Received April 6, 2009; Revised Manuscript Received June 19, 2009

The increased expression of the neurotensin (NT) receptor NTS1 by different cancer cells, such as pancreatic adenocarcinoma and ductal breast cancer cells, as compared to normal epithelium, offers the opportunity to target these tumors with radiolabeled neurotensin analogues for diagnostic or therapeutic purposes. The aim of the present study was to design and synthesize new neurotensin radioligands and to select a lead molecule with high in vivo tumor selectivity for further development. Two series of neurotensin analogues bearing DTPA were tested: a series of NT(8−13) analogues, with DTPA coupled to the α-NH_2, sharing the same peptide sequence with analogues previously developed for radiolabeling with technetium or rhenium, as well as an NT(6−13) series in which DTPA was coupled to the ε-NH_2 of Lys^6. Changes were introduced to stabilize the bonds between Arg^8-Arg^9, Pro^{10}-Tyr^{11}, and Tyr^{11}-Ile^{12} to provide metabolic stability. Structure−activity studies of NT analogues have shown that the attachment of DTPA induces an important loss of affinity unless the distance between the chelator and the NT(8−13) sequence, which binds to the NTS1 receptor, is increased. The doubly stabilized DTPA-NT-20.3 exhibits a high affinity and an elevated stability to enzymatic degradation. It shows specific tumor uptake and high tumor to blood, to liver, and to intestine activity uptake ratios and affords high-contrast planar and SPECT images in an animal model. The DTPA-NT-20.3 peptide is a promising candidate for imaging neurotensin receptor-positive tumors, such as pancreatic adenocarcinoma and invasive ductal breast cancer. Analogues carrying DOTA are being developed for yttrium-90 or lutetium-177 labeling.

INTRODUCTION

Pancreatic adenocarcinoma, the tenth most common human cancer, grows extremely rapidly, disseminates early, and occult metastases are frequent. Noninvasive staging modalities have shown limited ability to detect local invasion or small volume metastatic disease. ^{18}F-labeled 2-deoxy-2-fluoro-D-glucose (^{18}F-FDG), which has greatly improved the diagnosis and staging of numerous tumors, does not significantly increase the accuracy of the preoperative determination of resectability of pancreatic adenocarcinoma (*1*). Therefore, a noninvasive method to improve preoperative staging would be extremely useful. It has been shown that 75−88% of ductal pancreatic adenocarcinomas express neurotensin (NT) receptors (*2, 3*). These receptors have been proposed as new markers for this tumor, since they were not detected in normal pancreas and chronic pancreatitis (*2*). NT receptors were also identified in other tumor cells as, for example, Ewing's sarcoma, meningiomas, small cell lung carcinoma, and colon adenocarcinoma (*4*−*6*). In patients with invasive ductal breast cancers, 91% of tumors are positive for the neurotensin high-affinity receptor (NTS1), while it is poorly expressed or absent in normal cells (*7*). This recent work suggests that neurotensin contributes to human breast cancer progression and points out to the therapeutic potential of molecules targeting NTS1 receptor.

Three NT receptor subtypes have been cloned to date. Most NT biological effects are mediated by NTS1. NT(8−13) is the minimal sequence that mimics the effects of full-length NT (*8*). Numerous neurotensin analogues containing the (N^{α}His)Ac chelator and labeled with ^{99m}Tc or ^{188}Re have been synthesized (*9*−*15*). Since neurotensin is rapidly degraded in vivo by peptidases, changes were introduced to protect the three major sites of enzymatic cleavage, the Arg^8-Arg^9, Pro^{10}-Tyr^{11}, and Tyr^{11}-Ile^{12} bonds (*9*), to stabilize these molecules. The recently reported analogue NT-XIX with the three enzymatic cleavage sites stabilized displayed the highest tumor uptake described in the literature for radiolabeled neurotensin analogues, with low uptake in normal organs and particularly in kidneys (*12, 13*). Very encouraging therapy results of 50% reduction of tumor growth were obtained in nude mice with ^{188}Re-labeled NT-XIX. Significant activity detected in the intestines may nevertheless be a source of radiotoxicity (*12*). Peptides and proteins coupled to diethylenetriaminepentaacetic acid (DTPA) have been used successfully to deliver indium-111, gallium-67, and gallium-68 for imaging applications (SPECT and TEP) (*16*−*18*). By contrast, yttrium-90 needs macrocyclic chelators such as 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) to prevent leakage and bone marrow toxicity in targeted radionuclide therapy (*19*). Lutetium-177 has also

[a] Ahx: aminohexanoic acid. [b] Results already described (*22*).

been used with DOTA-substituted peptides and antibodies. However, with previously described DTPA/DOTA neurotensin analogues, tumor uptake was limited and accumulation of radioactivity in kidneys resulted in low tumor to kidney uptake ratios (*20*−*22*). In the present study, since DTPA is a suitable chelator for ^{111}In scintigraphy, new neurotensin analogues carrying DTPA have been synthesized to further investigate the peptide structural parameters influencing tumor targeting and normal tissue uptake and to select a lead molecule for further development. They were evaluated with regard to binding affinity, stability to enzymatic degradation, internalization rate, and biodistribution. Their properties were compared to those of a reference peptide [Lys^6(DTPA(^{111}In))]-NT in which DTPA was coupled to the Lys^6 ε-NH_2 of NT (*22*).

MATERIALS AND METHODS

Cells. Experiments were performed with the human colorectal carcinoma cell line HT29 (ATCC, Rockville, USA). Cells were grown in DMEM (Gibco, France) supplemented with 10% fetal calf serum, 2 mM glutamine, and 50 μg/mL gentamycin at 37 °C in 5% CO_2.

Synthesis of the DTPA-NT Analogues. All reagents used for the synthesis were obtained from Sigma-Aldrich (Saint Quentin Fallavier, France, or Bornem, Belgium), Novabiochem (Läufelfingen, Switzerland), Bachem (Bubendorf, Switzerland), and RSP (Shirley, USA). The purity of the compounds was checked by HPLC on a Nucleosil C_{18} (5 μm, 100 Å, Shandon, France) reverse-phase column or on a DiscoveryBIO SUPELCO Wide Pore (5 μm, 300 Å, Sigma-Aldrich) column with a gradient of A, water (0.05% TFA), and B, CH_3CN (0.05% TFA), at a flow rate of 1 mL/min on a Waters apparatus. The NT(8−13), NT-VI, NT-XI, NT-XII, and NT-XIX peptides (Table 1) were prepared by solid-phase peptide synthesis as described in detail elsewhere (*10*, *13*, *23*). Tris-*t*Bu-DTPA (3 equiv) (*24*) was coupled to the resin-bound neurotensin analogue in a mixture of DMF/CH_2Cl_2 using 2−1*H*(benzotriazol-1-yl)-1,1,3,3-tetramethylureum tetrafluoroborate (TBTU), 1-hydroxybenzotriazole (HOBt), and diisopropylethylamine (DIPEA) during 4 h. The acetylated NT(6−13) analogues were synthesized by NeoMPS (Strasbourg, France) and DTPA was coupled to the lysine ε-NH_2 as already described (*25*).

Radiolabeling. The DTPA-NT analogues were labeled with indium-111 ($^{111}InCl_3$, 60 or 180 MBq, CIS bio International, France) in 100 mM acetate, 10 mM citrate, buffer pH 5, for 22 h at room temperature, and then free DTPA groups were saturated with nonradioactive $InCl_3$ as already described (*26*).

Determination of the NTS1 Binding Affinities of the DTPA-NT Analogues. *Binding to HT29 Cell Membranes.* Cell membranes (60 μg protein) were incubated for 45 min at room temperature in 250 μL buffer (50 mM Tris HCl, 5 mM $MgCl_2$, 0.8 mM 1,10-phenanthroline, 0.2% BSA, pH 7.4) in the presence of 50 pM ^{125}I-Tyr^3-neurotensin (Perkin-Elmer) and increasing concentrations of nonradioactive DTPA(In)-NT analogues. Membrane-bound activity was recovered by filtration onto Whatman GF/B filters presoaked for 1 h with polyethyleneimine (0.2% in water) and rinsed twice with buffer. Nonspecific binding was evaluated in the presence of 10^{-6} M neurotensin. Radioactivity was counted, and results were analyzed with GraphPad Prism (GraphPad Software, Inc., San Diego, CA). All experiments were performed three times.

Binding to Living HT29 Cells and Internalization. IC_{50} values for the binding to living HT29 cells were determined from competition experiments between [Lys^6(DTPA(^{111}In))]-NT (150 pM) and the peptides without DTPA or DTPA(In)-Ahx-NT-XIX. For the other peptides, IC_{50} was evaluated using the labeled DTPA(^{111}In)-peptide and increasing concentrations of the corresponding nonradioactive DTPA(In)-peptide. Cells were rinsed with 500 μL DMEM and 0.2% BSA, and incubated with DTPA(^{111}In)-NT analogue (0.15×10^{-9} M, 300 μL DMEM, 0.2% BSA, 0.8 mM 1,10-phenanthroline, 60 min, 37 °C) in the presence of increasing concentrations of nonradioactive DTPA(In)-NT analogue. After washing the wells twice with ice-cold DMEM 0.2% BSA, cells were lysed in 500 μL 0.1 N NaOH, and radioactivity was counted. Nonspecific binding was evaluated in the presence of 10^{-6} M neurotensin. Competition curves were analyzed with the *Equilibrium Expert* software (*27*). All experiments were performed three times.

Incubation for internalization studies was performed with 0.15×10^{-9} M DTPA(^{111}In)-NT analogue as above except for the use of twelve-well plates (600 μL). At selected times, the total binding was evaluated as above. To determine the amount of internalized radioactivity, wells were incubated in DMEM/0.2% BSA, pH 2.0, for 15 min at 4 °C, to dissociate the surface-bound ligand. Internalized activity was then counted after washing. Nonspecific binding and internalization were evaluated in the presence of 10^{-6} M neurotensin. Results are expressed as the ratio between internalized and specifically bound radioactivity.

Metabolic Stability. *In Human Serum.* Serum from healthy donors (100 μL) was incubated with the DTPA(^{111}In) analogues

(2 pmol, 37 °C). Samples were collected at different time points, and proteins were precipitated with methanol and filtered. Then, methanol was evaporated under vacuum, and the sample was analyzed by C_{18} RP-HPLC as described above. Detection was performed with a radioactivity detector (HERM LB 500, Berthold, France). Elution was performed using, after 5 min 0% B, a linear 10 min gradient from 0% to 35% B and a linear 25 min gradient from 35% to 50%, flow rate 1.5 mL/min. The sample was also coinjected with the radioactive control to identify the peak corresponding to intact peptide.

In Vivo Stability. Female BALB/c mice were injected in the tail vein with ^{111}In-labeled DTPA-NT analogues (25 pmol). The mice were sacrificed 15 min after injection. Plasma and urine samples (50 μL) were added to 200 μL methanol and treated as above.

Biodistribution and Imaging Studies. All in vivo experiments were performed in compliance with the French guidelines for experimental animal studies and fulfill the UKCCCR guidelines for the welfare of animals in experimental neoplasia.

HT29 cells (6.7×10^5 cells) were injected subcutaneously in the flank of 6−8 week old athymic nu/nu mice (Harlan, France). Two weeks later, mice were i.v. injected with ^{111}In-labeled-DTPA-NT analogues (20−25 pmol in 100 μL PBS) and sacrificed at different times. Blood, organs, and tumors were collected, weighed, and radioactivity counted. Injected activity was corrected for losses by subtraction of noninjected and subcutaneously injected material (remaining in the animal tail). In blocked experiments, each mouse received a coinjection of the labeled peptide and of its unlabeled counterpart (60 nmol of NT or 180 nmol of NT-20.3). Statistical analysis of differences in the tissue uptake values was performed using unpaired *t* test for comparison between two groups, or ANOVA variance analysis followed by Newman-Keuls' test for multiple comparisons. Differences of $p < 0.05$ were considered significant.

Scintigraphic imaging was performed under pentobarbital anesthesia after i.v. injection with DTPA(^{111}In)-NT-20.3 (30−50 pmol, 9−13 MBq) using a dedicated small animal Gamma Imager-S/CT system (Biospace Mesures) equipped with parallel collimators (matrix 128 × 128, with 15% energy windows centered on both indium-111 peaks at 171 and 245 KeV). A planar anterior acquisition was performed from 0 to 60 min postinjection, and a dynamic series of images of 5 min each were computed from the recorded scintigraphy data. At 2 h postinjection, SPECT images (1 h acquisition) were obtained after volume reconstruction using an iterative algorithm. Tumor to background activity (evaluated in a ROI symmetrical to that of the tumor, counts per mm^2) ratio was evaluated on planar images. Radioactivity excretion in urine was determined from activity at 1 h postinjection in the bladder.

RESULTS

Synthesis of DTPA-NT Analogues. We synthesized two series of DTPA-bearing neurotensin analogues that were stabilized against enzymatic degradation at the bonds between Arg^8 and Arg^9, Pro^{10} and Tyr^{11}, or Tyr^{11} and Ile^{12} by changes introduced in the peptide sequence (Table 1). DTPA-NT-VI, DTPA-NT-XI, DTPA-Ahx-NT-XII, and DTPA-Ahx-NT-XIX are DTPA-NT(8−13) analogues. They share the same peptide sequence with analogues carrying (Nα-His)Ac for radiolabeling with technetium or rhenium described in the literature (*9*−*11,13,15*). These analogues were prepared by solid-phase synthesis as described previously, and tris-*t*Bu-DTPA was coupled to their N-terminus, followed by resin cleavage and HPLC purification.

We also synthesized analogues of the 6−13 sequence of [Lys^6(DTPA)]-NT, which provided encouraging in vivo tumor targeting results in earlier studies (*22*). The N terminal end was acetylated in order to decrease the positive charge that favors renal accumulation of radiometals (*28, 29*) and to protect it against amino-peptidases. These analogues were obtained by coupling DTPA to the free ε-NH$_2$ group of Lys. Coupling yields were approximately 80% except for DTPA-NT-20.2 (48%). All DTPA-peptides were purified to at least 92% purity (92−99%) and identified by mass spectrometry (Table 1).

Table 2. Affinity of Peptides

peptide	K_i (nM) membranes	IC_{50} (nM) cells
NT	0.28 ± 0.05	1.67 ± 0.40
[Lys^6(DTPA(In))]-NT	1.77 ± 0.39	17.3 ± 4.3
NT(8−13)	0.044 ± 0.009	0.68 ± 0.04
DTPA(In)-NT(8−13)	1.36 ± 0.39	21.7 ± 5.1
DTPA(In)-NT-VI	3.20 ± 0.81	14.7 ± 1.6
DTPA(In)-NT-XI	8.11 ± 1.03	101 ± 17
DTPA(In)-Ahx-NTXII	5.26 ± 1.24	132 ± 44
DTPA(In)-Ahx-NT-XIX	67 ± 11	626 ± 30
NT-20.1	0.072 ± 0.019	0.82 ± 0.08
NT-20.2	0.26 ± 0.07	2.46 ± 0.79
NT-20.3	0.16 ± 0.03	2.20 ± 0.31
DTPA(In)-NT-20.1	0.66 ± 0.1	6.73 ± 0.31
DTPA(In)-NT-20.2	1.55 ± 0.42	41.2 ± 6.2
DTPA(In)-NT-20.3	2.24 ± 0.21	15.9 ± 1.7

Radiolabeling. ^{111}In-labeling of all DTPA-NT was performed with >90% indium-111 incorporation. Specific activities between 220 and 260 MBq/nmol could be obtained and were used for in vitro and imaging studies. Lower specific activities were used for biodistribution studies.

Binding Affinity Profile. Affinity of the peptides for NTS1 was evaluated using HT29 cells. These cells from which NTS1 has been first cloned (*30*) have been used to evaluate most labeled NT analogues described in the literature. K_i values for binding to membranes and IC_{50} values for binding to cells were used to evaluate affinity. K_i values for binding to HT29 membranes were, for most peptides, about 10 times lower (5−27) than the IC_{50} for the binding to HT29 cells (Table 2). This can be attributed to the decreased affinity for binding to the NTS1 induced by sodium (*31*) and to the effects of internalization and externalization of radioactivity in cells. Nevertheless, the affinities of the different peptides for membranes and living cells show a similar rank order.

Shortening the NT(1−13) sequence increased the affinity of the N^{α}-acetyl-NT(6−13) analogue NT-20.1 as already reported for N^{α}-acetyl-Lys^6(acetyl)-NT(6−13) (*8*).

DTPA(In) coupled to the NH$_2$-α of NT(8−13) induced an important decrease in the affinity for membranes and for cells (by a factor of 31 and 32, respectively) as compared to NT(8−13). This loss of affinity is less important when the distance between the receptor-binding (8−13) sequence and DTPA is larger. When coupling DTPA to the ε-NH$_2$ of Lys^6 of NT, the affinity loss is only a factor of 6 for membranes and 10 for cells. Similarly, the affinity loss in DTPA(In)-NT-20.1 is only a factor of 9 and 8 as compared to NT-20.1. A lower decrease in affinity (by a factor of 3) was observed in a larger peptide described in previous studies: DTPA(In)-(Gly^0-Glu^1-[AcLys^6]NT) (*22*). As a result, the affinity of DTPA(In)-NT-20.1 was 2-fold higher than that of DTPA(In)-NT(8−13), even though NT(8−13) displayed an affinity slightly higher than that of NT-20.1.

In the NT(8−13) series containing the stabilized Lys-Ψ(CH$_2$-NH)-Arg bond (*13*), introduction of a tertiary leucine (Tle^{12}) reduced the affinity by a factor of 3 for membranes and 7 for living HT29 cells, resulting in the lower affinity of DTPA(In)-NT-XI.

N-Methylation of the Arg^8-Arg^9 bond and introduction of an aminohexanoic acid spacer between DTPA and the 8−13 receptor binding sequence did not improve the affinity of DTPA(In)-Ahx-NT-XII as compared to DTPA(In)-NT-XI.

Table 3. In Vitro and in Vivo Stability of Peptides

peptide	in vitro stability ($t_{1/2}$ h)[a]	in vivo stability (% intact peptide)[b]
[Lys^6(DTPA(In))]-NT	25 ± 2	4 (3−5)
DTPA(In)-NT-VI	ND	10 (5−15)
DTPA(In)-NT-XI	ND	47 (40−53)
DTPA(In)-NT-20.1	0.4 ± 0.02	0.8 (0.8−0.8)
DTPA(In)-NT-20.2	4.4 ± 0.6	10 (6−14)
DTPA(In)-NT-20.3	257 ± 71	26.5 (26−27)

[a] In vitro stability is expressed as the degradation half-life in human serum at 37 °C. [b] In vivo stability is expressed as the % intact peptide (mean (individual values)) recovered in plasma 15 min after tracer injection.

Replacement of Tyr^{11} by 2′,6′-dimethyltyrosine in DTPA(In)-Ahx-NT-XIX led to an additional loss of affinity.

Introduction of a Tle^{12} in the NT(6−13) series induced a decrease in affinity similar to that observed in the DTPA(In)-NT(8−13) series. N-Methylation of the Pro^7-Arg^8 bond had little effect on affinity. Because the affinity of NT-20.1 was higher than that of NT, DTPA coupling and sequence modifications to the doubly stabilized DTPA(In)-NT-20.3 analogue resulted in a high affinity, for membranes and for living cells, similar to those of the reference peptide [Lys^6(DTPA(In))]-NT.

The peptides exhibiting the highest affinities, [Lys^6(DTPA(In))]-NT, DTPA(In)-NT-VI, DTPA(In)-NT-XI, DTPA(In)-NT-20.1, DTPA(In)-NT-20.2, and DTPA(In)-NT-20.3, were further evaluated for stability and tumor targeting in vivo.

In Vivo and in Vitro Peptide Catabolism. The fraction of radioactivity associated to the intact DTPA(^{111}In)-peptide in serum and in urine was determined 15 min after iv injection to BALB/c mice (Table 3). Samples were analyzed by C_{18} RP-HPLC chromatography. Metabolites eluted at shorter retention times than the full-length radioactive peptide. The nonstabilized peptides [Lys^6(DTPA(In))]-NT and DTPA(^{111}In)-NT-20.1 were rapidly catabolized (Figure 1, Table 3). Protection of Arg^8-Arg^9 (DTPA(^{111}In)-NT-VI) or Tyr^{11}-Ile^{12} (DTPA(^{111}In)-NT-20.2) bonds improved slightly the stability. Doubly stabilized peptides were much more resistant. Higher amounts of intact tracer were recovered in serum and about 20% of the intact peptide was excreted in urine.

The in vitro stability in human serum was also evaluated for ^{111}In-labeled NT(6−13) analogues and for the reference peptide (Figure 2, Table 3). In agreement with the in vivo results, the unprotected peptide DTPA(^{111}In)-NT-20.1 was very rapidly degraded and DTPA(^{111}In)-NT-20.3 was more stable than DTPA(^{111}In)-NT-20.2. These results confirmed the stabilizing effect of the two modifications. By contrast to the rapid degradation observed in vivo, the unprotected [Lys^6(DTPA(^{111}In))]-NT displayed an in vitro stability higher than that of the monostabilized DTPA(^{111}In)-NT-20.2. These results point out the discrepancies that could occur between in vitro and in vivo degradation even when low tracer amounts are used in vitro in order to avoid saturation of peptidases (*9*).

In Vitro Internalization. As shown in Figure 3, DTPA(^{111}In)-NT-20.3 internalized rapidly in HT29 cells, reaching a 86 ± 3% plateau with a $t_{1/2}$ of 2.1 ± 0.4 min. Similar internalization curves were obtained with [Lys^6(DTPA(^{111}In))]-NT ($t_{1/2}$ 4.2 ± 1.1 min, plateau: 88 ± 6%) and DTPA(^{111}In)-NT-VI ($t_{1/2}$: 3.8 ± 1.2 min, plateau: 82 ± 6%).

Biodistribution and Imaging Studies. The results of biodistribution studies performed in female nude mice grafted with HT29 cells are presented in Tables 4 and 5. They are expressed as the percentage of injected dose per gram of tissue (%ID/g). DTPA(^{111}In)-NT-20.3 displayed the highest tumor uptake, about 3-fold higher than that of [Lys^6(DTPA(^{111}In))]-NT at 1 h (3.3 ± 0.2 vs 1.0 ± 0.3%ID/g, $P < 0.001$) and at 3 h (2.4 ± 0.2 vs 0.7 ± 0.2%ID/g, $P < 0.001$). The difference observed between

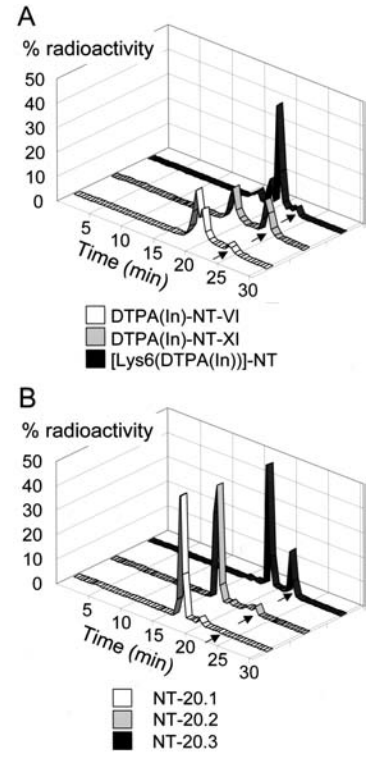

Figure 1. In vivo serum stability of DTPA(^{111}In)-peptides: representative C18 HPLC chromatograms of plasma samples collected 15 min postinjection to mice. (A) reference peptide and NT(8−13) analogues, (B) NT(6−13) analogues. Arrows show the intact peptide retention time identified by a coinjection of the sample with the radioactive control. Results are expressed as the fraction of radioactivity (%) which eluted with the intact peptide.

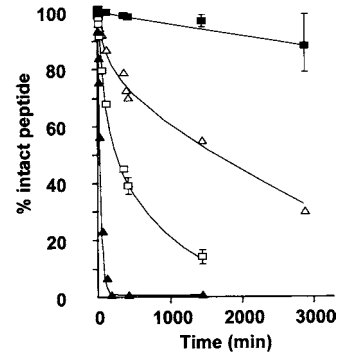

Figure 2. Degradation kinetics of DTPA(^{111}In)-peptides in human serum. Peptides (2 pmol) were incubated with human serum (100 μL) at 37 °C: Δ, [Lys6(DTPA(In))]-NT; ▲, DTPA(In)-NT-20.1; □, DTPA(In)-NT-20.2; ■, DTPA(In)-NT-20.3 (mean ± sem, three independent experiments).

tumor retention at 1 h and 3 h postinjection for DTPA(^{111}In)-NT-20.3 was not statistically significant, indicating a slow washout of radioactivity from the tumor, confirmed by the 0.33 ± 0.04%ID/g tumor uptake observed 100 h postinjection (Figure 4). Radioactivity uptake of other peptides in tumor was lower than that of [Lys^6(DTPA(^{111}In))]-NT, but the difference was not significant.

Tumor uptake of [Lys^6(DTPA(^{111}In))]-NT or DTPA(^{111}In)-NT-20.3 was receptor mediated, since it was significantly reduced by coinjection of their unlabeled counterpart (78% reduction, $P = 0.02$; and 94% reduction, $P < 0.0001$; respectively).

Radioactivity in blood at 1 h postinjection was significantly higher for DTPA(^{111}In)-NT-20.3 and [Lys^6(DTPA(^{111}In))]-NT

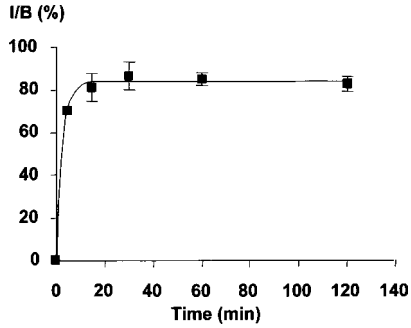

Figure 3. Internalization of DTPA(^{111}In)-NT20.3 in HT29 cells. Results are expressed as the ratio between internalized and specifically bound radioactivity (*I*/*B*, mean ± SEM, 3 experiments in triplicate).

than for other peptides. It decreased rapidly with time for both peptides. Radioactivity excretion in urine was fast and amounted to 69 ± 4% of the injected dose 1 h after injection for DTPA(^{111}In)-NT-20.3. Low activity accretion was observed in normal tissues for all peptides except in kidneys and, particularly for DTPA(^{111}In)-NT-20.3, in gastrointestinal tract. Nevertheless, for DTPA(^{111}In)-NT-20.3, high uptake ratios were obtained between tumor and stomach (7.2 ± 1.7 at 1 h and 30 ± 7 at 3 h), small intestine (1.8 ± 0.2 at 1 h and 3.5 ± 0.6 at 3 h), and colon (8.3 ± 0.8 at 1 h and 3.0 ± 0.5 at 3 h).

We investigated the basis of the gastrointestinal uptake of DTPA(^{111}In)-NT-20.3 (Table 5). In contrast to colon uptake, which was significantly decreased by coinjection of the unlabeled analogue ($P = 0.004$), stomach and small intestine uptakes were not significantly reduced by the coinjection, despite the expression of NTS1 in these organs. Most of the activity was associated to the content of the organs (stomach 68 ± 4%, small intestine 59 ± 6%, colon 73 ± 6%) indicating an elimination by the gastrointestinal route. When organ content was removed, coinjection of DTPA(^{111}In)-NT-20.3 with its unlabeled counterpart significantly decreased uptake at 3 h postinjection in stomach ($P = 0.04$), in small intestine ($P = 0.001$), and in colon ($P = 0.0002$). These results suggest that some uptake in these tissues is receptor mediated, but most of the activity comes from gastrointestinal elimination.

Kidney uptake of DTPA(In)-NT-20.3 in female nude mice was significantly lower than that of [Lys^6(DTPA(In))]-NT and significantly higher than that of other tested peptides at 1 and 3 h postinjection, with the exception of DTPA(^{111}In)-NT-XI for which the difference was not significant. As already reported in the literature for labeled octreotide analogues (*32*), kidney uptake of DTPA(^{111}In)-NT-20.3 was lower in males than in females. The difference was not significant at 6 h (2.8 ± 0.3% ID/g vs 3.6 ± 0.4%) but was highly significant at 100 h (0.83 ± 0.05% ID/g vs 0.48 ± 0.08, $P = 0.002$) (Figure 4). Therefore, tumor to kidney uptake ratio was higher in male than in female mice: at 6 h post injection (0.72 ± 0.09 vs 0.45 ± 0.03) and at 100 h (0.86 ± 0.13 vs 0.40 ± 0.04). DTPA(^{111}In)-NT-20.1 displayed the lowest renal accretion of the peptides tested in this study with 1.4 ± 0.25%ID/g as soon as 1 h post injection, but tumor uptake was also lower.

For DTPA(^{111}In)-NT-20.3, tumor to normal tissues uptake ratios were elevated for most organs; in particular, tumor/pancreas ratio was 17.5 ± 0.8 and 68.2 ± 6.5 at 1 and 3 h postinjection, respectively. They were markedly improved as compared to [Lys^6(DTPA(^{111}In))]-NT, particularly tumor/blood (60.5 ± 6.8 vs 10.9 ± 1.7 $P < 0.0001$ at 3 h postinjection), tumor/liver (19.1 ± 1.5 vs 9.3 ± 0.8 $P < 0.0001$), and tumor/muscle (91.6 ± 8.6 vs 33.1 ± 4.1 $P < 0.0001$) ratios. Tumor to kidney uptake ratio was also improved about 5-fold (0.49 ± 0.04 vs 0.11 ± 0.01 $P < 0.0001$, 3 h postinjection) as a result of higher activity uptake in tumor and lower accretion in kidney for DTPA(^{111}In)-NT-20.3.

Accumulation of DTPA(^{111}In)-NT-20.3 was clearly observed in tumors in planar at early (30 to 60 min, Figure 5) and late time points, 24, 48, and 100 h (not shown), postinjection, and in tomographic images recorded in male mice (Figure 6). Kidneys and bladder were the only other sites of activity accumulation. Tumor to background ratio increased with time reaching 2.8 ± 0.7 at 1 h and 4.5 ± 1.0 at 24 h. At 24 h, the activity ratio between tumor and kidneys was 1.3 ± 0.4 (tumor weight: 0.428 ± 0.095 g).

DISCUSSION

For imaging and therapy of neuroendocrine tumors, indisputable successes have been obtained with somatostatin analogues labeled with radiometals, such as ^{111}In, ^{68}Ga, ^{90}Y, or ^{177}Lu, PET imaging with ^{68}Ga potentially providing higher diagnostic efficacy than SPECT (*33*, *34*) and therapy with ^{90}Y or ^{177}Lu affording symptomatic improvement, prolonged survival, and better quality of life in some instances (*35*−*37*). NTS1 ligands bearing polyamino polycarboxylate chelators such as DTPA or macrocyclic chelators such as DOTA have also been developed (*20*−*22*). DTPA is considered a very powerful binder of indium-111 for single-photon emission computed tomography (SPECT), and no data suggest any superiority of macrocyclic ligands for imaging with this radionuclide. By contrast, yttrium-90 has been shown to leak out of DTPA too rapidly for therapeutic applications (*19*). Macrocyclic polyamino polycarboxylates such as DOTA are suitable chelators for ^{90}Y and ^{177}Lu, which afford promising treatment options for patients with inoperable or metastasized neuroendocrine tumors using DOTA-substituted somatostatin analogues (*35*−*37*). The situation with gallium is less clear: DTPA was used as a chelating agent in different gallium-labeled molecules (*16*−*18*). In vitro, the exchange of ^{111}In and ^{67}Ga from DTPA-albumin to transferrin occurs at approximately the same rate, which would be insignificant in studies with ^{68}Ga, a short half-life (68 min) isotope (*17*). In addition, the DTPA-albumin gallium-68 complex was found stable enough in vivo over the time span of studies possible with ^{68}Ga, since only 2% ^{68}Ga is transferred to transferrin 1 h after injection (*17*). Nevertheless, gallium-labeled DTPA-octreotide provided somewhat disappointing results (*38*). Many publications also deal with gallium-labeled DOTA-substituted somatostatin analogues (*38*) prepared for therapeutic application with yttrium-90 in the first place.

The aim of the present study was to design new polyamino polycarboxylic acid-substituted neurotensin radioligands providing higher tumor uptake and higher tumor to normal tissue uptake ratios, particularly for kidneys, than DTPA or DOTA neurotensin analogues previously described in the literature. To achieve this goal, intermediate objectives were (i) to better understand structure−activity relationships, particularly the effect on affinity induced by coupling the chelating agent and by amino-acid sequence modifications and (ii) to evaluate the relative impacts of affinity and stability on in vivo tumor uptake. In a first step, DTPA was the chelating agent since high radiolabeling efficiency under mild conditions can be obtained (*19*) and little difference is usually observed in terms of affinity, biodistribution, tumor accretion and tumor to nontumor uptake ratios between DTPA and DOTA-carrying peptides, when labeled with indium-111 (*21*). We synthesized a series of DTPA-peptides with the same sequence as the ^{99m}Tc- or ^{188}Re-labeled (N$^{\alpha}$His)Ac-NT(8−13) derivatives, which have already been described and which have shown promising targeting properties and encouraging preclinical therapy results (*10*−*13*). We also synthesized analogues of the C-terminal (6−13) part of [Lys^6-(DTPA(In))]-NT, which provided encouraging in vivo tumor

[a] Uptake is expressed as the percentage of injected dose per gram of tissue (%ID/g). [b] Blocked animals received a coinjection of the labeled peptide with NT-20.3 (180 nmol).

targeting. The α-NH_2 was acetylated to protect against aminopeptidases and to lower the number of positive charges, which may increase renal uptake (*28, 29*).

By contrast to the 5-fold affinity increase for HT29 cells provided by the introduction of [^{99m}Tc(CO)$_3$]-(Nα-His)Ac at the N-terminal end of NT(8−13) (*39*), DTPA(In) coupling led to an important loss of affinity, which was minimized by increasing the distance between DTPA and the NT(8−13) sequence. This observation may be attributed to steric hindrance due to the DTPA(In) complex, but also to structural changes induced by DTPA: it was recently reported that coupling DOTA to a 13 aminoacid peptide induced an α-helix structure, which was not observed in the free peptide (*40*). This possibility remains to be explored with NT analogues.

In the DTPA(In)-NT(8−13) series, the influence on affinity of most of the sequence modifications is in agreement with previously reported results for the [^{99m}Tc(CO)$_3$]-(Nα-His)Ac-NT(8−13) analogues (*10, 12, 13*). On the contrary, the loss of affinity induced by a Tle^{12} substitution, also observed in the NT (6−13) peptides and already reported in the literature for DTPA analogues (*20*), was not observed with the ^{99m}Tc-labeled NT(8−13) derivatives. As a result of the effect of DTPA coupling and Tle^{12} substitution, DTPA-NT-XIX displayed a low affinity, in opposition to its [^{99m}Tc(CO)$_3$]-(Nα-His)Ac counterpart (*13*). Since the affinity of NT-20.1 was higher than that of NT, the double-stabilized DTPA(In)-NT-20.3 exhibited an affinity in the low nanomolar range despite DTPA coupling and sequence modifications.

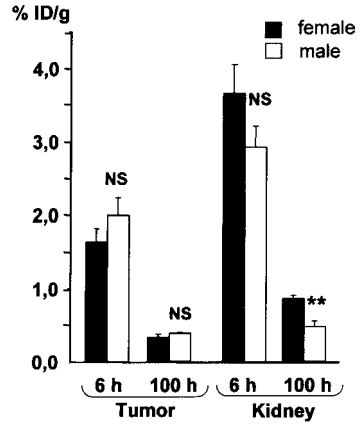

Figure 4. Tumor and kidney uptake in female and male nude mice, grafted with HT29 cells, after iv injection of DTPA((111In)-NT-20.3. Uptake is expressed as the percentage of injected dose per gram of tissue (%ID/g, mean ± SEM). **: $P < 0.005$.

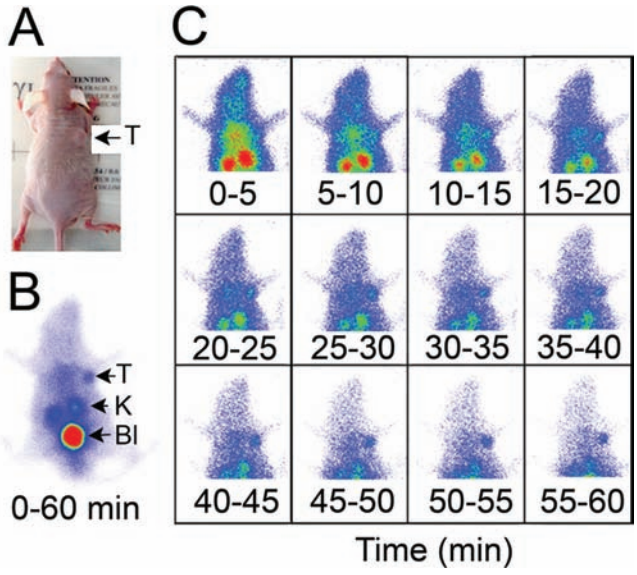

Figure 5. DTPA(111In)-NT-20.3 planar images of a male nude mice grafted with HT29 cells. (A) photograph, (B) planar image, (C) 5 min frames, acquisition from 0 to 60 min postinjection under anesthesia. Bl, bladder; K, kidney; T, tumor. Tumor weight: 240 mg.

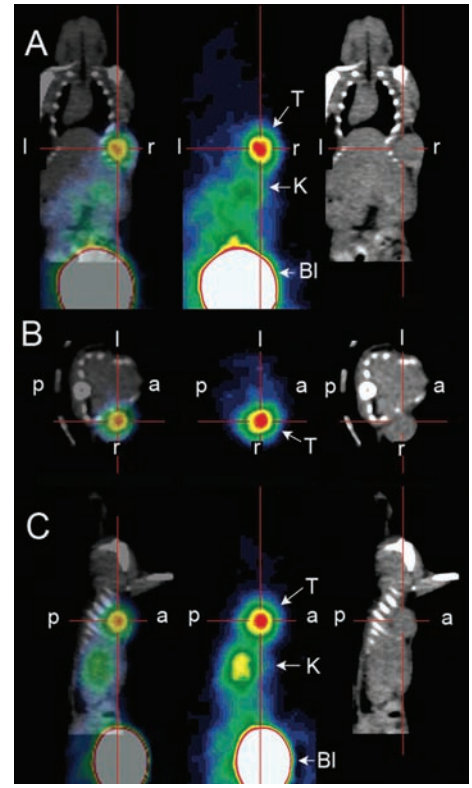

Figure 6. SPECT/CT imaging of a male nude mice grafted with HT29 cells in the right flank 2.5 h postinjection of DTPA(111In)-NT-20.3. Left, CT; center, SPECT; right, SPECT/CT fused images. Frames: A, coronal; B, axial; C, sagittal. Abbreviations as in Figure 5 and r, right; l, left; a, anterior; p, posterior. Tumor weight: 498 mg.

As expected, sequence modifications increased the in vitro and in vivo stability to enzymatic degradation and the peptides with two protected bonds were the most resistant. In vivo, increased stability had a major impact on tumor uptake in the DTPA-NT(6−13) series as already reported in the literature for bombesin analogues (*41*). Nevertheless, higher in vivo stability associated to lower affinity of DTPA(In)-NT-XI led to much lower tumor uptake as compared to DTPA(In)-NT-20.3.

Charge and charge distribution of radiolabeled peptides may produce various effects on renal uptake, but in general, it is increased by positive charges (*28, 29*). One objective of the present study was to lower kidney uptake as compared to the reference peptide. [Lys^6(DTPA(111In))]-NT may, after cleavage in the 1−6 N-terminal end, release labeled metabolites with a free positively charged α-NH_2, which could contribute to the high kidney uptake. To avoid the formation of these metabolites, we deleted the 1−6 N-terminal part of the molecule and acetylated its N-terminal end to neutralize the positive charge. The difference between the remarkably low renal accretion of DTPA(111In)-NT-20.1, compared to DTPA(111In)-NT-20.3, cannot be related to their charge or charge distribution at physiological pH which are identical. It may not be attributed to differences of hydrophobicity, as all peptides eluted with approximately the same acetonitrile percentage in HPLC (data not shown), indicative of similar hydrophobicity (*29*). It may only be ascribed to reabsorption and accumulation of metabolites. Cleavage of DTPA(111In)-NT-20.1 at the Arg^8-Arg^9 bond may produce labeled metabolites with only one positive charge (Arg^8). The same is true for DTPA(111In)-NT-20.2, which also exhibits low renal uptake. In DTPA(111In)-NT-20.3, the Arg^8-Arg^9 bond is stabilized, and it may be hypothesized that metabolites with two positively charged Arg are released that induce higher renal accumulation of radioactivity.

CONCLUSION

In summary, structure−activity studies of new NT analogues carrying DTPA have shown that this polyamino polycarboxylate chelating agent induces an important loss of affinity unless the distance between the chelating agent and the NT(8−13) sequence that binds to the NTS1 receptor is increased. Altogether, it was not possible to design a peptide with both the lowest kidney retention and highest tumor uptake, but DTPA(111In)-NT-20.3 is a good compromise with improved uptake ratio between tumor and kidneys, superior to previously published DTPA and DOTA neurotensin analogues. In spite of some excretion of activity by the gastrointestinal route and some receptor-mediated binding of the tracer to stomach, small intestine and colon, ratios between uptakes in the tumor and in these organs was high. The tumor to intestines ratio was higher than that of the ^{99m}Tc-labeled analogue NT-XIX described in the literature (*12*). In spite of a relatively high uptake in kidneys, DTPA(111In)-NT-20.3 showed specific tumor uptake and afforded high-

contrast planar and SPECT tumor images in nude mice. It may be considered as a promising candidate for imaging neurotensin receptor positive tumors, such as pancreatic adenocarcinoma and invasive ductal breast cancer. If therapeutic application of this neurotensin analogue is developed, infusion of basic amino acids, gelofusin, and albumin fragments may be considered to prevent nephrotoxicity, as with radiolabeled somatostatin analogues (*42*, *43*). Thus, an analogue carrying DOTA is being developed for therapy with ^{90}Y or ^{177}Lu. ^{68}Ga PET imaging with DOTA- and DTPA-NT20.3 will be evaluated.

ACKNOWLEDGMENT

The authors are grateful to E. Treca, S. Mendes, H Medjoudoum, A Darbois, and A. Augereau for help in affinity determination and to Pr. M. A. Pocidalo for providing human serum. Received April 8, 2009; Revised Manuscript Received May 29, 2009

The $\alpha_v\beta_3$ integrin is an adhesion molecule involved in physiological and pathological angiogenesis as well as in tumor invasion and metastasis, and therefore, there is a strong interest in developing novel agents interacting with this molecule. We report the synthesis and characterization of fluorescent $\alpha_v\beta_3$ integrin probes and their use to visualize integrin $\alpha_v\beta_3$ expression on human normal and cancer cells. The fluorescent probes we describe here may be of use for noninvasive imaging of $\alpha_V\beta_3$ integrin expression also *in vivo*.

INTRODUCTION

Integrins are heterodimeric transmembrane proteins expressed at the cell surface and involved in cellular adhesion to the extracellular matrix (*1*). A deregulated expression and/or function of integrins contributes to the progression of lethal pathologies including cancer (*2*, *3*). Among the integrin superfamily, the $\alpha_v\beta_3$ integrin has been the focus of considerable attention because of its expression in a restricted number of normal and malignant cell types such as platelets (*4*), osteoclasts (*5*), melanoma (*6*), glioblastoma (*7*), and osteosarcoma cells (*8*), and its elevated expression on activated endothelial cells during physiological and pathological angiogenesis (*9*). The $\alpha_v\beta_3$ integrin interacts with specific proteins of the extracellular matrix such as fibronectin, vitronectin, von Willebrand factor, and fibrinogen through the tripeptide Arg-Gly-Asp (RGD) sequence (*10*, *11*). Therefore, RGD-containing peptides targeting the $\alpha_v\beta_3$ integrin are attractive for studying and managing diseases related to its overexpression. Many research groups have in fact focused on developing RGD peptides and analogous compounds for biomedical studies (*12*−*16*).

Linear peptide sequences containing the RGD motif are known to bind integrins, and these have been used as cell-targeting agents (*17*). Due to the low affinity and promiscuity of such linear peptides, however, their utility for selective cell targeting is limited. Peptide derivatives, such as cyclo(RGDfV) or Cilengitide have been used as tumor-homing agents due to their selectivity for $\alpha_v\beta_3$ integrin (*18*, *19*).

Our group previously reported a library of cyclic RGD pentapeptide mimics based on 1-aza-2-oxobicyclo[*X.3.0*]alkane amino acids as dipeptide analogues (*20*, *21*). The replacement of the D-Phe-Val dipeptide in the lead structure cyclo(RGDfV) with such azabicycloalkane scaffolds showing different reverse-turn mimetic properties constrains the RGD sequence into different conformations and provides the required activity and selectivity for integrin antagonism. This library was found to contain specific high-affinity ligands for $\alpha_v\beta_3$ integrin, which are currently under evaluation as very promising antiangiogenic drugs. One of the peptides tested, **ST1646**, displayed the highest affinity to $\alpha_v\beta_3$, inhibiting echistatin binding to $\alpha_v\beta_3$ with an IC_{50} of 3.7 ± 0.6 nM (Figure 1).

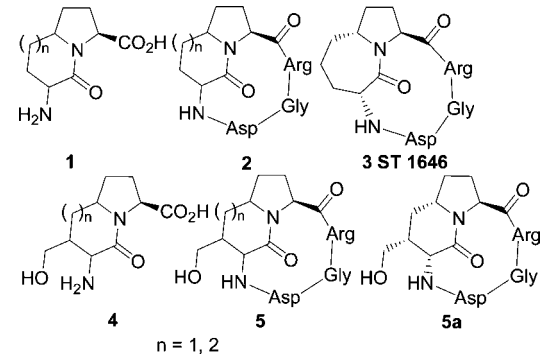

Figure 1. Integrin inhibitors and scaffolds for their preparation.

The functionalization of such azabicycloalkane scaffolds with heteroalkyl substituents enabled us to conjugate different diagnostic or therapeutic entities. Our group has recently reported an efficient and simple synthesis of functionalized azabicycloalkane amino acids mimicking a homoSer-Pro dipeptide (*22*) and their use in the preparation of cyclic RGD compounds (**5**, Figure 1) (*23*). These mimics present a heteroalkyl side chain ending with a hydroxy group that can easily be converted into other suitable functional groups (i.e., azide, amine, etc.) or directly used for conjugations (*23*, *24*). Such molecules are then attractive tools for the homing of drugs and biological tracers in cells highly expressing $\alpha_v\beta_3$ integrin. To this end, we explored the possibility to use these compounds as "markers" of the $\alpha_v\beta_3$ integrin expression in human cells. We selected the green fluorescent dye Fluorescein as a probe, because it is approved for human use in diagnostic techniques such as retinal angiography (*25*). Fluorescein is therefore advantageous because of its known safety profile in humans. Furthermore, the use of a RGD peptide−fluorescein conjugate in a fluorescent polarization assay has recently been reported (*26*), a technique that is often applied for high-throughput

screening in the drug discovery process. During the preparation of this paper, the work of the Li group has been published on a photostable fluorescent probe for imaging of tumor cells possessing integrin $\alpha_v\beta_3$ (*27*).

We report here the conjugation of cyclic RGD compounds containing the conformationally constrained homoSer-Pro dipeptide unit with the fluorescein probe, the study of their binding properties, and the biological effects of these compounds on human cell cultures. We demonstrate that such fluorescent compounds could be useful for $\alpha_v\beta_3$ integrin imaging, thus suggesting their possible use in diagnostic techniques.

MATERIALS AND METHODS

General. All chemicals and solvents were of reagent grade and were used without further purification. Solvents were dried by standard procedures and reactions requiring anhydrous conditions were performed under nitrogen or argon atmosphere. ^{1}H and ^{13}C NMR spectra were recorded at 300 K on a Bruker AVANCE-400 and 600 MHz. Chemical shifts δ are expressed in ppm relative to internal Me_4Si as standard. Mass spectra were obtained with an ESI apparatus Bruker Esquire 3000 plus. Column chromatography was carried out with the Biotage SP1 or SP4 systems using the Biotage cartridges.

*Compound **11***. A solution of c-RGD-N_3 **7** (498 mg, 0.56 mmol) in MeOH (25 mL) containing a catalytic amount of Pd/C 10% was stirred overnight under hydrogen atmosphere. After reaction completion (monitored by TLC: CH_2Cl_2/MeOH 9:1), the mixture was filtered through a pad of Celite and washed with MeOH. The collected organic phase was evaporated under reduced pressure. The crude was dissolved in dry DMF (5 mL) and mixed, under N_2 atmosphere and at room temperature, with a solution of spacer **10** (253 mg, 0.742 mmol), HATU (282 mg, 0.742 mmol), HOAt (94 mg, 0.689 mmol), and DIPEA (0.37 mL, 2.12 mmol) in dry DMF (5 mL). The reaction mixture was stirred overnight, and after reaction completion, the solvent was evaporated under reduced pressure. The pure product was obtained after reverse-phase column chromatography on a Biotage C_{18} 25+M cartridge eluting with water/acetonitrile (95:5 → 10:90). Yield: 85% (white solid). ^{1}H NMR (400 MHz, acetone-d_6): δ 1.31 (s, 6H, $C(CH_3)_2$ Pmc), 1.36 (m, 1H, *H*-5), 1.43 (s, 9H, $C(CH_3)_3$), 1.43−1.55 (m, 2H, *Hγ* Arg, *Hβ* Arg), 1.55−1.61 (m, 2H, *Hγ* Arg, *H*-7), 1.84 (t, 2H, J = 6.8 Hz, CH_2CH_2Ar Pmc), 1.99 (m, 1H, *H*-8), 2.07−2.25 (m, 4H, CH_3 Pmc, *Hβ* Arg), 2.33−2.48 (m, 3H, *H*-5, *H*-7, *H*-8), 2.52−2.64 (m, 7H, *Hβ* Asp, 2 CH_3 Pmc), 2.67 (t, 2H, J = 6.6 Hz, CH_2CH_2Ar Pmc), 2.80 (m, 1H, *H*-4), 3.03 (dd, 1H, J = 16.8 Hz, J = 6.8 Hz, *Hβ* Asp), 3.12−3.29 (m, 4H, 2 *Hδ* Arg, $NHCH_2$), 3.29−3.40 (m, 2H, NCH_2CH_2O), 3.45 (d, 1H, J = 13.6 Hz, *Hα* Gly), 3.57 (m, 2H, NCH_2CH_2O), 3.60−3.80 (m, 8H, 4 OCH_2), 3.90 (s, 2H, OCH_2CO), 4.16 (m, 1H, *H*-6), 4.19−4.36 (m, 3H, *Hα* Gly, *H*-9, *H*-3), 4.50−4.62 (m, 2H, *Hα* Arg, *Hα* Asp), 5.09 (s, 2H, CH_2Ph), 6.20−6.75 (m, 4H, $(NH)_2C{=}NH$, *NH*Cbz), 7.23 (m, 1H, $NHCH_2$), 7.28−7.45 (m, 6H, 5 *Aromatic protons*, N*H* bicycle.), 7.51 (m, 1H, N*H* Arg), 7.60 (m, 1H, N*H* Gly), 8.40 (m, 1H, N*H* Asp). ^{13}C NMR (100.6 MHz, acetone-d_6): δ 173.2, 171.5, 171.2, 170.3, 170.2, 170.0, 169.8, 156.4, 152.9, 137.6, 135.6, 135.0, 134.6, 128.3, 127.8, 127.7, 123.1, 117.8, 80.0, 73.4, 70.8, 70.2, 70.1, 70.0, 69.6, 65.6, 62.5, 55.7, 53.5, 51.3, 42.7, 40.7, 40.5, 39.8, 36.3, 35.0, 33.3, 32.6, 30.1, 28.2, 27.4, 26.1, 25.9, 21.1, 17.9, 16.8, 11.4. MS (ESI^+) m/z: 1183.7 $(M+H)^+$.

*Compound **12***. A solution of compound **11** (260 mg, 0.22 mmol) in MeOH (13 mL) containing a catalytic amount of Pd/C 10% was stirred for 3 h under hydrogen atmosphere. After reaction completion (monitored by TLC: CH_2Cl_2/MeOH 9:1), the mixture was filtered through a pad of Celite and washed with MeOH. The collected organic phase was evaporated under reduced pressure and submitted to the following deprotection step without any further purification.

A solution of protected compound (0.040 mmol) in TFA/thioanisole/1,2-ethanedithiol/anisole 90:5:3:2 (2 mL) was stirred at room temperature for 2 h. The solvent was evaporated under reduced pressure, and then the crude was dissolved in H_2O and washed with iPr$_2$O. The aqueous phase was evaporated under reduced pressure and the crude purified by HPLC (Atlantis C_{18} OBD 5 μm 19 mm × 10 cm, flow 20 mL/min, gradient 100% A for 1 min, from 100% A to 85% A over 8 min, from 85% A to 0% A over 8 min. A H_2O + 0.1% TFA, B CH_3CN + 0.1% TFA). Yield: 70%. White foam. ^{1}H NMR (400 MHz, D_2O): δ 1.23 (m, 1H, *H*-5), 1.44−1.70 (m, 4H, 2 *Hγ* Arg, *Hβ* Arg, *H*-7), 1.85 (m, 1H, *H*-8), 2.04 (m, 1H, *Hβ* Arg), 2.36−2.50 (m, 3H, *H*-8, *H*-7, *H*-5), 2.71 (dd, 1H, J = 7.1 Hz, J = 17.0 Hz, *Hβ* Asp), 2.39 (m, 1H, *H*-4), 3.07 (dd, 1H, J = 7.5 Hz, J = 17.0 Hz, *Hβ* Asp), 3.10−3.24 (m, 6H, 2 *Hδ* Arg, $NH_2CH_2CH_2O$, CH_2NH), 3.48 (d, 1H, J = 14.6 Hz, *Hα* Gly), 3.63−3.75 (m, 10H, 4 CH_2O, $NH_2CH_2CH_2O$), 3.90−4.06 (m, 3H, *H*-6, OCH_2CO), 4.20−4.30 (m, 2H, *H*-9, *Hα* Gly), 4.38 (m, 1H, *H*-3), 4.48−4.60 (m. 2H, *Hα* Asp, *Hα* Arg). ^{13}C NMR (100.6 MHz, D_2O): 174.8, 174.5, 174.1, 173.1, 172.6, 171.6, 170.1, 156.8, 70.3, 69.7, 69.6, 69.5, 69.4, 66.4, 62.2, 56.0, 53.1, 51.7, 51.4, 42.6, 40.5, 40.2, 39.2, 35.7, 33.3, 32.9, 32.6, 27.1, 24.5. MS (ESI^+) m/z: 727.1 $(M+H)^+$, 364.0 $(M+2H)^{2+}$.

*Compound **8***. A solution of protected compound **7** (324 mg, 0.365 mmol) in TFA/thioanisole/1,2-ethanedithiol/anisole 90:5:3:2 (15 mL) was stirred at room temperature for 2 h. The solvent was evaporated under reduced pressure, and then the crude was dissolved in H_2O and washed with iPr$_2$O. The aqueous phase was evaporated under reduced pressure. The crude was purified by HPLC (Atlantis C_{18} OBD 5 μm 19 mm × 10 cm, flow 20 mL/min, gradient from 5% A to 15% A over 10 min, A CH_3CN + 0.1% HCOOH, B H_2O + 0.1% HCOOH). Yield: 97%. White foam. ^{1}H NMR (400 MHz, D_2O): δ 1.32 (m, 1H, *H*-5), 1.43−1.61 (m, 3H, 2 *Hγ* Arg, *Hβ* Arg), 1.66 (m, 1H, *H*-7), 1.83 (m, 1H, *H*-8), 2.03 (m, 1H, *Hβ* Arg), 2.34−2.47 (m, 3H, *H*-8, *H*-7, *H*-5), 2.69 (dd, 1H, J = 7.1 Hz, J = 16.9 Hz, *Hβ* Asp), 2.78 (m, 1H, *H*-4), 3.05 (dd, 1H, J = 7.5 Hz, J = 16.9 Hz, *Hβ* Asp), 3.09−3.20 (m, 2H, 2 *Hδ* Arg), 3.32−3.42 (m, 2H, CH_2N_3), 3.47 (d, 1H, J = 14.7 Hz, *Hα* Gly), 3.96 (m, 1H, *H*-6), 4.20−4.32 (m, 3H, *Hα* Gly, *H*-9, *H*-3), 4.48−4.58 (m. 2H, *Hα* Asp, *Hα* Arg). ^{13}C NMR (100.6 MHz, D_2O): 175.0, 174.8, 174.1, 173.0, 171.6, 170.6, 156.7, 62.2, 56.0, 52.8, 52.0, 51.6, 51.3, 42.4, 40.4, 35.5, 33.2, 32.7, 30.1, 27.0, 24.4. MS (ESI^+) m/z: 564.1 $(M+H)^+$.

*Compound **13***. FITC (3.0 mg, 0.0075 mmol) dissolved in DMSO (0.4 mL) was mixed with compound **12** (6.0 mg, 0.0063 mmol) dissolved in sodium borate buffer pH = 9 (0.4 mL) in the dark and at room temperature. After stirring for ca. 18 h, the reaction was complete. The solvent was removed and the crude was purified by HPLC (Ascentis RPAMIDE 150 × 21.1 mm column, guard cartridge, RPAMIDE 20 × 4 mm; 12 mL/min flow; gradient 100% A for 2 min, from 100% A to 70% A over 3 min, from 70% A to 50% A over 20 min, from 50% A to 20% A over 5 min, then from 20% A to 0% A over 2 min A, H_2O + 0.2% TFA; B, CH_3CN + 0.2% TFA). Yield: 70%. Yellow foam. ^{1}H NMR (600 MHz, D_2O): δ 1.00 (m, 1H, *H*-5), 1.24−1.50 (m, 4H, 2 *Hγ* Arg, *Hβ* Arg, *H*-7), 1.65 (m, 1H, *H*-8), 1.87 (m, 1H, *Hβ* Arg), 2.13−2.28 (m, 3H, *H*-8, *H*-7, *H*-5), 2.48−2.62 (m, 2H, *Hβ* Asp, *H*-4), 2.77−2.91 (m, 3H, *Hβ* Asp, CH_2NH), 2.91−3.02 (m, 2H, 2 *Hδ* Arg), 3.25 (d, 1H, J = 15.6 Hz, *Hα* Gly), 3.42−3.69 (m, 12H, 5 CH_2O, $NH_2CH_2CH_2O$), 3.69−3.83 (m, 3H, OCH_2CO, *H*-6), 4.03−4.11 (m, 2H, *H*-9, *Hα* Gly), 4.18 (d, 1H, J = 8.4 Hz, *H*-3), 4.28 (m, 1H, *Hα* Asp), 4.36 (m. 1H, *Hα* Arg), 6.63. (m, 2H, *fluorescein protons*), 6.77 (m, 2H, *fluorescein protons*), 8.87−7.16 (m, 3H, *fluorescein*

protons), 7.56 (m, 1H, *fluorescein proton*), 7.95 (m, 1H, *fluorescein proton*). ^{13}C NMR HETCOR (600 MHz, D_2O): 130.7, 129.9, 122.8, 116.2, 102.5, 70.2, 69.4, 69.1, 61.8, 55.7, 52.7, 51.4, 51.3, 44.0, 42.1, 40.2, 39.9, 35.5, 33.0, 32.5, 29.8, 26.8, 24.3. MS (ESI^+) *m/z*: 1116.4 $(M+H)^+$, 558.8 $(M+2H)^{2+}$.

General Procedure for Click Reaction. To a solution of compound **8** (0.02 mmol) and the opportune alkynyl derivative (**14** or 1-hexyne) (0.02 mmol) in H_2O/*t*-BuOH 1:1 (500 μL.), a 0.9 M solution of sodium ascorbate (9 μL, 0.008 mmol, 0.4 mol equiv) and a 0.3 M solution of $Cu(OAc)_2$ (13 μL, 0.004 mmol, 0.2 mol eq) were added. The reaction was stirred at r.t. for ca. 18 h.

After reaction completion, compounds **15** or **16** were purified by HPLC (Waters X-Terra PR 18 19 × 50 mm, 5 μm column; 3.5 mL/min flow; gradient from 20% B to 35% B over 11 min, then washed 60% B for 1 min; A, 97% H_2O/3% CH_3CN + 0.1% TFA; B, CH_3CN + 0.1% TFA).

*Compound **15**.* Yield: 60%. White foam. ^{1}H NMR (600 MHz, D_2O): δ 1.10 (m, 1H, *H*-5), 1.41 (m, 2H, *H*γ Arg), 1.44 (m, 1H, *H*-7), 1.46 (m, 1H *H*β Arg), 1.49 (m, 2H, CH_2 spacer), 1.58 (m, 2H, CH_2 spacer), 1.69 (m, 2H, CH_2 spacer), 1.72 (m, 1H, *H*-8), 1.85 (m, 2H, CH_2 spacer), 1.95 (m, 1H, *H*β Arg), 2.19 (m, 1H, *H*-5), 2.23 (m, 1H, *H*-7), 2.31 (m, 1H, *H*-8), 2.56 (m, 1H, *H*β Asp), 2.91 (m, 1H, *H*β Asp), 3.03 (m, 1H, *H*δ Arg), 3.07 (m, 1H, *H*-4), 3.09 (m, 1H, *H*δ Arg), 3.24−3.55 (m, 8H, OCH_2 spacer), 3.29 (m, 1H, NHC*H* spacer), 3.36 (m, 1H, *H*α Gly), 3.44 (m, 1H, NHC*H* spacer), 3.84 (m, 1H, *H*6), 3.91 (m, 1H, COCH_2O), 3.99 (m, 1H, COCH_2O), 3.95 (m, 1H, HC*H*N), 4.07 (m, 1H, *H*-9), 4.11 (m, 1H, NHC*H* spacer), 4.15 (m, 1H, *H*α Gly), 4.28 (m, 1H, *H*-3), 4.30 (m, 1H, *H*α Asp), 4.32 (m, 2H, NCH_2=), 4.46 (m, 1H, *H*α Arg). ^{13}C NMR HETCOR (400 MHz, DMSO-d_6): 69.7, 68.9, 62.0, 55.5, 52.6, 51.1, 42.2, 40.1, 37.9, 35.9, 33.8, 33.3, 32.5, 32.2, 29.9, 28.0, 27.0, 24.3. δ MS (ESI^+) *m/z*: 1295.6 $(M+H)^+$, 648.3 $(M+2H)^{2+}$.

*Compound **16**.* Yield: 80%. Solid-Phase Receptor-Binding Assay. Purified $\alpha_v\beta_3$ and $\alpha_v\beta_5$ receptors (Chemicon International, Inc., Temecula, CA) were diluted to 0.5 μg/mL in coating buffer containing 20 mmol/L Tris-HCl (pH 7.4), 150 mmol/L NaCl, 1 mmol/L $MnCl_2$, 2 mmol/L $CaCl_2$, and 1 mmol/L $MgCl_2$. An aliquot of diluted receptors (100 μL/well) was added to 96-well microtiter plates (NUNC MW 96F MEDISORP STRAIGHT) and incubated overnight at 4 °C. The plates were then incubated with blocking solution (coating buffer plus 1% bovine serum albumin (Sigma) for additional 2 h at room temperature to block nonspecific binding followed by 3 h incubation at room temperature with various concentrations (10^{-10}−10^{-5} M) of test compounds in the presence of 1 μg/mL Vitronectin biotinylated using EZ-Link Sulfo-NHS-Biotinylation kit (Pierce, Rockford, IL). After washing, the plates were incubated for 1 h at room temperature with streptavidin−biotinylated peroxidase complex (Amersham Biosciences, Uppsala, Sweden) followed by 30 min incubation with 100 μL Substrate Reagent Solution (R&D Systems, Minneapolis, MN) before stopping the reaction by addition of 50 μL of 1 N H_2SO_4. Absorbance at 415 nm was read in a Synergy HT Multi-Detection Microplate Reader (BioTek Instruments, Inc.). Each data point is the result of the average of triplicate wells and was analyzed by nonlinear regression analysis with the *Prism GraphPad* program.

Reagents for Cellular Experiments. All reagents were purchased from Sigma-Aldrich (unless otherwise indicated). For all our tests, phosphate buffer saline supplemented with calcium and magnesium (Euroclone) was used.

Cell Lines and Culture. Human umbilical vein vascular endothelial cells (HUVECs) were obtained from Promocell GmbH (cat. no C-12200; Heidelberg, Germany) and were routinely cultured on tissue flasks (BD Biosciences, Franklin Lakes, NJ, USA) coated with 0.1% gelatin (Gibco) in medium M199 supplemented with 20% fetal calf serum (FCS), 2 mM L-glutamine, penicillin (100 U/mL), streptomycin (100 μg/mL), 100 μg/mL porcine heparin, and 10 ng/mL endothelial cells growth factor (ECGF). HUVEC cells were used until 5−6 passages. ECV-304 human bladder carcinoma cells were kindly provided by Prof. M. L. Villa (University of Milan, Italy). ECV-304 cells were grown on tissue flasks in medium M199 supplemented with 10% FCS, 2 mM L-glutamine, penicillin (100 U/mL), and streptomycin (100 μg/mL). MDA-MB-231 human breast adenocarcinoma cells, T98G human glioblastoma multiforme cells, and PC3 human prostate cancer cells were purchased from Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia (cat. nos BS TCL 223, BS TCL 175, and BS TCL 197, respectively; Brescia, Italy) and were grown on tissue flasks in medium RPMI supplemented with 10% FCS, 2 mM L-glutamine, penicillin (100 U/mL), and streptomycin (100 μg/mL). Caki-1 human renal clear cell carcinoma cells were purchased from the American type Culture Collection (ATCC) (cat. no HTB-46) and were grown on tissue flasks in medium RPMI supplemented with 10% FCS, 2 mM L-glutamine, penicillin (100 U/mL), and streptomycin (100 μg/mL). All cell lines were maintained at 37 °C in an atmosphere of 95% air and 5% CO_2.

Immunofluorescence on Adherent Cells. For $\alpha_v\beta_3$ staining, cells were washed in PBS and fixed in 4% paraformaldehyde (Fluka) for 10 min at room temperature. Cells were then washed and permeabilized with 0.1% Triton-X100 (Fluka) for 3 min at 4 °C. Blocking was performed in PBS with 5% bovine serum albumin (BSA) for 1 h at room temperature. We incubated cells with anti-$\alpha_V\beta_3$ antibody (clone LM609, Chemicon, Temecula, California) diluted in PBS + 5% BSA at a final concentration of 10 μg/mL, overnight at 4 °C. Cells were then extensively washed in PBS + 5% BSA and incubated with 3.75 μg/mL donkey-antimouse cy3-conjugated secondary antibody (Jackson Immunoresearch Laboratories Inc., UK) diluted in PBS + 5% BSA, for 1 h at RT in the dark. Nuclei were counterstained for 5 min at room temperature with 0.25 μg/mL 4′,6-diamidino-2-phenylindole (DAPI) diluted in PBS. Cells were finally mounted with Vectashield mounting medium and visualized with Zeiss Axio Observer A1 microscope (Carl Zeiss Inc., Chester, VA, USA). All fuorescence microscopy scans were acquired with Zeiss AxioCam MRm (Carl Zeiss Inc., Chester, VA, USA).

Treatment of Cells with Compounds and Analysis. Cells (1.6×10^4/cm^2) were seeded and allowed to adhere overnight in complete medium on glass slides. Cells were treated 4 h at 37 °C with selected compounds diluted in fresh medium supplemented with 0.1% FCS. After incubation, cells were extensively washed in PBS and fixed in 4% paraformaldehyde for 10 min at room temperature. Nuclei were then counterstained with 0.25 μg/mL DAPI diluted in PBS for 5 min at room

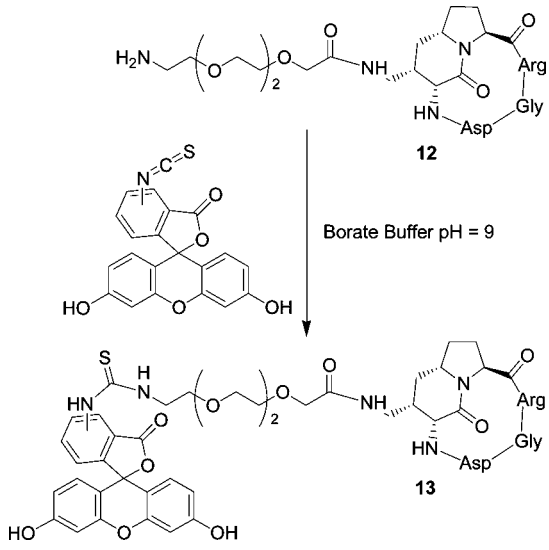
Scheme 2. FITC Conjugation



temperature. Cells were finally mounted and visualized as previously described. Experiments were repeated in triplicate.

RESULTS

Chemistry. Among a small collection of functionalized cyclic RGD (**5**, Figure 1) (*23*), we chose compound **5a** (Scheme 1) that showed the highest affinity for $\alpha_v\beta_3$ integrin in an *in vitro* binding assay (IC_{50} of 53.7 ± 17.3 nM) as a good candidate for fluorescein conjugation.

The fluorescent dye can be directly conjugated to the suitably fuctionalized RGD derivative, but, in order to avoid a decrease in the affinity due to steric hindrance, a spacer was introduced.

We decided to use two different synthetic strategies for conjugation. The first one involves the functionalization of the RGD cyclopeptide with a short poly(ethylene glycol) spacer armed with a terminal amine that can be reacted with fluoresceine isothiocyanate (FITC). The second approach involves the preparation of a fluorescein spacer derivative that can be directly reacted with an azide bearing RGD peptide through the copper-catalyzed click reaction (*28*, *29*).

The hydroxyl group of the pseudopentapeptide **6** was easily transformed into the azide using a reported procedure (*23*). The standard hydrogenation procedure was used to reduce the azide into amine **9**. After the coupling with spacer **10**, carried out using standard coupling procedure (HATU, HOAt, DIPEA), the Cbz was removed by hydrogenation, while the side-chain protecting groups (Pmc and *t*Bu) were cleaved by TFA in the presence of ion scavengers. Compounds **8** and **12** were obtained, after HPLC purification, in good yields.

Fluoresceine 5(6)-isothiocyanate (FITC) was used for direct conjugation to the amine derivative **12**. The reaction was performed dissolving compound **12** in sodium borate buffer (pH = 9) and adding FITC dissolved in DMSO. The obtained compound **13** was purified by HPLC.

The fluorescein-spacer derivative **14** was prepared by adding commercially available 5(6)-carboxyfluorescein-*N*-hydroxysuccinimide ester to a basic solution of the spacer (*24*). The 1,3-dipolar cycloaddition between compounds **8** and **14** was performed using $Cu(OAc)_2$ and Na ascorbate as catalysts in *t*-BuOH/H_2O 1:1 (Scheme 3). The reaction proceeded overnight at room temperature, and the desired product **15** was isolated after HPLC purification in good yield.

Compound **16** was synthesized in an analogous way to that reported above in order to evaluate the influence of the triazole moiety on the biological activity.

Receptor Binding Assay. The derivatives **13**, **15**, and **16** were examined *in vitro* for their abilities to inhibit the binding of biotinylated vitronectin to the isolated, immobilized $\alpha_v\beta_3$ integrin (Table 1). Affinities of commercially available compound c(RGDfV) and our compound ST1646 were determined as references, in the same assays. The functionalized cyclic pentapeptide **5a** displayed a lower binding affinity toward $\alpha_v\beta_3$ integrin when compared to the low nanomolar reference ligand ST1646. Nevertheless, the affinities in the nanomolar range toward $\alpha_v\beta_3$ integrin suggested that the functionalization of the scaffold does not influence the binding activity and it could be a suitable platform for targeted imaging. In order to evaluate the influence of a triazole moiety near the RGD sequence, we have

Scheme 3. Synthetic Pathway for Conjugate RGD Derivative with Click Reaction

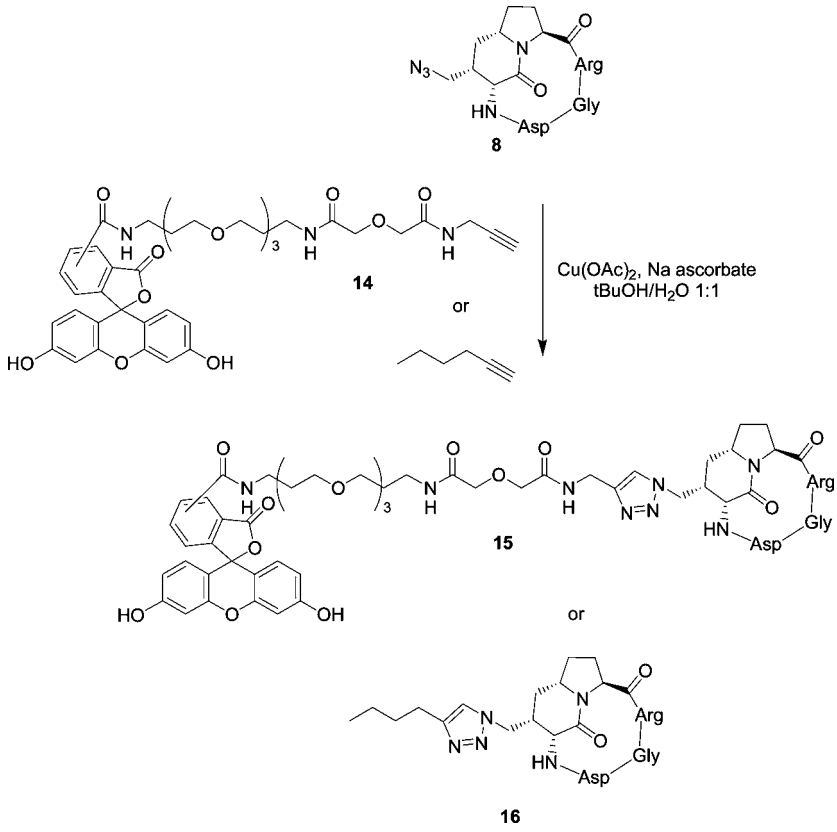


Table 1. Compound-Mediated Inhibition of Vitronectin Binding to $\alpha_v\beta_3$ Integrin[a]

entry	compound	IC_{50} (nM) ± SD for $\alpha_v\beta_3$
1	Vitronectin	47.1 ± 10.0
2	c(RGDfV)	3.2 ± 1.3
3	ST1646	1.0 ± 0.5
4	**5a**	53.7 ± 17.3
5	**13**	142 ± 6
6	**15**	207 ± 85
7	**16**	465 ± 297

[a] IC_{50} values were calculated as the concentration of compound required for 50% inhibition of biotinylated vitronectin binding as estimated by *Prism GraphPad* program. All values are the mean (±standard deviation) of triplicate determinations.

synthesized compound **16**, which showed a slightly lower affinity to $\alpha_v\beta_3$ compared with the compound **5a**, probably due the increased steric hindrance of the triazole. However, the affinity in the nanomolar range toward integrin receptors suggested that the "click reaction" could be a suitable method for the conjugation of molecules of biological interest. Compound **13** compared with **15** showed a slightly better binding affinity for the receptor; this could be due to the presence of a less hindered amide bond instead of triazole and also to a different length of the spacer between the RGD sequence and the fluoresceine moiety.

Fluorescein Detection in Human Cell Lines. The above results demonstrate that compounds **13** and **15** have a high affinity for the $\alpha_v\beta_3$ integrin; this prompted us to test their possible use as tracers of cells highly expressing $\alpha_V\beta_3$ integrin.

For this purpose, we tested each compound on cells highly expressing $\alpha_v\beta_3$ integrin, namely, human umbilical vein endothelial cells (HUVECs), and on a panel of cell lines deriving from solid tumors in which $\alpha_v\beta_3$ overexpression is reported (ECV304 bladder cancer cells, T98G glioblastoma multiforme cells, PC3 prostate cancer cells, Caki-1 renal clear cell carcinoma cells). We included also a cell line derived from human breast adenocarcinoma (MDA-MB-231 cells) as a control, because this cell line is known to express very low amounts of $\alpha_v\beta_3$ integrin (*31*). We first verified and confirmed by immunofluorescence that HUVECs and all tumor-derived cells highly expressed $\alpha_v\beta_3$ integrin, apart from MDA-MB-231 cells with very little expressed $\alpha_v\beta_3$ integrin (Figure 2).

All cell lines were exposed to scalar concentrations of compounds **13** and **15** for different incubation times. We found that a 4 h incubation with 10 μM of both compounds determined a good detection threshold for the fluorescein signal in vascular endothelial cells and all tumor-derived cells expressing $\alpha_v\beta_3$ integrin (Figure 3). In particular, compound **13** gave a signal stronger than that of compound **15**. Each compound displayed a fluorescence distributed both at the cell surface and in putative cytosolic vesicles, suggesting that both compounds were internalized upon binding with $\alpha_v\beta_3$ integrin. Moreover, the morphological analysis of cells showed no signs of toxicity or stress after 4 or 24 h incubation with 10 μM of either compound **13** or **15** (data not shown). Notably, breast adenocarcinoma cells subjected to the treatment previously described did not show any sign of fluorescence (Figure 3), suggesting that both compounds were highly specific for $\alpha_v\beta_3$ integrin.

DISCUSSION

The diagnostic approaches based on modern imaging techniques are important tools to prevent and cure lethal pathologies such as cardiovascular diseases and cancer. In this paper, we describe the characterization, the synthesis, and the biological activity of RGD-containing peptides conjugated with the fluorescent probe fluorescein as tracers for $\alpha_v\beta_3$ integrin expression on cells.

Using the solid-phase receptor binding assay, we demonstrated that compounds **13** and **15** were able to efficiently inhibit the binding of biotinylated vitronectin to immobilized $\alpha_v\beta_3$

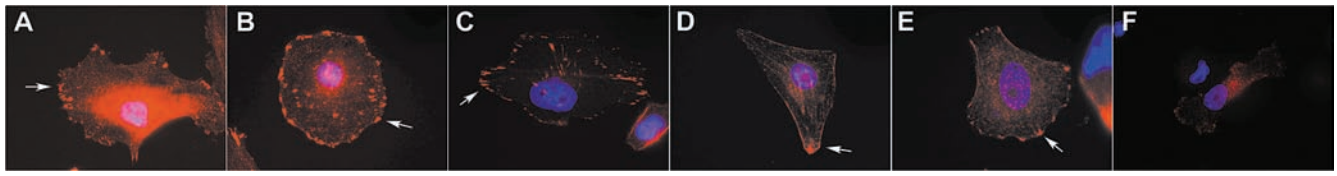

Figure 2. Expression of the $\alpha_v\beta_3$ integrin in the cell panel. HUVEC (A), ECV-304 (B), T98G (C), PC3 (D), Caki-1 (E), and MDA-MB-231 (F) cells were subjected to immunofluorescence staining for $\alpha_v\beta_3$ integrin (red). Nuclei were counterstained with DAPI (blue). (A,B,C,D,E) HUVEC, ECV-304, T98G, PC3, and Caki-1 cells showed high amounts of the $\alpha_v\beta_3$ integrin, which was predominantly clustered at focal contacts (arrows). (F) MDA-MB-231 cells expressed lower amounts of $\alpha_v\beta_3$ integrin, which was mainly diffused on the cell surface. Original magnification 63×.

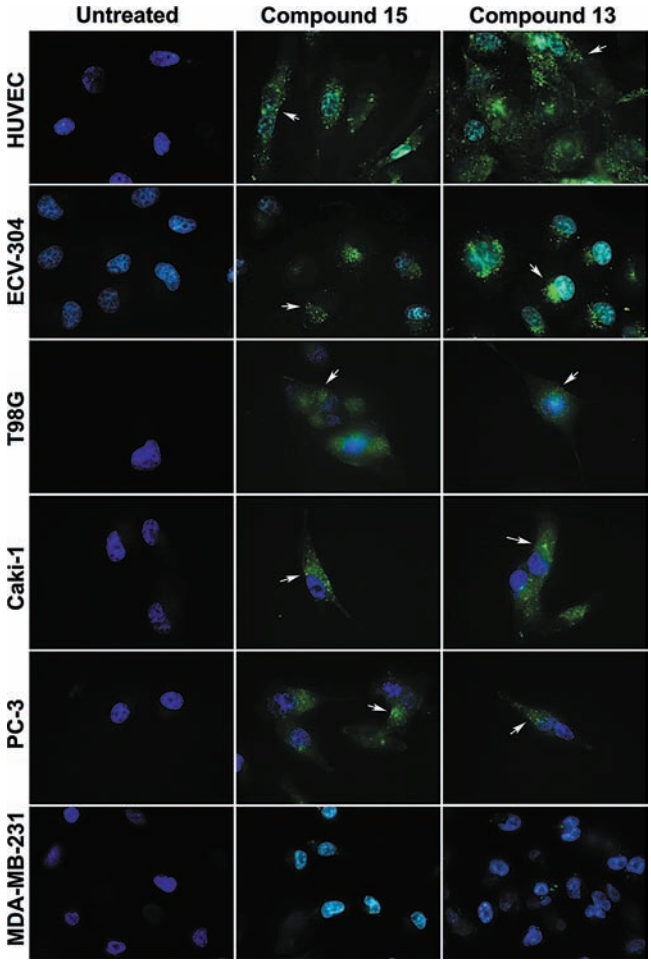

Figure 3. HUVEC, ECV-304, T98G, Caki-1, PC3, and MDA-MB-231 cells were incubated 4 h with treatment medium alone (left column), 10 μM compound **15** (middle column, green), or **13** (right column, green). Nuclei were counterstained with DAPI (blue). HUVEC, ECV304, T98G, Caki-1, and PC3 cells were positively stained after treatment with either compound **13** or **15**, even if the signal provided by compound **13** is stronger. In particular, the signal was highly detectable and located both at the cell surface and in putative cytosolic vescicles (arrows). Differently, MDA-MB-231 cells did not display any staining after treatment with either compound **13** or compound **15**. All three cell lines incubated with treatment medium alone displayed no fluorescence at all. Original magnification 63×.

integrin. Although we found that the binding affinity of both compounds for this integrin was less potent than the low nanomolar values of ST1646, their affinities in the nanomolar range prompted us to explore the possibility to use them as suitable platforms for $\alpha_v\beta_3$-targeted imaging. Therefore, we generated compounds **13** and **15** conjugated with the fluorescent probe fluorescein. We demonstrated that, after *in vitro* treatment with these two conjugated compounds, the fluorescein probe was detectable in a panel of cell lines highly expressing the $\alpha_v\beta_3$ integrin, namely, primary endothelial cells (HUVEC) and several human cell lines derived from solid tumors (bladder cancer, glioblastoma multiforme, prostate cancer, and renal clear cell carcinoma). According to the results of the solid-phase receptor binding assay, compound **13** gave a fluorescent signal stronger than that of compound **15** on cells. In both cases, the pattern of the detected fluorescence also suggested that the two compounds were dynamically internalized by cells. Notably, cancer cells expressing very faint levels of $\alpha_v\beta_3$ integrin (such as breast carcinoma cells) could not be visualized with these compounds. Moreover, treated cells retained their viability, making both molecules attractive as tools for the imaging of both angiogenic vessels and tumor masses specifically and highly expressing $\alpha_v\beta_3$ integrin.

In summary, the described fluorescent probes are able to efficiently target and "visualize" the $\alpha_v\beta_3$ integrin on human cells *in vitro*, suggesting their possible future use for a noninvasive imaging of the $\alpha_v\beta_3$ integrin expression also *in vivo*.

Facile Preparation of Fluorescent Neoglycoproteins Using *p*-Nitrophenyl Anthranilate as a Heterobifunctional Linker

Anthony Luyai, Yi Lasanajak, David F. Smith, Richard D. Cummings, and Xuezheng Song*

Department of Biochemistry, Emory University School of Medicine, Atlanta, Georgia 30322. Received April 23, 2009; Revised Manuscript Received June 10, 2009

A facile preparation of neoglycoconjugates has been developed with a commercially available chemical, *p*-nitrophenyl anthranilate (PNPA), as a heterobifunctional linker. The two functional groups of PNPA, the aromatic amine and the *p*-nitrophenyl ester, are fully differentiated to selectively conjugate with glycans and other biomolecules containing nucleophiles. PNPA is efficiently conjugated with free reducing glycans via reductive amination. The glycan−PNPA conjugates (GPNPAs) can be easily purified and quantified by UV absorption. The active *p*-nitrophenyl ester in the GPNPA conjugates readily reacts with amines under mild conditions, and the resulting conjugates acquire strong fluorescence. This approach was used to prepare several fluorescent neoglycoproteins. The neoglycoproteins were covalently printed on activated glass slides and were bound by appropriate lectins recognizing the glycans.

INTRODUCTION

Glycoconjugates including glycoproteins, glycolipids, and proteoglycans play important roles in many biological systems (*1*). Neoglycoconjugates, including neoglycolipids and neoglycoproteins as artificial mimics of natural glycoconjugates (*2*−*6*), have found many applications in various areas. One of the major applications is the development of carbohydrate-based vaccines and drugs (*7*−*11*).

To prepare neoglycoconjugates, and specifically neoglycoproteins, usually one or both of the molecules (glycan and protein) are derivatized with an appropriate functional group and then covalently linked. Theoretically, the linkages could be built through many different chemical reactions. Practically, however, derivatization is limited by several critical requirements. First, since glycans from natural sources or expensive synthetic approaches are often available only in small quantities, the glycan incorporation reaction should be highly efficient. Second, the reaction conditions should ideally be in aqueous buffer under physiological pH to avoid altering the glycan or denaturation of proteins, which might affect the solubility and immunogenicity of the conjugate. Third, the linkage itself should not decrease the immunogenicity of the conjugate and should be of minimal toxicity and antigenicity. There have been numerous methods developed for protein−carbohydrate conjugation, or neoglycoprotein synthesis, based on heterobifunctional or homobifunctional cross-linkers (*12*, *13*). Stowell et al. used 2-imino-2-methoxyethyl 1-thioglycosides to link glycans to proteins (*14*, *15*). Diethyl squarate has been used for efficient conjugation of proteins and carbohydrates; however, the potential immune response of the linker itself has impeded its application in vaccine development (*16*). Click chemistry (*17*) as well as a number of other protein− or peptide−carbohydrate conjugation methods have been employed for carbohydrate bioconjugation (*18*−*21*). Activated dicarboxylic acids can be used as homobifunctional linkers, but usually, no intermediate glycan derivatives can be separated. Wu et al. utilized bis-*p*-nitrophenylesters (*22*) to conjugate glycans and proteins. The intermediates can be separated and purified; however, the glycans need to be premodified to possess an active amine. Reductive amination has also been used in the conjugation of free reducing glycans (*23*) or ninhydrin-treated glycopeptides (*24*) to proteins; however, the reaction conditions are relatively harsh: they require large quantities of glycan and often the yields are very low.

Here, we describe a simple and efficient method to conjugate free reducing glycans with proteins using a commercially available chemical linker (Figure 1). The linker, *p*-nitrophenyl anthranilate (PNPA)[1], has two different functional groups: an aryl amine that can react with free reducing glycans by reductive amination and an active *p*-nitrophenyl ester that can react with nucleophiles. We show that this bifunctional linker is a useful reagent for preparing fluorescent neoglycoproteins from naturally occurring complex glycans. Moreover, the neoglycoconjugates acquire fluorescence upon linking, thus providing a ready means of following the reaction and quantifying the products.

EXPERIMENTAL PROCEDURES

Free reducing glycans were purchased from V-LABS and stored at −20 °C until use. All chemicals were purchased from Sigma-Aldrich and used without further purification. HPLC solvents were purchased from Fisher Scientific. An Ultraflex-II TOF/TOF system from Bruker Daltonics was used for MALDI-TOF mass spectrometry analysis of glycan conjugates.

Glycan−PNPA Conjugation. The conjugation of glycan with PNPA was carried out using the common reductive amination procedure for free glycan labeling with modifications on sample purification. Briefly, to a free reducing glycan (0.1

to 1 mg), freshly prepared PNPA solution (0.35 M in DMSO/AcOH = 7:3 (v/v), 25−50 μL) and an equal volume $NaCNBH_3$ solution (1 M in DMSO/AcOH = 7:3 (v/v)) were added. The mixture was heated at 65 °C for 2 h. The reaction mixture was quenched by addition of acetonitrile (0.5 to 1 mL). The mixture was cooled at −20 °C for 2 h and centrifuged at 10 000 *g* for 5 min. The supernatant was discarded and the pellet subjected to either C18 Sep-pak for desalting or C18 HPLC for direct purification. For reaction with ethylenediamine, LNnT-PNPA (0.1 to 1 mg) was dissolved in 20−200 μL 10% ethylenediamine, and the solution was kept at room temperature for 30 min and subjected to HPLC analysis.

HPAEC-PAD and High-Performance Liquid Chromatography (HPLC). High-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD) analysis was carried out with a Dionex ICS-3000 system with a Carbpac PA-100 column. The eluent gradient was set to 0−125 mM sodium acetate over 50 min in sodium hydroxide (100 mM).

A Shimadzu HPLC CBM-20A system was used for HPLC analysis and separation of glycan−PNPA conjugates. For reverse-phase HPLC, it was coupled with a Vydec C18 HPLC column and a UV detector SPD-20A. UV absorptions at 330 and 280 nm were used to detect and quantify GPNPAs and BSA−GPNPA conjugates. The mobile phase was acetonitrile and water with 0.1% trifluoroacetic acid (TFA). The concentration of acetonitrile increased from 1% to 90% in 30 min with a linear gradient. For SEC-HPLC, a Biobasic-60 SEC column was used. The eluent was ammonium acetate (10 mM) at pH 4.5. The flow rate was set at 1 mL/min for all HPLC runs.

Conjugation of Proteins with GPNPAs. Protein conjugation with GPNPAs was carried out in various buffers as described above. Protein concentration was kept at 5 mg/mL. Aqueous buffer with 1% DMSO was used. The protein conjugates were purified by SEC by collecting the eluent with strong absorption at UV 280 nm. Lyophilized fractions were dissolved in water or suitable buffer for MALDI-TOF characterization and printing.

Printing, Binding Assay, and Scanning. The printing of protein−glycan conjugates on NHS-activated slides and epoxy slides was carried out according to previous procedure (*25*). Biotinylated lectins were used in the binding assay, and the bound lectins were detected by a secondary incubation with cyanine 5-streptavidin. The slides were scanned with a Perkin-Elmer ProScanArray microarray scanner equipped with 4 lasers covering an excitation range from 488 to 633 nm. The scanned images were analyzed with the *ScanArray Express* software. For cyanine 5 fluorescence, 649 nm (Ex) and 670 nm (Em) were used. All the images obtained from the scanner were in grayscale and colored for easy discrimination.

RESULTS

Derivatization of Free Reducing Sugars with PNPA by Reductive Amination. The preliminary study of PNPA conjugation with free reducing glycans was carried out using lactoneotetraose (LNnT) (Galβ1−4GlcNAcβ1−3Galβ1−4Glc) as the model compound. The conjugation reaction is shown in Figure 2a. The reaction time was optimized by analyzing free LNnT and the product mixture after various reaction times using HPAEC-PAD (Figure 2b). The conversion of LNnT did not significantly increase after 2 h of heating at 65 °C, when >80% yield was obtained. The reaction mixture was precipitated in 10 volumes of acetonitrile, and the supernatant and precipitate were analyzed using RP-HPLC (Figure 2c). Most of the excess PNPA remained in the supernatant, and the LNnT−PNPA conjugate was precipitated in high yield (>90%). The major product peak was collected from RP-HPLC and analyzed by ESI-MS (Figure 2d), which showed an expected mass at 950.3237 [$M+H^+$] (calc. 950.3248) and confirmed the successful derivatization of the reducing glycan. Interestingly, the behavior of the LNnT-PNPA conjugate on MALDI-TOF-MS was quite different from ESI-MS. Although the expected molecular ion peak at 972.61 [$M+Na^+$] (calc. 972.3068) is evident in the spectrum, the most intense peak occurs at 958.63, along with other fragmentation peaks at 956.62 and 942.63 (Figure 2e). The fragmentation ions of −14, −16, and −30 Da caused by radical reactions on the nitro group (*26*) further confirmed the installation of PNPA. The pattern is highly reproducible and serves as an indicator for all glycan−PNPA conjugates in mass spectrometry analysis (Figure 2e).

Reaction of Glycan−PNPA (GPNPA) Conjugates with Nucleophiles. The reactivity of the GPNPAs toward nucleophiles was tested with ethylenediamine. This mild reaction at room temperature transforms the electrophilic *p*-nitrophenyl ester into a nucleophilic amino group (Figure 3a). Addition of 10% ethylenediamine at room temperature for 30 min quantitatively converted LNnT−PNPA to the expected LNnT−AEAB as shown by RP-HPLC (Figure 3b). The major product was purified by HPLC and characterized by MALDI-TOF (Figure 3c). This confirmed the formation of LNnT−AEAB conjugate, and therefore demonstrated the general reactivity of *p*-nitrophenyl ester toward alkylamines. The minor peak that eluted at 11.2 min with the reaction products matched the *p*-nitrophenol standard, confirming the PNPA conjugation with glycans and its reactivity toward amines (nucleophiles) as an active ester.

Conjugation of Proteins with GPNPAs. The conjugation of GPNPA with proteins was evaluated with BSA and

LNnT−PNPA. To optimize the conjugation, various buffers and temperatures were tested (Figure 4 and Table 1). Figure 4a is a schematic representation of the reaction between GPNPA and proteins. Lysine residues in proteins can attack the active *p*-nitrophenol ester to form a stable amide bond. In this reaction, glycan and protein are thus linked through a small fluorescent anthranilamide moiety. Figure 4b shows the MALDI-TOF analyses that compare the conjugation of LNnT−PNPA with

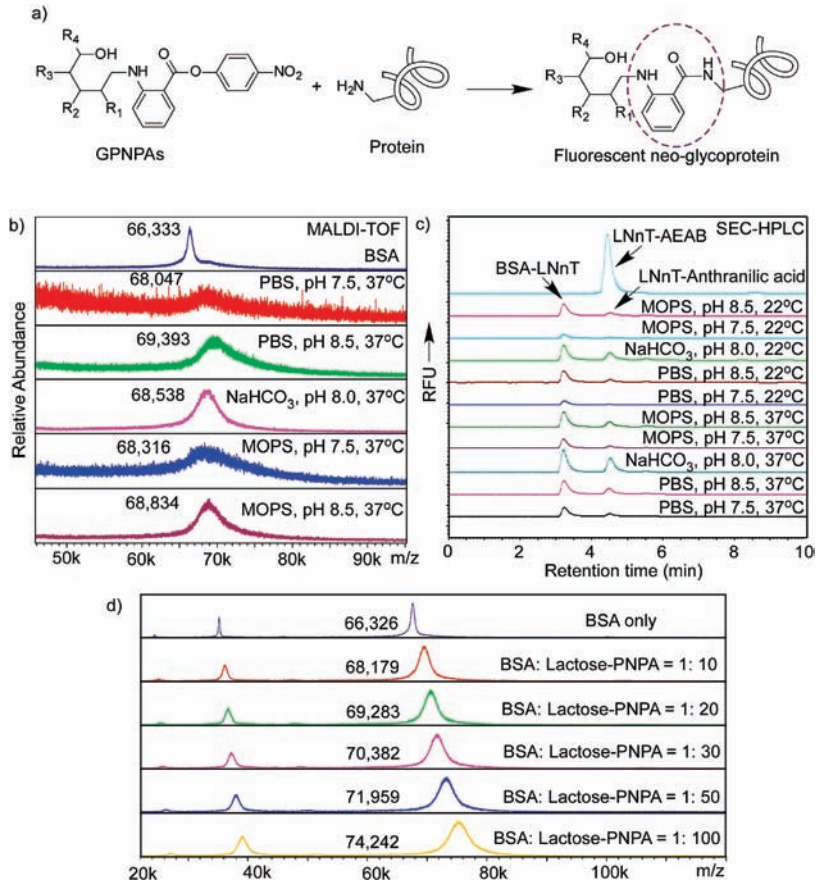

Figure 4. BSA conjugation with LNnT−PNPA: (a) the general equation of protein conjugation with GPNPAs; (b) overlay of MALDI-TOF profiles of BSA conjugation with LNnT−PNPA at 37 °C in various buffers; (c) fluorescent SEC-HPLC profiles of BSA conjugation with LNnT−PNPA at different temperatures and buffers; (d) overlay of MALDI-TOF profiles of BSA conjugation with lactose−PNPA at different ratios.

BSA in various buffers at 37 °C. The starting molar ratio of LNnT−PNPA and BSA was 10:1. While significant conjugation occurred in all buffers, reactions were faster in more basic conditions (pH 8.5 over pH 7.5). There was no significant conjugation difference seen in phosphate, MOPS, and carbonate buffers based on analysis by mass spectrometry. The conjugation efficiencies were estimated to be 2−3.5 glycans/protein molecule based on the MALDI-TOF peak values, indicating a yield of 20−35%. Figure 4c shows the fluorescent SEC-HPLC profiles of the conjugations in different buffers. The protein−glycan conjugates are fluorescent as expected (Ex 330 nm, Em 420 nm), and the intensity of the fluorescence can be directly correlated to the conjugation efficiency. Apparently, a relatively higher temperature (37 °C over 22 °C) and pH (8.5 over 7.5) significantly increased the conjugation efficiency. More interestingly, the fluorescence of the LNnT−BSA conjugate generated in carbonate buffer is stronger than those in PBS or MOPS buffer, suggesting a faster reaction. It is worthwhile to note that another fluorescent peak eluting at the same time as LNnT−AEAB is observed. This is presumably the hydrolysis product of LNnT−PNPA (LNnT-anthranilic acid, MW 828.77), which has a similar size to LNnT−AEAB (870.85). This peak is of significantly lower intensity than the protein peak, indicating that hydrolysis of GPNPA under these conditions is not seriously affecting the protein−glycan conjugation. To further evaluate the conjugation of GPNPAs with proteins, we tested the conjugation of lactose−PNPA (Galβ1−4Glc-PNPA) with BSA at different molar ratios (Figure 4d and Table 1). The increased amount of lactose−PNPA, as expected, increased the average number of lactose−PNPA conjugated per BSA molecule. At 100:1 ratio, ∼17−18 lactose/BSA were conjugated.

Table 1. Conjugation of BSA with Glycan−PNPA Conjugates in Different Buffers, pH, and Molar Ratios

glycan PNPA	temp (°C)	buffer	pH	starting molar ratio (glycan/BSA)	product molar ratio (glycan/BSA)
LNnT	37	PBS	7.5	10	2.1
LNnT	37	PBS	8.5	10	3.8
LNnT	37	$NaHCO_3$	8.0	10	2.7
LNnT	37	MOPS	7.5	10	2.4

Printing and Recognition of Glycan−BSA Conjugates on Microarray Slides. To validate the structural integrity of glycans after conjugation with proteins, we conjugated several GPNPAs (LNnT, LNFIII, and LSTc) with BSA using a 5:1 molar ratio of glycan/protein. The conjugates were purified by SEC-HPLC. The MALDI-TOF profiles in Figure 5a show the mass shifts compared to BSA alone, indicating that 1.5−2 glycans/protein molecule were conjugated. The purified BSA−glycan conjugates were printed on epoxy and NHS-activated glass slides and interrogated with several plant lectins. All three lectins showed expected bindings on both epoxy and NHS-activated slides (Figure 5b). AAL, a fucose binding lectin (*27*), bound to BSA−LNFIII conjugates. RCA I, a plant lectin that recognizes

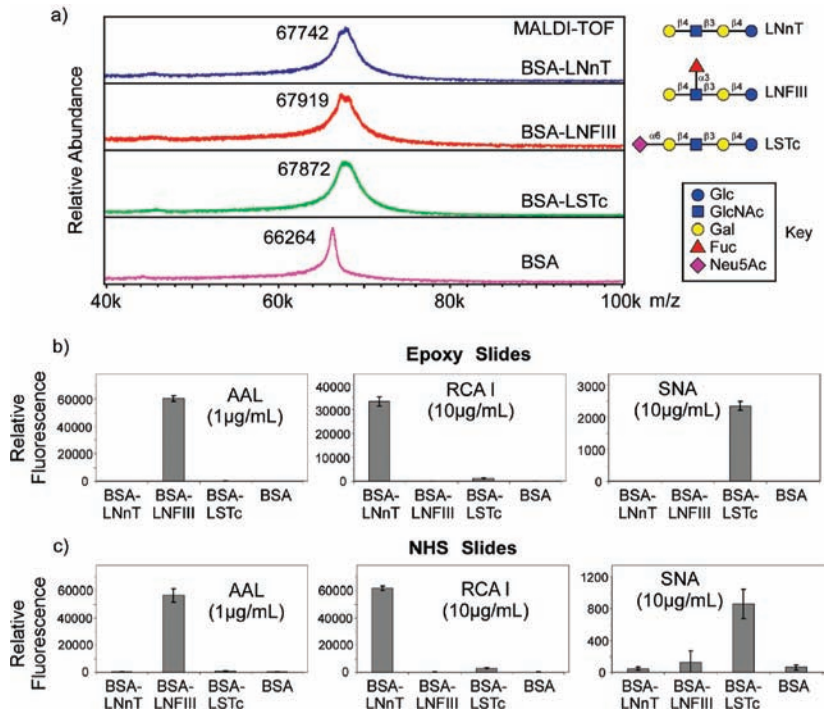

Figure 5. (a) MALDI-TOF of conjugates of BSA with LNnT−PNPA, LNFIII−PNPA, and LSTc−PNPA. (b,c) The conjugates of BSA−LNnT, −LNFIII, and −LSTc, and BSA alone printed on epoxy slides (b) and NHS slides (c) and interrogated with the lectins AAL, RCA I, and SNA. The glycan structures are indicated along with a key to the symbols.

β1,4-linked galactose residues (*28*) bound to BSA−LNnT conjugates and also to BSA−LSTc conjugates, weakly, since α2,6-sialylation does not fully abolish its binding to Galβ1,4-R moieties. SNA, a plant lectin that binds α2,6-linked sialic acid residues (*29*), bound to BSA-LSTc conjugates, as expected.

DISCUSSION

p-Nitrophenyl ester is known to be an active ester due to the strong electronegativity of the nitro group. This active ester, however, is well-tolerated by the aromatic amine group in PNPA, which is a nucleophile. The existence of two opposing but tolerant functional groups makes PNPA a promising heterobifunctional linker under finely tuned conjugation conditions. Reductive amination of PNPA with free reducing glycans does not interfere with the *p*-nitrophenyl ester, as shown by HPAEC, HPLC, and MALDI-TOF (Figure 2b−d). Although this reaction does not go to completion under the commonly used conditions, it is still highly efficient (>80% yield) and nonselective toward many glycans, as shown by LNnT, LNFIII, and LSTc conjugation profiles (Figure 2e). Furthermore, GPNPAs can be easily separated from unconjugated free glycans by C18 Sep-pak due to the strong hydrophobicity of the linker. The high conjugation efficiency, nonselectivity, and easy separation make this approach appropriate for extracting natural glycans as active esters for neoglycoconjugate preparation. We have noticed that, by direct reductive amination with glycans, the reducing end ring structure is opened. This is of concern in situations where the whole glycan structures are considered epitopes, such as conjugation of mono- and disaccharides or structures with epitopes close to the reducing end. In most cases, we are more interested in the terminal moieties as epitopes, which should not be affected by this strategy. Under these circumstances, the ability to utilize complex natural glycans directly without laborious synthesis is of more importance than the reducing end structural variation. On the other hand, this strategy could also be applied to any biomolecules with an aldehyde group, which could be installed at the glycan reducing end without breaking the ring structures (*30*).

It is worthwhile to note the interesting behavior of GPNPAs on MALDI-TOF. While ESI-MS clearly showed the molecular ion, MALDI-TOF of GPNPAs showed a reproducible fragmentation pattern besides the molecular ion. This radical reaction related pattern is specific to the nitro group. While it might complicate mass spectra to a certain extent, it could also serve as a fingerprint for confirming glycan−PNPA conjugates in mass spectrometry analysis. Nevertheless, this does not interfere with the reactivity of GPNPAs for conjugation with other molecules, as shown in Figure 3. LNnT−PNPA quickly reacts with ethylenediamine to form LNnT−AEAB. The electrophile (ester) of LNnT−PNPA is easily transformed to a nucleophile (amine), enabling its direct conjugation with electrophilic molecules such as epoxy and NHS esters. We have demonstrated the use of AEAB conjugation with glycans for generation of fluorescent natural glycan arrays (*31*), providing an alternative for this application. Although AEAB and PNPA are all heterobifunctional linkers that can be used to conjugate free reducing glycans with other biomolecules or solid surfaces, they are complementary in terms of the reactivity. GAEABs have a nucleophilic alkylamine, while GPNPAs have a good leaving group that is reactive toward nucleophiles. Application of both conjugations offers more flexibility in the design and preparation of bioconjugates.

Protein−carbohydrate conjugation has become an important route for generating glycan-related antibodies. Many methods have been developed, most of which focus on conjugating synthetic glycans through bifunctional linkers. In our effort to develop carbohydrate-based vaccines against schistosomiasis and other pathogens (*32*), we sought to conjugate complex glycans extracted from natural sources, which are usually very complicated to synthesize with appropriate linkers attached. Therefore, we needed an effective method to efficiently conjugate free reducing glycans with protein carriers. Although there are a number of methods developed for protein−carbohydrate conjugations, most of them are not targeting naturally occurring complex glycans, which are difficult to obtain through synthesis. Although direct coupling of glycans with proteins by reductive

amination has been used, the yields are often disappointing. To obtain homogeneous natural glycans is also a major challenge. PNPA, as a heterobifunctional linker, can react efficiently and selectively with glycans and proteins. GPNPAs can be easily prepared and purified from natural sources based on their UV absorbance. The GPNPAs can be efficiently conjugated with BSA, as shown by MALDI-TOF and HPLC (Figure 4). MALDI-TOF is the most common method used to determine the protein−carbohydrate conjugation efficiency based on the mass shift before and after conjugation. However, with more glycans and linkers added, the MALDI-TOF peak broadens quickly so that the peak value does not accurately represent the average molecular weight of protein conjugates. The protein−glycan conjugates prepared with the GPNPA strategy are fluorescent, which can greatly facilitate the quantification of conjugated glycans even at a minimal level (Figure 4c). Furthermore, with appropriate UV range fluorescence detection methods, this fluorescence could be used to detect small amounts of protein in purification steps and bioassays. On the basis of the mass and fluorescence of the conjugates, we confirmed that various glycans such as lactose, LNnT, and LSTc can be reproducibly conjugated to proteins. The molar ratio of glycans versus glycan−protein conjugates can be driven by increasing the molar ratio of glycans to proteins, reaching 17−18 glycans/conjugate at 100:1 glycan/protein molar ratio.

Upon conjugation of glycans to proteins, it is difficult to validate that the structures of glycans are not affected during the glycan−protein conjugation process. Therefore, we conjugated and printed several glycan−protein conjugates on activated glass slides and interrogated them with various lectins. The conjugation of LNnT, LNFIII, and LSTc GPNPAs to BSA showed similar mass shifts (Figure 5a), indicating the general applicability of this approach to different glycans. This is especially useful for sialylated structures, as the sialic acid is not compatible with many conjugation approaches relying on carboxylic acid activation. With *p*-nitrophenyl ester incorporated onto the glycan reducing end by reductive amination, sialylated glycans can be conjugated to proteins as easily as other glycans. When the BSA conjugates of LNnT, LNFIII, and LSTc were printed on activated glass slides (epoxy and NHS) and assayed with three lectins, AAL, RCA I, and SNA, expected specific binding was observed for each lectin. These results show that the glycan structures are presented after the conjugation process in a manner that is consistent with their predicted recognition, which implies that such conjugates can be used to explore biological functions of glycans. It is also worth noting that this approach provides an alternative platform for natural glycan microarray printing. While suitably derivatized glycans (*25*, *31*, *33*, *34*) can be directly printed on NHS or epoxy slides for successful carbohydrate binding protein screening, printing of protein−glycan conjugates presents the glycan structures in the context of protein. This somewhat addresses concerns about nonspecific surface interactions related to microarray slide presentation and may provide a desirable alternative presentation strategy under certain circumstances. The fact that the protein−glycan conjugates are fluorescent is also a major advantage when quantifiable microscale material is used in microarray printing.

One general issue in using protein−carbohydrate conjugates as potential vaccines is that the linker itself is sometimes immunogenic or alters immunogenic potential of the glycan. While no testing is yet available on the immunogenicity of anthranilamide derivatives, the fluorescent anthranilamide is generally considered safe as a chemical, and the closely related anthranilic acid is the precursor of the amino acid tryptophan. Thus, while not yet tested in vivo, we expect this linker to have minimal immunogenicity and toxicity.

In conclusion, we have developed a novel approach utilizing a commercially available chemical as a convenient fluorescent linker for protein−carbohydrate conjugation. The ease and efficiency, the ability to utilize natural glycans, and the acquired fluorescence of the final conjugates make this approach very promising in the development of carbohydrate antibodies and carbohydrate-based vaccines.

ACKNOWLEDGMENT

Received April 24, 2009; Revised Manuscript Received May 27, 2009

Technetium tricarbonyl chemistry has been a subject of interest in radiopharmaceutical development over the past decade. Despite the extensive work done on developing chelates for Tc(I), a rigorous investigation of the impact of changing donor groups and labeling conditions on radiochemical yields and/or distribution has been lacking. This information is crucially important if these platforms are going to be used to develop molecular imaging probes. Previous studies on the coordination chemistry of the $\{M(CO)_3\}^+$ core have established alkylamine, aromatic nitrogen heterocycles, and carboxylate donors as effective chelating ligands. These observations led to the design of tridentate ligands derived from the amino acid lysine. Such amino acid analogues provide a tridentate donor set for chelation to the metal and an amino acid functionality for conjugation to biomolecules. We recently developed a family of single amino acid chelates (SAAC) that serve this function and can be readily incorporated into peptides via solid-phase synthesis techniques. As part of these continuing studies, we report here on the radiolabeling with technetium-99m (^{99m}Tc) and stability of a series of SAAC analogues of lysine. The complexes studied include cationic, neutral, and anionic complexes. The results of tissue distribution studies with these novel complexes in normal rats demonstrate a range of distribution in kidney, liver, and intestines.

INTRODUCTION

Advances in molecular imaging and targeted radiotherapy of cancer are intimately dependent on technological advancements in radiochemistry. Recent reports show significant clinical benefit of targeted radiotherapeutics for the treatment of cancer; however, the arsenal of available compounds is limited despite the significant unmet clinical need (*1*−*4*). In addition, the desire to produce high specific activity radiopharmaceuticals for both imaging and therapy that bind to low-density, molecular targets has been clearly demonstrated (*5*).

The ability to incorporate readily available radionuclides with optimal decay characteristics into targeting molecules has been the foremost consideration in developing diagnostic radiopharmaceuticals. In this respect, ^{99m}Tc has become the mainstay of diagnostic nuclear medicine and in some chemical form is used in more than 85% of the diagnostic scans performed each year in hospitals (*6*). The preferential use of ^{99m}Tc radiopharmaceuticals reflects the ideal nuclear properties of the isotope, as well as its convenient availability from commercial generator columns. ^{99m}Tc emits a 140 keV γ-ray with 89% abundance which is close to optimal for imaging with commercial gamma cameras. The minimal tissue-damaging linear energy transfer radiation allows the injection of activities of more than 1 GBq with low radiation exposure to the patient. The six-hour half-life is sufficiently long for pharmaceutical preparation and *in vivo* accumulation in the target, yet short enough to minimize radiation dose to the patient or environmental repercussions. Furthermore, the combination of the medically useful radionuclides, ^{99m}Tc and rhenium-186/188 ($^{186/188}$Re), is attractive for developing molecular imaging and molecular radiotherapeutics due to the similarities in their coordination chemistry and their excellent physical decay characteristics, which enable imaging and therapy, respectively. The coordination chemistries of ^{99m}Tc and $^{186/188}$Re are remarkably similar in regard to the $\{M(CO)_3L_3\}^+$ core, where the coordination complexes of ^{99m}Tc and $^{186/188}$Re are isostructural (*7*−*9*).

Radiopharmaceuticals may be classified into two broad categories: (i) those with biological distribution determined strictly by blood flow, or perfusion, which target high capacity systems such as glomerular filtration, phagocytosis, hepatocyte clearance and bone absorption, and (ii) those with biological distribution determined by specific enzymatic or receptor mediated binding interactions, i.e., low-density sites. The latter approach, which necessitates high specific activity complexes, is achieved using two methods to chelate ^{99m}Tc in a receptor specific molecule, the conjugate/pendent approach and the integrated approach.

The conjugate or pendant approach, Scheme 1, involves tethering a ^{99m}Tc chelate moiety to a species known to possess high affinity binding to a receptor (*10*−*13*). This strategy has an inherent disadvantage in that incorporation of the metal chelate complex often decreases the affinity of the "native" biomolecule, requiring optimization of both the chelator and the physical−chemical properties of the tether to regain affinity, often at the expense of a favorable pharmacokinetic profile. The very nature of the bifunctional chelate is constructed from three independent components adding complexity to the optimization process: a side arm for linkage to the bioactive molecule, the tether between the side arm linker and the donor groups, and a set of appropriate ligand donor groups for coordination to the metal site, in this case, ^{99m}Tc. The "bifunctional" ligand serves two purposes. First, it complexes the metal (M) radionuclide securely, holding it to the radiopharmaceutical without leakage

in vivo, and second, it provides a side arm for antibody, peptide, or small molecule attachment while maintaining maximal integrity of the bioactive molecule (BAM). The bifunctional chelators must be capable of conjugation under rapid, mild, preferably aqueous conditions reasonably close to physiological pH, with minimal need for purification. In addition, the moiety that chelates the ^{99m}Tc must demonstrate significant kinetic stability under biological conditions.

Conversely, the integrated approach replaces a portion of the high affinity receptor ligand with a ^{99m}Tc chelate, so as to preserve the binding affinity (*14*−*16*). The SAAC system is an example of the integrated approach which simplifies the process of identifying the appropriate combination of linker and chelator. By combining the tether and chelator into one molecule, SAAC systems transform this from a two variable to a one variable challenge. In the case of the lysine SAAC systems (Figure 1), the components consist of constant functionalities (B,C,D) for conjugation to the biomolecules of interest and a set of functional donor groups (A). One advantage of this approach is that the SAAC systems can be tailored to produce desired pharmacokinetic profiles in a more straightforward manner, via modification of the chelator (A) since B, C, and D are held constant in lysine. Furthermore, SAAC ligands are compatible with solid-phase peptide synthesis and to this end have been successfully exploited to created vast libraries of SAAC-containing peptides to enable high-throughput screening. The fluorescent SAAC analogue, rhenium tricarbonyl 2-amino-6-(bis(quinolin-2-ylmethyl)amino)hexanoic acid (Re-DqK), has been successfully integrated into the chemotactic peptide sequence fMLFK which has been used for imaging bacterial infection (*17*), and into the *trans*-activating transcriptional activator (TAT) peptide for imaging neuronal stem cells (*18*).

The most stable and readily accessible oxidation states are often characterized by chemically robust core structures which may be exploited as platforms for the development of radiopharmaceutical reagents. The most extensively developed core structure is $\{Tc(V)O\}^{3+}$, particularly with tetradentate ligands of the $N_xS_{(4-x)}$ type. Past research has focused primarily on attachment of the bifunctional chelators for complexation of the $\{Tc(V)O\}^{+3}$ core into small tripeptides and tetrapeptides (*19*−*22*). This has been accomplished predominantly using N_3S and N_4 ligands. Other structural subunits which have attracted attention include the $\{TcN\}^{2+}$, $\{TcO_2\}^{+}$, and technetium 6-hydrazinonicotinic acid $\{Tc(HYNIC)_x\}^{3+}$ (where $x = 1$ or 2) cores. More recently, the Tc(I) core, technetium tricarbonyl $\{Tc(CO)_3\}^{+}$ has been shown to provide an ideal geometry for the labeling of chelators of the $\{Tc(CO)_3\}^{+}$ core with high specific activity. The Tc(I)-tricarbonyl core offers a number of advantages for the design of novel radiopharmaceuticals: (i) a facile route exists to the important intermediate $[M(H_2O)_3(CO)_3]^{+}$ through the work of Alberto and co-workers (*23*, *24*); (ii) $[M(H_2O)_3(CO)_3]^{+}$ is water-soluble and the water molecules readily undergo ligand exchange with appropriate donor ligands; (iii) the complexes containing the $\{Tc(CO)_3\}^{+}$ core are chemically robust and maintain their integrity under the most forcing conditions. Complex formation is facilitated by the facile substitution chemistry at the aqua sites of the $\{M(CO)_3(H_2O)_3\}^{+}$ (M = Tc, Re) and $\{Re(CO)_3X\ (H_2O)_2\}$ (where X = Cl, Br) intermediate species, and the coordination preferences of Tc(I) and Re(I) for nitrogen and oxygen donors.

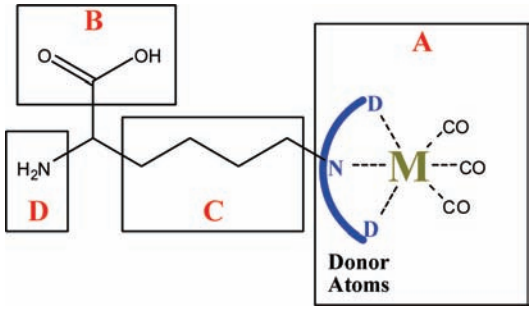

Figure 1. Components of the lysine SAAC analogues binding the group (VII) metals (M = Re or Tc).

Research in our laboratories focused on the derivatization of a single amino acid (L-lysine) for incorporation of the $\{Tc(CO)_3\}^{+}$ core. The advantages of this strategy include (i) decreased size and complexity of the chelator due to the ability to modify a single amino acid terminus, a feature which should minimize perturbations of the peptide receptor targeting small molecule or peptide by reducing the molecular weight and steric constraints of the bifunctional unit; (ii) the ease of derivatization of the amino acid or amino acid analogue; (iii) the use of a robust Tc-core, $\{Tc(CO)_3\}^{+}$, which is readily available from the $[Tc(CO)_3(H_2O)]^{+}$ precursor and undergoes substitution reactions at the aqua ligand sites with donor ligands (*25*−*28*). By reducing the size of the bifunctional unit, the lipophilicity of the complexes may be minimized, leading to diminished liver and gastrointestinal uptake and accumulation. These novel chelators should lead to ^{99m}Tc-radiopharmaceuticals with improved whole body clearance and thus enhanced image quality especially in the abdominal regions.

The use of $\{^{99m}Tc(CO)_3(H_2O)_3\}^{+}$ as the starting material leads to readily formed complexes of the *fac*-$[^{99m}Tc(CO)_3(L)_3]^{+}$ core. Recent work has demonstrated the high affinity of the $\{Tc(CO)_3\}^{+}$ core for this chelator system (*29*−*32*). The thermodynamic stability of the $\{Tc(I)(CO)_3\}^{+}$ core also adds *in vivo* stability, limiting complicating presence of metabolites and side products that may negatively effect the imaging properties of the final complexes and negate the true tracer characteristics.

We recently synthesized and characterized a series of bifunctional chelators derivatized from the ε-amine of L-lysine as stable, low molecular weight chelates for ^{99m}Tc and rhenium, including bis(2-pyridine), bis(dithiazole), bis(*o*-phenols), and 2-pyridine monoacetic acid (*33*) with the goal of investigating the impact of donor groups and labeling conditions on radiochemical yields and/or distribution that could be readily inserted into a solid-phase peptide synthesizer. Modification of the chelating moieties presents a facile way to vary the structural and physiochemical properties of our SAAC systems. The chelators prepared led to cationic, neutral and anionic complexes. Herein, are described the $\{^{99m}Tc(I)(CO)_3^{+}\}$ SAAC systems: $[^{99m}Tc(CO)_3(\eta^3$-{2-amino-6-(bis(pyridin-2-ylmethyl)amino)hexanoic acid}] (**7**), $[^{99m}Tc(CO)_3(\eta^3$-{2-amino-6-(bis(thiazol-2-

ylmethyl)amino)hexanoic acid}] (**8**), [^{99m}Tc(CO)$_3$(η^3-{2-amino-6-((carboxymethyl)(pyridin-2-ylmethyl)amino)hexanoic acid}] (**9**), and [^{99m}Tc(CO)$_3$(η^3-{6-[bis(2-hydroxy-benzyl)amino]-2-(9*H*-fluoren-9-ylmethoxycarbonylamino)hexanoic acid}] (**10**). All the ligands were evaluated for radiolabeling optimization, stability, and in addition, ligands **7**−**9** were evaluated for tissue distribution studies in normal rats providing crucial data relating characteristics of the chelates to pharmacokinetic profiles.

EXPERIMENTAL SECTION

General Methods. All reactions were carried out in dry glassware under an atmosphere of argon unless otherwise noted. Reactions were purified by column chromatography, under medium pressure using a Biotage SP4 or by preparative high-pressure liquid chromatography using a Varian Prostar 210 preparative HPLC system equipped with a semipreparative Vydac C18 reverse-phase column (250 mm × 10 mm × 5 μm) connected to a Varian Prostar model 320 UV−visible detector and monitored at a wavelength of 254 nm. The final product purifications were achieved using a binary solvent gradient of 5−95% B over 21 min (A = triethyl ammonium phosphate (TEAP) pH 3, B = methanol). Analytical HPLC of the radioiodinated compounds was performed using the same method with an analytical Vydac C18 reverse-phase column (250 mm × 4.6 mm × 5 μm). Microwave reactions were performed in a Biotage Initiator 60 microwave using 10 mL reactor vials. ^{1}H NMR spectra were obtained on a Bruker 400 MHz instrument. Spectra are reported as ppm and are referenced to the solvent resonances in $CDCl_3$, DMSO-d_6, or methanol-d_4. Elemental analysis was performed by Prevalere Life Sciences, Inc. High-resolution mass spectra were determined by M-Scan Inc. using positive ion electrospray with a Q-Tof API US hybrid quadrupole/time-of-flight mass spectrometer. ^{99m}Tc was used as a Na^{99m}TcO$_4$ solution in saline, as a commercial ^{99}Mo/^{99m}Tc generator eluant (Cardinal Health). The ^{99m}Tc-containing solutions were always kept behind sufficient lead shielding. The use of [^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ was prepared from commercially available Isolink kits (Mallinckrodt). The synthesis of the [ε-{*N*,*N*-di(pyridyl-2-methyl)}-α-(Fmoc)lysine], [ε-{*N*,*N*-di(thiazole-2-methyl)}-α-(Fmoc)lysine], and [ε-{*N*-(pyridyl-2-methyl)-*N*-(acetic acid}-α-(Fmoc)lysine] were reported previously by our group (*33*). All solvents were purchased from Sigma Aldrich. Reagents were purchased from Sigma Aldrich (St. Louis, MO), Bachem (Switzerland), Akaal (Long Beach, CA), or Anaspec (San Jose, CA). The following abbreviations are used: Fmoc = Fluorenylmethyloxycarbonyl, DMAP = *N*, *N*-dimethylaminopyridine, DMF = *N*,*N* -dimethylformamide, DCM = dichloromethane, NaOH = sodium hydroxide, ID/g = injected dose per gram, PBS = phosphate buffered saline, RCP = radiochemical purity, RCY = radiochemical yield.

SYNTHESIS

All ligands were prepared using standard reductive amination techniques and have been described previously by Zubieta et al. (*33*)

2-Amino-6-(bis(pyridin-2-ylmethyl)amino)hexanoic Acid (DpK) (1). In a 100 mL round-bottom flask was placed 2-(9*H*-fluoren-9-ylmethoxycarbonylamino)-6-(bis(pyridin-2-ylmethyl)-amino)hexanoic acid (0.20 g, 0.36 mmol) and an equal molar amount of DMAP. The solids were dissolved in 5 mL of DMF and 1 mL of methanol. The reaction mixture was allowed to stir at room temperature for 12 h. The crude reaction was concentrated and purified by column chromatography (SiO_2) (20% methanol/methylene chloride as eluent) to afford the final product as an off-white solid (100 mg, 0.30 mmol, 83% yield). ^{1}H NMR ($CDCl_3$) δ 8.64 (d, 2H). 8.24 (t, 2H), 7.80 (d, 2H), 7.72 (t, 2H), 4.31 (s, 2H), 3.20 (m, 2H), 3.14 (s, 9H), 3.04 (m, 2H), 2.25 (m, 2H),1.30 (m, 2H). ESMS *m*/*z*: 328 $(M+H)^+$. Anal. ($C_{18}H_{24}N_4O_2$) C, H, N.

2-Amino-6-(bis(thiazol-2-ylmethyl)amino)hexanoic Acid (DtK) (2). In a 100 mL round-bottom flask was placed 2-(9*H*-fluoren-9-ylmethoxycarbonylamino)-6-(bis(thiazol-2-ylmethyl)-amino)hexanoic acid (0.050 g, 0.089 mmol) and an equal molar amount of DMAP. The solids were dissolved in 5 mL of DMF and 1 mL of methanol. The reaction mixture was allowed to stir at room temperature for 12 h. The crude reaction was concentrated and purified by column chromatography (SiO_2) (0−40% methanol/methylene chloride as eluent) to afford the final product as an off-white solid (18 mg, 0.053 mmol, 60% yield). ^{1}H NMR (D_2O) δ 7.73 (d, 2H). 7.57 (d, 2H), 4.09 (s, 4H), 3.69 (t, H), 2.63 (t, 2H), 1.81 (m, 2H), 1.61 (m, 2H), 1.35 (m, 2H). ESMS *m*/*z*: 340 $(M+H)^+$. Anal. ($C_{14}H_{20}N_4O_2$) C, H, N.

2-Amino-6-((carboxymethyl)(pyridin-2-ylmethyl)amino)-hexanoate (PAMA-K) (3). In a 100 mL round-bottom flask was placed *t*-butyl 2-(9*H*-fluoren-9-ylmethoxycarbonylamino)-6-pyridin-2-ylmethyl)amino)hexanoate (0.070 g, 0.122 mmol) and an equal molar amount of DMAP. The solids were dissolved in 5 mL of DMF and 1 mL of methanol. The reaction mixture was allowed to stir at room temperature for 12 h. The crude reaction was concentrated and purified by column chromatography (SiO_2) (0−40% methanol/ methylene chloride as eluent). Subsequently, the *t*-butyl-6-pyridin-2-ylmethyl)amino)hexanoate was dissolved in 4 mL dichloromethane and 4 mL of trifluoroacetic acid. The reaction mixture was allowed to stir at room temperature for 1.5 h. The solution was blown dry under a stream of nitrogen. The crude reaction was purified by column chromatography (SiO_2) (0−40% methanol/ methylene chloride as eluent) to afford the final product as an off-white solid. (21 mg, 0.068 mmol, 55% yield). ^{1}H NMR ($CDCl_3$) ^{1}H NMR (d_6-DMSO) δ 8.62 (d, H), 8.15 (s, 2H), 7.92 (m, H), 7.56 (d, H), 7.47 (m, H), 4.40 (d, 2H), 3.87 (m, 2H), 3.01 (m, H), 2.50 (m, 2H), 1.75 (m, 2H), 1.62 (m, 2H), 1.39 (m, 2H). ESMS *m*/*z*: 295 $(M+H)^+$. Anal. ($C_{14}H_{21}N_3O_4$) C, H, N.

2-Amino-6-(bis-(2-hydroxybenzyl)amino)hexanoic Acid (Diphenol-K) (4). In a 100 mL round-bottom flask was placed 2-(9*H*-fluoren-9-ylmethoxycarbonylamino)-6-[bis-(2-hydroxybenzyl)amino]-hexanoic acid (0.050 g, 0.086 mmol), and an equimolar amount of DMAP and 5 mL of DMF and 1 mL of methanol was added. The reaction mixture was allowed to stir at room temperature for 12 h. The crude reaction was purified by column chromatography (SiO_2) (0−40% methanol/methylene chloride as eluent) to afford the final product as an off-white solid (16 mg, 0.047 mmol, 52% yield). ^{1}H NMR ($CDCl_3$) δ 7.10 (m, 4H), 6.90 (m, 4H), 4.20 (d, 2H), 3.92 (m, 2H), 3.0 (m, H), 2.50 (m, 2H), 1.78 (m, 2H), 1.55 (m, 2H), 1.42 (m, 2H). General Preparation of ^{99m}Tc-Complexes. The $\{^{99m}Tc(I)(CO)_3\}^+$ labeling was accomplished in two steps using commercially available IsoLink kits (Covidien) to form the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ intermediate, which was heated at 75 °C for 30 min with the appropriate SAAC (Figure 2) (10^{-4} to 10^{-6} M, pH 2−9, 75−100 °C) to form complexes $[^{99m}Tc(CO)_3(\eta^3$-{2-amino-6-(bis(pyridin-2-ylmethyl)amino)hexanoic acid}] = $[^{99m}Tc(CO)_3(DpK)]^+$ (**7**), $[^{99m}Tc(CO)_3(\eta^3$-{2-amino-6-(bis(thiazol-2-ylmethyl)amino)hexanoic acid}] = $[^{99m}Tc(CO)_3(DtK)]^+$ (**8**), $[^{99m}Tc(CO)_3(\eta^3$-{2-amino-6-((carboxymethyl)(pyridin-2-ylmethyl)amino)hexanoic}] = $[^{99m}Tc(CO)_3(PAMA\text{-}K)]$ (**9**), and $[^{99m}Tc(CO)_3(\eta^3$-{6-[bis(2-hydroxy-benzyl)amino]-2-(9*H*-fluoren-9-ylmethoxycarbonylamino)hexanoic acid}]=$[^{99m}Tc(CO)_3$(diphenol-K)]$^-$ (**10**). Likewise, the control ligands PADA and L-histidine (Figure 3) were labeled in a similar manner (10^{-6} M, pH 7, 75 °C) to form their ^{99m}Tc-complexes. Upon cooling, the reactions were purified by preparatory reverse-phase (RP) HPLC and the purity assessed by analytical RP-HPLC.

Microwave Preparation of $[^{99m}Tc(CO)_3(DpK)]^+$ (7). The $\{^{99m}Tc(I)(CO)_3\}^+$ labeling was accomplished in two steps using the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ intermediate, which was heated at 100 °C for 5 min with 2-amino-6-(bis(pyridin-2-ylmethyl)amino)-hexanoic acid (DpK) (**1**) (10^{-4} M, PBS pH 7.4) in 10 mL reactor tubes within the Biotage Initiator 60 microwave to form the complex $[^{99m}Tc(CO)_3(\eta^3$-{2-amino-6-(bis(pyridin-2-ylmethyl)-amino)hexanoic acid}] = $[^{99m}Tc(CO)_3(DpK)]^+$ (**7**).

Determination of the Optimal pH for the Radiolabeling. The effect of pH on the radiochemical yield (RCY) of the radiolabeling reactions was investigated at a constant temperature, concentration, and reaction time. Solutions of the ligands at a concentration of 10^{-6} M were radiolabeled at a temperature of 75 °C and analyzed for RCY at pH = 2, 5, 6, 7, 8, and 9 using sodium acetate and phosphate buffers. The optimal pH for all of the individual chelators was determined from the RCY at 30 min.

Determination of Complex Stability. The stability of the HPLC purified final complexes was assessed by simultaneous incubation with cysteine and histidine (final ligand concentration

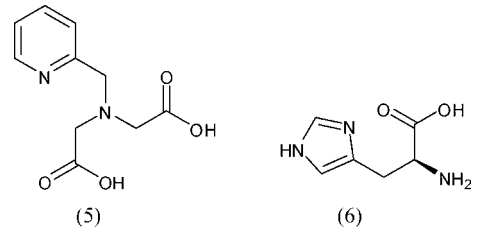

Figure 3. Structure of control ligands PADA (*5*) and histidine (*6*).

10^{-5} M) at pH = 7.4 and 37 °C at 1, 4, and 18 h. The complexes were prepared, purified by RP-HPLC to achieve carrier free complexes, and then incubated with an excess of cysteine and histidine. A solution of the ^{99m}Tc-SAAC complex was incubated under identical reaction conditions in the absence of cysteine and histidine as a control.

Determination of Log *P* Values. The Log *P* values of the ^{99m}Tc(I)-complexes were determined as follows. The ^{99m}Tc-SAAC complexes were prepared and purified by RP-HPLC. The desired peak was collected, and the sample was evaporated under a stream of nitrogen. The residue was dissolved in 25 μL of saline and placed in an equal volume of *n*-octanol (3 mL) and 25 mM pH = 7.4 phosphate buffer (3 mL). The samples were mixed under vortex for 20 min and centrifuged at 8000 rpm for 5 min, and three 100 μL aliquots were removed from both the aqueous and the organic layers for analysis on a gamma counter (Wallac 1282). Subsequently, 1 mL of the phosphate buffer-Tc-complex solution was removed, and the process was repeated with fresh *n*-octanol, for a total number of six extractions to ensure full extraction of all the organic components. The partition coefficients were calculated using the equation: P = (activity concentration in *n*-octanol)/(activity concentration in aqueous layer). The Log *P* values reported were calculated from the average of the different measurements.

Rat Tissue Distribution Studies. The distribution and pharmacokinetics of selected ^{99m}Tc-SAAC complexes (*7*−*10*) were evaluated in normal male Sprague−Dawley rats (180−200 g) administered via the tail vein as a bolus injection (approximately 10 μCi/rat) in a constant volume of 0.1 mL. The animals (n = 5 per time point) were euthanized by asphyxiation with carbon dioxide at 5, 30, 60, and 120 min post injection. Tissues (blood, heart, lungs, liver, spleen, kidneys, adrenals, stomach, intestines (with contents), testes, skeletal muscle, bone, and brain) were dissected, excised, weighed wet, and counted in an automated γ-counter (LKB Model 1282, Wallac Oy, Finland). Tissue time−radioactivity levels expressed as percent injected dose per gram of tissue (%ID/g) were determined.

RESULTS AND DISCUSSION

The novel tridentate ligands possess a unique primary amine which allows for the facile synthesis of large numbers of structural variants with diverse physiochemical properties. The synthetic ease of preparation of *N*-substituted derivatives allowed for the preparation of SAAC ligands with the potential to form neutral, cationic, and anionic ^{99m}Tc complexes. The chemistry utilized to prepare the bifunctional SAAC chelators was based on the use of the reductive alkylation reaction (*34*, *35*). The compounds were purified by column chromatography using silica gel to afford the pure prototype SAAC ligands, 2-amino-6-(bis(pyridin-2-ylmethyl)amino)hexanoic acid (**1**), 2-amino-6-(bis(thiazol-2-ylmethyl)amino)hexanoic acid (**2**), 2-amino-6-((carboxymethyl)(pyridin-2-ylmethyl)amino)hexanote (**3**), and 2-amino-6-(bis-(2-hydroxybenzyl)amino)hexanoic acid (**4**) in fair to moderate yields.

Radiolabeling of ^{99m}Tc-SAAC. Radiolabeling of SAAC systems was accomplished to form **7**−**10** on either the free

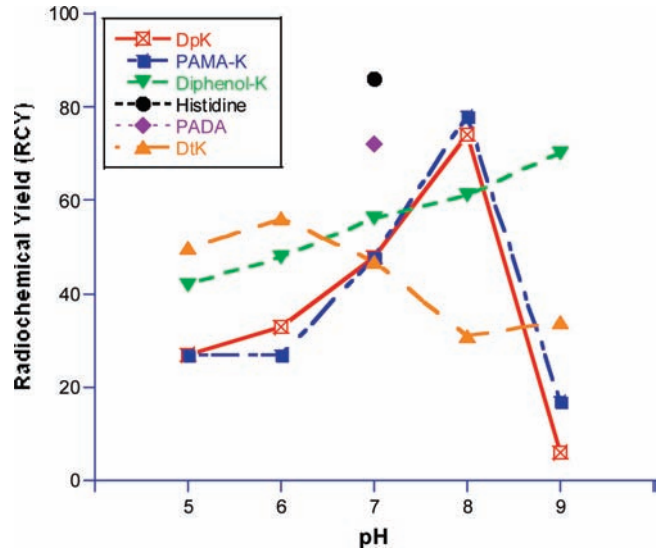

Figure 4. RCY as a function of pH for the formation of ^{99m}Tc-SAAC complexes at 75 °C for 30 min at a concentration of 10^{-6} M.

α-amino acids or as the appropriately *N*-protected amino acid derivative utilizing similar methodology, demonstrating the ease of preparation and the flexibility in the design of the SAAC systems. The ^{99m}Tc(I)$(CO)_3^+$ radiolabeling was accomplished in two steps using the commercially available IsoLink kits (Covidien) to form the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ intermediate, which was reacted with the appropriate SAAC ligand (10^{-6} to 10^{-4} M) in an equal volume mixture of 1:1 acetonitrile and phosphate buffer. The sealed vial was heated at 100 °C for 30 min. Upon cooling, the reaction was analyzed for purity via RP-HPLC. The radiochemical purity (RCP) after HPLC purification, resulting in "carrier-free" products, was determined via HPLC and shown to be consistently ≥95%. Although initial results demonstrated radiolabeling at concentrations as low as 10^{-6} M, the RCY was ≤80%. To achieve a RCY of >95% at 75 °C, the reaction concentration needed to be increased to 10^{-4} M.

Microwave Radiolabeling of $[^{99m}Tc(CO)_3(DpK)]^+$ (7). Heating with a Biotage Initiator 60 microwave was explored as an alternative to conventional heating, with the goal of reducing the time necessary to produce the ^{99m}Tc-SAAC complex in the highest yields. The conditions to produce **7** in >95% RCY were achieved (>97% RCY; n = 5) by employing microwave heating at 100 °C for 5 min at a concentration of 10^{-4} M in PBS, pH 7.4 (data not shown). The RCY decreased to <60% using lower concentrations (10^{-5} M and 10^{-6} M) under the same reaction conditions. These results represent a significant improvement in the radiolabeling time and warrant further studies using microwave heating to optimize the process.

pH Optimization. The RCY of the various chelators depended on the pH at which the radiolabeling reaction was conducted. The results shown in Figure 4, demonstrated that performing the radiolabeling at pH = 8 afforded higher yields for ligands **1** and **3** when compared to radiolabeling at higher (pH > 8) or lower (pH < 8) pH values where the RCY decreased significantly; however, for ligands **2** and **4**, slightly acidic and slightly basic reaction conditions were favored, respectively.

Further evaluation demonstrated that the starting material $[^{99m}Tc(CO)(H_2O)]^+$ is extremely stable at pH > 6 but undergoes significant (∼20%) degradation upon heating at temperatures required for effective radiolabeling (75−100 °C at ≤pH 5. When the radiolabeling was conducted at pH <5 the RCY for all the chelators studied was poor (<10%). Due to differences in the heterocyclic donating atoms of the chelating ligands, the optimal pH for effective radiolabeling varied for each of the SAAC

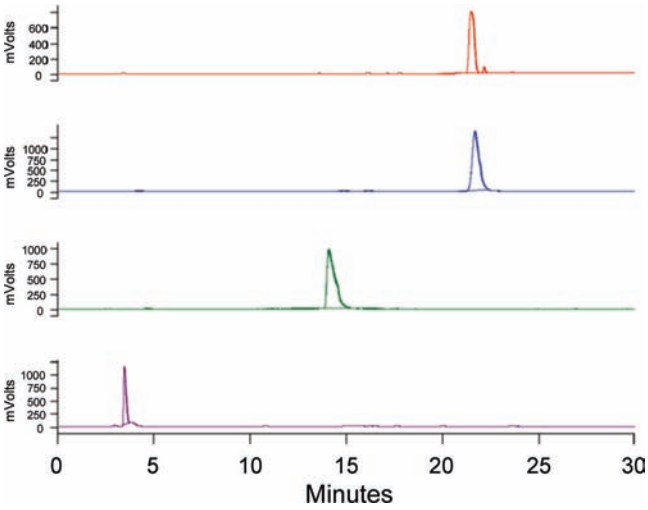

Figure 5. RP-HPLC chromatograms of (from top to bottom) $[Re(CO)_3(Fmoc\text{-}DpK)]^+$ (UV−vis chromatogram), $[^{99m}Tc(CO)_3(Fmoc\text{-}DpK)]^+$ (radiochromatogram), $[^{99m}Tc(CO)_3(DpK)]^+$ (**7**) (radiochromatogram), and the metal-free chelating agent DpK (**1**) (UV−vis chromatogram).

ligands studied. The pyridine-containing SAAC ligands, **1** and **3**, were labeled more efficiently at pH = 8. In contrast to the slightly basic optimal pH for radiolabeling of the pyridine containing SAAC ligands, the dithiazole containing SAAC ligand (**2**) produced a higher yield when the radiolabeling was conducted at a slightly acidic pH, pH = 6. The diphenol SAAC ligand (**4**), whose donating atoms are the phenolic oxygens, gave the highest yield when the radiolabeling was conducted at a slightly basic pH (pH = 9). The RCY of the SAAC ligands studied were only fair to good when the radiolabeling was performed at a concentration of 10^{-6} M (RCY ≤ 60%). The results were comparable for the two control ligands studied, 2,2′-(pyridin-2-ylmethylazanediyl)diacetic acid **(**PADA) (**5**) and L-histidine (**6**) which demonstrated similar results (RCY = 70−86%) at pH = 7.

The radiolabeling of the SAAC ligands could be accomplished on the Fmoc-protected ligand or on the unprotected free amine of the SAAC ligand utilizing identical reaction conditions, an advantage of the SAAC system compared to other chelators reported in the literature (see Figure 5). The complexes were analyzed by RP-HPLC and demonstrated >90% RCY when the radiolabeling was performed at a concentration of the SAAC ligand of $\geq 10^{-4}$ M and >50% RCY (at optimal pH) when the amount of SAAC ligand used was 10^{-6} M. The identities of the ^{99m}Tc-complexes were readily confirmed by RP-HPLC analysis after coinjection with the nonradioactive rhenium analogues as shown in Figure 5.

^{99m}Tc Challenge Experiments. The ^{99m}Tc-SAAC complexes were analyzed by RP-HPLC for stability against ligand challenge with excess histidine (100 mM) and cysteine (100 mM) in PBS, pH = 7.4 at 37 °C for 18 h. The ^{99m}Tc-SAAC complexes (carrier-free) demonstrated no degradation by HPLC analysis (see Figure 6) for **7**. In contrast, the negatively charged ^{99m}Tc-Diphenol-K complex proved to be much less stable, with significant degradation encountered upon purification by RP-HPLC, and therefore it was excluded from the tissue distribution study.

Determination of Lipophilicity (Log *P* Values). Log *P* values of the complexes were determined using the HPLC-purified ^{99m}Tc-SAAC complexes in *n*-octanol and 25 mM phosphate buffer (pH = 7.4). The Log *P* values (Table 1) demonstrated similar partition coefficients for all three of the stable complexes evaluated. The Log *P* values ranged from −1.80 to −2.20 regardless of differences in charge on the metal center or the heterocycle employed.

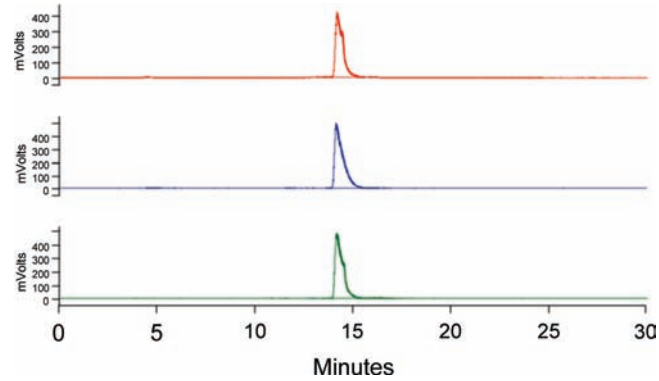

Figure 6. Radiochromatogram of HPLC purified $[^{99m}Tc(CO)_3(DpK)]$ (**7**) after 18 h incubation at 37 °C in PBS at pH = 7.4 (top), incubation at 37 °C with cysteine (100 mM) at pH = 7.4 (middle), and incubation at 37 °C with histidine (100 mM) at pH = 7.4 (bottom).

Rat Tissue Distribution Studies. Animal tissue distribution studies were performed on three of the SAAC complexes, $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DpK)\}]$ (**7**), $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DtK)\}]$ (**8**), and $[^{99m}Tc(CO)_3\{\eta^3\text{-}(PAMAK)\}]$ (**9**). A summary of the results for all three complexes in selected organs is shown in Table 2. Each SAAC complex demonstrated a unique hepatobiliary or renal clearance profile.

Tissue distribution studies with complexes **7**, Figure 7, and **9**, Figure 9, demonstrated rapid clearance from the blood and primary excretion through the kidneys and liver. The activity decreased in all tissues as a function of time, except in the gastrointestinal (GI) tract. There was no prolonged retention of radioactivity in any of the other organs analyzed. Qualitatively, $[^{99m}Tc(CO)_3\{\eta^3\text{-}(PAMAK)\}]$ (**9**) cleared more rapidly from the kidney and liver, while $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DpK)\}]$ (**7**) cleared more rapidly from the blood. In contrast, the blood clearance of $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DtK)\}]$ (**8**) (2.33 ± 0.26%ID/g at 30 min) was significantly slower than both **7**, 0.07 ± 0.01%ID/g at 30 min ($p < 0.001$), and **9**, 0.18 ± 0.02%ID/g at 30 min ($p < 0.001$). In contrast to complexes **7** and **9**, which were efficiently cleared, for $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DtK)\}]$ (**8**), Figure 8, the radioactivity was retained in both the liver and kidneys throughout the time course of the experiment. In addition, $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DtK)\}]$ (**8**) was retained longer in most nontarget organs as shown in Figure 8. Overall, $[^{99m}Tc(CO)_3\{\eta^3\text{-}(PAMAK)\}]$ (**9**) demonstrated lower hepatobiliary uptake at 30 min, 1.45 ± 0.21%ID/g, compared to 2.75 ± 0.11%ID/g for **7** ($p < 0.001$) and 1.93 ± 0.15%ID/g for **8** ($p < 0.015$).

The cationic complexes, $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DpK)\}]$ (**7**) and $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DtK)\}]$ (**8**), demonstrated increased clearance through the liver and GI compared to the neutral complex, $[Tc(CO)_3\{\eta^3\text{-}(PAMAK)\}]$ (**9**). For example at 120 min, $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DpK)\}]$ (**7**) and $[^{99m}Tc(CO)_3\{\eta^3\text{-}(DtK)\}]$ (**8**) both exhibited approximately 10-fold more radioactivity in the liver 2.12 ± 0.06% ID/g ($p < 0.001$) and 1.74 ± 0.12% ID/g ($p < 0.001$), respectively, compared to the uncharged complex $[^{99m}Tc(CO)_3\{\eta^3\text{-}(PAMAK)\}]$ (**9**) 0.20 ± 0.03% ID/g, which suggests increased lipophilic character of the cationic **7** and **8**.

Table 2. Comparison of the Rat Tissue Distribution Results of ^{99m}Tc-SAAC Complexes in Blood and Excretory Tissues, Expressed as Average %ID/g ± SEM

		time (min)			
compound	tissue	5	30	60	120
7	Blood	0.58 ± 0.05	0.07 ± 0.01	0.025 ± 0.005	0.013 ± 0.001
	Liver	3.36 ± 0.44	2.75 ± 0.11	2.59 ± 0.08	2.12 ± 0.06
	Kidney	6.05 ± 1.03	4.95 ± 0.11	4.93 ± 0.43	3.89 ± 0.42
	GI	0.49 ± 0.08	0.89 ± 0.07	1.46 ± 0.09	2.73 ± 0.57
8	Blood	3.32 ± 0.82	2.33 ± 0.26	1.4 ± 0.07	0.76 ± 0.12
	Liver	1.7 ± 0.42	1.93 ± 0.15	2.05 ± 0.41	2.61 ± 0.31
	Kidney	3.26 ± 1.04	4.71 ± 0.41	4.78 ± 0.14	4.83 ± 0.41
	GI	0.3 ± 0.15	0.59 ± 0.13	0.73 ± 0.29	0.87 ± 0.2
9	Blood	0.63 ± 0.12	0.18 ± 0.02	0.071 ± 0.003	0.034 ± 0.012
	Liver	1.26 ± 0.27	1.45 ± 0.21	0.56 ± 0.1	0.2 ± 0.06
	Kidney	6.4 ± 1.4	3.25 ± 0.47	1.14 ± 0.27	0.47 ± 0.09
	GI	0.18 ± 0.04	1.14 ± 0.23	1.82 ± 0.35	2.44 ± 1.18

It is unclear whether the increased hepatobiliary clearance is the result of the second heterocyclic ring (pyridine or thiazole) or the positively charged technetium metal center. Although the clearance of **7** is primarily via the hepatobiliary route, its clearance from the blood is the most rapid of the three SAAC complexes studied 0.013 ± 0.001% ID/g in the blood at 2 h compared to 1.09 ± 0.04% ID/g for **8** ($p < 0.001$) and 0.03 ± 0.01% ID/g for **9** ($p < 0.01$).

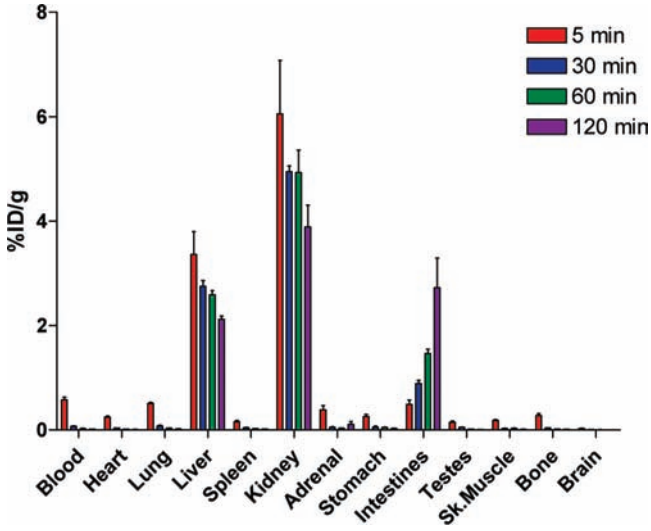

Figure 7. Tissue distribution results of [^{99m}Tc(CO)$_3${η^3-(DpK)}](**7**) expressed as average %ID/g.

One goal of the SAAC labeling technology is to design complexes that preferentially clear the body via renal excretion. It was anticipated that the lipophilicity of the ^{99m}Tc-SAAC complexes would influence the route of clearance. Therefore, the Log *P* values of the ^{99m}Tc-SAAC complexes were measured as an independent assessment of the lipophilic nature of the complexes to gain insight into the impact of overall lipophilicity of the metal complex on tissue pharmacokinetics and how it may effect future bioconjugates. The experimentally determined Log *P* values suggested that the complexes were very hydrophilic, **7** (Log $P = -1.9$), **8** (Log $P = -2.2$), and **9** (Log $P = -1.8$), were surprisingly very similar, and did not predict the differences in clearance described above. This lack of correlation between the Log *P* values and the clearance pathway suggests that the partition coefficient alone may be insufficient to assess the behavior of the ^{99m}Tc-SAAC complexes *in vivo*. Furthermore, this implies that differences in tissue distribution, pharmacokinetics, and clearance may be governed by parameters other than lipophilicity, such as the overall charge of the complex, complex sterics, the basicity of the nitrogen donor and/or the other properties of the heterocyclic rings themselves.

These studies suggest the physicochemical properties of the chelator portion of the SAAC complex affects the overall pharmacokinetics of the SAAC systems. While the impact of the chelator on the tissue pharmacokinetics of the biomolecule complex is anticipated to have a greater influence on small molecules and small peptides compared to larger peptides and proteins, it may be exploited in the design of chelators that, when incorporated into bioconjugates, offer preferred tissue distribution, pharmacokinetics, and clearance profiles. Impor-

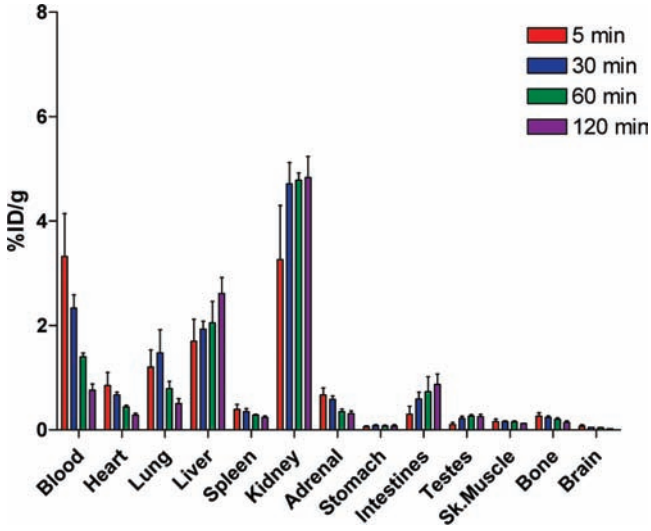

Figure 8. Tissue distribution results of [^{99m}Tc(CO)$_3${η^3-(DtK)}] (**8**), expressed as average %ID/g.

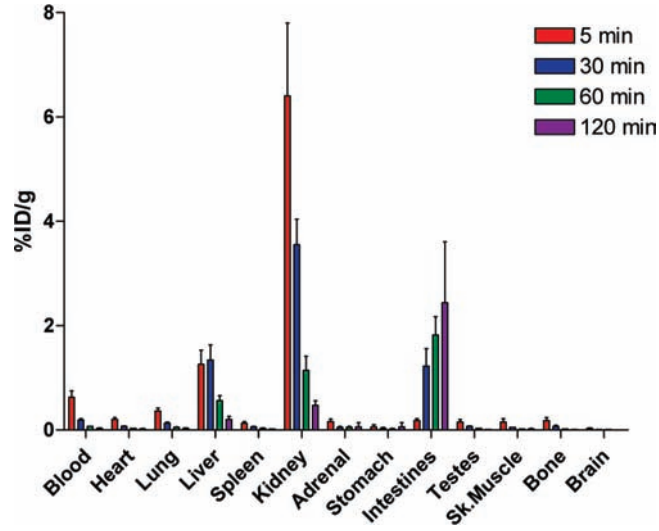

Figure 9. Tissue distribution results of [Tc(CO)$_3${η^3-(PAMAK)}] (**9**), expressed as average %ID/g.

tantly, the ability to modify the pharmacokinetic properties of a SAAC-conjugate through chelator selection should provide an advantage in the design and development of novel radiopharmaceuticals.

In summary, an examination of a set of SAAC ligands where the final technetium complex was neutral, cationic, or anionic at the metal center was accomplished. The SAAC systems could be efficiently radiolabeled in high yields with the $\{^{99m}Tc(CO)_3\}^+$ core to produce robust neutral or cationic ^{99m}Tc-SAAC complexes. The stability and optimal pH radiolabeling conditions were explored. The complexes were easily purified and are compatible with standard solid-phase peptide synthesis chemistries. The three stable SAAC complexes, cationic [^{99m}Tc(CO)$_3${η^3-(DpK)}] (**7**) and [^{99m}Tc(CO)$_3${η^3-(DtK)}] (**8**), neutral [^{99m}Tc(CO)$_3${η^3-(PAMAK)}] (**9**), and their role in the uptake, retention, and clearance in normal rats was evaluated; however, the anionic complex, [^{99m}Tc(CO)$_3${η^3-(Di-phenolK)}] (**10**), was unstable over time and was therefore eliminated from the rat tissue distribution studies. The pharmacokinetics of the complexes varied for each of the three stable complexes evaluated, with **9** demonstrating the most promise as a chelator for future technetium radiopharmaceuticals based on the efficient radiolabeling, high RCY, and favorable pharmacokinetic properties.

The advantageous pharmacokinetic profiles included rapid blood clearance for both **7** and **9** with decreased radioactivity in all background tissues (excluding GI tract) as a function of time. These experiments suggest that the SAAC systems, particularly those that clear rapidly, like [^{99m}Tc(CO)$_3${η^3-(PAMAK)}] (**9**) should serve well as a novel radiolabeling strategy for peptide library synthesis and radiolabeling of other important biomolecules.

Evaluation of a Novel Arg-Gly-Asp-Conjugated α-Melanocyte Stimulating Hormone Hybrid Peptide for Potential Melanoma Therapy

Jianquan Yang,[†] Haixun Guo,[†] Fabio Gallazzi,[⊥] Marianne Berwick,[‡,§] R. Steven Padilla,[§,||] and Yubin Miao*[,†,§,||]

College of Pharmacy, Department of Internal Medicine, Cancer Research Treatment Center, and Department of Dermatology, University of New Mexico, Albuquerque, New Mexico 87131, and Department of Biochemistry, University of Missouri, Columbia, Missouri 65211. Received April 28, 2009; Revised Manuscript Received June 5, 2009

The purpose of this study was to determine whether Arg-Gly-Asp (RGD)-conjugated α-melanocyte stimulating hormone (α-MSH) hybrid peptide could be employed to target melanocortin-1 (MC1) receptor for potential melanoma therapy. Methods: The RGD motif {cyclic(Arg-Gly-Asp-DTyr-Asp)} was coupled to [$Cys^{3,4,10}$, $DPhe^{7}$, Arg^{11}]α-MSH_{3-13} {(Arg^{11})CCMSH} to generate RGD-Lys-(Arg^{11})CCMSH hybrid peptide. The MC1 receptor binding affinity of RGD-Lys-(Arg^{11})CCMSH was determined in B16/F1 melanoma cells. The internalization and efflux, melanoma targeting and pharmacokinetic properties and single photon emission computed tomography/CT (SPECT/CT) imaging of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH were determined in B16/F1 melanoma cells and melanoma-bearing C57 mice. Clonogenic cytotoxic effect of RGD-Lys-(Arg^{11})CCMSH was examined in B16/F1 melanoma cells. Results: RGD-Lys-(Arg^{11})CCMSH displayed 2.1 nM MC1 receptor binding affinity. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH showed rapid internalization and extended retention in B16/F1 cells. The cellular uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was MC1 receptor-mediated. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH exhibited high tumor uptake (14.83 ± 2.94% ID/g 2 h postinjection) and prolonged tumor retention (7.59 ± 2.04% ID/g 24 h postinjection) in B16/F1 melanoma-bearing mice. Nontarget organ uptakes were generally low except for the kidneys. Whole-body clearance of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was rapid, with approximately 62% of the injected radioactivity cleared through the urinary system by 2 h postinjection. Flank melanoma tumors were clearly imaged by small animal SPECT/CT using ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH as an imaging probe 2 h postinjection. Single treatment (3 h incubation) with 100 nM of RGD-Lys-(Arg^{11})CCMSH significantly ($p < 0.05$) decreased the clonogenic survival of B16/F1 cells by 65% compared to the untreated control cells. Conclusion: Favorable melanoma targeting property of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH and remarkable cytotoxic effect of RGD-Lys-(Arg^{11})CCMSH in B16/F1 cells warranted the further evaluation of ^{188}Re-labeled α-MSH hybrid peptides as novel therapeutic peptides for melanoma treatment once the strategies of amino acid coinjection or structural modification of peptide sequence substantially reduce the renal uptake.

INTRODUCTION

Malignant melanoma is the most lethal form of skin cancer and the most commonly diagnosed malignancy among young adults with an increasing incidence. It was predicted that 62 480 cases would be diagnosed and 8420 fatalities would occur in the year 2008 (*1*). Melanoma metastases are very aggressive, and the survival time for patients with metastatic melanoma averages 3−15 months (*2, 3*). Unfortunately, no curative treatment exists for metastatic melanoma due to its resistance to current chemotherapy and immunotherapy regimens (*4*). Novel and effective treatment approaches are urgently needed to improve the effectiveness of melanoma treatment. The overexpression of melanocortin-1 (MC1) receptor on human and mouse melanoma cells (*5*−*9*) makes the MC1 receptor a distinct molecular target for developing novel diagnostic and therapeutic radiopharmaceuticals for melanoma (*10*−*17*). Radiolabeled α-melanocyte stimulating hormone (α-MSH) peptides can specifically bind the MC1 receptors with nanomolar binding affinities, can be rapidly internalized upon binding the MC1 receptors, and can selectively deliver the diagnostic and therapeutic radionuclides to melanoma tumor cells for imaging and therapy (*10*−*17*). The very promising preclinical therapeutic efficacies of ^{177}Lu-, ^{188}Re-, and ^{212}Pb-labeled metal-cyclized α-MSH peptides in melanoma-bearing mice demonstrated their potential as effective therapeutic agents for melanoma treatment (*15*−*17*).

Integrin receptors are involved in tumor metastasis and angiogenesis and mediate a variety of cell adhesion activities. Arg-Gly-Asp (RGD) peptide is recognized by many of the integrin receptors and is an important structural component of extracellular matrices that control physiological cell functions (*18*−*21*). Antagonists of $\alpha_v\beta_3$ integrin receptors promote tumor regression by inducing apoptosis of newly spouting blood vessels in the tumor (*20*). Besides the $\alpha_v\beta_3$ integrin receptors, several cytoplasmic members of the procaspase family of apoptosis genes, such as procaspase-1 and procaspase-3, contain RGD binding motif as well (*22*). It was reported that the RGD-containing peptide could induce cell apoptosis through activating cytoplasmic procaspase-3 directly after the RGD-containing peptide entering the cells without any requirement for integrin-mediated cell clustering or signals (*22*), highlighting the novel concept of using the RGD motif as an intracellular apoptosis inducer. Recently, the RGD motif has been used as an intracellular apoptosis inducer and been coupled to a somatostatin peptide (targeting somatostatin receptor-2) to examine

the cytotoxic effect of the hybrid somatostatin peptide {RGD-Lys-(^{111}In-DTPA)-Tyr^3-Octreotate} (*23*−*26*). RGD-Lys(^{111}In-DTPA)-Tyr^3-octreotate exhibited enhanced tumoricidal effects than ^{111}In-DTPA-Tyr^3-octreotate and ^{111}In-DTPA-RGD due to elevated tumor cell apoptosis (*23*), demonstrating the feasibility of employing the receptor-targeting peptides to target the RGD motif (as an intracellular apoptosis inducer) to cancer cells to enhance the synergistic therapeutic effectiveness of the radiolabeled hybrid peptides.

Favorable properties of radiolabeled α-MSH peptides, such as nanomolar MC1 receptor binding affinities, rapid internalization, and extended retention, underscore the potential to employ the α-MSH peptides as effective delivery vehicles. We hypothesized that the unique metal-cyclized α-MSH peptide could serve as an effective delivery vehicle to specifically transport the RGD motif into melanoma cells to induce apoptosis. In this study, we synthesized and evaluated a novel RGD-conjugated α-MSH hybrid peptide {RGD-Lys-(Arg^{11})CCMSH} to examine our hypothesis. The RGD motif {cyclic(Arg-Gly-Asp-DTyr-Asp)} was coupled to [Cys^{3,4,10}, DPhe^7, Arg^{11}]α-MSH$_{3-13}$ {(Arg^{11})CCMSH} through Lys to generate RGD-Lys-(Arg^{11})-CCMSH. We determined the internalization and efflux, melanoma targeting and pharmacokinetic properties, SPECT/CT imaging of ^{99m}Tc-labeled RGD-Lys-(Arg^{11})CCMSH in B16/F1 melanoma cells and B16/F1 melanoma-bearing mice. Furthermore, we examined clonogenic cytotoxic effect of RGD-Lys-(Arg^{11})CCMSH in B16/F1 melanoma cells.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Amino acid and resin were purchased from Advanced ChemTech Inc. (Louisville, KY) and Novabiochem (San Diego, CA). $^{99m}TcO_4^-$ was purchased from Cardinal Health (Albuquerque, NM). ^{125}I-Tyr^2-[Nle^4, DPhe^7]-α-MSH {^{125}I-(Tyr^2)-NDP-MSH} was obtained from PerkinElmer, Inc. (Shelton, CT). All other chemicals used in this study were purchased from Thermo Fischer Scientific (Waltham, MA) and used without further purification. B16/F1 murine melanoma cells were obtained from American Type Culture Collection (Manassas, VA).

Peptide Synthesis. Intermediate scaffold of H_2N-Arg-(Pbf)-Gly-Asp(OtBu)-DTyr(tBu)-Asp(*O*-2-phenylisopropyl)-Lys(Boc)-Cys(Trt)-Cys(Trt)-Glu(OtBu)-His(Trt)-DPhe-Arg(Pbf)-Trp(Boc)-Cys(Trt)-Arg(Pbf)-Pro-Val was synthesized on Sieber amide resin using standard 9-fluorenylmethyloxycarbonyl (Fmoc) chemistry by an Advanced ChemTech multiple-peptide synthesizer (Louisville, KY). The protecting group of 2-phenylisopropyl was removed, and the peptide was cleaved from the resin treating with a mixture of 2.5% of trifluoroacetic acid (TFA) and 5% of triisopropylsilane. After the precipitation with ice-cold ether and characterization by liquid chromatography−mass spectroscopy (LC-MS), the protected peptide was dissolved in H_2O/CH_3CN (50:50) and lyophilized to remove the reagents such as TFA and triisopropylsilane. The protected peptide was further cyclized by coupling the carboxylic group from the Asp with the α-amino group from the Arg at the N-terminus. The cyclization reaction was achieved by overnight reaction in dimethylformamide (DMF) using benzotriazole-1-yl-oxy-tris-pyrrolidino-phosphonium-hexafluorophosphate (PyBOP) as a coupling agent in the presence of *N*,*N*-diisopropylethylamine (DIEA). After characterization by LC-MS, the cyclized protected peptide was dissolved in H_2O/CH_3CN (50:50) and lyophilized to remove the reagents such as PyBOP and DIEA. The protecting groups were totally removed by treating with a mixture of trifluoroacetic acid (TFA), thioanisole, phenol, water, ethanedithiol, and triisopropylsilane (87.5:2.5:2.5:2.5:2.5:2.5) for 2 h at room temperature (25 °C). The peptide was precipitated and washed with ice-cold ether for four times, purified by reverse-phase high-performance liquid chromatography (RP-HPLC) and characterized by LC-MS.

In Vitro Competitive Binding Assay. The IC_{50} value of RGD-Lys-(Arg^{11})CCMSH was determined according to our previously published procedure (*27*). B16/F1 cells were harvested and seeded into a 24-well cell culture plate (5×10^5/well) and incubated at 37 °C overnight. After being washed with binding medium [modified Eagle's medium with 25 mM *N*-(2-hydroxyethyl)-piperazine-*N*′-(2-ethanesulfonic acid), pH 7.4, 0.2% bovine serum albumin (BSA), 0.3 mM 1,10-phenathroline], the cells were incubated at room temperature (25 °C) for 2 h with approximately 40 000 counts per minute (cpm) of ^{125}I-(Tyr^2)-NDP-MSH in the presence of increasing concentrations (10^{-12} to 10^{-5} M) of RGD-Lys-(Arg^{11})CCMSH in 0.3 mL of binding medium. The reaction medium was aspirated after the incubation. The cells were rinsed twice with 0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M phosphate buffered saline (PBS) and lysed in 0.5 mL of 1 N NaOH for 5 min. The activities associated with cells were measured in a Wallac 1480 automated gamma counter (PerkinElmer, NJ). The IC_{50} value for the peptide was calculated using *Prism* software (GraphPad Software, La Jolla, CA).

Peptide Radiolabeling. RGD-Lys-(Arg^{11})CCMSH was radiolabeled with ^{99m}Tc via a glucoheptonate transchelation reaction using methods described previously (*7*). Briefly, 100 μL of 2 mg/mL $SnCl_2$ in 0.2 M glucoheptonate aqueous solution and 200 μL of fresh $^{99m}TcO_4^-$ solution (37−148 MBq) were added into a reaction vial and incubated at room temperature (25 °C) for 20 min to form ^{99m}Tc-glucoheptonate. Then, 10 μL of 1 mg/mL RGD-Lys-(Arg^{11})CCMSH aqueous solution was added into the reaction vial, and the pH of the reaction mixture was adjusted to 8.5 with 0.1 M NaOH. The reaction mixture was incubated at 75 °C for 40 min. The radiolabeled peptide was purified to single species by Waters RP-HPLC (Milford, MA) on a Grace Vydac C-18 reverse-phase analytic column (Deerfield, IL) using a 20 min gradient of 16−26% acetonitrile in 20 mM HCl aqueous solution at a flow rate of 1 mL/min. The purified peptide sample was purged with N_2 gas for 20 min to remove the acetonitrile. The pH of the final solution was adjusted to 5 with 0.1 N NaOH and normal saline for animal studies. The stability of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was determined by incubation in mouse serum at 37 °C according to the published procedure (*27*) for various time periods, and monitored for degradation by RP-HPLC.

Cellular Internalization and Efflux of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH. Cellular internalization and efflux of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH were evaluated in B16/F1 cells as previously described by Miao et al. (*27*). After being washed once with binding medium, B16/F1 cells in 24-well cell culture plates were incubated at 25 °C for 20, 40, 60, 90, and 120 min ($n = 4$) in the presence of approximately 200 000 cpm of HPLC purified ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH. After incubation, the reaction medium was aspirated and the cells were rinsed twice with 0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS. Cellular internalization of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was assessed by washing the cells with acidic buffer [40 mM sodium acetate (pH 4.5) containing 0.9% NaCl and 0.2% BSA] to remove the membrane-bound radioactivity. The remaining internalized radioactivity was obtained by lysing the cells with 0.5 mL of 1 N NaOH for 5 min. Membrane-bound and internalized ^{99m}Tc activities were counted in a gamma counter. Cellular efflux of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was determined by incubating B16/F1 cells with ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH for 2 h at 25 °C, removing nonspecific-bound radioactivity with 2 × 0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS rinse, and monitoring radioactivity released into cell culture medium. At time points of 20, 40, 60, 90, and 120

min, the radioactivities in medium, on cell surface, and in cells were separately collected and counted in a gamma counter.

Specificity of Cellular Uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})-CCMSH. The specificity of cell binding was determined by incubating ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH with or without nonradioactive peptides. After being washed once with binding media, B16/F1 cells in 24-well cell culture plates were incubated with approximately 200 000 cpm of HPLC purified ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH at 25 °C for 120 min ($n = 4$) in the presence of 0.1 μM of RGD-Lys-(Arg^{11})CCMSH, NDP-MSH, (Arg^{11})CCMSH, or RGD peptide (Peptides International Inc., Louisville, KY) in 0.5 mL of binding media, respectively. The reaction medium was aspirated after the incubation. The cells were rinsed twice with 0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS, and lysed in 0.5 mL of 1 N NaOH for 5 min. The activities associated with cells were measured in a gamma counter.

Biodistribution Studies. All the animal studies were conducted in compliance with Institutional Animal Care and Use Committee approval. The pharmacokinetics of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was determined in B16/F1 melanoma-bearing C57 female mice (Harlan, Indianapolis, IN). C57 mice were subcutaneously inoculated on the right flank with 1×10^6 B16/F1 cells. The weight of tumors reached approximately 0.2 g 10 days post cell inoculation. Each melanoma-bearing mouse was injected with 0.037 MBq of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH via the tail vein. Groups of 5 mice were sacrificed at 0.5, 2, 4, and 24 h postinjection, and tumors and organs of interest were harvested, weighed, and counted. Blood values were taken as 6.5% of the whole-body weight.

The MC1 receptor specificity of the tumor uptake was determined at 2 h postinjection by coinjecting ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH with 10 μg (6.1 nmol) of unlabeled NDP-MSH. The $\alpha_v\beta_3$ integrin specificity of the tumor uptake was also determined by coinjecting ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH with 3.5 μg (6.1 nmol) of RGD peptide 2 h postinjection.

Imaging Melanoma with ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH. A B16/F1 melanoma-bearing C57 mouse was injected with 10.4 MBq of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH via the tail vein. The mouse was anesthetized with 1.5% isoflurane for small animal SPECT/CT (Nano-SPECT/CT, Bioscan) imaging 2 h postinjection. The 9 min CT imaging was immediately followed by the SPECT imaging of whole-body. The SPECT scans of 24 projections were acquired, and total acquisition time was approximately 45 min. After the SPECT imaging, the mouse was euthanized with CO_2 inhalation. Reconstructed data from SPECT and CT were visualized and coregistered using InVivoScope (Bioscan, Washington, DC).

Urinary Metabolites of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH. Urinary metabolites of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH were determined by injecting 3.7 MBq of ^{99m}Tc-RGD-Lys-(Arg^{11})-CCMSH into a B16/F1 melanoma-bearing C57 mouse through the tail vein. At 2 h after dose administration, the mouse was euthanized and the urine was collected. The radioactive metabolites in the urine were analyzed by injecting aliquots of urine into HPLC. A 20 min gradient of 16−26% acetonitrile/20 mM HCl was used for the urine analysis.

Clonogenic Cytotoxicity of RGD-Lys-(Arg^{11})CCMSH. Clonogenic cytotoxic effect of RGD-Lys-(Arg^{11})CCMSH was examined in B16/F1 melanoma cells according to the published procedure with slight modification (*23*). The B16/F1 cells were seeded in a 6 well plate (200 cells/well) and incubated at 37 °C overnight. After being washed once with culture medium (RPMI 1640 medium), the cells were incubated in the culture medium at 37 °C for 3 h in the presence of 0.1 μM of RGD-Lys-(Arg^{11})CCMSH, (Arg^{11})CCMSH, or RGD, respectively. Control cells were only incubated in the culture medium. After the incubation, the cells were washed with PBS twice and allowed to form colonies over 6 days in the culture medium. The medium was changed every other day. After 6 days, the cells were fixed with methanol/glacial acetic acid (3:1), stained with hematoxylin, and visually examined under microscope for survival. Colonies contained more than 50 cells were scored as survivors.

Statistical Methods. Statistical analysis was performed using the Student's *t* test for unpaired data to determine the significant differences between the groups in the studies of specificity of cellular uptake, biodistribution, and clonogenic cytotoxicity described above. Differences at the 95% confidence level ($p < 0.05$) were considered significant.

RESULTS

RGD-Lys-(Arg^{11})CCMSH was synthesized, purified by RP-HPLC, and the identity of peptide was confirmed by electrospray ionization mass spectrometry. RGD-Lys-(Arg^{11})CCMSH displayed greater than 95% purity with 30% overall synthetic yield. The synthetic scheme is presented in Figure 1. The competitive binding curve of RGD-Lys-(Arg^{11})CCMSH is shown in Figure 2A. The IC_{50} value of RGD-Lys-(Arg^{11})CCMSH was 2.1 nM in B16/F1 cells. The peptide was readily labeled with ^{99m}Tc using a glucoheptonate transchelation reaction with greater than 95% radiolabeling yield. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was completely separated from its excess nonlabeled peptide by RP-HPLC. The specific activity of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was 8.514×10^9 MBq/g. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH showed greater than 98% radiochemical purity after the HPLC purification. The retention time of ^{99m}Tc-RGD-Lys-(Arg^{11})-CCMSH was 12.2 min. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was stable in mouse serum at 37 °C for 24 h.

Cellular internalization and efflux of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was evaluated in B16/F1 cells. Figure 2 (B and C) illustrate cellular internalization and efflux of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH exhibited rapid cellular internalization and extended cellular retention. There was 76.28 ± 1.36% of the ^{99m}Tc-RGD-Lys-(Arg^{11})-CCMSH activity internalized in the B16/F1 cells 40 min postincubation. There was 85.93 ± 1.22% of the ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH activity internalized in the cells after 2 h incubation. Cellular efflux results demonstrated that 68.57 ± 3.77% of the ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH activity remained inside the cells 2 h after incubating cells in culture medium.

Specificity of cellular uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})-CCMSH was examined in B16/F1 cells. The results are presented in Figure 3. The cellular uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was MC1 receptor-mediated rather than $\alpha_v\beta_3$ integrin-mediated. Compared to the cellular uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH without peptide blockade, the cellular uptakes of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH decreased 88.1%, 90.5%, and 88.1% with 0.1 μM of RGD-Lys-(Arg^{11})CCMSH, NDP-MSH and (Arg^{11})CCMSH as blockades, respectively. Incubation of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH with 0.1 μM of RGD did not reduce the cellular uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH in B16/F1 cells.

The melanoma targeting and pharmacokinetic properties of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH were determined in B16/F1 melanoma-bearing C57 mice. The biodistribution results of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH are shown in Table 1. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH exhibited rapid and high tumor uptake in melanoma-bearing mice. The tumor uptake value was 11.06 ± 1.41% ID/g 0.5 h postinjection. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH reached its peak tumor uptake value of 14.83 ± 2.94% ID/g 2 h postinjection. There was 12.57 ± 2.53% ID/g of the ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH activity remained in the tumors 4 h postinjection. The tumor uptake value of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH gradually decreased to 7.59 ± 2.04%

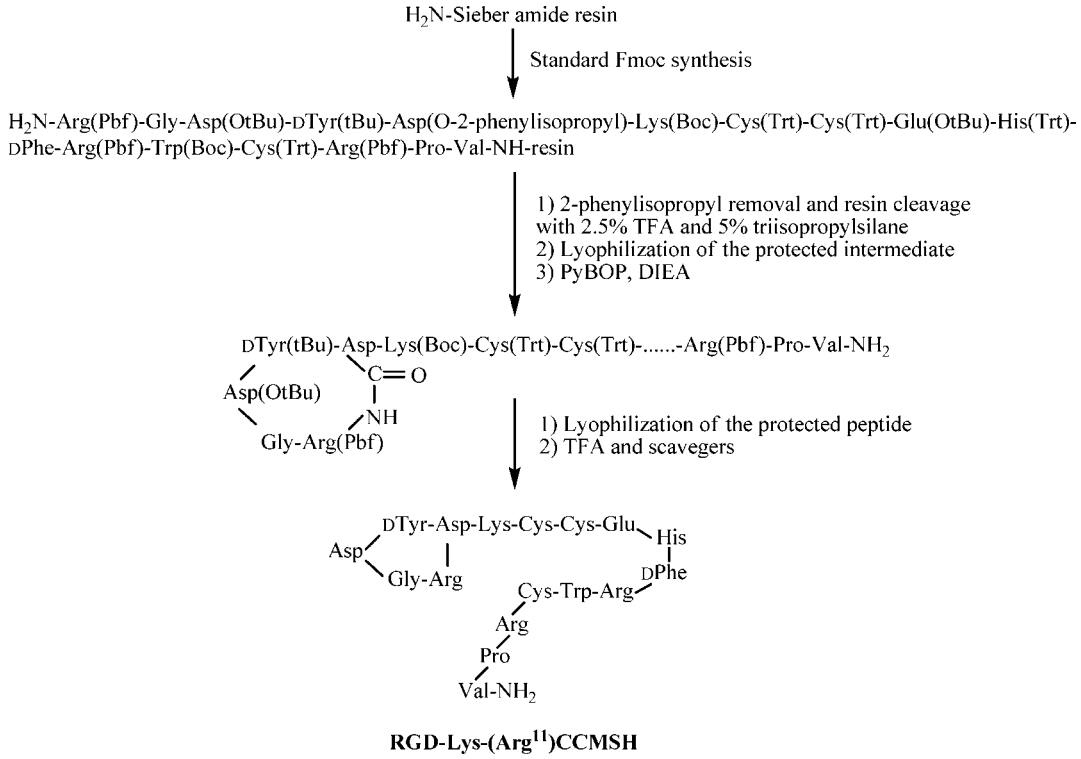

Figure 1. Synthetic scheme of RGD-Lys-(Arg^{11})CCMSH.

ID/g 24 h postinjection. In melanoma uptake blocking studies, the tumor uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH with 10 μg (6.1 nmol) of nonradiolabeled NDP-MSH coinjection was only 12.2% of the tumor uptake without NDP-MSH coinjection at 2 h after dose administration ($p < 0.01$), demonstrating that the tumor uptake was specific and MC1 receptor-mediated. Compared to the tumor uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})-CCMSH, coinjection of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH with 3.5 μg (6.1 nmol) of RGD decreased 29.2% of the tumor uptake value, demonstrating that the tumor uptake was $\alpha_v\beta_3$ integrin receptor-mediated as well. Whole-body clearance of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was rapid, with approximately 62% of the injected radioactivity cleared through the urinary system by 2 h postinjection (Table 1). Normal organ uptakes of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH were generally low (<3.2% ID/g) except for the kidneys after 2 h postinjection. High tumor/blood and tumor/muscle uptake ratios were demonstrated as early as 0.5 h postinjection (Table 1). The renal uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH reached its peak value of 69.37 $\pm$ 5.37% ID/g 0.5 h postinjection. The renal uptake decreased to 40.26 $\pm$ 10.83% ID/g 24 h postinjection.

One B16/F1 melanoma-bearing C57 mouse was injected with ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH through the tail vein to visualize the tumors 2 h after dose administration. The whole-body SPECT/CT image is presented in Figure 4A. Flank melanoma tumors were visualized clearly by ^{99m}Tc-RGD-Lys-(Arg^{11})-CCMSH 2 h postinjection. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH exhibited high tumor to normal organ uptake ratios except for the kidney. Radioactivity in the bladder demonstrated the urinary clearance of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH, which was coincident with the biodistribution results. In view of the substantial renal uptake values of ^{99m}Tc-RGD-Lys-(Arg^{11})-CCMSH in the biodistribution results, the urinary metabolites of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH were analyzed by RP-HPLC 2 h postinjection. The urinary HPLC profile of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH is shown in Figure 4B. Approximately 68% of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH remained intact, while 32% of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was transformed to two more lipophilic metabolites 2 h postinjection.

Clonogenic cytotoxic effect of RGD-Lys-(Arg^{11})CCMSH hybrid peptide was examined in B16/F1 melanoma cells. The results are presented in Figure 5. The clonogenic survival percentages of peptide-treated groups were normalized taking the clonogenic survival percentage of untreated group (in culture medium) as 100%. RGD-Lys-(Arg^{11})CCMSH exhibited remarkable cytotoxic effect in B16/F1 melanoma cells, with 65% decrease ($p < 0.05$) in clonogenic survival compared to that of the untreated group. In comparison with untreated cells, incubation with (Arg^{11})CCMSH and RGD peptides reduced 11% and 7% of clonogenic survival, respectively. However, the differences were not significant ($p > 0.05$).

DISCUSSION

Metastatic melanoma is very aggressive and is resistant to current available chemotherapy and immunotherapy. High mortality of malignant melanoma is associated with the occurrence of melanoma metastases. Hence, it is urgent to develop novel and effective therapeutic approaches to improve the therapeutic effectiveness of melanoma treatment. Peptide-targeted radionuclide therapy is a novel and effective treatment approach for melanoma. MC1 receptor-avid α-MSH peptides are employed as effective delivery vehicles to selectively and specifically target cytotoxic radiation generated from radionuclides to tumor cells, resulting in tumor cell death (*28*). In comparison with external beam radiation therapy and chemotherapy, peptide-targeted radionuclide therapy can specifically deliver the cytotoxic radiation to tumor cells, while sparing the normal tissues and organs. Unique metal-cyclized α-MSH peptides were labeled with various therapeutic radionuclides with low-energy β-emission (^{177}Lu), high-energy β-emission (^{188}Re), and high-energy α-emission (^{212}Pb, parent radionuclide of high-energy α-emitter ^{212}Bi) to examine their therapeutic efficacies in B16/F1 melanoma-bearing mice (*15*−*17*). ^{177}Lu-, ^{188}Re-, and ^{212}Pb-labeled metal-cyclized α-MSH peptides ex-

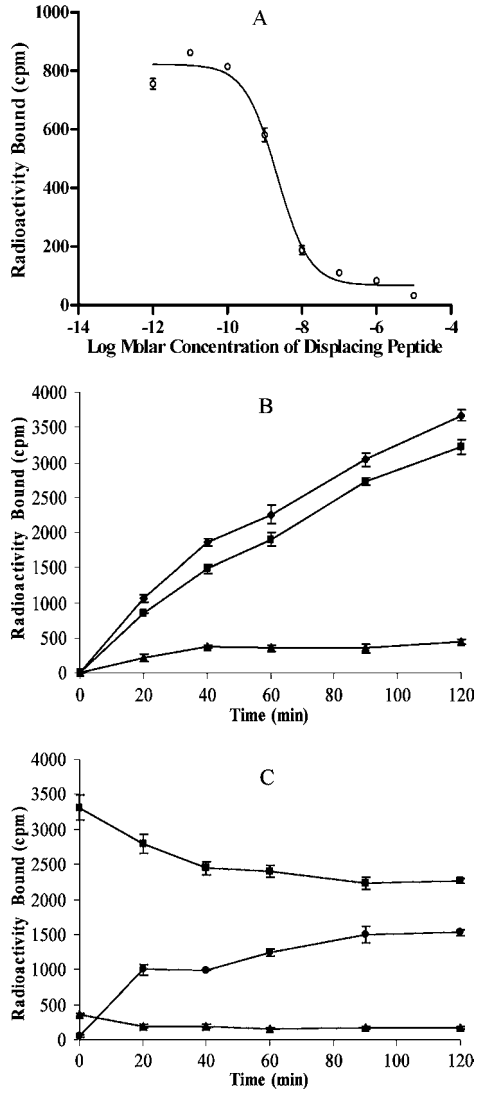

Figure 2. The competitive binding curve (A) of RGD-Lys-(Arg^{11})CCMSH in B16/F1 melanoma cells. The IC_{50} value of RGD-Lys-(Arg^{11})CCMSH was 2.1 nM. Cellular internalization (B) and efflux (C) of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH in B16/F1 melanoma cells at 25 °C. Total bound radioactivity (◆), internalized activity (■), cell membrane activity (▲), and cell culture medium activity (•) were presented as counts per minute (cpm).

hibited very promising therapeutic effects in preclinical melanoma-bearing mouse models (*15*−*17*), demonstrating the potential of peptide-targeted radionuclide therapy for human melanoma treatment. The findings of that RGD-containing peptide could induce cell apoptosis through activating cytoplasmic procaspase-3 directly after the peptide entering the cells (*22*) opened the avenue of using the RGD motif as an intracellular apoptosis inducer for cancer therapy. RGD-Lys(^{111}In-DTPA)-Tyr^3-Octreotate exhibited enhanced tumoricidal effects than ^{111}In-DTPA-Tyr^3-octreotate due to elevated tumor cell apoptosis (*23*), demonstrating the feasibility of coupling the RGD motif to the receptor-targeting peptides to enhance the synergistic therapeutic effectiveness of the radiolabeled hybrid peptides. In this study, we designed and synthesized a novel RGD-Lys-(Arg^{11})CCMSH hybrid peptide to examine whether the unique metal-cyclized α-MSH peptide [^{99m}Tc-(Arg^{11})CCMSH] could be used as an effective delivery vehicle to specifically transport the RGD motif into melanoma cells to induce apoptosis.

Synthetic hybrid RGD-Lys-(Arg^{11})CCMSH exhibited 2.1 nM MC1 receptor binding affinity (Figure 2), whereas (Arg^{11})-CCMSH displayed 1.7 nM MC1 receptor binding affinity (*8*), demonstrating that the coupling of the RGD motif did maintain the nanomolar MC1 receptor binding affinity of the hybrid peptide. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was easily prepared and was stable in mouse serum for 24 h. The coordination of ^{99m}Tc with three cysteines presented in the RGD-Lys-(Arg^{11})CCMSH simultaneously cyclized the hybrid peptide, making ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH stable against proteolytic degradation in vivo . As we anticipated, ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH exhibited rapid internalization and extended efflux in B16/F1 cells (Figure 2), warranting effective transportation of the RGD motif into the melanoma cells, as well as subsequent long-lasting apoptotic effect generated from the RGD motif after entering the melanoma cells. The cellular uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was MC1 receptor-mediated rather than $\alpha_v\beta_3$ integrin-mediated, since approximately 90% of the cellular uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was blocked by RGD-Lys-(Arg^{11})CCMSH, (Arg^{11})CCMSH, or NDP-MSH (rather than RGD) (Figure 3). The MC1 receptor-mediated cellular uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was consistent with the published immunohistochemical results that RGD-HuMab only localized at the endothelium of B16/F10 melanoma tumor rather than B16/F10 melanoma cells (*30*). Nanomolar MC1 receptor binding affinity, rapid internalization, and extended retention of the hybrid RGD-Lys-(Arg^{11})CCMSH in melanoma cells warranted further evaluation on melanoma targeting and pharmacokinetic properties of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH in melanoma-bearing mice.

^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH exhibited a rapid high B16/F1 melanoma uptake value of 11.06 ± 1.41% ID/g 0.5 h postinjection and reached its peak tumor uptake value of 14.83 ± 2.94% ID/g 2 h postinjection (Table 1). Meanwhile, ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH displayed prolonged retention in melanoma tumors. The tumor uptake value was 12.57 ± 2.53% ID/g 4 h postinjection, which was 85% of the tumor uptake value 2 h postinjection. Even 24 h postinjection, the tumor uptake value was 7.59 ± 2.04% ID/g, which was 51% of the tumor uptake value 2 h postinjection. The majority of melanoma uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was MC1 receptor-mediated demonstrated by the fact that 87.8% of the tumor uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was blocked by 6.1 nmol of NDP-MSH (Table 1), whereas 29.2% of the tumor uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was blocked by 6.1 nmol of RGD (Table 1). A minority of $\alpha_v\beta_3$ integrin-mediated melanoma uptake was likely due to the presence of $\alpha_v\beta_3$ integrin receptors in the B16/F1 tumor vasculature. It was reported that $\alpha_v\beta_3$ integrin receptors were overexpressed in B16/F10 tumor vasculature (*30*). The B16/F1 melanoma tumors consist of highly vascularized dense gelatinous masses. Interestingly, ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH showed a comparable tumor uptake value to ^{99m}Tc-(Arg^{11})CCMSH 4 h postinjection and longer tumor retention than ^{99m}Tc-(Arg^{11})CCMSH 24 h postinjection in the same B16/F1 melanoma-bearing mouse model (*13*). The tumor uptake values of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH were 1.1 and 2.3 times the tumor uptake values of ^{99m}Tc-(Arg^{11})CCMSH 4 and 24 h postinjection, respectively. The improved melanoma retention of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH are attributed to the introduction of the RGD motif in ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH. It was likely that the RGD motif in hybrid ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH bound to the $\alpha_v\beta_3$ integrin receptors presented on blood vessels in B16/F1 tumors, contributing the prolonged tumor retention of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH. Technetium-99m and ^{188}Re are matched-pair diagnostic and therapeutic radionuclides, sharing similar coordination chemistry. Hence, from the therapeutic point of view, high melanoma uptake and prolonged retention of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH warranted long-lasting synergistic therapeutic effects of apoptosis and targeted radiation from ^{188}Re-

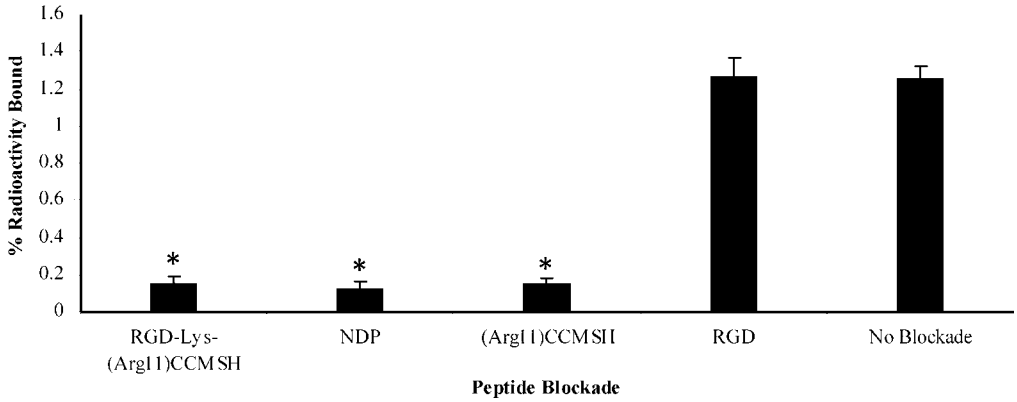

Figure 3. Blocking studies of cellular uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH in B16/F1 murine melanoma cells. The cells were incubated with ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH in the presence of 0.1 μM of RGD-Lys-(Arg^{11})-CCMSH, NDP-MSH, (Arg^{11})CCMSH, RGD, or no peptide blockade. * $p < 0.001$.

[a] The data was presented as percent injected dose/gram or as percent injected dose (mean ± SD, $n = 5$). [b] $p < 0.05$, significance comparison between ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH with or without blockade peptide.

labeled hybrid CCMSH peptide. Flank B16/F1 melanoma tumors were clearly visualized by SPECT/CT imaging using ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH as an imaging probe 2 h postinjection (Figure 4). ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH displayed high tumor to normal organ uptake ratios except for the kidneys, which was coincident with the biodistribution results (Table 1).

The RGD motif was attached to the somatostatin-2 receptor-targeting Tyr^3-octreotate via Lys to yield hybrid RGD-Lys(^{111}In-DTPA)-Tyr^3-octreotate. DTPA was attached to the amino group on the side chain of Lys for ^{111}In labeling (*24*). In this study, The RGD motif was conjugated to (Arg^{11})CCMSH via Lys to generate RGD-Lys-(Arg^{11})CCMSH. The advantage of using Lys as a linker to connect the RGD motif with the (Arg^{11})CCMSH moiety was that the amino group on the side chain of Lys could be used to attach DOTA for coordination with a variety of therapeutic radionuclides (i.e., ^{177}Lu, ^{90}Y, and ^{212}Pb) to generate synergistic therapeutic effects of targeted radiation from the therapeutic radionuclides and apoptosis from the RGD motif. The coupling of the RGD motif to the Tyr^3-octreotate through Lys increased the renal uptake value of RGD-Lys(^{111}In-DTPA)-Tyr^3-octreotate compared to ^{111}In-DOTA-Tyr^3-octreotate (*24*). The renal uptake value of RGD-Lys(^{111}In-DTPA)-Tyr^3-octreotate was 3.3 times the renal uptake value of ^{111}In-DOTA-Tyr^3-octreotate in CA20948 and AR42J tumor-bearing Lewis rats 24 h postinjection (*24*). Surprisingly, the renal uptake value of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was 12.5 times the renal uptake value of ^{99m}Tc-(Arg^{11})CCMSH in B16/F1 melanoma-bearing mice 4 h postinjection. Considering the structural difference between the ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH and ^{99m}Tc-(Arg^{11})CCMSH, the substantial increased renal uptake of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was due to the introduction of the RGD-Lys moiety. Further biodistribution comparison revealed that the renal uptake value of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH was only 1.2 times the renal uptake value of ^{188}Re-dLys-(Arg^{11})CCMSH (*31*), indicating that the Lys between the RGD motif and the (Arg^{11})CCMSH moiety played an important role in high renal uptake value of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH. It is necessary to note that the amino group on the side chain of the Lys was available in ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH and added a positive charge to the overall charge of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH, that might contribute to the high renal uptake value of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH due to the electrostatic interaction between positively charged peptide

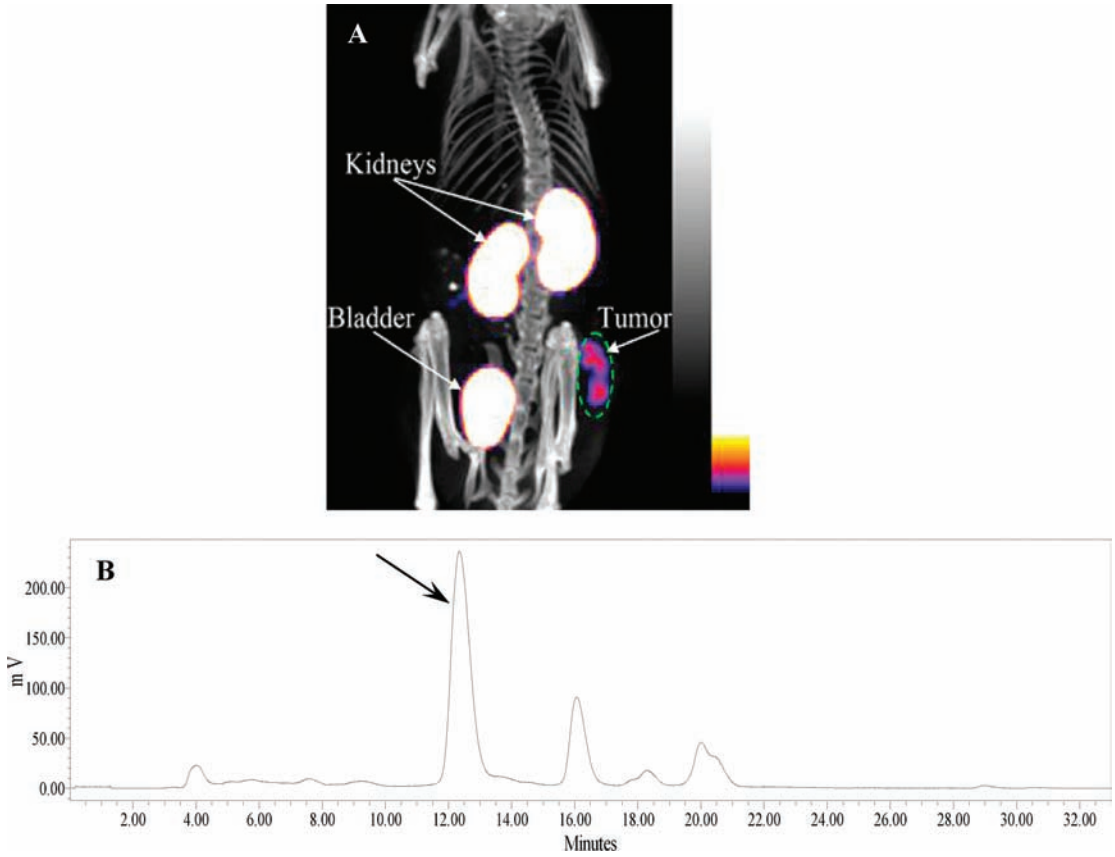

Figure 4. Whole-body SPECT/CT image (A) of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH in a B16/F1 melanoma-bearing C57 mouse at 2 h postinjection; HPLC profile (B) of radioactive urine sample of a B16/F1 murine melanoma-bearing C57 mouse at 2 h postinjection of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH. Black arrow indicates the retention time of the original compound of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH prior to the tail vein injection.

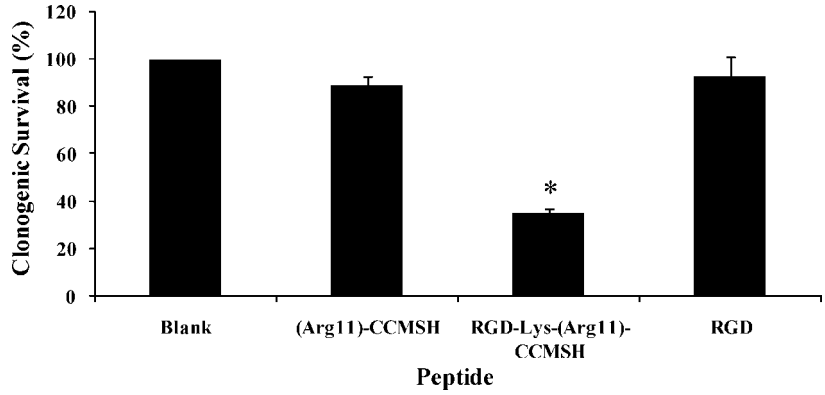

Figure 5. Clonogenic cytotoxic effect of RGD-Lys-(Arg^{11})CCMSH in B16/F1 melanoma cells. The cells were visually examined under microscope for survival. Colonies contained more than 50 cells were scored as survivors. * $p < 0.05$, significance comparison between RGD-Lys-(Arg^{11})CCMSH treated cells and untreated cells (blank).

molecules and negatively charged tubule cells. A direct way to shield this electrostatic interaction is to conjugate DOTA to RGD-Lys-(Arg^{11})CCMSH through the amino group on the side chain of the Lys. Conjugation of DOTA to the amino group on the side chain of the Lys in RGD-Lys-(Arg^{11})CCMSH can reduce the overall positive charge of radiolabeled hybrid CCMSH peptide, as well as provide an excellent metal chelator for the coordination of therapeutic radionuclides such as ^{177}Lu (low-energy β-emitter), ^{90}Y (high-energy β-emitter), and ^{212}Pb (parent radionuclide of high-energy α-emitter ^{212}Bi). Furthermore, strategies of coinjection of positively charged amino acid and structurally introduction of negatively charged amino acid into peptide sequence will also be options to employ to decrease the renal uptakes of the radiolabeled hybrid CCMSH peptides. Coinjection of lysine or arginine has effectively reduced the renal uptakes of ^{188}Re-labeled metal-cyclized CCMSH by 50% (*8*). Introduction of a negatively charged Glu at second position of metal-cyclized CCMSH peptide decreased 72% of the renal uptake values of ^{177}Lu- and ^{90}Y-DOTA-Re(Arg^{11})CCMSH 4 h postinjection (*32, 33*).

It will be attractive to determine the synergistic therapeutic effects of apoptosis and targeted radiation of ^{188}Re-labeled α-MSH hybrid peptides for melanoma once the strategies of amino acid coinjection or structural modification of peptide sequence substantially reduce the renal uptake. Targeted radionuclide therapy with ^{188}Re-(Arg^{11})CCMSH exhibited

therapeutic effects in both human and murine melanoma-bearing mice (*15*). Nonradioactive hybrid RGD-Lys-(Arg^{11})CCMSH showed very promising cytotoxic effect in B16/F1 cells in this report (Figure 5). Single treatment (3 h incubation) with 100 nM of RGD-Lys-(Arg^{11})CCMSH decreased 65% of the clonogenic survival of B16/F1 cells compared to untreated control cells (in culture medium) 6 days post-treatment (Figure 5). On the other hand, neither treatment with 100 nM of (Arg^{11})CCMSH nor that with 100 nM of RGD peptide reduced the clonogenic survival of B16/F1 cells significantly ($p > 0.05$), demonstrating that the cytotoxic effect of RGD-Lys-(Arg^{11})CCMSH hybrid peptide was due to the apoptotic effect of the RGD motif coupled to the hybrid peptide. The remarkable clonogenic cytotoxic effect of RGD-Lys-(Arg^{11})CCMSH warranted the further evaluation of ^{188}Re-labeled α-MSH hybrid peptides for melanoma treatment. Combination therapy of $\alpha_v\beta_3$ integrin receptor antagonist and ^{90}Y-DOTA-peptide ChL6 exhibited increased synergistic (apoptosis and targeted radiation) therapeutic effects in breast cancer xenografts without increased toxicity (*34*). RGD-Lys(^{111}In-DTPA)-Tyr^3-Octreotate displayed more profound tumoricidal effects than ^{111}In-DTPA-Tyr^3-octreotate and ^{111}In-DTPA-RGD due to elevated tumor cell apoptosis (*23*), highlighting the potential enhanced synergistic therapeutic effectiveness of ^{188}Re-labeled α-MSH hybrid peptides for melanoma in future studies.

CONCLUSIONS

Novel RGD-Lys-(Arg^{11})CCMSH showed 2.1 nM MC1 receptor binding affinity. ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH exhibited MC1 receptor-mediated rapid cellular internalization and extended retention. Furthermore, ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH displayed rapid high melanoma uptake and prolonged tumor retention in B16/F1 melanoma-bearing mice. Single treatment (3 h incubation) with 100 nM of RGD-Lys-(Arg^{11})CCMSH significantly ($p < 0.05$) decreased the clonogenic survival of B16/F1 melanoma cells by 65%. Technetium-99m and ^{188}Re are matched-pair diagnostic and therapeutic radionuclides, sharing similar coordination chemistry. Hence, favorable melanoma targeting property of ^{99m}Tc-RGD-Lys-(Arg^{11})CCMSH and remarkable cytotoxic effect of RGD-Lys-(Arg^{11})CCMSH warranted the further evaluation of ^{188}Re-labeled α-MSH hybrid peptides as novel MC1 receptor-targeting therapeutic peptides for melanoma treatment once the strategies of amino acid coinjection or structural modification of peptide sequence substantially reduce the renal uptake.

ACKNOWLEDGMENT

We appreciate Drs. Scott W. Burchiel and Larry A. Sklar for their valuable insights. We thank Mr. Benjamin M. Gershman for his technical assistance. Received May 4, 2009; Revised Manuscript Received June 15, 2009

Two types of 5′-β-CyD-DNA conjugates were synthesized using two different strategies and were hybridized with cDNA conjugates bearing various possible guest compounds at the 3′ ends. One of the β-CyD conjugates was synthesized on the basis of solid-phase postmodification of DNA with a monoamino-β-CyD derivative on a synthesis column for automated DNA synthesis. The other β-CyD conjugate was synthesized by the solution-phase coupling of DNA with a monomercapto-β-CyD derivative using a heterobifunctional cross-coupling reagent. When these 5′-β-CyD-DNA conjugates were hybridized with cDNA conjugates bearing 1-adamantaneacetic acid at the 3′ ends, significant stabilization of the duplexes was observed as compared with the control duplex without β-CyD. Duplexes of 5′-β-CyD-DNA conjugates and complementary 3′-dansyl-glycine-DNA conjugates were also moderately stabilized. Thermodynamic measurements revealed that the host−guest inclusion interactions between β-CyD and 1-adamantaneacetic acid or dansyl-glycine are roughly as strong as those found in bulk solution even if they are tethered to the ends of the DNA.

INTRODUCTION

Cyclodextrins (CyDs) are cyclic oligosaccharides composed of five or more α-D-glucopyranosides and are important players in supramolecular and molecular-recognition chemistry, as a result of their unique host−guest inclusion capabilities (*1*−*3*). Due to their rigid and well-defined ring structure, CyDs bind various small guest molecules in their hydrophobic inner cavity. β-CyD is composed of seven glucopyranosides and has an inner cavity of 7 Å diameter. Interactions between CyDs and various guest molecules such as adamantane have been widely studied, particularly for β-CyD, and many interesting applications of these inclusion phenomena have been proposed to date (*4*). For example, dansyl-modified cyclodextrins have been applied as a fluorescent probe, which can detect guest molecules based on the fluorescence change of the dansyl moiety (*5*−*9*).

Nucleic acids are another interesting subject of supramolecular chemistry, mainly due to their accurate complementary base-pairing and regularly formed double-helical structure. Recent progress with DNA and RNA modification techniques has widened the scope of their application in various research fields such as life science (*10, 11*), analytical chemistry (*12, 13*), and even nanotechnology (*14*−*16*). The conjugation of β-CyD and DNA should encourage further progress. However, few papers have been published on the actual synthesis of β-CyD−DNA conjugates (*17*−*19*), and almost no detailed studies have been undertaken regarding their guest inclusion capabilities. DNA bears many hydrophobic nucleobases, which are all possible guest compounds of β-CyD. The formation of a rotaxane-type complex between β-CyD and the linker moiety may also prevent desired guest inclusion by β-CyD. Thus, a clear-cut proof of guest inclusion by β-CyD-DNA conjugates is necessary.

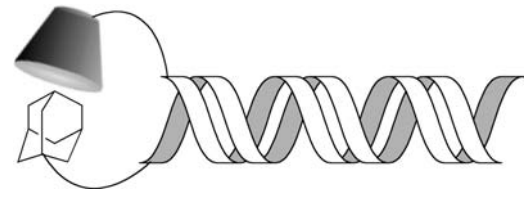

Figure 1. Schematic illustration of the present system. β-CyD is attached to the 5′ end of DNA, and possible guest molecules are attached to the 3′ end of the complementary strand such that they are placed in front of the β-CyD over the duplex.

In this study, we have synthesized two types of β-CyD−DNA conjugates that bear β-CyD at their 5′ ends via different linkers in order to evaluate the guest inclusion ability of β-CyD on DNA duplexes (Figure 1). In the measurements of melting profiles obtained using a variety of complementary strands modified with possible guest compounds at the opposite site, significant stabilization was observed for the duplexes of both of the two β-CyD−DNA conjugates (Figure 2) and their cDNA conjugates bearing 1-adamantane at the 3′ ends (Figure 3). Thermodynamic analyses revealed that the host−guest inclusion interaction between β-CyD and 1-adamantane is as strong as that observed in a bulk solution even if they are tethered to the ends of the DNA. Moderate stabilization was also observed for the duplexes between the β-CyD−DNA conjugate and complementary 3′-dansyl-glycine-DNA conjugates, which showed significant fluorescence enhancement upon hybridization.

EXPERIMENTAL PROCEDURES

MALDI-TOF mass spectra were measured on a Bruker Daltonics AutoFLEX MALDI TOF-MS spectrometer (Billerica, MA, USA). *N*-Succinimidyl 3-(2-pyridyldithio)propionate (SPDP) was purchased from Dojindo Laboratories (Kumamoto, Japan). All of the phosphoramidite monomers for DNA modification were purchased from Glen Research (Sterling, VA, USA).

Synthesis of Monotosylated-β-CyD (5). β-CyD (0.50 g, 0.43 mmol) was dissolved in 4.3 mL of dried pyridine under an argon

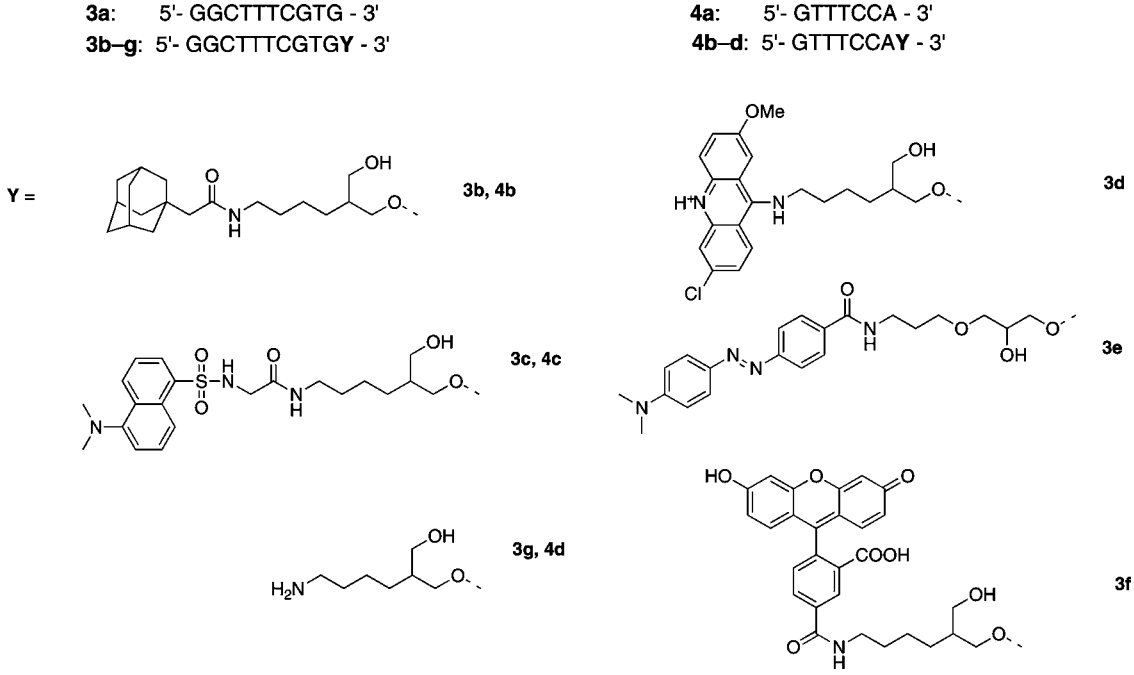

Figure 3. Structures of the complementary strands bearing possible guest molecules.

atmosphere. To the solution, *p*-toluenesulfonyl chloride (0.16 g, 0.85 mmol) was added in an ice bath and then stirred at room temperature. The progress of the reaction was intermittently monitored by thin-layer chromatography (TLC) (1-buthanol/ethanol/water = 5/4/3; indicator: *p*-anisaldehyde). The reaction was quenched by the addition of 0.35 mL of water after 3 h. Analysis by TLC indicated the presence of three spots for β-CyD (R_f = 0.30), monotosylated-β-CyD (0.48), and ditosylated-β-CyD (0.57) of almost the same density. The solution was concentrated to half of the volume in vacuo and poured into 8.5 mL of acetone with vigorous stirring. The resulting white solid was collected and repeatedly recrystallized from water.

White solid: 72 mg (12.7%). ^{1}H NMR (DMSO-d_6, 399.65 MHz) δ 2.43 (s, 3H), 3.10−3.45 (m, 14H), 3.45−3.66 (m, 28H), 4.10−4.60 (m, 6H), 4.76 (s, br, 2H), 4.83 (s, br, 5H), 5.60−5.85 (m, 14H), 7.42 (d, 2H, J = 8.3 Hz), 7.74 (d, 2H, 8.3 Hz) ppm.

Synthesis of Mono(6-amino-6-deoxy)-β-CyD (6). Mono(6-amino-6-deoxy)-β-CyD (**6**) was synthesized from **5** using sodium azide and aqueous ammonia according to a previous report (*20*).

Synthesis of Mono(6-deoxy-6-mercapto)-β-CyD (7). Compound **5** (0.50 g, 0.39 mmol) and thiourea (0.50 g, 6.6 mmol) were dissolved in 25 mL of 80% aqueous methanol and refluxed for 72 h. The solution was evaporated in vacuo. The resulting solid was suspended in 7.6 mL of methanol and stirred for 1 h at room temperature. The solid was then filtered and dissolved in 17 mL of a 10% aqueous solution of NaOH and stirred for 5 h at 50 °C. After the solution was acidified with 1 M HCl to pH 2, 1.2 mL of trichloroethylene was added to the solution. After stirring overnight, the precipitate was filtered and washed with water. Evaporation of trichloroethylene in vacuo was followed by repeated recrystallization from water, resulting in a white solid.

Table 1. MALDI-TOF/MS Analyses of the Conjugates

	calcd. *m/z* $[M+H]^+$	found
1b	4373.2	4370.1
1c	4379.2	4378.4

4c	2568.9	2564.4

White solid: 0.27 g (59.4%). TLC (silica): one spot (R_f = 0.23, CH_3CO_2Et/*n*-PrOH/H_2O, 7/7/5). MALDI-TOF/MS calcd for $[M+H]^+$: 1150.54; found: 1150.06.

Attachment of 6 to DNA. In the final coupling cycle for the synthesis of **1b**, 5′-Carboxy-Modifier C10 phosphoramidite, which is activated with *N*-hydroxysuccinimide ester, was attached. The CPG column was removed from the synthesizer and filled with 1 M solution of **6** in pyridine/water (3:1) using two 1 mL glass syringes on both sides of the column. After incubating the column overnight at room temperature, it was washed three times with 1 mL of water and with acetonitrile (1 mL × 3). The conjugate **1b** was detached from the support and deprotected with conc. aqueous ammonia at 55 °C for 8 h. The 7-mer conjugate **2b** was synthesized in the same manner.

Syntheses of DNA Conjugates Bearing Acridine (3d), Dabcyl (3e), and Fluorescein (3f). The conjugates bearing acridine (**3d**), dabcyl (**3e**), and fluorescein (**3f**) at the 3′ end were synthesized using the corresponding CPG supports purchased from Glen Research on an automated DNA synthesizer with standard phosphoramidite chemistry. Cleavage from the supports and deprotection of the conjugates were performed with conc. aqueous ammonia at 55 °C for 8 h for **3e** and **3f**, and 0.4 M methanolic NaOH (4:1 MeOH/H_2O) was used for **3d** at room temperature and allowed to react for 16 h (*21*). The crude mixtures were desalted with Poly-Pak cartridges (Glen Research) and evaporated to dryness for further purification as described below.

Purification and Characterization of 1b, 2b, and 3d-f. The conjugates **1b**, **2b**, and **3d-f** were purified using 20% denaturing polyacrylamide gel electrophoresis (PAGE) and then by reverse-phase HPLC (RP-HPLC) equipped with an RP-C18 column (Cica-Merck LiChroCART 125−4; room temperature; linear gradient 5−25% acetonitrile in 50 mM ammonium formate for 20 min; flow rate 0.5 mL/min). These were characterized by MALDI-TOF/MS in the positive ion mode (Table 1).

Syntheses of DNA Conjugates Bearing an Adamantane (3b, 4b) or Dansyl-Glycine (3c, 4c) Residue at the 3′ End. A DNA conjugate bearing a 3′-amino group (**3g** or **4d**) was synthesized with standard phosphoramidite chemistry using 3′-Amino-Modifier C7 CPG and purified using 20% denaturing PAGE and RP-HPLC, as described above. The activated 1-adamantaneacetic acid (for **3b** and **4b**) or dansyl-glycine (for **3c** and **4c**) was obtained by treating the corresponding carboxylic acid (0.1 mmol) with *N*,*N*′-dicyclohexylcarbodiimide (0.1 mmol) and *N*-hydroxysuccinimide (0.1 mmol) in DMSO (0.5 mL) overnight at room temperature. The supernatant of the above reaction mixture (20 μL) was added to the solution of **3g** (or **4d**, 10 nmol) in a pH 9.0 $NaHCO_3$ buffer (0.1 M, 100 μL); it was then allowed to react overnight at 37 °C, and 400 μL of water was added to the mixture. The desired conjugates were isolated by RP-HPLC after filtration and fully characterized using MALDI-TOF/MS.

Attachment of 7 to DNA. The purified aminopropyl-bearing DNA **1d** (100 nmol) was dissolved in 100 μL of pH 9.3 $NaHCO_3$ buffer (0.5 M). SPDP (1.5 mg, 4.6 μmol), dissolved in 50 μL of DMSO, was added to this solution. The resulting suspension was stirred overnight at room temperature. The solution was diluted to 400 μL with water. The resulting SPDP−DNA conjugate **1e** was purified by RP-HPLC (Wakosil-II 5C18 RS column; room temperature; linear gradient 5−30% acetonitrile in 0.1 M triethylammonium acetate for 30 min; flow rate 1.0 mL/min).

To the solution of **1e** (50 nmol) in 100 μL of pH 7.2 Na_2HPO_4/NaH_2PO_4 buffer (10 mM) was added **7** (5.8 mg, 5.0 μmol) dissolved in 60 μL of DMSO. The resulting suspension was stirred overnight at room temperature. The solution was diluted to 400 μL with water. The mixture was purified by RP-HPLC as described above and fully characterized using MALDI-TOF/MS. The 7-mer conjugate **2c** was synthesized in the same manner.

Measurement of Melting Temperature (T_m). The melting profiles of the duplexes were obtained with a JASCO V-530 spectrometer at 260 nm in a quartz cell with a 1-cm path length. The specimens contained the DNA conjugates (1−20 μM), Na_2EDTA (10 mM), and NaCl (1.0 M) in a pH 7 Na_2HPO_4/NaH_2PO_4 buffer (10 mM). The heating rate was 1.0 °C/min. Thermodynamic parameters of each duplex were calculated by plotting the reciprocals of the T_m values for various DNA concentrations according to a previous report (*22*).

Fluorescence Measurements. Fluorescence changes in the dansyl groups upon hybridization were obtained with a JASCO FP-6500 spectrofluorometer in a quartz cell at 25 °C for the **1**/**3c** combination and 10 °C for the **2**/**4c** combination. The specimens (50 μL) contained the DNA conjugates (5 μM each) and NaCl (1.0 M) in a pH 7 Na_2HPO_4/NaH_2PO_4 buffer (10 mM). The excitation wavelength was 343 nm.

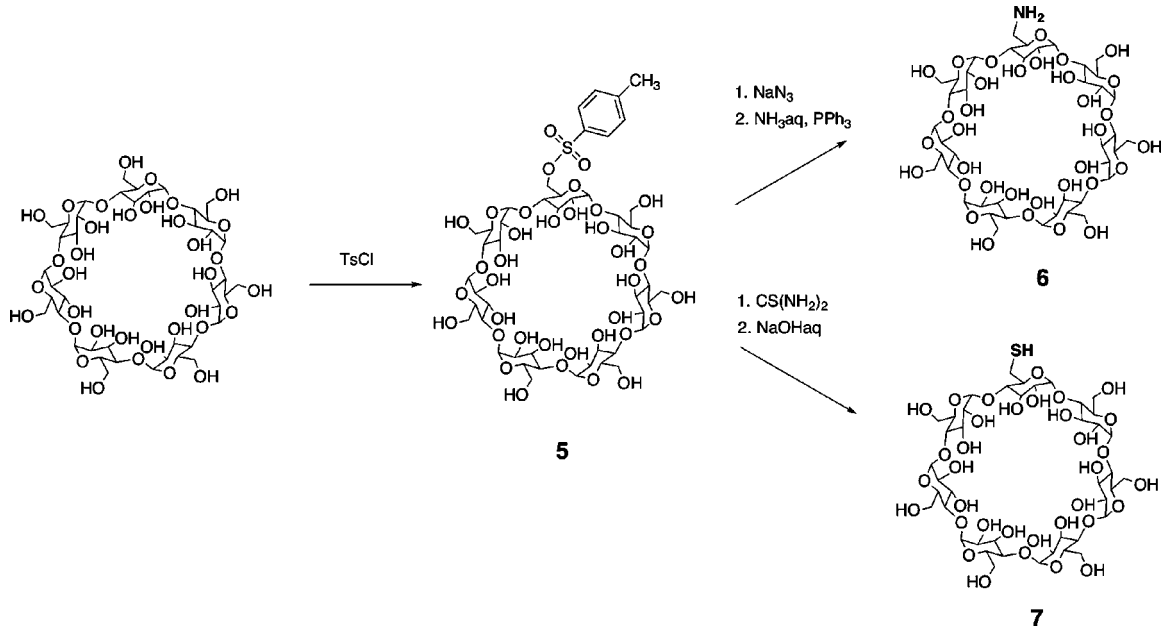
RESULTS AND DISCUSSION

Syntheses of DNA Conjugates. Two different types of DNA conjugates bearing β-CyD at the 5′ end were synthesized on the basis of two distinct strategies. The conjugates **1b** and **2b** were synthesized using a solid-phase DNA postmodification technique on a synthesis column for an automated DNA synthesizer. First, mono(6-amino-6-deoxy)-β-CyD (**6**) was prepared as described in the literature (*20*) (Scheme 1). Then, **6** was reacted with the activated carboxylic acid tethered to the 5′ end of DNA through a nonyl-linker to form an amide linkage between β-CyD and the DNA (Scheme 2). The resulting β-CyD−DNA conjugates were detached from the support and deprotected by a standard method with conc. aqueous ammonia at 55 °C for 8 h. The conjugates were further purified using 20% denaturing PAGE and RP-HPLC.

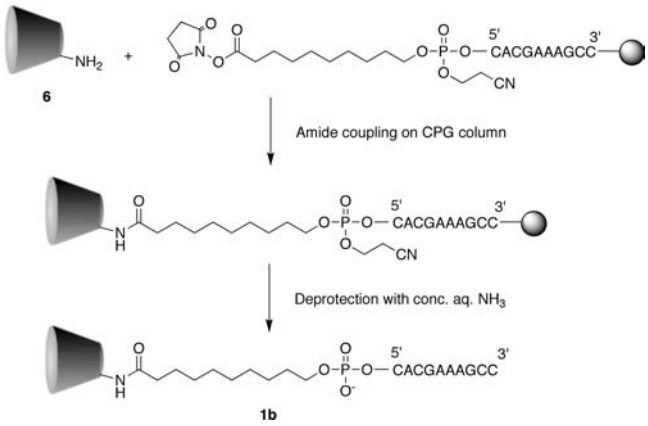
The other conjugates, **1c** and **2c**, were synthesized by the solution-phase coupling of DNA and thiolated β-CyD (Scheme 3). For example, the amino-modified DNA **1d** was first reacted with a heterobifunctional cross-coupling reagent, SPDP. The resulting dithio-functionalized DNA **1e** then reacted with mono(6-deoxy-6-mercapto)-β-CyD (**7**), prepared from mono-tosylated-β-CyD (*23*, *24*). The products in each step were purified by RP-HPLC.

The complementary conjugates bearing possible guest compounds at the 3′ end were also synthesized in two different ways. The conjugates bearing acridine (**3d**), dabcyl (**3e**), and fluorescein (**3f**) at the 3′ end were synthesized using commercially available corresponding CPG supports on an automated DNA synthesizer with standard phosphoramidite chemistry, and were purified using 20% denaturing PAGE and RP-HPLC in the same way as **1b**. The conjugates bearing 1-adamantaneacetic acid (**3b** and **4b**) and dansyl-glycine (**3c** and **4c**), by contrast, were

Scheme 1



Scheme 2



obtained by the solution-phase coupling of prepurified amino-modified DNA and corresponding activated esters. All of the conjugates used in this study were fully characterized with MALDI-TOF/MS (Table 1).

Thermodynamic Properties. To evaluate the strength of the interaction between β-CyD in the conjugates and possible guest compounds attached to the opposite position in the cDNA, the melting temperatures of the duplexes of the **1**/**3** (Table 2) and **2**/**4** (Table 3) combinations were measured. For the duplexes of unmodified **1a** and its complements (**3a**−**3f**), the attachment of possible guests did not significantly alter the stability of the duplexes, except for **3d**, which bears an acridine moiety (Table 2). This acridine has a positive charge on its aromatic nitrogen atom under neutral conditions and is known to stabilize duplexes by intercalation (*25, 26*). The β-CyD−DNA conjugate **1b**, in which β-CyD is connected to the linker portion via an amide bond, was used in place of **1a** and provided significant stabilization of the duplex between **1b** and its adamantane-modified complement **3b**. The difference in melting temperature was as high as 11 °C, when comparing the T_m values of **1b**/**3b** (62.0 °C) and **1a**/**3b** (51.3 °C). For other conjugates bearing aromatic rings (i.e., **3c**, **3d**, **3e**, and **3f**), the differences in the T_m values between the duplexes of **1b**/**3** and **1a**/**3** were very slight, although it has been reported that, in a bulk solution, the dansyl group in **3c** and the methyl red group, which has a ring structure identical to the dabcyl group in **3e**, are included in β-CyD cavities with significant binding constants (*27*−*30*).

More drastic T_m changes were observed for the duplexes of **1c**/**3b**, in which β-CyD is connected to the DNA via a disulfide bond. The T_m value of the duplex formed by the adamantane conjugate **3b** and **1c** was 73.9 °C, which is nearly 23 °C higher than that of the duplex of **3b** and unmodified **1a** (51.3 °C). Similarly, but in contrast to the **1b**/**3** series, a significant increase in the T_m values was observed for the duplexes of **1c**/**3c** (β-CyD/dansyl, $\Delta\Delta T_m$ = 2.4 °C), **1c**/**3e** (β-CyD/dabcyl, 9.1 °C), and **1c**/**3f** (β-CyD/FAM, 6.1 °C) combinations.

The above tendency was also observed for the shorter 7-mer duplexes of the **2**/**4** series with completely different sequences from the **1**/**3** series (Table 3). The T_m value of **2c**/**4b** (β-CyD/adamantane, 55.1 °C) is elevated by as much as 34.0 °C, as compared to that of **2c**/**4a** (β-CyD/unmodified, 21.1 °C), and by 36.8 °C, as compared to that of **2a**/**4b** (unmodified/adamantane, 18.3 °C); the T_m of **2c**/**4c** (β-CyD/dansyl, 29.7 °C) is 8.6 °C higher than that of **2c**/**4a** (β-CyD/unmodified, 21.1 °C) and is higher than the T_m of **2a**/**4c** (unmodified/dansyl, 19.4 °C) by 10.3 °C. The T_m elevations for the **2b**/**4** combinations, on the other hand, are both smaller than those of the **2c**/**4** combinations.

Previous studies have shown that adamantane is one of the best guest molecules for β-CyD, with an association constant of $\sim 10^5$ M^{-1}, due to its hydrophobic nature and because its size matches that of the cavity (*27, 31, 32*). The strong stabilization observed in the present study of the duplexes is presumably attributable to the strong interaction between the adamantane and β-CyD attached to the ends of the DNA strands. To more accurately evaluate the interaction between β-CyD and the possible guests on the complementary strand, the thermodynamic parameters of duplex formation for the **1**/**3** (Table 4) and **2**/**4** (Table 5) combinations were estimated. Differences in the ΔG_{37} values corresponding to adamantane incorporation are −8.1 kcal/mol for the duplex of **1c**/**3b**, −8.3 kcal/mol for **2c**/**4b**, −5.8 kcal/mol for **1b**/**3b**, and −4.3 kcal/mol for **2b**/**4b**. These values are in good accordance with, or even larger than, the values previously obtained in bulk solution by various measurements such as competitive reaction inhibition, proton uptake, competitive spectral displacement, and microcalorimetry (*27*). It has been noted that the binding of guest molecules in

cyclodextrin cavities is usually enthalpy-driven, since van der Waals forces (negative $\Delta H°$; negative $\Delta S°$) dominantly contribute to the binding more than the classical hydrophobic effect (near-zero $\Delta H°$; positive $\Delta S°$) (*1, 32*). The parameters obtained for the above conjugates agree well with this argument (see Supporting Information Tables 2−4 for the $\Delta\Delta H$ and $\Delta\Delta S$ values). The binding mode of a β-CyD/adamantane complex formed on a DNA duplex is thus expected to be almost the same as that in bulk solution.

For the duplexes of the **1b**/**3** combinations, dansyl-modified **3c** generated the largest ΔG_{37} change among the dye−DNA conjugates (**3c**−**f**) investigated in this study, although little change in T_m was observed. Differences in the ΔG_{37} values in the presence of a dansyl group (**1**/**3c** and **2**/**4c**) are all around −1 to −2 kcal/mol, as compared to the absence of the dansyl

in the duplexes (**1**/**3a** and **2**/**4a**). This is also in good agreement with the previous $\Delta G^{\circ} = -2$ to -3 kcal/mol calculated in a fluorimetric study (*28*). In contrast, significant stabilization of the duplex was observed in the presence of acridine (−3.0 kcal/mol) and dabcyl (−3.1 kcal/mol) in the duplexes involving the other β-CyD−DNA conjugate, **1c**.

Fluorescence Change of Dansyl Group upon Hybridization. The fluorescence of the dansyl group is significantly enhanced when the dye is included in the hydrophobic cavity of β-CyD, since it is protected from quenching by water (*5*−*9*). A slight but reproducible free energy decrease was observed, which suggests a weak interaction between the dansyl group and β-CyD on the conjugates, leading to an investigation of the fluorescence change in the dansyl groups upon hybridization. Figure 4 shows emission spectra of the dansyl groups in the duplexes with and without β-CyD. For 10-mer duplexes, the emission at 548 nm of **1b**/**3c** was 39% greater than that of **1a**/**3c**, and a 6 nm blue shift in the emission maximum wavelength from 548 to 542 nm was observed (Figure 4a). These changes were significantly larger for **1c**/**3c**, for which the enhancement of the emission was 115% and the blue shift was 18 nm. These are both typical changes that have been observed in previous systems of dansyl groups included in β-CyD cavities (*5*−*9*). Thus, it is strongly suggested that the dansyl group in **3c** is in fact included in the β-CyD units in **1b** and **1c**, even though the extent of interaction is somewhat different, depending upon the structure of the linker that connects β-CyD with the DNA.

A similar observation was made for the **2**/**4c** combinations (Figure 4b). The emission at 545 nm of the dansyl in **2c**/**4c** was 115% larger than that of **2a**/**4c**, and the blue shift was 16 nm, whereas the emission enhancement was only 10% with a 4 nm blue shift for the **2b**/**4c** combination.

Overall, the β-CyD in **1c** and **2c** showed superior inclusion ability, as compared to that in **1b** and **2b**. This may be due to an unoptimized linker structure in **1b** and **2b**. The linker portion in these conjugates consists solely of a hydrophobic alkyl chain, and β-CyD is directly connected to this chain via a rigid amide bond. Thus, the movement of β-CyD in the conjugates is expected to be somewhat limited, particularly in water, and the resulting unfavorable alignment of β-CyD and guest molecules over the DNA duplex prevents efficient guest inclusion. This may also be a factor in the failure of dabcyl inclusion in the **1b**/**3e** system (ΔG° in bulk is around −4 to −5 kcal/mol (*29*)).

In conclusion, β-CyD attached to the 5′ end of DNA forms inclusion complexes when adamantane or dansyl groups are attached to the opposite position in the complementary strand. These interactions are roughly equivalent to those of the systems in bulk solution, although the linker structure affects the interaction. The present findings should strongly encourage the development of versatile applications of β-CyD−DNA conjugates in a variety of research fields. Because the free energy changes estimated from duplex stability are comparable to those estimated in bulk solution, DNA could be used as a supporting device for measurements of binding interactions between β-CyD and rare biological compounds at low concentrations around the micromolar to nanomolar range.

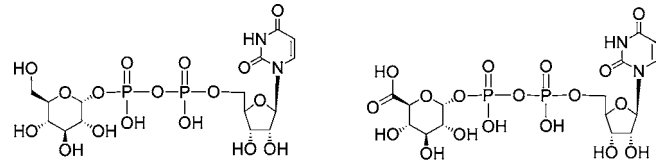
Received May 7, 2009; Revised Manuscript Received June 3, 2009

The $P2Y_{14}$ receptor is a G protein-coupled receptor activated by uridine-5′-diphosphoglucose and other nucleotide sugars that modulates immune function. Covalent conjugation of $P2Y_{14}$ receptor agonists to PAMAM (polyamidoamine) dendrimers enhanced pharmacological activity. Uridine-5′-diphosphoglucuronic acid (UDPGA) and its ethylenediamine adduct were suitable functionalized congeners for coupling to several generations (G2.5−6) of dendrimers (both terminal carboxy and amino). Prosthetic groups, including biotin for avidin complexation, a chelating group for metal complexation (and eventual magnetic resonance imaging), and a fluorescent moiety, also were attached with the eventual goals of molecular detection and characterization of the $P2Y_{14}$ receptor. The activities of conjugates were assayed in HEK293 cells stably expressing the human $P2Y_{14}$ receptor. A G3 PAMAM conjugate containing 20 bound nucleotide moieties (UDPGA) was 100-fold more potent (EC_{50} 2.4 nM) than the native agonist uridine-5′-diphosphoglucose. A molecular model of this conjugate docked in the human $P2Y_{14}$ receptor showed that the nucleotide-substituted branches could extend far beyond the dimensions of the receptor and be available for multivalent docking to receptor aggregates. Larger dendrimer carriers and greater loading favored higher potency. A similar conjugate of G6 with 147 out of 256 amino groups substituted with UDPGA displayed an EC_{50} value of 0.8 nM. Thus, biological activity was either retained or dramatically enhanced in the multivalent dendrimer conjugates in comparison with monomeric $P2Y_{14}$ receptor agonists, depending on size, degree of substitution, terminal functionality, and attached prosthetic groups.

INTRODUCTION

G protein-coupled receptors (GPCRs)[1] are cell membrane-spanning receptors that respond to extracellular signaling molecules to control cell function via specific signaling pathways. Direct or indirect modulation of GPCRs serves as the basis of many disease treatments (*1*). The P2 receptors for purine and pyrimidine nucleotides have diverse biological roles (*2*−*4*). P2 receptors are divided into two structurally unrelated subfamilies—the P2X receptors, which are ligand-gated ion channels (*5*), and the P2Y receptors (*2*), which are GPCRs. P2Y receptors are divided into two subgroups. The first subgroup consisting of the $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, and $P2Y_{11}$ receptors activate G_q and promote phospholipase C (PLC)-dependent inositol lipid signaling. The second consists of $P2Y_{12}$, $P2Y_{13}$, and $P2Y_{14}$ receptors, which preferentially activate G_i and inhibit adenylyl cyclase (*2*). P2Y receptors are activated by adenine and/or uracil nucleotides, while P2X receptors are principally activated by adenine nucleotides. P2Y receptors are widely distributed, for example, in the immune system (and widely distributed on hematopoietic cells), cardiovascular system, central and peripheral nervous system, endocrine system, and the renal and pulmonary systems (*3*−*10*).

Chart 1. Structures of a Native Agonist of the $P2Y_{14}$ Receptor 1 and a Carboxylic Acid Derivative 2 Suitable for Covalent Coupling to Carriers while Preserving Biological Activity



UDPG, 1 UDPGA, 2

The $P2Y_{14}$ receptor is activated by uridine-5′-diphosphoglucose (UDPG) **1** (Chart 1) and other UDP-sugars (*11, 12*). The $P2Y_{14}$ receptor affects immune function, but the physiological function of the receptor is not clearly established (*13, 14*). Extracellular **1** also acts as a weak full agonist at the $P2Y_2$ receptor (EC_{50} 10 μM) (*15*). We have studied the SAR of nucleotide derivatives at this receptor, which is among the most structurally restrictive of the P2Y family (*15*−*18*). Activity of synthetic analogues of **1** at the $P2Y_{14}$ receptor has been followed through the stimulation of phosphoinositide hydrolysis by coexpression in COS-7 cells of a PLC-activating chimeric G protein that responds to G_i-coupled receptors (*18*).

Dendrimers are tree-like polymeric macromolecular nanostructures, which can serve as nanocarriers for drug delivery (*19*−*21*). Dendrimer chemistry offers versatility in the control of the component functional groups and in feasibility for conjugation of multiple functional units at both the periphery and interior. Dendrimers recently have attracted considerable attention in biomedical research in the context of drug delivery (targeted/controlled release, encapsulation, or covalent/electrostatic attachment) (*22*−*24*), protein−carbohydrate interactions (multivalent effect) (*25*−*30*), medical diagnostics (signal amplification) (*31, 32*), and tissue engineering (*33, 34*).

Polyamidoamine (PAMAM) dendrimers have well-defined chemical structures in which a core is surrounded by successively added (and bifurcating) layers of methyl acrylate and ethylenediamine, which form each dendrimeric shell (or "generation") of the polymer. Different generations of PAMAM dendrimers have either primary amine (integral generations) or carboxylic acid (half-integral generations) groups on their surface, and the number of surface groups for conjugation to multiple functional units depends on the generation of the dendrimer. PAMAM dendrimers are relatively biocompatible, which allows many applications in biomedicine (*35*−*38*).

We recently reported the first example of application of dendrimers to multivalent GPCR-promoted signal transduction in a study of adenosine receptor-targeted dendrimers (*39*−*41*). Various adenosine receptor agonists were attached covalently to PAMAM dendrimers, and the resulting nucleoside conjugates displayed distinct biological properties, including potent inhibition of platelet aggregation.

Here, we report the first example of application of PAMAM dendrimers to covalently conjugate a P2Y receptor ligand resulting in the enhancement of its pharmacological activity. The $P2Y_{14}$ receptor agonist uridine-5′-diphosphoglucuronic acid (UDPGA) **2** and its ethylenediamine adduct **3a** were utilized as appropriately functionalized congeners to couple with several generations of PAMAM dendrimers with the goal of modulating pharmacological interaction with this receptor. We also attached prosthetic groups, such as biotin, AlexaFluor488, and the metal chelating group diethylenetriaminepentaacetic acid (DTPA) on the dendrimer-nucleotide conjugates for targeting the $P2Y_{14}$ receptor in vivo. Our long-term goal is to initiate the genesis of receptor probes that lead to improved biomedical diagnostics and possibly to novel conjugates for drug treatment.

EXPERIMENTAL PROCEDURES

Chemical Synthesis. *Materials and Methods.* All reactions were carried out under a nitrogen atmosphere. G2.5 PAMAM (10 wt % solution in methanol), G3 PAMAM (20 wt % solution in methanol), G5.5 PAMAM (5 wt % solution in methanol), and G6 PAMAM (5 wt % solution in methanol), dendrimer with an ethylenediamine core, EDC, UDPGA, $Gd(OAc)_3$, and ethylenediamine were purchased from Aldrich. Sulfo-NHS-LC-biotin was purchased from Pierce (Rockford, IL), and AlexaFluor488-carboxylic acid 2,3,5,6-tetrafluorophenyl ester (AlexaFluor488−5-TFP) was purchased from Invitrogen Corp. (Carlsbad, CA) and 2-(4-isothiocyanatobenzyl)-diethylenetriaminepentaacetic acid (*p*-SCN-Bn-DTPA) purchased from Macrocyclic (Dallas, TX). Dialysis membranes (Spectra/Pore Membrane, MWCO 3500, flat width 18 mm) were purchased from Spectrum Laboratories, Inc. (Rancho Dominguez, CA).

Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker DRX-600 spectrometer using D_2O as a solvent. The chemical shifts are expressed as relative ppm from HOD (4.80).

The electrospray ionization mass spectrometry (ESI MS) and matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) MS experiments were performed on a Waters LCT Premier mass spectrometer at the Mass Spectrometry Facility, NIDDK, NIH.

*Synthesis of G3 or G6 PAMAM-UDPGA Conjugates **8**, **9**, and **12.*** A commercial solution of G3 PAMAM **5** (100 μL, 2 μmol) or G6 PAMAM **7** (167 μL, 0.11 μmol) was added to a round-bottom flask, and the methanol was evaporated using a rotary evaporator. The dendrimer was treated with EDC-HCl (2.1 mg, 5.5 equiv for compound **8**; 13.8 mg, 36 equiv for compound **9**; and 5.4 mg, 256 equiv for compound **12**) and then dissolved with minimum volume of 0.1 M 2-(*N*-morpholino)ethanesulfonic acid (MES), pH 5 (1 mL). The reaction mixture was stirred and UDPGA **2** (7.7 mg, 6 equiv for compound **8**; 82.7 mg, 64 equiv for compound **9**; and 27.2 mg, 384 equiv for compound **12**) was added. The pH of the reaction was adjusted to the range 4.5−5.0 using 0.1 M HCl. The reaction mixture was stirred at room temperature under nitrogen atmosphere for 2 days and then diluted with water (1 mL). After that, the product was purified by extensive dialysis in water. The mixture was then lyophilized to give the pure product of the conjugates **8**, **9**, and **12**.

*G3 PAMAM-UDPGA Conjugate **8** (Low Loading).* Compound **8** (13.5 mg, 71%) was obtained as a white solid following the general procedure. The product was analyzed by NMR and MALDI-TOFF MS, which indicated approximately 4.3 UDPGA moieties attached per dendrimer. ^{1}H NMR (D_2O) δ 7.84 (d, J = 8.8 Hz, 4.3 H), 5.91 (d, J = 5.7 Hz, 8.6 H), 5.53 (m, 4.3 H), 4.28 (m, 8.6 H), 4.17 (m, 8.6 H), 4.08 (m, 8.6 H), 3.85 (m, 4.3 H), 3.63 (m, 8.6 H), 3.44 (m, 180 H), 3.3 (m, 120 H), 3.14 (m, 60 H), 2.72 (m, 120 H); *m/z* (M^+ ESI MS) found 9848.0; calc 9519.0.

*G3 PAMAM-UDPGA Conjugate **9** (High Loading).* Compound **9** (26 mg, 68%) was obtained as a white solid following the general procedure. The product was analyzed by NMR and MALDI-TOFF MS, which indicated approximately 20.1 UDPGA moieties attached per dendrimer. ^{1}H NMR (D_2O) δ 7.88 (d, J = 7.4 Hz, 20.1 H), 5.81 (d, J = 5.4 Hz, 40.2 H), 5.51 (dd, J = 3.3, 6.1 Hz, 20.1 H), 4.3 (m, 40.2 H), 4.2 (m, 40.2 H), 4.1 (m, 40.2 H), 3.65 (m, 20.1 H), 3.52 (m, 40.2 H), 3.41 (m, 180 H), 3.3 (m, 120 H), 3.14 (m, 60 H), 2.72 (m, 120 H); *m/z* (M^+ ESI MS) found 18721.4; calc 19113.7.

*G6 PAMAM-UDPGA Conjugate **12.*** Compound **12** (9.86 mg, 61%) was obtained as a white solid following the general procedure. The product was analyzed by NMR and MALDI-TOFF MS, which indicated approximately 147 UDPGA moieties attached per dendrimer. ^{1}H NMR (D_2O) δ 7.87 (d, J = 7.5 Hz, 147 H), 5.89 (d, J = 5.4 Hz, 294 H), 5.51 (m, 147 H), 4.29 (m, 294 H), 4.17 (m, 294 H), 4.09 (m, 294 H), 3.81 (m, 147 H), 3.7 (m, 294 H), 3.51 (m, 512 H), 3.41 (m, 512 H), 3.28 (m, 1020 H) 3.12 (m, 504 H), 3.07 (m, 504 H), 2.78 (m, 1020 H). The molecular weight was unable to be determined using ESI or MALDI-TOF MS, possibly due to stacking of the PAMAM dendrimer or because of the high molecular weight.

*Synthesis of G2.5 or G5.5 PAMAM−UDPGA Conjugates **10** and **11**.* A commercial solution of G2.5 PAMAM **4** (13.76 μL, 0.2 μmol) or G5.5 PAMAM **6** (115 μL, 0.1 μmol) was added to a round-bottom flask, and the methanol was evaporated. EDC-HCl (1.4 mg, 36 equiv, for compound **8**; and 1.9 mg, 100 equiv for compound **9**) was added to the residue, and then the mixture was dissolved in a minimum volume of 0.1 M MES, pH 5 (0.5 mL), and stirred under a nitrogen atmosphere. UDPGA-ethylenediamine (**3a**) was added to the reaction mixture (6.5 mg, 50 equiv, for compound **10**; and 13.1 mg, 200 equiv, for compound **11**). The pH of the reaction mixture was maintained within the range 4.5−5.0 using 0.1 M HCl. After 48 h, the small molecule impurities were removed by extensive dialysis in water. After dialysis, the mixture was lyophilized to give conjugate **10** or **11**.

*G2.5 PAMAM-UDPGA Conjugate **10.*** Compound **10** (2.4 mg, 66%) was obtained as a white solid following the general procedure. The product was analyzed by NMR and MALDI-TOF MS, which indicated approximately 17.3 UDPGA moieties attached per dendrimer. ^{1}H NMR (D_2O) δ 7.82 (d, $J = 7.7$ Hz, 17.34 H), 5.84 (d, $J = 5.5$ Hz, 34.68 H), 5.51 (dd, $J = 3$, 5.1 Hz, 17.34 H), 4.29 (m, 52.0 H), 4.15 (m, 52.0 H), 3.7 (m, 17.34 H), 3.51 (m, 98.7 H), 3.41 (m, 120 H), 3.31 (m, 90.7 H), 3.14 (m, 60 H), 2.68 (m, 34.7 H), 2.51 (m, 56 H); *m*/*z* (M^+ESI MS) found 18151.4, calc 18477.9.

*G5.5 PAMAM-UDPGA Conjugate **11.*** Compound **11** (4.5 mg, 63%) was obtained as a white solid following the general procedure. The product was analyzed by NMR and MALDI-TOF MS, which indicated approximately 29.9 UDPGA moieties attached per G5.5 dendrimer. ^{1}H NMR (D_2O) δ 7.85 (d, $J =$ 8.3 Hz, 29.94 H), 5.88 (d, $J = 6.5$ Hz, 59.9 H), 5.57 (dd, $J =$ 3.1, 5.7 Hz, 29.9 H), 4.26 (m, 89.8 H), 4.14 (m, 89.8 H), 3.72 (m, 29.94 H), 3.44 (m, 571 H), 3.23 (m, 1075.88 H), 2.84 (m, 504 H), 2.67 (m, 508 H), 2.48 (m, 564 H); *m*/*z* (M^+ESI MS) found 72626, calc 71651.

*Synthesis of G3 PAMAM-UDPGA-Biotin Conjugate **13**.* A mixture of G3 PAMAM complex **9** (20 mg, 1.04 μmol) and Sulfo-NHS-LC-Biotin **17** (361 μg, 0.65 μmol) in a flask was dissolved in bicarbonate buffer (1 mL, pH 8.5, 0.002 M Na_2CO_3, 0.048 M $NaHCO_3$, 0.15 M NaCl). After 48 h of stirring at room temperature, the reaction mixture was diluted with 1 mL water, and the product was purified by dialysis against water. The solution was then lyophilized, which provided G3 PAMAM-botin **13** (14.4 mg, 67%) as a white solid. The product was analyzed by NMR and MALDI-TOF MS, which indicated that approximately 4.87 biotin moieties attached per dendrimer. ^{1}H NMR (D_2O) δ 7.87 (d, $J = 7.4$ Hz, 20.1 H), 5.82 (d, $J = 5.4$ Hz, 40.2 H), 5.51 (m 20.1 H),4.55 (m, 9.74 H) 4.28 (m, 40.2 H), 4.18 (m, 40.2 H), 4.09 (m, 40.2 H), 3.67 (m, 20.1 H), 3.53 (m, 40.2 H), 3.42 (m, 180 H), 3.28 (m, 135 H), 3.11 (m, 60 H), 2.91(m, 9.74 H) 2.71 (m, 120 H), 2.12 (m, 19.5 H), 1.52 (m, 39.0 H), 1.27 (m, 19.5 H); *m*/*z* (M^+ESI MS) found 21114.0, calc 20767.0.

*Synthesis of G3 PAMAM-UDPGA-AlexaFluor488 Conjugate **14**.* G3 PAMAM complex **9** (20 mg, 1.04 μmol) was reacted with AlexaFluor488-5-TFP **18** (575 μg, 0.65 μmol) in bicarbonate buffer (1 mL, pH 8.5, 0.002 M Na_2CO_3, 0.048 M $NaHCO_3$, 0.15 M NaCl). The reaction mixture was stirred for 2 days at room temperature and then diluted with 1 mL of water. The mixture was purified by dialysis with water. Lyophilization of the solution gave the G3 PAMAM−AlexaFluor488 complex **14** (13.4 mg, 62%) as a red solid. The product was analyzed by NMR and MALDI-TOFF MS, which indicated approximately 2.3 AlexaFluor488 moieties attached per dendrimer. ^{1}H NMR (D_2O) δ 8.28 (m, 2.3 H), 8.01 (d, $J = 7.4$ Hz, 20.1 H), 7.85 (m, 4.6 H), 6.1 (m, 2.3 H), 6.9 (m, 2.3 H), 5.9 (d, $J = 5.4$ Hz, 40.2 H), 5.75 (m, 2.3 H), 5.53 (dd, $J = 3.1$, 5.9 Hz, 20.1 H), 5.3 (m, 2.3 H), 4.32 (m, 40.2 H), 4.21 (m, 40.2 H), 4.18 (m, 40.2 H), 3.94 (m, 40.2 H), 3.68 (m, 20.1 H), 3.43 (m, 180 H), 3.28 (m, 120 H), 3.15 (m, 60 H), 2.63 (m, 120 H); *m*/*z* (M^+ESI MS) found 22336.0, calc 20766.3.

*Synthesis of G3 PAMAM-UDPGA-DTPA Conjugate **15** and G3 PAMAM-UDPGA-DTPA-Gd Conjugate **16.*** G3 PAMAM complex **9** (20 mg, 1.04 μmol) was stirred with *p*-SCN-Bn-DTPA **19** (351 μg, 0.65 μmol) in bicarbonate buffer (1 mL, pH 8.5, 0.002 M Na_2CO_3, 0.048 M $NaHCO_3$, 0.15 M NaCl). The reaction mixture was stirred for 48 h, at room temperature, and then the small molecule impurities were removed by extensive dialysis in water followed by lyophilization to yield the G3 PAMAM-DTPA complex **15** (15.2 mg, 68%) as a white solid. The product was analyzed by NMR and MALDI-TOF MS, which indicated approximately 4.5 DTPA moieties attached per dendrimer. ^{1}H NMR (D_2O) δ 7.89 (d, $J = 7.4$ Hz, 20.1 H), 7.21 (m, 9 H), 7.31 (m, 9 H), 5.85 (d, $J = 5.4$ Hz, 40.2 H), 5.53 (dd, $J = 3.3$, 6.1 Hz, 20.1 H), 4.31 (m, 40.2 H), 4.24 (m, 40.2 H), 4.15 (m, 80.4 H), 3.71 (m, 20.1 H), 3.64 (m, 49.5 H), 3.44 (m, 180 H), 3.33 (m, 120 H), 3.16 (m, 69 H), 2.63 (m, 120 H), 2.66 (m, 27 H); *m*/*z* (M^+ESI MS) found 22744.0, calc 21546.1.

The chelating prosthetic group on conjugate **15** was used to complex Gd(III) by addition of $Gd(OAc)_3$. G3 PAMAM-UDPGA-DTPA **15** (10 mg, 0.46 μmol), Gd $(OAc)_2$ (94 μg, 0.28 μmol) were dissolved in 0.3 M citrate buffer (1 mL, pH 4.5). The mixture was stirred at room temperature for 48 h in dark. The mixture was dialyzed sequentially with 0.1 M NH_4OAc (pH 7.0) to remove the uncomplexed Gd(III) and then extensively against water. Lyophilization of the solution gave the product **16** (7.5 mg, 74%). Since the compound **16** contains Gd(III), we could not analyze the NMR spectra. We assume that all the DTPA moieties would complex with Gd(III), because we reacted **15** with excess $Gd(OAC)_3$ in this theoretically quantitative reaction. So, we assumed that compound G3 PAMAM-UDPGA-DTPA-Gd(III) **16** contained approximately 4.5 Gd(III) moieties attached per dendrimer based on the stoichiometry of the precursor, which was comparable to mass spectral data. *m*/*z* (M^+ESI MS) found 24175.0, calc 22311.2.

Biological Methods. *Materials.* IBMX was purchased from SigmaAldrich (St. Louis, MO). Compounds **1** and **2** were manufactured by Fluka and were purchased from SigmaAldrich (St. Louis, MO). [^{3}H]Adenine was purchased from American Radiolabeled Chemicals (St. Louis, MO). All cell culture media and sera were from Gibco (Invitrogen, Carlsbad, CA).

Cell Culture. Human embryonic kidney-293 cells stably expressing the human $P2Y_{14}$-R ($P2Y_{14}$−HEK293 cells) were generated as previously described by Fricks et al. (*46*). $P2Y_{14}$−HEK293 cells were grown in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 1% genticin (Gibco), and 1% antibiotic−antimocotic (Gibco) at 37 °C in a 5% CO_2 environment.

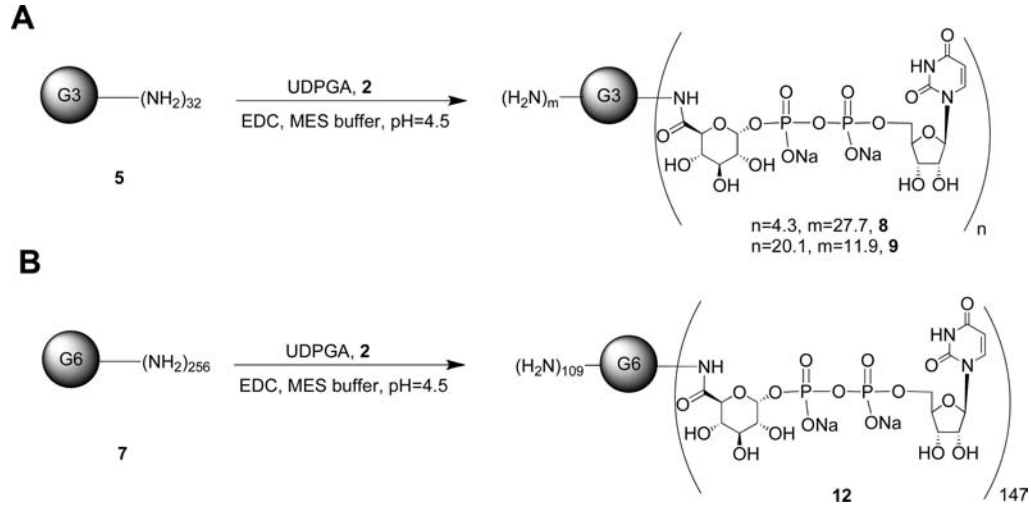
Cyclic AMP Accumulation. $P2Y_{14}$−HEK293 cells were grown in 24-well plates and incubated with 1 μCi [^{3}H]adenine/well in serum-free DMEM for at least 2 h prior to assay. Assays were initiated by addition of HEPES-buffered, serum-free DMEM containing 200 μM 3-isobutyl-1-methyl-xanthine (IBMX) and 30 μM forskolin, with or without drugs, and incubation continued for 15 min at 37 °C. Incubations were terminated by aspiration of the medium and addition of 450 μL ice-cold 5% trichloroacetic acid. [^{3}H]Cyclic AMP was isolated by sequential Dowex and alumina chromatography and quantified by liquid scintillation counting as previously described by Harden et al. (*55*).

Data Analysis. The concentrations of the dendrimer−ligand complexes were measured by the concentration of the dendrimer, not the attached ligand. EC_{50} values were determined using *Prism* software (GraphPad, San Diego, CA) and are presented as mean ± SE. All experiments were repeated at least three times.

RESULTS

Chemical Synthesis. We recently investigated the SAR (structure−activity relationship) of analogues of UDPG **1** at the $P2Y_{14}$ receptor (*15*, *16*), but few of the ligands displayed comparable pharmacological properties to those of the native ligand, and nearly all modifications of the uracil and ribose moieties abolished activity. We also reported that functionalized congeners of UDPGA **2** in which an amide-linked chain was extended from the terminal carboxylic acid group via *N*-acetylethylenediamine (e.g., **3b**) or *N*-(*t*-butyloxycarbonyl)ethylenediamine moieties did not significantly differ from **1** in their

Scheme 1. Covalent Coupling of the Carboxylic Acid Functionalized Congener UDPGA 2 to PAMAM Dendrimers of Integral Generations 3 and 6, by Carbodiimide Condensation with the Surface Amino Groups of the Dendrimer



pharmacological activity (*15*). This suggests that it is possible to incorporate structural modifications of the carboxylic acid chain in **2** that do not substantively affect interaction with the $P2Y_{14}$ receptor.

In this study, we first coupled **2** with the peripheral amino groups of a third-generation (G3) PAMAM dendrimer to yield **8** and **9** and to a sixth-generation (G6) PAMAM dendrimer to yield **12**. The coupling conditions used were the water-soluble carbodiimide reagent EDC in aqueous medium at pH 4.5 in 0.1 M MES buffer and under a nitrogen atmosphere (Scheme 1). The degree of substitution of the G3 dendrimer was varied to determine how the fraction of drug loading on the PAMAM surface would affect the pharmacological activity. Compound **8** contained an average of 4.3 bound nucleotide moieties (**2**) per dendrimer, and compound **9** an average of 20.1 bound nucleotide moieties per dendrimer, out of a theoretical 32. The degree of substitution was calculated using mass spectroscopy and integration of the 600 MHz ^{1}H NMR spectra. For compound **12**, we added excess nucleotide monomer to derivatize the maximum number of nucleotide moieties on the surface of a G6 dendrimer, in which the average number of drug moieties attached was found to be an average of 147 out of a theoretical 256. Following the coupling reaction, we removed all residual compound **2** that remained unreacted by extensive dialysis in water. Thus, we successively varied the number of covalently attached ligands, determined to be an average of 4.3, 20.1, and 147 per dendrimer in compounds **8**, **9**, and **12**, respectively.

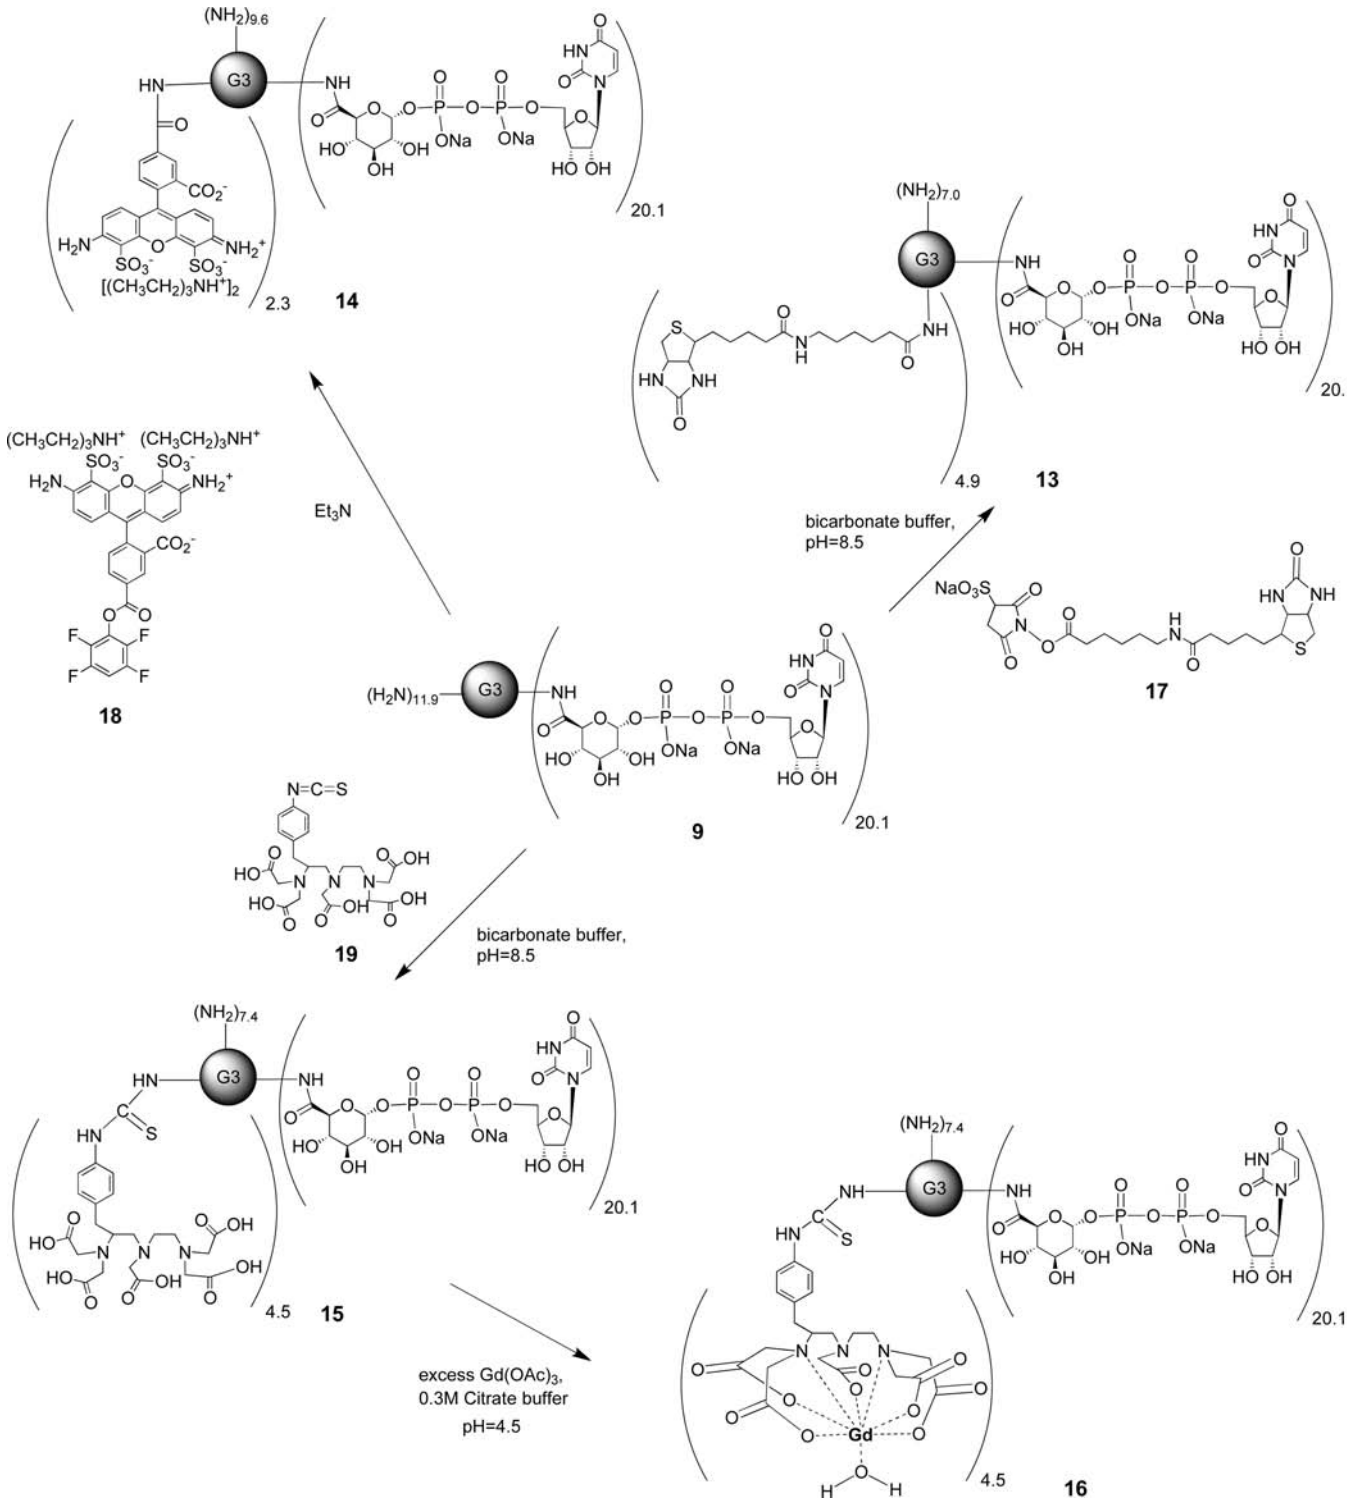
A G3 PAMAM-biotin conjugated UDPGA complex **13** also was prepared. Since biotin and its amide derivatives are known to bind strongly with the tetrameric protein avidin, compound **13** was designed as a multifunctional chemical probe of the $P2Y_{14}$ receptor. For the preparation of compound **13**, PAMAM-UDPGA **9** was reacted with a water-soluble *N*-hydroxysuccinimide (NHS) ester of a chain-elongated biotin **17** in bicarbonate buffer at pH 8.5 (Scheme 2) and the product **13** was subjected to dialysis in water. From the ^{1}H NMR and mass spectra, we confirmed that the average number of biotin units attached in compound **13** was 4.9 per dendrimer.

With the eventual goal of direct microscopic visualization of the $P2Y_{14}$ receptor in biological systems, we prepared a fluorescent dendrimer−UDPGA derivative **14**. Compound **14** was synthesized by reaction of **9** and an equimolar amount of 5-carboxy tetrafluorophenyl ester of AlexaFluor488 **18** in the presence of triethylamine in a minimum volume of water. AlexaFluor488 was chosen, because although its fluorescent properties are similar to fluorescein, it exhibits higher photostability, pH insensitivity, and good water solubility (*42*). We subjected compound **14** to dialysis in water to remove low MW impurities. The conjugated product was analyzed by ^{1}H NMR and mass spectroscopy, which showed that the average number of AlexaFluor488 units attached per dendrimer molecule was 2.3.

PAMAM dendrimers recently were used for magnetic resonance imaging (MRI) (*43*). MRI is one of the fastest growing diagnostic methods in medical technology because of its effectiveness in visualizing soft tissues with good resolution. Ionic gadolinium is a widely used reagent for MRI, and a chelated Gd(III) complex recently was covalently attached to PAMAM dendrimers for molecular imaging (*44*). As such, we derivatized the PAMAM−UDPGA conjugate **9** with the same MRI-active reagent for chelation of Gd(III). Compound **9** was reacted with an electrophilic reactive derivative (aryl isothiocyanate) of diethylenetriaminepentaacetic acid (DTPA) **19** in bicarbonate buffer at pH = 8.5 for two days to obtain compound **15**, which was purified by dialysis in water. The molecular weight of **15** was >10 000 D, and ^{1}H NMR and mass spectroscopic analyses revealed that the average number of DTPA moieties attached in compound **15** was 4.5 per dendrimer. We subsequently reacted compound **15** with excess $Gd(OAc)_3$ in the presence of 0.3 M citrate buffer (pH = 4.5) to obtain compound **16**, which was subjected to dialysis using 0.1 M ammonium acetate to remove low MW impurities. It was not possible to obtain a ^{1}H NMR spectrum for compound **16**, so we have assumed that the number of Gd(III) ions in compound **16** was 4.5 based on quantitative complexation of the attached DTPA with excess ionic Gd. We used $Gd(OAc)_3$ as a biological control to ensure that Gd(III) does not exhibit activity in the system examined and to anticipate eventual replacement of nonradioactive $Gd(OAc)_3$ with radioactive $Gd(OAc)_3$ for in vivo imaging.

The unreacted dendrimer surface in compounds **8**, **9**, and **12**−**16** contains amino groups, which are known to be associated with cell toxicity (*45*). Therefore, we also produced conjugates of carboxylic acid-containing PAMAM dendrimers by coupling an amine-functionalized congener of UDPGA **3a** to G2.5 (**4**) and G5.5 (**6**) PAMAM dendrimers to form compounds **10** and **11**. Compound **3a** was further purified by a subsequent HPLC step for subsequent biological testing. Compound **3a** was reacted with PAMAM dendrimer G2.5 **4** and G5.5 **6** by EDC coupling in 0.1 M MES buffer under a nitrogen atmosphere and at pH 4.5 to 5.0 to form products **10** and **11**, respectively. Each polymeric product was subjected to dialysis in water to remove

Scheme 2. Multiple Functionalization of a Covalent Conjugate 9 of UDPGA 2 on a PAMAM G3 Dendrimer, For the Purpose of Fluorescent Detection (14), Avidin Binding (13), and Chelation with Heavy Metal Gadolinium (16)



low MW impurities. Compounds **10** and **11** were analyzed by ^{1}H NMR and mass spectroscopy, which showed that the average number of monomers **3a** in compounds **10** and **11** was 17.3 and 29.9 per dendrimer, respectively.

Biological Activity. The activities of dendrimer conjugates were tested in human embryonic kidney (HEK293) cells stably expressing the human $P2Y_{14}$ receptor. Concentration effect curves were generated as previously described (*46*) comparing the relative capacities of UDPG **1** and the denrimer conjugates to inhibit forskolin (30 μM)-stimulated cyclic AMP accumulation. Neither compound **1** (*46*) nor any of the dendrimers tested (data not shown) exhibited activity in wild-type HEK293 cells.

The control dendrimers **4** and **5** were inactive in this test system. In contrast, compound **9**, derived from the G3 dendrimer and containing free residual amino groups, was a very potent agonist that exhibited an EC_{50} of 2.4 nM at the $P2Y_{14}$ receptor (Figure 1). This potency was approximately 100-fold greater than that of the native agonist UDPG **1**, which had an EC_{50} of 261 nM. UDPGA **2** was approximately equipotent to **1** in this assay. The corresponding dendrimer **8** (Figure 1), which had a

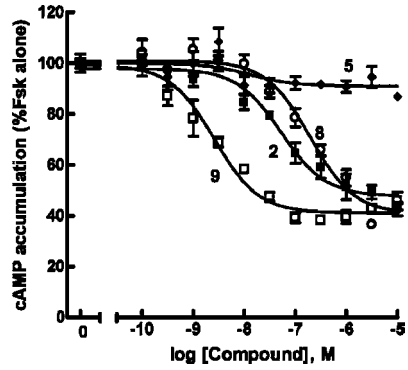


Figure 1. Comparison of G3 dendrimer conjugates as agonists at the human $P2Y_{14}$ receptor. The capacities of UDPGA **2** (■) and the G3 dendrimer conjugates **5** (◆), **8** (○), and **9** (□) to inhibit forskolin (30 μM) stimulated cyclic AMP accumulation were quantified in $P2Y_{14}$−HEK293 cells as described in Methods. Assays were carried out in triplicate, and all experiments were repeated at least three times. Data were pooled and normalized using forskolin-stimulated cyclic AMP accumulation as 100% and the phosphodiesterase inhibitor IBMX alone as 0%.

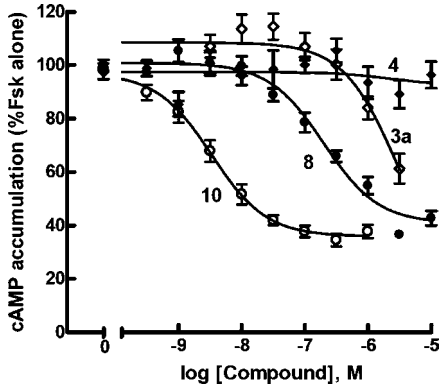

Figure 2. Comparison of G2.5 dendrimer conjugates as agonists at the human $P2Y_{14}$ receptor. The capacities of G2.5 dendrimer conjugates **3a** (◇), **4** (◆), **8** (●), and **10** (○) to inhibit forskolin (30 μM) stimulated cyclic AMP accumulation were quantified in $P2Y_{14}$−HEK293 cells as described in Methods. Assays were carried out in triplicate, and all experiments were repeated at least three times. Data were pooled and normalized using forskolin-stimulated cyclic AMP accumulation as 100% and IBMX alone as 0%.

lower degree of loading of the nucleotide on a G3 dendrimer, was considerably less potent than **9**, but similar in potency to **1**. Therefore, a distinct multivalent effect occurs in these compounds.

Compounds **10** and **11**, both of which were derived from half-integral dendrimers and contain free residual carboxylate groups, were very potent at the $P2Y_{14}$ receptor with EC_{50} values of 3.2 and 3.1 nM, respectively (Figure 2). The corresponding amine derivative **3a** of UDPGA, which also served as the synthetic precursor of conjugates **10** and **11**, was considerably less potent.

The higher molecular weight G6 dendrimer conjugate **12** was similar in relative composition to the smaller conjugate **9**, which had a high degree of loading of nucleotide. Compound **12** (EC_{50} = 0.8 nM) was significantly more potent than **9** (Figure 3). Both **9** and **12** contain significant fractions (but less than 50%) of residual amino groups.

The G3 dendrimer conjugates **13** and **15** were equivalent to the precursor dendrimer conjugate **12**, except that they both contain covalently attached prosthetic groups in addition to the nucleotide. Each of these dendrimers was essentially as potent as **9**. The G3 dendrimer conjugate **14**, which had approximately two covalently attached AlexaFluor488 moieties, was 17-fold less potent than the corresponding **9** but 7-fold more potent than

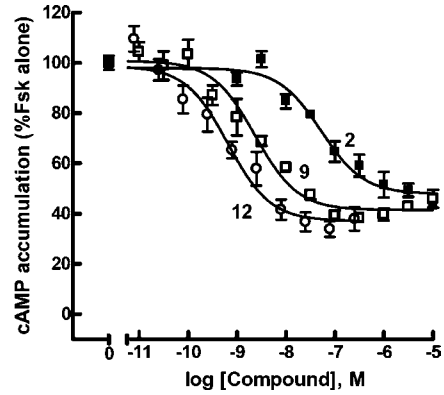

Figure 3. Comparison of larger dendrimer conjugates as agonists at the human $P2Y_{14}$ receptor. The capacities of UDPGA **2** (■), G3 dendrimer conjugate **9** (□), and G6 dendrimer conjugate **12** (○) to inhibit forskolin (30 μM)-stimulated cyclic AMP accumulation were quantified in $P2Y_{14}$−HEK293 cells as described in Methods. Assays were carried out in triplicate, and all experiments were repeated at least three times. Data were pooled and normalized using forskolin-stimulated cyclic AMP accumulation as 100% and IBMX alone as 0%.

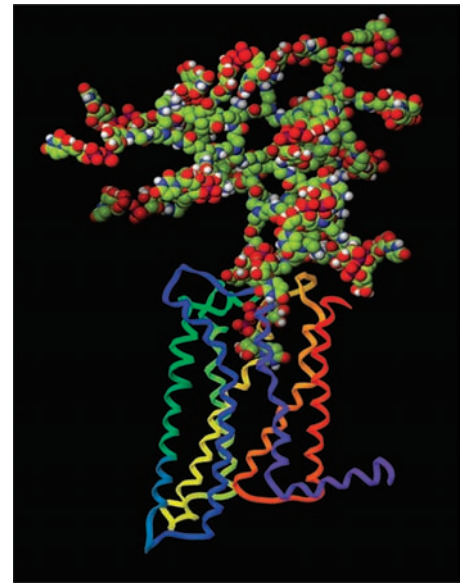

Figure 4. Molecular model of compound **9** docked in the human $P2Y_{14}$ receptor, obtained after docking to the receptor homology model built based on the crystal structure of the A_{2A} adenosine receptor (*47*). The receptor helices are colored by residue position: N-terminus in red, TM 1 in orange, TM 2 in ochre, TM 3 in yellow, TM 4 in green, TM 5 in cyan, TM 6 in blue, and TM 7 and C-terminus in purple.

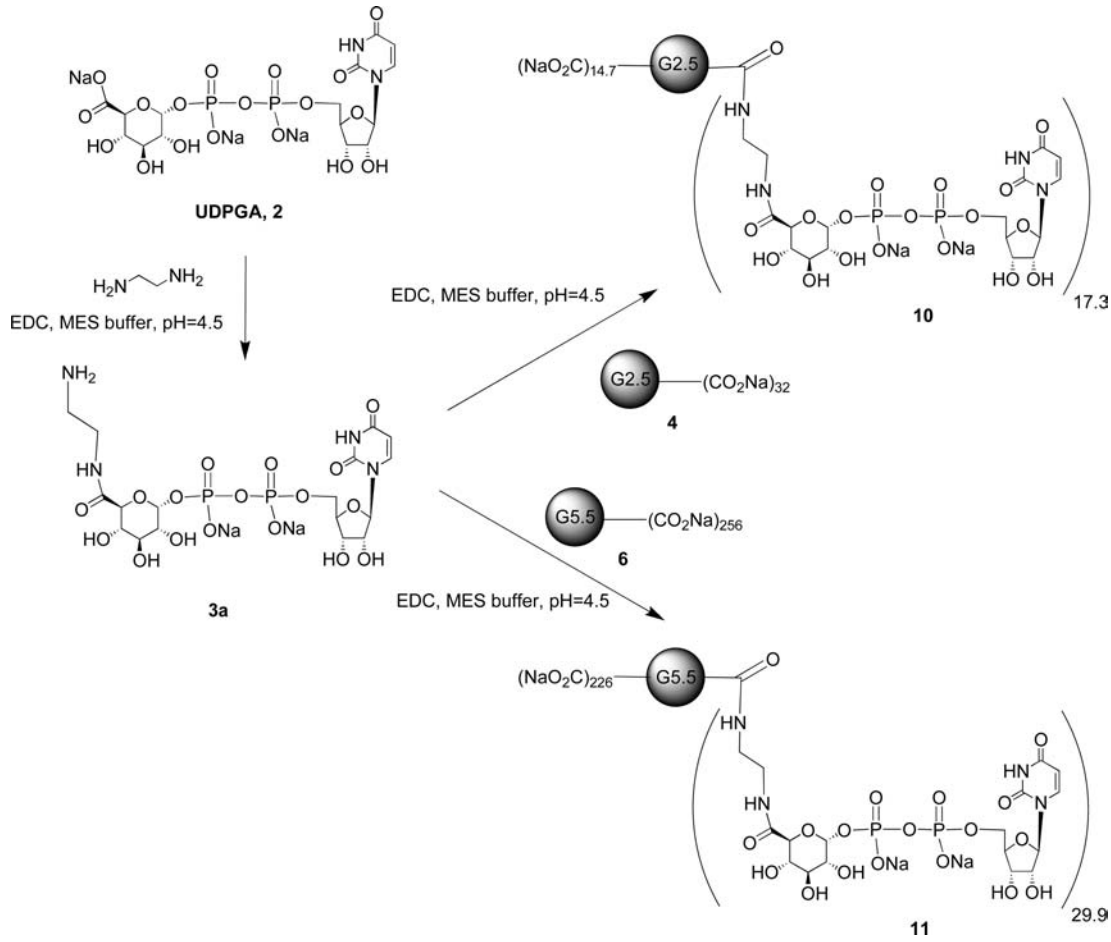
compound **1**. However, when the DTPA conjugate **15** was complexed with gadolinium, the potency was greatly reduced, to the level of **1**, the native agonist.

Molecular Modeling. A molecular model of compound **3b** docked to the human $P2Y_{14}$ receptor recently was constructed on the basis of the crystal structure of the human A_{2A} adenosine receptor (*15, 47*). This model was utilized to build a complex of the $P2Y_{14}$ receptor bound to a PAMAM G3 dendrimer using the same approach as reported for the docking of a polyvalent dendrimer−nucleoside conjugate to the human A_{2A} adenosine receptor (*48*). In particular, our published model of the conjugate of PAMAM (G3) with an A_{2A} receptor agonist (2-[*p*-(2-carboxyethyl)phenyl-ethylamino]-5′-*N*-ethylcarboxamidoadenosine, CGS21680) was utilized to build a model of dendrimer−nucleotide conjugate **9**, which was partially substituted with nucleotide moieties. Initially, all fragments of the carboxylic acid CGS21680 were removed from the model of PAMAM-

Scheme 3. Synthesis of an Amine-Functionalized Congener UDPGA 3a and Its Covalent Coupling to PAMAM Dendrimers of Half-Generations 2.5 and 5.5, by Carbodiimide Condensation with the Surface Carboxylic Groups of the Dendrimer



CGS21680, and hydrogen atoms were added to the remaining PAMAM structure. Twenty moieties of UDPGA **2** then were coupled to randomly selected amino groups of the PAMAM chains. The remaining 12 unacylated chains of the dendrimer were substituted with protonated amino groups.

The model of **9** was minimized in the OPLS2005 force field. The Polak−Ribier conjugate gradient (PRCG) minimization method with a maximum of 5000 iterations and with a convergence threshold of 0.05 $kJ \cdot mol^{-1} \cdot Å^{-1}$ was applied. One randomly selected UDPGA moiety attached to the dendrimer then was removed from the PAMAM model, and the UDPGA docked to the $P2Y_{14}$ receptor was attached to the dendrimer. Thus, an initial complex of **9** docked to the $P2Y_{14}$ receptor was obtained. The orientation of a few UDPGA moieties was manually adjusted to avoid overlays with the amino acid residues of the $P2Y_{14}$ receptor. The model was subjected to geometry optimization using the same protocol as mentioned above. After minimization, the binding mode of the UDPGA moiety located inside the $P2Y_{14}$ receptor was found to be similar to the binding mode of **1** itself (*15*). The ethylenediamine chain of PAMAM connected to the receptor-bound UDPGA moiety was located between extracellular loops of $P2Y_{14}$ receptor. In particular, the nucleotide moiety was surrounded by Ile173 (EL2), and Leu175 (EL2), Arg274 (EL3), and Lys277 (7.35). In addition, Lys277 formed an H-bond with the amide oxygen atom of the chain of PAMAM. The molecular model of compound **9** docked in the human $P2Y_{14}$ receptor (Figure 4) showed that the nucleotide-substituted branches of the dendrimer extended far beyond the dimensions of the receptor protein and thus would be available for multivalent docking to receptor dimers and higher-order aggregates (*49*).

DISCUSSION

A functionalized ethylenediamine-containing chain was incorporated in agonists of the human $P2Y_{14}$ receptor, and this chain provided a conjugation strategy for coupling nucleoside agonists to PAMAM dendrimer carriers. Uridine-5′-diphosphoglucuronic acid and its ethylenediamine adduct were suitable functionalized congeners (*50*) for coupling to several generations (G2.5−6) of dendrimers (both terminal carboxy and amino) to modulate potency of the intact conjugates. The observed biological activity of the dendrimer conjugates was clearly $P2Y_{14}$ receptor-dependent; the control dendrimers **4** and **5** lacking nucleotides were inactive. A G3 PAMAM conjugate containing 20 bound nucleotide moieties was 100-fold more potent than the native agonist **1**. Larger dendrimer carriers and those with greater loading favored higher potency as $P2Y_{14}$ receptor agonists. All of the dendrimer−nucleotide conjugates were full agonists at the receptor.

The molecular mechanism whereby these dendrimers exhibit increased activity relative to the native cognate agonist UDPG is unclear. One possible explanation is that these multivalent compounds may bridge multiple $P2Y_{14}$ receptor binding sites simultaneously. Molecular modeling has indicated this possibility for an analogous G3 PAMAM dendrimer conjugate of an A_{2A} adenosine receptor agonist (*48*). The dramatic enhancement in potency, especially in the more heavily substituted dendrimer derivatives, is highly suggestive of a multivalent effect. The ability to span multiple receptor binding sites would be further

Table 1. In Vitro Pharmacological Data for Various Nucleotides and Their Complexes with PAMAM Dendrimers

compound	name/composition	molecular weight (kD)	EC_{50} at $hP2Y_{14}$ receptor, nM

[a] NE, no effect.

promoted by the possible aggregation of dendrimer derivatives (*56*). Nanomolar and subnanomolar potencies have been achieved, which are unprecedented for any monomeric nucleotides acting at the $P2Y_{14}$ receptor. Dendrimer conjugates **10** and **11**, which are both more than half substituted with nucleotide moieties, are more than 800-fold more potent than a corresponding monomer, i.e., the ethylenediamine analogue **3a**. Lower loading of the same dendrimer with nucleotides resulted in a conjugate (compound **9**) that exhibited relatively lower potency. Variability of the potency depending on degree of loading will be the subject of future systematic studies. Such studies also might benefit from quantification of the relative activities of these compounds across a wide range of receptor expression levels in the same cell system.

It is possible that conjugation to dendrimers might protect the nucleotides against enzymatic degradation, but this is not the basis for the enhancement of potency in cAMP-inhibition with the multivalent dendrimers. Our earlier studies (*51*) indicated that little metabolism of extracellular **1** occurs under the conditions of these assays. Moreover, the concentration effect curve of **1** for decreasing cyclic AMP levels is similar whether quantified at times of <5 min or times up to 30 min.

Dendrimers containing several different prosthetic groups also were synthesized. Dendrimer conjugate **14**, which is tagged with AlexaFluor488, potentially will be useful for receptor visualization. Although the potency of **14** was 17-fold lower than that of the corresponding dendrimer lacking the fluorescent group (i.e., **9**), the EC_{50} of approximately 40 nM was comparable to previously introduced fluorescent ligand probes for other GPCRs (*52*). A similar approach in a previous study, using a fluorescent AlexaFluor488-tagged G3 PAMAM dendrimer, was used to detect the expression of the A_3 adenosine receptor in cultured cells (*41*). Gd(III) is a paramagnetic ion that is used for magnetic resonance imaging (*44*). Dendrimer conjugate **15**, which is tagged with the chelating group DTPA, is substantially less potent as its Gd(III) complex, thus limiting the potential utility of this derivative. The in vivo application of dendrimer conjugates is normally limited to i.p. or i.v. injection, but novel approaches for gaining greater bioavailability of dendrimers by other routes of administration have been discussed (*53*, *54*).

In conclusion, we have identified a site on a nucleotide agonist of the $P2Y_{14}$ receptor for chemical tethering to a macromolecular carrier without losing the ability to activate the receptor. Moreover, we have shown that the potency of the native ligand is greatly enhanced in these multivalent ligands. These biologically active drug conjugates do not require cleavage or cellular internalization for their action at the GPCR; in fact, these processes would reduce activity. Covalent conjugation of $P2Y_{14}$ receptor agonists to PAMAM dendrimers qualitatively altered their pharmacological activity. Thus, potency was either retained or dramatically enhanced in the multivalent dendrimer conjugates in comparison to the monomeric $P2Y_{14}$ receptor agonists, depending on size, degree of substitution, terminal functionality, and attached prosthetic groups. The ability to modulate the potency of a given GPCR ligand by the mode and stoichiometry of attachment to dendrimer carriers promises to have general applicability to this therapeutically important class of receptor proteins.

ACKNOWLEDGMENT

This research was supported in part by the Intramural Research Program of the NIH, NIDDK, and by NIH grant GM38213 to T.K.H. We thank Dr. Herman Yeh and Dr. Athena M. Keene-Klutz of NIDDK for helpful advice on the NMR experiments and chemical synthesis. We thank Dr. John Lloyd (NIDDK) for mass spectral measurements.

In Vivo Bioluminescence Imaging of Furin Activity in Breast Cancer Cells Using Bioluminogenic Substrates

Anca Dragulescu-Andrasi, Gaolin Liang, and Jianghong Rao*

Department of Radiology, Molecular Imaging Program at Stanford, Bio-X Program, and Cancer Biology Program, Stanford University School of Medicine, 1201 Welch Road, Stanford, California 94305. Received June 5, 2009; Revised Manuscript Received July 13, 2009

Furin, a proprotein convertases family endoprotease, processes numerous physiological substrates and is overexpressed in cancer and inflammatory conditions. Noninvasive imaging of furin activity will offer a valuable tool to probe furin function over the course of tumor growth and migration in the same animals in real time and directly assess the inhibition efficacy of drugs in vivo. Here, we report successful bioluminescence imaging of furin activity in xenografted MBA-MB-468 breast cancer tumors in mice with bioluminogenic probes. The probes are conjugates of furin substrate, a consensus amino acid motif R-X-K/R-R (X, any amino acid), with the firefly luciferase substrate D-aminoluciferin. In the presence of the luciferase reporter, the probes are unable to produce bioluminescent emission without furin activation. Blocking experiments with a furin inhibitor and control experiments with a scrambled probe showed that the bioluminescence emission in the presence of firefly luciferase is furin-dependent and specific. After furin activation, a 30-fold increase in the bioluminescent emission was observed in vitro, and on average, a 7−8-fold contrast between the probe and control was seen in the same tumor xenografts in mice. Direct imaging of furin activity may facilitate the study of furin function in tumorigenicity and the discovery of new drugs for furin-targeted cancer therapy.

INTRODUCTION

In vivo bioluminescence imaging (BLI) uses luciferase enzymes (such as firefly luciferase, *Renilla* luciferase, and green or red click beetle luciferase) as reporters to generate light emission during the catalytic oxidation of their substrates for noninvasive imaging of biological targets and processes in intact cells and living animals (*1*−*3*). Because of its extremely high sensitivity and relatively simple instrument setup, BLI has been extensively used as a molecular imaging technique in small animals, particularly for cancer imaging research. For example, BLI is used to measure the mass and location of implanted cells in animals (*4*), to evaluate the efficacy of anticancer drugs (*5*−*7*), and to detect protein−protein interactions in living cancer cells (*8*, *9*).

BLI employs both the enzyme and substrate to generate light emission, and many strategies have been developed to regulate the activity of the reporter enzyme at various levels (transcriptional, post-transcriptional, translational, and post-translational) for molecular imaging (*10*). Alternatively, the substrates may be chemically converted into an inactive caged form that can be activated by certain biological targets to generate the original substrates for imaging. For example, the substrates of firefly luciferase have been conjugated to a caspase-3 peptide substrate and β-lactam to produce bioluminogenic probes for imaging caspase-3 (*11*, *12*) and β-lactamase activity (*13*). Herein, we report the design of luminogenic probes based on D-aminoluciferin for imaging furin activity in breast cancer cells in vivo.

Furin, one of the seven endoproteases that belong to the proprotein convertases family, is ubiquitously expressed in mammalian cells processing and activating a wide variety of proprotein substrates (*14*). The physiological substrates of furin include growth factors and hormones (e.g., pro-β-NGF and TGF-β), receptors such as insulin proreceptor, plasma proteins, and as well as proteases such as membrane type 1-matrix metalloproteinase (MT1-MMP) and matrix metalloproteinases (*15*). Upregulation of furin mRNA was identified in head and neck tumors, breast tumors, and lung cancer by means of reverse transcription polymerase chain reaction (RT-PCR) and in situ hybridization (*16*). Recent reports have indicated that furin is a target of hypoxia-inducible factor 1 (HIF-1) and that hypoxia induces elevated levels of furin, leading to more aggressive tumors (*17*). It has been demonstrated that furin inhibition correlates with decreased invasiveness and tumorigenicity of several human cancer cells in vivo (*18*, *19*). Considering the vital role of furin in tumor formation and invasion, the ability to image its activity in vivo will offer a valuable tool to probe furin function over the course of tumor growth and migration in the same animals in real time and provide a means to assess the in vivo inhibition efficacy of drugs. However, no probes are currently available for noninvasive imaging of furin activity in living animals.

Furin performs a calcium-dependent proteolytic cleavage at the *C*-terminus of a consensus amino acid motif R-X-K/R-R (X, any amino acid) (*20*). This tetrapeptide motif provides sufficient specificity to bind the active furin (*21*). To take advantage of the high sensitivity of BLI, we developed bioluminogenic furin probes by conjugating the furin substrate to the luciferase substrate D-aminoluciferin. Here, we show that these bioluminogenic probes are specifically activated by furin and produce bioluminescence emission in the presence of firefly luciferase in vitro, in living breast cancer cells, and in breast cancer tumor xenografts in mice.

MATERIALS AND METHODS

Probe Syntheses. All peptides were synthesized using standard Fmoc-protocol on a trityl chloride resin (Novabiochem). After sequence completion, the peptides were cleaved from the solid support without removing the protecting groups of the amino acids (Pbf for Arg, Boc for Lys, and *t*Bu for Tyr)

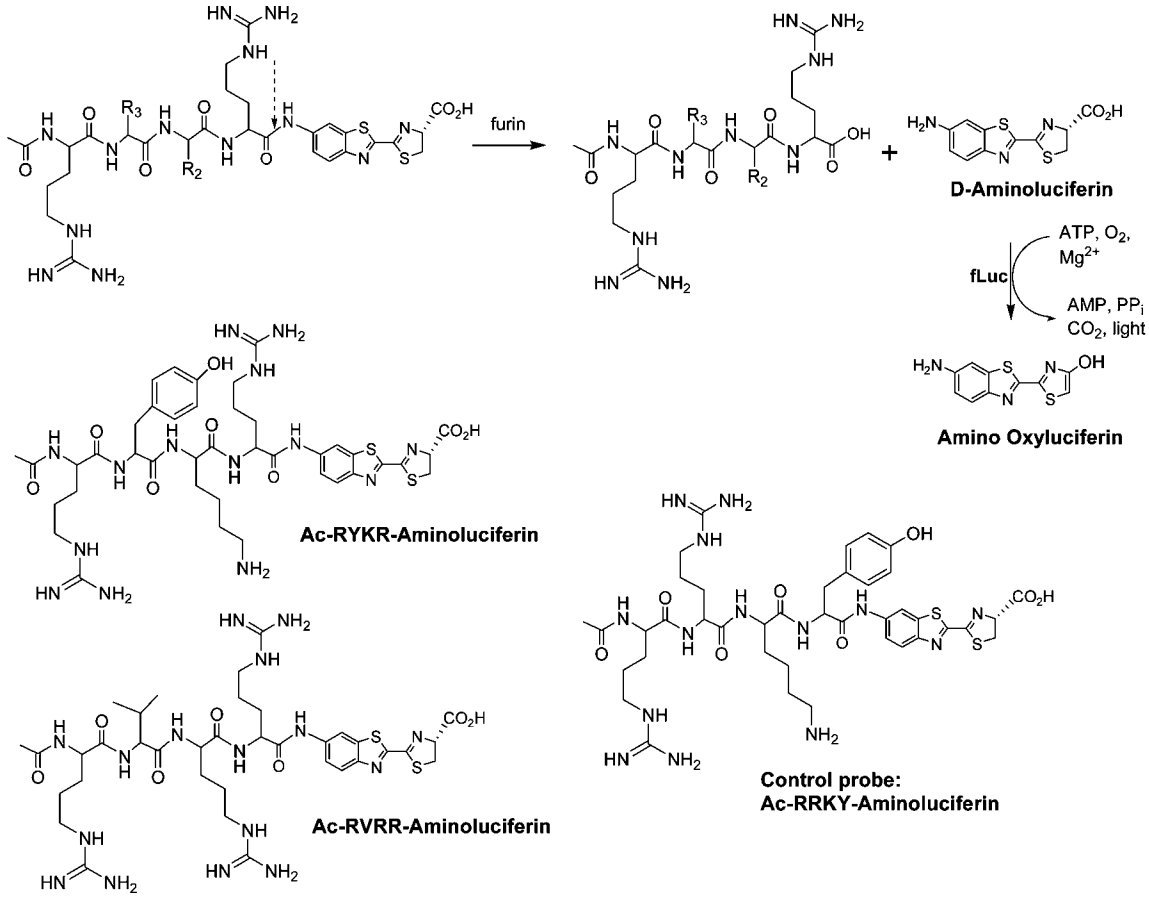
Scheme 1. Schematic of Bioluminogenic Probes for Detecting Furin Activity and Their Chemical Structures



using 1% trifluoroacetic acid (TFA) in dichloromethane. 2-Cyano-6-aminobenzothiazole (CABT) was synthesized as previously described (*22*). All aminoluciferin−peptide conjugates were obtained using a three-step postsynthetic protocol as described below.

First, CABT was coupled to the *C*-terminal carboxylic acid group using the following procedure: Ac-R(Pbf)VR(Pbf)R(Pbf)-COOH (300 mg, 0.22 mmol) was dissolved in dry tetrahydrofuran (THF) (3 mL). *N*-Methylmorpholine (65 μL, 0.56 mmol) and isobutyl chloroformate (32 μL, 0.27 mmol) were added. The reaction mixture was stirred at room temperature for 30 min. Afterward, CABT (60 mg, 0.34 mmol) was added, and the reaction mixture was stirred at room temperature overnight. The CABT−peptide conjugate was purified by RP-HPLC, and then the solvent was removed by rotary evaporation and dried.

Second, the protection groups were removed using 95% TFA, 2.5% water, and 2.5% triisopropylsilane (TIPS), and then the peptide was precipitated with ether, washed, dried, and used for the next step without further purification.

Third, the yellow solid was dissolved in PBS (1 mL). D-Cysteine hydrochloride monohydrate (38 mg, 0.22 mmol) was dissolved in water, adjusted at pH 8.5 with sodium carbonate, and added to the CABT−peptide solution. The reaction mixture was further adjusted to pH 8 and stirred at room temperature for 20 min. The product, Ac-RVRR-AmLuc, was purified by RP-HPLC and lyophilized to give a light-yellow foamy solid (total yield: 21%). The final identity of the products was confirmed with mass spectroscopic analyses (Supporting Information).

Cell Culture and Tumor Xenograft Generation. All cell culture reagents were purchased from Invitrogen unless otherwise noted. MDA-MB-468 (human breast adenocarcinoma) cells, transduced with a retrovirus (pMSCV/L2G) to express a dual reporter containing firefly luciferase (Fluc) and green fluorescent protein (GFP), were kindly supplied by Dr. Christopher Contag (Stanford University). MDA-MB-468 Fluc$^+$ cells were cultured in Dulbecco's modified Eagle's medium (DMEM) (high glucose, 4500 mg/L D-glucose, and 110 mg/L sodium pyruvate) supplemented with 10% fetal bovine serum (FBS) and penicillin−streptomycin (100 units/mL) at 37 °C in a humidified atmosphere in a 5% CO_2 incubator. To generate tumor xenografts in mice, MDA-MB-468 Fluc$^+$ cells (10×10^6) were implanted subcutaneously in the mid-dorsal region of each 4-weeks-old female nude mouse (*Nu/Nu*, Charles River). Tumors were allowed to grow for 10 days and reach sizes between 5−7 mm before imaging.

In Vitro Bioluminescence Measurements. Probes were diluted to a final concentration of 50 μM in Dulbecco's phosphate buffered saline (DPBS) containing Ca^{2+} and Mg^{2+}, and incubated for 1 h at room temperature with or without 4 U of furin (New England BioLabs). Subsequently, 20 μL of luciferase assay buffer (Promega) and 1 μL of QuantiLum recombinant luciferase solution (Promega), diluted to a concentration of 0.13 mg/mL in 1 mg/mL BSA solution in PBS, were added. The luminescence was immediately measured using a 20/20^n Single Tube Luminometer (Turner BioSystems) at a 1 s integration time every 5 min for 1 h.

Cell Bioluminescence Imaging. MDA-MB-468 Fluc$^+$ cells were grown in 60 mm dishes to reach 80−90% confluence. After washing twice with PBS, cells were detached using a plastic cell scraper, diluted in 2 mL of PBS, and counted. Next, cells were centrifuged down, dissolved in DPBS (containing Mg^{2+} and Ca^{2+}), and placed in the 96-well plate at 3×10^5 cells/well. The furin probes were added immediately before imaging. In the inhibition experiments, 300 μM furin inhibitor (Decanoyl-RVKR-CMK, CalBiochem) was added. Biolumi-

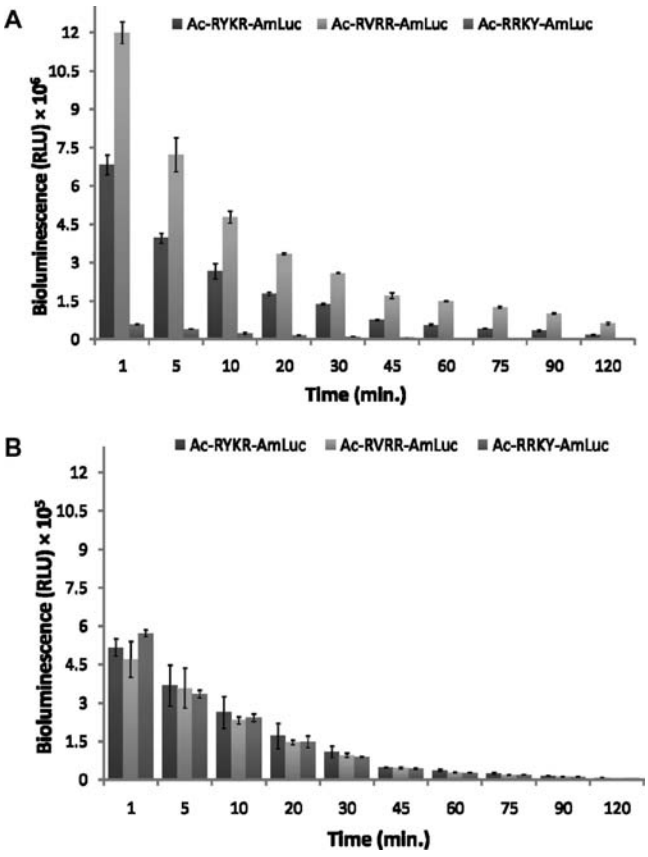


Figure 1. In vitro detection of furin activity. All substrates were incubated with (A) or without 4 U (B) of furin at room temperature for 1 h. Luciferase buffer and enzyme were added, and the bioluminescence signal was measured and plotted as a function of time.

nescence images were acquired every 5 min for 2 h using an optical imaging system (IVIS 200; Xenogen Corp.) at a 50 s integration time. Circular regions of interest (ROI) were drawn over each well and quantified using Living Image software (Xenogen Corp). The background of an empty well was subtracted from the total signal. The results were reported as total photon flux within an ROI in photons per second.

Fluorescence Immunostaining. MDA-MB-468 $Fluc^+$ cells were plated on glass coverslips in 24-well plates at 70% confluence and fixed with 4% paraformaldehyde for 20 min the next day. Subsequently, fixed cells were washed 3 times with DPBS and permeabilized with 1% Triton X-100/PBS for 20 min, followed by blocking with 1% nonfat milk solution in PBS for 20 min at room temperature. After blocking, cells were incubated with primary antibody (1:100, antifurin rabbit polyclonal antibody (Biomol International), diluted with 1% nonfat milk PBS solution) for 1 h at 37 °C. After washing three times with PBS and once with 1% nonfat milk, cells were incubated with secondary antibody (1: 100, goat polyclonal antirabbit IgG rhodamine conjugate) for 30 min at 37 °C. After washing with PBS and distilled water, the final samples were mounted on a glass slide with mounting media containing DAPI. Images were acquired using an Axiovert 200 M fluorescence microscope (MicroImaging, Inc., Thornwood, NY) equipped with a 63× objective. Acquisition time was 150 ms for 4′,6′-diamidino-2-phenylindole (DAPI) and 600 ms for the rhodamine channel. For MDA-MB-468 tumor tissue staining, tumors were sectioned at a thickness of 10 μm, placed on glass slides, and fixed with acetone on ice for 10 min. The same staining protocol for fixed cells applied to them for furin imaging.

In Vivo Bioluminescence Imaging. Animal handling was performed in accordance with Stanford University, Animal Research Committee guidelines. Prior to imaging, all mice bearing MDA-MB-468$Fluc^+$ subcutaneous tumors were anesthetized using isoflurane gas (2% isoflurane in oxygen, 1 L/min) during all injection and imaging procedures. Mice were imaged in a light-tight chamber using an in vivo optical imaging system (IVIS 200; Xenogen Corp.) equipped with a cooled charge-coupled device (CCD) camera. Mice were imaged 1 min after tail vein injection of 100 μL of 10 mM probe solution with an acquisition time of 1 min, and a gray scale reference image was obtained before the acquisition of a bioluminescence image. The pseudocolored bioluminescence images (in photons/s/cm2/steradian) were superimposed over the gray scale photographs of the animals. Circular ROIs were drawn over the tumor areas and quantified using Living Image software, version 3.0 (Xenogen Corp.). The results were reported as total photon flux within an ROI in photons per second.

RESULTS

Luminogenic Probes Specifically Detect Furin Activity in Vitro. D-Aminoluciferin, an analogue of D-luciferin, is a bioluminescent substrate for the luciferase enzyme. Derivatization of its amino group with amino acids renders D-aminoluciferin a poor substrate for luciferase with drastically decreased photon production efficiency presumably due to the steric hindrance at the active site of firefly luciferase (*23*). We therefore designed our bioluminogenic furin probes by coupling D-aminoluciferin to the *C*-terminus of furin recognition peptide sequences, such as previously reported furin substrates RVRR and RYKR (*24, 25*), affording two bioluminogenic furin probes: Acetyl-RVRR-aminoluciferin (Ac-RVRR-AmLuc) and Acetyl-RYKR-aminoluciferin (Ac-RYKR-AmLuc) (Scheme 1). Because furin cleaves at the C-terminal to the last arginine residue, small molecules at this site such as 7-amino-4-methylcoumarin can be attached at this position, and the resulting conjugate can still be recognized and processed by furin (*26*). Both probes should be poor substrates for firefly luciferase and would produce little light emission. In the presence of furin, the probes will be hydrolyzed to remove the peptide caging group and generate free D-aminoluciferin which will subsequently produce light emission in the presence of firefly luciferase. Therefore, the activity of furin can be measured from the firefly luciferase based bioluminescence assay. As a control, we synthesized another conjugate with a scrambled amino acid sequence that should not be recognized by furin, Acetyl-RRKY-aminoluciferin (Ac-RRKY-AmLuc) (Scheme 1).

First, we evaluated our probes in vitro by measuring the bioluminescent signal as a function of time in the presence or absence of furin. As shown in Figure 1A, Ac-RVRR-AmLuc and Ac-RYKR-AmLuc were incubated with furin for 1 h at room temperature, and upon the addition of luciferase, both produced an initial burst of bioluminescence resulting from free D-aminoluciferin generated during the incubation with furin, followed by a gradual decrease of the signal over time. At each time point, Ac-RVRR-AmLuc produced a higher bioluminescent signal than Ac-RYKR-AmLuc. In the absence of furin, both bioluminogenic probes generated negligible levels of bioluminescence (for example, at 1 min, for Ac-RVRR-AmLuc, 4.5×10^5 R.L.U., which is 3.8% of the signal observed in the presence of furin) demonstrating that both probes are stable and furin-specific (Figure 1B). The initial signals observed with three probes in the absence of furin are likely due to the trace amounts of D-aminoluciferin still present in the probes even after HPLC purification. This signal decreased with time as the trace D-aminoluciferin was consumed by the luciferase enzyme. At 30 min after the luciferase addition, the bioluminescent signal of Ac-RVRR-AmLuc in the presence of furin was 30-fold higher than that without furin. In contrast, the control probe Ac-RRKY-

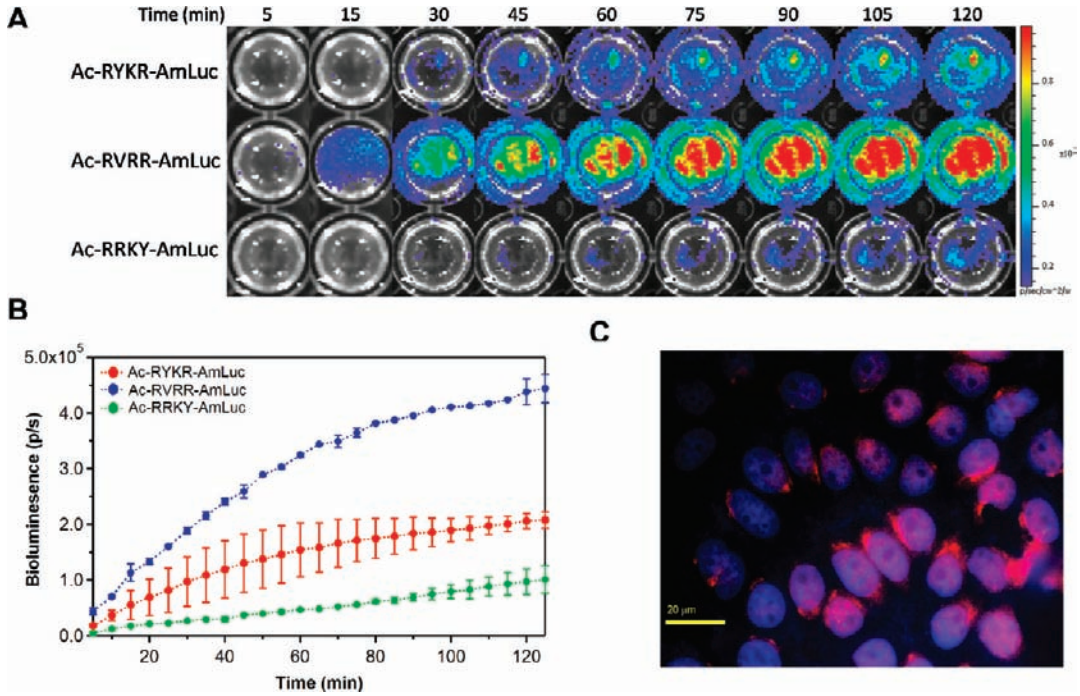

Figure 2. Furin activity detection in MDA-MB-468Fluc$^+$ cells. (A) Bioluminescence imaging of cells incubated with Ac-RYKR-AmLuc, Ac-RVRR-AmLuc, and Ac-RRKY-AmLuc at 2 μM. (B) Quantification of the bioluminescence signal; ROIs were drawn over individual wells, and the total flux in photon/s was plotted vs time for each probe. (C) Furin fluorescence immunostaining of MDA-MB-468 Fluc$^+$ cells. Red, furin (rhodamine-conjugated secondary antibody); blue, nucleus (DAPI).

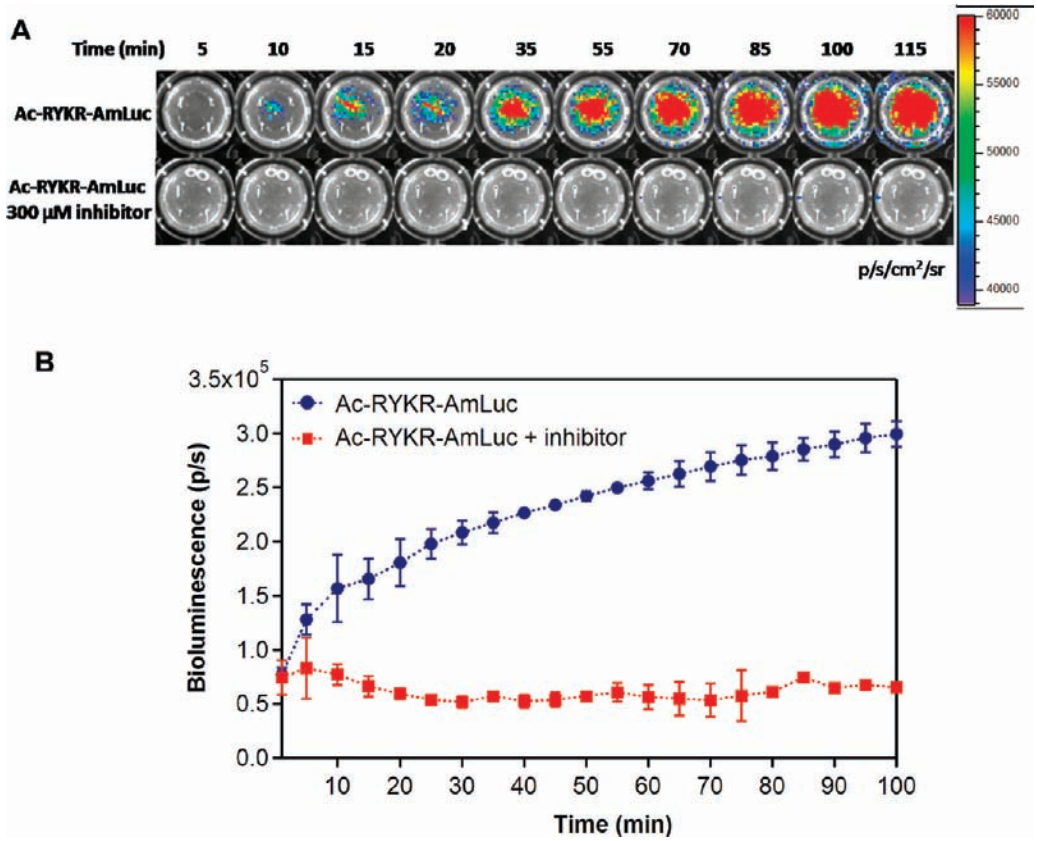

Figure 3. Imaging the furin inhibition in MDA-MB-468Fluc$^+$ cells. (A) Bioluminescence imaging of cells incubated with 20 μM Ac-RYKR-AmLuc in the absence or presence of 300 μM furin inhibitor. (B) Quantification of the bioluminescence signal; ROIs were drawn over individual wells, and the total flux in photon/s was plotted vs time.

AmLuc generated negligible light emission under identical conditions regardless of the presence of furin: 5.8×10^5 R.L.U at 1 min in the presence of furin and 5.6×10^5 R.L.U. in the absence of furin.

Bioluminescence Imaging of Furin Activity in Live Breast Cancer Cells. Next, we evaluated the capacity of the probes for detecting furin activity in live cells. It has been established that the majority of human breast cancer cells

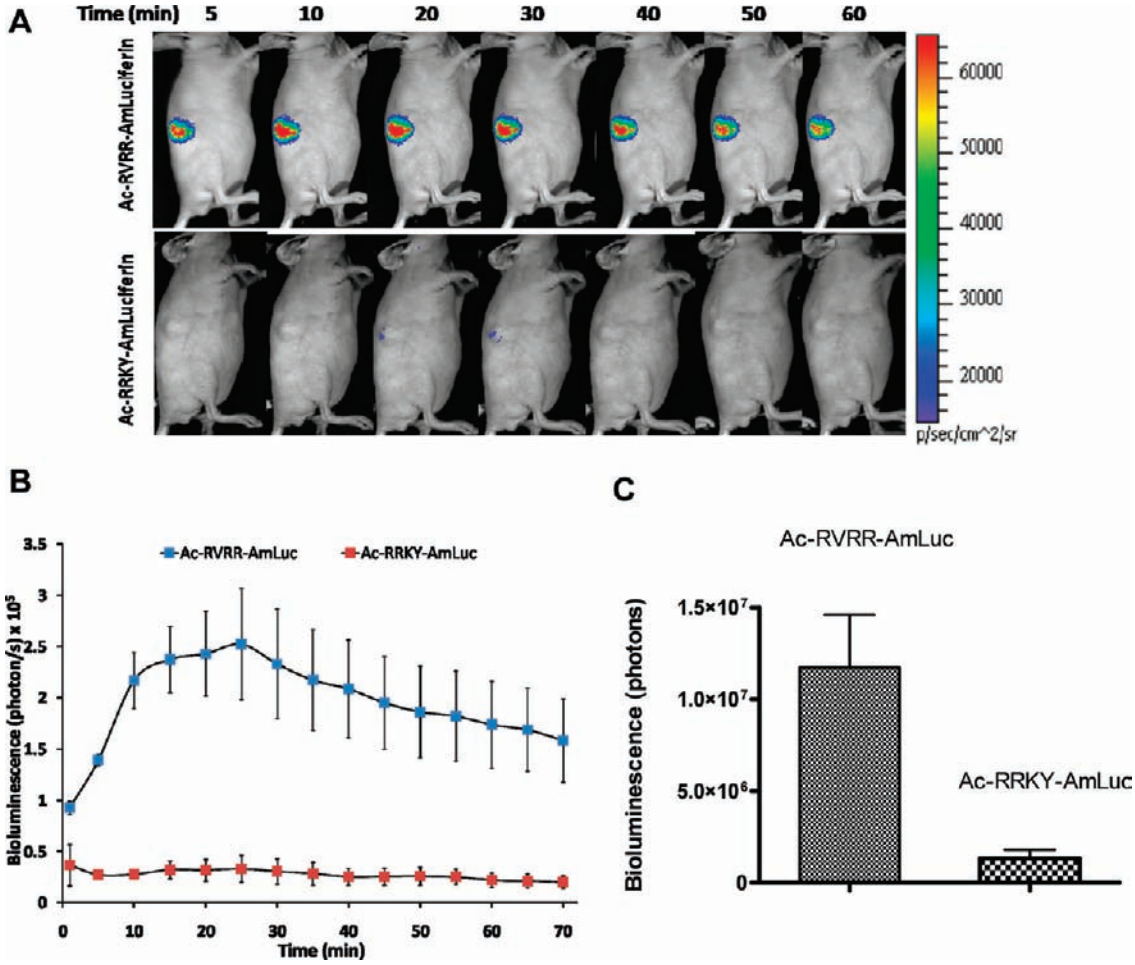

Figure 4. Bioluminescence imaging of furin activity in xenografted tumors in nude mice. (A) Representative bioluminescence imaging of furin activity in the implanted MDA-MB-468Fluc+ cells ($n = 4$). Images were acquired 1 min after tail vain injection of 100 μL (10 mM) of Ac-RVRR-AmLuc (top panel). After two days, the same protocol was applied with injecting Ac-RRKY-AmLuc in the same mice (lower panel). (B) Quantification of the total flux (photon/s) from the tumor area for Ac-RVRR-AmLuc and negative control, Ac-RRKY-AmLuc. (C) Integrated bioluminescence emission for mice injected with Ac-RVRR-AmLuc and Ac-RRKY-AmLuc; $p = 0.017$.

overexpress furin (*16*). We confirmed the expression of furin in breast cancer MDA-MB-468Fluc$^+$ cells by fluorescence immunostaining (Figure 2C), which showed strong furin staining predominantly in the trans-Golgi network, in agreement with previous reports (*27*). Consequently, we thus used this cell line to evaluate the probes for imaging furin activity. MDA-MB-468-Fluc$^+$ cells (3×10^5) were imaged at an interval of 5 min for 2 h after probe addition (2 μM) (Figure 2A). The signal from each well was quantified as photons/s and plotted as a function of time for each probe (Figure 2B). For both Ac-RVRR-AmLuc and Ac-RYKR-AmLuc, strong bioluminescent signals were detected, which gradually increased over time and nearly reached a plateau in 2 h. In contrast, the control probe showed just the background level of bioluminescence, which increased slightly in 2 h. After 60 min, Ac-RRVR-AmLuc generated ~6-fold higher bioluminescence signals in live cells than the control probe. This result correlates with the in vitro data observed with the probes, demonstrating that our probes are cell-permeable and can detect furin activity in live cells.

To further examine the kinetics of the probes in imaging furin activity in live cells, MDA-MB-468-Fluc$^+$ cells (3×10^5) were imaged for approximately 2 h starting immediately after the addition of 2, 10, or 20 μM Ac-RYKR-AmLuc (Figure 3A and Figure S6A, Supporting Information). The kinetics at 10 and 20 μM shared the same pattern with a fast increase in first 10 min followed by a slow increase, and the signal intensity was also similar, suggesting that intracellular furin was saturated at 10 μM of the probe (Figure 3B and Figure S6B, Supporting Information). At 2 μM, the bioluminescence signal gradually increased for 2 h and as expected, the intensity was lower than that at 10 or 20 μM (Figure S6B, Supporting Information).

Imaging the Inhibition of Furin Activity in Live Breast Cancer Cells. To demonstrate that the observed bioluminescent signal can be blocked by the furin inhibitor, we performed the same cell imaging study with Ac-RYKR-AmLuc in the presence of the inhibitor Decanoyl-RVKR-CMK (300 μM). The bioluminescence emission decreased significantly; for example, at 30 min, the bioluminescent signal for 20 μM of Ac-RYKR-AmLuc was 4-fold higher than that in the presence of the furin inhibitor (Figure 3A and B). This result further confirms that the bioluminogenic probe is specific to furin activity in MBA-MD-468 cells.

Imaging Furin Activity in Living Mice. Our in vitro and cell imaging data have indicated that the bioluminogenic probe Ac-RVRR-AmLuc produced a higher signal than Ac-RYKR-AmLuc; thus, Ac-RVRR-AmLuc was chosen for in vivo imaging of furin activity in tumor xenografts in nude mice. Ac-RVRR-AmLuc and the control Ac-RRKY-AmLuc were injected via the tail vain (100 μL of 10 mM probe in PBS) in the same tumor-bearing mice but two days apart. After injection, the animals were imaged every 5 min for 1 h (Figure 4A). For Ac-RVRR-AmLuc, the signal at the tumor site increased significantly at 10 min, peaked at 25 min, and then decreased slowly within 60 min (Figure 4B). In contrast, the control probe showed

low bioluminescence signals at the tumor site constantly over time (Figure 4B). The contrast between the two probes on average ($n = 4$ mice) reached 7.8-fold at 10 min and 7.6-fold between 25−35 min; at the same time point (25 min), the observed contrast between the two probes was 30-fold in vitro (Figure 1), and 7.1-fold in cell culture (Figure 2). Total emission from the tumors (substrates and control) was integrated over 1 h for all mice, and on average, the emission for Ac-RVRR-AmLuc was 8.7-fold higher than that of the control Ac-RRKY-AmLuc ($p = 0.017$) (Figure 4C). Histological staining of tumor dissections validated the expected expression of furin (Figure S7, Supporting Information). These results demonstrate that our bioluminogenic probes can specifically image furin activity in xenografted breast cancer tumors in mice.

DISCUSSION

Proteases as an important class of enzymes play vital roles in many biological processes such as cell replication, growth, differentiation, viral infection, tumor formation, and metastasis, and thus, extensive efforts have been made toward developing probes for imaging their activity in vivo (*28*−*30*). A generally used method is fluorescence-based by taking advantage of the enzymatic function of cleaving the amide bond between two adjacent amino acid residues to create smart or activatable probes through modulation of the fluorescence emission. It can be a specific peptide substrate sequence labeled by a fluorescent emitter at one side of the enzyme cleavage site and a light absorber (or fluorescent acceptor) at the other side of the cleavage site (*31, 32*), or fluorochromes attached to a polymer backbone via a specific peptide substrate (*33*−*35*). Because of fluorescence resonance energy transfer or proximity-based self-quenching, these probes emitted little fluorescence before encountering the target proteases, but enhanced fluorescent emission was observed from proteolytic activity. A similar concept has been applied to the bioluminescence-based method for imaging protease activity in vivo (*11, 12*). As shown in this work, it typically involves a conjugate between the substrate of a bioluminescent protein such as firefly luciferase and a synthetic peptide substrate. In comparison to fluorescence-based in vivo imaging, bioluminescence imaging offers greater sensitivity (*36*), although it requires the expression of luciferases at the target site.

After the initial demonstration of the commercially available DEVD-aminoluciferin substrate for imaging caspase-3 activity (*11, 12*), there have been few further reports of this method in the literature (*13*). The bioluminogenic probes we developed here for imaging furin activity represent a latest addition and further demonstrate the value and general applicability of this approach for imaging protease activity in vivo.

We have chosen the tetrapeptidyl substrates of furin over hexapeptidyl substrates even though hexapeptidyl substrates generally display more efficient hydrolytic kinetics because of the substrate inhibition observed with hexapeptidyl but not with tetrapeptidyl substrates (*37*). Between the two tetrapeptidyl probes we designed, Ac-RVRR-AmLuc showed higher activity than Ac-RYKR-AmLuc both in vitro and in vivo. Interestingly, similar substrates such as Boc-RVRR-MCA (Boc, *N-t*-butoxycarbonyl; MCA, methylcoumarinamide) have been reported to show less efficient kinetics (k_{cat}/K_m of 3.57×10^3 s^{-1} M^{-1} for furin purified from CHO cells) (*25, 26*) than Acetyl-RYKR-MCA (k_{cat}/K_m of 5.2×10^5 s^{-1} M^{-1} for human furin) (*24*), suggesting that the aminoluciferin group may have different effects than the coumarin moiety on the conjugate kinetics.

Furin has a strikingly diverse collection of physiological substrates from growth factors, hormones, receptors, and even other proteases, and plays crucial roles in development, homeostasis, and diseases ranging from anthrax, Ebola fever, Alzheimer's disease, and cancer (*15*). The previous fluorogenic substrate Boc-RVRR-MCA is just not useful to noninvasively image furin activity in vivo. Our bioluminogenic probes now fill in the gap and make the in vivo monitoring of furin activity in the same animals in real time feasible.

In summary, we report here caged bioluminogenic probes for imaging furin activity in vivo. The probes can be specifically activated by furin and produce bioluminescence emission in the presence of firefly luciferase in vitro, in living breast cancer cells, and in breast cancer tumor xenografts in mice. Noninvasive imaging of furin activity could provide a platform for in vivo assessment of furin-based prodrugs and screening of therapeutic furin inhibitors (*19*). Moreover, these bioluminogenic probes could allow for investigating the role of furin in hypoxia in vivo and provide a means for in vivo imaging of tumor hypoxia.

ACKNOWLEDGMENT

This work was supported by an IDEA award from Department of Defense Breast Cancer Research Program (W81XWH-09-1-0057) and the NCI's Small Animal Imaging Resource Program (SAIRP R24CA92862). We thank Dr. Contag (Stanford Medical School) for providing the MDA-MB-468 $Fluc^+$ cell line.

Supporting Information Available: Mass spectra of peptide amino-luciferin conjugates, imaging the furin inhibition in MDA-MB-468$Fluc^+$ cells (at 2 and 10 μM Ac-RYKR-AmLuc in the absence or presence of 300 μM furin inhibitor), and furin immunohistochemistry staining of tumor tissues. Tris-Nitrilotriacetic Acids of Subnanomolar Affinity Toward Hexahistidine Tagged Molecules

Zhaohua Huang,[†] Peter Hwang,[‡] Douglas S. Watson,[†] Limin Cao,[†] and Francis C. Szoka, Jr.*[,†]

Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, California 94143-0912, and Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143-2240. Received July 13, 2009

Nitrilotriacetic acid (NTA) has moderate affinity (10 μM) for hexahistidine (His6) and is widely used in the purification of His6-tagged proteins. The affinity can be increased significantly (10 nM) through multivalency such as using a tris-NTA. We show that the binding affinity of tris-NTA is dependent on the flexibility and length of the spacer between the mono-NTA and the scaffold: the shorter the spacer, the higher the affinity. A series of biotinylated tris-NTA having different spacers were synthesized and used to prepare tris-NTA sensor chips for surface plasmon resonance measurement of binding affinity. Subnanomolar affinity can be achieved with a short spacer. The new high-affinity tris-NTA enables the formation of stable complexes with hexahistidine containing molecules and provides a convenient method to noncovalently attach proteins to various surfaces.

INTRODUCTION

Nitrilotriacetic acid (NTA) and its derivatives have broad applications in the manipulation of hexahistidine (His6) tagged proteins such as in immobilized metal affinity chromatography (*1*, *2*), crystallization on lipid template (*3*), fluorescent labeling (*4*−*7*), and surface immobilization (*8*). The advantages of the NTA-His6 interaction are reversibility and selectivity. However, the relatively weak affinity (equilibrium dissociation constant $K_D \sim 10$ μM) between mono-NTA and His6 makes such technology unsuitable for applications where high affinity is required. Recent studies from Lata (*9*), van Broekhoven (*10*), and Huang (*11*) have demonstrated that a significant increase of binding affinity of NTA with His6-tagged proteins can be achieved through multivalency. For example, tris-NTA has a K_D around 10 nM toward His6-tagged proteins. Furthermore, the development of multifunctional tris-NTA provides a useful toolbox for the analysis and modification of His6-tagged proteins.

An important issue that has not been addressed is the influence of tris-NTA structure on the binding affinity. It remains a challenge to accurately predict the best scaffold and linker for a multivalent molecule (*12*). In the synthesis of tris-NTA, Lata used a tetraaza cyclam scaffold and glutamic acid spacer resulting in a K_D of 20 nM (*9*). We employed a dendritic lysine scaffold and a lysine spacer leading to a similar K_D (5−20 nM depending on the structure of His6-tagged protein) (*11*). Although the current generation of tris-NTAs exhibit high affinity, the interaction between the tris-NTA and His6 may not be strong enough to keep the conjugate intact in the biological environment, especially at a low concentration. Thus, it would be of interest to determine if higher-affinity multi-NTA molecules can be obtained by changing the spacer between the scaffold and the mono-NTA (Figure 1). Here, we report the structure−affinity relationship on modified tris-NTA and the realization of subnanomolar affinity with shorter spacers.

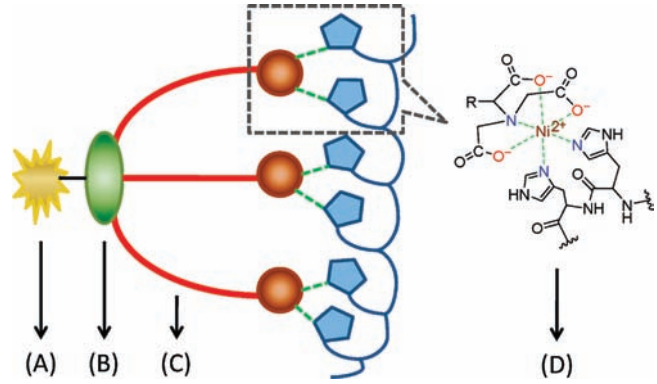

Figure 1. Schematic illustration of tris-NTA/His6 tag binding pair. (A) Functional unit. (B) Scaffold. (C) Spacer. (D) Structure of NTA/Ni^{2+}/His2. The flexibility and the length of the spacer play an important role in the overall binding affinity of tris-NTA toward His6 tag.

EXPERIMENTAL PROCEDURES

Materials and Methods. H-Lys(Z)-OtBu.HCl and H-Orn(Z)-OtBu.HCl were from BACHEM (Torrance, CA). N-CBZ-amido-dPEG4-acid was from QuantaBioDesign (Powell, OH). Other reagents were from Aldrich (Milwaukee, WI). ^{1}H NMR (400 MHz) spectra were recorded on a Varian 400 MHz instrument. Chemical shifts are expressed as parts per million using tetramethylsilane as internal standard. *J* values are in hertz. MALDI-TOF mass spectra were obtained at the Mass Spectrometry Facility, University of California, San Francisco. TLC analyses were performed on 0.25 mm silica gel F_{254} plates. High-performance flash chromatography (HPFC) was carried out on a Biotage (Charlottesville, VA) Horizon system with prepacked silica gel columns (60 Å, 40−63 μm). Unless noted otherwise, the ratios describing the composition of solvent mixtures represent relative volumes.

General Chemistry. Biotin−tris-NTAs (**6a**−**e**) were synthesized according to the previously published method for **6b** (*11*). The general synthetic route was outlined in Scheme 1. Various spacers were introduced in *tert*-butyl protected amino-

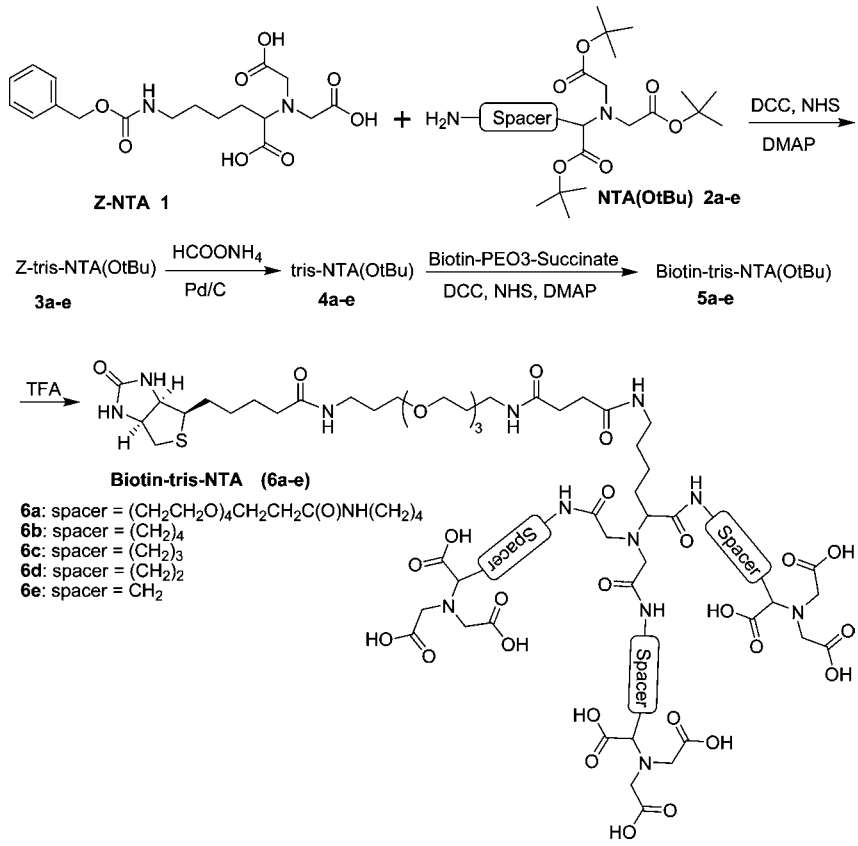
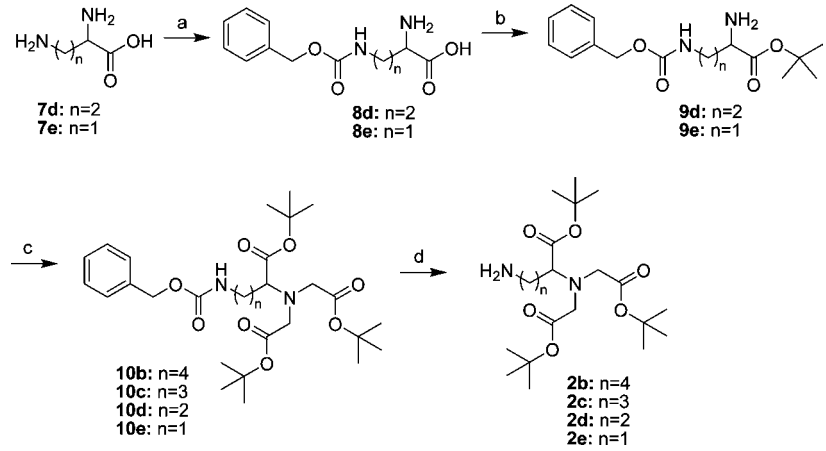
Scheme 1. General Synthetic Route for Biotin−tris-NTA



Scheme 2. Synthesis of Amino-NTA(O-tBu)[a]



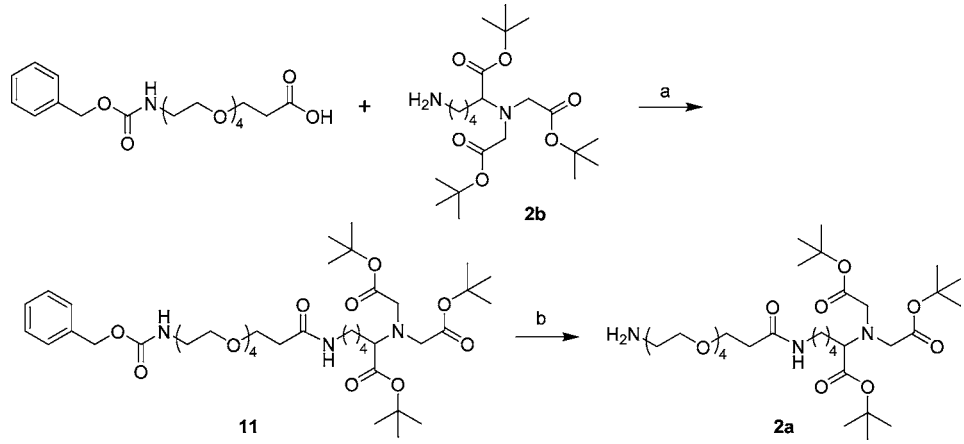
[a] (a) Benzyl chloroformate (1 equiv), pH 7.0 phosphate buffer, r.t.; (b) 2-methylpropene, conc H_2SO_4, dioxane, r.t.; (c) *tert*-butyl bromoacetate (4 equiv), DIPEA, DMF, 55 °C; (d) HCO_2NH_4 (6 equiv), 10% Pd/C, 90% methanol, 40 °C.

mono-NTA (**2a**−**e**) by using different amino acids as the starting material. Compounds **2b**,**c** were synthesized by using commercially available H-Lys(Z)-OtBu.HCl and H-Orn(Z)-OtBu.HCl, respectively. For the synthesis of compounds **2d**,**e**, 2,4-diaminobutyric acid and 2,3-diaminopropionic acid were selectively protected by the carbobenzyloxy (Z) group and *tert*-butyl group first, then converted to amino-mono-NTA by the same method as **2b** (Scheme 2). Compound **2a** was obtained by the coupling of N-CBZ-amido-dPEG4-acid to **2b** followed by the removal of the Z group (Scheme 3).

*2-Amino-3-(benzyloxycarbonylamino)propanoic Acid (**8e**) (13).* 2,3-Diaminopropanoic acid (10 g, 71.1 mmol) was dissolved in 150 mL pH 7 phosphate buffer. The pH of the solution dropped to 5.5 initially and was adjusted to 6.8 with 1 M sodium hydroxide. A solution of benzyl chloroformate (10.2 mL, 71.1 mmol) in 10 mL toluene was added dropwise into the reaction mixture with vigorous stirring at 0 °C over 80 min. The pH of the mixture was monitored with a pH meter and maintained between 6.7 and 7.0 by addition of 1 M sodium hydroxide. The mixture was kept at 0 °C for another 4 h after the completion of addition, then 8 h reaction at room temperature. The white precipitate was collected by filtration and washed with water and ether consecutively. The white solid was recrystallized from water. Yield: 12.8 g, 71%.

*tert-Butyl 2-amino-3-(benzyloxycarbonylamino)propanoate (**9e**) (14).* Compound **8e** (5 g, 21 mmol) was suspended in anhydrous dioxane (40 mL) in a 150 mL pressure vessel. After the addition of 4 mL conc H_2SO_4, the suspension turned clear.

Scheme 3. Synthesis of 2a[a]



[a] (a) DCC (1.2 equiv), DMAP, dry $CHCl_3$, r.t.; (b) HCO_2NH_4 (6 equiv), 10% Pd/C, 90% methanol, 40 °C.

Isobutene (ca. 50 mL, cooled by dry ice−acetone bath) was poured into the solution, and the vessel was sealed. After 16 h reaction at room temperature, the cap of the vessel was carefully loosened and the pressure was released slowly. The reaction mixture was poured into a mixture of cold ether and 1 M NaOH (150 mL/210 mL) in a separation funnel and shaken well. The ether layer was collected. The aqueous layer was washed with 100 mL cold ether. The ether layers were combined and dried over anhydrous sodium sulfate, evaporated under reduced pressure, and placed under high vacuum. Yield: 5.0 g. TLC: R_f = 0.52 in $CHCl_3$−MeOH (6:1). ^{1}H NMR ($CDCl_3$) δ: 1.46 (s, 9H); 3.29 (m, 2H); 3.48 (m, 1H); 5.08 (s, 2H); 5.92 (br, 1H); 7.33 (m, 5H).

*Compound **10e.*** Compound **10e** was synthesized according to the method of **10b** (*11*). ^{1}H NMR ($CDCl_3$) δ: 1.45 (s, 9H); 1.47 (s, 18H); 3.08 (m, 1H); 3.40 (m, 1H); 3.44 (m, 4H); 5.12 (s, 2H); 6.42 (br, 1H); 7.33 (m, 5H).

*Compound **2e.*** Compound **2e** was synthesized according to the method of **2b**. ^{1}H NMR ($CDCl_3$) δ: 1.45 (s, 9H); 1.47 (s, 18H); 2.86 (m, 1H); 3.36 (m, 5H); 3.72 (m, 1H); 4.9 (br, 2H).

*Compound **11.*** To a solution of N-CBZ-amido-dPEG4-COOH (1 g, 2.5 mmol) and **2b** (1.08 g, 2.5 mmol) in dry chloroform were added dimethylaminopyridine (cat.) and dicyclohexylcarbodimide (0.62 g, 3 mmol). The mixture was stirred at room temperature for 48 h. White precipitate was filtered off, and the filtrate was concentrated and applied to HPFC. The crude product was purified on a silica gel flash column with a gradient elution (1−5% methanol in chloroform). Yield: 1.7 g. TLC: R_f = 0.77 in $CHCl_3$−MeOH (9:1). ^{1}H NMR ($CDCl_3$) δ: 1.45 (s, 9H); 1.47 (s, 18H); 1.51 (m, 3H), 1.64 (m, 3H); 2.45 (t, J = 4.5, 2H); 3.22 (m, 2H); 3.28 (m, 1H); 3.40 (m, 2H), 3.44 (s, 2H), 3.46 (s, 2H); 3.60 (m, 14H), 3.71 (t, J = 4.2, 2H); 5.11 (s, 2H); 5.41 (br, 1H); 6.47 (br, 1H); 7.35 (m, 5H).

*Compound **2a.*** To a solution of **11** (1.58 g, 1.95 mmol) in methanol (35 mL) under nitrogen were added 10% Pd/C (0.2 g) and ammonium formate (1.4 g, 22 mmol) solution in 1 mL water and 9 mL methanol sequentially. The reaction mixture was vigorously stirred for 4 h under nitrogen at 40 °C. Pd/C was filtered off over Celite 545, and the filtrate was evaporated under reduced pressure. The residual was azeotropically dried with toluene. The crude product was purified by HPFC (10−18% methanol in chloroform). Yield: 1.2 g, 90% wrt **11**. TLC: R_f = 0.1 in chloroform−methanol (9:1). ^{1}H NMR confirmed the removal of CBZ group from **11**.

*Compound **6a.*** Compound **6a** was synthesized according to the method of **6b**. ^{1}H NMR ($CDCl_3$) δ: 1.32−1.78 (m, 34H); 2.38 (m, 6H); 2.52 (m, 4H); 2.62 (m, 2H); 2.80 (m, 2H); 3.14−3.30 (m, 18H); 3.37−3.63 (m, 45H); 3.76 (br, 26H); 4.22 (m, 1H); 4.41 (m, 1H).

*Compounds **6c−e.*** Compounds **6c−e** were synthesized according to the method of **6b**. Their ^{1}H NMR spectra were similar to that of **6b**. The mass of all biotin−tris-NTA (**6a−e**) were confirmed by MALDI-MS using 2,5-dihydroxybenzoic acid as matrix.

Synthesis of His6-peptide. His6-peptide (N−C sequence: GWGGHHHHHHG) was synthesized on an ABI 433A automated peptide synthesizer (Applied Biosystems) by solid-phase 9*H*-fluoren-9-ylmethoxycarbonyl chemistry according to standard Fastmoc procedures (*15*). The peptide was cleaved from the resin with 94% trifluoroacetic acid in the presence of water, ethanedithiol, and triisopropylsilane. The free peptide was separated from the resin by filtration followed by precipitation in cold diethyl ether. Peptide synthesis reagents were obtained from Novabiochem. The molecular weight of His6-peptide was confirmed by MALDI mass spectrometry (Voyager DE, Applied Biosystems) using α-cyano-4-hydroxycinnamic acid as matrix (Calcd 1254.3, found 1255.4). Lyophilized peptide was stored at −20 °C until use.

Peptide stock solutions of 1 to 5 mM were prepared by dissolution of lyophilized powders in ultrapure water (Milli-Q, Millipore) and filtration through 0.2 μm PTFE membranes (Whatman). Stock concentrations were determined by tryptophan absorbance at 280 nm as described by Pace (*16*). Each concentration measurement represented the mean of three dilutions, each providing absorbance values between 0.1 and 1.1. Prior to the SPR experiment, His6-peptide was further diluted to working concentrations in the SPR running buffer.

Surface Plasmon Resonance Experiment. Preparation of tris-NTA sensor chip (Figure 2A): A Series S Sensor Chip SA (Biacore, Piscataway, NJ) was pretreated with two injections of 50 mM NaOH in 1 M NaCl (20 μL/min, 60 s), then washed with pH 7.4 HBS-P running buffer until the baseline was stabilized. Flow cell #1 was reserved as blank; the remaining flow cells (#2−4) were coated with biotin−tris-NTA having specific spacers by injection of 20 μL 100 nM biotin−tris-NTA (10 μL/min for 2 min) to capture a 50 RU response. These low-density tris-NTA chips were used for the binding kinetics experiments. High-density tris-NTA chips (ca. 300 RU) were prepared by saturating the streptavidin chip surface with biotin−tris-NTA and were used for the immobilization of His6 protein on the surface.

Binding kinetics (Figure 2B): Various concentrations of the His-tagged molecules were injected to flow over the tris-NTA surfaces, according to the programmed cycles of the following sequence: (1) activation of tris-NTA with 5 mM $NiCl_2$, (2)

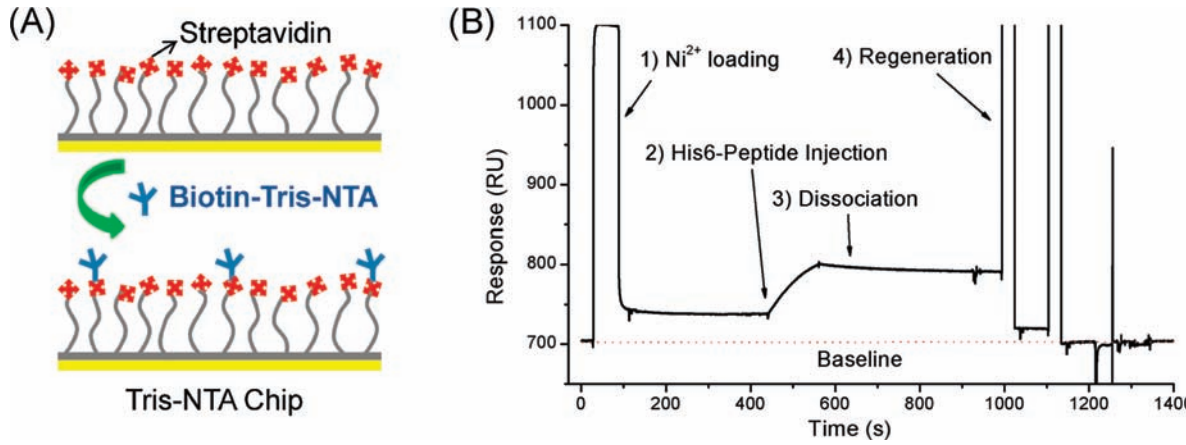


Figure 2. Measurement of binding kinetics by surface plasmon resonance using a tris-NTA chip. (A) Tris-NTA chip was prepared by coating a streptavidin chip with biotin−tris-NTA at low surface density. (B) Representative kinetics experiment cycle.

protein injection, (3) Ni(II) removal with 0.3 M EDTA, (4) rinse with 0.25% SDS and 0.5 M NaCl for baseline regeneration and stabilization. Both sample and control measurements were run in duplicate. The raw data were processed with *Biaevaluation T100* software, and the kinetic parameters were obtained by globally fitting the experimental curves with a 1:1 Langmuir binding model. The quality of the fitting was estimated by the *T* value and the residue (χ^2). $T(k) = k/\mathrm{SE}(k)$, where k is a fitted parameter such as ka and SE(k) is the standard error of k. A good fit should have a small residue and a large *T* value (*17*).

RESULTS

Synthesis of Biotin−tris-NTA. Biotin−tris-NTAs were synthesized according to previously published method (*11*) (Scheme 1). Briefly, the amino group of NTA *tert*-butyl ester (**2**) having various spacers was coupled to carboxyl acids of benzyloxycarbonyl-protected lysine NTA scaffold (**1**). Biotin was conjugated to tris-NTA after the removal of the benzyloxycarbonyl group so that the final product (**6**) can be immobilized on a streptavidin sensor chip for the surface plasmon resonance (SPR) measurement. In addition to the original lysine spacer (**6b**), four variants were introduced by either reducing the number of methylene groups (**6c**−**e**) or extending the lysine spacer with a flexible polyethylene oxide chain (**6a**). These alterations have the effect of varying the distance between adjacent mono-NTAs in the cluster.

Binding Parameters. The binding kinetics of tris-NTA/His6 complex were measured on a Biacore T100 SPR instrument. A customized tris-NTA chip was prepared by coating a Biacore streptavidin chip with biotin−tris-NTA at low surface density (around 50 response units, about 1/6 of the chip surface capacity, illustrated in Figure 2a). The surface density of tris-NTA was kept low to avoid the avidity effect but high enough to allow a good measurement (*18*). The mass transport effect on measured affinity was suppressed by using relatively high flow rate (50 μL/min) and was automatically isolated by the *Biaevaluation T100* program. Typical SPR sensorgrams of the tris-NTA/His6 complex are shown in Figure 3. All the data fit a simple 1:1 binding model well with negligible residue and satisfactory *T* values (>100). The binding parameters of tris-NTA with His6-tagged molecules are summarized in Table 1.

The kinetics data (Table 1) showed that the length of the spacer in tris-NTA has a significant effect on the binding affinity. The general trend is higher affinity and lower instant-off rate for the shorter spacer. The apparent binding affinity toward the same tris-NTA varies for different His6-tagged proteins and His6-peptides, which may relate to the accessibility of the His6-tag. Subnanomolar affinity was reached by **6d**, and no further improvement was achieved by **6e**.

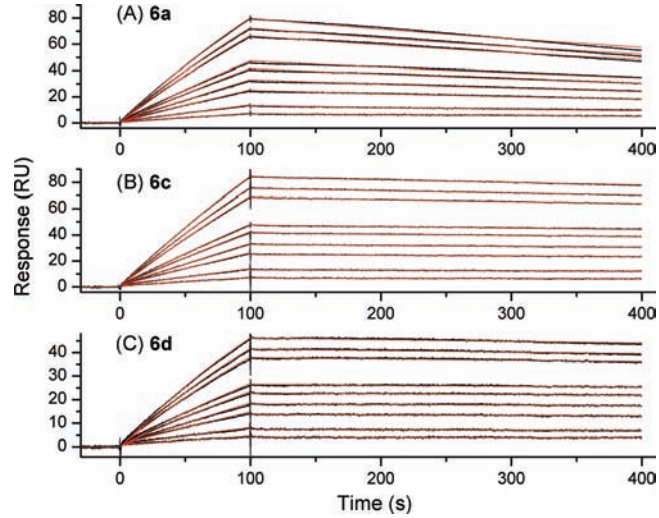

Figure 3. Double-referenced SPR sensorgrams of His6-mKate binding to tris-NTA having various spacer at a series of concentrations (1−10 nM at 1 nM increment excluding 7 nM). Experimental data were globally fitted with a 1:1 binding model. Black line, experimental data; red line, fitted data. The precision of the fitting was estimated by the *T* value that can be interpreted as the signal-to-noise ratio. A *T* value of 100 corresponds to 1% uncertainty. (A) mKate/**6a**, *T* (ka), 100; *T* (kd), 110. (B) mKate/**6c**, *T* (ka), 180; *T* (kd), 240. (C) mKate/**6d**, *T* (ka), 150; *T* (kd), 150.

DISCUSSION

We synthesized a series of biotin−tris-NTA to study the effect of a spacer on the binding affinity of tris-NTA nickel(II) complex toward His6-tagged molecules. The introduction of the biotin moiety in the tris-NTA conjugate allows the preparation of a customized low surface density tris-NTA chip for SPR measurement of the binding kinetics. SPR is a powerful and valid technique to measure molecular interactions in real time (*19*). We have used SPR in a previous study to measure the interaction between tris-NTA and His6-tagged proteins; the binding affinity was consistent with the data determined by the isothermal titration calorimetry (*9, 11*).

To quantify the interaction between multivalent binding pairs, it is important to keep the surface density low to avoid the avidity effect since the apparent affinity of His6 with mono-NTA was dependent on the surface density (*20*). The advantage of a tris-NTA surface over a mono-NTA surface is that tris-

NTA can provide a local high "effective concentration" even at low surface density. In our experiment, the surface density is about one-sixth of the total capacity of the chip and the experimental kinetics data can be globally fitted by a simple 1:1 binding model with very low residue and satisfactory *T* values (>100, indicating less than 1% uncertainty of the calculated data). In addition to low surface density, low analyte concentration is also required to minimize the undesired multisite interactions such as two His6 tags binding to one tris-NTA. Thus, a concentration that leads to maximum signal is not suitable for the 1:1 binding kinetics study on a multivalent binding pair as tris-NTA and His6. After systematic evaluation of the SPR conditions, we determined that 1−10 nM was a good concentration range for the kinetics study. Although quantification of multivalent interactions is still a challenge, we acquired kinetic data as accurate as possible through the combination of a sensitive instrument (Biacore T100) and careful experiment design: this included low surface density, low analyte concentration, and high flow rate.

The focus of current research is to investigate the influence of the spacer length on the binding affinity. We have synthesized tris-NTAs having five different spacers and included five His6-tagged molecules in order to determine if there is a general trend. Although the K_d value varies for different His6-tagged molecules, the trend is clear: as the spacer gets shorter, the affinity is higher. Different proteins have different binding affinities: these differences may arise from the extent of exposure of the His6 tag and other nonspecific interactions that are idiosyncractic for each protein. For example, TSG6 had an abnormally high affinity (0.02 nM, exceeded the detection limit of Biacore T100) toward **6c**. This cannot simply be attributed to the His6/tris-NTA interaction but is probably caused by other structural features of the protein in the vicinity of the local structure of the His6.

The His6-peptide may provide a closer model of the binding between His6 and tris-NTA. The high affinity of **6d** may be partly attributed to the short spacer that results in less conformational entropic cost of association than the flexible long spacers. When the spacer gets even shorter, such as in **6e**, the enthalpy of binding may become less favorable due to the increased steric hindrance and may offset the entropic effect. Thermodynamic studies of the tris-NTA/His6 binding by SPR at various temperatures (data not shown) were inconclusive, and we were unable to determine whether the entropy or enthalpy of binding was the predominant factor leading to the increased affinity. These measurements are most certainly complicated by the conformational change of the His6-tagged protein at different temperatures. Thus, it is difficult to quantify entropy and enthalpy changes of binding in such a complex system by the SPR technique. Nevertheless, it is clear the binding affinity of tris-NTA to His6 tag can be substantially improved by employing a shorter spacer.

Formation of a stable complex is essential to the broad applications of tris-NTA/His6 technology. One major problem in protein−protein interaction studies using the commercial SPR NTA chip is fast baseline drift due to the dissociation of protein immobilized on the surface through mono-NTA/His6 interaction. The new high-density tris-NTA chip (such as coated with **6e**) enables reversible yet stable immobilization of His6-tagged protein with a stable baseline. The high-density tris-NTA is now broadly used by researchers at University of California San Francisco for SPR analysis of various proteins (*21*). Derivatives of high-affinity tris-NTA can also be used to attach His6-tagged molecules to nanoparticles such as carbon nanotubes, gold particles, liposomes, magnetic particles, micelles, and quantum dots.

In conclusion, we have demonstrated that subnanomolar affinity to a His6 tag can be achieved by tris-NTA where the individual NTAs are separated by short spacers. The development of these high-affinity binding pairs opens the avenue to broader applications of His6-tagged molecules with enhanced stability.

Simple and scalable synthesis of 5- and 6-carboxytetramethylrhodamines (TAMRAs) is reported. Acylation of 3-dimethylaminophenol with 1,2,4-benzenetricarboxylic anhydride afforded a mixture of 4-dimethylamino-2-hydroxy-2′,4′(5′)-dicarboxybenzophenones, which can be easily separated into individual compounds upon recrystallization from methanol and acetic acid. Individual benzophenones were reacted with 3-dimethylaminophenol to give 5- or 6-carboxytetramethylrhodamines. The dyes were converted into hydroxyprolinol-based phosphoramidite reagents suitable for oligonucleotide synthesis. 5- and 6-TAMRA isomers on oligonucleotides showed similar absorption and emission spectra. Fluorescence quantum yield of the dyes correlates with the presence of dG nucleosides in the adjacent region of oligonucleotide sequence. Several energy transfer primers containing on their 5′-termini (6-FAM)dT$_n$(6-TAMRA) dye system (n = 0, 2, 4, 6, 8, 10, 12, 14) were prepared, and their spectral properties were studied.

INTRODUCTION

Xanthene fluorescent dye tetramethylrhodamine (TMR, TAMRA) is extremely popular for covalent labeling of various types of biomolecules (*1*−*3*), especially oligonucleotides for various formats of DNA analysis (*4*−*6*). The most convenient compounds for bioconjugation are 5- and 6-carboxy derivatives of tetramethylrhodamine. The mixture of isomers, easily prepared from 3-dimethylaminophenol and trimellitic anhydride (*7*), can be separated by chromatography (*8*) to give individual 5- and 6-isomers suitable for labeling of biomolecules, e.g., DNA (*9*), PNA (*10*), and peptides (*11*). TAMRA-labeled peptide substrates were used for determination of caspase-3 (*12*) and protein kinase (*13*) activity. Recent study showed that TAMRA conjugate with one of the sodium-dependent glucose cotransporter 2 (SGLT2) inhibitors is a 10-fold more potent agent than phlorizin (*14*).

However, more diverse applications have tetramethylrhodamine dye in the field of nucleic acids. Fluorescent properties of TAMRA-labeled oligonucleotides were thoroughly studied (*15*−*18*). The dye attached to the terminal position of an oligonucleotide showed little influence on the duplex stability (*19*). Changes in fluorescence polarization and intensity of singly TAMRA-labeled oligonucleotide probes were used for the monitoring of DNA−protein interactions (*20*−*25*). Fluorescence resonance energy transfer (FRET) dye pair fluorescein−tetramethylrhodamine on oligonucleotides can be used for the measurement of ribonuclease activity (*26*), hydroxyl radical detection (*27*), and in DNA−protein binding studies (*28, 29*). In DNA-related FRET investigations and applications, TAMRA was used as donor (*30*−*32*), acceptor (*33*−*38*), or energy bridge (*39*−*42*). The dye is an important label in four-color DNA sequencing (*43*−*48*). Many real-time PCR platforms have spectral channels suitable for TAMRA (*49*), and it is a standard reporter (*50*−*52*) or quencher (*53, 54*) dye for real-time PCR probes.

The widespread popularity of tetramethylrhodamine dye requires highly producible and easy scalable methods for the preparation of isomerically pure carboxytetramethylrhodamines. These would be suitable for the preparation of phosphoramidite reagents that can be automatically incorporated into oligonucleotides. Although several 5′-TAMRA and TAMRA-dT phosphoramidites for terminal and internal labeling are commercially available (*55, 56*), only two TAMRA phosphoramidite reagents have been described in the literature in detail (*57, 58*). Their disadvantage is that they are terminal, i.e., can be attached exclusively to the 5′-position of an oligonucleotide. On the other hand, phosphoramidites and solid supports derived from (3*R*,5*S*)-5-hydroxymethyl-3-hydroxypyrrolidine (*trans*-L-4-hydroxyprolinol) allow one to introduce modification into any position of an oligonucleotide (*59*−*72*). Hence, the aims of the present work are the development of a simple and easily scalable procedure for the synthesis of 5- and 6-carboxytetramethylrhodamines, the synthesis of phosphoramidite reagents from both isomers using

trans-L-4-hydroxyprolinol as a scaffold, and the study of spectral and photophysical properties of TAMRA-labeled oligonucleotides.

EXPERIMENTAL PROCEDURES

General. Reagents and solvents obtained from commercial suppliers were used without further purification. CH_2Cl_2 was used freshly distilled from CaH_2. HPLC-grade DMF was distilled under reduced pressure and stored over 4 Å molecular sieves under argon. Other solvents were used as received. *N*,*N*-Diisopropylamino-2-cyanoethoxychlorophosphine (*73, 74*), trimethylsilyl polyphosphate solution in chloroform (*75*), and (3*R*,5*S*)-5-[(4,4′-dimethoxytrityl)oxymethyl]-3-hydroxypyrrolidine (*69*) were prepared as described. 500 MHz ^{1}H, 125.7 MHz ^{13}C, and 202.4 MHz ^{31}P NMR spectra were recorded on a Bruker DRX-500 or Bruker Avance 500 spectrometers and referenced to $CDCl_3$ (7.26 ppm for ^{1}H and 77.1 ppm for ^{13}C), DMSO-d_6 (2.50 ppm for ^{1}H and 39.5 ppm for ^{13}C), CD_3CN (1.94 ppm for ^{1}H and 118.3 ppm for ^{13}C) (*76*), and 85% aq H_3PO_4 (0.00 ppm for ^{31}P). ^{1}H NMR coupling constants are reported in hertz (Hz) and refer to apparent multiplicities. High-resolution mass spectra (HRMS) were recorded in positive-ion mode using an IonSpec FT ISR mass spectrometer (MALDI) or PE SCIEX QSTAR pulsar mass spectrometer (ESI). Melting points were determined using a Boetius heating table and are uncorrected. Analytical thin-layer chromatography was performed on Kieselgel 60 F_{254} precoated aluminum plates (Merck); spots were visualized under UV light (254 nm). Silica gel column chromatography was performed using Merck Kieselgel 60 0.040−0.063 mm. The oligonucleotide synthesis was carried out on a BiosSet ASM-800 instrument on a 200 nmol scale using standard manufacturer's protocols. Oligonucleotides were isolated using electrophoresis in 20% denaturing (7 M urea) PAGE in Tris-borate buffer, pH 8.3, and desalted by gel filtration on a Sephadex G-25 column in 1×10^{-5} M Tris-HCl buffer, pH 7.5 ("saltless" buffer). MALDI-TOF mass spectra of oligonucleotide conjugates were recorded in positive-ion mode on a Bruker Ultraflex spectrometer. UV absorption spectra were recorded using a Varian Cary 500 spectrophotometer in 0.1 M bicarbonate buffer (pH 8.5). Fluorescence studies in the same buffer were performed using a Solar CM 2203 spectrofluorometer. Rhodamine 6G (R6G) in ethanol was used as a quantum yield standard. The fluorescence quantum yields (Φ_f) were calculated using the relative method according to the equation

$$\Phi_f = \Phi_{f(\mathrm{R6G})} \times \frac{I}{I_{\mathrm{R6G}}} \times \frac{A_{\mathrm{R6G}}}{A} \times \frac{n^2}{n_{\mathrm{R6G}}{}^2}$$

where $\Phi_{f(\mathrm{R6G})}$ is rhodamine 6G quantum yield in ethanol ($\Phi_{f(\mathrm{R6G})} = 0.94$ (*77*)); I and I_{R6G} are integrated intensities of sample and R6G dye solutions, respectively; A and A_{R6G} are optical densities of sample and R6G dye solutions, respectively; n and n_{R6G} are refractive indexes of ethanol and 0.1 M bicarbonate buffer, 1.3591 and 1.3340 at 20 °C, respectively. The measurements were performed at an angle of 90° to the exciting light beam. The optical density of the solutions in the 1 cm quartz cell at the excitation wavelength did not exceed 0.05. The samples used in quantum yield measurements were not degassed.

4-Dimethylamino-2-hydroxy-2′,4′(5′)-dicarboxy-benzophenones (1a,b). Freshly distilled 3-dimethylaminophenol (13.70 g, 0.10 mol) was dissolved in toluene (300 mL), heated to 60 °C, and pounded trimellitic anhydride (23.04 g, 0.12 mol) was added with magnetic stirring. The mixture was refluxed for 24 h and cooled. The residue was filtered off, washed with toluene (3×50 mL), dissolved in MeOH (300 mL), and refluxed for 10 min. Then, acetic acid (100 mL) was added and the mixture was evaporated to dryness. Crystalline solid was refluxed with MeOH (200 mL) for 2 h and kept at 4 °C overnight. The crystals formed were filtered off and washed with MeOH (50 mL) to give pure **1a** as brown crystalline solid (5.16 g, 16%). The mother liquid was evaporated to dryness, refluxed 1 h with acetic acid (150 mL), and stored at room temperature overnight. Crystals were filtered off and dried *in vacuo* at 115−120 °C to give mixture **1a**,**b** (9.66 g). This was recrystallized twice from acetic acid to give pure **1b** as a yellow crystalline solid (3.35 g, 10%). Filtered solutions can be combined, evaporated, and recrystallized succesively from MeOH and AcOH as above to give further amounts of individual **1a** and **1b**.

Carboxytetramethylrhodamines (*2a,b*); General Procedure. Benzophenone **1a**(**1b**) (3.29 g, 10.00 mmol) was mixed with 3-dimethylaminophenol (1.78 g, 13.00 mmol) and dissolved in DMF (80 mL). Trimethylsilylpolyphosphate solution in chloroform (20 mL) was added, and the mixture was refluxed for 3 h. Solvents were removed *in vacuo*; the residue was dissolved in 5% NaOH (70 mL) and stirred at room temperature overnight. Then, the solution was diluted with water (150 mL), and rhodamine was precipitated with concentrated hydrochloric acid (ca. 5 mL). The solid was filtered off, washed with water (50 mL), and dried *in vacuo* at 150 °C. Yields: 4.25 g, 99% of **2a**, or 4.27 g, 99% of **2b**. Carboxytetramethylrhodamines **2a**,**b** were used in the next step without additional purification. Analytical samples were purified on preparative silica gel TLC in Et_3N−MeOH−$CHCl_3$ 5:15:80 v/v/v as a mobile phase and characterized as triethylammonium salts.

RESULTS AND DISCUSSION

Like others rhodamine dyes, tetramethylrhodamine can exist in two tautomeric open-chain and lactone forms (Chart 1).

The fluorescent open-chain structure prevails in polar protic media, whereas in aprotic solvents, the dye becomes nonfluorescent switching to spirolactone form. It is worth noting that the alteration in tautomeric structure changes the numbering system. The major ring system in the open-chain form is xanthene changing to isobenzofuran in the lactone form (Chart 1). Thus, carboxyrhodamines derived from trimellitic anhydride are usually known as 5(6)-derivatives corresponding to spirolactone form. Actually, in cases these dyes exist in open-chain form: their correct name is 4′(5′)-derivatives.

Carboxytetramethylrhodamines can be easily obtained as a mixture of 5- and 6- isomers. However, in many analytical applications individual isomers are preferred. In a previous communication (*78*), we described an easy method for chromatographic separation of multigram quantities of 5(6)-carboxyfluorescein derivatives. The chromatographic technique (*8*) for the separation of 5(6)-carboxytetramethylrhodamines in our hands turned out to be ineffective: we were able to separate less than 1 g of isomeric mixture in one run. We found the method hardly scalable and not applicable for multigram synthesis of single TAMRA isomers.

In the present paper, we report a convenient procedure for the synthesis of isomerically pure carboxytetramethylrhodamines using a two-step approach (Scheme 1) with crystallization as a key stage leading to separation of isomers.

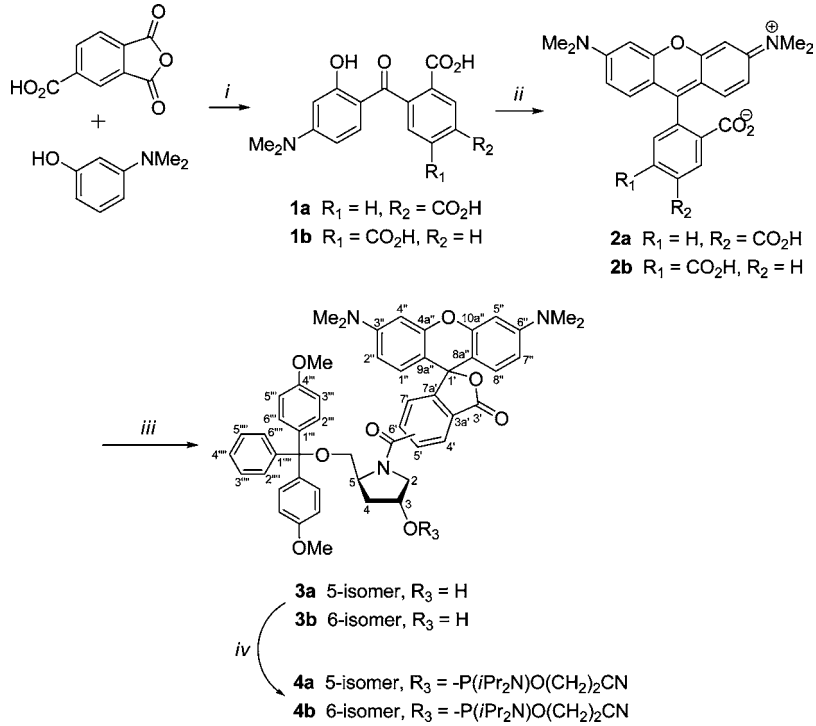
Benzophenones **1a**,**b** are easily available from trimellitic anhydride and 3-dimethylaminophenol by refluxing in toluene (*79*). After filtration, the crude mixture of benzophenones was obtained as an amorphous solid. Dissolving it in methanol and evaporation with addition of acetic acid promoted crystallization. The solubilities of benzophenones **1a** and **1b** in methanol differ significantly: **1a** is slightly soluble, whereas **1b** dissolves well. In that way, the major part of benzophenone **1a** was separated from the mixture by simple extraction **1b** with methanol. Evaporation of extract enriched with **1b** followed by double crystallization of the residue from acetic acid afforded pure 5′-carboxy substituted benzophenone **1b**. The simple, direct method using inexpensive starting compounds gives 16% of **1a** and 10% of **1b** together with mixture **1a**+**1b** (ca. 20%), suitable for further fractional crystallization. The procedure can be scaled up several times without difficulty.

The structures of isomeric benzophenones **1a**,**b** were determined using 2D ^{1}H−^{13}C HSQC and HMBC NMR techniques. Here, we consider signal assignment for benzophenone **1b** (the resulting ^{13}C NMR shifts assignment is shown in Chart 2). There are signals of two 1,2,4-trisubstituted benzene systems seen in the proton NMR spectrum of this compound (Figure 1A): one has signals at 6.11, 6.22, and 6.86 ppm with constants ^3J = 9.3 Hz and ^4J = 2.5 Hz; another one has shifts 7.83, 8.03, and 8.15 ppm and constants ^3J = 8.3 Hz and ^4J = 1.7 Hz. The direct correlation HSQC (Figure 1B) shows carbons attached to protons. The next step is the assignment of phenolic ring carbons. In the HMBC spectrum, the phenolic proton O*H* at 12.41 displays cross-peaks with carbon signals at 97.08, 109.43, and 164.40, which apparently belong to carbons 1, 2, and 3 (Figure 1C). Only the carbon at 97.08 is bound to a proton, evidently being C3. Thus, the high field proton system belongs to the phenolic ring, and the low field system is protons of the phthalic acid. From HSQC (Figure 1B), the assignment of C5 and C6 is clear. HMBC correlation of protons 3 and 5 shows that the signal at 109.43 originates from C1 (Figure 1D). Therefore, the signal at 164.40 belongs to C2. HMBC correlation of methyl protons (data not shown) allows assignment of C4. The assignment of C2 and C4 is confirmed by cross-peaks from H6 (Figure 1E). Thus, the assignment of carbon signals of the phenolic ring is complete. The carbonyl signal at 197.40 in HMBC spectrum gives cross-peaks with H6 and H6′ (Figure 1F). The assignment of C3′ and C4′ arises from the HSQC spectrum (Figure 1B). The assignment of closely located signals at 133.65 and 133.73 is carried out using the HMBC spectrum (Figure 1G). The signal at 133.73 displays cross-peaks with protons H4′ and H6′ thus coming from C2′. The signal at 133.65 gives a cross-peak with H3′ and is therefore C5′. Hence, the substitution pattern in the benzene ring is unambiguous: carboxyl groups are located in 2′- and 5′-positions. The assignment of carboxylic carbons is performed using cross-peaks in HMBC spectrum (Figure 1E): the carboxyl signal at 166.10 gives cross-peaks with H4′ and H6′ thus arising from 5′-carboxyl. The signal at 166.53 shows a cross-peak with H3′ and is therefore assigned as 2′-carboxyl.

The core of tetramethylrhodamine was assembled by refluxing **1a** or **1b** with an additional equivalent of 3-dimethylaminophenol in DMF using trimethylsilylpolyphosphate as a dehydrating agent and weak acid catalyst (*80, 81*). The resulting pure isomers of tetramethylrhodamine were obtained in almost quantitative yields and were used without additional purification. Thus, the two-step assembly method of tetramethylrhodamines allows us to obtain multigram quantities of isomerically pure dye in one run avoiding column chromatography. Carboxytetramethylrhodamines can be converted further into various useful derivatives: oxysuccinimide, maleimide, biotin, acetylene, azide, and so forth.

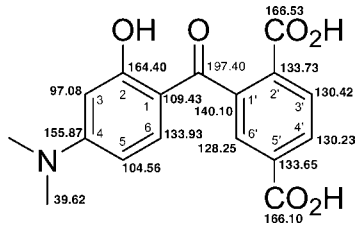
To demonstrate the utility of isomerically pure tetramethylrhodamines, two phosphoramidite reagents for the labeling of oligonucleotides in automated solid-phase synthesis were prepared. Acids **2a**,**b** were reacted with (3*R*,5*S*)-5-[(4,4′-dimethoxytrityl)oxymethyl]-3-hydroxypyrrolidine (*69*) using benzotriazol-1-yloxy-tris(pyrrolidino)phosphonium hexafluorophosphate (PyBOP) as a coupling reagent to afford amides **3a**,**b** in satisfactory yields. The phosphitylation of secondary alcohols **3a**,**b** with bis(*N*,*N*-diisopropylamino)-2-cyanoethoxyphosphine

Scheme 1[a]



[a] Reagents and conditions. *i*, PhMe, reflux, 24 h, 16% (**1a**), 10% (**1b**); *ii*, 3-dimethylaminophenol, trimethylsilylpolyphosphate, DMF, reflux, 3 h, 99% (**2a**), 99% (**2b**); *iii*, (3*R*,5*S*)-5-[(4,4′-dimethoxytrityl)oxymethyl]-3-hydroxypyrrolidine, PyBOP, DIEA, DMF, 2 h, 60% (**3a**), 46% (**3b**); *iv*, bis(*N*,*N*-diisopropylamino)-2-cyanoethoxyphosphine, diisopropylammonium tetrazolide, CH_2Cl_2, 1 h, 73% (**4a**), 47% (**4b**). For compounds **3a**,**b** and **4a**,**b**, the shown numbering is used for NMR assignments.

Chart 2. ^{13}C NMR Shifts in Benzophenone 1b (solvent DMSO-d_6)



in the presence of diisopropylammonium tetrazolide gave the desired phosphoramidites **4a**,**b**. The structures of the compounds were confirmed by ^{1}H, ^{13}C, and ^{31}P NMR spectra and by high-resolution mass spectra (HRMS). For the tetramethylrhodamine derivatives **2**−**4**, the assignment of ^{1}H and ^{13}C signals in NMR spectra was accomplished using 2D ^{1}H−^{1}H COSY and ^{1}H−^{13}C HSQC and HMBC techniques. In ^{13}C spectra, we observed the signal of C1-atom in compounds **2a**,**b** at ∼160 ppm (when dissolved in polar d_4-MeOD); however, it completely disappears (in compounds **3** and **4**) when dissolving in aprotic solvents $CDCl_3$, CD_3CN, or DMSO-d_6 due to the fast equilibrium process between lactone and open-chain forms (Chart 1).

Reagents **4a**,**b** were tested in automated oligonucleotide synthesis. TAMRA phosphoramidites **4a**,**b** are readily soluble in dry acetonitrile and were used as 0.1 M solutions. They reacted well with hydroxy groups of a growing oligonucleotide in tetrazole-assisted coupling conditions. The reaction time for **4a**,**b** was increased from 20 s to 7.5 min to achieve maximum coupling yield. After capping and oxidizing steps, the last dimethoxytrityl group was removed and coupling yield was estimated to be >95%. Using phosphoramidites **4a**,**b** oligonucleotides **ON1**−**ON4** carrying tetramethylrhodamines on 5′-terminus (Table 1) were synthesized. Reagent **4b** was also applied for the synthesis of the oligomer **ET**- and energy transfer oligonucleotides **ET0**−**ET14** carrying 6-TAMRA label in internal position and 6-FAM label (*78*) on the 5′ terminus (Chart 3). Similar energy transfer probes with poly-T linker between donor and acceptor dyes can be applied for construction of wavelength-shifting molecular beacons (*82*, *83*). Oligonucleotides were cleaved from solid support and deprotected by "TAMRA-cocktail"—*t*BuNH$_2$/MeOH/H$_2$O 1:1:2 mixture (*84*). Conjugates obtained were purified by PAGE and characterized by MALDI-TOF, UV−vis, and fluorescence spectra (Tables 1, 2, and Figures 2, 3).

Previous study of fluorescein-labeled oligonucleotides (*78*) showed that absorption spectra of 5- and 6-FAM-labeled oligonucleotides do not differ significantly, whereas in fluorescence spectra, the 5-isomer displays a 3−5 nm red shift against 6-isomer and emission band in the spectrum of 5-FAM is substantially broader. Like FAM-labeled oligonucleotides, different isomers of TAMRA show differences in fluorescence spectra but they are not so evident. 5-TAMRA on an oligonucleotide displays only 1−3 nm red shift vs 6-isomer. The emission band in the spectrum of 5-TAMRA is slightly broader (Figure 2).

Fluorescence quantum yield of the dye in TAMRA-labeled oligonucleotides is sequence dependent (Table 1). It is well-known that guanine residues quench fluorescence if they are near fluorescent label (*85*, *86*), this is also the case for TAMRA (*17*, *18*). Data show that quantum yield of TAMRA-labeled oligonucleotides **ON1**−**ON4** correlates with the presence or absence of guanine residues in proximity to the TAMRA label. The highest quantum yield (0.69) is observed for conjugate **ON1b** with no neighbor guanine. The conjugate **ON2b** with three closely located adjacent guanines shows decreased quantum yield (0.29). There are no significant differences in quantum yields between 5- and 6-isomers of carboxytetramethylrhodamines on oligonucleotides.

The synthesis of energy transfer primers **ET0**−**ET14** (Chart 3) demonstrates the internal labeling of oligonucleotides. The conjugates are 5′-labeled with the combined fluorophore (6-FAM)-(dT)$_n$(6-TAMRA) and their formal Stokes shift is ca. 85 nm (Table

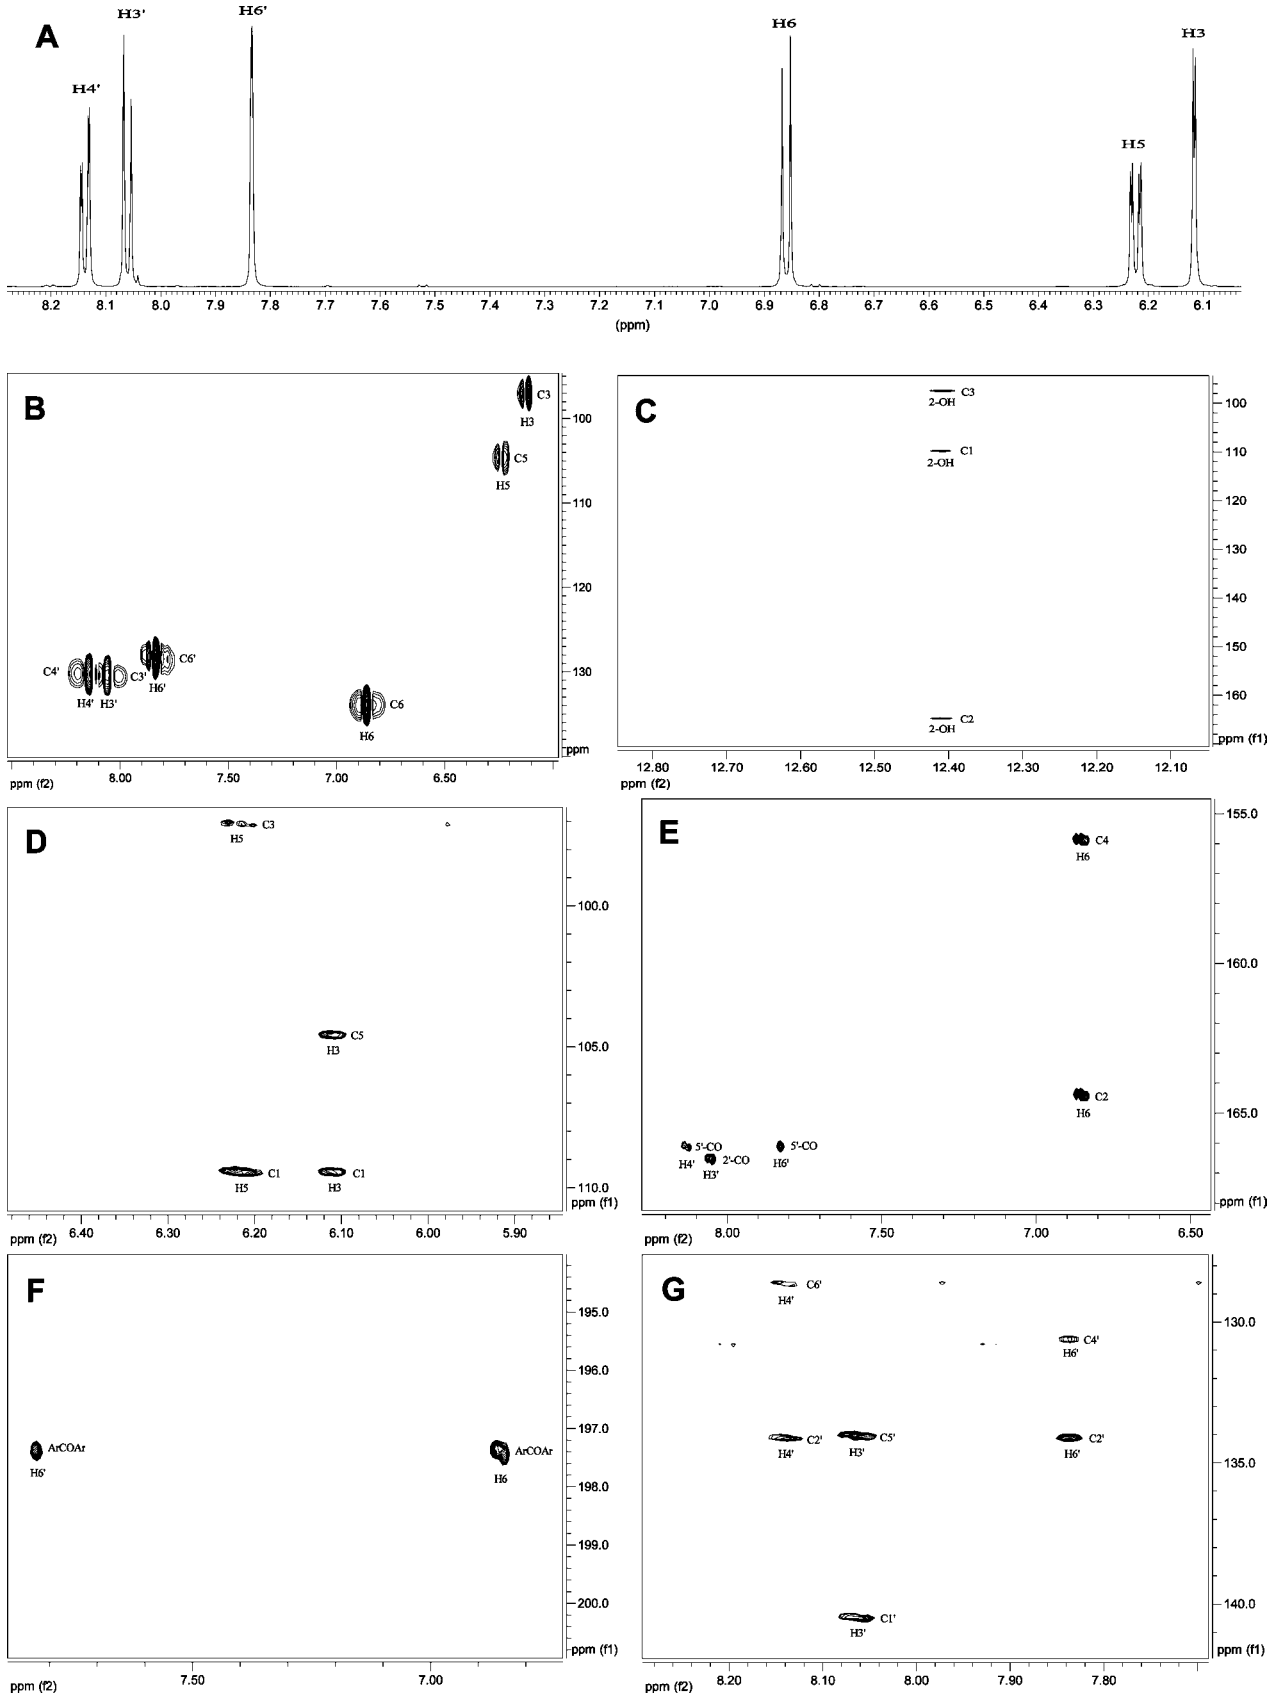


Figure 1. NMR spectra of benzophenone **1b**. (A) Proton spectrum of aromatic region; (B) $^{1}H-^{13}C$ HSQC spectrum of the aromatic region; (C−G) fragments of $^{1}H-^{13}C$ HMBC spectrum.

2). For detection purposes, FAM dye is usually excited at 480 nm; thus, the difference between FAM excitation and TAMRA emission (580−583 nm) for **ET** conjugates is about 100 nm.

The efficiency of energy transfer from donor to acceptor depends on the spacing between them (*37*, *87*, *88*). Increasing the length of the oligo-dT spacer decreases the quenching of the FAM label,

and its emission at 519 nm rises nearly linearly from **ET0** to **ET14** (Figure 3a). The behavior of the emission intensity of TAMRA label is more complicated. The spacer is very important for the intensity of TAMRA fluorescence: the insertion of $(dT)_2$ between dyes increases the acceptor emission of **ET2** four times in comparison to **ET0**. Maximal values of TAMRA emission are observed for conjugates **ET6**, **ET8**, and **ET10**—their emission is 16 times more intense as compared to single TAMRA label excited at 480 nm in conjugate **ET-** (Table 2, Figure 3a). The values are higher than expected, because the combined chromophore absorbance at the excitation wavelength 480 nm increases only ca. 10 times ($\varepsilon_{480(FAM)} + \varepsilon_{480(TAMRA)}/\varepsilon_{480(TAMRA)} = 10.5$).

The highest TAMRA/FAM (581 nm/519 nm) emission intensity ratio was observed for **ET2**, not for **ET0** (7.9 vs 5.2). The same behavior of the acceptor intensity was mentioned in other investigations when donor−acceptor distances were too close (*37, 87*). When two dyes appear in proximity, a contact quenching occurs, and the emission of both the donor and the acceptor diminishes. However, the insertion of a few nucleosides between two dyes prevents such a contact quenching; even with a spacer of two

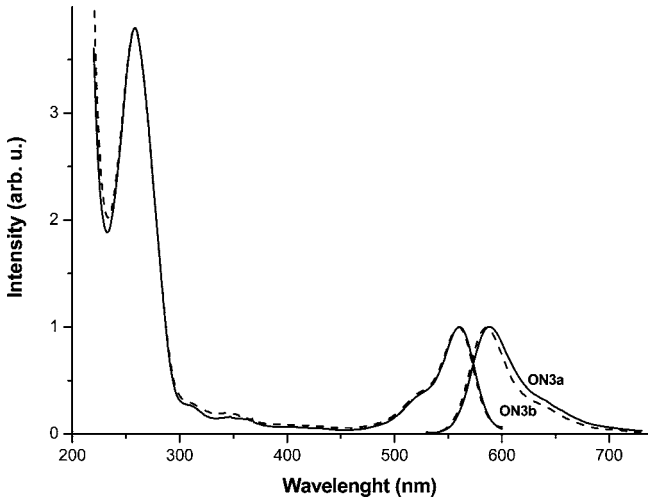

Figure 2. Normalized absorption (left) and fluorescence (right) spectra of conjugates **ON3a** (straight lines) and **ON3b** (dashed lines) in 0.1 M bicarbonate buffer (pH 8.5), excitation at $\lambda = 525$ nm.

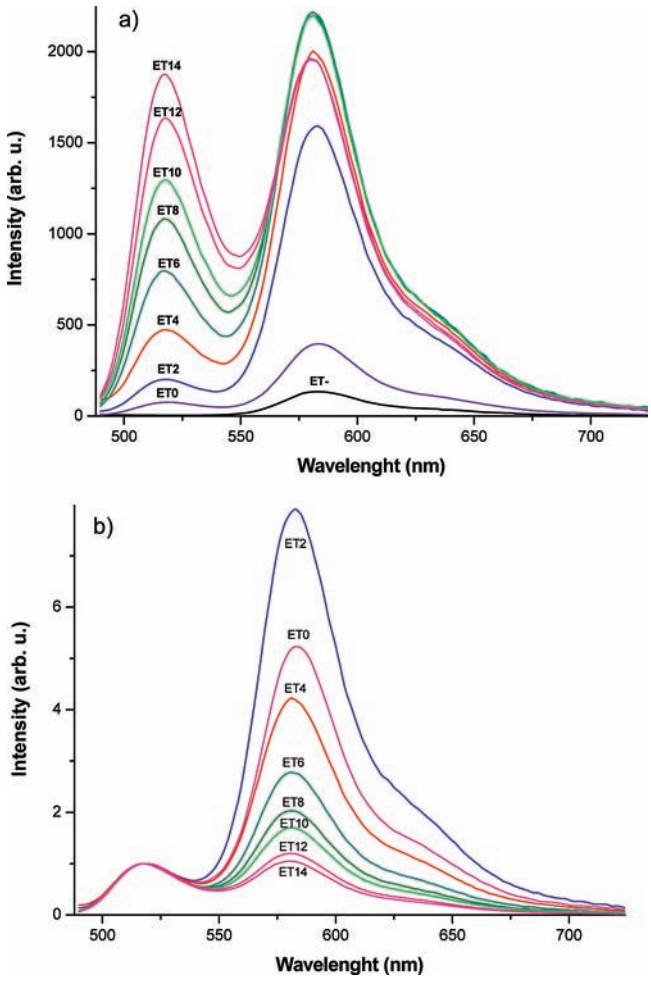

Figure 3. (a) Fluorescence spectra of oligonucleotides **ET-** and **ET0...ET14** in 0.1 M bicarbonate buffer (pH 8.5), excitation at $\lambda = 480$ nm, concentration 6×10^{-7} M; (b) fluorescence spectra of oligonucleotides **ET0...ET14** normalized to 6-FAM fluorescence maximum (519 nm).

nucleosides, no other interaction than dipole−dipole was observed within the donor−acceptor dye pair (*88*).

The TAMRA/FAM intensity ratio decreases rapidly in the series **ET2...ET14** (Table 2, Figure 3b). Conjugate **ET2** emits 90% of the integral light energy in the TAMRA fluorescence band (550−650 nm), and 10% in the FAM band (500−550 nm). However, the overall emission efficiency of the absorbed light (FAM emission + TAMRA emission) decreases in the series **ET14** > **ET12** ≈ **ET10** > **ET8** > **ET6** > **ET4** > **ET2** ≫ **ET0** (Figure 3a). Thus, conjugates **ET6**−**ET10** showed highest TAMRA emission, **ET14** the highest FAM+TAMRA overall emission, and **ET2** the highest TAMRA/FAM emission intensity ratio. The data may appear useful for design of energy transfer primers and probes.

To conclude, we have developed a simple and scalable procedure for the preparation of individual isomers of carboxytetramethylrhodamines, described hydroxyprolinol-based TAMRA phosphoramidite reagents containing individual dye isomers, prepared a series of oligonucleotides 5′- and internal labeled with carboxytetramethylrhodamines, and compared spectral and photophysical spectra of TAMRA−oligonucleotide conjugates. We also showed that in energy transfer primers the optimal spacer between donor (FAM) and acceptor (TAMRA) dyes for maximum acceptor fluorescence should contain 6−10 dT nucleotides.

ACKNOWLEDGMENT

The research was supported by BFBR (project B06R-004) and RFBR (projects 06-04-81019 and 08-03-90900). We thank Primetech ltd. (Minsk, Belarus) for the synthesis of labeled oligonucleotides, Alexander Peregudov for NMR spectra, Alexander Baranovsky and Alexey Ustinov for helpful discussion, and anonymous referees for their useful comments.

Proteolysis: A Biological Process Adapted in Drug Delivery, Therapy, and Imaging

Benedict Law*,† and Ching-Hsuan Tung‡

Department of Pharmaceutical Sciences, North Dakota State University, Fargo, North Dakota 58105, and The Methodist Hospital Research Institute, Weill Cornell Medical College, Houston, Texas 77030. Received November 19, 2008; Revised Manuscript Received January 15, 2009

In many diseases, protease expressions are found deregulated when compared with them at the healthy states. The unique ability to hydrolyze protein amide bonds has made those deregulated proteases attractive biological triggers in drug development. Proteolysis has been widely applied in pro-drug design to achieve favorable pharmacokinetics. Controlled drug delivery systems are also reported by incorporating protease-sensitive motifs onto bio-, inorganic-, or organic- materials. In addition, protease responsive molecular probes are developed for in vitro bioanalysis and in vivo diagnostic imaging. This review focuses on various proteolysis-dependent approaches to drug delivery, therapy, and imaging. References are selected to illustrate the concepts and demonstrate the potentials of these enzyme-responsive strategies.

INTRODUCTION

Proteolysis is a simple hydrolytic process that separates two adjacent amino acid residues at the amide bond, aided by proteases (or proteinase). Without the catalytic assistance of protease, protein hydrolysis is a very slow process. Proteolytic activities are tightly regulated through various mechanisms. For example, intracellular proteolysis is regulated by segregation within organelles such as lysosomes. Some proteases are expressed as pro-enzymes, while others are complexed with natural enzyme−inhibitors. Their enzymatic properties can be restored only when they are in demand. As disease initiated, misregulation of enzymatically active proteases or launching of new foreign proteases can occur, resulting in various host responses.

Diseases can be controlled by stopping or slowing disease-associated abnormal proteolysis. Protease inhibitors have a long history as therapeutic agents. Synthetic inhibitors targeting various proteases have been developed and clinically used in treating a large variety of diseases (*1*). Cancer is a well-known example. Protease inhibitors against matrix metalloproteinases (MMP) have been proposed to control tumor growth; unfortunately, the outcomes were not as originally expected (*2*). Beyond cancer, protease inhibitors have been applied or proposed for treating diseases such as thrombosis (*3*), hypertension (*4*), diabetes (*5*), cognitive disorders (*6*), infectious diseases (*7*), and others. Clinically approved protease inhibitors have supported

Table 1. Examples of Amino Acid and Peptide Caged Prodrugs That Are Activated by Their Target Proteases[a]

active drug metabolite	conjugated peptide-substrate	target protease	disease
Doxorubicin	L (*13*)	cathepsin B	cancer
Methotrexate	A (*20*)	carboxypeptidase	cancer
Methotrexate	Pyroglutamyl (*21*)	aminopeptidase	cancer
Amiloride	LFGGGG (*143*)	enkephalinase	ischemia
Cyclopamine	SSKYQ (*144*)	PSA	cancer
Doxorubicin	BLAL (*25*)	TOP	cancer
	PLGL (*32*)	MMP-2, MMP-9	cancer
		plasmin	cancer
	aFK (*145*)		
Fluorodeoxyuridine	HSSKLQL (*34*)	PSA	cancer
Gentamicin	GfPRGFPAGG (*70*)	thrombin	infection
Methotrexate	Pyr (*21*)	PYA	cancer
	aFKK (*146*)	cathepsin, plasmin	arthritis
Paclitaxel	aFK, vLK (*38*)	plasmin	cancer
Thapsigargin	HSSKLQL (*35*)	PSA	cancer
Vinblastine	Hyp-SS-Chg-QSSP (*33*)	PSA	cancer

[a] Note: The small letters in the peptide sequences indicate that particular amino acids are in D-configuration. All amino acid derivatives are shown by a group of three italics. Abbreviations: Chg, L-cyclohexylglycine; Hyp, trans-4-hydroxy-L-proline; PSA, prostate specific antigen; PYA, pyrogluatmate aminopeptidase; Pyr, L-pyroglutamic acid; TOP, thimet oligopeptidase.

the original hypothesis that active site blocking could relieve, correct, or slow disease progress.

In contrast, since upregulated proteolysis is often seen during disease progression, instead of blocking its catalytic property, proteolysis has been proposed as a unique in vivo process to assist therapy and diagnosis. Numerous approaches based on proteolysis have been crafted to manage diseases; for example, prodrugs are designed to be activated by proteases, delivery systems are constructed to release drugs in a controllable manner, and molecular reporters are prepared to be protease sensitive for disease detection and imaging.

APPLICATIONS OF PROTEOLYSIS

Protease-Activatable Prodrug. The rationale behind prodrug design is to improve bioactivity and/or bioavailability of a therapeutic agent. A prodrug generally has minimal pharmacological effect in its native form, but can be converted to its active pharmacophore when triggered in vivo. The concept of prodrugs is not new. For example, enalapril, an antihypertensive precursor of enalaprilat, was chemically modified to improve its absorption from the gastrointestinal tract (*8*), and capecitabine was designed to reduce the adverse effects of its cytotoxic metabolite, 5′-fluorouracil (FU) (*9*). Rational prodrug design requires an extensive knowledge of chemical entities that are likely to alter resulting pharmacokinetic properties. In addition, a profound understanding of disease molecular pathologies and their heterogeneities versus normal health states helps to identify potential activators. As mentioned, excessive proteolysis is involved in many diseases such as cancer, cardiovascular injury, and inflammation; thus, disease-associated proteases are attractive targets for pro-drug developments. In fact, numerous protease-activatable prodrugs have been reported (*10*, *11*), while the majority have been developed for cancer treatment (*12*) (Table 1).

Amino Acid Caged Prodrugs. To design a protease-activatable prodrug, a single amino acid or a dipeptide can simply be attached to a free drug via the formation of an amide bond; the resulting conjugate (prodrug) with significantly reduced potency can be hydrolyzed by selective aminopeptidase later to generate clinically effective metabolite (Figure 1A). L-Leucyl-doxorubicin is an early example developed in the 1980s (Figure 1B) (*13*). It is four times less toxic than its parent doxorubicin and has been shown to reduce cardiotoxicity in preclinical studies (*14*−*16*). Several studies of human breast, lung, and ovarian tumor

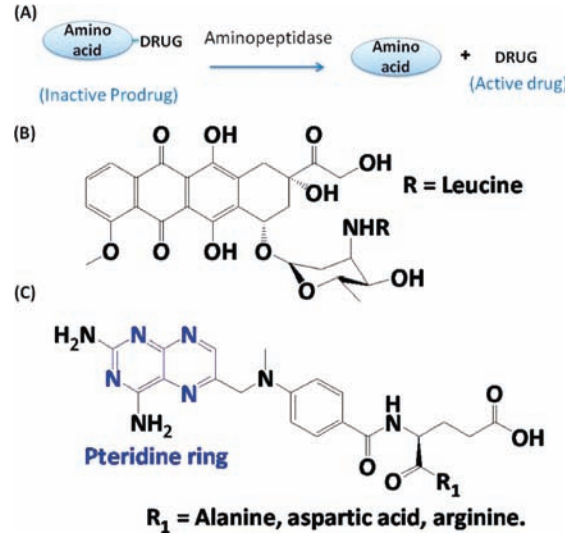

Figure 1. (A) Schematic presentation of an amino acid−drug conjugate activated by aminopeptidase. (B) The chemical structure of L-leucyl-doxorubicin. Leucine is covalently conjugated to the aminoglycoside portion of doxorubicin (*13*). (C) The chemical structure of various 2-α-carboxyl methotrexate derivatives (*21*).

xenografts demonstrated that L-leucyl-doxorubicin had not only a better therapeutic index, but also a greater efficacy than doxorubicin (*17*, *18*). A high concentration of active metabolite doxorubicin was found in tumor cells, suggesting that the enzymatic cleavage of L-leucyl-doxorubicin takes place either on the surface inside of the tumor cells. Tissue peptidases such as cathepsin B have been proposed to be the responsible activators (*19*). Prodrugs with a similar strategy have also been described for methotrexate (*20*). Amino acids such as alanine, aspartic acid, and arginine were conjugated to the α-carboxyl of methotrexate via an amide linkage (Figure 1C). Ex vivo studies indicated that the resulting alanine-conjugate was 100 times less toxic than its parent drug. On the other hand, cytotoxicity was greatly enhanced by carboxypeptidase activation. Protease selectivity could be altered by modifying a different position on methotrexate (*21*). A series of 2-L-leucyl, 2-L-valyl, 2-L-isoleucyl, and 2-L-pyroglutamyl methotrexate conjugates were synthesized by attaching the corresponding amino acids to the NH_2-group at the 2-position of the pteridine ring (*21*). Among all of these, 2-L-pyroglutamyl analogue was considered the best drug candidate, as it can be selectively activated by pyroglutamate aminopeptidase but is resistant to nonspecific enzymatic degradation in serum.

Peptide Caged Prodrugs. Although the amino acid caging approach shows promise, the prepared prodrugs are not stable enough in circulation. With L-leucyl-doxorubicin as an example, pharmacokinetic studies have shown that leucyl-doxorubicin was rapidly converted into free doxorubicin in plasma compartment (*19*). Its superior therapeutic efficacy over doxorubicin is most likely due to the higher accumulation of this metabolite (free doxorubicin) in tumor than in normal tissue. To design a more stable prodrug, a tetrapeptide conjugate, BLAL-doxorubicin (B = β-alanine), was synthesized (Figure 2) (*22*). The β-alanine at the N-terminus was incorporated to improve stability in blood. In vitro and in vivo studies with a similar prodrug analogue, *N*-(succinyl)-BLAL-doxorubicin (CPI-0004Na), have shown that extracellular activation is a multistep process (*22*−*24*): (1) The prodrug was first hydrolyzed extracellularly into AL-doxorubicin. This process was also proven to be the rate-limiting step; (2) AL-doxorubicin was subsequently cleaved into leucyl-doxorubicin; and (3) it finally entered the cell and was converted into fully active doxorubicin. Thimet oligopeptidase (TOP) and

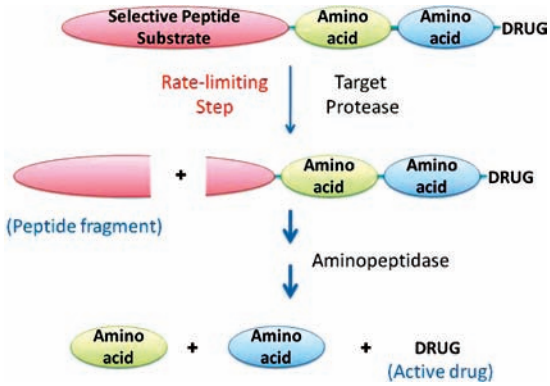

Figure 2. Schematic presentation of a peptide−prodrug conjugate activated by multiple proteases. Prodrug acylated with a specific peptide substrate is cleaved by its target protease, and the remaining peptide−drug intermediates can be further digested by different aminopeptidases to release the free drug.

neprilysin (CD10) were identified as the responsible initial activators (*25*, *26*).

However, the choice between aminopeptidase and carboxypeptidase is limited; more sequence selectivity would be favored to achieve disease-specific prodrug activation. Using the same construct as shown in Figure 2, conjugating longer specific peptide substrates recognized by endopeptidases to an active pharmacophore has been done to obtain better protease selectivity. Peptide-caged prodrugs activated by plasmin (*27*−*29*), MMPs (*30*−*32*), and prostate-specific antigen (PSA) (*33*−*36*) have all been reported.

In some cases, proteases do not accept a complex pharmacophore directly attached to the end of a peptide sequence. For example, in the early 1980s, vLK-doxorubicin prodrug was developed to treat cancer, but it turned out to be a poor substrate for plasmin, resulting in an unfavorable therapeutic effect, probably because of steric hindrance. To overcome this problem, self-immolative linkers were inserted between the peptide substrate and the drug molecule (*37*). Two types of self-immolative systems are known: electronic cascade spacers and cyclization spacers. Paclitaxel prodrugs prepared with both spacers have been reported (*38*). *p*-Aminobenzyl oxycarbonyl (PABC) and monomethylated ethylene diamine (MED) were employed as electronic cascade and cyclization spacers, respectively (Figure 3). Both conjugated prodrugs, which have significantly decreased cytotoxicity, could be readily activated by plasmin, followed by spontaneous spacer elimination and subsequent release of free paclitaxel. Interestingly, the two systems have distinct pharmacokinetic properties. Prodrug incorporated with the PABC spacer had a slower enzymatic hydrolysis (42 min vs 3.5 min) but a faster spacer elimination rate (instantaneous vs 23 h) than with the MED spacer (Figure 3).

Alternatively, a nonremovable enhancer can be covalently attached through an irreversible spacer to the drug molecule for better efficacy. The enhancer molecule to which the parent drug connects is carefully chosen to avoid significant loss of drug potency. For example, thapsigargin (TG) is an apoptotic agent with $LD_{50} = 30$ nM in TSU-Pr1 prostate cancer cell (*39*). Covalent attachment of a 12-aminododecanoyl linker yielded an analogue (L12ADT) that retains the same efficacy as TG (Figure 4) and can be further conjugated with a PSA substrate (HSSKLQ). The resulting prodrug is nontoxic to normal cells, because the attached peptide substrate prevents it from entering the cells (*35*). The prodrug has demonstrated selective cytotoxicity in PSA-producing LNCaP cells, while remaining nontoxic to PSA-negative HCT-116 cell lines.

Antibody−Drug Conjugates. Traditional anticancer drugs are highly toxic and have limited specificity to cancer cells. In

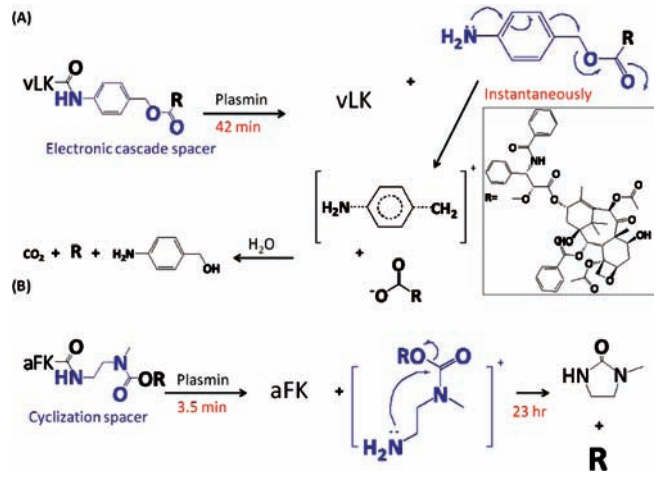

Figure 3. Example of paclitaxel prodrug derivatives incorporated with self-immolative spacers. (A) Paclitaxel prodrug analogues were designed by incorporating PABC to paclitaxel via a 2′-carbonate. PABC is inserted between the peptide substrate (vLK) and paclitaxel. The prodrug is proteolyzed by plasmin, followed by spontaneous solvolysis. (B) The paclitaxel-2′-carbamate derivative consisting of a MED spacer and tripeptide (aFK) is hydrolyzed, followed by spontaneous cyclization reaction to yield the pentacyclic urea (*38*).

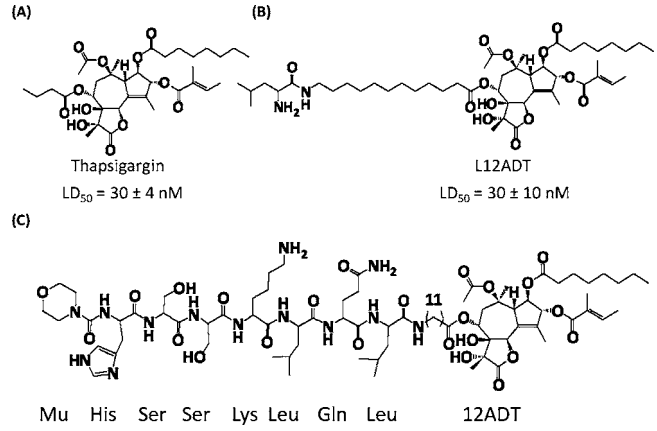

Figure 4. Chemical structures of (A) thapsigargin (TP), (B) 8-*O*-(12-[L-leucinoylamino]dodecanoyl)-8-*O*-debutanoylthapsigargin (L12ADT), and (C) a PSA substrate (HSSKLQL) conjugated with 12ADT (*35*).

contrast, monoclonal antibodies (mAbs) can selectively bind to tumor cells via specific surface markers, but only display moderate antitumor activity. Antibody−drug conjugates (ADCs) have been designed by covalently attaching cytotoxic agents to mAbs. This tumor-targeting technology utilizes the fact that mAbs can help to deliver the nonspecific toxic agents to the tumor sites, thus greatly reduce their undesired systemic toxicity. Moreover, the mAbs can also synergic elucidate the tumor cells. To design an ADC, a linker is required to connect the cytotoxic agent and the mAb. This linker should be stable in blood circulation but readily cleaved or disconnected to release the cytotoxic drugs. Various linkers have been designed and synthesized to enhance drug releases upon cellular internalization. These include the hydrazone-based or ester linkers that can be hydrolyzed in the acidic environment of lysosomes (*40*−*45*) and the disulfide exchange or self-immolative disulfide linkers that can be reduced by glutathione inside the cells (*46*−*48*). Peptide substrates have also been employed for designing ADCs; the resulting conjugates can be hydrolyzed by lysosomal proteases such as cathepsin B to release the active drugs (*45*, *49*, *50*). For example, *n*-butyl diacetate derivative of doxorubicin has been synthesized and attached to both the anti-CD70 and anti-CD30 mAbs via a dipeptide linker. A self-immolative PABC

Table 2. Examples of Polymeric Drug Carriers That Are Activated by Target Proteases[a]

polymer carrier	active drug	peptide linker	target protease	indication
CM-Dextran-PA	Exatecan (*147*)	GGFG	Cathepsin B	anticancer
Dextran	Methotrexate (*58*)	PVGLIG	MMP-2, MMP-9	anticancer
HPMA	Thapsigargin (*148*)	SSKYQL	PSA	anticancer
HPMA	TNP-470 (*149*)	GFLG	Cathepsin B	anticancer
L-PG	Paclitaxel (*150*)	EE	Cathepsin B	anticancer
PEG	Camptothecin (*56*)	GLFG	Cathepsin B	anticancer
PGC	Porphyrin (*110*)	KK	Cathepsin B	anticancer

[a] Abbreviations: CM-Dextran-PA, carboxymethyldextran polyalcohol; L-PG, polyglutamic acid; PEG, poly(ethylene glycol); PGC, poly-(L-lysine) grafted with monomethoxy-poly(ethylene glycol) copolymer; TPN-470, O-(chloracetyl-carbamoyl) fumagillol.

spacer was further introduced in between the dipeptide linker (valine-citrulline) and the daunosamine nitrogen of the doxorubicin derivative. Upon proteolysis, 2-pyrrolinodoxorubicin was self-eliminated as the active metabolite. The ADCs were >70-fold more potent than doxorubicin and also demonstrated >40-fold specificity when evaluated against their corresponding antigen negative cell lines (*51*).

Besides aiming for intracellular delivery of cytotoxic agents, peptide linkers can be employed to improve the therapeutic index of radio-immunotherapy by accelerating the liver clearance of radiometals from their immunoconjugates (ICs) (*52*), since cathepsin degradation of the peptide linkers could release the chelated radiometals into the circulation and subsequently eliminated by renal clearance. Cathepsin-degradable peptide-linked radio-ICs (RICs) and their corresponding 2-iminothiolane (2IT) nondegradable linked RICs have been designed to compare their pharmacokinetics in HBT-3488 human breast adenocarcinoma xenografts (*53*). The results indicated that the cumulative activities of peptide-linked RICs in liver were significantly lower (reduced from 59% to 68%) than their corresponding 2IT-linked RICs.

Protease-Responsive Carriers and Biomatrices. *Polymeric Carriers.* To extend the in vivo half-life of a therapeutic agent, multiple drugs can be covalently attached to the backbone of a polymer via peptide substrates. In general, drug−peptide conjugates are covalently attached to a synthetic polymer. In the presence of a target protease, the prodrug−polymer releases multiple peptide−drug fragments that subsequently hydrolyze into active metabolites (Figure 5). Various protease substrates have been reported as the linkers (examples in Table 2). The advantages of employing polymers as drug carriers are that they can be biocompatible, biodegradable, and soluble. Polymer−drug conjugation has become a popular approach to cancer delivery, as polymers with high molecular weights tend to accumulate at tumor sites via the enhanced permeability and retention (EPR) effect, or so-called passive targeting (*54, 55*). For example, 10-amino-7-ethylcamptothecin (SN-392) was conjugated to a linear methoxypoly(ethylene glycol) (mPEG) through a tetrapeptide (GLFG) spacer (*56*). The resulting polymeric conjugate had higher antitumor activity than free SN-392 in a Meth A fibrosarcoma (solid tumor) model. Another example is dextran-PVGLIG-methrotrexate conjugate. The prodrug was cleaved by both MMP-2 and MMP-9 (*57*), which could release a sufficient number of peptidyl methotrexate fragments to inhibit tumor growth (*58*). However, the tumor targeting mechanism relied predominantly on EPR. The same approach has been applied to other diseases, such as choroidal neovascularization (CNV) (*59*) and myocardial infarction (*60*), because the affected tissues also exhibit the similar anatomical characteristics to those of a tumor (i.e., hyperpermeable vessels and lack of effective lymphatic drainage).

Biomatrices. Hydrogels have been extensively developed for drug delivery and tissue engineering. They are usually three-dimensional networks formed by polymeric chains cross-linking via hydrophobic, electrostatic, and/or covalent interactions; for example, naturally derived polymers such as dextrans and gelatin have been used for protein delivery (*61, 62*). The state of the art in tissue engineering is to optimize matrix degradation for tissue regeneration processes, while allowing healing and remodeling to take place. Some of the employed matrices are natural and can be intrinsically digested by proteases. For example, the release of vascular endothelial growth factor (VEGF) from heparinized collagen matrices appeared to be controlled by both the presence of heparin from the matrices and the proteinases that are secreted from the fibroblasts (*63*). To modulate (increase or decrease) the rates of matrix degradations, reagents such as glutaraldehyde (*64*), polyepoxy compounds (*65, 66*), and carbodiimides (*67*) have been employed to cross-link the collageneous materials. Alternatively, the amino acid side chains on the collagen could be capped to prohibit cross-linking. For example, the lysine and arginine amino acid side chains on collagen were chemically modified by *n*-butylglycidyl ether and methylglyoxal, respectively (*68*). The modified collagen had a significant reduction in swelling property, but an increased solubilization when treated with proteases such as trypsin, acetyltrypsin, and cathepsin B, which was attributed to disruption of the collagen structure by chemical modifications.

Depending on the desired applications, environmentally sensitive hydrogels can be designed by chemically modifying their polymer components (*69*). Therapeutic molecules can be attached, encapsulated, or absorbed onto these matrices. Of particular importance, external stimuli such as temperature, electric fields, light, pH, or enzymes can be exploited to control their release rates. Various matrices that are sensitive to proteases have also been developed. An early example was the development of polyvinyl alcohol (PVA) hydrogels for bacterial prophylaxis (*70*). This approach was similar to that for polymeric−peptide conjugate, except an insoluble PVA matrix was grafted to gentamicin through multiple thrombin substrates (GfPRGFPAGG). Gentamicin molecules were selectively released from the matrix when incubated with thrombin-expressed *Staphylococcus aureus* infected wound fluid, while no biologically active antibiotic was released with noninfected wound fluid (*71*). Further evaluation in animals showed that the matrix was potent and specific for treating *Staphylococcus aureus* infected wounds (*70*). MMPs-activatable wafers were developed for local delivery of chemotherapeutic agent (*72*). Cisplatin complexed with an MMP substrate (CGLDD) was incorporated into poly(ethylene glycol) diacrylate hydrogel wafers. Drug release was dependent on MMPs expressed in a conditioned U-87 MG cell culture media.

A protease-responsive hydrogel based on the KLD-12 peptide (Ac-KLDLKLDLKLDL) was reported to control release of cytotoxic peptide (*73*). The peptide was able to form a self-

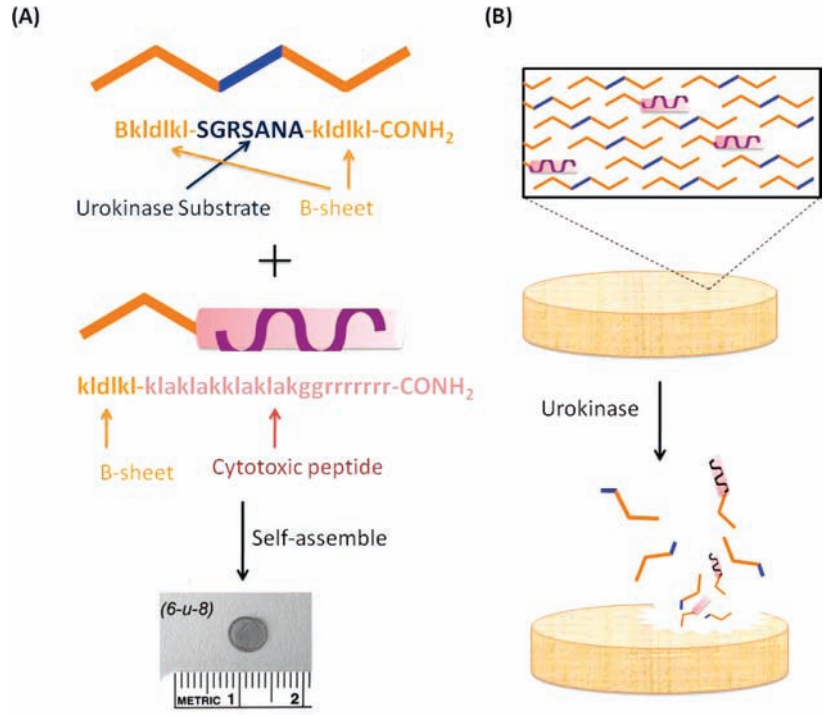

Figure 6. The design of a urokinase activatable hydrogel. (A) A self-assembling peptide (KLD-12) inserted with urokinase substrate was complexed with a cytotoxic peptide (kldlkl-r7-kla) to form a hydrogel system. (B) Upon addition of the targeted protease, the enzyme digests the preparations at the substrate cleavage site resulting in release of gel fragments and therapeutic peptides (*77*).

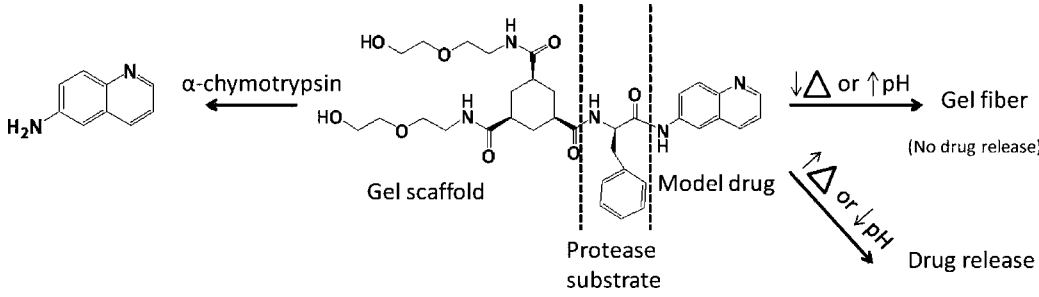

Figure 7. The design of a protease-cleavable LMWG−(model) drug conjugate system. Gel fiber formation is completely reversible by temperature and pH (*79*).

assembled matrix via β-sheet stacking (*74, 75*). An urokinase substrate sequence (SGRSANA) (*76*) was inserted between the assembling motifs with D-configuration, thus creating a uPA-responsive formulation when assembled (Figure 6). Cleavage of the protease substrate from the assembled matrix fragmented the building blocks, which in turn weakened the β-sheet interactions and caused matrix degradation. Further anchoring a cytotoxic peptide (r7-kla) into the matrix demonstrated that drug release was triggered by urokinase (*77*).

Recently, a recombinant gelatin (HU4) containing part of the amino acid sequence of the α1-chain from human type I collagen was synthesized as the polymeric construct for hydrogel (*78*). The HU4 gelatin was further modified with methacrylate residues, thus enabling chemical cross-linking and gel formation by radical polymerization. The assembled hydrogels were degraded by MMP-1. In addition to polymer gel based systems, drug delivery based on low molecular weight gelator (LMWG) has been synthesized (*79*). A model protease-activatable prodrug, L-phenylalanyl-amidoquinoline, and two ethylene glycol chains were conjugated to a cyclohexane trisamide gelator (Figure 7). The gel fiber system demonstrated a two-stage enzyme-mediated drug release mechanism. At room temperature, the assembled gel fibers protected the prodrug molecules from protease cleavage. When the temperature was raised (from 25 to 45 °C), the gel-to-solution transition equilibrium was shifted, and relaxed gelators became available for α-chymotrypsin cleavage to release the free 6-aminoquinoline.

Protease-Sensitive Imaging Probes. Immunohistological analysis showed high regional expression of disease-associated proteases in many disease tissues. Compared with adjacent normal tissues, the difference is significant; for example, in the case of colon adenoma, upregulated cathepsin B was observed in early phase tumor (*80*). Labeled antibodies against enzymes are suitable for ex vivo tissue analysis, but for in vivo detection of proteases, a more sensitive sensing approach would be favored. Since the proteases are catalytic enzymes, one protease could specifically activate tens, hundreds, or even thousands of its substrates. Amplification of the signal could be expected if the molecular probes are designed to be the substrates of their target proteases (*81*). The ability to repeatedly and noninvasively map protease expressions in real time in vivo can be an important tool for disease diagnosis (*82*). Recently, three major types of activatable fluorescent probes have been developed to report protease activity in living biological systems (Figure 8) (*83*). To distinguish background signal from true signal, in general, the principle mechanism of activation is based on quenching−dequenching upon enzymatic cleavage. The molecular probes are typically designed to be maximally quenched

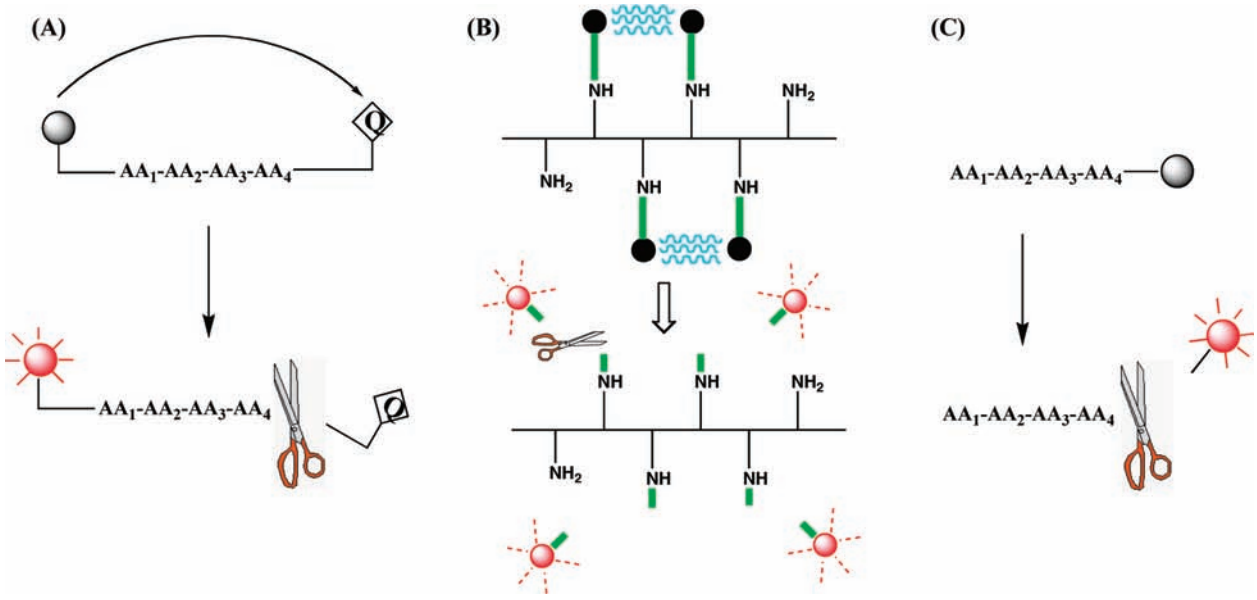

Figure 8. Schematic diagram of protease-activatable fluorescence probes. (A) Peptide-based enzyme sensitive probe. The molecular probe has a fluorescent donor at one end of the peptide substrate and a light absorber at the other end, (B) Self-quenched enzyme sensitive probe. Fluorochromes were covalently coupled to a polymer backbone via a synthetic peptide substrate (green line). Due to the proximity of the fluorochromes, self-quenching occurs so that almost no fluorescent signal can be detected in the nonactivated state. After designated enzyme cleavage of the peptide spacer, fluorochromes are released from the carrier and become brightly fluorescent. (C) Fluorogenic enzyme-sensitive probe. Fluorescence signal will be switched on when the probe is proteolytically activated.

in their native states and to brightly fluoresce in their cleaved states. On the basis of this quenching design, the background signal can be maintained at a minimum.

The first approach (Figure 8A) to producing a proteolysis-activatable probe is to flank an enzyme substrate with a fluorophore and a spectrally matched "quenching" molecule that effectively absorbs the energy from the fluorophore via fluorescence resonance energy transfer (FRET) (*84*). The second type (Figure 8B) of design is also based on energy transfer, but between the same types of fluorochromes. High numbers of fluorochromes were anchored onto a polymer template through cleavable peptide substrate sequences, which brought in protease selectivity. Loading the polymer with a large number of fluorochromes, typically 20−30 fluorochromes, results in nearly completely quenched fluorescence. The third type of protease-sensitive probe has the simplest design (Figure 8C). Only one fluorogenic reporter is needed for the probe. Typically, the intact probe emits no fluorescence until the amide bond between the peptide substrate and the dye is clipped.

Peptide-Based Molecular Probes. Various fluorochrome and quencher pairs have been selected for the best fluorescence energy transfer (Figure 8A). By linkage through a peptide substrate sequence, molecular probes could be selectively activated. A near-infrared fluorochrome Cy5.5 pairing with an absorber NIRQ820 was developed for MMP-7 imaging. Up to a 7-fold increase in fluorescence signal was observed when treated with MMP-7 (*85*). A recent example with Cy5.5/BHQ-3 pair was prepared to image osteoarthritis associated MMP-13 activity and to monitor therapeutic response in living animals (*86*).

Different from an optical quenching approach, a cell retention strategy was designed by integrating proteolysis and cell penetration signals (*87*). A polyarginine-based, cell-penetrating peptide was linked to a polyglutamate through an MMP-2/9 linker. Because of the intramolecular charge interaction, the cell-penetrating property was blocked until tumor-associated MMP-2/9 degraded the linker and then exposed the cell-penetrating peptide, which was able to direct the optical reporter into high MMP expressing tumors, reporting the location of the tumor. In addition to imaging, the same approach can be applied to provide site-selective drug delivery.

In a separate approach, regional proteolysis was applied to change the solubility of an imaging probe, resulting in local deposition of reporter (*88*). An MMP-7 substrate peptide was tethered with a chelated gadolinium (Gd) and a hydrophilic PEG chain. Upon proteolytic degradation, the PEG solubility enhancer was eliminated, causing solubility to drop in the Gd-containing peptide fragment. In vivo MR imaging indicated that Gd deposition correlated with MMP-7 expression and a protease inhibition effect by therapeutic inhibitor could be conveniently imaged by MR imaging.

Polymeric−Peptide Conjugate. The first protease-activatable optical contrast agent developed for in vivo imaging was reported in the late 1990s (*89*). The probe was a protected grafted copolymer (PGC) composed of a poly(L-lysine) backbone (PL) conjugated with multiple mPEGs and near-infrared fluorophores (Cy5.5). The fluorophores were enclosed in proximity resulting in significant quenching in their fluorescence emissions. Broad-spectrum proteases including cathepsin B and L could digest the polymeric backbone through the remaining free lysine residues, release the polymeric fragments, and subsequently initiate a dequenching process (i.e., fluorescent amplification). The approach was employed to image diseases such as cancer (*89*), arthritis (*90*), and atherosclerosis (*91*). To target different proteases, selective peptide substrates have been inserted between the fluorophores and the PGC (Figure 9). Simply by replacing the peptides, imaging probes were developed for detecting other disease-associated proteases such as cathepsins (*92*, *93*), MMPs (*94*, *95*), caspases (*96*), and thrombin (*97*). For example, a peptide substrate (GGSGRSANA) was employed for a uPA-sensitive probe (*98*). When the probe was tested in HT-1080 breast fibrosarcoma tumor-bearing mice, the observed fluorescence signals at the tumor sites were correlated with uPA activity (*99*).

Recently, self-assembled nanofibers have been designed to sense uPA activities (*100*). Their basic assembly constructs comprise (1) a peptide sequence (kldlkldlkldl) reported to form stable β-sheet platform; (2) a uPA substrate motifs (SGRSANA); (3) a nontoxic

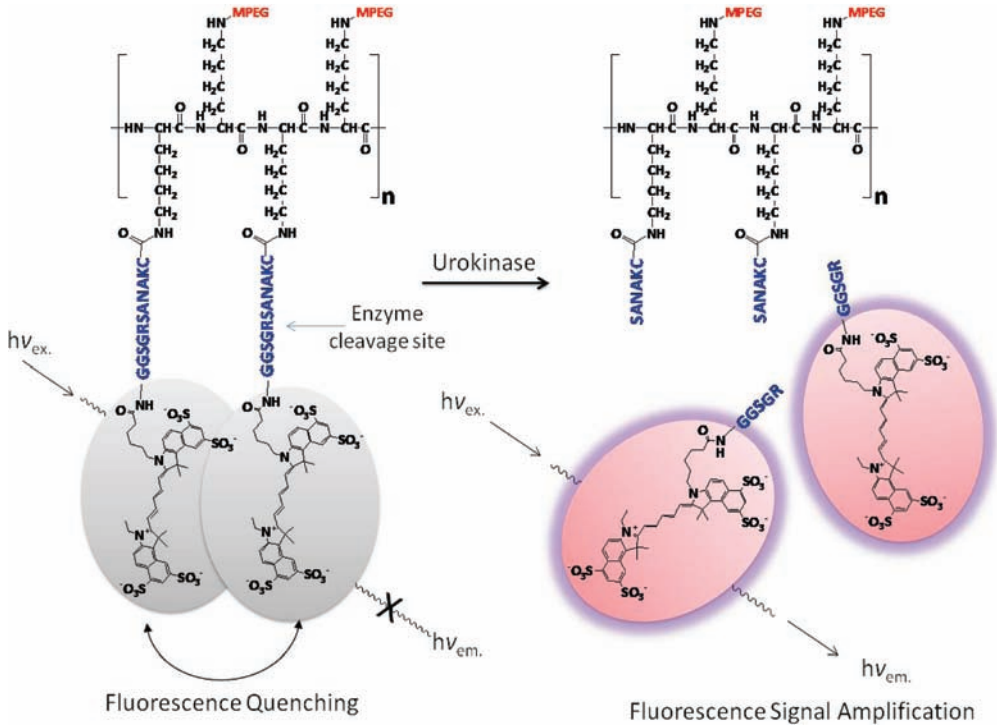

Figure 9. Schematic presentation of a urokinase-selective probe. The Cy5.5-peptide substrates (Cy5.5-GGSGRSANAKC) are attached to a PGC. The close spatial proximity of these multiple conjugates leads to fluorescence quenching. Upon urokinase cleavage, the released peptide fragments result in fluorescence signal amplification (*98*).

MPEG attached at the peptide N-terminus; and (4) a fluorescein as the optical reporter. Upon addition of proteases, the enzymes digest the nanofibers via their substrate cleavage sites, causing the release of hydrophilic fluorescent fragments and resulting in fluorescence emission. Interestingly, these nanofibers have the ability to compensate for the loss of intrinsic hydrophilicity; the remaining digested or partially cleaved nanofibers undergo morphological changes with time (*101*).

Fluorogenic Probes. On the basis of delocalization of the lone pair electrons, fluorogenic probes can be extremely simple (Figure 8C). Amino-4-methylcoumarin (AMC) is a widely used fluorogenic dye in measurements of protease activity. For in vivo applications, fluorophores having the excitation and emission at near-infrared (NIR) region (700−1000 nm) are generally preferred, since they have less interference from endogenous chromophores and also have deeper tissue penetrations while imaging. A series of fluorogenic dyes with benzo[*a*]phenoxazine core structure have been synthesized and evaluated (*102, 103*). Among them, 9-di-3-sulfonyl-propylaminobenzo[*a*]phenoxazonium perchlorate (2SBPO) has the best solubility and optical properties. Thus, it was selected as a scaffold to synthesize a panel of enzyme substrates, sensitive to amino peptidase (*103*), other proteases (*104*), and galactosidases (*105*). The assembled probes are nonfluorescent but display strong fluorescent emission at 670 nm following proteolytic release of 2SBPO. Bioluminogenic probe is another type of optical imaging agent designed by using the same concept as fluorogenic substrate. Peptide substrate was added to amino-luciferin, which was derived from the natural substrate of fire fly luciferase, D-luciferin. Because of steric hindrance, luciferase cannot recognize the peptide-modified luciferin. After proteolytic hydrolysis of the peptide, free luciferin was released and utilized by luciferase in situ. We have used a commercially available DEVD-luciferin substrate to study treatment effect of anticancer gene therapy (*106*). Expressed anticancer protein induced apoptosis of tested tumor cells, triggering caspase-3 expression. A bioluminescence signal was found associated with the gene therapy effect.

Protease-Mediated Photodynamic therapy. Photodynamic therapy (PDT) is currently used to treat several types of cancer. Regional therapeutic effect can be achieved only by combining photosensitizer (PS), light, and oxygen. Each component is harmless by itself, but when all three components get together, light excitation of a PS will locally generate highly cytotoxic singlet oxygen, $^1O_2$, which induces cell death and tumor ablation (*107*). Most PSs are porphyrin analogues that absorb light energy and then transfer to oxygen or emitted fluorescence. It has been reported that singlet oxygen generation is closely correlated with fluorescence intensity (*108*). When a PS is in a fluorescent quenched state, its ability to generate singlet oxygen is also reduced.

Using the same PGC platform used in imaging probes, a pro-PDT agent was synthesized by replacing Cy5.5 with a photosensitive agent, chlorin e6 (Ce6). When the assembled agent was in its native state, both the fluorescence and the singlet oxygen generation (SOG) of the anchored Ce6 were depopulated by energy transfer (Figure 10). The resulting pro-PDT agent had a lower toxicity (13%) than the free Ce6, but the hidden phototoxicity could be recovered after proteolysis (*109*). In an animal experiment with one single low dose of pro-PDT agent, tumor growth was slowed by 50% (*110*). In addition, local Ce6 concentrations could be simultaneously monitored by fluorescence imaging. A similar polymer-induced quenching approach was also reported, using pheophorbide-a as the PS (*111*). Phototoxicity was recovered when treated with a model protease, trypsin. Using the same concept as previously described for peptide-based molecular probes, short peptide-based protease-mediated PDT agents were also developed with a pyropheophorbide-a photosensitizer and a BHQ-3 quencher pair (*112*). Protease-mediated phototoxicity of target enzymes, caspase-3 and MMP-7, was demonstrated in vitro and in vivo (*112, 113*).

Protease and Nanoparticles. Particle sizes under 100 nm are unlikely to be eliminated by renal filtration but rather cleared by the liver and spleen or phagocytized by macrophages (*114*). Similar to polymeric carriers, nanoparticles ranging in size from

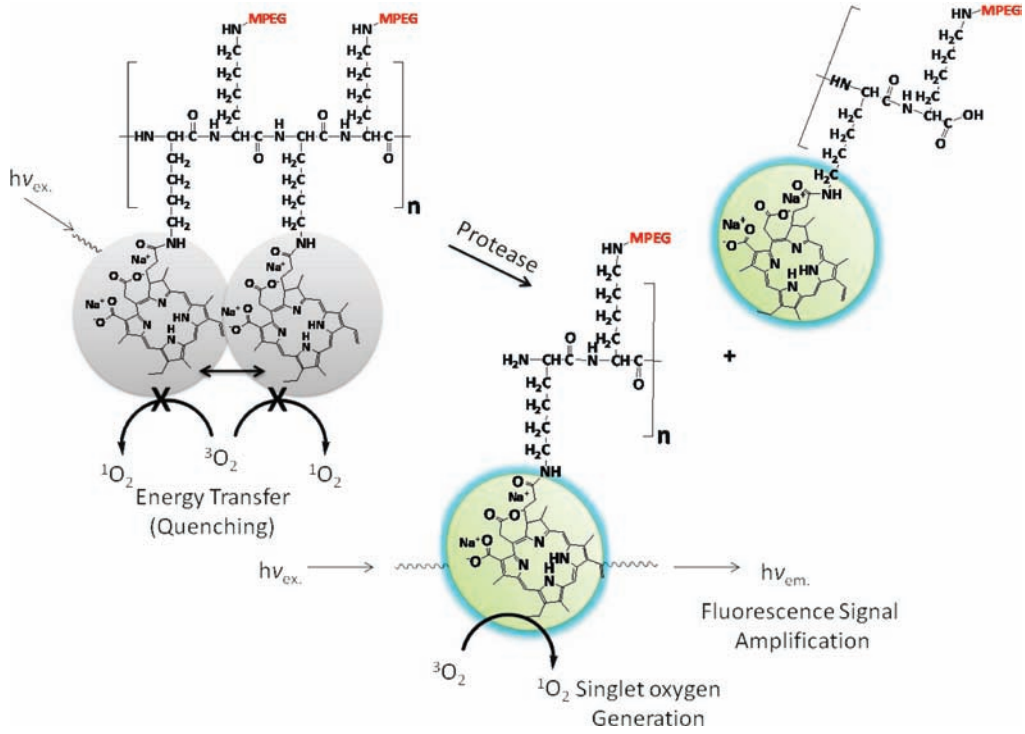

Figure 10. Schematic presentation of a protease-sensitive photodynamic therapeutic agent. Multiple photosensitizers (Ce6s) are attached to a PGC. Intramolecular energy transfer between the closely positioned Ce6 molecules contributes to a significant quenching of fluorescence emission and singlet oxygen generation. Following enzymatic cleavage of the poly(L-lysine) backbone, the released Ce6s-polymeric fragments regain their fluorescent properties and SOG (*110*).

20 to 150 nm tend to accumulate in tumor tissues via EPR effect (*54*). Nanomaterials such as nanofibers (*115*), carbon nanotubes (*116*), superparamagnetic iron oxide crystals (*117*), quantum dots (*118*), dendrimers (*119*), polymeric micelles (*32*), liposomes (*120*), nanospheres (*121*), and polyplexes (*122*) have been engineered as therapeutic carriers. Efficient drug delivery can be achieved by incorporating therapeutic agents into these inherent carriers (*55*). Some of them are designed to be degraded by natural proteases. For example, paclitaxel-loaded gelatin nanoparticles were developed for intravesical therapy of superficial bladder cancer (*123*). The particles are rapidly degraded by Pronase to release the free drug molecules.

To promote cellular internalization, protease-activatable liposomes were designed by conjugating an acetylated dipeptide substrate (N-Ac-AA) through its carboxyl terminus to the amino group of 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) (*124*). The resulting peptide−lipid (*N*-Ac-AA-DOPE), together with dioleoyl trimethylammonium propane (DOTAP) and phosphatidyl-ethanolamine (PE), were assembled into nonfusogenic liposomes. The liposomes were activated by elastase or proteinase K to become fusogenic for enhanced intracellular delivery (Figure 11).

In another study, a pegylated MMP-2 substrate (GPLGIAGQ) was conjugated to the amino group of DOPE (*125*). When assembled with disteraoyl phosphatidylcholine (DSPC), cholesteryl chloroformate, and cholesten-5-yloxy-*N*-(4-((1-imino-2-,*β*-D-thiogalactosylethyl)amino)butyl)formamide (Gal-C4-Chol) (*126*), the resulting liposomes (Gal-PEG-PD) were composed of (1) active targeting ligands (galactose moieties) recognized by the hepatic cell surface asialoglycoprotein receptors; and (2) a pegylated peptide substrate cleaved by MMP-2 (Figure 12). In the absence of enzymes, Gal-PEG-PD-liposomes could not be taken up by normal hepatocytes because of steric shielding of the targeting ligands. With the addition of MMP-2, the enzyme removed the bulky mPEGs, thus exposing the galactose ligands for targeting. The cytotoxicity of *N* (*4*)-

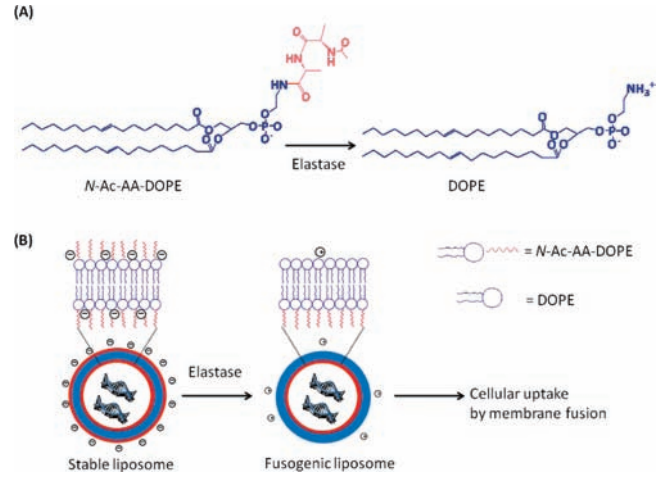

Figure 11. (A) Chemical structure of *N*-Ac-AA-DOPE. The lipid−peptide substrate can be converted into DOPE by elastase (*124*). (B) Activation of a non-fusogenic liposome. The liposome is stable with negatively charges. Removal of *N*-Ac-AA by elastase results in charge reversal, thus enhancing the ability to fuse with the plasma membrane for drug delivery.

octadecyl-1-*β*-D-arabinofuranosylcytosine (NOAC) incorporated Gal-C4-PD liposomes were significantly enhanced in cultured HepG2 cells after pretreatment with purified human MMP-2.

Quantum dots (QDs) that are activated by MMP-2 and MMP-7 were developed for cellular imaging (*127*). The QDs were attached with a peptide consisting of (1) a cationic tetraarginine as the transporter for intracellular delivery; (2) an anionic tetraglutamic acid as the blocker to inhibit cellular uptake; and (3) a peptide substrate sequence (PLVGR). Once the blockers are removed by MMPs, resurfaced tetraarginine signals direct QDs into cells. FRET pairs composed of QDs are also designed to sense protease activities (*128, 129*). Quenchers such as gold nanoparticles (*128*), organic fluoro-

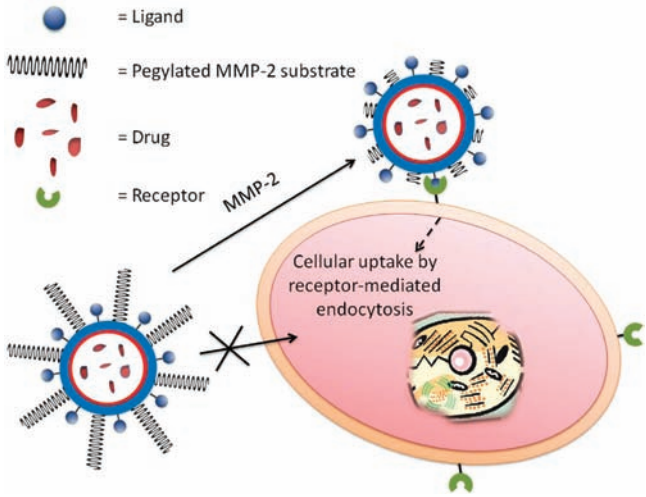

Figure 12. Schematic presentation of MMP-2 activatable targeting liposome (*126*). Cell-specific delivery was initiated when the masking PEG chain was eliminated by MMP-2.

phores (*129*), or fluorescent proteins (*130*) have been attached to the QDs via peptide substrates. QD photoluminescence was quenched through FRET. Protease cleavage of the peptide linkers released the quenchers, which subsequently recovered the QD luminescence emissions. This approach has been applied to study the protease activity in HTB126 cancer cell line (*131*).

A low nanometer-sized dendritic molecular probe having Cy5.5 as fluorescence reporter and AF750 as an internal reference was prepared for tumor detection (*132*). The AF750 was attached to a dendrimer directly, while Cy5.5 was linked through an MMP-7 spacer. In animal experiments, a bright Cy5.5 signal switched on by intestinal adenoma-associated MMP-7 was found in microsized adenomas. In another dendrimer example, anticancer agent Pt^{2+}-complex was attached to first-generation dendrimers through a cathepsin B releasable linker (*133*). Cell culture experiments confirmed the potential of applying this dendritic drug in anticancer therapy.

Organic nanoparticles have been formed by a "hydrophobic collapse-like" construct (*134*). In aqueous solution, a hydrophobic core was formed by multiple deoxycholic acids and was attached to a branched polyethyleneimine (PEI) chain. Multiple fluorescence-labeled caspase-3 substrates were then tethered to the surface of spherical particles, forming 80−100 nm organic nanoparticles. Because of a self-quenching mechanism, the fluorescence signal was shielded until the particle was recognized by target proteases. The described nanoprobe has been applied to following the apoptotic process under a fluorescence microscope.

CONCLUSION AND PROSPECTS

Proteolysis is a simple reaction that cleaves the peptide amide bond, but its applications have been proved enormous. Taking advantage of disease associated proteolysis, numerous prodrugs, biomaterials, and probes have been developed. Pharmacophores and reporters are first restrained or masked by various smart designs. Subsequent proteolysis by target proteases releases the active ingredients chemically or physically, regaining the desired therapeutic activity or imaging sensitivity in situ. Another advantage of proteolysis in drug development is catalytic capability. Operating like a self-propelled machine, one protease could potentially release a large number of drugs. Moreover, the catalytic function is a kind of in vivo PCR reaction that amplifies signal outputs and improves the detection limit significantly, which may have tremendous potential medical applications including disease detection and diagnosis.

In this brief review, only proteolysis was summarized, but it is not the only enzyme candidate used in drug engineering. Other natural enzymes have also been proposed, studied, and applied. For example, lactamase-responsive prodrugs (*135*), hydrogel biomaterials (*136*), and imaging probes (*137*) have all been reported. Another good example is transglutaminase, a type of enzyme usually found at the site of tissue healing and blood coagulation. It cross-links proteins through glutamate and lysine side chains. On the basis of this unique chemical linking property, transglutaminases are often used to increase toughness of hydrogels that can be applied to drug delivery systems or implants for tissue regeneration (*138, 139*). Imaging probes deposited by transglutaminase were also developed to understand healing and blood clotting processes (*140−142*). Many more enzymes have been identified but are waiting for creative twists, directing their enzymatic capability to assist in diagnosis and therapy.

Since disease-associated enzymatic activities vary during disease progression and between individuals, an enzyme-responsive delivery system potentially could provide an in situ self-regulated medicine, paving the way to personalized medicine. It can be envisioned that more and more intelligently designed enzyme-responsive systems will be developed for their environmental sensitivity. To achieve the ultimate goal, treating individual patients with personalized medicine, a more profound understanding of enzyme structure, mechanisms, distribution, and regulation in vivo is required.

The present work describes the pharmacokinetics of recently developed liposome−quantum dot (L-QD) hybrid vesicles in nude mice following systemic administration. Hydrophobic QD were incorporated into different bilayer compositions, and the serum stability of such hybrid vesicles was evaluated using turbidity and carboxyfluorescein release measurements. L-QD hybrid blood profile and organ biodistribution were also determined by elemental (cadmium) analysis. Following intravenous administration, different tissue biodistribution profiles and tissue affinities were observed depending on the L-QD lipid bilayer characteristics. Immediate blood clearance was observed with cationic (DOTAP/DOPE/Chol) hybrid with rapid lung accumulation, while incorporation of PEG at the surface of zwitterionic vesicles dramatically prolonged their blood circulation half-life after systemic administration. Overall, the L-QD hybrid vesicle system is considered a viable platform that allows QD delivery to different tissues through facile modulation of the hybrid vesicle characteristics. In addition, L-QD offers many opportunities for the development of combinatory therapeutic and imaging (theranostic) modalities by incorporating both drug molecules and QD within the different compartments of a single vesicle.

INTRODUCTION

Quantum dots (QD) are being intensively explored as fluorescent probes for long-term and multimodal imaging purposes *in vitro* and *in vivo* (*1*). However, the low hydrophilicity of QD is considered a major obstacle that impedes their widespread use in biology. Many strategies have been developed to improve the poor hydrophilicity, therefore biocompatibility, of QD, including attachment of hydrophilic moieties to their surface (*2, 3*), encapsulation within amphiphilic copolymer micelles (*4*), phospholipid micelles (*5*), silica polymers (*6*), emulsions (*7*), and polystyrene particles (*8*). These different coating strategies minimize QD nanocrystal aggregation (*9, 10*), protect the QD fluorescence character (*11*), and have also been reported to reduce their cytotoxicity (*2*). We have recently explored an alternative strategy by the self-assembly of lipids and quantum dots (L-QD) into hybrid bilayers, leading to the formation of nanoscale vesicles (*12*). The embedding of QD into the bilayers rendered nonfunctionalized QD compatible with the aqueous environment and enhanced the QD photostability, and most importantly, the L-QD vesicles labeled tumor cells efficiently *in vitro* and *in vivo*. L-QD hybrid vesicles are considered relevant for clinical use since their vesicular morphology allows loading of their internal aqueous phase with therapeutic molecules, in this way constituting a potential combinatory (theranostic) system for the simultaneous delivery of therapeutic and diagnostic agents.

In this work, we explored the use of various types of L-QD hybrid vesicles as delivery systems for *in vivo* systemic circulation applications. Their stability and release profiles in mouse serum were evaluated by turbidimetry and by using vesicle-encapsulated carboxyfluorescein. Further, the blood circulation and tissue biodistribution profiles of the different L-QD hybrid vesicles following intravenous (i.v.) administration in mice were determined, in comparison to the more widely used (and commercially available) poly(ethylene glycol) (PEG)-coated functionalized QD.

RESULTS

L-QD hybrids were prepared following the thin lipid film hydration protocol as previously described (*12*). Briefly, 5.6×10^{14} p/mL CdSe/ZnS QD (960 pmol/mL) were mixed with 8 μmol phospholipid molecules in chloroform, and vesicles were formed following film hydration and sonication, resulting in L-QD hybrid vesicles of 80−100 nm average diameter (Figure 1). The surface charge characteristics of the L-QD hybrid vesicles were in accordance with the characteristics of the lipid molecules used to form the bilayers. L-QD hybrids containing cationic (DOTAP[1]) and PEGylated (DSPE-PEG_{2000}) lipids exhibited surface charges of +47.5 mV and −20 mV, respectively (Figure 1). Also, the characteristics of the bilayers were dependent on the lipid composition selected, namely, fusogenic,

Figure 1. A schematic diagram showing a simplified structure of (a) TOPO-capped QD, (b) COOH-PEG QD, and the L-QD hybrids consisting of (c) DOTAP/DOPC/Chol (2:1:1.5), (d) DOPC/Chol/DSPE-PEG$_{2000}$ (1.8:1:0.2) and (e) DSPC/Chol/DSPE-PEG$_{2000}$ (1.8:1:0.2) (diagrams are not drawn to scale). The size, polydispersity index, and zeta potential of COOH-PEG QD and L-QD hybrids used in this study were obtained by dynamic light scattering using Nanosizer ZS.

fluid-phase using DOTAP/DOPE/Chol; fluid-phase using DOPC/Chol/DSPE-PEG$_{2000}$; and gel-phase using DSPC/Chol/DSPE-PEG$_{2000}$.

To evaluate the stability of L-QD hybrid vesicles in physiological conditions, 200 μL (1.6 μmol) of plain liposomes or L-QD vesicles in 5% dextrose were incubated with 1 mL 50% (v/v) CD-1 mouse serum at 37 °C to mimic the *in vivo* environment (approximately half of the volume of complete blood is serum (*13*)). The effect of serum on plain liposomes and L-QD vesicles was monitored by measuring the changes in the turbidity and mean vesicle diameter. Samples were incubated at 37 °C and analyzed at 2, 5, 10, 30, and 60 min using a Beckman DU 640 spectrophotometer (USA). Turbidity was measured at 400 nm with the corresponding amount of serum alone used as a reference. The mean vesicle diameter was measured by dynamic light scattering using the NanoZS (Malvern, UK). All samples were incubated for 60 min in serum.

Figure 2 depicts the stability of L-QD hybrid vesicles incubated in 50% (v/v) CD-1 mouse serum at 37 °C over time. Turbidity increased sharply for both liposomes (diamonds Figure 2a) and L-QD vesicles (diamonds Figure 2b) of the cationic DOTAP/DOPE/Chol lipid composition and was found to be constant over 60 min and 24 h (data not shown), similar to previous observations with cationic systems (*13*). Cationic vesicle aggregation was confirmed by light scattering, as evidenced by increases in the mean diameter from 100 nm to more than 300 nm after 60 min serum incubation (black bars, Figure 2c,d). To determine if changes in cationic vesicle size were due to incubation at 37 °C, all vesicle systems were also incubated in 5% dextrose under the same conditions; however, no changes in size were observed (white bars, Figure 2c,d). PEGylated (sterically stabilized) liposomes and L-QD vesicles (those containing DSPE-PEG$_{2000}$) showed no changes in turbidity (Figure 2a,b) and size (Figure 2c,d) due to the presence of PEG polymer on the vesicle surface (Figure 1) that reduces interactions with serum proteins (*14*). On the basis of these results, only sterically stabilized formulations were used further to determine the release profile of the vesicles.

In order to evaluate the integrity of L-QD vesicles in serum, a high concentration (0.2 M) of the aqueous marker carboxyfluorescein (CF) was encapsulated in the vesicles and free CF was removed by size exclusion chromatography. Release from plain liposomes and L-QD hybrid vesicles were studied by monitoring the increase in the CF fluorescence signal. Rapid release was observed from the L-QD (DOPC/Chol/DSPE-PEG$_{2000}$) vesicles that released 30% of encapsulated CF after 5 min and 50−70% between 0.5 and 4 h (□, Figure 3a). Similar results were obtained for the equivalent liposome system (■, Figure 3a), suggesting that the presence of QD in this vesicle bilayer did not dramatically change the bilayer characteristics that could lead to increased CF leakage.

Modification of the vesicle bilayer by substitution of the fluid-phase DOPC bilayer (Figure 1d) with the "rigid" DSPC (high phase transition lipid in gel phase at 37 °C) (Figure 1d,e),

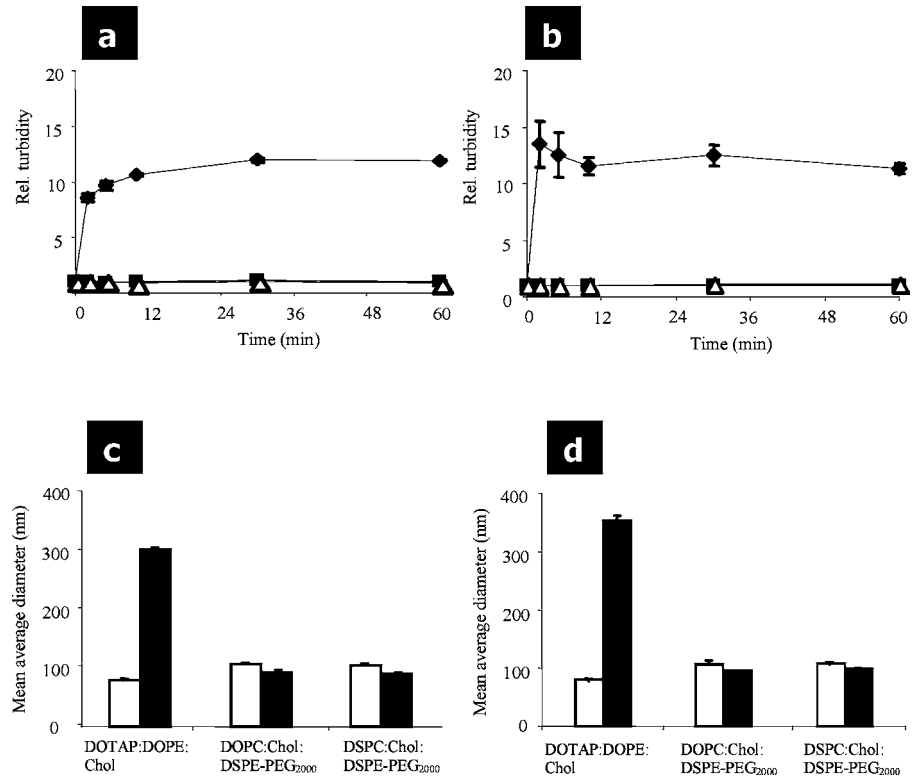

Figure 2. Stability of L-QD vesicles incubated in 50% mouse serum. Relative turbidity at 400 nm of (a) liposomes and (b) L-QD hybrid vesicles consisting of (◆) DOTAP/DOPE/Chol (2:1:1.5); (■) DOPC/Chol/DSPE-PEG$_{2000}$ (1.8:1:0.2); and (Δ) DSPC/Chol/DSPE-PEG$_{2000}$ (1.8:1:0.2); incubated for 2, 5, 10, 30, and 60 min in 50% mouse serum at 37 °C. Mean diameter (nm) of the (c) liposomes and (d) L-QD hybrids after 60 min incubation in 5% dextrose (white bars) and 50% mouse serum (black bars) at 37 °C. Data represent the mean ± S.D.(n = 3).

retarded the CF release from liposomes by a factor of 2, as described previously (*15*). The percentage of CF released from "rigid" [DSPC/Chol/DSPE-PEG$_{2000}$] liposome vesicles was 30−40% after 9 h incubation in serum (▲, Figure 3b). The presence of QD in the DSPC/Chol/DSPE-PEG$_{2000}$ bilayer almost completely prevented CF release up to 72 h (white bars, Figure 3c), indicating the dramatically improved stability of these PEGylated L-QD hybrids at physiological conditions. More biophysical studies are warranted to further elucidate the effect of QD embedding within the lipid bilayer and the interactions at the molecular level between the lipids and the hydrophobic QD self-assembling into vesicles.

We have previously reported that L-QD made of cationic and fusogenic lipid bilayers were capable of effectively labeling cancer cells *in vivo* following intratumoral administration (*12*). To investigate the behavior of L-QD hybrid vesicles in a living animal further, we studied their blood clearance and tissue biodistribution following intravenous (tail vein) administration compared to PEGylated, functionalized QD (COOH-PEG-QD). All pharmacokinetic and biodistribution data in this study were generated by detecting the amount of Cd atoms in the animal tissues using ICP-MS (Supporting Information for details).

Cationic L-QD hybrid vesicles (DOTAP/DOPE/Chol) exhibited rapid clearance from blood circulation with 20% and 1% of the injected dose (% ID) circulating in the blood after 2 and 10 min, respectively (Figure 4a, circles). The rapid clearance is due to transient lung accumulation, where more than 70% of ID was found after 10 min compared to 25% in the liver and spleen (Figure 4b, black bars). At 24 h, redistribution of the cationic L-QD led to their localization mainly in the liver (90% ID) and to a lesser extent in the spleen (5% ID), leaving only 4% in the lung (Figure 4c, black bars). Transient lung accumulation after systemic administration has been described previously for a variety of positively charged nanoparticles (*16*) and is thought to be due to the cationic L-QD interacting with the lung capillaries—the first capillary bed encountered following tail vein administration (*17*−*21*). At later time points, adsorption of negatively charged plasma proteins on the surface of the cationic vesicles hinders the nonspecific interaction with the pulmonary endothelium, leading to their redistribution to liver and spleen (at 24 h) (*17*−*22*). Similar observations have been previously reported for cationic liposome/plasmid DNA complexes (lipoplexes) (*23, 24*).

The blood circulation and tissue biodistribution of sterically stabilized L-QD hybrid vesicles containing 10 mol % of DSPE-PEG$_{2000}$ (*25*) was studied next. PEGylated L-QD (DOPC:Chol: DSPE-PEG$_{2000}$) vesicles exhibited 5−10-fold increase in blood circulation during the first 60 min (Figure 4a, empty diamonds) compared to cationic L-QD (Figure 4a, circles). However, only 10% ID could be detected in the blood after 10 min due to almost complete (>90%) and rapid liver uptake (Figure 4b, white bars). Substitution of DOPC for DSPC to form "rigid" L-QD vesicles (DSPC/Chol/DSPE-PEG$_{2000}$) exhibited up to 30-fold increase in blood circulation during the first 60 min (Figure 4a, squares) compared to DOPC/Chol/DSPE-PEG$_{2000}$ and cationic (DOTAP/DOPE/Chol) L-QD vesicles, with lower RES uptake (Figure 4b, gray bars) as has been previously reported for liposomes (*26*). However, the retention in the blood compartment of these "rigid" L-QD vesicles could not be maintained over time, with only 3% ID detected in the blood after 240 min (Figure 4a, squares).

The pharmacokinetic behavior of L-QD hybrid vesicles was also compared to that of commercially available hydrophilic QD (at 192 pmol—same concentration of QD used throughout) using carboxyl-functionalized poly(ethylene glycol) coated QD (COOH-PEG QD) (Evident Technologies, USA). The hydrodynamic diameter and surface charge of this material were found to be 39 nm and −7.6 mV (Figure 1) injected without further modification via the mouse tail vein. COOH-PEG QD showed prolonged blood circulation (Figure 4a, filled diamonds) as 90%

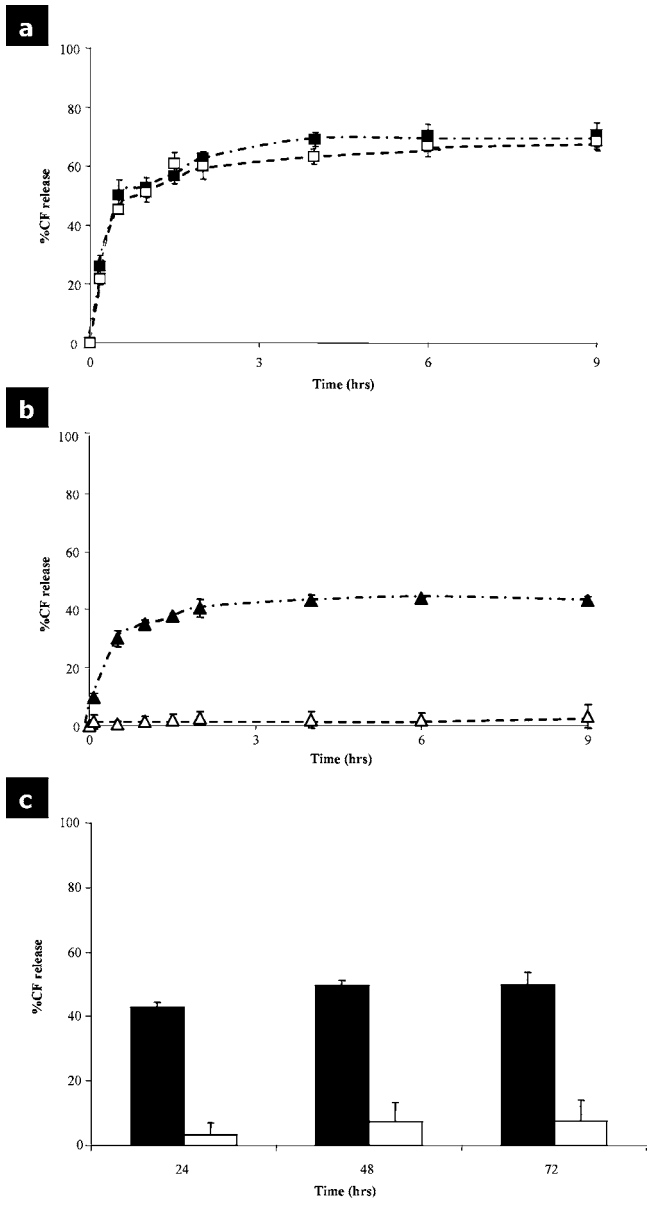

Figure 3. CF release profile from liposomes and L-QD hybrid vesicles incubated in 50% mouse serum. Percentage of CF release from (a) plain (■) and L-QD DOPC/Chol/DSPE-PEG_{2000} (1.8:1:0.2) (□) vesicles; (b) plain (▲) and L-QD DSPC/Chol/DSPE-PEG_{2000} (1.8:1:0.2) (Δ) vesicles incubated in 50% mouse serum at 37 °C for 9 h; and (c) 72 h (plain liposomes, black bars; and L-QD, white bars). Data represent the mean ± SD ($n = 3$).

ID and 20% ID were detected in the blood after 10 min and 24 h (Figure 4c, hatched bars). The tissue biodistribution of COOH-PEG QD was found to be sharply different from that of the L-QD hybrids at the early time point (10 min) with only 4% ID in the liver and spleen. At 24 h postinjection, the COOH-PEG QD concentration in the blood decreased due to accumulation primarily in the liver. No significant accumulation in the kidney, brain, and heart was obtained with either COOH-PEG QD or L-QD hybrids in this study, consistent with previous reports using COOH-PEG QD (*11, 27*).

DISCUSSION

QD have been previously investigated for *in vivo* imaging to visualize tumors, angiogenic endothelium, and lymph nodes in living animals (*1, 11, 28*−*30*). Better understanding of QD structure, surface, and elemental content on their pharmacological behavior *in vivo*, such as their blood circulation and organ biodistribution, is needed. Polymer-coated QD are the most relevant for clinical applications due to their stability *in vivo* and low toxicity (*2, 11*). Moreover, consistent with findings described here, decorating the QD surface with PEG_{2000} can significantly improve their blood circulation ($t_{1/2} = 4-5$ h) (Figure 4a) and reduce their recognition by the liver and spleen (Figure 4b,c) (*1, 11, 29*). We recently described an alternative approach to solubilize organic QD by engineering self-assembled liposome-QD (L-QD) hybrid vesicles that were capable of successful labeling of tumor cells *in vitro* and *in vivo* (*12*). One of the key advantages offered by the L-QD hybrid system is the versatility of potential structural and surface characteristics by selection of different lipid components with minimal manipulation of the QD nanocrystal. Also, they offer the possibility to encapsulate therapeutic agents (e.g., doxorubicin) in their internal aqueous phase for the construction of multimodal (therapeutic and diagnostic) delivery devices. In this study, we explored this versatility by constructing different types of L-QD by rational selection of different molecular (lipid) components (Figure 1) and correlated their composition with their stability *in vitro* and their pharmacokinetic profile *in vivo*.

Our *in vitro* investigations indicated that L-QD hybrids of cationic surface character and a fluid-phase bilayer were not stable in serum and released encapsulated carboxyfluorescein rapidly (Figures 2 and 3). On the other hand, L-QD hybrids consisting of a "rigid", gel-phase lipid bilayer (DSPC) and cholesterol exhibited longer blood circulation (Figure 4a) and slower accumulation in liver (Figure 4b,c) compared to fluid-bilayer or cationic formulations, which is in agreement with earlier observations regarding the effect of liposome compositions on their behavior *in vivo* (*25, 26*). L-QD hybrids with PEG on their surface exhibited higher serum stability (Figure 2), indicating that such L-QD hybrids could offer a platform for systemic multimodal applications (*31*). However, on systemic (i.v.) administration sterically stabilized, PEGylated L-QD showed rapid blood clearance compared to previous reports on similar liposome-alone systems (*25, 26*).

The rapid blood clearance of these hybrids, despite PEG surface coating, can be due to (a) translocation of the hydrophobic QD from the hybrid bilayer to the plasma proteins leading to subsequent uptake by the liver; (b) suboptimal PEGylation of the vesicles containing QD leading to rapid clearance of this vesicle population only (*25*). More work on improving the steric stabilization of L-QD vesicles and their pharmacological profile is warranted by using different lipid molar ratios, PEG of different molecular weights, and optimization of the PEG surface conformation (mushroom or brush) on the L-QD surface (*32*). On the basis of the pharmacokinetic data obtained, L-QD hybrid systems will not be suitable candidates as blood-pool imaging agents due to their rapid clearance from systemic circulation.

Several studies have reported the effect of QD surface coating on QD behavior *in vivo* (*27, 28*). Surface coating determines the overall QD size; therefore, high molecular weight polymers or organic coatings lead to considerable increases in QD diameter that accelerate QD blood clearance and liver entrapment. Such effects have been previously reported by Fischer et al. who observed remarkable differences in the blood profile of 25 nm mercaptoundecanoic acid cross-linked with lysine-QD (LM-QD) ($t_{1/2} = 60$ min), compared to 80 nm bovine serum albumin coated QD (BSA-QD) ($t_{1/2} = 38$ min) (*27*). In addition, QD surface charge was also found to significantly affect QD tissue biodistribution. The cationic LM-QD accumulated significantly in the lung and kidney compared to the zwitterionic BSA-QD that accumulated predominantly (99% ID) in the liver (*27*). More

Organ biodistribution in CD-1 nude mice of L-QD DOTAP/DOPE/Chol (2:1:1.5, black bars), L-QD DOPC/Chol/DSPE-PEG_{2000} (1.8:1:0.2, white bars), L-QD DSPC/Chol/DSPE-PEG_{2000} (1.8:1:0.2, gray bars), and COOH-PEG QD (hatched bars) nanoparticles (b) 10 min and (c) 24 h after tail vein injection. Data represent the mean $\pm$ SD ($n = 4$).

recently, Frangioni et al. reported that the QD surface charge had a profound effect on the ensuing size of QD under physiological conditions. Purely negative or positive QD surface character was associated with an overall increase in the QD hydrodynamic diameter above 15 nm, due to interaction with serum proteins. This increased QD size did not allow their renal excretion and enhanced their accumulation in the liver. That study indicated that only neutral organic coatings (e.g., cysteine) that maintained the QD size in the blood below 5.5 nm were rapidly excreted in the urine and eliminated from the body (*29*, *33*).

The pharmacological profiles of sterically stabilized QD using different molecular weight PEG have also been studied. QD conjugated to low molecular weight PEG (PEG_{750}) exhibited short blood circulation ($t_{1/2} < 12$ min) with predominant uptake in the liver, spleen, lymph nodes, and bone marrow (*28*). Increasing PEG molecular weight to 2000 and 5000 Da significantly reduced macrophage recognition and consequently increased their blood circulation $t_{1/2}$ to an average of 5 and 18.5 h, respectively (*11*, *29*, *34*). Interestingly, similar observations in relation to the size of PEG on the QD surface have also been illustrated after conjugation of ligands (such as epidermal growth factor and RGD) at the distal end of the PEG-coated QD to improve their systemic tumor targeting (*35*, *36*). It would be interesting to explore any differences in the pharmacokinetic profile of the L-QD systems after conjugation of targeting ligands on their lipid bilayer.

In the present study, cationic L-QD (DOTAP/DOPE/Chol) hybrid vesicles exhibited a different *in vivo* profile compared to previously reported 25 nm, cationic mercaptoundecanoic acid cross-linked with lysine-QD (*27*). Cationic L-QD hybrids cleared very rapidly from blood circulation after injection (2 min) (Figure 4b) and ~80% ID resided in the lung compared to 2%

ID of lysine-QD localized in the lung between 15 and 90 min. The low lung accumulation of lysine-QD can be explained by their small size (*37*) and lower cationic surface charge (*38*) compared to the highly positively charged L-QD hybrid vesicles (+47.5 mV). On the basis of this pharmacological profile, improvements in the dynamics of cellular uptake of cationic L-QD by the pulmonary endothelium by inclusion of an appropriate ligand may offer even more effective and specific delivery of QD to the lung tissue for imaging and tracking purposes.

CONCLUSION

In this work, we rationally modulated the surface and bilayer characteristics of the recently developed L-QD hybrid vesicles and correlated them to blood stability (*in vitro* and *in vivo*) and tissue biodistribution in mice after intravenous administration. Sterically stabilized L-QD hybrid vesicles have shown high serum stability *in vitro* comparable to corresponding liposome-alone systems. The *in vivo* profiles obtained for the different L-QD hybrid systems (by monitoring Cd atom deposition in blood and tissues) showed identical behavior between cationic L-QD and previously described cationic nanoparticles. However, in the case of PEGylated L-QD much shorter blood circulation times were observed compared to PEGylated liposomes of the same lipid composition. Such findings indicate that liposome−nanoparticle hybrid systems should not be expected to behave pharmacologically similarly to liposome-alone systems. Eventually (time points at 24 h or later), both the L-QD and functionalized QD accumulated primarily in the liver, which may cause toxicological concerns that will have to be overcome before further clinical development. Overall, the L-QD hybrid vesicle system in comparison to functionalized QD is considered a viable platform that allows the facile modulation of the hybrid vesicle characteristics for the rational design of QD delivery to different tissues such as the lung, particularly if therapeutic agents are encapsulated in the L-QD internal aqueous phase.

ACKNOWLEDGMENT

Materials: CdSe/ZnS core/shell TOPO-capped quantum dots (QD), supplied in toluene with a reported CdSe core size of 2.2 nm in diameter, and with overall size of 4-5 nm including 1-2 nm thickness of the organic coat (TOPO and ZnS) [1-3]; carboxyl functionalized polyethylene glycol-lipid coated QD (COOH-PEG QD) (Evident Technologies, USA). QD exhibited an absorption peak at 502 nm and an emission peak at 517 nm, which agree with their core size as described earlier by Peng et al.[4]. Dioleoylphosphatidylcholine (DOPC 98%); distearoylphosphatidylcholine (DSPC 98%); 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[methoxy(polyethyleneglycol)-2000] (ammonium salt) (DSPE-PEG_{2000} 98%) (Lipoid GmbH, Germany), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE 99%); 1,2-dioleoyl-3-trimethylammonium-propane (chloride salt) (DOTAP 99%) (Avanti Polar Lipid, USA), cholesterol (Chol); dextrose (Sigma, USA)

L-QD preparation*:* $5.6x10^{14}$ p/mL CdSe/ZnS QD (960 pmol/mL) were mixed with 8 μmol phospholipid molecules (DOTAP:DOPE:Chol, 2:1:1.5; DOPC:Chol:DSPE-PEG_{2000}, 1.8:1:0.2 and DSPC:Chol:DSPE-PEG_{2000}, 1.8:1:0.2) in chloroform and vesicles were formed following the lipid film hydration methodology as previously described [5]. After evaporation of the solvent in a rotary evaporator, a thin QD-containing lipid film was formed, effluxed with a stream of N_2 and kept until further use. Upon hydration of the L-QD lipid film with 1 mL 5% dextrose, multilamellar vesicles (MLV) were self-assembled, incorporating the QD into their lipid bilayers. Sonication using an ultrasonic bath (Ultrasonic cleaner, VWR) for 10-15 min at 30 °C and 50 °C with high phase transition formulation (DSPC), led to formation of QD-containing small unilamellar vesicles, so-called L-QD hybrids. Samples were flushed

with N_2 and left to anneal overnight. Dynamic light scattering (DLS) and surface charge were measured with Zetasizer Nano ZS (Malvern, UK, He-Ne laser).

CF-loaded vesicle preparation: Lipid films were hydrated with 0.2 M 5, 6-carboxyfluorescein (CF) (Fluka, USA) solution prepared in PBS buffer pH 7.4. The hydration was carried out gradually using 200µl aliquot of CF solution accompanied with votex mixing to achieve better hydration and higher CF entrapment. Unentrapped CF was removed with Sepharose CL-2B size exclusion chromatography column (5*1.5cm) (Sigma, USA). Liposomes were eluted by PBS buffer pH 7.4, and SUV-containing fractions were collected and diluted samples were concentrated to the original volumes using Vivaspin 4 concentrators MWCO 5000 (Vivascience, Sartorus, Germany) by centrifugation at 3000 rpm for 2 hr. The CF encapsulation efficiency for liposomes was identical to L-QD vesicles at 6mmol.

CF release experiment: CF release from plain liposomes and L-QD vesicles were studied by monitoring the increase in the fluorescence signal of CF during the release from the liposomes. At high concentration as encapsulated in the vesicles, CF is quenched. As CF is diluted (released to the surrounding medium) self-quenching decreases and fluorescence signals increases. To simulate the ensuing dilution in the blood plasma expected upon injection of 0.2 mL volume for 25g body weight, 100 µl of CF-loaded vesicles were diluted in 500 µl of 50% (v/v) CD-1 mouse serum (Sera Laboratories International, UK) in PBS and incubated at 37 $^{\circ}$C with gentle shaking. At different time points, 10 µl samples were withdrawn further diluted with PBS for fluorescence intensity measurement. Fluorescence measurements were carried out in quartz cuvette using PerkinElmer luminescence spectrometer (LS50B). The samples

were excited at 495 nm and the emission was read at 520 nm, with excitation and emission slit width of 2.5 nm and integration time of 2 seconds. CF release was determined by normalizing the intensity of the fluorescence signals:

$$\%CF\ release = (I_{(t)} - I_{\circ}) / (I_{\infty} - I_{\circ}) \times 100$$

Where $I_{\circ}$ is the initial signal, $I_{(t)}$ is the fluorescence signals at definite time point and I_{∞} is the CF signal after disrupting the liposomes with 10µl of 10% Triton X-100 solution and mixing for few seconds.

Intravenous administration of L-QD vesicle: All animal experiments were performed in compliance with the UK Home Office Code of Practice for the Housing and Care of Animals used in Scientific Procedures. 1.6 µmol/200 µl of L-QD hybrids (equivalents to 196 pmol QD) were injected in 14-16 weeks old female CD-1 nude mice (Charles River Laboratories, UK) via the tail vein. At different time points, the mice were anesthetized by inhalation isoflurane and bled by the tail vein puncture at 2, 10, 30, 60 min, 4 and 24 hr post injection and 50 µl blood was collected. Blood withdrawn did not exceed 10% of the mouse blood volume. The mice were killed after 10 min and 24 hr by cervical dislocation and dissected. In addition to blood, organs were collected, weighted and analyzed for Cd element by Inductively Coupled Plasma Mass Spectrometry (ICP-MS) as described elsewhere [6]. The total Cd concentration in the blood was determined by assuming the total blood volume was 7.3% of the body weight [7]. The percentage of injected dose (%ID) was expressed per organ. (n= 4 ± S.D).

Quantification of quantum dots in organs: Blood, liver, lung, kidney, spleen, heart and brain were collected. Mice organs (150-200 mg) were incubated in 500 µl lysate

buffer (1% SDS, 0.1 M NaCl, 0.05 M tris(hydroxylmethyl)aminomethane, Tris, pH 8) over night. The samples rendered soluble by the addition of 1 mL 70% nitric acid (HNO_3) (Fluka, UK). All the samples were prepared in disposal 10 mm *7.5-mL glass culture tubes that were fitted with polyethylene “snap cap”. With punctured cap, acid digestion of the samples was carried out by heating them in an oil bath at 115°C for 2-3hrs. Later on, the cooled samples were filtered using 0.45 μm pore poly (vinylidene fluoride) membrane syringe filter (VWR, UK). The filtrate was re-diluted to 5 mL by deionized water and transferred to 15 mL polypropylene centrifuge tubes for storage prior for the measurement. For all Inductively Coupled Plasma Mass Spectrometry (ICP-MS) measurements (PerkinElmer SCIEX ICP mass spectrometer, ELAN DRC 6100, USA) nitric acid blank, blank tissue samples, spiked samples with known QD for calibration curve and Cd standards were prepared and tested concurrently with test samples.

Institute of Genomics and Integrative Biology (CSIR), Mall Road, Delhi University Campus, Delhi-110 007, India, and Indian Institute of Toxicology Research (CSIR), Mahatma Gandhi Marg, Lucknow-226001, Uttar Pradesh, India. Received April 10, 2009; Revised Manuscript Received July 21, 2009

Oligonucleotide-based arrays are increasingly becoming useful tools for the analysis of gene expression and single-nucleotide polymorphism. Here, we report a method that allows the direct immobilization of thiolated oligonucleotides onto an epoxy-activated glass surface via a stable thioether linkage under microwaves. The described chemistry efficiently immobilizes the probes via terminal thiol groups with uniform spot morphology. The thioether linkage could endure repeated PCR-like heat cycling with only 2.5% loss after 20 cycles, indicating that the chemistry can be used in integrated PCR/microarray devices. The highlighting feature of the proposed method is that the detection limit for the probe concentration can be reduced to 0.25 μM with 20-mer oligonucleotides. The efficiency of the projected method (~33%) indicates its advantage over the existing standard methods, viz., NTMTA (~9.8%), epoxide-amine (~9.8%) and disulfide (~1.7%). The constructed microarrays were validated through the detection of base mismatches and bacterial meningitis. These features make the projected strategy ideal for manufacturing oligonucleotide arrays and detection of mismatches and bacterial diseases.

INTRODUCTION

Oligonucleotide microarrays have lately emerged into the academic and commercial arena owing to their usefulness in high-throughput, parallel gene expression, SNP analysis, and comparative genome hybridization (*1*−*4*).

DNA microarrays can be produced essentially in two different ways: (i) by direct chemical synthesis on the solid surface using photolithography technique (*5*, *6*); (ii) by immobilization of presynthesized oligonucleotides on selected surfaces (*7*−*10*). An example of the first approach is the Affymetrix method, which involves stepwise synthesis of oligonucleotides using photocleavable protecting groups. It is advantageous in generating high-density (10^6 sequences/cm^2) microarrays but lacks flexibility and economy. There are also some practical limits to the length of oligonucleotides to be synthesized. The immobilization method allows the tethering of long as well as modified base-incorporated oligonucleotide sequences and flexibility of a variety of ligands to be fixed on a surface of choice. That is why patterning of presynthesized oligonucleotides is preferred in research laboratories and commercial applications, where low to medium density arrays are required. In addition to the chemistry involved in fixing oligonucleotides to the polymer surface, the choice of polymer matrix, particularly glass, plays an important role in influencing the quality of the constructed microarrays.

Since oligonucleotides bind poorly to virgin glass, a number of methods for noncovalent and covalent immobilization of oligonucleotides on modified glass have been reported (*11*−*23*). The simplest is electrostatic adsorption of probes on polylysine and aminopropyl-coated microslides (*10*), but it results in low hybridization efficiency, as ionic interactions encourage the probes to lay flat on the surface. Therefore, a single terminal covalent attachment is preferred for short oligonucleotides, as it allows the entire oligonucleotide to be available for hybridization. Some common combinations of surface/oligonucleotide modifications that have been demonstrated include the following: carboxyl−amine, thiol−disulfide, amine−aldehyde, aldehyde−oxyamine, biotin−streptavidin, gold−thiol, zirconylated-surface−phosphate, epoxide−amine, and so forth. In addition, there are strategies employing heterobifunctional reagents, such as *N*-(2-trifluoroethanesulfonatoethyl)-*N*-(methyl)-triethoxysilylpropyl-3-amine (NTMTA) and *N*-(3-trifluoroethanesulfonyloxypropyl)anthraquinone-2-carboxamide (NTPAC), previously reported from the authors' laboratory (*7*), for construction of oligonucleotide microarrays. These methods make use of single terminal attachment of oligonucleotides on modified glass surfaces. In some cases, immobilization was also realized by photochemical methods (single or multipoint contact). All of the above-mentioned approaches have their own limitations with respect to factors like involvement of multisteps for the introduction of functional groups on either the oligomer or glass surface, time-consuming reactions to realize immobilization with low to moderate immobilization efficiency, low thermal and chemical stability, and so forth.

Recently, Bocking et al. (*9*) have reported the immobilization of thiolated oligonucleotides on epoxylated silicon (111) surface. The method involves a one-step DNA immobilization; however, the functionalization of silicon (111) to generate epoxy groups is quite tedious and requires a multistep reaction scheme. Similarly, Preininger et al. (*16*) have generated high-capacity epoxy surfaces by coating 1% epoxy resin using different methods for achieving signal enhancement and immobilized amine- and thiol-modified oligonucleotides. However, reproducibility of the coating process and enhanced background signals limit the viability of the protocol. In search of a simple and efficient immobilization method, which would overcome the limitations of the existing ones, we explored the thioether linkage for microarray fabrication.

In this Communication, we propose the covalent attachment of thiol-modified probes to epoxy-activated glass slides under microwaves, where it takes only 12 min for immobilization with

~24% immobilization efficiency. A major advantage of the projected method is that it requires neither a coupling reagent nor chemical manipulations for the immobilization of prefabricated oligonucleotides. The proposed strategy is demonstrated with respect to pH and thermal stabilities, immobilization efficiency, functional availability of the probes for hybridization, and detection of mismatches. Also, it has been compared with the standard methods, viz., NTMTA, epoxide−amine, and disulfide approaches, to highlight its advantages over the existing ones. Subsequently, the oligonucleotide-based biochip was validated for detection of bacterial meningitis in human samples.

EXPERIMENTAL PROCEDURES

Materials. Virgin glass microslides (75 × 22 mm^2), *N*-methylimidazole, and 3-glycidyloxypropyltrimethoxy silane (GOPTS) were procured from Sigma-Aldrich Chemical Co., St. Louis, MO. Tetrachlorocarboxyfluorescein (TET) phosphoramidite was obtained from Applied Biosystems Inc., Foster City, CA. Other reagents and chemicals were of analytical grade and used as received from commercial sources, unless indicated.

Buffers. Reaction buffer: 0.1 M *N*-methylimidazole containing DMSO (10%), pH 8.0. Hybridization buffer: 125 mM sodium citrate containing 750 mM NaCl, pH 7.0. Capping buffer: 0.1 M Tris containing 50 mM ethanolamine, pH 9.0.

Glass Silanization. *Step 1: Glass Cleaning.* Glass microslides were cleaned by immersing them in NaOH (1.0 M) for 2 h at 35 °C followed by rinsing with Milli Q water (2 × 100 mL). The slides were then subjected to treatment with a solution of hydrochloric acid (2.0 M) for 30 min, followed by rinsing with Milli Q water (3 × 100 mL), and finally submerged in ~95% ethanol for 1 h. The slides were dried under vacuum and stored in an inert atmosphere.

Step 2: Silanization of the Slides. The precleaned slides were immersed in a solution of GOPTS (2%, v/v) in toluene (75 mL) for 4−5 h at 50 °C, followed by washings with toluene (2 × 75 mL) and ethanol (2 × 75 mL), and dried under vacuum. Finally, these were baked for 1 h at 100 °C and stored in an inert atmosphere.

Oligonucleotide Synthesis and Purification. Oligonucleotides and their thiol-modified analogues (*23*) were synthesized at 0.2 μmol scale on a Pharmacia Gene Assembler Plus using the standard phosphoramidite approach following the manufacturer's protocol (Gene Assembler Plus Manual, Uppsala, Sweden, 1988). The oligonucleotide sequences were assembled, and their deprotection conditions and yields are given in Table 1. The ammoniacal solution of oligomers was concentrated in a speed vac concentrator; the residue obtained was redissolved in water (200 μL) and applied onto a desalting column (reverse-phase ODS-silica gel column). The oligomers were eluted with 30% acetonitrile in water, concentrated in a speed vac, purified on RP-HPLC, and stored at 4 °C.

Determination of Optimal pH Required for Immobilization of Thiolated Oligomers on Epoxy-Activated Glass Surface. In order to study the effect of pH on immobilization of thiolated oligonucleotides on epoxylated polymer surface, the attachment of the probe was carried out at different pH values ranging 6−12. Briefly, a labeled oligomer, viz., TET-d (TCT GTA TGT CTA TTC TCG TT)-OPO_3-$(CH_2)_6$-SH, dissolved in the reaction buffer of different pH, was spotted onto a functionalized glass microslide and incubated in a humid chamber for 12 h, followed by capping of the residual epoxy functionalities with the capping buffer for 15 min at 50 °C. The slide was subjected to washings with 1× SSC buffer (4 × 50 mL), pH 7.0, for 20 min, and Milli Q water (2 × 50 mL), dried under vacuum and scanned under a laser scanner.

Determination of Optimal Time Required for Immobilization of Thiolated Oligomers on Epoxy-Activated Glass Surface. The optimal time required for immobilization of 3′-thiolated oligonucleotide onto epoxylated surface was evaluated by spotting an oligomer sequence, TET-d (TCT GTA TGT CTA TTC TCG TT)-OPO_3-$(CH_2)_6$-SH (40 μM), onto functionalized glass surface in duplicates using a 2 μL micropipet. The slides were then subjected to microwave irradiation up to 20 min (120 × 10 s) in a domestic microwave oven operating at 800 W (with no exposure longer than 10 s in a humid chamber, after each exposure, the slide was cooled in an ice−water mixture to room temperature). The microslides were removed at different time intervals (4, 8, 12, 16, and 20 min), followed by capping and washings as mentioned above. After drying, the spots were visualized under a laser scanner.

Similarly, to find out the optimal time required for immobilization under thermal conditions, the slides were spotted with a labeled oligomer as mentioned above and kept at 35 °C, followed by their withdrawal at different time intervals (2, 4, 6, 8, and 20 h) and subjected to capping, washings, and scanning, as described above.

Determination of Threshold Concentration of Oligonucleotides Required for Fluorescence Detection. In order to arrive at the optimal probe concentration required for visualization of spotted oligonucleotides under a laser scanner, a kinetic study was undertaken to immobilize a labeled oligomer at different concentrations under microwaves. Briefly, a labeled oligomer, viz., TET-d (TCT GTA TGT CTA TTC TCG TT)-OPO_3-$(CH_2)_6$-SH, was serially diluted to concentrations (20, 10, 5, 2.5, 1.0, 0.75, 0.5, 0.25 μM) and spotted (0.5 μL) onto the functionalized glass slide. The slide was then subjected to microwave irradiation for 12 min (72 × 10 s). After capping and usual washings, the slide was visualized under a laser scanner and the spots were quantified using *QuantArray* software (Packard Biosciences, USA).

The extent of involvement of exocyclic amino groups of heterocyclic base (guanosine) and backbone phosphodiesters in reaction with epoxy functions on glass surfaces was evaluated

by immobilizing 5′-labeled-3′-thiolated and 5′-labeled-3′-OH oligonucleotides at 5 μM concentration on an epoxy-coated slide under microwaves, followed by usual washings and drying. The slide was then subjected to a laser scanner followed by quantification.

Thermal and pH Stabilities. To evaluate the thermal stability of the immobilization chemistry, a microarray was prepared by tethering a TET-labeled oligomer at 0.5 μM to a functionalized glass slide under microwaves, as mentioned above. The slide was then subjected to PCR-like conditions and 0, 5, 10, 15, and 20 cycles were performed. PCR parameters were as follows: 94 °C for 30 s (denaturing step), 54 °C for 30 s (annealing step), and 72 °C for 30 s (extension step). After thermocycling, the slide was thoroughly washed and scanned under a laser scanner.

In an analogous way, vulnerability of the projected chemistry was evaluated at different pHs by subjecting the constructed microarrays to washings (4 × 15 min) with buffers of different pH values, ranging 7−9.

Hybridization Assay. To study the hybridization kinetics, two glass slides, each one spotted (0.5 μL) with 5 μM concentration of probe, viz., HS-$(CH_2)_6$-OPO_3-d (ACG TAA GCA AAT CGA TCG TT), were subjected to microwave irradiation for 12 min (72 × 10s) and 12 h at 35 °C, respectively. After the usual capping, washings, and drying, the microarrays were hybridized with 40 μL of complementary labeled oligonucleotide sequence, TET-d (AAC GAT CGA TTT GCT TAC GT) (40 μM), under a coverslip. The slides were then kept in a humidified chamber for 1 h at 45 °C and overnight at 35 °C. After hybridization, the coverslips were gently removed and the slides were successively washed with 2× SSC (2 × 15 min) and 1× SSC buffers (1 × 5 min), followed by drying under vacuum. The slides were scanned under a laser scanner and fluorescence intensity of the spots was quantified.

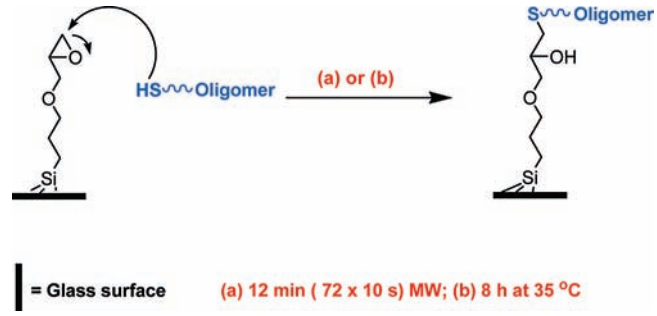
Detection of Mismatches. To investigate the sensitivity of the system, four oligonucleotides, viz., HS-$(CH_2)_6$-OPO_3-d (ACG TAA GCA AAT CGA TCG TT), HS-$(CH_2)_6$-OPO_3-d (ACG TAA GCA AAT CGA TCG GT), HS-$(CH_2)_6$-OPO_3-d (ACG TAA GCA TAT CGA TCG GT), and HS-$(CH_2)_6$-OPO_3-d (TTT TTT TTT TTT TTT TTT TT) having zero, one, and two base mismatches, and a noncomplementary sequence, respectively, were spotted at 5 μM onto an epoxy-coated glass slide followed by capping and usual washings. Subsequently, the microslide was subjected to hybridization experiment with a labeled oligomer, TET-d (AAC GAT CGA TTT GCT TAC GT), and washed with the hybridization buffer, as mentioned above. After drying under vacuum, the slides were subjected to a laser scanner.

Detection of Bacterial Meningitis. *PCR-Amplification.* Amplification of 430bp fragment of *Transposase* gene (*Neisseria meningitidis*; serogroup C) was performed by taking labeled forward primer TET-d (TCG ACG AAC TGA TCA TCC), labeled reverse primer TET-d (TCG GCA TAG ACG GTC GTA), genomic DNA, and Taq polymerase following a reported protocol (*22*). Analysis of the resulting PCR-amplicons was carried out on agarose gel electrophoresis.

Hybridization with PCR Amplicons. Two oligonucleotide sequences, HS-$(CH_2)_6$-OPO_3-d (TCG ACG AAC TGA TCA TCC) (probe) and HS-$(CH_2)_6$-OPO_3-d (CGT CGA GTT GTT CAT CTC GCA) (control) were immobilized on the glass slide, as described above. Amplicons were hot denatured (5 min, 95 °C), cooled on ice (10 min), and used for carrying out the hybridization assay. After usual washings and drying, the slide was subjected to laser scanning.

Signal Detection and Data Analysis. The arrays were imaged on a Scan Array Lite Scanner (GSI Lumonics) fitted with a Cy3 optical filter with 30 μm resolution. The laser power and PMT voltage were set accordingly to obtain optimum signal intensity. *QuantArray* software (Packard Bioscience) was used for analysis of intensity of the original images and the graphs were plotted in MS *Excel*. The fluorescence intensities in color images of slides were color coded, varying from blue (low) to green, yellow, and then white (saturation).

Scheme 1. Strategy for the Immobilization of Thiolated Oligonucleotides onto Epoxy-Activated Glass Microslides



DNA Quantification. In an attempt to quantify the density of immobilized oligonucleotides, varying amounts (0.0125, 0.025, 0.05, 0.1, 0.2, 0.3, 0.4, and 0.5 pmol) of an oligomer sequence, TET-d (TCT GTA TGT CTA TTC TCG TT)-OPO_3-$(CH_2)_6$-SH were spotted on a virgin glass microslide. After drying, the slide was scanned and the spots were quantified to obtain a standard calibration curve by plotting fluorescence intensity (A.U.) as a function of amount of the spotted probe (pmol) (Figure S1, Supporting Information).

For each experimental condition tested on the microarrays, oligomers were spotted in duplicates and the experiment was repeated at least three times. The immobilization and hybridization data presented are the averages of these repetitions, and the error bars represent the percentage error observed on this average.

RESULTS AND DISCUSSION

The use of oligonucleotide arrays is expanding beyond their high-profile role in genome sequencing to other fundamental applications like nucleic acid-ligand binding studies and medical diagnostics. The high-throughput screening technology enables researchers to rapidly profile the expression of thousands of genes simultaneously. Reports have shown that oligonucleotides immobilized through end-specific covalent linkage increase the availability of the immobilized probes for hybridization. Therefore, active groups are often introduced at either the 3′- or 5′-end (usually amino or thiol) of the oligonucleotides to allow end-specific immobilization onto the activated glass surface. For a new chemical method to be useful for the construction of microarrays, the functionalities on the surface should be compatible with the reactive groups on the probe molecules and the immobilization chemistry should be fast and reproducible and offer low background noise during detection. Holistic development of efficient chemistries for the manufacture of oligonucleotide arrays is essential to garner the potential of biochip technology. Microwave (MW) activation, as a nonconventional energy source, has become a very popular and useful technology in organic chemistry. A large number of articles describe significant acceleration in the reaction rates for a wide range of organic reactions, reducing the reaction time from hours to minutes with improved yields and reproducibility (*24, 25*). In contrast to thermal/photochemical reactions, the use of microwaves to construct oligonucleotide arrays has largely remained unexplored. We now present a method for covalent immobilization of 3′/5′-thiolated oligonucleotides onto an epoxy-activated glass surface under microwaves as illustrated in Scheme 1. The optimal pH for reaction, immobilization kinetics,

stability (thermal and pH), effect of probe, and target concentrations on hybridization efficiency have been optimized.

Immobilization of Thiolated Oligonucleotide onto Epoxy-Activated Glass Microslides. The optimal condition required for effective immobilization of thiol-modified oligonucleotides via thioether linkage was determined by spotting a labeled probe (at 1 μM) on epoxy-functionalized glass surface under different pH conditions, as mentioned in the Experimental Procedures. The results showed that maximum immobilization was achieved at pH 8.0 possibly through the availability of thiol groups in their anionic form (Figure 1A,B). As the pH was increased from 8 to 12, the fluorescence intensity decreased, which might have resulted due to partial oxidation of thiol functions at higher pH values, whereas the reason for lower attachment density attained at pH 6 could be due to the lower reactivity of thiol functionality at slightly acidic pH. On the basis of these findings, immobilization of thiol-modified probes was carried out at pH 8.0 for the rest of the experiments.

The kinetics of thioether linkage formation under both microwaves and thermal conditions were investigated by spotting a large excess of 3′-thiolated oligomer onto an epoxy-functionalized glass surface. The results show that the reaction between the thiolated probe and epoxy groups is essentially completed in 12 min under microwaves, while it takes ∼8 h at 35 °C under thermal conditions (Figure 2A,B). Therefore, the rest of the experiments were conducted for 12 min under microwaves for the immobilization of thiol-modified probes onto the functionalized glass surface. Similarly, to find the highest density of oligonucleotide attachment on the surface, a kinetics study of the probe immobilization at various amounts (0.125−10 pmol) was undertaken (Figure 3). It can be deduced from the results that the attachment density increases upon increasing the concentration of the probe, and the highest fluorescence intensity was obtained at 10 pmol in the spotting buffer (Figure 3). Subsequently, the immobilization efficiency was determined using a standard calibration curve (Figure 3, Lane 2) (Table S1, Supporting Information).

With the aim to determine the extent of involvement of terminal thiol groups of the probe with epoxy functions of glass surface, a microarray was prepared by spotting 5′-labeled oligonucleotides (5 μM) with and without thiol modification at 3′-terminus. After treatment with the capping buffer and usual

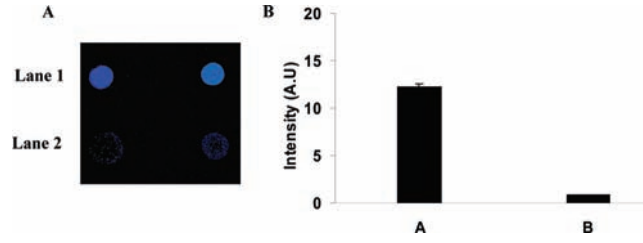

Figure 4. (a) Fluorescence map showing immobilization of TET-d (TCT GTA TGT CTA TTC TCG TT)-OPO_3-$(CH_2)_6$-SH (lane 1) and TET-d (TCT GTA TGT CTA TTC TCG TT) (lane 2) on epoxy-functionalized glass surface. (b) A graph representing the comparison of fluorescence intensity obtained by spotting thiol-modified (A) and unmodified oligomer (B) on epoxy-activated surface.

washings, the slide was visualized under a laser scanner (Figure 4A). The fluorescence intensity from spots of the unmodified oligonucleotide was found to be ∼6.5% of that measured from the probe with a 3′-thiol modification, implying specific binding of the terminal thiol groups to the epoxy-activated surface (Figure 4B). The low amount of fluorescent signal obtained with unmodified oligonucleotide could have arisen from weaker binding of internucleotidic phosphate groups and exocyclic amino groups of guanosine moieties in the probe with the epoxy-activated surface. Although nonspecific binding of the unmodified probe is small, a measurable fluorescent signal still resulted, indicating that the same interactions may result from the

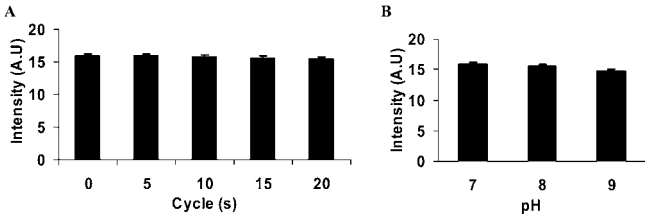

Figure 5. (a) Thermal stability of thioether linkage under PCR-like conditions and comparison of the fluorescent signal obtained after 0, 5, 10, 15, and 20 cycles; (b) stability of the constructed microarrays under a pH range of 7−9.

complementary targets during hybridization, leading to significant background and artifacts. This was eliminated by treating the spotted slides with a capping buffer to deactivate the residual epoxy functions.

Thermal and pH Stability. The heat stability of the constructed microarray was evaluated by submitting it to 0, 5, 10, 15, and 20 PCR-like heating cycles. The fluorescent signal of the heat-treated microarrays was found to be decreased by only ~1.4% after 10 cycles and ~2.5% after 20 cycles. Figure 5A shows a histogram obtained by comparing the fluorescent signal of heat-treated and pretreated microarray. This shows that the oligonucleotides immobilized on the activated glass surface following the projected strategy are sufficiently stable to be used in biological research.

In order to find the vulnerability of the constructed microarrays toward different pHs, the constructed microarrays were subjected to washings (4 × 15 min) with buffers of different pH, ranging 7−9. The quantification results reveal that the fluorescence intensity decreased by only 2.0% at pH 8.0 and 4.4% at pH 9.0 in comparison to that obtained at pH 7.0 (Figure 5B). Thus, the fabricated microarray can be used over a wide range of pH safely without significant change in its performance.

Hybridization Assay. The accessibility and specificity of the surface-bound probes during hybridization have been the major concern while preparing microarrays. In order to investigate these parameters, two microarrays were prepared by immobilizing oligonucleotide under microwaves (12 min) and thermal conditions (~8 h) (Scheme 1). After the hybridization experiment, the spots were visualized under a laser scanner as shown in Figure 6A,B. Negligible fluorescence was obtained during hybridization with the noncomplementary oligonucleotide, demonstrating that nonspecific hybridization did not occur. The signal-to-noise ratio was on average 96, as calculated from signals obtained from complementary hybridized spots and nonhybridized spots.

To demonstrate the dynamics of microarray hybridization, the kinetics of hybridization reaction for different target oligonucleotide concentrations was followed. The results showed that, in the initial stage, the hybridization signal increases on increasing the target concentration, then reaches a steady state between 40 and 60 μM (Figure 7A). The results of kinetics of hybridization for different probe concentrations are shown in Figure 7B. The plot of hybridization efficiency (efficiency defined as percent of covalently attached oligonucleotides that participated in duplex formation) for different amounts of immobilized probes reveals that it reaches a maximum (~33%) for an optimal immobilized probe concentration of 5 μM (Table S1, Supporting Information). Above this concentration, the efficiency did not increase, even if the concentration of the immobilized probe was increased, as the overloading of the surface with probe may cause a crowding effect that can lower the accessibility of the surface-bound probe molecules. In addition, the efficiency of hybridization depends on many factors like the number of epoxy groups on the surface accessible to

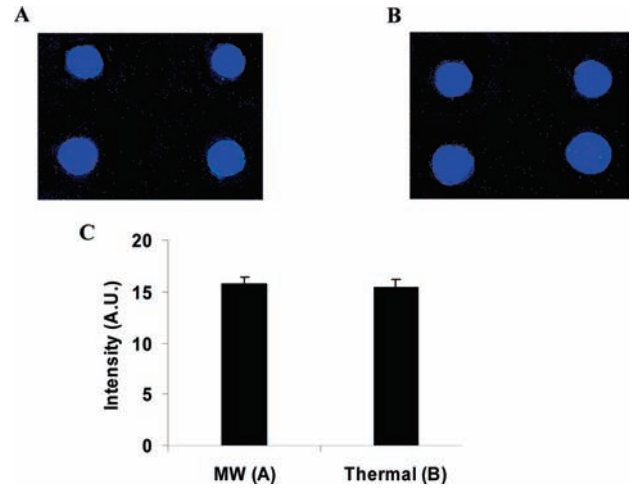

Figure 6. Fluorescence maps obtained after hybridization of HS-$(CH_2)_6$-OPO_3-d (ACG TAA GCA AAT CGA TCG TT) immobilized at 5 μM with target, TET-d (AAC GAT CGA TTT GCT TAC GT) (40 μM). Oligonucleotide is immobilized (A) under microwaves for 12 min (72 × 10s) at 800 W; (B) under thermal condition at 35 °C for ~8 h. (C) Quantification representation of hybridization results of the two methods, A and B.

the 5′-thiolated oligonucleotides, attachment efficiency of oligonucleotides to the epoxy-activated surface, and availability of immobilized probes to the target oligomer.

Specificity of Immobilization Chemistry for Detection of Mismatches. In order to demonstrate the specificity of the system, four oligonucleotides were immobilized onto an epoxy-functionalized glass microslide at 5 μM concentration of each probe as mentioned in the Experimental Procedures. After treatment with the capping buffer, the microslide was subjected to a hybridization step with a labeled oligomer (complementary to zero mismatch sequence). Figure 8 clearly shows the base mismatches. The perfectly matched sequence gave the maximum intensity (lane 1), while the spots having one (lane 2) and two (lane 3) showed fluorescence intensity in decreasing order. No measurable nonspecific hybridization signal from the noncomplementary control was detected. This may be because the residual epoxy groups on the surface got masked during treatment with the capping buffer to exclude nonspecific interactions with the target oligonucleotides.

Quantification and Surface Coverage of the Immobilized Oligonucleotides. Quantification of the microarrays prepared following the proposed method was carried out by using a standard calibration curve plotted between fluorescence intensity (a.u.) and amount of the spotted probe (pmol), as mentioned in the Experimental Procedures. Surface coverage of the immobilized probe was calculated from the following formula (*9b*):

$$\text{surface coverage (molecules/}\mu\text{m}^2) = \frac{\text{amt. of immobilized probe (pmol)} \times 6.023 \times 10^{23}}{\text{area of spot } (\mu\text{m}^2)}$$

(spotting vol.: 0.5 μL)

Comparison of the Proposed Method with the Standard Methods. The projected method for microarray preparation was compared with the three existing standard methods, viz., NTMTA (*7*), epoxide-amine (*21*), and disulfide (*19*) approach (Scheme 2). For comparison purposes, an equal concentration of the appropriate oligonucleotide was used. However, different reaction times, as reported therein, were employed in all the three methods. After immobilization, the spots were hybridized with the complementary labeled oligonucleotide, and the mi-

croslides were visualized under a laser scanner for quantification of spots (Table S2, Supporting Information). The hybridization efficiency of the proposed method (∼33%) is much higher than the method employing NTMTA reagent (∼9.8%), epoxide-amine immobilization chemistry (∼9.8%), and disulfide approach (1.7%), as shown in Figure 9.

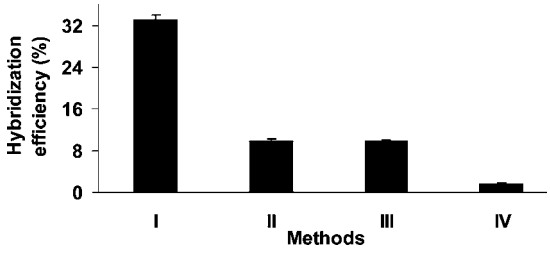

Figure 9. Comparison of hybridization efficiency of proposed method (I) with standard ones, viz., (II) = NTMTA, (III) = epoxide-amine, and (IV) = disulfide method.

Detection of Bacterial Meningitis. In order to demonstrate the ability of the constructed biochip to detect bacterial infection, a specific probe of the *Transposase* gene and a noncomplementary probe, as control, were immobilized onto an epoxylated glass slide, and after the usual washings, the spots on the glass surface were subjected to hybridization with the labeled PCR

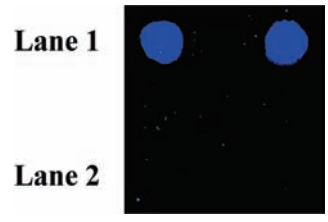

Figure 10. Detection of bacterial meningitis. Lane 1: Probe sequence, HS-$(CH_2)_6$-OPO_3-d (TCG ACG AAC TGA TCA TCC). Lane 2: Control sequence, HS-$(CH_2)_6$-OPO_3-d (CGT CGA GTT GTT CAT CTC GCA).

amplicons. After washings and drying, the slide was visualized under a laser scanner (Figure 10). Spots pertaining to probe sequence specific to *Transposase* gene of bacteria (*N. Meningitidis*, Serogroup C) showed fluorescence, while spots pertaining to the control did not fluoresce at all, signifying the specificity of the system to prepare biochips for the detection of bacterial meningitis in humans.

CONCLUSIONS

A simple and efficient method for preparation of oligonucleotide microarrays via a stable thioether linkage is established with rapid immobilization of thiolated oligomers onto epoxylated surface under microwaves with excellent immobilization efficiency (~24%), stable over a wide pH range and thermocyclic conditions, suggesting that the biochip could be integrated with PCR. The proposed chemistry enables the immobilized probes to be highly accessible to targets during hybridization with remarkable efficiency (~33%) and negligible background noise (signal-to-noise ratio 96). It also successfully discriminates the base mismatches and can detect bacterial diseases thus promising for other biomolecules and chemicals for diagnostic purposes.

A Fine Line Between Molecular Umbrella Transport and Ionophoric Activity

Wen-Hua Chen,[†] Vaclav Janout,[†] Masaharu Kondo,[†] Arevik Mosoian,[‡] Goar Mosoyan,[‡] Ravil R. Petrov,[†] Mary E. Klotman,[‡] and Steven L. Regen*[,†]

A persulfated molecular umbrella derived from one spermine, four lysine, and eight deoxycholic acid molecules was found to exhibit ionophoric activity, as shown by pH discharge and Na^+ and Cl^- transport experiments. In sharp contrast, a moderately more hydrophilic analogue derived from cholic acid showed no such ionophoric activity. Both molecular umbrellas crossed liposomal membranes by passive transport with experimental rates that were similar. These findings show how the interactions between such amphomorphic molecules and phospholipid bilayers are a sensitive function of the umbrella's hydrophilic/lipophilic balance (HLB). They also raise the possibility of exploiting molecular umbrellas in fundamentally new ways.

Molecular umbrellas are a unique class of conjugates made from two or more facial amphiphiles that have been covalently attached to a central scaffold (*1*). Such molecules are "amphomorphic" in the sense that they can produce a hydrophobic or hydrophilic exterior when exposed to a hydrophobic or hydrophilic environment, respectively. Because molecular umbrellas are capable of crossing lipid bilayers, even when strongly hydrophilic agents are coupled to them (e.g., oligonucleotides), they hold promise as drug carriers (*2*−*4*).

In previous work, we showed that highly sulfated molecular umbrellas, themselves, have interesting biological properties. Specifically, we showed that a bioconjugate derived from one spermine, four lysine, and eight cholic acid groups, having all of its hydroxyl groups sulfated (i.e., **1**), exhibits significant anti-HIV and anti-HSV activity (Figure 1) (*5*, *6*). In a related investigation, we showed that a fluorescently labeled analogue of **1** readily enters live HeLa cells and provided evidence that passive transport may be playing a significant role in this internalization process (*7*).

In the present study, we sought to test the feasibility of enhancing the membrane transport activity of a persulfated molecular umbrella by increasing its lipophilicity. Our motivation for this work was based on the presumption that, if molecules of this type could cross the blood-brain barrier, they could have therapeutic value as anti-HIV and anti-HSV agents (*8*). With this aim in mind, we investigated more lipophilic analogues of **1**. According to the classic solution-diffusion model for bilayer transport, the permeability coefficient (*P*) of a permeant is directly proportional to its water−membrane partition coefficient (*K*) and its diffusion coefficient (*D*), but inversely proportional to the thickness (*x*) of the bilayer (*1*, *9*, *10*). Since $P = (K \times D)/x$, any increase in lipophilicity is expected to increase *P* by increasing *K*, although exceptions to this model have already been noted for certain molecular umbrella−fluorophore conjugates (*11*). As documented in this paper, we have discovered that a moderate increase in the lipophilicity of a persulfated molecular umbrella does not enhance its transport activity but, instead, leads to *ionophoric activity*; that is, a "fine line" exists between umbrella transport and ionophoric activity based on the umbrella's hydrophilic/lipophilic balance.

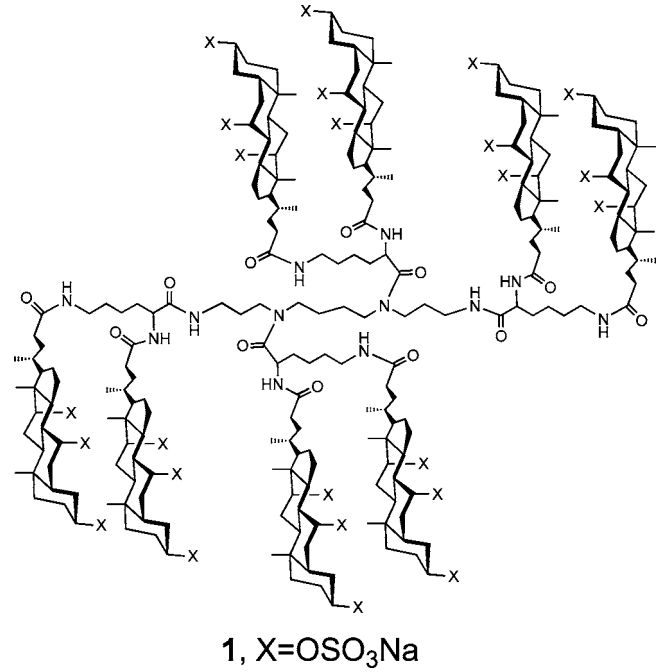

Figure 1. Molecular structure of a persulfated molecular umbrella having significant anti-HIV and anti-HSV activity.

Two specific molecular umbrellas that were chosen as synthetic targets for this work were **2** and **3** (Figure 2). Thus, replacement of all of the secondary amide groups with *N*-methylated amide units (i.e., **2**) was expected to result in a modest increase in lipophilicity. In contrast, removal of one sulfate group per sterol (i.e., **3**) was expected to lead to a more moderate increase in lipophilicity. As a control for umbrella-mediated transport, we chose a sulfonated polymer that was similar in size and charge to **1**, **2**, and **3**, but devoid of facial amphiphilicity, that is, a β-naphthalene sulfonate/formaldehyde condensation polymer (PRO 2000) (*12*). This synthetic polymer, which is currently in clinical trials as an anti-HIV microbicide, was a gift from Indevus Pharmaceuticals (Lexington, MA).

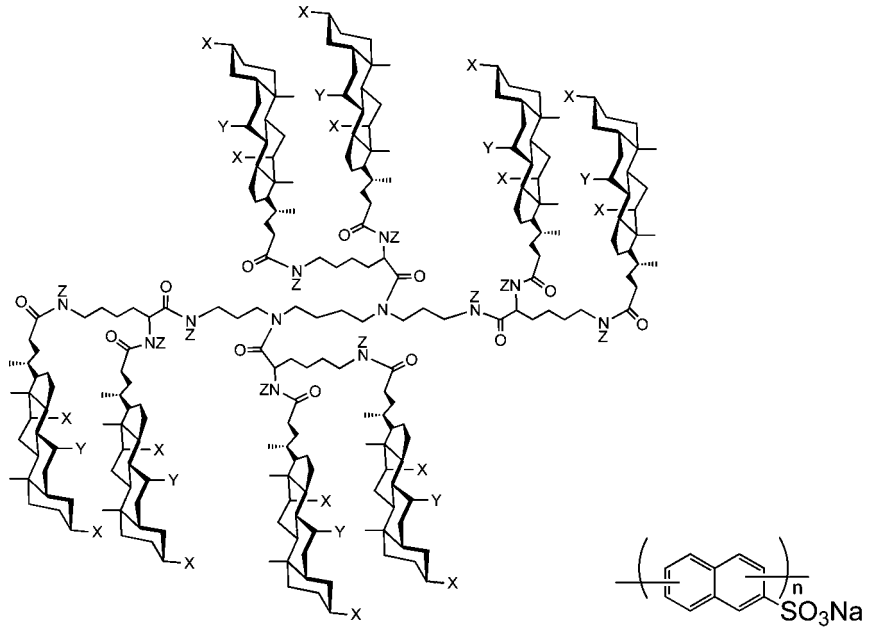

Figure 2. Molecular structures of **2** and **3** having a modest and moderate increase in lipophilicity, respectively, relative to **1**.

Umbrella **3** was synthesized using methods analogous to those previously described for the preparation of **1**. In this case, deoxycholic acid was used in place of cholic acid. Umbrella **2** was prepared in a similar way except that *N*-methylated derivatives of L-lysine-dicholamide (i.e., **8**) and spermine (i.e., **9**) were employed (Figure 3) (*5, 13, 14*). Relative lipophilicities were determined by measuring the affinity of each agent toward liposomes (200 nm, extrusion) derived from 1-palmitoyl-2-oleyol-*sn*-glycero-3-phosphocholine (POPC)/1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphatidylglycerol (POPG) (95/5, mol/mol). Partition coefficients, *K*, that are reported in Table 1 were calculated using the nonsaturable partitioning model (*10*). Thus, if C_o is the equilibrium concentration of the conjugate in solution as measured in the absence of liposomes, and *C* is the concentration in the presence of liposomes, then the partition coefficient is calculated as $K = [(C_o - C) \times W]/[C(L/2)]$. Here, $L/2$ is the concentration of the lipids in the external half of the bilayer with a weighted average molecular weight of 649 and *W* is the concentration of water, 55.5 M. If the inner leaflet contributes to binding, the true *K* values could be lower by a factor of 2. The efflux rate for each molecular umbrella obeyed first-order kinetics; experimental rate constants, k_{obsd}, are also reported in Table 1.

The increase in lipophilicity on going from **1** to **2** proved to be so modest that it could not be detected by binding measurements. In contrast, the increase in lipophilicity of **3** was substantial. For PRO 2000, even stronger affinity to these lipid membranes was observed. Despite this variation in lipophilicities, the observed efflux rates for all three molecular umbrellas were similar. With PRO 2000, no efflux could be detected after 250 h. An *in vitro* examination of **1** and **2** revealed that both molecular umbrellas had similar anti-HIV activity (Figure 4). In addition, neither of these agents showed any evidence of cytotoxicity at 1000 μg/mL. In sharp contrast, **3** was found to have significant cytotoxicity at 10 μg/mL. Because of its high toxicity, no attempt was made to determine the anti-HIV activity of **3**. On the basis of its relatively high lipophilicity, we hypothesized that the cytotoxicity associated with **3** was due to membrane-disrupting properties, possibly by acting as an ionophore (*9*). To test for membrane permeabilization, we carried out a series of pH discharge experiments using liposomes made from POPC/POPG (95/5, mol/mol) containing 0.1 mM of entrapped pyranine in 25 mM HEPES buffer (pH 7.0, 50 mM NaCl) (*15, 16*). After raising the pH of the external aqueous phase to 8.0, subsequent addition of 0.006 mol % of **3** led to a rapid increase in fluorescence intensity (Figure 5). A control experiment confirmed that exposure to **3** did not release any (i.e., <2%) of the dye from the aqueous interior of the liposomes within 4.5 h. Retention of this dye was quantified using an equilibrium dialysis cell, where the concentrations of dye in the source (i.e., liposome) and receiving sides were measured after 4.5 h. Taken together, these results show that **3** discharges the pH gradient across these liposomal membranes. Under similar conditions, **1**, **2**, and PRO 2000 showed no permeabilization activity; that is, their fluorescence profiles were the same as that found in the absence of an added umbrella. Increasing the concentration of **1** by 2 orders of magnitude (i.e., using 0.6 mol %) still showed no evidence of permeabilization activity.

To determine whether **3** might be creating pores or channels in these lipid bilayers, we examined its ability to promote the transport of Na^+ and Cl^- ions across liposomal membranes. Using established procedures, a paramagnetic shift reagent $[Dy(P_3O_{10})_2Na_7]$ plus NaCl was added to liposomal dispersions that were prepared from POPC (200 nm, extrusion) and 150 mM KCl (*17*). Subsequent addition of **3** resulted in an internalization of Na^+, which could be monitored by $^{23}Na^+$ NMR (Figure 6). The biphasic nature of this kinetic profile is a likely consequence of the use of substoichiometric amounts of umbrella, which are expected to be distributed according to binomial statistics. Thus, the fast phase is presumed to be due to those liposomes that contain one or more umbrella molecules, and the slow phase due to a redistribution of the molecular umbrellas among the liposomes. Under similar conditions, **1** had no detectable Na^+ transport activity (not shown). To test for Cl^- transport, we first attempted to monitor the kinetics of chloride ion influx

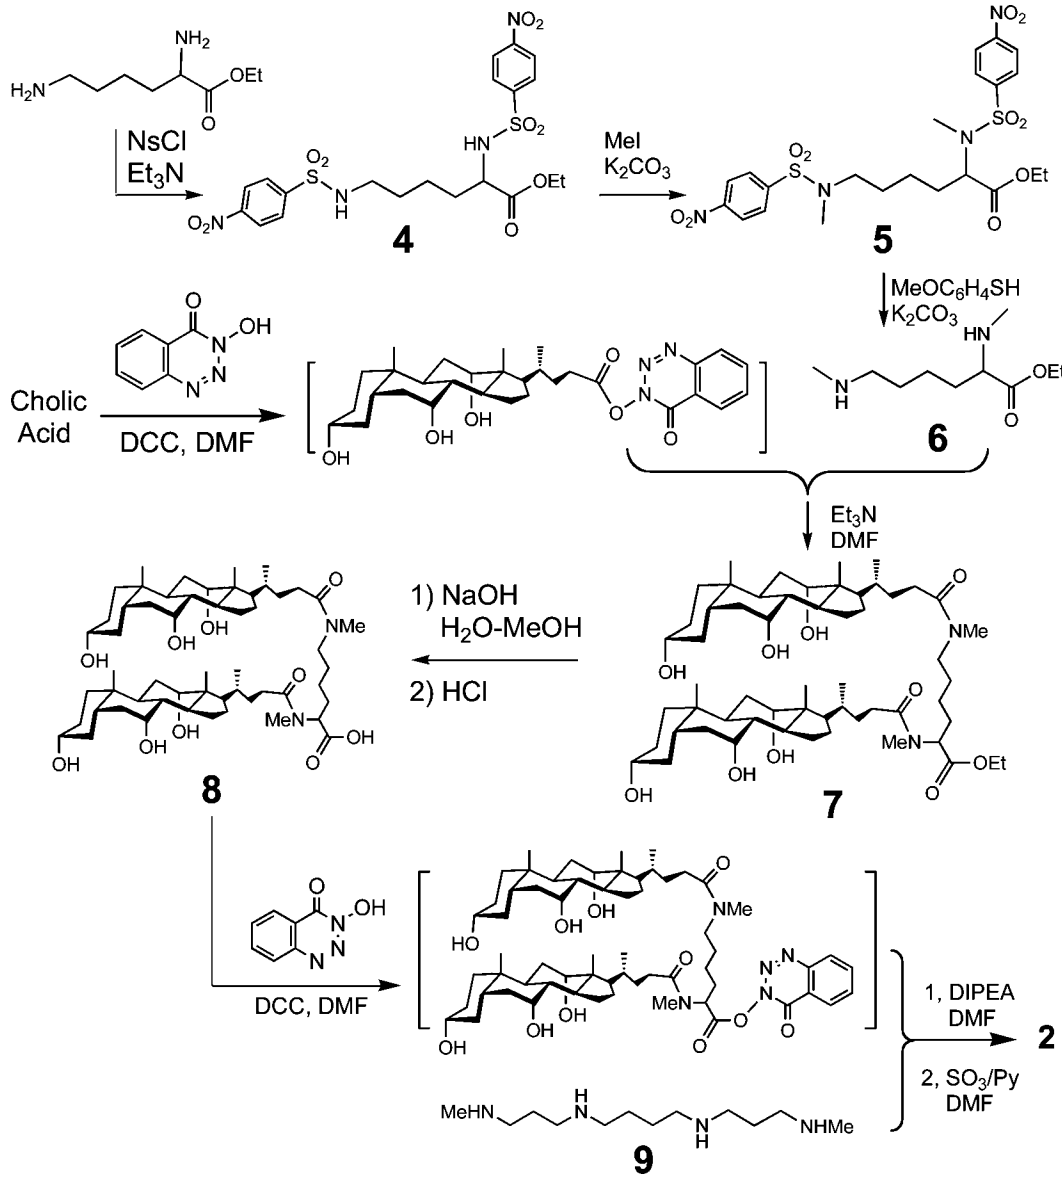

Figure 3. Synthetic approach used for the synthesis of **2**.

Table 1. Binding and Efflux Data[a]

entrapped permeant	binding (%)	K^b	$10^3 k_{obsd}{}^c$ (h^{-1})
1	3.4	590	12.1
2	2.8	490	7.7
3	19	4000	9.8
PRO 2000	74	41000	0.0

[a] Measurements were at 24 °C using POPC/POPG (95/5, mol/mol). [b] In all cases, equilibrium was reached within 24 h. [c] Experimental first-order rate constant for efflux.

using a liposome-entrapped chloride-sensitive dye (i.e., lucigenin) as a sensor. Such methods have previously been employed by other researchers (*18*). For our system, however, we found that the addition of **3** led to the complete release of the dye, as determined by equilibrium dialysis measurements. Because of this release, we chose an alternate approach, where we measured the efflux of chloride ion upon addition of **3**. Thus, a similar liposomal dispersion was first prepared from POPC and 100 mM NaCl in 10 mM sodium phosphate (pH 6.7). Subsequent dialysis against 100 mM $NaNO_3$ in 10 mM sodium phosphate (pH 6.7), followed by addition of 0.006 mol % of **3**, resulted in (61 ± 2)% release of the entrapped chloride ion after a 12 h at 23 °C (see Supporting Information). In the absence of **3**, only (18 ± 2)% of the entrapped chloride ion was released over this same time period. The fact that **3** promotes the transport of Cl^- ions rules out a simple carrier mechanism, since chloride ion and the molecular umbrella are both negatively charged. Rather, it lends support for **3** acting as a pore- or channel-forming agent. The fact that two distinct resonances are observed for Na^+ further indicates that these openings are too small to permit the passage of the paramagnetic shift reagent but large enough to allow for a flow of Na^+ ions. The difference between **1** and **3**, in terms of their interactions with phospholipid bilayers, is striking. One possible explanation for this difference is that **3**, being more lipophilic, prefers to reside within and across the bilayer, which leads to pore formation. In contrast, the more hydrophilic analogue, **1**, may favor binding to the inner and outer surfaces of the membrane, and its presence in the hydrocarbon interior is only transient as it crosses from one leaflet to the adjoining one. The strong dependency of molecular umbrella−lipid bilayer interactions on an umbrella's hydrophilic/lipophilic balance that we have discovered shows that a "fine line" exists between

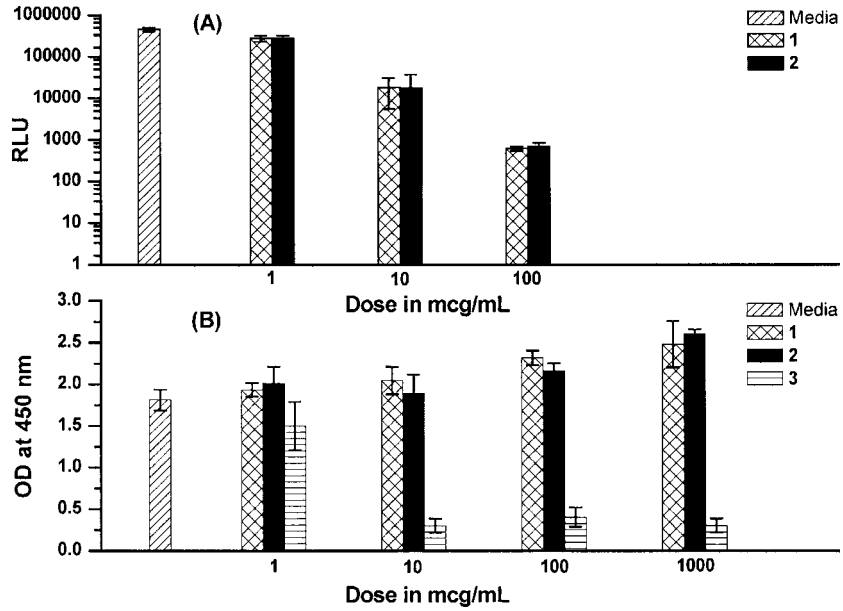

Figure 4. Dose-dependent inhibition of HIV-1 gene expression in U87 cells by different drugs. (A) U87 $CD4^+$ $CCR5^+$ cells pretreated with indicated concentrations of different drugs for 1 h followed by infection with JRFL envelope pseudotyped replication-defective HIV-1. Luciferase quantitation was performed on cell lysates 48 h post infection and is reported as relative light units (RLUs). (B) Cytotoxicity of compounds **1**, **2**, and **3** was done on U87 cells treated with different concentrations of the compounds. Cells were treated for 1 h with different drugs, and then compounds were aspirated and replaced with control medium and cultured for additional 3 days. This was followed by addition of 20 uL of MTS/PMS solution and incubation for 2 to 4 h. Optical densities (OD) were read at 450 nm.

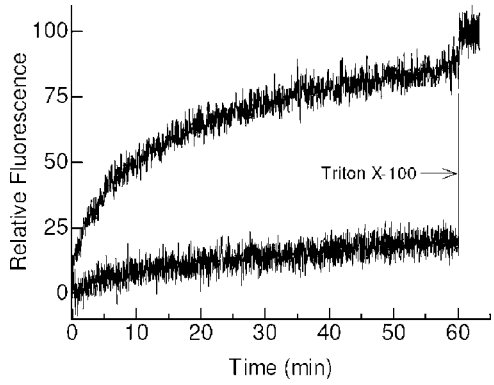

Figure 5. Fluorescence intensity as a function of time (23 °C) in liposomal dispersions made from POPC/POPG (95/5, mol/mol) in the absence (lower trace) and presence of 0.006 mol % of **3** (upper trace). An excess of Triton X-100 was used to destroy the liposomes by forming mixed micelles.

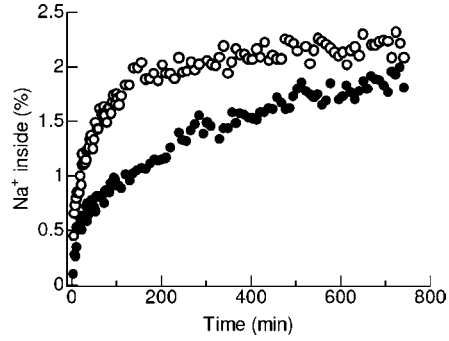

Figure 6. Entry of Na^+ into liposomes made from POPC as a function of time at 35 °C after addition of (●) 0.002 mol % and (○) 0.004 mol % of **3**. In the absence of **3**, there was no detectable entry of Na^+ after 12 h (not shown).

umbrella transport and ionophoric activity—a line that must not be crossed if such conjugates are to be used for drug delivery. At the same time, this finding raises the possibility of exploiting such molecules in fundamentally new ways, e.g., as biogenic ionophores and as cytotoxic drugs.

ACKNOWLEDGMENT

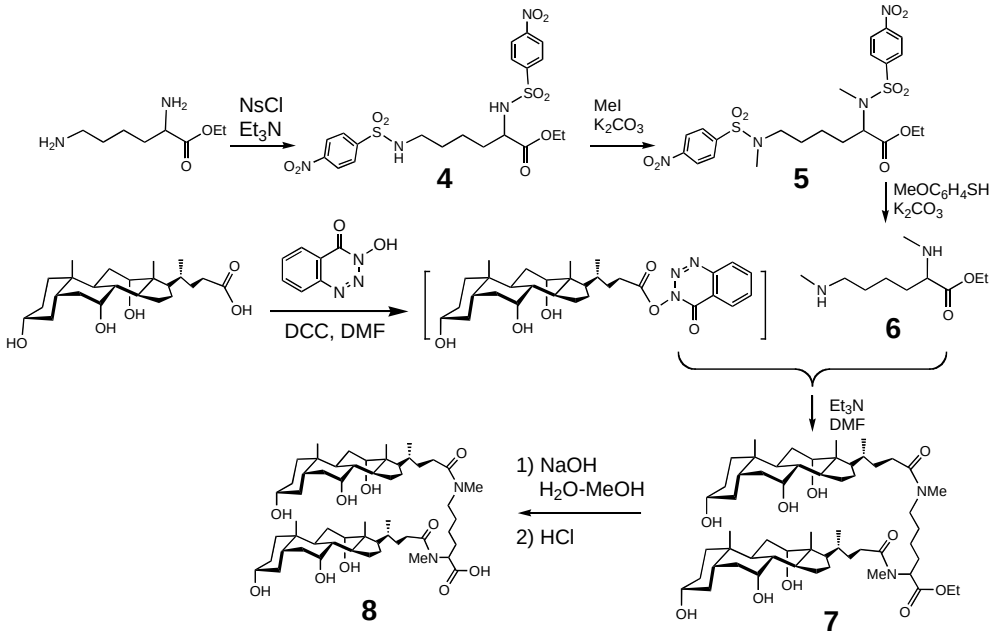
SUPPORTING INFORMATION

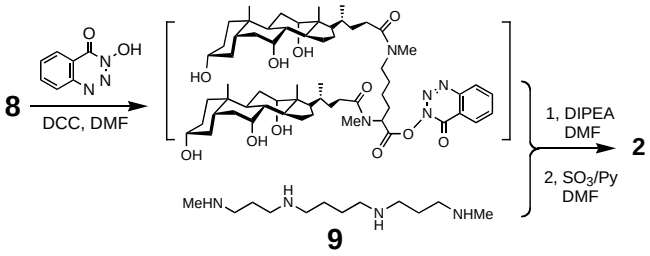
EXPERIMENTAL PROCEDURES

General Methods. ^{1}H NMR spectra were recorded in CD_3OD, DMSO-d_6 or $CDCl_3$ using a Bruker 500 spectrometer, and the solvent as a reference. HR-ESI mass spectra were recorded on an Agilent 6210 LCMS spectrometer. Silica gel 60 (EMD, particle size 0.063-0.200 mm, 70-230 mesh) was used for all column chromatographic purifications. Thin-layer chromatography (TLC) was performed on glass plates that were precoated with silica gel containing a fluorescence indicator (Whatman). Detection on TLC was made by use of 10% sulfuric acid in water, iodine, ninhydrin solution and UV (254 or 365 nm). All reagents and chemicals were obtained from commercial sources and used as received unless noted otherwise. Bioconjugate **1**, was prepared using established procedures.[1,2] A bis-N-methylated spermine (**9**) was synthesized using literature procedures.[3,4] Experimental methods that were used to measure binding constants and efflux rates constants, which are described below, were similar to those previously reported.[5] PRO 2000 was a gift from Indevus Pharmaceuticals (Lexington, MA) and was >99.3% pure, as indicated by the supplier.

Scheme 1



Scheme 2



Synthesis of *L*-Lysine-dideoxycholamide. The procedure used for the synthesis of *L*-lysine-dideoxycholamide was similar to that previously used to prepare *L*-lysine-dicholamide.[2] Thus, DCC (1.97 g, 9.55 mmol) was added to a solution of deoxycholic acid (2.5 g, 6.37 mmol) and *N*-hydroxysuccinimide (0.84 g, 7.30 mmol) in anhydrous THF (40 mL). The resulting mixture was stirred at room temperature for 4 h, and then filtered to remove the insoluble urea. The filtrate was then added, dropwise, to a solution of *L*-lysine (445 mg, 3.04 mmol) and triethylamine (2.9 mL) in H_2O (10 mL), and stirred overnight. The reaction mixture was concentrated under reduced pressure and poured into

1 M hydrochloride acid (250 mL). The resulting solid was collected by filtration and purified by chromatography on a silica-gel column, eluting with $CHCl_3$/MeOH/H_2O (40/10/1, v/v/v) to afford *L*-lysine-dideoxycholamide (1.88 g, 69%) having ^{1}H NMR (500 MHz, CD_3OD, 296 K) δ 4.35 (m, 1 H), 3.95 (s, 2 H), 3.52 (m, 2 H), 3.23 (t, *J* = 5.75 Hz, 2 H), 2.38-2.27 (m, 2 H), 2.24-2.15 (m, 2 H), 1.92 (m, 66 H), 0.70 (s, 6 H); and HR-ESI MS for $C_{54}H_{91}N_2O_8$ ($[M+H]^+$) calcd: 895.6781; found: 895.6792.

Synthesis of 3. To a solution of *L*-lysine-dideoxycholamide (750 mg, 0.838 mmol) and 3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one (DHBT) (157 mg, 0.96 mmol) in anhydrous DMF (10 mL) was added DCC (260 mg, 1.26 mmol). After the mixture was stirred for 4 h, a solution of spermine (34 mg, 0.17 mmol), and 4-dimethylaminopyridine (164 mg, 1.34 mmol) in anhydrous DMF (1.0 mL) was added. The reaction mixture was stirred at room temperature overnight, concentrated under reduce pressure, and poured into a 5% ammonia solution (200 mL). The resulting precipitate was collected by filtration and purified by chromatography on a silica-gel column, eluting with $CHCl_3$/CH_3OH/H_2O (40/10/1, v/v/v) to give the hydroxylated precursor to **3** (515 mg, 83%) having ^{1}H NMR (500 MHz, CD_3OD, 296 K) δ 4.73 (m, 2 H), 4.24 (m, 2 H), 3.94 (s, 8 H), 3.52 (m, 8 H), 3.47-3.36 (m, 8 H), 3.15 (m, 12 H), 2.37-2.04 (m, 16 H), 1.93-0.92 (m, 272 H), 0.70 (s, 24 H); and HR-ESI MS for $C_{226}H_{378}N_{12}O_{28}$ (M^+) Calcd: 3708.8524; found: 3708.8372.

Sulfation was then carried out by dissolving this hydroxylated precursor **(**204 mg, 0.06 mmol) in DMF (3 mL) at 0°C, followed by direct addition of sulfur trioxide/pyridine complex (560 mg, 3.52 mmol). After stirring overnight at room temperature, 2 mL of cold water was added, followed by addition of sodium carbonate until the pH of the

mixture was 10. The combined solvents were then removed under reduced pressure, and the resulting residue was purified by dialysis (MWCO 500) against water (250 mL) to give **3** (210 mg, 71%) as its sodium salt having ^{1}H NMR (500 MHz, DMSO-d_6, 296 K) δ 4.57 (br, 2 H), 4.35 (s, 8 H), 4.11 (br, 2 H), 3.92 (s, 8 H), 3.40-3.03 (m, 8 H), 2.95 (m, 12 H), 2.10-0.83 (m, 288 H), 0.61 (s, 24 H); and HR-ESI MS for $C_{226}H_{362}N_{12}O_{76}Na_{16}S_{16}$ (M^-) Calcd: 5339.8725; found: 5339.8843.

Synthesis of 4. A solution of 4-nitrobenzenesulfonyl chloride (2.70 g, 12.18 mmol) in CH_2Cl_2 (15 mL) was added dropwise to a mixture of *L*-lysine ethyl ester dihydrochloride (1.50 g, 6.07 mmol) and triethyl amine (5.0 mL, 35.9 mmol) in CH_2Cl_2 (20 mL). The resulting mixture was stirred at room temperature for 4 h, diluted with $CHCl_3$ (100 mL) and washed with water (150 mL, pH 1.0). The organic layer was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure. The resulting residue was purified by chromatography on a silica-gel column [$CHCl_3$/MeOH, 20/1 (v/v)] to afford compound **4** (3.13 g, 95%) having ^{1}H NMR (500 MHz, $CDCl_3$, 296 K) δ 8.34 (d, *J* = 7.96 Hz, 2 H), 8.32 (d, *J* = 7.93 Hz, 2 H), 8.04 (d, *J* = 7.90 Hz, 2 H), 8.01 (d, *J* = 7.90 Hz, 2 H), 5.80 (br, 2 H), 5.32 (unresolved, 1 H), 3.93 (q, 2 H), 2.97 (t, *J* = 6.11 Hz, 2 H), 1.77-1.70 (m, 1 H), 1.64-1.57 (m, 1 H), 1.55-1.43 (m, 2 H), 1.42-1.36 (m, 2 H), 1.08 (t, 3 H), and HR-ESI for $C_{20}H_{25}N_4O_{10}S_2$ ($[M+H]^+$) Calcd: 545.1007. Found: 545.1001.

Synthesis of 5. Iodomethane (1.08 mL, 17.31 mmol) was added to a mixture of compound **4** (3.10 g, 5.69 mmol) and potassium carbonate (2.36 g, 17.08 mmol) in anhydrous DMF (20 mL). The resulting mixture was stirred overnight at room temperature, and then diluted with $CHCl_3$ (150 mL) and washed with water (150 mL). The organic layer was dried over anhydrous Na_2SO_4 and concentrated under reduced

pressure. The obtained residue was purified by chromatography on a silica-gel column, eluting with $CHCl_3$/MeOH (50/1, [v/v)]) to give compound **5** (3.03 g, 93%) having ^{1}H NMR (500 MHz, $CDCl_3$, 296 K) δ 8.37 (d, *J* = 8.88 Hz, 2 H), 8.33 (d, *J* = 8.91 Hz, 2 H), 7.97 (d, *J* = 9.13 Hz, 2 H), 7.96 (d, *J* = 9.01 Hz, 2 H), 4.61-4.58 (m, 1 H), 3.99-3.89 (m, 2 H), 3.11-3.01 (m, 2 H), 282 (s, 3 H), 2.77 (s, 3 H), 1.95-1.87 (m, 1 H), 1.80-1.68 (m, 2 H), 1.60-1.52 (m, 1 H), 1.51-1.35 (m, 2 H), 1.08 (t, 3 H), and HR-ESI for $C_{22}H_{29}N_4O_{10}S_2$([M+H]$^+$) Calcd: 573.1320. Found: 573.1320.

Synthesis of 6. Solid potassium carbonate (3.42 g, 24.74 mmol) was added to a solution of compound **5** (2.64 g, 4.61 mmol) and 4-methoxybenzenethiol (2.59 g, 18.47 mmol) in DMF (10 mL).[6] The resulting heterogeneous mixture was stirred vigorously at room temperature for 3 h. Then the reaction mixture was added, dropwise, into ethanol (150 mL) and filtered. The filtrate was concentrated under reduced pressure, and the residue was purified by chromatography on a silica-gel column, eluting with MeOH/$NH_3{\cdot}H_2O$ (10/1, v/v) to afford compound **6** (797 mg, 85%) having ^{1}H NMR (500 MHz, CD_3OD, 296 K) δ 4.19 (q, 2 H), 3.16 (t, *J* = 6.60 and 6.64 Hz, 1 H), 2.80 (t, *J* = 7.58 and 7.70 Hz, 2 H), 2.55 (s, 3 H), 2.30 (s, 3 H), 1.70-1.58 (m, 4 H), 1.42-1.36 (m, 2 H), 1.27 (t, *J* = 7.12 and 7.13 Hz, 3 H), and HR-ESI for $C_{10}H_{23}N_2O_2$ ([M+H]$^+$) Calcd: 203.1754. Found: 203.1748.

Synthesis of 7. DCC (2.55 g, 12.36 mmol) was added to a solution of cholic acid (3.36 g, 8.22 mmol) and DHBT (1.54 g, 9.44 mmol) in anhydrous DMF (10 mL). The resulting reaction mixture was stirred at room temperature for 4 h and then added, dropwise, into a solution of dimethylated *L*-lysine **6** (793 mg, 3.92 mmol) and triethylamine (2.2 mL) in anhydrous DMF (5.0 mL). The reaction mixture was then

stirred overnight. After being concentrated to ca. 10 mL, the reaction mixture was poured into water (250 mL), and the resulting precipitate was collected by filtration. The solid precipitate was purified by chromatography on a silica-gel column [$CHCl_3$/MeOH, 6/1 (v/v)] to afford compound **7** (2.63 g, 68%) having ^{1}H NMR (500 MHz, CD_3OD, 292 K) δ 5.04-4.96 (m) and 4.63-4.57 (m) (1 H), 4.22-4.10 (m, 2 H), 3.96 (unresolved, 2 H), 3.79 (unresolved, 2 H), 3.39-3.34 (m, 4 H), 3.04-3.03 and 2.89-2.88 (3 H), 3.00-2.99 and 2.78-2.77 (3 H), 2.51-2.23 (m, 8 H), 2.03-0.91 (m, 61 H), 0.72 and 0.71 (ss, 6 H), and HR-ESI MS for $C_{58}H_{99}N_2O_{10}$ ($[M+H]^+$) Calcd: 983.7294. Found: 983.727.

Synthesis of 8. A solution of sodium hydroxide (1.07 g, 26.75 mmol) in water (10.0 mL) was added to a solution of compound **7** (2.63 g, 2.67 mmol) in MeOH (40 mL). The resulting mixture was stirred at room temperature until the starting material disappeared. After being concentrated to ca. 10 mL under reduced pressure, the reaction mixture was added, dropwise, to water (500 mL), and the pH was adjusted with diluted HCl to ca. 1. The resulting precipitate was collected by filtration and dried under vacuum to afford compound **8** (2.41 g, 95%) having ^{1}H NMR (500 MHz, CD_3OD, 296 K) δ 5.10-5.04 (m) and 4.58-4.52 (m) (1 H), 3.95 (unresolved, 2 H), 3.79 (unresolved, 2 H), 3.41-3.33 (m, 4 H), 3.05 and 2.91-2.90 (3 H), 2.99-2.98 and 2.80-2.79 (3 H), 2.52-2.22 (m, 8 H), 2.03-0.91 (m, 58 H), 0.71 (s, 6 H), and HR-ESI MS for $C_{56}H_{95}N_2O_{10}$ ($[M+H]^+$) Calcd: 955.6981. Found: 955.6958.

Synthesis of 2. DCC (165 mg, 0.80 mmol) was added to a solution of **8** (508 mg, 0.53 mmol) and DHBT (100 mg, 0.61 mmol) in anhydrous DMF (3.0 mL). After stirring for 3 h, a solution of **9** (24.5 mg, 0.11 mmol) and DIPEA (300 μL, 1.75 mmol) in anhydrous DMF (1.0 mL) was added to the reaction mixture. The obtained reaction mixture was

stirred at room temperature overnight, and then concentrated under reduced pressure. The resulting residue was purified by chromatography on a silica-gel column eluting with $CHCl_3$/MeOH/H_2O (50/10/1, v/v/v) to afford a hydroxylated precursor of **2** (213 mg, 50%) having ^{1}H NMR (500 MHz, CD_3OD, 296 K) δ 5.42 (br, 4 H), 3.95 (s, 8 H), 3.79 (s, 8 H), 3.40-3.25 (m, 28 H), 3.04-3.01 (m, 12 H), 2.94 (s, 12 H), 2.89 (s, 6 H), 2.48-0.91 (m, 272 H), 0.71 (s, 24 H), and HR-ESI MS for $C_{236}H_{398}N_{12}O_{36}$ (M^+) Calcd: 3976.9682. Found: 3976.8472.

Sulfation was then carried out by dissolving the hydroxylated precursor **(**108 mg, 0.027 mmol) in DMF (2.0 mL) at 0°C (ice cooling), followed by direct addition of sulfur trioxide/pyridine complex (415 mg, 2.61 mmol). The resulting solution was allowed to warm gradually to room temperature and stirred at room temperature overnight. Then, cold water (1.0 mL) was added, followed by addition of sodium carbonate until the pH of the mixture reached 10. The combined solvents were then removed under reduced pressure, and the resulting residue was purified by chromatography on a silica-gel column eluting with $CHCl_3$/MeOH/H_2O (4/4/1, v/v/v), followed by dialysis (MWCO 500) against water (500 mL), to give **2** (152 mg, 87%) as its sodium salt having ^{1}H NMR (500 MHz, CD_3OD, 296 K) δ 5.40 (br, 4 H), 4.66 (s, 8 H), 4.44 (s, 8 H), 4.12 (m, 8 H), 3.50-3.19 (m, 20 H, overlapping with solvent), 3.04-2.88 (m, 30 H), 2.45-0.93 (m, 272 H), 0.76 (s, 24 H), and HR-ES-MS for $C_{236}H_{374}N_{12}Na_{24}O_{108}S_{24}$ (M^-) Calcd: 6423.4983. Found: 6423.4253.

Anti-HIV Activity and Cytotoxicity. U87 glioblastoma cells were obtained from the NIH AIDS Research and Reference Reagent Program (Rockville, MD) and cultured in DMEM (Invitrogen Canada) supplemented with 15% fetal bovine serum (FBS), 1 μg/mL

puromycin, and 300 μg/mL G418. Approximately 6 x 10^4 cells were plated in triplicate in 96-well plates, and then treated with the different concentrations of compounds **1**, **2** and **3** for 1 h followed by infection with replication incompetent HIV_{JRFL} for 48 h. Control samples did not receive any treatment. After 48 h, luciferase assay was performed on lysed cell extracts.

Pseudotyped, replication-defective virus HIV_{JRFL} was generated in 293T cells using a three-plasmid cotransfection system.[7] These three plasmids include the packaging construct pCMVΔR8.2, the HIV-1 reporter construct pNL4-3.Luc.R-E with firefly luciferase gene inserted into the pNL4-3 *nef* gene, and the HIV-1 envelope-expressing construct, pJRFL. Transfection was performed in 75-cm^2 culture flasks using Lipofectamine 2000 (Invitrogen).

U87 cells were pretreated for 1 h with compounds **1**, **2** and **3**, followed by infection with replication incompetent HIV_{JRFL} for 3 h, and then virus was replaced with fresh growth medium. Viral infection was determined by quantifying luciferase activity using Luciferase Assay Substrate (Promega, Madison, WI).

Drug toxicity assays were done as previously described.[8] Thus, to determine the cytotoxicity of a giving compound, 50 × 10^3 U87 cells were plated in a 96-well plate, followed by treatment with varying concentrations of the drug. A standard colorimetric assay was then used for measuring the activity of enzymes that reduce MTT + PMS to formazan, according to the protocol, Promega, CellTiter 96 Non-radioactive Proliferation Assay (MTT). Here, yellow MTT (3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, a tetrazole) is reduced to purple formazan in the presence of phenazine

methosulfate (PMS), which produces a water-soluble formazan in living cells. The absorbance of this colored solution was then quantified by measuring the absorption at 570 nm. The amount of purple formazan produced by cells that were treated with a given concentration of compound was then compared with the amount of formazan produced by untreated control cells. The cytotoxicity of each compound was determined in triplicate.

Statistics Data are expressed as mean ± SD. Student *t*-test was used to compare the means of different samples (treated vs. control). $P < 0.05$ was considered to be statistically significant.

Liposome Formation and pH Discharge Experiments. Typically, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phospho-choline (POPC) and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphatidylglycerol (POPG) (a 20 mg mixture of POPC/POPG (95/5, mol/mol) in choloroform was transferred to a Pyrex test tube. While rotating the tube, the organic solvent was removed under a stream of argon, resulting in a thin lipid film. The last traces of solvent were then removed under reduced pressure (25 °C, 12 h, <0.2 Torr). To the dried film was added 1.0 mL of 0.1 mM pyranine in 25 mM HEPES buffer (pH 7.0, 50 mM NaCl), and the mixture vortexed for 1 min. The dispersion was then incubated for 5 min, followed by another 1 min of vortexing and 20 min of incubation at ambient temperature. The sample was subjected to five freeze/thaw cycles (77 K/325 K), followed by sequential extrusion through a 400 nm Nuclepore membrane (10 times) and a 200 nm membrane (10 times). After extrusion, the dispersion was incubated at room temperature for 1.25 h. The non-entrapped pyranine was then removed by gel filtration (Sephadex G-

25, 1 x 20 cm), eluting with 25 mM HEPES buffer (pH 7.0, 50 mM NaCl)). The concentration of lipid in the vesicle dispersion was calculated from volume after gel filtration.

To 0.3 mL of the above liposome dispersion was added 1.7 mL of a 25 mM HEPES buffer (pH 8.0, 50 mM NaCl) that contained 0.006 mol% of a given agent (relative to the total phospholipid to which it was added). The fluorescence intensity was monitored as a function of time (λ_{ex} 460 nm, λ_{em} 510 nm, slit width $\lambda_{ex}/\lambda_{em}$ 2.5 nm/2.5 nm) using a Perkin-Elmer Luminescence Spectrometer LS50B. Complete pH discharge was made by destroying the vesicles and forming mixed micelles after 60 min via the addition of 50 µL of aqueous solution of Triton X-100 (5 wt %).

Sodium Ion Transport. Typically, 2.5 mL of a 20 mg/mL solution of 1-palmitoyl-2-oleoyl-2-*sn*-glycero-3-phosphocholine (POPC) in chloroform was transferred to a pyrex test tube. While rotating the tube, the organic solvents were removed under a stream of nitrogen, resulting in a thin lipid film. The last traces of solvent were then removed under reduced pressure (25°C, 12 h, <0.2 Torr). To the dried film was added 1.0 mL of a 150 mM KCl solution that was 10% in D_2O and 90% in H_2O, and the mixture was vortexed for 1 min. The dispersion was then incubated for 5 min, followed by another 1 min of vortexing and 20 min of incubation at ambient temperature. The sample was subjected to five freeze/thaw cycles (77 K/325 K), followed by sequential extrusion through a 400 nm Nuclepore membrane (10 times) and a 200 nm membrane (10 times). After extrusion, the dispersion was incubated at room temperature for 1.25 h. In a quartz NMR tube, 1.5 mL of a 150 mM NaCl solution in 10% D_2O plus 90% H_2O was mixed with 0.3 mL of a shift reagent solution (10 mM $DyCl_3$; 30 mM $Na_5P_3O_{10}$ in 10% D_2O plus 90% H_2O) and the

desired amount of umbrella. To this solution was added 0.75 mL of the vesicle dispersion, and the resulting mixture was vortexed for 30 s. ^{23}Na NMR spectra were recorded continuously at 35°C overnight on a Bruker AMX 500 MHz NMR instrument.

Chloride Ion Transport. Typically, 9.0 mL of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) in chloroform (20 mg/mL) was transferred to a Pyrex test tube. While rotating the tube, the organic solvent was removed under a stream of argon, resulting in a thin lipid film. The last traces of solvent were then removed under reduced pressure (25 °C, 12 h, <0.2 Torr). To the 180 mg of dried film was added 3.60 mL of 100 mM NaCl in 10 mM sodium phosphate (pH 6.7), and the mixture was vortex mixed for 1 min. The dispersion was then incubated for 5 min, followed by another 1 min of vortex mixing and 20 min of incubation at ambient temperature. The sample was subjected to five freeze/thaw cycles (77 K/325 K), followed by sequential extrusion through a 400 nm Nuclepore membrane (10 times) and a 200 nm membrane (10 times). After extrusion, the dispersion was dialyzed (Nucleopore membrane, pore diameter 100 nm) using a equilibrium dialysis cell against same volume of 100 mM $NaNO_3$ in 10 mM sodium phosphate (pH 6.7) (10 times 1/2 h for each dialysis) to remove external NaCl. Four aliquots of 0.200 mL of the resulting vesicle dispersion were used to determine captured chloride ion.

Four Cl^- efflux experiments were then run simultaneously. Two experiments were carried out in presence of **3** and two control experiments were carried out in absence of **3**. Thus a 0.200 mL portion of the above liposomal dispersion was mixed in test tube with 30 μL of compound **3** (9.36×10^{-5} M) in 100 mM $NaNO_3$/10 mM sodium phosphate (pH 6.7). Thus, the concentration of **3** relative to POPC was 0.006 mol%. The resulting

mixture was gently shaken (Environ shaker, 150 rpm) for 12 h and placed in dialysis cell and dialyzed at room temperature against 0.73 mL of 100 mM $NaNO_3$ in 10 mM sodium phosphate (pH 6.7) for 30 min. The solution from the receiving side (0.400 mL) was then mixed with 220 μL of lucigenin (12.54×10^{-6} M) in 100 mM $NaNO_3$/10 mM sodium phosphate (pH 6.7), and the fluorescence intensity at 505 nm was used to determine concentration of chloride ion (λ_{ex} 368 nm, slit ex/em 3.0/3.0 nm. A calibration curve. was constructed in an similar way using standard solutions of NaCl (0.500 mM-10.00 mM in 10 mM phosphate buffer, pH 6.7. Experiments that were carried out in the absence of **3** were conducted in a similar way.

To determine the total amount of NaCl that was entrapped in POPC vesicles, 0.200 mL of the above liposome dispersion was mixed with water solution of 0.300 mL 5%w Triton X 100. To the resulting clear solution was added 0.360 mL of lucigenin (12.54×10^{-6} M) and maximum fluorescence intensity at 505 nm was used to determine the chloride concentration. This analysis was run two times for each experiment. Calibration curve was constructed in a similar way using standard solutions of NaCl ([NaCl]= 2-20 mM).

Efflux Measurements. A thin lipid film was formed on the inside walls of a glass test tube using a chloroform solution that contained 40.0 mg of POPC/POPG (95/5, mol/mol). Removal of solvent was carried out under a stream of argon. The resulting film was then hydrated with 2.0 mL of an aqueous buffer [PBS, pH 7.4], which was 0.50 mM in a given persulfated molecular umbrella**.**. The contents of the tube was then mixed via vortexing at room temperature for 30 min, and was subjected to six freeze-thaw cycles -192/40°C.

Subsequent extrusion through two Nuclepore membranes 0.4 mm (10 times) and 0.2 mm (15 times) afforded a dispersion, which was dialyzed against 300 mL of buffer for 18 h, using dialysis tubing with a MW cutoff of 100 000. This dialysis was then repeated using fresh buffer for another 18 h, and finally one additional dialysis for 16 h, again using fresh buffer. After this time, the percent capture of the umbrella was then monitored as a function of time.

To determine the amount of umbrella that was retained by the liposomes, typically, a 200 μL aliquot of the liposome dispersion was concentrated to dryness via freeze-drying (18 h). The lipids were then redissolved in 40 μL of mixture $CHCl_3$/MeOH/H_2O, 10/10/1, v/v/v with the aid of vortex mixing. An exact volume of the resulting solution (2-5 μL) was withdrawn and analyzed by TLC (5 × 10 cm thin layer chromatography plate, silica gel, 0.25 mm, J.T. Baker). The same volume of two or three standard solutions of given umbrellas (0.450 mM, 0.400mM, 0.250mM, 0.100mM, 0.050mM) was always co-deposited for calibration purposes. A mixture of $CHCl_3$/MeOH/H_2O (65/25/4, (v/v/w) was used as a eluent. After the plate was dried for 10 min at rt, it was sprayed with 10% H_2SO_4 and carefully heated with a heat gun to maintain uniformity of the background. The resulting spots were then quantitatively analyzed via densitometry. The density of each spot (the area that was measured for each spot was constant) was quantified by use of Scion Image Beta 4.02 for Windows 95 to XP software, which was available from the Internet (http://www.scioncorp.com/pages/download_now.htm). The intensity of each spot was determined in triplicate.

Carbamate-Linked Lactose: Design of Clusters and Evidence for Selectivity to Block Binding of Human Lectins to (Neo)Glycoproteins with Increasing Degree of Branching and to Tumor Cells

Sabine André,[†] Daniel Specker,[‡,||] Nicolai V. Bovin,[§] Martin Lensch,[†] Herbert Kaltner,[†] Hans-Joachim Gabius,*[,†] and Valentin Wittmann*[,‡]

Various pathogenic processes are driven by protein(lectin)-glycan interactions, especially involving β-galactosides at branch ends of cellular glycans. These emerging insights fuel the interest to design potent inhibitors to block lectins. As a step toward this aim, we prepared a series of ten mono- to tetravalent glycocompounds with lactose as a common headgroup. To obtain activated carbonate for ensuing carbamate formation, conditions for the facile synthesis of pure isomers from anomerically unprotected lactose were identified. To probe for the often encountered intrafamily diversity of human lectins, we selected representative members from the three subgroups of adhesion/growth-regulatory galectins as receptors. Diversity of the glycan display was accounted for by using four (neo)glycoproteins with different degrees of glycan branching as matrices in solid-phase assays. Cases of increased inhibitory potency of lactose clusters compared to free lactose were revealed. Extent of relative inhibition was not directly associated with valency in the glycocompound and depended on the lectin type. Of note for screening protocols, efficacy of blocking appeared to decrease with increased degree of glycan branching in matrix glycoproteins. Binding to tumor cells was impaired with selectivity for galectins-3 and -4. Representative compounds did not impair growth of carcinoma cells up to a concentration of 5 mM of lactose moieties (valence-corrected value) per assay. The reported bioactivity and the delineation of its modulation by structural parameters of lectins and glycans set instructive examples for the further design of selective inhibitors and assay procedures.

INTRODUCTION

A salient route of biological information transfer starts from glycan determinants of cellular glycoconjugates (*1*). These sugar-encoded signals act as ligands for target-specific receptors (lectins) (*1*, *2*). Physiologically, this interaction is involved in disease manifestation, e.g., during chronic inflammation, heart failure, or malignancy. Thus, the design of glycoclusters blocking target recognition of lectins has become an active research area (*2*−*4*). In view of their role as markers for unfavorable prognosis in human tumors (*5*−*7*), we focus here on the family of adhesion/growth-regulatory galectins.

Galectins share the specificity for β-galactosides at branch ends of glycans so that glycoclusters can conveniently be loaded with lactose as a common headgroup (*8*). Of note, the spatial presentation of lectin sites differs within this family (*2*). Thus, it is mandatory to examine at least one member of each subgroup in a comparative study. Hence, the following representatives were chosen: the homodimeric (prototype) galectin-1, the chimera-type galectin-3 with the ability for pentamerization in the presence of suitable ligands, the tandem-repeat-type galectin-4 with its two domains connected by a linker, and galectin-5 with its low degree of oligomer formation. Aside from the panel of lectins, it is equally important to take account of the local density of ligand. As work with different (neo)glycoproteins has revealed (*9*, *10*), lectin affinity and selectivity can be modulated by glycan substitutions and branching.

In detail, four different types of binding partner for the lectins were thus tested: lactosylated bovine serum albumin (LacBSA), a neoglycoprotein with rather random and widely spaced presentation of lactose units, and three glycoproteins with either biantennary (serum amyloid P component: SAP), triantennary (asialofetuin: ASF), or tetra-antennary N-glycans (α_1-acid glycoprotein: AGP). The listed (neo)glycoproteins were adsorbed to microtiter plate wells to serve as lectin binders. With these surfaces, solid-phase assays were carried out to determine inhibition of binding of the lectins to the surfaces by lactose or synthetic lactose clusters. Natural ligands on cell surfaces are known to be present in more complex form than these lactose derivatives (*11*, *12*). Since it is an open question whether the glycoclusters are capable of impairing the binding of lectins to cell surfaces, we performed fluorimetric binding assays with

human tumor cells. In addition to the galectins, a toxic plant lectin akin to ricin, i.e., the galactoside-specific mistletoe lectin (*Viscum album* agglutinin, VAA) with β-trefoil folding and two fully accessible lectin sites 87 Å apart in the dimer (*13*), was also tested.

The lactose derivatives that were tested for their potency to inhibit the lectin−matrix interaction varied in valency from one to four lactose moieties per inhibitor. However, the valency of the ligands is not the only factor that determines avidity. Case studies on selectins with a lipid anchor (i.e., 2-tetradecylhexadecyl) attached to the glycan, the cholera toxin B pentamer with spacered *p*-nitrophenyl galactopyranoside, and galectins with thiourea-linked ligands on calix[*n*]arenes showed that the spacer portion can notably contribute to the inhibitor's performance (*14*−*16*). Variations in this part can add to selectivity, because the vicinity of the lectin sites is quite divergent in galectins (*12*, *17*). Therefore, we employed two series of lactose clusters differing in the absence or presence of a butene diol linker leading to varied lactose spacing. Lactosyl carbamates were conveniently synthesized by coupling an activated lactosyl carbonate to a set of amines. Therefore, we first had to resolve the problem of finding conditions to produce the glycosyl carbonate from anomerically deprotected lactose as pure isomer.

Our report, combining synthesis of ten mono- to tetravalent lactose derivatives with biochemical/cell biological testing on plant/human lectins, will answer the following questions: (1) Which conditions are suitable to gain fast and easy access to pure isomers of activated lactosyl carbonates? (2) Will the inhibitory potency of conjugated lactose relative to free lactose be enhanced? (3) How will the structure and valency of the lactose clusters and the degree of glycan branching in the (neo)glycoprotein matrix influence inhibition in solid-phase assays? (4) Will lectin binding to cells be inhibited by the lactose derivatives? (5) Will potent lactose derivatives lack cytotoxicity?

EXPERIMENTAL PROCEDURES

General Methods. Analytical thin layer chromatography was performed using silica gel 60 F_{254} aluminum sheets from Merck (Darmstadt, Germany); compound spots were visualized by quenching of fluorescence and/or by charring after treatment with cerium molybdophosphate. Preparative flash column chromatography (FC) was carried out on Merck silica gel 60 (40−63 μm). ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker Avance DRX 600 instrument at a temperature of 300 K. ^{1}H Chemical shifts are referenced to residual protic solvent ($CDCl_3$, $\delta_H = 7.26$; D_2O, $\delta_H = 4.63$). ^{13}C Chemical shifts are referenced to the solvent signal ($CDCl_3$, $\delta_C = 77.0$) or in the case of D_2O to internal standard CD_3CN ($\delta_C = 1.32$ ppm). Assignments of proton and carbon signals were carried out by the aid of DQF-COSY, HMQC, and ROESY experiments. MALDI mass spectra were obtained on a Bruker Biflex III instrument with α-cyano-4-hydroxycinnamic acid as the matrix (positive mode). Elemental analyses were performed by the microanalytical facility at the Universität Konstanz.

4-Nitrophenyl-[2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl-(1→4)-2,3,6-tri-*O*-acetyl-α-D-glucopyranosyl] Carbonate (*18*) (α-3). Lactose derivative **1** (*19*) (100 mg, 0.16 mmol) was dissolved in CH_3CN (3.5 mL). A solution of *p*-nitrophenyl chloroformate **2** (48 mg, 0.24 mmol) in CH_3CN (0.5 mL) and 4-(dimethylamino)-pyridine (29 mg, 0.24 mmol) was added and the mixture was stirred for 30 min. The solvent was evaporated, and the remainder was dissolved in ethyl acetate and washed with water, 1 M HCl, and brine. The organic layer was dried (Na_2SO_4), concentrated, and purified by FC (petroleum ether/ethyl acetate 1:1→1:2) to yield α-**3** (122 mg, 95%) as a white solid: $R_f = 0.45$ (petroleum ether/ethyl acetate 1:2). ^{1}H NMR (600 MHz, $CDCl_3$): δ = 8.30−8.28 (m, 2 H, Ar), 7.43−7.42 (m, 2 H, Ar), 6.20 (d, J = 3.6 Hz, 1 H, H-1^{Glc}), 5.54 (dd, J = 10.1 Hz, J = 9.5 Hz, 1 H, H-3^{Glc}), 5.35 (dd, J = 3.3 Hz, J = 0.7 Hz, 1 H, H-4^{Gal}), 5.12 (dd, J = 10.4 Hz, J = 7.9 Hz, 1 H, H-2^{Gal}), 5.07 (dd, J = 10.3 Hz, J = 3.6 Hz, 1 H, H-2^{Glc}), 4.96 (dd, J = 10.4 Hz, J = 3.5 Hz, 1 H, H-3^{Gal}), 4.53−4.51 (m, 2 H, H-6^{Glc}, H-1^{Gal}), 4.17−4.06 (m, 4 H, H-5^{Glc}, H-6′^{Glc}, H-6^{Gal}, H-6′^{Gal}), 3.91−3.87 (m, 2 H, H-4^{Glc}, H-5^{Gal}), 2.15 (s, 3 H, C(O)CH_3), 2.13 (s, 3 H, C(O)CH_3), 2.07 (s, 3 H, C(O)CH_3), 2.05 (s, 3 H, C(O)CH_3), 2.04 (s, 3 H, C(O)CH_3), 2.04 (s, 3 H, C(O)CH_3), 1.95 (s, 3 H, C(O)CH_3). ^{13}C NMR (150 MHz, $CDCl_3$): δ = 170.2, 170.1, 170.0, 170.0, 169.7, 169.4, 168.9 (*C*(O)CH_3), 154.9 (OC(O)O), 150.7, 145.6, 125.4, 121.4 (Ar), 101.0 (C-1^{Gal}), 94.0 (C-1^{Glc}), 75.2 (C-4^{Glc}), 71.3 (C-5^{Glc}), 70.9 (C-3^{Gal}), 70.7 (C-5^{Gal}), 79.3 (C-2^{Glc}), 69.1 (C-3^{Glc}), 69.0 (C-2^{Gal}), 66.5 (C-4^{Gal}), 61.1 (C-6^{Glc}), 60.7 (C-6^{Gal}), 20.7−20.4 (C(O)*C*H). MALDI-MS: calcd *m*/*z* 824.2 [M + Na^+], 840.2 [M + K^+], found 824.0, 839.9. Anal. calcd for $C_{33}H_{39}NO_{22}$: C 49.44, H 4.90, N 1.75, found: C 49.24, H 4.98, N 1.76.

4-Nitrophenyl-[2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl-(1→4)-2,3,6-tri-*O*-acetyl-β-D-glucopyranosyl] Carbonate (*18*) (β-3). Lactose derivative **1** (*19*) (8.6 g, 13.5 mmol) was dissolved in CH_3CN (430 mL) and cooled to 0 °C. A solution of *p*-nitrophenyl chloroformate **2** (2.89 g, 14.3 mmol) in CH_3CN (20 mL) and 2,6-lutidine (1.66 mL, 14.3 mmol) was added, and the mixture was stirred overnight. The solvent was evaporated, and the remainder was dissolved in ethyl acetate and washed with water, 1 M HCl, and brine. The organic layer was dried (Na_2SO_4), concentrated, and crystallized from ethyl acetate/petroleum ether to yield β-**3** (5.40 g, 50%) as a white solid: R_f = 0.47 (petroleum ether/ethyl acetate 1:2). ^{1}H NMR (600 MHz, $CDCl_3$): δ = 8.30−8.28 (m, 2 H, Ar), 7.42−7.40 (m, 2 H, Ar), 5.63 (d, J = 7.8 Hz, 1 H, H-1^{Glc}), 5.35 (dd, J = 3.4 Hz, J = 0.8 Hz, 1 H, H-4^{Gal}), 5.26 (t, J = 9.0 Hz, 1 H, H-3^{Glc}), 5.15−5.10 (m, 2 H, H-2^{Glc}, H-2^{Gal}), 4.96 (dd, J = 10.4 Hz, J = 3.2 Hz, 1 H, H-3^{Gal}), 4.53−4.49 (m, 2 H, H-6^{Glc}, H-1^{Gal}), 4.16−4.06 (m, 3 H, H-6′^{Glc}, H-6^{Gal}, H-6′^{Gal}), 3.94−3.88 (m, 2 H, H-4^{Glc}, H-5^{Gal}), 3.83−3.81 (m, 1 H, H-5^{Glc}), 2.16 (s, 3 H, C(O)CH_3), 2.13 (s, 3 H, C(O)CH_3), 2.09 (s, 3 H, C(O)CH_3), 2.07 (s, 3 H, C(O)CH_3), 2.05 (s, 3 H, C(O)CH_3), 2.04 (s, 3 H, C(O)CH_3), 1.97 (s, 3 H, C(O)CH_3). ^{13}C NMR (150 MHz, $CDCl_3$): δ = 170.4, 170.2, 170.1, 169.6, 169.4, 169.0 (*C*(O)CH_3), 154.7 (OC(O)O), 150.7, 145.7, 125.4, 121.6 (Ar), 101.0 (C-1^{Gal}), 95.7 (C-1^{Glc}), 75.3 (C-4^{Glc}), 73.7 (C-5^{Glc}), 72.6 (C-3^{Glc}), 71.0 (C-3^{Gal}), 70.7 (C-5^{Gal}), 70.2 (C-2^{Glc}), 69.0 (C-2^{Gal}), 66.5 (C-4^{Gal}), 61.4 (C-6^{Glc}), 60.8 (C-6^{Gal}), 20.8−20.5 (C(O)*C*H$_3$). MALDI-MS: calcd *m*/*z* 824.2 [M + Na^+], 840.2 [M + K^+], found 824.1, 840.0. Anal. calcd for $C_{33}H_{39}NO_{22}$: C 49.44, H 4.90, N 1.75, found: C 48.98, H 5.22, N 1.82.

4-Hydroxy-(*Z*)-but-2-enyl 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl-(1→4)-2,3,6-tri-*O*-acetyl-β-D-glucopyranoside (6). Under argon Ag_2CO_3 (2.7 g, 9.7 mmol), $CaSO_4 \cdot 0.5\ H_2O$ (6.5 g, 45 mmol), an iodine crystal, and (*Z*)-but-2-ene-1,4-diol **5** (26 mL, 322 mmol) were stirred for 15 min at room temperature. Acetobromolactose **4** (*20*, *21*) (3 g, 4.3 mmol) was added and the mixture was stirred for further 24 h. After addition of CH_2Cl_2 (100 mL), the mixture was filtered through Celite. To the biphasic filtrate water (100 mL) was added, and the aqueous phase was separated and extracted with CH_2Cl_2 (50 mL). The combined organic layers were washed with water (3 × 100 mL) and brine and dried over Na_2SO_4. The solvent was evaporated and the remainder purified by FC (petroleum ether/ethyl acetate 1:2) to give **6** (1.85 g, 61%): $R_f = 0.25$ (petroleum ether/ethyl acetate 1:2). ^{1}H NMR (600 MHz, $CDCl_3$): δ = 5.85−5.81 (m, 1 H, H^{vinyl}), 5.63−5.59 (m, 1 H, H^{vinyl}), 5.34 (d, J = 3.0 Hz, 1 H, H-4^{Gal}), 5.19 (d, J = 9.3 Hz, 1 H, H-3^{Glc}), 5.10 (dd, J = 10.4 Hz, J = 7.9 Hz, 1 H, H-2^{Gal}), 4.95 (dd, J = 10.4 Hz, J = 3.5 Hz, 1 H, H-3^{Gal}), 4.90 (dd, J = 9.4 Hz, J = 8.0 Hz, 1 H,

H-2^{Glc}), 4.53−4.50 (m, 2 H, H-1^{Glc}, H-6^{Glc}), 4.49 (d, J = 7.9 Hz, 1 H, H-1^{Gal}), 4.28 (ddd, J = 19.9 Hz, J = 12.6 Hz, J = 6.7 Hz, 2 H, H^{allyl}), 4.18 (bd, J = 6.2 Hz, 2 H, H^{allyl}), 4.14−4.06 (m, 3 H, H-6′^{Glc}, H-6^{Gal}, H-6′^{Gal}), 3.87 (bt, J = 6.7 Hz, 1 H, H-5^{Gal}), 3.79 (t, J = 9.5 Hz, 1 H, H-4^{Glc}), 3.61 (ddd, J = 9.8 Hz, J = 5.0 Hz, J = 2.0 Hz, 2 H, H-5^{Glc}), 2.14 (s, 3 H, C(O)CH$_3$), 2.13 (s, 3 H, C(O)CH$_3$), 2.05 (s, 3 H, C(O)CH$_3$), 2.04 (s, 9 H, C(O)CH$_3$), 1.96 (s, 3 H, C(O)CH$_3$). ^{13}C NMR (150 MHz, CDCl$_3$): δ = 170.4, 170.3, 170.1, 170.0, 169.7, 169.7, 169.0 (*C*(O)CH$_3$), 133.3, 126.8 (CH^{olefin}), 125.3, 121.7 (Ar), 101.0 (C-1^{Gal}), 99.1 (C-1^{Glc}), 76.2 (C-4^{Glc}), 72.8 (C-3^{Glc}), 72.7 (C-5^{Glc}), 71.6 (C-2^{Glc}), 71.0 (C-3^{Gal}), 70.7 (C-5^{Gal}), 69.1 (C-2^{Gal}), 66.6 (C-4^{Gal}), 64.3 (CH$_2^{allyl}$), 61.9 (C-6^{Glc}), 60.8 (C-6^{Gal}), 58.5 (CH$_2^{allyl}$), 20.8−20.5 (C(O)*C*H$_3$).

4-(*p*-Nitrophenoxycarbonyloxy)-(*Z*)-but-2-enyl 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl-(1→4)-2,3,6-tri-*O*-acetyl-β-D-glucopyranoside (7). Compound **6** (1.72 g, 2.43 mmol) was dissolved in CH$_3$CN (80 mL). A solution of *p*-nitrophenyl chloroformate **2** (0.59 g, 2.92 mmol) in CH$_3$CN (5 mL) and pyridine (0.24 mL, 2.92 mmol) were added, and the mixture was stirred for 1 h. The solvent was evaporated and the remainder was dissolved in ethyl acetate and washed with water, 1 M HCl, and brine. The organic layer was dried (Na$_2$SO$_4$), concentrated, and purified by FC (petroleum ether/ethyl acetate 1:1→1:2) to yield **7** (1.84 g, 87%) as a white solid: R_f = 0.50 (petroleum ether/ethyl acetate 1:2). ^{1}H NMR (600 MHz, CDCl$_3$): δ = 8.29−8.28 (m, 2 H, Ar), 7.39−7.37 (m, 2 H, Ar), 5.83−5.78 (m, 2 H, H^{vinyl}), 5.34 (d, J = 3.0 Hz, 1 H, H-4^{Gal}), 5.19 (d, J = 9.3 Hz, 1 H, H-3^{Glc}), 5.09 (dd, J = 10.4 Hz, J = 7.9 Hz, 1 H, H-2^{Gal}), 4.95 (dd, J = 10.4 Hz, J = 3.4 Hz, 1 H, H-3^{Gal}), 4.90 (dd, J = 9.4 Hz, J = 8.0 Hz, 1 H, H-2^{Glc}), 4.87−4.79 (m, 2 H, H^{allyl}), 4.52 (d, J = 7.8 Hz, 1 H, H-1^{Glc}), 4.51 (dd, J = 11.8 Hz, J = 2.1 Hz, 1 H, H-6^{Glc}), 4.48 (d, J = 7.9 Hz, 1 H, H-1^{Gal}), 4.34 (ddd, J = 18.6 Hz, J = 13.3 Hz, J = 4.2 Hz, 2 H, H^{allyl}), 4.14−4.05 (m, 3 H, H-6′^{Glc}, H-6^{Gal}, H-6′^{Gal}), 3.86 (bt, J = 6.9 Hz, 1 H, H-5^{Gal}), 3.80 (t, J = 9.4 Hz, 1 H, H-4^{Glc}), 3.60 (ddd, J = 9.8 Hz, J = 4.7 Hz, J = 2.0 Hz, 1 H, H-5^{Glc}), 2.14 (s, 3 H, C(O)CH$_3$), 2.11 (s, 3 H, C(O)CH$_3$), 2.05 (s, 3 H, C(O)CH$_3$), 2.04 (s, 3 H, C(O)CH$_3$), 2.03 (s, 3 H, C(O)CH$_3$), 2.01 (s, 3 H, C(O)CH$_3$), 1.96 (s, 3 H, C(O)CH$_3$). ^{13}C NMR (150 MHz, CDCl$_3$): δ = 170.3, 170.3, 170.1, 170.0, 169.7, 169.6, 169.0 (*C*(O)CH$_3$), 155.4 (OC(O)O), 152.3, 145.5 (Ar), 130.8, 126.0 (Olefin CH), 125.3, 121.7 (Ar), 101.1 (C-1^{Gal}), 99.2 (C-1^{Glc}), 76.2 (C-4^{Glc}), 72.9 (C-3^{Glc}), 72.7 (C-5^{Glc}), 71.5 (C-2^{Glc}), 70.9 (C-3^{Gal}), 70.7 (C-5^{Gal}), 69.1 (C-2^{Gal}), 66.5 (C-4^{Gal}), 64.5, 64.4 (CH$_2^{allyl}$), 61.8 (C-6^{Glc}), 60.7 (C-6^{Gal}), 20.8−20.5 (C(O)*C*H$_3$). MALDI-MS: calcd *m*/*z* 894.2 [M + Na$^+$], 910.2 [M + K$^+$], found 894.0, 910.0. Anal. calcd for C$_{37}$H$_{45}$NO$_{23}$: C 50.98, H 5.20, N 1.61, found: C 50.80, H 5.23, N 1.61.

General Procedure 1 (GP 1) for Coupling of *p*-Nitrophenyl Carbonates to Primary Amines. The amine and *i*-Pr$_2$NEt (1 equiv per amino group) were added to a solution of activated carbonate β-**3** or **7** (1.1−1.3 equiv per amino group) in dry CH$_2$Cl$_2$ (3−10 mL per mmol of activated carbonate). After complete reaction (usually after few minutes), the solvent was removed under reduced pressure and the product was purified by FC.

General Procedure 2 (GP 2) for Deacetylation with NaOMe/MeOH. The acetylated compound was dissolved in MeOH (10−30 mL per mmol) and a 0.5 M solution of NaOMe in MeOH (0.05−0.25 mL per mL of reaction mixture) was added. After complete reaction, any precipitate formed was dissolved by addition of water or MeOH. The solution was neutralized by addition of acidic ion-exchange resin (Dowex 50W-X8 or Amberlite IRC-86, H$^+$ form) and filtered. The filtrate was concentrated and lyophilized.

General Procedure 3 (GP 3) for Deacetylation with EtNMe$_2$/MeOH. The acetylated compound was stirred with a 1:5 mixture of EtNMe$_2$/MeOH (10−30 mL per mmol). After complete reaction, the mixture was concentrated and the remaining product was then dried under vacuum and lyophilized.

(2,3,4,6-Tetra-*O*-acetyl-β-D-galactopyranosyl-(1→4)-2,3,6-tri-*O*-acetyl-β-D-glucopyranosyloxycarbonyl)benzylamine (Ac-A). According to GP 1, β-**3** (115 mg, 0.15 mmol) and benzylamine **8** (14 mg, 0.13 mol) were reacted in CH$_2$Cl$_2$ (3 mL). Purification by FC (petroleum ether/ethyl acetate 1:1) gave Ac-**A** (100 mg, 99%) as a white foam: R_f = 0.45 (petroleum ether/ethyl acetate 1:2). ^{1}H NMR (600 MHz, CDCl$_3$): δ = 7.35−7.27 (m, 5 H, Ar), 5.67 (d, J = 8.3 Hz, 1 H, H-1^{Glc}), 5.35 (d, J = 2.3 Hz, 1 H, H-4^{Gal}), 5.25 (t, J = 9.0 Hz, 1 H, H-3^{Glc}), 5.17−5.10 (m, 2 H, H-2^{Gal}, NHC(O)), 5.02 (t, J = 8.7 Hz, 1 H, H-2^{Glc}), 4.95 (dd, J = 10.4 Hz, J = 3.4 Hz, 1 H, H-3^{Gal}), 4.48−4.45 (m, 2 H, H-6^{Glc}, H-1^{Gal}), 4.38−4.36 (m, 2 H, CH$_2^{Bn}$), 4.17−4.07 (m, 3 H, H-6′^{Glc}, H-6^{Gal}, H-6′^{Gal}), 3.88−3.83 (m, 2 H, H-4^{Glc}, H-5^{Gal}), 3.78−3.76 (m, 1 H, H-5^{Glc}), 2.16 (s, 3 H, C(O)CH$_3$), 2.12 (s, 3 H, C(O)CH$_3$), 2.07 (s, 3 H, C(O)CH$_3$), 2.05 (s, 6 H, C(O)CH$_3$), 2.02 (s, 3 H, C(O)CH$_3$), 1.97 (s, 3 H, C(O)CH$_3$), 1.97 (s, 3 H, C(O)CH$_3$). ^{13}C NMR (150 MHz, CDCl$_3$): δ = 170.3, 170.2, 170.1, 169.7, 169.5, 169.0 (*C*(O)CH$_3$), 153.7 (OC(O)N), 137.4, 128.8, 127.8, 127.6 (Ar), 101.0 (C-1^{Gal}), 92.8 (C-1^{Glc}), 75.8 (C-4^{Glc}), 73.3 (C-5^{Glc}), 72.6 (C-3^{Glc}), 71.0 (C-3^{Gal}), 70.7 (C-5^{Gal}), 70.6 (C-2^{Glc}), 69.0 (C-2^{Gal}), 66.6 (C-4^{Gal}), 61.8 (C-6^{Glc}), 60.8 (C-6^{Gal}), 45.2 (CH$_2^{Bn}$), 20.9−20.5 (C(O)*C*H$_3$). MALDI-MS: calcd *m*/*z* 792.2 [M + Na$^+$], 808.2 [M + K$^+$], found 792.4, 808.4. Anal. calcd for C$_{34}$H$_{43}$NO$_{19}$: C 53.05, H 5.63, N 1.82, found: C 53.03, H 5.66, N 1.83.

(β-D-Galactopyranosyl-(1→4)-β-D-glucopyranosyloxycarbonyl)benzylamine (A). According to GP 2, Ac-**A** (100 mg, 0.13 mmol) was deacetylated with 0.5 M NaOMe solution (0.25 mL) in MeOH (3 mL) to give **A** (61 mg, 99%) as a white solid. ^{1}H NMR (600 MHz, D$_2$O): δ = 7.33−7.25 (m, 5 H, Ar), 5.36 (d, J = 8.2 Hz, 1 H, H-1^{Glc}), 4.35 (d, J = 7.9 Hz, 1 H, H-1^{Gal}), 4.26 (m, 2 H, CH$_2^{Bn}$), 3.86−3.82 (m, 2 H, H-4^{Gal}, H-6^{Glc}), 3.73−3.56 (m, 8 H, H-3^{Glc}, H-3^{Gal}, H-4^{Glc}, H-5^{Glc}, H-5^{Gal}, H-6′^{Glc}, H-6^{Gal}, H-6′^{Gal}), 3.47−3.40 (m, 2 H, H-2^{Glc}, H-2^{Gal}). ^{13}C NMR (150 MHz, D$_2$O): δ = 156.6 (OC(O)N), 138.2, 128.8, 127.5, 127.1 (Ar), 102.9 (C-1^{Gal}), 94.8 (C-1^{Glc}), 77.8, 75.4, 75.3, 74.1, 72.5 (C-3^{Glc}, C-3^{Gal}, C-4^{Glc}, C-5^{Glc}, C-5^{Gal}), 71.7 (C-2^{Glc}), 70.9 (C-2^{Gal}), 68.6 (C-4^{Gal}), 61.0 (C-6^{Glc}), 59.8 (C-6^{Gal}), 44.2 (CH$_2^{Bn}$). Lectins and (Neo)glycoproteins. Purification of VAA and of the galectins (human galectins-1, -3, and -4 as well as rat galectin-5) started from extracts of dried leaves and bacteria harboring the respective expression vector. One-step isolation used lactosylated Sepharose 4B, which was prepared after activation by divinyl sulfone and elution with 0.2 M lactose (*23*). The purity of the proteins was tested by one- and two-dimensional gel electrophoresis on 10% running gels and mass spectrometry by nanoESI-MS/MS on a QTOF instrument Q-Tof2 (Waters Micromass, Manchester, UK) (*24*). Their quaternary structure was analyzed on a Superose 12 HR 10/30 column (GE Healthcare, Munich, Germany), and lectin activity was tested in 2-fold dilutions by hemagglutination with trypsinized, glutaraldehyde-fixed rabbit erythrocytes (*25*−*27*). Biotinylation with the *N*-hydroxysuccinimide ester derivative

of biotin (Sigma, Munich, Germany) under activity-preserving conditions followed by mass spectrometric product analysis to quantify label incorporation was performed as described (*24*). Proteolytic truncation of human galectin-3 required 300 μg collagenase D from *Clostridium histolyticum* (Roche Diagnostics, Mannheim, Germany) in Tris-buffered saline with 10 mM $CaCl_2$ at pH 7 for 2 h at 37 °C and 1 mg lectin as substrate (*24*). The neoglycoprotein with average ligand density of 28 units attached as *p*-isothiocyanatophenyl derivatives was based on bovine serum albumin as carrier; the glycoproteins serum amyloid P component, asialofetuin, and α_1-acid glycoprotein were prepared as outlined (*28*−*30*).

Inhibition Assays. Adsorption of (neo)glycoproteins to the surface of microtiter plate wells from phosphate-buffered saline (50 μL) at 4 °C overnight established the ligand-bearing matrix. Residual sites for binding proteins were saturated with bovine serum albumin free of contaminating glycoproteins (Biomol, Hamburg, Germany; 100 μL, 1% w/v) for 1 h at 37 °C. The incubation with lectin-containing solution in the absence and presence of lactose and the glycocompounds lasted 1 h at 37 °C, and the extent of bound lectin was determined after thorough washing steps with aliquots of the indicator conjugate streptavidin−peroxidase (0.5 μg mL^{-1}; Sigma, Munich, Germany) and then with *o*-phenylenediamine (1 mg mL^{-1})/H_2O_2 (1 μL mL^{-1}) as chromogenic substrates (*31*). Cell assays were performed with the human B-lymphoblastoid line Croco II, the T-lymphoblast line MOLT-4 (T-ALL), the human pancreatic carcinoma line Capan-1, with reconstituted expression of the tumor suppressor $p16^{INK4a}$, which enhances galectin-binding capacity linked to susceptibility to anoikis (*32*; kindly provided by K. M. Detjen, Berlin, Germany), and the colon adenocarcinoma line SW480 in Dulbecco's phosphate-buffered saline (9.2 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 137 mM NaCl, and 2.7 mM KCl at pH 7.4) using standard conditions with lectin incubation for 30 min at 4 °C to minimize uptake and streptavidin/R-phycoerythrin as fluorescent indicator (1:40; Sigma, Munich, Germany). FACScan analysis and processing of data from fluorescence detection yielded the percentage of positive cells and the mean fluorescence intensity (*15*, *32*). Cell proliferation in the absence/presence of test compound in aliquots of cell suspension was monitored after 48 h by using the blue chromogen MTT (5 mg mL^{-1}; 3-(4,5-dimethyl-thiozol-2-yl)-2,5-diphenyltetrazolium bromide) (*33*).

RESULTS AND DISCUSSION

Synthesis of the Glycocompounds. A convergent strategy with lactose derivatives activated as *p*-nitrophenyl carbonates was set up, taking advantage of (a) the fast reaction of *p*-nitrophenyl carbonates with amines, (b) the high yields of resulting carbamates, and (c) the versatile nature of the reaction with a variety of amino-substituted scaffolds (*34*, *35*). To delineate any influence of sugar spacing on lectin binding, we synthesized two series of ligands with the carbamate either directly connected to the anomeric center (*O*-glycosyl carbamates **A**−**F**) or separated from the pyranose ring by a butene diol linker (**G**−**J**). The synthesis of *O*-glycosyl carbamates by addition of anomerically unprotected carbohydrates to isocyanates is, with few exceptions (*36*), not stereoselective (*37*−*39*) and requires extensive product purification and identification, especially if several carbohydrate moieties are attached in one step. Activated glycosyl carbonates and 1-imidazolylcarbonyl glycosides, on the other hand, are excellent precursors of *O*-glycosyl carbamates—provided they are available as pure isomers—because they react under retention of configuration at the anomeric center. However, the preparation of glycosyl carbonates and 1-imidazolylcarbonyl glycosides from anomerically unprotected carbohydrates usually leads to α/β mixtures,

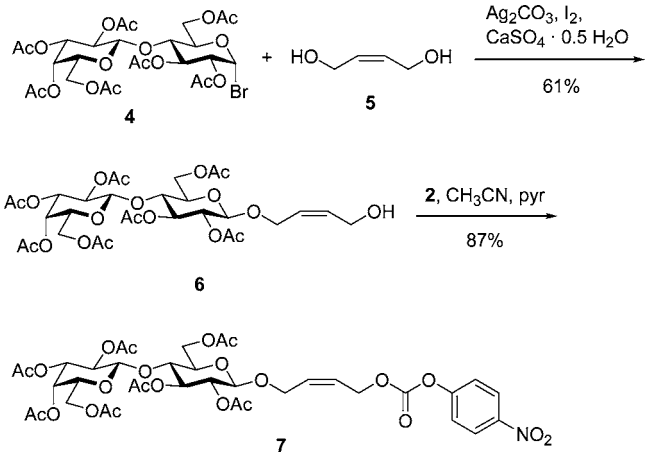
too (*18*, *40*−*45*). Leenders et al. reported high β-selectivity by hydrolysis of an intermediate anomeric silyl ether and immediate condensation of the resulting β-hydroxy group with succinimidyl chloroformate in an overall yield of 38% (*46*). When we applied this strategy to lactosyl carbonates, we also experienced a low overall yield (30−40%). Therefore, we searched for conditions that gain fast and easy access to pure isomers of activated lactosyl carbonates to answer the first question given in the Introduction.

Scheme 1 and Table 1 summarize our results for the stereoselective preparation of lactosyl carbonate **3**. From anomeric *O*-alkylation reactions, it is well-established that solvent and base have a tremendous influence on the selectivity at the anomeric center (*47*, *48*). To explore the effect of these parameters on stereoselective *O*-acylation, we reacted anomerically deprotected lactose **1** (*19*) and *p*-nitrophenyl chloroformate **2** in different base/solvent combinations. With K_2CO_3, NaH, Et_3N, and pyridine, only modest degrees of selectivity were observed regardless of the solvent. Similar results had been reported with CH_2Cl_2/pyridine (α/β = 2/1, 72%) and dimethoxyethane/NaH (α/β = 1/1, 55%) (*18*). In acetonitrile, however, 4-(dimethylamino)pyridine (DMAP) led to a remarkable α/β-selectivity of >19:1, and it was possible to isolate α-**3** in a yield of 95%. In contrast, the sterically hindered base 2,6-lutidine gave an α/β-mixture of 1:>10, from which β-**3** could be purified in a yield of 50%. Attempts to improve the yield with

Scheme 2. Synthesis of Activated Carbonate 7



conservation of the β-selectivity by prolonging reaction times, however, were unsuccessful. We also observed that the concentration of the reaction mixture is crucial for product generation. Increasing the concentration from 0.03 M (the concentration at which all reactions had been carried out) to 0.4 M gave quantitative turnover, but with complete loss of selectivity ($\alpha/\beta = 1/1$). At lower concentrations (0.003 M) no products were found.

The synthesis of spacer-separated carbonate **7** is depicted in Scheme 2. Acetobromolactose **4** (*20*, *21*) and excess (*Z*)-butenediol **5** were reacted under Koenigs−Knorr conditions to give the β-glycoside **6**. Treatment with chloroformate **2** and pyridine in acetonitrile resulted in *p*-nitrophenyl carbonate **7** with 87% yield. The activated carbonates β-**3** and **7** were coupled to a series of amines shown in Figure 1 to give the peracetylated lactosides Ac-**A**−Ac-**J**. These were deacetylated to the mono- to tetravalent lactose derivatives **A**−**J** in a straightforward manner (Schemes 3 and 4), completing the synthesis. These compounds were next tested for their potency relative to lactose to inhibit the binding of labeled lectins to the (neo)glycoproteins.

Solid-Phase Inhibition Assays. Commonly, solid-phase inhibition assays are performed with a single type of matrix. To address the issue of whether the inhibitory activity of glycoclusters depends on local density of glycans in the (neo)glycoprotein matrix, we employed four types of matrices. The (neo)glycoproteins (LacBSA, SAP, ASF, and AGP, respectively) were adsorbed to the surface of plastic wells of microtiter plates. In each experimental series, the binding of the lectins to the (neo)glycoproteins was saturable and inhibitable by blocking the carbohydrate-binding site of the lectins. Their concentration was adjusted to yield signal intensity in the linear range in each case. To assess the inhibitory profiles lectin incubation was carried out in the presence of different concentrations of lactose and the synthesized lactose derivatives **A**−**J**, respectively. Figure 2 shows examples for inhibition of the binding of biotinylated VAA to AGP and human galectin-4 to LacBSA, respectively, by lactose and lactose derivatives **B**, **D**, and **F**. From these inhibition curves, we determined the concentration of inhibitor leading to inhibition of bound lectin of 50% (IC_{50}). All IC_{50} values of multivalent ligands were calculated per lactose moiety contained; i.e., they were valency-corrected, leading to lower inhibitory potencies of some compounds (for example, trivalent **F**, Figure 2) compared to free lactose. Relative inhibitory potencies compared to free lactose (set to 1) were plotted for each type of matrix, test substance, and lectin (Figure 3A−D). Only data for inhibitors with values above 1 are given.

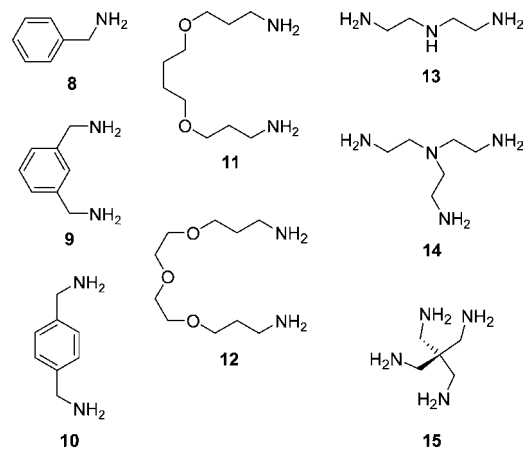


Figure 1. Amines used for preparation of **A**−**J**.

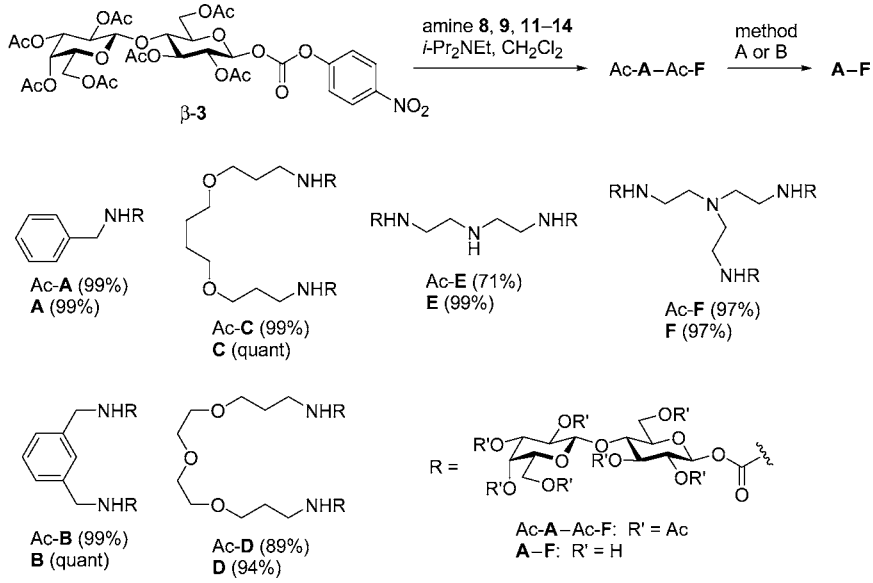
The inhibition tests revealed that conjugation of lactose to an aglycon by carbamate formation can increase inhibitory potency. Some selectivity of the bivalent lactose derivatives for certain galectins could be detected. The highest relative inhibitory potency (65 per lactose moiety), e.g., was observed for inhibition of binding of galectin-1 to the LacBSA surface by bivalent **E**. The insertion of the spacer (direct comparison for the pairs **B/G** and **D/I**) had favorable consequences only rarely. On average, these glycoclusters were more active than lysine-based compounds and surpass the activity of Tris- or aspartate-glycine-based compounds with 6-aminohexyl spacers in several cases (*31*, *49*).

Comparison of the different (neo)glycoprotein matrices revealed interesting insight into the dependence of the inhibitory activity of the lactose clusters on the local density of glycans in the matrix. For example, relative inhibition was generally lowered with increased degree of glycan branching, except for the chimera-type galectin-3 (Figure 3A−D). Since this lectin is a substrate for proteolytic processing by matrix metalloproteinases-3/-9 *in vivo* with impact for its activity in biosignaling (*50*, *51*), we tested the truncated version along with full-length galectin-3. Conspicuous selectivity for full-length galectin-3 but not its proteolytically processed derivative was observed for several ligands (**B**, **C**, **E**, **F**) with short spacers when the degree of glycan branching on the matrix was high (Figure 3D). This feature resembles the activity of 1,3,5-triiodobenzene-based inhibitors with rigidified 2-propynyl lactoside with its 7.6-fold enhancement relative to lactose and of an octavalent poly(amidoamine) starburst glycodendrimer (*52*, *53*). Under this special condition, even the monovalent compound **A** showed high activity with remarkable selectivity for galectin-3 (Figure 3D). As detailed comparison among the four panels A−D reveals, relative potency is a factor of ligand display on the matrix (see **E** in Figure 3A−D as instructive example). Inhibitory capacity should thus not be regarded as an absolute measure. Its emerging context-dependent nature confers some uncertainty to predictions for the impact on binding under physiological conditions, i.e., to cell surfaces. It is thus an obligatory step to determine whether the lactose derivatives can interfere with the binding of lectins to cells, using established tumor cells as model.

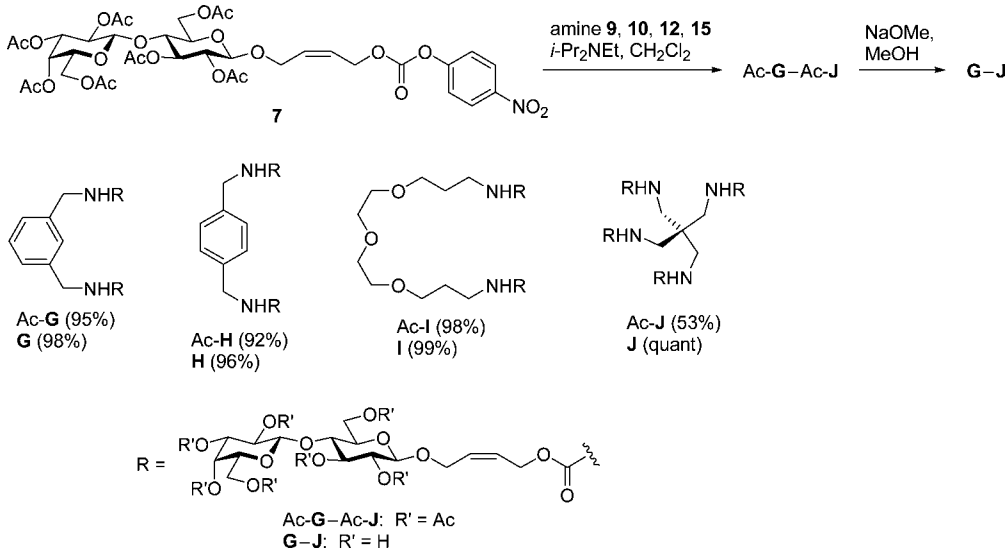
Cell-Binding Inhibition Assays. In these assays, biotinylated lectins were incubated with cells of different lines. The extent of binding of lectins to cells was measured by using fluorescently labeled streptavidin as second-step reagent. As described in the preceding part, concentration dependence of lectin binding was first determined to plot the linear range and plateau levels in each combination. Then, sugar specificity and constant reactivity of cells were ascertained in each case. An example for the carbohydrate dependence of lectin binding is given in Figure

Scheme 3. Synthesis of Lactosyl Carbamates A−F[a]



[a] Method A: NaOMe, MeOH (used for **A**−**D**). Method B: $EtNMe_2$, MeOH (used for **E**, **F**).

Scheme 4. Synthesis of Lactosyl Carbamates G−J



4. To preclude an impact of any variability in the cells' reactivity due to length of culture time during the passage, comparative measurements were performed with aliquots of cell batches in the same series. The obtained data, expressed in percentage of positive cells that show fluorescence above the control and mean fluorescence intensity (*F*), confirms that the test substances can

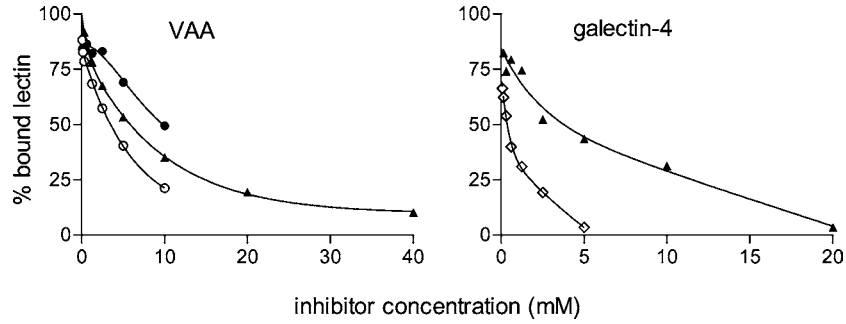


Figure 2. Inhibition of binding of biotinylated VAA (7.5 μg mL^{-1}; left) and human galectin-4 (5 μg mL^{-1}; right) to glycans of a (neo)glycoprotein-presenting matrix by a glycocompound and free lactose for comparison. The matrix presenting the lectin ligands was AGP (0.5 μg/well; left) and the neoglycoprotein LacBSA (0.25 μg/well; right). Lactose (▲) was used as control, and the bivalent compounds **D** (○) and **B** (◇) and the trivalent compound **F** (•) as inhibitors. The concentration of inhibitor is calculated with respect to its lactose contents present in the inhibition assay to normalize data.

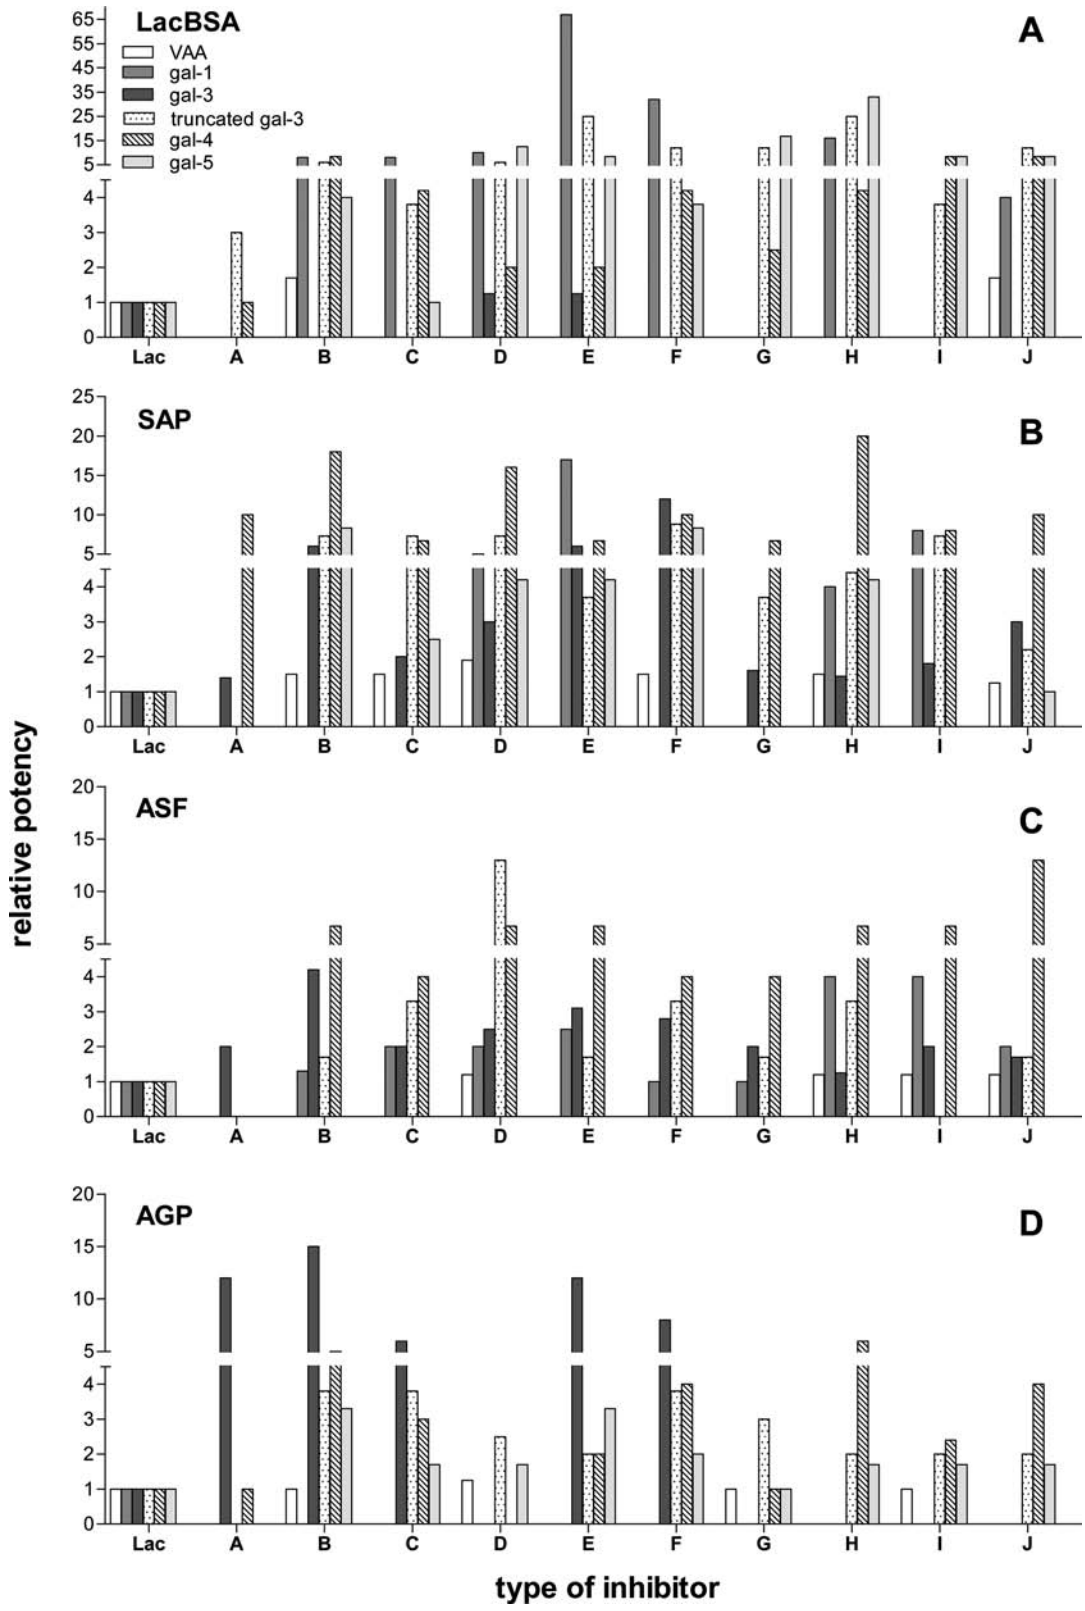

Figure 3. Relative potency of the panel of the synthetic lactose-containing compounds **A**−**J** (for structures, see Schemes 3 and 4; designations of lectins are given in the top panel) as inhibitor of lectin binding. The IC_{50} values are based on the lactose concentration with free lactose as standard (set to 1) and they were determined in each case by systematic inhibition assays (for an example, see Figure 2). Experiments were repeated up to six times; the standard deviation did not exceed 11%. All cases better than free lactose are given. The optimal conditions were as follows: (A) 0.25 μg/well neoglycoprotein (lactosylated bovine serum albumin: LacBSA) and 0.5 μg mL^{-1} VAA, 30 μg mL^{-1} galectin-1, 15 μg mL^{-1} galectin-3 (both versions), 5 μg mL^{-1} galectin-4, and 35 μg mL^{-1} galectin-5; (B) 0.5 μg/well serum amyloid P component (SAP) and 2 μg mL^{-1} VAA, 2.5 μg mL^{-1} galectin-1, 5 μg mL^{-1} full-length galectin-3, 30 μg mL^{-1} truncated galectin-3, 5 μg mL^{-1} galectin-4, and 15 μg mL^{-1} galectin-5; (C) 0.25 μg/well asialofetuin (ASF) and 0.5 μg mL^{-1} VAA, 5 μg mL^{-1} galectin-1, full-length galectin-3 and galectin-4, 30 μg mL^{-1} truncated galectin-3, and 10 μg mL^{-1} galectin-5; (D) 0.5 μg/well α_1-acid glycoprotein (AGP) and 7.5 μg mL^{-1} VAA, 30 μg mL^{-1} galectin-1, 10 μg mL^{-1} full-length galectin-3, 60 μg mL^{-1} truncated galectin-3, 20 μg mL^{-1} galectin-4, and 25 μg mL^{-1} galectin-5.

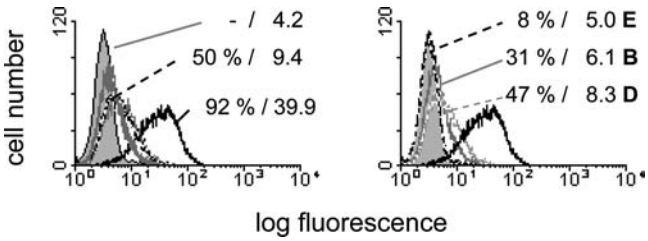

Figure 4. Semilogarithmic representation of the fluorescent surface staining of T-lymphoblast cells MOLT-4 (T-ALL) by labeled full-length galectin-3 (10 μg mL^{-1}). The control value representing staining by the second-step reagent in the absence of lectin is given as the shaded area; the peak for lectin binding in the absence of any inhibitor as the black line. Quantitative data on the percentage of positive cells that show fluorescence above the control and mean fluorescence intensity are given. The left diagram illustrates the inhibition curves obtained by increasing concentrations of lactose of 1 mM, 2 mM, 4 mM, 8 mM, and 10 mM. Given values are for the control (background staining without lectin), 2 mM lactose, and maximal lectin binding without inhibitor. Right diagram: inhibition curves obtained by glycocompounds **E**, **B**, and **D** at a concentration of 2 mM of lactose residues (i.e., a concentration of bivalent inhibitors of 1 mM).

act as inhibitors of lectin binding to cells. As shown in Figure 4, compound **E** at a concentration of 2 mM of lactose residues (i.e., a concentration of bivalent **E** of 1 mM) reduces binding of galectin-3 to the MOLT-4 T-lymphoblast cells from 92% (*F* 39.9) to 8% (*F* 5.0). In comparison, a 2 mM solution of free lactose leads to a reduction to 50% (*F* 9.4). This compound distinguishes the full-length lectin from its truncated derivative and is only rather weakly reactive with galectins-1 and -5. In general, none of the lactose clusters surpasses lactose as inhibitor for galectin-1. Compound **D**, at a concentration of 2 mM in lactose moieties reduces binding of truncated galectin-3 to MOLT-4 T-lymphoblasts from 53% (*F* 9.0) to 28% (*F* 9.0) and binding of galectin-5 to the colon adenocarcinoma line SW480 from 89% (*F* 50.8) to 60% (*F* 16.7). A 2 mM solution of lactose correspondingly leads to a reduction to 32% (*F* 7.6) and 69% (*F* 20.2), respectively. Binding of galectin-4 to the p16^{INK4a}-expressing pancreatic carcinoma line Capan-1 is impaired best by the bivalent compound **B**, a strongly active reagent in the solid-phase assays, with a reduction from 60% (*F* 47.0) to 16% (*F* 7.6) at a concentration of lactose residues of 4 mM. Here, even a 20 mM lactose solution results in a reduction to only 44% (*F* 24.5). To examine the influence of cell type, we tested galectin-3 binding also with pancreatic carcinoma cells. In this system, compound **F** was the best inhibitor with a nearly 4-fold enhancement relative to lactose. Similar results on influence of cell type were obtained with the plant toxin, with compound **D** yielding the best results at a nearly 2-fold increase (not shown).

Having delineated the activity of the lactose derivatives in lectin binding to tumor cells, any further consideration for potential applications will crucially depend on their lack of cytotoxicity. To answer this last question, we monitored cell proliferation over a period of 48 h in the presence of lactose as control and lactose clusters selected to represent the scaffolds all at the same concentration of sugar in parallel. Compounds **D**, **F**, **G**, and **I** did not influence the growth of SW480 colon adenocarcinoma cells at a concentration of lactose residues of 2 mM; compound **F** was also tested on Capan-1 pancreatic carcinoma cells at 5 mM without influence on proliferation.

CONCLUSIONS

In summary, we investigated inhibition of binding of adhesion/growth-regulatory galectins and a plant toxin to a series of immobilized (neo)glycoproteins and to tumor cells by mono- to tetravalent lactose derivatives. Our experiments enabled us to answer the five questions given at the end of the Introduction: (1) Synthetically, we developed conditions to stereoselectively produce activated lactosyl carbonates from the anomerically unprotected disaccharide. These derivatives have general application for the attachment of lactosyl residues to amino-substituted scaffolds yielding lactosyl carbamates. (2) In systematic solid-phase screening, bioactivity was found to increase by more than 1 order of magnitude relative to free lactose (valence-corrected values) for galectins. (3) Individual scaffold structure was more important than valency of lactose in the glycocompounds, and introduction of butene diol to extend the spacer's length led to enhancements only rarely. However, the inhibitory activity showed selectivity for lectin type (plant toxin vs galectins) and among galectins. In addition, the nature of the matrix glycans ranging from bi- to tetraantennary N-glycans and including the neoglycoprotein LacBSA also had a strong impact on inhibitory potency and selectivity. Interestingly, rather low activity was noted with the AGP matrix having the highest degree of branching except for the chimera-type galectin-3, an effector in cardiac dysfunction (*54*). This is why test series should routinely include cell assays to gauge potential for lectin blocking in a physiological context. (4) Strong inhibition of cell binding was detected for galectins-3 and -4 with distinct lactose-bearing compounds, and (5) we could show that representative examples of our compounds are not cytotoxic, emphasizing the suitability of carbamate-linked lactose derivatives in a lectin blocking approach.

Evidently, it is a reasonable long-term aim to tailor scaffolds adorned with lectin ligands for the ability to distinguish lectin groups or even members of a family based on reactivity. Due to arising evidence for functional antagonism among lectins, e.g., for galectins-1 and -3 in tumor growth regulation (*50*), such a discriminatory capacity is desirable. However, the impact of glycan branching revealed herein precludes immediate extrapolations from data in a single system. The measured relative reduction in inhibitory potency in cell assays could be compensated by tailoring the glycan part to the lectin. Extended structures such as histo-blood group ABH epitopes or other natural ligands will enhance affinity and selectivity (*9, 11, 55*−*57*).

ACKNOWLEDGMENT

We gratefully acknowledge the generous financial support by the research initiative LMU*excellent*, the Deutsche Forschungsgemeinschaft (FOR 434 "Oligosaccharide and DNA Chips - Analysis of Secondary Gene Products"), the Verein zur Förderung des biologisch-technologischen Fortschritts in der Medizin e.V. (Heidelberg, Germany), and an EC Marie Curie Research Training Network grant (contract no. MCRTN-2005-19561), the inspiring discussions with Drs. B. Friday and S. Namirha, the helpful advice and remarkable diligence of the reviewers as well as the expert technical assistance by B. Hofer and L. Mantel.

Phospholipid Conjugate for Intracellular Delivery of Peptide Nucleic Acids

Gang Shen, Huafeng Fang, Yinyin Song, Agata A. Bielska, Zhenghui Wang, and John-Stephen A. Taylor*

Department of Chemistry, Washington University in St. Louis, One Brookings Drive, St. Louis, Missouri 63130. Received January 31, 2009; Revised Manuscript Received July 18, 2009

Peptide nucleic acids (PNAs) have a number of attractive features that have made them an ideal choice for antisense and antigene-based tools, probes, and drugs, but their poor membrane permeability has limited their application as therapeutic or diagnostic agents. Herein, we report a general method for the synthesis of phospholipid-PNAs (LP-PNAs) and compare the effect of noncleavable lipids and bioreductively cleavable lipids (L and LSS) and phospholipid (LP) on the splice-correcting bioactivity of a PNA bearing the cell penetrating Arg9 group (PNA-R9). While the three constructs show similar and increasing bioactivity at 1−3 μM, the activity of **LP-PNA-R9** continues to increase from 4−6 μM, while the activity of **L-PNA-R9** remains constant and that of **LSS-PNA-R9** decreases rapidly in parallel with their relative cytotoxicity. The activity of both **LP-PNA-R9** and **L-PNA-R9** dramatically increased in the presence of chloroquine, as expected for an endocytotic entry mechanism. The constructs were also found to have CMC values of 1.0 and 4.5 μM, respectively, in 150 mM NaCl, pH 7 water, suggesting that micelle formation may play a hitherto unrecognized role in modulating toxicity and/or facilitating endocytosis.

INTRODUCTION

Compared to conventional drug inhibitors that target enzymes by a complex set of interactions, antisense and antigene agents such as oligonucleotides (ODNs), peptide nucleic acids (PNAs), and siRNA target nucleic acids by sequence-specific Watson−Crick base pairing, making them more easily programmable (*1*−*4*). Peptide nucleic acids contain repeating *N*-(2-aminoethyl)glycine units with the nucleobases attached through methylenecarbonyl linkers which mimic natural deoxyribose phosphate backbone of DNA (*5, 6*). Due to their non-native peptide backbone, PNAs have a number of attractive features for the development of probes, tools, and drugs (*7*−*9*). They exhibit higher binding affinity and specificity for RNA and DNA and can invade regions of secondary structure. They also do not activate RNaseH degradation of a target mRNA and are highly resistant to enzymatic degradation by nuclease and proteases. Therefore, PNAs have emerged as promising candidates for the development of antisense and antigene therapeutics and diagnostics.

Because of their size and polar nature, PNAs are not very membrane permeable and require attachment of cell penetrating groups or complexation with cationic lipid-based transfection agents to enter cells (*10*−*14*). Cationic peptides, such as Arg9 or the Tat peptide, have been found to facilitate entry of PNAs into cells via macropinocytosis, though a significant amount appears to be trapped in endosomes (*15*−*22*). PNAs have been hybridized to short ODNs to impart negative charge to the PNA to enable electrostatic delivery by cationic transfection agents (*11, 17, 23*), but the toxicity of these agents has limited their use *in vivo* (*13, 24*). More recently, a cationic nanoparticle has been developed that can deliver PNAs into cells with greater efficiency and less toxicity than cationic liposomes (*25*). As of yet, an efficient and nontoxic PNA delivery system for *in vivo* PNA delivery remains elusive.

It was reported recently that attachment of a phospholipid to an anti-telomerase thiophosphoramidate greatly improved its activity in cell culture (*26*−*28*). Subsequently, it was shown that attachment of a fatty acid to the N-terminus of PNAs bearing cell penetrating peptides also enhanced their bioactivity (*29, 30*), but nothing is known about the effect of attaching a phospholipid. We hypothesized that the phosphodiester group might be important for bioactivity, because it could function either as a part of a recognition element for some membrane mediated intracellular delivery mechanism or as a cleavable linker to release the PNA from the membrane once inside the cell. Herein, we report that a phospholipid conjugated to a PNA bearing an Arg9 cell penetrating peptide exhibits better bioactivity and lower cytotoxicity than the corresponding conjugates with a lipid or a bioreductively cleavable lipid in the 4−6 μM range.

EXPERIMENTAL PROCEDURES

General Procedures. All reactions were performed under an argon or nitrogen atmosphere unless otherwise specified. All commercially available materials were used without further purification unless otherwise noted. Anhydrous solvents for reactions, such as DMF, DCM, and acetonitrile were either used as obtained from Sigma-Aldrich or distilled from an appropriate drying agent. ^{1}H NMR, ^{13}C NMR, and ^{31}P NMR spectra were recorded on VarianUnityPlus-300. Trimethyl phosphate was used as the external reference for ^{31}P NMR. All PNAs and conjugates were purified by reversed-phase high-performance liquid chromatography (HPLC) on a Beckman System Gold instrument equipped with a UV−vis array detector. HPLC fractions were collected and concentrated under vacuum in a SpeedVac (Savant). Concentrations of PNAs were determined by UV absorption on a Bausch and Lomb Spectronic1001 spectrophotometer or on a Varian Cary 100 Bio UV−vis spectrophotometer using standard extinction coefficients. Fluorescence spectra were measured on a Varian Cary Eclipse fluorescence spectrophotometer. The PNAs were characterized by MALDI-TOF on a PerSpective Voyager MALDI-TOF mass spectrometer in linear mode using insulin as the internal reference.

2-Cyanoethyl 3-((4-methoxyphenyl)diphenylmethylamino) propyl Diisopropyl-Phosphoramidite (1). 3-((4-Methoxyphenyl)diphenylmethylamino)propan-1-ol (0.74 g, 2.33 mmol) was

dissolved in freshly distilled CH_2Cl_2 (23 mL). *N*,*N*-Diisopropylethylamine (1.63 mL, 9.34 mmol) was added, followed by 2-cyanoethyl *N*,*N*-diisopropylchlorophosphoramidite (1.04 mL, 4.67 mmol). The mixture was stirred at room temperature for 8 h before addition of saturated aqueous NH_4Cl solution (100 mL). The aqueous layer was extracted with EtOAc (3 × 100 mL). The combined organic extracts were dried (Na_2SO_4), filtered, and concentrated. The residue was used directly in the next step.

2,5-Dioxopyrrolidin-1-yl 12-((2-cyanoethyl)(3-((4-methoxyphenyl)diphenylmethyl-amino)propyl)phosphoryloxy)dodecanoate (3). Compound **1** from the previous step was dissolved in freshly distilled CH_2Cl_2 (9 mL) and CH_3CN (9 mL). 2,5-Dioxopyrrolidin-1-yl 12-hydroxydodecanoate (0.75 g, 2.38 mmol) was added, followed by diisopropylammonium tetrazolide (0.41 g, 2.38 mmol). The mixture was stirred at room temperature for 12 h before addition of *tert*-butyl hydroperoxide (5 M, 1.83 mL). The reaction was quenched after 2 h with saturated aqueous $NaHCO_3$ solution (100 mL). The aqueous layer was extracted with EtOAc (3 × 100 mL). The combined organic extracts were dried (Na_2SO_4), filtered, and concentrated. The oil was purified by chromatography (SiO_2, 50% EtOAc in hexanes) to afford **3** (0.75 g, 42%) as pale yellow oil: ^{1}H NMR (CD_2Cl_2, 300 MHz) δ 7.54 (m, 4H), 7.42 (m, 2H), 7.36 (m, 4H), 7.26 (m, 2H), 6.87 (m, 2H), 4.26 (m, 2H), 4.14 (m, 2H), 4.06 (m, 2H), 3.85 (s, 3H), 2.83 (s, 4H), 2.73 (t, J = 6.2 Hz, 2H, $\underline{CH_2}CN$), 2.65 (t, J = 7.5 Hz, 2H,$\underline{CH_2}CONHS$), 2.28 (m, 2H), 1.93 (m, 2H), 1.78 (m, 4H), 1.35 (m, 14H); ^{13}C NMR (CD_2Cl_2, 75 MHz) δ 169.6, 169.1, 158.3, 146.7, 130.0, 128.7, 128.0, 126.5, 117.0, 113.3, 70.6, 68.5, 66.6, 66.5, 62.0, 55.4, 40.0, 31.6, 31.1, 30.5, 29.7, 29.6, 29.3, 29.0, 25.9, 25.6, 24.9, 19.9; ^{31}P NMR (CD_2Cl_2, 121.4 MHz) δ −0.1; HRMS (ES^+) *m*/*z* 776.3684 (M^+ + H, $C_{42}H_{55}N_3O_9P$ requires *m*/*z* 776.3676).

***tert*-Butyl 3-((2-Cyanoethoxy)(diisopropylamino)phosphinooxy)propylcarbamate (2).** *tert*-Butyl 3-hydroxypropylcarbamate (0.13 g, 0.75 mmol) was dissolved in freshly distilled CH_2Cl_2. 2-Cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite (0.29 g, 0.97 mmol) in dry CH_3CN (4 mL) was added, followed by *N*,*N*-diisopropylammonium tetrazolide (0.15 g, 0.90 mmol). The mixture was stirred at room temperature for 8 h before addition of saturated aqueous NH_4Cl solution (80 mL). The aqueous layer was extracted with EtOAc (3 × 100 mL). The combined organic extracts were dried (Na_2SO_4), filtered, and concentrated. The residue was used directly in the next step.

***tert*-Butyl 3-(((2-Cyanoethoxy)(2,5-dioxopyrrolidin-12-yl)-dodecanoate)phosphoryl-oxy)propylcarbamate (4).** Compound **2** (0.18 g, 0.48 mmol) from the previous step was dissolved in freshly distilled CH_2Cl_2 (2.5 mL) and CH_3CN (2.5 mL). 2,5-Dioxopyrrolidin-1-yl 12-hydroxydodecanoate (0.10 g, 0.62 mmol) was added, followed by *N*,*N*-diisopropylammonium tetrazolide (0.04 g, 0.58 mmol). The mixture was stirred at room temperature for 12 h before addition of *tert*-butyl hydroperoxide (5 M, 0.5 mL). The reaction was quenched after 2 h with saturated aqueous $NaHCO_3$ solution (100 mL). The aqueous layer was extracted with EtOAc (3 × 100 mL). The combined organic extracts were dried (Na_2SO_4), filtered, and concentrated. The oil was purified by chromatography (SiO_2, 50% EtOAc in hexanes) to afford **4** (178 mg, 61%) as a colorless oil: ^{1}H NMR (CD_2Cl_2, 300 MHz) δ 5.05 (broad, NH), 4.26 (m, 2H), 4.12 (m, 4H), 3.24 (m, 2H), 2.84 (s, 4H), 2.80 (m, 2H), 2.63 (t, J = 7.5 Hz, 2H, $\underline{CH_2}CONHS$), 1.89 (m, 2H), 1.73 (m, 4H), 1.55 (m, 23H); ^{13}C NMR (CD_2Cl_2, 75 MHz) δ 169.6, 169.1, 156.1, 117.0, 79.1, 68.7, 65.8, 62.1, 37.0, 30.7, 30.5, 30.4, 29.6, 29.5, 29.3, 29.2, 28.9, 28.4, 25.9, 25.6, 24.8, 20.0, 19.9; ^{31}P NMR (CD_2Cl_2, 121.4 MHz) δ −3.6; HRMS (ES^+) *m*/*z* 626.2797 (M^+ + Na, $C_{27}H_{46}N_3O_{10}PNa$ requires *m*/*z* 626.2819).

2,5-Dioxopyrrolidin-1-yl palmitate (5). Palmitic acid (2.0 g, 7.8 mmol), *N*-hydroxy-succinimide (0.94 g, 8.2 mmol), and *N*,*N*′-dicyclohexylcarbodiimide (1.69 g, 8.2 mmol) were dissolved in dry 1,4-dioxane (30 mL). The mixture was stirred at room temperature for 12 h. The precipitate was filtered, and the resulting residue was washed with saturated aqueous $NaHCO_3$ (3 × 100 mL). The aqueous layer was extracted with EtOAc (3 × 100 mL). The combined organic extracts were dried (Na_2SO_4), filtered, and concentrated to afford **5** (1.88 g, 81%) as a white solid: ^{1}H NMR ($CDCl_3$, 300 MHz) δ 2.86 (s, 4H), 2.63 (t, J = 7.5 Hz, 2H, $\underline{CH_2}CONHS$), 1.77 (m, 2H), 1.29 (m, 24H), 0.91 (t, J = 6.5 Hz, 3H, $CH_2\underline{CH_3}$); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 169.4, 169.0, 32.2, 31.2, 29.9, 29.8, 29.6, 29.3, 29.1, 25.9, 24.8, 23.0, 14.4; HRMS (ES^+) *m*/*z* 354.2659 (M^+ + H, $C_{20}H_{36}NO_4$ requires *m*/*z* 354.2644).

***N*-(3-Hydroxypropyl)palmitamide (6).** 3-Amino-1-propanol (0.47 g, 6.3 mmol), palmitic acid (1.2 g, 4.2 mmol), and *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (0.81 g, 4.2 mmol) were dissolved in freshly distilled CH_2Cl_2 (46 mL) and pyridine (23 mL) at 0 °C. The mixture was then stirred at room temperature for 12 h before addition of 1 N HCl (250 mL). The aqueous layer was extracted EtOAc (3 × 50 mL); the combined organic extracts was dried (Na_2SO_4), filtered, and concentrated. The residue was purified by chromatography (SiO_2, 40% EtOAc in hexanes) to afford **6** (1.11 g, 76%) as a white solid: ^{1}H NMR ($CDCl_3$, 300 MHz) δ 5.77 (broad, NH), 3.65 (m, 2H), 3.47 (m, 2H), 3.26 (broad, 1H), 2.23 (s, 2H), 1.72 (m, 4H), 1.29 (m, 24H), 0.91 (t, J = 7.2 Hz, 3H, $CH_2\underline{CH_3}$); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 174.9, 59.3, 37.0, 36.3, 32.7, 32.2, 29.9 (3), 29.7, 29.6 (2), 26.1, 22.9, 14.1; HRMS (ES^+) *m*/*z* 314.3050 (M^+ + H, $C_{19}H_{40}NO_2$ requires *m*/*z* 314.3059).

General Procedures for the Synthesis of PNA and Its Conjugates. All PNAs and conjugates were synthesized on an Expedite 8900 PNA synthesizer (Applied Biosystems) on 2 μmol Fmoc-PAL-PEG-PS resin following the standard automated Fmoc PNA synthesis procedure with commercially available monomers (Panagene Inc., Korea). For nonautomated steps, the resin was removed from the column and transferred to a glass vial to which solvent and reagents were added and shaken. After the specified time, the resin was filtered, washed and dried, by filtering the suspension through the original column by drawing the solvent through the bottom with an attached syringe, and then washed with dry DMF (2 × 3 mL) and dry CH_2Cl_2 (2 × 3 mL), followed by drying under a stream of N_2. Final cleavage of the PNA from the resin and deprotection was carried out by transferring washed and dried resin to a vial and treating with trifluoroacetic acid (300 μL) and *m*-cresol (100 μL) at room temperature for 2 h. The solution was filtered from the resin and added into ice-cold Et_2O (5 mL) and kept in an ice bath for 1 h. The resulting precipitate was collected by centrifugation and purified by reverse-phase gradient HPLC with solvent A [0.1% TFA in H_2O] and solvent B [0.1% TFA in CH_3CN] on Varian Microsorb-MV column (C-18, 5 μm, 300 Å pore size, 4.6 × 250 mm) at 1 mL/min. HPLC method A: 40 min 0−40% B in A, 45 min 40−100% B in A. Method B: 15 min 0−40% B in A, 40 min 40−60% B in A. The desired PNAs eluted as single HPLC peaks, which were broader and tended to tail for lipidated PNAs (see Supporting Information). The HPLC fractions were collected, concentrated to dryness, and redissolved in water. PNA solutions were characterized by UV−vis, and their concentration was determined from their absorbance at 260 nm. PNAs were also characterized by MALDI-TOF analysis with insulin as an internal standard, and showed a single major molecular ion peak corresponding to the desired product (see Supporting Information).

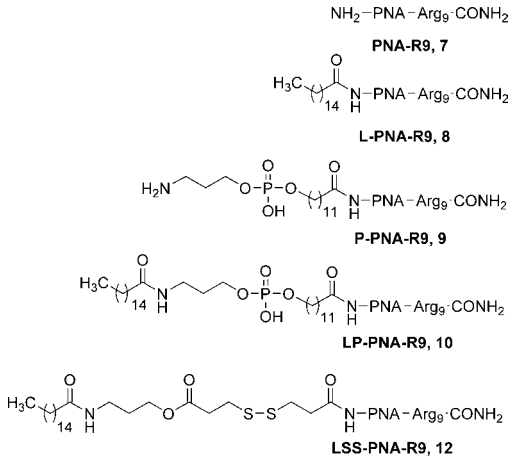

Figure 1. Structures of the PNA conjugates.

PNA-R9 (7). The PNA-R9 H-CCTCTTACCTCAGTTAC-ARRRRRRRRR-NH_2 was synthesized and purified by the general procedure described above using HPLC Method A. MALDI-TOF (matrix: α-cyano-4-hydroxy-cinnamic acid (CHCA)): average $[M+H]^+$ expected 6171.2, found 6172.9.

L-PNA-R9 (8). Following automated PNA synthesis of H-CCTCTTACCTCAGTTACARRRRRRRRR-NH_2 and washing and drying, but prior to cleavage and deprotection, the resin was removed from the column and shaken with piperidine (1 mL) and dry DMF (4 mL) in a vial for 30 min and then filtered, washed, and dried. The resin was then shaken for 12 h with palmitic acid (5.1 mg), *N*,*N*′-dicyclohexylcarbodiimide (4.1 mg), and 4-dimethylaminopyridine (2.4 mg) in dry DMF (100 μL) in a vial and then filtered, washed, and dried. The PNA was then cleaved from the resin, deprotected, and purified by HPLC method B. MALDI-TOF (matrix: CHCA): average $[M+H]^+$ expected 6409.7, found 6410.1.

P-PNA-R9 (9). Following automated PNA synthesis of H-CCTCTTACCTCAGTTACARRRRRRRRR-NH_2 and washing and drying, but prior to cleavage and deprotection, the resin was removed from the column and shaken with piperidine (1 mL) and dry DMF (4 mL) for 30 min in a vial and then filtered, washed, and dried. The resin was then shaken for 12 h with **4** (10 μmol, 11.5 mg) and *N*,*N*-diisopropylethylamine (10 μmol, 1.7 μL) in dry DMF (100 μL) in a vial and then filtered, washed, and dried. The resin was then shaken with pyridine (1.6 μL) and triethylamine (2.8 μL) in DMF (100 μL) for 20 h and then filtered, washed, and dried. The PNA was cleaved from the resin, deprotected, and purified by HPLC Method A. MALDI-TOF (matrix: CHCA): average $[M+H]^+$ expected 6506.6, found 6506.4.

LP-PNA-R9 (10). Following automated PNA synthesis of H-CCTCTTACCTCAGTTACARRRRRRRRR-NH_2 and washing, but prior to cleavage and deprotection, the resin was removed from the column and shaken with piperidine (1 mL) and dry DMF (4 mL) for 30 min in a vial and then filtered, washed, and dried. The resin was then shaken for 12 h with **3** (20 μmol, 15.5 mg) and *N*,*N*-diisopropylethylamine (20 μmol, 3.5 μL) in dry DMF (100 μL) in a vial and filtered, washed, and dried. The resin was then treated with 1% TFA in CH_2Cl_2 (2 × 3 mL) for 10 min in a vial and then filtered, washed, and dried. The resin was then shaken for 20 h with **5** (20 μmol, 7.1 mg) and *N*,*N*-diisopropylethylamine (40 μmol, 7.0 μL) in dry DMF (100 μL) in a vial and then filtered, washed, and dried. The resin was then shaken for 20 h with pyridine (1.6 μL) and triethylamine (2.8 μL) in DMF (100 μL) in a vial and then filtered, washed, and dried. The PNA was then cleaved from the resin, deprotected, and purified by HPLC method B. MALDI-TOF (matrix: CHCA): average $[M+H]^+$ expected 6744.9, found 6744.4.

LP-sPNA-R9 (11). This PNA was prepared by the same procedure used to prepare LP-PNA-R9 **10** except that the scrambled sequence ACATCACTTGTTACCCCT was used. MALDI-TOF (matrix: CHCA): average $[M+H]^+$ expected 6744.9, found 6745.3.

LSS-PNA-R9 (12). Following automated PNA synthesis of H-CCTCTTACCTCAGTTACARRRRRRRRR-NH_2 and washing, but prior to cleavage and deprotection, the resin was removed from the column and shaken in piperidine (1 mL) and dry DMF (4 mL) for 30 min in a vial and then filtered, washed, and dried. The resin was then shaken for 12 h with 3,3′-dithiodipropionic acid (5.1 mg), *N*,*N*′-dicyclohexylcarbodiimide (4.1 mg), and 4-dimethylaminopyridine (2.4 mg) in dry DMF (100 μL) in a vial and then filtered, washed, and dried. The resin was then shaken for 12 h with **6** (2.9 mg), *N*,*N*′-dicyclohexylcarbodiimide (4.1 mg), and 4-dimethylaminopyridine (2.4 mg) in dry DMF (100 μL) in a vial and then filtered, washed, and dried. The PNA was then cleaved from the resin, deprotected, and purified by HPLC method B. MALDI-TOF (matrix: α-cyano-4-chloro-cinnamic acid): average $[M+H]^+$ expected 6660.0, found 6659.4.

Cell Culture. pLuc705 HeLa cells were maintained in DMEM containing 10% FBS, streptomycin (100 μg/mL), penicillin (100 units/mL), G418 (100 μg/mL), and hygromycin B (100 μg/mL) at 37 °C in a humidified atmosphere with 5% CO_2.

Splice Correction Assay. pLuc705 HeLa cells were seeded in a 96-well microtiter plate at a density of 1×10^4 cells/well and cultured for 24 h in 100 μL DMEM containing 10% FBS. At the time of transfection, the medium was replaced with 80 μL fresh medium, and then a solution of PNA in 20 μL OPTI-MEM was added. After 24 h incubation, 100 μL Steady-Glo Luciferase assay reagent was added to each well. The contents were mixed and allowed to incubate at room temperature for 10 min to stabilize luminescence. Signals were recorded on a Luminoskan Ascent luminometer (Thermo Scientific) with an integration time of 1 s per well. For experiments requiring disulfide cleavage, the PNA was preincubated with DTT (10 mM) for 10 min before adding to the plate. For experiments requiring chloroquine, the chloroquine (Sigma-Aldrich Co.) was added 6 h after PNA addition to give a final concentration of 100 μM.

Cytotoxicity Assays. The cytotoxicity of the PNAs was evaluated by the CellTiter-Glo Luminescent Cell Viability Assay (Promega Co.). HeLa cells were seeded in a 96-well plate at a density of 1×10^4 cells/well and cultured for 24 h in 100 μL DMEM containing 10% FBS. Thereafter, the medium was replaced with 100 μL fresh medium containing various concentrations of the PNAs, Polyfect (positive controls), or no additive (negative control). After 24 h incubation at 37 °C, 100 μL of CellTiter-Glo reagent were added. The contents were mixed, and the plate was allowed to incubate at room temperature for 10 min to stabilize the luminescence signals. Luminescence intensities were recorded on a Luminoskan Ascent luminometer (Thermo Scientific) with an integration time of 1 s per well. The relative cell viability was calculated as the ratio of the luminescence in the presence and absence of PNA and fit to LC50 values using the Hill-Slope model (% viability $= 100/(1 + ([PNA]/LC50)^{slope})$.

Determination of Critical Micelle Concentration (CMC). Pyrene was purified by silica gel chromatography with cyclohexane to give a pale yellow solid. Stock solutions of **L-PNA-R9** (45.5 μM) and **LP-PNA-R9** (18.1 μM) were diluted in water to different concentrations. Pyrene in 1% methanol/water (50 μL, 10 μM) was added to each concentration of PNA (450 μL).

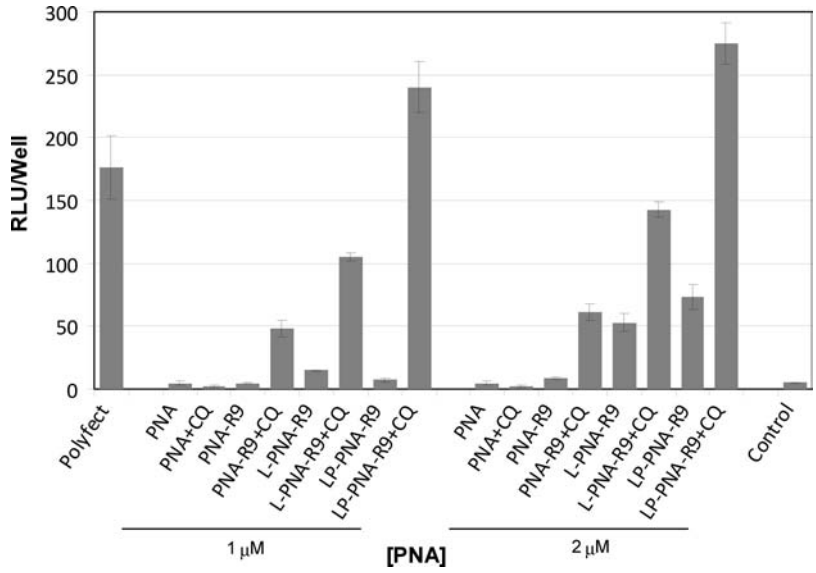

Figure 2. Luciferase splice-correcting bioactivity for 1 and 2 μM **PNA**, **PNA-R9**, **L-PNA-R9**, **LP-PNA-R9**, with and without 100 μM chloroquine (CQ), using a blank as a control.

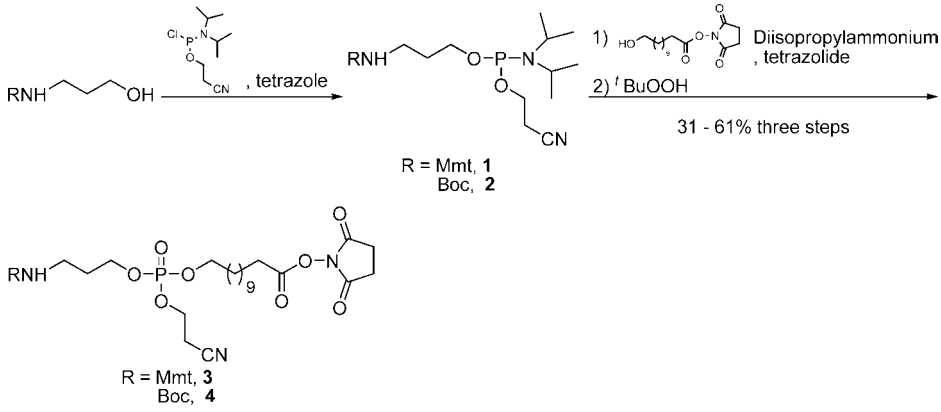
Scheme 1. Synthesis of Phosphodiester Building Blocks for Phospholipid PNA Synthesis



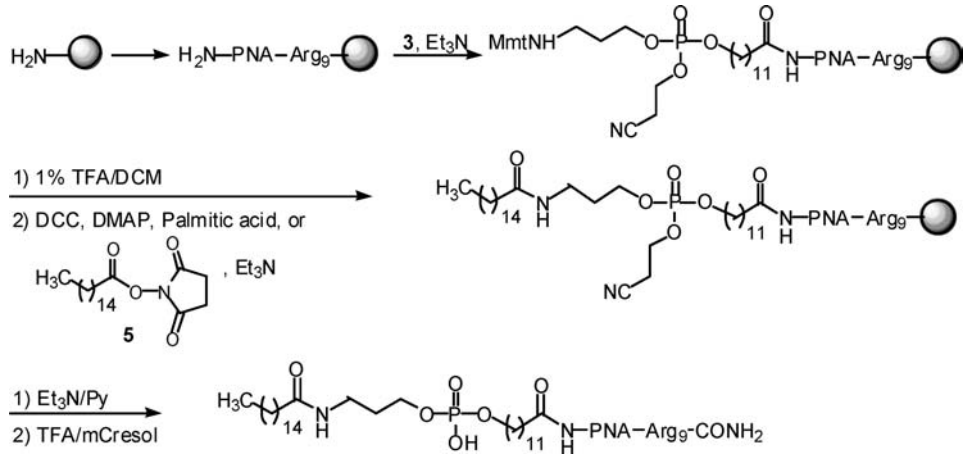
L-PNA-R9 and **LP-PNA-R9** were also diluted in a buffer (150 mM NaCl, 5 mM Tris, pH 7) to different concentrations. Pyrene in 1.4% methanol/buffer solution (50 μL, 10 μM) was added to each concentration of PNA (450 μL). Fluorescence emission spectra were obtained by exciting the pyrene at 332 nm. The ratio of intensity of the first (373 nm) and third (384 nm) emission peaks was plotted against PNA concentration to determine the CMC from the breakpoint in a bilinear fit to the data.

RESULTS AND DISCUSSION

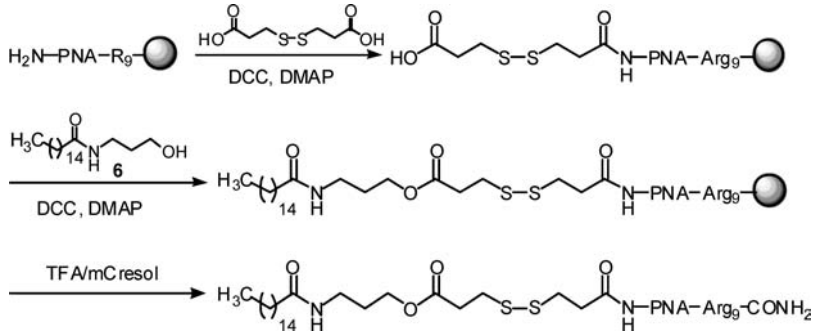
Building Block Synthesis. L-PNA-R9, **LSS-PNA-R9**, and **LP-PNA-R9** (Figure 1) were synthesized to study the effect of adding a lipid, a bioreductively cleavable lipid, and a phospholipid on the bioactivity of **PNA-R9**, a splice-correcting PNA linked to the well-studied cell penetrating peptide, D-Arg$_9$ (Figure 1) (*19, 31*). The unnatural D-enantiomer of arginine has been shown to affect membrane permeability in the same way as the L-enantiomer, and was used to minimize enzymatic degradation by proteases and increase the lifetime of the PNA construct (*32*). The PNAs were synthesized by a combination of standard solid-phase automated Fmoc peptide synthesis (*33*), and by on column and postsynthetic modification (*34*). The phosphotriester building blocks **3** and **4** were synthesized by treating *N*-methoxytrityl (Mmt) or *N*-Boc propanolamine with 2-cyanoethyl *N*,*N*-diisopropylchlorophosphoramidite in the presence of 1*H*-tetrazole, respectively. The resulting phosphites were then treated with the NHS ester of 12-hydroxydodecanoic acid in the presence of diisopropylammonium tetrazolide and oxidized with *tert*-butyl hydroperoxide, to give **3** and **4** in good yields (Scheme 1).

PNA-R9 was first synthesized in a 2 μmol scale by automated Fmoc PNA synthesis on an Fmoc-PAL-PEG-PS resin with Bhoc-protected monomers on ABI 8909 solid-phase PNA synthesis machine. The phosphate building block **3** was coupled to the amino terminus of the PNA on the resin and deprotected with 1% TFA in DCM to remove the Mmt protecting group. The resulting primary amine was coupled with succinimidyl palmitate, and the cyanoethyl protecting group was removed with pyridine/triethylamine. **LP-PNA-R9** was precipitated from cold ether after it was cleaved from the resin and deprotected with TFA/*m*-cresol (Scheme 2). It is worth noting that initial attempts to use Boc instead of Mmt as an amino-protecting ligand proved to be problematic because of competitive cleavage from the resin. Both 10% TFA/DCM and 10% v/v concentrated sulfuric acid/1,4-dioxane only gave the desired product in very low yields (*35*). It is likely that the TFA was not concentrated enough to efficiently deprotect Boc after treatment for 12 h, while the 10% sulfuric acid in 1,4-dioxane appeared to cause premature cleavage of PNA from the resin. **P-PNA-R9** (Figure

Scheme 2. Synthesis of Phospholipid PNA, LP-PNA-R9



Scheme 3. Synthesis of Lipid-Disulfide-PNA, LSS-PNA-R9



1) was prepared using the Boc-protected building block **4** and used for comparison to **LP-PNA-R9**, which has an additional lipid attached.

The disulfide-linked lipid−PNA **LSS-PNA-R9** (Figure 1) was designed and synthesized to compare the bioactivity of a bioreductively cleavable (*19, 36, 37*) lipid−PNA with that of **L-PNA-R9** and **LP-PNA-R9**. The synthesis was carried out on column by sequentially coupling with 3,3′-dithiodipropionic acid and then the building block **6** (Scheme 3).

MALDI-TOF Mass Spectrometry of the PNA Conjugates. In general, the standard MALDI matrix material, CHCA, gave good MALDI-TOF spectra for most PNAs. It was difficult, however, to get molecular ions for **LSS-PNA-R9** with CHCA. After an investigation of different matrices, the recently reported α-cyano-4-chloro-cinnamic acid (*38*) was found to be a good matrix for this PNA.

Luciferase Splice Correcting Bioactivity. The PNA sequence of **PNA-R9** corresponds to that of PNA-705, which has been used in a positive assay for the presence of intracellular, and more specifically, intranuclear PNA in a splice correction assay (*13, 39*). PNA-705 restores correct splicing of a luciferase transcript in HeLa pLuc cells by blocking splicesome assembly at the mis-splicing site, thereby resulting in functional luciferase and quantifiable light emission in the presence of luciferin. The bioactivity of 1 and 2 μM **PNA**, **PNA-R9**, **L-PNA-R9**, **P-PNA-R9**, and **LP-PNA-R9** was compared to that of 1 μM 2′-methoxy phosphorothioate ODN-705 transfected with Polyfect by incubating them with pLuc705 cells for 24 h and then assaying for luciferase activity (Figure 2). At 1 μM, **L-PNA-R9**, and **LP-PNA-R9** exhibit slightly higher bioactivity than **PNA-R9** and **P-PNA-R9**, but the difference in activity increased 7- and 10-fold respectively, when the concentrations were doubled to 2 μM.

To probe the mechanism of entry, we examined the effect of adding 100 μM chloroquine (CQ), which is known to enhance escape of PNA cell penetrating peptide conjugates from endosomes (*18, 20*). The concentration of chloroquine used is half that reported to result in an 18% loss in viability of HeLa cells and was therefore expected to have minimal toxicity (*40*). As expected for an endocytosis mechanism, CQ enhanced the bioactivity of 1 μM **PNA-Arg9** 10-fold and **L-PNA-R9** 7-fold, while the bioactivity of 1 μM **LP-PNA-R9** increased 33-fold (Figure 2). At 2 μM concentration, chloroquine increased their bioactivity about 7.4, 2.7, and 3.7 times, respectively. Furthermore, the relative bioactivity of the PNA derivatives in the presence of chloroquine increased for **PNA-R9**, **L-PNA-R9**, and **LP-PNA-R9** in the order 1:2.2:5.0 at 1 μM PNA and 1:2.3:4.5 at 2 μM PNA. The greater bioactivity of **LP-PNA-R9** suggested that more **LP-PNA-R9** had entered the endosomes and/or that it was better able to exit in the presence of chloroquine. One possibility is that the phosphate group is functioning as a recognition element for entry and/or is acting as cleavable linker to release it from the endosomal membrane. Addition of 100 μM sodium palmitate did not affect the amount of bioluminescence, suggesting that there were no palmitate-specific transporters involved in uptake of the lipid or phospholipid−PNAs.

Concentration Dependence of Splice-Correcting Bioactivity. We then examined the concentration dependence of the bioactivity of the various PNA conjugates over a larger concentration range. We found that **L-PNA-R9**, **LSS-PNA-R9**, and **LP-PNA-R9** had similar bioactivity that rapidly increased in the 1−3 μM range, in contrast to that of **PNA-R9** and **P-PNA-R9**, which had much lower activity and showed very little increase in this concentration range. The higher activity of the lipidated PNAs suggested that the lipid portion was aiding in binding to the cell membrane and/or facilitating endocytosis and endosomal release. When **LSS-PNA-R9** was preincubated with 10 mM DTT to precleave the disulfide bond, the bioactivity dropped more than 2-fold at 4 μM (data not shown), suggesting

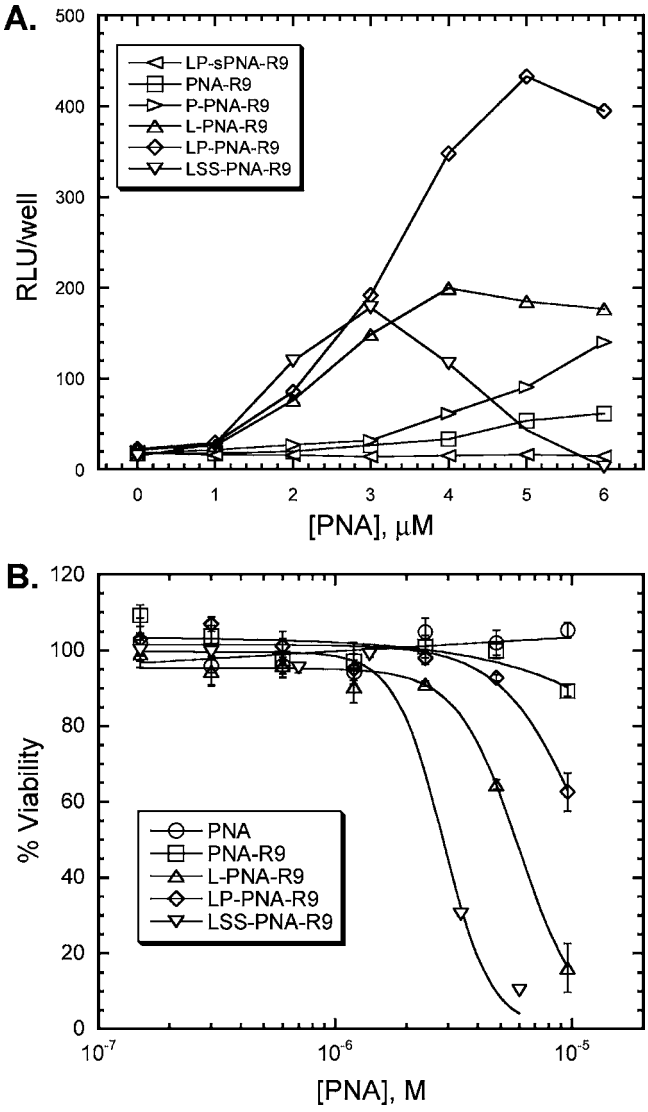


Figure 3. PNA concentration dependence of (a) splicing correction bioactivity and (b) cell viability as measured by the CellTiter-Blue cell viability assay and fit to a Hill-Slope model.

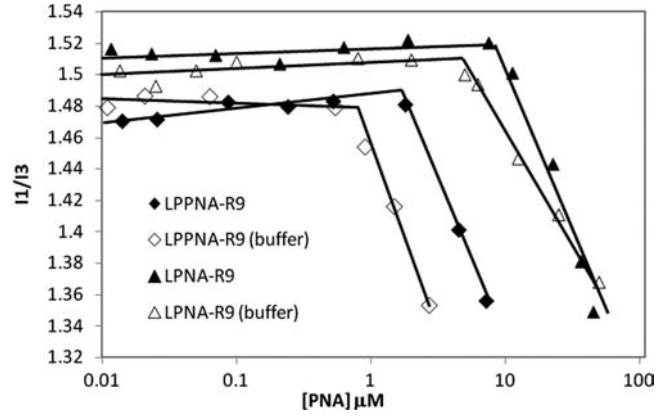

Figure 4. Determination of the critical micelle concentrations of **L-PNA-R9** and **LP-PNA-R9** (in water and in 150 mM NaCl, 5 mM Tris pH 7 buffer) from the break point in a bilinear plot of the ratio of the first (373 nm) and second (384 nm) emission bands of pyrene (I1/I3).

that the lipid chain did facilitate cellular uptake. The lower than expected decrease in activity might be the result of incomplete cleavage or some sort of thiol-facilitated entry mechanism. The similar activity of **L-PNA-R9**, **LP-PNA-R9**, and **LSS-PNA-R9**, which all had different linkers between the lipid and the PNA, at 1−3 μM suggested that the cleavability of the linker was not an important contributor to the bioactivity in this concentration range.

On increasing the concentration from 3 to 5 μM, the bioactivity of **LP-PNA-R9** increased more than 2-fold, while that of **L-PNA-R9** leveled off, and **LSS-PNA-R9** decreased dramatically (Figure 3a). In contrast, the bioactivities of **PNA-R9** and **P-PNA-R9** remained essentially the same from 1−3 μM and then increased with concentration from 4−6 μM. Interestingly, **P-PNA-R9** reached almost the same level of activity at 6 μM that was observed for **LP-**, **L-**, and **LSS-PNA**s at 3 μM and was almost 2-fold higher than PNA-R9 at 6 μM. It may be that the undecane linker between the PNA and the phosphodiester group imparts a sufficient amount of lipophilicity to enhance endocytosis. The scrambled **LP-sPNA-R9** did not show any significant bioactivity at any concentration, demonstrating that the observed bioluminescence was PNA sequence-specific and not related to other features of the constructs.

Cytotoxicity of the PNAs. The leveling off and decrease in bioactivity of some of the PNA constructs with increasing concentration suggested that they might have different cytotoxicities at higher concentrations. In accord with this idea, **L-PNA-R9** and **LSS-PNA-R9** showed the greatest cytotoxicity resulting in a 90% loss of viability at 9.6 μM and 6 μM, respectively, while **LP-PNA-R9** at 9.6 μM resulted in only a 33% loss (Figure 3b). From curve fitting, the LC50 values for **LSS-PNA-R9**, **L-PNA-R9**, and **LP-PNA-R9** were estimated to be 2.9 $\pm$ 0.2, 6 $\pm$ 0.2, and 11.7 $\pm$ 1.2 μM, respectively. **PNA** and **PNA-R9** were the least cytotoxic at 9.6 μM, resulting in zero and 10% loss in viability, respectively. The higher cytotoxicity of **L-PNA-R9** compared to **PNA-R9** might be due to its ability to anchor to the membrane, which might then disrupt membrane function at higher concentrations. The lower cytotoxicity of the **LP-PNA-R9** compared to **L-PNA-R9** might then be explained by enzymatic hydrolysis of the phosphodiester group of **LP-PNA-R9**, which would release the **PNA-R9** from the membrane. While **LSS-PNA-R9** should also be cleaved, at least internally, it is much more cytotoxic, possibly because it can undergo disulfide exchange with membrane proteins and interfere with their function, or because of some other toxic effect of the thiolipid.

Micelle Formation. Because the lipidated PNAs have hydrophobic tails and charged head groups and are therefore amphiphilic, it seemed likely that they would form micelles, which might explain their better uptake into cells through endocytosis or membrane fusion (*41*). Alternatively, micelle formation might reduce the cytotoxicity of lipids at higher concentrations by sequestering them. By using a pyrene-based fluorescence assay (Figure 4) (*42*), we determined that **LP-PNA-R9** has a critical micelle concentration (CMC) of 1.7 μM in water, while **L-PNA-R9** has a CMC of 9.2 μM. Because the positively charged Arg9 groups would be expected to repel each other in a micelle, we expected that CMC would be lower in the presence of salt. Indeed, addition of 150 mM NaCl in 5 mM Tris pH 7 caused the CMC of **L-PNA-R9** to drop to 4.5 μM and that of **LP-PNA-R9** to decrease to 1.0 μM. Though the CMCs are in the range in which **L-PNA-R9** and **LP-PNA-R9** show bioactivity, they do not correlate directly with the bioactivity or the cytotoxicity. We have yet to determine the role of micelle formation in facilitating cell uptake of the lipidated PNAs or their

cytotoxicity, though it appears that the spherical shape of a micelle may be optimal for macropinocytosis (*43*, *44*).

CONCLUSION

In conclusion, we find that conjugating a phospholipid to a luciferase splice-correcting PNA increases its bioactivity more than does a lipid or disulfide-linked lipid in the 4−6 μM range. Part of the higher bioactivity of the phospholipid PNA in this concentration range can be ascribed to its lower cytotoxicity, possibly because the lipid tail can be removed by enzymatic phosphodiester hydrolysis to yield less toxic products. We also find that lipidated PNAs form micelles which may also play a role in facilitating cell entry and/or lowering cytotoxicity, suggesting that altering the lipid portion to change the size, shape, and stability of the micellular form might lead to better and less toxic cell-penetrating PNAs. Further studies are in progress to study this novel PNA delivery system.

ACKNOWLEDGMENT

This work was supported in part by the National Heart Lung and Blood Institute of the National Institutes of Health as a Program of Excellence in Nanotechnology (NHLBI-PEN HL080729) and by NIH PO1 CA 104457. Received March 19, 2009; Revised Manuscript Received July 7, 2009

In this paper, we report the synthesis and biological activity of a series of dihydroisocoumarin analogues conjugated with fatty acids, alcohols, or amines, of varying hydrocarbon chain length and degree of unsaturation, to the dihydroisocoumarins, kigelin and mellein, at the C-7 and C-8 positions on the core dihydroisocoumarin structure. These compounds were evaluated for their antiproliferative activity against human breast cancer (MCF-7 and MDA-MB-468) and melanoma cells (SK-MEL-28 and Malme-3M) using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) assay. Two compounds conjugated with γ-linolenyl alcohol (18:3 n-6) demonstrated potent antiproliferative activity in vitro with one of these 4-hydroxy-3-oxo-1,3-dihydro-isobenzofuran-5-carboxylic acid octadeca-6,9,12-trienyl ester, demonstrating significant antitumor activity in vivo in a number of human tumor xenograft models.

INTRODUCTION

Isocoumarins represent an important class of naturally occurring lactones, isolated from a diverse range of natural organisms, including fungi, plants, and insects, that display a wide range of biological activities (*1*−*8*). Isocoumarins can be classified as secondary metabolites structurally related to coumarins but with an inverted lactone ring, and it is anticipated that substituents to the basic isocoumarin skeleton may influence their biological activity. Reported activities include protease inhibitory properties, antifungal, cytotoxic, antimicrobial, antiallergic, and antimalarial effects (*9*−*11*). Dihydroisocoumarins, lacking the double bond between the 3- and 4-positions present on the isocoumarin structure, have also been previously isolated in a limited number of studies. Dihydroisocoumarins in themselves are an important class of naturally occurring biologically active lactones, originating from a variety of natural sources, with multiple biological activities described ranging from antibacterial, antimalarial, antifungal, and anticancer activity in addition to their use as sweetening agents (*12*−*15*).

We previously identified the dihydroisocoumarins, kigelin and demethylkigelin, in extracts of the fruits of *Kigelia pinnata*, which in part accounted for some of the observed antiproliferative activity of extracted material from this tree against human cancer cells in vitro (*16*). Synthetic versions of the active isolated dihydroisocoumarin compounds failed to demonstrate the same degree of antiproliferative activity as their extracted counterparts. The presence of trace amounts of several fatty acids was noted in extracted material from the plant, suggesting that these minor contaminants may be acting in synergy with other components of the fruit extracts. Accordingly, such an interaction would explain the difference in biological activity observed between the extracted and synthesized compounds.

Several polyunsaturated fatty acids (PUFAs) containing 18 or more carbons are known. PUFAs have exhibited in vitro direct anticancer activity against numerous cancer cell lines, and their antitumor activity has been evaluated in preclinical and clinical studies (*17*−*22*). It is known that PUFAs are taken up avidly by tumor cells presumably for use as biochemical precursors and energy sources. In addition, PUFAs are known to be readily incorporated into lipid bilayers of cells, which can result in the disruption of both membrane structure and fluidity, factors which have been suggested to increase intracellular drug accumulation (*23*−*25*). All these factors strongly suggest the benefit of PUFAs in specifically targeting drugs to the tumor cells. Importantly, a number of PUFAs have been shown to selectively inhibit tumor cell proliferation and are significantly less toxic to normal cells (*26*). Several mechanisms of action have been proposed to account for the anticancer activity of PUFAs including alteration in gene expression, modulation of cellular proliferation, differentiation and apoptosis, increase in drug transport across the cell membrane, generation of free oxygen radicals, and lipid peroxidation (*27*).

One way to improve upon the therapeutic index of chemotherapy drugs is conjugation to fatty acids (*28*). Chemotherapy drugs conjugated to fatty acids have been shown to enhance tumor targeting and deliver prodrugs for intratumoral activation. Taxoprexin, a novel synthetic small molecule linking paclitaxel to the fatty acid docosahexaenoic (DHA) acid, demonstrated significantly enhanced tumor distribution and antitumor activity in various tumor models as compared with paclitaxel alone after equitoxic or equimolar doses (*29, 30*). In a lung cancer mouse model and in preclinical human studies, treatment with DHA−paclitaxel demonstrated better pharmacokinetic properties and a more favorable toxicity profile than that seen with

paclitaxel alone. In a number of preclinical models, data indicate that such conjugates are preferentially taken up by tumor cells compared to normal cells (*29*). A number of studies have also demonstrated an enhanced anticancer activity when PUFAs are given with conventional chemotherapeutic agents (*31*). Specific long-chain omega-3 PUFAs have been shown to enhance the cytotoxicity of paclitaxel, doxorubicin, and cyclophosphamide in cancer cells in vitro (*32, 33*). In addition, lipid aminoalcohols and diamines have been reported in the literature to have several biological activities including their anti-inflammatory activities and their cytotoxicity toward neoplastic cells (*34*−*36*).

Initially, we evaluated the biological activity of a number of fatty acids in combination with kigelin, a dihydroisocoumarin compound we had previously isolated from fruit extracts of *K. pinnata*. We previously noted that simple modifications to the dihydroisocoumarin core structure could alter the biological activity of this class of compounds and significantly enhance the antiproliferative activity observed (*16*). As a result, a synthetic chemistry program was undertaken to further study the structure−activity relationship (SAR) of this class of compounds. In this paper, we report the synthesis and biological activity of a series of dihydroisocoumarin analogues conjugated with fatty acids, alcohols, or amines, of varying hydrocarbon chain length and degree of unsaturation, to the dihydroisocoumarins, kigelin and mellein, at the C-7 and C-8 positions on the core dihydroisocoumarin structure. The antiproliferative activity of these compounds was assessed by MTT assay in two breast cancer cell lines, MCF-7 and MDA-MB-468, and two melanoma cell lines, SK-MEL-28 and Malme-3M. Further in vitro and in vivo activity of a highly active compound, 4-hydroxy-3-oxo-1,3-dihydro-isobenzofuran-5-carboxylic acid octadeca-6,9,12-trienyl ester **36** identified in the initial MTT screen, is also reported.

EXPERIMENTAL PROCEDURES

Materials and Instrumentation. UV spectra were recorded on two HPLC systems. System 1: Waters 2690, photodiode array detector (PDA) 996. System 2: Waters 2695, PDA 2996. IR spectra were recorded on a Perkin-Elmer FT-IR spectrometer SN, 50267; PO, 1118−5248. ^{1}H NMR (400 MHz) and ^{13}C NMR (100 MHz) were recorded on a Bruker 400 MHz Avance NMR spectrometer equipment (ID: BZH 299/400/70F D207/54−3914) (the chemical shifts are reported as ppm (δ) relative to TMS as internal standard). Mass spectra were obtained with a Finnigan LCQ DUO SN LDU 00253 mass spectrometer. In chromatographic fractionations, thin layer chromatographs (TLC) were run on silica gel 60F254 aluminum sheets (Merck). The reagent used for visualization was a solution of 10% phosphomolybdic acid in ethanol. For column chromatography, silica gel (Davisil grade 633, particle size 35−75 μM and/or Merck grade 9385, particle size 40−63 μM)) was used. All starting materials were commercially available. Solvents and reagents were used without further purification. γ-Linolenic acid (GLA; 18:3 n-6), oleic acid (OA; 18:1 n-9), linoleic acid (LA; 18:2 n-6), α-linolenic acid (ALA; 18:3 n-3), and docosahexanoic acid (DHA; 22:6 n-3) were purchased from Sigma Chemical.

Synthesis of Fatty Acid Conjugates at the C-8 Position of Racemic Kigelin (2−5) (Scheme 1). Under nitrogen atmosphere, the corresponding acid (100 mg; 1 equiv) was charged and dissolved in dichloromethane (4 mL) (for C21, a mixture of DCM/THF 1/1 was used as a solvent due to poor solubility of the acid in DCM only). To this solution were added dicyclohexyl carbodiimide (DCC; 1 equiv) and 4-*N*,*N*′-dimethylaminopyridine (DMAP; 1 equiv). The reaction mixture was cooled to 0 °C. Kigelin **1** (1 equiv) was added, and the reaction mixture stirred for 2 h at 0 °C. The precipitated dicyclohexyl urea was filtered, and the solvent was removed under reduced pressure. The residue was purified by column chromatography using hexane/ether (70/30) as eluent. The concentration of the appropriate fractions gave an oily residue, which was taken up in diethyl ether and washed 2−3 times with aqueous NaOH (2 M; 25 mL portions) to remove unreacted starting materials. The organic phase was separated, dried over magnesium sulfate, and the solvent concentrated under reduced pressure to give the fatty acid esters of (±)-kigelin.

Yield = 80 mg (45%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 6.54 (1H, s, ArH), 5.27 (2H, t, *J* 4.6 Hz, CH═CH), 4.50 (1H, m, CH−CH_3 lactone), 3.85 (3H, s, OCH_3), 3.73 (3H, s, OCH_3), 2.77 (2H, m, CH_2), 2.62 (2H, t, *J* 7.6 Hz, CH_2−CO), 1.95 (4H, d, br, CH_2), 1.72 (2H, m, CH_2), 1.38 (3H, d, *J* 6.3 Hz, CH_3 on lactone ring), 1.26−1.19 (20H, m, CH_2 acid), 0.80 (3H, t, *J* 6.8 Hz, CH_3 acid).^{13}C NMR ($CDCl_3$, 100 MHz): 171.9, 161.9, 157.5, 146.1, 141.3, 136.8, 129.9, 129.8, 111.1, 107.8, 74.2, 61.1, 56.2, 35.6, 34.7, 31.9, 30.3, 29.8, 29.7, 29.5, 29.3 (2 × C), 29.3, 29.2, 29.1, 27.2, 24.6, 22.7, 20.7, 14.1.

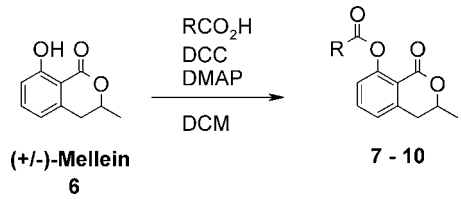
Racemic Kigelin Linoleyl Ester (3). Racemic kigelin linoleyl ester (**3**) was prepared from (±)-kigelin **1** and linoleic acid. Yield = 55 mg (31%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 6.54 (1H, s, ArH), 5.34 (4H, m, CH═CH), 4.57 (1H, m, CH−CH_3 lactone), 3.92 (3H, s, OCH_3), 3.80 (3H, s, OCH_3), 2.86 (2H, m, CH_2), 2.77 (2H, t, *J* 6.4 Hz, CH_2), 2.68 (2H, t, *J* 7.6 Hz, CH_2−CO), 2.05 (4H, m, CH_2), 1.77 (2H, m, CH_2), 1.41 (3H, d, *J* 6.3 Hz CH_3 on lactone ring), 1.34−1.27 (14H, m, CH_2 acid), 0.87 (3H, t, *J* 6.8 Hz, CH_3 acid).

Racemic Kigelin α-Linolenyl Ester (4). Racemic kigelin **1** α-linolenyl ester (**4**) was prepared from (±)-kigelin and α-linolenic acid. Yield = 68 mg (38%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 6.61 (1H, s, ArH), 5.38 (6H, m, 3 × CH═CH), 4.60 (1H, m, CH−CH_3 lactone), 3.92 (3H, s, OCH_3), 3.81 (3H, s, OCH_3), 2.84 (2H, m, CH_2), 2.81 (2H, t, *J* 6.4 Hz, CH_2), 2.69 (2H, t, *J* 7.6 Hz, CH_2−CO), 2.10 (4H, m, CH_2), 1.80 (2H, m, CH_2), 1.45 (3H, d, *J* 6.3 Hz, CH_3 on lactone ring), 1.36 (10H, m, CH_2 acid), 0.98 (3H, t, *J* 6.8 Hz, CH_3 acid). ^{13}C NMR ($CDCl_3$, 100 MHz) 171.9, 161.9, 157.5, 146.1, 141.3, 136.8, 131.9, 130.3, 128.3, 128.3, 127.7, 127.1, 111.1, 107.8, 102.0, 71.2, 61.1, 56.2, 35.6, 34.1, 29.6, 29.2, 29.1, 27.0, 25.6, 25.5, 24.6, 20.7, 20.5, 14.3.

Racemic Kigelin γ-Linolenyl Ester (5). Racemic kigelin **1** γ-linolenyl ester (**5**) was prepared from (±)-kigelin and γ-linolenic acid. Yield = 29 mg (16%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 6.61 (1H, s, ArH), 5.43−5.32 (6H, m, 3 × CH═CH), 4.60 (1H, m, CH−CH_3 lactone), 3.93 (3H, s, OCH_3), 3.81 (3H, s, OCH_3), 2.84 (4H, m, CH_2), 2.71 (2H, t, *J* 6.4 Hz, CH_2−CO), 2.14 (2H, m, CH_2), 2.05 (2H, m, CH_2), 1.82 (2H, m, CH_2), 1.53 (2H, m, CH_2), 1.46 (3H, d, *J* 6.3 Hz, CH_3 on lactone ring), 1.38−1.25 (8H, m, CH_2 acid), 0.88 (3H, t, *J* 6.8 Hz CH_3 acid).

Synthesis of Fatty Acid Conjugates at C-8 Position of Racemic Mellein (7−10) (Scheme 2). Under nitrogen atmosphere, the corresponding acid (100 mg; 1 equiv) was charged and dissolved in dichloromethane (4 mL) (for C21 a mixture of DCM/THF 1/1 was used as a solvent due to poor solubility of the acid in DCM only). To this solution were added

Scheme 2. Synthesis of Fatty Acid Esters of Racemic Mellein (7−10)



dicyclohexyl carbodiimide (DCC; 1 equiv) and 4-*N*,*N*′-dimethylaminopyridine (DMAP; 1 equiv). The reaction mixture was cooled to 0 °C. Mellein **6** (1 equiv) was added and the reaction mixture stirred for 2 h at 0 °C. The precipitated dicyclohexyl urea was filtered and the solvent was removed under reduced pressure. The residue was purified by column chromatography using hexane/ether (90/10) as eluent. The concentration of the appropriate fractions gave an oily residue, which was taken up in diethyl ether and washed 2−3 times with aqueous NaOH (2 M; 25 mL portions) to remove unreacted starting materials. The organic phase was separated, dried over magnesium sulfate, and the solvent concentrated under reduced pressure to give the fatty acid esters of (±)-mellein.

Racemic Mellein Oleyl Ester (7). Racemic mellein oleyl ester (**7**) was prepared from (±)-mellein **6** and oleic acid. Yield = 50 mg (40%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.51 (1H, t, *J* 7.9 Hz, ArH), 7.12 (1H, d, *J* 7.6 Hz ArH), 7.03 (1H, d, *J* 7.9 Hz, ArH), 5.36 (2H, t, *J* 4.6 Hz, CH═CH), 4.63 (1H, m, CH−CH_3 lactone), 2.93 (2H, m, CH_2 lactone), 2.64 (2H, t, *J* 7.6 Hz, CH_2−CO), 2.02 (4H, m, CH_2), 1.76 (2H, m, CH_2), 1.48 (3H, d, *J* 6.3 Hz, CH_3 on lactone ring), 1.44−1.27 (20H, m, CH_2 acid), 0.88 (3H, t, *J* 6.9 Hz, CH_3 acid). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 172.4, 162.1, 152.0, 141.2, 134.2, 129.7, 129.8, 125.0, 122.9, 118.0, 77.2, 74.6, 35.4, 34.2, 31.9, 29.8, 29.7, 29.5, 29.3, 29.2, 29.1, 27.2, 27.2, 24.4, 22.7, 20.6, 14.1.

Racemic Mellein Linoleyl Ester (8). Racemic mellein linoleyl ester (**8**) was prepared from (±)-mellein **6** and linoleic acid. Yield = 102 mg (65%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.51 (1H, t, *J* 7.8 Hz, ArH), 7.11 (1H, d, *J* 7.6 Hz, ArH), 7.02 (1H, d, *J* 8.1 Hz, ArH), 5.36 (4H, m, 2 × CH═CH), 4.62 (1H, m, CH−CH_3 lactone), 2.92 (2H, m, CH_2 lactone), 2.78 (2H, t, *J* 6.3 Hz, CH_2), 2.65 (2H, t, *J* 7.6 Hz, CH_2−CO), 2.05 (4H, m, CH_2−CH═CH), 1.78 (2H, m, CH_2), 1.47 (3H, d, *J* 6.3 Hz, CH_3 on lactone ring), 1.35−1.24 (14H, m, CH_2 acid), 0.89 (3H, t, *J* 6.8 Hz, CH_3 acid). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 172.4, 162.1, 151.9, 141.2, 134.2, 130.2, 130.1, 128.0, 127.9, 125.0, 122.9, 118.0, 74.6, 35.4, 34.2, 32.8, 31.5, 29.6, 29.3, 29.2, 29.1, 27.2, 27.2, 25.6, 24.4, 22.6, 20.6, 14.1.

Racemic Mellein α-Linolenyl Ester (9). Racemic mellein α-linolenyl ester (**9**) was prepared from (±)-mellein **6** and α-linolenic acid. Yield = 88 mg (56%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.51 (1H, t, *J* 7.8 Hz, ArH), 7.11 (1H, d, *J* 7.6 Hz, ArH), 7.02 (1H, d, *J* 8.0 Hz, ArH), 5.35 (6H, m, 3 × CH═CH), 4.62 (1H, m, CH−CH_3 lactone), 2.92 (2H, d, *J* 7.0 Hz, CH_2 lactone), 2.81 (2H, t, *J* 5.9 Hz, CH_2), 2.65 (2H, t, *J* 7.6 Hz CH_2−CO), 2.06 (4H, m, CH_2), 1.75 (2H, m, CH_2), 1.47 (3H, d, *J* 6.3 Hz, CH_3 on lactone ring), 1.44−1.32 (10H, m, CH_2 acid), 0.97 (3H, t, *J* 7.5 Hz, CH_3 acid). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 172.4, 162.1, 151.9, 141.2, 134.2, 131.9, 130.3, 128.3, 128.3, 127.7, 127.1, 125.0, 122.9, 118.0, 74.6, 35.4, 34.2, 29.6, 29.2, 29.1, 29.1, 27.2, 25.6, 25.5, 25.4, 24.4, 20.6, 14.3.

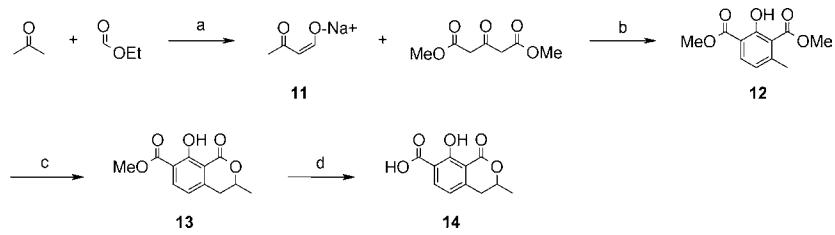
Racemic Mellein γ-Linolenyl Ester (10). Racemic mellein γ-linolenyl ester (**10**) was prepared from (±)-mellein **6** and γ-linolenic acid. Yield = 79 mg (50%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.51 (1H, t, *J* 7.9 Hz, ArH), 7.12 (1H, d, *J* 7.6 Hz, ArH), 7.02 (1H, d, *J* 8.0 Hz, ArH), 5.45−5.31(6H, m, 3 × CH═CH), 4.62 (1H, m, CH−CH_3 lactone), 2.93 (2H, d, *J* 6.8 Hz, CH_2 lactone), 2.82 (4H, m, CH_2), 2.67 (2H, t, *J* 7.5 Hz, CH_2−CO), 2.13 (2H, q, *J* 7.0 Hz, CH_2), 2.06 (2H, q, *J* 6.9 Hz, CH_2), 1.82 (2H, m, CH_2), 1.53 (2H, m, CH_2), 1.47 (3H, d, *J* 6.3 Hz, CH_3 on lactone ring), 1.39−1.25 (6H, m, CH_2 acid), 0.90 (3H, t, *J* 7.1 Hz, CH_3 acid). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 172.2, 162.1, 151.9, 141.2, 134.2, 130.4, 129.7, 128.4, 128.2, 127.6, 125.0, 122.9, 117.9, 74.6, 35.4, 34.1, 31.5, 29.3, 29.3, 29.1, 27.2, 26.9, 25.8 (2 × C), 22.6, 20.6, 14.1.

Preparation of 8-Hydroxy-3-methyl-1-oxo-isochroman-7-carboxylic Acid (14) (Scheme 3): Dimethyl 2-Hydroxy-4-methylbenzene-1,3-dicarboxylate (12). To a suspension of sodium methoxide (26.0 g, 0.48 mol, 1.12 equiv) in anhydrous THF (250 mL) under nitrogen at 0 °C was added dropwise a solution of ethyl formate (31.89 g, 0.43 mol, 1.0 equiv) and acetone (25.00 g, 0.43 mol, 1.0 equiv), maintaining the temperature at <5 °C. The reaction was stirred at 0 °C for 15 min then warmed to ambient temperature, at which it was then stirred for 15 min. The reaction was evaporated to dryness, to afford crude sodium formyl acetone **11**, which was dissolved in methanol (500 mL) under nitrogen. Dimethyl 1,3-acetonedicarboxylate (71.21 g, 0.41 mol, 0.95 equiv) was added dropwise, maintaining the temperature at <25 °C. The reaction mixture was stirred for 16 h at room temperature. The reaction was concentrated to dryness. The residue was diluted with 2 M HCl and extracted into ethyl acetate. The combined organic extracts were washed with saturated brine, dried over $MgSO_4$, filtered, and concentrated in vacuo. Purification by vacuum distillation (∼0.1 mbar, bp ∼115−120 °C) afforded dimethyl 2-hydroxy-4-methylbenzene-1,3-dicarboxylate **12** as a pale yellow oil, which solidified upon standing. Yield = 21.76 g (24%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.74 (1H, d, *J* 8.2 Hz, ArH), 6.72 (1H, d, *J* 8.2 Hz, ArH), 3.94 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 2.33 (3H, s, CH_3).

8-Hydroxy-3-methyl-1-oxo-isochroman-7-carboxylic Acid Methyl Ester (13). To a solution of LDA (54.5 mL, 1.8 M solution, 98.1 mmol, 2.2 equiv) in anhydrous THF (180 mL) under nitrogen cooled to −78 °C was added dropwise a solution of dimethyl 2-hydroxy-4-methylbenzene-1,3-dicarboxylate **12** (10.00 g, 44.6 mmol, 1 equiv) in anhydrous THF (20 mL) at −78 °C. After stirring for 20 min, acetaldehyde (6.12 g, 139.0 mmol, 3.1 equiv) was added dropwise at −78 °C. The reaction was stirred at −78 °C for 30 min, then warmed to 0 °C, and then stirred for 45 min. The reaction was quenched at 0 °C by the addition of acetic acid (5.15 mL) and then warmed to ambient temperature. The reaction was diluted with 2 M HCl and extracted into ethyl acetate. The combined organic extracts were washed with brine, dried over $MgSO_4$, filtered, and concentrated in vacuo. The residue was recrystallized from hexane/ethyl acetate to afford 8-hydroxy-3-methyl-1-oxo-isochroman-7-carboxylic acid methyl ester **13** as a beige solid. Yield = 5.12 g (49%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.04 (1H, d, *J* 7.9 Hz, ArH), 6.76 (1H, d, *J* 7.9 Hz, ArH), 4.72 (1H, m, OCH), 3.94 (3H, s, OCH_3), 2.97 (2H, d, *J* 7.2 Hz, CH_2), 1.54 (3H, d, *J* 6.3 Hz, CH_3); ESIMS *m*/*z* (M−1) = 235.

8-Hydroxy-3-methyl-1-oxo-isochroman-7-carboxylic Acid (14). To a suspension of 8-hydroxy-3-methyl-1-oxo-isochroman-7-carboxylic acid methyl ester **13** (4.75 g, 20.1 mmol, 1 equiv) in ethanol (75 mL) was added 10 w/v % sodium hydroxide aqueous solution (15 mL, 37.5 mmol, 1.9 equiv). The mixture was refluxed for 1 h and then cooled to ambient temperature. The reaction mixture was concentrated in vacuo. The residue was diluted with water and washed with ethyl acetate. The organic layer was discarded. The aqueous layer was adjusted to pH 1 with 2 M HCl, saturated with NaCl, and extracted with ethyl acetate. The combined organic extracts were dried over $MgSO_4$, filtered, and concentrated in vacuo. The solid was slurried in methanol to afford 8-hydroxy-3-methyl-1-oxo-

Scheme 3. Synthesis of 13 and 14[a]



[a] Reagents and Conditions: (a) NaOMe, Et_2O; (b) MeOH; (c) acetaldehyde, LDA, THF; (d) NaOH, EtOH.

Scheme 4. Synthesis of Fatty Alcohol Conjugates at C-7 Position

isochroman-7-carboxylic acid **14** as an off-white solid. Yield = 3.46 g (77%). ^{1}H NMR (MeOD, 400 MHz) δ 7.97 (1H, d, *J* 8.0 Hz, ArH), 6.89 (1H, d, *J* 8.0 Hz, ArH), 4.72 (1H, m, OCH), 2.91 (2H, m, CH_2), 1.40 (3H, d, *J* 6.3 Hz, CH_3). ^{13}C NMR (MeOD, 100 MHz) δ 168.8, 165.4, 161.8, 146.7, 136.5, 117.8, 115.7, 110.8, 74.8, 34.4, 20.2. ESIMS *m/z* (M+1) = 223.

Synthesis of Ester Linked Fatty Alcohol Conjugates at C-7 Position of Racemic Mellein (15−24) (Scheme 4). To the reaction vessel were charged 8-hydroxy-3-methyl-1-oxo-isochroman-7-carboxylic acid **14** (250 mg, 1.13 mmol, 1.0 equiv), the alcohol (1.0 equiv), DMAP (151 mg, 1.24 mmol, 1.1 equiv), and anhydrous DCM (10 mL) under nitrogen. To this was added DCC (255 mg, 1.24 mmol, 1.1 equiv), and the reaction mixture was stirred at room temperature overnight. The mixture was filtered through Celite and the filtrate concentrated in vacuo. The crude material was purified by column chromatography using hexane/EtOAc to afford pure 8-hydroxy-3-methyl-1-oxo-isochroman-7-carboxylic acid ester.

Ochratoxin Acid Hexyl Ester (15). Yield = 100 mg (41%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 8.3 Hz, ArH), 6.75 (1H, d, *J* 8.3 Hz, ArH), 4.71 (1H, m, CH), 4.34 (2H, t, *J* 6.7 Hz, CH_2), 2.96 (2H, d, *J* 7.2 Hz, CH_2), 1.77 (2H, q, *J* 7.1 Hz, CH_2), 1.53 (3H, d, *J* 6.3 Hz, CH_3), 1.44 (2H, m, CH_2), 1.34 (4H, m, CH_2), 0.89 (3H, t, *J* 6.3 Hz, CH_3). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 167.7, 166.2, 162.7, 145.2, 137.6, 117.4, 117.2, 110.3, 75.3, 65.6, 35.2, 31.4, 28.6, 25.6, 22.5, 20.7, 14.0. ESIMS *m/z* (M+1) = 307.

Ochratoxin Acid Dodecyl Ester (16). Yield = 300 mg (68%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 7.9 Hz, ArH), 6.74 (1H, d, *J* 7.9 Hz, ArH), 4.71 (1H, m, CH), 4.33 (2H, t, *J* 6.7 Hz, CH_2), 2.96 (2H, d, *J* 7.2 Hz, CH_2), 1.77 (2H, m, CH_2), 1.53 (3H, d, *J* 6.3 Hz, CH_3), 1.44 (1H, m, CH), 1.32 (17H, m, br), 0.88 (3H, t, *J* 6.8 Hz, CH_3). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 167.7, 166.2, 162.7, 145.2, 137.6, 117.4, 117.1, 110.3, 75.3, 65.6, 35.2, 31.9, 29.6, 29.6, 29.6, 29.5, 29.3, 29.3, 28.6, 25.9, 22.7, 20.6, 14.1. ESIMS *m/z* (M+1) = 391.

Ochratoxin Acid Oleyl Ester (17). Ochratoxin Yield = 319 mg (60%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 7.9 Hz, ArH), 6.74 (1H, d, *J* 7.9 Hz, ArH), 5.34 (2H, m, CH=CH), 4.71 (1H, m, CH), 4.33 (2H, t, *J* 6.7 Hz, CH_2), 2.96 (2H, d, *J* 7.0 Hz, CH_2), 2.02 (4H, m, CH_2), 1.76 (2H, m, CH_2), 1.53 (3H, d, *J* 6.4 Hz, CH_3), 1.47−1.22 (22H, m, 11 × CH_2), 0.88 (3H, t, *J* 6.9 Hz, CH_3). ESIMS *m/z* (M+1) = 473.

Ochratoxin Acid Linoleyl Ester (18). Yield = 191 mg (60%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 7.9 Hz, ArH), 6.74 (1H, d, *J* 7.9 Hz, ArH), 5.36 (4H, m, 2 × CH=CH), 4.71 (1H, m, CH), 4.33 (2H, t, *J* 6.7 Hz, CH_2), 2.96 (2H, d, *J* 7.2 Hz, CH_2), 2.77 (2H, t, *J* 6.5 Hz, CH_2), 2.05 (4H, m, CH_2), 1.76 (2H, m, CH_2), 1.53 (3H, d, *J* 6.3 Hz, CH_3), 1.49−1.25 (16H, m, 8 × CH_2), 0.88 (3H, t, *J* 6.9 Hz, CH_3). ESIMS *m/z* (M+1) = 471.6.

Ochratoxin Acid Eicosadienyl Ester (19). Yield = 225 mg (67%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 7.9 Hz, ArH), 6.74 (1H, d, *J* 7.9 Hz, ArH), 5.35 (4H, m, 2 × CH=CH), 4.70 (1H, q, *J* 6.4 Hz, CH), 4.33 (2H, t, *J* 6.7 Hz, CH_2), 2.96 (2H, d, *J* 7.1 Hz, CH_2), 2.77 (2H, t, *J* 6.5 Hz, CH_2), 2.05 (4H, m, CH_2), 1.76 (2H, m, CH_2), 1.53 (3H, d, *J* 6.3 Hz, $CHCH_3$), 1.47−1.24 (20H, m, 10 × CH_2), 0.89 (3H, t, *J* 6.9 Hz, CH_3). ESIMS *m/z* (M+1) = 500.2.

Ochratoxin Acid γ-Linolenyl Ester (20). Yield = 70 mg (40%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 7.9 Hz, ArH), 6.74 (1H, d, *J* 7.9 Hz, ArH), 5.36 (6H, m, 3 × CH=CH), 4.71 (1H, m, CH), 4.34 (2H, t, *J* 6.7 Hz, CH_2), 2.96 (2H, d, *J* 7.1 Hz, CH_2), 2.81 (4H, m, CH_2), 2.08 (4H, m, CH_2), 1.76 (2H, m, CH_2), 1.55 (3H, d, *J* 6.3 Hz CH_3), 1.49−1.25 (10H, m, 5 × CH_2), 0.88 (3H, t, *J* 6.3 Hz, CH_3).

Ochratoxin Acid α-Linolenyl Ester (21). Yield = 183 mg (58%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 7.9 Hz, ArH), 6.74 (1H, d, *J* 7.9 Hz, ArH), 5.35 (6H, m, 3 × CH=CH), 4.70 (1H, q, *J* 6.8 Hz, CH), 4.33 (2H, t, *J* 6.7 Hz, CH_2), 2.96 (2H, d, *J* 7.2 Hz, CH_2), 2.80 (4H, t, *J* 6.0 Hz, CH_2), 2.07 (4H, m, CH_2), 1.77 (2H, q, *J* 7.1 Hz, CH_2), 1.55 (3H, d, *J* 6.3 Hz, $CHCH_3$), 1.54−1.33 (10H, m, 5 × CH_2), 0.97 (3H, t, *J* 6.3 Hz, CH_3). ESIMS *m/z* (M+1) = 469.6.

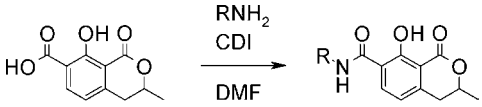
Ochratoxin Acid Docosatetraenyl Ester (22). Yield = 75 mg (46%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 7.9 Hz, ArH), 6.74 (1H, d, *J* 7.9 Hz, ArH), 5.40 (8H, m, 4 × CH=CH), 4.70 (1H, m, CH), 4.33 (2H, t, *J* 6.7 Hz, CH_2), 2.96 (2H, d, *J* 7.1 Hz, CH_2), 2.82 (4H, m, CH_2), 2.06 (4H, m, CH_2), 1.76 (2H, m, CH_2), 1.53 (3H, d, *J* 6.3 Hz, $CHCH_3$), 1.49−1.24 (12H, m, 6 × CH_2), 0.89 (3H, t, *J* 6.3 Hz CH_3). ESIMS *m/z* (M+1) = 523.5.

Ochratoxin Acid Docosapentaenyl Ester (23). Yield = 38 mg (23%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 7.9 Hz, ArH), 6.74 (1H, d, *J* 7.9 Hz, ArH), 5.36 (10H, m, 5 × CH=CH), 4.71 (1H, m, CH), 4.33 (2H, t, *J* 6.7 Hz, CH_2), 2.96 (2H, d, *J* 8.0 Hz, CH_2), 2.80 (4H, m, CH_2), 2.06 (2H, m, CH_2), 1.74 (2H, m, CH_2), 1.53 (3H, d, *J* 6.3 Hz, $CHCH_3$), 1.55−1.24 (8H, m, 4 × CH_2), 0.95 (3H, t, *J* 6.3 Hz, CH_3). ESIMS *m/z* (M+1) = 521.5.

Ochratoxin Acid Docosahexenyl Ester (24). Yield = 43 mg (26%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.02 (1H, d, *J* 7.9 Hz ArH), 6.74 (1H, d, *J* 7.9 Hz, ArH), 5.47−5.27 (12H, m, 6 × CH=CH), 4.71 (1H, q, *J* 5.6 Hz, CH), 4.35 (2H, t, *J* 6.5 Hz, CH_2), 2.96 (2H, d, *J* 7.1 Hz, CH_2), 2.80 (10H, m, CH_2), 2.24 (2H, q, *J* 6.8 Hz, CH_2), 2.08 (2H, q, *J* 7.3 Hz, CH_2), 1.86 (2H, q, *J* 7.0 Hz, CH_2), 1.53 (3H, d, *J* 6.3 Hz, $CHCH_3$), 0.97 (3H, t, *J* 7.5 Hz CH_3). ESIMS *m/z* (M+1) = 519.2.

Synthesis of Amide Linked Fatty Amine Conjugates at C-7 Position of Racemic Mellein (25−30) (Scheme 5). To a stirred solution of 8-hydroxy-3-methyl-1-oxo-isochroman-7-carboxylic acid **14** (250 mg, 1.12 mmol, 1.0 equiv) in dry DMF (10 mL) under nitrogen at room temperature was added solid

Scheme 5. Synthesis of Fatty Amine Conjugates at C-7 Position



14 **25 - 30**

N,N-carbonyl diimidazole (192 mg, 1.18 mmol, 1.05 equiv) and the reaction monitored by TLC. Once the reaction was judged complete (~1 h), the amine (1.0 equiv) was added and the reaction stirred further until TLC indicated that the reaction was complete. The crude mixture was then evaporated to dryness in vacuo. The residual oil was taken up into EtOAc or $CHCl_3$, washed with water, dried ($MgSO_4$), and evaporated to dryness to afford the amide of 8-hydroxy-3-methyl-1-oxo-isochroman-7-carboxylic acid.

Methyl Amide (25). Methyl amide **25** was prepared from **14**. The residual solid was taken up into chloroform and stirred with Amberlite IR-120+ resin, filtered off resin, dried ($MgSO_4$), and evaporated to dryness to afford the amide as a white solid. Yield = 161 mg (61%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 12.7−12.6 (1H, s, br, OH), 8.31 (1H, d, *J* 7.9 Hz, ArH), 7.96 (1H, s, br, NH), 6.76 (1H, d, *J* 7.9 Hz, ArH), 4.75−4.66 (1H, m, CH), 2.95−2.86 (5H, m, CH_2 and CH_3), 1.48 (3H, d, *J* 6.4 Hz, CH_3). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 170.5, 164.6, 160.1, 143.1, 138.9, 119.8, 118.5, 108.6, 77.3, 34.6, 26.5, 20.6. ESIMS *m/z* (M+1) = 236.1.

Hexyl Amide (26). Yield = 120 mg (35%) as a yellow solid. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 12.7−12.6 (1H, s, br, OH), 8.32 (1H, d, *J* 8.0 Hz, ArH), 8.00 (1H, s, br, NH), 6.76 (1H, d, *J* 8.0 Hz, ArH), 4.74−4.66 (1H, m, CH), 3.39 (2H, q, *J* 6.6 Hz, CH_2), 2.96−2.90 (2H, m, CH_2), 1.58−1.51 (2H, m, CH_2), 1.48 (3H, d, *J* 6.3 Hz, CH_3), 1.47−1.30 (6H, m, 3 × CH_2), 0.86−0.75 (3H, t, *J* 6.3 Hz, CH_3). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 170.5, 163.8, 160.2, 143.0, 139.0, 120.0, 118.5, 108.6, 76.4, 39.9, 34.6, 31.5, 29.4, 26.7, 22.5, 20.6, 14.0; ESIMS *m/z* (M+1) = 306.2.

***N*-Methyl-*N*-hexyl Amide (27).** Yield = 150 mg (52%) as a colorless oil. **27** was a 1:1 mixture of unassigned rotamers. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 11.37 (0.5H, s, OH), 11.35 (0.5H, s, OH), 7.45 (0.5H, d, *J* 7.6 Hz, ArH), 7.41 (0.5H, d, *J* 7.6 Hz, ArH), 6.75 (1H, d, *J* 7.6 Hz, ArH), 4.77−4.71 (1H, m, CH), 3.55 (1H, m, CH_2), 3.18 (1H, m, CH_2), 3.09 (1.5H, s, CH_3), 2.96−2.94 (2H, m, CH_2), 2.90 (1.5H, s, CH_3), 1.70−1.63 (1H, m, CH_2), 1.63−1.51 (3H, d, *J* 6.3 Hz, CH_3), 1.40−1.10 (7H, m, CH_2), 0.94−0.81 (3H, m, CH_3). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 169.7, 169.7, 167.6, 167.4, 157.9, 140.5, 140.4, 134.9, 134.7, 125.6, 125.3, 118.1, 118.0, 108.5, 108.4, 76.2, 50.8, 47.3, 36.0, 34.5, 32.4, 31.6, 31.3, 28.0, 26.9, 26.4, 26.0, 22.6, 22.4, 20.7, 14.0, 13.9. ESIMS *m/z* (M+1) = 320.3.

Dodecyl Amide (28). Yield = 298 mg (63%) as a yellow waxy solid. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.42 (1H, d, *J* 8.0 Hz, ArH), 8.07 (1H, s, br, NH), 6.85 (1H, d, *J* 8.0 Hz, ArH), 4.78 (1H, m, CH), 3.47 (2H, q, *J* 6.6 Hz, CH_2), 2.99 (2H, m, CH_2), 1.64−1.55 (9H, m, 4 × CH_2 and CH_3), 1.26 (14H, m, br), 0.88 (3H, t, *J* 6.3 Hz, CH_3). ESIMS *m/z* (M+1) = 390.3.

Oleyl Amide (29). Yield = 172 mg (32%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.42 (1H, d, *J* 8.0 Hz, ArH), 8.07 (1H, s, br, NH), 6.85 (1H, d, *J* 8.0 Hz, ArH), 5.35 (2H, m, CH=CH), 4.78 (1H, m, CH), 3.46 (2H, q, *J* 6.6 Hz, CH_2), 2.99 (2H, m, CH_2), 2.01 (4H, m, 2 × CH_2), 1.66−1.55 (8H, m, CH_2 and CH_3), 1.41−1.20 (19H, m, CH_2), 0.86 (3H, t, *J* 6.3 Hz, CH_3). ESIMS *m/z* (M+1) = 472.4.

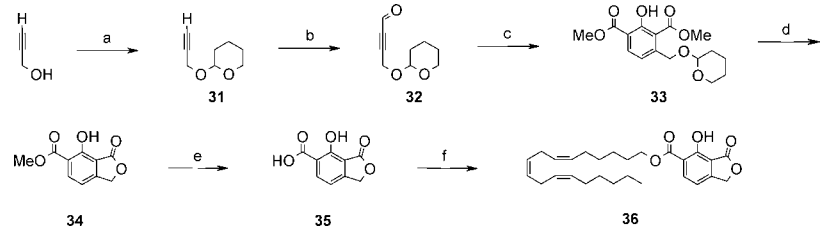
γ-Linolenyl Amide (30). Yield = 75 mg (21%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.33 (1H, d, *J* 7.9 Hz, ArH), 8.01 (1H, s, br, NH), 6.77 (1H, d, *J* 7.9 Hz, ArH), 5.36−5.24 (6H, m, 3 × CH=CH), 4.70 (1H, m, CH), 3.40 (2H, q, *J* 6.6 Hz, CH_2), 2.92 (2H, m, CH_2), 2.73 (4H, t, *J* 5.6 Hz, CH_2), 1.98 (4H, m, CH_2), 1.55 (2H, m, CH_2), 1.48 (3H, d, *J* 6.3 Hz, CH_3), 1.37−1.18 (10H, m, 5 × CH_2), 0.82 (3H, t, *J* 6.8 Hz, CH_3). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 170.5, 163.9, 160.2, 143.0, 139.1, 130.4, 130.0, 128.3, 128.2, 128.0, 127.6, 120.1, 118.5, 108.6, 76.4, 39.8, 34.6, 31.5, 30.9, 29.4, 29.3, 27.2, 27.1, 26.7, 25.6, 22.6, 20.7, 14.1. ESIMS *m/z* (M+1) = 468.4.

Synthesis of 4-Hydroxy-3-oxo-1,3-dihydro-isobenzofuran-5-carboxylic Acid Octadeca-6,9,12-trienyl Ester (36) (Scheme 6): 2-Prop-2-ynyloxy-tetrahydropyran (31). *p*-Toluenesulfonic acid monohydrate (20 mg, 0.1 mmol) was added to 3,4-dihydro-2*H*-pyran (33 g, 0.39 mol), and the mixture was stirred for 10 min. Propargyl alcohol (20 g, 0.36 mol) was added dropwise over 30 min. The reaction was stirred for 10 min, prior to the addition of sodium hydrogencarbonate (2.24 g, 27 mmol). The reaction was stirred overnight at room temperature. Filtration of the reaction mixture afforded 2-prop-2-ynyloxy-tetrahydropyran **31**. Yield = 49.40 g (99%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 4.82 (1H, t, *J* 3.3 Hz, CH), 4.25 (2H, m, CH_2), 3.84 (1H, m, CHH), 3.53 (1H, m, CHH), 2.47 (1H, t, *J* 3.8 Hz, CH), 1.64−1.89 (6H, m, CH_2). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 96.7, 79.7, 74.0, 61.9, 53.9, 30.1, 25.5, 19.1.

4-Tetrahydropyran-2-yloxy-but-2-ynal (32). *n*-Butyl lithium solution (2.1 M solution in hexanes, 83 mL, 0.175 mol, 1.05 equiv) was added dropwise to a solution of 2-prop-2-ynyloxy-tetrahydropyran **31** (23.3 g, 0.167 mol, 1.0 equiv) in dry THF (350 mL) under nitrogen at −45 °C at such a rate so as to ensure that the temperature remained below −35 °C. Upon complete addition, the mixture was stirred for a further 10 min before the dropwise addition of neat DMF (26 mL, 0.33 mol) again added at a rate ensuring the reaction temperature remained below 35 °C. After complete addition, the Dewar cooling bath was removed and the reaction was allowed to warm to ambient. The reaction mixture was then poured into a cooled (~0 °C) vigorously stirred biphasic solution of aqueous KH_2PO_4 (91 g, 0.67 mol, 4.0 equiv dissolved in 1 L water) and MTBE (1 L). The mixture was separated and the aqueous layer retained. The ethereal extracts were washed with water (2 × 600 mL). All aqueous layers were then combined and back-extracted with MTBE (500 mL). The organic extracts were combined, dried ($MgSO_4$), filtered, and evaporated to dryness to afford crude 4-tetrahydropyran-2-yloxy-but-2-ynal **32** as a brown oil, which was sufficiently pure to be reacted immediately in the next step. Yield = 23.7 g (85%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 9.24 (1H, s, CHO), 4.82−4.80 (1H, m, CH), 4.46−4.42 (2H, m, CH_2), 3.86−3.75 (1H, m, CHH), 3.59−3.54 (1H, m, CHH), 1.86−1.71 (2H, m, CH_2), 1.67−1.55 (4H, m, CH_2).

2-Hydroxy-4-(tetrahydropyran-2-yloxymethyl)isophthalic Acid Dimethyl Ester (33). A concentrated solution of dimethyl 1, 3-acetone dicarboxylate (24.2 g, 0.14 mol, 1.0 equiv) in dry THF (30 mL) was added dropwise to a stirred suspension of NaH (6.76 g, 0.17 mol, 1.2 equiv) in dry THF (120 mL) under nitrogen at 0 °C. After complete addition, the reaction was allowed to stir for a further 20 min before the slow, dropwise addition at ~0 °C of a solution of crude 4-tetrahydropyran-2-yloxy-but-2-ynal **32** dissolved in dry THF (100 mL) over approximately 1 h. The reaction mixture was allowed to warm to ambient temperature overnight. The crude reaction was then poured onto 2 M HCl (200 mL), separated, and then extracted with ethyl acetate (3 × 250 mL). All organic layers were combined and washed with brine, dried (Na_2SO_4), filtered, and evaporated to dryness. The oil was then preabsorbed onto silica and purified by column chromatography using 9:1 v/v hexanes/ethyl acetate to afford 2-hydroxy-4-(tetrahydropyran-2-yloxymethyl)-isophthalic acid dimethyl ester **33** as a yellow oil. Yield = 18.1 g (40%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 11.22 (1H, s, OH), 7.88 (1H, d, *J* 8.2 Hz, ArH), 7.01 (1H, d, *J* 8.2 Hz, ArH),

Scheme 6. Synthesis of Hydroxy-phthalide-6-carboxylic Acid γ-Linolenyl Ester 36[a]



[a] Reagents and Conditions: (a) 3,4-dihydro-2*H*-pyran, r.t., 30 min; (b) n-BuLi, DMF, −45°C; (c) dimethyl 1, 3-acetone dicarboxylate, NaH, THF, 0 °C; (d) p-TSA·H_2O, MeOH, r.t., 30 min; (e) NaOH, dioxane, reflux, 3 h; (f) γ-linolenyl alcohol, EDC·HCl, HOBt, DIPEA, DMF.

Table 1. Cytotoxic Activity of Fatty Acids

	IC_{50} (μg/mL)			
	MCF-7	MDA-MB-468	SK-MEL-28	Malme-3M
heneicosanoic acid (C21:0)	>200	>200	93.5 ± 2.1	90 ± 0.0
oleic acid (C18:1, n-9)	62.5 ± 0.7	67.5 ± 0.7	77.5 ± 7.8	65 ± 0.0
linoleic acid (C18:2, n-6)	>200	>200	>200	>200

γ-linolenic acid (C18:3, n-6)	54 ± 8.5	48 ± 14.7	64.5 ± 0.7	39.5 ± 2.1

[a] Data represent the mean IC_{50} ± SD (the concentration of each compound that inhibited 50% of the growth of the corresponding cancer cell line) of the tested compounds screened in an MTT assay against human breast cancer (MCF-7 and MDA-MB-468) and melanoma cells (SK-MEL-28 and Malme-3M).

4.82 and 4.58 (2 × 1H, d(AB), *J* 13.6 Hz, CHH), 4.65−4.63 (1H, t, *J* 3.5 Hz), 3.96 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 3.88−3.82 (1H, m), 3.55−3.50 (1H, m), 1.86−1.83 (1H, m), 1.75−1.65 (1H, m), 1.64−1.51 (4H, m, CH_2). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 169.9, 167.0, 158.9, 144.8, 131.3, 121.4, 118.4, 112.1, 98.0, 66.4, 62.1, 52.5, 52.3, 30.3, 25.3, 19.1. ESIMS *m*/*z* $(M-1)^-$ 323.4.

7-Hydroxyphthalide-6-carboxylic Acid Methyl Ester (34). Solid *p*-toluenesulfonic acid monohydrate (1.0 g, 5.6 mmol, 0.1 equiv) was added to a stirred solution of 2-hydroxy-4-(tetrahydropyran-2-yloxymethyl)isophthalic acid dimethyl ester **33** dissolved in methanol (180 mL) and stirred for ∼30 min. The white precipitate that had formed was filtered off and dried in air to afford 7-hydroxyphthalide-6-carboxylic acid methyl ester **34** as a white powder. Yield = 8.16 g (70%). ^1H NMR ($CDCl_3$, 400 MHz) δ 11.7 (1H, s, OH), 8.16 (1H, d, *J* 8.0 Hz, ArH), 6.97 (1H, d, *J* 8.0 Hz, ArH), 5.27 (2H, s, CH_2), 4.01 (3H, s, OCH_3). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 169.8, 167.9, 160.9, 155.3, 136.6, 113.5, 113.1, 112.5, 68.8, 52.9. ESIMS *m*/*z* (M−1) 207.4.

7-Hydroxyphthalide-6-carboxylic Acid (35). Sodium hydroxide solution (10 wt %, ∼8 mL) was added to a stirred suspension of 7-hydroxyphthalide-6-carboxylic acid methyl ester **34** (1.84 g, 8.8 mmol) in dioxane (20 mL) before heating to reflux under nitrogen for 3 h, at which time TLC analysis indicated complete conversion. The reaction mixture was evaporated to dryness. The residual oil was taken up into water (25 mL) and extracted with ethyl acetate (25 mL), The aqueous layer was then acidified to pH 1 with 2 M HCl, and the precipitate that formed was stirred for ∼10 min. The solid was isolated by filtration, washed with water (5 mL), dried in air, collected, and dried in a vacuum oven at 40 °C (over P_4O_{10}) to afford 7-hydroxyphthalide-6-carboxylic acid **35** as a white powder. Yield = 1.54 g (90%); mp 277 °C. ^1H NMR (d_6-DMSO, 400 MHz) δ 8.12 (1H, d, *J* 8.0 Hz, ArH), 7.11 (1H, d, *J* 8.0 Hz, ArH), 5.34 (2H, s, CH_2). ^{13}C NMR (d_6-DMSO, 100 MHz) δ 171.6, 167.5, 160.3, 156.0, 136.7, 113.1, 112.9, 112.3, 68.9. ESIMS *m*/*z* (M+1) 195.

7-Hydroxyphthalide-6-carboxylic Acid γ-Linolenyl Ester (36). To a mixture of 7-hydroxyphthalide-6-carboxylic acid **35** (2.30 g, 11.8 mmol), hydroxybenzotriazole (1.68 g, 12.5 mmol, 1.05 equiv) in anhydrous DMF (50 mL) under nitrogen and cooled to 0 °C was added diisopropylethylamine (2.52 g, 19.5 mmol, 1.7 equiv) followed by EDC·HCl (3.58 g, 18.7 mmol, 1.6 equiv). The reaction was stirred at 0 °C for 1 h and then warmed to room temperature. After stirring for 20 min, γ-linolenyl alcohol (3.13 g, 11.8 mmol, 1.0 equiv) was added, and the reaction stirred at room temperature overnight. The DMF was removed in vacuo. The residue was dissolved in $CHCl_3$ (100 mL) and washed sequentially with 10% citric acid solution (2 × 100 mL), sat. $NaHCO_3$ (2 × 100 mL) and brine (100 mL), dried over $MgSO_4$, and concentrated in vacuo to afford a yellow semisolid. Purification by flash chromatography on silica using hexane/EtOAc afforded 7-hydroxyphthalide-6-carboxylic acid γ-linolenyl ester **36**. Yield = 2.90 g (56%). ^1H NMR ($CDCl_3$, 400 MHz) δ 11.87 (1H, s OH), 8.16 (1H, d, *J* 8.0 Hz, ArH), 6.97 (1H, d, *J* 8.0 Hz ArH), 5.53−5.29 (6H, m, 3 × CH═CH), 5.27 (2H, s, CH_2), 4.40 (2H, t, *J* 6.3 Hz, CH_2), 2.81 (4H, m, CH_2), 2.02−2.12 (4H, m, CH_2), 1.82 (2H, m, CH_2), 1.47 (4H, m, CH_2), 1.31 (6H, m, CH_2), 0.89 (3H, t, *J* 6.1 Hz CH_3). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 169.4, 167.9, 161.0, 155.2, 136.5, 130.5, 129.7, 128.4, 128.2, 128.0, 127.5, 113.5, 113.3, 112.4, 77.2, 68.8, 66.2, 31.5, 29.3, 29.2, 28.4, 27.2, 27.0, 25.7, 25.5, 22.6, 14.1. ESIMS *m*/*z* (M+1) 441.2.

Cell Culture. The cell lines used in this study were human breast adenocarcinoma cell lines, MCF-7 and MDA-MB-468, human melanoma cells, SK-MEL-28 and Malme-3M, human colorectal cancer cell lines, HT-29 and RKO, human lung adenocarcinoma cell lines, NCI-H23 and NCI-H157, and human prostate cancer cell lines (PC3 and LnCap). All cell lines used were originally obtained from the American Tissue Culture Collection and routinely maintained as monolayer cultures in RPMI 1640 supplemented with 10% fetal calf serum (GIBCO, Grand Island, NY) and 2 mmol/L L-glutamine at 37 °C in a humidified atmosphere of 5% CO_2. To remove the adherent cells from the flask for passaging and counting, cells were incubated with 0.25% trypsin−EDTA solution (GIBCO, Grand Island, NY) for 5 min. All experiments were performed using cells in exponential cell growth phase.

Cytotoxicity Assay (MTT Assay). The MTT assay is a widely used colorimetric assay for assessing the antiproliferative activity and determining the cytotoxic effects of novel therapeutic agents. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), a thiazolyl blue tetrazolium salt, is reduced from a yellow material to an insoluble purple formazan in the mitochondria of living metabolically active cells (*37*). Cells were maintained in RPMI 1640 containing 1% penicillin−streptomycin and 10% fetal calf serum (Gibco, Grand Island, NY) at 37 °C in a humidified atmosphere of 5% CO_2. 180 μL of cells was seeded at 1 × 10^3 cells per well in 96 well plates with 6 replicates for each drug concentration. Following the attachment period, cells were treated with appropriate drug concentrations (20 μL added per well). Chemically synthesized compounds

[a] Data represent the mean IC_{50} (the concentration of each compound that inhibited 50% of the growth of the corresponding cancer cell line) of the tested compounds screened in an MTT assay against human breast cancer (MCF-7 and MDA-MB-468) and melanoma cells (SK-MEL-28 and Malme-3M).

were dissolved in DMSO. 10 mmol/L stock solutions of all test compounds were prepared in DMSO and stored in aliquots at −20 °C. Further dilutions were made in medium when required. Wells containing medium only were used as blanks. Cells were maintained at 37 °C 5% CO_2 for 96 h. MTT was added to the cells, and after 4 h, the MTT medium was removed and 100 μL DMSO added per well. Plates were agitated on an orbital mixer platform (Stuart Scientific) for 10 min. Absorbance was measured at 570 nm on a Biotrak II (Amersham Bioscience) plate reader. IC_{50} values were calculated comparing control and drug-treated cells. The IC_{50} value was defined as the concentration of samples that produced a 50% reduction in cell viability and calculated with GraphPad *Prism* software. Data for combination treatments examining multiple drug effects were analyzed using the Chou and Talalay method, based on the median effect principle, with the software calcusyn to examine the nature of interaction between drugs (*38*). Combination index (CI) values were calculated; briefly, CI values of less than 1 indicate synergy (and the smaller the value the greater the degree of synergy), values above 1 indicate antagonism, and values equal to 1 indicate additive effects.

Cell Counts. The effects of **20** and **36** treatment were also assessed by performing daily cell counts in the human breast cancer cell line, MDA-MB-468. Cells were seeded at 100 cells per well in 24 well plates and following an attachment period were treated with various concentrations of the compound to

[a] Data represents the mean IC_{50} (the concentration of each compound that inhibited 50% of the growth of the corresponding cancer cell line) of the tested compounds screened in an MTT assay against human breast cancer (MCF-7 and MDA-MB-468) and melanoma cells (SK-MEL-28 and Malme-3M).

be tested. Cell counts were determined on a Coulter counter daily for 5 days post-treatment. All treatments were performed in triplicate.

Cell Survival. Cells were seeded at 100 cells per well in 24 well plates and allowed to attach overnight. The following day, dilutions of the test compounds were added in medium to the appropriate wells and cells incubated for 96 h at 37 °C in a humidified atmosphere of 5% CO_2. Medium was then removed and replaced by fresh drug-free medium and cultured for a further 96 h. Cells were subsequently washed with phosphate buffered saline (PBS) solution, fixed with ice cold 70% ethanol for 5 min, and stained with a 2% crystal violet solution for 20 min. After staining, cells were thoroughly washed with water and allowed to dry. Crystal violet was resorbed using 0.1 M sodium citrate solution and the absorbance of the solution measured at 570 nm. Each treatment was performed in triplicate.

Cell Cycle Analysis. Cell cycle analysis was analyzed by propidium iodide staining. Briefly, exponentially growing cells were treated with different doses of the drug for 72 h. At the end of each treatment time, cells were collected by scraping the cells off the flask and washed with PBS containing 1% FCS after centrifugation at 1000 rpm for 5 min. Cells were resuspended in PBS and washed. Cells were subsequently fixed in ice-cold 70% ethanol overnight at 4 °C. Ethanol was removed following centrifugation at 1000 rpm for 5 min and the cells washed twice in PBS to remove residual ethanol. For cell cycle analysis, the cells were suspended in 1 mL of PBS containing 0.02 mg/mL of propidium iodide and 0.5 mg/mL RNase A and incubated at 37 °C for 30 min. Cell cycle profiles were obtained using A FACScan flow cytometer (Becton Dickinson, San Jose, CA), which measured the fluorescence emitted from the propidium iodide−DNA complex.

Human Tumor Xenografts. Female athymic nude (*nu*/*nu*) mice (Charles River) were used for in vivo testing of the test compounds. The animals were fed ad libitum and kept in isolators in air-conditioned rooms at 20 ± 2 °C with a 12 h light−dark cycle. Animal care and procedures were carried out in agreement with Home Office guidelines and approved by Queens University Belfast Ethics Committee. MCF-7, MDA-MB-468, or HT29 cells were inoculated s.c. in both flanks of female athymic nude mice (1×10^6 cells/flank) under asceptic conditions. Equal volumes of cell solution and matrigel was used in the cell suspension. Tumor growth was assessed every 2−3 days with digital calipers recording length and width of tumors. Tumor volume was determined according to the following formula: shortest tumor diameter^2 × longest tumor diameter × 0.5. Tumors were allowed to grow to an average volume of 100 mm^3 prior to randomization to the control and

[a] Data represents the mean IC_{50} (the concentration of each compound that inhibited 50% of the growth of the corresponding cancer cell line) of the tested isolated compounds screened in an MTT assay against human breast cancer (MCF-7 and MDA-MB-468) and melanoma cells (SK-MEL-28 and Malme-3M). [b] NT, compounds not tested.

treatment groups. Following randomization to treatment groups, animals (8−10 animals per group) received daily intraperitoneal (i.p.) injections of test compound (80 mg/kg) or solvent control for the duration of the study. Animal weights were also recorded every 2−3 days throughout the study. All animals were also monitored daily for signs of treatment toxicity or mortality. On autopsy, tumors and vital organs (heart, liver, lungs, kidney, and spleen) were collected and fixed in 10% neutral buffered formalin for subsequent pathological examination.

Statistics. Statistical analysis and *P* value determination were performed by two-tailed paired *t* test with a confidence interval of 95% for the determination of the significance difference between treatment groups. $P < 0.05$ was considered to be significant. ANOVA was used to test for significance among groups. *Prism* software was used for statistical analysis. Values are expressed as means ± SD.

RESULTS

The synthesis of all compounds tested are described in Schemes 1−6 and the structures contained within Tables 2−6. Racemic kigelin **1** and mellein **6** were synthesized from commercially available starting materials as previously described (*16*). Fatty acid esters of racemic kigelin (compounds **2** to **5**) and racemic mellein (**7** to **10**) were prepared by coupling with *N*,*N*′-dicyclohexylcarbodiimide (DCC) and 4-dimethylaminopy-

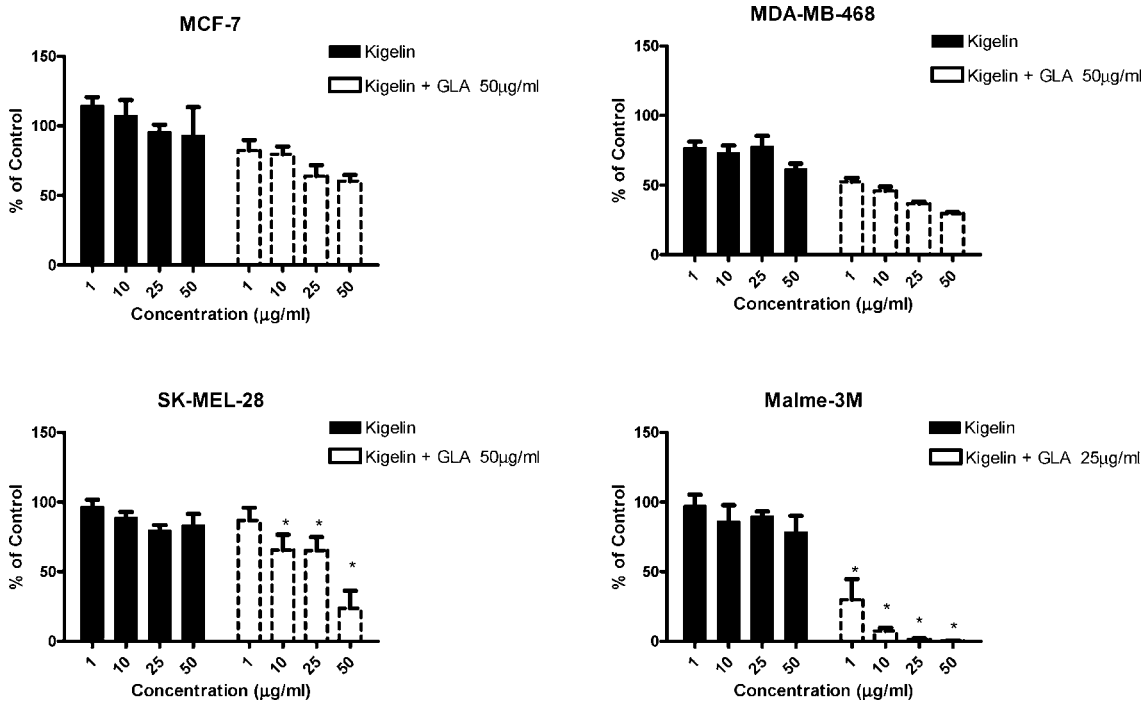

Figure 1. Cytotoxic activity of cells treated with kigelin **1** and the combination of kigelin and γ-linolenic acid (GLA). Data represent the mean values ± standard deviation of 3 replicates treated for 96 h and assessed using an MTT assay against human breast cancer (MCF-7 and MDA-MB-468) and melanoma cells (SK-MEL-28 and Malme-3M) expressed as the % of control untreated cells. * Indicates synergistic effect as determined using combination index values for drug interaction between kigelin and γ-linolenic acid. *a* indicates effect of GLA alone; MCF-7 50 μg/mL 97.28 ± 27.3%; MDA-MB-468 50 μg/mL 59.02 ± 11.84%; SK-MEL-28 50 μg/mL 91.95 ± 12.77%; Malme-3 M 25 μg/mL 78.28 ± 18.22%. Data for combination treatments examining multiple drug effects were analyzed using the Chou and Talalay method, based on the median effect principle, with the software *Calcusyn* to examine the nature of interaction between drugs (*38*). Combination index (CI) values were calculated; briefly, CI values of <1 indicate synergy.

ridine (DMAP) according to the general method described in Schemes 1 and 2, respectively.

Acid **14** and ester **13** were prepared on the basis of modifications of the previously reported synthetic sequence illustrated in Scheme 3 (*39*). Acetone and ethyl formate were reacted in the presence of sodium methoxide. The resulting intermediate **11** was then reacted with dimethyl 1,3-acetone dicarboxylate to yield 2-hydroxy-4-methylbenzene-1,3-dicarboxylate **12** in 24% yield over two steps. Deprotonation of **12** with LDA followed by reaction with acetaldehyde then cyclization under acidic conditions afforded ester **13**. Finally, saponification with aqueous sodium hydroxide in dioxane provided acid **14** in 9% overall yield. Esters (**15** to **24**) were then synthesized by coupling **14** with the corresponding fatty alcohol in presence of DCC and DMAP in dichloromethane according to the general conditions outlined in Scheme 4. Amides (**25** to **30)** were synthesized by coupling acid **14** with the corresponding fatty amine in the presence of *N,N′*-carbonyl diimidazole in dimethylformamide according to the general conditions outlined in Scheme 5.

36 was prepared as illustrated in Scheme 6. Propargyl alcohol was first protected with 3,4-dihydro-2*H*-pyran. Intermediate **31** was then reacted with dimethylformamide to yield aldehyde **32** in 85% yield. Reaction of **32** with dimethyl 1, 3-acetone dicarboxylate afforded intermediate **33** in 40% yield. Cyclization to **34** was effected under acidic conditions with *p*-toluene sulfonic acid monohydrate. Saponification with sodium hydroxide in dioxane afforded acid **35** in 21% overall yield. Finally, coupling with γ-linolenyl alcohol gave **36**.

In a previous study, kigelin **1**, a dihydroisocoumarin, was identified in extracts from the fruits of *Kigelia pinnata*, which demonstrated antiproliferative activity against human melanoma cells in vitro (*16*). Subsequently, kigelin was synthesized; however, the synthetic version did not demonstrate as potent an activity as observed with the extracted compound. Further fractionation and scaleup of the extraction process revealed the presence of trace amounts of fatty acids, both saturated and unsaturated, in their free form and as glycerol esters in some of the active fractions. A preliminary investigation of the antiproliferative activity of a number of fatty acids (oleic acid, heneicosanoic acid, linoleic acid (LA), α-linolenic acid (ALA), and γ-linolenic acid (GLA)) was carried out to determine if these had any direct effect on cell proliferation. The choice of the fatty acids was made to contain 0, 1, 2, or 3 double bonds of *cis*-configuration, since the majority of the unsaturated fatty acids occurring in the cell surface are of *cis*-configuration rather than the *trans* form and the *cis*-acid esters are assumed to be more favorably taken up into the cell (*40*−*44*).

The human breast cancer cell lines, MCF-7 and MDA-MB-468, and the melanoma cell lines, SkMel28 and Malme-3M, were selected for the preliminary screening of the panel of fatty acids (FAs) using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay to determine cell growth inhibition. Individual FAs demonstrated varying degrees of antiproliferative activity against the cell lines tested with GLA demonstrating the most potent activity against all four cancer cell lines. Neither heneicosanoic or linoleic acid demonstrated any activity in the breast cancercell lines (Table 1). We further investigated the effect of cotreating cells with kigelin and GLA to observe whether any synergistic activity could be observed in vitro. All cell lines with the exception of Malme-3 M were cotreated with 50 μg/mL GLA for combination experiments. As Malme-3 M cells were more sensitive to the effects of GLA, a lower dose of 25 μg/mL was used. Combination index values, a quantitative measurement of the degree of drug interactions, were calculated using the software *Calcusyn* (<0.9 synergy, 0.90−1.10 nearly additive, >1 antagonism) (*38*). As shown in

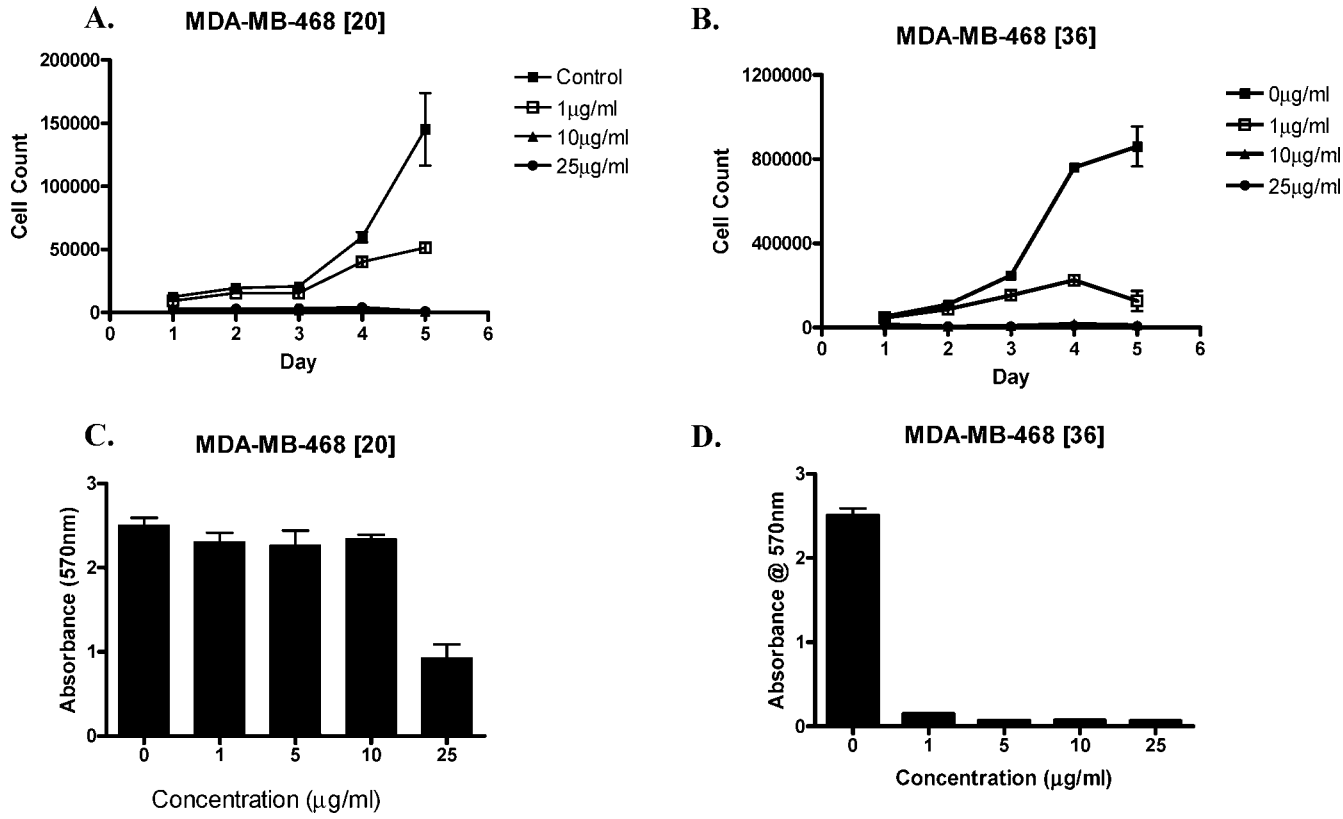

Figure 2. Antiproliferative effects of **20** and **36** treated MDA-MB-468 human breast cancer cells. (A) Five day cell counts for cells treated with **20** at indicated concentrations. (B) Five day cell counts for cells treated with **36** at indicated concentrations. (C) Cell survival assay for cells treated with **20** at indicated concentrations. (D) Cell survival assay for cells treated with **36** at indicated concentrations. Each value represents the mean ± standard deviation from triplicate treatments.

Figure 1, combining the GLA with kigelin did result in a synergistic interaction in each of the melanoma cell lines tested.

A number of compounds were synthesized by conjugating fatty acids, alcohols, or amines to dihydroisocoumarins, at either the C-7 or C-8 position by ester or amide linkages. The antiproliferative activity of all compounds synthesized was evaluated using the MTT assay in the human breast cancer cell lines, MCF-7 and MDA-MB-468, and melanoma cell lines, SK-MEL-28 and Malme-3 M (Tables 2−6).

Substitution of oleic, linoleic, α-linolenic, or γ-linolenic acid to kigelin at the C-8 position of the dihydroisocoumarin core structure generally increased the antiproliferative activity of the compounds against the breast cell lines, MCF-7 and MDA-MB-468, and the Malme-3 M melanoma cell line. There were no apparent antiproliferative effects observed in the SK-MEL-28 cell line treated with these compounds at the concentration range tested. γ-Linolenic acid conjugated to kigelin (**5**) and containing 3 double bonds on the hydrocarbon chain was the most potent of this series of compounds. Increasing the number of double bonds in the hydrocarbon chain was also observed to enhance the antiproliferative activity in these cells. The difference in potency observed between γ-linolenic and α-linolenic acid conjugated kigelin indicates that not only is the degree of saturation important but also the position of the starting double bond (Table 2).

Substitution of oleic, linoleic, α-linolenic, or γ-linolenic acid to mellein at the 8-position of the dihydroisocoumarin core structure did not significantly alter the antiproliferative activity of these compounds against the breast cell lines, MCF-7 and MDA-MB-468, or the melanoma cell lines SK-MEL-28 and Malme-3M, with all compounds not demonstrating an antiproliferative activity at the concentration range tested (Table 3).

A further series of compounds were synthesized conjugating fatty alcohols of increasing hydrocarbon chain length and number of double bonds by ester linkages at the C-7 position of mellein. The most potent antiproliferative activity was observed with compounds containing long hydrocarbon chains with three or more double bonds. The most potent compound, against the two breast cancer cell lines, was the γ-linolenyl ester compound (**20**) (IC_{50}s 4.2−23.9 μM). Generally, the breast cancer cell lines were more sensitive to this series of compounds than the melanoma cells. The difference in potency observed between γ-linolenyl and α-linolenyl alcohol conjugated mellein again indicates that not only is the degree of saturation important but also the position of the starting double bond (Table 4).

A similar series of compounds were also synthesized linking fatty amines at the C-7 position by an amide linkage rather than the ester linkage previously used. In this series of compounds, increasing the length of the hydrocarbon chain clearly increased the antiproliferative activity in three of the four cell lines tested. The most potent analogue in this series was the γ-linolenyl amide linked compound (**30**) in MCF-7, SK-MEL-28, and Malme-3 M cells with observed IC_{50}s ranging from 6.0 to 22.2 μM (Table 5).

As the γ-linolenyl compounds were the most potent compounds in all the series, we conjugated the γ-linolenyl alcohol to a 5-membered lactone as opposed to the 6-membered dihydroisocoumarin. This compound, 4-hydroxy-3-oxo-1,3-dihydro-isobenzofuran-5-carboxylic acid octadeca-6,9,12-trienyl ester (**36**), was subsequently tested. Both **20** and **36** were further evaluated against a panel of cancer cell lines including prostate and colon cancer cell lines (Table 6). In general, **36** was slightly more potent against all the cancer cell lines tested in the panel than the corresponding 6-membered lactone **20**. The most potent

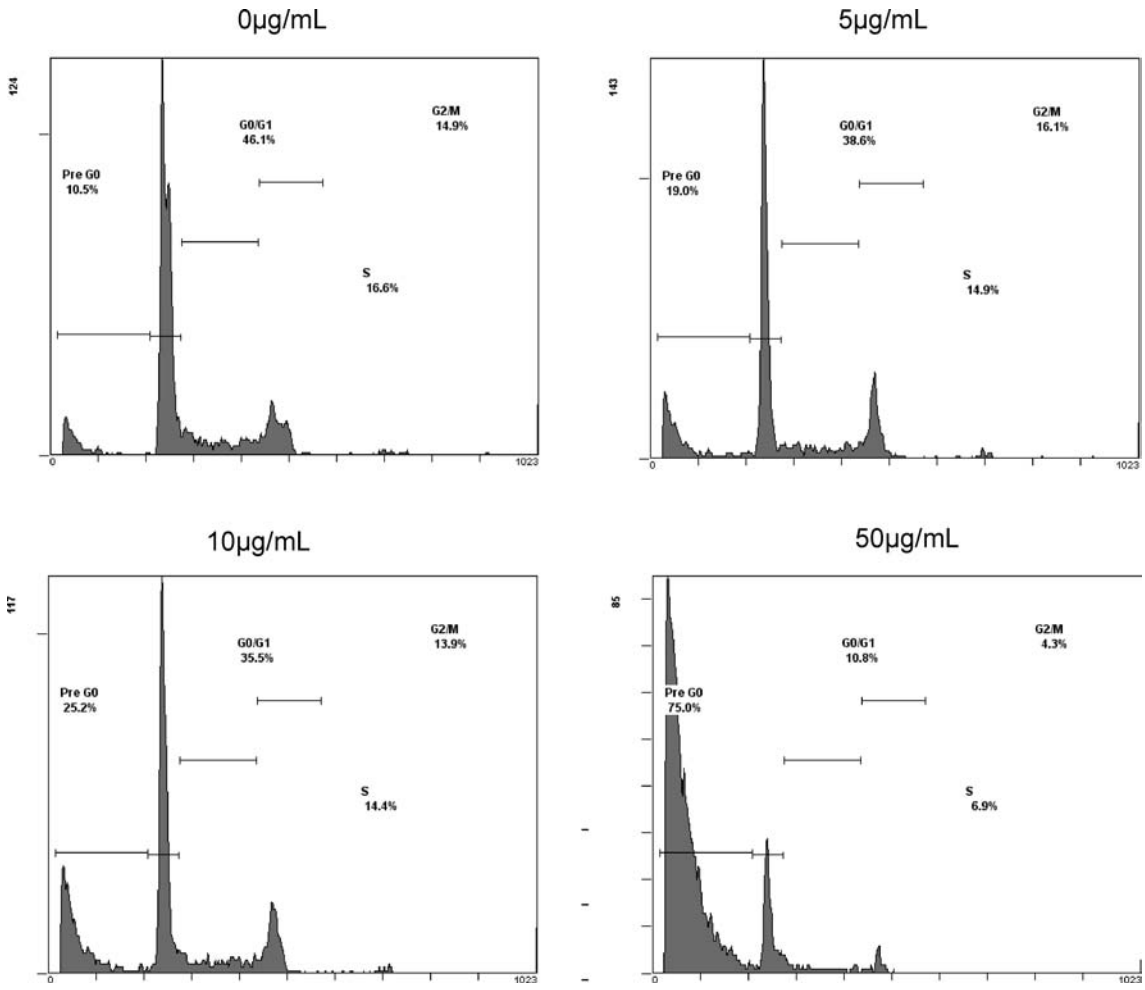

Figure 3. Flow cytometric analysis of the cell cycle profiles of MDA-MB-468 cells treated with **36** at the indicated concentrations. Cells were exposed for 72 h, stained with propidium iodide, and analyzed for perturbation in the cell cycle.

antiproliferative activity observed with **36** was against the breast cancer cell lines (IC_{50}s 2.5−4.9 μM). Both **20** and **36** were further evaluated for their antiproliferative activity using cell counts and cell survival assays (Figure 2). A clear difference in the effect on cell survival was observed between the two compounds with cells failing to recover from treatment with the drug. Flow cytometry analysis of MDA-MB-468 cells treated with increasing doses of **36** (0−50 μg/mL) over a 72 h period demonstrated a dose-dependent increase in cells in pre G0 phase of the cell cycle as assessed with propidium iodide staining (Figure 3) (% pre G0 cells: 0 μg/mL, 10.5%; 1 μg/mL, 19.6%; 5 μg/mL, 19.0; 10 μg/mL, 25.2%; 25 μg/mL, 41.0%; 50 μg/mL, 75.0%).

A preliminary MDA-MB-468 breast cancer xenograft study examined the in vivo antitumor efficacy of two compounds, **36** and **20**, selected on the basis of their potency in the original MTT screen. Following daily i.p. injections (80 mg/kg) of both compounds, **36**, clearly exhibited an antitumor effect in vivo. **20** failed to demonstrate an in vivo effect at the concentration tested in the MDA-MB-468 human xenograft model. A delay in tumor growth was observed with **36** from day 8 post-treatment and was maintained for the duration of the study. **36** was further evaluated in a HT29 colorectal cancer xenograft model and an MCF-7 human breast cancer xenograft model and demonstrated antitumor activity in both cases (Figure 4). In the MCF-7 and HT29 model, a significant delay in tumor growth was observed from day 6 and day 16, respectively. Both compounds demonstrated no toxicity in vivo, determined by monitoring of body weight and pathological evaluation of major organs (heart, liver, lung, spleen, and kidneys) at autopsy. The combined effect on tumor growth observed with compound **36** and its apparent lack of toxicity in tumor-bearing mice support further investigation of this compound for use as an anticancer agent.

DISCUSSION

In conclusion, these studies have demonstrated a synergistic interaction of the fatty acid, γ-linolenic acid and the dihydroisocoumarin kigelin, in their antiproliferative activity against cancer cell lines. We have demonstrated that the fatty acid GLA is capable of acting in synergy with kigelin, a dihydroisocoumarin identified from natural products, to increase the antiproliferative activity of this class of compounds against human melanoma and breast cancer cells in vitro.

In addition, we have described simple synthetic approaches to generate a series of dihydroisocoumarins linked to a long hydrocarbon chain of varying length and degree of unsaturation. We have described the synthesis and biological activity relating to the antiproliferative effect of this novel series of potential anticancer agents. Synthetic dihydroisocoumarin compounds conjugated with fatty alcohols or amines through an acid function demonstrated varying degrees of antiproliferative activity on the cancer cell lines tested. Ester-linked fatty alcohols, with three or more double bonds in the hydrocarbon chain, conjugated to intermediate **14** at the C-7 position were the most active of the series tested. The most potent compound tested, **36**, demonstrated both in vitro antiproliferative effects and in vivo activity against both breast and colon cancer human

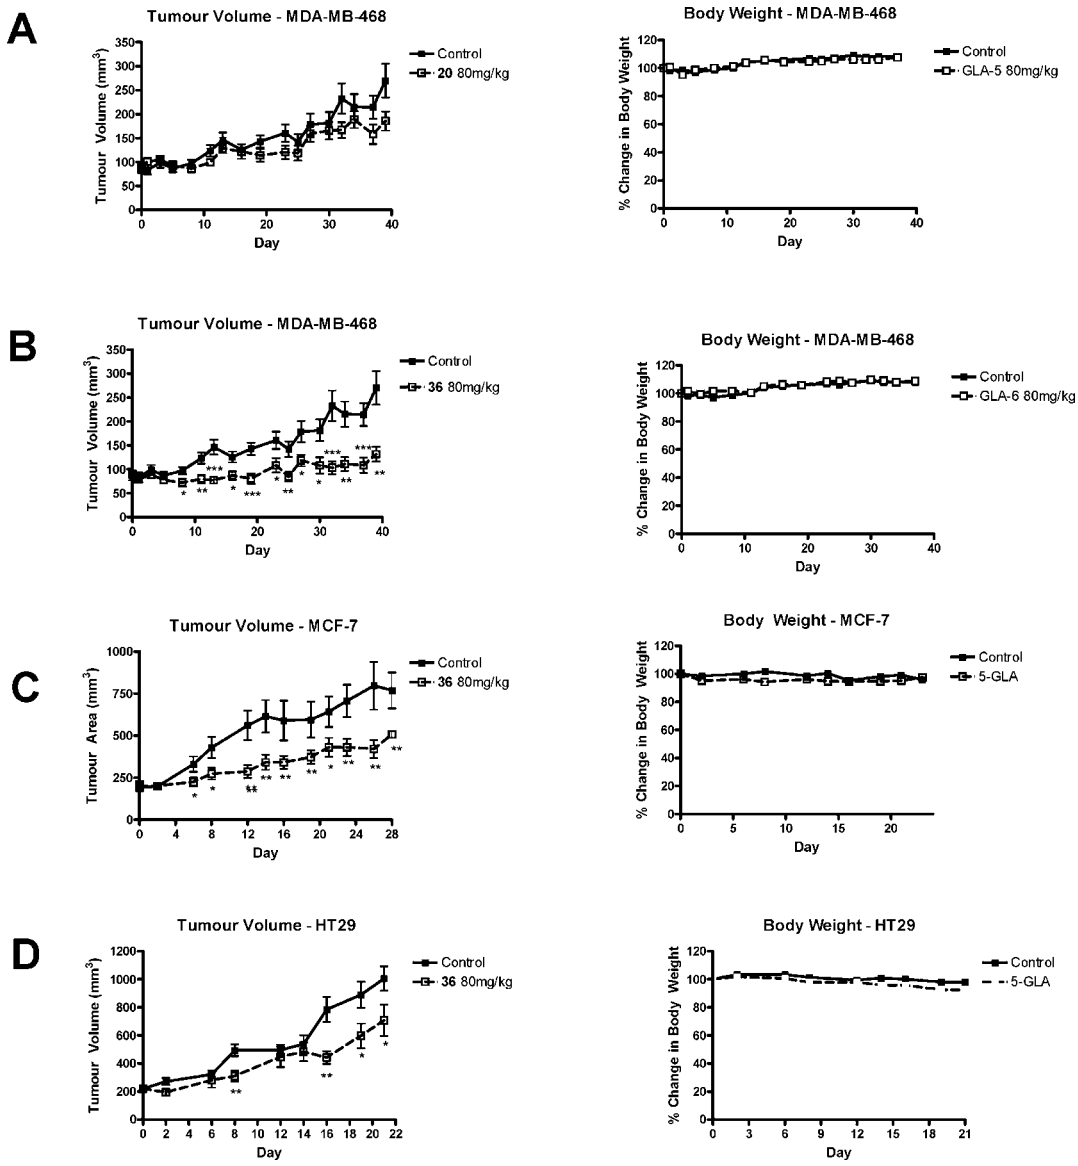

Figure 4. Growth of human tumor xenograft models and body weight. (A) MDA-MB-468 xenograft model treated with **20** (80 mg/kg, i.p.daily). (B) MDA-MB-468 xenograft model treated with **36** (80 mg/kg, i.p. daily). (C) MCF-7 xenograft model treated with **36** (80 mg/kg, i.p. daily). (D) HT29 xenograft model treated with **36** (80 mg/kg, i.p daily). Athymic nude mice implanted with MDA-MB-468, MCF-7, or HT29 cells as indicated were randomly assigned to treatment groups and injected intraperitonealy (i.p.) daily following establishment of tumors. Values represent the tumor volume (mean ± SD) for each group. Differences between treatment groups were determined using Students *t* test and by calculating subsequent p values. * $p < 0.05$, ** $P < 0.01$, *** $p < 0.005$.

xenograft models. This compound, containing a 5-membered lactone ring, showed superior in vivo activity compared to the corresponding 6-membered lactone ring compound **20**. The growth inhibitory activity of the compounds in cells and animal studies clearly support their promise as potential anticancer agents. The apparent lack of toxicity observed in vivo is also promising.

The data indicate that **36** may be suitable for further investigation as a possible therapeutic agent for the treatment of cancer. Since the early 1980s, it has been established that highly unsaturated fatty acids, including γ-linolenic acid, can be toxic to tumor cells while demonstrating much lower toxicity toward normal cells (*42*). The ability of fatty acids to increase the cytotoxic activity of some anticancer drugs has also previously been documented (*45*−*49*). Gamma linolenic acid (GLA) has been shown to inhibit tumor cell growth and tumor invasion in several studies across a diverse range of tumor types including prostate, melanoma, colon, liver, pancreatic, and lung cancer both in vitro and in vivo. GLA is believed to exert its antitumor effects by enhancing the formation of lipid peroxides and possibly the production of eicosanoids, themselves cytotoxic, generated from GLA supplementation. GLA has also been shown to enhance free radical generation such as superoxide and H_2O_2 generation in tumor cells but not normal cells. In an in vivo glioma model GLA has been shown to induce tumor regression and preserve the surrounding normal brain tissue (*19*). The lithium salt of GLA has being evaluated in phase II and III clinical trials for a variety of tumors (*18*, *46*). Intratumoral injection of GLA has been shown to induce significant reduction of glioma without any significant side effects. Agents that preferentially kill tumor cells without adversely affecting normal cells would clearly be of benefit for cancer treatment. Chemotherapy drugs conjugated to fatty acids have also been shown to enhance tumor targeting and deliver prodrugs for intratumoral activation (*28*−*30*).

Our study indicates that γ-linolenyl hydrocarbon side chain conjugated to dihydroisocoumarins clearly has potential for further investigation as potential anticancer drugs. Whether

esterification with γ-linolenyl alcohol is having a direct cytotoxic effect on the cancer cells or is facilitating the passage of the dihydroisocoumarin compound through the cell membrane and/or increasing the tumor delivery of the compound is currently unknown.

ACKNOWLEDGMENT

This work was supported by funding from Northern Ireland HSPSS (Cancer Research Recognised Group) and the McClay Trust. Dr. Lioe Tong is also acknowledged for his assistance and pathological evaluation of the in vivo studies.

Surface Coating Directed Cellular Delivery of TAT-Functionalized Quantum Dots

Yifeng Wei, Nikhil R. Jana,*,† Shawn J. Tan, and Jackie Y. Ying*

Institute of Bioengineering and Nanotechnology, 31 Biopolis Way, The Nanos, Singapore 138669. Received September 6, 2008; Revised Manuscript Received June 18, 2009

TAT peptide functionalized shell−core ZnS-CdSe quantum dots (QDs) have been prepared by three different methods, direct ligand exchange with cysteine-terminated TAT (TAT-$QD_{lig\ exch}$), and covalent conjugation to QDs coated with silanes (TAT-QD_{silica}) and polyacrylate derivatives (TAT-$QD_{polyacrylate}$). The silica and polyacrylate coatings incorporated multiple primary and secondary amines, introducing positive surface charges onto the QDs, providing high water solubility and sites for peptide conjugation, while inducing the "proton sponge effect". The different coating methods produced particles of different sizes, surface charges, and colloidal stability; these factors jointly influenced the cellular uptake and subcellular localization of these particles. As the particle size increased, (TAT-$QD_{lig\ exch}$ (6 nm) < TAT-QD_{silica} (10 nm) < $QD_{polyacrylate}$ (25 nm)), both the particle surface charge and cellular uptake increased. The smaller TAT-$QD_{lig\ exch}$ and TAT-QD_{silica} particles were localized mainly in the perinuclear regions, while the larger TAT-$QD_{polyacrylate}$ particles were localized in both the perinuclear regions and the lysosomes. Compared to the other TAT-QDs, TAT-$QD_{lig\text{-}exch}$ has a lower colloidal stability and was more cytotoxic due to the weak binding of the ligands.

INTRODUCTION

QDs are of interest to cell imaging due to their bright, sharp, stable, and tunable fluorescence, which can be excited by UV and visible light (*1*−*4*). Current research efforts are focused on greener QD syntheses (*5*), cadmium-free QDs (*6*), biocompatible coatings that allow for QD-bioconjugates (*7*−*13*), reduction of nonspecific binding (*14*), and bioaffinity molecules attachment to improve the labeling specificity and cellular trafficking of QDs (*15*−*19*). Although there have been many examples of QD-based labeling of fixed cells and tissues and of cell surface proteins, there has been limited success with live cell imaging using QDs (*3, 4*). One major difficulty is the delivery of QD-bioconjugates into live cells intact, as QDs usually either aggregate within the cytoplasm due to the instability of their coating (*9*) or are trafficked to vesicles or endosomes (*3, 4*). Thus, there is a need to develop coatings that can protect QDs from aggregation within cells and facilitate endosomal escape (*12*).

Cationic cell-penetrating peptides are widely used as cell transfection reagents for delivering macromolecules, nanoparticles, and QDs (*20*−*36*). Commonly used peptides include TAT peptide (a nuclear localization signal (NLS) peptide derived from the HIV-1 transcriptional activator protein TAT), SV40 NLS peptide, and oligoarginine or other variants (*20*−*36*). There are various ways to prepare peptide-functionalized QDs (*31*−*36*), e.g., biotin−streptavidin linkage (*33, 36*), covalent coupling with a terminal cysteine residue (*34*), self-assembly of terminal oligohistidine (*35*), or ligand exchange with cysteine-terminated peptide (*32*). The self-assembly and ligand-exchange methods are simple and produce smaller particles (<10 nm), but the weak binding of the peptides results in QDs with poor colloidal stability. In comparison, the biotin−streptavidin or covalent coupling approaches produce larger particles (10−50 nm), but the peptides are tightly bound and the resulting particles have a greater colloidal stability (*33, 34, 36*). This difference in size and colloidal stability affects the QDs' performance in cell labeling and subcellular localization. For example, QDs functionalized with TAT and mitochondrial localization signal peptide, which are prepared via the ligand-exchange method, target the respective cell organelles when delivered by microinjection (bypassing endocytosis), but undergo aggregation in lysosomes when subjected to direct incubation (*32*). QDs functionalized with SV40 NLS peptide, which are prepared via biotin−streptavidin linkage with silica-coated QDs, target the nucleus and perinuclear region when introduced by endocytosis (*33*). TAT-QDs, which are prepared from covalent linkage with silica-coated QDs, label rat brain tissue when delivered intra-arterially (*34*). TAT peptide coated QDs, which are prepared by biotin−streptavidin linkage with polyacrylate-coated QDs, are internalized via macropinocytosis and localized in the perinuclear region (*36*). These examples illustrate that the coating method and peptide conjugation strategy have a strong influence on the cell labeling applications of QDs.

We have developed various coatings that could protect nanoparticles with either multidentate ligands or a cross-linked shell, encapsulating each particle within a covalent polymeric network (*37*−*43*). These shell−core particles were very stable under physiological conditions, such as in the presence of a high salt concentration and competitive ligands. They further allowed for the synthesis of a variety of bioconjugates using different linking chemistry. For cellular delivery applications, *N*-(3-aminopropyl) methacrylamide and [3-(2-aminoethylamino)propyl]trimethoxysilane have been used as coating precursors to produce water-soluble cationic particles. The polymeric backbones consisted of multiple primary and secondary amines, which could provide a "proton sponge effect" as in polyethyleneimine (PEI) (*12, 44*−*48*). Zeta potential measurement showed that these types of coatings provided positive surface charge over a wide range of pHs; the particle surface charge continuously increased as the pH decreased from 7 to 4, suggesting that the coatings induced a "proton sponge effect" (*39, 43*). Such coatings

were used in this work to derive TAT-QD conjugates for cell imaging. We prepared the QDs functionalized with TAT peptides by three different methods, direct ligand exchange of cysteine-TAT (TAT-$QD_{lig\ exch}$), and covalent conjugation of TAT with silica-coated QD (TAT-QD_{silica}) and polyacrylate-coated QD (TAT-$QD_{polyacrylate}$). Cellular interaction, uptake, and subcellular delivery varied significantly for the three TAT-QD systems. The smaller and less cationic TAT-$QD_{lig\ exch}$ showed significantly lower cellular uptake than TAT-QD_{silica} and TAT-$QD_{polyacrylate}$. TAT-$QD_{lig\ exch}$ and TAT-QD_{silica} were localized mainly in the perinuclear region, but TAT-$QD_{polyacrylate}$ did not display such specificity. This study demonstrated that particle size and surface coating played significant roles in the cell labeling with QDs.

EXPERIMENTAL SECTION

Materials. Igepal CO-520 (Sigma), *N*-(3-aminopropyl) methacrylamide hydrochloride (Polysciences), poly(ethylene glycol) monomethacrylate (cat no 16712, Polysciences), *N*,*N*′-methylene bisacrylamide (Alfa Aesar), ammonium persulfate (Alfa Aesar), *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (Alfa Aesar), and PEG thiol (MW = 5000, NEKTAR) were used as received. [3-(2-Aminoethylamino)propyl]trimethoxysilane (AEAPS) (Merck) and 2-[methoxy(polyethyleneoxy)propyl]trimethoxysilane (PEG silane) (Gelest) were used as received. Succinimidyl-[(*N*-maleimidopropionamido)tetraethylene glycol] ester (NHS-PEO_4-MAL) (Pierce) was used as received. TAT peptide with terminal cysteine group (CGRKKRRQRRR) with 95% purity was purchased from GenScript.

Synthesis of QDs. Shell−core ZnS-CdSe QDs were synthesized according to published procedures with minor modifications (*5*). The ZnS shell was grown at 220 °C in octadecene via the alternate injection of Zn stearate in octadecene and elemental S dissolved in octadecene. The QDs were purified of free ligands by repeated precipitation with ethanol and redispersion in toluene. They were finally redispersed in either toluene or a reverse micellar solution of Igepal in cyclohexane.

Synthesis of TAT-QDs by Ligand Exchange. 5−10 mg of purified QDs were dissolved in 2 mL of a reverse micellar system, which was prepared by mixing 1 mL of Igepal CO-520 with 9 mL of cyclohexane. Next, 50 μL of aqueous TAT peptides (10 mg/mL) were added, followed by 50 μL of aqueous tetramethylammonium hydroxide (0.1 M) to induce the ligand exchange. After 1 min of sonication and 5 min of vortexing, ethanol (1−2 mL) was added to disrupt the reverse micellar system, and the TAT-QDs were collected by centrifugation. The precipitate was washed twice with the reverse micellar solution and three times with ethanol, and then redispersed in pH 7.0 tris(hydroxymethyl)aminomethane (Tris) buffer. A similar ligand-exchange approach was used to prepare the PEG thiol coated QDs.

Synthesis of TAT-QDs from Silica-Coated QDs. Silica-coated QDs were prepared according to our earlier protocol (*39*) with two significant modifications. First, 3-mercaptopropyltrimethoxysilane, used as a linker silane earlier, was removed to prevent interparticle cross-linking by NHS-PEO_4-MAL during the peptide conjugation step. Second, the silanization medium was changed from pure toluene to a toluene−methanol mixture (volume ratio = 1:1) to ensure effective coating in the absence of 3-mercaptopropyltrimethoxysilane. Typically, 1 mL of toluene solution of QDs was mixed with 1 μL of AEAPS, 10 μL of PEG silane, and 1 mL of tetramethylammonium hydroxide in methanol (0.01 M). The resulting solution was stirred at 80 °C for 1 h. The particles were precipitated with toluene, washed several times with toluene and chloroform, and redispersed in pH 9.5 borate buffer (0.1 M).

For peptide conjugation, 1 mg of NHS-PEO_4-MAL was dissolved in 100 μL of *N*,*N*′-dimethylformamide (DMF), which was immediately added to the QDs and incubated at room temperature for 1 h. The product was purified using a desalting column (Sephadex G25), followed by the addition of 20 μL of 5 mg/mL of TAT peptides and overnight incubation at 4 °C. Finally, the particles were purified by overnight dialysis against deionized water using a membrane of 12−14 kDa molecular weight cutoff (MWCO). The solution of peptide-conjugated QDs was diluted with Tris buffer (pH 7.0) and stored at 4 °C.

Synthesis of TAT-QDs from Polyacrylate-Coated QDs. Ten milliliters of QD solution in a reverse micellar system of 1 mL of Igepal CO-520 and 9 mL of cyclohexane were prepared. The QD concentration was adjusted using the absorbance value of ∼0.5 at the first absorption maximum. *N*-(3-Aminopropyl) methacrylamide hydrochloride (17 mg dissolved in 100 μL of water), 60 μL of poly(ethylene glycol) monomethacrylate, and methylene bisacrylamide (3 mg dissolved in 200 μL of water with 10 min of sonication) were added and mixed with the QD solution. Next, 50−100 μL of tetramethyl ethylene diamine was added as a basic catalyst. The solution was optically clear. It was placed in a 50 mL three-necked flask and purged with nitrogen for 10 min. An ammonium persulfate solution (3 mg dissolved in 100 μL of water) was injected to initiate the polymerization, which was continued at room temperature for 1 h. The polyacrylate-coated QDs were then precipitated with a few drops of ethanol, washed with chloroform and ethanol, and redispersed in deionized water.

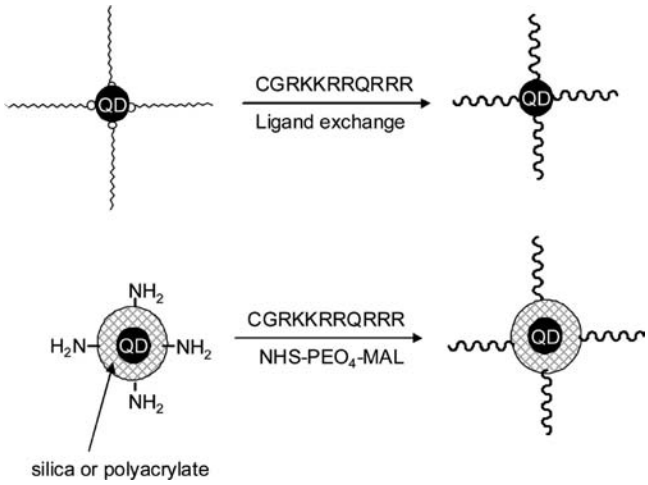
For peptide conjugation, the polymer-coated QDs were diluted with pH 9.5 borate buffer. The QD absorbance at the first absorption maxima was ∼0.2. Next, a freshly prepared DMF solution of NHS-PEO_4-MAL (1 mg dissolved in 100 μL of DMF) was added to the QDs and incubated at room temperature for 1 h. The product was purified using a desalting column (Sephadex G25), followed by the addition of 100 μL of 1 mg/mL of TAT peptide and overnight incubation at 4 °C. Finally, the particles were purified from free peptide by overnight dialysis against deionized water, using a membrane of 12−14 kDa MWCO. The solution of peptide-conjugated QDs was diluted with Tris buffer (pH 7.0) and stored at 4 °C.

Cell Labeling. The human hepatocellular carcinoma line HepG2 was cultured on 24-well plates in 0.5 mL/well of Dulbecco's Modified Eagle's Medium (DMEM) with 10% (v/v) fetal bovine serum (FBS) overnight. 10−100 μL of TAT-QD solution was added. After 2−24 h of incubation at 37 °C, cells were gently washed twice with phosphate buffered saline (PBS), and fresh cell culture medium was added. Cells were then observed with fluorescence microscopy (Olympus microscope IX71 with DP70 camera) using blue excitation. For confocal microscopy, the cells were cultured on glass cover slides placed at the bottom of the wells.

Flow Cytometry. Cells were first labeled with QDs after 1 h of incubation with different TAT-QDs. Cell were then washed with PBS and trypsinized to detach from the well plate. Next, cells were transferred into 15 mL centrifuge tubes containing ∼2 mL of complete media for trypsin inactivation. Cells were then separated by centrifuging at 1000 rpm for 5 min. Precipitated cells were collected after removing the supernatant and again resuspended in 2 mL of PBS for washing. The suspended cells were centrifuged again at 1000 rpm for 5 min. The cells precipitated were collected, resuspended in 1 mL of PBS, and used for flow cytometry analysis.

Cell Viability Study by MTT Assay. HepG2 cells were trypsinized and resuspended in DMEM culture medium. The cells were seeded to 96-well flat-bottom microplate in 100−200 μL of full DMEM culture medium and kept overnight at 37 °C and 5% CO_2. Next, various TAT-QDs of different concentrations were loaded to each well. After incubation for 20 h, 20 μL of MTT solution (5 mg/mL) were added to each well and incubated

Scheme 1. Synthetic Approaches Used in Preparing Three Different TAT-QD Systems



for 4 h. The medium was discarded by aspiration, and the formazan obtained was dissolved with 200 μL of dimethylsulfoxide (DMSO). The plates were read for absorbance at 550 nm. The optical density was directly correlated with cell quantity, and the cell viability was calculated by assuming 100% viability in the control set without any QDs.

Instrumentation. UV−vis absorption spectra were collected with Agilent 8453 spectrophotometer in a 1 cm quartz cell. Fluorescence spectra were obtained with Jobin Yvon Horiba Fluorolog fluorescence spectrometer. Dynamic light scattering (DLS) samples were first filtered through a Millipore syringe filter (0.2 μm pores) and then characterized with model BI-200SM instrument (Brookhaven Instrument Corporation). Particle surface charge was analyzed by ZetaPALS zeta potential analyzer (Brookhaven Instrument Corporation). Cell imaging was performed using Olympus microscope IX71 with DP70 digital camera. Confocal fluorescence imaging was performed using an Olympus Fluoview 300 confocal laser scanning system with 488 nm laser excitation. BD FACSCalibur flow cytometer (with four-color basic modular flow) was used to quantify cellular uptake. About 10 000−20 000 cells were examined for each sample.

RESULTS AND DISCUSSION

Synthesis and Characterization of TAT-QD Conjugate. Three methods were used to prepare TAT-conjugated QDs (see Scheme 1). In the ligand-exchange method, the hydrophobic ligands of the QDs were replaced by cysteine-terminated TAT peptide. To facilitate the ligand exchange, a reverse micellar medium was used to dissolve both the hydrophobic QDs and hydrophilic peptides, and ligand exchange took place smoothly and with minimal aggregation. The resulting particles were water-soluble, cationic, and stable in pH 7.0 Tris and PBS buffers for more than a week. However, partial precipitation was observed upon longer storage.

The silica- and polyacrylate-coated QDs were synthesized according to our earlier protocols (*39, 43*). For the silica coating, a mixture of AEAPS and PEG silane was polymerized in a toluene−methanol mixture in the presence of the hydrophobic QDs, replacing the hydrophobic ligands on the QDs with a thin, cross-linked and hydrophilic silica shell. A similar approach was used to prepare polyacrylate-coated QDs (*43*). The monomers *N*-(3-aminopropyl) methacrylamide, poly(ethylene glycol) monomethacrylate, and methylene bisacrylamide were dissolved in a reverse micellar solution of hydrophobic QDs, and polymerization was initiated with ammonium persulfate in an oxygen-free atmosphere, replacing the hydrophobic surfactant with a cross-linked hydrophilic polyacrylate shell. The particles prepared via both methods were water-soluble, buffer-stable, and cationic due to the amines on their surfaces. The TAT peptides were conjugated to the silica- and polyacrylate-coated QDs using a bifunctional NHS-PEG-MAL reagent. The NHS ester reacted with the primary amines on the silica and polyacrylate coatings, while MAL reacted with the thiol of the terminal cysteine of the peptide.

Figure 1 and Table 1 show the sizes of the three different TAT-QD systems. Transmission electron microscopy (TEM) reflected minimal particle aggregation after the coating, ligand exchange, and peptide conjugation processes. It illustrated that the QD core size remained the same (~4 nm) for all three TAT-QD systems. DLS showed a significant variation in their hydrodynamic diameters due to the different coating thicknesses. The low molecular weight TAT ligand increased the diameter of the QD by only 2−3 nm. In contrast, the particle diameter was increased by 6 and 21 nm due to the silica coating and polyacrylate coating, respectively. Particle size distribution was broadened after the silica coating and polyacrylate coating. Surface charge was positive for all three TAT-QD systems. It was lowest for TAT-$QD_{lig\ exch}$ and highest for TAT-$QD_{polyacrylate}$. The difference in surface charge was due to the combined effect of particle size, nature of coating, and number of TAT ligands bound to each QD. The lower positive surface charge of $QD_{lig\ exch}$ was possibly due to the lower surface area available for TAT adsorption on this smaller QD. In contrast, silica and polyacrylate coatings introduced positive surface charges (from amine functional groups) and provided access for multiple TAT conjugation on each QD, which further increased the overall surface charge. From our earlier work (fluorescamine titration to estimate the number of primary amines per particle (*38*)), 50−100 primary amines were estimated per particle (for silica- and polyacrylate-coated QDs), and only a fraction of these would be used for peptide conjugation (since conjugation was not 100% efficient). For ligand-exchanged QDs, several tens of peptides were estimated per particle, assuming that thiolated peptides were adsorbed on the surface of the 4 nm QDs.

The cell viability of various TAT-QDs was tested using HepG2 cells via standard MTT assay. We found that at QD concentrations of 20−40 nM, the cell viability (after 24 h) was up to 75% for silica- and polyacrylate-coated QDs, but was only 20% for ligand-exchanged QDs.

Cell Labeling with TAT-QDs. The cell labeling was studied using the human hepatocellular carcinoma line, HepG2. Different experimental conditions such as temperature, QD concentration, and incubation time were tested in order to optimize the labeling conditions. As QD uptake was very low at 4 °C, all uptake experiments were conducted at 37 °C. TAT functionalization significantly increased QD uptake for three types of coated QDs (Figures 2−5). We also found that the surface coating affected the internalization traffics. All three types of TAT-QDs attached to the cell surface within 15 min began to enter the cytoplasm in the next 1−2 h, and were trafficked to the endosome. In the next 2−8 h, the ligand-exchanged QDs and silica-coated QDs (Figure 4) entered the perinuclear region. However, the polyacrylate-coated QDs did not show further movements.

A quantitative study of cellular interaction was performed with flow cytometry (Figure 2). Control experiments were conducted with QDs without TAT conjugation, i.e., PEG thiol coated QD ($QD_{lig\ exch}$), silica-coated QD, and polyacrylate-coated QD. Control QDs were tested over a wide range of concentrations (5−100 nM). QDs without any surface-bound TAT displayed a significantly lower uptake, irrespective of the coating type. This was likely due to the presence of PEG on the QD

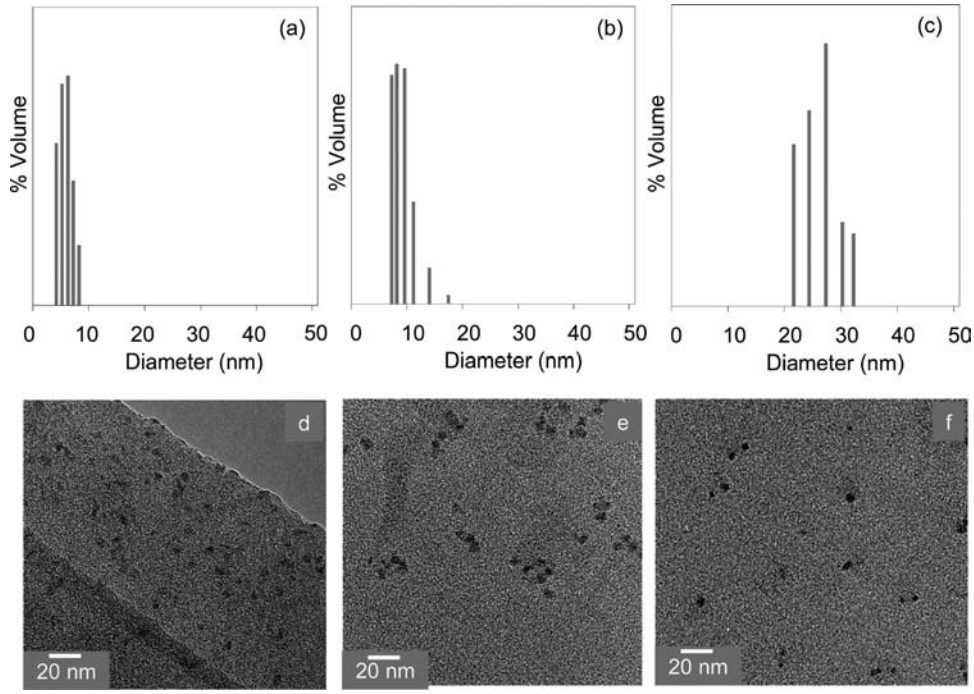


Figure 1. (a−c) DLS analyses and (d−f) TEM images of (a,d) TAT-$QD_{lig\ exch}$, (b,e) TAT-QD_{silica}, and (c,f) TAT-$QD_{polyacrylate}$.

Table 1. Characteristics of Three Different TAT-QD Systems

TAT-QD System	DLS particle size (TEM QD Size) (nm)	surface charge (mV)	cellular uptake (subcellular localization)
TAT-$QD_{lig\ exch}$	6 ± 2 (4 ± 1)	+8	low (perinuclear region)
TAT-QD_{silica}	10 ± 3 (4 ± 1)	+16	moderate (perinuclear region)
TAT-$QD_{polyacrylate}$	25 ± 5 (4 ± 1)	+35	high (perinuclear region and lysosome)

surface. Nonspecific uptake increased at higher QD concentrations; thus, subsequent experiments were performed in the concentration range of 5−40 nM.

Although TAT functionalization increased the cellular interaction and uptake of QDs, the percentage uptake and subcellular localization varied for different TAT-QD systems. The uptake of TAT-QDs increased from 5% to 50−90% as the QD concentration increased from 5 nM to 40 nM. TAT-$QD_{polyacrylate}$ and TAT-$QD_{lig\ exch}$ showed the highest uptake and the lowest uptake, respectively, at a given QD concentration.

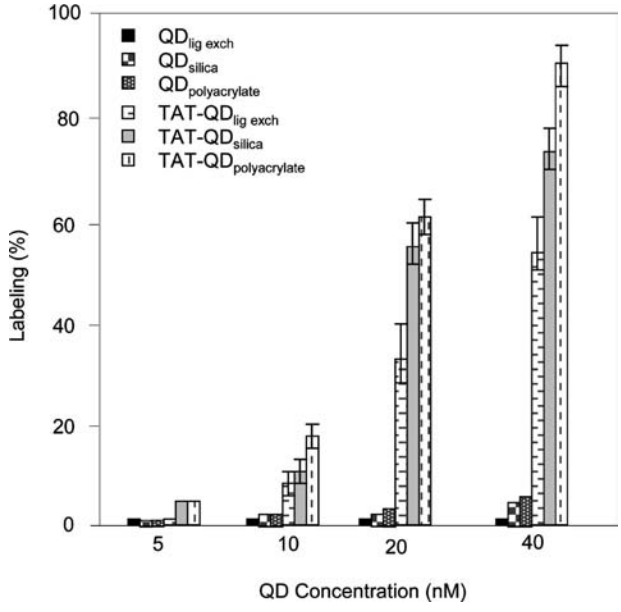

Figure 2. Flow cytometry quantification of the labeling of HepG2 cells by QDs and TAT-QDs.

Subcellular localization of QDs was investigated using confocal microscopy, and colocalization was studied with the nuclear Hoechst dye and the lysosomal dye lysotracker red, where necessary. The colocalization study was performed after overnight incubation of QDs with cells, followed by 5−10 min of incubation with Hoechst dye and lysotracker red. Subcellular localization clearly varied for different TAT-QD systems (Figures 3−5). TAT-$QD_{lig\ exch}$ and TAT-QD_{silica} were localized mainly in the perinuclear region, but TAT-$QD_{polyacrylate}$ was localized in both the lysosome and the perinuclear region. In addition, we observed that TAT-$QD_{lig\ exch}$ was more toxic, and since perinuclear labeling required longer incubation time (8−24 h), such labeling was difficult to achieve with the toxic TAT-$QD_{lig\ exch}$. In contrast, the less toxic TAT-QD_{silica} could be used for perinuclear labeling with >80% labeling efficiency.

Effect of Coating on QD-based Cell Labeling. TAT peptide has been used in the intracellular delivery of macromolecules, nanoparticles, and QDs (*22*−*36*). It generally enhances the cargo uptake and, in certain cases, causes it to localize in the perinuclear region. The delivery process starts with the binding of TAT to the plasma membrane due to its highly cationic nature associated with the arginine and lysine residues (*20, 28*). Arginine differs from other cationic amino acids, as it can make strong bidentate hydrogen bonds with sulfate, phosphate, and carboxylate anions via its guanidium group (*20, 28*). This feature leads to many possible interactions of TAT with the cell membrane, such as with the acidic regions of proteins, sulfated glycans, membrane phospholipid head groups, or a combination of these. Such interactions are responsible for the enhanced cellular interaction of TAT-QDs, as well as their membrane translocation.

We noted that the uptake of TAT-QDs was significantly reduced at 4 °C, as observed for other TAT-conjugated cargos,

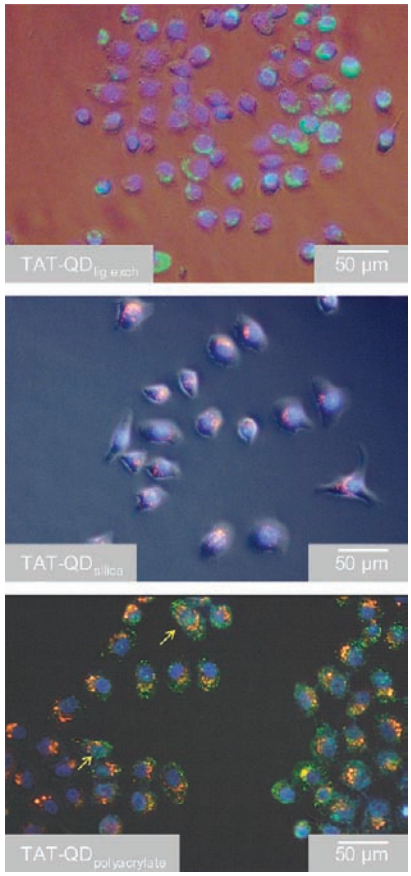

Figure 3. Fluorescence micrographs of TAT-QD labeled HepG2 cells. Green QDs were used for the TAT-QD$_{lig\ exch}$ and TAT-QD$_{polyacrylate}$ systems, and orange QDs were used for the TAT-QD$_{silica}$ system. Cell nucleus was colocalized with Hoechst 33342 dye (blue) in all cases. For TAT-QD$_{polyacrylate}$, the lysotracker red was used to label lysosome, in addition to the Hoechst dye. A QD concentration of 20 nM and an incubation time of 12 h were employed for all cases.

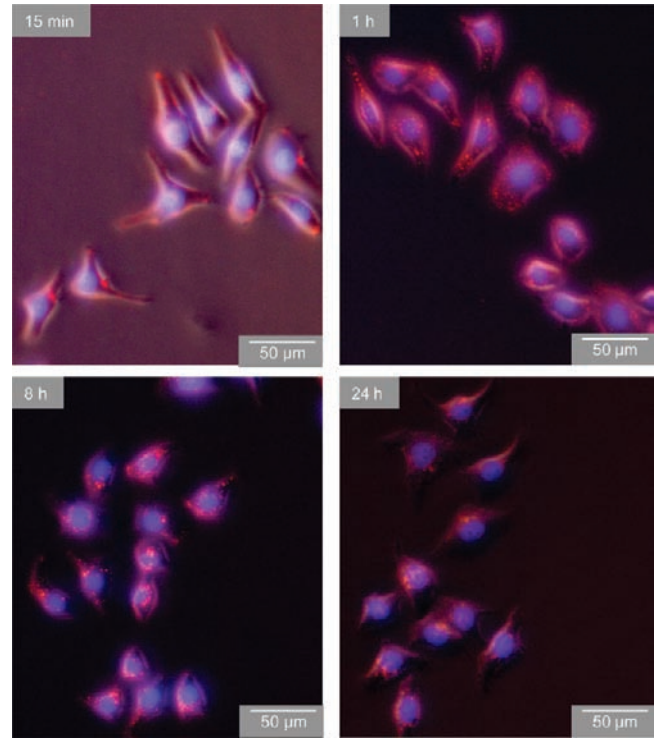

Figure 4. Fluorescence micrographs of TAT-QD$_{silica}$ labeled HepG2 cells, showing the time-dependent migration of QDs toward the nucleus. Cell nucleus was colocalized with Hoechst 33342 dye (blue) in all cases. A QD concentration of 20 nM was employed.

suggesting that the uptake was an active process (*28*). A variety of endocytic routes has been suggested earlier for TAT-mediated cargo delivery, such as caveolae-mediated endocytosis of TAT-protein and localization in the perinuclear region via actin cytoskeleton-mediated mechanism (*25*), clathrin-mediated endocytosis of TAT-peptide (*27*), lipid raft dependent macropinocytosis of TAT-protein (*26*), and macropinocytosis-directed uptake of TAT-QD via vesicle generation from plasma membrane, followed by active transport of QD-containing vesicle from cell periphery to the perinuclear region (*36*).

The cargo size and nature, surface charge of TAT-cargo conjugate, and nature of cell are important factors determining the endocytic pathway taken. Earlier studies showed that the endocytosis mechanism is particle size dependent (*49*, *50*). Clathrin- and caveolin-dependent endocytosis usually occurs with <200-nm-sized particles, while macropinocytosis takes place with larger particles (*50*). This is because of the larger size of macropinosomes compared to other endocytic vesicles (*28*,*49*). Size effect is also reported for TAT-mediated cargo delivery. For example, TAT-conjugated proteins of <10 nm have access to cytoplasm and would eventually enter the cell nucleus (*25*). In contrast, TAT-conjugated gold nanoparticles and QDs of >10 nm are trapped in vesicles, and their entry to nuclei is significantly restricted (*30*, *36*). Our results demonstrated that particle size has a significant role in cellular uptake and subcellular delivery. The three coating methods led to three different particle sizes with different overall surface charges. With increase in particle size from 6 to 25 nm, the surface charge also increased. This resulted in a combined effect in cellular uptake and subcellular delivery. The TAT-QD$_{lig\ exch}$ has a low positive charge and, thus, a lower cell uptake, but it could successfully reach the perinuclear region due to its smaller particle size. However, TAT-QD$_{lig\ exch}$ has less colloidal stability due to the weak adsorption of the peptide, and appeared more cytotoxic. TAT-QD$_{silica}$ has a higher positive charge, and thus a stronger cell interaction and a higher cell uptake; it could also reach the perinuclear region due to its small particle size. In contrast, TAT-QD$_{polyacrylate}$ has the highest positive charge, and thus a very strong interaction with the cell surface and a very high cell uptake. However, it was mostly trapped in the endosome and could not reach the perinuclear region. It was difficult to conclude how far the coating helped in the endosomal escape for TAT-QD$_{silica}$. Although most of the earlier studies showed that QDs were trafficked to endosomes and limited subcellular targeting (*3*, *4*), our TAT-QD$_{silica}$ successfully reached the perinuclear region. The time-dependent labeling study showed that TAT-QD$_{silica}$ was aggregated within the cell in 1 h and later migrated to the perinuclear region (Figure 4). This suggested a slow release mechanism of QD via endosomal escape, which might be affected by the coating. While TAT-QD$_{polyacrylate}$ was coated similarly, its larger size might have hindered the release of its aggregates.

CONCLUSION

We have synthesized TAT-functionalized QDs by different coating approaches, ligand exchange, silica coating, and polyacrylate coating, for cell labeling. The cellular uptake and subcellular localization were coating-dependent. Different coating methods produced TAT-QDs of different sizes and surface charges, which affected their cellular interaction and delivery. Smaller particles have lower cationic surface charge and cell uptake but a significant subcellular targeting specificity. In contrast, larger particles have a highly positive surface charge

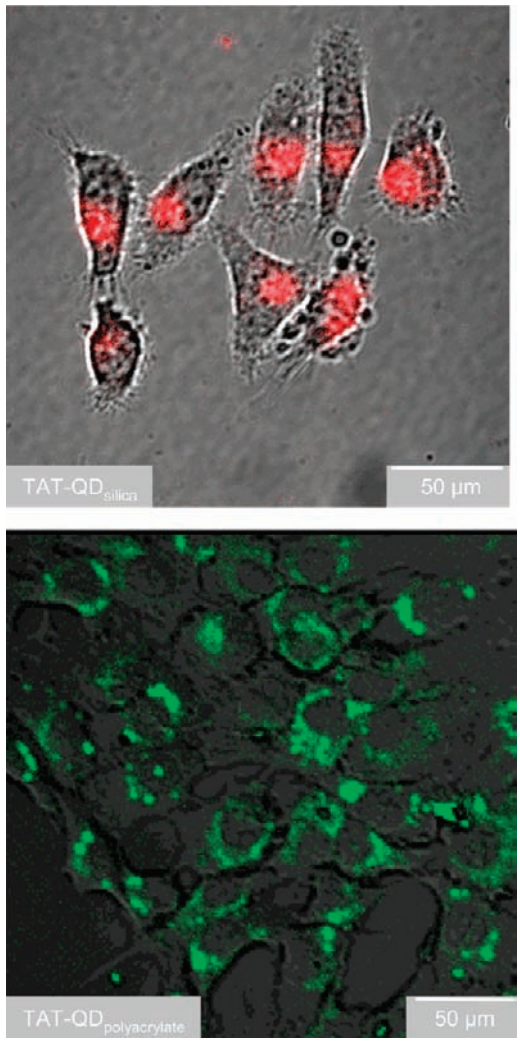

Figure 5. Confocal micrographs of HepG2 cells labeled with TAT-QD$_{silica}$ (top panel) and TAT-QD$_{polyacrylate}$ (bottom panel), showing different subcellular localization of QDs. A QD concentration of 20 nM and an incubation time of 12 h were employed for both cases.

and a high cell uptake, but a lower nuclear localization due to significant endosomal trafficking.

ACKNOWLEDGMENT

The authors would like to thank Dr. Jiang Jiang for TEM characterization. This work was supported by the Institute of Bioengineering and Nanotechnology (Biomedical Research Council, Agency for Science, Technology and Research, Singapore).

Promotion of Angiogenesis by an Artificial Extracellular Matrix Protein Containing the Laminin-1-Derived IKVAV Sequence

Makiko Nakamura,[†] Kumiko Yamaguchi,[‡] Masayasu Mie,[†] Makoto Nakamura,[§] Keiichi Akita,[‡] and Eiry Kobatake*,[†]

Department of Biological Information, Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology, Graduate School of Medicine and Dentistry, Tokyo Medical and Dental University, and Department of Biomedical Engineering, University of Toyama. Received March 20, 2009; Revised Manuscript Received July 7, 2009

The laminin-1-derived IKVAV sequence is known for its angiogenic function. We previously developed artificial extracellular matrix (ECM) proteins containing the IKVAV sequence. They were designed to have collagen-binding activity and active functional units that promote network formation of vascular endothelial cells. The resultant fusion protein, called EREI2CBD, was confirmed to bind to collagen type I and promote tubular network formation of endothelial cells cultured in collagen gel *in vitro*. In this study, EREI2CBD was applied to the chick chorioallantoic membrane (CAM) assay to investigate *in vivo* angiogenic activity. The CAM assay results showed that EREI2CBD caused the number and area of vascular branches to be increased. The constructed fusion protein and the engineering strategy of designing multifunctional ECM proteins support current tissue engineering techniques.

INTRODUCTION

In recent years, much attention has been focused on tissue engineering techniques to provide artificial tissue substitutes as an alternative for donor tissue and organs. Scaffold material is one of the essential factors for tissue engineering to support cell attachment and provide necessary signals for cell growth and organization.

In a previous study, we developed artificial extracellular matrix (ECM) proteins designed to have a stable structural unit and active functional units that promote cell attachment and network formation of vascular endothelial cells (*1*). To achieve that purpose, we constructed new fusion proteins with multiple activities of (i) cell adhesion, (ii) promoting tubular network formation, (iii) structural support, and (iv) affinity to collagen. As a functional part of these fusion proteins, the Ile-Lys-Val-Ala-Val (IKVAV) peptide sequence, located in the laminin α1 chain, was chosen as it has a variety of activities including promoting cell adhesion, neurite outgrowth (*2*), and angiogenesis (*3, 4*). An elastin-derived (APGVGV) motif was also adapted to produce a stable matrix protein. This polypeptide module had been studied in our laboratory as an artificial matrix protein and enabled the short active peptides such as IKVAV or GRGDS to work efficiently as a scaffold protein (*5*−*7*). The resultant protein was illustrated in Figure 1, shown as EREI2. The EREI2 fusion protein was constructed with recombinant DNA technology to conjugate the functional peptide sequences and the rigid poly (APGVGV) module. EREI2 was designed to be two repeats of $(APGVGV)_{12}$, RGD, $(APGVGV)_{12}$, and the IKVAV sequence because the activity of the smaller molecule (EREI) was shown to be less than EREI2 (*1*). As the GRGDS-IKVAV conjugated peptide was reported to have stronger cell-adhesive property than the IKVAV sequence (*8*),

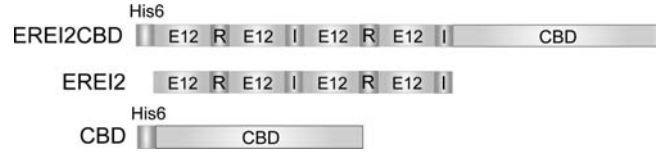

Figure 1. Construction of artificial ECM. (A) E12 means 12 repeats of the elastin-derived APGVGV sequence. R and I indicate the GRGDS sequence derived from fibronectin and the laminin-derived CS-RARKQAASIKVAVSADR sequence, respectively. Collagen-binding domain (CBD) was derived from fibronectin and fused to the C-terminus of the engineered protein. CBD and CBD-fused EREI2 had a histidine tag on their N-terminus.

GRGDS sequence was incorporated into EREI2 to enhance the interaction between cells and the scaffold. Furthermore, we introduced collagen-binding activity into the designed ECMs in order to enable the accumulation of ECM onto specific scaffold materials. Since collagen is biocompatible and is easily processed into several shapes such as membrane, gel, or sponge, it is considered to be a useful material for tissue engineering. Collagen-immobilized forms of engineered ECMs have the potential to provide a safe and functional angiogenesis model for enhancing the activity of necessary signals locally and effectively.

Here, we focused on the collagen-binding domain (CBD) of fibronectin (*9*). CBD sequences are widely used as fusion partners for chimera proteins, as they provide the option for localized application on collagen (*10*−*12*). The resultant collagen-specific, immobilized fusion ECM, called EREI2CBD, promoted angiogenic properties in a collagen type I gel model (*1*). Therefore, EREI2CBD promoted capillary formation of endothelial cells and revealed its potential to produce multifunctional artificial ECM. However, the *in vivo* angiogenesis process was dissimilar to an *in vitro* collagen gel model, and therefore, the application of EREI2CBD under *in vivo* conditions required further investigation.

In the present study, the angiogenic activity of EREI2CBD was determined using a chick chorioallantoic membrane (CAM) assay. The CAM assay is a simple technique for investigating

angiogenic behavior *in vivo* (*13*−*15*). EREI2CBD was immobilized on a permeable collagen membrane and the membrane was applied onto CAMs with a glass coverslip. Angiogenic activity, that is, growth of capillary vessels, was then investigated.

EXPERIMENTAL PROCEDURES

Materials. The artificial fusion ECMs, EREI2, EREI2CBD, and CBD were prepared as described in a previous study (*1*). The 19-mer peptide, CSRARKQAASIKVAVSADR, which we refer to as the IKVAV peptide, was synthesized by a solid-phase method using Fmoc. Permeable atelocollagen membrane (MEN-01) was purchased from Koken Co. Ltd. (Tokyo, Japan). All other chemicals were of analytical grade.

Preparation of Artificial Proteins Immobilized on a Collagen Membrane. Permeable atelocollagen membrane was cut into appropriate sizes, soaked with phosphate buffered saline (PBS), and put onto 13-mm-diameter glass coverslips (Thermo Fisher Scientific Inc.). After drying at room temperature, 2 μg of artificial proteins in PBS was added onto the membrane and dried again at room temperature. For the experiment described in the Results section "Concentration-dependent angiogenic behavior of EREI2CBD", EREI2CBD was applied at 0.5−2 μg. Negative control samples contained 20 μL of PBS only. Membranes adhering onto coverslips were stored at 4 °C until use.

Determination of Diffusion of CBD-Fused ECMs from the Collagen Membrane. Atelocollagen membranes immobilized with artificial proteins such as EREI2 and EREI2CBD were prepared as described above. Membrane-adhering coverslips were placed into each well of 24-well culture plates (Falcon), and 300 μL of PBS was added. After 3 h of incubation at 37 °C, 150 μL of supernatant PBS was sampled. Whole protein concentrations desorbed into bulk PBS were determined with the micro BCA protein assay kit (Pierce). Concentrations were calculated after subtraction of negative control membranes soaked with PBS only. Each assay was repeated three times.

Chick Chorioallantoic Membrane Assay. The chick chorioallantoic membrane (CAM) assay was performed using embryonated eggs. On embryonic day 3, 4 mL of ovalbumin was removed from each egg. After opening windows on embryonic day 10, glass coverslips with the protein-treated atelocollagen membrane were placed membrane side face-down onto the surface of the CAM and photographed. Two days later, glass coverslips were cut off together with egg membranes and photographed after washing with PBS. The mortality rate of the embryos supplied with each sample was calculated as the ratio of dead embryos to the sum of three repeated experiments. Quantitative evaluation of vessel areas was performed by determining the number of black pixels per field using Scion image software (Scion Corp.) and by manually counting the number of vessel branches. These numbers were calculated from the whole area of glass coverslips pictured at 0 and 48 h. Each assay was repeated three times using 8 to 12 eggs for each treatment.

Statistical Evaluation. Statistical significance of the results was determined using Student's *t* test. A value of $P < 0.05$ was considered to be significant. Mean ± standard deviation (s.d.) values of three experiments are presented.

RESULTS

Immobilization of CBD-Fused ECM to a Collagen Membrane. The previously constructed artificial ECM proteins (*1*) are illustrated in Figure 1. The EREI2 fusion protein consisted of two repeats of $(APGVGV)_{12}$, RGD, $(APGVGV)_{12}$, and the IKVAV sequence. Fibronectin-derived collagen-binding domain (CBD) and CBD-fused EREI2 were designed to immobilize the fusion construct onto the collagen-based material. CBD-fused ECM and CBD also contain a histidine tag sequence (His6) at their N terminals to aid purification.

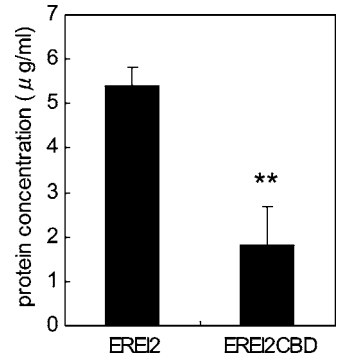

Figure 2. Determination of diffusion of ECMs from the atelocollagen membrane. Two micrograms of constructed ECMs were air-dried onto atelocollagen membranes and incubated in PBS for 3 h at 37 °C. Results show the diffused protein concentration into PBS. Each experiment was repeated 3 times. Error bars represent the standard deviation of the mean. $^{**}P < 0.01$.

Table 1. Mortality Rate of Chick Embryos Treated with Engineered Proteins

	amount (μg)	mortality rate
PBS		0/33
IKVAV pep.	2	0/26
CBD	2	1/26
EREI2CBD	0.5	2/33
	1	1/29
	2	0/31
	5	8/30

To confirm the localization of CBD-fused ECM on collagen membranes, EREI2 and EREI2CBD were fixed onto the membrane by air-drying, and then the amount diffused from the membranes was determined after 3 h of incubation in PBS. The results are shown in Figure 2. A higher protein concentration was detected in PBS from the EREI2-immobilized membrane than that of EREI2CBD, suggesting that more EREI2CBD remained fixed onto the collagen membrane than EREI2. We then confirmed EREI2CBD binding to the collagen membrane and determined its potential to function locally under *in vivo* conditions.

Concentration-Dependent Angiogenic Behavior of EREI2CBD. For the assessment of angiogenic behavior of EREI2CBD, serial amounts were immobilized on the collagen membrane and applied to the CAM assay. The CAM assay was performed as described in previous reports with some modifications for the collagen membrane (*16, 17*). The mortality rate of chick embryos supplemented with EREI2CBD is shown in Table 1. Since the negative control PBS samples survived the 2 day incubation, it was confirmed that our CAM assay protocol itself did not influence chick embryo survival. Table 1 also indicates that EREI2CBD did not significantly affect embryo mortality at concentrations ranging from 0.5 μg to 2 μg. In contrast, when 5 μg of EREI2CBD was applied, nearly 30% of embryos died after 2 days. The mortality table shows that high amounts of EREI2CBD could not be applied to our CAM assay and 5 μg of EREI2CBD was the limit for chick embryo survival. All subsequent experiments on capillary vessel formation were performed at concentrations ranging from 0.5 μg to 2 μg.

In our present study, angiogenesis was evaluated with two indexes, the vessel area and the number of vessel branches. The results are shown in Figure 3. Increases of vessel area in chick embryos were calculated from the black pixel ratio at 48 h compared to 0 h (Figure 3A). This indicated that 0.5 and 2 μg of EREI2CBD significantly increased vessel area. Vascular

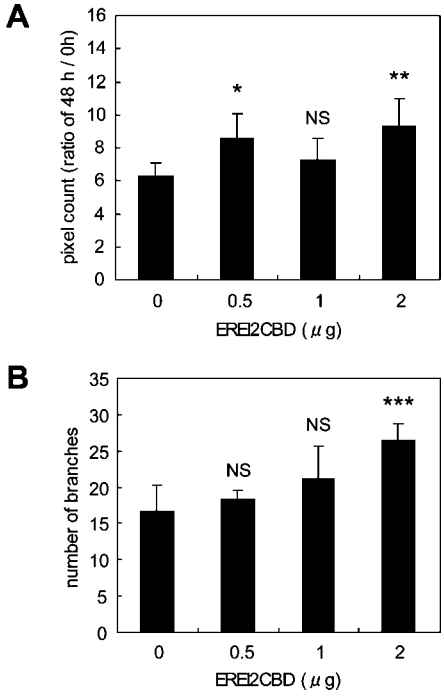

Figure 3. Angiogenic behavior of EREI2CBD. EREI2CBD was air-dried at the indicated concentrations onto atelocollagen membranes and applied to the CAM assay. Zero means the control sample with PBS alone. (A) Quantitative evaluation of vessel areas by determining the number of black pixels per field. The number of black pixels was calculated within the whole area of glass coverslips imaged at 0 and 48 h. Results show the ratio of pixel counts at 0 to 48 h. (B) The number of vessel branches after 48 h of incubation. Each experiment was repeated 3 times. Error bars represent the standard deviation of the mean. NS, not significant; $*P < 0.05$, $**P < 0.01$; $***P < 0.001$ compared to the PBS control sample (referred to as zero).

sprouting, an important factor for the angiogenic process, was evaluated by counting the number of vessel branches. The number of branches after 2 days was increased in a concentration-dependent manner and was significantly increased in the case of 2 μg EREI2CBD (Figure 3B). Therefore, EREI2CBD promoted vascular sprouting in an angiogenesis assay.

From the results of Table 1 and Figure 3, the angiogenic properties of EREI2CBD were confirmed in the CAM assay. The optimal amount of EREI2CBD was determined to be 2 μg, as this concentration did not significantly affect survival of the chick embryos but induced angiogenic activity. In the subsequent experiments, 2 μg of EREI2CBD was applied for further determination of angiogenic ability.

Determination of the Angiogenic Activity of EREI2CBD. The angiogenic activity of EREI2CBD was compared using the same amounts of CBD protein or IKVAV synthetic peptide. Two micrograms of CBD protein or IKVAV synthetic peptide were shown to be harmless to chick embryos (Table 1). Figure 4A indicated that the capillary vessel network was more complex when EREI2CBD was applied to CAM. The morphology of vessels was similar in PBS and IKVAV peptide treated CAMs. CBD caused an increase of vascular thickness, but EREI2CBD showed the greatest increase in the number of vascular branches. Quantitative results of angiogenic activity are shown in Figure 4B,C, and these corresponded to the above observations. The vessel areas of CBD- or EREI2CBD-treated CAMs were greatly increased compared to PBS and IKVAV peptide-treated CAMs (Figure 4B). CBD also increased the number of vascular branches compared to PBS. EREI2CBD further increased vascular branching, and this was significantly more than CBD-treated CAMs (Figure 4C).

Throughout the results, the angiogenic activity of EREI2CBD was confirmed. Although CBD showed some angiogenic properties such as increased vessel area, EREI2CBD was superior to CBD in promoting vessel sprouting. Therefore, the CBD-fused form of EREI2 is a promising approach for promotion of angiogenesis.

DISCUSSION

In the present study, we have determined the angiogenic properties of an artificial multifunctional extracellular matrix (ECM) protein. This novel ECM protein, referred to as EREI2CBD, was previously constructed by fusing functional peptide sequences derived from existing ECM proteins (*1*). We arranged two well-known active sequences with $(APGVGV)_{12}$ to construct ECMs that had strong cell-adhesive properties and the ability to induce cellular network signals. The sequences we focused on were GRGDS and CSRARKQAASIKVAVSADR. The latter IKVAV-containing sequence was reported to promote endothelial cell migration and tubular network formation (*3, 4*) through the interaction of an unknown receptor on the cellular surface. EREI2CBD also had a collagen-binding domain (CBD) fused to its C-terminus, and the CBD part enabled the fusion protein to be immobilized onto collagen. Since fixed forms of functional proteins such as growth factors could function locally, they have been recently reported to work more efficiently than their free forms (*12*). Furthermore, collagen is a well-known biocompatible material that has given satisfactory results for tissue regeneration (*18, 19*). Therefore, we focused on the collagen-immobilized form of the designed fusion protein for construction of an efficiently functioning ECM protein. We used atelocollagen-based material as it is free of immunogenicity as terminus telopeptides have been digested (*20, 21*). The CAM assay was performed with an EREI2CBD-immobilized atelocollagen membrane for assessment of angiogenesis *in vivo*.

Collagen-specific binding of EREI2CBD was confirmed by an ELISA assay using collagen type I-coated microplates in our previous study (*1*). Here, it was determined whether EREI2CBD could be fixed onto collagen membranes for *in vivo* applications. By determining the amount of atelocollagen diffused from the membrane into PBS (Figure 2), it was revealed that more EREI2CBD remained on the membrane than EREI2. After 3 h of incubation, only 0.6 μg of EREI2CBD (30% of the applied amount) was detected in PBS while 1.8 μg of EREI2 (90% of the applied amount) was released. The diffusion rate of EREI2CBD was much lower than EREI2, and EREI2CBD was confirmed to be immobilized onto the atelocollagen membrane. Therefore, the CBD part of the constructed ECM functioned as an anchor to atelocollagen-based material, and EREI2CBD was determined to have the potential to work efficiently in its localized form.

Next, EREI2CBD was applied to an *in vivo* angiogenic model, the CAM assay, and the optimized amount to evaluate its angiogenic ability was determined. The CAM assay is a well-known angiogenic model (*13*−*15*). Kleinman et al. introduced the CAM assay for assessment of anticancer drugs such as functional peptides (*16, 17*). Along with these previous reports, we examined the angiogenic properties of EREI2CBD using the CAM assay. Our first concern was biocompatibility of EREI2CBD. The designed fusion protein, EREI2CBD, was produced by means of recombinant DNA technology and *E. coli* fermentation. According to the related work reported by Urry et al. (*22*), high levels of purification were required so that *E. coli*-expressed recombinant proteins could be used *in vivo*. They tried to remove trace amounts of *E. coli* proteins by a series of purification steps. In contrast (*22*), EREI2CBD was purified with a simple single step. The mortality table (Table 1) indicated that a high concentration of EREI2CBD was fatal

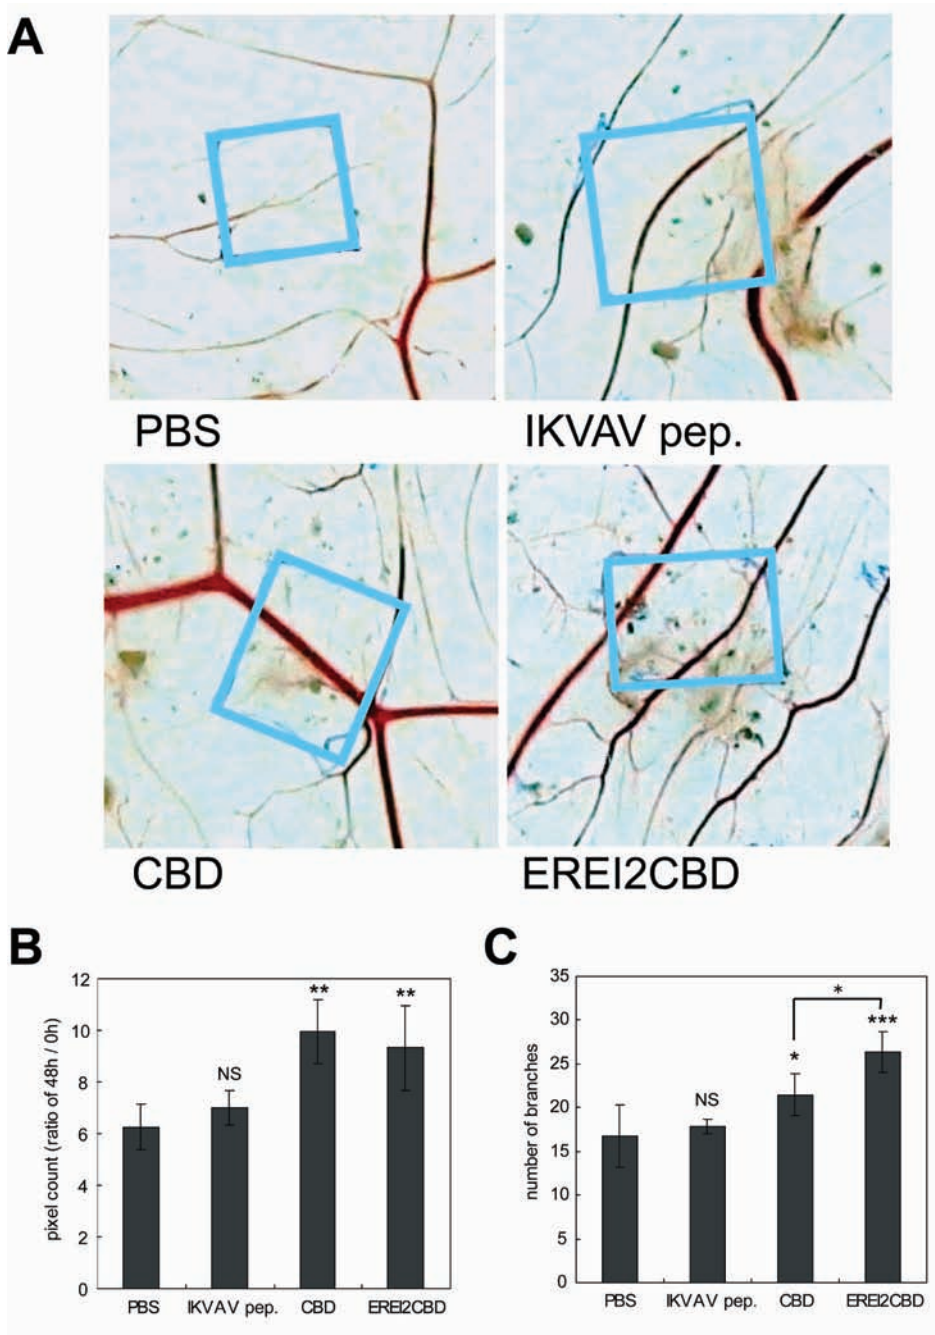

Figure 4. Angiogenic activity of EREI2CBD. Two micrograms of IKVAV synthetic peptide, CBD, or EREI2CBD were air-dried onto atelocollagen membranes and applied to the CAM assay. (A) Morphologies of capillary vessels treated with each sample. The squares indicate the position of the atelocollagen membrane. Each photo was pictured after 48 h of incubation. (B) Quantitative evaluation of vessel areas. The number of black pixels was calculated within the whole areas of glass coverslips imaged at 0 and 48 h. Results show the ratio of pixel counts at 0 to 48 h. (C) The number of vessel branches after 48 h incubation. Each experiment was repeated 3 times. Error bars represent the standard deviation of the mean. NS, not significant; $*P < 0.05$, $**P < 0.01$; $***P < 0.001$ compared to the PBS sample.

to chick embryos, which might be due to remaining harmful substances derived from *E. coli* cell lysates such as endotoxins (*23*). Table 1 showed that EREI2CBD should be applied at concentrations less than 5 μg. In the future, high levels of purity are required before pharmaceutical use of EREI2CBD.

To determine the angiogenic behavior of EREI2CBD, two semiquantitative methods were used (Figure 3). One was to determine the number of black pixels per field, a value that represented the vessel area of samples. The other method was to count the number of capillary vessel branches to evaluate the development of a vascular network. From the results of Figure 3B, the increase in the number of vessel branches was dependent on EREI2CBD concentration. EREI2CBD promoted cardiovascular sprouting and generation of neovessels. The laminin-1-derived IKVAV sequence included in EREI2CBD has been reported to affect endothelial migration, which is the first important process of angiogenesis (*3, 4*). Therefore, the CAM assay results suggested that EREI2CBD could retain the angiogenic properties of the functional peptide sequence in *in vivo* conditions. Furthermore, promotion of vessel sprouting caused an increase in vessel area, especially when 2 μg of EREI2CBD was added (Figure 3A). Figure 3 results showed the angiogenic function of EREI2CBD, and 2 μg was applied to all subsequent experiments.

To further analyze EREI2CBD angiogenic activity, EREI2CBD was compared to the IKVAV synthetic peptide and CBD protein

(Figure 4). For the IKVAV peptide, no effect was observed in either vessel area or the number of branches compared to a PBS control. Previous reports showed angiogenic activity of the IKVAV sequence using concentrations of 200 μg (*3, 4*), while only 2 μg was used in our present study. Therefore, the concentration of synthetic IKVAV peptide was too low to affect angiogenic activity. Since short IKVAV peptide sequences included in EREI2CBD were stably supported with a rigid $(APGVGV)_{12}$ scaffold and localized onto a collagen membrane, they may interact with the cellular surface more efficiently. Furthermore, the poly(APGVGV) sequence itself was reported to promote cell migration and may enhance the angiogenic effect of the IKVAV peptide (*24, 25*). Therefore, the EREI2CBD peptide was superior to synthetic IKVAV peptides for inducing angiogenesis, and our collagen-binding artificial ECMs were functional at lower concentrations than synthetic peptides, as expected.

In contrast to the IKVAV peptide, CBD itself showed some angiogenic effects compared with the PBS control. Vessel area was increased by the CBD protein at the same ratio as EREI2CBD, although the increase of vessel branches by CBD was inferior to that of EREI2CBD. CBD was determined to have cell adhesive activity and promoted tube formation of endothelial cells *in vitro* in our previous study (*1*). Those results suggested that CBD increased the thickness of capillary vessels through promotion of endothelial cell attachment and migration. The CBD sequence adopted here was Ala260-Trp 599 of fibronectin (*9*), and recently, Schor et al. reported that some Ile-Gly-Asp (IGD) peptide motifs included in this CBD sequence had cell adhesive ability and motogenic activity (*26, 27*). These reports correspond with our results and suggest that CBD plays some role in the cellular signaling pathway in addition to its collagen-binding property. Further analysis is required to determine the angiogenic function of CBD. However, our experiments (Figure 4) revealed that the angiogenic activities of CBD did not compete with EREI2CBD. Rather, EREI2CBD was superior to CBD in increasing the number of vessel branches, which suggests a specific effect for the designed ECM domain EREI2 that includes the IKVAV sequence.

In conclusion, the artificially designed fusion ECM protein, EREI2CBD, was shown to have angiogenic activity using an *in vivo* CAM assay. EREI2CBD could be immobilized onto atelocollagen membranes and increase vessel area, especially the number of capillary vessel branches. Our design strategy for constructing fusion proteins produced stable, functional ECM proteins that worked more efficiently than synthetic peptides. Atelocollagen-based material and collagen-binding engineered ECM proteins hold potential for generating functional tissues by tissue engineering.

Received April 10, 2009; Revised Manuscript Received July 20, 2009

A family of new anionic nucleotide based lipids featuring thymidine-3′-monophosphate as nucleotide and 1,2-diacyl-*sn*-glycerol as lipid moiety for *in vitro* delivery of nucleic acids is described. The nucleotide lipids were prepared in three steps starting from 1,2-diacyl-*sn*-glycerols and 2′-deoxythymidine-3′-phosphoramidite. Gel electrophoresis experiments show that nucleotide-based lipid−DNA complexes are observed at Ca^{2+} concentration higher than 1 mM. The transfection experiments carried out on mammalian Hek cell lines clearly demonstrate that the nucleotide moiety enhances the transfection efficacy of the natural anionic DPPA and DPPG lipids. SAXS studies indicate that the enhancement in transfection for nucleotide-based lipid formulations compared to those of the abasic natural derivative (DPPA) is likely due to the presence of the 2D columnar inverted hexagonal phase (H_{II}) with a unit cell parameter $a = 69.1$ Å in the nucleotide lipid formulations. The cytotoxicity studies of lipoplexes, evaluated against Hek cells using an MTS assay, revealed that palmitoyl nucleotide derivative complexes were not toxic even after 4 h of incubation, thus indicating that the anionic nucleotide lipids presented in this work offer an alternative to cationic transfection reagents.

INTRODUCTION

Therapies ± using natural or synthetic nucleic acids have emerged as promising strategies for developing cures against inherited and acquired disorders or diseases, including cancer (*1, 2*). One of the significant advantages of nucleic acid based drugs over low molecular weight pharmaceutical drugs is their selectivity for their biological target and their specificity of ± action (*3*). To be effective, nucleic acid based therapies require the use of vector platforms for delivering various genetic materials into cells. The earliest synthetic DNA delivery systems, first introduced in the 1980s (*4, 5*), were based on cationic lipids. Today, cationic lipids are still important transfecting tools for research, likely because of the researchers' ability to control their chemical and physical properties (*6*). However, most of these cationic systems exhibit specific problems outlined by Burgess et al. (*7*), including cytotoxicity, inactivation in the presence of serum, and inefficiency *in vivo*, that scientists are attempting to address (*8*−*12*). To overcome these limitations, alternative cationic synthetic vectors ± are currently under investigation by a number of research groups (*13*−*16*). In ± recent years, there has also been intense research activity in the development of various innovative lipid systems, including pH-sensitive fusiogenic polymer-modifed liposomes (*17*), pH-sensitive pegylated lipoplexes (*18*), nucleolipoplexes (*19*−*21*), imidazole (*22*) and charge reversal lipids (*23, 24*), lipopolythiourea (*25*), lipophilic peptides (*26*), zwitterionic lipids (*27*), and glycosylated lipids (*28*). Additionally, amphiphiles possessing a nucleoside as a lipid headgroup and lipophilic alkyl chains have been identified as promising tools for gene delivery into cells (*19*−*21*) (*28*−*30*) and for self-assembling nucleic acid−nucleolipid supramolecular systems (*31*−*40*).

Examples of anionic amphiphiles for gene delivery are rare. Recently, an anionic amphiphile (1,2-dioleoyl-*sn*-glyerol-3-[phospho-*rac*-(1-glycerol] sodium salt), zwitterionic amphiphile (DOPE), and Ca^{2+} system have been reported that exhibited transfection efficiencies similar to the cationic lipid lipofectamine (*7*) (*41*). To our knowledge, no reports of anionic nucleotide based amphiphiles for gene transfection have been reported.

Within this context, we hypothesized that an anionic amphiphile possessing a nucleotide polar head for DNA−lipid association would enable formation of lipoplexes in the presence of Ca^{2+} and afford *in vitro* tranfection. For this purpose, we synthesized a series of anionic nucleotide−lipids with a thymidine nucleotide polar head and various 1,2-diacyl-*sn*-glycerol of C_{12}, C_{14}, and C_{16} chain length as hydrophobic species. The potential of these novel anionic nucleotide based lipids for DNA delivery and expression was investigated. Herein, we report the synthesis, physicochemical studies, cytotoxicity, and *in vitro* transfection results of these new anionic nucleotide based lipids (Scheme 1).

EXPERIMENTAL PROCEDURES

Materials. *General Experiments and Analytical Conditions.* Unless noted otherwise, all starting materials and solvents were obtained from Aldrich, Bachem, Genzyme, and Glen Research and were used without further purification. All compounds were characterized using standard analytical and spectroscopic techniques such as ^{1}H, ^{13}C, and ^{31}P spectroscopy (apparatus Bruker Avance DPX-300, ^{1}H at 300.13 MHz, ^{13}C at 75.46 MHz, and ^{31}P at 121.49 MHz) and mass spectrometry (Instrument JEOL SX 102, NBA matrix). The NMR chemical shifts are reported in ppm relative to tetramethylsilane using the deuterium signal of the solvent ($CDCl_3$) as a heteronuclear reference for ^{1}H. The ^{1}H NMR coupling constants, *J*s, are reported in Hz. TEM microscopy experiments were performed

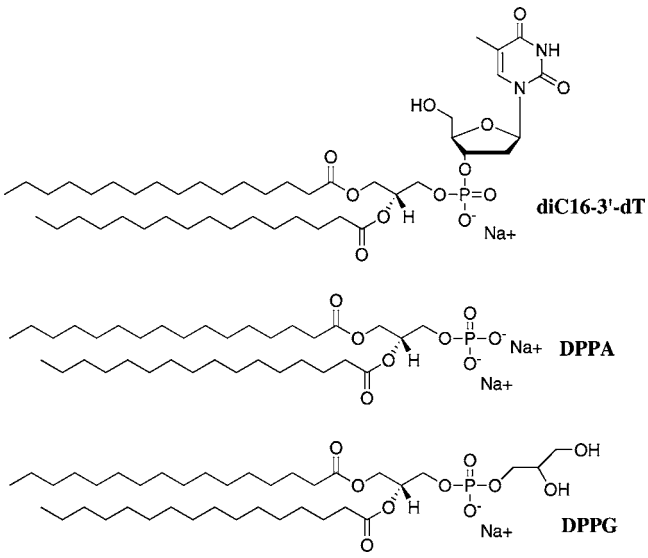
Scheme 1. Chemical Structure of an Anionic Nucleotide−Lipid Used in This Study, the Thymidine 3′-(1,2-dipalmitoyl-*sn*-glycero-3-phosphate) (di c_{16}dT) and Non-Nucleotide−Lipids DPPA and DPPG



with a Hitachi H 7650 (negative staining with uranyl acetate 1% in water, nickel carbon coated grids). Fluorescence microscopy experiments were performed on a Zeiss axiovert 200. Silica gel 60 (particle size: 45 μm) was used for flash chromatography (Biotage). Thin layer chromatograms were performed with aluminum plates coated with silica gel 60 F_{254} (Merck). The revealing solution for TLC is an anisaldehyde solution (85 mL ethanol, 10 mL acetic acid, 5 mL sulfuric acid, and 0.5 mL *p*-anisaldehyde).

Synthesis. *Thymidine 3′-(1,2-Dilauroyl-sn-glycero-3-phosphate), diC_{12}-3′-dT, Compound* **1.** 5′-*O*-(4,4′-Dimethoxytrityl)-2′-deoxythymidine-3′-[(2-cyano-ethyl)-*N*,*N*-diisopropyl)] phosphoramidite (0.500 g, 1 equiv, 0.67 mmol), 1,2-dilauroyl-*sn*-glycerol (0.398 g, 1.3 equiv, 0.87 mmol/dissolved in 3 mL of THF) and a tetrazole solution in acetonitrile (0.45 M, 2 mL, 1,3 equiv, 0,87 mmol) were dissolved in 3 mL of dry acetonitrile under argon. The reaction mixture was stirred for 7 h at room temperature followed by oxidation with 40 mL of a solution of I_2 (0.02 M in THF/Pyr/H_2O). After 12 h at room temperature, the solvent was evaporated under high vacuum to yield intermediate products. The contents of the reaction flask were dissolved in 10 mL of methylene chloride and then washed first with 3 × 10 mL of HCl (0.1 N) and second with 3 × 10 mL of a saturated solution of $Na_2S_2O_3$. Product **1** (160 mg) was isolated after purification on silica gel (DCM/MeOH/TEA from 98:2:1 to 50:49:1). Yield: 33% R_f = 0.5 (DCM/MeOH 7:3).

^{1}H NMR (300 MHz, $CDCl_3$): δ in ppm 0.83 (t, 6H, J = 6.8 Hz, $2CH_3$), 1.21 (m, 32H, $16CH_2$), 1.54 (m, 4H, $2CH_2$), 1.86 (s, 3H, Me base), 2.25 (m, 4H, $2CH_2$), 3.04 (t, 2H), 3.7−4.4 (m, 7H, $2CH_2$(glycerol), H4′, H5′), 5.28 (m, 1H, CH glycerol), 6.21 (t, 1H, J = 6.5 Hz, H1′), 7.61 (s,1H, H base).

^{13}C NMR (75 MHz, $CDCl_3$): δ in ppm 12.5 (CH_3 base), 14.0 (CH_3 chain), 19.6 (CH_2), 19.7 (CH_2), 22.6 (CH_2), 24.8 (CH_2), 29.0−29.5 (CH_2), 31.9 (CH_2), 33.9 (CH_2), 34.1 (CH_2), 61.5 (CH_2), 61.7 (CH_2), 62.5 (CH_2), 62.6 (CH_2), 66.1 (CH_2), 66.2 (CH_2), 69.1 (CH), 78.8 (CH), 85.5 (CH), 86.1 (CH), 110.7 (C base), 136.2 (CH base), 150.5 (C═O base), 164.0 (C═O base), 172.9 (C═O chain), 173.3 (C═O chain).

^{31}P NMR (121 MHz, $CDCl_3$): δ 2.1 ppm. High-resolution ESI MS^- $[M-H]^-$, theorical m/z = 759.4197, observed m/z = 759.4182.

Thymidine 3′-(1,2-Dimyristoyl-sn-glycero-3-phosphate) diC_{14}-3′-dT, Compound **2.** A procedure similar to that used for compound **1** was followed here. 5′-Dimethoxytrityl-2′-deoxythymidine, 3′-[(2-cyanoethyl)-*N*,*N*-diisopropyl)]-phosphoramidite (500 mg, 1 equiv, 0.67 mmol), 1,2-dimyristoyl-*sn*-glycerol (447 mg, 1.3 equiv, 0.87 mmol), and a tetrazole solution 0.45 M in acetonitrile (2 mL, 0.87 mmol) were dissolved in dry acetonitrile under argon. Product **2** (160 mg) was isolated after purification on silicagel (DCM/MeOH/TEA from 98:2:1 to 50:49:1). Yield: 17% R_f = 0.6 (DCM/MeOH 7:3).

^{1}H NMR (300 MHz, $CDCl_3$): δ in ppm 0.86 (t, 6H, J = 6.9 Hz, $2CH_3$), 1.24 (m, 40H, $16CH_2$), 1.57 (m, 4H, $2CH_2$), 1.90 (s, 3H, Me base), 2.28 (m, 4H, $2CH_2$), 2.98 (t, 2H), 3.7−4.4 (m, 7H, $2CH_2$(glycerol), H4′, H5′), 5.22 (m, 1H, CH glycerol), 6.22 (t, 1H, J = 6.5 Hz, H1′), 7.61 (s,1H, H base).

^{13}C NMR (75 MHz, $CDCl_3$): δ in ppm 12.5 (CH_3 base), 14.0 (CH_3 chain), 22.6 (CH_2), 24.8 (CH_2), 29.1−29.6 (CH_2), 31.8 (CH_2), 34.0 (CH_2), 34.2 (CH_2), 39.0 (CH_2), 39.1 (CH_2), 61.8 (CH_2), 62.5 (CH_2), 63.4 (CH_2), 63.5 (CH_2), 70.1 (CH), 74.3 (CH), 84.6 (CH), 85.8 (CH), 110.8 (C base), 136.2 (CH base), 150.4 (C═O base), 164.0 (C═O base), 173.0 (C═O chain), 173,4 (C═O chain).

^{31}P NMR (121 MHz, $CDCl_3$): δ 2.5 ppm.

High-resolution ESI MS^- $[M-H]^-$, theorical m/z = 815.4823, observed m/z = 815.4819.

Thymidine-3′-(1,2-dipalmitoyl-sn-glycero-3-phosphate) diC_{16}-3′-dT, Compound **3.** A procedure similar to that used for compound **1** was followed here. 5′-Dimethoxytrityl-2′-deoxythymidine, 3′-[(2-cyanoethyl)-*N*,*N*-diisopropyl)]-phosphoramidite (1 g, 1 equiv, 1.34 mmol), 1,2-dipalmitoyl-*sn*-glycerol (992 mg, 1.3 equiv, 1,75 mmol), and a tetrazole solution 0.45 M in acetonitrile (4 mL, 1.75 mmol) were dissolved in dry acetonitrile under argon. Product **3** (552 mg) was isolated after purification on silica gel (DCM/MeOH/TEA from 98:2:1 to 50:49:1). Yield: 47% R_f = 0.3 (DCM/MeOH 8:2).

^{1}H NMR (300 MHz, $CDCl_3$): δ in ppm 0.88 (t, 6H, J = 6.9 Hz, $2CH_3$), 1.25 (m, 48H, $16CH_2$), 1.42 (dd, 4H, J_1 = 8.4 Hz, J_2 = 15.6 Hz, $2CH_2$), 1.90 (s, 3H, Me base), 2.33 (m, 4H, $2CH_2$), 2.83 (t, 2H J = 5.6 Hz, H2′), 3.84 (m, 1H, H3′), 4.09−4.35 (m, 7H, $2CH_2$ (glycerol), H4′, H5′), 5.27 (s, 1H, CH glycerol), 6.21 (t, 1H, J = 6.7 Hz, H1′), 7.54 (s,1H, H base).

^{13}C NMR (75 MHz, $CDCl_3$): δ in ppm 12.4 (CH_3 base), 14.1 (CH_3 chain), 19.6 (CH_2), 19.7 (CH_2), 22.6 (CH_2), 24.8 (CH_2), 29.1−29.6 (CH_2), 31.9 (CH_2), 33.9 (CH_2), 34.1 (CH_2), 61.5 (CH_2), 61.7 (CH_2), 62.5 (CH_2), 62.6 (CH_2), 66.1 (CH_2), 66.2 (CH_2), 69.1 (CH), 78.8 (CH), 85.5 (CH), 86.1 (CH), 111.3 (C base), 136.8 (CH base), 150.5 (C═O base), 164.1 (C═O base), 173.0 (C═O chain), 173.5 (C═O chain).

^{31}P NMR (121 MHz, $CDCl_3$): δ 2.1 ppm.

ESI MS^- $[M-H]^-$, theorical m/z = 871.5449, observed m/z = 871.5473.

Preparation of Liposomes. Liposomes were prepared from binary mixtures of the negatively charged lipid nucleolipids (NL) and neutral lipid DOPE. Stock solutions of DOPE and (NL) (10 mg/mL in chloroform) were mixed at the desired ratio and placed in glass tubes. The mixture was dried under dry N_2 and then desiccated under vacuum overnight. Milli-Q Water was added to the dried lipids to obtain liposome solutions (1 mg/mL). This was followed by five thaw−sonication cycles using a water bath at 55 °C and an ultrasonic bath. The resultant solution was extruded at room temperature through a 50 nm pore-size nucleopore polycarbonate filter.

Preparation of Plasmid DNA. Plasmid containing a GFP reporter gene under the cytomegalovirus promoter, pE-GFP, was propagated in transformed *Escherichia coli* cells. *E. coli* cells were grown in standard luria Bertani medium at pH 7.0. Cells were harvested by centrifugation, and the plasmid DNA was

extracted and purified using a Qiagen Plasmid Maxi Kit (Qiagen, Santa Clarita, CA) as per the manufacturer's recommended protocols.

Preparation of Anionic Lipoplexes. DNA (250 μg/mL), liposomes (1 mg/mL), and divalent salt ($CaCl_2$ $2H_2O$, 200 mM) samples were mixed to yield anionic lipoplexes at different global salt concentrations. The DNA to lipid charge stoichiometry (*D*/*L* ratio) was defined as the total charge of DNA divided by the total charge of anionic nucleolipides.

Particle Size Determination. Anionic liposomes and lipoplexes were prepared as described above. Particle size was determined using Zetasizer 3000 HAS Malvern. All measurements were conducted at 25 °C.

Electrophoresis Studies. Electrophoresis studies were conducted in 0.8% agarose gels containing ethidium bromide in 0.5 Tris-borate without EDTA buffer. Anionic lipoplexes were prepared as described above. For this purpose, 20 μL of each sample was mixed with 4 μL loading buffer (glycerol 30% (v/v), bromophenol blue 0.25% (w/v), and xylene cyanol 0.25 (w/v)) and subjected to agarose gel electrophoresis for 35 min at 100 V. The electrophoresis gel was visualized and digitally photographed using a G.BOX camera.

Transmission Electronic Microscopy (TEM). Anionic liposomes and lipoplexes were prepared as described above and were visualized by negative staining microscopy. Ten microliters of liposomes (1 mg/mL) was transferred to a carbon-coated grid for 10 min. The sample was then dried and stained with 1% (W/W) of uranyl acetate for 30 s. The specimens were observed with a Hitachi H 7650 electron microscope.

Transfection Assays. Cell lines (Hek 293 human embryo kidney) were cultured in Dulbecco's Modified Eagle's Medium (D-MEM, Invitrogen) and supplemented with 10% fetal bovine serum (FBS, invitrogen) and 1% not essence AA and 1% L-glutamine at 37 °C in a 5% CO_2 atmosphere. Cells were split every 3−4 days to maintain monolayer coverage.

The day before transfection, cells were seeded in 24 well plates (50 000 cells/well). On the day of transfection, the medium containing serum was removed from the well plates and replaced with 200 μL of transfection medium without serum.

Lipoplexes were prepared by adding 4 μL of plasmid (250 ng/μL) in 50 μL of medium without serum and 42 μL of anionic liposome dispersions (1 mg/mL). Anionic lipoplex formation was achieved by the addition of various amounts of a calcium chloride solution (200 mM). These complexes were left at room temperature for 15 min before being added to the cells. In the case of fluorescence microscopy samples, a similar procedure was followed. In that case, an oligonucleotide fluorescein (random sequence, 18mers) was mixed with the DNA fraction and added to the sample. 50 μL of medium without serum, 42 μL of liposomes (1 mg/mL), and 3 μL DNA (250 μg/mL) + 1 μL oligonucleotide−fluorescein (250 μg/mL) were mixed. The complex formation was achieved by adding Ca^{2+} (final concentration 15 mM).

The cells were incubated with lipoplexes in a media without serum for 2 or 4 h to permit transient transfection. Afterward, the complex-containing suspension was removed and replaced by 200 μL of the complete growth medium. GFP expression was analyzed after 48 h and measured with flow cytometry. Lipofectamine transfections were performed, as per the manufacturer's instructions, using 2 μL of lipofectamine and an identical amount of plasmid 4 μL (250 ng/μL).

Flow Cytometry Studies. Cells were assayed for GFP expression 48 h after being exposed to the transfection agents. Cells in the well plates were rinsed with PBS, treated using 100 μL trypsine EDTA, and incubated for 5 min (37 °C) in 5% CO_2 incubator. The cell suspension was then diluted to 200 μL using PBS, pH 7,4. The cells were then assayed for expression of GFP. GFP expression was analyzed using a FACS Canto dual laser flow cytometry.

Toxicity Assay. The toxicity of the thymidine-3′-(1,2-diacyl-*sn*-glycero-3-phosphate) (compounds **1**, **2**, **3**) for the cells was determined 48 h after exposure to the transfection agents using the MTS tetrazolium. Cells in the well plates were treated using 50 μL of MTS tetrazolium and incubated for 2−4 h (37 °C) in a 5% CO_2 incubator. Once coloring developed, the absorbance of 200 μL of each sample was analyzed at 490 nm.

X-ray Diffraction. SAXS measurements were carried out on the Bruker Nanostar apparatus at the Centre de Recherche Paul Pascal (Pessac, France). The wavelength of the incident beam was $\lambda = 1.54$ Å, and the sample-to-detector distance was 0.25 m (q range investigated from 0.05 $Å^{-1}$ to 0.6 $Å^{-1}$). The diffraction patterns were recorded by a 2D multiwire gas-filled detector. Anionic membranes formulated with the negatively charged nucleolipids (NL) and the neutral lipid (DOPE) were mixed with deionized water to obtain solutions with a concentration of 10 mg/mL. A plasmid−DNA solution in water was prepared (300 mg/mL) and added to the membrane solution in order to get the molar ratio NL/DNA = 2. The complex formation was achieved by adding divalent salt ($CaCl_2$ $2H_2O$, 200 mM) with a final concentration $[Ca^{2+}] = 15$ mM. The suspension was held in a 1.5 mm size glass capillary and then centrifuged for a few minutes in order to locally concentrate the complex on the bottom of the capillary. The capillary was sealed and inserted in a sample holder at room temperature (25 °C). The collected 2D diffraction spectra were angularly integrated to get a 1D intensity vs q pattern.

RESULTS AND DISCUSSION

In this study, we hypothesized that anionic lipid−nucleic acid complexes could take advantage of lipid polar head groups featuring nonionic interactions such as hydrogen-bonding and base $\pi-\pi$ stacking. These additional interactions would likely influence the lipid−DNA associations and enhance the transfection efficacy of the natural anionic lipids previously reported (*7*). To demonstrate this hypothesis, the following constituting natural building blocks were selected to prepare the anionic nucleotide based lipids: thymidine (nucleotide polar head) and 1,2-diacyl-*sn*-glycerol (lauroyl, myristoyl, and palmitoyl acyl chains). Both moieties, the diacyl-*sn*-glycerol motif and the thymidine as a nucleotide polar head, were selected on the basis of their natural occurrence in biological systems. In this contribution, we report the synthesis of a family of thymidine-3′-(1,2-diacyl-*sn*-glycero-3-phosphate), the formation of lipoplexes between DNA and nucleotide based lipids in the presence of Ca^{2+}, SAXS studies, cytotoxicity, and successful *in vitro* gene delivery.

Synthesis. In order to evaluate the impact of the lipid structure on the transfection properties, a series of nucleotide derivatives composed of thymidine 3′-phosphates bearing natural 1,2-diacyl-*sn*-glycerol as hydrophobic building blocks was prepared. Although, to the best of our knowledge, nucleoside-5′-monophosphate lipids structures have been reported by Baglioni, Berti, and co-workers (*31*, *32*), no double-chain nucleoside-3′-monophosphate amphiphile has been described so far. The double-chain nucleoside-3′-monophosphate lipids were synthesized by using a recently published (*37*) synthetic approach for single-chain nucleolipids (Scheme 2). Coupling reactions between 5′-DMT protected commercial phosphoramidite (5′-dimethoxytrityl-2′-deoxythymidine,3′-[(2-cyanoethyl)-*N*,*N*-diisopropyl)]-phosphoramidite) and lipophilic 1,2-diacyl-*sn*-glycerol were undertaken in acidic conditions (tetrazole) similar to those found in oligonucleotide synthesis. The resulting phosphite intermediates were then oxidized with iodine in a THF/pyridine/water mixture at room temperature under argon to provide the

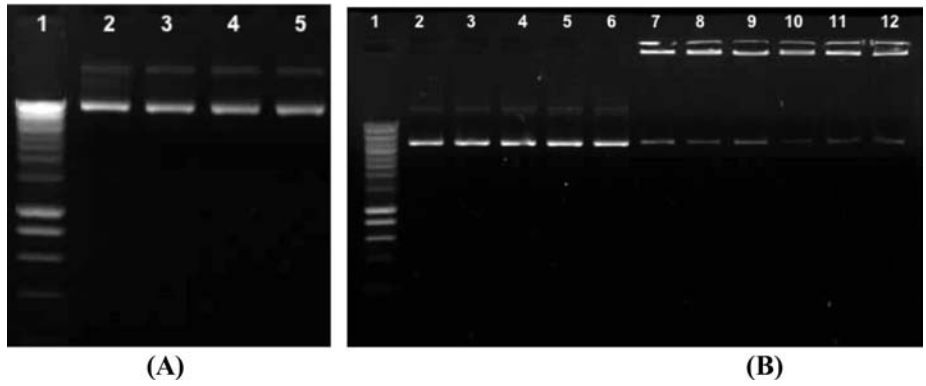

Figure 1. Effect of Ca^{2+} on the electrophoretic mobility of (A) Ca^{2+}−DNA complexes and (B) anionic lipoplexes (anionic liposome−Ca^{2+}−DNA) diC16T/DOPE (mol ratio 10/90). (A) The lanes represent control DNA ladder (1); plasmid DNA (2); and Ca^{2+}−DNA complexes at Ca^{2+} concentrations of 10 mM (3), 30 mM (4), and 50 mM (5). (B) The lanes represent control DNA ladder (1); plasmid DNA (2); plasmid DNA and empty anionic liposomes (3); anionic lipoplexes at Ca^{2+} concentrations of 1, 50, and 100 μM, and 1, 5, 10, 15, 30, and 60 mM (7−12).

cyanoethyl-protected phosphates. Removal of the DMT group led to the production of compounds **1**, **2**, and **3**, which were fully characterized by ^1H, ^{13}C, ^{31}P NMR, and HRMS. The cyanoethyl protecting group was removed via an elimination reaction under basic conditions (TEA). Importantly, the synthetic strategy developed allowed easy access to the expected thymidine-3′-(1,2-diacyl-*sn*-glycero-3-phosphate) in four steps from the commercially available starting materials.

Complexation Studies. Next, to determine whether or not the nucleotide based lipids **1**, **2**, and **3** complex nucleic acids, we performed a standard electrophoresis gel shift assay with plasmid−DNA for the assessment of DNA complexation. Since the lipid polar head bears an anionic charge, just as was the case for the previous anionic delivery vectors (*7*), the formation of lipid−DNA complexes was evaluated in the presence of different concentrations of divalent calcium. Standard agarose gel electrophoresis revealed two bands for naked DNA (supercoil, nonsupercoil forms, high and low mobility, respectively) (Figure 1A, lane 2). As a control, the addition of Ca^{2+} to the plasmid DNA samples in the absence of anionic liposomes did not affect the mobility of the plasmid DNA (Figure 1A, lanes 3−5). On the contrary, the presence of anionic liposomes and Ca^{2+} dramatically affected plasmid−DNA migration (Figure 1B). On the basis of the hypothesis that the nucleolipid/DNA stability depends on calcium concentration, we also evaluated the threshold Ca^{2+} concentration for complexation. Interestingly, we found that nucleolipid−DNA complexes are observed above a concentration of 1 mM (Figure 1B, lane 7), which is higher than the intracellular calcium concentration ([Ca^{2+}] 1 μM) indicating that the lipoplexes can release the DNA inside the cells. Next, we investigated the optimum ratio of nucleolipid−DOPE. As shown in Figure 2, based upon the lack of free DNA, an optimal ratio of 10/90 (diC16T/DOPE) was determined.

Nucleolipid−Ca^{2+}−DNA Lipoplexes. The hydrated mixtures of DOPE/diC$_{16}$-3′-dT in aqueous solution were investigated without plasmid−DNA by transmission electronic microscopy (TEM) and zetasizer (3000 HAS Malvern instrument). As was expected, the extruded mixtures were found to self-assemble at room temperature into liposome-like structures in aqueous solutions. Under these conditions, at room temperature, the DOPE/diC$_{16}$-3′-dT were in a "fluid" state. As seen in TEM images (Figure 3), in the absence of both nucleic acids and Ca^{2+} and after extrusion with a 50 nm filter, different sizes of liposomes ranging from 40 to 80 nm were observed. These sizes are consistent with the average sizes of the same samples measured by dynamic light scattering (hydrodynamic diameter: 84 nm polydispersity index 0.38). Interestingly, in the presence of DNA and Ca^{2+}, the mean aggregates size was increased from 84 to 128 nm, indicating the formation of larger aggregates. Dried samples of these aggregates investigated by TEM revealed objects possessing a nonvesicular morphology (data not shown). It is noteworthy that no modification of size was noticed for the samples containing liposomes in the presence of DNA without Ca^{2+}.

It should also be noted that the presence of anionic nucleolipids in DOPE/diC$_{16}$-3′-dT mixtures enhanced the hydration phenomenon during the preparation of liposomes, which resulted in much more homogeneous colloidal suspensions compared to DOPE/DPPA samples. This unexpected hydration behavior is likely due to the hydrophilic nucleotide polar head inserted in the molecular structure.

SAXS Studies. Next, to further characterize the molecular organization within the DOPE−NL−Ca^{2+}−DNA lipoplexes, small-angle X-ray scattering (SAXS) experiments were performed. Figure 4 shows the diffraction patterns of the DOPE−DPPA samples with (curve 2) and without (curve 1)

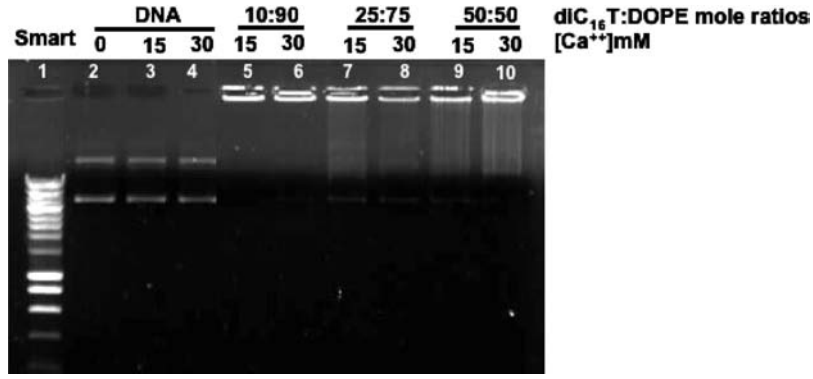

Figure 2. Electrophoretic mobility of different formulations and Ca^{2+} concentrations. The lanes represent control DNA ladder (1); plasmid DNA with different concentrations of Ca^{2+} (2−4); lipoplexes (anionic nucleotide lipid−Ca^{2+}−DNA) diC16T/DOPE mol ratios of 10/90 (5,6), 25/75 (7,8), and 50/50 (9,10) with $[Ca^{2+}] = 15$ and 30 mM, respectively.

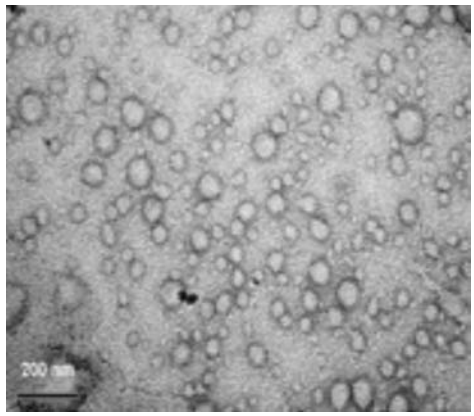

Figure 3. Transmission electron microscopic (TEM) images of anionic DOPE/diC$_{16}$-3′-dT liposomes (mol ratio of 10/90) in water with uranyl acetate (1%) as negative stainer. Scale bars, 200 nm.

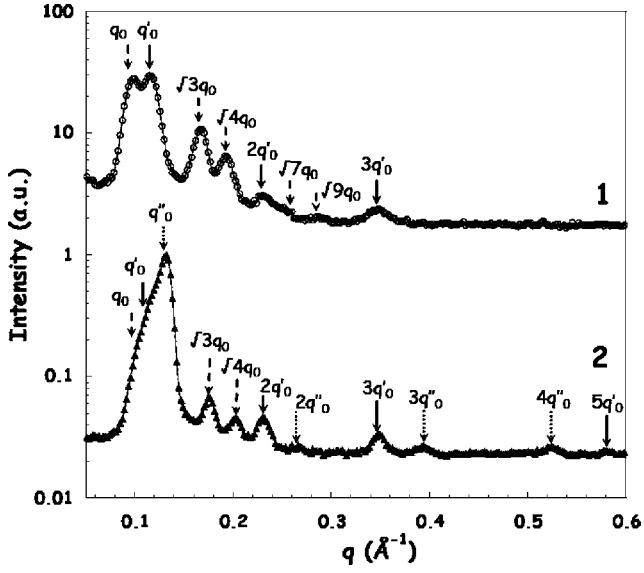

Figure 4. SAXS patterns of DOPE−DPPA−Ca^{2+} system without plasmid DNA (curve 1) and with plasmid DNA (curve 2).

the plasmid DNA. For the system without plasmid DNA, two distinct sets of peaks are identified. A 2D hexagonal lattice (q_0) with a unit cell spacing of $a = 72.6$ Å can be indexed. This pattern corresponds to the well-known 2D columnar inverted hexagonal phase (H_{II}). The second set of Bragg peaks can be attributed to a lamellar structure with a stacking period $d = 54$ Å. Bragg peaks up to the fifth and third order are observed for

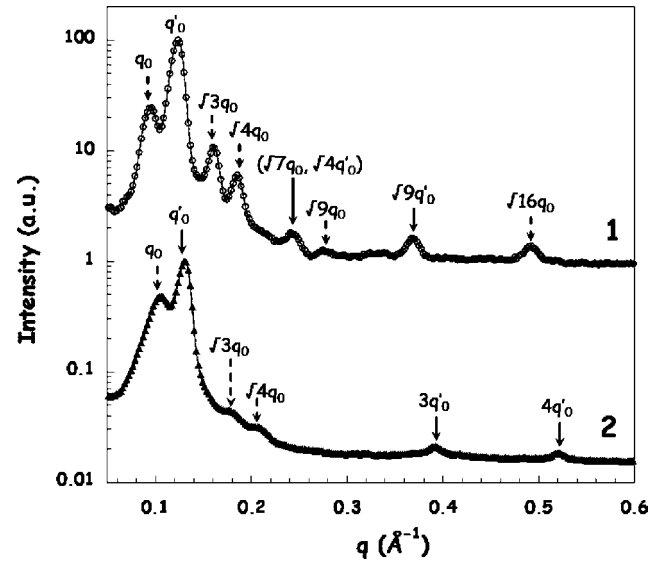

Figure 5. SAXS patterns of DOPE−diC$_{16}$-3′-dT−Ca^{2+} system without plasmid DNA (curve 1) and with plasmid DNA (curve 2).

the hexagonal and lamellar phases, respectively. The lamellar structure unambiguously corresponds to the lamellar phase observed (data not shown) for the pure DPPA system. On the other hand, the 2D hexagonal lattice seems to be very similar to that noticed for the pure DOPE system (*42*). These results suggest a very weak miscibility of the DPPA lipid in the DOPE membrane. The sample with plasmid DNA exhibits a more complicated pattern (empty circles) with a three-phase coexistence domain. We can identify the two phases previously observed for the free plasmid DNA system with a 2D hexagonal lattice (q_0) $a = 71.8$ Å and with a lamellar structure (q'_0) with a stacking period $d = 54$ Å. Interestingly, in the presence of plasmid DNA, a new lamellar phase (q''_0) can be indexed with a lamellar periodicity $d = 48$ Å. This new lamellar phase can be identified as lamellar complex made from DNA Ca^{2+} and DOPE (data not shown).

Figure 5 shows the diffraction patterns of the DOPE−diC$_{16}$-3′-dT samples with (curve 2) and without (curve 1) the plasmid DNA. For the system without plasmid DNA, two distinct sets of peaks are identified which can be indexed on a 2D hexagonal lattice (q_0 and q'_0) with different unit cell spacing, namely, $a = 77$ Å and $a' = 59$ Å. The sample with plasmid DNA also reveals two sets of peaks. The first set of peaks (q_0) corresponds to a H_{II} phase with a unit cell spacing with $a = 69.1$ Å. The second set of peaks (q'_0) can be indexed for a lamellar phase with a stacking period $d = 48$ Å. This lamellar structure is similar to that observed in the DOPE−DPPA−plasmid DNA sample. The

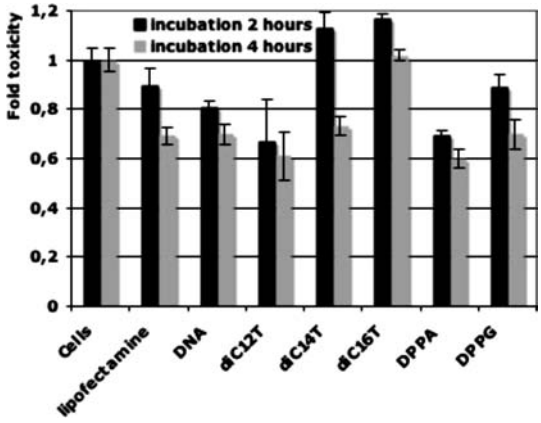

Figure 6. Cytotoxicities of anionic lipoplexes composed of nucleolipids ($diC_{12,14,16}T$), DPPA or DPPG and DOPE (10:90 mol ratio)−Ca^{2+} (15 mM)−DNA compared to lipofectamine and DNA with 15 mM Ca^{2+} and untreated cells.

differences for the structural parameters observed for the samples with and without plasmid DNA strongly suggest the presence of DNA inside the two phases H_{II} and L_α and a good miscibility of DOPE with the nucleotide lipid (diC_{16}-3′-dT). These results prove that the structure of the various complexes is formulation-dependent. In particular, the presence of the nucleotide lipid enhances the existence of a 2D inverse hexagonal phase (a = 69.1 Å) which does not occur in the nucleotide free lipid system (DOPE−DPPA−plasmid−DNA−Ca^{2+}), while the lamellar phase with a stacking period d = 48 Å is present in both systems.

Cell Proliferation. The effect on the proliferation of mammalian cell lines of the nucleolipid−Ca^{2+}−DNA lipoplexes was compared to a commercially available transfectant, lipofectamine and Ca^{2+}-DNA binary mixtures. The *in vitro* lipoplex cytotoxicity was evaluated against Hek cells using an MTS assay. The proliferation of cells is expressed as percentages of nontreated cells. As shown in Figure 6, after 2 h of incubation, the proliferation of Hek cells was not affected in the presence of myristoyl (DOPE/diC_{14}-3′-dT-Ca^{2+}-DNA) or palmitoyl derivatives (DOPE/diC_{16}-3′-dT-Ca^{2+}-DNA), since the cellular growth responses were essentially higher or the same as the negative controls (nontreated Hek cells). Note, furthermore, that no toxicity was observed even after 4 h of incubation for the palmitoyl derivative. In contrast, Hek cell viability decreased in the presence of lipofectamine, DOPE/DPPG−Ca^{2+}−DNA, and Ca^{2+}−DNA mixtures for both 2 and 4 h of incubation. The cytotoxic effect was much stronger for ternary mixtures featuring non-nucleotide lipid (DOPE/DPPA−Ca^{2+}−DNA) than for dipalmitoyl nucleolipid (diC_{16}-3′-dT), because the cell viability was reduced by 30% and 40% for 2 and 4 h, respectively. A similar cytotoxicity effect was observed with DOPE/diC_{12}-3′-dT-Ca^{2+}-DNA samples, indicating that an optimal chain length of C_{16} is required to avoid toxicity. Toxic effects of dilauroyl derivatives were previously reported for cationic lipids bearing 1,3-diamino-2-propanol backbone (*43*).

Fluorescence Microscopy Studies. We next used fluorescence microscopy to determine whether the DOPE/diC_{16}-3′-dT-Ca^{2+}-DNA complexes penetrated the cultured eukaryotic cells. For this purpose, DOPE/diC_{16}-3′-dT liposomes and a mixture of nucleic acids containing plasmid DNA (0.75 μg) and oligonucleotide−fluorescein (0.25 μg) were mixed. The complex formation was realized by adding Ca^{2+} (final concentration 15 mM). Hek cells were incubated later with the fluorescein-labeled complexes for 2 h at 37 °C. As shown in Figure 7 (left), the fluorescein-labeled complexes were internalized at 37 °C, indicating that anionic lipoplexes can transfer DNA into cells.

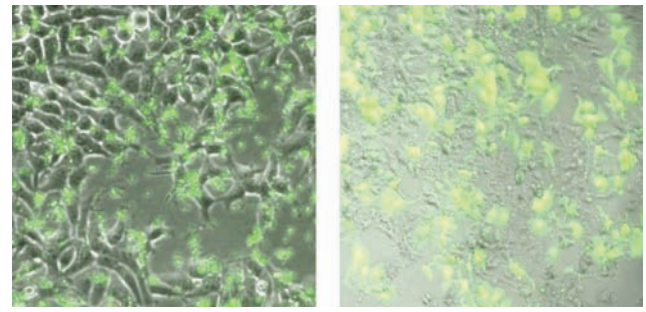

Figure 7. Fluorescence microscopy images of anionic lipoplexes ([Ca^{2+}] = 15 mM) carrying DNA fluorescein labeled (left) and transfected Hek cells (GFP expression) (right).

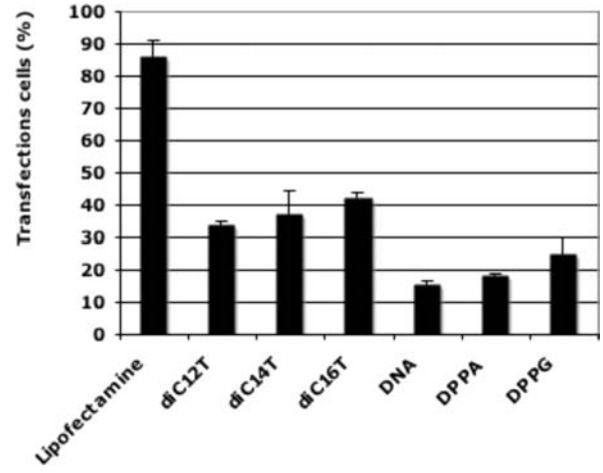

Figure 8. Transfection efficiencies of anionic lipoplexes composed of nucleolipids/DOPE (10:90 mol ratio) ($diC_{12,14,16}T$), DPPA/DOPE (10:90 mol ratio)−Ca^{2+}(15 mM)−DNA), DPPG/DOPE (10:90 mol ratio)−Ca^{2+}(15 mM)−DNA), compared with lipofectamine and DNA with 15 mM Ca^{2+}.

It is important to note that Hek cells incubated in the presence of anionic lipoplexes—prepared without fluorescein-labeled oligonucleotides—(DOPE/diC_{16}-3′-dT-Ca^{2+}-DNA), where the DNA is an expression vector (pEGFP) encoding GFP, confirm the release and the expression of the anionic lipoplexes from the GFP-plasmid DNA. (Figure 7 right).

Transfection. To investigate the efficiency of the anionic nucleotide based lipids to deliver DNA into cells, we performed a transient transfection assay of mammalian cell lines (Hek 293 human embryo kidney). The transfected DNA is an expression vector (pEGFP) encoding GFP, which enables the detection of fluorescence by FACS. Different formulations of anionic nucleolipids were mixed with 1 μg of pEGFP, and then lipoplexes were incubated with Hek cells. Single-cell suspensions were analyzed by FACS Canto dual laser flow cytometry. The GFP negative and positive gates were defined using the control experiment carried out in the absence of lipoplex. In each experiment, 50 000 cells were sorted, and the results are shown in Figure 8. Anionic lipoplexes are efficient for transfection at a concentration of liposomes (42 μg, DOPE/diC_n-3′-dT-Ca^{2+}-DNA) per well. As control experiments, the transfection capability of lipofectamine−DNA and calcium−DNA mixtures were evaluated. As expected for this cell line, lipofectamine appeared to be the most efficient transfecting reagent, whereas calcium salts alone remained less effective in transfecting EGFP. Likewise, with only 18% and 24% of transfection after 2 h of incubation, the DPPA−Ca^{2+}−DNA and DPPG−Ca^{2+}−DNA lipoplexes, respectively, exhibited weak transfecting activity. On the contrary, the nucleolipids exhibited higher transfecting efficacies. With a level of transfection higher

than 40%, the DOPE/diC$_{16}$-3′-dT-Ca^{2+}-DNA lipoplex shows the best efficacy among the anionic systems. Note that this level was increased to 55% after incubating the Hek cells in the presence of this complex for 4 h (data not shown). An explanation for the lower activity of dilauroyl derivatives could be found in the early work of Minsky and co-workers (*44*). They have suggested that fatty acid chains of 12 carbons are not long enough to create the hydrophobic environment required for efficient DNA compaction. Therefore, it appears that the anionic nucleotide lipids are more efficient compared to both DPPA−Ca^{2+}−DNA and Ca^{2+}−DNA transfecting systems, demonstrating that the nucleotide moiety influences the lipid−DNA associations and enhances the transfection efficacy of the natural anionic DPPA lipid.

CONCLUSION

In this study, we synthesized a new series of nucleotide-based lipids featuring thymidine-3′-monophosphate as nucleotide and 1,2-diacyl-*sn*-glycerol as hydrophobic moieties for *in vitro* delivery of nucleic acids. The amphiphilic structures were prepared in three steps from commercially available starting materials: 1,2-diacyl-*sn*-glycerols and 2′-deoxythymidine-3′phosphoramidite. Gel electrophoresis experiments indicate that nucleotide-based lipid−DNA complexes are observed above a concentration of 1 mM, which is higher than the intracellular calcium concentration ([Ca^{2+}] 1 μM) indicating that DNA can be released inside the cells. Electronic microscopy and dynamic light scattering investigations reveal that extrusion of DOPE −diC$_{16}$-3′-dT mixtures provide homogeneous liposomes, whereas larger aggregates are observed in the presence of DNA and Ca^{2+} confirming the formation of complexes.

SAXS studies indicate that the structure of the complexes is strongly dependent on the formulation. Different multiphase systems can be obtained for the DOPE−diC$_{16}$-3′-dT and DOPE−DPPA samples with and without plasmid DNA. The transfection experiments carried out on mammalian Hek cell lines clearly demonstrate that the nucleotide moiety enhances the transfection efficacy of the natural anionic DPPA and DPPG lipids. The SAXS studies also indicate that the enhancement in transfection is likely due to the presence of the 2D columnar inverted hexagonal phase (H_{II}) with a unit cell parameter a = 69.1 Å, which does not occur in the nucleotide free lipid system (DOPE−DPPA). These results confirm the interest of using anionic species (*45*) such as nucleotide lipids in formulations to optimize transfection efficacy.

The issue of transfection reagent cytotoxicity is particularly important in protocols that attempt to modulate gene function *in vitro* an/or *in vivo*. As nontoxic and efficient transfection reagents, the anionic nucleotide lipids presented in this work offer an alternative to cationic species, which can be, in some instances, especially toxic (*46*). These investigations further support the need for the synthesis and evaluation of nucleotide-based lipids as nucleotide acids delivery vehicles. *In fine*, nucleotide-based lipids further extend the possibilities of modulating the interactions between nucleic acids and lipids. Depending upon the nature of both partners, nucleotide lipids may offer new alternatives to lipids, and could be exploited in the case of small therapeutic oligonucleotides, for example.

Nucleic Acid Therapeutic Carriers with On-Demand Triggered Release

Siddarth Venkatesh,[†] Jacek Wower,*[,‡] and Mark E. Byrne*[,†]

Biomimetic and Biohybrid Materials, Biomedical Devices, and Drug Delivery Laboratories, Department of Chemical Engineering, and Department of Animal Sciences, Auburn University, Auburn, Alabama. Received April 23, 2009; Revised Manuscript Received July 28, 2009

Biohybrid platforms such as synthetic polymer networks engineered from artificial and natural materials hold immense potential as drug and gene delivery vehicles. Here, we report the synthesis and characterization of novel polymer networks that release oligonucleotide sequences via enzymatic and physical triggers. Chemical monomers and acrylated oligonucleotides were copolymerized into networks, and phosphoimaging revealed that 70% of the oligonucleotides were incorporated into the networks. We observed that the immobilized oligonucleotides were readily cleaved when the networks were incubated with the type II restriction enzyme *Bam*HI. The diffusion of the cleaved fragments through the macromolecular chains resulted in relatively constant release profiles very close to zero-order. To our knowledge, this is the first study which harnesses the sequence-specificity of restriction endonucleases as triggering agents for the cleavage and release of oligonucleotide sequences from a synthetic polymer network. The polymer networks exhibited an oligonucleotide diffusion coefficient of 5.6×10^{-8} cm^2/s and a diffusional exponent of 0.92. Sigmoidal temperature responsive characteristics of the networks matched the theoretical melting temperature of the oligonucleotides and indicated a cooperative melting transition of the oligonucleotides. The networks were also triggered to release a RNA-cleaving deoxyribozyme, which degraded a HIV-1 mRNA transcript *in vitro*. To tailor release profiles of the oligonucleotides, we controlled the structure of the macromolecular architecture of the networks by varying their cross-linking content. When incubated with DNase I, networks of cross-linking content 0.15%, 0.22%, and 0.45% exhibited oligonucleotide diffusion coefficients of 1.67×10^{-8}, 7.65×10^{-9}, and 2.7×10^{-9} cm^2/s, and diffusional exponents of 0.55, 0.8, and 0.8, respectively. The modular nature of our platform promises to open new avenues for the creation and optimization of a rich toolbox of novel drug and gene delivery platforms. We anticipate further inquiry into nucleic acid based programmable on-demand switches and modulatory devices of exquisite sensitivity and control.

INTRODUCTION

It is now a well-established paradigm that molecular therapeutics can be used for the pharmacological intervention of many diseases (*1*−*3*). Nucleic acids are emerging as important drug targets and versatile therapeutic agents, because they perform critical enzymatic activities and regulate gene expression (*4*−*6*). Nucleic acids are also attractive for nanotechnology because they can be programmed to bind metals, small organic compounds, nucleic acids, proteins, and even entire cells via SELEX (*7, 8*). Efforts are underway to design novel drug agents such as siRNA cocktails and double-stranded miRNA mimetics and antagonists, that interfere with the processing and functioning of endogenous coding and noncoding transcripts (*9*). Equally imperative is the parallel development of devices and shuttles that enable precise delivery of such novel therapeutics to the diseased tissue or cells at therapeutically relevant concentrations, and with controlled release rates (*10, 11*). Off-targeting, toxicity, reduced *in vivo* potency, and interferon responses are pressing concerns for the clinical viability of novel therapies such as RNAi therapeutics (*12*). Bottom-up synthesis of conjugates of synthetic polymers, lipids, and RNAi therapeutics can lower toxicity and could be remodeled into recognizable epitopes in order to pacify the immune response. These molecular therapeutics could be targeted to specific receptors and markers using their cognate ligands (*13, 14*).

Biohybrid platforms, particularly synthetic polymers engineered from artificial and natural materials, hold immense potential as controlled release vehicles (*15*−*17*). They possess striking properties such as biocompatibility, greater flexibility in their bottom-up design, and well-studied synthetic protocols. Polymer networks synthesized purely from artificial monomers such as methacrylic acid, acrylamide, and N-isopropylacrylamide demonstrate phase or volume transitions on varying pH (*18*), temperature (*19*−*21*), light (*22*), and electric field (*23*−*25*). Conjugates of polymers and biomolecules immobilized within the network transduce either a local physical or ionic stimulus into changes in tertiary structure and controllable macroscopic transitions (*26*−*30*). Novel synthetic networks cross-linked by peptides and recombinant proteins have gained significant attention (*31*−*33*), because they translate temperature- and pH-sensitive biomolecular conformation switches into observable volume transitions at the macromolecular level. In particular, the focus is either on networks whose cross-links are selectively hydrolyzed by enzymes or on chemically cross-linked polymer networks that carry pendant enzyme-sensitive moieties (*32, 34*−*37*). Affinity-based delivery systems consisting of bidentate peptides have been used to sequester proteins within fibrin matrices (*38*−*42*). One domain of the peptide consists of a transglutaminase substrate and facilitates cross-linking of the peptide into the matrix. The other domain has a heparin-binding domain and immobilizes heparin via

electrostatic interactions. Heparin, in turn, binds various proteins and can be triggered to release them via enzymatic triggers or by passive diffusion. Such a system has been shown to control the release of growth factors such as NGF, BDNF, and NT-3.

Much progress is being made in the development of biohybrid platforms for the intracellular delivery of RNAi therapeutics (*5, 10*). Conventional thinking leans toward the delivery of double-stranded RNAs from which siRNAs are derived by the enzymatic activity of Dicer, the direct delivery of artificial siRNAs, and the construction of miRNA or shRNA mimetics and antagonists (*43*). A variety of strategies to express siRNAs using viral vector-based cassettes have been developed (*44*−*46*). Furthermore, siRNAs have been rendered resistant to nucleases via modifications and have been conjugated to ligands such as folic acid, galactosamine, or transferrin, to enhance specificity (*12, 47*). Respiratory, urogenital, and ocular tissues can take up siRNAs after topical application or direct injection of naked siRNAs alone or in complexes with cationic lipids used for *in vitro* transfection, but most other tissues are refractory to the direct uptake of siRNAs (*48, 49*). Gold nanoparticles of sizes ranging 2−30 nm are readily taken up by cells without eliciting immune responses, although the exact mechanism of uptake remains unclear (*50*−*53*). Thus, biohybrid platforms composed of lipids, polymers, and RNA therapeutics are generating much excitement due to their multiple modalities and selective delivery properties (*17, 54*−*60*).

Branched DNA molecules with strategically programmed sticky ends have been assembled into hydrogels via the action of T4 DNA ligase (*61*). Nucleic acid sequences have also been used to cross-link polymer networks (*62, 63*). What has remained unresolved is whether the vast array of enzymes used for DNA cloning and analysis could be exploited for catalytic activity within synthetic polymer networks. To answer this question, we synthesized and characterized novel synthetic polymer networks that release oligonucleotide sequences in response to physical and enzymatic triggers. To our knowledge, this is the first study which harnesses the sequence-specificity of restriction endonucleases as triggering agents for the cleavage and release of oligonucleotide sequences from a synthetic polymer network. By remodeling our construct to include an anti-HIV deoxyribozyme, i.e., an oligonucleotide sequence bearing catalytic properties, we showed *in vitro* degradation of a HIV-1 Tat/Rev mRNA upon triggered release of the deoxyribozyme from the network. We further tailored the release rates by structurally controlling the macromolecular architecture of the synthetic polymer networks. The modules of our biohybrid platform, i.e., the macromolecular architecture, the oligonucleotide sequences, and the triggering agent can be individually optimized in order to obtain a rich toolbox of novel drug and gene delivery platforms.

EXPERIMENTAL PROCEDURES

Materials. The chemical monomers, acrylamide (AM), bisacrylamide, and 2-hydroxyethylmethacrylate (HEMA), were purchased from Sigma-Aldrich (Milwaukee, WI). Poly(ethylene glycol) (200) dimethacrylate (PEG200DMA) and poly(ethylene glycol) (600) dimethacrylate (PEG600DMA) was purchased from Polysciences, Inc. (Warrington, PA). T4 RNA ligase, DNA polymerase I (Klenow fragment), and restriction enzymes *Bam*HI and *Eco*RI were obtained from New England BioLabs. T4 polynucleotide kinase (3′ phosphatase-free) was purchased from Roche Diagnostics. SUPERase-In was obtained from Ambion. Modified oligonucleotides were synthesized by Operon Biotechnologies. All radiochemicals were purchased from ICN Biochemicals, Inc. Ribonucleoside triphosphates (rNTPs) were from Amersham. NAP-5 columns were from GE Healthcare.

All buffers were prepared according to standard recipes: TE buffer: 10 mM Tris-HCl (pH 7.5) and 1 mM EDTA. PNK buffer: 50 mM Tris-HCl (pH 7.5), 10 mM $MgCl_2$, and 5 mM dithiothreitol. TBE buffer: 100 mM Tris-100 mM H_3BO_4 (pH 8.3) and 2.5 mM EDTA. Hybridization buffer: 10 mM Tris-HCl (pH 7.5) and 5 mM $MgCl_2$. T7 RNA polymerase buffer: 20 mM Tris-HCl (pH 8), 3 mM $MgCl_2$, 5 mM dithiothreitol, and 1 mM spermidine. DNA/RNA extraction buffer: 500 mM CH_3COONH_4, 10 mM $(CH_3COO)_2Mg$, 0.1 mM EDTA, and 0.1% SDS.

***In Vitro* Hybridization and Restriction Enzyme Digestion of Oligonucleotides.** The anchoring 5′ acrydite-modified oligonucleotide (ANC, Figure 1a) and its complementary oligonucleotide (COMP-ANC, Figure 1a) were resuspended to 1 mM final concentration in TE buffer. The COMP-ANC oligonucleotide was labeled at its 5′ end with [γ-^{32}P]ATP and T4 polynucleotide kinase. Reaction mixtures consisted of 2 μL of the oligonucleotide (1 mM), 4.3 μL of TE buffer (pH 7.5), 1 μL of 10X PNK buffer, 2 μL of [γ-^{32}P]ATP (4500 Ci/mmol), and 0.7 μL of enzyme (10 U/μL). After incubation for 30 min at 37 °C, the ^{32}P-labeled oligonucleotide was purified on a denaturing 12% polyacrylamide gel in TBE buffer and 8 M urea, and visualized by autoradiography. The ^{32}P-labeled oligonucleotide was extracted from the gel using 400 μL of DNA/RNA extraction buffer, desalted on a NAP-5 column according to the manufacturer's specifications, and concentrated by freeze−drying in an Integrated SpeedVac System (Savant Instruments, Inc.).

Electrophoretic mobility shift assay was used to confirm annealing of oligonucleotides. Increasing amounts of ANC oligonucleotide (0, 100, 200, 300, and 500 pmoles) were added to aliquots of ^{32}P-labeled COMP-ANC oligonucleotide (5000 cpm). Reaction mixtures consisted of 5 μL of ANC oligonucleotide, 5 μL of COMP-ANC oligonucleotide, and 1.1 μL of 10× hybridization buffer. A negative control reaction mixture consisted of 5 μL of RNase-free water, 5 μL of COMP-ANC oligonucleotide, and 1.1 μL of 10× hybridization buffer. All hybridization reaction mixtures were heated for 3 min at 90 °C, cooled on ice, and analyzed by electrophoresis on a non-denaturing 12% polyacrylamide gel at 4 °C. Annealed oligonucleotides were quantified using Typhoon 9410 phosphoimager and *ImageQuant* software (Amersham Biosciences).

The annealed oligonucleotides were digested with restriction enzyme *Bam*HI for 1 h at 37 °C, as per the manufacturer's instructions. Digestion reactions consisted of 9.4 μL of the annealed oligonucleotides, 1.1 μL of 10× NEBuffer 3, and 0.6 μL of *Bam*HI enzyme. The digested products were fractionated on a non-denaturing 12% polyacrylamide gel and analyzed by autoradiography. Autoradiograms were quantified using Typhoon 9410 phosphoimager and *ImageQuant* software.

Synthesis and Characterization of Networks Conjugated with Oligonucleotides. Poly(AM-*co*-bisacrylamide-*co*-acrylated DNA), poly(AM-*co*-PEG200DMA-*co*-acrylated DNA), poly(HEMA-*co*-PEG600DMA-*co*-acrylated DNA) networks of varying cross-linking content were prepared via redox polymerization at 25 °C in the loading wells of a non-denaturing 12% polyacrylamide gel. Typically, 10 μL of acrylamide and bisacrylamide were copolymerized with 10 μL of the annealed oligonucleotides. When the poly(AM-*co*-PEG200DMA-*co*-acrylated DNA) and poly(HEMA-*co*-PEG600DMA-*co*-acrylated DNA) networks were synthesized, homogeneous mixtures of HEMA and PEG(200/600)DMA were prepared first and then copolymerized with 10 μL of the annealed oligonucleotides. After polymerization, the unreacted annealed oligonucleotides and unhybridized ^{32}P-labeled oligonucleotides were removed by

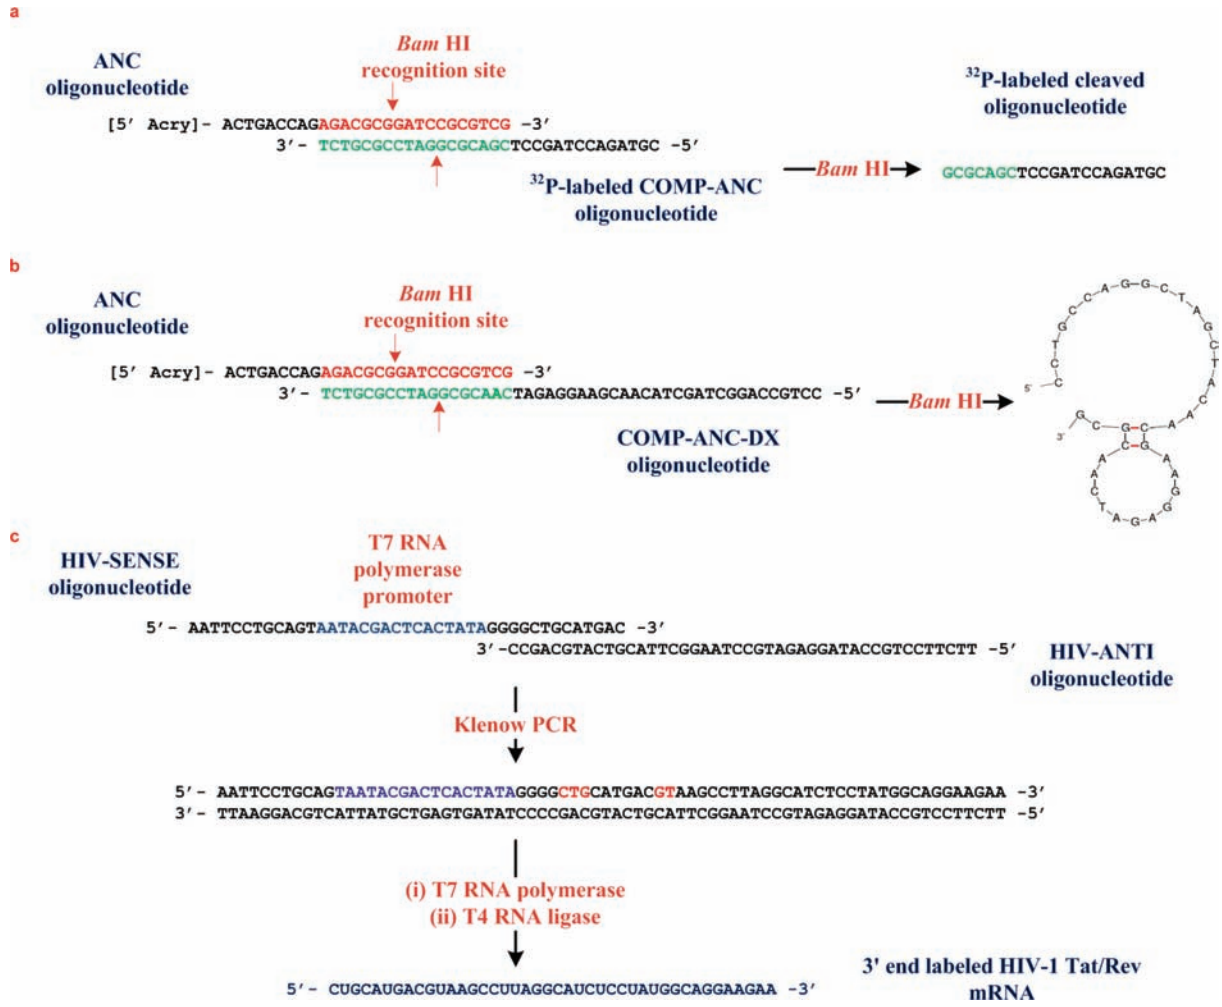

Figure 1. Oligonucleotide constructs used in this study. (a) The annealed ANC and ^{32}P-labeled COMP-ANC oligonucleotides were readily cleaved and yielded ^{32}P-labeled single-stranded fragments when the networks were incubated with *Bam*HI. (b) The annealed ANC and COMP-ANC-DX oligonucleotides released an anti-HIV-1 deoxyribozyme when the networks were incubated with *Bam*HI. (c) *In vitro* transcription and 3′ end labeling of the HIV-1 Tat/Rev mRNA.

electrophoresis. The polymer networks were cut out from the loading wells and incubated in 10 mM Tris-HCl buffer, pH 7.5. The efficiency of the polymerization reaction was determined by scanning the polyacrylamide gel in a Typhoon 9410 phosphoimager.

***In Vitro* Kinetic Release of Oligonucleotides upon Restriction Enzyme and Temperature Triggers.** Kinetic release studies of ^{32}P-labeled oligonucleotides from poly(AM-*co*-PEG200DMA-*co*-acrylated DNA) networks were conducted by incubating the networks with *Bam*HI in NEBuffer 3. The release of the DNA fragments was monitored by Cerenkov counting. The networks were incubated in reaction mixtures of 8 μL of 10× NEBuffer 3, 70 μL of 10 mM Tris-HCl buffer at pH 7.5, and 2 μL of *Bam*HI enzyme. In control experiments, the networks were incubated either without *Bam*HI or with *Eco*RI, a restriction endonuclease that does not cut DNA at the *Bam*HI recognition site. Temperature-responsive release characteristics of melted oligonucleotides were investigated between 30 and 85 °C.

The Stokes radii of the enzymes were determined using a calibration curve of standard proteins of known Stokes' radii: bovine thyroglobulin (85 Å), horse spleen ferritin (61 Å), bovine liver catalase (52.2 Å), rabbit muscle aldolase (48.1 Å), bovine serum albumin (35.5 Å), ovalbumin (30.5 Å), bovine pancreas chymotrypsinogen A (20.9 Å), and bovine pancreas ribonuclease A (16.4 Å).

***In Vitro* Kinetic Release of Oligonucleotides upon Deoxynuclease I Trigger.** Kinetic release studies of ^{32}P-labeled DNA from poly(HEMA-*co*-PEG600DMA-*co*-acrylated DNA) networks were conducted by incubating the networks with DNase I (a nonspecific endonuclease). The release of the cleaved fragments was monitored by Cerenkov counting. The effect of the macromolecular architecture of the polymer network on the diffusion of oligonucleotides was investigated using networks of varying cross-linking content (0.15%, 0.22%, and 0.45%). Cross-linking content was calculated on an acrylate DNA-free basis.

Analysis of the Release of Oligonucleotides upon Enzymatic Triggers. Diffusion of oligonucleotides from a thin polymer network was approximated to a plane sheet. Because geometries with aspect ratios (exposed surface length/thickness) greater than 10 edge effects could be ignored, the problem could be modeled as a one-dimensional process.

By using Fick's Law, the following partial differential equation, initial conditions, and boundary conditions were used to model the one-dimensional planar release from a synthetic polymer network (*64*, *65*).

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \qquad (1)$$

$$t = 0 \quad C(x, t) = C_0 \tag{2}$$

$$t > 0 \quad x = 0 \quad \frac{\partial C}{\partial x} = 0 \tag{3}$$

$$t > 0 \quad x = \pm L \quad C = C_s \tag{4}$$

where C_o represents the initial DNA concentration (assumed to be uniform in the homogeneous gel), x represents the distance from the center of the sample to the surface, C_s represents the surface concentration, C is the concentration of the DNA within the gel, D represents a diffusion coefficient independent of position and concentration, t is time, and $2L$ is the thickness of the network.

Using integral transform techniques, the solution of the PDE is given by

$$\frac{C - C_0}{C_s - C_0} = 1 - \frac{4}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{2n+1} \times \exp[-(2n+1)^2\pi^2 D/4L^2]t \cos\frac{(2n+1)\pi x}{2L} \tag{5}$$

If M_t is the total cumulative radioactive counts of DNA released at time t, and M_∞ is the total cumulative radioactive counts of DNA released at infinite time, M_t/M_∞ represents the fractional release of DNA with respect to the value at infinite time.

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=0}^{\infty}\frac{8}{(2n+1)^2\pi^2}\exp[-(2n+1)^2\pi^2 D/4L^2]t \tag{6}$$

The above expression is cumbersome to estimate a value of the diffusion coefficient, and hence, a solution is obtained in terms of error functions.

$$\frac{M_t}{M_\infty} = 4\left[\frac{Dt}{L^2}\right]^{1/2}\left[\frac{1}{\pi^{1/2}} + 2\sum_{n=1}^{\infty}(-1)^n i\,\mathrm{erfc}\left(\frac{nL}{2\sqrt{Dt}}\right)\right] \tag{7}$$

The integral complementary error function vanishes for short times (as $t \rightarrow 0$), and an expression is obtained for short times of diffusion.

$$\frac{M_t}{M_\infty} = 4\left[\frac{Dt}{\pi L^2}\right]^{1/2} \tag{8}$$

As indicated by eq 8, Fickian diffusional release is characterized by an initial $t^{0.5}/L$ dependence of the DNA released. This short time approximation is generally valid for the first 60% of the DNA released. For each synthetic polymer network, the fractional release of DNA *vs* ($t^{0.5}/L$) was plotted and the diffusion coefficient was calculated from the slope.

Most release processes are typically intermediates of Fickian and non-Fickian mechanisms (*66*, *67*). The fractional release of DNA with respect to the value at infinite time

$$\frac{M_t}{M_\infty} = kt^n \tag{9}$$

where k is a constant incorporating characteristics of the synthetic polymer network and DNA, and n is the diffusional exponent, which is indicative of the transport mechanism. For a thin slab, Fickian diffusion is defined by $n = 0.5$, non-Fickian diffusion is defined by $n > 0.5$, and zero-order release is defined by $n = 1$.

Validation of the Platform by the *in Vitro* Degradation of HIV-1 Tat/Rev mRNA. The COMP-ANC oligonucleotide sequence was modified to encode a deoxyribozyme that degrades HIV-1 Tat/Rev mRNA (COMP-ANC-DX, Figure 1b). It was hybridized with the ANC oligonucleotide, and copolymerized with acrylamide and bisacrylamide as described earlier.

The HIV-1 mRNA was synthesized *in vitro* by runoff transcription of synthetic DNA templates (*68*, *69*). The DNA templates were constructed from two DNA strands 41 and 44 nucleotides in length, having an 11-bp overlap region (HIV-SENSE and HIV-ANTI, Figure 1c). HIV-SENSE contained the T7 RNA polymerase promoter and encoded the 5′ region of the mRNA, while HIV-ANTI encoded the complement of the 3′ region. Full-length templates were generated by extension of the annealed HIV-SENSE and HIV-ANTI oligonucleotides with the Klenow fragment of DNA polymerase I. Reaction mixtures consisted of 2 μL of oligonucleotides (100 μM), 5 μL of 10× Klenow buffer (New England BioLabs), 5 μL of dNTPs (4 mM), 37.5 μL of water, and 0.5 μL of the enzyme.

In vitro transcription reaction mixtures consisted of 10 μL of 2× T7 RNA polymerase buffer, 5.1 μL of rNTPs (10 mM), 1.9 μL of water, 2 μL of DNA templates (4 μM), 0.5 μL of T7 RNA polymerase, and 0.5 μL of SUPERase-In (20 U/ μL) for 2 h at 37 °C.

The transcripts were labeled at their 3′ ends using [5′-^{32}P]pCp and T4 RNA ligase (*70*, *71*) and purified on a denaturing 12% polyacrylamide gel. The 3′-end labeled HIV-1 Tat/Rev mRNA was incubated with the poly(AM-*co*-bisacrylamide-*co*-acrylated DNA) networks and *Bam*HI in NEBuffer 3. Reaction products were fractionated on a denaturing 12% polyacrylamide gel and visualized by autoradiography. Autoradiograms were quantified using Typhoon phosphoimager and *ImageQuant* software.

RESULTS AND DISCUSSION

We reasoned that oligonucleotide sequences covalently immobilized in synthetic polymer networks would be amenable to the action of their cognate enzymes used in conventional DNA cloning and gene manipulation (Figure 2a). Observing that chemical cross-linking of modified oligonucleotides into interpenetrating poly(acrylic acid) and poly(allylamine) chains resulted in inefficient gelation and poor mechanical characteristics of polymer networks (data not shown), we designed all oligonucleotide constructs with 5′-acrydite functionality. This would incorporate the oligonucleotides into the backbone of the propagating chains during redox polymerization (*72*).

Our first construct was formed by hybridizing the ANC and ^{32}P-labeled COMP-ANC oligonucleotides (Figure 1a). The double-stranded region of the annealed oligonucleotides contained the recognition site of the restriction endonuclease *Bam*HI. We chose a type II restriction endonuclease as our model enzyme, because these enzymes have tight sequence specificity for DNA (*73*) and are used widely in genomic mapping, DNA cloning, and restriction fragment length polymorphism (RFLP) analysis.

In vitro hybridization conditions were optimized in various concentrations of Tris-HCl buffer (pH 7.5) and water. Hybridization was inefficient in water (Figure 2b, lane 2) and 20 mM Tris-HCl buffer (Figure 2b, lane 3). Magnesium was determined to be critical for hybridization of the oligonucleotides (Figure 2b, lane 4). About 10% of ^{32}P-labeled COMP-ANC oligonucleotides self-annealed. The chemical monomers used for polymer synthesis had no effect on hybridization efficiency (data not shown). The annealed oligonucleotides were readily digested by *Bam*HI (Figure 2c, lane 4). In the absence of *Bam*HI, the annealed oligonucleotides remained stable on ice (Figure 2c, lane 2) and at 37 °C (Figure 2c, lane 3). In control experiments,

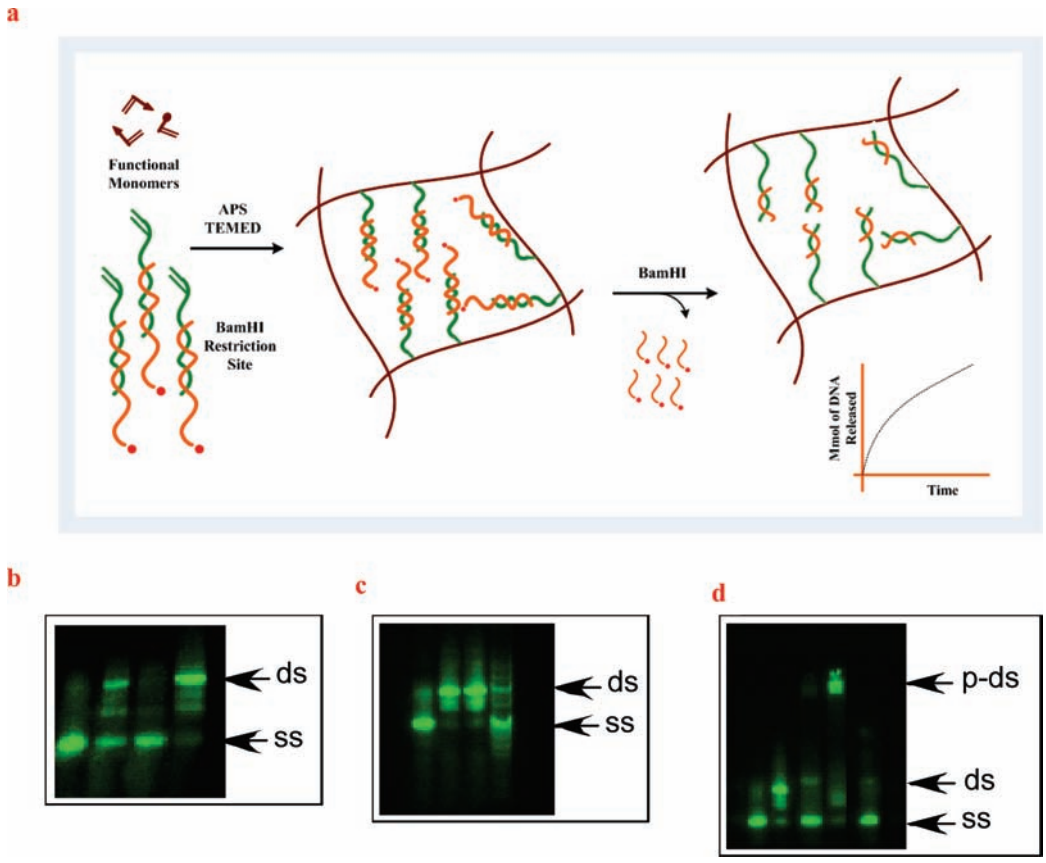

Figure 2. Synthesis and characterization of networks conjugated with oligonucleotides. (a) Redox copolymerization of chemical monomers and annealed oligonucleotides yields novel networks with pendant DNA helices. Restriction enzyme *Bam*HI specifically cleaves the sequence and releases an oligonucleotide from the network. (b) Mg^{2+} ions are critical for efficient hybridization of the acrylated DNA. (c) *Bam*HI cleaves the DNA double helix (lane 4). Single-stranded DNA is shown in lane 1. Single- and double-stranded DNA are denoted ss and ds, respectively. (d) Incorporation of the acrylated oligonucleotides and elution of single- and double stranded DNA by electrophoresis (lane 4). ^{32}P-labeled COMP-ANC elutes due to the absence of ANC oligonucleotide (lane 3). ^{32}P-labeled COMP-ANC (ss) and hybridized duplexes (ds) (lanes 1 and 2, respectively), were used as controls. p-ds is covalently incorporated ds DNA.

we verified that NEBuffer 3 did not disrupt the annealed oligonucleotides.

We synthesized poly(AM-*co*-bisacrylamide-*co*-acrylated DNA), poly(AM-*co*-PEG200DMA-*co*-acrylated DNA), poly(HEMA-*co*-PEG600DMA-*co*-acrylated DNA) networks by copolymerizing the relevant chemical monomers with the annealed oligonucleotides. During the polymerization reaction, unreacted single and double strands get entangled in the propagating macromolecular chains, and interfere with further analysis. The networks were synthesized in the loading wells of non-denaturing 12% polyacrylamide gels, in order to remove unreacted DNA by electrophoresis. A number of control experiments were performed to characterize the process. In order to test if the anchoring of the annealed oligonucleotides was due to the acrydite modification, the ^{32}P-labeled COMP-ANC oligonucleotide was copolymerized with acrylamide and bisacrylamide. The oligonucleotide eluted readily from the network during electrophoresis (Figure 2d, lane 3). On the other hand, the annealed oligonucleotides were polymerized into the backbone of the macromolecular chains (Figure 2d, lane 4). Phosphoimaging revealed that 70% of the annealed oligonucleotides were incorporated into the networks. To conclusively demonstrate that Watson−Crick pairing, and not physical entanglement, is responsible for the incorporation of DNA, acrylamide, and bisacrylamide were copolymerized with the ANC oligonucleotide and a ^{32}P-labeled oligonucleotide whose sequence was not complementary to it. As expected, the ^{32}P-labeled oligonucleotide eluted from the network during electrophoresis, as annealing did not occur between the two strands (Figure 2d, lane 5).

The poly(AM-*co*-bisacrylamide-*co*-acrylated DNA) networks were then incubated with *Bam*HI *in vitro* to evaluate their potential as controlled-release vehicles. We observed that the DNA helices were readily cleaved and diffusion of the ^{32}P-labeled cleaved fragments through the macromolecular chains resulted in relatively constant release profiles very close to zero-order (Figure 3a). The networks exhibited an oligonucleotide diffusion coefficient of 5.6×10^{-8} cm^2/s, and a diffusional exponent of 0.92. The release of the oligonucleotides depends on multiple steps: diffusion of the enzyme; binding, distortion, and cleaving of oligonucleotides by the enzyme; and diffusion of the cleaved oligonucleotide fragments. These processes are reflected in a lag time between the enzyme dosage and the initial detection of the ^{32}P-labeled cleaved oligonucleotides. We hypothesize that the rate-limiting step of the release process is the slow diffusion of the large enzyme molecule within the macromolecular structure.

In control experiments, we evaluated the specificity of restriction endonucleases within the macromolecular architecture of synthetic polymer networks. Incubating the networks in the absence of *Bam*HI did not result in DNA release (Figure 3a). Furthermore, *Eco*RI, a restriction endonuclease which does not recognize the *Bam*HI recognition site, did not trigger DNA release. It is important to note that *Eco*RI (M_r 31 057 Da, Stokes radius of 23.85 Å) has dimensions similar to *Bam*HI (M_r 24 569, Stokes radius of 22.22 Å), and

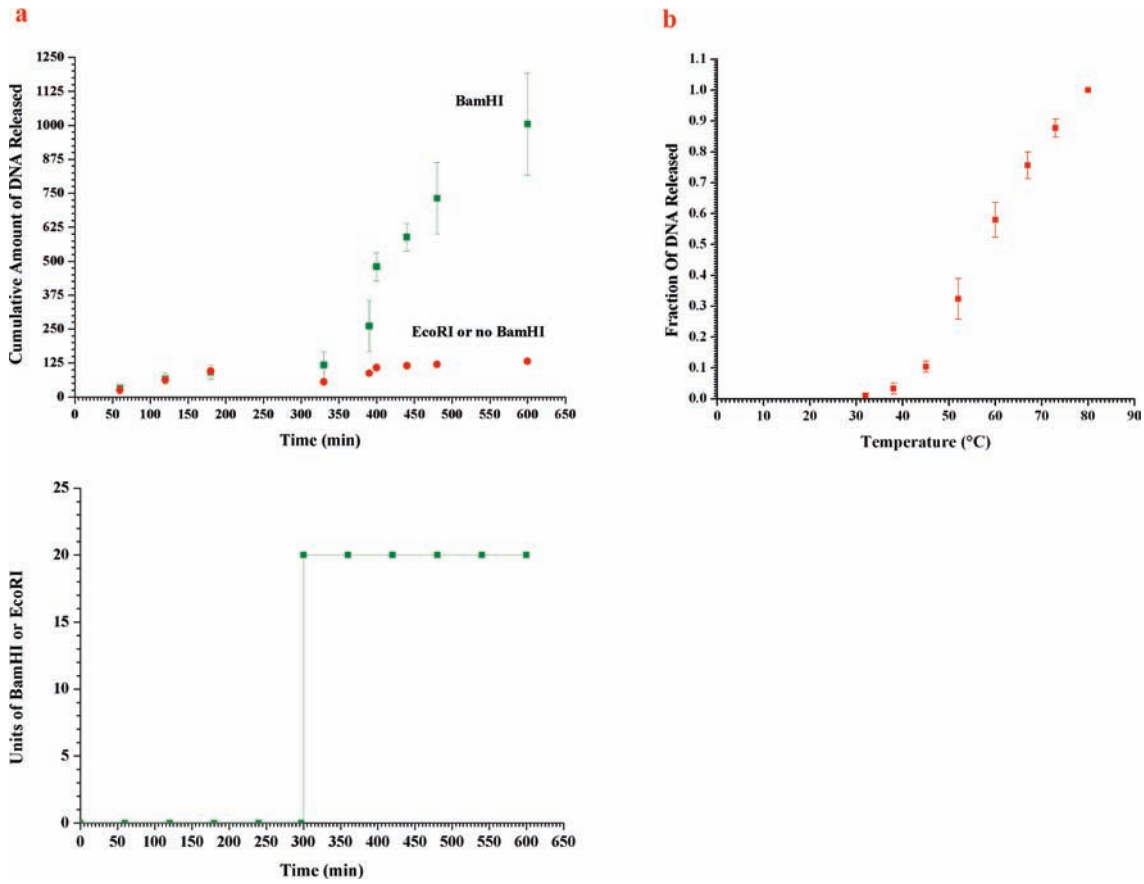

Figure 3. Dynamic tunable release profiles of oligonucleotides from synthetic polymer networks by enzymatic or temperature triggers. (a) Tailored release of oligonucleotides (top panel) by incubating the gels with *Bam*HI (green filled square, lower panel) as compared to incubating in buffer only (red filled circle). (b) Sigmoidal temperature dependent release of DNA (red filled square). $N = 5 \pm$ SD.

that these two globular enzymes are among the most efficient restriction enzymes known. The efficiency of these enzymes is enhanced by flanking sequences, which increase the binding affinity of the enzyme to the recognition site, and the stability of the ensuing interaction (*74*). Our findings suggest that release profiles could be delayed further by using restriction enzymes of lower efficiency or by modifying sequences flanking their recognition sites. In order to control the star activity of these enzymes, i.e., the relaxation of sequence specificity under extreme conditions, our experiments were carried out under tightly controlled pH conditions, low concentrations of glycerol and enzyme, and the absence of organic solvents or divalent cations such as Mn^{2+}, Cu^{2+}, or Zn^{2+}.

Incubation of annealed oligonucleotides at the melting temperature results in the separation of the DNA strands. Figure 3b illustrates the release characteristics of a poly(AM-*co*-bisacrylamide-*co*-acrylated DNA) network in response to a linear temperature gradient. The sigmoidal nature of the release indicated a cooperative melting transition of the immobilized oligonucleotides. The temperature gradient had no effect on the structural integrity of the network. The melting temperature of an oligonucleotide can be estimated from its sequence by the nearest-neighbor method (*75*). The observed melting temperature matched the estimated value of 58 °C. Hence, sequence can be used to tailor the temperature of release from this platform.

We next remodeled the oligonucleotide construct to encode an RNA-cleaving deoxyribozyme that possesses the catalytic 10−23 motif (*76*, *77*) and cleaves the overlapping sequences of the Tat and Rev exons (*78*, *79*). These genes are essential for viral replication and pathogenesis, and hence their mRNAs are attractive targets for gene therapy (*1*). The resulting poly(AM-*co*-bisacrylamide-*co*-acrylated DNA) networks were incubated with *Bam*HI and the HIV-1 Tat/Rev mRNA, which was transcribed *in vitro*. We hypothesized that *Bam*HI would trigger the release of the deoxyribozyme and degrade the HIV-1 Tat/Rev mRNA by trans-esterification (Figure 4a,b). As expected, incubation of the HIV-1 Tat/Rev mRNA along with the deoxyribozyme-loaded network and *Bam*HI resulted in specific cleavage (Figure 4c, lane 3). In control experiments, we incubated a network lacking the deoxyribozyme construct with *Bam*HI. The HIV-1 Tat/Rev mRNA was not degraded, demonstrating that catalytic activity of the deoxyribozyme is necessary for degradation of the transcript (Figure 4c, lane 2). Our data suggest that such platforms could be useful for developing delivery systems for siRNAs, aptamers, and ribozymes. Intriguingly, the oligonucleotide release could be triggered *in vivo* by endogenous nucleases such as RNase P (*80*−*82*), RNase L (*83*, *84*), and RNase 4 (*85*, *86*). These enzymes could be recruited by incorporating their cognate recognition sites in the constructs. This would enhance the targeting efficacy and specificity.

We hypothesized that macromolecular structure could affect oligonucleotide diffusion rates. To test this, we synthesized poly(HEMA-*co*-PEG600DMA-*co*-acrylated DNA) networks of varying cross-linking content (0.15%, 0.22%, and 0.45%). The release of oligonucleotides from these networks was triggered by the nonspecific endonuclease DNase I. Figure 5a,b illustrates the release characteristics of such networks. Our results suggest that cross-linking content, which is correlated with molecular parameters such as mesh

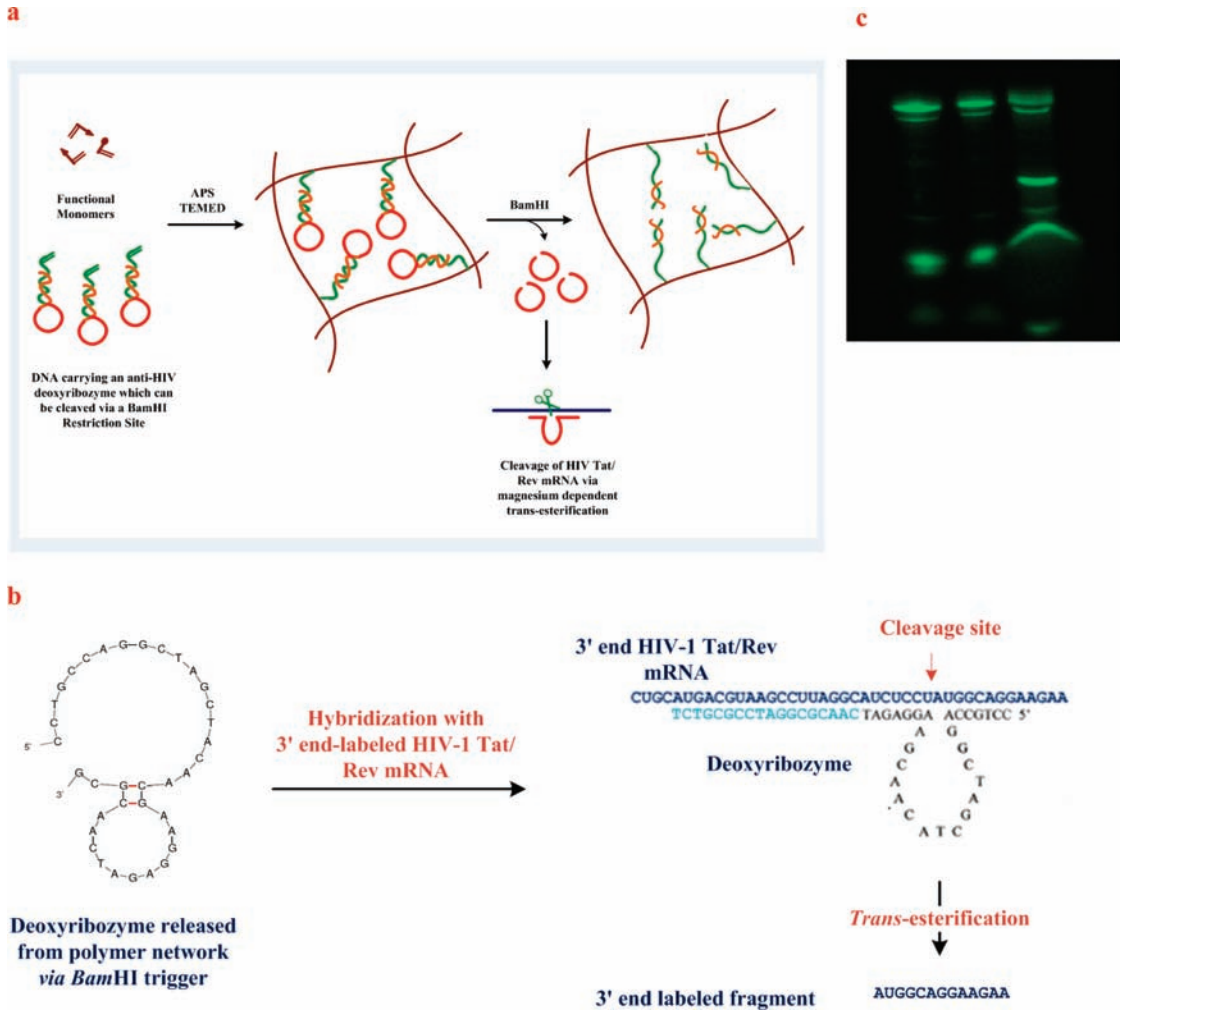

Figure 4. Degradation of a HIV-1 Tat/Rev mRNA by a deoxyribozyme released from a synthetic polymer network via a specific enzymatic trigger. (a) *Bam*HI cleaves the construct and releases the deoxyribozyme encoded in the loop of the hairpin. The deoxyribozyme then binds and cleaves the HIV-1 Tat/Rev mRNA. (b) Cleavage of the HIV-1 Tat/Rev mRNA via trans-esterification. (c) Degradation of HIV-1 Tet/Rev mRNA by deoxyribozyme released from a synthetic polymer network via *Bam*HI trigger (lane 3). No degradation is observed when *Bam*HI is incubated with a network lacking deoxyribozyme (lane 2). pCp-labeled HIV-A Tat-Rev mRNA was used as control (lane 1).

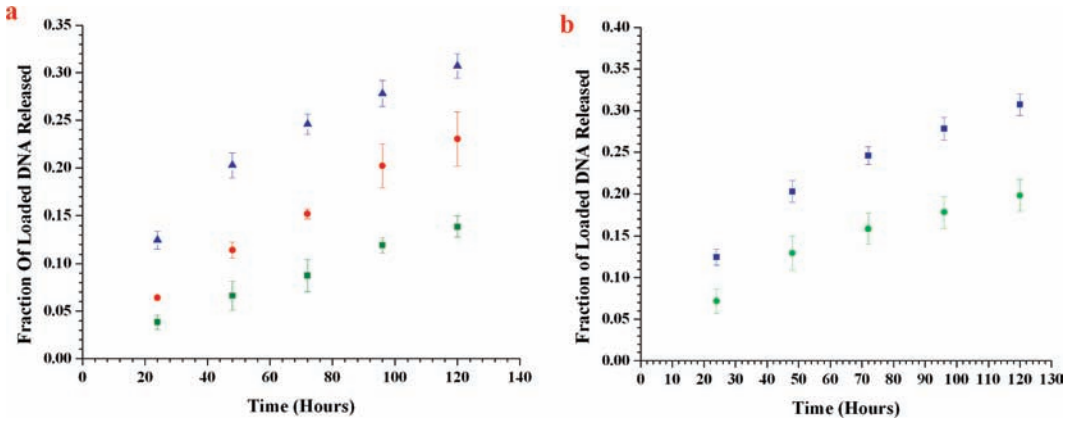

Figure 5. Tunable release profiles of oligonucleotides from synthetic polymer networks by controlling macromolecular architecture and enzymatic triggers. (a) Tailored release of oligonucleotides by incubating the poly(HEMA-*co*-PEG600DMA-*co*-acrylated DNA) networks of varying cross-linking content in DNase I. Cross-linking content of the networks, calculated on an acrylate DNA-free basis, were 0.15% (blue triangle), 0.22% (red circle), and 0.45% (green square). $N = 3 \pm$ SD. (b) Tailored release of oligonucleotides by incubating a gel of weak cross-linking content (0.15%) in DNase I at physiological conditions (blue square) as compared to incubating in buffer only (green circle).

size (*87*), can be used to tailor release rates. The networks of cross-linking content 0.15%, 0.22%, and 0.45% exhibited oligonucleotide diffusion coefficients of 1.67×10^{-8}, 7.65×10^{-9}, and 2.7×10^{-9} cm^2/s, respectively, and diffusional exponents of 0.55, 0.8, and 0.8, respectively. Our findings suggest that diffusion of oligonucleotides through the networks is Fickian at lower cross-linking content and moves closer to zero-order as cross-linking content is increased. The switch from Fickian to zero-order transport on increasing the cross-linking content occurs due to the following reasons:

hindrance of polymer chains to the diffusing enzyme, a decrease in the ratio between the polymer mesh size and the hydrodynamic radius of the enzyme, and decrease in the free volume available for diffusional transport (*87*). Further optimization of the polymer network structure can be performed to obtain desired release rates.

CONCLUSIONS

In summary, we have synthesized and characterized novel synthetic polymer networks that are versatile, programmable platforms for the controlled delivery of oligonucleotides via both enzymatic and physical triggers. We observed that the immobilized oligonucleotides were readily cleaved when the networks were incubated with the type II restriction enzyme *Bam*HI, and diffusion of the cleaved fragments through the macromolecular chains resulted in relatively constant release profiles very close to zero-order. The networks were triggered to release a RNA-cleaving deoxyribozyme, which degraded a HIV-1 mRNA transcript *in vitro*. Furthermore, the structural characteristics of the macromolecular polymer networks were controlled in order to tailor release profiles of the oligonucleotides. We envision that biohybrid platforms of oligonucleotide sequences and biodegradable synthetic polymers could be utilized for the intracellular delivery of multiple drugs from the same vehicle and as injectable systems targeted to specific cells using functionalized ligands such as folic acid.

Activity-Linked Labeling of Enzymes by Self-Immolative Polymers

Roy Weinstain,[†] Phil S. Baran,[‡] and Doron Shabat*[,†]

School of Chemistry, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel Aviv University, Tel Aviv 69978 Israel, and Department of Chemistry, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037. Received May 6, 2009; Revised Manuscript Received July 26, 2009

The development and application of tools that allow labeling of proteins *in vitro* and *in vivo* is a highly active and interdisciplinary area of research. Self-immolative polymers (SIPs) are a unique type of molecules that respond to external stimuli by undergoing head-to-tail disassembly through a self-immolative fragmentation. We have demonstrated how these polymers can be applied as activity-linked labeling probes for proteins with catalytic activity. A real-time detection of the protein labeling can be monitored due to a change in the fluorescence emission wavelength of the probe during the polymer disassembly process. The SIP-based labeling approach showed considerable conservation of catalytic activity of the labeled protein and significant preference toward labeling of the activating protein.

INTRODUCTION

The vital roles played by proteins in many cellular processes make studies of protein dynamics, localization, and interactions crucial. Fluorophore-labeled proteins allow such studies using fluorescent imaging (*1, 2*). In recent years, chemical labeling utilizing small molecules emerged as a powerful technique for *in vivo* and *in vitro* studies of cellular proteins, circumventing some problems presented by genetic encoding of large fluorescent proteins (*3, 4*). Various strategies have been developed in order to achieve specific labeling of proteins in their native competitive environment. These include the use of protein targeting sequences (*5*−*7*), peptide targeting sequences (*8*−*12*), unnatural amino acids (*13, 14*), and others (*15*−*18*). More recently, a new strategy for specific labeling of proteins is being explored. This strategy takes advantage of the protein's specific activity to achieve its selective labeling (*19, 20*). Nagano and co-workers developed an enzyme activity-based labeling probe, with a quinone-methide species generated by the catalytic activity of the enzyme (*21*). Quinone-methide chemistry has also been proven useful for chemical modification of cellular components such as nucleotides and proteins (*22*−*24*). A short time ago, we introduced novel "smart" polymers that respond to external stimuli by undergoing head-to-tail disassembly through self-immolative fragmentation (*25*). We have demonstrated the applicability of these self-immolative polymers (SIPs)[1] for signal amplification and controlled drug release (*26*). The disassembly of SIPs under aqueous conditions releases azaquinone-methide intermediates that react with water to generate fluorescent molecules. However, if the external stimulus that initiates the SIP disassembly is generated by an enzyme, the azaquinone-methide units can be trapped by a nucleophilic residue of the protein, thereby generating a labeled protein. Here, we report the use of SIPs as activity-linked fluorescent labeling agents for proteins.

[1]Abbreviations: SIP, Self-Immolative Polymer; DCM, Dichloromethane; DMF, Dimethylformamide; EtOAc, Ethyl acetate; Hex, *n*-Hexanes; PBS, Phosphate buffer saline; THF, Tetrahydrofuran; ACN, Acetonitrile; MeOH, Methanol; NaOH, Sodium hydroxide; AcOH, Acetic acid; DMSO, Dimethylsulfoxide; DIBAL-H, Diisobutylaluminium hydride; DBTL, Dibutyltin dilaurate; TFA, Trifluoroacetic acid; PNA, *p*-Nitroaniline; TBSCl, *tert*-butyldimethylsilyl chloride; PGA, Penicillin G-amidase; Ab38C2, Antibody 38C2.

MATERIALS AND METHODS

All reactions requiring anhydrous conditions were performed under an Ar or N_2 atmosphere. All reactions were carried out at room temperature unless stated otherwise. Chemicals and solvents were either A.R. grade or purified by standard techniques. Thin layer chromatography (TLC): silica gel plates Merck 60 F_{254}; compounds were visualized by irradiation with UV light. Flash chromatography (FC): silica gel Merck 60 (particle size 0.040−0.063 mm), eluent given in parentheses. ^{1}H NMR spectra were measured using Bruker Avance operated at 200 or 400 MHz as mentioned. ^{13}C NMR spectra were measured using Bruker Avance instrument operated at 50 or 100 MHz as mentioned. The chemical shifts are expressed in δ relative to TMS ($\delta = 0$ ppm) and the coupling constants J in Hz. The spectra were recorded in $CDCl_3$ as solvent at room temperature unless stated otherwise. All fluorescence and absorbance measurements were performed in a 96-well ELISA plate using a Molecular Devices SPECTRAmaxM2 plate reader. All general reagents, including salts and solvents, were purchased from Sigma-Aldrich. Antibody 38C2 was kindly obtained from the Scripps Research Institute.

Synthesis. The synthesis, including detailed procedures, synthetic schemes and full characterization of all new compounds presented in the manuscript, is described in the Supporting Information.

Competition Behavior between Morpholine and Methanol: The Concentration Ratio of MeOH to Morpholine is 900 to 1. Compound **4** (25 mg, 0.047 mmol) was dissolved in MeOH (10 mL, 900 equiv), morpholine (30 μL, 0.34 mmol, 1 equiv) was added, and the reaction was monitored to completion (2 h) by TLC (EtOAc/Hex 3:7). The solvent was removed under reduced pressure and the residue taken in EtOAc (30 mL). The organic phase was washed twice with saturated NH_4Cl solution, dried over $MgSO_4$, then filtered, and the solvent was removed under reduced pressure. The crude products were purified by column chromatography on silica gel (EtOAc/Hex 3:7) to give

10.1021/bc9002037 CCC: $40.75 © 2009 American Chemical Society
Published on Web 08/18/2009

compound **4c** (3 mg, 20%) as a yellow oil (see characterization of **4c** in Supporting Information) and compound **4b** (9 mg, 72%) as a yellow oil (see characterization of **4b** in Supporting Information).

Competition Behavior between Morpholine and Methanol: The Concentration Ratio of MeOH to Morpholine is 90 to 1. Compound **4** (25 mg, 0.047 mmol) was dissolved in MeOH (10 mL, 312.5 mmol, 90 equiv), and morpholine (300 μL, 3.44 mmol, 1 equiv) was added. The reaction was monitored to completion (1 h) by TLC (EtOAc/Hex 3:7). The solvent was removed under reduced pressure and the residue taken in EtOAc (30 mL). The organic phase was washed twice with saturated NH_4Cl solution, dried over $MgSO_4$, then filtered, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel (EtOAc/Hex 3:7) to give compound **4c** (12 mg, 79%) as a yellow oil.

Competition Behavior between Z-Lys(Boc)-OH and Methanol: The Concentration Ratio of MeOH to Z-Lys(Boc)-OH is 950 to 1. Compound **4** (35 mg, 0.066 mmol) was dissolved in MeOH (10 mL, 950 equiv), and Z-Lys-OEt **15** (102 mg, 0.33 mmol, 1 equiv) was added. The reaction was stirred at room temperature and monitored to completion (8 h) by TLC (EtOAc/Hex 1:3). After concentration to dryness, the residue was taken in EtOAc (30 mL) and washed twice with water. The organic phase was dried with $MgSO_4$, filtered, and the solvent removed under reduced pressure. The crude product was purified by column chromatography on silica gel (EtOAc/Hex 15:85) to give compound **4b** (8 mg, 46%) as a yellow oil.

Competition Behavior between Z-Lys(Boc)-OH and Methanol: The Concentration Ratio of MeOH to Z-Lys(Boc)-OH is 75 to 1. To a solution of Z-Lys-OEt **15** (12 mg, 0.04 mmol, 1 equiv) in methanol (95 μL, 3 mmol, 75 equiv) was added 5 μL of compound **4** (from stock solution of 10 mM in DMSO) and the reaction monitored to completion (6 h) by RP-HPLC-MS. Two major products were formed (not including the released *p*-nitroaniline) and characterized according to their recorded masses (see Supporting Information).

Fluorescence Emission of Probe 5 upon Activation with PGA. To a 95 μL solution of PGA (0.5 mg/mL) in PBS pH 7.4 was added 5 μL of probe **5** (from 10 mM stock solution in DMSO) for a final concentration of 250 μM. Fluorescence spectra (λ_{ex} = 270 nm) were recorded every 3 min. Small molecules were removed by means of column chromatography over Sephadex G-25 (eluent: PBS pH 7.4). The protein concentration in the eluted solution was assessed using a standard BCA kit (bicinchoninic acid kit, Pierce, USA). In all cases, more than 95% of the protein's initial amount was present in the eluted solution. Fluorescence (λ_{ex} = 270 nm, λ_{em} = 510 nm) was measured for 100 μL solution of the purified protein (28 μg).

Labeling Procedure of PGA. To a 0.5 mL solution of PGA (1 mg) in PBS pH 7.4 was added 12.5 μL of polymer **7** (from stock solution of 10 mM in DMSO) for a final concentration of 250 μM. The solution was kept at room temperature for 3 h, then diluted with 2 mL PBS pH 7.4, and small molecules were removed by means of column chromatography over Sephadex G-25 (eluent: PBS pH 7.4). The protein concentration in the eluted solution was assessed using a standard BCA kit (bicinchoninic acid kit, Pierce, USA). In all cases, more than 95% of the initial amount of the protein was present in the eluted solution. Fluorescence (λ_{ex} = 270 nm, λ_{em} = 510 nm) was measured for 100 μL solution of the purified protein (0.285 mg/mL).

Labeling Procedure of Ab38C2. To a 0.5 mL solution of Ab38C2 (1 mg) in PBS pH 7.4 was added 12.5 μL of polymer **8** (from stock solution of 10 mM in DMSO) for a final concentration of 250 μM. The solution was kept at room temperature for 14 h, then diluted with 2 mL PBS pH 7.4, and small molecules were removed by means of column chromatography over Sephadex G-25 (eluent: PBS pH 7.4). The protein concentration in the eluted solution was assessed using a standard BCA kit (bicinchoninic acid kit, Pierce, USA). In all cases, more than 95% of the initial amount of the protein was present in the eluted solution. Fluorescence (λ_{ex} = 270 nm, λ_{em} = 510 nm) was measured for 100 μL solution of the purified protein (0.285 mg/mL).

MS Measurements for Labeled and Nonlabeled Ab38C2. To a 0.5 mL solution of Ab38C2 (0.5 mg) in PBS pH 7.4 was added 0, 12.5, or 25 μL of polymer **8** (from stock solution of 10 mM in DMSO) for a final concentration of 0, 250, or 500 μM, respectively. The solution was kept at room temperature for 14 h and dialyzed against 2 L of deionized water in a dialysis cassette (Slide-A-Lyzer 10K, Pierce, USA) to remove excess monomers and salts. Samples were analyzed by MALDI-TOF-MS.

Enzymatic Activity of Labeled and Nonlabeled PGA. The relative enzymatic activity of labeled vs unlabeled PGA was tested for the cleavage of PGA-probe **25** (see Supporting Information) by monitoring the absorbance at λ = 378 nm.

Procedure: To a 190 μL solution of labeled or unlabeled PGA (0.285 mg/mL) in PBS pH 7.4 was added 10 μL of compound **25** (from stock solution of 5 mM in DMSO) to give a final concentration of 250 μM. The absorbance at λ = 378 nm was monitored every 20 s.

Enzymatic Activity of Labeled and Nonlabeled Ab38C2. The relative enzymatic activity of labeled vs unlabeled of Ab38C2 was tested for the *retro*-aldol reaction with methodol according to a published assay (*29*).

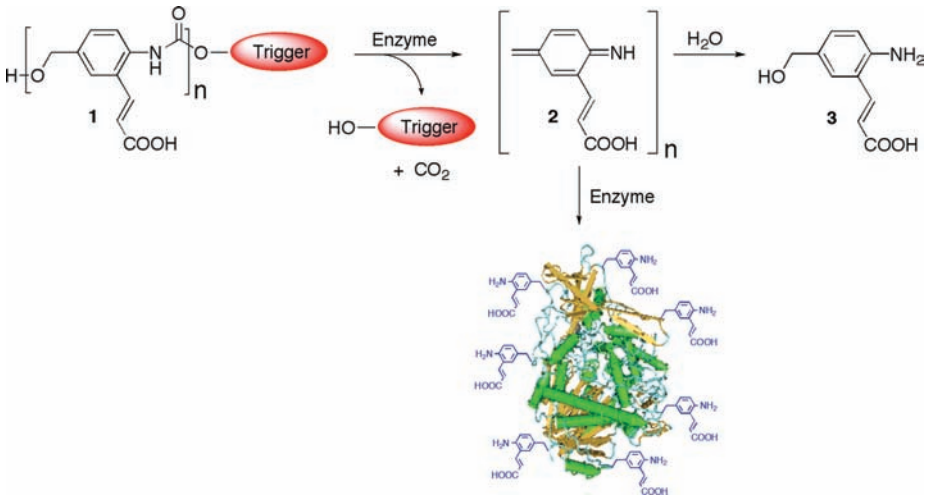
Procedure: To a 190 μL solution of labeled or unlabeled Ab38C2 (0.285 mg/mL) in PBS pH 7.4 was added 10 μL of methodol (from stock solution of 5 mM in ACN) to give a final concentration of 250 μM. Fluorescence (λ_{ex} = 355 nm, λ_{em} = 460 nm) was measured every 1 min.

Comparison of the Labeling Characters for Monomeric (10), Trimeric (11), and SIP (8) Probes. The labeling of Ab38C2 was performed for three aza-quinone methide concentrations, 3.5 mM, 2.1 mM, and 1.05 mM (see Supporting Information). All labeling experiments were performed on 1 mg Ab38C2 in 0.5 mL PBS 7.4. After the addition of the labeling probe (either **10**, **11**, or **8**) at the appropriate concentration, the solution was kept at room temperature for 14 h, then diluted with 2 mL PBS pH 7.4, and small molecules were removed by means of column chromatography over Sephadex G-25 (eluent: PBS pH 7.4). Fluorescence (λ_{ex} = 270 nm, λ_{em} = 510 nm) was measured for 100 μL solution of the purified protein (0.285 mg/mL).

Protein Labeling with Polymer 12 and Hydrogen Peroxide. To 1 mg Ab38C2 in 0.45 mL PBS pH 7.4 and polymer **12** (500 μM) (25 μL from stock solution of 10 mM in DMSO), hydrogen peroxide [1 mM] was added (50 μL from stock solution of 10 mM in PBS 7.4). The solution was kept at room temperature for 14 h, then diluted with 2 mL PBS pH 7.4, and small molecules were removed by means of column chromatography over Sephadex G-25 (eluent: PBS pH 7.4). Fluorescence (λ_{ex} = 270 nm, λ_{em} = 510 nm) was measured for 100 μL solution of the purified protein (0.285 mg/mL).

Selective Protein Labeling in the Presence of Nonactivating Protein. To a 0.5 mL solution of Ab38C2 or PGA (0.5 mg) and β-casein (0.5 mg) in PBS pH 7.4 was added 12.5 μL of polymer **8** or **7**, respectively, (from stock solution of 10 mM in DMSO) for a final concentration of 250 μM. The solution was kept at room temperature for 14 h and dialyzed against 2 L of PBS pH 7.4 in a dialysis cassette (Slide-A-Lyzer 10K, Pierce, USA) (PBS was replaced once during this time) to

Scheme 1. Proposed Labeling Pathway of Proteins by Self-Immolative Polymers



remove excess monomers. The protein solution was then put in an Amicon Microcon centrifuge tube with a 30 kDa cutoff membrane and centrifuged at 12 000 rpm for 7 min, until all fluids had passed through the membrane. This step was repeated twice. The described procedure should result in the permeation of the small β-casein (23 kDa) through the membrane, leaving the larger Ab38C2 (150 kDa) or PGA (85 kDa) on the membrane surface. The resulting protein slurry on the membrane surface was redissolved in 0.5 mL PBS pH 7.4. The presence of protein in the filtrate was confirmed using a standard BCA kit (bicinchoninic acid kit, Pierce, USA). Fluorescence (λ_{ex} = 270 nm, λ_{em} = 510 nm) was measured for 100 μL solution of the separated proteins.

Quantum Yield Calculations. The quantum yield of molecule **3** was calculated in comparison to 1-naphthylamine in ethanol (Φ_F = 0.43). For each compound, the absorbance at λ_{max} and the integrated fluorescence intensity were measured in various concentrations using a Molecular Devices SPECTRAmaxM2 plate reader. For 1-naphthylamine, the absorbance (OD) was measured for λ_{max} = 313 nm and the integrated fluorescence intensity was measured for λ_{ex} = 313 in the range 360−630 nm. For molecule **3**, the absorbance (OD) was measured for λ_{max} = 270 nm and the integrated fluorescence intensity was measured for λ_{ex} = 270 in the range 400−680 nm.

RESULTS AND DISCUSSION

The fragmentation of SIPs, such as **1**, generates multiple azaquinone-methide (**2**) units (Scheme 1). These reactive intermediates are rapidly entrapped by nearby nucleophiles, usually a solvent molecule like water, to give compound **3**. When a SIP-disassembly is triggered by an enzyme, azaquinone−methide **2** can react with nucleophilic residues of the enzyme, resulting in a covalent conjugation of **2** with the activating protein. An activity-linked fluorescent labeling probe, like **1**, has fluorescent building blocks (compound **3**) and an enzyme substrate as a trigger at the head of the polymer. The fluorescence generated by the released monomers during the fragmentation significantly differs from that of the unactivated probe (*25*) and could therefore facilitate real-time detection of the labeling process. The acrylic acid side-chain of the polymer's building block **3** adds aqueous solubility and generates a fluorescent chromophore through conjugation with the aromatic amine (*25*).

To verify the feasibility of the labeling pathway proposed in Figure 1, we initially evaluated the ability of a triggering nucleophile to trap the released azaquinone−methide in the presence of a polar solvent that can also act as a nucleophile. For this purpose, we designed and synthesized molecule **4** with *p*-nitroaniline as reporter and 4-alkoxide butanone as a trigger (Scheme 2). Removal of the trigger by morpholine, through a β-elimination reaction and spontaneous decarboxylation, results in the release of *p*-nitroaniline and the formation of azaquinone−methide **4a**. We incubated monomeric probe **4** with various concentrations of morpholine in a methanol solution. The morpholine served both as trigger-activator and as a nucleophile, which can attack the generated azaquinone−methide **4a**. When

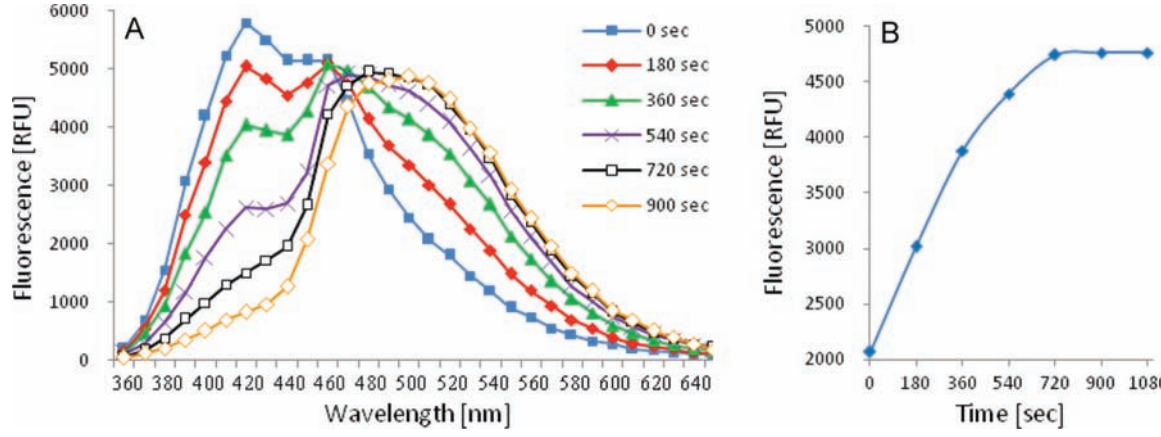


Figure 1. (A) Emission spectra of trimer **5** (final concentration 250 μM) when added to a solution of PGA (0.5 mg/mL) in PBS (pH 7.4, final volume 100 μL) at room temperature. Fluorescence emission spectra were measured every 3 min, λ_{ex} = 270 nm. (B) Fluorescence emission (λ_{ex} = 270 nm, λ_{em} = 510 nm) upon activation of trimer **5** (250 μM) with PGA (0.5 mg/mL) as a function of time.

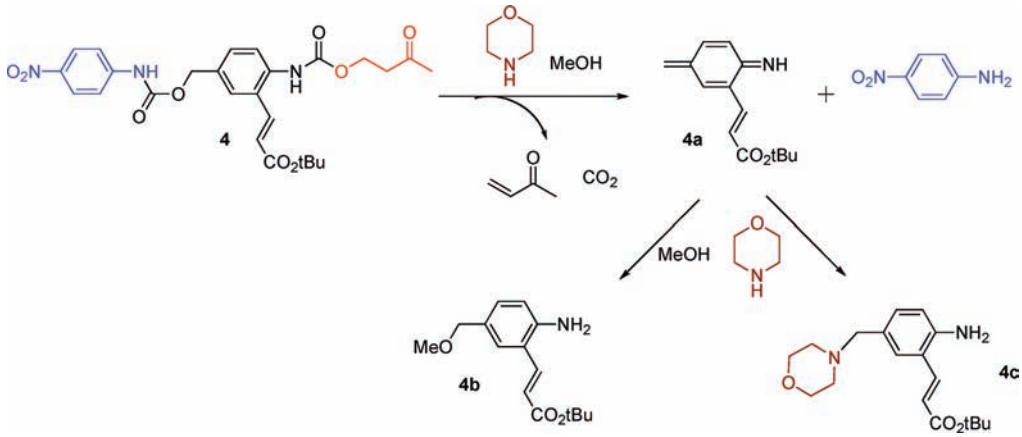
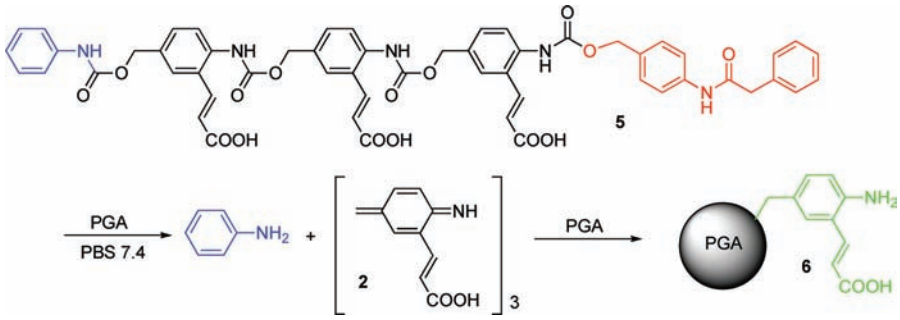


Scheme 3. Labeling Pathway of PGA by Self-Immolative Trimeric Probe 5



the equivalent ratio of solvent to morpholine was 900:1, the major product of the reaction was the solvent-trapped azaquinone−methide **4b**. However, when the ratio was reduced to 90:1, the sole product was the morpholine-trapped azaquinone−methide **4c**. This observation indicates that nucleophilic species such as amine residues can react with the azaquinone−methide intermediate in the presence of a polar solvent.

When the labeling probe is activated by an enzyme, the entrapment of the released azaquinone−methide (**2**) should occur through one of the nucleophilic amino acid residues of the activating protein. To evaluate the capability of an amino acid nucleophilic side residue to entrap the formed azaquinone−methide, we have synthesized Z-lysine-OEt (see Supporting Information). This amino acid derivative has a free ε-amine functional group that can serve as an activating base, for the β-elimination of the trigger of probe **4**, and as a nucleophilic side-residue, which can be labeled by the azaquinone−methide. Therefore, probe **4** was incubated with Z-Lysine-OEt in methanol at various ratios of methanol to Z-Lysine-OEt. When the ratio was 950:1 (respectively), the sole product of the reaction was the methanol-trapped azaquinone−methide. However, when the ratio of solvent to amino acid was decreased to 75:1, the major product was the lysine-trapped azaquinone−methide (see Supporting Information). The formation of lysine derivative with the azaquinone−methide product demonstrates the feasibility of protein labeling by nucleophilic residues of an activating enzyme.

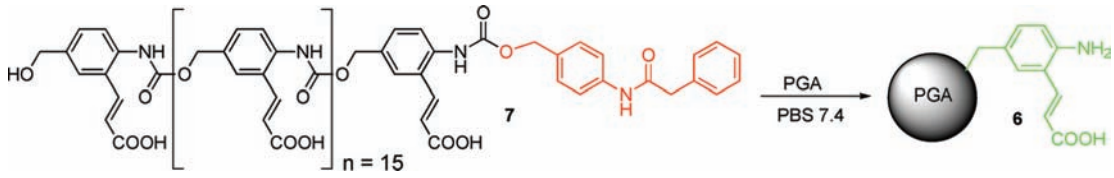
In order to evaluate the potential of our SIPs as probes that enable monitoring of the labeling process in real time, we synthesized a simple model of water-soluble self-immolative trimer (compound **5**). The trimer was equipped with a phenylacetamide trigger that is designed for cleavage by Penicillin-G-Amidase (PGA). Incubation of trimer **5** with PGA will result in the generation of three azaquinone−methide units from each trimer molecule (Scheme 3). Reaction of nucleophilic residues from the enzyme with azaquinone−methide units (**2**) should afford the labeled protein **6**.

To follow the labeling process of the enzyme by self-immolative trimer **5**, the probe was incubated with PGA in PBS (pH 7.4) and the fluorescence emission spectrum was recorded every 3 min (Figure 1A). The spectral changes over 12 min included a decrease in intensity at 410 nm and an increase at 510 nm. The fluorescence intensity at 510 nm is plotted vs time in Figure 1B.

Upon completion of the labeling process (12 min, as determined by following fluorescence emission), the enzyme was subjected to dialysis and purification by Sephadex G25 column. The fluorescence emitted (λ_{ex} = 270 nm, λ_{em} = 510 nm) by the purified enzyme was compared to that of native PGA. An 8-fold increase in fluorescence emitted by the protein that underwent the labeling process was observed (see Supporting Information). These results suggest that the labeling process can be detected in real time when using labeling probes such as **5**.

Next, we addressed the applicability of SIPs for labeling of proteins. We synthesized SIP probe **7** with a trigger that is cleaved by PGA (Scheme 4). Polymer **7** was incubated for 90 min in PBS (pH 7.4) in the presence of PGA (0.5 mg/mL). The enzyme was then purified over a Sephadex G-25 column and its labeling was quantified by determining emitted fluorescence. The fluorescence emission at 510 nm was increased with increasing initial concentrations of polymer **7** (Figure 2A). The fluorescence emission spectrum of the unlabeled protein is compared to that of the labeled protein in Figure 2B. In a control experiment, PGA was incubated with a SIP bearing a trigger that cannot be cleaved by PGA. The enzyme purified after the incubation showed no increase in its emitted fluorescence compared to that of the unlabeled enzyme (data not shown). These results indicate that fluorescent labeling of PGA was achieved using SIP **7** as a labeling probe.

Scheme 4. Activity-Linked Labeling of PGA with SIP Probe 7



To broaden the scope of this polymer-based labeling technique, we evaluated the labeling of catalytic antibody 38C2 (Ab38C2) using the same approach. We synthesized polymer **8** with a trigger designed for activation by the catalytic antibody 38C2 through a *retro*-Michael reaction (Scheme 5) (*27*, *28*). Removal of the trigger by the catalytic antibody should initiate the polymer disassembly to generate multiple azaquinone−methide units that will react with nucleophilic residues of the antibody to afford the labeled antibody **9**.

Similar labeling experiments, as described above for PGA, were performed with Ab38C2. The results showed an increase in fluorescence when a constant amount of Ab38C2 was incubated with growing concentrations of polymer **8** (Figure 3A). The number of labeling molecules per antibody was determined by MALDI-MS analysis. The average mass of Ab38C2 increased as the concentration of probe **8** in the reaction was increased (Figure 3B). Nine molecules of labeling agent per antibody were obtained at the highest concentration of probe evaluated. These results support our assumption that the degree of labeling corresponds to the concentration of labeling agent present. The MALDI-MS analysis also confirmed that the bond between the protein and the fluorescent molecule is indeed covalent. These observations confirm the labeling of Ab38C2, demonstrating the generality of the method and suggesting that other proteins can be labeled by this technique upon introduction of appropriate trigger at the head of the polymer.

It is critical that the activity of the labeled protein be retained in order to allow evaluation of behavior and function in the native environment. Therefore, we determined the catalytic activities of labeled PGA and Ab38C2. To evaluate the activity of labeled PGA, we synthesized a simple chromogenic probe constructed of *p*-nitroaniline linked to phenylacetamide (see Supporting Information). Cleavage of the amide bond by PGA leads to the release of *p*-nitroaniline and a notable shift in the UV spectrum (from $\lambda_{max} = 317$ nm to $\lambda_{max} = 378$ nm) that can be detected with a spectrophotometer. The probe was incubated with labeled and unlabeled PGA, and the absorbance at wavelength of 378 nm was monitored. As shown in Figure 4A, the activity of highly labeled PGA was comparable to that of the unlabeled enzyme.

The activity of labeled Ab38C2 was evaluated using the fluorogenic substrate methodol (*29*). This substrate undergoes *retro*-aldol reaction with the antibody to release the fluorescent compound 6-methoxy-2-naphthaldehyde. In contrast to labeled PGA, the activity of labeled Ab38C2 was decreased as the concentration of probe in the labeling reaction was increased (Figure 4B). The loss of activity of Ab38C2 upon labeling is probably associated with reaction of azaquinone−methide released by the probe with the nucleophilic lysine in the antibody's catalytic site. This lysine is involved with the catalytic activity of the antibody, and its alkylation leads to inactivation of the antibody. Nevertheless, the antibody preserved about 50% of its catalytic activity when moderately labeled. The difference in catalytic activity retained by PGA and Ab38C2 upon labeling is probably derived from the different amino acids responsible for each protein catalytic activity. The ε-amino lysine inside the active site of Ab38C2 is an efficient nucleophile for alkylation by the formed azaquinone−methides. On the other hand, the hydroxy serine functional group responsible for the catalytic activity of PGA (*30*, *31*) is a weaker nucleophile, thus less susceptible for the alkylation that inactivates the enzyme.

In general, labeling of proteins using the azaquinone−methide-based labeling approach can be achieved with large polymers, short oligomers, or even monomeric probes. Thus, we sought

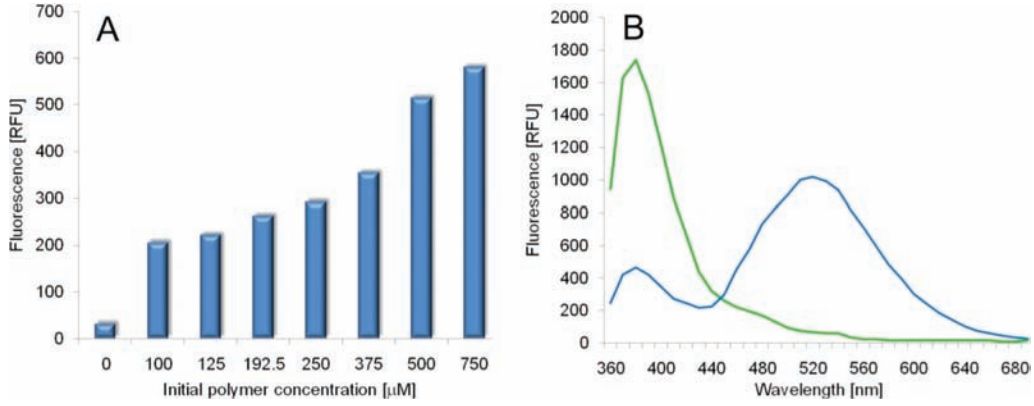


Figure 2. (A) Emitted fluorescence ($\lambda_{ex} = 270$ nm, $\lambda_{em} = 510$ nm) of PGA (28 μg) after incubation with indicated concentrations of polymer **7** in 100 μL PBS (pH 7.4). (B) Fluorescence emission spectra ($\lambda_{ex} = 270$ nm) of (▲) PGA (42 μg) and (■) purified labeled PGA (42 μg).

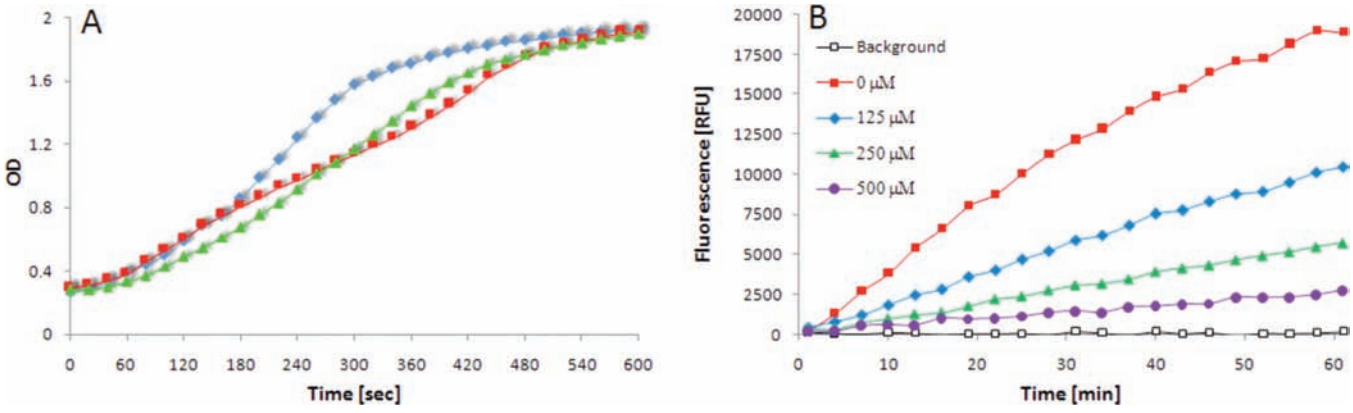

Figure 4. (A) Absorbance at 378 nm of PGA-probe (250 μM) in 200 μL PBS (pH 7.4) upon incubation with (♦) unlabeled PGA (28 μg), (■) moderately labeled PGA (28 μg), and (▲) heavily labeled PGA (28 μg) indicates that PGA retains enzymatic activity when labeled. (B) Fluorescence (λ_{ex} = 355 nm, λ_{em} = 460 nm) of methodol (250 μM) in 200 μL PBS (pH 7.4) upon incubation with Ab38C2 (28 μg) labeled with indicated concentrations of polymer **8**, indicates that catalytic activity is reduced at the extent of labeling degree.

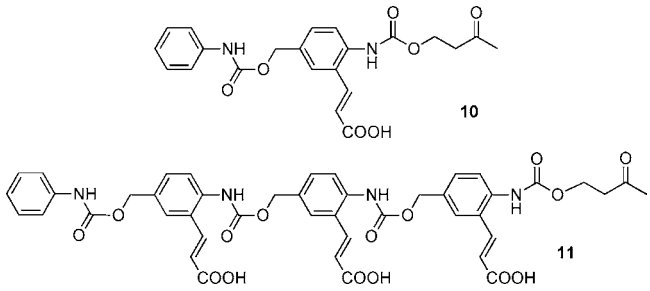
to evaluate the efficiency of labeling with the SIP probe to that of monomeric (**10**) and trimeric (**11**) probes (Scheme 6). For this, Ab38C2 was incubated with monomeric, trimeric, and polymeric (**8**) labeling probes at equivalent concentrations per azaquinone−methide units expected to be released. Complete activation of each labeling probe should result in the formation of identical azaquinone−methide concentrations. This experiment was performed with increasing azaquinone−methide concentrations, as presented in Figure 5A.

The emitted fluorescence of the antibody labeled with polymer **8** was significantly higher than the fluorescence of the antibody labeled with either monomeric (**10**) or trimeric (**11**) probes (Figure 5A). This indicates that a higher degree of labeling was achieved using the polymer-based probe **8** than probes **10** or **11**. In addition, the degree of labeling obtained using polymer **8** was significantly increased when the probe concentration was increased, whereas labeling with monomeric and trimeric probes showed very little concentration dependence. Interestingly, when the catalytic activity of the labeled antibodies was evaluated, the polymer-labeled antibody, although labeled to a higher degree, had the highest activity of the three (Figure 5B). The monomer-labeled antibody, which was labeled to a very low degree, showed significantly reduced catalytic activity compared to the polymer-labeled antibody.

The reduction of catalytic activity observed after labeling with probes **10** and **11** is probably a result of alkylation of the

Scheme 6. Chemical Structures of Monomeric (10) and Trimeric (11) Self-Immolative Probes for Labeling of Ab38C2



ε-amino lysine in the antibody active site by the released azaquinone−methide. Such alkylation also explains the extremely low degree of labeling by probes **10** and **11**, since rapid inactivation of the antibody's catalytic activity will inhibit the labeling process at an early stage. The ability of SIP **8** to achieve a high degree of labeling, while preserving much of the catalytic activity of the antibody, may be explained by the following hypothesis. Since the probe fragmentation process occurs within seconds to minutes (*25*), the polymer molecules can diffuse away from the antibody's active site after their activation. Therefore, it is likely that only the first azaquinone−methides released from the polymer chain have the possibility to react with the ε-amino lysine inside the catalytic site of the antibody. Most of the azaquinone−methides are probably generated far from the catalytic site, thus reacting with nucleophilic residues of the protein surface or with water. Each trigger activation results in the formation of an azaquinone−methide unit near the catalytic ε-amino lysine, increasing the likelihood for its alkylation. For the complete activation of all the monomeric probes, the antibody is required to perform 15 times more cleavages (on average) than for the polymeric probe. Therefore, the antibody is about 15 times less inclined for inactivation when using the polymeric probe over a monomeric one. This effect rationalizes both the higher labeling degree achieved by the polymeric probe and the better retention of catalytic activity upon labeling, demonstrating a major advantage for the use of such polymers as labeling probes.

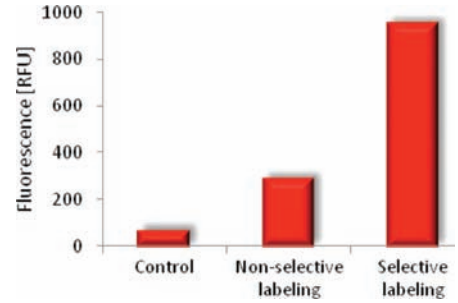


Figure 6. Emitted fluorescence (λ_{ex} = 270 nm, λ_{em} = 510 nm) of Ab38C2 (28 μg) in 100 μL PBS (pH 7.4) after incubation with polymer **8** (500 μM) (selective labeling), polymer **12** [500 μM] in the presence of H_2O_2 (nonselective labeling), or PBS (pH 7.4) (control).

Selective labeling of a specific enzyme in an environment containing other proteins, as in living cells, while preserving the enzyme catalytic activity, is highly valuable. Therefore, we investigated whether labeling of a protein will still occur when it is not involved in the activation process of a SIP probe. For this, we have designed and synthesized a SIP with a boronic ester trigger (compound **12**) that can be cleaved by hydrogen peroxide (*32*, *33*) (Scheme 7).

Ab38C2 was incubated for 5 h in PBS pH 7.4 solution of SIP **12** in the presence of hydrogen peroxide. Then, the antibody was purified and its emitted fluorescence was recorded. The labeling degree of the antibody in this experiment was found to be about four times less than the labeling level measured when activity-linked probe **8** was used (Figure 6). We assume that, when SIP **12** is activated, the protein is not necessarily positioned in close proximity to the generated azaquinone−methides, and therefore, they are mostly trapped by water molecules. Whereas when activity-linked probe **8** is applied, the antibody is placed close to the activated polymer, raising the likelihood for reaction of its nucleophilic residues with formed azaquinone−methides. This result suggests that, although some nonspecific labeling might still take place, specific labeling through a SIP probe activation could be achieved to a certain level.

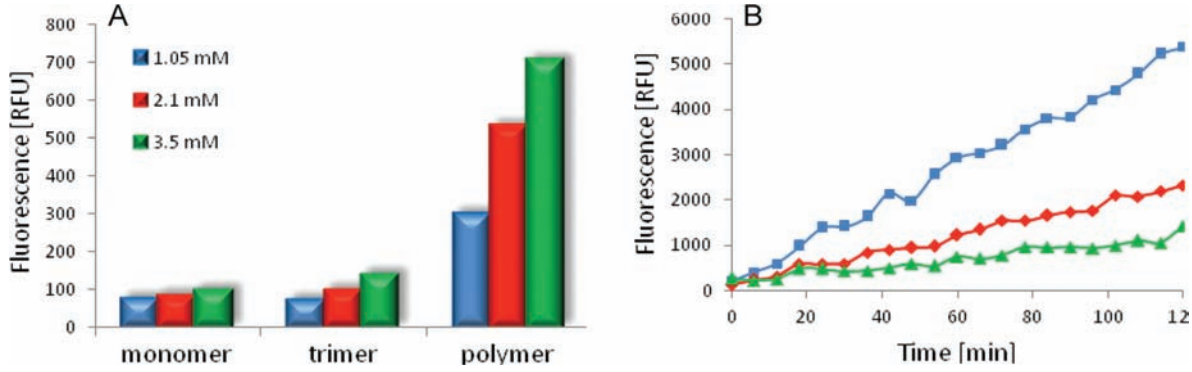

Figure 5. (A) Emitted fluorescence (λ_{ex} = 270 nm, λ_{em} = 510 nm) of Ab38C2 (14 μg) after incubation with monomeric (**10**), trimeric (**11**), and polymeric (**8**) labeling probes, at indicated monomer concentrations in 100 μL PBS (pH 7.4). (B) To evaluated the catalytic activity of the labeled antibodies, (■) polymer-labeled Ab38C2, (♦) trimer-labeled Ab38C2, and (▲) monomer-labeled Ab38C2 were incubated with methodol. The catalytic activities were monitored by measuring fluorescence (λ_{ex}= 355 nm, λ_{em}= 460 nm).

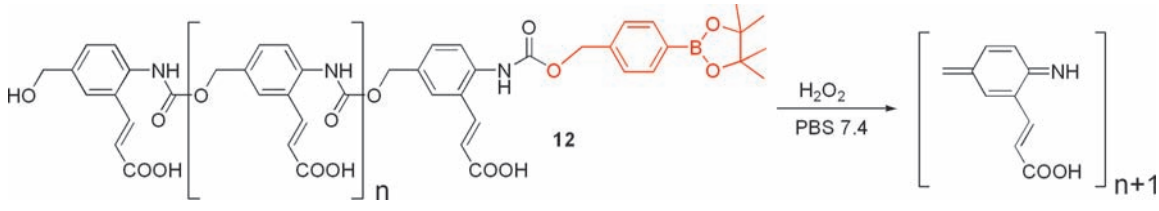
Scheme 7. Hydrogen Peroxide Initiated Disassembly of SIP 12 to Release Multiple Azaquinone−Methide Units



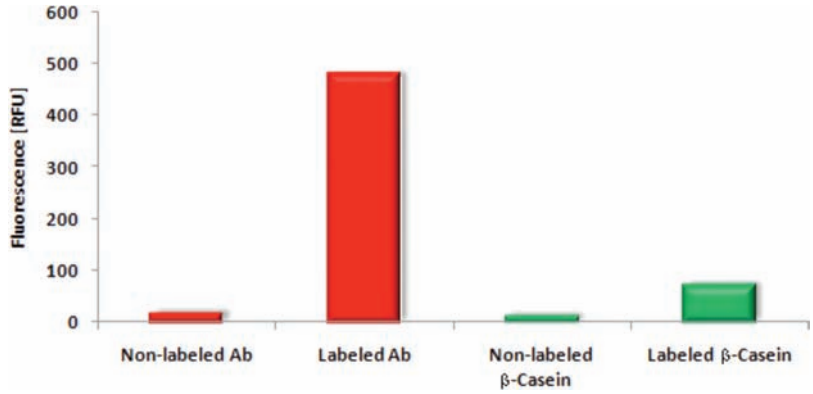


Figure 7. Fluorescence measurements (λ_{ex} = 270 nm, λ_{em} = 510 nm) of Ab38C2 and β-casein after labeling with polymer **8** (250 μM) in PBS (pH 7.4).

To investigate the labeling of SIPs in a more competitive environment, we evaluated the labeling specificity of polymer **8** in a solution containing an activating protein and a nonactivating protein. We incubated polymer **8** with both Ab38C2 (1 mg/mL) and the protein β-casein (1 mg/mL). After 14 h, the solution was dialyzed and the proteins were separated by size-exclusion apparatus (see Supporting Information). The emitted fluorescence of each protein was measured separately at identical concentration (Figure 7).

The extent of labeling observed for Ab38C2 was about eight times higher than that observed for β-casein, although both proteins were present in the initial solution at the same concentration. This suggests that the high reactivity of the azaquinone−methide units is sufficient to allow some labeling specificity. When polymer **8** was incubated with PGA in the presence of β-casein, preferential labeling of PGA was observed (see Supporting Information). The results of these experiments imply that SIPs could be used to achieve some specificity in labeling in a competitive environment. We chose to use β-casein only as a model protein. The labeling specificity observed by SIPs is most probably a consequence of a proximity effect between the polymer and the activating protein. Thus, structural differences in other inert proteins (like molecular weight and amino acid composition) should not significantly influence the specificity achieved by SIPs. Therefore, we anticipate that all inert proteins should be labeled to a much lesser degree in comparison with the triggering protein.

In order to efficiently visualize the labeling process by imaging techniques *in vivo*, the emitted fluorescence must preferably be at a wavelength of above 600 nm (near IR). The low quantum yield of fluorescent amine **3** (Φ_F =0.043 ± 10%, see Supporting Information) and its emission wavelength (λ_{em} = 510 nm) indicate that SIPs built of monomer **3** would be unsuitable for application in living cells. However, the activity-linked labeling polymer presented herein can be improved by using monomers with different fluorogenic characteristics, which will enable their use under physiological conditions. We are currently developing a SIP probe based on coumarin monomers that have significantly stronger fluorescence.

CONCLUSIONS

In summary, we have successfully demonstrated that self-immolative polymers can be used as activity-linked labeling probes to label enzymes such as PGA and Ab38C2. The synthetic strategy used allows introduction of various activating triggers, thereby allowing wide scope of enzymes to be labeled. A real-time detection of the enzyme labeling process is possible due to the change in fluorescence emission wavelength of the probe during the polymer disassembly process. In the SIP-based labeling approach, much of the catalytic activity of the labeled enzymes was conserved. Moreover, a significant preference toward labeling of the activating protein was observed in the presence of another protein, indicating that it is possible to achieve selective enzyme labeling. Although spectroscopic characteristics of the labeling fluorophore presented here are not suitable for *in vivo* study, it should be possible to construct SIPs from monomers with more desirable fluorogenic behavior and thereby to image specific intracellular labeling of the proteins. Current studies are focused on improving the fluorescent characteristics of the labeling agent to enable the use of SIPs in living cells.

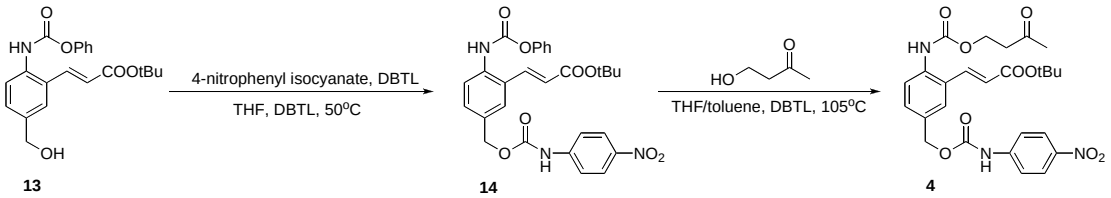
Synthetic schemes and experimental procedures S2 – S21

Spectral data of relevant compounds S22 – S23

Synthesis of monomeric labeling probe 13



Compound 13. Compound **13** was synthesized and characterized according to published procedure.(25)

Compound 14. To a solution of compound **13** (400 mg, 1.08 mmol, 1 eq) in THF (5 mL), 4-nitrophenyl isocyanate (178 mg, 1.08 mmol, 1 eq) and DBTL (32 μL, 0.054 mmol, 0.05 eq) were added. The reaction was heated to 50°C and monitored to completion (15 minutes) by TLC (EtOAc:Hex 3:7). The solvent was removed under reduced pressure and the crude product was purified by column chromatography on silica gel (EtOAc:Hex 1:3) to give compound **14** (510 mg, 88%) as a white solid.

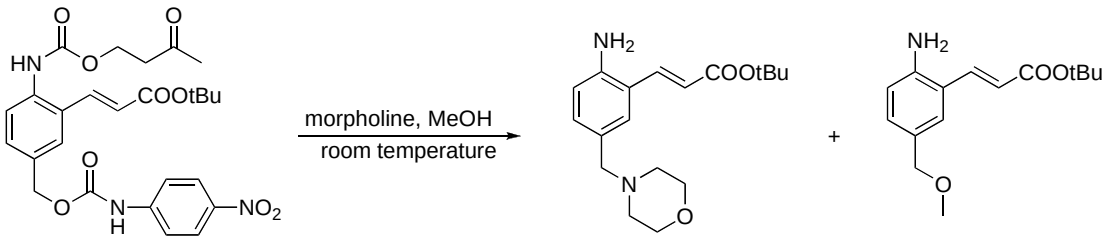
^{1}H NMR (400 MHz, DMSO-d^{6}): δ = 10.36 (1H, s), 9.27 (1H, s), 8.17 (2H, d, *J* = 7.0 Hz), 7.74 (1H, d, *J* = 15.7 Hz), 7.63-7.70 (3H, m), 7.52 (1H, s), 7.09-7.13 (5H, m), 6.66 (1H, d, *J* = 8.3 Hz), 6.24 (1H, d, *J* = 15.7 Hz), 4.98 (2H, s), 1.44 (9H, s). ^{13}C NMR (100 MHz, DMSO-d^{6}): δ = 166.4, 157.7, 153.7, 153.4, 148.7, 146.2, 146.0, 142.2, 142.0, 130.1, 129.8, 129.0, 123.7, 119.1, 118.4, 117.8, 116.7, 115.1, 80.4, 67.2, 28.4. MS (ESI): calculated for [M^{+}] $C_{28}H_{27}N_3O_8$ 533.2; found 533.2.

Compound 4. Compound **14** (240 mg, 0.45 mmol, 1 eq) was dissolved in a mixture of THF:toluene (10 mL, ratio 3:7), preheated to 105°C. 4-Hydroxy-2-butanoe (240 μL, 2.72 mmol, 6 eq) was added, followed by DBTL (15 μL, 0.022 mmol, 0.05 eq) and the reaction was monitored to completion (45 minutes) by TLC (EtOAc:Hex 4:6). The solvent was removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 4:6) to give compound **4** (205 mg, 85%) as a yellow solid.

^{1}H NMR (200 MHz, DMSO-d^{6}): δ = 10.50 (1H, s), 9.45 (1H, s), 8.20 (2H, d, *J* = 7.2 Hz), 7.89 (1H, s), 7.66-7.74 (3H, m), 7.37-7.48 (2H, m), 6.45 (1H, d, *J* = 15.8 Hz),

5.17 (2H, s), 4.25 (2H, t, *J* = 6.2 Hz), 2.82 (2H, t, *J* = 6.2 Hz), 2.14 (3H, s), 1.48 (9H, s). ^{13}C NMR (50 MHz, DMSO-d^{6}): δ = 206.8, 166.3, 154.8, 153.6, 148.7, 146.1, 142.0, 139.8, 133.6, 128.9, 126.7, 121.0, 118.0, 117.6, 116.7, 80.4, 67.2, 60.2, 42.5, 30.4, 28.3. MS (ESI): calculated for [M^{+}] $C_{26}H_{29}N_3O_9$ 527.2; found 527.2.

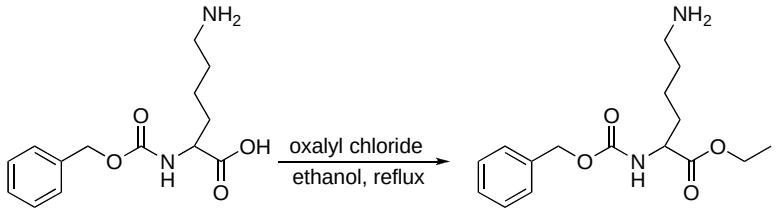
Competition behavior between a triggering nucleophile and polar solvent



4 **4c** **4b**

Compound 4b. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.72 (1H, d, *J* = 15.8 Hz), 7.31 (1H, s), 7.14 (1H, d, *J* = 8.3 Hz), 6.69 (1H, d, *J* = 8.3 Hz), 6.32 (1H, d, *J* = 15.8 Hz), 4.34 (2H, s), 3.36 (3H, s), 1.44 (9H, s). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 166.5, 147.0, 144.9, 130.3, 128.4, 124.4, 123.9, 120.3, 116.6, 80.4, 74.3, 57.7, 29.6. MS (FAB^{+}): calculated for $C_{15}H_{21}NO_3$ [M^{+}]: 263.1; found: 263.1.

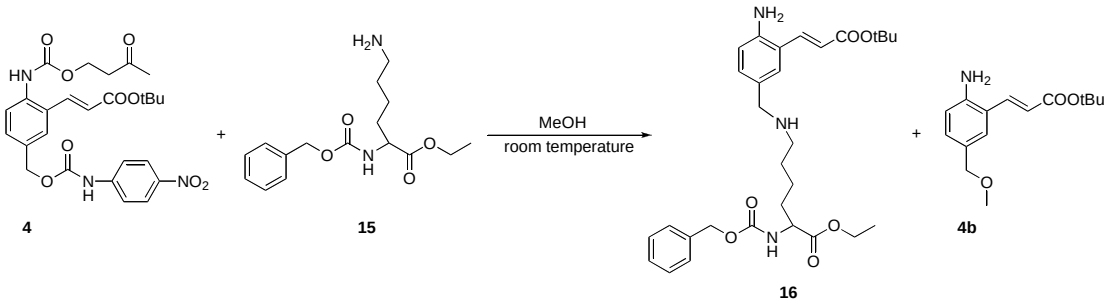
Compound 4c. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.71 (1H, d, *J* = 15.8 Hz), 7.30 (1H, s), 7.11 (1H, d, *J* = 8.2 Hz), 6.65 (1H, d, *J* = 8.2 Hz), 6.30 (1H, d, *J* = 15.8 Hz), 3.92 (2H, s), 3.69 (4H, t, *J* = 4.7 Hz), 3.38 (2H, s), 2.42 (4H, t, *J* = 4.7 Hz), 1.47 (9H, s). ^{13}C NMR (50 MHz, $CDCl_3$): 166.8, 144.5, 138.8, 132.1, 130.3, 128.9, 126.8, 120.1, 116.5. MS (FAB^{+}): calculated for [M+H^{+}] $C_{18}H_{26}N_2O_3$: 319.2; found: 319.2.



15

Compound 15. Z-Lys-OH (250 mg, 0.89 mmol, 1 eq) was suspended in ethanol (25 mL) and brought to reflux. Oxalyl-chloride (117 μL, 1.34 mmol, 1.5 eq) was added and the reaction was stirred for 45 minutes. After concentration to dryness, the residue was taken in EtOAc (100 mL) and washed with 1M NaOH. The organic phase was dried with $MgSO_4$, filtered and the solvent removed under reduced pressure to give compound **15** (257 mg, 93%) as yellowish oil.

^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.29-7.35 (5H, m), 5.42 (1H, d, *J* = 7.1 Hz), 5.10 (2H, s), 4.34 (1H, q, *J* = 7.1 Hz), 4.18 (2H, q, *J* = 7.0 Hz), 2.66 (2H, t, *J* = 6.4 Hz), 1.79-1.88 (1H, m), 1.60-1.71 (1H, m), 1.30-1.56 (6H, m), 1.26 (3H, t, *J* = 7.0 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): δ = 172.5, 155.9, 136.3, 128.8, 128.7, 128.3, 127.9, 127.6, 66.9, 61.4, 53.8, 41.8, 33.1, 32.5, 22.5, 14.4. MS (FAB^+): calculated for [$M+H^+$] $C_{16}H_{24}N_2O_4$: 309.2; found: 309.1.



RP-HPLC-MS chromatogram and analysis of competition between Z-Lys(Boc)-OH and MeOH (ratio 75:1).

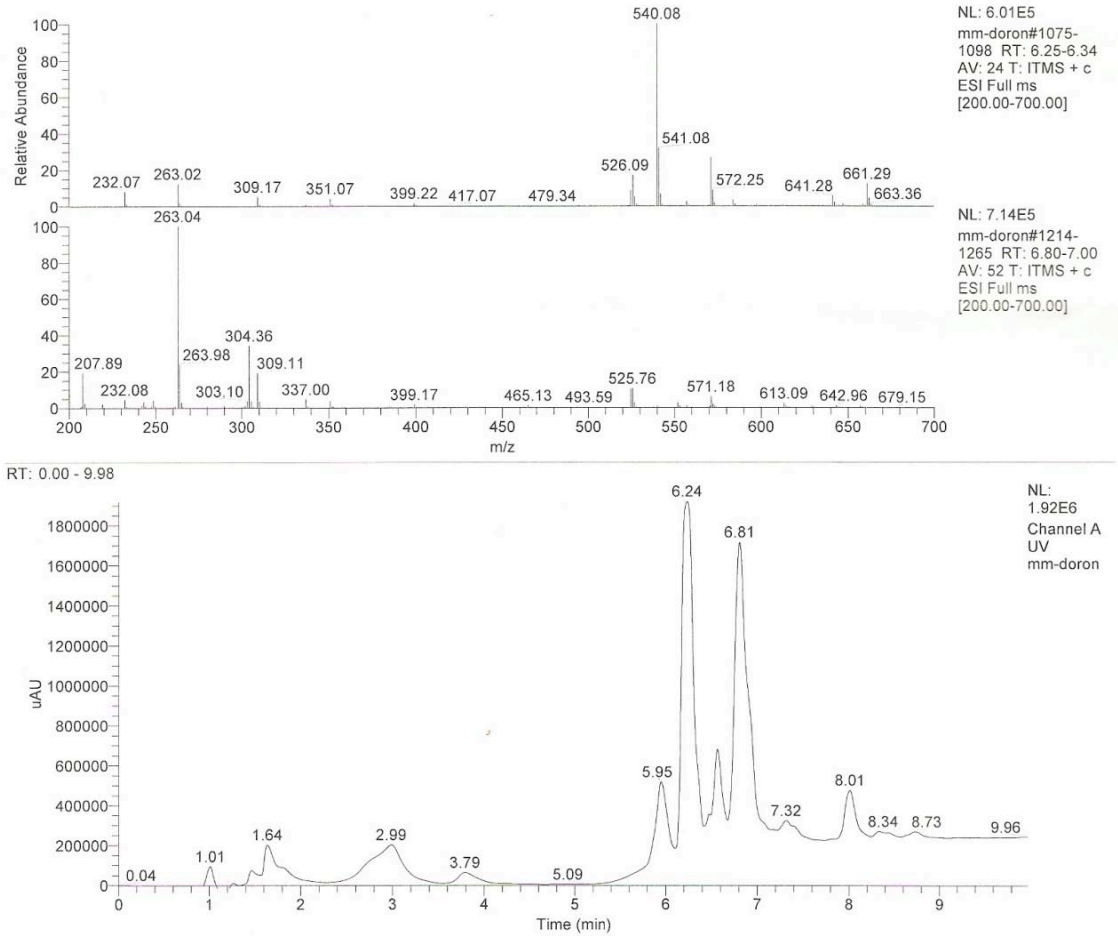


Figure 1S: RP-HPLC-MS chromatogram of compound **4** after incubated with Z-lys-OEt **15** in MeOH for 6 hours at Z-lys-OEt:MeOH ratio of 1:75. MS spectra of the peaks at 6.24 and 6.81 minutes are presented abouve.

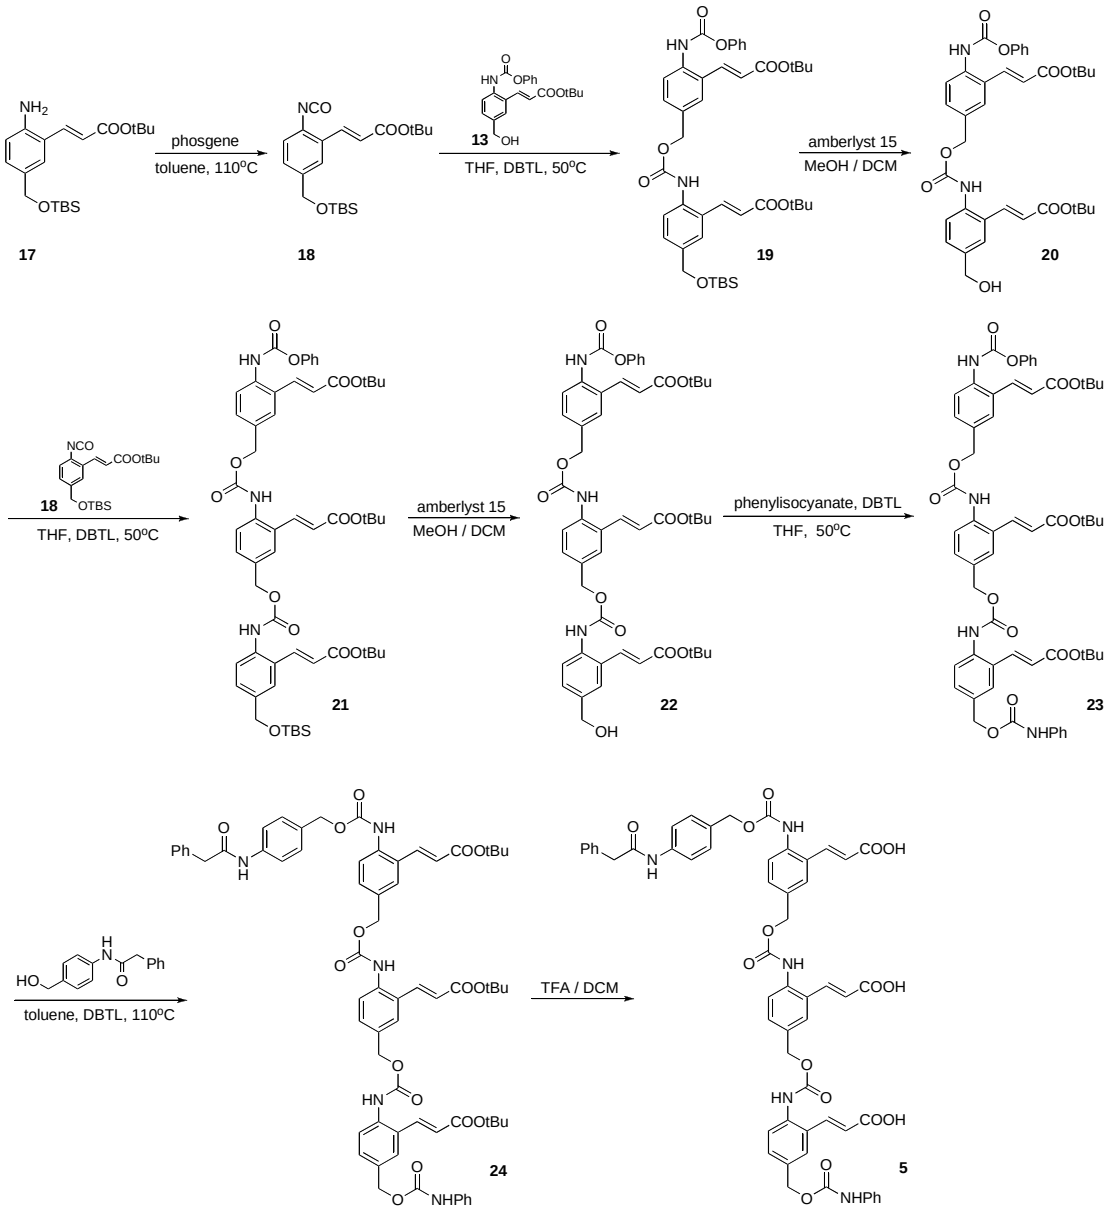
	Retention time [minutes]	**Chemical formula**	**Calculated mass**	**Recorded mass**
Compound **16**	6.24	$C_{30}H_{41}N_3O_6$	539.30	540.08 [M+H$^+$]
Compound **4b**	6.81	$C_{15}H_{21}NO_3$	263.15	263.04 [M$^+$]

Table 1S: Analysis of RP-HPLC-MS chromatogram.

In order to validate these results, we have independently synthesized and fully characterized molecule **4b**. The retention time observed for the synthesized molecule **4b**, under the same separation condition in RP-HPLC, was 6.81 minutes. Furthermore, when Z-lys-OEt's initial concentration was increased or decreased, the peak at 6.24 minutes grew or shrunk accordingly.

Synthesis of trimeric labeling probe 5



Compound 17. Compound **17** was synthesized and characterized according to published procedure.(25)

Compound 19. Compound **17** (750 mg, 2.06 mmol, 1 eq), dissolved in toluene (5 mL), was added drop-wise into a solution of refluxed phosgene in toluene (10.3 mL, 10.30 mmol, 5 eq) over 10 minutes. The reaction was stirred for 15 minutes and the solvent removed under reduced pressure yielding the corresponding isocyanate as brownish oil (**18**). Isocyanate **18** was re-dissolved in dry THF (5 mL) at 50°C. Compound **13** (760 mg, 2.06 mmol, 1 eq) was added, followed by DBTL (61 μL, 0.103 mmol, 0.05 eq) and the reaction was monitored to completion (20 minutes) by TLC (EtOAc:Hex 15:85). The solvent was then removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 15:85) to give compound **19** (1.12 g, 72%) as a yellow solid.

^{1}H NMR (400 MHz, DMSO-d^{6}): δ = 9.32-9.38 (2H, m), 7.68-7.83 (5H, m), 7.35-7.50 (4H, m), 7.14-7.18 (2H, m), 6.68-6.76 (2H, m), 6.35-6.40 (2H, m), 5.14 (2H, s), 4.70 (2H, s), 1.46 (18H, s), 0.9 (9H, s), 0.08 (6H, s). ^{13}C NMR (100 MHz, DMSO-d^{6}): δ = 166.4, 165.9, 157.7, 150.2, 149.4, 148.0, 145.7, 141.9, 137.6, 137.5, 129.8, 128.8, 128.4, 127.9, 127.1, 122.5, 121.1, 119.9, 118.3, 116.5, 116.3, 115.3, 80.3, 79.8, 65.8, 62.7, 28.3, 28.2, 26.2, 18.4, -4.8. MS (MALDI-TOF): calculated for [M+Na^{+}] $C_{42}H_{54}N_2O_9Si$ 781.3; found 781.3.

Compound 20. Compound **19** (1.12 g, 1.47 mmol) was dissolved in MeOH:DCM mixture (3:1), amberlyst 15 was added and the reaction was monitored to completion (30 minutes) by TLC (EtOAc:Hex 4:6). The amberlyst 15 beads were filtered out, the solvent removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 4:6) to give compound **20** (935 mg, 98%) as a white solid.

^{1}H NMR (400 MHz, $CDCl_3$): δ = 9.32-9.36 (2H, m), 7.69-7.80 (5H, m), 7.34-7.51 (4H, m), 7.14-7.18 (2H, m), 6.69-6.78 (2H, m), 6.37-6.41 (2H, m), 5.13 (2H, s), 4.49 (2H, d, *J* = 4.8 Hz), 1.47 (18H, s). ^{13}C NMR (100 MHz, DMSO-d^{6}): δ = 166.4, 166.0, 157.8, 150.2, 149.4, 148.0, 145.7, 141.9, 137.6, 137.5, 129.8, 128.8, 128.4, 127.9, 127.1, 122.5, 121.1, 119.9, 118.3, 116.5, 116.3, 115.6, 80.3, 79.8, 65.8, 64.1, 28.3, 28.2. MS (MALDI-TOF): calculated for [M+Na^{+}] $C_{36}H_{40}N_2O_9$ 667.2; found 667.2.

Compound 21. Compound **17** (545 mg, 1.50 mmol, 1 eq), dissolved in toluene (5 mL), was added drop-wise into a solution of refluxed phosgene in toluene (7.5 mL, 7.50 mmol, 5 eq) over 10 minutes. The reaction was stirred for 15 minutes and the solvent removed under reduced pressure yielding the corresponding isocyanate as brownish oil (**18**). Isocyanate **18** was re-dissolved in dry THF (5 mL) at 50^{o}C. Compound **20** (905 mg, 1.4 mmol, 0.9 eq) was added, followed by DBTL (45 μL, 0.07 mmol, 0.05 eq) and the reaction was monitored to completion (20 minutes) by TLC (EtOAc:Hex 2:8). The solvent was then removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 2:8) to give compound **21** (908 mg, 63%) as a yellow solid.

^{1}H NMR (400 MHz, $CDCl_3$): δ = 9.48-9.51 (2H, m), 9.32 (1H, s), 7.70-7.84 (6H, m), 7.37-7.52 (6H, m), 7.14-7.18 (2H, m), 6.70-6.77 (3H, m), 6.37-6.41 (3H, m), 5.13 (4H, s), 4.70 (2H, s), 1.47 (27H, s), 0.91 (9H, s), 0.08 (6H, s). ^{13}C NMR (100 MHz, DMSO-d^{6}): δ =166.1, 165.9, 157.7, 155.0, 148.6, 147.5, 139.9, 139.6, 139.4, 139.1, 137.1, 136.0, 134.3, 134.1, 132.3, 130.0, 129.8, 128.8, 128.5, 128.3, 126.8, 126.6, 124.6, 124.3, 120.9, 120.7, 119.2, 117.8, 117.4, 117.0, 116.8 ,115.6, 80.4, 79.8, 66.7, 65.8, 64.2, 28.3, 28.2, 26.2, 18.4, -4.8. MS (MALDI-TOF): calculated for [M+Na^{+}] $C_{57}H_{71}N_3O_{13}Si$ 1056.4; found 1056.4.

Compound 22. Compound **21** (600 mg, 0.61 mmol) was dissolved in MeOH:DCM mixture (3:1), amberlyst 15 was added and the reaction was monitored to completion (45 minutes) by TLC (EtOAc:Hex 1:1). The amberlyst 15 beads were filtered out, the solvent removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 1:1) to give compound **22** (512 mg, 90%) as a white solid.

^{1}H NMR (400 MHz, $CDCl_3$): δ = 9.44-9.56 (2H, m), 9.28 (1H, s), 7.67-7.83 (6H, m), 7.32-7.47 (6H, m), 7.11-7.22 (2H, m), 6.68-6.73 (3H, m), 6.35-6.39 (3H, m), 5.12 (4H, s), 4.45 (2H, d, *J* = 5.6 Hz), 1.47 (27H, s). ^{13}C NMR (100 MHz, DMSO-d^{6}): δ = 166.4, 165.9, 157.7, 155.0, 148.6, 147.5, 139.9, 139.6, 139.5, 139.1, 137.1, 135.8, 134.3, 134.1, 132.3, 130.0, 129.8, 128.9, 128.5, 128.3, 126.8, 126.6, 124.6, 124.3, 121.0, 120.6, 119.2, 117.8, 117.6, 117.0, 116.8 ,115.6, 80.3, 79.9, 66.8, 65.8, 62.7,

28.3, 28.2. MS (MALDI-TOF): calculated for [M+Na^+] $C_{51}H_{57}N_3O_{13}$ 942.3; found 942.3.

Compound 23. Compound **22** (477 mg, 0.52 mmol, 1 eq) was dissolved in dry THF (5 mL), preheated to 50°C. Phenylisocyanate (57 μL, 0.52 mmol, 1 eq) was added, followed by DBTL (16 μL, 0.026 mmol, 0.05 eq) and the reaction was monitored to completion (10 minutes) by TLC (EtOAc:Hex 1:3). The solvent was removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 2:8) to give compound **23** (416 mg, 77%) as a white solid.

^{1}H NMR (400 MHz, DMSO-d^6): δ = 10.01 (1H, s), 9.71 (1H, s), 9.64 (1H, s), 9.28 (1H, s), 7.71-7.87 (6H, m), 7.39-7.47 (9H, m), 7.22-7.26 (5H, m), 6.95 (1H, t, *J* = 7.4 Hz), 6.70-6.74 (1H, m), 6.40-6.45 (3H, m), 5.10 (6H, s), 1.45 (27H, s). ^{13}C NMR (100 MHz, DMSO-d^6): δ = 166.4, 165.9, 157.7, 155.0, 154.9, 153.7, 148.6, 139.9, 137.0, 134.3, 134.1, 132.4, 130.6, 130.3, 130.0, 129.8, 129.5, 129.2, 128.9, 127.1, 127.0, 124.3, 122.8, 121.1, 121.0, 119.2, 118.7, 118.5, 117.6, 116.8, 115.7, 80.4, 79.9, 66.8, 65.9, 65.6, 28.3, 28.2. MS (MALDI-TOF): calculated for [M+Na^+] $C_{58}H_{62}N_4O_{14}$ 1061.4; found 1061.4.

Compound 24. Compound **23** (150 mg, 0.14 mmol, 1 eq) was dissolved in toluene (7 mL), preheated to 110°C. PGA substrate (155 mg, 0.64 mmol, 4.4 eq) was added, followed by DBTL (9.5 μL, 0.014 mmol, 0.1 eq) and the reaction was monitored to completion (1 hour) by TLC (EtOAc:Hex 6:4). The solvent was removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 6:4) to give compound **24** (120 mg, 70%) as a white solid.

^{1}H NMR (200 MHz, $CDCl_3$): δ = 10.20 (1H, s), 9.73 (1H, s), 9.56 (1H, s), 9.51 (1H, s), 9.46 (1H, s), 7.81 (2H, s), 7.75 (1H, t, *J* = 3.2 Hz), 7.71 (1H, t, *J* = 3.2 Hz), 7.68 (2H, s), 7.58-7.61 (4H, m), 7.41-7.42 (6H, m), 7.19-7.33 (9H, m), 6.36-6.43 (3H, m), 5.17 (1H, t, *J* = 5.6 Hz), 5.05-5.10 (8H, m), 3.62 (2H, s), 1.44 (27H, s). ^{13}C NMR (50 MHz, DMSO-d^6): δ = 169.6, 165.9, 155.0, 154.9, 140.5, 139.9, 139.7, 139.5, 137.0, 136.9, 136.4, 135.8, 134.4, 134.3, 131.6, 130.6, 130.2, 129.8, 129.6, 129.5, 129.2,

129.0, 128.9, 128.4, 127.2, 127.0, 126.8, 125.4, 125.1, 124.9, 124.6, 121.3, 121.0, 120.6, 119.8, 119.5, 119.3, 119.0, 80.4, 80.3, 66.3, 65.9, 65.8, 62.7, 60.2, 43.7, 28.3, 28.1. MS (MALDI-TOF): calculated for $[M+Na^+]$ $C_{60}H_{66}N_4O_{14}$ 1208.5; found 1028.5.

Compound 5. Compound **24** (5 mg) was dissolved in a 1:1 mixture of TFA and DCM, stirred for 5 minutes and the solvents removed under reduced pressure. The obtained compound **5** was used without further purification.

^{1}H NMR (200 MHz, DMSO-d^6): δ = 10.11 (1H, s), 9.74 (1H, s), 9.62 (1H, s), 9.53 (1H, s), 9.46 (1H, s), 7.80 (2H, s), 7.75 (1H, t, *J* = 3.0 Hz), 7.70 (1H, t, *J* = 3.0 Hz), 7.68 (2H, s), 7.55-7.62 (4H, m), 7.40-7.45 (6H, m), 7.19-7.36 (9H, m), 6.36-6.43 (3H, m), 5.16 (1H, t, *J* = 5.6 Hz), 5.06-5.13 (8H, m), 3.62 (2H, s).

Fluorescence emission of PGA upon labeling with trimeric probe 5

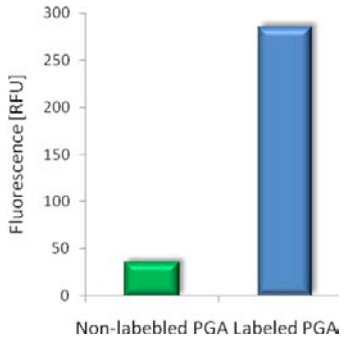


Figure 2S: Emitted fluorescence (λ_{ex} = 270 nm, λ_{em} = 510 nm) of PGA (28 μg) in PBS pH 7.4 (non-labeled PGA) and after treatment with trimer probe **5** [250 μM] (labeled PGA).

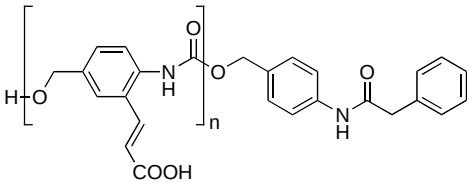
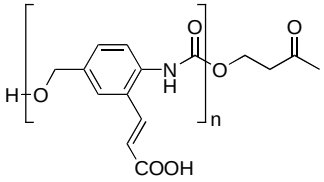
Synthesis of SIP labeling probe 7



7

Polymer 7. Polymer **7** was synthesized and characterized according to published procedure.(25) The formed polymer was constructed of 14 monomers in average (determined by ^{1}H-NMR).

Synthesis of SIP labeling probe 8



8

Polymer 8. Polymer **8** was synthesized and characterized according to published procedure.(25) The formed polymer was constructed of 15 monomers in average (determined by ^{1}H-NMR).

To exclude fluorescence increase due to flawed purification process, resulting in presence of free monomers in the purified PGA or Ab38C2 solution, we have incubated different amounts of protein with a fixed concentration of polymer **7** or **8**, correspondingly. Since in this experiment the same polymer concentration is used, if a certain percentage of monomers do pass through the purification process, a similar rise in fluorescence for all experiments would be expected. However, an increase in the fluorescence was observed upon growing amount of protein (Figure 3S), suggesting that presence of unattached monomers is not responsible for fluorescence change.

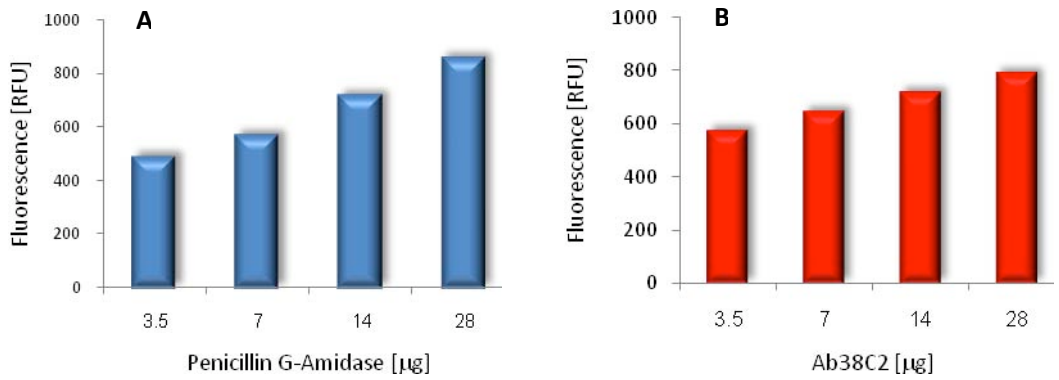


Figure 3S: Fluorescence measurements (λ_{ex} = 270 nm, λ_{em} = 510 nm) of increasing amounts of A) PGA after incubation with polymer **7** [250 µM], in 100 µL PBS pH 7.4. B) Ab38C2 after incubation with polymer **8** [250 µM], in 100 µL PBS pH 7.4.

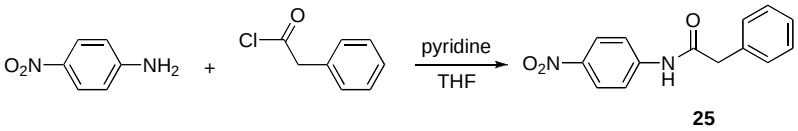
Relative enzymatic activity of PGA

Synthesis of PGA probe 25



25

Compound 25. Pyridine (161 µL, 1.99 mmol, 1.1 eq) was added to a solution of 4-nitroaniline (250 mg, 1.81 mmol, 1 eq) dissolved in THF (5 mL) at 0°C and the mixture was stirred for 10 minutes. Then, phenacetylchloride (239 µL, 1.81 mmol, 1 eq) was added. The reaction was warmed to room temperature and monitored to completion (10 hours) by TLC (EtOAc:Hex 3:7). Upon completion, the reaction mixture was diluted with EtOAc (50 mL) and washed with saturated solution of NH_4Cl and brine. The solvents were removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 3:7) to give compound **25** (428 mg, 92%) as a yellow solid.

^{1}H NMR (200 MHz, DMSO-d^6): δ = 9.74 (1H, s), 8.16 (2H, d, *J* = 7.3 Hz), 7.79 (2H, d, *J* = 7.3 Hz), 7.22-7.30 (5H, m), 3.67 (2H, s). ^{13}C NMR (50 MHz, DMSO-d^6): δ = 170.5, 145.7, 142.6, 135.7, 129.6, 128.7, 127.1, 125.3, 119.2, 43.7. MS (FAB$^+$): calculated for $C_{14}H_{12}N_2O_3$ [M$^+$]: 256.1; found: 256.1.

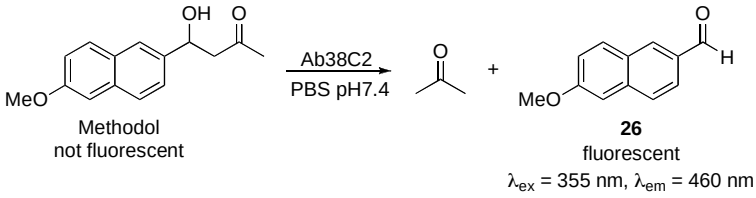
Relative enzymatic activity of Ab38C2



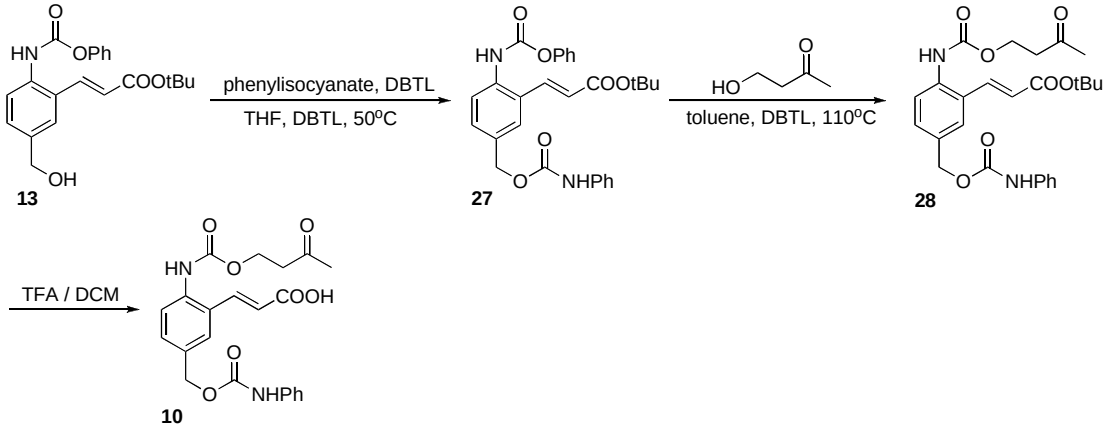
Methodol
not fluorescent

26
fluorescent
λ_{ex} = 355 nm, λ_{em} = 460 nm

The relative enzymatic activity of labeled and unlabeled of Ab38C2 was tested for the *retro*-aldol reaction with methodol according to a published assay.(29) When used as a substrate for *retro*-aldol reaction, methodol disintegrates into acetone and the fluorescent aldehyde 6-methoxy-2-naphthaldehyde (**26**) (λ_{ex} = 355 nm, λ_{em} = 460 nm). Experiments were conducted in a 96-wells fluorescence measuring plate and fluorescence was monitored using a Molecular Devices SPECTRAmaxM2 plate reader.

Comparison of the labeling characterizations for monomeric (10), trimeric (11) and SIP (8) probes

Synthesis of monomeric labeling probe 10



Compound 27. Compound **13** (250 mg, 0.68 mmol, 1 eq) was dissolved in dry THF (5 mL), preheated to 50°C. Phenylisocyanate (78 μL, 0.71 mmol, 1.05 eq) was added, followed by DBTL (22 μL, 0.033 mmol, 0.05 eq) and the reaction was monitored to completion (10 minutes) by TLC (EtOAc:Hex 1:3). The solvent was removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 2:8) to give compound **27** (345 mg, 95%) as a white solid.

^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.85 (1H, s), 7.89 (1H, d, *J* = 15.7 Hz), 7.56 (1H, s), 7.37-7.42 (5H, m), 7.27-7.32 (2H, m), 7.26 (1H, d, *J* = 1.6 Hz), 7.20-7.25 (2H, m), 6.80 (1H, s), 6.40 (2H, d, *J* = 15.7 Hz), 5.17 (2H, s), 1.56 (9H, s). ^{13}C NMR (100 MHz, $CDCl_3$): δ = 165.8, 153.2, 152.0, 150.5, 137.6, 137.2, 235.5, 132.8, 130.8, 129.5, 129.4, 127.2, 123.8, 121.8, 121.6, 121.3, 119.5, 118.7, 81.2, 66.2, 28.4. MS (MALDI-TOF): calculated for [M+Na^+] $C_{28}H_{28}N_2O_6$ 511.1; found 511.1.

Compound 28. Compound **27** (200 mg, 0.41 mmol, 1 eq) was dissolved in toluene (4 mL), preheated to 110°C. 4-Hydroxy-2-butanoe (108 μL, 1.23 mmol, 3 eq) was added, followed by DBTL (25 μL, 0.041 mmol, 0.1 eq) and the reaction was monitored to completion (30 minutes) by TLC (EtOAc:Hex 4:6). The solvent was removed under reduced pressure and the crude product purified by column

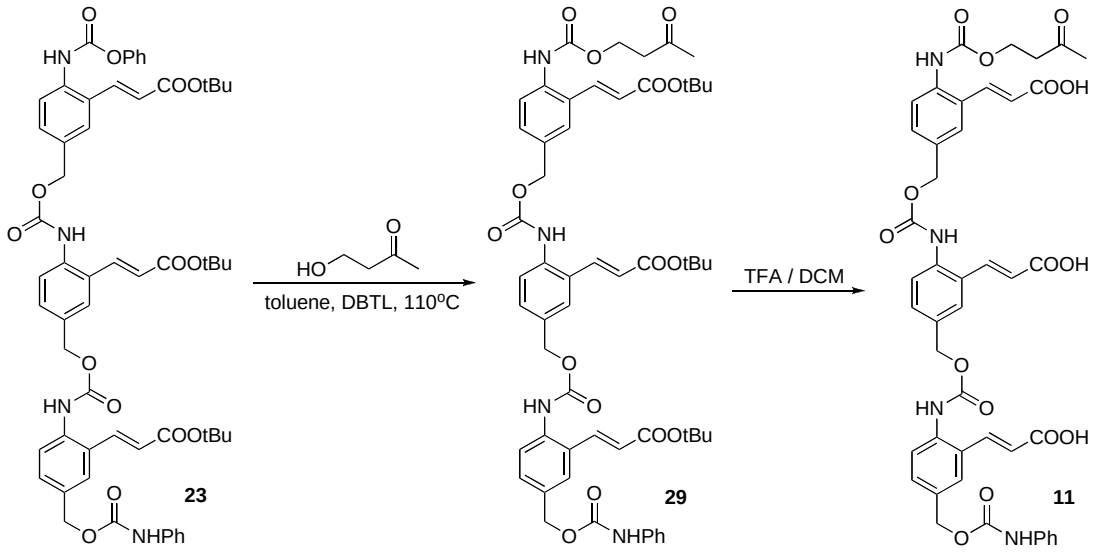
chromatography on silica gel (EtOAc:Hex 4:6) to give compound **28** (142 mg, 72%) as a white solid.

^{1}H NMR (400 MHz, DMSO-d^{6}): δ = 9.69 (1H, s), 9.38 (1H, s), 7.79 (1H, d, *J* = 1.2 Hz), 7.65 (1H, d, *J* = 15.9 Hz), 7.33-7.42 (4H, m), 7.23 (2H, t, *J* = 7.4 Hz), 6.95 (1H, t, 7.4 Hz), 6.39 (1H, d, *J* = 15.9 Hz), 5.08 (2H, s), 4.21 (2H, t, *J* = 6.2 Hz), 2.77 (2H, t, *J* = 6.2 Hz), 2.09 (3H, s), 1.44 (9H, s). ^{13}C NMR (100 MHz, DMSO-d^{6}): δ = 206.8, 166.0, 154.9, 153.7, 139.6, 139.4, 136.8, 134.4, 129.5, 129.2, 129.0, 126.8, 123.1, 121.0, 118.8, 80.6, 65.6, 60.3, 42.4, 30.3, 28.4. MS (MALDI-TOF): calculated for [M+Na^{+}] $C_{26}H_{30}N_2O_7$ 505.2; found 505.2.

Compound 10. Compound **28** (5 mg) was dissolved in a 1:1 mixture of TFA and DCM, stirred for 5 minutes and the solvents removed under reduced pressure. The obtained compound **10** was used without further purification.

^{1}H NMR (400 MHz, DMSO-d^{6}): δ = 9.71 (1H, s), 9.38 (1H, s), 7.79 (1H, s), 7.65 (1H, d, *J* = 15.8 Hz), 7.33-7.42 (4H, m), 7.23 (2H, t, *J* = 7.4 Hz), 6.95 (1H, t, 7.4 Hz), 6.39 (1H, d, *J* = 15.8 Hz), 5.09 (2H, s), 4.20 (2H, t, *J* = 6.3 Hz), 2.75 (2H, t, *J* = 6.3 Hz), 2.10 (3H, s).

Synthesis of trimeric labeling probe 11



Compound 29. Compound **23** (150 mg, 0.14 mmol, 1 eq) was dissolved in toluene (6 mL), preheated to 110°C. 4-Hydroxy-2-butanoe (80 μL, 0.86 mmol, 6 eq) was added, followed by DBTL (10 μL, 0.014 mmol, 0.1 eq) and the reaction was monitored to completion (45 minutes) by TLC (EtOAc:Hex 4:6). The solvent was removed under reduced pressure and the crude product purified by column chromatography on silica gel (EtOAc:Hex 4:6) to give compound **29** (134 mg, 93%) as a white solid.

^{1}H NMR (200 MHz, DMSO-d^{6}): δ = 9.74 (1H, s), 9.54 (2H, s), 9.47 (1H, s), 7.67-7.87 (6H, m), 7.37-7.48 (8H, m), 7.27 (2H, t, *J* = 7.5 Hz), 7.00 (1H, t, *J* = 7.5 Hz), 6.39-6.50 (3H, m), 5.13 (6H, s), 4.25 (2H, t, *J* = 6.2 Hz), 2.82 (2H, t, *J* = 6.2 Hz), 2.14 (3H, s), 1.46 (27H, s). ^{13}C NMR (50 MHz, DMSO-d^{6}): δ = 206.8, 166.3, 165.8, 155.0, 154.8, 153.7, 148.5, 139.9, 139.4, 137.6, 137.1, 136.9, 134.3, 134.1, 132.2, 130.6, 130.3, 129.1, 128.9, 128.8, 128.4, 126.7, 124.3, 122.8, 121.1, 118.6, 117.7, 117.6, 116.7, 80.4, 79.8, 66.7, 65.9, 65.5, 28.2. MS (MALDI-TOF): calculated for [M+Na^{+}] $C_{56}H_{64}N_{4}O_{15}$ 1055.4; found 1055.4.

Compound 11. Compound **29** (5 mg) was dissolved in a 1:1 mixture of TFA and DCM, stirred for 5 minutes and the solvents removed under reduced pressure. The obtained compound **11** was used without further purification.

^{1}H NMR (400 MHz, DMSO-d^{6}): δ = 9.77 (1H, s), 9.52 (2H, s), 9.45 (1H, s), 7.65-7.89 (6H, m), 7.33-7.50 (8H, m), 7.26 (2H, t, *J* = 7.5 Hz), 7.00 (1H, t, *J* = 7.5 Hz), 6.36-6.49 (3H, m), 5.14 (6H, s), 4.21 (2H, t, *J* = 6.2 Hz), 2.83 (2H, t, *J* = 6.2 Hz), 2.14 (3H, s).

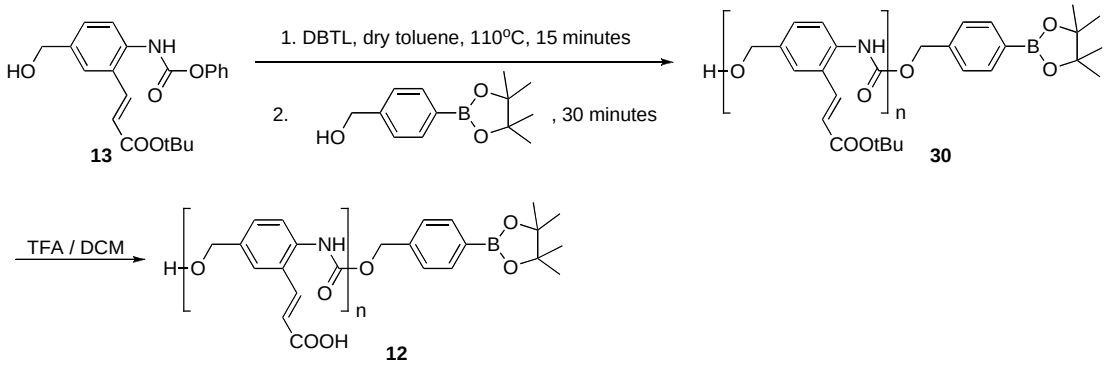
Labeling experiments

The labeling of Ab38C2 was performed for three final aza-quinone methide concentrations, as presented in Table 2S.

Final aza-quinone methide concentration	SIP 8[a] concentration	Trimer 11[b] concentration	Molecule 10[c] concentration
3.5 mM	250 μM	1.16 mM	3.5 mM
2.1 mM	150 μM	700 μM	2.1 mM
1.05 mM	75 μM	350 μM	1.05 mM

Table 2S: [a] SIP **8** is constructed of 15 monomers (on average), therefore, each polymer molecule is expected to release 14 aza-quinone methides. [b] Trimer **11** is constructed of 3 monomers, therefore, each trimer molecule is expected to release 3 aza-quinone methides. [c] Molecule **10** is constructed of one monomer, therefore, each molecule is expected to release one aza-quinone methide.

Synthesis of hydrogen-peroxide-activated SIP labeling probe 12



Polymer 30. Compound **13** (150 mg, 0.40 mmol, 1 eq) and DBTL (13 μL, 0.02 mmol, 0.05 eq) were dissolved in dry toluene (400 μL), preheated to 110°C, under

argon atmosphere. The reaction was stirred for 15 minutes and 4-(Hydroxymethyl)benzeneboronic acid pinacol ester (56 mg, 0.24 mmol, 0.6 eq) was then added. The reaction mixture was stirred for additional 30 minutes and then allowed to cool to room temperature. The polymer was precipitated from methanol, filtered and dried under reduced pressure for three hours. Polymer **30** (85 mg) was obtained as a white powder. The formed polymer was constructed of 15 monomers in average (determined by ^{1}H-NMR).

^{1}H NMR (400 MHz, DMSO-d^{6}): δ = 9.60 (15H, s), 7.86 (15H, s), 7.77 (17H, d, *J* = 15.6 Hz), 7.35 (30H, s), 7.30 (2H, s), 6.45 (15H, d, *J* = 15.6 Hz), 5.14 (30H, s), 4.49 (2H, s), 1.47 (135 H, s), 1.29 (12H, s).

Polymer 12. Polymer **30** (5 mg) was dissolved in a 1:1 mixture of TFA and DCM, stirred for 5 minutes and the solvents were then removed under reduced pressure. The obtained polymer **12** was used without further purifications.

^{1}H NMR (400 MHz, DMSO-d^{6}): δ = 9.59 (15H, s), 7.75-7.86 (32H, m), 7.29-7.36 (32H, m), 6.45 (15H, d, *J* = 15.7 Hz), 5.14 (30H, s), 4.47 (2H, s), 1.30 (12H, s).

Comparative quantum yield calculations

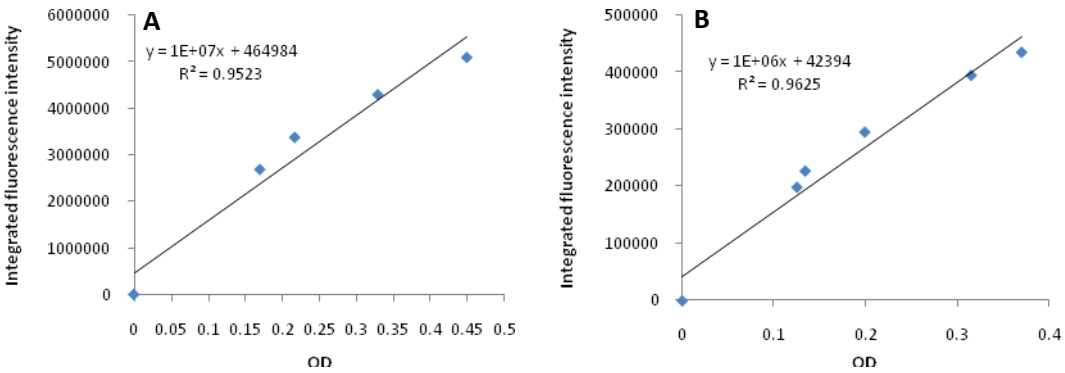


Figure 5S: Integrated fluorescence intensity *vs* absorbance at λ_{max} for: A) 1-naphtylamin and B) molecule **3**.

$$\Phi_X = \Phi_{ST} \cdot \left(\frac{Grad_X}{Grad_{ST}} \right) \left(\frac{\eta_X{}^2}{\eta_X{}^2} \right)$$

Equation 1: The subscripts ST and X denote standard and test respectively, Φ is the fluorescence quantum yield, *Grad* the gradient from the plot of integrated fluorescence intensity *vs* absorbance at λ_{max}, and η the refractive index of the solvent.

Since ethanol was used as solvent in all measurements, the influence of the refractive index of the solvent was dismissed and the quantum yield was calculated based on the results presented above using equation 1. The quantum yield found for molecule **3** in ethanol was $\Phi_F = 0.043 \pm 10\%$.

Received May 15, 2009; Revised Manuscript Received July 24, 2009

For the imaging of low pH circumstances *in vivo*, a pH-sensitive radical-containing-nanoparticle (RNP), which has an intense electron paramagnetic resonance (EPR) signal, was designed and developed using a self-assembling amphiphilic block copolymer (PEG-*b*-PCTEMPO) composed of a hydrophilic poly(ethylene glycol) (PEG) segment and a hydrophobic poly(chloromethylstyrene) (PCMS) segment in which the chloromethyl groups were converted to 2,2,6,6-tetramethylpiperidinyloxys (TEMPOs) via the amination of PEG-*b*-PCMS block copolymer with 4-amino-TEMPO. This RNP formed core−shell-type micelles in the physiological environment, and the cumulant average diameter of the RNP was about 50 nm. The cytotoxicity and acute toxicity studies for the RNP revealed that the median inhibitory concentration (IC_{50}) of TEMPO radicals in RNP core and median lethal dose (LD_{50}) of RNP were >8 mmol N(TEMPO)/L and >600 mg/kg (>960 μmol N(TEMPO)/kg), respectively, indicating fairly low toxicity. The blood circulation of the RNP was evaluated using ICR mice. Contrary to the rapid clearance of low-molecular-weight TEMPO derivatives such as 4-hydroxy-TEMPO (TEMPOL) from the bloodstream, the EPR signal of the RNP remained for a fairly long period of time. Actually, the signal was observed in the blood for more than 2 h, as monitored by EPR spectroscopy. The compartmentalization of the TEMPO radicals in the RNP core improved the stability in the bloodstream. Since an amino group was introduced in each repeating unit of the PCTEMPO segment, the disintegration of the RNP was caused by the protonation of the amino groups in response to the acidic pH environment (pH < 6.0), as confirmed by the dynamic light scattering (DLS) measurements. In addition, a drastic change in the EPR spectra from broad to sharp triplet was observed, accompanying the disintegration. This change was based upon the mobility of the TEMPO moieties covalently conjugated in the hydrophobic segment, which was confirmed by the rotational correlation time of the TEMPO moieties on the PCTEMPO segment. Note that the peak intensity of the EPR signal increased at around the phase transition point (ca. pH = 6.0). When pH-sensitive RNP solutions at pH values 5.6 and 7.4 were visualized using an L-band EPR imaging system, the phantom images showed a remarkable on−off regulation in response to the acidic pH environment. These results demonstrate that pH-sensitive RNPs are expected to serve as nanoprobes for the *in vivo* EPR imaging of low pH circumstances.

INTRODUCTION

Recently, the non-invasive *in vivo* imaging of low pH circumstances has attracted attention as a new means of detecting disease and response to clinical treatment. Low pH circumstances, which are an aberration of normal pH homeostasis, are caused by ischemia (*1, 2*), infection (*3*) or inflammation (*4*), extracellular acidosis in tumors (*5, 6*), wound healing (*7*), and so forth. However, there is currently no clinical tool available to capture an image of low pH circumstances *in vivo*. In order to image acidic pH regions *in vivo*, various molecular probes have been developed so far for magnetic resonance imaging (MRI) (*8*−*10*), positron emission tomography (PET) (*11*), and optical imaging (*12*). Under *in vivo* conditions, however, the diagnostic efficiency of such probes is still controversial. A more desirable design criterion for the imaging of acidic pH regions *in vivo* is believed to be the development of nanoprobes capable of the on−off regulation of the signal in response to the acidic pH environment (*8*, *12*).

Nitroxyl radicals, such as 2,2,6,6-tetramethylpiperidinyloxy (TEMPO), are organic molecules that have a stable radical and are therefore susceptible to electron paramagnetic resonance (EPR). Recently, the research on *in vivo* EPR imaging has been stepped up by several groups (*13, 14*). Some groups have reported on pH-sensitive nitroxyl radicals of the imidazolidine type or the imidazoline type for the noninvasive measurement of pH (*15, 16*) Under *in vivo* conditions, however, such low-molecular-weight nitroxyl radicals pose several problems, such as nonspecific accumulation in normal tissues, preferential renal

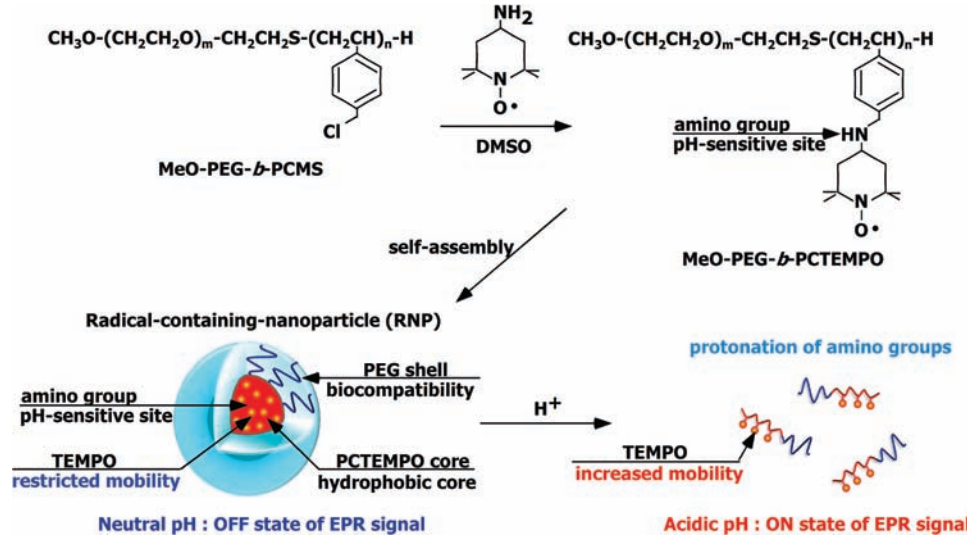

Figure 1. Schematic illustration of the pH-sensitive radical-containing-nanoparticle (RNP) prepared from PEG-*b*-PCTEMPO for the *in vivo* EPR imaging of low pH circumstances.

clearance, and rapid reduction of the nitroxyl radical form to the corresponding hydroxylamine form (*17*, *18*).

To solve these difficulties, we have designed and developed a radical-containing-nanoparticle (RNP) using a self-assembling amphiphilic block copolymer (PEG-*b*-PCTEMPO) composed of a hydrophilic poly(ethylene glycol) (PEG) segment and a hydrophobic poly(chloromethylstyrene) (PCMS) segment in which the chloromethyl groups were converted to TEMPOs via the amination of PEG-*b*-PCMS block copolymer with 4-amino-TEMPO (Figure 1) (*19*). This RNP formed core−shell-type micelles in the physiological environment; the cumulant average diameter of the RNP was about 50 nm, and the RNP emitted an intense EPR signal. We have previously reported that the TEMPO radicals in the core of the RNP showed fairly high resistance against reducing reactions compared with low-molecular-weight 4-hydroxyl-TEMPO (TEMPOL) even in the presence of 3.5 mM ascorbic acid (*19*). Thus, this RNP is anticipated to serve as a high-performance bionanoparticle which can be used *in vivo*. In this study, we evaluated the toxicity and the blood circulation of the RNP in view of its use *in vivo*. Since an amino group was introduced into each repeating unit on the PCTEMPO segment, the RNP emitted pH-sensitive EPR signals in response to the acidic pH environment due to the protonation of the amino groups. We demonstrated the drastic change in the EPR signal of the RNP as a function of pH. A pH-dependent phantom study of the RNP for the *in vivo* EPR imaging of low pH circumstances using L-band EPR spectroscopy is also described herein.

EXPERIMENTAL PROCEDURES

Synthesis of MeO-PEG-*b*-PCTEMPO. MeO-PEG-*b*-PCMS was synthesized by the radical telomerization of chloromethylstyrene (CMS) using MeO-PEG-SH ($M_n = 5000$) as a telogen, according to procedure described in the previous report (*19*) (see Supporting Information Scheme S1 and Figure S1). After the synthesis of PEG-*b*-PCMS, the chloromethyl groups on the PCMS segment of the block copolymer MeO-PEG-*b*-PCMS were converted to stable radicals via the amination of MeO-PEG-*b*-PCMS with 4-amino-TEMPO in DMSO (see Supporting Information Scheme S1 and Figure S2).

Preparation of the RNP. The RNP was prepared from MeO-PEG-*b*-PCTEMPO by the dialysis method described previously (*19*). Briefly, 400 mg of MeO-PEG-*b*-PCTEMPO was dissolved in 100 mL of DMF, and the polymer solution was transferred into a membrane tube (Spectra/Por, molecular-weight cutoff size 3500; Spectrum, USA) and then dialyzed for 24 h against 2 L of water, which was changed after 2, 5, 8, and 20 h. Dynamic light scattering (DLS) measurement was carried out to determine the diameter of the obtained RNP after dialysis. In order to adjust the concentration of the RNP solution, the obtained RNP solution was concentrated by a centrifugal evaporator (~60 mg/mL), followed by DLS measurement of the concentrated RNP to confirm the size of the RNP after the concentration.

Cytotoxicity Studies. Cell viability was determined by a quantitative colorimetric assay using WST-8 (DOJINDO Laboratories, Kumamoto, Japan). Briefly, 1×10^4 cells were seeded per well on a 96-well flat-bottom plate. At 24 h after treatment, 10 μL of WST-8 reagent was added to each well containing 100 μL of medium, according to the manufacturer's instructions. The plate was incubated for 1 h at 37 °C and read at an absorbance of 450 nm by a plate reader.

Median Lethal Dose (LD_{50}) Studies. Male ICR mice (5 weeks old, ca. 25 g) were purchased from Charles River Japan, Inc. The LD_{50} value of the RNP was determined by injecting the RNP saline solution with increasing doses into the ICR mice via the tail vein. There were five mice in each dose group. The doses of intravenous administration were elevated as follows: 75, 150, 300, and 600 mg/kg mouse body weight. The mice in all groups were observed for 2 weeks, and the number of surviving mice was recorded.

Blood Circulation of the RNP. The blood circulation of the RNP was examined as follows: after anesthesia with pentobarbital sodium (40 mg/kg), 200 μL of RNP saline solution (12 mg/mL) were injected into the tail vein of male ICR mice (ca. 25 g), and then blood samples were collected at 2 min, 10 min, 30 min, 1 h, and 3 h. Plasma samples were obtained by centrifugation (6200 rpm, 2000 × *g*, 10 min) of the blood. It was confirmed that no EPR signal was observed in the blood cell precipitates after centrifugation. The EPR signal intensities in these plasma samples were measured by an X-band EPR spectrometer (JES-TE25X, JEOL, Tokyo, Japan) at room temperature. In the case of the EPR intensities at 0 min, 50 μL of the RNP solution (12 mg/mL) was added to the blood (500 μL), followed by centrifugation (6200 rpm, 2000 × *g*, 10 min) of the blood and EPR measurement, assuming that the total blood volume in mice is 80 mL/kg. A free-TEMPOL saline solution with the same spin concentration as the RNP was used as a control. The EPR measurements were carried out under

the following conditions: frequency, 9.41 GHz; power, 8.00 mW; field, 333.8 ± 5 mT; sweep time, 1.0 min; modulation, 0.1 mT; time constant, 0.1 s. All procedures and animal care were approved by the Committee on the Ethics of Animal Experimentation of the University of Tsukuba, and were conducted according to the Guidelines for Animal Experimentation of the University of Tsukuba.

Potentiometric Titrations. An aqueous solution of RNP (1.0 mL: 20 mg/mL) was added to a solution of 0.01 M HCl (4.0 mL), followed by the adjustment of the NaCl concentration to 0.15 M (40 mL). The resulting RNP solution (40 mL) was titrated with 0.01 M NaOH containing 0.15 M NaCl at 25 °C. An automatic titrator (DL-25, Mettler) was used for the titration. In this case, the titrant was added in quantities of 0.05 mL after the pH values were stabilized (minimal interval: 30 s), and the titration curves in the pH range from about 3 to about 10 were recorded.

Dynamic Light Scattering (DLS) Experiments and X-Band Electron Paramagnetic Resonance (EPR) Experiments as a Function of pH. The light scattering intensities of the pH-sensitive RNP were measured as a function of pH using a light scattering spectrometer (Nano ZS, ZEN3600, Malvern Instruments, Ltd., U.K.) equipped with a He−Ne laser that produces vertically polarized incident beams at a detection angle of 173° at 25 °C. Briefly, 3.5 mg/mL of the RNP solution was prepared as stock solution A after the formation of the RNPs by the dialysis method. Britton-Robinson buffers (100 μL each) with various pH values, which were prepared from a stock solution containing 1 M phosphoric acid, 1 M boric acid, and 1 M acetic acid and by adjusting the pH value with NaOH, were added to stock solution A (400 μL). The mixtures with various pH values were transferred to the cells immediately, followed by DLS measurement. A nanoparticle (CMS-NP: CNP) prepared from PEG-*b*-PCMS was used as a control.

After DLS measurement, the samples were transferred to a capillary tube, followed by EPR measurement. To measure the EPR spectra of the pH-sensitive RNP as a function of pH, the EPR spectra were recorded at room temperature on a JEOL JES-TE25X spectrometer. The EPR measurements were carried out under the following conditions: frequency, 9.4190 GHz; power, 8.00 mW; field, 333.8 ± 50 mT; sweep time, 2.0 min; modulation, 0.1 mT; time constant, 0.1 s.

Phantom EPR Imaging. Phantom images were obtained using a capillary glass tube (1.2 mm i.d.) containing 80 mg/mL of RNP solution at pH 5.6 or 7.4. 2D spatial images perpendicular to the axes of the tubes using an L-band EPR spectrometer manufactured by JEOL (Tokyo, Japan), consisting of a 1 GHz microwave unit and a bridged four-gap loop-gap resonator (38 mm in diameter and 28 mm in length), were obtained in this study. The EPR conditions for these phantom studies were as follows: magnetic field, 370.0 ± 5.0 mT; modulation width, 2.0 mT; time constant, 0.03 s; microwave power, 0.25 mW; scanning time, 30 s. EPR images were constructed on 256 points × 256 points.

RESULTS AND DISCUSSION

Synthesis of the Polymer and Preparation of the RNP. As described in the previous report (*19*), MeO-PEG-*b*-PCMS was synthesized by the radical telomerization of CMS using MeO-PEG-SH as a telogen, as shown in Supporting Information Scheme S1. The molecular weight distribution of MeO-PEG-*b*-PCMS was evaluated by size exclusion chromatography (SEC), as shown in Supporting Information Figure S1a. The SEC profile of MeO-PEG-*b*-PCMS and the molecular weight of the PCMS segment after polymerization were almost the same as those of acetal-PEG-*b*-PCMS reported previously (*19*). The polymer backbone of PEG-*b*-PCMS consisted of PEG with a molecular weight of 5000 g/mol for the hydrophilic segment and 20 repeating units of PCMS for the hydrophobic segment (MW = 3300), as determined by the ^{1}H NMR data based on the M_n of PEG (see Supporting Information Figure S1b). MeO-PEG-*b*-PCTEMPO was synthesized by the substitution of the chloromethyl groups of the PCMS segment of MeO-PEG-*b*-PCMS with amino-TEMPO via amination in DMSO. After the purification of the obtained PEG-*b*-PCTEMPO, the substitution ratio of the modified TEMPO moieties per repeating unit of PCMS was 80%, as determined by EPR spectroscopy using the standard curve of free-amino-TEMPO in chloroform. The thus-obtained PEG-*b*-PCTEMPO was dialyzed against water to obtain the RNP. As shown in Supporting InformationFigure S3, the RNP after dialysis showed a unimodal distribution in the histogram analysis. The average diameter and polydispersity factor (μ_2/Γ^2), as determined by the cumulant method, were about 50 nm and 0.133, respectively.

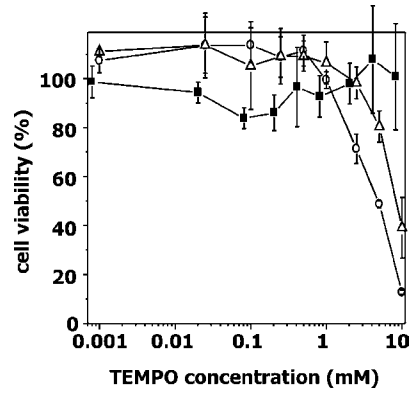

Figure 2. Cell viability against RNP (closed square), TEMPO (open triangle), and 4-amino-TEMPO (open circle) in colon cells (WST assay). The plotted data represent the average ± SEM of three experiments.

Toxicity Study of the RNP. TEMPO derivatives are known as biologically active substances (*20, 21*). Suy et al. have reported that the promotion of apoptosis by TEMPO is one of its physiological activities in cancer cells (*22*). Since each RNP carries several thousand TEMPO moieties (stable radicals) in its core, it is interesting to investigate the behavior of RNP *in vivo*. The cytotoxicity of the RNP was investigated by subjecting colon cells to the WST assay. As shown in Figure 2, the dose-dependent cell viabilities were observed in colon cells treated with TEMPO, 4-amino-TEMPO, and the RNP. The number on the horizontal axis of the figure indicates the concentration of TEMPO radical, as determined by EPR spectroscopy. The colon cell viabilities were progressively reduced after 24 h with increasing concentrations of low-molecular-weight TEMPO and amino-TEMPO. The median inhibitory concentrations (IC_{50}) of TEMPO and 4-amino-TEMPO were 8.3 mM and 4.8 mM, respectively. Because amino groups generally show high toxicity, the cytotoxicity of 4-amino-TEMPO might be higher than that of TEMPO. In contrast, the RNP induced no change in cell viability regardless of the concentration of RNP up to the concentration of 8 mmol N(TEMPO)/L. The extremely low toxicity of RNP is probably because the outer PEG layer constitutes an excellent stealth shield around the amino-TEMPO moieties in the RNP core. The median lethal dose (LD_{50}) of the RNP in ICR mice was then evaluated. For the evaluation of the LD_{50} value, RNP solution at a concentration of 60 mg/mL was employed, because the size of the RNP did not change up to this concentration (data not shown). 250 μL of RNP saline solution (0, 7.5, 15.0, 30.0, 60.0 mg/mL, which correspond to 0, 75, 150, 300, 600 mg/kg-dose, respectively) were intravenously administered to ICR mice (ca. 25 g).

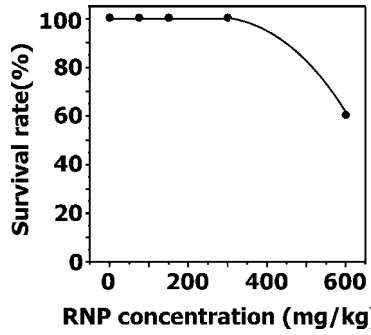

Figure 3. Survival rate of ICR mice injected with RNP. The RNP doses of the intravenous injections were gradually increased as follows: 0, 75, 150, 300, 600 mg/kg mouse body weight.

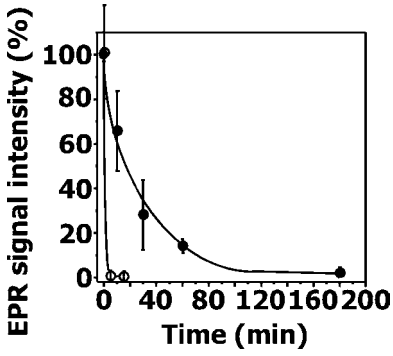

Figure 4. Blood circulation of the RNP (closed circle) and TEMPOL (open circle). The EPR intensity changes in the blood were measured at 2, 5, 30, 60, and 180 min after injecting RNP saline solution into the mice.

As shown in Figure 3, no dead mice were observed for 2 weeks after the administration of the RNP (0−300 mg/kg). Even at 600 mg/kg (concentration of amino-TEMPO moieties: 960 μmol N(TEMPO)/kg), 60% of the mice lived. Stefano et al. have reported that the LD_{50} of poly(L-lysine) with a molecular weight of 28 000−42 000 (polymerization degree = 135−203) was between 15 and 30 mg/kg (concentration of amino groups: 72.5−145 μmol N/kg) (*23*). The extremely low toxicity of RNP, viz., IC_{50} > 8 mmol N(TEMPO)/L and LD_{50} > 600 mg/kg (>960 μmol N(TEMPO)/kg), is considered to be due to the confinement of the polyamine segment of the block copolymer in the RNP core. The antioxidant character of the RNP might also have contributed to the reduced toxicity.

Blood Circulation of Nitroxyl Radicals. In order to obtain information on the circulation of nitroxyl radicals in the bloodstream, an EPR study was carried out. Figure 4 shows the time course of the spin concentration of the RNP in the blood after intravenous injection. When low-molecular-weight TEMPOL was administered, almost no EPR signals was observed even after 2 min in the bloodstream. The half-life of TEMPOL in blood is reported to be about 15 s (*24*). It is interesting to note, in contrast, that the EPR signal in the bloodstream was observed even 2 h after tail-vein injection of the RNP. The half-life of the RNP was 60 times longer (15 min) than that of low-molecular-weight TEMPOL. The rapid clearance of low-molecular-weight TEMPOL from the bloodstream was probably due to preferential renal clearance and the rapid reduction of the TEMPO radical form to the corresponding hydroxylamine form in the blood. We have previously reported that the TEMPO radicals in the RNP core showed high reduction resistance in the presence of 3.5 mM ascorbic acid (*19*). The compartmentalization of the TEMPO radicals in the RNP core resulted in the reduced reactivity of the TEMPO radicals toward ascorbic acid. The increased reduction resistance of the RNP must be one of the reasons for the prolonged blood circulation time. Since the observed EPR signals were broad singlet in blood (data not shown), it is considered that the TEMPO moieties are still located in the solid core of the RNP. Thus, slow dissociation is one of the important factors to improve blood circulation of nitroxyl radicals in bloodstream.

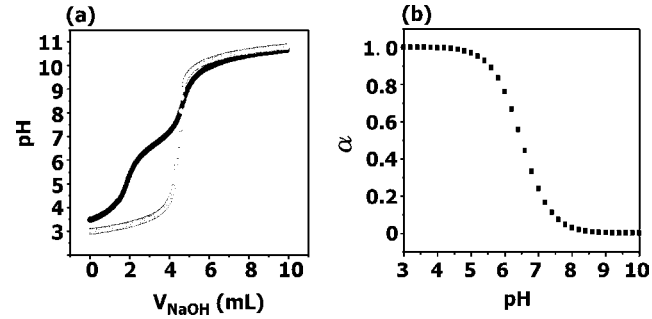

Figure 5. (a) Experimental titration curve obtained for aqueous solutions of CNP prepared from PEG-*b*-PCMS (open circle) and RNP prepared from PEG-*b*-PCTEMPO (closed circle) using 0.01 M NaOH. (b) The degree of protonation (α) as a function of solution pH for the pH-sensitive RNP prepared from PEG-*b*-PCTEMPO.

pH Response of the RNP. *Potentiometric Titration and Dynamic Light Scattering (DLS) Measurements.* Polyamine with the appropriate hydrophobicity is known to show phase transition as a function of pH (*25*, *26*). For example, the poly[2-(*N*,*N*-diethylamino)ethyl methacrylate] (PEAMA) homopolymer exhibits precipitation above pH 7.5 owing to the deprotonation of the amino groups of the PEAMA (*27*). It is reported that the self-assembly structure of block copolymer micelles can be controlled by the environmental pH when PEAMA is used as one of the segments in the block copolymer (*28*, *29*). Because the PCTEMPO segment possesses an amino group in each repeating unit, a similar phenomenon is anticipated in response to acidic pH environments due to the protonation of the amino groups. In order to confirm the pH-response of the RNP, potentiometric measurement of the RNP was performed. As shown in Figure 5a, the CNP, prepared as a control from PEG-*b*-PCMS (no amino groups), did not show buffer action at all, while the titration curve of the RNP showed a clear inflection point at pH 6−8, which was regarded as a buffer action. From the obtained titration curves, the pK_a of RNP was confirmed to be 6.5. The α-pH curves calculated using the Henderson-Hasselbach equation indicated that the amino groups on the PCTEMPO segment were almost completely protonated at pH values below 5.0, as shown in Figure 5b. In order to investigate the effect of the protonation of the PCTEMPO segment on the self-assembly structure of the RNP, the light scattering intensities of RNP solutions were measured as a function of pH. As shown in Figure 6, the light scattering intensity of CNP prepared from PEG-*b*-PCMS (no amino groups) did not change at all, whereas it drastically decreased at pH values below 6.0 in the case of RNP prepared from the PEG-*b*-PCTEMPO block copolymer. According to the Rayleigh approximation ($I \propto d^6$, where I is the scattering intensity and d is the particle size) (*30*), it is clear that the RNP disintegrated at pH values below 6.0. These results suggest that the PCTEMPO segment cannot form the hydrophobic core of the RNP due to the increased solubility of the PCTEMPO segment, which may be due to the protonation of the amino groups. On the basis of the obtained data, viz., titration and DLS measurements, it is concluded that the disintegration of the RNP at around pH = 6.0 was due to the protonation of the amino groups on the PCTEMPO segment and the molecular dissolution of the PEG-*b*-PCTEMPO copolymer in the acidic solution.

Electron Paramagnetic Resonance (EPR) Measurement. EPR spectra are known to give information on the local environment

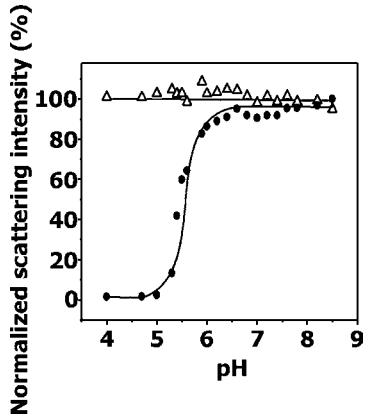

Figure 6. Effect of pH on the light scattering intensity of RNP prepared from PEG-*b*-PCTEMPO (closed circle) and CNP prepared from PEG-*b*-PCMS (open triangle). The normalized scattering intensity (%) is expressed as the value relative to that at pH 8.2.

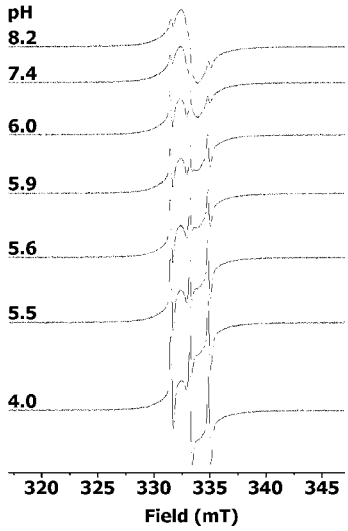

Figure 7. X-band EPR spectra of the RNP as a function of pH, at pH 4.0, 5.5, 5.6, 5.9, 6.0, 7.4, and 8.2, in Britton-Robinson buffer prepared from a stock solution containing 1 M phosphoric acid, 1 M boric acid, and 1 M acetic acid, and by adjusting the pH value with NaOH.

around the spin probe (*31*). The EPR measurement of the polymers carrying nitroxyl radicals thus gives us the dynamics of the polymer chain (*32*, *33*). Since the assembly of PEG-*b*-PCTEMPO depends on the protonation of the amino groups, as described above, the EPR spectra must be influenced by the environmental pH. In order to obtain detailed information on the EPR signals, the EPR measurement of the RNP under various pH conditions was carried out using an X-band EPR spectrometer. Figure 7 shows the EPR spectra of the RNP under various pH conditions, from pH = 4.0 to 8.2. Contrary to the clear triplet signals of low-molecular-weight TEMPO derivatives resulting from the interaction between the ^{14}N nuclei and the unpaired electron in the dilute solution (*19*), broad signals of the RNP were observed at pH values above 6.0, in same manner as the EPR signal after the dialysis. The EPR spectra of the RNP at pH values above 6.0 are due to the confinement of the TEMPO radicals in the solid core of the RNP. With decreasing pH, the EPR signals gradually changed, and typical triplet signals were observed under acidic pH (pH < 6.0) conditions, which is consistent with the disintegration region of the RNP. Since the spin probe is covalently conjugated in the PCTEMPO segment of the PEG-*b*-PCTEMPO block copolymer, the relative anisotropy observed in the EPR spectrum is directly related to the rotational mobility of the probe. In order to confirm the

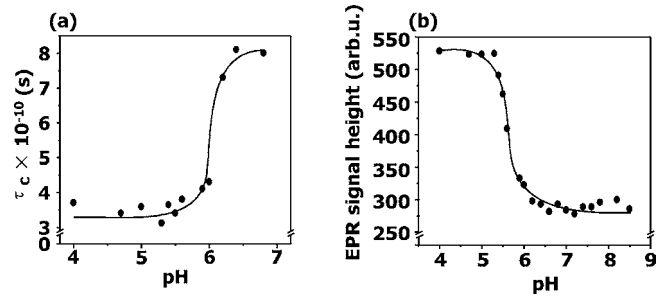

Figure 8. (a) Rotational correlation times (τ_c) of the TEMPO moieties on the PCTEMPO segment of RNP as a function of pH, which were calculated using eq 1 (see Supporting Information Figure S4).(b) EPR signal height of RNP as a function of pH.

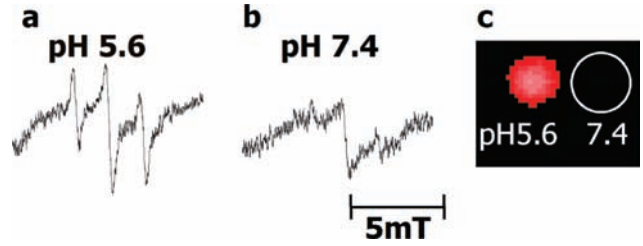

Figure 9. Phantom images of the RNP obtained by L-band EPR spectroscopy at pH 5.6 and 7.4. EPR spectrum of the RNP at pH 5.6 (a) and pH 7.4 (b). (c) Phantom images of the RNP at pH 5.6 (left) and pH 7.4 (right).

change in the rotational mobility factor, the rotational correlation time, τ_c (see Supporting Information Figure S4), was determined as a function of the environmental pH (Figure 8a). Under neutral conditions, the τ_c was about 8.0×10^{-10} s. Its abrupt decrease was observed again at around the phase transition region (ca. pH = 6.0). Actually, the τ_c was about $(3-4) \times 10^{-10}$ s at pH values below 6.0. The lower τ_c indicates the higher mobility of the TEMPO moieties, which is certainly correlated with the disintegration of the RNP. Crucially, the mobility of the TEMPO moieties as side chains of the PCTEMPO segments increased along with the disintegration of the RNP core, and the distance between the TEMPO radicals increased due to the electrostatic repulsion between the protonated amino groups. In conjunction with the phase transition, a change in the EPR signal height was observed, as shown in Figure 8b. Indeed, a significant increase in signal height was observed at pH values below 6.0, which confirms that the RNP shows a phase transition at a specific pH (around pH = 6.0). If this phenomenon is also observed in the L-band EPR spectra, low pH circumstances might be visualized by *in vivo* EPR imaging. L-band EPR imaging systems operating in the lower-frequency microwave bands (less than 1.2 GHz), where the dielectric losses are lower, have been developed and utilized for the *in vivo* imaging of animals using a spin probe (*34*). After two different RNP samples (80 mg/mL) were transferred to a capillary glass tube at pH values 5.6 and 7.4, phantom images were obtained using the L-band EPR imaging system. Figure 9a,b shows the EPR spectra of the RNP at pH values 5.6 and 7.4, as measured by L-band EPR spectroscopy. The EPR spectrum of the RNP at pH 5.6 showed a clear triplet signal due to the disintegration of the RNP, in the same manner as the X-band EPR spectroscopy (Figure 9a). On the other hand, almost no narrow-line-width EPR signals were observed at pH 7.4 (Figure 9b). The signal-to-noise (*S*/*N*) ratios of the spectra at pH values 5.6 and 7.4 were about 12.5 and 7.8, respectively. The improvement of the *S*/*N* ratios in response to the acidic pH environment is remarkable. Figure 9c shows phantom images of the RNPs at pH values 5.6 and 7.4. The appropriate threshold (cutoff: 40%)

was used for de-noising. The phantom images clearly show a remarkable on−off regulation in the capillary glass tube. If the RNP is able to accumulate in low pH circumstances *in vivo*, then the RNP might disintegrate and emit strong EPR signals. This is our strategy for imaging of low pH circumustances using pH-sensitive RNP. From these results, the RNP might be used as a nanoprobe for the *in vivo* EPR imaging of low pH circumstances.

CONCLUSIONS

We have developed an EPR-imaging nanoprobe based on a pH-sensitive radical-containing-nanoparticle (RNP), which consists of PEG-*b*-PCTEMPO block copolymer. The RNP was confirmed to attain long-term spin circulation in the blood compared with low-molecular-weight TEMPOL. The RNP was also confirmed to show extremely low toxicity due to the confinement of the amino-TEMPO moieties in the RNP core. It is interesting to note that the disintegration and drastic change in the EPR signal of the RNP were observed at pH values below 6.0; this change was caused by the protonation of the amino groups on the PCTEMPO segments in response to the acidic pH environment. The phantom images indicate that the RNP can implement a remarkable on−off regulation of the EPR signal in response to acidic pH environments (pH < 6.0). These results demonstrate that pH-sensitive RNPs are expected to serve as an EPR imaging nanoprobes, which can image low pH circumstances *in vivo*.

ACKNOWLEDGMENT

We appreciate Dr. Kazuko Toh of the University of Tsukuba for her helpful assistance in this study. This work was partly supported by a Grant-in-Aid for Scientific Research A (21240050) and the World Premier International Research Center Initiative (WPI Initiative) on Materials Nanoarchitronics of the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of Japan.

Supporting Information Available: The SEC diagram and ^{1}H NMR spectrum of MeO-PEG-*b*-PCMS and MeO-PEG-*b*-PCTEMPO and the size distribution of the RNP are provided. Also, the materials and calculation method for the rotational correlation time (τ_c) are described. This material is available free of charge via the Internet at http://pubs.acs.org.

S1. Materials

2,2'-Azobisisobutyronitrile (AIBN) (Kanto Chemical Co., Inc., Tokyo, Japan) was purified by recrystallization from methanol. Chloromethylstyrene (CMS) was kindly provided by Seimi Chemical Co., Ltd. (Kanagawa, Japan) and purified on a silica gel column to remove the inhibitor, followed by vacuum distillation under a nitrogen atmosphere. 2,2,6,6-Tetramethylpiperidinyloxy (TEMPO), 4-amino-TEMPO, 4-hydroxy-TEMPO (TEMPOL) (Aldrich Chemical Co., Inc., U.S.A.), 2-propanol, diethyl ether, dimethyl sulfoxide (DMSO) and N,N-dimethylformamide (DMF) (Wako Pure Chemical Industries, Ltd., Osaka, Japan) were used without further purification. PEG possessing a methoxy group at the α-chain end and a sulfanyl group at the □-chain end (MeO-PEG-SH) (NOF CORPORATION Co., Ltd., Japan) was used without further purification.

S2. Synthesis of MeO-PEG-*b*-PCMS

Method: After 0.2 mmol (1 g) of MeO-PEG-SH (Mn = 5,000) and 0.1 mmol of AIBN were weighed into a flask, the inside of the reactor was degassed and filled with nitrogen gas. The degassing-N_2-purge cycle was repeated three times. Ten millimoles (1.38 mL) of CMS and 10 mL of benzene were then added to the flask. Polymerization was conducted for 24 h at 60 °C in an oil bath. The reaction mixture was recovered by precipitation into 40 mL of hexane, followed by freeze-drying with benzene. The reacted polymer was washed with diethyl ether three times in order to eliminate the PCMS homopolymer, followed by freeze-drying with benzene. The yield of the obtained MeO-PEG-*b*-PCMS copolymer was 87.5% (1.4 g).

Results: MeO-PEG-*b*-PCMS was prepared by the radical telomerization of CMS using MeO-PEG-SH (Mn = 5,000) as a telogen, according to the previous report, as shown in Scheme 1. The molecular weight distribution of the MeO-PEG-*b*-PCMS thus prepared was evaluated by SEC, as shown in Figure S1a. The SEC profile of MeO-PEG-*b*-PCMS after polymerization showed a bimodal distribution similar to that of previously reported acetal-PEG-*b*-PCMS. In the previous study, ^{1}H NMR analysis performed after the two peaks were separated by SEC fractionation showed that the composition ratios of PEG to PCMS in the two fractions were almost the same. The Mn

value of PCMS was determined by the ^{1}H NMR data based on the Mn of PEG (Mn = 5,000). From the SEC profile, it can be seen that the number-average molecular weight (Mn) of the first fraction was two times higher than that of the second fraction. Based on the Mn value of PEG as determined by SEC, the Mn values of the PCMS segments for the two fractions were determined to be 3,300 and 6,600, respectively. The products were a mixture of di-block and tri-block copolymers possessing the same composition, as reported previously. The ratios of di-block to tri-block copolymer were determined to be 59 % and 41 %, respectively, based on the chromatogram.

S3. Synthesis of the radical-containing blockcopolymer (MeO-PEG-*b*-PCTEMPO)
Method: After 177 μmol (1.25 g) of the obtained MeO-PEG-*b*-PCMS (Mn = 8,000) were weighed into a 100 mL flask, a DMSO solution (40 mL) of 4-amino-TEMPO (17.7 mmol, 3 g) was added to the flask and stirred for 12 h at room temperature. The reacted polymer was recovered by precipitation into 80 mL of cold 2-propanol (-15 °C) and centrifugation for 30 min at 5,000 rpm (4,500 × *g*). In order to purify the obtained polymer, the precipitation-centrifugation cycle was repeated three times, followed by freeze-drying with benzene. The yield of the obtained MeO-PEG-*b*-PCTEMPO copolymer was 74.4 % (1.26 g).

Results: The chloromethyl groups in the PCMS segment of the block copolymer MeO-PEG-*b*-PCMS were converted to stable radicals via the amination of MeO-PEG-*b*-PCMS with 4-amino-TEMPO in DMSO (Scheme S1). When PEG-*b*-PCMS was reacted with 4-amino-TEMPO, the CH_2Cl signal of the PCMS segment in the ^{1}H NMR spectrum disappeared. After the TEMPO radicals were reduced by phenylhydrazine, the entire ^{1}H NMR spectrum was examined, as shown in Figure S2b. After the reducing reaction, it was confirmed that the signal for the methylene protons of the chloromethyl group in the PCMS unit at 4.5 ppm completely disappeared. On the basis of these results, it was confirmed that the TEMPOs were successfully introduced into the polymer.

S4. Preparation of the RNP
Results: The size of the obtained RNP after dialysis was estimated by DLS measurement. As shown in Figure S3, the RNP thus obtained showed a unimodal distribution in the histogram analysis. The average diameter and polydispersity factor (μ_2/Γ^2), as determined by the cumulant method, were about 50 nm and 0.133, respectively.

S5. Calculation method for the rotational correlation time, τ_c

The rotational correlation time, τ_c (s), which is the time taken for the axis of the nitroxyl group to rotate one radian, is highly sensitive to the motion of the TEMPO radicals on the PCTEMPO segment, and is calculated using the following equation[1]:

---

[1] Yoshioka, H., Haga, H., Kubota, M., Sakai, Y., and Yoshioka, H. (2006) Interaction of (+)-Catechin with a Lipid Bilayer Studied by the Spin Probe Method. *Biosci. Biotechnol. Biochem. 70*, 395-400.

$$\tau_c = B \times \Delta H_{(m=+1)}[(I_{m=+1} / I_{m=-1})^{1/2} - 1] \quad (1)$$

Here, B is a constant determined from the principal values of A and the g factor; the value of 6.6×10^{-10} s/Gauss is used. $\Delta H_{(m+1)}$ is the peak-to-peak width in gauss of the low-field lines, as shown in Figure S4. $I_{(m=+1)}$ and $I_{(m=-1)}$ are the peak-to-peak heights in arbitrary units of the low- and high-field lines, respectively. The value of τ_c reflects the mobility of the probe and the rigidity of the surroundings of the probe. An increase in τ_c means that the motion of the probe is suppressed.

Triazine Dendrimers as Nonviral Gene Delivery Systems: Effects of Molecular Structure on Biological Activity

Olivia M. Merkel,[†,‡] Meredith A. Mintzer,[†,§] Johannes Sitterberg,[‡] Udo Bakowsky,[‡] Eric E. Simanek,[§] and Thomas Kissel*[,‡]

Department of Pharmaceutics and Biopharmacy, Philipps-Universität, Marburg, Germany, and Department of Chemistry, Texas A&M University, College Station, Texas 77843-3255. Received June 4, 2009; Revised Manuscript Received July 23, 2009

A family of generation 1, 2, and 3 triazine dendrimers differing in their core flexibility was prepared and evaluated for their ability to accomplish gene transfection. Dendrimers and dendriplexes were analyzed by their physicochemical and biological properties such as condensation of DNA, size, surface charge, morphology of dendriplexes, toxic and hemolytic effects, and ultimately transfection efficiency in L929 and MeWo cells. Flexibility of the backbone was found to play an important role with generation 2 dendrimer displaying higher transfection efficiencies than 25 kDa poly(ethylene imine) or SuperFect at a lower cytotoxicity level. This result is surprising, as PAMAM dendrimers require generations 4 or 5 to become effective transfection reagents. The ability to delineate effects of molecular structure and generation of triazine dendrimers with biological properties provides valuable clues for further modifying this promising class of nonviral delivery system.

INTRODUCTION

Gene therapy has gained importance in recent years due to its potential for targeting genetic diseases and inhibiting tumor growth. However, clinical application is limited by numerous biological barriers to delivering plasmid DNA (*1*). Both viral and nonviral vector systems have been developed to overcome these hurdles. Viral delivery systems, which include retroviruses, lentiviruses, and adenoviruses, have encountered potential safety problems such as recombination, insertional mutagenesis, and immunogenicity, as well as scale-up difficulties (*2*). Therefore, synthesis and evaluation of nonviral vector systems becomes increasingly important in spite of their comparatively lower transfection efficiency (*3*).

Nonviral vectors such as cationic liposomes, linear and branched polycations, and dendrimers have been shown to be effective transfection agents and offer advantages over viral vectors regarding safety and manufacturing. Several nonviral gene delivery systems based on poly(amidoamine) (PAMAM) (*4*−*6*), poly(propylene imine) (PPI) (*7, 8*), and poly(ethylene imine) (PEI) (*9, 10*) have yielded efficient transfection *in vivo* with relatively low toxicity. The potential of triazine dendrimers as gene delivery systems is largely unexplored, but has been described by us in a study involving generation 2 rigid structures (*11*), which reveal an optimized peripheral group for further study. These dendrimers may be attractive candidates, as they can be synthesized in high yields via a divergent strategy that creates multiple surface functionalities in a completely monodisperse manner (*12*). In addition, triazine dendrimers show low toxicity, both *in vitro* and *in vivo*: mice tolerate i.p. doses up to 40 mg/kg (*13*). This level of toxicity is comparable to PAMAM (*14*) suggesting that triazine dendrimers could be considered as a platform for transfection studies. Here, the physicochemical properties, cytotoxicities, and transfection efficiencies of a panel of triazine dendrimers were evaluated to establish structure−function relationships. The effect of dendrimer size (generations) as well as core structure is probed in an attempt to maximize transfection efficiency. Increasing generation increases size and the number of available cations. Changing the composition of the core affords dendrimers that differ in flexibility, a characteristic that is thought to influence interactions with p-DNA (*6*). The dendrimers used in this study are shown in Figure 1. Here, we present results from the synthesis, physicochemical and biological *in vitro* evaluation of a panel of five triazine dendrimers, and compare them to commercially available PAMAM dendrimers of different generations to define structural parameters such as generation and core flexibility for the design of triazine dendrimers as nonviral gene delivery systems.

EXPERIMENTAL SECTION

Materials. Poly(ethylene imine) (Polymin, 25 kDa) was a gift from BASF (Ludwigshafen, Germany); PAMAM (ethylenediamine core, amino surface) second and third generations were bought from Sigma-Aldrich Laborchemikalien GmbH, Seelze, Germany, and SuperFect from Qiagen, Hilden, Germany. All chemicals used for synthesis were obtained from Sigma-Aldrich (St. Louis, MO).

Synthesis. The synthesis of all dendrimers used in this study proceeded via a divergent strategy originating from cyanuric chloride. The rigid, first-generation dendrimer was synthesized by reacting a tris(piperazyl) triazine core with **MCT1**, followed by deprotection. The rigid, second-generation dendrimer, **G2-1**, was synthesized as previously described (*11*). To form the third-generation rigid dendrimer, **G3-1**, the rigid, deprotected G1-dendrimer, **G1-C**, was reacted with di(Boc-piperazyl)monochlorotriazine. This second generation structure was deprotected and reacted with **MCT1** to form the protected third-generation compound, which was deprotected using HCl (Supporting Information). A detailed description of the synthesis is provided in the Supporting Information.

The flexible core dendrimer, **F2-1**, was synthesized by reacting cyanuric chloride with mono-Boc-protected *O*,*O*′-bis(3-aminopropyl)di(ethylene glycol). This core was deprotected with

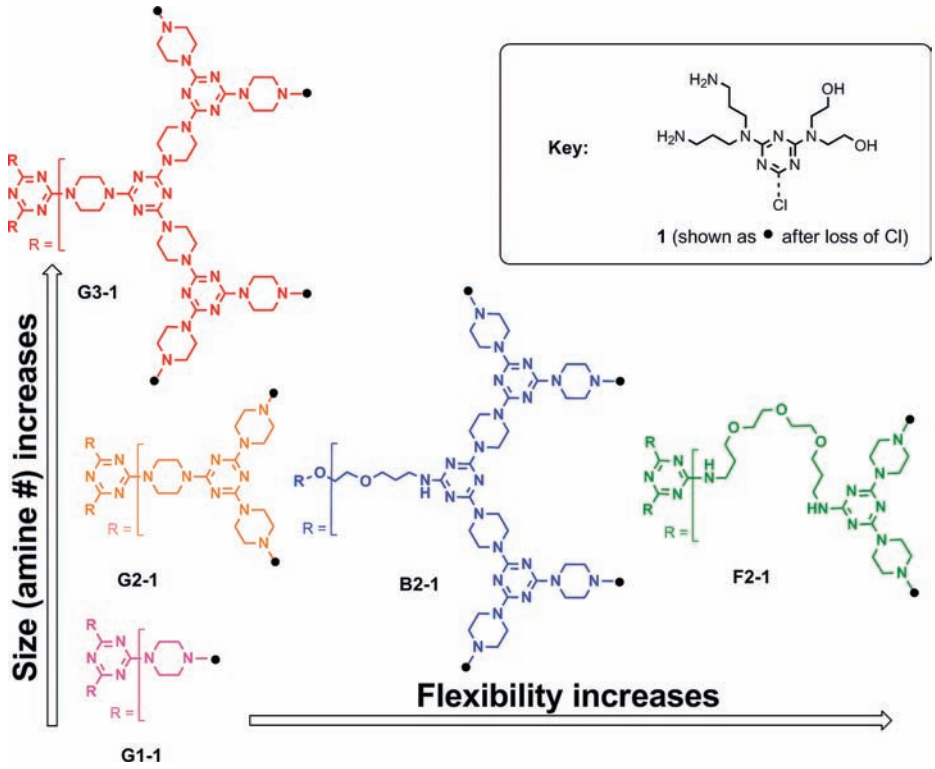

Figure 1. The dendrimer panel is given as chemical structures and sketches in a color code used throughout the study. Structure−activity relationships of the dendrimers in Table 1 were investigated in a two-dimensional approach: By variation of the generation (vertical arrows) and the core structure (horizontal arrows), influences of both parameters were investigated.

Table 1. Summary of Properties of the Screened Dendrimers Concerning *in Vitro* Parameters

	generation-1 rigid	generation-2 rigid	generation-3 rigid	generation-2 flexible	generation-2 bow tie
primary amines	6	12	24	12	16
amine density [Da/N atom]	211.27	245.30	262.20	262.32	262.20

HCl, reacted with Boc-piperazyl-dichlorotriazine, and capped with Boc-piperazine. After removal of the protecting groups with HCl, the compounds were reacted with **MCT1** and deprotected to form the flexible, second-generation dendrimer, **F2-1** (Supporting Information). A detailed description of the synthesis is provided in the Supporting Information.

Finally, the second-generation bow tie structure, **B2-1**, was synthesized by reacting di(Boc-piperazyl)monochlorotriazine with *O*,*O*′-bis(3-aminopropyl)di(ethylene glycol). This core structure was deprotected with HCl and reacted with di(Boc-piperazyl)monochlorotriazine to form a first-generation bow-tie structure. This structure was deprotected, reacted with **MCT1**, and deprotected again to afford the dendrimer **B2-1** (Supporting Information). A detailed description of the synthesis is provided in the Supporting Information.

Cell Culture. L929 murine fibroblasts and MeWo human melanoma cells were purchased from LG Promochem, Wesel, Germany, and maintained in DMEM low or high glucose (PAA Laboratories, Cölbe, Germany), respectively, and supplemented with 10% fetal calf serum (Cytogen, Sinn, Germany) in humidified atmosphere with 5% CO_2 at 37 °C.

Preparation of Dendriplexes. Dendriplexes were formed by adding 25 μL of a calculated concentration depending on "protonable unit" and N/P ratio) of dendrimer to an equal volume of the DNA solution (pCMV-Luc, Plasmid Factory, Bielefeld, Germany) and then mixing the two components before letting them mature for 20 min. The final concentration of pDNA in the dendriplex solution was 0.02 μg/μL. Both pDNA and dendrimers were diluted with 10 mM HEPES buffer, pH 7.4, and the appropriate amount of dendrimer was calculated by considering the desired N/P ratio and the "protonable unit" of each dendrimer, which represents the mass of dendrimer per protonable nitrogen atom. For comparison, standard transfection reagents, including poly(ethylene imine) (PEI 25 kDa), second- and third-generation PAMAM (ethylenediamine core, amino surface), and SuperFect (Qiagen, Hilden, Germany) were used. Polyplexes with PEI 25 kDa and dendriplexes with PAMAMs of second and third generation were formed as described above, whereas dendriplexes with SuperFect were prepared as recommended by the manufacturer.

Ethidium Bromide Quenching Assay. To quantify condensation efficiency of the dendrimers, an indirect dye-quenching assay was performed as previously reported (*15*). Briefly, 4 μg of herring testes DNA (Sigma-Aldrich Chemie GmbH, Schnelldorf, Germany) was complexed with increasing amounts of dendrimer in a final volume of 280 μL 10 mM HEPES buffer. After incubation for 20 min at room temperature, 20 μL of a 0.1 mg/mL ethidium bromide solution (Carl Roth GmbH, Karlsruhe, Germany) was added and incubated for 20 min in the dark following intensive mixing. Intercalation-caused fluorescence was quantified using a fluorescence plate reader (LS 50 B, Perkin-Elmer, Rodgau-Jügesheim, Germany) at 518 nm

excitation and 605 nm emission wavelengths. Results are given as relative fluorescence intensity values where intercalation of free DNA represents 100% fluorescence and non-intercalating ethidium bromide in buffer represents 0% remaining fluorescence. Results are given as means of triplicate measurements ± standard deviation (SD).

Dynamic Light Scattering and Zeta Potential Analysis. Polyplex size and zeta potential were determined as previously reported (*15*). Briefly, dendriplexes of 0.6 μg pCMV-Luc and the corresponding amount of dendrimer were prepared as described above. Complexes were incubated for 20 min and then diluted to a total volume of 800 μL with 10 mM HEPES buffer, pH 7.4, to be measured using a Zetasizer Nano ZS, Malvern, Herrenberg, Germany. Position and attenuator were optimized by the device. The accuracy of the size measurements was routinely checked using reference polymer particles (Nanosphere Size Standards; 50, 100, and 200 nm; Duke Scientific Corp., Palo Alto, CA, USA), and the zeta potential values were calibrated with the Zeta Potential Transfer Standard (Malvern Instruments, Herrenberg, Germany). The data was analyzed using a high-resolution mulitmodal algorithm. All measurements were conducted in triplicate. For better characterization of the size distributions, in addition to *Z* average, the PDI of the distribution is given as the mean value of three independent measurements ± SD.

Atomic Force Microscopy. The size and morphology of dried dendriplexes were analyzed by atomic force microscopy as previously described for polyplexes (*16*). Briefly, dendriplexes were prepared by mixing 1 μg pCMV-Luc and a dendrimer at an N/P ratio of 5 as described above, incubating for 20 min, and drying on silicon chips. Microscopy was performed on a NanoWizard (JPK instruments, Berlin, Germany). Commercial NSC16 AlBS-tips (Micromasch, Estonia) on an I-type cantilever with a length of 230 μm and a nominal force constant of 40 N/m were used. All measurements were performed in tapping mode to avoid damage to the sample surface. The scan frequency was 0.6 Hz and scan size was 5×5 μm^2. Multiple images were recorded, of which one representative topograph is presented.

Erythrocyte Aggregation and Hemolysis. Unspecific cell interaction was visualized by erythrocyte aggregation and quantified by the measurement of hemolysis according to previously described procedures (*17*). Briefly, human erythrocytes were isolated from fresh citrated blood from healthy volunteers by centrifugation, washed with PBS buffer, and diluted to 500 000 000 cells/mL. Dendriplexes of 0.1 μg pDNA per mL were prepared at N/P 5, and 50 μL aliquots of dendriplex solutions, 1% Triton-X 100 (100% lysis) or PBS (0% lysis) were mixed with 50 μL erythrocyte suspension. After incubation for 30 min at 37 °C, samples were centrifuged at 850 *g*. Hemolysis was measured by VIS-absorption of supernatants at 541 nm and the data are given as a mean percentage ($n = 3$) of the released hemoglobin ± SD, normalized to total hemolysis induced by 1% Triton-X 100. Pelleted erythrocytes were resuspended in 50 μL PBS and microscopically examined to determine erythrocyte aggregation.

Cell Viability. The cytotoxicity of the dendrimers was investigated using an MTT assay (*15*). Murine L929 fibroblasts were seeded on 96-well plates at a density of 8000 cells per well approximately 24 h before they were treated with dendrimer solutions of increasing concentrations in the range 0.001−1 mg/mL. Another 24 h later, the medium was changed. MTT solution was added into fresh serum-free medium and incubated for 4 h. The remaining mitochondrial enzyme activity as compared to untreated cells was determined by measuring the absorbance of enzymatically formed formazane at 580 nm with 690 nm background corrections after cell lysis in 200 μL DMSO. The results are given as mean values of a replicate of 4 ± SD.

Transfection Experiments. To compare transfection efficiency in different cell lines, murine 3T3 fibroblasts (L929) and human melanoma cells (MeWo) were seeded in 96 well plates at a seeding density of 8000 cells per well. Approximately 24 h later, the cells were transfected with dendriplexes consisting of 0.25 μg pCMV-Luc per well and the amount of dendrimer calculated to be N/P 2.5, 5, or 7.5. Branched PEI of 25 kDa, second- and third-generation PAMAM, and fourth-generation SuperFect were used as standards and free plasmid was used as a negative control.

Polyplexes were added to full serum-containing medium, and cells were incubated for 4 h before the medium was changed. Another 44 h later, the cells were washed with PBS, lysed with CCLR (Promega, Mannheim, Germany), and assayed for luciferase expression using a commercial luciferase assay kit (Promega, Mannheim, Germany) on a BMG LUMIstar OPTIMA luminometer plate reader (BMG Labtech, Offenburg, Germany). Transfection assays were performed in triplicate and the mean values ± SD are given.

RESULTS AND DISCUSSION

Nomenclature Adopted. Throughout the manuscript, the targets are named to reflect common and disparate features in structure with the core/generation-surface groups identified. The cores increase in flexibility from **G** (standard) to **B** (bow tie) to **F** (flexible), and the effect of size is determined over three (**1**, **2**, **3**) generations using the standard core structure. Each dendrimer contains a common surface group (**1**) that was previously reported to avoid obtaining variations in transfection efficiency that result from the peripheral functionalities (*11*).

Synthesis and Design Criteria. As the products of multistep organic syntheses, triazine dendrimers allow us access to well-defined structures to investigate structure−activity relationships such as the influence of size and backbone structure on transfection efficiency and cytotoxicity. For this purpose, a preliminary panel of dendrimers was synthesized consisting of different generations (**G1**, **G2**, **G3**) with a rigid backbone and a common surface group (**1**), yielding 6, 12, or 24 amino groups in the periphery. With each increase in generation number, the number of primary amino groups presented in the periphery doubles.

In addition to generation number, the flexibility of the core could hypothetically affect transfection efficiency by influencing the distribution and accessibility of the peripheral groups for interacting with p-DNA (*18*). The role of flexibility has been supported experimentally by Szoka who showed enhanced transfection efficiency resulting from fragmentation of PAMAM dendrimers (*6*). In this study, this effect was investigated with second-generation triazine dendrimers, each having differing core flexibilities (**G2-1**, **F2-1**, **B2-1**). Synthetic yields and NMR data are provided within the Supporting Information.

The composition of the panel is summarized in Figure 1 and Table 1. Branched poly(ethylene imine) of 25 kDa (PEI 25 kDa) was used as a control. The transfection efficiencies of the triazine dendriplexes were additionally compared to SuperFect, a commercially available fourth-generation fractured PAMAM dendrimer, and to second- and third-generation PAMAM as dendrimer standards.

Condensation Properties of Triazine Dendrimers. The formation of dendriplexes results from electrostatic interactions between polycationic dendrimers and negatively charged DNA. The quantification of condensation properties was performed using an ethidium bromide quenching assay (*15*), which reveals the fraction of uncomplexed DNA that is accessible for intercalation with ethidium bromide at a given N/P ratio.

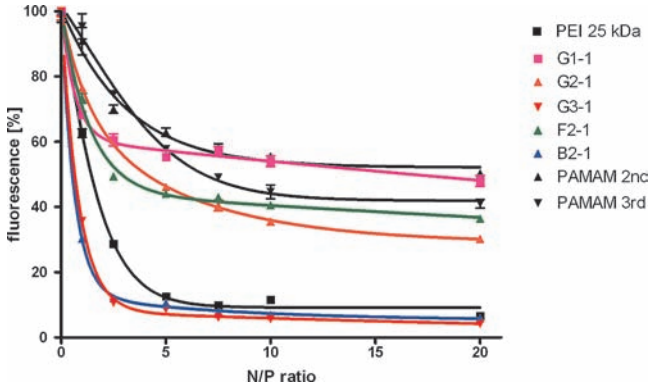

Figure 2. DNA condensation efficiency was quantified by ethidium bromide quenching assays and compared to PAMAMs of the same generations and PEI 25 kDa.

PAMAM dendrimers of generations 2 and 3 showed significant residual fluorescence leading to a plateau around N/P 7.5 (compare Figure 2). A similar trend was seen for several triazine dendrimers, including **G1-1**, **G2-1**, and **F2-1**. The third-generation triazine dendrimer, **G3-1**, yielded higher condensation than PEI, even at low N/P ratios. Interestingly, the bow tie dendrimer **B2-1** showed better DNA condensation than PEI, with a condensation profile comparable to that of the third-generation rigid dendrimer **G3-1**.

Similar to PAMAM, triazine dendrimers showed an increase in condensation efficiency with increasing generation. The first-generation dendrimer **G1-1** condensed DNA less effectively than the second-generation analogue, **G2-1**, which in turn was less efficient than the third-generation dendrimer, **G3-1**. However, the effect of the core structure on condensation efficiency seems minimal. This may result from the type of amines present in the triazine core. The reason that more flexible dendrimers are thought to complex with DNA more effectively than rigid analogues has been attributed to the increased capacity of flexible dendrimers to interact with DNA, as all amine groups, both inside the core and at the surface, contributed to the electrostatic interactions for binding (*19*). This increased availability of internalized amines in flexible structures results in the formation of more compact complexes (*7*, *20*, *21*). However, in the case of triazine dendrimers, the nitrogen atoms in the core are part of a delocalized electron system and hence not available for protonation under physiologic conditions (pH 7.4). Therefore, only the primary amino functional groups at the dendrimer periphery contribute to DNA condensation due to their accessibility to protonation (*22*). As the perhipheral groups are identical and the triazine core amines remain unprotonated at physiological pH, the trend of increased condensation efficiency for more flexible structures is not apparent; the semiflexible bow tie dendrimer **B2-1** more effectively condenses DNA than either the rigid **G2-1** or flexible **F2-1** analogues.

Dendriplex Sizes and Surface Charges. Polyplexes with diameters <200 nm in size are internalized by most cell lines (*23*), while larger particles can sediment more rapidly leading to enhanced transfection efficiency under *in vitro* conditions (*24*). A positive surface charge generally facilitates endocytosis, whereas negatively charged particles are often repelled by the negatively charged cell surface. Previous studies have shown that the complexation of DNA with PEI decreases polyplex sizes for increasing N/P ratios up to 20 (*25*). This trend could not be observed for the triazine dendrimers (data not shown). In the case of triazine dendriplexes, there seems to be an optimal N/P ratio at which minimal sizes can be achieved. When this N/P ratio is exceeded, larger dendriplexes (and possibly aggregates) form. By comparing rigid **G1-1**, **G2-1**, and **G3-1** dendrimers (Figure 3A), no clear trend between dendriplex sizes and the

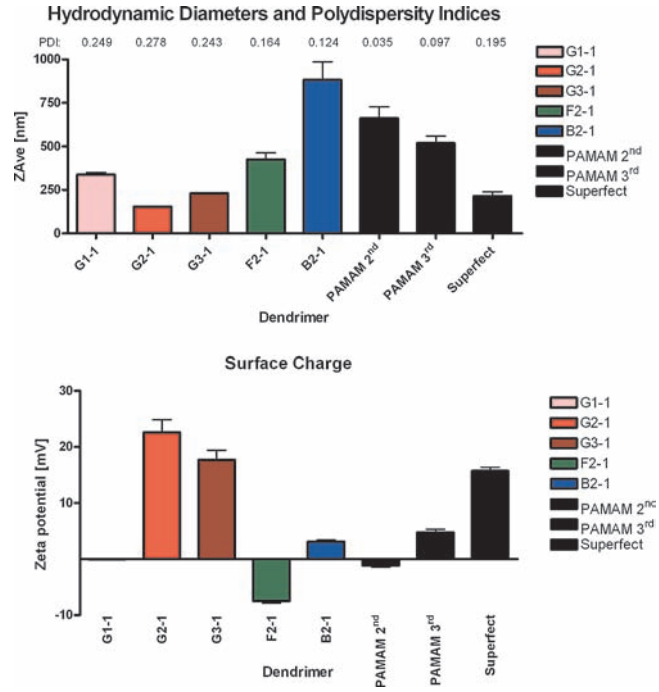

Figure 3. Hydrodynamic diameters and polydispersity indices (PDI) (A) and zeta potentials (B) of various dendriplexes at an N/P of 5 were determined in 10 mM HEPES buffer, pH 7.4.

generation number emerges. Generally, dendrimers with a higher number of primary amines on the periphery tend to form smaller polyplexes with DNA, as shown for PAMAM in this study. This behavior is not observed for the rigid triazine dendrimers, **G2-1**, **G2-1**, and **G3-1**. Our findings indicated that the rigid second-generation dendrimer, **G2-1**, forms the smallest complexes. This may be due to the "nitrogen density" (*26*) or "charge density" (*27*, *28*), a parameter that is known to influence the interaction of polycations with pDNA. This parameter is defined as the density of protonable amines in the polycation per molecular weight and can also be called the "protonable unit". The protonable unit can therefore be measured in g/mol N and helps to characterize polycations. The charge density of PEI, where every third atom is a nitrogen atom, is 43.1 g/mol N (*29*), which is a comparably high charge density considering that the charge density in our triazine dendrimers is about 200 g/mol N: **G1-1** has a density of primary amines of 211.27 Da/N atom, **G2-1** has a density of 245.3 Da/N atom, and **G3-1** has a density of 262.2 Da/N atom. Therefore, **G2-1** may form smaller complexes as compared to **G3-1** because of the difference in charge density. However, despite the lower charge density of **G2-1**, **G2-2** formed smaller complexes, which can be explained by the 2-fold increase in primary amines per molecule. The formation of large dendriplexes using the flexible dendrimer, **F2-1**, and the bow tie dendrimer, **B2-1**, may result partially from the low charge densities of these dendrimers (**F2-1**, 262.32 Da/N atom; **B2-1**, 262.2 Da/N atom). These values may be too low for the formation of very small complexes. Additionally, the sizes of dendriplexes formed with the flexible dendrimer, **F2-1,** were much larger than those of **G2-1**, suggesting that loose structures were obtained, in accordance with data from ethidium bromide quenching assay. The bow tie dendrimer **B2-1** formed the largest dendriplexes despite its DNA condensation efficiency, possibly caused by the formation of interdendriplex aggregates (*7*). The dendriplex size distributions were monomodal but showed polydispersity indices around 0.2 (Figure 3A) as reported previously for dendriplexes (*30*−*32*).

Zeta potentials of the PAMAM dendriplexes generally increased as particle size decreased. For example, the PAMAM

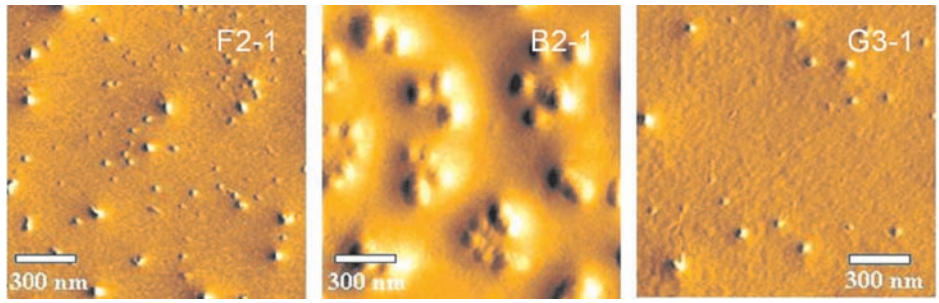

Figure 4. Morphology and density of dendriplexes were investigated by AFM revealing spherically shaped nanoplexes. Differing polyplex sizes as measured by dynamic light scattering are probably due to sample preparation (drying).

second generation dendrimer did not condense DNA efficiently, as illustrated by a negative zeta potential and large complexes sizes. As the number of primary amines on the periphery (generation) increases, the PAMAM dendrimers condensed DNA more efficiently (Figure 2) due to their very high number of primary amines (PAMAM G4 = SuperFect: 64 surface amines) and charge density (PAMAM G4: 222.10 Da/N atom). The rigid triazine dendrimers (**G1-1**, **G2-1**, and **G3-1**) did not show a clear generation-dependent trend for surface charge. **G1-1** exhibited a zeta potential of −0.0513 mV. The zeta potential of **G2-1** dendriplexes, which had proven to form the smallest particles among the rigid dendrimers, was observed to be strongly positive. By further increasing the generation of the rigid dendrimer, not only did sizes increase (Figure 3A), but the zeta potential decreased also (Figure 3B). Taken together, third-generation dendrimers condense and protect DNA (Figure 2) efficiently, but may result in larger aggregates in solution. It is possible that, due to their rather low charge density at the same N/P ratio and molecular composition, **G3-1** dendrimers do not shield the negative charge of DNA effectively, which results in lower electrostatic repulsion and stronger aggregation of dendriplexes. According to the data acquired in the ethidium bromide assay (Figure 2B), the flexible dendrimer **F2-1** only loosely bound DNA and was not able to fully protect the complex. Therefore, it seems reasonable to assume that the net negative charge measured for **F2-1** dendriplexes was caused by segments of free DNA which were not incorporated into any particle but were only bound to the surface of the flexible polycation. The dendriplexes formed with the bow tie dendrimer **B2-1** exhibited a low but positive surface charge, which can again be explained by interdendriplex interaction.

Atomic Force Microscopy. Although dynamic light scattering is an effective method for measuring particle size, the method is limited because it assumes spherically shaped particles. Therefore, atomic force microscopy (AFM) was used to characterize the morphology and heterogeneity of dendriplexes (*33*). The broad polydispersities observed with the dynamic light scattering experiments were also reflected in the AFM micrographs (Figure 4). The flexible core dendrimer, **F2-1**, produced two populations or particles: very small complexes (<50 nm) as well as larger ones (>100 nm). The bow tie dendrimer, **B2-1**, formed clusters of aggregates, which supports the assumption of interdendriplex interactions (*7*). The third-generation dendrimer **G3-1** showed the most uniform distribution.

Both the formation of clusters and the discrepancy between size measurement of dried particles and complexes in solution are not surprising: Similar observations have been made for PAMAM dendriplexes (*21*). The sizes measured for **F2-1** and **G3-1** dendriplexes by DLS are confirmed by AFM. In AFM, a distribution of 20−100 nm (**F2-1**) and narrow size distribution of particles of 100 nm (**G3-1**) could be observed. The larger sizes measured by DLS can be explained by the high number of short ethylene glycol chains that might be hydrated in solution but carry no weight after drying the sample for AFM. The picture of the **B2-1** dendriplex-clusters confirmed the DLS determined size of ∼900.

Erythrocyte Aggregation and Hemolysis. Red blood cells can be used to visualize and quantify the membrane interactions of dendriplexes by determining erythrocyte aggregation or hemolysis. Positive surface charges can lead to unspecific binding, membrane interactions, and the cytotoxicity associated with amino groups (*34*). The concentration-dependent hemolysis and perturbation of red blood cells after incubation with PAMAM, diaminobutane (DAB), diamonoethane (DAE), and poly(ethylene oxide) (PEO) grafted carbosilane (CSi-PEO) was reported previously (*35*). Generation-dependent hemolysis similar to PAMAM was seen with triazine dendrimers as well, though not as pronounced (Figure 5A). The hemolytic activity of triazine dendrimers seems to depend on their core structure, as hemolysis of the flexible dendrimer, **F2-1**, was markedly decreased compared to the rigid analogue, **G2-1**. However, dendriplexes formed from the bow tie dendrimer, **B2-1**, caused hemolytic effects comparable to **G3-1** dendriplexes. A possible explanation is the strong aggregation of **B2-1** dendriplexes, which could facilitate electrostatic interactions with cells. The extent of hemolytic activity of a dendriplex was clearly shown to be influenced by the zeta potential.

Cytotoxicity. Cell viability or cytotoxicity can routinely be measured by quantification of mitochondrial enzyme activity using an MTT assay. In order to mimic the "worst case scenario", murine fibroblasts (L929) were incubated with various concentrations of free dendrimer, ranging from 0.001 to 1 mg/mL (Figure 6). The half enzyme inhibitory concentrations (IC_{50}) were determined. While PEI 25 kDa exhibited the strongest toxic effects for the panel investigated, there was a clear trend between cytotoxicity and generation number for the rigid triazine dendrimers. For **G1-1**, we determined an IC_{50} value of 501.2 μg/mL, which is about 100-fold higher than the IC_{50} value of PEI 25 kDa (4.9 μg/mL; compare Figure 6). The IC_{50} values decreased with increased generation among the rigid dendrimers, which can be explained by the increasing number of peripheral primary amino groups. Nontheless, **G3-1**, the dendrimer that contains the highest number of primary amines per molecule, was approximately 5-fold less toxic than PEI 25 kDa and showed a 2.5-fold lower IC_{50} value than the third-generation PAMAM (*35*). The **F2-1** dendrimer showed a higher toxicity profile than **G2-1**, which can be explained as resulting from an increased accessibility of both the core and the terminal amine groups, although the hemolytic activity we measured for **F2-1**/DNA complexes was comparably low. The effect on remaining cell viability, on the other hand, which is expressed in the IC_{50} values, can have various causes. Highly surface active substances are expected to strongly impede the phospholipids double layer, leading to decreased cell viability and cell death. However, substances that do not exhibit strong membrane toxicity can still alter cellular mechanisms, leading to decreased

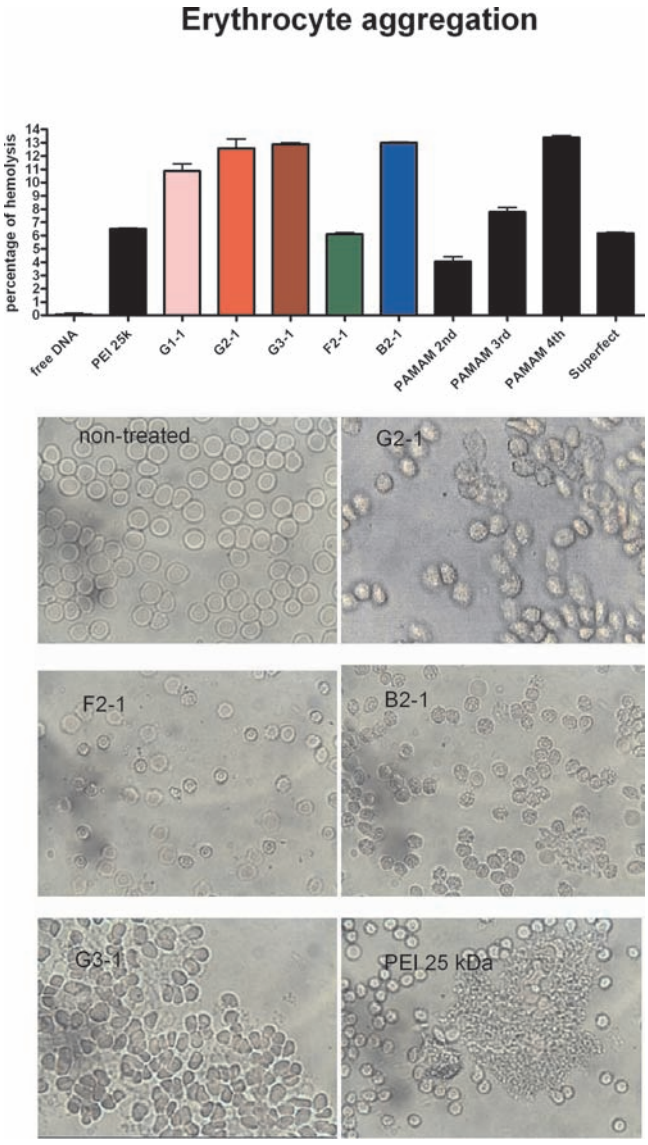

Figure 5. (A) Hemolysis after incubation with dendriplexes at an N/P of 5 was UV-metrically quantified and (B) morphologic changes of erythrocytes were microscopically captured. Hemolysis depended strongly on the core structure, whereas erythrocyte aggregation increased by generation.

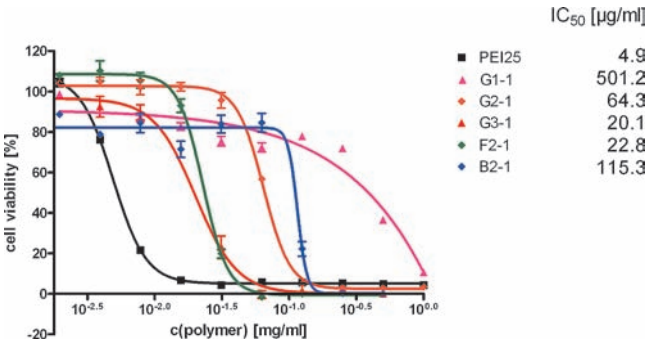

Figure 6. Toxicity profiles of all the dendrimers according to the MTT assays were compared to that of PEI 25 kDa, and for clarity, IC_{50} values are given.

cell viability. It is therefore not surprising that **F2-1**, which shows comparably low hemolysis, is more toxic than **G2-1** and **B2-1**, which have higher hemolytic potentials.

The bow tie dendrimer **B2-1**, on the other hand, exhibited lower toxicity than the rigid dendrimer **G2-1**, despite causing

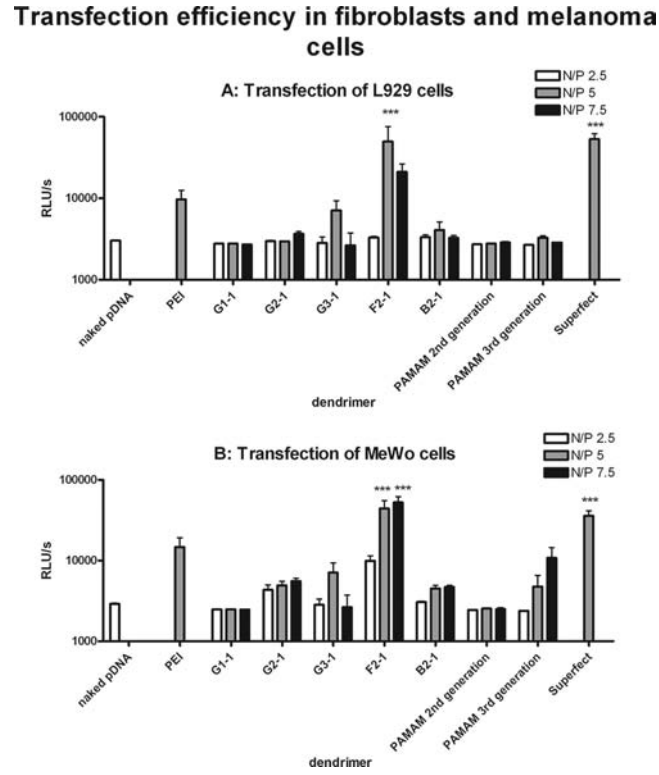

Figure 7. Transfection efficiency of the dendrimers at various N/P ratios in (A) L929 and (B) MeWo cells are given as relative light units detected by luciferase assay. **F2-1** and Superfect exhibited significantly (***$p < 0.01$) higher transgene expression than PEI 25 kDa and all other dendrimers.

comparable hemolytic effects. For all of the triazine dendrimers, our cytotoxicity results are in line with an earlier report (*13*) revealing an IC_{50} value of 0.1 mg/mL for a related melamine structure. Triazine dendrimers seem to be less toxic than PEI and therefore more suitable for possible *in vivo* studies. Moreover, cytotoxicity strongly depends on the core structure and can be significantly reduced by dendriplex formation.

Transfection Efficiency. The primary interest for nonviral vectors is the efficiency of transfection. This property was studied using a luciferase-expressing plasmid in two different cell lines, namely, murine L929 fibroblasts (Figure 7A) and human MeWo (Figure 7B) melanoma cells. The transfection efficiency of dendriplexes at different N/P ratios was quantified using a commercial luciferase assay and was compared to the transfection efficiencies of PEI 25 kDa, SuperFect, and second- and third-generation PAMAM.

PAMAM (second and third generation) dendrimers showed little transfection efficiency with increasing N/P ratios, as reported in the literature (*5*). An increase in transfection efficiency with increasing generation was revealed for rigid triazine dendrimers (**G1-1**, **G2-1**, and **G3-1**). The lowest-generation dendrimer, **G1-1**, did not induce transgene expression in L929 or MeWo cells, while **G2-1** successfully transfected MeWo and L929 at N/P ratio of >7.5. Interestingly, **G3-1** yielded a maximum luciferase expression at N/P 5 in both cell lines. The reduced transfection efficiency at a higher N/P ratio for the higher-generation dendrimer may be caused by cytotoxic effects. In both cell lines, **F2-1** achieved the highest transgene expression, even higher than the expression of PEI 25 or SuperFect. The bow tie dendrimer, **B2-1**, exhibited moderate transfection efficiency at N/P ratio of 5 in L929 and at N/P 5 and 7.5 in MeWo cells.

These results demonstrate that triazine dendrimers could provide a promising platform for gene delivery systems as they induce transfection at generation two, while established transfection reagents such as PAMAM are ineffective at that size. Similarly, the phosphorus-containing dendrimers of Majoral show a transfection optimum at generation 5 (*36*). Higher-generation, flexible triazine dendrimers are therefore under investigation with the goal of providing more efficient transfection reagents.

Because the flexible dendrimer, **F2-1**, formed larger complexes than the third-generation dendrimer, **G3-1**, it presumably sedimented more rapidly (*24*). This could have contributed to the higher transfection efficiency seen for this dendriplex. However, this route of endocytosis may not prove viable for *in vivo* applications, but also, a higher availability to RNA polymerase inside the nucleus of DNA in these less compact dendriplexes, as reported by Yamagata et al. (*37*), might be an explanation. Hence, the colloidal stability and the systematic variation of the triazine dendrimer surface are further goals for synthetic modifications.

CONCLUSION

Efforts to optimize the triazine dendrimers will require consideration of a number of lessons learned from these studies. The first-generation rigid dendrimer, **G1-1**, yielded very low condensation efficiency, and although the structure had a good biocompatibility profile, it did not show any transfection efficiency. The second-generation rigid dendrimer **G2-1** showed improved DNA condensation, formed small dendriplexes, and was less toxic but more hemolytic than PEI. However, it showed intermediate transfection efficiency. The **G3-1** dendrimer condensed DNA well, formed small particles within a narrow size distribution, but exhibited erythrocyte aggregation. Transfection efficiency of this dendrimer was possibly limited by toxic effects at higher N/P ratios.

The change in core structure had the most profound impact on physicochemical as well as biologic properties of the triazine dendrimers. While the rigid, second-generation dendrimer, **G2-1**, formed comparably small dendriplexes, both **B2-1** and **F2-1** assembled DNA into larger complexes with lower or even negative surface charge. DNA condensation was affected differently: DNA condensation with **F2-1** and **G2-1** was similar, whereas **B2-1** protected DNA even better than PEI 25 kDa. The flexible dendrimer **F2-1** was most effective in transfection experiments. The low-density particles exhibited the lowest hemolytic effect and almost no erythrocyte aggregation.

The bow tie dendrimer, **B2-1**, caused the most pronounced hemolytic effects, which are attributed to the formation of aggregates and clusters as observed with DLS and AFM. Due to their large size, **B2-1** dendriplexes were not effectively taken up by L929 or MeWo cells, leading to low transfection efficiency. We remain optimistic that triazine dendrimers demonstrate a promising platform for nonviral delivery systems, meriting further investigations, while our most important result is that flexible triazine dendrimers that are biocompatible may be highly efficient vectors for nonviral gene delivery at comparably low generations. This is especially true for the flexible dendrimer **F2-1**, which exhibits higher transfection efficacy than SuperFect.

ACKNOWLEDGMENT

We thank Eva Mohr and Sandra Engel (DPB, Marburg, Germany) for their support in the cell culture lab and Michael Dutescu (Dept. of Clinical Chemistry, Marburg, Germany) for providing us with fresh blood samples. E.E.S. acknowledges support of the NIH (NIGMS R01 45640).

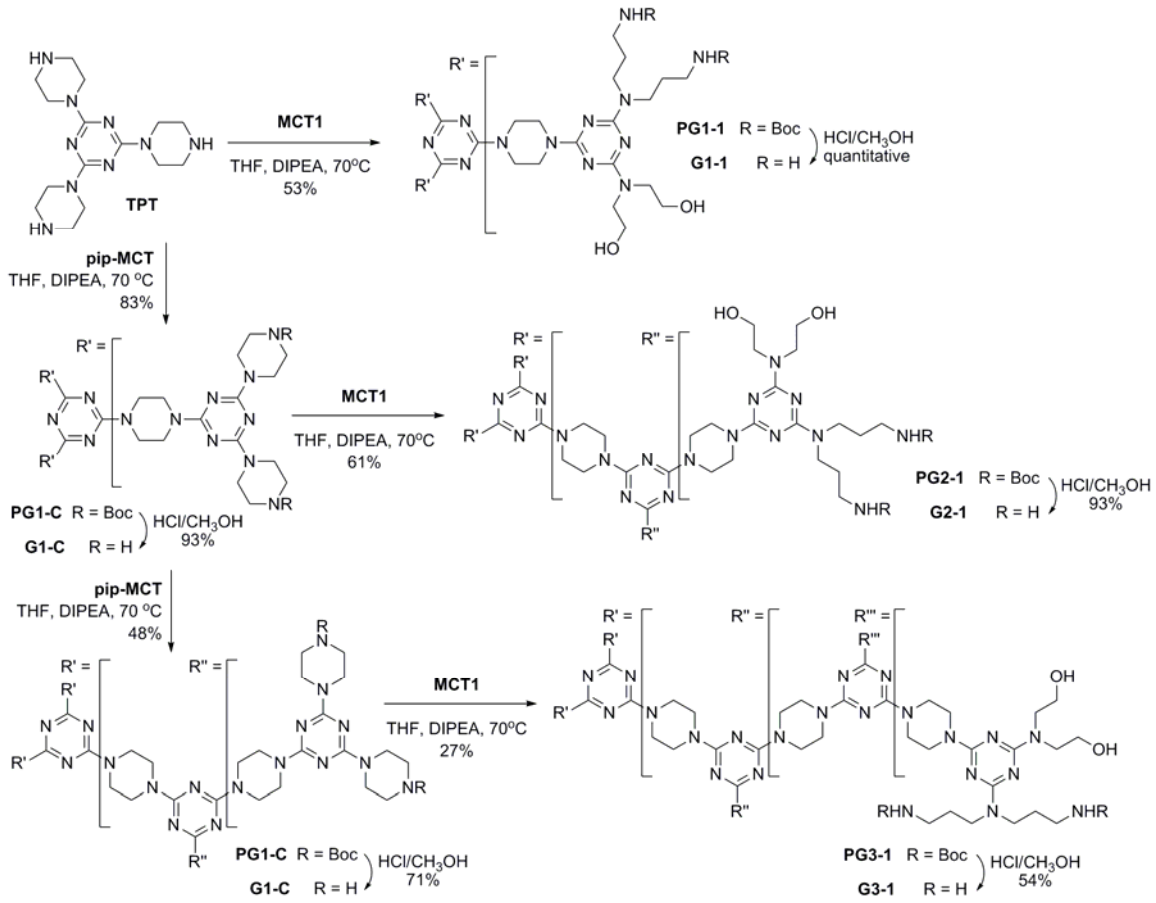
Supplementary Material:

Synthesis of Triazine Dendrimers:

Monochlorotriazine 1 (MCT1). Cyanuric chloride (0.9220g, 5.000 mmol) and Boc-protected 3,3'-bisaminopropylamine (1.6575g, 5.00 mmol) were each dissolved in 60 mL tetrahydrofuran and cooled to 0 °C. The Boc-protected triamine was added dropwise to cyanuric chloride followed by the addition of DIPEA (1.75 mL, 10.046 mmol). After 3 hours, diethanolamine (0.5276g, 5.018 mmol) and DIPEA (1.75 mL, 10.046 mmol) were dissolved in 60 mL tetrahydrofuran, cooled to 0 °C, and added dropwise to the reaction mixture. The mixture was allowed to warm to room temperature. After 20 hours the solvent was evaporated under reduced pressure. The crude product was dissolved in dichloromethane and the salt byproducts were extracted with distilled water. The organic layer was condensed and the product purified by column chromatography (10:1 CH_2Cl_2:ethyl acetate) to yield MCT1 (2.4937g, 91%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.76 (b, 1H, O**H**) 5.36 (t, 2H, N**H**Boc), 3.77 (d, 4H, C**H**$_2$OH), 3.67 (d, 4H, NC**H**$_2$CH$_2$OH), 3.51-3.43 (br, 4H, NC**H**$_2$CH$_2$CH$_2$), 3.01 (m, 4H, C**H**$_2$NHBoc), 1.79-1.67 (m, 4H, CH$_2$C**H**$_2$CH$_2$), 1.37 (s, 18H, C(C**H**$_3$)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 168.4 (C_3N_3), 165.0 (C_3N_3), 164.1 (C_3N_3), 156.3 (CO), 79.3 (O**C**(CH$_3$)$_3$), 61.7 (**C**H$_2$OH), 51.7 (NC**H**$_2$CH$_2$OH), 44.6 (NC**H**$_2$CH$_2$CH$_2$), 38.0 (**C**H$_2$NHBoc), 28.2 (C(**C**H$_3$)$_3$), 27.7 (CH$_2$**C**H$_2$CH$_2$). MS (ESI): calcd 547.29 (M^+); found 548.30 ($M + H^+$).



Scheme S1: Synthesis of rigid generation 1-3 dendrimers (G1-1, G2-1, G3-1)

Protected G1-1 Dendrimer (P-G1-1). Tris(piperazyl)triazine (TPT) (0.1837g, 0.551 mmol) and MCT1 (0.9071g, 1.655 mmol) were dissolved separately in 10 mL dichloromethane. The monochlorotriazines solution was added to the solution containing TPT followed by the addition of DIPEA (0.6mL, 3 mmol), and the mixture was heated to reflux. After two days reaction mixture was washed three times with H_2O, condensed under reduced pressure, and purified by column chromatography (1:1 CH_2Cl_2:ethyl acetate with 4% CH_3OH → 1:1 CH_2Cl_2:ethyl acetate with 20% CH_3OH) to afford G1-1

in 53% yield. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.68 (s, 3H, O**H**) 5.10 (s, 6H, N**H**Boc), 3.85 (br, 12H, C**H**$_2$OH), 3.80 (br, 24H, piperazine), 3.75 (br, 12H, NC**H**$_2$CH$_2$OH), 3.59-3.48 (br, 12H, NC**H**$_2$CH$_2$CH$_2$), 3.08-3.15 (br, 12H, C**H**$_2$NHBoc), 1.73 (br, 12H, CH$_2$C**H**$_2$CH$_2$), 1.42 (s, 54H, C(C**H**$_3$)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 167.2 (C_3N_3), 164.6 (C_3N_3), 164.6 (C_3N_3), 156.1 (CO), 79.3 (O**C**(CH$_3$)$_3$), 63.0 (**C**H$_2$OH), 51.3 (NC**H**$_2$CH$_2$OH), 44.1 (NC**H**$_2$CH$_2$CH$_2$), 43.5 (piperazine), 38.1 (**C**H$_2$NHBoc), 28.6 (C(**C**H$_3$)$_3$), 27.8 (CH$_2$**C**H$_2$CH$_2$). MS (MALDI): calcd 1867.17 (M^+); found 1869.07 (M + H^+).

G1-1. P-G1-1 (0.3326g, 0.178 mmol) was dissolved in 3 M HCl:CH_3OH. After 2 days, the reaction was condensed and neutralized with $NaCO_3$ to pH=7. NaCl byproduct was removed from the mixture using an Amicon apparatus and a millipore membrane with NMWL = 1,000 under 35 psi N_2. The water that was pushed through the membrane was tested for Cl^- using $AgNO_3$. When no AgCl precipitate formed from the filtrate, the solution remaining inside the Amicon vessel was condensed *in vacuo* to afford G1-1 (0.5276 g, 129%). MS (MALDI): calcd 1267.59 (M^+); found 1267.91 (M + H^+).

Protected G2-1 (P-G2-1). MCT1 (0.5686g, 1.037 mmol) and G1-C (0.1826g, 0.1698 mmol) were each dissolved in 10mL of 9:1 CH_2Cl_2:CH_3OH. The solutions were mixed at room temperature followed by the addition of DIPEA (0.5mL, 2.8704 mmol). The reaction mixture was heated to 70 °C. After 10 days the reaction mixture was condensed, re-dissolved in dichloromethane, and washed with distilled water. The organic layer was condensed and purified by column chromatography (4:1 CH_2Cl_2:ethyl acetate with 1 → 3% CH_3OH) to yield P-G2-1 (0.4267g, 61%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.64 (s,

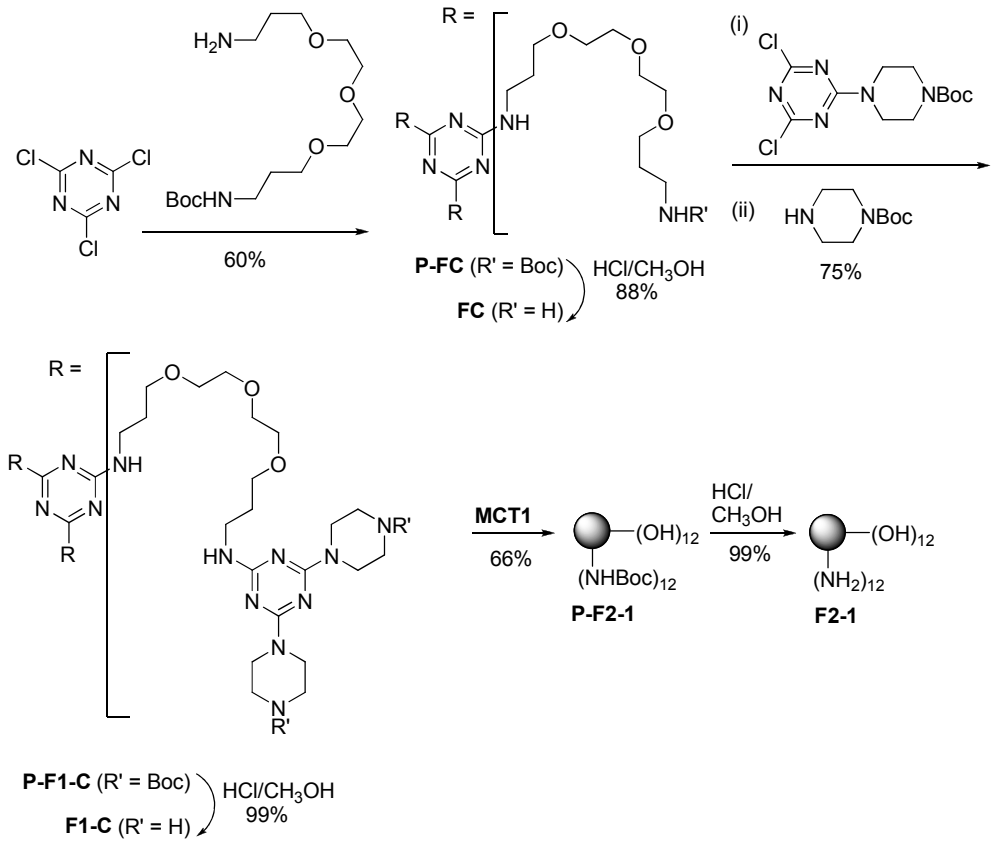
12H, O**H**) 5.09 (s, 12H, N**H**Boc), 3.87 (br, 24H, C**H**$_2$OH), 3.81 (br, 72H, piperazine), 3.77 (br, 24H, NC**H**$_2$CH$_2$OH), 3.61 (br, 24H, NC**H**$_2$CH$_2$CH$_2$), 3.11 (br, 24H, C**H**$_2$NHBoc), 1.67 (br, 24H, CH$_2$C**H**$_2$CH$_2$), 1.44 (s, 108H, C(C**H**$_3$)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 165.6 (C_3N_3), 165.5 (C_3N_3), 156.2 (CO), 79.2 (O**C**(CH$_3$)$_3$), 62.0 (**C**H$_2$OH), 51.3 (NC**H**$_2$CH$_2$OH), 44.2 (NC**H**$_2$CH$_2$CH$_2$), 43.6 (piperazine), 38.2 (**C**H$_2$NHBoc), 28.7 (C(**C**H$_3$)$_3$), 27.9 (CH$_2$**C**H$_2$CH$_2$). MS (MALDI): calcd 4142.57 (M^+); found 4142.71 ($M + H^+$).

G2-1. P-G2-1 was dissolved in 3 M HCl:CH_3OH. After 2 days the reaction was condensed and neutralized with $NaCO_3$ to pH=7. NaCl byproduct was removed from the mixture using an Amicon apparatus and a millipore membrane with NMWL = 1,000 under 35 psi N_2. The water that was pushed through the membrane was tested for Cl^- using $AgNO_3$. When no AgCl precipitate formed from the filtrate, the solution remaining inside the Amicon vessel was condensed *in vacuo* to afford G2-1 (0.2463g, 93%). MS (MALDI): calcd 2941.94 (M^+); found 4142.90 ($M + H^+$). HPLC (2:1 H_2O with 0.14% TFA:acetonitrile): 3.196 min.

Protected G3-1 (P-G3-1). G2-C (0.0408g, 0.016 mmol) and MCT1 (0.1053g, 0.192 mmol) were each dissolved in 1 mL of 9:1 $CHCl_3$:CH_3OH. The monochlorotriazine solution was added to the G2-C solution at room temperature. The reaction was heated to 70 ºC. After 6 days the reaction mixture was condensed, dissolved in chloroform and washed with distilled water. The organic layer was condensed and purified by column chromatography (10:1 CH_2Cl_2:EtOAc → 1:1 CH_2Cl_2:EtOAc) to yield P-G3-1 (0.0374g, 27%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.01-5.69 (s, 24H, N**H**), 3.82 (br, 192H, C**H**$_2$OH,

piperazine), 3.75 (br, 48H, NC**H**$_2$CH$_2$OH), 3.47-3.57 (br, 48H, NC**H**$_2$CH$_2$CH$_2$), 3.09 (br, 48H, C**H**$_2$NHBoc), 1.71 (br, 48H, CH$_2$C**H**$_2$CH$_2$), 1.43 (s, 216H, C(C**H**$_3$)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 167.0 (**C**$_3$N$_3$), 165.7 (**C**$_3$N$_3$), 164.6 (**C**$_3$N$_3$), 164.4 (**C**$_3$N$_3$), 156.2 (**C**O), 79.3 (**C**(CH$_3$)$_3$), 63.0 (**C**H$_2$OH), 51.4 (N**C**H$_2$CH$_2$OH), 46.0 (N**C**H$_2$CH$_2$CH$_2$NHBoc), 43.0 - 43.3 (N**C**H$_2$**C**H$_2$N), 38.2 (**C**H$_2$NHBoc), 28.7 (C(CH$_3$)$_3$), 27.9 (NCH$_2$**C**H$_2$CH$_2$NHBoc). MS (MALDI): calcd 8693.4 (M^+); found 8700.1 (M + H^+).

G3-1. P-G3-1 (0.0330g, 0.004 mmol) was dissolved in 3 mL CH_3OH. Concentrated HCl (2 mL) was added to the solution. After 24 hours the reaction was condensed and neutralized using NaOH. NaCl byproduct was removed from the solution using an Amicon apparatus and a millipore membrane with NMWL = 3,000 under 25 psi N_2. The filtrate was tested for Cl^- using $AgNO_3$. When no AgCl precipitate formed the solution remaining inside the Amicon vessel was condensed *in vacuo* to afford G3-1 (0.0129g, 54%).



Scheme S2: Synthesis of second generation flexible dendrimer (F2-1)

Protected Flexible Core (P-FC). Cyanuric chloride (0.1596g, 0.866 mmol) and N-Boc-4,7,10-trioxa-1,13-tridecanediamine (0.9512g, 2.769 mmol) were each dissolved in 15 mL THF. The N-Boc-diamine solution was added to the cyanuric chloride solution and the mixture was heated to 70 ºC. After 4 days the reaction mixture was condensed, dissolved in dichloromethane, and washed three times with distilled water. The organic layer was collected, condensed, and purified by column chromatography (30:1 CH_2Cl_2:CH_3OH → 10:1 CH_2Cl_2:CH_3OH) to yield P-FC (0.5338g, 60%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.09 (s, 4H, NH), 3.45-3.62 (m, 36H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**), 3.41 (q, 6H, NHC**H$_2$**), 3.20 (q, 6H, C**H$_2$**NHBoc),1.81 (m, 6H, NHCH$_2$C**H$_2$**), 1.73 (m, 6H, C**H$_2$**CH$_2$NHBoc), 1.41 (s, 27H, C(C**H$_3$**)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 165.9

(**C**$_3$N$_3$), 156.2 (**C**O), 79.0 (**C**(CH$_3$)$_3$), 70.7-70.8 (**C**H$_2$O**C**H$_2$), 70.4-70.5 (**C**H$_2$CH$_2$OCH$_2$**C**H$_2$), 69.6-69.7 (NHCH$_2$CH$_2$**C**H$_2$O), 39.1 (NH**C**H$_2$), 38.7 (**C**H$_2$NHBoc), 29.8 (**C**H$_2$CH$_2$NHBoc), 29.0 (NH**C**H$_2$**C**H$_2$). (N**C**H$_2$**C**H$_2$NBoc), 28.6 (C(**C**H$_3$)$_3$). MS (MALDI): calcd 1035.7 (M^+); found 1036.7 ($M + H^+$).

Flexible Core (FC). P-FC (0.5332g, 0.5166 mmol) was dissolved in 7.5 mL CH$_3$OH. Concentrated HCl (2.5 mL was added to the solution. After 24 hours, the reaction mixture was condensed, and 5 M NaOH was added to obtain a basic solution (pH=14). The product was extracted from the aqueous solution with dichloromethane. The organic fractions were condensed to yield FC (0.3331g, 88%). ^{1}H NMR (300 MHz, CDCl$_3$) δ: 5.15 (s, 3H, NH), 3.52-3.62 (m, 36H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**), 3.41 (q, 6H, NHC**H$_2$**), 2.76 (q, 6H, C**H$_2$**NHBoc),1.79 (m, 6H, NHCH$_2$C**H$_2$**), 1.69 (m, 6H, C**H$_2$**CH$_2$NHBoc), 1.58 (s, 6H, NH$_2$). ^{13}C NMR (300 MHz, CDCl$_3$) δ: 166.3 (**C**$_3$N$_3$), 70.7-70.8 (**C**H$_2$O**C**H$_2$), 70.3-70.4 (**C**H$_2$CH$_2$OCH$_2$**C**H$_2$), 69.5-69.6 (NHCH$_2$CH$_2$**C**H$_2$O), 39.8 (**C**H$_2$NH$_2$), 38.3 (**C**H$_2$NH), 33.5 (CH$_2$CH$_2$NH$_2$), 29.8 (**C**H$_2$CH$_2$NH). MS (MALDI): calcd 735.5 (M^+); found 736.8 ($M + H^+$).

Protected, Flexible G1 Core (P-F1-C). FC (0.3069g, 0.417mmol) and Boc-piperazyldichlorotriazine were each dissolved in 10 mL THF and cooled to 0 ºC. The dichlorotriazine solution was added dropwise to the FC solution followed by the addition of DIPEA (0.7 mL, 4.019 mmol). The mixture was allowed to warm to room temperature, and 1M K$_2$CO$_3$ was added to the solution. After 16 hours, Boc-piperazine was added to reaction, and the solution was heated to 70 ºC. After 24 hours the reaction

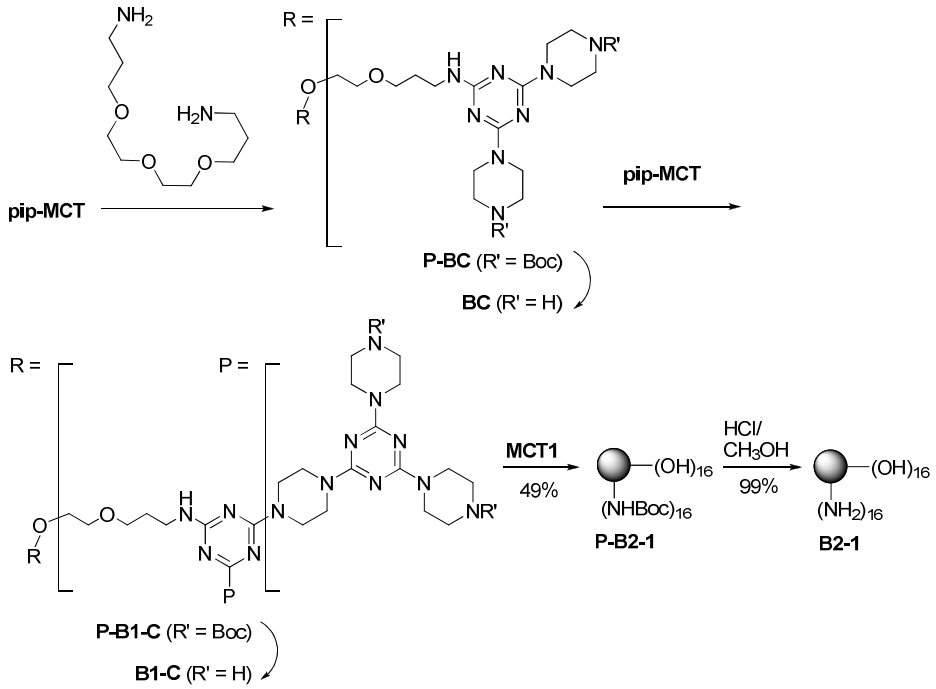
was condensed, dissolved in dichloromethane, and washed three times with distilled water. The organic layer was purified by column chromatography (30:1 CH_2Cl_2:CH_3OH → 15:1 CH_2Cl_2:CH_3OH) to yield P-F1-C (0.6529g, 75%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.23 (s, 6H, NH), 3.71 (s, 24H, NC**H$_2$**CH_2NBoc), 3.53-3.63 (m, 36H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**), 3.42 (br, 36H, NHC**H$_2$**, CH_2C**H$_2$**NBoc), 1.82 (m, 12H, C**H$_2$**NH), 1.46 (s, 54H, C(C**H$_3$**)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 166.5 (**C**$_3$N$_3$), 165.4 (**C**$_3$N$_3$), 155.0 (**C**O), 80.1(**C**$(CH_3)_3$), 70.78 (**C**H_2O**C**H_2), 70.4 (**C**$H_2CH_2OCH_2$**C**H_2), 69.5 ($NHCH_2CH_2$**C**H_2O), 43.1 (piperazine), 38.3 (**C**H_2NH), 29.8 (**C**H_2CH_2NH), 28.6 (C(**C**$H_3)_3$). MS (MALDI): calcd 2077.3 (M^+); found 2078.6 ($M + H^+$).

Flexible G1 Core (F1-C). P-F1-C (0.6295g, 0.303 mmol) was dissolved in 7.5 mL CH_3OH. Concentrated HCl (2.5 mL) was added to the solution. After 24 hours, the reaction mixture was condensed and the solution was made basic by adding 5 M NaOH. The product was extracted with dichloromethane to yield F1-C (0.4438g, 99%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.23-5.33 (s, 6H, NH), 3.69 (s, 24H, NC**H$_2$**CH_2NBoc), 3.53-3.63 (m, 36H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**), 3.41 (br, 12H, NHC**H$_2$**, CH_2C**H$_2$**NBoc), 2.83 (s, 24H, NCH_2C**H$_2$**NH), 1.80 (m, 12H, C**H$_2$**NH). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 166.5 (**C**$_3$N$_3$), 165.3 (**C**$_3$N$_3$), 70.73 (**C**H_2O**C**H_2), 70.4 (**C**$H_2CH_2OCH_2$**C**H_2), 69.4-69.5 ($NHCH_2CH_2$**C**H_2O), 46.1 ((CH_2**C**$H_2)_2NH$), 44.3 ((**C**$H_2CH_2)_2NH$), 38.3 (**C**H_2NH), 29.8 (CH_2**C**H_2CH_2NH). MS (MALDI): calcd 1477.0 (M^+); found 1478.2 ($M + H^+$).

Protected F2-1 (P-F2-1). MCT1 (0.2804g, 0.512 mmol) and P-F1-C (0.1006g, 0.068 mmol) were each dissolved in 5mL dichloromethane. The MCT1 solution was added to

the solution containing F1-C followed by the addition of DIPEA (0.2 mL, 1.148 mmol). The mixture was heated to 70 ºC. After two days the reaction mixture was washed three times with distilled water. The organic layer was condensed and purified by column chromatography (30:1 CH_2Cl_2:CH_3OH → 4:1 CH_2Cl_2:CH_3OH) to yield P-F2-1 (0.2058g, 66%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.68 (s, 6H, NH), 5.23 (s, 12H, NH), 3.84 (br, 24H, C**H$_2$**OH), 3.75 (s, 72H, NC**H$_2$**CH_2OH, piperazine), 3.59 (br, 60H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**, NC**H$_2$**CH_2CH_2NHBoc), 3.45 (br, 48H, piperazine), 3.08-3.14 (br, 24H, NCH_2CH_2C**H$_2$**NHBoc), 1.80 (m, 12H, C**H$_2$**NH), 1.72 (br, 24H, NCH_2C**H$_2$**CH_2NHBoc), 1.42 (s, 108H, C(C**H$_3$**)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 167.1 (**C**$_3N_3$), 166.5 (**C**$_3N_3$), 165.3 (**C**$_3N_3$), , 164.6 (**C**$_3N_3$), 164.4 (**C**$_3N_3$), 156.5 (**C**O), 79.2 (**C**$(CH_3)_3$), 70.8 (**C**H_2O**C**H_2), 70.4 (**C**$H_2CH_2OCH_2$**C**H_2), 69.4 ($NHCH_2CH_2$**C**H_2O), 62.4 (**C**H_2OH), 51.3 (N**C**H_2CH_2OH), 43.5 (N**C**$H_2CH_2CH_2$NHBoc), 43.0 (piperazine), 38.3 (**C**H_2NH), 37.5 (**C**H_2NHBoc), 29.8 (**C**H_2CH_2NH), 28.7 (C(**C**$H_3)_3$), 27.9 (NCH_2**C**H_2CH_2NHBoc). MS (MALDI): calcd 4544.9 (M^+); found 4546.5 ($M + H^+$).

F2-1. P-F2-1 (0.2056g, 0.045 mmol) was dissolved in 7.5 mL methanol. Concentrated HCl (2.5 mL) was added to the solution. After 24 hours the reaction was condensed and neutralized with NaOH. NaCl byproduct was removed from the solution using an Amicon apparatus and a millipore membrane with NMWL = 1,000 under 35 psi N_2. The filtrate was tested for Cl^- using $AgNO_3$. When no AgCl precipitate formed the solution remaining inside the Amicon vessel was condensed *in vacuo* to afford F2-1 (0.1506g, 99%).



Scheme S3: Synthesis of second generation bow-tie dendrimer (B2-1)

Protected Bow-tie core (P-BC). Pip-MCT (0.9713g, 2.007 mmol) and 4,7,10-trioxa-1,13-tridecanediamine (0.2009g, 0.912 mmol) were each dissolved in 7.5 mL THF. The monochlorotriazine solution was added to the diamine solution, and the mixture was heated to 70 ºC. After 24 hours the reaction mixture was condensed and purified by column chromatography (10:1 CH_2Cl_2:EtOAc → 1:1 CH_2Cl_2:EtOAC) to yield P-BC (0.5802g, 91%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.09 (t, 2H, NH), 3.71 (s, 16H, NC**H$_2$**CH_2NBoc), 3.53-3.66 (m, 12H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**), 3.43 (br, 20H, NHC**H$_2$**, CH_2C**H$_2$**NBoc), 1.82 (m, 4H, C**H$_2$**CH_2NH), 1.46 (s, 36H, C(C**H$_3$**)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 166.5 (**C**$_3$N$_3$), 165.4 (**C**$_3$N$_3$), 155.0 (**C**O), 80.1(**C**$(CH_3)_3$), 70.8 (**C**H_2O**C**H_2), 70.4 (**C**$H_2CH_2OCH_2$**C**H_2), 69.6 (NHCH_2CH_2**C**H_2O), 43.1 (piperazine), 38.5

(**C**H_2NH), 29.8 (**C**H_2CH_2NH), 28.6 (C(**C**H_3)$_3$). MS (MALDI): calcd 1114.7 (M^+); found 1115.6 ($M + H^+$).

Bow-tie Core (BC). P-BC (0.2384g, 0.214 mmol) was dissolved in 7.5 mL methanol. Concentrated HCl (2.5 mL) was added to the solution. After 24 hours the reaction was condensed and NaOH was added until the solution was at pH 14. The product was extracted from solution using dichloromethane to yield BC (0.0896g, 59%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.03 (t, 2H, N**H**CH_2), 3.70 (s, 16H, NC**H$_2$**CH_2NBoc), 3.53-3.63 (m, 12H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**), 3.41 (q, 4H, NHC**H$_2$**), 2.84 (s, 16H, NCH_2C**H$_2$**NH), 1.82 (m, 4H, C**H$_2$**CH_2NH), 1.57 (br, 4H, N**H**). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 166.6 (**C**$_3N_3$), 165.4 (**C**$_3N_3$), 70.8 (**C**H_2O**C**H_2), 70.5 (**C**$H_2CH_2OCH_2$**C**H_2), 69.6 ($NHCH_2CH_2$**C**H_2O), 46.2 ((CH_2**C**$H_2)_2$NH), 44.4 ((**C**$H_2CH_2)_2$NH), 38.4 (**C**H_2NH), 29.8 (CH_2**C**H_2CH_2NH).

Protected G1 Bow-tie Core (P-B1-C). BC (0.0778g, 0.109 mmol) and pip-MCT (0.2158g, 0.446 mmol) were each dissolved in 2 mL 9:1 $CHCl_3$:CH_3OH. Pip-MCT solution was added to the core solution followed by the addition of DIPEA (1.4 mL, 8.037 mmol). The solution was heated to 70 ºC. After 24 hours the reaction was condensed, dissolved in chloroform and washed three times with distilled water. The organic layer was condensed and purified by column chromatography (30:1 CH_2Cl_2:CH_3OH) to yield P-B1-C (0.2017g, 74%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.12 (t, 2H, N**H**CH_2), 3.77 (s, 32H, NC**H$_2$**C**H$_2$**N), 3.74 (s, 32H, C**H$_2$**CH_2NBoc), 3.53-3.63 (m, 12H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**), 3.43 (q, 36H, NHC**H$_2$**, NCH_2C**H$_2$**NBoc), 1.85 (m, 4H, C**H$_2$**CH_2NH), 1.47 (s, 72H, C(C**H$_3$**)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 166.6

(**C**$_3$N$_3$), 165.5 (**C**$_3$N$_3$), 155.0 (**C**O), 80.1 (**C**(CH$_3$)$_3$), 70.8 (**C**H$_2$O**C**H$_2$), 70.5 (**C**H$_2$CH$_2$OCH$_2$**C**H$_2$), 69.6 (NHCH$_2$CH$_2$**C**H$_2$O), 43.2-44.0 (piperazine), 38.4 (**C**H$_2$NH), 29.9 (CH$_2$**C**H$_2$CH$_2$NH), 28.6 (C(**C**H$_3$)$_3$). MS (MALDI): calcd 2503.5 (M^+); found 2504.8 ($M + H^+$).

G1 Bow-tie Core (B1-C). P-B1-C (0.1794g, 0.072 mmol) was dissolved in 4 mL methanol. Concentrated HCl (2 mL) was added to the solution. After 24 hours the reaction mixture was condensed, and the product was precipitated using 5 M NaOH. The precipitate was dissolved in chloroform and washed with 1 M NaOH. The organic layer was condensed to yield P-B1-C (0.1201g, 98%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.12 (t, 2H, N**H**CH$_2$), 3.76 (s, 32H, NC**H$_2$**C**H$_2$**N), 3.73 (s, 32H, NC**H$_2$**CH$_2$NH), 3.55-3.65 (m, 12H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**), 3.46 (q, 4H, NHC**H$_2$**), 2.85 (s, 32H, NCH$_2$C**H$_2$**NH), 1.83 (m, 4H, C**H$_2$**CH$_2$NH). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 166.6 (**C**$_3$N$_3$), 165.6 (**C**$_3$N$_3$), 70.8 (**C**H$_2$O**C**H$_2$), 70.5 (**C**H$_2$CH$_2$OCH$_2$**C**H$_2$), 69.6 (NHCH$_2$CH$_2$**C**H$_2$O), 46.2 (NCH$_2$**C**H$_2$NH), 44.5 (N**C**H$_2$CH$_2$NH), 43.3 (N**C**H$_2$**C**H$_2$NH), 38.4 (**C**H$_2$NH), 29.9 (CH$_2$**C**H$_2$CH$_2$NH). MS (MALDI): calcd 1703.1 (M^+); found 1704.2 ($M + H^+$).

Protected B2-1. MCT1 (0.1138g, 0.208 mmol) and B1-C (0.0294g, 0.017 mmol) were each dissolved in 3 mL 10:1 $CHCl_3$:CH_3OH. The MCT1 solution was added to the core solution followed by the addition of DIPEA (0.1 mL, 0.574 mmol). The solution was heated to 70 ºC. After three days the reaction was condensed, dissolved in chloroform, and washed three times with distilled water. The chloroform solution was condensed and

purified by column chromatography (30:1 CH_2Cl_2:CH_3OH → 9:1 CH_2Cl_2:CH_3OH) to yield P-B2-1 (0.0492g, 49%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.12 (t, 16H, N**H**Boc), 3.83 (s, 32H, C**H$_2$**OH), 3.77 (s, 128H, NC**H$_2$**C**H$_2$**N, NC**H$_2$**CH_2OH), 3.67 (s, 32H, NC**H$_2$**CH_2CH_2NHBoc), 3.58 (m, 12H, C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**C**H$_2$**OC**H$_2$**), 3.47 (q, 4H, NHC**H$_2$**), 3.07-3.15 (br, 32H, NCH_2CH_2C**H$_2$**NHBoc), 1.85 (m, 4H, C**H$_2$**CH_2NH), 1.72 (s, 32H, NCH_2C**H$_2$**CH_2NHBoc), 1.42 (s, 144H, C(C**H$_3$**)$_3$). ^{13}C NMR (300 MHz, $CDCl_3$/CD_3OD) δ: 167.0 (**C**$_3N_3$), 165.4 (**C**$_3N_3$), 164.4 (**C$_3$**N_3), 156.2-156.5 (**C**O), 79.2-79.3 (**C**$(CH_3)_3$), 70.8 (**C**H_2O**C**H_2), 70.4 (**C**$H_2CH_2OCH_2$**C**H_2), 69.5 ($NHCH_2CH_2$**C**H_2O), 62.4-63.1(**C**H_2OH), 51.3 (N**C**H_2CH_2OH), 44.2 (N**C**$H_2CH_2CH_2$NHBoc), 43.0-43.5 (N**C**H_2**C**H_2N), 38.2 (**C**H_2NH), 37.5 (**C**H_2NHBoc), 29.8 (OCH_2**C**H_2CH_2NH), 28.7 (C(**C**$H_3)_3$), 27.9 (NCH_2**C**H_2CH_2NHBoc). MS (MALDI): calcd 5793.6 (M^+); found 5794.9 ($M + H^+$).

B2-1. P-B2-1 (0.0453g, 0.008 mmol) was dissolved in 7 mL methanol. Concentrated HCl (2.5 mL) was added to the solution. After 24 hours the solution was condensed and neutralized with sodium hydroxide. NaCl byproduct was removed from the solution using an Amicon apparatus and a millipore membrane with NMWL = 1,000 under 35 psi N_2. The filtrate was tested for Cl^- using $AgNO_3$. When no AgCl precipitate formed the solution remaining inside the Amicon vessel was condensed *in vacuo* to afford B2-1 (0.0365g, 99%).

TECHNICAL NOTES

Seta-633 - A NIR Fluorescence Lifetime Label for Low-Molecular-Weight Analytes

Received June 4, 2009; Revised Manuscript Received July 3, 2009

We describe the photophysical properties of Seta-633, a commercially available near-infrared (NIR) dye, and its use as a fluorescent label to study the interaction between low-molecular-weight analytes and proteins using fluorescence lifetime as the readout parameter. In a model assay, we demonstrate that a biotinylated Seta-633 tracer binds to antibiotin with high specificity. Importantly, the lifetime of Seta-633−biotin increases about 1.8-fold upon binding to a specific antibody (antibiotin, MW = 160 kDa), while the titration with bovine serum albumin (BSA) or nonspecific antibody does not result in a noticeable change in lifetime. This behavior is contrary to that of fluorescent tracers like Cy5 or Alexa 647, which typically exhibit much smaller lifetime changes upon binding to antibodies.

INTRODUCTION

Fluorescence detection is widely used in biomedical research applications (*1*−*3*). A majority of these applications are based on the use of extrinsic labels (*4*−*8*). Red and near-infrared (NIR) dyes exhibit advantages over short-wavelength absorbing and emitting dyes due to reduced autofluorescence from biological samples beyond 600 nm. Among these labels, the cyanine-based labels of the Cy, Alexa, Atto, and Dy series are the most common ones used for bioanalytical applications (*5*−*13*).

Seta dyes are another group of commercially available dyes based on squaraines (*14, 15*). Squaraines are 1,3-disubstituted squaric acid derivatives. They show high extinction coefficients ($e > 200\,000$ L mol^{-1} cm^{-1}) in the red region, display high photostability, and allow the introduction of reactive functional groups such as *N*-hydroxysuccinimide (NHS) esters (*16*). As previously reported (*14*−*18*), these dyes exhibit shorter lifetime in aqueous solutions but increased lifetimes upon covalent or noncovalent binding to proteins (BSA, antibodies, and avidin). The phenomena of quantum yield and lifetime increases of squaraine dyes upon noncovalent binding to BSA and covalent binding to an antibody were thouroughly investigated and desribed in detail earlier (*14, 17*). Briefly, squaraines are considered more polar molecules as compared to open-chain cationic cyanines (*19*) (e.g., Cy5 or Alexa 647), and therefore, the quantum yields and fluorescence lifetimes of squaraines are significantly decreased in polar, protic solvents such as water or aqueous buffers (*15*) and substantially increase in hydrophobic microenvironments (e.g., upon binding to proteins (BSA, IgG)) (*16, 17*) or in aprotic solvents (*15*).

Fluorescence lifetime is one of the most robust readout parameters available for fluorescence detection (*20*). It is mostly independent of the fluorophore concentration, and therefore to some degree unaffected by changes in the probe volume and photobleaching effects (*20*).

In frequency domain (FD) measurements, the intensity of the excitation light is sinusoidally modulated at a specific frequency (*21*). Upon excitation of a fluorescent molecule with modulated light, the emitted fluorescence will also be modulated with the same frequency. However, depending on the frequency of the excitation and the lifetime of the fluorescent molecule, the modulation depth of the emitted light vs the excitation light will be decreased. In addition, the phase will be shifted in the emitted light. This phase and modulation change is then used to calculate the lifetime based on ref 21

$$\omega\tau = \tan \Phi = (1/M^2 - 1)^{1/2} \qquad (1)$$

where ω is the angular modulation frequency (2π times modulation frequency); τ is the lifetime; θ is the phase angle; and M is the modulation. To recover the fluorescence decay parameters from the signal response of the emission, a nonlinear least-squares fitting procedure is performed (*21*).

Here, we discuss the use of Seta-633 as a lifetime label for tracing the interaction of small molecules with proteins, wherein the interaction is accompanied by a change in the fluorescence lifetime. We use the biotin/antibiotin interaction as a model system and demonstrate that binding of proteins to the Seta-633−biotin is accopanied by a distinct increase in lifetime that could be easily measured with inexpensive instrumentation such as a light source modulated at a fixed wavelength and a long-in amplifier. Single label assays that are based on a lifetime readout

are preferred, as they are not limited by factors such as size or distance of binding partners.

EXPERIMENTAL PROCEDURES

Chemicals, Proteins, and Media. Seta-633 (catalog no: K8−1663), a reactive dye containing one NHS ester group, is commercially available from SETA Biomedicals, Urbana, IL (http://www.setabiomedicals.com) and was used as is. Cy5 and Alexa Fluor 647 are commercially available from GE Healthcare and Invitrogen.

Bovine serum albumin (BSA, essentially fatty acid free), immunoglobulin G (IgG) from bovine serum (reagent grade, ≥95%), biotin, approximately 99% TLC, biotin-NHS, anti-biotin antibody produced in goat, affinity isolated antibody, Sephadex G25, and Sephadex G50 are commercially available from Sigma; all other chemicals and solvents were from Aldrich. All chemicals were used without further purification.

Phosphate buffer pH 7.4 (PB) (67 mM) was prepared by mixing of 808 mL of $Na_2HPO_4 \cdot 2H_2O$ (11.876 g L^{-1}) and 192 mL of KH_2PO_4 (9.078 g L^{-1}). Bicarbonate buffer of pH 9.0 (50 mM) was obtained by dissolving 2.1 g of $NaHCO_3$ in 500 mL of distilled water.

General Protein Labeling Procedures and Dye-to-Protein Ratios. Protein labeling reactions were carried out using 50 mM bicarbonate buffer (pH 9.0). A stock solution of 1 mg of dye in 200 μL of anhydrous DMF was prepared; 5 mg of BSA or 3 mg of immunoglobulin G (IgG) protein were dissolved in 1 mL of a 50 mM bicarbonate buffer pH 9.0, and various amounts of dye from the stock solution were added, and the mixture was allowed to stir for 2 h at room temperature.

Unconjugated dye was separated from the labeled proteins using gel permeation chromatography with Sephadex G25 for BSA conjugates or Sephadex G50 for IgG (1.5 cm × 20 cm column) and a 67 mM phosphate buffer solution of pH 7.4 as the eluent. The first colored fraction containing the dye−protein conjugate is isolated, while the blue or bluish-green band with a much higher retention time (free label) is discarded. A series of labeling reactions as described above were set up to obtain different dye-to-protein ratios.

The molar dye-to-protein ratio (degree of labeling) (*22*) for each purified dye conjugate was calculated as the molarity of dye divided by the molarity of protein. The dye concentration of the conjugate was determined according to Lambert−Beer's law from the absorbance of the dye at the absorption maximum. The protein concentration was assessed by measurement of the absorption of the protein at 278 nm. The dye-to-protein ratios (*D*/*P*) were calculated using the following formula (with the assumption that the extinction coefficients for the free and conjugated dyes are about the same) (*22*−*24*)

$$D/P = \frac{A_{\mathrm{conj}(\lambda\mathrm{max})}\varepsilon_{\mathrm{p}}}{(A_{\mathrm{conj}(278)} - xA_{\mathrm{conj}(\lambda\mathrm{max})})\varepsilon_{\mathrm{dye}}} \qquad (2)$$

where $A_{\mathrm{conj}(\lambda\mathrm{max})}$ and $A_{\mathrm{conj}(278)}$ are the absorbances at absorption maxima and at 278 nm of the dye−protein conjugate, respectively; $\varepsilon_{\mathrm{dye}}$ is the extinction coefficient of the dye at λ_{max}, ε_{p} is the extinction coefficient of the protein at 278 nm: for BSA, ε_{p} = 45 540 M^{-1} cm^{-1}, and for IgG, ε_{p} = 201 700 M^{-1} cm^{-1}. The factor x in the denominator accounts for dye absorption at 278 nm ($A_{\mathrm{dye}(278)}$), which is a percent of the absorption of the dye at its maximum absorption ($A_{\mathrm{dye}(\lambda\mathrm{max})}$) ($x = A_{\mathrm{dye}(278)}/A_{\mathrm{dye}(\lambda\mathrm{max})}$).

Absorption Spectra and Extinction Coefficients. Absorption spectra were measured at room temperature on a Perkin-Elmer Lambda 35 UV/vis spectrophotometer. Absorption maxima were recorded with an accuracy of 0.5 nm.

For determination of the extinction coefficients, each dye (7−10 mg) was dissolved in 50 mL of phosphate buffer pH 7.4 (PB). The stock solution was diluted (1:2000) and the absorbance (A) was measured in a 5 cm standard quartz cell. All dye concentrations were between 0.1 and 0.2 μM. The extinction coefficients were calculated according to Lambert−Beer's law. The reproducibility for determining the extinction coefficients was 1000 M^{-1} cm^{-1}.

Emission Spectra and Quantum Yields. Emission spectra and quantum yields of the dyes, dye-BSA, and dye-IgG conjugates were measured in PB at room temperature on a Varian Cary Eclipse spectrofluorometer in a standard 1 cm quartz cell. All dyes were excited with an excitation slit width of 5 nm and emission slit width of 2.5 nm. The spectra were corrected. All concentrations of the fluorophores were chosen to be between 0.1 and 0.2 μM.

For the determination of the quantum yields (QY), the integrated relative intensities of the dyes or dye−protein conjugates were measured against Cy5 as the reference. All absorbances at the excitation wavelength (λ_{exc}) were in the range 0.12−0.18 (when measured in a 5 cm cell). The fluorescence spectra of the solutions were measured and the QYs were determined relative to Cy5 (QY = 27% (*25*)) using the formula (*26*)

$$\mathrm{QY} = \mathrm{QY}_{\mathrm{Cy5}}\left(\frac{F}{F_{\mathrm{Cy5}}}\right)\left(\frac{A_{\mathrm{Cy5}}}{A}\right) \qquad (3)$$

where $\mathrm{QY}_{\mathrm{Cy5}}$ is the quantum yield of Cy5, F_{Cy5} and F are the integrated areas of the fluorescence spectra ($F = \int I(\lambda)\, d\lambda$), and A_{Cy5} and A are the absorbencies at the excitation wavelength of Cy5 and the fluorophore under examination, respectively.

The QY of each sample was independently measured 3−4 times, and the average value was calculated. The QYs of the dye−BSA conjugates were measured for various D/P ratios, and then, the QYs for $D/P = 1$ were determined by a nonlinear interpolation.

Fluorescence Lifetime Measurements. Fluorescence lifetime measurements were acquired on ChronosFD − the laser-diode based frequency domain instrument produced by ISS Inc., Champaign, IL, USA. A 635 nm laser diode was used as the excitation source. Two synthesizers (model IFR2023) providing modulation frequencies in the range from 9 kHz to 1.2 GHz were utilized for the measurements. Data analysis was done with Vinci - Multidimensional Fluorescence Spectroscopy − a comprehensive software package for the analysis of time-resolved data from ISS. The analysis of the time-resolved fluorescence data was carried out using the traditional nonlinear least-squares method. This method evaluates how close a model selected by the user matches the data acquired with the instrument; the Marquardt−Levenberg algorithm was utilized for the minimization routine of the χ^2-function that compares the selected model with the experimental data. In all lifetime measurements, the dye concentration in PB (pH 7.4) was between 0.1 and 1 μM.

Mass Spectrum. The mass spectrum of *N*-[2-(D-biotinylamino)ethyl]amine was recorded on a Varian 1200 L mass spectrometer system using the electron ionization (EI) method.

Photostability. Photostability measurements were performed in aqueous solutions with Cy5, Alexa Fluor 647, and Seta-633 and their IgG conjugates. The optical density of the long-wavelength maximum was controlled to be between 0.09 and 0.10, and all measurements were carried out in 1 cm cells. These solutions were placed at the distance of approximately 30 cm from a 500 W lamp and irradiated with occasional stirring. The absorption and emission spectra of the solutions were measured before irradiation and during light exposure. The relative photostabilities were calculated as the ratio between (i) the measured absorbances at the longwavelength maximum before

Table 1. Spectral Properties for Seta-633 and Seta-633 Conjugates

dye or dye conjugate	λ_{max} (abs) (nm)	ε ($M^{-1}\cdot cm^{-1}$)	λ_{max} (em) (nm)	QY (%)	Stokes' shift ($\Delta\nu$) (cm^{-1})

and after exposure (A/A_0) and (ii) the relative fluorescence intensities before and after exposure (I/I_0), and the corresponding plots were generated.

Biotin Conjugation. *N-[2-(D-Biotinylamino)ethyl]amine.* To a stirred solution of 63 mg (0.18 mmol) of D-biotin-NHS in 1.5 mL DMF were added 500 μL (7.48 mmol) of ethylenediamine, and stirring was continued for 1 h at room temperature. The product was precipitated with the addition of 50 mL diethyl ether, filtered, and dried under vacuum. Yield: 49 mg (93%).

^{1}H NMR (200 MHz, DMSO-d_6), δ, ppm: 8.00 (1H, s), 7.91−7.67 (2H, m), 6.40 (2H, d, 13.3 Hz), 4.36−4.24 (1H, m), 4.18−4.06 (1H, m), 3.17−2.92 (5H, m), 2.82 (1H, dd, 5.0, 12.6 Hz), 2.57 (1H, d, 12.2 Hz), 2.06 (2H, t, 7.2 Hz), 1.69−1.15 (6H, m). MS-EI spectrum (m/z 40−600): calcd mass using formula $C_{12}H_{22}N_4O_2S$, $[M+H]^+$ 287.15; found m/z 287.

Seta-633-CONH-$(CH_2)_2$NH-biotinyl. A mixture of 20 mg (19.8 mmol) of Seta-633, 8.1 mg (28.3 mmol) of *N*-[2-(D-biotinylamino)ethyl]amine, and 5 μL (28.7 mmol) of DIPEA in 1 mL of DMF was stirred for 2 h at room temperature. The reaction was monitored by HPLC (Discovery Bio Wide Pore C18, gradient from 0.05% trifluoroacetic acid (TFA) in water to 50:50 (0.05% TFA in water:0.05% TFA in acetonitrile). The reaction mixture was diluted with 20 mL of water and then purified by column chromatography (Lichroprep RP-18, MeOH−water (1:9, v/v) as eluent) to give Seta-633-mono-CONH-$(CH_2)_2$NH-biotinyl as a dark-blue solid with yield 18.7 mg (79%). The purity of Seta-633-CONH-$(CH_2)_2$NH-biotinyl was 89.3% by HPLC. The structure of Seta-633-CONH-$(CH_2)_2$NH-biotinyl was confirmed by ^{1}H NMR (200 MHz, DMSO-d_6) spectroscopy. The corresponding signals of the biotin moiety which can be found at 7.88 (2H, broad s), 6.41 (2H, d, 11.8 Hz), 4.37−4.23 (1H, m), 2.82 (1H, dd, 5.0, 12.6 Hz), 2.57 (1H, d, 12.1 Hz) are visible. All other proton signals of the biotin moiety overlap with dye proton signals.

Immunoassay. The immunoassay experiments included a titration of Seta-633−biotin with specific (antibiotin antibody produced in goat, affinity isolated antibody, Sigma) and nonspecific (IgG from bovine serum (reagent grade, ≥95%, Sigma) antibodies. A 0.6 μM solution of Seta-633−biotin was prepared in PB pH 7.4.

During each titration step, 0.06 μM of the antibody was added to the labeled biotin solution. After each addition of the antibodies, the solution containing the labeled antigen and antibodies was incubated at 37 °C for 5 min in the dark, followed by measurement of the fluorescence lifetime.

RESULTS AND DISCUSSION

Absorption, Emission Spectra, and Stokes' Shifts. The spectral characteristics of Seta-633 and their BSA- and IgG-conjugates in PB pH 7.4 are given in Table 1; a representative absorption and emission spectrum of Seta-633 is shown in Figure 1.

The absorption and emission maximum of Seta-633 (Table 1) makes it perfectly suited for use with the 635 nm diode laser. Covalent binding of Seta-633 to BSA produces a red-shift of both the absorption (13 nm) and emission (12 nm) maxima, while the red-shift for the IgG conjugates is substantially smaller (4 and 3 nm, respectively).

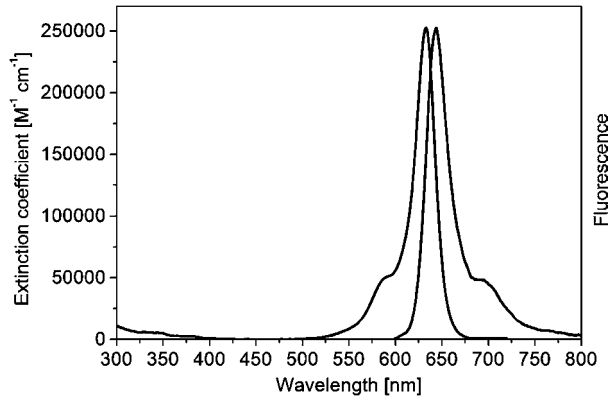

Figure 1. Absorption and emission spectrum of Seta-633.

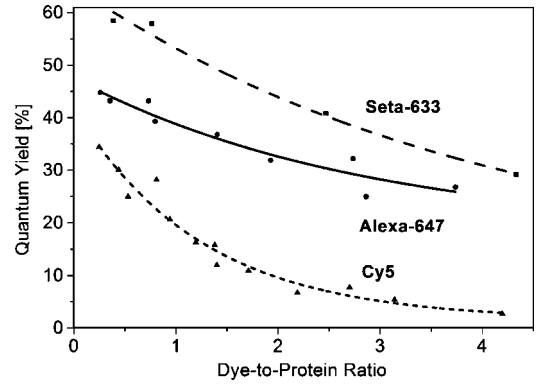

Figure 2. Quantum yield vs dye-to-protein ratio of dye−BSA conjugates in PB pH 7.4.

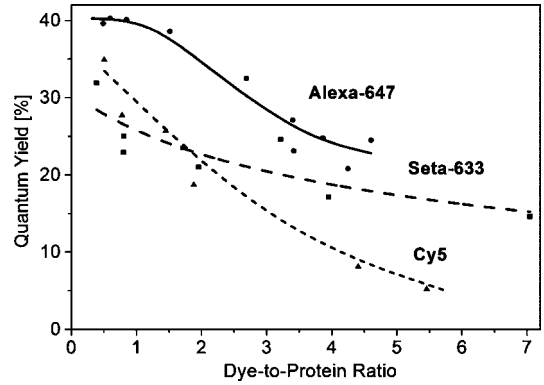

Figure 3. Quantum yield vs dye-to-protein ratio of dye−IgG conjugates in PB pH 7.4.

Seta-633 exhibits a lower quantum yield in aqueous solutions, but these quantum yields (QYs) substantially increase after binding to proteins. The QYs of the Seta-633-BSA conjugates are as high as 50% and generally exceed those of Cy5-BSA and Alexa Fluor 647-BSA conjugates for the same dye-to-protein ratios (Figure 2). The QY increase is less pronounced upon binding to proteins such as IgG (Figure 3, Table 1).

Photostability. The photostability of dyes plays important role for their practical use. We investigated the photostabilities of Seta-633 and its IgG conjugates and compared them to Cy5 and Alexa Fluor 647. These measurements were carried out in PB pH 7.4. The relative photostabilities for the free dyes and the IgG conjugates are presented in Figure 4a and b. Figure 4b clearly demonstrates reduced photobleaching for Seta-633-IgG conjugates upon prolonged exposure to light.

Fluorescence Lifetimes. As expected, the mean fluorescence lifetime (τ_{mean}) of Seta-633 measured in PB 7.4 is shorter than

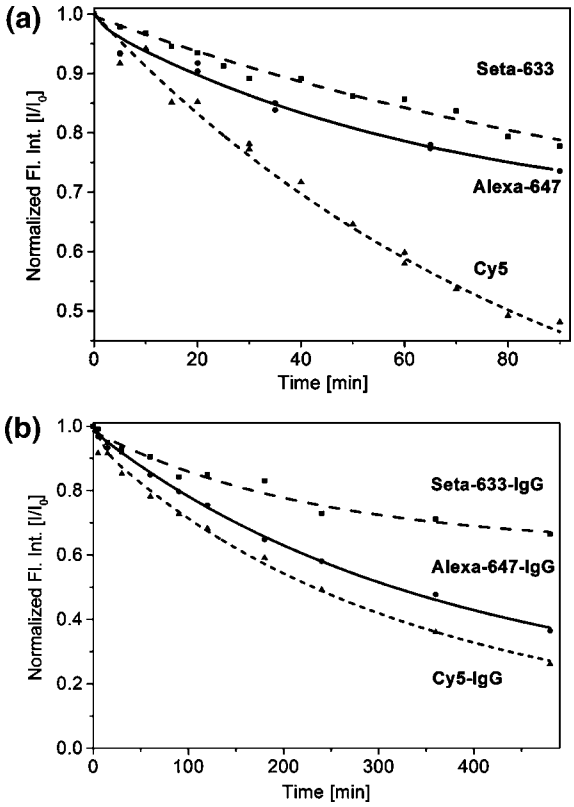

Figure 4. a. Normalized fluorescence intensity changes for free dyes upon exposure to light from a halogen lamp (500 W). b. Normalized fluorescence intensity changes for dye-conjugates upon exposure to light from a halogen lamp (500 W).

Table 2. Dye-to-Protein Ratios, Lifetimes, and Fractional Contributions for Selected Dyes and Dye-Conjugates

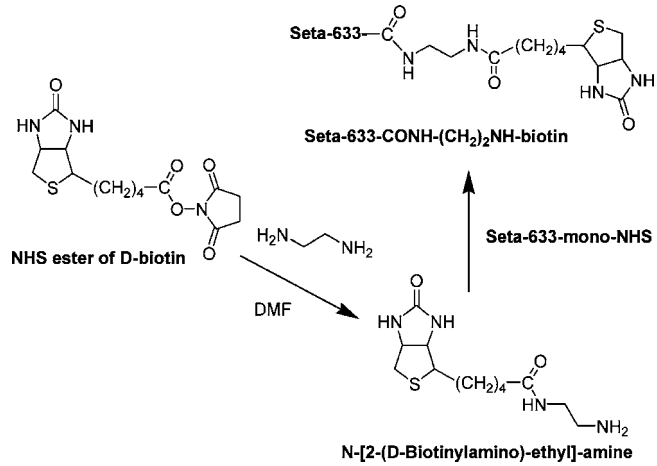
dye or dye conjugate	*D/P*	τ_1 (ns)	f_1	τ_2 (ns)	f_2	χ^2	τ_{mean} (ns)
Cy5	—	1.00	1.00	—	—	1.20	1.00
Cy5-BSA	0.94	0.28	0.10	1.88	0.90	1.49	1.72
Cy5-IgG	1.90	0.28	0.23	1.47	0.77	1.95	1.20
Alexa 647	—	1.17	1.00	—	—	1.99	1.17
Alexa 647-BSA	0.90	0.33	0.07	1.91	0.93	0.63	1.80
Alexa 647-IgG	1.83	0.31	0.20	1.29	0.80	1.87	1.09
Seta-633	—	0.12	0.61	0.46	0.39	0.58	0.25
Seta-633-biotin	—	0.27	0.33	0.87	0.67	1.22	0.66
Seta-633-BSA	0.90	0.56	0.05	2.93	0.95	0.94	2.81
Seta-633-IgG	1.10	0.40	0.26	1.88	0.74	1.19	1.49

those for Cy5 and Alexa Fluor 647 (Table 2), which is because polar compounds are quenched in polar solvents and squaraine dyes can be considered more polar than cyanine dyes (*17*). While the intensity decays for Cy5 and Alexa Fluor 647 are well-fitted with monoexponential curves, the decays for Seta-633 are better fitted with a biexponential decay curve (*15*). The observed biexponential decay times for Seta-633 and Seta-633−biotin are most probably due to dye−solvent effects (*27*).

The fluorescence lifetime of Seta-633 as well as Seta-633-biotin increase several-fold after binding to proteins. Covalent binding of Seta-633 to BSA leads to an 10-fold lifetime increase from 250 ps to 2.81 ns, while the average lifetime increase between the free and IgG-bound Seta-633 is about 6-fold. This is in contrast to cyanine-based labels, which show less pronounced fluorescence lifetime changes upon labeling to proteins − especially antibodies (Table 2).

The observed large fluorescence lifetime changes between Seta-633 free in solution and coupled to IgG were instrumental to our decision to evaluate Seta-633 in a lifetime-based immunoassay. We intentionally chose the immunoassay format

Scheme 1. Synthesis of Seta-633−Biotin



over the biotin−avidin/streptavidin interaction because of its broader applicability. In general, biotin could be replaced by any other low-molecular-weight antigen.

Model Immunoassay. For the model immunoassay, a labeled biotin-conjugate of Seta-633 as shown in Scheme 1 was synthesized. Coupling between D-biotin and Seta-633 was facilitated by introducing an ethylenediamine linker into biotin (*28*). *N*-[2-(D-Biotinylamino)ethyl]amine was synthesized analogously to a literature procedure but by using biotin-NHS instead of biotin and CDI (1,1′-carbonyldiimidazole) (*29*). Dimer formation was prohibited by using an excess of ethylenediamine. Subsequently, the amino-group of *N*-[2-(D-biotinylamino) ethyl]amine was conjugated to Seta-633 to yield Seta-633-CONH-$(CH_2)_2$NH-biotin (see Biotin Conjugation).

The introduction of the biotin-ethylenediamine moiety into Seta-633 causes an increase in the average lifetime from 0.25 to 0.66 ns (Table 2). Titration of the small-molecular-weight tracer with its specific antibody (antibiotin, MW = 160 kDa) leads to a steady increase of the fluorescence lifetime to a maximum value of 1.82 ns, a 176% increase compared to the unbound tracer. Importantly, no change is observed when the tracer was titrated with nonspecific antibody or BSA, indicating that the nonspecific interactions due to hydrophobic binding of are minimal (Figures 5 and 6).

We also made an attempt to demonstrate a competitive lifetime-based phase-modulation assay with the biotin/antibiotin model system. In this competitive assay, fixed concentrations of 0.65 μM Seta-633−biotin tracer and antibiotin (ratio = 1:1) were incubated with increasing concentrations of free biotin.

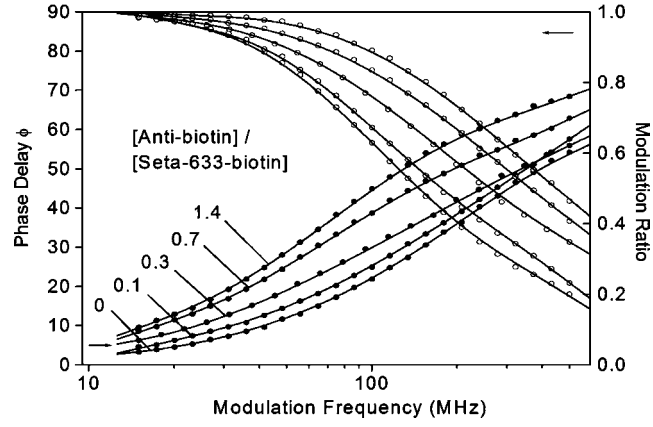


Figure 5. Frequency response curves (phase angle and modulation ratio vs modulation frequency) of Seta-633−biotin (0.65 μM) upon titration with antibiotin (specific antibody).

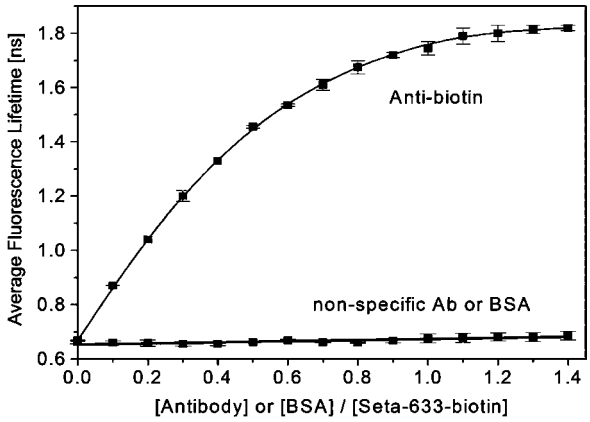

Figure 6. Average fluorescence lifetime changes of Seta-633−biotin (0.65 μM) upon titration with antibiotin (specific), (nonspecific) human IgG, or BSA.

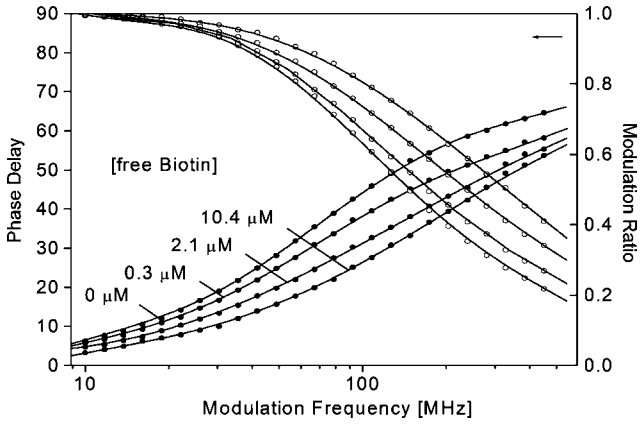

Figure 7. Frequency response curves for the titration of the Seta-633−biotin−antibiotin complex with free biotin (competitive reaction).

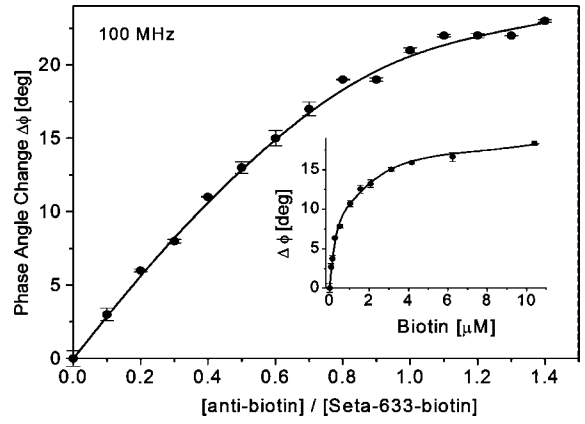

Figure 8. Changes in phase angle upon titration of Seta-633−biotin (0.65 μM) with antibiotin (specific antibody), measured at 100 MHz. The inset shows phase angle changes of a mixture of 0.65 μM Seta-633−biotin and 0.65 μM antibiotin (ratio of 1) upon titration with free biotin, measured at 100 MHz.

Replacement of the labeled biotin tracer by free biotin leads to a shift of the frequency response curves to higher frequencies (Figures 7, 8) and thus shortening of the fluorescence lifetime. Addition of 0 to 10 μM concentrations of biotin leads to a total change of 18° in phase angle. Present instrumentation allows the phase angle to be measured accurately to 0.1° and modulation with an accuracy of 0.005 (*30*).

Homogeneous immunoassays can be performed even in whole blood, because red and NIR dyes allow excitation beyond the absorptive bands of hemoglobin and tissue.

CONCLUSIONS

The hydrophilic, amine-reactive NIR fluorescent label Seta-633 exhibits favorable properties as a lifetime label for the measurement of small-molecular-weight analytes. The label is compatible with readily available light sources (635 nm or 640 nm diode lasers) and filter sets (as for Cy5 or Alexa Fluor 647). Seta-633 exhibits lower quantum yields and shorter fluorescence lifetimes when free in solution, but these values substantially increase upon interaction with proteins, which is contrary to fluorescent tracers like Cy5 or Alexa 647, which typically exhibit much smaller lifetime changes in particular upon binding to antibodies. Importantly, Seta-633 and its conjugates are also more photostable as compared to Cy5 and Alexa Fluor 647.

COMMENT

Intelligent Drug Delivery Systems

Yu-Kyoung Oh

School of Pharmacy, Seoul National University, Sinlim-dong, Kwanak-gu, Seoul 151-742, South Korea

Peter D. Senter

Seattle Genetics, 21823 30th Drive SE, Bothell, Washington 98021

Soo-Chang Song

Division of Life Science, Korea Institute of Science and Technology, Seoul 130-650, South Korea. Received June 12, 2009; Revised Manuscript Received July 28, 2009

There has been a great deal of research in recent years toward improving drug delivery and selectivity through the use of macromolecular-based drug carriers such as monoclonal antibodies, liposomes, polymers, dendrimers, micelles, and hydrogels (*1*−*3*). These areas were featured at the 2009 International Symposium on Intelligent Drug Delivery Systems that was held at the Korea Institute of Science and Technology (KIST) in Seoul, South Korea on April 29−30, 2009. The meeting was sponsored by the Korean Ministry of Education, Science and Technology and the Korea Biotech R & D Group in an initiative to promote drug delivery research within the country. We felt that readers of *Bioconjugate Chemistry* would be interested in several of the presentations at the meeting, given the relevance to the scope of the journal.

Kinam Park from Purdue University provided a keynote address entitled "Practical nanotechnology and microfabrication for drug delivery" (*4*). The history of drug delivery systems was overviewed, beginning with examples of the first delayed and sustained release technologies in the 1950s and 1960s, through the development of nanotechnologies that are under active investigation. This has led to the approval of several macromolecular-based drugs such as Doxil, Abraxane, and Genexol for cancer therapy (*3*). "Smart polymers" and newer materials allow for controlled released of drugs under specific conditions (*5*). Advancements in material science has allowed for the production of solid supports for drug delivery in which imprinting technologies are used to produce novel scaffolds for drug attachment and controlled release (*6*). Several of the issues are being resolved including biocompatibility, scale-up, drug loading, and control of release kinetics. Some elegant examples of such technologies were provided by Ping Lee at the University of Toronto who described the development of osmotic tablets which are used in more than 20 approved drugs. Other delivery systems of great interest include osmotically driven miniaturized implants, hydrogel capsules, polymeric drug derivatives, and inhalable formulations (*7*). While these technologies may offer significant advantages over current formulations, the regulatory, cost, and compliance issues are significant.

Nanotechnology-based drug delivery systems were described that allow for both spatial and temporal control of drug release. Yongdoo Park from Korea University described biomimetic hydrogels that not only allowed for controlled drug release, but also could be devised to release mechanistically distinct drugs in a sequential manner (*8*). In a complementary approach, Keun-Hong Park from CHA University in Seoul described a dual drug delivery strategy involving a nanoparticle consisting of a drug-loaded poly(lactic acid)−poly(glycolic acid) copolymer (PLGA) with ionically associated drug−polyethyleneimine complexes (*9*). These

novel carriers allowed for dual drug release in vivo over extended time periods. Kazuo Maruyama from Teikyo University in Japan described the preparation of liposomes containing perfluoropropane bubbles together with anticancer drugs, siRNA, or proteins of therapeutic interest (*10*). Upon exposure to ultrasonic radiation, the exploding bubbles disrupted liposomal structure, leading to drug release. The technology was applied to the delivery of antigens to dendritic cells for active tumor immunotherapy. Tatsuhiro Ishida from the University of Tokushima in Japan described how liposomal drug formulations can be used in combination with systemic drug therapy in metronomic therapeutic protocols. Low and frequent dosing regimens of various liposomal and free drug combinations resulted in pronounced intratumoral drug delivery and therapeutic efficacy (*11*).

The meeting featured talks on drug formulations that greatly extend the use and activities of clinically approved agents. Han-Gon Choi from Yeungnam University in Korea described how a solid dispersion system of poorly soluble drugs such as paclitaxel, valsartan, and tacrolimus improved drug solubility and pharmacologic properties such as AUC, C_{max}, and T_{max} values (*12*). Another example was provided by Han-Kwang Yang from Seoul National University who described the effects of biodegradable, thermosensitive hydrogels for drug encapsulation and release (*13*). Preparations were described that allowed for in vivo anticancer drug release over a period of 50 days, and these led to pronounced activity over systemic chemotherapy. It was possible to use such preparations for direct intratumoral injection. Doo Sung Lee from the Sungkyunkwan University in Suwon, South Korea, discussed pH-responsive micelles for therapy and diagnostics (*14*). Carboxylic acids were incorporated into the hydrophilic backbone of drug-loaded micelles, and upon acidification below pH 6.8, disruption of the micelle structure led to rapid and quantitative drug release. Pronounced therapeutic efficacy was obtained in tumor xenograft models. The technology was extended to include imaging agents, which were applied to both cancer and stroke indications.

While it is widely known that macromolecules penetrate slowly through solid tumors, little is known about low molecular weight anticancer drugs. Hyo-Jeong Kuh from the Catholic University in Korea utilized three-dimensional multicellular layer and spheroid models to track the penetration of doxorubicin, paclitaxel, and siRNA into tumors (*15, 16*). She found that penetration were functions of both the drug and the tumor model being tested. In some cases, penetration was uniform, but in other cases, it was biphasic. This type of work could provide insight into the development of synergistic drug combinations acting on tumor cells that are either near or distal to vascular beds. The power of attacking distinct cell populations was illustrated by Tae Woo Kim from Korea University, who demonstrated that large tumor masses could be eradicated using a multimodality approach that included anticancer drugs combined with agents that stimulate tumor-specific CD8 positive cells (*17*).

Claude Meares from the University of California at Davis provided the other keynote address in a presentation that overviewed radioimmunotherapy targeting technologies. An approach that has been clinically validated involves pretargeting, exemplified by antibody−streptavidin fusion protein administration, followed by a biotin-macrocyclic metal chelating agent, DOTA, radiometal chelate. This approach circumvents extensive radiation exposure to normal tissues, since the biotin−DOTA complex is rapidly cleared (*18*). The technology was extended to include genetically engineered antibodies with cysteine residues near the antigen binding sites that form covalent adducts with an electrophilic form of the DOTA hapten. These antibodies were referred to as antibodies with infinite affinity (*19, 20*). A variant of this technology included the imaging of tumors in vivo that were transfected with the cysteine-mutated antibodies. Felix Kratz from the Tumor Biology Center in Freiburg, Germany, described a novel form of anticancer drug delivery involving the administration of anticancer drugs that contain appended maleimides that form covalent bonds with cysteine-34 in albumin (*21, 22*). This leads to a macromolecule that has much longer circulating times than the free drug and has the ability to penetrate into tumors. The drug can be released from albumin through acid-mediated or enzymatic hydrolysis, depending on the linker system used. This is a versatile technology that allows for multidrug and targeted delivery approached. The lead agent, 6-maleimidocaproyl hydrazone derivative of doxorubicin (doxorubicin-EMCH), has provided evidence of response in early stage clinical testing. Peter Senter from Seattle Genetics utilized monoclonal antibodies for the delivery of highly potent drugs such as auristatins to tumors (*23*−*25*). The results from a phase I clinical trial demonstrated that 86% of patients with CD30 positive lymphomas experienced tumor reduction, which included complete and partial remissions. The results underscore the importance of drug potency, linker stability, and tumor selectivity in generating therapeutically effective drug conjugates for cancer therapy. This work was extended by Qiang Zhang from Peking University, China, to include the delivery of TNFα to tumors by administration of PEG-peptide-TNFα that could be cleaved by tumor-associated proteases. The conjugates with the cleavable linker were more active than those without.

One of the central aspects involved in drug delivery includes technologies for adhering drugs to the carriers of interest. Haeshin Lee from the Korea Advanced Institute of Science and Technology described adhesive molecules derived from those used by mussels for sticking to solid surfaces in water (*26, 27*). A series of catechol derivatives were able to form cross-links in water through either oxidative addition or through metal chelation chemistry. These agents were used to adhere proteins to surfaces for use in capturing cells through receptor-mediated interactions.

In summary, the 2009 International Symposium on Intelligent Drug Delivery Systems featured research in areas of great promise for new therapeutics. In particular, new micellar, liposomal, and hydrogel formulations allow for extended drug release, and new applications of water-insoluble drugs that are otherwise difficult to administer. Developments in nanotechnologies have produced materials that release drugs in a sequential manner or release complementary drugs under well-defined conditions. Specific targeting has advanced significantly, with clinically effective antibody−drug and radionuclide conjugates. Some of the challenges that lie ahead were illustrated by Hiroshi Kikuchi from Eisai Corporation in Japan and Kuchan Kimm of MSD Korea, the Korean branch of Merck & Co., both of whom discussed the difficulties in getting novel and expensive agents like those described in the meeting approved and widely utilized. However, as these agents progress through clinical trials and demonstrate activity beyond what is achievable with conventional agents, it is expected that they will comprise the drugs of the future. The next meeting will be held in May, 2010, at KIST in Seoul, South Korea.

Functionalized congeners, in which a chemically functionalized chain is incorporated at an insensitive site on a pharmacophore, have been designed from the agonist and antagonist ligands of various G protein-coupled receptors (GPCRs). These chain extensions enable a conjugation strategy for detecting and characterizing GPCR structure and function and pharmacological modulation. The focus in many studies of functionalized congeners has been on two families of GPCRs: those responding to extracellular purines and pyrimidines—i.e., adenosine receptors (ARs) and P2Y nucleotide receptors. Functionalized congeners of small molecule as ligands for other GPCRs and non-G protein coupled receptors have also been designed. For example, among biogenic amine neurotransmitter receptors, muscarinic acetylcholine receptor antagonists and adrenergic receptor ligands have been studied with a functionalized congener approach. Adenosine A_1, A_{2A}, and A_3 receptor functionalized congeners have yielded macromolecular conjugates, irreversibly binding AR ligands for receptor inactivation and cross-linking, radioactive probes that use prosthetic groups, immobilized ligands for affinity chromatography, and dual-acting ligands that function as binary drugs. Poly(amidoamine) dendrimers have served as nanocarriers for covalently conjugated AR functionalized congeners. Rational methods of ligand design derived from molecular modeling and templates have been included in these studies. Thus, the design of novel ligands, both small molecules and macromolecular conjugates, for studying the chemical and biological properties of GPCRs have been developed with this approach, has provided researchers with a strategy that is more versatile than the classical medicinal chemical approaches.

INTRODUCTION

G protein-coupled receptors (GPCRs[1]) serve as the mechanistic basis for a large fraction (roughly half) of the pharmaceuticals currently in clinical use. These receptors may serve as the direct target of an agonist or antagonist drug, or the activity of a given receptor induced by its naturally occurring extracellular transmitter may be modulated indirectly (through an allosteric mechanism or by alteration of uptake or metabolism) (*1*). GPCRs have an overall structural motif of seven transmembrane helical domains (TMs) that are embedded in and traverse the plasma membrane. Such heptahelical proteins constitute ~4% of the human genome.

The functionalized congener approach (Figure 1) is a widely applicable conceptual framework for the design of small, biologically active molecules that bind to biopolymers, such as receptor proteins on the cell surface. Beginning in the early 1980s, this approach was found to be particularly useful in the design of certain Family A GPCR ligands (*2*, *3*), and since that time, it has been applied to a wide range of GPCRs. This strategy allows the affinity or selectivity of a nonpeptide drug for its receptor to be greatly influenced by functions introduced at the terminus of an attached chain at a permissive site on the drug molecule. Ideally, the steric constraints of the pharmacophore-binding site are relaxed at the distal region of this chain. Figure 1A details this approach schematically, as it was conceived in 1987 (*4*) and applied to the adenosine receptors (ARs), long before knowledge of the structure of these receptors was available.

A further benefit of this approach is the ability to couple a biologically active ligand to a carrier such as a peptide and maintain or enhance its pharmacological profile (*5*, *6*). A distal moiety of an appended chemically functionalized chain may provide secondary favorable interactions with the receptor

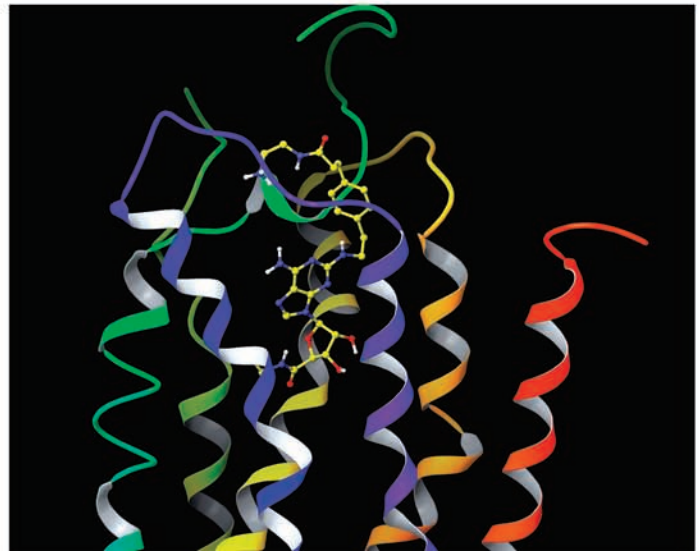

Figure 1. (A) Hypothetical interaction of adenosine functionalized congeners with the A_1 AR, as depicted in 1987. This figure is modified from ref 4, to illustrate the historical development of this conceptual approach prior to the structural elucidation of GPCRs. (B) Objectives and general considerations in functionalized congener approach to derivatizing ligands of GPCRs (applies to both small molecule agonists and antagonists). An amino group or carboxylic group is shown for conjugation, but those are only examples. The carrier moiety may be, for example, a prosthetic reporter group for radioactive or spectrospcopic detection, an electrophilic cross-linker for covalent receptor binding, or a macromolecular for targeting or immobilization. Many other approaches to conjugation chemistry are applicable. (C) A three-dimensional molecular model of APEC **39** bound to the human A_{2A} AR. The automatic docking of **39** to the recently published X-ray crystallographic structure (*22*) was carried out using the Schrodinger Glide XP program. The model shows that the functionalized chain of **39** protrudes into the extracellular regions of the receptor, as envisioned much earlier. The receptor helices are colored by residue position: N-terminus in red, TM 1 in orange, TM 2 in ochre, TM 3 in yellow, TM 4 in green, TM 5 in cyan, TM 6 in blue, TM 7 and C-terminus in purple.

(Figure 1A) to enhance ligand affinity and selectivity. This makes possible the design of spectroscopic probes of high receptor affinity, dual-acting drugs, carrier-bound drugs, and so forth (Figure 1B) (*4, 7*−*11*). Thus, prosthetic groups to provide various chemical or physical properties may be covalently coupled to these small molecules through an appropriately designed functionalized chain.

Beginning in 1984, a research group that later became the Molecular Recognition Section (MRS) of the National Institute of Diabetes and Digestive and Kidney Diseases sought to expand this design approach to a relatively unexplored GPCR as a test system and selected the ARs for this purpose. At the time, the newly discovered ARs were appealing because there were few potent ligands with which to probe these receptors pharmacologically (*12*). The widely used antiasthmatic drug theophylline (1,3-dimethylxanthine) had recently been identified as a prototypical adenosine antagonist (*13, 14*), and institute scientists delineated properties that distinguished an AR that stimulates adenylate cyclase from one that inhibits (*15*). Today, the ARs are considered one of the more advanced examples of GPCRs used in medicinal chemical development, with highly selective agonists and antagonists of nanomolar affinity at each of the four AR subtypes (*16*).

BACKGROUND: PROBING GPCR STRUCTURE AND FOCUS ON RECEPTORS FOR EXTRACELLULAR PURINES AND PYRIMIDINES

GPCRs sense chemical signals from the exofacial side of a cell membrane and transmit the activation signal via both signaling cascades that are G protein dependent and those that are not, such as arrestin (*17*). The ligand-binding function of Family A GPCRs occurs at the extracellular side and/or within the TM cleft of the GPCR, and signaling propagation depends on cytosolic regions of the receptors. Nonpeptide ligands tend to bind deeper in the TM domain than do peptide ligands, which typically associate largely with the extracellular domains of the receptor (*18*). The binding of an agonist ligand induces a conformational change of the receptor that enables the second and third intracellular loops to contact the G protein(s) (*19*).

The receptor concept remained a theoretical construct for decades, until the cloning of the β_2-adrenergic receptor by Lefkowitz and co-workers in 1986 (*20*). Because the drug-relevant GPCRs are membrane-bound proteins, directly determined structural information was unavailable until the recent X-ray structural determination of the adrenergic receptors (*21*). The X-ray structures of other GPCRs, including the A_{2A} AR (Figure 1C), followed closely on the heels of this initial breakthrough (*22*). Before this development, rhodopsin-based homology modeling was the only means of looking into the three-dimensional structure of the GPCRs, and this approach was used successfully in conjunction with site-directed mutagenesis and ligand docking (*23*−*25*). Often, it has been possible to correlate the structure−activity relationship (SAR) studies of ligands with structural insights gained from molecular modeling hypotheses. Hypotheses about ligand binding and receptor activation gleaned from molecular modeling have been supported by studies involving reengineered GPCRs and chemical cross-linking of strategically placed Cys residues in the TM regions (*19, 26*).

When our lab began medicinal chemical studies of GPCRs, we recognized the potential value for drug design of structural exploration of what were then elusive proteins. Knowledge of the three-dimensional structure of GPCRs (gained by indirect methods) could contribute to the design of novel agonists and antagonists. We began our testing with purine and pyrimidine receptors. With the synthesis of chemically related agonist and antagonist classes for a given GPCR, recognition elements that

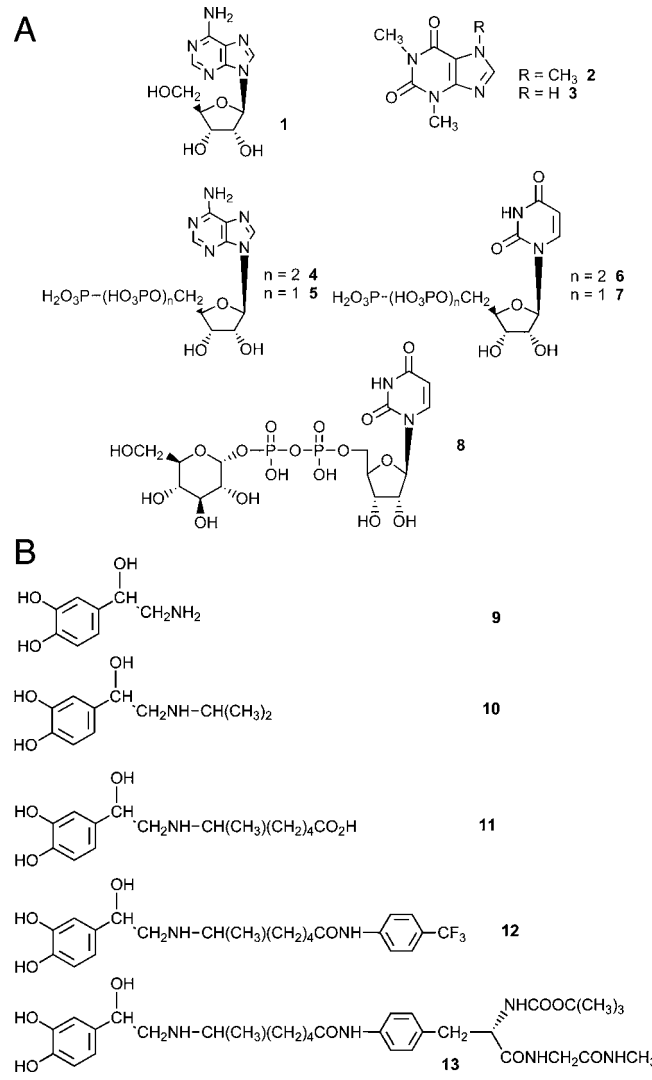

Figure 2. Structures of several classes of GPCR ligands: A) purines and pyrimidines as the native ligands of the adenosine and P2Y nucleotide receptors, and B) the naturally occurring catecholamine norepinephrine **9** and synthetic chain-elongated analogues of isoproterenol **10**.

distinguish these pharmacological actions can be pinpointed, thereby providing insights into the activation mechanisms (*27, 28*). Subtle structural differences within the same class of GPCR ligands for a given GPCR can alter the spectrum of activation of different signaling pathways. Elucidating how these GPCRs function in ligand recognition and activation as "nanomachines" is important because of the therapeutic potential of modulation of this large family of nucleoside and nucleotide receptors. If general phenomena can be identified, the analysis can be extended to other members of the GPCR superfamily.

Many studies of functionalized congeners have focused on GPCRs that respond to extracellular purines and pyrimidines, i.e., ARs for purine nucleosides and P2Y receptors for nucleotides. Extracellular adenosine **1** (Figure 2) acts as a depressant neuromodulator, and the alkylxanthine stimulants such as caffeine **2** and theophylline **3** competitively antagonize the actions of adenosine (*16*). Purine and pyrimidine nucleotides (such as ATP **4**, ADP **5**, UTP **6**, UDP **7**, and UDP-glucose **8**) act as neurotransmitter/neuromodulators at their own GPCRs (*29*). These ubiquitous signaling molecules modulate the function of diverse mammalian cell types and tissues under both normal and pathophysiological conditions. The receptors for extracellular nucleosides and nucleotides have been character-

ized through medicinal chemical, molecular biological, and pharmacological approaches. The nucleotide receptors (denoted P2) include both ligand-gated ion channels, termed P2X, and GPCRs, termed P2Y (*30*). The P2Y receptors are distinct from the ARs, for which four subtypes (A_1, A_{2A}, A_{2B}, and A_3, all GPCRs) have been defined (*16*).

In collaboration with Ad IJzerman, we initiated molecular modeling of the A_1 and A_{2A} ARs soon after their cloning in 1989 (*31*) and developed the first computer models of the putative binding sites of adenosine agonists and antagonists with the TM domain (*32*). The first model of a P2Y receptor (chick $P2Y_1$) was published in 1994 and was one of the first models based on rhodopsin (*33*). The initial purine receptor models, before 2000, were based on the structures of bacteriorhodopsin and earlier poorly resolved or incomplete structures of rhodopsin; yet even these early models suggested some features of ARs and the $P2Y_1$ receptor that were substantiated by more sophisticated modeling derived from the high-resolution rhodopsin structure. This computational probing of the architecture of both purine and pyrimidine receptors has been supported by our site-directed mutagenesis and SAR studies (*34, 35*).

These structural insights have successfully guided the design of new ligands for these GPCRs. In the course of the modeling studies, our laboratory discovered the importance of "meta" binding sites on the extracellular loops, particularly the EL2, in directing small-molecule ligands, such as ATP, to their principal binding sites in the transmembrane cleft (*36*). Later, when a high-resolution structure of rhodopsin was determined by Palczewski et al. (*37*), the conformation of the TM domains of a purine receptor almost exactly overlaid the X-ray structure.

Thus, these important GPCRs have been studied from the convergent perspectives of SARs of ligands and of structural probing of the receptor protein targets through mutagenesis and computational modeling. The protein structure of the first AR determined by X-ray crystallography also was closely estimated by the three-dimensional model predicted through homology modeling, including side chain orientations in the ligand-binding region (*38*).

BIOGENIC AMINE RECEPTOR LIGANDS AND ORIGINS OF THE FUNCTIONALIZED CONGENER APPROACH

In the late 1970s, Murray Goodman and co-workers at the University of California, San Diego, derivatized β-adrenergic receptor agonists and other biogenic amines for attachment to peptides as drug carriers (*3, 39*). Isoproterenol **10** (Figure 2) was the first analogue of a biogenic amine (norepinephrine **9**) successfully derivatized this way. A functionalized chain terminating in a carboxylic acid **11** was created as an extension of the *N*-isopropyl group of **10**. Unfortunately, the early experiments lacked a stereochemical control at the secondary carbon of the alkyl chain, which can have pharmacological consequences (*40*). These studies, a collaboration with Kenneth Melman at Stanford University, aimed to design drugs that could be attached to polypeptides for in vivo targeting (*40, 41*). The project grew out of a collaboration between Goodman and Nathan Kaplan at the University of California, San Diego, and his graduate student Craig Venter on immobilized drugs, which were later shown to be chemically heterogeneous (*41*).

While scrutinizing and modeling the chemistry of linkage of the catecholamines to peptides by means of small-molecule derivatives with elongated chains, Goodman and colleagues found β_2-adrenergic agonists that were superpotent. A *p*-trifluoromethylanilide derivative **12** (which was later resolved into four pure stereoisomers (*40*)) and a dipeptide conjugate **13** were significantly more potent than **10** at the β_2-adrenergic receptor. This potency enhancement was accomplished by manipulating the molecules at points distal from the pharmacophore (the business end). The pharmacological profile of the substances could be tuned without altering the pharmacophore moiety. The strategy of catecholamine derivatization depended on treating the hypothetical construct of β-adrenergic receptors as distinct molecular entities on the cell surface, which indeed they were shown to be, nearly a decade later (*20*).

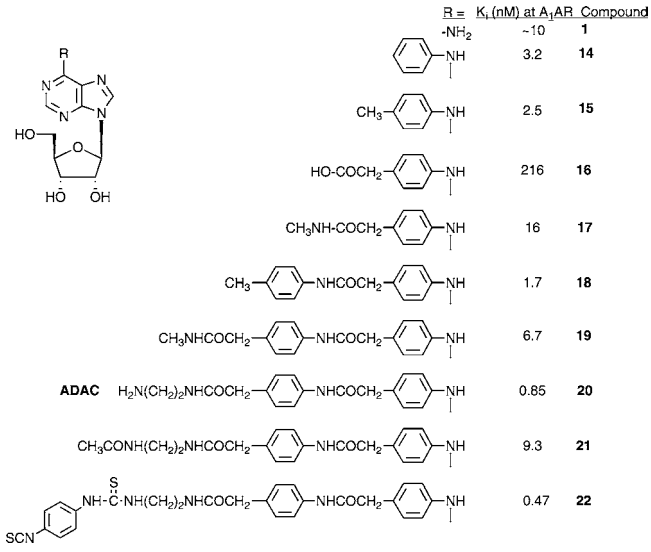

Figure 3. Stepwise derivatization of chain-functionalized adenosine derivatives designed to maintain and optimize rat A_1 AR receptor binding affinity. The N^6 position was most suitable as a derivatization site for functionalized congeners that selectively bound to and activated the A_1 AR. *N*-Aryl substitution at that site was favored over *N*-alkyl substitution. The structural elements of the chain were added in stepwise fashion, with affinity optimized at each step.

ADENOSINE AND P2Y RECEPTOR FUNCTIONALIZED CONGENERS

Extracellular adenosine **1** is involved in many of the body's cytoprotective functions through its actions at the four subtypes of ARs. For example, adenosine serves to precondition heart muscle against ischemia and toxicity by activation of the A_1 and A_3 ARs on the surface of cardiac myocytes (*42*). We showed that activation of the low-affinity A_{2B} AR by high concentrations of adenosine in the heart protects the muscle in the postreperfusion period (*43*). Adenosine counteracts the damaging effects of excitotoxicity and seizure activity in the central nervous system by activation of neuonal A_1 ARs, and it suppresses excessive immune and inflammatory responses by activation of the A_{2A} AR on immune cells. Selective agonist and antagonist ligands for all four of the AR subtypes are used as essential pharmacological probes. Selective ligands for the A_3 AR have therapeutic potential as anti-inflammatory (*44*), cardioprotective (*45, 46*), cerebroprotective (*47*), anticancer (*48*), and antiglaucoma (*49*) agents.

Functionalized congeners of ligands of the A_1 AR were first introduced in our laboratory in collaboration with John W. Daly (all of the National Institute of Diabetes & Digestive & Kidney Diseases), who was already exploring SAR at this receptor of simple derivatives of the agonist adenosine **1** and antagonist theophylline **3** (*2, 12*). In the agonist series, we hypothesized that the N^6-substituent had the greatest freedom of substitution; aryl and arylalkyl were the favored substitutions (*50*). Therefore, we incorporated functionalized chemical chains on an N^6-phenyl substituent in **14** and extended them in a stepwise fashion, optimizing affinity in binding to the rat brain A_1 AR at each stage (Figure 3).

It was evident that the substitution of the phenyl ring with electron-donating groups was conducive to high affinity.

However, it was not known whether the binding-site geometry within the receptor would accommodate a long extension of the chain. To answer this question, we expanded a *p*-methyl group in **15** into a carboxymethyl group to form **16** for attachment to larger moieties. Not only did amide derivatives at this position still bind to the A_1 AR, but aromatic amides (e.g., **18**) were clearly favored over aliphatic amides (e.g., **17**), suggesting that a distal region of the receptor-binding site was not sterically constrained and was hydrophobic and/or aromatic. The motif of p-substitution was continued with the attachment of an additional *p*-aminophenyl acetyl moiety, e.g., **19**.

The preferred terminal group at this stage of the chain extension was found to be a 2-aminoethylamido group in **20**, which was considerably more potent than a neutral amide in A_1 AR binding. This suggested that a distal negatively charged region exists on the receptor or in its vicinity. Thus, this prototypical adenosine amine congener **20** (ADAC) was used for additional derivatization, which indicated an essentially unlimited ability to elongate the carrier moiety (*2*). This suggested that the primary amino group of ADAC **20** protrudes out of the binding region for the adenosine pharmacophore, toward or into the extracellular medium, as shown in Figure 1A. Later, it was found that the charged residues in the extracellular regions of the ARs are predominantly anionic, which explained the observed affinity enhancement in positively charged functionalized congeners (*31, 32*). Acylation of **20** to form the neutral compound **21** somewhat reduced the potency of binding to the A_1 AR. Because an amino group in the chain enhances affinity at the ARs, we introduced a new functionalized congener **25**, which is related to ADAC but containing an extra amino group in the chain and also has favorable affinity at the human A_1 AR (Table 1). This secondary amine would remain free following coupling of the terminal primary amine to a carrier (*51*). Certain conjugates of ADAC with long chain fatty acids and other lipid derivatives displayed unusually high binding affinity at the A_1 AR, suggestive of distal anchoring of the hydrophobic chain in a lipid-rich environment surrounding the receptor (*137*).

Although the potency the rat A_1 AR was enhanced in this agonist series by the stepwise chain derivatization, the selectivity in comparison to the rat A_{2A} AR was not increased. The selectivities of N^6-phenyladenosine **14** and ADAC **20** were 200- and 250-fold, respectively.

A similar derivatization scheme was applied to xanthines, e.g., **26** and **27**, as AR antagonists (Table 1) (*52*). Curiously, as with adenosine, an attachment of a phenyl ring at the C8 position was highly favored in A_1 AR binding over aliphatic groups at that site. Chain extension with simple functionalized 8-alkyl chains greatly reduced AR-binding affinity. Thus, the 8-aryl ring is a specific recognition element for receptor binding and was therefore included in the functionalized congener series. The 1,3-dipropyl substitution of the methyl groups present in theophylline **3** was also included because it is known to enhance the A_1 AR affinity by 30- to 40-fold. Also, as in the N^6 position in the agonist series, the substitution of the 8-phenyl ring in the xanthine series with an electron-donating group was conducive to high affinity (*6, 53*). Thus, a methoxy substituent was elaborated into a carboxymethyloxy group for attachment to larger moieties through an amide linkage. This xanthine carboxylic congener **26** (XCC) and the elongated 2-aminoethylamide (xanthine amine congener, XAC **27**) overcame the biologically limiting low water solubility of the 8-arylxanthines noted previously (*12*).

As in the agonist series (Figure 3), the A_1 AR-preferred terminal group is an amine as in **27**, again suggesting that a distal negatively charged region exists on or near the receptor. As a systematic means of probing the effects of varied functionality at the distal end of the xanthine chain, amino acid conjugates of XAC such as **34** were prepared and analyzed in binding and functional assays (*6*). In general, a free amino group on a wide variety of amino acid conjugates, such as the diamine **34**, favored higher binding affinity at the A_1 AR, suggesting an electrostatic cause. The D-Lys conjugate **34** was intended for enhanced in vivo stability toward in the presence of peptidases through the pendant unnatural D-amino acid.

After the successes with the A_1 AR, we explored functionalized congeners of ligands of the A_{2A} AR, in collaboration with Gary L. Stiles (Figure 4) (*54*). In 1989, Michael Jarvis, Michael Williams, and co-workers reported the first potent A_{2A} AR-selective agonists (*55*). This group, which first reported CGS21680 **37** as an A_{2A} AR agonist, partnered with our lab to see if the functionalized congener approach could be extended to the A_{2A} AR. This resulted in a series of long-chain functionalized congeners of adenosine (more precisely, of its 5′-ethyluronamide derivative, NECA **36**) derivatized at the C2 position instead of the N^6 position. As with the A_1 AR, the chain was optimized in receptor binding at each stage of elongation. Consistent with the previous pattern, an amino terminal group was found to be beneficial for affinity at this receptor subtype.

The potent A_{2A} AR agonist CGS21680 **37** was condensed with an ethylenediamine unit to form APEC **39** (2-[[2-[4-[2-(2-aminoethyl)aminocarbonyl]ethyl]-phenyl]ethylamino]-5′-*N*-ethyl-carboxamidoadenosine), which became a prototypical amine functionalized congener with selectivity and higher affinity for the rat A_{2A} AR than for the rat A_1 AR. In Figure 1C, APEC is shown in its docked complex with the human A_{2A} AR, and its functionalized chain reaches the extracellular regions of the receptor. The A_{2A} AR, which induces vasodilitation to lower blood pressure, has been the subject of numerous biological investigations over several decades. It was not until a photoaffinity label selective for the A_{2A} AR derived from APEC was introduced that the molecular form of this receptor was proven to be distinct from the A_1 subtype (*56*). Compound **40**, which contains a *p*-aminophenylacetyl (PAPA) prosthetic group, could be radioiodinated on the aryl amine and then cross-linked to the receptor, either by conversion to the 4-azide or by chemical cross-linking with *N*-succinimidyl 6-(4′-azido-2′-nitrophenylamino)hexanoate (SANPAH). APEC itself is also useful for the study of behavioral effects, because it penetrates into brain better than its precursor carboxylic acid derivative (*57*).

8-Styrylxanthine derivatives that act as selective antagonists for the A_{2A} AR were also designed as functionalized congeners, e.g., the carboxylic acid derivative **44** (*58*). These 8-styrylxanthine derivatives include a 7-methyl group and could therefore be considered analogues of caffeine. Chain extension at the 7-alkyl position was not tolerated in receptor binding. Careful probing of the SAR identified the aryl ring of the styryl group as the most insenstitive site for functionalization in this series.

Selective ligands of the A_{2B} AR derived from functionalized congeners were recently reported. The same group that was used for xanthine antagonists of the A_{2B} AR (C8 substituted chain containing a 4-carbonylmethyloxy phenyl group) was introduced at the N^6 position in the agonist series (*59, 60*) resulting in A_{2B} AR selectivity.

Functionalized congeners of selective A_3 AR agonists were first studied in the ribose series, in which a functionalized chain extended from the 3 position of an N^6-benzyl group, e.g., **45**, where tolerance for steric bulk was discovered and quantified in a CoMFA (comparative molecular field analysis) model (*61*). Simple amino acid moieties could be coupled through a 3-aminobenzyl group with retention of moderate affinity. However, even at this position, which was somewhat removed from the nucleoside pharmacophore, we observed constraints

Table 1. Functionalized Congeners for ARs and P2Y Purine Receptors and Representative Conjugates

Structure	Conjugated to:	Name	Target Receptor and Function	Affinity K_i, nM (species)[a]	Ref.

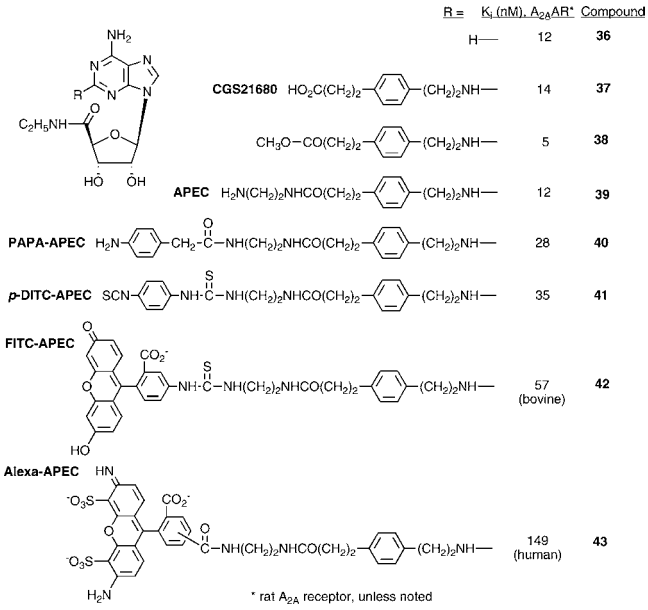

Figure 4. Stepwise derivatization of chain-functionalized adenosine derivatives that were designed to maintain and optimize A_{2A} AR receptor binding affinity. The adenine C2 position was most suitable as a derivatization site for functionalized congeners that selectively bound to and activated the A_{2A} AR. 2-Alkylamino substitution was selected as a favorable linkage based on previous SAR and further structural probing.

on the amount of steric bulk tolerated in A_3 receptor binding. Only a β-alanyl conjugate **45** was relatively unimpaired in binding. Later, we modified the linking chemistry for similar A_3 AR agonists to include a 3-alkynylbenzyl group of linear geometry, e.g., **46**, which better preserved nanomolar affinity (*46*).

Functionalized congeners were also reported for a series of selective A_3 AR agonists consisting of 5′-*N*-methylcarboxamidoadenosine analogues containing the (*N*)-methanocarba (bicyclo[3.1.0]hexane) ring system as a ribose substitute, e.g., **47** amd **48** (*62*). The rigid bicyclic ring system in this class of agonists provided a steric constraint of the riboselike moiety to enhance A_3 AR selectivity. Functionalized ethynyl chains terminating in amino or carboxylate groups were incorporated at both the N^6 and C2 positions and effects on affinity compared. Substitution at the C2 position of the purine moiety in the (*N*)-methanocarba series, e.g., **48**, preserved A_3 AR selectivity more effectively than similar chains attached at the 3 position of the N^6-benzyl group, e.g., **47**.

We also applied the functionalized congener approach to antagonists of the A_3 AR (*63*). 1,4-Dihydropyridine (DHP) derivatives containing 4-phenylethynyl and 6-phenyl groups are high-affinity antagonists at this receptor. We probed various sites of chain substitution on these DHPs to identify the least-sensitive position in receptor binding. Such functionalization of the 4-arylalkynyl moiety was not tolerated in A_3 AR binding. A para-substituted *O*-benzyl ester group at either the 3 or 5 position of the DHP was suitable for the attachment of a functionalized chain, which could then be linked to prosthetic groups. An amine derivative of a 3-benzyl ester **49** was conjugated to biotin to provide **50**.

MACROMOLECULAR CONJUGATES OF AR LIGANDS

At the time ADAC **20** and XAC **27** were first reported, little was known of the physical or chemical nature of the A_1 AR or of any GPCR. The structural similarity to rhodopsin was not yet evident. Thus, the functionalized congener approach served as a means of "blindly" exploring the solvent accessibility and environment of the hypothesized binding site for the pharmacophore. An early study by Ray Olsson and co-workers, in which adenosine agonists were coupled to polymeric carbohydrates (oxidized stachyose) with the retention of vasodilatory activity, led to the conclusion that the AR was located on the cell surface (*64*). More chemically well-defined, biologically active macromolecular conjugates were needed, and the functionalized congener approach proved useful for this purpose. The types of conjugates used in this effort are now more sophisticated. For example, dendrimers have recently been used as macromolecular carriers of AR functionalized congeners.

The ability to substitute ADAC **20** with a macromolecular carrier was first demonstrated through the biotin−avidin system (*65*−*67*). Acylation of **20** with biotin or with various chain-elongated derivatives of biotin provided conjugates **54** and **55**, which retained a relatively high affinity at the A_1 AR (Figure 5). Precomplexation of these ADAC−biotin conjugates with the tetrameric protein avidin of molecular weight ~68 000 Da only slightly reduced the receptor affinity. This clearly indicated that the steric constraints of the pharmacophore-binding site were entirely overcome. Thus, this functionalized chain must protrude toward the exofacial side of the receptor. The sequential elongation of the chain connecting biotin to the adenosine moiety allowed a crude estimation of the depth of the binding site, i.e., a "dipstick" approach to exploring the binding site. This calculation was based on the extended conformation of the shortest chain to be unimpaired in its ability to bridge the pharmacophore and the macromolecular carrier, i.e., avidin. By this method, the depth of the binding site of adenosine was estimated to be $\leq$12 Å. Later, molecular modeling of the receptor confirmed that this was a reasonable approximation. We used a similar method to conjugate the A_{2A} AR agonist APEC to biotin to provide **56**. Xanthine biotin conjugates **57**−**60**, when complexed to avidin, required a longer chain length to achieve moderate A_1 AR-binding affinity.

DUAL-ACTING LIGANDS: BINARY DRUGS

We designed ligands to interact equipotently with multiple subtypes of GPCRs, whether by tethering two components or by either fusing or merging favorable structures to create a dual selectivity in a single functional unit (*68*). Successes in the design of multiple ligands were recently reviewed by Morphy and Rankovic (*9*). One of the first examples of tethering two pharmacophoric units was reported by Portoghese and co-workers; this was achieved with the opioid system, in which ligands for either the same or different GPCRs were covalently coupled through flexible chains (*8*). The objective of tethering two GPCR ligands is to achieve a synergistic, net biological effect of activation or antagonism of multiple pathways (*46*) and potentially to bridge GPCR dimers (Figure 2C) (*8*, *69*, *70*). An approach to designing dual-acting ligands (termed binary drugs) derived from functionalized congeners was reported in 1987 (Figure 6) (*71*).

A functionalized congener antagonist of the A_1 AR, the 1,3-dialkylxanthine derivative XAC **27** (Table 1), was attached through an L-Lys linker to a segment derived from the neurotransmitter peptide substance P (SP) to form binary drug **61** (Figure 6A). The Lys linker preserved a free amino group in the spacer chain, which increased A_1 AR affinity and solubility. This binary conjugate bound to the rat A_1 receptor with a K_i value of 35 nM and to the NK1 (neurokinin type 1) receptor with a K_i value of 300 nM (*71*). Coupling of the functionalized adenosine agonist N^6-[4-(carboxymethyl)phenyl]-adenosine **16** (Figure 2A) to an SP C-terminal peptide also resulted in a binary drug **62** that bound to both receptors. The

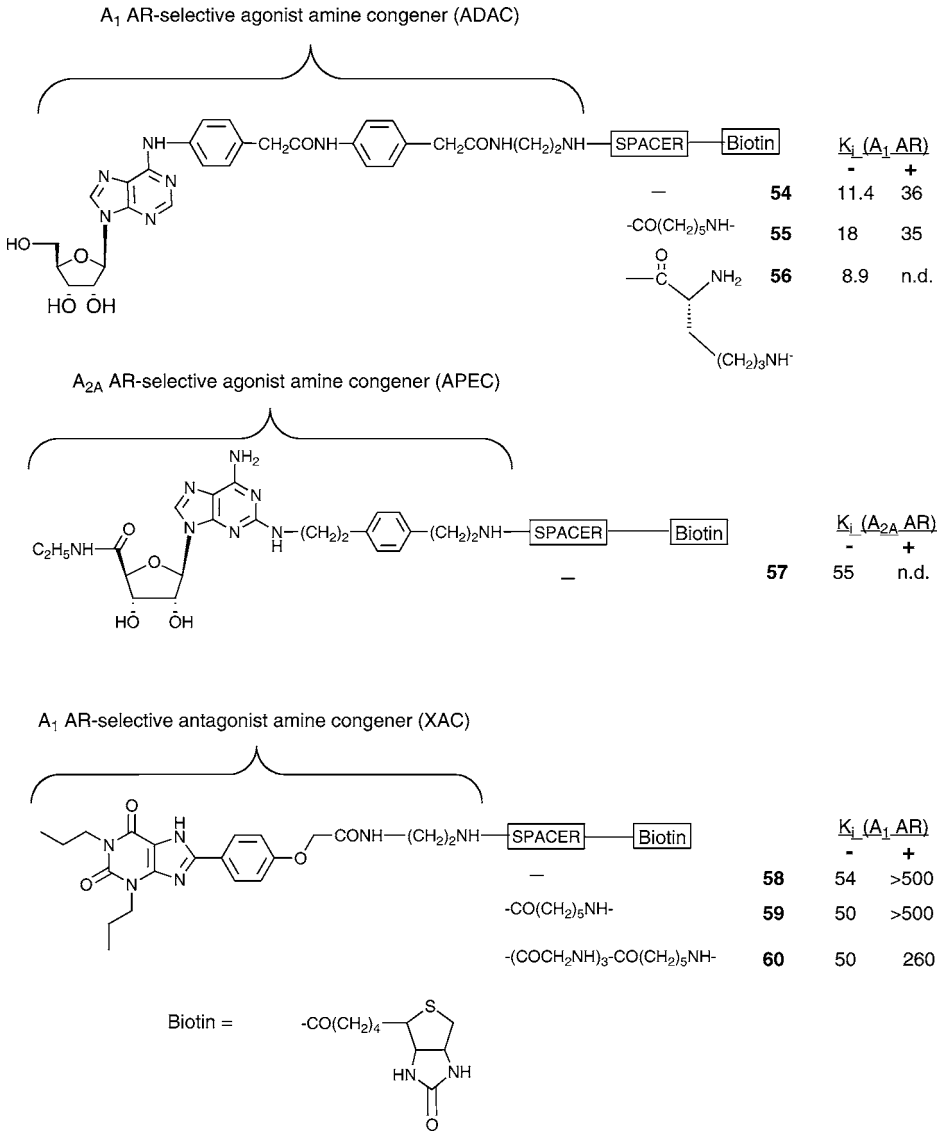

Figure 5. Use of biotin−avidin methodology to detect and characterize the A_1 AR (using agonist ADAC and antagonist XAC) and the A_{2A} AR (using agonist APEC). In several cases, the length and chemical fiunctionality of the spacer chain were varied to find the optimal receptor affinity of the biotin conjugate, both alone and as its avidin complex. K_i values (nM) at one of the rat ARs in the absence (−) and presence (+) of excess avidin are given. N.D. − not determined.

demonstration that the biochemical properties of two unrelated drugs, both of which act through binding at extracellular receptors, may be combined in the same molecule suggested a novel strategy for drug design. In principle, two different substances that produce the same final effect (e.g., hypotension by adenosine agonists and by SP analogues) should produce a combined effect. Adenosine analogues have analgesic properties, and the binary drugs derived from SP and adenosine agonists or antagonists were intended to serve as ligand tools for probing interrelationships of NK pathways and sites for the antinociceptive action of adenosine.

Considering the antinociceptive properties of AR ligands, we also sought to combine such ligands with opioid receptor agonists. Thus, nonpeptide ligands of the opioid receptors were conjugated to AR ligands, resulting in conjugates that retain affinity for both the A_1 AR and the μ-opioid receptor (Figure 6B) (*72*). We probed three structural classes of opioids, derivatives of tetrahydrooripavine, etonitazine, and fentanyl, for sites of functionalization for chain attachment. An amino group on the 7-*a* position of 6,14-endoethenotetrahydrooripavine was suitable for derivatization with long-chain substituents, such as Cbz-glycyl-glycine, without loss of affinity for the μ-opioid receptor. A binary conjugate of this tetrahydrooripavine with an alkylxanthine moiety **63** had morphinelike activity in the paraphenylquinone in vivo assay. Thiourea-linked conjugates of a benzimidazole derivative that was a potent opioid ligand and an AR functionalized congener, either ADAC **20** or XAC **27**, bound effectively to both receptors. For example, the ADAC conjugate **64** bound to the rat A_1 receptor with a K_i value of 31 nM and to the rat μ-opioid receptor with a K_i value of 150 nM.

Binary drugs that activate two subtypes of ARs have been proposed for cardioprotection (Figure 6C) (*73*). Adenosine released during cardiac ischemia exerts a potent, protective effect in the heart via activation of A_1 and A_3 receptors (*42, 45, 74*), which activate separate protective signaling cascades. To explore the interaction between these two cardioprotective ARs and the question of which receptor is the more important anti-ischemic receptor, we designed specialized binary ligands by tethering functionalized congeners. One objective was to use this ligand tool to test the hypothesis that activation of both receptors exerts a cardioprotective effect significantly greater than activation of either receptor individually. We used a novel design in which new binary conjugates of adenosine functionalized congeners that were pharmacologically complementary were synthesized

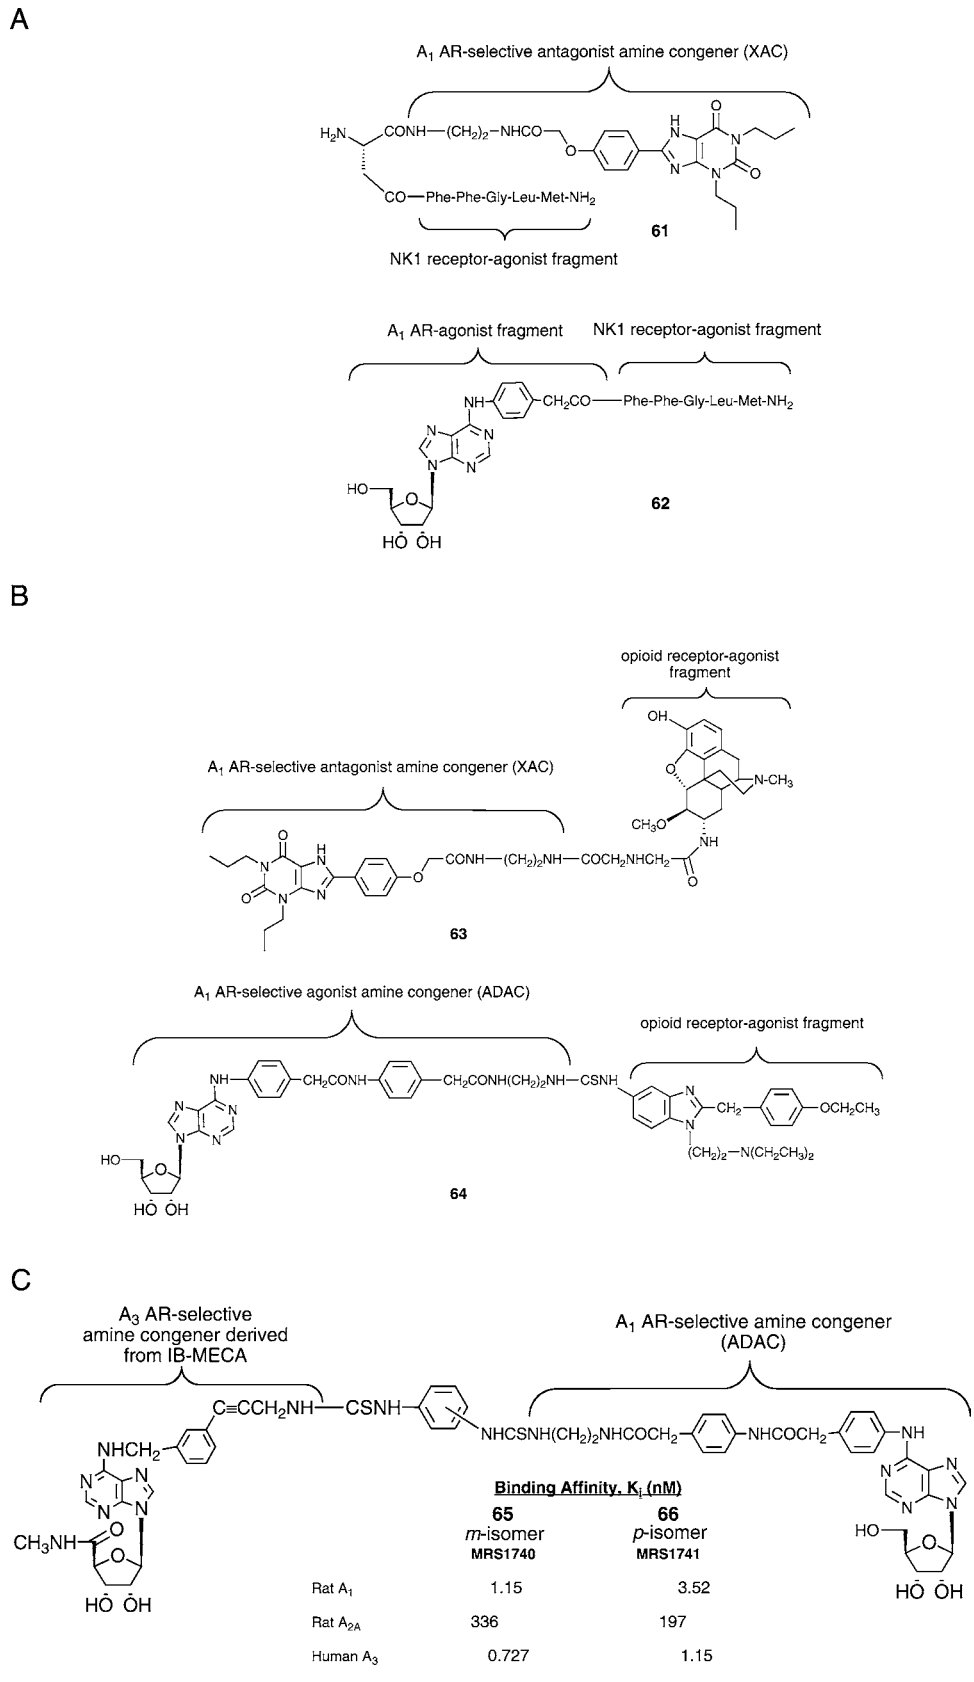

Figure 6. Binary drugs for a given AR in covalent combination with ligands for another GPCR. (A) Combination of A_1 AR-binding purines and substance P peptides as NK1 receptor ligands; (B) Combination of A_1 AR-binding purines and nonpeptide opioid receptor ligands; (C) Combination of agonist ligands for A_1 and A_3 ARs, which have cardioprotective properties. High-affinity binding to the A_{2A} AR remains excluded by this linking approach.

and tested in a novel cardiac myocyte model of adenosine-elicited cardioprotection.

Binary drugs with mixed selectivity for both A_1 and A_3 ARs were created through the covalent linking of functionalized

congeners of adenosine agonists, each of which is selective for either the A_1 or the A_3 AR subtype. MRS 1740 **65** and MRS 1741 **66**, thiourea-linked regioisomers of a binary conjugate, were highly potent and selective in radioligand-binding assays for the A_1 and A_3 ARs (K_i values of 0.7−3.5 nM) compared with the A_{2A} AR. The myocyte models used cultured myocardial muscle cells from chick embryo, either ventricular cells expressing native adenosine A_1 and A_3 ARs or engineered atrial cells, expressing either human A_3 receptors alone or both human A_1 and A_3 receptors. The binary agonist **66** activated both A_1 and A_3 receptors simultaneously, with full cardioprotection (EC_{50} ~0.1 nM) dependent on the expression of both receptors. Thus, coactivation of both adenosine A_1 and A_3 receptors by the binary A_1/A_3 agonists represents a novel general cardioprotective approach for the treatment of myocardial ischemia.

Scammells et al. recently reported bivalent conjugates of ligands of β2-adrenergic and adenosine A_1 receptors that activated both receptors and exploited crosstalk between these receptors (*75*). The N^6 position of adenosine was used as the site for chain derivatization. Hexyl and butyl-linked variations in the connecting chain were compared. The hexyl-linked conjugate displayed K_i values of 436 and 311 nM at A_1 and β2 receptors, respectively, and was even more potent in activation of the β2-adrenergic receptor with an EC_{50} of 6 nM.

IRREVERSIBLY BINDING AR LIGANDS FOR RECEPTOR INACTIVATION AND CROSS-LINKING

In collaboration with Gary Stiles and Mark Olah, then at Duke University, we coupled AR functionalized congeners in both the A_1 agonist and A_1 antagonist series to a variety of bifunctional cross-linking reagents present in excess to achieve a 1:1 stoichiometry in the product, thus leaving one chemically reactive group (*76*, *83*). These cross-linking reagents were typically symmetrical amine-reactive electrophiles. For example, 1,3- and 1,4-phenylene diisothiocyanates were conjugated to amine congeners that were potent and selective A_1 AR ligands. The resulting reactive conjugates, i.e., the A_1 AR agonist *p*-DITC-ADAC **22** (Figure 2) and the A_1 AR antagonist *p*-DITC-XAC **28** (Table 1), effectively and irreversibly bound to the A_1 AR at very low concentrations (10 nM to 1 μM) (*77*).

We coupled radiolabeled bifunctional reagents designed for photoaffinity labeling to the same amine congeners. One example of such a cross-linking group is the PAPA moiety, as in **30** and **40**, which was readily iodinated and then converted to the photoactivatable *p*-azide (*78*). Thus, XAC (available in its [^{3}H] form) served as the first high-affinity radiolabeled adenosine antagonist suitable for chemical or photochemical affinity cross-linking to the A_1 AR protein. This photoaffinity probe labeled the same receptor protein to which A_1 selective agonists bind, as indicated by molecular weight determined by gel electrophoresis. A comparison of proteolytic digests of agonist- and antagonist-occupied receptor proteins identified fragments formed at cleavage sites, which differ in accessibility. In addition to the electrophilic isothiocyanate group, the sulfonyl fluoride group was also effective for ligand cross-linking to the ARs because of its reactivity with nucleophiles on proteins with a sufficient aqueous stability (*79, 80*).

We also used chemically reactive bifunctional cross-linkers to prepare affinity labels from amine functionalized congeners for A_{2A} AR agonists. We found that *p*-DITC-APEC (2-[[2-[4-[2-[2-[(4-isothiocyanatophenyl)aminothiocarbonylamino]ethyl]-aminocarbonyl]-ethyl]phenyl]ethylamino]-5′-*N*-ethyl-carboxamidoadenosine) **41** effectively and irreversibly bound to the A_{2A} AR at very low concentrations (~10 nM) (*81*). Curiously, when this derivative was infused into the coronary artery of guinea pigs, there was a prolonged A_{2A} AR activation that could not be reversed by washing, leading to sustained vasodilitation.

We introduced trifunctional probes by simultaneously cross-linking a GPCR functionalized congener with a reporter group and a chemically reactive group, through a central symmetrically trisubstituted aryl unit (Figure 7) (*82, 83*). To further extend the use of isothiocyanates to covalently cross-link high-affinity ligands to the ARs, we prepared a series of analogues of *m*-DITC-XAC containing a third substituent in the phenyl isothiocyanate ring. Thus, the central aryl linker could consist of 1,3,5-triisothiocyanatobenzene (**67**, R = 5-NCS), although we also prepared some variants of conjugates containing 1,3,5-trichlorotriazine as a central aryl linker. This third substituent (R of **67**), when appropriately derivatized, modifed the physiochemical or spectroscopic properties of the conjugate. Thus, an amine congener reacted with a symmetrical trifunctional cross-linking intermediate bearing two isothiocyanate groups, which already contained a third substituent. We were thus able to synthesize derivatives of XAC containing hydrophilic, fluorescent, or reactive substituents, linked via an amide, thiourea, or methylene group in the 5 position of the central aryl ring, and found them to be irreversible inhibitors of the A_1 AR.

We examined the effects of modifying the 5-substituent on water solubility and on affinity. A conjugate of XAC and 1,3,5-triisothiocyanato-benzene, i.e., a trifunctional ligand intermediate (**68**, R = NCS), was 894-fold selective in binding to the rat A_1 AR. Reporter groups, such as fluorescent dyes and a spin label, were included as substituents in the third position of irreversibly binding analogues, which were designed for spectroscopic assays, histochemical characterization, and biochemical characterization of the receptor protein. We also designed and synthesized trifunctional ligands for the A_1 AR that contain a cleavable disulfide linkage in the chain, for chemically induced regeneration of the receptor-binding site for the purine by reduction of the disulfide (*82*).

RADIOACTIVE PROBES

Because functionalized congeners are used as a modular approach to ligand design, it is feasible to couple these derivatized pharmacophores to prosthetic groups for radiolabeling. For example, we used the active ester intermediate for the Bolton-Hunter reagent, *N*-succinimidyl-3-(4-hydroxy-phenyl)propionate, to incorporate a group for radioiodination both in simple functionalized congeners and in our trifunctional A_1 AR antagonists (Figure 7B) (*83*). The resulting conjugate covalently labeled the receptor protein, which was readily detectable on a Western blot.

We also introduced other novel prosthetic groups for radiolabeling. We selected a prosthetic group for radiofluorination by the ease of replacement of benzyl bromides with nucleophilic ^{18}F-fluoride and applied it to derivatization of insulin for imaging of insulin receptors (*84*). Other groups are now used for incorporating ^{18}F into peptides because of the in vivo lability of benzyl fluorides (*85*). Chelating groups capable of complexing radioactive metal ions were coupled to amine-functionalized congeners, e.g., **33**, with the retention of moderate affinity at the A_1 AR (Table 1) (*4*).

IMMOBILIZED AR LIGANDS FOR AFFINITY CHROMATOGRAPHY TO ISOLATE THE RECEPTOR PROTEIN

Amine functionalized congeners of AR agonists and antagonists have been used as immobilized high-affinity ligands for both A_1 and A_{2A} receptors, for the purpose of affinity chromatography leading to the isolation of the receptors and purification to homogeneity (*86*−*88*). For example, XAC was immobilized on a Sephadex column for isolation of the bovine A_1 receptor and for the isolation of the recombinant human A_{2A} receptor

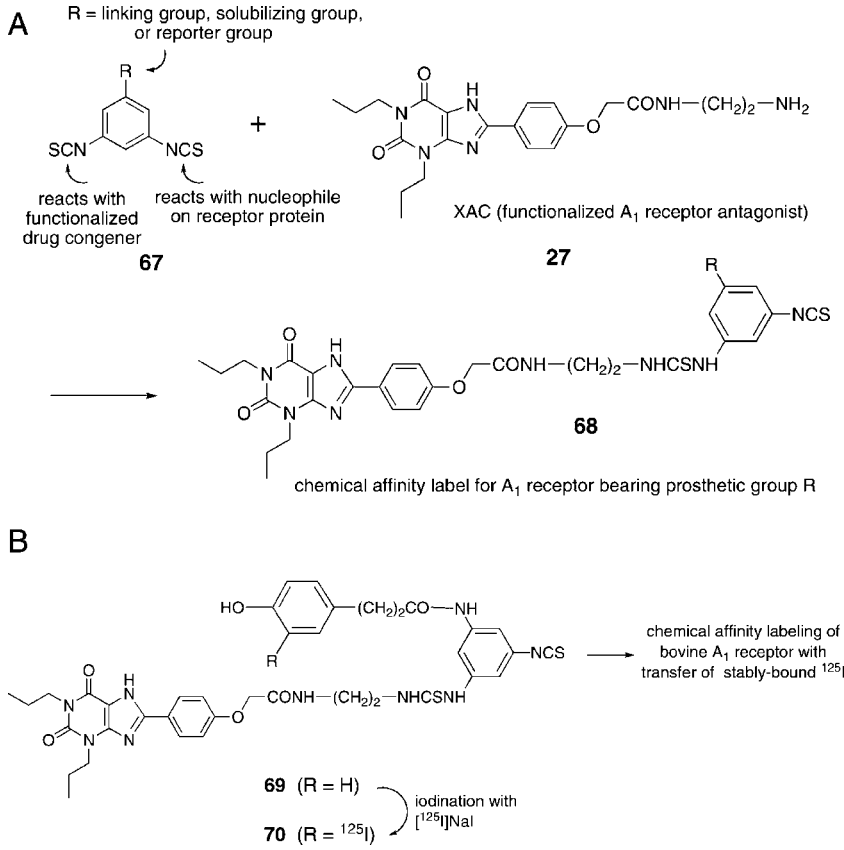

Figure 7. Trifunctional reagents for covalent binding to ARs. (A) General scheme for using a high affinity antagonist (XAC) to target a prosthetic group to the A_1 AR, at which it will bind covalently by virtues of the electrophilic isothiocyanate group, and (B) Application of this scheme to a prosthetic reporter group for radioiodination.

expressed in *E. coli*. The use of the agonist N^6-(4-aminobenzyl)adenosine for affinity chromatography allowed the isolation of the A_1 AR along with its associated G protein (*89*).

FUNCTIONALIZED AR LIGANDS AS SPECTROSCOPIC PROBES

Fluorescent probes of high affinity for GPCRs are being explored as an alternative to the use of radioligands in binding assays and histochemical studies (*90*). Fluorescent conjugates of both small-molecule ligands (*91*, *92*) and peptide ligands (*93*) of GPCRs have been used. A fluorescent-labeled naloxone has been used in confocal scanning laser microscopy to demonstrate specific binding to the μ-opioid receptor (*92*). Moreover, more detailed information about the binding site and its microenvironment can be obtained from fluorescent ligands than from radioisotopes. For example, flow cytometry analysis and confocal laser-scanning microscopy of living cells showed that a fluorescent BODIPY (6-(((4,4-difluoro-5-(2-thienyl)-4-bora-3*a*,4*a*-diaza-*s*-indacene-3-yl)styryloxy)acetyl)aminohexanoic acid) derivative of prazosin labels not only α1-adrenergic receptors on the cell surface, but also those localized inside the cell (*94*).

A conjugate of fluorescein isothiocyanate (FITC) with the amine functionalized congener APEC, which was a A_{2A} AR-selective agonist, has proven useful as an alternative to radioligands in receptor assays (*95*). FITC-APEC **42** was of suitably high affinity for use in the quantitative characterization of ligand binding to the bovine A_{2A} AR. Fluorescence measurements provided a B_{max} value of 2.3 $\pm$ 0.3 pmol/mg protein and K_D value of 57 $\pm$ 2 nM. This observed specific binding was saturable and rapid in its rates of association and dissociation, and the parameters were comparable to those obtained in competition studies that used a tritiated agonist radioligand at the same receptor. The potencies of chemically diverse A_{2A} AR ligands (and control compounds of low AR affinity), estimated by inhibition of FITC-APEC binding, were also in good agreement with their potencies determined by radioligand-binding techniques. Schulte and co-workers characterized another fluorescent conjugate **43** of APEC, in which the fluorescent moiety consisted of Alexafluor488; they were able to follow internalization into cells (Table 1) (*96*). Various other fluorescent derivatives have been prepared for the ARs through derivatization at sites on known ligands that are insensitive in receptor binding and are used for fluorescence correlation spectroscopy and other detection techniques (*4*, *7*, *51*, *97*−*99*). Hill and colleagues have prepared and characterized such fluorescent probes of the ARs, including a fluorescent derivative of XAC **35** (*7*).

We and others have reported spin label probes and highly fluorinated analogues derived from ADAC and XAC and other purine AR ligands obtained by a similar attachment method (*4*, *100*). For example, XAC was conjugated to the TEMPO moiety to yield **31**, which contains a nitroxyl radical, with the retention of high A_1 AR affinity (*4*). Compound **32** contained a perfluorinated acyl prosthetic group. The intended use of these analogues was receptor characterization by electron spin resonance (ESR) spectroscopy and fluorine-NMR, respectively (*101*, *102*).

FUNCTIONALIZED CONGENERS OF P2Y NUCLEOTIDE RECEPTOR LIGANDS

Although ARs constitute a mature field of medicinal chemistry, the P2Y nucleotide receptors are in the early stages of ligand development (*29*). The currently defined eight subtypes of P2Y receptors fall into two structural and functional clusters

of sequences (in general, low homology among subtypes), ligand preference, second messengers, and receptor sequence analysis (*103*). The distribution of P2Y receptors is broad, and the therapeutic interests include antithrombotic therapy, modulation of the immune system, cardiac ischemia, neurodegeneration, diabetes, and treatment of cystic fibrosis and other pulmonary diseases (*29, 104*−*107*).

$P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, and $P2Y_{11}$ receptor subtypes belong to a structurally distinct cluster of P2Y receptor sequences and couple through $G\alpha_q$ to activate phospholipase C. The remaining three subtypes, $P2Y_{12}$, $P2Y_{13}$, and $P2Y_{14}$ receptors, couple via $G\alpha_i$ to inhibit adenylate cyclase. $P2Y_{12}$ receptors stimulate an important proaggregatory signal in platelets, $P2Y_{13}$ receptors occur in immunocytes and neuronal cells, and the $P2Y_{14}$ receptor that is found in dendritic cells is activated by UDP-glucose **8**. $P2Y_1$, $P2Y_2$, and $P2Y_{11}$−$P2Y_{13}$ receptors are activated by adenine nucleotides, and $P2Y_2$, $P2Y_4$, $P2Y_6$, and $P2Y_{14}$ receptors are activated by uracil nucleotides. Pharmacological antagonism of the $P2Y_{12}$ receptor is widely used for antiplatelet therapy. We showed that a $P2Y_1$ antagonist can serve as an antithrombotic agent (*104*). Other potential therapeutic approaches, involving other P2Y subtypes, have been aided by the availability of recently introduced pharmacological probes.

A variety of factors have tended to confound the pharmacological characterization of both native and recombinant P2Y receptors. These include the dependence of P2Y receptor classification on the use of unstable nucleotides as agonists and a lack of potent, selective, and bioavailable antagonists. In addition to a lack of selectivity for the different P2Y receptors, commonly used P2Y receptor agonists (and their metabolite nucleosides) and antagonists often have the potential to interact with other biological targets. Thus, new P2Y receptor ligands of clearly defined selectivity, chemical and biological stability, and bioavailability are needed. P2Y receptor ligands that would pass the blood−brain barrier when administered peripherally are desperately needed by neuroscientists to study the role of these receptors in the central nervous system.

We have explored functionalized congeners of $P2Y_1$ receptor agonists (*108*). A functionalized chain was attached at the adenine C2 position of ATP derivatives. This design feature was based on the SAR of $P2Y_1$ receptor agonists, which indicates high potency of 2-thioethers compared with 2-amino or 2-oxo derivatives (*109, 110*). A tolerance for long extensions of this chain was found, by contrast to chain extension at the N^6 position of ATP, which eliminates $P2Y_1$ receptor recognition. Thus, in the putative binding site of the $P2Y_1$ receptor, only small hydrophobic groups in the N^6-region are tolerated; the C2 region has much less restricted tolerance of steric bulk. For example, N^6-(2-phenylethyl)-ATP was inactive at the $P2Y_1$ receptor; 2-(2-phenylethyl)thio ethers of ATP, such as **51**, were highly potent (*33, 108*). A biotinylated nucleotide analogue potentially suitable for specific $P2Y_1$ receptor isolation was reported (*111*). A functionalized chain was attached as a 2-thioether in this agonist series.

We employed $P2Y_1$ receptor nucleotide antagonists that display similar SAR to the agonist series in a functionalized congener approach. The high-affinity $P2Y_1$ receptor antagonist MRS2500, a 3′,5′-bisphosphate derivative that contains an (*N*)-methanocarba ring system as a 2′-deoxyribose substitute, was subjected to the functionalized congener approach. MRS2500 was effective in reducing thrombus formation in vivo, and it is more resistant to degradation than the related 9-riboside derivatives (*104*). Although the substitution in this family at other positions decreases antagonist potency at the $P2Y_1$ receptor, a 2-alkynyl substitution of the adenine ring maintains antagonist potency. We have extended our search for antagonists of the $P2Y_1$ receptor by modifying the adenine 2 position with various long-chain alkynyl subtituents that retain receptor affinity (*112*). Congener **52** was one such carboxylic acid derivative that was a potent $P2Y_1$ receptor antagonist (Table 1).

We prepared functionalized congeners of $P2Y_{14}$ receptor agonists that retain biological activity (*113*). The most insensitive site for derivatization on the native ligand **8** is through the glucose moiety. In fact, the 6-carboxylate of UDP-glucuronic acid was found to be suitable for chain derivatization, e.g., by amide coupling to an *N*-acetyl-ethylenediamino group to form **53**.

FUNCTIONALIZED CONGENERS OF LIGANDS FOR OTHER GPCRs AND NON-G PROTEIN COUPLED RECEPTORS

Functionalized congeners of ligands for other GPCRs and non-G protein coupled receptors have been reported. This review includes a few representative studies on chain attachment and tethering of GPCR and non-GPCR ligands.

Portoghese and colleagues reported novel bivalent ligands for opioid and other receptors. Separate pharmacophores representing a δ-antagonist and a κ-agonist were tethered and found to bridge δ 2 and κ1 opioid receptors (*114*). These heterodimeric conjugates contained the δ-antagonist naltrindole and the κ-agonist ICI-199,441 tethered by oligoglycine linkers of variable length. Novel tethered bivalent ligands for two different classes of GPCRs were found to induce the direct association of μ-opioid and CCK_2 (cholecystokinin) receptors (*115*). These bivalent ligands appear to induce the association of these two divergent GPCR subtypes.

In our studies of biogenic amine neurotransmitter receptors, we explored muscarinic acetylcholine receptor agonists (Figure 8A) and antagonists with a functionalized congener approach (*116*−*118*). We first used a chain extension method for muscarinic antagonists with the known antagonist pirenzepine **71** (*117*) and then extended our investigation to the more potent and selective M1 receptor antagonist telenzepine **73** (Figure 8B) (*118*). Sites for chain derivatization were compared, and the attachment of a spacer chain to a distal piperazinyl nitrogen, common to both antagonists, was the generally insensitive site. We varied the chain at this position in the pirenzepine series **72** was varied and compared the binding affinities. We observed a progressive increase in affinity in the longer members of the series (6 or more methylenes). We applied the findings to the telenzepine series, and a derivative containing a 10-aminodecyl group (TAC, telenzepine amine congener, analogous to **72e** but in the telenzepine series) was highly potent in receptor-binding affinity and provided a nucleophilic functionality for further derivatization. The K_i value of TAC was 2.39 nM at the recombinant m1 receptor and 15.8 nM for the corresponding pirenzepine derivative.

We synthesized conjugates of TAC to contain prosthetic groups for radioiodination, protein cross-linking, photoaffinity labeling, and fluorescent labeling and biotin for avidin complexation. A *p*-aminophenyacetyl derivative for radioiodination and photoaffinity labeling had a K_i value of 0.29 nM at rat forebrain M1 muscarinic receptors; by contrast, the K_i value for telenzepine was 4.7 nM). A biotin conjugate displayed a K_i value of 0.60 nM at cardiac M2-receptors and a 5-fold selectivity for M2 compared with the M1 receptor. The high affinity of these derivatives makes them suitable for the characterization of muscarinic receptors in pharmacological and spectroscopic studies, for peptide mapping, and for histochemical studies.

The telenzepine amine congener TAC has been used as the functionalized pharmacophore in other fluorescent probes of

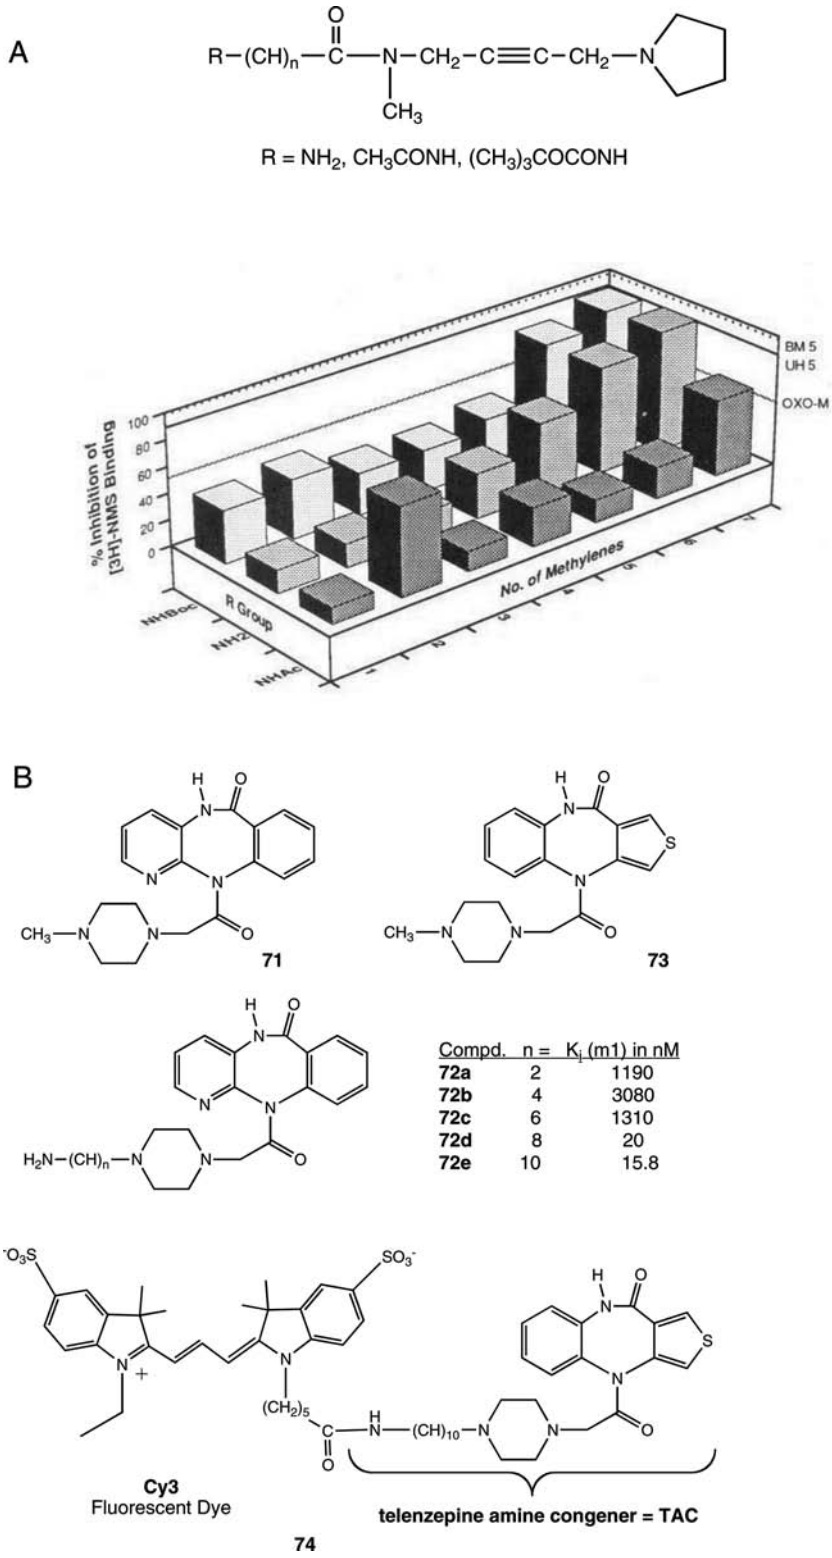

Figure 8. Functionalized congeners of ligands of the muscarinic acetylcholine receptors. (A) Dependence of the inhibition of radioligand binding at the m3 receptor (SK-N-SH cell membranes) on the chain length and terminal chemical functionality in the agonist series of butynyl amides (*116*). The levels corresponding to inhibition by the pharmacological standards oxotremorine-M, *N*-methyl-*N*-[4-[1-(pyrrolidinyl)]-2-butynyl]acetamide (UH5), and *N*-methyl-*N*-(1-methyl-4-pyrrolidino-2-butynyl)-acetamide (BM5) are shown (reproduced from ref (*138*), copyright 1990 Springer Science and Business Media). (B) Muscarinic antagonists and their amine fucntionalized congeners (affinity of **72** shown at the recombinant rat m1 receptor expressed in A9L cells). Use of a functionalized congener of the muscarinic antagonist telenzepine to provide a high affinity fluorescent tracer (*119*).

muscarinic receptors. For example, this approach recently resulted in a high-throughput screening method that uses live cells, made possible by the high-affinity fluorescent conjugate **74** of TAC with the cyanine dye Cy3B (*119*). The same fluorescent ligand was used recently by Birdsall et al. for single-molecule fluorescent imaging of muscarinic receptors (*120*).

Fluorescent pirenzepine analogues labeled with BODIPY were synthesized for studying fluorescence resonance energy transfer between the antagonist ligand and muscarinic M1 receptors that were fused to enhanced green fluorescent protein (*121*). Attachment of the fluorophore in these pirenzepine derivatives occurred through a functionalized chain at the

4-piperazine position. It appears that these analogues bridge the putative binding sites of the agonist acetylcholine and an allosteric modulator brucine.

A variety of other GPCRs have been studied using chain functionalization of small molecular ligands. For example, naltrexamine and 5′-guanidinonaltrindole have been linked through a polyamide spacer to form KDN-21, which is designed for interaction with heterodimeric delta-kappa opioid receptors (*122*). Numerous other examples of linkage of GPCR pharmacophores for the simultaneous activation of heteromeric receptors (*123, 124*) or homomeric receptors (*125, 126*) have been described. Symmetric bivalent ligands have been described for serotonin and for dopamine receptors (*125*), muscarinic acetylcholine receptors (*126*), and for melatoninergic receptors (*127*). Dual-acting drugs for activation of multiple receptors, even if not targeting GPCR dimers, have become important in drug development, for example, the antipsychotic agent ziprasidone was designed with separate pharmacophores to antagonize both the D2 dopamine receptor and the 5-HT_2 serotonin receptors (*128*). Combined ligands for the H1 histamine receptor and the 5-HT_2 serotonin receptors have been studied (*129*).

Although GPCRs are a major focus of studies of functionalized congeners, application to other classes of cell surface receptors and even nuclear hormone receptors is feasible (*130*). One of the earliest applications of a chain attachment approach to the study of receptors was carried out by Kosower and colleagues (*131*). Biologically active barbital and amphetamine derivatives were appended with an alkyl chain that terminated in a chemically reactive moiety, such as a thiol-reactive maleimide, designed for covalent bonding to the biopolymer with which these drugs interacted. The main mechanism of action of barbiturates is now known to be through the $GABA_A$ receptor chloride channel complex.

Antagonists of the $P2X_7$ receptor, an ATP-gated ion channel, have also been reported. We functionalized modified tyrosyl derivatives that block the action of adenine nucleotides at the $P2X_7$ receptor with extended chains at various positions (*132*). We observed only moderate antagonistic potency for these derivatives.

MULTIVALENT NANOCARRIERS FOR AR FUNCTIONALIZED CONGENERS

We are using the multivalency of dendrimer conjugates to test for interaction with dimeric and higher-order multimeric GPCR assemblies, as have been detected (*133*). Kim et al. recently reported the first poly(amidoamine) (PAMAM) dendrimer to which a functionalized congeners of a GPCR ligand was covalently attached (*134*). Specifically, 31 moieties of the A_{2A} AR agonist CGS21680 **37** were coupled to a G3 (3rd generation) PAMAM polyamine. This conjugate acted as a potent A_{2A} AR agonist and displayed characteristic antithrombotic activity. With multivalency of ligand substitution—e.g., 31 out of 32 possible substitutions on a G3 PAMAM dendrimer, of varying relative orientation—there could be a greater likelihood of bridging GPCR dimers than by tethering only two pharmacophores. We are expanding the application of nanotechnology to the study of GPCRs, for example, in dendrimer conjugation to a wide variety of ligands for ARs (*51, 135*) and other receptors. These dendrimer conjugates will be studied in diverse biological models.

We also employed the chemically reactive nucleoside A_{2A} AR agonist DITC-APEC (**41**, Figure 4) to derivatize the surface of G3 PAMAM dendrimers (*126*). The resulting conjugates carried multiple copies of the agonist attached through a thiourea linkage, and they differed in the number of attachments and in the presence of a fluorophore or additional surface modification. In vitro radioligand competition experiments showed effective binding of these PAMAM-DITC-APEC dendrimer conjugates at the human A_{2A} and A_3 ARs with submicromolar K_i values and in their weak activity at the human A_1 AR. Furthermore, these nucleoside-loaded dendrimers exhibited an A_{2A} AR-mediated inhibitory effect on ADP-induced aggregation of human platelets.

To target the human A_1 AR with dendrimer derivatives, we selected the amine functionalized congener ADAC **20** for covalent coupling (*51*). We used two variations on the linking chain: one was created by acylation of the terminal amine of **20**, and the other maintained an affinity favoring a free amino group (secondary) within the chain (i.e., **25** as an amine functionalized congener). The AR-binding profile of the latter derivative (MRS5183) unexpectedly indicated a shift toward A_3 AR selectivity, both in binding affinity and in functional potency. The key to this selectivity of >100-fold in both binding at the human A_3 AR (K_i app = 2.4 nM) and functional assays (EC_{50} = 1.6 nM in human A_3 AR-mediated inhibition of adenylate cyclase) was maintaining a free amino group (secondary) in an amide-linked chain.

We explored the interaction of dendrimer conjugates of GPCR ligands with their receptors through molecular modeling (*136*). The theoretical possibility was investigated for bivalent binding to a homodimer of a GPCR of a dendrimer, covalently appended with multiple copies of a small ligand (*25*). We constructed a molecular model of a G3 PAMAM dendrimer condensed with multiple copies of the potent A_{2A} AR agonist CGS21680 (Figure 2C). The dendrimer was bound to an A_{2A} AR homodimer. Two units of the nucleoside CGS21680 occupied the A_{2A} receptor homodimer simultaneously. The binding mode of CGS21680 moieties linked to the PAMAM dendrimer and docked to the A_{2A} receptor was similar to the binding mode of a monomeric CGS21680 ligand.

CONCLUSIONS

The development of functionalized congeners as selective ligands for ARs, P2Y nucleotide receptors, and other receptors has provided valuable new research tools and candidates for therapeutics. In general, medicinal chemistry has made possible and driven the biological exploration of the study of GPCRs that respond to purines and pyrimidines. Molecular modeling based on a rhodopsin template has provided structural insights into both binding and activation steps of the receptors, which have been adapted to structure-based design of ligands.

The functionalized congener approach, as introduced for GPCR drug design, involves structural variation at the distal unit of a preexisting ligand to improve the drug's pharmacological effects. The key pharmacophore unit of a small molecular ligand for a GPCR, especially Family A, generally binds within its heptahelical TM domain. In the case of functionalized congeners, the distal moiety of an appended chemically functionalized chain may reside and potentially interact at or near the extracellular domain of the GPCR. Indeed, providing a secondary interaction by this approach can significantly enhance the affinity and selectivity of certain ligands. Such modulation of the pharmacological profile can be achieved at the distal unit through a variation of the linker length, functional group manipulation, or a combination of both techniques.

A_1, A_{2A}, and A_3 AR functionalized congeners have thus far yielded macromolecular conjugates, irreversibly binding AR ligands for receptor inactivation and cross-linking, radioactive probes that use prosthetic groups, immobilized ligands for affinity chromatography, and dual-acting ligands as binary drugs. PAMAM dendrimers act as nanocarriers for covalently conjugated AR functionalized congeners. These studies employ rational methods of ligand design derived from molecular modeling and templates. Thus, the design of novel ligands, both

small molecules and macromolecular conjugates, for studying the chemical and biological properties of GPCRs has provided researchers with a strategy that is more versatile than the classical medicinal chemical approaches.

The review provides the historical background to functionalized congeners, as well as a summary of recent advances. In spite of the lack of that no drugs have yet evolved out of this approach, now several decades old, this field is now reenergized due to recent developments, such as the emerging concept of functional GPCR dimers. One possible reason for the lack of pharmaceuticals designed by this approach is that the molecular weight and H bonding character are increased, which is usually considered a disadvantage in conventional drug development. However, with the advent of biological therapeutic agents and other large molecular weight molecules in clinical use, the functionalized congener approach seems to have a new appeal. In fact, the full potential of such approaches as binary drugs and macromolecular conjugates has not been fully realized.

"Zipper" Molecular Beacons: A Generalized Strategy to Optimize the Performance of Activatable Protease Probes

Juan Chen, Tracy W. B. Liu,† Pui-Chi Lo, Brian C. Wilson, and Gang Zheng*

Department of Medical Biophysics, Ontario Cancer Institute, University of Toronto, Toronto, Ontario M5G 1L7, Canada.
Received May 7, 2009; Revised Manuscript Received August 31, 2009

We report the proof-of-principle concept for zipper molecular beacons (ZMB) comprising an asymmetrical polyarginine/polyglutamate electrostatic "zipper" hairpin-linked fluorophore−quencher pair. The objective is to balance maximal quenching efficiency and optimal two-step activation (protease cleavage/zipper dissociation), while enhancing target cell uptake. This strategy also eliminates the peptide sequence dependence of conventional protease beacons. This ZMB concept is a generalizable approach to improve the functionality of a wide range of diagnostic/therapeutic probes through a simple switching of substrate sequences.

INTRODUCTION

Optical molecular imaging has become a powerful tool for biochemical and cellular studies (*1*). With the continual development of peptide-based "smart probes", the *in vivo* optical imaging of specific molecular targets, biological pathways, and disease progression is gaining momentum. Many of the initial fluorescent probes had limited image contrast due to poor target specificity. Hence, activatable optical probes (*2*−*9*) that require enzyme-triggered separation of an inhibitory moiety from an active partner were developed. More recently, we and others have extended this concept to photodynamic molecular beacons (*10*−*14*) for increased specificity in photodynamic therapy. These activatable protease probes comprise an enzyme-specific linker with a fluorophore (or photosensitizer) and quencher conjugated at its opposite ends. The probes are inactive until the linker is cleaved by a target-specific enzyme. Although such activatable imaging and therapeutic beacons have shown great promise, several challenges have arisen.

First, the quenching depends on the natural peptide folding of the enzyme-specific linker. Thus, the probes are limited to sequences with natural conformations that bring the quencher and active moiety in close proximity in order for effective silencing to occur. In other words, different peptide sequences have different background fluorescence. A second concern is most protease-specific probes are activated extracellularly, so that the activated probes may diffuse to nontarget cells/tissues before target cell uptake occurs. Third, probes that target soluble proteases may be activated at sites distant from the target due to leakage of the enzyme from the target cells into the general circulation (*15*−*17*), thereby contributing to background signal and reduced contrast. Lastly, the probes use nonspecific/passive delivery to the target cells/tissues, which is suboptimal.

Recently, the concept of activatable cell-penetrating peptides (ACPP) was introduced to address the passive delivery of first-generation activatable optical probes. These are based on the electrostatic formation of a polycation/polyanion "zipper", whose linker can be selectively cleaved by a protease to locally unleash the delivery function of cell-penetrating peptides (CPP) (*15*−*17*). The underlying mechanism is functionally reminiscent of molecular beacons themselves that require enzyme-triggered separation of an inhibitory moiety from an active partner: here, the separation is between a polyanionic peptide (polyanion) and a polycationic peptide (polycation). Inclusion of a quencher may improve imaging contrast by suppressing the active partner before cleavage of the linker (*15*). The concept is illustrated in Scheme 1.

MATERIALS AND METHODS

All amino acid derivatives and the Sieber amide resin were purchased from Novabiochem (San Diego, CA, USA). The black hole quencher3 carboxylic acid succinimdyl ester (BHQ3-NHS) was obtained from Biosearch Technologies (Novato CA, USA). The pyropheophorbide carboxylic acid succinimidyl ester (Pyro-NHS) was prepared according to a published procedure (*18*). Other chemicals were obtained from Aldrich (Oakville, ON) and were used as received. Reverse-phase HPLC was preformed on a XBridgeTM-C8 column (2.5 μm, 4.6 × 150 mm) using a Waters 2695 controller with a 2996 photodiode array detector and a Waters ZQTM mass detector (Waters Limited, Mississauga, ON).

Synthesis of ZMB. The peptide sequence Fmoc-[D-Glu(Ot-Bu)]$_x$-protected activatable peptide linker-[D-Arg(Pbf)]$_y$Lys(Mtt) was synthesized on the Sieber resin according to a solid-phase peptide synthesis (SPPS) protocol using a PS3 peptide synthesizer (Protein Technologies) with commercially available *N*-α-Fmoc-protected amino acids. After the last Fmoc group had been removed from the peptide resin with 20% piperidine in *N*,*N*-dimethylformamide (DMF), the resin was washed with DMF. BHQ3-NHS was then coupled to the N-terminal of the peptide in DMF with *N*,*N*-diisopropylethylamine (DIPEA) (BHQ3/peptide = 3:1 molar ratio). The mixtures were shaken under argon overnight at room temperature. The acquired dark-blue resin was washed with DMF and then treated with 95%

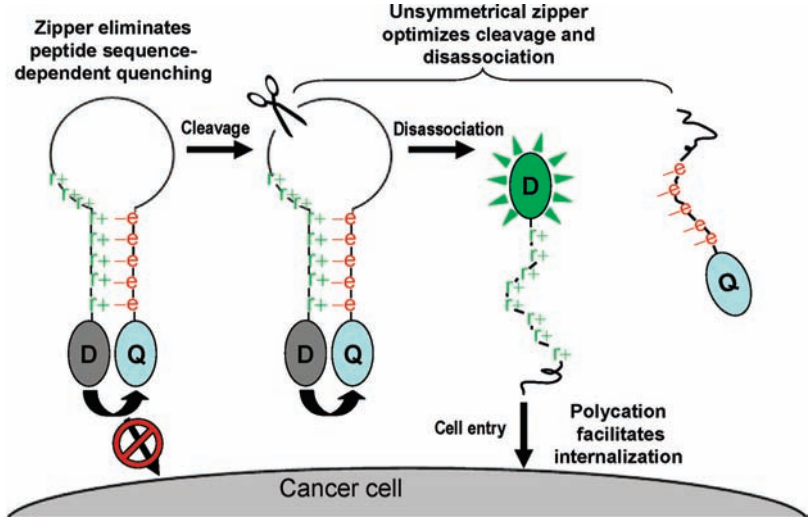
Scheme 1. Universal Zipper Molecular Beacon Design[a]



[a] The "zipper" is composed of a pair of polycation and polyanion arms holding the dye (D) and quencher (Q) in close proximity due to electrostatic attraction. This results in silenced dye activity independent of peptide linker variations. Upon specific enzymatic cleavage of the linker, the dye and quencher dissociate, resulting in dye photoactivity and unleashing the polycation, which increases cellular uptake.

trifluoroacetic acid (TFA) with 5% triisopropylsilane (Tis) to remove the protected groups on the peptide and cleave the peptide from the resin. After removing the solid support by filtration, the filtrates were concentrated and precipitated by diethyl ether to give the BHQ3-conjugated peptide, BHQ3-$_D$(e)x-activatable peptide linker-$_D$(r)yK(NH_2). The peptide was then reacted with Pyro-NHS in anhydrous DMSO with 1% DIPEA at ambient temperature for 6 h. The reaction mixture were then purified by HPLC to give pure BHQ3-$_D$(e)x-activatable peptide linker (r)yK(Pyro), which were characterized using UV−vis and ESI mass spectroscopy.

Synthesis of Controls. The synthesis of nonquencher control, Pyro-GPLGLARK (PP), and nonzipper control, Pyro-GPLGLARK-(BHQ3) (nonzip1), were reported previously (*12*). Nonzip2, Pyro-RPLALWRSK(BHQ3), was synthesized using the similar procedure as nonzip1. FITC-labeled polycation control, Fmoc-$_D$(r)x-K(FITC), was synthesized as follows: Fmoc-[D-Arg-(Pbf)]x-K(Mtt) was synthesized on the Sieber resin. The resin was then treated with 95% TFA with 5% Tis to remove the protected groups on the sequence and cleave the sequence from the resin. The acquired Fmoc-$_D$(r)x-K(ε-NH_2) was then reacted with fluorescein isothiocyanate (FITC) in anhydrous DMSO with 1% DIPEA at ambient temperature for 6 h. The reaction mixture were then purified by HPLC to give pure Fmoc-$_D$(r)x-K(FITC). Nonquencher ACPP control, Fmoc-$_D$(e)$_5$GPLGLA$_D$(r)$_8$K(Pyro) (Pyro-ACPP), was synthesized using a similar protocol to Fmoc-$_D$(r)x-K(FITC). The differences are in (1) replacing the peptide sequence and (2) conjugating Pyro-NHS on the C-terminal rather than FITC.

pH Dissociation Assay of ZMB. 0.5 μM of ZMB samples were prepared in adjusted PBS solutions with different pH (pH = 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 13). Their fluorescence emission was measured on a HORIBA FluoroMax-4 spectrofluorometer (excitation 650 nm, emission 675 ± 5 nm). Using the sample of pH = 7 as reference, the fluorescence increase in different pH conditions was calculated to evaluate the structure stability of ZMB.

Activation Studies. ZMB or nonzipper probes (1 nmol) were first dissolved in 2.5 μL of DMSO and 0.5 μL of Tween 80. The solution was diluted with 1 mL of phosphate-buffered saline (PBS) or minimum essential medium (MEM) Eagle cell media, and then incubated with 10 μL of human Proteinase K (2 μg) (ZMB/Proteinase K ∼ 50:1 molar ratio). The activation was monitored by the fluorescence increase, which was calculated by normalizing the sample's fluorescence emission on real-time to its initial fluorescence. $FI_{protease}$ and FI_{TFA} were used to define the fluorescence increase at 2 h post-Proteinase K cleavage and following fluorescence increase after adding 1% TFA to the cleavage solution.

Evaluation of Polycation Delivery Capability. MT1 cells were grown to 60% confluence in Nunc Lab-TekII-CC2 chambered slides. Eagle's minimum essential medium (MEM) medium with 10% fetal bovine serum containing 5 μM of Fmoc-$_D$(rrrrr)-K(FITC) and Fmoc-$_D$(rrrrrrr)-K(FITC) were added and incubated for 10 min at 37 °C. The cells were washed 3 times with PBS. The chamber slides were then imaged on an Olympus FluoView 1000 laser scanning confocal microscope equipped with a 488 nm argon laser.

Evaluation of Cell Uptake of ZMB before and after Activation. (1) Preparing nonactivation sample: Fresh MEM medium with 10% fetal bovine serum (without proteases) was used to prepare a 10 μM concentration of the probes. (2) Preparing postactivation samples: MT1 cells were grown in Nunc Lab-TekII-CC2 chambered slides for 3 days. A 10 μM concentration of the probes were prepared in this 3-day-old cell incubation medium (contains secreted proteases including MMP7) and incubated until the peptide linkers of probes were cleaved (monitored by HPLC). (3) Confocal study: 200 μL of these samples were incubated with MT1 cells in the chamber slides for 30 min. The chamber slides were washed with PBS 3 times and then imaged by a confocal microscope equipped with a 633 nm He−Ne laser.

RESULTS AND DISCUSSION

To test this concept, we designed a ZMB with four functional modules: (1) a protease cleavable peptide as the linker, (2) a polycation and a polyanion attached to each end of the linker, forming a "zipper" structure via electrostatic attraction, (3) pyropheophorbide as a fluorescent dye (D), and (4) a Black Hole Quencher 3 as a quencher (Q), conjugated to the end of the polycation and polyanion, respectively. As shown in Scheme 1, the zipper provides several potential advantages: (1) the formation of the polycation/polyanion "zipper" through electrostatic attraction improves the silencing of the beacon by bringing D and Q into closer contact, (2) a "hairpin" conformation of the substrate sequence occurs as a result of the zipper,

Table 1. Abbreviations of Protease Probes

nonzip1	Pyro-GPLGLARK(BHQ3)
nonzip2	Pyro-RPLALWRSK(BHQ3)
zipXe	BHQ3-$_D$(e)$_X$GPLGLA$_D$(r)$_X$K(Pyro)
zip8e2	BHQ3-$_D$(e)$_8$ RPLALWRS$_D$(r)$_8$K(Pyro)
zip5e8r	BHQ3-$_D$(e)$_5$ GPLGLA$_D$(r)$_8$K(Pyro)
PP	Pyro-GPLGLARK

improving the cleavage rate of the enzyme-specific linker, (3) the polyanionic arm of the zipper prevents the probe from entering cells, by blocking the cell-penetrating function of the polycation, (4) the polycationic arm enhances cellular uptake of the dye after linker cleavage, and (5) quenching is no longer dependent upon the natural folding of the peptide linker, since the zipper is solely responsible for the "dormant" state. In the presence of a target protease, the peptide linker is first specifically cleaved; the Q-attached polyanion then dissociates from the D-attached polycation, becoming photoactive, and unleashes the polycation, which enhances the delivery of the activated dye locally into the target cells.

In order to examine the effect of the zipper conformation on the photophysical properties, two matrix metalloproteinase 7 (MMP7)-specific peptide sequences, GPLGLARK (*19*) and RPLALWRSK (*20*), were used to synthesize two ZMBs, zip8e and zip8e2, and their corresponding nonzipper controls, nonzip1 and nonzip2 (see Table 1). Eight consecutive D-arginines, $_D$(rrrrrrrr), and D-glutamates, $_D$(eeeeeeee), were selected as the polycation and polyanion, respectively, as these can assemble into a stable zipper hairpin structure (*15*). D-Amino acids were used for the zipper arms, since they are stable against proteolysis (*21*). Also, D-amino acid-based polycationic peptides present similar cell penetrating capabilities to the natural L-amino acids (*22*).

The fluorescence emission of these probes was evaluated, normalized to that of the nonquencher probe, PP. As shown in Figure 1C, a marked difference in the fluorescence of nonzip1 and nonzip2 was observed (<2% and 27.2%, respectively). There was only a slight difference in the length and solubility of the peptide linkers in nonzip1 and nonzip2, indicating that the fluorescence quenching efficiency in the nonzipper probes does depend on the natural folding of the linkers (Supporting Information Figure S1 and Table S1, HPLC retention time). However, with the inclusion of the zipper, the quenching efficiencies were enhanced, with the fluorescence of zip8e and zip8e2 being reduced to 0.4% and 0.9%, respectively. This comparable quenching in zip8e and zip8e2 indicates that the quenching dependence on the natural folding of the peptide linker has been eliminated. Moreover, in aqueous solution, the specific absorption peaks of Pyro (414 nm) and BHQ3 (676 nm) in zip8e were shifted relative to their corresponding nonzipper probes (nonzip1) (Figure 1A). By adjusting the solution to a low pH condition (pH = 2) to neutralize the polyanion sequence and unfold the peptide sequence, the fluorescence of zip8e was increased 4-fold and its specific absorption was restored (Figure 1B), while nonzip1 did not show any obvious changes. Therefore, the enhanced quenching efficiency in the ZMB is presumably the result of both the improved fluorescence resonance energy transfer (FRET) effect and the ground-state complex quenching (contact quenching) caused by annealing D and Q through the electrostatic attraction of the zipper arms.

We next verified the electrostatic nature of the zipper conformation using a pH dissociation assay. As shown in Figure 1D, the fluorescence values of both zip8e and nonzip1 were very stable at pH ~ 5−9. At pH < 5, the fluorescence of zip8e increased continually with decreasing pH, while that of nonzip1 was unchanged. This suggests that the zipper conformation disassociates at pH around 4, coinciding with the isoelectric point of the glutamic acid, and so confirming the electrostatic nature of the zipper conformation. The fluorescence increase at pH ≥ 10 observed in zip8e and nonzip1 is due to decomposition of BHQ3.

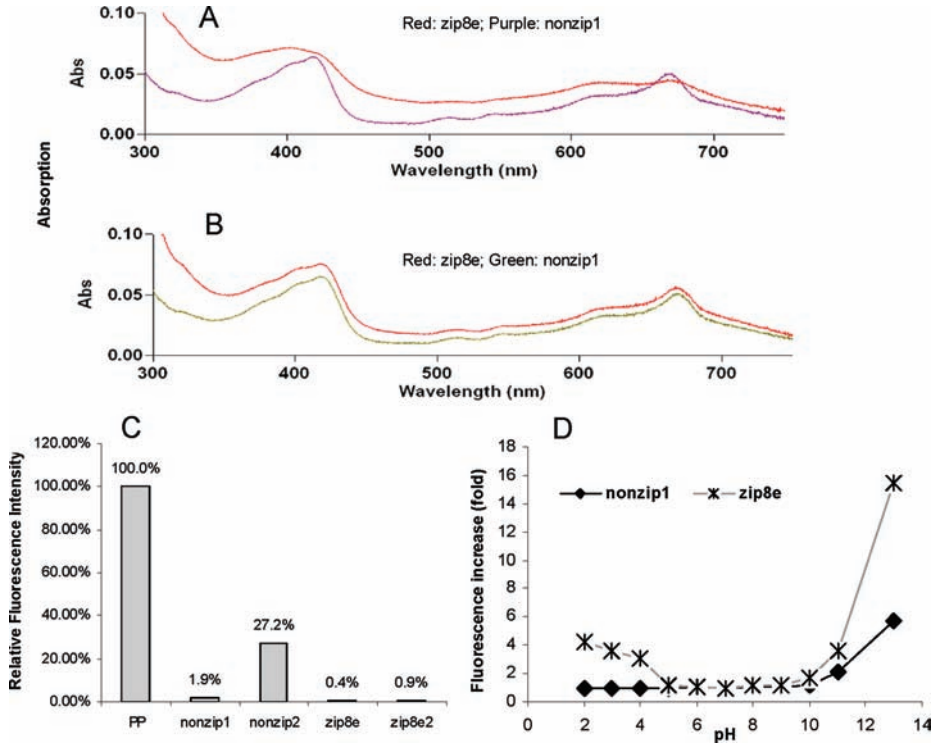

Figure 1. (A) Absorption spectra of zip8e and nonzip1 in (A) PBS buffer and (B) low-pH solution (pH = 2). (C) Relative fluorescence intensity of protease activatable probes (normalized to the fluorescence emission of PP). (D) The fluorescence stability of zip8e and nonzip1 in PBS buffer in the pH range 2−13.

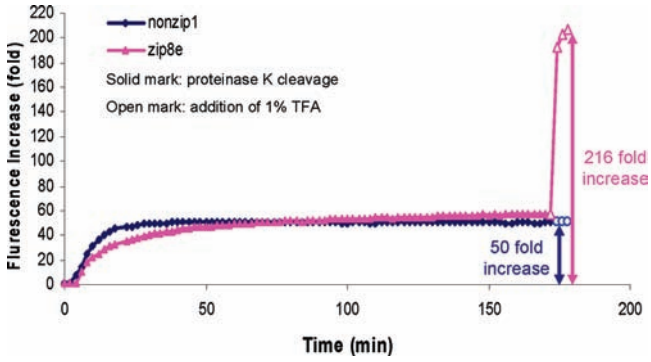

Figure 2. Comparison of the protease-mediated activation of ZMB and nonzipper probes: Cleavage kinetic profiles of probes depict increase in fluorescence after 3 h protease incubation and post TFA-induced disassociation.

Examining the protease-triggered activation of ZMB (Figure 2), we determined that the activation of ZMB is a two-step process. The first step is cleavage of the peptide linker and the second is dissociation of the zipper arms. Kinetic cleavage profiles of zip8e and nonzip1 were evaluated using Protease K to ensure complete proteolysis of the linker, and upon achieving stable fluorescence intensity, trifluoroacetic acid (TFA) was added. This decreased the pH to 2, neutralizing the polyanion arm and consequently causing dissociation of the zipper to produce maximum fluorescence. Both the nonzip1 and zip8e constructs were completely cleaved by Protease K in 3 h and produced similar maximum fluorescence. However, the fluorescence increases of these two probes were significantly different due to the enhanced quenching efficiency afforded by the zipper mechanism. As shown in Figure 2, nonzip1 resulted in a 50-fold fluorescence increase due to proteolysis with no further fluorescence increase after the addition of 1% TFA. In contrast, zip8e produced an overall 216-fold fluorescence increase. However, only a 57-fold fluorescence increase was observed 3 h after proteolysis and a 159-fold increase was contributed by forced dissociation of the zipper arms after the addition of 1% TFA. These results demonstrate that ZMB activation is a two-step process. When compared with the nonzip1 construct, ZMB offers much higher signal/background ratio after activation (216-fold vs 50-fold) due to a lower fluorescence background of intact ZMB, generated by zipper-enhanced fluorescence quenching.

This two-step activation creates a dilemma that is also observed in activatable cell-penetrating peptide probes in which the liberation of the peptide has a different mechanism on a much slower time scale (*15*). On one hand, a stable zipper conformation is necessary to achieve maximum quenching efficiency, which is critical for improving the probe sensitivity (by reducing the background fluorescence) and for creating the sequence-independent universal probe. On the other hand, if the zipper structure is too stable, it prevents or slows the prompt dissociation of the D- and Q-zipper arms upon target activation. This results in nonspecific diffusion of D from the target cells and diminishes the gain in probe selectivity. Hence, the optimal ZMB should have a high quenching efficiency balanced by rapid dissociation of the zipper arms after proteolysis.

Although zip8e provides near-maximum quenching efficiency (99.6%), its activation only produces a partial fluorescence increase (26%) from general proteolysis. In order to balance the quenching efficiency and activation, a collection of ZMBs with different zipper arm lengths (zip3e, zip4e, zip5e, zip6e) were synthesized (Supporting Information Figure S1 and Table S1). By comparing their fluorescence emission in PBS buffer, we found that the longer the zipper arm (polycation/ polyanion pair), the greater the quenching efficiency (Figure 3A). Upon

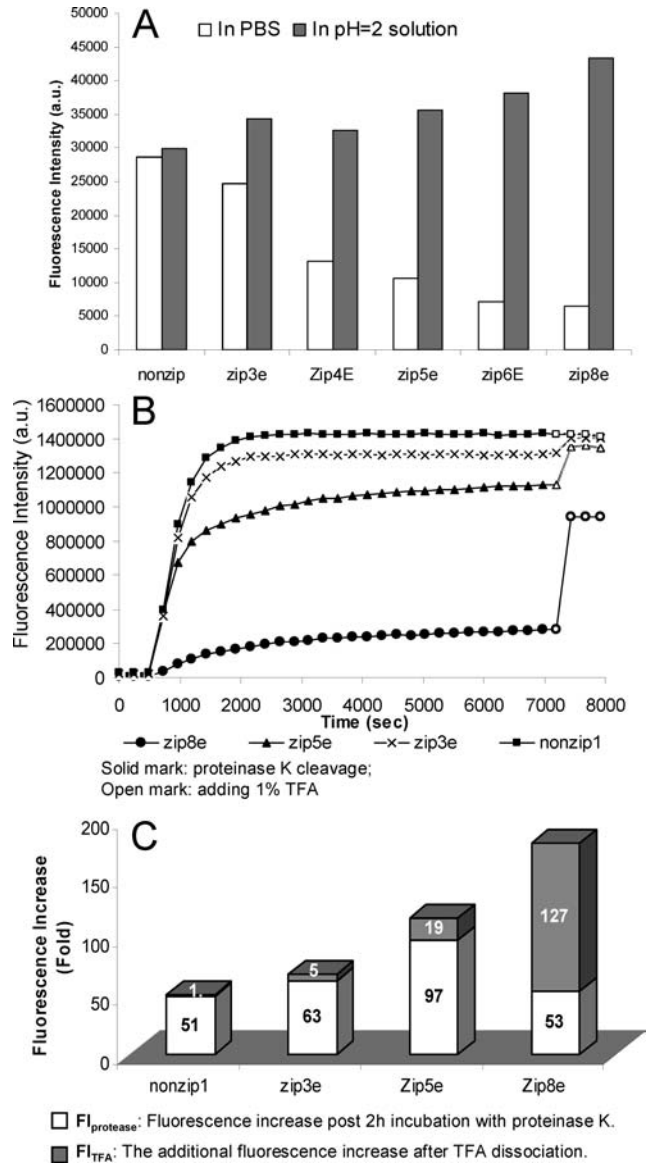

Figure 3. (A) Fluorescence emission of intact ZMBs in PBS and low pH condition (pH = 2). (B) Protease cleavage monitored by real time fluorescence. (C) $FI_{protease}$ and FI_{TFA} values for ZMBs and nonzipper controls.

adjusting the pH to 2, little to no fluorescence increase was observed in zip3e, suggesting that a zipper structure was not formed in this molecule, while a significant fluorescence increase, due to the low pH condition, was observed in zip4e, zip5e, zip6e, and zip8e, indicating that a zipper structure was formed in these molecules. The low pH conditions neutralize the polyanionic arm eliminating the electrostatic attraction between the zipper arms causing dissociation. This results in fluorescence release, as the D and Q are no longer electrostatically held together in close proximity.

As seen in Figure 3B, the activation of zip3e and zip5e was compared with that of nonzip1 and zip8e upon Proteinase K cleavage. Zip3e showed similar activation kinetics as nonzip1, further indicating that a 3-amino acid zipper arm length does not form a stable zipper. It had been previously observed that the 4-glutamate motif does not effectively attenuate the translocation of CPPs prior to proteolytic cleavage (*17*). Thus, these characteristics suggest that a stable zipper is formed when the ZMB is composed of more than 4 consecutive polycations and polyanions, resulting in enhanced fluorescence quenching efficiency and the two-step activation process. In Figure 3C, a

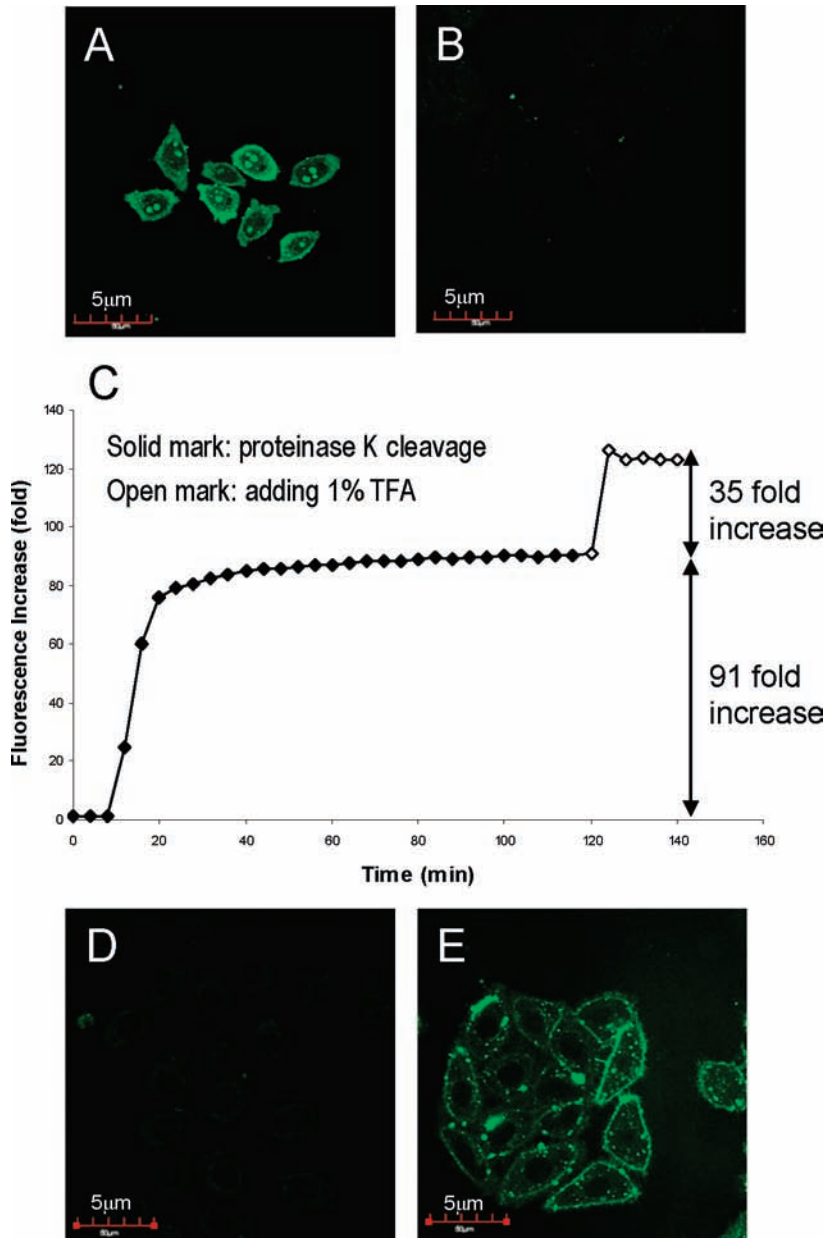

Figure 4. Confocal images of 5 μM (A) Fmoc-$_D$(rrrrrrrr)-K(FITC) and (B) Fmoc-$_D$(rrrrr)-K(FITC) in MT1 cells showing fluorescence in each case. (C) Activation kinetics of zip5e8r by Proteinase K in PBS. Confocal images of cell uptake of (D) nonzip1 and (E) zip5e8r at 30 min after cleavage by 3-day-old MT1 cell culture media.

97-fold fluorescence increase was seen in zip5e after proteolysis of the peptide linker ($FI_{protease}$), while only a 19-fold increase occurred after addition of TFA (FI_{TFA}). Thus, the dissociation of the zipper arms in zip5e is a much more efficient process than that of zip8e.

As all of the above fundamental studies were performed in PBS solution, we further evaluated the stability of the zipper arms in cell culture MEM media. Although the dissociation of the zipper arms is slightly increased in different buffered conditions, a 3−5% increase in fluorescence occurred; we assume that this buffer change will not greatly influence the kinetic profile of the zip PMBs (Supporting Information Figure S3).

Although zip5e has optimal cleavage and zipper arm dissociation rates, the practicality of a 5-amino acid polycation arm assisting in the internalization of the fluorophore is questionable. It has been reported that effective cell penetration requires at least 6 consecutive cationic amino acids (*23*). To validate this, *in vitro* confocal fluorescence microscopy was performed on Fmoc-$_D$(rrrrr)-K(FITC) and Fmoc-$_D$(rrrrrrrr)-K(FITC). As shown in Figure 4A,B, the 5-consecutive arginine cannot deliver the FITC into cells, whereas the 8-consecutive arginine showed a rapid uptake, within both the cytoplasm and nucleus after only 10 min incubation. This should address the limitation of nonspecific diffusion of the probe upon extracellular activation. Thus, by combining the optimal activation (cleavage and dissociation) of zip5e with the strong cell penetrating ability of 8-consecutive arginines, we designed an asymmetric ZMB with 8-consecutive arginines and 5-consecutive glutamates (zip5e8r): BHQ3-$_D$(eeeee)GPLGLA$_D$(rrrrrrrr)K(Pyro). This produces almost identical fluorescence quenching efficiency as zip5e (99.4% vs 99.3%), a similar rate of cleavage (2 h to completion) (Figure 4C) and comparable overall activation (72% vs 84%).

On the basis of these positive findings, zip5e8r was further evaluated in MT1 breast carcinoma cells *in vitro*, comparing the cell delivery of nonzip1 and zip5e8r after activation by 3-day-old cell incubated media. Although the peptide linker sequence is considered MMP7-specific (*12*), the old cell media

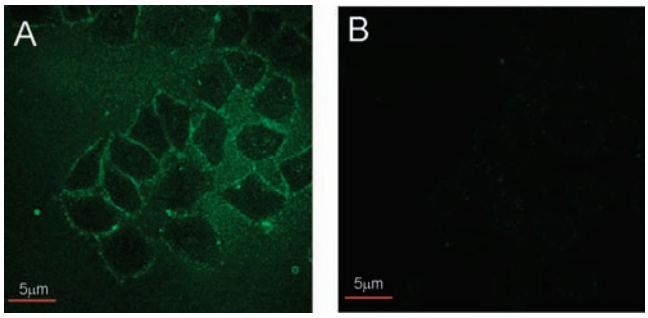

Figure 5. Confocal images comparing the background fluorescence in Pyro-ACPP (A) and zip5e8r (B).

contains a variety of different proteases, which might also lead to beacon activation. As shown in Figure 4D,E, the cleaved moiety of 8-consecutive arginine with Pyro (8r-Pyro) after zip5e8r activation accumulated inside the cells within 30 min, while the nonzip1 showed very weak uptake after activation. The improvement of zip5e8r ZMB over the corresponding nonquencher ACPP control, Pyro-ACPP, is shown in Figure 5 and Supporting Information Figure S5. By confocal imaging of the uptake of zip5e8r and Pyro-ACPP in fresh cell culture media and 3-day-old cell incubation media, we observed that the addition of a quencher significantly decreased the background signal, both before and after probe cleavage. Thus, ZMBs increased the resolution of activated probes and the contrast between the intact and activated beacon.

In summary, encoding a suitable zipper structure into protease-activatable probes significantly improves their functionality. First, by forming a stable zipper conformation, protease probes with different quenching efficiency can reach comparable maximum values (99.6% for zip8e and 99.1% for zip8e2). This effectively eliminates the peptide substrate sequence dependence of the quenching. Second, an optimal balance between high quenching efficiency and rapid activation (protease cleavage + zipper dissociation) can be achieved with 5-consecutive arginine paired with 5-consecutive glutamate (for both zip5e and zip5e8r). However, only the asymmetric zip5e8r with the extended polyarginine arm can facilitate rapid cell internalization. Thus, by incorporating an asymmetric zipper control, the quenching efficiency, activation, and delivery can all be optimized simultaneously, and the probe is no longer dependent on the specific peptide substrate sequence. Consequently, by simply switching the substrate sequences, the ZMB design can potentially be applied to a wide range of protease probe applications, with predictably similar functional performance.

This ZMB design has universal applications in targeted cancer fluorescence imaging/diagnostics, since in principle, any tumor biomarker can be targeted. Future advances may rely upon ZMBs targeted to novel early and reliable tumor markers that can discriminate malignant from benign lesions and detect micrometastases at distant sites. The application of ZMBs in cancer therapeutics is achievable by simply switching D to a fluorescent photosensitizer, such as pyropheophorbide. The ZMBs will then possess novel targeting capabilities for photodynamic therapy (PDT). With the activatable nature of ZMBs, another level of PDT selectivity should be achievable, improving the accuracy and reliability of this noninvasive therapeutic technique. Furthermore, with the fluorescent production upon activation of ZMBs, a "see and treat" approach in cancer therapeutics is also possible. The novelty of the ZMB construct is that it provides a universal design for any combination of Q and D or photosensitizer and any disease biomarker target. Thus, the applications of activatable molecular beacons in cancer diagnosis and therapy can be expanded with the incorporation of the "zipper" mechanism.

STED Nanoscopy in Living Cells Using Fluorogen Activating Proteins

Received June 5, 2009; Revised Manuscript Received August 18, 2009

We demonstrate the effectiveness of a genetically encoded malachite green (MG) binding fluorogen activating protein (FAP) for live cell stimulated emission depletion nanoscopy (STED). Both extracellular and intracellular FAPs were tested in living cells using fluorogens with either membrane expressed FAP or as an intracellular FAP-actin fusion. Structures with widths of 110−122 nm were observed. Depletion data, however, suggest a resolution of 70 nm with the given instrument.

Fluorescence microscopy has experienced explosive growth of use over the past three decades, transforming from a disparate set of optical techniques to a cohesive tool set of imaging methodologies for biological research. This transformation has been greatly facilitated by the development of bright photostable fluorescent probes ranging from organic dyes (*1, 2*) to genetically expressible fluorescent proteins (*3*) as targeted fusions at the molecular level. This, in conjunction with the development of new lasers and low-noise photodetectors, has enabled the observation of many aspects of cell structure that were previously unseen. However, despite these incredible advances, conventional optical microscopy is inherently mismatched with biological length scales due to the far-field diffraction limit of light ($\sim\lambda$/2NA); i.e., one cannot resolve objects that are separated by less than half the wavelength of light. This is particularly restrictive when the spatial location of multiple interacting objects is desired, especially when the size of most protein complexes are on the order of 10−50 nm, and even subcellular organelles have dimensions on the order of 100 nm. To overcome this fundamental obstacle, the past decade has seen the birth of the completely new field of far-field super-resolution optical microscopy, which has revealed many aspects of cellular ultrastructure previously only discernible in electron microscopy. Currently, there are two distinct methodologies, one of which is based on single-molecule localization approaches, PALM (photoactivation localization microscopy) (*4, 5*) and STORM (stochasic optical reconstruction microscopy) (*6*), and the other on ensemble imaging employing either point-spread function engineering or low-frequency structured illumination (*7, 8*).

The latter methods rely on the manipulation of the point-spread function (PSF) of the microscope while imaging a complete ensemble of molecules. One very successful approach is stimulated emission depletion (STED) nanoscopy (*9*). In this method, an excitation laser beam is overlaid with a depletion laser that has an optically engineered point-spread function, resulting in a much smaller effective fluorescing spot. Currently, the best attained STED resolution is 6 nm, obtained for photonic crystal centers (*10*).

Compared to localization, such ensemble methods do not routinely yield the same spatial resolution enhancements (especially in biological samples), but do provide much higher temporal resolution. In the case of STED, video rate imaging of 28 frames/s has been achieved allowing the observation of synaptic vesicle movement in living neurons (*11*). This is almost 3 orders of magnitude faster than the fastest PALM-based dynamic imaging reported to date at 0.04 frames/s (*12*). Further live cell STED with fluorescent proteins has been successfully demonstrated in imaging both dendritic spines (*13*) and the endoplasmic recticulum (*14*), both making use of yellow fluorescent proteins (YFP). To minimize potential phototoxic effects in long-term live cell imaging experiments, especially with the high laser powers required for effective depletion, it is highly desirable to operate at wavelengths far to the red.

The far-red organic dye Atto647N has been applied in the case of video-rate STED of synaptic vesicle movement in living neurons (*11*) and to explore the nanoscale dynamics of lipid membranes using FCS-STED methodology (*15*). In addition, Atto655 has been used in conjunction with the Halo-Tag labeling technology to visualize β1-integrin in nonliving HeLa cell filiapodia (*16*). Both of these dyes are compatible with the commercial Leica TCS STED system. Unfortunately, these live cell approaches are inherently restrictive, as they require either the uptake of a dye-labeled lipid or antibody or internalization of an impermeant dye prebound to a genetic tag, which is not always biologically convenient. At present, no fluorescent protein has been reported to work with the commercial STED system in the same spectral range. As such, STED imaging of living cells in the far red has been limited to specific applications compatible with these labeling approaches. In order for the STED method to become generally useful for live cell imaging in the far red, it is highly desirable to have genetically targetable far-red fluorescent probes with quantum yields and spectral characteristics similar to those of the Atto Dyes. In this brief communication, we describe the first use of genetically expressed fluorogen activating proteins (FAPs) that bind and activate the far-red fluorogenic dye malachite green for live-cell STED nanoscopy. These results using extra and intracellular compatible FAPs have widespread implications in the development of live cell STED nanoscopy for high-speed dynamic super-resolution imaging.

Malachite green is a far-red nonfluorescent organic dye that has been used to generate fluorescent signal when bound specifically to selected proteins (such as FAPs (*17*)) and nucleic acid aptamers (*18*). Because the dye exists in a nonfluorescent

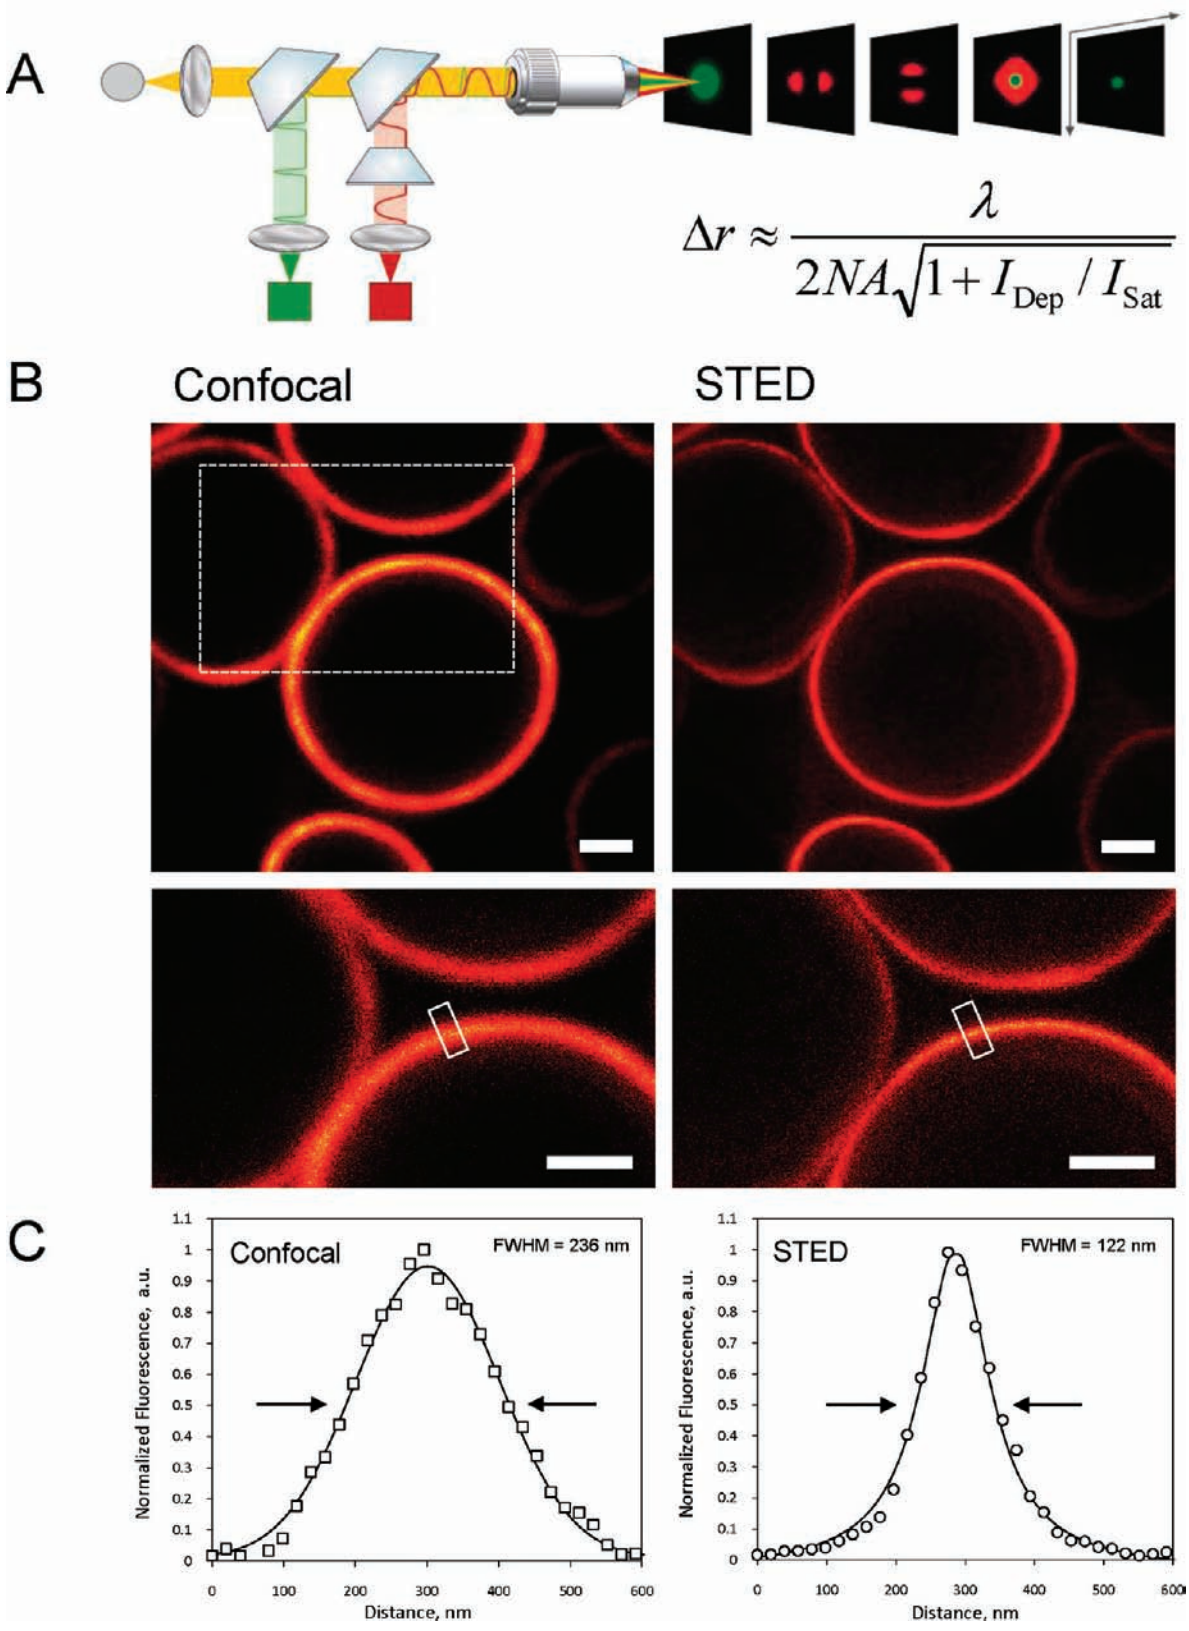

Figure 1. STED nanoscopy in living yeast cells. (A) Schematic of commercial Leica TCS STED optical setup. A pulsed 635 nm excitation diode laser is overlapped with the "donut"-shaped pulsed depletion infrared laser beam to produce a subdiffraction limited fluorescing spot whose diameter is approximated by $\Delta r \approx \lambda/2\mathrm{NA}(1 + I_{\mathrm{Dep}}/I_{\mathrm{Sat}})^{1/2}$ (*22*) where NA is the objective numerical aperture, I_{Dep} is the depletion intensity and I_{Sat} is the intensity of saturation which is fluorophore dependent. (B) Confocal and STED images of living yeast cells surface expressing the extracellular L5-MG-L90S FAP module labeled with MG-2p fluorogen. Hollow white bar denotes a 10-pixel-wide region of interest. (C) Line profiles generated from the averaged fluorescence intensity within the region of interest plotted as a function of distance. Solid lines indicate a fit to one-dimensional Gaussian (confocal) or Lorentzian (STED) functions. FWHM are 236 nm (confocal) and 122 nm (STED). Solid white lines indicate 1 μm scale bars.

form, it can be added to cells in media and/or buffer with no appreciable background signal. When the dye interacts specifically with its target, the fluorescence is activated up to ~20 000-fold resulting in genetically targetable, bright far-red emission.

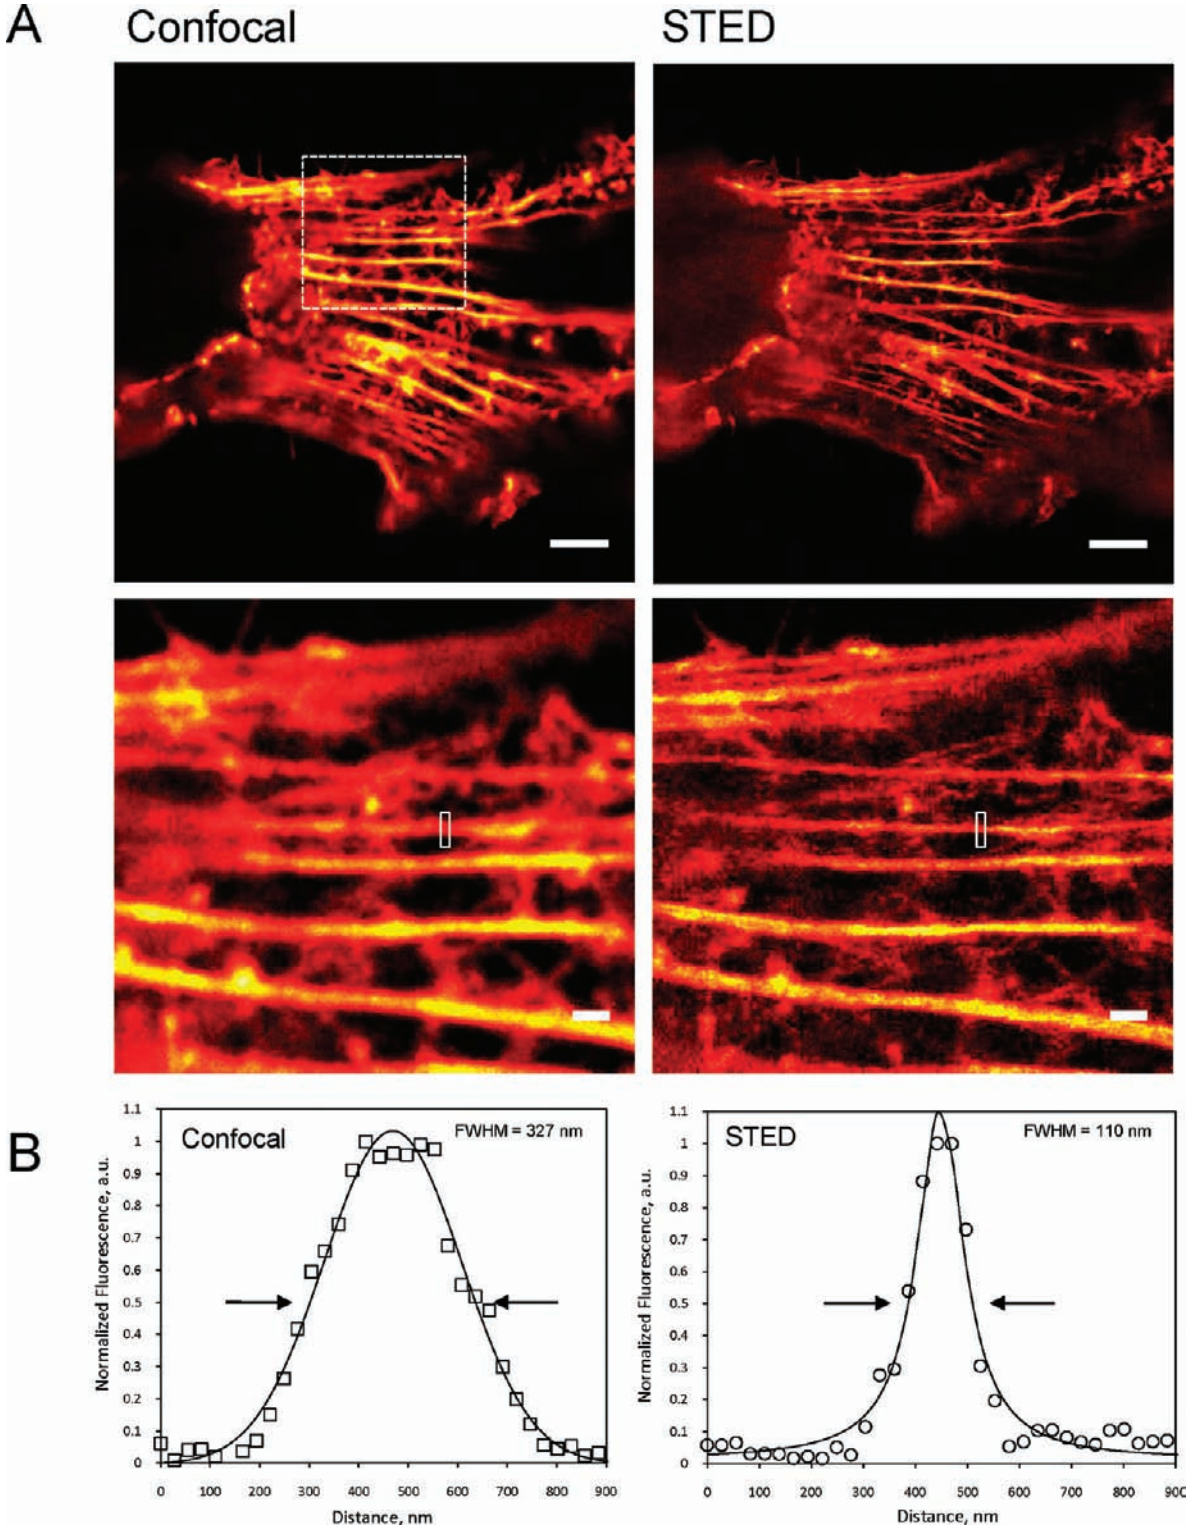

Figure 2. STED nanoscopy in living HeLa cells. (A) Living HeLa cells expressing the H6.2-MG disulfide free FAP module expressed as an N-terminal fusion to actin labeled using the MG-ester fluorogen (upper left panel confocal, upper right panel STED, with an enlarged region denoted by the dashed line box below each image). Hollow white bar denotes a 5-pixel-wide region of interest. (B) Line profiles generated from the averaged fluorescence intensity within the region of interest plotted as a function of distance. Solid lines indicate a fit to a one-dimensional Gaussian (confocal) or Lorentzian (STED) functions. The fitted FWHM are 327 nm (confocal) and 110 nm (STED). Solid white lines indicate 5 μm scale bars in the upper images and 1 μm scale bars in the cropped images.

The photophysical properties of malachite green are well-suited to excitation and depletion in the red and near-infrared spectral range as is available on the Leica TCS STED system.

The STED potential for different malachite green binding extracellular FAP modules was evaluated using yeast cells displaying the FAP on the cell surface. Yeast cells were grown and induced as described in Szent-Gyorgyi et al. (*17*) and imaged as described in the Supporting Information. Figure 1A illustrates the implementation of the STED microscope in a commercial apparatus. Briefly, a visible red excitation spot is overlapped with a "donut"-shaped engineered PSF of the infrared laser to enable shrinkage of the effective fluorescing spot size by stimulated emission. A variety of MG binding FAPs with 100nM of the MG-2p

Table 1. Comparison of the Photophysical Characteristics of Malachite Green Binding Fluorogen Activating Proteins, MG FAPs (obtained from Szent-Gyorgyi et al. (*17*)) and the Atto-Tec Organic Dyes (obtained from http://www.atto-tec.com/) Used in Far-Red STED Nanoscopy

Atto655	−	663	684	125 000	0.30	37

* QY determined relative to native L5-MG.

fluorogen were tested throughout a range of wavelengths (730−750 nm) to elucidate which gave the most efficient depletion of fluorescence. The most promising module was L5-MG-L90S, which is a single-point mutation of the native single-chain FAP (L5-MG). Figure 1B illustrates both confocal and STED images with the extracellular L5-MG-L90S expressed on the surface of yeast (average image acquisition times were 5 s at a 100 Hz scan speed, and images were averaged 4 times to improve the signal-to-noise ratio). This FAP has a quantum yield of 0.23 and excitation and emission characteristics comparable to the organic dye Atto647N, which makes it amenable to commercial STED nanoscopy (see Table 1 for the characteristics of different FAP modules and Atto dyes). In order to quantify the gain in lateral resolution, a 10-pixel-wide region of interest was designated in the enlarged confocal and STED images (denoted by hollow white bars) and the fluorescence intensity was averaged using NIH *ImageJ* to generate the line profiles depicted in Figure 1C. The line profiles were fitted to one-dimensional Gaussian (confocal) or Lorentzian (STED) functions, which yielded full-width half-maximum (FWHM) values of 236 nm and 122 nm, respectively. This measured fwhm is somewhat higher than the expected subdiffraction limited STED resolution from the measured depletion curves, which is expected to be ∼70 nm for the given system and dye (see Supporting Information) but is consistent with current estimates of the yeast cell wall thickness (*19*).

As stated previously, the major benefit of using MG FAPs for STED nanoscopy is the unique ability to produce genetically targeted fusions in living cells. However, despite this advantage, to make the most use of STED as a high-speed super-resolution imaging technology for cellular applications it is necessary to have a fluorescent probe that functions within the cytoplasm of living cells. Given the noted folding problems of scFvs in reducing environments due to the loss of the stabilizing disulfide bridges (*20*), the H6-MG FAP has been modified via site-directed mutagenesis to remove the cysteine residues and subsequent affinity maturation to regain fluorogenic activation (H6.2-MG; manuscript submitted to Protein Engineering Design and Selection). This FAP has been expressed transiently as an N-terminal fusion to actin in living HeLa cells. Figure 2A illustrates visible stress fibers after labeling with 300nM of the permeant MG-ester fluorogen (average image acquisition times were 4 s at a 400 Hz scan speed, and images were averaged 8−10 times to improve the signal-to-noise ratio). The optically enlarged panels show the increase in the lateral resolution with many features obscured in the confocal image becoming distinct in the STED image. To determine structure size, a 5-pixel-wide region of interest was designated (denoted by the hollow white bar) and the fluorescence intensity averaged in NIH *ImageJ* to generate the line profiles depicted in Figure 2B. As before, the profiles were fitted to one-dimensional Gaussian and Lorentzian functions, yielding the fwhm of each peak. In the confocal image, the fitted fwhm was 327 nm, and in the STED image, it was 110 nm. This resolution is consistent with previous measures of actin stress fiber diameter via transmission electron microscopy (TEM) (*21*). In addition, living NIH 3T3 fibroblast cells also expressing the H6.2-MG FAP fused to actin, which were fixed and permeabilized and then labeled with 100nM MG-2p, still showed visible stress fibers despite the fixation process (see Supporting Information). Hence, these probes can be used for live cell STED and combined with conventional immunofluorescence assays in fixed cells.

We have demonstrated the first use of fluorogen activating proteins for STED nanoscopy in living cells. The biological structures imaged exhibited FWHMs in STED that were reduced by up to a factor of 3 over confocal microscopy. In this case, the measured fwhm is likely due to the sizes of the actual biological structures measured (*21*) and does not reflect the true subdiffraction limit of the probe and instrument. The ultimate achievable resolution as indicated by the depletion curves is equivalent to that of Atto647N which was determined to be ∼70 nm for the system used (see Supporting Information). These new genetically targetable far-red probes coupled with STED nanoscopy have the potential for making long-term dynamic measurements of living cells at near video rate and high resolution with reduced phototoxicity relative to conventional fluorescent proteins.

ACKNOWLEDGMENT

We would like to acknowledge the NIH National Technology Center for Networks and Pathways for financial support under grant number 5U54RR022241 and Dr. Erik Snapp for his kind assistance with cell culture and transfection experiments in HeLa cells. M.B. also wishes to acknowledge Carnegie Mellon University for faculty start-up funds.

Supporting Information Available: (1) Materials and methods for the growth, transfection and imaging of yeast and mammalian cells; (2) depletion efficiency of various different malachite green binding FAP modules; (3) survival of the intracellular FAP module through fixation and permeabilization; (4) methods used to fit Gaussian and Lorentzian functions to extracted line profiles; (5) estimating the maximum achievable resolution using the Leica TCS-STED system. 1. Materials and Methods

Yeast cells were grown and expression of surface displayed scFvs induced as described in Szent-Gyorgyi *et al.*(*1*). Cells were washed in modified PBS containing 2 mM EDTA and 0.1% Pluronic F127(*1*) resuspended in modified PBS before plating onto 35mm petri dishes with 14mm optical microwells (MatTek Corporation, Ashland, MA) pre-treated with concanavalin-A to ensure immobilization of yeast cells. After cells had bound to optical microwell surface (typically 5-10 minutes) either MG-2p (impermeant) or MG-Ester (permeant) fluorogens were incubated at a resultant dye concentration of 100nM for 5 minutes prior to imaging.

NIH 3T3 and HeLa cells expressing the H6-AFM-MG FAP as an N-terminal fusion to actin were generated by transient transfection using Lipofectamine 2000 (Invitrogen, Eugene OR) and were grown in base DMEM with 10% bovine calf serum and 1% penicillin/streptomycin. Cells were plated and imaged under identical conditions to yeast described above. Positive transfectants were identified via confocal fluorescence microscopy (5-10% efficiency) with visible stress fibers after labeling with the MG-ester at 300nM concentration. In the NIH 3T3 cells actin stress fibers were only partially visible due to the large volume of monomeric actin. To counter this, dishes containing another subsequent round of transients were fixed in 4% para-formaldehyde and permeabilized and washed in 0.5% and 0.1% Triton-X respectively. Addition of MG-2p at 100nM concentration resulted in strong labeling of stress fibers without the diffuse background of monomeric actin.

The confocal and STED images shown in Figure 1, 2 and S3 were recorded with a commercially available system equipped with a specially corrected Oil objective (HCX Pl APO 100x 1.4NA STED): the Leica TCS STED. Excitation and depletion were provided by a 635nm pulsed diode laser (PicoQuant, Germany) and a tunable Spectra Phyics Mai Tai HP, respectively. For the chosen intensity settings 1.4 – 69µW were measured for the 635nm excitation in the back aperture of the objective. The spectral range of the fluorescence to be detected by the avalanche photodiode was selected applying 2 Semrock Brightline filters (FF01-685/40-25).The pinhole was set to values between 0.5 and 1 Airy to allow optical sectioning. Pixel sizes were kept between 19.2nm x 19.2nm and 27.7nm x 27.7nm to avoid undersampling. Shrinking the effective excitation spot results not only in increased resolution but also in less total signal in STED compared to confocal microscopy. In some cases this loss in signal intensity was compensated by raising the excitation power when recording the STED image, but to allow a fair comparison all other imaging parameters were always kept the same between the confocal and the according STED image. STED images for the MG-FAPs were recorded with the wavelength of the depletion laser set to 740nm. Depletion power at 740nm was up to 165mW measured at the back aperture of the objective.

All images were post-processed with a 1 pixel median filter within ImageJ. Confocal images were displayed at the full range of intensities (0-255) with the equivalent STED images displayed at three-quarters of that (0-192).

2. Depletion curves

To compare depletion efficiencies normalized fluorescence intensities are plotted against STED power. To generate these so called depletion curves for a given fluorogen/FAP combination two line sequential series of images of yeast were recorded with an Airy function used as depletion PSF overlaid with the excitation PSF. 50.5µW of excitation laser (635nm) were measured at the back aperture of the objective. The pinhole was set to Airy 0.5. The fluorescence collected on an internal PMT of the Leica TCS STED was selected with a Semrock Brightline filter (FF01-685/40-25). The power applied to the sample by the depletion laser was controlled via an AOM and varied for the individual images of a given series. For the first and second series 0, 5, 10, 15, 20, 25, 30, 35% and 0, 40, 50, 60, 70, 80, 90, 100% were chosen, respectively. The power of the STED laser was measured at the back aperture of the objective.

Typical images contained several yeast cells. The fluorescent regions to analyze (i.e. the cell wall) were identified applying a mask obtained by thresholding and median filtering For both image series background subtracted fluorescence intensity values obtained were normalized to the according 0% AOM frame and plotted against the STED power at the back aperture for the corresponding AOM setting. For a given fluorogen/FAP combination at least three depletion curves were recorded from different fields of views and averaged for a given wavelength. Figure S1 shows the depletion curves for L5-MG-L90S at three different depletion wavelengths (730, 740, 750nm). Figure S2 shows three different FAP clones depleted at 740nm compared to the organic dye Att647N used in indirect immunofluorescence and depleted at 750nm. Data for Atto647N were recorded with 39µW measured at the back aperture of the objective for the excitation laser. The areas to analyze were selected defining regions of interest on Atto647N stained Vero cells.

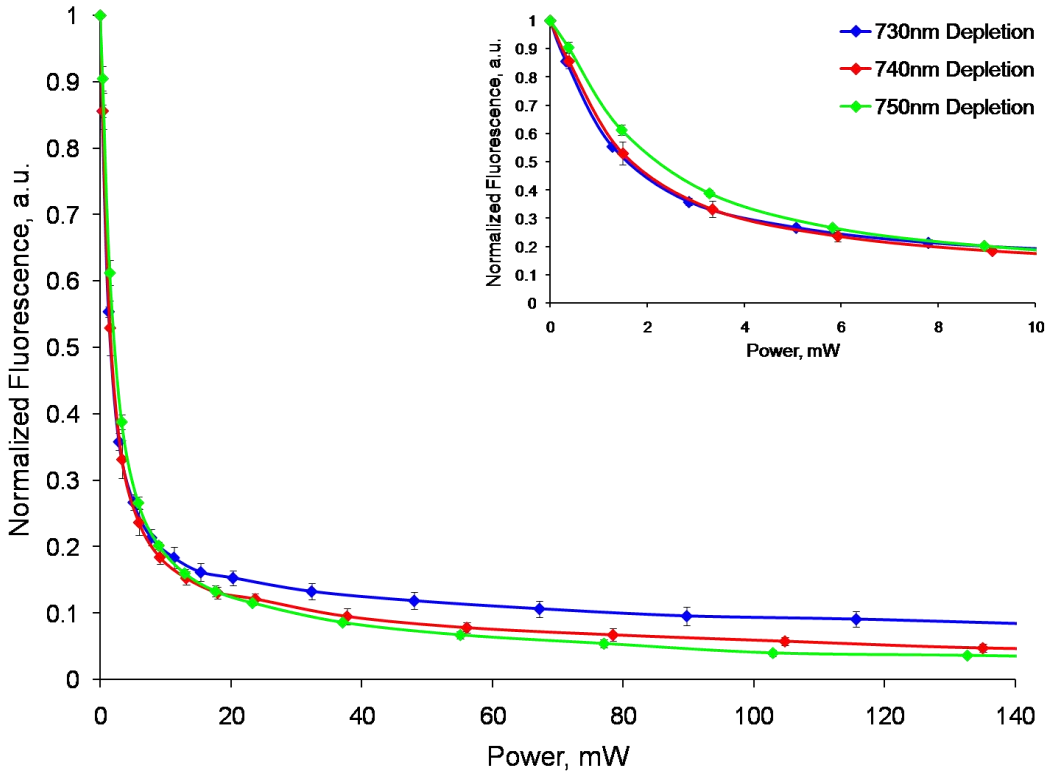

Figure S1. Depletion curves for L5-MG-L90S. Averaged curves (n=3) with standard deviation shown. Inset graph shows same depletion data for power range 0-10mW.

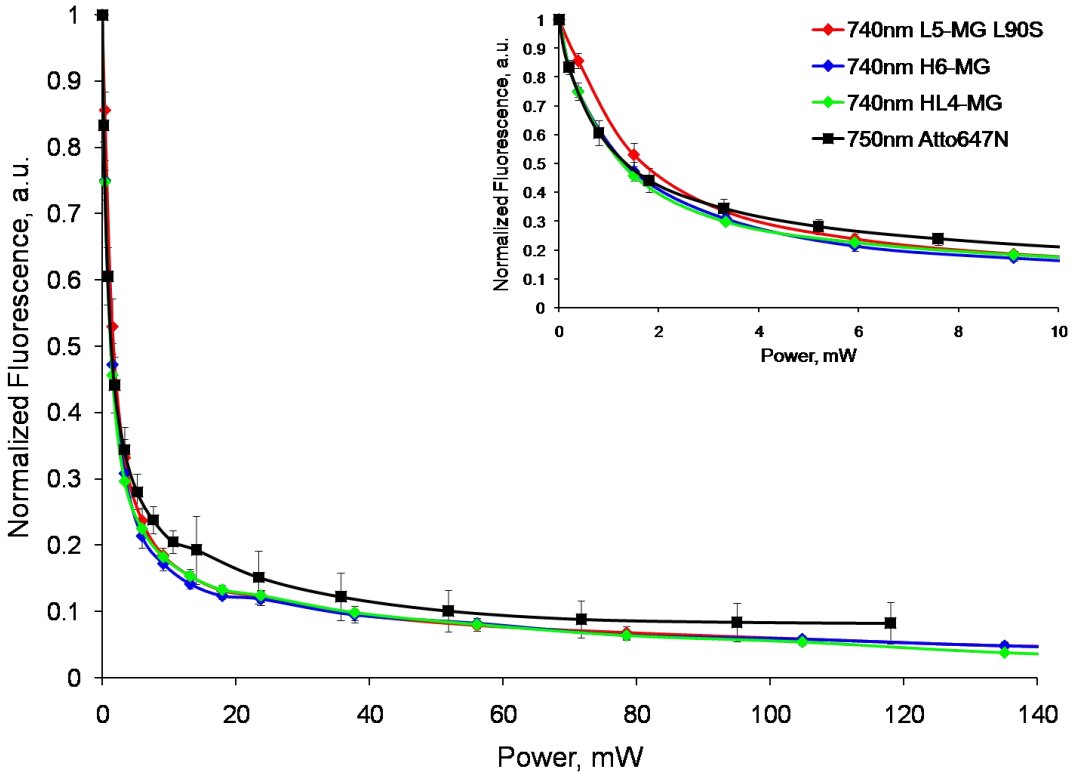

Figure S2. Depletion curves for L5-MG-L90S FAP depleted at 740nm and Atto647N organic dye depleted at 750nm. Note the similar depletion behavior of the probes which indicates that the same resolution increase can be expected. With the given commercial system a FWHM of ~70nm was measured for single fluorescent point sources for Atto647N (compare Figure S4). Averaged curves (n=3) with standard deviation shown.

3. Fixation of NIH 3T3 H6-AFM-MG-actin cells

Due to the presence of a diffuse background of fluorescence from monomeric actin in the H6-AFM-MG-actin construct expressed in living NIH 3T3 cells. These transfectants were fixed and permeabilized as described above to washout the monomeric actin and showed visible stress fibers upon labeling with 100nM of MG-2p. Figure S3 shows both confocal and STED images of fixed cells.

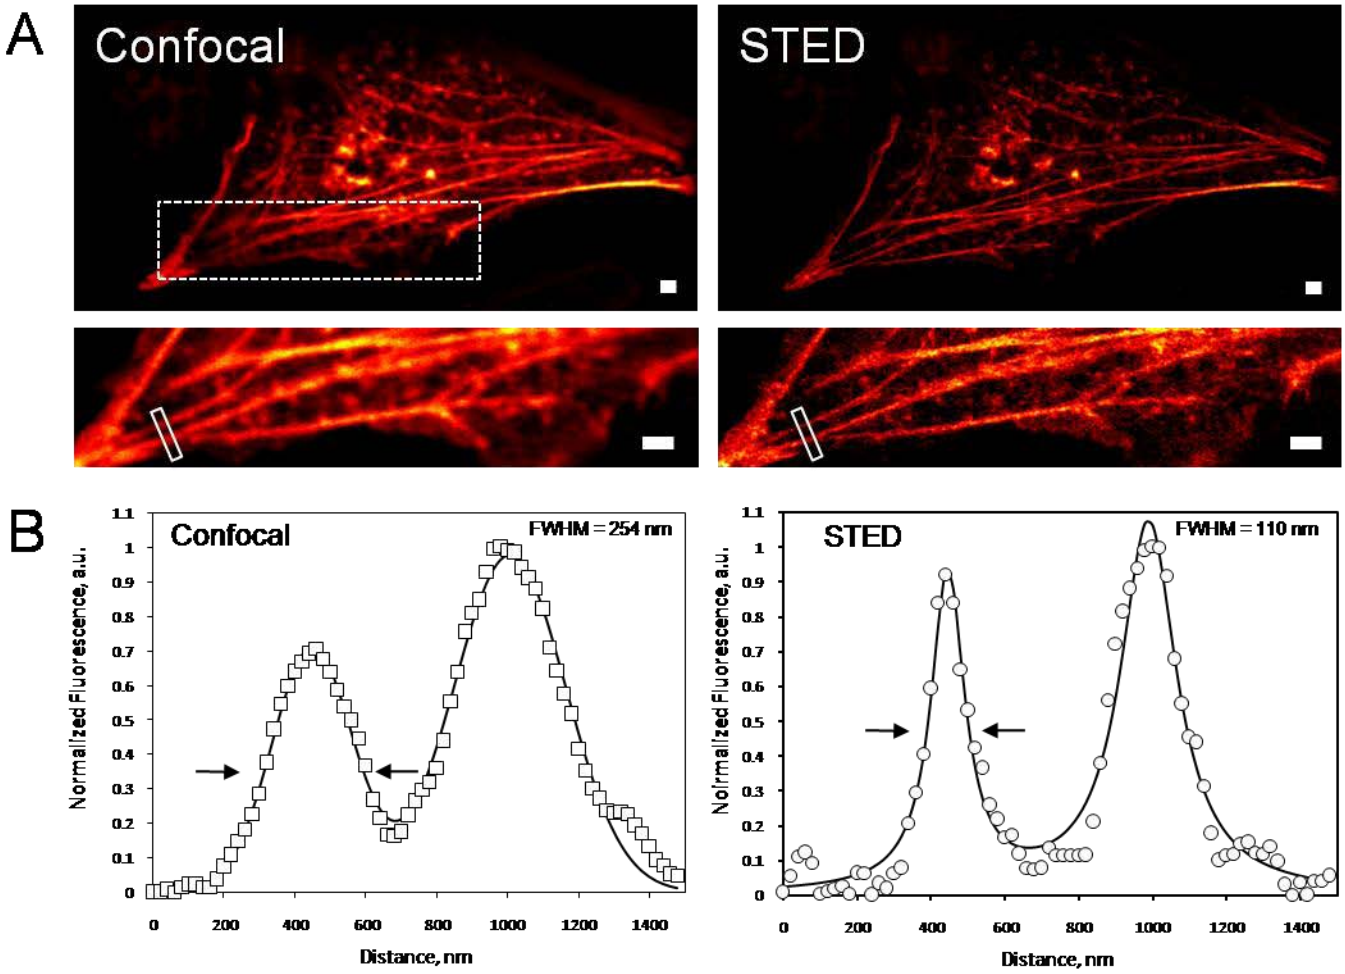

Figure S3. A. Fixed and permeabilized NIH 3T3 cells expressing the H6-MG-AFM disulfide free FAP module expressed as an N-terminal fusion to actin labeled using the MG-ester fluorogen (upper left panel confocal, upper right panel STED, with a zoomed in region denoted by the dashed line box below each image). Hollow white bar denotes a 10 pixel wide region of interest. **B.** Line profiles generated from the averaged fluorescence intensity within the region of interest plotted as a function of distance. Solid lines indicate a fit to a linear sum of one-dimensional Gaussian (confocal) or Lorentzian (STED) functions. The upper fiber in the image represents the first peak in the line profile whose FWHM are 254nm (confocal) and 110nm (STED). Solid white lines indicate 1μm scale bars.

4. Fitting confocal and STED line profiles

Line profiles were generated by taking a 10 pixel wide region of interest and averaging the fluorescence intensity over those 10 pixels as a function of lateral distance. Confocal line profiles were fitted to a one-dimensional Gaussian function of the form:

$$f(x) = ae^{-\frac{(x-x_0)^2}{\sigma^2}}$$

where *a* represents the peak intensity, x_0 the peak position and σ is related to the full-width at half maximum (FWHM) by the following equation: $\mathrm{FWHM} = 2\sqrt{2\ln 2}\,\sigma$. STED line profiles were instead fitted to a one-dimensional Lorentzian function of the form:

$$f(x) = a\left[\frac{\gamma}{(x-x_0)^2 + \gamma^2}\right]$$

where *a* represents the peak intensity, x_0 peak position and γ represents the true half-width at half maximum.

5. Estimating the resolution achievable for Atto647N with the given Leica TCS STED

The point spread function was experimentally determined on fluorescent point sources. For this purpose glass-adsorbed primary antibodies stained by Atto647N-labeled secondary antibodies mounted in Mowiol were imaged (as described in(*2*) with a depletion wavelength of 750nm). 183 objects were fitted with a 2D Lorentzian function. The obtained FWHM in x and y yielded an average of 71nm and 72nm, respectively.

For illustration, signals obtained for 183 single fluorescent point sources were overlaid (see **Figure S4**).

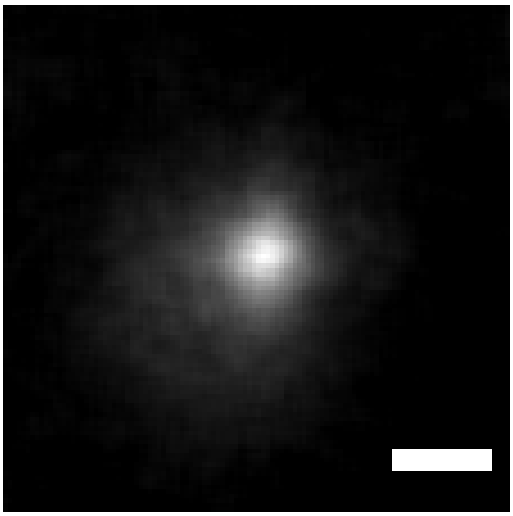

Figure S4. Overlaid signals from 183 single fluorescent point sources. Image is 112x112 pixels with pixel dimensions of 4.46nm (scale bar is 100nm).

Given the almost identical nature of the Atto647N and L5-MG-L90S depletion curves and I_{50} values, it is reasonable to project that the maximum resolution attainable with the L5-MG-L90S FAP module and the given system (Leica TCS-STED) will also be similar ~70nm.

We propose a new approach to optical virus detection based on the spatial assembly of gold nanoparticles on the surface of viruses. Since JC virus-like particles (VLPs) comprise a repeating viral capsid protein that binds to sialic acid, the conjugation of sialic acid-linked Au particles with VLPs enables the spatial arrangement of Au particles on the VLP surface. This structure produced a red shift in the absorption spectrum due to plasmon coupling between adjacent Au particles, leading to the construction of an optical virus detection system. Our system depends not on the simple cross-linking of VLPs and Au particles, but on an ordered Au structure covering the entire surface of the VLPs and can be applied to various virus detection systems using the inherent ligand recognition of animal viruses.

Plasmonic nanostructures have received increasing attention due to their potential application to the optical sensing of biological and chemical analytes. A metal nanoparticle sensor is based on the analyte-induced assembly of metal nanoparticles (*1*−*4*). The assembly of nanoparticles leads to a red shift in the peak wavelength of the surface plasmon resonance frequency. This principle has been applied to various sensing systems, including DNA (*5*), lectin (*6*), protein A (*7*), potassium ion (*8*), heavy metal ion (*9*), and nitrate detection (*10*). These methods require the cross-linking of nanoparticles by an analyte to form aggregations, in which the gap between nanoparticles is small enough to allow interparticle plasmon coupling. However, the analytes are much larger in size than the metallic nanoparticle, such as with viruses and bacteria; the nanoparticles cannot easily aggregate within the plasmon coupling distance.

In this paper, we propose a novel approach to the optical detection of viruses using gold nanoparticles. Recently, inorganic nanostructures prepared with viruses as templates have been often reported (*11*−*16*). However, there have been no reports on the use of their inherent molecular recognitions for the spatially ordered arrangement of metal nanoparticles, which can be applied to virus detection. Since the virus has multiple recognition sites for ligands on its surface, the ligand-displaying nanoparticles could be specifically arranged on the viral surface (Figure 1A). In this case, viruses can be detected from the plasmon shift derived from the assembled gold nanoparticles on the virus surface rather than the analyte-induced aggregation of metallic nanoparticles. The surface plasmon resonance shift strongly depends on both the interparticle distance and the number of coupled particles (*17*). The plasmon shift for multiple (more than two) nanoparticles in linear arrangement is larger than that for two nanoparticles; thus, the multiple coupling of nanoparticles on the virus is expected to cause a large shift of the plasmon band. In addition, the assembly of metallic nanoparticles into a shell-shaped structure is expected to lead to a large plasmon shift. Metallic clusters formed on a spherical body, such as silica particles (diameter∼100 nm) (*18*) or liposomes (diameter∼50 nm) (*19*), show a large red shift (∼200 nm) of the plasmon band. The virus-templated assembly of metallic nanoparticles in a shell-shaped structure is thought to contribute to this large plasmon shift.

To test our approach to the detection of viruses, we used JC virus, which belongs to the Polyomavirus family. This animal virus is a non-enveloped virus that infects humans through an *N*-glycoprotein with α2,6-linked sialic acid on the cell surface (*20*). The capsids contain 360 copies of viral protein 1 (VP1), arranged in 72 VP1 pentamers in an icosahedral lattice (*21*), and each VP1 monomer can bind to the α2,6-linked sialic acid. Since, without the inner DNA genome, the VP1s self-assemble to form virus-like particles (VLPs) *in vitro*, we used the VLPs as a model of native viruses. Using the binding affinity of VP1 to sialic acid, it is expected that the nanoparticles can be arranged on the virus surface corresponding to the spatial pattern of the VP1s (Figure 1A). Herein, using scanning transmission electron microscopy (STEM), we demonstrate that sialic acid-linked gold nanoparticles (sialyl-Au particles) can be assembled on the surface of VLPs. With the aid of a macromolecular crowding reagent, which promotes the association between VLPs and sialyl-Au particles, the interparticle plasmon coupling of the sialyl-Au particles on the viral surface could be detected in a solution as a red shift of the surface plasmon resonance band.

On the basis of previous literature (*22*, *23*), we synthesized a sialic acid-linked lipid (Figure 1B). Synthetic details are shown in the Supporting Information. On the surface of commercially available gold nanoparticles, a ligand-exchange reaction was carried out in the presence of the sialic acid-linked lipid (10 μM) in water. We prepared three sizes of sialyl-Au particles with diameters of 5, 10, and 15 nm, respectively. The binding of the sialic acid-linked lipid to the Au nanoparticles was qualitatively confirmed by FT-IR spectrometry (see Supporting Information Figure S1).

JC capsid protein VP1s recombinantly expressed in *Escherichia coli* spontaneously self-assemble into virus-like particles (VLPs) as described in our previous report (*24*). The conjugation

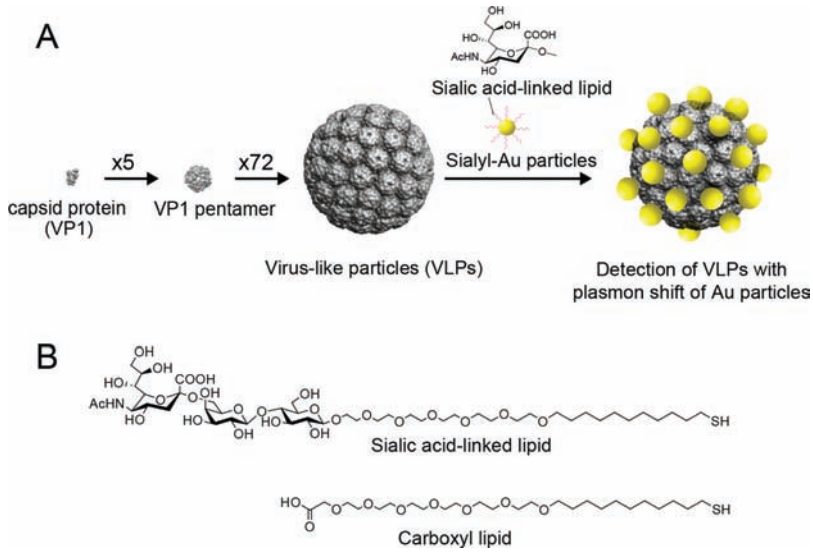

Figure 1. Schematic representation of the detection of virus particles. (A) The formation of the sialyl-Au particle array based on virus-like particles (VLPs) through viral ligand recognition. (B) Structures of the sialic acid-linked and carboxyl lipids used in the preparation of sialyl-Au and carboxyl-Au particles.

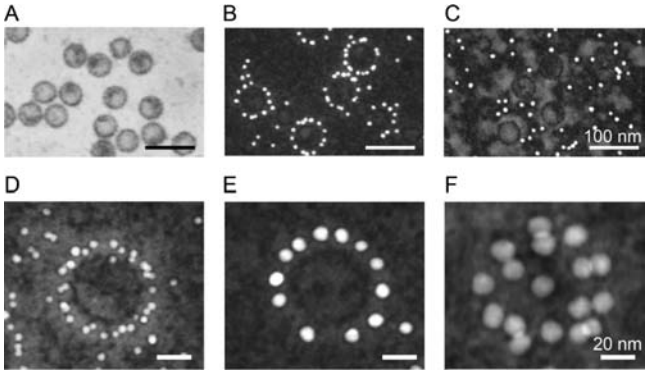

Figure 2. STEM images of (A) VLPs alone, (B) VLPs incubated with 10-nm sialyl-Au particles, and (C) VLPs with 10 nm carboxyl-Au particles. The scale bars represent 100 nm. Sialyl-Au particles were arranged on VLPs, and the diameters of the sialyl-Au particles were (D) 5 nm, (E) 10 nm, and (F) 15 nm, respectively. The scale bar represents 20 nm. The samples were stained with 2% phosphotungstic acid.

of sialyl-Au particles with VLPs was confirmed by STEM. VLP solutions were mounted and immobilized on a carbon-coated TEM grid. After bovine serum albumin (BSA) blocking, a solution of sialyl-Au particles was placed on the VLP-immobilized grid. It is important to note that, for effective binding, this solution was gradually concentrated by evaporation of the solvent on the TEM grid. After washing the grid surface with pure water to remove unbound nanoparticles, the samples were stained with 2% phosphotungstic acid. We observed a homogeneous population of VLPs of around 40 nm in diameter by STEM (Figure 2A). After incubation of the sialyl-Au particles (10 nm) with VLPs for 90 min, binding was confirmed by visualization (Figure 2B). In a control experiment, Au nanoparticles covered with carboxyl lipids were found not to bind onto the VLPs (Figure 2C), indicating that the binding is based on specific recognition between the sialyl-Au particles and the VLPs. The dark background observed in Figure 2B,C is due to BSA blocking.

Figure 2D,E,F shows the typical binding behavior between VLPs and sialyl-Au particles of 5 nm, 10 nm, and 15 nm, respectively. Using 5 and 10 nm sialyl-Au particles, the only observable nanoparticle assembly is in the form of a "ring" structure surrounding the VLPs. These "ring" TEM images have often been observed in noncovalent DNA interaction-driven nanoparticle assemblies (*25*, *26*). In the case of the 15 nm sialyl-Au particles, however, the particles were observed over the entire VLP surface (Figure 2F). We believe that the larger contact area of the 15 nm particles produces an increased number of sialic acid-VP1 interactions affording a stronger affinity between the VLPs and Au particles than that of 5 nm and 10 nm particles.

When Au nanoparticles are assembled, their surface plasmons combine, and the aggregate can be considered a single large particle. This causes a red shift and a broadening of the surface plasmon band. However, the dissociation constant of the native sialic acid-containing glycoprotein and VLPs is on the order of 10^{-7} M (*24*); thus, the concentration used in this study (nM order) was too low for the conjugation of Au nanoparticles with VLPs in solution. Thus, we added dextran as a macromolecular crowding reagent. Molecular crowding enhances the equilibrium association of dilute macromolecules (*27*−*29*). We expected the addition of dextran to induce complex formation, leading to a clear red shift in the plasmon spectra. Figure 3A shows the effect of the molecular crowding reagent on the red shift of the surface plasmon band. At above 30 wt %, dextran induced effective association between the 15 nm sialyl-Au particles and VLPs. As a control, without VLPs, no such shifts were observed, supporting the notion that the red shift can be attributed to the specific interaction between sialyl-Au particles and VLPs. The color of the sialyl-Au particle solution was changed from red to purple after the addition of VLPs (Supporting Information Figure S2). The surface plasmon spectrum of the 15 nm sialyl-Au particles in the presence of VLPs and 40 wt % dextran is shown together with the control spectra in Figure 3B. A 22 nm red shift was observed when 15 nm sialyl-Au particles were incubated with VLPs. To exclude the possibility of nonspecific binding driven by electrostatic interaction, we prepared other negatively charged gold nanoparticles coated with a carboxyl lipid (carboxyl-Au particles). The zeta potential of the sialyl-Au and carboxyl-Au particles were almost the same (-31 ± 1.9 mV and -29 ± 3.8 mV, respectively), indicating that the carboxyl-Au particles afford a suitable control for the negatively charged sialyl-Au particles. The addition of carboxyl-Au particles to a solution of VLPs did not cause a plasmon shift.

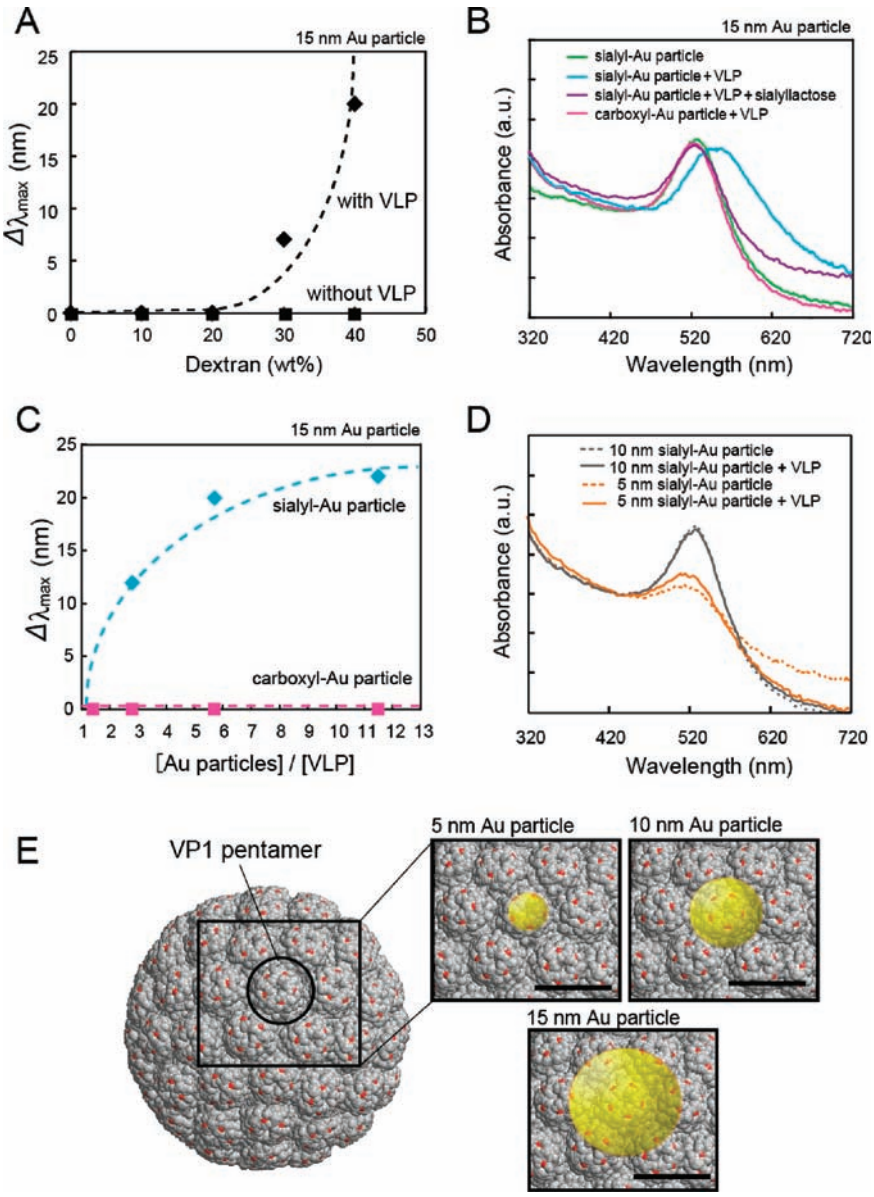

Figure 3. (A) The effect of dextran on the red shift of the surface plasmon band of sialyl-Au particles with or without VLPs ([sialyl-Au particles] = 4 nM, [VLPs] = 0.8 nM). (B) UV−vis spectra for sialyl-Au and carboxyl-Au particles with VLPs in the presence of 40 wt % dextran. As negative controls, 15 nm sialyl-Au particle solutions without VLPs in the presence of 40 wt % dextran and 15 nm sialyl-Au particle solutions containing 5.5 mM sialyllactose as an inhibitor were measured. (C) The red shift of the surface plasmon band of 15 nm sialyl-Au and carboxyl-Au particles in 40 wt % dextran-containing buffered solution as a function of the ratio of Au particles to VLPs. VLP concentration remained at 0.8 nM. (D) UV−vis spectra of solutions of 5 nm and 10 nm sialyl-Au particles containing 40 wt % dextran, with or without VLPs. (E) Schematic representations of the binding of each size of Au nanoparticle to the VLP structure (*35*). Red dots on VLP represent sialic acid binding sites, with each single VP1 pentamer having five binding sites in total. The yellow areas represent the area occupied by each size of Au nanoparticles. The 15 nm Au nanoparticle can be seen to overlap with the adjacent VP1 pentamers. The scale bar represents 10 nm.

Moreover, no red shift of the sialyl-Au particles was observed in the presence of VLPs and an excess amount of sialyllactose (Figure 3B).

This indicates that the red shift in Figure 3B is due to specific binding between the sialyl-Au particles and VLPs. Keating et al. have demonstrated the effect of macromolecular crowding reagents, such as dextran and poly(ethylene glycol) (PEG) solutions, on the thermodynamics of DNA-linked nanoparticle assembly (*30*). They reported that the macromolecular reagents induced not only DNA hybridization-driven nanoparticle assembly, but also undesired nonspecific nanoparticle aggregation. In our experiment on carbohydrate−virus interaction, we clearly demonstrate that the macromolecular crowding reagent is effective in enhancing the specific association of the nanoparticle−biomolecule conjugation. The degree of the red shift was increased in a dose-dependent manner as a function of sialyl-Au particle concentration (Figure 3C), indicating that the interparticle distances were gradually shortened and collective surface plasmon resonance (SPR) changed through modulation of dipole coupling. As an important control, the addition of carboxyl-Au particles to VLPs did not affect the wavelength of the plasmon peak.

On the other hand, the addition of dextran to solutions of 5 nm and 10 nm sialyl-Au particles in the presence of VLPs had no observable effect on the red shift (Figure 3D). Figure 3E shows the difference in size between each Au-particle and a VLP. Each VLP is composed of 72 VP1 pentamers, the diameter of which is approximately 8 nm. A single 5 nm Au particle is able to cover five binding sites of a single VLP pentamer. A 10 nm Au particle is larger than a VP1

pentamer, but it is not large enough to reach the binding sites located on adjacent VP1 pentamers. A 15 nm Au particle disposed on a particular VP1 pentamer, however, can reach six adjacent VP1 pentamers. The number of linkages between the single sialyl-Au particle and the recognition sites of the VLP proportionally influences the binding enthalpy due to cooperative interaction. The larger Au nanoparticles, which have a larger contact area, form a larger number of sialic acid-VLP linkages. Therefore, we can attribute the large plasmon shift of the 15 nm sialyl-Au particles in solution to the increased affinity.

The main factors controlling plasmon coupling are interparticle gap and particle size, and the relationship between these which can be quantitatively expressed as $D/(2r)$, where D is the distance between the centers of adjacent particles, and $2r$ is the diameter of the metal nanoparticle (*31*). It is known that strong interparticle coupling between a pair of adjacent nanoparticles occurs when $D/(2r)$ is smaller than 1.2. In the case of sialyl-Au particles, since the molecular length of the sialic acid lipid is approximately 4.5 nm, the minimum gap when two particles are attached to each other between the metal cores of two sialyl-Au particles is calculated to be 9 nm ($D/(2r) = 1.6$ for the 15 nm Au particles) (Supporting Information Figure S3). According to previous theoretical and experimental data (*17*, *32*), a plasmonic-coupled pair of Au particles having a $D/(2r)$ value of 1.6 cannot explain the pronounced shift (22 nm) observed in this study. Arrayed colloidal nanoparticles, however, have been reported to demonstrate near-field coupling, although the $D/(2r)$ value was larger than 1.2, leading to coherent interactions between multiple adjacent colloidal nanoparticles (*33*, *34*). Therefore, the shift observed here might be caused not by the interparticle coupling from a single pair of metal particles, but by multiple particle arrays.

In summary, we found that the 15 nm sialyl-Au particles are suitable to the optical detection of JC virus VLPs through sialic acid recognition with the aid of a crowding reagent. STEM images supported the notion of multiple Au particle interactions on the surface of a single VLP, leading to a red plasmon shift. Since animal viruses often show inherent molecular recognition, for example, recognizing carbohydrate molecules, the use of ligand-specific interactions could provide a versatile approach to virus detection. Furthermore, we propose that this method is not only applicable to virus detection but also as a simple approach to the investigation of the optical properties of a nanospace surrounded by multiple metal nanoparticles.

ACKNOWLEDGMENT

This study was supported in part by grants from the Ministry of Education, Culture, Sports, Science and Technology; the Ministry of Health, Labor and Welfare, Japan; and the Program of Founding Research Centers for Emerging and Reemerging Infectious Diseases, MEXT, Japan. Nagakawa and Ohtake appreciate the financial support provided by JSPS. The analysis of STEM was carried out at the OPEN FACILITY, Hokkaido University Sousei Hall and HINTS.

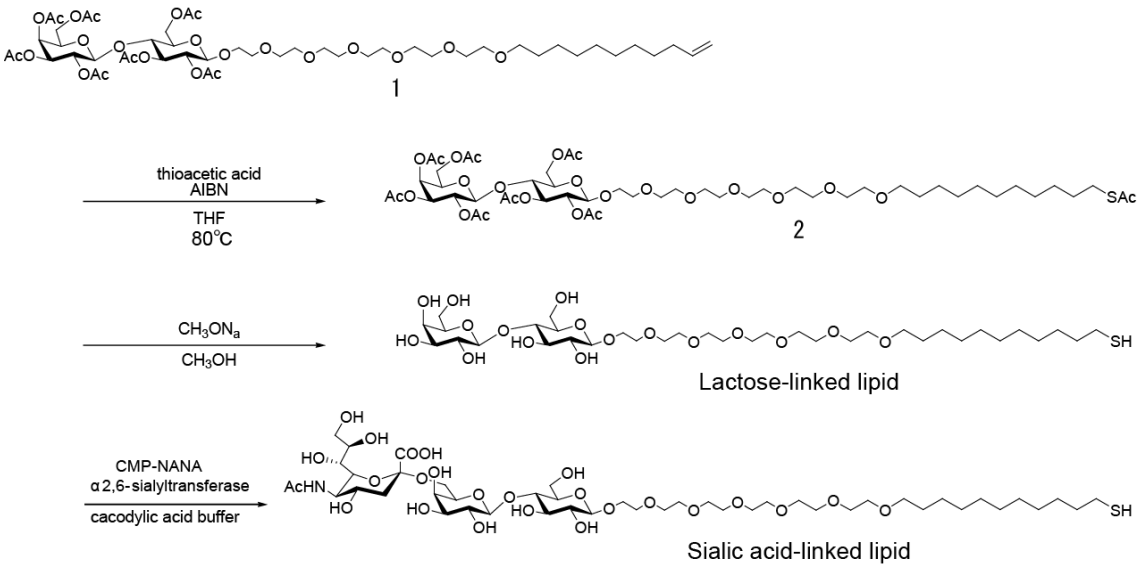
Experimental Section

General Methods.

Carboxyl-lipid was purchased from TOYOBO (Japan). CMP-*N*-acetylneuraminic acid disodium salt (CMP-NANA, 2Na) and α2, 6-Sialyltransferase was obtained from Nacalai Tesque, Inc. (Japan), and Japan Tobacco, Inc. (Japan), respectively. Gold nanoparticles (Diameter = 5, 10, or 15 nm) were purchased from BB International (UK). All commercial reagents were purchased from Wako Pure Chemical Industries (Japan) and used as received. MALDI-TOF MS spectra were measured with a Voyager-DE STR-H spectrometer (Applied Biosystems, USA) using 2, 5-dihydroxybenzoic acid (Bluker, Germany) as the matrix. NMR spectra were measured with a JEOL 400 spectrometer.



Scheme S1. Synthesis of sialic acid-linked lipid.

Synthesis of Compound 2

Compound **1** was synthesized according to Penadés' method.[1,2] To solutions of compound **1** (500 mg, 0.47 mmol) in THF (20 ml) was added thioacetic acid (50 µl, 0.7 mmol) and azobis(isobutyronitrile) (AIBN, 70 mg, 0.43 mmol). The mixture was refluxed for 16 h at 70-80 ˚C under illumination with UV light. The crude of reaction mixture was concentrated and purified by chromatography on silica gel using mixture solvents (AcOEt:CH_2Cl_2= 1:1). Compound **2** was obtained as a colorless syrup (400 mg, 0.35 mmol, 75 %).

^{1}H-NMR(400MHz, $CDCl_3$): δ = 5.34 (d, 1H, *J*= 3.2 Hz), 5.19 (t, 1H, *J*= 9.2Hz), 5.10 (dd, 1H, *J*= 11 and 7.8 Hz), 4.95 (dd, 1H, *J*= 3.6 and 11 Hz), 4.89 (t, 1H, *J*= 8.2 Hz), 4.56 (d, 1H, *J*= 7.9 Hz), 4.50-4.47 (m, 2H, *J*= 7.9 and 4.1 Hz), 4.10 (m, 3H), 3.89 (m, 2H), 3.79 (t, 1H, *J*= 9.4 Hz), 3.7 (m, 1H), 3.64 (m, 23H), 3.44 (t, 2H, *J*= 6.8 Hz), 2.86 (t, 2H, *J*= 7.4 Hz), 2.32-1.97 (s, 24H), 1.56 (m, 4H), 1.26 (m, 14H); MALDI-TOF MS (m/z) calcd. for $C_{51}H_{84}O_{25}SNa$: 1152.26 $[M+Na]^+$, found 1151.42.

Synthesis of Lactose-linked lipid

A solution of compound **2** (400 mg, 0.35 mmol) in dry MeOH (20 ml) was treated with a 28% methanolic solution of NaOMe (10 µl, 0.72 mmol). The reaction mixture was left for 1 h to complete the oxidation of the thiol group. The reaction was then neutralized with Dowex ion-exchange resin (Dowex 50WX8-200). Purification by reverse phase chromatography (Wakogel 50C18, water:methanol = 1:0.1-1) gave the lactose-linked lipid as a white powder (190 mg, 0.25 mmol, 70 %).

^{1}H NMR(400MHz, CD_3OD) : δ = 4.35 (t, 2H, *J*= 7.3 and 7.6 Hz), 3.4-4 (m, 37H), 3.26 (t, 1H, *J*= 8.3 Hz), 2.68 (t, 1H, *J*= 7.2 Hz), 2.49 (t, 1H, *J*= 7.2 Hz), 1.68 (qn, 1H, *J*= 7.4 Hz), 1.57 (qn, 3H, *J*= 7.0 Hz), 1.45-1.3 (m, 14H); MALDI-TOF MS (m/z) calcd. for $C_{35}H_{67}O_{17}SNa$: 814.97 $[M+Na]^+$, found 815.01.

Synthesis of Sialic acid-linked lipid

Sialylation of the lactose-lipid (5.0 mg, 6.6 µmol) was performed using recombinant α2,6-sialyltransferase (40 µl, 50 mU/ml) in 20 mM cacodylate buffer (1 ml, pH 7.5) containing CMP-NANA (15 mg, 23 µmol) at 30 ºC for 24 h. α2,6-sialyltransferase was used to enzymatically add *N*-acetylneuraminic acid (sialic acid) to the lactose-linked lipid. Purification by size exclusion chromatography (Sephadex G-25 Fine,GE Healthcare UK Ltd., England) gave the sialic acid-linked lipid as a white powder (3.4 mg, 47 %).

^{1}H NMR (400MHz, CD_3OD): δ = 4.30 (dd, 2H, *J*= 10Hz and 9.2 Hz), 3-4.23 (m, 45H), 2.79 (q, 1H, *J*= 12 Hz), 2.68 (t, 1H, *J*= 7.1 Hz), 2.49 (t, 1H, *J*= 6.6 Hz), 1.99 (s, 3H), 1.65 (t, 1H, *J*= 12 Hz), 1.6-1.2 (m, 18H); MALDI-TOF MS (m/z) calcd. for $C_{46}H_{84}NO_{25}S$: 1083.22 $[M-H]^-$, found 1082.05.

Synthesis of carboxyl-Au and sialyl-Au particles

Au nanoparticles (OD_{520nm}=1.0, 2 nM for 15-nm diameter Au particles) were stirred with 10 μM carboxyl-lipid or sialic acid-linked lipid in 5 ml of water for 16 h. The solution was passed through a spin filter (Microcon YM-30, Millipore, USA) to remove excess lipids. The Au nanoparticles remaining on the filter were washed with water several times, and then redispersed in HEPES buffer (pH 7.4, 20 mM HEPES-NaOH, 150 mM NaCl, 1 mM $CaCl_2$). The zeta potential of the carboxyl- and sialyl-Au particles was measured using a zetasizer nano ZS (Malvern, UK).

Scanning transmission electron microscopy (STEM) analysis

A VLP solution (2 μl) was mounted onto a carbon-coated TEM grid (400-mesh with a collodion film, Nisshin EM, Japan) for 5 min and the grid was washed with buffered solution. A BSA (40 mg/ml)-dissolved aqueous solution (2 μl) was dropped onto the VLP-immobilized grid and incubated for 5 min. After removal of the BSA solution by absorption using filter paper, a solution of sialyl-Au particles (5 nM) was dropped onto the grid. The gold nanoparticle solutions were concentrated for 90 min in a N_2 desiccator, and then negatively stained with 2 % phosphotungstic acid (pH 7.4). After desiccation overnight, VLP morphology was confirmed by scanning transmission electron microscopy (STEM) (HD-2000, Hitachi, Japan).

UV-vis spectroscopy analysis

To a 20 μl solution of VLPs (0.8 nM) in HEPES buffer (pH 7.4, 20 mM HEPES-NaOH, 150 mM NaCl, 1 mM $CaCl_2$) was added dextran (Mw 60,000, final concentration = 0~40 wt%) and gold nanoparticles. After incubation for 3 h at room temperature, the plasmon band of the gold nanoparticles was monitored using UV-vis spectroscopy (Nanodrop ND-1000, THERMO, USA).

Inhibition of sialyl-Au particle binding to VLP

To a 20 μl solution of VLPs (0.8 nM) containing sialyl-Au particles (9 nM) and dextran (40 wt%) was added an excess amount of sialyllactose (73 μg, 110 nmol, final concentration = 5.5 mM). After incubation for 3 h at room temperature, the plasmon band of the gold nanoparticles was monitored using UV-vis spectroscopy (Nanodrop ND-1000, THERMO, USA).

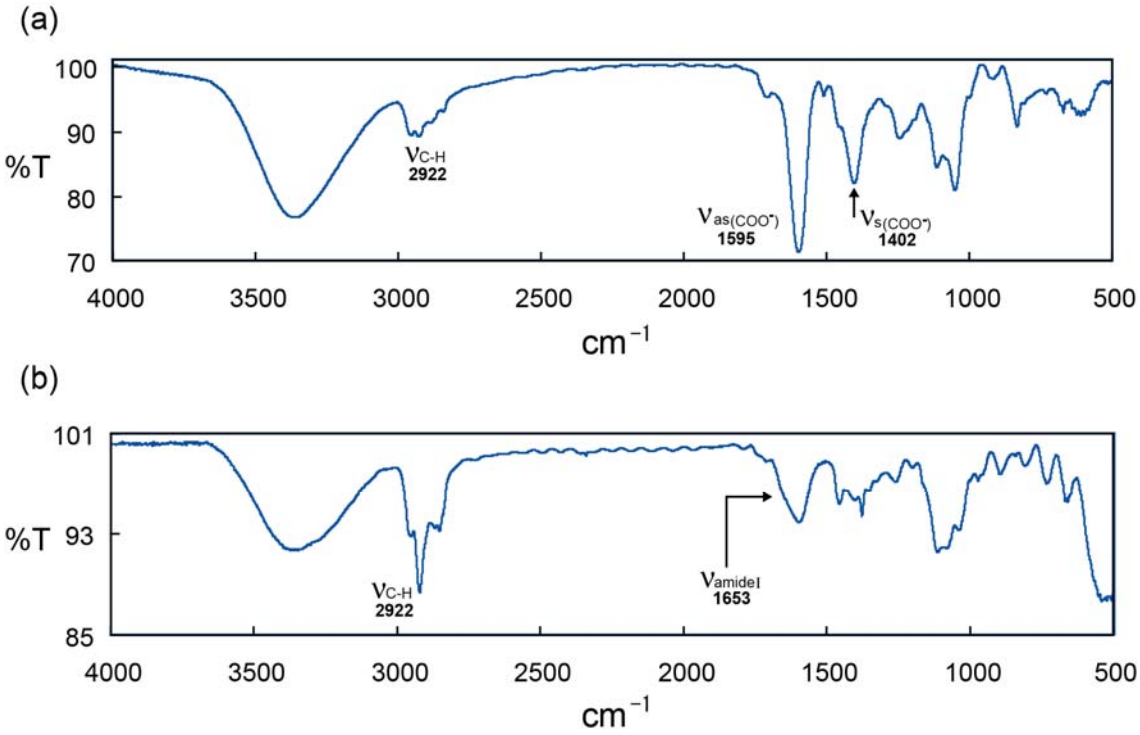


Figure S1. FT-IR spectrum of the Au nanoparticles a) before and b) after the ligand-exchange reaction. a) Before the ligand-exchange reactions, there were large peaks at 1595 cm^{-1} and 1402 cm^{-1}, corresponding to the asymmetric v_{as} (COO^-) and symmetric v_s (COO^-) stretching peaks of the carboxylate (citric acid)[3] on the surface of the Au nanoparticles. b) After ligand exchange to the sialic acid-linked lipid, the peak at 2922 cm^{-1}, corresponding to the C-H stretching vibration, was increased, indicating the presence of the alkyl chains in the sialic acid-linked lipid.[4] The characteristic peak of amide I derived from sialic acid [3] also appeared as a shoulder region peak at 1653 cm^{-1}.

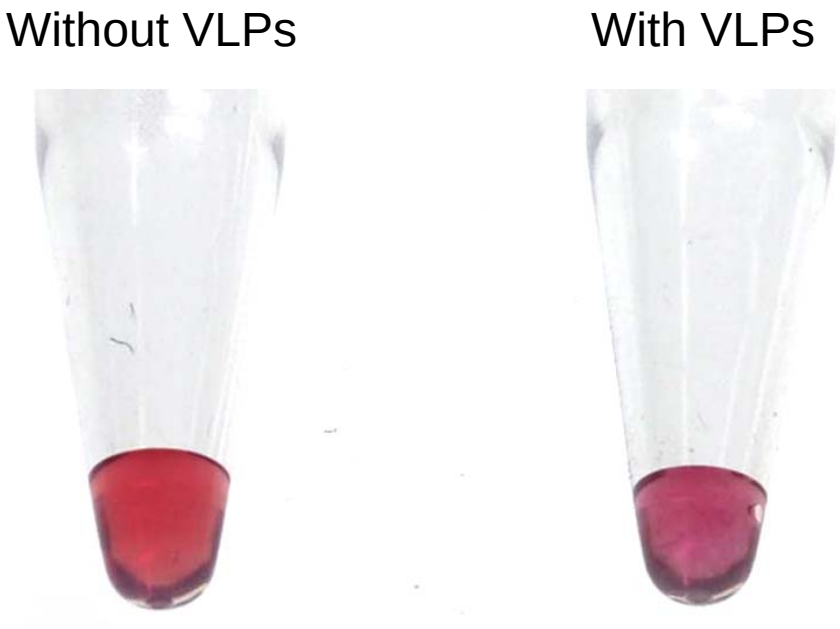

Figure S2. Photographs of particle solutions containing 15-nm sialyl-Au particles and 40 wt% dextran after incubation with or without VLPs. The solution with VLPs shows a red-shift of 20 nm.

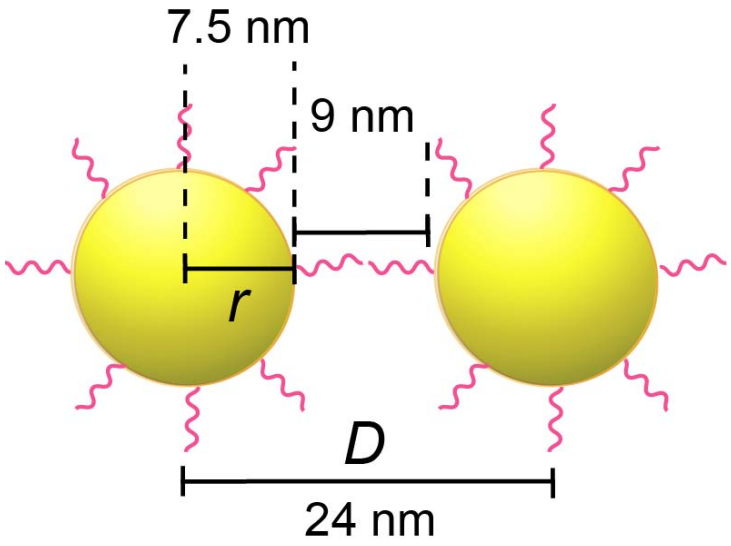

Figure S3. A scematic representation of the direct attachment of two sialyl-Au particles. The extended length of the sialic acid-linked lipid was determined to be 4.5 nm by Chem3D. The minimum gap between two Au-particles and the value of *D/(2r)* were calculated to be 9 nm and 1.6 nm, respectively.

Poly(amidoamine) (PAMAM) dendrons were synthesized with c(RGDyK) peptide on the surface to create a scaffold for cellular targeting and multivalent binding. Binary dendron-RGD conjugates were synthesized with a single Alexa Fluor 488, biotin, methotrexate drug molecule, or additional functionalized dendron at the focal point. The targeted dendron platform was shown to specifically target $\alpha_V\beta_3$ integrin expressing human umbilical vein endothelial cells (HUVEC) and human glioblastoma cells (U87MG) *in vitro* via flow cytometry. Specific targeting of the dendron−RGD platform was further confirmed by confocal microscopy. Biological activity of the targeted drug conjugate was confirmed via XTT assay. The orthogonal reaction chemistry used at the dendron focal point gives a precise 1:1 ratio of the attachment of multiple functionalities to a small-molecular-weight, chemically stable, high avidity molecule. These studies serve as a framework to selectively combine biologically relevant functions with enhanced specific binding activity to substitute for antibodies in many diagnostic and therapeutic applications.

INTRODUCTION

The development of specific targeting molecules for diagnostic and therapeutic applications is an important goal being pursued by the biomedical community. Precise targeting of molecules, cellular compartments, or tissues has the potential to positively affect a broad range of disciplines including diagnostic and imaging technologies, and could enhance the treatment of a wide range of conditions such as inflammation, infectious diseases, and cancer. The most common molecules currently employed for numerous applications are monoclonal antibodies (*1, 2*) or immunoconjugates of these antibodies, which take advantage of their high specific binding affinities for antigens. Almost all specific diagnostics are now based on some form of immunoconjugate (*3*−*7*), and numerous monoclonal antibody-based therapeutics are FDA-approved to meet clinical needs (*8, 9*).

Despite these successes, immunoconjugates suffer from significant disadvantages. There are many small molecules that are not immunogenic, and therefore cannot be identified by antibodies. In addition, antibodies are proteins that denature under many chemical and thermal conditions, and therefore necessitate strict refrigeration requirements for diagnostic kits or therapeutics based on immunoconjugates. The large size (approximately 150 kDa) of immunoconjugates limits blood clearance and potentially causes slow tumor penetration (*10, 11*). Being foreign proteins, antibodies elicit immunogenic responses in patients that limit their therapeutic utility (*12, 13*). Finally, biological molecules are difficult and costly to produce in bulk (*14*). Thus, alternative molecules to antibodies are needed.

Poly(amidoamine) (PAMAM) dendritic macromolecules are controllable in size and have defined, monodisperse (PDI = 1.02) structures. The macromolecule is significantly smaller than antibodies, which allows the device to enter the cell to potentially treat multiple proliferation pathways. In addition, the polyamide backbone helps the macromolecule maintain water solubility and minimizes immunogenicity (*15, 16*). The dendritic macromolecules also have large numbers of surface primary amines created by a branched architecture that allow for the attachment of multiple molecules with various functions. This has been demonstrated with targeting ligands, imaging agents, and therapeutics (*17, 18*). The ability to conjugate multiple targeting moieties provides the opportunity to create a platform with increased binding avidity through polyvalent cell interactions (*19*). Targeted dendrimer delivery platforms have been successfully tested in *in vitro* and *in vivo* model tumor systems (*20*−*29*).

To increase the utility of the dendritic scaffold, orthogonal and modular pathways can be used to construct binary devices with a greater degree of specificity and flexibility. However, current research pursuing such pathways to create functional

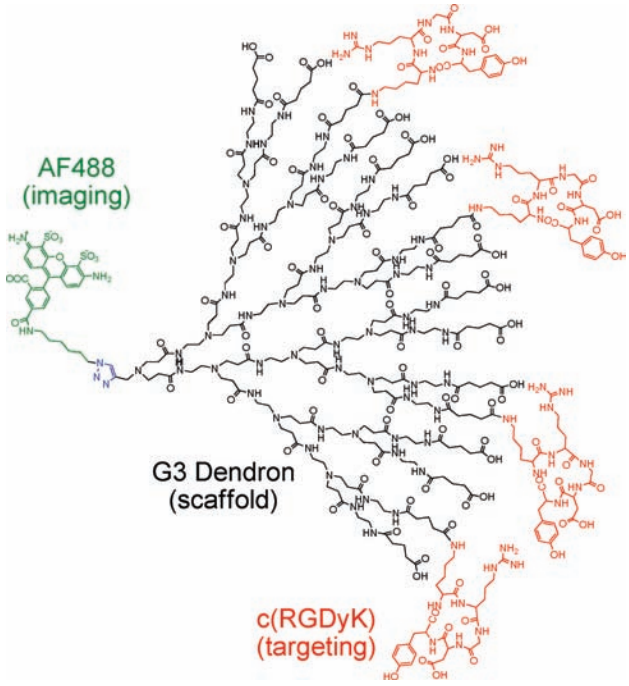

Figure 1. Dendron conjugate AF-G3$(COOH)_{11.9}(RGD)_{4.1}$ (**4**) where Alexa Fluor 488 is conjugated to the dendron focal point via a 1,3-dipolar cycloaddition. The targeting moiety, c(RGDyK) peptide, is conjugated to the carboxylated surface of the dendron.

dendritic devices has been sparse. PAMAM dendrimers have been developed with unique surface groups for modular synthesis via click chemistry (*30*), complementary oligonucleotide hybridization (*31*), or orthogonal functionalization (*32*). Dendrons with a bis-MPA backbone have been utilized by exploiting the unique reactive site at the focal point to create bifunctional materials (*33*). These approaches offer the potential to construct individual combinations for a specific targeting application from a common library of functionalized devices in a versatile manner and overcome the inefficiencies of stepwise conjugations on a single dendritic macromolecule. However, the central advantage of these techniques is that they provide increased homogeneity products by reducing the complexity of ligand distributions created by multifunctional platforms.

Herein, we present the synthesis and evaluation of *in vitro* biological activity for a targeted, PAMAM dendron avidity platform (Figure 1). The functionalized PAMAM dendron can maintain the binding specificity and multivalency of previous dendritic models (*25, 34*) while creating an orthogonally coupled scaffold more suitable for personalized medicine and applications. Binary devices were synthesized through a unique alkyne group at the dendron focal point. The alkyne is reacted with an azide-functionalized dye, biotin, therapeutic molecule or a second dye-conjugated dendron in a copper-catalyzed 1,3-dipolar cycloaddition, commonly referred to as "click chemistry" (*35*). This strategy is attractive because it provides high versatility and yields, mild reaction conditions, and no alteration to neighboring functional groups that eliminates the need for protecting groups. The platform itself gives a precise 1:1 ratio of the attachment of multiple functionalities, preventing aggregate formation. A dendron with multiple Arg-Gly-Asp (RGD) adhesion ligands on the surface and an additional function at the focal point can specifically target $\alpha_V\beta_3$ integrin expressing human umbilical vein endothelial cells (HUVEC) and human glioblastoma cells (U87MG), displaying the biological utility of the platform. The dendron−RGD platform also successfully inhibits tumor growth when conjugated to a therapeutic drug, such as methotrexate (MTX). Thus, the ability to conjugate specific and varied effector sites to the dendron periphery to generate a high avidity binding agent and use orthogonal reaction chemistry at the focal point to add additional functionalities makes these "dendro-bodies" an attractive alternative to antibodies for targeting applications.

EXPERIMENTAL PROCEDURES

General. Alexa Fluor 488 azide and Prolong Gold mounting agent were obtained from Invitrogen. c(RGDyK) peptide was obtained from Peptide International. Biotin-$dPEG_{3+4}$-azide was obtained from Quanta Biodesign. Sephadex G15 and G25 were obtained from GE Life Sciences. Spectra/Por 7 dialysis membrane (MWCO 1000) was obtained from Spectrum Laboratories. NeutrAvidin-Dylight 405 was obtained from Pierce. All other chemicals were obtained from Sigma. All purified reaction products were characterized by ^1H NMR, HPLC, and matrix-assisted laser desorption-ionization time-of-flight (MALDI-TOF) mass spectrometry.

Synthesis of Alkyne-G3-PAMAM Dendron (1). Alkyne-G3-PAMAM dendron was prepared as previously reported (*36*) and analyzed by ^1H and ^{13}C NMR and MALDI-TOF. MS (MALDI), 3479 Da; calculated for $C_{153}H_{305}N_{61}O_{30}$, 3479.45 Da.

Synthesis of Alkyne-G3$(COOH)_{16}$ (2). Glutaric anhydride (0.0164 g, 0.144 mmol) dissolved in anhydrous MeOH (0.8 mL) was added dropwise to a solution of **1** (0.0200 g, 0.00575 mmol) and triethylamine (Et_3N) (0.0186 g, 0.184 mol) in anhydrous MeOH (0.2 mL) while stirring, and the reaction mixture was allowed to stir for 24 h at room temperature. All solvent was removed in vacuo, and the reaction material was dissolved in H_2O, purified on a G-15 Sephadex column and lyophilized. MS (MALDI), 5305 Da; calculated for $C_{233}H_{401}N_{61}O_{78}$, 5305.04 Da.

Synthesis of Alkyne-G3$(COOH)_{11.9}(RGD)_{4.1}$ (3). 1-(3-(Dimethylamino)propyl)-3-ethylcarbodiimide HCl (EDC) (0.0838 g, 0.437 mmol) was allowed to react with **2** (0.0145 g, 0.00273 mmol) in 1:1 H_2O/DMSO (2 mL) for 2 h to form an active ester. c(RGDyK) (0.0169 g, 0.0273 mmol) in 4:1 H_2O/DMSO (1.25 mL) was added dropwise to the EDC and dendron solution and stirred for 2 days at room temperature. The DMSO was removed via dialysis in H_2O for 1 h. The resulting solution was lyophilized, redissolved in H_2O, purified on a G-15 Sephadex column, and again lyophilized. MS (MALDI): 5300−12 000 Da (broad).

Synthesis of AF-G3$(COOH)_{11.9}(RGD)_{4.1}$ (4). A mixture of azide-functionalized Alexa Fluor 488 (0.00022 g, 0.00026 mmol) and **3** (0.0015 g, 0.00019 mmol) in H_2O (1 mL) in the presence of copper(II) sulfate (2.5×10^{-5} g, 0.00010 mmol) and sodium ascorbate (4.0×10^{-5} g, 0.00020 mmol) was stirred for 36 h at room temperature. The solution was purified on a G-25 Sephadex column and lyophilized. MS (MALDI): 5300−12 600 Da (broad).

Synthesis of MTX-azide (5). Methotrexate (0.0238 g, 0.0524 mmol) was dissolved in DMF (1 mL) and cooled in a water/ice bath. *N*-Hydroxysuccinimide (0.0067 g, 0.057 mmol) and EDC (0.0110 g, 0.0576 mmol) were added, and the resulting mixture was stirred in the ice bath for 30 min to give a white precipitate. A solution of 11-azido-3,6,9-trioxaundecan-1-amine (0.0120 g, 0.0550 mmol) in DMF (0.5 mL) was added, and the resulting mixture was allowed to warm to room temperature and stirred for 24 h. The mixture was poured into water (50 mL) and washed with chloroform (50 mL × 3). The aqueous layer was lyophilized and further purified on a G-25 Sephadex column. MS, 654.7 Da; calculated for $C_{28}H_{38}N_{12}O_7$, 654.68 Da.

Synthesis of MTX-G3$(COOH)_{11.9}(RGD)_{4.1}$ (6). A mixture of **5** (0.0019 g, 0.0029 mmol) and **3** (0.0025 g, 0.00032 mmol) in H_2O (1 mL) in the presence of copper(II) sulfate (2.5×10^{-5} g, 0.00010 mmol) and sodium ascorbate (4.0×10^{-5} g, 0.00020 mmol) was stirred for 36 h at room temperature. The solution

was purified on a G-25 Sephadex column and lyophilized. MS (MALDI): 5300−12 600 Da (broad).

Synthesis of Biotin-G3(COOH)$_{11.9}$(RGD)$_{4.1}$ (7). A mixture of biotin-dPEG$_{3\ +\ 4}$-azide (0.0045 g, 0.0063 mmol) and **3** (0.0080 g, 0.00010 mmol) in 1:1 DMSO/H_2O (1 mL) in the presence of copper(II) sulfate (2.5×10^5 g, 0.0010 mmol) and sodium ascorbate (4.0×10^5 g, 0.00020 mmol) was stirred for 36 h at room temperature. The solution was purified on a G-25 Sephadex column and lyophilized. MS (MALDI): 5300−12 700 Da (broad).

Synthesis of Azide-G2-PAMAM Dendron (8). Azide-G2-PAMAM dendron was prepared as previously reported (*37*) and analyzed by ^{1}H and MALDI-TOF. MS (MALDI), 1698.1 Da; calculated for $C_{73}H_{148}N_{32}O_{14}$, 1698.16 Da.

Synthesis of Azide-G2(AF)$_2$(OH)$_{24}$ (9). Alexa Fluor 488 sulfodichlorophenol ester (0.0050 g, 0.0061 mmol) dissolved in 0.5 mL DMF was added dropwise to **8** (0.0028 g, 0.0016 mmol) in 0.5 mL 0.1 M sodium bicarbonate buffer while stirring, and the reaction mixture was allowed to stir for 24 h at room temperature. Solvent was removed in vacuo, and the resulting product was dissolved in 2 mL H_2O. Glycidol (0.0112 g, 0.1511 mmol) was added to the solution, and the mixture was allowed to stir for 24 h at room temperature. The solution was purified on a G-25 Sephadex column and lyophilized. MS (MALDI): 3000−7000 Da (broad).

Synthesis of (OH)$_{24}$(AF)$_2$G2-G3(COOH)$_{11.9}$(RGD)$_{4.1}$ Co-Dendron (10). A mixture of **9** (0.0030 g, 0.00067 mmol) and **3** (0.0044 g, 0.00056 mmol) in H_2O (1 mL) in the presence of copper(II) sulfate (2.5×10^5 g, 0.00010 mmol) and sodium ascorbate (4.0×10^5 g, 0.00020 mmol) was stirred for 36 h at room temperature. The solution was first purified on a G-25 Sephadex column and lyophilized. The product was further purified via HPLC to remove excess azide-G2(AF)(OH). MS (MALDI): 5000−29 000 Da (broad), 17 500 Da maximum.

Cell Culture and Incubation with the Dendron. HUVEC cells were obtained from Invitrogen (Cascade Biologics). U87MG and KB cells were obtained from American type Tissue Collection (Manasass, VA). HUVEC (cat. # C-015−10C), U87MG, and KB cells were grown and maintained according to the supplier's protocol. Compounds were prepared in non-supplemented cell culture medium (Medium 200) and incubated in cell suspensions for 2 h at 37 °C in a 5% CO_2 incubator. Blocking experiments were run by preincubating the cells with a 200 equiv excess of c(RGDyK) for 10 min at room temperature prior to incubation.

Flow Cytometry. Cells were washed with 5 mL of PBS, spun at 150 G for 7 min, and resuspended in 1 mL of PBS prior to being examined. Cells were examined quantitatively for dendron uptake via a flow cytometer (Beckman Coulter Epics XL-MCL). The FL1 fluorescence of 10 000 cells was measured, and the mean fluorescence of cells was quantified.

Confocal Microscopy. HUVEC cells were seeded and grown on 35 mm glass-bottomed culture dishes (MatTek Corp., Ashland, MA). After 2 days, cells were treated with 0.5 μM co-dendron **10** or biotin-conjugated dendron **7**. Blocked samples were run by preincubating the cells with a 200 equiv excess of c(RGDyK) for 10 min at room temperature prior to incubation. After the 2 h incubation period, biotin-conjugated dendron **7** treated cells were treated with 4 mg/mL BSA for 30 min to limit nonspecific binding followed by treatment with 0.5 μM NeutrAvidin-Dylight 405 for 30 min. Media was aspirated from the cells, washed 3 times with PBS, and fixed with 2% paraformaldehyde. The samples were again aspirated, washed 3 times, and aspirated before mounting with Prolong Gold, and a coverslip was added. Samples were imaged using an Olympus FluoView 500 Laser Scanning confocal microscope using 60×, 1.5 NA oil immersion objective. Fluorescence and differential interference contrast (DIC) images were collected simultaneously using either an argon laser with 488 nm excitation or a solid state diode laser with 405 nm excitation and *FluoView* software.

Cytotoxicity Assay. For cytotoxicity experiments, cells were seeded in 96-well microtiter plates (2500 cells/well) in Medium 200. The cells were treated in triplicate with different concentrations of free MTX or dendron conjugates for 72 h with a replenishing of 100 μL medium and the conjugates after 48 h. A colorimetric XTT assay (Invitrogen) was performed following the vendor's protocol. An aliquot of 30 μL of XTT working solution prepared according to manufacturer instructions was added to each well using a multichannel pipet followed by the addition of 20 μL of PBS. After 1 h incubation in the dark at 37 °C, the absorbance at 490 nm was recorded using a plate reader. 690 nm was selected as a reference wavelength. Cell viability was calculated on the basis of optical density (OD) from untreated cells. Statistical significance was assessed using two-way ANOVA with posthoc Bonferroni tests checking for main effects of conjugate and concentration. *P*-values less than 0.05 were considered significant.

RESULTS AND DISCUSSION

The surface amines of the G3 PAMAM dendron **1** were allowed to react with excess glutaric anhydride in MeOH, in the presence of Et_3N as base, to form carboxylic acids (Figure 2 i). The reaction yielded carboxyl terminal groups and eliminates potential nonspecific charge interactions with the cell

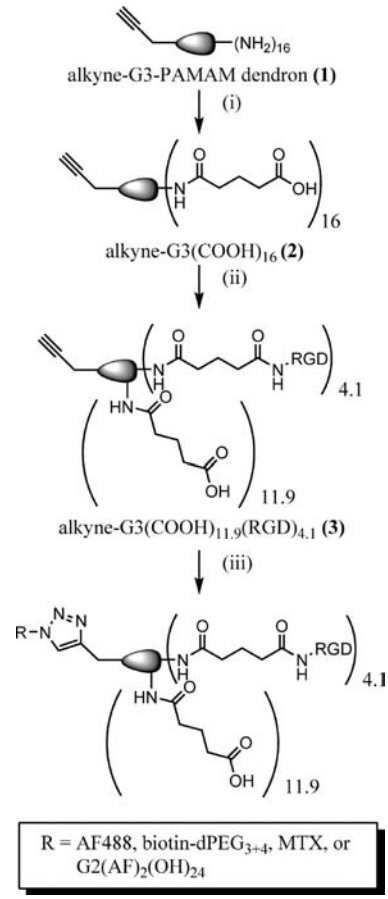

Figure 2. Reaction scheme for creating click-conjugated dendrons employed in the *in vitro* studies: (i) glutaric anhydride, MeOH, 24 h, r.t. (ii) EDC, c(RGDyK), H_2O/DMSO, 2 days, r.t. (iii) Alexa Fluor 488 azide OR biotin-dPEG$_{3+4}$-azide OR MTX-azide (**5**) OR azide-G2(AF)$_2$(OH)$_{24}$ (**9**), sodium ascorbate, copper(II) sulfate, H_2O, 36 h, r.t.

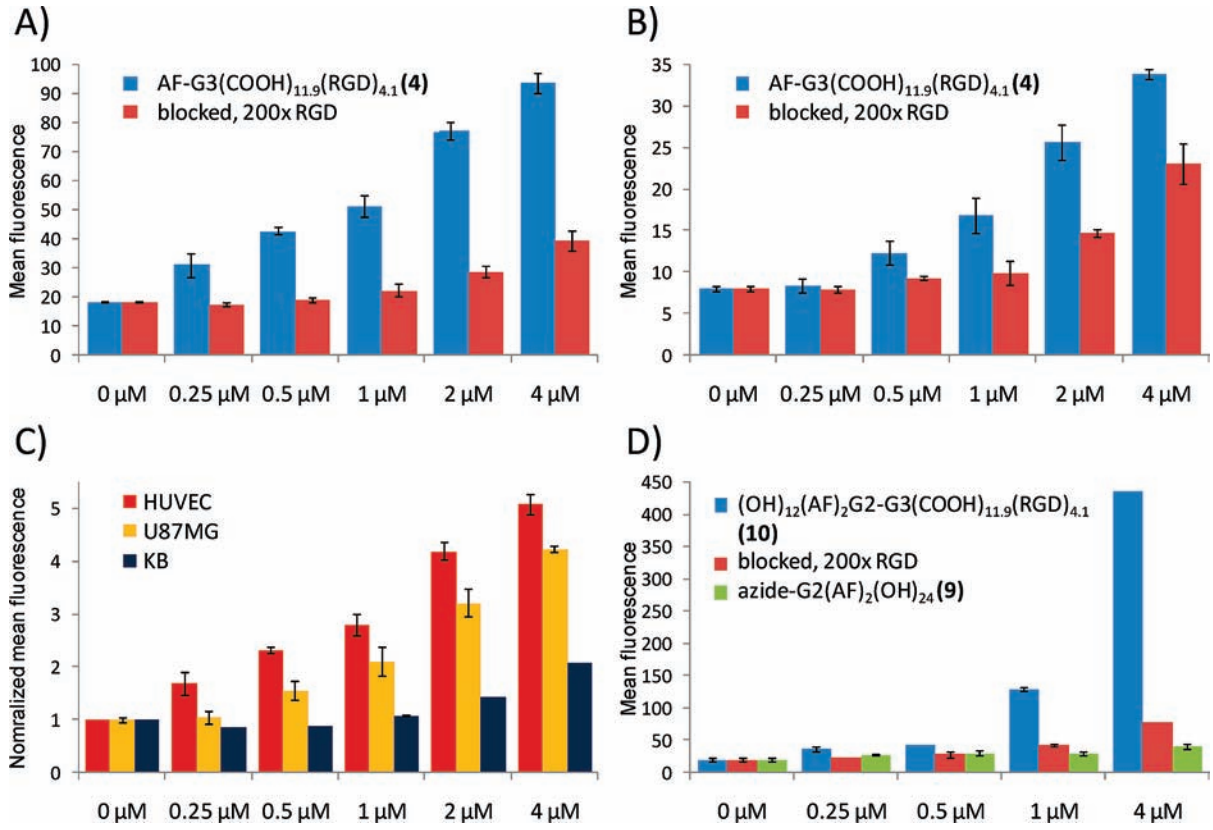

Figure 3. Dose-dependent uptake and specific targeting of binary dendrons determined via flow cytometry, with mean fluorescence plotted against the concentration of the dendron conjugate. Specific targeting of AF-G3$(COOH)_{11.9}(RGD)_{4.1}$ (**4**) was displayed in human umbilical vein endothelial cells (HUVEC) (A), and U87MG human glioblastoma cells (B). Blocking of **4** at all tested concentrations with a 200-fold molar excess of c(RGDyK) confirms specific targeting of the $\alpha_V\beta_3$ integrin by the dendron. A cell-line comparison among HUVEC, U87MG, and $\alpha_V\beta_3$ integrin deficient KB cells (C) shows that dendron uptake is greater in cell lines with increased $\alpha_V\beta_3$ integrin expression, demonstrating the active targeting capability of the binary dendron. A significant increase in mean fluorescence was displayed for a co-dendron structure capable of carrying additional dye, $(OH)_{24}(AF)_2$G2-G3$(COOH)_{11.9}(RGD)_{4.1}$ (**10**), in HUVEC (D). The specific uptake of the co-dendron was confirmed by inhibition with free RGD as well as from a nontargeted control, azide-G2$(AF)_2(OH)_{24}$ (**9**). Error bars indicate standard deviation as computed from the half-peak coefficient of variation.

plasma membrane caused by primary amines. ^{1}H NMR spectroscopy confirmed complete conversion of the primary amines and formation of dendron **2** by the loss of methylene peaks ($-CH_2CH_2NH_2$) at δ 2.80 and 3.30 ppm and the formation of new methylene peaks ($-NHCO(CH_2)_3COOH$) at δ 1.84, 2.21, and 2.27 ppm.

The targeting moiety, RGD peptide, was conjugated to the carboxylated surface of the PAMAM dendron (Figure 2(ii)). RGD binds to the $\alpha_V\beta_3$ integrin found on the luminal surface of endothelial cells during angiogenesis (*38*, *39*). This makes the $\alpha_V\beta_3$ integrin a unique marker that differentiates newly formed capillaries in the tumor vasculature from their mature counterparts (*40*−*42*). Antiangiogenic therapies, such as those that employ RGD targeting, prevent neovascularization by inhibiting differentiation, migration, and proliferation of endothelial cells (*43*).

The surface carboxyl groups were activated with EDC, followed by the addition of 12 equiv of c(RGDyK) to give dendron **3**. The product was purified by size exclusion chromatography and lyophilized. The ^{1}H NMR spectrum of the dendron−RGD body shows some of the aliphatic signals of the peptide overlap with the aliphatic signals of the dendron; however, using the peak integration values in the aromatic region from the phenyl ring of the peptide, an average of 4.1 attached RGD per dendron was calculated.

The dendron AF-G3$(COOH)_{11.9}(RGD)_{4.1}$ **4** (Figure 2(iii)) was synthesized by the reaction of azide-functionalized Alexa Fluor 488 with **3** in a copper-catalyzed 1,3-dipolar cycloaddition. Alexa Fluor 488 was chosen as the fluorescent label for detection

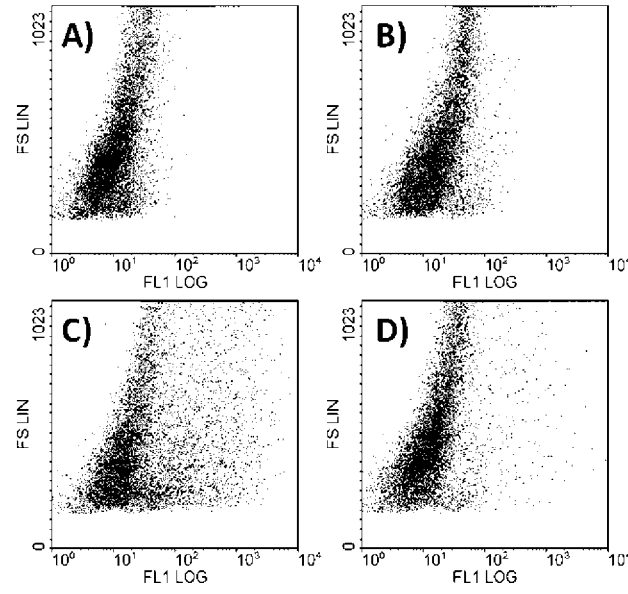

Figure 4. Flow cytometry plot of fluorescence versus forward scatter for $(OH)_{24}(AF)_2$G2-G3$(COOH)_{11.9}(RGD)_{4.1}$ (**10**) at 4 μM. The co-dendron conjugate (C) shows a significant broading in cell population compared to the untreated control (A). When preincubated with a 200-fold molar excess of free RGD (D), **10** is partially blocked, but outcompetes the excess monomeric RGD. The nontargeted control (B), azide-G2$(AF)_2(OH)_{24}$ (**9**), shows no significant change in cell population when compared to the control.

of conjugates by flow cytometry because it is brighter than fluorescein conjugates and more resistant to photobleaching. The products were purified via size exclusion chromatography and lyophilized. The characteristic triazole proton peak of a successful click reaction (δ 8.10 ppm) partially overlaps with the peaks for Alexa Fluor 488.

The specific binding of **4** to $\alpha_V\beta_3$ integrin expressing HUVEC and U87MG cells was examined via flow cytometry (Figure 3). KB cells, which express lower levels of $\alpha_V\beta_3$ integrin, were also evaluated. Cells were treated with dendron−RGD conjugates at final concentrations of 0.25, 0.50, 1, 2, and 4 μM, either with or without preincubation with 200-fold molar equivalents of free RGD peptide. Specific binding and dose dependence of dendron bodies to integrin expressing cells were evaluated after the 2 h incubation at 37 °C. The addition of excess free peptide to inhibit the uptake of the binary dendron by HUVEC and U87MG cells significantly blocked uptake. The inability to completely inhibit binding of the dendron may be due to a higher avidity of the dendron conjugate when compared to free RGD.

A co-dendron structure, $(OH)_{24}(AF)_2$G2-G3$(COOH)_{11.9}(RGD)_{4.1}$ **10** was created by reacting an Alexa Fluor 488 conjugated dendron **9** with an azide focal point with **3**. The product was purified via HPLC to remove excess **9**. The co-dendron structure offers an increased carrying capacity for conjugates, including the Alexa Fluor 488 used in this study. NMR of **9** showed an average of two Alexa Fluor 488 molecules attached per dendron; thus, it was expected to emit a stronger signal when conjugated to **3** compared to a single dye at the focal point.

The specific binding of co-dendron **10** to $\alpha_V\beta_3$ integrin-expressing HUVEC cells was determined via flow cytometry (Figure 3D). The co-dendron-treated samples see the expected increase in mean fluorescence compared to monodye conjugated **4**. Specific binding could be significantly blocked (Figure 4), but again, the higher avidity dendron conjugate out-competed free RGD. Nontargeted control **9** showed minimal nonspecific uptake.

The specific binding evaluated by flow cytometry was confirmed by confocal microscopy. HUVEC cells were treated with 0.5 μM **10** or biotin-conjugated **7** and incubated for 2 h. The biotin conjugate was detected by the addition of an avidin-functionalized dye. Confocal images confirm the uptake of the dendrons (Figure 5 B,D), as seen from the punctuate pattern within the cytoplasm. Partial inhibition of the dendron conjugates by preincubation with free RGD was also established (Figure 5C,E).

A drug conjugate, **6**, was synthesized to show the therapeutic potential of the platform. MTX was reacted with 11-azido-3,6,9-trioxaundecan-1-amine to yield an azide-functional drug. The resulting MTX-azide was then attached to the dendron at the focal point via click chemistry. The inhibition of cell growth induced by the dendron conjugates was tested by XTT colorimetric assay. **6** and free MTX showed comparable cytotoxicity to HUVEC cells after 3 days (Figure 6). Cell numbers were between 55% and 80% for all **6** and free MTX-treated samples at concentrations greater than 0.125 μM. The effects of **6** and MTX were not significantly different at these concentrations. **6** had a significantly greater effect on cell viability vs **3** for concentrations greater than 0.125 μM. **6** has an approximately equivalent concentration of MTX compared to free drug; the drug-conjugated dendron **6** treatments may have slightly lower drug concentration due to any remaining uncoupled dendron. The similar toxicities of **6** and free MTX show that the dendron scaffold is effective at delivering a therapeutic to cells.

We have shown that by exploiting the initiation point as a unique binding site in PAMAM dendrons, selective coupling

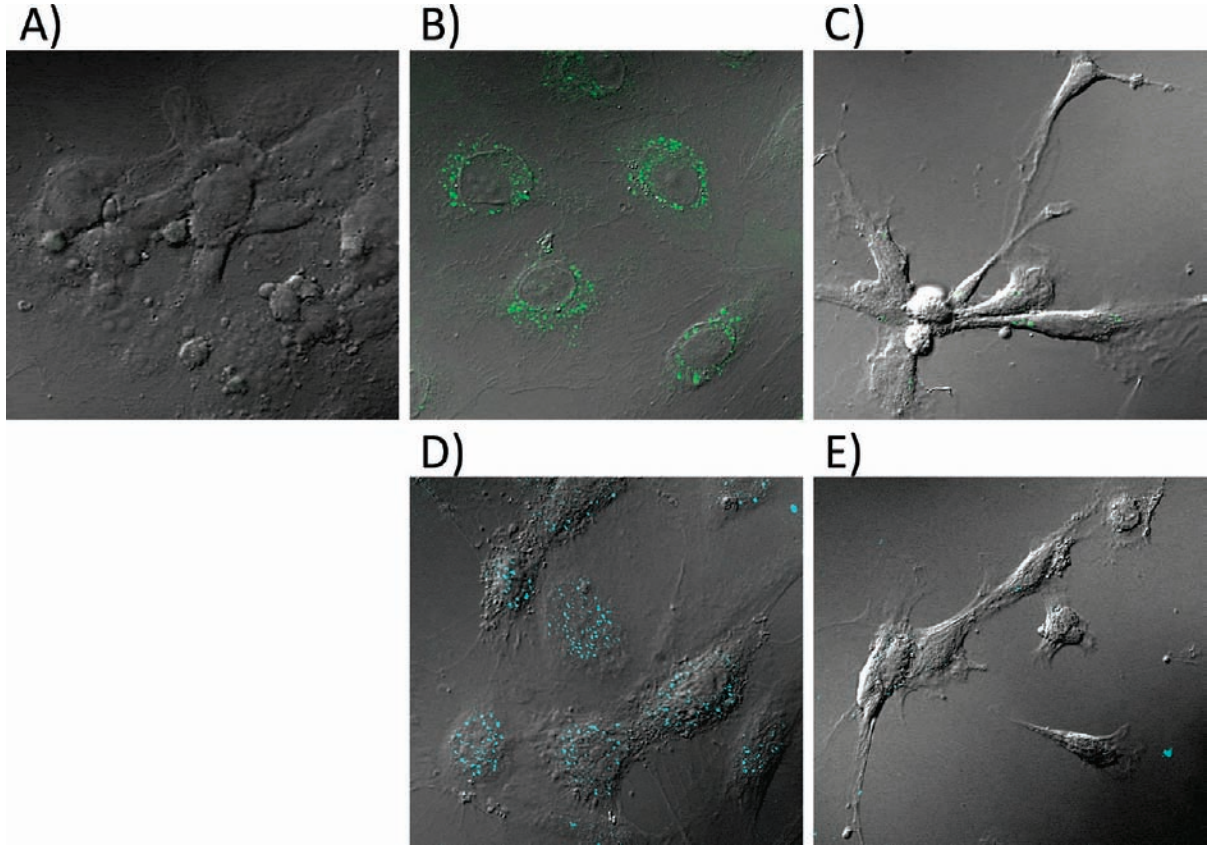

Figure 5. Confocal images of HUVEC cells either untreated (A) or treated with 0.5 μM $(OH)_{24}(AF)_2$G2-G3$(COOH)_{11.9}(RGD)_{4.1}$ (**10**) (B,C) or biotin-G3$(COOH)_{11.9}(RGD)_{4.1}$ (**7**) (D,E) dendron for 2 h. Samples C and E were preincubated with 100 μM c(RGDyK). Biotin-conjugated dendrons were detected by the addition of NeutrAvidin-Dylight 405.

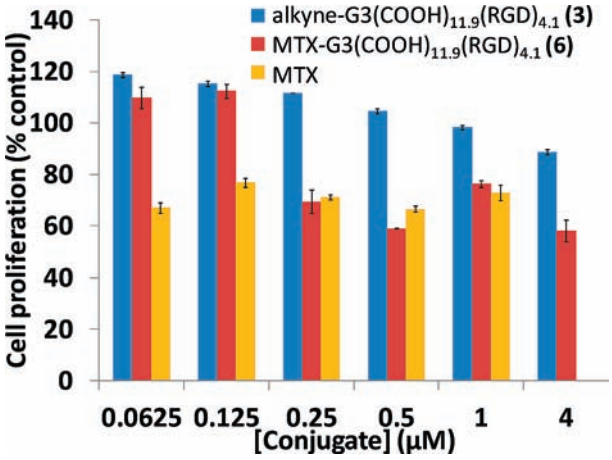

Figure 6. The antiproliferative effect of MTX-G3$(COOH)_{11.9}(RGD)_{4.1}$ (**6**). The dose-dependent inhibition of cell growth of **6** was compared to free MTX and alkyne-G3$(COOH)_{11.9}(RGD)_{4.1}$ control (**3**) using a XTT assay. The cells were treated with different concentrations of free MTX or dendron conjugates for 72 h with a replenishing of 100 μL medium and the conjugates after 48 h. **6** and MTX were determined to not be significantly different for concentrations greater than or equal to 0.25 μM. The effects of **6** and MTX were not significantly different for concentrations greater than 0.125 μM. **6** had a significantly greater effect on cell viability vs **3** for concentrations greater than 0.125 μM.

reactions can yield highly defined binary devices that exhibit the ability to bind to specific cells. Employing a 1,3-dipolar cycloaddition to the focal point of the dendron allows for additional functional moieties to be added in a precise manner without altering other molecules on the dendron. The prototype molecule, synthesized **4**, successfully displayed specific targeting to $\alpha_V\beta_3$ integrin, behaving similarly to RGD conjugates on previously studied multifunctional G5 PAMAM dendrimers (*25*,*34*) that lack the same degree of synthetic control. Detection can be enhanced by attaching an additional dendron with an increased carrying capacity, shown with **10**. The dendron can be combined with biotin, allowing it to interact with a variety of avidin-functionalized molecules. **6** was shown to successfully inhibit the growth of HUVEC cells similarly to free drug. The PAMAM dendron platform has potential to be important in targeted delivery chemistry, as our binary device can serve as a framework to selectively attach diagnostic and imaging agents, therapeutics, or other biologically relevant moieties and surfaces. In addition, coupling a second functionalized dendron or dendrimer to the dendron could address other applications requiring the delivery of multiple drugs or imaging agents.

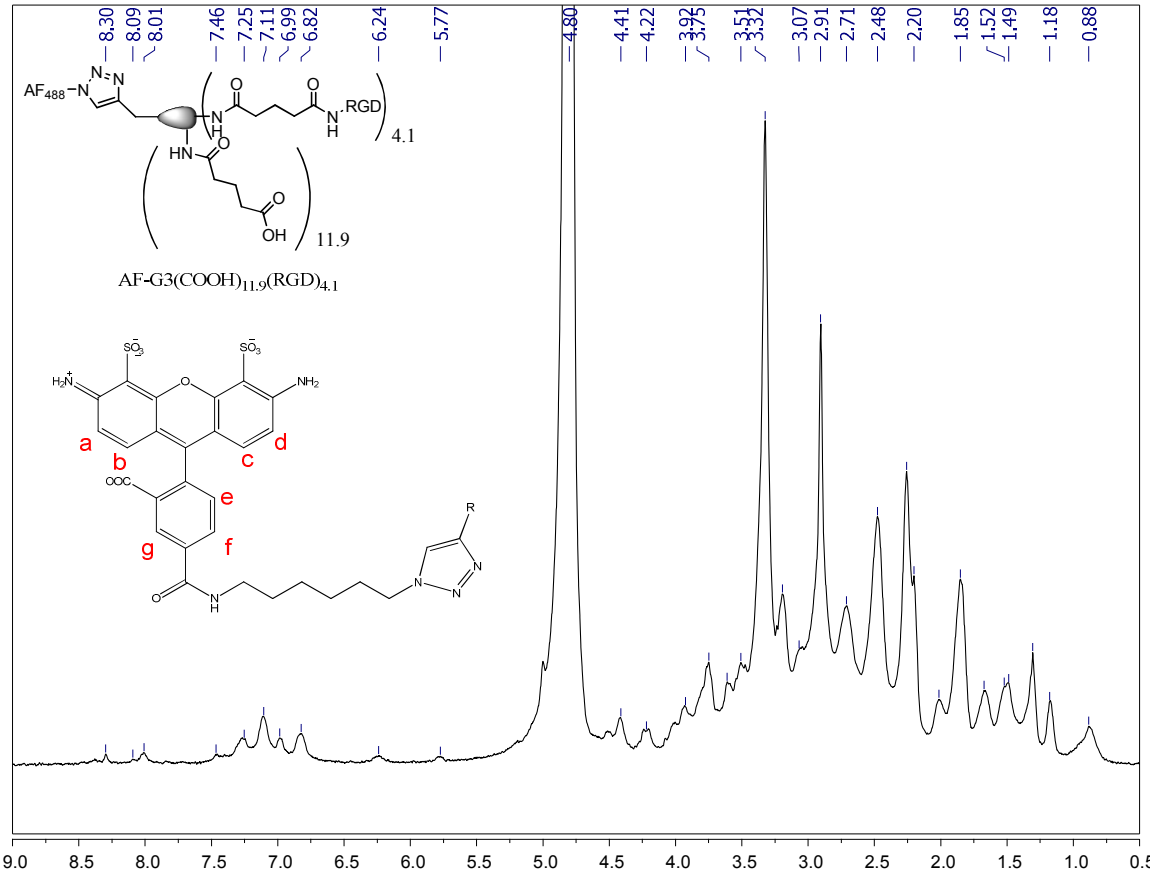
^{1}H NMR (400 MHz, D_2O): δ =

Dendron backbone: 3.42 (s, 2H, N-C*H*$_2$-CH), 3.30 (m, 92H, NH-C*H*$_2$-CH$_2$-NH$_2$, NH-C*H*$_2$-CH$_2$-N, NH-CH$_2$-C*H*$_2$-NH$_2$), 2.80 (m, 60H, N-C*H*$_2$-CH$_2$-CO,), 2.62 (b, 28H, NH-CH$_2$-C*H*$_2$-N), 2.41 (b, 60H, N-CH$_2$-C*H*$_2$-CO), 2.24 (b, 48H, CO-C*H*$_2$-CH$_2$-CH$_2$-CO-OH, CO-CH$_2$-CH$_2$-C*H*$_2$-CO-OH, from unreacted glutarate terminal groups “i an k”), 2.10-1.75 (m, 48H, “j” and “i’, j’, and k’” from conjugated glutarate terminal groups).

Conjugated RGD: 7.40-6.80 (16.4 H, aromatic RGD protons), 4.40 (8.2H), 4.20 (8.2H), 3.72 (8.2H), 3.10, 1.70 (8.2H), 1.53 (8.2H), 1.35 (8.2H) 1.17 (16.4H). Additional peaks are overlapping with peaks from the dendron backbone.

Figure S4: ^{1}H NMR spectrum of AF-G3(COOH)$_{11.9}$(RGD)$_{4.1}$ dendron (4)



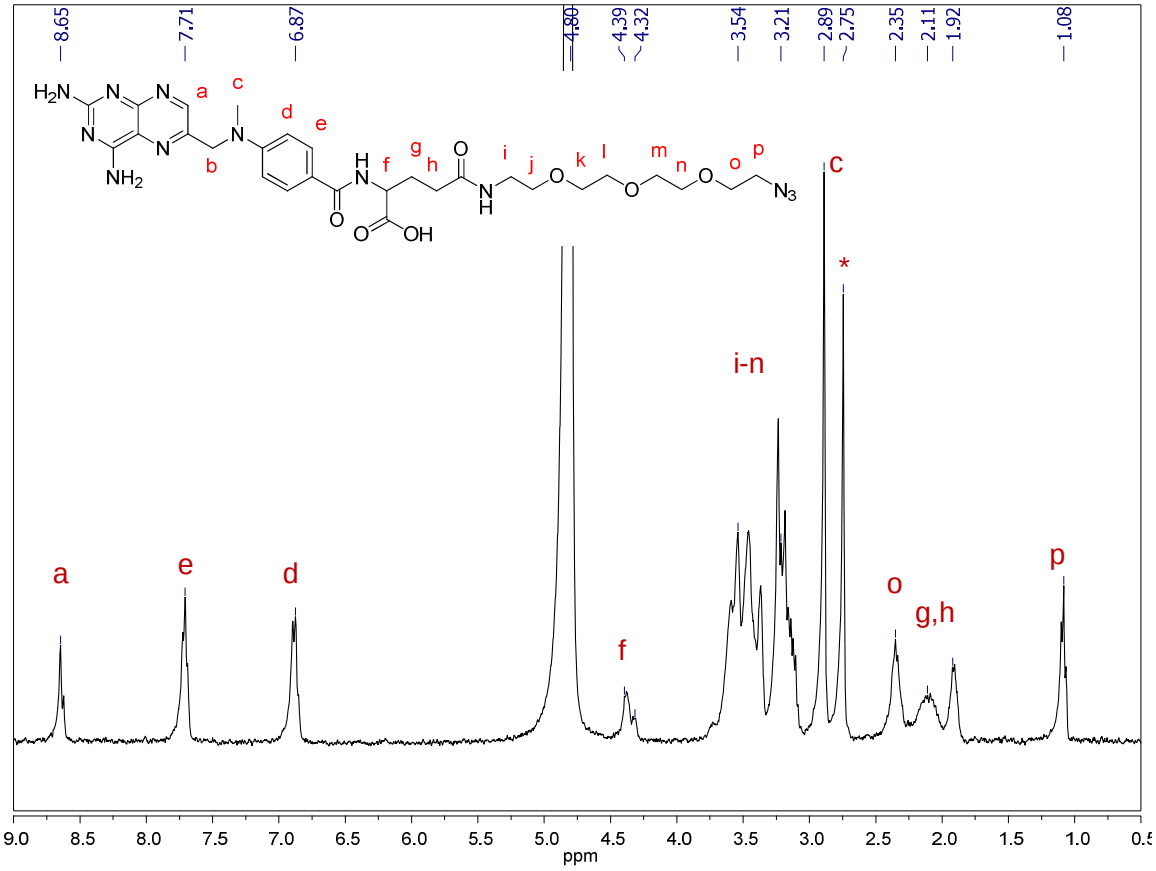
R = G3(COOH)$_{11.9}$(RGD)$_{4.1}$

^{1}H NMR (500 MHz, D_2O):

Aromatic Alexa Fluor 488 peaks at 8.30 (~0.65H, “g”), 8.09 (~0.65H, “f”), and 7.46 (~0.65H, “e”) can be resolved. Peaks “b” and “c” (expected at 7.17) and “a” and “d” (expected at 6.94) are overlapped by the aromatic RGD peaks.

Peaks from the $(CH_2)_6$ spacer are overlapped with the aliphatic dendron and RGD peaks.

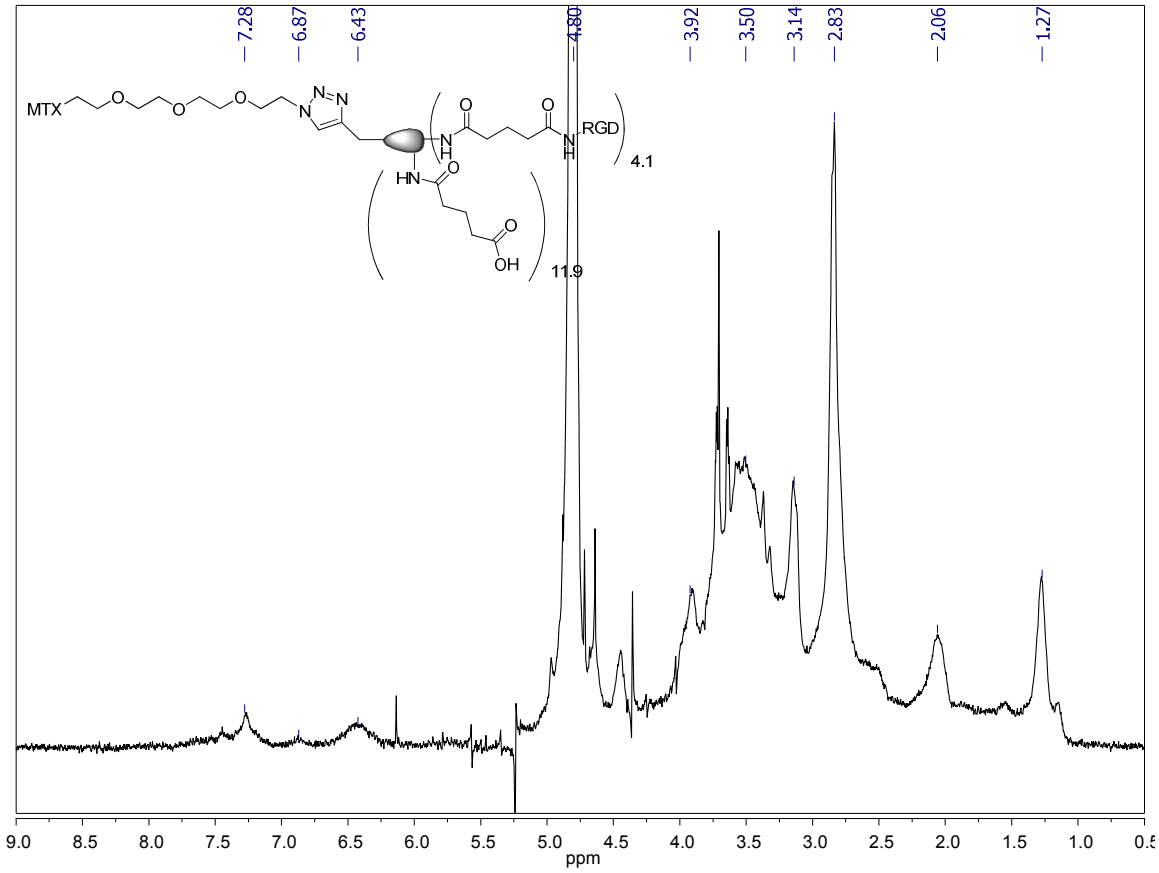
Figure S5: ^{1}H NMR spectrum of MTX-azide (5)



^{1}H NMR (500 MHz, D_2O): δ = 8.65 (1H, N-CH-C, “a”), 7.71 (d, 2H, C-C-CH-CH-C-CO, “e”), 6.87 (d, 2H, C-C-CH-CH-C-CO, “d”), 4.40-4.30 (b, 1H, NH-C*H*C-CH2, “f”), 3.7-3.05 (m, O-CH2-CH2-O, “i-n”), 2.89 (s, N-CH_3, “c”), 2.35 (b, 2H, O-CH_2-CH_2-N_3, “o”), 2.11 (b, 2H, CH-CH_2-CH_2-CO, “g”), 1.92 (b, 2H, CH-CH_2-CH_2-CO, “h”), 1.08 (t, 2H, O-CH_2-CH_2-N_3, “p”).

* denotes *N*-Hydroxysuccinimide impurity (3.4H)

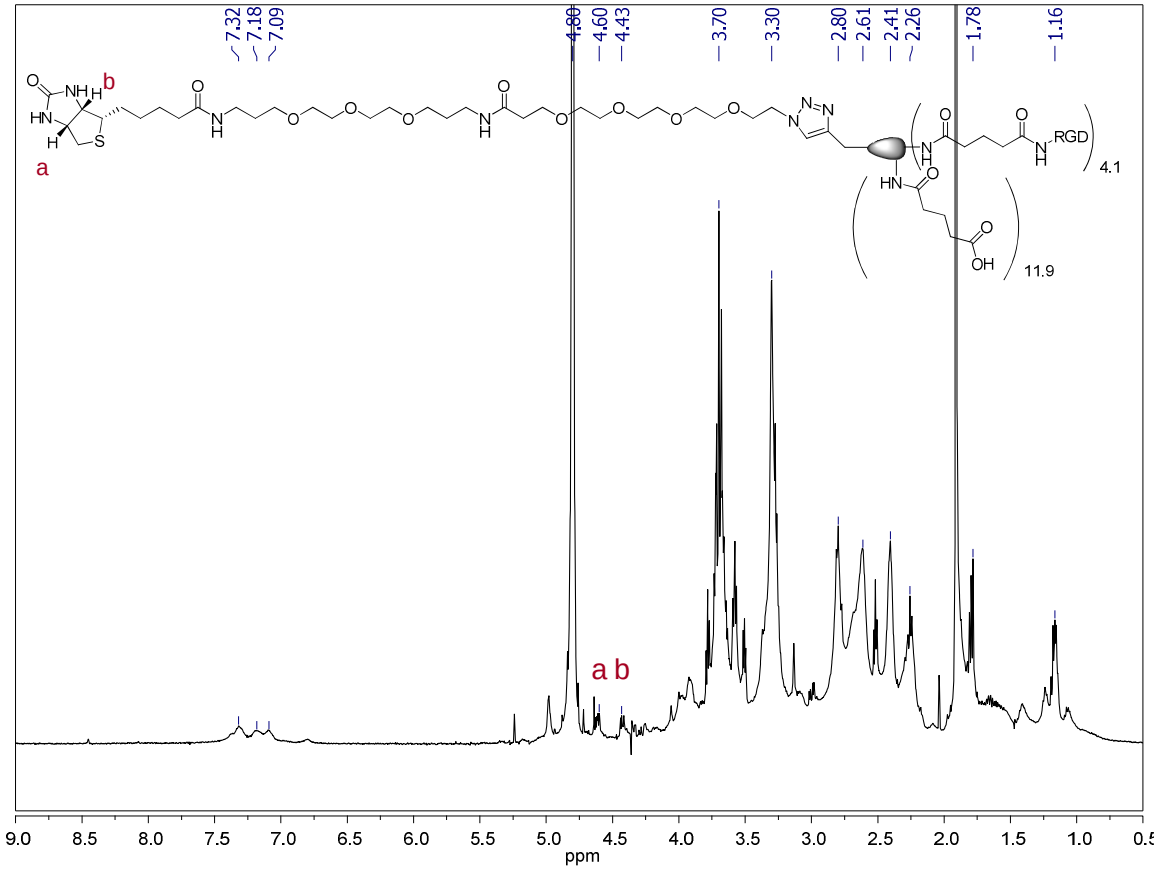
Figure S6: ^{1}H NMR spectrum of MTX-G3(COOH)$_{11.9}$(RGD)$_{4.1}$ dendron (6)



^{1}H NMR (500 MHz, D_2O)

Peaks were not resolved for this sample. MALDI, UPLC and *in vitro* functional assays were used to confirm the successful formation of the product.

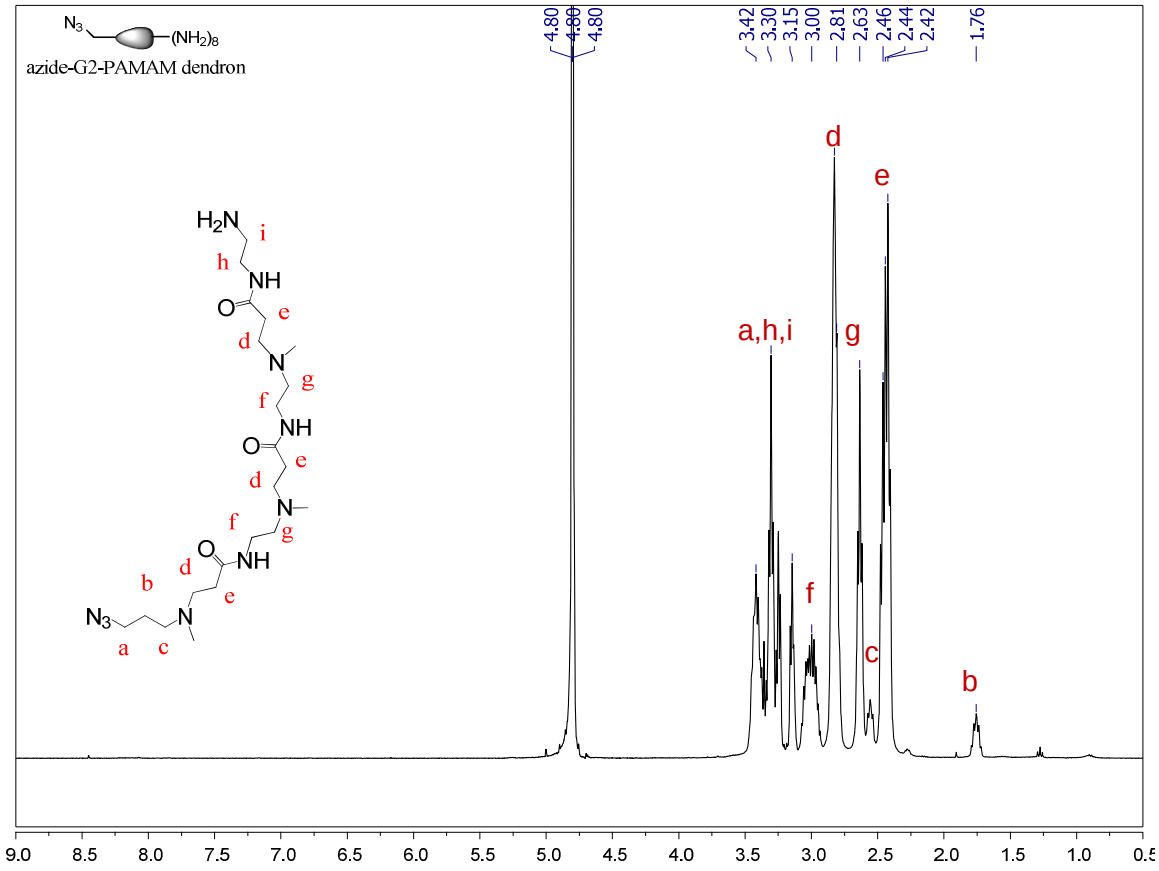
Figure S7: ^{1}H NMR spectrum of Biotin-G3(COOH)$_{11.9}$(RGD)$_{4.1}$ dendron (7)



^{1}H NMR (400 MHz, D_2O): δ = 4.60 (1H, "a"), 4.43 (1H, "b"). The unassigned biotin peaks are overlapping with the aliphatic conjugated dendron peaks. The d-PEG spacer is overlapping in the dendron region (expected at 3.75-3.0)

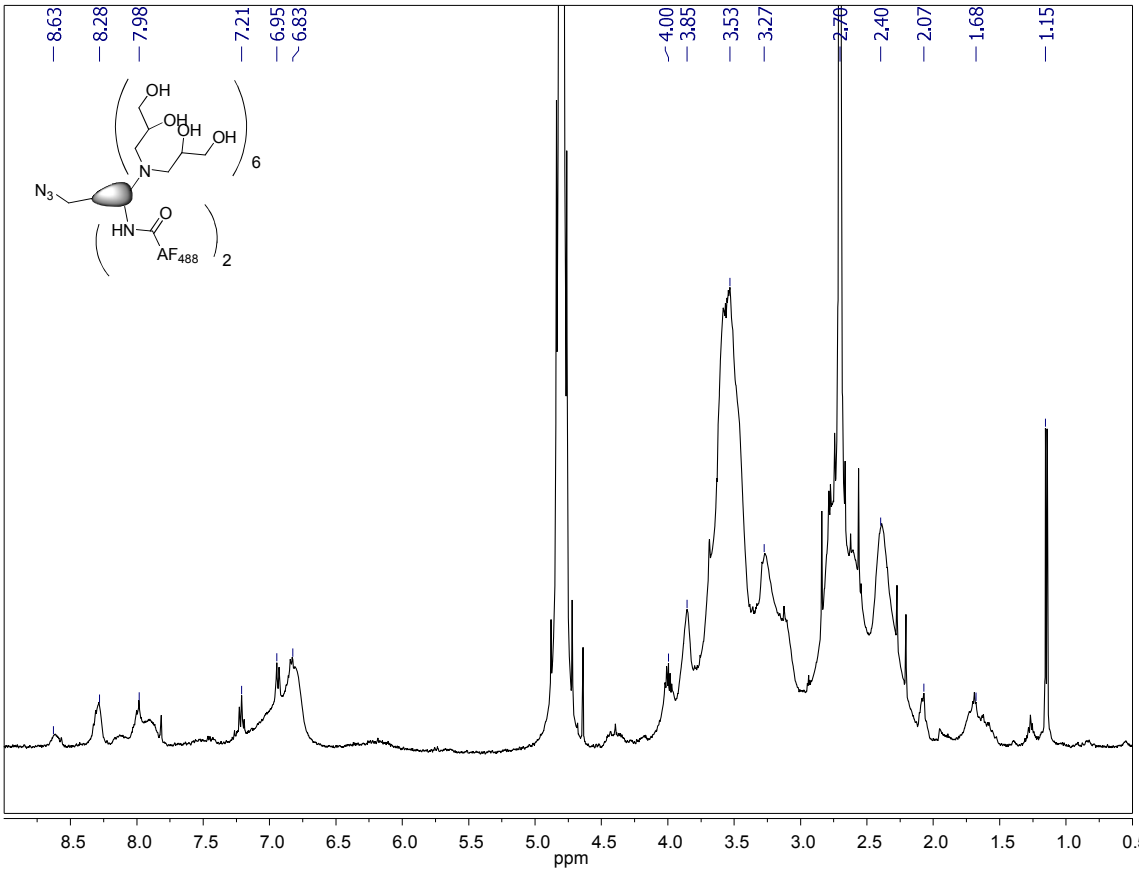
An unknown impurity is present at 1.91.

Figure S8: ^{1}H NMR spectrum of azide-G2-PAMAM dendron (8)



^{1}H NMR (400 MHz, D_2O): δ = 3.50-3.10 (34H, “a, h, and i”), 3.00 (12H, NH-C*H*$_2$-CH$_2$-N, “f”), 2.81 (28H, N-C*H*$_2$-CH$_2$-CO, “d”), 2.63 (12H, NH-CH$_2$-C*H*$_2$-N, “g”), 2.55 (2H, N$_3$-CH$_2$-CH$_2$-C*H*$_2$-N, “c”), 2.44 (28H, N-CH$_2$-C*H*$_2$-CO, “e”), 1.76 (2H, N$_3$-CH$_2$-C*H*$_2$-CH$_2$-N, “b”).

Figure S9: ^{1}H NMR spectrum of azide-G2(AF)$_2$(OH)$_{24}$ dendron (9)

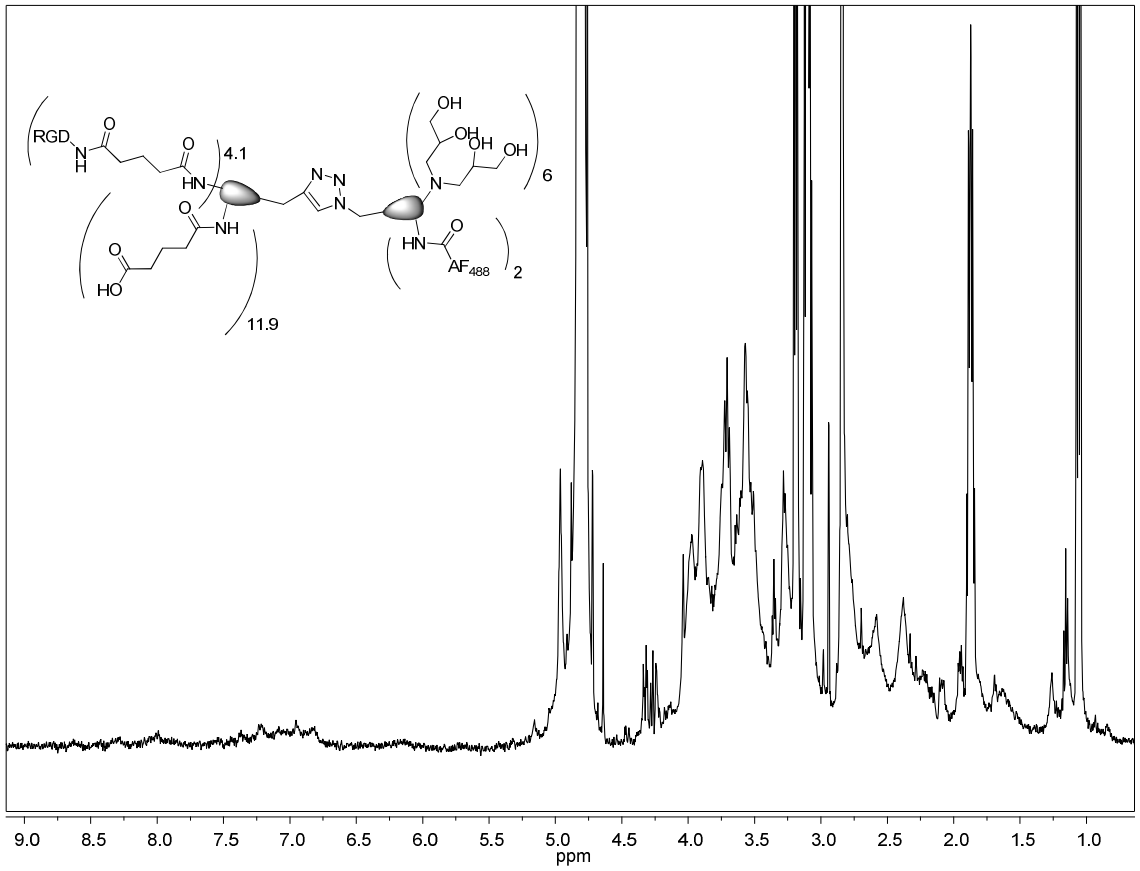


^{1}H NMR (500 MHz, D_2O)

Dendron peaks are indistinguishable between 4.0 and 1.0 ppm.

Sharp aromatic Alexa Fluor 488 peaks suggest that small free dye impurities were still present in this sample. The removal of detectable free dye after the attachment of this dendron to alkyne-G3(COOH)$_{11.9}$(RGD)$_{4.1}$ was confirmed via HPLC.

Figure S10: ^{1}H NMR spectrum of $(OH)_{24}(AF)_2G2\text{-}G3(COOH)_{11.9}(RGD)_{4.1}$ (10)



^{1}H NMR (500 MHz, D_2O)

The complexity and low concentration of the isolated co-dendron sample does not allow for proper assignments to be made. Aromatic RGD and Alexa Fluor 488 peaks are identifiable. MALDI, UPLC and *in vitro* experiments were used to confirm the successful formation of the product.

Received February 2, 2009; Revised Manuscript Received July 24, 2009

Molecular imaging of cells and cellular processes can be achieved by tagging intracellular targets such as receptors, enzymes, or mRNA. Seeking to visualize the presence of specific mRNAs by magnetic resonance (MR) imaging, we coupled peptide nucleic acids (PNA) with gadolinium-based MR contrast agents using cell-penetrating peptides for intracellular delivery. Antisense to mRNA of DsRed2 protein was used as proof of principle. The conjugates were produced by continuous solid-phase synthesis followed by chelation with gadolinium. Their cellular uptake was confirmed by fluorescence microscopy and spectroscopy as well as by MR imaging of labeled cells. The cell-penetrating peptide D-Tat$_{57-49}$ was selected over two other derivatives of HIV-1 Tat peptide, based on its superior intracellular delivery of the gadolinium-based contrast agents. Further improved delivery of conjugates was achieved upon coupling peptide nucleic acids (antisense to mRNA of DsRed2 protein and nonsense with no natural counterpart). Significant enhancement in MR contrast was obtained in cells labeled with concentrations as low as 2.5 μM of these agents. Specific binding of the targeting PNA containing conjugate to its complementary oligonucleotide sequence was proven by *in vitro* cell-free assay. In contrast, a lack of specific enrichment was observed in transgenic cells containing the target due to nonspecific vesicular entrapment of contrast agents. Preliminary biodistribution studies showed conjugate-related fluorescence in several organs, especially the liver and bladder, indicating high mobility of the agent in spite of its high molecular weight. No conjugate related toxicity was observed. These results are encouraging, as they warrant further molecular optimization and consecutive specificity studies *in vivo* of this new generation of contrast agents.

INTRODUCTION

Recently, remarkable progress in the understanding of cellular processes, at both the molecular and genetic levels, has been made by the development of molecular-biological assays. Despite this, a myriad of questions about biological processes under normal as well as diseased conditions remain. Of late, the new field of molecular imaging has evolved with the intent of translating knowledge gained from *in vitro* systems into studies of complete biological systems. Molecular imaging aims at noninvasive visualization of biological processes amid the complex networks and interactions in the intact individual (*1*−*3*). Imaging modalities being extensively used for this purpose are positron emission tomography (PET), single-photon emission computed tomography (SPECT), optical imaging using fluorescence or bioluminescence, and magnetic resonance imaging (MRI) (*4, 5*).

MRI is a powerful tool in clinical diagnostics as well as for understanding developmental and biological processes. It visualizes the differences in tissues and organs, as well as between normal and pathological changes, as a function of water concentration and relaxation times, T_1 and T_2, in a given volume element (*6*). The main advantages of MRI over other imaging techniques are its high spatial and temporal resolution, the absence of harmful ionizing radiation, and the ability to noninvasively scan entire organisms in one, two, or three dimensions. The intrinsic contrast of MR images can be augmented by the use of contrast agents (CAs). Chelated paramagnetic metal ions, in particular gadolinium, have been primarily used as T_1-based CAs to increase the contrast in MR images (*7*). An assortment of gadolinium-based CAs are commercially available, and these agents are frequently employed for clinical diagnosis. However, their utility is based on enhancement of anatomical information due to differential biodistribution in the body (*8, 9*). For example, in the brain, these agents do not cross the blood−brain barrier (BBB) except when the BBB is broken because of pathology; as such, they lack specificity. Advancing from these agents toward extracellular targeting by conjugation of CAs to certain proteins and especially to monoclonal antibodies or antibody fragments has been explored. Most of the investigations were related to the development of tumor-specific agents (*10*−*14*).

Numerous intracellular imaging targets are available, however, and these can be tagged to provide molecular information. Regardless of the low number of targets at DNA level, molecules at RNA (overexpressed) or protein level could serve as potential targets (*1*). A possibility for monitoring gene expression by targeting a tumor-specific mRNA was evaluated by Heckl et

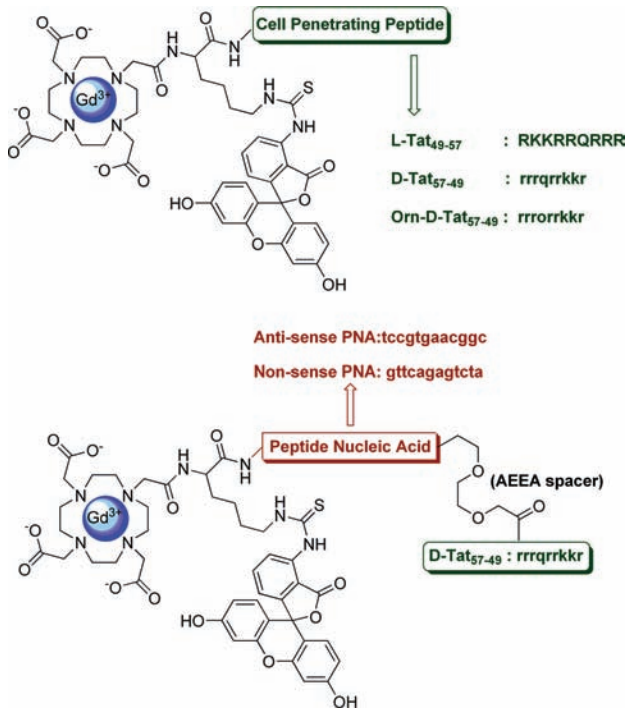

Figure 1. Schematic structures of CPP and PNA conjugated Gd(DOTA) based intracellular contrast agents. All amino acids are represented in a single letter code: R, arginine; K, lysine; Q, glutamine; and O, ornithine. D-Amino acids are represented in lower case. The PNA building blocks are represented as follows: a, adenine; t, thymine; g, guanine; c, cytosine.

al. (*15*). Our group has also reported the development of a gadolinium-based CA coupled to peptide nucleic acids (PNA) to target mRNA (*16*). Both studies utilized peptide-based delivery of their constructs to penetrate through the cell membrane. Such cell-penetrating peptides (CPPs) emerged as an extremely efficient way to overcome the most challenging delivery barrier. CPPs are a class of short peptides that have been reported to import a wide range of cell-membrane impermeable cargos into cells (*17*−*20*). Thus far, there is no consensus on the mechanism of uptake of CPPs and the maintenance of functionality of cargos after delivery. This is reflected by differences in reported labeling techniques, non-standardized protocols regarding uptake evaluation, and discrepancies caused by the use of different cellular model systems (*21*−*23*).

Keeping these issues in mind, we began by evaluating the most appropriate CPP, selected from three derivatives of the well-established CPP HIV-1 Tat peptide, to deliver CA into cells. The cargo attached to the CPP was a gadolinium-loaded chelator, 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (Gd-DOTA), for MR imaging, and fluorescein isothiocyanate (FITC) for optical imaging (Figure 1). Using the selected CPP, a targeting PNA (either targeting DsRed2 mRNA or a nonsense sequence) was introduced into the above-mentioned conjugate (Figure 1). DsRed2 protein, a variant of the DsRed protein, was used as a model system for proof-of-principle in a transgenic DsRed2-expressing cell line (*24*). The aim was to assess the intracellular delivery and distribution of these larger molecules in the presence or absence of target mRNA in the cells. The ability of the agents to bind with targets in a cell-free *in vitro* system, as well as by labeling cells, was also evaluated. The biodistribution of the CA containing the antisense PNA will also be briefly presented here using fluorescence for detection.

EXPERIMENTAL PROCEDURES

General. All chemicals were purchased at HPLC or peptide synthesis grade from commercial sources. Trifluoroacetic acid (TFA), dimethylformamide (DMF), dichloromethane (DCM), *N*,*N*-diisopropylethylamine (DIEA), triisopropylsilane (TIPS), methyl tertiary butyl ether (MTBE), and FITC were obtained from Acros Organics (Germany). All standard, protected Fmoc amino acid derivatives (the side chains of lysine and ornithine were protected by Boc and arginine by Pbf), 2-(1-*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), preloaded Wang resin, and 1-hydroxybenzotriazole (HOBt) were purchased from Novabiochem, United Kingdom. For PNA synthesis, all Fmoc/Bhoc protected monomers and 2-(1-*H*-7-azabenzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) were purchased from Applied Biosystems, Germany. 1,4,7,10-Tetraazacyclododecane (cyclen) was purchased from Strem Chemicals, France.

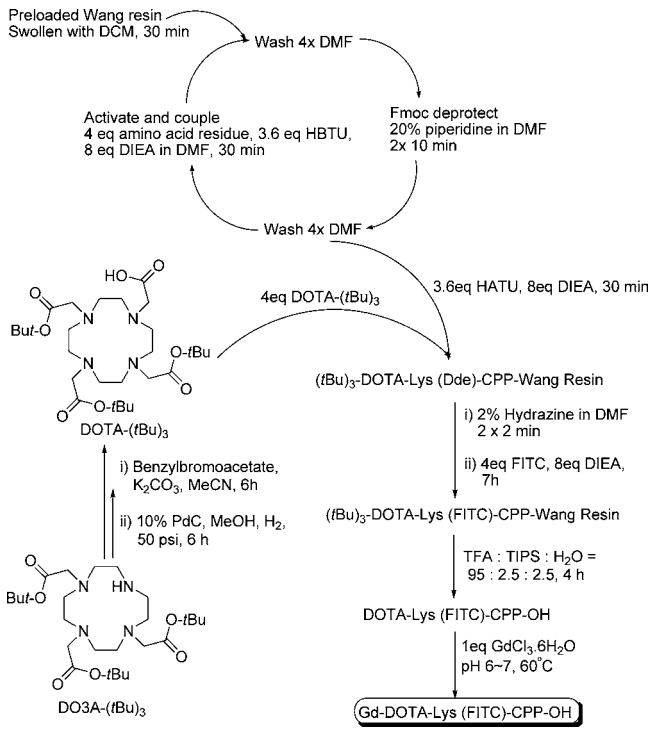
Analytical and semipreparative RP-HPLC was performed at room temperature on a Varian PrepStar Instrument (Australia) equipped with PrepStar SD-1 pump heads. UV absorbance was measured using a ProStar 335 photodiode array detector at 260 nm. A Varian Polaris C18-Ether column (4.6 × 250 mm, particle size 5 μm, particle pore diameter 100 Å) was used for analytical RP-HPLC. For semipreparative HPLC, a Varian Polaris C18-Ether column (21.2 × 250 mm, 5 μm, 100 Å) was used.

Gd-DOTA-conjugated CPPs and PNAs were analyzed and purified using one of the following two methods. Method A: A linear gradient was used starting from 90% solvent A (0.1% TFA in water) and 10% of solvent B (0.1% TFA in acetonitrile) to 90% B in 30 min. Method B: A linear gradient was used starting from 90% solvent A (0.05% TFA in water) and 10% of solvent B (0.05% TFA in acetonitrile) to 90% B in 30 min (flow rate of 1 mL/min for analytical and 3 mL/min for semipreparative HPLC).

ESI-MS was performed on Agilent SL 1100 Series LC/MSD Trap system (Agilent, Germany): nebulizer, 20.0 psi; dry gas, 5.0 L/min; dry temperature, 250 °C.

General Synthesis of Gd-DOTA-CPP(FITC) Conjugates. All the CPPs used in this work were chemically synthesized by solid-phase peptide synthesis with Fmoc/*t*Bu-strategy on a Heidolph Synthesis 1 synthesizer (Germany). As shown in Scheme 1, polystyrene-based Wang resin (substitution level of 0.50−0.60 mmol/g) was swollen in DCM for 30 min and washed four times with DMF. The resin was treated twice with a solution of 20% piperidine (3 mL) in DMF for 10 min, and subsequently washed four times with DMF. In a separate vial, Fmoc-protected amino acid (4 equiv), HBTU (3.6 equiv), and HOBt (3.6 equiv) were dissolved in DMF (2 mL), and DIEA (8 equiv) was added. The resulting solution was added to the resin and allowed to react under N_2 for 30 min. The resin was drained and rinsed four times with DMF. This procedure was repeated until Fmoc-protected CPPs (L-Tat$_{49-57}$, D-Tat$_{57-49}$, and Orn-D-Tat$_{57-49}$ peptides) bound to Wang resin were obtained. The resin-bound peptides were deprotected with 20% piperidine (3 mL) in DMF for 10 min, and coupled with one Fmoc-Lys(Dde)−OH residue by using HBTU and HOBt coupling agents. After deprotection with 20% piperidine (3 mL) in DMF for 10 min, in-house synthesized DOTA (*tert*-butyl)$_3$ ester was coupled to the α-NH_2 group of Lys (coupling condition: DOTA (*tert*-butyl)$_3$/HATU/DIEA = 4:3.6:8) (*16*). The resin was drained and rinsed four times with DMF. The resin-bound DOTA-conjugated L-Tat$_{49-57}$, D-Tat$_{57-49}$, and Orn-D-Tat$_{57-49}$ peptides were treated twice with hydrazine hydrate (2% in DMF, 2 min) to remove the Dde group. The ε-amino group of N-terminal

Scheme 1. Synthesis of CPP Conjugated MR Contrast Agents by Continuous Solid-Phase Synthesis



lysine was manually labeled with FITC (4-fold excess) mixed with triethylamine (1:2) in DMF overnight. The solvent was removed and the resin was washed with DMF, DCM, and MeOH subsequently four times. After drying under vacuum, DOTA-Lys(FITC)-conjugated peptides (L-Tat_{49-57}, D-Tat_{57-49}, and Orn-D-Tat_{57-49}) were cleaved off the resin using TFA/TIPS/H_2O (95:2.5:2.5, v/v/v). In the entire procedure described above, completion of Fmoc deprotection, coupling and thiourea formation were monitored by Kaiser Test (*25*).

Purification. All peptide conjugates were precipitated with cold MTBE. The precipitates were collected by centrifugation and resuspended in cold MTBE two times. Pellet was dissolved in water and *tert*-butyl alcohol (1:4) with 2% acetic acid, and lyophilized. All crude samples were purified by semipreparative RP-HPLC using linear gradients as described in the General Experimental Procedures before. The product-containing fractions were defined by analytical RP-HPLC.

Preparation of Gd Complexes. The ligands (DOTA-conjugated FITC-labeled CPPs) were dissolved in 5 mL water; a solution of $GdCl_3 \cdot 6H_2O$ (1 equiv) in water was added and the pH was periodically adjusted to 6.0−7.0 using a solution of 1 N NaOH or 1 N HCl as needed. The residues were purified by semipreparative RP-HPLC using method B to separate unstably bound Gd^{3+}. Afterward, the product was dialyzed (Float-ALyzer, cellulose ester membranes, MWCO 1000; Spectrum Laboratories Inc., Germany) to remove inorganic impurities. The solutions were lyophilized, and yellowish orange solids were obtained. The absence of free Gd^{3+} was checked with xylenol orange indicator (*26*).

Gd-DOTA-Lys(FITC)-L-Tat_{49-57}-OH. ESI-MS (+): calcd *m*/*z* 2397.08; found 800.2[$(M + 3H)^{3+}$], 600.2 [$(M + 4H)^{4+}$], 480.4 [$(M + 5H)^{5+}$], and 400.5 [$(M + 6H)^{6+}$].

Gd-DOTA-Lys(FITC)-D-Tat_{57-49}-OH. ESI-MS (+): calcd *m*/*z* 2397.08; found 799.7 [$(M + 3H)^{3+}$], 600.2 [$(M + 4H)^{4+}$], 480.3 [$(M + 5H)^{5+}$], and 400.7 [$(M + 6H)^{6+}$].

Gd-DOTA-Lys(FITC)-Orn-D-Tat_{57-49}-OH. ESI-MS (+): calcd *m*/*z* 2383.10; found 796.2 [$(M + 3H)^{3+}$], 596.5 [$(M + 4H)^{4+}$], 477.7 [$(M + 5H)^{5+}$], and 398.4 [$(M + 6H)^{6+}$].

Two PNA-containing conjugates, anti-dsred CA and nonsense CA were synthesized using the same synthetic scheme as reported before (*16*). In brief, PNA building blocks were coupled through an AEEA spacer to D-$Tat_{(57-49)}$ by a continuous solid-phase synthesis scheme. On completion of the PNA sequence, a Fmoc and Dde protected Lys residue was conjugated. DOTA tris(*tert*-butyl) ester was synthesized in-house (*27*) and coupled to the Lys on its α-NH_2 group after deprotection of Fmoc. Next, FITC was conjugated with the ε-NH_2 group of the Lys. The conjugates were cleaved off the resin and loaded with gadolinium under mild conditions. After purification by HPLC and dialysis, the products were characterized by ESI-MS.

Concentration Estimation. Peptide conjugates were dissolved in Milli-Q water to obtain a 10 mM solution by weight. For the determination of the real concentration, these stock solutions were diluted 1:100 in Dulbecco's Modified Eagle's Medium (DMEM; Biochrom AG, Germany). The absorbance of the solutions was measured in a multiplate reader (BMG Labtech, Germany) at 485 nm with ratiometric correction of turbidity at 690 nm. The concentrations of the stock solutions were calculated assuming $\varepsilon_{\text{carboxyfluorescein 485 nm}} = 81\,000$ L/(mol·cm), and all further dilutions were done according to this calculated concentration.

Cell Culture. NIH 3T3 cells were obtained from DSMZ, Germany, CCL-11 fibrosarcoma cells from ATCC, USA, and the DsRed2 protein-expressing fibrosarcoma CCL-11 cell line (DsRed cells) was a kind gift of Dr. Marna Ericsson, University of Minnesota, USA. NIH 3T3 mouse fibroblasts were cultured as a monolayer at 37 °C with 10% CO_2 in DMEM supplemented with 10% fetal bovine serum (FBS), 4 mM L-glutamine, 100 μg/mL streptomycin, and 100 U/mL penicillin (all purchased from Biochrom AG, Germany). Cultures of DsRed cells and the parent cell line CCL-11 were maintained at 37 °C with 5% CO_2 in NCTC 135 medium (Sigma, Germany) supplemented with 10% heat-inactivated fetal horse serum, 2.2 g/L sodium bicarbonate, and pH adjusted to 7.2. All cells were passaged by trypsinization with trypsin/EDTA 0.05/0.02% (w/v) in phosphate-buffered saline (PBS; Biochrom AG, Germany) every second to third day.

***In Vitro* Binding Assay.** The *in vitro* proof of specific binding of anti-dsred CA was obtained in a cell-free FITC immunoassay with slight modifications (*28*). A synthetic 45-mer single-stranded deoxynucleotide sequence containing the complementary target site of anti-dsred CA was obtained commercially (Eurofins MWG, Germany). The target oligodeoxynucleotide sequence extended by a 12-mer C linker was immobilized on DNA binding plates (Corning, Germany) in DNA binding buffer (50 mM sodium phosphate, 1 mM EDTA, pH 8.5) at 4 °C for 24 h. After washing off excess oligodeoxynucleotide with PBS, the plates were incubated with blocking buffer (DNA binding buffer containing 10% FBS and 3% bovine serum albumin (BSA)) for 2 h at 37 °C. Following a PBS wash, incubation with 16 nM of either anti-dsred CA or nonsense CA in 10 mM sodium phosphate, pH 6.5 was performed. For hybridization, the binding temperature was maintained at 60 °C for 1 h and then slowly decreased to 37 °C for another 1 h. The plates were left overnight at room temperature. The following day, plates were washed 3 times for 5 min each with wash buffer (PBS containing 0.01% Tween). Incubation with an anti-FITC-horseradish peroxidase (HRP)-conjugated antibody (Invitrogen, Germany) was carried out. Subsequent to thorough PBS washing to remove unbound antibody, the signal was developed with tetramethyl benzidine for 30 min at room temperature and absorbance was measured at 650 nm in a multiplate reader (BMG Labtech, Germany). Experiments were run at least three

times for each CA with two replicates. Statistical analysis was performed by Student's *t*-test. *P* values < 0.05 were considered significant.

Cellular Uptake Assay. Internalization experiments on cells were performed in 96 well microplates. At 70−80% confluency, cells were incubated with different concentrations of peptide-coupled CAs in complete culture medium for additional 18 h at routine culture conditions. After incubation, the labeling CAs were removed and cells were incubated with Bisbenzimid 33342 (Hoechst 33342), a nuclear stain, in order to assess the DNA content per well (correlates to the number of cells) (*29, 30*). Cells were washed with HBSS (Biochrom AG, Germany) and extracellular fluorescence was quenched by incubation with cold trypan blue (0.05% (w/v) in PBS) for 3 min followed by repeated washes with HBSS (*31*). Cell-related FITC fluorescence (Ex 485 nm/Em 530 nm) and cell number (Ex 346 nm/Em 460 nm) was evaluated in the multiplate reader. Experiments were run at least three times for each CA with six replicates. Statistical analysis was performed by ANOVA with Tukey's post test. *P* values < 0.05 were considered significant.

Microscopy. The cells in plates processed for fluorescence spectroscopic measurement, as mentioned above, were used for complementary fluorescence microscopy. Microscopy was performed without fixation using a Zeiss Axiovert 200 M microscope (Germany) with an LD Plan NeoFluor 40× objective. For high-resolution microscopy, 5×10^5 cells/mL were cultured on channel slides (Ibidi, Germany) for 24 h. Then, cells were incubated with CA in culture medium for another 18 h under normal culture conditions. These cells were subjected to nuclear staining and trypan blue quenching followed by extensive washing with HBSS. Images were made using a Zeiss Plan APOCHROMAT 63×/1.4 oil DIC objective. OptiGrid (Improvision, England), a structured light device, was used for acquiring images of confocal quality, and Volocity Acquisition and Visualization software (Improvision, England) was used for high-speed image capture and high-resolution rendering of data sets as images or movies. The imaging conditions were kept constant for the observation of all the different samples. Cellular localization and distribution of the peptide was observed by irradiating with blue light (Ex 470/40 nm) and observing at Em 525/50 nm. Apart from FITC fluorescence, the nuclear labeling by Hoechst was observed by Ex 365/15 nm and Em 460/50 nm and trypan blue fluorescence viewed by Ex 535/50 and Em 645/75 nm. Also, phase contrast images with differential interference contrast (DIC) microscopy of the same area were made to observe whether the cells maintain their normal morphology in the presence of CAs.

MR Measurement in Cells. For MR imaging of cells, exponentially growing cells were labeled with different concentrations of CAs in 175 cm^2 tissue culture flasks for 18 h. After repeated washes with HBSS, cells were trypsinized, centrifuged, and resuspended in 1.5 mL Eppendorf tubes at 2×10^7 cells for DsRed and CCL-11 in 500 μL complete medium. Cells were allowed to settle before MR measurements. Tubes with medium only and cells without CA were used as controls.

MR imaging of the cell pellets at room temperature (~21 °C) was performed in a 3 T (123 MHz) human MR scanner (MAGNETOM Tim Trio, Siemens Healthcare, Germany), using a 12-channel RF head coil and slice-selective measurements from a slice with a thickness of 1 mm positioned through the cell pellet.

T_1 was measured using an inversion−recovery sequence, with an adiabatic inversion pulse followed by a turbo−spin−echo readout. Between 10 and 15 images were taken, with the time between inversion and readout varying from 23 to 3000 ms. With a repetition time of 10 s, 15 echoes were acquired per scan and averaged six times. For T_2, a homewritten spin−echo sequence was used with echo times varying from 19 to 1000 ms in about 10 steps and a repetition time of 8 s. Diffusion sensitivity was reduced by minimizing the crusher gradients surrounding the refocusing pulse. All experiments scanned 256^2 voxels in a field-of-view of 110 mm in both directions resulting in a voxel volume of $0.43 \times 0.43 \times 1$ mm^3.

Data analysis was performed by fitting to relaxation curves with self-written routines under *MATLAB 7.1 R14* (The Mathworks Inc., United States). The series of T_1 and T_2 relaxation data were fitted to the following equations:

$$T_1 \text{ series with varying } t = T_I\text{: } S = S_0(1 - \exp(-t/T_1)) + S(T_I = 0)\exp(-t/T_1) \quad \text{(a)}$$

$$T_2 \text{ series with varying } t = TE\text{: } S = S_0 \exp(-t/T_2) \quad \text{(b)}$$

Nonlinear least-squares fitting of three parameters S_0, $S_{(TI = 0)}$, and T_1/T_2 was done for manually selected regions of interest with the Trust Region Reflective Newton algorithm implemented in *MATLAB*. The quality of the fit was controlled by visual inspection and by calculating the mean errors and residuals.

Biodistribution Study. C57BL/6 mice were used to study the *in vivo* distribution of anti-dsred CA. The CA was injected intravenously via the tail vein at a dose of 10 μmol/kg in 100 μL saline. An equivalent volume of saline was injected into the control animal. After 20 min, animals were sacrificed and biodistribution was assessed. Tissues harvested included lungs, liver, spleen, kidney, heart, bladder, and brain. All tissues were rinsed with PBS to remove blood or hair, and a slice of arbitrary thickness from each tissue was placed on a glass slide for microscopic observation. Microscopy was performed using a Zeiss EC Plan-NEOFLUOR 20×/0.5 objective. Fluorescence and bright field images of the tissues were obtained and observed for CA-related FITC fluorescence.

RESULTS AND DISCUSSION

Evaluation of Optimal CPP. Among the increasing number of transduction peptides that are being characterized, HIV-1 Tat and polyarginines represent two of the particularly well studied. Over the years, more efficient sequences have been derived by modifications of Tat CPP (*32, 33*). Although polyarginines were the foremost to be used for intracellular delivery of CAs (*34*), of late a higher toxicity of polyarginines has been suggested in comparison to Tat (*35*). Therefore, we decided to evaluate the efficiency of three HIV-1 Tat derivatives to translocate MR CAs together with FITC into cells. Thus far, there are only a few publications about the use of HIV-1 Tat to transport CAs for MRI (*36*−*38*). Large amounts of CA need to be transported into cells to obtain maximum MR contrast enhancement because of the low sensitivity of MRI. Therefore, we chose long incubation times. On the other hand, labeling protocols more close to *in vivo* conditions were applied using incubation in the presence of culture medium containing serum instead of serum-free buffer formulations and an incubation temperature of 37 °C. We observed that in the presence of serum the rate of uptake was slowed down (data not shown). This might be due to an interaction of the conjugates with serum components. A routine laboratory embryonic mouse fibroblasts cell line NIH 3T3 was selected for comparison of uptake efficiency.

We synthesized the Gd-DOTA-Lys(FITC) conjugates of L-$Tat_{(49-57)}$ (L-Tat CA), D-$Tat_{(57-49)}$ (D-Tat_{inv} CA), and Orn-D-$Tat_{(57-49)}$ (substitution of the glutamine residue with ornithine) (Orn-D-Tat_{inv} CA) in-house (*32*) (Figure 1). Peptide segments were synthesized by an online solid-phase synthesis scheme. Using an additional lysine as linker, DOTA tris(*tert*-butyl) ester was coupled on its α-NH_2 group and FITC on the ε-NH_2 group.

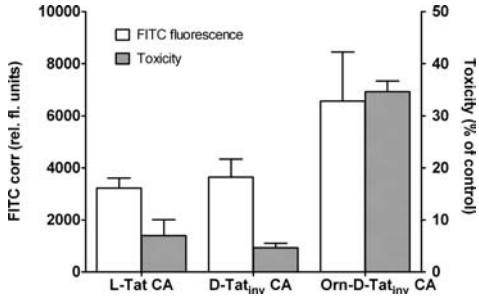


Figure 2. CA related fluorescence measured by fluorescence spectroscopy in NIH 3T3 embryonic mouse fibroblast cells. Cells were incubated with contrast agents at a concentration of 20 μM in complete medium for 18 h. External fluorescence was quenched with trypan blue and subsequent washes with HBSS. Values are means ± SEM; $n = 3$ with six replicates each.

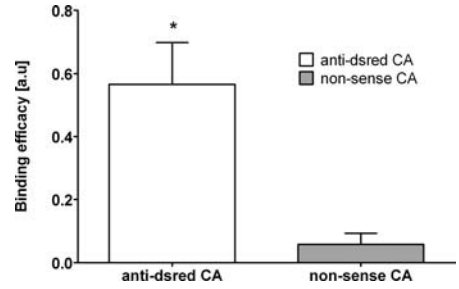

Figure 3. Binding efficacy of anti-dsred and nonsense CA in an *in vitro* binding assay. Synthetic single-stranded target DNA was immobilized on DNA binding plates, and nonspecific binding sites were blocked with BSA/FBS. Hybridization was performed with anti-dsred and nonsense CA, followed by extensive washing to eliminate nonspecific binding. Detection by anti-FITC-HRP-conjugated antibody. Values are means ± SEM, $n = 3$ with two replicates each. *: $p < 0.05$ statistically significantly different between contrast agents, Student's *t*-test.

The final gadolinium-loaded compounds were used to label cells. Fluorescence spectroscopy was applied to assess cellular uptake by FITC fluorescence and toxicity by nuclear DNA content estimation after staining with Hoechst 33342 (*29, 30*).

Of the three sequences tested, Orn-D-Tat$_{(57-49)}$ was the most efficient in delivering the conjugates across the cell membrane (Figure 2). However, its uptake was accompanied by a significant reduction of DNA content (directly correlated to the number of cells), thus limiting its exploitation. Our results did not reveal much difference in the uptake of conjugates with L-Tat$_{(49-57)}$ or D-Tat$_{(57-49)}$, both of which had negligible toxicity (although D-Tat$_{(57-49)}$ has been reported to be a more efficient transporter for other cargos (*39*)). This difference could be attributed to the influence of the Gd-loaded chelate on the molecular charge or three-dimensional conformation of the conjugate. Furthermore, it is well-established that D-isomers of amino acids are resistant to enzymatic cleavage and remain longer in the circulation (*39*). Thus, we chose D-Tat$_{(57-49)}$ as the CPP for experiments on further coupling of PNA sequences together with Gd-DOTA and FITC to obtain bimodal targeting agents.

Design and Synthesis of mRNA-Targeted CA. PNA was selected to target unique mRNA sequences. These polyamide nucleic acids are reported to be resistant to enzymatic cleavage in biological fluids and hybridize with DNA or RNA with high specificity and affinity (*40*). As per the base pairing rule, these PNA could bind sequences in cellular mRNA and, therefore, serve as high-affinity probes for molecular imaging. Although most mRNAs are expressed at low copy numbers under normal conditions (50−1000 per cell at any particular time point), these numbers increase manyfold in certain situations like disease or stress (*1*). The use of PNA for imaging specific mRNA could potentially serve for early detection of anomalies by monitoring molecular processes. Because PNAs have poor cellular uptake, they need to be coupled to delivery agents such as CPPs in order to pass through the biological membrane and interact with the intracellular target (*41*).

The intention of our study was to design a multimodal probe by the use of a facile building block approach. The blocks could easily be altered according to the target requirement without significant modification in the synthetic scheme. The molecule eventually designed contained MR and optical imaging moieties linked to PNA for targeting and CPP for intracellular transport. In order to establish proof of principle, mRNA from a variant of the red fluorescent protein, DsRed2, was chosen as the target. Through a BLAST database search, a 12mer antisense sequence (tcc gtg aac ggc, anti-dsred) specific to the DsRed2 mRNA was identified (*16*). Another sequence (gtt cag agt cta) that did not correspond to any known mammalian gene was selected as the nonsense control sequence (*16*).

Two PNA-containing conjugates, anti-dsred CA and nonsense CA, were synthesized using the same synthetic scheme as reported before (*16*) (Figure 1). The chelation of gadolinium in the macrocyclic chelator was confirmed by relaxivity measurements of CA in aqueous solutions. The relaxivity values for both the CAs (2.8 ± 0.3 $mM^{-1}s^{-1}$ for antisense CA and 4.3 ± 0.2 $mM^{-1}s^{-1}$ for nonsense CA) corresponded with values for compounds with one DOTA complexed gadolinium.

***In Vitro* Proof for Binding Specificity of Antisense CA.** The hybridization properties of PNA are crucial for specific antisense targeting. It is established that oligonucleotides of 12 or more bases are adequate for targeting unique genomic sequences (*42*). The targeting specificity of anti-dsred CA in comparison to nonsense CA was determined *in vitro* using a synthetic single-stranded oligodeoxynucleotide sequence (45-mer) as described in Experimental Procedures. Significant specific binding of the antisense CA to the synthetic target was observed (Figure 3). The nonsense counterpart almost completely failed to bind, such that the hybridization signal obtained can be mainly ascribed to specific binding. Thus, *in vitro* studies clearly demonstrated the applicability of the selected antisense PNA sequence for mRNA targeting. Gel retardation studies further verified the specific binding affinity of the antisense CA compared to the nonsense CA (data shown in Supporting Information). A retarded mobility of only the synthetic single-stranded DNA hybridized with the antisense PNA was observed, while the unhybridized DNA and DNA incubated with nonsense PNA showed no change in mobility.

Cellular Uptake and Internalization Studies. CPPs have been used for the delivery of a vast variety of biomolecules. The ability of D-Tat$_{(57-49)}$ to transport our covalently conjugated PNAs along with the imaging moieties was next investigated in whole cells. Murine fibrosarcoma cells transfected with the DsRed2 gene, referred to as DsRed cells (*24*), and their parent cell line CCL-11 were used for internalization assessment by fluorescence spectroscopy and microscopy.

The antisense CA as well as the nonsense CA very efficiently labeled DsRed cells (Figure 4a). Both CAs showed a concentration-dependent transfer into cells up to a labeling concentration of 5 μM. Saturation in internalization was observed at labeling concentrations of >2.5 μM, and a further dose increase was accompanied by increased toxicity but only a marginal improvement in cellular delivery. Thus, for subsequent studies a labeling concentration of 2.5 μM of the PNA-containing CA was used. A comparable uptake profile for both CAs was observed in the nontarget containing CCL-11 cells (data not shown).

Additionally, observations of DsRed and CCL-11 cells by fluorescence microscopy revealed similar uptake and distribution for both the PNA-containing CAs (Figure 4b). These agents

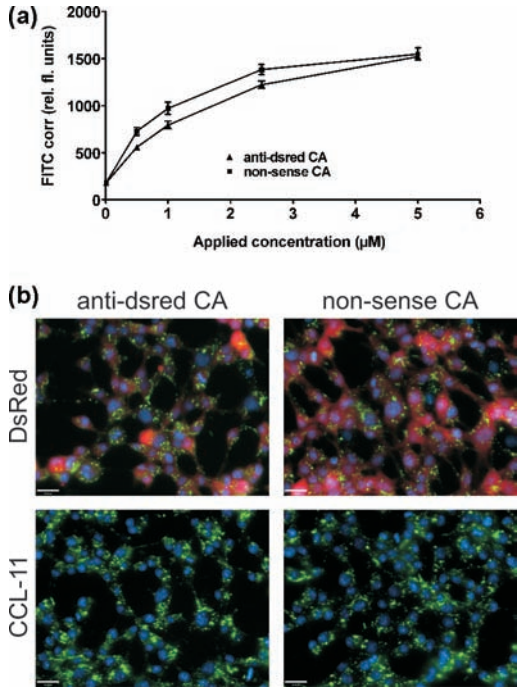

Figure 4. Internalization of anti-dsred and nonsense CA in DsRed and CCL-11 mouse fibrosarcoma cells. Fluorescence spectroscopy (a) and microscopy (b) were performed on cells incubated with 2.5 μM of either anti-dsred or nonsense CA for 18 h. External fluorescence was quenched with trypan blue and subsequent washes with HBSS; values are means $\pm$ SEM, $n = 3$ with six replicates each. The bar represents 20 μm.

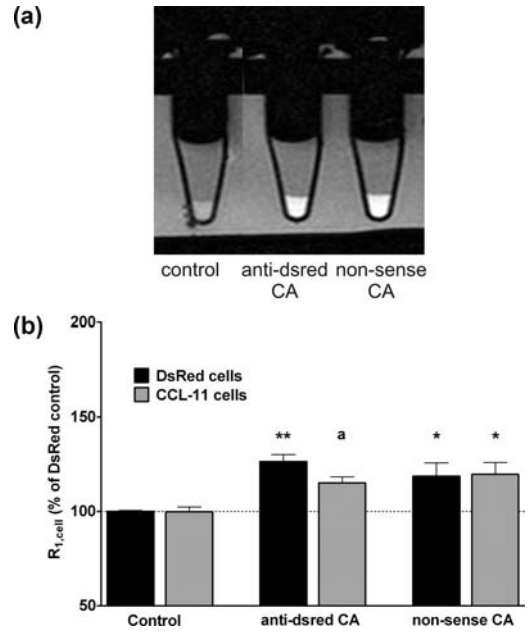

Figure 5. T_1-weighted MR images of DsRed cells after loading with 2.5 μM of anti-dsred and nonsense CA for 18 h (a). Cellular relaxation rate $R_{1,cell}$ in DsRed and CCL-11 cells after labeling with anti-dsred or nonsense CA (b). After treatment with DsRed CA for 18 h, cells were trypsinized, centrifuged, and resuspended in 1.5 mL Eppendorf tubes at 2×10^7 cells/500 μL in complete medium for MR studies. The measured relaxation rates were plotted vs the applied extracellular labeling concentration. Control: cells incubated with culture medium without CA. Values are means $\pm$ SEM; $n = 3$ with two replicates each. *: $p < 0.05$, **: $p < 0.01$ statistically significantly different to control. a: $p < 0.05$ statistically significantly different between cell lines, ANOVA with Tukey's post test.

were distributed in the perinuclear area as bright punctuate dots in both cell lines. This indicates that, despite the difference in the base composition of the two PNA sequences, both antisense and nonsense CA have similar cellular internalization efficacy and properties.

In our study, therefore, the feasibility of using D-Tat$_{(57-49)}$ as a transport vector for large-sized cargos has again been demonstrated. In fact, efficiency similar to that of the D-Tat$_{inv}$ CA was observed when an almost 10 times lower labeling concentration of the PNA-containing CAs was used. Attaching PNA to D-Tat$_{inv}$ largely increased the molecular weight and also raised the hydrophobic nature of the conjugates. We hypothesize that the CPP-PNA CAs might interact better with the cell membrane and hence enhance uptake. The high hydrophobicity of the conjugates containing PNA also reduced their solubility in water. Therefore, the PNA-containing conjugates could be used only at low micromolar concentrations for labeling cells.

Enhancement of MR Contrast in Cells. Previously, we reported that CPP-PNA CAs were highly efficient intracellular CAs yielding contrast enhancement in NIH 3T3 cells at concentrations as low as 0.5 μM (*16*). The possibility to utilize these PNA-containing conjugates as MR contrast-enhancing agents in target-containing cells has now been assessed. Cells producing target mRNA as well as nontarget expressing cells were labeled with 2.5 μM of either the antisense CA or nonsense CA. Cells were labeled for 18 h followed by repeated washings with Hank's buffered saline solution (HBSS, Biochrom AG, Germany). After trypsinization, an average of 2×10^7 cells were transferred into Eppendorf tubes for T_1 and T_2 measurements. Cells were also treated in a similar way but in the absence of any contrast agent to establish background control values.

In agreement with our earlier observations, both conjugates showed significant contrast enhancement in cells (*16*). The T_1 relaxation times in DsRed cells were substantially altered by the nonsense as well as antisense CA at concentrations as low as 2.5 μM (Figure 5a). Remarkably, this labeling concentration was 20−1000 times lower than the amount of CPP linked Gd-based chelators used for delivery into cells (*14, 15, 34, 36, 43*). T_1-weighted images of CCL-11 cells showed similar contrast changes at these low concentrations. The extended incubation times used for CA delivery into cells could be the reason this low concentration is sufficient for significant contrast enhancement.

The target-containing DsRed cells demonstrated a slightly higher cellular relaxation rate $R_{1,cell}$ for the antisense CA compared to the parent CCL-11 cells (Figure 5b). Whether a specific interaction between our anti-dsred CA and the cellular target mRNA was responsible for this observed effect remained unclear and is still under investigation. A decreased rotational correlation time and thus a greater τ_r effect was expected upon binding of antisense CA with DsRed2 mRNA (*44*). However, no such effect was observed even in the target-containing cells. In addition, no specific accumulation of the antisense CA in comparison to the nonsense CA could be detected in DsRed cells. Due to the predominantly endosomal uptake, a mainly unspecific accumulation could be observed. Additionally, the efflux from nontargeted cells would be disturbed and at least slowed down. These findings suggest that, although the CPP-PNA CAs efficiently permeate cells, their interaction with the target mRNA appears limited. This could arise due to the localization of the conjugates and the target in different cellular compartments.

Fluorescence Microscopy Studies. High-resolution microscopy was performed to elucidate the intracellular distribution of the FITC-containing CPP-PNA conjugates. DsRed cells were cultured in channel slides and labeled with antisense CA. After removal of surface-bound fluorescence by trypan blue and nuclear staining with Hoechst, cells were examined under the microscope. Confocal-like 3D image data were acquired using

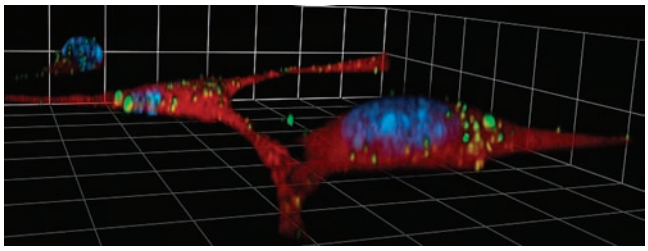

Figure 6. Endosomal localization of anti-dsred CA in DsRed cells. Cells were incubated with anti-dsred CA and cell nuclei were counterstained by Hoechst 33342. External fluorescence was quenched by trypan blue and subsequently washed with HBSS; DsRed CA, green (FITC fluorescence); nuclei, blue (Hoechst 33342). The 3D image was rendered from obtained 2D slices. A single unit represents 13.3 μm.

the OptiGrid Structured Illumination device that eliminates all out-of-focus information from the image (*45*). A high-speed Micro-Shutter was also integrated into the Zeiss microscope to control the exposure times and reduce sample photobleaching. Z-stacks were collected for a single time point using a multiple channel acquisition protocol. The combination of hardware and software used for microscopic evaluation was optimal for rapid and high-resolution observation of living cells with minimized damage to samples. 3D images were reconstructed from the 2D slice images thus obtained.

Examination of DsRed cells labeled with antisense CA in 3D clearly revealed encapsulation of green fluorescent CA in intracellular vesicles around the nucleus (Figure 6). Although the target mRNA cannot be visualized by microscopy, it is expected to be distributed mainly throughout the cytosol, as is the case with the red fluorescent DsRed2 protein itself. On the other hand, the CA seemed to be entering cells by endocytosis and subsequently entrapped in endosomal/lysosomal vesicles with little or no release into the cytosol. Hence, the absence of target binding in cells can be explained by the localization of both the antisense PNA and target mRNA in segregated compartments within the same cell.

As more information is obtained about the mechanism of cellular delivery by CPPs, it is becoming evident, as also reported by other groups, that endocytosis is the main route of trans-membrane movement (*46*−*48*). However, there is a lack of definitive evidence on the maintenance of functionality of the CPP-associated cargo once it is conveyed into cells. Some studies indicate successful PNA interaction with the target after being delivered by membrane-transducing peptides (*49*−*51*). Other studies indicate limited PNA binding with the target due to entrapment of PNA conjugates in endosomes (*52, 53*).

Another interesting observation was that subsequent to quenching with trypan blue no traces of green fluorescence binding to the cellular membrane were noticed (*31*). Trypan blue interacts with the aromatic groups on FITC, and therefore, the fluorophore in the extracellular environment as well as the FITC in cells with compromized cell membrane integrity becomes quenched. This justifies the use of this stain to efficiently eliminate extracellular and membrane-bound fluorescence. Microscopic examination also indicates that, because of the quenching step in our washing protocol, only the internalized probe signal is quantified by fluorescence spectroscopy.

Biodistribution Properties. Coupling of PNA with Gd-DOTA-CPP(FITC) more than doubles the size of the conjugate. Thus, it was important to investigate the mobility of this large molecule *in vivo*. Fluorescence studies performed 20 min after i.v. injection showed that within minutes the compound entered various organs via the bloodstream, and was by no means limited to the injection site (Table 1). The fluorescence observed in the liver and bladder was very high, and the exposure time for fluorescence images was reduced almost 3.5 times in comparison

Table 1. Biodistribution of the Antisense CA in Various Tissues Represented Qualitatively[a]

tissue	fluorescence intensity
liver	+++
urinary bladder	+++
kidney	++
spleen	++
lungs	+
heart	±
brain	−
blood	−

[a] Tissues from C57/BL6 mice were extracted 20 min after CA administration and tissue slices were assessed for antisense CA-related green fluorescence. Tissues from animals injected with saline alone served as control.

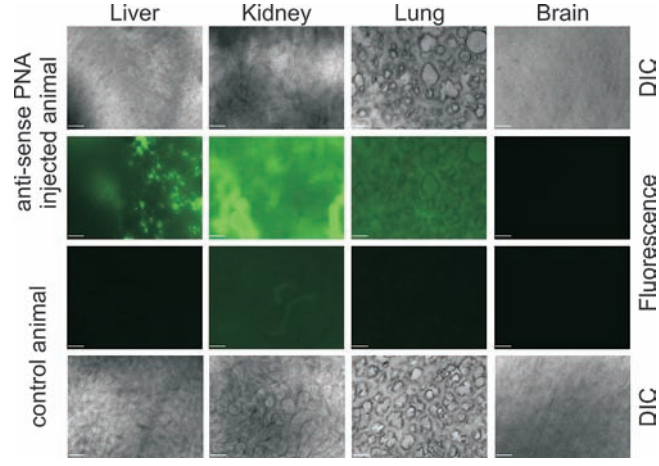

Figure 7. Distribution of anti-dsred CA in different tissues after *in vivo* labeling. Tissues were extracted 20 min after intravenous administration of anti-dsred CA to C57/BL6 mice. Fluorescence and bright field images of the tissues were obtained. For fluorescence images of liver, an exposure time of 175 ms was used, while for all other tissues, it was adjusted to 600 ms. The bar represents 160 μm.

to the rest of the tissues (Figure 7). The lipophilic nature of the PNA-containing CA explains the affinity of the conjugate for liver tissues. Kidneys and spleen were moderately labeled, whereas heart and lungs were only faintly fluorescent. Absolutely no penetration of the CA into the brain was detected, thus indicating a lack of penetration of the blood−brain barrier. Although these biodistribution studies are preliminary, they clearly indicate that the bulky PNA-containing antisense CA spontaneously disperses in the organism after injection and also rapidly enters the excretory system.

In conclusion, we report here the synthesis of a couple of cell-penetrating gadolinium-based conjugates, the most efficient of which was selected for coupling with PNA sequences. Both the PNA-CPP CAs labeled cells very well, regardless of whether they contained the specific target. mRNA targeting could not be realized; nevertheless, we have succeeded in generating highly efficient and nontoxic cell-internalizing and contrast-enhancing MR agents. Future studies need to be focused on the improvement of vesicular release after endocytosis or finding methods for direct cytosolic uptake and developing targeted contrast agents for better understanding of the mechanism of contrast enhancement at the cellular level.

ACKNOWLEDGMENT

The authors thank Dr. Marna Ericsson, University of Minnesota, for the generous gift of the DsRed2-transfected CCL-11 cell line. The authors especially acknowledge the help of Ms. Hildegard Schulz, High Field Magnetic Resonance Center,

Max Planck Institute for Biological Cybernetics, in carrying out these studies. This work was supported by the Max-Planck Society and was performed in the frame of COST action D38.

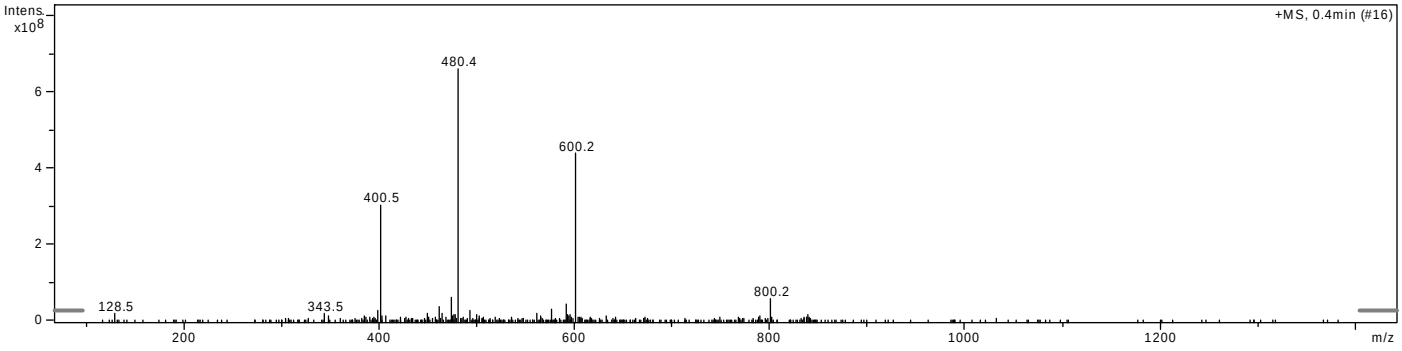
Running title: Evaluation of CPP-PNA coupled MR contrast agents

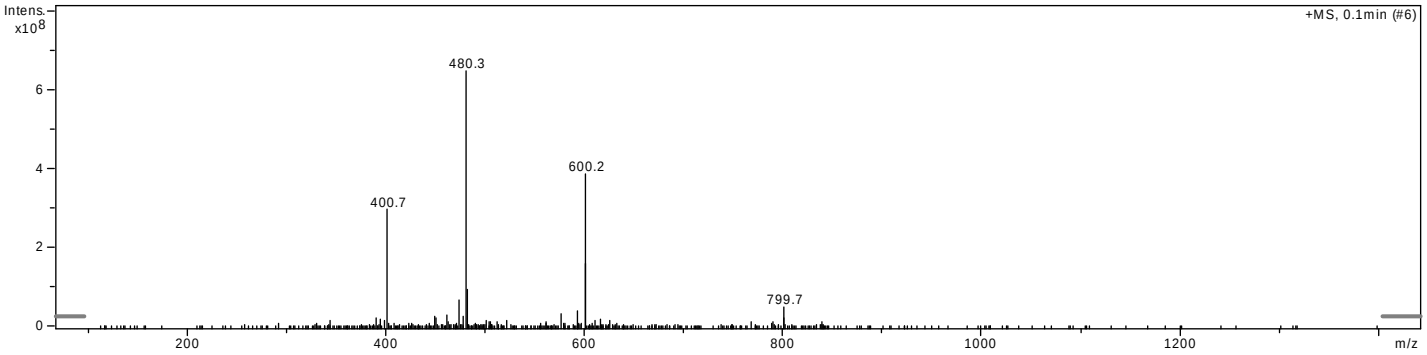
ESI-MS.

ESI-MS spectra obtained for the conjugates were as follows:

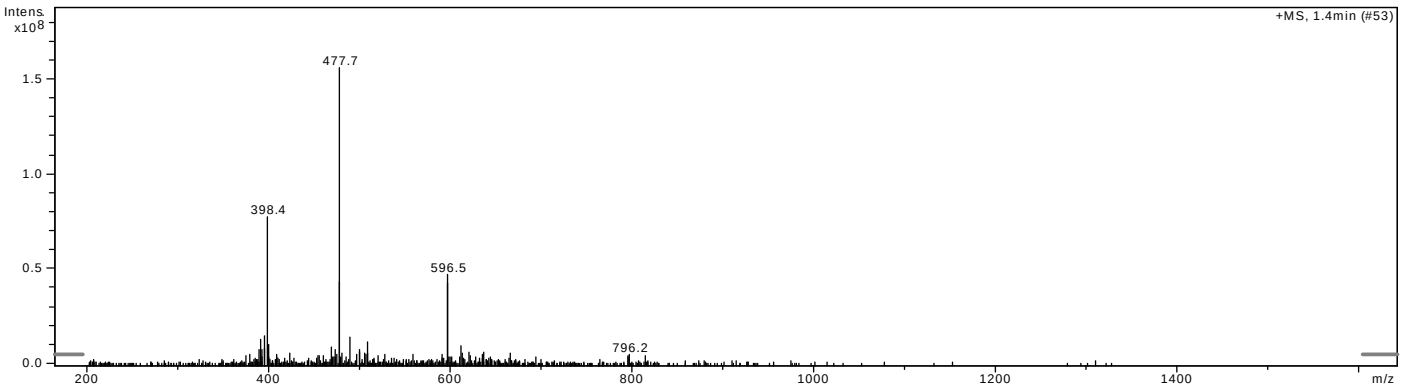
Gd-DOTA-Lys(FITC)-L-Tat$_{49-57}$-OH. (MW=2397.08)



Gd-DOTA-Lys(FITC)-D-Tat$_{57-49}$-OH. (MW=2397.08)



Gd-DOTA-Lys(FITC)-Orn-D-Tat$_{57-49}$-OH. (MW=2383.10)



GELRETARDATION ASSAY.

The specificity of interaction between the anti-sense PNA and target sequence after pre-gel hybridization was verified by gel retardation assay (*1*). A 45-mer single-stranded deoxynucleotide sequence (5'-CTC GAA CTC GTG GCC GTT CAC GGA GCC CTC CAT GCG CAC CTT GAA GCG CAT GAA CTC CTT GAT-3'), selected from the DsRed2 cDNA was obtained commercially (Eurofins MWG, Germany). This sequence contained a stretch of bases complementary to the anti-sense sequence used in the anti-sense CA. The anti-sense CA or non-sense CA (10 pmol) were incubated with the synthetic 45-mer single-stranded deoxynucleotide (12.5 pmol) in hybridization buffer (12.5 mM Tris buffer, pH 8 containing 2.5 mM sodium chloride, 0.5 mM magnesium chloride and 0.05 mM dithiothritol (DTT)). This pre-loading hybridization was performed at 60°C for 1 h followed by a gradual reduction to room temperature. The samples were then run on 8% native acrylamide gel and subjected to electrophoresis in running buffer (200 mM Tris-acetate buffer, pH 8.3, 1 mM EDTA). Silver staining was used to detect the mobility of the DNA on the gel.

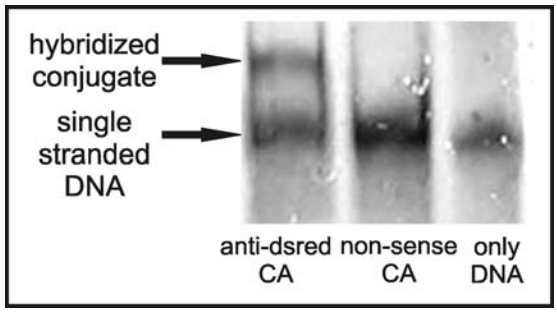


Figure S-1. Retardation of the mobility of the target oligodeoxynucleotide after hybridization with anti-sense CA. The hybridized synthetic DNA with anti-sense CA

shows a gel shift. The DNA does not interact with the non-sense CA and the excess of anti-sense CA and thus the unhybridized DNA has the same mobility on the gel as the control DNA. Since these PNA-CPP conjugated CAs have a positive charge, they tend to run out of the gel if they are unhybridized and cannot be visualized under the gel running conditions used.

Peptide Targeting of Platinum Anti-Cancer Drugs

Margaret W. Ndinguri,[†] Rajasree Solipuram,[‡] Robert P. Gambrell,[§] Sita Aggarwal,*[,‡] and Robert P. Hammer*[,†,||]

Department of Chemistry, Louisiana State University, Baton Rouge, Louisiana 70803, William Hansel Cancer Prevention Laboratory, Pennington Biomedical Research Center, Baton Rouge, Louisiana 70808, Department of Oceanography and Coastal Sciences, Louisiana State University, Baton Rouge, Louisiana 70803, and New England Peptide, Gardner, Massachusetts 01440.
Received February 11, 2009; Revised Manuscript Received August 24, 2009

Besides various side effects caused by platinum anticancer drugs, they are not efficiently absorbed by the tumor cells. Two Pt−peptide conjugates; cyclic mPeg-CNGRC-Pt (**7**) and cyclic mPeg-CNGRC-Pten (**8**) bearing the Asn-Gly-Arg (NGR) targeting sequence, a malonoyl linker, and low molecular weight miniPEG groups have been synthesized. The platinum ligand was attached to the peptide via the carboxylic end of the malonate group at the end of the peptide. The pegylated peptide is nontoxic and highly soluble in water. Platinum conjugates synthesized using the pegylated peptides are also water-soluble with reduced or eliminated peptide immunogenicity. The choice of carboplatin as our untargeted platinum complex was due to the fact that the malonate linker chelates platinum in a manner similar to that of carboplatin. Cell toxicity assay and competition assay on the PC-3 cells (CD13 positive receptors) revealed selective delivery and destruction of PC-3 cells using targeted Pt−peptide conjugates **7** and **8** significantly more than untargeted carboplatin. Platinum uptake on PC-3 cells was 12-fold more for conjugate **7** and 3-fold more for conjugate **8** compared to that of the untargeted carboplatin, indicating selective activation of the CD13 receptors and delivery of the conjugates to CD13 positive cells. Further analysis on effects of conjugates **7** and **8** on PC-3 cells using caspase-3/7, fluorescence microscopy, and DNA fragmentation confirmed that the cells were dying by apoptosis.

INTRODUCTION

Platinum compounds are widely used in cancer chemotherapy (*1, 2*). Cisplatin is an FDA-approved drug that is widely used for treatment of many types of cancers including lung, ovarian, as well as head and neck cancer (*3, 4*). Carboplatin, an analogue of cisplatin, is being used more often because it has decreased nonspecific toxicity and is active against cisplatin-resistant tumors (*2, 5*−*7*). Both carboplatin and cisplatin have been shown to form similar adducts with DNA by the formation of covalent bonds with the N7 of purine bases. This results in interference with normal transcription and DNA replication mechanisms leading to eventual cell death. While these drugs are effective, they have very serious side effects that include nephrotoxicity, myelotoxicity, neurotoxicity, vomiting, and nausea (*8*). Certain cancers can also develop resistance to drugs such as cisplatin via efflux pumps as reported by Katano et al. (*9, 10*).

One method to make toxic drugs more effective is by incorporation of a cell-specific targeting group. A number of peptide sequences are capable of mediating the delivery of therapeutic or imaging drugs (*11, 12*). Using phage display libraries, several peptide sequences that have the ability to target tumors have been discovered (*13, 14*). The Asn-Gly-Arg (NGR) motif was identified as a peptide that uniquely homed specifically to solid tumors in murine breast carcinoma models and that bound strictly to the endothelium of angiogenic blood vessels (*15*). Besides the NGR motif, other peptide sequences such as Arg-Gly-Asp (RGD) and luteinizing hormone releasing hormone (LHRH) have been used to target specific receptors found mainly in certain tumor cells (*16*−*20*). The NGR motif may be superior to the RGD-related motif for targeting because of the many types of cells that express the $\alpha V\beta_3$ and $\alpha V\beta_5$ integrins that bind the RGD-type sequence, which may lead to nonspecific targeting and toxicity (*14*). Recently, doxorubicin (DOX) and 5-fluoro-2′-deoxyuridine (5-FdUrd) conjugates have successfully been targeted using the NGR motif (*21, 22*). Specifically, the DOX−peptide conjugate treated animals had increased life expectancies relative to that of animals treated with DOX alone (*23*), and a 5-FdUrd−NGR conjugate produced selective accumulation of 5-FdUrd in tumor cells having CD 13 receptors (*24*). Haubner et al. revealed that radiolabeled RGD peptide was found to concentrate rapidly in the liver, which can lead to liver toxicity in drugs that are based on RGD targeting, hence limiting the usefulness of these drugs (*14*).

New blood vessels are required for tumor growth (*15, 25*). Thus, around solid tumors, angiogenesis is stimulated, and endothelial cells proliferate to form new blood sources to support the growing tumor. Modulating the growth of blood vessels is one of the effective ways to control the growth and spread of tumors. Therefore, the search for targets that can regulate angiogenesis is important. Aminopeptidase N (APN), also referred to as CD13, is a cell-surface antigen that binds specifically to NGR peptides (*26, 27*). CD13/APN is expressed selectively on the endothelial cells of angiogenic tissues and the vasculature of various carcinomas including kidney, colon, pancreas, prostate, and lung (*28*−*31*). It is not expressed in normal vasculature, which explains the tumor-specific destination of the NGR peptide (*3, 32*).

By conjugating the water-soluble cyclic peptide CNGRC to the conventional drugs cisplatin and dichloro(ethylenediamine)-platinum(II) ($PtenCl_2$), we hypothesized that we could increase specificity for CD13-expressing cancerous tissues and reduced toxicity to normal tissues. In this work, we describe the preparation of several malonoyl CNGRC peptides and their

platinum conjugates and evaluate their specific targeting on tumor cells with CD13 receptors.

EXPERIMENTAL SECTION

All starting reagents listed below were obtained from commercial sources and used without further purification: di-*tert*-butyl malonate, dry solvents, $AgNO_3$, 3-bromopropylphthalimide, dichloro(ethylenediamine)platinum(II), cis-diammineplatinum(II) dichloride, and glutaric anhydride were obtained from Aldrich (Milwaukee WI); Fmoc-11-amino-3,6,9-trioxaundecanoic acid (miniPEG, $mPEG_3$) was obtained from Peptides International (Louisville, KY), and all amino acids were from Novabiochem (Gibbstown, NJ).

NMR Spectroscopy. ^1H NMR spectra were recorded on either 300 or 400 MHz spectrometers. Peak positions are referenced to TMS. All NMR data were processed with *XWINNMR* and *Mestre-C* software.

HPLC. HPLC was performed using a Water 600E multisolvent delivery system with a model 486 tunable detector controlled by Empower software and a Water Deltaprep system, with detection at 220 nm. Different columns were used for analysis and purification of the peptides. Analytical and semipreparative chromatography was performed on a Delta-Pak C_4 (5 μm; 100 Å) reverse phase column (8 × 100 mm) at 1 mL/min (Column 1). Preparative HPLC was performed on Waters Delta-Pak C_4 (15 μm; 100 Å) reverse phase column (25 × 100 mm) at 15 mL/min (Column 2). Linear gradients of 0.1% TFA[1] in H_2O (Eluent A) and 0.1% TFA in MeCN (Eluent B) in all HPLC were used.

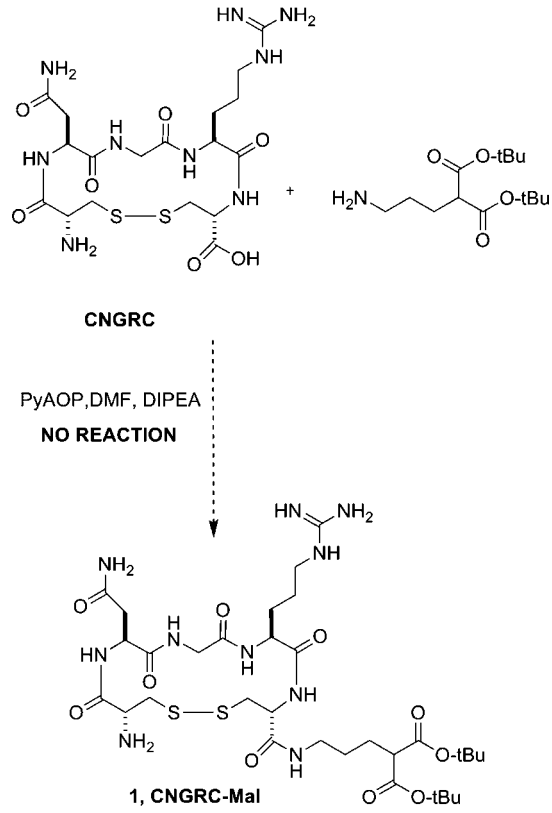
Mass Spectrometry. Compounds were analyzed using ESI on an Agilent Technologies instrument processed with Analyst QS1.1 (Applied Biosystems) or Mass Hunter (Agilent).

Inductive Coupled Plasma−Optical Emission Spectroscopy. Platinum uptake was analyzed using a Varian, Vista MPX CCD simultaneous spectrometer. PlasmaCal Pt (1000 μg/mL) from SCP Science was used for calibration by diluting it to standard solutions of known concentration.

Synthesis. *Peptide Synthesis.* All peptides were synthesized using standard Fmoc solid phase chemistry. Fmoc-PAL-PEG-PS (Peptide Amide Linker resin: 0.2 mmol, 0.24 mmol/g loading) was placed in a normal resin column and washed with DMF in continuous flow mode using a Pioneer Peptide Synthesizer. The side chain-protected amino acid derivatives used in the sequence were Fmoc-Cys(Acm)-OH, Fmoc-Arg-(Pbf)-OH, Fmoc-Gly-OH, Fmoc-Asn(Trt)-OH, and Fmoc-Cys(Acm)-OH. Fmoc-mini-peg-3 and the derivatized malonate linker di-*tert*-butyl 2-(3-glutaricaminopropyl)malonate were also used, depending on the peptide sequence. All couplings utilized four equivalents each of amino acids, malonate, and PyAOP (*33*) dissolved in 0.5 M DIEA in DMF (final concentration, 0.25 M) for 1 h at room temperature; minimal preactivation time was used in coupling. DMF was used for washing between coupling and deprotection cycles. The Fmoc group was removed using 20% piperidine in DMF for 5 min. Final washing was with DMF and dichloromethane.

*Synthesis of CNGRC-Mal (***1***).* In an attempt to synthesize CNGRC-Mal, we synthesized cyclic CNGRC using the method described by Anizon et al. using NovaSyn TGT alcohol resin (0.20 mmol, 0.20 mmol/g loading) (*23*). Conjugation of CNGRC with di-*tert*-butyl 2-(3-aminopropyl)malonate was unsuccessful (Scheme 1).

Scheme 1. Coupling of CNGRC with Di-*tert*-butyl 2-(3-aminopropyl)malonate

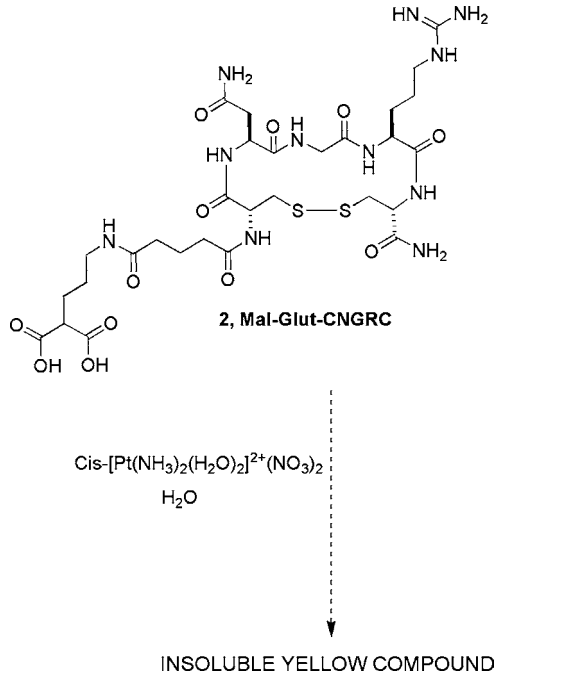


*Synthesis of Mal-Glut-CNGRC (***2***).* Using standard Fmoc chemistry, we synthesized Mal-Glut-CNGRC using the procedure described in the peptide synthesis section, using PAL-PEG-PS resin without the Fmoc-mini-peg-3 solubilizing group. Coupling the peptide with di-*tert*-butyl 2-(3-glutaricaminopropyl)malonate gave crude Mal-Glut-CNGRC peptide, which was purified by reverse phase HPLC on column 1 using a linear gradient from 5% to 70% B eluent in 60 min, t_R 11 min. The adduct gave the expected $(M + H)^+$ peak at 807.2893, calculated for $C_{29}H_{48}N_{11}O_{12}S_2$ 807.2925 (see Supporting Information). Using the procedure described for the preparation of cyclic mPeg-CNGRC-Pt, the peptide was reacted with cis-$[Pt(NH_3)_2(H_2O)_2]^{2+}(NO_3)_2$ to give an insoluble yellow solid (Scheme 2) which was not suitable for further characterization.

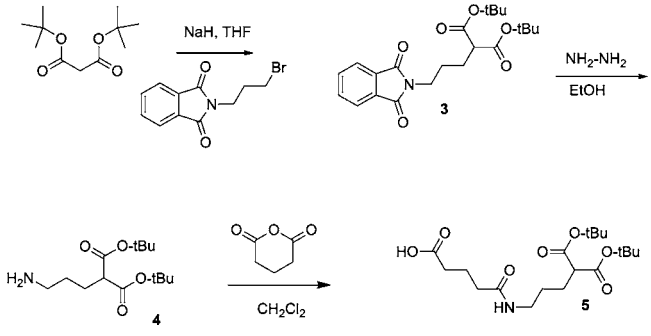
*Synthesis of Di-tert-butyl 2-(3-phthalimidopropyl)malonate (***3***).* Di-*tert*-butyl 2-(3-phthalimidopropyl)malonate was synthesized by a known method (Scheme 3) with slight modifications (*34*). NaH (0.38 g, 16 mmol) was suspended in dry THF (100 mL), and dry di-*tert*-butyl malonate (4.4 mL, 20 mmol) was added to the reaction mixture (with stirring) until gas evolution ceased. A solution of 3-bromopropylphthalimide (2.68 g, 10 mmol) was added dropwise to the reaction mixture, followed by stirring overnight. The THF was removed by evaporation, and the product was redissolved in CH_2Cl_2 and washed with 5% aqueous acetic acid. The organic fractions were combined, dried over $MgSO_4$, and concentrated. The final product was isolated using silica column chromatography (95% hexane; 5% ethyl acetate). Di-*tert*-butyl 2-(3-phthalimidopropyl)malonate was crystallized using a mixture of CH_2Cl_2 and hexane to give colorless plates (see Supporting Information). The yield was 80% (3.22 g). Spectroscopic data obtained for this compound were in agreement with literature values (*34*).

[1]Abbreviations. PyAOP, (7-azabenzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate; DMF, *N*,*N*-dimethylformamide; TFA, trifluoroacetic acid; DIEA, *N*,*N*-diisopropylethylamine; TIPS, triisopropylsilane; DMSO, dimethyl sulfoxide; Fmoc, fluorenylmethoxy carbonyl; PBS, phosphate-buffered saline; FBS, fetal bovine serum; ESI-MS, electrospray ionization mass spectrometry; TOF, time-of-flight; KOt-Bu, potassium *tert*-butoxide; PAL, 5-(4-aminomethyl-3,5-dimethoxyphenoxy)valeric acid (Peptide Amide Linker); PEG-PS, poly(ethylene glycol)-polystyrene; Pten, ethylenediamine platinum(II).

Scheme 2. Platination Reaction Using Mal-Glut-CNGRC



Scheme 3. Synthesis of Di-*tert*-butyl 2-(3-glutaricaminopropyl)-malonate



*Synthesis of Di-tert-butyl 2-(3-aminopropyl)malonate (***4***).* Compound **4** was prepared by a known method as described by Aronov et al. (*34*). Di-*tert*-butyl 2-(3-phthalimidopropyl)-malonate was deprotected using absolute hydrazine to give di-*tert*-butyl 2-(3-aminopropyl)malonate. The ^{1}H NMR spectrum of compound **4** (Scheme 3) in $CDCl_3$ matched the reported values.

*Synthesis of Di-tert-butyl 2-(3-(4-Carboxybutanamido)propyl)-malonate (***5***).* Compound **5** was synthesized as previously described in the literature (*34*). Glutaric anhydride was used for acylation in this reaction, yielding the glutaroyl(aminopropyl)malonic ester **5** (Scheme 3). The yield was 92%.^{1}H NMR ($CDCl_3$) (ppm): 3.27 (q, 2H), 3.14 (t, 1H), 2.41 (t, 2H), 2.28 (t, 2H), 1.98 (m, 2H), 1.81(m, 2H), 1.56 (m, 2H), 1.45(s, 18H).

*Synthesis of Cyclic mPeg-CNGRC-mal (***6***).* After synthesizing the linear mPeg-CNGRC-mal peptide and confirming its purity, the resin was suspended in DMF (60 mL) and the reaction mixture cooled to 0 °C in an ice bath before the addition of I_2 (10 equiv). The mixture was stirred at 0 °C for 2 h, filtered, and washed with DMF (10 × 10 mL) and CH_2Cl_2 (10 × 10 mL). Using a cocktail of TFA/phenol/water/TIPS (88:5:5:2) (15 mL), the peptide was cleaved from the resin, precipitated with ether, and dried under vacuum to give crude peptide **6**. The crude peptide was purified using reverse phase HPLC on column 1 with a linear gradient from 5% to 70% B eluent in 60 min; t_R 28 min. This yielded cyclic mPeg-CNGRC-mal (**6**) in 35% yield. ESI-MS (TOF) gave a signal at 1184.4764 $(M + H)^+$, calculated for $C_{45}H_{77}N_{13}O_{20}S_2$ 1184.4849 (see Supporting Information).

*Synthesis of Cyclic mPeg-CNGRC-Pt (***7***).* Cyclic mPeg-CNGRC-mal was dissolved in water, and the pH of the solution was adjusted to 7, by titration with 1 M NaOH (See Supporting Information). A solution of cis-$[Pt(NH_3)_2(H_2O)_2]^{2+}(NO_3)_2$ was made by stirring cis-$PtCl_2(NH_3)_2$ and $AgNO_3$ vigorously overnight in water in the dark. A precipitate was formed (AgCl) and then filtered to give cis-$[Pt(NH_3)_2(H_2O)_2]^{2+}(NO_3)_2$ (*35, 36*). A 2-fold excess of cis-$[Pt(NH_3)_2(H_2O)_2]^{2+}(NO_3)_2$ (10 mmol) was reacted with compound **6** (30 mg, 5 mmol) to form the crude cyclic mPeg-CNGRC-Pt conjugate (**7**), which was then purified by gel filtration on a Sephadex-G10 column to give the final product in 15% yield. ESI-MS (TOF) gave a signal at 1412.4913 $(M + H)^+$, calculated for $C_{45}H_{81}N_{15}O_{20}PtS_2$ 1412.4955 (see Supporting Information).

*Synthesis of Cyclic mPeg-CNGRC-Pten (***8***).* Cyclic mPeg-CNGRC-mal was dissolved in water, and the pH of the solution was adjusted to 7, by titration with 1 M NaOH. cis-$[Pten(H_2O)_2]^{2+}(NO_3)_2$ was synthesized by stirring $PtenCl_2$ and $AgNO_3$ vigorously overnight, in water in the dark. A precipitate was formed (AgCl) and then filtered to yield cis-$[Pten(H_2O)_2]^{2+}$-$(NO_3)_2$ (*37*−*39*). A 2-fold excess of cis-$[Pten(H_2O)_2]^{2+}(NO_3)_2$ (10 mmol) was reacted with compound **6** (30 mg, 5 mmol) to give the crude cyclic mPeg-CNGRC-Pten conjugate, which was then purified by gel filtration on a Sephadex-G10 column to give cyclic mPeg-CNGRC-Pten (**8**) in 10−12% yield. ESI-MS (TOF) gave a signal at 719.7571 $(M + H)^{2+}$, calculated for $C_{47}H_{83}N_{15}O_{20}PtS_2$ 719.7593 (see Supporting Information).

*Synthesis of Cyclic mPeg-CNGRC (***9***).* Free peptide (**9**) was assembled as described in the Peptide Synthesis section, without the malonate linker **5**. The crude peptide was purified by reverse phase HPLC on column 1 with a linear gradient from 5% to 70% B eluent in 60 min and t_R 10 min to give cyclic mPeg-CNGRC (**9**) in 38% yield. ESI-MS (TOF) gave a signal at 927.4032 $(M + H)^+$, calculated for $C_{34}H_{62}N_{12}O_{14}S_2$ 927.4023 (see Supporting Information).

Cell Culture. The prostate cancer cell line PC-3 (CRL-1435) was obtained from the American type Culture Collection (Manassas, VA). Penicillin, streptomycin, RPMI 1640, and fetal bovine serum (FBS) were obtained from Invitrogen (Grand Island, NY). The cell line was cultured in RPMI 1640 supplemented with 10% FBS, 100 units/mL penicillin, and 100 μg/mL streptomycin.

Fluorescence Microscopy. PC-3 cells were seeded on 6-well plates (500,000 cells/well) and incubated for 24 h in RPMI 1640 media. The cells were treated with 200 μM carboplatin, a mixture of carboplatin and free peptide **9**, or Pt−peptide conjugates **7** or **8** for 48 h. After incubation, the cells were washed once with RPMI and stained with JC-1 dye for 30 min. The stained cells were analyzed using a Leica DM RXA fluorescent microscope with Xenon lamp illumination, using a 40 × dip objective with an N.A. of 0.80. The filter cube for the green channel had the following characteristics: a 480/40 excitation filter, a 527/30 emission filter, and a 505 nm dichroic mirror. The filter cube used for the red channel had the following characteristics: a 537/45 excitation filter, an LP 590 emission filter, and a 580 nm dichroic mirror.

Cytotoxicity Assay. The cytotoxicity of the free carboplatin, free peptide cyclic mPeg-CNGRC-mal (**6**), the mixture of carboplatin, and mPeg-CNGRC (**9**) as well as the two platinum conjugates (cyclic mPeg-CNGRC-Pt (**7**) and cyclic mPeg-CNGRC-Pten (**8**)) was assayed using the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay as described (*40*). Briefly, 2000 cells/well were incubated in 96-well plates in triplicate, using different concentrations of platinum complexes in a cell growth medium. Three wells were used as

controls, receiving an equivalent volume of RPMI medium alone. The cells were treated with different concentrations (0, 50, 150, 200, and 300 μM) of carboplatin, free peptide **6**, the mixture of carboplatin and mPeg-CNGRC (**9**), and the Pt−peptide conjugates **7** and **8** for 48 h. After 48 h, a solution of MTT (5 mg/mL in PBS) was added to each well, and the cells were incubated for 2 h at 37 °C. The cells were then lysed using a lysis buffer (20% SDS and 50% DMSO). The lysed cells were incubated for 3 h at 37 °C, before the absorbance of the cell suspension was measured at 590 nm using an MRX Revelation 96-well multiscanner (Dynex Technologies, Chantilly, VA).

Drug Competition Assay. Using various concentrations of mPeg-CNGRC (**9**), a cell competition assay for carboplatin and conjugate **8** was carried out using the MTT assay. Two thousand cells/well were incubated in 96-well plates one day prior to the treatment to allow the cells to adhere to the plate in triplicate. On the next day, the cells were treated using various concentrations of the free peptide mPeg-CNGRC (**9**) (1, 2, 4, 8, and 10 mM) with simultaneous addition of 200 mM carboplatin and conjugate **8** for 48 h, respectively. The plate was analyzed as described in the cell cytotoxicity assay.

Drug Uptake Measurements. One million PC-3 cells were plated in a 6-well plate a day before for adherence. On the next day, the cells were treated with fresh medium containing 200 μM carboplatin, and Pt−peptide conjugates **7** and **8** for 24 h. After incubation, the cells were washed with PBS once and collected in a tube for further analysis. The collected samples were dissolved in 0.25 mL nitric acid (trace metal grade) and heated for 2 h at 60 °C for digestion. Upon cooling, approximately 5 mL of deionized water was added to dilute the samples to the minimum volume required for the ICP spectrometer.

Apo-ONE Homogeneous Caspase-3/7 Assay. The homogeneous caspase-3/7 assay kit (Promega, Madison, WI), which provides a profluorescent substrate with an optimized bifunctional cell lysis/activity buffer for caspase-3/7 activity assays, was used. PC-3 cells were treated with free peptide **9** or a mixture of free peptide **9** and carboplatin, conjugate **7**, or conjugate **8** at 100 μM concentration. After 24 h of incubation, the apo-ONE homogeneous caspase-3/7 assay was performed according to the manufacturer's protocol. The buffer and substrate were mixed and added to the samples. Upon sequential cleavage and removal of the DEVD (Asp-Glu-Val-Asp) peptides by caspase-3/7 activity and excitation at 499 nm, the rhodamine 110 leaving group became intensely fluorescent with an emission maximum at 512 nm (*41*). The excitation/emission was recorded on FlexStation from Molecular Devices (Sunnyvale, CA) with softMax Pro, version 4.8 software. This experiment was performed in duplicate, and the statistical analysis was done.

DNA Fragmentation Assay. The evaluation of nuclear morphological events such as internucleosomal DNA fragmentation was performed by standard agarose gel electrophoresis as described previously (*42*). Briefly, treated cells (one million cells) were washed in ice-cold PBS, resuspended in 0.2 mL of PBS in 1.5 mL Eppendorf tubes. Next, 0.2 mL of lysis buffer (20 mM Tris-HCl, pH 7.4, 1% triton x-100.10 mM EDTA, and 0.1 mg/mL proteinase K) was added, and the mixture was incubated at 55 °C for 2 h. Proteinase K was then heat inactivated at 70 °C for 10 min, and the sample was cooled to room temperature. RNase was added (10 μL of 20 mM Tris-HCl, pH 7.4, containing 0.5 mg/mL RNase) to the sample, which was further incubated for 2 h at 37 °C. Extraction of DNA was achieved with a 1:1 mixture of phenol/chloroform and precipitated with two volumes of cold ethanol and one-tenth volume of sodium acetate. The sample was centrifuged, and the pellet was resuspended in 50 μL of deinonized water. Samples were loaded on a 1.5% agarose gel and electrophoresed at 60 V for 2 h in TBE. The gel was stained with EtBr and visualized by UV trans-illumination using a Bio-Rad Versa Doc Imaging system (Model 3000).

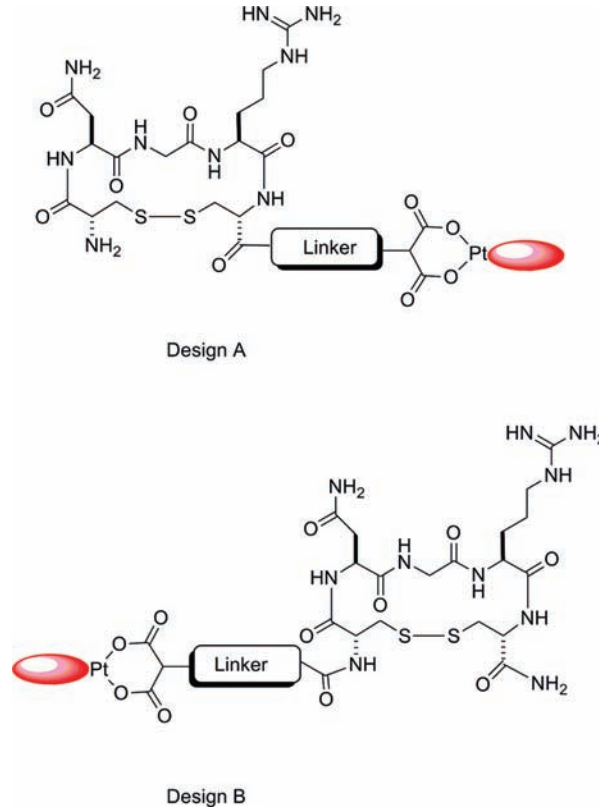


Figure 1. CNGRC model conjugate with platinum pro-drug.

RESULTS AND DISCUSSION

In order to evaluate the optimal construct for delivering a platinum−peptide conjugate, several CNGRC-chelator constructs were evaluated. Figure 1 shows the two designs that we tested for the formation of Pt−peptide complexes, with design B being the more successful of the two. Design A was based on attaching the chelator to the C-terminus of the peptide acid as had been done for the DOX−NGR conjugate (*23*). Design B has the linker attached to the N-terminus, which has potential advantages for incorporation by solid-phase synthesis.

Following design A, our initial attempt was to couple the cyclic CNGRC peptide with di-*tert*-butyl 2-(3-aminopropyl)-malonate using solution phase chemistry by conjugating the free carboxylic end of the cysteine with the free amine end of di-*tert*-butyl 2-(3-aminopropyl)malonate (Scheme 1). The cyclic CNGRC peptide was prepared as described by Anizon et al. (*23*), where the trityl alcohol resin was converted to the trityl chloride derivative with acetyl chloride. This was followed by loading of the Fmoc-Cys(Acm)-OH onto resin resulting in a 0.14 mmol/g (70%) loading yield. The resin was treated with Fmoc-Arg(Pbf)-OH, Fmoc-Gly−OH, Fmoc-Asn(Trt)-OH, and Fmoc-Cys(Acm)-OH to give crude CNGRC. The HPLC chromatogram and the mass spectrum revealed the expected $(M + H)^+$ peak at 550.76, which was in agreement with the reported values. Di-*tert*-butyl 2-(3-aminopropyl)malonate was prepared as described in the Experimental Section using a slight modification of the Aronov method (*34*). The malonate was alkylated using a strong base to give product in 80% yield. A similar synthesis was achieved by the Aronov group using KOt-Bu as a base; however, using a stronger base (NaH) in the reaction improved the yields from 60% to 80% yield. A 2-fold excess of di-*tert*-butyl malonate was used to ensure monoalky-

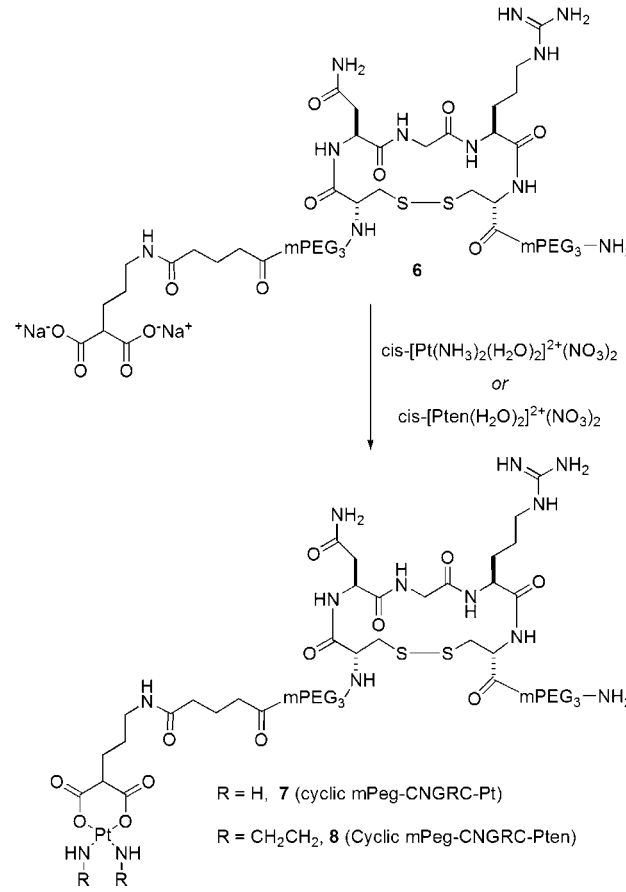
lation and the ease of separation between the malonate and di-*tert*-butyl 2-(3-phthalimidopropyl)malonate. The excess of the di-*tert*-butyl malonate that was used was easily removed by column chromatography (*34*). Attempts to couple the cyclic peptide CNGRC and di-*tert*-butyl 2-(3-aminopropyl)malonate (Scheme 3) using various coupling reagents were unsuccessful (Scheme 1). We do not understand why the reaction failed as similar reactions between CNGRC and DOX with similar functional groups have been successful (*23*). Analysis of the crude product revealed high amounts of the starting materials, including CNGRC, di-*tert*-butyl 2-(3-aminopropyl)malonate, and coupling reagents.

In order to overcome the above problem, we explored design B. This enabled us to conjugate the linker on the N-terminus of peptide resin, thereby avoiding solution phase chemistry in the conjugation of the linker−chelator group to the peptide CNGRC, as shown in Scheme 2. To achieve this synthesis, malonate linker with a carboxylic acid end (**5**) was synthesized using glutaric anhydride and di-*tert*-butyl 2-(3-aminopropyl)-malonate (**4**), as shown in Scheme 3. Starting from an amide-based resin and using Fmoc chemistry, the peptide was assembled, then conjugated to di-*tert*-butyl 2-(3-glutaricamino-propyl)malonate, and cyclized on the solid support to yield Mal-Glut-CNGRC. After purification, HPLC and mass spectral analysis confirmed the purity and identity of the cyclic Mal-Glut-CNGRC. Platination of the purified Mal-Glut-CNGRC using cis-$[Pt(NH_3)_2(H_2O)_2]^{2+}(NO_3)_2$ gave an insoluble yellow compound in most solvents, including water, DMSO, DMF, MeOH, acetone, MeCN, CH_3Cl, and CH_2Cl_2. The compound could not be characterized by mass spectra to confirm the formation of the platinum complex.

Our third and final approach was to increase the solubility of the CNGRC sequence by adding short oligomeric PEG-based residues to both the N- and C-termini of the peptide. Additionally, the PEG linker would provide additional spacing of the Pt ligand from the targeting peptide. Various studies have shown that pegylation does not affect targeting and may have other positive effects such as an increase in stability that reduces the chance of the drug efflux (*34*), and it reduces or eliminates immunogenicity (*43*−*45*). We chose the $mPEG_3$ derivative as the spacer as it is conveniently available as an Fmoc-protected amino acid derivative. The peptide was prepared as before, adding on these residues at each terminus. The glutaric anhydride and linker-malonate were added at the N-terminus, and the linear peptide was cyclized on solid support and cleaved to give target compound **6** (Scheme 4), which was purified by HPLC, and its identity was confirmed by mass spectroscopy (see Supporting Information).

Peptide−Platinum Complexes. Platination with a 2-fold excess of activated cis-$[Pt(NH_3)_2(H_2O)_2]^{2+}(NO_3)_2$ and cis-$[Pten(H_2O)_2]^{2+}(NO_3)_2$ using a standard procedure gave Pt−peptide conjugates **7** and **8** as shown in Scheme 4. The platinum complexes could not be purified by HPLC using either an acidic or a neutral buffer system because the platinum complexes dissociated. The products were, therefore, purified by gel filtration to remove the excess platinum. Fractions containing the Pt−peptide complex in water were identified by ESI-MS and then combined and lyophilized to give pure platinum complexes for cyclic mPeg-CNGRC-Pt (**7**) and cyclic mPeg-CNGRC-Pten (**8**) in a 10−15% yield. Mass spectra revealed the expected $(M + H)^+$ peak at 1412.4913 for conjugate **7** and the $(M + 2H)^{2+}$ peak at 719.7571 for conjugate **8**. During the study, we noticed that platinum conjugate **7** was not very stable in PBS at −20 °C and formed precipitates after a day of storage. Any experiment with conjugate **7** had to use freshly dissolved conjugate. The ethylene diamine Pt conjugate **8** was stable at −20 °C, and the stock solutions could be used in later

Scheme 4. Formation of Cyclic mPeg-CNGRC-Pt (7) and Cyclic mPeg-CNGRC-Pten (8)



experiments. Both Pt conjugates were stable as lyophilized powders at −20 °C, and fresh samples were made by reconstituting the dry samples to the desired concentration. The integrity of redissolved Pt−peptide conjugates was confirmed by ESI mass spectrometry before use.

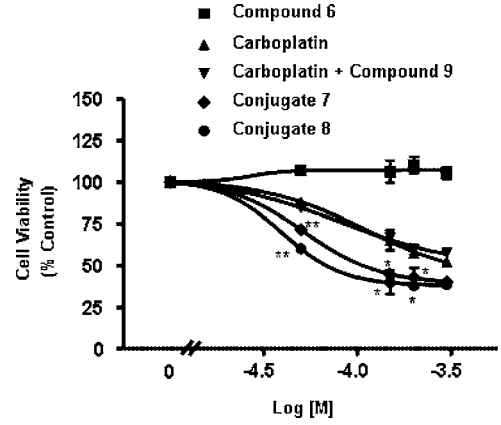


Figure 2. Cytotoxic effects of Pt complexes on PC-3 cells. Cyclic mPeg-CNGRC-mal (**6**), carboplatin, mixture of carboplatin and free peptide **9** (carboplatin + compound **9**), and Pt−peptide conjugates; cyclic mPeg-CNGRC-Pt (**7**) and cyclic mPeg-CNGRC-Pten (**8**) on the proliferation of prostate cancer PC-3 (CD13 positive) cells. PC-3 cells were exposed to the compounds listed above and incubated for 48 h at different concentrations. All points are a representative of the mean ± SD of triplicate readings of three independent experiments. $*P = 0.0190$ (carboplatin and conjugate **7**); $P = 0.0126$ (carboplatin and conjugate **8**); $*P = 0.0407$ (conjugates **7** and **8**). The difference is statistically significant as $P < 0.05$ at 150 μM concentration. Statistical difference was determined by Student's *t*-test; one tailed by using Graph Pad Prism software, version 5.0.

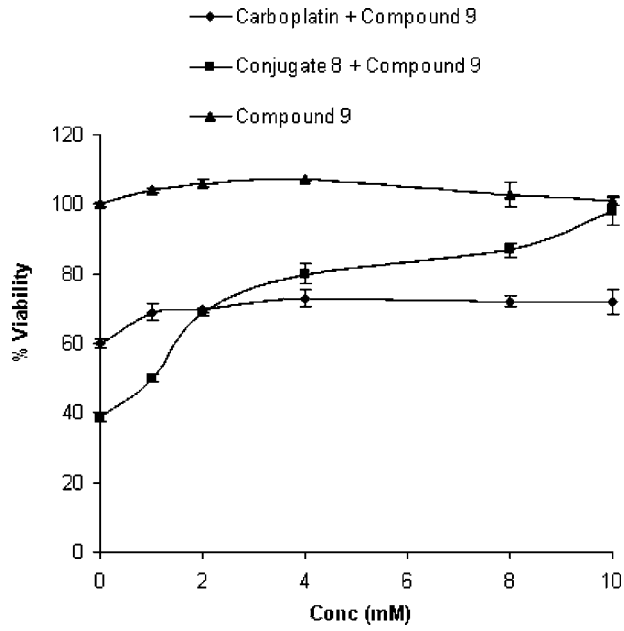

Figure 3. Role of the NRG peptide in cytoxicity. The effect of various concentrations of the free peptide **9** on 200 μM carboplatin and conjugate **8**. Two thousand PC-3 cells were incubated with various concentrations of the free peptide mPeg-CNGRC (**9**), 200 μM carboplatin, and conjugate **8** for 48 h. All points are representative of the mean ± SD of triplicate readings of three independent experiments.

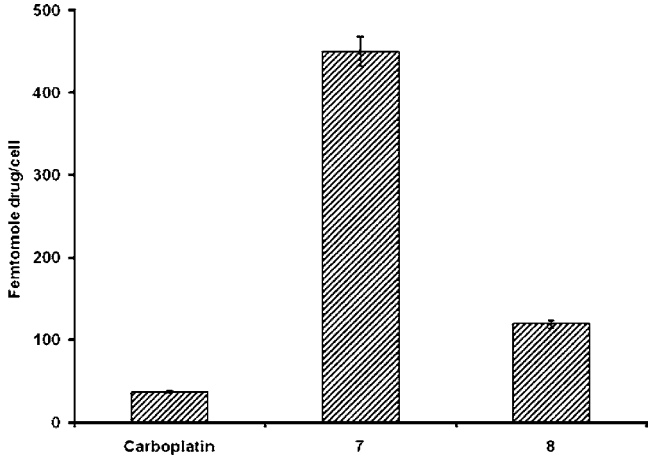

Figure 4. Platinum uptake of PC-3 (CD13 positive) cancer cells. One million cells were incubated with 200 μM carboplatin or Pt−peptide conjugates **7** or **8** for 24 h. Pt levels in the washed cells were measured by atomic absorption spectroscopy as described in the Experimental Section. All points are representative of the mean ± SD of triplicate readings of three independent experiments.

In Vitro Studies on Pt Conjugates: Their Toxicity and Uptake. It has been shown that the NGR motif binds specifically to the CD13 receptors that are expressed on some tumor cells. We examined the effect of the free peptide as a control experiment to determine the effect of the peptide. As shown in Figure 2, the free peptide (**6**) was not toxic to the PC-3 cells and caused a slight increase in the MTT assay, suggesting that the PC-3 receptors were activated by the NGR ligand. Two CNGRC platinum conjugates were prepared to test our hypothesis. As expected, the targeted Pt−peptide conjugates **7** and **8** were more toxic to the PC-3 cells at all concentrations tested compared to the untargeted carboplatin (even at concentrations as low as 50 μM). Pt conjugate **8** shows the highest effect on the suppression of cell proliferation, followed by Pt conjugate **7** and carboplatin. Carboplatin was the least toxic to PC-3 cells of this series of platinum compounds, indicating that the

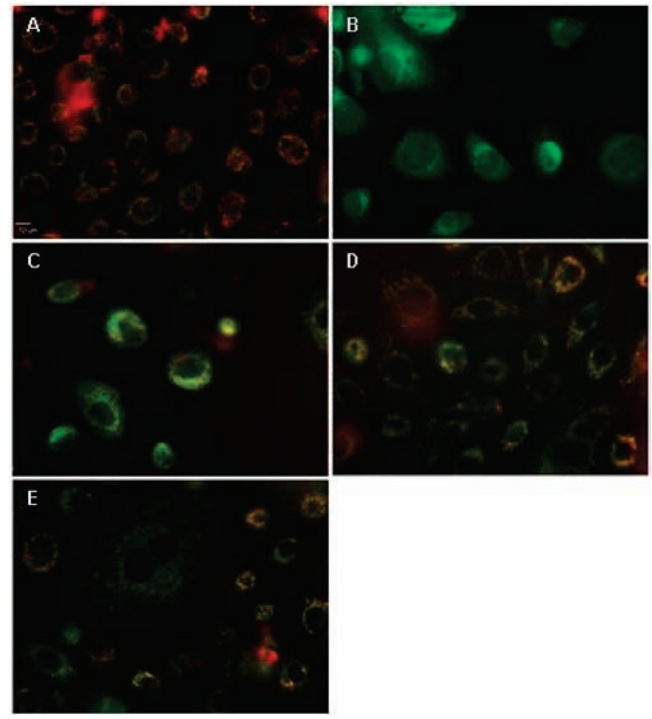

Figure 5. JC-1 dye staining of cells treated with Pt compounds. Fluorescence microscopy of cells that have been treated with various compounds, incubated for 48 h at 37 °C and then imaged by JC-1 staining after a further 30 min of incubation. Image A shows PC-3 cells, treated with RPMI media only. Image B shows PC-3 cells, treated with 50% DMSO. Image C shows PC-3 cells, treated with 200 μM of Pt−peptide conjugate **8** in RPMI media. Images D and E show PC-3 cells incubated with a mixture of carboplatin/free peptide **9** (1:50) and carboplatin only (200 μM), respectively. Scale bar: 10 μm.

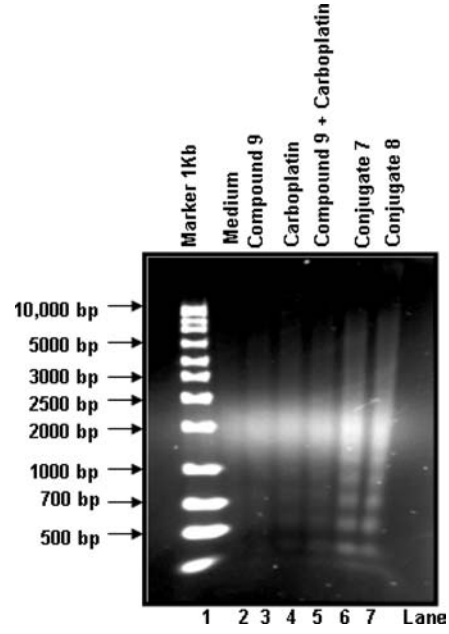

Figure 6. DNA fragmentation assay. PC-3 cells were treated with 5 μL of 1 kb DNA marker (lane 1), medium only (lane 2), and 100 μM each of compound **9** alone (lane 3), carboplatin alone (lane 4), compound **9** + carboplatin (lane 5), conjugate **7** (lane 6), and conjugate **8** (lane 7) for 48 h. DNA was extracted and internucleosomal cleavage visualized on a 1.5% agarose gel. Image is representative of three independent experiments.

platinum complexes bearing the CNGRC sequence are more effective at suppressing tumor cell proliferation. The % growth inhibition on PC-3 cells caused by the mixture of mPeg-CNGRC

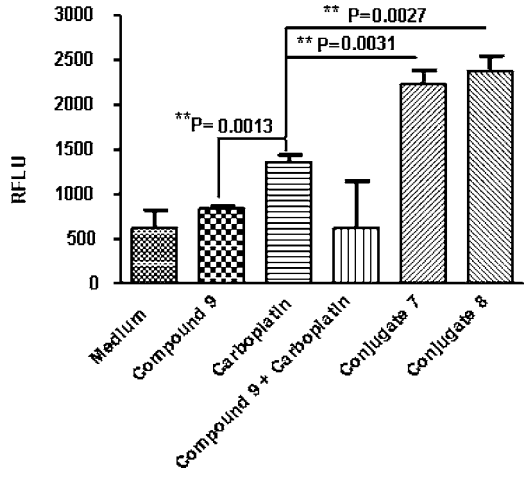

Figure 7. Caspase activation as a result of Pt drug treatment. The apo-ONE homogeneous caspase-3/7 assay where PC-3 cells (10,000 cells/well) in triplicate were treated with medium only and 100 μM concentration of the compound **9**, carboplatin alone, mixture of compound **9** and carboplatin, conjugate **7**, and conjugate **8** for 24 h. After 24 h, the caspase activity was measured in the wells by adding 100 μL of the apo-ONE caspase-3/7 assay reagent. The cells were incubated for an additional hour at ambient temperature prior to recording fluorescence (485 Ex/527Em). The *P* values are statistically significant and calculated by Student's *t*-test; one tailed.

(**9**); (peptide not bearing a Pt chelating group) and carboplatin was similar to that caused by carboplatin alone, suggesting that there was no effect of the peptide on the toxicity of carboplatin. At 150 μM, less than 50% of the PC-3 cells were viable when exposed to the targeted Pt−peptide conjugates, compared to greater than 60% for the untargeted carboplatin drug. A concentration of 200 μM showed the most substantial effect on cell proliferation (Figure 2). These results suggest that higher uptake of Pt leads to greater suppression of the proliferation of PC-3 cells. Our results are in agreement with those of the other groups, who have shown that the CNGRC motif contributes to the increased intracellular concentration of drugs that are attached to this motif because of targeting to CD13 positive cells. A 5-FdUrd conjugate bearing the homing peptide CNGRC was found to penetrate into the CD13 positive cells (HT-1080) but not in CD13 negative cells (MDA-MB-231). This enhanced the selective accumulation of 5-FdUrd, resulting in a more effective immunotherapy (*24*). IC_{50} values for conjugates **7** and **8** are 149 mM and 115 μM, respectively.

Competition Assay. Figure 3 demonstrates that the free peptide **9** had no cytotoxic effect on the PC-3 cells and can effectively compete off the NGR−Pt conjugate toxicity by simultaneous incubation of the free peptide **9** and conjugate **8**. A slight increase in the % viability with peptide **9** suggests the activation and nourishment of the PC-3 cells. The use of free peptide **9** instead of free peptide **6** was to ensure that carboplatin was not chelated by free peptide **6**, which has a free malonate group that is capable of reacting with the hydrolyzed carboplatin to give ambiguous results. Carboplatin and conjugate **8** were incubated with various concentrations of free peptide **9**. Incubation of carboplatin with various concentrations of free peptide **9** had the same effect on the % viability irrespective of the amount of free peptide **9** used. Incubation of conjugate **8** with various concentrations of free peptide **9** showed that the free peptide was competing with conjugate **8** in targeting the CD13 receptors. With an initial 5-fold excess of free peptide **9**, conjugate **8** was more cytotoxic than free carboplatin, but with a 10-fold excess, the free peptide **9** was able to compete away the effect of conjugate **8** in comparison to carboplatin. A further 50-fold increase in the free peptide concentration resulted in the elimination of the cytotoxic effect from conjugate **8**. The results also demonstrate that the CNGRC motif contributes to the accumulation of platinum in tumor cells, causing a significant difference in the suppression of the proliferation of PC-3 tumor cells.

High uptake seems related to the toxicity of Pt−peptide conjugates **7** and **8**, supporting the hypothesis that high uptake of platinum drugs results in high cytotoxicity. When other targeting ligands have been used, platinum uptake in some cell lines show comparable values and trends closely related to our results, where targeted drugs had a higher uptake than untargeted platinum drugs (*46*−*49*). To confirm the cell toxicity results obtained above, the uptake of platinum by PC-3 cells was determined by exposing the cells to 200 μM carboplatin, Pt−peptide conjugate **7**, and Pt−peptide conjugate **8** for 24 h. The greatest Pt uptake occurred with Pt−peptide conjugate **7** followed by conjugate **8**, and the lowest uptake occurred with carboplatin, in PC-3 cells. The uptake of untargeted carboplatin was determined to evaluate the difference with the targeted complexes. From the data in Figure 4, platinum uptake by the PC-3 cells was 12-fold greater when using conjugate **7** and 3-fold greater when using conjugate **8** compared to that of untargeted carboplatin. These results clearly suggest that the PC-3 cells more readily take up Pt when it is conjugated with the CNGRC-containing ligands, most likely mediated by the CD13 receptors. However, there is no direct correlation between the amount of Pt that is taken in and how toxic the compounds are. For example, Pten complex **8** has a lower IC_{50} but shows less uptake of platinum. Thus, the form of the Pt complex may make a difference in the ultimate effectiveness of the drug. This may explain why Pten complex **8** still is more toxic to the PC-3 cells than the more readily taken up Pt−amine complex **7**. Clinical trials of ethylenediamine platinum complexes were suspended, as previous animal studies have shown high nephrotoxicity relative to cisplatin (*50*, *51*). Our findings suggest that targeting of the Pten conjugate **8** may be a mechanism to reduce the nonspecific toxicity of this extremely potent compound. This shows that care should be taken when interpreting whether high platinum uptake has a direct relationship with cell death and that more studies need to be done in this area. Our major concern during this experiment was to ensure that the cisplatin/carboplatin moiety detaches from the carrier at the right place at the right time. With this in mind, we chose carboplatin as our control drug in the experiment because we expected that our targeted compound would release the drug in a manner similar to that of carboplatin.

Mechanism of Action of Pt Complex Toxicity. The putative mechanism of action of Pt drugs is cross-linking of nuclear DNA through reaction with the N7 of purines, and there are several competing hypotheses that suggest that Pt compounds may react with effector molecules in the mitochondria that lead to apoptosis (*52*). We have investigated the mechanism of action of the Pt−peptide conjugates relative to carboplatin. Since it was established that both the diamino-Pt conjugate **7** and the ethylenediamino-Pt complex **8** have cellular toxicity mediated by binding to the CD13 receptor and that Pt was getting into the cells, we wanted to further establish the mechanism of action of these complexes. It is known that Pt drugs act by a variety mechanisms on cells including interaction with the mitochondria resulting in apoptosis (*52*, *53*). To determine whether Pt−peptide conjugates **7** and **8** can induce apoptosis, we used a series of experiments to further elucidate their mechanism of toxicity relative to that of carboplatin. We investigated various steps of the apoptotic pathway that are in response to Pt compounds. Decrease in mitochondrial membrane potential during apoptosis, leads to the loss of outer mitochondrial membrane integrity and release of cytochrome *c* from the mitochondria. The released cytochrome *c* binds APAF1, forming an apoptosome that

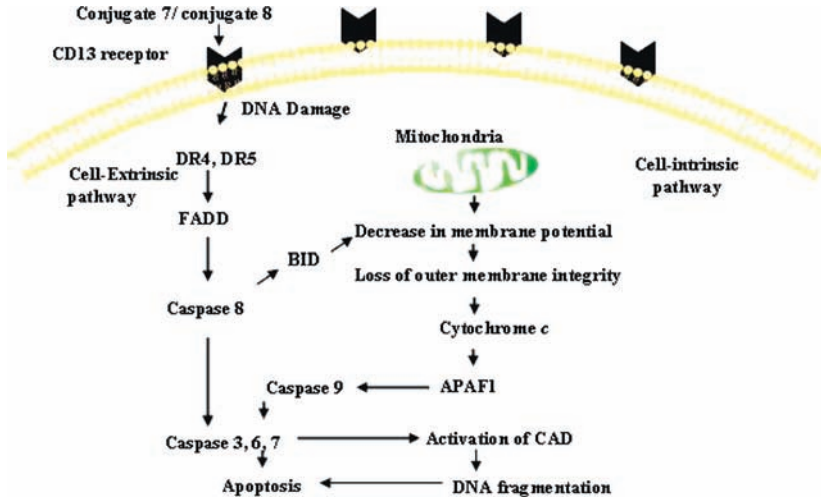

Figure 8. Predicted pathways of apoptosis by conjugate **7** or **8**. Cell-extrinsic apoptosis is engaged through death receptors (DR4 and DR5), and cell-intrinsic apoptosis is triggered through mitochondrial receptors.

activates the apoptotic protease caspase 9, which, in turn activates downstream caspases, such as caspase 3, 6, and 7 (*54*), leading to the final stages of apoptosis, which is typified by DNA fragmentation.

Using the JC-1 dye that is sensitive to mitochondrial membrane potential, we qualitatively examined the action of Pt−peptide conjugates on PC-3 cells (Figure 5) by fluorescence microscopy. Image A shows untreated, healthy cells grown in media which have aggregated JC-1 dye concentrated in their mitochondrial membranes that give a predominantly red fluorescence. Apoptotic cells have a low membrane potential resulting in a green fluorescence, which is evident in image B. Fifty percent DMSO was used to induce 100% cell cytotoxicity. The results shown in Figure 5C confirmed that targeted Pt−peptide conjugate **8** (see Supporting Information for data on compound **7**) causes a decrease in the membrane potential, suggesting death by apoptosis in the PC-3 cell line. Images D and E show PC-3 cells treated with a mixture of carboplatin/free peptide **9** (1:50) and carboplatin alone, respectively. The images show more cells with normal membrane potentials when compared to PC-3 cells treated with targeted conjugate **7** (*55*).

DNA Fragmentation Assay. The microscopy results suggest that the Pt−peptide conjugates may be acting by an apoptotic mechanism. To confirm that conjugates **7** and **8** induce internucleosomal DNA fragmentation, we incubated PC-3 cells with 100 μM each of conjugates **7** and **8** for 48 h along with appropriate controls. Results from Figure 6 clearly indicate that conjugates **7** and **8** displayed increased DNA fragmentation relative to that of carboplatin alone.

An intermediate step in apoptosis is the activation of caspase 9 and eventual activation of caspase 3. Figure 7 shows the results of the apo-ONE caspase assay of cells treated with Pt−peptide conjugates and carboplatin relative to that of controls. Treatment of the cells with carboplatin alone induces the caspase-3/7 activity significantly relative to treatment with medium alone or a non-Pt-containing peptide **9**. This result is consistent with literature reports that anticancer Pt drugs act at least in part through an apoptotic pathway (*56*). Incubation of PC-3 cells with 100 μM conjugate **7** and conjugate **8** results in significantly higher activation of caspase-3/7 relative to carboplatin treatment, which suggests stronger induction of apoptosis in PC-3 cells with the Pt−peptide conjugates. This is consistent with the DNA fragmentation assay as well as the microscopy results with JC-1 that supports targeted conjugates being much more efficient at entering and activating apoptosis than the nontargeted carboplatin alone.

Besides the interaction of the Pt(II) compound with DNA, other effectors in the cell including mitochondrial RNA and sulfur-containing enzymes such as metallothionein and glutathione also bind to platinum (*1, 2*). Although, much attention has been focused on various Pt-DNA adduct formation (*57*−*59*), their role in cytotoxicity and antitumor activity is still unclear (*60*−*62*). There are many studies that have described the depolarization of the mitochondrial membrane as an important characteristic of the mitochondrial or intrinsic pathway leading to apoptosis (*63, 64*). However, data with reduction in mitochondrial membrane potential argues for and against apoptosis and therefore remains controversial (*65*). From fluorescence microscopy and caspase-3/7 and DNA fragmentation data, it is clear that the intrinsic pathway is engaged through mitochondria, leading to cell death, but we cannot exclude the extrinsic pathway. However, more studies need to be done to delineate the exact pathway leading to apoptosis. Figure 8 shows the suggested pathway that is leading to the apoptotic death of the PC-3 cells incubated with conjugates **7** and **8.**

CONCLUSIONS

Our work focused on synthesizing novel targeted Pt−peptide conjugates using the NGR motif and a malonoyl linker. The advantage of the targeted platinum analogues that we synthesized and studied in this work is that they increase the selectivity and specificity of the cancer cells and are less toxic to normal tissues. This study reveals two new low molecular weight Pt−peptide conjugates that effectively deliver the cisplatin and $PtenCl_2$ to the tumor cells, thereby increasing the toxicity toward PC-3 tumor cells. Pegylation of the peptide CNGRC allowed us to study the carrier at physiological conditions; however, the solubility problem did not allow us to compare the difference in cytotoxicity of the nonpegylated peptides. The presence of the bidentate dicarboxylate ligand in carboplatin has been shown to slow the degradation of carboplatin into potentially damaging derivatives, thereby reducing nonspecific toxicity and increasing the potency relative to cisplatin (*66, 67*). With the aid of the miniPEG and the bidentate ligand, we show that Pt−peptide conjugates **7** and **8**, which are analogues of carboplatin, were able to target tumor cells that had CD13 receptors.

ACKNOWLEDGMENT

We thank Dr. Azeem Hasan for mass spectra analysis, Martha Juban for expert technical support with peptide synthesis and purification, and Dr. Matthew Brown for assistance with

fluorescence microscopy. Cell Biology and Bioimaging Core at Pennington Biomedical Research Center are supported in part by COBRE (NIH P20-RR021945) and CNRU (NIH 1P30-DK072476).

Self-Assembly and Cellular Uptake of Degradable and Water-Soluble Polyperoxides

Tamami Fujioka, Shuji Taketani, Takeshi Nagasaki,* and Akikazu Matsumoto*

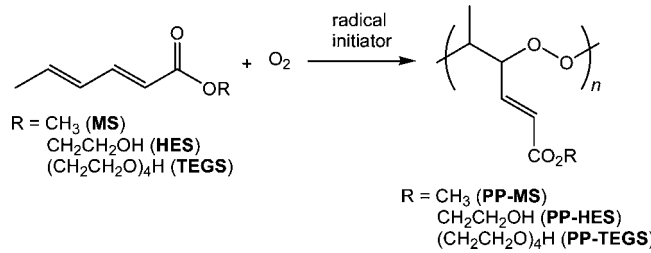
Department of Applied Chemistry and Bioengineering, Graduate School of Engineering, Osaka City University, 3-3-138, Sugimoto, Sumiyoshi-ku, Osaka 558-8585, Japan. Received April 10, 2009; Revised Manuscript Received August 7, 2009

Water-soluble polyperoxides (**PP**s) as a new type of degradable and polymeric material were synthesized by the radical alternating copolymerization of sorbic derivatives containing a tetra(ethylene oxide) unit in the ester group using molecular oxygen. The obtained **PP**s showed a lower critical solution temperature (LCST)-type phase separation, and the transition temperature decreased according to the content of the hydrophobic ester group in the **PP**s. The **PP**s formed nanoaggregates with a diameter of 250−370 nm in water under the LCST. These **PP** aggregates were revealed to include 1-anilinonaphthalene-8-sulfonic acid as the fluorescence probe and epirubicin as the anticancer drug in their hydrophobic compartment. We evaluated the cytotoxicity and cellular uptake of the **PP**s in order to test their ability as a carrier used for the delivery of anticancer drugs. The cell viability in the presence of the **PP**s was comparable to those for the other biodegradable polymers, and epirubicin was taken up into the A549 efficiently with the **PP**s via an endocytosis mechanism.

INTRODUCTION

Polymeric micelles are spontaneously formed by the self-assembly of amphiphilic polymers containing hydrophobic and hydrophilic segments. Nonpolar molecules are incorporated into the core part of the micelles formed in an aqueous medium. Such polymeric micelles have attracted significant attention in the fields of cosmetics, agrichemicals, and medicines, because of their many advantages such as greater solubility of included compounds, stability of the formed micelles, narrow size distribution, and reduced toxicity in the human body (*1*−*8*). Drug delivery systems (DDS) are useful for the controlled release of drugs in humans and the effective delivery of drugs to target tissues and cell in order to increase drug bioavailability (*9*−*16*). For example, more prolonged circulation of carriers allows them to be preferentially accumulated at a certain site by enhanced permeation and retention (EPR) effects (*17*). Controlled release using various types of stimuli, such as biological molecules (*18*), pH change (*19*−*21*), irradiation (*22*−*24*), and heating (*25*−*27*), have also been investigated. The success of DDS depends on the availability of a suitable carrier. There is a significant need for biocompatible and biodegradable delivery polymers, because of reducing toxicity, avoiding accumulation, and enhancing the drug release. Poly(ethylene oxide), poly(lactic acid), poly(ε-caprolactone), poly(aspartic acid), and several other polymers with an excellent biocompatibility and biodegradability (*28*−*30*) have been intensively investigated as pharmaceutical carriers in various forms, e.g., dendrimers (*31*−*33*), microcapsules (*34*−*36*), liposomes (*37*), and micelles (*38*−*40*). Recently, polyperoxides (**PP**s) containing peroxy repeating units in the main chain were developed as new types of degradable polymers (*41*−*47*). The **PP**s are readily synthesized by the radical copolymerization process using sorbic derivatives and molecular oxygen as the starting materials (Scheme 1). The degradation of the **PP**s is induced by the action of any stimulus, for example, heating, photoirradiation, reducing agents, and enzymes, and the degradation reaction

Scheme 1



proceeds via a radical chain reaction mechanism to yield well-defined and low-molecular-weight products (*48*, *49*). We prepared water-soluble **PP**s by the introduction of the tetra(ethylene oxide) units in the ester group of the side chain, and preliminary experiments revealed the formation of aggregates of the amphiphilic **PP**s in water by self-assembly and their LCST (lower critical solution temperature)-type phase separation behavior (*50*). The water-soluble **PP**s are expected to be used as degradable drug carriers. In the present study, we characterized the features of the water-soluble **PP**s and evaluated the cytotoxicity and cellular uptake of the **PP**s as a fundamental research study for DDS.

EXPERIMENTAL SECTION

General Procedures. The number- and weight-average molecular weights (M_n and M_w) were determined by gel permeation chromatography (GPC) at 30 °C in tetrahydrofuran (THF) using a Tosoh GPC-8000 series system and calibrated with standard polystyrenes. The NMR spectra were recorded using a JEOL JMN A-400 spectrometer. Dynamic light scattering (DLS) measurements were carried out using a Zetasizer Nano Series Nano-ZS (Malvern Instruments, Ltd.) photometer. The UV−vis spectra were recorded using a JASCO V-550 photometer with an ETC-505T temperature controller. In order to determine the cloud point (T_{cp}), the transmittance was monitored at 500 nm in the UV−vis spectrum. The turbidity was determined after the solution was kept at each temperature for 5−10 min. A fresh solution was prepared for each measure-

ment in order to avoid the effect of any degradation. When the transmittance value was not constant at a high temperature due to the occurrence of degradation, an initial value was used. The fluorescence spectra were recorded using a JASCO FP-6600 photometer at room temperature. In the WST assay, an absorbances at 450 and 620 nm were determined using a Multiskan Ascent microplate reader (Thermo Labsystems). The fluorescence emitted from the cells was analyzed by a FACS Calibur flow cytometer (BD Biosciences) with excitation at 488 nm using an emission filter of 585 ± 21 nm. The microscopic images were obtained using an Olympus IX-71 fluorescence microscope with a Yokogawa CSU-10 confocal scan unit and a Hamamatsu Photonics ORCA-ER CCD camera.

Materials. 2,2′-Azobis-(4-methoxy-2,4-dimethylvaleronitrile) (AMVN) (Wako Pure Chemical Industries, Ltd., Japan) was used after recrystallization from methanol. Commercially available methyl sorbate (Tokyo Kasei Kogyo Co., Ltd., Japan) was used after distillation under reduced pressure. The solvents were used after distillation. Other reagents were used without any further purification. Epirubicin was purchased from Pfizer Japan, Inc. The A549 cells were supplied from the American type Culture Collection and grown in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum (FBS), 100 U/mL penicillin, 100 mg/mL streptomycin, and 0.1 mmol/L nonessential amino acid at 37 °C under a 5% CO_2 atmosphere.

Synthesis of Tetraethylene Glycol Monosorbic Ester (TEGS). Sorbic acid (5.6 g, 50 mmol), tetraethylene glycol (9.7 g, 50 mmol), and 4-(dimethylamino)pyridine (0.56 g, 4.6 mmol) were dissolved in 40 mL of 1,2-dichloroethane. To the solution, *N*,*N*′-dicyclohexylcarbodiimide (11 g, 53.4 mmol) in 5 mL of 1,2-dichloroethane was dropwise added over 15 min with stirring at 0 °C. After the addition, the reaction mixture was further stirred at room temperature overnight. The reaction mixture was filtered, washed with a 1 mol/L HCl aqueous solution, the $NaHCO_3$ aqueous solution, and brine, and then the solvent was evaporated. The obtained crude product was purified by silica gel column chromatography with *tert*-butyl methyl ether. The TEGS monomer was obtained in 41% yield.

TEGS. Viscous and colorless liquid; ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.28 (dd, J = 15.6 and 9.2 Hz, C*H*═CHCO, 1H), 6.11−6.23 (m, CH_3CH═C*H*, 2H), 5.79 (d, J = 15.6 Hz, CH═C*H*CO, 1H), 4.31 (t, CO_2CH_2, 2H), 3.73−3.75 (m, $CH_2O(CH_2CH_2O)_2CH_2CH_2OH$, 4H), 3.66 (s, $(CH_2CH_2O)_2CH_2CH_2OH$, 8H), 3.60−3.63 (t, CH_2CH_2OH, 2H), 2.53 (broad, CH_2CH_2OH, 1H), 1.85 (d, J = 5.6 Hz, CH_3CH═CH, 3H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 167.09 (C═O), 145.30 (*C*H═CHCO), 139.51 (CH_3CH═*C*H), 129.60 (CH_3CH═CH), 118.42 (CH═*C*HCO), 72.38 (CH_2CH_2OH), 70.19, 70.38, 70.41, 70.49 ($(CH_2CH_2O)_2CH_2CH_2OH$), 69.12 ($CO_2CH_2CH_2$), 63.22 (CO_2CH_2), 61.53 (CH_2OH), 18.54 (CH_3CH═CH).

Synthesis of Tetraethylene Glycol Disorbic Ester (TDS). To the mixture of sorbic acid (5.6 g, 50 mmol), tetraethylene glycol (4.85 g, 25 mmol), and 4-(dimethylamino)pyridine (0.56 g, 4.6 mmol) in 40 mL of 1,2-dichloroethane, *N*,*N*′-dicyclohexylcarbodiimide (11 g, 53.4 mmol) in 5 mL of 1,2-dichloroethane was dropwise added over 15 min with stirring at 0 °C. The reaction mixture was further stirred at room temperature overnight. The solution was filtered, washed, and the solvent evaporated, followed by purification using silica gel column chromatography (chloroform/*tert*-butyl methyl ether = 6/1). The TDS monomer was obtained in 52% yield.

TDS. Viscous and colorless liquid; ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.28 (dd, J = 15.6 and 10.0 Hz, C*H*═CHCO, 2H), 6.11−6.23 (m, CH_3CH═C*H*, 4H), 5.79 (d, J = 15.6 Hz, CH═C*H*CO, 2H), 4.30 (t, $CO_2CH_2CH_2$, 4H), 3.73 (t, $CO_2CH_2CH_2$, 4H), 3.67 (s, $CO_2CH_2CH_2(OCH_2CH_2)_2$, 8H), 1.85 (d, J = 5.6 Hz, CH_3CH═CH, 6H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 167.20 (C═O), 145.37 (*C*H═CHCO), 139.57 (CH_3CH═*C*H), 129.76 (CH_3CH═CH), 118.63 (CH═*C*HCO), 70.62 ($CO_2CH_2CH_2O(CH_2CH_2O)_3H$), 69.27 ($CO_2CH_2CH_2$), 63.38 ($CO_2CH_2$), 18.65 ($CH_3CH$═CH).

Synthesis of 1-Pyrenylmethyl Sorbate (PyMS). Sorbic acid (0.5 g, 4.4 mmol), 1-pyrenylmethanol (1.02 g, 4.4 mmol), and 4-(dimethylamino)pyridine (0.5 g, 4.1 mmol) were dissolved in 5 mL of 1,2-dichloroethane, and then *N*,*N*′-dicyclohexylcarbodiimide (1.0 g, 4.8 mmol) in 5 mL of 1,2-dichloroethane was dropwise added with stirring at 0 °C. After stirring at room temperature overnight, **PyMS** was isolated by a procedure similar to those for the synthesis of the other sorbates, and purified by recrystallization from 1,2-dichloroethane/*n*-hexane. Yield 42.3%.

PyMS. Colorless solid; mp 113−114 °C; ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.39−8.01 (m, Ar, 9H), 7.31 (dd, J = 10.0 and 15.6 Hz, C*H*═CHCO, 1H), 6.13 (m, CH_3CH═C*H*, 2H), 5.91 (s, CH_2, 2H), 5.84 (d, J = 15.6 Hz, CH═C*H*CO, 1H), 1.82 (d, J = 6.0 Hz, CH_3CH═CH, 3H); ($CDCl_3$, 100 MHz) δ 167.5 (C═O), 145.9 (*C*H═CHCO), 140.1 (CH_3CH═*C*H), 132.0, 131.5, 131.0, 130.0, 129.8, 129.4, 128.4, 128.0, 127.9, 127.6, 126.2. 125.7, 125.6, 125.1, 124.9, and 123.3 (Ar), 130.1 (CH_3CH═CH), 118.9 (CH═*C*HCO), 64.8 (CH_2), 19.0 (CH_3CH═CH).

Polymerization. The polymerization was carried out in a two-necked flask with bubbling oxygen at 30 °C in the presence of AMVN (monomer/initiator = 50/1 by weight). 1,2-Dichloroethane was used as the solvent (monomer/solvent = 1/1 by weight). After the polymerization, the contents of the flask were poured into a large amount of *n*-hexane to precipitate the resulting **PP**s. The solvent was removed by decantation and the precipitated **PP**s were dried in a vacuum overnight at room temperature. In the case of **PP-TEGS/TDS**, to remove a gel fraction, the polymerization product was soaked in THF at room temperature for 6 h and filtered. The filtrate was concentrated and the **PP** was precipitated into a large amount of *n*-hexane.

Cytotoxicity of PPs by WST Assay. The cytotoxicity of **PP-TEGS** and **PP-TEGS/TDS**−70/30 was determined by the WST assay method. The A549 cells were seeded onto a 96-well plate at a density of 1×10^4 cells/well in 100 μL of a cell culture medium, and incubated for 1 day at 37 °C, under atmospheric conditions controlled at 5% CO_2. The culture medium of each well was then replaced by 100 μL of a fresh medium containing various concentrations of the **PP**s. After the cells were further incubated for 1 day, the medium was aspirated and 100 μL of a fresh medium was added, followed by the addition of 10 μL of the WST-8 solution (cell counting kit-8, Dojindo Laboratory). After the cells were incubated for additional 2 h at 37 °C, the absorbance of each well was measured at 450 and 620 nm using a microplate reader.

Confocal Microscopic Observation of Internalized Fluorophore. The A549 cells were seeded onto a 35 mm dish containing a cover glass treated with 2 mmol/L HCl aqueous solution at a density of 2×10^5 cells in 2 mL of the cell culture medium and incubated for 1 day (37 °C, 5% CO_2). The culture medium was replaced with 2 mL of fresh medium containing the fluorescent samples. After incubation for a certain period, the cells were washed with a phosphate buffer solution (PBS), fixed with 3.7% HCHO, and used for the fluorescence microscopic observations.

Internalization Efficiency of Epirubicin in the Presence of PPs. The A549 cells (1×10^5 cells/well) were grown to just before confluence in a 12-well culture plate in an atmosphere of 5% CO_2 at 37 °C. The culture medium of each well was replaced with 0.5 mL of fresh medium containing 0.49 mg/mL of the polymers and 0.37 mg/mL of epirubicin. After the cells were further incubated for 3 h, the medium was aspirated and the cells were treated with 0.25% trypsin solution. The cell

[a] Copolymerization was carried out with bubbling oxygen in 1,2-dichloroethane for 6 h at 30 °C. Monomer/solvent = 1/1 by weight. Monomer/AMVN = 50/1 by weight. [b] Determined at room temperature. s: soluble, i: insoluble. [c] Not determined because of thermal degradation. [d] Apparently soluble at a temperature below the T_{cp}. [e] Not determined. [f] The values in parentheses are the yield of a soluble part. [g] Determined for the soluble fraction.

suspension was washed twice with PBS. The intracellular fluorescence of epirubicin (λ_{ex} = 480 nm, λ_{em} = 580 nm) was measured by flow cytometry. A minimum of 2×10^4 events were analyzed for each histogram.

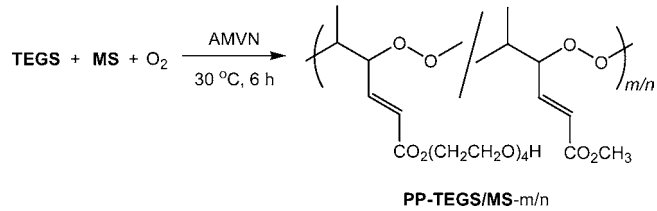
RESULTS AND DISCUSSION

Self-Assembly of Water-Soluble PP. The **PP**s were produced by the radical copolymerization of the sorbates and molecular oxygen. Table 1 summarizes the yield, M_n, M_w, and M_w/M_n values, and the solubility of the produced **PP**s. The M_n values were $(3-4) \times 10^3$ and independent of the structure of the ester group in the side chain. The low-molecular-weight **PP**s, which are classified as an oligomer rather than a high polymer, were formed as a result of the slow addition of a peroxy radical as the propagating chain end to a sorbate monomer and the frequent occurrence of a chain transfer reaction during the copolymerization (*44*, *51*). The formation of the 5,4-structure of the sorbates as the predominant repeating unit (Scheme 1) was confirmed on the basis of the peaks due to the methine (CH−CH in the main chain) and vinylene (CH═CH in the side chain) hydrogens observed at 4.2−5.2 and 6.1−7.0 ppm, respectively, in the NMR spectra of the **PP**s (*44*, *45*). The water-soluble **PP** was obtained by the introduction of a tetra(ethylene oxide) unit into the ester group in the side chain, while the **PP**s with the methyl and 2-hydroxyethyl esters were insoluble in water due to the presence of the hydrophobic main chain.

The **PP-TEGS** aqueous solution was transparent at room temperature, while the solution readily became turbid upon heating. This phenomenon is called LCST-type phase separation, which is typically observed for the aqueous solutions of poly(*N*-isopropylacrylamide) (*52*) and poly(vinyl ether)s (*53*). The intermolecular interaction between the polymer chains is enhanced by the dehydration upon heating, which results in macroscopic aggregation of the polymers. For the **PP-TEGS** solution in the present study, an accurate cloud point (T_{cp}) was not determined because the **PP**s readily degraded upon heating. Therefore, we fabricated **PP-TEGS/MS**-m/n as copolymers of **TEGS** with **MS** with a different ratio in the feed in order to increase the hydrophobicity of the produced polymers (Scheme 2). Here, *m*/*n* is the molar ratio of **TEGS** and **MS** monomers in the feed. The results of the copolymerization are shown in Table 1. The **PP-TEGS/MS**s were apparently soluble in water at room temperature when the **TEGS** concentration was greater than 60 mol % in the feed.

The phase diagrams of the **PP-TEGS/MS**s with different compositions are shown in Figure 1a. Here, the T_{cp} was defined as the temperature corresponding to a 50% decrease in the transmittance. The T_{cp} value decreased from 78 to 18 °C with

Scheme 2



PP-TEGS/MS-m/n

an increase in the concentration of the hydrophobic **MS** in the feed. In order to confirm reversibility in the LCST-type phase separation behavior, the transmittance of **PP-TEGS/MS**−60/40 was repeatedly traced during the heating and cooling processes. In this experiment, the temperature was stepwise changed every 10 min using the same sample. As shown in Figure 1b, similar curves during the first and second heating processes were obtained. Hysteresis observed during the cooling process was very small due to the low molecular weight of the **PP**.

(○) **PP-TEGS/MS**−60/40, (□) **PP-TEGS/MS**−70/30, (Δ) **PP-TEGS/MS**−75/25, (×) **PP-TEGS/MS**−80/20. (b) Traces for **PP-TEGS/MS**−60/40 on (■) the first heating, (□) the cooling, and (●) the second heating.

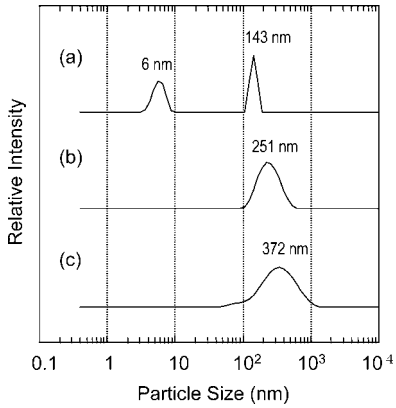


Figure 2. Particle size distribution of the **PP**s determined by DLS at 25 °C. (a) **PP-TEGS** in water, (b) **PP-TEGS/TDS**−80/20 in water, and (c) **PP-TEGS/TDS**−70/30 in water. The polymer concentration is 0.24 mg/mL.

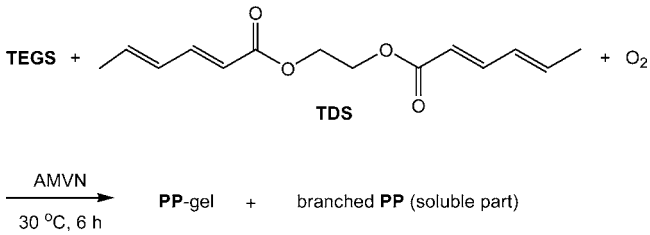
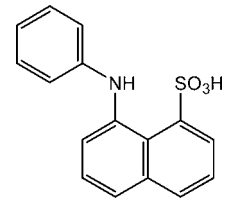
Scheme 3



The **PP-TEGS** molecules are self-assembled in water and form an aggregate with a size smaller than the wavelength of visual light. The aggregates can be dispersed in water at a temperature lower than the LCST, resulting in a transparent solution. The DLS analysis confirmed the formation of the **PP-TEGS** assembly, which consists of a bimodal distribution with average diameters of 6 and 143 nm (Figure 2). The assembly with a diameter of 143 nm is probably produced by the secondary aggregation of the small particles of less than a 10 nm size. The peak intensity of the distribution curves in Figure 2 is based on the relative intensity of the observed scattering light, but not based on the number and weight fractions of the particles. Therefore, the number of the smaller particles with an average diameter of 6 nm is much greater than that of the larger one with a 143 nm diameter. In a 20 mol % aqueous solution of glycerin, no assembly with a particle size larger than 1 nm was observed. This is due to fragmentation of the assemblies into free polymer chains by the addition of glycerin, which decreases the hydrophobic interaction between the **PP-TEGS** molecules.

As an attempt to synthesize a high-molecular-weight **PP**, we carried out the copolymerization of **TEGS** and **TDS**, which is a difunctional sorbate monomer (Scheme 3). The results of the copolymerization are already shown in Table 1. The **PP** recovered after copolymerization was fractionated into the soluble and insoluble parts, which consist of the branched **PP** and **PP**-gel, respectively, by extraction with THF. The amount of the soluble fraction decreased with an increase in the ratio of **TDS** in the feed. The M_n values of the soluble **PP-TEGS/TDS** were only (1.7−2.0) × 10^3, smaller than those for **PP-TEGS**. This result was opposite from the expected one. Fortunately, however, we found that the aggregates of the **PP-TEGS/TDS** in water provided a monomodal distribution with a diameter of 250 and 370 nm when the **TDS** content was 20 and 30 mol %, respectively, in the feed (Figure 2b,c). This suggests that the **PP-TEGS/TDS**s are favorable for the fabrication of a large-sized molecular assembly, although the reason is still unclear.

Scheme 4



ANS

These **PP** assemblies can include many molecules. For example, the wavelength and intensity of the fluorescent emission of 1-anilinonaphthalene-8-sulfonic acid (ANS) as a fluorescence probe (Scheme 4) changed depending on the concentration of the **PP**s. With an increase in the amount of the **PP-TEGS**, the wavelength of the emission peak shifted to a shorter wavelength region and the intensity increased. From a plot of the wavelength of the emission peak ($\lambda_{em,max}$) versus the ANS concentration (Figure 3a), the critical micelle-formation concentration (cmc) of **PP-TEGS** was evaluated to be 5 × 10 μg/mL at room temperature. The formed assembly was stable, and no change was observed in the emission spectrum over 7 days. It was also revealed that the **PP-TEGS/TDS** with a greater TDS content more effectively included ANS and afforded a more hydrophobic environment (Figure 3b). This is due to the formation of the aggregates with a larger size from the **PP-TEGS/TDS** containing a high TDS content, as shown in Figure 2.

Cytotoxicity and Cellular Uptake of PP. The in vitro cytotoxicity of **PP-TEGS** was investigated using the A549 cells (human lung carcinoma) by the WST assay at 37 °C. The change in the cell viability is shown in Figure 4. The A549 cells showed excellent cell viability during the short incubation time (within 3 h) even in the presence of a high concentration of **PP-TEGS** up to 1 mg/mL. No toxicity of **PP-TEGS** was simultaneously confirmed at a low concentration of less than 10^2 μg/mL similar to the conditions for use as a drug carrier, irrespective of the incubation period. The viability decreased at a high **PP-TEGS**

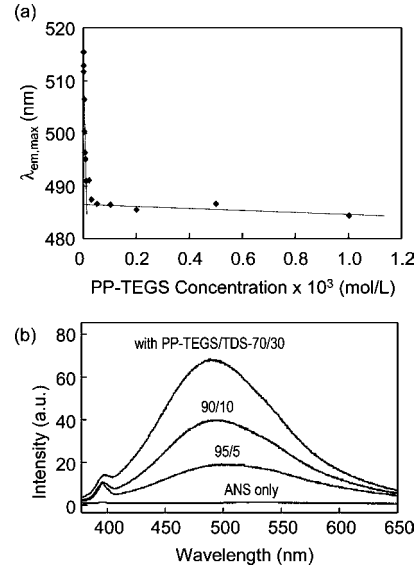


Figure 3. (a) Shift in the peak wavelength for the emission of ANS versus the **PP-TEGS** concentration at room temperature. (b) Fluorescence spectrum of ANS in the presence and absence of the **PP-TEGS/TDS**s at room temperature.

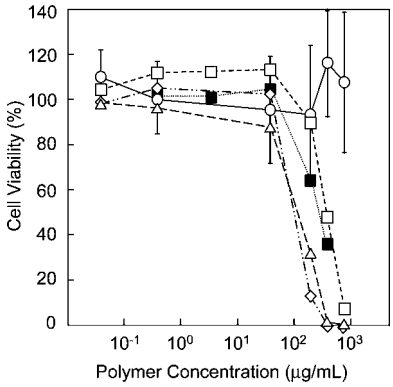

Figure 4. Cytotoxicity of **PP**s using the A549 cell lines after incubation for different times at 37 °C. (○) **PP-TEGS** for 3 h, (□) 24 h, (Δ) 48 h, (◊) 96 h, and (■) **PP-TEGS/TDS**−70/30 for 24 h. Determined by the WST assay. Error bars are shown for only the 3 h incubation data for clarity.

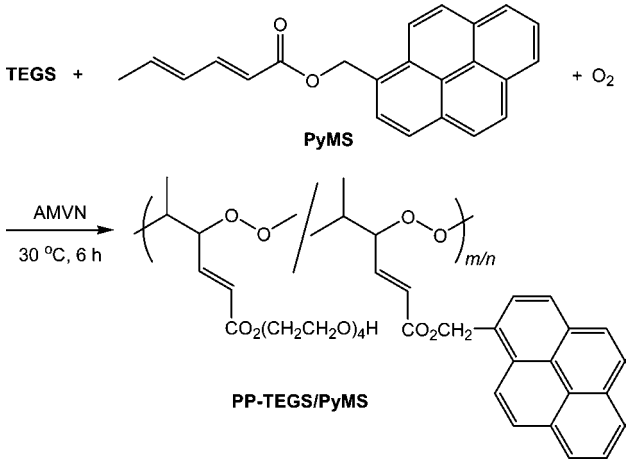
Scheme 5



concentration (>10^2 μg/mL) and a long incubation time (>24 h). The effect of the degradation of the **PP**s is not negligible under the conditions at a concentration and for a log time, as described later. It was also revealed that the branched structure of the **PP**s had no effect on the cell viability, as shown in the results of the experiments using **PP-TEGS** and **PP-TEGS/TDS**−70/30. It is concluded that the cell viability in the presence of the **PP**s is comparable to those for the other biodegradable polymers such as poly(D,L-lactide-*co*-glycolide) and poly(aspartic acid)-*block*-polylactide in the literature (*21*, *35*, *54*−*56*).

To directly monitor the cellular uptake of the **PP**s, we synthesized a fluorescence-labeled **PP** by the copolymerization of **TEGS** with oxygen in the presence of 1 mol % of **PyMS** (Scheme 5). The solubility of **PP-TEGS/PyMS** was similar to that of **PP-TEGS**, because of the low content of the **PyMS** unit (1 mol % in the feed). In this experiment, the exact composition of the repeating units in the **PP-TEGS/PyMS** was not determined. The average number of the **PyMS** unit internalized into the **PP-TEGS** is calculated to be ca. 0.05−0.1 per a **PP** chain on the basis of the M_n values for the **PP-TEGS**. The fluorescence spectra of the **PyMS** monomer and **PP-TEGS/PyMS** are shown in Figure 5. A fluorescent emission due to the eximer of the pyrene moieties (λ_{max} = 470 nm) was observed from the ethanol solution containing 1% of **PyMS**. In contrast, the aqueous solution of **PP-TEGS/PyMS** mainly provided a monomer emission. This indicates that the **PyMS** repeating unit as the fluorophore is isolated in a hydrophobic compartment of the **PP-TEGS/PyMS** aggregates, because the average number of the **PyMS** repeating unit per a **PP-TEGS/PyMS** chain is

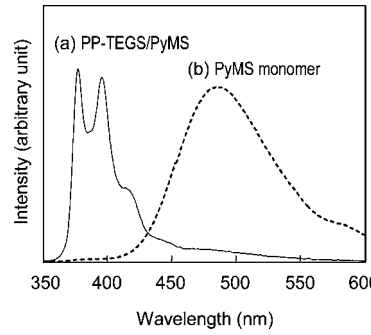


Figure 5. Fluorescence spectra of (a) **PP-TEGS/PyMS** at 0.195 mg/mL in water and (b) **PyMS** monomer at 2 μg/mL in ethanol at room temperature.

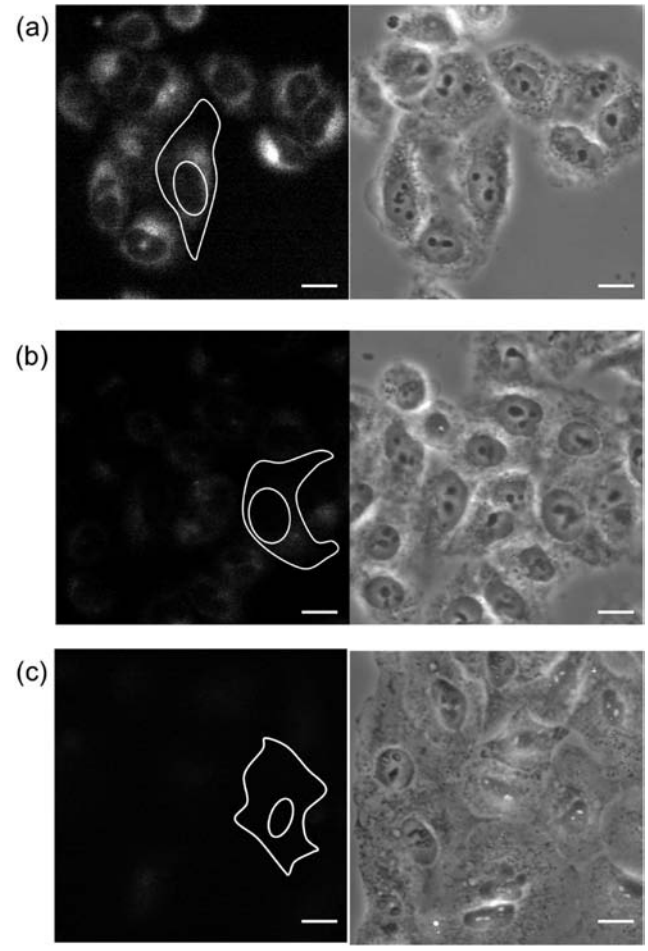

Figure 6. Fluorescence microscopic images of the A549 cells in the presence of **PP-TEGS/PyMS** after incubation for 3 h at (a) 37 and (b) 4 °C. (c) Control (in the absence of **PP-TEGS/PyMS**). much lower than unity and the nonpolar pyrene moiety is surrounded by the **PP-TEGS** segments, while the pyrenyl group of **PyMS** tends to aggregate even in a dilute solution in ethanol.

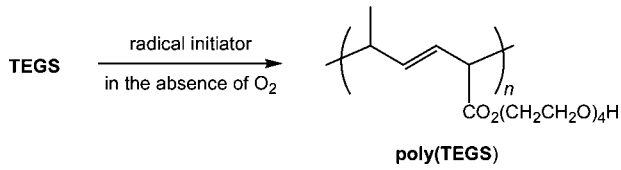
The cellular uptake and intracellular distribution of **PP-TEGS/PyMS** are confirmed by confocal fluorescence microscopy (Figure 6). The microscopic images revealed that the **PP-TEGS/PyMS** was distributed in the cytoplasm rather than in the nucleus of the cell. The **PP-TEGS/TDS-70/30-PyMS** showed a similar fluorescence microscopic image (data not shown). In the literature, many polymer micelles may involve the mechanism of energy-dependent endocytosis during a

Scheme 6



cellular uptake process (*57*). For example, large-sized substances, such as proteins, DNA, enzymes, and polymers, favorably enter the inside of the cells via an endocytosis mechanism. Polar and ionic substances generally inhibit their membrane penetration due to the presence of a hydrophobic area in the cell membranes. The fluorescence intensity of internalized **PP-TEGS/PyMS** at 37 °C is obviously stronger than that at 4 °C (Figure 6a,b). The temperature dependence of the uptake of the **PP**s has supported the fact that PPs are energy-dependently internalized by the endocytic pathway. However, the energy-dependent uptake of **PP-TEGS/PyMS** was not completely inhibited at 4 °C. The **PP-TEGS** with tetra(ethylene glycol) units in the side chain may have a fusogenic activity, similar to water-soluble polymers, such as poly(ethylene glycol) (*58*).

The **PP**s were stable in organic solvents, such as chloroform and THF, and in pure water, as already shown in the results of the NMR, GPC, and LCST experiments, but the degradation rate of the **PP**s may be accelerated in the cell conditions, because the degradation of the **PP**s is induced by the biochemical and redox systems (*49, 59*). The biochemical decomposition of the **PP**s by horseradish peroxidase (HRP) was already reported in a previous paper (*49*). The conversion of the **PP**s was 46% during the degradation in the presence of HRP for 3 days at 30 °C. We also reported that the **PP**s readily degraded by the addition of base and the weight loss of the **PP**s increased with an increase in the basicity of the additives (*59*). A small amount of triethylamine induced the immediate degradation of the **PP**s within a few minutes, while the addition of a weaker base, such as *N*,*N*-dimethylformamide and aniline, resulted in degradation at a moderate rate. In fact, we confirmed the slow degradation of the **PP**s in a phosphate saline buffer solution (pH = 7.4). In the present study, however, we could not directly evaluate the degradation rate of the **PP**s under the cell conditions because of the difficulty of the isolation of the unreacted **PP**s and the degradation products from the incubation mixture.

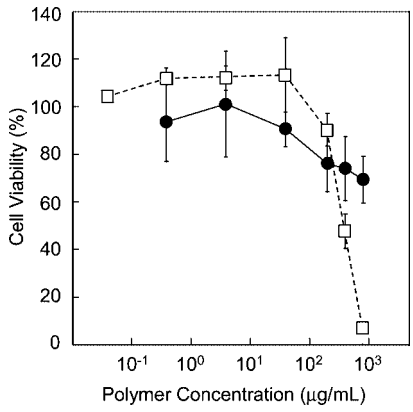


Figure 7. Comparison of the cytotoxicity of poly(TEGS) and **PP-TEGS** using the A549 cell lines after incubation at 37 °C for 24 h. (●) Poly(TEGS) and (□) **PP-TEGS**. Determined by the WST assay. Data for **PP-TEGS** are the same as those in Figure 4.

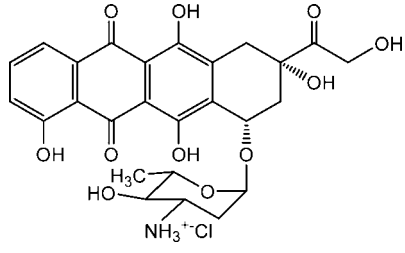

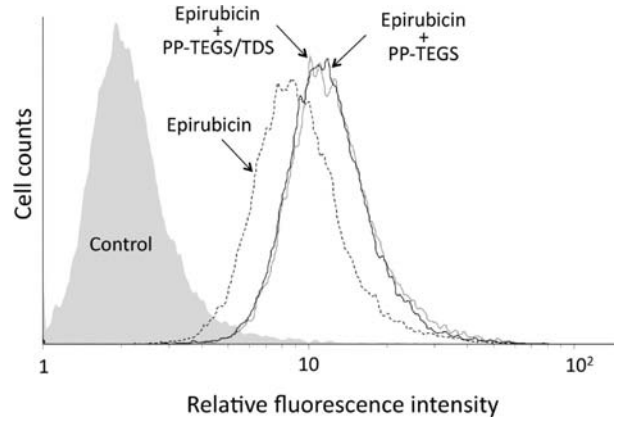

Figure 8. Flow cytometry analysis of the uptake of epirubicin in the A549 cells after incubation for 3 h at 37 °C. Black curve: with **PP-TEGS**. Gray curve: with **PP-TEGS/TDS**−70/30. Dotted curve: without **PP**. Monitored by emission from epirubicin at 585 nm. Control experiment was incubated in the absence of **PP** and epirubicin.

Table 2. Epirubicin Uptake into the A549 Cells in the Presence and Absence of the PPs

sample	temperature, °C	average fluorescence intensity[a]
PP-TEGS	37	1.59
	4	0.65
PP-TEGS/TDS−70/30	37	1.70
	4	0.68
none (only epirubicin)	37	1.00 (standard)
	4	0.42
control (without epirubicin)	37	0.23

[a] Relative values versus the fluorescence intensity obtained using only epirubicin in the absence of the **PP**s at 37 °C.

In order to further investigate the effects of the peroxy repeating structure in the main chain of the **PP**s on the cellular uptake behavior and cytotoxicity, the homopolymer of **TEGS** [poly(TEGS)] was synthesized as the reference material. The radical polymerization was carried out in the absence of oxygen using di-*tert*-butyl peroxide as a radical initiator (Scheme 6) in toluene for 6 h at 120 °C (**TEGS**/initiator = 50/1 and **TEGS**/toluene =1/1 by weight) to obtain poly(TEGS) (*60*). As a result for the polymerization under these conditions, the poly(TEGS) with the M_n and M_w/M_n values of 2.0×10^3 and 1.5, respectively, were obtained in 13.7% yield, and it was soluble in chloroform, THF, methanol, and water at room temperature. The NMR spectrum of poly(TEGS) confirmed its 5,2-trans repeating structure; that is, the peaks due to the CH═CH units in the main chain were observed at 5.4 ppm and those for the CH−CH unit were at 1.7−2.9 ppm as the broad and split signals, similar to the spectra previously reported for the polymers obtained from the other sorbates (*60*). The chemical shifts for poly(TEGS) differed from those of **PP-TEGS** observed at 6.1−7.0 and 4.2−5.2 ppm for the CH═CH and CH−CH units, respectively.

We revealed that poly(TEGS) also formed self-assembly with the average diameters of 160 nm in water and carried out the in vitro cytotoxicity experiments using poly(TEGS) under the conditions identical to that for the experiments using **PP-TEGS** (Figure 4). Figure 7 shows the comparison of the cytotoxicity of poly(TEGS) and **PP-TEGS**. As a result, no decrease in the

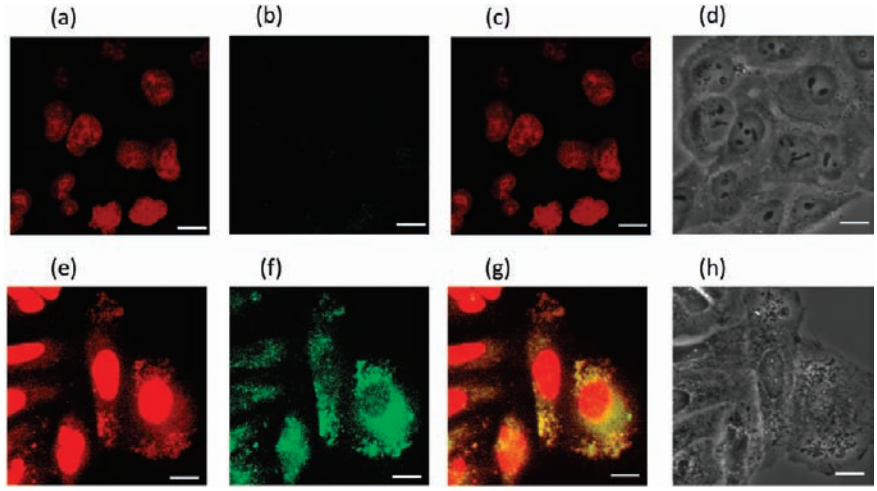

Figure 9. Cellular distribution of epirubicin (red, a and e, monitored at 585 nm) and **PP-TEGS/TDS/PyMS** (green, b and f, monitored at 420−460 nm) in the A549 cells after incubation in the presence of 0.37 mg/mL epirubicin without (a−d) and with (e−h) 0.49 mg/mL **PP-TEGS/TDS/PyMS** for 1 h at 37 °C. The images shown in c and g are the overlay of the red and green images (a+b and e+f) and in d and h are the phase contrast images. Scale bar, 10 μm.

viability was observed even at a concentration around 10^3 μg/mL in the presence of poly(TEGS), while the viability decreased in the presence of **PP-TEGS** under the same concentration conditions. This result suggests that the cell viability is influenced by the slow decomposition of **PP-TEGS** at 37 °C. It is expected that the oxy radicals and aldehydes produced from **PP-TEGS** by the decomposition induce the death of the A549 cells.

Cellular Uptake of Epirubicin in the Presence of PP. A flow cytometric analysis was carried out in order to quantitatively estimate the uptake of epirubicin (*61*), which is an anticancer drug (Scheme 7) and the stereoisomer of doxorubicin, into A549 cells in the presence and absence of **PP**s after incubation at 37 and 4 °C for 3 h. The fluorescence emission from the epirubicin molecules was monitored at 585 nm to count the number of cells containing epirubicin. Figure 8 shows the typical results for counting the number of cells with different fluorescence intensities, that is, including different amounts of epirubicin in the A549 cells. These results are summarized in Table 2. The amount of epirubicin internalized into the cells was enhanced in the presence of **PP-TEGS** and **PP-TEGS/TDS**−70/30 compared to the case using the free epirubicin. No difference was observed between the results for the experiments using **PP-TEGS** and those using **PP-TEGS/TDS**. The uptake of epirubicin depended on the temperature. In contrast to the facile uptake at 37 °C, only a small amount of epirubicin was incorporated into the cells at 4 °C, irrespective of the presence and absence of the **PP**s (Table 2). These results suggest that the epirubicin and the epirubicin/**PP** complex mainly enter the cells via an endocytosis mechanism.

We used confocal fluorescence microscopy and the emissions of different colors from the epirubicin molecules and the **PyMS** unit in the **PP**s in order to analyze the intracellular distribution of epirubicin and the **PP**s in the A549 cells. Figure 9a indicates that epirubicin was accumulated in the nucleus after a 1 h incubation. When the A549 cells were incubated in the presence of both epirubicin and **PP-TEGS/TDS/PyMS** (Figure 9e), some epirubicin molecules are still present in the cytoplasm. The migration of the free epirubicin into the nucleus of the cell has readily occurred, but epirubicin has remained in the cytoplasm for a certain time in the presence of the **PP**. The distribution of the **PP** in the cytoplasm was also confirmed by an experiment using fluorescent **PP-TEGS/TDS/PyMS** (Figure 9f). The overlay of the red and green images (Figure 9g) indicates that epirubicin as the free form is imported into the nucleus (red part in Figure 9g) and the epirubicin incorporated into the cell with the **PP** is localized in the cytoplasm, especially endocytic vesicles such as endosomes (yellow part in Figure 9g). Thus, some epirubicin molecules remain in a hydrophobic compartment in the **PP** aggregates in the cytoplasm during the short incubation period such as 1 h, but the epirubicin molecules gradually migrated into the nucleus after a longer incubation period. The free epirubicin molecules, which entered the cells, immediately migrated and accumulated in the nucleus due to its cationic charge. On the other hand, the epirubicin molecules incorporated into the **PP-TEGS** assembly are slowly released. Therefore, the epirubicin molecules combined with the **PP** are slowly imported into the nucleus. Finally, the stronger fluorescence emission of epirubicin in the presence of **PP-TEGS** than that of the absence of **PP-TEGS** (Figure 9) also supported the increased efficiency of cellular uptake with **PP-TEGS** (Figure 8) followed by the nuclear import of the epirubicin molecules. Figure 10 shows a schematic illustration for the process of the formation of self-assemblies of the **PP**s in the presence of an anticancer drug, uptake into the cell by endocytosis, and the release of the drug in the cell, followed by the import of the drug into a nucleus.

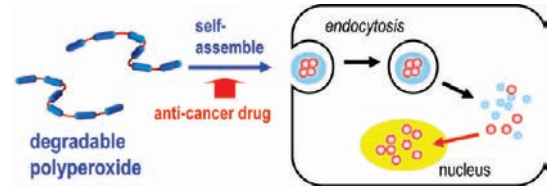

Figure 10. Schematic illustration for the formation of self-assembly of the PPs and an anticancer drug, uptake into the cell by endocytosis, and the release of the drug.

In conclusion, the water-soluble **PP**s were prepared by the radical copolymerization of a sorbic ester containing a tetra(ethylene oxide) unit with molecular oxygen. The obtained **PP**s showed an amphiphilic property and formed assemblies in water. We further evaluated the cytotoxicity and cellular uptake of the **PP**s in order to test the ability as a carrier used for drug delivery systems. It was also revealed that epirubicin as an anticancer drug is taken up into cells more efficiently in the presence of the **PP**s than in the absence of the **PP**s via an endocytosis mechanism. Such a water-soluble and degradable polymer assembly bearing a hydrophobic domain could be one of the candidates of a carrier for drugs. Any synergy effect as an

anticancer drug by the degradation of the **PP** is also expected because the **PP**s are readily degraded by various stimuli. Further investigation of the use of the **PP**s as drug carriers is now underway.

PEGylated Dendritic Unimolecular Micelles as Versatile Carriers for Ligands of G Protein-Coupled Receptors

Yoonkyung Kim,[†,§] Béatrice Hechler,[‡] Zhan-Guo Gao,[†] Christian Gachet,[‡] and Kenneth A. Jacobson*[,†]

Molecular Recognition Section, Laboratory of Bioorganic Chemistry, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20892, and UMR 5949 INSERM, Université de Strasbourg, Etablissement Français du Sang-Alsace, Strasbourg, France. Received April 13, 2009; Revised Manuscript Received August 12, 2009

Despite its widespread application in nanomedicine, poly(ethylene glycol) (PEG) is seldom used for covalent modification of ligands for G protein-coupled receptors (GPCRs) due to potential steric complications. In order to study the influence of PEG chains on the biological activity of GPCR ligands bound to a common macromolecular carrier, we prepared a series of G3 polyamidoamine (PAMAM) dendrimers derivatized with Alexa Fluor 488, varying numbers of PEG_{550}/PEG_{750}/PEG_{2000}, and nucleoside moieties derived from the A_{2A} adenosine receptor (AR) agonist CGS21680 (2-[4-(2-carboxylethyl)phenylethylamino]-5′-*N*-ethylcarboxamidoadenosine). These dendrimer conjugates were purified by size exclusion chromatography and characterized by ^{1}H NMR and MALDI MS. In radioligand binding assays, some PAMAM-PEG conjugates showed enhanced subtype-selectivity at the human A_{2A} AR compared to monomeric ligands of comparable affinity. The functional potency was measured in the A_{2A} AR-mediated activation of adenylate cyclase and inhibition of ADP-induced platelet aggregation. Interestingly, the dendrimer conjugate **10c** bearing 11 PEG_{750} chains (out of theoretical 32 amino end groups) and 14 nucleoside moieties was 5-fold more potent in A_{2A} AR-mediated stimulation of cyclic AMP formation than **10d** with 4 PEG_{2000} chains and 21 nucleosides, although the binding affinities of these 2 compounds were similar. Thus, a relatively small (≤10 nm) multivalent ligand **10c** modified for water solubility maintained high potency and displayed increased A_{2A} AR binding selectivity over the monomeric nucleosides. The current study demonstrates the feasibility of using short PEG chains in the design of carriers that target ligand−receptor interactions.

INTRODUCTION

Nanocarriers such as polymeric/inorganic nanoparticles, liposomes, micelles, dendrimers, and nanotubes present a superior means to tackle various challenging issues in biomedical research, such as *in vivo* lability and insolubility of pharmaceutical substances (*1*). Despite the excellent functional improvements over small molecules as shown in numerous examples, the ultimate success of recruiting these unnatural nanostructures for therapy/diagnosis will depend on meeting the rigorous safety standards that apply to humans.

Dendritic scaffolds (*2*) offer a robust spatial control, particularly valuable when the imparted multivalency (*3*) can significantly enhance the desired effects. Previously, we employed polyamidoamine (PAMAM) dendrimers (*4*) to conjugate multiple copies of a nucleoside-based agonist CGS21680 (2-[4-(2-carboxylethyl)phenylethylamino]-5′-*N*-ethylcarboxamidoadenosine, **1**, Figure 1 (*5*)) of the A_{2A} adenosine receptor (AR) (*6*), a member of the G protein-coupled receptor (GPCR) family, in an effort to enhance the therapeutic potential through a multivalent effect (*3*). Generally, small-molecule agonists of GPCRs bind primarily at their heptahelical transmembrane domains (*7*), to trigger various intracellular signaling pathways. Diseases related to the actions of extracellular adenosine include cancer, arthritis, thrombosis, ischemia, and sleep disorders. Here, we report a simple PEGylation (*8*) strategy to improve the bioavailability (*9*) of dendritic carriers for GPCR ligands, which did not impose significant sterics and manifested potent biological activities in comparison to the monovalent species, using a third generation (G3) PAMAM dendrimer as an example.

EXPERIMENTAL PROCEDURES

Materials and Methods. Glassware was oven-dried and cooled in a desiccator before use. All reactions were carried out under a dry nitrogen atmosphere at room temperature. Solvents were purchased as anhydrous grade and used without further purification. Suppliers of the commercial compounds are listed as follows: amine-terminated G3 PAMAM dendrimer with an ethylenediamine core, poly(ethylene glycol) methyl ether (PEG, M_n = 550, 750, and 2000), acetic anhydride (Ac_2O), and triethylamine were purchased from Aldrich; (benzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate (PyBOP) was purchased from NovaBiochem; CGS21680 (**1**) hydrochloride hemihydrate was purchased from Tocris; Alexa Fluor 488 (AF_{488}) 5-carboxylic acid 2,3,5,6-tetrafluorophenyl (TFP) ester (AF_{488}−OTFP) was purchased from Invitrogen; dimethyl sulfoxide (DMSO)-d_6 and D_2O were purchased from Cambridge Isotope Laboratories. 2-[4-(2-Aminoethylaminocarbonylethyl)phenylethylamino]-5′-*N*-ethylcarboxamidoadenosine (APEC, **2**) bistrifluoroacetic acid was provided by NIMH Chemical Synthesis and Drug Supply Program. Compound **3** (*11*) and PEGylated PAMAM dendrimer conjugates (**4a**, **4b**, **4c**, and **4d** (*17*)) were prepared as described before.

Preparative size exclusion chromatography (SEC) was performed on Bio-Beads S-X1 beads (BIO-RAD, molecular weight (MW) operating range 600−14 000 Da), 200−400 mesh, with DMF (Aldrich 99.8%, anhydrous) as an eluent at ambient pressure.

[a] M_n of the commercial PEG monomethyl ether (Aldrich) originally used to prepare compound **4**. [b] Based on ^{1}H NMR integration determined in DMSO-d_6. *m* = number of PEG repeat unit, *n* = number of PEG, *x* = number of acetamide, *y* = number of AF_{488}, *z* = number of CGS21680 (see Scheme 1). [c] Based on the stoichiometry of addition. [d] Dendrimer conjugates were assumed to be made from the commercial PAMAM dendrimer with 32 peripheral amino groups and no structural defects. Counterions of sulfonate for AF_{488} were assumed to be triethylammonium groups. [e] Number-average molar mass. [f] Weight-average molar mass. [g] Polydispersity index. [h] Based on MALDI MS results. No matrix adduct was considered for the estimation. ΔM_w between **9**/**10** and its precursor **7**/**8** was divided by the MW increase upon the covalent attachment of a CGS21680 ligand (481.5 Da) to the PAMAM amino group. Purification by SEC was assumed not to affect the MW distribution. [i] n.d. = not determined. [j] Mass range selected for the average MW calculations contained a part of the peak region corresponding to the half-size of each desired compound.

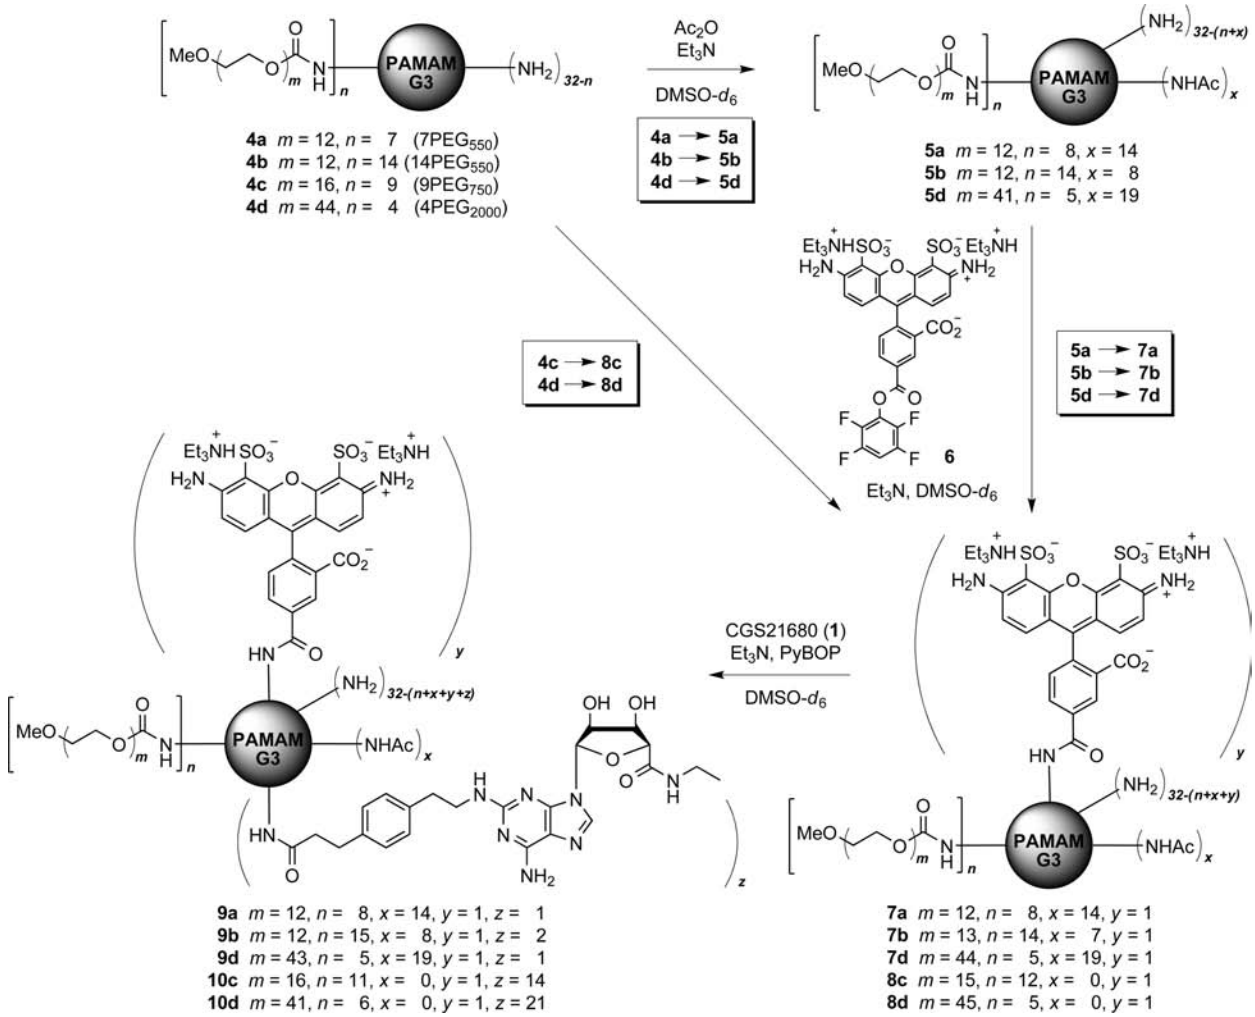
NMR spectra were recorded on a Bruker DRX-600 spectrometer at 25.0 °C under an optimized parameter setting for each sample, unless otherwise mentioned. ^{1}H NMR chemical shifts were measured relative to the residual solvent peak at 2.50 ppm in DMSO-d_6 and at 4.80 ppm in D_2O. Complete NMR peak assignments were made possible with 2D COSY and NOESY experiments. Each PAMAM dendrimer conjugate was not unimolecular, and thus, the characterization by NMR represented the average value from its polymeric distribution. The integration values were reported only for the peaks clearly resolved (i.e., with a relatively good baseline-separation) in the ^{1}H NMR spectra and in two decimal places. Assignments of peaks for the PEGylated PAMAM dendrimer conjugates were based on the labeling method shown in Supporting Information Figure S2. A methylene peak of the G3 PAMAM dendrimer at 2.18 ppm in DMSO-d_6 ("c"; see Supporting Information Figure S2) was used as an internal standard (set at 120 H) for the integration, assuming 32 peripheral groups without any defects in the structure. Detailed methods used for the structural analysis of dendrimers by NMR in DMSO-d_6 were described before (as Supporting Information *10, 17*). The stoichiometry and the average MWs of the PAMAM dendrimer conjugates determined as such are summarized in Table 1 and Supporting Information Figures S1 and S2.

MALDI-TOF MS experiments were performed on an Applied Biosystems Voyager-DE STR spectrometer at the Mass Spectrometry Laboratory, University of Illinois. 2,5-Dihydroxybenzoic acid (DHB) or 2,4,6-trihydroxyacetophenone (THAP) was used as the matrix for the MALDI samples. Average MWs determined by MALDI are listed in Table 1 and the spectra are shown in Supporting Information Figures S7 and S8.

General Procedure for Acetylation of G3 PAMAM-PEG Dendrimer Conjugates. PEGylated G3 PAMAM dendrimer **4a**, **4b**, or **4d** was dried *in vacuo* extensively and then was dissolved in DMSO-d_6. To this stirred dendrimer solution was added triethylamine, followed by a 0.317 M solution of Ac_2O in DMSO-d_6 (30.0 μL/1.00 mL, total volume). The final concentration of the dendrimer solution was ca. 0.5−1.1 mM. The reaction was stirred at room temperature for 21 h, then purified by SEC in DMF, and dried *in vacuo* to give dendrimer **5** as a colorless glassy solid.

Acetylated PAMAM-PEG Dendrimer 5a. PAMAM-PEG dendrimer **4a** (*17*) (12.1 mg, 1.10 μmol) in DMSO-d_6 (944 μL) was treated with triethylamine (8.10 μL, 58.1 μmol) and 0.317 M Ac_2O solution in DMSO-d_6 (48.5 μL, 15.4 μmol). The crude mixture was loaded on a SEC column (H 47 cm × O.D. 4.5 cm) to isolate the dendrimer conjugate **5a** (9.28 mg). ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.06−7.82 (m, NH_{G3}, NH_{Ac}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.23 (br s, 7.44H, NH_{PEG} of major isomer), 6.81 (br s, 0.61H, NH_{PEG} of minor isomer), 4.03 (t, 16.25H, J = 4.2 Hz, H_{hPEG}), 3.62−3.38 (m, 389.27H, satellites J = 69.0 Hz, H_i, H_j, and H_k), 3.23 (s, 30.11H, H_l), 3.12−2.99 (m, H_d,

Scheme 1. Synthetic Route to PAMAM-PEG-CGS21680 Dendrimer Conjugates



H_f, H_{fAc}, H_{gAc}, H_{fPEG}, and H_{gPEG}), 2.64 (m, 118.64H, H_b and H_g), 2.42 (m, 60.10H, H_e and H_a), 2.18 (m, 120.00H, H_c), 1.79 (s, 41.73H, H_{hAc}).

Acetylated PAMAM-PEG Dendrimer 5b. PAMAM-PEG dendrimer **4b** (*17*) (11.3 mg, 0.746 μmol) in DMSO-d_6 (1.28 mL) was treated with triethylamine (3.30 μL, 23.7 μmol) and 0.317 M Ac_2O solution in DMSO-d_6 (16.5 μL, 5.24 μmol). The crude mixture was loaded on a SEC column (H 40 cm × O.D. 3.0 cm) to isolate the dendrimer conjugate **5b** (11.44 mg). ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.04−7.81 (m, NH_{G3}, NH_{Ac}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.23 (br s, 12.70H, NH_{PEG} of major isomer), 6.81 (br s, 1.14H, NH_{PEG} of minor isomer), 4.03 (t, 27.47H, J = 4.1 Hz, H_{hPEG}), 3.62−3.38 (m, 659.19H, satellites J = 70.7 Hz, H_i, H_j, and H_k), 3.23 (s, 47.25H, H_l), 3.12−2.99 (m, H_d, H_f, H_{fAc}, H_{gAc}, H_{fPEG}, and H_{gPEG}), 2.64 (m, 117.00H, H_b and H_g), 2.42 (m, 57.69H, H_e and H_a), 2.18 (m, 120.00H, H_c), 1.79 (s, 21.64H, H_{hAc}).

Acetylated PAMAM-PEG Dendrimer 5d. PAMAM-PEG dendrimer **4d** (*17*) (13.3 mg, 0.895 μmol) in DMSO-d_6 (944 μL) was treated with triethylamine (7.70 μL, 55.2 μmol) and 0.317 M Ac_2O solution in DMSO-d_6 (48.0 μL, 15.2 μmol). The crude mixture was loaded on a SEC column (H 45 cm × O.D. 4.5 cm) to isolate the dendrimer conjugate **5d** (13.28 mg). ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.07−7.83 (m, NH_{G3}, NH_{Ac}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.24 (br s, 4.45H, NH_{PEG} of major isomer), 6.82 (br s, 0.43H, NH_{PEG} of minor isomer), 4.03 (t, 9.77H, J = 4.1 Hz, H_{hPEG}), 3.62−3.38 (m, 795.81H, satellites J = 70.7 Hz, H_i, H_j, and H_k), 3.23 (s, 17.88H, H_l), 3.12−2.99 (m, H_d, H_f, H_{fAc}, H_{gAc}, H_{fPEG}, and H_{gPEG}), 2.64 (m, 114.51H, H_b and H_g), 2.42 (m, 58.04H, H_e and H_a), 2.18 (m, 120.00H, H_c), 1.79 (s, 57.24H, H_{hAc}).

General Procedure for Conjugation of AF_{488}. PEGylated G3 PAMAM dendrimer **5a**, **5b**, **5d**, **4c**, or **4d** was dried *in vacuo* extensively, and then was dissolved in DMSO-d_6. To this stirred dendrimer solution was added triethylamine, followed by a freshly prepared 11.3 mM solution of AF_{488}−OTFP in DMSO-d_6 (1.00 mg/100 μL). The final concentration of the dendrimer solution was ca. 0.4−1.0 mM. The reaction was stirred for 22 h protected from light, and then a portion of crude product **7**/**8** was transferred into another flask for the next step without any purification. The remaining reaction mixture was subjected to purification by SEC in DMF, and the column fractions corresponding to the first major fluorescent band were combined and dried *in vacuo* to give dendrimer **7**/**8** as a colored glassy solid.

PAMAM-PEG-AF_{488} Dendrimer 7a. PAMAM-PEG dendrimer **5a** (9.77 mg, 0.804 μmol) in DMSO-d_6 (1.53 mL) was treated with triethylamine (1.50 μL, 10.8 μmol) and 11.3 mM AF_{488}−OTFP solution in DMSO-d_6 (71.0 μL, 0.802 μmol). 1.10 mL of the crude reaction mixture was taken for the next step and the remainder was purified by SEC (H 23 cm × O.D. 2.5 cm) to isolate the dendrimer conjugate **7a** (3.78 mg). The color of a 1.0 mM solution of **7a** in water (HPLC grade, Aldrich) prepared for the biological assay was light yellow. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.04−7.81 (m, 76.71H, NH_{G3}, NH_{Ac}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.21 (br s, 8.38H, NH_{PEG} of major isomer), 6.79 (br s, 0.85H, NH_{PEG} of minor isomer), 4.03 (t, 15.98H, J = 4.2 Hz, H_{hPEG}), 3.62−3.38 (m, 377.45H, satellites J = 70.0 Hz, H_i, H_j, and H_k), 3.23 (s, 30.54H, H_l), 3.13−2.99

(m, 182.37H, H_d, H_f, H_{fAc}, H_{gAc}, H_{fPEG}, and H_{gPEG}), 2.64 (m, 118.15H, H_b and H_g), 2.42 (m, 57.66H, H_e and H_a), 2.18 (m, 120.00H, H_c), 1.79 (s, 42.58H, H_{hAc}).

PAMAM-PEG-AF$_{488}$ Dendrimer 7b. PAMAM-PEG dendrimer **5b** (11.2 mg, 0.702 μmol) in DMSO-d_6 (1.44 mL) was treated with triethylamine (1.10 μL, 7.89 μmol) and 11.3 mM AF_{488}−OTFP solution in DMSO-d_6 (62.0 μL, 0.701 μmol). 1.00 mL of the crude reaction mixture was taken for the next step, and the remainder was purified by SEC (H 38 cm × O.D. 3.0 cm) to isolate the dendrimer conjugate **7b** (4.29 mg). The color of a 1.0 mM solution of **7b** in water (HPLC grade, Aldrich) prepared for the biological assay was yellowish orange. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.42 (br s, 0.37H, H_F), 8.22 (br s, 0.65H, H_E), 8.04−7.79 (m, 69.52H, NH_{G3}, NH_{Ac}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.30 (br s, 0.68H, H_D), 7.20 (br s, 14.83H, NH_{PEG} of major isomer), 6.79 (br s, 1.32H, NH_{PEG} of minor isomer), 6.45 (br s, 0.64H, H_B/H_C), 6.35 (br s, 0.55H, H_B/H_C), 4.03 (t, 28.68H, J = 4.2 Hz, H_{hPEG}), 3.62−3.38 (m, 696.24H, satellites J = 70.2 Hz, H_i, H_j, and H_k), 3.23 (s, 48.74H, H_l), 3.11−2.99 (m, 188.79H, H_d, H_f, H_{fAc}, H_{gAc}, H_{fPEG}, and H_{gPEG}), 2.64 (m, 120.55H, H_b and H_g), 2.42 (m, 56.57H, H_e and H_a), 2.18 (m, 120.00H, H_c), 1.79 (s, 22.34H, H_{hAc}).

PAMAM-PEG-AF$_{488}$ Dendrimer 7d. PAMAM-PEG dendrimer **5d** (12.9 mg, 0.788 μmol) in DMSO-d_6 (1.63 mL) was treated with triethylamine (1.20 μL, 8.61 μmol) and 11.3 mM AF_{488}−OTFP solution in DMSO-d_6 (70.0 μL, 0.791 μmol). 1.16 mL of the crude reaction mixture was taken for the next step and the remainder was purified by SEC (H 38 cm × O.D. 3.0 cm) to isolate the dendrimer conjugate **7d** (4.52 mg). The color of a 1.0 mM solution of **7d** in water (HPLC grade, Aldrich) prepared for the biological assay was light yellow. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.05−7.82 (m, 83.64H, NH_{G3}, NH_{Ac}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.22 (br s, 5.69H, NH_{PEG} of major isomer), 6.80 (br s, 0.68H, NH_{PEG} of minor isomer), 4.03 (t, 9.22H, J = 4.2 Hz, H_{hPEG}), 3.62−3.38 (m, 800.08H, satellites J = 70.9 Hz, H_i, H_j, and H_k), 3.24 (s, 21.04H, H_l), 3.12−2.99 (m, 198.41H, H_d, H_f, H_{fAc}, H_{gAc}, H_{fPEG}, and H_{gPEG}), 2.64 (m, 120.33H, H_b and H_g), 2.42 (m, 59.43H, H_e and H_a), 2.18 (m, 120.00H, H_c), 1.79 (s, 57.95H, H_{hAc}).

PAMAM-PEG-AF$_{488}$ Dendrimer 8c. PAMAM-PEG dendrimer **4c** (*17*) (12.2 mg, 0.888 μmol) in DMSO-d_6 (809 μL) was treated with triethylamine (2.85 μL, 20.5 μmol) and 11.3 mM AF_{488}−OTFP solution in DMSO-d_6 (78.7 μL, 0.889 μmol). 592 μL of the crude reaction mixture was taken for the next step and the remainder was purified by SEC (H 38 cm × O.D. 3.0 cm) to isolate the dendrimer conjugate **8c** (3.37 mg). The color of a ca. 0.5 mM solution (not fully homogeneous) of **8c** in water (HPLC grade, Aldrich) prepared for the biological assay was yellowish orange. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.17−7.80 (m, 71.97H, NH_{G3}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.21 (br s, 11.31H, NH_{PEG} of major isomer), 6.79 (br s, 1.68H, NH_{PEG} of minor isomer), 4.03 (t, 23.61H, J = 4.1 Hz, H_{hPEG}), 3.62−3.38 (m, 703.42H, satellites J = 70.4 Hz, H_i, H_j, and H_k), 3.23 (s, 44.08H, H_l), 3.11−2.99 (m, 182.07H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.64 (m, 136.23H, H_b and H_g), 2.42 (m, 58.27H, H_e and H_a), 2.18 (m, 120.00H, H_c).

PAMAM-PEG-AF$_{488}$ Dendrimer 8d. PAMAM-PEG dendrimer **4d** (*17*) (7.63 mg, 0.512 μmol) in DMSO-d_6 (1.15 mL) was treated with triethylamine (2.30 μL, 16.5 μmol) and 11.3 mM AF_{488}−OTFP solution in DMSO-d_6 (46.0 μL, 0.520 μmol). 850 μL of the crude reaction mixture was taken for the next step, and the remainder was purified by SEC (H 23 cm × O.D. 2.5 cm) to isolate the dendrimer conjugate **8d** (3.44 mg). The color of a ca. 0.5 mM solution (not fully homogeneous) of **8d** in water (HPLC grade, Aldrich) prepared for the biological assay was yellowish orange. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.13−7.80 (m, 69.31H, NH_{G3}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.23 (br s, 7.21H, NH_{PEG} of major isomer), 4.03 (t, 10.57H, J = 4.1 Hz, H_{hPEG}), 3.62−3.38 (m, 945.12H, satellites J = 71.1 Hz, H_i, H_j, and H_k), 3.24 (s, H_l), 3.12−2.99 (m, 161.83H, H_d, H_f, H_{fPEG}, and H_{gPEG}), 2.64 (m, 132.91H, H_b and H_g), 2.42 (m, 56.76H, H_e and H_a), 2.19 (m, 120.00H, H_c).

PAMAM-PEG$_{550}$-Ac-AF$_{488}$−CGS21680 Dendrimer 9a. To a crude reaction mixture of fluorescent dendrimer **7a** in DMSO-d_6 (1.10 mL), was added triethylamine (3.50 μL, 25.1 μmol) and CGS21680 (**1**, as a hydrochloride hemihydrate form, 4.95 mg, 9.08 μmol). Subsequently, a freshly prepared 42.2 mM solution of PyBOP in DMSO-d_6 (180 μL, 7.60 μmol) was added slowly to the stirred mixture of **7a**. The reaction was stirred for 20 h, and the reaction mixture was loaded directly on a SEC column (H 43 cm × O.D. 4.5 cm) in DMF for purification, and the fractions containing the desired product were identified by ^{1}H NMR. The first and last SEC fractions that were confirmed by NMR to contain minor amounts of the desired dendrimer were eliminated deliberately to reduce the polydispersity of the dendrimer conjugates. The SEC fractions selected as such were combined and dried *in vacuo* to give 5.55 mg of **9a′** (structure not shown). Unfortunately, the analysis of **9a′** by ^{1}H NMR in DMSO-d_6 indicated only ca. 0.38 CGS21680 groups were attached out of ca. nine available PAMAM amino groups. In an attempt to bring the CGS21680 attachment to completion, dendrimer **9a′**, the isolated derivative of **7a**, underwent another round of conjugation reaction, but this time under an exhaustive coupling condition. In a separate flask, CGS21680 (**1**, as a hydrochloride hemihydrate form, 23.3 mg, 42.8 μmol) in DMSO-d_6 (978 μL) was treated with triethylamine (21.8 μL, 156 μmol) and PyBOP (20.3 mg, 39.1 μmol) [Solution A], and stirred for 15 min. Subsequently, dendrimer **9a′** (5.55 mg) in DMSO-d_6 (190 μL) was treated with 220 μL (8.59 μmol) of Solution A, and the reaction mixture was stirred for 72 h protected from light. Another batch of preactivated ester of CGS21680 (**1**, as a hydrochloride hemihydrate form, 19.6 mg, 36.0 μmol) was freshly prepared in DMSO-d_6 (985 μL) by treating with triethylamine (14.8 μL, 106 μmol) and PyBOP (17.4 mg, 33.5 μmol) [Solution B], which was stirred for 12 min. The dendrimer mixture was treated with 120 μL (4.02 μmol) of Solution B and stirring continued for 39 h. The crude mixture was loaded on a SEC column (H 38 cm × O.D. 3.0 cm) for purification in DMF, and the fractions containing the desired compound were determined similarly by ^{1}H NMR. The selected SEC fractions were combined and dried *in vacuo* to give dendrimer **9a** (6.20 mg) as a glassy solid. The color of a 1.0 mM solution of **9a** in water (HPLC grade, Aldrich) prepared for the biological assay was light yellow. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.04−7.80 (m, 80.15H, H_8, H_{8Ad} NH_{G3}, NH_{Ac}, NH_{CGS}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.22 (br s, 8.54H, NH_{PEG} of major isomer), 7.15, 7.10 (d (each), 5.42H, H_4 and H_5), 6.79 (br s, 2.75H, H_{6Ad}, NH_{PEG} of minor isomer), 6.19 (s, 0.91H, H_1), 5.84 (d, 0.86H, J = 6.5 Hz, $H_{1'}$), 5.63, 5.56 (br s (each), 1.70H, $H_{3'\text{-}OH}$ and $H_{2'\text{-}OH}$), 4.72 (m, 0.86H, $H_{2'}$), 4.25 (s, $H_{4'}$), 4.19 (s, 1.03H, $H_{3'}$), 4.03 (t, 16.34H, J = 4.4 Hz, H_{hPEG}), 3.62−3.38 (m, 388.25H, satellites J = 70.1 Hz, H_i, H_j, and H_k, one of H_2), 3.23 (s, 30.93H, H_l), 3.13−2.99 (m, 190.69H, H_d, H_f, H_{fAc}, H_{gAc}, H_{fCGS}, H_{gCGS}, H_{fPEG}, H_{gPEG}, and H_9), 2.76 (m, H_3 and H_6), 2.64 (m, 110.80H, H_b and H_g), 2.42 (m, 58.01H, H_e and H_a), 2.34 (t, H_7), 2.18 (m, 120.00H, H_c), 1.79 (s, 42.84H, H_{hAc}), 0.97 (t, 3.60H, J = 7.1 Hz, H_{10}).

PAMAM-PEG$_{550}$-Ac-AF$_{488}$−CGS21680 Dendrimer 9b. The conjugation reaction was performed following a procedure similar to that described for **9a**. To a crude reaction mixture of fluorescent dendrimer **7b** in DMSO-d_6 (1.00 mL), was added triethylamine (2.50 μL, 17.9 μmol) and CGS21680 (**1**, as a hydrochloride hemihydrate form, 3.50 mg, 6.42 μmol). Subsequently, a freshly prepared 42.2 mM solution of PyBOP in

DMSO-d_6 (129 μL, 5.45 μmol) was added slowly to the stirred mixture of **7b**. The reaction was stirred for 20 h, and then the reaction mixture was loaded directly on a SEC column (H 38 cm × O.D. 3.0 cm) in DMF and purified to give 8.82 mg of **9b′** (structure not shown). Unfortunately, the analysis of **9b′** by ^{1}H NMR in DMSO-d_6 indicated only ca. 1.24 CGS21680 groups were attached out of ca. nine available PAMAM amino groups. Next, dendrimer **9b′** (8.82 mg) in DMSO-d_6 (148 μL) was treated with 170 μL (6.64 μmol) of Solution A (*vide supra*, stirred for 12 min), and the reaction mixture was stirred for 72 h protected from light. Then, the dendrimer mixture was treated with 100 μL (3.35 μmol) of Solution B (*vide supra*, stirred for 11 min), and stirring continued for 39 h. The crude mixture was loaded on a SEC column (H 43 cm × O.D. 4.5 cm) for purification in DMF, and the fractions containing the desired compound were determined similarly by ^{1}H NMR. The selected SEC fractions were combined and dried *in vacuo* to give dendrimer **9b** (7.87 mg) as a glassy solid. The color of a 1.0 mM solution of **9b** in water (HPLC grade, Aldrich) prepared for the biological assay was orange. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.86 (br s, 0.45H, NH_{AF}), 8.43 (br s, 0.98H, H_F), 8.21 (br s, H_E), 8.04−7.80 (m, 74.60H, H_8, H_{8Ad} NH_{G3}, NH_{Ac}, NH_{CGS}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.30 (br s, 0.72H, H_D), 7.21 (br s, 14.06H, NH_{PEG} of major isomer), 7.14, 7.10 (d (each), 10.14H, H_4 and H_5), 6.79 (br s, 5.23H, H_{6Ad}, NH_{PEG} of minor isomer), 6.45 (br s, 0.69H, H_B/H_C), 6.35 (br s, 0.66H, H_B/H_C), 6.19 (s, 1.73H, H_1), 5.84 (d, 1.72H, J = 5.9 Hz, $H_{1'}$), 5.63, 5.56 (br s (each), 2.57H, $H_{3'\text{-}OH}$ and $H_{2'\text{-}OH}$), 4.71 (m, 1.62H, $H_{2'}$), 4.26 (s, 2.29H, $H_{4'}$), 4.19 (s, 1.97H, $H_{3'}$), 4.03 (br s, 29.99H, H_{hPEG}), 3.62−3.38 (m, 720.52H, satellites J = 70.6 Hz, H_i, H_j, and H_k, one of H_2), 3.23 (s, 51.65H, H_l), 3.19−2.99 (m, 189.36H, H_d, H_f, H_{fAc}, H_{gAc}, H_{fCGS}, H_{gCGS}, H_{fPEG}, H_{gPEG}, and H_9), 2.76 (m, 18.44H, H_3 and H_6), 2.64 (m, 111.40H, H_b and H_g), 2.42 (m, 54.30H, H_e and H_a), 2.34 (t, 8.37H, H_7), 2.18 (m, 120.00H, H_c), 1.79 (s, 22.70H, H_{hAc}), 0.97 (t, 6.01H, J = 6.9 Hz, H_{10}).

PAMAM-PEG$_{2000}$-Ac-AF$_{488}$−CGS21680 Dendrimer 9d. The conjugation reaction was performed following a procedure similar to that described for **9a**. To a crude reaction mixture of fluorescent dendrimer **7d** in DMSO-d_6 (1.16 mL), was added triethylamine (2.70 μL, 19.4 μmol) and CGS21680 (**1**, as a hydrochloride hemihydrate form, 3.83 mg, 7.03 μmol). Subsequently, a freshly prepared 42.2 mM solution of PyBOP in DMSO-d_6 (138 μL, 5.81 μmol) was added slowly to the stirred mixture of **7d**. The reaction was stirred for 20 h, and then the reaction mixture was loaded directly on a SEC column (H 41 cm × O.D. 4.5 cm) in DMF and purified to give 8.81 mg of **9d′** (structure not shown). Unfortunately, the analysis of **9d′** by ^{1}H NMR in DMSO-d_6 indicated only ca. 0.65 CGS21680 groups were attached out of ca. seven available PAMAM amino groups. Next, dendrimer **9d′** (8.81 mg) in DMSO-d_6 (300 μL) was treated with 180 μL (7.03 μmol) of Solution A (*vide supra*, stirred for 8 min), and the reaction mixture was stirred for 72 h protected from light. Then, the dendrimer mixture was treated with 100 μL (3.35 μmol) of Solution B (*vide supra*, stirred for 10 min) and stirring continued for 39 h. The crude mixture was loaded on a SEC column (H 38 cm × O.D. 4.5 cm) for purification in DMF, and the fractions containing the desired compound were determined similarly by ^{1}H NMR. The selected SEC fractions were combined and dried *in vacuo* to give dendrimer **9d** (8.82 mg) as a glassy solid. The color of a 1.0 mM solution of **9d** in water (HPLC grade, Aldrich) prepared for the biological assay was light orange. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.87 (br s, NH_{AF}), 8.43 (br s, H_F), 8.05−7.81 (m, 83.00H, H_8, H_{8Ad} NH_{G3}, NH_{Ac}, NH_{CGS}, NH_{G2}, NH_{G1}, and NH_{G0}), 7.22 (br s, 4.43H, NH_{PEG} of major isomer), 7.14, 7.10 (d (each), 5.22H, H_4 and H_5), 6.80 (br s, 1.95H, H_{6Ad}, NH_{PEG} of minor isomer), 6.47 (br s, H_B/H_C), 6.36 (br s, H_B/H_C), 6.19 (s, 0.67H, H_1), 5.84 (d, 0.68H, J = 6.7 Hz, $H_{1'}$), 5.65, 5.58 (br s (each), 0.61H, $H_{3'\text{-}OH}$ and $H_{2'\text{-}OH}$), 4.72 (m, 0.78H, $H_{2'}$), 4.26 (s, 1.71H, $H_{4'}$), 4.19 (s, 0.90H, $H_{3'}$), 4.03 (t, 9.47H, J = 4.0 Hz, H_{hPEG}), 3.62−3.39 (m, 810.85H, satellites J = 70.7 Hz, H_i, H_j, and H_k, one of H_2), 3.24 (s, 20.59H, H_l), 3.14−2.99 (m, 190.63H, H_d, H_f, H_{fAc}, H_{gAc}, H_{fCGS}, H_{gCGS}, H_{fPEG}, H_{gPEG}, and H_9), 2.76 (m, H_3 and H_6), 2.64 (m, 115.71H, H_b and H_g), 2.42 (m, 55.85H, H_e and H_a), 2.34 (t, H_7), 2.18 (m, 120.00H, H_c), 1.79 (s, 57.89H, H_{hAc}), 0.97 (t, 3.42H, J = 7.0 Hz, H_{10}).

PAMAM-PEG$_{750}$-AF$_{488}$−CGS21680 Dendrimer 10c. CGS21680 (**1**, as a hydrochloride hemihydrate form, 14.7 mg, 27.0 μmol) in DMSO-d_6 (242 μL) was treated with triethylamine (10.4 μL, 74.6 μmol) and PyBOP (12.9 mg, 24.9 μmol) [Solution C] and stirred for 8 min. Subsequently, in a separate flask, a crude reaction mixture of fluorescent dendrimer **8c** in DMSO-d_6 (592 μL) was treated with 150 μL (14.8 μmol) of Solution C, and the reaction mixture was stirred for 50 h protected from light. Then, the dendrimer mixture was treated with 220 μL (7.37 μmol) of Solution B (*vide supra*, stirred for 7 min) and stirring continued for 14 h. The crude mixture was loaded on a SEC column (H 38 cm × O.D. 4.5 cm) for purification in DMF, and the fractions containing the desired compound were determined similarly by ^{1}H NMR. The selected SEC fractions were combined and dried *in vacuo* to give dendrimer **10c** (9.98 mg) as a glassy solid. The color of a 1.0 mM solution of **10c** in water (HPLC grade, Aldrich) prepared for the biological assay was intense orange. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.85 (br s, NH_{AF}), 8.44 (br s, H_F), 8.05, 8.02 (s (each), 36.49H, H_8 and H_{8Ad}), 7.93, 7.89 (br s, 47.73H, NH_{G3}, NH_{CGS}), 7.80 (br s, 25.82H, NH_{G2}, NH_{G1}, and NH_{G0}), 7.20 (br s, 12.52H, NH_{PEG} of major isomer), 7.13, 7.09 (d (each), 60.79H, H_4 and H_5), 6.80 (br s, 25.16H, H_{6Ad}, NH_{PEG} of minor isomer), 6.19 (s, 12.19H, H_1), 5.85 (d, 13.94H, J = 6.1 Hz, $H_{1'}$), 5.62, 5.56 (br s (each), 21.91H, $H_{3'\text{-}OH}$ and $H_{2'\text{-}OH}$), 4.72 (m, 13.13H, $H_{2'}$), 4.26 (s, 14.50H, $H_{4'}$), 4.19 (s, 13.88H, $H_{3'}$), 4.03 (br s, 22.64H, H_{hPEG}), 3.61−3.38 (m, 704.59H, satellites J = 67.0 Hz, H_i, H_j, and H_k, one of H_2), 3.23 (s, 63.37H, H_l), 3.17−2.99 (m, 209.06H, H_d, H_f, H_{fCGS}, H_{gCGS}, H_{fPEG}, H_{gPEG}, and H_9), 2.76 (m, 76.79H, H_3 and H_6), 2.64 (m, 115.47H, H_b and H_g), 2.42 (m, 54.39H, H_e and H_a), 2.33 (t, 39.56H, J = 7.3 Hz, H_7), 2.18 (m, 120.00H, H_c), 0.96 (br s, 42.16H, H_{10}).

PAMAM-PEG$_{2000}$-AF$_{488}$−CGS21680 Dendrimer 10d. The conjugation reaction was performed following a procedure similar to that described for **9a**. To a crude reaction mixture of fluorescent dendrimer **8d** in DMSO-d_6 (850 μL), was added triethylamine (5.10 μL, 36.6 μmol) and CGS21680 (**1**, as a hydrochloride hemihydrate form, 6.96 mg, 12.8 μmol). Subsequently, a freshly prepared 42.2 mM solution of PyBOP in DMSO-d_6 (280 μL, 11.8 μmol) was added slowly to the stirred mixture of **7d**. The reaction was stirred for 43 h, and the reaction mixture was loaded directly on a SEC column (H 43 cm × O.D. 4.5 cm) in DMF and purified to give 9.44 mg of **10d′** (structure not shown). Unfortunately, the analysis of **10d′** by ^{1}H NMR in DMSO-d_6 indicated only ca. 18.49 CGS21680 groups were attached out of ca. 26 available PAMAM amino groups. Next, dendrimer **10d′** (9.44 mg) in DMSO-d_6 (300 μL) was treated with 170 μL (6.64 μmol) of Solution A (*vide supra*, stirred for 6 min), and the reaction mixture was stirred for 72 h protected from light. Then, the dendrimer mixture was treated with 100 μL (3.35 μmol) of Solution B (*vide supra*, stirred for 8 min) and stirring continued for 14 h. The crude mixture was loaded on a SEC column (H 38 cm × O.D. 3.0 cm) for purification in DMF, and the fractions containing the desired compound were determined similarly by ^{1}H NMR. The selected SEC fractions were combined and dried *in vacuo* to give dendrimer **10d** (8.39 mg) as a glassy solid. The color of a 1.0

mM solution of **10d** in water (HPLC grade, Aldrich) prepared for the biological assay was intense red. ^{1}H NMR (600 MHz, DMSO-d_6) δ 8.05, 8.02 (s (each), 47.63H, H_8 and H_{8Ad}), 7.93, 7.89 (br s, 54.71H, NH_{G3}, NH_{CGS}), 7.80 (br s, 25.60H, NH_{G2}, NH_{G1}, and NH_{G0}), 7.21 (br s, 7.03H, NH_{PEG} of major isomer), 7.13, 7.09 (d (each), 85.97H, H_4 and H_5), 6.81 (br s, 36.71H, H_{6Ad}, NH_{PEG} of minor isomer), 6.19 (s, 19.05H, H_1), 5.85 (d, 20.03H, J = 6.5 Hz, $H_{1'}$), 5.62, 5.56 (br s (each), 35.34H, $H_{3'\text{-OH}}$ and $H_{2'\text{-OH}}$), 4.72 (m, 18.36H, $H_{2'}$), 4.26 (s, 20.93H, $H_{4'}$), 4.19 (s, 18.93H, $H_{3'}$), 4.02 (br s, 11.19H, H_{hPEG}), 3.62−3.37 (m, 930.57H, satellites J = 73.3 Hz, H_i, H_j, and H_k, one of H_2), 3.23 (s, 23.17H, H_l), 3.19−2.99 (m, 240.33H, H_d, H_f, H_{fCGS}, H_{gCGS}, H_{fPEG}, H_{gPEG}, and H_9), 2.76 (m, 99.23H, H_3 and H_6), 2.64 (m, 110.31H, H_b and H_g), 2.41 (m, 55.64H, H_e and H_a), 2.33 (t, 54.85H, J = 7.7 Hz, H_7), 2.18 (m, 120.00H, H_c), 0.96 (br s, 61.52H, H_{10}).

Receptor Binding and Functional Assays[1]. *Materials.* [^{125}I]N^6-(4-Amino-3-iodobenzyl)adenosine-5′-*N*-methyluronamide (I-AB-MECA; 2000 Ci/mmol) and other radioligands were purchased from Perkin-Elmer Life and Analytical Science (Boston, MA). [^{3}H]2-chloro-N^6-cyclopentyladenosine (CCPA) was a custom synthesis product (Perkin-Elmer). Samples for binding and functional assays were prepared as follows: compounds **1**, **2**, and **3** as 5.0 mM stock solutions in DMSO (ACS spectroscopic grade, >99.9%, Aldrich); dendrimers **7a**, **7b**, **7d**, **9a**, **9b**, **9d**, **10c**, and **10d** as 1.0 mM stock solutions in water (HPLC grade, Aldrich). Achieving a complete dissolution of dendrimer **8c** or **8d** in water (1.0 mM) was difficult, and thus, experiments were not performed for these compounds. Stock solutions were stored frozen at −80 °C.

Cell Culture and Membrane Preparation (18). Chinese hamster ovary (CHO) cells stably expressing the recombinant human (*h*) A_1, hA_{2B}, or hA_3 AR or human embryonic kidney (HEK)-293 cells stably expressing the recombinant hA_{2A} AR were cultured in DMEM (Dulbecco's modified Eagle's medium) and F12 (1:1, v/v) supplemented with 10% fetal bovine serum, 100 units/mL penicillin, 100 μg/mL streptomycin, 2 μmol/mL glutamine, and 800 μg/mL Geneticin. After harvest, homogenization, and suspension, cell membranes were centrifuged at 500 × *g* for 10 min, and the pellet was resuspended in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM $MgCl_2$ and 1 mM EDTA. The suspension was homogenized with an electric homogenizer for 10 s and was then re-centrifuged at 20 000 × *g* for 20 min at 4 °C. The resultant pellets were resuspended in buffer in the presence of 3 U/mL adenosine deaminase, and the suspension was stored at −80 °C until the binding experiments. The protein concentration was measured using the Bradford assay (*19*).

Binding Assays at the hA_1 and hA_{2A} ARs. For binding to hA_1 ARs (*20, 21*), membranes (40 μg/tube) from CHO cells stably expressing the receptor were incubated with [^{3}H]N^6-[(*R*)-phenylisopropyl]adenosine (R-PIA; 2 nM) or [^{3}H]CCPA (0.5 nM) at 25 °C for 60 min in 50 mM Tris-HCl buffer (pH 7.4, 10 mM $MgCl_2$) and increasing concentrations of the test ligands in a total assay volume of 200 μL. Nonspecific binding was determined using 10 μM of N^6-cyclopentyladenosine (CPA).

For hA_{2A} AR binding (*22*), membranes (20 μg/tube) from HEK-293 cells stably expressing the receptor were incubated with [^{3}H]CGS21680 (15 nM) at 25 °C for 60 min in 50 mM Tris-HCl buffer (pH 7.4, 10 mM $MgCl_2$) and increasing concentrations of the test ligands in a total assay volume of 200 μL. Nonspecific binding was determined using 10 μM of 5′-*N*-ethylcarboxamidoadenosine (NECA).

For hA_3 AR binding (*22*), membranes (20 μg/tube) from CHO cells stably expressing the receptor were incubated with [^{125}I]I-AB-MECA (0.2 nM) (*23*) at 37 °C for 60 min in 50 mM Tris-HCl buffer (pH 7.4, 10 mM $MgCl_2$) in a total assay volume of 200 μL. Nonspecific binding was determined using 10 μM of Cl-IB-MECA.

Binding reactions were terminated by filtration through Whatman GF/B filters under reduced pressure using an MT-24 cell harvester (Brandell, Gaithersburg, MD). Filters were washed three times with 9 mL ice-cold buffer. Radioactivity was determined in a Beckman 5500B γ-counter. IC_{50} values were converted to K_i values as described (*24*).

Cyclic AMP Accumulation Assay. CHO cells expressing the A_{2A} or A_{2B} AR were seeded in 24-well plates and incubated at 37 °C overnight. The following day the medium was removed and replaced with DMEM containing 50 mM HEPES, 10 μM rolipram, 3 U/mL adenosine deaminase, and increasing concentrations of agonists. The medium was removed, and the cells were lysed with 200 μL of 0.1 M HCl. 100 μL of the HCl solution was used in the Sigma Direct cAMP Enzyme Immunoassay following the instructions provided with the kit. The results were interpreted using a Bio-Tek ELx808 Ultra Microplate reader at 405 nm.

Statistical Analysis. Binding and functional parameters were calculated using *Prism 4.0* software (GraphPAD, San Diego, CA). IC_{50} values obtained from competition curves were converted to K_i values using the Cheng-Prusoff equation (*24*). Data were expressed as the mean ± standard error. Statistical analysis was performed using analysis of variance (ANOVA) with post hoc test or Student's *t*-test where appropriate with *p* values less than 0.05 being considered significant.

Studies of Human Washed Platelets. *Preparation.* Human washed platelets were prepared as previously described (*25*). Briefly, fresh blood obtained from healthy donors was centrifuged at 175 × *g* for 15 min at 37 °C, platelet-rich plasma was removed, and centrifuged at 1570 × *g* for 15 min at 37 °C. The platelet pellet was washed twice in Tyrode's buffer (137 mM NaCl, 2 mM KCl, 12 mM $NaHCO_3$, 0.3 mM NaH_2PO_4, 1 mM $MgCl_2$, 2 mM $CaCl_2$, 5.5 mM glucose, 5 mM Hepes, pH 7.3) containing 0.35% human serum albumin, and finally resuspended at a density of 3 × 10^5 platelets/μL in the same buffer in the presence of 0.02 U/mL of the adenosine 5′-diphosphate (ADP) scavenger apyrase (adenosine 5′-triphosphate diphosphohydrolase, EC 3.6.1.5), a concentration sufficient to prevent desensitization of platelet ADP receptors during storage. Platelets were kept at 37 °C throughout all experiments.

Platelet Aggregation Studies[1]. Aggregation was measured at 37 °C by a turbidimetric method in a dual-channel Payton aggregometer (Payton Associates, Scarborough, Ontario, Canada). The stock solutions for platelet aggregation and internalization studies were prepared as follows: compounds **1**, **2**, and **3** as 5.0 mM solutions in DMSO (ACS spectroscopic grade, >99.9%, Aldrich); dendrimers **7a**, **7b**, **7d**, **9a**, **9b**, **9d**, **10c**, and **10d** as 1.5 mM solutions in water (HPLC grade, Aldrich); dendrimers **8c** and **8d** as 750 μM solutions in water (HPLC grade, Aldrich). A small amount of DMSO in monomer was previously demonstrated not to affect the platelet aggregation (*10*). A 450 μL aliquot of platelet suspension was stirred at 1100 rpm and activated by addition of ADP (5 μM), in the presence or absence of various monomers/dendrimers and in the presence of human fibrinogen (0.8 mg/mL), in a final volume of 500 μL. The extent of aggregation was estimated quantitatively by measuring the maximum curve height above the baseline level.

[1]All of our *in vitro* assay results (including platelet studies) are reported in dendrimer concentrations, not in ligand concentrations. This was intended because of potential limitations in simultaneously achieving full accessibility to receptors of all ligands covalently bound to a single carrier such as in our dendrimer conjugates. We maintain that our system is different from those carriers loaded with drugs as either physically entrapped or covalently bound through cleavable linkers for their release for activation as monomeric forms.

Flow Cytometry Analysis[1]. Human washed platelets (3×10^5 platelets/μL) were incubated with various dendrimers for 30 min at 37 °C. The platelet suspension was then centrifuged at 1900 $\times$ *g* for 8 min at 37 °C and platelets were resuspended in Tyrode's buffer containing 0.35% human serum albumin and fixed with paraformaldehyde 2% for 15 min. A 5 μL aliquot of sample was then diluted with 500 μL PBS for flow cytometry analysis. Samples were analyzed using a Becton Dickinson FACScalibur flow cytometer and *Cell Quest* software (Becton Dickinson, San Jose, CA). All parameters were acquired on a logarithmic scale, and 20 000 events were recorded in the platelet population.

RESULTS AND DISCUSSION

Molecular Design. Our recent investigation showed that a relatively low degree of surface modification (ca. $\leq$25%) by short poly(ethylene glycol) monomethyl ether (PEG) chains (M_n = 550/750) sufficiently increased water solubility and reduced the cytotoxicity of G3 PAMAM dendrimers (*17*). Here, our goal was to examine whether this PEGylation principle could be effectively applied to our earlier dendrimer constructs bearing GPCR ligands that interact within the transmembrane domain of the receptor to induce biological effects. Accordingly, three G3 PAMAM dendrimers (theoretical 32 end groups) containing relatively small weight portions of PEG that differ in number and size ($7PEG_{550}$ (**4a**), $14PEG_{550}$ (**4b**), and $4PEG_{2000}$ (**4d**); Scheme 1) were initially selected for a comparative study. We planned partial substitution of the dendrimer with a fixed number of agonist ligands (CGS21680) and with all remaining free amino groups concealed by prior acetylation in order to precisely evaluate the influence of different PEG groups on receptor-mediated activity. A fluorophore was also attached to the dendrimers for detection in biological systems. In addition, preparation of an unacetylated fluorescent PAMAM-$4PEG_{2000}$ derivative with an increased number of CGS21680 ligands was intended to determine whether any multivalent effect is discernible with this PEGylated system. The stoichiometry in the substitution reactions of the amine-terminated G3 PAMAM dendrimers has been well-controlled (*10, 11, 17*). To summarize, our original molecular design considered the following: (1) partial acetylation of three G3 PAMAM-PEG dendrimers to leave similar numbers of free amino groups; (2) attachment of 1 equiv of Alexa Fluor 488 (AF_{488}) for fluorescent imaging; (3) conjugation of CGS21680 at all remaining amino groups.

Synthesis. Acetylation of **4a**, **4b**, and **4d** was achieved with a relatively efficient stoichiometric control to leave a similar fraction of free amino groups (31% for **5a**; 35% for **5b**; 25% for **5d**) (Scheme 1). Purification by SEC in DMF after each step slightly shifted the composition (*m* and *n*) of each dendrimer mixture and its MW distribution as determined by ^{1}H NMR integration (see Supporting Information) (*17*). Subsequently, each acetylated PAMAM-PEG dendrimer **5** was treated with an equimolar amount of AF_{488} as an activated ester (**6**). Some unreacted dye **6** was recovered during the SEC purification from all three reactions (**5**$\rightarrow$**7**). In contrast, no free dye **6** was found when unacetylated dendrimer **4d** was reacted similarly.

Next, the fluorescent dendrimers **7a**, **7b**, **7d**, and **8d** were treated with CGS21680 in slight excess for its conjugation to the PAMAM periphery via PyBOP-mediated coupling. Unfortunately, the conversion fraction in these reactions determined after SEC purification turned out to be low, being more prominent for the acetylated dendrimers **7** (0.38 CGS21680 attachments for **7a** out of approximately nine remaining peripheral amino groups, 1.24 for **7b**, 0.65 for **7d**, and 18.5 for **8d** by ^{1}H NMR integration). The low coupling yield was in contrast to the full substitution of the G3 PAMAM amino ends with CGS21680 under the same reaction conditions (*10*). Obviously, the presence of an adjacent PEG chain, irrespective of its number and size, interfered sterically with the coupling reaction. Furthermore, we speculate that applying the partial acetylation at the PEGylated PAMAM surface may further phase-separate these unimolecular micelles intramolecularly (into microphase domains of hydrophobic core and hydrophilic PEG corona) to shrink the PAMAM surface and lower the reactivity of the remaining amino groups considerably. To overcome the low reactivity, the SEC-purified dendrimer mixture was further treated with two separate additions of the excess preactivated ester of CGS21680 and was allowed to react for several additional days. Nevertheless, application of this exhaustive coupling condition did not substantially improve the total conversion for all cases. Among the three acetylated dendrimers, **7b** with a lower proportion of acetamide groups showed a slightly better coupling efficiency. Since our goal was to systematically study the influence of adjacent PEG chains in eliciting biological activity through ligand-receptor interactions, attachment of CGS21680 earlier in the synthetic sequence was avoided in order to facilitate the stoichiometric control in PEG derivatization. Moreover, the activated form of PEG (as a *p*-nitrophenyl carbonate) potentially reacts with the hydroxy and the adenine amino groups of CGS21680. Another unacetylated fluorescent dendrimer analogue **10c** with shorter PEG chains was prepared similarly from **4c** ($9PEG_{750}$), in order to compare the influence of PEG on the chemical reactivity and the biological effects between unacetylated dendrimer conjugates. Again, a complete conjugation of CGS21680 to **8c** was not achieved.

Characterization by ^{1}H NMR and MALDI-TOF MS. The final dendrimer conjugates **7**$-$**10** used for biological assays were characterized by analysis of ^{1}H NMR integrals in DMSO-d_6 (Table 1). NMR analysis of **9a**, **9b**, and **9d** in D_2O gave similar results; however, analysis of **10c** and **10d** in D_2O was not feasible due to the significant peak broadening. This may have resulted from poor desolvation in D_2O (*26*) of the relatively hydrophobic interior$-$CGS21680 moieties and the PAMAM domain. The average MW of each dendrimer was also determined by MALDI MS in two different matrices (DHB and THAP) to give somewhat underestimated values compared to those obtained by NMR (Table 1). Underestimation of MWs of similar PAMAM conjugates by MALDI was previously noted (*10, 17*). The number of CGS21680 groups (*z*) attached to each dendrimer calculated by MALDI was similar to (or slightly higher for **9b** and **10d**) NMR-estimated values.

Solution Conformation of Dendrimer Conjugates by NOESY. To predict the solution conformation of PAMAM-PEG-CGS21680 dendrimer conjugates (Figure 2) in the aqueous phase, 2D NOESY experiments were carried out for selected dendrimers **9b**, **10c**, and **10d** in D_2O (see Supporting Information Figures S4$-$S6). Our previous investigation on various PAMAM-PEG conjugates (without ligands) suggested no backfolding of the PEG chains into the interior of the PAMAM domain (*17*). Intense NOE cross-peaks were found between the peaks from PAMAM and CGS21680 segments of dendrimers **10c** and **10d** with high loading of CGS21680, but much weaker (or no) signals were detected from the corresponding cross-peaks (if any) of **9b**. Related to this observation, it may be important to note the small difference in the chemical shift ($\Delta\delta \approx 0.15$ ppm) of the methyl group of the 5′-uronamide moiety of CGS21680 in 1D NMR in D_2O, between the dendrimers with low loading (0.97$-$0.98 ppm for **9a**, **9b**, and **9d**) and high loading (0.85 ppm for **10c**; 0.82 ppm for **10d**) of ligands. Hardly any NOE cross-peaks were observed between the peaks from CGS21680 and PEG regions in all three spectra. Detection of the NOE cross-peaks between those from PAMAM and PEG regions was difficult due to the severe overlapping of peaks. However, weak NOE cross-peaks between PAMAM and PEG peaks were indicated, particularly with dendrimer **10c**, which were more vivid for the isolated PEG peaks (h_{PEG}, i; see Supporting

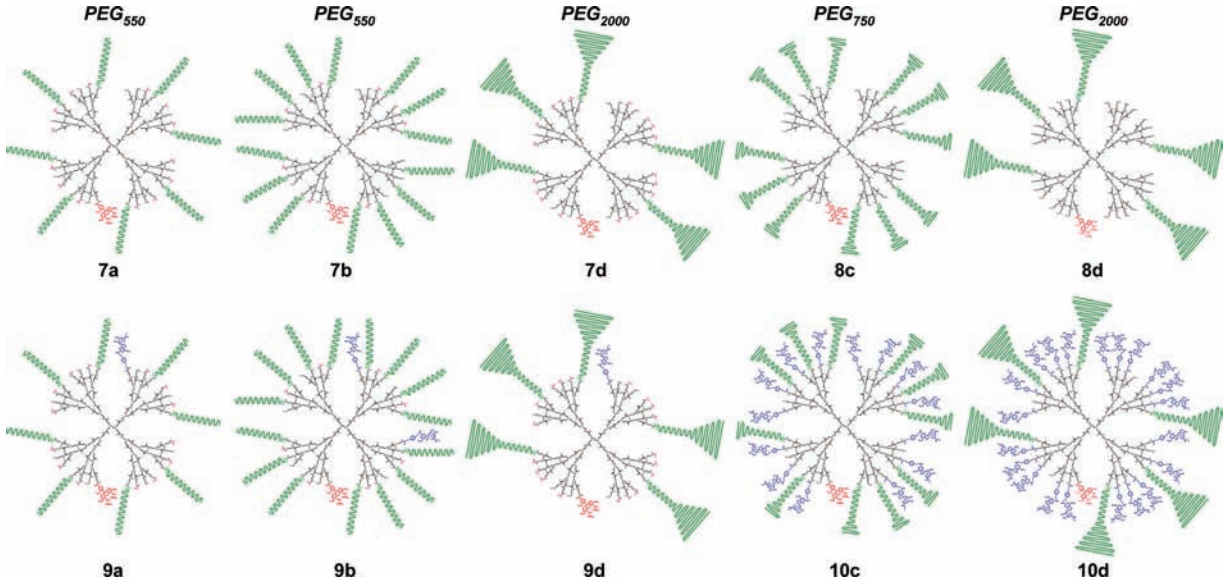


Figure 2. Structures of PEGylated PAMAM dendrimer conjugates **7**−**10** (black, PAMAM; green, PEG; pink, acetyl; red, AF_{488}; blue, CGS21680). The illustration of dendrimer conjugates shows the average number of attached pendant groups in each statistical mixture as determined by ^{1}H NMR integrals and reflects the approximate PEG length (550/750/2000) relative to the size of the CGS21680 ligand. The geometry of each component as drawn, particularly of the PEG chains, does not represent the actual solution conformation.

[a] Values are presented as the mean ± standard error of three or more independent experiments. The hA_1, hA_{2B}, and hA_3 ARs were expressed in CHO cells and the hA_{2A} AR in HEK-293 cells for binding and in CHO cells for the functional assay. [b] K_i values were determined through the radioligand binding, and the percent inhibition refers to the inhibition of binding at 1 μM. [c] EC_{50} values were determined by measuring the degree of stimulation of adenylate cyclase in cells stably expressing hA_{2A} or hA_{2B} AR. Percent activation refers to the activation of adenylate cyclase in comparison to the effects exerted by the full agonist NECA (100%) at 10 μM. [d] n.d. = not determined, i.e., binding/functional experiment was not conducted, or n.a. = no binding/activation was detected under the given assay conditions. [e] Performed only once.

Information Figure S5) close to the PAMAM region. Taken together, NOESY analysis suggests that CGS21680 ligands attached to the PEGylated PAMAM are more likely positioned in proximity to the PAMAM domain—by adhering to its surface or by partially backfolding into its interior void—rather than in the outer hydrophilic PEG layer in contact with the water molecules.

***In Vitro* Binding Assay at *h*ARs.** Next, the biological activities of these PEGylated PAMAM-CGS21680 conjugates **9** and **10** were examined by binding and functional assays in cell membranes (CHO or HEK-293 cells) expressing each *h*AR (Table 2) (*11*). Each of the four subtypes of ARs (A_1, A_{2A}, A_{2B}, and A_3) is associated with characteristic pathways of signaling, typically in a species-dependent manner (*12*). Recent evidence indicates the importance of secondary binding near the extracellular domain of a GPCR in enhancing selectivity and affinity of GPCR ligands (*27, 28*). Here, we compared the binding and activity profiles of these five dendrimers (**9** and **10**, Figure 2) with dendritic controls (precursors without the ligand, **7**, Figure 2) and three monomeric controls (**1**−**3**, Figure 1). APEC (**2**) is an analogue of CGS21680 (**1**) with an ethylenediamine extension at the distal unit (*28*) that exhibits a higher binding affinity at the hA_{2A} AR compared to **1**, but only threefold selectivity in comparison to the hA_3 AR. We also envisioned that **2**, particularly with a free amino group, may serve as a rough topological mimic for some of the dendrimer-attached CGS21680 moieties that are adjacent to the unreacted PAMAM amino groups. Compound **3** (*11*) was intended as a monomeric mimic of the dendrimer-attached form of **1**, because its terminal portion was identical to the linking segment in the dendrimer conjugates.

Overall, the inhibition constants (K_i) of the dendritic ligands at all tested AR subtypes (hA_1, hA_{2A}, and hA_3) were higher than those of the monovalent ligands **1**−**3**. Interestingly, this reduced affinity of dendritic ligands was more prominent at hA_1 and hA_3 compared to hA_{2A} AR. The selectivity for hA_{2A} compared to hA_3 AR was nearly an order of magnitude for the dendritic ligand **10c** ($hA_{2A,Ki}/hA_{3,Ki}$ = 0.13; 0.16 for **10d**), whereas the monomeric mimic of the dendrimer-attached nucleoside **3** showed selectivity (3.62-fold) for the hA_3. Indeed, high-loaded dendrimer conjugates **10** successfully achieved similar K_i values at hA_{2A} AR to that of **3**. In contrast, dendrimers **9** with low-loading of CGS21680 showed a reduction in binding

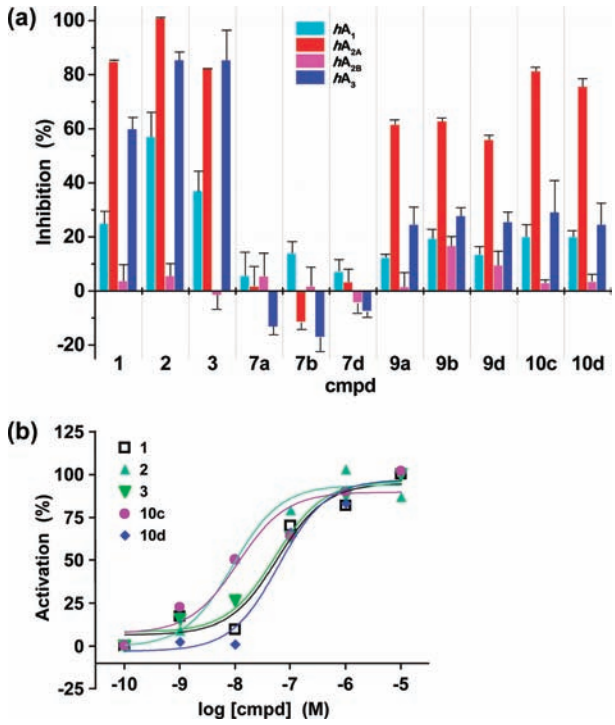

Figure 3. In vitro assay results of monomers (**1**−**3**) and selected dendrimers (**7**−**10**). (a) Interaction with four subtypes of *h*ARs (percent inhibition of specific radioligand binding at hA_1, hA_{2A}, and hA_3 ARs at a fixed concentration of 1 μM, and percent activation of adenylate cyclase at hA_{2B} AR at 10 μM); (b) agonistic effect at hA_{2A} AR as determined by measuring the degree of stimulation of adenylate cyclase in cells stably expressing the hA_{2A} AR. The hA_1, hA_{2B}, and hA_3 ARs were expressed in CHO cells and the hA_{2A} AR in HEK-293 cells for binding and in CHO cells for the functional assay.

affinity compared to monovalent ligand **3**, where **9d** bearing longer PEG_{2000} chains was the weakest. This may suggest an increased degree of steric inhibition (by neighboring PEG chains or the PAMAM backbone) experienced by a single ligand moiety in a macromolecular carrier with fewer ligands, significantly impairing ligand accessibility.

A similar trend was observed when comparing the inhibition at a fixed concentration of 1 μM (Figure 3a, Table 2). The dendritic controls **7** displayed essentially no inhibitory effect (<15%) at all subtypes of ARs. Inhibition of radioligand binding at the hA_{2A} AR was more pronounced for dendrimers **10** with high loading of CGS21680 compared to **9** with low loading, and similar to the effects by CGS21680 (**1**) and monomeric control **3**, but somewhat lower than inhibition by APEC (**2**). The differences in K_i values at hA_{2A} AR between dendrimers **9** and dendrimers **10** are statistically significant ($p < 0.01$). The relative inhibitory effect at the hA_{2A} vs the hA_3 AR was more than twice as high ($hA_{2A,\%inhibition}/hA_{3,\%inhibition} = 2.20-3.09$) for all PAMAM-PEG-CGS21680 dendrimer conjugates and nearly three times as high for dendrimers **10** with high loading of CGS21680. This represented an improvement in hA_{2A} selectivity in comparison to the hA_3 AR (0.96−1.42), considering the low selectivity of monomers **1**−**3**. Furthermore, selectivity for hA_{2A} compared to hA_1 has also increased (3.25−5.03 by **9** and **10**; 1.77−3.40 by **1**−**3**).

Cyclic AMP Accumulation Assay. The potency (i.e., agonistic effects) of monomers and dendrimers at hA_{2A} AR was determined by measuring the stimulation of adenylate cyclase—to produce intracellular adenosine 3′,5′-cyclic monophosphate (cAMP)—in CHO cells (Figure 3b, Table 2) (*12*). Dendrimer **10c** ($EC_{50} = 11.2 \pm 4.9$ nM, with PEG_{750}) was more potent than dendrimer **10d** ($EC_{50} = 60.6 \pm 12.8$ nM, with PEG_{2000}) in activating the hA_{2A} AR ($p < 0.05$). Considering the numbers of CGS21680 ligands (ca. 14 for **10c**; ca. 21 for **10d**) and PEG chains attached to these dendrimers, the longer PEG_{2000} chains appeared to significantly impede the ligand-receptor interaction, whereas the shorter PEG_{750} chains negligibly affected receptor binding and activation.

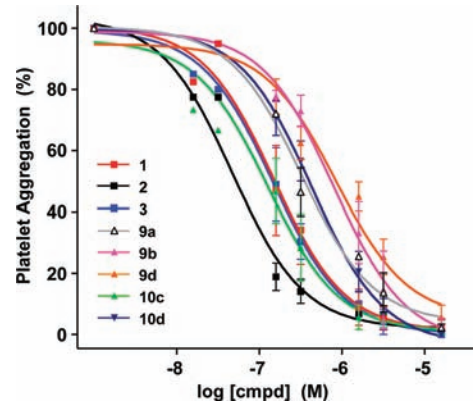

Figure 4. Platelet aggregation induced by ADP (5 μM) in the presence of various monomeric or dendritic A_{2A} agonists at 37 °C. The degree of platelet aggregation was normalized against that induced by ADP at 5 μM (100%). The extent of aggregation was estimated quantitatively by measuring the maximum curve height (i.e., percent light transmission) above the baseline level.

The EC_{50} values at the hA_{2A} AR of dendrimer **10c** (11.2 ± 4.9 nM, with PEG_{750}) and its corresponding monomer **3** (51.0 ± 8.0 nM) are significantly different ($p < 0.05$), although the hA_{2A} AR binding affinity of **10c** ($K_i = 151 \pm 36$ nM) was not significantly different from that of monomer **3** (210 ± 19 nM). Unlike the potency determined by measuring cAMP concentration that is directly associated with the intracellular signaling cascade initiated through AR activation, binding affinity was measured in isolated membranes of mammalian cells heterologously expressing specific ARs (see Experimental Section).

Recent reports described the dynamic behavior of GPCRs including receptor reorganization and oligomerization (*7, 29, 30*), which can be potentially regulated allosterically upon binding of a ligand. In such case, usage of clustered multivalent ligands would be particularly advantageous to amplify the desired cellular response. Therefore, this substantial enhancement in EC_{50} of a high-loaded dendrimer **10c** might reflect the involvement of more than one receptor-ligand interaction simultaneously. Indeed, a recent computer modeling study showed the possibility to bridge both primary binding sites at the transmembrane domain of a GPCR homodimer by two separate CGS21680 units covalently attached to a single G3 PAMAM dendrimer (*31*). Nevertheless, although enhancement of potency and/or selectivity was observed here, it was not sufficient to prove receptor clustering or oligomerization in this system.

Platelet Aggregation Studies. The effective inhibition of ADP-induced platelet aggregation was previously demonstrated using PAMAM dendrimers with multiple copies of an A_{2A} AR agonist (added as a DMSO solution) (*10, 11*). Here, the anti-aggregatory effect of *water-soluble* PAMAM-PEG-CGS21680 dendrimer conjugates **9** and **10** was measured (Figure 4, Supporting Information Table S1). A submicromolar inhibitory effect on platelet aggregation of **10c** ($IC_{50} = 151 \pm 53$ nM) was validated, which was better than that of another high-loaded dendrimer **10d** (495 ± 145 nM) with longer PEG chains. Unlike the cAMP assay, here the potency of **10c** was similar to those of CGS21680 **1** (192 ± 90 nM) and the dendrimer-attached mimic **3** (173 ± 72 nM), but lower than that of APEC **2** (35.9 ± 17.0 nM). Dendrimer **9a** bearing eight units of short PEG chains but with only one ligand on average ($8PEG_{550}$-1CGS21680), exhibited a similar or slightly lower IC_{50}

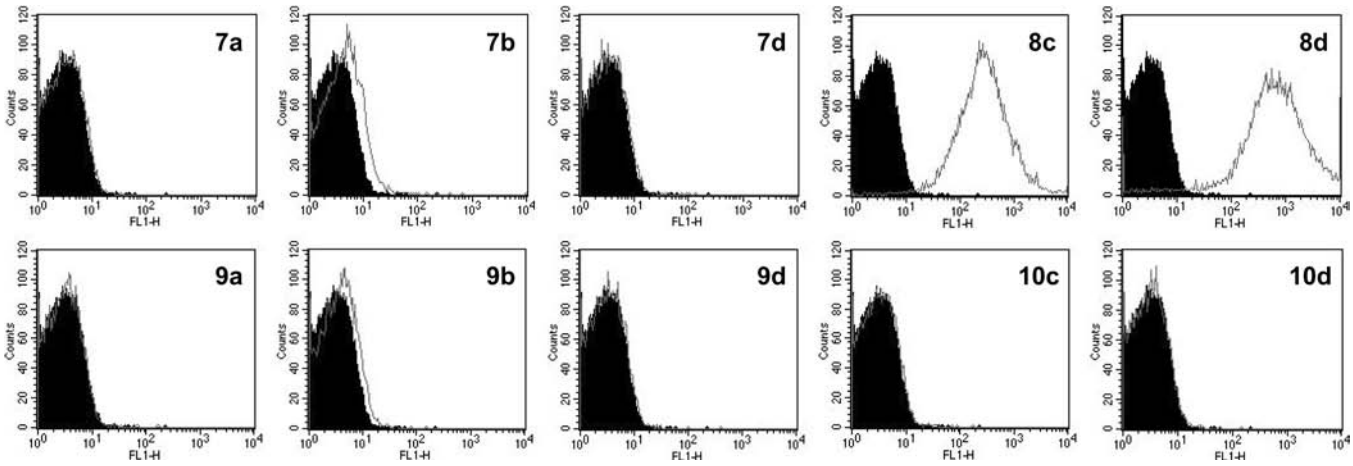

Figure 5. Flow cytometry histograms (AF_{488}, control: black area) obtained from human washed platelets incubated with 3 μM of each G3 PAMAM dendrimer conjugate for 30 min at 37 °C.

value (337 ± 77 nM) than **10d** carrying ca. 21 CGS21680 units. Accordingly, it seems apparent that the intracellular activity triggered by ligand-receptor interactions is more influenced by the length of the PEG chains (i.e., sterics) than the total number of ligands available on the dendrimer surface for a potential multivalent binding. Obviously, when the PEG size and the number of ligands were similar ($8PEG_{550}$-1CGS21680 (**9a**) vs $15PEG_{550}$-2CGS21680 (**9b**)), the dendrimer with a smaller number of PEG chains showed higher activity. Likewise, when the PEG size and its number were more or less the same ($6PEG_{2000}$-21CGS21680 (**10d**) vs $5PEG_{2000}$-1CGS21680 (**9d**); $11PEG_{750}$-14CGS21680 (**10c**) vs $8PEG_{550}$-1CGS21680 (**9a**)), the dendrimer carrying more ligands exhibited higher agonistic potency. The weakest activity was shown by **9b** and **9d**, either highly substituted with PEG or carrying long PEG chains, and both having only ca. 1−2 ligand attachments. Also, APEC **2** was found most potent in this study as in the cAMP assay, suggesting the importance of the terminal amino group in enhancing the agonistic effect. In fact, the number of unreacted amines in PAMAM-PEG-CGS21680 conjugates **9** and **10** estimated from the ^{1}H NMR integration (Table 1) was in a similar range (ca. 5−7), and thus, the modulation of the agonistic effects among dendrimers by the PAMAM amino groups is somewhat unlikely. It is important to note the moderate inhibitory effects in platelet aggregation exerted by two of the dendrimers without any ligands, **7d** (71% at 15 μM) and **8d** (40% at 7.5 μM) (Supporting Information Figure S9), suggesting the involvement of longer PEG_{2000} chains in inhibiting platelet aggregation possibly through a mechanism unrelated to the A_{2A} AR.

Flow Cytometry Analysis. Our earlier platelet uptake studies using PAMAM-CGS21680 conjugates (no PEG) showed a sustained anti-aggregatory effect, which might have resulted from the slow release of internalized conjugates as monitored by fluorescent confocal microscopy (*10*). Despite its known benefits, the presence of PEG groups on the surface of nanocarriers generally hampers the internalization process (*4*). Here, we investigated by flow cytometry[2] the potential for internalization of the PEGylated PAMAM dendrimers into human washed platelets (Figure 5; Supporting Information Figures S10 and S11). The best internalization efficiency at 3 μM (30 min incubation) was achieved by dendrimers **8c** and **8d**, which did not carry any ligand and had relatively poor water solubility. Interestingly, the water solubility of **4c** and **4d** dropped significantly upon conjugation of 1 equiv of AF_{488}, whereas that of partially acetylated **5a**, **5b**, and **5d** was not affected. A minor degree of uptake was detected from **9b** ($15PEG_{550}$-2CGS21680) and its precursor **7b**. Neither of the high-loaded dendrimers **10c** and **10d** showed any indication of internalization at 3 μM. When the dendrimer concentration was increased to 50 μM (30 min incubation), some internalization was detected from **10c** and **10d** (Supporting Information Figure S10), with **10c** being slightly higher in its efficiency. Similar observations were made in the fluorescent confocal microscopy studies (data not shown) to confirm these results. It is difficult to conclude whether the low water solubility (as demonstrated by the fully conjugated water-insoluble PAMAM-CGS21680 dendrimer (*10*)) or the presence of many cationic amino groups (*11*)—or the combination of both—aided in the effective internalization of PEGylated PAMAM dendrimers **8c** and **8d**. In any case, the internalization of dendritic controls **8c** and **8d** conceivably did not involve ligand interactions with the A_{2A} AR. This suggests the involvement of uptake pathways other than GPCR-mediated endocytosis (*16, 32, 33*) for PEGylated dendrimers into the platelets.

In conclusion, an approach to the design and synthesis of potent and water-soluble macromolecular ligands of GPCRs was demonstrated through our systematic studies on dendritic carriers. A PAMAM dendrimer conjugate bearing multiple copies of a nucleoside ligand and relatively short PEG chains manifested enhanced receptor subtype-selectivity and highly potent agonistic effects, without experiencing any disadvantageous steric effects. Longer PEG chains reduced affinity at the A_{2A} AR. With growing evidence to support the oligomerization of GPCRs and the potential intervention of ligands in GPCR clustering (*7, 29, 30*), acquiring synergistic cooperativity among ligands through multivalent binding may be desirable for GPCR therapeutics based on ligand-receptor interactions. Dendrimers of higher generations are envisioned for use in exploring multiple interactions with higher-order GPCR aggregates. In addition, the potential of PEGylated PAMAM dendrimers as carriers to deliver genes across the blood-brain barrier by derivatizing their periphery with the brain-targeting ligands has been demonstrated recently (*34, 35*). Consequently, our PEGylation strategy described in this communication may find versatile utility in various nanomedical applications aimed at multivalent ligand-receptor interactions.

[2]Strictly, fluorescent confocal microscopy analysis detects fluorescence only from the internalized dendrimers, while flow cytometry measures fluorescence from both internalized and surface-bound dendrimers. Accordingly, the estimation of internalization efficiency by flow cytometry analysis may be limited.

ACKNOWLEDGMENT

This research was supported in part by the Intramural Research Program of the NIH, NIDDK. We thank Dr. Haijun Yao at the Mass Spectrometry Laboratory of the University of Illinois for collecting MALDI spectra of our dendrimer samples,

and Dr. Herman Yeh at the NIDDK for the helpful advice on the NMR experiments. Y.K. thanks the Can-Fite Biopharma for financial support.

[a] Values are presented as the mean ± standard error of three independent experiments. Aggregation was measured at 37 °C by a turbidimetric method in a dual-channel Payton aggregometer (Payton Associates, Scarborough, Ontario, Canada). A 450 μL aliquot of human washed platelet suspension was stirred at 1100 rpm and activated by addition of ADP (5 μM), in the presence or absence of various monomers/dendrimers and in the presence of human fibrinogen (0.8 mg/mL), in a final volume of 500 μL. The extent of aggregation was estimated quantitatively by measuring the maximum curve height above the baseline level.

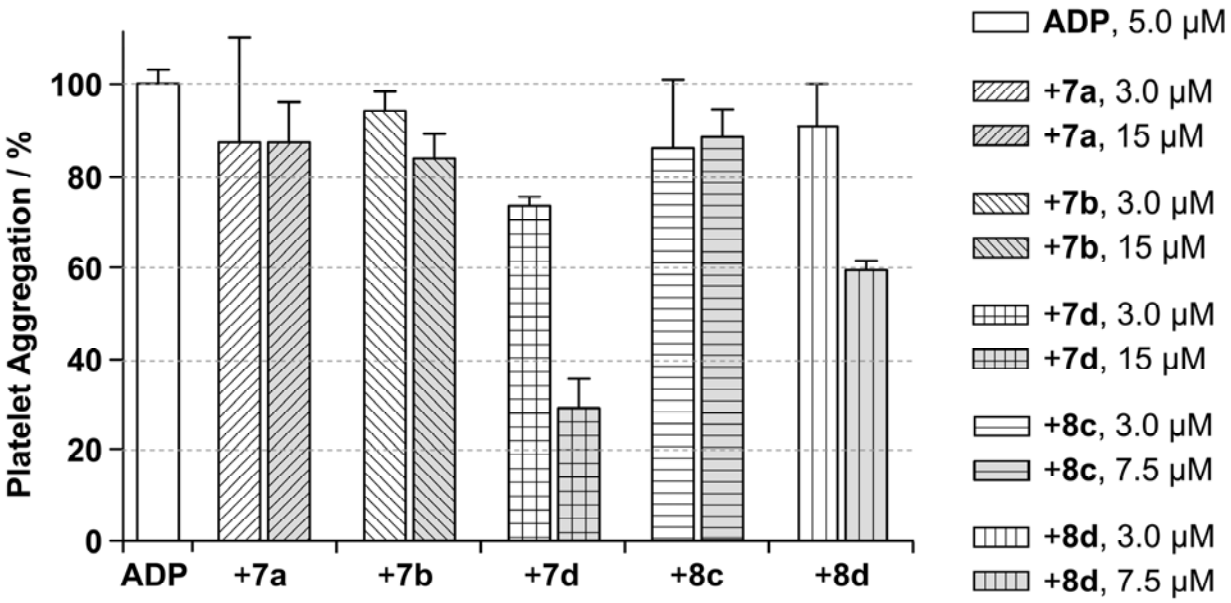

Figure S9. Platelet aggregation studies at 37 °C for dendrimer controls **7**/**8**, which did not bear any CGS21680 ligands. The degree of platelet aggregation was normalized against that induced by ADP at 5 μM (100%). A suspension of human washed platelets was incubated in the presence or absence of dendrimers, to which ADP was added 30 s later to induce the platelet aggregation. Dendrimers were added as aqueous solutions and the final concentration of each dendrimer in the media is shown (final volume: 500 μL). Each experiment was repeated three times (n = 3).

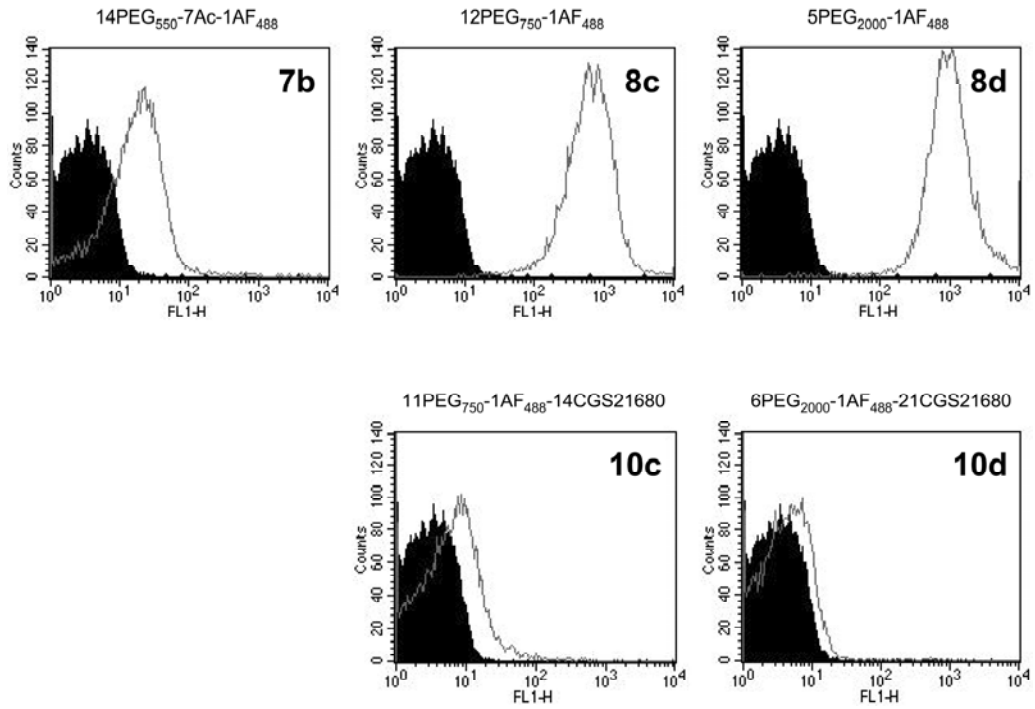

Figure S10. Flow cytometry histograms (AF_{488}, control: black area) obtained from human washed platelets incubated with 50 μM of each selected G3 PAMAM dendrimer conjugate for 30 min at 37 °C.

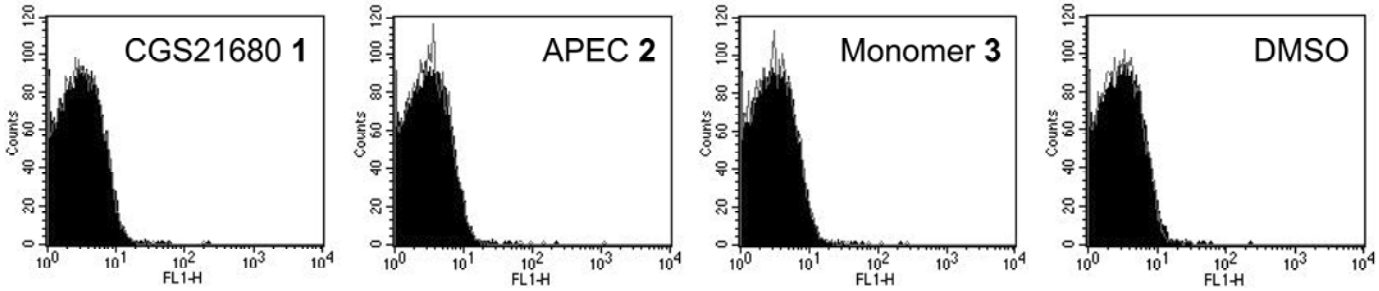

Figure S11. Flow cytometry histograms (AF_{488}, control: black area) obtained from human washed platelets incubated with 3 μM of monomeric ligands **1**–**3** or DMSO (control, same volume) for 30 min at 37 °C. Unlike dendrimer samples, stock solutions of monomeric ligands **1**–**3** were prepared in DMSO (see Experimental Section).

A New Method to Produce MonoPEGylated Dimeric Cytokines Shown with Human Interferon-α2b

Chien-Hsing Chang,*[,†,‡] Edmund A. Rossi,[†] Thomas M. Cardillo,[‡] Diane L. Nordstrom,[‡] William J. McBride,[‡] and David M. Goldenberg[§]

Received April 17, 2009; Revised Manuscript Received June 24, 2009

We have adapted the dock-and-lock (DNL) method into a novel PEGylation technology using human interferon-α2b (IFN-α2b) as an example. Central to DNL is a pair of distinct protein domains involved in the natural association between cAMP-dependent protein kinase (PKA) and A-kinase anchoring proteins (AKAPs). These domains serve as linkers for site-specific conjugation of poly(ethylene glycol) (PEG) to a dimeric form of IFN-α2b. The combination of a fusion protein comprising IFN-α2b and the dimerization-and-docking domain (DDD) of PKA with a PEG-derivatized anchoring domain (AD) of an interactive AKAP results in facile formation of a trimeric complex containing two copies of IFN-α2b and a single site-specifically linked PEG chain. Three such monoPEGylated dimers of IFN-α2b have been generated, the first with a 20 kDa linear PEG, referred to as α2b-362, the second with a 30 kDa linear PEG (α2b-413), and the third with a 40 kDa branched PEG (α2b-457). All three retained antiviral and antitumor activity *in vitro* and showed improved pharmacokinetic properties in mice, which translated into potent and prolonged therapeutic efficacy in the Daudi human lymphoma xenograft model. We anticipate wide applicability of the DNL method for developing long-acting therapeutics that are dimeric and monoPEGylated with the increased bioavailability allowing for less frequent dosing.

INTRODUCTION

Interferons (IFNs[1]), in the half-century since their discovery, have been found to regulate infections with RNA and DNA viruses, enhance innate and acquired immunity, and affect normal and tumor cell growth and death (*1*). The therapeutic effectiveness of IFNs has also been validated to date by the approval of IFN-α2 for treating hairy cell leukemia, chronic myelogenous leukemia, malignant melanoma, follicular lymphoma, condylomata acuminata, AIDS-related Kaposi sarcoma, and chronic hepatitis B and C; IFN-β for treating multiple sclerosis; and IFN-γ for treating chronic granulomatous disease and malignant osteopetrosis. Despite a vast body of literature on this group of autocrine and paracrine cytokines, their functions in health and disease are still being elucidated, including more effective and novel forms being introduced clinically (*2, 3*).

As demonstrated by PEGINTRON (*4*) and PEGASYS (*5*), the efficacy of IFNs can be enhanced by improving the bioavailability with PEGylation, a process of chemically linking PEG to the therapeutic agent of interest, with the resulting conjugate exhibiting an increased serum half-life (*6*). Additional advantages of PEGylation in general include reduced immunogenicity, decreased dosing frequency, increased solubility, enhanced resistance to proteolysis, and exclusion of renal clearance. For example, a popular approach for improving the therapeutic efficacy of an enzyme has been to prepare conjugates containing multiple PEGs of small size, as known for methioninase (*7*), L-methione γ-lyase (*8*), arginine deiminase (*9*), adenosine deaminase (*10*), L-asparaginase (*11*), and liver catalase (*12*). PEGylations of nonenzyme proteins, such as bovine serum albumin (*13*); small molecules, such as inhibitors of integrin α4β1 (*14*); anti-VEGF aptamer (*15*), and oligodeoxynucleotides (*16*), have also been described.

Because the most common reactive sites on proteins (including peptides) for attaching PEG are the ε-amino groups of lysine and the α-amino group of the N-terminal residue, most methods of PEGylation result in modification of multiple sites, yielding not only monoPEGylated conjugates consisting of mixtures of positional isomers (*4, 5*), but also adducts comprising more than one PEG chain. Nevertheless, site-specific attachment of a single PEG to the α-amino group of the N-terminal residue was reported to be the predominant product upon reacting PEG-aldehyde at low pH with IFN-β1b (*17*) or IFN-β1a (*18*). Similar strategies were applied to prepare N-terminally linked PEG to G-CSF (*19*) or type I soluble necrosis factor receptor (*20*). Site-directed PEGylation of an endogenous or engineered free cysteine residue in a target protein has also been demonstrated with PEG-maleimide for G-CSF (*21*), hemoglobin (*22*), IL-2 (*23*), IFN-α2 (*24*), GM-CSF (*25*), EPO (*26*), scFv (*27*), Fab (*28*), and miniantibodies (*29*). Moreover, the feasibility of reversible or releasable PEGylation, wherein covalently attached

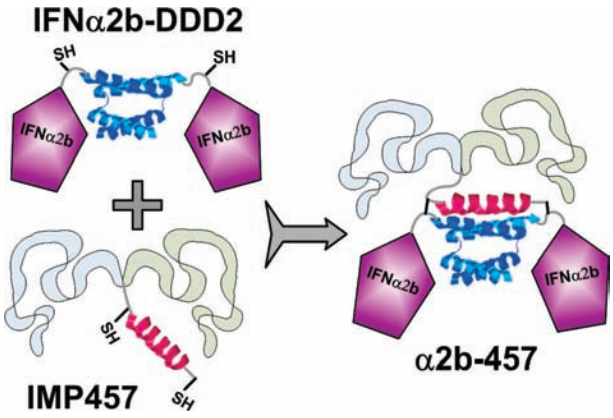

Figure 1. Schematics of IMP457, α2b-DDD2, and α2b-457. Ribbons indicate 40 kDa branched PEG; red helix, AD2; blue helix, DDD2; SH, free sulfhydryl groups of engineered cysteine residues.

PEG can be cleaved *in vivo*, has been achieved with a variety of degradable linkages as exemplified by linking a 40-kDa PEG-SH to IFN-α2 with a 2-sulfo-9-fluorenylmethoxycarbonyl-containing bifunctional reagent (*30*), by attaching linear or branched PEG-BCN3 to lyzosome or IFN-*β*1b (*31*), or by conjugating PEG to lysozyme via a dithiobenzyl urethane linkage (*32*). Recently, an innovative strategy for site-specific PEGylation of disulfide bonds has been reported (*33*), but its use may be limited to only those proteins with native disulfide bonds that are suitably oriented for such modification.

The dock-and-lock (DNL) method developed by us (*34*, *35*) provides a unique approach to build multivalent, multifunctional complexes of defined composition and retained bioactivity. The key to the DNL method is the exploitation of the specific protein−protein interactions occurring in nature between the regulatory (R) subunits of cAMP-dependent protein kinase (PKA) and the anchoring domain (AD) of A-kinase anchoring proteins (AKAPs) (*36*, *37*). Isozymes of PKA are found with two types of R subunits (RI and RII), and each type has α and *β* isoforms (*38*). The R subunits have been isolated only as stable dimers and the dimerization domain has been shown to consist of the first 44 amino-terminal residues (*39*). The AD of AKAPs for PKA is an amphipathic helix of 14−18 residues (*40*). Interestingly, AKAPs will only bind to dimeric R subunits. For human RIIα, the AD binds to a hydrophobic surface formed by the 23 amino-terminal residues (*41*). Thus, the dimerization domain and AKAP binding domain of human RIIα are both located within the same N-terminal 44 amino acid sequence (*39,42*), which is termed the dimerization and docking domain (DDD) herein.

Because an entity derivatized with the DDD (termed the DDD-module) is expected to self-associate to form a dimer, thereby creating a docking site for an entity derivatized with the AD (termed the AD-module), combining a DDD-module with an AD-module results in the formation of a noncovalent complex containing three entities, which can be stably tethered by introducing cysteine residues into the DDD and AD at strategic positions, as demonstrated with the DDD2 and AD2 (*34*).

Here, with a DDD2-module of IFN-α2b expressed as a fusion protein and three synthetic AD2-modules of different mPEG, we describe the successful adaptation of the DNL method into a novel PEGylation technology, which has the salient feature of monoPEGylating a dimeric form of IFN-α2b at a specific site that is outside the sequence of native IFN-α2b (Figure 1).

EXPERIMENTAL PROCEDURES

Generation of IMP360. The AD2-peptide with an EDANS at its carboxyl terminus to provide a fluorescent tag was termed IMP360 and made at 0.1 mmol scale with EDANS resin (Novabiochem, EMD Biosciences, Inc., San Diego, CA) on a PS3 peptide synthesizer (Protein Technologies, Tucson, Az) using Fmoc methodology. Starting from the C-terminus, the protected amino acids used were Fmoc-Cys(t-Buthio)-OH, Fmoc-Gly-OH, Fmoc-Ala-OH, Fmoc-Gln(Trt)-OH, Fmoc-Gln-(Trt)-OH, Fmoc-Ile-OH, Fmoc-Ala-OH, Fmoc-Asn(Trt)-OH, Fmoc-Asp(OBut)-OH, Fmoc-Val-OH, Fmoc-Ile-OH, Fmoc-Gln(Trt)-OH, Fmoc-Lys(Boc)-OH, Fmoc-Ala-OH, Fmoc-Leu-OH, Fmoc-Tyr(But)-OH, Fmoc-Glu(OBut)-OH, Fmoc-Ile-OH, Fmoc-Gln(Trt)-OH, Fmoc-Gly-OH, and Fmoc-Cys(Trt)-OH. The peptide was cleaved from the resin, purified by RP-HPLC, and determined to have a molecular mass of 2660 Da. The sequence of IMP360 is CGQIEYLAKQIVDNAIQQAGC(SS-tbu)-EDANS.

Generation of IMP362 and IMP413. The two linear PEG-AD2 modules were prepared by coupling IMP360 to mPEG-OPTE (Nectar Therapeutics, San Carlos, CA) of 20 kDa or 30 kDa, resulting in IMP362 or IMP413, respectively. The sulfhydryl group of the N-terminal cysteine of IMP360 displaces pyridine-2-thiol from mPEG-OPTE and forms a thioester bond to mPEG. A subsequent reaction of the adjacent amino group with the carbonyl group of the thioester leads to the formation of a more stable amide bond and the regeneration of the sulfhydryl group. To prepare IMP362, IMP360 (11.5 mg) was mixed with 20 kDa mPEG-OPTE (127 mg) in 7 mL of 1 M Tris-HCL, pH 7.8. Acetonitrile (1 mL) was added to dissolve some suspended material. The reaction was stirred at room temperature for 4 h to effect the attachment of mPEG to the amino-terminal cysteine via an amide bond. Subsequently, 41 mg of Tris [2-carboxyethyl] phosphine hydrochloride (TCEP) and 43 mg of cysteine were added to deprotect the remaining cysteine. The reaction mixtures were stirred for 1 h and desalted using PD-10 columns, which had been equilibrated with 20% methanol in water. The samples were lyophilized to obtain approximately 150 mg of IMP362 (MH^+ 23 713). IMP413 (MH^+ 34 499) was made similarly using 30 kDa mPEG-OPTE (190 mg).

Generation of IMP421 and IMP457. The AD2-containing peptide (IMP421, MH^+ 2891, Figure 2) was made for derivatizing mPEG2-MAL-40K (Nectar Therapeutics) to obtain the branched PEG-AD2 module (IMP457). IMP421 was synthesized on NovaSyn TGR resin (487.6 mg, 0.112 mmol) by adding the following amino acids to the resin in the order shown: Fmoc-Gly−OH, Fmoc-Cys(t-Buthio)-OH, Fmoc-Gly-OH, Fmoc-Ala-OH, Fmoc-Gln(Trt)-OH, Fmoc-Gln(Trt)-OH, Fmoc-Ile-OH, Fmoc-Ala-OH, Fmoc-Asn(Trt)-OH, Fmoc-Asp(OBut)-OH, Fmoc-Val-OH, Fmoc-Ile-OH, Fmoc-Gln(Trt)-OH, Fmoc-Lys(Boc)-OH, Fmoc-Ala-OH, Fmoc-Leu-OH, Fmoc-Tyr(But)-OH, Fmoc-Glu(OBut)-OH, Fmoc-Ile-OH, Fmoc-Gln(Trt)-OH, Fmoc-Gly-OH, Fmoc-Cys(t-Buthio)-OH, Fmoc-NH-PEG_3-COOH, Fmoc-Cys(Trt)-OH. The peptide was then cleaved from the resin and purified by RP-HPLC to yield 32.7 mg of a white solid. The N-terminal cysteine of IMP421 has its amino group protected as an acetyl derivative and provides a sulfhydryl group to react with the maleimide of mPEG2-MAL-40K.

IMP457 was made as follows. To a solution of IMP421 (15.2 mg, 5.26 *μ*mol) and mPEG2-MAL-40K (274.5 mg, 6.86 *μ*mol) in 1 mL of acetonitrile was added 7 mL of 1 M Tris pH 7.8. After 3 h at room temperature, the excess mPEG2-MAL-40K was quenched with L-cysteine (49.4 mg), followed by S-S-*t*Bu deprotection over 1 h with TCEP (59.1 mg). The resulting solution was dispensed into two 10K Slide-A-Lyzer dialysis cassettes (4 mL in each) and dialyzed overnight at 2−8 °C against 5 L of 5 mM ammonium acetate, pH 5.0. Following three additional 5 L buffer changes, the dialyzed solution (19.4 mL) was transferred into two 20 mL scintillation vials, frozen,

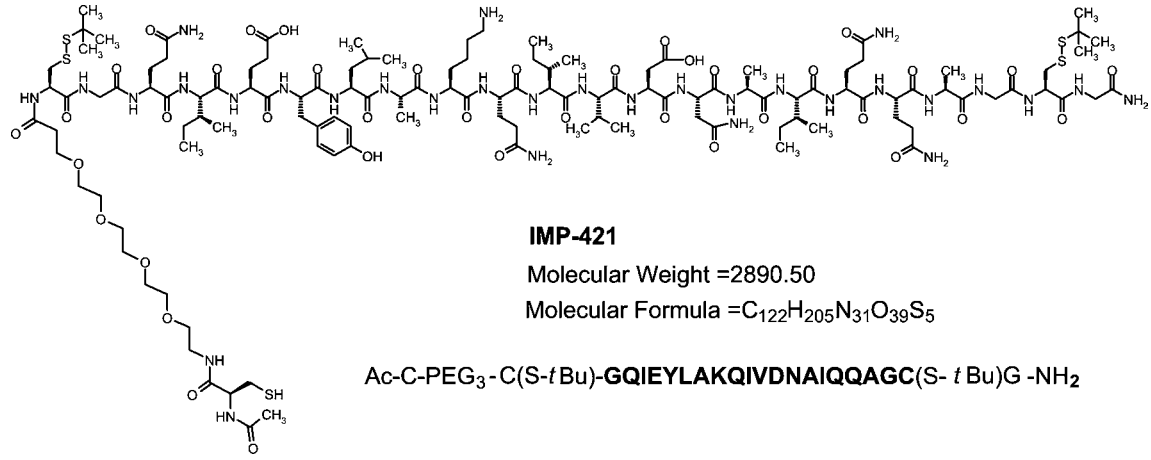

Figure 2. Schematic structure of IMP421.

and lyophilized to yield a white solid (246.7 mg). The molecular mass as determined by MALDI-TOF was 42 982 for mPEG2-MAL-40K (Supporting Information Figure S1A) and 45 500 for IMP457 (Supporting Information Figure S1B).

Generation of α2b-DDD2. All restriction enzymes were purchased from New England Biolabs (Beverly, MA). A full-length human IFN-α2b cDNA clone (Invitrogen Ultimate ORF human clone cat# HORF01Clone ID IOH35221) was used as a template for amplification by PCR to generate a sequence comprising XbaI—SP—IFN-α2b—6 His—*Bam*HI, where XbaI/*Bam*HI, SP, and 6 His are restriction sites, the signal peptide native to IFN-α2b, and a hexahistidine tag, respectively. The following oligonucleotides were synthesized by Sigma Genosys (Haverhill, UK) and used as primers.

IFNA2 XbaI left

5′-TCTAGACACAGGACCTCATCATGGCCT-TGACCTTTGCTTTACTGG-3′

IFNA2 *Bam*HI right

5′-GGATCCATGATGGTGATGATGGTGT-GACTTTTCCTTACTTCTTAAACTTTCTTGC-3′

PCR reactions were performed using Amplitaq polymerase (Applied Biosystems, Foster City, CA) and a Perkin-Elmer (Wellesley, MA) GeneAmp PCR system 9600. The PCR amplimer was cloned into the pGemT vector (Promega) from which the IFN-α2b amplimer was excised with XbaI and *Bam*HI and ligated to a DDD2-pdHL2 mammalian expression vector (*34*) previously digested with XbaI and *Bam*HI to generate *IFNα2b-DDD2-pdHL2*, the expression vector for α2b-DDD2.

IFNα2b-DDD2-pdHL2 (30 μg) was linearized by digestion with *Sal*I and stably transfected by electroporation (450 V, 25 μF) into Sp/ESF myeloma cells (2.8×10^6 cells), an engineered derivative of Sp2/0 that can be grown and transfected in serum-free medium. Transfectants were cultured in Hybridoma SFM (Invitrogen, Carlsbad, CA) supplemented with 0.2 μM methotrexate (Calbiochem, La Jolla, CA) in 96-well plates, and screened for IFN-α2b expression with a human interferon alpha ELISA kit (PBL Interferon Source, Piscataway, NJ) following the manufacturers' instructions.

α2b-DDD2 was purified from terminal batch cultures of a select clone grown in roller bottles. Briefly, the supernatant fluid was clarified by centrifugation, filtered through 0.2 μm membranes, diafiltered into 1× binding buffer (10 mM imidazole, 0.5 M NaCl, 50 mM NaH_2PO_4, pH 7.5), concentrated 20-fold, and loaded onto a Ni-NTA column (Qiagen). After washing with 0.02% Tween 20 in 1× binding buffer and then 30 mM imidazole, 0.02% Tween 20, 0.5 M NaCl, 50 mM NaH_2PO_4, pH 7.5, α2b-DDD2 was eluted with 250 mM imidazole, 0.02% Tween 20, 150 mM NaCl, 50 mM NaH_2PO_4, pH 7.5, and stored in the same buffer at 2−8 °C until needed. The mass of α2b-DDD2 was determined by MALDI-TOF to be 52 185, indicating a dimer. The monomeric form of α2b-DDD2 consists of IFN-α2b fused at its carboxyl-terminus to a 63-residue peptide of K S H H H H H H G S G G G G S G G G C G H I Q I P P G L-TELLQGYTVEVLRQQPPDLVEFAVEYFTRLREARA.

Preparation and Purification of α2b-362, α2b-413, and α2b-457. Conjugations of α2b-DDD2 with IMP362, IMP413, and IMP457 were performed to generate PEGylated α2b-362, α2b-413, and α2b-457, respectively. In general, a 10-fold molar excess of reduced and lyophilized IMP362, IMP413, or IMP457 was added to 2.25 mg of α2b-DDD2 in 3.5 mL of 250 mM imidazole, 0.02% Tween 20, 150 mM NaCl, 1 mM EDTA, 50 mM NaH_2PO_4, pH 7.5. After 6 h at room temperature in the dark, the reaction mixture was dialyzed against CM loading buffer (150 mM NaCl, 20 mM NaAc, pH 4.5) at 4 °C in the dark. The PEGylated product was purified by cation exchange chromatography using a 1 mL Hi-Trap CM-FF column (Amersham), which was equilibrated with CM loading buffer. After sample loading, the column was washed with CM loading buffer to baseline, followed by washing with 15 mL of 0.25 M NaCl, 20 mM NaAc, pH 4.5. The PEGylated product was eluted with 12.5 mL of 0.5 M NaCl, 20 mM NaAc, pH 4.5.

SDS-PAGE, Fluorescence Imaging, and Immunoblot. SDS-PAGE analyses were performed using 4−20% gradient Tris-glycine gels (Cambrex Bio Science Rockland, Rockland, ME). To normalize the samples for direct protein mass comparison, each fraction eluted from the CM-FF column was concentrated to 3.5 mL to match the reaction volume. Samples were diluted with an equal volume of 2× sample buffer (2% SDS, 5% glycerol, 62.5 mM Tris-HCl, pH 6.8) and heated to 95 °C before loading 10 μL per lane. For reducing gels, 5% of β-2-mercaptoethanol was included in the sample buffer. Gels were imaged by direct fluorescence to visualize bands containing the EDANS tag using a Kodak Image Station 4000R before staining with Coomassie blue to visualize the protein bands. Duplicate gels were transferred to PVDF membranes for immunoblot analysis. Blots were probed with rabbit anti-interferon alpha polyclonal antibody (AB1434, Chemicon International) diluted 1:1000 in 1% BSA-PBST. Signal was detected with HRP-conjugated goat antirabbit IgG (Jackson Immunoresearch) and Pierce ECL Western Blotting Substrate (Pierce Biotechnology, Rockford, IL).

Antiviral Assay. The reduction of viral cytopathic effect (CPE) was determined by an independent laboratory (PBL Interferon Source, Piscataway, NJ) using encephalomyocarditis virus (EMCV) to infect human lung epithelial A549 cells. Plates were stained with crystal violet and the OD was measured by spectrophotometry on a 96-well plate reader following solubilization of the dye. The data were analyzed with GraphPad *Prism*

software (Advanced Graphics Software, Encinitas, CA) using a sigmoidal fit (variable slope) nonlinear regression. The antiviral titer was determined by comparison of EC_{50} values with that of an IFNα standard.

Antiproliferative Assay. Each test article was diluted to 500 pM in RPMI 1640 media supplemented with 10% FBS, from which triplicate, 3-fold serial dilutions were made in 96-well tissue culture plates (50 μL/well). Daudi cells were diluted to 4 × 10^5 cells/mL and 50 μL was added to each well (20K/well). After 4 days at 37 °C, viable cell densities were determined by MTS using a CellTiter 96 Cell Proliferation Assay (Promega, Madison, WI). Dose−response curves were generated and EC_{50} values were obtained by sigmoidal fit nonlinear regression using GraphPad *Prism* software. Specific activities were determined by comparison of EC_{50} values with PEGINTRON using the specific activity provided with the product insert.

Reporter Gene Assay. The iLite Human Interferon Alpha Cell-Based Assay Kit (PBL Interferon Source) was used to determine specific activities following the manufacturers' suggested protocol. Briefly, samples were diluted in 1% BSA-PBS to 5, 1.25, and 0.3125 ng/mL for α2b-362 and α2b-413; to 10, 2.5, and 0.625 ng/mL for α2b-457 and PEGASYS; and to 1, 0.25, and 0.0625 ng/mL for PEGINTRON. Each dilution was assayed in triplicate and incubated overnight with the supplied cells. Specific activities were extrapolated from a standard curve generated with the supplied standard.

Pharmacokinetics in Mice. The initial study evaluating α2b-362, α2b-413, PEGINTRON, and rhIFN-α2a (Chemicon IF007, lot 06008039084) was performed in 4 groups of adult female Swiss-Webster mice (∼35 g) with 2 animals in each group. Each test article was administered as a single bolus i.v. injection at mole-equivalent dose: rhIFN-α2a, 3 μg; PEGINTRON, 5 μg; α2b-362, 11 μg; and α2b-413, 13 μg. Mice were bled via the retro-orbital method at various time points (predose, 5 min, and 2, 8, 24, 48, 72, 96, and 168 h postinjection). The subsequent study evaluating α2b-457, α2b-413, PEGINTRON, and PEGASYS was performed in 4 groups of adult male Swiss-Webster mice (∼40 g) with 4 animals in each group. Each test article was administered as a single s.c. injection at mole-equivalent dose (100 pmol) in equal volumes (250 μL). Mice were bled via the retro-orbital method at various time points (30 min, and 2, 8, 24, 48, 72, and 96 h postinjection). For each study, the blood was allowed to clot, centrifuged, and the serum removed for storage at −70 °C until analysis. Concentrations of IFN-α in the serum samples were determined using a human interferon alpha ELISA kit (PBL Interferon Source) following the manufacturers' instructions. Briefly, the serum samples were diluted appropriately according to the human IFN-α standard provided in the kit. The antibody immobilized to the microtiter plate wells captures interferon. A second antibody is then used to reveal the bound interferon, which is quantified by antisecondary antibody conjugated to horseradish peroxidase (HRP) following the addition of tetramethyl benzidine. The plates were read at 450 nm. The amount of IFN in the serum for each animal was used to determine the various PK parameters. These data were analyzed with *WinNonLin PK* software (v 5.1; Pharsight Corp.; Mountain View, CA) using noncompartmental analysis (representing the best-fit model for the data).

***In Vivo* Antitumor Efficacy.** All four studies were performed with the approval of the local animal care and use committee in eight-week-old female SCID mice injected i.v. with 1.5 × 10^7 Daudi cells per animal. Therapy commenced 1 day after the Daudi transplantation. Mice were observed daily for signs of distress and paralysis. They were weighed weekly. In the event a mouse lost greater than 15% of its body weight (but <20%), it was weighed every 2 days until it either gained back its weight to <15% loss or was sacrificed due to >20% loss.

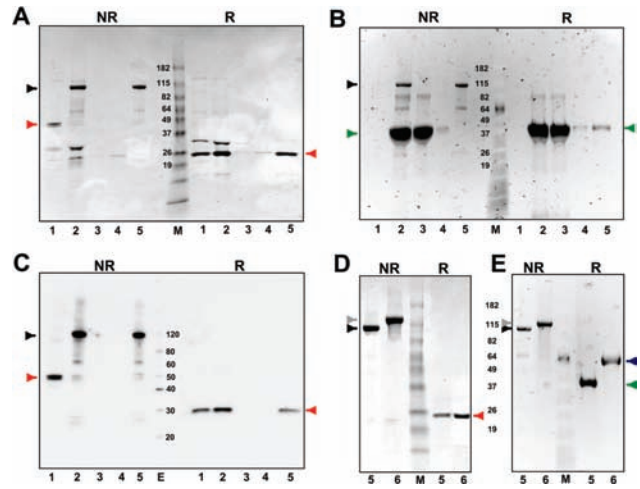

Figure 3. Reducing (R) and nonreducing (NR) SDS-PAGE analysis of the conjugation and purification of α2b-362 and α2b-413. Gels were stained with Coomassie blue (A,D), imaged with direct fluorescence (B,E), or transferred to PVDF membranes and probed by immunoblotting with anti-IFN-α (C). Arrowheads show the positions of α2b-362 (black), α2b-413 (gray), IFNα2b-DDD2 (red), IMP362 (green), and IMP413 (blue). Lane 1, IFNα2b-DDD2; Lane 2, the reaction mixture of α2b-362 before purification; Lane 3, unbound fraction of α2b-362; Lane 4, wash fraction of α2b-362 (0.25 M NaCl elution); Lane 5, purified α2b-362 (0.5 M NaCl elution); Lane 6, purified α2b-413; Lane M, prestained molecular weight markers; Lane E, ECL molecular weight markers.

Mice were also terminated when hindlimb paralysis developed or if they became otherwise moribund.

For the first study, there were 10 different treatment groups of 5 mice each. Equivalent units of activity of PEGINTRON, α2b-362, and α2b-413 were administered once every 7 days via s.c. injection in either the left or right flank at 3 different doses (3500, 7000, and 14 000 IU). In the second study, 14 000 IU of PEGINTRON or α2b-413 was administered s.c. with varied dosing schedules: once weekly for 4 weeks (q7d×4), once every other week over 8 weeks (q2wk×4), and once every 3 weeks over 12 weeks (q3wk×4). There were 7 different treatment groups of 6−7 mice each. All mice received a total of 4 injections. The third study was performed in 4 treatment groups of 10 each, evaluating 14 000 IU of α2b-413, PEGASYS, or PEGINTRON given s.c. once every 4 weeks vs once weekly. In the fourth study, α2b-457 was compared with α2b-413, PEGINTRON, and PEGASYS in 2 different doses (20 and 10 pmol) given 4 weeks apart.

RESULTS AND DISCUSSION

Design and Characterization of α2b-362 and α2b-413. We produced a DDD2 module of IFN-α2b with a hexahistidine tag in myeloma cells and synthesized two AD2 modules of linear PEG, one with a 20 kDa PEG, designated IMP362, and the other with a 30 kDa PEG, designated IMP413. In addition, each PEG-AD2 module also contains EDANS as a fluorescent tag. The fusion protein (α2b-DDD2) was reacted with IMP362 and IMP413 in excess to yield the two PEGylated conjugates, α2b-362 and α2b-413, respectively, which were purified by cation exchange chromatography at pH 4.5. The DNL process for generating α2b-362 was analyzed by nonreducing (NR) and reducing (R) SDS-PAGE with three visualization methods: Coomassie blue staining (Figure 3A,D), fluorescence imaging (Figure 3B,E), and immunoblotting (Figure 3C). The Coomassie blue-stained gel shown in Figure 3A revealed the presence of a major band of ∼110 kDa in the reaction mixture (lane 2, NR), which was absent in the unbound (lane 3, NR) or 0.25 M NaCl wash (lane 4, NR), but evident in the 0.5 M NaCl fraction (lane

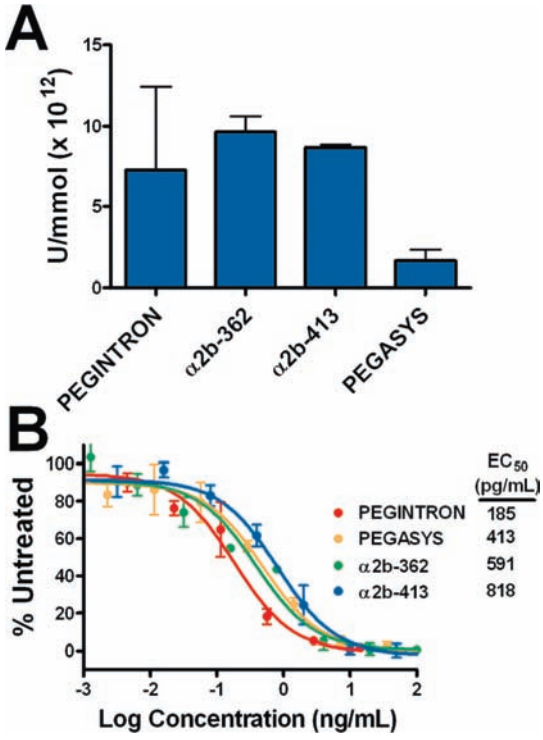

Figure 4. *In vitro* bioactivity assays. (A) Reduction of CPE was performed with EMCV challenge of A549 cells to determine the antiviral specific activity of each test article. The antiviral titer was determined by comparison of EC_{50} values with that of an IFNα standard. (B) Antitumor activity was determined be measuring the inhibition of Daudi proliferation *in vitro*. Dose−response curves were generated from a 4 day MTS assay. The percent of the signal obtained from untreated cells was plotted vs the log of the concentration in ng/mL. EC_{50} values were obtained with GraphPad *Prism* software. Data shown are representative of multiple repeated experiments.

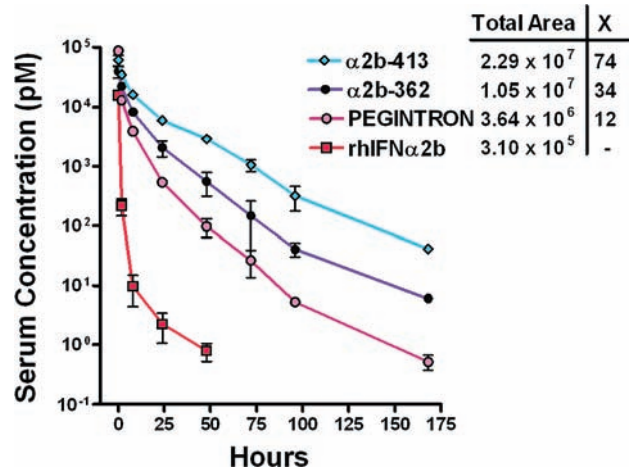

Figure 5. Blood clearance in Swiss-Webster mice following a single i.v. injection of each agent at equimolar protein dose, with concentrations in serum at various time points determined by ELISA. The data shown were the mean values from two animals. X denotes the fold-increase of total area over that of rhIFNα2b.

5, NR). Fluorescence imaging was used to detect the EDANS tag on IMP362, and the results shown in Figure 3B indicate the presence of covalently attached IMP362 in the 110 kDa band (lanes 2 and 5, NR) as well as the presence of excess IMP362, which does not stain with Coomassie blue. Immunoblotting with anti-IFN-α confirmed the inclusion of IFN-α2b in the 110 kDa band (Figure 3C, lanes 2 and 5, NR and R). The average mass of α2b-326 was determined by MALDI-TOF to be 76 728 Da, which is close to the sum (75 898 Da) of the mass of one dimeric IFN-α2b-DDD2 (52 185 Da) and one IMP362 (23 713 Da). The observed discrepancy between the measured mass (∼77 kDa) by MALDI- TOF and the estimated molecular weight (∼110 kDa) by SDS-PAGE is due to PEG, which is known to increase the apparent molecular weight of PEGgylated products as determined by SDS-PAGE or SE-HPLC (*43*, *44*). In all reducing gels, the components of α2b-362 (lane 5) are dissociated into IMP362 and the monomeric form of α2b-DDD2, as expected. For α2b-413, which was generated and purified similarly, both Coomassie blue staining (Figure 3D) and fluorescence imaging (Figure 3E) show a major band of ∼125 kDa (lane 6, NR) migrating behind α2b-362 (lane 5, NR). Moreover, reducing SDS-PAGE shows only the presence of a single band corresponding to the monomeric form of α2b-DDD2 for both α2b-362 (lane 5, R) and α2b-413 (lane 6, R) by Coomassie blue staining, and the two distinct bands corresponding to IMP362 (Figure 3E, lane 5, R) and IMP413 (Figure 3E, lane 6, R) by fluorescence imaging. These results demonstrate that α2b-362 and α2b-413 were generated as designed and substantially pure.

The biological activities of α2b-362 and α2b-413 were compared with PEGINTRON and PEGASYS by measuring the cytopathic effect (CPE) of encephalomyocarditis virus (EMCV) on human lung epithelial A549 cells, and the resulting EC_{50} values were calculated to determine the antiviral specific activities based on a validated IFN-α2b standard. As shown in

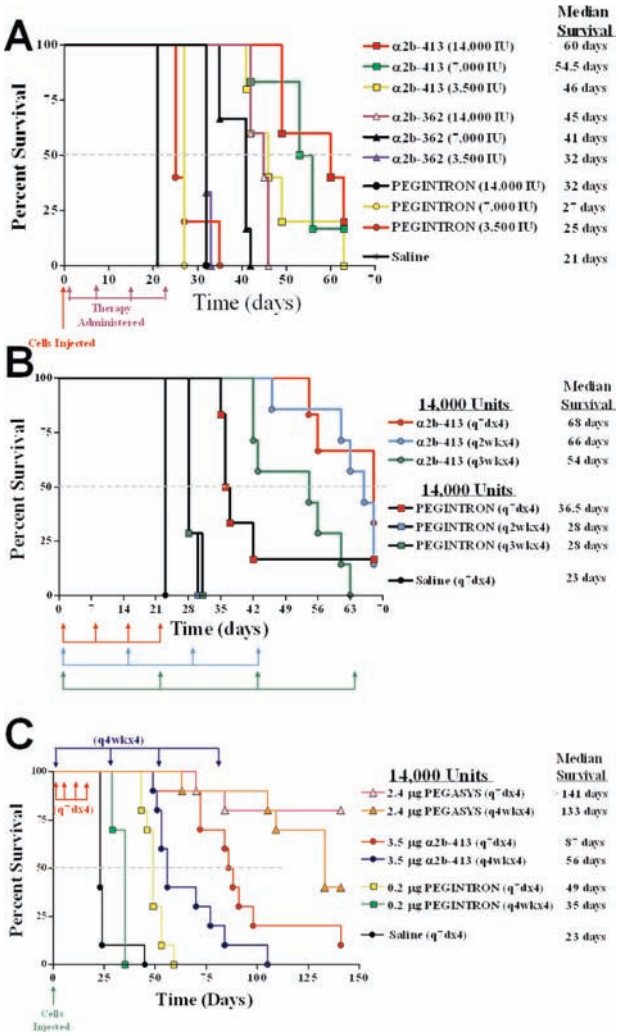

Figure 6. Antitumor efficacy in Daudi models. Units of activity were based on *in vitro* antiproliferation assay. Injection times are indicated with arrows, and median survival is shown for each treatment regimen. (A) Three different doses of each test article were given s.c. weekly for 4 weeks one day after inoculating Daudi cells. (B) Three different dosing schedules (q7d×4, q2wk×4, and q3wk×4) were evaluated in groups of 6−7 mice administered 4 × 14 000 IU s.c. of PEGINTRON or α2b-413. (C) Two different dosing schedules (q7d×4 and q4wk×4) were evaluated in groups of 10 mice administered 14 000 IU s.c. of PEGASYS, PEGINTRON, or α2b-413.

Figure 4A, on a molar basis, α2b-362, α2b-413, and PEGINTRON all have similar specific activities (averaging 7×10^{12} to 9×10^{12} U/mmol) and are about 5-fold more potent than PEGASYS. These data indicate that site-specific PEGylation by DNL may preserve biological activity better, particularly when using large PEG molecules. In addition, a cell-based kit, which utilizes a transgenic human pro-monocyte cell line carrying a reporter gene fused to an interferon-stimulated response element, was used to determine the specific activities of α2b-362 and α2b-413 to be 2940 IU/pmol and 816 IU/pmol, respectively, both of which were higher than PEGASYS (170 IU/pmol) but lower than PEGINTRON (3400 IU/pmol).

We also compared the antiproliferative activity of α2b-362 and α2b-413 with PEGINTRON and PEGASYS in Daudi lymphoma, with the finding (Figure 4B) that α2b-362 and α2b-413 had 2−3-fold lower EC_{50} values than PEGINTRON (~1×10^{12} U/mmol vs 2.2×10^{12} U/mmol), but comparable to PEGASYS.

We next determined the pharmacokinetics (PK) of α2b-362 and α2b-413 in mice following a single i.v. injection and compared to those of PEGINTRON and recombinant human

IFN-α2b (rhIFN-α2b). The PK properties of each agent are summarized in Table 1 and the elimination curves are plotted in Figure 5. As expected, rhIFN-α2b cleared most rapidly from the blood of injected mice, approximately 3-fold faster than PEGINTRON and more than 13-fold faster than 2b-362 or 2b-413, either of which clears about 4-fold more slowly than

PEGINTRON, with little difference in the elimination rates between α2b-362 and α2b-413. As for mean residence time (MRT), a clear correlation with size is apparent among the various agents: the larger the molecular size, the longer the MRT. Finally, a test for bioequivalence showed that none of the agents tested were the same in terms of PK.

We then investigated the antitumor therapeutic efficacy of α2b-362 and α2b-413 in a Daudi mouse xenograft model. In the initial study, PEGINTRON, α2b-362, and α2b-413, at equivalent units of activity based on the *in vitro* growth inhibition assay, were each administered once weekly at three different doses (3500, 7000, and 14 000 IU), commencing 1 day after tumor inoculation. Survival curves and median survival time (MST) are provided in Figure 6A, which shows that PEGINTRON, α2b-362, and α2b-413 all demonstrate significant improvement in survival when compared to saline control ($P < 0.0016$), and the efficacy of α2b-362 or α2b-413 at the lowest dose (3500 IU) was similar to or better than that of PEGINTRON at the highest dose (14 000 IU). Both α2b-362 and α2b-413 at the two higher doses (7000 and 14 000 IU) were significantly superior to PEGINTRON ($P < 0.0027$). Moreover, α2b-413 was significantly more active than α2b-362 ($P < 0.0025$) when administered at equivalent doses. Although the MST of mice treated with the 14 000 IU dose was 60 days compared to 46 days of those treated with the 3500 IU dose, there were no statistically significant differences in survival benefit among the three doses of α2b-413 ($P = 0.1255$). These *in vivo* efficacy results correlate well with the PK data and demonstrate that the two monoPEGylated dimers of IFN-α2b made by the DNL method are more potent and longer-lasting than PEGINTRON, which prompted us to test whether less frequent dosing would be feasible with α2b-413.

We performed a second study in which PEGINTRON and α2b-413 at equal units of activity were administered with varied dosing schedules (Figure 6B). All animals that received either form of IFN at any of the various schedules had significantly improved survival in comparison to saline control mice ($P < 0.0009$). For biweekly (q2wk×4) therapy, mice treated with α2b-413 had significantly improved survival compared to those treated with PEGINTRON (MST = 66 days vs 28 days; $P = 0.0002$). Importantly, mice treated on a three-week schedule with α2b-413 (q3wk×4) not only had significantly improved survival in comparison to those treated with PEGINTRON at the same schedule (MST = 54 days vs 28 days; $P = 0.0002$), but also showed longer MST than those treated with PEGINTRON biweekly (MST = 28 days; $P = 0.0002$). However, when compared with mice treated with PEGINTRON weekly (MST = 36.5 days), the *P* value (0.3901) is statistically insignificant, as one mouse survived in this group.

In a third study (Figure 6C), we found that administering α2b-413 at 14 000 IU on a four-week schedule increased the MST to 56 days from 23 days of the saline control and was more potent than PEGINTRON given 14 000 IU every week. However, the group of mice treated with PEGASYS on a four-week schedule at 14 000 IU had a median survival of 133 days, which was considerably longer than that observed with α2b-413.

***In Vitro* and *In Vivo* Characterization of α2b-457.** For a better comparison with PEGASYS, we also conjugated IFNα2b-DDD2 to IMP457, an AD2-module of 40 kDa branched PEG, and obtained the resulting α2b-457 of substantial purity in the 0.5 M NaCl fraction off the CM column, as shown in Figure 7 (lane 1, NR and R). The average mass of α2b-457 was determined by MALDI-TOF to be 97 831 Da (Supporting Information Figure S1C), which is close to the sum (97 685 Da) of the mass of one dimeric α2b-DDD2 (52 185 Da) and one IMP457 (45 500 Da). The *in vitro* biological activities of α2b-457 were determined by three different assays (Figure 8A−C) to be lower than that of PEGINTRON, comparable to that of α2b-413, and considerably higher than that of PEGASYS. The PK data obtained in mice with a single s.c. injection are shown in Figure 9, which indicates a longer circulating half-life of α2b-457 than either α2b-413 or PEGASYS, with all three clearing much more slowly than PEGINTRON. Table 2 summarizes the key PK parameters calculated; the observed differences in AUC or C_{max} between α2b-457 and each of α2b-413, PEGASYS, and PEGINTRON, or between α2b-413 and PEGASYS or PEGINTRON, are significant by statistical analysis (data not shown). When given on a four-week schedule at a low dose of 20 pmol, α2b-457 extended the median survival of Daudi-bearing mice to 47 days from 23 days of the saline group (Figure 10) and was significantly better than either α2b-413 or PEGINTRON at 20 pmol (MST = 47 days vs 41 and 37 days, respectively; $P < 0.0151$) but was inferior to PEGASYS given either at 10 or 20 pmol. The 20 pmol dose of α2b-413 also improved survival in comparison to PEGINTRON ($P = 0.002$). At 10 pmol, there was no difference between α2b-457

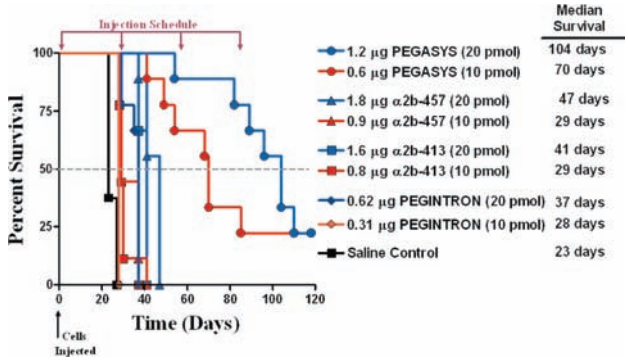

Figure 10. Antitumor efficacy of α2b-457, α2b-413, PEGINTRON, and PEGASYS in a Daudi xenograft model. Two different doses of each agent were given s.c. once every 4 weeks. Not all groups received all four injections. Treatment started one day after inoculating Daudi cells.

and α2b-413, but both significantly improved survival over PEGINTRON-treated mice ($P < 0.001$).

CONCLUSIONS

These studies show that the *in vitro* antiviral and antiproliferative activities of α2b-362, α2b-413, and α2b-457 are higher than PEGASYS but lower than or similar to PEGINTRON. The PK data obtained in mice indicate superiority of all three DNL complexes over PEGINTRON and comparability of α2b-413 and a2b-457 to PEGASYS. Both α2b-413 and α2b-457 display potent antitumor activity in Daudi human Burkitt lymphoma models superior to PEGINTRON. Intriguingly, α2b-457, despite its more favorable PK, is not as effective as PEGASYS in the Daudi model. Noting that the antiproliferative and antiviral activities of IFN-α are separate (*45*), such suboptimal antitumor response may be an attractive property of α2b-457, since it could suggest less toxicity of α2b-457 than PEGASYS to hematological and other normal cells *in vivo*. The generation of antibodies to IFN in patients during IFN therapy is well-known (*46*). For example, the incidence of neutralizing antibodies to various IFN preparations was found to be 20−38% for rhIFN-α2a, 3−10% for rhIFN-α2b, and less than 2% for natural IFN-α (*47*). For PEGASYS, 2% (8/409) of patients developed low-titer neutralizing antibodies and 6% (24/409) of patients developed binding antibodies to IFN-α2a (*48*). In mice, recombinant human IFN-α2a was reported to induce neutralizing antibodies, whereas its 40 kDa branched PEGylated form (PEGASYS) appeared to be little or not immunogenic (*5*). Because α2b-457 also comprises the 40 kDa branched PEG as PEGASYS, we would expect similarly reduced immunogenicity of α2b-457 in mice and even more so in humans. Thus, although the immunogenicity of α2b-457 is still a valid concern, these encouraging preliminary results provoke clinical evaluation of α2b-457 as well as the anticipation of a broader use of the DNL method for developing other PEGylated cytokines.

ACKNOWLEDGMENT

We thank Meiyu Loo and Eric Chan for producing α2b-DDD2 in cell culture, John Kopinski for preparing α2b-362, α2b-413, and α2b-457, Christopher D'Souza for providing IMP421 and IMP457, Diana Pilas and Preeti Trisal for processing PK data, and Anju Nair and Maria Zalath for performing animal studies.

PAMAM-RGD Conjugates Enhance siRNA Delivery Through a Multicellular Spheroid Model of Malignant Glioma

Carolyn L. Waite[†] and Charles M. Roth*[,†,‡]

Department of Chemical and Biochemical Engineering and Department of Biomedical Engineering, Rutgers University, 599 Taylor Road, Piscataway, New Jersey 08854. Received June 1, 2009; Revised Manuscript Received August 14, 2009

Generation 5 poly(amidoamine) (PAMAM) dendrimers were modified by the addition of cyclic RGD targeting peptides and were evaluated for their ability to associate with siRNA and mediate siRNA delivery to U87 malignant glioma cells. PAMAM-RGD conjugates were able to complex with siRNA to form complexes of approximately 200 nm in size. Modest siRNA delivery was observed in U87 cells using either PAMAM or PAMAM-RGD conjugates. PAMAM-RGD conjugates prevented the adhesion of U87 cells to fibrinogen-coated plates, in a manner that depends on the number of RGD ligands per dendrimer. The delivery of siRNA through three-dimensional multicellular spheroids of U87 cells was enhanced using PAMAM-RGD conjugates compared to the native PAMAM dendrimers, presumably by interfering with integrin-ECM contacts present in a three-dimensional tumor model.

INTRODUCTION

Gene silencing using RNA interference (RNAi) is a powerful platform technology being developed clinically for a variety of diseases including cancer, where it is typically considered as part of a multipronged approach (*1, 2*). While RNAi holds promise as an anticancer therapeutic modality, the ability to efficiently and safely deliver siRNA molecules to cells is the main barrier limiting its widespread clinical use (*3*). The use of synthetic, nonviral delivery vectors such as polymers and liposomes has shown promise in mediating cellular delivery of siRNA molecules (*4*). Benefits of synthetic delivery vectors include their ability to be manufactured on a large-scale, low immunogenic response compared to their viral counterparts and the ability to chemically tailor their structure for a particular application.

Poly(amidoamine) (PAMAM) dendrimers are a family of highly branched, synthetic polymers that have garnered interest as potential delivery vectors for nucleic acids, recently including siRNA. Several studies have demonstrated successful delivery of siRNA using PAMAM dendrimers or their derivatives (*5*−*10*). The branched architecture of dendrimers makes them particularly attractive for targeted delivery applications, as they can present targeting ligands in a manner favorable to promote multivalent binding to target cellular receptors. Multivalent ligand presentation from PAMAM dendrimers has been demonstrated for various targeted systems including folic acid (*11*), mannose, and glucose (*12, 13*).

Integrin proteins are a family of cell-surface receptors, several of which are known to be overexpressed on the surface of cancer cells. The $\alpha_v\beta_3$ integrin is particularly known for its role in cancer progression and is overexpressed in melanomas, glioblastoma, ovarian, breast, and prostate cancers (*14*). The high-affinity interaction between RGD peptides and cancer-related integrins has led to the widespread use of RGD peptide sequences as ligands for integrin-targeted drug and gene delivery applications (*15*). Several examples of PAMAM dendrimer-RGD conjugates have been reported to enhance the delivery of imaging agents to target carcinoma cells (*16, 17*). PAMAM-RGD conjugates have also been found to mediate cellular binding and adhesion (*18, 19*).

As significant promise has been shown for PAMAM-RGD conjugates in drug delivery and imaging applications, the goal of this study was to evaluate this bioconjugate for use as a siRNA delivery vector. Specifically, we sought to investigate the effects of extent of ligand functionalization (multivalency) on cellular delivery. To this end, the ability of dendrimers to deliver siRNA to malignant glioma cells with varying extents of RGD conjugation was evaluated. Furthermore, we hypothesized that the ligand presentation would have a greater impact on delivery in a three-dimensional tumor, where the interactions among the delivery vector, extracellular matrix, and cells are more pronounced. To evaluate this hypothesis, the ability of PAMAM-RGD conjugates to interfere with cell−ECM interactions and to mediate siRNA delivery in a three-dimensional cell-culture model of malignant glioma was studied.

EXPERIMENTAL PROCEDURES

Materials. A 22 nt siRNA sequence previously identified as an effective inhibitor of pd1EGFP expression (*20*) (sense strand 5′-UUG UGG CCG UUU ACG UCG CCG U-3′, antisense strand 3′-UGA ACA CCG GCA AAU GCA GCG G-5′) and an irrelevant siRNA sequence (targeted against firefly luciferase; sense strand 5′-CUU ACG CUG AGU ACU UCG A dTdT-3′, antisense strand 5′-UCG AAG UAC UCA GCG UAA G dTdT-3′) were purchased from Dharmacon (Chicago, IL). A fluorescently labeled anti-GFP siRNA sequence (5′ Cy3 end modified on the sense strand) was purchased from Integrated DNA Technologies (Coralville, IA, USA). A 20 nt phosphorothioated antisense oligonucleotide targeted against pd1EGFP with a fluorescent label was also purchased from Integrated DNA Technologies (5′-Cy5-TTG TGG CCG TTT ACG TCG CC-3′). The lyophilized powder was resuspended according to the manufacturer's protocol before use. Generation 5 PAMAM dendrimers with an ethylenediamine core and amine terminal groups were purchased as a 5 wt % solution in methanol from Dendritech (Midland, MI). Unless otherwise stated, all chemicals

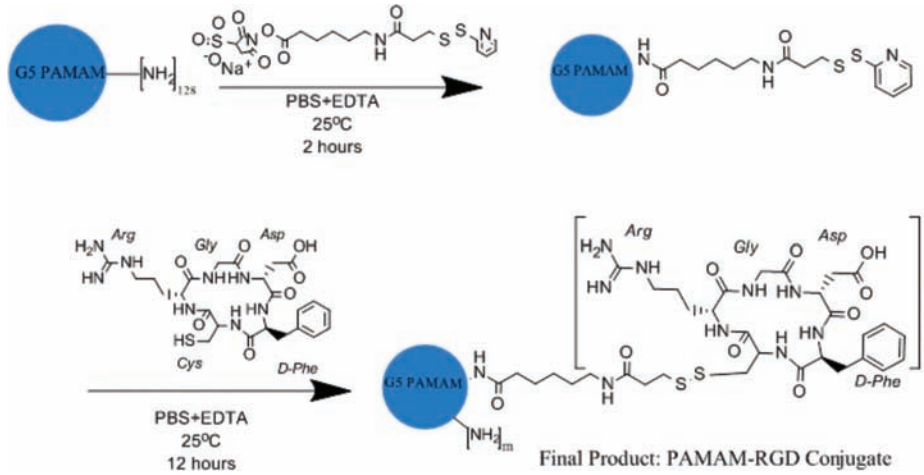

Figure 1. PAMAM dendrimers are reacted with Sulfo-LC-SPDP to yield SPDP-activated PAMAM intermediates. SPDP-activated PAMAM was reacted with cyclic RGD peptides to obtain final PAMAM-RGD conjugates.

were purchased from Sigma, and all cell culture products were obtained from Invitrogen (Carlsbad, CA).

Conjugation of PAMAM Dendrimers with RGD Peptides. Approximately 6 mg of dry generation 5 PAMAM dendrimers was obtained after the removal of methanol from the storage solution using rotary evaporation. The polymer residue was dissolved in ~2 mL of phosphate buffered saline (PBS) with 1 mM EDTA (reaction buffer). Various molar equivalents (6, 9, 12, or 15) of a Sulfo-LC-SPDP cross-linker (Pierce, Rockford, IL) were added to the polymer solution to yield SPDP-activated PAMAM after a 2 h reaction at room temperature. Dialysis with a 10 000 MWCO Slide-A-Lyzer dialysis cassette (Pierce, Rockford, IL) was performed against 1 L of reaction buffer overnight to remove any unreacted SPDP cross-linker. Following dialysis, 1.5 mol equiv (to SPDP groups added) of cyclic RGDfC peptide (Peptides International, Louisville, KY) were added to the SPDP-activated PAMAM dendrimers to yield PAMAM-RGD conjugates after an overnight reaction (Figure 1). Following conjugation, 10 000 MWCO dialysis was performed against reaction buffer followed by water to remove any unreacted RGD peptide. Purified PAMAM-RGD conjugates were lyophilized overnight to obtain a white powder.

UV Spectrophotometry of PAMAM-RGD Conjugates. A series of PAMAM-RGD conjugates were characterized using UV spectrophotometry to determine the number of RGD peptides conjugated to each dendrimer. A disulfide reducing agent, DTT, was used to cleave the disulfide bond present in the SPDP cross-linker to release pyridine-2-thione (P2T), which has a UV absorbance at 343 nm. This analysis of pyridine-2-thione release was first performed on the intermediate product, PAMAM-SPDP, and used to quantify the average number of SPDP groups added to each dendrimer. After removal of excess SPDP by dialysis, 50 μL of the PAMAM-SPDP solution was added to 450 μL of reaction buffer, and the absorbance of the solution at 343 nm was read using a Unicam UV 300 model UV spectrophotometer (Thermo Spectronics, Rockford, IL) (this reading indicated background absorbance). To the same sample, 5 μL of DTT (Pierce, Rockford, IL) (15 mg/mL) was added, and the absorbance at 343 nm was recorded after a 15 min incubation at room temperature. The increase in UV absorbance observed after the addition of DTT corresponded to the addition of LC-SPDP groups to dendrimers. The average molar ratio of SPDP:PAMAM was calculated according to the manufacturer's protocol (Pierce, Rockford, IL). The same analysis was performed on the final PAMAM-RGD conjugate to confirm replacement of all SPDP groups with RGD peptides. After the replacement of P2T groups by RGD peptides, an increase in UV absorbance at 343 nm was not observed.

MALDI-TOF Mass Spectrometry. PAMAM-RGD conjugates were dissolved in water at a concentration of 1 mg/mL prior to MALDI-TOF MS analysis. A matrix solution of 2′-4′-6′-trihydroxyacetophenone monohydrate (THAP) (10 mg/mL THAP in 50%ACN/(50% H_2O with 0.1% trifluoroacetic acid)) was used. The matrix solution and PAMAM dendrimers were mixed 1:1 by volume and spotted on a 100-well stainless steel sample plate. MALDI-TOF MS analysis was performed in linear positive mode of a Voyager DE Pro instrument (Applied Biosystems) using 25 kV accelerating voltage, 95% grid voltage, 0.3% guide wire voltage, and a delay time of 700 ns. For each spectrum, 75 shots were taken, and a minimum of 3 spectra were accumulated for each sample.

PicoGreen Assay for PAMAM/siRNA Complexation. Complexes were prepared at various charge ratios by mixing equal volumes of PAMAM with siRNA in PBS. Charge ratios (N/P) were calculated as a ratio of the number of primary amines in the polymer to the number of anionic phosphate groups in the siRNA. The samples were then vortexed and incubated at room temperature for 15 min to ensure complex formation. The complexes were prepared at a final siRNA concentration of 0.2 μg of siRNA/100 μL of solution and varying polymer concentrations to reach the desired charge ratio. One hundred microliter aliquots of each complex were transferred to a 96-well (black-walled, clear-bottom, nonadsorbing) plate (Corning, NY, USA). A total of 100 μL of diluted PicoGreen dye (Molecular Probes, Eugene, OR) (1:200 dilution in Tris-EDTA (TE) buffer) was added to each sample. Fluorescence measurements were made after a 30 min incubation at room temperature using a DTX800 Multimode Detector (Beckman Coulter, CA), at exitation and emission wavelengths of 485 and 535 nm, respectively. All measurements were corrected for background fluorescence from a solution containing only buffer and PicoGreen dye.

Dynamic Light Scattering. Dynamic light scattering (DLS) analysis was performed using a Malvern Instruments Zetasizer Nano ZS-90 instrument (Southboro, MA) with reproducibility verified by collection and comparison of sequential measurements. Polymer/siRNA complexes (siRNA concentration = 100 nM, N/P = 15) were prepared using purified water (resistivity = 18.5 MΩ cm). DLS measurements were performed at a 90° scattering angle at 37 °C. *Z*-average sizes of three sequential measurements were collected and analyzed approximately 30 min after the polymer/siRNA complexes were formed.

Cell Culture. U-87 MG cells (ATCC HTB-14) were maintained in D-MEM medium supplemented with 10% fetal bovine serum (FBS), L-glutamine, and penicillin−streptomycin solution. A U87 cell line containing a stably integrated destabilized EGFP (d1EGFP) transgene (U87-d1EGFP) was generated as described

previously (*10*) and was maintained under constant selective pressure by G418 (500 ug/mL), and the growth medium was supplemented with sodium pyruvate and nonessential amino acids. All cell lines were cultivated in a humidified atmosphere of 5% CO_2 at 37 °C.

Multicellular Spheroid Formation. Multicellular tumor spheroids (MCTS) were formed from the U87 or U87-d1EGFP malignant glioma cell lines using the hanging drop method as described previously (*21*). Cells from a confluent T-25 flask were detached using trypsin-EDTA and resuspended in 5 mL of culture medium to a concentration of $\sim 10^6$ cells/mL. Twenty microliter droplets of this concentrated cell suspension were deposited into the lid of a Petri dish. The bottom of the Petri dish was filled with 2 mL of cell culture medium to facilitate moisture transfer. The lid containing the drops was inverted over the Petri dish to form hanging drops. The Petri dish was placed in the incubator for a period of 3 days, after which visible cell aggregates were formed in the hanging drops. The cell aggregates were harvested from the hanging drop suspension by adding ~2 mL of culture medium to suspend the aggregates. The cell aggregates were individually transferred in 100 μL of culture medium to wells of a 96-well tissue culture plate that was base-coated with 2% agarose. After 24 h on agarose, cell aggregates formed MCTS of diameters ranging from ~600 to 800 μm and were subjected to siRNA transfection and confocal imaging analysis.

SiRNA Delivery Assay. U87-d1EGFP cells were plated at a density of 1.5×10^5 cells/well in 12-well plates ~18 h prior to transfection. Prior to treatment of cells, PAMAM/siRNA complexes were prepared as described above in 200 μL of PBS (N/P = 15). PolyFect (Qiagen, Valencia, CA), a commercially available dendrimer transfection reagent, was used as a positive control. Eight hundred microliter aliquots of OptiMEM medium were mixed with each sample to obtain a final siRNA concentration of 100 nM. The serum-containing culture medium was aspirated from the cells, and each well was treated with 1 mL of the PAMAM/siRNA complexes in OptiMEM medium. After a 4 h incubation period, the transfection mixture was replaced with serum-containing culture medium and maintained under normal growth conditions until the cells were assayed for fluorescence by flow cytometry at various time points after initial treatment. For cells being analyzed for GFP fluorescence, unlabeled siRNA was utilized. To determine intracellular siRNA uptake, non-transformed U87 cells were treated with a Cy-3 labeled siRNA.

To analyze siRNA delivery in multicellular tumor spheroids, a similar transfection protocol was performed as with cells on 12-well tissue culture plates. MCTS transfections were performed in 96-well plates that had been base-coated with 2% agarose. Transfections were performed in a total volume of 150 μL in OptiMEM medium. MCTS were exposed to a Cy3-labeled siRNA sequence to enable confocal imaging of siRNA localization throughout the spheroids at both 4 and 24 h post-transfection. Spheroids generated from the U87-d1EGFP cell line were treated with a Cy5-labeled (red) antisense oligonucleotide (AON) targeted against d1EGFP so that the label and transgene fluorescence spectra would not overlap. U87-d1EGFP spheroids were imaged at 24, 48, and 72 h after the initial treatment to evaluate both GFP silencing and localization of the AON with the various dendrimer/ODN formulation conjugates.

Flow Cytometry. Cells were washed with PBS, detached with trypsin-EDTA, and collected in growth medium, before they were pelleted by centrifugation for 3.5 min at 200 *g* and resuspended in 150 μL PBS. Samples were maintained on ice before being subjected to flow cytometry analysis. Ten thousand cells were analyzed on a FACSCalibur two-laser, four-color flow cytometer (BD Biosciences) for GFP fluorescence (FL-1) or Cy3 fluorescence (FL-2). *CellQuest* software was used to acquire and analyze the results. Viable cells were gated according to their typical forward/side scatter characteristics.

Competitive Cell Adhesion Assay. High-binding 96-well plates (Nunc Maxi SORP) were coated with fibrinogen protein by adding 100 μL/well of fibrinogen solution (100 μg/mL in PBS) overnight at 4 °C. The next day, the plate was blocked with 150 μL/well of bovine serum albumin (BSA) solution (10 mg/mL in PBS) for 1 h at 37 °C. The plate was washed in triplicate with cold PBS. Ten microliter aliquots of test compounds (RGD-conjugated polymers) at various concentrations were added to wells of the fibrinogen-coated plate on ice in triplicate. Following the addition of test compounds, 90 μL of U87 cells in culture medium (330 000 cells/mL) were added to the plate and mixed thoroughly with a multichannel pipet. The plate was incubated at 37 °C for 3 h until the cells attached to the plate. Nonadherent cells were washed from the plate with PBS, and adherent cells were fixed by the addition of 100 μL of 70% ethanol for 30 min at room temperature. Following one wash with PBS, 100 μL of PicoGreen dye in TE buffer were added to the plate for 30 min to detect adherent cells. PicoGreen fluorescence was measured using a DTX800 Multimode Detector (Beckman Coulter, CA) at excitation and emission wavelengths of 485 and 535 nm, respectively. PicoGreen fluorescence values of wells treated with a RGD-containing competitor was normalized to wells that received no competitor (maximum cells adhering). Data analysis and calculation of IC_{50} values was performed using *GraphPad Prism 4* software (GraphPad Software, La Jolla, CA).

Confocal Microscopy of Multicellular Spheroids. Uptake and distribution of Cy3-labeled siRNA or Cy5-labeled AS ODN in U87 MCTS or U87-d1EGFP MCTS, respectively, were analyzed using confocal microscopy. Imaging was performed at various time points after siRNA transfection of spheroids using an Olympus IX81 model confocal microscope (Olympus, Center Valley, PA). Images of MCTS were performed directly on agarose-coated 96-well plates at 10× magnification. *Z*-stack imaging was performed to take image slices through spheroids at 20 μm intervals for a total depth of 100 μm. The following excitation and emission wavelengths were used to detect the fluorophores used in this study: GFP fluorescence (excitation = 482 nm, emission = 536 nm), Cy3 siRNA (excitation = 543 nm, emission = 593 nm), and Cy5 AS ODN (excitation = 628 nm, emission = 692 nm).

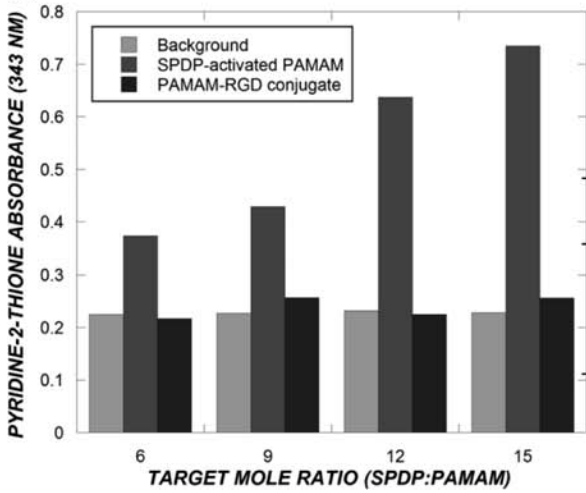
Image Analysis of Multicellular Spheroid Fluorescence. The fluorescence intensities of both the Cy5 and GFP channels of the confocal images of the U87-d1EGFP spheroids were quantified using *ImageJ* software (*22*).

Statistics. All statistical comparisons among treatment groups were performed using a one-way ANOVA test with Fisher's all-pairs post hoc comparison test. To compare among IC_{50} fits in the cell adhesion assay, a Monte Carlo procedure was employed. The standard error of measurement was used to randomly perturb individual experimental values around their means. Fits were then applied to the perturbed data and compared across groups. This procedure was repeated 10 000 times. If a particular group had a lower IC_{50} in at least 95% of the Monte Carlo trials, then the fitted IC_{50} value was considered significant at the $p < 0.05$ level.

RESULTS

Reaction and Characterization of PAMAM-RGD Conjugates. Generation 5 PAMAM dendrimers were conjugated with various amounts of a cyclic RGD targeting peptide, RGDfC, using a Sulfo-LC-SPDP cross-linker in a scheme depicted in Figure 1. The PAMAM-RGD conjugates were characterized

A



B

Theoretical Molar Ratios	Actual Ratios by DTT Release	Sample Name
6	2.12	G5-2RGD
9	3.21	G5-3RGD
12	7.07	G5-7RGD
15	9.65	G5-10RGD

using UV spectrophotometry at various stages during the cross-linking process. For this purpose, a disulfide reducing agent, DTT, was added to the conjugates to break the disulfide bond present in the SPDP cross-linker, enabling the release of pyridine-2-thione, a molecule that is UV active at 343 nm. PAMAM dendrimers were first reacted with various molar equivalents (6, 9, 12, or 15) of Sulfo-LC-SPDP to attain SPDP-activated PAMAM. After the addition of DTT, increasing amounts of pyridine-2-thione absorbance were detected with increasing SPDP/PAMAM ratios, as expected (Figure 2A). This information was used to calculate the average molar ratios of SPDP/PAMAM yielded in this reaction, ranging from approximately 2 to 10 SPDP/PAMAM. Following reaction with cyclic RGD peptides, the pyridine-2-thione absorbance decreased back to baseline, indicating complete replacement of pyridine-2-thione groups from the cross-linker with RGD peptides. The resulting PAMAM-RGD conjugates are denoted by their experimentally determined extents of RGD conjugation (rounded to whole numbers) as G5−2RGD, G5−3RGD, G5−7RGD, and G5−10RGD.

PAMAM-RGD conjugates were further characterized using MALDI-TOF mass spectrometry to confirm conjugation of RGD peptides to the dendrimers. Several previous studies have successfully utilized MALDI-TOF MS to characterize PAMAM bioconjugates by observing an increase in molecular weight of dendrimers upon conjugation to other molecules (*23, 24*). As expected, a shift to the right of MALDI MS curves correlated to increased extents of RGD conjugation, indicating an increase in the molecular weight of the conjugates (Supporting Information). As MALDI MS has been shown to underestimate the actual molecular weight of high-generation dendrimers (*23*), it was not used to estimate the molecular weight of PAMAM-RGD conjugates, but as a tool to confirm successful cross-linking of RGD to PAMAM dendrimers. The molecular weight of the PAMAM-RGD conjugates was calculated instead from the RGD cross-linking extent determined using UV spectrophotometry as described above.

Characterization of Dendrimer/siRNA Complexes. To facilitate siRNA delivery, cationic polymers such as PAMAM dendrimers should form electrostatic complexes with anionic siRNA molecules. The ability of PAMAM-RGD conjugates to complex with siRNA was evaluated using a dye exclusion assay. The amount of unbound siRNA in solutions of PAMAM/siRNA was determined by measuring the fluorescence of a commercially available dye, PicoGreen, that fluoresces upon binding

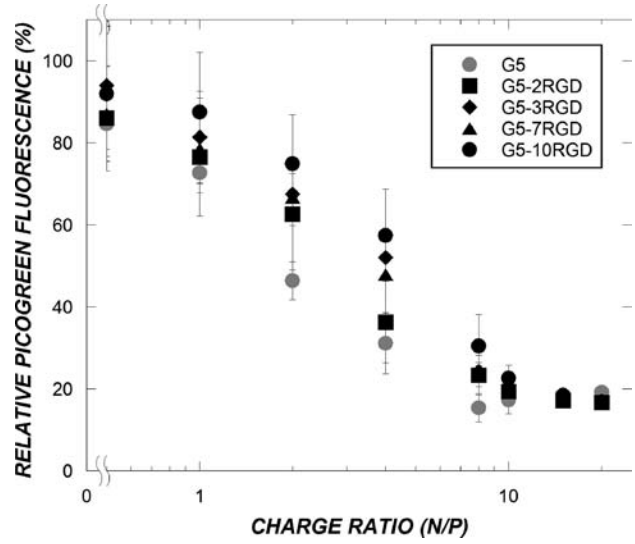

Figure 3. PAMAM/siRNA complexes were formed in PBS (final siRNA concentration = 2 μg/mL) and allowed to incubate for 15 min before measurement. Relative PicoGreen fluorescence corresponds to unbound siRNA present in solution. The data represent mean ± SEM ($n \geq 3$).

to double-stranded DNA or RNA. The fluorescence intensity of PicoGreen decreased following incubation of increasing amounts of polymer with added to a fixed amount of siRNA, indicating association of siRNA with the polymer (Figure 3). For all dendrimer conjugates tested, most of the PicoGreen fluorescence was quenched by N/P = 10, indicating that the dendrimers had formed complexes with siRNA. At lower charge ratios, however, it is possible to discern trends in siRNA complexation as a function of RGD cross-linking extent, with higher extents of RGD conjugation corresponding to somewhat less siRNA complexation. To ensure the presence of stable complexes, N/P = 15 was chosen for subsequent experiments.

Having demonstrated the ability of PAMAM-RGD conjugates to complex with anionic siRNA, the characteristics of the siRNA/PAMAM complexes formed at N/P = 15 were evaluated further by dynamic light scattering (DLS) measurements. Particle size analysis by DLS showed the formation of ~200 nm complexes between dendrimers and siRNA, regardless of extent of RGD conjugation (Table 1).

Table 1. Particle Diameter of Dendrimer/siRNA Complexes As Determined by Dynamic Light Scattering[a]

sample	particle diameter (nm)
G5	192 ± 3
G5−2RGD	166 ± 36
G5−3RGD	187 ± 14

G5−10RGD	182 ± 5

[a] The data represent mean ± standard deviation ($n = 3$).

siRNA Delivery and GFP Silencing in U87 Cells. The ability of PAMAM-RGD conjugates to deliver siRNA to U87 cells and elicit a gene silencing response was evaluated. A fluorescently labeled siRNA sequence was delivered to U87 cells with PAMAM-RGD conjugates to evaluate siRNA uptake into cells, which was assayed using flow cytometry. Separately, but under the same conditions, a siRNA sequence targeted against the short half-life green fluorescent protein, d1EGFP, was delivered to U87-d1EGFP cells, and relative GFP expression was assayed using flow cytometry.

Significant intracellular siRNA levels were observed 24 h after exposure of U87 cells to PAMAM-RGD/Cy3-siRNA complexes (Figure 4A). If cell binding is a limiting step in dendrimer-mediated siRNA delivery, intracellular siRNA levels would be expected to increase with increasing extent of RGD conjugation onto PAMAM dendrimers, as U87 cells express $\alpha_v\beta_3$ receptors for which cyclic RGD peptides have high binding affinities (*25*). In this system, a statistically significant increase in siRNA delivery was not observed upon conjugation of dendrimers with RGD peptides ($p > 0.05$).

Having observed intracellular siRNA delivery by PAMAM-RGD conjugates, the ability of the system to deliver siRNA to elicit a GFP silencing response was evaluated by flow cytometry. Modest silencing (approximately 40%) of the GFP transgene was observed in U87-d1EGFP cells using unmodified G5 PAMAM dendrimers compared to control cells receiving no siRNA treatment. The extent of GFP silencing achieved was not significantly altered after the conjugation of RGD peptides to PAMAM dendrimers ($p > 0.05$) (Figure 4B). An irrelevant siRNA sequence not targeted against d1EGFP was used as a control and resulted in ~20% silencing relative to no siRNA treatment. As these values are rather low and not statistically different from each other ($p > 0.05$), it appears that, even with RGD modification, uptake of G5 PAMAM dendrimers is nonspecific and does not result in intracellular trafficking sufficient for robust gene silencing (*10*). A commercially available dendrimer-based transfection reagent, PolyFect, was used as a positive control in this experiment and elicited ~60% GFP knockdown, which was statistically greater than that induced when the irrelevant sequence was delivered with PolyFect (Figure 4B).

Competitive Binding Cell Adhesion Assay. Having observed that the addition of RGD peptides to PAMAM did not significantly alter the ability of PAMAM to deliver siRNA to U87 cells, probably due to significant nonspecific cellular uptake of PAMAM/siRNA complexes, we sought to study whether active integrin targeting was occurring to any extent by the use of a cell adhesion assay. Here, the ability of PAMAM-RGD bioconjugates to bind specifically to $\alpha_v\beta_3$ integrin receptors on cells and prevent their adhesion to a fibrinogen-coated plate was evaluated. Polymers functionalized with various numbers of RGD peptides inhibited adhesion of U87 cells to fibrinogen protein in a concentration-dependent manner (Figure 5A). In contrast, unmodified G5 PAMAM dendrimer did not prevent the adhesion of U87 cells to fibrinogen, demonstrating the specificity of this assay to integrin-RGD binding, and the lack of nonspecific effects by PAMAM. This result indicated that, in all PAMAM-RGD constructs, RGD was presented to the cells in a manner such that it binds to $\alpha_v\beta_3$ integrin receptor proteins and is sufficient to prevent adhesion of U87 cells to the extracellular matrix protein, fibrinogen.

To discern trends in adhesion as a function of RGD conjugation extent, binding curves were fit to a competitive binding model to determine a concentration of RGD at which each dendrimer inhibited 50% of cells from adhering to the plate (IC_{50}) (Figure 5B). Fitted IC_{50} values were compared statistically using a Monte Carlo procedure described in the Experimental Procedures section. When a low number of RGD peptides were conjugated to the dendrimers (2 or 3), a significantly lower IC_{50} concentration (or a higher binding avidity) was achieved than with free RGD peptide ($p < 0.05$). However, by increasing the number of peptides per dendrimer (7 or 10), a sharp increase in the IC_{50} value was observed, corresponding to a decreased net avidity of these PAMAM-RGD conjugates to the integrin protein compared to those conjugates containing just 2 or 3 RGD peptides ($p < 0.05$). Further, a significant difference was observed between the IC_{50} values of dendrimers containing 7 or 10 RGDs ($p < 0.05$). Using this assay, we found that three RGD peptides per dendrimer were optimal for preventing U87 adhesion to fibrinogen protein on a flat plate.

siRNA Delivery through Multicellular Glioma Spheroids. The strong effect of PAMAM-RGD on U87 cell adhesion suggests that these bioconjugates can interfere with integrin−ECM interactions, which would likely influence delivery in a three-dimensional tumor. To investigate this hypothesis, the ability of PAMAM-RGD to deliver siRNA through a three-dimensional multicellular tumor spheroid (MCTS) model of U87 cells was evaluated. As carcinoma cells cultured as 3D spheroids are known to secrete ECM proteins and feature active integrin−ECM interactions (*26*), we expected that PAMAM-RGD conjugates would be able to facilitate siRNA delivery through MCTS by interfering with integrin−ECM interactions formed by cells in three dimensions. To this end, cellular aggregates of U87 cells were formed using the hanging drop method, and aggregates were then transferred to agarose-coated tissue-culture plates to promote the formation of spheroids. U87 spheroids on agarose were treated with PAMAM-RGD/Cy3-siRNA complexes in a similar manner as for cells cultured on standard 12-well tissue culture plates. PAMAM-RGD polymers containing either 3 or 10 RGDs were used for this study, as G5−3RGD was found to be optimal in the cell adhesion assay and G5−10RGD represents the highest extent of RGD conjugation used in this work. Confocal imaging was performed at 4 and 24 h after transfection to evaluate the delivery and localization of Cy3-siRNA within U87 spheroids.

When delivered by G5 PAMAM dendrimers not containing RGD targeting ligands, siRNA fluorescence was observed primarily on the periphery of U87 spheroids (Figure 6). This result is consistent with previous studies on DNA delivery to MCTS using polyethylenimine (PEI), where poor tissue penetration using PEI/DNA complexes was observed (*27*). However, when PAMAM-RGD conjugates were used, siRNA was delivered successfully throughout the spheroid volume, suggesting that tissue penetration was enhanced by the presence of RGD targeting ligands (Figure 6). Significant siRNA delivery to the center of spheroids was observed when using PAMAM-RGD conjugates containing either 3 or 10 RGD ligands.

Having observed the ability of PAMAM-RGD conjugates to enhance siRNA delivery through U87 MCTS, spheroids generated from U87-d1EGFP cells were used to study simultaneously the delivery of a fluorescently labeled antisense oligonucleotide (AON) and its target GFP silencing. Consistent with the Cy3-siRNA localization observed in U87 spheroids, AON fluorescence was observed primarily on the spheroid periphery, at a

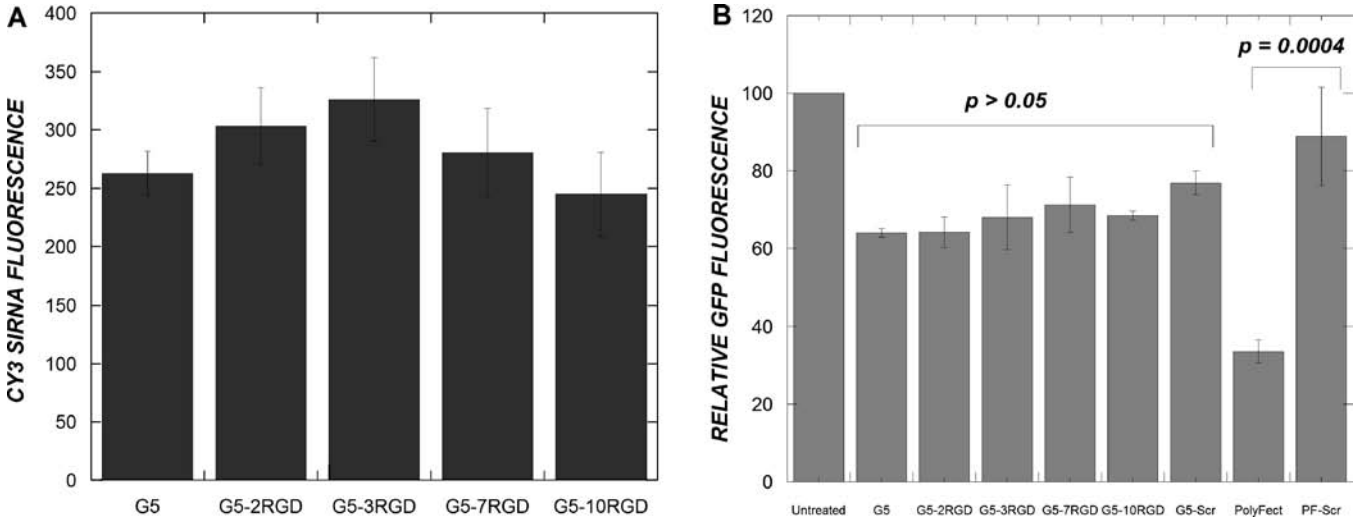

Figure 4. U87 cells (A) or U87-d1EGFP cells (B) were treated with PAMAM-RGD/siRNA complexes at a final siRNA concentration of 100 nM for 4 h under serum-free conditions. Cells were analyzed using flow cytometry for Cy3 fluorescence (A) or GFP fluorescence (B) 24 h after the initial treatment. A 5:1 wt ratio of PolyFect/siRNA was used (B). A scrambled siRNA sequence was delivered with PolyFect and G5 PAMAM dendrimer denoted by PF-Scr and G5-Scr, respectively. Data represent mean ± SEM.

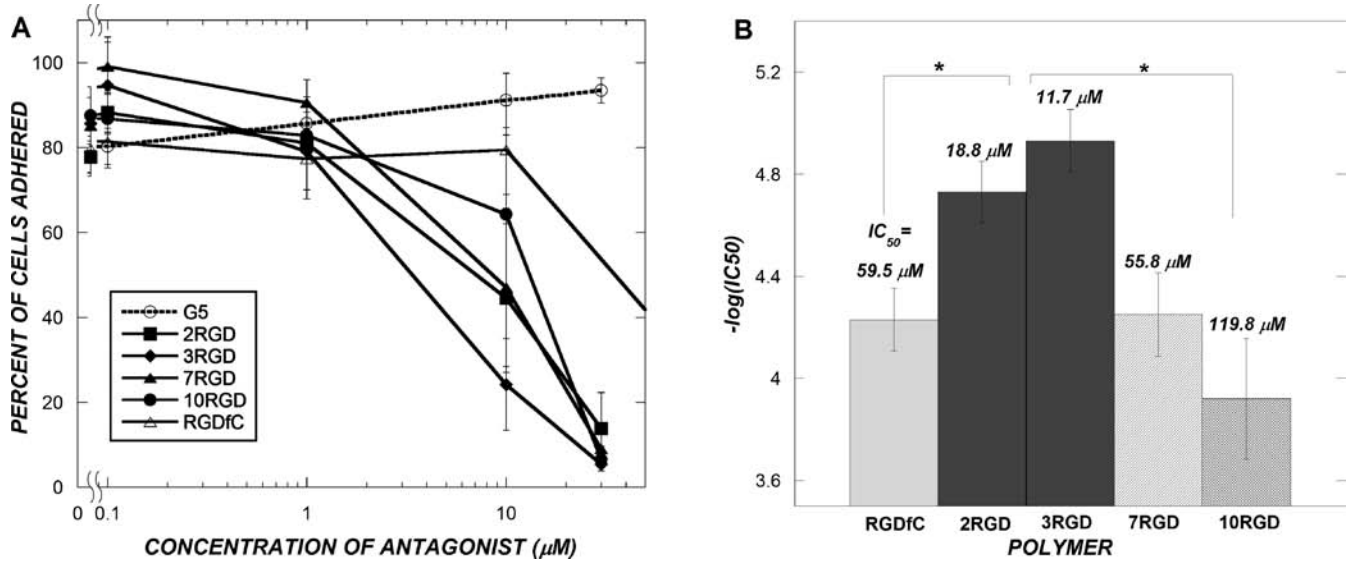

Figure 5. Competitive binding curves for U87 cells binding to fibrinogen-coated plates in the presence of RGD-containing antagonists (A). Results of IC_{50} values obtained from binding curves for each antagonist used (B). Differently colored bars represent statistically different IC_{50} values ($p < 0.05$) as determined using a Monte Carlo curve fitting algorithm (B). depth of 80 μm into the MCTS, when delivered by unmodified G5 PAMAM (Figure 7A). When delivered by PAMAM-RGD conjugates, however, AON fluorescence was observed throughout the spheroid volume. A statistically significant increase in Cy5 AON fluorescence was observed in the interior of the spheroids when AON was delivered by dendrimers containing RGD peptides compared to the native dendrimers at both 48 ($p < 0.002$) and 72 h ($p < 0.0001$) after treatment (Figure 7B). Despite the accumulation of AON within the MCTS, quantification of the GFP levels did not reveal significant gene silencing, consistent with the two-dimensional cell culture results (Figure 4B).

DISCUSSION

Integrins have proven to be promising targets for macromolecular drug and nucleic acid delivery systems for cancer. Several bioconjugate molecules containing RGD motifs have been successfully targeted to integrins to promote enhanced uptake and bioactivity in carcinoma cells. However, few studies have systematically evaluated how the number of RGD targeting ligands affects the bioactivity of targeted delivery systems. Hence, in this work, we conjugated cationic PAMAM dendrimers with various amounts of cyclic RGD targeting peptides to evaluate the ability of these bioconjugates to deliver siRNA to U87 glioma cells.

PAMAM dendrimers functionalized with varying levels of RGD peptides (2−10 RGDs/PAMAM) were able to deliver siRNA to U87 glioma cells, which express the $\alpha_v\beta_3$ integrin receptor, to elicit modest GFP silencing. However, contrary to our initial hypothesis, the attachment of RGD to PAMAM dendrimers did not enhance their ability to deliver siRNA to U87 glioma cells. This is likely due to the fact that nonspecific uptake of PAMAM dendrimers, mediated by their high cationic charge density, was more considerable than integrin-mediated

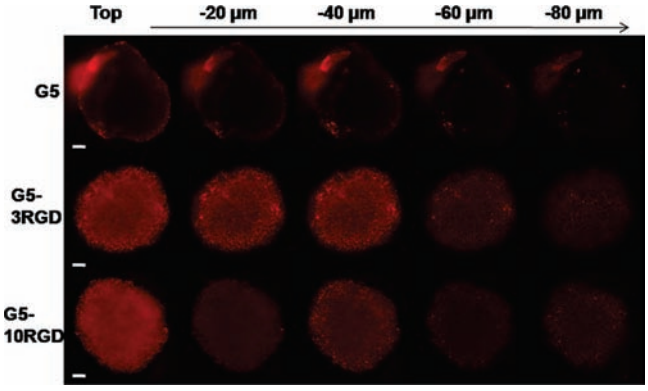

Figure 6. Confocal images of U87 spheroids 24 h after treatment with dendrimer/siRNA complexes. Cy3 siRNA fluorescence is shown in red. *Z*-stack images were obtained starting at the top of the spheroid in 20 μm intervals for a total of 100 μm into the spheroids. Images of each treatment were taken from three independent experiments with representative images shown here. The scale bar represents 100 μm.

uptake mediated by the presence of RGD ligands. This result is consistent with other literature reports that have found poor active tumor cell targeting from cationic polymers such as PEI and PAMAM when a short cross-linker was used to conjugate a targeting peptide (*5*, *28*, *29*). However, in addition to enhancing uptake of macromolecules into integrin-expressing cells, RGD targeting strategies can serve other purposes, such as interfering with integrin-mediated tumor cell adhesion to ECM proteins (*30*). This in turn may affect delivery of cargo in a tissue as opposed to a two-dimensional cell culture.

The integrin $\alpha_v\beta_3$ is intimately involved in tumor cell growth, proliferation, and angiogenesis. Thus, the ability to interfere specifically with the activity of this integrin could help to slow tumorigenesis in malignant glioma, and indeed a cyclic RGD peptide, Cilengitide, is undergoing clinical trials for glioma therapy (*31*, *32*). The PAMAM-RGD conjugates developed in this study inhibited the adhesion of U87 cells to the extracellular matrix protein, fibrinogen. A trend in inhibition of adhesion was observed as a function of RGD conjugation extent, with a maximum inhibition of cell adhesion observed with 3 RGD/PAMAM. Thus, a pronounced effect of RGD conjugation was observed in this cell adhesion model, contrasting the results obtained for siRNA delivery in which a trend was not observed as a function of RGD conjugation. Hence, the results of this assay support the ability of the PAMAM-RGD conjugates to perform active integrin binding.

MCTS models for cancer are garnering significant attention for anticancer drug screening as they mimic the microenvironment of tumors found in vivo more accurately than standard two-dimensional culture models (*33*, *34*), and they have recently been shown to display angiogenic phenotypes akin to those observed in vivo (*35*). Previous studies using spheroid cell culture models to evaluate nucleic acid delivery by synthetic polymers such as PEI or lipids have found that gene delivery using these carriers was confined to the outer layers of cells in spheroids due to poor penetration through the cell-matrix network (*27*). However, one study reported that conjugating lactose targeting moieties onto a polymeric micelle delivery system enabled deeper penetration of siRNA into a spheroid model of human hepatocarcinoma (*36*). Further, the presence of ECM proteins was found to inhibit the transport of nanoparticles through tumor spheroids (*37*). Since PAMAM-RGD conjugates were found to interfere with cell adhesion mediated by ECM, we hypothesized that using PAMAM-RGD conjugates would facilitate deeper penetration into a spheroid model of malignant glioma than unmodified PAMAM dendrimers via RGD modulation of cell−ECM interactions present in three-dimensional culture. As expected, PAMAM dendrimers conjugated with either 3 or 10 RGD peptides significantly improved the PAMAM-mediated delivery of siRNA to the spheroid interior compared to the native G5 dendrimer, suggesting that the addition of RGD peptides was able to overcome the poor tissue penetration of PAMAM dendrimers through spheroids. Notably, the PAMAM-RGD conjugates, in contrast to the G5 dendrimer, continued to penetrate into the MCTS throughout the 72 h time course of the experiment, suggesting a dynamic interaction among bioconjugate, ECM, and cell. However, despite the significant increases in tumor penetration, silencing levels of GFP remained insignificant. This outcome highlights the fact that cellular accumulation is not sufficient for efficient gene silencing. The siRNA must also be internalized by the cell and trafficked efficiently intracellularly, particularly with regards to endosomal escape. Modification of the dendrimers

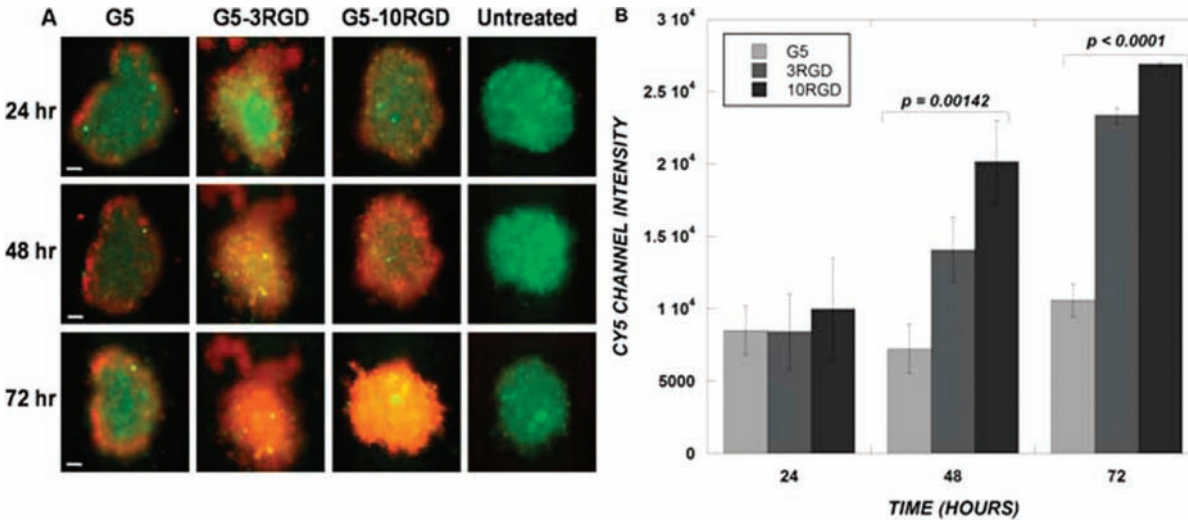

Figure 7. (A) Confocal images of U87 GFP spheroids treated with dendrimer/Cy5-ODN complexes. GFP fluorescence of U87 GFP cells is shown in green, and Cy5 ODN fluorescence is shown in red. All images shown are from a depth of 80 μm into each spheroid. The time points shown indicate the time post-transfection. The scale bar represents 100 μm. Error bars represent mean $\pm$ standard deviation.

to enhance these steps is necessary for ultimate application to tumor oncogene silencing.

A major goal of this work was to study how the number of RGD peptides on a PAMAM dendrimer affects its ability to interfere with important cell−ECM interactions. Previous studies have found that controlling RGD ligand presentation from a nanoparticle platform can significantly impact the extent of integrin-targeting that is achieved (*38*, *39*). Here, three RGDs per dendrimer were found to exhibit the strongest integrin-binding response using a competitive binding cell adhesion assay, and a greater number of peptides per dendrimer did not provide any additional benefit. However, in contrast to the trend observed in the competitive binding cell adhesion assay, dendrimers displaying 10 RGD peptides yielded significantly greater delivery of oligonucleotides to U87 spheroids than did dendrimers containing 3 RGD peptides. The three-dimensional architecture of the spheroids likely confers a greater advantage to dendrimers with a greater RGD multivalency, allowing for multiple contacts with ECM molecules within the MCTS. The results of this study highlight the importance of screening novel chemical entities and drug delivery systems in three dimensions.

Taken together, these results suggest that RGD-conjugated dendrimers hold promise for siRNA delivery to solid tumors. Their ability to interfere with integrin−ECM interactions can potentially enable penetration into malignant tumors to improve siRNA delivery, and they may also interfere directly with tumor angiogenesis and integrin-mediated growth signaling by malignant cells. Such multifunctional delivery systems that can modify the biological processes of cancer cells and deliver a therapeutic cargo in concert represent a new venue for cancer therapy. Due to the architecture of dendrimers with many exterior functional groups, the concept can be extended easily to incorporation of conventional drugs and/or imaging agents. Such developments will amplify the impact of siRNA on human disease.

ACKNOWLEDGMENT

We are grateful for financial support from the NIH (R01 GM65913), Charles and Johanna Busch Memorial Fund, and an NSF IGERT Fellowship (DGE-0504497) to CW. The authors thank the following people for access to and assistance with various instruments: Dr. Sobin Kim and Daniel Duffield (MALDI-ToF MS), Dr. Rene Schloss and Jeffrey Barminko (confocal microscope), and Dr. Kathryn Uhrich and Sarah Sparks (dynamic light scattering). We also thank Dr. Kathryn Uhrich, Dr. Prabhas Moghe, and Lavanya Peddada for helpful discussions and Paul Gianella for technical assistance.

Photo-Cross-Linking Induces Size Change and Stealth Properties of Water-Dispersible Cinnamic Acid Derivative Nanoparticles

Dongjian Shi, Michiya Matsusaki, and Mitsuru Akashi*

Department of Applied Chemistry, Graduate School of Engineering, Osaka University, 2-1 Yamada-oka, Suita 565-0871, Japan. Received June 3, 2009; Revised Manuscript Received August 4, 2009

Hydrophilic poly(ethylene glycol) (PEG) was grafted onto poly(4-cinnamic acid)-*co*-poly(3,4-cinnamic acid) (PCA) by Michael addition. The chemical structures of the PCA-*graft*-PEG (PCA-PEG) copolymers were confirmed by FT-IR and ^{1}H NMR measurements. The PCA-PEG nanoparticles were self-assembled by the solvent mixing method, in which additional water was dropped into a DMSO solution of the copolymer. The diameter of the PCA-PEG nanoparticles was below 100 nm, and decreased to about 30 nm upon increasing the composition ratio and molecular weight of PEG. The PCA-PEG nanoparticles showed [2 + 2] cyclobutane formation (cross-linking) following UV irradiation at $\lambda > 280$ nm. Moreover, the photo-cross-linking induced size decrement of the nanoparticles depending on the grafting degree and molecular weight of PEG. The amount of protein adsorption onto the surface of the nanoparticles was less than 30 ng/cm^2, due to the high density of PEG chains on their corona layers. Furthermore, photo-cross-linking induced a significant decrement in protein adsorption, due to an increase in PEG chain density triggered by the size decrement of the nanoparticles. These water-dispersible and photoresponsive nanoparticles would be useful as novel, functional carriers for drug delivery systems and biological diagnosis.

INTRODUCTION

Polymeric nanoparticles are typically useful as carriers for drugs and proteins and as catalyst molecules in biomedical and environmental applications because of their high surface area compared to nanofibers and films (*1*−*3*). Many studies have focused on nanoparticles composed of biodegradable polymers, such as poly(lactic acid) (PLA), poly(ε-caprolactone) (PCL), and polysaccharides, for drug delivery systems (DDS) (*4*−*6*). We have also reported various self-assembling synthetic (*7, 8*) and biodegradable (*9*−*12*) nanoparticles and hollow capsules (*13, 14*) as controlled release carriers and nanosphere-based vaccines. In using the nanoparticles as carriers for biomedical applications, there is a serious problem with nonspecific protein adsorption onto the surface of the nanoparticle, which affects the stable dispersity of the nanoparticle and targeted delivery of a drug or protein. To solve this problem, it is necessary to prepare a bioinert surface, which can inhibit the nonspecific adsorption of serum proteins and hemocytes, for maintaining their stable circulation and property in the blood without being scavenged nonselectively (*15, 16*). Therefore, introduction of hydrophilic groups onto the material surface for protein resistance had been reported to develop a bioinert surface on the nanoparticles. By increasing the density of hydrophilic groups on the material surface, the resistance against protein adsorption onto the nanoparticles was improved (*17*−*19*). However, there was no report on improving the resistance of the protein adsorption by external stimuli such as light stimuli. Light-induced responses have been attracted much attention, since it is one of the most desirable methods for the easy, rapid, and efficient control of material properties by tuning the light wavelength or energy (*20*). Photoresponsive materials have great potential applications in DDS, RNA/DNA recognition, and shape-memory systems and as recording and switching sensors (*21*−*23*). Therefore, photoresponsive, nanoscaled materials such as nanoparticles, nanofibers, and nanofilms are expected to have applications not only in nanotechnologies, but also in biomedical fields.

Cinnamic acid and its derivates exist in plant cell walls as an intermediate metabolite in the biosynthetic pathway of lignin and other biological materials, and show photoreactions such as [2 + 2] cycloaddition and trans/cis isomerization, which lead to the transformation of the photoactive yellow protein in photosynthetic bacteria (*24*). We have reported a series of cinnamic acid derivative homopolymers and copolymers possessing liquid crystal phases, photoreactivities, degradabilities, and cell compatibilities (*25*−*29*). Moreover, wholly aromatic polyester, poly(3,4-dihydroxycinnamic acid-*co*-4-hydroxycinnamic acid) (PCA), was synthesized from the phenolic phytomonomers 3,4-dihydroxycinnamic acid (3,4DHCA) and 4-hydroxycinnamic acid (4HCA) (*30*). The PCA copolymer has high photosensitivity and degradability, as well as strong mechanical properties. Zhao's group also reported polymer micelles with coumarin moieties as side chains for cross-linking and de-cross-linking of micelles with UV irradiation, and controlled the release rate of the encapsulated component with a tunable photo-cross-linking density (*31*). Therefore, nanoparticles containing cinnamate groups are useful for developing photoresponsive nanoscaled materials for biomedical and environmental applications. However, conventional photosensitive nanoparticles cannot induce a significant size change because they contain only a few chromophoric groups.

In previous studies, we reported that the self-assembled PCA nanoparticles underwent a significant diameter change property following photo-cross-linking and photocleavage of cinnamate groups with UV irradiation (*32, 33*). Furthermore, the size change phenomena of these nanoparticles depending on the photo-cross-linking degree during hydrolysis were also observed (*34*). However, the nanoparticles could not disperse in aqueous

solution, which limited their applications in biomedical fields. If water-dispersible PCA nanoparticles were developed, the photoresponsive nanoparticles might be useful for drug delivery systems.

Poly(ethylene glycol) (PEG) is well-known as a water-soluble and nontoxic polymer, which is useful for obtaining the water-dispersibility and biocompatibility, especially resistance against the nonspecific adsorption of serum proteins and hemocytes for material and particle surfaces (*35*−*37*). Herein, we used α-mercaptoethyl-*ω*-methoxy poly(ethylene glycol) (SH-PEG-OCH_3) to prepare biocompatible and photoresponsive PCA-*graft*-PEG (PCA-PEG) nanoparticles by Michael addition (Scheme 1). The nonspecific protein adsorption onto the surfaces of the nanoparticles was evaluated, and the effects of photo-cross-linking on the nanoparticle size and nonspecific protein adsorption related to the PEG density on the surface of the nanoparticles were investigated in detail.

EXPERIMENTAL PROCEDURES

Materials. 4-Hydroxycinnamic acid (4HCA) and 3,4-dihydroxycinnamic acid (3,4DHCA) were purchased from Tokyo Chemical Industry (TCI, Japan) and Wako Pure Chemical Industries, Ltd., Japan, respectively, and used as received. α-Mercaptoethyl-*ω*-methoxy poly(ethylene glycol) (SH-PEG-OCH_3; M_n: 2, 10, and 20 kDa) were purchased from NOF Corp. Japan. *N*,*N*-Dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and trifluoroacetic acid (TFA) were purchased from Wako Pure Chemical Industries Ltd., Japan, and used without further purification. Bovine serum albumin (BSA) was purchased from Sigma (St. Louis, MO, USA).

Synthesis of PCA-PEG Copolymers. The PCA copolymer was prepared from 3,4DHCA and 4HCA monomers at the same molar ratio by thermal polycondensation at 200 °C for 6 h, according to a previous report (*30*). The PEG grafted PCA copolymers (PCA-PEG) were synthesized by Michael addition (*38*,*39*) in the presence of a few drops of triethylamine as a catalyst at 60 °C for 12 h. After a predetermined time, the reacted solutions were precipitated from methanol. The obtained precipitates were dissolved in DMSO and filtered to remove any unsubstituted PCA, and then reprecipitated in methanol to remove any unreacted PEG twice. The products were then dried under vacuum at room temperature overnight. The average molecular weights of the PCA-PEG copolymers were determined by gel permeation chromatography (GPC) using a HLC-8220 GPC (Tosoh co. Ltd., Japan) with TSK-GEL super H2000 and H4000 columns in DMF containing 10 mM lithium chloride (LiCl) and calibrated with monodispersed polystyrene standards (Shodex, Japan) at a flow rate of 0.6 mL/min at 40 °C. The structures of the copolymers were confirmed by Fourier transform infrared spectroscopy (FT-IR) on a FT-IR spectrometer (Spectrum 100, Perkin-Elmer, Japan) using an attenuated total reflection (ATR) method. ^{1}H NMR spectrum was measured using a JNM-GSX400 spectrometer (JEOL, 400 MHz, Japan) in dichloromethane (CD_2Cl_2). The grafting degrees of PEG were calculated from the ^{1}H NMR spectrum by comparing the peak areas of the cinnamate and methylene groups and UV−vis spectrum (U3010 spectrometer, Hitachi, Japan) by comparing the absorbance of the cinnamate groups using a calibration curve of the copolymer solution.

Preparation and Photo-Cross-Linking of Water-Dispersible PCA-PEG Nanoparticles. The obtained PCA-PEG copolymers were dissolved in DMSO to a concentration of 1 mg/mL, and additional water was dropped into the copolymer solution until formation of a turbid solution. The nanoparticles were purified by dialysis in distilled water for 4 days and then collected by lyophilization for 3 days. The obtained nanoparticles were redispersed in pure water at a concentration of 0.5 mg/mL, and then the aqueous solution was filled in a quartz cell and irradiated with focused UV light at $\lambda > 280$ nm (80 mW/cm^2) by a 350 W high-pressure mercury lamp (Supercuere-352S UV light source, SAN-EI electric co. Ltd., Japan). The distance between the solution and the lamp was approximately 5 cm. The photo-cross-linking of the cinnamate groups was confirmed by UV−vis and ^{1}H NMR spectra. Dynamic light scattering (DLS, Malvern Zeta-sizer Nano ZS Instruments, Japan) was used to measure the diameter of the nanoparticles in water at a concentration of 0.5 mg/mL at room temperature. Scanning electron microscopy (SEM, JEOL JSM-6701F, Japan) was used to observe the size and surface morphology of the PCA-PEG nanoparticles after casting the sample solutions onto a stage and subsequent drying in vacuo overnight. Transmission electron microscopy (TEM, JEM-100CS-S1, JEOL, Japan) images were obtained after dropping the nanoparticle solutions onto a collodion-coated copper mesh grid, drying at ambient condition, and then carbon sputtering.

Protein Adsorption onto the Surface of the PCA-PEG Nanoparticles. The PCA-PEG nanoparticles were dispersed in phosphate buffered saline (PBS, pH 7.4) at 10 mg/mL and

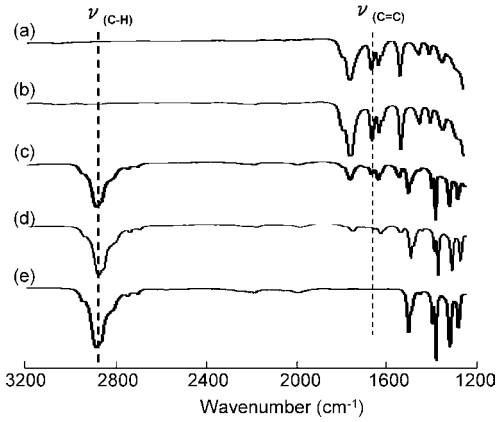

Figure 1. FT-IR spectra of the copolymers: PCA (a), PCA-PEG2k-0.5 (b), PCA-PEG2k-10 (c), PCA-PEG2k-100 (d), and PEG2k (e).

incubated with equivalent of a 4 mg/mL protein (BSA) solution in PBS at 4 °C for 24 h. The nanoparticles were collected by centrifugation, washed twice with PBS, and resuspended at 5 mg/mL in PBS. The amount of protein adsorbed onto the nanoparticles was determined by the Lowry method (*40*). Briefly, the obtained nanoparticle solution was added to the same volume of 4% sodium dodecyl sulfate solution (SDS) to dissolve the nanoparticles, and then the amount of adsorbed BSA was determined on a microplate reader (BIO-RAD, model 680, Japan) by a reduction in Folin-phenol to molybdenum blue using the copper ion-catalyzed oxidation of aromatic acids under alkaline conditions.

RESULTS AND DISCUSSION

Synthesis of the PCA-PEG Copolymers. PCA copolymers were synthesized from phytomonomers 3,4DHCA and 4HCA at the same molar ratio by thermal polycondensation based on our previous report (*32*). The molecular weight and structure of the PCA copolymer were confirmed by GPC measurements and the ^{1}H NMR spectra. Amphiphilic PEG grafted PCA (PCA-PEG) copolymers were synthesized by Michael addition (Scheme 1a).

Figure 1 shows FT-IR spectra of the PCA-PEG2k copolymers with different grafting degrees of PEG2k (PCA-PEG2k as examples). The peak at 1630 cm^{-1} was assigned to the double carbon bond ($\nu_{C=C}$) of the cinnamate groups in the PCA segments (Figure 1a−d). The peak area of the double carbon decreased upon increasing the PEG grafting degree (Figure 1b,c), and the peak disappeared when the PEG grafting degree reached almost 100% (Figure 1d), indicating successful substitution of the double carbon bond (CH═CH) to S−CH bond by Michael addition. The peak at 2860 cm^{-1} was assigned to stretching vibration of the C−H group in the PEG chains (Figure 1c−e), and the peak area for the PCA-PEG copolymers increased with increasing grafting degree of PEG (Figure 1b−d). Figure 2 shows ^{1}H NMR spectra of PCA, PEG2k, and PCA-PEG2k copolymers with different grafting degrees. Peaks at 6.8 and 8.2 ppm were assigned to the double carbon bonds of the cinnamate groups in PCA (Figure 2a−d). The peak appearing at ∼3.8 ppm was assigned to the PEG methylene groups (Figure 2b−e). When the grafting degree of PEG was above 10%, a new peak at approximately 3.0 ppm appeared, which was assigned to the S-CH group (Figure 2c,d), indicating the PEG chain was successfully introduced into PCA. When the grafting degree was 100%, the peaks at 6.8 and 8.2 ppm disappeared, suggesting the complete introduction of the PEG chains into the double carbon bonds of PCA (Figure 2d). The degree of grafting of the PCA-PEG copolymers was calculated from ^{1}H NMR spectrum by comparing the peak area between cinnamate groups at 6.8 ppm and methylene groups of the PEG repeat units at 3.8 ppm, as summarized in Table 1. Moreover, the results from UV−vis spectra also revealed a decrement of double carbon bond depending on the PEG grafting degree (data not shown), supporting the formation of the PCA-PEG copolymers. By calculating the absorbance of the cinnamate groups using a calibration curve derived from the PCA-PEG copolymer solution, the grafting degrees were obtained from UV−vis spectra as summarized in Table 1, and the values agreed well with the grafting degrees estimated from ^{1}H NMR measurements.

These results suggested that the PEG chains were successfully introduced into PCA by Michael addition. By controlling the molecular weight of PEG and the molar ratio between the cinnamate groups in PCA and the thiol groups in PEG, PCA-
