **1** (5.3 mg, 18.5 μmol, 1 eq.), prepared by the known procedure (Yang, J. *et al. Org. Lett.* 2003.*5*, 2223), was reduced by reacting with H_2 and 10% Pd/C in MeOH (5 mL) for 30 min. The reaction mixture was filtered though a Celite pad and the filtrate was concentrated under the reduced pressure to give **2** as a quantitative yield. To a stirred solution of **2** (3.5 mg, 13.5 μmol, 1 equiv.) in CH_2Cl_2 (300 μL) was added EDC (3.9 mg, 20.3 μmol, 1.5 equiv.), DMAP (0.8 mg, 6.75 μmol, 0.5 equiv.) and **3** (5.8 mg, 13.5 μmol, 1 equiv.). The reaction mixture was stirred for 4 h at room temperature. The reaction mixture was diluted with CH_2Cl_2 and the organic layer was washed with water. The organic layer was dried over anhydrous $MgSO_4$, filtered, and then concentrated under the reduced pressure. The crude product was used for the next reaction without further purification. To a stirred solution of the above compound in CH_2Cl_2 (250 μL) was added TFA (250 μL). The reaction mixture was stirred for 1 h. The volatile solvent was removed under the reduced pressure. The crude product was purified by preparative reversed phase-HPLC (Vydac C_{18} column, 250 x 22 mm, pore size: 5 μm) with a gradient 2-100% CH_3CN in water over 90 min to give **4** in 80% yield: ^{1}H NMR (250 MHz, CD_3OD) δ 8.54 (t, 1 H, J = 13.4), 7.56-7.28 (m, 8 H), 6.43 (d, 1 H, J = 12.5), 4.48-4.39 (m, 1 H), 4.28-4.14 (m, 5 H), 3.99-3.94 (m, 2 H), 3.69 (s, 3 H), 2.71-2.52 (m, 4 H), 1.77 (m, 14 H); ^{13}C NMR (125 MHz, CD_3OD) δ 175.6, 175.0, 172.7, 151.1, 143.0, 142.4, 141.1, 141.0, 129.0,

128.9, 125.8, 125.7, 122.4, 122.3, 111.4, 111.2, 102.8, 102.7, 85.9, 81.9, 80.7, 80.3, 76.2, 76.1, 63.1, 49.6, 49.5, 43.9, 42.6, 32.7, 30.7, 27.3, 26.8, 22.3; MALDI-TOF-MS calcd for $C_{35}H_{46}N_3O_6$ $[M]^+$ 604.3387, found 604. 3284.

Synthesis of Cy3-GlcA conjugate 8



To a stirred solution of **5** (120 mg, 0.33 mmol, 1 equiv.), prepared by the known procedure (Wong, A. W. *et al*. *Can. J. Chem.* 2001*, 79*, 510), in CH_2Cl_2 (3 mL) was added EDC (95.0 mg, 0.50 mmol, 1.5 equiv.) and *t*-butyl *N*-(2-aminoethyl)carbamate (63.1 mg. 0.39 mmol, 1.2 equiv.). The reaction mixture was stirred for 3 h at room temperature. The reaction mixture was diluted with CH_2Cl_2 and the organic layer was washed with water. The organic layer was dried over anhydrous $MgSO_4$, filtered and then concentrated under the reduced pressure. The crude product was purified by flash column chromatography (1:1 to 1:3 hexane/EtOAc) to give **6** (121 mg, 0.24 mmol) in 74% yield: ^{1}H NMR (250 MHz, CD_3OD) δ 6.38 (d, 1 H, *J* = 3.6), 5.48 (t, 1 H, *J* = 10.1), 5.21 (t, 1 H, *J* = 10.1), 5.12 (dd, 1 H, *J* = 3.6, 10.1), 4.29 (d, 1 H, *J* = 10.1), 3.22 (t, 2 H, *J* = 5.36), 3.16-3.13 (m, 2 H), 2.19 (s, 3 H), 2.03 (s, 3 H), 2.02 (s, 3 H), 2.00 (s, 3 H), 1.43 (s, 9 H); ^{13}C NMR (62.5 MHz, CD_3OD) δ 171.6, 171.5, 171.4, 171.3, 171.2, 171.0, 170.5, 169.5, 169.2, 158.2, 92.7, 90.0, 80.3, 74.7, 73.4, 72.4, 71.6, 71.0, 70.9, 70.6, 70.5, 40.9, 29.1, 20.8, 20.7, 20.6, 20.4; MALDI-TOF-MS calcd for $C_{21}H_{32}N_2O_{12}$ $[M+Na]^+$ 527.1955, found 527.1928.

To a stirred solution of **6** (30 mg, 59.5 μmol, 1 equiv.) in CH_2Cl_2 (500 μL) was added TFA (500 μL). After 1 h, the volatile solvent was removed under the reduced pressure. The crude product was used for next reaction without further purification. A solution of the above compound (18.2 mg, 45 μmol, 1 equiv.), EDC (12.9 mg, 67.5 μmol, 1.5 equiv.), DMAP (2.7 mg, 22.5 μmol, 0.5 equiv.) and **3** (19.3 mg, 45 μmol, 1 equiv.) in CH_2Cl_2 (300 μL) was stirred for 4 h at room temperature. The reaction mixture was diluted with CH_2Cl_2 and the organic layer was washed with water. The

organic layer was dried over anhydrous $MgSO_4$, filtered, and then concentrated under the reduced pressure. The crude product was purified by flash column chromatography (15:1 to 5:1 EtOAc/MeOH) to give **7** (26.1 mg, 31.5 μmol) in 70 % yield: ^{1}H NMR (250 MHz, $CDCl_3$) δ 8.72 (bs, 1 H), 8.53 (bs, 1 H), 8.40 (t, 1 H, *J* = 13.1), 7.43-7.34 (m, 4 H), 7.29-7.23 (m, 2 H), 7.18-7.15 (m, 2 H), 7.04 (d, 1 H, *J* = 14.0), 6.95 (d, 1 H, *J* = 14.0), 6.38 (d, 1 H, *J* = 3.63), 5.52 (t, 1 H, *J* = 9.70), 5.38 (t, 1 H, *J* = 9.96), 5.19 (dd, 1 H, *J* = 3.63, 9.96), 4.48 (d, 1 H, *J* = 9.96), 4.21 (bs, 2 H), 3.75 (s, 3 H), 3.43 (m, 4 H), 2.52 (bs, 2 H), 2.08 (s, 3 H), 2.03 (s, 3 H), 2.00 (s, 3 H), 1.98 (s, 3 H), 1.87 (m, 4 H), 1.73 (s, 6 H), 1.72 (s, 6 H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 174.4, 173.9, 173.7, 170.0, 169.5, 169.4, 169.1, 166.8, 150.8, 142.7, 141.8, 140.5, 140.4, 128.9, 128.8, 125.3, 122.0, 121.8, 111.1, 110.9, 104.4, 103.9, 88.7, 71.1, 69.6, 69.3, 69.2, 49.0, 48.9, 44.0, 39.9, 38.8, 35.2, 31.8, 29.6, 28.2, 28.1, 28.0, 26.3, 22.6, 21.0, 20.7, 20.6, 20.4; MALDI-TOF-MS calcd for $C_{45}H_{57}N_4O_{11}$ $[M]^+$ 829.4024, found 829.4041.

A solution of **7** (26.1 mg, 31.5 μmol) and 0.5 M NaOMe (63 μL) in MeOH (567 μL) was stirred for 2 h at room temperature. After neutralization with Dowex 50W-X8 ion exchange resin, the resin was filtered and washed with MeOH twice. The solvent was removed under the reduced pressure. The crude product was purified by preparative RP-HPLC (Vydac C_{18} column, 250 x 22 mm, pore size: 5 μm) with a gradient 2-100% CH_3CN in water over 90 min to give **8** (15.2 mg, 23.0 μmol) in 73 % yield: ^{1}H NMR (250 MHz, CD_3OD) δ 8.60 (t, 1 H, *J* = 13.8), 7.55-7.48 (m, 2 H), 7.45-7.42 (m, 2 H), 7.38-7.28 (m, 4 H), 6.46 (d, 2 H, *J* = 13.5), 4.27-4.08 (m, 4 H), 3.93-3.82 (m, 2 H), 3.69 (s, 3 H), 2.28 (bs, 2 H), 1.86 (s, 16 H); MALDI-TOF-MS calcd for $C_{37}H_{49}N_4O_7$ $[M]^+$ 661.3601, found 661.3453.

Measurement of the density of a carbohydrate immobilized on the surface. Various concentrations (500 μM–0.5 μM) of Cy3-Gal were printed on the hydrazide-coated slide in three replicates and their fluorescence intensities were read by a microarray scanner. After 12 h incubation at 50 ^{o}C, the slide was washed with PBST (0.1% Tween 20) buffer (5 min x 3). The fluorescence intensities were read by a microarray scanner.

The number of immobilized Cy3-Gal (*No*) is calculated by the following equation.

$No = CVN_AQ_{post}/Q_{pre}$

where C is the printing concentration (500 μM–0.5 μM), V is the printing volume (1 nL), N_A is Avogadro's Number, Q_{post} is the fluorescence intensity after immobilization of a carbohydrate, and Q_{pre} is the fluorescence intensity before immobilization of a carbohydrate.

When the surface is saturated (around 500 to 100 μM Cy3-Gal), the ratio from Q_{pre} and Q_{post} is 0.92. The density of maximum carbohydrate immobilized on the surface is between 2.2 x 10^{14} and 1.09 x 10^{15} molecules/cm^2. Each spot in the microarray is around 0.18 mm diameter.

The efficiency of nonviral vectors for gene delivery may be enhanced by understanding the key barriers that limit the translocation of the therapeutic DNA into the nucleus. One such barrier is the instability of DNA in the cytoplasm. In this work, we have developed a method to dual-label plasmid DNA to be utilized as a tool to elucidate DNA instability during its trafficking in the intracellular microenvironment. Plasmid DNA containing rhodamine and maleimide groups linked using peptide nucleic acid (PNA) linkers was utilized for conjugation. Covalent conjugation of the maleimide group with a second fluorophore, fluorescein, did not alter the electrophoretic mobility or the structural integrity of the DNA, as confirmed by gel electrophoresis. The intact DNA was visualized as a single color (yellow) due to the close proximity of the green and red fluorophores. DNA degradation was simulated using restriction endonucleases (*Bam*H1 and *Pfl*MI) to cut the DNA at two or more sites resulting in color separation. Confocal time-lapse imaging was utilized to follow DNA stability upon incubation of Lipofectamine2000/dual-labeled DNA complexes in CHO-K1 cells. Yellow fluorescent voxels were seen in the cell cytoplasm indicating the presence of intact DNA. Red and green fluorescent voxels were also seen in a few cells, suggesting separation of the fluorophores and probable DNA degradation. The methodology developed in this report provides a new tracking tool for investigators to explore DNA degradation at the molecular level inside single cell.

INTRODUCTION

Transfection of therapeutic DNA mediated by nonviral gene delivery has been investigated over the past three decades as a safer alternative to viral vectors for use in the treatment of genetic, infectious, and acquired diseases (*1*−*6*). However, the transfection efficiencies that can be achieved using nonviral vectors are relatively low when compared to viral-based delivery systems (*4*, *7*, *8*). Although several different approaches have been investigated to enhance transfection, success has been limited and low efficiency remains a concern (*9*−*12*). Consequently, only approximately 26% of all gene therapeutics in clinical trials utilize nonviral vectors, whereas approximately 68% utilize viral vectors (the remaining 6% utilize RNA transfer, yeast, bacterial, or unknown vectors) (http://www.wiley.co.uk/genmed/clinical) (*13*).

Gene trafficking is being investigated to understand the barriers that hinder the translocation of nonviral vectors and their payload from outside the cell into the nucleus (*11*, *14*−*19*). Such information could then be used to redesign nonviral vectors for improved transfection. Gene trafficking of nonviral vectors involves cellular binding and uptake, endosomal escape, safe transport through cytosol, and nuclear delivery. Several reviews have been recently published that describe gene trafficking in detail and the dependency of the trafficking process on the nature of the delivery vector (*5*, *11*, *20*−*22*). Depending on the vector used, one or more of these steps may limit transfection efficiency.

Cellular binding and uptake of gene delivery vectors is well-understood and depends on the interaction between the vector and the cell surface (*5*, *7*, *11*, *12*). Vectors are usually transported into the cell in endosomes. The environment within the endosomes (low pH and the presence of nucleases) is hostile to DNA. Much research has been conducted and vectors have been developed that promote rapid escape from endosomes (such as fusogenic lipids, peptides, and lysosomotropic agents *23*−*25*). Depending on the nature of the vector, the DNA may be released

into the cytoplasm together with the vector or as free DNA. Free DNA is subject to degradation by the many endo- and exonucleases that are present in the cell. Although the majority of these reside in the nucleus, some are located within the cytoplasm (*26, 27*). Degradation of free DNA by nucleases present in the cytoplasm may be considerable due to the significant time required for transport through the cytoskeletal network (*22*). Finally, the DNA must be translocated into the nucleus that may occur by passive entry during mitotic cell division and/or by active process through pores in the nuclear membrane. This is dependent on the DNA conformation as well as cellular characteristics (*28, 29*). Although much work has been conducted to understand these transport processes, the amount of DNA lost at these various steps is unknown. For example, although a vector may be designed to promote endosomal escape, some DNA may be degraded prior to escape. Consequently, it would be useful to have a method to track DNA degradation throughout the entire trafficking process.

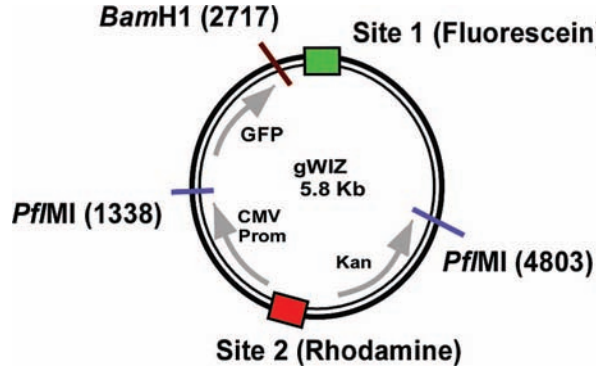
To date, there are only a few reports that describe investigations into DNA degradation. These include studying nuclease activity on plasmid DNA with different cytosolic extracts using gel electrophoresis (*30, 31*); monitoring intracellular disappearance of DNA by fluorescence in situ hybridization (FISH); visualization of plasmid DNA fragmentation using terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) assay; and radiolabeled ^{32}P-release from end-labeled fragmented DNA (*30, 31*). These studies have provided important information on the effect of cytosolic nucleases on DNA, but are limited since they have been performed using microinjected materials in single cells and require isolated cell fractions or fixed cells, which may not represent events that occur in living cells (*30, 31*).

Investigations based on labeling techniques have involved monitoring gold-labeled DNA by transmission electron microscopy (TEM) (*32, 33*) and single dye labeled delivery vector/DNA (oligonucleotides or plasmid DNA) by confocal imaging (*34,35*). TEM only provides static images of cells, and the dye labeled DNA complexes have been imaged immediately following microinjection and therefore lack critical information about DNA stability once released from the complex.

On the basis of the above, there is a great need to develop a tool to monitor real-time degradation processes in live cells. Live cell tracking is commonly performed using fluorescent dyes to label biomolecules such as antibodies, peptides (*36*), and small oligonucleotides (*37, 38*). Labeling of plasmid DNA can be challenging, since chemical modification may render the DNA nonfunctional (*39*−*41*). However, we have previously demonstrated successful labeling of plasmid DNA with quantum dots using peptide nucleic acid (PNA) chemistry without loss of functionality for long-term single cell tracking studies (*19*).

In this study, we have demonstrated a novel approach to monitor plasmid DNA degradation that utilizes dual-labeled DNA as a probe. The DNA was labeled with two different fluorophores (rhodamine and fluorescein) via PNA linkers. The two dyes are expected to be seen as a single color in intact DNA due to colocalization, but when the DNA strands are broken and the segments move apart, color separation may be observed. This concept was demonstrated using restriction enzymes to cut the DNA. Confocal time-lapse imaging was used to follow cellular uptake of DNA as well as probable degradation, as demonstrated by color separation, occurring within the cytoplasm. The plasmid DNA was shown to have retained its structural integrity following dual labeling. This dual-labeling technique provides a novel approach to visualize plasmid DNA instability at a single cell level throughout the trafficking pathway.

Scheme 1. Schematic Illustration of pGeneGrip-gWIZ DNA Dual-Labeled with Fluorescein and Rhodamine Labels at Site-1 and and Site-2, Respectively[a]



[a] The plasmid with restriction enzymes (*Bam*H1 and *Pfl*MI) used to digest at single and double recognition sites, respectively, on the dual-labeled plasmid DNA are shown.

MATERIALS AND METHODS

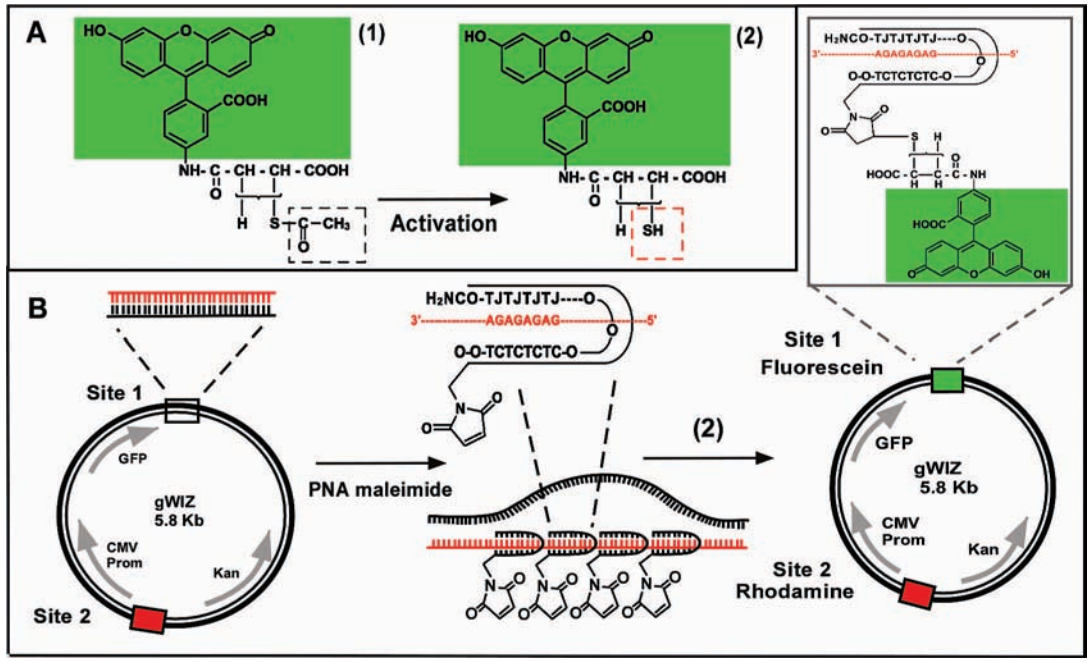
Plasmid DNA Preparation. Green fluorescent protein encoding pGeneGrip-gWIZ plasmid DNA (∼5.8 kb) with hCMV IE promoter−enhancer gene sequence was purchased from Genlantis (San Diego, CA). The pGeneGrip plasmid contains two PNA binding sites (sites −1 and −2) that are attached to maleimide and rhodamine (Rh) labels through PNA linkers, respectively (*19, 40*). The general method for chemical conjugation of plasmid DNA to PNA linkers has been reported in detail in our previously published work (*19*). The total concentration and purity of DNA in solution was determined spectroscopically at 260 and 280 nm using a Beckman DU 7400 spectrophotometer. Plasmid DNA structural integrity was analyzed using a 0.8% w/v DNA agarose gel.

Dual Labeling of Plasmid DNA with Fluorophores. pGeneGrip-gWIZ plasmid was dual-labeled by covalent conjugation of the maleimide group at site-1 with fluorescein (Schemes 1 and 2). For this reaction, 5-((2-(and-3)-*S*-(acetylmercapto)succinoyl)amino)fluorescein (SAMSA fluorescein, A-685) (**1**) (Molecular probes, Invitrogen Corp., Carlsbad, CA) was utilized as a fluorophore (Scheme 2). It was activated prior to the conjugation reaction to expose free thiol residues as described below (Scheme 2).

Activation of SAMSA Fluorescein. Activation of **1** was performed by incubating the stock solution (10 mg/mL) of SAMSA fluorescein prepared in 0.1 N sodium hydroxide for 15 min at room temperature. It was then neutralized with 6 N hydrochloric acid and buffered with 0.5 M sodium phosphate buffer, pH 7.0−7.2 to generate **2**; Scheme 2.

Reaction of Activated Fluorescein with Maleimide-PNA Labeled Plasmid DNA. The maleimide−PNA labeled plasmid (6.5 nanomol) was immediately reacted with approximately 12-fold excess of fluorescein (**2**) freshly prepared (80 nanomol) in 500 μL 0.5 M sodium phosphate buffer. The reaction mixture was incubated for 30 min at room temperature and the uncoupled **2** was removed by buffer exchange with five washes of 10 mM HEPES buffer (pH 7.4) using 100 kDa Centricon, ultrafiltration centrifugal filter units (YM-100, Millipore, Billerica, MA) and centrifuging at 2000 rpm, for 20 min. The filtrate was discarded and the supernatant consisting of the final conjugate mixture was stored in 10 mM HEPES buffer, pH 7.4, 4 °C, until further use.

Scheme 2. Schematic Illustration of Conjugation of Activated SAMSA Fluorescein to Rhodamine/Maleimide Labeled pGeneGrip-gWIZ Plasmid DNA[a]



[a] (A) Activation of SAMSA fluorescein (**1**): 0.1 N sodium hydroxide, 15 min incubation; 6 N hydrochloric acid; and 0.5 M sodium phosphate buffer, pH 7.2. This removes the acetyl protecting group in SAMSA fluorescein and exposes the thiol groups (**2**). (B) The free thiol residue on activated SAMSA fluorescein (**2**) covalently reacts with the maleimide group on the plasmid DNA to generate the dual-labeled plasmid DNA.

Agarose Gel Electrophoresis. 0.8% w/v agarose gel electrophoresis was run at 67 V/cm, for 2 h. As a control, a 1 Kb (1 μg/μL) DNA ladder was run by mixing with loading dye (6× solution, 0.25% Bromophenol Blue, 50% glycerol in 1× TAE buffer) (Invitrogen Corp., Carlsbad, CA). Plasmid DNA labeled to rhodamine (Rh) and purified dual-labeled DNA (Rh and activated SAMSA fluorescein) were mixed with a drop of 100% glycerol and 1× TAE buffer prior to electrophoresis. Glycerol was used for sample preparation of the labeled DNA to avoid any interference in fluorophore imaging with the dyes present in the loading dye solution. A Bio-Rad Molecular Imager FX (Hercules, CA) equipped with the appropriate excitation and emission standard filters for Rh and SAMSA fluorescein was used (495/520 nm for fluorescein and 560/590 nm for Rh) to image the labeled DNA bands. The gel was then stained with ethidium bromide nucleic acid stain (final concentration, 0.5 μg/mL) for 30 min followed by three water washes to remove any excess stain and visualized using appropriate filters for ethidium bromide (Ex/Em, 518/605 nm). Bio-Rad Quantity One software was used for analysis of the gel images before and after ethidium bromide staining. The direction of the gel run is shown by (+) and (−) signs.

Restriction Digestion Reaction and Analysis by Gel Electrophoresis. Single and double restriction digestion sites on the dual-labeled pGeneGrip gWIZ-GFP plasmid were identified using New England Biolabs NEBcutter v 2.0 sequence software. The restriction endonucleases *Bam*H1 (20 000 units/mL) and *Pfl*MI (8000 units/mL) (New England BioLabs, Ipswich, MA) were used to digest single and double recognition sites in a non-encoding region of the gWIZ-GFP plasmid, respectively, as shown in the schematic (Scheme 1). The reactants were mixed according to the manufacturers' protocol and incubated for 2 h in a water bath maintained at 37 °C. Gel electrophoresis studies were performed to analyze the digestion reaction fragments (1% w/v agarose, run in 1× TAE buffer, at 67 V/cm, for 1 h). A 1 Kb DNA ladder (1 μg/μL) and purified dual-labeled DNA before digestion were used as controls. *Bam*H1 and *Pfl*MI digested fragments were fully loaded onto the wells in the presence of glycerol prior to gel electrophoresis. Bio-Rad Molecular Imager FX and Quantity One software were used as described above.

Cell Transfection. Transfection studies were conducted in CHO-K1 cells (ATCC, Manassas, VA) by plating 0.5 × 10^6 cells/dish in Bioptechs Delta T dishes (Bioptechs Inc., Butler, PA) one day before the experiment. When the cell population reached 70−80% confluency, they were washed with Hanks' Balanced Salt Solution (HBSS) media, and transfection was carried out in serum-free F12-K media (Invitrogen Corp., Carlsbad, CA). Lipofectamine2000 (Invitrogen Corp., Carlsbad, CA) transfection reagent was used following the manufacturer's protocol. The transfection complexes prepared by complexing dual-labeled DNA conjugates (pGeneGrip gWIZ) (2.76 μg) with Lipofectamine2000 (8.6 μg) at a DNA/lipid ratio of 0.8 μg /2.5 μg w/w were incubated for 15 min before addition to the cells.

Confocal Microscopy. Leica SP2 confocal laser scanning microscope equipped with Ar/Kr, Kr/Ne, and He/Ne lasers (Bannockburn, IL) was used for live cell imaging. Time-lapse imaging with sequential scanning for individual fluorophores was performed following addition of the dual-labeled DNA complexes to CHO-K1 cells. Z-Sectioning was conducted to assist in locating the dual-labeled DNA within the boundaries of the cell membrane. The temperature of the cells during observation was maintained at 37 °C, using a Bioptechs ΔT4 open dish system in a L-15 carbon dioxide free medium.

RESULTS

pGeneGrip gWIZ plasmid DNA containing maleimide/rhodamine groups was successfully dual-labeled via PNA/DNA hybridization using two different PNA linkers at site-1 and site-2 (Scheme 1). The green fluorophore (SAMSA fluorescein) (**1**) was covalently conjugated with the maleimide groups, which are present at site-1, a non-encoding site, as shown in Scheme 2. Prior to the conjugation reaction, (**1**) was activated with sodium hydroxide to remove the acetyl protecting group generating its thiol functionality (**2**). The free thiol moiety on

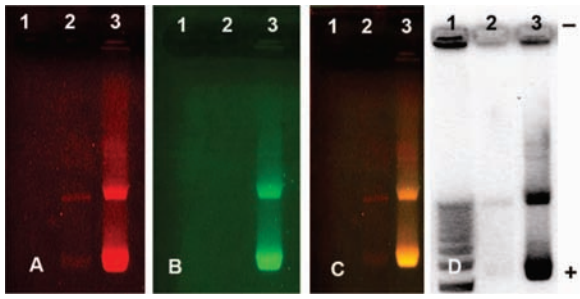


Figure 1. Agarose gel electrophoresis of dual-labeled DNA before and after staining with ethidium bromide DNA stain. Lane 1, DNA ladder; lane 2, DNA labeled with rhodamine (Rh) alone; and lane 3, purified dual-labeled DNA conjugate (Rh (red) and activated SAMSA fluorescein (green)). Panels A and B show exposure at wavelengths that excite the red and the green dyes, respectively. Panel C is the overlap of A and B. Panel D is the UV-excited photoluminescence emission of ethidium bromide (EtBr) stain.

the activated fluorescein was then reacted with the maleimide groups on the plasmid DNA to form a covalent sulfide linkage. pGeneGrip gWIZ plasmid DNA contains approximately 6−10 rhodamine groups and 6−10 PNA−maleimide sites for fluorescein attachment. To maximize conjugation with the plasmid DNA, a 12-fold excess of fluorescein, i.e., a ratio of fluorescein/DNA of 120:1, was used. Unbound fluorophores were removed by ultrafiltration using a 100 kDa membrane (see Materials and Methods section), and this was confirmed by gel electrophoresis. The conjugates remained stable over the 3 month study period.

Gel electrophoresis was used to confirm the dual labeling of plasmid DNA. Detection of the two fluorophores (Rh and fluorescein) conjugated to the DNA was based on direct laser excitation fluorescence imaging using Molecular Imager FX equipped with multichannel excitation and emission filters. The agarose gel revealed two different forms of DNA (lower and higher mobility bands corresponding to open circular forms and supercoiled DNA, respectively) with the majority of the DNA being in the supercoiled conformation (Figure 1). The absence of a band corresponding to rhodamine-labeled DNA upon excitation for fluorescein confirmed lack of any spectral overlap between the two fluorophores used (Figure 1A,B, lane 2). The overlap of panels A and B resulted in yellow bands in lane 3 due to the close proximity of the fluorophores (red and green) on the intact dual-labeled DNA (Figure 1C, lane 3). For comparison, ethidium bromide stained DNA bands are shown in Figure 1D.

To simulate DNA degradation, a model experiment was conducted using the restriction endonucleases *Bam*H1 and *Pfl*MI that cut the plasmid DNA in non-encoding regions at specific single and double recognition sites, respectively (Scheme 1). Gel electrophoresis confirmed the different DNA digestion fragments (Figure 2). Panels A and B in Figure 2 show the emission bands of rhodamine and fluorescein, respectively, after separate excitation using the appropriate filters. Prior to the addition of the restriction enzymes, the DNA bands (open circular and supercoiled forms) are yellow due to the close proximity of the red and green labels on the intact DNA (Figure 2C, lane 2). Upon digestion with the restriction enzyme (*Bam*H1) that cuts at a single site, the circular DNA is linearized, resulting in a single linear strand which has a lower mobility than the supercoiled DNA in lane 2. This linearized DNA is visualized as a yellow band due to the close proximity of the fluorophores (Figure 2C, lane 3). Upon addition of the restriction enzyme *Pfl*MI, which cuts the DNA into two fragments (dual site cutter), the DNA is seen as individual red and green bands, as the two fluorophores are now separated (Figure 2C, lane 4). The DNA fragment containing rhodamine has a lower molecular weight than the fragment containing fluorescein. This difference is observed on the gel electrophoresis with the rhodamine-containing DNA fragment possessing higher mobility than the fluorescein-containing fragment.

On the basis of these observations, dual-labeled DNA was used to explore intracellular trafficking of DNA following transfection in CHO-K1 cells with the cationic liposome, Lipofectamine2000. The lipoplexes containing DNA conjugates were observed using confocal imaging at both the red and green channels (Figure 3I). At the initial time point prior to cellular uptake, imaging was conducted at a focal plane above the cells (0 h, Figure 3I). The overlapped image is visualized as yellow fluorescent voxels due to colocalization of the red and green fluorophores on the intact DNA. Live cell time-lapse imaging at various time points over a 3 h period showed the uptake and intracellular distribution of the DNA conjugates (Figure 3). Optical Z-sectioning was performed to locate the labeled DNA within the boundaries of the cell. Time-lapse imaging at 1, 2, and 3 h revealed yellow as well as individual red and green fluorescent voxels (Figure 3II, A−C) shown by arrows and enlarged images (B1 and C1). The uptake of the DNA conjugates increased with time with only a few conjugates observed at 1 h. At the 1 h time point (Figure 3IIA), only 18% of cells showed uptake of labeled DNA. By 2 h (Figure 3IIB), ∼59% of cells showed uptake of labeled DNA, with ∼32% of cells showing color separation due to DNA degradation. At the 3 h time point (Figure 3IIC), ∼72% of the cells showed uptake of the labeled DNA, with 41% of cells showing DNA degradation.

DISCUSSION

The methodology reported here to dual-label plasmid DNA through PNA linkers shows promise as a bioimaging tool to efficiently elucidate intracellular DNA degradation. pGeneGrip plasmid DNA contains rhodamine fluorophores. SAMSA fluorescein (green) was chosen as a second fluorophore due to its efficient coupling to the pendant maleimide groups on the plasmid DNA. This dual-labeling method did not change the mobility or the supercoiled conformation of the plasmid DNA as confirmed by gel electrophoresis studies.

Gel electrophoresis studies following restriction enzyme digestion demonstrated the utility of dual-labeled plasmid DNA to visualize differences in the plasmid DNA when intact or degraded. This study confirmed visualization of the undigested intact plasmid DNA as a yellow color (due to the close proximity of the two fluorophore labels) with the majority being in the supercoiled form. On the other hand, fragmented DNA, cut at the *Pfl*MI sites (Scheme 1), was seen as two colors (red and green), due to separation of the two fluorophores. The DNA that had undergone only a single site cut (i.e., linearized plasmid DNA) at the *Bam*H1 site is visualized as a yellow color. This could lead to discrepancies in the discrimination of intracellular DNA degradation fragments during tracking studies, since degradation must be at an advanced stage (i.e., beyond at least a single cut) before it can be detected using this methodology. There is a good probability of two or more double strand breaks to occur in a single plasmid intracellularly, since at the onset of endonuclease activity, exonucleases will quickly start the degradation process at the free ends of linearized DNA. Although the possibility of a single cut in DNA is unlikely, a normalization factor can be developed to account for the nondiscernable single cut event. This normalization factor can be determined as a function of enzymatic digestion measured using gel electrophoresis. Single cut and intact DNA can be distinguished in gel electrophoresis, since the single cut DNA, which cannot be in the supercoiled form, has a different mobility (lane 3, Figure 2).

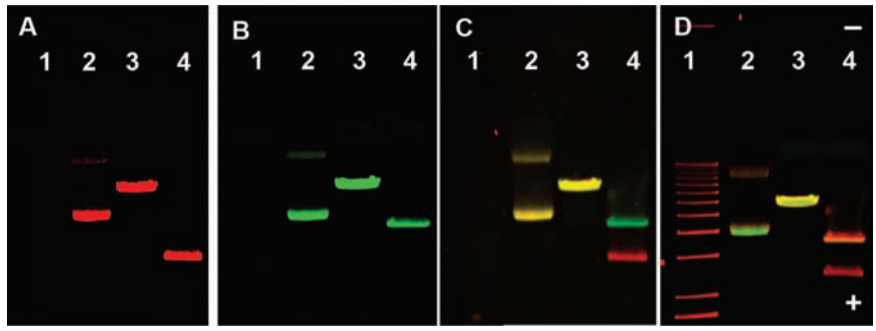

Figure 2. Agarose gel electrophoresis of dual-labeled DNA after treatment with *Bam*H1 and *Pfl*MI restriction enzymes. Lane 1, DNA ladder; lane 2, dual-labeled DNA (Rh (red) and activated SAMSA fluorescein (green)) before digestion; lane 3, *Bam*H1 treated (single site cutter); lane 4, *Pfl*MI treated (two site cutter). Panels A and B show exposure at wavelengths that excite the red and the green dyes, respectively. Panel C is the overlap of A and B. Panel D is the overlapped image after ethidium bromide (EtBr) staining. In panel C, the yellow bands in lanes 2 (DNA before digestion) and 3 (linearized DNA after *Bam*H1 digestion) are due to the close proximity of the red and green dyes on the DNA, whereas in lane 4, the red and green colors are separated after *Pfl*MI digestion at two sites. In panel D, EtBr staining compromises the dye colors in lanes 2−4.

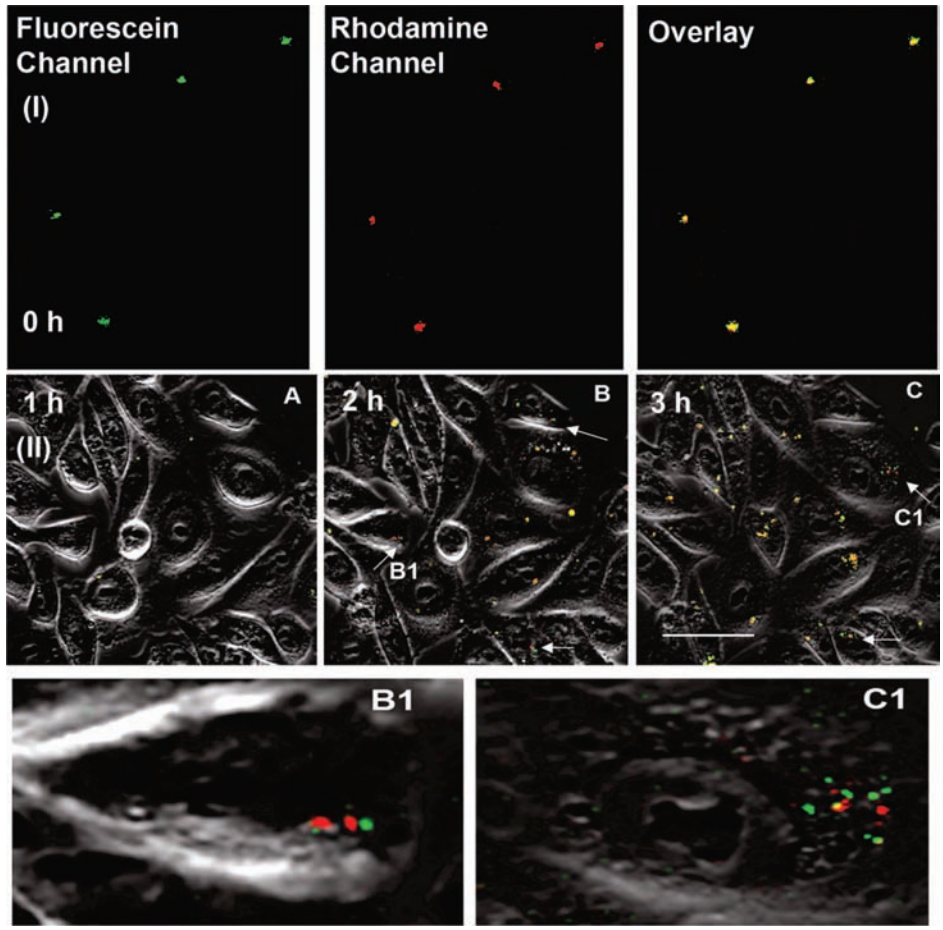

Figure 3. Confocal imaging for uptake of dual-labeled plasmid DNA (rhodamine and activated SAMSA fluorescein) incubated for 0−3 h in the presence of Lipofectamine2000 in CHO-K1 cells. (I) Sequential scanning at the initial time point (0 h). Panels are shown in the following order: green fluorescence (activated SAMSA fluorescein); red fluorescence (rhodamine); and overlap of red and green channels. (II) Time-lapse imaging with sequential scanning for 0−3 h post-transfection (bar 10 μm). Panels A−C overlapped images of all channels at 1, 2, and 3 h, respectively, and revealed yellow as well as individual red and green fluorescent voxels shown by arrows and enlarged images (B1 and C1). The yellow fluorescent voxels in the overlapped images are due to the close proximity of green and red fluorophores in intact dual-labeled DNA. The uptake of the DNA conjugates increased with time with only a few conjugates observed at 1 h. The amount of red and green separation also appears to increase with time (as shown in B1 and C1), indicating progressive DNA degradation.

The practical application of dual-labeled DNA to indicate DNA instability was verified following uptake in CHO-K1 cells using confocal microscopy. The combination of time-lapse imaging and dual-labeled DNA tracking revealed yellow fluorescent voxels in the cytosplasm (which likely represent intact plasmids), as well as color separation, which is indicative of DNA degradation. The yellow fluorescent voxels, evident in the cytoplasm at the 1, 2, and 3 h time points post-transfection, indicate that this DNA is probably in the supercoiled form and/or protected by the cationic liposome vector. Lechardeur et al. reported that lipid-encapsulated plasmid DNA enhanced the stability to degradation (∼25%) when compared to naked plasmid DNA (∼75%) within 4 h after microinjection into the cytosol (*31*). Supercoiled DNA is less susceptible to degradation by cytosolic nucleases, especially endoexonucleases when compared to linearized plasmid or open, circular forms of

plasmid DNA (*42*−*45*). In addition, the more compact nature of supercoiled DNA increases diffusion through the actin and mictrotubular network, thereby allowing a more rapid migration toward the perinuclear region when compared to linear DNA (*42*).

At the 1 h time point post-transfection, only a few yellow fluorescent voxels were seen and there was no red and green separation. The low number of yellow fluorescent voxels observed at the 1 h time point is due to incomplete uptake. This is in agreement with our previous studies, which revealed that maximum uptake of these complexes occurred at approximately 3 h in CHO-K 1 cells (*19*). The amount of red and green separation also appears to increase with time (as shown in Figure 3II), indicating progressive DNA degradation.

Since cationic lipoplexes are generally taken up via the endosomal route (*46*), it is possible that the degradation observed may be due to either entrapment of some complexes in the lysosomal compartment (*33, 46*) or degradation by cytosolic nucleases following release from the endosomes (*31, 46*−*48*). To further elucidate this, future experiments will require labeling of the various subcellular compartments. To address any complexity involved in detection of colocalization or fluorophore separation, we propose to label DNA using similar technology at more than two sites. Imaging of DNA conjugates longer than 3 h was not feasible due to photobleaching of the conjugated fluorophores. This is expected to be alleviated by the use of quantum dots as opposed to organic fluorophores (*19*). Nevertheless, this technique enabled observation of DNA degradation within cells by concurrent tracking using confocal time-lapse imaging. It is anticipated that the use of the dual-labeling technique described here, in combination with organelle stains and nuclease inhibitors (*30, 31, 34, 45, 49*), will be very valuable in elucidating inefficiencies at the different DNA cellular trafficking stages.

CONCLUSIONS

Plasmid DNA was successfully dual-labeled with rhodamine and fluorescein at two separate sites. Gel electrophoresis confirmed the mobility and structural integrity of the dual-labeled DNA. Cellular DNA degradation, simulated using restriction endonucleases, revealed intact DNA as a single color and degraded DNA as two separate colors. Confocal time-lapse imaging and intracellular tracking studies enabled simultaneous visualization of DNA distribution and degradation. A major limitation of this study was the photo-instability of the organic fluorophores used, which significantly limited the time over which DNA tracking at a single cell level could be conducted. More stable fluorophores, such as quantum dots (*19, 50*−*52*) as described in our previous work (*19*), could be used to perform long-term tracking studies.

Center for Molecular Imaging Research, Massachusetts General Hospital and Harvard Medical School, Building 149, 13th Street, Boston, Massachusetts 02129, and Center for Systems Biology, Massachusetts General Hospital and Harvard Medical School, 185 Cambridge Street, Boston, Massachusetts 02114. Received September 15, 2008; Revised Manuscript Received November 4, 2008

The biotin/avidin system is one of the most widely used affinity detection and affinity capture systems in biology. However, the determination of the exact number of biotin tags attached onto a substrate is complicated by the fact that biotin does not present any light-absorbing or -emitting properties. Here, we describe a fluorescent biotinylation reagent designed from the general multifunctional single-attachment-point (MSAP) reagent concept. A Lys-Cys dipeptide scaffold was used to display a biotin functional group and a fluorescein functional group along with an *N*-hydroxysuccinimide ester reactive group. The resulting bifunctional MSAP reagent, Fl-Biotin-NHS, was used to prepare a monobiotinylated version of cetuximab, which was further reacted with avidin to obtain a soluble avidin-based cetuximab oligomer. The MSAP peptide-scaffold approach allows fluorophores, chromophores, or reactive groups to be combined with biotin and provides a broad approach to obtain multifunctional biotin-based reagents.

INTRODUCTION

The recognition of biotinylated molecules by avidin (or streptavidin) is one of the most widely exploited affinity capture systems in immunohistochemistry, biochemical purification, and a variety of assay systems (*1*). In many systems, where either avidin or biotin is immobilized, the capture is not highly sensitive to the number of biotins per mole of biotinylated protein. However, when the reaction between avidin and a biotinylated protein occurs in solution, the degree of biotinlylation of the protein is of considerable importance. The self-assembly of biotinylated proteins into avidin-mediated protein oligomers can produce profound changes in bioactivity, such as those that occur when biotinylated MHC molecules form streptavidin-based tetramers (*2*).

Reacting avidin with biotinylated proteins containing more than one biotin per mole can lead, not to tetramers, but to extended complexes of avidin and biotinylated proteins, which eventually precipitate (Figure 1A). Reacting avidin with biotinylated proteins containing an average of less than one biotin per mole leads to mixtures of avidin-mediated oligomers and non-biotinylated proteins (Figure 1B). Reacting avidin with proteins containing an average of one biotin per mole maximizes the formation of soluble avidin-mediated oligomers (Figure 1C). Thus, when synthesizing soluble avidin-mediated protein oligomers, there is a need to obtain proteins that have (on average) a single biotin per mole. This in turn requires a simple, sensitive, and accurate method for determining the numbers of biotins.

We describe here an *N*-hydroxysuccinimide (NHS) ester-activated version of biotin and fluorescein, which can be used to determine the degree of biotinylation of proteins based on fluorescein's absorbance or fluorescence. The reagent, termed

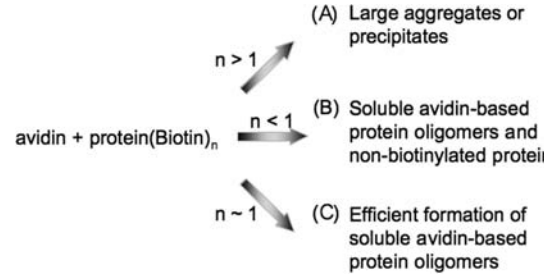

Figure 1. Reactions of biotinylated proteins with a tetrameric avidin. (A) When biotinylated proteins are over-biotinylated, with multiple biotins per mole ($n > 1$), large soluble aggregates or precipitates form, due to avidin tetravalency. (B) When biotinylated proteins are under-biotinylated, $n < 1$, non-biotinylated protein is present. (C) Mono-biotinylated proteins, $n \sim 1$, maximize the formation of soluble avidin-based protein oligomers.

"Fl-Biotin-NHS", employed our multifunctional single-attachment-point (MSAP) technology (*3*), where fluorescein, biotin, and the NHS ester are attached to a peptide scaffold. The Fl-Biotin-NHS reagent was used to obtain a mono-biotinylated cetuximab that was further reacted with avidin to prepare a soluble avidin-based cetuximab oligomer. To demonstrate the flexibility of the MSAP peptide scaffold approach to reagent design, a second fluorescent biotin reacting with thiol groups, "Fl-Biotin-MAL", is also presented.

EXPERIMENTAL PROCEDURE

Synthesis of Biotin-Lys(monosuccinimidylsuberate)-Cys(5-acetamidofluorescein)-NH_2, Fl-Biotin-NHS. The linear biotin-Lys(Boc)-Cys(Trt) sequence was elongated onto the Rink amide MBHA resin using standard Fmoc/*t*Bu solid-phase peptide synthesis procedures described earlier (*3*). Peptide full deprotection and cleavage from the resin with TFA/TIS/H_2O/EDT (95:2:2:1) afforded the biotin-Lys(H)-Cys(H)-NH_2 peptide as a white powder after lyophilization. ($C_{19}H_{34}N_6O_4S_2$) Calc. exact mass 474.2; found m/z $[M + H]^+ = 475.1$. Solutions of Biotin-

Lys(H)-Cys(H)-NH_2 (12.1 mg, 25.5 μmol) in 510 mL anhydrous DMF, fluorescein-5-iodoacetamide (8 mg, 15.5 μmol, 0.6 equiv) in 155 μL anhydrous DMF and DIPEA (5 μL, 28.7 μmol, 1.1 equiv) were mixed together overnight at room temperature. The reaction mixture was purified by RP-HPLC, and the fraction collected was lyophilized. Biotin-Lys(H)-Cys(5-acetamidofluorescein)-NH_2 (8.4 mg, 9.7 μmol, 63% yield) was obtained as a yellow powder. ($C_{41}H_{47}N_7O_{10}S_2$) Calc. exact mass 861.3; found m/z $[M + H]^+ = 862.0$. A solution of biotin-Lys(H)-Cys(5-acetamidofluorescein)-NH_2 (5.9 mg, 6.8 μmol) in 274 μL anhydrous DMF containing DIPEA (1.3 μL, 7.5 μmol, 1.1 equiv) was added slowly to a solution of DSS (50 mg, 135.7 μmol, 19.8 equiv) in 1360 μL anhydrous DMF. The reaction mixture was stirred for 48 h at room temperature. The reaction mixture was purified by RP-HPLC and the fraction collected lyophilized. Biotin-Lys(monosuccinimidylsuberate)-Cys(5-acetamidofluorescein)-NH_2 (5.2 mg, 4.7 μmol, 68% yield) was obtained as a yellow powder. ($C_{53}H_{62}N_8O_{15}S_2$) Calc. exact mass 1114.4; found m/z $[M + H]^+ = 1115.0$, $[M + Na]^+ = 1137.0$.

Synthesis of Biotin-Lys(γ-maleimidobutyryloxy)-Cys(5-acetamidofluorescein)-NH_2, Fl-Biotin-MAL. A solution of Biotin-Lys(H)-Cys(5-acetamidofluorescein)-NH_2 (4.2 mg, 4.9 μmol) in 240 μL anhydrous DMF containing DIPEA (1.0 μL, 5.7 μmol, 1.2 equiv) was added to a solution of GMBS (6.9 mg, 24.6 μmol, 5.1 equiv) in 246 μL anhydrous DMF. The reaction mixture was stirred overnight at room temperature. The reaction mixture was purified by RP-HPLC and the fraction collected lyophilized. Biotin-Lys(γ-maleimidobutyryloxy)-Cys(5-acetamidofluorescein)-NH_2 (3.3 mg, 3.2 μmol, 66% yield) was obtained as a yellow powder. ($C_{49}H_{54}N_8O_{13}S_2$) Calc. exact mass:1026.3; found m/z $[M + H]^+ = 1027.0$, $[M + Na]^+ = 1149.9$.

Biotinylation of Cetuximab with Fl-Biotin-NHS. Various amounts of a solution of Fl-Biotin-NHS in DMSO (10 mM) were added to Erbitux (2 mg/mL). Typically, 1.35 equiv of reagent for a final degree of biotinylation of 1 were used. The reaction was left for 1 h at room temperature and purified by size-exclusion chromatography using a Sephadex PD-10 column. Immunoconjugates were prepared in phosphate buffer pH 8 at 0.8 mg mL^{-1}.

Absorbance Measurements. Absorption spectra were measured on a Varian Cary 50 Bio UV−visible sprectrophotometer. Solutions of increasing concentrations of Fl-Biotin-NHS in phosphate buffer pH 8 were used to obtain a standard curve of optical density versus Fl-Biotin concentration. The absorbance was measured at the 493 nm absorbance maximum of Fl-Biotin-NHS. Solutions of cetuximab-(Fl-Biotin)$_n$ immunoconjugates were diluted two times. Absorbance was measured at 496 nm, absorbance maximum of cetuximab-(Fl-Biotin)$_n$. Each measurement was repeated three times. The number of biotin tags for each immnunoconjugate was obtained from the standard curve.

Fluorescence Measurements. Fluorescence emission spectra were recorded on a Varian Cary Eclipse fluorescence spectrophometer. Solutions of increasing concentrations of Fl-Biotin-NHS in phosphate buffer pH 8 were used to obtain the standard curve of fluorescence intensity at 519 nm versus Fl-Biotin concentration. Solutions of cetuximab-(Fl-Biotin)$_n$ immunoconjugates were diluted two times. Each measurement was repeated three times. The number of biotin tags for each immnunoconjugate was obtained from the standard curve.

Preparation of the Cetuximab−Avidin Oligomer. A solution of Avidin-Cy3.5$_{1.4}$ (0.8 mg/mL; 800 μL, 10 nmol) in phosphate buffer pH 7.2 was added to a solution of cetuximab-Fl-Biotin$_{1.1}$ (3.1 mg/mL; 2.75 mL, 57 nmol). The mixture was stirred overnight at 4 °C and purified by size exclusion chromatography using a Sephacryl 300-HR column (volume = 59.2 mL). The high valency was eluted in 34−40 mL phosphate buffer pH 7.2.

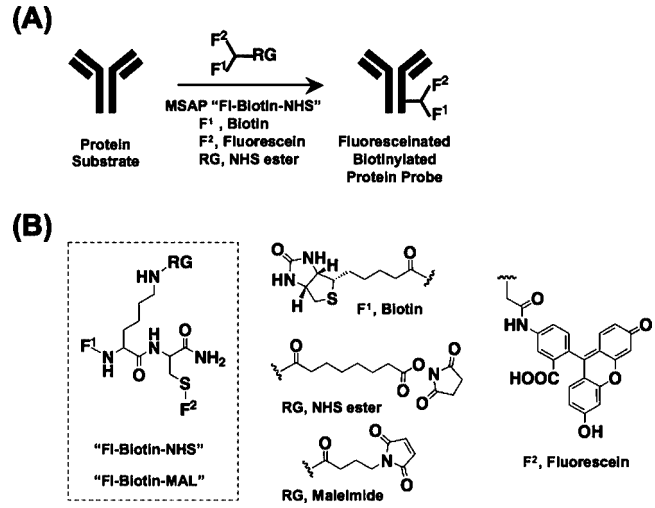

Figure 2. Multifunctional single-attachment-point (MSAP) reagents for the synthesis of biotinylated proteins. (A) A protein substrate, such as a monoclonal antibody, reacts with the MSAP reagent "Fl-Biotin-NHS" to yield a fluorescent (F^2), biotinylated (F^1) probe in one step. (B) Design of the "Fl-Biotin-NHS" and "Fl-Biotin-MAL" MSAP reagents. To the Lys-Cys dipeptide scaffold are attached the F^1 functional group biotin, the F^2 functional group fluorescein-acetamide, and either an *N*-hydroxysuccinimide (NHS) ester or a maleimide (MAL) reactive group RG.

Determination of the Number of Cetuximab in the Cetuximab−Avidin Oligomer by Absorbance. Absorption spectrum (200−800 nm) of the cetuximab−avidin oligomer was measured in phosphate buffer pH 7.2. Absorbance at 583 nm gave the concentration of Cy3.5 in the complex (150 000 M^{-1} cm^{-1}), without interference from fluorescein. Absorbance at 496 nm, corrected for the absorption of the Cy3.5 fluorochrome at this wavelength (18 000 M^{-1} cm^{-1}), gave the concentration of fluorescein in the complex (74 000 M^{-1} cm^{-1}). The ratio between fluorescein and Cy3.5 concentrations enabled an estimation of the number of cetuximab per avidin based on 1.1 Fl-Biotin per cetuximab and 1.4 Cy3.5 per avidin.

Photon Correlation Spectroscopy. Volume-weighted average diameters were obtained by light scattering using a Nano-2S Zetasizer (Malvern Instruments). Solutions of (a) ferritin (1 mg/mL), (b) cetuximab (1 mg/mL), (c) avidin (1 mg/mL), (d) avidin (1 mg/mL) + cetuximab (1 mg/mL), and (e) cetuximab−avidin oligomer, were measured.

"Native" Gel Electrophoresis. "Native" SDS-PAGE was performed using a Tris-HCl gel from 4% to 15% polyacrylamide. Samples were prepared by using 20 μL of protein solution and 5 μL of a buffer containing Tris (25 mM), glycine (192 mM), pH 8.3, 10% glycerol, and bromophenol. Electrophoresis was run (from the anode to the cathode) with a buffer containing SDS (3.5 mM), Tris (25 mM), and glycine (192 mM) at pH 8.3. No reducing agent (β-mercaptoethanol) was used.

RESULTS AND DISCUSSION

The principles behind the MSAP reagent concept are shown in Figure 2. As shown in Figure 2A, the MSAP reagent, "Fl-Biotin-NHS", had two functional groups (F^1 = biotin, F^2 = fluorescein) and a reactive group (RG) as an NHS ester. The chemical structure of Fl-Biotin-NHS is further clarified in Figure 2B. A Lys-Cys dipeptide scaffold was employed for the attachment of biotin (F^1), fluorescein (F^2), and a reactive *N*-hydroxysuccinimide ester reactive group (RG).

To demonstrate some of the flexibility possible with the peptide scaffold-based MSAP strategy, we prepared "Fl-Biotin-

Table 1. Fluorescent Biotin MSAPs

peptide scaffold	F^1	F^2	RG	MW (g mol^{-1})	designation
F^1-Lys(RG)-Cys(F^2)-NH_2	biotin	fluorescein-5-acetamide	*N*-hydroxysuccinimide ester	1115.2	Fl-biotin-NHS
F^1-Lys(RG)-Cys(F^2)-NH_2	biotin	fluorescein-5-acetamide	maleimide	1027.1	Fl-biotin-MAL

MAL", where a maleimide RG replaced the NHS ester. Fl-Biotin-MAL becomes a site-specific labeling reagent when reacted with bioengineered proteins containing a single thiol. The properties of Fl-Biotin-NHS and Fl-Biotin-MAL are given in Table 1. All subsequent experiments employed Fl-Biotin-NHS.

The Fl-Biotin-NHS MSAP, formally biotin-Lys(monosuccinimidylsuberate)-Cys(5-acetamidofluorescein)-NH_2, was synthesized as shown in Figure 3. Biotin was attached to the N-terminus of the protected Lys(Boc)-Cys(Trt) peptide on the solid phase. After deprotection and release from the resin, the thiol and amine groups were selectively reacted with fluorescein-5-iodoacetamide and with the cross-linker dissuccinimidyl suberate (DSS), respectively. Full characterization of Fl-Biotin-NHS is provided in the Supporting Information accompanying this manuscript. Fl-Biotin-MAL was prepared similarly by using an amine to thiol heterobifunctional cross-linker (*N*-[γ-maleimidobutyryloxy]succinimide, GMBS).

Fl-Biotin-NHS was employed to prepare biotinylated versions of the monoclonal antibody cetuximab where the number of biotins varied from 0.1 to 2.5 per mol of antibody. Absorbance and fluorescence standard curves acquired with Fl-Biotin-NHS were used to determine the number of Fl-Biotin moieties per antibody. A perfect fit between the absorbance of the immunoconjugates and the amount of Fl-Biotin-NHS reagent used per cetuximab was obtained. The fluorescein absorption signal (496 nm) enabled direct quantification of a wide range of biotinylation levels (Figure 4A and C). Samples containing from 0.5 up to 25 biotins per antibody could be measured from a single standard curve. Biotinylation levels obtained from fluorescence and absorbance signals were in very good concordance until the number of biotins reached a value of 15 (Figure 4C). Indeed, fluorescence quenching was noticed to occur when the conjugates contained more than 15 Fl-Biotin motifs. However, in the case of a low degree of biotinylation, the exact number of biotin per antibody can be more accurately determined by fluorescence than by absorbance (Figure 4B). Indeed, when the Fl-Biotin content of the immunoconjugate is low, the fluorescence peak can still be distinguished from the background conversely to the absorbance signal.

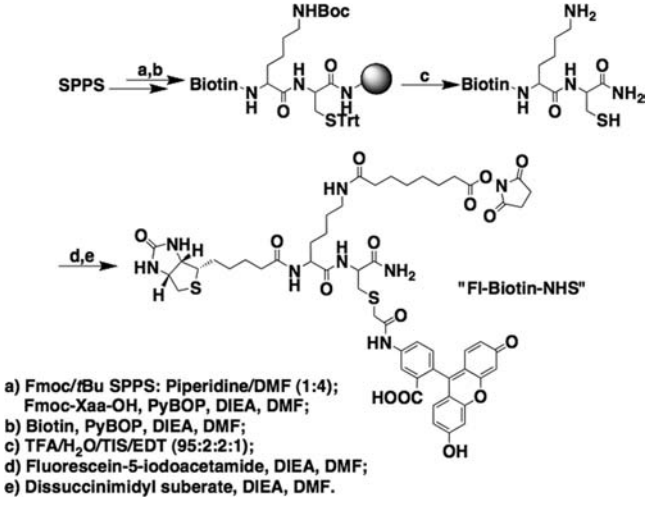

Figure 3. Synthesis of the "Fl-Biotin-NHS" MSAP or biotin-Lys-(monosuccinimidylsuberate)-Cys(5-acetamidofluorescein)-NH_2 ($C_{53}H_{62}N_8O_{15}S_2$; MW = 1115.23 g mol^{-1}). Biotin was attached to the N-terminus of the protected Lys-Cys peptide on the solid phase. After deprotection and release from the resin, the thiol and amine groups are selectively reacted with fluorescein-5-iodoacetamide and the cross-linker dissuccinimidyl suberate, respectively. The high flexibility of the synthetic strategy allows various substitutions of the Lys-Cys peptide scaffold and thus various MSAPs compositions.

In every case, we found both absorbance and fluorescence methods of Fl-Biotin more sensitive than the HABA method (Figure 4A and B). The commonly used method for estimating the extent of biotinylation of proteins, i.e., the molar ratio of biotin to protein, is based on the displacement of the HABA dye (4′-hydroxyazobenzene-2-carboxylic acid) from an HABA−Avidin complex absorbing visible light at 500 nm. Replacement of HABA by biotin in the complex translates into a decrease in the absorption intensity at 500 nm proportionally to the number of bound biotins. In the microplate assay format suggested in the EZ Biotin Quantitation Kit (Pierce), the decrease in absorbance for a regular antibody (MW 150 kDa, at 1 mg.mL^{-1}) containing an average of five biotins per protein is around 0.057, corresponding to a 10% decrease of the initial absorbance value. For the same antibody modified with only one biotin, the decrease is 0.011, corresponding to a 2% decrease of the initial absorbance value. This method lacks accuracy for low biotinylation levels.

We then considered the preparation of an avidin-based cetuximab oligomer from a monobiotinylated cetuximab and a tetrameric avidin. Fl-Biotin-NHS was thus used to modify cetuximab with 1.1 Fl-Biotin motifs per antibody. The latter was further incubated with avidin modified with the Cy3.5 fluorochrome. (Figure 5). Modification of the antibody and of the avidin with fluorescein and Cy3.5 fluorochromes, respec-

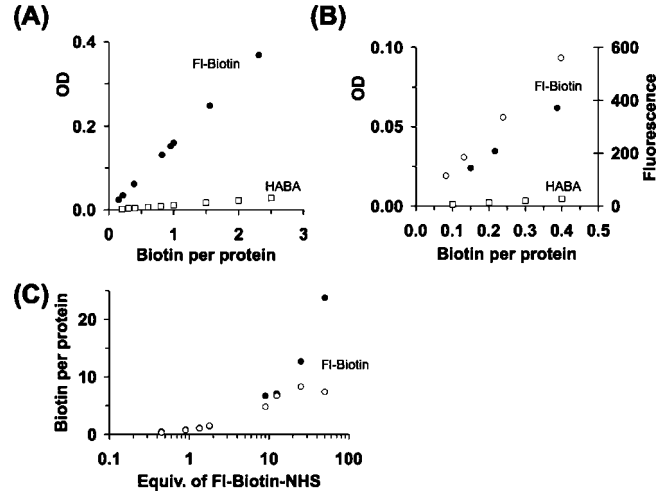

Figure 4. Comparison of the sensitivity of Fl-Biotin-NHS with the HABA dye displacement-based method for the determination of biotinylation of a monoclonal antibody (cetuximab). (A) Biotin per protein determined by Fl-Biotin's absorbance (496 nm, •) versus the HABA method (500 nm, □). Fl-Biotin is more sensitive than the HABA method, based on the displacement of the HABA dye from the HABA−Avidin complex by biotin (A_{500} = A_{500}HABA−Avidin − A_{500}HABA−Avidin−Biotin). (B) Biotin per protein at low biotinylation levels determined by Fl-Biotin absorbance (496 nm, •), the HABA method (500 nm, □), and Fl-Biotin fluorescence (519 nm, ○). (C) Quenching of Fl-Biotin fluorescence with high numbers of Fl-Biotin per mole of protein. At high levels of Fl-Biotin (n > 15), fluorescence quenching causes an underestimation of the number of Fl-Biotin per protein. Note that each measurement is the average of three replicates; error bars are included.

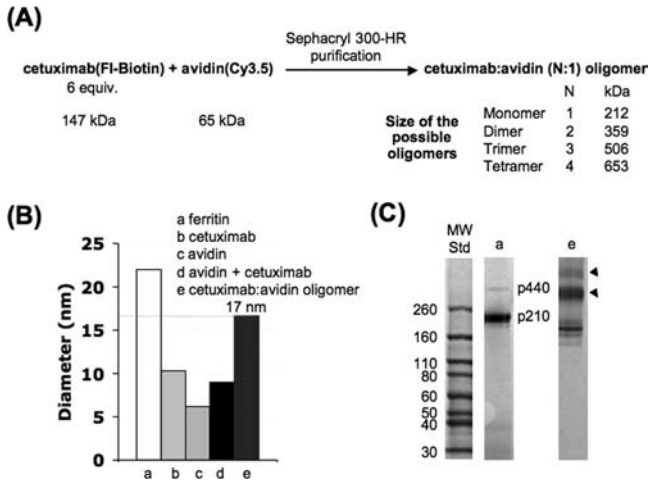

Figure 5. Synthesis and characterization of a cetuximab−avidin oligomer. (A) Synthesis of the oligomer. Six molar equivalents of a monobiotinylated cetuximab was reacted with avidin(Cy3.5). The reaction mixture was purified by gel filtration and the oligomer was isolated. (B) Characterization of the cetuximab oligoner by laser light scattering. The volume-weighted diameter was 17 nm. (C) Characterization of the cetuximab oligomer by SDS-PAGE (no mercaptoethanol). Lane "MW Std" shows various molecular weight standards. Lane "a" is a ferritin standard which gave species of 210 and 440 kDa. Lane "e" is the cetuximab−avidin oligomer. The most prominent species was slightly smaller than 440 kDa ferritin. The cetuximab−avidin oligomer contains a mixture of the dimer, 359 kDa, and of the trimer, 506 kDa.

tively, facilitated (i) the separation of the complex by gel filtration (Sephacryl 300-HR) and (ii) the determination of the ratio of cetuximab to avidin in the cetuximab−avidin oligomer. Absorbance measurements concluded 2.3 cetuximab per avidin (data not shown). The oligomer was characterized by dynamic laser light scattering and gel electrophoresis. The size of the oligomer was 17 nm (volume-weighted) as measured by light scattering (Figure 5B). The size of the oligomer was also assessed by "native" (no reducing agent) SDS-PAGE and compared to ferritin, a globular protein, presenting two major bands, p210 and p440, at 210 and 440 kDa, respectively. The oligomer presents two species. The most prominent species is slightly smaller than 440 kDa ferritin. Altogether, the results of the three characterization methods converge to the conclusion that the cetuximab oligomer obtained is a mixture of the dimer, 359 kDa, and of the trimer, 506 kDa.

An advantage of the MSAP synthetic strategy shown in Figure 3 is its ability to allow substitutions of the functional groups or reactive groups on the biotin-Lys-Cys dipeptide. Since the dipeptide is made by manual solid-phase synthesis, sufficient dipeptide was obtained to allow it to be split into portions for reactions with different functional groups. In particular, the single amine and single thiol of the dipeptide can be reacted in a chemoselective manner with a variety of reagents under mild conditions, to generate a variety of biotinylated molecules. Since fluorescein was not exposed to the harsh conditions of deprotection, any thiol-reactive fluorochrome can be substituted for fluorescein-5-iodoacetamide, including near-infrared fluorochromes, some of which do not survive the harsh conditions of deprotection. Thus, MSAP chemistry provides a broad new strategy for designing biotinylated reagents that can feature a variety of possible reporter groups (e.g., chromophores, fluorochromes, chelators) and, as we have shown, *N*-hydroxysuccinimide ester or maleimide reactive groups.

CONCLUSION

A peptide scaffold based, multifunctional, single-attachment-point reagent (MSAP) was used to obtain the fluorescent biotin, Fl-Biotin-NHS. Fl-Biotin-NHS was then used to attach 1.1 biotins per mole to cetuximab, and the biotinylated antibody reacted with avidin to obtain an avidin−cetuximab oligomer. The Fl-Biotin-NHS can be used to biotinylate protein substrates with the degree of biotinylation determined by absorbance or fluorescence. In addition, MSAP reagents provide a broad new approach to the design of multifunctional biotins.

Single photon emission computed tomography (SPECT) imaging provides a three-dimensional method for exactly locating gamma emitters in a noninvasive procedure under in vivo conditions. For characterization of siRNA delivery systems, molecular imaging techniques are extremely helpful to follow biodistribution under in experimental animal studies. Quantification of biodistribution of siRNA and nonviral delivery systems using this technique requires efficient methods to stably label siRNA with a gamma emitter (e.g., ^{111}In or ^{99m}Tc) and to purify labeled material from excesses of radiolabel or linkers. In the following study, we have optimized labeling and purification of siRNA, which was then applied as free siRNA or after complexation with polyethylenimine (PEI) 25 kDa for in vivo real-time gamma camera and SPECT imaging. Quantification of scintillation counts in regions of interest (ROIs) was compared to conventional scintillation counting of dissected organs, and the data acquired by imaging was shown to corroborate that of scintillation counting. This optimization and proof of principle study demonstrates that biodistribution and pharmacokinetics of siRNA and the corresponding polyplexes can be determined using SPECT, leading to comparable results as conventional methodology.

INTRODUCTION

Single photon emission computed tomography (SPECT) imaging is an attractive method which allows three-dimensional localization of gamma emitters such as ^{111}In ($E\gamma = 171$ and 245 keV) or ^{99m}Tc ($E\gamma = 140$ keV) using a noninvasive procedure under in vivo conditions. Such techniques would be extremely helpful for assessing siRNA and their corresponding nonviral delivery systems with regard to biodistribution and targeting.

SPECT, compared to positron emission tomography (PET), is less elaborate and expensive and shows additionally a higher resolution in small animals. The disadvantage of SPECT and PET providing only functional but no morphological information can be alleviated by either combining SPECT or PET and computed axial tomography (CT), magnetic resonance imaging (MRI), or anatomical landmarking. For the latter, bones are visualized using radioactively ^{99m}Tc-labeled bisphosphonates. Dual-isotope SPECT recordings can then be recorded in separate channels for each energy window and superimposed to generate 3D images. This dual-isotope SPECT method has not been utilized to investigate siRNA delivery systems so far. Although it does not provide the same information as SPECT/CT or SPECT/MRI, it, of course, gives better insight than single-isotope SPECT.

The field of siRNA delivery has rapidly evolved in recent years; however, only few in vivo studies combining siRNA delivery with noninvasive molecular imaging techniques such as SPECT or PET have appeared in the literature (*1*, *2*). Several groups have labeled siRNA with ^{32}P (*3*, *4*), which is a beta emitter and can only be determined using scintillation counting or autoradiography in an end point study but not in in vivo imaging. Phosphodiester and phosphorothioate siRNA have been reported to be labeled with ^{123}I and ^{125}I (*5*), but radiometal labeling is usually preferred over radiohalogen labeling because of stability reasons (*6*, *7*). In an earlier report, siRNA had been labeled with ^{111}In, but biodistribution was only quantified invasively (*8*). A recent PET/bioluminescence study (*2*) using DOTA-chelated ^{64}Cu was the first report of assessing siRNA delivery by PET imaging. An earlier study (*9*) quantitated distribution of ^{99m}Tc-labeled single strands using a gamma camera, but unfortunately allowed only for an estimation of biodistribution of duplexes. SPECT, compared to PET, provides better spatial resolution in small animals and does not require synthesis of short-lived and high-energy emitters. Additionally, using high-resolution SPECT imaging based on multi-pinhole collimation, which is a prototype of the latest small animal scanners, allowed us to use a clinical camera (*10*).

Quantification of biodistribution of siRNA and their delivery systems using SPECT or two-dimensional gamma camera imaging requires efficient methods for stably labeling siRNA with a gamma-emitting isotope as well as fast and efficient purification of labeled materials from excesses of radiolabel or linkers.

The fate of pDNA after intravenous application of different nonviral vectors, such as polyethylenimine (PEI) or PEGylated PEI (PEG-PEI), has been reported previously (*11*, *12*), but it cannot be assumed that siRNA polyplexes would perform identically under in vivo conditions. In fact, several studies demonstrated differences between siRNA and DNA containing polyplexes (*13*, *14*). Hence, dual isotope SPECT would be of interest for in vivo live imaging the biodistribution of siRNA

polyplexes. As ^{111}In can be complexed with chelators such as p-SCN-Bn-DTPA, we have developed an optimized a method (*8*) for covalently labeling amine-modified siRNA and applied this labeled siRNA in real time live imaging of the distribution of our previously in vitro investigated PEI/siRNA polyplexes (*15*).

MATERIALS AND METHODS

Materials. Amine-modified luciferase GL3 siRNA with a C6-NH_2 linker at each 3′ of the double strand was purchased from Dharmacon (Lafayette, CO, USA). 2-(4-Isothiocyanatobenzyl)diethylenetriaminepentaacetic acid (p-SCN-Bn-DTPA) was purchased from Macrocyclics (Dallas, TX, USA), arsenazo(III), yttrium(III) chloride, and diethyl pyrocarbonate (DEPC) from Sigma-Aldrich Laborchemikalien GmbH (Seelze, Germany). The purification columns miRACLE were purchased from Stratagene (La Jolla, CA, USA), RNeasy Mini from Qiagen (Hilden, Germany), and PD-10 from Amersham Pharmacia Biotech (Freiburg, Germany). The radioactive substances $^{111}InCl_3$ and ^{99m}Tc-alendronate were purchased from Covidien Deutschland GmbH (Neustadt a.d. Donau, Germany), and balb/c mice from Charles River WIGA (Sulzfeld, Germany).

Polyethylenimine, PEI 25 kDa (Polymin, 25 kDa), was a gift from BASF (Ludwigshafen, Germany); all other chemicals used were of analytical grade. All buffers were treated with 0.1% diethyl pyrocarbonate (DEPC).

Methods. *p-SCN-Bn-DTPA Coupling.* Amine-modified luciferase GL3 siRNA was dissolved in siRNA buffer provided by the manufacturer. Coupling of p-SCN-Bn-DTPA was accomplished by a previously described method (*8*). Briefly, 20 nmol siRNA in 10 μL siRNA buffer, adjusted to pH 8.5 with an equal volume of 0.2 M $NaHCO_3$, was mixed with a 50-fold excess of the chelator dissolved in 36 μL DMSO. In our experiments, we used the amine-reactive variant of DTPA (p-SCN-Bn-DTPA) instead of DTPA-dianhydride (cDTPA). Incubation times were varied from 45 min as reported to 3 h. The coupling degree was determined after purification by quantification of DTPA in a nonradioactive assay described by Pippin et al. (*16*). Briefly, absorption of a complex of arsenazo(III) and yttrium(III) at 652 nm is measured, and sample DTPA content can be calculated or a calibration curve can be recorded due to decreasing absorption of the complex falling apart after addition of DTPA.

PD-10 Size Exclusion Chromatography (SEC). One method used for separation of labeled siRNA from p-SCN-Bn-DTPA or radiolabel was size exclusion chromatography SEC employing a PD-10 Sephadex G25 prepacked column. The column was equilibrated with 50 mL DEPC-treated PBS before the reaction mixture was applied to the column. Fractions of 13 droplets each were collected. RNA content was measured UV-metrically at 260 nm using a Pharmacia Ultrospec 2000 UV/vis, Pharmacia Biotech (Freiburg, Germany), and the radioactive signal in 10 μL of each fraction was determined using a Gamma Counter Packard 5005 (Packard Instruments, Meriden, CT, USA).

miRACLE and RNeasy Purification. Spin column purification was conducted as described for the miRACLE columns. Briefly, 1 or 100 μg siRNA for miRACLE or RNeasy columns, respectively, were diluted to 600 μL with 2 M sodium acetate, ethanol, and guanidinium salts containing "binding buffer" provided in the miRACLE kit and applied to a spin column. Columns were centrifuged for 2 min at 16 000 *g* and washed 3 times with 600 μL "low salt wash buffer" by centrifugation for 1 min at 16 000 *g*. The membranes were dried by a fifth centrifugation step without applying any solution. RNA was then eluted by incubating the membrane with 50 μL 60 °C warm DEPC-treated RNase free water for 2 min and following centrifugation for 1 min at 16 000 *g*. This step was repeated and followed by a third incubation where 25 μL DEPC-treated 0.5 M sodium acetate, pH 4.5, were applied instead of water to achieve a final concentration of 0.1 M sodium acetate in the siRNA solution.

Radiolabeling. Radiolabeling of the p-SCN-Bn-DTPA-coupled siRNA was accomplished in 0.1 M sodium acetate buffer, pH 4.5. For the validation of the method, small amounts of 10 nmol siRNA were incubated with 16.2 MBq $InCl_3$ for 30 min at room temperature. For in vivo experiments, 111 nmol siRNA were incubated with 28.9 MBq $InCl_3$ for 30 min at room temperature, followed by either PD-10 SEC or spin column binding, washing, and elution, or a combination of both methods. For in vivo experiments, siRNA was purified using a PD-10 column first. Fractions 5−9 (compare Figure 4A and B), which showed both a high radioactive signal and the strongest UV absorption at 260 nm and do not contain any free p-SCN-Bn-DTPA or indium, were combined and further purified as well as concentrated using RNeasy columns as described above.

Animal Studies. All animal experiments were carried out according to the German law of protection of animal life and approved by an external review committee for laboratory animal care.

For in vivo experiments in 4-week-old balb/c mice (∼20 g), 35 μg Bn-DTPA coupled thiourea derivative of siRNA, corresponding to 2.57 nmol and 0.255 MBq, were either administered as free siRNA or after complexation at an N/P ratio of 6 with 25 kDa branched PEI. Free siRNA or complexes were injected i.v. to the tail vein, and biodistribution was followed by perfusion live imaging and static imaging acquired with a Siemens e.cam gamma camera (Siemens AG, Erlangen, Germany). Biodistribution 2 h post-injection was investigated by

(B) Purification with a PD-10 column did not effectively separate siRNA from an excess of unreacted p-SCN-Bn-DTPA. RNeasy columns did not desalt from $InCl_3$, and therefore, a combined purification after annealing was employed.

high-resolution SPECT imaging using a custom-built multiplexing multi-pinhole collimator, mounted on the Siemens e.cam gamma camera, quantified by analysis of regions of interest (ROIs) in the planar gamma camera images, and was eventually compared to conventional gamma counting of dissected organs.

For anatomical landmarking in the SPECT images, mice were additionally injected with 4 MBq ^{99m}Tc-labeled phosphonate 4 h before imaging.

Statistics. Analytical measurements were conducted in triplicate. Animal experiments include 5 animals per group; results are given as mean values. Two-way ANOVA and statistical evaluation was accomplished using GraphPad *Prism 4.03* (GraphPad Software, LaJolla, USA).

RESULTS AND DISCUSSION

While labeling of amine-modified siRNA with p-SCN-Bn-DTPA was accomplished differently from the method previously reported (*8*) and could not be improved by variation of incubation time, purification of the reaction mixture, on the other hand, was extensively optimized. For coupling the amine-modified siRNA, we preferred the use of p-SCN-Bn-DTPA over cyclic DTPA anhydride (cDTPA) (*8*), since in the coupling reaction with the latter, one of the chelating teeth is used for amide formation in a ring opening reaction. The advantage of formation of a thiourea derivative in a standard reaction of amines and the benzyl-isothiocyanate modified DTPA is the fact that each chelating tooth is available for complex formation after DTPA is unaffected by the reaction of the benzyl-spaced isothiocyanate, which is shown in Figure 1. In search of a faster purification method than extensive dialysis, which would yield a higher percentage of siRNA recovery and protect the siRNA from degradation, a method was employed that is known from RNA isolation from cells or tissues. First of all, spin columns specifically developed for miRNA isolation (miRACLE, Stratagene) were used to validate the method and to quantify the yield. The basic principle of this purification or isolation method is the binding of RNA in the presence of chaotropic salts to the silica membrane of the spin columns. Additionally, RNA is made insoluble by a high concentration of ethanol of at least 70% v/v in the presence of 10% v/v 2 M sodium acetate buffer, and therefore can be washed extensively but rapidly with low salt buffers containing 70% v/v ethanol. Finally, the RNA is eluted with water or TE buffer. Due to the chelating activity of EDTA in TE buffer, which could later complex parts of radioactive indium, all siRNA was eluted with DEPC-treated water.

The miRACLE spin columns proved to be applicable for siRNA, as the yield of eluted siRNA was 92.6 ± 6.4% and the coupling degree determined after purification was 16.9 ± 2.1% (compare Figure 2A). Because of their low binding capacity (1 μg RNA per column) and bigger reaction feeds needed for in vivo application, the use of RNeasy Mini columns (Qiagen) that hold 100 μg of RNA was validated in the next step. Since the buffer composition of the binding and washing buffers in the RNeasy kit is proprietary, buffers from the miRACLE kit, which were assured to be free of chelators, were used for all spin column purifications. The yield of the siRNA recovery could extensively be increased from 40%, which had been eluted with 25 °C warm DEPC−water to 79.6 ± 4.1% after incubating the siRNA on the membrane for 2 min with 60 °C warm DEPC−water.

The coupling degree of such purified siRNA was determined to be 32.9 ± 1.8% as shown in Figure 2A.

For purification after radiolabeling, in the first approach, PD-10 (Amersham) SEC was employed as described by Van de Water et al. (*8*). After analysis of the collected fractions for UV-metrically determined siRNA concentration and gamma-counted radioactivity, RNA peak fraction and peak fraction of the radioactivity seemed to be shifted, as shown in Figure 3A, and the radioactive signal slowly decreased before a second peak appeared. Due to the principle of SEC, big particles are eluted first, then smaller ones in later fractions. Since the siRNA had only been brought into contact with DEPC-treated buffers upon receipt, we precluded degradation. One possible explanation was that siRNA had not been fully annealed, and possibly only the single strands had been effectively labeled with p-SCN-Bn-

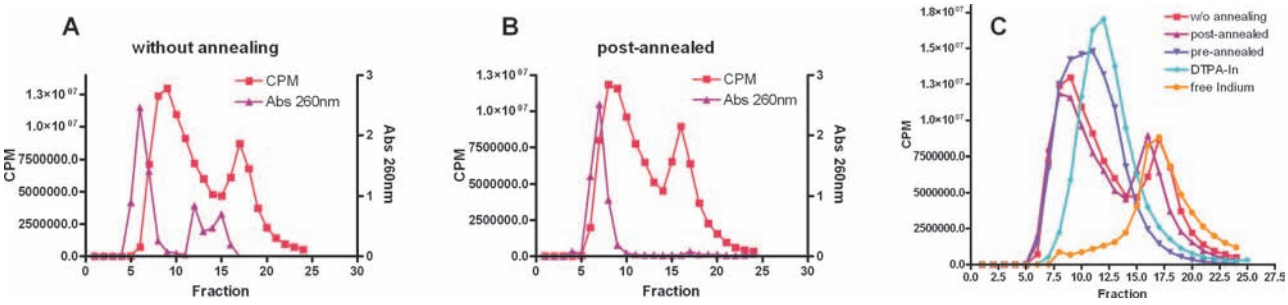

Figure 3. PD-10 size exclusion chromatographs of purified siRNA. (A) RNeasy purified siRNA without annealing. Radioactivity and RNA peaks are shifted. (B) RNeasy purified siRNA after postannealing. Peaks are concurrent, but radioactivity signal decreases slowly. (C) Overlay of radioactivity signals. p-SCN-Bn-DTPA-Indium appears after fraction 7 and is the reason for the slow decrease of signal in RNeasy purified siRNA and the broad peak in PD-10 purified preannealed siRNA (blue). Free indium peaks at fraction 17 and is not apparent in PD-10 purified preannealed siRNA due to excess of free p-SCN-Bn-DTPA.

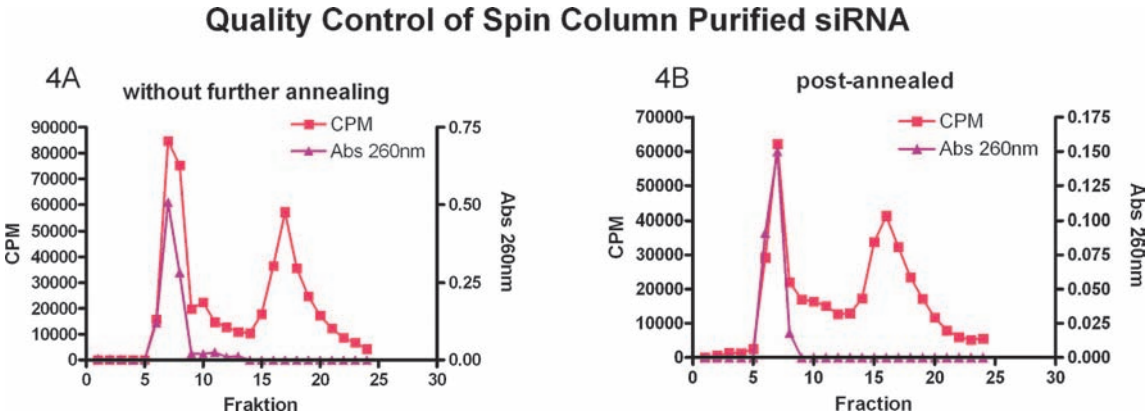

Figure 4. PD-10 size exclusion chromatographs of siRNA that was purified with RNeasy spin columns after coupling and after radiolabeling. RNA and radioactivity peaks are concurrent in climax and anticlimax, but a substantial amount of free indium is left in solution.

DTPA. To prove this, radiolabeling was repeated (a) without annealing and (b) with annealing of the siRNA strands by heating up to 94 °C for 2 min after p-SCN-Bn-DTPA-labeling, and with (c) preannealed siRNA. To make sure that the annealed double strands would not be separated on the membranes of the spin columns or under harsh conditions such as 16 000 *g* centrifugal force, this reaction mixture was purified on a PD-10 column. Here, a mathematically calculated coupling degree of theoretically 323% and therefore an excess of at least 123% of free p-SCN-Bn-DTPA was determined, as shown in Figure 2A.

The same amounts of free indium (orange line, Figure 3C) or free p-SCN-Bn-DTPA-chelated indium (green line, Figure 3C), which had been in the reaction mixtures, were each applied to a PD-10 column in separate experiments. This allowed us to detect when free indium and when indium chelated by residual free p-SCN-Bn-DTPA would be eluted from the PD-10 column and which peak in the chromatographs represented each of those two compounds. Free indium showed a peak at fraction 17, with p-SCN-Bn-DTPA-indium at fraction number 12. The overlay of each indium signal in Figure 3C allowed us to clearly identify the second, smaller peak in Figure 3A,B to be the free Indium.

Reannealing of the precoupled siRNA strands finally caused concurrence of the radioactivity and the siRNA peak, which is shown in Figure 3B. Without annealing, again a shift of both peaks was observed (compare Figure 3A). However, the decrease of the radioactivity signal of the reannealed sample (Figure 3B) fell less steeply than the RNA signal. In the preannealed sample (blue line in Figure 3C), which obviously contained a high amount of free p-SCN-Bn-DTPA (compare Figure 2A), the indium peak was even broader and did not show a free indium peak after fraction 15.

Since spin column purification after p-SCN-Bn-DTPA coupling had proven to be much more effective than SEC, it was next employed for purification after radiolabeling of another sample of which small aliquots were applied to a PD-10 column for quality control either without further treatment (Figure 4A) or after reannealing (Figure 4B). The chromatographs of those two aliquots did not show significant differences, but finally, the peaks of RNA concentration and radioactivity matched in both peak and valley. However, as a second, smaller peak appeared again after fraction 15, it must be admitted that the spin column purification is highly effective for separation of siRNA (approximately 13.6 kDa) from small molecules like p-SCN-Bn-DTPA (650 Da), but cannot fully separate siRNA from large excesses of salts like $InCl_3$. The best strategy therefore seemed to be a combination of SEC and spin column purification, as another benefit of a following spin column purification is the fact that the peak fractions from SEC can be combined and concentrated on the columns, as shown in Figure 2. Annealing of siRNA should be accomplished after p-SCN-Bn-DTPA coupling to achieve a high coupling degree.

The final yield after combined purification of 125 nmol siRNA of which 111 nmol siRNA was labeled with 28.8 MBq was 81.2% with a specific activity of 99 MBq/μmol.

Functionality of the labeled siRNA was investigated in vitro and found not to be significantly different from a nonlabeled duplex of the same sequence (data not shown).

In the in vivo experiments, labeled and purified siRNA was either administered as free siRNA, as reported earlier (*8*), or after complexation with 25 kDa branched PEI, which has already been characterized concerning in vivo biodistribution and pharmacokinetics after complexation of pDNA and ODNs (*11*, *17*, *18*) and has lately been used for in vivo siRNA delivery (*19*−*24*).

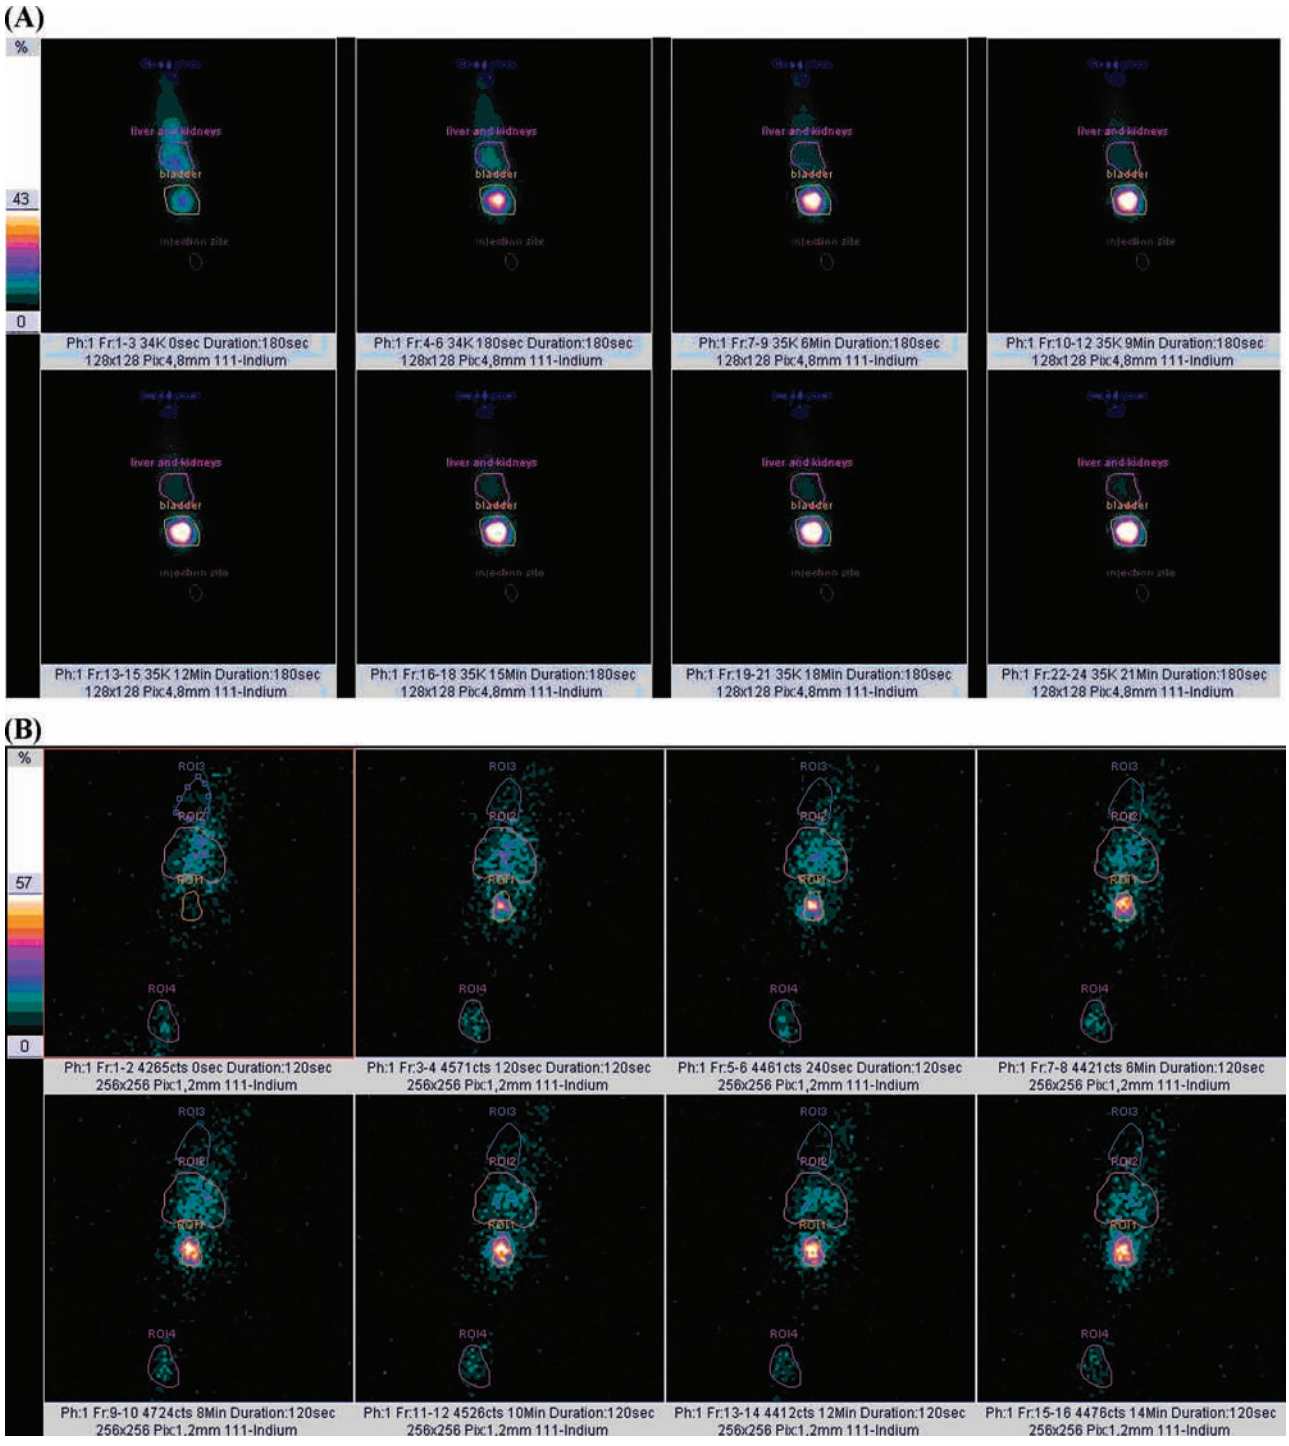

Figure 5. Planar gamma camera perfusion movie with regions of interest for lifetime quantification after injection of 35 μg siRNA, corresponding to 2.57 nmol and 0.255 MBq ^{111}In (A) as free siRNA and (B) complexed at N/P of 6 with 25 kDa bPEI.

In the real-time perfusion study, rapid accumulation of PEI-complexed siRNA in the liver and in the kidneys could be observed, as well as an increasing signal in the bladder, as shown in Figures 5B, 6B, and Movie 4 (Supporting Information). Quantification of scintillation counts in the ROIs as a function of time, as shown in Figure 6B, reveal that the half-life of PEI-complexed siRNA in the blood pool (blue line, Figure 6B and C) is only 168.5 s, which is in good agreement with published data (*25*). The signal in the liver and kidneys decreases to a plateau after initial accumulation (pink line, Figure 6B), and the signal of residual radioactive material in the injection site (purple line, Figure 6B) decreases as well to a certain extent. Free siRNA, on the other hand, showed initial uptake into the liver and kidneys, as shown in Figure 6A (pink line), but no accumulation. Our real time perfusion recording shows very rapid excretion into the bladder (Figure 5A and Movie 1, Supporting Information), which is visualized and quantified in Figure 6A. While activity in the liver and kidneys decreases (Figure 6A, pink line), it increases to the same extent in the bladder (Figure 6A, orange line).

SPECT images recorded 2 h post-injection corroborated the observation of accumulation of PEI-complexed siRNA in liver, kidneys, and bladder by providing more three-dimensional, regional information (compare Figure 7B and Movie 2, Supporting Information), and gamma scintillation counting of dissected organs confirmed that PEI 25 kDa complexed siRNA

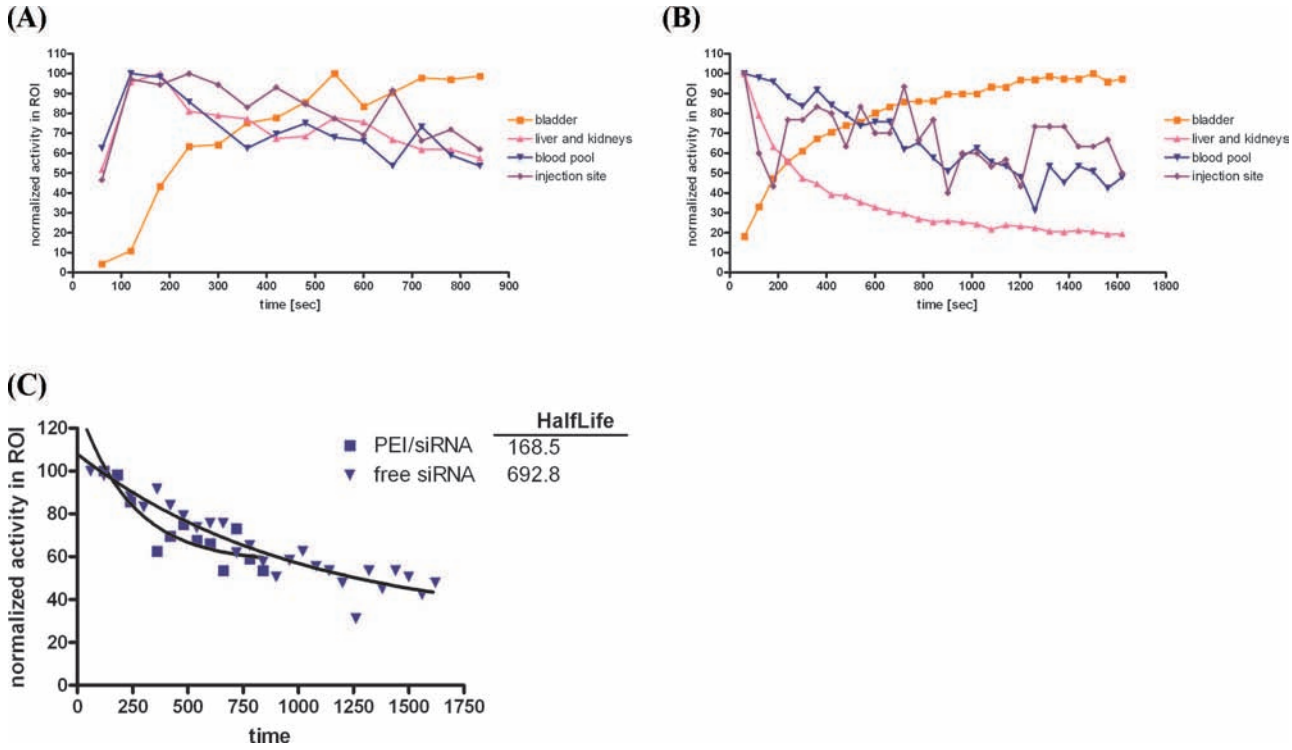

Figure 6. Normalized graphical analysis of activity in regions of interest in Figures 5A and 5B. 6A: Free siRNA, 6B: PEI-complexed siRNA, 6C: Pharmacokinetic analysis of siRNA in circulation. 273 × 162 mm (300 × 300 DPI).

accumulated in the liver and was renally excreted, as it was found to be in the urine and not in the bladder tissue (compare Figure 8A). Confirmation of noninvasive data by invasive data, which has been reported in drug delivery (*26*) and gene therapy (*27*) studies, was the critical part of this investigation and was successfully achieved.

Free siRNA could be measured in the kidneys, as reported earlier (*8*), and partly in the liver, but was also eliminated through the bowel. Due to their instability in serum, free siRNA duplexes are rapidly degraded upon injection. Therefore, small fragments bearing the label supposedly circulate in the blood pool and show a different behavior than macromolecules or nanoplexes.

Fast renal clearance and a high signal in the urine in biodistribution studies with PEI/pDNA polyplexes had so far been interpreted as degraded plasmid being excreted (*28*). In our study, on the other hand, we found higher signals in the urine for PEI-complexed siRNA compared to free siRNA, 2 h after injection. One reason could be that the free siRNA had been excreted to the bladder faster than PEI-complexed siRNA and got lost by urination before the animals were sacrificed. However, the signal in the urine cannot only be caused by degradation products, knowing that renal clearance might even be faster than siRNA degradation (*25*). In fact, free siRNA, which for sure had partly been degraded after injection, showed a different profile from complexed siRNA. In the case of free siRNA, no distinct deposition in any certain organ could be observed (Figure 8A), and the percentage of injected dose that was still in circulation after 2 h was 9% per mL blood compared to 1% for PEI 25 complexed siRNA (Figure 8). The half-life of free siRNA was 692.8 s (compare Figure 6A and C). SPECT images of mice treated with free siRNA (Figure 7A) showed no distinct deposition in any organ either, except for the bladder. One explanation for this could be long circulation and almost no deposition of small fragments of degraded siRNA or a binding of amine-modified siRNA to blood components. It is known that siRNA is degraded rapidly in vivo by serum nucleases and that this can be prevented or retarded by chemical modification of the nucleotides or by complexation with an appropriate delivery system (*29*−*31*). In our earlier publication, we showed that bPEI 25 kDa as well as PEGylated derivatives do have the potential to protect siRNA from RNase degradation (*15*). As formulation with the polymer seemed to drive kinetics and distribution, PEI-complexed siRNA showed a clear accumulation in the liver of 15% injected dose per organ (Figure 8A), although not as prominent as observed with pDNA, which had been reported to be up to 40% (*11*). Accumulation in the spleen could not be observed either, although more labeled polymer (2.9%, data not shown) than labeled siRNA (0.9%, Figure 8A) was found to be taken up—possibly by macrophages. This again supports the assumption by Merdan et al. (*11*) of polyplexes at least partly falling apart into free polymer, which is then especially taken up by the liver and spleen, and into siRNA, which is excreted or degraded upon release from the complex.

A primary deposition in the lungs and secondary redistribution, which had been assumed for PEI/pDNA complexes earlier (*11*, *32*), could not be observed in our perfusion studies. Nor did we observe acute or lethal toxicity, which had been described by several groups investigating biodistribution and kinetics of PEI/pDNA polyplexes (*33*). The fact that we did not observe any lethality or lung accumulation is in good agreement with former reports that explained death of laboratory animals after embolism to be caused by entrapment of aggregates of polyplexes and blood components in the lung capillaries (*34*).

The disadvantage of imaging techniques not differentiating between free label, degraded, or intact labeled compound can only be overcome by verification using autoradiography or after specific siRNA isolation and purification of intact 21-mers and photometric quantification. This aspect also stresses the importance of efficient purification after the labeling process.

A shortcoming of the imaging compared to gamma scintillation of dissected organs is the fact that planar pictures do not allow for differentiation among organs in the same plane of projection, such as liver and kidneys or urine and

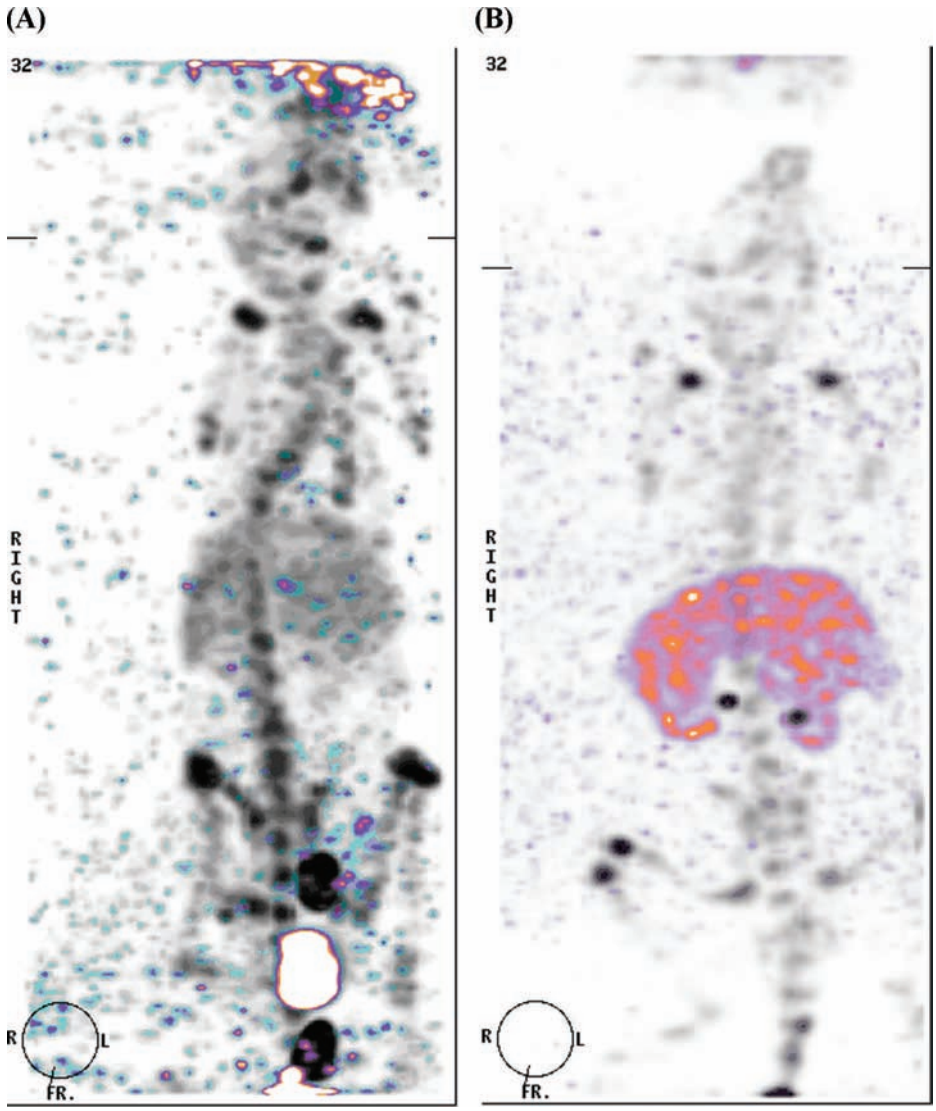

Figure 7. SPECT image of 4 week old male balb/c mouse injected with 35 μg siRNA, corresponding to 2.57 nmol and 0.255 MBq ^{111}In (purple, blue, and orange), and 8 MBq ^{99m}Tc-labeled phosphonate (grayscale) for anatomical landmarking. (A) free siRNA, (B) complexes at N/P 6 with 25 kDa bPEI.

bladder (Figure 8). Regions of interest always expressing the total scintillation counts of all organs in the plane of projection and organs, which do not show significant uptake, can hardly be analyzed. In our study, only the liver, kidneys, urine, and bladder showed strong signals and could easily be detected in planar images, but the significant difference

in uptake to the liver of free siRNA and PEI/siRNA polyplexes could only be shown after dissection of organs (Figure 8A).

CONCLUSION

In summary, we developed an optimized and simple method for coupling p-SCN-Bn-DTPA to siRNA and purification of those radiolabeled siRNA complexes with high yields of these expensive materials. Once the siRNA bears the radioactive label, it can be applied in noninvasive perfusion, kinetics, and biodistribution studies, which corroborate the results from end point scintillation counting methods but offer the advantage of live imaging and examination at various time points in the same animal, reducing the number of animals needed in comparison to conventional techniques. Dual isotope SPECT and gamma camera imaging are very useful methods to follow biodistribution of polyplexes especially with respect to the kinetics of distribution. For determination of exact scintillation counts in every single organ, the latter have to be dissected. However, imaging clearly is able to assess siRNA delivery, biodistribution, and even pharmacokinetics, if a ROI is placed in the blood pool, without sacrificing animals. This proof of principle allows us to investigate distribution and kinetics of a variety of our vectors by multiple methods, including double labeling of vector and load, in the future.

ACKNOWLEDGMENT

The authors are grateful to Ulla Cramer and Klaus Keim for excellent technical support, and to Helmut Höffken, MD, for expert medical advice. The financial support of Deutsche Forschungsgemeinschaft (DFG Forschergruppe 627) is gratefully acknowledged.

REVIEWS

Bioconjugate-Based Molecular Umbrellas

Vaclav Janout and Steven L. Regen*

Department of Chemistry, Lehigh University, Bethlehem, Pennsylvania 18015. Received July 14, 2008; Revised Manuscript Received September 23, 2008

Molecular umbrellas are "amphomorphic" compounds that can produce a hydrophobic or hydrophilic exterior when exposed to a hydrophobic or hydrophilic microenvironment, respectively. Such molecules are composed of two or more facial amphiphiles that are connected to a central scaffold. Molecular umbrellas that have been synthesized to date, using bile acids as umbrella "walls", polyamines such as spermidine and spermine as scaffold material, and L-lysine as "branches", have been found capable of transporting certain hydrophilic peptides, nucleotides, and oligonucleotides across liposomal membranes by passive diffusion. They have also have been shown to increase water solubility and hydrolytic stability of a hydrophobic drug, and to exhibit significant antiviral activity. The ability of a fluorescently labeled molecular umbrella to readily enter live HeLa cells suggests that such conjugates could find use as drug carriers.

INTRODUCTION

Membranes play a central role in the structure and function of cells by serving as barriers that permit the transport of only those ions and molecules that are necessary for maintaining the living state (*1*). Due to their strongly hydrophobic interior, delivering hydrophilic drugs across these naturally occurring lipid bilayers into the cytoplasm of cells has proven to be difficult (*2*−*20*). Finding ways to promote the transport of hydrophilic agents across lipid bilayers, in general, by passive diffusion represents a major challenge (Figure 1).

A common approach to this problem has been to synthesize drug analogues that are smaller in size and more lipophilic (i.e., lipid-soluble) based (*1*, *4*, *5*, *7*). Thus, according to the classic solution-diffusion model of bilayer transport, the permeability coefficient (*P*) of a permeant is directly proportional to its water-membrane partition coefficient (*K*) and its diffusion coefficient (*D*), but inversely proportional to the thickness (*x*) of the bilayer (*1*). Since $P = (K \times D)/x$, an increase in lipophilicity is expected to increase *P* by increasing *K*. Also, a decrease in the size of a permeant is expected to increase *P* by increasing *D*, due to a reduction in the resistance toward diffusion.

In this review, we describe a fundamentally different approach to this transport problem that is based on the concept of "molecular umbrellas". We also show how these unique amphiphilic molecules have potential as drug modifiers, and as drugs, themselves.

MOLECULAR UMBRELLA CONCEPT

To overcome the incompatibility that exists between a hydrophilic agent and the hydrophobic interior of a lipid bilayer, we conceived of a class of molecules that was intended to function like "molecular umbrellas" (*21*). Specifically, such molecules were expected to cover the attached agent and shield it from the hydrophobic environment as it crosses the membrane. Our approach to the synthesis of molecular umbrellas has been to couple two or more facial amphiphiles (molecules having a hydrophobic and a hydrophilic face) to a central scaffold. For

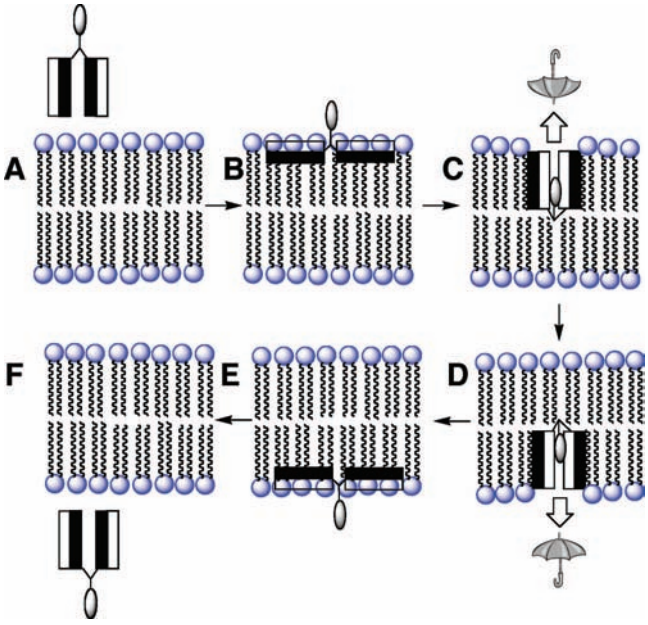

Figure 3. A hypothetical mechanism of bilayer transport for a diwalled molecular umbrella.

convenience, we refer to each such an amphiphilic unit as a "wall". When immersed in a hydrocarbon environment, a molecular umbrella is expected to adopt a shielded conformation in which the facially amphiphilic units mask not only their own hydrophilicity, but also that of the attached hydrophilic agent. When immersed in an aqueous environment, they are then expected to form an exposed conformation that allows each hydrophilic face and the attached agent to make direct contact with water. We have introduced the term "amphomorphic" to describe the ability of such molecules to produce a hydrophobic or hydrophilic exterior on demand.

A stylized illustration of a molecular umbrella in an exposed and in a shielded conformation is shown in Figure 2. Here, the shaded and unshaded rectangles represent the hydrophobic and hydrophilic faces of each amphiphilic unit, respectively, and the lightly shaded oval represents a covalently attached, hydrophilic agent.

How could a molecular umbrella cross a lipid bilayer? Our working hypothesis is illustrated in Figure 3. In brief, the molecular umbrella first approaches the lipid bilayer in a fully exposed conformation (structure A). Hydrophobic interactions with the membrane interior then lead to an adsorbed state in which the hydrophilic faces are in contact with the polar headgroup region and the hydrophobic faces are in intimate contact with the hydrocarbon region of the lipid bilayer (structure B). Subsequent absorption into the interior of the membrane, being driven by hydrophobic forces, then affords structure C. Translocation to the adjoining leaflet, 180° rotation, then produces D. Finally, reversal of the steps leading to B and A, affording E and F, respectively, then releases the conjugate from the other side of the membrane. In essence, the molecular umbrella functions by masking the hydrophilicity of the hydrophilic agent as it crosses the hydrocarbon interior of the membrane.

UMBRELLA FRAMEWORKS

Our work in this area has focused on the use of naturally occurring starting material for the synthesis of molecular umbrellas, based on the belief that they would be biodegradable and nontoxic. Thus, we have made extensive use of facially amphiphilic bile acids as umbrella "walls", polyamines such as spermidine and spermine as scaffold material, and L-lysine as "branches" (Figure 4). Representative di-walled and tetra-walled frameworks that we have employed are shown in Figure 5. Here, "X" represents the "handle" of the umbrella where a desired agent is attached. To date, the "R" groups that have been used include OCH_3, OH, $OCONH_2$, and OSO_3Na. For all of the studies that are described in the following sections, the molar ratio of molecular umbrella/lipid that has been used is typically $<1/100$. In all cases where molecular umbrella conjugates have been reacted with glutathione, the conversions have been found to be quantitative.

UMBRELLA TRANSPORT OF PEPTIDES, NUCLEOTIDES, AND OLIGONUCLEOTIDES ACROSS LIPOSOMAL MEMBRANES

Peptide Transport. Glutathione (Glu-Cys-Gly, GSH) is a simple tripeptide that exists in millimolar concentrations in the cytoplasm of mammalian cells. It is strongly hydrophilic and does not readily cross lipid bilayers by passive diffusion. Because of these properties, and also because its thiol moiety can be used for covalent attachment to a molecular umbrella, we have used GSH for feasibility studies.

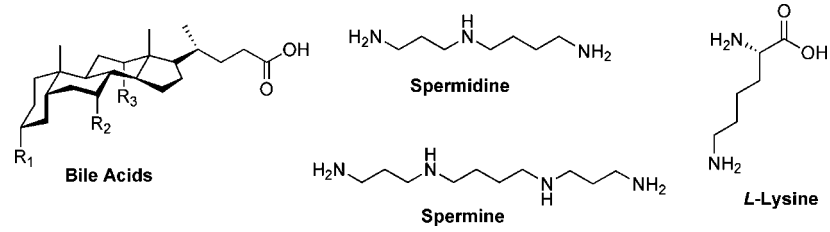

Figure 4. Representative building blocks for the synthesis of molecular umbrellas. Typical "R" groups that have been used to date include OCH_3, OH, $OCONH_2$, and OSO_3Na.

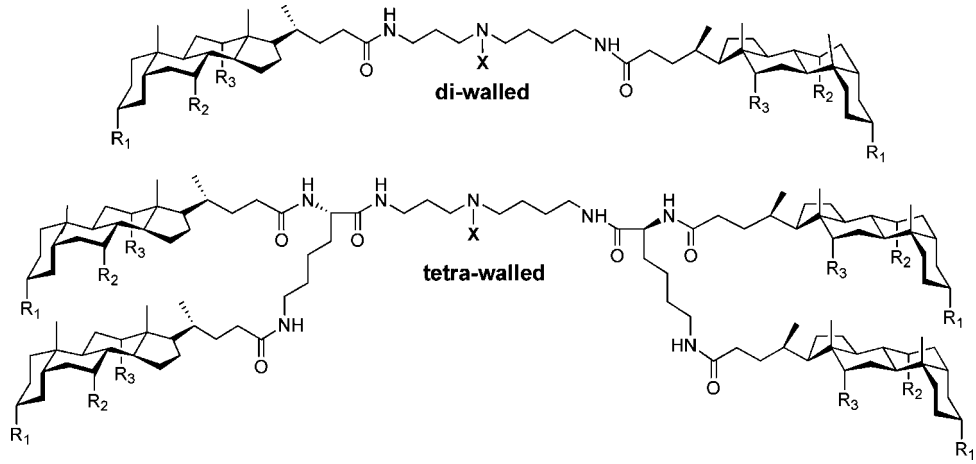

Figure 5. Common frameworks used in the synthesis of molecular umbrellas. Here, "X" represents the "handle" of the umbrella that can bind to a desired agent is attached. Typical "R" groups that have been used to date include OCH_3, OH, $OCONH_2$, and OSO_3Na.

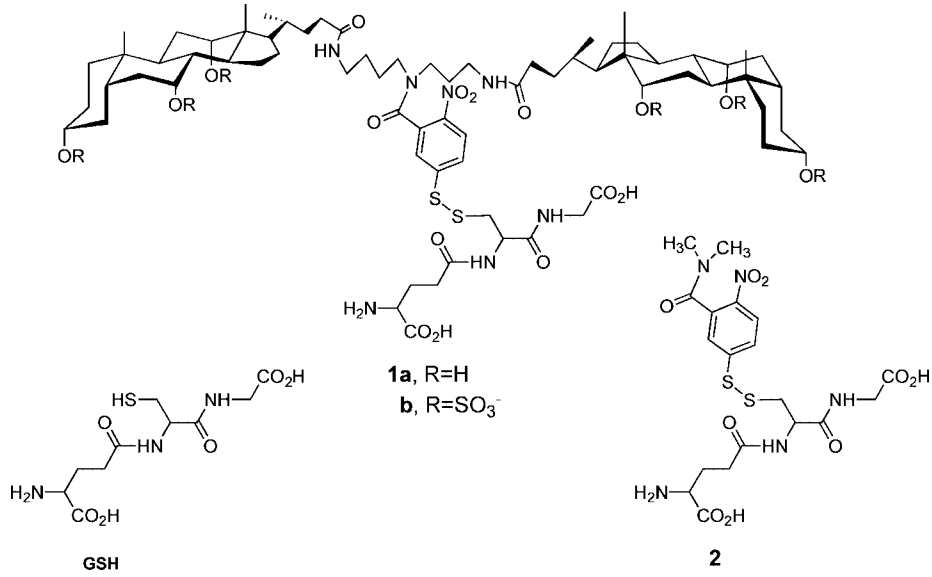

Figure 6. Structures of glutathione (**GSH**), di-walled molecular umbrellas that have been covalently attached to glutathione (**1a** and **1b**), and a control conjugate, **2**.

Two specific molecular umbrella−glutathione conjugates that were synthesized (i.e., **1a** and **1b**) are shown in Figure 6 (*22, 23*). In each case, a 5-thiol(2-nitrobenzoyl) group serves as the "handle". Also shown in Figure 6 is a non-umbrella analogue, **2**, which has been used as a control. The methods of synthesis for preparing **1a** and **1b** are outlined in Figures 7 and 8, respectively.

The ability of **1a** and **1b** to cross phospholipid bilayers by passive diffusion was demonstrated by adding a solution of each conjugate to liposomes made from 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC, 200 nm, extrusion), which contained GSH within their aqueous interior. Thus, the appearance of the 5-thiol(2-nitrobenzoyl) "handle" (i.e., the formation of USH via thiolate−disulfide interchange) provided evidence for liposomal entry (Figure 9). That this exchange reaction occurred within the interior of the liposomes was confirmed by quantifying the amount of cystine (GSSG) that had been produced and entrapped in the liposomes. In sharp contrast to **1a** and **1b**, addition of **2** to similar liposomal dispersions did not produce any detectable USH under similar experimental conditions.

A similar entry by **1a** has been found to occur with liposomes having thicker membranes made from 1,2-di(13-*cis*-docosenoyl)-*sn*-glycero-3-phosphocholine (C22:1) (*24*). However, in contrast to POPC membranes, where the formation of USH exhibited a first-order dependency on the molecular umbrella and the entrapped GSH, only a first-order dependency of the molecular umbrella was found when we used thicker membranes; that is, the rate of formation of USH was independent of the entrapped GSH. These results indicated that the rate-determining step for umbrella entry into POPC liposomes was the thiolate−disulfide interchange reaction, but it was membrane permeation for the (C22:1) liposomes. At the same time, they indicated the involvement of transport-active monomers for the latter system.

Related experiments that have been carried out using an analogue of **1a**, which contained only a single facial amphiphile (i.e., **6a**), showed that transport across the thicker liposomes was still possible (Figure 10) (*24*). In this case, however, the rate of appearance of USH showed a second-order dependency on the concentration of this "skimpy" molecular umbrella and independent of the concentration of entrapped GSH. Control experiments established that GSH did not leak out of the liposomes during the thiolate−disulfide exchange reaction and that GSSG was formed within the aqueous interior. Taken together, these results indicated that membrane permeation was rate-limiting for the skimpy molecular umbrella and that dimers are the transport-active species, most likely operating in a "face-to-face" orientation (Figure 10).

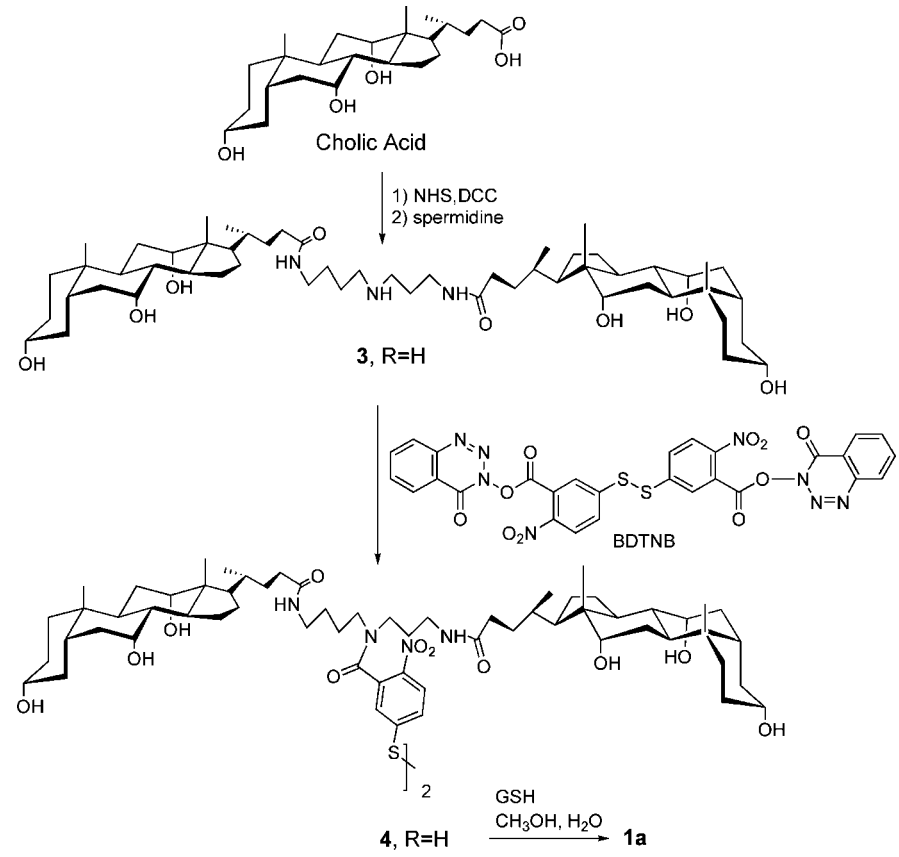

Figure 7. Synthetic scheme for the preparation of **1a**.

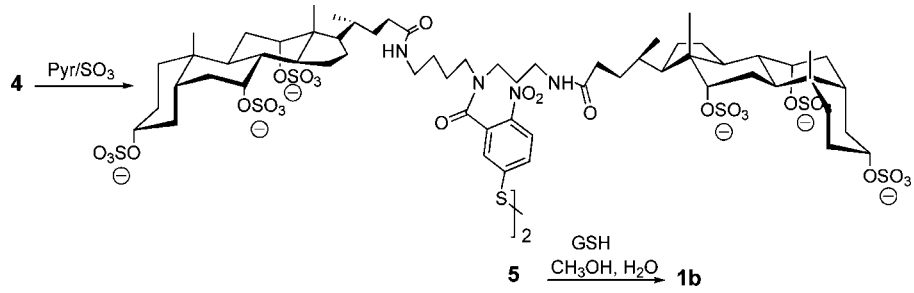

Figure 8. Synthetic scheme for the preparation of **1b**.

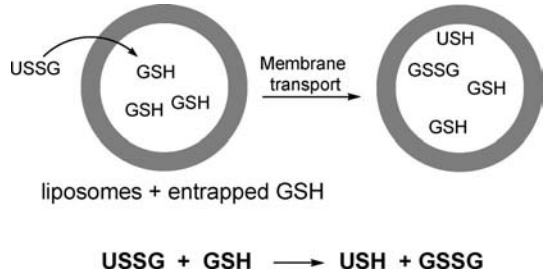

Figure 9. Stylized illlustration of a molecular umbrella-glutathione conjugate (USSG) crossing into a liposome loaded with glutathione (GSH), followed by thiolate−disulfide interchange to form oxidized glutathione (GSSG) and USH.

Similar experiments that were carried out with **6b**, which is devoid of facial hydrophilicity, showed no evidence of reaction (*24*). Control experiments that were carried out in which **6b** was first bound to both the inner and outer leaflets of the liposomes (double-sided addition), followed by treatment with external GSH, showed that 55% of the conjugate underwent rapid reaction. The fact that ca. one-half of **6b** was unreactive toward externally added GSH provided strong evidence that this conjugate crosses lipid bilayers very slowly, if at all. These results were significant because they ruled out the possibility that the ability of **6a** to cross lipid bilayers was simply due to an increase in the overall hydrophobicity of the peptide after attachment to the molecular umbrella. Thus, it provided strong evidence for an novel mechanism of transport, requiring the presence of facial amphiphilicity.

For all of the molecular umbrellas described thus far, a 2-nitrobenzoyl-5-dithio moiety was used as a detachable handle. Since the cytoplasm of cells is rich in glutathione, such a handle could be considered in the design of prodrugs. Two limitations of the use of this handle, however, are the following: (i) the presence of a cysteine residue is necessary for coupling the peptide to the umbrella, and (ii) the peptide is released in a non-native state; that is, it leaves as a glutathione conjugate (Figure 11).

As an alternative to the 2-nitrobenzoyl-5-dithio handle, we explored a prodrug strategy that was based on a thiol-induced reductive fragmentation of a *o*-dithiobenzyl carbamate (Figure 12) (*25*, *26*). For feasibility studies, a molecular umbrella

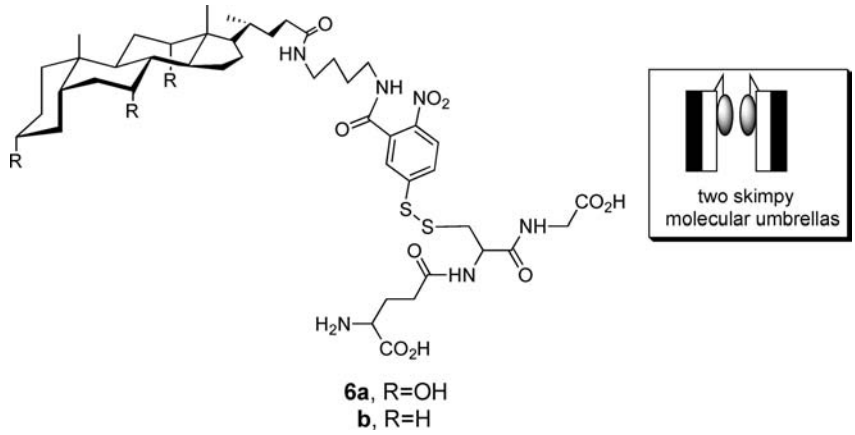

Figure 10. Structure of a single-walled ("skimpy") molecular umbrella bearing glutathione (**6a**), a non-umbrella analogue (**6b**), and a stylized illustration showing two skimpy molecuar umbrellas in a face-to-face orientation.

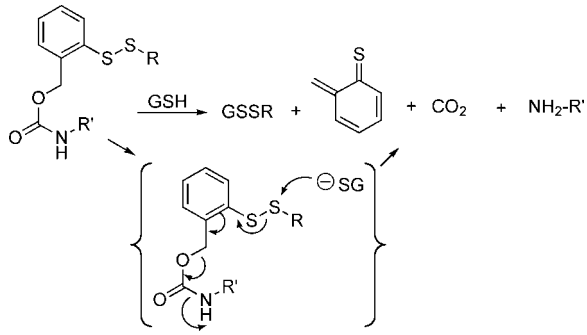

Figure 12. Thiol-induced reductive fragmentation of a *o*-dithiobenzyl carbamate liberating an organic amine.

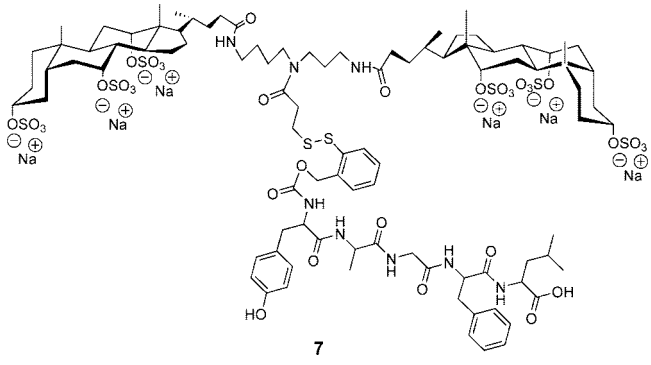

Figure 13. Structure of a di-walled molecular umbrella bearing DADLE with a fully detachable handle.

conjugate of an opioid peptide was synthesized; that is, **7**; DADLE, H-Tyr-D-Ala-Gly-Phe-D-Leu-OH (Figure 13) (*27*).

The fact that **7** was capable of releasing the native DADLE was confirmed by treating a solution of the conjugate with excess GSH. As expected, the solution became effervescent and the appearance of the *o*-thiobenzoquinone methide product was detected by UV (264 nm). At the end of the reaction, thin layer chromatography confirmed the complete disappearance of **7** and the appearance of the free form of DADLE, which could be isolated in 82% yield. Using liposomal targets loaded with excess GSH, it was then demonstrated that **7** could cross lipid bilayers and release DADLE to their aqueous compartment.

Nucleotide Transport. In an effort to expand the scope of molecular umbrellas as membrane transporters, we became keenly interested in antisense oligonucleotides. Currently, antisense oligonucleotides are believed to have considerable promise as therapeutic agents for the treatment of a wide range of diseases; e.g., non-small cell lung cancer, Crohn's disease, malignant melanoma, chronic lymphocytic leukemia, and multiple myeolma. To date, most, if not all, approaches that have been used to deliver antisense oligonucleotides into cells have taken advantage of endocytotic pathways. Release from resulting endosomal−lysosomal compartments by some unknown and inefficient mechanism then delivers a portion of the oligonucleotide to the cytoplasm where it can reach intended targets. In principle, the delivery of antisense oligonucleotides, directly into the cytoplasm via passive transport, could lead to greater overall efficacy.

Before exploring oligonucleotide transport, we sought to demonstrate the feasibility of transporting cleavable forms of adenosine 5′-monophosphate (AMP) and adenosine 5′-triphosphate (ATP) across phospholipid bilayers. Although several studies have been aimed at creating prodrugs of nucleoside 5′monophosphates, reports of membrane transporters of nucleoside 5′-triphosphates are rare.

Two conjugates that we prepared using 5-thiol(2-nitrobenzoyl) as an umbrella handle and thiol forms of AMP and ATP were **8a** and **8b** (Figure 14) (*28*). Synthetic methods that were used to prepare these conjugates were similar to those used for the molecular umbrella−glutathione conjugates.

In principle, attack by glutathione on the disulfide moiety could occur by two different pathways. In one pathway, attack on the sulfur atom of the 5-thiol(2-nitrobenzoyl) moiety by glutathione would result in the direct release of the free nucleotide (Figure 15). Subsequent attack by a second glutathione molecule would then liberate USH plus the oxidized form of glutathione (GSSG). An alternative pathway (not shown) is one in which glutathione initially attacks the sulfur atom of the nucleotide, thereby liberating USH, directly. Further attack by GSH on the glutathione−nucleotide conjugate would then afford the free nucleotides plus GSSG. By monitoring the reaction of **8a** and **8b** with GSH by UV, we were able to obtain strong evidence for a two-stage release that occurs by the first pathway, as shown in Figure 15. Subsequent transport experiments that were carried out with **8a** and **8b** and liposomes loaded with GSH resulted in the release of these nucleotides within the aqueous compartment of the liposomes.

10

Figure 16. Structure of a di-walled molecular umbrella bearing a guanidinium handle, and a probable structure for the guanidinium moiety binding to a phosphate group.

In related studies, molecular umbrella **10** was found capable of transporting ATP across liposomal membranes in a catalytic manner (Figure 16) (*29*). In this case, a guanidinium moiety was chosen as an umbrella handle because of its ability to bind phosphate groups via hydrogen bonding and electrostatic association. Thus, incubation of liposomes containing co-entrapped ATP and GSH with **10** resulted in the selective release of ATP. The fact that GSH was retained by these liposomes showed that the integrity of the membrane was retained during this transport process.

Oligonucleotide Transport. The ability of molecular umbrellas to transport nucleotides across lipid bilayers encouraged us to consider similar transport of an oligonucleotide. An obvious concern, however, was the size of an oligonucleotide relative to that of the molecular umbrella. Specifically, di- and tetra-walled molecular umbrellas would not be capable of shielding an entire oligonucleotide. In Figure 17, we show a mechanism by which umbrella transport of an oligonucleotide across a lipid bilayer might be possible. Here, the conjugate first penetrates the membrane to produce a shielded conformation (A). Subsequent opening of the umbrella across the bilayer, and simultaneous folding of the oligonucleotide into a partial "U", then leaves most of the membrane-internalized phosphate groups pointing toward the hydrophilic faces of the umbrella (B), allowing for translocation and umbrella closure to form C.

To test the feasibility of umbrella-mediated oligonucleotide transport, conjugates **11a**, **11b**, **12a**, and **12b** were synthesized using a 16-mer oligonucleotide (S-dT_{16}) as a prototype (Figure 18) (*30*, *31*). Similar to our studies with umbrella−glutathione conjugates, liposomes were loaded with GSH and the release of USH monitored by UV. In all cases, oligonucleotide delivery to the interior of the liposomes was observed. Control experiments confirmed the absence of release of entrapped GSH throughout the course of these influx experiments. Comparison

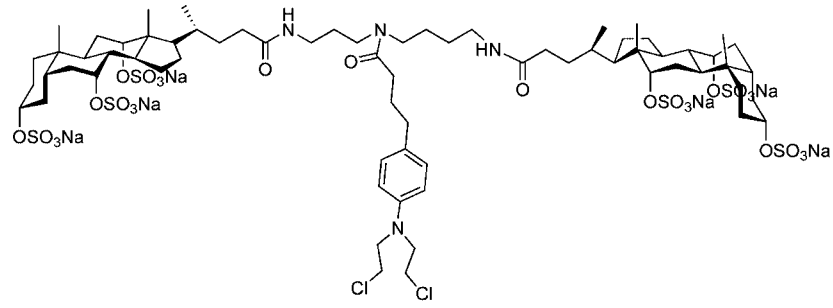
of these molecular umbrella−oligonucleotide conjugates revealed greater transport rates with the tetra-walled umbrellas as compared with their di-walled analogues. The deoxycholic acid−based, di-walled molecular umbrella conjugate (**11b**) was found to be ca. 50% more active than the cholic acid−based analogue (**11a**), but the reverse was found to be the case for the tetra-walled molecular umbrella conjugates.

MOLECULAR UMBRELLAS AS DRUG MODIFIERS

While molecular umbrellas were originally designed to promote drug transport across hydrophobic barriers, they can also improve the water solubility and hydrolytic stability of certain hydrophobic drugs. A molecular umbrella conjugate of the anticancer agent, chlorambucil (CMB), illustrates both of these features.

Chlorambucil is an alkylating agent that undergoes a rate-limiting intramolecular displacement to form an aziridinium ion (Figure 19). Subsequent reaction with nucleophiles (e.g., DNA) or water then produces alkylated and hydrolyzed products, respectively. Because charge is developed in the transition state leading to the aziridinium ion, its rate of formation should be faster in a polar environment. Conversely, slower rates are expected in hydrophobic environments. Thus, if CBM were



13

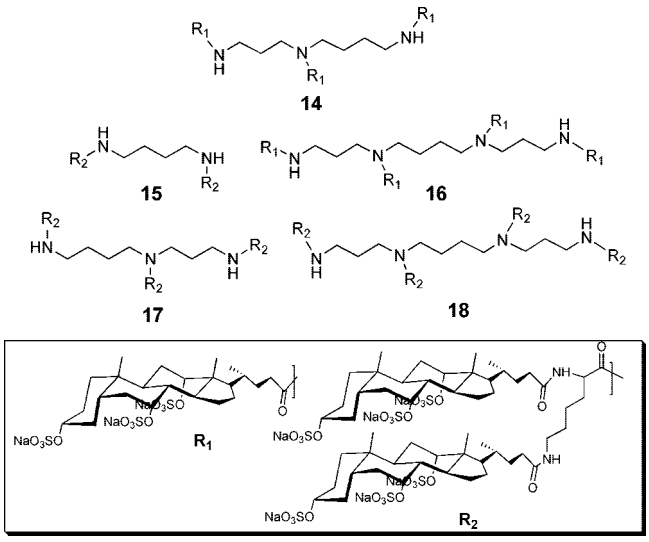

Figure 22. Structures of molecular umbrellas bearing three (**14**), four (**15**, **16**), six (**17**), and eight (**18**) persulfated choloyl groups.

attached to a molecular umbrella, and if the umbrella were to adopt a shielded conformation in water—where the CMB is covered by the hydrophobic faces of the umbrella—this could lead to enhanced stability. An illustration of such shielding is shown in Figure 20, where CMB is represented by a darkened oval, and the shaded and unshaded rectangles represent the hydrophobic and hydrophilic face of each amphiphilic unit, respectively. In addition, by exposing each hydrophilic face of the amphiphilic units to the aqueous phase, a significant increase in water solubility would also be expected.

Experimentally, chlorambucil was found to have a solubility in water that was less than 500 μg/mL. In sharp contrast, **13** showed a water solubility that was 1.20 g/mL (Figure 21) (*32*). Thus, attachment of CMB resulted in an increase in water solubility of more than 3 orders of magnitude! In addition, whereas CMB showed a half-life in phosphate buffer (pH 7.4) of 16 min, the molecular umbrella conjugate **13** had a half-life of ca. 40 min. Thus, covalent attachment of CMB to this di-walled molecular umbrella resulted in a dramatic increase in water solubility and a modest increase in hydrolytic stability. In preliminary studies, we compared the activity of chlorambucil with **13** in inhibiting the growth of human lymphoblastic leukemia (CCRF-CEM) cells, as well as human colon carcinoma (HCT-116) cells. For the leukemia cells, the activity of the molecular umbrella conjugate was substantially lower relative to CMB; that is, the concentrations needed to inhibit 50% growth were 173 and 2.15 μM for **13** and CMB, respectively. For the colon cancer cells, the difference was less pronounced. In this case, the concentrations needed to inhibit 50% growth were 53.7 and 11.4 μM, respectively.

MOLECULAR UMBRELLAS AS ANTIVIRAL AGENTS

Anionic polymers such as dextran sulfate and cellulose sulfate are known to inhibit cellular binding of HIV and HSV by competing for viral envelope glycoproteins. The possibility that persulfated molecular umbrellas might behave in a similar way, together with their potential for crossing hydrophobic barriers (e.g., the blood−brain barrier), suggests that such compounds could function as novel therapeutic agents as well as microbicides.

With this thought in mind, five persulfated molecular umbrellas (**14**, **15**, **16**, **17**, and **18**) were synthesized, and their anti-HIV activity measured using U87.CD4.CCR5 cells, replication defective HIV-1 virus, and a luciferase assay (Figure 22) (*33*). At a dosage of 1 μg/mL, **18** showed moderate activity; **15**, **16**, and **17** were less active, and **14** was inactive. At 100 μg/mL, all conjugates showed significant activity and inhibition was >95% with **18**. The anti-HSV activity of these conjugates was also compared by conducting plaque reduction assays with HSV-2(G) and human cervical epithelial cells (CaSki). At a concentration of 100 μg/mL, all of the conjugates completely inhibited HSV-2. At a concentration of 10 μg/mL, complete and very significant inhibition was found for **18** and **17**, respectively. In contrast, the activities of **14**, **15**, and **16** were only modest at this concentration.

Toxicity studies that have been carried out with **18** has shown that it is non-cytotoxic toward CaSki cells (*33, 34*). Thus, human cervical cells were exposed to serial dilutions of **18** (in the absence of virus) overnight (acute) or for 3 h each day for 4 consecutive days (chronic) to examine the effects on cell growth and viability using an MTS assay. No cytotoxicity was observed following chronic or acute exposure even at concentrations as high as 1000 μg/mL.

CELLULAR UPTAKE OF MOLECULAR UMBRELLAS

An important question that bears directly on the potential of molecular umbrellas as drug carriers is whether they are capable of crossing the plasma membrane of living cells. To address this question, we synthesized a fluorescently labeled molecular umbrella analogue of **18** (i.e., **19**) and investigated its interaction with live HeLa cells (Figure 23) (*35*).

In these experiments, confocal microscopy was used to section optically through the cellular volume to establish that the fluorescent label was dispersed within the cell and not bound to its outer surface. Cells were also labeled with Syto-59 to mark their nucleus and their cytoplasm. After a 10 min incubation period with 4 μM of **19**, this molecular umbrella could be readily detected inside the cells. Thus, **19** was found to be diffuse in the cytoplasm and punctate in the nucleus. The former is generally considered to be an indication of cellular entry via passive diffusion. In addition, the molecular umbrella within the nucleus was bound in spots that colocalize with nucleoli. In preliminary studies, treatment of HeLa cells with NaN_3 and 2-deoxyglucose (to deplete ATP production) only modestly inhibited the cellular uptake of **19**. This observation lends further support for passive diffusion playing a significant role in the cellular entry of this molecular umbrella. The fact that **19** is concentrated at the nucleus of these cells is intriguing, but the basis for this localization is not presently understood. It does raise the possibility, however, that molecular umbrellas of this type could be used for the nuclear targeting of drugs.

OTHER RIGID FACIAL AMPHIPHILES USED IN PROMOTING MEMBRANE TRANSPORT

Although this review has focused, sharply, on molecular umbrellas as membrane transporters, it should be noted other types of rigid facial amphiphiles have been devised that promote the transport of ions and small molecules. In a recent report, for example, it was shown that cholic acid could be transformed into cyclotrimeric and cyclotetrameric "toroidal amphiphiles" with inward-directed ammonium substitutents, and that the cyclotrimeric form was capable of transporting chloride anions across vesicle bilayers (*36*). In an earlier study, four Amphotericin B molecules were coupled to a calix[4]arene and found to promote the transport of K^+ across liposomal membranes (*37*). Finally, a variety of novel scaffolds (e.g., *p*-octaphenyl unit) have been used to construct a rich assortment of membrane-spanning pores having facial amphiphilicity (*38, 39*).

PROSPECTUS

The feasibility of synthesizing molecular umbrellas from bioconjugates, which are capable of transporting hydrophilic agents across lipid bilayers, has been established. Thus, it has been shown that molecular umbrellas derived from certain bile acids, polyamines, and amino acids (e.g., cholic acid, spermidine, and lysine) can transport hydrophilic peptides, nucleotides, and oligonucleotides across liposomal membranes. It has also been demonstrated that molecular umbrellas can enhance the water solubility and hydrolytic stability of a hydrophobic drug. Certain persulfated molecular umbrellas also show promise as antiviral agents for use as microbicides and as therapeutic agents.

To gain a deeper understanding of how molecular umbrellas cross lipid bilayers, additional studies are needed that provide fundamental insight into the interactions of these novel amphomorphic molecules with lipid bilayers. Further studies that show how transport rates and membrane binding are influenced by systematic changes in the structure and composition of (i) the molecular umbrella, (ii) the attached agent, and (iii) the lipid membrane should also prove valuable in clarifying probable mechanism(s) of membrane transport. The fact that **19** readily enters live HeLa cells, and that passive transport appears to play a significant role in this entry process, implies that fundamental insight gained from model studies should aid the rational design of molecular umbrellas as drug carriers.

Received October 10, 2008; Revised Manuscript Received December 12, 2008

Cationic nucleoside lipids based on a 3-nitropyrrole universal base were prepared from D-ribose using a straightforward chemical synthesis. Several studies including DLS, TEM, and ethidium bromide (EthBr) assay demonstrated that these amphiphilic molecules form supramolecular organizations of nanometer size in aqueous solutions and are able to bind nucleic acids. siRNA knockdown experiments were performed with these nucleolipids, and we observed protein knockdown activity similar to the siPORT *NeoFX* positive control. No significant cytotoxicity was found.

Nucleolipids—amphiphiles possessing both nucleic acid recognition and lipophilic alkyl chain components—are emerging as tools both for constructing supramolecular assemblies and for nucleic acid delivery (*1*−*13*). The area of nucleic acid delivery is particularly interesting, since gene delivery provides a mechanism to introduce new genes in cells for basic in vitro research experiments as well as to replace or supplement a defective or missing gene in a patient as part of a clinical therapy (*14*−*20*). Consequently, synthetic lipids, as well as other DNA carriers such as calcium phosphate particles, dendrimers, or surface-mediated assemblies (*21*), are highly sought after. Minimally toxic to cells, these lipids also afford high DNA or RNA transfection activity. Recently, we have reported the synthesis and transfection activity of a series of cationic and glycosylated nucleolipids which are both nontoxic and active DNA transfection agents (*11, 13*). In an ongoing effort to expand the scope and properties of this family of lipids, we are synthesizing analogues where the thymine nucleobase is replaced by the synthetic 3-nitropyrrole universal base and evaluating the potential of these nucleolipids for siRNA delivery. Herein, we report the synthesis, physicochemical properties, and siRNA transfection efficiency of a universal-base nucleolipid, the tosylate salt of 1-(2′,3′-dioleyl-5′-trimethylammonium-(α,*β*)-D-ribofuranosyl)-3-nitropyrrole.

The target nucleolipid, **7**, which is shown in Figure 1, possesses three key components: a quaternized amine at the 5′ position, two oleic acid chains linked at the 2′ and 3′ positions, and a 3-nitropyrrole attached at the anomeric position. The cationic charge is responsible for electrostatic binding to the nucleic acids and the oleyl chains contribute to stabilization of the resulting nucleic acid−nucleolipid assembly through hydrophobic chain−chain interactions. The 3-nitropyrrole, which is perhaps the best characterized universal base analogue, was introduced to circumvent the restrictive hydrogen bonding pattern controlling typical purine−pyrimidine hydrogen motifs by incorporating the weakly hydrogen bonding nitro substituent (*22*−*24*). It is known that the 3-nitropyrrole group can form complementary base pairs with all four natural bases without significantly destabilizing neighboring base pair interactions. As a result, it has been used for diverse applications including hybridization of DNA duplexes, oligonucleotide probes and primers, peptide nucleic acids, and sequencing by MALDI mass spectrometry (*25*).

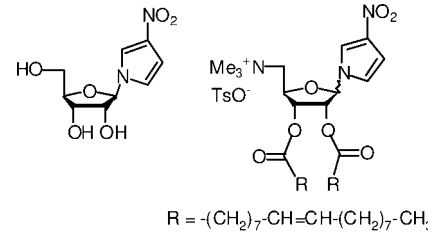

Figure 1. Chemical structure of the universal nucleobase and nucleolipid (tosylate salt of 1′-(2′,3′-dioleyl-5′-trimethylammonium-α,*β*-D-ribofuranosyl)-3-nitropyrrole).

The α and *β* anomers of 1′-(2′,3′-dioleyl-5′-trimethylammonium-D-ribofuranosyl)-3-nitropyrrole, **7a** and **7b**, respectively, were synthesized from D-ribose as shown in Scheme 1. Briefly stated, 5-*O*-*tert*-butyldimethylsilyl-2,3-*O*-isopropylidene-D-ribose, **2**, was prepared in two steps from D-ribose following a published procedure (*26*). Next, the stereoselective chlorination of the protected sugar, **2**, with CCl_4 and hexamethylphosphorus triamide (HMPT) (*27*) was followed by coupling with the anion

of 3-nitropyrrole formed from the commercially available 1-(triisopropylsilyl)pyrrole (*28*). Deprotection of the resulting derivative **3** afforded the mixture of (α) **4a** (53%) and (β) **4b** (18%) anomers with the (α) form as the major isolated polar isomer. The relative stereochemistry of these compounds was assigned by NOESY and COSY experiments (data not shown). Compounds **4a** and **4b** were then separately tosylated with TsCl/TEA to give **5a** and **5b** (structures not shown), deprotected with TFA/H_2O, and coupled with oleic acid using DCC/DMAP to afford the nucleolipids **6a** and **6b**. Finally, **6a** and **6b** were reacted with trimethylamine for two days in a sealed tube to afford the nucleolipids **7a** and **7b**. The complete characterization data, including ^{1}H NMR, ^{13}C NMR, and elemental analysis, can be found in the Supporting Information. A differential scanning calorimetry (DSC) trace of the hydrated nucleolipid **7a** or **7b** shows no phase-transition temperature from −40 to 80 °C.

Next, to determine whether the universal base nucleolipids **7a** and **7b** bind nucleic acids, we performed a standard ethidium bromide fluorescence displacement assay with calf thymus DNA as a model system (*29*). DNA binding was observed for **7a** and **7b** as the fluorescence intensity decreased rapidly (see Supporting Information for curves and details). The nucleolipids formed a 6:1 and 2:1 complex for **7a** and **7b** with a binding constant of $\sim 10^{-7}$ M,$^{-1}$ similar in magnitude to DOTAP (*30*). This universal base, 3-nitropyrrole, was expected to bind DNA or RNA based on the published data. Previous thermal denaturation studies with 1-(2′-deoxy-β-D-ribofuranosyl)-3-nitropyrrole showed that this base pairs with the four naturally occurring bases with little discrimination (*31, 32*). The nitro group of 3-nitropyrrole polarizes the π-aromatic system enhancing the π-stacking interactions, and yet as a poor hydrogen bond participator, it does not distinguish among the bases. Considering the minor differences between DNA and siRNA in terms of base composition and ability to hydrogen bond and from π-stacking arrangements, the 3-nitropyrrole base is likely to interact with the bases of siRNA as well as DNA.

As **7a** and **7b** are amphiphilic, the dispersion of these nucleolipids in water by sonication leads to vesicles in the presence and absence of DNA. Again, DNA was used as a model system. In the absence of DNA, vesicle size, as measured by DLS, was 84.7 and 458.4 nm for compounds **7a** and **7b**, respectively. For **7b**, we observed a broad

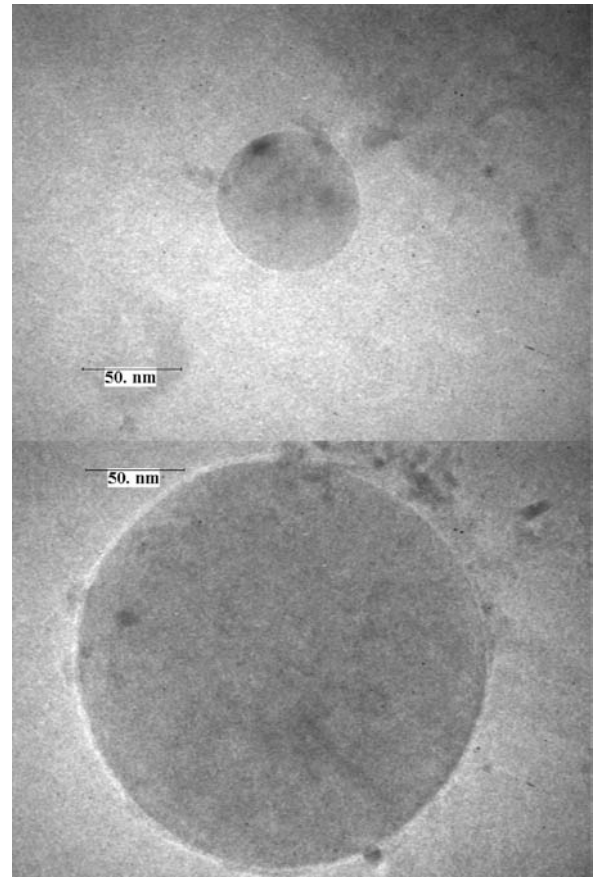

Figure 2. TEM image of single isolated vesicles obtained with **7a** (top) and **7b** (bottom).

distribution of vesicle sizes. In the presence of DNA, and at different compound/DNA charge ratios, lipoplexes were formed of 132.4 nm (**7a**/DNA 2:1), 179.3 nm (**7a**/DNA 5:1), and 469.8 nm (ratio **7b**/DNA 2:1), 516.1 nm (ratio **7b**/DNA 5:1). Transmission electron microscopy (TEM) experiments were performed on vesicle samples **7a** and **7b** using a Philips CM 10 (negative staining with ammonium molybdate 1% water, Cu/Pd carbon-coated grids). Both anomers (α and β) of the nucleolipids formed small vesicles. Representative images of vesicles formed by **7a** and **7b** with diameters of roughly 80 and 220 nm, respectively, are shown in Figure 2. Similar experiments performed with vesicles formed from nucleolipid−DNA solutions were inconclusive as to the location of the DNA within the structure.

The transfection of siRNA with **7a** and **7b** was next performed to evaluate the reduction in protein synthesis. Experiments were performed using glyceraldehyde-3-phosphate dehydrogenase (GAPDH) siRNA (Ambion). Complete details can be found in the Supporting Information, and the transfection experiments were performed in the presence of serum. Three distinct cell lines were used, including human liver (HepG2), mouse fibroblast (NIH 3T3), and Chinese hamster ovarian (CHO) cells. siRNA transfection results were accessed after 48 h as a function of both anomer and cation/anion (N/P) mole ratio. In each experiment, controls using GAPDH siRNA and negative control siRNA were used at 30 mM. siPORT *NeoFX* was used as the positive control. As shown in Figure 3, siRNA knockdown was observed for both nucleolipids in the three different cell lines, with values comparable, not significantly significant, to the positive control *NeoFX*. The transfection activity of **7a** was significant vs siRNA ($p < 0.05$) in NIH 3T3 and CHO cells with N/P ratios of 1, 5, 15, and 20 and 1 and 5, respectively. The transfection activity of **7b** was significant vs siRNA ($p <$

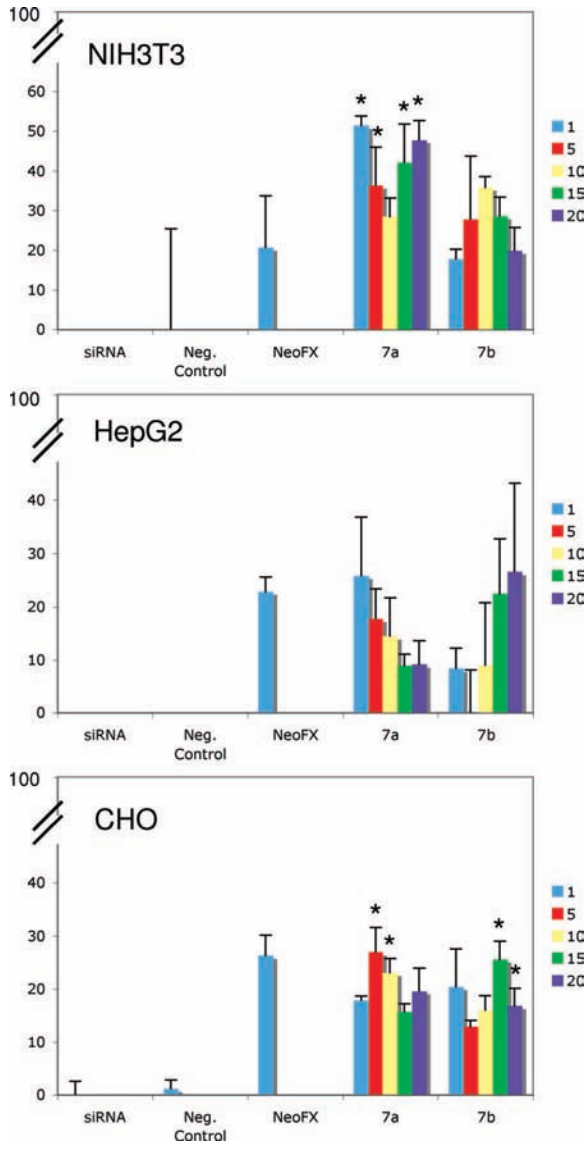

Figure 3. siRNA transfection results after 48 h in HepG2, NIH 3T3, and CHO cells as a function of nucleolipid (**7a** and **7b**) and N/P mole ratio. $N = 3$; $*p < 0.05$ vs siRNA control.

0.05) in CHO cells with N/P ratios of 15 and 20, respectively. The configuration of the anomeric position does not have a significant role in the transfection. In addition, none of the nucleolipids showed a significant cytotoxicity at this concentration using an MTS assay with CHO cells, as the viability was similar to the negative control (see SI).

In summary, we have synthesized and characterized a new universal base nucleolipid for siRNA delivery. The nucleolipids possess a cationic charge, a 3-nitropyrrole base, and two oleyl chains, and these lipids form vesicles in the presence and absence of nucleic acids. siRNA delivery and resulting protein knockdown were observed in three separate cell lines: hamster ovarian, mouse fibroblast, and human liver cells. This is the first report of such activity with a nucleolipid. Work is in progress to synthesize additional universal nucleolipids (including the nitroindole and nitroimidazole analogues for siRNA delivery), as well as to develop a structure−activity relationship. Nucleolipids are one of the newest types of synthetic lipid vectors being explored and, like others in the lipid family, offer the potential advantages of ease of synthesis, carriers of large and small nucleic acid payloads, and minimal toxicity (*11*, *14*−*17*, *33*−*42*). The synthesis and evaluation of new lipids that possess unique head groups, backbones, or hydrophobic chains for nucleic acid binding and/or self-assembly will facilitate the identification of optimal carriers for nucleic acids in vitro and in vivo; efforts in this area should be encouraged and promoted.

ACKNOWLEDGMENT

Experimental Section

Material. Unless noted otherwise, all starting materiel were purchased from Sigma-Aldrich, Acros or Alfa Aesar and used as received. Some solvents were distilled under argon over appropriate drying agent: tetrahydrofuran and diethylether over sodium/benzophenone, dichloromethane over $CaCl_2$. Unless otherwise stated, the other solvents were used as commercially available. All compounds were characterized by ^{1}H NMR, ^{13}C NMR and mass spectroscopy. 250 MHz and 62.5 MHz 13C Nuclear Magnetic Resonance (NMR) spectra were recorded either on a Bruker AC 250. The spectra were taken at 20 °C and referenced against residual proton-solvent signals (^{1}H: $CDCl_3$: 7.26 ppm, and ^{13}C: 77 ppm). The ^{1}H NMR coupling constants (J) are reported in Hz. ESI-MS and elemental analyses were performed at the spectropole of the *Faculte des Sciences et Techniques de Saint Jerôme*, Marseille, France. Electrospray Ionisation Mass Spectra (ESI-MS) were recorded with an API///Plus sciex triple quadripole spectrophotometer in the positive mode. Elemental analyses were recorded with a Thermo Finnigan EA 1112 elemental analysis apparatus driven by the Eager 300 software. TEM

microscopy experiments were performed on a Philipps CM10 (negative staining with ammonium molybdate 1% in water, Cu/Pd carbon coated grids). Analytical thin layer chromatography (tlc) was performed on pre-coated glass plates with kieselgel 60F254 neutral with aluminium support plate (0.25mm layer thickness), SDS. The developed plates were air-dried and exposed to UV light and (or) sprayed with a solution of cerium sulphate (1%) and molybdic acid (1.5%) in 10% aqueous sulphuric acid and heated at 150°C. Preparative thin layer chromatography was performed on glass plates with Merck silica gel 60F-254 as the adsorbent (layer thickness 2mm or 1mm). Column chromatography was performed on Merck silica gel 60 (0.063-0.200mm). Melting point (mp) were measured with an Electrothermal 9100.

2,3-O-isopropylidene-D-ribose, 1 To a stirring solution of D-ribose (10g, 0.06 mol) in dry acetone (200 mL) was added a catalytic amount of H_2SO_4 at room temperature. Then $CuSO_4$ was added. After being stirred for 40h at 37 °C, the solution was filtered and washed with small quantities of acetone. The filtrate was neutralized with $Ca(OH)_2$ and stirred for 15 minutes. The mixture was filtered and the filtrate was evaporated under reduced pressure (T<40 °C) to give **1** (11.76g, 94%) as a yellow syrup.^{1}H NMR ($CDCl_3$): δ 5.39 (1H,m); 4.82 (1H, d, J=6.00Hz); 4.57 (1H, d, J=6.00Hz); 4.40 (1H,m); 4.22 (2H, m); 2.17 (2H,s); 1.48 (3H,s); 1.31 (3H,s). ^{13}C NMR (CDCl3): δ 102.31, 95.56, 82.36, 73.12, 72.01, 63.45, 29.03. FAB, MS m/z : 191(M+1)

5-O-*tert*-butyldimethylsilyl-2,3-O-isopropylidene-D-ribofuranose, 2

2,3-O-isopropylidene-D-ribose (6.27 g; 0.03 mol) was dissolved in dry dichloromethane (10ml) containing triethylamine (5.11 mL; 36.72 mmol) and 4-(dimethylamino)pyridine (DMAP) (450 mg; 3.69 mmol). The solution was cooled to 0°C and *tert*-butyldimethylsilylchloride (TBDMSCl) (5.40 g; 35.76 mmol) dissolved in dry dichloromethane (20 mL) was added

dropwise. The mixture was stirred at ambient temperature overnight. The mixture was then concentrated under reduced pressure, and the residue was triturated with THF. The organic phase was filtered andevaporated before the crude product was purified by flash column chromatography (90/10: pentane/Et_2O) to give **2** (3.46 g, 35%) as a yellow oil.

^{1}H NMR ($CDCl_3$): δ 5.33 (1H,d , J=11.37Hz); 4.70 (1H, d, J=6.00Hz); 4.57 (1H, d, J=6.00Hz); 4.36 (1H,m); 3.76 (2H, d, J=2.50Hz); 1.58 (1H,sl); 1.48 (3H,s); 1.32 (3H,s); 0.92(9H,s); 0.09 (3H,s) 0.06 (3H,s)^{13}C NMR ($CDCl_3$): δ 111.03, 102.44, 100.01, 88.64, 85.98, 80.73, 65.79, 27.36, 26.01, 24.93, 19.11, -6.01, -6.03. FAB, MS m/z : 305 (M+1)

1'-(5'-O-*tert* -butyldimethylsilyl-2',3'-O-isopropylidene-D-ribofuranosyl)-3-nitropyrrole, 3

First step : Carbon tetrachloride (433 µL, 4.49 mmol) was added to a stirring solution of **2** (1.22 g; 2.87 mmol) in anhydrous THF (10 mL). The solution was cooled to -70°C and hexamethylphosphorous triamide (700 µL, 3.82 mmol) was added dropwise for 5 minutes, and the mixture was allowed to stir at the same temperature for 5 minutes. The resulting compound was allowed to warm to room temperature and further stirred for 2 hours. The solvent was evaporated and the residue dissolved in diethyl ether. The resulting insoluble materiel was removed by decantation and the organic layer was evaporated to give the crude compound **3** as an orange oil.

Second step: To a cooled solution (0 °C) of 3-nitropyrrole (629 mg, 5.61 mmol) dissolved in anhydrous acetonitrile (9 mL) was added NaH (60%, 223 mg, 5.6 1mmol); the solution was stirred at room temperature for 30 minutes. To the resulting bright yellow solution, the chloro sugar obtained from the first step was dissolved in anhydrous acetonitrile and transferred via canula. The reaction mixture was then warmed to room temperature and stirred for 40 hours. The mixture was poured into H_2O (50 mL) and extracted with CH_2Cl_2 (3*50 mL). The organic layers

were combined and successively washed with saturated aqueous NH_4Cl and saturated aqueous NaCl. The organic layer was dried over $MgSO_4$ and concentrated in vacuo. The residue was purified by flash column chromatography (70/30: cyclohexane/EtOAc) to give **3** (579mg, 40%) as a yellow oil. ^{1}H NMR ($CDCl_3$): δ 7.71 (1H, m); 6.72 (2H, m); 5.93 (1H, d, J=4.26Hz); 4.87 (1H, dd, J=0.63Hz, J=6.00Hz); 4.42 (1H, dd, J=2.21Hz, J=2.00Hz);); 3.89 (1H, dd, J=2.21Hz, J=11.21Hz); 3.76 (1H, dd, J=2.00Hz, J=11.05Hz); 1.42 (3H,s); 1.32 (3H,s); 0.93 (9H, s); 0.10 (6H,s). ^{13}C NMR ($CDCl_3$): δ 137.40, 119.24, 118.76, 114.14, 105.88, 95.22, 86.21, 86.14, 81.04, 63.44, 27.20, 25.77, 25.19, 18.26, -5.61, -5.71. FAB, MS m/z : 398 (M+1)

1'-(2',3'-O-isopropylidene-D-ribofuranosyl)-3-nitropyrrole, 4a and 4b

To a solution of **3** (596 mg, 1.49 mmol) in dry THF (5 mL) was added TBAF (1M in THF) (3 mL, 2.98 mmol) at room temperature and the mixture was stirred for 30 minutes. The solution was evaporated under reduced pressure, diluted with CH_2Cl_2 and washed with brine. The organic layer was dried on $MgSO_4$ and evaporated under reduced pressure. The crude product was purified by flash column chromatography (cyclohexane/EtOAc : 70/30 to 50/50) to give the anomer α **4a** (227 mg, 53%) as a white solid and the anomer β **4b** (75 mg, 18%) as a yellow oil.

1'-(2',3'-O-isopropylidene-α-D-ribofuranosyl)-3-nitropyrrole, 4a

mp=107°C. ^{1}H NMR ($CDCl_3$): δ 7.73 (1H, t, J=2.05Hz); 6.73 (2H, d, J=2.05Hz); 5.94 (1H, d, J=4.42Hz); 4.92 (1H, dd, J=1.11Hz, J=6.00Hz); 4.85 (1H, dd, J=4.42Hz, J=6.16Hz);); 4.46 (1H, t, J=2.84Hz); 3.94 (1H, td, J=2.84Hz, J=11.34Hz); 3.81 (1H, td, J=3.16Hz, J=11.21Hz); 1.40 (3H,s); 1.32 (3H,s)

^{13}C NMR ($CDCl_3$): δ 140.23, 121.12, 120.20, 113.80, 104.99, 90.73, 83.30, 81.94, 80.60, 64.30, 22.51, 24.20. FAB-MS m/z : 285 (M+1), 302 (M+16), 307 (M+23), 323 (M+29)

1'-(2',3'-O-isopropylidene-β-D-ribofuranosyl)-3-nitropyrrole, 4b

^{1}H NMR ($CDCl_3$): δ 7.80 (1H, dd, J=2.21Hz, J=4.11Hz); 6.80 (1H, dd, J=2.37Hz, J=3.32Hz); 6.74 (1H, dd, J=1.90Hz, J=3.32Hz); 5.62 (1H, d, J=3.32Hz); 4.89 (1H, dd, J=2.84Hz, J=6.32Hz);); 4.76 (1H, dd, J=3.32Hz, J=6.48Hz); 4.35 (1H, q, J=3.16Hz); 3.96 (1H, dd, J=3.47Hz, J=11.85Hz); 1.59 (3H,s); 1.36 (3H,s). ^{13}C NMR ($CDCl_3$): δ 141.68, 119.69, 119.33, 114.73, 106.22, 94.79, 85.90, 82.27, 80.74, 62.56, 27.19, 25.22. 1'-(2',3'-O-isopropylidene-5-O-tosyl-α-D-ribofuranosyl)-3-nitropyrrole, 5a

Compound **4a** (100mg, 0.35mmol) was dissolved in dry dichloromethane (4 mL) and the solution was cooled to 0°C. NEt_3 (196 μL, 1.41 mmol) was added, as well as tosyl chloride (200 mg, 1.05 mmol), in small portions. The solution was then allowed to warm to room temperature and stirred overnight. Dichloromethane was added and the solution was successively washed with brine and aqueous $NaHCO_3$ 5% w/v. The organic layer was dried on $MgSO_4$, filtered and concentrated under reduced pressure. The residue was purified by preparative layer chromatography (cyclohexane/EtOAc:60/40) to give **5a** (145 mg, 94%) as a white solid. mp = 111-113°C. ^{1} H NMR ($CDCl_3$): δ 7.78 (2H, d, J=8.22Hz); 7.64 (1H,m); 7.37 (2H, d, J=8.10Hz); 6.69 (2H, m); xx (1H, d, J=3.63Hz); 4.82 (2H,m); 4.51 (1H, t, J=2.35Hz); 4.19 (2H, d, J=2.60Hz); 2.44 (3H,s); 1.37 (3H,s); 1.27 (3H,s). ^{13}C NMR ($CDCl_3$): δ 145.82, 137.01, 131.83, 130.26, 127.86, 120.93, 120.11, 114.29, 105.55, 90.72, 81.55, 80.53, 80.20, 71.06, 25.47, 24.17, 21.69. FAB-MS m/z : 439 (M+1)

1'-(2',3'-O-isopropylidene-5-O-tosyl-β-D-ribofuranosyl)-3-nitropyrrole, 5b

Compound **5b** was obtained in 56% yield from compound **4b** by the procedure described above. Purification by preparative layer chromatography (cyclohexane/ EtOAc : 70/30) gave a yellow oil. ^{1}H NMR ($CDCl_3$): δ 7.75 (2H, d, J=8.37Hz); 7.60 (1H,t, J=2.05Hz); 7.34 (2H, d, J=8.50Hz); 6.72(2H, t, J=1.9Hz); 5.56(1H, d, J=3.32Hz); 4.84 (1H,dd, J=3.32Hz, J=6.30Hz); 4.45 (1H, q, J=2.84Hz); 4.28 (1H, dd, J=3.00Hz, J=11.06Hz); 4.13 (1H, dd, J=3.00Hz, J=11.06Hz); 2.44 (3H,s); 1.57 (3H,s); 1.35 (3H,s). ^{13}C NMR ($CDCl_3$): δ 145.69, 137.81, 131.10, 127.88, 119.31, 118.93, 115.08, 106.35, 94.71, 85.13, 82.78, 80.55, 68.56, 27.06, 25.13, 26.67. FAB-MS m/z : 439 (M+1)

1'-(2',3'-dioleyl-5-O-tosyl-α-D-ribofuranosyl)-3-nitropyrrole, 6a

At 0°C, compound **5a** (145 mg, 0.33 mmol) was dissolved in 3.5 mL of an aqueous trifluoroacetic acid / H_2O (6/1) solution and stirred for 1 hour at 0°C. The solvents were co-evaporated with methanol under reduced pressure, and the residue was dried in vacuo. The crude product was dissolved in dry CH_2Cl_2 (7 mL) and the solution was cooled to 0°C. Dicyclohexylcarbodiimide (271 mg, 1.32 mmol), (dimethylamino)pyridine (161 mg, 1.32 mmol) and oleic acid (372 mg, 1.32 mmol) were added, and the mixture was stirred at room temperature overnight. DCU was then filtered, and the filtrate was successively washed with aqueous 2N HCl and aqueous saturated $NaHCO_3$ solutions. The organic layer was dried on $MgSO_4$, filtered and evaporated under reduced pressure. The crude product purified by flash column chromatography (cyclohexane/EtOAc : 95/5) gave **6a** (236mg, 77%) as a yellow oil. ^{1}H NMR ($CDCl_3$): δ 7.80 (1H, d, J=8.22Hz); 7.66 (1H,t, J=2.05Hz); 7.37 (2H, d, J=7.90Hz); 6.67 (1H, dd, J=1.90Hz, J=3.32Hz); 6.59(1H, dd, J=2.53Hz, J=3.32Hz); 5.88 (1H, d, J=5.53Hz); 5.44(2H,m); 5.33 (4H,m); 4.54 (1H, q, J=2.84Hz); 4.31 (1H, dd, J=3.00Hz, J=11.37 Hz), 4.18 (1H, dd, J=2.68Hz , J= 11.21Hz); 2.45 (3H,s);); 2.33 (2H, t, J=3.00Hz); 2.31 (4H, t, J=3.00Hz); 1.99 (8H,m); 1.25

(44H,m); 0.86 (6H, t, J=6.32Hz). ^{13}C NMR ($CDCl_3$): δ 172.15, 145.59, 137.44, 132.21, 130.10, 130.05, 130.82, 130.01, 129.63, 129.60, 120.82, 105.20, 88.21, 75.86, 73.26, 70.90, 70.54, 60.34, 31.88, 29.74, 29.67, 29.51, 29.10, 29.02, 27.20, 27.14, 22.67, 14.19. FAB-MS m/z : 927 (M+1), 944 (M+18), 949 (M+23), 965 (M+29)

1'-(2',3'-dioleyl-5-O-tosyl-β-D-ribofuranosyl)-3-nitropyrrole, 6b

Compound **6b** was obtained from **5b** with the same procedure described above. Purification by flash column chromatography (cyclohexane/EtOAc : 95/5) gave **6b** as a yellow oil in 87% yield. ^{1}H NMR ($CDCl_3$): δ 7.84 (2H, d, J=8.21Hz); 7.62 (1H,t, J=2.05Hz); 7.37 (2H, d, J=8.53Hz); 6.77 (2H,m); 5.61 (1H, d, J=5.05Hz); 5.34 (6H,m); 5.34 (6H,m); 5.23 (1H,m); 4.34 (2H, m); 2.45 (3H,s), 2.33 (4H,m); 2.00 (8H,m); 1.67 (4H, m); 1.26 (44H, m); 0.87 (6H,m). ^{13}C NMR ($CDCl_3$): δ 172.05, 143.64, 136.44, 131.94, 131.72, 130.75, 129.43, 129.22, 123.58, 122.75, 121.02, 105.85, 82.12, 76.93, 70.92, 69.54, 60.29, 33.94, 33.30, 32.52, 30.32, 30.10, 29.76, 25.42, 23.14, 14.12. FAB-MS m/z : 927 (M+1), 944 (M+18), 949 (M+23), 965 (M+29)

Tosylate salt of 1'-(2',3'-dioleyl-5'-trimethylammonium-α-D-ribofuranosyl)-3-nitropyrrole, 7a

Anhydrous triethylamine (1 mL) was transferred to a pressure tube cooled at -50°C via canula. Next, anhydrous acetonitrile (2 mL) and a solution of **6a** (118 mg, 0.13 mmol) in dry THF (2 mL) were added. The tube was sealed and heated in an oil bath at 50°C during 48h then cooled to -20°C and opened. The solvents were evaporated under reduced pressure to give **7a** (125mg, quantitative) as a brown oil. ^{1}H NMR ($CDCl_3$): δ 7.68 (2H, d, J=8.06Hz); 7.64 (1H,m); 7.12 (2H, d, J=8.06Hz); 6.62 (2H,m); 6.26 (1H, d, J=4.42Hz); 5.67 (1H, t, J=4.74Hz); 5.33 (44H,m); 4.79 (1H, m); 4.46 (1H, m); 4.20 (1H,m), 3.37 (9H,s); 2.32 (3H,s); 1.99 (8H, m); 1.60 (4H, m); 1.26 (44H,m); 0.87 (6H, t, J=6.48Hz). ^{13}C NMR ($CDCl_3$): δ 173.21, 142.25, 140.51, 131.94, 137.52,

Tosylate salt of 1'-(2',3'-dioleyl-5'-trimethylammonium-β-D-ribofuranosyl)-3-nitropyrrole, 7b

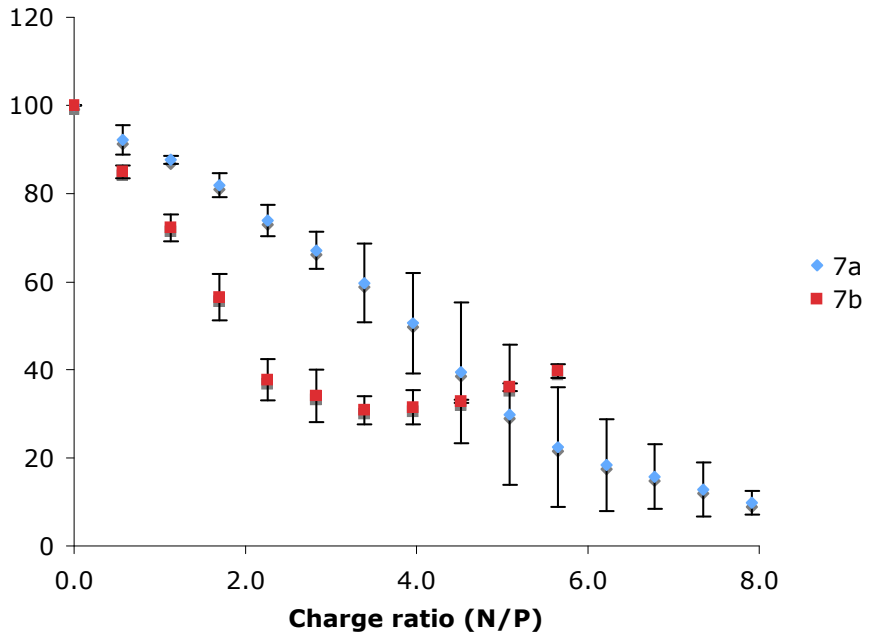
This compound was prepared from **6b** with the same procedure described above to yield **7b** as a brown oil with quantitative yield. ^{1}H NMR ($CDCl_3$): δ 7.80 (1H,m); 7.70 (2H, d, J=8.06Hz); 7.12 (2H, d, J=8.22Hz); 7.03 (1H,m); 6.60 (1H, m); 5.68 (1H, d, J=6.00Hz); 5.32 (4H,m); 4.66 (1H, dd, J=4.11Hz, J=10.27Hz); 4.42 (1H, t, J=11.05Hz); 4.06 (1H,m), 3.33 (9H,s); 2.84 (2H, d, J=7.42Hz); 2.32 (3H, m); 1.98 (8H, m); 1.56 (4H,m); 1.25 (44H,m); 0.86 (6H, t, J=6.00Hz). ^{13}C NMR ($CDCl_3$): δ 173.21, 142.25, 140.51, 131.94, 137.52, 132.53, 130.73, 125.25, 123.14, 121.56, 106.83, 82.48, 78.41, 73.46, 67.88, 64.48, 51.91, 33.92, 33.32, 32.56, 30.42, 30.32, 30.12, 29.78, 26.48, 24.12, 21.19, 14.12. FAB-MS m/z : 814 (M cation). Anal Calc C,66.97 ; H, 9.30 ; N ,4.26 ; Found calc C,66.30 ; H, 9.46; N, 4.00.

Vesicles Preparation

1 mg/mL of compounds **7a** or **7b** was dissolved in chloroform or dichloromethane. The solution was evaporated and dried on vacuum for 2 hrs. 1mL of DI water was added, and the solution was hydrated overnight at 4°C. The resulting solution was sonicated for 20 min. prior to any measurements.

DNA – Cationic Amphiphile Displacement Assay

A competitive displacement fluorescence assay using ethidium bromide (EthBr) was used for the DNA binding studies. This assay involves the addition of aliquots of the compound to a 3 mL solution of EthBr (1.3 μM) and calf thymus DNA (3 μM) in buffer (100 mM NaCl, 100 mM Tris, pH 7.4) with the decrease of fluorescence (λ_{exc}=546 nm, λ_{em}=600 nm; 1 cm path length glass cuvette, slit width 3 nm) recorded after 5 minutes of equilibrium time following each addition. Calf thymus DNA was used instead of siRNA due to the high costs associated with required amount of siRNA for this experiment.



Dynamic light scattering

The diameter of the liposomes and lipid/DNA assemblies was measured at a 90° angle using 90 Plus particle size analyzer (Brookhaven Instruments Model 90 Plus). All solutions used in the study were filtered through a 0.02 μm membrane prior to use. The vesicles of lipid and

DNA were prepared as described above in the vesicle preparation section. The diameter reported corresponds to the average of three experiments in aqueous solution. The 90 Plus particle sizing software was used for data acquisition and analysis. Calf thymus DNA was used instead of siRNA due to the high costs associated with required amount of siRNA for this experiment

siRNA transfection

Trypsine adherent cells were diluted in normal growth medium to 1 x 10^5 cells per mL. The transfection reagent was diluted in serum free medium and incubated at room temperature for 10 min before use. Next siRNA (GAPDH siRNA or negative control siRNA, Ambion) was diluted in serum free medium. The siRNA and the tranfection reagent were mixed, incubated for 10 min at room temperature and dispensed into a culture plate with cells and serum containing medium. Depending on the experimental design, the ration of lipid, siRNA, and incubation time was varied. The cell suspension was then overlayed onto the transfection mixture. The sample was then incubated at 37 °C and 5% CO_2. Gene knockdown activity was assessed after 48 h.

The gene knockdown assay performed was KDalert™ GAPDH Assay (Ambion) following the manufacturer protocol. Briefly, 48 hr after siRNA transfection, the serum-containing culture medium was aspirated from the transfected cells. Next, 200 μL KDalert Lysis Buffer was added to each sample well. The cells were incubated at 4 °C for 20 min to lyse them. The cell lysate was pipeted up and down 4–5 times to homogenize the lysate. 10 μL of each lysate or GAPDH enzyme dilution (including the GAPDH Working Stock) was transfered to the wells of a clean 96 well plate. Finally, 90 μL of KDalert Master Mix was added to each sample using a multi-channel pipettor. The increase in fluorescence of the samples was measured at

room temp.

Cytotoxicity

Cytotoxicity was assessed using both a formazan-based proliferation assay (CellTiter 96 AQueous One Solution Cell Proliferation Assay kit, Promega) and a total protein-based assay (Pierce). Chinese hamster ovarian cells (CHO, ATCC, Manassas, VA) were cultured in complete F12K media (ATCC) containing 10% fetal calf serum (Sigma) and 1% penicillin and streptomycin (500 IU/mL and 5000 μg/ml, respectively, Mediatech, Herndon, VA) at 37 ^{o}C in 5% CO_2 with humidity. When the CHO cells reached about 90% confluency, the cells were split into 24-well plates with a 1:4 ratio using a standard trypsin-based technique. For these experiments, CHO cells were seeded onto a 24-well plate with an appropriate density of 1 x 10^6 cells per well. After 48h the MTS substrate was added to each well and the plate was incubated for 4 h at 37 ^{o}C in a humidified, 5% CO_2 incubator. The amount of soluble formazan produced by cellular reduction of the substrates MTS was recorded at 490 nm using a multi-well plate reader. For the total protein-based proliferation assay, cells were lysed at the same time when transfection efficiency was assayed. A 10 μL of lysates were transferred to a separate multi-well plate. Total protein contents were assessed using the Coomassie Blue protein kit (Pierce, Rockford, IL) following the manufacturer protocol. Negative and positive controls were non-treated cells and commercial lipids treated cells, respectively. The proliferation results were expressed as percentages of non-treated cells.

Protein C-Terminal Modification through Thioacid/Azide Amidation

Xiaohong Zhang, Fupeng Li, Xiao-Wei Lu, and Chuan-Fa Liu*

Division of Chemical Biology and Biotechnology, School of Biological Sciences, Nanyang Technological University, 60 Nanyang Drive, Singapore 637551. Received November 10, 2008; Revised Manuscript Received January 6, 2009

The preparation of protein bioconjugates has been largely dependent on the development of selective chemistries that are orthogonal to the diverse functionalities present in a protein. Here, we report a new method for C-terminus-directed modification of recombinant proteins. The method is based on the thioacid/azide amidation reaction. Essentially, hydrothiolytic cleavage of the thioester intermediate in protein splicing yields a recombinant protein with a unique thioacid group at the C-terminus, which is then chemoselectively amidated with an electron-poor organic azide carrying a biofunctional tag. The small ubiquitin protein was used as a model system to demonstrate the utility of this new bioconjugation method. C-terminal PEGylation or biotinylation of ubiquitin was readily achieved through amidation of ubiquitin thioacid with a sulfonazide-functionalized PEG or biotin derivative. Our data validate that thioacid/azide amidation is a mechanistically novel and practically useful method for site-selective protein modification.

Site-selective protein modification techniques are important tools for protein structure−function study and drug discovery (*1*−*3*). For instance, such techniques can be used to label proteins with a special biophysical probe for structural and biochemical studies (*4*) or with a biocompatible polymer for the development of protein-based therapeutic agents (*5*). They are also useful as immobilizing techniques to tether proteins to solid supports for the fabrication of protein chips (*6*).

Traditional methods for protein modification rely mainly on classic acylation or alkylation chemistries involving the side chain functional groups of Lys, Asp/Glu, and Cys residues (*1*). However, the use of these methods is often limited by the fact that proteins typically carry multiple copies of the targeted residue, making it difficult to control the degree and site of modification. This commonly results in product mixtures with considerable structural heterogeneity. Nontraditional methods have also been developed recently that target the electron-rich side chain aromatic rings of Trp or Tyr residues (*7*). Because these aromatic amino acids are found less frequently on the protein surface, it may be possible to achieve single-site modification if one such residue is solvent-exposed (*8*). However, these new techniques also have limitations because of the low likelihood of having a single solvent-exposed aromatic residue in most proteins. Molecular biology methods that make use of the cell's protein synthesis machinery offer powerful alternatives to chemically based techniques for protein modification. Recent excitement is seen with the methodology developed by Schultz's group and others (*9*). These methods rely on the use of an amber stop codon and a corresponding suppressor tRNA to incorporate into a protein a desired unnatural amino acid which may already carry the biophysical probe of interest in place or contain a unique chemical/photochemical reactivity for later use (*9*).

Compared to modifying the internal residues, protein C-terminal modification offers some distinct advantages. The C-terminal tail of a protein is usually flexible and solvent-exposed, which makes it easily accessible by the tagging reagent. Modifying the C-terminus is also less likely to adversely affect a protein's biological activity as the active spot of a protein is often distant from the terminal end. Moreover, since there is only one C-terminus in a protein, in principle it should be possible to distinguish it from the internal residues for single-site modification. There exist several enzymatic and biosynthetic methods to introduce a C-terminal modification onto a protein. For instance, C-terminal specific labeling has been carried out by catalytic transacylation reactions using carboxypeptidase Y (*10, 11*). Puromycin-based techniques have also been developed that allow the incorporation of various C-terminal tags (*12, 13*). Exploitation of intein-mediated protein splicing (*14*) has generated very useful approaches to protein C-terminal modification (*15*−*17*), which are mostly based on the thioester-mediated ligation chemistry (*18*).

In our efforts to develop new chemoselective methods for protein synthesis and modification, we have paid much attention to a unique functional group, the thioacid. For instance, we have made use of the soft and powerful nucleophilicity of thioacids in the development of a highly effective thioacid capture peptide ligation method (*19*). The synthetic utility of the thioacid group is also experiencing renewed interest in the thioacid/azide amidation reaction (*20*) for the preparation of complex amides (*21*). Thorough mechanistic studies by Williams et al. suggest that this reaction proceeds through the formation of a thiatriazoline intermediate which subsequently decomposes to yield the amide product (*21, 22*). The reaction is especially fast with electron-deficient azides such as sulfonazides, owing to a highly efficient prior capture mechanism (*22*). Although previous studies have only demonstrated thioacid/azide coupling with small thioacids such as thiobenzoic acid and N-protected amino thioacids (*21, 23*−*25*), its unique reaction features imply that it should have the required chemical orthogonality to work in a chemoselective manner with large and complex thioacid compounds such as peptides and proteins. In our recent work, clean and near-quantitative formation of the amidation products was shown between unprotected thioacid peptides and tosyl azide in highly dilute solutions (*26*). In the present study, we extend the application of thioacid/azide amidation to C-terminal modification of recombinant proteins (Figure 1).

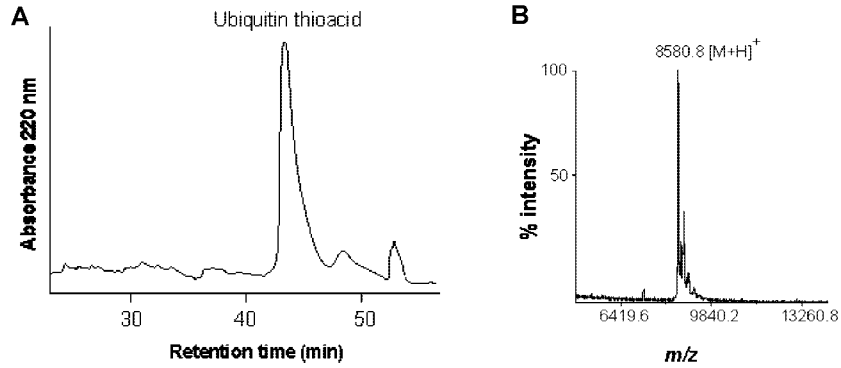

Figure 2. Purification and characterization of ubiquitin thioacid. (A) HPLC profile of C8 semiprep purification of the ubiquitin thioacid eluate from chitin beads after hydrothiolysis. The ubiquitin thioacid was eluted by a linear gradient of buffer B in buffer A from 0% to 60% in 60 min. (B) MALDI-TOF MS of purified ubiquitin thioacid. *m*/*z* $[M + H]^+$ found: 8580.8, MW calcd: 8580.9 (average)/8576.3 (isotopic). The higher MW species in the spectrum were due to adducts of the sinapic acid matrix.

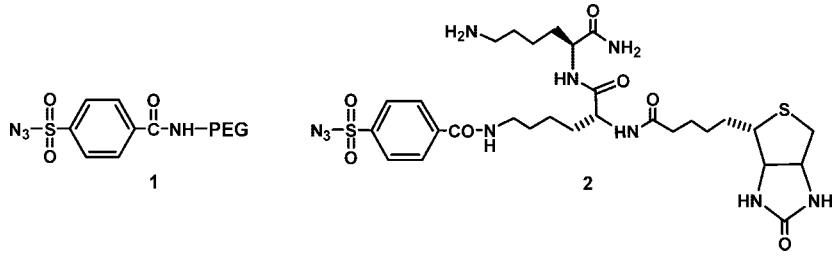

Figure 3. Sulfonazides useful for C-terminal PEGylation (**1**) or biotinylation (**2**) of recombinant thioacid proteins.

We chose the small ubiquitin protein as a model system to test this new protein C-terminal modification method. A crucial step is to obtain the thioacid protein in a sufficient amount. We referred to the method previously proposed by Begley et al. for the production of recombinant proteins with a C-terminal thioacid (*27*), which is based on the mechanism of capturing and cleaving the thioester intermediate of protein splicing with hydrosulfide ions. Although the potential utility of this method was discussed by the authors (*27*), no application examples have been reported since its publication. Therefore, in our work, we cloned the ubiquitin gene into the pTYB1 vector (New England Biolabs), which contains the VMA intein from *S. cerevisiae*. The ubiquitin-intein-CBD fusion protein was overexpressed in *E. coli* and affinity-purified by binding to chitin beads. The cleavage of ubiquitin from the fusion protein was performed by incubation at 37 °C of the bound fusion protein in the hydrothiolytic cleavage buffer (0.1 M Na_2S, 0.25 M HEPES, 0.5 M NaCl, 1 mM EDTA, pH 8.0) overnight. These conditions were similar to those used for hydrothiolysis of synthetic peptide thioesters (*26, 28*). In the previous work by Begley et al. of preparing a 66-residue protein thioacid ThiS-COSH, the cleavage was done with 30 mM ammonium sulfide at 4 °C (*27*). The cleaved ubiquitin thioacid was eluted from chitin beads and purified by RP-HPLC (Figure 2A). High-resolution MS analysis confirmed the presence of the thioacid group (Figure 2B). The yield of the ubiquitin thioacid was typically 4−5 mg per liter of cell culture.

Two benzenesulfonazide-functionalized tagging agents **1** and **2** (Figure 3) were prepared for introducing a PEG or biotin moiety, respectively, onto the C-terminus of the recombinant ubiquitin (see Supporting Information for the synthesis of these two compounds).

The PEGylation reagent or PEG-sulfonazide **1** (Figure 3) contains a PEG component with an average MW of ca. 5000 Da. It was synthesized to test thioacid amidation with large sulfonyl azides. The amidation reaction of the ubiquitin thioacid with the PEGylation reagent **1** was performed in an aqueous solution: 0.3 mM ubiquitin thioacid, 2 mM PEG sulfonazide **1** in 6 M Gdn-HCl containing 3 mM 2,6-lutidine. The reaction took about 10 h to complete at r.t. and was accompanied by some hydrolysis (Figure 4). 2,6-Lutidine is the recommended base catalyst from previous studies with small thioacids (*21, 22*). We observed that, if the reaction was conducted in a HEPES-buffered solution (pH 7 or 8) instead, more hydrolysis occurred and the hydrolyzed ubiquitin-COOH appeared immediately after the ubiquitin thioacid was mixed with the azide (data not shown). Therefore, the use of 2,6-lutidine helped minimize the hydrolysis of the ubiquitin thioacid. On the basis of HPLC analysis, the yield of the PEGylation reaction was about 65%. Despite an excess amount of PEGylation agent used, only the mono-PEGylation product (Figure 4A, peak 3 from trace b) was formed in the reaction, which was also confirmed by MS analysis (Figure 4B), indicating that tagging PEG to the protein was highly chemoselective and site-specific. The relatively lengthy reaction time and some degree of hydrolysis may be a result of the large molecular weight and steric hindrance of the PEGylation reagent **1** in which the relatively hydrophobic sulfonylazide may be made less accessible by a surrounding long and hydrophilic PEG chain. The small Gly residue at the C-terminus of ubiquitin may also have contributed to the hydrolysis of the thioacid.

The biotinylation reagent or biotinyl-Lys(N_3SO_2Bz)-Lys-NH_2 **2** (Figure 3) was prepared by solid-phase synthesis. In this compound, the biotin and sulfonyl azide moieties are linked to

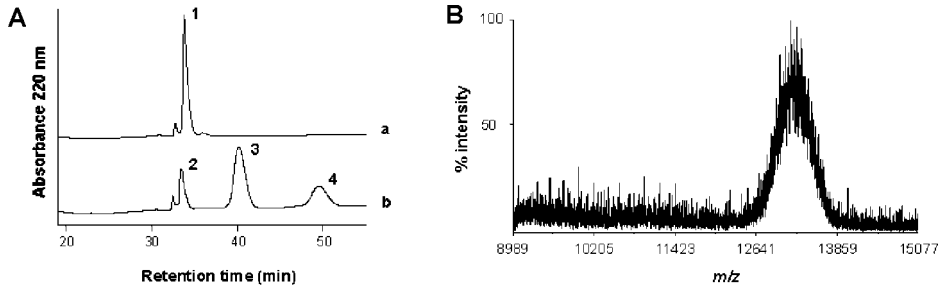

Figure 4. PEGylation of ubiquitin thioacid. (A) Analytical RP-HPLC (Vadyc C4 column) monitoring of the amidation of ubiquitin thioacid with the PEGylation reagent. HPLC gradient: 0−60% of buffer B in buffer A for 60 min. (B) MALDI-TOF of the PEGylated product, average *m*/*z* $[M + H]^+$ found ∼13 350, average MW calcd ∼13 500).

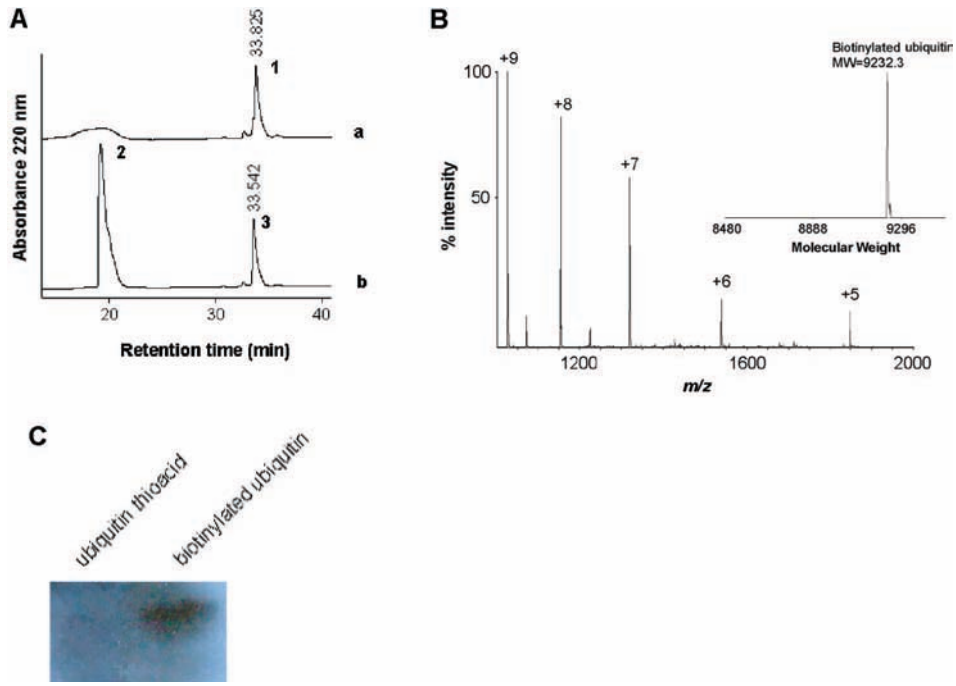

Figure 5. Reaction of ubiquitin-COSH with biotin-Lys(N_3SO_2Bz)-Lys-NH_2. (A) Analytical RP-HPLC monitoring of amidation of ubiquitin thioacid with biotinyl-Lys(N_3SO_2Bz)-Lys-NH_2 **2** on a Vadyc C4 column. HPLC gradient: 0−40% of buffer B in buffer A for 40 min. Trace a, peak 1: ubiquitin thioacid. Trace b, the reaction mixture at 4 h. Peak 2, biotinyl-Lys(N_3SO_2Bz)-Lys-NH_2 **2**; peak 3, the biotinylation product containing some minor amount of hydrolyzed ubiquitin in the front. (B) ESI-MS spectrum profile of the last three quarters of peak 3 which contained the biotinylated ubiquitin. MW found 9232.3, MW calcd 9228.5. (C) Western blot analysis of the biotinylated ubiquitin using an avidin-HRP conjugate (Bio-Rad Laboratories, USA).

the respective α- and ε-amino groups of a Lys residue. A second Lys residue is included to increase its water solubility. In the thioacid/azide coupling reaction, 0.3 mM ubiquitin thioacid in 6 M Gdn-HCl containing 3 mM 2,6-lutidine was reacted with ca. 10 equiv of biotinyl-Lys(N_3SO_2Bz)-Lys-NH_2 **2** at r.t. for about 4 h to give the biotinylated ubiquitin product (Figure 5). The ligation product eluted a little earlier than the thioacid and almost coeluted with (only slightly behind) the hydrolysis product. In fact, according to MS analysis, the first quarter of fractions of the product peak (peak 3 of trace b, Figure 5A) contained about 30% ubiquitin-COOH (see Supporting Information), and the last three quarters of the peak contained only the ligation product (Figure 5B). No remaining ubiquitin-COSH was detected. The desired amidation product had the expected molecular weight as analyzed by ESI-MS (Figure 5B). As it is much smaller than the PEGylation reagent, the biotinylation reagent reacted faster with the ubiquitin thioacid. Again, except for a minor amount of hydrolysis, no other side reactions were detected. The amidation yield was estimated to be at least 85% by HPLC analysis. The biotinylated ubiquitin was able to bind to avidin as shown by Western blot analysis (Figure 5**C**).

PEG has been used as a biofunctional group for protein modification since 1977 (*29*). Covalent attachment of PEG to therapeutic proteins has some desirable functions such as increasing their in vivo stability and solubility (*5*). It is also very common to covalently tag biotin to a biomolecule such as a protein for use in biochemical assays (http://en.wikipedia.org/wiki/Biotinylation). Traditional PEGylation and biotinylation methods are nonspecific and introduce PEG or biotin nonspecifically onto nucleophilic amino acids in proteins, giving a mixture of product isomers (*30*). Thioacid/azide amidation represents a novel method for bioconjugation with a distinctly different mechanism from the intermolecular acylation reactions of conventional amidation. The amidation of thioacids with electron-poor azides involves a prior capture step followed by efficient intramolecular addition to give a thiatriazoline intermediate which spontaneously collapses to form the amide bond (*22*). These unique features determine the highly chemoselective nature of this reaction, as demonstrated herein by the C-terminus-specific PEGylation or biotinylation of ubiquitin. The reaction can accommodate a broad range of solvents from organic to aqueous (*21*−*26*). Notably, in this study the amidation

of ubiquitin with both the PEG and biotin azide compounds was conducted in a denaturing solution containing 6 M GdnHCl, which will be useful for minimally soluble biomolecules such as membrane proteins. In conclusion, we have demonstrated herein that thioacid/azide amidation is a simple and efficient method for specific C-terminal modification of recombinant proteins. Amidation of ubiquitin thioacid with excess PEG and biotin sulfonazides shows that this reaction is highly specific despite the presence of a large number of functional groups in the protein and remains effective even with large azide compounds. Since protein and peptide thioacids can be easily prepared through hydrothiolysis of the corresponding thioesters (*26*−*28*), the thioacid/azide amidation reaction has the potential to become one of the most useful methods for C-terminal modification of bioactive peptides and proteins.

SUPPORTING INFORMATION

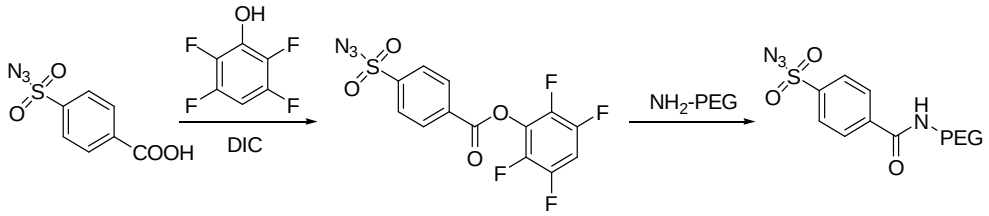
INSTRUMENTATION

Analytical and semi-prep HPLC were performed on a Shimadzu UFLC system equipped with a PDA-100 photodiode array detector. A C4 reverse phase column (Vydac, 250 x 4.6 mm) was used for analytical analysis. A C8 reverse phase column (Vydac, 250 x 10 mm) was used for semi-prep purification. The analytes were eluted using a gradient mixture of two solvents: buffer A was distilled deionized water containing 0.05% TFA and buffer B was 90% ACN in distilled deionized water containing 0.05% TFA. The flow rate was 1 mL/min for analytical analysis, 2.5 mL/min for semi-prep purification.

ESI mass spectra were recorded using a bench-top ion trap mass spectrometer (FINNIGAN LCQ Deca XP MAX). High resolution MALDI mass spectra were recorded using a 4800 MALDI TOF/TOF Analyzer (Applied Biosystems) and sinapic acid as the matrix. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker DRX-400 (400 MHz) NMR spectrophotometer. ^{13}C spectra were recorded in broad band decoupled mode. ^{1}H and ^{13}C chemical shifts are quoted in ppm relative to the internal standard tetramethylsilane (TMS) or the residual solvent proton signals.

SYNTHESIS OF SULFONAZIDE COMPOUNDS

1. PEG sulfonazide **1**



1

4-Carboxybenzensulphonylazide (113.6 mg, 0.5 mmol), 2,3,4,6-tetrafluorophenol (91.4 mg, 0.55 mmol) and N,N'-diisopropylcarbodiimide (DIC) (117 μL, 0.75 mmol) were dissolved in dry DCM (2 mL) at 0 ℃, and two drops of TEA was added. The reaction mixture was stirred at room temperature overnight. H_2O was added to quench the reaction. The mixture was extracted with DCM and the combined DCM layer was washed with brine, dried and concentrated to yield a light yellow solid (180 mg). 20 mg of this product without any further purification was dissolved in dry DCM (2 mL), followed by addition of aminopolyethylene glycol 5,000 monomethylether (266 mg, 1 eq.) and DIEA (27 μL) at 0 ℃. The mixture was allowed to stir at room temperature for 2 h. DCM was removed and the residue was washed with cold ether and centrifuged to get a white precipitate. The precipitate was washed two more times with cold ether. The crude product was purified by preparative HPLC. The functionized PEG product had good UV absorption at the wavelengths of 220 and 260 nm used for HPLC detection, which facilitated its purification. MALDI-TOF was used to determine the molecular weight of the product (Fig. S1).

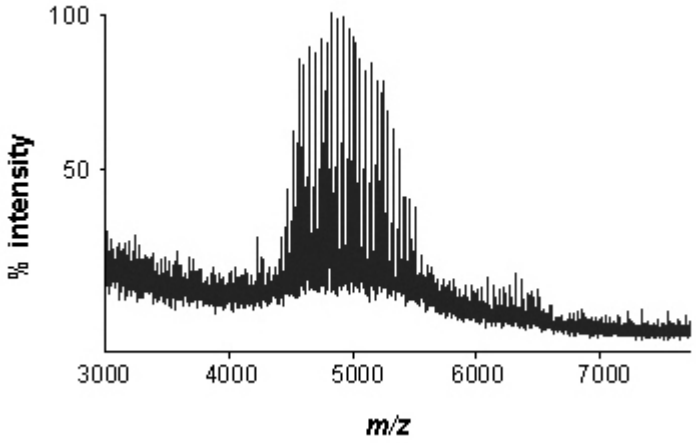


Figure S1. MALDI-TOF mass spectrum of purified PEG sulfonazide **1**.

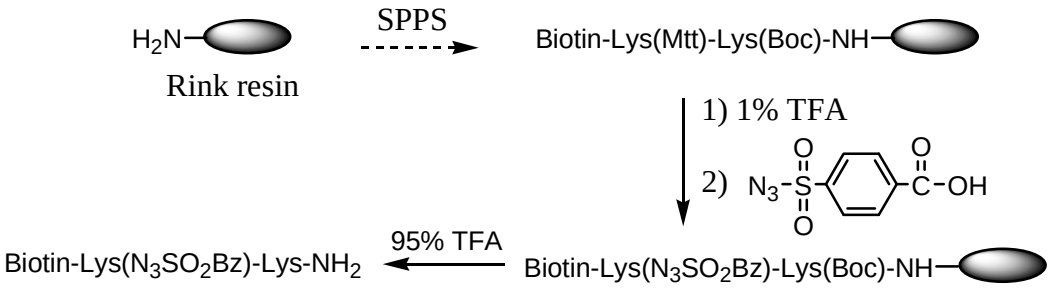
2. Biotin-Lys(N_3SO_2Bz)-Lys-NH_2 **2**



4 eq. of Fmoc-Lys(Boc)-OH was used to load to the Rink resin. The second Lys was coupled using Fmoc-Lys(Mtt)-OH. After Fmoc deprotection, 4 eq. of *D*-biotin was used to couple to the N-terminal amine. The protecting group Mtt was removed by 1% TFA in DCM (1×10min, 1×20min). Then 4 eq. of 4-carboxybenzensulphonylazide, 4 eq. of PyBOP and 10 eq. of DIEA were mixed and added to the resin. The reaction was done at room temperature for 2 h. This biotinyl-Lys(N_3SO_2Bz)-Lys-NH_2 **2** was cleaved from the resin with 95% TFA/ 5% H_2O, and purified by RP-HPLC. The molecular weight was determined by ESI-MS. *m/z* $[M+H]^+$ found: 709.3, MW calcd: 708.3.

PREPARATION OF UBIQUITIN THIOACID

The plasmid containing human ubiquitin gene obtained from Dr. Peter Chong's lab was the resource of ubiquitin. Ubiquitin gene was amplified by PCR using the primers:

Ubi_F: 5'-GGTGGTCATATGCAGATCTTTGTGAAG-3' and

Ubi_R:5'-GGTGGTTGCTCTTCCGCAGCCACCTCGCAGGCG-3'. The PCR condition was 95 ℃ for 3 min, 30 cycles of 95 ℃ 30 s, 54 ℃ 30 s, 72 ℃ 30s, and 72 ℃ 10 min for final extension. The PCR product was purified and ligated into the T-easy vector (Promega). The T-Ubi vector was transformed into E.Coli cell and amplified. The extracted and purified vector T-Ubi was digested with *Nde*I and *Sap*I restriction enzymes, the digested segment was purified and ligated into the identically digested pTYB1 vector (New England Biolabs). And the correct insert was then confirmed by DNA sequencing.

The plasmid pTYB1-Ubi was transformed into *E. Coli* BL21(DE3) $CaCl_2$ competent cells. The cells were grown in LB medium containing 100μg/ml Ampicillin at 37 ºC with shaking at 250 rpm to an OD_{600} of 0.6-0.8. The target protein was induced by 50 μM IPTG at 15 ºC for 18 h. After centrifuge at 6000 rpm for 10 min, cell pellets from 1 liter culture were suspended in 50 mL of lysis buffer (20 mM HEPES, 0.5 M NaCl, 1 mM EDTA, pH 7.0). Cells were broken by a microfluider (Microfluidics, Newton, USA, chamber press, 12K/50 psi), and cell debris was removed by centrifugation at 20,000 g for 30 min. SDS PAGE gel analysis showed the expression of the fusion protein in its soluble form (Fig. S2A). The obtained supernatant was mixed with 10

mL chitin beads (New England Biolabs) pre-equilibrated with the lysis buffer (20 mM HEPES, 0.5 M NaCl, 1 mM EDTA, pH 7.0) at 37 ºC for 2 h. And the beads were then poured into a column and washed with lysis buffer. The fusion protein was cleaved by adding 10 mL of cleavage buffer (100 mM Na_2S, 0.25 M HEPES, 0.5 M NaCl, 1 mM EDTA, pH 8.0) and incubating at 37 ºC overnight. The cleaved product was purified by semi-prep C8 RP-HPLC (Vydac C8 column, 250×10 mm) and analyzed by SDS-PAGE gel (Fig. S2B) and MALDI-MS (Fig. 2B).

Lane M, protein markers; lane 1, the cleaved ubiquitin thioacid.

THIOACID/AZIDE AMIDATION FOR PROTEIN C-TERMINAL LABELING

For demonstrating the C-terminal labeling of proteins by a biophysical or other functional group, ubiquitin thioacid was subject to amidation reaction with either the PEG sulfonazide **1** or biotinyl-Lys(N_3SO_2Bz)-Lys-NH_2 **2**. In the reaction, 0.3 mM ubiquitin thioacid, 5-10 eq. of PEG azide **1** or biotin-Lys(N_3SO_2Bz)-Lys-NH_2 **2,** and 3 mM 2,6-lutidine were dissolved in 6 M Gdn-HCl. The reactions were conducted at room temperature. Analytical RP-HPLC (Vydac C4 column) was used to monitor the

reactions. For the biotinylation reaction, ESI-MS (Fig. S3) showed a minor amount of hydrolysis product (Fig. S3A) which eluted closely with the biotinylated product in HPLC (Fig. 5A).

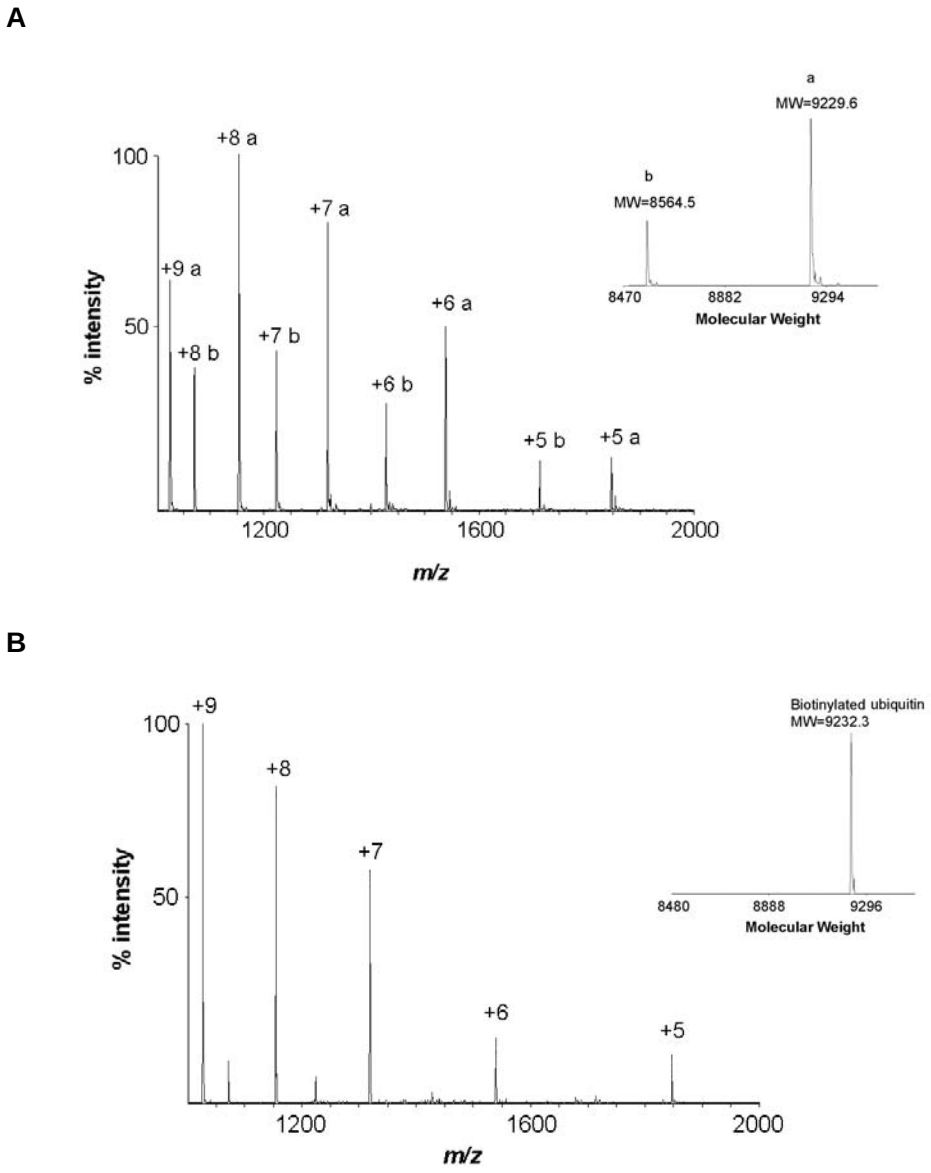


Figure S3. ESI-MS spectra of the amidation product between ubiquitin thioacid and biotinyl-Lys(N_3SO_2Bz)-Lys-NH_2 **2.** (**A**) The first quarter of peak 3 in Figure 5(A) contained the biotinylated ubiquitin (**a**, calcd. MW 9228.5) and hydrolyzed ubiquitin (**b**, calcd MW 8564.8). (**B**) Same as Fig. 5B. ESI-MS of the last 3 quarters of peak 3 in Figure 5A in which only the amidation product was detected. The inserts are the deconvoluted MW spectra.

WESTERN BLOT ANALYSIS OF BIOTINYLATED UBIQUITIN

After electrotransferring the samples from 18% SDS-PAGE gel to the PVDF (polyvinylidene difluoride) membrane (Pall Life Sciences, USA), the membrane was blocked by 5% (w/v) non-fat milk in TBS buffer (100 mM Tris-HCl, 150mM NaCl, pH 7.5) containing 0.1% Tween-20. A 1:10,000 diluted avidin-HRP conjugate (Bio-Rad, USA) was used to detect the biotinylated product as visualized by chemiluminescence (SuperSignal West Dura Trial Kit, Pierce, USA).

Dual Labeled Peptides as Tools to Study Receptors: Nanomolar Affinity Derivatives of TIPP (Tyr-Tic-Phe-Phe) Containing an Affinity Label and Biotin as Probes of δ Opioid Receptors

Jane V. Aldrich,* Vivek Kumar,[†,§] Thomas F. Murray,[‡] Wei Guang,[†] and Jia Bei Wang[†]

Department of Medicinal Chemistry, School of Pharmacy, 1251 Wescoe Hall Drive, University of Kansas, Lawrence, Kansas 66045, Department of Pharmaceutical Sciences, School of Pharmacy, University of Maryland, Baltimore, Maryland 21201, and Department of Pharmacology, College of Medicine, Creighton University, Omaha, Nebraska 68178.
Received October 1, 2008; Revised Manuscript Received December 10, 2008

A general strategy for the design of dual labeled peptides was developed, and derivatives of the δ opioid receptor (DOR) selective antagonist TIPP (Tyr-Tic-Phe-PheOH) containing both an affinity label and biotin were prepared by solid-phase synthesis. Tyr-Tic-Phe-Phe(*p*-X)-Asp-NH$(CH_2CH_2O)_2$-CH_2CH_2NH-biotin (where X = N═C═S or $NHCOCH_2Br$) exhibit nanomolar DOR affinity. The ability to detect receptors labeled with these peptides following solubilization and SDS-PAGE demonstrate the applicability of this design approach for dual labeled peptide derivatives.

Affinity labels, ligands that bind to their target in a nonequilibrium manner, are important pharmacological tools to study receptors and their biological effects. These irreversible ligands bind to their targets in a two-step process, first binding reversibly, followed by formation of a covalent bond with their target (*1*). These ligands are useful pharmacological tools to study receptors (*1*) and, by determining their point of attachment to their target, can be used to examine receptor−ligand interactions at the molecular level (*2, 3*).

While affinity labels without an additional functionality are useful pharmacological tools, a second label is required to detect the labeled receptors and take full advantage of this class of ligands. This typically has involved using radiolabeled derivatives of affinity labels (see, for example, *refs 2, 4, 5*), but the preparation of radiolabeled ligands requires specialized facilities and handling to incorporate the radioactive atom. Biotin or a fluorescent group are attractive alternatives to a radioactive label for incorporation into ligands (*6*). Ligands containing a biotin or a fluorescent group in addition to a reactive affinity label can have several advantages, both in ease of preparation and in application in various pharmacological assays. To date, the only such ligands described for opioid receptors are "reporter affinity labels" (see ref *7*) in which an *o*-phthalaldehyde group on the ligand functions as an affinity label that reacts with an amine and a thiol on the receptor and yields a fluorescent isoindole group. This approach to affinity labeling is very limited, however, because it requires that two nucleophilic receptor residues be in close proximity to one another and to the phthalaldehyde on the ligand.

Our research focuses on the synthesis of labeled derivatives of opioid peptides as tools to study opioid receptors. We have been particularly successful in identifying electrophilic affinity label derivatives of several peptides selective for δ opioid receptors (DOR) (*8*−*11*), including analogues of the potent and selective DOR antagonist TIPP (Tyr-Tic-Phe-PheOH, where Tic = 1,2,3,4-tetrahydroisoquinoline-3-carboxylic acid)[1] (*9, 10*). The [Phe(*p*-X)[4]]TIPP derivatives (where X is an isothiocyanate or bromoacetamide group) have high affinity for DOR (IC_{50} = 5 nM) and inhibit binding in a wash-resistant manner (*9, 10*).

We have also incorporated biotin into TIPP, attached to the C-terminus via a hydrophilic diamine linker to separate biotin from the small hydrophobic peptide (*12*). This maintains the basic N-terminal amine, which is important for the interaction of most opioid peptides with opioid receptors; Asp was also incorporated in the peptide to maintain an acidic C-terminal functionality, which is important for high DOR selectivity (*12, 13*). The resulting peptide TIPP-Asp-NH$(CH_2CH_2O)_2CH_2CH_2$NH-biotin (**1a**) exhibits high affinity (K_i = 12 nM) for DOR (*12*).

Combining an affinity label and second labeling functionality into the same molecule is a particularly appealing approach for peptide derivatives because of their polymeric nature. This approach has been applied to label neurokinin receptors with substance P derivatives containing both a photoaffinity label and a biotin derivative and to study peptide ligand−receptor interactions (see ref *14*). Here, we describe the synthesis and evaluation of the first dual labeled opioid peptide derivatives containing both an affinity label and a second nonradioactive labeling functionality as tools to study opioid receptors.

On the basis of our success with initial TIPP derivatives, we combined an affinity label and biotin in the same peptide to give the dual labeled peptides **1c** and **1d** (Figure 1). The corresponding amine-containing peptide **1b** was prepared as a

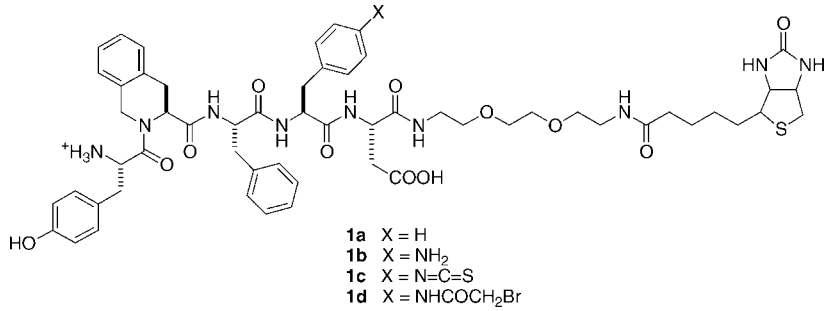

Figure 1. Dual labled TIPP derivatives.

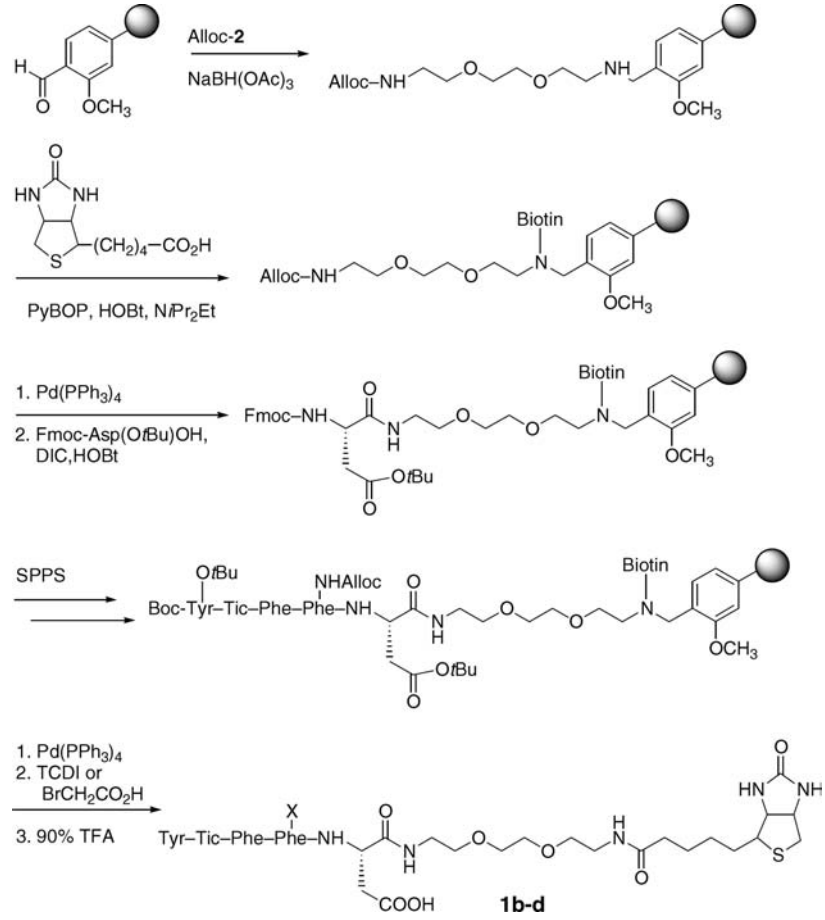
Scheme 1



reversible control compound for the pharmacological assays. The dual labeled TIPP derivatives were prepared by solid-phase synthesis using a modification of the strategy developed in our laboratory to prepare the reversible biotinylated peptide **1a** (Scheme 1) (*12*). This strategy uses the Alloc (allyloxycarbonyl) group for orthogonal protection of the amine groups to which both the biotin and affinity label groups are attached. Following reductive amination of an an aldehyde-containing solid-phase resin with the monoprotected hydrophilic diamine linker Alloc-$NH(CH_2CH_2O)_2CH_2CH_2NH_2$ (Alloc-**2**) and introduction of the biotin, the peptide was assembled on the resin by standard procedures (see Supporting Information for detailed procedures). Following completion of the peptide chain, the Alloc group was removed from Phe(*p*-NHAlloc)[4] and the resin then treated with thiocarbonyl diimidazole (TCDI) or bromoacetic acid plus *N*,*N*-diisopropylcarbodiimide (DIC) to yield the isothiocyanate and bromoacetamide derivatives, respectively. The dual labeled peptides **1c** and **1d** plus the amine-containing peptide **1b** were cleaved from the resins and deprotected using 90% aqueous trifluoracetic acid (TFA). Mass spectrometric analysis verified the formation of the desired derivatives (see Supporting Information, Table S1).

X = $NHCOCH_2Br$ (**1d**)	10.4 ± 2.0

[a] Using [^{3}H]DPDPE (*cyclo*[D-Pen^2,D-Pen^5]enkephalin) as the radioligand. Results are mean ± SEM of 3 independent experiments. [b] IC_{50} > 10 000 nM at MOR for all compounds. [c] Linker = $-NH(CH_2CH_2O)_2CH_2CH_2NH-$.

The purified peptides were initially evaluated for DOR and μ opioid receptor (MOR) affinities in radioligand binding assays under standard conditions (*15*) (Table 1). The dual labeled peptides **1c** and **1d** and the amine-containing analogue **1b** retain nanomolar DOR affinity, with comparable or, in the case of

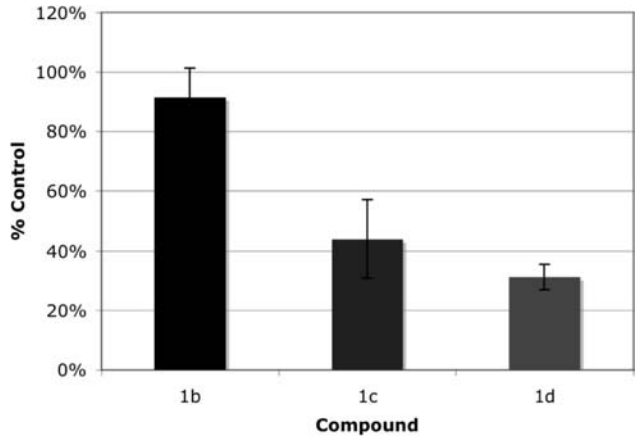

Figure 2. Wash-resistant inhibition of [^{3}H]DPDPE binding to DOR by TIPP derivatives **1b**−**1d** compared to untreated control membranes following preincubation at 33, 40, and 10 nM, respectively, for 90 min. The results are the average of 3 independent experiments.

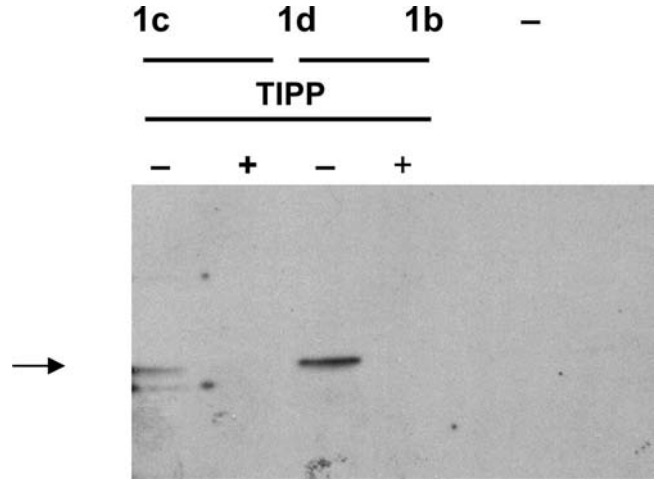

Figure 3. Detection of labeled DOR by streptavidin−HRP conjugate following solubilization and SDS-PAGE. Myc-mδ/hμ CHO cells were incubated with the test peptide for 20 min at 25 °C at the following concentrations: (1) 200 nM **1c**, (2) 200 nM **1c** + 20 μM TIPP, (3) 50 nM **1d**, (4) 50 nM **1d** + 20 μM TIPP, (5) 165 nM **1b**, and (6) no peptide; when TIPP was included, it was added 15 min prior to the test peptide. See the Supporting Information for the isolation procedure. The arrow points to the band for the labeled DOR.

1d, higher affinity to the parent biotinylated peptide **1a**. Thus, the combination of an affinity label on Phe^4 and a C-terminal biotin is well tolerated by DOR. These results parallel those found for the TIPP affinity label derivatives without the C-terminal extension (*9, 10*), although the DOR affinity of the dual labeled peptides containing biotin is somewhat lower (8- and 2-fold for **1c** and **1d**, respectively) than that of the corresponding affinity labeled tetrapeptides. Peptides **1a**−**1d** all exhibit negligible affinity for MOR.

The ability to combine the affinity label and biotin with retention of nanomolar affinity for DOR is dependent on the position of the affinity label. In contrast to the results described here, when the affinity label was incorporated in Phe^3, the DOR affinity of the resulting dual labeled derivatives decreased dramatically to micromolar concentrations (Aldrich, Kumar, and Murray, manuscript in preparation), even though incorporation of an affinity label on Phe^3 is well tolerated in the shorter tetrapeptide TIPP (*9*).

The ability of the affinity label derivatives **1c** and **1d** to inhibit DOR binding in a wash-resistant manner was then assessed as previously described (*8*), with the amine-containing peptide **1b** serving as a reversible control (Figure 2). Incubation with peptides **1c** and **1d** at concentrations equal to their IC_{50} values for 90 min at room temperature, followed by extensive washing of the membranes, resulted in recovery of only 44 ± 13% and 31 ± 4%, respectively, of the binding to control membranes. Thus, the C-terminal extension does not appear to alter the orientation of the reactive functionality on Phe^4 in the receptor site, so that, like the shorter TIPP derivatives (*9, 10*), both **1c** and **1d** exhibit wash-resistant inhibition of binding. These peptides are much more potent DOR affinity labels than the enkephalin affinity label derivative DALCE ([D-Ala^2,Leu^5, Cys^6]enkephalin), which requires a concentration of 3 μM to cause 50% loss of DOR binding sites (*16*). Peptide **1d** appears to be comparable to FIT (fentanyl isothiocyanate), SUPERFIT ((+)-*cis*-3-methylfentanyl isothiocyanate) and NTII (5′-naltrindole isothiocyanate), which cause approximately 50% loss of DOR at concentrations of 1−10 nM (*17*−*19*), although differences in experimental procedures make it difficult to directly compare the results from the different studies.

Membranes treated with the reversible amine-containing peptide **1b** exhibited >90% of the control membrane binding, indicating that the washing procedure effectively removed noncovalently bound peptide. These results for **1b** are in marked contrast to the very lipophilic fluorescent Dmt-Tic derivative Dmt-Tic-Glu-NH$(CH_2)_5$NH-fluorescein (Dmt = 2′,6′-dimethyltyrosine), which cannot be removed from the mouse vas deferens preparation by extensive washing (*20*). This marked difference illustrates the advantage of our design strategy in which a hydrophilic linker is incorporated to decrease the hydrophobicity of our peptides, thereby minimizing nonspecific interactions.

The utility of the dual labeled peptides **1c** and **1d** was demonstrated by solubilizing labeled DOR, followed by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE, Figure 3). The cells were incubated with peptides **1b**−**1d** in the presence or absence of TIPP, and following solublization with RIPA+ buffer and immunoprecipitation according to procedures previously described (*21*), the proteins were subjected to SDS-PAGE. After Western blotting, proteins labeled with the biotinylated peptide were detected using a streptavidin−horseradish peroxidase (HRP) conjugate and a chemoluminescent substrate. Labeled proteins were detected when the cells were incubated with the affinity labels **1c** or **1d** alone, but not when the cells were incubated with peptides **1c** or **1d** in the presence of TIPP or with reversible peptide **1b** (Figure 3). These results clearly demonstrate that peptides **1c** and **1d** are binding covalently and specifically to DOR. To our knowledge, this represents the first report where an affinity labeled opioid receptor has been detected on a gel without using a radiolabeled ligand and demonstrates the utility of the dual labeled peptides to directly detect labeled receptors using the biotin functionality.

Thus, we have developed a strategy for the preparation of dual labeled peptides containing both an affinity label and a second label such as biotin. The applicability of the design and synthetic strategies was demonstrated by the preparation of dual labeled TIPP derivatives containing both functionalities. The results for these TIPP derivatives show that an affinity label and biotin can be combined in the same peptide with retention of both high opioid receptor affinity and covalent binding of the affinity labels to the receptor. The detection of the labeled receptors following solubilization illustrates the immense potential for application of these derivatives as pharmacological tools to study opioid receptors; these studies are currently underway in our laboratories. This strategy can be applied to other peptides, including ligands for other biological targets as well as for opioid receptors.

ACKNOWLEDGMENT

This research was supported by a grant from the National Institute on Drug Abuse (R01 DA10035). The authors thank Jennif Chandler and B. Marinda Thomas for performing the radioligand binding assays.

Supporting Information Available: Experimental procedures and analytical data (HPLC, capillary electrophoresis and mass spectral analysis) for peptides **1b**−**1d**. This material is available free of charge via the Internet at http://pubs.acs.org.

EXPERIMENTAL PROCEDURES

Synthesis. Stepwise solid-phase peptide synthesis was carried out on a Biosearch 9500 automated peptide synthesizer using a modification of the procedure described previously (*1*). The monoprotected hydrophilic diamine linker Alloc-NH$(CH_2CH_2O)_2CH_2CH_2NH_2$ (Alloc = allyloxycarbonyl) (*2*) was prepared and attached to an aldehyde-containing solid phase resin (4-(4-formyl-3-methoxyphenoxy)butyryl AM resin, 0.85 mmol/g, Novabiochem, San Diego, CA) by reductive amination using triacetoxysodium borohydride in trimethylorthoformate / dichloromethane (1:2), as described previously (*1*). Following introduction of biotin using benzotriazole-1-yl-oxy-tris-pyrrolidino-phosphonium hexafluorophosphate (PyBOP), 1-hydroxybenzotriazole (HOBt) and *N*,*N*-diisopropylethylamine (DIEA) in dimethylsulfoxide/ *N*,*N*-dimethylformamide (1:1) for 6 h and removal of the Alloc group using $Pd(PPh_3)_4$ (*1*), Fmoc-Asp(OtBu) (Fmoc = fluorenylmethoxycarbonyl) was attached to the resulting primary amine using *N*,*N*-diisopropylcarbodiimide (DIC) and HOBt (4 equivalents each relative to the resin) in *N*,*N*-dimethylacetamide (DMA) (*1*). Following removal of the Fmoc protecting group with 20% piperidine in DMA, Fmoc-Phe(*p*-NHAlloc), prepared in our laboratory (*3*), was coupled to the resulting free amine using PyBOP, HOBt, and DIEA in DMA. The peptide chain was extended, using DIC and HOBt and a 4-fold excess of reagents to couple Fmoc-Phe and Fmoc-Tic. PyBOP plus HOBt and DIEA (4:4:8 equiv, respectively, relative to the resin) was used to couple Boc-Tyr(O*t*Bu) (4 equivalents) to the secondary amine of Tic^2. Following completion of the peptide chain, the Alloc group was removed from $Phe(p\text{-}NHAlloc)^4$ using $Pd(PPh_3)_4$. The resin was then treated with thiocarbonyl diimidazole or bromoacetic acid plus DIC in DMA to yield the isothiocyanate and bromoacetamide derivatives, respectively. The dual labeled peptides **1c** and **1d** plus the amine-containing peptide **1b** were cleaved from the resins and deprotected using 90% aqueous trifluoroacetic aicd (TFA).

The peptides were purified to >98% homogeneity by semipreparative HPLC on a Vydac column 218-TP column (22 x 250 mm) with a Vydac guard cartridge using a linear gradient of 20 to 50% aqueous acetonitrile containing 0.1% TFA over 30 min at a flow rate of 20 ml/min.

Purity was confirmed by analytical HPLC and capillary electrophoresis. Electrospray ionization mass spectrometric (ESI-MS) analysis verified the formation of the desired derivatives. Analytical data for peptides **1b-1d** are provided in Table S1.

Pharmacological evaluation. The peptides were initially evaluated for DOR and MOR affinities in radioligand binding assays under standard conditions (*4*) using cloned receptors stably expressed on Chinese hamster ovary (CHO) cells and [^{3}H]DPDPE (*cyclo*[D-Pen^2,D-Pen^5]enkephalin) and [^{3}H]DAMGO ([D-Ala^2,NMePhe^4,glyol^5-enkephalin), respectively, as the radioligands.

The ability of the peptides to inhibit DOR binding in a wash-resistant manner was then assessed according to the previously described procedure (*5*). Using concentrations equal to their IC_{50} values (33, 40 and 10 nM, respectively), the peptides **1b-1d** were preincubated with CHO cell membranes for 90 min at room temperature followed by washing the membranes (5 times) by dilution and centrifugation (*5*). The membranes were then evaluated for [^{3}H]DPDPE binding compared to untreated control membranes. The results are the average of 3 independent experiments.

Labeled DOR were detected with streptavidin-horse radish peroxidase (HRP) conjugate following solubilization and sodium dodecylsulfate polyacrylamide electrophoresis (SDS-PAGE). Myc-mouse DOR /human MOR expressing CHO cells were incubated with the test peptide as indicated in Figure 1 for 20 min at 25 ˚C; when TIPP was included it was added 15 min prior to the test peptide. The proteins were extracted with RIPA+ buffer containing protease inhibitors (1% NP-40, 0.5% sodium deoxycholate, 0.1% SDS, 5 mM EDTA, 10 mM NaF, 10 mM Na^2 pyrophosphate, 1 µM okadaic acid, 0.1 mM phenylmethanesulfonyl fluoride, 10 µg/mL leupeptin and 1 µg/mL pepstatin A in phosphate buffered saline) and subjected to immunoprecipitation with anti-Myc antibody (Sigma) (*6*). The proteins were then separated on 8% SDS-PAGE gels. Following Western blotting onto PVDF membranes, the membranes were treated with diluted streptavidin-HRP conjugate (Pierce, 1:1,000,000 dilution) and SuperSignal West Femto Maximum Sensitivity Chemoluminescent Substrate (Pierce). DOR (~65 kDa) were detected for all the samples on the same Western blot using the Myc antibody (data not shown).

Table S1. Characterization of dual labeled peptides by HPLC, capillary electrophoresis (CE) and ESI-MS.

			ESI-MS *m/z*	
Peptide	**HPLC t_r (min)** [a]	**CE t_m (min)** [b]	**Found**	**Calcd**
1b	9.41	10.26	1121.0	1121.5 $(M+H)^+$
1c	17.42	17.38	1163.0	1163.5 $(M+H)^+$
1d	13.00	15.93	1241.0, 1243.0[c]	1241.4 $(M+H)^+$

[a] HPLC conditions: Vydac 218-TP column (4.6 x 250 mm) with guard cartridge, solvent A = 0.1% TFA in water and solvent B = 0.1% TFA in MeCN, flow rate 1 mL/min, linear gradient of 20 to 50% over 20 min; peptide purity was >98%.

[b] CE conditions: 50 cm capillary, 50 mM phosphate buffer, pH 2.5, 15 kV; peptide purity was >98%.

[c] Two peaks were observed due to isotopes of bromine.

Self-Assembling DNA Quadruplex Conjugated to MRI Contrast Agents

Jianfeng Cai, Erik M. Shapiro,* and Andrew D. Hamilton*

Department of Chemistry, Yale University, 225 Prospect Street, New Haven, Connecticut 06511, and Department of Diagnostic Radiology, Yale University School of Medicine, 300 Cedar Street, New Haven, Connecticut 06520. Received October 1, 2008; Revised Manuscript Received November 12, 2008

We report the preparation and magnetic resonance (MR) characterization of new MRI contrast agents based on gadolinium complexes conjugated to a self-assembling DNA quadruplex scaffold. As a single gadolinium−DOTA chelated DNA strand, the r_1 molar relaxivity is 6.4 mM^{-1} s^{-1} per Gd and increases to 11.7 mM^{-1} s^{-1} per Gd upon formation of a DNA quadruplex. Similar results were obtained when a gadolinium−DOTA dendrimer was conjugated to DNA, with the r_1 molar relaxivity increasing to 12.9 mM^{-1} s^{-1} per Gd upon the formation of DNA quadruplex, compared to that of 6.0 mM^{-1} s^{-1} for a single strand of gadolinium−DOTA dendrimer chelate. This yields an r_1 molar relaxivity of 154.8 and 46.8 mM^{-1} s^{-1} per DNA quadruplex based on DOTA dendrimer or monomer, respectively. Importantly, the DNA quadruplex scaffold is approximately 2.5 nm^3 in size, potentially enabling this type of contrast agent to be used for targeted delivery in vivo to detect specific cells or tissues, even behind intact blood vessels.[1]

The targeted and non-invasive detection of specific pathologies in humans is a major research focus in the broad area of bioimaging sciences. To this end, magnetic resonance imaging (MRI) has emerged as an important and useful imaging strategy. As a noninvasive imaging technique, MRI provides three-dimensional images of anatomic structures of living organisms at high spatial resolution (~100 μm isotropic) at scan times of less than 30 min (*1*). Similar to other molecular imaging technologies, targeted MRI requires the delivery of specific probes to detect underlying biological abnormalities. Commonly used MR targeting constructs include paramagnetic liposomes (*2*), paramagnetic perfluorocarbon nanoparticles (*3*), superparamagnetic iron oxide nanoparticles (*4*), and small paramagnetic chelates (*5*). Almost always, the paramagnetic metal used is Gd^{3+} because of its ability to increase the longitudinal relaxation rate (R_1) of water protons and therefore to enhance the observable signal. Superparamagnetic iron oxide nanoparticles create local magnetic field distortions, which increases the transverse relaxation rate (R_2), effectively destroying signal and making dark contrast in images.

Targeted MRI has had a major impact on the detection and treatment of cancer (*6*) and atherosclerosis (*7*). This is largely due to the accessibility of blood vessels in these diseases, as most nanoparticle formulations are on the order of 30 to >100 nm in diameter and are too large to extravasate from undamaged blood vessels (*8*). Furthermore, even if they were to escape into the extracellular space, their large size limits their diffusion within the tissue (*9*). Diseases, such as small, nonaggressive tumors, Alzheimer's plaques, and ischemic tissues, which manifest themselves without leaky blood vessels or behind the intact blood−brain barrier, have been challenging to target. Thus, the large size of most nanoparticle constructs limits their general usage, and there is much interest in synthesizing ultrasmall nanoparticles for targeted MRI (*10*).

A significant barrier to the development of new generations of small Gd-based MR agents is the low molar relaxivity (r_1) of chelated gadolinium. Clinical contrast agents have molar r_1 values of 3−7 mM^{-1} s^{-1} (*8*), resulting in the need for high concentrations to enhance the MRI signal (*11*). Significant research has focused on increasing the rotational correlation time (τ_c) of the gadolinium-containing complex to increase molar relaxivity and, hence, to obtain more efficient contrast agents (*12*). For example, clinically used small molecule contrast agents have been conjugated to high-molecular-weight macromolecules including proteins (*11*), polymers (*13*), and self-assembled peptide amphiphile nanofibers (*14*). This has resulted in the increase of r_1 to 7.3, 19.3, and 22.8 mM^{-1} s^{-1}, respectively. Recently, several contrast agents with even higher relaxivities have been reported. For example, Aime et al. showed that a lipophilic Gd-AAZTA complex bound to albumin had a relaxivity of 84 mM^{-1} s^{-1} (*15*). Yang et al. also designed protein-based contrast agents and demonstrated relaxivities of 35−130 mM^{-1} s^{-1} (*16*). Caravan et al. reported dual-binding GdDTPA tetramers that showed relaxivities of 46−50.8 mM^{-1} s^{-1} when bound to albumin (*17*). Wilson et al. prepared gadolinium−carbon nanotube complexes with relaxivities of 159−179 mM^{-1} s^{-1} (*18*). However, MRI contrast agents designed for general use in targeting multiple epitopes are rare.

Here, we report the design, preparation, and characterization of new MR agents based on ordered and self-assembling DNA quadruplex scaffolds (*19*). The quadruplex-based DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) derivatives have almost 30-fold increased r_1 versus clinical Gd-chelate contrast agents and 2-fold increased r_1 compared to the single oligonucleotide (ODN)−DOTA conjugate. These constructs further allow integration of bioactive functions to the quadruplex scaffolds leading potentially to the design of targeted contrast agents. Thus, these new agents provide a general template with high r_1 molar relaxivity and ultrasmall size.

The ODN conjugated DOTAs were prepared by DNA solid-phase coupling on a 1 μmol scale. The 5′-ends of the quadruplex-forming oligonucleotides were tethered with DOTA (**1X** and **1Y**) (Figure 1). In **2X** and **2Y**, DOTA and DOTA

* andrew.hamilton@yale.edu and erik.shapiro@yale.edu.

[1]By assuming an average distance of 3.4 Å between base pairs, and a distance of 11 Å between adjacent guanines in each tetrad, the volume of the DNA quaduplex scaffold was calculated to be 1.1 × 1.1 × 2.04 = 2.5 nm^3.

Figure 1. (a) Functionalized parallel G-quadruplex with DOTA appendages. (b) Sequences of the designed oligonucleotides where G-quadruplex **1X** and **2Y** are tethered to DOTA or DOTA dendrimer fragments, respectively. **2X** and **2Y** are DOTA or DOTA dendrimer appended single strands that cannot form quadruplex structure

dendrimers, respectively, were tethered to a single-strand sequence that is incapable of forming self-assembled structures (Figure 1).

The synthesis of the modified oligonucleotides and the incorporation of Gd(III) ions (*20*) are detailed in the Supporting Information. Briefly, ODNs on the solid support were tethered with modifiers [5′-amino- modifier C6 was used to prepare **1X** and **2X**, while tribler phosphoramidite and 5′-amino-modifier 5 (see Supporting Information) were used to prepared **1Y** and **2Y**], which were then coupled with DOTA using PyBOP and DIPEA in DMF overnight. The DOTA-conjugated ODNs were subjected to deprotection in concentrated aqueous ammonia at 55 °C for 16 h and incubated with gadolinium (III) citrate overnight at room temperature. The ODN conjugates were then purified by HPLC and confirmed by MALDI-TOF. Functionalized parallel quadruplexes were prepared in buffer (10 mM Tris-HCl, 80 mM KCl, pH 7.5) and incubated for 48 h (*21*). The secondary structures of the complexes were confirmed by circular dichroism (CD) spectroscopy (Figure 2). The designed functionalized quadruplexes **1X** and **1Y** showed a positive ellipticity at 263 nm and a negative peak at 241 nm, which is characteristic of a tetramolecular parallel quadruplex (*22*−*24*). In contrast, incubation of **2X** and **2Y** only showed a weak signal at 273 nm and a negative peak at 250 nm in the CD spectrum, indicating no quadruplex formation.

The r_1 of the contrast agents was measured by MRI with concentrations of samples confirmed by inductively coupled plasma (ICP)-MS measurements (see Supporting Information for methods). Compared to the single DNA−DOTA counterpart

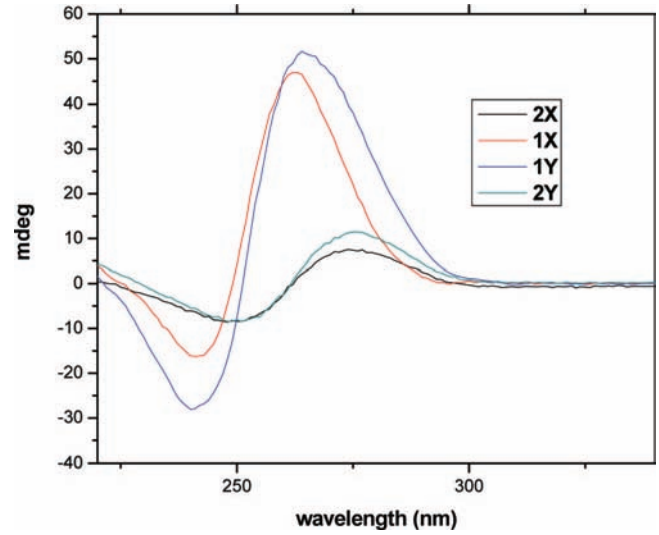

Figure 2. Circular dichroism spectra of ODNs after self-assembly. All measurements were done in 80 mM KCl, 10 mM Tris-HCl, pH 7.5 buffer. Concentrations of all ODNs were 60 μM for the single strand.

2X, the efficacy of the contrast agents has been greatly improved through formation of the quadruplex. **1X** displays a relaxivity of 11.7 mM^{-1} s^{-1} per Gd(III) ion and 46.8 mM^{-1} s^{-1} per DNA quadruplex, while **2X** has a relaxivity of 6.4 mM^{-1} s^{-1} per Gd(III) and per molecule (Supporting Information Figure S1).

Table 1. Gd(III) Ionic and Molecular Relaxivities of Standard MRI Contrast Agents and New Agents 1X, 2X, 1Y, and 2Y at 4.0 T and 20.5 °C

DNA	MW (g/mol) (based on DNA single strand)	Gd ionic r_1 (mM^{-1} s^{-1})	no. of Gd	molecular r_1 (mM^{-1} s^{-1})
1X	4150.1	11.7	4	46.8
2X	4315.0	6.4	1	6.4
1Y	5920.9	12.9	12	154.8
2Y	6088.0	6.0	3	18
Gd-DTPA (*8*)	743	4.5	1	4.5
Gd-DOTA (*25*)	561	3.5	1	3.5

The relaxivity of **2X** is in the normal range of currently used clinical contrast agents, yet **1X** shows a 2-fold increased relaxivity per Gd(III). This per complex r_1 is higher than that of contrast agents based on a previously reported genetically engineered protein (*11*) and synthetic dendrimer-based contrast agent ($\sim$35 mM^{-1} s^{-1}) (*26*). Importantly, this is the case even though our quadruplex-based agents have much lower molecular weight and the increase in r_1 is likely due to the more ordered features of the DNA aggregate. Of note, the r_1 of **1X** matches that of a recently reported, similarly sized (14 kDa) Gd-conjugated contrast agent (*5*). This agent is a Gd-conjugated to the C2A domain of synaptotagmin, which is specific for phosphatidylserine (PS), whereas **1X** is designed for general use in targeting multiple epitopes.

The hypothesis that quadruplex formation increases the relaxivity of DNA-linked contrast agents is further supported by studying a Gd-DOTA dendrimer conjugated DNA system. **1Y** displays a relaxivity of 12.9 $mM^{-1}s^{-1}$ per Gd(III) ion and 154.8 $mM^{-1}s^{-1}$ per DNA quadruplex complex, while **2Y** has a relaxivity of 6.0 $mM^{-1}s^{-1}$ per Gd(III) and per molecule (Supporting Information Figure S1). The relaxivities are comparable between **2X** to 2**Y**, probably due to the flexibility of the linkers within the DOTA dendrimers. But again, **1Y** shows a 2-fold increased relaxivity per Gd(III) compared to **2Y** and a much higher relaxivity per quadruplex than **1X**, since three Gd (III) ions are contained within each strand. We also observe an increase in relaxivity per Gd(III) ion from **1X** to **1Y**, which is probably because formation of the ordered DNA quadruplex offsets the flexibility of the linkers within the dendrimer.

Other contrast agents conjugated to viruses, various proteins, and synthetic polymers have been reported to display higher r_1 values per molecule (*27, 28*). However, the Gd-conjugated DNA quadruplex contrast agents reported here have several advantages including a low molecular weight and small size (2−3 nm), which could prove critical for targeted delivery and detection of specific cells or tissues, even behind intact blood vessels. Second, the DNA construct occurs naturally and is biodegradable, potentially mitigating toxic effects. Third, the size of the quadruplex contrast agents can be modified by varying the lengths of the DNA sequences. Fourth, it may be possible to obtain quadruplex CAs with higher relaxivity if DOTA dendrimers with more rigid and shorter linkers can be tethered on the end of the DNA quadruplex scaffold. Lastly, functionalized DNA quadruplexes have been shown to target specific proteins (*19, 29*), leaving open the possibility of functionalizing the quadruplex with fragments that target specific cells or tissues.

In conclusion, we have described the design and synthesis of high-relaxivity DNA quaduplexes that can serve as improved MRI contrast agents. The ordered structure of the quadruplex leads to an increase in the relaxivities of the new MRI contrast agents. Further improvements in gadolinium relaxivity and packaging can be expected by conjugating Gd-DOTA dendrimers with rigid and shorter linkers as well as tethering bioactive groups to the DNA for use in targeted diagnosis.

ACKNOWLEDGMENT

We thank the National Institute of Health (NIH) (P30 NS-052519) and the National Science Foundation (NSF) (CHE-0750357) for financial support of this work.

Experimental section

Materials and instruments

DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) was purchased from Sigma-Aldrich and used without further purification. The core oligonucleotides sequences were synthesized by W. M. Keck Foundation Biotechnology Resource Laboratory, Yale University using automated solid phase synthesis. The modified phosphoramidite 5'-amino-modifier C6 (6-(4-Monomethoxytritylamino)hexyl-(2-cyanoethyl)-(N,N-diisopropyl)-phosphoramidite), 5'-amino-modifier 5 (2-[2-(4-Monomethoxytrityl) -aminoethoxy]ethyl-(2-cyanoethyl)-N,N-diisopropyl)-phosphoramidite), and trebler phosphoramidite (Tris-2,2,2-[3-(4,4'-dimethoxytrityloxy)propyloxymethyl]ethyl-[(2-cyanoethyl)-(N,N-diisopropyl)]-phosphoramidite) were obtained from Glen Research. The oligonucleotides were first subjected to gel filtration using Microspin G-25 columns (GE health care), then purified by reverse-phase HPLC (Varian Prostar) equipped with a timberline TL-105 column heater. The concentrations of the purified oligonucleotides were determined based on their absorption at 260 nm using an Agilent A453 UV-vis spectrometer. The molecular weights of the purified oligonucleotides were obtained by MALDI-TOF (Matrix-Assistant Laser Desorption Ionization-Time of Flight) using an Applied Biosystems Voyager-DE PRO workstation. The Formation of DNA quadruplexes was confirmed by circular dichroism (CD) spectroscopy. ICP analysis was done by Bodycote testing group.

Standard preparation of oligonucleotides

To 4 mg of DOTA (12 mg for the preparation of dendrimers **1Y** and **2Y**) in a vial was added 4mg Pybop (12 mg for the preparation of dendrimers **1Y** and **2Y**), 1 ml of anhydrous DMF and 60 μl DIPEA and the mixture was stirred for 1 min. Then the solution was transferred into syringes and attached to the cartridge for solid-phase coupling. The cartridge contained the resin tethered with the activated amino modified oligonucleotide (1.0 μmol). The activated DOTA solution was pushed through the cartridge 3 times and agitated for 1 hr. This procedure was repeated three times and then the cartridge was allowed

to shake overnight. The solution was removed and the cartridge was washed two times with 2 ml DMF and 3 times with 2 ml acetonitrile. The resin was dried by blowing argon through the cartridge for 1 hr, and then the DNA was cleaved from the solid support with 30% NH_4OH for 2h at RT, followed by global deprotection with 30% NH_4OH (3 ml) at 55 ℃ for 16 h. The gadolinium (III) was introduced by adding 15 mol equiv of gadolinium (III) citrate and the mixture was stirred overnight at ambient temperature.

The GOTA tethered oligonucleotides were purified by an HPLC column maintained at 65 ℃. The molecular weights of the de-salted purified oligonucleotides were analyzed by MALDI-TOF using 9:1:1 mixture of 2,4,6-trihydroxyacetopheone (THAP) (10 mg/ml in 50% CH_3CN/water), ammonium citrate (50 mg/ml in water), and oligonucleotide solution, repectively.

Oligonucleotide **1X**. MALDI-TOF Calculated: 4153.0, found: 4150.1

Oligonucleotide **2X**. MALDI-TOF Calculated: 4315.01, found: 4311.4

Oligonucleotide **1Y**. MALDI-TOF Calculated: 5920.9, found: 5921.5

Oligonucleotide **2Y**. MALDI-TOF Calculated: 6088.0, found: 6085.7

Exposure to quadruplex self-assembly conditions

Typically, the purified aliquot of ODNs in an Eppendorf tube was diluted to the desired concentration by using the buffer (10 mM Tris-HCl, 80 mM KCl, pH 7.5). Then the tube was tightly capped and sealed with parafilm, and heated at 95 ℃ for 15 min. The solution was slowly cooled to room temperature and then incubated at 4 ℃ for 48 hr. The formation of quadruplexes was assessed by CD spectroscopy.

The measurements of relaxivity

Molar relaxivity was measured at the field strength of 4.0 Tesla at 20.5 ^{o}C on a Bruker Biospec MRI instrument. Four concentrations were used for both the single strand construct and the quadruplex, including a zero concentration control. A saturation recovery T_1 mapping protocol was used employing spin echo readouts, incorporating ten TRs ranging from 50 msec to 10 seconds. T_1s were calculated for each concentration and inversely plotted in seconds versus concentration in millimolar, the slope yielding molar relaxivity. All concentrations were verified by ICP emission spectroscopy.

PNIPAM Gel-Coated Gold Nanorods for Targeted Delivery Responding to a Near-Infrared Laser

Takahito Kawano,[†] Yasuro Niidome,[†] Takeshi Mori,[†,‡] Yoshiki Katayama,[†,‡,§] and Takuro Niidome*[,†,‡,#]

Received November 6, 2008; Revised Manuscript Received December 22, 2008

Gold nanorods can be used as photothermal converters, permitting near-infrared (NIR) light to be transmitted deep into tissues without causing damage. We prepared hybrid nanorods with a core−shell structure, i.e., a single gold nanorod encapsulated in a poly (*N*-isopropylacrylamide) nanogel. Hybrid nanorods demonstrated remote, reversible, pulsatile phase transition and in vivo action after irradiation using a NIR laser.

The development of in vivo delivery of drugs using functional nanomaterials is a cornerstone of successful cancer therapy (*1*−*4*). Strategies for the accumulation and release of drugs with nanomaterials have been intensively developed, including those caused by external stimuli (e.g., temperature, light, magnetic field, ultrasound, specific molecules) (*5*−*9*). External stimuli trigger conversion of the physicochemical properties of the drug carrier, so the pharmacokinetics of the injected drug could be remotely controlled from outside the tissues in vivo. Among stimuli-responsive drug carriers, thermo-responsive polymers such as poly(*N*-isopropylacrylamide) (PNIPAM) induced phase transition at a lower critical solution temperature (LCST) and are widely used in biomaterial science (*10, 11*). Ultraviolet- and visible light-sensitive materials can be delivered and release drugs after responding to external stimuli (*12*). Current strategies have not enabled the accumulation and release of drugs to be controlled within a limited area without tissue damage.

In this study, as a new class of external stimuli, we focused on near-infrared (NIR) light (650−900 nm). This allowed maximal penetration of light of tissues due to minimal optical absorption by intrinsic components such as hemoglobin (<650 nm) and water (>900 nm) (*13*). NIR light can be transmitted deep into tissue without significant damage and could have biomedical applications. Rod-shaped gold nanoparticles ("gold nanorods") have an intense absorption band in the NIR region and show highly efficient photothermal conversion (*14*−*16*). The photothermal effect of gold nanorods actuated by irradiating NIR light induces phase transition of the thermo-responsive polymer. Using PNIPAM hydrogel-coated gold nanorods, NIR light can trigger conversion of the hydrophobic nanorod surface and formation of aggregates. In targeted delivery, PNIPAM-coated gold nanorods circulate freely after systemic injection; the NIR laser then irradiates to the targeted site, and nanorods form aggregates and accumulate at the irradiated site without tissue damage (*17, 18*).

Our research group has prepared capillary PNIPAM hydrogels containing gold nanorods; irradiation by an NIR laser induced rapid shrinkage of the gels and released the incorporated drug (*19*). Kumacheva et al. prepared hybrid PNIPAM microgels, which successfully absorbed cationic surfactant-stabilized gold nanorods on submicrometer-sized spheres of PNIPAM-*co*-acrylic acid hydrogels by electrostatic interaction (*20*). Recently, this group showed that electrostatic interaction alone was not the governing force driving the absorption gold nanorods into microgels (*21*). However, for in vivo delivery based on systemic injection, applying the hybrid microgels would be disadvantageous because the size was too large to circulate in blood flow. PNIPAM gels loaded with gold nanorods should be nanosized and well-dispersed within the blood to enable targeted drug delivery using hybrid PNIPAM nanogels after systemic injection.

Our strategy involved using hybrid nanogels with a well-defined core−shell structure, i.e., a single gold nanorod encapsulated in a PNIPAM nanogel. The core−shell structure of NIPAM gel-coated nanorods prevented aggregation and dissociation by nonspecific interaction with blood components. We developed a novel preparation of core−shell PNIPAM gel-coated gold nanorods by colloid−template polymerization. Hybrid nanogels were used to demonstrate photothermal phase transition by an NIR laser and remote actuation after systemic injection in vivo.

PNIPAM gel-coated gold nanorods were prepared by colloid−template polymerization and silica etching (Figure 1). Gold nanorods had a length of 54.8 nm and an aspect ratio of 5.7. They were stabilized by the cationic detergent cetyltrimethylammonium bromide (CTAB) in aqueous solution (Figure 2A) (*22*−*24*).

First, gold nanorods were modified with the amphiphilic polymer poly(ethylene glycol) (PEG) (*25*). PEG-modified gold nanorods were coated with a silica layer using the modified Stöber method, which is based on the hydrolysis of tetraethyl orthosilicate (TEOS) in ethanol/water mixture in the presence of nanorods, which act as "seeds" (*26, 27*). After coating with silica shells, nanorods were dispersed without aggregation. Silica shells with a thickness of 16.7 nm around the nanorods were observed by transmission electron microscopy (Figure 2B). Spectra of the silica-coated nanorods showed a red shift of the surface plasmon band corresponding to the longitudinal oscillation mode because of an increase in local refractive index around the nanorods produced by the silica shells (Figure 2G) (*28, 29*). The silane-coupling agent 3-(methacryloxy)propyl triethoxysilane (MPS) was used to modify the surface of the silica-coated nanorods, which led to the formation of methacryl groups on the surface.

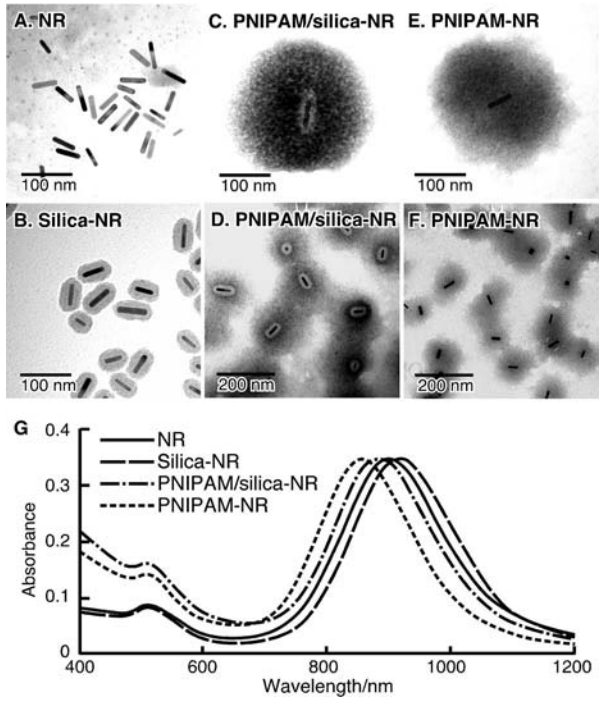

Figure 2. (A−F) Transmission electron microscopy (TEM) images of gold nanorods. (G) UV−visible-NIR spectra of gold nanorods.

Second, silica-coated nanorods were modified with PNIPAM shells by precipitation polymerization (*30, 31*). In the presence of MPS-modified silica nanorods, precipitation polymerization of NIPAM and *N*,*N*′-methylene bisacrylamide (MBA) as cross-linker was done using potassium persulfate (KPS) as an initiator, resulting in the formation of PNIPAM gel/silica-coated gold nanorods. Figure 2C,D shows the core of a single silica-coated gold nanorod modified with the shell of PNIPAM gel. Successful PNIPAM modification involved polymerization at a low concentration of gold nanorod solution (final gold atom concentration of 0.5 mM): this prevented aggregation between nanorods. Thickness of the PNIPAM shells could be adjusted by changing the amount of the NIPAM monomer and concentration of the silica-coated gold nanorods. A blue shift of the longitudinal surface plasmon band would be due to a change in the local refractive index produced by the PNIPAM shell. Silica templates were selectively etched using hydrofluoric acid. A hollow PNIPAM nanocapsule containing a single gold nanorod was observed (Figure 2E,F). Increase of absorption in the visible region (∼500 nm) was due to light scattering of PNIPAM nanogels (Figure 2G).

The temperature-induced change in size of the PNIPAM-coated gold nanorods with different cross-linking densities was measured by dynamic light scattering. All nanogels exhibited thermoresponse discontinuous phase-transition behavior (Figure 3A). Nanogels with lower cross-linking density (7.5%) showed a sharper phase transition curve than those with higher cross-linking densities (10% and 12.5%). Phase transition of all nanogels occurred at the same temperature (about 34 °C).

We investigated the photothermal phase transition of nanogels by irradiation using a focused NIR laser of wavelength 807 nm (Figure 3B). Here, to avoid aggregation, we employed a low concentration (50 μg/mL) of the nanogels. Small shrinkage of nanogels was observed after irradiation using an NIR laser for 10 min at low power (2.1 W/cm^2). Nanogels shrank considerably and rapidly when irradiated using a laser at high power (3.4 W/cm^2 and 4.2 W/cm^2). A cycle of shrinkage and swelling could be induced by switching the laser on and off. We roughly calculated input energy into a gold nanorod and required energy to increase the temperature of the NIPAM layer on the gold nanorod by 20 °C. The nanogel was assumed as a sphere (ϕ = 300 nm), the volume of the nanorod in the gel was insignificat, and the specific heat was the same as that of water. As a result of the calculation, the input energy into one gold nanorod (1.1×10^{-7} J) was 100-fold higher than the required energy to increase the temperature (1.2×10^{-9} J). It is enough to induce the phase transition of the PNIPAM layer, even the heat diffused into the silica layer and the surroundings. Gold nanorods did not exhibit a decrease or shift of the absorption peak due to irradiation by the NIR laser (data not shown). Dansylamide (which gives a fluorescent spectrum sensitive to hydrophobic environment) was mixed with nanogels, and then the mixture was irradiated by the NIR laser at various powers to investigate the nanogel environment. When the power of the NIR laser was raised, the fluorescence peak was blue-shifted and its intensity increased (Figure 3C). This indicated that the dye molecules

were in a more hydrophobic environment than the original environment due to phase transition of the PNIPAM gel.

Next, we tried a feasible study on in vivo application, that is, accumulation of nanogels at laser-irradiated site in mice due to the hydrophobic surfaces induced by the photothermal effect. The hydrophobic surface could interact with cellular membrane or extracellular matrix. The nanogels with high concentration (2.5 mg/mL) were systemically injected into mice. The right kidney was immediately irradiated using the NIR laser (807 nm, 3.4 W/cm^2) (Figure 4A). Organs were subsequently collected, and the amounts of the gold nanorods in organs were evaluated by inductively coupled plasma mass spectrometry (ICP-MS; Figure 4B). When a solution of PNIPAM-coated gold nanorods was injected, nanogels were distributed primarily in the blood (47%) and lungs (46%) after 10 and 30 min, respectively. The LCST of the nanogels was 34 °C lower than body temperature, but they circulated in the blood within 10 min because of a slow phase transition response to a jump in environmental temperature (*19*). After 30 min, nanogels accumulated in the lungs. This was due to formation of a hydrophobic surface on the nanogel after full phase transition at body temperature. Significant accumulation of gold in the irradiated right kidney was observed after irradiation of the right kidney for 10 min immediately after injection of nanogels. Accumulation was not observed in the left kidney, and the amount of gold in the blood was lower than in the case without laser irradiation. PNIPAM-coated gold nanorods, which circulated in the blood after injection, accumulated due to induced rapid photothermal phase transition in the irradiated site. Gold nanorods were also detected in the lungs. Hydrophobic nanogels that could not accumulate in the irradiated site would be trapped in the capillary vessels in the lungs. In the case of injection of PEG-modified gold nanorods followed by laser irradiation, gold nanorods were primarily found in the blood, similar to the case of nanogels without laser irradiation. These results suggested that accumulation of nanogels in targeted sites was due to photothermal phase transition and aggregation of PNIPAM nanogels after irradiation using a NIR laser.

In summary, we prepared hybrid nanogels (a single gold nanorod encapsulated in a PNIPAM nanogel) by colloid−template polymerization and silica etching. PNIPAM-coated gold nanorods demonstrated photothermal phase transition and accumulation in local targeted sites which were irradiated. For in vivo application, hybrid nanogels should be optimized with respect to the LCST, size, and sensitivity by changing monomer composition and nanorod size to induce a sharp transition in the relevant physiologic range (38−42 °C). We used gold nanorods as a photothermal agent to absorb NIR light that can penetrate tissues. Gold nanorods are also used as probes for in vivo imaging techniques (two-photon luminescence, photoabsorption) (*32, 33*). NIPAM gel-coated nanorods may enable simultaneous application of targeted delivery of drugs, photothermal therapy, and bioimaging using a NIR laser.

Experimental

Preparation of gold nanorods

Gold nanorods were supplied by Mitsubishi Materials Corporation (Tokyo, Japan). Average length and width of prepared gold nanorods was 54.8 nm and 9.6 nm, respectively (aspect ratio: 5.7). PEG-modified gold nanorods were prepared as follows. A solution of gold nanorods containing cetyltrimethylammonium bromide (CTAB) was centrifuged at 14,000 × g for 10 min, decanted, and resuspended in water to remove excess CTAB. One milliliter of a solution of 1 mM gold nanorods (concentration of gold atom) was added to 200 μL of 1 mM $PEG_{20,000}$-SH. The mixture was stirred overnight, and was dialyzed.

Silica-coating of gold nanorods

A solution of the prepared PEG-modified gold nanorods was concentrated by centrifugation. One-hundred microliters of a solution of 10 mM PEG-modified gold nanorods was diluted with 780 μL of ethanol. The mixture was added to 20 μL of 5% ammonia solution, and 100 μL of 50 mM tetraethyl orthosilicate (TEOS). The reaction was allowed to proceed for 24 h at room temperature. The reaction mixture was added to 100 μL of 100 mM 3-(methacryloxy) propyl triethoxysilane (MPS) to graft methacryl groups on the surface. The mixture was stirred for 24 h and dialyzed against ethanol/water solution (9/1) to remove excess MPS.

PNIPAM-modification of gold nanorods

The resulting solution of silica-coated gold nanorods was centrifuged, decanted, and resuspended in water. In the polymerization procedure, silica-coated gold nanorods grafted with MPS were used as seeds for the precipitation polymerization of *N*-isopropylacrylamide (NIPAM) and *N*,*N*'-methylene bisacrylamide (MBA) using sodium dodecyl sulfate (SDS) as a stabilizer and potassium sulfate (KPS) as an initiator. The reaction was allowed to proceed for 4 h at 70°C. Typical components for modification of PNIPAM shells were: 1 mL of 2 mM silica-coated gold nanorods; 1.8 mL of 100 mM NIPAM solution; 0.4 mL of 50 mM MBA solution; 0.04 mL of 100 mM SDS solution; 0.4 mL of 10 mM KPS solution; and 0.36 mL of distilled water. The solution was bubbled through nitrogen for 5 min to remove residual oxygen.

Characterization and measurements

Absorption spectra of gold nanorods from the visible to near-infrared light region were measured with a spectrophotometer, JASCO V-570 (Tokyo, Japan). Morphologies of gold nanorods were observed with a transmission electron microscope JOEL JEM-2010 (Tokyo, Japan) after staining with 1% phosphotungstic acid. Sizes of PNIPAM-coated gold nanorods in water were evaluated with Malvern Zetasizer Nano ZS (Worcestershire, UK). Nanogels solutions were diluted to 50 μg/mL and allowed to equilibrate at appropriate temperatures for 5 min before data collection of scattered light from a He–Ne laser (633 nm).

Laser irradiation experiments

Photothermal-driven size change of nanogels was measured at 25°C with Zetasizer Nano ZS. The nanogels solutions in water (50 μg/mL, 1 mL) were irradiated using a NIR continuous-wave diode laser of wavelength at 807 nm with a beam diameter of 5.5 mm (Alfright Corporation, Madison, USA). The NIR laser irradiated from the top of the solution. The laser was turned-off during measurements of nanogel size due to the effects of scattered light produced by the laser. Fluorescence intensities of dansylamide (20 μM) mixed with nanogels (0.5 mg/mL) were measured with a spectrofluorophotometer Shimadzu RF-5300PC (Tokyo, Japan). Fluorescence spectra were measured at an excitation wavelength of 340 nm.

In-vivo experiments

After mice were anesthetized, an incision was made in the back and the right kidney exposed. PNIPAM-coated gold nanorods (2.5 mg/mL, 300 μL) were injected (*i.v.*) into mice. A NIR laser (wavelength, 807 nm; power, 3.4 W/cm^2; beam diameter, 5.5 mm) immediately irradiated light into the right kidney for 10 min. Blood and organs were isolated and completely lysed in aqua regia. Mixtures were evaporated and dissolved in water. Quantitative analysis of gold was done by inductively coupled plasma mass spectrometry using Agilent 7500c (Tokyo, Japan). Data were represented as percentage of injection dose.

HPMA Polymer-Based Site-Specific Delivery of Oligonucleotides to Hepatic Stellate Cells

Ningning Yang, Zhaoyang Ye, Feng Li, and Ram I. Mahato*

Department of Pharmaceutical Sciences, University of Tennessee, Health Science Center, Memphis, Tennessee 38103. Received June 12, 2008; Revised Manuscript Received December 4, 2008

The objective was to determine whether bioconjugation of type I collagen specific triplex forming oligonucleotide (TFO) to N-(2-hydroxypropyl) methacrylamide (HPMA) containing tetrapeptide Gly-Phe-Leu-Gly (GFLG) and mannose 6-phosphate (M6P) can provide their targeted delivery to hepatic stellate cells (HSCs). Following bioconjugation, M6P-GFLG-HPMA-GFLG-^{32}P-TFO was characterized by PAGE, HPLC, and GPC, and then its biodistribution was determined. TFO was dissociated from the conjugate when incubated with papain and formed triplex with the target DNA duplex. Type 1 collagen gene expression was significantly inhibited when HSC-T6 cells were transfected with this conjugate. Following tail vein injection into rats, M6P-GFLG-HPMA-GFLG-^{32}P-TFO was rapidly cleared from the circulation and accumulated mainly in the liver. The plasma concentration versus time profile was biphasic, with 12.37 min as $t_{1/2}$ of distribution and 2886.48 min as $t_{1/2}$ of elimination. A large proportion of the injected M6P-GFLG-HPMA-GFLG-^{32}P-TFO was taken up by the HSCs of both normal and fibrotic rats, which were isolated by liver perfusion at 30 min post-injection. Preinjection of M6P-GFLG-HPMA-GFLG-ONP into fibrotic rats decreased the liver uptake of the conjugates from 60% to 13%, suggesting M6P/TGFII receptor-mediated endocytosis of the conjugates by HSCs. Almost 80% of the total liver uptake in fibrotic rats was contributed by HSCs. In conclusion, conjugation with M6P-HPMA-GFLG significantly increased TFO delivery to the HSCs and could be potentially used for treating liver fibrosis.

INTRODUCTION

Chronic liver injury and inflammation of hepatocytes may lead to overproduction of type I collagen and other extracellular matrix (ECM) by hepatic stellate cells (HSCs), which are distributed throughout the hepatic lobule and serve as the principle fibrogenic cells (*1*). Activation of HSCs affects liver architecture and eventually liver function (*2*). Until now, no pharmaceutical intervention is available to treat this fibrotic disease (*3*). The application of most antifibrotic drugs has not been successful, partly because these drugs do not accumulate in the target liver cells or cause serious side effects elsewhere in the body. Alteration of the pharmacokinetic profiles of antifibrotic drugs by means of drug targeting represents a promising approach in the development of an effective antifibrotic drug (*4*).

Direct inhibition of type I collagen synthesis by HSCs is a potential target to prevent liver fibrosis. Earlier, we developed a triplex-forming oligonucleotide (TFO), which can form a triplex with the target sequence (C1) located in the rat α1(I) collagen gene promoter and inhibit the transcription of this gene (*5*). Mannose-6-phosphate/insulin-like growth factor II (M6P/IGFII) receptor is expressed on HSCs, and its expression is upregulated upon activation of these cells due to acute or chronic liver injury (*6*). Therefore, this TFO molecule is a potential candidate for treating liver fibrosis.

Following systemic administration, oligonucleotides (ODNs) widely distribute throughout the body with higher accumulation in the liver and kidney (*7*−*9*). We determined the in vivo distribution of the TFO molecules in normal and fibrotic rats (*10*). Almost 45% of the injected dose was accumulated in the liver at 30 min post-tail vein injection in normal rats, but only 35% of the injected dose in fibrotic rats. Since the intrahepatic distribution of the TFO was nonspecific, we synthesized mannose-6-phosphate−bovine serum albumin (M6P-BSA) and conjugated to TFO via a disulfide bond for its enhanced delivery to HSCs (*11*). Since the treatment of liver fibrosis may require repeated injections of TFO at high dose, high molecular weight globular BSA (66430 Da) may not be a suitable carrier for TFO delivery to the HSCs due to possible immune reaction. *N*-(2-Hydroxypropyl) methacrylamide (HPMA) copolymer has shown great potential for delivery of small molecular drugs (*12*−*14*). Although HPMA has also been used for oligonucleotide delivery, no targeting ligands were used for its site-specific delivery to target cells, and its biodistribution and uptake by different liver cell types was not determined after systemic administration. Even though biodistribution of oligonucleotides to the liver has been reported before (*15*−*17*), the authors did not determine oligonucleotides delivery to HSCs, which are the principal liver fibrotic cells.

In this study, we conjugated M6P to HPMA and then to TFO via GFLG linker, which is known to be cleaved by lysosomal enzymes (*15*). Following bioconjugation and purification, we determined (i) whether TFO can be released from the conjugate

after cellular uptake and (ii) biodistribution of M6P-GFLG-HPMA-GFLG-^{32}P-TFO at the whole body, organ (liver), and cellular (liver cells) levels after tail vein injection into rats.

EXPERIMENTAL PROCEDURES

Materials. Poly (HPMA-*co*-GFLG-ONP) was purchased from Varian Inc. (Amherst, MA). *p*-Nitrophenyl-α-D-mannopyranoside (pnpM), phosphorus oxide chloride, palladium (10 wt % on activated carbon), papain, methylene blue, *N*,*N*′-diisopropylethylamine, Histodenz (nycodenz), and pronase were purchased from Sigma-Aldrich (St. Louis, MO). Sephadex G75 (superfine) was procured from Pharmacia Fine Chemicals AB (Uppsala, Sweden). Dialysis tubing (molecular weight cutoff of 1000 Da) was purchased from Spectrum Laboratories, Inc. (Houston, TX). BioGel *P*6 DG Gel was from Bio-Rad Laboratories (Hercules, CA). [γ-^{32}P]-dATP was purchased from MP Biomedicals (Irvine, CA), and T4 polynucleotide kinase was from New England Biolabs (Beverly, MA). Soluene-350 (tissue solubilizer) and HionicFluor (scintillation fluid) were purchased from Perkin-Elmer (Boston, MA). Hydrogen peroxide (H_2O_2) was purchased from Fisher Chemical (Fair Lawn, NJ). Heparin was purchased from American Pharmaceutical Partners, Inc. (Los Angeles, CA). Ca^{2+}/Mg^{2+}-free Hank's balanced salt solution (Cellgro) was purchased from MediaTech (Washington, DC), and type IV collagenase was from Worthington Biochemical Corporation (Lakewood, NJ). Isoflurane was purchased from Baxter Pharmaceutical Products, Inc. (Deerfield, IL). TFO, which was a 25mer antiparallel fully phosphorothioate ODN (3′-GAGGGGGGAGGAGGGAAAGGAAGGG-5′) targeting rat α1 (I) collagen gene promoter, and TFO-3′-NH_2 were synthesized by Invitrogen (Carlsbad, CA). All solvents and chemicals used in this study were used as available without further purification.

Animals. Male Sprague−Dawley rats weighing 130−150 g were purchased from Harlan Co. (San Diego, CA) and were housed individually under the controlled light (12/12 h) and temperature conditions and had free access to food and water.

Synthesis of *p*-Isothiocyanatophenyl-6-phospho-α-D-mannopyranoside. *p*-Nitrophenyl-α-D-mannopyranoside (pnpM) (3 g, 10 mmol) was dissolved in pyridine (4 mL, 50 mmol), acetonitrile (10 mL, 190 mmol), and water (0.4 mL, 22 mmol). To this solution, phosphorus oxide chloride (4 mL, 44 mmol) was added, and the mixture was stirred for 1 h at 0 °C. The reaction mixture was poured onto 120 g of ice. pH was adjusted to 7.0 by slowly adding 2.5 M NaOH on ice, and the neutralized solution was evaporated to dryness. The solid material was dissolved in 150 mL water. The solution was concentrated under reduced pressure at 35 °C in a rotary evaporator to a final volume of 3−4 mL. The concentrated solution was kept at 4 °C overnight for crystallization and crystals was filtered and washed with 10 mL absolute ethanol. The compound was recrystallized from a 10 mL water/100 mL ethanol mixture, redissolved in water, and lyophilized to give *p*-nitrophenyl-6-phospho-α-D-mannopyranoside (pnpM6P). pnpM6P (1 mmol) was dissolved in 20 mL of a 4:1 (v/v) methanol−water mixture. To this solution, 30 mg of 10% palladium on activated carbon was added. The suspension was stirred under hydrogen (1 atm) at room temperature for 2 h. After filtration, the methanolic solution was evaporated under reduced pressure at 40 °C and lyophilized to give *p*-aminophenyl-6-phospho-α-D-mannopyranoside (papM6P).

Synthesis of M6P-GFLG-HPMA-GFLG-TFO Conjugate. The synthesis scheme of M6P-GFLG-HPMA-GFLG-TFO is shown in Figure 1. Poly(HPMA-*co*-MA-GFLG-ONP) (5 mg, 2.25 μmol of ONP) and TFO-NH_2 (0.8 mg, 0.1 μmol) were dissolved in anhydrous dimethyl sulfoxide (DMSO, 100 μL). Then, *N*,*N*′-diisopropylethylamine (DIPEA, 3 μL) was added and reacted overnight at room temperature. papM6P (3 mg, 10 μmol) was dissolved in H_2O (100 μL) and dimethyl sulfoxide (DMSO) (200 μL) mixture, and DIPEA (3 μL) was added.

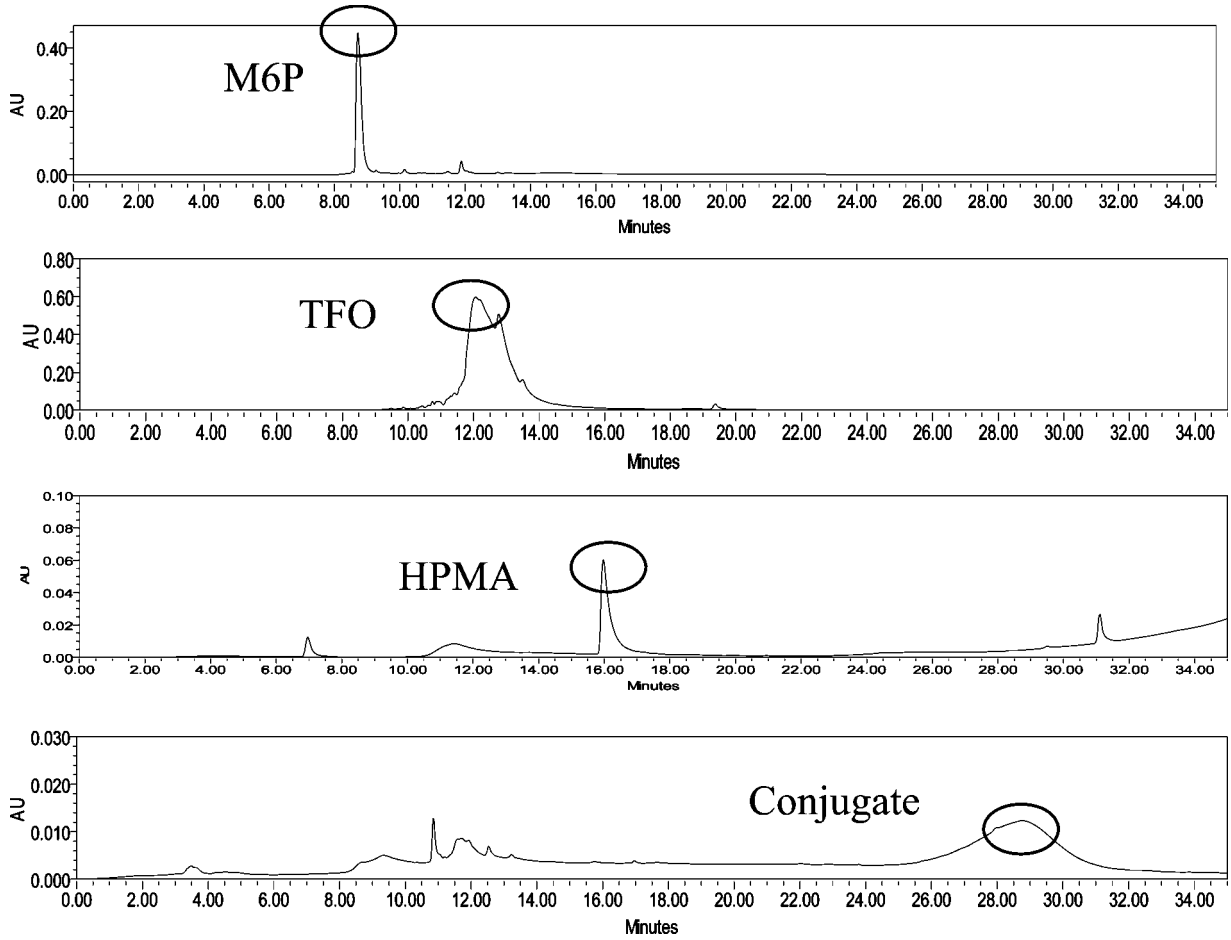

Figure 2. HPLC chromatography of M6P-GFLG-HPMA-GFLG-TFO conjugate. There is a new peak for conjugate different from the reactants, such as M6P, poly(HPMA-*co*-GFLG-ONP), and TFO.

Reaction was allowed to proceed for 24 h at room temperature. The reaction mixture was dialyzed against H_2O for a day, purified on a Sephadex G75 Gel column with pure water, freeze−dried, kept at −80 °C, and resuspended in 0.9% saline before use.

In Vitro Characterization. The purity of intermediate and final products was monitored by reverse phase-high performance liquid chromatography (RP-HPLC), which was carried on Altech Prosphere C18 column (250 mm × 4.6 mm × 5 μm) by Waters Breeze HPLC/GPC system (Waters, Milford, MA) with detection at 260 nm using a gradient of 40% to 100% acetonitrile in 0.1 M triethylammonium acetate (TEAA) at a flow rate of 1 mL/min at room temperature. M6P-GFLG-HPMA-GFLG-^{32}P-TFO was analyzed by 20% polyacrylamide gel electrophoresis (PAGE) at 80 V for 2 h. The gels were stained with methylene blue or autoradiographed.

The molecular weight of M6P-GFLG-HPMA-GFLG-TFO was also measured by gel permeation chromatography (GPC), which was carried on Waters Ultrahydrogel 250 column (7.8 × 300 mm) by Waters Breeze HPLC/GPC system (Waters, Milford, MA) with Waters 2414 Refractive Index detector and mobile phase containing 0.02% sodium azide (NaN_3) in HPLC water, at a flow rate of 0.5 mL/min. Polyethylene oxide (PEO) of different molecular weights (MW = 20 000, 31 380, 50 450, and 71 700 Da) was used as standard for calibration. HPMA-*co*-MA-ONP was used as a positive control and the molecular weight of M6P-GFLG-HPMA-GFLG-TFO was determined.

Determination of Sugar Content. Sugar content was determined by the resorcinol−sulfuric acid method (*18*). 200 μL of 6 mg/mL resorcinol and 1 mL of 75% sulfuric acid were added to M6P-GFLG-HPMA-GFLG-TFO solution containing 5−100 nmol of sugar in 200 μL. The mixtures were vortexed and heated at 90 °C for 30 min and subsequently placed in a cold-water bath for 30 min in the dark. The optical density of the solution was measured at 430 nm. PnpM was used to generate the standard curve to calculate the number of M6P per conjugate.

In Vitro Enzymatic Dissociation and Triplex Formation of M6P-GFLG-HPMA-GFLG-^{32}P-TFO. To determine whether TFO will be dissociated from M6P-GFLG-HPMA-GFLG-TFO conjugate after cellular uptake, papain (10 μM), glutathione (GSH, 250 mM), and M6P-GFLG-HPMA-GFLG-^{32}P-TFO (TFO concentration 100 μM) were incubated together at 37 °C in 0.1 M phosphate buffer containing 1 mM EDTA (PE buffer, total volume of 300 μL). At 1, 2, 8, and 24 h, 100 μL of the sample was collected and analyzed by 20% PAGE at 80 V for 2 h, followed by autoradiography.

To determine whether the TFO released from M6P-GFLG-HPMA-GFLG-TFO can still form triplex, the target duplex DNA was prepared by equal amounts of ODNs, T1: 5′-GAG GGG GGA GGA GGG AAA GGA AGG GAA AGG-3′ and T2: 5′-CCT TTC CCT TCC TTT CCC TCC TCC CCC CTC-3′, being heated at 80 °C for 5 min in 0.25 M NaCl, followed by slow cooling to room temperature. Triplex formation was initiated by the mixing of 3 μL of 3× buffer [135 mM Tris−acetate, pH 7.0, 30 mM $MgCl_2$], 3.5 μL of duplex DNA (∼3 μg), and 2.5 μL of the released ^{32}P-TFO (∼1 × 10^5 cpm). The reaction mixture was incubated at 37 °C for another 24 h. Two microliters of a 50% glycerol solution containing bromophenol blue was added, and samples were directly loaded

onto 15% native polyacrylamide gel, prepared in a buffer containing 50 mM Tris−acetate, pH 7.0, and 10 mM $MgCl_2$. Electrophoresis was performed at 8 V/cm at 4 °C in the buffer containing 89 mM Tris−Borate and 20 mM $MgCl_2$. The gel was autoradiographed at 4 °C overnight.

Transfection of TFO and M6P-GFLG-HPMA-GFLG-TFO. Immortalized rat hepatic stellate cells (HSC-T6) kindly provided by Dr. Scott Friedman of Mount Sinai School of Medicine, New York, were seeded in 6-well plates at a density of 11×10^5 cells for 12 h until 50% confluence in DMEM containing 10% of FBS. The growth medium was replaced with a prewarmed serum-free DMEM medium. TFO was mixed with pyridinium cationic liposome at 3/1 (±) charge ratio and then used for transfection at the dose of 5 μg TFO/well. For the conjugate, M6P-GFLG-HPMA-GFLG-TFO was dissolved in saline and applied to the cells at the dose of 5 μg TFO. Negative control wells were added the same amount M6P-GFLG-HPMA. Six hours later, 10% FBS was added to each well, and then the cells were cultured for additional 72 h. Following transfection, the cell culture medium was concentrated using Microcon YM-30 columns (Millipore) to retain proteins of >30 kDa. The concentrated medium was lysed using 2× Laemmli sodium dodecyl sulfate (SDS) sample buffer containing 100 mM Tris, pH 6.8, 200 mM dithiothreitol (DTT), 4% SDS, 20% glycerol, and 0.2% bromophenol blue. To detect β-actin, which was used as an intrinsic reference of sample loading, the cells were lysed directly with 1× Laemmli SDS sample buffer. The lysate samples were boiled at 100 °C for 5 min and subjected to 4% to 15% SDS-polyacrylamide (SDS-PAGE) gel electrophoresis and subsequently transferred to Immobilon polyvinylidene fluoride (PVDF) membrane (Millipore). After blocking with 5% nonfat dried milk in 1× PBST containing 0.05% Tween-20 in PBS for 1 h at room temperature, the membrane was incubated with goat antirat type I collagen and β-actin primary antibodies (Santa Cruz) for 16 h at 4 °C. The membranes were then incubated with horseradish peroxidase (HRP)-conjugated donkey antigoat secondary antibody (Santa Cruz) for 1 h at room temperature. Target proteins were detected by enhanced chemiluminescence (ECL, GE Healthcare).

Biodistribution of M6P-GFLG-HPMA-GFLG-^{32}P-TFO. The animal protocol was approved by the Animal Care and Use Committee (ACUC), Department of Comparative Medicine, University of Tennessee Health Science Center, Memphis, TN 38163. Male Sprague−Dawley rats weighing 130−150 g were used in this study, and three rats were used for each time point. Unlabeled and M6P-GFLG-HPMA-GFLG-^{32}P-TFO were mixed in saline to give a final concentration of 1 mg/mL and specific activity of 1×10^6 cpm/mL. Rats were anesthetized by inhalation of isoflurane, and M6P-GFLG-HPMA-GFLG-^{32}P-TFO was injected via tail vein at a dose of 0.2 mg/kg body weight. At 2.5, 5, 15, 30, 60, and 90 min postinjection, 0.5 mL blood was collected by cardiac puncture in heparinized tubes, and urine was collected directly from the bladder using a 0.26 gauge needle syringe. The animals were then sacrificed, and major tissues (liver, kidney, spleen, heart, and lung) were collected, washed, blotted dry, weighed, and stored at −80 °C. The radioactivity of the urine sample was counted directly after adding 10 mL of scintillation fluid. 150 μL of plasma and 150 mg of each tissue were incubated with 2 mL tissue solubilizer for 3 h at 55 °C and overnight at 37 °C in a shaker. 400 μL of H_2O_2 was added and incubated at 55 °C for another 30 min. Ten milliliters of scintillation fluid was added to each sample and the radioactivity was counted using a liquid scintillation counter.

Determination of Pharmacokinetic Profiles. Plasma data were analyzed using *WinNonlin Professional* (version 5.2, Pharsight Corporation, Mountain View, CA). M6P-GFLG-HPMA-GFLG-^{32}P-TFO plasma concentration data versus time were fitted into a two-compartment model, where

$$\frac{dx_1}{dt} = k_{21} \times X_2 - (k_{10} + k_{12})X_1 = \frac{d\,C_p}{d\,t} \times V_1 \quad (1)$$

$$\frac{d\,x_2}{d\,t} = k_{21} \times X_1 - k_{21} \times X_1 = \frac{d\,C_t}{d\,t} \times V_2 \quad (2)$$

where X_1 is amount of drug in the central compartment, and X_2 is the amount of the drug in the peripheral compartment. Since we assumed that elimination only occurred from the central compartment, k_{12} and k_{21} are the rate constants for efflux from the plasma to tissues and from tissues to the plasma, respectively. k_{10} is the elimination constant of the central compartment. The change in the amount of radioactivity of M6P-GFLG-HPMA-GFLG-^{32}P-TFO in the plasma with time can be described as a biexponential equation.

$$C_p(t) = A \times e^{-\alpha t} + B \times e^{-\beta t} \quad (3)$$

where α and β are the hybrid constants for distribution and elimination, respectively. C_p represents the plasma concentration at time t; A and B are the Y-axis intercepts, where

$$A = \frac{\text{dose} \times (\alpha - k_{21})}{V_1 \times (\alpha - \beta)} = \frac{\text{dose} \times (k_{21} - \beta)}{V_1 \times (\alpha - \beta)} \quad (4)$$

The change in the amount of radioactivity in a tissue with time can be described as follows:

$$Q(t) = \frac{\text{dose} \times k_{12}}{V_2 \times (\alpha - \beta)}(e^{-\alpha t} - e^{-\beta t}) \quad (5)$$

where $Q(t)$ (% of dose/g) represents the amount of radioactivity in 1 g of the tissue, and $C_p(t)$ (% of dose/mL) is the plasma concentration of radioactivity.

$$\frac{dQ(t)}{dt} = k_{12} \times C_p(t) - k_{21} \times C_t(t) \quad (6)$$

where k_{12} (h^{-1}) and k_{21} (h^{-1}), as mentioned above, are the rate constants for efflux from the plasma to the tissue and from the tissue to the plasma, respectively. In the present study, the efflux process can be considered negligible during the initial time points up to 90 min. Hence, eq 6 integrates to

$$k_{12} = \frac{Q(t_1)}{\int_0^{t_1} C(t)\,dt} = C_t(t_1)/\text{AUC}_{0-t_1} \quad (7)$$

From eq 7,

$$\text{CL}_{\text{in}} = \frac{Q(t_1)}{\int_0^{t_1} C(t)\,dt} = Q(t_1)/\text{AUC}_{0-t_1} \quad (8)$$

where t_1 (h) is the sampling time. $C(t)$ (μg TFO/mL plasma) is the plasma concentration of radioactivity, and CL_{in} ($mL \cdot h^{-1} \cdot g^{-1}$) is the tissue uptake rate index from the plasma to the tissue. According to eq 8, the tissue uptake rate index is calculated using the amount of radioactivity in the tissue and the area under the plasma concentration−time curve (AUC). Then, the organ clearance (CL_{org}) is expressed as follows:

$$\text{CL}_{\text{org}} = \text{CL}_{\text{in}} \times W \quad (9)$$

where W (g) is the total weight of the organ. When the tissue uptake process followed nonlinear kinetics, CL_{in} values would represent an average value for the overall experimental period. Total body clearance (CL_{total}) was calculated from AUC for infinite time (AUC_∞) by the following equation:

$$\text{CL}_{\text{total}} = \text{Dose}/\text{AUC}_\infty \quad (10)$$

The tissue uptake clearance and index were calculated using the values up to 90 min after injection, assuming that TFOs were fairly stable within this period.

Induction of Liver Fibrosis. Dimethylnitrosamine (DMN) induced liver fibrosis in rats has been shown to have a pathology closely resembling that of human cirrhosis. Male Sprague−Dawley rats weighing 130−150 g (Harlan Co., San Diego, CA) were housed individually under controlled light (12/12 h) and temperature conditions and had free access to food and water. To induce liver fibrosis, DMN was injected intraperitoneally into rats at a dose of 10 mg/kg of body weight in saline. Injections were given in the afternoons of the first 3 consecutive days of each week for 4 weeks.

Competition in Hepatic Uptake of M6P-BSA-^{32}P-TFO. Two minutes before the injection of M6P-GFLG-HPMA-GFLG-^{32}P-TFO at a TFO dose of 0.2 mg/kg (specific activity: 1×10^6 cpm/mL), liver fibrotic rats received 10 mg/kg of $(M6P)_{16}$-GFLG-HPMA. At 30 min postinjection, blood and other major organs were harvested as described above for radioactivity measurement.

Isolated Rat Liver Perfusion. To determine the effect of M6P on the hepatic uptake of TFOs by hepatocytes, HSCs, Kupffer, and endothelial cells, the livers of normal and fibrotic rats were perfused in situ after intravenous administration of M6P-GFLG-HPMA-GFLG-^{32}P-TFO, HPMA-GFLG-^{32}P-TFO, or ^{32}P-TFO at the dose of 0.2 mg of TFO/kg body weight. At 30 min postadministration, rats (200−250 g) were anesthetized by inhalation of isoflurane, 100 U heparin was injected via the tail vein, the abdomen was opened, and the portal vein was cannulated with a PE-60 polyethylene tube. The liver was first perfused with 2 mL of diluted heparin solution at 20 units/mL to avoid blood clots in the liver. The liver was preperfused in situ with 200 mL of Ca^{2+}/Mg^{2+}-free Hank's balanced salt solution at a flow rate of 15 mL/min and was then perfused with Hank's balanced salt solution containing 0.05% type IV collagenase and 0.1% Pronase for an additional 250 mL at a flow rate of 10 mL/min. All the perfusion solutions were incubated at 37 °C. After perfusion, different liver cell types were separated and radioactivity was measured as described by Cheng et al. (*10*). The contributions of various cell types to the total liver accumulation were calculated as the percentage of total hepatic uptake.

Statistical Analysis. Data were expressed as the mean ± standard deviation (SD). The difference between any two groups was determined by ANOVA. $p < 0.05$ was considered statistically significant.

RESULTS

Synthesis and in Vitro Characterization of M6P-GFLG-HPMA-GFLG-^{32}P-TFO. The synthesis scheme of M6P-GFLG-HPMA-GFLG-TFO is shown in Figure 1. *p*-Nitrophenyl-α-D-mannopyranoside (pnpM) was phosphorylated to give *p*-nitrophenyl 6-phospho-α-D-mannopyranoside (pnpM6P). This intermediate product was characterized by electron spray ionization−mass spectrum (ES-MS) as described before (*11*) (data not shown). RP-HPLC was used to monitor the purity of the intermediate and final products. From the RP-HPLC chromatograms of M6P, TFO, HPMA, and M6P-GFLG-HPMA-GFLG-TFO (Figure 2), almost all free M6P and TFOs were removed from the conjugate after purification. M6P-GFLG-HPMA-GFLG-TFO was separated from free TFO using a G75 column. As shown in Figure 2, M6P-GFLG-HPMA-GFLG-^{32}P-TFO conjugate was eluted earlier than ^{32}P-TFO. PAGE analysis of M6P-GFLG-HPMA-GFLG-^{32}P-TFO also confirmed successful conjugation and purity of the conjugate. As shown in Figure 3, unlike free TFO, there was no band shift for the conjugate. We also measured the molecular weight of M6P-GFLG-HPMA-GFLG-TFO by gel permeation chromatography (GPC) and determined that molecular weight was 51 418 Da, which matched well with the calculated molecular weight of 51 362 Da. Although poly(HPMA-*co*-GFLG-ONP) contains 8.33 mol % of ONP, the average number of M6P per conjugate was determined to be 14.67.

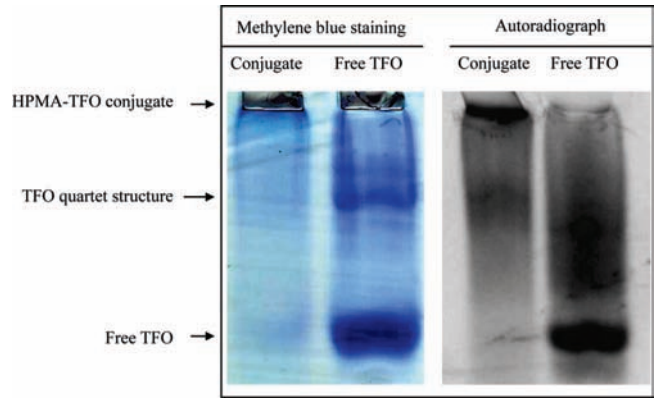

Figure 3. Polyacrylamide gel electrophoresis (PAGE) of M6P-GFLG-HPMA-GFLG-TFO. (A) Methylene blue staining. (B) Autoradiography. There was no band shift for the conjugate.

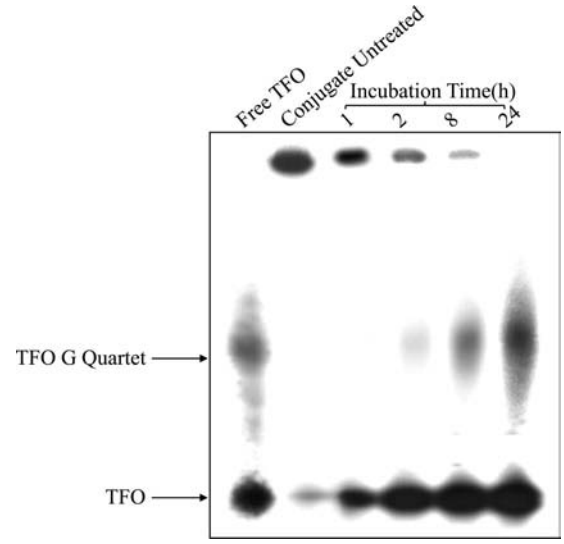

Figure 4. TFO dissociation from M6P-GFLG-HPMA-GFLG-TFO by papain. The conjugate was treated with papain for 1, 2, 8, and 24 h, followed by polyacrylamide gel electrophoresis (PAGE) and autoradiography. The conjugate not treated with papain was used as a control.

In Vitro Enzymatic Dissociation and Triplex Formation of M6P-GFLG-HPMA-GFLG-^{32}P-TFO. To determine whether TFO can be dissociated from M6P-GFLG-HPMA-GFLG-^{32}P-TFO endocytosis in the lysosome, the radioactivity was measured after polyacrylamide gel electrophoresis and autoradiography at 1, 2, 8, and 24 h post-incubation of the conjugate with papain at 37 °C (*19*). The band of the conjugate gradually disappeared along the incubation time (Figure 4). In contrast, this conjugate resulted in no band shift in the absence of papain.

GFLG linker is expected to be stable in the bloodstream but cleaved inside the cells by enzymatic dissociation by lysosomal enzymes (*20*). The release from the M6P-GFLG-HPMA-GFLG-TFO conjugate will enable TFO to traffic to the nucleus for triplex formation with genomic DNA. There should be no adverse effect on triplex formation due to this conjugation and cleavage. The M6P-GFLG-HPMA-GFLG-TFO conjugate was treated with papain and incubated with the target duplex DNA for another 24 h, and the sample was then applied on a 15%

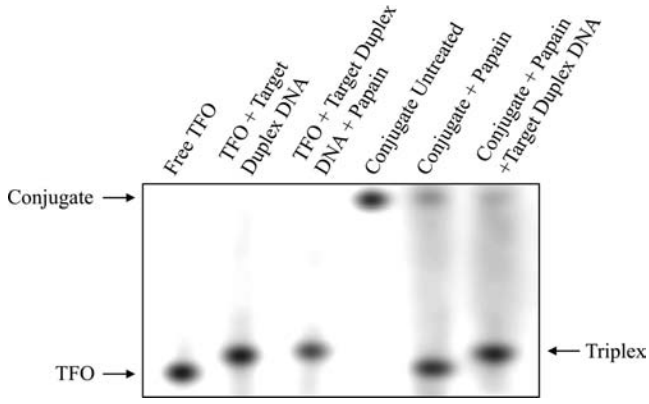

Figure 5. Triplex formation with target duplex DNA after release from M6P-GFLG-HPMA-GFLG-^{32}P-TFO conjugate. Samples were applied on 15% native PAGE at 4 °C in 89 mM Tris−borate buffer, containing $MgCl_2$ (20 mM) for 4 h. Lane 1: ^{32}P-TFO. Lane 2: duplex DNA/^{32}P-TFO (200:1) incubated for 24 h. Lane 3: Duplex DNA/^{32}P-TFO (200:1) and papain incubated for 24 h. Lane 4: M6P-GFLG-HPMA-GFLG-^{32}P-TFO. Lane 5: M6P-GFLG-HPMA-GFLG-^{32}P-TFO incubated with papain for 24 h at 37 °C. Lane 6: duplex DNA/M6P-GFLG-HPMA-GFLG-^{32}P-TFO (200:1) incubated for 24 h at 37 °C with papain.

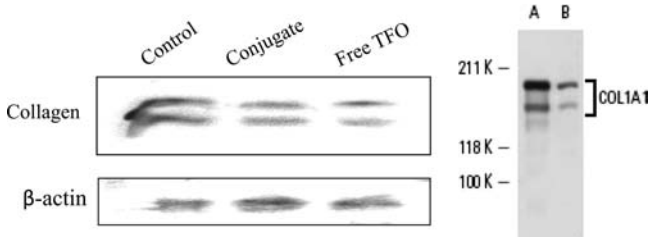

Figure 6. Inhibition of collagen gene expression. Transfection of HSC-T6 cells with TFO (lane 3) and M6P-GFLG-HPMA-GFLG-TFO (lane 2) inhibited collagen gene expression compared to the control group (lane 1). Western blot analysis of collagen primary antibody provided Santa Cruz is also shown in the right figure.

native polyacrylamide gel at 4 °C. Following electrophoresis, the gel was autoradiographed at 4 °C overnight. As shown in Figure 5, there was triplex formation observed with target duplex DNA not only for free TFO (lane 2) but also for released TFO (lane 6), which was at a molar ratio of 200 between duplex DNA and TFO.

Inhibition of Collagen type I Gene Expression by M6P-GFLG-HPMA-GFLG-TFO. To confirm that TFO conjugation to M6P-HPMA does not adversely affect its ability to inhibit the transcription of type I collagen, we transfected HSC-T6 cells with TFO and M6P-GFLG-HPMA-GFLG-TFO. Compared to the control cells treated with M6P-HPMA (lane 1), type I collagen gene expression by the cells treated with M6P-GFLG-HPMA-GFLG-TFO (lane 2) decreased as efficiently as that by the cells treated with the TFO (lane 3) (Figure 6). Since the molecular weight of collagen type 1 precursor is 130−140 kDa and that of mature collage type 1 is 70−90 Da, there were 2 bands for collagen, which is in good agreement with the supplier's Western blot analysis.

Biodistribution of M6P-GFLG-HPMA-GFLG-TFO. Following synthesis and purification of M6P-GFLG-HPMA-GFLG-^{32}P-TFO, we determined the biodistribution of this conjugate at 2.5, 5, 15, 30, 60, and 90 min post-injection into the rat tail vein. Figure 7 shows the time course of radioactivity in the plasma, urine, liver, kidney, lung, and heart. Conjugation with M6P-GFLG-HPMA-GFLG-ONP significantly increased the accumulation of ^{32}P-TFO in the liver, as compared to our previously reported biodistribution data of free ^{32}P-TFO (*10*). Almost 70% of the conjugate accumulated in the liver at 30

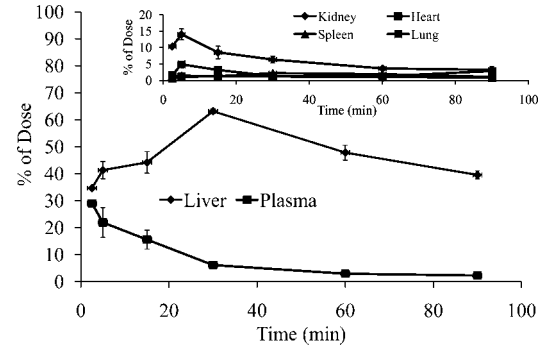

Figure 7. Biodistribution of M6P-GFLG-HPMA-GFLG-^{32}P-TFO and free ^{32}P-TFO after tail vein injection into rats at a dose of 0.2 mg TFO/kg of body weight.

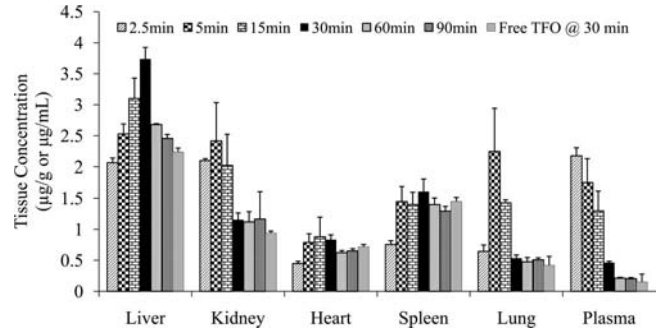

Figure 8. Concentration time profiles of radioactivity in different organs and the plasma after tail vein injection of M6P-GFLG-HPMA-GFLG-^{32}P-TFO and free ^{32}P-TFO into rats at a dose of 0.2 mg TFO/kg of body weight.

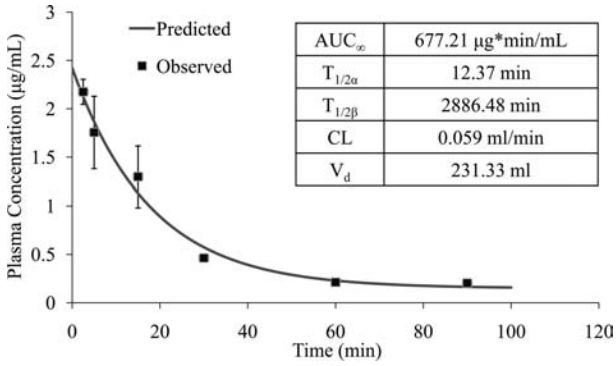
min post-injection and 60% at 60 min post-injection (Figure 7); however, only 40% of free ^{32}P-TFO was in the liver at 30 min (*10*). Figure 8 shows the tissue concentration of M6P-GFLG-HPMA-GFLG-^{32}P-TFO in the plasma (μg/mL) and tissues (μg/g) after tail vein injection into rats. The conjugation with M6P-GFLG-HPMA-GFLG-ONP significantly increased the accumulation of radioactivity in the liver and was highest at 30 min post-injection. The conjugate concentration was high not only in the liver, but also in the spleen and kidney. However, radioactivity in the kidney rapidly decreased with time. We also included the tissue accumulation data of ^{32}P-TFO at 30 min post-injection for comparison.

We also calculated the pharmacokinetic profiles using a two-compartment model by plotting plasma concentration versus time, analyzing data using *WinNonlin* professional software. As shown in Figure 9, there was good fit between observed and predicted results. Plasma elimination of M6P-GFLG-HPMA-GFLG-^{32}P-TFO was biphasic with a distribution half-life ($T_{1/2\alpha}$) of 12.37 min and elimination half-life ($T_{1/2\beta}$) of 2886.48 min. Figure 9 also summarizes the pharmacokinetic parameters such as AUC, V_d, and CL. Consistent with the rapid clearance (0.059 mL/min), M6P-GFLG-HPMA-GFLG-^{32}P-TFO had a large V_d of 231.33 mL; Table 1 summarizes the AUC, tissue uptake rate index, and organ clearance for representative organs at 90 min after systemic administration of ^{32}P-TFO and M6P-GFLG-HPMA-GFLG-^{32}P-TFO in rats. The liver uptake rate indices and clearance of the conjugate were significantly higher than those of ^{32}P-TFO: 2176 ± 58 vs 376 ± 38 μL h^{-1}g^{-1} and 11 531 ± 308 vs 2218 ± 206 μL/h, respectively. The tissue uptake rate indices and organ clearances of heart, kidney, and lung were significantly higher than those of ^{32}P-TFO, possibly due to an increase in the in vivo stability of TFO upon conjugation with M6P-GFLG-HPMA-GFLG-ONP.



AUC_∞	677.21 μg*min/mL
$T_{1/2\alpha}$	12.37 min
$T_{1/2\beta}$	2886.48 min
CL	0.059 ml/min
V_d	231.33 ml

Figure 9. Pharmacokinetic profiles of M6P-GFLG-HPMA-GFLG-^{32}P-TFO at 30min after post vein injection. Plasma data was analyzed using a two-compartment model with *WinNonlin Enterprise* (v 5.2) software. AUC = area under the curve; CL = clearance; V_d = volume of distribution.

Effect of Fibrosis on Biodistribution. We recently reported significant decrease in the hepatic uptake of ^{32}P-TFO when injected into fibrotic rats (*10*). To make sure that there is no decrease in the hepatic uptake of M6P-GFLG-HPMA-GFLG-^{32}P-TFO, we determined the biodistribution of this conjugate at 30 min post-injection in fibrotic rats. To exclude the possibility that HPMA, the backbone, is not involved in the specific uptake of the TFO, we also determined the biodistribution of HPMA-GFLG-^{32}P-TFO at 30 min post-injection. There was no decrease in the hepatic uptake of M6P-GFLG-HPMA-GFLG-^{32}P-TFO in fibrotic rats (Figure 10). As expected, HPMA-GFLG-^{33}P-TFO accumulation in the liver was much lower than that of M6P-GFLG-HPMA-GFLG-^{32}P-TFO and decreased when fibrotic rats were used (Figure 10). This may be due to the fact that M6P/IGFII receptors are up-regulated during fibrosis (*21*), which should increase the uptake by HSCs via receptor-mediated endocytosis and cancel out any adverse effect created by a decrease in the sinusoidal gap.

Competition in Hepatic Uptake. To determine whether the hepatic uptake of M6P-GFLG-HPMA-GFLG-^{32}P-TFO is mediated by M6P/IGFII receptor-mediated endocytosis, we preinjected an excess amount of $(M6P)_{16}$-GFLG-HPMA followed by injection of the conjugate in fibrotic rats. This resulted in a significant decrease in the hepatic uptake of the conjugate in fibrotic rats (Figure 11), possibly due to M6P/IGFII receptor-mediated endocytosis of the conjugates.

Hepatic Cellular Localization. To determine the uptake of M6P-GFLG-HPMA-GFLG-^{32}P-TFO by different liver cell types, the livers of normal and fibrotic rats were perfused at 30 min post tail vein injection, and hepatocytes, HSCs, Kupffers, and endothelial cells were isolated for determination of the amount of radioactivity in these cells. As shown in Figure 12, HSCs were the major site for the uptake of this conjugate. Furthermore, the uptake of M6P-GFLG-HPMA-GFLG-^{32}P-TFO by HSCs was significantly higher compared to that of free ^{32}P-TFO. Although there was no significant decrease in the overall hepatic recovery of M6P-GFLG-HPMA-GFLG-^{32}P-TFO, uptake by the HSCs of DMN-induced liver fibrotic rats was much higher than that of normal rats (79.63 ± 2.56% vs 51.55 ± 2.02%) (Figure 12). We also perfused the livers of both normal and fibrotic rats at 30 min post-injection of HPMA-GFLG-^{32}P-TFO and determined the intrahepatic distribution of the TFO by different liver cells. As can be seen in Figure 12, the conjugation of ^{32}P-TFO with GFLG-HPMA did not significantly increase the TFO uptake by HSCs of both normal and fibrotic rats, suggesting that the HPMA backbone is not involved in the specific uptake of the TFO.

DISCUSSION

Excessive production of extracellular matrix (ECM), primarily type I collagen, by activated HSCs is known to be one of the major causes of liver fibrosis (*1*). The entire region spanning from −140 to −200 of α1(I) collagen gene promoter exists as a symmetric polypurine−polypyrimidine tract in which the polypyrimidine sequence at −141 to −170 is called the C1 region present on the noncoding strand, whereas the adjacent polypurine sequence from −171 to −200 is called the C2 region located on the coding strand. The cis-acting element is the C1 and C2 regions, playing an important role in collagen transcription (*22*). We have previously demonstrated that TFOs could form a triplex in this region and inhibit the activity of the α1(I) collagen promoter in vitro (*5, 23*). In addition, TFOs have been shown to partly reverse fibrosis in a dimethylnitrosamine (DMN) induced liver fibrosis rats, indicating the therapeutic potential of these TFOs (*10*).

M6P is a ligand for the M6P/IGF II receptor, which is up-regulated in activated HSCs during liver fibrosis, enabling selective accumulation of M6P-conjugated carrier or drug molecules (*24*). M6P conjugation to albumin increased the uptake of M6P-BSA by HSCs in liver fibrotic rats (*25*). Conjugation of M6P to virus recombinant interleukein-10 (*v*IL-10) significantly increased the hepatic uptake of *v*IL-10 by the liver.

To avoid the use of polycations, Rajur et al. conjugated ODNs to asialoorosomucoid via a disulfide bond (*26*). However, this strategy is not suitable for the TFO, since direct conjugation of molecules to the TFOs often disrupts the triplex-forming ability of the TFOs, which is essential for transcription inhibition. Furthermore, liver fibrosis results in the loss of sinusoidal fenestrae, suggesting that particulate delivery systems may not be good for TFO delivery to the HSCs.

To avoid any nonspecific ionic interaction and the large particle size, we recently conjugated TFO to M6P-BSA via a disulfide bond and demonstrated enhanced uptake by the HSCs after systemic administration of M6P-BSA-TFO into normal and fibrotic rats (*27*). However, repeated administration of this conjugate is likely to cause an immune reaction due to BSA, and thus, we synthesized M6P-GFLG-HPMA-GFLG-ONP and conjugated to TFO, where GFLG is a lysosomally degradable tetrapeptide and thus will facilitate lysosomal release of TFO and its escape to the cytoplasm after cellular uptake. Following synthesis and characterization using RP-HPLC and GPC, we determined whether TFO could be dissociated from the conjugate by incubating M6P-GFLG-HPMA-GFLG-TFO with papain, and TFO release was monitored. As shown in Figure 4, free TFO release concentration increased with incubation time with papain, which is consistent with the literature (*20*). Papain is a cysteine protease hydrolase enzyme and belongs to the same family as cathepsin B, which is the most important enzyme in the lysosomes to cleave GFLG spacer (*17, 19, 20*).

To make sure the TFO released from the conjugate can form a triplex to the target duplex DNA, we incubated M6P-GFLG-HPMA-GFLG-TFO with papain for 24 h and then used the released TFO to form a triplex with the target duplex DNA. As can be seen in Figure 5, the TFO released from the conjugate formed a triplex with duplex DNA.

To confirm that TFO conjugation to M6P-GFLG-HPMA does not adversely affect its ability to inhibit the transcription of type I collagen, we transfected HSC-T6 cells with M6P-GFLG-HPMA-GFLG-TFO. Compared to the control cells treated with M6P-HPMA, type I collagen gene expression by the cells treated with M6P-GFLG-HPMA-GFLG-TFO decreased as efficiently as that by the cells treated with the TFO (Figure 6).

Table 1. Tissue Uptake Rate Index and Clearance of ^{32}P-TFO and M6P-GFLG-HPMA-GFLG-^{32}P-TFO after Systemic Administration into Rats

		tissue uptake rate index (μL/h/g)					organ clearance (μL/h)				
sample	AUC_{90} (μg min/mL)	liver	kidney	heart	spleen	lung	liver	kidney	heart	spleen	lung
conjugate	67.11	2176 ± 58	1033 ± 391	578 ± 31	1146 ± 68	450 ± 112	11531 ± 308	1137 ± 430	318 ± 17	436 ± 26	383 ± 26
TFO	95.15	376 ± 38	235 ± 29	49 ± 3	205 ± 10	55 ± 9	2218 ± 206	241 ± 41	23 ± 2	83 ± 7	42 ± 8

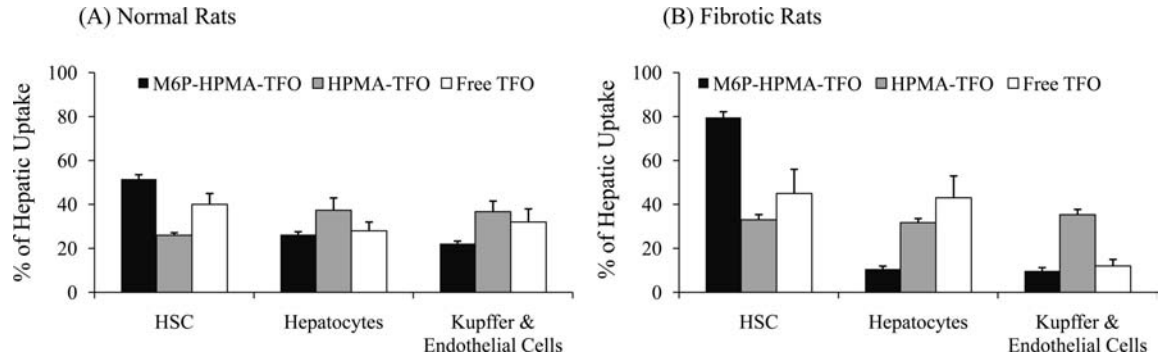


Figure 12. Intrahepatic distribution of M6P-GFLG-HPMA-GFLG-^{32}P-TFO in normal and fibrotic rats. The liver was perfused in situ by collagenase/Pronase digestion at 30 min post-injection of M6P-GFLG-HPMA-GFLG-^{32}P-TFO, HPMA-GFLG-^{32}P-TFO, or ^{32}P-TFO at dose of 0.2 mg TFO/kg of body weight. Hepatocytes, Kupffer and endothelial cells, and hepatic stellate cells (HSC) were separated, and the associated radioactivity was measured. The contribution of each liver cell type was exposed as percentage of total liver uptake. Results are expressed as the mean ± SD (n = 3).

Conjugation of TFO to M6P-GFLG-HPMA-GFLG-ONP significantly increased TFO delivery to the liver from 47% for ^{32}P-TFO to 70% for M6P-GFLG-HPMA-GFLG-^{32}P-TFO at 30 min post-injection. To determine whether the hepatic uptake of M6P-GFLG-HPMA-GFLG-^{32}P-TFO is mediated by M6P/IGF II receptor-mediated endocytosis, we preinjected rats with an excess amount of M6P-GFLG-HPMA-GFLG-ONP. This resulted in a significant decrease in the hepatic accumulation of this conjugate in fibrotic rats (Figure 11). This confirmed the receptor-mediated uptake of this conjugate, since the M6P/TGF II receptor is up-regulated in liver fibrotic rats; the hepatic accumulation was almost completely inhibiting by saturating this receptor. Rachmawati et al. also demonstrated almost 50% inhibition in the hepatic uptake of M6P-IL-10 conjugates in fibrotic rats (*28*).

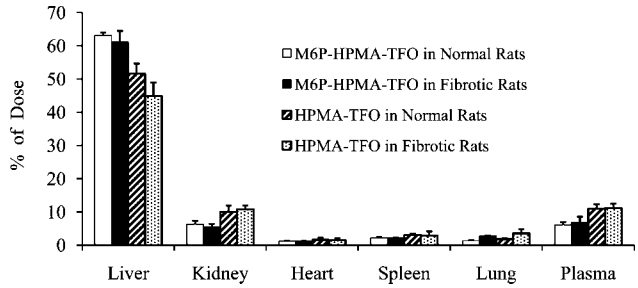

Figure 10. Effect of fibrosis on hepatic uptake of M6P-GFLG-HPMA-GFLG-^{32}P-TFO and HPMA-^{32}P-TFO after systemic administration into DMN-induced fibrotic rats. At 30 min post-injection of this conjugate (1×10^6 cpm) at a dose of 0.2 mg/kg, blood was collected by cardiac puncture. Rats were sacrificed; major organs were isolated, washed with saline, and subjected into scintillation counting. Values are the mean ± SD of 3 rats.

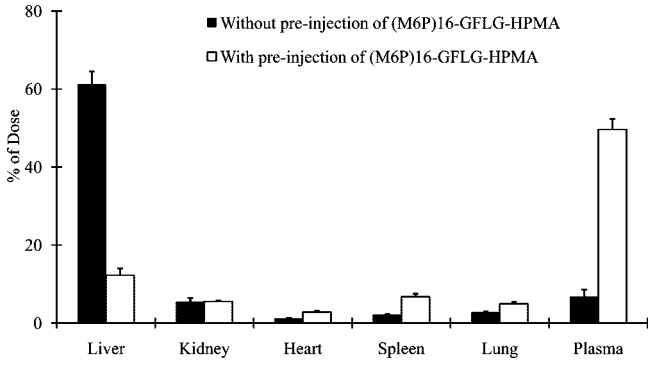

Figure 11. Effect of excess M6P-GFLG-HPMA on the biodistribution of M6P-GFLG-HPMA-GFLG-^{32}P-TFO in fibrotic rats.

To determine the hepatic cellular localization, the liver was perfused at 30 min post-injection of M6P-GFLG-HPMA-GFLG-^{32}P-TFO, HPMA-GFLG-^{32}P-TFO, or ^{32}P-TFO and different liver cells were separated by fractionation on the Histodenz gradient. As shown in Figure 12, almost 80% of the total liver uptake was contributed by HSCs cells of fibrotic rats, but only 55% by HSCs of normal rats. The percentage of uptake by hepatocytes was relatively low in both normal and fibrotic rats. However, the conjugation of TFO with GFLG-HPMA did not significantly increase the TFO uptake by HSCs of both normal and fibrotic rats (Figure 12); suggesting that the HPMA backbone is not involved in the specific uptake of the TFO.

In conclusion, conjugate with M6P-GFLG-HPMA-GFLG-ONP significantly enhanced the uptake of the TFO by HSCs, and thus, this conjugate may be suitable for inhibiting α1 (I) collagen gene expression by HSCs and may potentially treat liver fibrosis.

Optimizing a Waveguide-Based Sandwich Immunoassay for Tumor Biomarkers: Evaluating Fluorescent Labels and Functional Surfaces

Harshini Mukundan,[†] Hongzhi Xie,[†] Aaron S. Anderson,[†] W. Kevin Grace,[†] John E. Shively,[‡] and Basil I. Swanson*[,†]

MS: J567, Physical Chemistry and Applied Spectroscopy, Los Alamos National Laboratory, Los Alamos, New Mexico 87545, and Beckman Research Institute, City of Hope, 1450 East Duarte Road, Duarte, California 91010. Received July 8, 2008; Revised Manuscript Received November 25, 2008

The sensor team at the Los Alamos National Laboratory has developed a waveguide-based optical biosensor for the detection of biomarkers associated with disease. We have previously demonstrated the application of this technology to the sensitive detection of carcinoembryonic antigen in serum and nipple aspirate fluid from breast cancer patients. In this publication, we report improvements to this technology that will facilitate transition to a point-of-care diagnostic system and/or robust research tool. The first improvement involved replacing phospholipid bilayers used for waveguide functionalization with self-assembled monolayers. These thin films are stable, specific, and robust silane-based surfaces that reduce nonspecific binding and enhance the signal to background ratio. Second, we have explored four different fluorescent labeling paradigms to determine the optimal procedure for use in the assay. Labeling the detector antibody with an organic dye (AlexaFluor 647) in the hinge region allows for unusual signal enhancement with repeat excitation (at 635 nm) in our assay format, thereby facilitating a better signal resolution at lower concentrations of the antigen. We have also labeled the detector antibody with photostable quantum dots through either the amine groups of lysine (Fc, NH) or using a histidine tag in the hinge region of the antibody (Hinge, H). Both labeling strategies allow for acceptable signal resolution, but quantum dots show much greater resistance to photobleaching than organic dyes.

INTRODUCTION

Breast cancer affects 200 000 women annually in the United States. The probability of survival is much higher with early diagnosis (95%) compared to metastatic disease (26%) (*1*). Current diagnostic techniques are, however, unsatisfactory when applied to early detection. For example, mammography can detect the tumor only when palpable, suffers from high false positive and negative rates, and requires confirmatory invasive biopsies as a consequence. In addition, it cannot be used on women less than 40 years of age because of intrinsically denser breasts in that population (*2*). Other methods are also either expensive (e.g., magnetic resonance imaging) or are associated with nonspecific results (standard immunoassays) (*3*). Thus, there is a need for a sensitive, specific, quantitative, rapid, and noninvasive diagnostic for breast cancer.

Certain "biomarkers" are differentially expressed in cancer, typically very early in disease onset, and can potentially be used for detection. Since no single biomarker can effectively predict all stages of cancer, detection of a suite of these molecules is a requisite of any diagnostic strategy that utilizes them. However, current immunoassay techniques cannot accomplish this in complex, small-volume patient samples. Therefore, the American Society for Clinical Oncology does not currently recommend these markers for the early detection of breast cancer (*4*).

The sensor team at the Los Alamos National Laboratory has developed a waveguide-based optical biosensor for the sensitive detection of such markers in a sandwich immunoassay format. The optical properties and assay procedures have been outlined elsewhere (*5*). Briefly, a sandwich immunoassay using a fluorescently labeled detector antibody is performed on the functionalized surface of single-mode planar optical waveguides. Only fluorescent molecules within the evanescent field of the waveguide (0−250 nm from the surface) are excited, facilitating optical separation of surface-bound entities from solution contaminants. This spatial filtering minimizes the background fluorescence associated with complex biological samples such as blood and sputum. We have previously demonstrated the application of this technology to the sensitive detection of breast cancer (unpublished data) (*6*), influenza viruses (*7*), and *Bacillus anthracis* protective antigen (*5*). We have successfully adapted the optical biosensor to the detection of carcinoembryonic antigen (CEA), a breast cancer biomarker in serum and nipple aspirate fluid from patients with abnormal mammograms (unpublished data) (*6*). CEA was detected in a small cohort of patient samples with excellent sensitivity (limit of detection = <0.5 pM), specificity (low nonspecific binding or false results), and speed (15 min). We have assessed the reproducibility of our assay by two different approaches. Repeat measurements were made with 25 pM human CEA on the same waveguide as a measure of intra-assay variability. The signal observed with each measurement was completely eliminated by photobleaching before subsequent measurements were made. The waveguide background was low (∼16 relative fluorescence units (RFU)) with a standard deviation of 3 between measurements. 25 pM CEA yielded, on average, 1046 RFU with a standard deviation of 119 between measurements. We have also assayed for interassay variability by measuring CEA concentrations in a human patient sample in 4 different waveguides in entirely different experiments. Although the raw values for background and signal differ among waveguides, the extrapolated CEA concentration (based on an internal human purified CEA

standard) was 78 pM ($n = 4$ repeats) with a standard deviation of <1.5. These numbers establish both the inter- and intra-assay reproducibility of our waveguide-based assay for CEA (*5*). However, our waveguide assay still required optimization to make it more amenable for use in clinical or research setting. For instance, phospholipid bilayers (PLBs) used in the initial demonstration for waveguide surface functionalization, are neither robust nor stable, and allow nonspecific interactions in complex biological samples. Our team has developed alternative functional surfaces that overcome these disadvantages. Silane-based self-assembled monolayers (SAMs) are robust (can be washed with detergents) and stable (>300 days in air), effectively resist nonspecific interactions, and are potentially regenerable (*8*). The present manuscript demonstrates the superior performance of SAMs (in comparison with PLBs) when applied to the detection of CEA.

In our initial demonstration of the CEA assay, the detector antibody was labeled with an organic dye (AlexaFluor 647, AF647) in the Fc region (primary, NH labeling) using the NH groups on the lysine residues. The current study compares this strategy to one where the antibody is labeled with AF647 in the hinge region (H labeling) using a histidine tag. In addition to organic dyes, we have also analyzed the use of photostable quantum dots (QDs) as the fluorescent label. QDs have been extensively researched as fluorescence reporters or probes for several biological applications (*9*). They consist of nanometer-scale atom clusters with a semiconductor core and shell and an amphiphilic polymer coating (*10*) that provides a protective, water-soluble surface that can be differentially modified. QDs show a direct, predictable relationship between their physical size and the energy of the exciton (and, therefore, the wavelength of emitted fluorescence). This "tuneability" has allowed for the development of a series of QDs that have common excitation profiles but different fluorescent emission maxima. Exploiting this property, one can potentially envision a multiplex detection format using QDs that emit at different wavelengths. In addition, QDs exhibit excellent brightness and much greater photostability than traditional organic fluorophores (*9*). This makes long-term imaging/excitation possible under conditions that would lead to the photoinduced deterioration (photobleaching) of other types of fluorophores. These features have facilitated the use of QDs in several bioapplications such as immunofluorescence assays, live cell imaging, biotechnology detection, single molecule biophysics, and in vivo animal imaging (*11*−*13*). NH-and H-labeling with both QDs and organic dyes were evaluated in the current study. NH labeling has been shown to sometimes compromise antigen binding activity of the antibody. Therefore, we chose to evaluate two different labeling protocols and determine the one that offered the best sensitivity.

EXPERIMENTAL PROCEDURES

Materials. Purified CEA and antibodies (T84.1, capture and T84.66, detector) were obtained from our collaborators at the City of Hope. These antibodies were selected by epitope mapping and therefore form an effective sandwich by binding orthogonal epitopes of CEA (unpublished data) (*6*). Amino-functionalized QD (655 nm, QD655), Qdot655 ITK carboxyl quantum dots, and AF647-*N*-hydroxysuccinimide (NHS) ester labeling kits were purchased from Invitrogen. Biotinylation, protein estimation, and electrophoresis reagents were obtained from Pierce. Tri-*n*-octylphosphine oxide (TOPO) and tri-*n*-octylphosphorine (TOP) capped CdSe/ZnS core/shell QDs were a generous gift from Dr. S. Jeong (Los Alamos National Laboratory) (*14, 15*).

Gel filtration columns and spin filters were from Harvard Apparatus. Buffers, chemicals, immunoblot materials, and other components were purchased from Sigma Aldrich or Fisher Scientific unless otherwise specified. Waveguides were obtained from nGimat, Atlanta, GA. 1,2-Dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(cap biotinyl) (sodium salt) were purchased from Avanti Polar Lipids. Materials required for SAM preparation are listed in detail elsewhere (*8*).

Methods. *Biotinylation of the Capture Antibody.* The capture antibody (2 mg/ml, 500 μL) was incubated with Sulfo-NHS biotin (10 mM, 20 molar excess) for 1 h at room temperature (RT) on a rotator. Macro Spin gel filtration columns (molecular weight cutoff (MWCO) 100 kD, 150 μL capacity) were hydrated for 2 h with PBS, and the biotinylated antibody was separated from free-biotin by centrifugation in the hydrated columns for 5 min. The extent of biotinylation was determined using an EZ Biotin Quantitation Kit (Pierce) that measures the degree of biotinylation using 4′-hydroxyazobenzene-2-carboxylic acid. Protein concentration was determined by measuring absorbance of the conjugate at 280 nm using bovine serum albumin (BSA) as the standard.

Functionality of the biotinylated antibody (i.e., ability to bind antigen) was assessed by immunoblot analysis. For this, CEA (1 nM, 3 μL) was blotted on nitrocellulose filter paper and allowed to air-dry. The paper was subsequently blocked with fish gelatin (4.5% v/v solution in PBS) for 2 h at RT and probed overnight at 4 °C with the biotinylated antibody. Unbound antibody was removed by washing with PBS/Tween-20 (0.1% v/v, 3×, 1 min each) followed by PBS (4×, 1 min each). The blot was then incubated with a secondary antibody (goat−anti-mouse labeled with alkaline phosphatase, 0.001 mg/mL, 2 mL, 1 h at RT). Again, unbound antibody was removed by washing and specific staining detected with NBT-BCIP (one-step alkaline phosphatase substrate). Unlabeled antibody was used as the positive control and PBS-0.5% BSA as the negative. The same protocol was also used for the evaluation of the fluorescently labeled detector antibodies (see below).

Biotinylation of the capture antibody (i.e., incorporation of biotin on the antibody) was also assessed by immunoblot. One nanomolar antibody was blotted on nitrocellulose filter paper. Following blocking, the blot was probed using streptavidin labeled with alkaline phosphatase (0.001 mg/mL in PBS, 2 mL) for 1 h at RT. Unbound antibody was removed by washing, and the blot was developed as described earlier. Unlabeled antibody was used as the negative control and sulfo-NHS-biotin as the positive control.

Fluorescent Labeling of the Detector Antibody. Multiple strategies were used for generating fluorescent detector bioconjugates. In each case, protein concentration was measured by determining absorbance at 280 nm using bovine serum albumin (BSA) as standard. Functionality of the labeled antibody was evaluated by immunoblot analysis (as outlined earlier). Labeling was verified, where applicable, by gel electrophoresis. Both agarose and polyacrylamide (PAGE) gel electrophoresis techniques were employed.

Primary Labeling of Detector Antibody with AF647 (T84.66-NH-AF647). An AF647-NHS ester labeling kit (catalogue #A20173, Invitrogen) was used, and the reaction was carried out according to the manufacturer's recommendation. Briefly, the antibody (2 mg/mL, 500 μL) was reacted with AF647-NHS ester in the dark for 1 h at RT on a rotator. Labeled protein was separated from free dye by gel filtration (G-25, Sephadex). Degree of labeling was determined by UV/vis spectroscopy to be 4 mol of dye per mole of protein based on the corrected ratio of absorbance at 650 and 280 nm, respectively.

Hinge Labeling of Detector Antibody with AF647 (T84.66-H-AF647). Detector antibody (8 mg/mL, 500 μL) in PBS, pH 8.0, was reacted with 20 mM tris(2-carboxylethyl) phosphine (TCEP) (400 nmol, 30-fold molar excess) at 37 °C for 2 h under

argon. The mixture was purified by spin filtration (G-25, Sephadex) and then reacted with a 50 molar excess of AF647-maleimide in PBS at 37 °C for 2 h under argon on a rotator. The reaction mixture was again purified by G-25 spin filtration (MWCO 100 kD), and labeled protein was collected. Protein reduction was confirmed by nonreducing gel electrophoresis.

NH Labeling of Detector Antibody with QD (T84.66-NH-QD655). Carboxyl-coated QD655 stock solution (8 μM, 20 μL) was blended in borate buffer (25 mM, pH 7.3) and mixed with the antibody (47 μM, 10 μL). *N*-Ethyl-*N*′-dimethylaminopropylcarbodiimide hydrochloride (EDC, 100 mM, 2.4 μL) was added to this reaction mixture and gently stirred for 2 h at RT. The reaction was quenched by addition of borate buffer (50 mM, 100 μL, pH 9.0) and further incubated for 2 h at RT.

Free and conjugated QDs were visualized by sodium dodecyl sulfate (SDS)-PAGE followed by UV illumination at 366 nm. Proteins were stained with GelCode (blue) reagent. The conjugate was separated by spin filtration (membrane MWCO 100 kDa) followed by at least five exchanges with borate buffer (50 mM, pH 8.5). Absorbance of QD655 was measured to calculate its concentration ($\varepsilon_{638} = 8 \times 10^5\ M^{-1}\ cm^{-1}$). The molar ratio of antibody to QD in the conjugate was 3:1.

Hinge Labeling of Detector Antibody with QD625 (T84.66-H-QD625). [TOP/TOPO]-capped CdSe/ZnS core/shell quantum dots with an emission maximum at 625 nm were used to prepare dihydrolipoic acid (DHLA)-coated QDs (*16*). DHLA was freshly prepared from α-lipoic acid by sodium borohydride reduction (*17*). DHLA-QD625 (1 μM, 100 μL) was diluted with borate buffer (25 mM at pH 9.0, 78 μL), mixed with His_6-anti-CEA antibody (18 μM, 22 μL), and incubated overnight at 4 °C. Conjugation was verified by running the His_6-anti-CEA-DHLA-QD625 on native polyacrylamide (4−15% gradient) and agarose (1%) gels. This confirmed the absence of free QDs in the conjugate. Absorbance of the conjugate was used to determine QD625 concentration ($\varepsilon_{605} = 4.5 \times 10^5\ M^{-1}\ cm^{-1}$). Antibody concentration was determined by the Bicinchoninic acid assay (BCA) using BSA as standard. The average number of antibodies per QD was about 4.

Preparation of the Waveguides and Coating with Sensing Film(s). Single-mode planar optical waveguides consisting of a polished fused silica substrate (lower refractive index) coated with silicon oxy nitride (SiON*x*, high refractive index) with a 10 nm coating of SiO_2 (lower refractive index, which allows the functionalization of the waveguide surface) were used. Waveguides and glass coverslips were cleaned by sonication in chloroform and ethanol (5 min each), followed by exposure to UV-light and ozone (40 min). The cleaned surfaces were functionalized using either PLBs or SAMs.

The preparation of biotinylated (1%) unilamellar vesicles (PLBs) by sonication has been previously described (*5*). Briefly, thin films of DOPC (5 mM stock in $CHCl_3$, 50 μL) with 1% cap biotinyl (v/v, sodium salt, 5 mM stock in $CHCl_3$, 0.6 μL) were deposited on the walls of test tubes by evaporation of chloroform under argon. The films were rehydrated in PBS (1×, ∼0.01 M, 40 min) and subsequently subjected to eight freeze−thaw cycles (frozen in liquid nitrogen and thawed in warm tap water) and sonicated with a probe tip sonicator (Branson, 50% duty cycle for 5 min).

Waveguides and coverslips were assembled into a flow cell using a gasket to form a tight seal between them as has been outlined earlier (*5*−*7*). A supported bilayer was then formed on the cleaned flow cell surface by injecting the vesicle solution into the flow cell and allowing it to stabilize overnight. It is important to ensure that there are no air bubbles generated during the coating as they can damage the PLBs. The functionalized surface was subsequently blocked with PBS containing 2% BSA for 1 h before use for most experiments. These bilayer-coated waveguides remained stable for a maximum of 1 week under refrigeration.

Preparation of SAMs has also been described previously (*8*). Briefly, waveguide and coverslip surfaces were cleaned as described above. The substrates were submerged in water, blown dry, and placed in a vacuum desiccator with a small volume (∼50 μL) of 1-(3-aminopropyl)-1-methyldiethoxy silane (AP-MDES). The vacuum chamber was evacuated to ∼200 Torr and allowed to stand for 2 h. After coating, the substrates were baked at 110 °C for 30 min, allowed to cool in a drying desiccator, rinsed with ethanol, blown dry, and analyzed by contact angle. Poly(ethylene glycol) (PEG) reagents containing a carboxylic acid at one end and either a methoxy group (99−99.99% of the total PEG volume) or a protected amine (0.01−1% of the PEG volume) at the other were coupled to the amine surfaces overnight using standard peptide coupling conditions, again followed by contact angle analysis. The protecting groups were removed by immersion in a piperidine/NMP solution, and biotin was attached to the resulting free amine via its commercially available *N*-hydroxysuccinimide ester. All steps after aminosilanization were carried out in *N*-methylpyrrolidinone (NMP) as the solvent, and the slides were rinsed thoroughly between steps. After biotinylation, the slides were rinsed with NMP, acetone, and ethanol and were blown dry under a stream of argon. SAM-coated waveguides and coverslips were mounted into flow cells as described for the preparation and use of phospholipid bilayers, but the SAMs were not blocked and were therefore available for immediate use.

Waveguide-Based Sandwich Immunoassay for CEA. All experiments used the same batch of waveguides, functionalized and mounted in flow cells as described before. However, intrinsic waveguide background can vary, which accounts for some differences in the measured signal/background (S/B) (see Results).

A general schematic of the assay on the waveguide-based biosensor is shown in Figure 1 (unpublished data) (*6*). To provide a facile method of coupling light, diffraction gratings are etched on the surface of the waveguide. Excitation light is coupled into these gratings by positioning the laser beam at the appropriate angle of impingement. Two different excitation lasers were used: 532 nm (diode pumped Neodinium YAG laser, CrystaLaser, Reno, Nevada) for all QD experiments and 635 nm (Diode Laser, Coherent, Auburn, CA) for AF647 experiments. We selected waveguides that couple in approximately the same laser power (∼50% of the incident beam). A USB 2000 fiberoptic spectrometer (Ocean Optics, Dunedin) was used to collect isotropic emissions from the waveguide. Appropriate long-pass optical filters were used to filter out the excitation light. It is important to note that these filters do not affect the specific signal or alter the ratio of observed intensities.

All experiments used 100 nM each of the capture and detector antibodies and PBS-0.5% BSA as the wash buffer, with an injection volume of 200 μL. The flow cells were incubated for 5 min at room temperature and rinsed with approximately 20 flow cell volumes of buffer before measurement (3 s integration) unless otherwise specified. The following experimental groups were assessed: (1) SAMs vs PLBs as the functional surface for detection of CEA using T84.66-NH-AF647; (2) detection of CEA using T84.66-H-AF647 detector antibody; (3) detection of CEA using T84.66-NH-QD655 detector antibody; (4) detection of CEA using T84.66-H-QD655 detector antibody. All experiments were repeated at least twice using SAMs with 1% biotin except experiment 1.

The general experimental design is outlined in Figure 1. The first measurement acquired is the waveguide background, which quantifies a determination of the background fluorescence associated with intrinsic impurities in the waveguide surface.

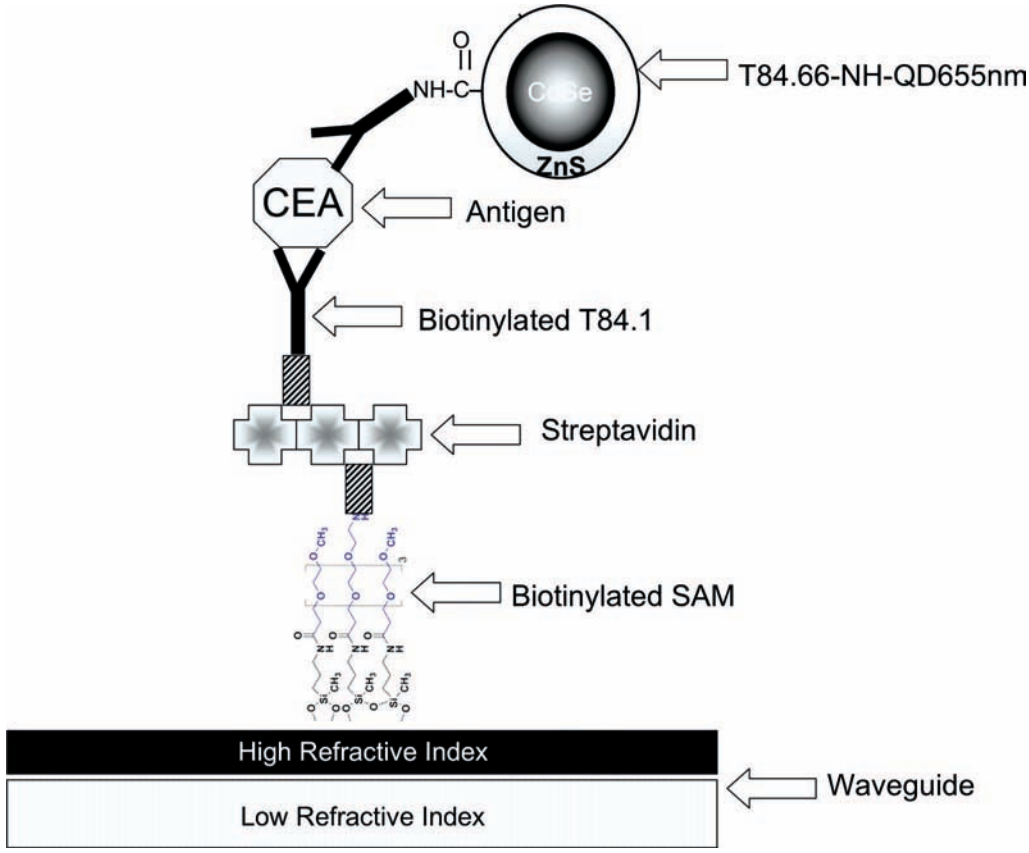

Figure 1. Schematic representation of the sandwich assay for CEA on a functionalized waveguide surface. Surface is functionalized with SAMs containing 1% biotin. Alternatively, PLBs can be used. This illustration depicts a detector antibody labeled with the QD in the NH domain. Both QDs and AF647 have been used for fluorescent labeling. Antibodies can be labeled in the NH domain or in the hinge region. See text for details. Diagram not to scale.

The assay utilizes the well-known biotin−avidin interaction to trap the biotinylated capture antibody to the waveguide surface. For this, the biotin on the PLB or SAM surface is entirely saturated with streptavidin (10 nM). A small concentration of streptavidin (1 pM) is fluorescently labeled with an organic dye (AF647 or 565 depending on the excitation wavelength used). The fluorescent signal (∼200−400 RFU) obtained from this is used as an indicator of system and surface functionality. Fluorescence measurements are relative to the instrument being used. The units reported in this manuscript are as measured on our waveguide-based optical biosensor using an Ocean Optics Spectrometer interface. Fluorescence measurements made using our biosensor will be reported as RFU in this manuscript. This signal is completely removed by repeat excitation with the laser (photobleaching, 15 s) before addition of the capture antibody to avoid skewing the results. Once the capture antibody is trapped, NSB associated with complex fluids is assessed by measuring the autofluorescence of a 50% solution of bovine serum in PBS. Next, the NSB of the fluorescent detector (the fluorescently labeled antibody used that particular experiment) is determined. This measurement is an indication of the nonspecific interaction of the fluorescent detector with the active surface in the absence of the antigen. The NSB signal is completely removed by photobleaching for the organic dyes before specific measurement is made. In the case of photostable QDs, the signal is subtracted from the final specific signal. In either case, repeat additions of the detector to the active surface are made (data not shown) to determine that there is no further increase in NSB.

Assessment of NSB is followed by antigen addition (CEA, 100 pM, 200 μL in PBS with 0.5% BSA). Following antigen incubation and wash, the detector antibody (100 nM, 200 μL in PBS) is added. Specific binding of the detector to CEA (effective sandwich) results in a positive signal, which is measured. Repeat excitations are performed to measure photostability.

RESULTS

CEA Detection Using T84.66-NH-AF647 Detector Antibody on a SAM vs PLBs. Figure 2A demonstrates detection of CEA (100 pM, 200 μL) on a SAM surface without any blocking. A signal of 3636 RFU over a waveguide background of 8 results in a S/B of 483. The NSB associated with 50% serum is 69 RFU, whereas that associated with the detector antibody is 193. In contrast, the S/B for the same assay using a PLB surface without blocking (Figure 2B) is only 44 (specific signal of 1143 over a background of 26 RFU). Some of the difference in measured S/B is attributed to the lower intrinsic background of some waveguides compared to the others. Yet, the NSB associated with serum (115 RFU) and the fluorescent detector (238 RFU) are also higher than that seen with SAMs, and the specific signal is greatly compromised with the use of PLBs. Assay performance on PLBs is dramatically improved when the defect sites in the bilayer that presumably give rise to NSB are preblocked with PBS containing 2% BSA for 2 h before use (Figure 2C). A S/B of 74 is realized (specific signal of 3030 RFU over a background of 41 RFU). When the PLBs are blocked, NSB associated with serum and detector antibody are both lower than seen in the absence of blocking, which is consistent with our previous results against other targets (*5*, *7*). However, the assay performance is still poorer than that achieved with the use of SAMs.

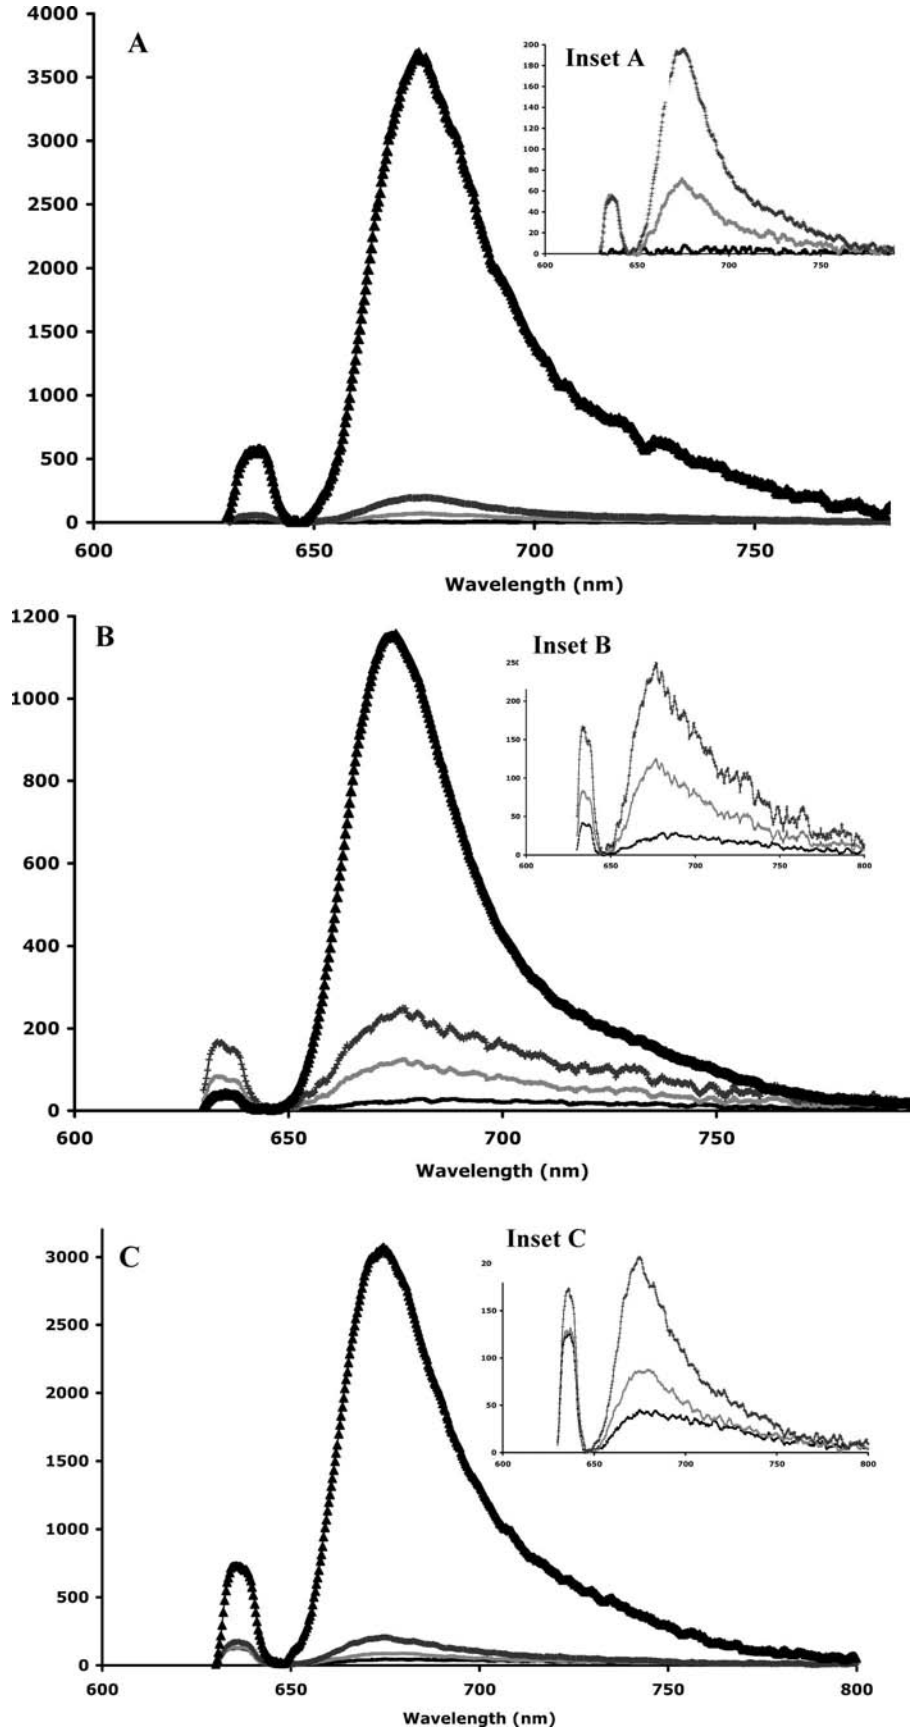

Figure 2. Determination of optimal surface for waveguide functionalization. CEA [100 pM] detection using T84.66-nH-AF647 detector antibody on a (A) SAM surface with 1% biotin, (B) PLB with 1% biotin without blocking, and (C) PLB with 1% biotin and blocking with PBS containing 2% BSA. Data are plotted as relative fluorescence units as a function of wavelength. Assay performance on a SAM surface (A) gives the maximal signal/background (483) and lowest NSB (69 RFU) for 100 pM CEA. Insets (in each graph) are an enlarged representation of the waveguide background and nonspecific binding curves redrawn for clarity. Key: Boxed squares (■) indicate waveguide background, gray circles (•) indicate nonspecific background associated with serum. + indicates detector associated nonspecific binding. Black triangles (▲) indicate specific signal with the addition of 100 pM CEA.

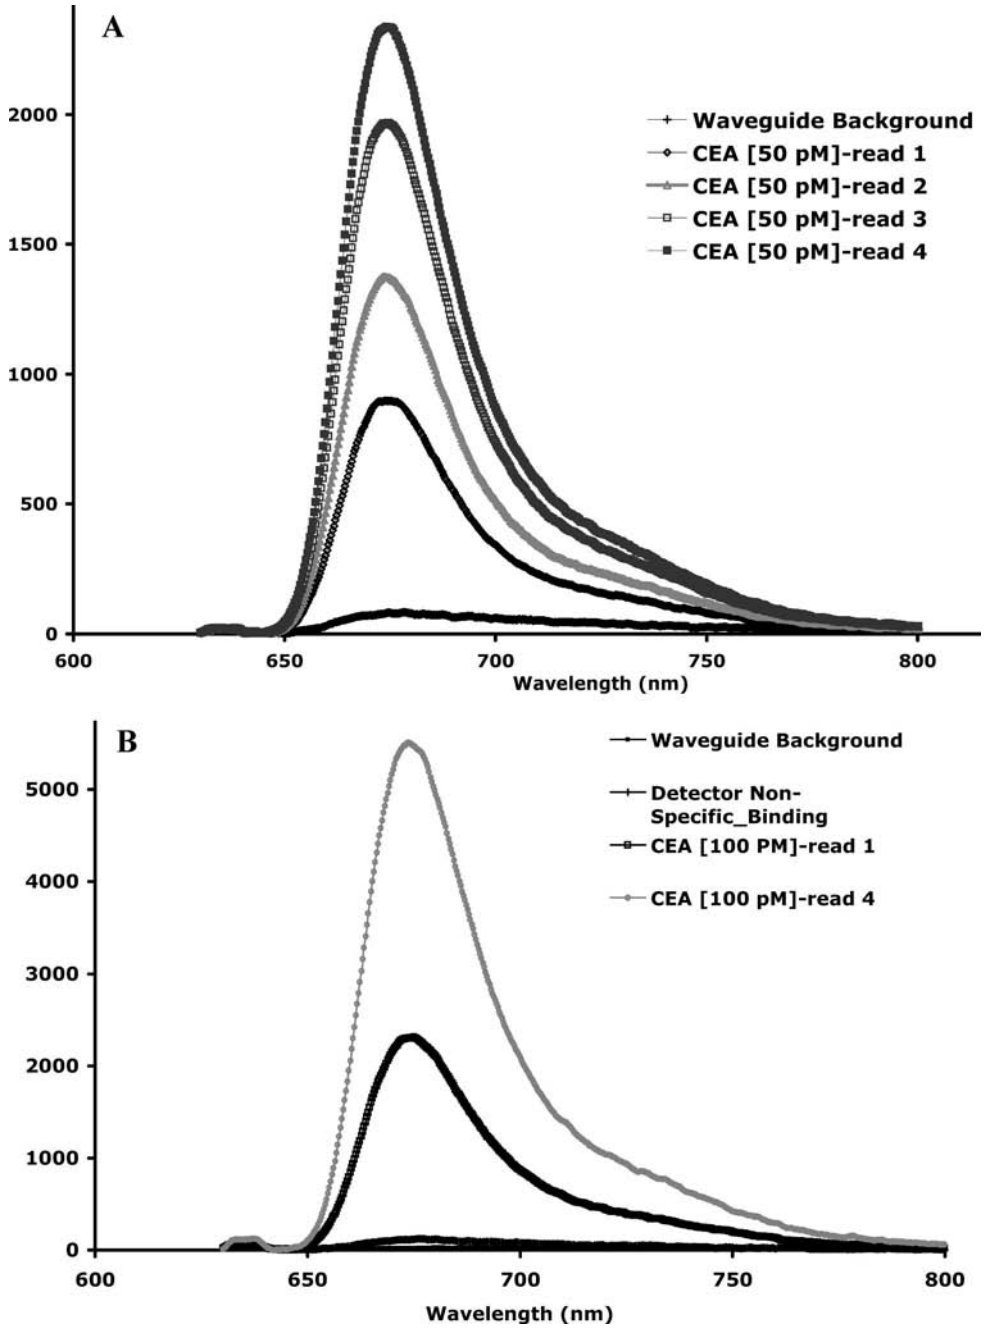

Figure 3. Unusual signal amplification using T84.66-H-AF647. Hinge labeling of the detector antibody with AF647 resulted in unusual signal amplification with repeat excitation (A). The amplitude of the measured signal almost doubled (over an unchanged background) after 4 repeat excitations. Figurer 3B demonstrates the initial (read 1, S/B of ~11) and final (read 4, S/B of 82) signals observed with [100 pM] CEA using this detector antibody.

Table 1. Summary of Measured Signal Intensity at Different Concentrations of CEA Using the Waveguide-Based Optical Biosensor[a]

[CEA] pM	signal (3 s) (RFU)	max signal (RFU)	integration time (s)	S/B (3 s)	S/B (12 s)
Bg	31.97 ± 8				
NSB	75 ± 14				
1	118.27	154.87	6	3.7	4.8
50	1212.6	2767.8	12	37.9	86.6
100	2302.72	5474.85	12	72.0	171.2
200	3033.08	6033.08	18	94.9	188.7

[a] T84.66-H-AF647 was used as the detector antibody.

Unusual Signal Amplification using T84.66-H-AF647 as the Detector. Hinge labeling of the detector antibody resulted in unusual signal amplification with repeat excitation (3 s integration each, Figure 3). Figure 3A demonstrates this increase in signal amplitude with repeat excitation in the detection of 50 pM CEA using T84.66-H-AF647. The initial signal (read 1) measured is 893 RFU over a waveguide background of 80 RFU, resulting in a S/B of 11.2. The amplitude of the measured signal increases to 1365 RFU (read 2) with repeat excitation corresponding to a S/B of 17 for the same concentration of CEA. The maximum signal measured for 50 pM CEA in this labeling format is 2320 RFU (read 4) resulting in a S/B of 29. Subsequent excitation results in photobleaching (data not shown). The exact reasons for this response are unclear but potential explanations are outlined in the Discussion. Figure 3B demonstrates signal obtained during the detection of CEA (100 pM) using this labeling strategy. An "initial" signal of 2303 RFU (read 1) over a waveguide background of 28 RFU corresponds to a S/B of

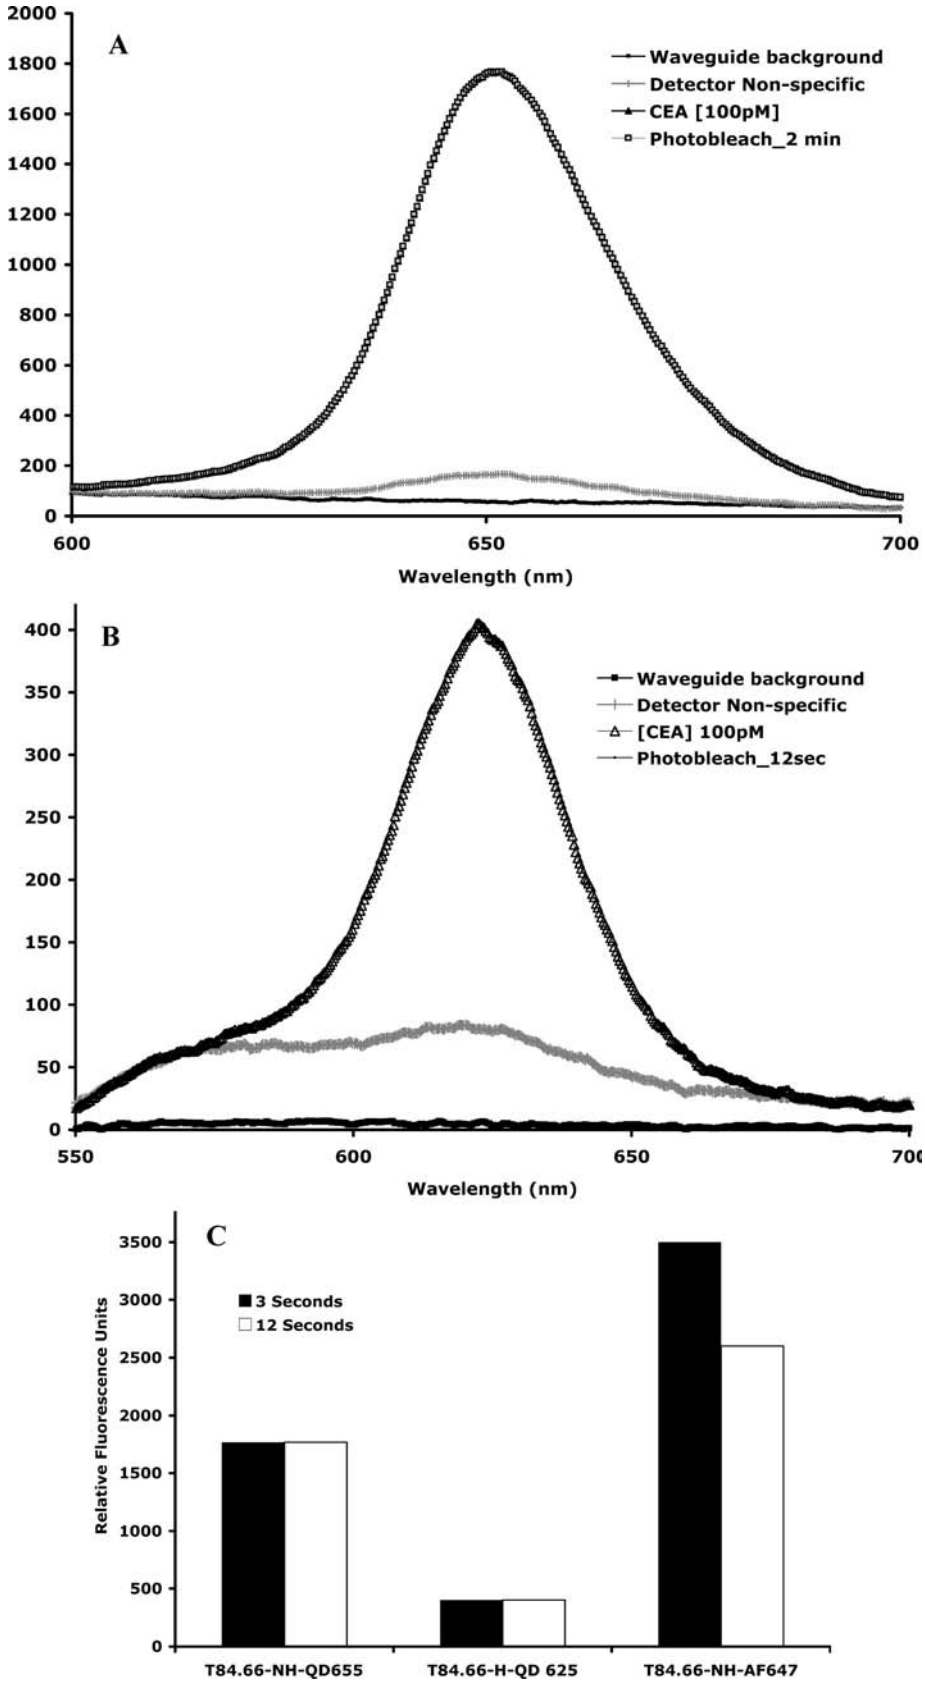

Figure 4. Detection of CEA using QD labeled antibodies. Both NH (QD655, A) and hinge (QD625, B) labeled antibodies were evaluated for the detection of 100 pM CEA. Whereas observed S/B is lower compared to that reported in Figure 2A, there is no photobleaching of the observed fluorescence after 2 min of excitation with the laser (C). As indicated in part C, the signal remains stable following 3 and 12 s of exposure to the laser when the antibody is labeled with QDs, whereas a significant decrease in intensity is seen when the antibody is labeled with AF647. Key: Boxed squares (■) indicate waveguide background, gray circles (•) indicate photobleaching after 12 s of exposure. + indicates detector associated nonspecific binding. Black triangles (▲) indicate specific signal with the addition of 100 pM CEA.

82, which is similar to that obtained with T84.66-NH-AF647 detector (Figure 2C, curve 1) for the same concentration of CEA. Repeat excitation resulted in increase in signal and a maximum signal intensity of 5498 RFU (read 4, S/B of 195), which is much higher than was observed with T84.66-NH-AF647 under similar experimental conditions. There is no increase in the detector antibody associated NSB with repeat excitation (6 repeats, 100 nM antibody in each addition, data not shown).

Table 1 summarizes signal amplification at different concentrations of CEA. The data was obtained from different waveguides, which explains the lack of absolute linearity in measured signals. The waveguide background and NSB values are averages of those obtained in the different experiments (all numbers were within the expected range). Repeat excitation of the fluorescent detector results in signal amplification in each case. Note that the excitation time required to achieve maximum signal is dependent on antigen concentration. Whereas the signal maximizes in 6 s with 1 pM CEA, it takes 18 s of excitation with 200 pM CEA. After the maximum signal is reached, photobleaching commences in each case. Thus, the maximum S/B obtained with any given concentration of CEA is significantly increased using this labeling strategy. Because the number of excitations required is dependent on the CEA concentration, it is difficult to use this approach for quantitative detection in unknown samples. However, this strategy could be advantageous in a purely qualitative test.

Detection of CEA Using QD Labeled Antibodies. Both NH (655 nm QD) and hinge (625 nm QD) labeling of T84.66 with QDs were evaluated. Figure 4A shows the signal obtained for the detection of 100 pM of CEA using 100 nM of T84.66-NH-QD655. A signal intensity of 1767 RFU is observed over a NSB (associated with detector antibody) of 167 RFU. Upon correction for NSB, a S/B of 3 is obtained. There is no apparent photobleaching observed despite 2 min excitation with the laser (532 nm) followed by a single reading at 3 s integration. We also evaluated hinge labeling of the detector antibody (Figure 4B). The observed signal intensity (402) was much lower than that seen with the other labeling paradigms, but the NSB and waveguide background were also lower. When corrected for NSB, a S/B of ~55 is evidenced for this labeling strategy. Again, the observed signal was extremely photostable, and there was no decrease in signal intensity following a 2 min excitation. A comparison of initial signals and the signal after 12 s exposure is shown in Figure 4C. Up to 10 μM of free QDs does not contribute to any measurable signal (data not shown).

DISCUSSION

This study addresses the surface and antibody labeling strategies to improve our current test for CEA. Generally, biodetection using the optical biosensor requires functionalization of the waveguide with a surface that allows for conjugation of antibodies or other recognition ligands. We have previously demonstrated the use of PLBs for waveguide functionalization and sensitive detection of CEA (*6*) (unpublished data). These surfaces are composed of lipid molecules, which make up all biological membranes. These structures are responsible for the selective permeability of cells, a factor that contributes to the low NSB associated with their use in most in vitro studies. In addition, bilayers are inexpensive, easy to prepare, and are well-suited for ligand attachment. However, lipid bilayers are unsuitable for a point-of-care diagnostic setting because they cannot endure prolonged storage (>1 week), harsh environments such as elevated temperatures, or passage through an air−water interface. Furthermore, high concentrations of lipids or urea in some biological samples (such as urine) results in elevated NSB, which limits the successful application of PLBs to biodiagnostic approaches. To overcome these disadvantages, we utilized PEG-modified, silane-based thin films. These coatings facilitate covalent attachment and chemical flexibility, and minimize NSB. We have previously demonstrated the application of these surfaces to the sensitive detection of the *Bacillus anthracis* protective antigen. Alkane SAMs terminated with PEG groups have been used for minimizing NSB (*8*). Concurrent with these results, use of SAMs as the functional surface in our assay abrogates the necessity for blocking. As shown in Figure 2A,B, lack of blocking diminishes the signal resolution obtained with PLBs as the functional surface, but it does not adversely affect functionality of the SAMs (data not shown).

Antibodies labeled with fluorescent dyes are inherently more stable. Of such dyes, long wavelength dyes (such as AF647) have lower background fluorescence (*18*−*20*). Alexa Fluor dyes are suited for bioapplications because of their brightness, photostability, water solubility, and pH compatibility. AF647, in particular, shows relatively small change in the fluorescence spectra and intensity when conjugated to antibodies in contrast with other dyes such as Cy5 (*20, 22*). Following this reasoning, we selected AF647 for our experimental setup. As indicated in Figure 2, use of T84.66-NH-AF647 as the labeled reporter antibody results in a significant S/B with 100 pM of CEA. There is a 15−20% decrease in signal with repeat excitation (photobleaching) as is typically expected from such dyes.

We also explored labeling T84.66 with AF647 in the hinge region. Labeling in this area is advantageous, since it directs the modification away from the antigen-binding region. This can be especially critical for larger reporters such as QDs. Mild reduction allowed for the generation of two half-antibody fragments containing free sulfhydryl groups in the hinge region. The fluorescent dye was then conjugated to the hinge region. When used as the detector for CEA, however, this material resulted in unusual signal enhancement (rather than photobleaching) with repeat excitation. It has been demonstrated that AF647 is more photostable and resistant to fluorescence quenching (at optimal degree of labeling) upon protein conjugation (*20, 22*). But the novel signal increase reported here is unprecedented. This antibody had 4 mol of AF647 per mole of protein, which is an optimal degree of labeling, according to the manufacturer. We have separated the labeled antibody from free AlexaFluor dye by gel filtration. In any case, we have also tested NSB associated with free AF647 in our assay and found no increase in fluorescence (data not shown). We speculate that, since multiple AF647 molecules are associated with a single antibody, some dye molecules are excited only after the fluorescence associated with others is quenched. This phenomenon, in combination to the relative photostability of AF647 dyes, could result in an increase in fluorescence. These hypotheses may explain why the increase in fluorescence is proportional to the concentration of the antigen, and hence the concentration of detector antibody in the system. Why this does not occur with T84.66-NH-AF647 (which also has ~4 mol of the dye/mol of protein) is, however, unclear. A possible explanation involves the conformation of the antibody when labeled in the hinge region, which allows for fluorescence quenching and subsequent photon release. It is apparent that the unusual signal amplification allows for a better S/B with lower concentrations of the antigen. This feature may be advantageous in attempting to develop a point-of-care diagnostic for breast cancer, especially in low volume samples such as NAF. However, since the degree of excitation and extent of amplification are dependent on the antigen concentration, quantitation of this phenomenon is not easy. This is a disadvantage for cancer detection, because most tumor biomarkers are normally expressed in the body at basal concentrations, even without cancer present. Therefore, a test for cancer should be quantitative for accurate diagnosis. This labeling strategy does

have potential for applications where a yes/no answer is adequate, e.g., infectious diseases like tuberculosis.

No single biomarker is an accurate indicator of cancer. Therefore, an efficient diagnostic strategy should be able to detect multiple biomarkers in a single sample. To achieve this eventuality, we explored the use of QD labeled antibodies as a fluorescence detector in our assay system.

In this manuscript, we evaluated both NH and SH labeling of antibodies. Both strategies allowed for the detection of CEA at a concentration of 100 pM, although the S/B was lower than that seen with T84.66-NH-AF647. The signal intensity measured with hinge labeling (Figure 4B) is lower than that seen with primary NH labeling (Figure 4A). However, the NSB is also lower. Therefore, the extrapolated S/B is comparable in both labeling strategies. Also, the observed signal is stable for over 2 min of excitation with the laser (Figure 4), a time over which signal from AF647 would be almost entirely photobleached. This photostability of core−shell quantum dots is a distinct advantage for multiplex detection as well, especially in attempting to engineer a multichannel sensor for simultaneous detection. It is also possible to envision an internal photostable standard (in lieu of streptavidin-AF647) that is used for both system functionality assessment and quantitation of antigen in unknown samples (unpublished data) (*6*).

To conclude, we have improved a sandwich assay for CEA on our waveguide-based OB by incorporating better surfaces and photostable detectors. These modifications will enable our biosensor to function as a robust research tool to probe biological interactions or as a point-of-care diagnostic method to detect a variety of disease targets.

ACKNOWLEDGMENT

Versatile Cyclic Templates for Assembly of Axially Oriented Ligands

Neeraj Chopra,[§] Wenxun Gan,[‡] Hans Schreiber,[§] Josh W. Kurutz,[†] and Stephen C. Meredith*[,§,†]

Departments of Pathology, Chemistry, and Biochemistry and Molecular Biology, The University of Chicago, Chicago, Illinois.
Received July 21, 2008; Revised Manuscript Received November 12, 2008

In this paper, we describe two novel types of planar cyclic peptide templates for the facile addition of ligands that extend axially from the plane of the template ring. The first uses β-amino acids of alternating D- and L-chirality, since the insertion of the additional methylene group in the peptide backbone was predicted and subsequently shown by NMR and molecular modeling, to reorient ligands attached to amino acid side chain axially with respect to the template ring. A second contains alternating D- and L-amino acids with an achiral Gly residue interposed between each chiral amino acid. The inserted Gly residues also tend to reorient side chains axially rather than radially, as was demonstrated by NMR and molecular modeling. The axial orientation of attached ligands is intended to foster or allow interactions among attached ligands in situations in which this is desired. Two such situations that we consider are (1) development of immunological reagents with avidity effects and (2) modeling of oligomers in fibril-forming peptides. Toward the first of these goals, we demonstrated that these templates are suitable for attaching macromolecules, by incorporating two types of protein, neutravidin and trypsinogen. Toward the second goal, we demonstrate the attachment of two different fibril-forming peptides to the template. The templates described herein thus have many of the desirable traits of such molecules, i.e., (1) multivalency for the attachment of multiple ligands, (2) suitable chemical functions for facile attachment of ligands, (3) versatility as to the number and spacing of ligand attachment sites, (4) sufficient rigidity so that the attached ligands can be similarly oriented with respect to the template, and (5) sufficient flexibility to allow even large ligands, such as proteins, to attach and interact.

INTRODUCTION

Cyclic peptides and their peptidomimetic homologues are versatile molecules with distinctive self-assembly properties. The concept of template-assisted peptide synthesis (TASP) was introduced and first developed by Mutter and colleagues (*1*−*3*) (see also *refs 4*−*11* for review and more recent examples). Ghadiri and co-workers described planar, cyclic peptides containing alternating D- and L-amino acids that self-assemble into tubular structures with a β-sheet-like structure. The planarity of the rings derives from the cancellation of the innate twists of the β-strands by the alternation of D- and L-amino acids (*12, 13*). Some of these compounds have antibacterial activity because of their ability to stack into nanotubes that insert into bacterial membranes (*14*−*16*), while others self-assemble into artificial transmembrane ion channels (*17, 18*). In addition to these properties attributable to self-assembly, cyclic peptides and peptidomimetics can also serve as templates for attaching and assembling a wide variety of ligands (*10, 11, 19*−*27*).

In the templates designed by Ghadiri et al. (*12*−*17*), the amino acid side chains are oriented radially from the ring, which, depending on the nature of the side chains, can either promote or prevent lateral association of the rings. In addition, the rigidity and β-sheet-like structure render these molecules prone to self-association into tubular aggregates, unless measures are taken to prevent this, such as N-methylation (*28*). As schematized in Figure 1A, the radial orientation of side chains would also orient any ligands attached to these side chains radially, which therefore tends to prevent interactions among these ligands.

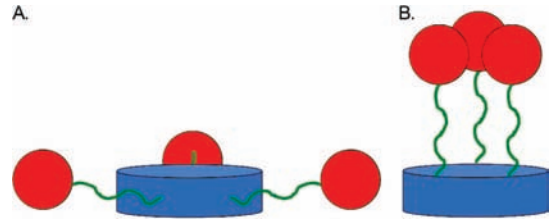

Figure 1. Schematic depiction of planar cyclic peptide templates. Peptides made of alternating D- and L-α-amino acids, such as those described by Ghadiri and colleagues (*12*−*17*) have been observed to project their side chains radially, as depicted in (A). The use of alternating D- and L-β-amino acids (chiral α-carbon atom) or the addition of an odd number of atoms between alternating D- and L-α-amino acids, is predicted to project the side chains axially, as depicted in (B).

There are situations, however, in which it would be desirable to promote interaction among ligands attached to a template. Two such instances are (1) attachment of high-affinity single-chain antibodies fragments (scFv molecules) and high-affinity single-chain T-cell receptors (scTCR) "payloads", in which avidity effects are desirable; and (2) controlled modeling of intermediates in the formation of amyloid fibrils. In both of these cases, it would be desirable to orient ligands attached to amino acid side chains oriented axially rather than radially, as demonstrated schematically in Figure 1B. The incorporation of amino acids with reactive side chains into the template could allow facile attachment of protein or other ligands to the ring.

For these reasons, we have developed two strategies for synthesizing cyclic planar templates with axially oriented side chains. In addition to allowing interactions among attached ligands, we also reasoned that such templates would also have a reduced tendency toward aggregation into tubular β-sheet-like structures than previously described structures. The two strategies are the following:

(1) We have synthesized cyclic peptides containing β-amino acids with alternating D- and L- chirality about the α-carbon atom, i.e., amino acids containing an "extra" methylene carbon atom in the backbone chain. Preliminary modeling studies suggested that the insertion of this additional odd-numbered atom into the backbone chain would have the effect of reorienting the side chains axially with respect to the template backbone, as opposed to radially. For brevity, these templates will be referred to as type 1 axial templates.

(2) We have also synthesized cyclic peptides that retain the alternation of D- and L-α-amino acids, but insert the nonchiral amino acid, glycine, between each of the chiral amino acids. Like the scheme above using β-amino acids, preliminary modeling studies suggested that the addition of glycine would have the effect of reorienting side chains axially. In addition, the insertion of glycines in this manner would also impart additional flexibility to the ring, in those cases in which such flexibility is needed to allow interactions between ligands attached to the side chains. For brevity, these templates will be referred to as type 2 axial templates.

In this paper, we describe the synthesis and structural characterization of these two types of templates and the facile attachment of protein ligands to reactive amino acid side chain groups. Ideally, such templates should have the following characteristics: (1) multivalency for the attachment of multiple ligands; (2) suitable chemical functions for facile attachment of ligands; (3) versatility as to the number and spacing of ligand attachment sites; (4) sufficient rigidity so that the attached ligands can be similarly oriented with respect to the template; and (5) sufficient flexibility to allow even large ligands, such as proteins, to attach and interact. Since these ligands could include scFv and scTCR molecules, the template should be flexible enough to allow avidity effects to occur and, in the case of fibril-forming peptide, to allow for conformational rearrangements to occur. We will show, below, that the templates significantly satisfy these criteria.

EXPERIMENTAL PROCEDURES

Materials. Boc-Leu-OCH_2-PAM resins, Boc-amino acids, *S*-trityl-β-mercaptopropionic acid and 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluroniumhexafluorophosphate (HBTU) were from Peptides International. Benzotriazole-1-yl-oxy-tris-(dimethylamino)-phosphonium hexafluorophosphate) (BOP) and *N*-α-Fmoc-L-aspartic acid β-4-{*N*-[1-(4,4-dimethyl-2,6-dioxocyclohexylidene)-3-methylbutyl]-amino} benzyl ester (α-Fmoc-β-ODMAB-Asp) were from Novabiochem. 4-Dimethylaminopyridine (DMAP) was from Aldrich. *N*-α-Boc-*N*-β-Fmoc-D-2,3-diaminopropionic acid (α-Boc-β-Fmoc-D-DAP) was from ChemImpex, Inc. *N*-α-Fmoc-L-aspartic acid α-*t*-butyl ester (Fmoc-Asp-α-OtBu) was from Bachem International. All other amino acids were from Novabiochem, Applied Biosystems, Midwest Biotech, or Anaspec. *N*,*N*-Diisopropylethylamine (DIEA) was obtained from Applied Biosystems. *N*,*N*-Dimethylformamide (DMF), dichloromethane (DCM), diethyl ether, HPLC-grade acetonitrile, and guanidine hydrochloride were from Fisher Chemicals. Trifluoroacetic acid (TFA) was obtained from Halocarbon Products. HF was from Matheson.

Peptide Synthesis and Purification. Most peptides and peptide-α-thioesters were made manually by solid-phase peptide synthesis using tBoc chemistry with "in situ neutralization", essentially as described previously (*29, 30*). In general, after chain assembly was complete, peptides were simultaneously deprotected and cleaved from the resin by treatment with anhydrous HF containing *p*-cresol (90:10, v/v) for 1 h at 0 °C. After evaporation of the HF under reduced pressure, crude products were precipitated and triturated with chilled diethyl ether, and the peptide products were dissolved in 50% aqueous acetonitrile and purified, or lyophilized for storage.

For synthesis of peptides with β-peptide bonds, i.e., Peptides 1, C1, and C1-Mal and its derivatives, we used standard FMOC chemistry to form β-peptide bonds using the reagents described above. PAM resin was activated with 1 mmol of α-FMOC-β-ODmab-Asp and 10% (w/v) 4-(dimethylamino)pyridine (DMAP), essentially as described (*31*−*33*), so that this amino acid was immobilized to the resin through its α-carboxyl group. For the cyclization reaction, the DMAB group was removed by three 20 min incubations with 2% hydrazine (v/v), followed by three washes with 5% DIEA (v/v). The cyclization reaction was carried out using BOP at 22 °C for 36 h, followed by HOBt/DIC/DIEA for 48 h. Maleimide hexanoic acid (Sigma Chemicals) was added to the N-terminus or to DAP side chains of selected peptides (described below) by the usual coupling method, prior to HF cleavage.

Crude peptides were purified by RP-HPLC on a preparative C18 (Zorbax) column using gradients of water (0.1% TFA, v/v) and acetonitrile (0.1% TFA, v/v). In some cases, isocratic mixtures of water and acetonitrile (0.1% TFA, v/v) were needed instead of gradients for peptides that were difficult to purify. Peptide purity was typically greater than 97% by analytical RP-HPLC (Supporting Information, Figure S1). The molecular masses of the peptides were verified by ESI and MALDI-TOF mass spectrometry.

Electron Microscopy. Peptide solutions were adsorbed onto a glow-discharged, 400-mesh, carbon-coated support film and stained with 1% uranyl acetate. Micrographs were recorded using a FEI Tecnai F30st-STEM Microscope at magnifications of 15 000×, 39 000×, and 98 000×.

Circular Dichroism. Circular dichroic (CD) spectra were collected using an Aviv model 202 CD spectrophotometer (Lakewood, NJ) equipped with a temperature-controlled holder. Peptides were dissolved in 10 mM sodium phosphate, pH 7.40. A 1 or 10 mm path length was used for the measurements, which were collected at 0.2−0.5 nm intervals from 260 to 190 nm, with a 1 s averaging time and a 1 nm bandwidth. Five scans were collected, and the data were averaged and baseline-corrected.

NMR. NMR was performed at 14 °C using a 600 MHz Varian Unity Inova spectrometer equipped with a cryogenic probe. Peptide concentration was ∼3.1 mM in 100 mM sodium phosphate, pH 4.52. A 1.0 mM solution of sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS, Cambridge Isotope Laboratories) was used for external chemical shift referencing. Two-dimensional experiments included TOCSY and NOESY for spin assignments, CT-COSY for measurement of $^3J_{NH\alpha}$.

Molecular Dynamics Simulations. The initial coordinates of cyclic peptides were modeled using the *Chem3D* program. Hydrogen atoms were built to the initial structure using the HBUILD module of the CHARMM molecular simulation program (*34*). The all-atom structure was then solvated in a $38.7 \times 38.7 \times 38.7$ Å^3 cubic solvent box with TIP3P (*35*) water so that water extended at least 10 Å away from the surface of the peptide. Four Na^+ ions and seven Cl^- ions were added to the system to neutralize the charge of the peptide. Periodical boundary conditions were applied with the images generated by the CRYSTAL module in CHARMM. Covalent bonds involving hydrogen atoms were constrained with SHAKE (*36*), and the particle mesh Ewald (PME (*37*)) was used to treat long-range electrostatic interactions. After an initial minimization of the system, MD simulations were performed for 1 ns at a constant temperature of 300 K using the CHARMM version 33a2 with the CHARMM27 force field (*38*).

RESULTS

Design and Synthesis of Cyclic Template Peptides. A list of the peptides synthesized for these studies is given in Table

Table 1. Peptides Synthesized for These Studies

name	sequence
Peptide 1	(α-Boc-^{D}DAP-α-tBu-Asp)$_2$-α-Boc-^{D}DAP-Asp(α-PAM Resin)
Peptide C1	Cyclo-(^{D}DAP-Asp)$_3$
Peptide C1-Mal	Cyclo-(^{D}DAP(β-hexanoylmaleimide)-Asp)$_3$
Peptide 2	NH_2-(^{D}CysGlyArgGly)$_3$-SCH_2CH_2C(O)-Leu-OH
Peptide C2	Cyclo-(^{D}CysGlyArgGly-)$_3$
Peptide 3	NH_2-(^{D}CysGlyCysGly)$_3$-SCH_2CH_2C(O)-Leu-OH
Peptide C3	Cyclo-(^{D}CysGlyCysGly)$_3$
Peptide 4	Mal-PEG-GNNQQNY-OH
Peptide 5	Mal-SDDYYYGFGSNKFGRPRDP-OH
Peptide 6	Mal-GEGEGEGK-OH
Peptide 6(Biotin)	Mal-GEGEGEGK(Biotin)-OH
Peptide 7	Cyclo-(^{D}Cys(S-Mal-GEGEGEGK-OH)-Gly-Arg-Gly)$_3$
Peptide 7(Biotin)	Cyclo-(^{D}Cys(S-Mal-GEGEGEGK(Biotin)-OH)-Gly-Arg-Gly)$_3$

1. Peptide 1, the linear precursor for Peptide C1 and Peptide C1-Mal, was synthesized as shown in Figure 2. In Peptides 1 and C1, all residues are linked by β-peptide bonds. Synthesis started by activating PAM resin (see Experimental Procedures) with 1 mmol of α-FMOC-β-ODmab-Asp and 10% (w/v) DMAP, so that this amino acid was immobilized to the resin through its α-carboxyl group. After removing the FMOC, the free α-amino group was coupled to α-Boc-β-FMOC-^{D}DAP by standard FMOC chemistry. Standard FMOC chemistry was then employed to extend the peptide, alternately with Fmoc-Asp-α-OtBu and α-Boc-β-FMOC-^{D}DAP, until the hexapeptide, Peptide 1, had been synthesized. Peptide C1 is derived from Peptide 1 (Figure 2) by coupling the free β-COOH group of the C-terminal Asp to the free β-NH_2 group of ^{D}DAP on the resin after the ODmab groups had been removed by three 20 min incubations with 2% (v/v) hydrazine, as described elsewhere (*39*−*41*). For this reaction, the free amino and carboxyl termini of the peptide were coupled by reaction for 36 h with BOP; followed by 48 h with HOBt/DIC/DIEA, at the end of which a ninhydrin test was negative. To produce Peptide C1-Mal, the α-tBOC protecting groups on the DAP residues were removed by TFA, after which maleimide hexanoic acid was coupled to the free α-amino groups. Finally, the derivatized, cyclized Peptide C1 or Peptide C1-Mal was removed from the resin using anhydrous HF.

Type 2 axial template peptides were synthesized from thioester-containing linear precursors, such as Peptides 2 and 3. The scheme for synthesizing Peptides C2 (or C3) is shown in Figure 3. Peptides 2 and 3 contain both of the groups needed for native chemical ligation, i.e., an N-terminal Cys and a C-terminal thioester (*44*, *43*). Briefly, the linear peptide was synthesized on a PAM resin loaded with Leu to which mercaptopropionic acid had been attached, producing a thioester upon extension of the peptide chain to produce Peptide 2 or 3 (*29*). Peptides were synthesized using optimized Boc solid phase peptide synthesis (*30*). The linear peptides were cyclized by native chemical ligation, as described elsewhere (*44*). Peptide 2C (Figure 3) is derived from Peptide 2 by native chemical ligation of the deprotected peptide. Peptides at ∼2 mg/mL were dissolved in 100 mM sodium phosphate, pH 7.20, containing 6 M guanidine HCl and 10 mM tris(2-carboxyethyl)phosphine (TCEP). To monitor the course of the reaction, small aliquots of the reaction mixture were examined by analytical RP-HPLC. Cyclization of the deprotected linear peptides was remarkably clean and rapid. Examples of reactions using this chemistry are shown in Supporting Information, Figures S2 and S3, for Peptide C1-Mal (m/z = 1184.2, expected = 1183.1); MALDI-TOF mass spectrometry of Peptide C2 showed m/z = 1120 as compared to its linear precursor, for which m/z = 1339, in both cases matching the expected masses. For Peptide C1-Mal, the reactions were performed on resin, while for Peptide C2, the reaction was carried out with the peptide in solution.

Electron Microscopy. The inclusion of charged amino acids, Arg, Asp, and α,β-diamino propionic acid (DAP), into the sequence, was sufficient to yield highly soluble products and prevent the formation of insoluble nanotube structures. For Peptides 1, C1, 2, and C2, no precipitate was visible after centrifugation (10 min, 16 000 × *g*), and electron microscopy revealed only a small amount of amorphous material that appeared to be protein dried on the grid (Figure 4B shows Peptide C2, which is typical of these peptides). In contrast to Peptides 1, C1, 2, and C2, Peptide C3, cyclo-(^{D}CysGlyCysGly)$_3$, made well-ordered, insoluble nanotubes in buffer (Figure 4A).

Circular Dichroic Spectroscopy. As anticipated for peptides containing residues of alternating chirality, Peptides 1, C1-Mal (Figure 5A), 2, and C2 (Figure 5B) showed little ellipticity. The spectrum could not be measured for Peptides 3 and C3 because of their poor solubility. The linear peptides 1 and 2 showed a small amount of negative ellipticity, increasingly so at wavelengths of <220 nm. The cyclic peptides, C1-Mal and C2, showed virtually no ellipticity, suggesting that they are roughly planar.

NMR Spectroscopy. The structure and state of aggregation of Peptide C1-Mal and C2 were examined further using one- and two-dimensional NMR spectra (Figures 6 and 7, respectively). 1D-^{1}H NMR spectra of Peptides C1-Mal and C2 (Figures 6B and 7B, respectively) showed sharp lines, indicating that these peptides were not highly aggregated (or necessarily aggregated at all). The TOCSY spectra (*45*), shown in Figures 6C and 7C, for Peptides C1-Mal and C2, respectively, were remarkable in showing only one set of cross peaks for each spin system, indicating a time-averaged symmetrical structure, and consistent with the predicted 3-fold axis of symmetry.

$^3J_{NH\alpha}$ coupling constants were calculated from CT-COSY (*46*) spectral data (Figures 6D and 7D, for Peptides C1-Mal and C2, respectively) using the Karplus equation (*47*) $^3J_{NH\alpha} = 6.4\cos^2(\phi - 60) - 1.4\cos(\phi - 60) + 1.9$. $^3J_{NH\alpha}$ coupling constants were 6.6 Hz for Cys and 6.3 Hz for Arg for Peptide C2, from which one calculates values for ϕ for Arg and ^{D}Cys that are consistent with an extended structure such as a β-sheet, i.e., −157° and −165°, respectively[1] (*47*−*50*). For Gly, the apparent $^3J_{NH\alpha}$ coupling constant was 11.4 Hz for Peptides C2. This anomalously high value likely arises from additional contributions from coupling between the two Hα atoms, as well as the individual NH-α couplings.

For the CT-COSY spectrum of Peptide C1-Mal, which contains amide bonds between β-amino acids, the following interpretations can be made. First, the $^3J_{2.HN-2.HB}$ coupling constant (see figure for nomenclature) was 8.3; this ^3J is analogous a $^3J_{NH\alpha}$ coupling constant for α peptides, and suggests an extended, β-strand-like conformation. Second, the $^3J_{1.HN1-1.HB}$ coupling constant was 12.3. Like the $^3J_{NH\alpha}$ coupling constants for the Gly residues of Peptide C2, this ^3J is anomalously high, and also likely arises from additional contributions from coupling between the two Hα atoms, as well as the individual NH-α couplings. Finally, the $^3J_{1.HN2-1.HA}$ coupling constant is 8.1 and also suggests an extended conformation around this amide bond.

NOESY (*51*, *52*) spectra (Figures 6E and 7E, for Peptides C1-Mal and C2, respectively) showed no medium- or long-range cross peaks, as is typical of β-sheet structures. Notably, for Peptide C1-Mal there is only one resonance for each type of spin system, consistent with the expected threefold axis of the peptide. For Peptide C2, there were two distinguishable

[1]Two important limitations pertain to this statement, however. First, other values for the parameters have been reported (*49*, *50*), which yield other values for ϕ. Second, because J coupling is a time-averaged observable, values of $^3J_{NH\alpha}$ in the range of 6−7 are difficult to interpret, since they may represent either β-sheet or random coil (*47*).

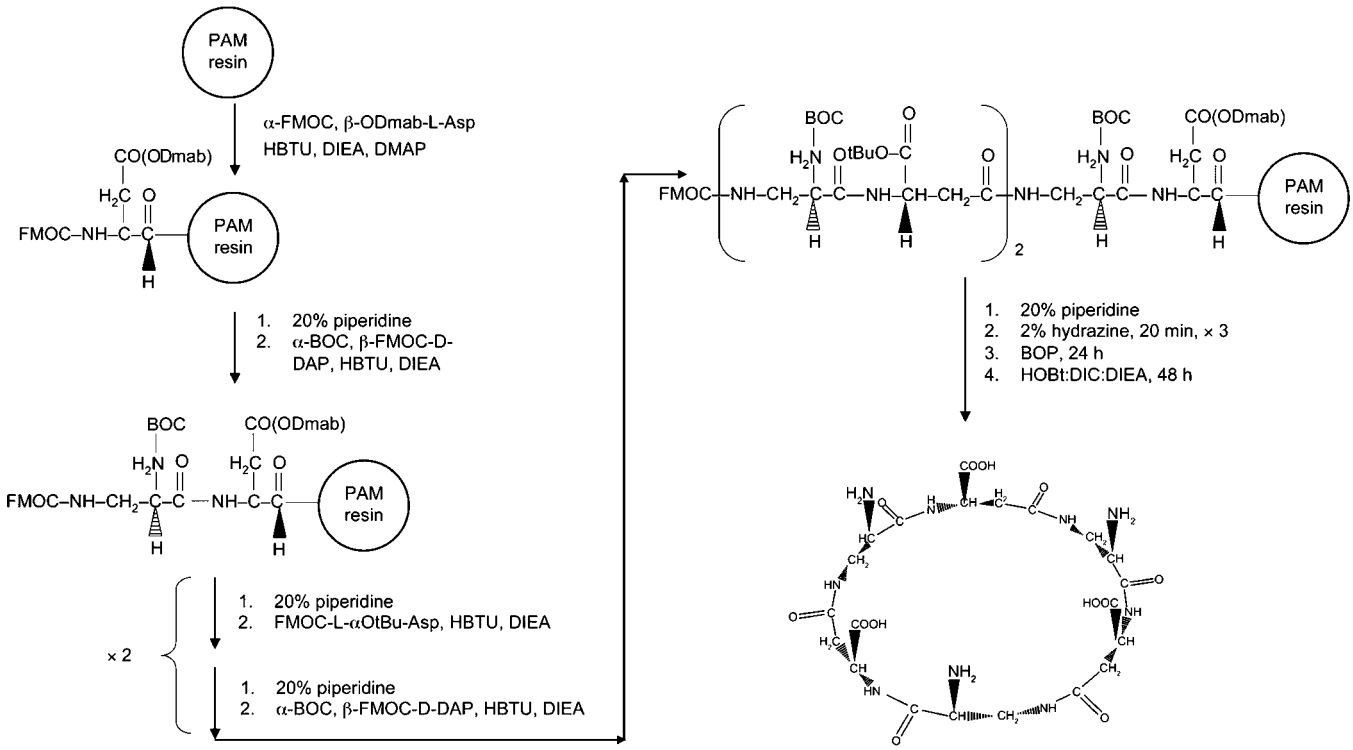

Figure 2. Synthetic schemes for Peptide C1, Cyclo-(^{D}DAP-Asp)$_3$.

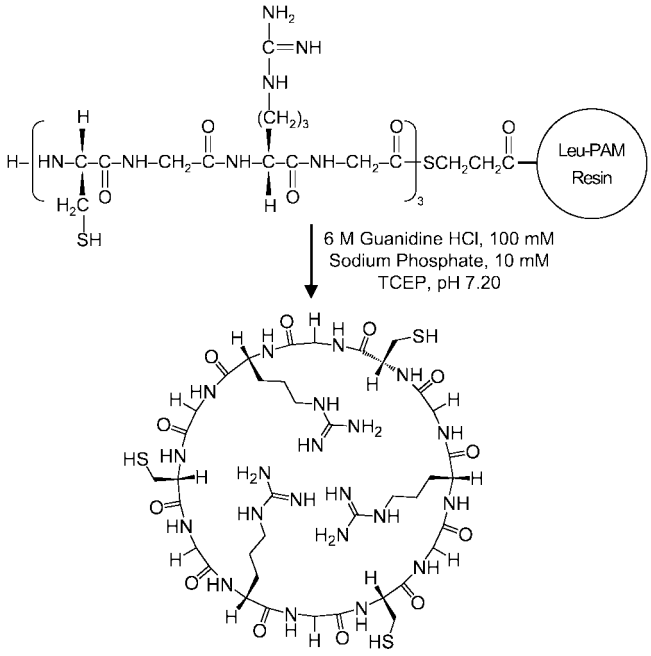

Figure 3. Synthetic scheme for Peptide C2, Cyclo-(^{D}CysGlyArgGly)$_3$.

resonance frequencies for the Gly HN and Hα atoms of Peptide C2, suggesting that, in the repeating sequence -^{D}CGRG-, the two Gly residues are in nonequivalent environments. The fact that there were *only* two cross peaks for Gly, however, is again consistent with the expected threefold symmetry axis of the peptide. Chemical shifts of the HN and Hα resonances were compared to random coil values to assess the prevalence of backbone torsion angles consistent with canonical secondary structures (*53*). None of the secondary chemical shifts was greater than 0.1 ppm, indicating no consistent difference from random coil conformation.

Molecular Modeling of Peptides C1 and C2. We performed explicit solvent molecular dynamics simulations of Peptides C1-Mal and C2 using the CHARMM program (*34*). The structures resulting from molecular dynamic simulations and energy minimization are illustrated in Figure 8A,B (for Peptides C1-Mal and C2, respectively), which again indicate that the amino acid side chains are oriented approximately axially, rather than radially with respect to the backbone of the cyclic peptide. This is especially true for Peptide C1-Mal, in which the hexanoyl-maleidimo group project above the plane of the ring. For Peptide C2, the axial orientation is more consistent for the Arg than Cys residues. Although one of the Cys residues projects axially, the others appear somewhat dispersed around the plane of the cyclic peptide, perhaps owing to the flexibility imparted to the peptide chain by the Gly residues.

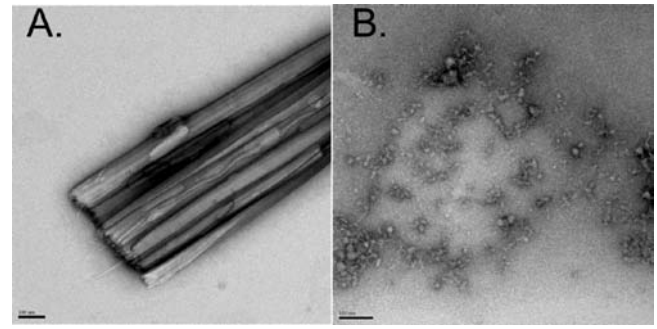

Figure 4. Electron micrographs of cyclized Peptide C3 (A, Cyclo-(^{D}CysGlyCysGly)$_3$) and Peptide C2 (B, Cyclo-(^{D}CysGlyArgGly)$_3$). Peptide C2 showed no fibrils or nanotubes; similarly, when Peptides 1, C1, and C2 were centrifuged (10′, 16 000 × *g*), no precipitate was visible, and electron microscopy revealed only a small amount of amorphous material that appeared to be protein dried on the grid. In contrast, Peptide C3 showed insoluble material that appeared to be nanotubes in electron micrographs. Magnifications shown are 39 000 X (A) and 49 000 X (B).

Attachment of Protein Ligands to Reactive Side Chains of Peptides C1-Mal and C2. The ultimate use of these templates will be to attach peptide and protein ligands, such as high-affinity scFv molecules and fibril-forming peptides. Toward

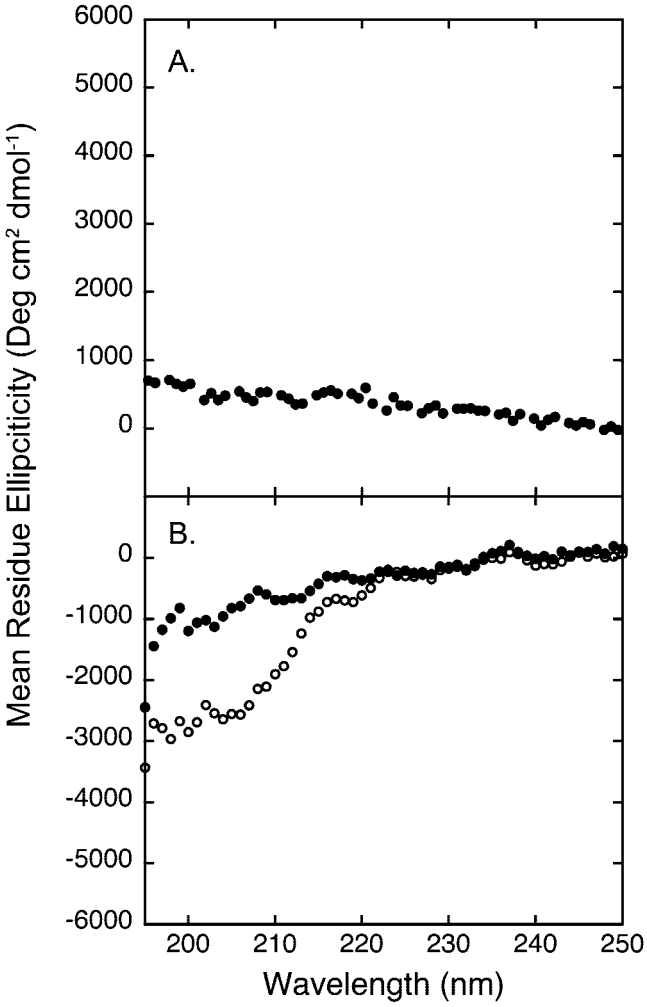

Figure 5. Circular dichroic spectrum of Peptide C1-Mal (A, ●), Cyclo-(^{D}DAP(β-hexanoylmaleimide)-Asp)$_3$), and Peptides 2 (B, ○), NH_2-(^{D}CysGlyArgGly)$_3$-SCH_2CH_2C(O)-Leu-OH and C2 (B, ●), Cyclo-(^{D}CysGlyArgGly-)$_3$). The spectra were taken with peptide concentrations of ∼100 μM, in 10 mM sodium phosphate, pH 7.40.

this end, we developed schemes for attaching such ligands to Peptides C1-Mal and C2. The ligands we tested included two proteins, trypsinogen (25 kD) and neutravidin (64 kD), and two fibril-forming peptides, Peptides 4 and 5. Figure 9A shows a generalizable scheme for attaching proteins and peptides with free α-amino groups to Peptide C1-Mal. The reagent SATA (*N*-succinimidyl-*S*-acetylthioacetate) contains an N-hydroxysuccinimidyl group that reacts with primary amines to yield a protected sulfhydryl (*54*). This sulfhydryl is later deprotected by a brief reaction with hydroxylamine, yielding an N-terminal thiolated protein, which is reactive toward a maleimide group. For this reaction, we used Peptide C1-Mal, in which hexanoylmaleimide had been attached to the α-amino groups of DAP.

We derivatized a sample protein, trypsinogen (Sigma), using SATA by a slightly modified version of the procedure described by Duncan et al. (*54*). Briefly, trypsinogen (∼2 mg/mL) was dissolved in 10 mM sodium phosphate, pH 7.50, also containing 1 mM EDTA. Twenty microliters of 100 μM SATA in DMSO was added to 2 mL of the protein solution, which was then allowed to react at 22 °C for 30 min. The acetyl group was then removed by allowing the protein to react with 50 mmol of hydroxylamine HCl and 2.5 mmol EDTA (added as solids), after readjustment of pH to 7.40. C1-Mal was dissolved in DMSO and added to derivatized trysinogen in a molar ratio of approximately 1:3. The derivatized trypsinogen was then allowed to react with Peptide C1-Mal at 22 °C for 16 h. As shown in Supporting Information, Figure S4A, the reaction leads to the disappearance of unreacted trypsinogen and template, and the appearance of three new peaks, with apparent molecular weights consistent with one, two, and three molecules of trypsinogen attached to the template, of which the largest peak is that containing three molecules of trypsinogen.

We developed an alternate strategy (Figure 9B) for attaching protein ligands to Peptide C2, for the purpose of assessing the ability of this cyclic template to accommodate macromolecule ligands. This strategy is for use primarily for proteins that bind with moderate or high affinity to a specific ligand (in this case, biotin) or are expressed as a fusion protein with a partner that binds a ligand. Accordingly, we synthesized Peptide 6, which consists of a short hydrophilic "spacer" peptide, with a biotinyl group on the ε-amino group of the C-terminal Lys residue and an N-terminal maleimide. Peptide 6 readily reacted with the Cys residues of Peptide C2, with essentially quantitative attachment to the three thiols, thus forming Peptide 7. Figure S5A (Supporting Information) shows the results of analytical RP-HPLC of the reaction mixture. One of the peaks (peak 4 in the chromatogram) contains the desired reaction product, as shown by MALDI-TOF mass spectrometry (Supporting Information, Figure S5B, m/z = 3987.7, expected = 3985.1). Peak 3 in the chromatogram is unreacted Peptide 6. Peaks 1 and 2 are the template with one and two copies of Peptide 6 attached. Similar results were also obtained with Peptide 6(Biotin), which contains an ε-NH_2-biotinylated Lys residue.

In order to attach neutravidin to Peptide 7(Biotin), the latter peptide was dissolved in 100 mM sodium phosphate, pH 7.20, also containing 2% (v/v) DMSO, after which neutravidin was added to the solution. The reaction was monitored by size exclusion chromatography using Superdex 200. After incubation of neutravidin with Peptide 7, the reaction product eluted from the column with an apparent molecular weight of ∼200 kD, i.e., consistent with a trimer, whereas the unreacted neutravidin eluted at a later time, with apparent molecular weights of ∼60 and 120 kD, i.e., monomer and dimer (Supporting Information, Figure S4B). These results show the potential of these cyclic peptide templates to accommodate macromolecules of the size of ∼64 kD, indicating that they could also be used as carriers of other molecules of similar size.

Attachment of Fibril-Forming Peptide Ligands to Reactive Side Chains of Peptide C2. Another goal of these studies is to produce templates that can be used to model soluble oligomeric intermediates of the fibrillogenesis pathyway. Two such peptides are Peptides 4 and 5. Peptide 4 is an N-terminal maleimidyl homologue of a short fibril-forming polyglutamine/asparagine peptide from the yeast prion protein Sup35 (*55*−*61*). Peptide 5 is an N-terminal maleimidyl homologue of a peptide described in an earlier paper (*62*), which was discovered fortuitously to form amyloid fibrils. For this ligation reaction, Peptide 4 or 5 was dissolved in a ligation buffer containing 7.5% (v/v) DMSO and 8 M urea; Peptide C2 was added to give a 3-fold molar excess of Peptide 4 or 5. The reaction was monitored by analytical RP-HPLC and mass spectrometry. Although this reaction was considerably slower than the reactions of Peptide 6 (∼48 h for completion of reaction), MALDI-TOF mass spectrometry demonstrated that peptide had added to all three thiol sites of Peptide C2. The reaction was not complete, and some of the template molecules contained only one or two copies of Peptide 4 or 5 (Supporting Information, Figures S6 and S7, respectively).

DISCUSSION

In this paper, we have described two schemes for synthesizing cyclic planar templates, to which ligands can be attached in an axial rather than radial orientation with respect to the ring of

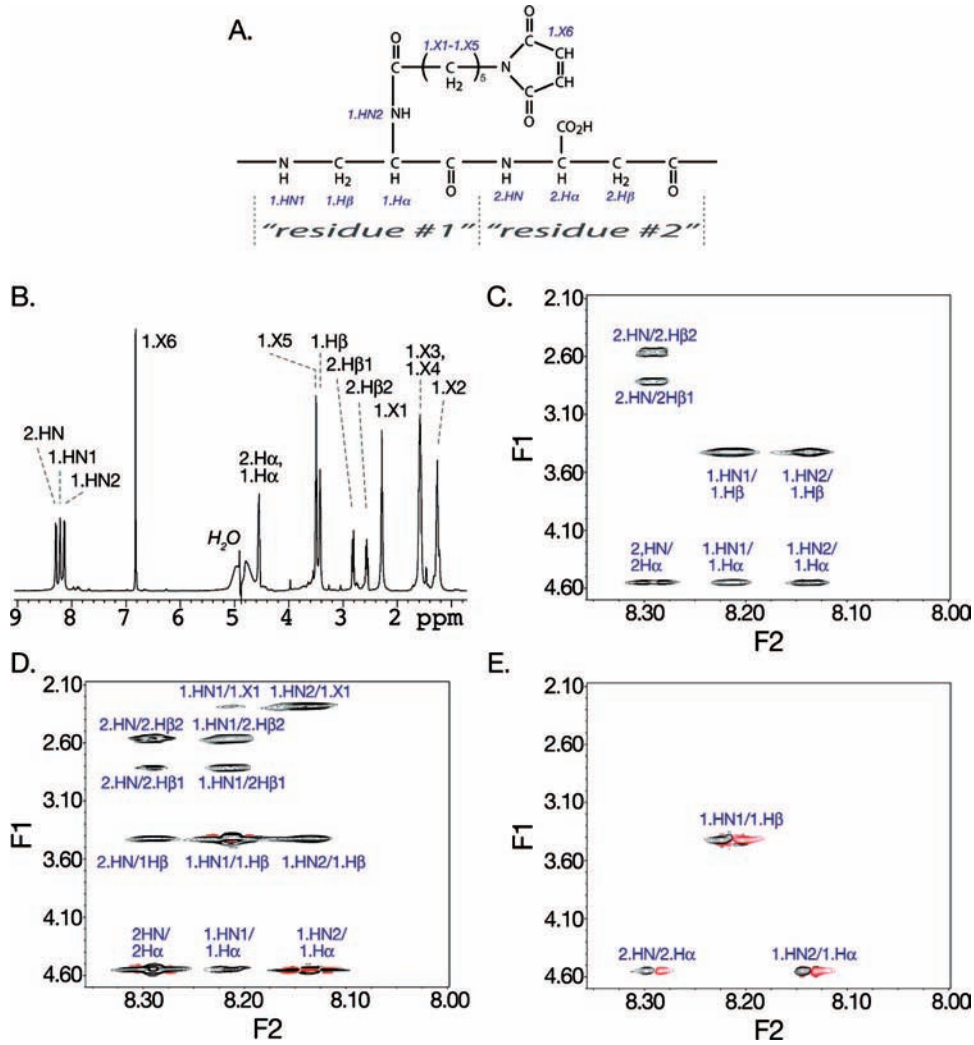

Figure 6. NMR spectra of Peptide C1-Mal. (A) Schematic for the sequence of Peptide C1-Mal, showing nomenclature for the relevant atoms. (B) 1D-^{1}H spectrum of this peptide showing narrow NMR lines, consistent with an ordered structure. (C) Amide to aliphatic region of the TOCSY spectrum of Peptide C1-Mal. the template. Previous templates, such as those described by Ghadiri and co-workers, used alternating D- and L-α-amino acids, which leave the side chains oriented approximately radially. As mentioned above, such peptides have served as a scaffold of a variety of ligands. These include α-helical bundles (*10, 19*), some of which model hemoproteins (*20*) or metalloproteins (*21*), a von Willebrand Factor domain (*22*), the peptide hormone, relaxin (*23*), and class I MHC molecules (*2*). Several templates also offer the advantage of regioselectivity (*11,24,25*). In addition to cyclic peptides, macrocyclic peptidomimetics have also served as templates for molecular assembly (*26, 27*). Finally, a novel strategy uses a set of plant cyclic peptides, the cyclotides, as a scaffold for a natural combinatorial peptide template (*63, 64*). The cyclotides are exceptionally stable and resistant to denaturation, making them excellent for engrafting biologically active peptides.

The cyclic planar templates described in this paper are highly versatile. The choice of three ligand-binding sites per peptide was arbitrary, and the choice of protein ligands was somewhat generic. There is no obvious reason that the peptide chain could not be extended to include additional ligand binding sites, since the cyclization reactions are, if anything, simpler for longer peptide chains than the relative short ones we have chosen. Similarly, trypsinogen was chosen as a rather generic, unremarkable ligand, and any protein containing a free amino terminus should be amenable to this approach. Neutravidin was chosen because of its high affinity for biotin, which is readily incorporated into the template through reaction with a short, hydrophilic, "spacer" peptide. Neutravidin was also chosen because the avidins are so widely used as tools in immunoenzymology and molecular biology (*65*−*74*).

The versatility of these approaches notwithstanding, we developed these molecules with two particular classes of ligands in mind, for two separate but complementary purposes. First, these templates, especially the type 1 axial template peptides containing β-amino acid (i.e., with β-peptide bonds), can be used to model the intermediates in the formation of amyloid fibrils. Amyloid fibrils form by a multistep process in which monomeric peptides first aggregate into soluble oligomers and then form partially ordered "protofibrils" and eventually form ordered β-sheet-rich fibrils. Protein aggregation underlies many neurodegenerative diseases, such as Alzheimer's Disease, Parkinson's Disease, Huntington's Disease, and amyotrophic lateral sclerosis. In addition, protein aggregation and "misfolding" are implicated in the pathogenesis of many diseases outside of the central nervous system, including diabetes mellitus, transthyretin-associated cardiomyopathies, several peripheral polyneuropathies, and pediatric cirrhosis associated with mutations in α1-antitrypsin. Although fibrillar aggregates are readily visualized, much recent attention has focused on soluble oligomeric

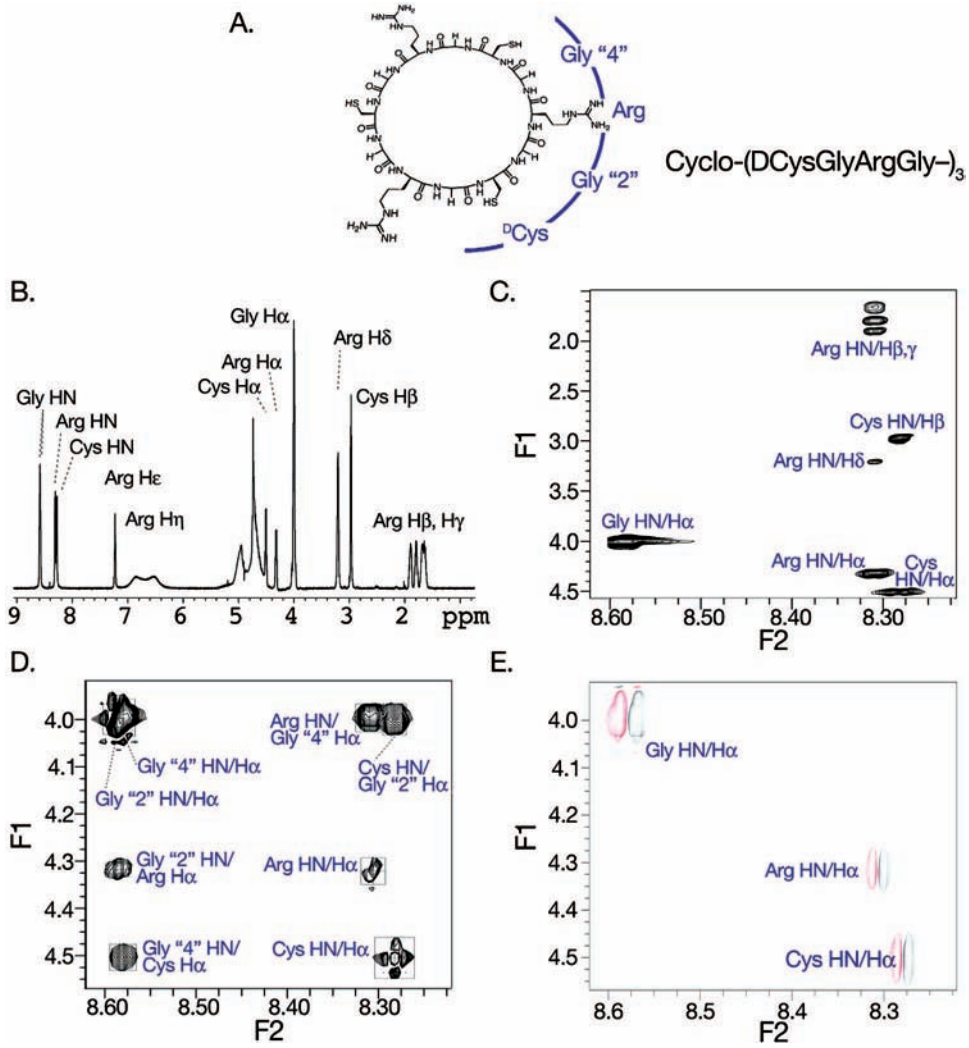

Figure 7. NMR spectra of Peptide C2. (A) Schematic for the sequence of Peptide C2, showing nomenclature for the relevant atoms. (B) 1D ^{1}H spectrum of this peptide showing narrow NMR lines, consistent with an ordered structure. (C) Amide to aliphatic region of the TOCSY spectrum of Peptide C2. (D) Amide to H_α region of the NOESY spectrum of this peptide. (E) CT-COSY spectrum of Peptide C2, showing a only single spin system for each type of amino acid, but separate spin systems for Gly "2" and Gly "4".

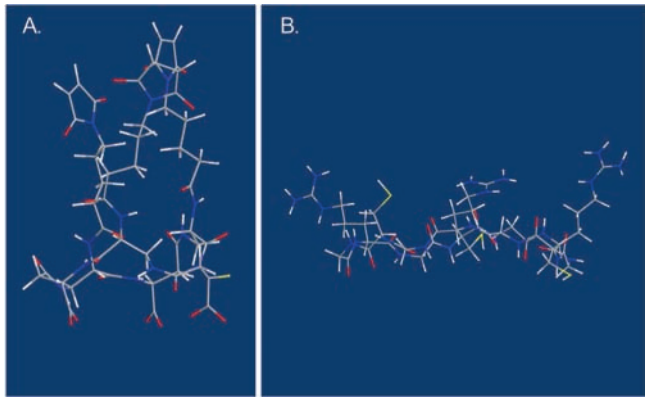

Figure 8. Molecular modeling of Peptides C1-Mal and C2 (A and B, respectively) using the CHARMM force field, with modified parameters for Cys residues. The peptides are approximately planar, and most side chains project axially with respect to the plane of the ring.

precursors of the fibrils as possibly important cytotoxic and neurotoxic species (*75*−*79*). Little is known about the structure of the oligomers, and there are several important unanswered questions about how such oligomers assemble. Structural studies have been impeded by the fact that oligomers are at low abundance and are inherently unstable and heterogeneous. Furthermore, while aggregation into fibrils is believed to proceed by a nucleation-growth mechanism, an unanswered question is whether formation of oligomers, protofibrils, and fibrils proceeds solely by the addition of monomers to nuclei and fibril growth sites. An alternate view holds that fibrils can grow through the addition of "quanta" of multiple peptides, as small oligomers, to the growing fibril. The cyclic templates described in this paper can be used to form stable oligomers of defined stoichiometry, and hence can be used for structural studies. In addition, such oligomers can be used to address the latter question of whether extension of nuclei and fibrils proceeds by addition of single molecules or oligomeric packets. Two recent papers have described the use of a similar approach, primarily with the goal of performing high-throughput screens of fibrillogenesis inhibitors. One study reports the comparison of monomeric and multimeric displays of quinacrine derivatives, as a design principal for a new class of inhibitors against β-amyloid fibril formation (*80*). These multimers exhibited a cluster of four quinacrine derivatives on a rigid cyclopeptidic scaffold. In a second paper, the same group performed high-throughput screening for compounds that block β-amyloid fibril formation (*81*). These studies used a covalent assembly of four β-amyloid fragments, $(A\beta_{16-37}Y_{20}K_{22}K_{24})_4$. Using this tool, they were able to perform screens of potential inhibitors with greatly improved

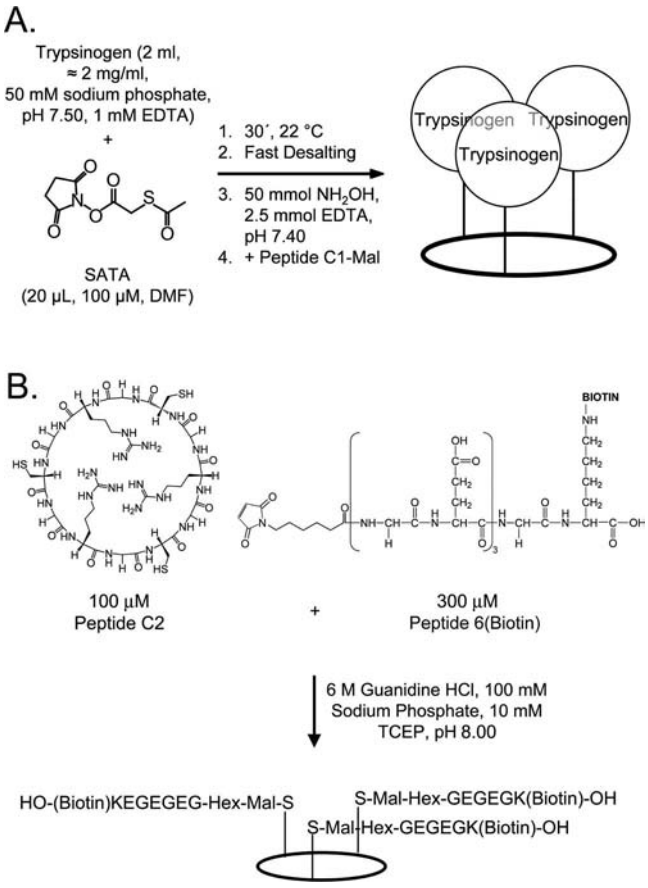

Figure 9. Strategies for attaching protein and peptide ligands to cyclic axial templates. (A) For attachment of protein or peptide ligands to Peptide C1-Mal, the ligand (in this case, trypsinogen) is allowed to react with the agent, SATA, under the conditions shown in the figure and described in the text. This yields an N-terminal thiol group after removal of the acetyl group using hydroxylamine. The thiolated protein then reacts readily with Peptide C1-Mal. (B) Attachment of a protein to Peptide C2 proceeds by first attaching a short, hydrophilic "spacer" sequence, Peptide 6(Biotin), which also contains the ligand for the protein in question, here a biotin moiety attached to the side chain of a Lys residue. Peptide 6(Biotin) is attached to the template Peptide C2 by thioether ligation, a reaction between the maleimido function of Peptide 6(Biotin) and the thiols of the Cys side chains in Peptide C2. Biotin then serves as a ligand for a protein, neutravidin. This approach could be extended to other proteins that bind with moderate or high affinity to a ligand, or to fusion proteins containing a ligand-binding partner.

speed compared to convential methods using thioflavin fluorescence assays of fibril formation.

Second, the cyclic templates described in this paper can be used to attach "payload" molecules, such as high-affinity single-chain antibodies fragments (scFv molecules) and high-affinity single-chain T cell receptors (scTCR) molecules for the eventual development of immunological reagents. The protein ligands that we attached to the templates have little to distinguish them from many others, suggesting that it should be straightforward to extend these approaches to many other protein ligands. As a "proof-of-principle", we described the attachment of trypsinogen and neutravidin to templates, demonstrating that proteins are not sterically hindered from binding to the template.

In conclusion, the templates described in this paper fulfill the criteria defined at the outset, namely, that they are multivalent for the attachment of multiple ligands; specifically and readily reactive for the facile attachment of ligands; versatile as to the number and spacing of ligand attachment sites; sufficiently rigid to define the orientation of ligands with respect to the template; and yet flexible enough to allow attachment of and interactions among macromolecular ligands. We believe that these templates will be useful for a variety of purposes that may extend well beyond those outlined above.

ACKNOWLEDGMENT

3. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of Peptide C2, cyclo(–NH–(^{D}CysGlyArgGly)–CO–)$_3$.

4. (A) Reaction of Peptide C1-Mal with trypsinogen, after reaction of trypsinogen with SATA, as monitored by size exclusion chromatography using Superdex 200. (B) Reaction of Peptide 7, Cyclo-(^{D}Cys(S-Mal-GEGEGEGK(Biotin)-OH)-Gly-Arg-Gly)$_3$, with neutravidin, as monitored by size exclusion chromatography using Superdex 200.

5. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of products of the reaction of Peptide 6, Mal-GEGEGEGK–OH (Mal = maleimidylhexanoyl), with cyclic template Peptide C2, cyclo(–NH–(DCysGlyArgGly)–CO–).

6. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of products of the reaction of the fibril-forming Peptide 4, Mal-PEG-GNNQQNY–OH, with the cyclic template Peptide C2, cyclo(–NH–(DCysGlyArgGly)–CO–).

7. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of products of the reaction of the fibril-forming Peptide 5, Mal-SDDYYYGFGSNKFGRPRDP–OH with Peptide C2, cyclo(–NH–(^{D}CysGlyArgGly)–CO–).

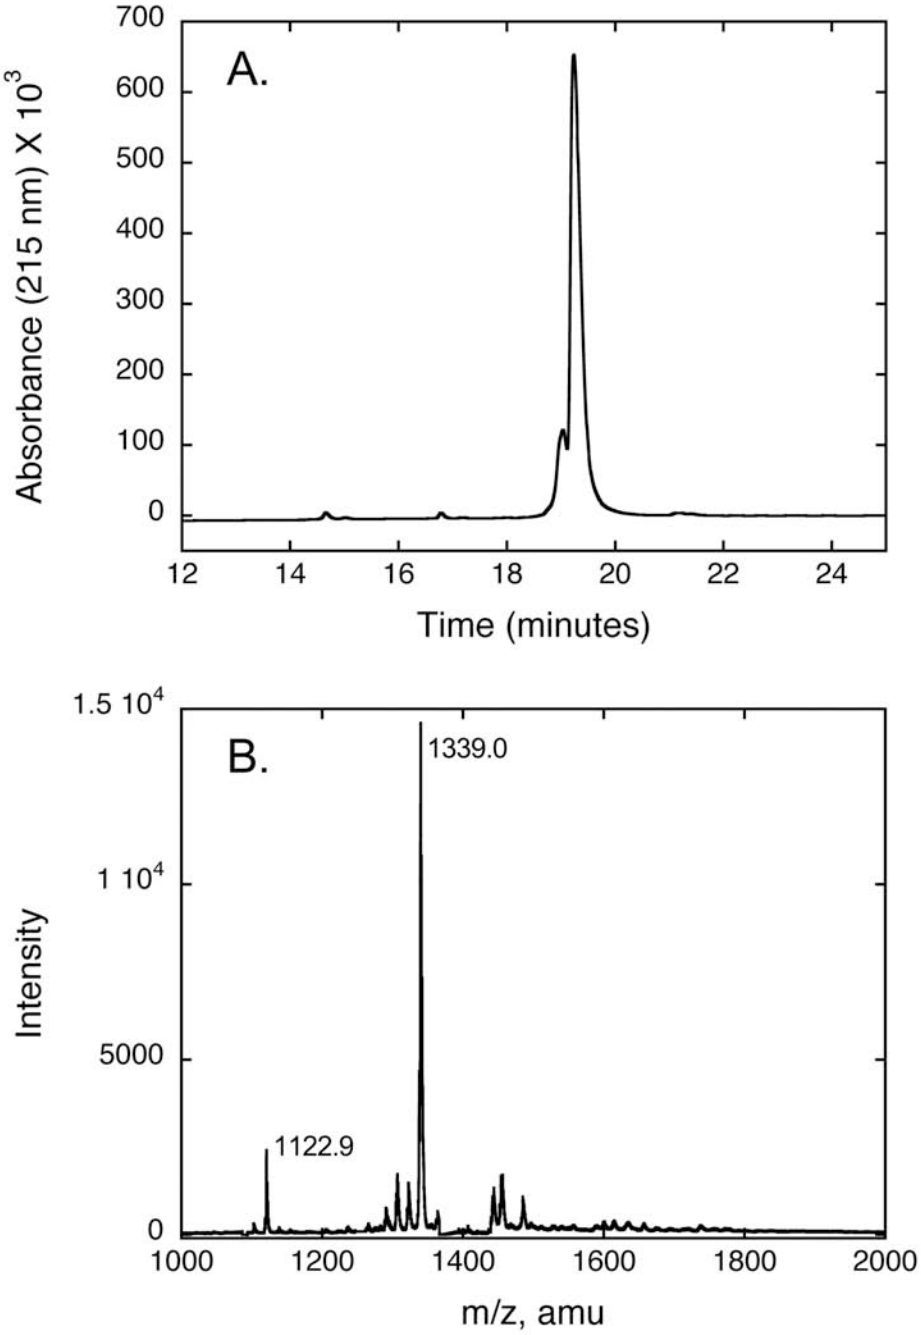

Figure S1. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of Peptide 2, NH2–(^{D}CysGlyArgGly)$_3$–$SCH_2CH_2C(O)$–Leu-OH. The mass spectrometry was performed on the peptide eluting as the largest peak. The peak was collected and used for further reactions.

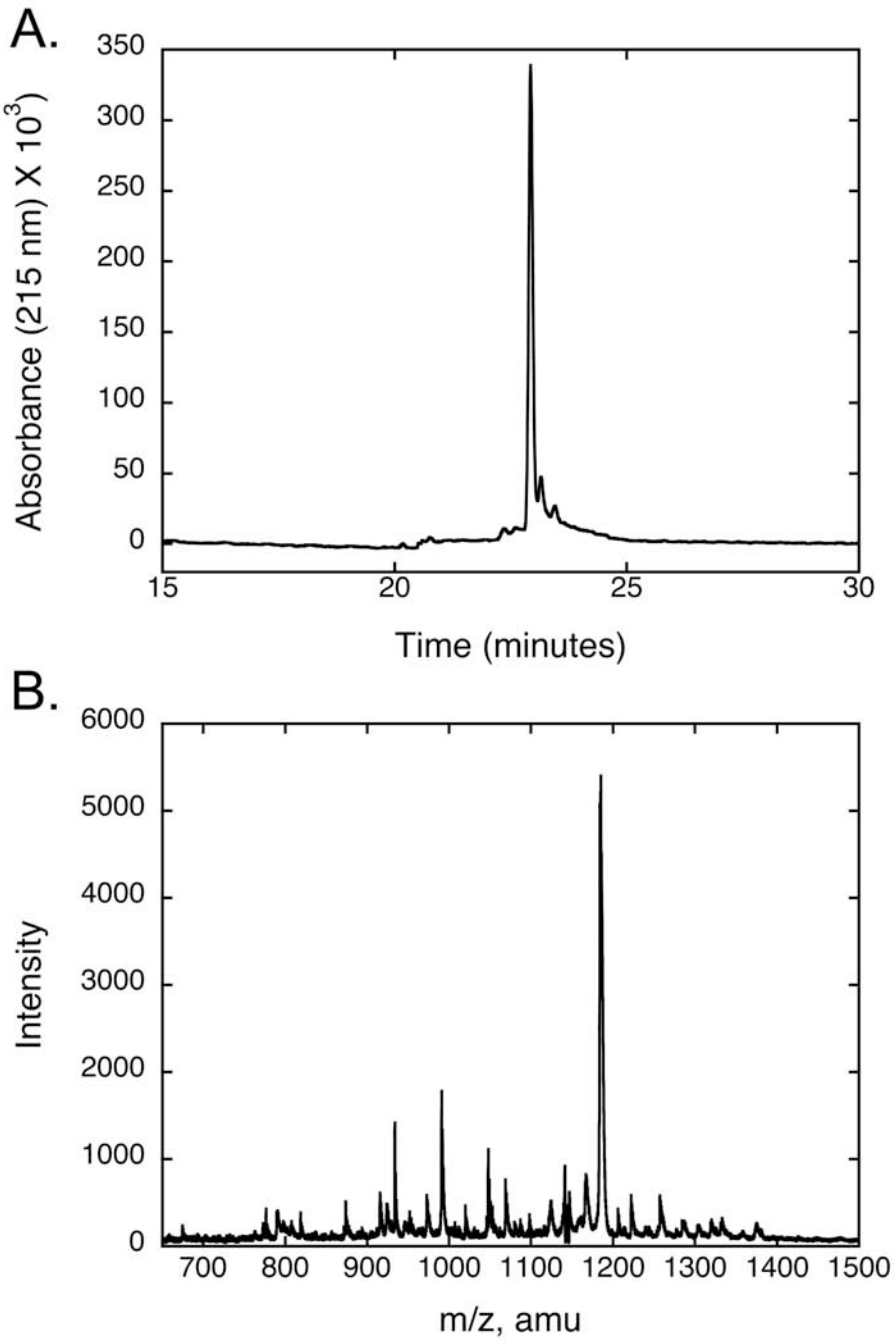
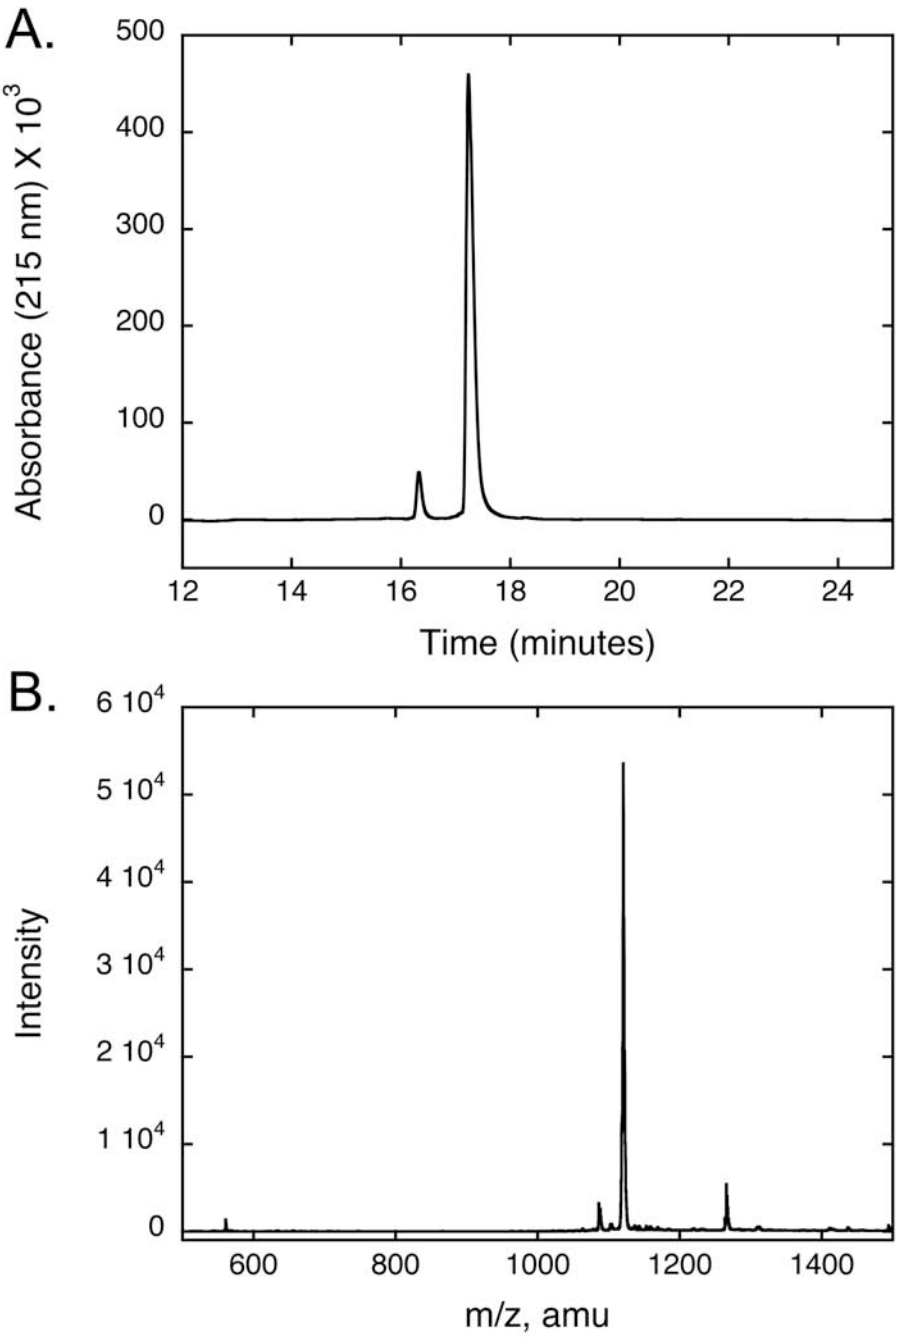
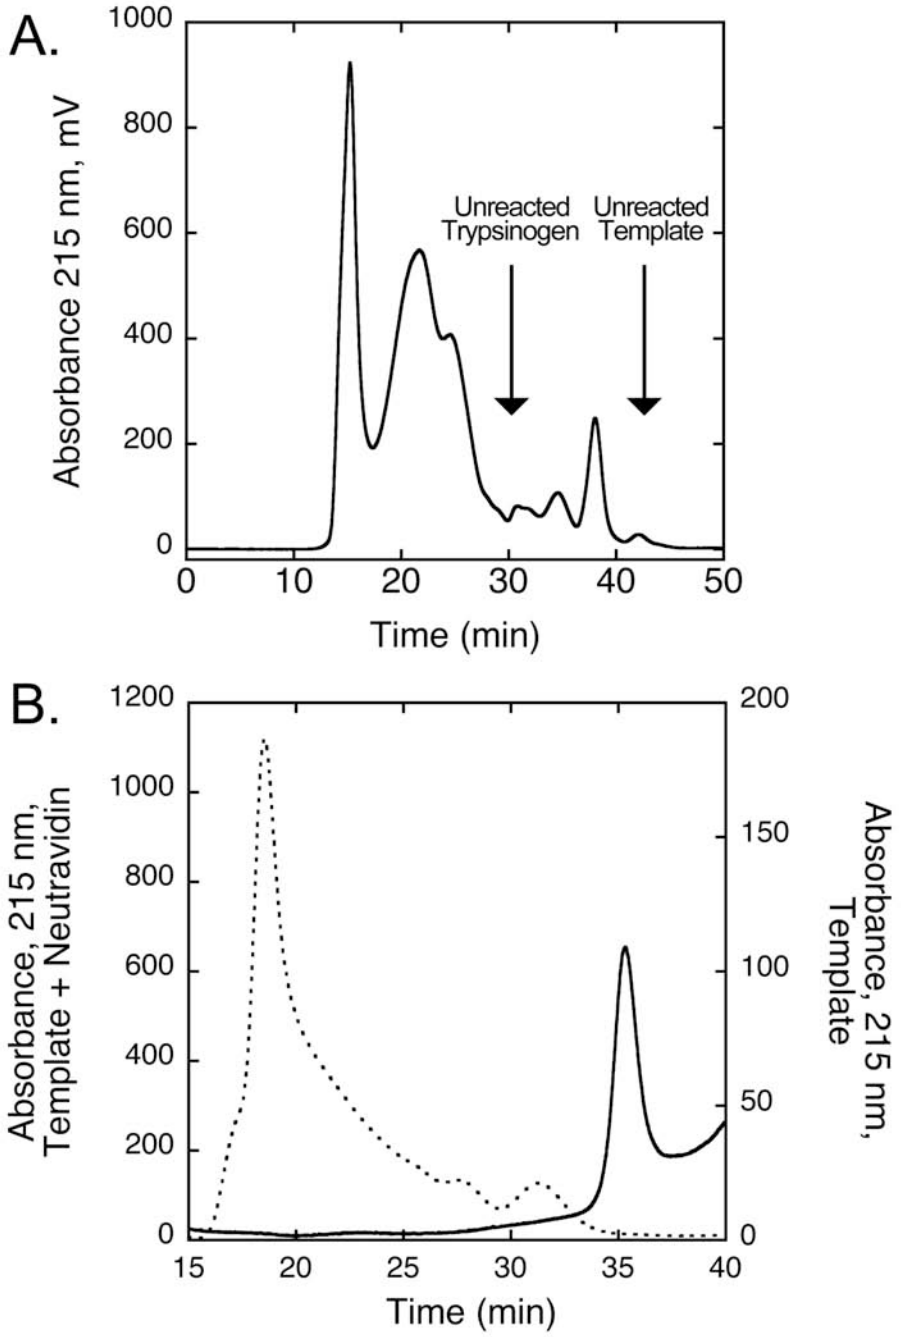


S2. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of Peptide C1-Mal, Cyclo-(^{D}DAP(β-hexanoylmaleimide)-Asp)$_3$. The gradient was water to acetonitrile (both containing 0.1 % TFA, v:v), 0 to 60% over 30 minutes.

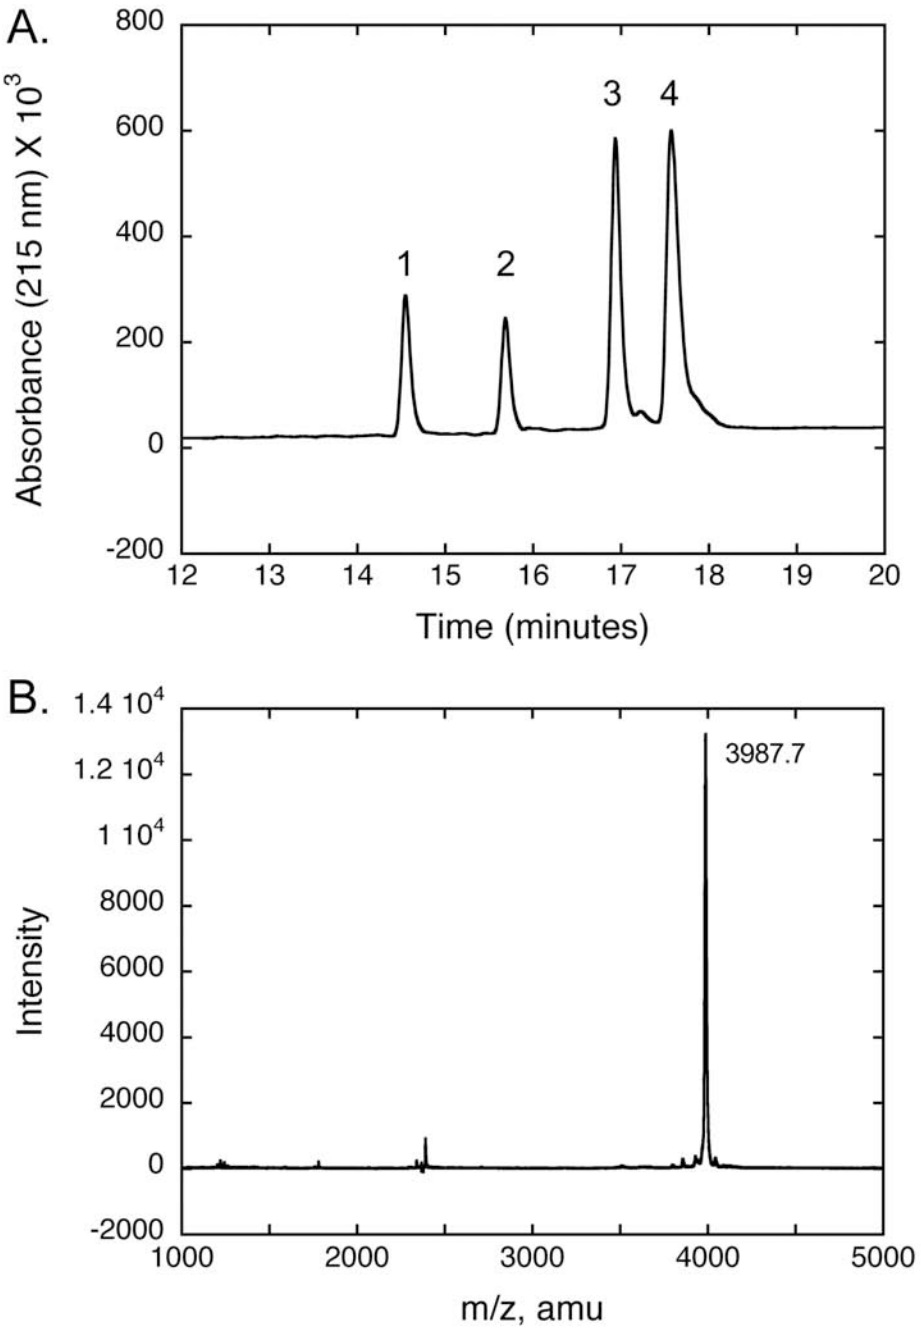


S3. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of Peptide C2, cyclo(–NH–(^{D}CysGlyArgGly)–CO–)$_3$. Conditions are as described in the paper in for Figure S2. The peak is well separated from the other reaction products.



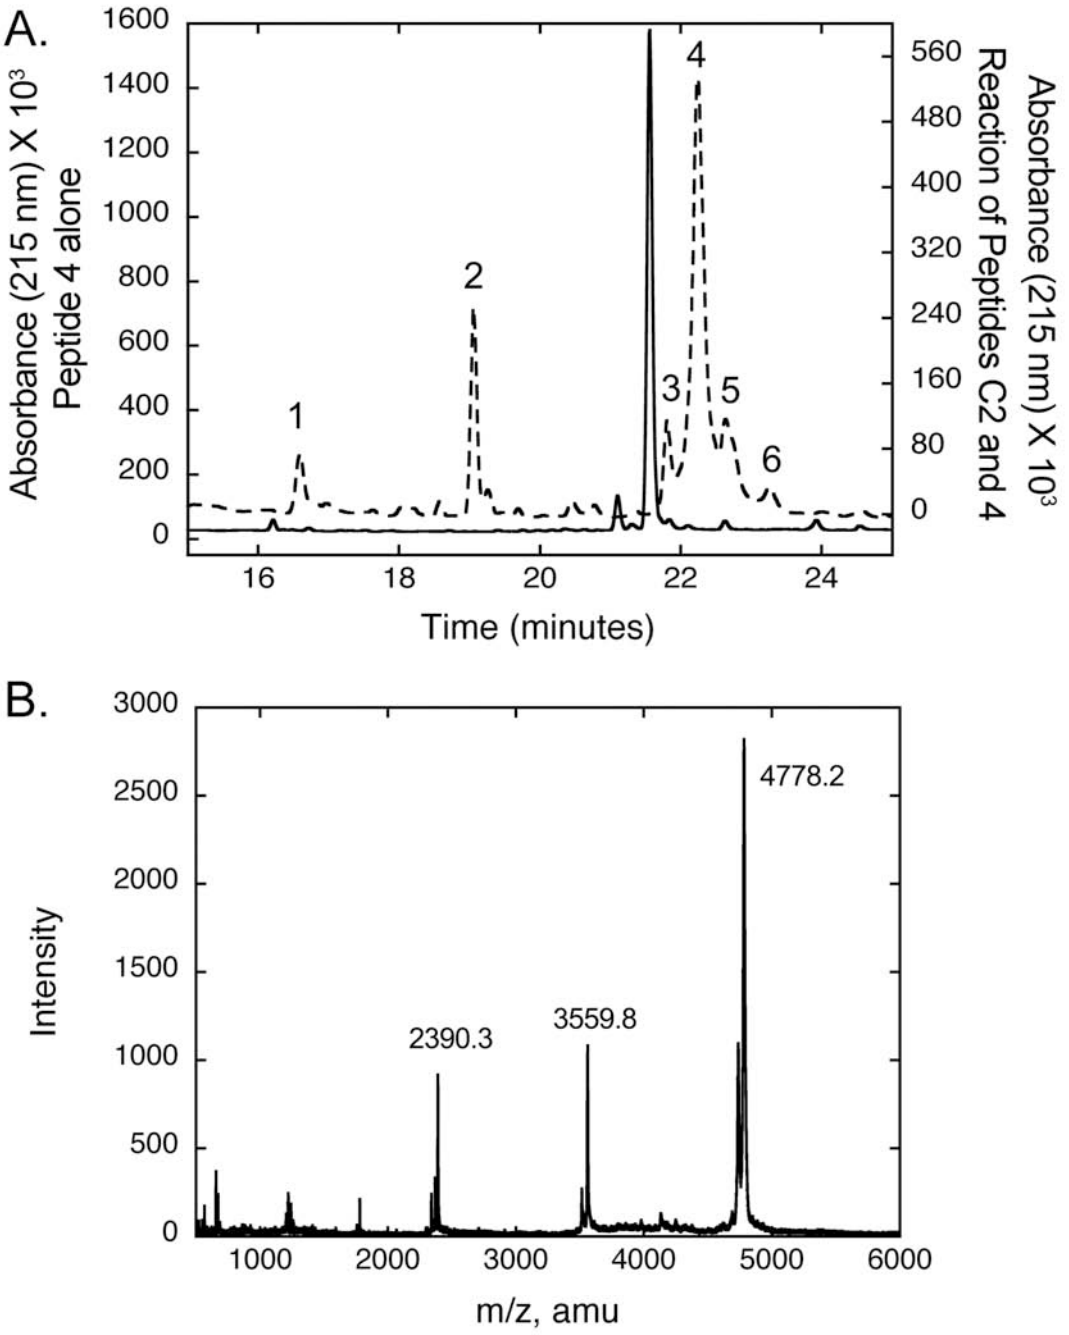
S4 (A) Reaction of Peptide C1-MaI with trypsinogen, after reaction of trypsinogen with SATA. The course of the reaction was monitored by size exclusion chromatography using Superdex 200. The figure shows a large peak consisting of the template peptide with three molecules of trypsinogen attached, and two smaller peaks containing one or

two molecules of trypsinogen. The elution positions of unreacted trypsinogen and unreacted template are marked by arrows. (B) Reaction of Peptide 7, Cyclo-(^{D}Cys(S-Mal-GEGEGEGK(Biotin)-OH)-Gly-Arg-Gly)$_3$, with neutravidin, as monitored by size exclusion chromatography using Superdex 200. Effluent is monitored at 215 nm. A large total volume peak, attributable to DMSO, is not shown. Elution of Peptide 7 alone is shown with a solid line; the product of reaction of neutravidin and Peptide 7 is shown with the dotted line.



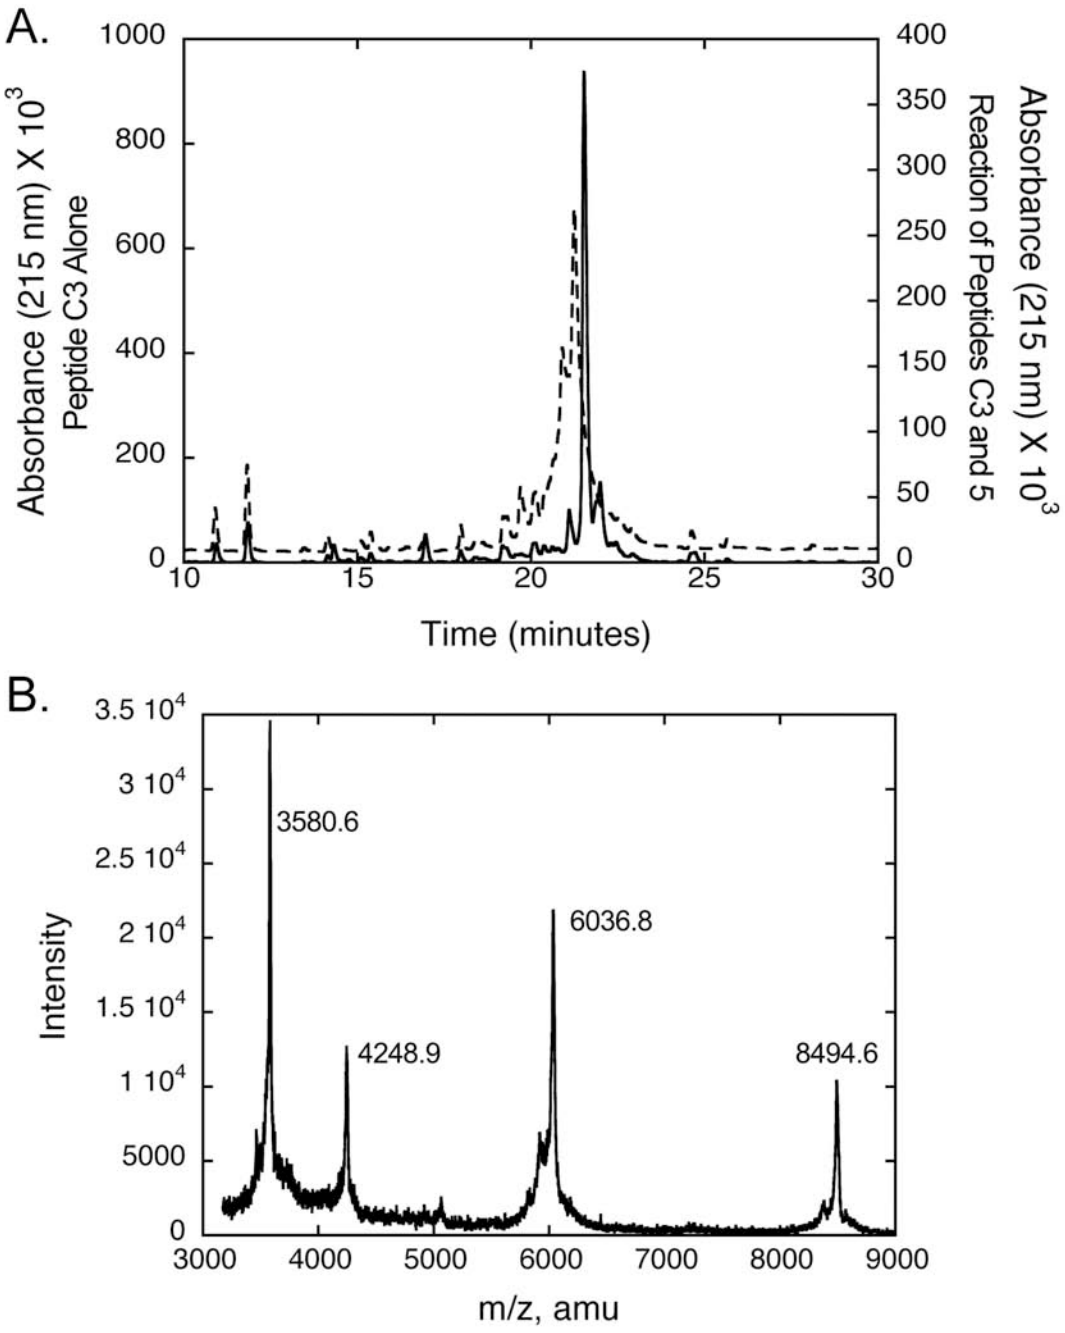
S5. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of products of the reaction of Peptide 6, Mal-GEGEGEGK–OH (Mal = maleimidylhexanoyl), with cyclic template Peptide C2, cyclo(–NH–(DCysGlyArgGly)–CO–). MALDI-TOF mass spectrometry identifies peak 4 in the preparative RP-HPLC chromatogram as the

template with three attached molecules of Peptide 6. The purified product has m/z = 3987.7 (expected = 3985.1). Peak 3 in the chromatogram is unreacted Peptide 6; peaks 1 and 2 are the template with one and two molecules of Peptide 6 attached.



S6. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of products of the reaction of the fibril-forming Peptide 4, Mal-PEG-GNNQQNY–OH, with the cyclic template Peptide C2, cyclo(–NH–(DCysGlyArgGly)–CO–). The tracing shows Peptide C2 alone (solid line) and the products of the reaction (dashed line). MALDI-TOF mass

spectrometry shows a mixture of products. The predominant product, labelled peak 4, is the cyclic Peptide C2 with three ligated copies of Peptide 4 (m/z = 4778.2); the peak also contains Peptide C2 with one or two ligated copies of Peptide 4 (m.z = 3559.8 and 2390.3, respectively). No attempt was made to separate the products of this reaction.



S7. Reverse phase HPLC (A) and MALDI-TOF mass spectrometry (B) of products of the reaction of the fibril-forming Peptide 5, Mal-SDDYYYGFGSNKFGRPRDP–OH with Peptide C2, cyclo(–NH–(^{D}CysGlyArgGly)–CO–). The products (dotted line) elute from the column slightly earlier than unreacted Peptide 5 (solid line), indicating an increase in

the apparent molecular weight. MALDI-TOF mass spectrometry shows that the products are a mixture of compounds, i.e. the Peptide C2 containing one, two or three ligated copies of Peptide 5. No attempt was made to isolate the individual species.

Antigen Delivery with Poly(Propylacrylic Acid) Conjugation Enhances MHC-1 Presentation and T-Cell Activation

Suzanne Flanary, Allan S. Hoffman, and Patrick S. Stayton*

Department of Bioengineering, University of Washington, Seattle, Washington 98195. Received July 24, 2008; Revised Manuscript Received October 3, 2008

While many infectious diseases are controlled by vaccine strategies, important limitations continue to motivate the development of better antigen delivery systems. This study focuses on the use of a pH-sensitive polymeric carrier based on poly(propylacrylic acid) (PPAA) to address the need for more potent CD8 cytotoxic T-cell (CTL) responses. An MHC-1/CD8 CTL cell model system with ovalbumin as the protein antigen was used to test whether PPAA could enhance the delivery of ovalbumin into the MHC-1 display pathway. Ovalbumin was conjugated to poly(propylacrylic acid-*co*-pyridyldisulfide acrylate) (PPAA-PDSA) by disulfide exchange to make reversible conjugates that could be reduced by the glutathione redox system in the cytosol of antigen presenting cells. The PPAA-PDSA ovalbumin conjugates displayed the pH-sensitive membrane disruptive properties of the parent polymer as determined by their hemolysis activities (sharply active at the endosomal pH values of 6−6.5). The polymer−ovalbumin conjugates exhibited strong 22-fold increases in the MHC-1 presentation and ovalbumin-specific CTL activation compared to free ovalbumin. No CTL activation was observed with control conjugates of ovalbumin and poly(methylacrylic acid) (PMAA) that do not display membrane disruptive activies, suggesting that it is the membrane destabilizing properties of the polymer that result in increased MHC-1 display and CTL activation. Further mechanistic studies quantitated the time course of stable intracellular localization of radiolabeled conjugates. 52% of initially internalized PPAA-conjugated ovalbumin remained in the cells after 4 h, compared to less than 10% of ovalbumin or PMAA−ovalbumin. These results showing enhanced cytosolic delivery and MHC-1 presentation for the PPAA−antigen conjugates suggest that they warrant future characterization as a CD8-enhancing vaccine delivery system.

INTRODUCTION

Vaccines currently play an important role in medicine, but many pathogens remain resistant to vaccine development, and therapeutic vaccines against cancer have faced considerable efficacy challenges. One of the most general challenges in the vaccine field is generating a robust and efficacious CD8 cytotoxic T-lymphocyte response, even though many potentially suitable antigens against tumors and infectious agents have been identified (*1*−*3*). $CD8^+$ cytotoxic T-lymphocytes (CTLs) are able to directly kill diseased cells and are critical to effective immunotherapy (*4, 5*), while $CD4^+$ helper T-lymphocytes also play an important role in a sustained immune response (*6, 7*). Helper T-lymphocytes are activated upon recognition of antigens presented by major histocompatibility complex class 2 (MHC-2) proteins. This pathway is accessed by exogenous antigens that are processed and combined with MHC-2 molecules within modified endosomal compartments of the APC. CTLs are activated by recognition of antigenic peptides displayed by MHC-1 proteins that are accessed primarily via the cytoplasm, although class I cross-presentation of antigens present in vesicular compartments can occur to some degree, especially in the case of larger particulate substances taken up by phagocytosis (*8*−*10*).

Exogenous proteins enter APCs through macropinocytosis and are often degraded, sequestered, or exocytosed in the endosomal−lysosomal pathway without gaining access to the cytoplasm (*11*−*13*). Enhancing the escape of therapeutic protein antigens from the compartments in which they are endocytosed could potentially increase the efficacy of protein vaccines through increased activation of CTLs (*14, 15*). Several groups have explored the use of pH-sensitive polymer-based delivery systems that take advantage of the decreased pH in the endosome. Carrier particles containing acid-degradable linkages, such as acetal (*14*−*16*), hydrozone (*17, 18*), or ketal (*19*) bonds, have been developed to degrade more rapidly in the acidic endosomal environment to trigger release of their cargo. Block ionmer complexes have been developed that increase in positive charge at endosomal pH, which could potentially result in endosomal membrane interaction (*20*). A popular approach has utilized cationic polymer systems, which enhance endosomal release via the "proton sponge effect" (*21*−*25*). Additionally, particles formed from poly(D,L-lactic-*co*-glycolic acid) (PLGA) have been widely investigated for antigen delivery and have resulted in increasing MHC-1 presentation of encapsulated antigens (*26*−*28*). While some endosomal escape is observed for this system (*27*), a mechanism for cytosolic delivery is not well established.

Our group has developed synthetic polymers based on alkyl(acrylic acid) monomers that display pH-sensitive, membrane-destabilizing activities (*29*−*36*). In the ionized state, the polymers are inactive at membrane destabilization, but at the decreased pH levels typical of the endosome (pH 5.5−6.5), the carboxyl groups become protonated and the polymers transition to a state that is membrane-destabilizing. This mechanism mimics the pH-dependent membrane disruptive activity of pathogenic proteins such as hemaglutinin (*37, 38*) and diphtheria toxin (*39, 40*), and of synthetic fusogenic peptides such as GALA (*41*). The mechanistic utility of pathogenic proteins has demonstrated the importance of endosomal release in MHC-1 presentation and CTL activation (*42*−*46*), but

corresponding biological responses to the pathogenic proteins has limited their clinical translation.

Here, we report the characterization of a pH-responsive, membrane-destabilizing polymeric carrier for cytosolic protein antigen delivery in a model MHC-1 presentation system. This model utilizes CD8+ T-cells that is activated upon T-cell receptor ligation to an MHC-1/ovalbumin peptide complex displayed from a model RAW macrophage cell (*14*, *47*). The poly(propylacrylic acid-*co*-pyridyldisulfide acrylate) (PPAA-PDSA) polymer was designed to conjugate ovalbumin by disulfide exchange between thiolated protein and the PDSA monomers. The resulting protein−polymer disulfide bond can be reduced by the cytosolic glutathione reduction system to leave the free antigen for subsequent proteolytic processing. Results showing a strong enhancement of CTL activation suggest that the intracellular pharmacokinetic step of vesicular release is a limiting barrier to subsequent protein processing and MHC-1 presentation.

MATERIALS AND METHODS

Polymer Synthesis. All chemicals and reagents were ACS grade purchased from Sigma-Aldrich, St. Louis, MO, and used without further purification unless otherwise noted. For the synthesis of the PPAA-PDSA polymer, 0.007 mol propylacrylic acid (PAA) (Gateway Chemical Technology, St. Louis, MO), 0.00011 mol PDSA (*33*), and 0.000056 mol free-radical initiator azobisisobutyronitrile (AIBN, purified by recrystallization from methanol) were combined in a 5 mL flask and degassed by 4 rounds of freeze−vacuum−thaw, then reacted at 60 °C for 24 h. The polymer was dissolved in 3 mL dimethyl formamide (DMF) and purified by 3 rounds of precipitation in 500 mL diethyl ether. Poly(methacrylic acid-*co*-PDSA) (PMAA-PDSA) was synthesized for use as a control polymer. It was formed by reversible addition fragmentation chain transfer polymerization (RAFT) by combining 0.016 mol methacrylic acid (MAA) (purified by distillation), 0.00022 mol PDSA, 0.000052 mol chain transfer agent 4-cyanopentanoic acid dithiobenzoate (CTP) (*48*), 0.000052 mol initiator 2,2′-azobis (2,4-dimethyl valeronitrile) (V-65, Wako Chemicals USA, Richmond VA), and 3 mL DMF in a 5 mL round-bottom flask. The reaction was degassed by purging with N_2 for 20 min, then polymerized at 40 °C for 24 h. Six milliliters DMF was added, and the polymer was purified by 3 rounds of precipitation in 1 L diethyl ether.

Polymer compositions were determined by ^{1}H NMR using a Bruker AVance 300 MHz instrument and deuterated dimethyl sulfoxide (DMSO-d_6, Fisher Chemical, Pittsburgh, PA). The characteristic ^{1}H NMR (DMSO-d_6) polymer peaks were as follows: 4.0 ppm (2H, O-CH_2-R, PDSA), 7.2 ppm (1H, aromatic, PDSA), 7.8 ppm (2H, aromatic, PDSA), 8.5 ppm (1H, aromatic, PDSA), 12.1 ppm (1H, -COOH, PAAc/MAAc). PDSA content was determined both by NMR and by the absorbance at 343 nm of pyridine-2-thione released from the polymer following reduction with excess of dithiothreitol (DTT). The polymer molecular weights were determined by GPC using a Viscotek VE2001 sample module and VE3580 refractive index detector (Viscotek, Houston, TX), and Tosoh TSK-GEL α-3000 and α-4000 columns (Tosoh Biosciences, Montgomeryville, PA). Polymer molecular weights were determined on the basis of poly(methacrylic acid) (PMMA) standards using HPLC-grade DMF with 0.1% lithium bromide as the mobile phase. The pK_a of the PPAA-PDSA was determined by acid/base titration of 50 mg polymer in distilled, deionized water, starting at pH 12.5 and titrating with 0.1 N HCl.

Polymer−Protein Conjugation and Characterization. Conjugation was performed via disulfide exchange between the PDSA component of the polymer and free thiols introduced onto ovalbumin by reaction with Traut's reagent (2-iminothiolane, Pierce Biotechnology, Rockford, IL). Ten milligrams ovalbumin was mixed with a 10× molar excess of Traut's reagent in conjugation buffer (0.1 M phosphate buffer, pH 7.8, 0.15 M NaCl, 5 mM EDTA) for 1 h at room temperature. The reaction mixture was purified using a PD-10 desalting column containing Sephadex G-25 (MWCO 5kD, GE Healthcare, Piscataway, NJ) and the degree of modification was estimated by Ellman's assay (Pierce Biotechnology, Rockford, IL). A 2.5× molar excess of polymer, either PPAA-PDSA or PMAA-PDSA, was immediately added to the modified protein and allowed to react 2 h at room temperature in conjugation buffer. The degree of conjugation was estimated by measuring the absorbance at 343 nm (A_{343}) of the pyridine-2-thione group released from PDSA upon disulfide exchange, and the conjugate was purified on a PD-10 column and lyophilized for storage.

Radioactively labeled PPAA-PDSA and PMAA-PDSA−ovalbumin conjugates were formed for use in the cellular uptake and exocytosis experiments. The procedure was identical to that listed above, with the following exceptions. Ovalbumin was mixed with a 20-fold molar excess of Traut's reagent. A 3× molar excess of ^{14}C-iodoacetamide (MP Biomedical, Solon, OH) was then added to react with some of the introduced thiol groups. After reacting for 1 h, the 2.5× molar excess of polymer was added to form the conjugate.

The molecular weight distribution was determined by GPC (Viscotek VE2001 sample module, VE3580 RI Detector, Waters Corp. Ultrahydrogel columns) in 0.1 M sodium phosphate buffer, pH 8, using poly(ethylene oxide) (PEO) standards (Polysciences, Inc., Warrington, PA). The final weight percent of ovalbumin in the conjugates was determined by the BCA protein assay (Pierce Biotechnology, Rockford, IL), using an ovalbumin standard curve. SDS-PAGE (polyacrylamide gel electrophoresis) was performed to detect any unreacted ovalbumin in the conjugate solution. Precast Tris-HCl polyacrylamide gels, 4−20% gradient, sample and running buffer, and protein standards were purchased from Bio-Rad, Hercules, CA. On the basis of the results of the BCA assay, conjugates were loaded onto the gels in the appropriate amounts to give 10 μg of ovalbumin per lane. Gels were run for 45 min at 100 mA, then visualized using Coomassie staining (Bio-Rad, Hercules, CA).

Red Blood Cell Hemolysis. The pH-dependent membrane-disruptive ability of the polymers and polymer−protein conjugates was estimated using a red blood cell hemolysis assay, described previously (*29*). Briefly, red blood cells were isolated and added to polymer and conjugate solutions (normalized to equivalent polymer amounts) of varying concentrations in 0.1 M phosphate buffer at pH values of 5.8, 6.6, and 7.4. The degree of RBC membrane disruption (% hemolysis) was quantified by measuring the absorbance at 541 nm of the hemoglobin released into the solution by lysed cells, in comparison with complete lysis by Triton X-100 detergent. Sample concentrations were all normalized to contain 5 μg/mL of polymer, and samples were performed in triplicate with error reported as ±1 standard deviation.

MHC- I Antigen Presentation and CTL Activation Assay. The ability of the polymer to increase cytoplasmic delivery and subsequent MHC class I antigen presentation was evaluated using the *lacZ* antigen presentation assay (*14*, *47*). This assay utilizes a specialized *LacZ* B3Z CTL hybridoma. These CTLs produce β-galactosidase upon recognition of the ovalbumin class I antigenic epitope SIINFEKL complexed with the MHC class I molecule H-2K^b, present on RAW 309.1 CR macrophages. Therefore, a measure of β-galactosidase activity can be used to determine the degree to which delivered ovalbumin is presented as a class I antigen. All tissue culture reagents were purchased from Invitrogen Corp., Carlsbad, CA, unless otherwise noted.

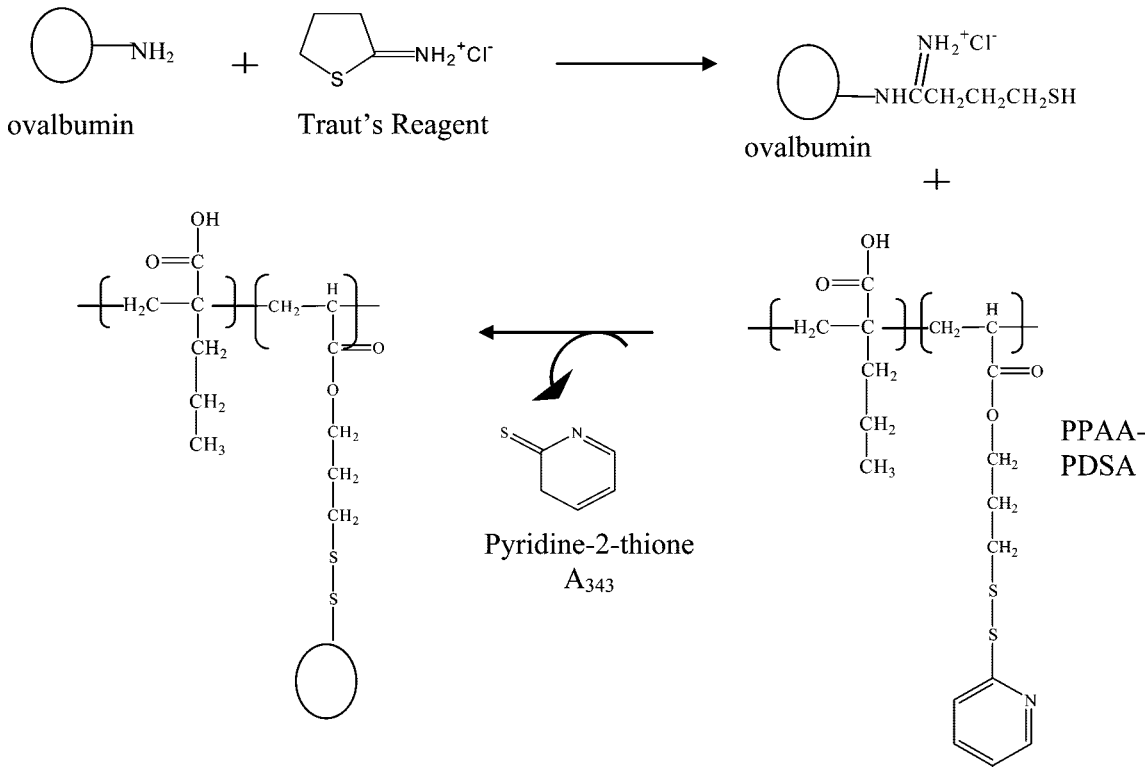

Figure 1. Schematic of chemistry for conjugation of ovalbumin to the PDSA moiety of the PPAA-PDSA polymer. The protein is first modified using Traut's reagent to convert primary amines to thiols, then the polymer is added and a disulfide exchange reaction occurs, releasing pyridine-2-thione. Reaction progress can be monitored by measuring A_{343} of released pyridine-2-thione. PPAA and PMAA conjugates consisting of 1.7 μg polymer per μg ovalbumin were formed.

RAW 309.1 CR macrophages (ATCC, Manassas, VA) were cultured in 90% DMEM with D-glucose and L-glutamine, 10% fetal bovine serum (FBS), supplemented with 100 U/mL penicillin/100 μg/mL streptomycin. B3Z CTLs were a gift from Dr. Nilabh Shastri, UC Berkeley. They were cultured in 90% RPMI medium with D-glucose and L-glutamine, 10% FBS, supplemented with 100 U/mL penicillin/100 μg/mL streptomycin, 50 μM 2-mercaptoethanol (Sigma-Aldrich, St. Louis, MO), and 1 mM sodium pyruvate. For the assay, RAW cells were plated at 5×10^4 cells per well in a 96-well plate and grown overnight. PPAA−ovalbumin conjugates and control samples were added to the cells and incubated 6 h in DMEM with 5% FBS. Three sample concentrations were tested: 50 μg/mL, 100 μg/mL, and 150 μg/mL (samples were normalized to represent equivalent ovalbumin concentrations). RAW cells were rinsed with DMEM; then, 1×10^5 B3Z cells per well were added and incubated 16 h. Cells were rinsed with phosphate buffered saline, then 100 μL lysis buffer [100 μM mercaptoethanol (Sigma-Aldrich, St. Louis, MO), 9 mM $MgCl_2$ (Sigma-Aldrich, St. Louis, MO), and 0.15 mM chlorophenol red β-D-galactoside (EMD Biosciences, San Diego, CA) in PBS] was added. After 4 h, the absorbance of released chlorophenol red was measured at 595 nm. All samples were evaluated in triplicate and errors are reported as ± 1 standard deviation. Maximum possible β-galactosidase production was determined by chemically stimulating the B3Z cells in media containing 3.15 μM ionomycin (Sigma-Aldrich, St. Louis, MO) and 10 ng/mL phorbol 12-myristate 13-acetate (Sigma-Aldrich, St. Louis, MO) for 4 h before rinsing and adding the lysis buffer.

Cellular Uptake and Exocytosis of ^{14}C-Ovalbumin and Ovalbumin−Polymer Conjugates. The cellular uptake and exocytosis of ^{14}C-labeled ovalbumin and the PPAA and PMAA−ovalbumin conjugates was studied in RAW 309.1 CR macrophages, using a procedure similar to that described by Besterman et al. (*49*). For measurement of the cellular accumulation of ^{14}C ovalbumin over time, RAW macrophages were plated in a 48-well plate at 75 000 cells/well and allowed to grow overnight. Ovalbumin, PPAA−ovalbumin conjugate, PMAA−ovalbumin conjugate, or a PPAA and ovalbumin physical mixture was added to the cells at a concentration of 50 μg/mL of ovalbumin. Samples were incubated for 15 min, 30 min, 1 h, or 2 h. The cells were then washed 2× with PBS and lysed using 1% Triton X-100 in water. Radioactivity in the cell media, PBS wash, and cell lysate was measured using a Beckman-Coulter LS 6500 liquid scintillation counter. EcoScint scintillation fluid was obtained from National Diagnostics, Atlanta, GA. Uptake of ^{14}C-ovalbumin is presented as the % radioactivity present in the cell lysate compared to the total radioactivity delivered. The experiment was performed with a minimum of $n = 3$.

To measure the exocytosis of ^{14}C-ovalbumin, RAW macrophages were again plated at 75 000 cells/well in a 48-well plate and allowed to grow overnight. Ovalbumin, PPAA−ovalbumin conjugate, PMAA−ovalbumin conjugate, or a PPAA and ovalbumin physical mixture was added to the cells at a concentration of 50 μg/mL of ovalbumin. Samples were incubated for either 1 or 15 min, then non-internalized conjugate was removed and cells were washed 2× with media. Fresh media was added to the cells at the following time points: 5 min, 10 min, 20 min, 30 min, 1 h, 2 h, and 4 h. The reappearance of ^{14}C-ovalbumin in the supernatant was measured at each time point. After 4 h, cells were lysed with 1% Triton X-100 and the radioactivity in the lysate was measured. The amount of ovalbumin internalized after the 1 or 15 min incubation time was determined as a percentage of the total delivered. The amount of ovalbumin exocytosed at each time point, as well as the amount remaining in the cells after 4 h, was then determined as a percentage of the total internalized. The experiments were performed with a minimum of $n = 3$.

In Vitro Cytotoxicity of Polymers and Conjugates. The cytotoxicity of the PPAA and PMAA polymers and conjugates was determined for both the RAW and B3Z cell lines used in the MHC-1 presentation assay. Cytotoxicity was evaluated using the LDH (lactate dehydrogenase) assay (Roche Applied Sciences, Indianapolis, IN). This assay allows colorimetric measurement of LDH activity in the supernatant, which correlates to the proportion of dead or damaged cells. Cells were plated at 5×10^4 cells/well in their normal culture media, and polymer and conjugate samples were added to concentrations up to 300 μg/mL, then incubated for 24 h. Cells were centrifuged at 250 *g* for 10 min, then 100 μL supernatant was removed and combined with 100 μL LDH reagent. The absorbance at 490 nm (reference 650 nm) was recorded every 5 min for 30 min, and cell survival was determined by comparing to untreated cells and cells lysed with 1% Triton X-100 in water. Each sample was evaluated in triplicate, and errors are reported as the standard error of the mean (SEM).

Statistical Anaylsis. Statistical testing was performed on all data using analysis of variance (ANOVA). The least significant difference (LSD) method was subsequently used for comparison of specific groups in the ANOVA analysis.

RESULTS AND DISCUSSION

Synthesis and Characterization of Polymers and Conjugates. The conjugation scheme for attaching ovalbumin to PPAA-PDSA is shown in Figure 1. The conjugates are formed through disulfide exchange of the ovalbumin thiol with the PDSA group in the polymer and are designed to be reduced by glutathione in the cell cytoplasm, freeing the protein for processing and MHC-1 presentation. The membrane-disruptive PPAA-PDSA polymer was synthesized by free-radical polymerization and resulted in a polymer with 3 mol % PDSA and $M_w = 26$ kD, $M_n = 10$ kD, and PDI = 2.6, based on GPC analysis using PMMA standards. The pK_a of this polymer was determined by acid/base titration to be 6.8, which is in the range of the early endosome. A non-membrane-disruptive polymer, PMAA-PDSA, of similar size ($M_w = 34$ kD, $M_n = 12$ kD, PDI = 2.8) containing 2 mol % PDSA was synthesized as a control. Methacrylic acid is less hydrophobic than propylacrylic acid in the protonated form and does not cause any membrane disruption in the RBC hemolysis assay.

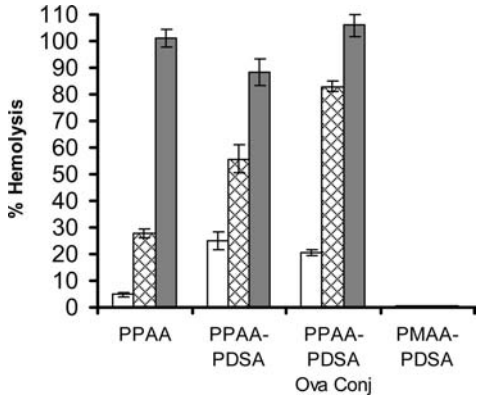

Figure 2. pH-dependent hemolysis properties of PPAA polymers and ovalbumin conjugates. Red blood cells were isolated and added to polymer and conjugate solutions (polymer concentrations = 5 μg/mL) in 0.1 M phosphate buffer at pH values of 7.4 (□), 6.6 (×), and 5.8 (■). Hemolysis is reported as a percentage of complete lysis by Triton X-100. PPAA-PDSA shows high membrane-disruptive activity at pH 5.8 but considerably lower membrane disruption at pH 7.4. The polymer retains its hemolysis capabilities after conjugation to the hydrophilic protein ovalbumin. PMAA-PDSA, however, does not lyse red blood cells at any pH due to the decreased hydrophobicity of its methyl side chain compared with the propyl side chain of PPAA.

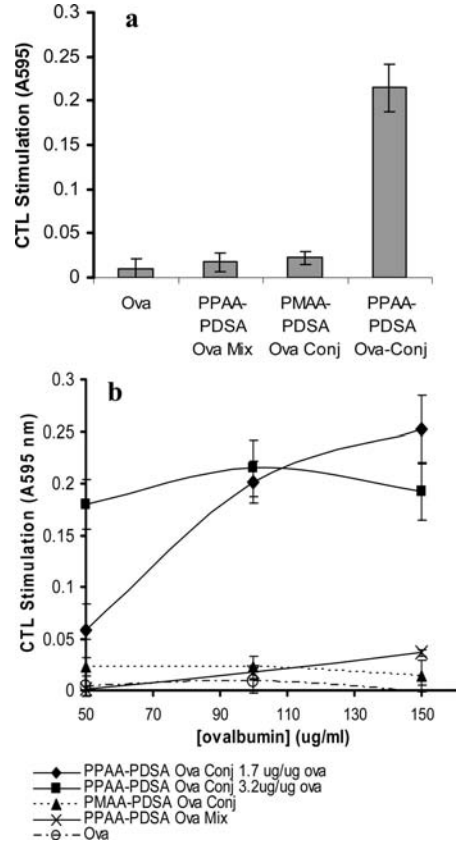

Figure 3. CTL activation/MHC-I presentation of PPAA−ovalbumin conjugates. Samples were incubated with RAW macrophages for 6 h then removed and B3Z T-cells were added for 16 h. Cells were rinsed and incubated 4 h with lysis buffer containing chlorophenol red β-D-galactoside, then absorbance of released chlorophenol red was measured at 595 nm. Samples were evaluated in triplicate and errors are reported as ±1 standard deviation. For reference, the maximum possible β-galactosidase production was determined by chemically stimulating the B3Z cells using PMA/ionomycin for 4 h, which gave an A_{595} of 0.56. (a) Ovalbumin concentration = 100 μg/mL. The PPAA−ovalbumin conjugate shows significantly greater CTL activation than do any of the control samples ($p < 0.0005$). This is likely due to the endosomal disruption provided by PPAA, which allows the protein to more efficiently access the MHC-I pathway in the cytoplasm. However, PMAA conjugation results in low CTL activation, similar to that for free ovalbumin or a PPAA ovalbumin physical mixture ($p = 0.2$). This suggests that the increase in MHC-1 presentation provided by PPAA is due to its endosomal disruptive properties rather than solely to increased uptake due to its larger size compared to free ovalbumin. (b) The PPAA−ovalbumin conjugates enhance CTL stimulation is a dose-dependent manner. When the polymer ratio is increased from 1.7 μg/μg ova to 3.2 μg/μg ova, maximal CTL activation is reached at a lower ovalbumin concentration.

The degree of thiolation of the ovalbumin used to form the polymer−ovalbumin conjugates was determined by Ellman's assay to be 15% of the total available lysines. The ovalbumin conjugates formed from both the PPAA-PDSA and PMAA-PDSA polymers were found by BCA assay to contain 37 weight % ovalbumin and 63 weight % polymer, or 1.7 μg polymer per μg protein, and GPC analysis gave $M_w = 200$ kD, $M_n = 45$ kD, PDI = 4.4 for the PPAA-PDSA−ovalbumin conjugate and $M_w = 130$ kD, $M_n = 57$ kD, PDI = 2.3 for the PMAA-PDSA−ovalbumin conjugate. The ^{14}C-labeled conjugates used for the cellular internalization studies were of similar sizes: $M_w = 140$ kD, $M_n = 40$ kD, PDI = 3.5 for the PPAA conjugate and $M_w = 120$ kD, $M_n = 50$ kD, PDI = 2.4 for the PMAA conjugate. The degree of thiolation of the ovalbumin used to form these conjugates was determined by Ellman's assay to be 30%. The radiolabeled PPAA and PMAA conjugates were found

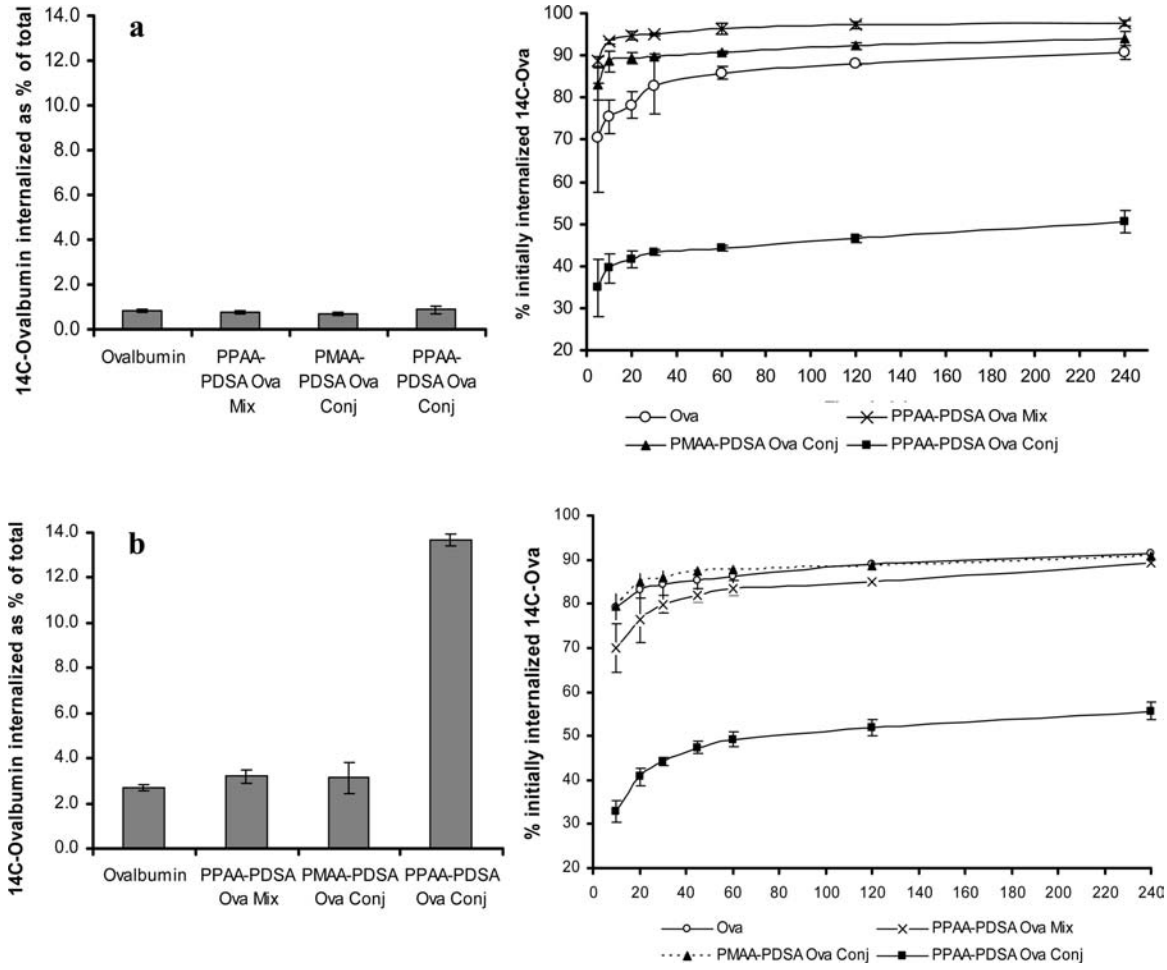

Figure 4. Exocytosis of ^{14}C-ovalbumin after (a) 1 min uptake time and (b) 15 min uptake time. Samples were incubated with RAW macrophages and non-internalized conjugate was removed. Fresh media was added to the cells at various time intervals and the reappearance of ^{14}C-ovalbumin in the supernatant was measured. After 4 h, cells were lysed with 1% Triton X-100 and the radioactivity in the lysate was measured. Samples were evaluated with a minimum of $n = 3$. The amount of ovalbumin initially internalized was determined as a percentage of the total delivered (left-side panels). It can be seen that the amount of ovalbumin taken into the cells in 1 min is similar for all samples ($p = 0.66$) giving a uniform starting point for the exocytosis measurements. However, the preferential accumulation of PPAA−ovalbumin is already noticeable at the 15 min uptake time. The amount of ovalbumin exocytosed at each time point was then calculated as a percentage of the amount initially internalized (right-side panels). Most exocytosis occurred in the first 30 min, and exocytosis rates were similar for all samples. However, the amount of ovalbumin that remained in the cells and was not exocytosed was greatly enhanced for PPAA conjugates. This effect is likely due to the ability of the polymer to disrupt the endosomal membrane and deliver the ovalbumin to the cytosol before exocytosis can occur.

to be 34 and 40 wt % ovalbumin, or 1.9 μg polymer per μg protein and 1.5 μg polymer per μg protein, respectively. SDS-PAGE was performed to ensure that free protein did not remain in the conjugate mixtures, as it could interfere with interpretation of the MHC-1 presentation assay results.

Red Blood Cell Hemolysis. Red blood cell hemolysis assays were performed to evaluate the pH-dependent membrane-disruptive activity of the polymers and polymer−protein conjugates (*50*). Hemolysis assays were conducted at three pH values (7.4, 6.6, and 5.8) in order to approximate physiological conditions and the conditions found in early and late endosomes. Conjugate concentrations were adjusted to contain 5 μg/mL of polymer. The results of this assay are detailed in Figure 2. As expected, the PPAA-PDSA polymer and conjugates were considerably more hemolytic at the lower pH characteristic of the endosome (pH 5.8). The PPAA-PDSA polymer shows slightly higher hemolyis at physiological pH than does a PPAA homopolymer of the same size, which consistently gives less than 10% hemolysis. This increased hemolyis at pH 7.4 is likely due to the hydrophobicity added by the PDSA monomer, especially the pyridyl group, which is removed upon conjugation. The increased hemolysis at pH 7.4 has not resulted in increased cytotoxicity at the concentrations and incubation times used. The PPAA−ovalbumin conjugates have similar hemolysis profiles to the PPAA-PDSA polymer alone, indicating that the polymer retains its hemolytic activity when attached to the 40 kD ovalbumin protein.

MHC-I Antigen Presentation and CTL Activation Assay. The ability of the polymer to enhance delivery of protein antigen into the MHC class I pathway was evaluated using the *LacZ* class I presentation assay (*14*, *47*). The PPAA-PDSA−ovalbumin conjugate resulted in a strong 22-fold increase in MHC-I presentation and CTL activation compared to free ovalbumin ($p = 0.0001$), as shown in Figure 3. The ovalbumin must be chemically attached to the PPAA in order to be effectively delivered into the MHC-1 pathway, as physical mixtures showed only background CTL activation levels ($p = 0.20$ compared to free ovalbumin). The PMAA−ovalbumin conjugates did not significantly enhance CTL activation over delivery of free ovalbumin ($p = 0.72$). These results correlate the membrane destabilizing activity of the polymer to the level of MHC-1 pathway and CTL activation, and suggest that the increase in presentation is not solely the result of increased cellular uptake due to the larger size of the conjugate compared to free ovalbumin. Furthermore, PPAA conjugation increases the CTL activation in a dose-dependent manner, whereas higher

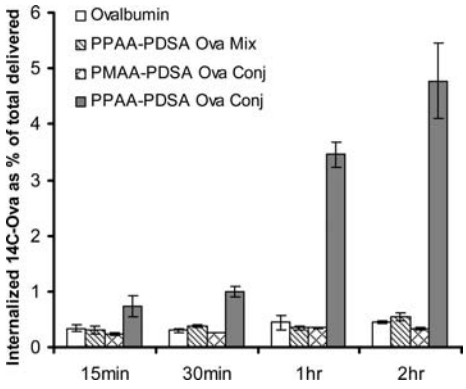

Figure 5. Uptake of ^{14}C-ovalbumin−PPAA increases over time. RAW macrophages were incubated with samples at a concentration of 50 μg/mL of ovalbumin. The cells were then washed with PBS and lysed using 1% Triton X-100. Radioactivity in the cell media, PBS wash, and cell lysate was measured; and uptake of ^{14}C-ovalbumin was calculated as the % radioactivity present in the cell lysate compared to the total radioactivity delivered. Experiments were performed in triplicate and error is expressed as ±1 standard deviation. It can be seen that PPAA-conjugated ovalbumin continually accumulates significantly in the cell, whereas the control sample levels remain fairly constant ($p > 0.09$). This is likely due to the ability of PPAA−ovalbumin to escape the endosome before being exocytosed.

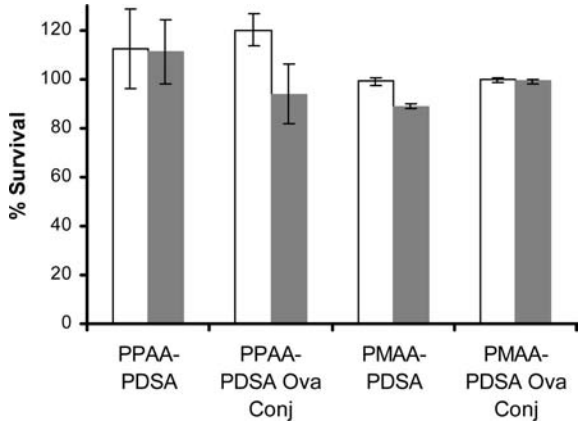

Figure 6. Cytotoxicity of PPAA and PMAA polymers and conjugates. Cytotoxicity was determined for both RAW and B3Z cells using the LDH assay. Samples were added to cells for 24 h at a concentration of 300 μg/mL polymer, twice the highest concentration used in the MHC-1 presentation assay. The cell supernatant was then combined with LDH reagent and the absorbance at 490 nm was recorded. Percent survival $= 1 - [(A_{490}$ of sample $- A_{490}$ of untreated cells control)/(A_{490} of TritonX control $- A_{490}$ of untreated cells control)] $\times$ 100%. Samples were evaluated in triplicate and error is expressed as ± SEM. It can be seen that excessive toxicity was not observed for any of the samples.

concentrations of control samples do not result in significant increases in CTL activation ($p < 0.2$) (Figure 3b). Increasing the amount of PPAA in the conjugate further exaggerates this effect: when the weight ratio of polymer/protein is doubled from 1.7 to 3.2 μg polymer per μg protein, CTL activation increases, becoming maximized at a lower ovalbumin concentration. While direct comparisons to other similar antigen delivery systems are not possible due to the different carrier architectures (soluble vs particulate) and differences in experimental conditions and data presentation, the PPAA conjugates perform similarly to those reported previously with the B3Z CTL activation assay. Acid-degradable particles used to deliver ovalbumin have resulted in maximal A_{595} values (the measure of CTL activation) in the range 0.25−0.4 (*14*, *16*), which is similar to that reported in our study, and PLGA particles have been shown to provide a 5-fold increase in CTL activation over delivery of ovalbumin alone (*26*).

Cellular Uptake and Exocytosis of ^{14}C-Ovalbumin and Ovalbumin−Polymer Conjugates. In order to further explore the mechanism of PPAA action, the cellular uptake and internalization of radiolabeled ovalbumin was studied in RAW macrophages. It was found that the major effect of PPAA was to reduce the amount of ovalbumin recycled back out of the cell after initial internalization. The samples were incubated with RAW macrophages for 1 min, and fresh media was applied after washing of the cells at regular time intervals from 5 min to 4 h. The amount of radioactivity that reappeared in the supernatant at each time interval was measured, as well as the radioactivity remaining in the cells. This method is similar to methods previously employed for the study of exocytosis of radiolabeled sucrose in guinea pig alveolar macrophages (*49*), hapten−protein conjugates in murine macrophages (*51*), and PLGA nanoparticles in vascular smooth muscle cells (*52*). The initial amount of ^{14}C-ovalbumin taken up by the cells was statistically similar for all the sample groups ($p = 0.66$) and was approximately 0.8% of the total amount delivered (Figure 4a, left panel). However, less PPAA-conjugated ovalbumin was exocytosed compared to the control groups, which is detailed in the exocytosis profiles shown in Figure 4a, right panel. This resulted in the greater and more stable accumulation of the PPAA−ovalbumin inside the cells, even after 4 h of exocytosis. 52% of the internalized PPAA−ovalbumin was found inside the cells at 4 h, whereas less than 10% of the ovalbumin remained for the free ovalbumin, the physical mixture, and the non-membrane-active PMAA conjugate.

Similar exocytosis trends are found when the initial incubation was extended to 15 min (Figure 4b). At this uptake time, the amount of PPAA-conjugated ovalbumin initially inside the cell was already considerably greater than the control groups (left panel). When normalized to the initial amount taken up, the exocytosis profiles were similar to those for the 1 min uptake (right panel). Furthermore, between 15 min and 2 h, the amount of intracellular PPAA−ovalbumin increased from 0.75% of the total amount delivered to 4.8%, whereas the control groups remain within experimental error of the initial values ($p > 0.09$) (Figure 5). These results support the hypothesis that PPAA−ovalbumin accumulates in the cell as a result of endosomal escape to the cytosol with an accompanying decrease in exocytosis. It can be noted that, for all samples, reappearance of the radiolabeled ovalbumin in the supernatant was observed as early as 5 min after the cells were washed, and the majority of exocytosis occurred in the first 30 min, a time scale which is in accordance with previous exocytosis studies (*49*, *51*, *52*).

In Vitro Cytotoxicity of Polymers and Polymer−Ovalbumin Conjugates. The cytotoxicity of the PPAA-PDSA and PMAA-PDSA polymers and conjugates was tested in both the RAW macrophages and B3Z T-cells. Concentrations up to 300 μg/mL, twice the concentration used in the MHC-I presentation assay, were tested using the LDH assay. Cell survival was calculated by comparing the polymer-treated cells with untreated cells and with cells lysed with 1% Triton X-100. It can be seen in Figure 6 that none of the PPAA-PDSA or PMAA-PDSA polymers or their ovablumin conjugates induce toxicity in either cell type at this concentration.

CONCLUSIONS

In this study, a pH-sensitive, membrane-disruptive polymer, poly(propylacrylic acid) (PPAA), was synthesized and used to enhance the cytoplasmic delivery and MHC-I presentation of a model protein antigen, ovalbumin. The protein was derivatized to have a thiol group, which was reacted with the pendant PDSA

disulfide bond on the polymer to yield a polymer−protein conjugate linked by a disulfide bond. This polymer−S-S-protein linkage was designed to allow release of the protein by glutathione reduction in the cytoplasm. The polymer exhibited low toxicity in vitro and retained its membrane-disruptive capabilities after attachment to the hydrophilic protein, as indicated by a red blood cell hemolysis assay. Conjugation to the PPAA polymer was shown to result in increased intracellular accumulation and decreased exocytosis of ovalbumin, which corresponded to significantly enhanced MHC-I presentation of ovalbumin and subsequent CTL activation. This effect is attributed to destabilization of the endosomal membrane by PPAA in the low pH environment of the endosome and is in accordance with previous studies investigating the destabilizing action of PPAA (*32*, *33*, *53*). This system shows promise for protein vaccine strategies against cancer and viruses and is also applicable to any technique requiring improved delivery of a protein cargo to the cytoplasm of a cell.

ACKNOWLEDGMENT

This project was supported by funding from the National Institutes of Health (grant R01EB2991-01) and the Whitaker Foundation. We also thank Nilabh Shastri (UC Berkeley) for the B3Z hybridoma cells, which were essential to this study.

There are a growing number of reports showing the usefulness of cell-penetrating peptides (CPPs) including oligoarginines for intracellular delivery of macromolecules. Although the covalent attachment of the CPP segments to the cargo molecules is usually required to ensure effective delivery, conventional methods of conjugation need several manipulation steps that are often time-consuming and laborious. Here, we report a novel approach to allow easy modification of cargo molecules with oligoarginine CPPs. The key feature is the employment of oligoarginines (R8 and R12) equipped with a sulfosuccinimidylsuberyl moiety (BS^3-R8 and -R12). One-pot modification is achieved simply by mixing BS^3-R8 and -R12 with cargos in an aqueous buffer. The usefulness of this approach was exemplified through the conjugate formation with Fab fragments of immunoglobulin G, amino-functionalized poly(ethylene glycol)s (amino-PEGs), and amino quantum dots (amino-QDs), yielding an efficient cellular uptake.

INTRODUCTION

Cell penetrating peptides (CPPs) including oligoarginines have been reported as a potent tool for intracellular delivery. Conjugated with CPPs, various molecules with low membrane-permeability have successfully been delivered into cells simply by adding the conjugates to the cells without the need of special apparatus (*1*−*3*). These molecules include peptides and proteins (*4*), oligonucleotides and their derivatives (*5*), nanoparticles such as liposomes and quantum dots, synthetic polymers, and so on (*6*); easy and efficient delivery of these molecules was difficult with pre-existing methodologies (e.g., microinjection and electroporation). This technology has been opening new avenues not only for basic studies on cell functions but also for future therapies including drug delivery and cell manipulations. This also provides access by chemists to elucidate and control cell functions using synthetic agonists/antagonists, fluorescently labeled/caged molecules, and so on (*7*).

For the efficient introduction of the above bioactive cargo molecules into cells, modification of the cargo molecules with CPPs is inevitable. One of the popular methods for this is to prepare recombinant fusion proteins bearing CPP segments (*4, 8*). However, this approach is only applicable to proteins, and it takes some days for the preparation of the fusion proteins. In addition, the addition of the CPP segments sometimes results in a decrease in yields in production of the recombinant proteins in *E. coli* and in purification compared with the parent proteins (*9*). If the cargo is relatively small peptides (e.g., <20 amino acids), direct solid-phase synthesis of peptides having tandem alignment of CPP (∼10 amino acids) and cargo sequences can be employed. However, an increase in the total chain length should diminish the overall synthetic yields, and therefore, chemical conjugation of the CPP segments to the cargo becomes an alternative idea.

This approach is not limited to proteins but is applicable to various types of molecules and thus has wider applicability. Cargo molecules can be prepared so as to be equipped with CPP segments from the beginning as a part of their structures (*8, 10*). Alternatively, the CPP segments may be attached via disulfide cross-linking (*11, 12*) or via suitable cross-linkers to the pre-existing cargo molecules (*13, 14*). However, in the former cross-linking, the cargo molecules must have a free sulfhydryl moiety that has to be selectively cross-linked with CPPs. In the latter case, various types of hetero/homobifunctional cross-linkers are commercially available; typical ones are designed to have functional groups to form cross-links between amino moieties (e.g., succinimidyl esters) and/or thiol moieties (e.g., maleimides or alkyl halides). Amino moieties are more popularly found in proteins, as their N-terminus and the ε-position of lysine side chains rather than cysteines provide more feasibility in the design of cross-linking. However, conventional methods of cross-linking formation employ stepwise introduction of CPPs and cargos on cross-linkers (*13, 15*). This usually requires purification using gel filtration or dialysis in each step, which is laborious and time-consuming and may lead to inactivation of the cargo molecules. In addition, insoluble aggregate formation is often observed during these treatments. Therefore, development of easier methods of introducing CPPs to cargo moieties has been desired.

Here, we report a novel approach to allow easy modification of cargo molecules with oligoarginine CPPs equipped with a preactivated sulfosuccinimidylsuberyl moiety (BS^3-R8 and -R12) in one pot (Figure 1). Oligoarginines (R8 and R12) are known as representative and reliable CPPs to achieve efficient intracellular delivery. Functionalization of R8/R12 with the sulfosuccinimidyl-suberyl moiety then provides an activated system for simple mixing

and conjugating with amino moieties of different cargo molecules. The usefulness of this approach was exemplified through the conjugate formation with immunoglobulin Fab fragments, amino-functionalized poly(ethylene glycol)s (amino-PEGs) and amino quantum dots (amino-QDs).

EXPERIMENTAL PROCEDURES

Preparation of BS^3-R8 and BS^3-R12. *R8 and R12 Peptides.* Peptide segments of R8 [$(Arg)_8$-amide] and R12 [$(Arg)_{12}$-amide] were similarly prepared as reported using Fmoc (9-fluorenylmethyloxycarbonyl) solid-phase peptide synthesis and HPLC purification (*16*). Fluorescently labeled R8 and R12 [R8(Alexa): $(Arg)_8$-Gly-Cys(Alexa)-amide; R12(Alexa): $(Arg)_{12}$-Gly-Cys(Alexa)-amide] were also prepared by the treatment of $(Arg)_8$-Gly-Cys-amide and $(Arg)_{12}$-Gly-Cys-amide (similarly prepared as above) with Alexa Fluor 488 C_5 maleimide sodium salt (Invitrogen) as reported (*16*).

BS^3 Derivatization. The bis(sulfosuccinimidyl)suberate (BS^3) cross-linker (Pierce) (1.5 equiv to each peptide) in H_2O (400 μL) was added to an aqueous solution (600 μL) of R8 or R12 (0.5−0.7 μmol). After adjusting the pH of the solution to 7−8 with *N*-methylmorpholine (NMM), the mixture was gently stirred at 20 °C for 20 min. In the case of modification of R8(Alexa) and R12(Alexa), these peptides were similarly reacted with BS^3 in H_2O/CH_3CN (3:1) in 1 mL. Progress of the reaction was monitored by HPLC, and the product was directly purified by HPLC using a Chromolith Performance RP-18 column (4.6 × 100 mm) (Merck). Subsequent lyophilization yielded a fluffy powder of the respective products. The mass of the products was confirmed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOFMS). Yield in the BS^3 derivatization: BS^3-R8, BS^3-R12, BS^3-R8(Alexa), BS^3-R12(Alexa) 67%, 61%, 79%, 74%, respectively. MALDI-TOF MS for BS^3-R8, BS^3-R12, BS^3-R8(Alexa), and BS^3-R12(Alexa): 1599.8 [expected for $(M + H)^+$ 1599.9]; 2225.6 [expected for $(M + H)^+$ 2224.6]; 2479.6 [expected for $(M + Na)^+$ 2479.7]; 3104.8 [expected for $(M + Na)^+$ 3104.5], respectively.

Conjugation of Alexa 488-Labeled Fab Fragment [Fab(Alexa)] with Oligoarginine Peptides. *Alexa 488-Labeled Fab Fragments [Fab(Alexa)].* The Fab fragments were prepared from a commercially available polyclonal antibody preparation (Venogloblin-IH, Mitsubishi Pharma) using the ImmunoPure Fab Preparation Kit (Pierce) as already reported (*15, 17, 18*). Alexa 488-labeling was then conducted by the treatment of Fab (36 mg/mL) in phosphate-buffered saline (PBS) (250 μL) with Alexa 488 carboxylic acid, succinimidyl ester (Invitrogen) (5 equiv to Fab) in DMF (5 μL), and 1 M $NaHCO_3$ (25 μL) at room temperature for 2 h with gentle stirring. The mixture was loaded on a Microcon YM-30 ultrafilter (molecular weight cutoff 30 000) (Millipore) and concentrated on the filter. Repetitive addition of PBS and filtration (×5) was conducted to remove the unreacted Alexa reagent.

One-Pot Modification of Fab(Alexa) Using BS^3-R8 and BS^3-R12. BS^3−R*n* (*n* = 8 and 12) [3 equiv to Fab(Alexa)] in H_2O (3 μL) were added to Fab(Alexa) in PBS (13.3 mg/mL, 100 μL), and the mixture was gently stirred at room temperature for 2 h. The mixture was then loaded on a Microcon YM-30 ultrafilter, concentrated, and washed with PBS (×5) to remove unreacted BS^3−R*n* peptides as described above to yield Fab(Alexa)-R8 and Fab(Alexa)-R12, respectively. The yields were calculated by comparing the absorbance (280 nm) of Fab before and after R*n* (*n* = 8 or 12) modification. The number of the respective R*n* peptides conjugated to Fab(Alexa) was estimated by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE).

Conjugation of Fab(Alexa) with R8 and R12 Using Conventional Heterobifunctional Agent (EMCS). To a PBS solution of Fab(Alexa) (13.3 mg/mL, 100 μL), *N*-(6-maleimidocaproyloxy)succinimide (EMCS) (Dojindo) [3 equiv to Fab(Alexa)] in dimethylformamide (DMF) (1 μL) was added, and the mixture was gently stirred at room temperature for 2 h. Subsequently, the mixture was loaded on a Microcon YM-30 ultrafilter, concentrated, and washed with PBS (×3) to remove the unreacted EMCS reagent. R12GC [$(Arg)_{12}$-Gly-Cys-amide (*18*)] [3 equiv to Fab(Alexa)] in PBS (3 μL) was then added to the above Fab(Alexa) solution (100 μL), and the mixture was gently stirred at room temperature for 2 h. Subsequently, the mixture was filtered and washed with PBS (×5) using a Microcon YM-30 to remove unreacted R12GC to obtain Fab(Alexa)-EMCS-R12.

Conjugation of Oligoarginine Peptides with Poly(ethylene glycol)s (PEGs). Amino-PEGs (propylamine-functionalized poly(ethylene glycol)s, Sunbright PA series, NOF) (0.45−0.65 μmol) in H_2O (400 μL) were added to a solution of BS^3-R8(Alexa) or BS^3-R12(Alexa) (0.5−0.7 μmol, 1.1 equiv) in H_2O/CH_3CN (600 μL, 7:5) in the presence of NMM (0.2 μL), and the mixture was stirred at room temperature for 1−2 h, followed by RP-HPLC purification to yield the desired conjugates (53−87%) (Table 2). The mass of the conjugates was confirmed by MALDI-TOF MS (Supporting Information).

Table 1. Yield of Fab(Alexa)-R*n* Conjugates

conjugates	amount of Fab(Alexa) before conjugation	yield
Fab(Alexa)-R8	1.33 mg	0.84 mg (60%)
Fab(Alexa)-R12	1.33 mg	1.07 mg (75%)
Fab(Alexa)-EMCS-R12	1.33 mg	0.45 mg (31%)

Table 2. Yield of PEG-R*n*(Alexa) Conjugates

conjugates	amount of PEG before reaction	yield
PEG5000-R8(Alexa)	1.3 mg	1.2 mg (66%)
PEG12000-R8(Alexa)	1.3 mg	1.1 mg (72%)
PEG30000-R8(Alexa)	3.0 mg	2.8 mg (87%)
PEG5000-R12(Alexa)	1.2 mg	1.0 mg (53%)
PEG12000-R12(Alexa)	2.8 mg	2.2 mg (64%)
PEG30000-R12(Alexa)	7.0 mg	5.7 mg (75%)

Modification of Quantum Dots with R12 peptides. To a borate buffer (pH 8.3) solution of quantum dots (QDs) coated with amino-functionalized PEG (Q-dot 605 ITK, Invitrogen) (8 μM, 25 μL), BS^3-R12 (18 nmol, 1 equiv to amino groups of QDs) in H_2O (475 μL) was added, and the mixture was gently stirred at room temperature for 2 h, followed by dialysis for 36 h (molecular weight cutoff 7000) against H_2O (500 mL) at 4 °C. To obtain information on the number of the R12 molecules introduced on a particle of QDs, the QDs were similarly treated with BS^3-R12(Alexa) instead of BS^3-R12 for 2 h and then ultrafiltered. By measuring the absorbance (495 nm) of the filtrate, it was determined that approximately 60 molecules of R12 were conjugated on each particle.

Cell Culture. The human cervical cancer-derived HeLa cells were maintained in α-minimum essential medium (α-MEM) with 10% heat-inactivated calf serum. Cells were grown on 100 mm dishes and incubated at 37 °C under 5% CO_2 to approximately 70% confluence. A subculture was performed every 3−4 days.

Confocal Microscopy of Peptide Internalization. HeLa cells (2×10^5) were plated on 35 mm glass-bottomed dishes (Iwaki) and cultured in α-MEM with 10% heat-inactivated calf serum for 48 h. After complete adhesion, the culture medium was exchanged, and the cells were then incubated at 37 °C with fresh medium (200 μL) containing the peptide conjugates and washed with PBS (×3). The concentration of the respective conjugates is given in the figure legends. Distribution of the peptide conjugates was then analyzed using a confocal laser scanning microscope FV300 (Olympus) equipped with a 40× objective without fixing the cells to avoid artifactual localization of the internalized peptides (*19*). For detection of Alexa 488-labeled conjugates, the fluorescence signals were detected by excitation with the 488 nm Ar laser using an emission filter (510−530 nm). For detection of QD605, fluorescence signals were detected following excitation with the 543 nm He−Ne laser using a >565 nm emission filter.

Flow Cytometry. HeLa cells (7.0×10^4) in fresh culture medium (1 mL) were plated into 24-well microplates (Iwaki) and cultured for 48 h in α-MEM containing 10% heat-inactivated calf serum. After complete adhesion, the cells were incubated at 37 °C for 30 min with fresh medium (200 μL) containing peptide conjugates prior to washing with PBS (400 μL). The cells were then treated with 0.01% trypsin in PBS (200 μL) at 37 °C for 10 min prior to the addition of PBS (300 μL). The cells were centrifuged at 3000 rpm for 5 min. After

the supernatant was removed, the cells were washed with 400 μL of PBS and centrifuged at 3000 rpm for 5 min. After this washing cycle was repeated, the cells were suspended in PBS (400 μL) and subjected to fluorescence analysis on a FACS-calibur (BD Biosciences) flow cytometer using 488 nm laser excitation and a 515 to 545 nm emission filter.

RESULTS AND DISCUSSION

Design and Preparation of BS^3-Modified Oligoarginine Peptides. Chemical conjugation is one of the practical methods for attaching cargo molecules to be delivered into cells with CPPs. Various chemical cross-linkers have already been employed for the conjugation of cargo molecules with CPPs (*13, 20, 21*). However, as described in the introduction, stepwise attachment of CPPs and cargos on cross-linkers is often laborious and time-consuming due to the necessity of purification after the respective steps of attachment. The prolonged treatment and purification often is accompanied by insoluble aggregate formation that makes the handling of the conjugates difficult and diminishes the functions and biological activities of the cargo molecules (*9*). Therefore, development of simple and easy methods of CPP modification has been desired.

The succinimidyl ester is one of the most popularly employed and effective active esters for carboxylic acids, and this leads to prompt amide bond formation with amino moieties (*22*). Oligoarginines (R*n*, $n = 6-12$) are among the representative classes of CPP, and the internalization efficiencies are comparable to or not less than those of popularly employed Tat (*23*) and antennapedia (penetratin) (*24*) peptides. The guanidino moiety of arginine is a stronger base (pK_a 12.5) compared with the α-amino moiety of lysine (pK_a 9.0). However, the nucleophilicity of the guanidino moiety is much less than that of the amino group (*25*). Therefore, if we could prepare oligoarginine peptides bearing a carboxylic acid preactivated as a succinimidyl ester, a simple mixing of these peptides with the cargo molecules may lead to efficient cross-linking formation (Figure 1).

In this article, we have employed a commercially available homobifunctional cross-linker bis(sulfosuccinimidyl)suberate (BS^3), which has sulfonated succinimidyl esters on both carbonyl moieties of suberic acid (Figure 2). Treatment of oligoarginine peptides (R8 and R12) with an excess amount of this reagent would predominantly yield BS^3−oligoarginine conjugates (BS^3-R8 and BS^3-R12) resulting from the nucleophilic attack of the N-terminus amino moiety of the oligoarginines at one of the carbonyl moieties of BS^3.

For the preparation of the BS^3-R8 and BS^3-R12 conjugates, we took the approach of direct modification of the free oligoarginine peptides with BS^3 reagents. The R8 and R12 peptides [(Arg)$_n$-amide, $n = 8$ and 12] were prepared using Fmoc solid-phase peptide synthesis and purified by HPLC. The resulting peptides without protection groups were treated with 1.5 equiv of BS^3 cross-linking agent in H_2O at room temperature for 20 min, and the product was directly purified by HPLC (Figure 2A). The reaction proceeded very smoothly to produce the desired BS^3−oligoarginine conjugates in high yields (67% and 61% for BS^3-R8 and BS^3-R12, respectively). No significant byproducts were observed by HPLC including any suffering from hydrolysis of the succinimidyl ester of the BS^3-conjugates or the dimers of R8/R12 where two molecules of the peptides were introduced on both of the carbonyl moieties of the BS^3 agent (Figure 2C). The BS^3 conjugates of Alexa 488-labeled R8 and R12 [(Arg)$_n$-Gly-Cys(Alexa)-amide, $n = 8$ and 12] were similarly prepared without difficulty with a yield of 79% and 74%, respectively (Figure 2B). Preparation of other BS^3-activated CPPs [HIV-1 Rev(34−50), Thr-Arg-Gln-Ala-(Arg)$_2$-Asn-(Arg)$_4$-Trp-Arg-Glu-Arg-Gln-Arg (*13*); SAP, (Val-Arg-Leu-Pro-Pro-Pro)$_3$ (*26*); (Arg-Ahx-Arg)$_4$ (Ahx = 6-aminohexyl)

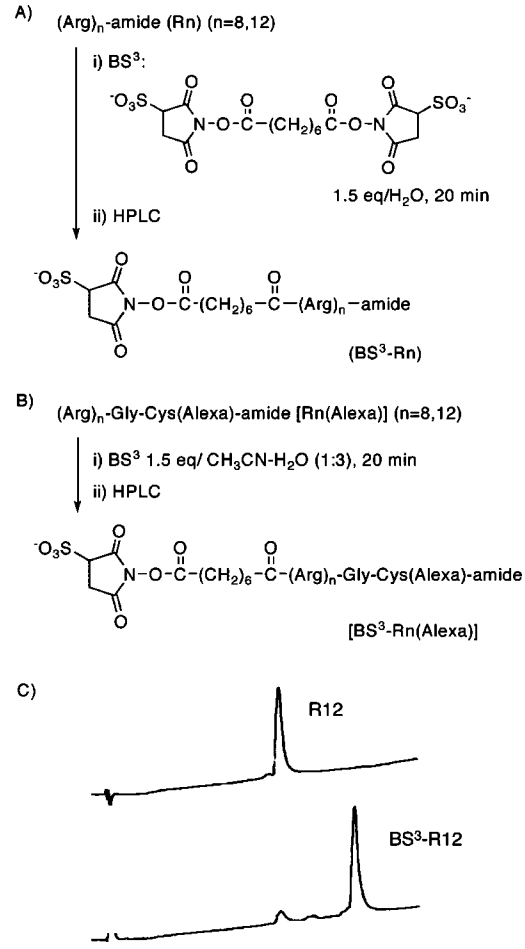

Figure 2. Preparation of BS^3-R*n* (A) and BS^3-R*n*(Alexa) (B) agents ($n = 8$, 12). Modification of the oligoarginine peptides with BS^3 reagent proceeds without difficulty as exemplified in the reaction monitored by HPLC in the preparation of BS^3-R12 (C) [column, Chromolith Performance RP-18; gradient, linear gradient of CH_3CN (4−20%) in 0.1% aqueous TFA over 8 min; flow, 4 mL/min; detection, 215 nm].

(*27*); (Arg-Ahx)$_6$-Arg (*28*)] was also performed without difficulty (details of their preparation and analysis of the cellular uptake of their conjugates with Fab (Alexa) is shown in the Supporting Information). The obtained powders of these BS^3-conjugates were fairly stable when stored in a −20 °C freezer, and no significant decomposition of the samples was observed by HPLC after one month.

Application of BS^3-Modified Oligoarginines to the Preparation of Fab-Oligoarginine Conjugates. To assess the usefulness of the above BS^3-modified oligoarginines for the conjugation of proteins with oligoarginines as intracellular delivery vectors, the Fab segment of immunoglobulin G (IgG) was employed as a model. Recently, antibodies have been regarded as promising and powerful molecular target drugs, and the intracellular delivery of antibodies is also a challenge in antibody therapy (*29−31*). The Fab fragments of the antibodies are regarded as functional low-molecular-weight components retaining the antibody specificities (*32, 33*). It has already been reported that conjugation of antibodies with CPPs greatly increases the internalization efficiency of antibodies into cells (*34*). We also reported that in vivo distribution of Fab segments was considerably affected by the conjugation with CPPs (*17, 18*).

The Fab segments prepared from human polyclonal IgG were labeled with Alexa 488 so that one or two molecules of Alexa 488 were attached to one Fab molecule. Conjugation of the above fluorescently labeled Fab segments [Fab(Alexa)] was

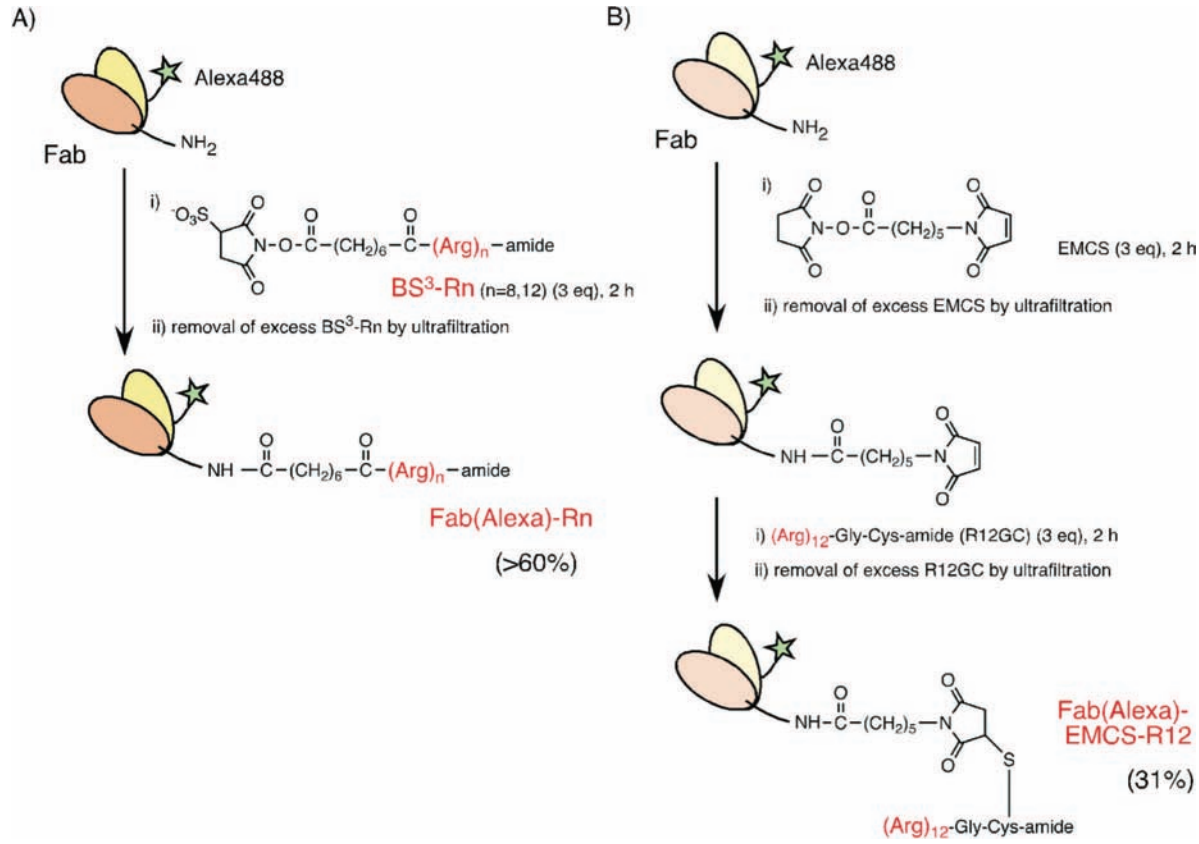

Figure 3. Simple one-pot modification of Fab(Alexa) with oligoarginines using BS^3-R*n* agents (A). A conventional modification method using heterobifunctional cross-linker *N*-(6-maleimidocaproyloxy)succinimide (EMCS) required extra steps for manipulation with a lower yield (B).

conducted using the BS^3−oligoarginine conjugates (Figure 3A). The Fab(Alexa) was treated with 3 equiv of BS^3−R*n* ($n = 8$ and 12) at 20 °C for 2 h. The procedure was very simple, and aqueous solutions of both Fab(Alexa) and BS^3−R*n* were just mixed and gently stirred. There was no obvious aggregation observed during the reaction. The mixture was then charged on an ultrafilter and washed with PBS repetitively to remove unreacted BS^3−R*n*. Through SDS-PAGE, it was confirmed that an average of one or two R*n* segments were introduced onto a Fab segment (Figure 4A). The yields of Fab(Alexa) following modification with R8 and R12 were 60% and 75%, respectively (Table 1).

As a control experiment of conjugation using a conventional heterobifunctional cross-linker, *N*-(6-maleimidocaproyloxy)succinimide (EMCS) was simultaneously conducted (Figure 3B). First, Fab(Alexa) was treated with EMCS [3 equiv to Fab(Alexa)] at room temperature for 2 h to form amide bonds between the amino groups of Fab(Alexa) and the activated carbonyl group of EMCS. The unreacted EMCS was removed by washing on an ultrafilter. R12GC [3 equiv to Fab(Alexa)] was then added to Fab(Alexa)-EMCS so that the thiol group of R12GC could attack the maleimide moiety of EMCS. Two hours later, the excess R12GC was removed by ultrafiltration. During the incubation of Fab(Alexa)-EMCS with R12GC, a certain amount of insoluble aggregates was formed, and this diminished the overall yield in the conjugate formation [31% from Fab(Alexa)].

To analyze this further, Fab(Alexa)-EMCS was similarly treated with the R12 peptide [$(Arg)_{12}$-amide] that lacks the Gly-Cys residue to interact with the maleimide moiety. Addition of the R12 peptide to the Fab(Alexa) solution resulted in spontaneous formation of precipitate, and approximately 60% of the protein was precipitated in the first 8 min, and 70% in 60 min. Similar results were obtained following addition of R12GC to Fab(Alexa)-EMCS. These results suggested that modification with EMCS hampered the hydrophilic and ionic balance of Fab(Alexa), and the addition of the R12 peptide then enhanced precipitate formation. Detailed optimization of the cross-linking condition using EMCS may reduce this effect and so increase yield, but this would be time-consuming, requiring larger amounts of starting material. However, the amount of formed precipitate is much smaller when using BS^3-R8/R12, presumably because it has a relatively lower effect on the solubility of the Fab protein, and thus gives higher conjugate yields.

SDS-PAGE of the obtained conjugate Fab(Alexa)-EMCS-R12 suggested that an average of one to two molecules of R12GC was conjugated with one Fab(Alexa) molecule (Figure 4A).

Internalization of Fab(Alexa)-R8 and Fab(Alexa)-R12 conjugates was then confirmed by incubating HeLa cells with the respective conjugates (1 μM) in serum containing α-MEM [α-MEM (+)] at 37 °C for 3 h. After washing with PBS, intracellular fluorescence was monitored by confocal microscopy (Figure 4B). Distinct signals of the Fab(Alexa)-R*n* conjugates were observed for both cells treated with Fab(Alexa)-R8 and Fab(Alexa)-R12, and the intensity of the signals was comparable to those of the cells similarly treated with Fab(Alexa)-EMCS-R12. In contrast, few signals were observed for the cells treated with Fab(Alexa) without bearing oligoarginine segments.

The above results strongly suggest the practicability of the BS^3−oligoariginine conjugates for introduction of the CPP segments to proteins. Simply by mixing the BS^3−oligoarginine conjugates with the proteins to be delivered into cells, efficient modification with the oligoarginine CPPs was achieved *in one pot*. The procedures are very easy while saving time for modification and ensuring high yields. If the conventional stepwise cross-link formation as was shown is compared with the use of EMCS, it is clear that skipping the steps of reaction and purification would diminish the loss of the products by aggregation and physical adsorption on the experimental ap-

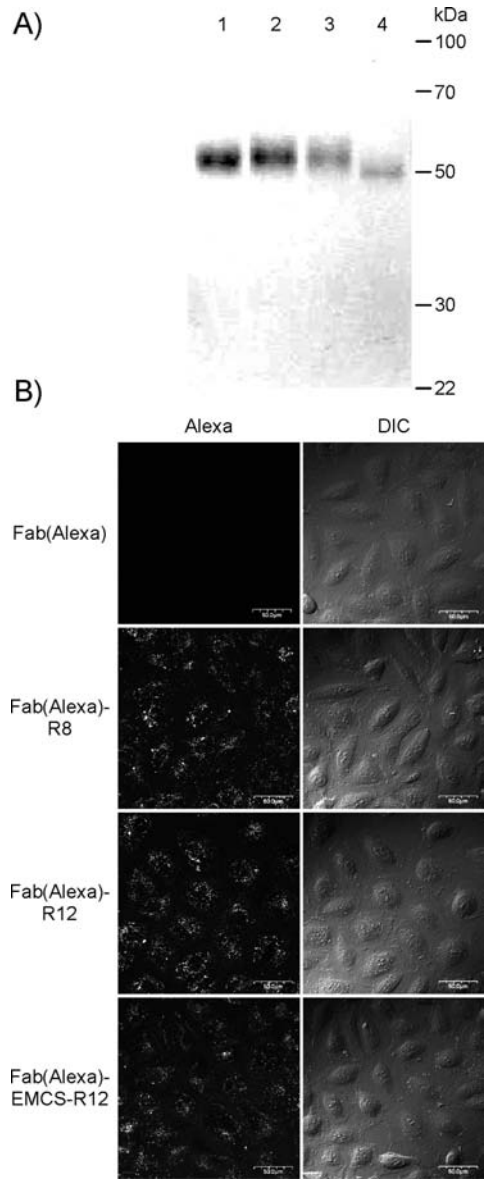

Figure 4. (A) SDS-PAGE of Fab(Alexa)-oligoarginine conjugates [10% acrylamide; Coomassie Brilliant Blue staining; Lanes 1−4, Fab(Alexa)-R8, Fab(Alexa)-R12, Fab(Alexa)-EMCS-R12, and Fab(Alexa), respectively (10 μg each)]. The sample buffer employed here did not contain reducing agents (e.g., 2-mercaptoethanol) to maintain disulfide bonds in Fab during electrophoresis. (B) Cellular uptake of Fab was considerably accelerated by conjugation with oligoarginine vectors [cells, HeLa; incubation, 1 μM in α-MEM (+) for 3 h at 37 °C; Scale bars, 50 μm]. Fluorescence images of the green layer (Alexa) and differential interference contrast (DIC) images are shown.

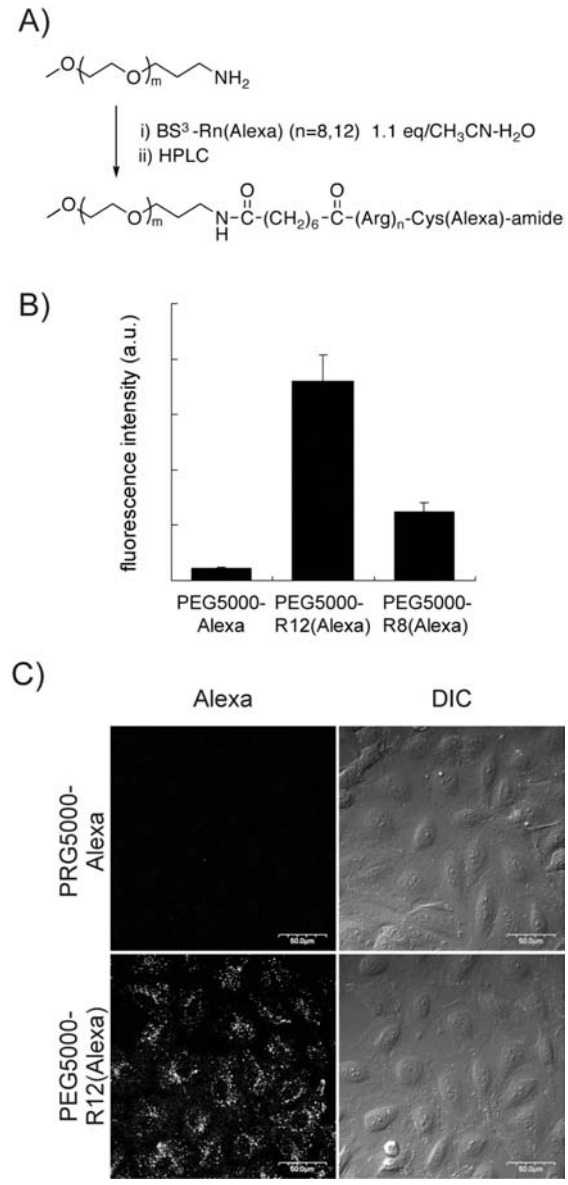

Figure 5. Application of BS^3-R*n* agents to the oligoarginine modification of synthetic polymers. (A) Conjugation of BS^3-R*n*(Alexa) (n = 8, 12) with amino-PEGs. (B) FACS analysis of cellular uptake of PEG5000-R*n*(Alexa) (n = 8 and 12). HeLa cells were treated with the conjugates (10 μM) in α-MEM(+) for 30 min at 37 °C. (C) Cellular uptake of PEG-R12(Alexa) (10 μM) by HeLa cells incubated in α-MEM(+) for 30 min at 37 °C. PEG5000 labeled with Alexa488 but lacking the R12 segment was prepared as a reference by the treatment of amino-PEG5000 with Alexa Fluor 488 carboxylic acid, succinimidyl ester (Invitrogen), followed by the HPLC purification. Scale bars, 50 μm. Fluorescence images of the green layer (Alexa) and the DIC images are shown.

paratus. This criterion is critical when precious proteins have to be conjugated with CPPs. In addition, an ultrafilter was employed here to minimize the loss of the samples by physical adsorption and deformation of the protein structures during manipulation. The use of gel filtration or dialysis for purification steps would further emphasize the advantages of this approach in yields and reduction of labor compared to the conventional methods.

It may be difficult to modify specific lysine residues in proteins with CPPs when the proteins contain multiple lysines, and biological activity might be affected in some cases where there are multiple cross-links or when cross-linking inactivates a critical residue. However, we believe that this simple conjugation approach has great impact for delivery of proteins or other compounds into cells, especially post-translationally modified proteins (e.g., with sugars) or other less-characterized macromolecules. This approach should also be useful for cellular assays investigating multiple numbers of proteins or compounds; optimization of the cross-linking methods would then be considered at later stages.

PEG−Oligoarginine Conjugates. To further assess the applicability of this approach to the modification of synthetic polymers, the conjugation of terminal amino-functionalized poly(ethylene glycol)s (amino-PEGs) with oligoarginine was conducted (Figure 5). PEGs have been widely utilized for elongation of drug retention time in the blood, especially for high molecular weight pharmaceuticals (*35*, *36*). Indeed, CPP-modified liposomes were targeted to tumor tissues with a decrease in nonspecific tissue distribution by the PEGylation (*6*, *37*).

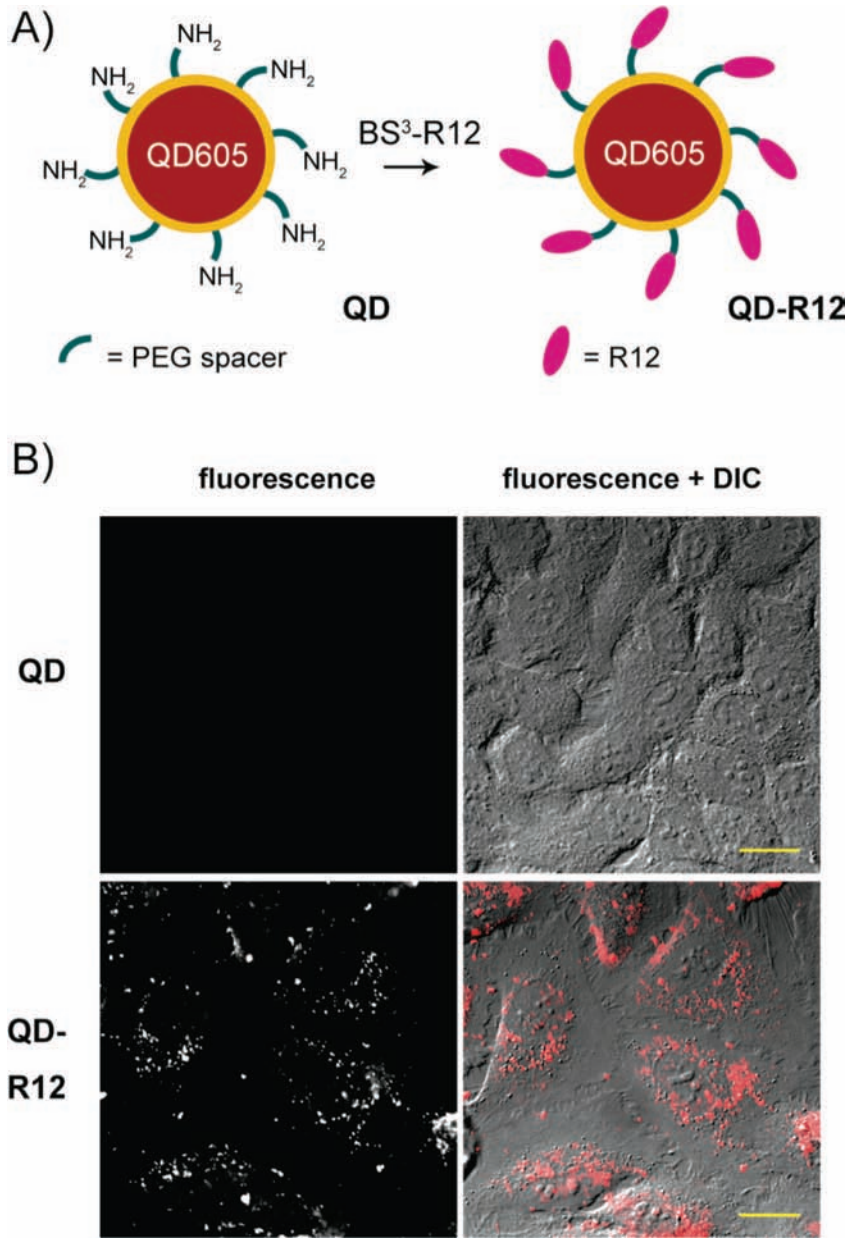

Figure 6. (A) A scheme of modification of QDs with oligoarginine using the BS^3-R12 agent. (B) R12 modification was highly effective in improving the cellular uptake of QDs. HeLa cells were treated with 30 nM QD and QD-R12 in α-MEM (+) for 2 h at 37 °C followed by removing those samples and incubation in fresh α-MEM (+) for 4 h at 37 °C. Scale bars, 20 μm. Fluorescence images of the red layer and the merged pictures of the fluorescence and the DIC images (fluorescence + DIC) are shown.

Here, amino-PEGs of different average molecular weights, namely, amino-PEG5000, amino-PEG12000, and amino-PEG30000, were subjected to modification with oligoarginines. Slight excess amounts of BS^3-R8(Alexa) and BS^3-R12(Alexa) were treated with amino-PEGs of different molecular weights for 1−2 h. All of the reactions proceeded smoothly without difficulty even in the cases of PEGs of high molecular weights. A single purification with HPLC gave the desired PEG−oligoarginine conjugates [PEG5000-R*n*(Alexa), PEG12000-R*n*(Alexa), and PEG30000-R*n*(Alexa) (n = 8 and 12), respectively] in satisfactory yields (53−87%) (Table 2). The mass of the products was confirmed by MALDI-TOFMS. Thus, the usefulness of BS^3−oligoarginine conjugates was also exemplified for the modification of synthetic polymers.

Additionally, the cellular uptake of PEG5000-R8(Alexa) and PEG5000-R12(Alexa) was examined (Figure 5B,C). The PEG5000 conjugates in α-MEM(+) were incubated with HeLa cells at 37 °C for 30 min, and the cellular uptake of the conjugates was monitored by confocal microscopy and assessed by flow cytometry. Conjugation with oligoarginine significantly reinforced the cellular uptake of PEG5000 even in the presence of serum. In contrast to the distinct signals of the internalized PEG5000-R12(Alexa), which were observed by microscopic observation, very few signals were observed for the cells treated with PEG without bearing the R12 peptide (Figure 5C). Elevenfold and 4-fold increases in the cellular uptake of PEG5000 were, respectively, observed when conjugated with R12 and R8 (Figure 5B). Increase in the molecular weight of PEG diminished the cellular uptake of the conjugates. However, the amount of cellar uptake of PEG30000-R12(Alexa) was still five times higher than that of free PEG5000-Alexa (Supporting Information Figure S4).

QD−R12 Conjugates. Finally, the applicability of BS^3-R12 peptides for the modification of quantum dots (QDs) was demonstrated (Figure 6). Quantum dots, colloidal semiconductor nanocrystals prepared in the size 1−20 nm, have unique optical

and spectroscopic properties that are tunable to a desired narrow emission spectrum, are relatively insensitive to the wavelength of excitation light, have a high quantum yield, and are photostable bright fluorophores (*38*, *39*). These properties should be beneficial as fluorescent probes for the analysis of intracellular functions.

Intracellular delivery of QDs by conjugation with CPPs (*40*) has already been reported. Usually, QDs are coated with synthetic polymers or proteins including streptavidins to improve water solubility and feasibility of surface modification. In previous reports, CPPs were conjugated with QDs via avidin−biotin interaction and heterofunctional (amine−thiol directed) cross-linkers. These methods also need multiple steps and had difficulties in workup. The molecular size of streptavidin-derivatized QDs is largely increased, and modification of the QDs with suitable cross-linkers before the introduction of thiol-functionalized CPPs is needed (*41*, *42*). These stepwise conjugation methods usually require purification using gel filtration (*43*, *44*) and dialysis in each step, which is laborious and time-consuming and may lead to loss of QDs. Therefore, our system may provide QDs by the easy and facile means of modification with CPPs. Here, we employed QDs (diameter, 16 nm) functionalized with PEGs bearing ∼90 free amino termini per particle (Figure 6A). The QDs were treated with equimolar amounts of BS^3-R12 to the amino termini of QDs for 2 h, similarly to the case of modification of amino-PEGs as described above. The reaction proceeded with the lowest amount of aggregate formation, and dialysis of the samples to remove unreacted BS^3-R12 yielded the R12-modified QDs (QD-R12) bearing approximately 60 molecules of the R12 peptide per particle.

Modification of R12 also resulted in an increase in internalization efficiency of the QDs (Figure 6B). The QD−R12 conjugate (30 nM) was treated with HeLa cells in α-MEM(−) at 37 °C for 2 h, and the cells were then incubated with fresh α-MEM(+) at 37 °C for 4 h. Bright fluorescent signals of QDs were intracellularly observed, whereas very few signals were obtained for the cells treated with QDs without conjugation with the R12 peptide. As previously reported (*45*), there was a significant influence of cargo size on the intracellular delivery using CPPs, and larger cargoes usually required longer incubation periods before showing evidence of being internalized.

CONCLUSIONS

We have synthesized oligoarginine peptides bearing succinimide-preactivated carboxylates using the homobifunctional BS^3 cross-linkers. Synthesized BS^3-modified oligoarginine peptides (BS^3−R*n*) were used for the conjugation with cargo molecules possessing amino groups such as Fab fragments of antibodies, amino-PEGs, and QDs. These oligoarginine−cargo conjugates were efficiently internalized into the cells. The procedure for oligoarginine modification was quite simple, involving simply mixing BS^3−R*n* with the cargos. Reactions proceeded very smoothly and in high yields with no significant aggregate formation. Therefore, the application of this novel one-pot system for intracellular delivery of various other substances containing reactive amino groups is widely expected in the future.

ACKNOWLEDGMENT

This work was supported in part by Grants-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science, and Technology of Japan. K. T. is grateful for JSPS Research Fellowship for Young Scientists and S. P. for a FPU fellowship and a temporary stay grant from the Ministerio de Ciencia e Innovación.

Supporting Information Available: HPLC retention times for the BS^3-modified oligoarginine peptides, preparation of BS^3−Rev, BS^3−SAP, BS^3-(R-Ahx-R)$_4$, and BS^3-(R-Ahx)$_6$-R, cellular uptake of their conjugates with Fab(Alexa), MALDI-TOFMS of PEG5000-R12(Alexa), and the cellular uptake of PEG-R12(Alexa) conjugates. 1. Retention times in HPLC for BS^3-R8, BS^3-R12, BS^3-R8(Alexa), and BS^3-R12(Alexa)

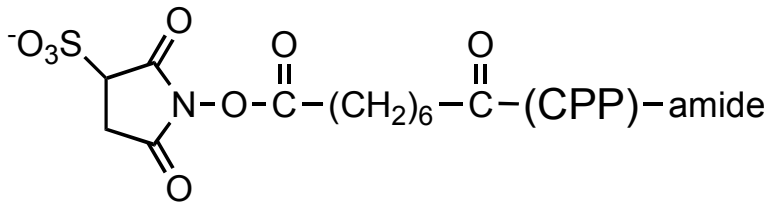
BS^3-R8: 8.96 min (gradient 5–85%, 30 min)
BS^3-R12: 9.38 min (gradient 5–85%, 30 min)
BS^3-R8(Alexa): 9.38 min (gradient 10–60%, 25 min)
BS^3-R12(Alexa): 9.26 min (gradient 10–60%, 25 min)

Condition:
Column: Cosmosil $5C_4$-AR-300, 4.6 × 150 mm
Solvent system: linear gradient of CH_3CN containing 0.1% trifluoroacetic acid (TFA) in 0.1% aqueous TFA
Flow rate: 1 mL/min
Detection: 215 nm.

2. Structures, yields, and characterization of BS^3-Rev, BS^3-SAP, BS^3-(R-Ahx-R)$_4$, and BS^3-(R-Ahx)$_6$-R



BS^3-Rev: (CPP) = Thr-Arg-Gln-Ala-$(Arg)_2$-Asn-$(Arg)_4$-Trp-Arg-Glu-Arg-Gln-Arg
Yield: 75%
MALDI-TOFMS: 2769.2 [expected for $(M+H)^+$ 2769.1]
Retention time in HPLC: 11.55 min (gradient 5–55%, 25 min) [Column: Cosmosil $5C_4$-AR-300, 4.6 × 150 mm: solvent system: linear gradient of CH_3CN containing 0.1% TFA in 0.1% aqueous TFA; flow rate: 1 mL/min; detection: 215 nm]

BS^3-SAP: (CPP) = $(Val-Arg-Leu-Pro-Pro-Pro)_3$
Yield: 70%
MALDI-TOFMS: 2329.5 [expected for $(M+H)^+$ 2328.8]
Retention time in HPLC: 17.83 min (gradient 5–55%, 25 min) [Column: Cosmosil $5C_4$-AR-300, 4.6 × 150 mm: solvent system: linear gradient of CH_3CN containing 0.1% TFA in 0.1% aqueous TFA; flow rate: 1 mL/min; detection: 215 nm]

BS^3-(R-Ahx-R)$_4$: (CPP) = $(Arg-Ahx-Arg)_4$
Yield: 58%
MALDI-TOFMS: 2052.4 [expected for $(M+H)^+$ 2051.5]
Retention time in HPLC: 10.42 min (gradient 5–55%, 25 min) [Column: Cosmosil $5C_4$-AR-300, 4.6 × 150 mm: solvent system: linear gradient of CH_3CN containing 0.1% TFA in 0.1% aqueous TFA; flow rate: 1 mL/min; detection: 215 nm]

BS^3-(R-Ahx)$_6$-R : (CPP) = $(Arg-Ahx)_6$-Arg
Yield: 50%
MALDI-TOFMS: 2122.0 [expected for $(M+H)^+$ 2121.6]
Retention time in HPLC: 11.27 min (gradient 5–55%, 25 min) [Column: Cosmosil $5C_4$-AR-300, 4.6 × 150 mm: solvent system: linear gradient of CH_3CN containing 0.1% TFA in 0.1% aqueous TFA; flow rate: 1 mL/min; detection: 215 nm]

3. Conjugation of Alexa 488-labeled Fab fragment [Fab(Alexa)] with Rev, SAP, $(R\text{-}Ahx\text{-}R)_4$, and $(R\text{-}Ahx)_6\text{-}R$

These conjugates were prepared as described for Fab(Alexa)-R8 and Fab(Alexa)-R12 using BS^3-Rev, BS^3-SAP, BS^3-$(R\text{-}Ahx\text{-}R)_4$, and BS^3-$(R\text{-}Ahx)_6$-R, respectively. Preparative yields for Fab(Alexa)-Rev, Fab(Alexa)-SAP, Fab(Alexa)-$(R\text{-}Ahx\text{-}R)_4$, and Fab(Alexa)-$(R\text{-}Ahx)_6$-R were 21%, 53%, 53%, and 52%, respectively.

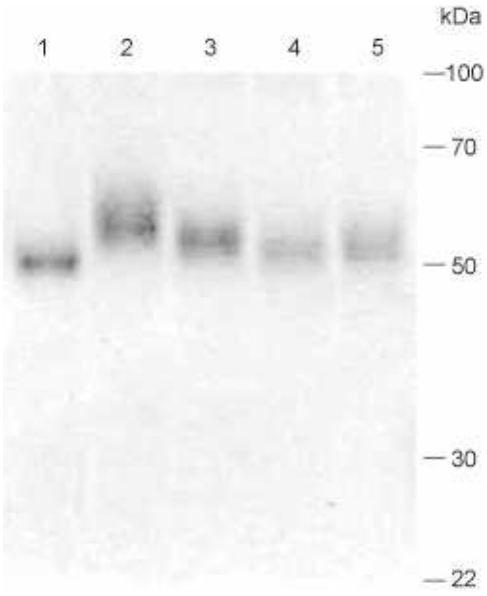


Figure S1. SDS-PAGE of Fab(Alexa)-Rev, Fab(Alexa)-SAP, Fab(Alexa)-$(R\text{-}Ahx\text{-}R)_4$, and Fab(Alexa)-$(R\text{-}Ahx)_6$-R. Lane 1-5: Fab, Fab(Alexa)-SAP, Fab(Alexa)-Rev, Fab(Alexa)-$(R\text{-}Ahx\text{-}R)_4$, and Fab(Alexa)-$(R\text{-}Ahx)_6$-R, respectively. On average 1-2 molecules of peptides were attached to Fab.

4. Cellular uptake of Fab(Alexa)-Rev, Fab(Alexa)-SAP, Fab(Alexa)-$(R\text{-}Ahx\text{-}R)_4$, and Fab(Alexa)-$(R\text{-}Ahx)_6$-R

The conjugates were incubated with HeLa cells and cellular uptake was monitored using confocal microscopy as shown in Figure 4B. In contrast to Fab(Alexa)-Rev Fab(Alexa)-R8 and Fab(Alexa)-R12, showing high efficiency of cellular uptake, the cellular uptake of Fab(Alexa)-SAP, Fab(Alexa)-$(R\text{-}Ahx\text{-}R)_4$, and Fab(Alexa)-$(R\text{-}Ahx)_6$-R was much lower. Although these CPPs have been reported as efficient intracellular delivery vectors, efficiency of these CPPs to internalize Fab (~50 kDa) was found to be lower than that of R12 and Rev peptides.

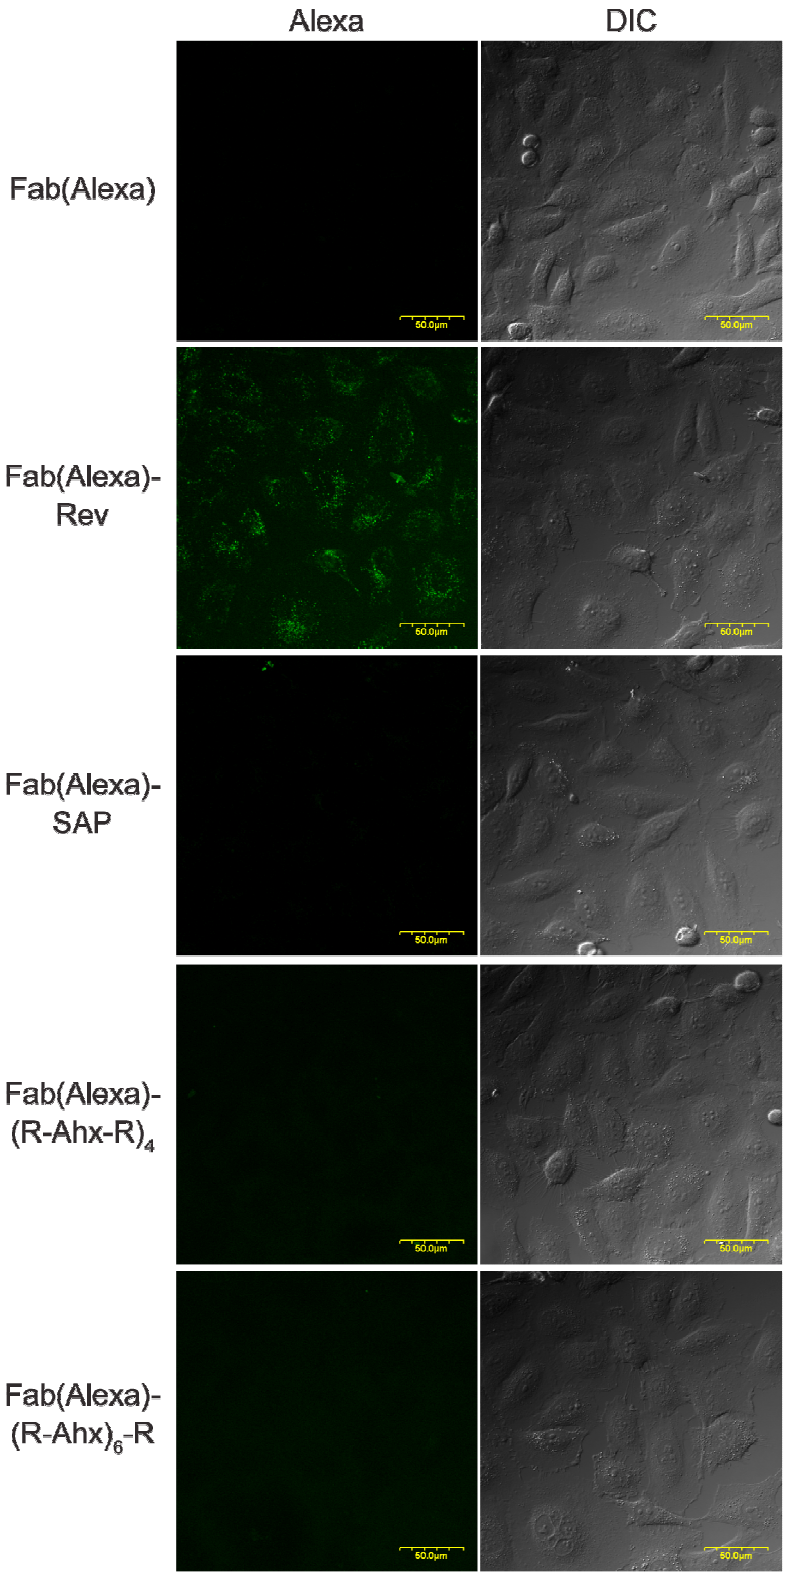

Figure S2. Cellular uptake of Fab(Alexa)-Rev, Fab(Alexa)-SAP, Fab(Alexa)-(R-Ahx-R)$_4$, and Fab(Alexa)-(R-Ahx)$_6$-R. Conjugates, 1 μM; incubation, 3 h.

5. MALDI-TOFMS of PEG5000-R12(Alexa)

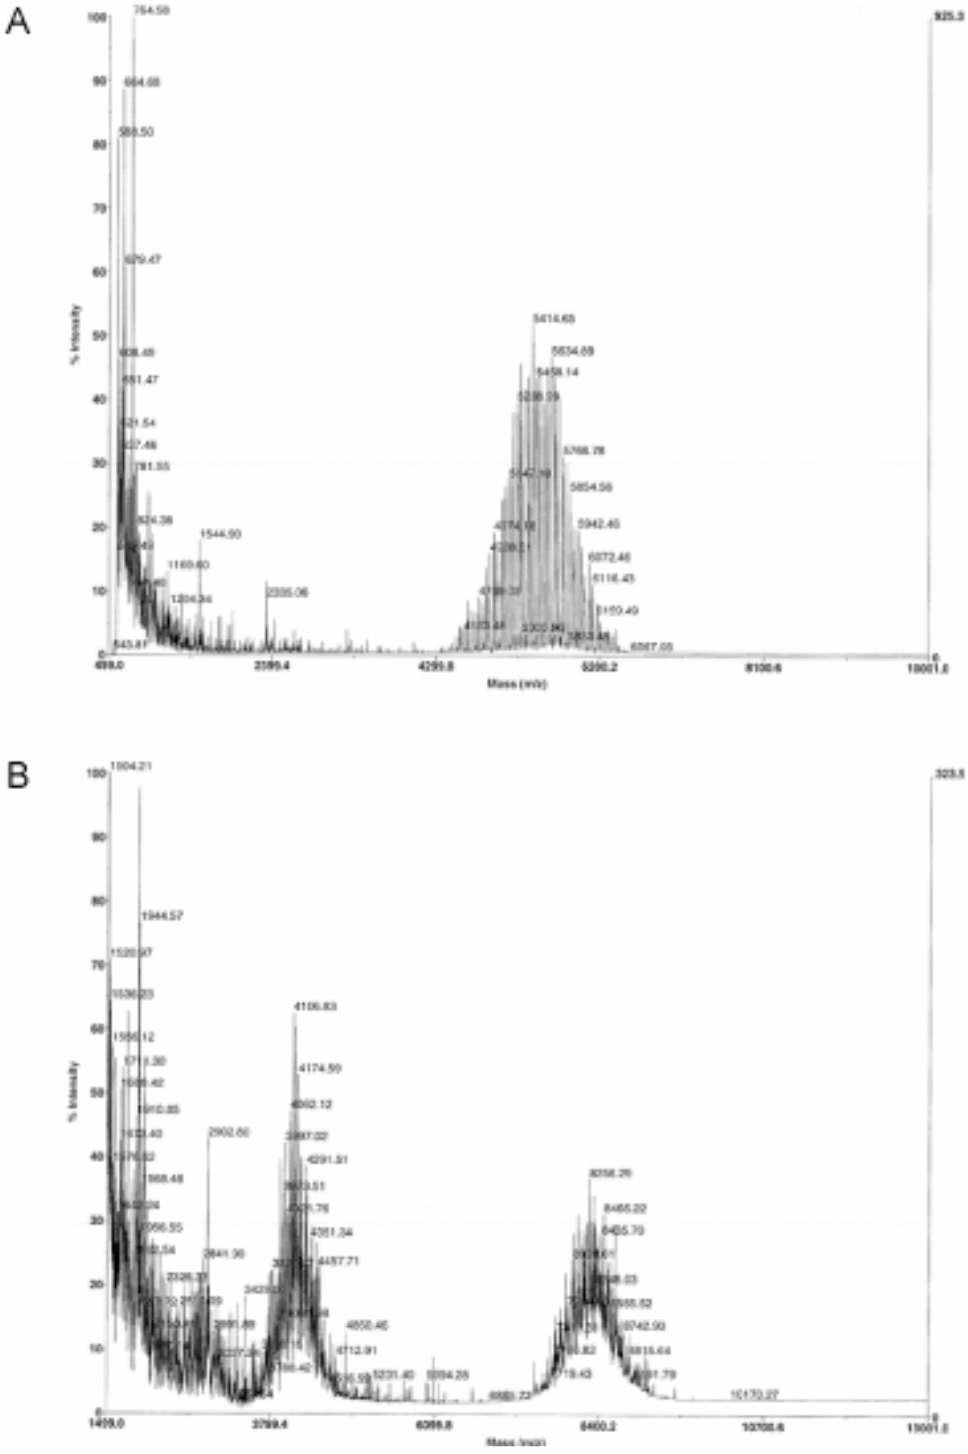

Figure S3. MALDI-TOFMS of amino-PEG5000(A) and PEG5000-R12(Alexa) (B)

6. Cellular uptake of PEG-R12(Alexa) conjugates

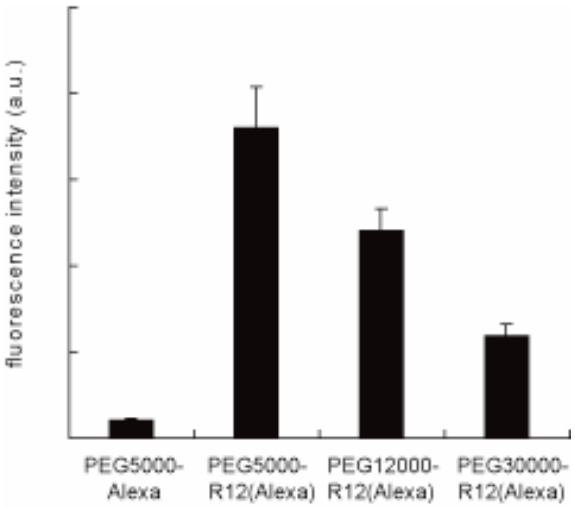

Figure S4. Cellular uptake of PEG-R12(Alexa) conjugates. These conjugates were incubated with HeLa cells and cellular uptake was analyzed as in Figure 5B.

Modulation of pK_a of Brooker's Merocyanine by DNA Hybridization

Hiromu Kashida, Kanae Sano, Yuichi Hara, and Hiroyuki Asanuma*

Graduate School of Engineering, Nagoya University, Furocho, Chikusa, Nagoya 464-8603, Japan, and Core Research for Evolution Science and Technology (CREST), Japan Science and Technology Agency (JST), Kawaguchi, Saitama 332-0012, Japan. Received August 5, 2008; Revised Manuscript Received December 15, 2008

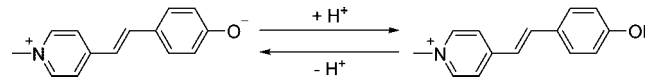
Brooker's merocyanine (BM), which changes its emission and absorption maxima upon protonation, was introduced into oligodeoxyribonucleotide (ODN) via D-threoninol by postsynthetic modification on a CPG (controlled-pore glass) support. The pK_a of BM in the modified ODN increased from 9.5 to 10.1 upon hybridization. As a result, absorption maxima shifted from 492 to 432 nm at pH 10.0 by the presence of its complementary strand. This spectral shift was sufficiently large so that DNA hybridization could easily be discriminated even by the naked eye; the color of the solution changed from orange to yellow upon hybridization. In addition, the fluorescence emission was strongly quenched upon hybridization, demonstrating that this probe can also detect the target DNA by the fluorescence change. Ratiometric detection of hybridization was also possible by simultaneous excitation of both protonated and deprotonated BMs. Furthermore, we could also modulate its pK_a by the antiparallel stacking of two BM molecules in the duplex; the pK_a of BM decreased from 10.1 to 9.7 by the stacking of two BMs in an antiparallel manner. Thus, control of the microenvironment around the BM molecule allowed modulation of its pK_a, which is applicable to the sequence-specific recognition of target DNA.

INTRODUCTION

Folding of biomacromolecules creates specific regions or internal spaces in which the microenvironment is different from the bulk solution due to the effective shielding from the solvent. Such shielded space is advantageous to modulate the properties of a specific amino residue, such as pK_a, for the effective recognition of a substrate or enzymatic reaction. For example, enzymes modulate the pK_a of the side chains (functional groups) of amino acid residues at their active sites, which are usually located in a cavity or cleft, to catalyze the reaction effectively (*1*). Since pK_a significantly affects proton transfer or proton-mediated charge relay that is closely related to the catalytic reaction, pK_a is strictly controlled by salt bridges, hydrogen bonding, hydrophobic interactions, and so on (*1*, *2*). Similarly, "folded" oligonucleotides modulate the pK_a of functional groups because they significantly affect the catalytic activity of ribozymes or triplex-forming efficiency (*3*−*5*). Since a duplexed oligonucleotide is composed of a hydrophobic core of base pairs that are surrounded by highly charged polyanions, its inside is considerably "negative". Such a negative microenvironment raises the pK_a of the nucleobases (*6*); an increase in pK_a of cytidine in a third strand facilitates triplex formation (note that N-3 of cytosine is protonated in a triplex) (*5*). Intercalated molecules are also affected by a negative microenvironment; 3,8-diamino-6-phenylphenanthridine (DAPP), which is known as a typical intercalator, changes its pK_a from 5.80 to 8.00 upon binding to DNA (*7*, *8*).

Previously, we utilized the pK_a change of a dye by tethering it to an oligodeoxyribonucleotide (ODN) for the detection of duplex formation (*9*). Naphthyl Red, which is one of the pH-responsive dyes and changes its λ_{max} by protonation, was incorporated into the middle of ODN on D-threoninol. In the single-stranded state, the pK_a of Naphthyl Red was 5.8, whereas it increased to 6.5 upon duplex formation. NMR analyses revealed that Naphthyl Red was intercalated in the duplex between adjacent base pairs, and the dimethylamino group of Naphthyl Red was located in the vicinity of phosphodiesters of the complementary strand. On the basis of these analyses, we confirmed that the increase in pK_a by duplex formation was attributed to the accumulated negative charge of phosphate anions around the intercalated Naphthyl Red. This pK_a change was advantageous to the sequence-specific probing of DNA simply by color change. Naphthyl Red in a single-stranded state was completely deprotonated at pH 7.0, whereas it was partially protonated by the presence of its complementary strand. Such protonation−deprotonation induced a significant change of λ_{max} (from 466 to 545 nm by hybridization), which allowed detection of DNA with the naked eye (Note: This large shift at pH 7.0 was induced not only by the pK_a change but also by the decrease in electron density on the dimethylamino group due to the negative microenvironment). To the best of our knowledge, it was the first example of a DNA probe based on a pK_a change by hybridization. However, since Naphthyl Red did not exhibit fluorescence, detection of DNA was possible only by the change of absorption maximum.

Scheme 1. Protonation and Deprotonation of Original Brooker's Merocyanine



In the present study, we introduced Brooker's merocyanine (BM) instead of Naphthyl Red into ODN on D-threoninol. Brooker's merocyanine is known to exhibit large solvatochromism and is widely used as a probe to detect the polarity of the microenvironment (*10*−*13*). Unlike the previous Naphthyl Red, BM changes not only its absorption but also emission spectrum upon protonation (Scheme 1) (*14*, *15*). Hence, incorporation of BM into ODN is expected to change its pK_a by hybridization, which allows sequence-specific detection of DNA both by absorption and emission spectra.

EXPERIMENTAL PROCEDURES

Materials. All the conventional phosphoramidite monomers, CPG columns, reagents for DNA synthesis, and Poly-Pak II

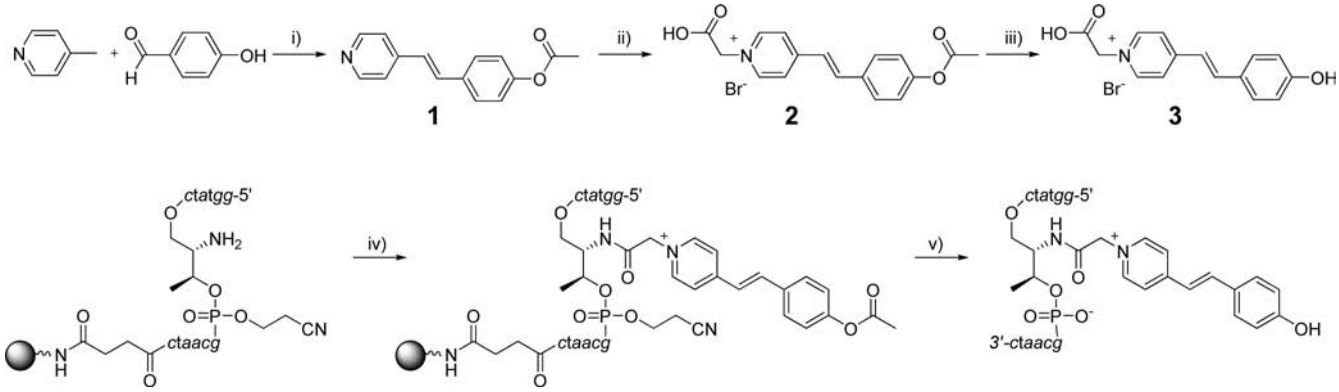
Scheme 2. Synthesis of Modified ODN (BM1)[a]



[a] (i) Acetic anhydride, reflux, 1 day, 32%; (ii) bromoacetic acid, CH_3CN, rt, 3 h, quant.; (iii) basic alumina, MeOH, 16%; (iv) **2**, PyBOP, PPTS, *N*-methylmorpholine, DMF, rt, 3 days; (v) 25% aqueous ammonia solution, 55 °C, 8 h.

cartridges were purchased from Glen Research. Other reagents for the synthesis of phosphoramidite monomers were purchased from Tokyo Kasei Co., Ltd., and Aldrich.

Synthesis of the Brooker's Merocyanine (compound 3). Compound **3** was synthesized as follows (*16*, *17*): 6.0 mL (62 mmol) of 4-picoline was added to a solution of 5.0 g (41 mmol) of 4-hydroxybenzaldehyde dissolved in acetic anhydride (20 mL). After the mixture was refluxed for 24 h, the solution was removed by evaporation. Then, the crude product was dissolved into CH_2Cl_2 and washed with an aqueous saturated solution of $NaHCO_3$ aq. (twice), and then dried over Na_2SO_4. Finally, the solvent was removed in vacuo, and the product was subjected to recrystallzation from EtOH/water to afford compound **1** (yield: 32%). ^{1}H NMR for **1** [DMSO-d_6 (TMS), 500 MHz] δ = 8.59 (d, 2H, J = 6.0 Hz), 7.71 (d, 2H, J = 6.5 Hz), 7.57 (m, 3H), 7.25 (d, 1H, J = 16.5 Hz), 7.19 (d, 2H, J = 8.5 Hz), 2.28 (s, 3H).

1.0 g (4.2 mmol) of **1** was dissolved in acetonitrile and reacted with 0.58 g (4.2 mmol) of bromoacetic acid for 3 h at room temperature. After the reaction was completed, the precipitate was filtered and dried in vacuo. The product (compound **2**) was used without purification (yield: quant.). ^{1}H NMR for **2** [DMSO-d_6 (TMS), 500 MHz] δ = 8.90 (d, 2H, J = 7.0 Hz), 8.29 (d, 2H, J = 7.5 Hz), 8.06 (d, 1H, J = 16.5 Hz), 7.82 (d, 2H, J = 8.5 Hz), 7.54 (d, 1H, J = 16.5 Hz), 7.29 (d, 2H, J = 8.5 Hz), 5.42 (s, 2H), 2.31 (s, 3H).

0.73 g (1.9 mmol) of **2** was subjected to column chromatography over basic alumina (methanol). The fraction of merocyanine was collected and recrystallized from ethanol to afford 0.10 g of compound **3** (yield: 16%). ^{1}H NMR for **3** [DMSO-d_6 (TMS), 500 MHz] δ = 8.11 (d, 2H, J = 6.5 Hz), 7.64 (d, 1H, J = 15.5 Hz), 7.53 (d, 2H, J = 6.5 Hz), 7.29 (d, 2H, J = 8.0 Hz), 6.54 (d, 1H, J = 15.0 Hz), 6.13 (d, 2H, J = 9.0 Hz), 4.49 (s, 2H).

Synthesis of the Modified DNA Tethering Brooker's Merocyanine. ODNs involving Alloc- (allyloxycarbonyl-) protected D-threoninol residues were synthesized on an automated DNA synthesizer (H-8-SE DNA synthesizer, NIHON TECHNO SERVICE Co., Ltd.) by using the corresponding phosphoramidite monomer according to a previous report (*18*) and other conventional methods. The postsynthetic procedure for introducing merocyanine on CPG anchoring ODN was as follows: The Alloc group was deprotected by treatment with $Pd(PPh_3)_4$ (10 equiv) and *N*-methylaniline (1000 equiv) as a scavenger in CH_2Cl_2. The amino group on D-threoninol was coupled with **2** (Scheme 2: 100 equiv) with PyBOP (250 equiv) as a coupling reagent in DMF. In addition, *N*-methylmorpholine (300 equiv) and pyridinium *p*-toluenesulfonate (100 equiv) were added to accelerate the reaction. After the Poly-Pak treatment,

Scheme 3. Sequences of ODNs Synthesized in This Study

they were purified by reversed-phase HPLC. The yield of amide coupling was 44% as estimated from HPLC analysis. The modified ODNs were characterized by MALDI-TOFMS (Autoflex II, Bruker Daltonics).

MALDI-TOFMS for **BM1**: Obsd. 4048.9 (Calcd. for [**BM1** + H^+]: 4049.8). **BM2**: Obsd. 4048.6 (Calcd. for [**BM2** + H^+]: 4048.8). **BM3**: Obsd. 4056.8 (Calcd. for [**BM3** + H^+]: 4056.8). **cBM1**: Obsd. 4048.5 (Calcd. for [**cBM1** + H^+]: 4049.8).

BM-modified ODNs did not decompose at −20 °C under dark conditions at either pH 7.0 or 10.0. However, when the ODNs were kept at room temperature in the presence of ambient light, about 20% was degraded after 1 week.

Spectroscopic Measurements. UV−vis and CD spectra were measured on a JASCO model V-550 and a JASCO model J-820, respectively, with a 10 mm quartz cell. Fluorescence spectra were measured on a JASCO model FP-6500 with a microcell. All of them were equipped with programmed temperature controllers. Conditions of the sample solutions were as follows: [NaCl] = 100 mM, [DNA] = 5 μM. For measurements at pH 7.0, 9.1, or 10.0, 10 mM phosphate, Tris, or CAPS (*N*-cyclohexyl-3-aminopropanesulfonic acid) buffer was used. All the samples were incubated at 60 °C for 5 min and then cooled at a rate of 4 °C min^{-1} before the measurement.

Titration Experiments. The pK_a was determined from the absorbance of the sample at 20 °C. The pH was adjusted by adding small amounts of conc. NaOH solution to the sample. Conditions of the sample solutions were as follows: [NaCl] = 100 mM, [Na_2HPO_4/NaH_2PO_4] = 10 mM. Since pH titration could not be conducted at pH higher than 10 due to the dissociation of the duplex, pK_a was determined by assuming a following equation with a curve-fitting program equipped with *KaleidaGraph 3.5* (Synergy Software):

$$A = A_{HA} + \frac{(A_A - A_{HA})}{10^{(pK_a - pH)} + 1} \quad (1)$$

where A_{HA} and A_A denote absorbance of fully protonated and deprotonated forms. Errors of pK_a's were estimated within 0.04.

Measurement of Melting Temperature. The melting curve of duplex DNA was obtained with the above apparatus by

Table 1. Effects of pH on the Melting Temperature (T_m) of BM1/N1 and Absorption Maxima of Single-Stranded BM1 and BM1/N1[a]

		λ_{max}/nm[b]	
pH	T_m/°C	**BM1**	**BM1/N1**
7.0	39.5	407	418
8.0	38.7	408	415
9.1	37.2	410	421
10.0	32.2	492	432
10.5	23.8	476	478

[a] Solution conditions: [ODN] = 5 μM, [NaCl] = 100 mM. [b] UV−vis spectrum was measured at 0 °C.

measuring the change of absorbance at 260 nm versus temperature. The melting temperature (T_m) was determined from the maximum in the first derivative of the melting curve. Both the heating and cooling curves were measured, and the T_m obtained from them coincided with each other within 2.0 °C. The temperature ramp was 1 °C min^{-1}.

RESULTS AND DISCUSSION

Synthesis of Modified ODN Tethering BM on D-Threoninol. For the incorporation of BM into ODN, we could not adopt conventional phosphoramidite chemistry because amide coupling of BM (compound **2** in Scheme 2) with D-threoninol did not proceed for some reason. We also tried conventional postsynthetic modification in aqueous solution (*19*, *20*): the *N*-hydroxysuccinimidyl ester of BM (compound **2** in Scheme 2) was reacted with the amino group of D-threoninol incorporated into ODN in aqueous solution under several reaction conditions according to the literature (*21*, *22*). However, decomposition of this activated ester proceeded much faster than the desired coupling reaction. In order to overcome this difficulty, we recently developed a new postsynthetic modification of DNA on a controlled-pore glass (CPG) column by the use of allylic protection (*18*). First, Alloc- (allyloxycarbonyl-) protected D-threoninol was incorporated into the desired position of ODN. Then, the Alloc group was selectively deprotected on CPG column after DNA synthesis by $Pd(PPh_3)_4$ with other protecting groups on nucleobases keeping intact, followed by the coupling of acetyl-protected BM (compound **2** in Scheme 2) with the deprotected amino group on D-threoninol for 3 days. Finally, ODNs were cleaved from CPG and deprotected by conventional treatment with ammonium hydroxide solution. Although the total yield was not high (about 40% or below), we successfully obtained the desired ODN. In Scheme 3, modified ODNs tethering BM synthesized in the present study are listed.

Effect of the Introduction of BM on Duplex Stability. Before evaluating the pK_a of BM, we first investigated the effect of the incorporation of BM on duplex stability. The melting temperature (T_m) of **BM1/N1** involving one **X** residue at the center of the sequence was determined as 39.5 °C at pH 7.0 from the change of absorbance at 260 nm (see Table 1). Since the T_m of native duplex without BM residue (**N0/N1**) was 47.7 °C, the introduction of BM significantly destabilized the duplex. The T_m did not change from pH 7 to 9, and slightly decreased at pH 10 as shown in Table 1. However, T_m significantly decreased to 23.8 °C at pH 10.5, due to the deprotonation of imino protons of guanine and thymine. Therefore, spectroscopic measurements were carried out below 20 °C where duplexes sufficiently formed even at pH 10.5.

Hybridization of BM-tethered ODN with its native complementary strand showed both bathochromicity and hypsochromicity at pH 7.0 where the BM residue was protonated (*vide infra*) (Note: UV−vis spectra of single-stranded **BM1** and **BM1/N1** are in Supporting Information). In addition, a very weak and slightly negative circular dichroism (CD) was induced at around 400 nm where BM had its characteristic absorption (compare dotted line with solid line in Figure 1). These spectroscopic behaviors are characteristic of intercalated chromophores (*23*−*25*). Previously, we reported the solution structure of modified ODN tethering an azobenzene moiety and found that azobenzene was completely intercalated in the DNA duplex (*26*). In that case, both bathochromicity and negatively induced weak CD were observed (*27*). Thus, we conclude that BM is intercalated between the neighboring base pairs. The instability of the duplex tethering BM is attributed to the nonplanar structure of the BM residue, because steric hindrance between the benzene ring and the C═O of the amide bond twists the methylene chain (see Supporting Information).

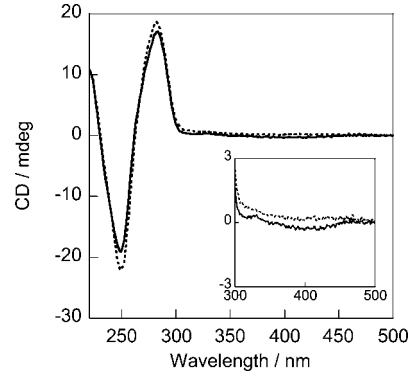


Figure 1. CD spectra of **BM1/N1** (solid line) and **N0/N1** (dotted line) at pH 7.0 (10 mM phosphate buffer), 0 °C. Induced CD at around 400 nm is magnified in inset.

Evaluation of the pK_a of BM. *Intrinsic pK_a of BM before Incorporation into DNA.* In order to evaluate the intrinsic spectroscopic properties of BM before incorporation of ODN, we first measured the absorption spectrum of compound **3** that involves a carboxylate group. An absorption maximum for **3** appeared at 381 nm at pH 7.0 (see Supporting Information), which was 6 nm longer than that for original BM without the carboxylate group (Scheme 1). When the pH was raised above 8, a new peak appeared at 451 nm as shown in Figure 2, demonstrating that compound **3** was deprotonated. From a titration curve monitored at 450 nm as shown in Figure 2b, the pK_a of **3** was determined to be 8.8 (Note: Addition of native duplex (**N0**/**N1**) to the buffer solution of compound **3** (pH 9.1, 0 °C) did not change the UV−vis spectra. See Supporting Information). Kuder et al. reported a relationship between temperature and pK_a of original BM (*14*). From their equation, the pK_a of original BM at 20 °C was estimated to be 8.6, which almost coincided with that of **3**. In addition, the absorption maximum of deprotonated **3** largely shifted depending on the polarity of the solvent as is observed for original BM (See Supporting Information) (*10*−*13*).

pK_a of BM in the Single-Strand and Duplex. To investigate whether protonation was enhanced upon hybridization, UV−vis spectra of **BM1** and **BM1/N1** were measured by changing the pH of the solution (Figures 3A and 4A). λ_{max} at each pH is listed in Table 1. At around pH 7, **BM1** in the single-stranded state gave λ_{max} at 407 nm, indicating that most of BM was protonated. An increase of pH diminished the peak at 407 nm and produced a new peak at around 490 nm due to the deprotonation of BM. From the titration curve monitored at 490 nm shown in Figure 3B (Note: As shown in Table 1, λ_{max} shifted to shorter wavelength above pH 10.2. Thus, pK_a of **BM1** was determined from the absorbance at pH 7.18–10.16), pK_a was determined to be 9.5 at 20 °C, which is 0.7 higher than that of 3. The pK_a difference between the compound **3** and single-stranded **BM1** might be attributed to the electrostatic interaction

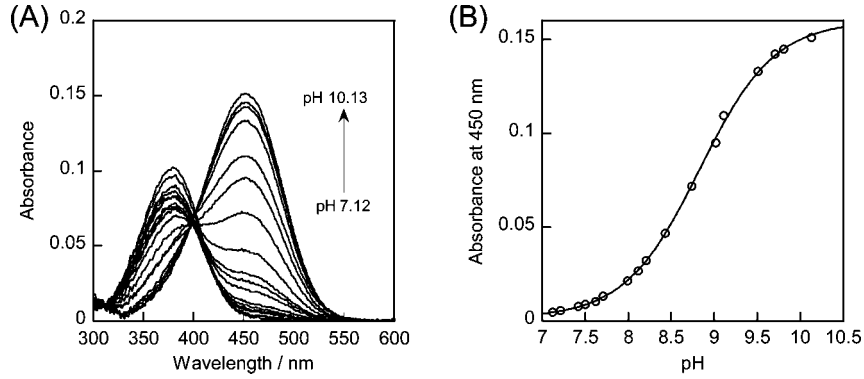

Figure 2. (A) UV−vis spectra of Brooker's merocyanine (compound **3**) at various pH (from 7.12 to 10.13) and (B) plots of the absorbance of **3** at 450 nm as a function of pH values at 20 °C. Solution conditions are as follows: [**3**] = 5 μM, [NaCl] = 100 mM, [NaH_2PO_4/Na_2HPO_4] = 10 mM.

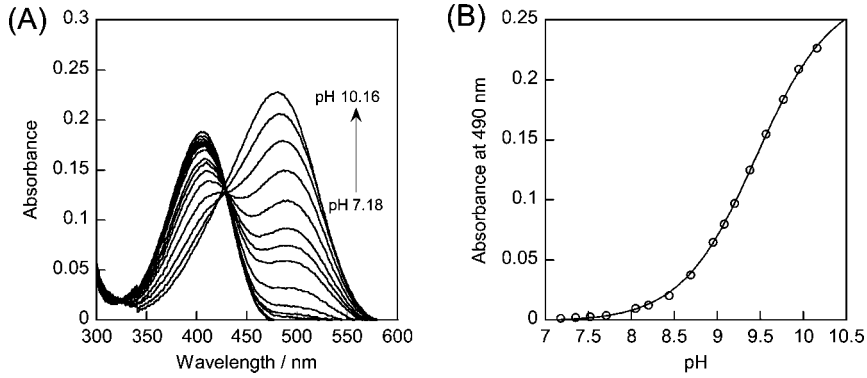

Figure 3. (A) UV−vis spectra of **BM1** at various pHs (from 7.18 to 10.16) and (B) plots of the absorbance of **BM1** at 490 nm as a function of pH values at 20 °C. Solution conditions are as follows: [ODN] = 5 μM, [NaCl] = 100 mM, [NaH_2PO_4/Na_2HPO_4] = 10 mM.

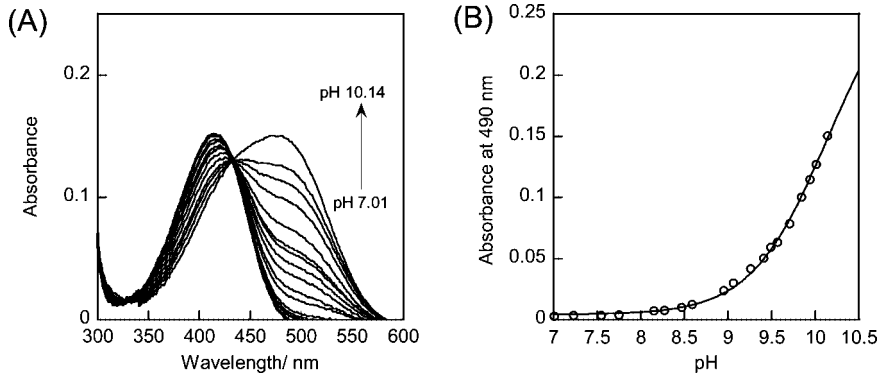

Figure 4. (A) UV−vis spectra of **BM1/N1** at various pHs (from 7.01 to 10.14) and (B) plots of the absorbance of **BM1/N1** at 490 nm as a function of pH values at 20 °C. Solution conditions are as follows: [ODN] = 5 μM, [NaCl] = 100 mM, [NaH_2PO_4/Na_2HPO_4] = 10 mM.

of phosphate anions and hydrophobic environment generated by natural bases.

The pK_a was further increased upon hybridization as shown in Figure 4. Protonated BM in **BM1/N1** gave λ_{max} at 414 nm, and a new peak appeared at a longer wavelength as pH increased. The pK_a of BM in **BM1/N1** was determined to be 10.1 from absorbance at 490 nm (Figure 4B), which is 0.6 higher than that of single-stranded **BM1**. Such an increase in pK_a by hybridization, namely, the suppression of deprotonation from BM, is attributed to the negative charges on phosphodiesters surrounding the intercalated BM.

Detection of DNA Hybridization by Use of pK_a Change. The change of pK_a is applicable to the detection of DNA hybridization. Figure 5 shows UV−vis spectra of **BM1/N1** and single-stranded **BM1** at pH 10.0. At this pH, BM in the single strand was almost deprotonated and λ_{max} appeared at 492 nm. On the other hand, hybridization with its complementary strand, **N1**, raised the pK_a from 9.5 to 10.1, and thus, about half of BM was deprotonated. Consequently, λ_{max} shifted from 492 to 432 nm by hybridization. A spectral shift between the single strand and the duplex was as large as 60 nm and hybridization could easily be discriminated by the naked eye as shown in Figure 6. The solution of single-stranded ODN was colored orange, whereas it changed to yellow by adding the complementary strand. Interestingly, the color change of BM is opposite to that of Naphthyl Red, which shows a red shift upon hybridization (*9*). DNA probes that provide both red and blue shifts upon hybridization were successfully prepared by selecting the appropriate dyes on D-threoninol.

Fluorescence Detection of DNA Hybridization. *Fluorescence Change by Hybridization.* Unlike Naphthyl Red that we previously reported (*9*), both protonated and deprotonated BMs

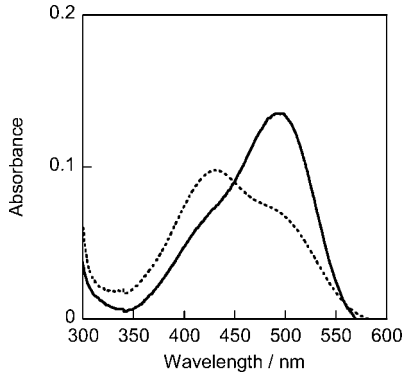

Figure 5. UV−vis spectra of single-stranded **BM1** (solid line) and **BM1/N1** (dotted line) at 0 °C. Solution conditions are as follows: [ODN] = 5 μM, [NaCl] = 100 mM, pH 10.0 (10 mM CAPS buffer).

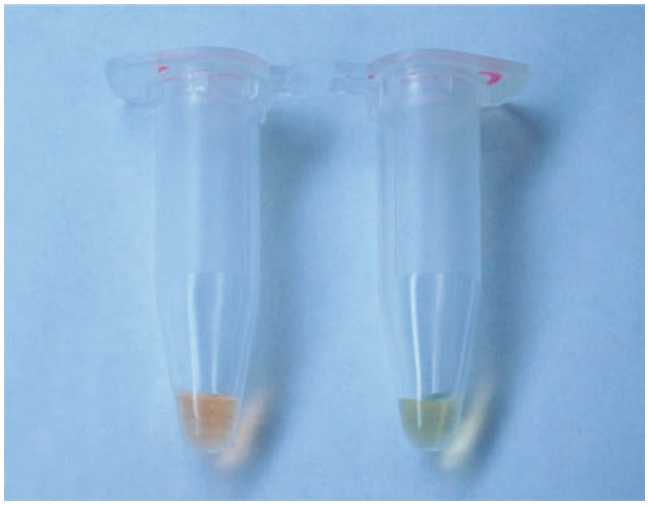

Figure 6. Color change upon hybridization at pH 10.0 (10 mM CAPS buffer). Single-stranded **BM1** (left) and **BM1/N1** (right).

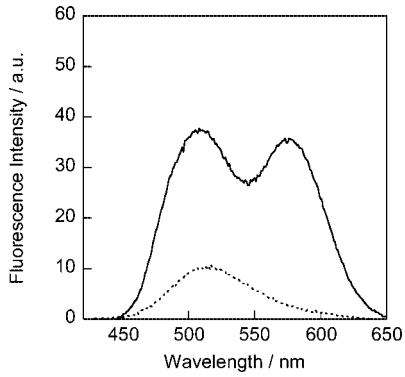

Figure 7. Fluorescence emission spectra (400 nm excitation) of **BM1** (solid line) and **BM1/N1** (dotted line). Solution conditions are as follows: [ODN] = 5 μM, [NaCl] = 100 mM, pH 7.0 (10 mM phosphate buffer), 0 °C.

are known to emit fluorescence by exciting them with a different wavelength. Figure 7 shows fluorescence emission spectra of single-stranded **BM1** and **BM1/N1** at pH 7.0 excited at 400 nm where protonated BM has its λ_{max}. Although the protonated form was dominant at pH 7.0, BM showed two peaks at 505 and 574 nm in the single-stranded state. We first assigned these two fluorescences as protonated (505 nm) and deprotonated (574 nm) BM, respectively. However, since the fluorescence at 574 nm was not observed in **BM2** and **BM3** (see Supporting

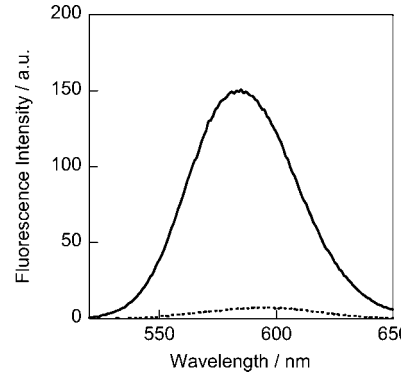

Figure 8. Fluorescence emission spectra (500 nm excitation) of **BM1** (solid line) and **BM1/N1** (dotted line). Solution conditions are as follows: [ODN] = 5 μM, [NaCl] = 100 mM, pH 9.1 (10 mM Tris buffer), 0 °C.

Information), this might be derived from exciplex formation of BM and a nucleobase (probably cytosine or guanine) (*28, 29*) (Note: Excitation spectra of single-stranded **BM1** monitored at 505 and 574 nm almost coincided. In both excitation spectra, two peaks at around 260 and 408 nm were observed. See Supporting Information for excitation spectra of single-stranded **BM1**). When the complementary strand (**N1)** was added to **BM1**, a peak at 574 nm disappeared, and emission at 510 nm assignable to the protonated BM fluorescence decreased.

Emission from deprotonated BM was observed at higher pH. Figure 8 shows fluorescence emission spectra from excitation at 500 nm of **BM1** and **BM1/N1** at pH 9.1. At this pH, BM was almost protonated in the duplex, whereas that in the single strand was partly deprotonated. Hence, fluorescence from deprotonated BM was relatively strong in the single-stranded state, whereas it was very weak in the duplex (compare the dotted with solid line in Figure 8). Since the intensity of the emission at 570 nm was 26 times higher than that of duplex, duplex formation was detectable even by fluorescence change as well as absorption spectra (Note: At a temperature below T_m, **BM1** showed similar behavior upon hybridization. At 20 °C, intensity of **BM1** at 570 nm was 14 times higher than that of **BM1/N1** (data not shown)). Addition of an excess amount of noncomplementary ODN (such as T_{11}) to either single-stranded **BM1** or **BM1/N1** solution did not affect the emission spectra (see Supporting Information). Furthermore, a one-base mismatch could be discriminated from a full-matched complementary strand by tuning the measurement temperature (Note: Incorporation of one-base mismatch greatly destabilized the duplex. Hence, a full-matched sequence could be discriminated from a mismatched one by measuring the spectra at the temperature between these T_ms. See Supporting Information for the actual data), demonstrating that sequence-specific recognition is possible with this probe. We also examined other sequences and found that fluorescence became smaller by hybridization with all the modified ODNs involving BM we synthesized (see Figure 9), although the degree of quenching depended on the sequence. It is assumed that a neighboring guanosine residue in **BM1** also contributed to the fluorescence quenching (Note: The following three factors contribute to the quenching of fluorescence from BM, although we cannot evaluate the contribution of each factor to the quenching quantitatively: protonation (or deprotonation), hybridization, and quenching by neighboring natural nucleobases).

Ratiometric Detection of Hybridization. The advantage of using BM as a chromophore is that ratiometric analysis is possible, since simultaneous excitation of both protonated and deprotonated forms gives two different emissions. As shown in Figure 9, the excitation of only the deprotonated form (at

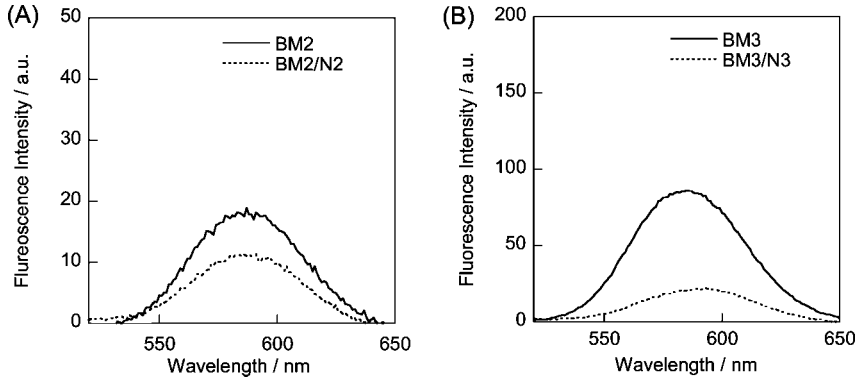

Figure 9. Fluorescence emission spectra (500 nm excitation) of single strands (solid lines) and duplexes (dotted lines) of (A) **BM2** and (B) **BM3**. Solution conditions are as follows: [ODN] = 5 μM, [NaCl] = 100 mM, pH 9.1 (10 mM Tris buffer), 0 °C.

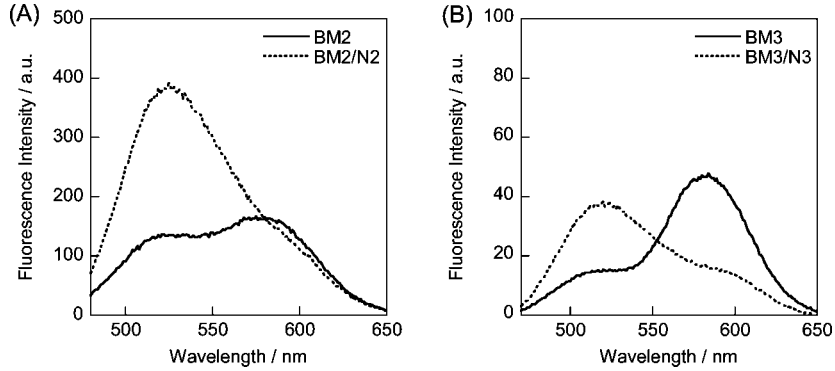

Figure 10. Fluorescence emission spectra (460 nm excitation) of single strands (solid lines) and duplexes (dotted lines) of (A) **BM2** and (B) **BM3**. Solution conditions are as follows: [ODN] = 5 μM, [NaCl] = 100 mM, pH 9.1 (10 mM Tris buffer), 0 °C. Note that the sensitivity of the spectrometer was high for **BM2** and **BM2**/**N2**, and it was medium for **BM3** and **BM3**/**N3**.

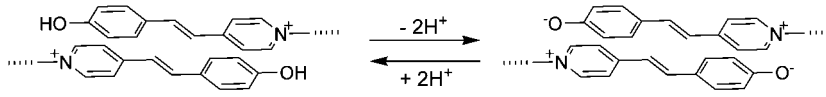
Scheme 4. Decrease in pK_a by Anti-Parallel Stacking between Two BMs



500 nm) did not sufficiently discriminate single-stranded **BM2**, **BM3**, and **BM2/N2**, **BM3/N3** duplexes due to the small change in fluorescence intensity. However, ratiometric analysis by simultaneous excitation (at 460 nm) fairly improved the discrimination efficiency. Figure 10B shows emission spectra of **BM3** and **BM3**/**N3** excited at 460 nm where both protonated and deprotonated BM have absorption. In the single-stranded state, emission at 584 nm from deprotonated BM was dominant. However, hybridization of its complementary strand made emission at 584 nm weak, and a new peak appeared at 520 nm (compare dotted with solid lines in Figure 10). Accordingly, hybridization was detectable from the change of the ratio of the emission intensities at 584 and 520 nm: I_{520}/I_{584} was 0.3 for **BM3**, whereas it was 2.4 for **BM3**/**N3**. Similarly, **BM2**, for which it was hard to probe cDNA by 500 nm excitation, induced a reasonable change of I_{520}/I_{584}; the I_{520}/I_{584} of **BM2** was 0.8 and that of **BM2**/**N2** was 2.5. Ratiometric detection of other sequences was further investigated (see Supporting Information).

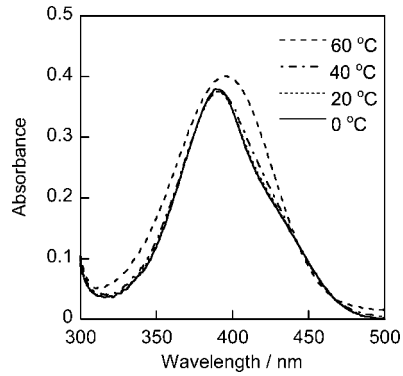


Figure 11. UV−vis spectra of **BM1/cBM1** at various temperatures. Solution conditions are as follows: [ODN] = 5 μM, [NaCl] = 100 mM, pH 7.0 (10 mM phosphate buffer).

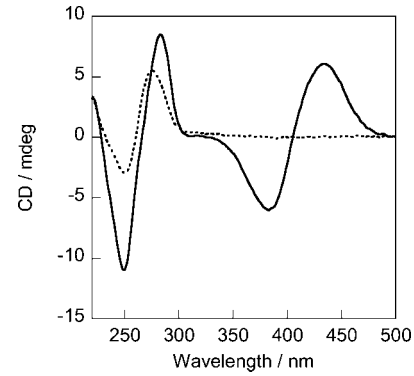

Figure 12. CD spectra of **BM1/cBM1** at 0 °C (solid line) and 70 °C (dotted line). Solution conditions are as follows: [ODN] = 2 μM, [NaCl] = 100 mM, pH 7.0 (10 mM phosphate buffer).

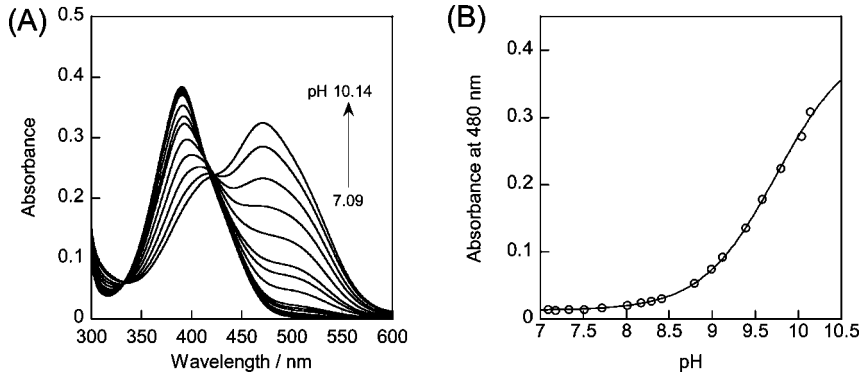

Figure 13. (A) UV−vis spectra of **BM1/cBM1** at various pH (from 7.09 to 10.14) and (B) plots of the absorbance of **BM1/cBM1** at 480 nm as a function of pH values at 20 °C. Solution conditions are as follows: [ODN] = 5 μM, [NaCl] = 100 mM, [NaH_2PO_4/Na_2HPO_4] = 10 mM.

Although the I_{520}/I_{584} value depended on the neighboring sequences, all the sequences we examined changed its value upon hybridization, demonstrating the wide availability of BM tethered ODN for the sequence-specific recognition of DNA. We also found that neighboring GC pairs quenched the fluorescence of protonated merocyanine much more strongly than that of the deprotonated form, which contributed to the sequence dependence of I_{520}/I_{584}. The detection limit of this probe was around 50 nM as estimated from the I_{520}/I_{584} value under the conditions employed here (see Supporting Information). Other dyes such as SNAFL (seminaphthofluoresceins) and SNARF (seminaphthorhodafluors) (*30*), which also change emission and absorption by protonation, might be utilized for ratiometric detection of hybridization by this method.

Modulation of pK_a by "Base-Pairing" between BMs. Recently, we reported that "threoninol-nucleotides" tethering functional molecules (such as dyes) on D-threoninols at the center of ODNs allowed interstrand "base-pairing" of the dyes by hybridization (*31*), such as a **BM1/cBM1** combination, both of which involve a BM as a "threoninol-nucleotide". In this duplex, "base-paired" BMs are stacked in an antiparallel manner as depicted in Scheme 4. Since a positive charge on the BM of one strand is located at close proximity to the hydroxyl group on that of its counter strand, the negatively charged microenvironment will be partially compensated for by this positive charge (left side of Scheme 4), and thus, the pK_a of BM is expected to decrease. In addition, the betaine structure of deprotonated BM possessing both positive and negative charges on an identical molecule will stabilize the stacked BMs due to electrostatic interactions (right side of Scheme 4). This effect might also contribute to the decrease of pK_a of BM.

We verified the "base-pairing" from the spectroscopic behavior of BM by the hybridization of **BM1/cBM1** at pH 7.0. At 60 °C, where the duplex was dissociated into two single strands (note that the T_m of **BM1/cBM1** is 49.9 °C), a broad peak was observed at 396 nm in UV−vis spectra (Figure 11). When the temperature was lowered below its T_m, however, the peak shifted to a shorter wavelength, and narrowing of the band was observed. The absorption maximum of **BM1/cBM1** at 0 °C appeared at 389 nm, which was 29 nm shorter than that of **BM1/N1**. Such a hypsochromic shift and narrowing of the band are characteristic of dye aggregation stacked in a face-to-face manner. The increase in the melting temperature of **BM1/cBM1** (49.9 °C) compared with that of **BM1/N1** (39.5 °C) also supports the antiparallel stacking of BM (Note: Insertion of one-base mismatch to **BM1/cBM1** destabilized duplex. Melting temperature of duplex containing C-T mismatch (5′-GGTATC**X**TCAATC-3′/3′-CCATAG**X**CGTTAG-5′) was 45.5 °C, which was 4.4 °C lower than that of **BM1/cBM1**. This result indicates that incorporation of tentative "base-pair" of two BMs did not disturb the recognition of its complementary strand). In addition, induced CD also supported the dimerization of BMs in **BM1/cBM1** (see Figure 12). At 70 °C, where **BM1** and **cBM1** were completely dissociated to single strands, there was no CD at 350−500 nm. However, a positive couplet was distinctly observed at around 400 nm when the temperature was lowered to 0 °C, far below the T_m. This result clearly shows that two BMs in **BM1/cBM1** were stacked and excitonically coupled (Note: **BM1/cBM1** did not exhibit excimer emission but showed quenching of fluorescence from BM fluorophore at pH 7.0. This self-quenching also supports the dimerization of BM in the duplex. See Supporting Information). On the basis of these results, we concluded that two BMs were stacked in an antiparallel manner as depicted in Scheme 4.

Figure 13 shows the pH dependence of the absorption spectrum of **BM1/cBM1**. Plots of absorbance at 480 nm vs pH (Figure 13B) determined the pK_a of BM to be 9.7. As we expected, this value was 0.4 lower than that of **BM1/N1**, demonstrating that the pK_a of BM was controllable by antiparallel stacking as depicted in Scheme 4. This pK_a shift is applicable to the detection of sequence-specific DNA by quencher-free molecular beacons that have two BMs on both sides (*32*). When the beacon is closed, two BMs are stacked in an antiparallel manner and deprotonated. An opened beacon by hybridization with the target promotes the protonation of BM and induces the spectral change (Note: T_m of **BM1/cBM1** was 10 °C higher than that of **BM1/N1**, indicating that introduction of "base-paired" BMs into molecular beacon stabilize closed state rather than open state. Accordingly, shorter stem and longer loop would be appropriate for designing BM-tethered molecular beacon).

CONCLUSIONS

Brooker's merocyanine was introduced into ODN and its pK_a was modulated by hybridization. The pK_a of BM in the single-stranded ODN increased by hybridization due to the "negative" microenvironment in the duplex. Concurrently, the color of the solution changed from orange to yellow so that duplex formation was easily detected even by the naked eye. Fluorescence emission spectra as well as absorption also changed upon hybridization. In addition, ratiometric detection of DNA hybridization was also possible. The pK_a of BM was also modulated by antiparallel stacking between two BMs. These ODNs involving BM whose pK_a is controllable by its microenvironment are applicable to the detection of mismatched DNA and quencher-free molecular beacons.

Modulation of pK_a of Brooker's Merocyanine by DNA Hybridization

Hiromu Kashida, Kanae Sano, Yuichi Hara and Hiroyuki Asanuma*

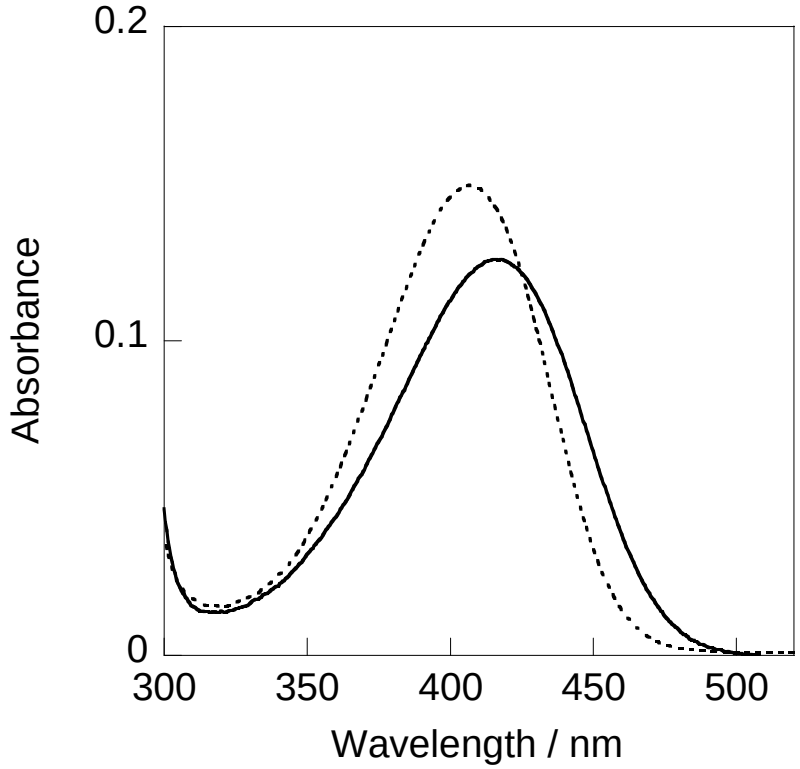

Figure S-1. UV-Vis spectra of **BM1**/**N1** (solid line) and single-stranded **BM1** (dotted line) at pH 7.0 (10 mM phosphate buffer), 0 ^{o}C, in the presence of 100 mM NaCl.

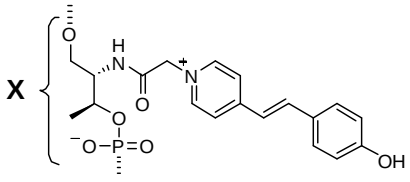
BM1 : 5'-GGTATC**X**GCAATC-3'
N1 : 3'-CCATAGCGTTAG-5'



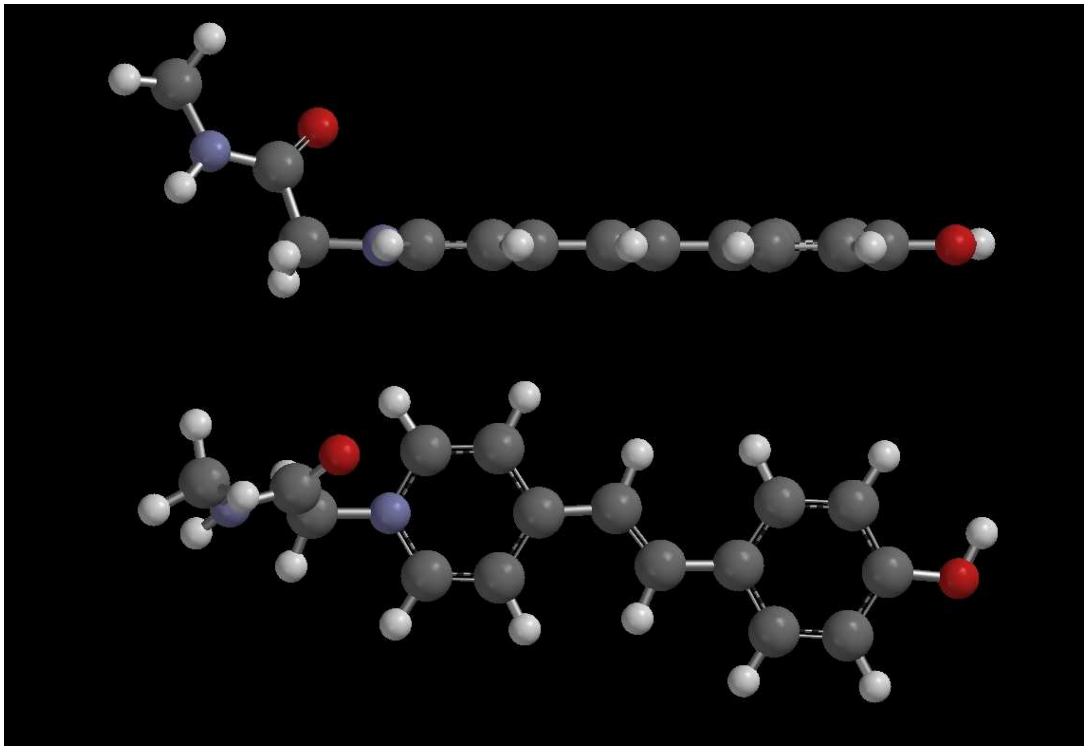


Figure S-2. Top and side views of energy-minimized structure of Brooker's merocyanine calculated by HF/6-31G*. The calculated structure is shown below.

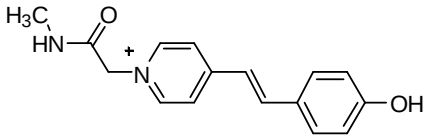

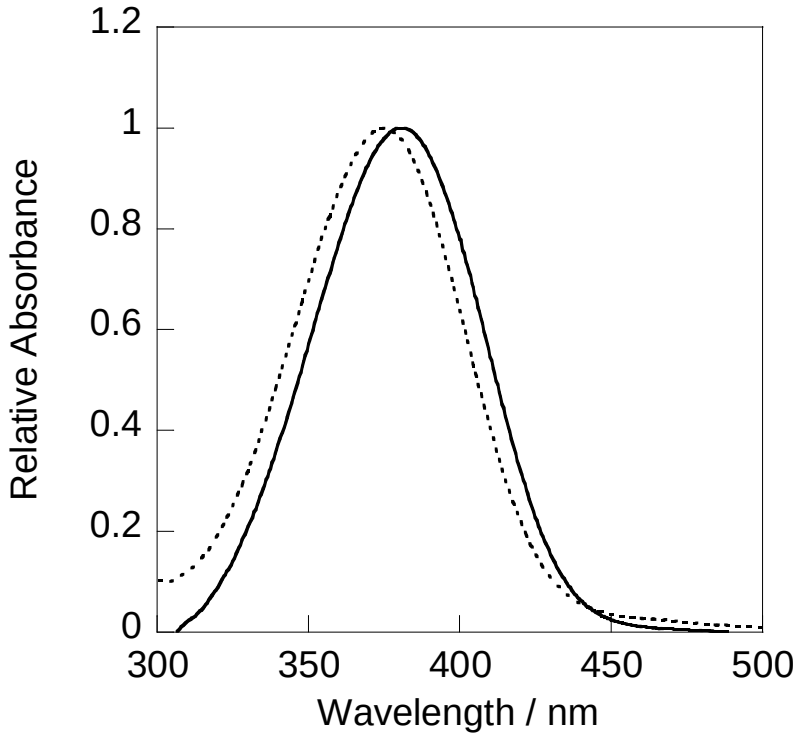

Figure S-3. UV-Vis spectra of **3** (solid line) and Brooker's merocyanine (BM: dotted line) at pH 7.0 (10 mM phosphate buffer), 0 ^{o}C, in the presence of 100 mM NaCl. Each spectrum was normalized at the absorption maximum. Chemical structures of **3** and BM were shown below.

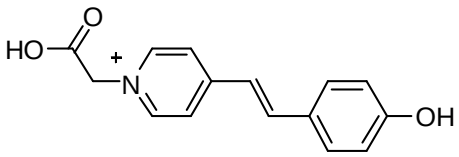
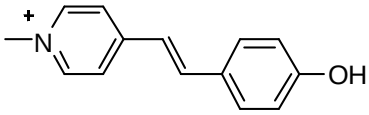


3



Brooker's merocyanine

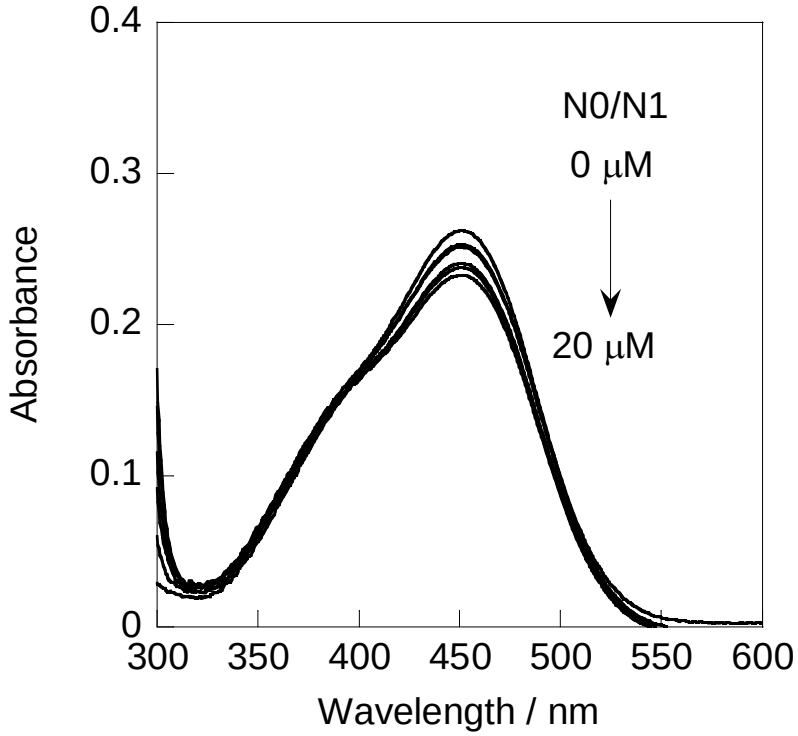


Figure S-4. UV-Vis spectra of **3** with various concentration of native DNA duplex (**N0**/**N1**).The concentration of **N0**/**N1** were 0, 4, 8, 12, 16 and 20 μM.
Solution conditions are as follows:
[**3**] = 10 μM, [NaCl] = 100 mM, pH 9.1 (10 mM Tris buffer), 20 ^{o}C.

N0 : 5'-GGTATCGCAATC-3'
N1 : 3'-CCATAGCGTTAG-5'

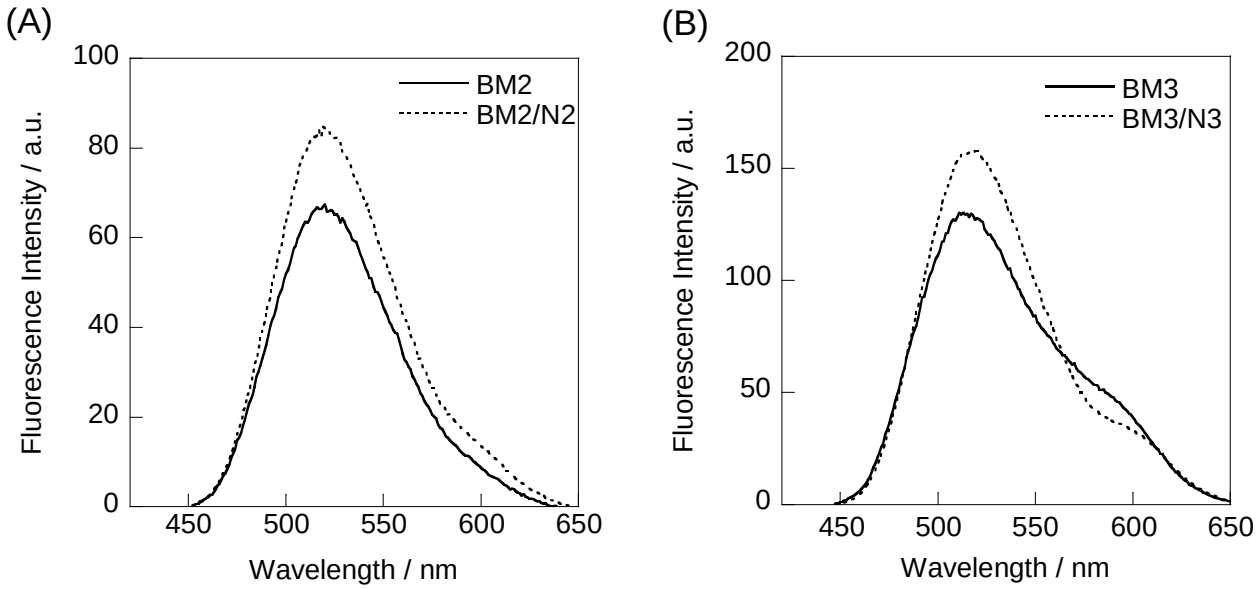

Figure S-5. Fluorescence emission spectra excited at 400 nm of single strands (solid lines) and duplexes (dotted lines) of (A) **BM2**, (B) **BM3**. Solution conditions are as follows:
[ODN] = 5 μM, [NaCl] = 100 mM, pH 7.0 (10 mM phosphate buffer), 0 ^{o}C.

BM2 : 5'-GGTATA**X**TCAATC-3'
N2 : 3'-CCATATAGTTAG-5'
BM3 : 5'-GGTATA**X**ACAATC-3'
N3 : 3'-CCATATTGTTAG-5'

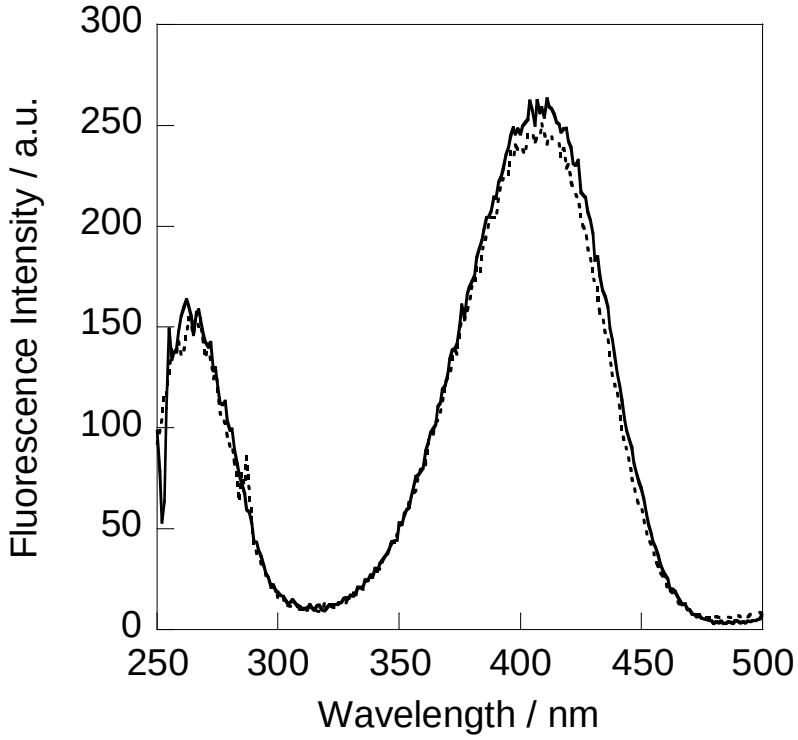

Figure S-6. Fluorescence excitation spectra of **BM1** monitored at 505 nm (solid line) and 574 nm (dotted line). Solution conditions are as follows:
[**BM1**] = 5 μM, [NaCl] = 100 mM, pH 7.0 (10 mM phosphate buffer), 0 ^{o}C.

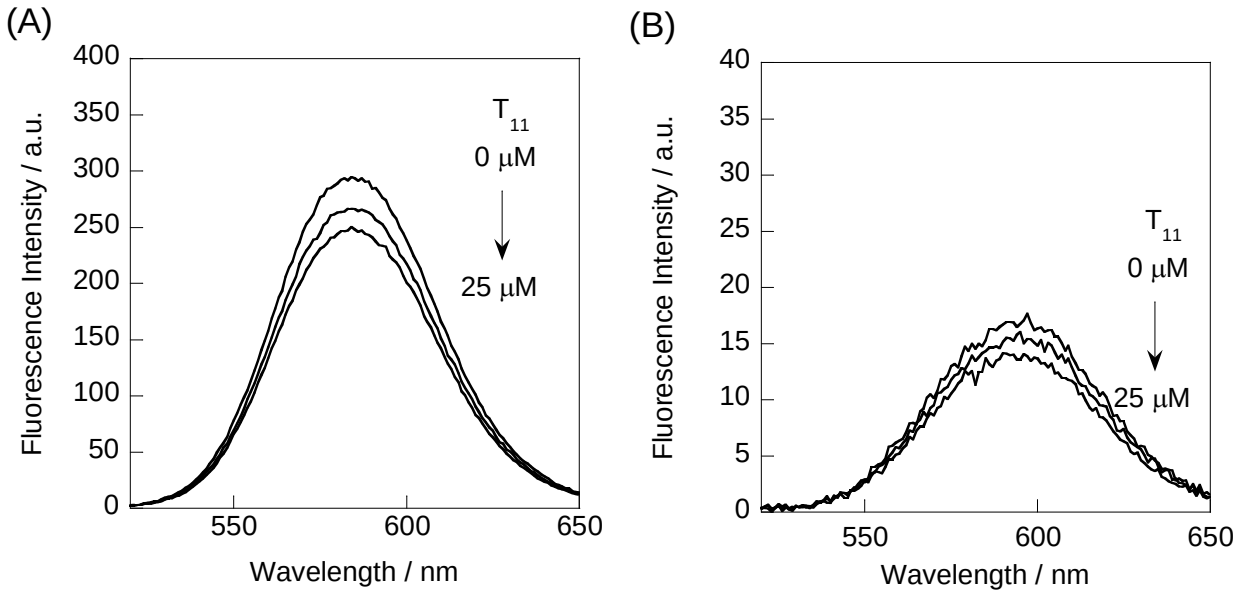

Figure S-7. Fluorescence emission spectra excited at 500 nm of (A) **BM1** and (B) **BM1**/**N1** with and without T_{11}. Concentrations of T_{11} were 0, 12.5 and 25 μM.
Solution conditions are as follows:
[**BM1**] = [**N1**] = 5 μM, [NaCl] = 100 mM, pH 9.1 (10 mM Tris buffer), 0 ^{o}C.

T_{11} : 5'-T_{11}-3'

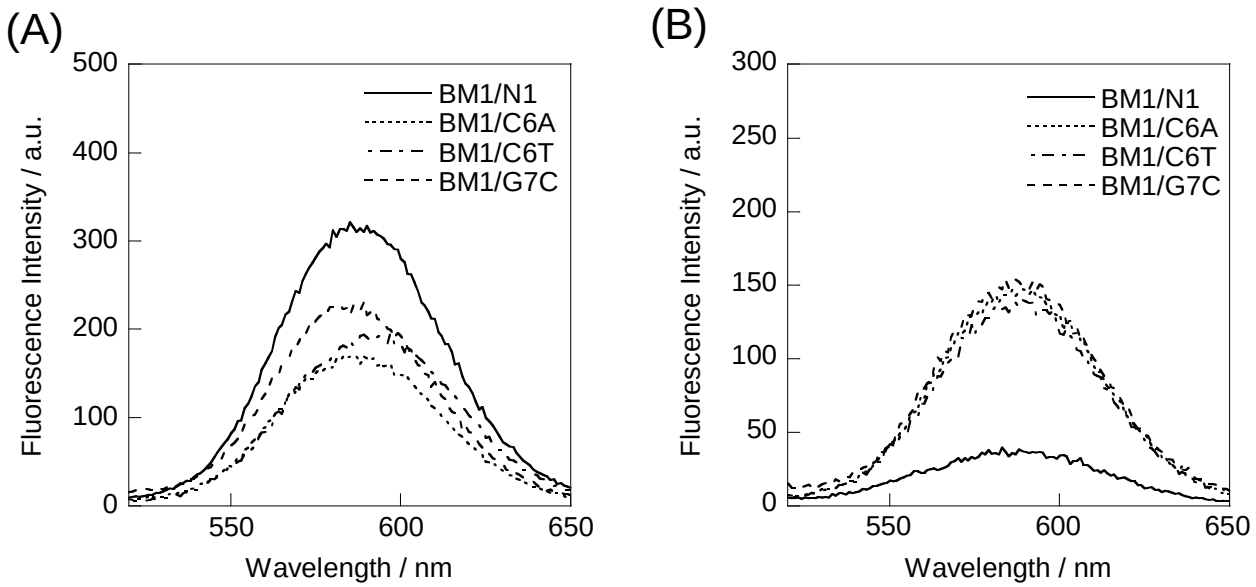

Figure S-8. Fluorescence emission spectra excited at 500 nm of full-matched (**BM1**/**N1**) and mismatched (**BM1**/**C6A**, **BM1**/**C6T** and **BM1**/**G7C**) duplexes at (A) 0 ^{o}C and (B) 30 ^{o}C. Melting temperatures of each duplex was 37.2 ^{o}C (**BM1**/**N1**), 24.8 ^{o}C (**BM1**/**C6A**), 26.8 ^{o}C (**BM1**/**C6T**) and 24.6 ^{o}C (**BM1**/**G7C**).
Solution conditions are as follows:
[ODN] = 5 μM, [NaCl] = 100 mM, pH 9.1(10 mM Tris buffer).
Note that the sensitivity of the spectrometer was high for these spectra while medium for spectra in Figure 8 of the main text.

BM1 : 5'-GGTATC**X**GCAATC-3'
N1 : 3'-CCATAGCGTTAG-5'
C6A : 3'-CCATAGAGTTAG-5'
C6T : 3'-CCATAGTGTTAG-5'
G7C : 3'-CCATACCGTTAG-5'

Received August 23, 2008; Revised Manuscript Received December 17, 2008

We present a labeling system for direct chemiluminescence-based cellular bioassays using the stable pro-chemiluminescent, luminol precursor, 3-aminophthalimide (API). API-coupled reporter molecules are detected chemiluminometrically after treatment with hydrazine, which converts the API label to luminol. API derivatives containing a variety of functional groups are readily synthesized, allowing for ease of coupling via the imide nitrogen to a host of reporter molecules. The fluorescent nature of APIs further allows for dual fluorescence and chemiluminescence studies. To highlight the utility of this label, we show that API-labeled insulin can be successfully utilized in cellular binding and transport assays and that an API-coupled mitochondrial probe (API−triphenylphosphonium^{+}) can be used to both fluorescently and chemiluminometrically investigate mitochondrial function. We also assess the use of API as a polysaccharide and nucleic acid label, and we show that API-labeled palmitic acid undergoes cellular transport and lipid metabolism.

INTRODUCTION

Chemiluminescence-based bioassays are highly sensitive, quantitative, reproducible, less hazardous, and less costly than radio-isotope-based methodologies. Assays are often indirect; i.e., the chemiluminescent signal is generated when an enzyme label, coupled to a reporter molecule, catalyzes the oxidation of a chemiluminescent substrate. However, direct assays, where a reporter molecule is tagged with a compound that undergoes direct chemiluminescence upon induction, offers a number of potential advantages over indirect assays. These include increased simplicity, the attachment of multiple labels to the reporter, and the avoidance of large enzyme-coupled reporter molecules, which can exhibit significantly reduced affinity for the target and negates their use in cellular probe-based investigations (*1*). Luminol (3-aminophthalhydrazide) is one of the most widely used chemiluminescent substrates. Its oxidation by a variety of oxidizing agents at pH 10−11, catalyzed by metal ions (e.g., Cu^{2+}, Co^{2+}, Mn^{2+}, Fe^{2+}, and ferricyanide) to 3-aminophthalate, with the emission of light at 425 nm, was reported in 1928 (*2*−*4*). Commonly used luminol-based indirect bioassays, typically catalyzed by peroxidase coupled reporter molecules, are broadly linear and practically efficient (*5*). However, luminol is seldom used in direct assays due to label instability, and the finding that the coupling of this molecule (often via its amino function) to reporters leads to a significant reduction in quantum yield (*6*).

Here, we present direct chemiluminescent cellular bioassays using the luminol precursor, 3-aminophthalimide (API). Our rationale for doing so is founded on the fact that, although not directly chemiluminescent, 3-aminophthalimide can be considered a pro-chemiluminescent substrate since it reacts with hydrazine (the Ing-Manske procedure) to form a primary amine and "free" (noncovalently linked) luminol (*7*). Thus, assays involve the use of API-coupled reporter molecules, detected chemiluminometrically after treatment with hydrazine, which converts the API label to unconjugated luminol, circumventing the problems associated with covalently linked luminol (Figure 1). The use of the API system offers the additional advantages of ease of synthesis: 3-aminophthalimide derivatives containing a variety of functional groups can be readily synthesized, allowing for ease of coupling via the imide nitrogen to a host of reporter molecules. Fluorescence properties: 3-aminophthalimides are highly fluorescent molecules (*8*), allowing for dual fluorescence and chemiluminescence studies.

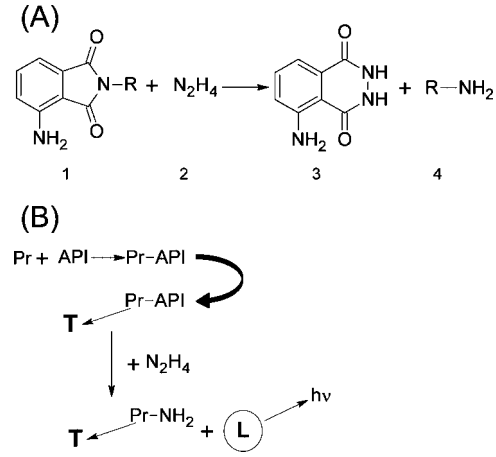

Figure 1. Assay principle. (A) 3-Aminophthalimide derivatives (API) (**1**) are converted by hydrazine (**2**) to luminol (**3**) and a primary amine (**4**). (B) Cellular probes (Pr) are labeled with API moieties. Labeled probes bind to or enter target (T). Hydrazine treatment converts the API-probe to unconjugated luminol (L), which is quantified chemiluminometrically.

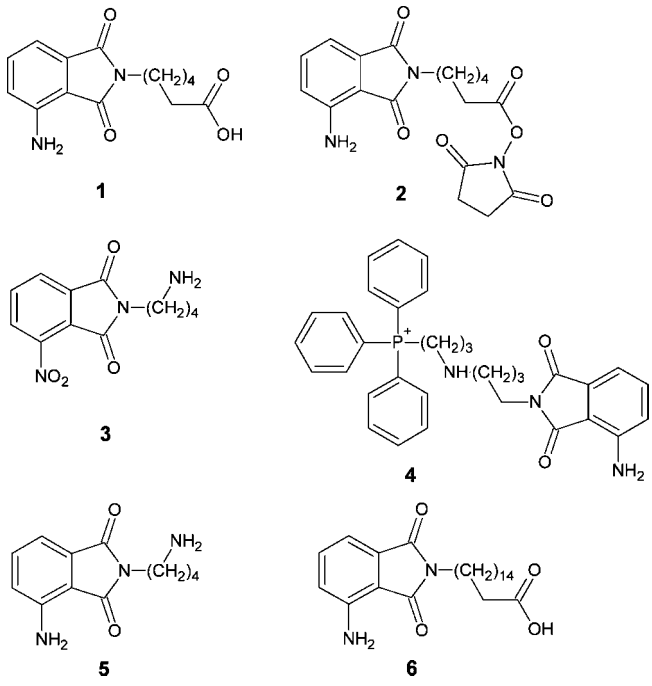

Figure 2. Structures of API derivatives and intermediates. (**1**) 4-Amino-2-(hexanoic acid)-isoindole-1,3-dione, (**2**) 4-Amino-2-(hexanoic acid-*N*-hydroxysuccinimido ester)-isoindole 1,3-dione, (**3**) 2-(4-Aminobutyl)-4-nitro-isoindole-1,3-dione, (**4**) 4-Amino-2-[4-(3-triphenylphosphonium-propylamino)-buytl]-isoindole-1,3-dione bromide, (**5**) 4-Amino-2-(4-aminobutyl)-isoindole-1,3-dione, (**6**) 4-Amino-2-(hexadecanoic acid)-isoindole-1,3-dione.

We show that API-labeled insulin can be successfully utilized in cellular binding and transport assays and that an API-coupled mitochondrial probe can be used to investigate mitochondrial function by chemiluminescence and fluorescence microscopy. We also assess the use of API as a polysaccharide and nucleic acid label, and we show that API-labeled palmitic acid can be readily synthesized and undergoes cellular transport and incorporation into complex lipid species. Our study illustrates that the use of API in dual fluorescence and chemiluminescence assays has potentially broad application in the biomedical sciences.

MATERIALS AND METHODS

Materials. Unless otherwise stated, all reagents were from Sigma-Aldrich, Dorset, U.K. Cell culture medium and supplements were from Gibco, Invitrogen, Paisley, U.K. The structures of API derivatives and intermediates are shown in Figure 2.

Cell Culture. HepG2 hepatoma cells (ECACC, Wiltshire, U.K.) were cultured in α-MEM or DMEM supplemented with 10% FBS, 100 units/mL penicillin, and 100 μg/mL streptomycin. Cells were maintained at 37 °C in 5%CO_2.

Time-Resolved Chemiluminescence Studies. A 24 μM NH_2-API aqueous solution (50 μL) was mixed with an equal quantity of 98% hydrazine hydrate and heated for 30 min at 60 °C. Thereafter, 50 μL of the hydrazine-treated sample was transferred to a well of a 96-well chemiluminescence plate, to which was added 15 μL of a 0.02 g/mL iodophenol solution (in 1 N NaOH). Time-resolved luminescence was then determined using a Tropix TR717 multiplate luminometer with injector, in kinetics mode, after luminescence induction by the injection of 100 μL 0.045% ferricyanide solution into the well.

Determination of API to Luminol Conversion Efficiency by GC-MS Analysis. HepG2 cell lysates (2 mg/mL total protein) or PBS samples (100 μL) were spiked with 56 nmol of API-palmitate in DMSO such that 100% conversion of API to luminol by hydrazine treatment would yield 56 nmol (10 μg) luminol. Samples were then incubated with an equal volume of 98% hydrazine hydrate for 30 min at 60 °C. Luminol was extracted from hydrazine-treated samples using ENV^+ reverse-phase extraction columns (Isolute SPE products). In brief, the samples were dissolved in 1 mL Tris-HCl buffer (20 mM, pH 8.0) and extracted on an ENV^+ column, which had already been prewashed with 1 mL methanol and 4 mL of Tris-HCl buffer (pH 8.0). The columns were washed with water and eluted with 2 mL of methanol. Purified samples were dried under vacuum and derivatized to the *tert*-butyl dimethylsilyl derivative by the addition of 20 μL of diisopropylethylamine, 30 μL dimethylformamide, and 30 μL of *N*-(*t*-butyl dimethylsilyl)-*N*-methyltrifluoroacetamide for 1 h at 60 °C. Derivatized samples were dried under nitrogen and redissolved in 20 μL of *n*-undecane. Samples were applied to a GC equipped with a 15 m DB-1701 (J&W Scientific, Folsom, CA) capillary column (0.25 mm internal diameter, 0.25 mm film thickness) interfaced with a mass spectrometer (Trio 1000; Fisons Instruments, Beverly, MA). The ion source and interface temperatures were set at 200 and 320 °C, respectively. Samples were analyzed in negative-ion chemical ionization mode with ammonia as the reagent gas, using 1 μL of each sample for injection. The initial column temperature was maintained at 150 °C for 1 min increasing to 300 at 20 °C/min. The mass spectrum obtained for silylated luminol is shown in Figure 3C. The major fragment ion for derivatized luminol has an *m*/*z* of 404, which corresponds to a deprotonated molecular ion for the silylated derivative. For quantitative measurement of luminol, ions were monitored by single ion monitoring at 404 *m*/*z* and their concentrations determined against known amounts of standards.

Preparation of NHS-API. 4-Amino-2-(hexanoic acid-*N*-hydroxysuccinimido ester)-isoindole-1,3-dione (NHS-API) (**2**) was synthesized by the esterification of 4-amino-2-(hexanoic acid)-isoindole-1,3-dione (**1**) with di(*N*-succinimidyl) carbonate. Initially, (**1**) was synthesized by fusing equal quantities (2.6 mmol) of 3-nitrophthalic anhydride and 6-amino-*n*-caproic acid at 153 °C for 10−15 min. The melt [crude 2-(hexanoic acid)-4-nitro-isoindole-1,3-dione] was washed with boiling water and resuspended in 10 mL 10% sodium dithionite. Reduction was carried out for at least 20 min with maintenance of the pH at 7−7.5, until most of the suspension had dissolved. After the removal of insoluble residue, the pH was adjusted to 3.0 with HCl and crude (**1**) precipitated with brine. The resultant oily yellow pellet was washed with water, lyophilized, and reacted with 2.6 mmol di(*N*-succinimidyl) carbonate in 2 mL pyridine/3 mL acetonitrile for 1 h at 60 °C, then dried at 60 °C for a further hour under nitrogen. The resultant crude (**2**) was purified on a silica gel 60 column using dichloromethane/acetone (40/80) as the mobile phase and/or recrystallized from ethyl acetate. Lyophilized aliquots were stored desiccated at −20 °C until use. ^{1}H NMR ($CDCl_3$, 500 MHz): 8.11−8.05 (2H, m, 2 × ArH), 7.92 (1H, t, j = 7.7 Hz, ArH), 5.21, (2H, br s, NH_2), 3.72 (2H, t, j = 7.2 Hz, CH_2), 2.83 (4H, br s, 2 × CH_2), 2.60 (2H, t, j = 7.2 Hz, CH_2CO), 1.82−1.61 (6H, m, 3 × CH_2) ppm.^{13}C NMR ($CDCl_3$, 125 MHz): 170.3 (s, C═O), 169.2 (s, 2 × C═O), 165.9 (s, C═O), 163.0 (s, C═O), 145.2 (s, C(Ar)), 135.2 (d, CH(Ar)), 128.5 (d, CH(Ar)), 127.0 (d, CH(Ar)), 38.4 (t, CH_2), 30.9 (t, CH_2), 27.9 (t, CH_2), 25.6 (t, 2 × CH_2), 24.1 (t, CH_2). FTIR (thin film, cm^{-1}): 3476 w, 3374 w, 2943 m, 1780 m, 1735 s, 1715 s, 1695 s, 1633 m, 1341 m. LRMS (CI + ve): 404 (55%), 374 ($[MH]^+$, 37%), 259 ($[M\text{-}ONSu]^+$, 100%). $C_{18}H_{19}N_3O_6$ requires 373.1274.

Preparation of API and Fluorescein-Labeled Insulin. Lyophilized human recombinant insulin (3.5 mg) (Novo Nordisk) was resolubilized in 1 mL of 50 mM borate buffer (pH 9.0) to which was added 0.3 μmol of NHS-API synthesized as

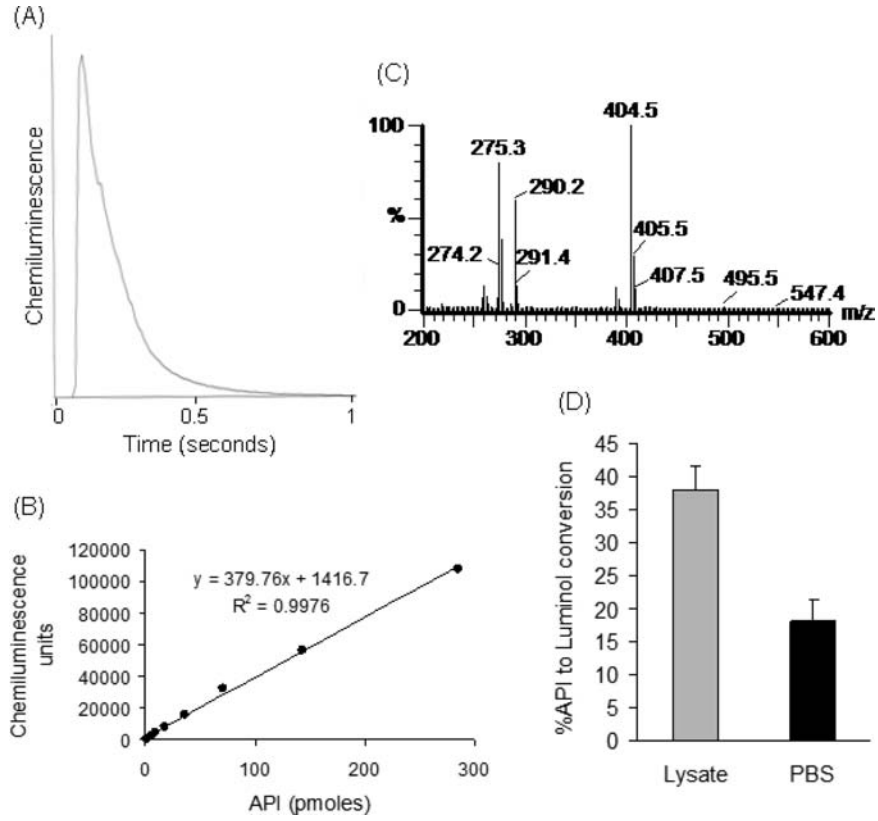

Figure 3. (A) Rate of light emission for 0.6 nmol of NH_2-API treated with hydrazine and induced by ferricyanide in the presence of the enhancer, iodophenol. (B) Typical standard curve for API. NHS-API stocks were doubly diluted in 1:1 DMSO/Tris-HCl (pH 8.5) solution. Triplicate dilutions were treated with an equal volume of hydrazine and chemiluminescence determined as for insulin studies. (C) Mass spectrum obtained for silylated luminol. The major fragment ion for derivatized luminol has an *m*/*z* of 404, which corresponds to a deprotonated molecular ion for the silylated derivative. (D) Conversion (%) of 56 nmol of API-palmitate in 100 μL cell lysate (gray bar) or PBS (black bar) to luminol after treatment with an equal volume of hydrazine as described for insulin studies. Complete (100%) conversion is assumed to yield 56 nmol (10 μg) of luminol. After hydrazine treatment, luminol was detected and quantified by GC-MS using a luminol standard curve, $n = 3$, $\pm$ SD. Assays were carried out in triplicate.

above, or 0.3 μmol of commercially available fluorescein-5(6)-carboxamidocaproic acid *N*-succinimidyl ester (NHS-Fluorescein) (Sigma, U.K.) in 200 μL DMSO. After 1 h at room temperature the API or fluorescein-labeled insulin was purified on PD-10 columns (GE Health Sciences, Amersham, U.K.) and the concentration of eluted, labeled insulin determined by the BCA assay (*9*). The concentration of insulin-bound API was determined by measuring the absorbance of the labeled insulin fractions at 395 nm (peak absorbance for API (395 nm) was determined for 5 mM NH_2-API in DMSO with a Unicam UV300 spectrophotometer). Insulin-bound fluorescein was determined by measuring the absorbance of labeled insulin fractions at 495 nm (*10*). Molar values were determined from API and fluorescein−albumin standard curves.

API-Insulin Binding Studies. HepG2 cells maintained in 12-well culture dishes until 80% confluence were used for insulin binding assays as previously described (*11*). After washing with HBSS, cells were exposed to 1 mL binding buffer (*11*), containing 5, 2.5, 1.25, and 0.625 μM API-insulin and incubated at 4 °C in the dark for 19 h. Thereafter, labeled binding buffer was removed from the cells, the cells were washed with 3 × 1 mL PBS, removed from the wells by scraping, pelleted, resuspended in 200 μL water, sonicated, and 10 μL of the lysate used for protein quantification by the BCA assay. For API measurement, cell lysates or labeled binding buffer (100 μL) were mixed with an equal volume of 98% hydrazine hydrate, heated at 60 °C for 30 min and 50 μL of the hydrazine treated sample mixed with 15 μL of a 0.02 g/mL iodophenol solution (in 1 N NaOH). Luminescence was then quantified for 10 s using a Tropix TR717 multiplate luminometer after luminescence induction by the injection of 100 μL 0.045% ferricyanide solution to each sample.

Insulin Transport Studies. For a comparison of API and fluorescein-labeled insulin uptake, HepG2 cells maintained in 6-well culture plates until 80% confluence were exposed to 2 mL binding buffer containing 10 μM API or fluorescein-labeled insulin. After 19 h, cells were washed with 2 × 2 mL unlabeled binding buffer and incubated for a further hour at 37 °C to induce insulin uptake. Thereafter, cells were washed with 2 × 2 mL PBS (pH 7.4), incubated with 2 mL PBS (pH 3.8) for 10 min, washed twice more with the latter buffer to remove remaining externally bound insulin, pelleted, and sonicated in 400 μL water. API chemiluminescence was determined as above, while for fluorescein−insulin, cell lysates (100 μL) were mixed with an equal volume of 1.5 M Tris buffer (pH 8.8) and fluorescence quantified using a cytofluor spectrofluorimeter at 485 nm excitation/530 nm emission.

Preparation of TPP-API. 4-Amino-2-[4-(3-triphenylphosphonium-propylamino)-butyl]-isoindole-1,3-dione bromide (TPP-API) (**4**) was synthesized by the coupling of 2-(4-aminobutyl)-4-nitro-isoindole-1,3-dione (**3**) with [2-(1,3dioxan-2yl)ethyl]-triphenylphosphonium bromide (DETP) (Aldrich, Dorset, U.K.) using reductive amination. Initially, crude (**3**) was prepared as follows: 6.2 mmol of putrescine dihydrochloride was combined with 0.012 mol of sodium hydroxide in 1 mL methanol and vortexed until dissolution of the hydroxide pellets. The suspension was centrifuged at 3500 *g* for 5 min and the supernatant (1 mL) placed in a thick walled 50 mL glass tube, to which was added 2.6 mmol 3-nitrophthalic anhydride. The mixture was rapidly heated at 180 °C until converted to a yellow melt.

The warm melt (crude (**3**)) was dissolved in 10 mL methanol and dried under nitrogen, yielding a yellow solid, which was coupled to DETP as follows: DETP (3.1 mmol) was stirred with 0.03 g *p*-toluene sulfonic acid (in 20 mL methanol) to allow for dioxan hydrolysis. After 1 h, crude (**3**) (dissolved in 10 mL water) was added to the above and the solution adjusted to pH 7. Reductive amination was initiated by the addition of 3.1 mmol sodium cyanoborohydride and the pH maintained at 6.8−7.0 for 1 h with HCl, yielding crude 4-nitro-2-[4-(3-triphenylphosphonium-propylamino)-butyl]-isoindole-1,3-dione bromide, which was reduced by the addition of 3 g (10%) sodium dithionite. The resultant yellow precipitate (crude (**4**)) was washed extensively with water. Crude product was lyophilized and stored desiccated at −20 °C until use or as frozen DMSO stocks.

Fluorescence Microscopy. HepG2 cells grown on Falcon Tissue culture-treated slides and stained with API-derivatives or JC-1 were viewed with a Nikon Eclipse TE 200 microscope using Nikon 1CH31010 Lucifer Yellow and 1CH31003 R & B Phycoerythrin (PE) filter sets, respectively, and *LuciaG* v 4.8 imaging software.

Preparation of NH_2-API. 4-Amino-2-(4-aminobutyl)-isoindole-1,3-dione (**5**) for heparin studies was prepared from mono-Boc-protected putrescine and 3-nitrophthalic anhydride (3NPA). Initially, equivalent amounts (0.023 mol) of putrescine and $(Boc)_2O$ were reacted in methanol in the presence of an iodine catalyst (0.0023 mol) according to the method of Varala et al. (*12*). The resultant precipitate (crude monoprotected diamine) was washed extensively with water, lyophilized, and 0.5 g fused with an equivalent amount of 3NPA at 153 °C for 10 min. The melt (crude 2-(4-Boc-aminobutyl)-4-nitro-isoindole-1,3-dione was dissolved in 10 mL THF and reduced to Boc protected (**5**) with 10% dithionite. Phase separation was achieved by the addition of excess sodium bicarbonate, and the organic phase collected and dried under nitrogen. Crude Boc-protected (**5**) was purified by silica gel chromatography, deprotected with trifluoroacetic acid for 10 min, dried under nitrogen, and redissolved in water. The resultant water-soluble, 4-amino-2-(4-aminobutyl)-isoindole-1,3-dione, trifluoroacetate salt was lyophilized and stored desiccated at −20 °C until use. FTIR (thin film, cm^{-1}): 2950 m, 1686 s, 1634 m, 1535 m. LRMS (CI + ve): 264 ($[M + MeOH]^+$, 20%), 234 ($[MH]^+$, 15%), 217 ($[M - NH_2]^+$, 15%), 148 (100%). HRMS (CI + ve): $[MH]^+$, $C_{12}H_{15}N_3O_2$ requires 234.12425. Found 234.12428.

Heparin Labeling. Porcine heparin (2 mg) was dissolved in 0.5 mL acetate buffer (100 mM, pH 5.5) to which was added 10 μL of a 0.5 M sodium periodate stock solution. After 5 min in the dark, 10 μL 0.5 M NaOH was added along with 0.5 mL 2% sodium tetraborate to give a final pH of 9.3. To this oxidized heparin solution, 2 mg of NH_2-API in 50 μL DMSO was then added, along with 100 μL of a 1 M sodium cyanoborohydride stock and coupling achieved by incubation at room temperature for 18 h. Labeled heparin was purified on PD-10 columns, and the concentration of eluted, labeled API-heparin determined by the carbazole assay (*13*). The concentration of heparin-bound API was determined by measuring the absorbance of the labeled heparin fractions at 395 nm.

Preparation of API-Palmitic Acid. Ω-Labeled API-palmitic acid (4-amino-2-(hexadecanoic acid)-isoindole-1,3-dione) (**6**) was synthesized as follows: 16-Bromopalmitic acid (1.5 mmol) (Aldrich) in 10 mL ethanol was added to excess (20 mL) 30% ammonia solution and heated in a boiling water bath for 1 h in a 50 mL capped tube with constant mixing. The resultant white precipitate (crude 16-aminopalmitic acid, ammonium salt) was converted to the potassium salt with potassium hydroxide, lyophilized, and 0.4 g fused with 0.5 g 3NPA at 180 °C until the formation of a light brown melt was evident. The cooled melt was washed with boiling water and reduced with 10% sodium dithionite solution as above, yielding a yellow solid (crude (**6**)), which was acidified and washed with water. Crude API-palmitic acid was purified by silica gel chromatography using ethyl acetate and/or recrystallized from dichoromethane and stored desiccated at −20 °C until use. ^1H NMR ($CDCl_3$, 500 MHz): 7.58 (1H, dd, j = 8.5, 7.2 Hz, ArH), 7.35 (1H, d, j = 7.2 Hz, ArH), 7.04 (1H, d, j = 8.5 Hz, ArH), 5.41 (2H, br s, NH_2), 3.92 (1H, t, j = 7.4 Hz, NCHH), 3.85 (1H, t, j = 7.2 Hz, NCHH), 2.56 (2H, t, j = 7.5 Hz, CH_2CO_2H), 1.94−1.79 (4H, m, 2 × CH_2), 1.61−1.42 (22H, m, 11 × CH_2). ^{13}C NMR ($CDCl_3$, 125 MHz): 179.8 (s, C═O), 167.5 (s, C═O), 166.0 (s, C═O), 145.2 (s, C(Ar)), 135.1 (d, CH(Ar)), 128.5 (d, CH(Ar)), 126.9 (s, C(Ar)), 121.0 (d, CH(Ar)), 112.7 (s, C(Ar)), 38.9 (t, CH_2), 37.7 (t, CH_2), 34.1 (t, CH_2), 29.7 (t, 2 × CH_2), 29.5 (t, 2 × CH_2), 29.3 (t, 2 × CH_2), 29.1 (t, 2 × CH_2), 28.8 (t, CH_2), 28.4 (t, CH_2), 26.9 (t, CH_2), 24.8 (t, CH_2). FTIR (thin film, cm^{-1}): 3394 w, 2918 s, 2847 s, 1753 m, 1718 s, 1697 s, 1634 m, 1541 m, 1467 m. LRMS (EI + ve): 416 (M^+, 32%), 175 ($[M - (CH_2)_{14}CO_2H]^+$, 100%). HRMS (EI + ve): M^+, $C_{24}H_{36}N_2O_4$ requires 416.26696. Found 416.26604.

Lipid Metabolism Studies. HepG2 cells grown to 80% confluence in 50 cm^2 flasks in DMEM were labeled with 5 mL of medium containing 240 μM API-palmitic acid for 24 h. Thereafter, labeled medium was collected and lyophilized, and cells washed with PBS, detached by scraping, and pelleted. Both cell pellets and lyophilized medium were lipid extracted by the Folch method (*14*). Lipid extracts were dried under nitrogen, resuspended in 20 μL Folch reagent, and spotted (6 μL) onto C18 silica TLC plates (Aldrich, UK) and lipid species separated using 95% methanol.

Lipase Treatment of Folch Extracts. Dried Folch extracts from cell pellets were resuspended in 300 μL 0.25 M Tris-HCl (pH 7.3) containing 0.4% sodium deoxycholate. Samples were warmed briefly to 80 °C and vortexed to emulsify lipids. Samples (100 μL) were treated with lipase (28 units) (4 μL of a 7 unit/μL stock in water) or water alone for 1 h at 30 °C. These were then lyophilized, Folch extracted, and separated on C18 TLC plates as above.

Chemiluminescent Quantification of Lipid Transport. HepG2 cells grown to 80% confluence in 25 cm^2 flasks in DMEM as above were washed with 2 × 5 mL PBS (pH 7.4) and to each flask was added, 5 mL fatty acid transport medium, with or without 5 μg/mL Filipin complex. After 30 min at 37 °C, 50 μL of an API-palmitic acid solution in DMSO (2.4 mM) was added to flasks (final concentration 24 μM). Cells were incubated for 30 min at 37 °C and washed with cold medium (2 × 5 mL), detached by scraping, pelleted, resuspended in 0.4 mL PBS, and sonicated. Lysates (200 μL) were chemiluminometrically quantified, as for insulin, while total protein was assayed using the BCA assay.

Labeling of DNA with API. Initially, to introduce allylamine dUTP into a DNA probe, which would allow for labeling with API, a 529bp AMPKα2 fragment was amplified by PCR from a pcDNA3 plasmid construct containing the full-length cDNA sequence. The following primers and conditions were used: Forward (F) 5′-tggctgagaagcagaagcac-3′ and reverse (R) 5′-ggcgatccacagctagttcg-3′. PCR mix: Buffer (Qiagen), 0.5 mM $MgCl_2$, 0.1 mM dATP, 0.1 mM dCTP, 0.1 mM dGTP, 0.05 mM dTTP, 0.05 mM allyl-amine dUTP, 5 ng DNA, 0.5 μM primer F, 0.5 μM primer R, 1 unit Taq DNA polymerase (Qiagen). Final volume 20 μL.

Cycling conditions: 94 °C 3 min; (94 °C 30 s, 57 °C 30 s, 72 °C 1 min) 30 cycles; 72 °C 10 min. PCR amplified product (11 × 20 μL samples) either having been synthesized using allylamine dUTP: dTTP in a 1:1 ratio or dUTP alone was pooled and concentrated using Qiaquick PCR purification kit (Qiagen). Samples were eluted with 50 μL 4 mM potassium phosphate

buffer (pH 8.5), to which was added 30 μL 0.3 M bicarbonate buffer (pH 9.1). To this, 20 μL of a NHS-API stock was added (17 mg/mL in a 1:11 pyridine/DMSO solution), the mixture mixed for 3 min and then incubated for a further 40 min at room temperature. Labeled DNA was purified again as above, with an additional 80% ethanol wash step, eluted with a final volume of 150 μL (50 μL 10 mM Tris-HCl (pH 8.5) and 2 $\times$ 50 μL H_2O) and quantified using a Nanodrop microspectrophotometer. Samples were lyophilized and stored at -80 °C until use.

Transfection Studies. API-DNA or unlabeled DNA (1.6 μg) in 100 μL αMEM was added to 4 μL Lipofectamine 2000 (Invitrogen) in 100 μL αMEM. After 20 min, the 200 μL DNA/Lipofectamine complex was added to 90% confluent HepG2 cells in 12 well plates. Control wells were exposed to 200 μL medium alone, medium with labeled or unlabeled DNA without Lipofectamine, and medium with only Lipofectamine. After 5 h, incubation at 37 °C, 1 mL αMEM supplemented with 10% FBS was added to the wells and cells cultured for a further 16 h as above. Thereafter, cells were washed with 2 $\times$ 2 mL PBS, harvested with a cell scraper, pelleted, resuspended in 300 μL PBS, sonicated and 100 μL lysates treated with an equal volume of hydrazine hydrate, and chemiluminometrically quantified as for insulin studies. Total protein was determined by the BCA assay. For fluorescence microscopy, half the volume of DNA/Lipofectamine mixture was added to HepG2 cells on tissue-culture treated Falcon slides. After 4.5 h, cells were washed with 2 $\times$ 0.5 mL PBS and viewed with a Lucifer yellow filter as above.

RESULTS

API derivatives treated with hydrazine and induced by ferricyanide in the presence of the enhancer iodophenol underwent rapid chemiluminescence with maximum light emission occurring within 0.25 s (Figure 3A). Assays were broadly linear (typically from 0.6 nmol to 1 pmol) with a detection limit of 0.3 pmol (Figure 3B). Furthermore, GC-MS analysis indicates that hydrazine treatment of API-spiked cell lysates results in an approximately 40% API to luminol conversion efficiency (Figure 3C,D).

We investigated the use of the API system in cellular binding studies. NHS-API, an amine-reactive *N*-hydroxysuccinimide ester coupled API derivative was synthesized and used to label human recombinant insulin. The resultant API-labeled insulin was used in insulin binding and uptake studies using HepG2 cells according to Calzi et al. (*11*): (a) Insulin receptor-dependent insulin binding was assessed by quantifying cell-bound label relative to unbound, or free, label still present in the binding buffer. (b) Insulin receptor mediated insulin endocytosis was assessed by quantifying internalized label by chemiluminometry, after treatment of cell pellets with hydrazine.

A Scatchard plot (bound ligand/free ligand vs bound ligand) revealed that API-insulin produced a typical curvilinear plot (Figure 4A), previously shown to be indicative of insulin binding using ^{125}I-labeled insulin (*15*). Endocytosis studies showed that insulin receptor mediated insulin uptake, for cells exposed to 10 μM API-insulin, was 24-fold greater than that for cells exposed to the same concentration of fluorescein-labeled insulin, which was prepared from commercially available NHS-fluorescein in an identical manner to that of API-insulin (Figure 4B).

We have also used the API system in dual fluorescence and chemiluminescence mitochondrial studies. API was coupled to triphenylphosphonium bromide (TPP), a well-established mitochondrial probe, which accumulates in mitochondria in a membrane potential-proportional manner (*16*). Cells stained with TPP-API and viewed by fluorescence microscopy exhibited

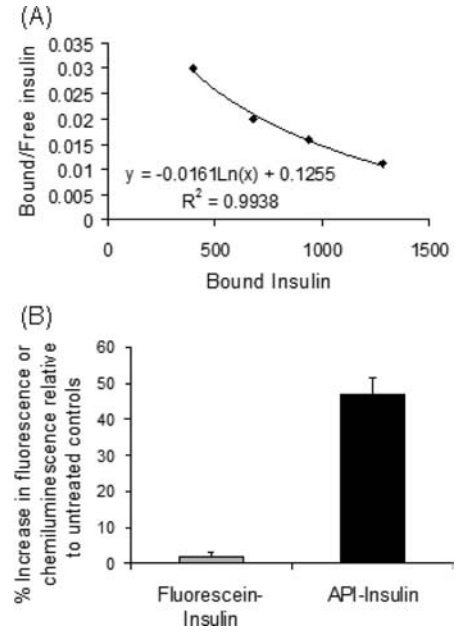

Figure 4. (A) Scatchard plot of cell bound, API-labeled insulin, normalized for total cellular protein (mg/mL), over unbound labeled insulin remaining in the binding buffer vs cell-bound, labeled insulin. (B) Comparison of API and fluorescein-labeled insulin uptake by HepG2 cells. HepG2 cells were exposed to 10 μM API or fluorescein-labeled insulin for 19 h and then for 1 h at 37 °C to induce insulin uptake. Fluorescein fluorescence (gray bar) and API-luminescence (black bar) in 100 μL cell lysate were determined and expressed as a % increase relative to untreated control lysates. Samples were normalized for total protein as above, $n = 3$, $\pm$ SE. Assays were carried out in triplicate.

green, brightly fluorescent foci (white arrow) indicating the accumulation of this compound within mitochondria (Figure 5A). In the presence of a mitochondrial respiration inhibitor cocktail, focal staining was abolished (Figure 5B), clearly indicating that TPP-API accumulated within mitochondria in a membrane potential-dependent manner. Cells stained with the mitochondrial dye JC-1 exhibited identical focal staining, which was significantly diminished, although not completely abolished by incubation of cells with the same mitochondrial respiration inhibitor cocktail (Figure 5C,D).

To quantify TPP-API mitochondrial accumulation, HepG2 cells were labeled with 65 μM TPP-API with or without mitochondrial respiration inhibitor cocktail for 45 min. Cells were then homogenized, the mitochondrial fraction obtained by centrifugation (*17*), and mitochondria assessed for internalized label by chemiluminometry, after treatment with hydrazine. Mitochondria from cells exposed to inhibitor cocktail exhibited a 25% reduction in TPP-API chemiluminescence in comparison to cells exposed to TPP-API alone (Figure 5E).

To illustrate the use of the API-system in polysaccharide labeling, an API molecule containing a terminal amine group was synthesized and coupled to heparin by periodate oxidation and reductive amination. API-labeled heparin was used in cellular uptake studies according to Dudás et al. (*18*). HepG2 cells incubated with 5 μg API-heparin for 18 h and viewed by fluorescence microscopy exhibited fluorescent cytosolic and nuclear staining, indicating cellular uptake of heparin in a manner similar to that observed using biotinylated heparin and fluorescein-labeled streptavidin detection (*18*) (Figure 6A,B). Heparin uptake could also be quantified chemiluminometrically after hydrazine treatment of cell lysates, as above (Figure 6C).

We also investigated the use of the API system in lipid studies; an API-labeled long chain fatty acid, API-palmitic acid, was synthesized and used to investigate cellular uptake and lipid

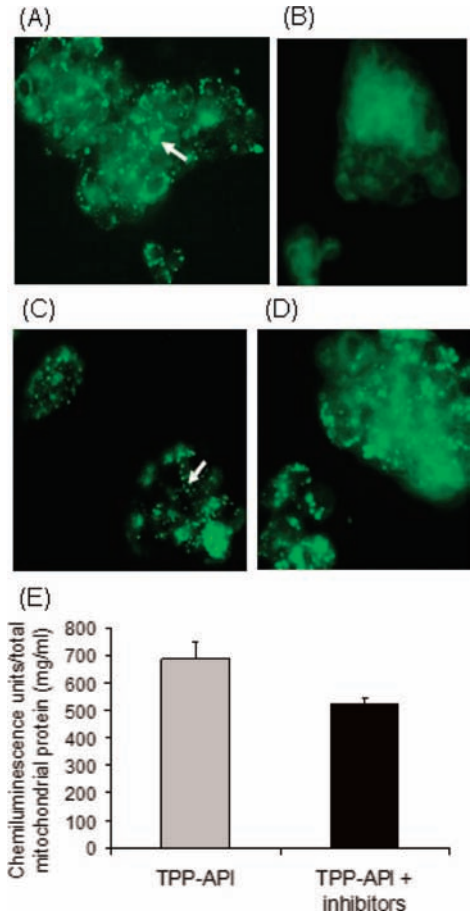

Figure 5. HepG2 cells on Falcon tissue culture-treated slides were incubated with 65 μM API-TPP for 45 min without (A) or with (B) respiration-inhibitor cocktail (13 μg/mL Oligomycin, 10 μg/mL Antimycin A, 5 μM Rotenone), washed with PBS and viewed by fluorescence microscopy (Lucifer yellow filter, 40× magnification). White arrow indicates fluorescent foci. (C) Fluorescence microscopy for HepG2 cells exposed to the mitochondrial probe JC-1. Cells cultured on tissue culture slides in 0.5 mL DMEM were stained with 6.5 μM JC-1 for 45 min and viewed by fluorescence microscopy using a PE filter at 40× magnification. (D) JC-1 stained HepG2 cells in the presence of inhibitor cocktail, as above. (E) Cells exposed to 65 μM API-labeled TPP for 45 min without (gray bar) or with respiration-inhibitor cocktail (black bar) were washed with PBS, harvested, and cell-mitochondrial fractions obtained as previously described (*17*). Mitochondrial pellets were sonicated in 200 μL water and 50 μL lysates, hydrazine treated, and assayed as for API-insulin. Chemiluminescence values are per total mitochondrial protein (mg/mL), $n = 3$, $\pm$ SE. Assays performed in triplicate.

metabolism. HepG2 cells incubated with 24 μM API-palmitic acid for 23 h and viewed by fluorescence microscopy exhibited both membrane staining and discrete cytosolic accumulation (Figure 7A). Total lipid extracts from cells incubated with API-palmitate and separated using C18/silica thin layer chromatography contained fluorescent API-labeled lipid species with increased hydrophobicity. This indicated the incorporation of API-palmitic acid into more complex lipid species, a proportion of which was exported into culture medium (Figure 7B). In addition, a significant proportion of these fluorescent API-labeled lipid species was degraded by lipase treatment, indicating the incorporation of API-palmitic acid into acyl-glycerides (Figure 7C). To quantify lipid transport using the API chemiluminescence system, HepG2 cells were incubated with 24 μM API-palmitate for 30 min with or without filipin complex, an inhibitor of caveolin-dependent fatty acid transport (*19*). Cell pellets were assessed for internalized fatty acid by chemiluminometry, following sonication, as above. HepG2 transport of API-palmitic

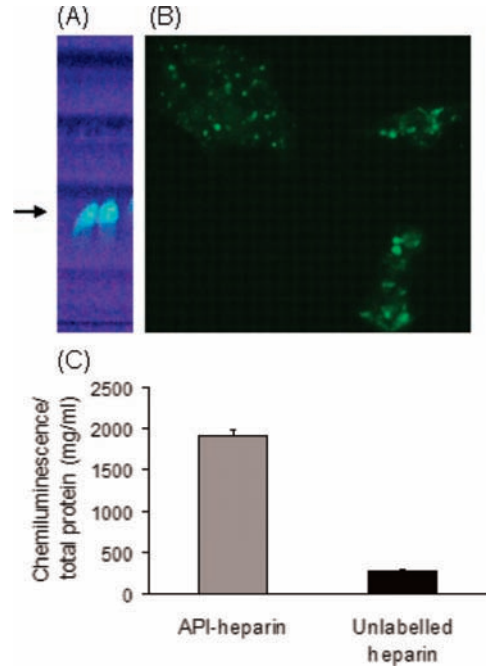

Figure 6. (A) API-heparin on a 4−20% TBE polyacrylamide gel, visualized using a transilluminator (arrow). (B) Fluorescence microscopy for HepG2 cells exposed to 5 μg API-labeled heparin for 18 h, indicating discrete cytosolic and nuclear staining (Lucifer yellow filter, 40× magnification). (C) API-heparin nuclear transport. Cells were exposed to 10 μg API-heparin (gray bar) or unlabeled heparin (black bar) for 18 h. Thereafter, cells were washed with PBS, lysed with 1% NP40, and nuclear pellets obtained by centrifugation at 900 *g*. Pellets were sonicated in 200 μL PBS, and 100 μL samples treated with hydrazine and assayed for chemiluminescence as for insulin studies. Samples are normalized for total protein (mg/mL), $n = 3$, $\pm$ SD. Assays performed in duplicate.

acid was reduced (20%) in the presence of filipin (Figure 7D), indicating that API-palmitic acid transport was partly caveolin-dependent. This is in agreement with a previous study which utilized NBD-labeled stearic acid (*19*).

To test the applicability of the API system as a nucleic acid label, a 529 base pair DNA fragment was amplified from a plasmid containing the AMP-activated kinase alpha subunit (AMPKα2) by PCR using allylamine-dUTP, a modified base containing an allylamine functional group. This allowed for the incorporation of terminal amine groups within the PCR product. The resultant allylamine PCR product was then labeled with the amine reactive NHS-API, yielding a fluorescent API-DNA conjugate. The API-labeled DNA was then used for transfection studies using HepG2 cells. HepG2 cells were transfected with 0.8 μg labeled DNA using Lipofectamine 2000 for 4.5 h and viewed by fluorescence microscopy. Discrete regions of fluorescent DNA/lipofectamine complex were visibly incorporated into membranes (Figure 8A). In addition, fluorescent DNA/lipofectamine complexes were also evident on the surfaces of cells and on the slide surface (Figure 8A).

To quantitatively assess DNA uptake using lipofectamine transfection, cells were transfected with 1.6 μg of labeled DNA or 1.6 μg of unlabeled control DNA with or without lipofectamine for 16 h. Cells were then sonicated and assayed for chemiluminescence after hydrazine treatment, as previously described. Cells exposed to API-DNA exhibited significant levels of chemiluminescence while all controls displayed only background levels (Figure 8B).

DISCUSSION

In this study, we investigated the use of the luminol precursor, 3-aminophthalimide in direct chemiluminescence cellular bio-

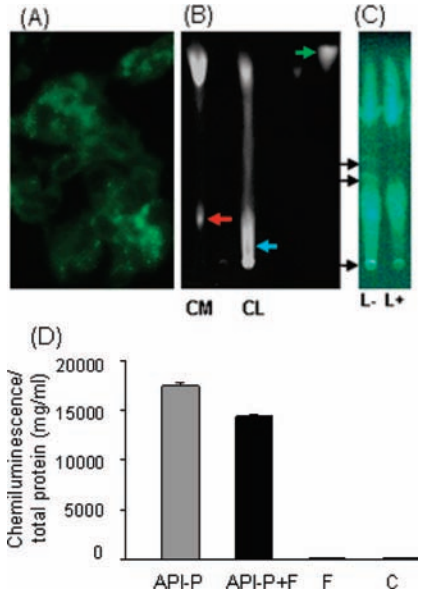

Figure 7. (A) HepG2 cells exposed to 24 μM API-palmitic acid (Lucifer yellow filter, 40× magnification). (B) Lipid profiles of HepG2 cells exposed to 240 μM API-palmitic acid. Total lipid extracts from culture medium (CM) and lysates (CL) were separated on C18/silica TLC plates. Mobility is inversely proportional to hydrophobicity. (green →) API-palmitic acid reference, (blue →) fluorescent API-lipid species in cell lysates, and (red →) lipid exports into cell culture medium. (C) Untreated (L−) or lipase-treated (L+) extracts. Arrows indicate fluorescent acyl-glyceride lipid species susceptible to lipase degradation. (D) Effect of filipin on API-palmitate transport in HepG2 cells exposed to 24 μM API-palmitic acid, without (API-P, gray bar) or with 5 μg/mL filipin complex (API-P+F, black bar). Chemiluminescence was also determined for cells exposed to fillipin (F) or medium (C) alone. Normalized for total protein (mg/mL), $n = 3$, ± SD. Assays performed in triplicate.

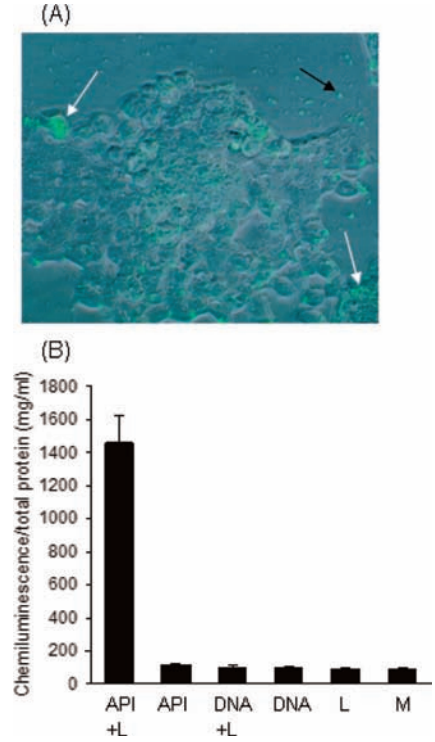

Figure 8. (A) HepG2 cells transfected with 0.8 μg API-labeled DNA using lipofectamine 2000 for 5 h and viewed by fluorescence microscopy (Lucifer yellow filter, 20× magnification). Fluorescent DNA/lipofectamine complexes were incorporated into membranes (white arrows), and fluorescent DNA/lipofectamine complexes were evident on the surfaces of both cells and slide (black arrow). (B) API-DNA uptake for cells exposed to αMEM with 1.6 μg API-DNA +Lipofectamine (API + L), API-DNA alone (API), 1.6 μg unlabeled DNA +Lipofectamine (DNA + L), unlabeled DNA (DNA), Lipofectamine alone (L), and medium alone (M) for 16 h. Cell lysates (100 μL) were treated with hydrazine and assayed as above. Normalized for total protein (mg/mL), $n = 4$, ± SD. Assays performed in triplicate.

assays. We established that API assays are rapid, sensitive, and broadly linear; and the ease of synthesis of API derivatives, with a variety of functional groups, makes this molecule applicable for a range of cellular applications. We clearly demonstrate its utility in (a) receptor-dependent binding and transport of API-labeled insulin, (b) the qualitative (fluorescence) and quantitative (chemiluminescence) assessment of mitochondrial function by API-TPP, (c) polysaccharide (heparin) transport, (d) lipid transport and metabolism using API-palmitate, and (e) assessment of DNA transfection efficiency using API-labeled DNA.

The API assay system would therefore serve as a sensitive and economical substitute for a variety of radio-isotope-based methodologies and, importantly, offers the advantage of fluorescence monitoring of probe or substrate entry and localization within live cells, prior to chemiluminescent quantification. Although concern may arise over the use of hydrazine hydrate as a developing agent, due to its toxicity and corrosive properties, the use of appropriate protective clothing and eyewear and the carrying out of assays in well-ventilated laboratories and fume hoods, when developing samples, significantly reduces the risk of harmful exposure. Furthermore, unlike radioactive waste, which is hazardous and burdensome to dispose of, dilute hydrazine solutions and hydrazine-contaminated waste are effectively neutralized by hypochlorite, allowing for safe and rapid disposal.

Additional advantages of this label are its neutrality and relatively small size in comparison to other bulky and/or charged fluorophores. The latter advantages making API particularly useful for metabolic studies, as illustrated using API-palmitic acid, which was clearly incorporated into more complex lipid species by HepG2 cells, a proportion of which was actively exported from the cell. The neutrality and smaller size of API in comparison to fluorescein are also the likely reasons for the observed increase in cellular transport of API-insulin in comparison to the fluorescein-labeled peptide. Although fluorescein−insulin has been previously used in insulin binding studies (*20*, *21*), we found that not only did labeling insulin with NHS-API yield a higher specific activity than commercially available NHS-fluorescein, but Scatchard analysis for fluorescein−insulin yielded an atypical negative cooperativity plot (data not shown). This suggested that fluorescein labeling altered the affinity of insulin for its receptor. Therefore, a combination of steric hindrance, charge, and lower specific activity all likely contributed to reduced receptor binding and transport for fluorescein−insulin in comparison API-insulin.

Another potential application for the API system lies in the finding that aminophthalimides display solvatofluorochromism (i.e., altered emission wavelength in response to polarity changes) (*22*). Although not explored in this study, it is envisaged that API-based investigations could yield valuable information regarding the total quantity of labels within cells (determined chemiluminometrically) and its distribution within distinct microenvironments (e.g., lipid bodies c/o cytosol), determined fluorometrically.

Finally, although we have focused on cellular-based bioassays in this study, the simplicity of the API system would allow for its potential utility in a variety of non-cell-based bioassays such as high-throughput competitive binding studies, kinase assays, and enzyme assays utilizing API-labeled substrates. Indeed,

preliminary studies have found that both gold nanoparticles and beta-eliminated kinase substrates could be labeled with terminal thiol-containing API derivatives, which further highlights the versatility and broad applicability of this labeling system.

ACKNOWLEDGMENT

We thank UCL Business PLC for providing proof of concept funding for this research. This work is funded by a private company and the author, L. H. Damelin, declares that he has a financial conflict of interest.

Compared to Purpurinimides, the Pyropheophorbide Containing an Iodobenzyl Group Showed Enhanced PDT Efficacy and Tumor Imaging (^{124}I-PET) Ability

Suresh K. Pandey,[†] Munawwar Sajjad,*[,§] Yihui Chen,[†] Anupam Pandey,[†,||] Joseph R. Missert,[†] Carrie Batt,[†] Rutao Yao,[§] Hani A. Nabi,[§] Allan R. Oseroff,[‡] and Ravindra K. Pandey*[,†]

PDT Center, Cell Stress Biology and Department of Dermatology, Roswell Park Cancer Institute, Buffalo, New York 14263, and Department of Nuclear Medicine, State University of New York, Buffalo, New York 14214. Received August 25, 2008; Revised Manuscript Received December 15, 2008

Two positional isomers of purpurinimide, 3-[1′-(3-iodobenzyloxyethyl)] purpurin-18-*N*-hexylimide methyl ester **4**, in which the iodobenzyl group is present at the top half of the molecule (position-3), and a 3-(1′-hexyloxyethy)purpurin-18-*N*-(3-iodo-benzylimide)] methyl ester **5**, where the iodobenzyl group is introduced at the bottom half (N-substitued cyclicimide) of the molecule, were derived from chlorophyll-*a*. The tumor uptake and phototherapeutic abilities of these isomers were compared with the pyropheophorbide analogue **1** (lead compound). These compounds were then converted into the corresponding ^{124}I-labeled PET imaging agents with specific activity >1 Ci/μmol. Among the positional isomers **4** and **5**, purpurinimide **5** showed enhanced imaging and therapeutic potential. However, the lead compound **1** derived from pyropheophorbide-*a* exhibited the best PET imaging and PDT efficacy. For investigating the overall lipophilicity of the molecule, the 3-*O*-hexyl ether group presnt at position-3 of purpurinimide **5** was replaced with a methyl ether substituent, and the resulting product **10** showed improved tumor uptake, but due to its significantly higher uptake in the liver, spleen, and other organs, a poor tumor contrast in whole-body tumor imaging was observed.

INTRODUCTION

Positron emission tomography (PET) has wide appeal for research at the drug development stage as it allows studying the drug distribution noninvasively (*1*). Dedicated animal PET systems whose resolution could reach near 1 mm have intensified this field by enabling drug studies with murine disease models. In recent years, ^{18}F-fluorodeoxyglucose (^{18}F-FDG) has been the primary PET tracer. It is being used in the evaluation of several neoplasms, both before and after therapy, as well as the planning of the radiotherapy in various cancers. Its use in the assessment of cancer after therapy, including restaging tumors and monitoring tumor response has been of particular interest for oncologists. However, ^{18}F-FDG suffers from pitfalls in cases such as where tumors are not metabolically active enough. Additionally, a short half-life of ^{18}F-isotope (110 min) limits its use in studies involving antibodies and photosensitizers (PS) related to porphyrins for use in photodynamic therapy (PDT), which take considerably longer time to accumulate in a tumor in high concentrations (*2*). In this respect, ^{124}I is a better choice due to its half-life of 4.2 days (*3, 4*). The labeling technique for ^{124}I-nuclide is now well established, and this approach is continuously being followed to label a variety of biologically active molecules (*5*−*12*). In the past few years, various porphyrin-based photosensitizers have been labeled/chelated with ^{111}In, ^{113}Sn, and ^{99}mTc radionuclide for the purpose of scintigraphy (SPECT) (*13*−*21*). The metalation of the porphyrin core, however, alters the physicochemical characteristics of the molecule. The clinically effective PS have also been labeled with ^{131}I, ^{14}C, and ^{3}H mainly for the purpose of understanding their pharmacokinetic and phamacodynamic characteristics (*22*−*26*). There are a few reports in the field of PDT where various F-18 based radiotracers such as ^{18}F-FDG (*27*−*29*), ^{18}F-FHBG{9-(4-^{18}F-fluoro-3-hydroxymethyl-butyl)guanine} (*30*), ^{18}F-FLT (3′-deoxy-3′-18F-fluorothymidine) (*31*), and ^{99}mTc-Annexin V (*32*) have been used to monitor cellular events during and post-PDT in vivo.

One of the main reasons for using the porphyrin-based compounds in phototherapy is their ability to retain in tumor (*33*−*35*). The tumor localizing ability of certain porphyrins has also been explored in developing multifunctional agents, where these compounds were used as vehicles to deliver the desired imaging moieties (fluorescence, MRI, and PET) to tumors (*36*−*41*).

For quite some time, one of the objectives of our laboratory has been to develop photosensitizers with long absorption wavelengths >700. Irradiation of tumors with light in this range should allow deeper tissue penetration, which may help in treating the large and deeply seated tumors. To achieve our goal, we modified the in vivo unstable purpurin-18 and bacteriopurpurin systems, and synthesized a series of tumor-avid *N*- and *O*-alkyl- or the corresponding trifluoromethylbenzyl substituted purpurinimides (700 nm) and bacteriopurpurinimides (800 nm) with variable lipophilicity (*42, 43*). Some of the synthetic analogues showed promising in vivo activity. Interestingly, among the compounds with similar lipophilicity, the position of the substituents at various peripheral positions of the tetrapyrrolic system showed a significant difference in long-term tumor response.

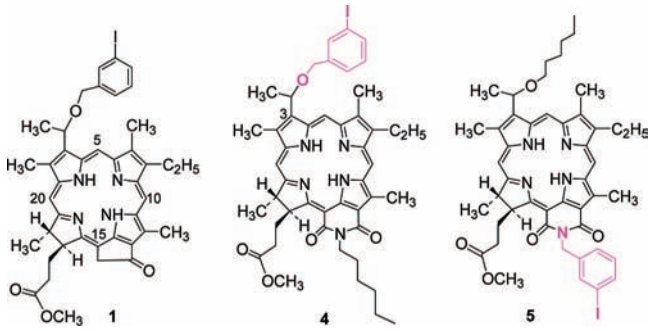

Figure 1. Structures of 3-(1′-*m*-iodobenzyloxy) pyropheophorbide **1** and the iodobenzyl purpurinimides **4** and **5** (isomers).

Herein, we report the synthesis of the iodobenzyl substituted purpurinimides **4** and **5** (positional isomers; Figure 1) and their significant difference in PDT efficacy. The comparative biodistribution properties of the corresponding ^{124}I-analogues as well as their tumor imaging (PET) abilities are also discussed.

EXPERIMENTAL PROCEEDURES

Chemistry. All chemicals were of reagent grade and used as such. Solvents were dried using standard methods. Reactions were carried out under nitrogen atmosphere and were monitored by precoated (0.20 mm) silica TLC plastic sheet (20 × 20 cm) strips (POLYGRAM SIL N-HR) and/or UV−visible spectroscopy. Silica gel 60 (70−230 mesh, Merck) was used for column chromatography. Melting points were determined on a Fisher−Johns melting point apparatus. UV−visible spectra were recorded on a Varian (Cary-50 Bio) spectrophotometer. ^{1}H NMR spectra were recorded on a Brucker AMX 400 MHz NMR spectrometer at 303 K. Proton chemical shifts (δ) are reported in parts per million (ppm) relative to $CDCl_3$ (7.26 ppm), pyridine-d_5 (7.22 ppm, most downfield), or TMS (0.00 ppm). Coupling constants (J) are reported in Hertz (Hz), and s, d, t, q, p, m, and br refer to singlet, doublet, triplet, quartet, pentet, multiplet, and broad, respectively. HRMS data were obtained from the Mass Spectroscopy facility of Michigan State University. Analytical HPLC was used to assess the purity of compounds. A Waters (Milford, MA) system including a Waters 600 Controller, a Delta 600 pump, and a 996 Photodiode Array Detector was used. A reverse phase, Symmetry C18, 5 μm, 4.6 × 150 mm column (Waters, Made in Ireland) was used under an isocratic setting of MeOH/H_2O for final compounds (**1**, **4**, **5**, and the corresponding trimethyl stannyl analogues). The solvent flow rate was kept constant at 1.00 mL/min, and the detector was set at 254, 410, 535, and 660 nm (for pyropheophorbides-*a* **1**, and its trimethyl stannyl derivative) and 254, 415, 545, and 700 nm (for purpurininimides **4**, **5**, and their trimethyl stannyl derivatives). All final products were found to be >95% pure, and their retention time is reported in the characterization section. Reactions were first carried out for nonradioactive iodine and analyzed in the above HPLC system. However, in the case of final I-124 radiolabeling HPLC data obtained from the above system were transferred to another system comprising a Chrom Tech Iso-2000 pump, Hitachi L-4000 UV detector, and a radiation detector. These detectors are connected to a computer with HP Chemstation software via an HP 35900E interface. A Bioscan system 200 imaging scanner was used for thin layer chromatography of the radiolabeled compounds.

Synthesis of 3-{1′-(3-Iodobenzyloxy)ethyl}pyropheophorbide-*a* Methyl Ester (1). It was synthesized by following our previously reported procedure (*40*). Yield: 77%. MP = 112−114 °C; analytical RP HPLC (95/5: MeOH/H_2O): t_R = 20.97min, >96%. UV−vis (MeOH): 662 (4.75 × 10^4), 536 (1.08 x10^4), 505 (1.18 × 10^4), 410 (1.45 × 10^5). ^{1}H NMR ($CDCl_3$; 400 MHz): δ 9.76, 9.55 and 8.56 (all s, 1H, meso-H); 7.76(s, 1H, ArH); 7.64 (d, J = 6.8, 1H, ArH); 7.30 (d, J = 8.0, 1H, ArH); 7.05 (t, J = 8.2, 1H, ArH); 6.00 (q, J = 6.9, 1H, 3^1-H); 5.28 (d, J = 19.8, 1H, 13^2-CH_2); 5.13 (d, J = 19.8, 1H, 13^2-CH_2); 4.70 (d, J = 12.0, 1H, OCH_2Ar); 4.56 (dd, J = 3.2,11.6, 1H, OCH_2Ar); 4.48−4.53 (m, 1H, 18-H); 4.30−4.33 (m, 1H, 17-H); 3.72 (q, J = 8.0, 2H, 8-C$\underline{H}_2$CH$_3$); 3.69, 3.61, 3.38 and 3.21 (all s, all 3H, for 17^3-CO_2CH_3 and 3 × ring CH_3); 2.66−2.74, 2.52−2.61 and 2.23−2.37 (m, 4H, 17^1-H and 17^2-H); 2.18 (dd, J = 2.8, 6.4, 3H, 3^1-CH_3); 1.83 (d, J = 8.0, 3H, 18-CH_3); 1.72 (t, J = 7.6, 3H, 8-CH$_2$C$\underline{H}_3$); 0.41 (brs, 1H, NH); −1.71 (brs, 1H, NH). HRMS for $C_{41}H_{43}N_4O_4I$: 783.2329 (calculated, M + 1); found, 783.2407. Anal. Calcd. for $C_{41}H_{43}N_4O_4I$: C, 62.91; H, 5.54; N, 7.16; I, 16.21. Found: C, 62.60; H, 5.59; N, 7.13; I16.45.

Synthesis of 3-{1′-(3-Iodobenzyloxy)ethyl}purpurin-18-*N*-hexylimide Methyl Ester (4). 30% Hydrobromic acid (HBr) in acetic acid (2 mL) was added to purpurin-18-*N*-hexylimide methyl ester (100 mg, 0.15mmol) (*23*), and the reaction was stirred at room temperature for 2 h. After evaporating the acids under high vacuum (0.1 mmHg), excess of 3-iodobenzyl alcohol (0.45 mL, 20-fold excess), dry dichloromethane (5 mL), and anhydrous potassium carbonate (40 mg) were added. The reaction mixture was stirred under nitrogen atmosphere for 45 min. It was then diluted with dichloromethane (200 mL), washed with aqueous sodium bicarbonate solution (100 mL), and then with water (2 × 200 mL). The dichloromethane layer was dried over anhydrous sodium sulfate, concentrated, and treated with diazomethane. Evaporation of the solvent gave a syrupy residue, which was chromatographed over a silica column using (1:4) ethyl acetate/hexane as eluant to remove excess 3-iodobenzylalcohol, followed by (1:1) ethyl acetate/hexane to yield 110 mg (81%) of the desired compound **4**, which is sticky in nature. Analytical HPLC (Symmetry C18; 99/1: MeOH/H_2O): t_R = 38.71 min, >96%. UV−vis (MeOH): 701(4.31 × 10^4), 545 (2.15 × 10^4), 508 (7.32 × 10^3), 414 (1.31 × 10^5). ^{1}H NMR ($CDCl_3$; 400 MHz): δ 9.72 (s, 1H, meso-H); 9.66 (s, 1H, meso-H); 8.58 (s, 1H, meso-H); 7.75 (s, 1H, ArH); 7.64 (d, J = 9.2, 1H, ArH); 7.29 (d, J = 7.2, 1H, ArH); 7.06 (dt, J = 2.4, 7.4, 1H, ArH); 5.88 (q, J = 6.2, 1H, 3^1-H); 5.41 (d, J = 8.8, 1H, 17-H); 4.68 (dd, J = 2.6,12.6, 1H, OCH_2Ar); 4.55 (dd, J = 3.2,12.0, 1H, OCH_2Ar); 4.45 (t, J = 6.8, 2H, NC$\underline{H}_2$(CH$_2$)$_4$CH$_3$); 4.37 (q, J = 7.2, 1H, 18-H); 3.84 (s, 3H, 12-CH_3); 3.68 (q, J = 7.6, 2H, 8-C$\underline{H}_2$CH$_3$); 3.56 (s, 3H, 17^2-CO_2CH_3); 3.31 (split s, 3H, 2-CH_3); 3.14 (s, 3H, 7-CH_3); 2.63−2.72 (m, 1H, 17^1-H); 2.38−2.48 (m, 1H, 17^2-H); 2.26−2.36 (m, 1H, 17^1-H); 2.12 (dd, J = 2.2, 6.6, 3H, 3^1-CH_3); 1.95−2.05 (m, 3H, 17^2-H, and NCH$_2$C$\underline{H}_2$(CH$_2$)$_3$CH$_3$); 1.77 (d, J = 7.2, 3H, 18-CH_3); 1.68 (t, J = 7.6, 3H, 8-CH$_2$C$\underline{H}_3$); 1.56−1.61 (m, 2H, N(CH$_2$)$_2$C$\underline{H}_2$(CH$_2$)$_2$-CH$_3$); 1.38−1.50 (m, 4H, N(CH$_2$)$_3$(C$\underline{H}_2$)$_2$CH$_3$); 0.95 (t, J = 7.0, 3H, N(CH$_2$)$_5$C$\underline{H}_3$); −0.14 (brs, 1H, NH); −0.19 (brs, 1H, NH). HRMS for $C_{47}H_{54}N_5O_5I$: 896.3171 (calculated, M + 1); found, 896.3241.

Synthesis of 3-{1′-(Hexyloxy)ethyl}purpurin-18-*N*-(3-iodo)-benzylimide Methyl Ester (5). Hydrobromic acid (HBr) (30%) in acetic acid (2 mL) was added to purpurin-18-*N*-(3-iodo)benzylimide methyl ester (100 mg, 0.125 mmol) (*23*), and the reaction was stirred at room temperature for 2 h. After evaporating the acids under high vacuum (0.1 mmHg), an excess of *n*-hexanol (0.5 mL, 30-fold excess), dry dichloromethane (5 mL), and anhydrous potassium carbonate (25 mg) were added to the residue. The reaction mixture was stirred under nitrogen atmosphere for 45 min. It was then diluted with dichloromethane (200 mL), washed with aqueous sodium bicarbonate solution (100 mL), and then with water (2 × 200 mL). The dichloromethane layer was dried over anhydrous sodium sulfate,

concentrated, and treated with diazomethane. Evaporation of the solvent gave a syrupy residue, which was chromatographed over a silica column using 1% acetone in dichloromethane as eluant to yield 95 mg (85%) of the desired compound **5**, which is sticky in nature. Analytical HPLC (Symmetry C18; 99/1: MeOH/H_2O): t_R = 48.97 min, >96%. UV−vis (MeOH): 700 (4.31×10^4), 545 (2.05×10^4), 508 (7.76×10^3), 414 (1.29×10^5). ^{1}H NMR ($CDCl_3$; 400 MHz): δ 9.75 (splits, 1H, meso-H); 9.62 (s, 1H, meso-H); 8.53 (s, 1H, meso-H); 8.09 (s, 1H, ArH); 7.70 (d, J = 7.6, 1H, ArH); 7.66 (d, J = 8.0, 1H, ArH); 7.60 (d, J = 7.6, 1H, ArH); 7.32 (d, J = 8.4, 1H, ArH); 7.10 (t, J = 7.8, 1H, ArH); 5.77 (q, J = 6.8, 1H, 3^1-H); 5.61 (s, 2H, NC$\underline{H}_2$Ar); 5.37(d, J = 8.4, 1H, 17-H); 4.35 (q, J = 7.2, 1H, 18-H); 3.81 (s, 3H, 12-CH_3); 3.65 (m, 4H, 8-C$\underline{H}_2CH_3$, OC$\underline{H}_2(CH_2)_4CH_3$); 3.56 (s, 3H, 17^2-$CO_2CH_3$); 3.30 (s, 3H, 2-$CH_3$); 3.18 (s, 3H, 7-$CH_3$); 2.62−2.72 (m, 3H, OCH_2-C$\underline{H}_2(CH_2)_3CH_3$ and 17^1-H); 2.30−2.45 (m, 2H, 17^2-H and 17^1-H); 2.05 (dd, J = 2.4, 6.8, 3H, 3^1-CH_3); 1.95−2.02 (m, 1H, 17^2-H); 1.70−1.80 (m, 5H, 18-CH_3 and $O(CH_2)_2C\underline{H}_2$-$(CH_2)_2CH_3$); 1.67 (t, J = 8.0, 3H, 8-$CH_2C\underline{H}_3$); 1.23 (m, 4H, $O(CH_2)_3(C\underline{H}_2)_2CH_3$); 0.78 (m, 3H, $O(CH_2)_5C\underline{H}_3$); 0.04 (brs, 1H, NH); −0.07 (brs, 1H, NH). HRMS for $C_{47}H_{54}N_5O_5I$: 896.3171 (calculated, M + 1); found, 896.3241.

Synthesis of 3-{1′-(3-Trimethylstannylbenzyloxy)ethyl}purpurin-18-*N*-hexylimide Methyl Ester (6). To a solution of 3-{1′-(3-iodobenzyloxy)ethyl}purpurin-18-*N*-hexylimide methyl ester (**4**) (15 mg, 0.017 mmol) in dry THF (10 mL) were added hexamethylditin (15 μL, 0.072 mmol) and bis-(triphenylphosphine)palladium (II) dichloride (5 mg), and the reaction mixture was stirred at 60 °C for 2 h. The reaction mixture was rotavapoed to dryness, and the crude product was purified over a silica gel column using CH_2Cl_2 as eluant to yield 12 mg (77%) of title compound **6**. Analytical HPLC (Symmetry C18; 99/1: MeOH/H_2O): t_R = 48.19 min, >95%. ^{1}H NMR ($CDCl_3$; 400 MHz): δ 9.73 (s, 1H, meso-H); 9.66 (s, 1H, meso-H); 8.56 (s, 1H, meso-H); 7.42 (m, 2H, ArH); 7.34 (m, 2H, ArH); 5.90 (m, 1H, 3^1-H); 5.41 (dd, J = 2.6, 9.0, 1H, 17-H); 4.76 (dd, J = 4.4,11.6, 1H, OCH_2Ar); 4.55 (dd, J = 1.2,12.0, 1H, OCH_2Ar); 4.45(m, 2H, NC$\underline{H}_2(CH_2)_4CH_3$); 4.36 (q, J = 7.3, 1H, 18-H); 3.85 (s, 3H, 12-CH_3); 3.68 (q, J = 7.6, 2H, 8-C$\underline{H}_2CH_3$); 3.55 (s, 3H, 17^2-CO_2CH_3); 3.31 (split s, 3H, 2-CH_3); 3.11 (s, 3H, 7-CH_3); 2.63−2.72 (m, 1H, 17^1-H); 2.38−2.48 (m, 1H, 17^2-H); 2.26−2.36 (m, 1H, 17^1-H); 2.12 (dd, J = 2.4, 6.8, 3H, 3^1-CH_3); 1.95−2.05 (m, 3H, 17^2-H and $NCH_2C\underline{H}_2(CH_2)_3CH_3$); 1.77 (d, J = 7.2, 3H, 18-CH_3); 1.68(t, J = 7.6, 3H, 8-$CH_2C\underline{H}_3$); 1.61(m, 2H, $N(CH_2)_2C\underline{H}_2(CH_2)_2CH_3$);1.38−1.50 (m, 4H, $N(CH_2)_3(C\underline{H}_2)_2CH_3$); 0.95 (t, J = 7.2, 3H, $N(CH_2)_5C\underline{H}_3$); 0.18 (s, 9H, $Sn(CH_3)_3$); −0.09 (brs, 1H, NH); −0.16 (brs, 1H, NH).

Synthesis of 3-{1′-(Hexyloxy)ethyl}purpurin-18-*N*-(3-trimethylstannyl)benzylimide Methyl Ester (7). It was synthesized following the procedure described above for **6** from the respective compound 3-{1′-(hexyloxy)ethyl}purpurin-18-*N*-(3-iodo)benzylimide methyl ester (**5**). Yield: 75%. Analytical HPLC (Symmetry C18; 99/1: MeOH/H_2O): t_R = 53.13 min, >95%. ^{1}H NMR($CDCl_3$; 400 MHz): δ 9.75 (splits, 1H, meso-H); 9.64 (s, 1H, meso-H); 8.53 (s, 1H, meso-H); 7.89 (s, 1H, ArH); 7.66 (d, J = 8.0, 1H, ArH); 7.39 (d, J = 7.2, 1H, ArH); 7.32 (m, H, ArH); 5.78 (q, J = 6.6, 1H, 3^1-H); 5.68 (q, J = 13.8, 2H, NCH_2Ar); 5.38 (d, J = 8.0, 1H, 17-H); 4.35 (m, 1H, 18-H); 3.83 (s, 3H, 12-CH_3); 3.57−3.68 (m, 4H, 8-C$\underline{H}_2CH_3$, OC$\underline{H}_2(CH_2)_4CH_3$); 3.54 (s, 3H, 17^2-$CO_2CH_3$); 3.30 (s, 3H, 2-$CH_3$); 3.18 (s, 3H, 7-$CH_3$); 2.62−2.72 (m, 3H, $OCH_2C\underline{H}_2$-$(CH_2)_3CH_3$ and 17^1-H); 2.30−2.45 (m, 2H, 17^2-H and 17^1-H); 2.05 (dd, J = 2.6, 6.6, 3H, 3^1-CH_3); 1.95−2.02 (m, 1H, 17^2-H); 1.73 (d,J=7.6,3H,18-CH_3); 1.67 (t, J = 7.6, 3H, 8-$CH_2C\underline{H}_3$); 1.25 (m, 6H, $O(CH_2)_2(C\underline{H}_2)_3CH_3$); 0.78 (m, 3H, $O(CH_2)_5C\underline{H}_3$); 0.27 (s, 9H, $Sn(CH_3)_3$); −0.01(brs, 1H, NH); −0.13 (brs, 1H, NH).

Synthesis of 3-{1′-(Methoxy)ethyl}purpurin-18-*N*-(3-iodo)-benzylimide Methyl Ester (10). It was prepared by following the method described for compound **5** except the intermediate bromo-derivative was reacted with methanol, instead of *n*-hexanol. Pure product was obtained by column chromatography over a silica column using 1% acetone in dichloromethane as eluant. Analytical HPLC (Symmetry C18; 99/1: MeOH/H_2O): t_R = 31.42 min, >98%. UV−vis (CH_2Cl_2): 700 (4.31×10^4), 545 (2.12×10^4), 414 (1.29×10^5). ^{1}H NMR ($CDCl_3$; 400 MHz): δ 9.66 (s, 1H, meso-H); 9.64 (s, 1H, meso-H); 8.54 (s, 1H, meso-H); 8.08 (s, 1H, ArH); 7.70 (d, J = 8.0, 1H, ArH); 7.60 (d, J = 8.0, 1H, ArH); 7.10 (t, J = 8.0, 1H, ArH); 5.73 (q, J = 6.9, 1H, 3^1-H); 5.63 (s, 2H, NC$\underline{H}_2$Ar); 5.38 (dd, J = 1.6, 8.4, 1H, 17-H); 4.35 (q, J = 7.2, 1H, 18-H); 3.84 (s, 3H, 12-CH_3); 3.67 (q, J = 7.4, 2H, 8-C$\underline{H}_2CH_3$); 3.56 (s, 3H, 17^2-CO_2CH_3); 3.54 (d, J = 2.8, 3H, OCH_3); 3.32 (s, 3H, 2-CH_3); 3.19 (s, 3H, 7-CH_3); 2.62−2.72 (m, 1H, 17^1-H); 2.30−2.45 (m, 2H, 17^2-H and 17^1-H); 2.06 (dd, J = 2.2, 6.6, 3H, 3^2-CH_3); 1.92−2.02 (m, 1H, 17^2-H); 1.76 (d, J = 6.0, 3H, 18-CH_3); 1.68 (t, J = 7.6, 3H, 8-$CH_2C\underline{H}_3$); 0.03 (brs, 1H, NH); −0.07 (brs, 1H, NH). HRMS for $C_{42}H_{44}N_5O_5I$: 826.2387 (calculated, M + 1); found, 826.2470.

Synthesis of 3-{1′-(Methoxy)ethyl}purpurin-18-*N*-(3-trimethylstannyl)benzylimide Methyl Ester (11). The title compound was synthesized following the procedure described above for compound **7** from the respective compound 3-{1′-(methoxy)ethyl}purpurin-18-*N*-(3-iodo)benzylimide methyl ester (**10**). Yield: 80%. Analytical HPLC (Symmetry C18; 99/1: MeOH/H_2O): t_R = 35.79 min, >98%. ^{1}H NMR ($CDCl_3$; 400 MHz): δ 9.68 (s, 1H, meso-H); 9.65 (s, 1H, meso-H); 8.56 (s, 1H, meso-H); 7.90 (s, 1H, ArH); 7.68 (d, J = 7.6, 1H, ArH); 7.40 (d, J = 6.8, 1H, ArH); 7.34 (t, J = 7.2, 1H, ArH); 5.60−5.80 (m, 3H, 3^1-H and NC$\underline{\mathbf{H}}_2$Ar); 5.38 (dd, J = 2.0, 6.8, 1H, 17-H); 4.36 (q, J = 7.2, 1H, 18-H); 3.84 (s, 3H, 12-CH_3); 3.67 (q, J = 7.4, 2H, 8-C$\underline{H}_2CH_3$); 3.56 (s, 3H, 17^2-CO_2CH_3); 3.55 (d, J = 2.8, 3H, OCH_3); 3.33 (s, 3H, 2-CH_3); 3.20(s, 3H, 7-CH_3); 2.62−2.72 (m, 1H, 17^1-H); 2.30−2.50 (m, 2H, 17^2-H and 17^1-H); 2.08 (dd, J = 2.2, 6.6, 3H, 3^2-CH_3); 1.92−2.02 (m, 1H, 17^2-H); 1.76 (d, J = 7.2, 3H, 18-CH_3); 1.68 (t, J = 7.8, 3H, 8-$CH_2C\underline{H}_3$); 0.28 (s, 9H, $Sn(CH_3)_3$); −0.03 (brs, 1H, NH); −0.12(brs, 1H, NH).

Radioactive Labeling. ^{124}I-analogues of **4**, **5**, and **10** were prepared from the corresponding trimethylstannyl analogues **6**, **7**, and **11**, respectively, by following the procedure as described below for the ^{124}I-analogue of compound **4**.

Synthesis of ^{124}I-Labeled Analogue of 3-{1′-(3-iodobenzyloxy)ethyl}purpurin-18-*N*-hexylimide Methyl Ester (4). The trimethyltin analogue **6** (50 μg) was dissolved in 50 μL of 5% acetic acid in methanol. Then, 100 μL of 5% acetic acid in methanol was added to $Na^{124}I$ in 10 μL of 0.1 N NaOH. The two solutions were mixed, and an IODOGEN bead (Pierce Biotechnology, Inc., Rockford, IL 61106) was added. The reaction mixture was incubated at room temperature for 15 min, the iodobead was removed, and the reaction mixture was injected on an HPLC column (Symmetry C18 5 μm, 150 × 4.6 mm), which was eluted with an isocratic 99/1 MeOH/H_2O at a flow rate of 1 mL/min. The UV detector was set at 254 nm wavelength. The labeled product (**4**) eluted at 46.7 min was collected, and the solvent was evaporated to dryness under a stream of N_2 at 60 °C. The product was formulated in saline containing 10% ethanol for in vivo experiments. RadioTLC confirmed the radiochemical purity (>95%) of the product. A standard curve was generated between peak area versus mass by injecting known mass of carrier **4** onto the column. The mass

associated with the labeled product was calculated by relating the peak area of the UV absorbance peak of **4** in the labeled product to the standard curve. The specific activity was obtained by dividing the activity of the labeled product collected by the calculated mass in micromoles. Specific activity of the radio labeled product was >1 Ci/μmol. The radiochemical yield was found to be 40%.

PET Imaging. Mice were imaged in the micropet FOCUS 120, a dedicated 3D small-animal PET scanner (Concorde Microsystems Incorporated) at State University of New York at Buffalo (south campus) under the Institutional Animal Care and Use Committee (IACUC) guidelines. The C3H mice were subcutaneously injected with 3×10^5 RIF cells in 30 μL complete α- MEM (into the axilla), and tumors were grown until they reached 4−5 mm in diameter (approximately 5 days). All tumored C_3H mice were injected via the tail vein 50−200 μCi of **1**, **8**, **9**, and **12**.

After 24, 48, 72, and 96 h postinjection, the mice were anesthetized by inhalation of isoflurane/oxygen, placed head first prone for imaging, and the acquisition time was set for 30 min. Radioiodine uptake by the thyroid or stomach was not blocked.

Biodistribution Studies. All studies were performed as per IACUC guidelines. The mice were injected with 50−200 μCi of **1**, **8**, **9**, and **12** via tail vein, and 3 or 4 mice each at 24, 48, 72, and 96 h time interval were sacrificed and body organs (tumor, heart, liver, spleen, kidney, lung, muscle, etc.) removed immediately. After weighing, the amount of radioactivity in the tumor (50−150 mg), body organs, and blood was measured by a gamma well counter. Radioactivity uptake was calculated as the percentage of the injected dose per gram of the tissue (%ID/g). Statistical analyses and data (%ID/g vs time point) were plotted using Microsoft Excel.

In Vitro Photosensitizing Efficacy. The photosensitizing activity of **4**, **5**, and **10** was determined in the RIF tumor cell line. The RIF tumor cells were grown in α-MEM with 10% fetal calf serum, L-glutamine, penicillin, streptomycin, and neomycin. Cells were maintained in 5% CO_2, 95% air, and 100% humidity. For determining the PDT efficacy, these cells were plated in 96-well plates at a density of 5×10^3 cells/well in complete media. After an overnight incubation at 37 °C, the photosensitizers were added at variable concentrations and incubated at 37 °C for 24 h in the dark. Prior to light treatment, the cells were replaced with drug-free complete media. Cells were then illuminated with an argon-pumped dye laser set at 700 nm at a dose rate of 3.2 mW/cm^2 for 0−6 J/cm^2. After PDT, the cells were incubated for 48 h at 37 °C in the dark. Following the 48 h incubation, 10 μL of 5.0 mg/mL solution of 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetra-zoliumbromide (MTT) dissolved in PBS (Sigma, St. Louis, MO) was added to each well. After a 4 h incubation at 37 °C, the MTT and media were removed, and 100 μL DMSO was added to solubilize the formazin crystals. The 96-well plate was read on a microtiter plate reader (Miles Inc. Titertek Multiscan Plus MK II) at an absorbance of 560 nm. The results were plotted as percent survival of the corresponding dark (drug no light) control for each compound tested, and each experiment was done with 4 replicate wells.

In Vivo Photosensitizing Efficacy. The in vivo PDT experiments were performed in C3H mice when tumors grew to 4−5 mm in diameter (approximately day 5 post inoculation). The day before laser light treatment, all hair was removed from the inoculation site, and the mice were injected intravenously with varying photosensitizer concentrations. At 24 h postinjection, the mice were restrained without anesthesia in Plexiglas holders and then treated with laser light from an argon-pumped dye laser tuned to emit drug-activating wavelengths as set by the monochromator (665 nm for **1**, 705 nm for **4**, **5**, and **10**). The compounds were treated with light under similar treatment parameters under the fluence rate of 75 mW/cm^2 with a light dose of 135 J/cm^2. The mice were observed daily for signs of weight loss, necrotic scabbing, or tumor regrowth. If tumor growth appeared, the tumors were measured using two orthogonal measurements L and W (perpendicular to L), and the volumes were calculated using the formula $V = (L \times W^2)/2$ and recorded. Mice were considered cured if there was no sign of tumor regrowth by day 60 post-PDT treatment.

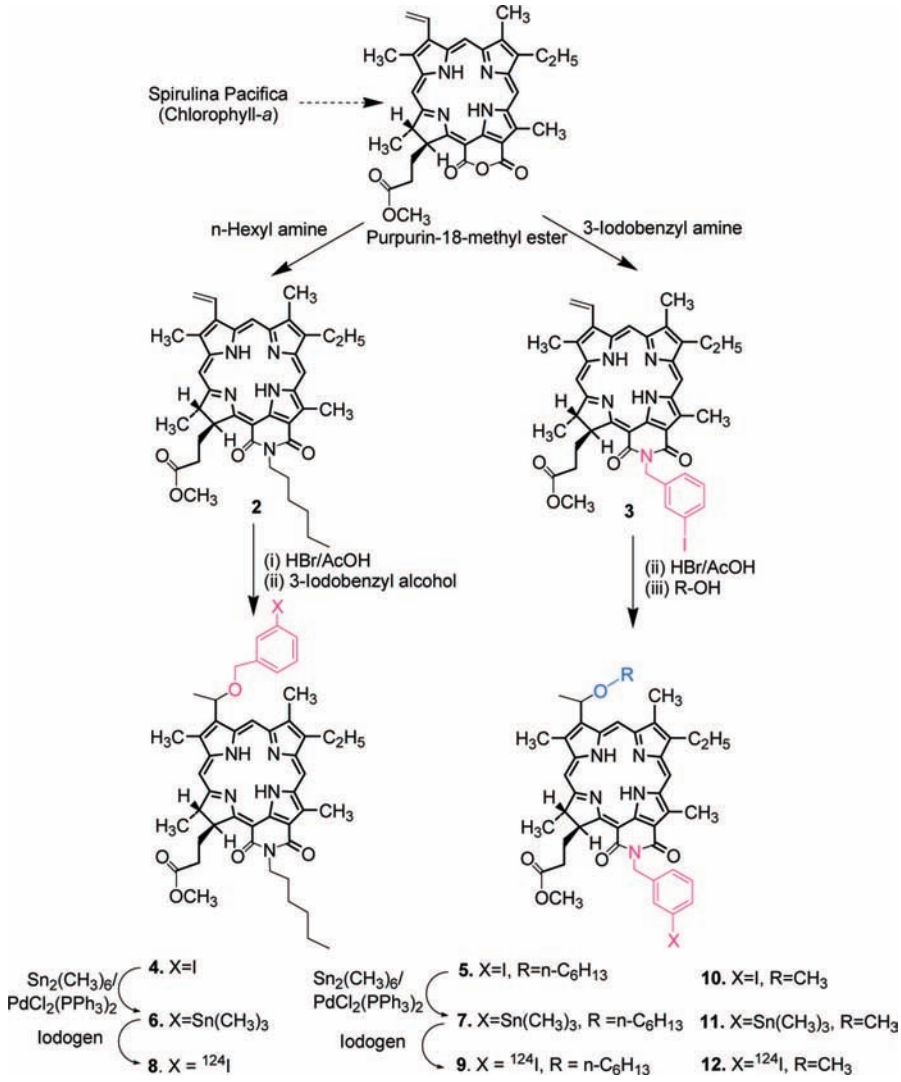
RESULTS AND DISCUSSION

Chemistry. For the synthesis of desired compounds, methylpheophorbide-*a*, isolated from *Spirulina pacifica* was converted into purpurin-18 methyl ester by following the known methodology (*44*). For the preparation of 3-(1′-*m*-iodobenzyloxyethyl) analogue **4**, it was first reacted with *n*-hexylamine, the intermediate amide derivative (isomeric mixture) so obtained on intramolecular cyclization under basic reaction conditions, and gave **2** in excellent yield. Further reaction of purpurinimide **2** with HBr/AcOH at room temperature produced the intermediate bromo-analogue, which was dried under vacuum and immediately reacted with *m*-iodobenzyl alcohol to afford **4** as a mixture of methyl ester and the corresponding carboxylic acid, which on treating with diazomethane produced the methyl ester derivative **4** in >70% yield. For the synthesis of the related isomer **5**, the purpurin-18 methyl ester was first refluxed with *m*-iodobenzyl amine, and the intermediate **3** thus obtained on reacting with 1-hexanol by following the approach depicted in Scheme 1 gave the desired photosensitizer in modest yield. Compound **10** was synthesized from **3** following the methodology outlined for **5** and by replacing *n*-hexanol with methanol. For the preparation of the corresponding ^{124}I-analogues **8**, **9**, and **12**, the trimethylstannyl substituted analogues **6**, **7**, and **11** on electrophilic aromatic iodination with Na^{124}I in the presence of iodogen beads afforded the ^{124}I-labeled purpurinimides **8**, **9**, and **12** with >95% radioactive specificity. The purity of the final compounds (**4**, **5**, and **10**) was confirmed by NMR (experimental section) and HPLC analysis (see Supporting Information).

Biological Studies. *Comparative Imaging and Biodistribution of ^{124}I-Labeled Purpurinimide Isomers **8**, **9**, and **12**.* The PET imaging and biodistribution study of the radioactive purpurinimides **8** were performed in C3H mice bearing RIF tumors. In a typical experiment, 12 tumored mice were injected with each compound (50−200 μCi), and 3 mice/group were imaged at 24, 48, 72, and 96 h for 30 min with microPET (Siemens Preclinical Solutions, Knoxville, TN), and finally sacrificed after the 96 h time point. Mice used in longitudinal imaging received higher activity (150−200uCi) compared to the mice used in biodistribution alone (50−100 uCi).

For the biodistribution studies, selected organs [tumor, muscle, kidney, lungs, intestine (gut), stomach, spleen, heart, and lung] were removed, weighed, and measured in a gamma well counter. The tail was also taken into consideration in biodistribution studies to determine the accuracy of the injection. Interestingly, the two isomers showed a remarkable difference in imaging and biodistribution characteristics. The imaging and biodistribution data also correlated well with each other. Between the two isomers, isomer **8** (*O*-iodobenzyloxyethyl purpurinimide) had a higher background (liver and spleen), and the tumor was not visualized. Although the tumor was also not significantly visualized with isomer **9** (*N*-(3-iodobenzyl purpurinimide), compared to compound **8**, the background images were not as high (Figure 2). If compared with lead compound **1** (^{124}I-labeled), purpurinimide **9** also exhibited higher tumor uptake at 72 and 96 h PI, and unfortunately, higher background uptake negated tumor visualization (Figure 3). However, in

Scheme 1[a]



[a] Purpurinimides **4**, **5** (isomers), **10** and the corresponding ^{124}I-analogues **8**, **9**, and **12**, respectively.

comparison with the ^{124}I- analogue of pyropheophorbide **1**, both purpurinimide isomers **8** and **9** showed exceptionally high liver (32-fold and 8-fold, respectively) and spleen uptake (85-fold and 3-fold, respectively) at 24 h PI. The significantly high uptake of purpurinimides **8** and **9** in the liver and spleen resulted in nonvisualization of the tumor and thus produced a poor contrast in whole body PET-imaging. Among isomers **8** and **9**, isomer **9** was selected for further modifications. The 1′-hexyloxyethyl group present at the top half of the molecule (position-3) was replaced with a methyl substituent. The resulting product **10**, with a reduced overall lipophilicity, was labeled with ^{124}I (compound **12**) and the PET imaging biodistribution data were performed in C3H mice bearing RIF tumors. The results obtained from the biodistribution studies suggest that the reduction in the overall lipophilicity of the molecule substantially reduces the uptake of purpurinimide **12** in the spleen and liver and therefore enhances its tumor imaging capability at 96 h postinjection. The biodistribution and whole-body PET imaging results obtained from compounds **1**, **8**, **9**, and **12** suggest that for an efficient tumor imaging agent it is of utmost important to have a high uptake of the contrast agent in the tumor with a faster clearance profile from other organs. This characteristic possibly explains the improved imaging capability of lead compound **1** over that of the other agents studied so far.

Comparative in Vitro PDT Efficacy. The in vitro phototosensitizing ability of the structural isomers **4** and **5** was compared

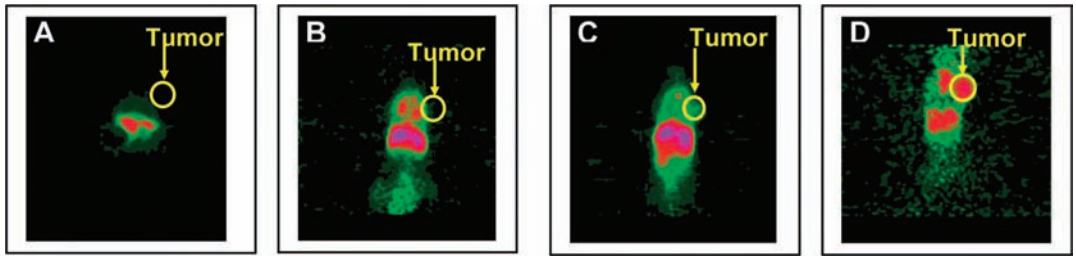


Figure 2. Comparative microPET emission images (coronal view) of C3H mice with RIF tumors at 48 h PI of ^{124}I-124 labeled purpurinimides **8** (A), **9** (B), **12** (C), and the lead compound **1** (D).

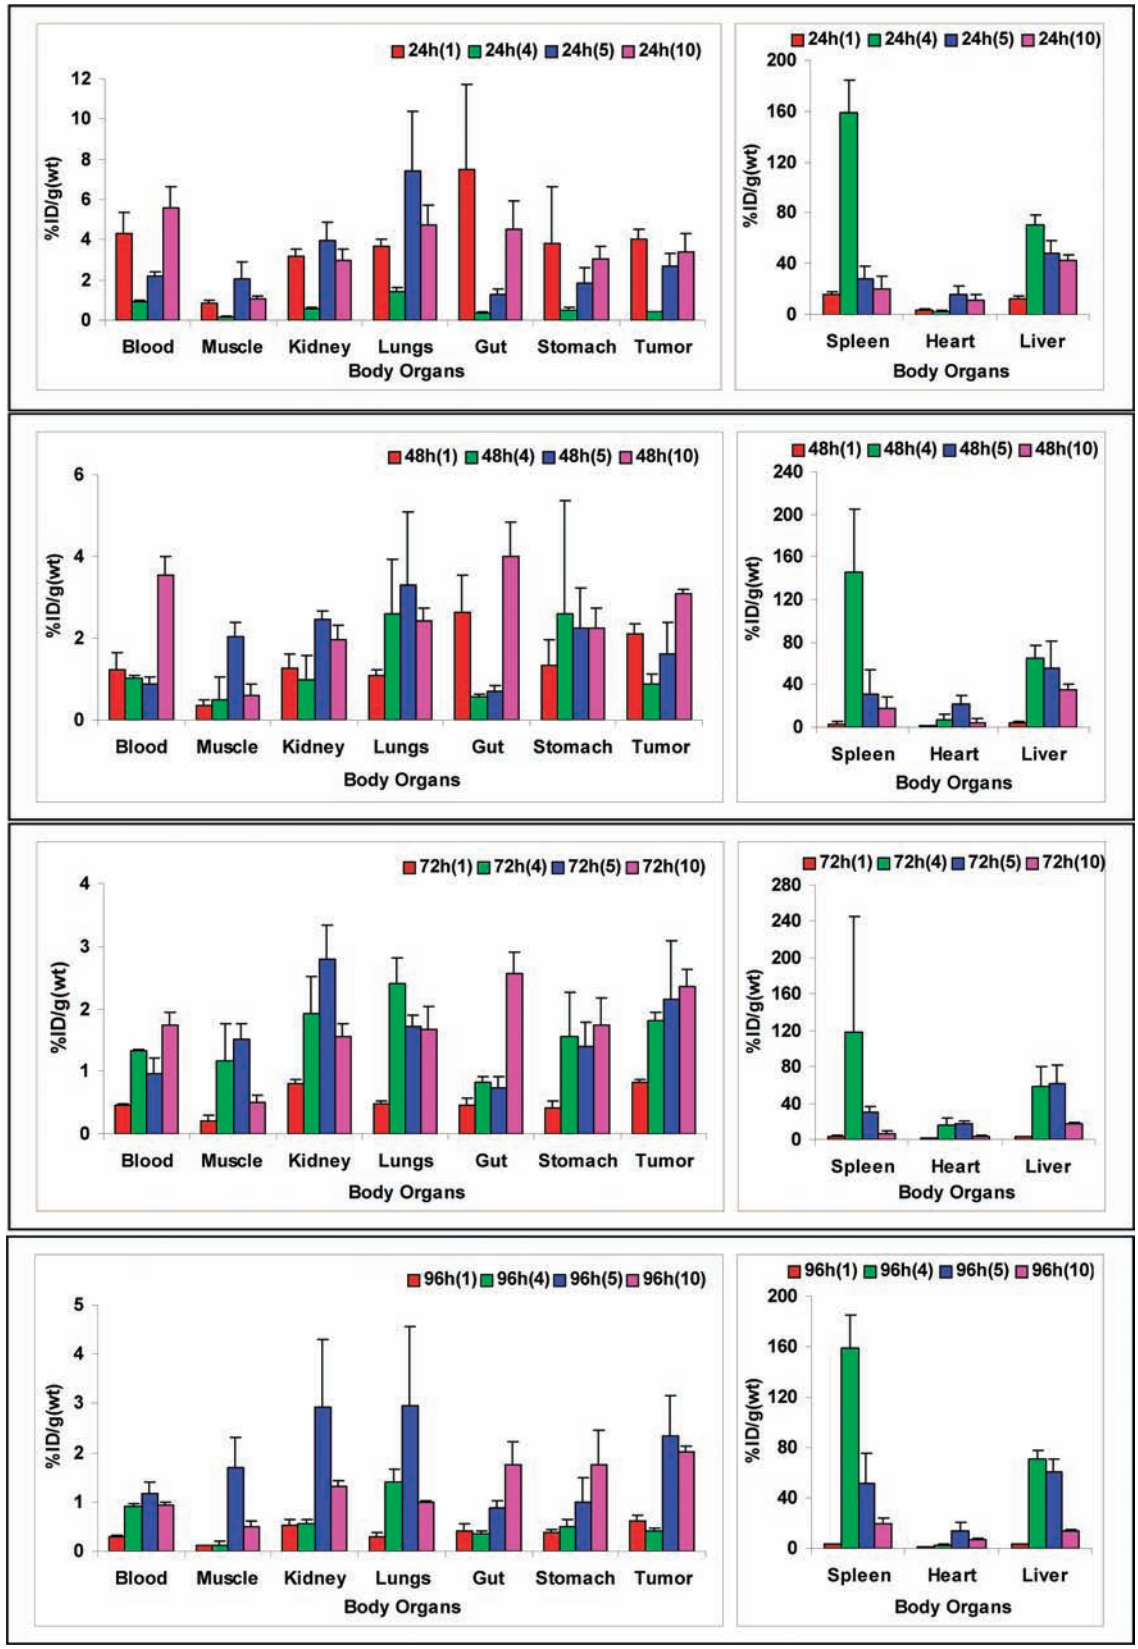

Figure 3. Comparative biodistribution of (^{124}I-labeled) pyropheophorbide-**1** and the purpurinimides-**8**, **9**, and **12** at 24, 48, 72, and 96 h PI in C3H mice bearing RIF tumors (4 mice/time point). Note: compounds **8**, **9**, and **12** are ^{124} L-labeled **4**, **5**, and **10**, respectively.

at variable experimental conditions (MTT assay; see Experimental Procedures) in RIF cells. Both isomers were ineffective in vitro at lower light and drug doses. However, as can be seen from Figure 4, at 24 h postincubation and higher light dose (6.0 J/cm^2, drug concentration (1.0 μM and higher), isomer **5** was more effective than the structural isomer **4**. Reducing the overall lipophilicity of **5**, by replacing the O-hexyl group at position-3 with an O-methyl group **10** produced enhanced efficacy over isomers **4** and **5**.

In Vivo PDT Efficiency of Pyropheophorbide-a **1** *and Purpurinimide Isomers 4 and 5.* The in vivo PDT efficacy of isomers **4** and **5** was determined at three doses (1.0, 2.0, and

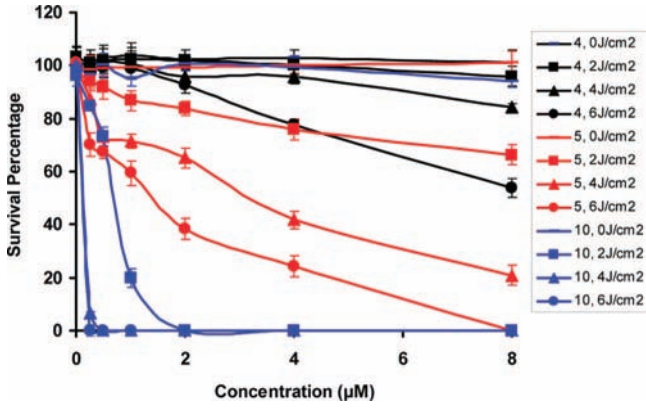

Figure 4. Comparative in vitro photosensitizing activity of **4**, **5**, and **10** at variable drug concentrations and light doses in RIF tumor cells at 24 h post incubation.

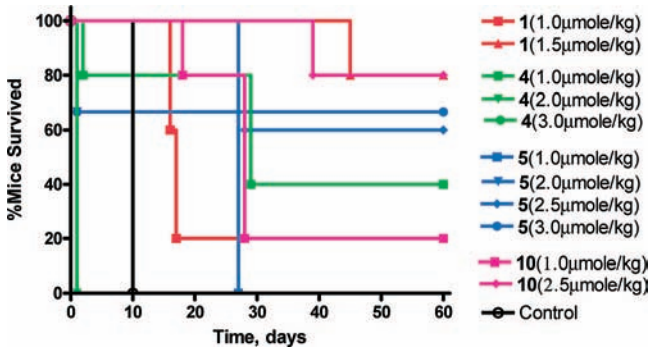

Figure 5. Kaplan−Meier plot for compounds **1**, **4**, **5**, and **10** at various doses. C3H mice bearing RIF tumor (5 mice/group) on the shoulder. Light dose: 135 J/cm^2, 75 mW/cm^2 mice/group.

3.0 μmol/kg) and was compared with lead compound **1** in C3H mice bearing RIF tumors (5 mice/group). The tumors were exposed to light (λ_{max} = 705 nm for **4** and **5**; 665 nm for **1**, 135 J/cm^2, 75 mW/cm^2) at 24 h postinjection. The tumor regrowth was measured daily. From the results summarized in Figure 5, it can be seen that compound **4**, having the iodobenzyl group at the top half of the molecule, at a dose of 1.0 μmol/kg gave a good response (2/5 mice were tumor free on day 60). At the same dose, the isomer **5** in which the iodobenzyl group is present at the lower half of the molecule did not gave any significant long-term tumor response. Under the same treatment parameters, compound **1** produced some tumor response; however, it was more effective at a dose of 1.5 μmol/kg, and 4/5 mice were tumor free on day 60. Among isomers **4** and **5**, at higher doses (e.g., 2 μmol/kg) compound **4** was toxic, and all mice died within 24 h PDT treatment (Figure 5), whereas compound **5** did not show any significant activity. However, at higher doses (2.5 and 3.0 μmol/kg) it was found to be quite effective.

To investigate the effect of the overall lipophilicity in PDT efficacy, the hexyl ether group present at position-3 in **5** was replaced with a methyl ether substituent **10**, and the biological efficacy of both the analogues was compared at doses of 1.0 and 2.5 mmol/kg. The tumors were treated with a laser light (λ_{max} = 705 nm, 135 J/cm^2, 75 mW/cm^2) at 24 h postinjection. From the results summarized in Figure 5, it can be seen that among the two analogues, methyl ether derivative **10** showed enhanced activity than the corresponding hexyl ether analogue **5**; however, it was at least 1.5-fold less effective over lead compound **1** derived from methyl pyropheophorbide-*a*. For an accurate reflection of the actual therapeutic response, further studies with a larger group of mice under variable treatment parameters are currently in progress.

CONCLUSIONS

Our results suggest that the nature and the position of the substituents in purpurinimides make a significant difference in tumor uptake, which also reflects their imaging and PDT potential. Between the two structural isomers **4** and **5**, compound **5** containing an N-iodobenzyl group introduced at the bottom half of the purpurinimide showed improved imaging and phototherapeutic abilities than **4** where the iodobenzyl group was present at position-3 of the molecule. Decreasing the overall lipophilicity of compound **5** by substituting the hexyl ether with a methyl ether group (compound **10**) further improved its PET imaging ability and PDT efficacy. However, for establishing a correlation between the overall lipophilicity and tumor imaging potential, it is necessary to investigate a series of compounds within a particular system, and these studies are currently in progress.

ACKNOWLEDGMENT

The financial support from the NIH (CA 114053, CA 127369, and CA 55791), the Oncologic Foundation of Buffalo, Roswell Park Alliance Foundation, and the shared resources of the RPCI support grant (P30CA16056) is highly appreciated.

Figure : Radio- HPLC chromatograms showing the purity of the ^{124}I-labeled purpurinimides **8, 9** and **12.**

Note:

The difference in the retention times between the labeled and non-labeled compounds is due to the difference of the size of the HPLC column and the polarity of the eluting solvents.

Maghemite (γ-Fe_2O_3) nanoparticles were obtained by the coprecipitation of Fe(II) and Fe (III) salts with ammonium hydroxide followed by oxidation with sodium hypochlorite. Solution radical polymerization of *N*,*N*-dimethylacrylamide (DMAAm) in the presence of maghemite nanoparticles yielded poly(*N*,*N*-dimethylacrylamide) (PDMAAm)-coated maghemite nanoparticles. The presence of PDMAAm on the maghemite particle surface was confirmed by elemental analysis and ATR FTIR spectroscopy. Other methods of nanoparticle characterization involved scanning and transmission electron microscopy, atomic adsorption spectroscopy (AAS), and dynamic light scattering (DLS). The conversion of DMAAm during polymerization and the molecular weight of PDMAAm bound to maghemite were determined by using gas and size-exclusion chromatography, respectively. The effect of ionic 4,4′-azobis(4-cyanovaleric acid) (ACVA) initiator on nanoparticle morphology was elucidated. The nanoparticles exhibited long-term colloidal stability in water or physiological buffer. Rat and human bone marrow mesenchymal stem cells (MSCs) were labeled with uncoated and PDMAAm-coated maghemite nanoparticles and with Endorem as a control. Uptake of the nanoparticles was evaluated by Prussian Blue staining, transmission electron microscopy, T_2-MR relaxometry, and iron content analysis. Significant differences in labeling efficiency were found for human and rat cells. PDMAAm-modified nanoparticles demonstrated a higher efficiency of intracellular uptake into human cells in comparison with that of dextran-modified (Endorem) and unmodified nanoparticles. In gelatin, even a small number of labeled cells changed the contrast in MR images. PDMAAm-coated nanoparticles provided the highest T_2 relaxivity of all the investigated particles. In vivo MR imaging of PDMAAm-modified iron oxide-labeled rMSCs implanted in a rat brain confirmed their better resolution compared with Endorem-labeled cells.

INTRODUCTION

Recently, superparamagnetic iron oxide nanoparticles have found widespread application in medicine, in particular as contrast agents in magnetic resonance imaging (MRI) (*1*). Contrast agents in MRI improve the detection and characterization of lesions by changing the signal intensity of target tissues when compared with the surrounding tissue (*2*). Understanding the interactions between the nanoparticles and cells is crucial for improving their behavior in vivo and in vitro. The direct use of nanoparticles as in vivo MRI contrast agents results in their biofouling in the blood plasma and the formation of aggregates that are quickly sequestered by cells of the reticular endothelial system (RES) such as macrophages. Both small particle size and surface chemical structures are key parameters determining the blood half-life in the circulation, opsonization, biokinetics, and the biodistribution of magnetic nanoparticles (*3–5*). It is therefore essential to engineer the surface of the iron oxide to minimize biofouling and the aggregation of the particles under physicochemical conditions (i.e., high salt and protein concentrations) for long periods. Surface modifications of magnetic iron oxide nanoparticles with biocompatible polymers are potentially beneficial for preparing MR contrast agents for in vivo applications. Such particles can circulate in the plasma for long periods by escaping uptake by the RES. Iron oxide nanoparticles coated with dextran and its derivates, such as Feridex (Endorem) and Resovist, are commercially available. Iron oxide nanoparticles also show potential for in vitro cell labeling followed by in vivo MRI tracking, an approach that is being investigated for stem cell therapy (*6*, *7*). Dextran-coated agents are, however, insufficiently taken up by the cells during cultivation; consequently, modifications of the iron oxide surface are attempted in order to increase the internalization of the nanoparticles. One promising approach toward increasing the local concentration of the nanoparticles in cells is to conjugate them with targeting molecules that have a high affinity for tumor cells (*8–10*). Target-specific molecules, including monoclonal antibodies (*11*), proteins (*12*), peptides, and folic acid (*10*), have been investigated to increase the site-specific accumulation of MR contrast agents in tumor cells. Several transfection agents have been suggested to facilitate the effective magnetic labeling of cells by endocytosis into endosomes (*13*). These are mostly cationic, positively charged compounds (*14*). Superparamagnetic

iron oxide nanoparticles have thus been incorporated into hemoglobin within red cells, short human immunodeficiency virus-transactivator transcription (TAT) proteins (*15*), polyamines (polycationic poly(L-lysine) (PLL) (*16*)), magnetodendrimers (*17*), and antigen-specific internalizing monoclonal antibodies (*18*). The complexing of PLL with iron oxide occurs through electrostatic interactions of the negatively charged iron oxide nanoparticles with the polycation, allowing for the efficient incorporation of iron oxide nanoparticles into endosomes for magnetic cell labeling. A disadvantage of PLL-modified iron oxides is, however, that they aggregate in the presence of some electrolytes.

In our previous reports, the efficiency of cellular uptake was investigated following D-mannose and PLL modification of the iron oxide surface (*19*, *20*). These systems were relatively stable in cell culture media; however, their further modification with antibodies, enzymes, or proteins, was difficult. In an attempt to design a novel coating of iron oxide nanoparticles that would not only ensure their very good colloidal stability but also enable the subsequent covalent attachment of highly specific biomolecules (antibodies, enzymes, peptides, etc.), PDMAAm was selected. Its advantage consists in the easy formation of homogeneous networks and copolymers with various functional monomers (*21*). Our preliminary biological experiments confirmed not only the nontoxicity of the PDMAAm coating but also its ability to enhance cellular uptake. In this study, PDMAAm coating of iron oxide particles was investigated in more detail utilizing in vitro cell labeling followed by MR cell tracking. As a model, rat and human mesenchymal stem cells (rMSCs and hMSCs) were labeled with PDMAAm-coated nanoparticles, and nanoparticle internalization into cells was visualized with light and TEM microscopy. In addition, the effect of PDMAAm-coated iron oxide nanoparticles on cell viability and labeling efficiency was quantified. Moreover, MR relaxometry of labeled cells was used to measure relaxation times, which are responsible for contrast enhancement in MR images.

EXPERIMENTAL SECTION

Materials. *N*,*N*-Dimethylacrylamide (DMAAm; Aldrich, Milwaukee, USA) was distilled (56 °C/266 Pa). 4,4′-Azobis(4-cyanovaleric acid) (ACVA), $FeCl_2 \cdot 4H_2O$, and $FeCl_3 \cdot 6H_2O$ were purchased from Fluka (Buchs, Switzerland) and used without further purification. All other chemicals were supplied by Aldrich and used as received. Endorem, a MRI contrast agent based on superparamagnetic dextran-coated iron oxide nanoparticles, was obtained from Guerbet (Roissy, France). Ultrapure Q water ultrafiltered on a Milli-Q Gradient A10 system (Millipore, Molsheim, France) was used for preparation of the solutions.

Preparation of Ferrofluid. Two procedures are generally used for the preparation of iron oxide nanoparticles: an in situ and a stepwise method. In this report, a two-step procedure was used. Colloidal $Fe(OH)_3$ was first precipitated from $FeCl_3 \cdot 6H_2O$ added to less than an equimolar amount of ammonia, followed by the addition of $FeCl_2 \cdot 4H_2O$ (molar ratio Fe(III)/Fe(II) = 2). Mixing was simply achieved by rapid sonication. The mixture was then poured into an excess of ammonia, and a magnetite (Fe_3O_4) coagulate was formed. The key step in the formation of a stable magnetite colloid after the synthesis consists in its careful purification from all impurities by washing and magnetic separation in water, a process called peptization. Briefly, 12 mL 0.2 M $FeCl_3 \cdot 6H_2O$ aqueous solution was mixed with 12 mL 0.5 M NH_4OH solution under sonication (Sonicator W-385; Heat Systems-Ultrasonics, Inc., Farmingdale, USA) for 2 min at laboratory temperature to form the $Fe(OH)_3$ colloid. Then, 6 mL of 0.2 M $FeCl_2 \cdot 4H_2O$ aqueous solution was added under sonication and the mixture poured into 36 mL of 0.5 M NH_4OH aqueous solution. The resulting magnetite coagulate was left to grow for 15 min, magnetically separated, and repeatedly (7−10×) washed with Q-water to remove all impurities (including NH_4Cl) remaining after the synthesis. The above-formed pure magnetite was sonicated for 3 min with 2 mL of 0.1 M sodium citrate solution and oxidized at room temperature with 1.5 mL of 5 wt % sodium hypochlorite to maghemite. The precipitate was again repeatedly (7×) washed with Q-water using magnetic separation/decantation to obtain a stable colloid.

Coating by Solution Radical Polymerization of DMAAm in the Presence of Maghemite Nanoparticles. In a typical experiment, 1 g of DMAAm and 0.01 g of ACVA initiator were dissolved in 30 mL of aqueous colloid containing 0.5 g of γ-Fe_2O_3, and the mixture was purged with nitrogen to remove oxygen for 10 min. PDMAAm was synthesized under stirring (400 rpm) at 70 °C for 8 h. The resulting colloid was washed 8 times with water by centrifugation/redispersion to remove excessive polymer, unreacted monomer, and initiator, and redispersed.

For comparison, iron oxide nanoparticles were also encapsulated in neat PDMAAm added to the particles, followed by a thorough purification by repetitive centrifugation/redispersion in water.

Characterization of the Particles. The particles were observed in a scanning electron microscope (SEM, JEOL JSM 6400). A drop of particle dispersion was smeared between glasses for microscopy to obtain a thin layer, dried, and surface-coated with a 4-nm platinum layer using a SCD 050 sputtering device (BalTech, Lichtenstein). Transmission electron microscopy (TEM) was performed on a JEOL JEM 200 CX to determine the particle size of the iron oxides. The average diameter and particle size distribution PDI (weight-number-average particle diameter ratio D_w/D_n) were obtained by statistical analysis of at least 500 particles using the Atlas program (Tescan Brno, Czech Republic). The X-ray diffraction measurement was carried out with a Bruker D8 diffractometer using Cu Kα radiation and a Sol-X energy dispersive detector. The amount of iron in the coated nanoparticles was found by AAS (Perkin-Elmer 3110) of an extract of the sample obtained with dilute HCl (1:1) at 80 °C for 1 h. The amount of PDMAAm bound to the particles after polymerization was determined after their lyophilization by elemental analysis (Perkin-Elmer 2400 Series II CHNS/O Analyzer, Shelton, CT, USA).

The coating of PDMAAm on the surface of magnetic nanoparticles was investigated using a Thermo Nicolet NEXUS 870 FTIR Spectrometer (Madison, WI, USA) in a water-purged environment with a DTGS detector in the wavenumber range from 400 to 4000 cm^{-1}. A Golden Gate Heated Diamond ATR Top-Plate (MKII Golden Gate single reflection ATR system) (Specac Ltd., Orpington, Great Britain) was used for measuring the spectra of powdered samples by ATR spectroscopy. Typical parameters used were 256 sample scans, 4 cm^{-1} resolution, Happ-Genzel apodization, and KBr beamsplitter.

The hydrodynamic diameter D_h and the zeta-potential of both the unwashed colloid (0.2 mL of original colloid diluted to 2 mL) and the colloid repeatedly (8×) washed with water through ultracentrifugation/redispersion were determined by dynamic light scattering (DLS) with an Autosizer Lo-C (Malvern Instruments Ltd., Malvern, UK). Colloidal stability was evaluated visually according to the presence of sediment on the bottom of the vial.

To determine the molecular weight (M_w) of PDMAAm bound to maghemite, maghemite was first dissolved in concentrated HCl. The resulting dark yellow solution was diluted with water and PDMAAm separated on a PD 10 desalting column (Amersham Biosciences, Buckinghamshire, UK). Finally, PD-

MAAm was lyophilized and dissolved in acetate buffer ($c \sim 3$ mg/mL). The M_w was determined by size-exclusion chromatography in an aqueous methanol solution on a Shimadzu HPLC system equipped with RI, UV, and multiangle light scattering DAWN EOS (Wyatt Co., USA) detectors using a mobile phase consisting of 20% 0.3 M acetate buffer (pH 6.5; 0.5 g/L NaN_3) and 80% methanol (flow rate 0.5 mL/min) with a GPC column TSKgel G6000PW (300 × 7.8 mm; 15 μm; Tosoh Bioscience, Japan).

The conversion versus DMAAm polymerization time was calculated from the concentration of monomers during polymerization monitored after the addition of hydrochinone (50 mg/mL) by a GC Perkin-Elmer (Norwalk, CT, USA) with FID detector using 30 m length, 0.32 mm inner diameter Rtx-624 column with 1.8 μm thick film (Restek, Bellefonte, PA, USA). Calibration was performed using an external standard.

Cell Cultures and Cell Labeling. In vitro cellular uptake experiments were performed using rat and human bone marrow mesenchymal stem cells. Rat bone marrow mesenchymal stem cells (rMSCs) were obtained from the tibia and femur of 4-week-old Wistar rats. The ends of the bones were cut, and the marrow was extruded with Dulbecco's modified Eagle's medium (DMEM, PAA Laboratories, Linz, Austria) by using a needle and a syringe (*22*). Marrow cells were plated in a 75-cm^2 tissue culture flask (TPP, Trasadingen, Switzerland) in DMEM medium containing 10% fetal bovine serum (FBS, PAA Laboratories, Linz, Austria), 100 units/mL penicillin (Gibco BRL, Paisley, Scotland), and 0.1 mg/mL streptomycin (Gibco BRL). After 24 h, the nonadherent cells were removed by replacing the medium.

Human bone marrow mesenchymal stem cells (hMSCs) were obtained from the bone marrow of healthy donors after obtaining informed consent. Bone marrow aspirates were diluted in phosphate-buffered saline (PBS) and centrifuged through a density gradient (Ficoll-Paque Plus, GE Healthcare Life Sciences, Vienna, Austria) for 30 min at 1000 *g* (*22*, *23*). Nucleated cells from the interface were plated in a 75-cm^2 tissue culture flask in α-modified Eagle's medium (α-MEM, Gibco BRL) containing 10% FBS, 100 units/mL penicillin, and 0.1 mg/mL streptomycin. After 48 h, the nonadherent cells were removed by replacing the medium.

Both types of cells were cultured in a humidified 5% CO_2 incubator. The medium was replaced every 3 days as the cells grew to confluence. The cells were labeled with iron oxide nanoparticles. For cell labeling, either uncoated γ-Fe_2O_3 nanoparticles, the contrast agent Endorem, or PDMAAm-coated γ-Fe_2O_3 nanoparticles were used at the same concentration −15 μg Fe_2O_3/mL of media. After 72 h, the contrast agent was washed out by replacing the culture medium.

Transmission Electron Microscopy (TEM). Nanoparticle localization inside the cells was observed by transmission electron microscopy. MSCs were incubated with the nanoparticles for 72 h, transferred onto polylysine-coated coverslips, fixed in 2.5% glutaraldehyde in 0.1 M Sörensen buffer for 48 h at 4 °C, and stained by 1% osmium tetraoxide in 0.1 M Sörensen buffer for 2 h. Cells were then dehydrated in ethanol, immersed in propylene oxide, and flat embedded in Epon 812 using gelatin capsules. After polymerization for 72 h at 60 °C, coverslips were removed by liquid nitrogen. Ultrathin sections of 60 nm were examined with a Philips Morgagni 268D transmission electron microscope (FEI Inc., Hillsboro, OR, USA).

Cell Viability. The viability of cells was analyzed using a colorimetric assay based on the cleavage of the tetrazolium salt WST-1 (4-[3-(4-iodophenyl)-2-(4-nitrophenyl)-2*H*-5-tetrazolio]-1,3-benzene disulfonate) (Roche Diagnostics, Mannheim, Germany) to a highly water-soluble formazan dye by mitochondrial dehydrogenases in viable cells (*24*). rMSCs or hMSCs (2nd and 5th passages) were plated on 96-well plates (TPP, Trasadingen, Switzerland) at a density of 5×10^3 cells/well. The cells were cultured and labeled with iron oxide nanoparticles as described above. Twelve wells of each cell type were labeled with Endorem and 12 wells with PDMAAm-coated maghemite nanoparticles, and 12 wells were not labeled and served as control samples. On the day that nanoparticles were withdrawn (day 3), 10 μL of the WST-1 solution was added to 100 μL of culture medium per well, and the cells were kept in the incubator (37 °C) for an additional 2 h. The absorbance was measured using an ELISA plate reader (Tecan Spectra, Tecan Trading, Switzerland) at a wavelength of 450 nm.

Labeling Efficiency and Staining Intensity. Labeling efficiency was determined by manually counting the number of Prussian Blue-stained and unstained cells in 96-well plates and measuring the staining intensity of Prussian Blue-stained cells colorimetrically. Twelve optical fields from each plate were scanned using an Axioplan Imaging II microscope at 100× magnification using a 10×/0.75 objective lens, an AxioCam digital camera, and AxioVision 4 software (microscope setup from Zeiss, Oberkochen, Germany). All of the cells in the scanned images were manually labeled as Prussian Blue-stained or unstained using Jasc Paint Shop Pro 8 (Corel Corporation, Ottawa, Canada). The scanned images with manually labeled cells were processed by the Image analysis toolbox of MATLAB software (The MathWorks, Inc., MA, USA). Before the analysis, we validated the colorimetric scale from the image colors corresponding to the increasing intensities of the Prussian Blue staining of the cells. Then we processed each Prussian Blue-stained cell in the image and determined the intensity of the cytoplasmic staining as the intensity of the color of the cytoplasm on the scale. As a result, two parameters were obtained: (i) the presence or absence of a label inside the cells expressed as the percentage of labeled cells and (ii) the amount of label inside the cells, which correlates with the intensity of the staining.

In Vitro MR Relaxometry and MR Imaging of Labeled Cells Suspended in Gelatin. MR relaxometry of the particles was performed using a Bruker MiniSpec 0.5 T relaxometer and a Bruker BioSpec 4.7 T imager (both Etlingen, Germany). The latter apparatus was also used for MR imaging. Two types of labeled cells, rat and human MSCs, were dispersed in gelatin in the following concentrations: 50, 100, 200, 400, and 800 cells/μL. Control samples containing suspensions of unlabeled cells and Endorem-labeled cells were measured at the same concentrations. For T_1 relaxometry, the standard saturation recovery sequence was used; T_2 relaxometry was performed with a CPMG multispin−echo sequence. Measured relaxation times were converted to relaxation rates and related to cell concentrations. MR imaging was performed with T_2-weighted turbo-spin echo (effective echo time TE = 35 ms, repetition time TR = 3 s) and T_2*-weighted gradient echo (TE = 5 ms, TR = 100 ms) sequences that are commonly used in in vivo measurements.

Iron Analysis. The amount of iron in the cells after mineralization was determined by spectrophotometry. Cell-containing samples were mineralized by the addition of 5 mL of HNO_3 and 1 mL of H_2O_2 in an ETHOS 900 microwave mineralizator (Millestone, Sydney, Australia). Deionized water was added to reach a total volume of 100 mL. The iron content was determined using a Spectroflame M120S apparatus (Spectro, Littleton, MA, USA) calibrated with a standard Astasol solution (Analytika, Prague, Czech Republic). The measurements were repeated four times, and the average mean value was determined.

Cell Grafting. The rats (n = 5) were anesthetized with isoflorane and mounted in a stereotactic frame. Using an aseptic technique, a burr hole (1 mm) was made in the skull to expose the dura overlying the cortex. PDMAAm-modified iron oxide-

labeled cells or Endorem-labeled cells (5,000 cells suspended in 5 μL of PBS) were slowly injected intracerebrally into the brain over a 10-min period using a Hamilton syringe. Unlabeled cells were injected as a control. The opening was closed by bone wax, and the skin was sutured.

MR Imaging. The in vivo MR images were obtained on a 4.7 T Bruker imager equipped with a homemade surface coil. The rat was anesthetized by passive inhalation of 1.5−2% isoflorane in air. Breathing was monitored during the measurements. Single sagittal, coronal, and transversal images were obtained by a fast gradient echo sequence for localizing, then both T_2-weighted (turbospin echo sequence, TE = 35 ms, TR = 3 s, number of acquisitions AC = 8, matrix size 256 × 256, field of view FOV = 3.5 × 3.5 cm, slice thickness 0.75 mm) and T_2*-weighted (gradient echo sequence, TE = 12 ms, TR = 180 ms, number of acquisitions AC = 48, same geometry) axial images were acquired.

RESULTS AND DISCUSSION

Preparation of Maghemite. Maghemite (γ-Fe_2O_3) nanoparticles are one of the most commonly used ferric oxide particles because of their simple synthesis and chemical stability. Their advantage is that iron participates in human metabolism and is thus well tolerated by the living organism. First, magnetite was precipitated; its colloidal stability was achieved by charges induced by Fe^{3+} ions. However, because the above colloid is chemically unstable, undergoing uncontrolled oxidation upon contact with air, it was controllably chemically oxidized to maghemite, which shows long-term stability in either alkaline or acidic media. The ultimate advantage of the above procedure consists in the simplicity of purification by magnetic separation/decantation, which is much more convenient than the commonly used but more elaborate and time-consuming method of ultracentrifugation.

TEM and SEM images (Figure 1a,b) show agglomerated maghemite particles in a dry state. The agglomerates consist of primary particles with an average size D_n = 6.3 nm and a polydispersity index PDI = 1.33. X-ray diffraction measure-

ments of the synthesized particles evidenced the typical spinel structure of γ-Fe_2O_3 (Figure 2). With respect to a small size of the crystallites, weak superstructural patterns indicated for the standard material were not detectable. Detailed Mössbauer spectra were published elsewhere (*25*).

Solution Radical Polymerization of DMAAm in the Presence of Maghemite Nanoparticles. The surface modification of nanoparticles is a general strategy for enhancing the permeability of nanoparticle-based therapeutics. To modify the iron oxide surface, the solution radical polymerization of DMAAm in aqueous ferrofluid was investigated. This could produce a dispersion of maghemite nanoparticles stable in a medium suitable for subsequent polymerization of DMAAm, thus facilitating their subsequent incorporation in the polymer microspheres. At the same time, it provides a model for investigating the effect of iron oxide nanoparticles on the polymerization process. In the system, ACVA was preferred over 2,2′-azobisisobutyronitrile (AIBN) as an initiator because its solubility in an aqueous monomer solution is much higher than that of AIBN. An additional advantage of ACVA consists in its carboxyl group's ability to interact with iron oxide. The polymerization conditions are summarized in Table 1. The effect of several polymerization parameters, such as the concentrations

(a) Before modification, (b) coating by solution polymerization in the presence of γ-Fe_2O_3 nanoparticles No. 3, (c) coating by encapsulation of γ-Fe_2O_3 nanoparticles in the polymer No. 2, (b-a) and (c-a) the corresponding differential spectra of coated and uncoated γ-Fe_2O_3, and (d) pure PDMAAm.

of the monomer, the initiator, and the iron oxide in the feed, on particle size and the amount of PDMAAm bound to the particles was investigated. For the sake of comparison, the characteristics of neat (uncoated) maghemite nanoparticles and of nanoparticles coated with a solution of preprepared PDMAAm are also shown in Table 1.

Conversion Curves. Conversion curves were determined in order to estimate the effect of maghemite on the polymerization process. The presence of maghemite colloid in the feed affected the molecular weight of the resulting PDMAAm compared to solution radical polymerization without maghemite. The mo-

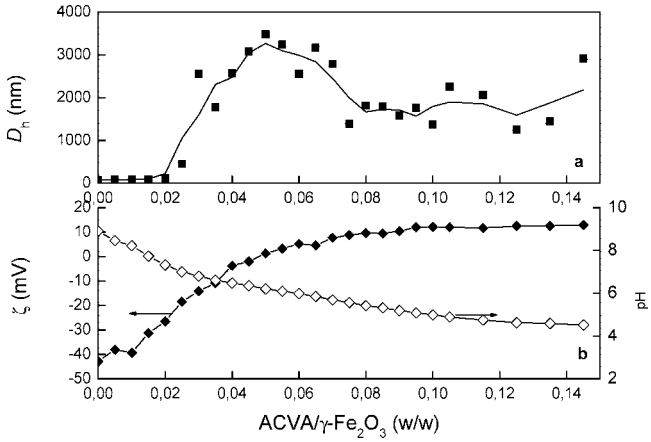

Figure 5. Dependence of the (■) hydrodynamic diameter D_h (a), (◆) ζ-potential, and (◇) pH (b) on the ACVA/γ-Fe_2O_3 ratio.

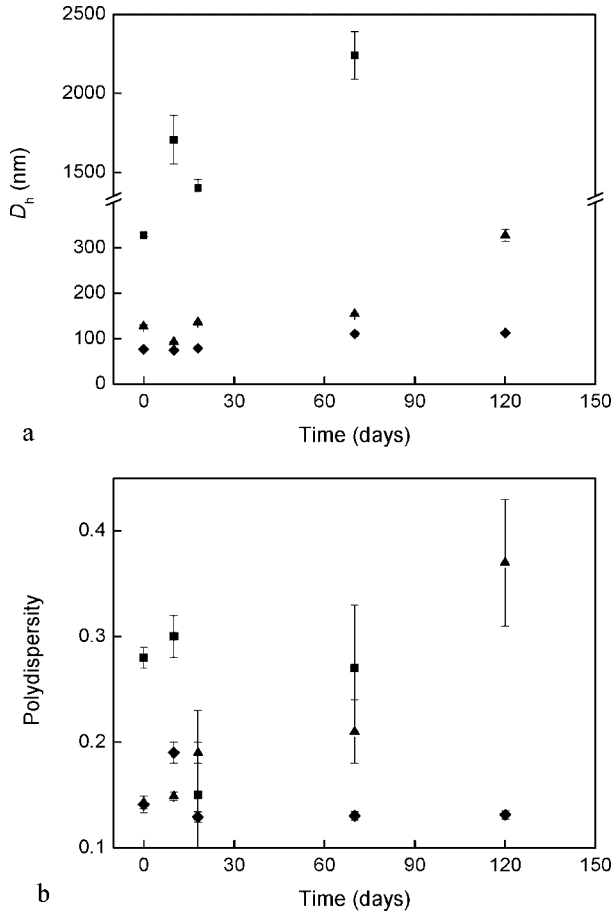

Figure 6. Dependence of the (a) hydrodynamic particle diameter D_h and (b) polydispersity, measured by dynamic light scattering, on storage time; (▲) uncoated γ-Fe_2O_3 No. 1, PDMAAm-coated γ-Fe_2O_3 (◆) No. 18, and (■) No. 13.

lecular weight of PDMAAm prepared in the presence of maghemite was 717,900, i.e., lower than that prepared in its absence (965,200). This can be attributed to the growing polymer chains probably terminating on the nanoparticle surface as documented by the slower consumption of monomers in the initial and final stages of the polymerization (Figure 3). Because of the termination, PDMAAm can be attached to the maghemite surface. The possible complexation of the ACVA initiator with maghemite Fe atoms can contribute to additional DMAAm initiation. At γ-Fe_2O_3/DMAAm ratios of 0.5/0.375 (w/w) and lower, free PDMAAm was present in the mixture after polymerization. The colloidal stability then decreased with an increasing γ-Fe_2O_3/DMAAm ratio.

FTIR Spectra. The structure of the surface and the efficiency of the coating of magnetic nanoparticles were analyzed by surface-sensitive ATR FTIR spectroscopy. FTIR spectra of iron oxide before modification, after coating by solution radical polymerization in the presence of γ-Fe_2O_3 nanoparticles, after coating by encapsulation of maghemite nanoparticles in the polymer, the corresponding differential spectra of coated and uncoated surfaces, and the spectrum of pure PDMAAm are shown in Figure 4. The spectrum of coating by encapsulation of maghemite γ-Fe_2O_3 nanoparticles (see corresponding differential spectrum) is relatively weak and is very close to the spectrum of pure PDMAAm. This signifies that some amount of polymer adheres to the surface of the nanoparticles. The spectrum of coating by solution radical polymerization in the presence of maghemite nanoparticles (see corresponding differential spectrum) is stronger and differs from the spectrum of pure PDMAAm in some aspects. The band of Amide I (*26*) observed at 1618 cm^{-1} is shifted to 1608 cm^{-1}, and the intensity of the band of Amide II observed at 1404 cm^{-1} increased after polymerization. The peaks of CH_3 deformation vibration at about 1495 and 1354 cm^{-1} decreased in their relative intensity. We hypothesize that these changes correspond to the interaction of the protonated NH^+ groups of PDMAAm with citrates complexed on the iron oxide surface. Citrate is adsorbed on the ferric oxide surface via one or two carboxylate moieties, allowing the use of one of the ungrafted carboxylic acid groups to bind a polycation. This confirms that the PDMAAm shell has effectively formed at the surface of the iron oxide particles.

DLS, TEM, and Elemental Analysis. Particle size and its distribution have a strong effect on the physical and biochemical properties of colloidal dispersions. Many methods have been described for the measurement of average particle size, such as electron microscopy, dynamic light scattering, and chromatographic methods; the former two techniques were used in this study.

ACVA-initiated solution polymerization of DMAAm in the presence of maghemite nanoparticles produced a very stable colloid, with the particles typically in the hydrodynamic size (D_h) range of 50−170 nm. Because DLS provides information on the hydrodynamic particle size of whole particle clusters, including polymer coating layers and the magnetic core, the size of the iron oxide core alone was examined by TEM. Figure 1c,d shows TEM and SEM images of the obtained DMAAm-coated nanoparticles with an average size $D_n = 7.5$ nm and a polydispersity index PDI = 1.20. A comparison of Figure 1a,b and Figure 1c,d reveals that both the shape and the size of the particles after the coating process effectively did not change from those of the uncoated particles. It is worth pointing out that the particle size determined by TEM was smaller compared with the particles size of the same latex obtained from DLS measurements (Table 1). These results confirm the presence of a hydrophilic polymer hairy layer on the particle surface, which increases the value of the average hydrodynamic diameter during the DLS measurements and which is collapsed onto the particle surface during the drying of the TEM sample. It should also be remembered that while TEM provides the number-average particle size, DLS gives the z-average, which is sensitive to large-size particles.

Effect of the Reaction Parameters. The effect of the amount of the monomer in the polymerization feed on colloidal stability, hydrodynamic particle size, and the percentage of PDMAAm bound to the particles (determined from elemental analysis) at a constant initiator concentration (1 wt % in the monomers) is documented in Table 1 for experiments Nos. 3−6. Particles aggregated at low amounts of bound PDMAAm. The percentage

Table 2. Cell Labeling Efficiency with Surface-Modified and Unmodified Iron Oxide Nanoparticles

	percentage of labeled cells	
	rMSC	hMSC
Endorem	39 ± 6	68 ± 5
uncoated γ-Fe_2O_3	46 ± 5	70 ± 5
PDMAAm-coated γ-Fe_2O_3	59 ± 5	82 ± 5

of bound PDMAAm generally reached up to ca. 2 wt %, while free PDMAAm was removed during washing. The more DMAAm in the polymerization feed, the more PDMAAm was bound to the particles.

The effect of the amount of initiator in the feed on colloidal stability, hydrodynamic particle diameter, and the percentage of bound PDMAAm is documented in Table 1 for experiments Nos. 5 and 7−10. At <10 mg of ACVA in the polymerization feed, the D_h of the resulting particles was smaller than that of the primary maghemite particles (Table 1). This can be explained by the steric repulsion of PDMAAm chains on their surface, which decreases the number of particle associates measured by DLS. At higher ACVA amounts, the stability of the colloidal system was lost, and the particles aggregated. Both the hydrodynamic particle size D_h and the percentage of bound PDMAAm determined from elemental analysis increased with increasing amounts of the initiator in the feed up to 15 mg of ACVA (Nos. 5, 7, and 8 in Table 1). The increasing percentage of bound PDMAAm at higher initiator concentrations can be ascribed to a larger number of carboxyl groups available to anchor more PDMAAm chains on the maghemite particle and/or a greater tendency toward particle aggregation. To explain why steric stabilization occurred only at concentrations lower than 15 mg of ACVA in the feed, ACVA was added to the maghemite colloid, and hydrodynamic diameter D_h, ζ-potential, and pH were monitored depending on the ACVA/γ-Fe_2O_3 ratio. With the ACVA/γ-Fe_2O_3 ratio increasing from ~0.02 (w/w), hydrodynamic diameter sharply increased (Figure 5a). This can be explained by the increase of ζ-potential from ca. −43 mV, reaching a critical value at −30 mV and accompanied by a steep decrease of pH till the ACVA/γ-Fe_2O_3 ratio reached 0.02 (Figure 5b). It should be noted that ± 30 mV is the limiting value for effective electrostatic stabilization. Further ACVA addition thus increased ζ-potential up to 13 mV, which was inadequate to stabilize the particles; consequently, they aggregated. The coating efficiency of PDMAAm was further deduced from a comparison of maghemite modified by solution radical polymerization of DMAAm with a sample obtained by the addition of separately prepared PDMAAm to the maghemite colloid. The data shown in Table 1 (Nos. 2 and 4) argue in favor of solution polymerization.

The effect of the amount of the monomer in the polymerization feed at constant amounts of initiator and maghemite is shown in Table 1 for experiments No. 5 and 11−14. Particle aggregation occurred with amounts of 1.5 g or more DMAAm in the feed, probably because of the undesirable physical cross-linking of PDMAAm chains and the increased viscosity of the reaction mixture. At a constant amount of initiator in the feed, the percentage of PDMAAm bound to the particles did not change with increasing amounts of DMAAm (with the exception of No. 14 in Table 1 because of the high viscosity of the mixture), thus documenting the key role of the amount of initiator on encapsulation efficiency.

The effect of the amount of γ-Fe_2O_3 added in the feed under otherwise identical conditions is documented by experiments No. 5 and 15−18 in Table 1. While the particle diameter was almost constant (within the experimental error), the amount of bound PDMAAm decreased with increasing amounts of γ-Fe_2O_3 in the feed, as expected.

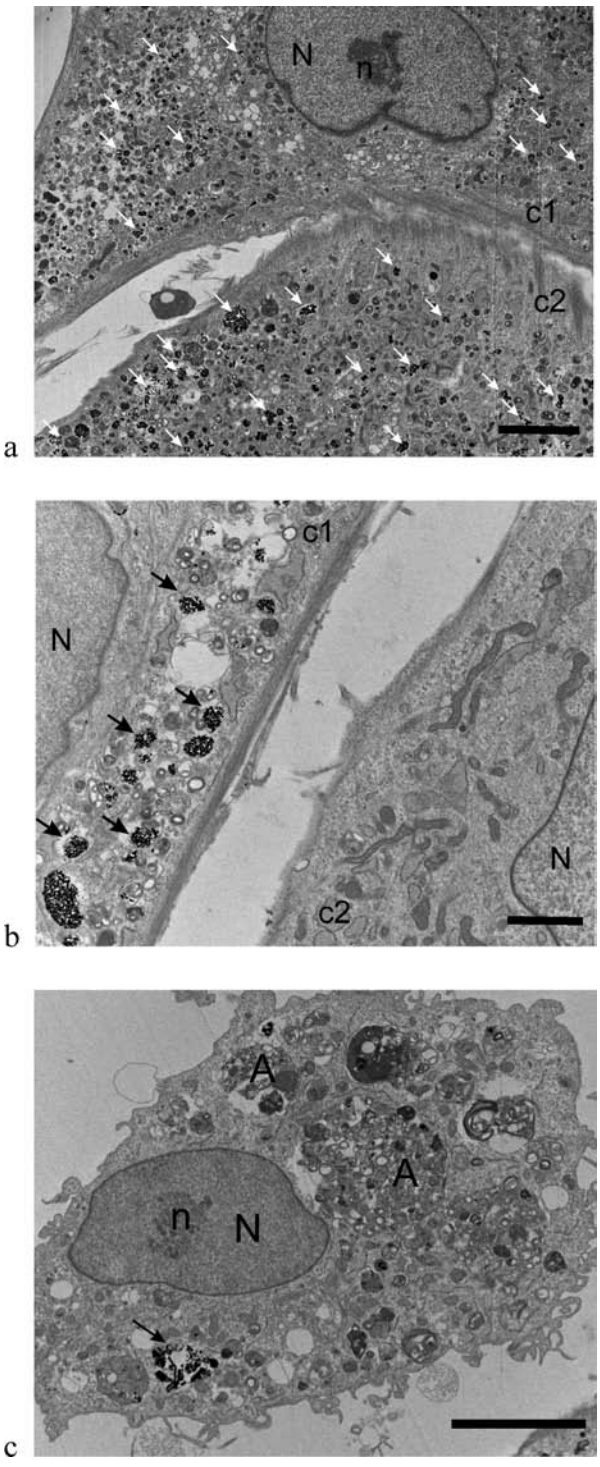

Figure 8. TEM micrographs of rMSCs labeled with (a) PDMAAm-coated γ-Fe_2O_3 nanoparticles, (b) Endorem, and (c) uncoated γ-Fe_2O_3. Arrows indicate nanoparticles inside the endosomes. A, autophagosome; N, nucleus; n, nucleolus; c1 and c2, cell 1 and cell 2, respectively. Scale bar: a,c, 500 nm; b, 200 nm.

Colloidal Stability. The long-term colloidal stability of PDMAAm-coated maghemite nanoparticles is of utmost importance for prospective biological applications. The stability of some dispersions over time was determined by DLS (Figure 6). Almost no increase in the hydrodynamic size and consistently low polydispersity over several months were observed in colloid No. 18, thus documenting its perfect stability in water due to the presence of the PDMAAm coating. The colloidal stability of such samples is denoted as very high in Table 1. The good colloidal stability suggests that the stabilization of the maghemite nanoparticles was primarily dependent on the steric repulsion of the attached hydrophilic PDMAAm chains. In comparison, uncoated nanoparticles No. 1 were unstable. Both the hydrodynamic diameter and polydispersity of these particles increased with time because of aggregation. Similarly, the stability of nanoparticles No. 13, prepared in the presence of large amounts of monomer, was poor. This can be explained by the high viscosity of the polymerization mixture, as a consequence of which the PDMAAm chains could entangle, resulting in particle aggregation. This is documented by the extremely large size and polydispersity determined by DLS in Figure 6a,b.

Viability of Cells. In order to examine the acute toxicity of PDMAAm-coated maghemite nanoparticles, both rMSCs and hMSCs were incubated for 72 h with sample No. 7, uncoated nanoparticles No. 1, and Endorem (control) at concentrations of 15 μg γ-Fe_2O_3/mL, and cell viability was assessed using the WST-1 assay. The viability of both rat and human MSCs labeled with PDMA nanoparticles did not markedly decrease compared to that of unlabeled MSCs (control). When mesenchymal stem cells were labeled with Endorem, their viability decreased by 32%, and uncoated nanoparticles decreased the viability by 15% (Figure 7a). However, the TEM images showed that the cells labeled with uncoated nanoparticles were undergoing programmed cell death (see below); therefore, in long-term follow up the viability would be affected.

Cell Labeling Efficiency. To investigate the role of the PDMAAm coating and its effect on the internalization of the maghemite nanoparticles by target cells, both hMSCs and rMSCs were incubated with PDMAAm-coated nanoparticles No. 7 or Endorem; uncoated maghemite nanoparticles served as controls. The uptake of nanoparticles into the cells (expressed as the percentage of labeled cells) was investigated using Prussian Blue staining. The cellular uptake of particles generally depends on the cell type and the particle size and surface properties, including surface charge and surface hydrophilicity (*27, 28*). It also depends on the number of passages of the cells, which is a characteristic physiological cell property. The lower the passage, the more efficient the cell labeling. The most intensive staining of any iron oxide nanoparticles was thus observed for cells from the first and second passages, while the intensity of the blue staining decreased in the fifth passage (only 30% of cells were labeled with Endorem). rMSCs cultured with PDMAAm-coated maghemite nanoparticles showed considerably higher nanoparticle uptake (59%) than those cultured with Endorem (39%; Table 2). This means that the number of rMSCs labeled by PDMAAm-coated γ-Fe_2O_3 was more than 50% higher than the number labeled by Endorem. Moreover, the labeling efficiency (percentage of labeled cells) was stable and was not dependent on the number of passages (Figure 7b). Even higher PDMAAm-nanoparticle uptake was observed in hMSCs (82%; Table 2), whereas Endorem uptake was 68%. The number of hMSCs labeled by PDMAAm-coated γ-Fe_2O_3 was thus more than 20% greater than the number labeled by Endorem. Histograms showing the intensity of Prussian Blue staining, which corresponds to the amount of label inside the cell, revealed that more cells were intensely stained with PDMAAm-coated nanoparticles than with Endorem or maghemite (Figure 7c). These results were even more apparent or amplified in hMSCs (Figure 7d). Although a relatively large number of cells were labeled with uncoated maghemite nanoparticles, the advantage of the PDMAAm coating consists in the possibility of its modification, thus introducing desired functional groups. An additional substantial advantage of PDMAAm-coated γ-Fe_2O_3 exists in the stability of the formed colloid, in contrast to uncoated γ-Fe_2O_3 nanoparticles that coagulate after the addition of the culture media. Coagulation of uncoated maghemite nanoparticles also leads to the attachment of the nanoparticles

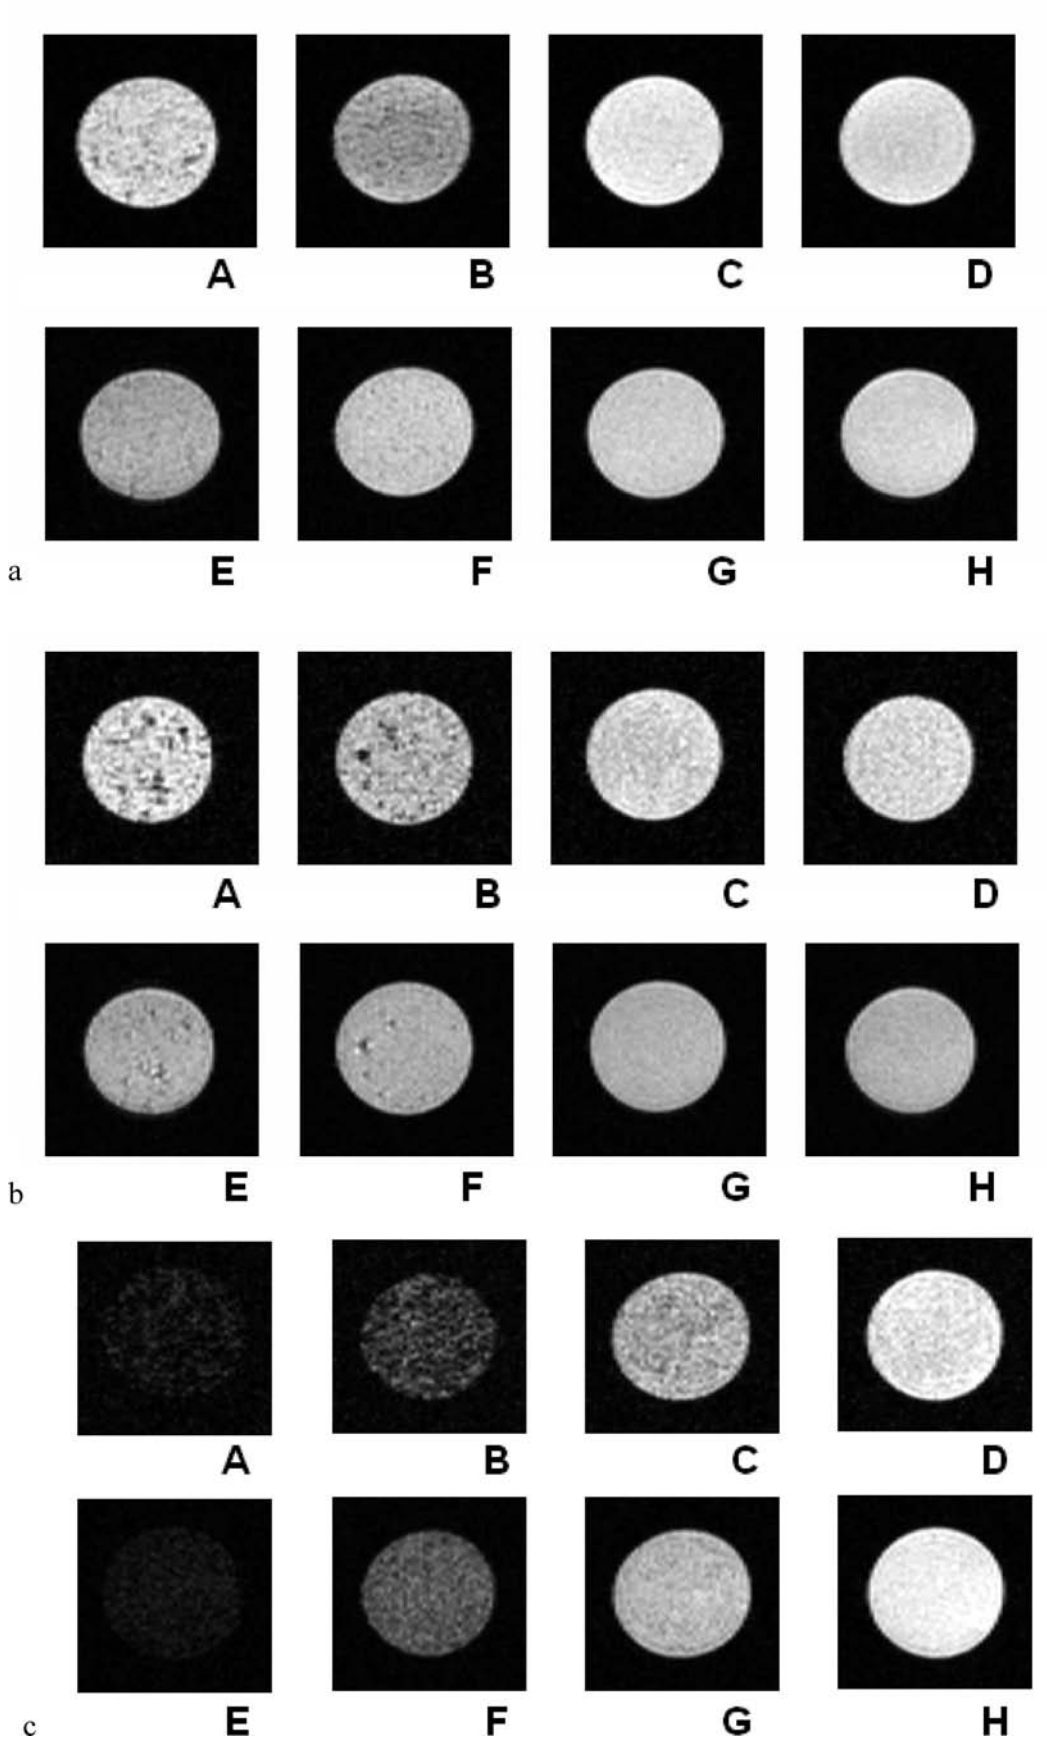

Figure 9. MRI of phantoms containing labeled (a) human and (b) rat mesenchymal stem cells suspended in gelatin measured by a T_2*-weighted gradient echo sequence (A−D) and by a T_2-weighted turbo-spin echo sequence (E−H). A,E, cells labeled by PDMAA-coated maghemite nanoparticles No. 7; B,F, cells labeled by uncoated maghemite nanoparticles No. 1; C,G, cells labeled by Endorem; D,H, unlabeled cells. Each sample (0.5 mL) contained 25,000 cells, yielding on average 1 cell per image voxel. For comparison, an MRI of phantoms containing a high number (400,000) of labeled human cells is shown in c; the phantoms are in the same order as in a.

Table 3. Relaxation Rates r_1 and r_2 (Related to Cell Concentration) of hMSCs and rMSCs Labeled with Endorem (Control), Uncoated (Control) No. 1, and PDMAAm-Coated Maghemite Nanoparticles No. 7, and the Amount of Iron Internalized Inside the Cells[a]

	hMSCs ($s^{-1}/10^6$) cells/mL)				rMSC ($s^{-1}/10^6$ cells/mL)			
	r_1 (0.5 T)	r_2 (0.5 T)	r_2 (4.7 T)	Fe (pg/cell)	r_1 (0.5 T)	r_2 (0.5 T)	r_2 (4.7 T)	Fe (pg/cell)
Endorem	undetectable	0.88 ± 0.34	1.7 ± 0.5	3.2 ± 0.5	0.21 ± 0.19	0.13 ± 0.14	0.72 ± 0.09	undetectable

[a] Measured at 0.5 and 4.7 T.

Figure 10. T_2-weighed MR image of a rat brain with 5,000 rMSCs labeled with PDMAAm-coated nanoparticles No. 7 or Endorem, implanted in the left or right hemisphere, respectively. White and black arrows indicate the injection sites in the head and the nanoparticles in the brain, respectively.

to the cell surface. This effect is also responsible for the high labeling efficiency of uncoated maghemite nanoparticles. It was difficult to distinguish using light microscopy whether the nanoparticles were inside the cells or just attached to the cell surface. Cells with iron oxides attached to the surface are better targets for macrophages after transplantation, and iron oxides incorporated into macrophages can also give a false positive signal on MRI.

TEM Images. Intracellular uptake was also visualized with TEM as it provides higher resolution than does light microscopy. While these methods cannot provide a quantitative measurement of cellular uptake, they demonstrate the importance of visualization to determine the distribution of particles on a cellular and subcellular level. PDMAAm chains are thought to form a complex with surface charges on the cell surface or else have an affinity with the cell membrane that facilitates endocytosis. A TEM image (Figure 8) shows that the cells internalized the PDMAAm-coated maghemite nanoparticles in large numbers and accumulated them in endosomes. Organelles and cell structures were not affected by the presence of coated nanoparticles inside the cells. However, the majority of cells labeled with uncoated maghemite were undergoing programmed cell death, probably by autophagia. The cells contained large autophagosomes, recognized in micrographs as membrane bound organelles with other organelles clearly contained within them, together with uncoated nanoparticles (Figure 8b). MSCs stained with Endorem showed a heterogeneous distribution of the nanoparticles. Some of the cells contained numerous endosomes filled with nanoparticles, others only a few or none (Figure 8c). The results obtained from TEM images are in agreement with those of our colorimetric analysis of the intensity of Prussian Blue staining (Figure 7c) as well as with those obtained from MR relaxometry (see text below and Table 3).

NMR Relaxometry. The iron oxide concentration of labeled rat and human cells was assessed using MR relaxometry. Relaxation rates measured at 0.5 and 4.7 T are listed in Table 3. Relaxation rates r_1 and r_2 are related to the number of cells per mL after subtracting the contribution of unlabeled cells. At a higher field strength (4.7 T), the contribution of all the particles to total r_1 was negligible; the values are therefore not provided. PDMAAm-coated iron oxide-labeled human cells provided significantly higher r_1 and r_2 at both 0.5 and 4.7 T fields than Endorem- and uncoated-iron-oxide-labeled cells. Large differences were obtained in the relaxation rates of PDMAAm-labeled human and rat cells, with r_2 several times higher for human cells. PDMAAm-coated iron oxide-labeled rat cells provided higher relaxation rates than Endorem-labeled ones; however, they were quite comparable to data obtained from uncoated-iron-oxide-labeled cells. Iron analysis proved that the higher relaxation rates of PDMAAm-coated or uncoated iron-oxide-labeled cells compared with Endorem-labeled ones are caused mainly by higher iron internalization (Table 3). It is interesting to note that human cells prefer PDMAAm-coated nanoparticles to both Endorem and uncoated ones, whereas in the case of rat cells, uncoated iron particles are internalized slightly better than PDMAAm-coated ones (both nanoparticles are internalized at a markedly higher rate than Endorem). These results are in good agreement with the relaxometry results.

MR Imaging of Cells after Nanoparticle Internalization in Gelatin. Gelatin samples with suspended cells labeled by PDMAAm-coated iron oxide nanoparticles, Endorem, and bare particles were examined by MRI to evaluate the potential of PDMAAm-coated iron oxide nanoparticles as a targeted MR contrast agent. Figure 9 compares MR images of cell phantoms. The T_2-and T_2*-weighted MR images of phantoms containing cells incubated with PDMAAm-coated and uncoated iron oxide nanoparticles show a significant negative contrast enhancement (signal darkening) over those containing cells labeled with Endorem and unlabeled cells (Figure 9a,b). As the MR images are normalized during processing, it is not possible to decide (based on observation with the naked eye) which of the two types of nanoparticles provides better contrast. However, the MR image of phantoms containing a high number of cells (Figure 9c) unambiguously proves that cells labeled by PDMAAm-coated iron oxide nanoparticles show significantly higher negative contrast enhancement. The results thus confirm that there is a preferential uptake of PDMAAm-coated iron oxide nanoparicles, i.e., the amount of internalized iron is markedly higher (see also Table 3), especially in human cells.

In Vivo MR Imaging. Magnetic labeling and MRI were used to noninvasively monitor cells injected into rats. PDMAAm-coated iron-oxide- and Endorem-labeled rMSCs (5,000 cells in 5 μL of PBS) were injected into the left and right rat hemispheres, respectively. Only cells labeled with PDMAAm-coated iron-oxide nanoparicles (left hemisphere) were detected (Figure 10).

CONCLUSIONS

In this article, PDMAAm-coated γ-Fe_2O_3 nanoparticles were obtained by the solution radical polymerization of DMAAm in the presence of maghemite nanoparticles obtained by the

chemical coprecipitation of Fe(II) and Fe (III) salts with ammonium hydroxide and subsequent oxidation with sodium hypochlorite. The presence of the PDMAAm coating on the maghemite surface was confirmed by both elemental analysis and ATR FTIR spectroscopy. PDMAAm coating provided good dispersibility of the magnetic nanoparticles in an aqueous medium and substantially improved iron oxide colloidal stability in the culture medium compared with uncoated maghemite, which immediately precipitated or aggregated within 1 h. A key parameter determining the amount of PDMAAm bound on maghemite nanoparticles is the amount of initiator in the polymerization feed. The amount of the initiator also influences the stability of the colloid. A narrow range of reaction conditions (5−15 mg of ACVA in the feed) was found under which particle aggregation was avoided, and at the same time, PDMAAm coating of the particles was high. DLS data revealed that the particle sizes were not altered even after several months of incubation in water. The surface of the particles is the determining factor for the efficiency of cellular uptake. Magnetic cellular labeling was evaluated by Prussian Blue staining for iron content, T_2 relaxometry, and MR imaging of labeled cell suspensions. PDMAAm coating did not adversely affect the penetration of the iron oxide nanoparticles into cells. After 72 h of culture in media containing 15 μg of iron oxide per 1 mL, the morphology and viability of both rMSCs as well as hMSCs were close to those of unlabeled cells, suggesting the biocompatibility of the nanoparticles. PDMAAm-coated maghemite nanoparticles turned out to be particularly suitable for labeling rat and human MSCs for in vivo MR cell tracking. The PDMAAm-coated maghemite nanoparticles were shown to be taken up by the target cells at significantly higher levels than were Endorem nanoparticles coated with dextran, thus allowing a minimum amount of imaging agent to be used. In addition, the labeling was not dependent on cell passage number, which can be particularly useful for cell expansion. Significant contrast enhancement was demonstrated by cells labeled with PDMAAm-coated maghemite nanoparticles and implanted in a rat brain over cells labeled with Endorem.

The fact that PDMAAm coating of iron oxide nanoparticles improves cellular uptake is, to the best of our knowledge, a new observation yet to be published. In subsequent research, PDMAAm-coated maghemite nanoparticles can be further modified by covalent attachment of highly specific biomolecules (antibodies, peptides, etc.) to make labeling more specific. In potential applications, cells can be labeled in vitro with the nanoparticles prior to transplantation. After transplantation of the labeled cells, in vivo imaging monitors cell migration throughout the body. The ability to track the extent of migration following direct implantation or systemic injection in vivo using noninvasive MR imaging techniques is the greatest advantage of the described procedure. Cellular monitoring is particularly important for evaluating cell-based therapies.

ACKNOWLEDGMENT

The financial support of the Center for Cell Therapy and Tissue Repair No. 1M0538, the Grant Agency of AS CR (grants KAN201110651 and KAN200200651), the Grant Agency of the Czech Republic (203/09/1242) and the EC-FP6 project DiMI (LSHB-CT-2005-512146) is gratefully acknowledged.

Poly(ethylene glycol) (PEG) 5 kDa and 20 kDa have been previously conjugated to two anti-sialoadhesin (Sn) monoclonal antibodies (mAbs), SER-4 and 3D6, and shown to dramatically increase their inhibitory potency in solid-phase red blood cell binding assays. In the present study, we evaluated the effect of anti-Sn SER-4 and 3D6 mAbs PEGylation on their inhibition of cell adhesion in mouse peritoneal macrophages. We also examined whether Sn-mediated PEGylation could affect plasma membrane functions of macrophages as to prevent accessibility, binding, and endocytosis of macromolecules and particles. Conjugation of PEG to plasma membrane is known to cause immune tolerance by impairing protein−protein and cell−cell interactions. PEGylation of SER-4 and 3D6 mAbs increased by 4-fold their inhibition of Sn-mediated erythrocyte binding to macrophages. PEGylated SER-4 and 3D6 mAbs did not impair macrophage membrane integrity, cell metabolism, nor pinocytosis of macromolecules and phagocytosis of latex particles. Thus, PEGylation of antibodies directed to cell surface receptors could be potentially exploited in a therapeutic setting to increase inhibitory potency of antibodies without impairing vital functions of cells.

INTRODUCTION

The covalent coupling of poly(ethylene glycol) (PEG) to proteins is a well-established technique to enhance the therapeutic potential of peptides and proteins. Multiple benefits of PEGylation include prolongation of protein half-life in the body and elimination of its immunogenicity (for reviews, see *refs 1, 2*:). PEGylation has also been extended to cells and tissues. Red blood cells (RBC) were the first example of cell surface PEGylation to produce transfusable universal blood (*3*). The covalent coupling of PEG (molecular weight, MW, 5 kDa) to proteins exposed on RBC surfaces could attenuate the immunologic recognition of surface antigens without adversely affecting viability, morphology, deformability, and other membrane functions (*4, 3*). Interestingly, PEGylation of proteins exposed on the surface of rat pancreatic islets (PEG MW, 5 kDa) conferred immunotolerance of the islets without interfering with glucose homeostasis and islet viability in vitro (*5*). In vivo, the PEGylation of the islets extended their survival despite a reduced dose of immunosuppressive medication (*6*). The immunoprotective effect of PEG was mainly due to the large steric exclusion volume provided by the flexibility of PEG molecules.

In a recent study, we explored an additional benefit of PEGylation based on the concept of PEG-dependent steric hindrance. We showed that PEGylation of two monoclonal antibodies (mAbs), SER-4 and 3D6, directed to the macrophage adhesion molecule, sialoadhesin (Sn), dramatically increased their efficacy for blocking Sn-mediated interactions (*7*). Sn (Siglec-1, CD169) is a 185 kDa macrophage-restricted adhesion molecule and a member of the Siglec family of sialic acid binding immunoglobulin (Ig)-like lectins (*8*). Sn mediates sialic acid-dependent adhesion of macrophages to a range of cell types including lymphoid and myeloid cells (*9*). Sn was originally characterized in the mouse as a nonphagocytic sialic acid-dependent sheep erythrocyte receptor expressed on macrophage subsets (*10*), especially those in secondary lymphoid organs (*11*). Sn can be upregulated on monocytes and macrophages during inflammatory responses, including autoimmune diseases (*12, 13*), and on macrophages that infiltrate human breast tumors (*14*). The inhibitory potencies of PEGylated mAbs were evaluated using a well-defined solid-phase RBC binding assay in which recombinant Sn was coated on a plate and allowed to bind RBC in the presence and absence of anti-Sn mAbs. In this assay, neither unconjugated SER-4 nor 3D6 mAb was able to inhibit RBC binding to Sn when added alone, whereas both mAbs were originally identified as blocking antibodies for RBC binding to peritoneal macrophages (*15*). These contradictory results might be explained by the density of Sn coated on the microplate versus that expressed on macrophages. Considering that the interaction of Sn with sialoglycoconjugates is multivalent, the large amount of Sn coated on the plate generated a higher-order multivalency with sialoglycoconjugates on RBC surfaces (*16, 17*). Therefore, the high-density coating of Sn used in the solid-phase RBC binding assay led to higher avidity binding of RBC, which were less efficiently inhibited by SER-4 or 3D6.

The present study aimed to evaluate the inhibitory potency of PEGylated SER-4 and 3D6 in a cellular environment using peritoneal macrophages induced to express Sn (*18*). As PEGylation of cells, such as RBC, and pancreatic islets were shown to camouflage their surface and repel the binding of immune cells and proteins, we also tested the specificity of the inhibition, that is, we evaluated if Sn PEGylation, using PEGylated SER-4 and 3D6, only affected Sn-mediated macrophage interactions or led to Sn receptor-independent side effects, as to prevent the

[a] Plasma membrane integrity and cell metabolism of Sn-expressing TPM were assessed by LDH release, Trypan blue exclusion, and MTT reduction. Data are the mean ± SD of 3 pooled independent experiments (carried out in duplicate). [b] Tukey test, $p < 0.0001$.

accessibility, binding, and endocytosis of macromolecules and particles by macrophages.

EXPERIMENTAL PROCEDURE

Animals. Female C57BL6 mice were bred at the Faculty of Medicine animal facilities of the Université catholique de Louvain (Belgium) and used between 7 and 11 weeks of age. Animals had free access to tap water and laboratory diet during the experimental period. All experimental protocols with mice were approved by the Institutional Animal Care and Use Committee of the Faculty of Medicine of the Université catholique de Louvain.

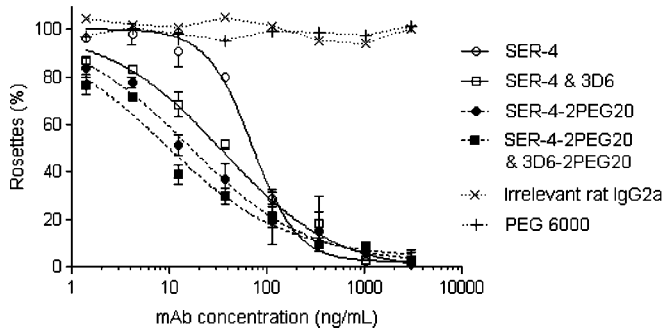
Preparation of Sn-Expressing Peritoneal Macrophages. Thioglycollate-elicited peritoneal macrophages (TPM) from female C57BL6 mice were obtained 4 days after intraperitoneal injection of 1 mL Brewer's modified thioglycollate broth. About 15 million cells per mouse were recovered by peritoneal lavage with 5 mL HBSS of which ~70% are macrophages (*19*). TPM were seeded at 1.25×10^6 macrophages/cm^2 on collagen I precoated multiwell tissue culture plate (Corning Life Sciences, Lowell, MA, USA) in RPMI 1640 supplemented with 2 mM L-glutamine and 10% fetal bovine serum. Nonadherent cells were removed by washing after 40 min of incubation in a humidified atmosphere at 37 °C in 5% CO_2. In order to induce sialoadhesin expression, TPM were incubated in fresh medium supplemented with 2 mM L-glutamine and 10% C57BL6 mouse serum during 3 days (*18*).

PEGylation of SER-4 and 3D6 mAbs. The most amine reactive groups of SER-4 and 3D6 mAbs were conjugated to 1 or 2 molecules of PEG 5 kDa or 20 kDa, as previously described (*7*). Modification of mAb with PEG molecules was abbreviated; for example, SER-4−2PEG 5 kDa and denotes a modification of SER-4 mAb with 2 linear PEG chains of 5 kDa.

Evaluation of Cell Membrane Integrity and Cell Metabolism. After 3 days in culture with mouse serum, Sn-expressing TPM were washed with RPMI + 0.1% BSA and precooled at 4 °C. Fcγ receptors on TPM surfaces were blocked using a rat monoclonal antibody against mouse CD16/32 receptors (clone 2.4G2, 1:150) at 4 °C for 20 min. Cells were then incubated with fresh serum-free medium containing 10 μg/mL of SER-4−2PEG 20 kDa, 3D6−2PEG 5 kDa, 3D6−1PEG 20 kDa, 3D6−2PEG 20 kDa, or a combination of SER-4−2PEG 20 kDa and 3D6−2PEG 20 kDa at 4 °C for 45 min. Cells were finally transferred in a humidified atmosphere at 37 °C in 5% CO_2 during 4 h. Plasma membrane integrity of cells after incubation with PEGylated mAbs was assessed by the release of lactate dehydrogenase (LDH) and the exclusion of Trypan blue. LDH activity was assessed by measuring the NADH consumption during the reduction of pyruvate into lactate (*20*). Results were expressed as the percentage of activity detected in the medium over the sum of the activities in the medium and in the cells. Trypan blue exclusion results were expressed as the percentage of viable cells. Cell metabolism was assessed by the reduction of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT), a yellow water-soluble tetrazolium dye reduced by metabolically active cells to a water-insoluble purple formazan (*21*). Results were expressed as the percentage of metabolically active cells. In all assays, untreated cells and Triton-treated cells were used as controls.

Red Blood Cell Rosetting Assay. 5×10^4 TPM were added in wells of a collagen I precoated 48-well tissue culture plate and induced to express Sn by culture in 10% mouse serum for 3 days. Cells were washed with RPMI + 0.1% BSA and precooled at 4 °C. Fcγ receptors on TPM surface were blocked, as described above, at 4 °C for 20 min. Cells were then incubated with 300 μL of 3-fold serial dilutions of the different species of SER-4-PEG or 3D6-PEG alone or in combination at 4 °C for 45 min. Three hundred microliters of freshly prepared human RBC at 1% vol/vol was added directly to the wells and incubated at 37 °C for 30 min. Unbound RBC were removed by repeated washing with medium. The percentage of macrophage binding of >4 RBC, i.e., rosettes, was determined under optical microscopy (100 cells counted; Axiovert S100, Zeiss, Minneapolis, MN, USA) (*22*). The percentage of rosettes was normalized to the percentage of rosetting activity in the absence of mAbs (considered to be equal to 100%). As controls, TPM were incubated with an irrelevant rat IgG2a, to test the specificity of mAbs, or with nonfunctional PEG in RPMI + 0.1% BSA, to evaluate a possible nonspecific effect of the polymer on RBC binding. In the latter case, the concentration of PEG solution was adjusted to the number of PEG molecules found in a solution composed of a mixture of both PEGylated mAbs.

Characterization of Endocytosis Modes. *Nonspecific Adsorptive Endocytosis.* FITC-albumin was used as tracer of nonspecific adsorptive endocytosis (*23*). Sn-expressing TPM were first washed with warm medium without serum and incubated at 37 °C during 30 min. The uptake of FITC-albumin by Sn-expressing TPM was measured using increasing concentrations of FITC-albumin in serum-free medium at 37 °C for 2 h. After 6 washes for 30 s with PBS-Ca^{2+}-Mg^{2+} (removing 75−80% of tracers bound at 4 °C), intracellular uptake of FITC-albumin was measured in cell lysates prepared in 0.05% (vol/vol) Triton X-100 by fluorimetry (λ_{exc} 485 nm, λ_{em} 530 nm; Packard Fluorocount Microplate Fluorometer, Packard Instrument Company, Meriden, CT, USA). For competition studies, fresh serum-free medium containing 700 μM bovine albumin (A4378, Sigma-Aldrich, St Louis, MO, USA) was incubated with Sn-expressing TPM 1 h at 4 °C prior to a coincubation with 7 μM FITC-albumin at 37 °C for 2 h. Cells were then washed 6 times with PBS-Ca^{2+}-Mg^{2+} and digested with 0.05% (vol/vol) Triton X-100. Energy depletion of Sn-expressing TPM was performed by incubation with 5 mM sodium azide (NaN_3) and 60 mM 2-deoxy-D-glucose (2-DOG) in serum-free medium (ATP depletion medium). Cells were preincubated in ATP



Inhibitor	IC_{50} (ng/mL)
SER-4	70.2 ± 3.5
3D6	71.2 ± 6.7
SER-4 & 3D6	36.7 ± 9.2
SER-4-2PEG20	16.0 ± 2.6
3D6-2PEG5	8.8 ± 1.0
3D6-1PEG20	9.1 ± 0.7
3D6-2PEG20	10.7 ± 2.3
SER-4-2PEG20 & 3D6-2PEG20	8.8 ± 2.2

Figure 1. Inhibition of RBC binding to Sn-expressing TPM by PEGylated SER-4 and 3D6 mAbs. Data are the mean ± SD of two pooled independent experiments (carried out in duplicate). Rosette formation is the % of macrophages that bound >4 RBC. IC_{50} are concentrations inhibiting 50% of rosette formation. Experiments with irrelevant IgG2a and PEG 6 kDa used in comparable concentrations did not show any inhibitory effect on rosette formation.

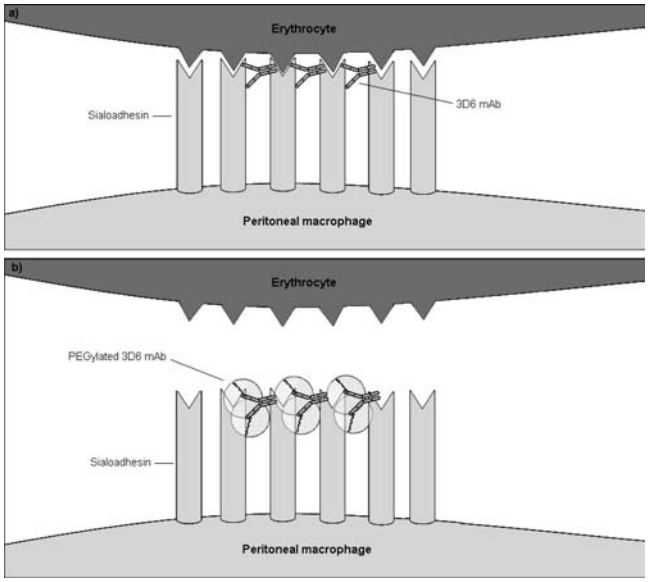


Figure 2. Creation of a sterical hindrance by PEG on Sn molecules. Interaction between an erythrocyte and a macrophage occurs when both sialic acids and Sn cluster, to create high-avidity binding. At the same concentration, unmodified 3D6 mAb did not inhibit erythrocyte binding to the macrophage (a), whereas PEGylated 3D6 mAb did (b). The higher potency of PEGylated mAbs to inhibit erythrocyte binding was likely due to a sterical effect created by PEG molecules around Sn.

depletion medium at 37 °C for 20 min and incubated with 7 μM FITC-albumin in ATP depletion medium for 2 additional hours. Cells were then washed 6 times with PBS-Ca^{2+}-Mg^{2+} and digested with 0.05% (vol/vol) Triton X-100.

Receptor-Mediated Endocytosis. Iron-saturated transferrin was labeled with ^{125}I using iodogen-precoated tubes to a specific radioactivity of 2600−3300 cpm/ng protein. Sn-expressing TPM surface binding of ^{125}I-transferrin was determined by incubating cells precooled at 4 °C with increasing concentrations of ^{125}I-transferrin in serum-free medium supplemented with 0.1% BSA for 1 h. Cells were then washed and radioactivity was measured in cell lysates prepared in 0.05% (vol/vol) Triton X-100 (Minaxiγ gamma counter, Packard Instrument Company, Meriden, CT, USA). For competition studies, human serum was incubated with Sn-expressing TPM 1 h at 4 °C prior to a coincubation with 50 nM ^{125}I-transferrin for one additional hour at 4 °C. Cells were then washed 6 times with PBS-Ca^{2+}-Mg^{2+} and surface-digested with 0.2% (wt/vol) Pronase in RPMI at 4 °C for 45 min to distinguish transferrin accessible on the plasma membrane (Pronase-sensitive) from sequestered transferrin (Pronase-resistant) (*24*). Pronase-resistant fraction (containing intracellular ^{125}I-transferrin) was pelleted by centrifugation at 250 × *g* at 4 °C for 5 min. The supernatant (containing surface-accessible transferrin) was kept, and the pellet was finally washed twice with PBS-Ca^{2+}-Mg^{2+} and lysed in 0.05% (vol/vol) Triton X-100. Radioactivity was measured in Pronase-resistant and Pronase-sensitive fractions. Energy depletion of Sn-expressing TPM was performed by incubation in ATP depletion medium at 37 °C for 20 min (see above). Cells were then precooled at 4 °C and incubated with 50 nM ^{125}I-transferrin in ATP depletion medium for 1 h. Cells were washed and reincubated at 37 °C in fresh prewarmed ATP depletion medium for 10 min. Cells were then rapidly cooled down to 4 °C, washed 6 times with PBS-Ca^{2+}-Mg^{2+}, surface digested, and radioactivity in Pronase-resistant and Pronase-sensitive fractions were measured.

Internalisation Assays. Sn-expressing TPM were first washed with warm medium without serum and incubated at 37 °C over 30 min. Cells were washed and precooled at 4 °C. Fcγ receptors on TPM surface were blocked as described above at 4 °C for 20 min. Cells were finally washed and incubated with a combination of SER-4−2PEG 20 kDa and 3D6−2PEG 20 kDa at 4 °C for 45 min prior to incubation with tracers of endocytosis.

FITC-Albumin Endocytosis. FITC-albumin was directly added to cells at a final concentration of 7 μM and incubated at 37 °C for the indicated intervals. Cells were washed 6 times with PBS-Ca^{2+}-Mg^{2+}, and intracellular uptake of FITC-albumin was measured on sonicated cell lysates prepared in 0.05% (vol/vol) Triton X-100 by fluorimetry.

^{125}I-Transferrin Endocytosis. ^{125}I-transferrin was directly added to cells at a final concentration of 50 nM and allowed to bind at 4 °C for 1 h. Cells were washed 6 times at 4 °C with PBS-Ca^{2+}-Mg^{2+} and reincubated at 37 °C in fresh prewarmed serum-free medium supplemented with 0.1% BSA for the indicated intervals. Cells were then rapidly cooled down to 4 °C, washed, and surface-digested with 0.2% (wt/vol) Pronase in RPMI at 4 °C for 45 min. Radioactivity was measured in Pronase-resistant and Pronase-sensitive fractions to distinguish intracellular from surface-accessible transferrin.

Phagocytosis. Red fluorescent carboxylate-modified latex beads of 2 μm were used as tracer of phagocytosis. Following the incubation with PEGylated mAbs, an equivalent volume of latex beads in serum-free medium was added directly to the wells at a final concentration of 270 beads/nL, mixed, and incubated at 37 °C for the indicated intervals. After 6 washes for 30 s with PBS-Ca^{2+}-Mg^{2+} (removing more than 80% of the beads bound at 4 °C), uptake of the beads was measured on sonicated cell lysates prepared in 0.05% (vol/vol) Triton X-100 by fluorimetry (λ_{exc} 485 nm, λ_{em} 610 nm). To inhibit phagocytosis (*25*), Sn-expressing TPM were first preincubated with 10 μM cytochalasin B in serum-free medium at 37 °C for 30 min

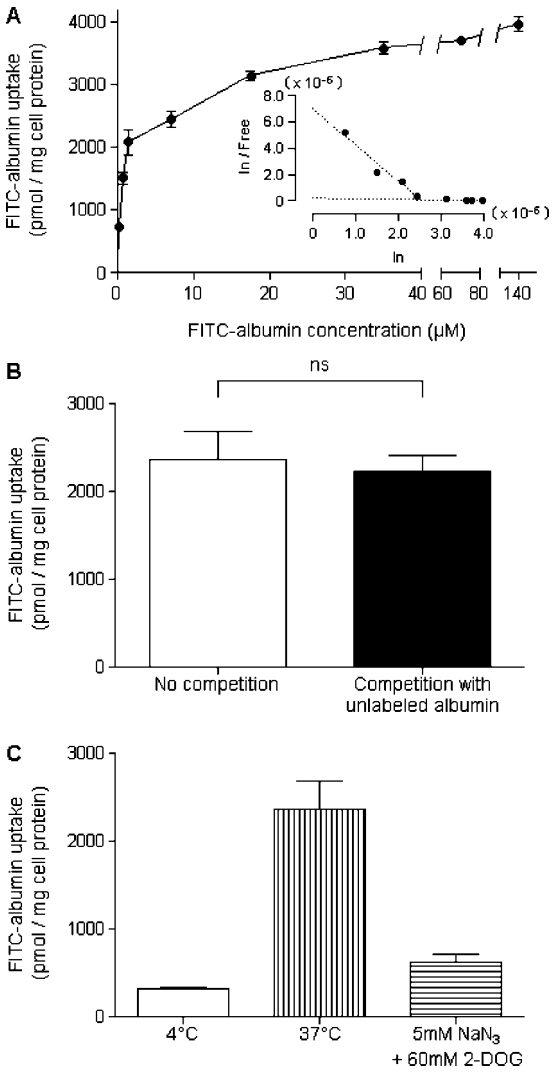

Figure 3. FITC-albumin is taken up by nonspecific adsorptive endocytosis in Sn-expressing TPM. (A) Adsorptive uptake of FITC-albumin. FITC-albumin uptake was measured as a function of substrate concentration in untreated cells at 37 °C for 2 h. Inset, scatchard analysis of the uptake (In values in abscissa are in μmol/μg cell protein; In/Free ratios in the ordinate are in L/μg cell protein). Two components of internalization were revealed with a high internalization constant ($K_{uptake} = 0.36\ \mu$M) for the first one and a low internalization constant for the second one ($K_{uptake} = 18.88\ \mu$M). (B) No competition for FITC-albumin uptake at 37 °C for 2 h. Cells were incubated with 7 μM FITC-albumin alone (open bar) or with a 100-fold excess of unlabeled albumin (filled bar); ns: no significant difference (*t* test, $p > 0.05$). (C) Endocytic uptake of FITC-albumin is evidenced by inhibition at low temperature and upon energy depletion. Cells were incubated with 7 μM FITC-albumin at 4 °C for 1 h (open bar) or at 37 °C for 2 h (vertically striped bar). Cellular ATP was depleted by incubating cells in ATP depletion medium at 37 °C for 20 min. Cells were then incubated with 7 μM FITC-albumin in ATP depletion medium at 37 °C for 2 h (horizontally striped bar).

and incubated with latex beads (270 particles/nL) in serum-free medium containing 10 μM cytochalasin B at 37 °C for the indicated intervals. Cells were then washed 6 times 30 s with PBS-Ca^{2+}-Mg^{2+} and digested with 0.05% (vol/vol) Triton X-100.

Localization of Fluorescent Latex Beads in Sn-Expressing TPM by Confocal Microscopy. Untreated and PEGylated cells, that is, pretreated with the combination of SER-4−2PEG 20 kDa and 3D6−2PEG 20 kDa, were incubated with 1 μm green-fluorescent latex beads or 2 μm red-fluorescent latex beads at 37 °C for 3 h, washed 6 times 30 s with PBS-Ca^{2+}-Mg^{2+}, and were fixed at room temperature in 4% paraformaldehyde for 30 min. Cells were then washed 5 times with PBS and aspecific sites were blocked by incubation in BSA/lysine solution at room temperature for 30 min. To label the surface membrane of Sn-expressing TPM, rat antimouse F4/80 mAb (1:200) was incubated in BSA/lysine solution at room temperature for 1 h. Cells were then washed 6 times 5 min with BSA/lysine and incubated with Alexafluor 647-conjugated goat antirat IgG antibody (1:200) at room temperature for 1 h. Cells were finally washed 6 times 5 min with PBS, postfixed in 4% paraformaldehyde, washed 3 times with PBS, and mounted on glass slides with mowiol. Cells were observed with a Zeiss confocal laser scanning microscope LSM510 Meta-multiphoton. Data were analyzed with Zeiss LSM software to obtain $x-y$, $x-z$, and $y-z$ views of cells.

Fate of Anti-Sn mAbs. 3D6 mAb was labeled with ^{125}I using iodogen-precoated tubes to a specific radioactivity of 2800−3500 cpm/ng of protein. Fcγ receptors on Sn-expressing TPM surface were blocked, and cells were then surface-labeled with 5 μg/mL ^{125}I-3D6 mAb in serum-free medium supplemented with 0.1% BSA at 4 °C for 45 min. Fresh prewarmed serum-free medium was then directly added to ^{125}I-3D6 solution in wells, and cells were incubated at 37 °C for the indicated intervals. Cells were then rapidly cooled down to 4 °C, washed 6 times with PBS-Ca^{2+}-Mg^{2+}, and surface-digested with 0.2% (wt/vol) Pronase in RPMI for 45 min as described above.

Analysis. All data were normalized to the cell protein content. Protein concentrations were measured by microBCA protein assay using BSA as the protein standard. Unless otherwise stated, results were expressed as mean ± standard deviation (SD) of 3 wells of 1 representative experiment. Statistical comparisons of experimental values (by unpaired *t* test or one-way analysis of variance (ANOVA) test and Tukey post-test) and other mathematical analyses were performed using the GraphPad *Prism* software for Windows (v 5.00, La Jolla, CA, USA). Differences were considered significant at $p < 0.05$.

RESULTS AND DISCUSSION

SER-4 and 3D6 are monoclonal rat IgG2a anti-Sn antibodies directed to two distinct epitopes of mouse Sn, domains 2 and/or 3 for SER-4, and domain 1 for 3D6 (*9*). We showed previously in solid-phase binding assays that PEGylation of SER-4 and 3D6 mAbs strongly promoted their inhibitory potencies against RBC binding (*7*). SER-4 carrying 2 molecules of PEG 20 kDa (SER-4−2PEG 20 kDa) or 3D6 carrying 2 molecules of PEG 5 kDa (3D6−2PEG 5 kDa) alone each resulted in about 75% inhibition, which was only reached by the combination of unmodified mAbs. Moreover, 3D6 carrying 1 or 2 molecules of PEG 20 kDa (3D6−1PEG 20 kDa or 3D6−2PEG 20 kDa) could totally inhibit RBC binding as shown by serial dilutions. When SER-4-PEG and 3D6-PEG were tested in combination, their inhibitory potency further increased in line with the degree of PEGylation.

In the present study, only these derivatized mAbs and the combination of SER-4 and 3D6 with 2 molecules of 20 kDa were tested. SER-4 and 3D6 mAbs with other extents of derivatization that did not inhibit RBC binding in solid-phase assays were not studied.

Effect of PEGylated Anti-Sn mAbs Binding on Sn-Expressing TPM Viability. PEG molecules larger than 400 Da are considered nontoxic, and PEG has been approved by the FDA for use in food and cosmetics (*26*). However, Murad et al. showed that, when surface of RBC was highly derivatized with PEG 5 kDa, PEGylation induced adverse structural and functional effects on cells (*4*). Therefore, in the present assay, we evaluated the effect of PEGylated SER-4 and 3D6 on Sn-expressing TPM viability and cell function using different cytotoxicity assays (Table 1): LDH release and Trypan blue

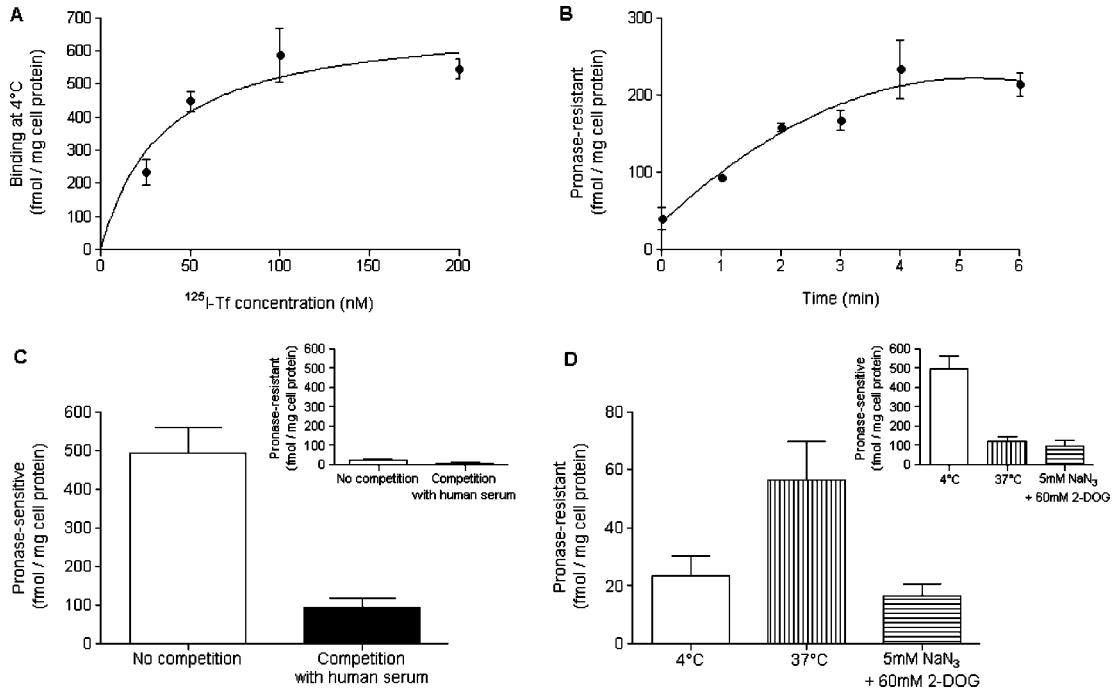

Figure 4. ^{125}I-transferrin endocytosis by Sn-expressing TPM. (A) Specific binding of ^{125}I-transferrin at increasing concentrations at 4 °C. (B) Kinetics of ^{125}I-transferrin internalization. Cells were surface-labeled with 50 nM ^{125}I-transferrin at 4 °C, washed, and reincubated at 37 °C in transferrin-free medium for the indicated intervals. Increase in Pronase-resistant counts indicate values of intracellular transferrin. (C) Competitive binding of ^{125}I-transferrin at 4 °C. Cells were incubated with ^{125}I-transferrin in serum-free medium for 1 h (open bar) or incubated with human serum for 1 h then with ^{125}I-transferrin in human serum for an additional hour (filled bar). Pronase-sensitive counts indicate values of surface-accessible transferrin. Inset, Pronase-resistant counts of the same cells. (D) Endocytosis of ^{125}I-transferrin is evidenced by incubation at low temperature and upon energy depletion. Cells were surface-labeled with 50 nM ^{125}I-transferrin at 4 °C and then washed (open bar) or further reincubated at 37 °C in transferrin-free medium for 10 min (vertically striped bar). ATP-depleted cells were surface-labeled at 4 °C with 50 nM ^{125}I-transferrin in ATP depletion medium for 1 h, washed, and reincubated at 37 °C in ATP depletion conditions for 10 min (horizontally striped bar). Inset, Pronase-sensitive counts of the same cells.

exclusion to assess plasma membrane integrity and MTT reduction to determine the metabolic activity. In these assays and in the subsequent ones, we tested the PEGylated mAbs concentration that inhibited with the highest efficacy the binding of RBC to Sn in solid-phase binding assay (*7*). Whatever the PEGylated mAbs, none of them showed any appreciable damage to the plasma membrane or alteration of metabolic activity of TPM.

Inhibition of RBC Binding to Sn-Expressing TPM by PEGylated Anti-Sn mAbs. In order to assess the inhibitory potency of PEGylated SER-4 and 3D6 mAbs on Sn-mediated interaction in a cellular environment, we used peritoneal macrophages induced to express Sn. As already shown (*22*), parent SER-4 and 3D6 mAbs inhibited RBC binding to macrophages with a high efficacy when used alone (Figure 1). However, PEGylated mAbs used alone were all better inhibitors than unconjugated SER-4 or 3D6 mAbs used alone or in combination. On the basis of IC_{50}, SER-4 containing 2 molecules of PEG 20 kDa was a 4-fold stronger inhibitor than unlabeled SER-4. The combination of SER-4 and 3D6, each carrying 2 molecules of PEG 20 kDa resulted in an IC_{50} of ~9 ng/mL, a 4-fold reduction IC_{50} as compared to the mixture of the non-PEGylated mAbs. This suggested that PEG molecules conferred an additional sterical hindrance around the antibody and, hence, around the receptor that prevented with higher efficacy the RBC approach (as illustrated in Figure 2). To verify that the decreased RBC binding was not the result of a nonspecific interaction of PEG molecules with macrophage surfaces, RBC binding to TPM was evaluated after incubation with PEG alone (Figure 1). PEG was not able to inhibit RBC binding by itself, indicating that the increased inhibitory potency provided by PEGylated mAbs was not due to a nonspecific binding of the polymer to the macrophage surface. Because it was the most efficient, further studies were carried out with the combination of SER-4 and 3D6 coupled with 2 molecules of PEG 20 kDa.

Effect of Sn-Mediated PEGylation of Macrophages on Albumin and Transferrin Endocytosis. Scott et al. have shown that, when erythrocytes are PEGylated, the rapid motility and molecular flexibility of the heavily hydrated PEG chains affect the global surface of cells and prevent protein−protein interactions as antibody-mediated RBC agglutination via blood group antigen (*27*). Therefore, PEGylation of Sn-expressing TPM with PEGylated SER-4 and 3D6 mAbs could affect the entire cell surface and thereby impair endocytosis mechanisms of macrophages, one of their key functions. This was examined by a series of endocytosis assays.

Nonspecific Adsorptive Endocytosis of Albumin by Sn-Expressing TPM. Nonspecific adsorptive endocytosis is a saturable process at high concentration involving, prior to internalization, interaction with nonspecific sites on the plasma membrane. In contrast to kidney proximal tubules or endothelial cells, albumin is internalized in macrophages by nonspecific interaction (*23*) and is accepted as a tracer of nonspecific adsorptive endocytosis in this cell type (*28*). To characterize the nonspecific adsorptive endocytosis of albumin in Sn-expressing TPM, its uptake was investigated in various conditions (Figure 3). FITC-albumin uptake was measured as a function of substrate concentration in untreated cells. Figure 3A shows saturation of uptake at a concentration of 17.5 μM indicating that FITC-albumin is internalized via a process saturable at high concentration, characteristic of adsorptive endocytosis. The efficiency of accumulation after 2 h was estimated at about 150×10^6 molecules per cell, i.e., 2 orders of magnitude higher than fluid-phase endocytosis. Subsequent studies were carried out at a nonsaturating albumin concentration (7 μM). To further clarify whether the binding of FITC-albumin

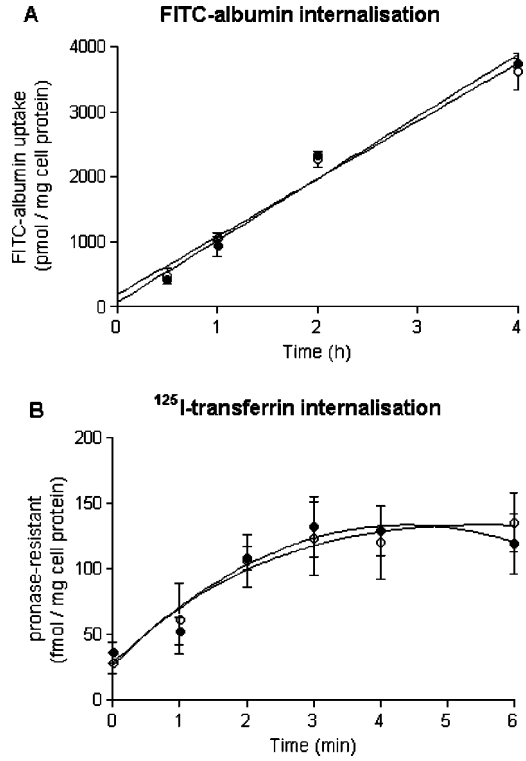

Figure 5. Effect of PEGylated anti-Sn mAbs on nonspecific adsorptive endocytosis of FITC-albumin (A) and on receptor-mediated endocytosis of ^{125}I-transferrin (B) in Sn-expressing TPM. Cells were either left untreated (open circles) or pretreated with a combination of SER-4−2PEG20 and 3D6−2PEG20 both at 10 μg/mL (filled circles) at 4 °C for 45 min. (A) FITC-albumin was added at a final concentration of 7 μM and cells were reincubated at 37 °C for the indicated intervals. Experiments were reproduced twice with similar results. (B) After incubation with 50 nM ^{125}I-transferrin at 4 °C for 1 h, cells were reincubated at 37 °C in transferrin-free medium for the indicated intervals. Increase of Pronase-resistant counts indicate the amounts of intracellular transferrin. Experiments were reproduced three times with similar results.

to Sn-expressing TPM was specific or not, a competition study was carried out using a 100-fold excess of unlabeled albumin (Figure 3B). Unlabeled albumin did not affect the uptake of FITC-albumin, indicating that this tracer binds nonspecifically to Sn-expressing TPM surface. To confirm that FITC-albumin was taken up by endocytosis, we looked at the effect of low temperature and energy depletion. Figure 3C shows that both treatments dramatically reduced the uptake of FITC-albumin in macrophages. Taken together, these results confirm that TPM induced to express Sn internalize albumin by nonspecific adsorptive endocytosis.

Receptor-Mediated Endocytosis of Transferrin by Sn-Expressing TPM. Receptor-mediated endocytosis is a specific adsorptive endocytosis mode characterized by the specific binding of a ligand to its cell surface receptor followed by internalization of ligand−receptor complexes. Transferrin is the most commonly used tracer of receptor-mediated endocytosis, and its internalization was at first studied in peritoneal macrophages induced to express Sn (Figure 4). As shown in Figure 4A, ^{125}I-transferrin binding at 4 °C to untreated TPM reached saturation at ∼600 fmol/mg cell protein, corresponding to ∼35 000 binding sites/cell, with an apparent K_d of 30 nM. Further studies were carried out with an initial concentration of 50 nM ^{125}I-transferrin (below saturation). Pronase-resistant or intracellular transferrin increased very rapidly (∼3500 molecules/cell/min) to level off after ∼6 min (Figure 4B), a time sufficient for apotransferrin−receptor complexes to be recycled on the cell surface (*29*). In a competition study, human serum (containing 35 μM transferrin) significantly decreased the binding of ^{125}I-transferrin to the cell surface, indicating that this tracer specifically binds to Sn-expressing TPM in a receptor-dependent manner (Figure 4C, Pronase-sensitive fraction). As expected for endocytosis, acquisition of intracellular ^{125}I-transferrin was largely inhibited at 4 °C (Figure 4D). Since formation of clathrin-coated pits and -vesicles supporting receptor internalization requires cellular ATP, receptor-mediated endocytosis is an energy-dependent process (*30*). Cellular ATP of Sn-expressing TPM was depleted, and ^{125}I-transferrin internalization was studied for 10 min. Figure 4D shows that ATP depletion significantly reduced the uptake of ^{125}I-transferrin in macrophages. Cellular ATP depletion also reduced the binding of ^{125}I-transferrin (Figure 4D, inset), as ATP is also needed for the recycling of transferrin receptors (*31*). These results indicate that TPM induced to express Sn internalize transferrin via receptor-mediated endocytosis.

Effect of PEGylated Anti-Sn Mabs on Nonspecific Adsorptive Endocytosis of Albumin and Receptor-Mediated Endocytosis of Transferrin. To assess the effect of PEGylated anti-Sn mAbs on FITC-albumin and ^{125}I-transferrin uptake in Sn-expressing TPM, the combination of SER-4−2PEG 20 kDa and 3D6−2PEG 20 kDa mAbs was incubated with cells at 4 °C prior to addition of 7 μM FITC-albumin or 50 nM^{125}I-transferrin. PEGylation of Sn-expressing TPM using PEGylated SER-4 and 3D6 impaired neither the binding nor the kinetics of internalization of either FITC-albumin or ^{125}I-transferrin at any time (Figure 5). Uptake of FITC-albumin (Figure 5A) and intracellular accumulation of ^{125}I-transferrin into cells (Figure 5B) were comparable in PEGylated and untreated TPM. PEGylation of Sn expressed on the TPM surface using PEGylated mAbs inhibited neither nonspecific adsorptive nor specific receptor-mediated protein interactions, and this might be explained in two ways. First, as Jang et al. showed that surface PEGylation of pancreatic islets could not completely prevent the infiltration of cytotoxic molecules into the islets (*32*), we suggest that PEG molecules coupled to antibodies directed to Sn on the TPM surface did not prevent the passage of macromolecules, such as albumin and transferrin, across the meshes of PEG. Second, it remains possible that the specific and local PEGylation of Sn expressed on TPM surface using PEGylated mAbs had no sterical impact on the whole cell surface and therefore did not prevent the approach, the binding and the internalization of albumin and transferrin (as illustrated in Figure 6). Indeed, the studies on pancreatic islets showed that an efficient immunocamouflage of cells by PEG is in part governed by the surface concentration of PEG (*33*): the higher the cell surface covered by PEG molecules, the higher the PEG hindrance.

Effect of Sn-Mediated PEGylation of Macrophages on Phagocytosis of Latex Beads. Phagocytosis is a receptor- and actin-dependent process utilized by mononuclear phagocytes and neutrophils to ingest and clear large particles (>0.5 μm) (*34*). This internalization process serves to remove foreign particles such as parasites or to remove host cells such as apoptotic bodies (*35*). Scott et al. showed that PEGylation of sheep erythrocytes could inhibit their phagocytosis without impairing protein interactions such as antibody-mediated agglutination via blood group antigen (*27*). Therefore, although PEGylation of Sn expressed on the TPM surface did not affect the internalization of macromolecules such as albumin and transferrin, it could negatively affect phagocytosis of particles. In comparison with macromolecules, particles of larger size could not easily escape the sterical effect created by PEG molecules on the cell surface.

Phagocytosis of Latex Beads by Sn-Expressing TPM. The effect of PEGylation of TPM surface on phagocytosis was investigated by studying the accumulation of red fluorescent

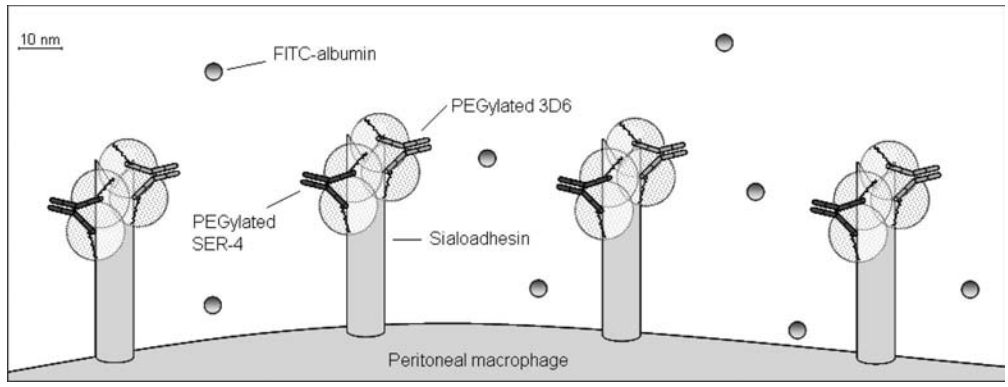

Figure 6. SER-4 and 3D6 mAbs modified with 2 molecules of PEG 20 kDa did not inhibit protein interactions with Sn expressing macrophages. The specific and local PEGylation of Sn expressed on macrophage surface using PEGylated SER-4 and 3D6 mAbs had no sterical impact on the whole cell surface and therefore did not prevent the approach, the binding and the internalization of albumin. The number of Sn molecules per cell was estimated from the number of ^{125}I-3D6 mAbs bound per cell (see Figure 10), and Sn molecules were homogenously distributed on the macrophage surface.

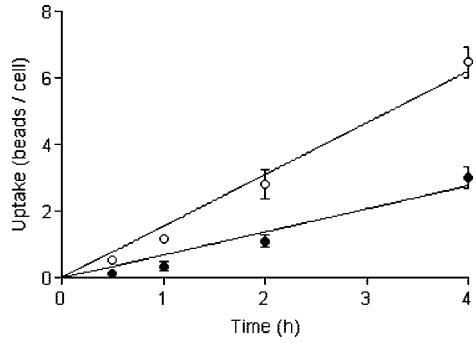

Figure 7. Inhibition of 2 μm red fluorescent latex beads phagocytosis in Sn-expressing TPM by 10 μM cytochalasin B. Sn-expressing TPM were either left untreated (open circles) or preincubated with 10 μM cytochalasin B at 37 °C for 30 min (filled circles). A final concentration of 270 beads/nL was added and cells were reincubated at 37 °C for the indicated intervals.

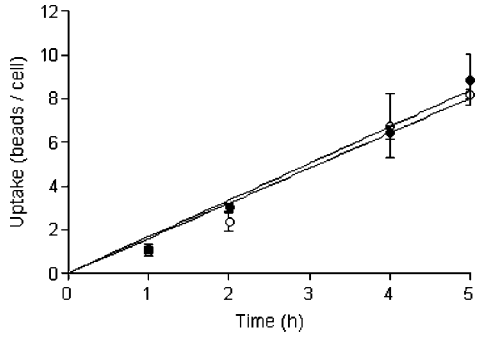

Figure 8. Effect of PEGylated anti-Sn mAbs on phagocytosis of 2 μm red fluorescent latex beads in Sn-expressing TPM. Cells were either left untreated (open circles) or pretreated with a combination of SER-4−2PEG20 and 3D6−2PEG20 both at 10 μg/mL (filled circles) at 4 °C for 45 min. A final concentration of 270 beads/nL was added, and cells were reincubated at 37 °C for the indicated intervals. Experiments were reproduced three times with similar results.

carboxylate-modified polystyrene latex beads of a large size (2 μm, 270 particles/nL). Latex beads can be taken up by both pinocytosis and phagocytosis, but the relative contribution of phagocytosis increases with the particle diameter (*25*). Figure 7 shows that 2-μm-diameter latex beads were largely internalized by phagocytosis, as suggested by a ∼50% inhibition by cytochalasin B, an inhibitor of microfilaments formation during phagocytosis (*36*).

Effect of PEGylated Anti-Sn Mabs on Phagocytosis of Latex Beads. To assess the effect of PEGylation of Sn-expressing TPM on phagocytosis, the combination of SER-4−2PEG 20 kDa and 3D6−2PEG 20 kDa mAbs was first incubated with cells at 4 °C prior to addition of latex beads at a final concentration of 270 particles/nL. Figure 8 shows that PEGylation of Sn on TPM did not detectably interfere with phagocytosis. The rate of accumulation of the beads was constant and identical in PEGylated cells as compared with untreated cells. Internalization of latex beads by both untreated and PEGylated cells was confirmed by confocal microscopy. Internalization of 1 μm latex beads was observed into both untreated (Figure 9A) and PEGylated cells (Figure 9B) by reference to the plasma membrane that was immunolabeled in blue using anti-F4/80 mAb. The same observations were made with 2 μm latex beads (data not shown).

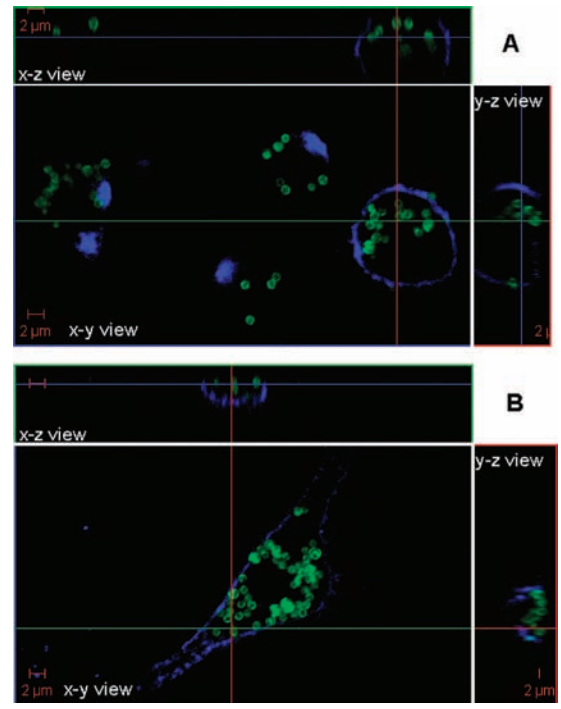

Figure 9. Effect of PEGylated anti-Sn mAbs on phagocytosis of latex beads in Sn-expressing TPM: localization of latex beads in untreated (A) and PEGylated (B) macrophages. After incubation with 1 μm latex beads (green; 270 beads/nL) for 3 h, cells were fixed and incubated wit rat antimouse F4/80 mAb, then with Alexafluor 647-conjugated goat antirat IgG antibody to identify the plasma membrane (blue).

These results suggest that PEGylation of Sn expressed on the TPM surface using PEGylated mAbs only hindered the

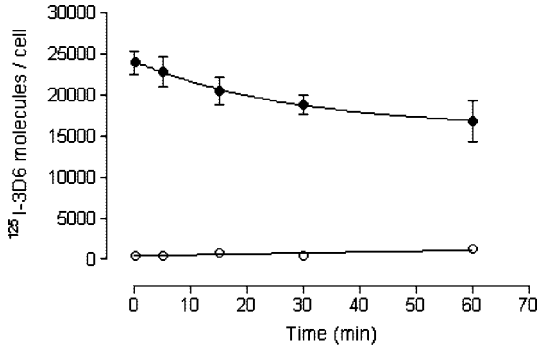

Figure 10. Fate of ^{125}I-3D6 mAb in Sn-expressing TPM. Cells were surface-labeled with 5 μg/mL ^{125}I-3D6 mAb at 4 °C for 45 min. Fresh, prewarmed serum-free medium was then directly added to ^{125}I-3D6 solution in wells, and cells were incubated at 37 °C for the indicated intervals. Intracellular 3D6 mAb molecules (open circles) were distinguished from surface-accessible 3D6 mAb molecules (filled circles) by digestion of cell surface with 0.2% (wt/vol) Pronase.

receptor and its environment. Consequently, the PEG hindrance did not affect the whole cell surface and did not impair the binding and uptake of particles.

Fate of ^{125}I-Anti-Sn mAb in Sn-Expressing TPM. Our present study shows that Sn-mediated PEGylation of macrophages improves the inhibition of cell adhesion activity of Sn without affecting pinocytosis of macromolecules and phagocytosis of particles. To verify that the absence of effect on endocytosis and phagocytosis was not due to a shedding of PEGylated mAbs from the cell surface, we studied the fate of ^{125}I-3D6 mAb in Sn-expressing cells (Figure 10). ^{125}I-3D6 mAb was not detectably internalized when cells were incubated at 37 °C (Figure 10, open circles, Pronase-resistant counts), and shedding of ^{125}I-3D6 mAb bound to the cell surface was moderate (Figure 10, Pronase-sensitive counts) over 1 h. Binding of ^{125}I-3D6 mAb at 4 °C to Sn-expressing TPM reached 400 fmol/mg cell protein, corresponding to ~24 000 molecules/cell. A slight release of ^{125}I-3D6 mAb was observed during the first 15 min at 37 °C (~230 molecules/cell/min), decreasing the number of binding sites to ~20 000 molecules/cell. Then, an equilibrium between bound mAbs and free mAbs in solution kept the binding of ^{125}I-3D6 mAb to Sn-expressing cell surface almost constant over 1 h. The release of mAbs from the cell surface slowed down to ~80 molecules/cell/min, and ~17 000 molecules of ^{125}I-3D6 mAb remained bound to the cell surface after 1 h at 37 °C (Figure 10, filled circles, Pronase-sensitive counts).

In conclusion, this study reports that PEGylation of SER-4 and 3D6 mAbs directed to the macrophage adhesion molecule, Sn, greatly increases their efficacy to inhibit RBC Sn-mediated binding to macrophages as compared with unmodified mAbs. Flexibility and motility of PEG molecules on SER-4 and 3D6 mAbs most likely create a steric hindrance around antibodies that increases the inhibition of RBC specific binding to Sn. Moreover, we show that a local Sn-mediated PEGylation of macrophages and the consequent steric effects of PEG are safe to cells, as PEGylated SER-4 and 3D6 mAbs did not impair membrane integrity, cell metabolism nor the pinocytosis of macromolecules and the phagocytosis of particles close to the size of bacteria. Thus, PEGylation of antibodies directed to cell surface receptors could be potentially exploited in a therapeutic setting, such as autoimmune or inflammatory diseases, to increase the inhibitory potency of antibodies without impairing vital cell functions.

Target antigen-specific cytotoxic T lymphocytes (CTLs) play a key role in anticancer and antivirus immunity in the body, and purification of CTLs from heterogeneous immune cells is desired for an efficient cancer immunotherapy and fundamental research. Herein, a novel magnetic nanoparticle conjugated with major histocompatibility complex (MHC)/peptide complexes was developed for the magnetic separation of melanoma-specific CTLs. To conjugate biotinylated MHC/peptide complexes on nanosized bacterial magnetic particles (BacMPs), which were synthesized intracellularly by magnetotactic bacteria, phased modification of biotin and streptavidin onto BacMPs was investigated. When biotin was modified on BacMPs, a polyethylene oxide (PEO)-linker contributed to the maintenance of the high dispersion properties of BacMPs. Furthermore, nonspecific binding of BacMPs to cell surface was prevented by controlling the level of streptavidin bound on BacMPs and through PEO blocking of the empty streptavidin sites on BacMPs. Finally, single-step magnetic separation of melanoma-specific CTLs was demonstrated using developed MHC/MAGE-1 A24 peptide complex-conjugated BacMPs. Melanoma-reactive cells and melanoma-specific CTLs were successfully separated from stimulated peripheral blood mononuclear cells derived from a vaccinated melanoma patient with 93.1% and 87.7% purity, respectively, and specificity of antigen recognition and cytokine secretion from separated CTLs were confirmed. The potential of MHC/peptide complex-conjugated BacMPs was indicated for efficient separation of antigen-specific CTLs in cancer immunotherapy and fundamental research.

INTRODUCTION

Cytotoxic T lymphocytes (CTLs) become activated when, through T cell receptors (TCRs), they recognize major histocompatibility complex (MHC)/peptide complexes that are present on the surface of cancer cells and other infected cells. Once activated, they clonally expand and trigger a cytotoxic response against these cells. CTLs play a key role in anticancer and antivirus immunity. Single CTLs, which express individual TCRs, recognize a pair of antigenic peptides and polymorphic helices of MHC proteins with one-to-one correspondence (*1, 2*). For effective immunotherapy using CTLs, target antigen-specific CTLs must be purified from various cell mixtures, such as those in blood samples, and significant demand persists for the development of efficient CTL separation technology.

Separation of target cells from a heterogeneous cell mixture is used widely in biological and medical applications. Among current cell separation techniques, magnetic cell sorting is a popular tool for isolating cells such as monocytes, B-lymphocytes, and hematopoietic stem cells (CD14, CD19, and CD34 positive cells, respectively) from peripheral blood (*3*−*6*). The use of antibody-conjugated magnetic particles (immunomagnetic particles) is a proven, rapid, and simple technique relative to fluorescence-activated cell sorting (FACS) (*7*). Antibodies conjugated on magnetic particles usually recognize antigens on the surface of target cells (e.g., CD markers), and cells labeled with magnetic particles are successfully separated from unlabeled cells. However, for the separation of antigen-specific CTLs, immunomagnetic particles are not effective, and alternative magnetic particles are required. For the separation of antigen-specific CTLs from cell mixtures, tetrameric MHC/peptide complexes, which combine purified and biotinylated single MHC/peptide complexes with PE-labeled streptavidin (MHC/peptide tetramer), have been used to label target cells that are then separated by flow cytometric sorting (*8*−*10*). However, improvements in throughput and absolute sterility of the flow cytometer are required, and thus, a magnetic separation system that uses magnetic particles to recognize antigen-specific CTLs was considered suitable for the separation of CTLs.

The magnetotactic bacterium synthesizes intracellular nanosized bacterial magnetic particles (BacMPs) of 50 to 100 nm in diameter that are covered with a stable lipid bilayer. BacMPs, which have a single magnetic domain of magnetite and exhibit strong ferrimagnetisms, can be collected easily with commercially available permanent magnets. The lipid membrane provides BacMPs with a high surface area and good dispersion properties, creating various applications for BacMPs. Magnetic cell separation using BacMPs has been reported previously (*11*−*14*), and many cell types were separated with high purity from peripheral blood mononuclear cells (PBMCs) or whole blood directly using BacMPs displaying protein A or protein G, which are IgG binding proteins, conjugated to antibodies. Furthermore, this system is not only simple but also noninvasive to the separated cells, because BacMPs are collectable using available permanent magnets rather than the special magnetic columns needed for the collection of commercialized magnetic nanoparticles. Therefore, we hypothesized that the magnetic cell separation system using BacMPs will be suitable for efficient

separation of antigen-specific CTLs, furthering the application of CTLs in immunotherapy.

In this report, novel magnetic particles were developed for the separation of melanoma-specific CTLs. First, MHC/MAGE-1 A24 peptide complexes that are presented on the surface of melanoma cells were conjugated on BacMPs by a chemical procedure. The prevention of nonspecific binding of BacMPs to the cell surface was considered critical in this process. Furthermore, antibody-independent magnetic separation of melanoma-specific CTLs from in vitro stimulated PBMCs derived from a vaccinated melanoma patient was performed using the MHC/MAGE-1 A24 peptide complex-conjugated BacMPs, and the function of separated CTLs was confirmed.

EXPERIMENTAL PROCEDURES

Cultivation of Magnetic Bacteria. *M. magneticum* AMB-1 was microaerobically cultured in magnetic spirillum growth medium at 28 °C as previously described (*15*). Microaerobic conditions were established by sparging the cultures with argon gas. Batch cultures were prepared in 10 L media bottles. AMB-1 transformants were cultured under these conditions in 5 μg/mL ampicillin.

Preparation of BacMPs. BacMPs were purified from AMB-1, according to the methods of Tanaka and Matsunaga (*16*). Cultured cells were collected by centrifugation, suspended in 40 mL of HEPES (10 mM) buffer (pH 7.4), and disrupted by three passes through a French press cell at 1500 kg/cm^2 (Ohtake Works Co. Ltd., Tokyo, Japan). BacMPs were collected from cell debris using a neodymium−iron−boron (Nd−Fe−B) magnet. Collected BacMPs were washed with HEPES buffer at least 10 times. During each wash, BacMPs were dispersed by ultrasonication and collected using the Nd−Fe−B magnet. The concentration of BacMPs in suspension was estimated by optical density at 660 nm (OD_{660}) using a spectrophotometer (UV-2200, Shimadzu, Kyoto, Japan). Purified BacMPs were stored at 4 °C in phosphate buffered saline (PBS) solution.

Immobilization of Streptavidin on BacMPs. BacMPs (5 mg) were incubated with 1 mM Sulfo-NHS-LC_2-Biotin (Pierce, Rockford, IL, USA) or 1 mM Sulfo-NHS-PEO_{12}-Biotin (Pierce) in 5 mL of borate buffer (pH 8.0) for 1 h at room temperature with pulsed sonication every 3 min (Figure 1-I). After incubation, biotin-modified BacMPs were magnetically separated from the reaction mixture using the Nd−Fe−B magnet and washed with PBS buffer containing 0.1% (v/v) Tween 20 (one time) and then PBS buffer (two times). BacMPs (3 mg) were then incubated with 0.125−1 μM Alexa488-labeled streptavidin (Invitrogen, Carlsbad, CA, USA) in 3 mL of PBS buffer for 1 h at room temperature with pulsed sonication (Figure 1-II). Streptavidin-immobilized BacMPs (SA-BacMPs) were washed three times with PBS buffer using the Nd−Fe−B magnet to remove excess non-immobilized streptavidin and suspended in PBS buffer containing 0.1% sodium azide before use. In the three washing steps, all supernatants were collected, and the fluorescence intensity of each solution was measured using a microplate reader at an excitation of 485 nm and an emission of 520 nm. The amount of Alexa488-labeled streptavidin that was not immobilized on biotin-modified BacMPs was calculated from the fluorescence intensity attained from a calibration curve, and streptavidin immobilized on biotin-modified BacMPs was then calculated by deducing the amount of non-immobilized streptavidin from initially added streptavidin. The number of streptavidin immobilized on a single BacMP was calculated from the amount of streptavidin immobilized on biotin-modified BacMPs (BacMP diameter = 75 nm and BacMP density = 5.2 g/cm^3).

Analysis of Size Distribution of SA-BacMPs. The size distributions of SA-BacMPs biotinylated with Sulfo-NHS-LC_2-Biotin or Sulfo-NHS-PEO_{12}-Biotin were analyzed using an electrophoretic light scattering spectrophotometer (ELS-8000, Otsuka Electronics, Osaka, Japan). SA-BacMPs were added to 3 mL of deionized distilled water to achieve a final concentration of 10 μg/mL. Solutions were sonicated prior to measurement.

Conjugation of MHC/Peptide Complexes to SA-BacMPs. SA-BacMPs (300 μg) were incubated with 0.75 μM biotinylated MHC/MAGE-1 A24 peptide (NYKHCFPEI) complexes (MBL, Nagano, Japan) or biotinylated MHC/HIV A24 peptide (RYLRDQQLL) complexes (MBL) in 600 μL of TNE buffer (10 mM Tris, 150 mM NaCl, 0.5 mM EDTA, and 0.1% sodium azide; pH 8.0) for 30 min at room temperature with pulsed sonication every 10 min (Figure 1-III). After three washes in PBS buffer, Amine-PEO_3-Biotin (10 mM, Pierce) in PBS buffer was added to MHC/peptide complex-conjugated BacMPs (500 μg/mL) to block empty streptavidin sites on BacMPs (Figure 1-IV). After incubation for 30 min at room temperature, MHC/peptide complex-conjugated BacMPs with PEO blocking were washed magnetically and preserved in PBS buffer containing 0.1% sodium azide until use.

The average number of MHC/peptide complexes conjugated on a single SA-BacMP was evaluated using alkaline phosphatase (ALP)-labeled antibodies. MHC/peptide complexes conjugated on SA-BacMPs (20 μg) were incubated with mouse IgG2a anti-β2 microglobulin monoclonal antibodies (40 μL sample, 30 μg/mL, Immunotech, Marseille, France) for 60 min at room temperature. After three washes, BacMPs were incubated with ALP-labeled antimouse IgG (20 μL sample, 10 μg/mL, Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA) for 30 min at room temperature. After three washes, the resuspended complexes (20 μL sample, 100 μg of BacMPs/mL) were mixed with 80 mL of Lumi-Phos 530 including Lumigen PPD {4-methoxy-4[3-phosphatephenyl]spirio[1,2-dioxetane-3,2′-adamantane] disodium salt} (3.3×10^{-4} M) as a luminescence substrate for alkaline phosphatase, and the resulting luminescence intensity

was measured by a Lucy-2 luminescence reader (Aloka, Co. Ltd., Tokyo, Japan). The numbers of ALP-labeled IgG (molecular weight of $F(ab)_2$ IgG = 100 kDa) were calculated from the luminescence intensity attained from a calibration curve. The values for the number of ALP-labeled IgGs were used to attain the number of MHC/peptide complexes conjugated on a single SA-BacMP.

Evaluation of Nonspecific Binding of BacMPs to Cell Surfaces. Raji cells (2×10^5 cells) in 50 μL of separation buffer (PBS buffer containing 0.5% bovine serum albumin (BSA) and 2 mM EDTA) were mixed with 10 μg of SA-BacMPs, MHC/MAGE-1 A24 peptide complex-conjugated BacMPs, or MHC/MAGE-1 A24 peptide complex-conjugated BacMPs with PEO blocking for 10 min at 4 °C. After washing by centrifugation, the cell suspension (1 mL) was transferred to a test tube (10 mm × 75 mm) and magnetically collected using the Nd−Fe−B magnet for 5 min. The dimensions of magnets used for cell separation were $20 \times 12 \times 5$ mm^3. The surface magnetic flux density of the magnets was 400 mT. The number of cells that were nonspecifically separated during magnetic separation was determined by direct cell counting under a microscope.

Preparation of CTLs. All PBMCs were derived from a metastatic melanoma patient given dendritic cell (DC) vaccines. Clinical research using PBMCs from melanoma patients was approved by the Institutional Review Board of the Shizuoka Cancer Center, Shizuoka, Japan. All patients gave written informed consent. PBMCs were stimulated twice in vitro with MAGE-1 A24 peptide-pulsed autologous DCs at a ratio of 1:10 to 1:100 in GT-T507 medium (Kohjin Bio Co., Saitama, Japan) supplemented with 2 mM L-glutamine, 100 U/mL penicillin, 100 μg/mL streptomycin, 50 μg/mL gentamycin, 50 μM β-mercaptoethanol, 1 mM sodium pyruvate, and 5% AB human serum (Cambrex, Walkerville, MD, USA) (referred to as CTL medium). Additionally, cultured CTLs were boosted weekly with two rounds of stimulation at a ratio of 1:10 with MAGE-1 A24 peptide-pulsed T2-A24 cells, which are a human hybrid (B and T lymphoblast) cell line transfected with the HLA-A24 gene (*17*).

Magnetic Cell Separation using MHC/MAGE-1 A24 Peptide Complex-Conjugated BacMPs. Stimulated PBMCs (1.5×10^7 cells) in 120 μL of staining buffer (PBS containing 2% fetal bovine serum (FBS) and 0.1% sodium azide) were reacted with 120 μL of allophycocyanin (APC)-labeled anti-CD8 mAb (BD Biosciences, San Jose, CA, USA) for 30 min on ice. After removing excess antibody by centrifugation, cell aliquots (2×10^6 cells) in 80 μL of separation buffer were incubated with 20 μL of MHC/MAGE-1 or HIV A24 peptide complex-conjugated BacMPs for 10 min at 4 °C. After washing by centrifugation, cells suspended in 1 mL of separation buffer were transferred to a test tube, and cells labeled by BacMPs were separated magnetically as described above. The magnetic separation was performed three times at intervals of 5 min. Magnetically separated cells were resuspended in staining buffer as a positive fraction. To analyze the ratio of melanoma-specific CTLs to CTLs suspension, CTLs (2×10^6 cells) stained with APC-labeled anti-CD8 mAb were reacted further with PE-labeled MHC/MAGE-1 A24 peptide tetramer (MBL) for 30 min on ice and washed with excess tetramer by centrifugation. The purity of targeted cells in separated cells and CTL suspensions was analyzed using a BD FACS Canto flow cytometer (Becton Dickinson, Franklin Lakes, NJ, USA). A total of 50 000 events were analyzed for each sample.

Measurement of IFN-γ Secreted by Separated Melanoma-Specific CTLs. MHC/MAGE-1 A24 peptide complex-conjugated BacMPs were fabricated by immobilizing 1 μM streptavidin and conjugating 0.5 μM MHC/MAGE-1 A24 peptide complexes on the biotin-modified BacMPs, and melanoma-specific CTLs were separated using the MHC/MAGE-1 A24 peptide complex-conjugated BacMPs using the protocol described above. After an overnight incubation in CTL medium, separated CTLs (1×10^5 cells) and MAGE-1 A24 peptide-pulsed TISI cells (1×10^5 cells), a human B-lymphoblastoid cell line presenting HLA-A24, were coincubated in a round-bottom 96-well microculture plate for 24 h in RPMI-1640 medium containing 5% FBS. Finally, supernatants were collected, and the amount of IFN-γ in the supernatants was measured using an ELISA kit specific for human IFN-γ (Biosource, Camallilo, CA, USA).

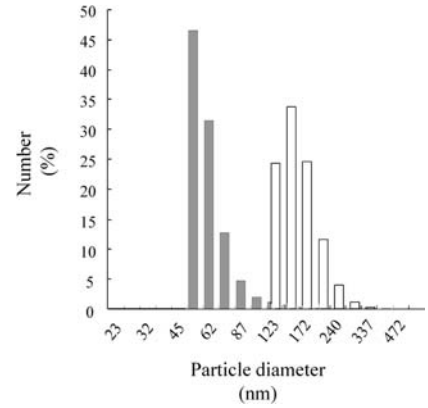

Figure 2. Particle size distribution of SA-BacMPs biotinylated with Sulfo-NHS-LC_2-biotin (empty bars) or Sulfo- NHS-PEO_{12}-biotin (solid bars).

RESULTS

Introduction of Biotin on BacMPs. To conjugate biotinylated MHC/peptide complexes on BacMPs, phased modifications of biotin and streptavidin onto BacMPs were studied. In the first step, biotin introduction onto BacMPs was performed by modifying the amine group on the surface of BacMPs. To modify biotin once on BacMPs, two amino-reactive cross-linkers, Sulfo-NHS-LC_2-Biotin (linker length: 30.5 Å) and Sulfo-NHS-PEO_{12}-Biotin (linker length: 56 Å), were individually reacted in the presence of BacMPs for covalent linkage between the amine group of BacMPs and the cross-linker. The dispersion of streptavidin-immobilized BacMPs (SA-BacMPs) that were biotinylated with LC_2-linker or PEO_{12}-linker was evaluated as the size distribution of the BacMPs in solution (Figure 2). The average diameter of SA-BacMPs biotinylated with the LC_2-linker was 159.4 ± 36.0 nm, and the average diameter of SA-BacMPs biotinylated with the PEO_{12}-linker was 63.3 ± 17.7 nm. SA-BacMPs biotinylated with the PEO_{12}-linker showed better dispersion due to the hydrophilic linker. Furthermore, as the diameter of BacMP is 50 to 100 nm, it was considered that multiple biotin-modified BacMPs did not bind to a streptavidin molecule.

Correlation Between the Number of Streptavidin Molecules Bound on BacMPs and Nonspecific Binding of BacMPs to Cell Surfaces. Streptavidin molecules were immobilized onto biotin-modified BacMPs with PEO_{12}-linker. Excessive immobilization of streptavidin, a highly hydrophobic molecule (*18*), on BacMPs was predicted to cause nonspecific binding of SA-BacMPs to cells. Therefore, the correlation between the number of streptavidin molecules bound on BacMPs and nonspecific binding of SA-BacMPs to cell surfaces was investigated. SA-BacMPs, which were prepared by reacting streptavidin with biotin-modified BacMPs at different concentrations, were incubated with Raji cells, and the number of cells, which were separated magnetically as a result of nonspecific binding of SA-BacMPs to cell surfaces, were counted directly

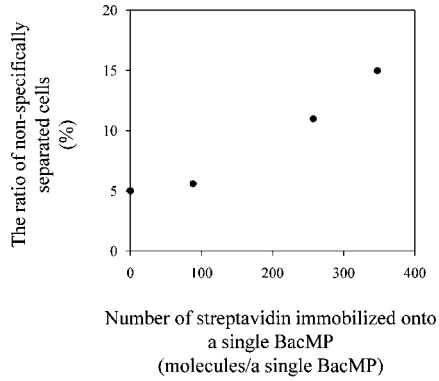

Figure 3. Correlation between the number of streptavidin molecules bound on a single BacMP and nonspecific binding of BacMPs to cell surface. The number of streptavidin molecules bound on a single biotin-modified BacMP was evaluated by measuring the fluorescence intensity of non-immobilized streptavidin in the supernatant. The numbers of Raji cells separated nonspecifically using each SA-BacMPs were counted, and then, the ratio of nonspecifically separated Raji cells was calculated

Table 1. Number of MHC/MAGE-1 Peptide Complexes Conjugated on a Single SA-BacMP on Which Different Number of Streptavidin Molecules Immobilized

Number of Streptavidin or MHC/MAGE-1 Peptide Complexes on a Single SA-BacMP (Molecules/a Single BacMP)	
streptavidin	MHC/MAGE-1 peptidecomplex
339 ± 10	16.0 ± 1.3
132 ± 21	17.9 ± 2.1

under a microscope. Then, the correlation between the number of streptavidin molecules immobilized on a single BacMP and nonspecific binding of SA-BacMPs to cell surfaces was estimated (Figure 3). The number of nonspecifically separated cells increased in proportion to the number of streptavidin molecules immobilized on BacMPs. Immobilization of approximately 100 streptavidin molecules on a single BacMP did not influence the nonspecific binding property of BacMPs. These results show that value of less than 100 streptavidin molecules per BacMP are suitable for efficient cell separation.

Fabrication of MHC/Peptide A24 Complex-Conjugated BacMPs with Little Nonspecific Binding to Cells. MHC/peptide complex-conjugated BacMPs were fabricated by reacting biotinylated MHC/peptide complexes with SA-BacMPs. The number of MHC/peptide complexes conjugated on a single SA-BacMP was evaluated using mouse anti-β2 microglobulin mAb and ALP- labeled antimouse IgG. Eighteen MHC/MAGE-1 A24 peptide complexes were conjugated per BacMP on which 100 streptavidin molecules were immobilized, and the number of MHC/MAGE-1 A24 peptide complexes per BacMP was almost equal to that of BacMPs on which over 300 streptavidin molecules were immobilized (16 MHC/MAGE-1 A24 peptide complexes, Table 1). From these results, we speculated that only 1 or 0 MHC/peptide complexes was bound to a single streptavidin molecule on BacMPs, and confirmed that many empty streptavidin sites remained immobilized on BacMPs. For blocking of these empty streptavidin sites and, therefore, suppression of nonspecific binding of BacMPs to cells, MHC/peptide complex-BacMPs were incubated with amine-PEO_3-biotin. The nonspecific binding of three different MHC/peptide complex-conjugated BacMPs to cells was evaluated (Figure 4), and nonspecific binding of BacMPs to cell surfaces was decreased markedly by PEO blocking on BacMP surfaces. The ratio of cells separated nonspecifically using MHC/MAGE-1 A24 peptide complex-conjugated BacMPs with PEO blocking was approximately one-sixth that observed using BacMPs without PEO blocking. These results suggest that PEO blocking

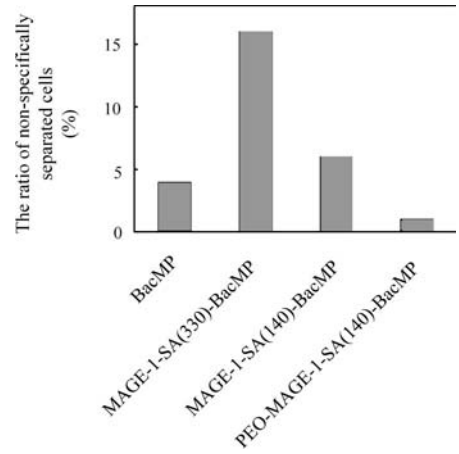

Figure 4. Nonspecific binding of BacMPs to the cell surface. The numbers of Raji cells separated nonspecifically using wild-type BacMPs (BacMP), MHC/MAGE-1 peptide complex-conjugated BacMPs on which 330 streptavidin molecules per BacMP (MAGE-1-SA(330)-BacMP), and 140 streptavidin molecules per BacMP (MAGE-1-SA(140)-BacMP) were immobilized, and MHC/MAGE-1 peptide complex-conjugated BacMPs with PEO blocking (PEO-MAGE-1-SA(140)-BacMP), on which 140 streptavidin molecules per BacMP were immobilized, were counted. Then, the ratio of nonspecifically separated Raji cells was calculated.

of MHC/MAGE-1 A24 peptide complex-conjugated BacMPs is necessary for the high-purity magnetic separation required for melanoma-specific CTLs. Therefore, we used PEO-blocked MHC/MAGE-1 A24 peptide complex-conjugated BacMPs for the following CTL separation experiments.

Magnetic Separation of Melanoma-Specific CTLs Using MHC/MAGE-1 A24 Peptide Complex-Conjugated BacMPs. Magnetic separation of melanoma-specific CTLs from in vitro stimulated PBMCs prepared from a vaccinated melanoma patient using MHC/MAGE-1 A24 peptide complex-conjugated BacMPs was performed and evaluated using a PE-labeled MHC/MAGE-1 A24 peptide tetramer and APC-labeled anti-CD8 mAb. The purity of melanoma-reactive cells (PE-MAGE-1 tetramer positive in Figure 5A) and melanoma-specific CTLs (PE-MAGE-1 tetramer positive and APC-anti-CD8 mAb positive in Figure 5A) in the stimulated PBMC from a melanoma patient were 31.2% and 30.1%, respectively. Most melanoma-reactive cells were melanoma-specific CTLs. MHC/MAGE-1 or HIV (negative control) A24 peptide complex-conjugated BacMPs were incubated in stimulated PBMCs, and the number of magnetically separated cells was counted. The number of cells separated nonspecifically using MHC/HIV A24 peptide complex-conjugated BacMPs was approximately one-sixth of the number of cells separated using MHC/MAGE-1 A24 peptide complex-conjugated BacMPs. Therefore, it was concluded that the target cells, which react to melanoma cells, were separated by the interaction with MHC/MAGE-1 A24 peptide complexes conjugated on BacMPs. Then, according to analysis of the separated cells using MHC/MAGE-1 A24 peptide complex-conjugated BacMPs, 93.1% of the separated cells were melanoma-reactive cells (Alexa-488-MAGE-1-BacMPs positive in Figure 5B), and 87.7% of those were melanoma-specific CTLs (Alexa-488-MAGE-1-BacMPs positive and APC-anti-CD8 mAb positive in Figure 5B). These results indicate that MHC/MAGE-1 A24 peptide complex-conjugated BacMPs bind to targeted melanoma-specific CTLs with high selectivity and that these cells were separated with high purity using this system.

Function of Separated Melanoma-Specific CTLs. The specificity of antigen recognition and cytokine secretion of CTLs following magnetic separation using MHC/MAGE-1 A24 peptide complex-conjugated BacMPs were evaluated. The amount

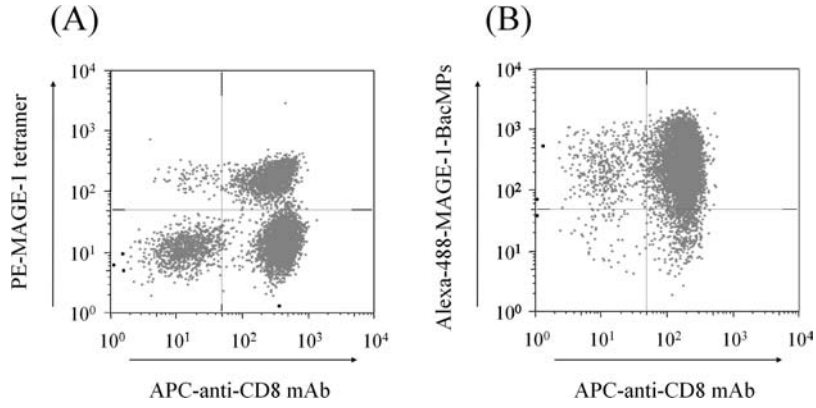

Figure 5. Magnetic separation of melanoma-specific CTLs using MHC/MAGE-1 peptide complex-conjugated BacMPs. Cells before (A) and after (B) magnetic separation were analyzed by flow cytometry and are shown accordingly. Prior to magnetic separation, the cells were stained with APC-labeled anti-CD8 mAb (APC-anti-CD8 mAb). For the analysis of cells before magnetic separation, PE-labeled MHC/MAGE-1 peptide tetramers (PE-MAGE-1 tetramer) were used. Upon magnetic separation, the cells were analyzed with reference to the fluorescence intensity of Alxa-488 labeled to the MHC/MAGE-1 peptide complex-conjugated BacMPs (Alexa-488-MAGE-1-BacMPs).

Table 2. Levels of IFN-γ Secreted by Separated Melanoma-Specific CTLs Incubated with TISI Cells or MGAE-1 Peptide-Pulsed TISI Cells

	Amount of Secreted IFN-γ (pg/mL)
MAGE-1 peptide-pulsed TISI cells	1049 ± 24.7
TISI cells	34 ± 4.4

of IFN-γ in the supernatants of CTLs cultured with MAGE-1 A24 peptide-pulsed TISI cells was measured (Table 2). The separated CTLs cultured with peptide nonpulsed TISI cells, which did not express MAGE-1 A24 peptide and MHC (HLA-A24) complexes on the cell surface, secreted little IFN-γ. It was indicated that the CTLs cultured with peptide nonpulsed TISI cells did not activate. Furthermore, it was suggested that BacMPs on CTLs were not a cytotoxin and did not activate the CTLs. On the other hand, the amount of IFN-γ secreted by the separated CTLs cultured with MAGE-1 A24 peptide-pulsed TISI cells was approximately 30 times more than that of the CTLs cultured with peptide nonpulsed TISI cells. These results indicate that the CTLs separated using MHC/MAGE-1 A24 peptide complex-conjugated BacMPs were stimulated specifically by MAGE-1 A24 peptide and MHC complexes expressed on TISI cells, and the stimulated CTLs were able to secrete IFN-γ, a normal function of melanoma-specific CTLs.

DISCUSSION

In preparing a population of target cells for applications such as cell translation or cell immunotherapy, techniques for separating these cells from a heterogeneous cell mixture must produce large numbers of highly pure target cells. For magnetic cell separation, the magnetic strength, size, and surface characteristics of magnetic particles influence the purity of separated cells. It is possible to reduce nonspecific binding to cells, which causes decreased purity, by controlling the particle surface characteristics. Specially, various surface modifications, such as the addition of poly(ethylene glycol) and polysaccharide to add hydrophilicity to the particles, have been demonstrated to reduce nonspecific interactions with the cell surface (*19*−*22*). In this report, BacMPs, which are known to elicit little nonspecific binding, were developed for the magnetic separation of melanoma-specific CTLs. First, the surfaces of BacMPs were coated with a PEO linker, and the hydrophilicity and steric barrier of the PEO contributed to the progress of distribution of BacMPs (*23*). Then, the number of streptavidin molecules immobilized on single BacMPs was controlled. This was performed, as it was speculated that excessive immobilization of streptavidin augments hydrophobicity and therefore accelerates nonspecific binding of BacMPs to nontarget cells (*18*). It has also been known that animal cells prefer to attach to particles as they increase in hydrophobicity (*20*). In the present study, nonspecific binding of BacMPs to nontarget cells was reduced markedly by controlling the number of immobilized streptavidin molecules per BacMP and via further modification of PEO on BacMPs. Finally, BacMPs that specifically target CTLs through the conjugation of MHC/peptide complexes on their surfaces allowed for the isolation of target CTLs with high purity.

In all previous reports, magnetic separation of antigen-specific CTLs has been demonstrated using both a PE-labeled MHC/peptide tetramer for targeting the cells and magnetic particles displaying anti-PE antibodies for magnet marking of the cells via the tetramer (*24*−*27*). This two-step separation lacks precision, is time-consuming, and is difficult to automate, and for these reasons, this technique is limited in its application toward immunotherapies. Therefore, we proposed the novel separation system in which antigen-specific CTLs are separated in a single-step process using BacMPs with directly conjugated MHC/peptide complexes as a more suitable process for use in immunotherapy. Conjugation of MHC/peptide complexes on magnetic nanoparticles for cell separation and single-step separation of antigen-specific CTLs was the first trial.

In this report, we demonstrated efficient melanoma-specific CTL separation using MHC/MAGE-1 A24 peptide complex-conjugated BacMPs. The BacMPs conjugated with MHC/MAGE-1 A24 peptide complexes bound to targeted melanoma-specific CTLs with little nonspecific binding to nontarget cells, and a single-step magnetic separation of the melanoma-specific CTLs from stimulated PBMCs derived from a vaccinated metastatic melanoma patient was achieved while maintaining CTL function. CTLs separated efficiently and with high purity will be useful in developing immunotherapies and in fundamental research.

Membrane lipids act as important regulators of a litany of important physiological and pathophysiological events. Many of them act as site-specific ligands for cytosolic proteins in binding events that recruit receptors to the cell surface and control both protein function and subcellular localization. Phosphatidylinositol phosphates (PIP_ns) are a family of signaling lipids that regulate numerous cellular processes by interacting with a myriad of protein binding modules. Characterization of PIP_n-binding proteins has been hampered by the lack of a rapid and convenient quantitative assay. Herein, microplate-based detection is presented as an effective approach to characterizing protein-PIP_n binding interactions at the molecular level. With this assay, the binding of proteins to isolated PIP_n headgroups is detected with high sensitivity using a platform that is amenable to high-throughput screening. In the studies described herein, biotinylated PI-(4,5)-P_2 headgroup analogue **1** was designed, synthesized, and immobilized onto 96-well streptavidin-coated microplates to study receptor binding. This assay was used to characterize the binding of the PH domain of β-spectrin to this headgroup. The high affinity interaction that was detected for surface association ($K_{d,\ surf} = 6$ nM $\pm$ 3), demonstrates that receptor binding modules can form high affinity interactions with lipid headgroups outside of a membrane environment. The results also indicate the feasibility of the assay for rapid characterization of PIP_n-binding proteins as well as the promise for high-throughput analysis of protein-PIP_n binding interactions. Finally, this assay was also employed to characterize the inhibition of the binding of receptors to the PIP_n-derivatized microplates using solution phase competitors. This showcases the viability of this assay for rapid screening of inhibitors of PIP_n-binding proteins.

INTRODUCTION

Lipids present in cellular membranes act as key regulators of important biological processes. A primary role of these species is to act as site-specific ligands in molecular recognition events that result in the recruitment of cytosolic effector proteins to the membrane surface, a process that generally regulates both protein function and subcellular localization (*1*−*3*). Protein−lipid binding interactions lie at the heart of many of the most important cellular pathways, which is likely due to the ability to transmit information from the membrane into cellular signaling cascades.

One family of phospholipids involved in many crucial biological events consists of phosphate derivatives of phosphatidylinositol, collectively known as phosphoinositides (PIP_ns) (*3*−*7*). The study of PIP_ns is vital as these lipids have been heavily implicated in several high-profile pathophysiological events including the onset of cancer, leukemia, and diabetes (*8*). A prominent example involves the conversion of phosphatidylinositol-4,5-bisphosphate (PI-(4,5)-P_2) to phosphatidylinositol-3,4,5-trisphosphate, with the forward and reverse reactions catalyzed by phosphoinositide 3-kinase (PI-3K) (*9*) and the phosphatase PTEN (*10*), respectively. Both PI-3K (*11*) and the tumor suppressor PTEN (*12*) are among the most frequently mutated enzymes in tumorigenesis.

The PIP_n family consists of seven isomeric phosphodiester-linked *myo*-inositol headgroups containing every possible combination of phosphorylation at the 3-, 4-, and 5-positions. Because of the structural similarity and yet functional diversity of these compounds, their study generally requires a synthetic approach to obtain homogeneous samples of the natural lipid or analogues thereof. However, the synthesis of PIP_ns represents a significant barrier to these efforts. In addition to this synthetic difficulty, the study of PIP_n-effector protein binding events generally faces additional challenges. For example, the complexity of the membrane environment complicates binding characterization due to its inherent heterogeneity.

An important question pertaining to protein−PIP_n binding is what structural features are required for membrane binding to occur, as some proteins show strong binding to the lipid headgroup alone, while others require the full membrane environment for interaction (*4*, *6*). In particular, crystal structures of certain pleckstrin homology (PH) domains indicate a shallow binding pocket, which, combined with other evidence, indicates predominantly headgroup-driven association (*3*). However, instances of PH domain membrane-insertion are documented (*13*, *14*), and other domains (phox homology (PX) and Fab1, YOTB, Vac1, and EEA1 (FYVE)) require the membrane for lipid headgroup binding. This disparity makes it necessary to determine the headgroup-binding affinities of PIP_n-binding proteins to understand how PIP_ns drive the specific membrane recruitment of diverse effectors for cell regulation.

A rapidly growing number of cellular proteins are known to bind PIP_ns. Many of these proteins contain specialized PIP_n-binding modules, such as the PH, PX, FYVE, and the more recently discovered β-propellers that bind PIP_n (PROPPIN) domains (*3*). Among the large number of reported PIP_n-binding modules, PIP_n affinities and specificities are known to vary widely, requiring the careful investigation of each distinct receptor with each PIP_n isomer. Such studies are hampered by the diversity of domain families, exemplified by the PH domains, for which recent sequence homology searches have implicated

over 250 family members in humans (*3*), many of which remain uncharacterized. Finally, proteins exist that interact with PIP_ns but lack a well-defined PIP_n-binding site. Characterization of these important groups of proteins would be advanced by a rapid and reliable quantitative assay for determining the affinity and specificity for each PIP_n isomer. Herein, we present a new microplate-based quantitative assay for PIP_n binding, which can be applied to large scale high-throughput screening.

EXPERIMENTAL PROCEDURES

General Experimental Details. Dry solvents were obtained from a Pure Solv solvent delivery system purchased from Innovative Technology, Inc. Column chromatography was performed using 230−400 mesh silica gel purchased from Sorbent Technologies. NMR spectra were obtained using a Bruker AC250 spectrometer updated with a TecMag data collection system, a Varian Mercury 300 spectrometer, and a Bruker Avance 400 spectrometer. Mass spectra were obtained with JEOL DART-AccuTOF spectrometer with high resolution capabilities and an ABI Voyager DE Pro MALDI spectrometer. HPLC data was obtained using an HP series 1100 HPLC with an Alltech Lichrosphere SI 60 50U column with HPLC grade solvents purchased from Fisher. Optical rotation values were obtained using a Perkin-Elmer 241 polarimeter. Microplate-based chemiluminescence measurements were performed using a BioTek Synergy 2 multidetection microplate reader. White reacti-bind streptavidin high binding capacity (HBC) coated 96-well microplates for chemiluminescence studies were purchased from Pierce Biotechnology (Rockford, IL). Goat polyclonal anti-GST tag HRP-conjugate was purchased from Novus Biologicals (Littleton, CO). Supersignal ELISA femto maximum sensitivity substrate was purchased from Pierce Biotechnology (Rockford, IL). The GST-tagged PH domain of β-spectrin was expressed and purified as previously described (*15*).

1D-4,5-*O*-Bisbenzyl-1-*O*-(*tert*-butyldiphenylsilyl-2,3,6-*O*-tris-(benzyloxymethyl)-myo-inositol (3). To a solution of **2** (0.586 g, 0.96 mmol) in 1,2-dichloroethane (21 mL) were added diisopropylethylamine (1.7 mL, 9.83 mmol) and benzyloxychloromethyl ether (1.4 mL, 10.1 mmol). The reaction mixture was stirred at reflux for 24 h. Diisopropylethylamine (1.7 mL, 9.83 mmol) and benzyloxychloromethyl ether (1.4 mL, 10.1 mmol) were added to the solution, and the mixture was stirred at reflux for another 24 h. After the reaction was finished, water was added, and the crude reaction mixture was extracted with methylene chloride (2 × 50 mL). The organic phase was dried with magnesium sulfate, filtered, and then concentrated. The crude product was then purified by chromatography on silica gel (acetone/hexane 1:5) giving **3** (0.631 g, 68%) as a syrup.

$[\alpha]_D^{296K}$ 25.8 ($c = 0.95$, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.88 (dd, J = 13.6, 7.3 Hz, 4H), 7.75 (t, J = 7.6 Hz, 4H), 7.42−7.14 (m, 23H), 6.94−6.89 (m, 4H), 5.92 (t, J = 10.1 Hz, 1H), 5.50 (t, J = 9.7 Hz, 1H), 5.05 (d, J = 6.8 Hz, 1H), 4.86−4.80 (m, 3H), 4.73 (d, J = 6.8 Hz, 1H), 4.55−4.45 (m, 2H), 4.33−4.02 (m, 7H), 3.67 (dd, J = 10.3, 2.0 Hz, 1H), 3.58 (m, 1H), 1.11 (s, 9H); ^{13}C NMR (100.5 MHz, $CDCl_3$) δ 166.0, 165.6, 138.2, 137.7, 137.4, 136.0, 135.9, 133.8, 132.8, 130.2, 130.0, 129.7, 129.6, 128.2, 128.1, 127.9, 127.7, 127.4, 127.3, 96.6, 95.5, 91.8, 77.7, 74.9, 74.5, 73.0, 72.8, 72.2, 69.9, 69.4, 68.9, 27.3, 27.2, 19.3. MALDI-HRMS $[M + Na]^+$ calcd for $C_{60}H_{62}O_{11}SiNa$, 1009.3959; found, 1009.3936.

1D-1-*O*-(*tert*-Butyldiphenylsilyl-2,3,6-*O*-tris-(benzyloxymethyl)-myo-inositol (4). A solution of **3** (0.631 g, 0.650 mmol) in methanol (40 mL) was treated with sodium methoxide (1.6 g, 29.6 mmol) at room temperature for 18 h. Then sodium methoxide (1.0 g, 18.5 mmol) was added to the reaction solution, and the mixture was stirred at room temperature for 3 h, after which the contents were filtered. The resulting residue was dissolved in water (50 mL), and the aqueous solution was extracted with methylene chloride (2 × 50 mL). In addition, the previous filtrate was concentrated in vacuum and then extracted with methylene chloride (2 × 50 mL) from water (50 mL). The combined organic layer was then dried with magnesium sulfate, filtered, concentrated, and purified by chromatography on silica gel (hexanes/acetone, 3:1) to provide pure diol **4** (0.393 g, 80%) as a syrup.

$[\alpha]_D^{296K}$ 86.1 ($c = 1.36$, $CHCl_3$); ^{1}H NMR (250 MHz, $CDCl_3$) δ 7.68 (t, J = 7.3 Hz, 4H), 7.41−7.19 (m, 21H), 5.02 (d, J = 6.8 Hz, 1H), 4.90−4.83 (m, 2H), 4.73−4.45 (m, 8H), 4.34−4.25 (m, 2H), 3.99−3.91 (m, 2H), 3.77−3.75 (m, 2H), 3.40 (dd, J = 9.6, 1.8 Hz, 1H), 3.13−3.10 (m, 1H), 2.78 (m, 1H), 1.03 (s, 9H);^{13}C NMR (62.9 MHz, $CDCl_3$) δ 138.2, 135.9, 135.6, 134.1, 133.4, 129.9, 129.5, 128.5, 128.4, 128.3, 128.02, 127.98, 127.72, 127.66, 127.5, 127.4, 95.5, 93.5, 85.2, 76.3, 75.7, 74.2, 73.2, 72.2, 70.3, 69.2, 27.0, 19.4. HRMS $[M + O_2]^-$ calcd for $C_{46}H_{54}O_{11}Si$, 810.34354; found, 810.34393.

1D-1-*O*-(*tert*-Butyldiphenylsilyl-2,3,6-*O*-tris-(benzyloxymethyl)-myo-inositol 4,5-bis-(dibenzyl phosphate) (5). To a solution of diol **4** (0.73 g, 0.958 mmol) and 1-*H*-tetrazole (17 mL, 7.67 mmol, 0.45 M in acetonitrile) in methylene chloride (30 mL) was added dibenzyl *N*,*N*-diisopropylphosphoramidite (1.93 mL, 5.75 mmol) under nitrogen gas, and the mixture was stirred at room temperature for 18 h. The reaction solution was cooled to − 60 °C, and *m*-CPBA (2.2 g, 57−86%) was added. The mixture was stirred at this temperature for 60 min and then slowly warmed to room temperature after the removal of the cooling bath. The solution was diluted to 180 mL with methylene chloride and washed with saturated aqueous sodium bicarbonate (2 × 100 mL), and the aqueous phase was extracted with methylene chloride (100 mL). The combined organic phase was dried with magnesium sulfate, filtered, and concentrated, and the residue was purified by chromatography on silica gel (hexanes/acetone, 3:1) giving bis-phosphodiester **5** (1.17 g, 81%) as a syrup.

$[\alpha]_D^{296K}$ −2.5 (c = 0.805, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.68−7.78 (m, 4H), 7.03−7.35 (m, 41H), 4.93−5.22 (m, 12H), 4.77−4.80 (m, 3H), 4.59 (d, J = 12.0 Hz, 1H), 4.39−4.47 (m, 3H), 4.28−4.32 (m, 2H), 4.16 (d, J = 6.8 Hz, 1H), 4.05 (d, J = 12.4 Hz, 1H), 3.95 (d, J = 7.2 Hz, 1H), 3.49 (s, 1H), 3.39 (dd, J = 10.0, 1.6 Hz, 1H), 1.11 (s, 9H); ^{13}C NMR (100.5 MHz, $CDCl_3$) δ 133.7, 132.6, 130.1, 130.0, 128.5, 128.4, 128.3, 128.2, 128.2, 128.0, 128.0, 127.9, 127.8, 127.6, 127.5, 127.3, 96.6, 95.5, 93.2, 78.4, 77.8, 75.2, 75.1, 74.0, 73.7, 70.7, 69.5, 69.5, 69.4, 69.3, 69.1, 69.1, 27.3, 19.3; ^{31}P NMR (161.8 MHz, $CDCl_3$) δ −0.83 (s, 1P), −1.21 (m, 1P). MALDI-HRMS $[M + Na]^+$ calcd for $C_{74}H_{80}O_{15}P_2SiNa$, 1321.4634; found, 1321.4602.

1D-2,3,6-*O*-Tris-(benzyloxymethyl)-myo-inositol 4,5-bis-(dibenzyl phosphate) (6). A solution of fully protected inositol **5** (1.17 g, 0.90 mmol) in *N*,*N*-dimethylformamide (30 mL) was treated with tetrabutylammonium fluoride trihydrate (0.90 g, 2.85 mmol) at room temperature for 12 h. After the reaction was finished, the solution was partitioned between ethyl acetate (200 mL) and H_2O (150 mL). The aqueous layer was further extracted with ethyl acetate (100 mL), and the combined organic layer was washed with brine (150 mL), dried with magnesium sulfate, and filtered. Following concentration, the residue was purified by chromatography on silica gel (hexanes/acetone, 2:1) to give alcohol **6** (0.854 g, 88%) as a syrup.

$[\alpha]_D^{296K}$ −36.3 (c = 1.0, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.14−7.35 (m, 35H), 4.92−5.19 (m, 11H), 4.61−4.79 (m, 6H), 4.39−4.54 (m, 4H), 4.29 (s, 1H), 4.24 (d, J = 2.1 Hz, 1H), 3.88 (t, J = 9.3 Hz, 1H), 3.72 (d, J = 10.2 Hz, 1H), 3.55 (d, J = 9.3 Hz, 1H); ^{13}C NMR (100.5 MHz, $CDCl_3$) δ 138.0, 137.7, 136.9, 136.3, 136.2, 136.2, 136.1, 136.0, 128.7, 128.6,

128.5, 128.5, 128.4, 128.4, 128.3, 128.2, 128.1, 128.1, 128.0, 128.0, 127.9, 127.8, 127.7, 127.7, 97.3, 95.8, 95.0, 83.5, 79.5, 79.5, 78.1, 78.0, 75.8, 75.3, 70.7, 70.6, 69.9, 69.7, 69.6, 69.6, 69.6, 69.4, 69.4, 69.3; ^{31}P NMR (161.8 MHz, $CDCl_3$) δ −1.13 (s, 1P), −1.50 (s, 1P). MALDI-HRMS $[M + Na]^+$ calcd for $C_{58}H_{62}O_{15}P_2Na$, 1083.3456; found, 1083.3410.

Benzyl (6-benzyloxycarbonylaminohexyl) 1D-2,3,6-*O*-tris-(benzyloxymethyl)-myo-inosit-1-yl phosphate 4,5-bis-(dibenzyl phosphate) (7). To a solution of cbz-aminohexanol (0.694 g, 2.76 mmol) in methylene chloride (30 mL) under nitrogen was added 1-*H* tetrazole (4.6 mL of a 0.45 M solution in acetonitrile, 2.07 mmol) and benzyloxy-bis(diisopropylamino)-phosphine (1.392 g, 4.11 mmol). This mixture was allowed to stir at room temperature for 2 h, at which point the solution was extracted with methylene chloride (3 × 80 mL) from saturated sodium bicaronate (80 mL). The combined organic phase was then dried with magnesium sulfate, filtered, concentrated and the residue was purified by chromatography on silica gel (eluant: hexane/ethyl acetate/triethylamine 100:10:1). The resulting colorless liquid (0.983 g, 2.0 mmol) was then added to a solution of alcohol **6** (0.854 g, 0.805 mmol) and 1-*H* tetrazole (5.3 mL of a 0.45 M solution in acetonitrile, 2.4 mmol) in methylene chloride (36 mL) under nitrogen, and the mixture was allowed to stir at room temperature for 18 h. The reaction solution was then cooled to −60 °C and *m*-CPBA (0.7 g, 57−86%) was added. Stirring was continued at this temperature for 60 min before the reaction was slowly warmed to room temperature. The solution was then extracted with methylene chloride (3 × 80 mL) from saturated sodium bicarbonate (60 mL). The combined organic phase was dried with magnesium sulfate, concentrated, and the residue was chromatographed on silica gel (hexanes/acetone, 3:1) to afford tris-phosphotriester **7** (0.53 g, 45%) as a syrup.

$[\alpha]_D^{296K}$ −22.9 (c = 1.0, $CHCl_3$); ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.16−7.34 (m, 45H), 4.41−5.20 (m, 28H), 4.20−4.34 (m, 2H), 3.88−3.95 (m, 2H), 3.71 (d, J = 9.0 Hz, 1H), 3.07−3.14 (m, 2H), 1.20−1.48 (m, 8H); ^{13}C NMR (100.5 MHz, $CDCl_3$) δ 156.4, 138.2, 137.9, 137.5, 136.7, 136.2, 136.1, 136.0, 135.9, 135.8, 135.8, 128.6, 128.4, 128.4, 128.4, 128.3, 128.2, 128.2, 128.0, 128.0, 127.9, 127.8, 127.7, 127.7, 127.6, 127.5, 127.4, 96.6, 95.6, 94.6, 78.8, 76.4, 74.9, 74.7, 74.6, 74.5, 70.4, 70.4, 69.7, 69.7, 69.6, 69.5, 69.4, 69.3, 69.3, 68.1, 67.9, 66.5, 40.8, 30.0, 29.9, 29.7, 26.0, 24.9; ^{31}P NMR (161.8 MHz, $CDCl_3$) δ −1.19 (m, 3P). MALDI-HRMS $[M + Na]^+$ calcd for $C_{79}H_{88}NO_{20}P_3Na$, 1486.5005; found, 1486.5027.

1-(6-Aminohexyl sodium phosphate)-1D-myo-inositol-4,5-bis-(disodium phosphate) (8). To a solution of compound **7** (0.57 g, 0.389 mmol) in methanol (50 mL) was added 20% palladium hydroxide on charcoal (0.67 g). The mixture was then stirred for 3 days at room temperature with 1 atm of hydrogen (balloon). Next, the catalyst was removed by filtration, and the residue was with washed with methanol. The solvent was removed in vacuum, and the crude product was dissolved in water and stirred for 3 h with Chelex 100 resin (Sigma, Na^+ form). The resin was removed by filtration, and the filtrate was lyophilized to give amino-conjugate **8** (0.245 g, 100%) as a white solid.

$[\alpha]_D^{296K}$ −14.9 (c = 1.0, H_2O); ^{1}H NMR (300 MHz, D_2O) δ 4.19−4.24 (m, 2H), 3.88−4.00 (m, 5H), 3.69 (dd, J = 9.6, 2.7 Hz, 1H), 2.99 (d, J = 7.8 Hz, 2H), 1.63−1.70 (m, 4H), 1.40−1.43 (m, 4H); ^{13}C NMR (100.5 MHz, D_2O) δ 80.0, 78.6, 78.0, 74.2, 74.1, 73.3, 68.9, 42.1, 32.0, 29.2, 27.7, 27.0; ^{31}P NMR (121.5 MHz, D_2O) δ 5.20 (s, 1P), 4.78 (s, 1P), 0.92 (s, 1P). MALDI-HRMS (free acid, $[M + H]^+$) calcd for $C_{12}H_{28}NO_{15}P_3H$, 520.0745; found, 520.0729.

1-(6-(14-Biotinamido-3,6,9,12-tetraoxatetradecanamido)hexyl sodium phosphate)-1D-myo-inositol 4,5-bis-(disodium phosphate) (1). Succinimidyl ester **9** was dissolved in dimethylformamide (1 mL) and compound **8** (7 mg, 0.011 mmol), dissolved in TEAB (0.5 M, 1 mL), was added. The mixture was stirred at room temperature for 24 h. The solvent was removed under reduced pressure, and the residue was washed with acetone (4 × 2 mL) and then dried in vacuo. The resulting white solid was dissolved in water, and the solution was stirred for 3 h with Chelex 100 resin (Sigma, Na^+ form). The resin was removed by filtration, and the filtrate was lyophilized to give the product (13 mg, 100%) as a white solid.

^{1}H NMR (300 MHz, D_2O) δ 4.56−4.58 (m, 1H), 4.38−4.41 (m, 1H), 4.04−4.25 (m, 3H), 3.82−3.95 (m, 4H), 3.58−3.74 (m, 14H), 2.93−3.40 (m, 14H), 2.72−2.85 (m, 2H), 2.24 (d, J = 6.9 Hz, 2H), 1.33−1.79 (m, 16H); ^{31}P NMR (121.5 MHz, D_2O) δ 5.79 (s, 1P), 5.70 (s, 1P), 0.87 (s, 1P). MALDI-HRMS (free acid, $[M + H]^+$) calcd for $C_{32}H_{61}N_4O_{22}P_3SH$, 979.2784; found, 979.2775.

Microplate Analysis of PI-(4,5)-P_2 Headgroup-β-spectrin PH Domain Binding. Binding assays were performed using streptavidin-coated 96-well microplates. The wash buffer that was used was 20 mM Tris buffer at pH 8.0 with 0.05% tween as a blocking additive to avoid nonspecific surface adsorption. In general, the wells that were to be used for analysis were washed with 200 μL of wash buffer for 30 min. This was removed, followed by the addition of the appropriate solutions of biotin-TEG-PI-(4,5)-P_2 ligand **1** or control **8** or **13** in water, and incubation for 1 h. Next, these solutions were removed, and the wells were washed with 3 × 250 μL wash buffer. Following this, 200 μL of GST-tagged β-spectrin PH domain solutions in wash buffer were added to each well. After a 1 h incubation, the protein solution was removed, and the wells were washed with 3 × 250 μL wash buffer. Next, 200 μL of a solution of goat polyclonal anti-GST tag HRP-conjugate was added to each well and allowed to incubate for 1 h. This solution was then removed, and the wells were washed with 3 × 250 μL wash buffer. Chemiluminescence detection of bound antibody was next performed using supersignal ELISA femto maximum sensitivity substrate. Here, a 1:1 mixture of the substrate and peroxide solutions were mixed, 100 μL of which was added to each well. The microplate was then immediately placed in the microplate reader, and the chemiluminescence at 425 nm was repeatedly measured for ∼5 min. Several readings that provided optimal signal were then averaged, and the change in chemiluminescence was plotted verses the concentration of the varying component. The resulting curve was fit via the program SigmaPlot using the Langmuir isotherm: $C = C\text{max}*[P]/(K\text{d, surf} + [P])$ (C = chemiluminescence; P = protein) to calculate dissociation constants. For Figure 1A, solutions of **1** varied from 0−500 nM, β-spectrin PH domain added was fixed at 100 ng/mL, and anti-GST Ab was added at 10 ng/mL. For Figure 1B, [**1**] immobilized was fixed at 500 nM, β-spectrin PH domain solutions ranged from 0−15 nM, and the anti-GST Ab solution was 100 ng/mL. For Figure 2, [**1**] immobilized was fixed at 500 nM, solutions of fixed β-spectrin PH domain (200 ng/mL) and varying competitor **8** (0−4 μM) were used, and anti-GST Ab solution was 10 ng/mL.

RESULTS AND DISCUSSION

Because of the importance of the PIP_ns in cell regulation and the diversity of proteins that target these lipids in terms of structure and the details of recognition, it is imperative to develop efficient approaches for characterizing PIP_n recognition at the molecular level. Current assays for detecting interactions utilize lipid-functionalized nitrocellulose membranes (such as PIP strips, Echelon Biosciences, Salt Lake City, UT), vesicle pelleting, fluorescence, isothermal titration calorimetry (ITC), or SPR-based methods (*16*). However, these methods do not

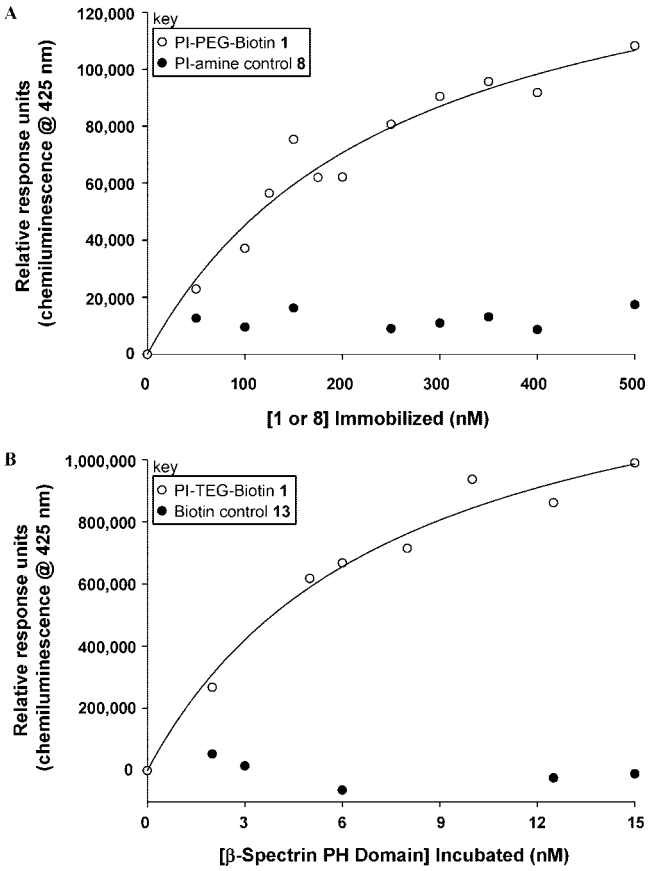

Figure 1. Microplate assay results obtained with (A) varying concentration of ligand **1** with fixed [receptor] and (B) fixed [**1**] with changing [receptor]. Both results indicate sensitive detection of headgroup binding.

allow for high-throughput quantification, which is required to elucidate the grand scope of complexities associated with receptor-PIP_n binding.

Microarray analysis has proven highly effective for high-throughput quantification of protein−ligand binding, including cell surface receptor−ligand binding interactions. Generally, optical detection is utilized, which benefits from high sensitivity and easy access to studies. Another advantage is that the surface display of target ligands allows for the formation of multivalent binding interactions, which are common in membrane-based biological recognition events (*17, 18*), and are known to occur with certain PIP_n-targeting proteins (*3*). Detection in a multivalent context is important as ligand preferences of receptors can differ between solution-phase studies and those using a multivalent surface (*19, 20*). In microarray analysis, ligand density can be directly controlled via the amount of ligand that is deposited on the surface. In fact, binding affinities have been found to vary depending upon the concentration of ligand immobilized in microarray analysis, indicating the occurrence of multivalent interactions (*21, 22*). The described advantages have been exhibited in the development of DNA (*23, 24*), protein and peptide (*25*−*27*), and carbohydrate (*20, 22, 28*−*34*) microarray systems, while lipid microarrays have only recently emerged (*21, 35*).

Toward our goal of a high-throughput microarray platform for efficient characterization of PIP_n-binding, we have initially devised a microplate-based detection system. The first task in this pursuit was the development of a ligand-immobilization strategy, for which synthetic biotinylated PI-(4,5)-P_2 headgroup analogue **1** (Scheme 1) was designed. PI-(4,5)-P_2 was chosen for initial studies as it is the most abundant member of the PIP_n family. The isolated headgroup motif was employed to directly investigate the extent to which effector proteins interact with this moiety outside of the membrane environment. Ligand **1** also contains a biotin group for immobilization onto streptavidin surfaces, as this high affinity noncovalent interaction enforces quantitative immobilization while avoiding potential nonspecific surface attachment. Finally, a tetraethylene glycol (TEG) spacer was introduced between the headgroup and biotin to distance the ligand from the microplate surface.

The synthesis of PI-(4,5)-P_2-TEG-biotin conjugate **1** benefited from protocols previously developed for accessing inositol headgroups (*36*−*38*) and amino-functionalized tetherable analogues thereof (*39*−*42*). Specifically, the synthetic route to protected PI-(4,5)-P_2 headgroup **6** (Scheme 1) employed a procedure modified from that reported by Bruzik and co-workers (*38*). First, compound **2** was obtained in four steps from *myo*-inositol as previously described. This contains benzoyl groups at positions 4 and 5, the phosphorylation sites in the final compound, and a silyl group at the 1 position, where the phosphodiester linkage occurs in the natural lipid. At this point, we accessed compound **3** by installing benzyloxymethyl (BOM) groups at the 2, 3, and 6 positions to allow for convenient global deprotection via hydrogenolysis at the end of the synthesis. After benzoyl group removal to **4**, phosphoramidite chemistry was used to access fully protected headgroup analogue **5**. Following silyl deprotection to **6**, a protected amine group attached via a phosphodiester linkage was introduced to generate **7**. Global deprotection by hydrogenolysis then yielded conveniently functionalizable PI-(4,5)-P_2-amine **8**. Finally, coupling of **8** with biotin-TEG-NHS ester reagent **9** (synthesized in seven steps from TEG; see Supporting Information for details) provided PI-(4,5)-P_2-TEG-biotin conjugate **1**.

The experimental approach to PIP_n microplate analysis using ligand **1** employed a surface-based antibody assay as depicted in Scheme 2. First, PI-(4,5)-P_2 headgroup immobilization was achieved by incubating conjugate **1** in different wells of a streptavidin-coated 96 well microplate, followed by thorough buffer washes. Next, the ligand was incubated with the effector protein. For our initial study, we sought to characterize the PI-(4,5)-P_2 headgroup-binding of the PH domain of the protein β-spectrin. To do so, we expressed and purified this domain with an appended glutathione-*S*-transferase (GST) tag, used for detection and purification purposes, as previously described (*15*). Following buffer washes to remove unbound protein, a horseradish peroxidase (HRP)-conjugated anti-GST antibody was used, followed by further washing. Finally, chemiluminescence-

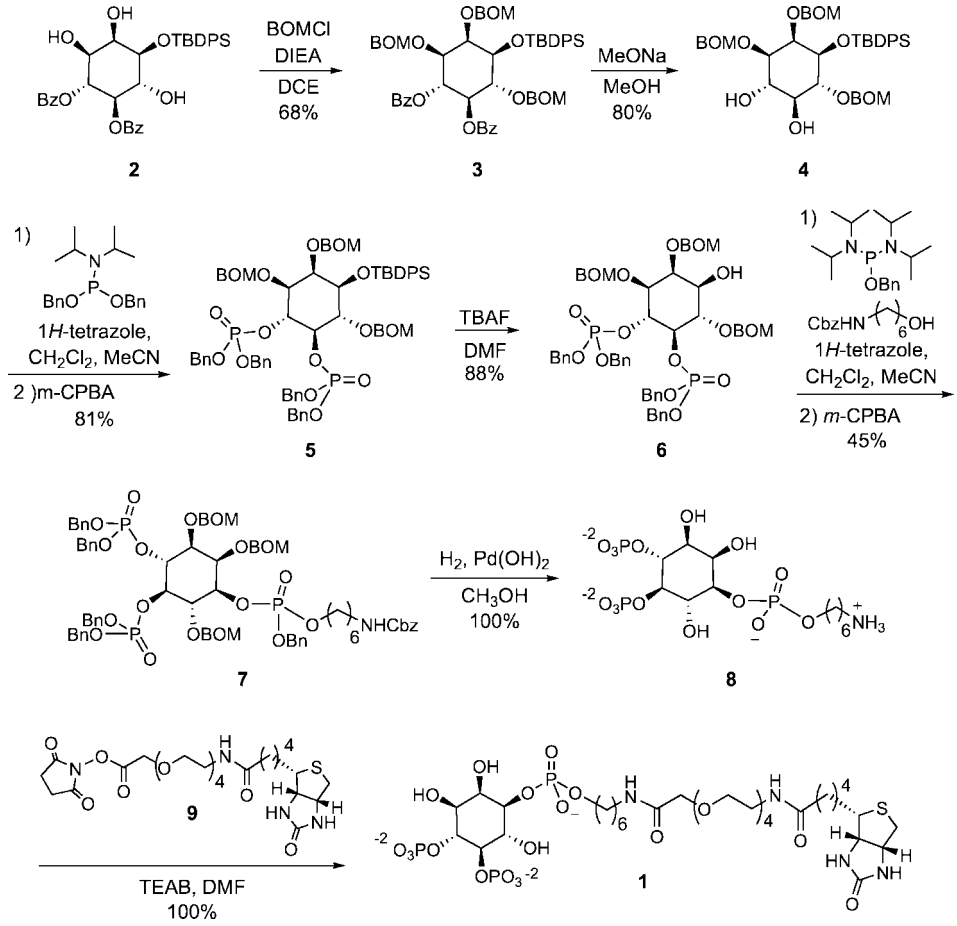
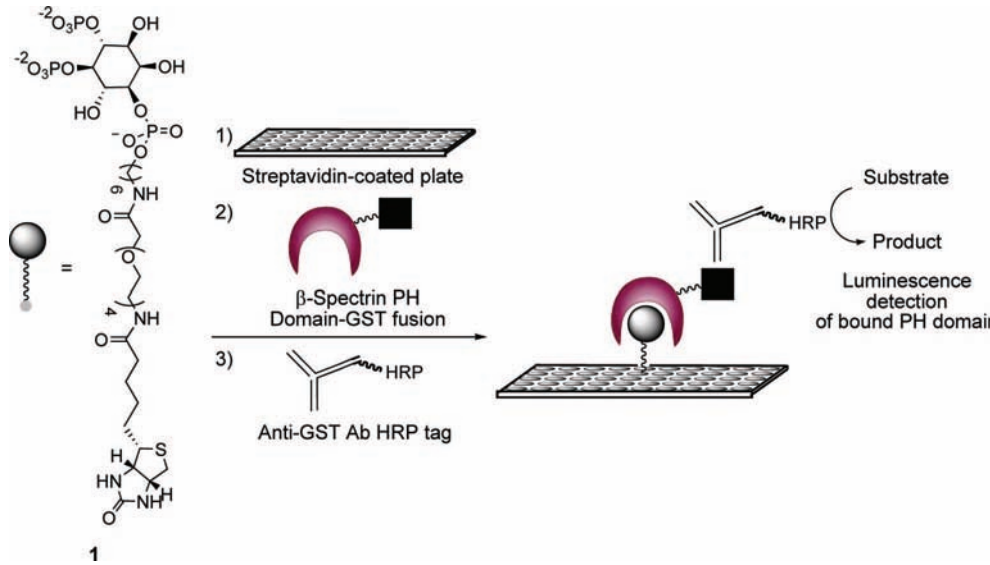


Scheme 2. Microplate-Based Assay for the Detection of Receptor-PIP_n Headgroup Binding Interactions



based detection of the secondary antibody using a microplate reader was performed to transduce the presence of bound protein.

The described microplate assay was successfully employed to probe PI-(4,5)-P_2 headgroup-β-spectrin PH domain association via multiple approaches. First, analysis was performed by introducing varying concentrations of ligand **1** into the plate and incubating with fixed protein and antibody concentrations. A representative binding curve indicating enhanced protein recruitment upon increasing immobilized ligand is shown in Figure 1A. The results show highly sensitive detection of binding, as the rise in the curve corresponds to less than 50 pmol of ligand immobilized in the plate. Also shown in Figure 1A is a control study in which PI-amine compound **8**, which lacks the biotin moiety, was incubated in place of **1**. This resulted in the background signal, which indicates that the biotin group of **1** is required for surface deposition and rules out potential nonspecific ligand and protein adsorption onto the plate.

The microplate binding assay was also carried out by depositing a fixed concentration of ligand **1** that correlates to strong protein recruitment from the previous study (500 nM) and varying the receptor concentration, for which results are shown in Figure 1B. Once again, sensitive detection of binding was obtained. Here, results were used to calculate a dissociation constant ($K_{d,\ surf}$) value by fitting the data to the Langmuir isotherm (*22*), with multiple readings yielding an average value of 6 nM ± 3. Figure 1B also includes a second control in which biotin-TEG compound **13** (see Supporting Information for structure), which lacks the PI-(4,5)-P_2 headgroup, was immobilized in place of ligand **1**, again resulting in no signal. The combined results for the controls in Figure 1A and B show that both the PI-(4,5)-P_2 headgroup and biotin moieties of compound **1** are necessary for protein binding.

The binding affinity of the GST-tagged PH domain of β-spectrin interacting with liposomes containing full PI-(4,5)-P_2 lipids was previously determined (K_d = 125 nM ± 18) using a surface plasmon resonance assay (*15*). While the value reported herein differs from this previous study, this is to be expected since the current assay was designed to detect binding in a different environment, that in which the interaction with the lipid headgroup is studied outside of the membrane. As a result, the two assays utilize different formats, and thus, each K_d value is specific to the model system employed for analysis. For example, the presentation and clustering of the PI-(4,5)-P_2 headgroup will vary between microplate surfaces that are directly derivatized with the biotinylated ligand (current assay) compared with studies employing the full lipid incorporated into immobilized liposomes (previous assay). For this reason, we have qualified the dissociation constant measured herein as $K_{d,\ surf}$, as has been indicated in similar approaches employing surface-based binding measurements (*22*).

The results from this assay indicate that receptor binding domains can form high affinity interactions with PIP_n headgroups outside of the membrane environment. The strong binding affinity that was observed using the isolated headgroup provides evidence that PI-(4,5)-P_2-binding is primarily driven by interactions with the headgroup in the case of this particular receptor. These results are in line with previous reports in which strong interactions (K_d = 27.3 nM) between other PH domains and solubilized PIP_n headgroup analogues were observed and the fact that these soluble headgroups effectively displaced receptor-full PIP_n lipid complexes (*43*). However, different PIP_n-binding receptors are known to require the membrane context for binding (*4*, *6*), indicating that the headgroup is not sufficient to enforce association. This diversity in receptor binding mode dictates that each protein must be analyzed independently to determine the molecular-level details of each particular receptor. Therefore, deconvolution of the complexities of receptor−PIP_n affinities, specificities, and binding modes requires a high-throughput assay such as the approach described herein.

In order to extend the described microplate-based strategy, we sought to perform competitive assays to detect the perturbation of protein-binding to the ligand-functionalized microplate surface. Here, microplate wells functionalized with PI-(4,5)-P_2-TEG-biotin conjugate **1** at a fixed concentration were simultaneously incubated with β-spectrin PH domain and a varying amount of soluble PI-(4,5)-P_2-amine headgroup analogue **8**. Figure 2 shows a resulting dose-dependent response curve, in which the extent of protein bound to the surface is diminished through incubation with increasing concentrations of competitive binding partner **8**. These results further confirm the strong association of receptors with the PI-(4,5)-P_2 headgroup outside of the membrane context and showcase the efficacy of our microplate assay for detecting the inhibition of receptor−PIP_n interactions.

The described microplate-based approach provides highly sensitive detection of PIP_n-binding as well as competitive inhibition of recognition. As such, this assay is applicable to a range of studies aimed at characterizing binding at the molecular level, including the determination of PIP_n-binding specificities of receptors, the extent to which headgroup binding drives association with different proteins, and the evaluation of compounds that inhibit binding. Currently, we are extending these studies toward our goal of a high-throughput microarray assay for systematic analysis of the headgroup-binding affinities and specificities of the diverse effector domains and proteins that interact with the PIP_ns. The eventual goal in this regard is the implementation of biotinylated headgroup analogues of all naturally occurring PIP_n isomers for simultaneous microarray analysis of receptors of interest.

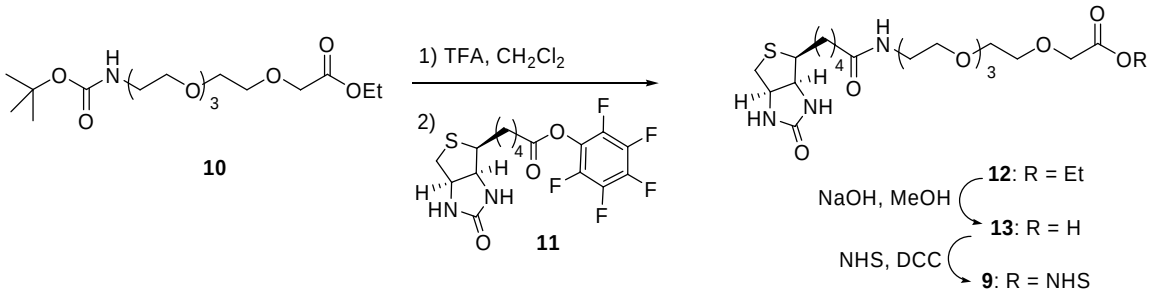
Supporting Information

Synthesis of biotin-PEG linker 9: Biotinylated PEG linker **9** was synthesized from tetraethyleneglycol (Supporting Information Figure 1). First, literature procedures were used to access known compound **10** in four steps.[1, 2] The amine group of **10** was then deprotected, followed by direct biotinylation to **12**, ethyl ester hydrolysis to **13** and coupling of the resulting carboxyl group to *N*-hydroxysuccinimide to produce activated ester **9**.



Supporting Information Figure 1. Synthesis of biotinylated PEG linker **9**.

Ethyl 14-biotinamido-3,6,9,12-tetraoxatetradecan-1-oate (12) PEG analog **10** (723 mg, 1.959 mmol) was dissolved in dry dichloromethane (3 mL) along with trifluoroacetic acid (3mL). The solution was stirred at room temperature for 3 hours and then the solvent was removed under reduced pressure and placed on a vacuum line for 3-4 hours. The crude deprotected amine was then directly biotinylated. This crude was dissolved in anhydrous N,N-dimethylformamide (15 mL) and triethylamine (3 mL) was added. With stirring was added biotin pentafluorophenyl ester **11** (804 mg, 1.959 mmol). The reaction was allowed to stir overnight at room temperature. The reaction solution was then concentrated under reduced pressure and purified by chromatography on silica gel with a gradient system of 0-20% methanol/chloroform to afford **12** as a white solid (704 mg, 71% over 2 steps).

^{1}H NMR (300MHz, $CDCl_3$) δ 7.04 (bs, 1H), 6.83 (bs, 1H), 6.03 (bs, 1H), 4.52 (bs, 1H), 4.32-4.15 (m, 5H), 3.90-3.43 (m, 16H), 3.22-3.14 (m, 1H), 2.92-2.74 (m, 2H), 2.24 (bs, 2H), 1.68-1.26 (m, 9H) HRMS $[M+H]^+$ cacld for $C_{22}H_{39}N_3O_8S$ 506.25361, found 506.25310. ^{13}C NMR (100.5 MHz, $CDCl_3$) δ 173.4, 170.4, 70.9, 70.5, 70.4, 70.1, 70.0, 68.6, 61.8, 60.8, 60.3, 55.8, 40.5, 39.1, 36.0, 28.3, 28.2, 25.7, 14.2; HRMS $[M+H]^+$ calcd for $C_{22}H_{39}N_3O_8S$ 506.25361, found 506.25310.

14-biotinamido-3,6,9,12-tetraoxatetradecanoic acid (13) Ester **12** (122mg, 0.242 mmol) was dissolved in methanol (2 mL). With vigorous stirring, 2M NaOH (2 mL) was added. After 45 minutes, TLC showed no starting material remaining. The reaction was neutralized with Dowex 50WX8-200 H+ resin to a pH of ~5. The resin was removed by filtration and the solvent was removed under reduced pressure to afford **13** as a tan solid (118 mg, quantative).

^{1}H NMR (300MHz, CD_3OD) δ 4.38-4.34 (m, 1H), 4.19-4.15 (m, 1H), 3.93-3.88 (m, 2H), 3.49-3.80 (m, 14H), 3.16 (t, J = 4.7 Hz, 2H), 3.08-3.00 (m, 1H), 2.75-2.69 (m, 1H), 2.52-2.48 (m, 1H), 2.00 (t, J = 7.2 Hz, 2H), 1.51-1.19 (m, 6H). ^{13}C NMR (100.5 MHz, CD_3OD) δ 176.13, 174.34, 165.95, 130.79, 127.10, 71.62, 71.44, 71.22, 70.60, 69.28, 63.37, 61.65, 56.96, 41.06, 40.32, 36.72, 29.73, 29.47, 26.84; HRMS $[M+H]^+$ calcd for $C_{20}H_{36}N_3O_8S$ 478.22231, found 478.22030.

14-biotinamido-3,6,9,12-tetraoxatetradecanoic acid *N*-hydroxysuccinimidyl ester(**9**) To a solution of biotin-PEG-carboxylic acid **13** (40 mg, 0.084 mmol) in dimethylformamide (2 mL) was added *N*-hydroxysuccinimide (12 mg, 0.10 mmol) and 1-Ethyl-3-(3-

dimethyllaminopropyl)carbodiimide hydrochloride (EDC•HCl, 20 mg, 0.10 mmol). The mixture was stirred at room temperature for 24 h. The reaction solution was concentrated under reduced pressure, and the residue was washed with ethyl ether (3 x 2 mL) and then dried in vacuum. The resulting light yellow gum was used directly in the next step without further purification.

Kit-Like ^{18}F-Labeling of Proteins: Synthesis of 4-(Di-*tert*-butyl[^{18}F]fluorosilyl)benzenethiol (Si[^{18}F]FA-SH) Labeled Rat Serum Albumin for Blood Pool Imaging with PET

Björn Wängler,*[,†] Gabriele Quandt,[||,†] Ljuba Iovkova,[||,#] Esther Schirrmacher,[‡] Carmen Wängler,[§] Guido Boening,[†] Marcus Hacker,[†] Michael Schmoeckel,[⊥] Klaus Jurkschat,[#] Peter Bartenstein,[†] and Ralf Schirrmacher*[,§]

Department of Nuclear Medicine, Hospital of the Ludwig-Maximilians-University, Munich, Germany, Lady Davis Institute, Jewish General Hospital, and McConnell Brain Imaging Centre, Montreal Neurological Institute, McGill University, Montreal, Canada, Department of Cardiac Surgery, Ludwig-Maximilians-University, Munich, Germany, and Department of Inorganic Chemistry II, University of Dortmund, Dortmund, Germany. Received September 29, 2008; Revised Manuscript Received November 24, 2008

Radiosyntheses of ^{18}F-radiopharmaceuticals for positron emission tomography (PET) normally require an extraordinarily high effort of technical equipment and specially trained personnel. We recently reported a novel method for the introduction of fluorine-18 into peptides for PET-imaging based on silicon-^{18}F-chemistry (SiFA technique). We herewith introduce the first SiFA-based Kit-like radio-fluorination of a protein (rat serum albumin, RSA) and demonstrate its usefulness for in vivo imaging with μPET in normal rats as well as in a rat heterotropic transplanted heart model. As a labeling agent, we prepared 4-(di-*tert*-butyl[^{18}F]fluorosilyl)benzenethiol (Si[^{18}F]FA-SH) by simple isotopic exchange in 40−60% radiochemical yield (RCY) and coupled it directly to a Sulfo-SMCC derivatized RSA in an overall RCY of 12% within 20−30 min. The technically simple labeling procedure does not require any elaborated purification procedures and is a straightforward example of a successful application of Si−^{18}F chemistry for in vivo imaging with PET.

INTRODUCTION

Molecular imaging in life sciences has positioned itself as a driving force in understanding in vivo interactions of biologically active compounds within the human body (*1*−*5*). As a result of the rising medicinal interest in positron emission tomography (PET) (*6*)—an imaging modality noninvasively depicting the distribution of radiolabeled biomarkers in vivo—the syntheses of radiolabeled biomarkers with the positron-emitting radiohalide fluorine-18 have gained widespread interest in the life sciences (*7, 8*). Although its important role in life sciences has been validated, numerous PET tracers are still far from being considered a routine method for in vivo imaging in patients. This is mainly a result of the complicated syntheses of PET imaging agents. Up until now, only one PET imaging agent, namely, the glucose derivative [^{18}F]fluorodeoxyglucose (2-[^{18}F]FDG), has gained widespread application in nuclear medicine and can be prepared in a fully automated synthesis unit by technicians (*9*). 2-[^{18}F]FDG is a rather simple radiotracer in terms of radiochemistry, and the method of ^{18}F-fluorination (a simple one-step radiolabeling) cannot be transferred to the synthesis of more complex compounds such as peptides and proteins. Simple methods for the ^{18}F-labeling of these substances are highly sought after, because a great number of new compounds intended for PET imaging are based on peptides and antibodies. Most labeling methods for the introduction of ^{18}F into proteins so far described are cumbersome and problematic as a result of the high technical skill needed for preparation (*10*−*13*). Most recently, two chemoselective methods for the ^{18}F-labeling of peptides and proteins have been reported using [^{18}F]FDG-maleimidehexyloxime (*14*) and [^{18}F]-FBA (*15*) as prosthetic labeling agents. Our group and others have searched for novel pathways to introduce ^{18}F into peptides and small molecules based on the formation of Si−^{18}F bonds. The formation of Si−^{18}F bonds as a tool in radiochemistry was communicated in 1985 for the first time (*16*) and proposed again in 1999 (*17*). We recently introduced simple one- and two-step ^{18}F-fluorination methods for peptides (*18, 19*). The described procedures are based on the formation of silicon−^{18}F bonds (in contrast to conventional carbon−^{18}F chemistry) originating from the unexpectedly efficient isotopic nonradioactive ^{19}F for radioactive ^{18}F exchange, which we named the silicon−fluorine-acceptor (SiFA) method. It has been shown most recently that Si−^{18}F chemistry can also be applied under no-carrier-added conditions, giving rise to high specific activities (*20*), and this chemistry was used for the labeling of a bombesin analogue intended for tumor imaging (*21*). We therefore endeavored to (1) transfer the SiFA method to the labeling of proteins, (2) demonstrate in vivo stability of the introduced ^{18}F-label with μPET (small PET camera for animals), and (3) show successful in vivo imaging. As proof of feasibility, we chose rat serum albumin (RSA) as a suitable protein for demonstrating the Kit-like labeling by the SiFA method. The resulting compound, [^{18}F]SiFA-labeled RSA for blood pool imaging with μPET, was applied in healthy rats ($n = 3$) as well as in a heterotropic heart model rat, demonstrating its usefulness compared to [^{18}F]FDG as a viability marker in the latter case.

Illustra Nap-5 and Nap-10-columns were obtained from GE Healthcare Europe GmbH (Freiburg, Germany).

Instruments. NMR experiments were carried out with Bruker DRX 400, Bruker DRX 300, and Varian Mercury 200 spectrometers. The chemical shifts δ are given in ppm and are referenced to the solvent peaks with the usual values calibrated against tetramethylsilane (^{1}H, ^{13}C, ^{29}Si) and $CFCl_3$ (^{19}F). The high-resolution mass spectra were obtained with LTQ Orbitrap mass spectrometer (Thermo Electron) using acetonitrile as the mobile phase. The acetonitrile solutions were injected via a TriPlus Autosampler onto a DFS system (Perfluorkerosene as reference), connected with a Trace GC Ultra 2000 system (column DB-5MS (25 m, 0.25 mm ID, film 0.1 mm). FT infrared spectra were recorded using a Bruker IFS28 spectroemeter. Elemental analyses were performed on a LECO-CHNS-932 analyzer.

For analysis of the reaction mixtures and quality control, an Agilent series 1200 HPLC was used with a multiwavelength UV detector and a Raytest (Straubenhardt, Germany) radioactivity detector. The columns used were a Chromolith Performance RP-18 (100 × 4.6 mm) (Merck, Darmstadt, Germany) and a Superdex 75 size exclusion column (GE Healthcare Europe Freiburg, Germany), eluted with 10 mM phosphate buffer at pH 7.2, for quality control. UV/vis spectra were recorded using a Ultrospec 1100 pro (Amersham Biosciences Europe GmBH, Freiburg, Germany) apparatus. The PET scan was performed using a Siemens Inveon 120 small animal PET system (Siemens Preclinical Imaging, Knoxville, TN).

1-(*tert*-Butyldimethylsilanylsulfanyl)-4-(di-*tert*-butylfluorosilanyl)benzene. At −78 °C and under magnetic stirring, a solution of *t*-butyllithium in pentane was added to a solution of 4-bromophenylsulfanyl-*tert*-butyldimethylsilane (*22*) (2.61 g, 8.60 mmol) in diethyl ether (30 mL). After the reaction mixture had been stirred for 30 min at −78 °C, the resulting suspension was added dropwise over a period of 20 min to a cooled solution (−78 °C) of di-*tert*-butydifluorosilane (*23*) (1.86 g, 10.32 mmol) in diethyl ether (30 mL). The reaction mixture was allowed to warm to room temperature over a period of 12 h. The reaction mixture was hydrolyzed with a saturated solution of NaCl. The organic layer was separated, and the aqueous layer was extracted three times with diethyl ether at 50 mL each. The combined organic layers were dried over magnesium sulfate. After the magnesium sulfate had been filtered, the filtrate was evaporated in vacuo to give a residue that contained 16% di-*tert*-butylfluorophenylsulfanylsilane and 84% 1-(*tert*-butyldimethylsilanylsulfanyl)-4-(di-*tert*-butylfluorosilanyl)benzene. The latter was purified by distillation under reduced pressure (bp 188−190 °C, 5×10^{-3} Torr) to provide 2.74 g (7.13 mmol, 83% yield) of 1-(*tert*-butyldimethylsilanylsulfanyl)-4-(di-*tert*-butylfluorosilanyl)benzene as a yellow oil.

^{1}H NMR (300.13 MHz, $CDCl_3$): δ 7.44 (m, 4H, H_{arom}), 1.03 (d, $^4J(^1H-^{19}F) = 1.1$ Hz, 18H, CH_3), 0.95 (s, 9H, CH_3), 0.17 (s, 6H, CH_3). ^{13}C{^{1}H} NMR (100.63 MHz, $CDCl_3$): δ 134.5 (s, C_i), 134.0 (d, $^3J(^{13}C-^{19}F) = 4$ Hz, C_m), 133.6 (s, C_o), 131.7 (d,$^2J(^{13}C-^{19}F) = 14$ Hz, C_p), 27.2 (s, CH_3), 26.3 (s, CCH_3), 20.1 (d,$^2J(^{13}C-^{19}F) = 12$ Hz, CCH_3), 18.9 (s, CH_3), −6.8 (s, SiCH_3). ^{19}F NMR (282.38 MHz, $CDCl_3$): δ −191.5 (s, $^1J(^{19}F-^{29}Si) = 298$ Hz). ^{29}Si{^{1}H } NMR (59.63 MHz, $CDCl_3$): δ 14.4 (d, $^1J(^{29}Si-^{19}F) = 298$ Hz). Elemental analysis calculated (%) for $C_{20}H_{37}FSSi_2$ (384.74 g/mol): C 62.4, H 9.7, found C 62.3, H 9.4. GC-EI-HRMS: Calculated for $C_{20}H_{37}F^{32}S^{28}Si_2$ 384.2133, found 384.2146.

4-(Di-*tert*-butylfluorosilanyl)benzenethiol (SiFA-SH). A solution of 1-(*tert*-butyldimethylsilanylsulfanyl)-4-(di-*tert*-butylfluorosilanyl)benzene (2.6 g, 6.75 mmol) in dichloromethane 10 mL to which had been added trifluoracetic acid (7.7 g, 5.2 mL, 67.5 mmol) was stirred for 24 h (*22*). The volatiles were evaporated in vacuo (up to 10^{-3} Torr) to afford 4-(di-*tert*-butylfluorosilanyl)benzenethiol as a yellowish oil in quantitative yield.

^{1}H NMR (300.13 MHz, C_6D_6): δ 7.47 (d, $^3J(^1H-^1H) = 8$ MHz, 2H, H_{arom}), 7.07 (d, $^3J(^1H-^1H) = 8$ MHz, 2H, H_{arom}), 3.12 (s, 1H, SH), 1.09 (d, $^4J(^1H-^{19}F) = 1$ Hz,18H, CH_3). ^{13}C{^{1}H} NMR (75.48 MHz, C_6D_6): δ 134.5 (d, $^3J(^{13}C-^{19}F) = 4$ Hz, C_m), 133.9 (s, C_i), 129.9 (d, $^2J(^{13}C-^{19}F) = 14$ Hz, C_p), 128.2 (s, C_o), 27.2 (s, CH_3), 20.2 (d,$^2J(^{13}C-^{19}F) = 12$ Hz, CCH_3). ^{19}F NMR (282.38 MHz, $CDCl_3$): δ −190.7 (s, $^1J(^{19}F-^{29}Si) = 298$ Hz). ^{29}Si{^{1}H } NMR (59.63 MHz, $CDCl_3$): δ 14.2 (d, $^1J(^{29}Si-^{19}F) = 298$ Hz). IR (KBr): ν (SH) 2571 cm^{-1}. Elemental analysis: calculated (%) for $C_{14}H_{23}FSSi$ (270.48 g/mol) C 62.2, H 8.6, found C 62.0, H 8.7. GC-EI-HRMS: Calculated for $C_{14}H_{23}F^{32}S^{29}Si$ 270.1268, found 270.1269.

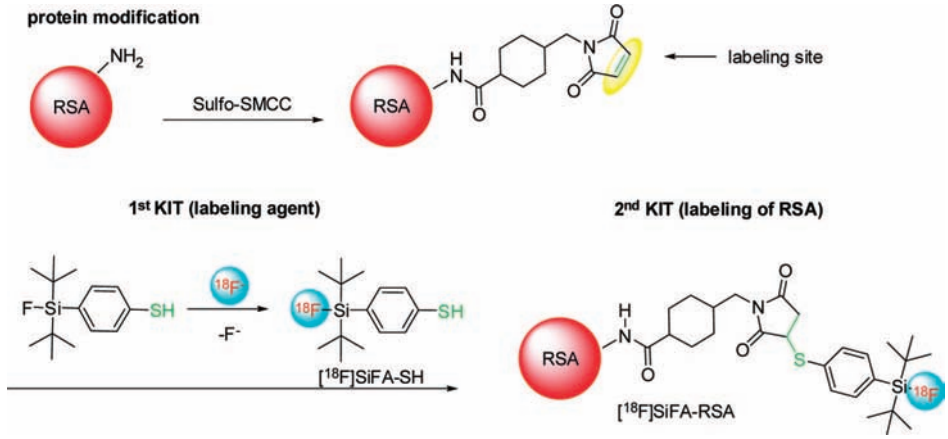
Modification of RSA with Sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate Sodium Salt (Sulfo-SMCC). RSA (5 mg, 75 nmol) was dissolved in 0.5 mL phosphate buffer (PB) (0.1 M, pH 7.2). 10 μL (2.1 mg, 4.81 μmol in 100 μL DMSO) of a freshly prepared 48 mM Sulfo-SMCC stock solution was added and reacted at room temperature for 1 h. The derivatized protein was purified by using a Nap-5 column (equilibration buffer: 0.1 M PB, pH 6.5) and obtained in quantitative yield. The degree of maleimide modification was determined using Ellman's assay (cf. Supporting Information) applying MESNA (sodium 2-mercaptoethanesulfonate) and revealed approximately 2.5 maleimide groups per albumin (*24*).

1st Kit (Labeling Agent): Radiosynthesis of [^{18}F]SiFA-SH. The azeotropically dried [^{18}F]F^-/tetrabutylammoniumbicarbonate complex (∼1−2 GBq, cf. Supporting Information) was dissolved in dry DMSO (100 μL). SiFA-SH (10 μg, 37 nmol, 10 μL of a 1 mg/mL stock solution in DMSO) was added and reacted at room temperature for 5 min without stirring. Reaction control via RP-HPLC (Chromolith RP-18 performance, 4 mL/min, linear gradient starting from 100% water + 0.1% TFA to 100% acetonitrile + 0.1% TFA in 5 min) revealed a radiochemical yield of 40−60% for this step (R_t = 5.5min). The [^{18}F]SiFA-SH/DMSO solution was used for protein labeling without further purification.

2nd Kit (Labeling of Protein); Reaction of [^{18}F]SiFA-SH with RSA. One milliliter of the maleimide-functionalized RSA 5 mg, 75 nmol, in buffer (0.1 M PB, pH 7.2), as obtained in the protein derivatization step, was added to [^{18}F]SiFA-SH (100 μL of the DMSO solution as obtained above) and reacted at room temperature for 10 min without stirring. The ^{18}F-labeled protein was purified using a Nap-10 column (equilibration buffer: 0.1 M PB, pH 7.2) where only the first milliliter of the eluent was collected to ensure high purity of the product. The decay-corrected radiochemical yield was approximately 12%, and quality control using size exclusion HPLC revealed a radiochemical purity of ≥97% (Superdex 75 size exclusion column, 1 mL /min 10 mM PB pH 7.2, R_t = 14.5 min).

In Vivo Biodistribution of [^{18}F]SiFA-RSA in Healthy Rats and in a Heterotropic Rat Heart Transplantation Model. CD rats were housed according to German animal protection laws and protocols of the local committee. Experiments were performed under inhalation anesthesia (oxygen 1.2 L/min, isofluran 1.5 vol %) and appropriate warming to prevent hypothermia. 20−60 MBq of [^{18}F]SiFA-RSA was intravenously administered via a lateral tail vein. List mode data were acquired over 30 min using a Siemens Inveon 120 small animal PET system (Siemens Preclinical Imaging, Knoxville, TN) and divided into temporal frames of increasing length varying from 20 s to 5 min for the assessment of temporal changes in regional tracer accumulation. Tomographic volumes were created using three iterations of 3D OSEM, followed by 16 iterations of 3D

Scheme 1[a]



[a] Derivatization of rat serum albumin (RSA) applying sulfo-SMCC (protein modification step: RSA 5 mg, 75 nmol, was reacted with Sulfo SMCC (210 μg, 481 nmol) for 1 h at room temperature and subsequently purified by means of size exclusion gel cartridge filtration (illustra NAP-5), synthesis of [18]F]SiFA-SH (1st Kit, dried [18]F]F/tetrabutylammoniumbicarbonate complex 1−2 GBq in 100 μL DMSO were reacted 5 min at room temperature with SiFA-SH (10 μg, 37 nmol dissolved in 10 μL DMSO) and subsequent [18]F labeling of RSA (2nd Kit, the crude mixture obtained in the 1st Kit was added to derivatized RSA 5 mg, 75 nmol in PB (0.1 M, pH = 6.5) and reacted at ambient temperature for 10 min. Finally, the desired product was purified with an illustra Nap-10 cartridge).

OS-MAP iterative reconstruction, yielding a transaxial spatial resolution of approximately 1.4 mm (*25*). Additional experiments were performed using a heterotropic rat heart transplantation model, where the aorta of the transplanted heart was connected to the aorta abdominalis of the recipient rat. The aortic valve of the graft was occluded so that blood was circulating through the coronary arteries into the myocardium and was drained through coronary veins into the right atrium and ventricle. Arteria pulmonalis was connected with the inferior vena cava of the recipient rat.

RESULTS AND DISCUSSION

The SiFA labeling procedure of proteins with [18]F is based on the preceding synthesis of a small [18]F-labeled compound, which then reacts in good yields with the modified protein. In order to call it a true Kit labeling procedure, making it more applicable to a wide range of potential users, no step in the preparation of the labeled protein must use costly equipment such as HPLCs or sophisticated purification procedures. The SiFA labeling of RSA is based on the thiol-maleimide labeling concept and includes (1) derivatization of RSA with maleimido groups before the labeling of RSA to make it amenable to the SiFA labeling approach, (2) synthesis of the thiol-bearing [18]F]SiFA labeling agent from the nonradioactive SiFA compound by isotopic exchange—as a suitable SiFA compound for [18]F-labeling, we chose 4-(di-*tert*-butylfluorosilyl)benzenethiol (SiFA-SH), which was yielded quantitatively by treating the intermediate compound 1-(*tert*-butyldimethylsilanylsulfanyl)-4-(di-*tert*-butylfluorosilanyl)benzene with TFA (cf. Experimental Section), and (3) reaction of [18]F]SiFA-SH with RSA. The maleimido moieties could be easily introduced into the protein by reacting RSA with the heterobifunctional cross-linking reagent sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate sodium salt (Sulfo-SMCC) in a simple procedure (Scheme 1, protein modification) and a gel cartridge purification step (*26*).

The first labeling step involved the introduction of [18]F]fluorine into the small, thiol moiety bearing prosthetic SiFA-SH compound by fast isotopic exchange for further labeling of the maleimido-modified RSA (Scheme 1, first Kit labeling agent). [18]F]SiFA-SH is supposed to selectively react with maleimido groups via a Michael Addition. Nonradioactive SiFA-SH (10 μg, 37 nmol) was labeled with up to 1−2 GBq of azeotropically dried $^{18}F^-$ in 100 μL dimethylsulfoxide (DMSO) at room temperature for 5 min. The incorporation of the radioactive $^{18}F^-$ into SiFA-SH was between 40% and 60% as determined by radio-HLPC. The calculated specific activity for [18]F]SiFA-SH was between 11 and 34 GBq/μmol (298 and 919 Ci/mmol) and is sufficient for protein labeling in general. The unexpected efficiency of the isotopic exchange has been elucidated by performing DFT calculations on some model fluorosilanes previously (*19*). Purification of [18]F]SiFA-SH thus formed was not necessary, as the unreacted $^{18}F^-$ does not compromise the subsequent conjugation reaction with RSA. The crude [18]F]SiFA-SH was mixed with 1 mL of the sulfo-SMCC derivatized RSA (5 mg, 75 nmol) in phosphate buffer (0.1 M, pH 7.2) originating from the protein modification step (Scheme 1, second Kit labeling of RSA). After gel cartridge (Illustra Nap-10) purification, the product [18]F]SiFA-RSA was isolated in 1 mL phosphate buffer and sterile-filtered for injection. The chemical and radiochemical purity was >97% according to size exclusion LC.

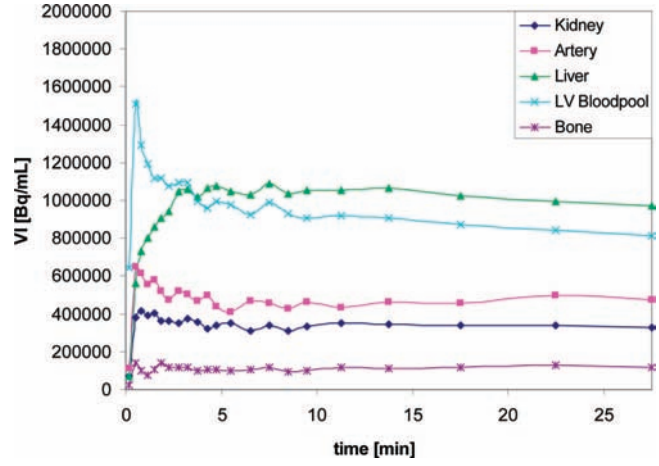


Figure 1. Time−activity curves of a CD rat after application of [18]F]SiFA-RSA, derived from the image data. Radioactivity was measured over 30 min in the liver, the kidney, the arteries, the bone, and the left ventricle (LV) using the volume of interest (VOI) technique. Curves are reflecting [18]F]SiFA-RSA blood pool activity.

To assess the in vivo applicability of the [18]F]SiFA-RSA, 25−60 MBq were injected in healthy rats (n = 3) and evaluated by means of μPET. Rat biodistribution data showed nearly constant whole blood radioactivity from minute 2 over the next

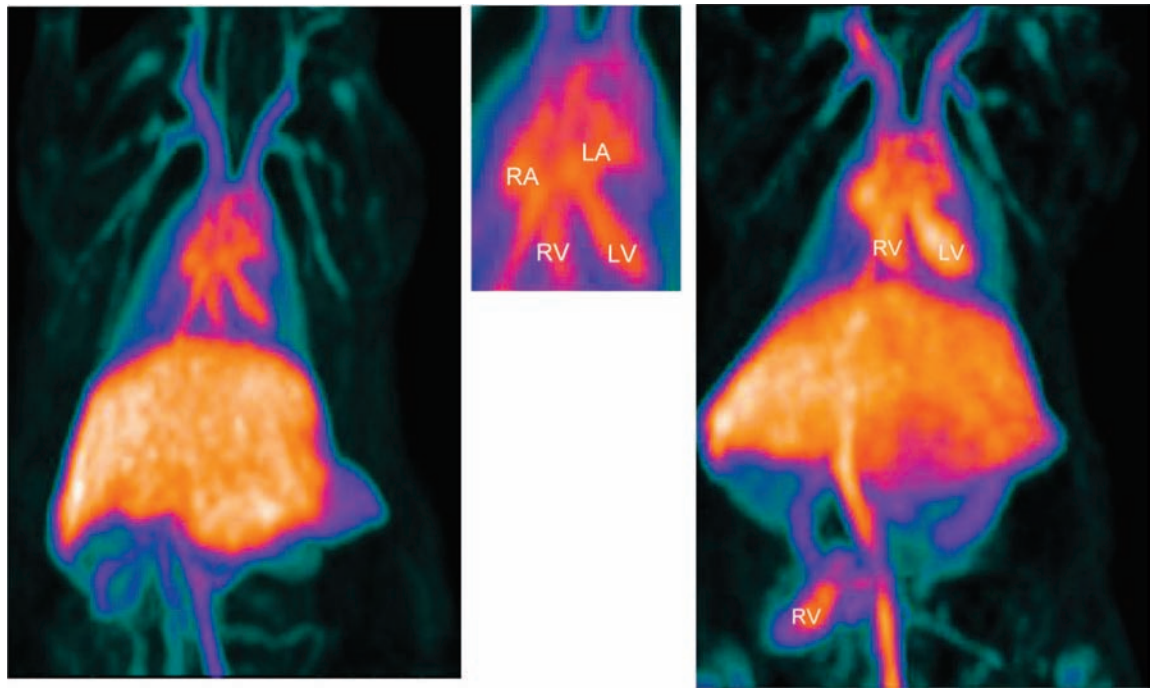

Figure 2. (left) Maximum intensity projection image ("best septal view") of an [^{18}F]SiFA-RSA blood pool scan of a healthy rat acquired over 30 min, showing radiotracer accumulation in the large arteries, the liver, and the heart. As indicated in the enlarged image cutout (middle), atria and ventricles can easily be identified. (right) Heterotopic rat heart transplantation model showing [^{18}F]SiFA-RSA blood pool in both the orthotopic and the heterotopic heart placed in the abdomen. Only right atrium and right ventricle are filled with blood in this model. RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle.

25 min after injection. While the liver as an organ with a large blood volume showed high uptake similar to the blood pool, kidney uptake was in the range of the arterial blood volume (Figure 1). Only slight radioactivity accumulation was registered in the bone, demonstrating minimal disposal of unbound [^{18}F]fluoride *in vivo*. Due to these characteristics, ^{18}F-labeled RSA represents a nearly ideal tracer for small animal PET blood pool studies. Blood pool imaging in planar or single photon emission computer tomography (SPECT) technique was shown to accurately estimate left and right ventricular volumes and ejection fractions in both humans (*27*) and mice (*28*) and, thus, can be used for monitoring different kinds of cardiac or cardiotoxic oncological therapies. Additionally, as demonstrated in Figure 2, PET blood pool imaging could serve for more advanced applications like monitoring blood pool in a heterotopic rat heart transplantation model. For this model, common [^{18}F]-FDG imaging glucose metabolism of the transplant was not feasible, as the heterotopic heart does not metabolize ^{18}F-FDG due a myocardial shift to fatty acid metabolism after denervation (cf. Supporting Information). Using [^{18}F]SiFA-RSA, the heterotopic heart blood pool and with it the endocardial borders could easily be visualized.

These examples proved applicability of this new labeling technique in nuclear medicinal imaging, and we intend to introduce SiFA-labeled human serum albumin as a blood pool tracer for human imaging studies. It is anticipated that for all proteins the same procedure can be applied. Step 1: SiFA-SH is incubated with dried $^{18}F^-$ at room temperature for 5 min. Step 2: The crude mixture is added to the sulfo-SMCC-derivatized protein in aqueous buffer and reacted at room temperature for the appropriate time. Step 3: The final purification is performed using a gel cartridge (Nap-10) to obtain the labeled protein in an injectable solution. The overall time for the synthesis of [^{18}F]SiFA-RSA takes 20−30 min only and is therefore one of the fastest ^{18}F-labeling procedures for proteins to date, which completely omits the use of costly technical equipment such as HPLC.

In anticipation of human applicability of this labeling Kit procedure, it is noteworthy to state that we entirely avoided toxic substances commonly applied in ^{18}F-chemistry such as harmful solvents like acetonitrile and kryptand (Kryptofix2.2.2.), which in turn also facilitates a clinical application of this new labeling method. Due to the high convenience of the radiochemistry presented here, we are currently investigating whether SiFA-SH labeled single-chain antibodies and other biologically active proteins might serve as valuable imaging agents for PET.

CONCLUSIONS

In conclusion, we demonstrated that the synthesis of a ^{18}F-labeled sulfo-SMCC derivatized protein (RSA) could be easily achieved using the novel silicon-based labeling synthon [^{18}F]SiFA-SH in sufficient overall RCYs of 12% after 20−30 min only. The entire procedure is independent of using complicated equipment such as HPLC and only needs two consecutive gel cartridge purification steps including protein modification. Injection of the purified [^{18}F]SiFA-RSA into healthy rats as well as into a rat bearing an abdominally transplanted second heart confirmed its usefulness as a new ^{18}F-labeled blood pool imaging agent with PET.

Supporting Information Available: Preparation of azeotropically dried [^{18}F]F^-/tetrabutylammoniumbicarbonate-complex, Ellman's assay to determine maleimide group derivatization of proteins, supplementary videos showing rotating maximum-intensity projections of healthy rats as (a) dynamic images, as summed images (b) with and (c) without ECG gating, as well as (d) a rat with a heterotopic (abdominally) transplanted heart, connected to the descending aorta and the inferior vena cava. This material is available free of charge via the Internet at http://pubs.acs.org.

Kit-like ^{18}F-labeling of proteins: Synthesis of 4-(di-tert-butyl[^{18}F]fluoro-silyl)benzenethiol (Si[^{18}F]FA-SH) labeled rat serum albumin for blood pool imaging with PET

Björn Wängler, Gabriele Quandt, Ljuba Iovkova , Esther Schirrmacher, Carmen Wängler, Guido Boening, Marcus Hacker, Michael Schmoeckel, Klaus Jurkschat , Peter Bartenstein and Ralf Schirrmacher

Supporting Information:

Preparation of [N(*n*-Bu)$_4$]^{18}F using [N(*n*-Bu)$_4$]HCO$_3$ for SiFA labeling Aqueous [^{18}F]fluoride (5000-9000 MBq) that had been prepared by the ^{18}O(p,n)^{18}F nuclear reaction on an enriched [^{18}O]water (95 %) was loaded onto a Chromafix PS-HCO$_3$ (GE-Healthcare Europe) cartridge and eluted with a mixture of 800µL acetonitrile and 200µL aqueous tetrabutylammonium hydrogen carbonate solution (c = 0.075 mmol/mL, ABX, Radeberg, Germany) and azeotropically dried using acetonitrile (2 x 1 mL, stream of nitrogen, 80°C). The "dried" [N(*n*-Bu)$_4$]^{18}F complex was dissolved in DMSO (100 - 250 µL) and this stock solution was used for labeling.
