[a] 2k, 10k, and 20k mean the molecular weight of PEG as 2, 10, and 20 kDa, and 0.5, to 100 mean grafting degree of PEG against double bond of cinnamic acid, respectively. [b] GPC measurement in DMF with monodispersed polystyrene standards. [c] (1) in feed of molar ratio of PEG. [c] (2) the grafting degree calculated from ^{1}H NMR spectrum. [c] (3) the grafting degree calculated from UV−vis spectrum. [d] The diameter by DLS measurement. [e] CV (coefficient of variation, %) = standard deviation/mean diameter. [f] Not detected. [g] No particle formation.

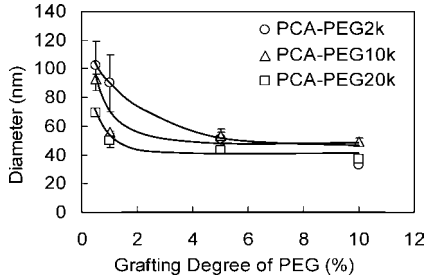

Figure 3. Diameters of PCA-PEG nanoparticles with different molecular weights and grafting degrees of PEG chains by DLS measurements ($n = 3$).

PEG copolymers with different composition ratios were obtained (Table 1). The molecular weights of the PCA-PEG copolymers obtained from the GPC measurements are also listed in Table 1, and the results showed that the molecular weights of the copolymers increased upon increasing the composition and molecular weight of PEG.

Preparation of the PCA-PEG Nanoparticles. A turbid solution appeared by adding water into the copolymer solution in DMSO (Scheme 1b), suggesting the formation of PCA-PEG nanoparticles. We observed the formation of the regular and monodispersed nanoparticles at DMSO/water = 1:2 (v/v). Thus, all of the nanoparticles were prepared at 1:2 volume ratios of DMSO and water. The nanoparticle size was detected by DLS measurements, and is shown in Table 1 and Figure 3. The diameter of the PCA-PEG 2k, 10k, and 20k nanoparticles was approximately 100, 90, and 70 nm, respectively. When the grafting degree of PEG was increased, the diameters gradually decreased to about 30 to 50 nm (Figure 3). The increase in the hydrophilic chains induced the formation of a smaller nanoparticle size due to a decrement in the hydrophobic interactions. However, when the grafting degree was over ca. 50%, particle formation was not observed even after adjusting the volume ratio of DMSO and water or the concentration of the copolymers, maybe due to a disruption of the hydrophilic−hydrophobic balance between hydrophilic PEG and hydrophobic PCA chains. The obtained PCA-PEG nanoparticles showed a unimodal distribution by DLS measurements.

Figure 4 shows SEM and TEM observations of the nanoparticles (PCA-PEG with 1% grafting degree as examples). Both

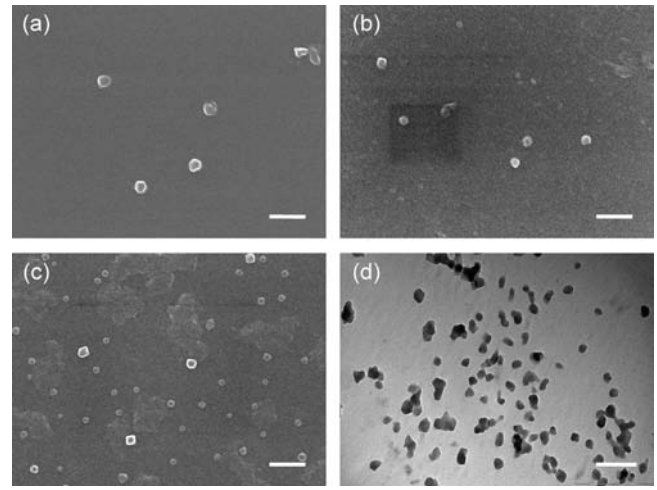

Figure 4. SEM images of the PCA-PEG2k-1 (a), PCA-PEG10k-1 (b), and PCA-PEG20k-1 (c) nanoparticles and a TEM image of the PCA-PEG20k-1 nanoparticle (d). The scale bars are 250 nm.

SEM (Figure 4a−c) and TEM (Figure 4d) images revealed the spherical morphology of the PCA-PEG nanoparticles, suggesting the successful preparation of monodispersed nanoparticles. The average diameters calculated from SEM images were 90, 60, and 50 nm for PCA-PEG2k-1, PCA-PEG10k-1, and PCA-PEG20k-1 nanoparticles, respectively, indicating good agreement with the results from DLS measurements (Table 1 and Figure 3).

These results demonstrated that the homogeneous nanoparticles were self-assembled from PCA-PEG copolymers by hydrophilic−hydrophobic balance and the grafting degrees and molecular weights of PEG strongly affected the nanoparticles size.

Effect of Photo-Cross-Linking on the PCA-PEG Nanoparticle Size. Cinnamic acid and its derivates show well-known [2 + 2] cycloaddition (cross-linking) formation with UV irradiation at $\lambda > 280$ nm (Figure 5a) (*20*−*22*). To evaluate the photoreactivities of the PCA-PEG nanoparticle, PCA-PEG10k-2 nanoparticles in aqueous solution were irradiated with UV light at $\lambda > 280$ nm for 10 min, and then the UV−vis spectra were measured to assay the cross-linking formation as shown in

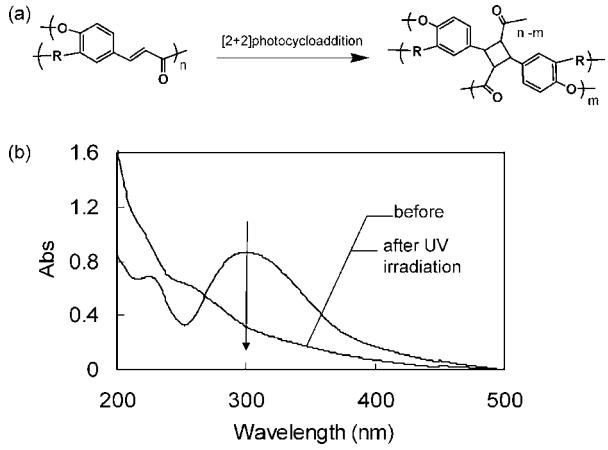

Figure 5. (a) Chemical structure of UV irradiation at $\lambda > 280$ nm induced [2 + 2] cycloaddition (cross-linking) formation of the cinnamate groups. (b) UV−vis spectra of PCA-PEG10k-2 in aqueous solution before and after photo-cross-linking with UV irradiation at $\lambda > 280$ nm for 10 min.

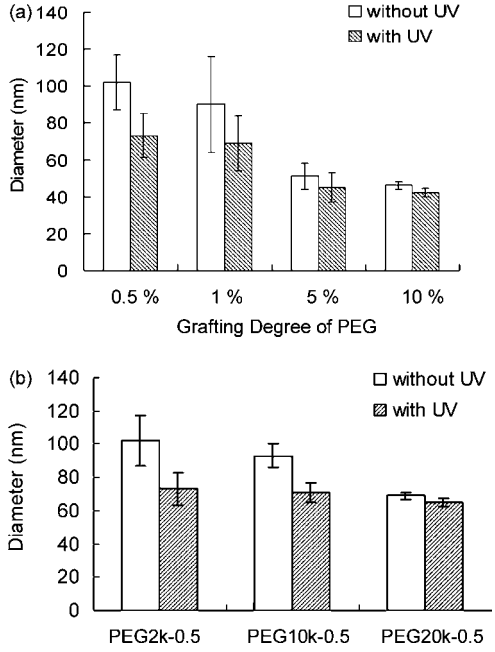

Figure 6. Diameter and size change ratio of PCA-PEG2k nanoparticles with different grafting degrees (a) and molecular weights (b) of PEG-0.5 before and after photo-cross-linking with UV irradiation at $\lambda > 280$ nm to reach 90% cross-linking degree as determined by DLS measurements ($n = 3$).

Figure 5b. The absorbance of the cinnamate groups at 300 nm strongly decreased with UV irradiation, demonstrating cross-linking formation. The cross-linking degree calculated from the change of the cinnamate group in absorbance at 300 nm was about 90%. These results indicated the formation of cross-linking in the core part of the nanoparticles.

The effects of photo-cross-linking on nanoparticle size were investigated by DLS measurements. Figure 6a shows the diameter change of the PCA-PEG2k nanoparticles with different grafting degrees of PEG before and after photo-cross-linking (90% cross-linking degree). The diameter of the nanoparticles decreased after cross-linking, and the size change ratio varied depending on the PEG composition. The size change ratio was about 28% for the PCA-PEG2k nanoparticles with 0.5% grafting degree, and decreased to 8% at a 10% grafting degree (Figure 6a). The higher PEG compositions (over 5%) had a lower amount of the cinnamate groups in the nanoparticles, resulting in a smaller size change property of the nanoparticles after photo-cross-linking. The size change ratio of the nanoparticles decreased upon increasing the molecular weight of PEG (Figure 6b), possibly due to the hydrophobic−hydrophilic balance. In the case of PCA-PEG20k nanoparticles, the occupied volume of the hydrophilic PEG (corona layer) should be larger than that of hydrophobic PCA (core part); accordingly, the size change phenomena might not be observed well. Moreover, a longer hydrophilic chain stretching well into the aqueous solution would maintain the size even after photo-cross-linking. The size distribution of the PCA-PEG nanoparticles was a unimodal peak after photo-cross-linking.

From these results, the driving force for the diameter decrement after UV irradiation should be the photo-cross-linking of the cinnamate groups in the nanoparticles, and the obtained particle size was strongly influenced by the character of the PEG chains.

Surface PEG Density of the Nanoparticles and Protein Adsorption onto the Surface with and without Photo-Cross-Linking. The number of PEG chains on a single nanoparticle was determined by per unit mass of the PEG methylene peak in the region 3.5−3.8 ppm as compared with the methyl proton peak of DSS at 0 ppm from the ^{1}H NMR spectrum in D_2O (*18*). The number of PEG chains on a single nanoparticle ($N(\mathrm{PEG})_{\mathrm{surface}}$) and the surface density of the PEG chains (σ_{PEG}) were calculated from the size (as determined by DLS measurements) and density (generally assumed to be 1.05 g/cm^3) of the nanoparticles, and the results are summarized in Table 2. These results showed that a large amount of PEG chains were on the nanoparticles and that the $N(\mathrm{PEG})_{\mathrm{surface}}$ increased with an increasing composition ratio and molecular weight of PEG, suggesting a brush conformation for the PEG chains on the surface of the PCA-PEG nanoparticles. The PEG densities of the nanoparticles were estimated to be 0.11 (PCA-PEG2k-0.5), 0.19 (PCA-PEG2k-1), 0.4 (PCA-PEG2k-5), 0.29 (PCA-PEG10k-0.5), and 0.59 (PCA-PEG10k-1) chains/nm^2, respectively. Upon photo-cross-linking formation of the cinnamate groups, the $N(\mathrm{PEG})_{\mathrm{surface}}$ showed almost no change (Table 2), indicating that it was not effective for the number of the surface PEG chains. Interestingly, the σ_{PEG} for the PCA-PEG2k-0.5 and PCA-PEG2k-1 nanoparticles increased to about twice after photo-cross-linking, due to a size decrement of the nanoparticles

Table 2. Structure of PEG Chains on the PCA-PEG Nanoparticles and BSA Adsorption onto the Surface of the PCA-PEG Nanoparticles

	$N(\mathrm{PEG})_{\mathrm{surface}}$[a]		σ_{PEG} (chains/nm^2)[b]		diameter (nm)[c]		BSA adsorption (ng/cm^2)[d]

[a] $N(\mathrm{PEG})_{\mathrm{Surface}}$ means the number of PEG chain on a single nanoparticle surface, and was estimated by ^{1}H NMR spectrum in D_2O using DSS as reference. [b] σ_{PEG} means the surface density of PEG chains on the nanoparticles. [c] Diameter was measured by DLS. [d] BSA adsorption of the nanoparticles was calculated by Lowry method. [e] Before photo-cross-linking of the cinnamate groups. [f] After photo-cross-linking of the cinnamate groups.

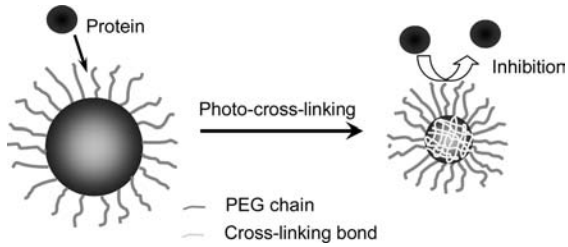

Figure 7. Schematic illustration of protein adsorption onto the nanoparticle surface before and after photo-cross-linking of the cinnamate groups with UV irradiation at $\lambda > 280$ nm.

(Figure 6). However, in the case of nanoparticles with higher grafting degrees and molecular weights of PEG, the σ_{PEG} showed a negligible change after photo-cross-linking. To the best of our knowledge, this is the first report on controlling PEG chain density on the nanoparticles by controlling the size of the nanoparticle with UV irradiation.

To evaluate the stealth properties against nonspecific protein adsorption onto the nanoparticles, bovine serum albumin (BSA) was used because albumin is one of the major proteins in serum. Table 2 shows the BSA adsorption against the surface area of the nanoparticles. The amount of adsorbed BSA onto the PCA-PEG2k-0.5 nanoparticles was about 30 ng/cm^2, and the amount of BSA decreased with increasing PEG grafting degree and molecular weight. However, the amount of adsorbed BSA was not detected when the grafting degree of PEG10k was over 5% and the molecular weight of PEG was 20k. These results suggested that PEG chains in the coronal layers can inhibit nonspecific protein adsorption. Interestingly, after photo-cross-linking of the cinnamate groups in the PCA-PEG nanoparticles with UV irradiation, the BSA adsorption significantly decreased to almost one-half as compared to the un-cross-linked one. From the results, the decrement in BSA adsorption after cross-linking seemed to contribute to the high density of the PEG brush on the coronal layer of the nanoparticles (Figure 7). Interestingly, PCA-PEG2k-5, 2k-10, 10k-0.5, and 10k-1 also showed a significant decrement in BSA adsorption, although the diameter change was not observed even after photo-cross-linking. The reason of the decrement in BSA adsorption of these samples after photo-cross-linking is still unclear. One of the possibilities for the phenomena might be a fraction of conformational and morphological change of the PEG chains in the corona layer triggered by cross-linking of PCA chains in core part. The detailed experiments to clarify these phenomena are now in progress. Although many researchers have reported controlling stealth properties by the introduction of a high density of hydrophilic groups (*17*−*19*), there is no report on improving the stealth properties by only UV irradiation. This is the first example of a significant improvement of the stealth properties of a hydrolyzable nanoparticle by controlling its photo-cross-linking-induced size change.

CONCLUSIONS

Amphiphilic PCA-PEG copolymers were prepared by Michael addition of PEG, and the copolymers were self-assembled into nanoparticles by the solvent mixing method. The nanoparticle size could be altered by the composition ratio and molecular weight of PEG. Photo-cross-linking formation of the cinnamate groups induced a size decrement of the nanoparticles depending on the grafting degree and molecular weight of PEG. Protein adsorption onto the surface of the nanoparticles was very low due to the high density of PEG chains (brush conformation). Moreover, photo-cross-linking induced a significant decrement in protein adsorption, due to an increase in the PEG chain density triggered by the size decrement of the nanoparticles. The water-dispersible and photoresponsive nanoparticles would be useful as novel functional carriers for drug delivery systems and biological diagnosis.

Precise Site-Selective Termination of DNA Replication by Caging The 3-Position of Thymidine and Its Application to Polymerase Chain Reaction

Akinori Kuzuya,* Fuminori Okada, and Makoto Komiyama*

Research Center for Advanced Science and Technology, The University of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo 153-8904, Japan. Received June 9, 2009

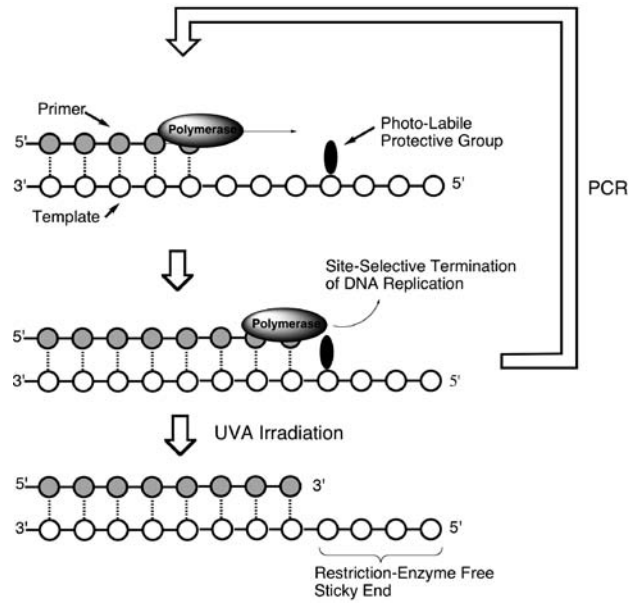
A new caged thymidine, 3-*N*-(2-(2-nitrophenyl)propyloxymethyl)thymidine (T^{NPPOM}) was synthesized and used as a site-selective terminator of DNA-polymerase reaction in light-assisted cohesive-ending PCR (LACE-PCR), which directly gives sticky-ended PCR products after brief UVA irradiation. Primer-extension experiments using a template involving T^{NPPOM} have shown that this caged nucleotide efficiently and site-selectively blocks reactions of a variety of polymerases commonly used in PCR. Misincorporation of nucleobases, observed with the use of other previously reported caged thymidines, scarcely occurred. It has turned out that a slight structural difference of caging groups can significantly improve the termination yield of polymerase reactions. A LACE-PCR product coding GFP gene was prepared by using primers containing T^{NPPOM} and was ligated with a vector fragment prepared using restriction enzymes. The resulting recombinant vector successfully transformed *E. coli*.

INTRODUCTION

Photocaging of oligonucleotides has become an attractive topic because of its potential to control genetic events simply by irradiating light without changing either chemical nor physical conditions (*1, 2*). Various oligonucleotides protected with photocleavable groups (caged oligonucleotides) have been reported. Recently, we have developed a quite simple and effective new PCR system for easily preparing sticky-ended products utilizing caged nucleotides (*3, 4*).

In current molecular biology and biotechnology, vectors are usually constructed by digesting plasmid DNA with restriction enzymes, followed by connection of this vector with predetermined gene fragment using ligase (*5*). In many cases, those gene fragments are prepared by PCR from various sources, and the blunt ends of the PCR products are converted to cohesive ends by the restriction enzymes for ligation with the vector. Although this technology has been mostly successful, two problems still remain unsolved for further developments of the field. First, recognition sites of commonly used restriction enzymes are mostly limited to some palindromic sequences, and it is sometimes difficult to find appropriate enzyme to digest DNA at (or near) the target manipulation site. Second, most of these enzymes recognize only 4 to 8 DNA-base sequences; thus, precise manipulation of large vectors such as adenovirus (30−38 kbp) with restriction enzymes is not very practical since their digestion occurs at too many sites in such large DNA. In light-assisted cohesive-ending (LACE) PCR (*4*), however, products with desired sticky ends on both ends are directly prepared after standard PCR procedures following a brief UVA irradiation, and thus no restriction enzyme treatment is necessary (Scheme 1). In order to terminate the polymerase reaction at a desired position, a caged nucleotide is incorporated into PCR primers. Within PCR cycles, elongation of the nascent strand (5′→3′ direction) is site-selectively terminated at the 3′ side of the caged nucleotide. Accordingly, the 5′ portion in the primer from the caged nucleotide remains single-stranded throughout the cycles, and predetermined sticky ends are obtained after the removal of the protecting group by brief UVA irradiation. In the previous studies, we have used a caged nucleotide 4-*O*-(2-(2-nitrophenyl)propyl)thymidine developed by Heckel et al. (T^{NPP} in Figure 1) as the site-selective terminator (*6*). We found that T^{NPP} is stable enough to survive repetitive thermal cycles for PCR and indeed terminates polymerase reaction site-selectively. The LACE-PCR products coding green fluorescent protein (GFP) gene was successfully prepared, directly ligated to vectors, and used to transform *E. coli*.

Scheme 1. Outline of the Light-Assisted-Cohesive-Ending PCR (LACE-PCR) Using a Caged Nucleotide



Although it was successful for an initial trial, some difficulties in using T^{NPP} as the terminator have come to light. Particularly, some of the polymerases misincorporate dG in front of T^{NPP} almost quantitatively, probably because the hydrogen-bonding property of T^{NPP} is similar to that of dC. Ligase is known to be a very strict enzyme; thus, such mismatches at the ends of a PCR product are unfavorable for making recombinant plasmids for standard cloning. Another difficulty of T^{NPP} is the necessity

of using special phosphoramidite monomers in automated DNA synthesis. Chemically synthesized DNA is usually treated with conc aqueous ammonia at elevated temperatures (typically 55 °C for 8 h) to deprotect nucleobases. However, T^{NPP} under such vigorous condition is easily transformed to dC via ammonolysis of the substituted 4-*O*. Thus, in combination with T^{NPP}, it is essential to use ultramild dG and dA phosphoramidite monomers that can be deprotected under much milder conditions. This is not a very convenient situation for wider use of LACE-PCR.

To solve these problems, we decided to introduce an NPP group to the 3-*N* position of the thymine base instead of 4-*O*, and have designed a new caged thymidine in this study. The 3-*N*-(2-(2-nitrophenyl)propyloxymethyl)thymidine (T^{NPPOM}, Figure 1) bears a 2-(2-nitrophenyl)propyloxymethyl (NPPOM) group on the 3-*N* position. This group was stable enough to survive vigorous deprotection conditions in standard DNA synthesis, and thus can be used with normal phosphoramidite monomers. Primer-extension experiments using a template involving T^{NPPOM} have shown that this caged nucleotide in fact efficiently and site-selectively blocks the reaction of a variety of polymerases commonly used in PCR. An application of LACE-PCR using T^{NPPOM} as the site-selective terminator for constructing recombinant plasmid was also examined.

While we were preparing this paper, Young et al. proposed the usage of 3-(6-nitropiperonyloxymethyl)thymidine (T^{NPOM}) residues, which also possess a caging group on the 3-*N*, in light regulating mutagenesis (*7*). We have examined the detailed termination efficiency of T^{NPOM} as well.

EXPERIMENTAL PROCEDURES

Syntheses of Oligonucleotides Containing Caged Thymines. The phosphoramidite monomer of T^{NPPOM} was synthesized from thymidine as shown in Scheme 2 (see Supporting Information for the details). Phosphoramidite monomers of T^{NPP} and T^{NPOM} were synthesized according to the literature (*6, 8*). The oligonucleotides containing T^{NPPOM} (**10**, **12**, and **15**) or T^{NPOM} (**13**) were prepared using standard phosphoramidite monomers on an automated DNA synthesizer. An extended 10 min coupling step was employed for T^{NPPOM} incorporation. After deprotection with conc aqueous ammonia at 55 °C for 8 h, they were purified using denaturing PAGE (except for **10**) and reverse-phase (RP) HPLC, and characterized by ESI (for **10**, Hitachi M-8000) and MALDI-TOF/MS (Bruker AutoFLEX). The oligonucleotide containing T^{NPP} (**11**) was prepared using a set of ultramild cyanoethyl phosphoramidites (phenoxyacetyl protected dA and 4-isopropyl-phenoxyacetyl protected dG monomers from Glen Research), and the deprotection was performed with conc aqueous ammonia at room temperature for 24 h. Their sequences are shown in Figure 1.

Analyses of Uncaging Oligonucleotides. UVA irradiation ($300 < \lambda < 400$ nm) on a mixture containing the caged oligonucleotide substrate **10** (1 mM) was performed by using UV Spot Light Source (Hamamatsu Photonics; 200 W) through a UTVAF-50S-36U filter (Sigma Koki) at 2.5 mW/cm^2. After predetermined times, 10 μL aliquots were analyzed on RP-HPLC with a linear gradient of acetonitrile from 5% to 50% in 45 min in the presence of ammonium formate (50 mM). The peaks at 12.8, 17.0, and 17.3 min in Figure 2A were collected and further analyzed by ESI-MS in negative ion mode for identification.

Primer Extension Reaction Using Caged Oligonucleotides as the Template. A mixture containing the caged oligonucleotide substrate **14** (2 μM), the primer oligo **11**−**13** (1 μM), and dNTPs (1.35 mM for each) was prepared. Unintended light exposure was carefully avoided throughout the process. After ExTaq polymerase (Takara) was added to the solution (0.1 U/μL), the following cycles were repeated 30 times on a thermal cycler: denaturation, 94 °C (15 s); annealing, 50 °C (30 s); elongation, 60 °C (70 s). The product was then analyzed on 20% denaturing PAGE. Extension with other polymerases were also examined under the following concentration without UV irradiation: [KOD -Plus- polymerase (Toyobo)] = 0.02 U/μL, [KOD Dash polymerase (Toyobo)] = 0.05 U/μL, and [*Pfu* DNA polymerase (Stratagene)] = 0.05 U/μL. The thermal cycles for KOD -Plus- and KOD Dash were the same as for ExTaq. For *Pfu*: denaturation, 94 °C (30 s); annealing, 55 °C (30 s); elongation, 72 °C (70 s). Imaging and quantification of gel electrophoresis were carried out on a FLA-3000G fluorescent imaging analyzer (Fujifilm, Japan).

Light-Assisted Cohesive-Ending PCR (LACE-PCR). Using pQBI T7-GFP (Wako, 0.96 ng/μL) as the template, PCR was performed under the following conditions: [**12** and **15**] = 300 nM, [dNTPs] = 200 μM, and [*Pfu* Ultra polymerase] = 0.05 U/μL. Thermal cycles are the same as described in the primer extension experiments.

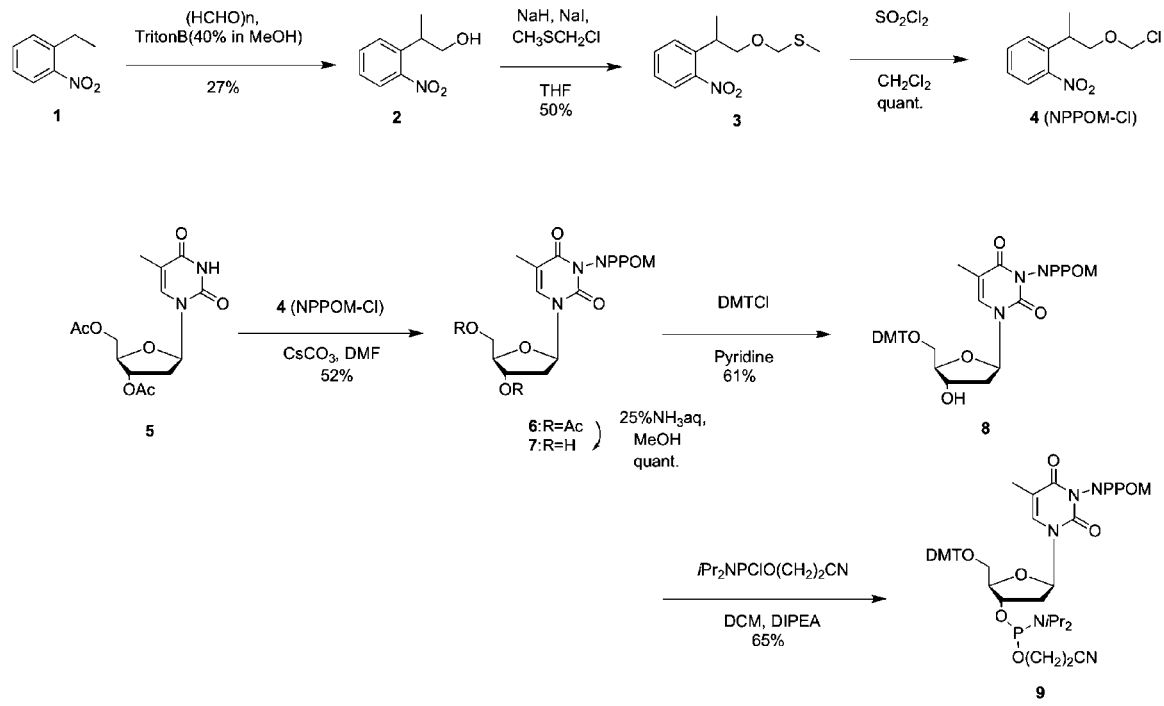
After purification with a QIAquick PCR Purification kit (Qiagen), the product in TE buffer (pH 8.5) was irradiated with UVA for 30 min at room temperature.

Construction of a Recombinant Plasmid (Scheme 3). The vector for the LACE-PCR product was prepared by cutting pUC18 with *Eco*RI and *Hind*III. The product was then dephosphorylated with alkaline phosphatase. To a 1:3 mixture of this vector and LACE-PCR product, the same volume of DNA Ligation Kit (Mighty Mix) solution was added. After incubation overnight at 16 °C, JM109 (Toyobo) was transformed with the ligation product and cultured on LB-agar media containing ampicillin (50 μg/mL) and X-gal (40 μg/mL). White colonies were subjected to colony direct PCR, and a positive colony was picked up and cultured in LB media. The recombinant vector was purified with a QIAprep spin Miniprep Kit (Qiagen), and its sequence starting 150 bp away from each conjunction was determined on a 3130× Genetic Analyzer (Applied Biosystems). For both the colony direct PCR and sequencing, 5′-TCGCCATTCAGGCTGCGCAAC-3′ (243−263 bp region of pUC18 plasmid) and 5′-TGGAAAGCGGGCAGTGAGC-3′ (590−608 bp region of pUC18 plasmid) were used as the primers. In order to observe the fluorescence from expressed GFP, the purified vector was introduced into BL21-Gold (DE3) (Stratagene). The picture of the culture was taken on a Safe Imager blue-light transilluminator equipped with a Safe Imager amber filter unit (Invitrogen).

RESULTS AND DISCUSSION

Synthesis of Phosphoramidite Monomer of T^{NPPOM} and the Caged Oligonucleotides. The structures of the caged thymidines and oligonucleotides used in this study are shown

Scheme 2. Synthetic Route of the Phosphoramidite Monomer of T^{NPPOM}



in Figure 1. T^{NPP} is the caged thymidine we used in our previous studies, and bears an NPP group on the 4-*O* position. T^{NPPOM} is the newly designed caged thymidine that bears an NPP group on the 3-*N* position via a methoxy group. T^{NPOM} is another caged thymidine that bears a caging group on the 3-*N* position. All of the oligonucleotides were synthesized on an automated DNA synthesizer using standard phosphoramidite chemistry. The phosphoramidite monomer of T^{NPPOM} was synthesized from thymidine and 2-ethylnitrobenzene as shown in Scheme 2 (see Supporting Information for the details). Phosphoramidite monomers for T^{NPOM} and T^{NPP} were prepared according to the literature (*6*, *8*). For the synthesis of **11** containing T^{NPP}, a set of ultramild cyanoethyl phosphoramidite monomers were used for dA and dG, and the deprotection was done with conc aqueous ammonia at room temperature for 24 h. Other oligonucleotides bearing T^{NPPOM} or T^{NPOM} were synthesized with standard monomers and protocols. The short oligonucleotide **10** was purified using reversed-phase (RP) HPLC and characterized by ESI and MALDI-TOF/MS analyses. Oligonucleotides **11**−**15** were purified using denaturing polyacrylamide gel electrophoresis (PAGE) and RP-HPLC, and characterized by MALDI-TOF/MS analyses (see Supporting Information).

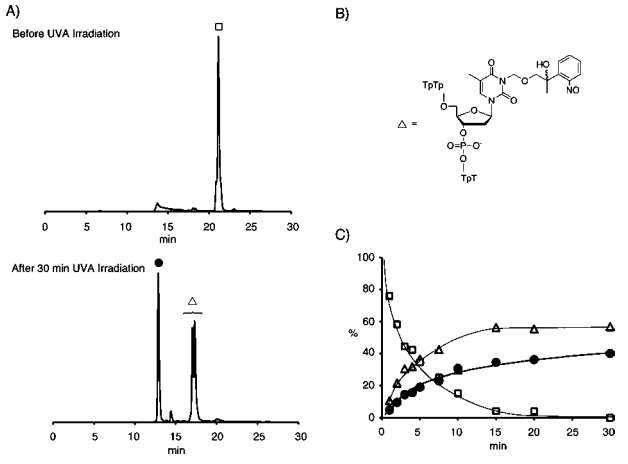


Figure 2. Uncaging of T^{NPPOM}. (A) RP-HPLC analyses of **10** before (upper) and after (lower) 30 min UVA irradiation. The peak indicated by the hollow square is **10**, the filled circle is the desired T_5, and those indicated by the hollow triangle are the byproduct bearing nitroso-species. (B) Proposed structure of the byproduct. (C) Time-course of the uncaging.

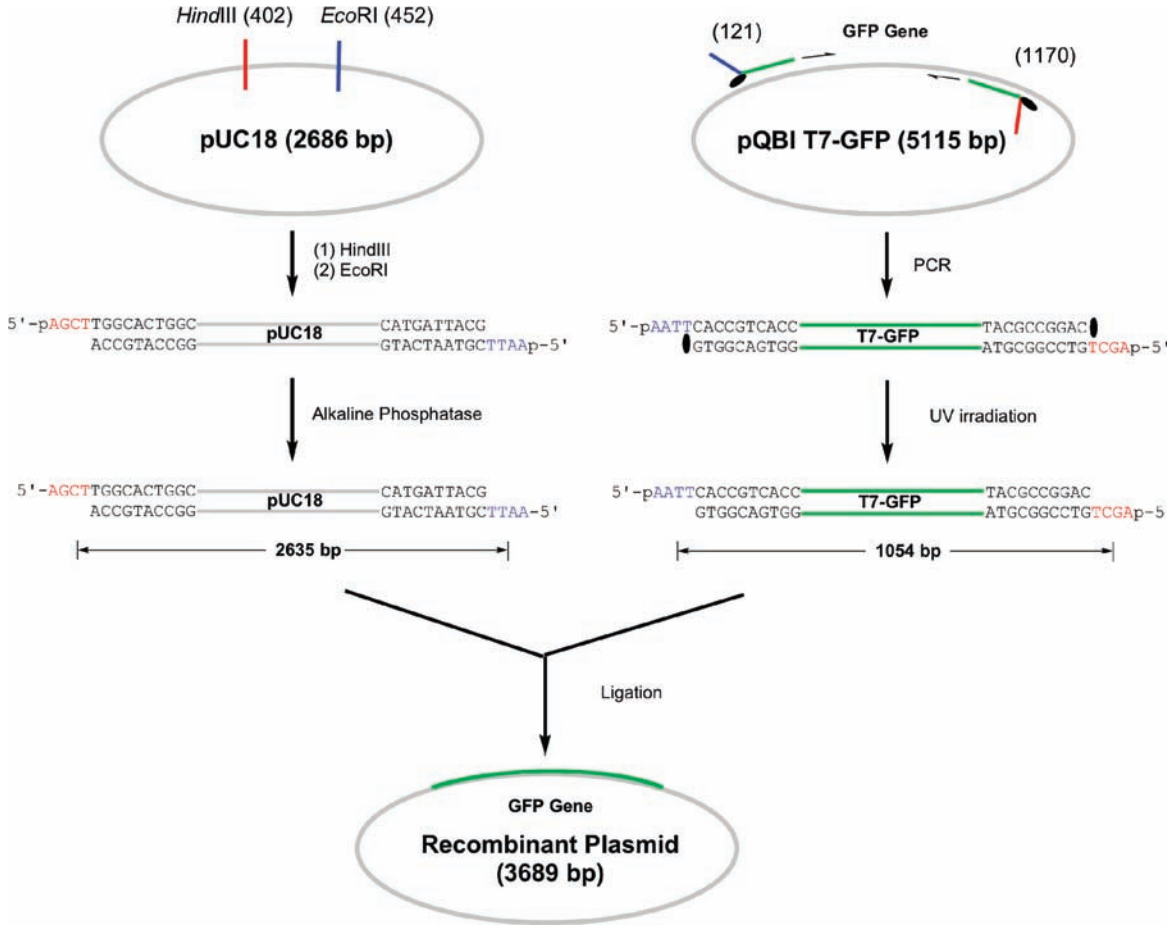
Photoremoval of NPPOM Group. Photoremoval of NPPOM group from thymine ring was examined by irradiating UVA light of $300 < \lambda < 400$ nm on a buffered solution of **10** and analyzing it on RP-HPLC. Figure 2A shows RP-HPLC charts of the mixture before and after 30 min UVA irradiation. Before UVA irradiation, a sharp peak of the caged **10** was observed at 22 min. After UVA irradiation, on the other hand, the peak at 21 min completely disappeared, and three new peaks were observed at 12.8, 17.0, and 17.3 min. MALDI-TOF/MS analyses of the isolated peak at 12.8 min showed that this is the desired product, T_5. The two peaks around 17 min, the areas of which are always equivalent to each other, were also separately isolated and subjected to ESI-MS analyses. The observed masses for them are the same in relation to each other (824.19 $[M-2H]^{2-}$, 549.85 $[M-3H]^{3-}$, 412.05 or 412.25 $[M-4H]^{4-}$), showing that these species are the diastereomers bearing a nitrosobenzene formed via the side reaction of photoremoval pathway of NPP group (Figure 2B) (*9*).

Figure 2C shows the time dependence of the yield of each species. Photoremoval of NPPOM (and also the side reaction) rapidly proceeds, and almost saturates after 15 min UVA irradiation. The average yield of the desired T_5 was around 34% in five independent reactions. Considering the mechanism of NPP photoremoval that proceeds via an ionic nitronic acid intermediate (*9*), the low yield of the desired T_5 may be caused by pH dependence of NPP removal. However, the yield did not improve much even when the pH was raised up to 9.0 or an Mg^{2+} ion was added to the solution. Higher pH is not favorable for the present system, since it elevates the risk of oxidative base damages (*10*), so we decided to fix the pH at 8.5 for UVA irradiation.

Site-Selective Termination of Polymerase Reaction by the Three Caged Thymines in the Template under PCR Conditions. Although the yield of photoremoval is unexpectedly low for T^{NPPOM}, its ability to terminate site-selective replication

Scheme 3. Construction of a Recombinant Plasmid Coding GFP Gene Using LACE-PCR



turned out to be significantly superior compared to the other two caged thymidines. Site-selective termination of polymerase reaction by the three caged thymines was first examined by primer-extension experiments under PCR thermal cycle conditions in Figure 3A. By using various polymerases commonly used for PCR, FAM-labeled primer **14** (17 nt, FAM = 6-fluoresceinamide) was extended on the modified oligonucleotide template **11**−**13** (24 nt), which contains one T^{NPP}, T^{NPPOM}, or T^{NPOM} at the fourth position from the 5′-end. When **11** was used as the template and Ex Taq was used as the polymerase, the longest product formed after predetermined thermal cycles was 20 nt, showing that primer extension was efficiently terminated at the 3′-side of T^{NPP} (lane 2 in Figure 3B). This result is completely consistent with our previous report (*4*). Similar efficient termination was observed for another template **12**, in which T^{NPPOM} is introduced in place of T^{NPP} (lane 3). The yields of the 20-mer product for the systems employing **11** and **12** was 94% and 94%, respectively. MALDI-TOF/MS analysis of the reaction mixture also confirmed that d(GAC) was correctly added to the 3′-end of **12** (Figure 4A). When T^{NPOM} was introduced in place of T^{NPPOM}, on the other hand, significant amounts of further elongated products were obtained (lane 4). The yields of the 20-mer, 21-mer, and 23-mer products in lane 4 were 65%, 25%, and 10%, respectively. No undesired removal of NPPOM (or NPOM) was observed in the control HPLC analysis of the template **12** (or **13**) even after the corresponding PCR thermal cycles (Supporting Figure 1 in Supporting Information). Thus, the difference between T^{NPPOM} and T^{NPOM} cannot be ascribed to the difference in the thermal stability of the caging group, but may be related to their structural aspects.

Similar differences in termination ability were observed for other polymerases such as KOD and *Pfu*. Figure 3C,D shows primer-extension experiments using *Pfu* polymerases. Two commercially available cocktails of this polymerase, which are optimized to the amplification of different length of the templates, were examined. Both of the cocktails showed fairly good termination for all of the three caged thymidines. Particularly, the yield of the 20-mer product for both of the NPPOM systems was around 92−94%, which is one of the best numbers we have observed so far. For NPP and NPOM systems, on the other hand, ca. 30% formation of 21-mer product was observed. Primer-extension experiments were performed with KOD polymerase and its related cocktails, as well. In our previous study, this proofreading polymerase was found to introduce dG in front of T^{NPP} almost quantitatively as in lane 3 in Figure 3E. As a result, the major product using KOD polymerase in combination with T^{NPP} is 21-mer (the yield is 43%), and significant amount (up to 40%) of longer products was also produced. In contrast, introduction of T^{NPPOM} in the template resulted in fairly good termination of the KOD reaction in front of T^{NPPOM} as in lane 4. The yield of the desired 20-mer product was 77%, and that of the longer byproduct was only 20%. Quite interestingly, the desired 20-mer product was obtained only with 16% yield by use of the template bearing T^{NPOM} (**13**) even if the hydrogen bonding face of thymine is completely blocked by T^{NPOM}. The major product was the 21-mer (58% yield). MALDI-TOF/MS analysis of the reaction mixture revealed that both 20- and 21-mer products are a mixture of two or more species with different sequences around the end (Figure 4D). The mass difference between the smaller peaks corresponding to 21-mer and 20-mer is 200−230, which

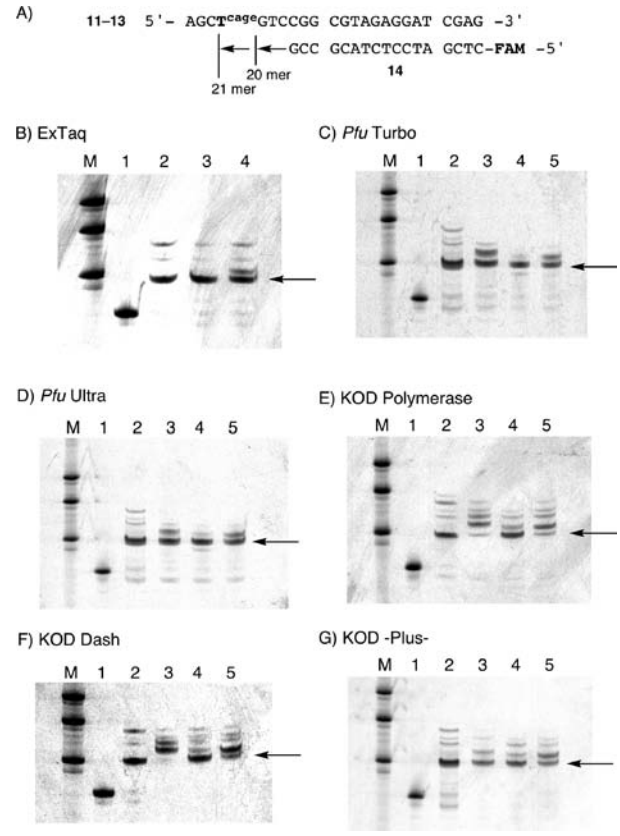


Figure 3. 20% denaturing PAGE patterns for primer extension reaction using caged oligonucleotides **11**−**13** as a template. (A) Structures of the oligonucleotides. (B) Lane 1, unreacted **14**; lane 2, **11** + **14**; lane 3, **12** + **14**; lane 4, **13** + **14**. (C−G) Lane 1, unreacted **14**; lane 2, **11** + **14** with ExTaq (the same as (B) lane 2); lane 3, **11** + **14**; lane 4, **12** + **14**; lane 5, **13** + **14**; M, size markers (20-, 25-, and 30-mer single-stranded DNA). The 20-mer products are indicated by the arrows.

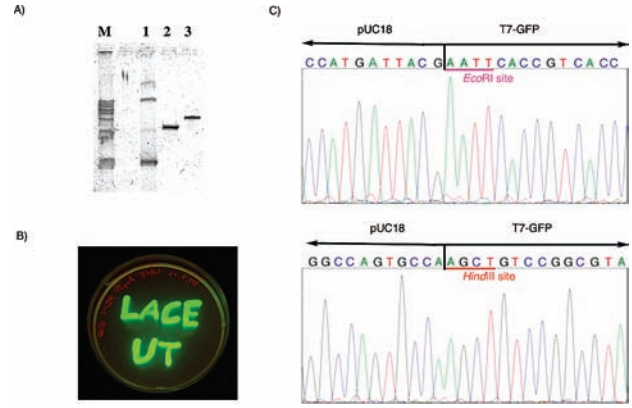

Figure 5. Analyses of the recombinant vector. (A) Agarose gel electrophoresis patterns for the LACE-PCR product and the recombinant vector. Lane 1, LACE-PCR product; lane 2, pUC18 plasmid treated with *Eco*RI and *Hind*III; lane 3, the recombinant plasmid extracted from JM109 and linearized with *Eco*RI; lane M, 1 kbp ladder. (B) The fluorescence of GFP expressed from the recombinant vector in BL21-Gold (DE3) cells. (C) Sequencing of the cloned recombinant vector extracted from JM109 around the *Eco*RI conjunction and the *Hind*III site conjunction.

is significantly smaller than the minimum mass increase of native DNA elongation (addition of one dC is +289). Considering that multiple peaks were observed even for the 20-mer products, it is presumed that KOD polymerase misincorporates the wrong nucleotide also in front of the adjacent residues in the 3′ side of T^{NPOM} (marginally for T^{NPPOM} as well), which is upstream of elongation. It is possible that the present finding is related to the mutation mechanism induced by 3-Me-thymidine lesion in cells (*11*). KOD Dash, which is a cocktail of KOD polymerase and KOD exo(-) variant gave very similar PAGE patterns to KOD polymerase (Figure 3F). The yields of the 20-mer product with T^{NPP}, T^{NPPOM}, and T^{NPOM} were 8%, 65%, and 26%, and the yields of the 21-mer were 54%, 17%, and 52%, respectively. Undesired additional incorporation of the 21st nucleotide in front of T^{NPP} and T^{NPOM} was rather marginal for KOD -Plus-, another cocktail of KOD polymerase with customized buffer contents (Figure 3G). The yield of the desired 20-mer product using T^{NPP} improved to 73% (lane 3), which is almost the same as 74% yield with the use of T^{NPPOM} (lane 4). However, the major product for the reaction using T^{NPOM} was still the 21-mer (47%), and only 42% of the product was the desired 20-mer.

Construction of a Recombinant Vector Coding GFP Gene with LACE-PCR Using Primers Containing T^{NPPOM}. To check whether the site-selective termination practically occurs and desired sticky ends can be obtained after LACE-PCR using T^{NPPOM} as the site-selective terminator, PCR products bearing sticky ends complementary to *Eco*RI and *Hind*III termini were prepared. By using **12** and **15** as the primers, the 121−1170 bp region of pQBI T7-GFP plasmid was amplified. This portion of the plasmid involves GFP gene with T7 promoter. For this experiment, *Pfu* Ultra was used as the polymerase for its high fidelity and excellent termination by T^{NPPOM} observed above. Deprotection of NPPOM groups in the PCR product was performed with UVA irradiation for 30 min on the purified product solution. Considering the yield of NPP removal (ca. 40% for each NPP), approximately 16% of the product is expected to have fully deprotected, desired sticky ends at both ends. As shown in Figure 5A, a product of desired length (1 kbp) was successfully amplified (lane 1).

The insert obtained above was ligated to a vector fragment, which was prepared by digesting pUC18 with *Eco*RI, *Hind*III, and was dephosphorylated with alkaline phosphatase. Then, JM109 competent cells were transformed with the ligation

product. After overnight incubation on a culture plate containing ampicillin and X-gal, ca. 500 white colonies were obtained (only one blue colony was observed). A total of eight colonies were subjected to direct PCR using primers complementary to pUC18 plasmid 150 bp away from each of the digestion site, and one colony gave the expected amplicon of 1.4 kbp from the designed recombinant. The size of the extracted plasmid from this colony (linearized with *Eco*RI, lane 3 in Figure 5A) was significantly larger than the parent pUC18 fragment and consistent with the expected 3689 bp. The other seven colonies gave no apparent amplicon. Taking into account that all of these colonies are white, the latter seven colonies are presumed to have pQBI T7-GFP, which was the template for LACE-PCR.

When the extracted plasmid was introduced into BL21-Gold (DE3) competent cells, in which T7 polymerase is expressed, emission of green fluorescence from the expressed GFP was clearly observed (Figure 5B), showing that no undesired and critical DNA mutation was induced in the gene in this clone by UVA irradiation. Precise construction of the recombinant vector was directly confirmed by sequencing the extracted plasmid (Figure 5C). The sequences near the *Eco*RI site and the *Hind*III site were both completely consistent with the expected ones. Successful formation of both of the sticky ends by LACE-PCR using T^{NPPOM} as the site-selective replication terminator, and its practical use has been evidenced.

Recent studies have shown that UVA radiation as well as UVB causes various oxidative damages on DNA, which result in DNA degradation or mutation (*12*). According to the calculation in the previous study, ca. 4% of the population can contain one damage bases such as cyclobutane pyrimidine dimer (CPD) formation, purine oxidative damage, pyrimidine oxidative damage, and abasic damage in total, and the other 96% are expected to be intact after the UVA irradiation. However, the competent cells commonly used today lack the RecA system, which is mainly responsible for repairing such damage. Thus, the cells transformed with plasmids containing such damaged bases cannot multiply themselves, and consequently, only the intact ones will be selected. We have not yet found any mutation in more than twenty kinds of recombinant plasmids we have obtained with LACE-PCR so far (data not shown). Similarly, it is strongly expected that the byproduct formed after UVA irradiation is not ligated to the vector fragment because of the strict selectivity of the ligase, and nothing to do with the recombinants.

CONCLUSIONS

The newly synthesized T^{NPPOM} residue site-selectively and efficiently blocks polymerase reaction under PCR conditions, and the selectivity was the best among the three caging group examined in this study. The caged primers involving T^{NPPOM} can be synthesized in combination with conventional phosphoramidite monomers on an automated DNA synthesizer, and no change in deprotection conditions is necessary. Although the yield of light triggered deprotection is not very high under the conditions employed in this study, the 1-kbp LACE-PCR products using the caged primers involving T^{NPPOM} were successfully ligated with a vector fragment prepared by restriction-enzyme treatments, and the GFP coded in the resulting recombinant plasmid was efficiently expressed in the transformed bacteria.

The present findings in primer-extension reactions using three kinds of caged thymidines have shown that the blocking of hydrogen bonding between nucleobases is not the only requirement to achieve efficient and selective termination of the polymerase reaction. A significant difference in termination efficiency and selectivity was observed between T^{NPPOM} and T^{NPOM}. A noticeable difference between these two caging groups is the position of just one methylene: in the main chain or on the benzene ring. Structural aspects of the caging group may play an important role here in a close connection with the enzymatic mechanisms of substrate recognition for each of the polymerases. Future detailed study on this topic may be relevant to understanding the mechanism of mutation in vivo as well.

Synthesis of 3-*N*-(2-(2-nitrophenyl)propyloxymethyl)thymidine phosphoramidite 9.

2-(2-nitrophenyl)propanol (2)

2-Ethylnitrobenzene **1**(6.0 g, 40 mmol) and $(HCHO)_n$ (1.5 g, 40 mmol) were added to TritonB (40% in MeOH) (17 g) and the mixture was refluxed for 7 h. The solvent was evaporated, and the residue was dissolved in EtOAc. The organic layer was washed with 5% HCl, dried over Na_2SO_4, filtered and evaporated. The product was purified by silica gel column chromatography using hexane/EtOAc (3:1) as eluent affording **2** as reddish purple oil in 27% yield (1.95 g 10.7 mmol).
^{1}H NMR ($CDCl_3$) δ 1.34 (3H, d, CH_3), 3.50–3.58 (1H, m, CH), 3.77–3.86 (2H, m, CH_2), 7.36 (1H, t, Ar-H), 7.50 (1H, d, Ar-H), 7.58 (1H, t, Ar-H), 7.76 (1H, d, Ar-H).

2- (2-nitrophenyl) methylthiomethoxypropane (3)

Compound **2**(1.95 g 10.7 mmol) was added in 20 mL of THF and stirred at 0 ˚C under nitrogen. Sodium hydride (60% assay) (0.6 g) was added to the solution and stirred at 0 ˚C. After 45min sodium iodide (1.62 g, 10.7 mmol) was added to the reaction mixture and then chloromethyl methyl sulfide (1.29 g, 13.35 mmol) was added. After 4h the reaction mixture was warmed to room temperature and the solvent was evaporated. The residue was poured into 30 mL of water and extracted with ether. The organic layer was dried over Na_2SO_4, filtered and evaporated. The product was purified by silica gel column chromatography using CH_2Cl_2 as eluent affording **3** as brown oil in 50% yield (1.32 g, 5.43 mmol).
^{1}H NMR ($CDCl_3$) δ 1.36 (3H, d, CH_3), 2.00 (3H, s, CH_3), 3.63–3.76 (3H, m, CH, CH_2), 4.58 (2H, d, CH_2), 7.34 (1H, t, Ar-H), 7.52 (2H, m, Ar-H), 7.75 (1H, d, Ar-H).

2-(2-nitrophenyl)chloromethoxypropane (4)

Compound **3**(1.32 g, 5.43 mmol) was added in 20 mL of CH_2Cl_2 and stirred at 0 ˚C under nitrogen. SO_2Cl_2 (0.94 g, 6.96 mmol) was added to the solution and stirred for 4 h. The reaction mixture was warmed to room temperature and the solvent and excess SO_2Cl_2 was evaporated in vacuo. This procedure afforded **4** as brown oil (quantitative conversion) which was directly used without purification.
^{1}H NMR ($CDCl_3$) δ 1.37 (3H, d, CH_3), 3.66 (1H, m, CH), 3.81 (2H, m, CH_2), 5.43 (2H, q, CH_2), 7.36 (1H, t, Ar-H), 7.48 (1H, d, Ar-H), 7.57 (1H, t, Ar-H), 7.76 (1H,d, Ar-H).

Thymidine diacetate (5)

Thymidine (2.93 g, 12.1 mmol) and DMAP (40 mg, 0.327 mmol) were added in 60 mL of Ac_2O under nitrogen. Pyridine (30 mL) was added to the solution and stirred at room temperature over night. The solvent and excess Ac_2O was evaporated in vacuo and the residue was poured into 100 mL of $CHCl_3$. The organic layer was washed with 100 mL of water, dried over Na_2SO_4, filtered and evaporated. The product was purified by silica gel column chromatography using EtOAc/hexane (3:1) as eluent affording **5** as white solid foam in 71% yield (2.82 g, 8.64 mmol).

^{1}H NMR ($CDCl_3$) δ 1.94 (3H, s, CH_3), 2.10-2.22 (8H, m, $2CH_3$, CH_2), 2.46 (1H, m, CH), 4.36 (2H, dd, CH_2), 5.22 (1H, d, CH), 6.32 (1H, q, CH), 7.29 (1H, s, CH), 8.65 (1H, s, NH).

3-*N*-(2-(2-nitrophenyl)propyloxymethyl)thymidine diacetate (6)

Compound **5** was dissolved in 20 mL of DMF. Cs_2CO_3 was added to the solution and stirred for 1 h at room temperature. The reaction mixture was then cooled to 0 ˚C. Compound **4** (1.26 g, 5.47 mmol, dissolved in 10 mL of DMF) was added dropwise to the reaction mixture and stirred at room temperature over night. The solvent was evaporated in vacuo and the residue was poured into EtOAc. The organic layer was washed with 2 × 30 mL of water and 30 mL of a sat. $NaHCO_3$ solution. Then the organic layer was dried over Na_2SO_4, filtered and evaporated. The product was purified by silica gel column chromatography using EtOAc/hexane (2:1) as eluent affording **6** as yellow foam in 52% yield (1.50 g, 2.89 mmol).

^{1}H NMR ($CDCl_3$) δ 1.31 (3H, dd, CH_3), 1.93 (3H, d, CH_3), 2.11 (8H, m, $2CH_3$, CH_2), 3.57 (1H, m, CH), 3.74–3.88 (2H, m, CH_2), 4.25 (1H, s, CH), 4.34 (2H, m, CH_2), 5.21 (1H, d, CH), 5.36 (2H, m, CH_2), 7.28 (1H, s, CH), 7.31 (1H, t, Ar-H), 7.46 (1H, d, Ar-H), 7.51 (1H, t, Ar-H), 7.71 (1H, t, Ar-H).

3-*N*-(2-(2-nitrophenyl)propyloxymethyl)thymidine (7)

Compound **6**(1.50 g, 2.89 mmol) was dissolved in 20 mL of MeOH. Concentrated aqueous ammonia (8 mL) was added to the solution and stirred for 1 h at room temperature. The solvent was evaporated in vacuo. This procedure afforded **7** as yellow foam (quantitative conversion) which was directly used without purification.

^{1}H NMR ($CDCl_3$) δ 1.31 (3H,d, CH_3), 1.90 (3H, d, CH_3), 2.31–2.42 (2H, m, CH_2), 3.55–3.65 (1H, m, CH), 3.75–3.95 (4H, m, $2CH_2$), 3.97 (1H,q, CH), 4.55 (1H, m, CH), 5.34 (2H, m, CH_2), 7.31 (1H, t, CH), 7.43 (2H, t, 2Ar-H), 7.52 (1H, t, Ar-H), 7.70 (1H, dd, Ar-H).

3-*N*-(2-(2-nitrophenyl)propyloxymethyl)thymidine dimethoxytrityl ether (8)

Compound **7** (1.26 g, 2.89 mmol) and dimethoxytrityl chloride (1.19 g, 3.51 mmol) were dissolved in 20 mL of Pyridine under nitrogen and stirred at room temperature over night. The solvent was evaporated in vacuo and the residue was poured into 30 mL of EtOAc. The organic layer was washed with brine, dried over Na_2SO_4, filtered and evaporated. The product was purified by silica gel column chromatography using hexane/EtOAc (1:1) and 3% TEA as eluent affording **8** as yellow foam in 61% yield (1.31 g, 1.77 mmol).

^{1}H NMR ($CDCl_3$) δ 1.31 (3H, d, CH_3), 1.92 (3H,d, CH_3), 2.28–2.50 (2H, m, CH_2), 3.56 (1H, m, CH), 3.76–3.90 (10H, m, $2CH_2$, $2CH_3$), 3.92 (1H, m, CH), 4.56 (1H, m, CH), 5.37 (2H, m, CH_2), 6.16 (1H, d, CH), 6.84 (4H, d, 4Ar-H), 7.17 (3H, d, 3Ar-H), 7.27–7.36 (7H, m, 6Ar-H, CH), 7.36 (1H, d, Ar-H), 7.47 (1H, d, Ar-H), 7.51 (1H, q, Ar-H), 7.71 (1H, d, Ar-H).

ESI-MS: *m/z* 760.8 $[M+Na]^+$.

3-*N*-(2-(2-nitrophenyl)propyloxymethyl)thymidine phosphoramidite (9)

Compound **8** (0.30 g, 0.406 mmol) was dissolved in 2 mL of AN under nitrogen. DIPEA and

2-cyanoethyl-diisopropyl-chloro phosphoramide (200 µL, 0.912 mmol) were added to the solution and stirred for 1.5 h at room temperature. The solvent was evaporated. The residue was poured into sat. $NaHCO_3$ solution and extracted with EtOAc. The organic layer was washed with brine. The organic layer was dried over Na_2SO_4, filtered and evaporated. The product was purified by silica gel column chromatography using $CHCl_3$/MeOH (20:1) with 3% TEA as eluent affording **9** as yellow foam in 65% yield (0.25 g, 0.26 mmol).

ESI-MS: *m/z* 961.7 $[M+Na]^+$.

Metalloenzymes and electron transfer proteins influence the electrochemical properties of metal cofactors by controlling the second-sphere environment of the protein active site. Properties that tune this environment include the dielectric constant, templated charge structure, van der Waals interactions, and hydrogen bonds. By systematically varying the binding of a redox-active ligand with a protein, we can evaluate how these noncovalent interactions alter the electronic structure of the bound metal complex. For this study, we employ the well-characterized avidin−biotin conjugate as the protein−ligand system, and have synthesized solvatochromic biotinylated and desthiobiotinylated iron(II) bipyridine tetracyano complexes ($[Fe(BMB)(CN)_4]^{2-}$ (**1**) and $[Fe(DMB)(CN)_4]^{2-}$ (**2**)). The binding affinities of **1** and **2** with avidin are 3.5×10^7 M^{-1} and 1.5×10^6 M^{-1}, respectively. The redox potentials of **1** and **2** (333 mV and 330 mV) shift to 193 mV and 203 mV vs Ag/AgCl when the complex is bound to avidin and adsorbed to a monolayer-coated gold electrode. Upon binding to avidin, the **MLCT1** band red-shifts 20 nm for **1** and 10 nm for **2**. Similarly, the **MLCT2** band for **1** red-shifts 7 nm and the band for **2** red-shifts 6 nm. For comparison, the electronic properties of **1** and **2** were investigated in organic solvents, and similar shifts in the MLCT bands and redox potentials were observed. An X-ray crystal structure of **1** bound to avidin was obtained, and molecular dynamics simulations were performed to analyze the protein environment of the protein-bound transition metal complexes. Our studies demonstrate that changes in the binding affinity of a ligand-receptor pair influence the outer-sphere coordination of the ligand, which in turn affects the electronic properties of the bound complex.

INTRODUCTION

The properties of coordinatively saturated transition metal complexes can be profoundly influenced by their environment (*1*−*7*). The ligands of a transition metal complex can interact with surrounding solvent molecules, macromolecular species, or proteins to affect the electronic state of the metal complex. These noncovalent interactions (known as outer-sphere or second-sphere coordination) include hydrogen bonding, $\pi-\pi$ stacking, electrostatic, hydrophobic, and van der Waas interactions (*8*−*11*).

The concept of outer-sphere coordination was introduced by Werner to explain phenomena such as solvents of crystallization and the formation of adducts between amines and coordinatively saturated complexes (*12, 13*). In 1981, Stoddart and co-workers presented the first crystallographic evidence of this type of interaction, in which a crown ether is associated with a Pt-ammine complex through noncovalent interactions (*14*). In recent years, it has been shown that interactions with the second sphere of coordination complexes affect the physical properties. For example, interaction of 18-crown-6-ether with the second sphere of a series of ruthenium-ammine complexes results in changes in the spectroscopic and electrochemical properties of the complexes (*6, 7*).

Second-sphere coordination is important in biological processes such as iron siderophore recognition, and is currently being investigated as a means to mimic the diverse functionality of metalloenzymes (*9, 15, 16*). The ability to modulate the properties of transition metal complexes through second-sphere ligand design is of interest for the development of artificial metalloenzymes that combine the features of both heterogeneous and enzyme catalysis (*17, 18*). Ward and co-workers use chemogenetic protein engineering to optimize artificial metalloenzymes comprising a catalyst anchored to a biological macromolecule (*19*−*21*). Second-sphere coordination is known to play an important role in activity and enantioselectivity in these catalytic reactions (*17, 19*−*22*).

Previously, we reported a series of redox active transition metal-modified biotin complexes designed to probe the effects of protein binding on the electrochemical response (Figure 1) (*23*). The biotin−avidin system was chosen as a model due to its strong binding interaction ($K_a = 10^{15}$ M^{-1}) and extensive structural characterization (*24*−*26*). Electrochemical studies demonstrated that the avidin-bound complexes are shielded and unable to effectively interact with the electrode. However, the bound complexes can be accessed via electrochemical mediators, suggesting that the complex is only partially shielded in the binding pocket of the protein (*23*). Quantitative results could not be obtained for the electrochemical potential of the protein-bound complex. Therefore, to investigate the effects of the protein binding on the electronic properties of the bound complex, we chose to use $[Fe(bpy)(CN)_4]^{2-}$ complexes (Figure 1). $[Fe(bpy)(CN)_4]^{2-}$ complexes possess electrochemical and optical properties that are highly sensitive to the local environment (*4, 27*−*29*).

To investigate how differences in ligand-receptor binding energetics influence the second-sphere coordination environment

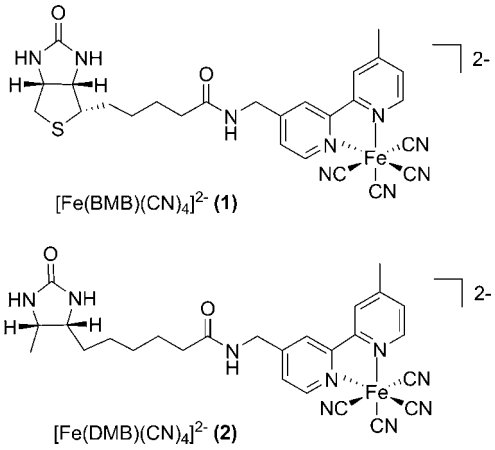

Figure 1. Structures of $[Fe(BMB)(CN)_4]^{2-}$ and $[Fe(DMB)(CN)_4]^{2-}$. Solvatochromic $[Fe(bpy)(CN)_4]^{2-}$ complexes are targeted to bind avidin by modification with biotin (**1**) or desthiobiotin (**2**) through amide derivatization of 4-aminomethyl-methyl-2,2′-bipyridine.

of a small molecule when bound to a protein, we designed two redox-active, solvatochromic transition metal complexes that bind to avidin with different affinities. Herein, we directly correlate systematic modifications of the complex environment to observed changes in electrochemical and spectroscopic signals. The influence of avidin binding on the electrochemical and spectroscopic properties of $[Fe(BMB)(CN)_4]^{2-}$ (**1**) and $[Fe(DMB)(CN)_4]^{2-}$ (**2**) is discussed in light of X-ray crystallographic, electrochemical, optical, computational, and thermodynamic studies.

EXPERIMENTAL SECTION

Materials and Methods. Deglycosylated avidin was used for crystallization studies and obtained from Belovo, Inc. Egg white avidin, used for thermodynamic studies, was obtained from Molecular Probes. Poly(ethylene glycol) was obtained from Fisher Scientific. All other chemicals were obtained from Aldrich. $K_2[Fe(BMB)(CN)_4]$ (**1**) and $K_2[Fe(DMB)(CN)_4]$ (**2**) were prepared according to previously reported methods (*23*).

Electrochemistry. Cyclic voltammetry experiments were carried out in a conventional three-electrode cell using a CH Instruments 660A workstation (Austin, TX), glassy carbon working electrode (3 mm dia, CH Instruments), Pt wire counter electrode, and Ag/AgCl reference electrode. The reference electrode was calibrated to Fc/Fc^+. The electrode was polished with alumina on a polishing cloth and the sample purged with N_2 before each experiment. All electrochemical potentials ($E_{1/2}$) are reported vs Ag/AgCl [where $E_{1/2}$ is defined as $(E_{pa} + E_{pc})/2$].

Cyclic voltammograms of **1** were collected in solvents of varying acceptor number (AN). A 200 μL aliquot of a 50 mM aqueous solution of **1** was added to 3 mL of a 50/50 solvent/100 mM PBS buffer (pH 7.2) mixture where the solvents were water (AN = 55), methanol (AN = 41), DMSO (AN = 19), or DMF (AN = 16) (*30*). Cyclic voltammograms of **1** and **2** in 0%, 10%, 20%, 30%, 40%, and 50% DMF in PBS buffer were collected. Samples were prepared by adding appropriate amounts of solvent and water to 1.5 mL 100 mM PBS buffer (pH 7.2) to make a 3 mL sample with a constant electrolyte concentration of 50 mM. A 200 μL aliquot of a 50 mM aqueous solution of **1** or **2** was added to the solution. For example, the 10% DMF sample was prepared by adding 0.3 mL DMF and 1.2 mL water to 1.5 mL 100 mM PBS buffer.

In order to obtain cyclic voltammograms of **1** and **2** bound to avidin, a gold ball electrode was prepared by melting the end of a 0.127-mm-diameter gold wire into a ball approximately 0.75 mm in diameter. The electrode was cleaned electrochemically by immersing it in 2 N H_2SO_4 and cycling the potential between 0 and 1.6 V at a scan rate of 500 mV/s. The electrode was rinsed with water followed by ethanol and immediately immersed in a 5 mM ethanolic solution of 11-mercaptoundecanoic acid for 16 h. The electrode was washed with ethanol followed by water and 10% $NH_4OH_{(aq)}$. It was then immersed in an aqueous solution consisting of 0.1 mM **1** or **2** and 4 mg/mL avidin for 2 h. The electrode was washed with water, and cyclic voltammograms were obtained in 100 mM PBS buffer (pH 7.2).

Absorption Spectroscopy. UV−vis absorption studies were performed using an Agilent 8453 spectrophotometer (Foster City, CA). Samples were prepared as described for electrochemical experiments. UV−vis spectra of **1** and **2** bound to avidin were obtained by preparing a solution of each in 100 mM PBS buffer and adding a 1.5-fold excess of avidin.

Isothermal Titration Calorimetry. Thermodynamic studies of **1** and **2** were carried out using a VP-ITC microcalorimeter from MicroCal, Inc. (Northampton, MA). In a typical experiment, the reference cell was filled with pure distilled water. The reaction cell was filled with 1.8 mL of a 6 μM solution of avidin (24 μM avidin protomer) in pH 7.0 phosphate buffer. The injection syringe was filled with a 300 μM solution of **1**. After thermal equilibration to 25 °C, **1** was injected into the reaction cell in 5 μL aliquots every 200 s until saturation was achieved (18 injections). A reference offset of 25% was used. The experiment was repeated injecting **1** into pH 7.0 phosphate buffer. The data were subtracted from the binding data to correct for heats of dilution. The data were fit using the *Origin 7.0* OneSites model to determine binding constants (K_a) and heats of binding (ΔH). The above procedure was repeated for compound **2**.

Crystallization and Data Collection. The $K_2[Fe(BMB)(CN)_4]$ complex was incubated with avidin for 1 h at room temperature. The avidin-$[Fe(BMB)(CN)_4]^{2-}$ complex was crystallized at 18 °C by using the sitting drop vapor diffusion method. A protein solution containing 3.0 mg/mL avidin bound by $[Fe(BMB)(CN)_4]^{2-}$ in phosphate buffer pH 7.0 was combined with an equal volume of precipitant solution comprising 100 mM sodium acetate (pH 4.6) and 25% PEG 3000. The resulting crystals were harvested after six weeks. The crystals were hexagonal, space group $P3_221$, with unit cell dimensions $a = b = 74.20$, $c = 85.82$.

X-ray data were collected at 100 K at the Advanced Photon Source on beamline 5-ID from crystals flash-frozen in liquid nitrogen after soaking in a cryo-protectant composed of the well solution plus 20% ethylene glycol. The diffraction data were integrated with MOSFLM (*31*) and scaled by using SCALA (*32*). The statistics are presented in Table 5.

Structure Determination and Refinement. Phases were determined by molecular replacement using the program PHASER (*33*) and avidin from the pdb file 1LDO as the search model. The ligand-bound form of avidin was modeled with XtalView (*34*), refined with CNS (*35*), and validated with PROCHECK (*36*).

Molecular Modeling. Force field parameters were derived for $[Fe(BMB)(CN)_4]^{2-}$ and $[Fe(BMB)(CN)_4]^{2-}$. Atomic partial charges were taken from the Mulliken population analysis of ab initio geometry minimizations. These calculations were carried out at the Hartree−Fock (HF) level in the program Gamess (*37*). A Hay−Watt effective core potential was used to describe the iron atoms (*38*). The carbon and nitrogen atoms in the bipyridyl and cyano ligands were described by 6-31+G* basis set (*39*). All other atoms were described by the 6-31 G* basis set (*40*). Geometries and charges were calculated for both 2+ and 3+ metal ionization states.

Table 1. Variation of MLCT Wavelengths and Electrochemical Potential of K_2[Fe(BMB)$(CN)_4$] with Acceptor Number (AN)

solvent	AN	**MLCT1** (nm)	**MLCT2** (nm)	$E_{1/2}$ (mV)
water	55	480	341	333
MeOH	41	496	348	257
DMSO	19	512	356	195
DMF	16	519	357	181
avidin	−	500	348	193

Iron-ligand bonds were modeled using the points-on-a-sphere methodology (*41*). In this method, iron−nitrogen and iron−carbon bond lengths are held constant (acquired from crystal structures of similar compounds) (*42*) and the atom−iron−atom bond angles are determined by the electrostatic interaction of the atoms around the metal center.

The crystal structure of the biotin−avidin complex (obtained from the Protein Data Bank) was used as the starting geometry for the molecular dynamics simulation (*26*). Hydrogen atoms and other atoms missing from the crystal structure were added referencing standard amino acid residues from AMBER. The ab initio optimized geometry coordinates for the [Fe(bpy)-$(CN)_4]^{2-}$ complex were appended to the coordinates of the crystal structure of avidin bound biotin for each of the four binding avidin protomers. The energy of the avidin/{[Fe(BMB)-$(CN)_4]^{2-}\}_4$ tetrameric complex was minimized using a combined steepest descent and conjugate gradient minimization technique. The minimized structure was solvated with a 75 Å × 75 Å × 75 Å box of water of approximately 13 800 TIP3P water molecules. The solvated protein structure was minimized using the method described above.

Molecular dynamics (MD) simulations were carried out for the avidin/$\{[Fe(BMB)(CN)_4]^{2-}\}_4$ tetrameric complex using the *Amber 94* force field (*43*). Constant volume periodic boundary conditions were employed; the simulation boundary box constructed was slightly larger than the extent of the water buffer used to solvate the protein. A dielectric constant of 4 was assigned to the boundary box to dampen the effects of electrostatics on the system. MD simulations were run for 1 ns recording energy and trajectory information every picosecond.

The isopotential surfaces were rendered with HARLEM from a calculation of the electrostatic potential by solving the Poisson−Boltzmann equation using the method of finite differences (*44*). Electrostatic calculations were carried out using the partial charges on the avidin/$\{[Fe(BMB)(CN)_4]^{2-}\}_4$ complex to represent the charge distribution. The static dielectric constant as a function of position, also used in the Poisson equation, was mapped by defining the low dielectric volume of the protein by a solvent-accessible surface (SAS). A solvent probe radius of 1.4 Å was used to define the SAS. Atoms contained inside the boundary of the surface are assigned a low dielectric constant of 4, outside the surface the dielectric is assigned value of 80 for water. These calculations yield the isopotential surface surrounding the modified ligands. Calculations were made for atoms within a 10 Å shell around the binding ligand. This calculation provides an estimate of the electric field immediately surrounding the ligand and indicates portions of the protein with net positive or net negative charge.

RESULTS

Electrochemistry. The $E_{1/2}$ of **1** and **2** in PBS pH 7.2 are 333 mV and 330 mV, respectively. These values are in agreement with previously reported values and comparable to that of [Fe(4,4′-dimethyl-2,2′-bipyridine)$(CN)_4]^{2-}$ (312 mV) (*23*, *45*). The $E_{1/2}$ of **1** increases with increasing solvent acceptor number (AN) where AN describes the Lewis acidity of the solvent (Table 1, Figure 2) (*30*, *46*). When DMF is introduced incrementally to an aqueous solution of **1** or **2**, the $E_{1/2}$ decreases linearly (Tables 2 and 3, Figure 3). The plot of current (*i*) vs

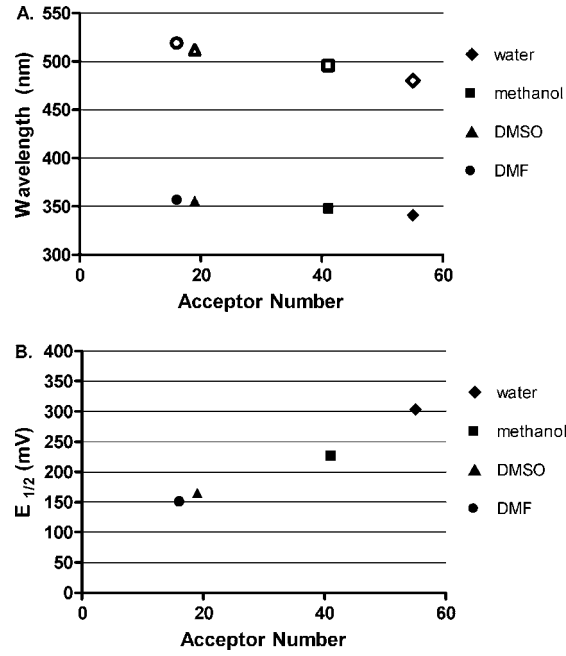

Figure 2. (A) Correlation of the K_2[Fe(BMB)$(CN)_4$] MLCT bands with solvent acceptor number. Closed (•) symbols represent **MLCT2**; open symbols (○) represent the **MLCT1**. (B) Correlation of the K_2[Fe(BMB)$(CN)_4$] $E_{1/2}$ with solvent acceptor number. Cyclic voltammograms were collected at 100 mV/s using a glassy carbon electrode and Ag/AgCl reference. Values are reported vs Ag/AgCl.

square root of scan rate (υ) is linear for **1** and **2** in all solvent systems. The average ΔE_p (difference of the peak potentials) for **1** and **2** is 64 mV and is consistent for all solvent systems. The i_a/i_c ratio is 0.8 for **1** and 1.0 for **2** in all solvent systems.

An electrochemical signal is not observed for **1** or **2** bound to avidin in solution (*23*). When adsorbed to a mercaptoundecanoic acid (MUA) SAM-coated gold electrode, **1** has an $E_{1/2}$ of 193 mV and **2** has an $E_{1/2}$ of 203 mV. At 100 mV/s, the ΔE_p for **1** in this experiment is 85 mV with an i_a/i_c ratio of 1.1 (Supporting Information Figure S1). The ΔE_p for **2** is 75 mV with an i_a/i_c ratio of 1.1 (Figure 4).

Absorption Spectroscopy. For an aqueous solution of **1**, a charge transfer (CT) band is observed at 293 nm and two MLCT bands are observed at 341 nm [metal dπ → bipyridine π^* (2) (**MLCT2**)] and 480 nm (metal dπ → bipyridine π^* (1) (**MLCT1**)) (*47*). The λ_{max} of the MLCT peaks are red-shifted

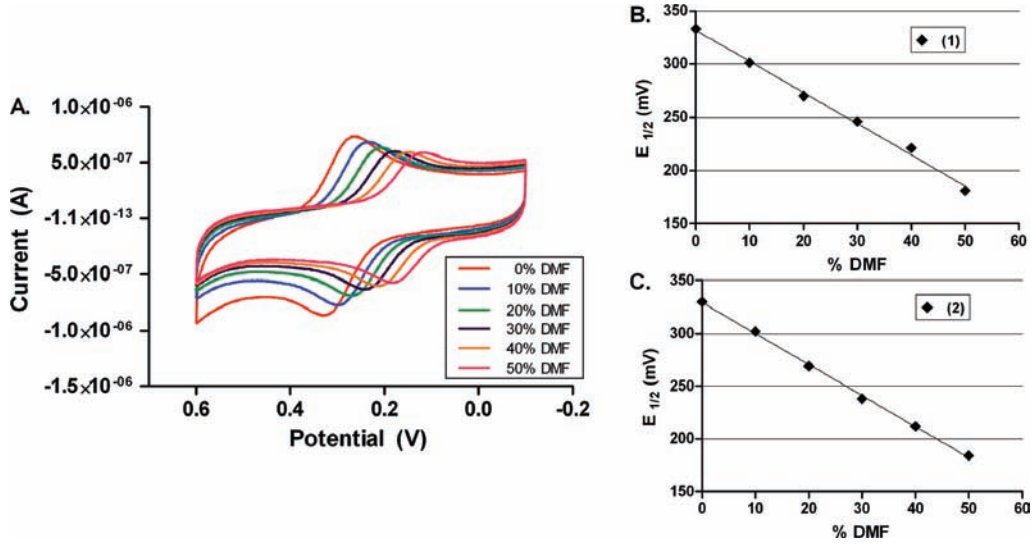

Figure 3. Electrochemistry of $K_2[Fe(BMB)(CN)_4]$ and $K_2[Fe(DMB)(CN)_4]$ in increasing concentrations of DMF in PBS buffer at pH 7.2. (A) Representative cyclic voltammograms of $K_2[Fe(DMB)(CN)_4]$ (B) Correlation of the $E_{1/2}$ of $K_2[Fe(BMB)(CN)_4]$ with increasing amounts of DMF (C) Correlation of the $E_{1/2}$ of $K_2[Fe(DMB)(CN)_4]$ with increasing amounts of DMF. Cyclic voltammograms were collected at 100 mV/s using a glassy carbon electrode and Ag/AgCl reference. Values are reported vs Ag/AgCl.

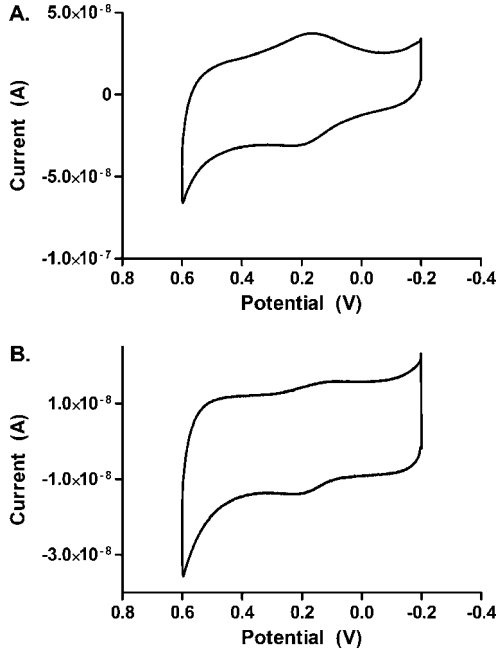

Figure 4. Cyclic voltammogram of (A) $K_2[Fe(DMB)(CN)_4]$ and (B) $K_2[Fe(BMB)(CN)_4]$ adsorbed to a mercaptoundecanoic acid SAM on a gold ball electrode. The cyclic voltammograms were collected at 100 mV/s in 100 mM PBS at pH 7.2 with Ag/AgCl as a reference.

linearly with decreasing solvent acceptor number (Table 1, Figure 2). When DMF is introduced incrementally to an aqueous solution of **1**, the λ_{max} values of the MLCT peaks are red-shifted proportionally (Table 2, Figure 5). Upon addition of avidin to **1** in PBS buffer, the **MLCT1** band shifts 20 nm (833 cm^{-1}) and the **MLCT2** band shifts 7 nm (590 cm^{-1}) (Table 2). When an excess of biotin is added to the solution of **1**-avidin, the λ_{max} values of the MLCT peaks are shifted back to the original values.

For an aqueous solution of **2**, a CT band is observed at 293 nm and two MLCT bands are observed at 345 nm (**MLCT2**) and 486 nm (**MLCT1**). When DMF is introduced incrementally to an aqueous solution of **2**, the λ_{max} values of the MLCT peaks are red-shifted proportionally (Table 3, Figure 5). Upon addition of avidin to **2** in buffer, the **MLCT1** band shifts 10 nm (415 cm^{-1}) and the **MLCT2** band shifts 6 nm (495 cm^{-1}) (Table 3). When an excess of biotin is added to the solution of **2**-avidin, the λ_{max} values of the MLCT peaks are shifted back to the original values.

Isothermal Titration Calorimetry. For **1** and **2**, the amount of energy released per mole of complex titrated was plotted versus the molar ratio of complex to protein. The curve was best fit using the Origin OneSites model to give the binding constant (Supporting Information Figure S1). The reduced χ^2 value was 1.3 and 1.1 for **1** and **2**, respectively. Binding constants and heats of binding for **1** and **2** binding to avidin are summarized in Table 4.

Structure of the $[Fe(BMB)(CN)_4]^{2-}$-Avidin Complex. Complex **1** bound to both protomers in the 3.1 Å resolution crystal structure of the avidin complex is shown in Figure 6. As expected, the biotin group binds to a site identical to one previously characterized (*26*). In one protomer, electron density for the $[Fe(BMB)(CN)_4]^{2-}$ group is observed on the surface of the protein, sandwiched among three loops: L3,4; L5,6; and L7,8 (Figure 6B). This configuration appears stabilized by several hydrogen bonding pairs including interactions of N12, S16, Y33, T35, T77, and N118 with the ureido portion of the complex, S73 and S75 with the carbonyl of the amide bond, and S31 and S102 with the transition metal portion of the complex. In the second protomer, electron density for the $[Fe(BMB)(CN)_4]^{2-}$ group and residues 41−44 on the L3,4 loop were not observed.

Molecular Modeling. In the course of the molecular dynamics simulation, several conformations were found to be accessible to **1** when bound to avidin (Supporting Information Figure S2). The conformation in closest agreement with the crystal structure was chosen to compare the second-sphere environment of **1** and **2** when bound to avidin. In this conformation, the distances from the α carbon of Ser 41 and the metal atom of **1** and **2** are 5.76 and 5.92 Å, respectively. The distance between Ser 101 and the metal atom was found to be approximately 10 Å for both **1** and **2**. The distance between Ser 102 and the metal atom was found to be approximately 5 Å for both **1** and **2**. Loss of β architecture in strands 3 and 4 is observed and loops 7,8 and 5,6 are disordered for **2** bound to avidin. The models of **1** and **2** bound to avidin are compared in Figure 7. The isopotential surface of the portion of the protein that surrounds avidin (Figure

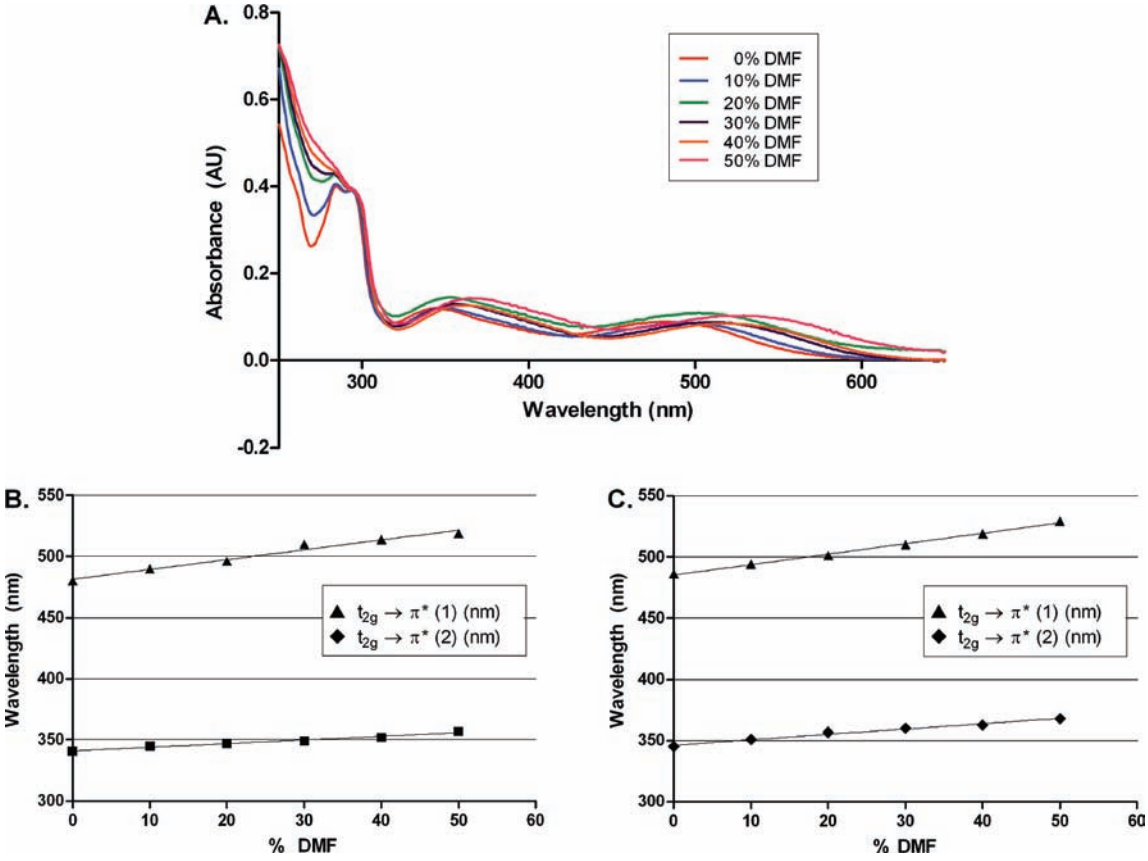

Figure 5. Absoprtion spectroscopy of $K_2[Fe(BMB)(CN)_4]$ and $K_2[Fe(DMB)(CN)_4]$ in increasing concentrations of DMF in PBS buffer at pH 7.2. (A) Representative UV−vis spectra of $K_2[Fe(DMB)(CN)_4]$. (B) Correlation of the $K_2[Fe(BMB)(CN)_4]$ MLCT bands. (C) Correlation of the $K_2[Fe(DMB)(CN)_4]$ MLCT bands with increasing amounts of DMF. The wavelengths of the MLCT bands are linearly correlated to the solvent fraction indicating that no preferential solvation of the complexes occurs.

ligand	K (M^{-1})	ΔH (kcal/mol)
$K_2[Fe(BMB)(CN)_4]$	3.5×10^7	−104
$K_2[Fe(DMB)(CN)_4]$	1.5×10^6	−80

8) is mainly positive in nature. This portion of the protein should have favorable interactions with the net negative charge of **1** and **2**.

DISCUSSION

The redox properties of metal complexes in proteins are influenced by changes in the surrounding protein environment (e.g., cytochrome c and blue copper proteins) (*48*−*50*). Metal cofactors bound to proteins experience a solvation environment with a lower local dielectric constant than that of aqueous buffer. The dielectric constant (ε) of water is 80, whereas ε is estimated to be between 4 and 20 inside a protein (*51*−*53*). Changes in the dielectric constant affect the energetics for electronic transitions of metal redox centers. Further, the protein imparts a structured charge environment around the metal complex due to the partial charges of each atom. This charge structure, with its partial positive or negative properties, stabilizes more strongly either the reduced or oxidized state of the metal. Finally, the protein can be viewed as a scaffold containing electrophilic or nucleophilic residues capable of multiple interactions with the metal cofactor.

In order to probe changes in outer-sphere coordination induced by changes in ligand-receptor binding, we have synthesized a biotinylated iron(II) complex (**1**) and a desthiobiotinylated iron(II) complex (**2**). These redox-active, solvatochromic transition metal complexes are designed to bind to the protein avidin. Biotin and desthiobiotin bind to avidin with K_a's of 10^{15} M^{-1} and 10^{13} M^{-1}, respectively (*54*). Therefore, weaker ligand-receptor binding is expected to give the $[Fe(DMB)(CN)_4]^{2-}$ complex slightly more flexibility within the binding pocket as compared to $[Fe(BMB)(CN)_4]^{2-}$. Therefore, the dielectric constant, charge structure, van der Waals, and

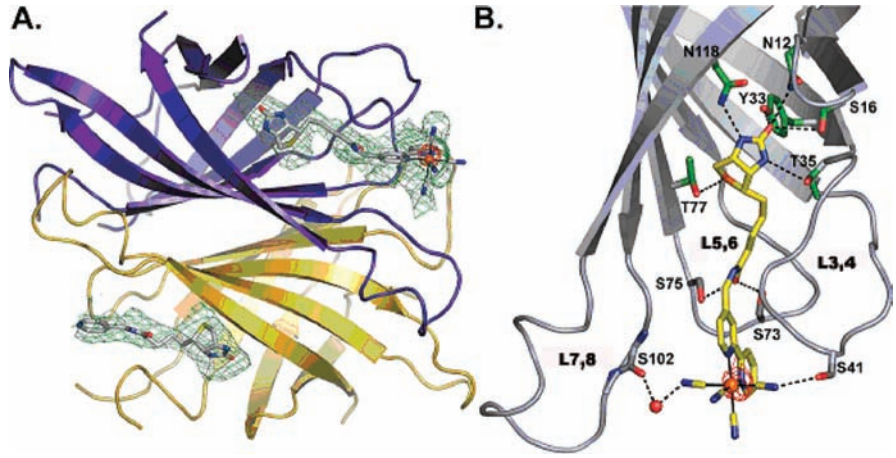

Figure 6. Structure of $[Fe(BMB)(CN)_4]^{2-}$ bound to avidin. (A) The asymmetric unit shows $[Fe(BMB)(CN)_4]^{2-}$ bound to two avidin protomers. The other two protomers are related by crystallographic symmetry. $2|F_o| - |F_c|$ omit maps are depicted around the modeled ligand at 1σ (green) and 4σ (red). (B) View of ligand−protein interactions. Amino acids in green interact with biotin as observed in crystal structures of native D-biotin bound to avidin (*26*). Residues in gray hydrogen bond to the $[Fe(bpy)(CN)_4]$ portion of the complex. The $2|F_o| - |F_c|$ omit density is superposed at 4σ.

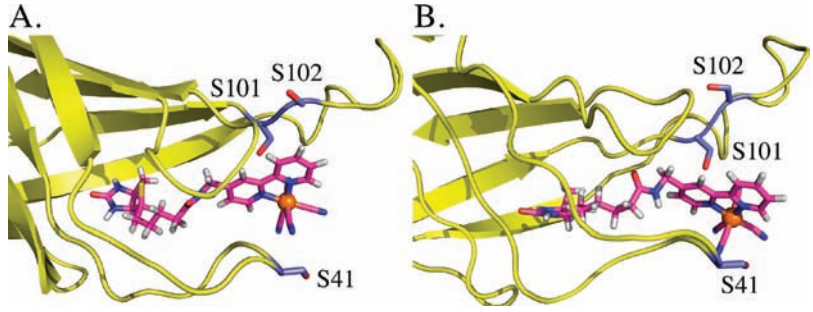

Figure 7. A view of the final structure of the molecular dynamics simulation of avidin bound by (A) $[Fe(BMB)(CN)_4]^{2-}$ and (B) $[Fe(DMB)(CN)_4]^{2-}$. One monomer of the tetramer avidin is shown.

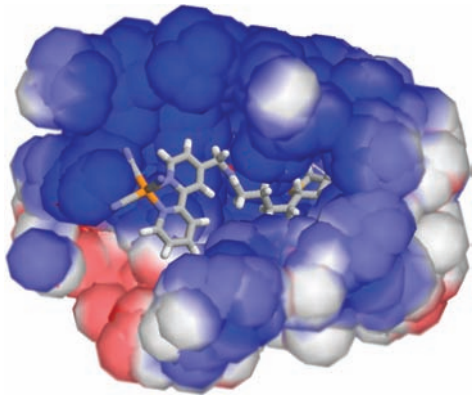

Figure 8. Isopotential surfaces of the avidin binding pocket (shown in space filling mode) as calculated by the program HARLEM. Blue corresponds to positive charges, and red corresponds to negative charges. This representation indicates that there are favorable interactions between the binding pocket and the negatively charged **1** (shown) and **2**.

hydrogen bonding contacts near the metal will differ for **1** and **2**. We have used a variety of techniques to observe differences in the electronic structure of these complexes as imparted by the protein.

Electronic Structure, Solvatochromism, and Acceptor Number. Iron(II) tetracyano complexes are known to be highly sensitive to changes in environment (*4, 27, 29, 55, 56*). $[Fe(bpy)CN)_4]^{2-}$ is a paramagnetic complex with C_{2v} symmetry that has completely filled $d\pi$ orbitals (d_{xy}, d_{xz}, d_{yz}), and these orbitals act as the HOMO set for the molecule. Oxidation of the iron(II) to iron(III) species requires removal of an electron from one of these metal-centered orbitals.

The environmental sensitivity of these complexes is largely due to noncovalent interactions with the lone pair electrons on the cyano ligands. Solvent molecules interact noncovalently with these lone pairs. Strong electron acceptors such as water decrease the electron density at the CN and therefore increase π backbonding with the metal ion. This interaction stabilizes the iron(II) state with respect to the iron(III) state. Depending on solvent, the LUMO in $[Fe(bpy)(CN)_4]^{2-}$ might be either the unfilled metal d-orbitals (d_{z2} and d_{x2-y2}) or the π^* levels of the bipyridine ligands (*28*). The first optically allowed transitions from the $d\pi$ orbitals, however, are to the π^* orbitals of the bipyridine ligand (*47*). Weak acceptors such as DMF decrease the π backbonding as compared to water. Therefore, as DMF is added to the system, water molecules are displaced and the iron(II) state becomes destabilized. A solvent with a high acceptor number such as water will result in a higher-energy metal to ligand charge transfer (MLCT) as compared to weak acceptors such as DMF. These changes in MLCT energy are significant enough to be observed spectroscopically. Likewise, stabilization of the iron(II) complex will result in higher oxidation potentials that can be observed by electrochemical methods such as cyclic voltammetry.

The absorbance of **1** in various solvents was measured to investigate the sensitivity of the physical properties of **1** to second-sphere effects. The solvents were chosen to represent a range of ANs. We observed a larger shift of the low-energy **MLCT1** band compared to the **MLCT2** band. This result indicates that the solvent is interacting with both the cyano and bipyridine ligands to stabilize the π^* orbitals of the bipyridine

ligand to varying degrees. This phenomenon has been described for cyanoiron(II) complexes by Toma and co-workers and demonstrates that changes in the second-sphere environment around any part of the molecule, whether it is the bipyridine or the cyano ligands, result in spectroscopic changes (*56*).

As increasing amounts of DMF are added to an aqueous solution of **1** or **2**, the energy of MLCT bands decreases linearly (Table 2, Figures 3 and 5). This linear correlation in a binary solvent system demonstrates the effect of an increasingly nonpolar environment and indicates that no preferential solvation of the complexes occurs (*56*). DMF displaces water molecules from the second sphere of the metal complex, and the complexes do not have a tendency to maintain a solvation shell of water when a nonpolar solvent is introduced.

To investigate the sensitivity of the redox potentials of **1** and **2** to second-sphere coordination, the electrochemical potential $E_{1/2}$ of **1** and **2** was determined in a variety of solvents. As the AN is decreased, the $E_{1/2}$ decreases (Table 1, Figure 2). Further, as increasing amounts of DMF are added to an aqueous solution of **1** or **2**, the $E_{1/2}$ decreases linearly (Table 2, Figures 3 and 5).

These solvent experiments provide a basis for rough comparison with avidin-binding results. Upon addition to an aqueous solution of **1** or **2**, DMF replaces water in the vicinity of the metal complex; when **1** or **2** binds to avidin, water will be displaced from the metal center in a similar way.

X-ray Crystal Structure and Binding Properties. Isothermal titration calorimetry was used to measure the binding constants of **1** and **2** to avidin. The binding affinities of **1** and **2** for avidin are $3.5 \times 10^7\ M^{-1}$ and $1.5 \times 10^6\ M^{-1}$, respectively. These values demonstrate a significant decrease in binding affinity compared to that of native D-biotin ($K = 1 \times 10^{15}\ M^{-1}$) and D-desthiobiotin ($K = 1 \times 10^{13}\ M^{-1}$). The data fit best to the case where all four binding sites are identical, and binding is independent. Previous studies by Livnah and co-workers demonstrate that when bound to avidin, modification of biotin at the carboxyl terminus by a caproic acid results in disruption of the hydrogen bonding of Thr 38, Ala 39, and Thr 40 with the carboxyl terminus of biotin. This disruption results in a decrease in binding affinity (7 to 8 orders of magnitude) for biotin analogues that have an amide at the carboxylic acid (*57*).

The crystal structure shows two unique protomers (Figure 6). Avidin is a tetramer; the other two protomers are related by crystallographic symmetry. It is apparent that **1** is in a relatively hydrophobic (low dielectric) environment and interacts directly with the protein via electrostatic and hydrogen bonding interactions. While several biotinylated-transition metal complexes have been synthesized, only one other has been structurally characterized bound to avidin (*20, 23, 58*−*61*). Similar to the observations of Ward et al., there are short contacts between the metal center of **1** and amino acid residues. Importantly, there is no major reorganization of the host protein.

The three-dimensional structure of **1** bound to avidin shows that the cyano ligands of the iron complex interact with specific residues in the avidin binding pocket. In one protomer, the Ser 41 residue of the L3,4 loop interacts directly with a CN group on the iron(II) complex, and Ser 102 of the L5,6 loop interacts with a CN group through a water molecule. We expect these interactions with the cyano groups to have an observable effect on the electrochemical properties of **1** and **2** bound to avidin. The stabilizing, attractive interaction of the protein with the cyano groups prevents the loops from opening as they do in the cases where the carboxyl terminus is derivatized by caproic acid (*40, 57, 62*).

In the second protomer, electron densities for the $[Fe(bpy)CN)_4]^{2-}$ moiety of **1** and residues 41−44 on the L3,4 loop were not observed. These differences are most likely due to disorder imposed by crystal packing. This conclusion is supported by ITC data that are best fit for a system with four identical binding events.

We have used the program HARLEM to calculate the isopotential surface of avidin and show that the binding pocket of avidin is positive in nature (Figure 8). **1** and **2** are negatively charged and have small polar ligands that should promote interactions with the protein. This portion of the protein should have favorable interactions with the net negative charges of **1** and **2**.

Molecular Dynamics Simulations. Molecular dynamics simulations were carried out with **1** and **2** bound to avidin to compare the local environments of the transition metal complexes when bound to avidin. Several similar conformations were found to be accessible to **1** and **2** when bound to avidin in the course of the molecular dynamics simulation (conformations of **1** shown in Supporting Information Figure S2). The conformation in closest agreement with the crystal structure of **1** bound to avidin was chosen to compare the second-sphere environment of **1** and **2** when bound to avidin. For comparison, the distance between the apex of loop 3,4 (Ser 41) and the metal center was measured. This distance is specifically of interest because the crystal structure shows that Ser 41 has a direct interaction with **1**. The distance from the α-carbon of Ser 41 to the iron center in **1** is 5.76 Å, whereas in **2**, the distance is 5.92 Å. We did not observe a water molecule between Ser 102 and the cyano group in the molecular dynamics simulation, as was observed in the crystal structure of avidin with **1**. The MD simulations show that Ser 101 has a stronger interaction with the binding ligand than does Ser 102. The distance between Ser 101 and the iron center is ∼5 Å, while the distance between Ser 102 and the iron atom is ∼10 Å. These observations are slightly different than values determined from the crystal structure; however, they are reasonable due to the fluxional nature of the protein in the molecular dynamics simulations. While the location of the ligand within the protein in the crystal structure is very informative, it is only a snapshot of the ensemble of configurations that the metal complex samples during a spectral or electrochemical measurement. The MD simulations further show that, when **2** is bound, the protein structure is more disordered. Figure 7 shows the disorder in strands 3 and 4 and loops 7,8 and 5,6 for **2** as compared to **1** bound to avidin. The environment of **2** is slightly more open and water-accessible than the environment that **1** experiences.

Electronic Affects of Avidin Binding. UV−vis spectroscopy was used to measure roughly the HOMO−LUMO gaps of **1** and **2** while bound to the protein. The optical spectra in aqueous solution show two MLCT bands, one to each of the first two π^* levels of the bipyridine ligands (**MLCT1** at lower energies, 480 nm for **1** and 486 nm for **2**; and **MLCT2** at higher energies, 341 nm for **1** and 345 nm for **2**). Upon binding of avidin to **1**, the **MLCT1** band red-shifts 20 nm and the **MLCT2** band red-shifts 7 nm. Upon binding of avidin to **2**, the **MLCT1** band red-shifts 10 nm and the **MLCT2** band red-shifts 6 nm. When an excess of biotin is added to displace **1** or **2** from avidin, the λ_{max} of the MLCT bands shifts back to the original values reported for the compounds in aqueous solution. These results demonstrate that the outer-sphere coordination of the molecule changes with the ligand receptor binding. The UV−vis studies show that the molecule with the lower binding constant (**2**) has smaller changes in MLCT bands compared to that of **1**, consistent with a higher acceptor number environment.

The spectroscopic shifts upon avidin binding to **1** and **2** are similar to the shifts observed when increasing amounts of DMF are added to aqueous solutions of **1** or **2**. The protein binding event displaces water molecules from the metal center just as DMF replaces water molecules that are interacting with the metal center. This solvent system provides a convenient model

for systematically varying the environment to crudely mimic protein binding.

Electrochemistry. The redox potentials of **1** and **2** while bound to avidin were found to shift by −140 and −127 mV, respectively. These potentials were measured by electrostatically adsorbing the protein to a monolayer of mercaptoundecanoic acid (MUA). These dramatic shifts are most likely due to the interaction of the complex with the monolayer as well as the protein. Being sandwiched between the protein and the monolayer minimizes any interaction with bulk water and places the complexes in an even lower dielectric environment compared to avidin in solution. The protein/monolayer combination destabilizes the iron(II) state with respect to the iron(III) state, compared with the complex in aqueous solution, raising the energy level of the orbitals that comprise the HOMO. The HOMO is destabilized by 1130 cm^{-1} and 1050 cm^{-1} for **1** and **2**, respectively.

Immobilization techniques are commonly used to study electroactive proteins (*61*, *63*−*70*). In our case, a monolayer of MUA was formed and then washed with $NH_4OH_{(aq)}$ in order to leave a number of negatively charged acids on the surface (the pI of avidin is ∼10, and therefore the protein should be positively charged at pH 7). Figure 8 shows the charge distribution at the binding pocket of avidin at pH 7. There is a significant area with a positive charge near the binding site. This positive charge ensures that a portion of the avidin on the monolayer will be oriented so that the bound iron complexes will make effective contact. The observed electrochemical signal is likely from these bound complexes (*61*). Since avidin is a tetramer, it is likely that a maximum of two of the binding sites are in contact with the monolayer at any given time.

CONCLUSION

We have established that the electronic structures of $[Fe(BMB)(CN)_4]^{2-}$ and $[Fe(DMB)(CN)_4]^{2-}$ are highly sensitive to noncovalent interactions. The optical spectrum shifts up to 20 nm in organic solvents with lower acceptor numbers than water. The shift is linearly dependent on the solvent acceptor number indicating there are specific interactions between the solvent and the CN and bpy ligands. Similarly, the electrochemical response of **1** and **2** in various organic solvents shows a shift that is linearly dependent on solvent AN; shifts of up to 150 mV are observed. These data suggest that the electronic structure of **1** and **2** is sensitive to second-sphere coordination changes and solvation.

The results from solvent studies confirm that the complexes can be used as sensitive probes to investigate the electronic properties of protein binding sites. Binding of **1** and **2** to avidin results in visible changes in the electronic spectra. The shifts are similar to those observed in the solvent studies. We expect the binding event to exclude water from the metal complex, resulting in a lower AN environment. For example, binding of **1** to avidin can be compared to a solution of **1** in 23% DMF in water.

Our data show that the environments of **1** and **2** in avidin are observably different. ITC measurements show that the binding of **2** is weaker than that of **1** by a factor of ∼20. Therefore, we expect **1** and **2** to sample slightly different environments in the binding pocket. Indeed, small differences are observed in both the optical and electrochemical data. Upon binding to avidin, the optical spectrum shifts 20 and 7 nm for **1**, while the same transitions shift 10 and 6 nm for **2**. The binding of **2** can be compared to 12% DMF in water. The difference in redox potential shifts is small (10 mV), yet well above the error for such a measurement.

The three-dimensional X-ray structure of **1** bound to avidin shows **1** partially buried in a hydrophobic pocket with a direct interaction between the protein and the transition metal complex. An open-loop conformation, expected from the presence of the amide, would prevent the avidin from shielding the complex from bulk water and minimize the observable change in electrochemical potential and absorbance properties. Isopotential calculations, however, show a patch of positive charge near the binding site that should favor binding of the negatively charged **1** and **2**. These interactions may partially counteract the effects of having the amide in place of the carboxylic acid. Finally, molecular dynamics simulations show that, when **2** is bound to avidin, the protein structure is slightly more disordered. However, for the MD snapshot most resembling the crystal structure, the distances between the metal center and select residues are nearly the same as when **1** is bound.

Together, these results demonstrate that even small changes in the binding of a ligand (**1** or **2**) result in small yet experimentally observable changes in second-sphere coordination imposed by the protein. Specifically, these changes include the partial charge structure, van der Waals interactions, and hydrogen bonds. Small changes in these weak interactions are powerful enough to induce changes in the electrochemical and optical properties of the metal cofactors.

The synthetic versatility and the sensitivity of $[Fe(bpy)(CN)_4]^{2-}$ complexes to local environmental changes makes these complexes candidates for use in electronic and optical protein detection devices for any number of ligand-receptor pairs. For example, by systematic change of the protein binding ligand (e.g., adding or removing hydrogen bond donors) and observing the effect of protein binding on the spectroscopic properties, the nature of an unknown binding pocket can be evaluated. Further, the shift in the electrochemical potential indicates whether solvent is being excluded from the metal center and therefore can be used to evaluate the hydrophobicity of the binding site.

Sensitivity to small changes in binding affinities indicates that these species can be used as probes for remotely evaluating the noncovalent factors that affect ligand-receptor binding. Our future studies will translate this approach to self-assembled monolayer systems for investigating the effects of protein binding on the electrochemical properties of the metal complex.

ACKNOWLEDGMENT

We thank Belovo, Inc. for providing deglycosylated avidin. We thank Harry Gray, Igor Kurnikov, Baudilio Tejerina, and Alec Durrell for helpful discussions. This work was funded by the Nanoscale Science and Engineering Initiative of the National Science Foundation under NSF Award Number EEC-0647560 and Ohmx Corporation. MR thanks the MURI program of the DoD for support.

Supporting Information

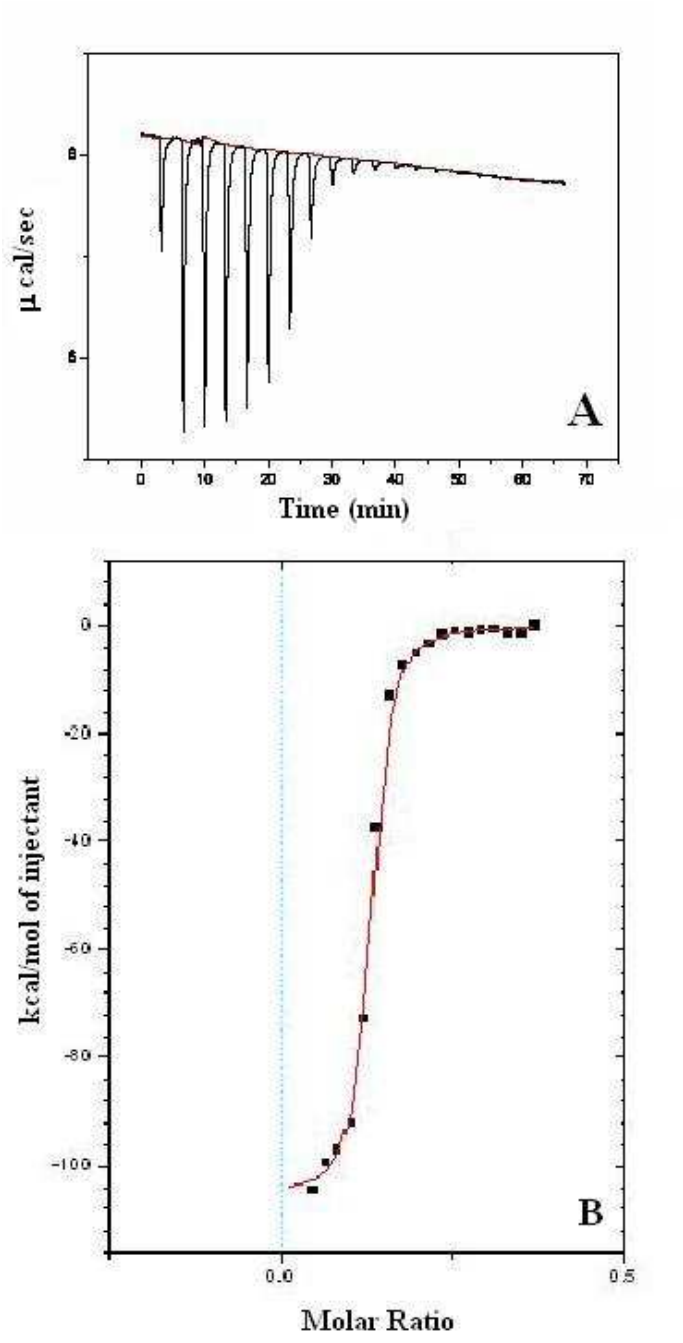

Figure S1: Calorimetric titration of avidin (24 µM in protomer) with $K_2[Fe(BMB)(CN)_4]$ (300 µM) at 25 ºC. (A) Raw data obtained for 18 injections of 4 µL each plus an initial injection of 2 µL; (B) Heat of reaction plotted versus molar ratio of metal complex to protein at each injection point. This plot is fit using Origin 7.0 OneSites model to obtain thermodynamic information and a reduced χ^2 value of 1.3 was obtained for the fit.

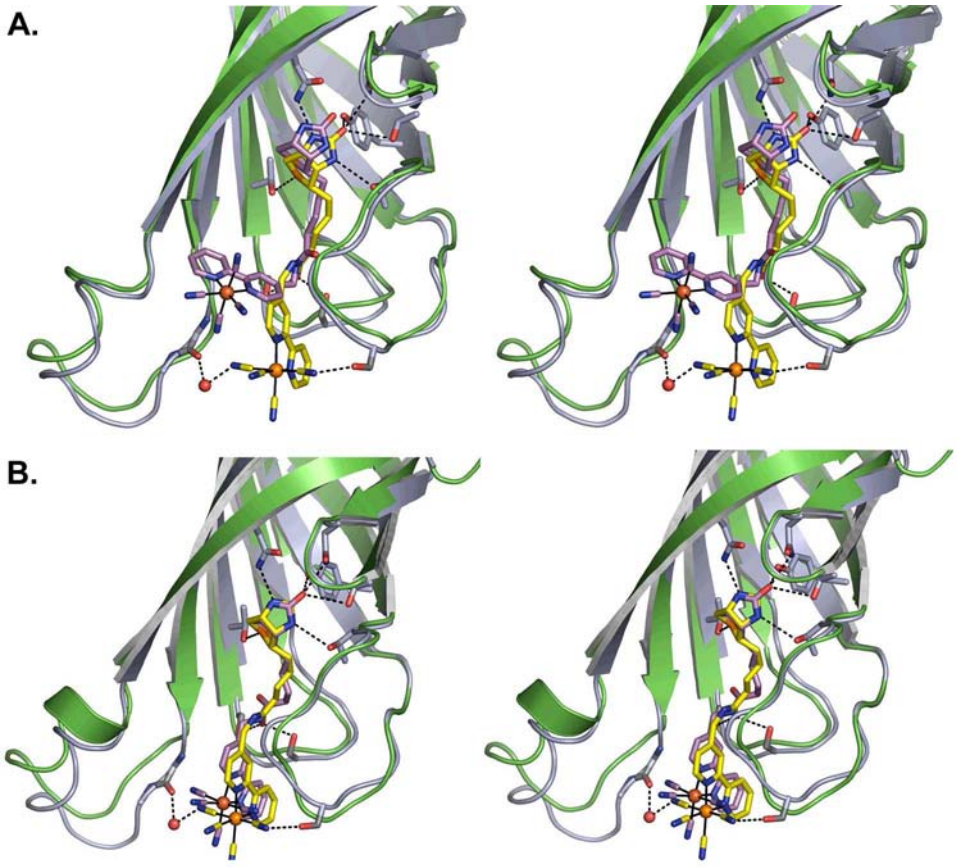

Figure S2: The crystal structure of $[Fe(BMB)(CN)_4]^{2-}$ (white) bound to avidin (gray) overlayed by molecular models of $[Fe(BMB)(CN)_4]^{2-}$ (pink) bound to avidin (yellow). Molecular modeling predicts four thermodynamically stable conformations at room temperature. (A) The structure of the molecular model is in agreement with that of the crystal structure. (B) The model shows the probe in a similar conformation as in the crystal structure however, the avidin pocket is in a more open configuration. This conformation is similar to the open loop conformation observed by Livnah and coworkers for avidin bound by amide derivatized biotin ligands (*9*). (C) The iron complex is rotated about the methylene between the biotin and the redox portion of the probe situating the redox portion about 180º from that in the crystal structure. (D) The iron complex is rotated about the methylene between the biotin and the redox portion of the probe in a slightly different conformation from that of (C).

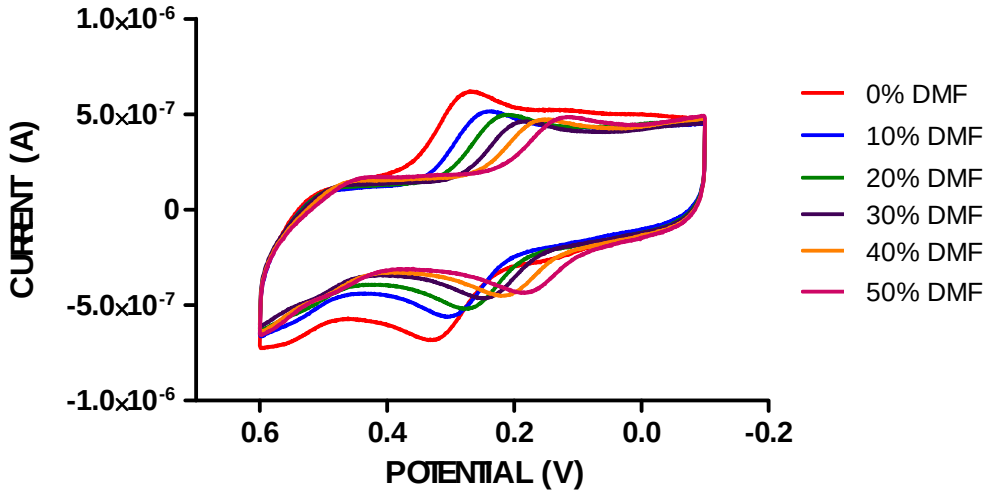

Figure S3: Cyclic voltammograms of $K_2[Fe(BMB)(CN)_4]$ in increasing concentrations of DMF in PBS buffer pH 7.2. Cyclic voltammograms we collected at 100 mV/s using a glassy carbon electrode with a Ag/AgCl reference.

A "Click Chemistry" Approach to the Efficient Synthesis of Multiple Imaging Probes Derived from a Single Precursor

Different imaging modalities can provide complementary information on biological processes at the cellular or molecular level *in vitro* and *in vivo*. However, specific molecular probes suitable for a comparison of different imaging modalities are often not readily accessible because their preparation is usually accomplished by individually developed and optimized syntheses. Herein, we present a general, modular synthetic approach that provides access to multiple probes derived from a single precursor by application of the same, efficient functionalization strategy, the Cu(I)-catalyzed cycloaddition of terminal alkynes and azides (click chemistry). To demonstrate the viability and efficiency of this approach, folic acid (FA) was selected as a targeting vector because the preparation of FA-based imaging probes used for SPECT, PET, MRI, and NIRF by reported synthetic strategies is usually difficult to achieve and often results in low overall yields. We prepared a versatile γ-azido-FA precursor as well as a set of alkyne functionalized probes and precursors including ligand systems suitable for the chelation of various (radio)metals, an NIR dye and ^{18}F- and ^{19}F-derivatives, which enabled the parallel development of new FA-imaging probes. The Cu(I)-mediated coupling of the alkynes with the γ-azido-FA precursor was accomplished in high yields and with minimal use of protective groups. The various probes were fully characterized spectroscopically as well as *in vitro* and *in vivo*. *In vitro*, all new FA-derivatives exhibited high affinity toward the folic acid receptor (FR) and/or were specifically internalized into FR-overexpressing KB cells. *In vivo* experiments with nude mice showed that all probes (except the MRI probes which have not been tested yet) accumulated specifically in FR-positive organs and human KB-cell xenografts. However, *in vivo* imaging revealed significant differences between the various FA-derivatives with respect to unspecific, off-target localization. In general, the comparison of different probes proved the superiority of the more hydrophilic, radiometal-based imaging agents, a result which will guide future efforts for the development of FA-based imaging probes and therapeutic agents. In addition, the strategy presented herein should be readily applicable to other molecules of interest for imaging and therapeutic purposes and thus represents a valuable alternative to other synthetic approaches.

INTRODUCTION

Molecular imaging can be defined as the noninvasive visualization of biological processes at the cellular or molecular level *in vivo* (*1*). To this end, different imaging modalities can be applied (e.g., single photon emission computed tomography (SPECT), positron emission tomography (PET), magnetic resonance imaging (MRI), and near-infrared fluorescence imaging (NIRF)), each of which has certain advantages as well as limitations (*2, 3*). Regardless the modality employed, targeted imaging approaches require the use of specific molecular probes. These are usually composed of a suitable imaging entity which is covalently linked to a targeting (bio)molecule (vector). The multifunctional character of both components can complicate the preparation of such conjugates, in particular, because of potential side reactions or the lack of specificity of the coupling step. As a consequence, multistep syntheses including the use of protective groups are often employed that can lower significantly the overall efficiency of the preparation procedure. In addition, the syntheses of related imaging probes (e.g., for a comparison of different imaging modalities) are usually developed and optimized individually, which reflects the lack of general synthetic transformations for the connection of structurally diverse precursors and building blocks. Therefore, new, efficient, and universally applicable synthetic strategies are needed.

The discovery of the Cu(I)-catalyzed version of Huisgen's dipolar [2 + 3] cycloaddition of terminal alkynes and azides by the groups of Sharpless (*4*) and Meldal (*5*) has had a great impact on the scientific community as demonstrated by countless reports describing its application in different areas of research (*6*). In general, the formation of 1,4-disubstituted 1,2,3-triazoles by the cycloaddition proceeds efficiently and selectively under benign (aqueous) reaction conditions and in the presence of various other functionalities (*7*). Termed a "click reaction" (*8*), this transformation has also found application in the development of targeted or nontargeted imaging agents (*9, 10*). The majority of reported applications of the click cycloaddition

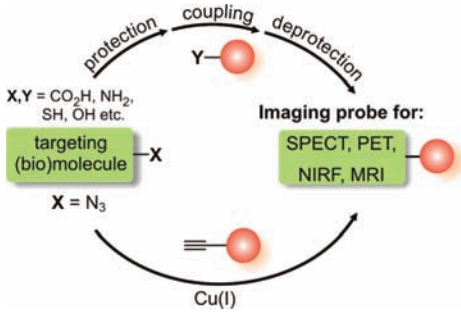

Figure 1. Sequential synthesis of imaging probes via "classical" synthetic strategies (top) in comparison to a parallel approach by which reaction of a common azide precursor with various alkyne-functionalized probes gives directly imaging agents suitable for different modalities (bottom). Spheres represent various probes or precursor thereof to be attached to the targeting (bio)molecule.

employ the 1,2,3-triazole formed as a stable linker to connect two chemical/biochemical entities. This conjugate design has been successfully applied to the preparation of optical (*11*, *12*) and MR imaging agents (*13*) and radioactive tracers suitable for SPECT (*14*) and PET (*15*−*17*). More recently, applications which make use of the 1,2,3-triazole heterocycle as a part of a probe (integrated design) have also been described (*18*−*20*).

We recognized that, once a "clickable" derivative of a targeting (bio)molecule has been prepared, a number of imaging probes would become readily available in a parallel fashion rather than by sequential synthesis (Figure 1). Such a parallel approach can significantly reduce the number of precursors and intermediates required for the synthesis of different imaging agents based on the same vector. Folic acid (FA) was chosen as a tumor-targeting molecule to demonstrate that multiple imaging probes can be derived from a single precursor using the same functionalization strategy. FA is an essential nutrient (vitamin B_9) required by eukaryotic cells for the biosynthesis of nucleotide bases. As a consequence, acquirement of the vitamin is essential for cell survival and proliferation. A number of cancer cell lines exhibit high levels of the cell surface folate receptor (FR), while its expression is highly restricted in most normal tissues and organs (*21*). These circumstances allow the specific delivery of conjugated diagnostic probes and therapeutic agents to FR overexpressing tumors (*22*, *23*). Herein, we wish to report a modular, general click chemistry approach for the short and efficient synthesis of FA-based probes suitable for SPECT, PET, NIRF, and MRI and their assessment *in vitro* and *in vivo*.

EXPERIMENTAL PROCEDURES

Compounds **1** and **10** (*24*), **9** (*16*), **15** and **16** (*25*), as well as **20** (*26*) have been previously published. For details on the synthesis and characterization of intermediates and final products, please see the references.

Syntheses. *General Methods.* Melting points were taken on a Büchi-535 apparatus and are uncorrected. Infrared spectra were recorded on a Jasco FT/IR-6200 ATR-IR and UV-spectra on a Cary 300 (Varian). Nuclear magnetic resonance spectra were recorded with a Bruker 400 or 500 MHz spectrometer with the corresponding solvent signals as an internal standard. Chemical shifts are reported in parts per million (ppm) relative to tetramethylsilane (0.00 ppm). Values of the coupling constant, *J*, are given in Hertz (Hz); the following abbreviations are used in the experimental section for the description of ^{1}H-NMR spectra: singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), doublet of doublets (dd), and bs (broad singlet). The chemical shifts of complex multiplets are given as the range of their occurrence. High-resolution mass spectra (HRMS-ESI) were recorded with a Bruker FTMS 4.7T BioAPEXII (ESI) using either the positive or negative ionization mode.

Reactions were monitored by thin layer chromatography (TLC, performed on EM Science 0.25-mm-thick, precoated silica gel 60 F-254 glass supported plates) or HPLC. HPLC was performed on a Merck-Hitachi L-7000 system equipped with an L-7400 tunable absorption detector and a Berthold LB 506 radiometric detector. The following systems were used for HPLC: Analytical HPLC: XBridge column (C18, 5 μm, 4.6 × 150 mm, Waters); 0.1% aq TFA (solvent A), acetonitrile (solvent B); 0−1 min, 95% A; 1−15 min, 95→5% A; 15−20 min, 5% A; 20→22 min, 5→95% A; 22→25 min, 95% A; flow rate: 1 mL/min. Semipreparative HPLC was performed with an XBridge column (C18, 5 μm, 10 × 150 mm, Waters) using the solvent system and gradient as indicated in the description of the individual experiments. Flow rate: 3 mL/min.

[In-111] $InCl_3$ and [Ga-67] $GaCl_3$ were purchased from Mallinckrodt, Petten (The Netherlands), CY5.5-$(CH_2)_5CO_2H$ was provided by M. Rudin and ^{3}H-folic acid was purchased from Moravek Biochemicals Inc. (USA). All other commercially available reagents and solvents were purchased from Sigma-Aldrich and used as supplied unless stated otherwise.

CY5.5-Alkyne Derivative ***4.*** CY5.5-$(CH_2)_5$COOH (tripotassium salt; 4.5 mg, 4.4 μmol) was dissolved in dry DMF (400 μL) and DIPEA (50 mg, 0.5 mmol) and HBTU (9.5 mg, 25 μmol) were added. The solution was stirred at rt in the dark for 30 min, propargyl amine (16 mg, 0.3 mmol) was added, and stirring was continued for 30 min. The mixture was diluted with water (400 μL) and purified by semipreparative HPLC (CH_3CN (A)/aq NH_4HCO_3 10 mM (B), gradient 5→50% (A) within 13 min). Concentration of the collected material and lyophilization provided compound **4** as a blue solid (4 mg, 80% yield as determined by UV/vis: $\lambda_{(max)} = 675$ nm, $d = 1$ cm, $\varepsilon = 250\,000$ M^{-1} cm^{-1}; purity according to HPLC >95%): HRMS-ESI *m*/*z* $[M]^+ = 954.2071$ (calcd. for $C_{44}H_{48}N_3O_{13}S_4$: 954.2064).

DOTA-Alkyne Derivative ***5.*** DOTA-NHS (82 mg, 0.1 mmol) was dissolved in CH_2Cl_2 (1.5 mL) and a solution of propargyl amine (11 mg, 0.2 mmol) and DIPEA (50 μL, 0.3 mmol) in CH_2Cl_2 (0.5 mL) was added. The solution was stirred at rt for 1 h and then diluted with CH_2Cl_2 (5 mL) and washed with aq citric acid (0.1 M) and water. The aqueous phases were extracted twice with CH_2Cl_2. The organic extracts were then combined, dried over Na_2SO_4, and concentrated under reduced pressure yielding compound **5** as a solidified white foam (60 mg, 98%): IR (neat) ν 2979, 2840, 1727, 1680, 1369, 1156, 823 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ 7.19 (bs, 1H), 3.98 (dd, 2H, $J = 5.5$ and 2.2 Hz), 3.66 and 3.60 (each s, each 2H), 3.42 (s, 4H), 3.06, 3.01, 2.95, and 2.91 (each s, each 4H), 2.18 (t, 1H, $J = 2.2$ Hz), 1.46 (s, 9H), 1.44 (s, 18H) ppm. ^{13}C NMR ($CDCl_3$) δ 169.7, 169.4, 168.4, 83.0, 82.7, 79.6, 71.6, 56.5, 55.9, 52.3, 52.2, 50.4, 50.3, 29.3, 28.4, 28.3 ppm. HRMS-ESI *m*/*z* $[M+Na]^+ = 632.3994$ (calcd for $C_{31}H_{55}N_5O_7Na$: 632.3999).

Deprotected DOTA-Alkyne Derivative ***6.*** DOTA(^{t}Bu)$_3$-propargyl amide **5** (12 mg, 0.02 mmol) was dissolved in CH_2Cl_2/TFA (4:1, 1 mL) and stirred at rt for 18 h, after which time tlc (CH_2Cl_2/MeOH 9:1) indicated complete conversion of the substrate. Removal of the volatile components under reduced pressure yielded compound **6** as a yellow oil (15 mg; multiple TFA salt): HRMS-ESI *m*/*z* $[M+Na]^+ = 464.2118$ (calcd for $C_{19}H_{31}N_5O_7Na$: 464.2121).

DTPA-Alkyne Derivative ***7.*** *p*-NH_2-Bn-DTPA(^{t}Bu)$_5$ (97 mg, 0.13 mmol) was dissolved in THF (2.0 mL) and propargyl bromide (80% in toluene; 42 μL, 0.39 mmol) and pyridine (31 μL, 0.39 mmol) were added. The solution was stirred at reflux for 16 h, after which time the volatile components were removed under reduced pressure. Purification of the crude product by flash chromatography on silica gel with mixtures of ethyl acetate

and hexane containing 0.5% Et_3N yielded compound **7** as a yellow oil (56 mg, 55%): IR (neat) ν 2977, 2927, 1731, 1519, 1365, 1252, 1216, 1148, 843 cm^{-1}; ^1H NMR ($CDCl_3$) δ 7.04 and 6.57 (each d, 2H, $J = 8.4$ Hz), 3.88 (d, 2H, $J = 2.5$ Hz), 3.43 and 3.42 (each s, 2H), 3.38 (s, 4H), 3.34 (s, 2H), 3.05−2.98 (m, 1H), 2.82−2.65 (m, 7H), 2.54−2.45 (m, 2H), 2.18 (t, 1H, $J = 2.5$ Hz), 1.43 and 1.42 (each s, each 18H), 1.38 (s, 9H) ppm. ^{13}C NMR ($CDCl_3$) δ 171.6, 171.5, 170.9, 145.1, 130.9, 130.2, 113.8, 81.4, 80.9, 80.6, 71.4, 63.4, 56.4, 56.2, 55.9, 53.8, 53.1, 52.8, 36.5, 34.1, 28.4, 28.3 ppm. HRMS-ESI *m/z* $[M+H]^+ = 817.5322$ (calcd for $C_{44}H_{73}N_4O_{10}$: 817.5327).

Deprotected DTPA-Alkyne Derivative ***8.*** Propargyl-*p*NH-BnDTPA(^{t}Bu)$_5$ **7** (8 mg, 0.01 mmol) was dissolved in CH_2Cl_2/TFA (4:1, 1 mL) and stirred at rt for 18 h, after which time tlc (EtOAc/hexane 1:2, containing 0.1% Et_3N) indicated complete conversion of the substrate. Removal of the volatile components under reduced pressure yielded compound **8** as a yellow oil (11 mg; multiple TFA salt): purity according to HPLC >98% (retention time: 4.95 min); HRMS-ESI *m/z* $[M+Na]^+ = 559.2009$ (calcd for $C_{24}H_{32}N_4O_{10}Na$: 559.2016).

F-19 Folate Derivative ***11.*** Folate-γ-(4-azido)-butane amide **1** (pentahydrochloride, 29 mg, 40 μmol) was dissolved in ^{t}BuOH/aq NH_4HCO_3 10 mM (1:1; 6 mL) and $Cu(OAc)_2$ (1.5 mg, 20 mol %), sodium ascorbate (3 mg, 40 mol %), and 3,3,3-tris(trifluoromethyl)-1-propyne (**3**; 49 mg, 0.2 mmol) were added. The reaction flask was sealed and the mixture was stirred at rt for 18 h. Centrifugation (5 min, 13 000 rpm) and decantation of the solution gave a brown solid. The crude product was dissolved in warm MeOH (2 mL) and precipitated by addition to dilute aq HCl (buffered to pH 3−4 by addition of dilute NaOH; 6 mL). The solid was isolated by centrifugation and dried under reduced pressure to give compound **11** as an orange solid (5 mg; purity according to HPLC >92%): mp: >200 °C (decomposition); IR (neat) ν 3356, 2914, 1593, 1406, 1340, 1252, 1016, 972 cm^{-1}; ^{1}H-NMR (DMSO-d_6) δ 8.82 (s, 1H), 8.67 (bs, 1H), 8.18 (bs, 1H), 7.85 (s, 1H), 7.65 (d, 2H, $J = 8.4$ Hz), 7.09−6.73 (m, 3H), 6.64 (d, 2H, $J = 8.4$ Hz), 4.54−4.42 (m, 4H), 4.28 (bs, 1H), 3.11−3.00 (m, 2H), 2.23−2.11 (m, 2H), 2.10−1.78 (m, 4H), 1.37−1.27 (m, 2H), 1.22 (bs, 1H) ppm; ^{19}F-NMR (DMSO-d_6) δ −64.71 ppm; ^{13}C-NMR (DMSO-d_6) δ 173.9, 171.5, 166.3, 160.8, 156.5, 153.7, 150.7, 148.7, 148.5, 129.9, 128.9, 127.2, 121.4, 120.8 (q, $J = 290$ Hz), 111.2, 58.9 (q, $J = 30$ Hz), 52.1, 49.8, 46.0, 37.7, 32.0, 27.1, 26.6, 26.0 ppm (one aromatic carbon is not observed presumably because of overlapping signals); HRMS-ESI *m/z* $[M-H]^- = 780.2063$ (calcd for $C_{29}H_{27}F_9N_{11}O_5$: 780.2053).

NIRF Folate Derivative ***12.*** CY5.5-propargylamide (**4**; 4 mg; approximately 3.5 μmol) was dissolved in water (1.5 mL), and a solution of folate-γ-butylazide (**1**; pentahydrochloride salt; 2.9 mg, 4.0 μmol) in aq NH_4HCO_3 (10 mM, 100 μL) and $Cu(OAc)_2$ (0.7 mg, 10 mol %) and sodium ascorbate (1.5 mg, 20 mol %) were added. The mixture was stirred at rt in the dark for 18 h and purified by semipreparative HPLC (CH_3CN (A)/aq NH_4HCO_3 10 mM (B), gradient: 5→28% (A) within 13 min). Concentration of the collected solutions of product under reduced pressure, dissolving of the residue in water (2.0 mL), and lyophilization provided compound **12** as a blue fluffy solid (3.3 mg; 60% yield as determined by UV/vis: $\lambda_{(max)} = 675$ nm, $d = 1$ cm, $\varepsilon = 250\,000$ M^{-1} cm^{-1}; purity according to HPLC >95%): HRMS-ESI *m/z* $[M]^+ = 1491.4284$ (calcd for $C_{67}H_{75}N_{14}O_{18}S_4$: 1491.4261).

DOTA-Folate Derivative ***13.*** To a solution of folate-γ-(4-azido)-butane amide **1** (pentahydrochloride, 30 mg, 0.04 mmol) and DOTA(^{t}Bu)$_3$-propargyl amide **5** (25 mg, 0.04 mmol) in ^{t}BuOH/DMF/H_2O (2 mL, 1:1:1) containing DIPEA (70 μL, 0.4 mmol) at 85 °C was added dropwise over 30 min a solution of $Cu(OAc)_2$ (0.4 mg, 0.05 equiv) and sodium ascorbate (0.8 mg, 0.2 equiv) in water (0.6 mL). For the removal of the ^{t}Bu protective groups, aq HCl (1 M, 3 mL) was added and stirring was continued at 85 °C for 30 min. Complete conversion of azido folate **1** and the ^{t}Bu-protected intermediate, respectively, was confirmed by HPLC for each step. The mixture was filtered through Celite and purified by semipreparative HPLC (isochratic MeOH (18%) and aq 0.1% TFA (82%)). The product obtained was dissolved in water and lyophilized to yield FA-(γ)-DOTA **13** as a yellow solid (18 mg, 45% (2 steps); purity according to HPLC: >98%): mp 169−171 °C; IR (neat) ν 3282, 3097, 2953, 2861, 1677, 1636, 1611, 1511, 1406, 1198, 1129, 832, 720 cm^{-1}. ^{1}H NMR (DMSO-d_6) δ 8.96 (bs, 1H), 8.68 (s, 1H), 8.20 (d, 1H, $J = 7.5$ Hz), 7.95 (s, 1H), 7.88 (bs, 1H), 8.0−7.3 (broad signal, ca. 4H, exchange with MeOD), 7.66 and 6.65 (each d, each 2H, $J = 8.2$ Hz), 4.52 (s, 2H), 4.35 (d, 2H, $J = 5.2$ Hz), 4.32−4.25 (m, 3H), 4.06 and 3.92 (each bs, each 2H), 3.62 (bs, 4H), 3.37 (bs, 6H), 3.14 (bs, 10H) 3.06−3.00 (m, 2H), 2.18 (t, 2H, $J = 7.5$ Hz), 2.08−2.01 (m, 1H), 1.93−1.85 (m, 1H), 1.79−1.73 (m, 2H), 1.35−1.30 (m, 2H) ppm; ^{13}C NMR (DMSO-d_6) δ 174.0, 171.6, 168.9, 166.5, 165.8, 160.5, 158.7, 158.4, 158.2, 153.5, 150.7, 149.6, 148.3, 143.6, 129.0, 128.0, 123.0, 121.4, 120.2, 117.8, 155.5, 113.1, 111.2, 54.6, 53.9, 52.7, 52.1, 50.5, 50.5, 50.4, 49.0, 48.5, 48.2, 45.9, 37.8, 34.6, 32.0, 27.2, 26.6, 26.1 ppm; HRMS-ESI *m/z* $[M+Na]^+ = 1001.4308$ (calcd for $C_{42}H_{58}N_{16}O_{12}Na$: 1001.4318).

Preparation of ^{67}Ga-DOTA-Folate ***14*** *[^{67}Ga(**13**)].* Radiolabeling of FA-(γ)-DOTA **13** (20 μL, 10^{-3} M in water) was performed in sodium acetate buffer pH 5.0 (200 μL). A solution of $^{67}GaCl_3$ was added (50 MBq, 20 μL), and the reaction solution was incubated for 30 min at 85 °C. Then, Na-DTPA (10 μL, 5 mM, pH 5.0) was added to the solution for chelation of potential traces of free radionuclides. HPLC analysis of SPECT tracer **14** was performed to determine radiochemical yield (>90%).

Cold Gallium Standard of Compound ***14.*** The cold analogue of complex **14** ([Ga(**13**)]) was prepared by the reaction of FA-(γ)-DOTA **13** (5 mg, ca. 5 μmol) and $GaCl_3$ (0.9 mg, 1.5 equiv) in water (0.3 mL) at 75 °C for 30 min. The crude reaction mixture was purified by semipreparative HPLC (5%→90% CH_3CN within 14 min; rest: 0.1% aq TFA) to yield the cold analogue of complex **14** ([Ga(**11**)]) as a yellow solid after lyophilization (3 mg, 58%; purity according to HPLC >95%): mp >200 °C (decomposition). IR (neat) ν 3342, 2937, 1680, 1605, 1401, 1206, 1180, 1130, 1010, 721 cm^{-1}; HRMS-ESI *m/z* $[M+H]^+ = 1045.3521$ (calcd for $C_{42}H_{56}GaN_{16}O_{12}$: 1045.3519).

Preparation of Gd-DOTA-Folate ***17:*** *[Gd(**13**)].* FA-(γ)-DOTA **13** (5 mg, ca. 5 μmol) and $GdCl_3$ (hexahydrate; 2.8 mg, 1.5 equiv) were dissolved in water (0.5 mL) and stirred at reflux for 10 min. The crude reaction mixture was purified by semipreparative HPLC (5%→90% CH_3CN within 14 min; rest 0.1% aq TFA) to yield Gd complex **17** ([Gd(**13**)]) as a yellow solid after lyophilization (4 mg, 71%; purity according to HPLC >95%): mp >240 °C (decomposition). IR (neat) ν 3339, 2933, 1688, 1607, 1407, 1206, 1187, 1136, 723 cm^{-1}; HRMS-ESI *m/z* $[M+H]^+ = 1156.3320$ (calcd for $C_{42}H_{55}GdN_{16}NaO_{12}$: 1156.3324).

DTPA-Folate Derivative ***18.*** Propargyl-*p*-NH_2-Bn-DTPA-(^{t}Bu)$_5$ (**7**; 38 mg, 46 μmol) and folate-γ-(4-azido)-butane amide **1** (pentahydrochloride, 33 mg, 46 μmol) were dissolved in water (1.25 mL), and $Cu(OAc)_2$ (0.6 mg, 10 mol %) and sodium ascorbate (1.2 mg, 20 mol %) were added. The resulting mixture was stirred at 85 °C for 25 min. After cooling to rt, the precipitated product was isolated by centrifugation (3 min, 13 000 rpm). The crude product was dissolved in MeOH/ethyl acetate (1:1, 4.0 mL) and precipitated by slow addition of hexane (20 mL) yielding the protected intermediate FA-(γ)-*p*-Bn-DTPA(^{t}Bu)$_5$ as a brown solid (23 mg, 41%; purity according to HPLC >95%): mp >200 °C; IR (neat) ν 3280, 2977, 2932,

1724, 1699, 1607, 1519, 1367, 1248, 1148, 843 cm^{-1}; HRMS-ESI *m/z* $[M+Na]^+$ = 1354.7529 (calcd for $C_{67}H_{100}N_{15}O_{15}$: 1354.7523). (NMR analysis was inconclusive presumably because of micelle formation.)

The intermediate FA-(γ)-*p*-Bn-DTPA(^{t}Bu)$_5$ (15 mg, 11 μmol) was dissolved in CH_2Cl_2/TFA (2:1, 3.0 mL) and kept at rt for 18 h. The mixture was concentrated under reduced pressure, and the residue was dissolved in aq NaOH (0.1 M; 2 mL). The turbid solution was centrifuged (5 min, 13 000 rpm), and the yellow solution was decanted. Acidification of the solution by addition of dilute aq HCl (0.1 M) to a final pH ~3 resulted in precipitation of the product, which was isolated by centrifugation. Drying under reduced pressure yielded DTPA-folate derivative **18** as an orange solid (11 mg; multiple hydrochloride salt; purity according to HPLC >93%; retention time = 6.84 min): mp >200 °C (decomposition); IR (neat) ν 3353, 2918, 1596, 1507, 1403, 1333, 1178, 1053, 1024, 834 cm^{-1}; ^{1}H NMR (D_2O with one drop of NaOD 5% in D_2O) δ 8.34 (s, 1H), 7.47 (d, 2H, J = 8.0 Hz), 7.40 (s, 1H), 6.86 (d, 2H, J = 9.3 Hz), 6.61 (d, 2H, J = 8.0 Hz), 6.50 (d, 2H, J = 9.3 Hz), 4.33 (s, 2H), 4.22 (dd, 1H, J = 9.6 and 3.6 Hz), 4.08 (s, 2H), 3.85 (t, 2H, J = 7.3 Hz), 3.53−3.12 (m, 7H), 3.46 (s, 4H), 3.10−2.67 (m, 8H), 2.39−1.88 (m, 6H), 1.41−1.28 (m, 1.5H), 1.22−1.06 (m, 0.5H), 1.04−0.89 (m, 2H) ppm (^{13}C NMR was not conclusive due to overlapping signals); HRMS-ESI *m/z* $[M+H]^+$ = 1074.4372 (calcd for $C_{47}H_{60}N_{15}O_{15}$: 1074.4393).

*Preparation of ^{111}In-DTPA-Folate **19**: [^{111}In(**18**)]*. A stock solution (50 μL) of DTPA-folate derivative **18** (10^{-3} M) was mixed with 200 μL PBS pH 6.5. Then, $^{111}InCl_3$ was added (40 MBq, 50 μL) and the reaction solution was incubated for 1 h at room temperature. Then, Na-DTPA (10 μL, 5 mM, pH 5.0) was added to the solution for chelation of potential traces of free radionuclides. HPLC analyses was performed to determine the radiochemical yield of **19** (>95%).

*Cold Indium Standard of Compound **19**.* The cold In-analogue of complex **19** ([In(**18**)]) was prepared by to the following procedure: DTPA-folate derivative **18** (multiple hydrochloride salt; 5 mg, ca. 4 μmol) was dissolved in water (3 mL), and $InCl_3$ (1 mg, ca. 4 μmol) was added (resulting pH ~2). The mixture was heated for 1 min with a heat gun (~reflux), and the pH was adjusted to pH 4 by addition of dilute NaOH (0.05 M). The precipitated product was isolated by centrifugation and dried under reduced pressure: (3 mg yellow powder; multiple hydrochloride; quantitative conversion according to HPLC; purity according to HPLC > 95%): mp >220 °C (decomposition); IR (neat) ν 3326, 2927, 1602, 1512, 1392, 1329, 916 cm^{-1}; HRMS-ESI *m/z* $[M+H]^+$ = 1186.3181 (calcd for $C_{47}H_{57}InN_{15}O_{15}$: 1186.3197).

***In Vitro* Experiments.** *In vitro* binding assays (competition binding assays of cold FA derivatives with ^{3}H-folic acid) and internalization studies (including blocking experiments with excess folic acid) were performed with FR overexpressing KB cells according to previously reported procedures (*24*−*26*). For details, see the Supporting Information.

In order to image the internalization of NIRF probe **12** into KB cells *in vitro*, monolayers were generated on Falcon PET-insert (polyethylene terephthalate) after 3 days of growth and incubated with the test compound (**12**) at a final concentration of 11 nM. The specificity of this uptake was challenged by the presence of folic acid at high concentration (1.1 μM). Cells were mounted with fixation and scanned using a Zeiss CLSM 410 inverted microscope. 3D multichannel image processing was performed using the *IMARIS* software (Bitplane AG, Switzerland).

***In Vivo* Experiments.** All animal experiments were performed in accordance to the Swiss law of animal protection. A human nasopharyngeal epidermoid carcinoma (KB) cell line (American type Culture Collection, ATCC, Manassas, VA) with folate receptor (FR) overexpression was cultured at 37 °C in a humidified atmosphere containing 5% CO_2 in folate-deficient medium RPMI 1640 (Cell Culture Technologies, Gravesano, Switzerland) with 10% fetal calf serum (Gibco BRL/Life Technologies, Rockville, MD). To induce solid tumors for optical imaging studies, 10^6 KB cells were injected subcutaneously into the left shoulder of male nude Balb/c mice at day 0. Within 7−10 days after inoculation, mice developed tumors with mean diameter of 8 mm. For SPECT/CT scans, the female Balb/c mice were used bearing KB tumor xenografts on each shoulder. Mice were kept on folic acid free diet (*25*) prior to administration of the folic acid tracers in order to minimize interference with dietary folate. For all imaging studies, animals were anesthetized using 1.8% isoflurane delivered in air/oxygen (4:1). Body temperature of the animals was maintained at 36.5 ± 0.5 °C for both SPECT and NIRF experiments.

SPECT/CT Imaging Studies. SPECT/CT experiments were performed approximately 18 h after injection of the radiofolates with a small-animal SPECT/CT device (X-SPECT, Gamma Medica Inc. Northridge, CA, USA). ^{111}In-DTPA-folate **19** (20 MBq) or ^{67}Ga-DOTA-folate **14** (15 MBq) were diluted in 0.9% NaCl and administered via a lateral tail vein. SPECT data were acquired and reconstructed by software *LumaGEM* (version 5.407 lum 10). CT data were acquired by the manufacturer's software and reconstructed with the software *COBRA* (version 4.5.1). Fusion of SPECT and CT data was performed by software *IDL Virtual Machine* (version 6.0). Images were generated by the software *Amira* (version 4.0.1).

NIRF Imaging Studies. NIRF imaging was performed using a time-domain *in vivo* small animal fluorescence imager, eXplore Optix (ART Advanced Research Technologies, Montreal, Canada) composed of a pulsed laser diode at 666 nm as light source and a photomultiplier tube (PMT) coupled with a time-correlated single-photon-counting system for detection. A combination of filters was installed for optimal Cy5.5 fluorescence measurement. KB tumor bearing Balb/c mice were measured approximately 24 h after intravenous injection of the NIRF probe FA-(γ)-CY5.5 **12** at a dose of 2 nmol. Images were analyzed using a program written in *MATLAB* (MathWorks, Natick, US).

RESULTS AND DISCUSSION

In the past, a number of FA derivatives conjugated to various diagnostic probes suitable for different imaging techniques and their (pre)clinical evaluations have been reported. For example, FA-based radiotracers for SPECT (*24*, *27*−*32*) and PET (*26*, *33*, *34*) as well as FA conjugates suitable for optical imaging (*35*, *36*) and potentially MRI (*37*) have been described. However, the synthesis of FA derivatives functionalized via the glutamic acid moiety (but not the pteroic acid pharmacophore) is not a trivial task, especially because of the poor solubility of FA and/or intermediates. In general, two synthetic approaches have been described for the preparation of FA conjugates in solution: (1) The direct modification of FA by amide coupling protocols. This approach yields mixtures of products functionalized via either the α- or γ-carboxylate of the glutamic acid moiety (see Figure 2) and requires the laborious separation of the isomers obtained (*38*). (2) A fragment coupling approach by which FA derivatives are obtained by the coupling of pteroic acid precursors with glutamates (*39*). This strategy entails the individual synthesis of glutamic acid derivatives which are functionalized specifically via the α- or γ-carboxylate. Even under optimized reaction conditions as reported in some cases, both solution-phase syntheses tend to provide the final FA conjugate in low yields (often <10–30%), a potential issue for the future development of FA-based imaging probes and therapeutic agents.

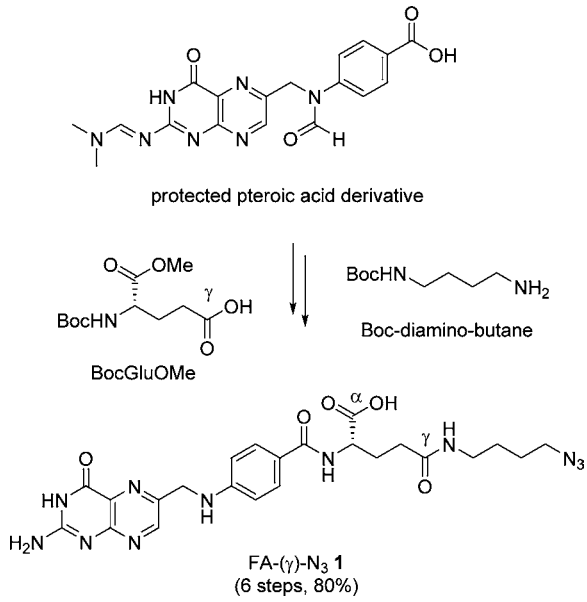

Figure 2. Synthesis of common azido-folic acid precursor FA-(γ)-N_3 **1** from a protected pteroic acid derivative and commercial building blocks BocGluOMe and Boc-diamino-butane (see ref 24).

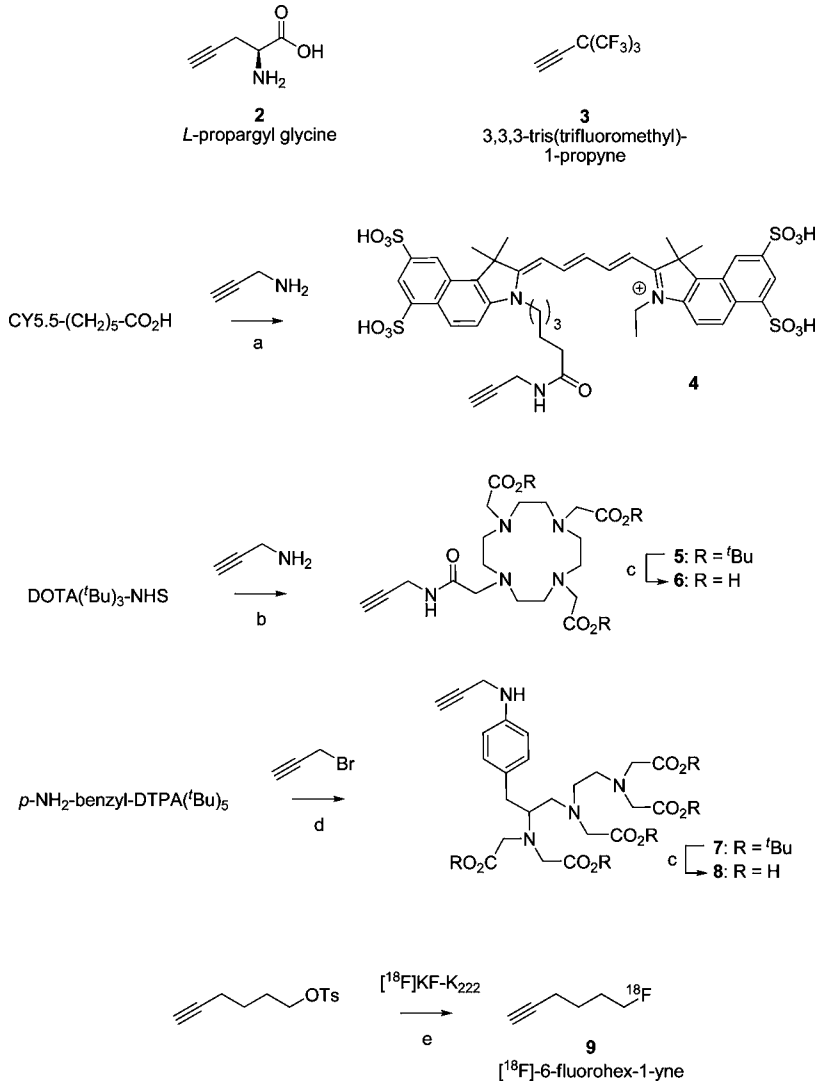
Syntheses. Folic acid-γ-(4-azido)-butylamide **1** (FA-(γ)-N_3) was prepared selectively as previously described (Figure 2) (*24*). In brief, amide coupling of a protected pteroic acid derivative (N_2-*N*,*N*-dimethylaminomethylene-10-formyl-pteroic acid) with glutamic acid γ-(4-azido)-butylamide (derived from Boc-diaminobutane and BocGluOMe) followed by removal of protective groups provided the desired azido-FA precursor in a total of 6 steps and 80% yield.

Alkyne substrates described in the following were either commercially available (L-propargyl glycine **2** and 3,3,3-tris(trifluoromethyl)-1-propyne **3**) or prepared in 1−2 steps and high yields (Scheme 1). Thus, coupling of the near-infrared (NIR) dye derivative CY5.5-$(CH_2)_5CO_2H$ with propargyl amine under standard amide coupling conditions provided alkyne **4**. Similarly, reaction of DOTA(^{t}Bu)$_3$-NHS with propargyl amine yielded DOTA(^{t}Bu)$_3$-propargyl amide **5**. DTPA derivative **7** was synthesized by alkylation of *p*-NH_2-Bn-DTPA(^{t}Bu)$_5$ with propargyl bromide. For the experiments described below, samples of alkyne derivatives **5** and **7** were deprotected under acidic conditions to yield the free carboxylic acids **6** and **8**, respectively. Finally, [^{18}F]-6-fluorohex-1-yne (**9**) was prepared from 6-tosyl-hex-1-yne according to a literature procedure (*16*).

With the precursor FA-(γ)-N_3 **1** and a set of alkyne derivatives of imaging probes or precursors thereof, respectively, in hand, we next investigated their coupling via a 1,4-disubstituted 1,2,3-triazole by click chemistry (Scheme 2). Near-infrared fluorescence (NIRF) probe FA-CY5.5 **12** and F-19 MRI probe **11** were prepared efficiently according to the procedure initially described by the Sharpless group (*4*). Thus, reaction of FA-(γ)-N_3 **1** with the alkyne derivative of CY5.5 **4** or 3,3,3-tris(trifluoromethyl)-1-propyne (**3**) was performed at rt in aqueous media (H_2O/^{t}BuOH, 1:1) at room temperature in the presence of catalytic amounts of *in situ* generated Cu(I) catalyst ($Cu(OAc)_2$/sodium ascorbate). Notably, starting from the valuable precursor CY5.5.-$(CH_2)_5CO_2H$, application of click chemistry provided NIRF probe **12** in only 2 steps and good yield, an improved procedure compared to reported syntheses of FA-based optical probes (*35*,*36*), which employ the direct modification strategy (see above) and thus, require the separation of FA isomers. Similarly, unprotected L-propargyl glycine (**2**) (*7*) was reacted with FA-(γ)-N_3 **1** resulting in the simultaneous formation of a 1,2,3-triazole-containing, tridentate chelating system and its attachment to FA. The intermediate obtained could be used directly for the *in situ* complex formation with $[^{99m}Tc(CO)_3(H_2O)_3]^+$ (*40*), thus providing SPECT probe **10** in quantitative yields by a convenient one-pot procedure (*24*). F-18 PET tracer **20** was prepared under optimized conditions in good radiochemical yields and high specific activity by the reaction of FA-(γ)-N_3 **1** with [^{18}F]-6-fluorohex-1-yne (**9**) at 60 °C in a mixture of CH_3CN/DMF/water and in the presence of amine bases (DIPEA and 2,6-lutidine) (*26*).

While the synthesis of metal ligand systems of low denticity (*19*) can readily be achieved by the click cycloaddition (*41*), employment of multidentate chelators such as DTPA (diethylene triamine pentaacetic acid) or DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) in this context can pose additional challenges. Particularly, in unprotected form, these ligand systems are excellent chelators for copper which could lead to the sequestering of copper ions required for the formation of the catalyst. Indeed, attempted click reaction of FA-(γ)-N_3 **1** using unprotected alkynes **6** or **8** and catalytic amounts of Cu(I) did not yield detectable amounts of the corresponding 1,2,3-triazole conjugates (data not shown). Furthermore, it is important to remove carefully all copper species because they could impact with the subsequent radiolabeling step (*42*). It has been reported that the Cu-catalyst can be removed efficiently from click reaction mixtures even if the formed 1,2,3-triazole products represent potentially potent chelating agents for the metal catalyst itself. Examples of separation procedures described in the literature include extraction steps with aqueous solutions of EDTA (ethylenediaminetetraacetic acid) (*43*−*45*) or ammonium salts (*19*, *45*) and precipitation procedures with sodium sulfide (*15*). In addition, we have reported that commercial metal scavenger resins can be applied in this context (*18*). Alternatively, separation of 1,2,3-triazole derivatives of DTPA or DOTA from copper species can be accomplished by HPLC purification (*14*, *18*). We were pleased to find that reaction of protected DTPA derivative **7** with FA-(γ)-N_3 **1** in aqueous media and in the presence of catalytic amounts of Cu(I) (10 mol %) at 85 °C for 25 min cleanly provided the desired coupling product in good yields. These results are in agreement with reports of other groups describing the use of protected DTPA derivatives or related ligand systems for click chemistry applications (*43*−*45*). Subsequent removal of the *tert*-butyl protective groups of intermediate FA-(γ)-DTPA(^{t}Bu)$_5$ by treatment with TFA gave the desired FA-(γ)-*p*NHBnDTPA **18**. Radiolabeling of compound **18** with $^{111}InCl_3$ was performed in PBS (pH 6.5) at rt for 1 h yielding efficiently SPECT probe **19** ([^{111}In(**18**)]). In contrast, attempted click reaction of FA-(γ)-N_3 **1** with the alkyne derivative of protected DOTA **5** by simple mixing of the substrates with catalytic amounts of Cu(I) at different temperatures yielded only a mixture of unreacted alkyne **5** along with the Cu complex of the desired coupling product FA-(γ)-DOTA(^{t}Bu)$_3$ in yields that corresponded approximately to the amount of copper catalyst employed (HPLC, MS). Employment of excess Cu(I) catalyst as reported by Knör et al. (*15*) followed by removal of the copper metal by any of the extraction/precipitation procedures described above did not give satisfying results in our hands. After some experimentation, we found that slow addition of a solution of Cu(I) (0.05 mol % $Cu(OAc)_2$/sodium ascorbate) to a mixture of FA-(γ)-N_3 **1** and DOTA(^{t}Bu)$_3$-propargylamide **5** at elevated temperature (85 °C) gave the desired compound FA-(γ)-DOTA(^{t}Bu)$_3$ in high yields. We speculate that the slow addition of the copper catalyst enables the cycloaddition to take place before the metal is complexed by the DOTA ligand present. The intermediate FA-(γ)-DOTA(^{t}Bu)$_3$ was deprotected *in situ* under acidic conditions (aq HCl, 1 M), and the final product FA-(γ)-DOTA **13** was separated by HPLC from small amounts (∼5%) of the corre-

Scheme 1. Alkyne Derivatives Employed in This Study and Their Syntheses[a]



[a] (a) HBTU, DIPEA, DMF, rt; (b) CH_2Cl_2, DIPEA, rt; (c) CH_2Cl_2/TFA, rt; (d) pyridine, THF, reflux; (e) see ref 26.

sponding Cu-complex (MS) inevitably formed under the conditions applied. Unlike other ligand systems described herein, application of DTPA and DOTA required the employment of protective groups for the click cycloaddition conjugation step, however, the desired compounds specifically in a short reaction sequence and with high efficiency.

The macrocyclic chelating system DOTA has the advantage that it can be used for the complexation of different radiometals providing stable metal complexes suitable for *in vivo* applications (*46*). Thus, radiolabeling of FA-(γ)-DOTA **13** with $^{67}GaCl_3$ performed in sodium acetate buffer (pH 5.0) at 85 °C provided SPECT probe **14** in high radiochemical yield. On the other hand, complex formation of FA-(γ)-DOTA **13** with $GdCl_3$ in water at reflux gave MRI probe **17** in excellent yield and purity. In addition, we have previously reported that FA-(γ)-DOTA **13** can be labeled with ^{111}In and ^{177}Lu, giving rise to SPECT probes **15** and **16**, the latter of which also represents a potential therapeutic agent (*25*). It is likely that other radiometals known to form well-defined and stable complexes with the DOTA chelator (e.g., ^{64}Cu, ^{67}Cu, ^{68}Ga, ^{90}Y) could also be employed for the preparation of a set of additional FA-based imaging probes and therapeutic agents.

***In Vitro* Experiments.** Folic acid derivatives functionalized via the γ-carboxylate of the glutamic acid moiety have been shown to retain high specific affinity to the FR *in vitro* and *in vivo*. Nevertheless, the folic acid probes (or derivatives thereof) presented in this work were evaluated *in vitro* prior to *in vivo* experiments (see Supporting Information for details). In brief, NIRF probe **12**, the cold gallium analogue of **14** and the F-19 analogue of PET probe **20** (*26*) were assessed regarding their receptor affinity with FR overexpressing KB cells by competition studies using ^{3}H-FA according to a protocol previously described (*24*−*26*). Experimentally determined IC_{50} values were higher compared to that of folic acid ($IC_{50} = \sim 1$ nM) but still in the low nanomolar range (~2−20 nM). Thus, the compounds were considered to be well-suited for *in vivo* investigations. FA derivatives **19** and the **14** were characterized by internalization experiments with FR-overexpressing KB cells by published procedures (in analogy to compounds **15** and **16**) (*25*). For both SPECT probes, a cell uptake of approximately 50% of total added radioactivity was observed of which roughly one-third was found internalized. Experiments performed with excess folic acid resulted in an almost complete blockade of the internalization, thus proving FR-specific uptake. In the case of the NIR optical probe **12**, confocal microscopy was also employed to demonstrate specific cell uptake *in vitro* (Figure 3). Again, blocking experiments with excess folic acid proved FR-specific internalization of the optical probe.

***In Vivo* Experiments.** In order to assess the novel FA probes *in vivo* and compare different imaging modalities, experiments

Scheme 2. Synthesis of Multiple Imaging Probes from a Single Precursor by Click Chemistry[a]

Cell nuclei (blue) were stained with DAPI for visualization.

with nude mice bearing KB tumor xenografts were performed. SPECT and NIRF images were acquired approximately 18 and 24 h p.i., respectively. PET scans were performed 15−45 min p.i. All FA imaging probes accumulated specifically in the tumors (white arrows) which could clearly be visualized by either modality SPECT, NIRF, and PET (Figure 4). Besides in the tumor xenografts, substantial amounts of radiotracers **10**, **14**, **19**, and **20** were found in the FR-positive kidneys (orange arrows). High renal retention of folate-based probes is a known phenomenon due to reabsorption after filtration via FRs that are highly expressed at the luminal side of the proximal tubule cells (*47*). The apparent attenuated accumulation of the NIRF probe **12** in the kidneys does not necessarily reflect a significant difference of the pharmacokinetic profile of the NIRF probe compared to that of the radiotracers, but is likely to be the result of the limited tissue penetration depth of current optical imaging techniques operating in the reflectance mode. For this reason, it cannot be estimated reliably to what extent NIRF probe **12** is present in other organs such as the liver and the intestines.

Of the metallic SPECT tracers investigated, the Ga-67 and In-111 probes **14** and **19**, respectively, exhibited favorable characteristics in comparison to the Tc-99m tracer **10**, which accumulated to a higher extent in the liver and also in the intestines (yellow arrow). This is presumably a consequence of the increased lipophilicity of the Tc-99m derivative in comparison to the DTPA or DOTA derivative as previous studies have shown (*48*). Thus, a pre-selection of the most promising SPECT probe(s) for future investigations could be made on the basis of images obtained. F-18 PET probe **20** also showed high accumulation in the bile and intestines. This indicates strong hepatobiliary elimination as the result of its lipophilic character (*26*). Imaging at later time points p.i. of the ^{18}F-tracer, after clearance of the tracer and/or metabolites thereof, was not possible because of the short half-live of F-18. Overall, the direct comparison of different FA-based SPECT, PET, and NIRF probes revealed the superiority of hydrophilic tracers, a result which will guide future efforts for the development of FA-based radiotracers and other imaging probes.

Two MRI probes **11** (F-19) and **17** (Gd) were synthesized of which, in particular, the F-19 probe is a promising candidate for FR imaging applications, because unlike ^{1}H MRI, ^{19}F MRI measurements do not suffer from interference or low contrast

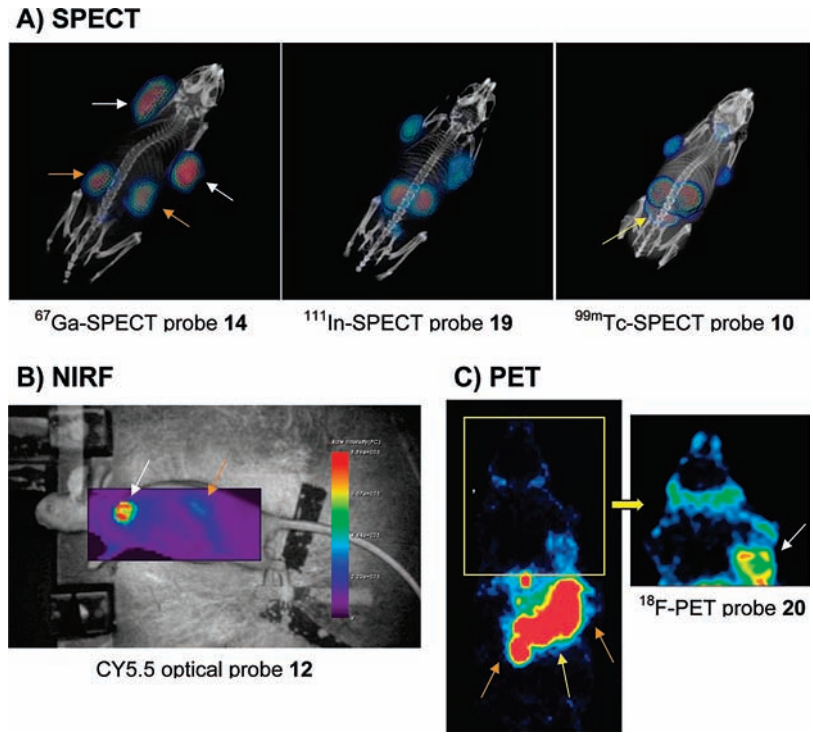

Figure 4. *In vivo* evaluation of novel folate-based imaging probes by SPECT (A), NIRF (B), and PET (C). Imaging of the xenografted FR-positive tumors (white arrows) was achieved with all probes. Accumulation of the probes in FR-positive kidneys (orange arrows) was also observed in each case. Unfavorable enrichment in the intestines and bile (yellow arrows) was detected only with the more lipophilic probes **10** and **20**. Figure 3C was adapted from ref 26.

due to background signals (*49*). In addition, compound **11** contains nine chemically and magnetically identical fluorine atoms (introduced in 1 step) which, in comparison to mono-fluorinated compounds, increases the apparent concentration of F-19 by almost 1 order of magnitude. Thus, this class of compounds could provide a useful tool for improving the sensitivity limitations of MR-based molecular imaging applications. Studies investigating the applicability of the MRI probes for *in vivo* experiments are currently ongoing.

CONCLUSIONS

We have demonstrated that multiple imaging probes for different imaging modalities can be obtained from a single precursor by application of the same general conjugation strategy, the Cu(I)-promoted click cycloaddition of alkynes and azides. Starting from a readily available azido-folic acid derivative, targeted imaging probes suitable for SPECT, PET, NIRF, and potentially MRI were prepared in few synthetic steps and high yields.

The modular synthetic approach facilitates not only the assessment of different probes for a given technique (e.g., SPECT probes based on different radiometals or metallic (Gd) vs organic (^{19}F) MRI probes) but also a comparison of different imaging modalities, the latter of which may find future applications for the collection of complementary data by taking advantage of the strengths of individual imaging techniques. *In vivo* evaluation using SPECT, PET, and NIRF showed that the novel folate probes presented are all suitable for the imaging of FR-positive tumors however, differed significantly in terms of their overall pharmacokinetics and rate and route of excretion. We were able to correlate the observed differences of metallic SPECT tracers to their physical properties (hydrophilicity), a result important for the future development of folic acid-based diagnostics and therapeutic agents.

In summary, the presented "click chemistry" approach will expedite the parallel development of new imaging probes and facilitate a comparison of different imaging modalities and, thus, the selection of the optimal probe and technique for *in vitro* and *in vivo* studies.

ACKNOWLEDGMENT

We thank Merck Eprova AG, Switzerland for providing the precursor *N2*−*N*,*N*-dimethyl-aminomethylene-10-formyl-pteroic acid, Dr. Bernhard Pfeiffer (ETH) for assistance with NMR spectroscopic measurements, Christine DePasquale (PSI) for assistance with animal experiments, and Maja Günthert (ETH) for confocal microscopy.

(38) Most folate derivatives reported for diagnostic or therapeutic applications are functionalized via the gamma-caboxylate of the glutamic acid moiety, which is the major product obtained by direct modifications of FA. However, employment of the alpha-

analogue, mixtures of the two isomers and pteroic acid derivatives lacking the entire glutamic acid moiety have also been reported in this context (see, e.g., Müller, C., Hohn, A., Schibiger, P. A., and Schibli, R. (2006) Preclinical evaluation of novel organometallic ^{99m}Tc folate and ^{99m}Tc-pteroate radiotracers for folate receptor-positive tumour targeting. *Eur. J. Nucl. Med. 33*, 1007–1016.

(39) The fragment coupling approach has also been successfully developed in the context of solid phase synthesis (see, e.g., ref 28.).

4. IN VITRO EXPERIMENTS

4.1. IC50 Determination of NIRF Probe 12, cold Gallium Analogue of Derivative of 14 and F-19 Analogue of PET Probe 20

The IC50 of NIRF probe **12** and cold Gallium analogue of derivative of **14** as well as the F-19 analogue of PET probe **20** were determined according to the method described by Westerhof et al.[1,2] with slight modifications.[3] Briefly, FR–positive KB cells were gently trypsinized in 0.25% trypsin in phosphate-buffered saline (PBS) at 37°C for 3 min and then diluted in FFRPMI containing 10% heat-inactivated fetal calf serum. After a 3-min 300 *g* spin and one PBS wash, the final cell pellet was suspended in FFRPMI 1640 (no serum). Cells were incubated for 15 min on ice with 20 nM of 3H-folic acid in the absence and presence of increasing concentrations [5E-6 to 5E-12 M final] of the test compounds. Samples were centrifuged at 800 *g* for 10 min; cell pellets were suspended in PBS, transferred to individual vials containing 4 mL of scintillation cocktail, and then counted for radioactivity. Negative control tubes contained only the ^{3}H-folic acid in FFRPMI (no competitor). Positive control tubes contained a final concentration of 1 mM folic acid, and counts per minute (cpm) measured in these samples (representing nonspecific binding of label) were subtracted from all samples. All measurements were performed in triplicates. Notably, IC50 values were defined as the concentration of competing ligand which displaces 50% of the specific binding of the radioligand, ^{3}H-folic acid bound to the FR on KB cells.

[3] For details see also : T. Ross et al *Bioconj. Chem.* **2008**, *19*, 2462.

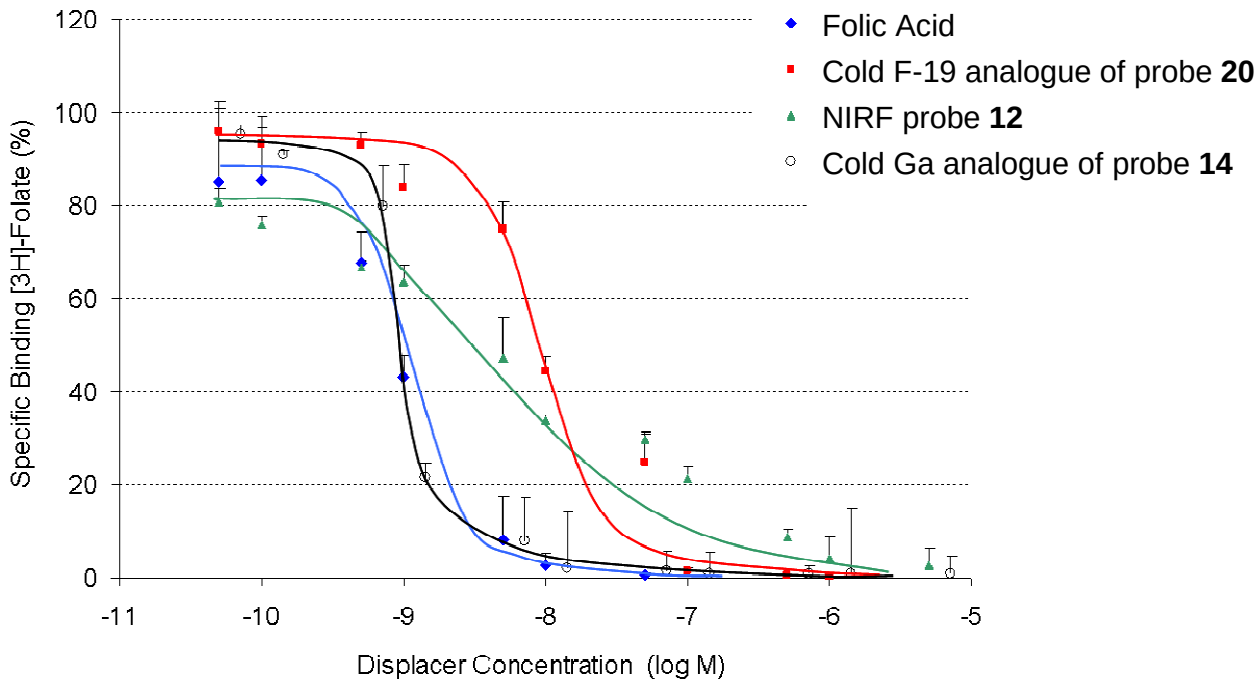

Figure S1. Competitive blocking of ^{3}H-folic acid binding to KB cells with test compounds and native folic acid (reference). KB cells were incubated for 15 min on ice with 20 nmol/L ^{3}H-folic acid in the presence and absence of increasing concentrations of the test compounds. Error bars represent 1 SD (*n* =3).

Folate conjugates are typically analyzed using an in vitro relative affinity assay that measures a ligand's ability to directly compete with folic acid for binding to cell surface FRs. Thus, ^{3}H-folic acid is used as the radioligand, whereas unlabeled folic acid serves as the reference compound. We have previously reported that the cold F-19 analogue of PET probe **20** has an IC50 value of 18.0 ± 7.1 nM.[3] As shown in Figure S1, NIRF probe **12** and the cold Gallium analogue of derivative **14**, were determined to have an IC50 value of 12.3 nM and 1.6 nM, respectively. Although binding affinity of the cold F-19 analogue of PET probe **20** and NIRF probe **12** for the FR is lower compared to that of folic acid (IC50 = 1.12 ± 0.44 nM), all new agents are considered to be a high-binding ligand for the FR (consistent with in vivo findings).

4.2. Cell Internalization Studies of SPECT Probes 15 and 19

Eighteen hours prior to the experiment, the KB cells were seeded in 12-well plates (7.5×10^5 cells/well) to form confluent monolayers overnight. The experiments were performed in triplicate. Cell binding experiments of the radiofolates **15**[4] and **19** were performed according to the following procedure: Cell monolayers were rinsed twice with PBS (pH 7.4). Pure FFRPMI medium (without FCS/L-glutamine/antibiotics, 975 μL) was added into each well. Blocking studies were performed with FFRPMI medium (475 mL) and a folic acid solution (200 μM, 500 μL). The well plates were pre-incubated at 37°C for 40 min. A solution of the corresponding radiotracer (25 μL, 1.5 MBq/mL) was added, and the well plates were incubated for 1 h at 37°C. Then, the monolayers were washed several times: radioactivity counted in samples washed with only PBS (pH 7.4) could be ascribed to the sum of FR-bound radiotracer on the cell surface and the internalized fraction. Cell samples washed with stripping buffer (an aqueous solution of 0.1 M acetic acid and 0.15 M NaCl, pH 3) in order to release radiotracers from FRs on the cell surface enabled determination of the internalized fraction of radioactivity. The monolayers were lysed in 1 N NaOH (1 mL), transferred into 4 mL-tubes, and homogenized by vortex. The radioactivity of each sample was measured with a γ-counter. The concentration of proteins was determined for each sample in order to normalize measured radioactivity of the samples with respect to the averaged sample protein content. The raw data were converted from counts per minute (cpm) into percentage of total radioactivity added.

In vitro cell binding experiments were performed with ^{111}In labelled compounds **15** and **19**. For both SPECT probes, a cell uptake of approximately 50% of total added radioactivity was observed of which roughly one third was found internalized. FR-specific binding of the radiofolates was proved by an experiment with excess cold folic acid that resulted in an almost

[4] C. Müller et al. *Eur. J. Nucl. Med. Mol. Im.* **2009**, on-line.

complete blockade of radiofolate uptake (<0.5% cell binding of total added radioactivity). The time-dependent experiment showed a constantly increasing cellular uptake of radiofolate 1 until steady state was reached after 2 h at 37°C. The time course of the cellular uptake of the two ^{111}In-labelled compounds was largely comparable to the results found with organometallic ^{99m}Tc radiofolates as previously reported by our group.[5]

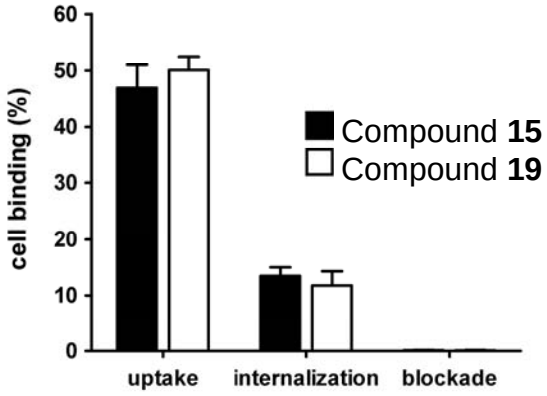

Figure S2. FR-specific internalization of radioactive probes **15** and **19** into FR-over expressing KB cells.

5. TIME-DEPENDANT IN VIVO EXPERIMENTS WITH NIRF PROBE 12

KB tumor bearing Balb/c mice were divided in 3 groups. Animals of group 1 received 2 nmol of the NIRF tracer **12**, group 2 received 2 nmol Cy5.5-CO_2H (Scheme S3) and group 3 was co-injected with the NIRF tracer **12** (2 nmol) and free folic acid (600nmol) to test for competitive inhibition. For all groups NIRF imaging was performed 10-12 days after tumor inoculation and prior (-1h) and 1, 5, 24, 48 h after intravenous injection of the respective dye. Additionally animals from group 1 and 2 were measured 120 h after tracer administration.

[5] C. Müller et al. *Eur. J. Nucl. Med. Mol. Im.* **2006**, *33*, 1007.

NIRF imaging was carried out on a time-domain in vivo small animal fluorescence imager, eXplore Optix (ART Advanced Research Technologies, Montreal, Canada) equipped with a pulsed laser diode at 666 nm as light source. The fluorescent light emitted from the sample (mouse) was detected by photomultiplier tube (PMT) coupled with a time correlated single-photon-counting system. A combination of filters was installed for optimal Cy5.5 fluorescence measurement. Exposure time was set to 0.5-2 s per scanned image point, and the rectangular region of interest (ROI) was manually placed within the visible tumor margins. The maximum excitation power (10-35μW) was set at 80% of the PMT saturation limit which was measured within the ROI. Images were analyzed using a program written in MATLAB (MathWorks, Natick, US) where the ROI within the tumor region is placed manually. The mean fluorescence intensity of the tumor area above a certain threshold (applied to all images) was calculated for each animal. The fluorescence intensity data are presented as mean and standard error of the mean (SEM). Statictical analysis was performed using OriginPro 8.0 (Origin Lab corporation, Northampton, US).

In mice bearing KB tumors fluorescence intensity can be detected at the first measurement time-point 1h after administration of the NIRF tracer **12** at a dose of 2 nmol. Time-course analysis shows that signal intensity peaked at 1h post injection and decreased over the duration of the experiment. A similar time course can be observed in mice which were injected with the control dye Cy5.5-CO_2H (Figure S3). However a clear difference is observed between NIRF tracer **12** and the control tracer Cy5.5-CO_2H at time point 1h as demonstrated for representative animals of the two groups (Figure S4). Signal intensity in group 1 was significantly higher ($p<0.05$, two-sample t-test) compared to group 2. Albeit not significant a clear reduction in signal intensity can be measured after co-injection of NIRF tracer **12** with excessive folic acid indicating competitive uptake and hence specificity of the synthetic NIRF tracer **12**. Both Cy5.5-CO_2H and NIRF tracer

12 show a transient pattern reaching signal intensity values at around 20% of maximum peak intensity after 120 h.

The data obtained is in good agreement with results published by Moon et al investigating a structurally different folate-based NIRF probe.[6]

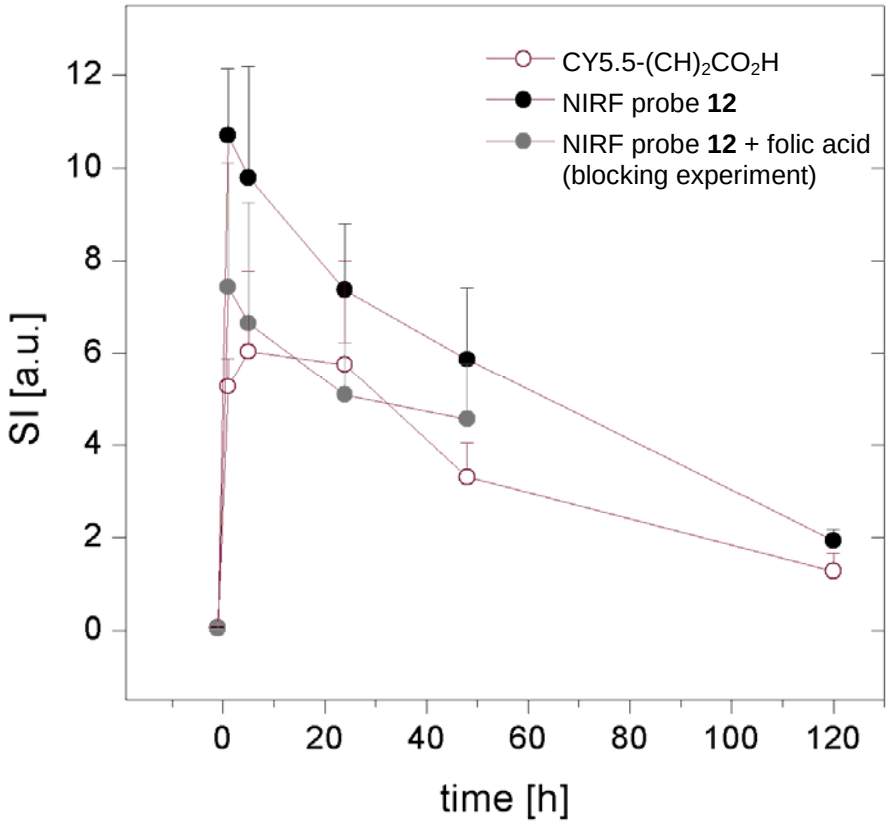

Figure S3. Time course of fluorescent signal intensities derived from ROI in KB tumors prior and after systemic administration of various probes. Signal intensities are given in arbitrary units (a.u.) plotted as mean±SEM for all three groups: NIRF tracer **12**, Cy5.5-CO_2H as control dye and the NIRF tracer **12** co-injected with folic acid (blocking experiment).

Received June 27, 2009; Revised Manuscript Received August 18, 2009

This paper describes a method for a single-step, site-specific conjugation of bioactive peptides to proteins that exploits the monitoring advantages provided by the unique UV signature absorbance of a bis-arylhydrazone. The utility of this method is demonstrated by the conjugation of a decapeptide molecular adjuvant, YSFKDMP(MeL)aR (EP67), to two test proteins, ovalbumin (OVA) and bovine serum albumin (BSA), and to proteins expressed on intact influenza virons and fungal arthroconidia (spores) of *Coccidioides*. Conjugation is accomplished with a version of EP67 in which its N-terminus is modified with succinimidyl-4-benzoylhydrazino-nicotinamide (S4BHyNic) (peptide **7**), thus enabling conjugation to these large entities via formation of amide bonds with surface-exposed amino groups. The presence of the strongly absorbing bis-arylhydrazone S4BHyNic ($\varepsilon_{354\ nm}$ = 29 000 L mol^{-1} cm^{-1}) allows for determination of EP67-to-protein molar substitution ratios (MSR), which are in good agreement with the MSRs determined by amino acid analysis. Conjugation to OVA does not compromise the ability of EP67 to engage C5a receptor bearing antigen presenting cells (APC) as measured by the EP67-mediated release of interleukin-6 (IL-6) from APCs. Mice immunized with the resulting OVA-EP67 vaccine conjugate produce high serum titers of OVA-specific IgG antibodies relative to OVA alone. Also, the conjugation of EP67 does not affect the surface integrity of influenza virons or the biological viability of *Coccidioides* spores. This method of conjugating bioactive peptides to proteins and other large biological entities may represent a convenient and effective way of generating various bioconjugates for use in mechanistic studies or novel therapeutic entities such as EP67-containing vaccines.

INTRODUCTION

Conjugation of bioactive peptides to proteins with retention of biological activity requires a method of chemoselective ligation that does not interfere with or obscure the essential topochemical features that impart biological activity to the peptide. Typically, this is achieved by first modifying the protein with a functional group that possesses reactive specificity for a complementary functional group introduced on a specific site on the peptide.

An innovative example of such chemoselective ligation is the formation of a bis-arylhydrazone linkage between a protein modified with an aromatic aldehyde (4-formyl benzoic acid) and a peptide modified with a hydrazinonicotinamide (HyNic) moiety (*1*, *2*). This method has the advantage that the resulting bis-arylhydrazone conjugate possesses a strong signature absorbance at 354 nm (ε = 29 000 L mol^{-1} cm^{-1}), which can be used to follow the course of the conjugation reaction and to determine the final peptide-to-protein molar substitution ratio (MSR). However, this conjugation method requires multiple steps, the first being modification of the protein with an excess of the OSu ester of 4-formylbenzoic (S4FB) at high pH (7.5−8.0). Unreacted S4FB is removed via dialysis and the high pH buffer is replaced with low pH buffer (4.5−6.0) for the formation of the bis-arylhydrazone linkage with the HyNic-modified peptide. Unreacted peptide is removed via dialysis and the low pH reaction buffer replaced with a more physiologically compatible buffer. The principal encumbrance of this multistep conjugation is that it presents opportunities for inadvertent loss of protein at each modification, conjugation, and buffer exchange step. Another drawback is that not all 4SFB moieties on the protein will react with the HyNic-containing peptide, leaving behind 4SFB-modified sites that could unnecessarily alter certain biological attributes of the protein such as immunogenicity.

In this paper, we describe a method of conjugating bioactive peptides to proteins that retains the chemoselective and monitoring advantages of the bis-arylhydrazone conjugation, but is accomplished in a single step. This is achieved by conjugating the intact protein with a peptide modified with a self-contained bis-arylhydrazone in the form of succinimidyl-4-benzoylhydrazino-nicotinamide (S4BHyNic). Conjugation occurs efficiently in a single step through the formation of stable amide bonds via the OSu ester on the peptide. This single-step method does not require prior modification of the protein and retains the same monitoring advantages provided by the bis-arylhydrazone in the multistep conjugation method described above.

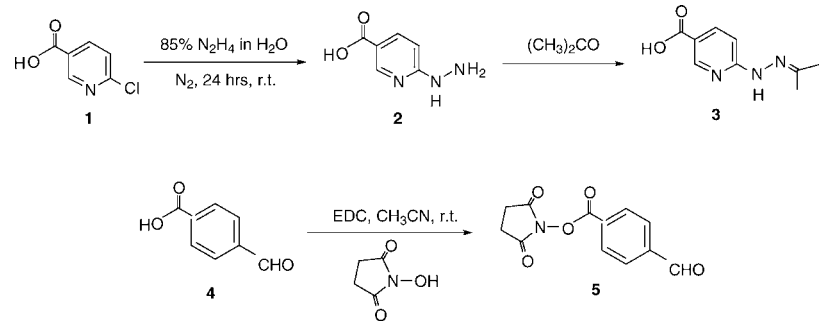
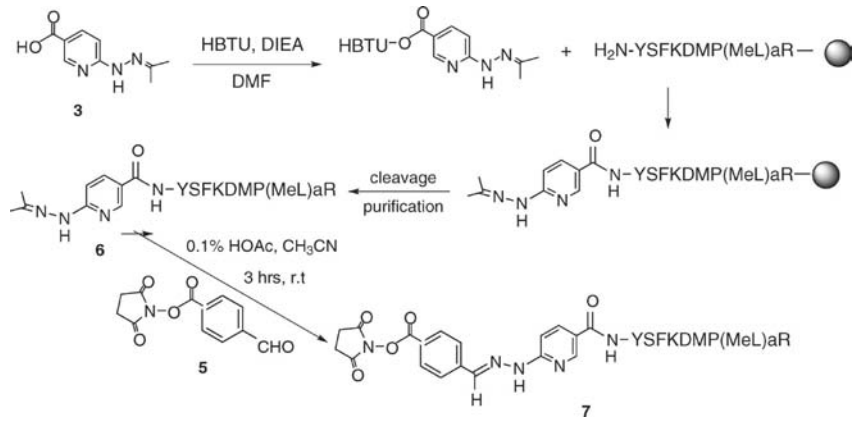
Scheme 1



Scheme 2



The utility of this single-step process is demonstrated by the conjugation of our molecular adjuvant EP67 (Tyr-Ser-Phe-Lys-Asp-Met-Pro-N-methylLeu-D-Ala-Arg or YSFKDMP(MeL)aR) to two test proteins ovalbumin (OVA) and bovine serum albumin (BSA) as well as with intact influenza virons and live *Coccidioides* spores. EP67 is a conformationally biased, response-selective agonist of human C5a and operates as a molecular adjuvant by targeting covalently attached antigens (Ag) to and stimulating the Ag processing and presentation capacity of antigen presenting cells (APC) via interaction with C5a receptors (C5aR) expressed on the surface of these cells (*3*−*6*).

Conjugation of EP67 to these larger molecular and biological entities is accomplished by modifying the N-terminus of EP67 with S4BHyNic, which in the presence of the selected proteins, virons, and live fungal spores, forms stable amide linkages with ε-amino groups of Lys residues on the exposed proteins. This single-step conjugation method exploits the bis-aryhydrazone signature absorbance as a convenient method of following the course of the conjugation reaction and determination of the peptide-to-protein MSR. A key feature of this method is that it allows conjugation at a specific site on EP67, the N-terminus, which leaves the biologically important C-terminal region of EP67 free to interact withC5aRs expressed on APCs.

The results presented in this paper are discussed against the backdrop of a new generation of EP67-containing vaccines in which whole intact proteins and biological entities such as viruses and live attenuated fungal spores can be used as target Ags. This not only expands the repertoire of Ags that can be used in such vaccines, but enables the EP67-activated APCs to process and present multiple epitopes within the protein(s) in the context of MHC classes I and II.

EXPERIMENTAL PROCEDURES

Reagents and General Methods. Chemicals and reagents for peptide synthesis were purchased from Sigma-Aldrich (St. Louis, MO), AAPPTEC (Louisville, KY), Creosalus (Louisville, KY), and AnaSpec (San Jose, CA). All reagents were used as supplied by the manufacturer without further purification. UV-inactivated influenza virus (A/Puerto Rico/8/34) was obtained from Charles River Laboratory. Conjugation of EP67 to live spores of *Coccidioides posadasii,* which has been designated as a select agent by the Centers for Disease Control and Prevention (http://www.selectagents.gov/agentToxinlist.htm), was performed in a certified biological safety level 3 (BSL3) laboratory at the University of Texas at San Antonio.

For protein conjugate analyses, single-wavelength absorbance measurements were obtained with a Shimadzu BioSpec-1601 spectrometer in 1.5 mL quartz cuvettes (1 cm path length). Scanning spectra for proteins, viral, and fungal conjugates were obtained using a Molecular Devices Spectra Max M2 spectrometer in 1.5 mL quartz cuvettes (1 cm path length) against a water standard.

Mice. Female C57BL/6 mice (2−3 months old) were purchased from Harlan−Sprague−Dawley and housed in the Sidney Kimmel Cancer Center (SKCC) vivarium under specific pathogen free conditions. All animal experiments were approved by the SKCC Institutional Animal Care and Use Committee (IACUC) and performed in compliance with the institute's guidelines.

Synthesis. Compounds **3** and **5** were synthesized by the reactions shown in Scheme 1 and the bis-arylhydrazone-containing peptide, S4BHyNic-YSFKDMP(MeL)aR (**7**), as shown in Scheme 2.

6-Hydrazinonicotinic Acid Acetone Hydrazone (3). 6-Chloronicotinic acid (**1**) (2.1 g, 13.3 mmol) was dissolved in 10 mL of 85% hydrazine in water and stirred overnight under a N_2 atmosphere to generate the hydrazine **2** (*7*). The reaction solution was placed on ice and cooled for several minutes and the hydrazone (**3**) precipitated by the slow addition of acetone (ca. 150 mL) with stirring. The precipitate was collected by filtration

and washed three times with dichloromethane (DCM) to remove the acetone hydrazone impurity. Yield 81%. mp 260−262 °C. ^{1}H NMR (500 MHz, DMSO-d_6) δ 1.94 (s, 3H), 1.97 (s, 3H), 7.07 (d, J = 8.8 Hz, 1H), 7.99 (d, J = 8.8 Hz, 1H), 8.60 (s, 1H), 9.89 (s, 1H) 12.55 (brs, 1H). ^{13}C NMR (125.7 MHz, DMSO-d_6) δ 17.36, 25.41, 105.62, 116.81, 138.82, 149.96, 150.49, 160.33, 166.76. $C_9H_{11}N_3O_2$, M_{calc} = 193, MH^+ = 194.08.

Succinimidyl 4-Formylbenzoate (5). 4-Formyl benzoic acid (**4**) (2.0 g, 13.3 mmol) was dissolved in acetonitrile (CH_3CN) (ca. 50 mL) along with 1.1 equiv each of *N*-hydroxysuccinimide and *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide HCl (EDC) and stirred overnight at room temperature. CH_3CN was removed in vacuo and replaced by DCM (ca. 100 mL) and washed three times with water. The solution was dried over $MgSO_4$ and DCM removed in vacuo to yield **5** as a white powder. Yield 91%. mp 173−175 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ 2.94 (s, 4H), 8.03 (d, J = 7.8 Hz, 2H), 8.31 (d, J = 7.8 Hz, 2H), 10.14 (s, 1H). ^{13}C NMR (125.7 MHz, $CDCl_3$) δ 25.64, 129.70, 129.92, 131.15, 140.28, 161.02, 168.95, 191.18.

EP67 and HyNic-EP67 (6). EP67 was synthesized by standard solid-phase methods (AAPPTEC Apex 396 synthesizer) on a preloaded Arg Wang resin using the Fmoc (9-fluorenylmethoxycarbonyl) method of orthogonal synthesis with HBTU [2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetra-methyluronium hexafluorophospate]-activated esters of the amino acids. HyNic-EP67 (**6**) was generated by coupling the HBTU-activated ester of **5** to the Fmoc-deprotected and exposed N-terminus of EP67 while still attached to the Wang resin. The course of this HyNic coupling reaction was monitored by the loss of the free amine using the ninhydrin reaction.

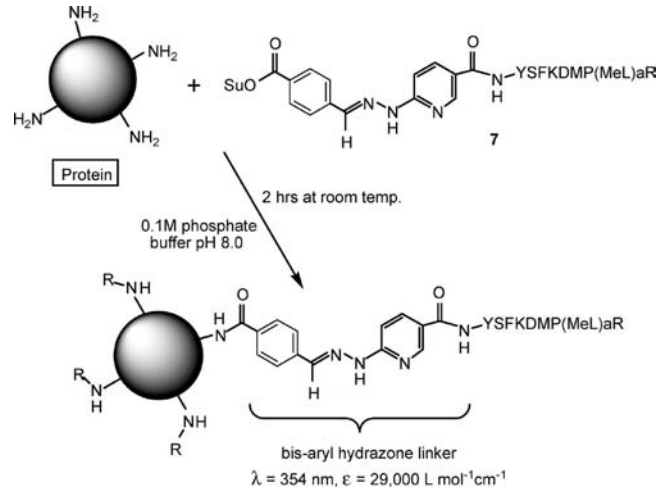
EP67 was cleaved from the resin and side-chain protecting groups removed by stirring the peptide resin for 1.5 h at room temperature in a cleavage cocktail made of TFA (87.5%), phenol (5%), water (5%), and triisopropylsilane (2.5%). NyNic-EP67 was cleaved under identical conditions but with a cocktail made of TFA (92.5%), water (2.5%), triisopropylsilance (2.5%), and acetone (2.5%), which was added in order to generate the acetone hydrazone **6**.

EP67 and HyNic-EP67 were precipitated by the addition of cold ether (ca. 50 mL) to the cleavage cocktails and were collected by centrifugation. Peptides were purified by analytical and preparative reverse-phase HPLC on C18-bonded silica columns with a running buffer of 0.1% TFA (solvent A) and 60% CH_3CN in 0.1% TFA (solvent B) as the eluant. Peptides were characterized by confirmation of molecular mass using MALDI mass spectrometry. EP67: M_{calc} = 1240, MH^+ = 1241.3. HyNic-EP67: M_{calc} = 1604, MH^+ = 1605.2.

Succinimidyl-4-benzoylhydrazinonicotinamide-EP67 (S4B-HyNic-EP67) (7). HyNic-EP67 (**6**) (20 mg, 0.015 mmol), 1.1 equiv of S4FB (**5**), and 1.0 μL of anisole were dissolved in 15 mL of 0.1% acetic acid and CH_3CN (70:30) and stirred at room temperature for 3 h. The solution was frozen and lyophilized to yield **7** as a dry yellow powder, which was purified using the HPLC conditions described above and characterized by MALDI mass spectrometry, M_{calc} = 1603, MH^+ = 1604.4.

Conjugation of EP67 to Proteins. Conjugation of **7** to proteins was accomplished via the reaction shown in Scheme 3. BSA and OVA (ca. 5 mg) were dissolved in 1.0 mL of 0.1 M phosphate buffer pH 8.0. To these solutions was added 100 μL of a stock solution of **7** dissolved in dimethylsulfoxide (DMSO) such that at least a10-fold molar excess of **7** was introduced. The protein−peptide reaction solutions were mixed at room temperature for 2 h, after which unreacted peptide removed and buffer replaced with water by centrifugation dialysis (MW cutoff 10K).

Scheme 3



Conjugation of EP67 to Influenza. Conjugation of **7** to UV-inactivated influenza was performed under identical conditions with the 10-fold molar excess of **7** estimated from the known total protein content and composition of the virus. Unreacted peptide was removed and buffer replaced with water by centrifugation dialysis (MW cutoff 100K).

Conjugation of EP67 to Fungal Spores. Conjugation of **7** to live spores of *C. posadasii* isolated from a genetically engineered, attenuated vaccine strain (*8*) was performed by a modification of the above method. Spores were harvested from Petri plate cultures of *C. posadasii* grown on GYE medium (1% glucose, 0.5% yeast extract, 1.5% agar) after 4 weeks of incubation at 30 °C. The plates were washed and spores suspended in 0.1 M phosphate buffer, pH 8.0. The concentration of viable spores in the buffer suspension was calculated by hemocytometer counts compared to serial dilutions of the suspension to determine plate counts of colony-forming units grown on GYE medium. A stock solution of **7** dissolved in DMSO was prepared as above. Aliquots of the spore suspension, each containing 1.0×10^7 viable cells, were mixed with **7** at different concentrations (10 μg to 1000 μg) in a final volume of 1.0 mL of phosphate buffer pH 8.0. The spore suspensions were incubated for 2 h at room temperature with mild agitation and then washed twice with PBS to remove unreacted **7** and resuspended in 1.0 mL of PBS.

Determination of Molar Substitution Ratios (MSR). At the end of the 2 h conjugation reaction of **7** with OVA or BSA, 20 μL of the reaction solution was diluted with water to 1.0 mL in a quartz cuvette (1 cm path length). The concentration of the protein−**7** conjugate was determined by measuring the absorbance (A) of the bis-arylhydrazone linker at 354 nm and using Beer's law to determine final concentration: $A = \varepsilon lc$, where ε = 29 000 L mol^{-1} cm^{-1}, l = cuvette path length, and c = concentration in mol/L. MSR was determined by dividing the concentration of the bis-arylhydrazone-containing protein−peptide conjugate by the known concentration of the protein used in the conjugation reaction. MWs for OVA and BSA used in these calculations were 45 000 and 66 400, respectively.

MSR also was determined by amino acid compositional analysis, which was performed by the Protein Structure Core Facility at the University of Nebraska Medical Center using a Hitachi L-8800A amino acid analyzer. Conjugate samples were hydrolyzed for 20 h at 110 °C in 6 N HCl vapor under an argon atmosphere with 1% phenol and 0.5% sodium sulfite in the hydrolysis mix. After hydrolysis, the samples were dissolved in 200 μL of 0.02 N HCl and 50 μL was injected automatically onto the amino acid analyzer. Norleucine was added to a

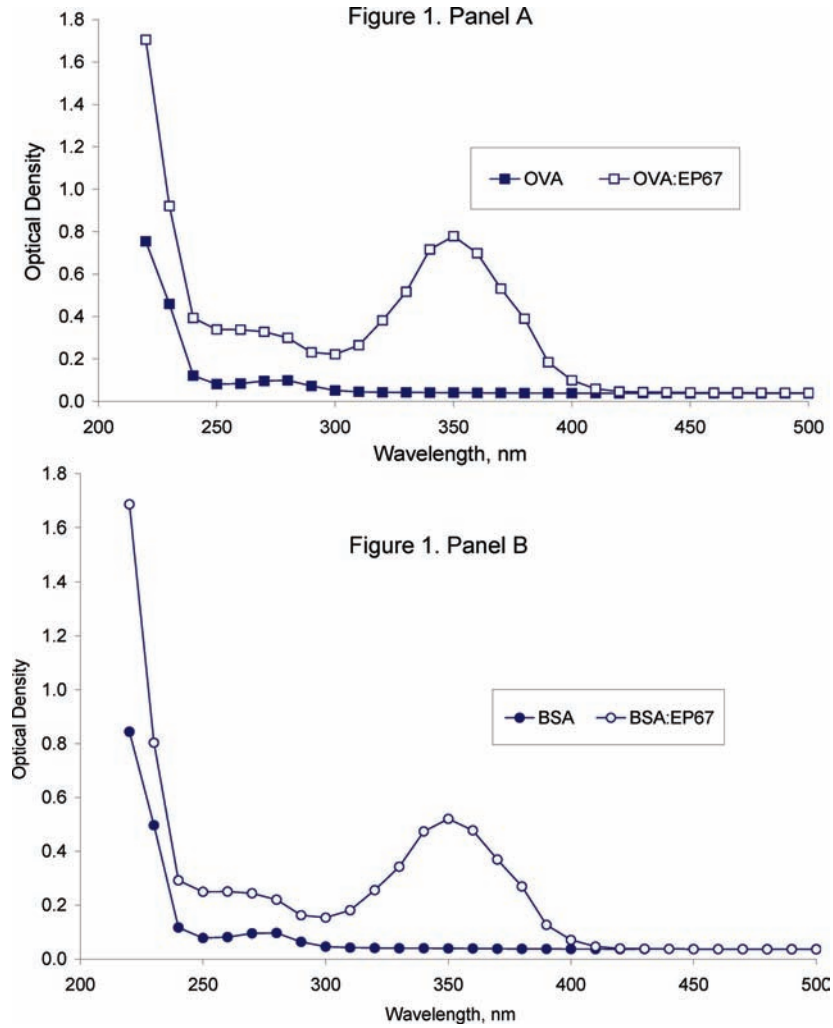


Figure 1. Panel A. Absorbance spectra of 4.3 mg OVA and OVA reacted in the presence of a 20-fold molar excess of **7** in 1.0 mL of phosphate buffer pH 8.0 for 2 h at room temperature. Spectra were generated from 20 μL of the solutions (after dialysis) diluted to 1.0 mL with water. Panel B. Absorbance spectra of 4.0 mg BSA and BSA reacted in the presence of a 20-fold molar excess of **7** in 1.0 mL of phosphate buffer pH 8.0 for 2 h at room temperature. Spectra were generated from 20 μL of the solutions (after dialysis) diluted to 1.0 mL with water.

measured amount of sample as an internal standard. Chromatographic runs were monitored at 570 and 440 nm. In data analysis, a correction was made to the amount of the internal standard, thus minimizing dilutional errors.

Post-Conjugation Determination of EP67 Biologic Activity. Prior to assaying for biological activity in vitro or in vivo, the OVA-EP67 conjugates were depleted of any potentially interfering endotoxin by utilizing an AffinityPak Detoxi-Gel endotoxin removal kit (ThermoScientific, Rockford, IL) according to the manufacturer's instructions. Retention of biologic activity of EP67 after its conjugation to OVA was assessed by measurement of the EP67-medated release of interleukin-6 (IL-6) from C5aR-bearing APCs derived from the spleens of C57BL/6 mice. Spleen cells were cultured for 48 h in the presence of EP67 or OVA-EP67, supernatants collected, and assayed for the presence IL-6 by a sandwich ELISA as described previously (*9*).

Immunologic activity of the OVA-EP67 conjugate vaccine was assessed by measuring the titers of OVA-specific antibodies (Ab) in the sera of C57BL/6 mice immunized with the OVA-EP67 construct. Mice were immunized by intraperitoneal injection of 100 μg (100 μL) of OVA-EP67 on day 0 and bled on day 21. Anti-OVA Ab titers (total IgG) were measured by a direct ELISA as previously described (*10*).

Electron Microscopy. Viral particles were negatively stained with a mixture of uranyl acetate and methyl cellulose (25 cPs, Sigma M-6385) in water at a final concentration of 1.3% each for 10 min at room temperature. Images were obtained with a Morgagni 268D electron microscope equipped with a MegaView III digital camera at 100 kV.

Viability and Immunofluorescence. Serial dilutions of known number of spores incubated with different initial concentrations of **7** as described above, or spores incubated in buffer alone, were plated on GYE medium and the numbers of CFUs were determined. The percent spore viability was calculated as CFUs of EP67-conjugated spores/CFUs of non-conjugated spores X 100.

For immunofluorescence studies, the EP67-conjugated spores (reacted with 1000 μg of **7**/mL in phosphate buffer) and nonconjugated spores incubated as described above. The cells were subsequently fixed with 1% paraformaldehyde for 15 min at room temperature, washed with PBS, blocked with10% fetal bovine serum at 4 °C overnight, and then incubated with rabbit anti-EP67 Ab followed by fluorescein isothiocyanate (FITC)-labeled goat antirabbit IgG. The cells were examined with a Leica DM6000 fluorescence microscope equipped with a DFC 300FX digital camera.

RESULTS

EP67 Conjugates to OVA and BSA. A 10-fold molar excess of S4BHyNic-modified EP67 (**7**) effectively conjugates to the proteins OVA (Figure 1, panel A) and BSA (Figure 1, panel

Table 1. MSR Determination of OVA-EP67 and BSA-EP67 Conjugates

method	MSR(OVA-EP67)	MSR(BSA-EP67)
Beer's law[a]	10	13
amino acid analysis[b]	14	19

[a] Average of 3 measurements. [b] Average of 2 measurements.

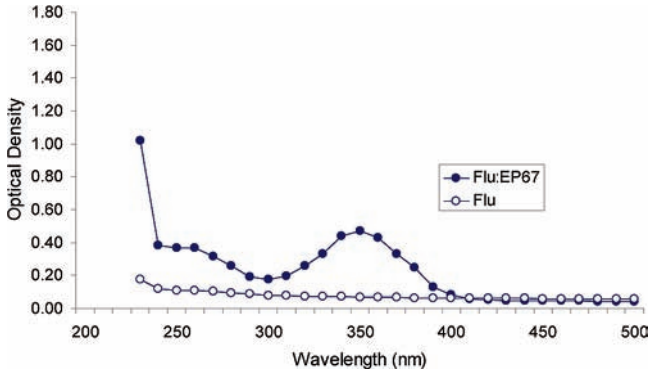

Figure 2. Absorbance spectra of intact, UV-inactivated influenza virons equivalent to 1.7 mg of protein in the presence of an approximate 20-fold molar excess of **7** in 1.5 mL phosphate buffer pH 8.0 for 3 h at room temperature. The spectrum was generated from 50 μL of the reaction solution (after dialysis) diluted to 1.0 mL with water.

B) in 0.1 M phosphate buffer pH 8.0 after a 2 h reaction as indicated by the increased absorbance at 354 nm from the bis-arylhydrazone on the peptide. MSRs determined by Beer's law are in good agreement with those determined by amino acid analysis of the conjugates (Table 1). Neither total absorbance at 354 nm nor MSR (as determined by Beer's law) were changed significantly by reaction with a 20-fold molar excess of **7** or increased reaction time up to 16 h (data not shown). Conjugation of **7** to protein appears to go to completion, since eluents obtained from dialysis of the reaction mixtures were free of **7** as indicated by a lack of ninhydrin-detectable amino groups from the available Lys in EP67.

EP67 Conjugates to Intact Influenza. An absorbance peak at 354 nm is observed after reaction of **7** with intact UV-inactivated influenza for 2 h in 0.1 M phosphate buffer pH 8.0 (Figure 2). Electron micrographs of the influenza virus are shown in Figure 3 prior to (Panel A) and after (Panel B) conjugation of **7**. A comparison of these electron micrographs shows that the conjugation process does not appear to alter overall viral structure.

EP67 Conjugates to Live Spores of Coccidioides. Figure 4 shows an absorbance peak at 354 nm after reaction of 10^7 viable spores of *C. posadasii* with 1000 μg/mL of **7** in 0.1 M phosphate buffer pH 8.0 for 2 h at room temperature, stored at 4 °C for 24 h, and followed by incubation at room temperature for an additional period of 4 h. The absorbance peak at 354 nm increased with higher concentrations of **7** added to equal numbers of spores of *C. posadasii* with a maximum being obtained at 1000 μg/mL of **7**. Determination of the CFUs of spore suspensions incubated with different concentrations of **7** revealed no statistically significant difference between the viability of EP67-conjugated and nonconjugated cells (Figure 5, Student's t test, $P < 0.05$).

Immunofluorescence microscopy of EP67-conjugated spores (Figure 6, Panel A) and EP67-conjugated spores incubated with primary rabbit anti-EP67 antiserum followed by secondary FITC-labeled goat antirabbit IgG clearly show the presence of EP67 on the surface of the live fungal cells (Figure 6, Panel B). The spores were universally labeled, although they displayed variable levels of fluorescence intensity. Spores that were not conjugated with EP67 but were incubated with both the primary and secondary FITC-conjugated Ab, showed an absence of the fluorescent label (Figure 6, Panels C and D).

S4B-HyNic-EP67 (*7*) is not Self-Reactive. Conjugation of **7** to proteins is accomplished via amide bond formation between the activated OSu ester of **7** with ε-amino groups on the side chains of Lys residues on the protein surface. Because a potentially reactive ε-amino group is also available from the lone Lys residue in EP67, the possibilities of self-reactivity cannot be ignored. Thus, to determine whether the OSu-activated ester of the bis-arylhydrozone moiety of one EP67 peptide can react with the free ε-amino group on the Lys side chain of another EP67, 2.1 mg of **7** was dissolved in 1 mL of 0.1 M phosphate buffer pH 8.0 and mixed at room temperature for 2.5 h. The concentration of the ε-amino group contributed by EP67 was determined with a quantitative ninhydrin reaction as previously described (*11*). The concentration of free ε-NH_2 was 1.13×10^{-6} M after 5 min and 1.10×10^{-6} M after 2.5 h, indicating negligible self-reactivity under the conditions used in the conjugation reactions described above.

Conjugation of EP67 to OVA Does Not Interfere with EP67 Activity. Conjugation of the small decapeptide, EP67, to a whole protein raises the possibilities that the bulk introduced by the protein may sterically hinder the biologically important C-terminal region of EP67 from interacting with C5aRs on APCs. To assess for this possibility, OVA-EP67 constructs were evaluated for the EP67-mediated release of IL-6 from C5aR-bearing splenic APCs obtained from C57BL/6 mice. The OVA-EP67 conjugate effectively engages C5aR-bearing APCs to induce the release of IL-6 relative to OVA alone (Table 2).

To further demonstrate that EP67 activity is unaffected by conjugation to a large protein, C57BL/6 mice were immunized once either with OVA alone or with an OVA-EP67 conjugate vaccine, and the postinjection Ab titers were measured 21 days later by direct ELISA. As shown in Table 3, mice immunized with OVA-EP67 showed a significantly greater anti-OVA Ab response than mice immunized with OVA alone. These results indicate that the EP67 moiety of these conjugates retains biological activity in vivo.

DISCUSSION

This paper describes a convenient method for the single-step conjugation of bioactive peptides to proteins, viruses, and live fungal cells via formation of stable amide bonds with a peptide modified at a specific site with S4BHyNic. The presence of the bis-arylhydrazone moiety in the conjugation linkage provides a unique UV signature for monitoring/verifying the conjugation reaction and determining the final peptide-to-protein molar substitution ratio. An important benefit of this method is that it enables conjugation via a site chosen on the peptide that will not interfere with topochemical features required for biological activity. This is readily accomplished by first modifying a specific amino group on the peptide with the HBTU-activated ester of HyNic (**3**) while attached to the solid-phase resin. The HyNic-modified peptide is cleaved from the resin, purified, and then used in the solution-phase formation of the bis-arylhydrazone by reaction with OSu4FB (**5**). The resulting S4BHyNic-modified peptide (**7**) now can be conjugated to intact proteins in a single step via formation of amide linkages with ε-amino groups on the protein surface.

An important advantage of this single-step method is that it does not require the prior modification of the protein in order to achieve the chemoselective ligation with the peptide. Thus, there are fewer chances for the inadvertent and irreversible modification of important biologic or immunologic features on the protein. Also, since conjugation is accomplished in a single step, there are fewer chances of protein loss.

The applicability of this single-step chemoselective ligation is demonstrated by the successful conjugation of the im-

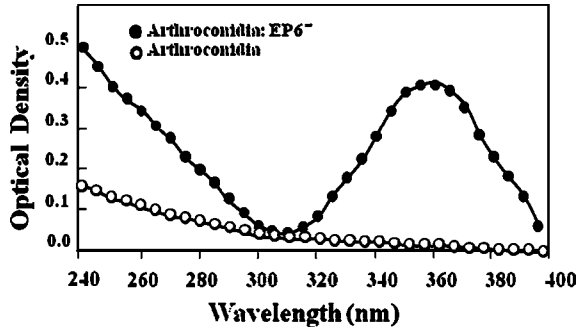

Figure 4. Absorbance spectra of arthroconidia (10^7 viable cells) incubated with **7** (1000 μg/mL) in 0.1 M phosphate buffer pH 8.0 for 2 h at room temperature (closed circles) and arthroconidia (10^7 viable cells) only (open circles).

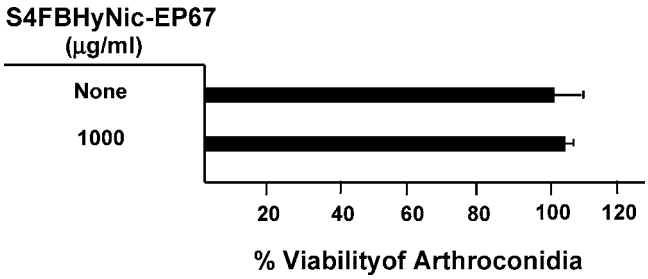

Figure 5. Arthroconidia of *C. posadasii* (isolate C735) grown on GYE plate cultures for 4 weeks at 30 °C, harvested in PBS (ca. 10^7 cells), incubated for 2 h with and without 1000 μg/mL of **7** at room temperature, and assessed for viability.

munologically active decapeptide EP67 to proteins, influenza virons, and *Coccidioides* spores. EP67 is a conformationally biased, response-selective agonist of complement component C5a. The unique conformational features biased in EP67 are well-accommodated by C5aRs expressed on APCs, but not on inflammatory neutrophils (*3*−*5*). Thus, EP67 has the ability to induce C5a-like immune stimulatory responses via engagement of C5aR-bearing APCs at the expense of C5a-like inflammatory responses via engagement of C5aR-bearing neutrophils.

We have used EP67 (YSFKDMP(MeL)aR) and an earlier sister analogue EP54 (YSFKPMPLaR) as molecular adjuvants in peptide-based vaccines made by the covalent attachment of well-characterized peptide epitopes to their N-termini. The EP67/EP54 moiety targets the attached epitope to and simultaneously activates C5aR-bearing APCs such that the Ag processing and presentation capacity of the APC is enhanced (*6*). Immunization with these EP67/EP54-containing vaccines in the absence of added adjuvants results in robust Ag-specific humoral and/or cell-mediated immune outcomes with no discernible inflammatory side effects (*10, 12*−*16*). However, these adjuvant activities of EP67/EP54 are abrogated if the C-terminal carboxyl group is blocked (*10, 12*), which underscores the necessity of chemoselective ligation via the N-terminus of EP67 if proteins are to be used as the target Ags in protein−EP67 conjugate vaccine constructs.

The ability to effectively conjugate EP67 to proteins is significant, because until now such EP67/EP54-containing vaccines have been restricted to the use of well-characterized peptide epitopes as the target Ags. This was because the only effective way of covalently attaching the epitope to the N-terminus of EP67 was by the solid-phase synthesis of the entire eptiope-EP67 peptide. While such EP67/EP54-containing vaccines are easy to generate, their effectiveness is dependent upon an intimate knowledge of the specific immunogenic epitope(s) within a particular disease-associated protein. Typically, this information is difficult to come by and, consequently, has imposed severe limitations the broad applicability of EP67/EP54-containing vaccines.

The results presented in this paper show that EP67 retains its adjuvant activities following single-step conjugation to large immunogenic entities. The ability to conjugate EP67 to intact proteins, viruses, or live fungal spores greatly expands the repertoire of Ags that can now be used in such molecular adjuvant-containing vaccines. The entire immunogenic entity can now be used as the target Ag with *all* potential immunoreactive epitopes contained therein available for processing and presentation by the EP67-activated APCs.

Results presented in this study indicate that the bulk contributed by the protein (OVA) does not interfere with the ability of EP67 to engage C5aR-bearing APCs. It is not know whether this will hold true for all possible EP67-containing vaccine conjugates. However, should the bulk contributed by other large target Ag entites interfere with the ability of EP67 to engage C5aR-bearing APCs, it is a straightforward synthetic process to introduce a variety of spacers between the bis-arylhydrazone moiety and EP67 to more effectively expose the C-terminal region of EP67 for C5aR interactions.

Also encouraging was the observation of negligible self-reactivity between S4BHyNic-modified EP67 peptides. This can be explained by a general inaccessibility of the ε-amino group on the Lys side chain of one EP67 to the reactive S4HyNic moiety on the N-terminus of another. Such inaccessibility may be due to the conformational constraints imposed on the EP67

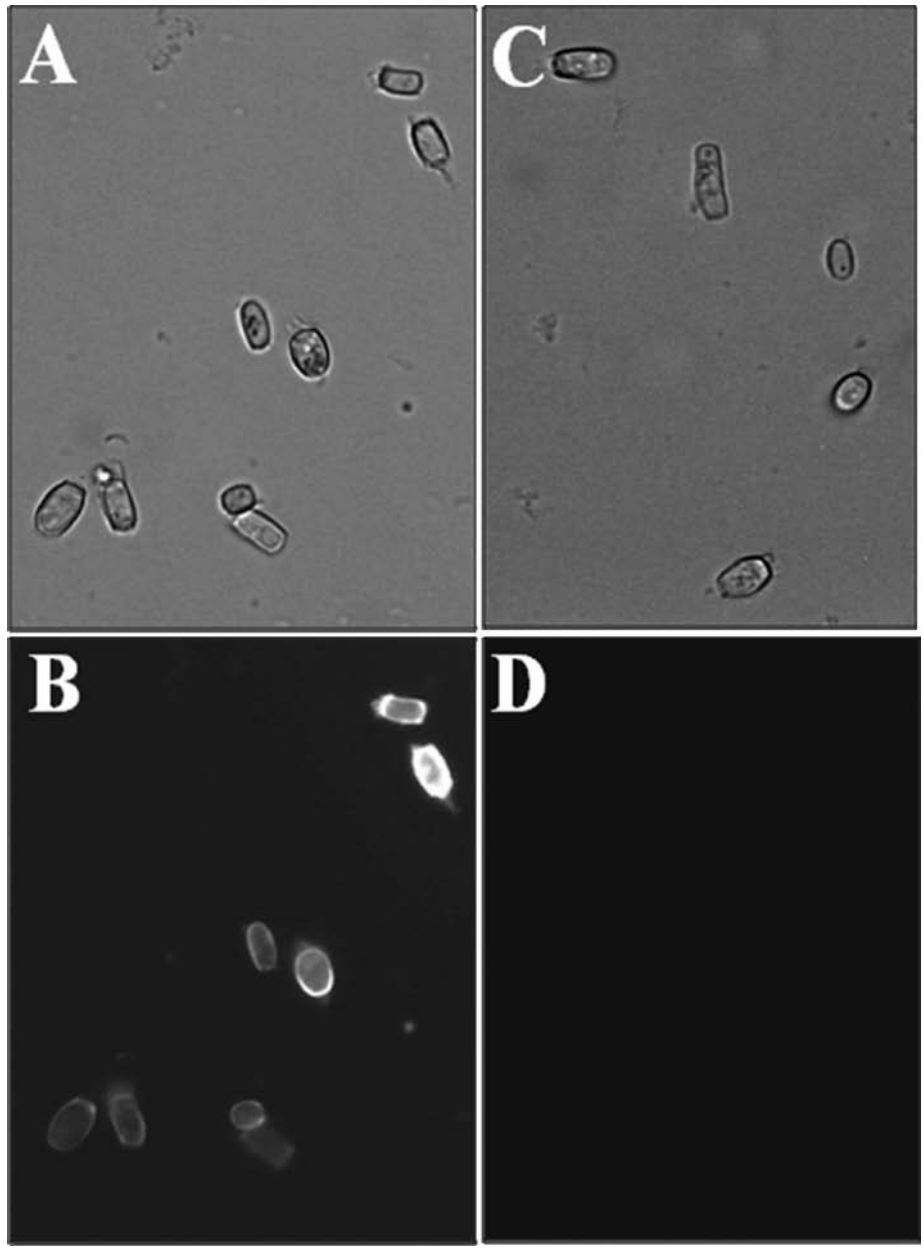

Figure 6. Arthroconidia of *C. posadasii* (isolate C735) grown on GYE plate cultures for 4 weeks at 30 °C. Panel A: Cells (ca. 10^7) incubated with **7** (1000 μg/mL) for 2 h at room temperature in 0.1 M phosphate buffer pH 8.0, washed with PBS, fixed with 1% paraformaldehyde, washed with PBS, and blocked with 10% FBS overnight at 4 °C. Panel B: Cells from Panel A incubated with rabbit anti-EP67 followed by incubation with FITC-labeled goat antirabbit IgG and examined by fluorescence microscopy. Control cells (Panels C and D) were not incubated with **7**, but were otherwise prepared and examined as in Panels A and B.

Table 2. EP67-Induced IL-6 Production

activator	μg/mL	IL-6 (pg/mL ± S.D.)
none	0	125 ± 7
OVA-EP67	500	420 ± 11
OVA	500	200 ± 3

Table 3. EP67-Induced Enhancement of Anti-OVA IgG Responses in C57BL/6 Mice

activator	IgG (OD ± SEM)[a]
OVA	0.064 ± 0.002
OVA-EP67	0.306 ± 0.013[b]

[a] 1:1000 dilution. [b] $p < 0.05$, using a single-tailed *t*-test.

backbone and resulting topographic masking of this side chain along with the likelihood of a salt bridge between the side-chain carboxyl moiety of the adjacent Asp residue (*3, 5*).

Finally, it is worth noting that the immunogenicity of the target Ag does not appear to be affected by the conjugation of EP67. This is supported by the robust humoral response seen in mice vaccinated with OVA-EP67. Serum titers of anti-OVA Abs were significantly higher in mice immunized with OVA-EP67 than mice immunized with OVA alone. Immune outcomes of the influenza virus-EP67 vaccine and the live attenuated fungal spore-EP67 vaccine are currently being evaluated in our laboratories.

ACKNOWLEDGMENT

Received July 23, 2009

We have studied biocompatible spherical carriers carrying a dodecapeptide, HHLGGAKQAGDV (H12), on their surface as platelet substitutes. This peptide is a fibrinogen γ-chain carboxy-terminal sequence (γ400−411) and specifically recognizes the active form of glycoprotein IIb/IIIa on activated platelets. Our purpose is to assess the possibility of making a novel platelet substitute consisting of disk-shaped nanosheets having a large contact area for the targeting site, rather than conventional small contact area spherical carriers. The H12 peptide was conjugated to the surface of the free-standing nanosheets made of biodegradable poly(D,L-lactide-*co*-glycolide) (PLGA). These H12-PLGA nanosheets were fabricated onto 3 μm disk-shaped patterned hydrophobic octadecyl regions on a SiO_2 substrate. By way of comparison, spherical H12-PLGA microparticles with the same surface area and conjugation number of H12 were also prepared. The resulting H12-PLGA nanosheets specifically interacted with the activated platelets adhered on the collagen surface at twice the rate of the H12-PLGA microparticles under flow conditions, and showed platelet thrombus formation in a two-dimensional spreading manner. Thus, H12-PLGA nanosheets might be a suitable candidate novel platelet alternative substitute for infused human platelet concentrates for the treatment of bleeding in patients with severe thrombocytopenia.

INTRODUCTION

Transfusion of platelet concentrates by blood donation is currently the only means of efficiently treating or preventing bleeding caused by quantitative platelet disorders. Particularly, the supply of platelet concentrates is always in a critical situation because of the short shelf life (4 days in Japan, 5−7 days in the United States and Europe) under stringent storage conditions. Moreover, the risk of blood-borne infections such as bacterial sepsis and acute immune reactions remains a major concern for allogeneic platelet transfusion (*1, 2*). For these reasons, a number of trials have been conducted to develop platelet substitutes (artificial platelets) reproducing platelet functions such as infusible platelet membranes (IPMs) (*3*), fibrinogen-bonded red blood cells (*4*), fibrinogen-bearing liposomes (*5*), fibrinogen-coated albumin microcapsules (Synthocyte) (*6*), and arginine-glycine-asparaginic acid (RGD) peptide-bound red blood cells (Thromboerythrocytes) (*7*). All platelet substitutes proposed so far consist of materials derived from blood components and are micrometer sized.

Glycoprotein (GP) IIb/IIIa exists on the membrane of distinctive disk-shaped platelets at the dimensions of 2.5−3.0 by 0.2−0.5 μm and changes its shape from inactive to active when platelets adhere to collagen exposed on the sites of vascular injury (*8, 9*). The activated GPIIb/IIIa acts as a receptor for bifunctional fibrinogen, which leads to platelet aggregation. Several sequences in fibrinogen have been designated as GPIIb/IIIa recognition sites: the RGD-based sequences ^{95}RGDF^{98} and ^{572}RGDS^{575} in the Aα chains and ^{400}HHLGGAKQAGDV^{411} (H12, the fibrinogen γ-chain dodecapeptide) in the carboxyl-terminal of the γ-chain (*10, 11*). We selected H12 for this study from general observations that H12 interacts with GPIIb/IIIa specifically, whereas RGD-related peptides are promiscuous for many integrins from various cell types (*12*).

Our strategy for the development of platelet substitutes has been straightforward: biocompatible spherical carriers such as phospholipid vesicles (liposomes) (*13*−*15*) and polymerized albumin particles (*16, 17*) are specifically accumulated at sites of vascular injury, and fill up the injury sites by virtue of their own mass. In order to construct carriers having a specific accumulation ability for the activated GPIIb/IIIa on the platelet, we conjugated an H12 sequence to these carriers and succeeded in the preparation of H12-conjugates, which dose-dependently reduced the bleeding time in rats or rabbits with thrombocytopenia *in vivo* (*14, 15, 18*−*20*).

Sheet-shaped carriers, having a large contact area for a targeting site, would have an ultimate advantage over spherical carriers, which have an extremely small contact area. Recently, several approaches have been implemented for fabrication of free-standing nanosheets (often called nanofilms and nanomembranes), including the use of polymers and/or inorganic materials such as cast films (*21*), layer-by-layer films of polyelectolytes (*22*−*24*), cross-linked amphiphilic Langmuir−Blodgett films (*25*), and self-assembled monolayers (SAMs) (*26*). They have been developed as applications in a variety of fields such as nanoseparation membranes, nanosensors, and functional nanofilms for electrochemical and photochemical applications. However, there have been no reports on the fabrication of free-standing nanosheets with suitable biocompatibility and biodegradability for biomedical application.

Organosilane SAMs have been widely used in applications designed to change the physical and chemical properties of the surfaces of glass, quartz, and SiO_2/Si wafers (*27*). It is generally

easy to construct patterned SAMs with uniform size and shape on SiO_2 using conventional photolithography processes (*28*). They are excellent tools for immobilization of proteins (redox proteins (*29*) and enzymes (*30*)) via covalent or noncovalent bonding with various terminal groups of the SAMs, and for two-dimensional close-packed particle array via a micromold method and lateral capillary force (*31*). Recently, we proposed a novel method for the preparation of free-standing 100 nm thick, uniformly shaped microsized nanosheets derived from polystylene nanoparticles using patterned hydrophobic SAMs on the SiO_2 substrate (*32*).

Our main purpose here was to assess the possibility of constructing disk-shaped nanosheets as a novel platelet substitute. In this study, H12 was conjugated to the surface of free-standing biodegradable poly(D,L-lactide-*co*-glycolide) (PLGA) platelet-like nanosheets (H12-PLGA nanosheets), which had been attached to a SiO_2 substrate patterned with 3 μm disk-shaped hydrophobic regions of octadecyltrimethoxysilane-SAM (ODS-SAM). Furthermore, we explore the enhanced effects on platelet thrombus formation of the H12-PLGA nanosheets in comparison with that of the H12-PLGA microparticles under flow conditions.

MATERIALS AND METHODS

Reagents. P-type Si (100) wafers (below 0.02 Ω cm) covered with thermally grown silicon oxide (approximately 200 nm) were purchased from KST World Co. (Fukui, Japan). *n*-Octadecyltrimethoxysilane (ODS, 97%) and 2-methyl[(polyethyleneoxy)propyl] trichlorosilane (Cl_3Si-mPEO, M_w: 422−558, >97%) were purchased from Gelest Inc. (Morrisville, PA). Poly(D,L-lactide-*co*-glycolide) (PLGA) (lactide/glycolide = 85:15, M_w 20 kDa) was purchased from Polysciences Inc. (Warrington, PA). Chitosan (M_w 88 kDa) and poly(vinyl alcohol) (PVA, M_w 22 kDa (99% hydrolyzed), 20 kDa (87−89% hydrolyzed)) were obtained from Nacalai Tesque, Inc. (Kyoto, Japan) and Sigma-Aldrich Co. (Saint Louis, MO), respectively. Poly(ethylene glycol), α-(3-[3-maleimido-1-oxopropyl]amino) propyl-ω-succinimidyl carboxypentyloxy poly(ethylene glycol) (MALPEG-NHS, M_w 5.0 kDa) was purchased from NOF Co. (Tokyo, Japan). Fibrinogen γ-chain dodecapeptide (C-HHLGGAKQAGDV, Cys-H12) was synthesized with a solid-phase synthesizer by BEX Co. (Tokyo). The platelet fluorescent dye 3,3′-dihexyloxacarbocyanine iodide ($DiOC_6$) and dioctadecyloxacarbocyanine perchlorate ($DiOC_{18}$), a fluorescent dye for PLGA particles, were purchased from Invitrogen Co. (Eugene, OR). Fluorescamine was purchased from Sigma-Aldrich Co.

SAM Preparation. Silicon wafers (size 3 cm × 3 cm) were treated with a piranha solution (96% H_2SO_4/30% H_2O_2 = 4:1 (v/v)) at 120 °C followed by rinsing with distilled water. The resulting wafers were placed in a 100 mL Teflon vial containing a glass cup filled with 200 μL ODS liquid. The vials were sealed with a cap and then heated for 8 h at a constant temperature of 110 °C in a glovebox to prepare a hydrophobic ODS-SAM on the silicon oxide (*33*).

Patterning Processes. The ODS/mPEO-SAM patterned with hydrophobic octadecyl regions and hydrophilic poly(ethylene oxide) regions on the substrate was prepared by conventional photolithography and chemical conjugation processes. The ODS-SAM on the silicon oxide (size 3 cm × 3 cm) was covered with photoresist (OFPR-800 500 cP, Tokyo Ohka Kogyo, Co. Ltd., Kanagawa, Japan), and was irradiated with a UV lamp (350 nm, MA-10, Mikasa Ltd., Tokyo) using a photomask (size 5 cm × 5 cm, patterning 3 μm disk, Topic Co., Ltd., Saitama, Japan). After developing (NMD-3), the substrate was exposed to an oxygen plasma (Plasma Reactor PR301, Yamato Scientific Co. Ltd., Tokyo) at an input power of 200 W and an oxygen flow rate of 80 sccm for removal of the ODS. The photoresist was removed by acetone washing, and then the patterned ODS-SAM substrate was immersed in a 2 mM solution of Cl_3Si-mPEO in toluene at r.t. for 24 h in a glovebox in order to reduce the nonspecific adsorption of the PLGA nanoparticles, as suggested in an original report by Cecchet et al. (*34*).

Preparation of PLGA Nano- and Microparticles. PLGA nanoparticles were prepared by a very successful emulsion diffusion−evaporation technique, as reported previously (*35*). The methodology in brief is described as follows. First, 200 mg of PLGA was dissolved in 10 mL ethyl acetate at r.t. The organic phase was then added to an aqueous solution (10 mL) containing 200 mg PVA (87−89% hydrolyzed) as a stabilizer and 30 mg chitosan with stirring. The emulsion was stirred at r.t. for 3 h before homogenizing at 30 000 rpm for 10−70 min (Physcotron NS-51, Microtec, Co. Ltd., Chiba, Japan). Distilled water (50 mL) was gradually added to the emulsion with stirring, and then stirring was continued in a water bath maintained at 40 °C to remove the organic solvent. The uncoated polymer reagents such as PVA and chitosan were removed by repeated centrifugation (35 000*g*, 10 min, 4 °C) and washing with phosphate buffer (PB, pH 7.4) to obtain the purified PLGA nanoparticles. The particle diameter was analyzed by a dynamic light-scattering (DLS) method (N4 PLUS; Beckman-Coulter, Fullerton, FL).

In addition, PLGA microparticles were prepared by the same technique. Two hundred milligrams of PLGA was dissolved in 10 mL methylene chloride at r.t. The organic phase was then added to an aqueous solution (10 mL) containing 200 mg PVA (87−89% hydrolyzed) and 30 mg chitosan at r.t. under 1000 rpm stirring without homogenization. Distilled water (50 mL) was gradually added to the emulsion under stirring, and then stirred at 40 °C to remove the organic solvent. The uncoated polymer reagents such as PVA and chitosan were removed by repeated centrifugation (2200*g*, 5 min, 4 °C) and washing with PB (pH 7.4) to obtain the purified PLGA microparticles.

The particle concentration was calculated from the volume ratio of the PLGA particles in the suspension as follows: the suspension was mixed with a PEG solution (M_w = 100 kDa, final concentration 25 mg/mL), inserted into a hematocrit capillary tube, and then precipitated by centrifugation (15 000*g*, 10 min, r.t.) to measure the volume ratio of PLGA particles. The particle concentration (N, particles/mL) was calculated by eq 1:

$$N = 3B/(A - B) \times 4\pi r^3 \times 10^3 \quad (1)$$

where $A(m)$, $B(m)$, and $r(m)$ were the height of the suspension surface from the bottom of the capillary tube, the height of the particle precipitate, and the particle radius, respectively.

The amino groups in the surface of the PLGA nano- and microparticles, which were derived from chitosan, were calculated from the fluorescent intensity after a fluorescamine reaction as follows: fluorescamine in acetone (0.1 M, 10 μL) was added to the PLGA particle suspension in a boracic acid buffer (pH 8.0) at a concentration of 2.0×10^{11} /mL. The same experiment was performed for the control PLGA particles (not modified with chitosan). The fluorescent intensities after incubation at r.t. for 10 min were measured (E_x = 390 nm, E_m = 475 nm) with a spectrofluorometer (FP-750, JASCO, Tokyo), and the amino groups par PLGA particle were calculated from the difference in intensities between particles before and after chitosan modification and the extrapolation of calibration was performed using a glycine solution of which concentration was varied from 0.1 to 2 μM.

The glass transition temperature (T_g) of the PLGA particles was measured by differential scanning calorimetry (DSC, Thermo plus DSC 8230, Rigaku Co., Osaka, Japan). The analysis was performed with an approximately 10 mg freeze−dried

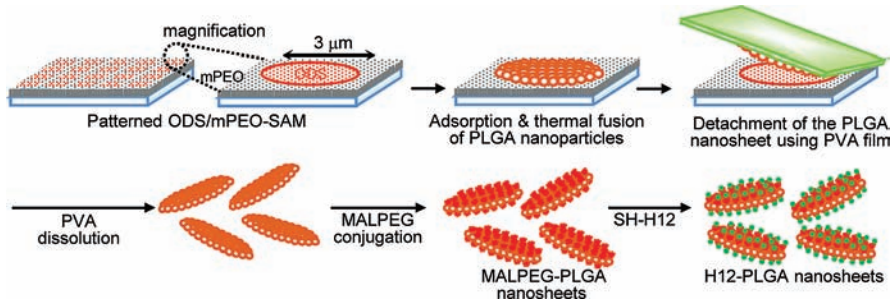

Figure 1. Preparative scheme of free-standing PLGA nanosheets carrying H12 using a patterned ODS/mPEO-SAM on a SiO_2 substrate.

sample under a dynamic nitrogen atmosphere at a heating rate of 10 °C/min.

Preparation of the Free-Standing PLGA Nanosheets Carrying H12. As shown in Figure 1, the substrate having the patterned ODS/mPEO-SAM on the surface was immersed into a PB suspension (pH 7.0) of the PLGA nanoparticles at a concentration of 1.0×10^{12} /mL. After withdrawing the substrate from the suspension, the suspension remaining on the substrate was slowly blown off with a horizontal N_2 flow in order to adsorb the PLGA nanoparticles onto the hydrophobic octadecyl patterned region, and then the substrate was immediately washed with distilled water. The operations of adsorption and washing of PLGA nanoparticles on the substrate was repeated ten times to obtain a closely packed pattern of PLGA nanoparticles. After drying the substrate under N_2 flow, it was heated at 70 °C for 2 min to initiate thermal fusion of the adsorbed PLGA nanoparticles. A PVA solution (50 mg/mL, 0.5 mL) was cast on the substrate and dried at r.t. for 15 h to make a supporting film. After peeling off the resulting PVA film, it was dissolved in a PB solution at pH 7.0, and PVA was removed by centrifugation (8000*g*, 5 min, 4 °C) to obtain a suspension of free-standing PLGA nanosheets. A solution of MALPEG in DMSO (1 mM, 100 μL) was added to the suspension and incubated at r.t. for 20 min. The unreacted MALPEG was removed by centrifugation (8000*g*, 5 min, 4 °C). Finally, the nanosheet suspension was reacted with H12 in PB (1 mM, 70 μL) at r.t. for 12 h, and the unreacted reagents were removed by repeated centrifugation (8000*g*, 5 min, 4 °C) to obtain the purified (MALPEG)PLGA nanosheets carrying H12 (H12-PLGA nanosheets).

The densities of MALPEG and H12 conjugated to the surface of the PLGA nanosheet were determined by quantifying each unreacted reagent in the supernatant of the nanosheets using high-pressure liquid chromatography (HPLC) on a TSK-GEL G3000PW_{XL} column (7.8 mm o.d. × 300 mm h using a mobile phase of 36% acetonitrile and 0.1% trifluoroacetic acid at 1 mL/min). The unreacted reagents were detected using a refractive index (RI) detector and the absorbance at 220 nm.

The concentration of PLGA nanosheets was calculated as follows. First, $DiOC_{18}$ (1 mM, 300 μL) in DMSO was added to the solution of PLGA in ethyl acetate before addition to an aqueous stabilizer as described above. After preparation of the free-standing PLGA nanosheets using $DiOC_{18}$-labeled PLGA nanoparticles, the nanosheets were dissolved in DMSO and the fluorescent intensity was measured (E_x = 485 nm, E_m = 500 nm, ARVO SX, LKB-Wallac, Bromma, Sweden). The PLGA nanosheet concentration was calculated from an extrapolation of the calibration curve of the $DiOC_{18}$-labeled PLGA nanoparticles at a concentration of 1.2×10^9 to 1.5×10^{11} /mL, assuming that the PLGA nanoparticles were arranged and closely packed as a monolayer.

The resulting nanosheets were observed with a Hitachi S-4500 field emission scanning electron microscope (SEM) as follows: the nanosheets adsorbed on a silicon substrate and the free-standing nanosheets collected on glass plate (diameter 24 mm, thickness 0.12−0.17 mm) coated with a poly(L-lysine) were coated with osmium tetroxide (thickness: ca. 20 nm) using an osmium plasma coater (NL-OPC80, Nippon Laser & Electronics Lab., Nagoya, Japan), and were observed with an SEM at an accelerating voltage of 10 kV.

Interaction of Platelets or H12-PLGA Nanosheets with the Collagen Surface Using Imitation Thrombocytopenia Blood under Flow Conditions. Imitation thrombocytopenia blood was prepared as follows. Whole blood treated with a thrombin inhibitor, D-Phe-Pro-Arg-chloromethylketone (PPACK, 40 μM), was filtered with a leukocyte removal filter (NEO1J, Nihon Poll Co., Ltd., Tokyo), which removed platelets as well as leukocytes. The residual platelet count of the filtered blood was determined to be $(6.0 \pm 2.0) \times 10^3$ /μL, and the final platelet count was adjusted to 2.0×10^4 /μL by PRP addition. This blood preparation was termed imitation thrombocytopenia blood.

Collagen I-A (3.0 mg/mL) was suspended in PBS at 4 °C (30 μg/mL), and a glass plate (diameter 24 mm, thickness 0.5 mm) was immersed into the collagen suspension at 4 °C for 8 h. The glass plate was carefully rinsed with PBS and immersed in a bovine serum albumin solution (20 mg/mL) at r.t. for 2 h before a perfusion study was performed as described below.

In the perfusion study, either platelets or H12-PLGA nanosheets were labeled with a fluorescent marker (platelets, $DiOC_6$; nanosheets, $DiOC_{18}$). The imitation thrombocytopenia blood ($2.0 \times 10^4/\mu$L) in the absence or presence of the H12-PLGA nanosheets ($2.0 \times 10^5/\mu$L) were placed in a recirculating flow chamber mounted on an epifluorescent microscope (ECLIPS TE300, Nikon, Tokyo) equipped with a CCD camera, and the interaction of the nanosheets with the collagen immobilized on the surface was observed. All perfusion studies were performed at 37 °C. Calculation of the surface coverage of platelets or the H12-PLGA nanosheets on the plates was carried out with an image processor, Argus-20 (Hamamatsu Photonics, Hamamatsu, Japan). The interaction of nanosheets with platelets was observed with an SEM as described above.

RESULTS AND DISCUSSION

Fabrication of the Free-Standing H12-PLGA Nanosheets. Fabrication of the free-standing PLGA nanosheets carrying H12 involved several sets of procedures. This section summarizes the results at each stage. The nanosheets themselves were prepared starting from unimodal PLGA nanoparticles prepared, as described above, by a combination of emulsion−diffusion−evaporation and homogenization, following the original report of Ravi-Kumar et al. (*35*). We used a blend of PVA and chitosan as a stabilizer for the PLGA nanoparticles. A recent paper indicates that PVA will remain on the surface of the nanoparticles despite repeated washing of the stabilizer because PVA forms an interconnected network with the polymer at the interface (*36*). Chitosan on the surface of the nanoparticles is

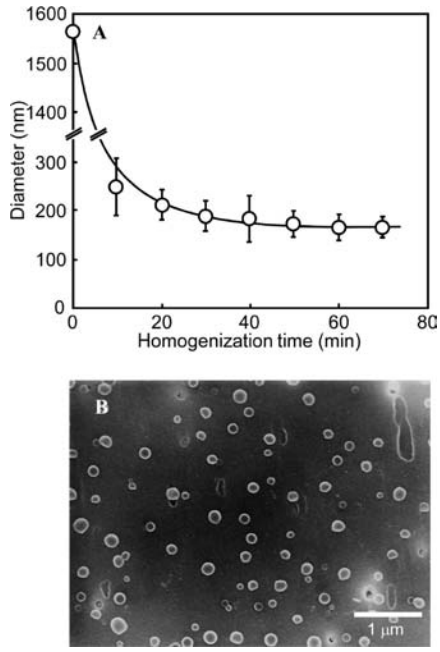

Figure 2. PLGA nanoparticles prepared by a combination of emulsion−diffusion−evaporation plus homogenization techniques. (A) Control of the diameter of the PLGA nanoparticles by the homogenization time. (B) SEM image of the resulting nanoparticles after homogenization for 60 min collected on a membrane filter (pore size: 0.05 μm).

used to conjugate various molecules to its amino groups. The concentration of the stabilizers (PVA and chitosan) has also been optimized for the smallest particle size (*35*). According to the optimum procedure, the emulsion of PLGA in the PVA−chitosan solution was stirred for 3 h at r.t. to produce particles with a diameter of 1563 ± 768 nm (Figure 2A). When the emulsion was homogenized at 30 000 rpm, the diameter decreased with increasing homogenization time and plateaued at 164 ± 26 nm at 60 min after homogenization (Figure 2A). We also confirmed that the diameter of the resulting PLGA nanoparticles was approximately 160 nm by SEM observation (Figure 2B). The amount of the amino groups introduced on the surface of the PLGA nanoparticle was quantified to be approximately 3.8×10^3 molecules, indicating that the surface of the PLGA nanoparticles was fully coated with chitosan to be conjugated H12 molecules.

Using the PLGA nanoparticles, we prepared free-standing PLGA nanosheets carrying H12 by a combination of the four processes shown in Figure 1:

1. Specific adsorption of the PLGA nanoparticles onto the disk-patterned hydrophobic ODS regions of ODS/mPEO-SAM.

2. Fabrication of PLGA nanosheets via thermal fusion of the adsorbed nanoparticles.

3. Preparation of the free-standing nanosheets by detachment from the disk-patterns using a water-soluble PVA as a sacrificial supporting film.

4. Conjugation of H12 to the surface of the nanosheets.

In the first step, a conventional dry patterning process was adopted for the specific adsorption of the PLGA nanoparticles onto the disk-patterned ODS/mPEO-SAM. When the dispersion of the nanoparticles was dropped on the substrate and the dispersion remaining on the substrate was then slowly blown off with a horizontal stream of N_2 gas, the nanoparticles were arranged as a monolayer on the entire substrate, regardless of hydrophobic or hydrophilic regions (data not shown). It is possible that assembly of the PLGA nanoparticles leads to nucleation initiated by capillary forces and growth driven by a laminar flow to evaporate water, thereby forcing the particles to arrange in a monolayer (*37*). The following immediate and repeated washings of the substrate with PB (pH 7.0) detached the PLGA nanoparticles from the hydrophilic mPEO region, leaving nanoparticles firmly adsorbed on the hydrophobic disk patterns of ODS (3 μm) via a hydrophobic interaction. In fact, the net charge of the PLGA nanoparticles at pH 7.0 was nearly zero from the ζ-potential analysis. After repeating the adsorption of the PLGA nanoparticles and washing cycle ten times, the PLGA nanoparticles were closely packed in a monolayer pattern, as shown in Figure 3A,B.

Furthermore, the substrate could be reused at least ten times by sonication in acetone and distilled water (Supporting Information Figure S1). In the case of substrates having bare SiO_2 regions (not modified with mPEO), the nanoparticles were nonspecifically adsorbed to the SiO_2 region as well as the ODS region, and the substrate could not be reused even after heavy sonication (Supporting Information Figure S2A). Using PLGA nanoparticles at 1/10th of the usual concentration (1.0×10^{11}/mL) could prevent the nonspecific adsorption. However, repeated adsorption plus washing over 60 times were required for closely packing of the PLGA nanoparticles in this case (Supporting Information Figure S2B). These results indicated that mPEO modification to the SiO_2 region contributes not only to the inhibition of nonspecific adsorption of the nanoparticles, but also to drastic shortens the preparation time.

Next, the T_g of freeze−dried PLGA nanoparticles was found to be 58.8 °C by a DSC measurement in order to set the temperature required for thermal fusion of the nanoparticles adsorbed on the disk patterns. When the nanoparticle-covered substrate was heated at 60 °C for 2 min with a hotplate, the neighboring PLGA nanoparticles were sufficiently fused to form nanosheets. Heating at 60 °C for 1 min or less was insufficient to properly fuse the particles into nanosheets. On the other hand, heating over 5 min resulted in melting and spreading of the PLGA outward from the disk patterns.

In the second step, the transference of the nanosheets to a supporting PVA film is a convenient method to obtain an aqueous dispersion of the nanosheets (*32*). In practice, the PVA solution was cast on the patterned substrate on which the nanosheets had been fabricated, and dried at r.t. for 15 h. The PVA film peeled off from the substrate was tough and transparent as shown in Figure 3C. SEM observation of the PVA film confirmed that the PLGA nanosheets were completely transferred to the PVA film, and no nanosheets were remained on the substrate (data not shown). Such complete transfer is possible because the hydrogen bonding between the PVA film and the PLGA nanosheets is stronger than the van der Waals interaction of the dried nanosheets with the CH_3-terminal ODS. These results are in agreement with the report by Stroock et al. (*38*), describing the exquisite transfer of an LbL film prepared on hydrophobic SAM patterns to a poly(acrylic acid) (PAA) film. They obtained a suspension by dispersing the PAA film in an aqueous solution. We also used this latter technique for our nanosheets, using PVA as a supporting film. In this case, we could obtain free-standing PLGA nanosheets by dissolution of the PVA film, which is readily soluble in PB at pH 7.4. The nanosheets were collected on a glass plate coated with poly(L-lysine). Thanks to efficient adsorption as a result of the electrostatic interaction, abundant nanosheets with a disk-shaped structure were observed on the plate by SEM, as shown in Figure 3D. This result confirmed that the neighboring PLGA nanoparticles had fused effectively and were sufficiently connected to retain a two-dimensional shape. Fluorescence measurements gave an estimate of approximately 1.2×10^7 nanosheets/mL for the concentration of the resulting disk-shaped nanosheets.

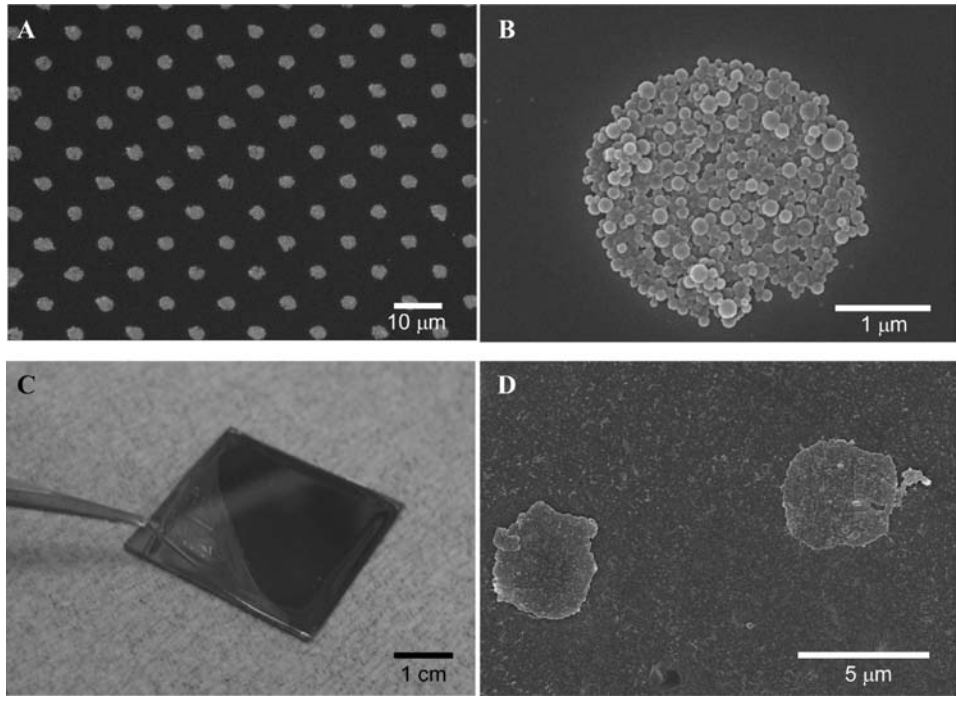

Figure 3. (A) SEM image of the PLGA nanoparticles adsorbed specifically onto the disk-patterned ODS/mPEO-SAM. (B) Magnified SEM image of (A). (C) Photo of the PLGA nanosheets transferred from the ODS/mPEO-SAM to the PVA film. (D) SEM image of the free-standing PLGA nanosheets after dissolution of the resulting PVA film.

In the final step, H12 molecules were conjugated to the surface of the PLGA nanosheets via the maleimide group of MALPEG-NHS as a cross-linker, which targeted the amino groups derived from chitosan. The number of H12 molecules on one nanosheet was indirectly estimated to be approximately 6.1×10^5 molecules from the quantification of free H12 molecules. For an average surface area per nanosheet of 14.9 μm^2, the resulting conjugation density on the nanosheet surface was approximately 4.1×10^4 molecules/μm^2. The density seems to be sufficient for our purposes for the following reasons: In our previous studies on H12-nanoparticles (liposomes and albumin nanoparticles), a conjugation density of H12 over 4.0×10^4 molecules/μm^2 was necessary to maintain the binding ability toward activated platelets, based on flow cytometric analyses and the hemostatic evaluation of the nanoparticles using thrombocytopenic rats *in vivo* (*18*−*20*).

Fabrication of H12-PLGA Microparticles. In order to reveal the differences in hemostatic abilities of disk-shaped and spherical carriers, we also tried to fabricate H12-PLGA microparticles having the same surface area and conjugation number of H12 as those of disk-shaped nanosheets. Using conventional emulsion−diffusion−evaporation methodology with PVA/chitosan as a stabilizer, we obtained PLGA microparticles with an average diameter of 2.2 ± 0.5 μm, corresponding to a surface area per microparticle (15.2 μm^2) that is almost the same as that of the nanosheet. After H12 molecules were bonded to the surface of the particles via MALPEG-NHS, the number of H12 molecules on one microparticle were indirectly estimated to be approximately 6.5×10^5 molecules, corresponding to a conjugation density of approximately 4.2×10^4 molecules/μm^2, a value very close to that of H12-PLGA nanosheets.

Enhanced Effects of H12-PLGA Nanosheets on Platelet Aggregation under Flow Conditions. In order to explore whether the H12-PLGA nanosheets have a specific binding ability toward activated platelets under flow conditions, we prepared imitation thrombocytopenia blood, adjusting the platelet count to 2.0×10^4 /μL (corresponding to one-tenth of that of normal blood). In comparison, we also performed the same experiment using the H12-PLGA microparticles having the same surface area and H12 conjugation number as the nanosheets. When the blood containing the H12-PLGA nanosheets or H12-PLGA microparticles, which were labeled with the fluorescent marker $DiOC_{18}$, was allowed to flow over the collagen surface at a shear rate of 150 s^{-1}, both carriers gradually adhered and accumulated significantly on the surface in a time-dependent manner (Supporting Information movie S1). It was interesting to note that the H12-PLGA nanosheets adhered on the surface at twice the rate of the H12-PLGA microparticles; the adhesive rates of the H12-PLGA nanosheets and H12-PLGA microparticles were calculated to be 14.5 ± 2.3 and 7.7 ± 1.3 /mm^2/s, respectively (Figure 4). A simulation by Mortensen et al. suggests that ellipsoidal particles tend to align in the near-wall region of the turbulent shear flow, and that their alignment increases with an increase in the particle aspect ratio between the semiminor and semimajor axis of ellipsoid from 10 to 50

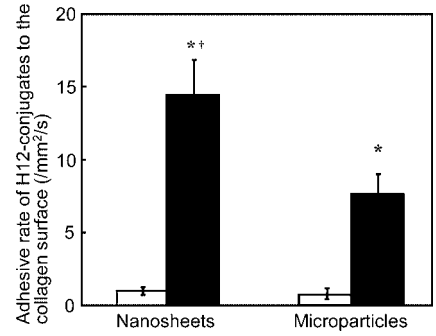

Figure 4. Adhesive rates of the H12-PLGA nanosheets and H12-PLGA microparticles in the thrombocytopenic blood toward the collagen-immobilized surface at a shear rate of 150 s^{-1}. Solid or open columns show H12-conjugates or nonconjugates, respectively. Count of platelets and the H12-PLGA nanosheets or H12-PLGA microparticles was $2.0 \times 10^4/\mu$L. *$P < 0.05$ for H12-PLGA nanosheets or H12-PLGA microparticles group vs PBS group, and †$P < 0.05$ for H12-PLGA nanosheets group vs H12-PLGA microparticles group. Data are expressed as the mean ± SD of three independent experiments.

(*39*). Decuzzi et al. reported on the adhesive strength of ellipsoidal particles toward endothelial cells under a linear shear flow (*40*). They found that ellipsoidal particles adhered more effectively to the cells than classical spherical particles with the same volume because of multivalent bonding of ellipsoidal particles to the cells, and that the adhesive strength was significantly increased by increasing the particle aspect ratio from 1 to 10. On the basis of these studies, we estimate that the high adhesive rate of the H12-PLGA nanosheets is due to an aspect ratio of approximately 20 for the nanosheet. Such a thin sheet can easily flow in the near-wall region (collagen surface) of the flow chamber. The asymmetric shape of the sheets also produces a higher adhesive strength than the spherical microparticles. These experiments clearly demonstrate that the adhesive rate of the carriers on the collagen surface could be controlled solely by changing their shape.

On the other hand, neither carrier adhered to the surface when the platelet count in the blood was below (5.0 ± 1.0) × $10^3/\mu$L (data not shown). Furthermore, both control carriers (without the H12 modification) failed to adhere to the surface (Figure 4). This indicated that the adhesion of the both H12-conjugated carriers was triggered by a specific interaction with the activated platelets, which had already adhered on the surface of the collagen plate. Additionally, we also tried to perform the same flow experiment using 5 by 10 μm rectangular H12-PLGA nanosheets having a very high aspect ratio of over 60 (Supporting Information Figure S3). However, these nanosheets did not adhere to the collagen surface even when H12 was well-conjugated and the shear rate was low (10 s^{-1}) (Supporting Information movie S2). We speculate that this failure to adhere was because it was difficult for these larger nanosheets, together with erythrocytes, to flow in the near-wall region of the flow chamber, and hence they, then did not attach to the activated platelets on the collagen surface. At present, we can say that the platelet-like disk-shaped PLGA-nanosheets with a size of 3 μm have an optimal size and aspect ratio.

Next, in order to know whether the H12-PLGA nanosheets actually have the ability to reinforce platelet thrombus formation under flow conditions, we employed platelets, with an adjusted platelet count of 2.0 × $10^4/\mu$L, were labeled with the fluorescent marker, $DiOC_6$. With the addition of PBS as a control, the flowing platelets gradually adhered to and aggregated on the collagen surface; the surface coverage of platelets after flowing for 300 s increased to 4.7 ± 1.6% as shown in Figure 5A (■) and B (a). When the H12-PLGA nanosheets were added instead of PBS to the thrombocytopenic blood, the surface coverage after 300 s flow was significantly higher at 14.6 ± 1.9% (Figure 5A (○) and B (b)). Furthermore, we confirmed that H12-PLGA nanosheets labeled with rhodamine were involved in the platelet thrombi labeled with $DiOC_6$ by a double-staining method (data not shown). These data indicate that the H12-PLGA nanosheets were specifically bound on the activated platelets adhered on

the collagen surface, and that the number of the H12 peptides on the nanosheets would be sufficient to act as binding sites for the flowing platelets. In case of the H12-PLGA microparticles, their surface coverage was also significantly higher (6.6 ± 1.3%) than that of PBS; however, their effect was lower than that of H12-PLGA nanosheets (Figure 5A (Δ) and B (c)).

In order to clarify the reason the H12-PLGA nanosheets had a more pronounced effect on platelet aggregation than did H12-PLGA microparticles, we calculated the mean area of one platelet thrombus. The numbers of platelet thrombi formed on the collagen surface after 300 s flow were almost comparable in each experiment (PBS, $(7.2 \pm 1.1) \times 10^2/mm^2$; H12-PLGA nanosheets, $(8.1 \pm 1.7) \times 10^2/mm^2$; and H12-PLGA microparticles, $(7.5 \pm 2.1) \times 10^2/mm^2$) (Figure 5C (○)). On the basis of the total area of platelet thrombi, the mean area of one platelet thrombus with the addition of PBS as a negative control was calculated to be $6.1 \pm 1.2\ \mu m^2$. In the presence of the nanosheets, it was interestingly to note that the mean area was significantly increased to $16.6 \pm 2.3\ \mu m^2$ (Figure 5C). The mean area in the presence of the H12-PLGA microparticles was also significantly higher than that of the PBS control at $8.9 \pm 0.7\ \mu m^2$, although this value was significantly lower than that of H12-PLGA nanosheets. This indicates that the H12-PLGA nanosheets make the platelet thrombi spread in a two-dimensional manner.

We also observed with an SEM the surface of the collagen plate after the flow experiments. There were abundant platelet thrombi containing nanosheets or microparticles, where the platelets had adhered first on the collagen surface (Figure 5D,E, respectively). In particular, the H12-PLGA nanosheets two-dimensionally spread the platelet thrombi on the collagen surface, producing a low contrast over the entire SEM image (Figure 5D). On the other hand, the H12-PLGA microparticles made the platelet thrombi pile up dramatically, and the SEM image showed relatively high contrast (Figure 5E). We suggest that the difference may arise from one of the following mechanisms: (1) the adhesion of the both carriers (H12-PLGA nanosheets and H12-PLGA microparticles) could be initiated by the activated platelets, which had already adhered on the surface of the collagen plate, (2) the flat nanosheets adhering to the activated platelets could act as broader scaffolds for binding of the flowing platelets than spherical microparticles, which can only effect point contact with the flowing platelets, or (3) the nanosheets could accelerate two-dimensional platelet thrombus formation because of their ultrathin disk structure, whereas the spherical microparticles would naturally tend to lead to the formation of piled up thrombi. From the viewpoint of hemostasis, the H12-PLGA nanosheets should be more effectively occluded in the thrombi on the collagen exposed at the bleeding site in comparison with H12-PLGA microparticles. Moreover, the biological implications of platelets that have a distinctive disk-shape may be following: the platelets find it easy to adhere to the collagen at the vascular injury, and then their aggregation is two-dimensionally accelerated.

In conclusion, we have successfully prepared biocompatible and biodegradable free-standing, disk-shaped, PLGA nanosheets using patterned ODS/mPEO-SAM, and modified their surfaces with fibrinogen-derived dodecapeptide (H12). The resulting H12-PLGA nanosheets specifically interacted under flow conditions with activated platelets on a collagen surface faster than did H12-PLGA microparticles. Furthermore, the nanosheets, but not the microparticles, induced two-dimensional spreading of platelet thrombi on collagen-immobilized plates. Therefore, H12-PLGA nanosheets might be a suitable candidate as novel platelet substitutes and an alternative to human platelet concentrates infused to treat bleeding in patients with severe thrombocytopenia. We are assessing the *in vivo* hemostatic ability of the H12-PLGA nanosheets to treat animals with severe thrombocytopenia. Moreover, this experimental strategy can be applied to other situation than platelet substitutes, such as other drug delivery carriers like antihemostatic reagents and wound dressings for burn injury, and others.

Content:

1. Three Supporting Figures (Figure S1-S3)

2. Two Supporting Movies (Movie S1, S2)

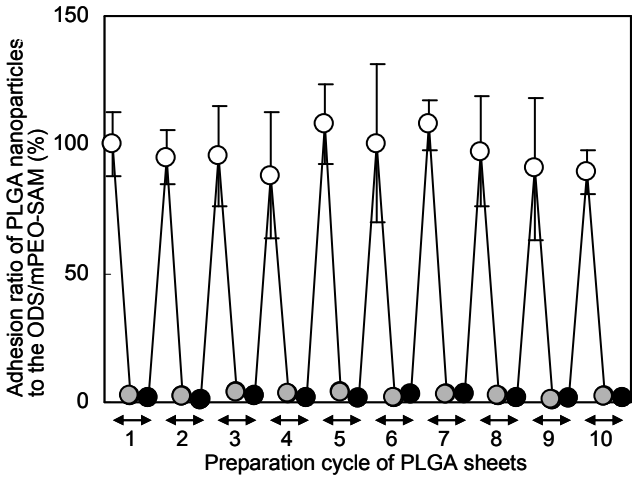

Figure S1 Recycle-tests of ODS/mPEO-SAM on the substrate before and after adsorption & detachment of PLGA particles. Percent of Adhesion ratio of PLGA nanoparticles to the ODS/mPEO-SAM were calculated as follows; the same magnified images of ODS/mPEO-SAM after (○) adsorption & thermal fusion of PLGA particles, (◎) detachment of nanosheets by the PVA film, and (●) Washing of sonication into acetone and distilled water were taken. Pixel number of the PLGA nanoparticles on the ODS region was calculated by Adobe softwere Photoshop 6.0. The pixel number after the first adsorption of the PLGA nanoparticles was calculated as 100%.

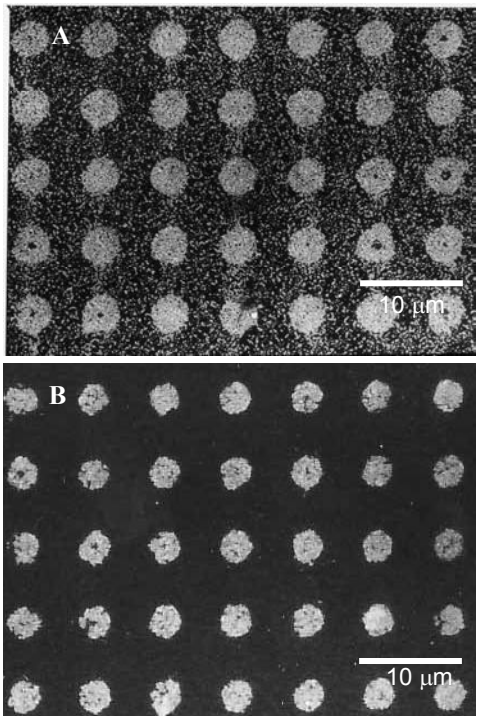

Figure S2 SEM images of patterned ODS-SAM without mPEO modification after adsorption of the PLGA nanoparticles at a concentration of **(A)** 1.0 x 10^{12} /mL and **(B)** 1.0 x 10^{11} /mL.

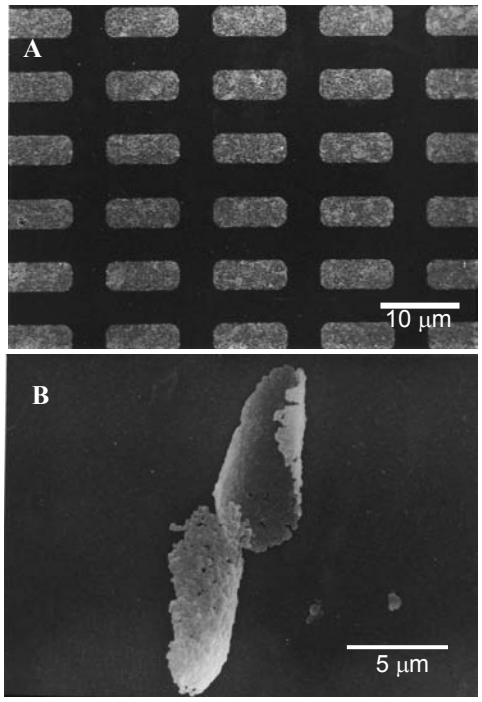

Figure S3 (A) SEM image of PLGA nanoparticles specifically adsorbed onto the 5 x 10 μm rectangle patterned ODS/mPEO-SAM. **(B)** SEM image of free-standing PLGA nanosheets peeled by PVA film on the glass plate. The rectangle patterned ODS/mPEO-SAM substrate was prepared as follows. The ODS-SAM on the silicon oxide (size: 4 cm x 4 cm) was covered with photoresist, and was irradiated with a 350 nm UV lamp using a photomask (size: 5 cm x 5 cm, patterning; 5 x 10 μm rectangle, Topic Co., Ltd., Saitama, Japan). After developing (NMD-3), the substrate was exposed to oxygen plasma at an input power of 200 W and an oxygen flow rate of 80 sccm for removal of ODS. The photoresist was removed by acetone washing, and then a patterned ODS-SAM substrate was immersed in a 2 mM solution of Cl_3Si-mPEO in toluene at r.t. for 24 hrs in a glovebox.

The resulting nanosheets were observed with a Hitachi S-4500 field emission scanning electron microscope (SEM) as follows: the nanosheets adsorbed on a silicon substrate and the free-standing nanosheets collected on glass plate (diameter 24 mm, thickness 0.12-0.17 mm) coated a poly-L-lysine were coated with osmium tetroxide (ca. 20 nm thick) using an osmium plasma coater (NL-OPC80, Nippon Laser & Electronics Lab., Nagoya, Japan), and were observed at an accelerating voltage of 10 kV.

Movie S1 Adhesion of H12-PLGA nanosheets at a size of 3 μm in imitation thrombocytopenia blood (platelet counts: 2.0 x 10^4 /μL) to a collagen surface under flow condition at a shear rate of 150 s^{-1} (H12-PLGA nanosheets: 2.0 x 10^4 /μL).

Movie S2 Adhesion of H12-PLGA nanosheets at a rectangular size of 5 x 10 μm in imitation thrombocytopenia blood (platelet counts: 2.0 x 10^4 /μL) to a collagen surface under flow condition at a shear rate of 10 s^{-1} (H12-PLGA nanosheets: 2.0 x 10^4 /μL).

Single-Domain Antibody-Nanoparticles: Promising Architectures for Increased *Staphylococcus aureus* Detection Specificity and Sensitivity

Shannon Ryan,[†,‡] Arnold J. Kell,[†,§] Henk van Faassen,[‡] Li-Lin Tay,[||] Benoit Simard,[§] Roger MacKenzie,[‡,⊥] Michel Gilbert,[‡] and Jamshid Tanha*[,‡,⊥,#]

Received July 27, 2009

Because antibodies are highly target-specific and nanoparticles possess diverse, material-dependent properties that can be exploited in order to label and potentially identify biomolecules, the development of antibody−nanoparticle conjugates (nanoconjugates) has huge potential in biodiagnostics. Here, we describe a novel superparamagnetic nanoconjugate, one whose recognition component is a single-domain antibody. It is highly active toward its target *Staphylococcus aureus*, displays long shelf life, lacks cross-reactivity inherent to traditional homologue whole antibodies, and captures a few dozen *S. aureus* cells in a mixed cell population with ∼100% efficiency and specificity. We ascribe the excellent performance of our nanoconjugate to its single-domain antibody component and recommend it as a general purpose recognition element.

INTRODUCTION

An area where antibody−nanoparticle conjugates (nanoconjugates) would be of great benefit is in the field of bacteria detection such as for identifying the presence of potentially harmful bacterial pathogens in food and water and in hospitals and elderly care facilities (*1*−*6*). Effective and timely preventive measures against such bacteria require that they be detected in trace amounts, thus calling for a detection system which is highly specific, sensitive, and fast. Superparamagnetic nanoconjugates are an attractive option for bacterial detection. By virtue of their magnetic property, they can magnetically confine/preconcentrate bacterial samples, leading to an increase in detection sensitivity. Though whole antibodies (e.g., IgGs, Figure 1) have been previously employed in a number of biodiagnostic applications to interface superparamagnetic nanoparticles (SPNs) to bacteria, antibodies have an inherent cross-reactivity associated with them because the Fc region is common to different antibodies and can interact with multiple targets despite the fact that their variable region (F_V) is unique. For example, Ho et al. recently demonstrated that IgG-based nanoparticles interact with protein A (a surface protein unique to *Staphylococcus aureus*) as well as other surface markers such as protein M present on the surface of other bacteria (*3, 7, 8*). To avoid the cross-reactivity problems associated with traditional antibodies, smaller, single-chain variable fragments (scFv) lacking the Fc region can be utilized (Figure 1), but these fragments are frequently unstable and prone to aggregation. For many scFvs, the two binding domains can dissociate and then reassociate intermolecularly; on the surface of nanoparticles, this would lead to nanoparticle agglutination. A more attractive approach is to employ single-domain antibodies (sdAbs) (*9*). sdAbs (e.g., V_H, Figure 1) can be readily cloned, resulting in small, chemically/thermally stable, and highly selective targeting moieties (*10, 11*). Nanoparticle agglutination is not an issue with V_Hs because of their single domain nature. Additionally, V_Hs display a lower number of reactive sites, and as a result, unlike larger IgGs or scFvs, very few V_Hs become linked to more than one nanoparticle during conjugation reactions, greatly reducing conjugation-induced nanoparticle aggregation. Smaller size also translates to higher binding density on the surface of nanoparticles.

In this article, we demonstrate that a sdAb-SPN nanoconjugate can interact strongly and selectively with protein A expressed on the surface of *S. aureus*, leading to its sensitive magnetic confinement even in competition with other bacterial species (*12*). The nanoconjugate captures a few dozen *S. aureus* cells in a mixed-cell population with ∼100% efficiency and specificity.

EXPERIMENTAL PROCEDURES

Materials. *Salmonella typhimurium* (ATCC19585), *S. aureus* (ATCC12598), *Streptococcus pyogenes* (ATCC12385), and *Staphylococcus saprophyticus* (ATCC15305) were obtained from American type Culture Collection (Manassas, VA). *Streptococcus pneumoniae* 35C was from an in-house stock (NRCC 4758). Xylose lysine desoxycholate (XLD), Baird-Parker (BP) agar, and chocolate agar plates were purchased from Oxoid (Nepean, ON, Canada). (By titration studies, it was shown that the XLD plate only supported the growth of *S. typhimurium* and not *S. aureus* and the BP plate only the growth of *S. aureus* and not *S. typhimurium*. The titers obtained when *S. typhimurium* and *S. aureus* were grown on nutrient broth (NB) and brain heart infusion (BHI, EMD Chemicals Inc., Darmstadt, Germany) media plates, respectively, were the same as those on selective media.) Protein A R-PE conjugate (1 mg/mL) was purchased from Innova Biosciences Ltd. (Babraham, Cambridge, UK).

Methods. *Synthesis of the Carboxylic Acid-Modified Superparamagnetic Nanoparticle,* **SPN**, *and Its Conjugate Derivative,* **1-SPN.** The synthesis of the silica encapsulated iron oxide

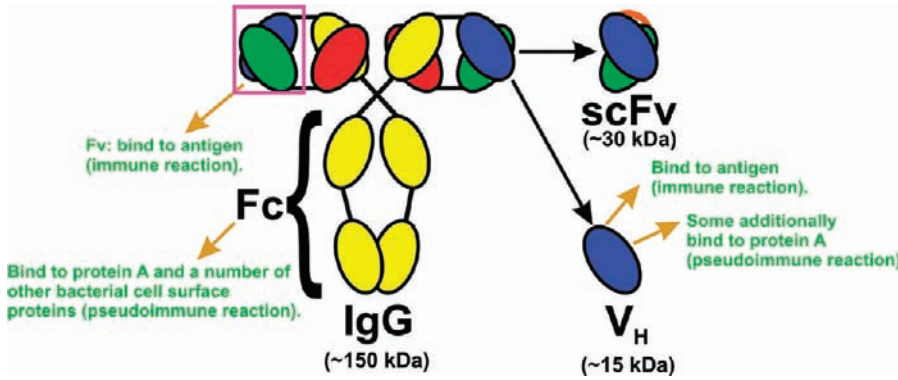

Figure 1. Cartoon representation of an antibody and antibody fragments. The antibody domains are shown as ovals. An antibody, e.g., an IgG, comprises two identical heavy chains (yellow and blue) and two identical light chains (red and green). The Fc region of the IgG can interact indiscriminantly with several different bacterial targets, decreasing specificity. Alternatives to whole antibodies include scFv (a light chain binding domain (V_L) plus a heavy chain binding domain (V_H) covalently joined by a linker (orange)) and, most simply, V_H domain.

nanoparticles has been previously described by us (*13*). Specifically, a commercially available ferrofluid (0.4 mL, ferrotec EMG304) was diluted to 400 mL with 18 Ω Millipore water. The resulting stock solution was further diluted (12 mL diluted to 45 mL) in Millipore water, and the solution was sonicated for 30 min. Following sonication, the ferrofluid solution was transferred to a 500 mL flask containing 400 mL isopropanol and mechanically stirred. Tetraethoxyorthosilane (0.140 mL) was added to the flask and stirred for ~1 min at which time 6 mL of concentrated ammonium hydroxide was added. The nanoparticles were then stirred overnight. The resulting nanoparticles were ~49 ± 7 nm in diameter consisting of a 10 nm iron oxide core and a smooth silicon dioxide shell with a thickness of 20−25 nm.

Surface Modification of the Silica Encapsulated Iron Oxide Nanoparticles. Six 45-mL samples of the crude nanoparticle solution described above were transferred to 50 mL Falcon tubes, and 1.0 mL of aminopropyldiethoxymethylsilane (APDEMS) was added to each tube in order to modify the surface with a functional amine group. The mixture was shaken for 24 h and centrifuged at 5300 *g* for 20 min in order to precipitate the amine-modified nanoparticles. The contents of all of the tubes were combined and washed with ethanol (15 mL) and dimethylformamide (DMF, 15 mL) through repeated centrifugations. Following purification, the amine-modified nanoparticles were dispersed in a 1% solution of succinic anhydride and shaken overnight. The resulting carboxylic acid modified nanoparticles (SPN) were washed with fresh DMF several times to ensure all succinic anhydride had been removed. The nanoparticles were then dispersed in MES buffer (30 mM MES, 70 mM NaCl, pH 6.0) and centrifuged and redispersed in fresh MES buffer. The conversion efficiency for the reaction between the amine and the succinic anhydride was determined by reacting the resulting nanoparticle with fluorescamine, which did not result in a fluorescence response, suggesting that all of the accessible amine moieties had reacted with the succinic anhydride.

The resulting **SPN** were surface modified with HVHP428 V_H (**1**) (*12*) by first activating **SPN** (10 mL in MES buffer, 1×10^{14} nanoparticles) with *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC, 5 mg) and *N*-hydroxysuccinimiude (NHS, 5 mg) to yield the NHS-ester modified **SPN**. Following purification to remove any unreacted EDC and NHS, the nanoparticles were mixed with **1** (100 μL of a 1.8 mg/mL solution in phosphate-buffered saline (PBS)) and gently vortexed for at least 5 h. It is believed that **1** is covalently bound to the nanoparticle surface through primary amines, of which there are 7 on each antibody. Following modification with **1**, the resulting **1-SPN** particles were purified via repeated centrifugation cycles and redispersion in MES buffer to remove any unbound **1**. Finally, the nanoparticles were redispersed in 10 mL of MES buffer.

In order to elucidate the number of HVHP428 (**1**) anchored to the surface of each **SPN**, **1-SPN** was reacted with tetramethylrhodamine isothiocyanate (TRITC). The reaction was carried out in MES buffer with **1-SPN** (6×10^{12} nanoparticles) and TRITC (50 μg, 1.2×10^{-7} mol) and the resulting TMR-modified **1-SPN** was purified and analyzed by UV−visible spectroscopy in order to elucidate the number of sdAbs (**1**) on the surface of the nanoparticle. The UV−visible absorption spectra of freshly prepared, day-old **1-SPN** and one-year-old **1-SPN** (6×10^{12} nanoparticles/mL) and the original **1-SPN** are presented in the Supporting Information (Figure S1). Analysis of these spectra suggests that TMR has reacted with the sdAb on **1-SPN**, where there is an increase in absorption centered at 550 nm in comparison to the unmodified **1-SPN**. When the number of TMR molecules was known, the number of sdAb (**1**) per nanoparticle could be elucidated by assuming that only one of the seven amine groups on **1** is responsible for anchoring it to the surface of the **SPN**. Construction of a calibration curve for TRITC in MES-buffered water and the comparison of the absorption intensity for the **1-SPN** samples suggest that there are 12 and 4 sdAbs per **1-SPN** for one-day-old nanoparticles and nanoparticles sitting in MES buffer at pH 6 for 1 year, respectively. This data are also presented in the Supporting Information (Figure S2). The slow loss of **1** over several months is consistent with the slow hydrolysis of silica surface ligands in aqueous solution.

Construction and Binding Analysis of Pentamers. Standard cloning techniques were used to construct V_H and V_L (Figure 1) pentamers, $\mathbf{1}^{\mathbf{P}}$ and $\mathbf{2}^{\mathbf{P}}$, respectively (*14*). $\mathbf{2}^{\mathbf{P}}$ serves as the control pentamer. Pentamers were expressed, purified, and quantified as described (*14*, *15*). The binding kinetics for the interaction of $\mathbf{1}^{\mathbf{P}}$ with protein A and $\mathbf{2}^{\mathbf{P}}$ with protein L were determined from surface plasmon resonance (SPR) data collected with BIACORE 3000 biosensor system (GE Healthcare, Baie d'Urfé, QC, Canada). For the $\mathbf{1}^{\mathbf{P}}$ analysis, 520 resonance units (RUs) of protein A or a Fab reference were immobilized on research grade CM5 sensor chips (GE Healthcare). For the $\mathbf{2}^{\mathbf{P}}$ analysis, 680 RUs of protein L or 870 RUs of the Fab reference were immobilized. Immobilizations were carried out at protein concentrations of 25 μg/mL (protein A) or 50 μg/mL (protein L and Fab) in 10 mM sodium acetate buffer pH 4.5, using the amine coupling kit provided by the manufacturer. In all instances, analyses were carried out at 25 °C in 10 mM HEPES, pH 7.4, containing 150 mM NaCl, 3 mM EDTA, and 0.005% P20 at a flow rate of 20 μL/min, and surfaces were regenerated by washing with 50 mM HCl for 3 s. Data were evaluated using *BIAevaluation 4.1* software (GE Healthcare).

Association rate constants, k_as, were independently calculated from plots of k_{obs} vs concentration. More than one dissociation rate constant, k_d, could be calculated due to the heterogeneity in multivalent binding among the pentamer population. Therefore, more than one affinity (K_A) could be obtained (see Figure 4 legend).

Growth of Cells. A single *S. aureus* colony from a plate of BHI media was used to inoculate 15 mL of BHI media. The bacteria were grown overnight at 37 °C and 200 rpm. In the morning, the culture was spun down in a fixed rotor, Sorval RT6000B refrigerated centrifuge at 4000 rpm for 10 min, the supernatant was removed, and the cell pellet was resuspended in an appropriate buffer. The cells were respun, the supernatant was removed, and the cell pellet was resuspended followed by measuring cell density at OD_{600}. Serial dilutions of the cells were spread on BHI plates at 37 °C for overnight growth. The cell titer was determined in the morning. An OD_{600} of 1.0 corresponded to 1×10^8 cells/mL. *S. typhimurium* was grown as described for *S. aureus* but with NB media (5 g peptone and 3 g meat extract in 1 L water, pH 7.0) (*16*). For *S. typhimurium*, an OD_{600} of 1 corresponded to 3×10^8 cells/mL. *S. saprophyticus* was prepared as outlined for *S. aureus*. An OD_{600} of 1 corresponded to 1×10^8 cells/mL. *S. pyogenes* was streaked onto chocolate agar plates from frozen stock and grown at 37 °C overnight. Plate contents were scraped into sterile PBS and adjusted to an OD_{600} of 1 which corresponded to 1×10^8 cells/mL. *S. pneumoniae* was grown in media (Columbia broth 17.5 g, Todd Hewitt broth 15 g, 1% glucose in 1 L water, pH 7.0) at 37 °C, 5% CO_2, without shaking. The cells were spun down as stated for *S. aureus*. An OD_{600} of 1 corresponded to 1×10^8 cells/mL. Cells were used in microagglutination assays, transmission electron microscopy (TEM), and scanning electron microscopy (SEM) experiments and capture studies.

Binding Analysis by Flow Cytometry. Samples of 100 μL **1-SPN** or **SPN** (10^{12} particles) were blocked in PBS/0.1% (v/v) Tween-20 overnight at 4 °C. To these, 1 μL aliquots of various concentrations of fluorescently active protein A (protein A R-PE conjugate) were added and the reaction volumes were increased by adding 200 μL of PBS/0.75% Tween-20. The samples were incubated for 1 h at 4 °C and were directly used for flow cytometry analysis with a FACSCanto Analyzer (BD Biosciences, Mississauga, ON, Canada). The R-PE fluorescence of 100 000 events per sample was analyzed, and data were generated using *BD FACSDiva* software (BD Biosciences).

Binding Analysis by Cell Microagglutination. Cell microagglutination assay was performed to find out if $\mathbf{1^P}$ and **1-SPN** bind multivalently to *S. aureus*, in other words, find out if the apparent K_A values of $\mathbf{1^P}$ and **1-SPN** are increased compared to that of monomeric **1**. If multivalent—and functional—$\mathbf{1^P}$ and **1-SPN** would be expected to cross-link and agglutinate cells. In the absence of agglutination, the cells settle out over time and form a circular dot at the center of the well. If there is agglutination, the cells settle out as a sheet (diffused pattern). Cell microagglutinations were performed essentially as described by Saito et al. (*17*). Twofold dilutions of pentamers or nanoparticles were performed in MES buffer from wells 1 to 11 of a microtiter plate. Well 12 had only buffer, and the total volume in each well was 50 μL. Subsequently, 1 OD_{600} unit of cells (see *Growth of Cells*) in 50 μL buffer was added to all wells, and the plate was incubated overnight at 4 °C. In the morning, photos of the plates were taken for further analysis. Minimum agglutination concentration (MAC), the minimum concentration of nanoparticles or pentamers that promoted bacterial agglutination, was used to express the agglutination activity of nanoparticles and pentamers.

Binding Analysis by TEM Experiments. In general, we found that the most effective TEM images of the **1-SPN** or **SPN** interacting with the variety of bacteria could be obtained by extracting ~1 μL of the solution in the microagglutination plates described above. That is, where the nanoparticles agglutinate effectively, 1 μL of the solution was extracted and expelled directly onto the TEM grid, dried, and analyzed via TEM. In the case where poor or no microagglutination is observed, the 1 μL of solution is extracted from the precipitate that has settled to the bottom of the microtiter plate. Here, because both **1-SPN** and **SPN** are colloidally stable, there are significantly fewer nanoparticles interacting with the bacteria than in the case where agglutination is effective. The TEM images of the nanoparticle—cell conjugates were acquired using a Philips CM20 FEG microscope operating at 200 keV.

Capture Studies. **1-SPN** and **SPN** were first blocked with 0.1% (v/v) Tween 20 in MES buffer overnight at 4 °C in an Eppendorf tube. One hundred microliters of the blocked nanoparticles (1×10^{12} **1-SPN**) were mixed with 1 μL of cells in MES buffer. The mixture was incubated at room temperature for 2 h with gentle rocking followed by a 1-h-long capture with a neodynium-based rare earth magnet ($Nd_{0.23}Fe_{0.74}B_{0.03}$, Lee Valley, Ottawa, ON, Canada). The magnetic is rated at 5000 gauss. Fixing the sample on a homemade magnet stand, the supernatant was removed and plated on BHI media at various dilutions to determine the number of noncaptured cells. The nanoparticles were separated from the magnet, resuspended in 100 μL of MES buffer, and used to determine the number of captured cells. Capture efficiency was calculated as follows:

$$\text{capture efficiency} = (\text{no. of captured cells}/[\text{no. of captured cells} + \text{no. of non-captured cells}]) \times 100$$

In specificity capture studies, 1 μL of each of *S. aureus* and *S. typhimurium* cells was added to 99 μL of overnight blocked conjugated or unconjugated nanoparticles (1×10^{12} **1-SPN**) in MES buffer/1% Tween 20. Incubation, nanoparticle capture, and fractionation of mixtures into captured and noncaptured cells were performed as above. Cell titration was performed as above except that the fractionated cells were plated on both XLD (selective for *S. typhimurium*) and BP (selective for *S. aureus*) media. Capture specificity was calculated on the basis relative number of *S. aureus* and *S. typhimurium* in the captured fraction, after normalizing for the total number of cells:

$$\text{capture specificity} = \text{no. of } \textit{S. aureus} \text{ in the captured fraction}/\text{no. of } \textit{S. typhimurium} \text{ in the captured fraction}$$

Alternatively, capture specificity was determined by direct comparison of the number of captured *S. aureus* vs the number of captured *S. typhimurium* in the mixed cell captured fraction. In some instances, a single wash step between the binding step and the fractionation step was included. The wash step comprised (i) resuspending the nanoparticles in 100 μL MES buffer/1% Tween 20, (ii) capturing the nanoparticles for 30 min, and (iii) removing the wash solution, which was subsequently titrated. Control experiments in which cells (*S. aureus* alone, *S. typhimurium* alone, or a mixture of both cells) were incubated with the MES buffer had the same total titer as the nanoparticle-treated cells.

Binding Analysis by Capture/SEM Experiments. Cell were grown as described above, centrifuged in a benchtop centrifuge (800 *g*, 5 min), resuspended in 1/2 MES buffer, and pelleted again. Cells were resuspended in 10^{12} **1-SPN** in MES buffer/0.1% Tween 20 (v/v) and incubated for binding for 30 min. The solutions were magnetically confined for 3 min and the supernatant removed—leaving the last 20 μL behind to ensure the confined materials are not disturbed and lost. The captured materials were resuspended in 200 μL MES buffer. This step was repeated, but the captured materials were resuspended in

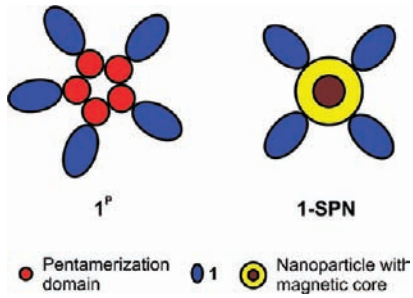

Figure 2. Cartoon representations of the pentameric sdAbs (**1**^{P}), comprising five identical monomeric V_H units (blue) assembled on a pentamerization domain, and the multivalent nanoparticles comprising a superparpamagnetic nanoparticle covalently modified with sdAbs (**1-SPN**). The average valency of the year-old **1-SPN** preparation used in this study was 4 sdAb.

200 μL sterile double-distilled H_2O (ddH_2O). The magnetic confinement was performed once more and the captured materials were resuspended in 50 μL ddH_2O. One microliter suspensions were used for SEM imaging. SEM was performed on cells plated on Si substrate with a Hitachi S-4700 field-emission scanning electron microscope. Samples were imaged with an acceleration voltage of 3 KV and at a working distance of 6 mm. Identical experiments were carried out with **SNP**.

RESULTS

Synthesis of 1-SPN Nanoconjugate and Its Binding Activity Assessment by Flow Cytometry. In this investigation, we utilize a silica encapsulated iron oxide nanoparticle (**SPN**) that can be readily modified with a V_H sdAb (HVHP428) (*12*) previously demonstrated to selectively interact with protein A (**1**), a surface marker unique to *S. aureus* bacteria, to generate **1-SPN** (Figure 2). Details of the synthesis and modification of the **SPN** and the conjugation chemistry employed in this investigation are provided in the Methods section. To assess the functionality of **1-SPN**, nanoparticles were incubated with fluorophore-conjugated protein A (protein A R-PE) and analyzed in a series of flow cytometry experiments. As highlighted in Figure 3, there is a gradual shift in the population of fluorescently active nanoconjugate for **1-SPN** as a function of protein A R-PE concentration, whereas the nanoparticle without the V_H on its surface (**SPN**) does not show any binding activity (i.e., there is no significant shift in the fluorescence, suggesting the protein A does not interact with the nanoparticles). This demonstrates that **1-SPN** effectively interacts with protein A through its sdAb moiety.

Construction of 1^{P}, the Pentameric Version of HVHP428 V_H. An attractive feature of sdAbs—a consequence of their stability—is the flexibility they allow for in terms of choosing optimal conjugation chemistry conditions and nanoparticle purification protocols (*10, 11*). Though the interactions between sdAbs and their ligand are quite selective, monomeric sdAbs may exhibit low affinities for target ligands. For example, the sdAb utilized in this investigation (**1**) has an affinity (K_A) of 5.6×10^5 M^{-1} with protein A (*12*), the surface marker that will allow the modified SPN to interact selectively with *S. aureus*. Interestingly, the apparent K_A, determined by SPR experiments, is increased by at least 1000-fold following the generation of a pentameric version of **1** (**1**^{P}, Figures 2 and 4) (*18*). The increase of apparent K_A is rationalized through the increased avidity brought on by the multivalent interactions between protein A and **1**^{P}. Because **1** is quite small (more than 10× smaller than IgGs), it can be conjugated to the surface of **SPN**s with a high binding density (>5-fold compared to IgGs and 2-fold compared to scFvs) (Figure 1) and will not promote nanoparticle aggregation as expected with scFvs and IgGs. The resulting **1-SPN** is also expected to improve the apparent K_A between the **SPN**-bound **1** and protein A simply because of increased avidity inherent to the now multimeric interactions (i.e., multiple **1** per **SPN**). To elucidate how the incorporation of the sdAb onto the nanoparticle surface affects the apparent K_A between **1** and protein A, the binding of the **1-SPN** was benchmarked against **1**^{P} by means of a cell microagglutination assay. (Attempts to obtain an apparent K_A for the interaction of **1-SPN** with protein A by SPR were not successful, presumably because the relatively large size of the nanoparticles prevented

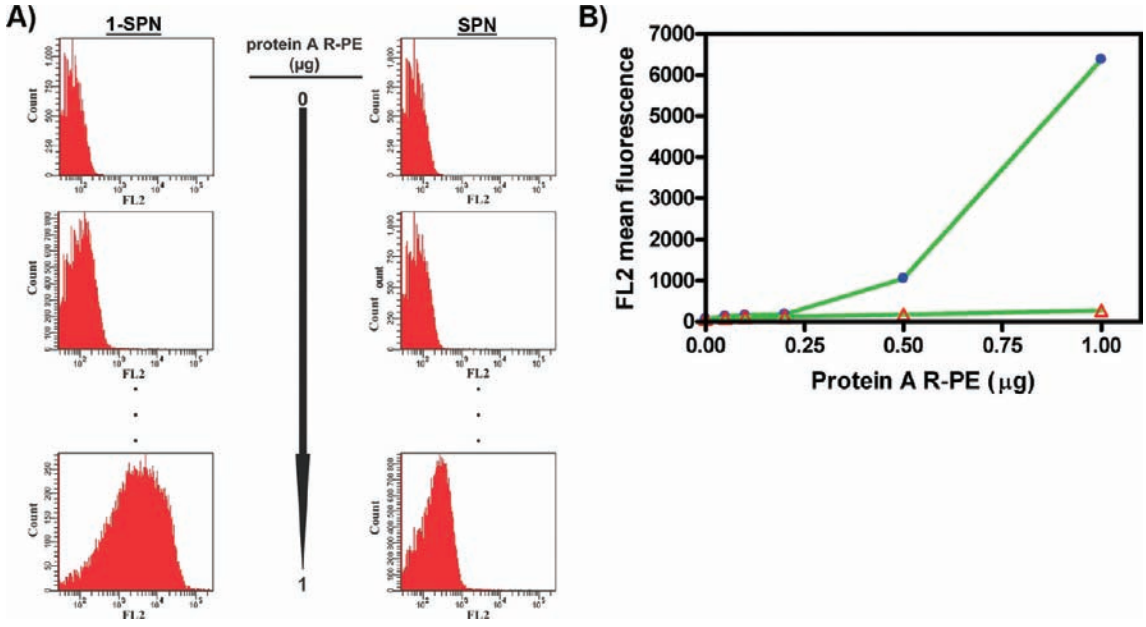

Figure 3. Assessing the functionality of **1-SPN** by flow cytometry. Nanoparticles were incubated with 0, 0.05, 0.1, 0.2, 0.5, and 1 μg of fluorescently active protein A (protein A R-PE) and assessed directly for binding by flow cytometry. (A) Binding, indicated as the rightward fluorescence shifts of nanoparticle populations, can be seen with the increase in protein A R-PE concentration. (B) Binding is shown as the mean fluorescence, extracted from data in (A), vs protein A R-PE concentration. Blue circles, **1-SPN**; red triangles, **SPN**.

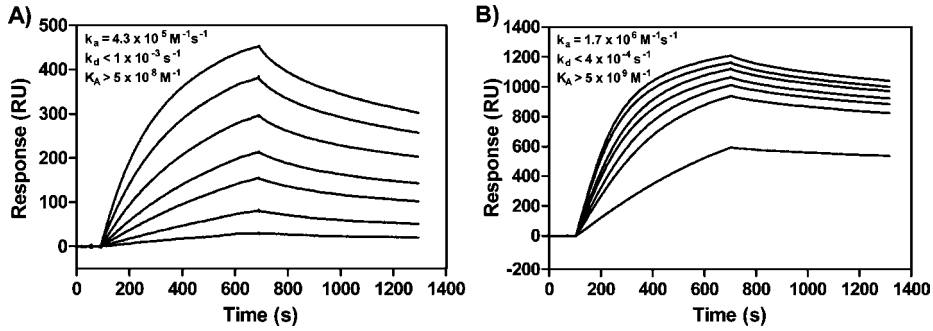

Figure 4. Assessing the binding activity of V_H and V_L pentamers by surface plasmon resonance. Sensorgram overlays showing the binding of $\mathbf{1^P}$ to immobilized protein A at 1, 2, 3, 4, 6, 8, and 10 nM concentrations (A) and of $\mathbf{2^P}$ to immobilized protein L at 1, 2, 2.5, 3, 3.5, 4, and 4.5 nM concentrations (B). Association and dissociation rate constants, k_a and k_d, respectively, and equilibrium constants, K_A, for the bindings of $\mathbf{1^P}$ and $\mathbf{2^P}$ to proteins A and L, respectively, are shown on the graphs. $\mathbf{1^P}$ and $\mathbf{2^P}$ had minimum K_As of $5 \times 10^8\ M^{-1}$ and $5 \times 10^9\ M^{-1}$, respectively. With slower k_ds, $\mathbf{1^P}$ and $\mathbf{2^P}$ had K_As as high as $1.1 \times 10^9\ M^{-1}$ and $1.1 \times 10^{10}\ M^{-1}$, respectively. RU, resonance units.

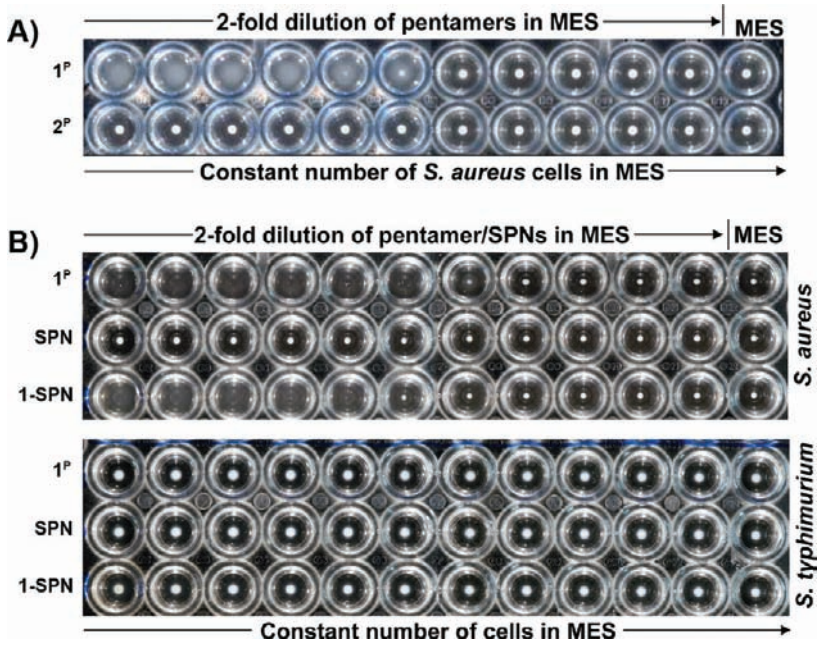

Figure 5. Representative microagglutination assays, where the concentrations of pentamers and SPNs decrease 2-fold from well 1 to well 11 with well 12 having only MES buffer.

their penetration into the dextran matrix on the sensor chip, making them inaccessible to essentially all of the immobilized protein A).

Assessing the Binding Activity of 1-SPN Against $\mathbf{1^P}$ by Microagglutination Assays. Microagglutination assays are typically performed by incubating a constant number of target cells (in this case, *S. aureus*) with decreasing concentrations of an antibody (in this case, either $\mathbf{1^P}$ or **1-SPN**) along a row of wells in a microtiter plate. In the absence of interactions between $\mathbf{1^P}$ (or **1-SPN**) and *S. aureus*, the bacteria simply precipitate into a circular pellet in the bottom of the well (Figure 5, column 12 contains only bacteria cells). However, when $\mathbf{1^P}$ or **1-SPN** are present and interact with the *S. aureus* there is a clumping or agglutination characterized by the absence of the circular pellet and the presence of a diffuse pattern in the well. As highlighted in Figure 5A, $\mathbf{1^P}$ is capable of agglutinating *S. aureus* cells up to well 6 (evidenced by the diffuse cell morphology), and beyond well 6, the concentration of $\mathbf{1^P}$ is too low for agglutination and the cells sediment as round dots. A control pentamer ($\mathbf{2^P}$), whose pentameric nature was confirmed by SPR (Figure 4), does not show any agglutination (Figure 5A), demonstrating that the activity of the $\mathbf{1^P}$ is due to its V_H binding component and not the pentamerization domains (Figure 2). Interestingly **1-SPN** is also capable of strongly interacting with the *S. aureus* cells in the agglutination assay, where agglutination occurs up to well 5 (Figure 5B). Note that the starting concentrations of $\mathbf{1^P}$ and **1-SPN** are 1.0×10^{15} pentamers/mL and 2.5×10^{12} nanoparticles/mL, respectively. There is a 2-fold dilution across the rows, translating to a MAC value of 3×10^{13} pentamers/mL and 1.5×10^{11} particles/mL for $\mathbf{1^P}$ and **1-SPN**, respectively. That is, **1-SPN** binds to protein A expressed on the surface of *S. aureus* 200 times more strongly than $\mathbf{1^P}$. Importantly, in the absence of **1**, **SPN** itself does not agglutinate with *S. aureus* under identical conditions. It is also noteworthy that **1-SPN** is specific to *S. aureus* exclusively. As highlighted in Figure 5B, neither **1-SPN** nor $\mathbf{1^P}$ agglutinate with *S. typhimurium* under identical conditions to that for the aforementioned *S. aureus* (only the circular pellet appears in these wells). Finally, the long-term stability of **1-SPN** is impressive; the MAC values do not significantly decrease even following a year of storage in a pH 6 MES buffer at 4 °C, presumably due to the multivalency inherent to the four remaining sdAb on the surface of the **1-SPN**.

Assessing Capture Efficiency and Specificity of 1-SPN. In this series of experiments, **1-SPN** is first incubated with *S. aureus* cells. If effectively and strongly labeled with **1-SPN**, the resulting bacteria will be magnetically responsive, making it possible to isolate the cells from bulk solution with a simple

Figure 6. (A) Scheme representing the steps involved in the magnetic capture studies. Capture efficiency and specificity were calculated as described in the Methods section. (B) Capture efficiency of **1-SPN** nanoconjugate toward *S. aureus*. The data are an average of five trials. (C) Capture specificity of **1-SPN** in terms of the ratio of the number of *S. aureus* to *S. typhimurium* in the captured fraction. This is the average of two trials. *S. aureus* and *S. typhimurium* data were normalized for the total number of cells. The inset shows the number of cells (average of the two trials) captured with **1-SPN** (white bars) and **SPN** (black bars). (D) Tabular presentation of results.

rare earth magnet (Figure 6A). In agreement with the microagglutination results, *S. aureus* cells are readily labeled with **1-SPN** and can be magnetically confined. Nonspecific capture could be completely suppressed by coating nanoparticles overnight with 0.1% Tween 20 and performing the binding in the presence of 1% Tween 20. It is noteworthy that such conditions may denature other antibody fragments, but the chemical stability inherent to sdAbs allows them to maintain activity under these conditions. As can be seen in Figure 6 (B,D), **1-SPN** is able to label and capture *S. aureus* with a capture efficiency of over 90% with as few as 180 cells (the number of cells subjected to capture studies ranged from 180−4000). As expected, the capture is mediated by **1**, as evidenced by the poor capture efficiency exhibited by **SPN** (5%). Finally, a competition assay was performed involving several samples containing both *S. aureus* and *S. typhimurium* cells.

In these competition assays, mixtures of both bacteria were incubated with **1-SPN** and subsequently magnetically confined. The capture selectivity was determined through the enumeration of the captured cells onto selective culture plates (BP plates for *S. aureus*, XLD plates for *S. typhimurium*), where the ratio of the *S .aureus* to *S. typhimurium* in the captured fraction was used to determine capture specificity. The total numbers of cells in the **1-SPN** mixtures were 1170 *S. aureus* and 525 *S. typhimurium* cells in one trial and 2780 *S. aureus* and 2420 *S. typhimurium* in the second trial. As can be seen in Figure 6C,D, **1-SPN** discriminately captures *S. aureus* over *S. typhimurium* with a ratio of 13:1. The number of *S. typhimurium* cells captured by **1-SPN** is at the background level and is essentially the same as the numbers captured by **SPN** in the case of both bacteria (Figure 6C, inset).

The capture selectivity could be further improved simply by including a wash step immediately following the binding step. As highlighted in Figure 7A,C, the capture efficiency was as high as 98% for **1-SPN** vs only 0.8% for the **SPN**. (The total number of *S. aureus* cells was 338 in the **1-SPN** mixture and 278 in the **SPN** mixture; the wash step removed 6 *S. aureus* from the **1-SPN** mixture and 24 from the **SPN** mixture.) Without the wash step, **1-SPN** capture efficiency would have remained at exactly the same level, but that of **SPN** would have been as high as 9%. This demonstrates that there is very little nonspecific absorption contributing to the interaction between **1-SPN** and the *S. aureus* cells. In the case of specificity capture studies, we used a mixture of cells with as few as 80 *S. aureus* cells and 56 *S. typhimurium* cells (Figure 7B,C). The capture specificity was adequate (80 *S. aureus*/4 *S. typhimurium*) immediately following incubation and magnetic confinement and extremely high following the washing step after confinement (78 *S. aureus* and no *S. typhimurium*; the wash step removed 2 *S. aureus* and 4 *S. typhimurium*). Thus, without the wash step the capture specificity ratio would have been significantly lower.

Assessing the Binding Specificity of 1-SPN by Capture Studies and Electron Microscopy. The binding (or lack of interaction) of both **1-SPN** and **SPN** to *S. aureus* cells could also be qualitatively assessed by means of TEM analysis. Examples of these TEM binding experiments are provided in Figure 8. From these images, two factors are clear. First, **1-SPN** interacts much more effectively over the entire surface of the *S. aureus* cells (Figure 8A) as opposed to **SPN** (Figure 8B), indicating that the sdAb mediates the specific interaction between the nanoparticles and the *S. aureus* cells. Second, in agreement with the microagglutination and capture specificity investigations highlighted above, the TEM analysis suggests that there is very little interaction between **1-SPN** and the *S. typhimurium* cells (Figure 8C). Also as expected, there was essentially no interaction between **SPN** and *S. typhimurium* (data not shown).

Previously an IgG-modified SPN conjugate was reported to interact with *S. aureus*, *S. saprophyticus*, and *S. pyogenes* (group A *Streptococcus*) through the Fc-region of the antibody (Figure 1) and surface ligands on the various bacteria (*3*). It is expected that such constructs may also cross-react with group C and G *Streptococci* through interaction with bacterial protein G (*19*). Because specificity/selectivity is an important characteristic that is required for most biodiagnostic applications, we also assessed the specificity of **1-SPN** through capture/SEM experiments with *S. saprophyticus*, *S. pyogenes*, *and S. pneumoniae* (a protein G-containing *Streptococcus* species of bacteria). Mixtures of nanoparticles (10^{12}) and cells (10^{8}) were incubated for binding and were subsequently subjected to magnetic confinement. While in the case of **1-SPN**/*S. aureus*, the solution became clear in a couple of minutes following the magnetic confinement with cells clumped against the vessel wall, indicating a very strong

Without wash	98%	9%	80/4

Figure 7. Cell capture efficiency and specificity of **1-SPN** nanoconjugate when a single wash step is included after the binding step. Capture specificity is shown by comparing the number of *S. aureus* vs *S. typhimurium* in the mixed capture fraction. (C) Tabular presentation of results.

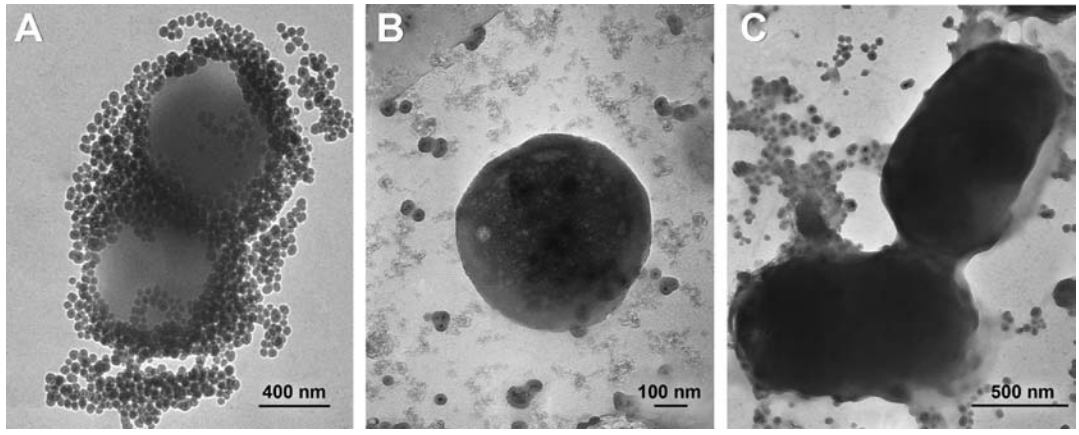

Figure 8. Representative TEM images of the **1-SPN**−bacteria conjugates where there is a strong interaction between **1-SPN** and *S. aureus* cells (A) in contrast to the inefficient labeling of *S. typhimurium* by the same nanoparticles (C). Control TEM images were also acquired confirming that **SPN** does not interact effectively with *S. aureus* cells in the absence of **1** (B).

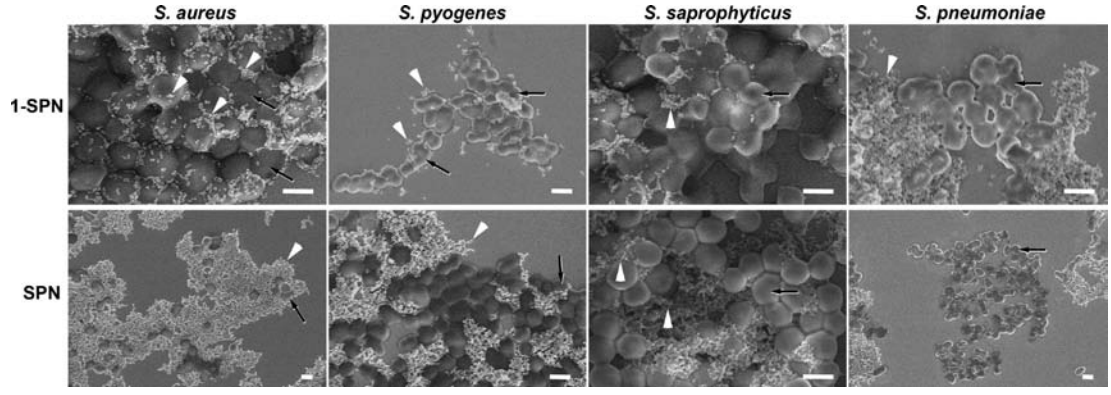

Figure 9. Assessing the cross-reactivity of **1-SPN** toward *S. saprophyticus*, *S. pneumoniae*, and *S. pyogenes* by SEM experiments. Cells and nanoparticles are shown by black and white arrows, respectively. The scale bar corresponds to 1 μm.

binding interaction between **1-SPN** and *S. aureus*, in the case of **SPN**/*S. aureus*, the solution stayed cloudy over the course of the confinement and there was no visible captured cells. With *S. pyogenes* and *S. pneumoniae*, both **1-SPN** and **SPN** hardly gave any captured cells, and by the end of the two washes (cycles of resuspension and confinement), there was no visible pack of confined cells. Only in the case of *S. saprophyticus* was some capture observed, albeit with a significant amount of cells still in the supernatant fraction. However, the capture was the same for both **1-SPN** and **SPN**, indicating some nonspecific interactions between **SPN** and *S. saprophyticus*. An aliquot of the confined materials following the last wash was used for SEM imaging.

Figure 9 summarizes results of the capture studies in a series of SEM images. The top panels of Figure 9 depict the interaction of cells with **1-SPN**, while bottom panels are the control experiments performed with **SPN**. In the *S. aureus* interaction with **1-SPN** capture study, SEM images showed each of the captured cells (dark sphere, ~1 μm) are flanked with **1-SPN** with most cells partially covered by the NP aggregates, which indicates positive binding response between cells and **1-SPN**. On the contrary, in the control experiment (*S. aureus* vs **SPN**), very large aggregates of **SPN** were observed with a few cells embedded in the **SPN** aggregates. Unlike the *S. aureus* vs **1-SPN** interaction, the captured cells in the control experiment have no **SPN** on their surface, nor were they flanked by the

nanoparticles. This suggests the lack of interaction between the control nanoparticles and *S. aureus*. It is possible that the few cells trapped in the control experiment were from the remaining 20 μL of the solution left after the capture step rather than magnetically confined. SEM images of the interaction between **1-SPN** with *S. pyogenes* and *S. pneumoniae* showed very similar patterns. Both images showed clusters of cells without any nanoparticles binding to their surfaces nor flanked in between the cells, which suggests the non-interactive nature of the **1-SPN** to both *S. pyogenes* and *S. pneumoniae*. Control experiments of both species exposed to **SPN** also showed a similar noninteraction pattern. Despite the observation of very large aggregates of **SPN** in the images of the control study, there were no nanoparticles binding to the surface of the cells as observed in the case of *S. aureus* vs **1-SPN** image. Since, in the case of both *S. pyogenes* and *S. pneumoniae*, there is no binding seen in the images as well as during the earlier confinement step, it is very likely that the cells seen in the images are carryover from the nonbinding fraction (see above and Experimental Procedures). We did, however, observe some interaction between both **1-SPN** and **SPN** with *S. saprophyticus* as suggested by Figure 9. In both *S. saprophyticus* vs **1-SPN** and *S. saprophyticus* vs **SPN** images, cells are flanked and partially covered by the nanoparticles, indicating a positive interaction between the nanoparticles and the cell. Because this is observed in both experiments, it is likely that the interactions are nonspecific, a conclusion that is also supported by the results of the capture step above. It is possible that such nonspecific interaction can be further reduced by passivating the nanoparticles surfaces with agents that suppress nonspecific interactions such as serum albumins. It is also very likely that the interaction between **1-SPN** and *S. saprophyticus* could be distinguished from the interaction between **1-SPN** and *S. aureus* in a real detection situation simply by looking at all of these interactions together.

DISCUSSION

Protein A is (i) highly characteristic of *S. aureus* with some 99% of *S. aureus* strains having protein A on their surface (*20, 21*) and (ii) highly abundant on the surface of *S. aureus* (*22*). These characteristics make protein A an attractive marker for effective and specific detection of *S. aureus* (*3, 21, 23*−*25*). In fact, the commercially available latex agglutination test, which is a standard method for *S. aureus* detection, is based on protein A−antibody interaction (*23, 25*). Recently, a gold nanoparticle-based immunochromatographic test developed for *S. aureus* detection and based on IgG−protein A interaction gave an impressive sensitivity of 100% for 130 *S. aureus* strains and specificities of 94.7% and 100% for *S. aureus* when also tested against 19 and 17 *Staphylococus* spp. (non-*S. aureus*) and non-*Staphylococci* strains, respectively (*25*). The latex agglutination test, which operates on the same recognition principle as the immunochromatographic test, gave identical results (*25*). The one false positive seen in the case of *S. xylosus* in the *Staphylococus* spp. group was presumably due to the presence of protein G on the surface of *S. xylosus*, which can cross-react with antibodies. This protein G-based cross-reactivity should not exist in the case of our nanconjugate, a conclusion supported by the lack of interaction between **1-SPN** and the protein G-displaying *S. pneumoniae* (Figure 9). Thus, on the basis of the above facts, the highly selective nature of the antibody−protein A pseudoimmune interaction (see Figure 1) and our own specificity/cross-reactivity studies, we expect **1-SPN** architecture to be *at least* as specific as the previously described detection systems, which rely on whole antibody−protein A interactions.

A potential advantage to the approach presented here involves the logical extension to dye or quantum dot-labeled superparamagnetic nanoparticles, which in addition to target preconcentration would provide detection signals. Alternatively, the detecting signals can be provided with SERS (surface enhanced Raman scattering)-active sdAb nanoconjugates (*10*) when used in combination with the present superparamagnetic nanoconjugates. Standard clinical detection methods, e.g., latex agglutination test for *S. aureus*, are time-consuming (takes a few days to obtain results) and laborious, as they involve steps such as plating and bacterial enrichment (*21, 26*). Detection platforms based on the present concept, besides offering better specificity (see above), would be fast and simple to perform. We have shown that it takes as little as 10 min to capture *S. aureus* with **1-SPN** (unpublished results) and no more than 10 min to detect the captured *S. aureus* by SERS-active sdAb conjugates, with single cell sensitivity (*28*). Additional advantages inherent to nanoparticle-based targeting agents include superior labeling efficiencies owing to large surface area to volume ratios and the fact that the nanoparticles are colloidally stable and are small, so binding kinetics should be significantly improved in comparison to micrometer-sized analogues (*27*).

On the basis of the performance of the present nanoconjugates and previously described SERS-active sdAb-silver nanoparticles (*10*) and the aforementioned properties of sdAbs, we strongly recommend sdAbs over other antibody formats as the recognition moiety of nanoparticles and nanowires.

CONCLUSION

In summary, sdAbs are highly stable, active, and specific agents capable of mediating interactions between superparamagnetic nanoparticles and a few tens of pathogenic bacteria in mixed cell populations with exceptionally high specificity and efficiency. The use of sdAb eliminates much of the cross-reactivity previously reported for nanoconjugates utilizing whole antibodies to interface the nanoparticles with the bacteria (*3*). These superparamagnetic nanoconjugates owe their excellent performance to a combination of multivalency and the unique properties of its sdAb component. A previously reported *S. aureus*-specific silver nanoconjugate which also relied on a sdAb for its recognition also performed very well (*10*), and it is expected that a combination of such nanoparticles could lead to very effective magnetic confinement and optical detection scaffolds for sensitive pathogen detection.

ACKNOWLEDGMENT

This is National Research Council of Canada Publication 50005. We acknowledge Rebecca To for constructing pentameric single-domain antibodies, Tomoko Hirama for performing surface plasmon resonance experiments, and Tom Devecseri for preparing publication quality figures. We are indebted to Catherine Bibby for acquiring the TEM images. We also thank NRC-NSC-ITRI for funding.

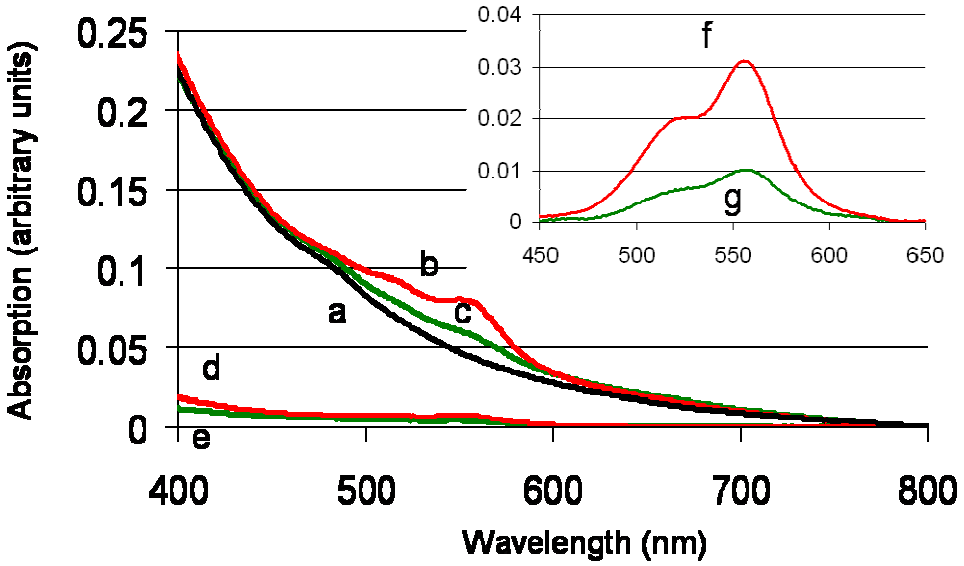
EXPERIMENTAL PROCEDURES

In order to elucidate the number of single-domain antibodies (sdAbs) anchored to the surface of each SPN, **1-SPN** was reacted with tetramethylrhodamine isothiocyanate (TRITC). The reaction was carried out in MES buffer with **1-SPN** (6×10^{12} nanoparticles) and TRITC (50 µg, 1.2×10^{-7} moles) and the resulting TMR-modified **1-SPN** was purified and analyzed by UV-visible spectroscopy in order to elucidate the number of sdAbs (**1**) on the surface of the nanoparticle. The UV-visible absorption spectra of freshly prepared, day-old **1-SPN** and one-year-old **1-SPN** (6×10^{12} nanoparticles/mL) and the original **1-SPN** are presented in Figure S1. Analysis of these spectra suggests that TMR has reacted with the sdAb on **1-SPN**, where there is an increase in absorption centered at 550 nm in comparison to the unmodified **1-SPN**. Note that an accurate absorption spectrum of the TMR can be obtained by subtracting the unmodified **1-SPN** from the **1-SPN(TMR)** (Figure S1). When the number of TMR molecules was known, the number of sdAb (**1**) per nanoparticle could be elucidated by assuming that only one of the six amine groups on **1** is responsible for anchoring it to the surface of the SPN. Construction of a calibration curve for TRITC in MES-buffered water and the comparison of the absorption intensity for the **1-SPN** samples suggest that there are 12 and 4 sdAbs per **1-SPN** for one-day-old nanoparticles and nanoparticles sitting in MES buffer at pH 6 for 1 year, respectively. This data is presented in Figure S2.



a) 1-SPN ($6x10^{12}$ particles)

b) One-day-old 1-SPN modified with TMR ($6x10^{12}$ particles)

c) Year-old 1-SPN modified with TMR ($6x10^{12}$ particles)

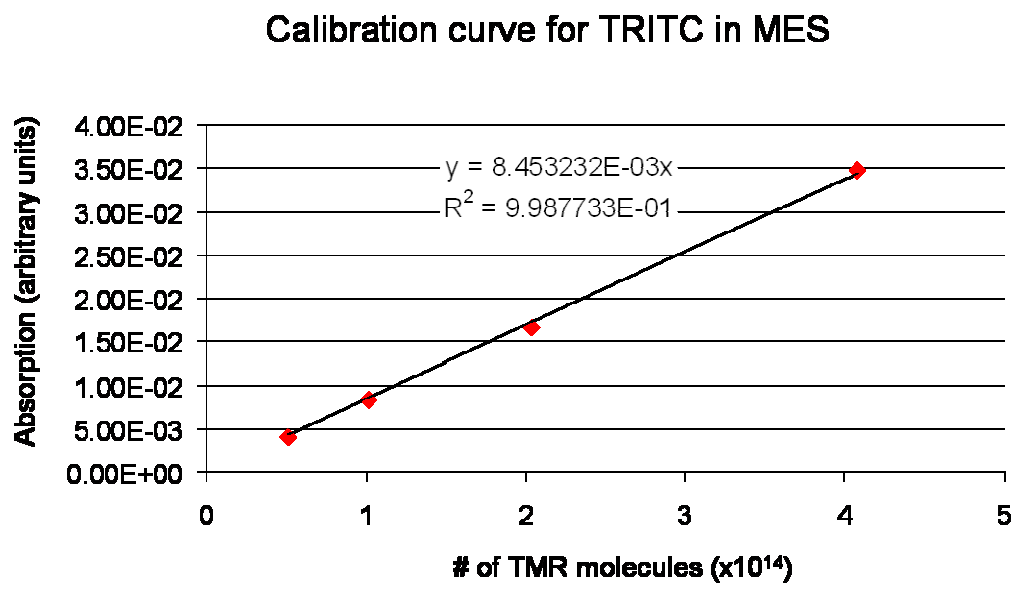
d) Magnetically confined one-day-old 1-SPN modified with TMR ($6x10^{12}$ particles)

e) Magnetically confined year-old 1-SPN modified with TMR ($6x10^{12}$ particles)

f) Corrected absorption spectra for one-day-old 1-SPN modified with TMR ($6x10^{12}$ particles) (i.e., b – a)

g) Corrected absorption spectra for year old 1-SPN modified with TMR ($6x10^{12}$ particles) (i.e., c – a)

Figure S1. The UV-visible absorption spectra of **1-SPN** (black), one-day-old **1-SPN** reacted with TRITC (red) and a year-old **1-SPN** reacted with TRITC (green). Note that when the nanoparticle absorption is subtracted, there is a clear absorption consistent with TMR (inset). Upon magnetic confinement, the absorption intensity of both the nanoparticle and TMR have decreased (bottom two spectra) suggesting that the TMR is covalently linked to the **1-SPN** in both cases.



One-day-old 1-SPN modified with TMR (6×10^{12} particles)

Absorption = 0.031
# of TMR molecules = 3.7×10^{14}
# TMR molecules per SPN = 61
# TMR molecules per sdAb = 5
# sdAb per SPN = ~12

Year-old 1-SPN modified with TMR (6×10^{12} particles)

Absorption = 0.010
# of TMR molecules = 1.2×10^{14}
# TMR molecules per SPN = 19.7
# TMR molecules per sdAb = 5
# sdAb per SPN = ~4

Figure S2. The calibration curve for TRITC in MES buffer and the calculations used to determine the average number of sdAb (**1**) on each nanoparticle. The calculations are based on the UV-visible absorption data shown in Figure S1.

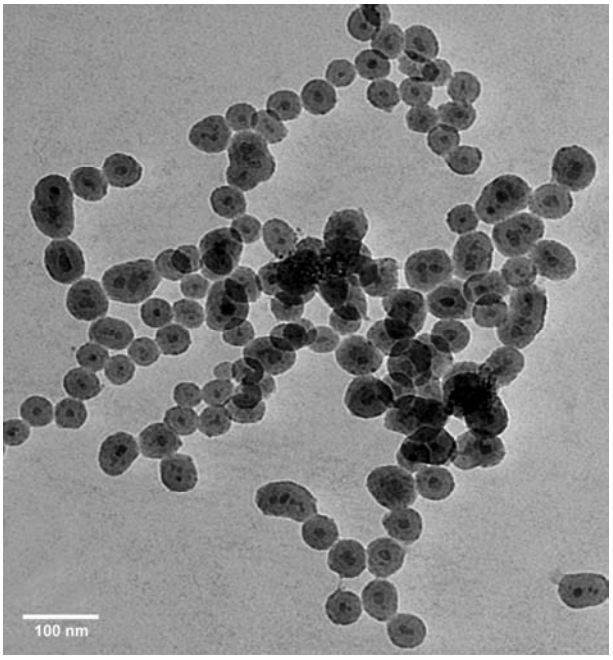


Figure S3. A representative TEM image of the nanoparticles employed in this investigation (**1-SPN**).

The average size of **1-SPN** was determined to be 49 ± 7 nm.

Antibody Internalization after Cell Surface Antigen Binding is Critical for Immunotoxin Development

Shu-Ru Kuo, Randall W. Alfano, Arthur E. Frankel, and Jen-Sing Liu*

Cancer Research Institute of Scott & White Hospital; Department of Internal Medicine, Health Science Center, College of Medicine, Texas A&M University, 5701 South Airport Road, Temple, Texas 76502. Received July 27, 2009; Revised Manuscript Received September 3, 2009

Immunotoxin potency is dependent on cell surface binding specificity as well as internalization efficiency. Current approaches for immunotoxin development are dependent on existing antibodies that were selected for high affinity and/or high production yield. However, these antibodies may demonstrate low internalization efficiency upon cell surface binding and thus are not necessarily the best candidates for immunotoxin design. Here, we have developed an assay with a novel protein, DTG3, to compare and evaluate the internalization efficiency of monoclonal antibodies in order to circumvent the possibility of low internalization. DTG3 is a fusion protein containing the N-terminus of diphtheria toxin (DT) and three copies of streptococci Protein G immunoglobulin binding domains. We show that antibody-DTG3 complexes formed in the test tube are able to bind their antigen on the target cell surface, resulting in cell internalization, DT-mediated protein synthesis inhibition, and host cell apoptosis. We tested this system with two well-studied antibodies, antihuman CD3ε, and anti-PSMA antibodies and were able to show efficiency of this assay. We further examined commercially available anti-CD123 antibodies for potential leukemia-targeting immunotoxin development. Finally, we applied this system in the early-stage screening of newly generated anti-CD123 hybridomas. Our data showed that this internalization assay system is sensitive, time efficient, and reproducible, and has provided a tool to compare monoclonal antibodies for the clinical development of effective immunotoxins for the treatment of a variety of neoplasms.

INTRODUCTION

Attempts to explicitly target proliferating tumor cells, and thus enhance therapeutic efficacy, have led to the development of targeted immunotoxins (*1*). These agents direct the powerful lethal action of recombinant bacterial or plant toxins to tumor cells through the fusion to growth factors, monoclonal antibodies, or antibody fragments that recognize tumor cell-specific epitopes. Toxins typically utilized for this application are referred to AB-toxins due to their structural organization. The A moiety consists of an enzymatic domain that modifies a specific intracellular target, causing the disruption of cell functions that are critical for cell survival. The B moiety, which is often modified for tumor cell targeting, comprises one or multiple subunits that bind cell surface receptors and permit the translocation of the A moiety into the host cytosol. Rapid progress in the understanding of toxin structure and function has fueled the development of numerous novel immunotoxins for use in hematological cancer therapy (*2*).

The selection of cell-binding peptides that have high specificity to the intended target cell as well as high internalization efficiency upon cell surface binding is critical in immunotoxin design. Traditional methods used to study internalization efficiency of cell surface targeting peptides were dependent on the use of isotopes such as ^{125}I or microscopy techniques (*3*−*6*). However, these methods proved to have inadequate sensitivity. More sensitive techniques included chemically conjugating the cell-targeting antibody to a toxin to measure cell killing directly (*7*). Since catalytic toxins are able to kill cells with as few as one molecule per cell, this assay can have much higher sensitivity than isotope or fluorescent-based techniques. However, chemical conjugation is time-consuming, costly, and has poor reproducibility. Recently, Mazor et al. (*8*) reported the development of a novel IgG binding toxin fusion protein (ZZ-PE38) for antibody internalization assays. The ZZ-PE38 fusion protein contains two copies of IgG-binding motif from Streptococcal protein A and a truncated *Pseudomonas* exotoxin A (PE38). The strong binding of protein A to the IgG Fc domain generated a bridge between the IgG and the catalytic toxin and, therefore, conveniently eliminated the need for chemical conjugation. Purified ZZ-PE38 and antibody complexes were shown to be homogeneous with antigen-binding domain exposed. This method has proved to be an invaluable tool to be further developed for antibody internalization studies.

Our laboratory has been studying the therapeutic potential of several diphtheria toxin based immunotoxins for treatment in leukemia (*9*). Efforts have been focused on targeting the interleukin-3 (IL3)[1] receptor via a fusion protein composed of the catalytic and translocation domains of diphtheria toxin (DT_{388}) linked to the IL3 cytokine (*10*−*13*). This fusion protein, known as DT_{388}IL3, is currently under evaluation for efficacy and safety in phase I clinical trials (*9*). Although still ongoing, alternative approaches for IL3R targeting are already underway. The α subunit of IL3R (CD123) has been shown to be up-regulated in acute myeloid leukemias, acute lymphoblastic leukemias, plasmacytoid dendritic cell leukemias, and some chronic myeloid leukemias (*3*, *14*−*17*). In contrast, the IL3R common β subunit (CDw131) is not always coexpressed in those leukemias (*18*). Thus, therapeutic agents targeting CD123 alone have potential for broader applications.

These findings prompted the development of immunotoxins targeting CD123. Du et al. (*19*) produced constructs consisting of *Pseudomonas* exotoxin PE38 and single-chain Fv of anti-CD123 antibodies. *In vitro* potency assays showed that an optimized construct, 26292(Fv)-PE38KDEL, had an IC_{50} in leukemia cells at around 500 pM. Although encouraging, this construct exhibited lower cytotoxicity than that of $DT_{388}IL3$ (IC_{50} at ~10 pM) (*12*, *20*). Since 26292(Fv)-PE38KDEL showed strong cell-surface binding to the targeted cells, the observed 50-fold lower potency might have been a result of low internalization efficiency.

In order to address these preliminary findings, we have developed a new antibody internalization assay with a novel recombinant protein, DTG3. This protein consists of the truncated diphtheria toxin (DT_{388}) fused to 3 copies of IgG biding motif from group G streptococci Protein G (*21*). Here, we describe the efficiency of this method using the well-studied antihuman CD3ε and PSMA antibodies in order to demonstrate biological activity and thus provide proof of principle. Our results indicate that the DTG3 coupling system described here provides a rapid method with high sensitivity to compare and evaluate antibody internalization efficiencies. We further prove that this method can be used in the early stage of hybridoma screening to identify new anti-CD123 antibodies with high internalization efficiency.

EXPERIMENTAL PROCEDURES

Plasmids. (1) pDTG1-His, pDTG2-His, and pDTG3-His: The plasmids expressing DT-proteinG fusion proteins were made of 2 parts: the sequence of the N-terminal 388 amino acids of diphtheria toxin (DT) was derived from pRKDTIL3 (*22*); and the DNA fragment containing the codon-maximized sequence for IgG binding proteins and linkers was synthesized by GenScript (Piscataway, NJ). To construct IgG binding protein, the sequence of the second IgG binding domain of wild-type group G streptococci Protein G (GBII) (*21*) was used. Seven and 8 amino acids immediately adjacent to the N-terminus and C-terminus, respectively, of the 55-amino-acid GBII core domain were also added to provide spacers when multiple copies were cloned. This amino acid sequence was reverse translated into the DNA sequence following preferred codon usage in *E. coli*. Six-nucleotide linkers recognized by restriction enzyme *Bam*H 1 and *Bgl*II were added to the 5′ and 3′ ends, respectively. To the 3′ end, DNA sequence of 6 histidines, a termination codon (TGA) and a *Hind* III recognition site were then added. The entire sequence was synthesized by GenScript and delivered within pUC57 plasmid (pUC57-G1-His). The *Bam*H 1-*Hind* III fragment of pUC57-G1-His was inserted to pET-EE plasmid (*23*) to generate pET-EE-G1-His. The *Bam*H 1-*Bgl*II fragment from pUC57-G1-His was then inserted to *Bam*H1 site of pET-EE-G1-His to produce pET-EE-G2-His. The same strategy was used to generate pET-EE-G3-His. The *Nde* I-*Hind* III fragments from pET-EE-G1-His, pET-EE-G2-His, and pET-EE-G3-His were inserted into pRKDTIL3 to create pDTG1-His, pDTG2-His, and pDTG3-His expression plasmids. (2) pcDNA-CD123: The cDNA of human CD123 was reverse-transcribed and amplified from leukemia cell line TF1 using Qiagen RNeasy mini and onestep RT-PCR kits. The PCR primers used are 5′-CCGGAGCTAGCGTTCCCGATGGTCC-3′ with one underlined *Nhe* I recognition site and 5′-TGGCCCGGCCGGG-GAGATTGAGGCA-3′. The 1.2 kb PCR product was first cloned into the pDrive vector using Qiagen PCR cloning kit and followed by subcloning into the *Kpn*I and *Nhe* I sites of a eukaryotic expression vector pcDNA3.1/Zeo (Invitrogen, Carlsbad, CA) to generate pcDNA-CD123.

Cell Lines and Antibodies. Jurkat cells, kindly provided by Dr. David M. Neville, and TF1/H-ras (*24*) cells were maintained in RPMI medium containing 10% FBS. PSMA-stably transfected NIH3T3 cells, a kind gift from Dr. Michel Sadelain, were maintained in DMEM medium containing 10% FBS. CHO-K1 cells (ATCC, Manassas, VA) were maintained in ATCC-formulated F-12K medium containing 10% FBS. pcDNA-CD123-stably transfected CHO-K1 cells expressing high copy number of CD123 were cultured in F-12K medium supplemented with 10% FBS and 0.4 mg/mL zeocin (Invitrogen, Carlsbad, CA).

Antihuman CD3ε antibody UCHT1 and antihuman PSMA antibody J591 were kindly provided by Drs. Jung Hee Woo and Neil H. Bander. Anti-CD123 antibodies 7G3 and 6H6 were purchased from BD Biosciences (San Jose, CA) and Abcam (Cambridge, MA), respectively. Anti-CDw131 antibody 1C1 was purchased from eBioscience (San Diego, CA).

Expression and Purification of DTG1, DTG2, and DTG3. Bacteria BL21(DE3) transformed with pDTG1-His, pDTG2-His, or pDTG3-His were cultured in SuperBroth containing 1.6 mM $MgCl_2$, 0.5% glucose, and 100 μg/mL ampicillin. A 4 mL overnight culture was added to 200 mL fresh medium at 37 °C until OD^{600} reached 0.6. The culture was cooled down to 18 °C (~1 h) before addition of IPTG to a final concentration of 0.2 mM. The induction was continued at 18 °C for 18 h. The cells were harvested and treated with 100 μg/mL lysozyme on ice for 30 min. The cell pellet was then resuspended in 20 mL of ice-cold hypotonic buffer (20 mM HEPES-K^+ pH 7.5, 5 mM KCl, 1 mM $MgCl_2$) on ice for 5 min. Cells were lysed by sonication once at 35 W for 30 s, followed by the addition of 5 mL 5 M NaCl, and three more sonications at 35 W for 30 s on ice. After centrifugation at 15 000 × *g* for 10 min, clear supernatant was mixed with 1 mL of $NiCl_2$-charged Chelator Sepharose beads (GE Healthcare, Piscataway, NJ) at 4 °C for 2 h. Beads were spun down and washed with 20 mM HEPES-K^+ pH 7.5 with 1 M NaCl followed by 5 mL each of Buffer A (20 mM HEPES-K^+ pH 7.5 with 100 mM NaCl), Buffer A with 2 mM imidazole, and Buffer A with 20 mM imidazole. The bound proteins were eluted with Buffer A with 200 mM imidazole. The collected protein peak fraction (about 1 mL) was loaded immediately into a 10/30 Superose 200 column (GE Healthcare, Piscataway, NJ) pre-equilibrated with Buffer A using a Purifier system (GE Healthcare, Piscataway, NJ). The fractions containing DT-proteinG fusion proteins (about 1.5 mL) was pooled, aliquoted, and stored at −20 °C.

Protein Gel Analysis. In a 10 μL reaction, 1 μg of DTG1, DTG2, or DTG3 was mixed with 0, 2, or 4 μg of antibody in phosphate buffer saline (PBS) pH 7.4 at room temperature. Control reactions had only 4 μg of antibody. For native gel analysis, the mixture was incubated at room temperature for 60 min. Two microliter aliquots of loading buffer (20 mM Tris-HCl pH 8.0, 50% glycerol) were added to each reaction before loading to a 5% native polyacrylamide gel. Electrophoresis was carried out at 60 V for 4 h on ice. The gel was then fixed with 35% methanol and 15% acetic acid for 10 min followed by Coomassie blue staining (BioRad, Hercules, CA) for 30 min. After destaining, images were taken by a gel documentation system and labeled by Photoshop.

For denatured gel analysis, the same reactions as described above were incubated at room temperature for 45 min before the addition of 1 μL 200 mM freshly prepared dimethyl pimelimidate (DMP; Sigma-Aldrich, St. Louis, MO) in PBS. The reactions were incubated for another 15 min before the addition of 1 μL of 1 M Tris−HCl pH 8.0 to neutralize unused DMP. Four microliters of 4× SDS sample buffer (Invitrogen, Carlsbad, CA) were added into each reaction and analyzed by an 8% SDS polyacrylamide gel running at 120 V for 90 min.

The gel was stained and destained as described above. Images were taken by a gel documentation system and labeled by Photoshop.

Chemical Conjugation. Antibodies were conjugated to CRM9 (a mutated DT) following the protocol of Zangemeister-Wittke (*7*). Ten milligrams of nicked CRM9 was prepared at 5 mg/mL in 50 mM sodium borate pH 8.0 with 1 mM EDTA. A fresh solution of SMCC (Pierce, Rockford, IL) was prepared at a concentration of 10 mM in dry DMF (Sigma-Aldrich, St. Louis, MO). A 20-fold molar excess of SMCC (Pierce, Rockford, IL) over CRM9 was added and mixed for 1 h at room temperature. This would add maleimide groups to CRM9 proteins. The filtered mixture was then added to a PD-10 desalting column (GE Healthcare, Piscataway, NJ) equilibrated with nitrogen flushed 10 mM sodium phosphate pH 7.0. The first peak was collected according to Bradford reading (BioRad, Hercules, CA), which corresponds to the derivitized toxin. The derivitized CRM9 was kept at 4 °C until use.

Two milligrams of antibodies was prepared in 50 mM sodium borate pH 8.0 and 1 mM EDTA. They were derivitized by adding a 20-fold molar excess of fresh 10 mM 2-IT (iminothiolane) solution (Pierce, Rockford, IL) in borate buffer, pH 8.3. This would add terminal sulfhydryl groups to antibodies. The mixture was allowed to react at room temperature for 1 h before it was applied to a PD-10 column (GE Healthcare, Piscataway, NJ) equilibrated with nitrogen-flushed 10 mM sodium phosphate pH 7.0. The first protein peak was collected and added to the derivitized CRM9 in a 15 mL conical tube. The mixture was allowed to react for 20 h at room temperature. Conjugates were purified through a Superdex 200 column (GE Healthcare, Piscataway, NJ) equilibrated by 10 mM sodium phosphate pH 8.0, 90 mM sodium sulfate, and 1 mM EDTA. The peak corresponding to the monoconjugated antibody was subsequently collected and concentrated using the centrifugal filter (Millipore, Billerica, MA). Concentration was determined via Bradford assay (BioRad, Hercules, CA).

Complex Formation. In a 10 μL reaction, 4 μg of monoclonal antibody was mixed with 2.5 μg of DTG3 at room temperature for 45 min. One microliter of 200 mM freshly prepared DMP in PBS was then added into each reaction and incubated for another 15 min before the addition of 1 μL 1 M Tris-HCl pH 8.0 to neutralize unused DMP. For the control, either antibody or DTG3 was omitted from the reactions.

Potency Assays. Potency of antibodies complexed with DT-proteinG fusion proteins or antibody−CRM9 conjugates was evaluated by their ability to suppress 50% of H^3-thymidine incorporation in treated cells (IC_{50}). The reactions were first diluted with fresh culture medium to the highest testing concentration (from 3 to 100 nM) based on antibody contents into the first column of 96-well round-bottom plates. Each sample was either triplicated or quadruplicated in the same plate. The first column was then diluted 1:3 to the second column and 3-fold dilution continued all the way to the 12th column. 50 μL aliquots of the diluted complexes were added to 96-well cell plates containing 1×10^4 cells in 100 μL per well. The cells were incubated at 37 °C in CO_2 incubator for 48 h before the addition of 1 μCi of H^3-thymidine to each well. After additional 18 h incubation at 37 °C in CO_2 incubator, the cells were harvested and counted in a β-counter. The potency curves were graphed using Prism fitted with sigmoid dose response curve with variable slopes.

Hybridoma Cell Line Production. All experiments involving animals were preapproved by IACUC of Scott & White Hospital (2008-049-R). Briefly, groups of 3 Balb/c mice were intraperitoneally injected with 5 million CD123-transfected CHO-K1 cells at day 1, day 15, and day 29. Blood samples were collected at day 36 to evaluate antibody titer induced in each animal by C-ELISA (see below) with parental or CD123-transfected CHO-K1 cells. The mouse with higher antibody titer was given a final boost at day 57 with intravenous injection of 2 million CD123-transfected CHO-K1 cells. Splenocytes were harvested at day 60 and fused with P3 × 63Ag8.653 myeloma cells (ATCC, Manassas, VA) following the published protocol (*25, 26*). Hybridoma cells were mixed in HAT selection medium containing methylcellulose and Hybridoma Fusion and Cloning Supplement (HFCS; Roche, Basel, Switzerland) and plated in ten 100-mm Petri dish (*26*). Ten days later, single colonies were picked and expanded in 96-well flat bottom plates with 200 μL of hybridoma culture medium. Culture supernatant from each well was diluted 1:10 and tested in C-ELISA with parental or CD123-transfected CHO-K1 cells to select clones that produced anti-CD123 antibodies. The initial culture supernatant from positive clones was used for iso-type identification with an Iso-Gold kit (BioAssay Works, Ijamsville, MD) and for IgG quantification with a mouse-IgG ELISA kit (Roche, Basel, Switzerland). The identified anti-CD123 antibody-producing hybridomas cell lines were expanded for further antibody purification.

Cell-Based ELISA (C-ELISA). One day prior to the experiment, 5×10^4 parental or CD123-transfeced CHO-K1 cells were seeded in each well of a flat-bottom 96-well plate. The next day, cells were washed with PBS and fixed with 3% formaldehyde in PBS at room temperature for 10 min. Fixed cells were washed thrice with PBS with 0.5% Tween 20 and incubated in Blocking Solution (PBS with 10% goat serum) for 30 min. Primary antibodies were then added at room temperature for 60 min followed by HRP-conjugated secondary antibodies (Jackson Lab, West Grove, PA) at room temperature for 45 min. The HRP activity was detected by HRP substrate (R&D, Minneapolis, MN) for 10 min and stopped by 0.5 M H_2SO_4. The plates were read by a plate reader set at 450 nm.

Antibody Purification. Hybridoma culture supernatant (200 mL) was mixed with 400 mL of 20 mM Tris-HCl pH8.0 at room temperature and applied to a 5 mL Q-Sepharose column (GE Healthcare, Piscataway, NJ). Total bound proteins were eluted with 20 mM Tris-HCl pH 8.0 with 1 M NaCl, adjusted to a final NaCl concentration of 3 M, and applied to a 2 mL Protein G Sepharose column (Pierce, Rockford, IL). Antibodies were eluted with 100 mM glycine pH 3.0 and neutralized immediately with 1/10 volume of 1.5 M Tris-HCl pH 8.8. Desalting column PD-10 (GE Healthcare, Piscataway, NJ) was used to exchange the buffer of purified antibodies to PBS with 20% glycerol. Protein concentrations were measured by Bradford assays (BioRad, Hercules, CA) with BSA (Pierce, Rockford, IL) as standards and verified by reduced SDS-PAGE.

RESULTS

Construction, Expression, and Production of DTG1, DTG2, and DTG3. DT-proteinG fusion proteins carrying one to three copies of the protein G IgG binding domains were expressed and purified from bacteria transformed with overexpression plasmids. These DT-ProteinG fusion proteins carry the N-terminus of diphtheria toxin (DT_{388}) that contains the catalytic and translocation domains but not the cell surface-binding domain (Figure 1A). The purified proteins with expected sizes were ≥95% pure (Figure 1B).

Complex Formation and Stabilization. The ability of the DT-ProteinG fusion proteins to form complexes with monoclonal antibodies was examined by native protein gel electrophoresis. Increasing amounts of anti-PSMA antibody J591 were titrated to fixed amounts of DT-proteinG fusion proteins. While both DTG2 and DTG3 formed stable complexes with J591 and appeared as a more slowly migrating band (compare lanes 6 and 9 to lane 10), DTG3 had a higher complex-forming

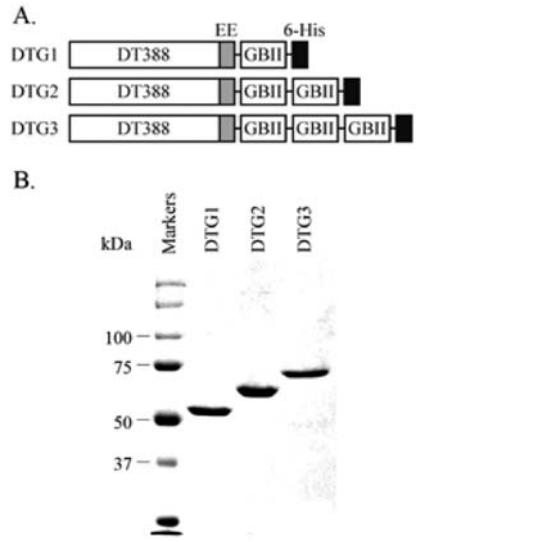

Figure 1. Construction and production of DTG1, DTG2, and DTG3. (A) N-terminal 388 amino acids of diphtheria toxin (DT388) was fused to a 9-amino-acid EE spacer (*32*) and 1−3 copies of the second copy of protein G IgG binding domain (GBII). The C-terminal histidine tag (6-His) allows easy purification. (B) Purified DTG1, DTG2, and DTG3 migrated in a 10% SDS-PAGE between markers of 50 and 75 kDa.

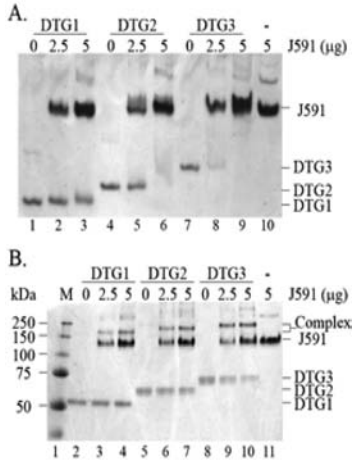

Figure 2. J591 and DT-proteinG fusion protein complex formation. (A) Native gel analysis. One microgram of DTG1, DTG2, or DTG3 was mixed with 0, 2.5, or 5 μg of J591 in PBS pH 7.4 at room temperature for 1 h. Protein mixtures were then loaded to a 5% native polyacrylamide gel and run on ice at 60 V for 4 h. (B) SDS-PAGE analysis. The same reactions as in (A) were added with 20 mM DMP to stabilize the complexes and loaded to a nonreduced 8% SDS-PAGE. Migration of each protein monomer, complexes, and the sizes of protein markers are labeled on the sides of each diagram. The faster migration of J591 at ~130 kDa (lane 10) was caused by DMP cross-linking.

efficiency (Figure 2A). The complete shift of 1 μg of DTG3 appeared at lane 8 where the antibody to DTG3 molar ratio was at about 1:1. Unfortunately, the protein complexes migrated only slightly more slowly than J591 alone, and J591-DTG1 complexes, if present, were not distinguishable from J591 (lanes 1−3).

In order to separate J591 from the complexes, a bifunctional cross-linker dimethyl pimelimidate (DMP) was added to stabilize these complexes and then analyzed in SDS-PAGE (Figure 2B). While DMP cross-linked only ~70% of the complexes (compare Figure 2A, lanes 8 and 9 to Figure 2B, lanes 9 and 10), this reagent does help to maintain the complex stability between J591 and DTG1 (Figure 2B, lanes 2 and 3). On the basis of the migration of the complexes to calculate their molecular weights,

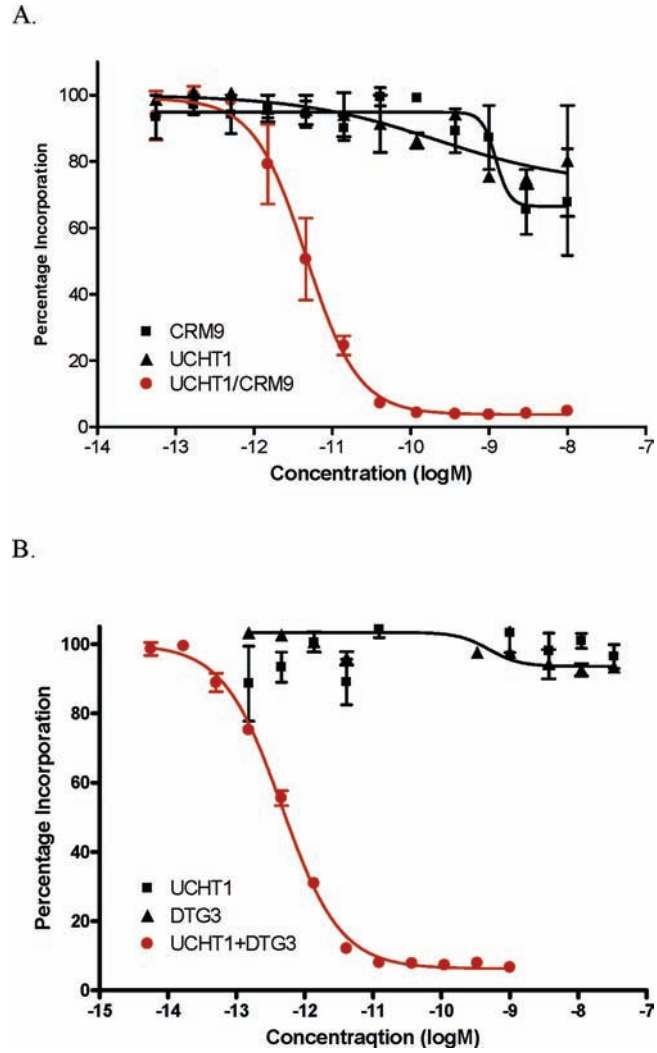

Figure 3. Potency of (A) UCHT1-CRM9 conjugates and (B) UCHT1-DTG3 complexes in Jurkat cells.

J591 and DT-proteinG fusion proteins formed complexes at 1:1 ratio. We concluded that a single copy of GBII has the ability to form complex with antibodies while multiple copies of GBII can help to increase stability of the complexes. On the basis of these results, we chose DTG3 to further evaluate the system.

Potency of UCHT1 and DTG3 Complexes. We subsequently determined the potency of DTG3/monoclonal antibody complexes. In order to do this, we chose the well-characterized immunotoxin A-dmDT390-bisFv(UCHT1) (*27*). This construct consists of diphtheria toxin fused to bivalent antihuman CD3ε antibody. The parental monoclonal antihuman CD3ε antibody UCHT1 was chemically conjugated to a cell surface binding-deficient diphtheria toxin mutant CRM9 using a set of cross-linkers and subsequently purified (Materials and Methods). Potency of UCHT1-CRM9 was tested in Jurkat cells. The IC_{50} of two separated batches of UCHT1-CRM9 conjugates were at 4 pM and 13 pM (Figure 3A and data not shown).

The DTG3 was then used to replace CRM9 in the same tests. UCHT1 was mixed with DTG3 in PBS in 10 μL reactions at room temperature. The complexes were stabilized by DMP. Without further purification, potency of these complexes was tested directly on Jurkat cells. While UCHT1 or DTG3 alone had no toxicity to treated cells, UCHT1 coupled with DTG3 had IC_{50} at 0.32 pM (Figure 3B).

Potency of J591 and DT-Protein G Fusion Protein Complexes. The potential of using DTG3 to study antibody internalization was further evaluated in another ongoing project

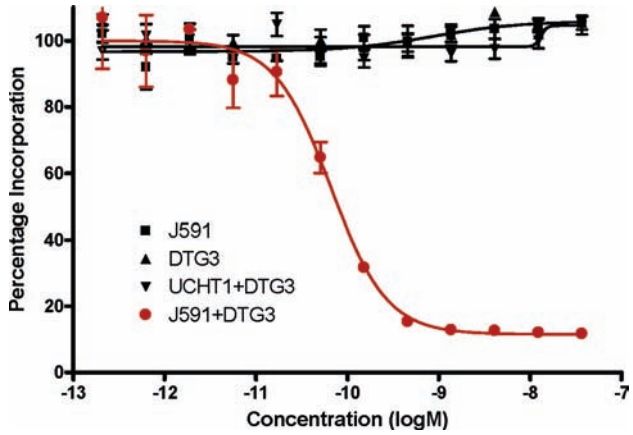

Figure 4. Potency of J591-DTG3 complexes in PSMA-transfected NIH3T3 cells.

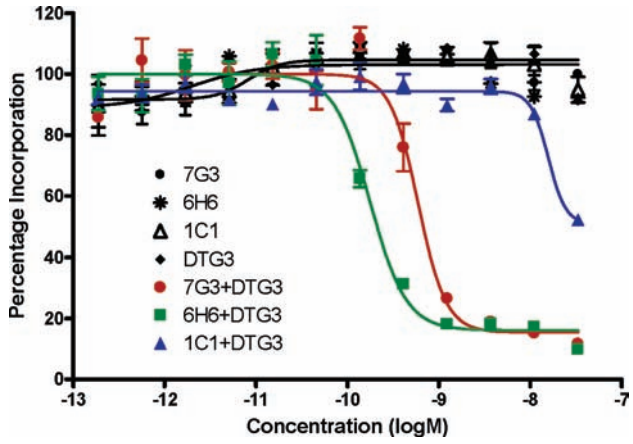

Figure 5. Potency of anti-IL3R antibodies-DTG3 complexes in CD123-transfected CHO-K1 cells.

in our group. Anti-PSMA antibody J591 was shown to have a high internalization rate upon binding to cell-surface PSMA proteins (*28*). When J591 was mixed with DTG3 at room temperature and stabilized by DMP, the potency of the complexes was tested in PSMA-transfected NIH3T3 cells. As shown in Figure 4, while J591 or DTG3 alone and UCHT1-DTG3 complexes had no toxicity to treated cells, J591-DTG3 complexes had an IC_{50} at 36 pM.

Potency of αIL3R Antibodies and DT Fusion Protein Complexes. Our optimal goal is to evaluate the possibility of generating an anti-IL3R immunotoxin for leukemia treatment. Two most commonly used anti-IL3Rα (CD123) antibodies 7G3 and 6H6 and anti-IL3Rβ (CDw131) antibody 1C1 were obtained commercially and mixed with DTG3 at room temperature. The complexes were stabilized by DMP. The potency of these complexes was then tested in CD123-transfected CHO-K1 cells. The IC_{50} for two different lots of 7G3 coupled with DTG3 was at 423 ± 66 pM (Figures 5 and 8, Table 1, and data not shown). Conversely, in repeated experiments, two different lots of 6H6 showed inconsistent results from 180 pM to 1.2 nM (Figures 5 and 8, Table 1, and data not shown) for unclear reasons. Regardless of their moderate potency as efficient immunotoxin candidates, they clearly showed that different clones of antibodies can have different internalization efficiency. Since there is no cell surface CDw131 (IL3Rβ) on CHO-K1 cells, 1C1 coupled with DTG3 showed only low toxicity at a very high immunotoxin concentration (Figure 5).

Production of New Anti-CD123 Antibodies. To produce anti-CD123 antibodies that have higher internalization efficiencies, Balb/c mice were immunized with CD123-transfected CHO-K1 cells. Hybridoma cells were generated by fusing splenocytes from the immunized mice and myeloma cells. To identify the antibody producing hybridoma, the culture supernatants from individual clones were screened for their ability to bind CD123-transfected CHO-K1 cells but not parental CHO-K1 cells in C-ELISA. These CHO-K1 cells were seeded in 96-well plates and fixed with formaldehyde before the addition of antibodies to prevent potential internalization. Among ~600 selected hybridoma clones from 1 immunized mouse, 5 clones (12F1, 12E8, 12H12, 12E7, 16G7) showed positive response. The specific binding was further confirmed by flow cytometry analysis. The cytometry graph showed that all five clones bind CD123-transfected CHO-K1 and leukemia cells TF1/H-ras but not parental CHO-K1 or lymphocyte Jurkat cells (data not shown).

Table 1. Antibodies Qualification and Quantification

		culture supernatant			purified antibody	
clones	subtype	μg/mL	nM	IC_{50} (pM)	K_d	IC_{50} (pM)
12F1	$IgG_{2b}\kappa$	4.7	29	34	50 ± 1	42 ± 7
12E8	$IgG_{2a}\kappa$	5.3	33	76	65 ± 20	175 ± 11
12H12	$IgG_{2b}\kappa$	4.8	30	30	57 ± 17	42 ± 5
12E7	$IgG_{2a}\kappa$	0.8	5	217	63 ± 15	117 ± 2
16G7	$IgG_{2a}\kappa$	5.2	33	77	75 ± 29	120 ± 7
7G3[a]	$IgG_{2a}\kappa$				131 ± 29	423 ± 66
6H6[a]	$IgG_{1}\kappa$				175 ± 43	620 ± 500

[a] 7G3 and 6H6 are commercial antibodies and the iso-type information was provided by venders.

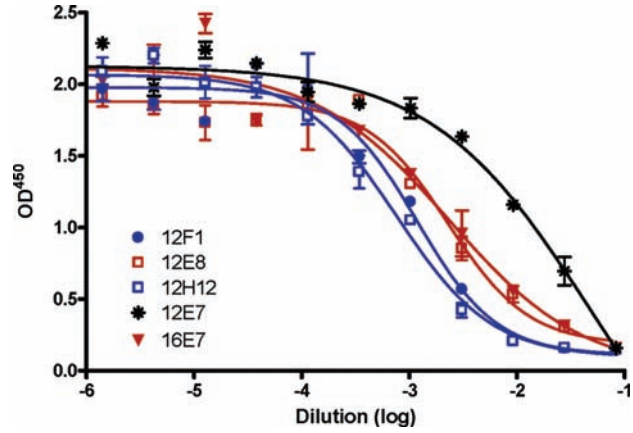

Figure 6. Cytotoxicity assay. Hybridoma culture supernatant coupled with DTG3 was tested in CD123-transfected CHO-K1 cells.

One hundred microliters of initial culture supernatant from these five positive clones were saved from the 96-well plates to be used in several assays. The first one is an immunoglobulin iso-typing assay. 12F1 and 12H12 were identified to be $IgG_{2b}\kappa$; and 12E7, 12E8 and 16G7 were $IgG_{2a}\kappa$ (data not shown; Table 1). Mouse IgG ELISA quantification assays were then used to measure antibody concentrations in these crude culture supernatants. Four of the five clones had very similar antibody concentrations at 4−5 μg/mL or ~30 nM, but slower-growing 12E7 had a much lower concentration (0.8 μg/mL; ~5 nM) than the others (Table 1).

Twenty microliters of each culture supernatant (80−100 ng, or 16 ng of 12E7) were mixed with an excess amount of DTG3 (200 ng) at room temperature for 1 h and stabilized with DMP. DTG3 alone at this dose range does not have any nonspecific cytotoxic effect (data not shown, but see Figure 8). Serial dilutions of these antibody-DTG3 mixtures were tested in potency assays with CD123-transfected CHO-K1 cells. As shown in Figure 6, different internalization rates were observed among these five clones. On the basis of the titration curve and

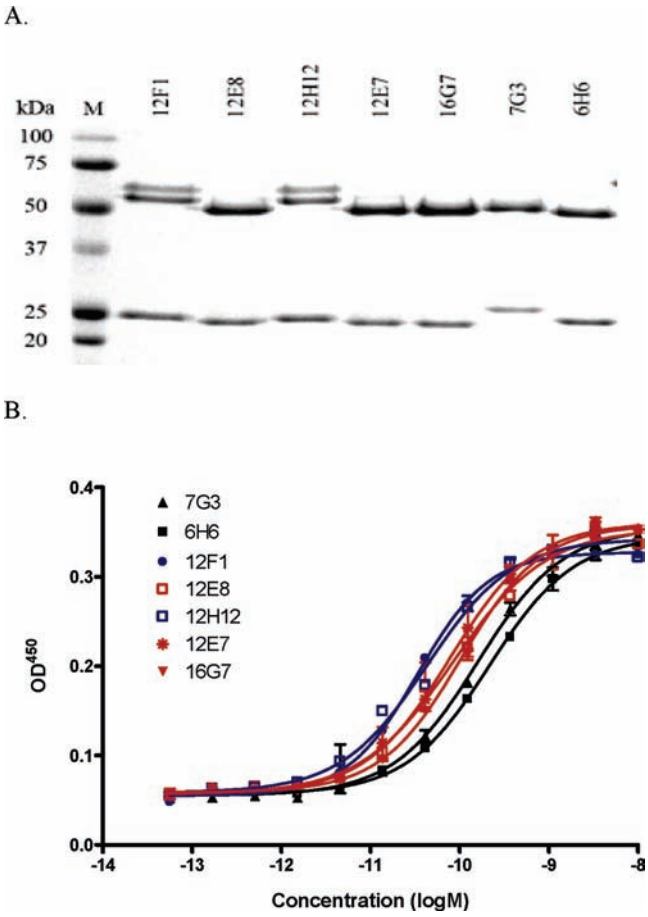

Figure 7. Protein quantification and qualification. (A) 2 μg of purified antibodies and commercial available 7G3 and 6H6 were analyzed by a reduced 12.5% SDS-PAGE. (B) Cell binding affinity of purified antibodies was tested in C-ELISA with CD123-transfected CHO-K1 cells.

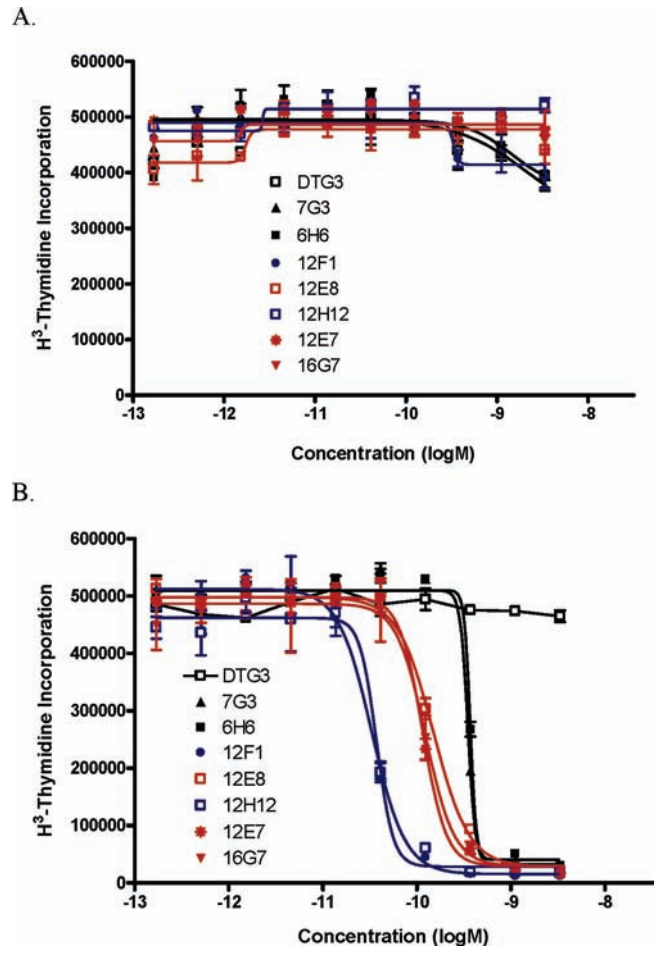

Figure 8. Cytotoxicity assays. Anti-CD123 antibodies-DTG3 complexes were tested in (A) parental CHO-K1 cells and (B) CD123-transfected CHO-K1 cells for their potencies.

individual concentration, DTG3-coupled 12F1 and 12H12 showed higher potency in CD123-transfected CHO-K1 cells with IC_{50} calculated to be at around 30−35 pM (Table 1).

To further confirm our findings, these hybridoma cell lines were expanded for antibody production. Monoclonal antibodies were purified via protein-G chromatography (Figure 7A). Both 12F1 and 12H12 had higher levels of modifications, possibly glycosylation, on the heavy chains. C-ELISA was used again to examine their binding affinity (Figure 7B; Table 1). All five new anti-CD123 antibodies showed higher CD123 binding affinity than the commercially available 7G3 or 6H6. The same amounts of purified antibodies were then mixed with DTG3, stabilized by DMP and tested for their cytotoxicity with parental CHO-K1 cells or CD123-transfected CHO-K1 cells. The dilutions of 7G3 and 6H6 were also used as a comparison. As shown in Figure 8A,B, when coupled with DTG3, 12F1 and 12H12 had an IC_{50} of approximately 42 pM, very similar to what was found with initial culture supernatants from 96-well plates (Table 1). These antibodies alone had no effect on cell growth (data not shown). 12F1 and 12H12 had ∼2−10-fold higher internalization activities than existing antibodies and appeared to be the best candidates for immunotoxin production.

DISCUSSION

Current monoclonal antibody production utilized in immunotoxin design is based on the selection of hybridoma cell lines that are able to produce large quantities of antibodies that have high affinity for the intended target. However, this approach may not be adequate for the design of successful conjugates, as immunotoxin efficacy is critically dependent on antibody internalization after cell surface antigen binding. We have reported here the development of DTG3, a novel protein conjugate specifically for the quantification of antibody internalization.

Conventional chemical conjugation of monoclonal antibodies to the cell-surface binding deficient mutant diphtheria toxin CRM9 was previously used to determine antibody internalization efficiency. However, this method has proven too costly, inefficient, and time-consuming. In order to minimize wasted reagents, the reaction was scaled down by our laboratory. Regardless, 10 mg CRM9 and 2 mg antibody were still required for the acquisition of adequate amounts of immunoconjugates for cytotoxicity analysis. Purification of the conjugate from free toxin and unconjugated antibody also proved to be time-consuming and tedious. After product purification and concentration determination, enough pure products remained for 1−2 cytotoxicity assays. Further, since chemical linkers are randomly conjugated to nonspecific sites on the proteins, activity of functional groups has the potential to be reduced, causing false negative results and low reproducibility between batches.

Conversely, DTG3 fusion proteins require only 2 to 3 μg of antibody per duplicate cytotoxicity assay. The preferential binding of Protein G to the immunoglobulin F_c region permits full exposure of the antigen binding domains. In addition, this system has proven to be extremely time efficient. Coupling reactions can be performed in about 1 h without any additional purification or concentration of the final product. Therefore,

these results indicate that the utilization of DTG3 facilitates the investigation of the internalization efficiency of monoclonal antibodies, and thus eases the cost and labor of immunotoxin development. As shown in Figure 6 and Table 1, we are able to use culture supernatant at the earliest stage of screening to examine their ability to be internalized upon binding to the cell surface antigens.

Inspiration for the generation of this novel DTG3 fusion protein was achieved from earlier work by Mazor et al. (*8*). This group demonstrated that a fusion protein consisting of the *Pseudomonas* exotoxin (PE) and two copies of Protein A IgG binding domain, known as ZZ-PE38, was useful to determine antibody internalization efficiency. However, several considerations resulted in numerous modifications in order to optimize this system for the application in our laboratory. Primarily, a specific cellular trafficking mechanism is required for PE to reach the cytosol, inhibit ribosome function, and thus kill the target cells. It is known that many cell types, including myeloid cells, have an inefficient translocation mechanism and are more resistant to PE (*29*). Our primary interests in myeloid cell malignancies prompted the substitution of PE to DT in order to circumvent this faulty trafficking mechanism, since the catalytic subunit of diphtheria toxin (DT) can be released from endosome to cytosol directly (*30*, *31*).

Additionally, Protein A demonstrates a differential affinity for immunoglobulins based on the species of origin and immunoglobulin iso-types. It has been shown that murine monoclonal antibody iso-type IgG_2 has the highest affinity for Protein A, causing a limited usefulness of ZZ-PE38. However, Protein G has a much broader spectrum of immunoglobulin binding ability. Protein G is therefore chosen in order to enhance the convenience of this assay.

Finally, our studies indicate that DTG3 was able to bind all antibodies tested within 60 min at a 1:1 ratio. In contrast to the published data (*8*), further purification of antibody-DTG3 complexes is not necessary. However, titration of the antibody-DTG3 complexes into cell culture medium without prestabilization by DMP will result in the dissociation of these complexes via exchange reactions with immunoglobulins in the media serum (data not shown). In order to eliminate the competition effects, we adapted Jurkat cells to serum free AIM-V medium (Invitrogen) and used them in UCHT1-DTG3 potency assays. Indeed, under serum free condition, UCHT1-DTG3 without pretreated with DMP had an IC_{50} in Jurkat cells at ~40 pM (data not shown). However, this number is still about 2 orders higher than DMP-stabilized UCHT1-DTG3 complexes (Figure 3). After consulting with technical service at Invitrogen, they indicated that the BSA added in the AIM-V medium could contain a low amount of immunoglobulin. When UCHT1-DTG3 was titrated down to ~10 pM or 1 ng/mL, a small amount of immunoglobulin contaminant could have a big effect. These findings indicate that the inclusion of DMP to stabilize antibody-DTG3 complexes is essential for the success of this assay.

In conclusion, antibody internalization by the target cell is critical in immunotoxin development. We have described a rapid protocol to quantify antibody internalization via potency on the target cell. The development and validation of this user-friendly system has potential to facilitate the design of viable immunotoxins and thus reduce the time and cost needed for clinical development.

ACKNOWLEDGMENT

We would like to thank Drs. JH Woo, NH Bander, DM Neville, and M Sadelain for providing antibodies and cell lines, Johnny Lee for assisting in the operation of flow cytometer, and Kent Claypool (Institute for Regenerative Medicine, TAMU) for performing cell sorting to isolate transfected CHO-K1 cells with high copy number of cell surface CD123. This project is supported by Scott & White setup fund to JSL.

TECHNICAL NOTES

Reagents for Astatination of Biomolecules. 4. Comparison of Maleimido-*closo*-Decaborate(2-) and *meta*-[^{211}At]Astatobenzoate Conjugates for Labeling anti-CD45 Antibodies with [^{211}At]Astatine

D. Scott Wilbur,*[,†] Monica S. Thakar,[||,⊥] Donald K. Hamlin,[†] Erlinda B. Santos,[⊥] Ming-Kuan Chyan,[†] Hirohisa Nakamae,[⊥] John M. Pagel,[‡,⊥] Oliver W. Press,[‡,§,⊥] and Brenda M. Sandmaier[‡,⊥]

Departments of Radiation Oncology, Medicine, Biological Structure, and Pediatrics, University of Washington, Seattle, Washington, and Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, Washington. Received February 19, 2009; Revised Manuscript Received August 8, 2009

An investigation was conducted to compare the in vivo tissue distribution of a rat antimurine CD45 monoclonal antibody (30F11) and an irrelevant mAbs (CA12.10C12) labeled with ^{211}At using two different labeling methods. In the investigation, the mAbs were also labeled with ^{125}I to assess the in vivo stability of the labeling methods toward deastatination. One labeling method employed *N*-hydroxysuccinimidyl *meta*-[^{211}At]astatobenzoate, [^{211}At]**1c**, and *N*-hydroxysuccinimidyl *meta*-[^{125}I]iodobenzoate, [^{125}I]**1b**, in conjugation reactions to obtain the radiolabeled mAbs. The other labeling method involved conjugation of a maleimido-*closo*-decaborate(2-) derivative, **2**, with sulfhydryl groups on the mAbs, followed by labeling of the mAb-**2** conjugates using Na[^{211}At]At or Na[^{125}I]I and chloramine-T. Concentrations of the ^{211}At/^{125}I pair of radiolabeled mAbs in selected tissues were examined in BALB/c mice at 1, 4, and 24 h post injection (pi). The co-injected anti-CD45 mAb, 30F11, labeled with [^{125}I]**1b** and [^{211}At]**1c** targeted the CD45-bearing cells in the spleen with the percent injected dose (%ID) of ^{125}I in that tissue being 13.31 ± 0.78; 17.43 ± 2.56; 5.23 ± 0.50; and ^{211}At being 6.56 ± 0.40; 10.14 ± 1.49; 7.52 ± 0.79 at 1, 4, and 24 h pi (respectively). However, better targeting (or retention) of the ^{125}I and ^{211}At was obtained for 30F11 conjugated with the *closo*-decaborate(2-), **2**. The %ID in the spleen of ^{125}I (i.e., [^{125}I]30F11-**2**) being 21.15 ± 1.33; 22.22 ± 1.95; 12.41 ± 0.75; and ^{211}At (i.e., [^{211}At]30F11-**2**) being 22.78 ± 1.29; 25.05 ± 2.35; 17.30 ± 1.20 at 1, 4, and 24 h pi (respectively). In contrast, the irrelevant mAb, CA12.10C12, labeled with ^{125}I or ^{211}At by either method had less than 0.8% ID in the spleen at any time point, except for [^{211}At]CA12.10C12-**1c**, which had 1.62 ± 0.14%ID and 1.21 ± 0.08%ID at 1 and 4 h pi. The higher spleen concentrations in that conjugate appear to be due to in vivo deastatination. Differences in ^{125}I and ^{211}At concentrations in lung, neck, and stomach indicate that the *meta*-[^{211}At]benzoyl conjugates underwent deastatination, whereas the ^{211}At-labeled *closo*-decaborate(2-) conjugates were very stable to in vivo deastatination. In summary, using the *closo*-decaborate(2-) ^{211}At labeling approach resulted in higher concentrations of ^{211}At in target tissue (spleen) and higher stability to in vivo deastatination in this model. These findings, along with the simpler and higher-yielding ^{211}At-labeling method, provide the basis for using the *closo*-decaborate(2-) labeling reagent, **2**, in our continued studies of the application of ^{211}At-labeled mAbs for conditioning in hematopoietic cell transplantation.

INTRODUCTION

Our laboratory is investigating the application of antibody-targeted α-particle emitting radionuclides as a replacement to total body irradiation (TBI) in conditioning for hematopoietic cell transplantation (*1*). In prior studies, we demonstrated that anti-CD45 and anti-TCR$\alpha\beta$ monoclonal antibodies (mAbs) labeled with the α-emitting radionuclide [^{213}Bi]bismuth could replace TBI in a conditioning regimen to obtain stable hematopoietic cell engraftment in a dog model (*2*−*4*). Although the studies successfully demonstrated that stable chimera could be obtained by combining the targeted alpha therapy with immunosuppression, the cost and availability of the parent radionuclide [^{225}Ac]actinium required to generate the ^{213}Bi precluded translation into a clinical study.

The ability to produce the α-emitting radionuclide [^{211}At]-astatine at our institution led us to consider that radionuclide as an alternative to ^{213}Bi in the conditioning regimen. In planning the transition to ^{211}At, we deliberated about the best method for coupling ^{211}At to the mAb. It has been well-established that direct coupling of ^{211}At to mAbs through electrophilic astatination results in proteins that are rapidly deastatinated in vivo (*5*). To circumvent the in vivo deastatination, our research group (*6*) and other research groups (*7*−*11*) have developed reagents for astatination using ^{211}At-labeled aryl-containing pendant groups for conjugation with proteins. The ^{211}At-labeled aryl

Figure 1. Conjugation reagents used to radiolabel mAbs with ^{211}At. The stannylbenzoate ester **1a** is reacted with ^{211}At or ^{125}I to prepare [^{211}At]**1c** or [^{125}I]**1b** prior to conjugation with the mAb. The maleimide-*closo*-decaborate(2-) reagent, **2**, is conjugated with the mAb, and that conjugate is subsequently labeled with ^{211}At or ^{125}I. (Note: the open circles in the *closo*-decaborate(2-) cage structure in compound **2** represent B or B−H atoms.)

conjugates are now widely used to radiolabel mAbs with ^{211}At for preclinical studies. Importantly, one of the astatination reagents, *N*-hydroxysuccinimidyl *meta*-[^{211}At]astatobenzoate, [^{211}At]**1c**, has been used for labeling mAbs in a clinical trial for therapy of malignant brain tumors (*12*).

Our studies have shown that ^{211}At-labeled benzoates can be relatively stable to in vivo deastatination on intact mAbs, but are quite unstable when used with more rapidly metabolized mAb Fab′ fragments (*6*, *13*) or smaller biomolecules such as biotin derivatives (*14*). To improve in vivo stability, we have evaluated protein conjugates that contain boron cage moieties as ^{211}At-labeling functionalities. From those studies, it was found that ^{211}At-labeled conjugates containing *closo*-decaborate(2-) are stable to in vivo deastatination (*15*). One conjugate in particular, a maleimido-*closo*-decaborate(2-) derivative, **2** (Figure 1), was found to have high stability to deastatination while having minimal effect on the conjugated protein.

Both of the ^{211}At labeling reagents, [^{211}At]**1c** and **2**, have features that make them attractive for use in labeling mAbs for conditioning regimens. The fact that the astatinated benzoate [^{211}At]**1c** had previously been used in a clinical trial made that reagent particularly attractive. However, that fact did not override the issues of the potential for (a) radiolysis in the preparation of [^{211}At]**1c** (*16*−*18*), (b) hydrolysis of the active ester during mAb conjugation of [^{211}At]**1c**, and (c) in vivo instability to deastatination on the ^{211}At-labeled mAb. The simplicity of direct labeling of proteins conjugated with the maleimide-*closo*-decaborate(2-) derivative, **2**, and the high in vivo stability observed for the ^{211}At-labeled proteins when using the reagent made this novel reagent attractive for our studies. To choose between the two reagents, we conducted an investigation to compare the ^{211}At-labeling efficiency and in vivo stability of a rat antimurine-CD45 mAb (30F11) and an irrelevant mAb (CA12.10C12) in mice. The results of that investigation are described herein.

MATERIALS AND METHODS

Reagents. All reagents obtained from commercial sources were used without further purification. Bismuth metal used as the target for preparation of ^{211}At was obtained from Alpha Aesar (Ward Hill, MA) as Puratronic 99.999%. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Chloramine-T (ChT) and phosphate buffered saline (PBS) were obtained from Sigma (St. Louis, MO). Sephadex G-25 desalting columns (PD-10 and NAP-10) were obtained from Amersham Biosciences (Piscataway, NJ). Vivaspin 20 ultrafiltration concentrators were obtained from Sartorius Stedim North America, Inc. (Edgewood, NY). The reagents, **1a** and **2**, used in labeling the antibodies, 30F11 and CA12.10C12, were prepared prior to the study. The *N*-hydroxysuccinimidyl *meta*-(tri-*n*-butylstannyl)benzoate, **1a**, was prepared as previously described (*19*). The protein modification reagent, *N*-(15-(aminoacyl-*closo*-decaborate)-4,7,10-trioxatridecanyl)-3-maleimidopropionamide, **2**, was prepared as previously described (*15*).

Antibodies. The rat antimurine CD45 mAb, 30F11, employed in the study is a rat IgG2b antibody that recognizes all murine CD45 isoforms (*20*). A 30F11 hybridoma cell line expressing the rat antimurine CD45 mAb was a gift from Dr. Irv Bernstein (FHCRC). The 30F11 was produced by injecting the hybridoma into pristane-primed mice to generate ascites. The 30F11 was purified from ascitic fluid by protein G immunoabsorption column chromatography. The irrelevant mAb, CA12.10C12, is an IgG1 anti-CD45 canine-specific antibody (*21*). A hybridoma producing monoclonal antibodies against canine CD45 was provided by Dr. Peter Moore (School of Veterinary Medicine, University of California, Davis). This mAb was produced and purified at the Biologics Production Facilities of the Fred Hutchinson Cancer Research Center (Seattle, WA) as described previously (*22*). A fluorescein isothiocyanate (FITC) labeled goat $F(ab')_2$ antirat antibody was obtained from Biosource International (Camarillo, CA) for murine hematopoietic cell binding (serum) using flow cytometry. The 30F11 mAbs, both native and conjugated with **2**, were conjugated with fluorescein isothiocyanate according to manufacturer's standard protocols, and were also used in flow cytometry studies.

Radioactivity. All radioactive materials were handled according to approved protocols at the University of Washington. Na[^{125}I]I was purchased from Perkin-Elmer Life and Analytical Sciences, Inc. (Waltham, MA) as a high concentration solution in 0.1 N NaOH. ^{211}At was produced by irradiation of a thin layer of bismuth metal with a 28 MeV α-particle beam on a Scandatronix MC-50 cyclotron (University of Washington). Isolation of Na[^{211}At]At was conducted in a charcoal-filtered glovebox (Innovative Technologies, Inc., radioisotope glovebox) by distillation from the irradiated target using the conditions previously described (*13*, *15*). Radiohalogenations were conducted within a charcoal-filtered Plexiglas enclosure (Biodex Medical Systems Inc., Shirley, NY) housed in a radiochemical fume hood. Radiohalogenation reactions were carried out in vials capped with Teflon-coated septa vented through a 10 mL charcoal-filled syringe.

Measurement of ^{125}I and ^{211}At quantities was accomplished on the Capintec CRC-15R Radioisotope Calibrator using the manufacturer's settings for those radionuclides. Tissue samples were counted in a γ-counter (PACKARD COBRA GMI, Inc., Minnesota, USA), using the open window setting: channels 20−2000. In experiments, $^{211}At/^{125}I$ counting was conducted twice, soon after animal sacrifice to obtain total counts and after samples had decayed for 3−5 days to obtain the ^{125}I counts. ^{211}At counts were obtained by subtracting ^{125}I counts from the total counts. All ^{211}At counts were corrected for decay during the counting process using 1 μL of injectate as standards.

Analytical Chromatography. HPLC separations of the nonradioactive compounds, **1a** and **2** (and their precursors), were obtained using a system that contained a Hewlett-Packard quaternary 1050 gradient pump, a variable wavelength UV detector (254 nm), and an ELSD 2000 evaporative light-scattering detector (Alltech, Deerfield, IL). Analyses of the HPLC data were conducted on Hewlett-Packard HPLC Chem-

Station software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. The gradient mixture was composed of MeOH (eluant A) and 0.05 M, pH 5.5, aqueous triethylammonium acetate (eluant B). The gradient started with 40% MeOH and 60% eluant B for two minutes; then, the % MeOH was increased linearly to 100% over a 13 min period; following this, the elution continued with 100% MeOH for an additional 5 min.

Radio-HPLC. The product mixtures from the preparation of [^{125}I]**1b** and [^{211}At]**1c** were analyzed by HPLC using a 5 μm C-18 column (PartiSphere C-18, Whatman) eluting at a flow rate of 1 mL/min with a gradient beginning with 40% MeOH/60% of an aqueous Et_3NHOAc solution. The HPLC equipment used in the analyses consisted of a HP 1050 quaternary pump, a Waters 481 UV detector (254 nm), a 1050 A/D converter, and a Beckman model 170 radioisotope detector.

Isoelectric Focusing. IEF were obtained on a Novex PowerEase 500 instrument with the XCell II chamber using Invitrogen (Novex) precast gels, pH 3−10 (1.0 mm, 12 well) or pH 3−7 (1.0 mm, 12 well) running under the standard IEF Program. The protein was stained with GelCode Blue Stain (Pierce). IEF standards used were from Serva Electrophoresis GmbH (Heidelberg, Germany): (pI) 10.7, cytochrome C; 9.5, ribonuclease A; 8.3, 8.0, 7.8, lectin; 7.4, 6.9, myoglobin; 6.0, carbonic anhydrase; 5.3, 5.2, β-lactoglobulin; 4.5, trypsin inhibitor; 4.2, glucose oxidase; 3.5, amyloglucosidase.

Fluorescein Isothiocyanate (FITC) Conjugation. One milligram of fluorescein isothiocyanate (Sigma-Aldrich, Wisconsin, MI) was dissolved in 0.05 mL of DMSO and further diluted to a concentration of 1 mg/mL with 1 M sodium bicarbonate, pH 9.4. Then, 0.25 mL of this solution is added to 1 mg/mL of the antibody in 1× phosphate buffered saline (PBS). After incubation at 37 °C, CO_2 humidified incubator, the antibody was transferred to a dialysis cassette, 10 MW cutoff (Pierce Biotechnology, Rockford, IL) and dialyzed against 1× PBS to remove unbound FITC. Antibody concentration was measured using a BioMate spectrophotometer (Thermo Electron Corporation, Madison, WI).

Flow Cytometry. Flow cytometry was used to assess antigen binding after modification of the anti-CD45 mAb, 30F11, with the maleimido-*closo*-decaborate(2-) reagent, **2**. SL2 cells, a mouse cell line expressing the CD45 antigen, was grown in 10% fetal bovine serum−RPMI until ready for use. Two hundred thousand SL2 cells in 50 μL of 15% horse serum (HS)−1× PBS were incubated with 50 μg/mL of the 30F11 or 30F11−**2** conjugate on ice for 20 min. After washing, cells were resuspended in 50 μL of 15% HS-PBS and added 10 μg/mL of the secondary antibody, goat F(ab′)$_2$ antirat FITC (Biosource, Camarillo, CA), and incubated on ice for 20 min. To test the blocking ability of the antibody, FITC conjugated 30F11 was added to cells incubated with 30F11 or 30F11-**2**, respectively. After incubation, cells were washed once with 2% HS-PBS, then once with 1× PBS, and resuspended in 200 μL of 1% paraformaldehyde. Cells were analyzed on a FACScan Flow cytometer (Becton Dickinson, San Jose, CA).

Radioiodination of 30F11 using [^{125}I]1b. To 100 μL of a solution of **1a** (1 mg/mL in MeOH/5% HOAc) was added 3.5 μL (1.2 mCi) of Na[^{125}I]I in 0.1 N NaOH followed by 20 μL of a *N*-chlorosuccinimide solution (1 mg/mL in MeOH). After 10 min at room temperature, 20 μL of a sodium metabisulfite solution (1 mg/mL in H_2O) was added to quench the reaction. A small amount of the mixture was injected on the HPLC to check the reaction yield (require at least 90%). The mixture was then reduced to dryness under a stream of argon and a mixture containing 500 μL of a 0.5 M sodium borate solution, pH 8.0, and 100 μL of 30F11 solution (6.7 mg/mL in PBS) was added. The conjugation reaction was allowed to run for 15 min at room temperature before eluting on a PD-10 column with PBS, pH 7.2. The protein fractions were pooled to give [^{125}I]30F11-**1b** with a specific activity of 0.8 mCi/mg and a radiochemical yield of 61%.

Radioiodination of CA12.10C12 with [^{125}I]1b. This reaction was conducted using the same conditions as described for preparation of [^{125}I]30F11-**1b** with the following differences. 1.5 μL of Na[^{125}I]I (920 μCi) in 0.1 N NaOH and 147 μL of 2.7 mg/mL CA12.10C12 were used. [^{125}I]CA12.10C12-**1b** was obtained with a specific activity of 0.92 mCi/mg and a radiochemical yield of 63%.

Astatination of 30F11 with [^{211}At]1c. To a 200 μL solution of **1a** (1 mg/mL in MeOH/5% HOAc) was added 20 μL (780 μCi) of Na[^{211}At]At (in 0.05 N NaOH) followed by 20 μL of a *N*-chlorosuccinimide solution (1 mg/mL in MeOH). After 10 min at room temperature, 20 μL of a sodium metabisulfite solution (1 mg/mL in H_2O) was added to quench the reaction. A small amount of the mixture was injected on the HPLC to check the reaction yield (90% [^{211}At]**1c** required). The mixture was then reduced to dryness under a stream of argon and a mixture containing 500 μL of a 0.5 M sodium borate solution, pH 8.0, and 90 μL of 30F11 solution (6.7 mg/mL in PBS). The conjugation reaction was allowed to run for 15 min at room temperature before eluting on a PD-10 column with PBS. The protein fractions were pooled to give [^{211}At]30F11-**1c** with a specific activity of 0.03 mCi/mg and a radiochemical yield of 4.4%.

Astatination of CA12.10C12 with [^{211}At]1c. This reaction was conducted under the same conditions as those used to prepare [^{211}At]30F11-**1c**, with the following changes. A 100 μL quantity of **1c**, 150 μL of Na[^{211}At]At (1.2 mCi), 30 μL of 1 mg/mL *N*-chlorosuccinimide, and 147 μL of a CA12.10C12 solution (2.7 mg/mL in PBS) were used. [^{211}At]CA12.10C12-**1c** was obtained with a specific activity of 0.03 mCi/mg and a radiochemical yield of 4.8%.

Conjugation of 30F11 with 2. To a 2 mL solution containing 5.3 mg/mL 30F11 in PBS, pH 7.2, was added 270 μL of 100 mM dithiothreitol. After 1 h of gentle mixing at room temperature, the reduced protein was eluted over a PD-10 column with PBS (pH 6.5 containing 1 mM EDTA). The protein-containing fractions were pooled to give 7 mL at a concentration of 1.5 mg/mL (UV 280 nm). To that solution was added 49.3 μL (10 equiv) of a 10 mg/mL solution of **2** in DMF. The reaction solution was gently mixed for 30 min at room temperature before quenching with 2.4 mg of sodium tetrathionate. The protein was concentrated in a Vivaspin 30K MWCO concentrator and washed 5× with 10 mL each of PBS pH 7.2, concentrating between each wash. The isolated 30F11-**2** was obtained in 4 mL solution at a concentration of 2.4 mg/mL (90% protein recovery).

Conjugation of CA12.10C12 with 2. The same procedure as described for conjugation with 30F11 (above) was used, with the following difference in reagent quantities. To 1.5 mL solution containing 6.1 mg/mL CA12.10C12 in PBS was added 200 μL of 100 mM dithiothreitol. The CA12.10C12-**2** was obtained in 6.5 mL at a concentration of 1.2 mg/mL (85% protein recovery).

Radioiodination of 30F11-2. To 25 μL of a 0.5 M solution of sodium phosphate, pH 7.4, was added 1.5 μL (274 μCi) of Na[^{125}I]I solution (0.1 N NaOH), followed by 163 μL (400 μg) 30F11-**2** and 20 μL of a chloramine-T solution (1 mg/mL in H_2O). The reaction was allowed to run for 30 s at room temperature before quenching with 20 μL of a sodium metabisulfite solution (1 mg/mL in H_2O). The mixture was eluted over a NAP-10 column using PBS, pH 7.2. The protein fractions

were pooled to give [^{125}I]30F11-**2** with a specific activity of 0.63 mCi/mg and a radiochemical yield of 81%.

Radioiodination of CA12.10C12-2. The radioiodination was conducted using the same conditions as used for preparation of [^{125}I]30F11-**2**, with the following changes. One microliter (484 μCi) of Na[^{125}I]I in 0.1 N NaOH was added, followed by 250 μL (300 μg) CA12.10C12-**2** and 30 μL of chloramine-T solution (1 mg/mL in H_2O). [^{125}I]CA12.10C12-**2** was obtained with a specific activity of 1.5 mCi/mg and a radiochemical yield of 62%.

Astatination of 30F11-2. To 100 μL of a 0.5 M aqueous sodium phosphate solution, pH 7.4, was added 400 μL (580 μCi) of Na[^{211}At]At solution (0.05 N NaOH) followed by 163 μL (400 μg) 30F11-**2** and 80 μL of a chloramine-T solution (1 mg/mL in H_2O). The reaction was allowed to run for 30 s at room temperature before quenching with 80 μL of sodium metabisulfite solution (1 mg/mL). The mixture was eluted over a NAP-10 column using PBS. The protein fractions were pooled to give [^{211}At]30F11-**2** with a specific activity of 0.9 mCi/mg and a radiochemical yield of 65%.

Astatination of CA12.10C12-2. The astatination was conducted using the same conditions as described for preparation of [^{211}At]30F11-**2**, with the following changes. One hundred microliters (577 μCi) of Na[^{211}At]At in ~0.05 N NaOH, followed by 250 μL (300 μg) CA12.10C12-**2** and 50 μL of a chloramine-T solution (1 mg/mL in H_2O). [^{211}At]CA12.10C12-**2** was obtained with a specific activity of 1.6 mCi/mg and a radiochemical yield of 81%.

Biodistribution Studies. Biodistribution studies were conducted under a protocol approved by the Institutional Animal Care and Use Committee (IACUC) at the Fred Hutchinson Cancer Research Center. Female BALB/c mice were obtained from the Jackson Laboratory (Bar Harbor, Maine, USA). In each biodistribution experiment, the radioactive mAbs isolated from size-exclusion columns (Sephadex G25; PD-10) were mixed to prepare an admixture. The admixture was diluted with phosphate buffered saline (PBS) to prepare injection quantities of ~200 μL. This quantity was injected into each of 15 mice via the lateral tail vein. The actual amount of injectate each animal received was determined by weighing the administering syringe before and after injection. Groups of 5 mice were sacrificed at 1, 4, and 24 h post injection. Selected tissues were excised, blotted free of blood, weighed, and counted. Blood weight was estimated to be 6% of the total body weight (*23*). Calculation of the percent injected dose per gram (%ID/g) and percent injected dose (%ID) in the tissues was accomplished using internal standards for the ^{211}At and ^{125}I counts. The tissues examined, quantities injected, and biodistribution data obtained in the studies are provided in Tables S1−S4 (Supporting Information).

RESULTS

mAb Modification and Labeling. The rat antimurine CD45 mAb, 30F11, and canine-specific (irrelevant) mAb, CA12.10C12, were each radiolabeled with ^{211}At and ^{125}I by two different methods. One labeling method involved preparation of *N*-hydroxysuccinimidyl *meta*-[^{211}At]astatobenzoate, [^{211}At]**1c**, and *N*-hydroxysuccinimidyl *meta*-[^{125}I]iodobenzoate, [^{125}I]**1b** from *N*-hydroxysuccinimidyl *meta*-tri-*n*-butylstannylbenzoate **1a** (Figure 1). Radioiodination and astatination of **1a** was accomplished by reaction with *N*-chlorosuccinimide (NCS) in MeOH/5% HOAc at room temperature for 10 min. Preparation of the radiolabeled intermediates [^{125}I]**1b** and [^{211}At]**1c** was accomplished in >90% purity by HPLC analyses (see Figures S1−S4 in Supporting Information). Once prepared, [^{125}I]**1b** was reacted with 670 μg of 30F11 or 397 μg of CA12.10C12 in borate buffer, pH 8.0, for 15 min at room temperature to give

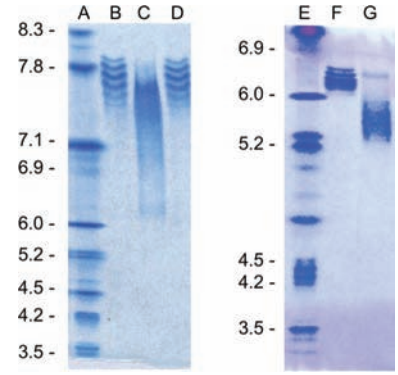

Figure 2. Isoelectric focusing gels showing protein bands of 30F11 (left gel, Novex 3−10) and CA12.10C12 (right gel, Novex 3−7) before and after the proteins were conjugated with maleimide-*closo*-decaborate(2-), **2**. Lanes are as follows: (A) IEF markers, (B) unmodified 30F11, (C) 30F11-**2**, (D) unmodified 30F11, (E) IEF markers, (F) unmodified CA12.10C12, and (G) CA12.10C12-**2**. IEF markers (Serva) are as follows: (pI) 10.7, cytochrome C; 9.5, ribonuclease A; 8.3, 8.0, 7.8, lectin; 7.4, 6.9, myoglobin; 6.0, carbonic anhydrase; 5.3, 5.2, β-lactoglobulin; 4.5, trypsin inhibitor; 4.2, glucose oxidase; 3.5, amyloglucosidase.

conjugation yields of 61% and 63%, respectively. In contrast to the radioiodinations using [^{125}I]**b**, astatinations under the same conditions using [^{211}At]**1c** produced very low yields, providing only 4.4% of [^{211}At]30F11-**1c** and 4.8% of [^{211}At]CA12.10C12-**1c**. The reason for the difference in radiochemical (conjugation) yields between the astatinated benzoates, [^{211}At]**1c**, and the radioiodinated benzoates, [^{125}I]**1b**, is unknown. Since the quantities of mAb employed (603 μg 30F11 and 397 μg CA12.10C12) in the conjugation reactions using [^{211}At]**1c** were similar to those used in the conjugations of [^{125}I]**1b**, differences in protein concentrations does not appear to be the reason for the lower yields. Although the radiolabeled intermediates in each reaction were >90% pure by HPLC analyses prior to removal of the solvents, it is possible that impurities or differences in pH of the astatinated preparations led to a more rapid hydrolysis of [^{211}At]**1c** upon removal of the solvents. The volumes of aqueous Na[^{125}I]I solution used (1.5 or 3.5 μL) in the radiolabeling reactions were considerably lower than the volumes of aqueous Na[^{211}At]At solution used (i.e., 20 and 150 μL), making this possibility plausible. Irrespective of the low conjugation yields for the astatinated proteins, enough labeled protein was obtained after purification in each case to conduct the animal studies.

The second method of labeling mAbs involved conjugation of the maleimide-*closo*-decaborate(2-) reagent, **2** (Figure 1), followed by direct radiolabeling of the mAb conjugates. In the conjugation, 30F11 or CA12.10C12 was treated with dithiothreitol (DTT) for 1 h at room temperature, then 10 mol equiv of **2** in DMF was added and the reaction mixture was stirred for 30 min at room temperature. After that time, sodium tetrathionate was added to stop the reaction by reformation of disulfide bonds (*24*). The resulting mAb conjugates, 30F11-**2** and CA12.10C12-**2**, were purified by Sephadex G-25 size exclusion chromatography (PD-10). Although the number of *closo*-decaborate(2-) conjugates per modified mAb was not readily obtained, the extent of modification was assessed by the change in protein isoelectric point (pI) observed with isoelectric focusing (IEF) gel electrophoresis. Each conjugation of **2** changes the overall protein charge by −2. Scanned IEF gels are shown as Figure 2. In Figure 2, it is apparent that the two unmodified IgG have very different pI values (30F11, ~7.5−7.9; CA12.10C12, ~6.2−6.6) and that the proteins are modified in the conjugation reaction. While not quantifiable, it appears that at least one *closo*-decaborate derivative, **2**, was conjugated to each protein molecule, as all of the bands (lanes

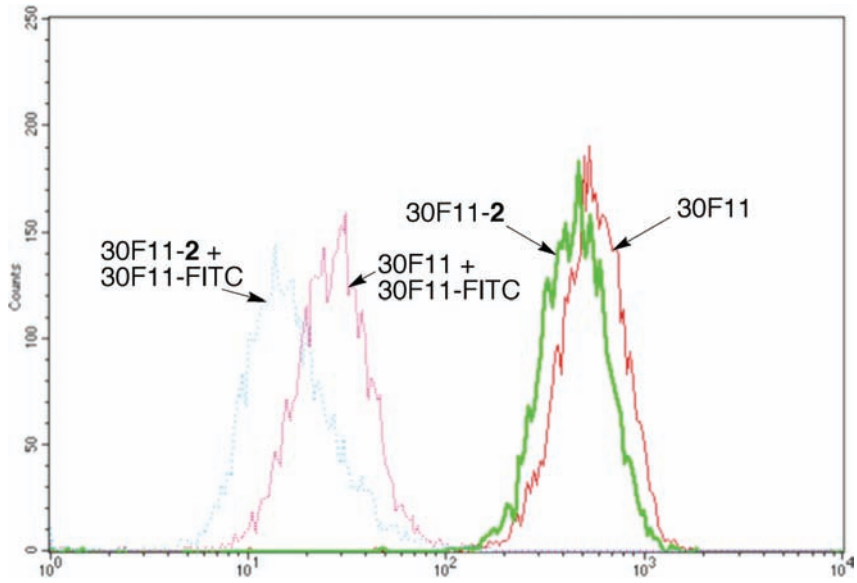

Figure 3. Histograms from flow cytometry showing cell binding of unmodified 30F11 (red) and *closo*-decaborate(2-) modified 30F11 (green). Competitive binding of 30F11-FITC with 30F11 (purple) and 30F11-**2** (blue) is also shown.

C and G) of the native protein are shifted to a more negative pI in the conjugation reaction. Further characterization was conducted to determine if the CD45 cell binding was affected in the 30F11. Cell binding for the 30F11-**2** and nonmodified 30F11 as measured by a FITC-labeled goat antirat $F(ab')_2$ mAb are shown in Figure 3. The graphed data indicate that there is similar binding of 30F11-**2** relative to the nonmodified 30F11. Running the samples in the presence of excess FITC-labeled 30F11 shows that the cell-bound 30F11-**2** (and 30F11) is CD45 specific binding, as it can be displaced.

Direct labeling of 30F11-**2** and CA12.10C12-**2** was accomplished by reaction of Na[^{211}At]At or Na[^{125}I]I with chloramine-T in sodium phosphate buffer. The reactions were quenched after 30 s to provide high yields of the labeled anti-CD45 mAb, [^{211}At]30F11-**2** or [^{125}I]30F11-**2** (65% and 81%, respectively), and the labeled irrelevant mAb, [^{211}At]CA12.10C12-**2** or [^{125}I]CA12.10C12-**2** (81% and 62%, respectively), after purification by size exclusion chromatography.

Biodistribution Studies. Four biodistribution studies were conducted in this investigation. Two biodistributions were conducted with the rat antimurine CD45 mAb, 30F11, and two biodistributions were conducted with a canine-specific irrelevant mAb, CA12.10C12. In all biodistribution studies, 10 μg quantities of ^{125}I-labeled (1−5 μCi) and ^{211}At-labeled (1−10 μCi) mAbs were mixed (20 μg total protein) and were injected into 15 BALB/c mice. Sacrifices of groups of 5 mice were conducted at 1, 4, and 24 h post injection (pi). The data obtained are shown graphically as panels A−D in Figure 4 and are provided in Tables S1−S4 (Supporting Information). Note that the concentrations in spleen shown in Figure 4, which can be very high (as high as 546%ID/g in panel A; 1409%ID/g in panel B), are graphed off-scale so that the concentrations in the other tissues can be compared visually. There was a large animal-to-animal variance in the concentration of radionuclides in the groups. The %ID/g variation in spleen from individual mice appeared to correlate with the spleen size. Indeed, the variance was much smaller when the size of spleen was not factored in; thus, the percent total injected dose (%ID) of each radionuclide in the spleen was used for comparison of CD45 targeting. Presumably, some of the spleen size variance was due to a decreased weight after ^{211}At was localized to the spleen. Because of the large variation in radionuclide concentrations in spleens of mice from the same group, discussions of localization or retention in that organ in the following paragraphs are limited to the percent of injected dose rather than injected dose per gram. The %ID in spleens for the ^{211}At and ^{125}I-labeled mAbs in the four biodistributions is shown graphically in Figure 5 and is provided in Table S5 (Supporting Information).

In an initial biodistribution study, [^{125}I]30F11-**1b** and [^{211}At]30F11-**1c** were coinjected and their tissue concentrations were evaluated. The concentrations (%ID/g) of ^{125}I and ^{211}At in selected tissues is shown graphically as Figure 4, panel A (Table S1, Supporting Information). Specific targeting of the CD45-containing cells in spleen can be seen in the average (±std dev) percent injected dose (%ID) of [^{125}I]30F11-**1b** in that tissue, which was 13.31 ± 0.78; 17.43 ± 2.56; 5.23 ± 0.50; and for [^{211}At]30F11-**1c** was 6.56 ± 0.40; 10.14 ± 1.49; 7.52 ± 0.79 at 1, 4, and 24 h sacrifice times (respectively). The concentrations of ^{211}At and ^{125}I in blood taken from mice at 1 h pi were found to be significantly different (Student's *t* test, $P < 0.05$), as were their concentrations in lung, liver, neck, and stomach. The fact that the concentrations of ^{211}At are higher than ^{125}I in lung, neck, and stomach is an indication that deastatination has occurred (*5*).

In a second biodistribution study, [^{125}I]30F11-**2** and [^{211}At]30F11-**2** were coinjected and their tissue concentrations were evaluated. The concentrations (%ID/g) of ^{125}I and ^{211}At in selected tissues are shown graphically as Figure 4, panel B (Table S2, Supporting Information). Specific targeting of the CD45-containing cells in spleen can be seen in the average (±std dev) of %ID in spleens of mice injected with [^{125}I]30F11-**2**, which was 21.15 ± 1.33; 22.22 ± 1.95; 12.41 ± 0.75; and [^{211}At]30F11-**2**, which was 22.78 ± 1.29; 25.05 ± 2.35; 17.30 ± 1.20 at 1, 4, and 24 h pi (respectively). It should be noted that the %ID values found in spleen for the radiolabeled 30F11 modified with a *closo*-decaborate(2-), **2**, is higher than that obtained for the same mAb modified using the *meta*-halobenzoate, **1b**/**1c**, labeling approach. This difference may be due to retention of the dianionic radiolabeled *closo*-decaborate(2-) mAb or metabolites rather than a difference in the labeled mAb targeting. Indeed, the fact that the liver and kidney concentrations of the radiolabeled *closo*-decaborate(2-) conjugate, 30F11-**2**, do not appear to decrease as quickly as the blood or lung concentrations seems to support retention in the metabolizing/excretory tissue. It is important to note that the only significant differences in distributions at 1 and 4 h pi of the two radionuclides, when using 30F11-**2**, was noted in the neck (1 h) and liver (4 h).

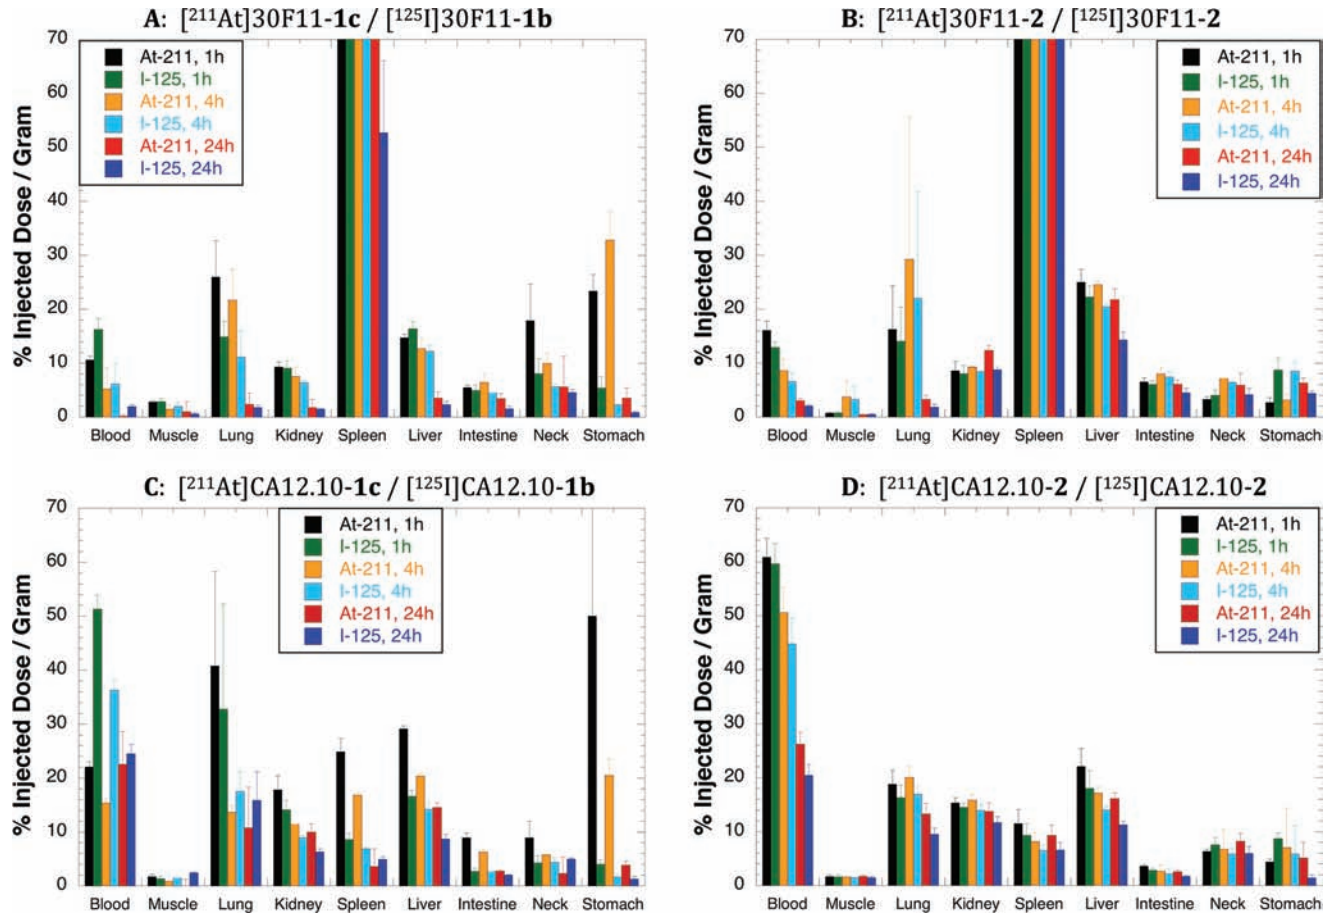

Figure 4. Graphs in panels A−D show concentrations of ^{211}At and ^{125}I in selected tissues of BALB/c mice. The four graphs are plots of data for the two mAbs labeled using two different methods. Black, brown, and red bars represent ^{211}At concentrations (%ID/g) at 1, 4, and 24 h pi (respectively), and green, light blue, and dark blue bars represent ^{125}I concentrations at 1, 4, and 24 h pi (respectively). The graphed data are from 5 mice per time point ± standard deviation (error bars). The highest concentration value has been limited to 70% ID/g so that the tissues with lower concentrations than spleen can be compared (see Tables S1−S4 in Supporting Information for complete data, including spleen values).

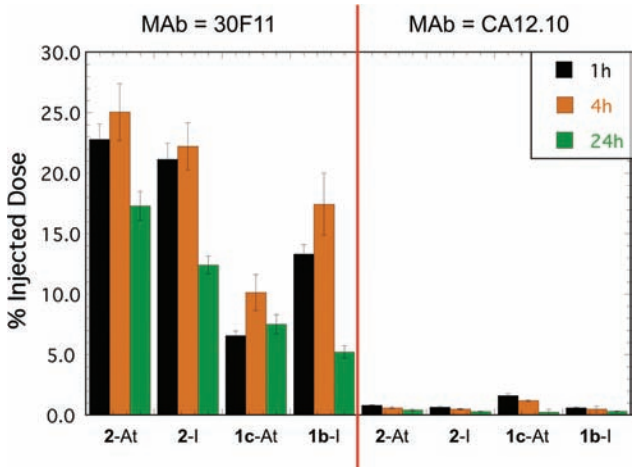

Figure 5. Graphed percent injected dose (%ID) of radiolabeled mAb conjugates in spleens of BALB/c mice. Each set of 3 bars represents the amount of ^{211}At- or ^{125}I-labeled mAb in spleen at 1 h (black), 4 h (brown), and 24 h (green) post injection. The conjugate on the antibody and radionuclide attached (At = ^{211}At; I = ^{125}I) are listed below each set of bars. The antibodies used are shown above the graph, with a red line separating the CD45 specific mAb (30F11) and the irrelevant mAb (CA12.10C12). Data were obtained from 5 mice per time period (per bar) and are plotted as the average %ID/g ± standard deviation (error bars).

The significant difference in neck concentrations at 1 h was not brought about by release of ^{211}At (it is lower), but rather by release of ^{125}I. Our studies have shown that the ^{211}At only reacts with the *closo*-decaborate(2-) (*15*). However, the ^{125}I appears to react with the *closo*-decaborate(2-) moiety (primarily), but also with tyrosine residues. Reaction with tyrosine residues permits release of [^{125}I]iodide after degradation of the protein (*25*). The low ^{211}At quantities in lung, stomach, and neck support our belief that there is a high stability of ^{211}At toward deastatination when attached to the *closo*-decaborate(2-) moiety.

In a third biodistribution, [^{125}I]CA12.10C12-**1b** and [^{211}At]CA12.10C12-**1c** were coinjected and their tissue concentrations were evaluated. The concentrations (%ID/g) of ^{125}I and ^{211}At in selected tissues is shown graphically as Figure 4, panel C (Table S3, Supporting Information). As expected, the canine-specific irrelevant antibody did not target the spleen. Significant differences (Student's *t* test; $P < 0.05$) between the ^{125}I and ^{211}At were seen in most tissues at all three time points. The differences in radionuclide concentrations in lung, spleen, neck, and stomach are visible on the graph. The higher concentrations of ^{211}At in those tissues indicate that deastatination has occurred.

In a fourth biodistribution, [^{125}I]CA12.10C12-**2** and [^{211}At]CA12.10C12-**2** were coinjected and their tissue concentrations were evaluated. The concentrations (%ID/g) of ^{125}I and ^{211}At in selected tissues is shown graphically as Figure 4, panel D (Table S4, Supporting Information). Interestingly, the blood concentrations for the irrelevant mAb are what might be expected for an intact mAb that does not localize in any tissue and does not release the ^{211}At. There were no significant differences (Student's *t*; $P < 0.05$) in ^{211}At or ^{125}I concentrations for most tissues. Although there are significant differences in intestine and stomach at 1 h pi, and

lung, kidney, and liver at 4 h pi, the differences are quite small. Deastatination does not appear to occur, and again, the significant difference between the radionuclides at 1 h pi appears to be due to deiodination rather than deastatination.

DISCUSSION

Our interest in switching from ^{213}Bi-labeled anti-CD45 mAb to ^{211}At-labeled anti-CD45 mAb as a replacement for TBI in a conditioning regimen required additional preclinical studies to be conducted. Prior to evaluation of ^{211}At-labeled anti-CD45 mAb in the dog model, we felt it was important to gain a better understanding of the differences between ^{211}At- and ^{213}Bi-labeled anti-CD45 mAbs in the mouse model. The mouse represents a better model to observe the differences that were expected as larger numbers of animals could be assessed to gain statistical significance in the data (*26*). Before initiating that study, a decision on the method to be used for labeling the mAb with ^{211}At was required.

Labeling of proteins with ^{211}At is very different from labeling with its nearest halogen neighbor, radioiodine, as directly astatinated proteins are readily deastatinated in vivo (*5*). To circumvent this inherent instability, indirect (two-step) protein labeling approaches employing protein reactive reagents that have ^{211}At-aryl bonds were developed (*27, 28*). One of those reagents, *N*-hydroxysuccinimidyl *meta*-[^{211}At]astatobenzoate, [^{211}At]**1c**, has been used in preparation of an astatinated antibody for clinical evaluation (*12*). That fact made the [^{211}At]**1c** labeling reagent of particular interest, as its prior use in a clinical study may make it easier to conduct another clinical study employing that labeling approach from a regulatory standpoint. Further, literature examples demonstrating that intact mAbs labeled with aryl conjugates can be relatively stable to in vivo deastatination (*6,29,30*) offered hope that would be the case for our anti-CD45 mAbs. However, the two-step procedure for labeling with the benzoate NHS ester can be quite problematic. While labeling the stannylbenzoate, **1a**, provides high yields, issues with hydrolysis of the active ester in the second step often decrease the yields substantially (maximum yields 40−60% being obtained). Recent reports indicate that this is particularly true when scaling up to clinical levels of ^{211}At. Although the initial report on using the [^{211}At]**1c** in clinical preparations indicated that radiolysis was not a factor in labeling (*31*), subsequent studies indicated that there was a problem with radiolysis in higher-level clinical preparations (*16*−*18*). This difficulty in obtaining high labeling yields, along with the fact that aryl-^{211}At conjugates are not always stable toward in vivo deastatination, made it prudent to evaluate another labeling approach as well.

Results from our studies of boron cage moieties as reactive groups for labeling with ^{211}At also made that approach to labeling of interest for astatination of the anti-CD45 mAb. In prior studies, it was demonstrated that mAb Fab′ fragments conjugated with a halogen-reactive *closo*-decaborate(2-), **2**, then astatinated had a high in vivo stability toward deastatination (*15*). The same mAb Fab′ labeled with *N*-hydroxysuccinimidyl *para*-[^{211}At]benzoate was quite unstable to in vivo deastatination, making it apparent that ^{211}At-labeled mAb conjugates containing the *closo*-decaborate(2-) moiety had higher in vivo stability to deastatination. In addition to the high stability, the simplicity of direct labeling of the protein (same as radioiodination reactions) and high yields obtained (70−80%) in the prior studies made this new labeling approach very attractive for the anti-CD45 study. Further, direct labeling of mAb-decaborate(2-) conjugates with ^{211}At eliminates the issues of hydrolysis and/or radiolysis of the labeling reagents used in the two-step approach. The direct labeling approach should also minimize radiolysis of the labeled protein as the reactions are conducted in aqueous medium and the fast labeling kinetics (i.e., 30 s) allows rapid introduction of a radioprotective reagent such as citrate or ascorbate.

The differences in ^{211}At labeling yields for the two approaches were surprising. While the high labeling yields for the mAbs conjugated with the *closo*-decaborate(2-) were expected, the low yields obtained with [^{211}At]**1c** were unexpected. Our prior experiences with labeling mAbs using the astatinated benzoate esters suggest that the conjugation yields should be in the range 40−60%. On the basis of the purity of the ^{211}At-labeled benzoate NHS ester (see Figures S1 and S3, Supporting Information), it seems likely that hydrolysis of the NHS ester occurred during isolation or conjugation, resulting in the low yields. Importantly, the results point out the potential for difficulties in labeling using the ^{211}At-labeled benzoate approach.

The in vivo distribution might be considered the most important measure of the value of each ^{211}At-labeling approach. Specific targeting of radiolabeled 30F11 to CD45-containing cells within the spleen was achieved irrespective of the method of labeling; however, higher quantities appeared to be attained with radiolabeled 30F11-**2** (Figure 5). The difference seen may be reflective of a higher retention of the radiohalogenated *closo*-decaborate(2-) metabolites rather than lower amounts accumulated with the radiohalogenated benzoate conjugates. While the amounts of ^{125}I and ^{211}At in spleen are similar for radiolabeled 30F11-**2**, they are very different for 30F11-[^{211}At]**1c** and 30F11-[^{125}I]**1b**. That difference is likely due to deastatination of the benzoate, but that does not occur unless the protein is metabolized. We did not expect to observe deastatination of mAbs labeled with [^{211}At]**1c** in these studies, as the CD45 antigen is not internalized. However, this example is consistent with other examples in the literature that suggest stability toward in vivo deastatination may be dependent on the antibody/cell targeting system involved (*9, 10, 32*).

The deastatination decreases the amount of ^{211}At in the target organ (spleen) and increases it in the nontarget tissues, e.g., lung. On the other hand, the ^{211}At-labeled *closo*-decaborate(2-) conjugate, [^{211}At]30F11-**2**, has a higher uptake in liver than the *meta*-benzoate conjugate, [^{211}At]30F11-**1c**. This might be perceived as a problem of nonspecific localization (or retention) in the liver. However, after comparison of the liver ^{211}At concentrations in Figure 4, panels B, C, and D, it appears that the higher concentrations in liver may be due to specific binding with CD45 antigens in that tissue. This statement is based on the fact that the amount of radioiodinated irrelevant mAb, CA12.10C12, in the liver is the same irrespective the method of the labeling.

CONCLUSIONS

This investigation was conducted to compare ^{211}At labeling of an anti-CD45 mAb, 30F11, and an irrelevant mAb, CA12.10C12, using a conventional astatination approach, i.e., conjugation of *N*-hydroxysuccinimidyl *meta*-[^{211}At]astatobenzoate, and a new labeling approach where the mAbs were labeled after conjugation with a *closo*-decaborate(2-) derivative. The studies demonstrated the utility of *closo*-decaborate(2-) mAb conjugates over the *meta*-[^{211}At]benzoate conjugates for labeling with ^{211}At. The studies further confirmed that the ^{211}At-labeled mAb conjugates had a high in vivo stability to deastatination. Additionally, it was demonstrated that CD45 specific targeting was not adversely affected by the protein modification step. These factors, along with the simplicity of labeling using this method and the potential benefit for scale-up to clinical levels of ^{211}At labeled mAbs, make the mAb-*closo*-decaborate(2-) conjugates our preferred choice for continuing studies with ^{211}At-

labeled anti-CD45 mAbs as a replacement of TBI in conditioning for hematopoietic cell transplantation.

Box 162366, Orlando, Florida 32816-2366, and Winship Cancer Institute, Emory University School of Medicine, Atlanta, Georgia 30322. Received July 8, 2009; Revised Manuscript Received September 8, 2009

Closely involved in the progression of nonlinear bioimaging is the development of optical probes for investigating biological function and activity. Introduction of new fluorescent compounds possessing enhanced nonlinearities is essential for advancing the utility of two-photon absorption (2PA) processes in the biological sciences. Herein, we report the synthesis of fluorene-based fluorophores tailored for multiphoton imaging, incorporating the succinimidyl ester and thioester functionality as reactive linkers for further coupling with a wide variety of biologically relevant molecules. The succinimidyl ester amine reactive probe was conjugated with the cyclic peptide RGDfK and polyclonal antirat IgG protein. Upon conjugation, the basic molecular architecture and photophysical properties of the active 2PA chromophore remain unchanged. Conventional and two-photon fluorescence microscopy (2PFM) imaging of COS-7 and HeLa cells, incubated with either the fluorene−RGD peptide conjugate or the fluorene−IgG conjugate, was demonstrated. The fluorene−IgG conjugate was used to image cell spindles at early mitotic developmental stages.

INTRODUCTION

In recent years, enormous interest in the design, synthesis, and characterization of fluorescent compounds with high two-photon absorption (2PA) cross sections has been increasing because of their recognized application in a number of multidisciplinary areas, particularly in the rapidly developing fields of multiphoton fluorescence imaging, optical data storage and switching, optical sensor protection, laser dyes, three-dimensional (3D) microfabrication, and photodynamic therapy (*1*−*6*). Multiphoton fluorescence bioimaging is one of the most promising among these applications, using fluorescent markers or intrinsic fluorescence in biological samples to gain insight into 3D cell structure.

Compared to conventional optical microscopy, two-photon excited fluorescence (2PEF) microscopy has a number of advantages, with the first being the inherent 3D localization of excitation and fluorescence arising from the quadratic dependence on the input intensity. This quadratic or nonlinear dependence limits excitation to a tiny focal volume, which restricts both out-of-focus background excitation and provides intrinsic confocality, since only fluorophores in the plane of the focused beam will be excited. This prevents the need for a confocal aperture in front of the detector, thus maximizing the amount of light detected (*7*). Second, 2PEF microscopy utilizes the near-infrared (NIR) spectral window, so the imaging depth is much greater and scattering is reduced, resulting in less photodamage and photobleaching than that caused by one-photon excited fluorescence techniques (*8*−*10*). In addition, higher signal-to-background ratios for fluorescence detection are possible resulting from well-separated excitation and emission wavelengths and reduced attenuation of NIR light in biological specimens relative to UV and visible wavelengths (*7*). To overcome depth of light penetration challenges, recently, progress has been reported in the use of luminescence upconversion using lanthanide ion-doped nanoscrystals (*11*). The lanthanide ion-doped nanocrystals exhibit good photostability and show reduced auotfluorescence, though spatial resolution is still an issue, since the excitation relies on sequential linear absorption of two photons.

The potential of two-photon excitation (2PE) as a tool in fluorescence microscopy of biological samples cannot be realized without fluorescent probes or dyes possessing high 2PA cross sections for labeling nonfluorescent molecules, such as proteins, nucleic acids (NA), and peptides. Fluorescent dyes such as Alexa Fluor 405, ethidium bromide, 4′,6-diamidine-2-phenylindole (DAPI), and Hoechst, which are widely used in fluorescence studies, have been shown to undergo 2PE fluorescence when complexed with NAs (*12*, *13*) though their 2PA cross sections are low.

Fluorescent probes with reactive groups are highly desirable since they can be conjugated with a vast number of biomolecules (*14*−*21*). Fluorene derivatives typically exhibit high fluorescence quantum yields and excellent photostability (*22*, *23*). Recently, fluorene-based bioconjugates have been reported as excellent 2PF materials, possessing high 2PA cross sections (*24*−*28*). As part of our efforts to develop high-efficiency 2PA fluorene derivatives as novel fluorescent biomarkers, we found that A-$\pi-\pi-\pi$-A type compounds (where A is an electron withdrawing moiety and π represents a conjugated system of π bonds), such as 2,7-bis[4-(9,9-didecylfluoren-2-yl)vinyl]phenylbenzothiazole, exhibited reasonably high 2PA cross sections in the NIR, e.g., ∼1185 GM at 800 nm (1 GM = 10^{-50} cm^4 s photon^{-1}) (*25*, *28*) with near-unity fluorescence quantum yield. However, this compound is rather hydrophobic, thereby limiting its applications in biological imaging.

By introducing one or two ethylene glycol moieties at the 9-position of the fluorene, the water solubility of the fluorene-based fluorescent probes can be greatly improved, facilitating

the use of these dyes for cellular imaging. In addition, substitution at the fluorenyl 9-position with a succinimidyl-containing moiety provides a reactive linker for further biomolecule conjugation. Herein, we report the synthesis and comprehensive characterization of a new fluorescent probe and a simple protocol of attaching this fluorescent label on an antibody to increase immunoassay sensitivity. In this work, goat antirat IgG antibody labeled with fluorene-NHS (**1**) was used to stain microtubules and mitotic cells.

EXPERIMENTAL SECTION

Materials and Methods. 2-(4-Vinylphenyl)benzothiazole **E** was synthesized as previously reported (*25*). The cyclic peptide (Ar-Gly-Asp-D-Phe-Lys) c(RGDfK) was purchased from Peptides International, Inc. Polyclonal antirat IgG (whole molecule) was purchased from Aldrich. All other chemicals and reagents were purchased from Aldrich or Acros Organics, and used as received unless otherwise noted. ^{1}H and ^{13}C NMR spectroscopic measurements were performed using Varian 500 or 300 NMR spectrometers at 500 or 300 MHz for ^{1}H (referenced to TMS at $\delta = 0.0$ ppm) and 125 or 75 MHz for ^{13}C (referenced to $CDCl_3$ at $\delta = 77.0$ ppm). Elemental analyses were performed at Atlantic Microlab, Inc., Norcross GA. High-resolution mass spectrometry (HR-MS) analysis was performed in the Department of Chemistry, University of Florida, Gainesville, FL.

Synthesis of 9-(2-(2-Methoxyethoxy)ethyl)-fluorene (A). A solution of fluorene (6 g, 36.09 mmol) in dry THF (120 mL) was treated under nitrogen at −78 °C with *n*-BuLi (1.6 M in hexanes, 24 mL) over a 25 min period. After addition, the temperature was allowed to rise to room temperature and stirring continued for 1 h. The mixture was then cooled to −78 °C and treated with a solution of bromo-2-(methoxyethoxy)ethane (4.9 mL, 36.1 mmol) in THF (30 mL). The temperature was then allowed to rise to room temperature, and the mixture was stirred overnight. The yellow solution was neutralized with 5% HCl, and the THF was evaporated in vacuo. Extraction of the aqueous phase with CH_2Cl_2 yielded yellow oil. Purification was carried out by column chromatography using hexane/ethyl acetate (4:2) to give 7.45 g of colorless oil (77% yield). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.75 (d, 2H, Ph-H), 7.53 (d, 2H, Ph-H), 7.37 (m, 4H, Ph-H), 4.11 (t, 1H, CH), 3.5 (m, 10H, CH_2O, CH_3), 2.31 (q, 2H, CH_2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 147.01, 140.94, 127.03, 126.92, 124.55, 119.86, 71.94, 70.15, 68.42, 59.13 (CH_3), 44.52 (C9), 32.85 (CH_2). Anal. Calc. for $C_{18}H_{20}O_2$ (MW: 268.35): C, 80.56; H, 7.51; O, 11.92. Found: C, 80.55; H, 7.56.

Synthesis of 3-(9-(2-(2-Methoxyethoxy)ethyl)-fluoren-9-yl)-propanenitrile (B). 9-(2-(2-Methoxyethoxy)ethyl)-fluorene (4.44 g, 16.54 mmol) was dissolved in *p*-dioxane (28 mL) at room temperature. The solution was degassed under vacuum and nitrogen, after which it was treated with 40% aqueous solution of Triton B (0.25 mL). After addition, the mixture turned from light yellow to reddish brown color. The resulting solution was then treated with acrylonitrile over a 10 min period. The reaction temperature was maintained between 30 and 40 °C by occasional cooling with ice−water throughout the addition period. The red solution thus obtained was then stirred at room temperature for 16 h. The reaction was neutralized with 10% HCl, followed by addition of distilled water. Extraction with CH_2Cl_2 afforded orange oil. The crude product was purified by column chromatography using hexane/ethyl acetate (3:2) as eluent to afford 4.43 g of colorless oil (83% yield). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.72 (d, 2H, Ph-H), 7.41 (m, 6H, Ph-H), 3.29 (bd, 7H), 2.81 (t, 2H, CH_2), 2.45 (q, 4H, CH_2), 1.49 (t, 2H, CH_2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 146.74, 140.80, 128.07, 127.90, 122.93, 120.23, 119.60 (CN), 71.71, 69.95, 67.08, 59.01, 52.31, 39.04 (C9), 35.94, 11.76 (CH_2). Anal. Calc. for $C_{21}H_{23}NO_2$ (MW: 321.41): C, 78.47; H, 7.21; N, 4.36. Found: C, 78.37; H, 7.19; N, 4.44.

Synthesis of 3-(9-(2-(2-Methoxyethoxy)ethyl)-2,7-dibromo-fluoren-9-yl)propanenitrile (C). To a solution of 3-(9-(2-(2-methoxyethoxy)ethyl)-fluoren-9-yl)propanenitrile (4.71 g, 14.66 mmol) in propylene carbonate (31 mL) at 60 °C, *N*-bromosuccinimide (NBS, 7.38 g, 44.02 mmol) was added in one portion and the mixture was kept at 60 °C for 24 h. The reaction was diluted with water and extracted with CH_2Cl_2. The organic phase was washed several times with water, dried over $MgSO_4$, filtered, and concentrated under reduced pressure to give viscous brown oil. Purification was carried out by silica gel column chromatography using hexanes/ethyl acetate (3.5:1.5) as eluent to afford 4.5 g of a white solid (64% yield) mp = 92.5−93.5 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.54 (m, 6H, Ph-H), 3.31 (s, 5H), 3.22 (t, 2H), 2.87 (t, 2H), 2.43 (t, 2H), 2.36 (t, 2H), 1.53 (t, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 148.77, 138.75, 131.54, 126.54, 122.23, 121.66, 118.94 (CN), 71.70, 70.06, 66.79, 59.07, 52.93, 38.93 (C9), 35.53, 11.90 (CH_2). Anal. Calc. for $C_{21}H_{21}Br_2NO_2$ (MW: 479.2): C, 52.63; H, 4.42; Br, 33.35; N, 2.92; O, 6.68. Found: C, 52.50; H, 4.43; N, 2.93.

Synthesis of 3-(9-(2-(2-Methoxyethoxy)ethyl)-2,7-dibromo-fluoren-9-yl)propanoic Acid (D). A mixture of 3-(9-(2-(2-methoxyethoxy)ethyl)-2,7-dibromo-fluoren-9-yl)propanenitrile (2.1 g, 4.38 mmol), ethylene glycol (100 mL), and aqueous NaOH (3M, 14 mL) was heated to reflux for 24 h. Ethylene glycol was removed under vacuum distillation producing yellow oil that was then neutralized with 10% HCl (aq) and extracted with CH_2Cl_2. The crude product was purified via column chromatography using hexanes/ethyl acetate (1:1) as eluent to afford 1.65 g of a white solid (76% yield) mp = 96−97 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.44 (m, 6H, Ph-H), 3.23 (bm, 7H, CH_2O, CH_3), 2.73 (t, 2H, CH_2), 2.31 (m, 4H, CH_2), 1.51 (t, 2H, CH_2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 178.10 (COOH), 149.94, 138.81, 131.04, 126.55, 121.90, 121.43, 71.69, 69.96, 66.92, 59.04, 52.85, 39.08 (C9), 34.50, 28.21. Anal. Calc. for $C_{21}H_{22}Br_2O_4$ (MW: 498.2): C, 50.63; H, 4.45; Br, 32.08; O, 12.85. Found: C, 50.68; H, 4.56.

Synthesis of 3-(9-(2-(2-Methoxyethoxy)ethyl)-2,7-bis(4-(benzothiazol-2-yl)styryl)-fluoren-9-yl)propanoic Acid (F). 3-(9-(2-(2-Methoxyethoxy)ethyl)-2,7-dibromo-fluoren-9-yl)propanoic acid (0.25 g, 0.50 mmol), 2-(4-vinylphenyl)benzothiazole (0.26 g, 1.51 mmol), $Pd(OAc)_2$ (0.04 g, 0.19 mmol), and P(*o*-tolyl)$_3$ (0.10 g, 0.34 mmol) were transferred to a high-pressure Schlenk tube. To this, 8 mL of DMF/Et_3N (5:1) mixture was added. The Schlenk tube was then sealed and stirred at 90 °C for 90 h. The mixture was cooled to room temperature and filtered. The solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel, eluting first with hexane/THF (1:1), then hexane/ethyl acetate (1:1) as eluent to afford a yellow solid 0.28 g (70% yield) mp = 179−180 °C. ^{1}H NMR (500 MHz, DMSO) δ: 11.95 (s, 1H, COOH), 8.08−8.04 (m, 6H, Ph-H), 7.98 (d, 2H, Ph-H), 7.84 (s, 2H, Ph-H), 7.79−7.74 (m, 6H, Ph-H), 7.59 (d, 2H, Ph-H), 7.50−7.37 (m, 4H, CH═CH, and 4H, Ph-H), 3.27 (q, 2H, CH_2O), 3.04−3.017(m, 5H, CH_2O, CH_3), 2.64 (t, 2H, CH_2O), 2.39−2.30 (m, 4H, CH_2), 1.33 (t, 2H, CH_2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 174.46 (COOH), 167.42 (Ar−C═N), 154.12, 149.95, 140.79, 140.52, 136.78, 134.90, 132.10, 128.21, 128.05, 127.78, 127.62, 127.18, 126.86, 123.35, 123.18, 122.93, 122.73, 121.61, 121.46, 121.09, 71.55, 69.62, 67.07, 58.18, 52.39, 38.86 (C9), 34.20, 28.99. HR-MS-ESI theoretical *m*/*z* $[M+H]^+$ = 811.26, found 811.26.

Synthesis of Fluorene−NHS (1). 3-(9-(2-(2-Methoxyethoxy)-ethyl)-2,7-bis(4-(benzothiazol-2-yl)styryl)-fluoren-9-yl)propanoic acid (0.2 g, 0.246 mmol) was dissolved in dimethylformamide

(DMF) (3.5 mL) under N_2; then, *N*-hydroxysuccinimide (0.031 g, 0.27 mmol) was added to the mixture at room temperature. *N*,*N*′-Dicyclohexylcarbodiimide (DCC) (0.057 g) was added via syringe and the mixture was stirred at room temperature for 36 h. The mixture was then filtered and diluted with 3−4 volumes of ether to precipitate the dye. The solid was collected by filtration, redissolved in a minimum volume of DMF, and then reprecipitated by addition of ether. The solid was collected and dried to afford 0.2 g of a yellow solid (90% yield) mp = 217−218 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.13 (dd, 6H, Ph-H), 7.93 (d, 2H, Ph-H), 7.72 (t, 6H, 4H, CH═CH, and 4H, Ph-H), 7.61 (s, 2H, Ph-H), 7.58 (d, 2H, Ph-H), 7.52 (t, 2H, Ph-H), 7.41 (t, 2H, Ph-H), 7.33 (m, 4H, Ph-H), 3.23 (m, 7H, OCH_2, CH_3), 2.88 (t, 2H, OCH_2), 2.76 (s, 4H, CH_2), 2.58 (m, 4H, CH_2), 1.95 (m, 2H, CH_2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 170.54 (C═O), 167.41 (Ar−C═N), 157.10, 154.17, 149.36, 140.85, 140.51, 137.07, 135.01, 132.23, 131.35, 128.26, 127.85, 127.31, 123.42, 122.97, 121.77, 71.85, 69.92, 58.76, 55.73, 52.60, 48.34, 34.23, 26.22, 25.38. HR-MS-ESI theoretical *m*/*z* $[M+H]^+$ = 908.27, found 908.28, theoretical *m*/*z* $[M+Na]^+$ = 930.26, found 930.26.

Synthesis of Fluorene−RGD Conjugate (2). Cyclic peptide (Ar-Gly-Asp-D-Phe-Lys) c(RGDfK) (15 mg, 0.024 mmol) was dissolved in DMSO (1.5 mL) and the pH was adjusted to 9 by adding aqueous $NaHCO_3$ (0.1 M). Fluorene−NHS (24 mg, 0.027 mmol) was added to the reaction mixture and stirred for 22 h. The mixture was then diluted with 4 volumes of ether to precipitate the dye. The solid was collected by filtration, redissolved in a minimum volume of DMSO, and then reprecipitated by addition of ether. The solid was collected and dried to afford 32 mg of a yellow solid (94% yield) mp = 236−236.5 °C. HR-MS-ESI theoretical *m*/*z* $[M+H]^+$ = 1396.56, found 1396.54, theoretical *m*/*z* $[M+Na]^+$ = 1418.55, found 1418.52. ^{13}C NMR (125 MHz, $CDCl_3$) δ:172.63, 172.10, 171.75, 171.48, 171.10, 167.66 (Ar−C═N), 157.37, 154.37, 150.50, 141.04, 140.80, 138.98, 136.97, 135.14, 132.33, 131.60, 129.62, 128.66, 128.37, 127.92, 127.60, 127.42, 126.66, 126.21, 123.50, 123.08, 121.87, 121.20, 107.66, 71.79, 69.84, 67.30, 58.65, 55.53, 53.44, 52.81, 51.48, 49.27, 43.77, 38.94, 33.84, 31.42, 29.58, 29.01, 25.82, 25.12, 24.26, 23.69.

Synthesis of *S*-Benzyl 3-(9-(2-(2-methoxyethoxy)ethyl)-2,7-bis(4-(benzo[d]thiazol-2-yl)styryl)-9*H*-fluoren-9-yl)propanethioate (3). The reaction was performed under dry N_2 atmosphere. Benzylmercaptan (140 μL, 1.2 mmol) was slowly added to a mixture of 0.6 mL of 2.0 M $Al(CH_3)_3$ (1.2 mmol) in hexane and 2.5 mL of anhydrous CH_2Cl_2 cooled to 0 °C. The reaction mixture was allowed to warm to room temperature over 30−40 min. A 2.5 mL solution of fluorene−NHS (50 mg, 0.05 mmol) in DMF was added slowly to the reaction mixture and stirred under nitrogen for 16 h. The reaction mixture was then poured into distilled water and extracted with CH_2Cl_2. The organic phase was dried over $MgSO_4$ and concentrated by vacuum. The mixture was then filtered and diluted with 4 volumes of ether to precipitate the dye. The solid was collected by filtration, redissolved in a minimum volume of DMF, and reprecipitated by addition of ether. The solid was collected and dried to afford 28 mg of a yellow solid (70% yield) mp = 164−165 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.04 (t, 6H, Ph-H), 7.84 (d, 2H, Ph-H), 7.61 (q, 6H, Ph-H), 7.49 (m, 6H, Ph-H), 7.33 (t, 2H, Ph-H), 7.16 (m, 10H, Ph-H), 3.88 (s, 2H, CH_2), 3.23 (m, 7H, OCH_2, CH_3), 2.78 (t, 2H, OCH_2), 2.47(q, 4H, CH_2), 1.82 (t, 2H, CH_2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 198.72 (C═O), 167.94 (Ar−C═N), 156.94, 154.47, 149.25, 140.77, 140.26, 137.67, 136.85, 135.27, 132.84, 130.62, 139.66, 129.37, 128.99, 128.80, 128.79, 128.73, 128.21, 127.93, 127.52, 127.45, 127.30, 127.27, 127.20, 126.63, 125.44, 123.40, 121.88, 121.27, 120.65, 71.97, 70.24, 67.48, 59.27, 52.48, 49.39, 39.75, 38.51, 34.20. HR-MS-ESI theoretical *m*/*z* $[M+H]^+$ = 917.28, found 917.28, theoretical *m*/*z* $[M+Na]^+$ = 939.27, found 939.26.

Preparation of Fluorene−IgG Conjugate (4). A solution of IgG (1 mg/mL) in freshly prepared $NaHCO_3$ (0.1 M, pH 9) solution was used. A stock solution of the amine-reactive probe **1** dissolved in anhydrous DMF (1.43×10^{-3} M) was freshly prepared and aliquots added dropwise into the IgG solution (0.3 mL) with gentle stirring. The concentration of the probe solution was varied such that a 1:15, 1:10, and a 1:5 mol ratio of protein to probe was prepared to obtain the desired dye to protein molar ratios. The reaction was kept in the dark and allowed to stir at room temperature for 2 h. The reaction mixtures were purified from the unreacted dye by size exclusion chromatography column (12 cm length, Bio-Rad Econo-Pac 10DG) equilibrated in and eluted with phosphate buffered saline (PBS, pH 7.2; Fisher). Fractions containing the IgG−fluorene bioconjugate were identified spectrophotometrically by monitoring both the protein fraction at 280 nm and the dye at 418 nm. The degree of labeling (DOL) was determinated as the ratio of moles of fluorophore to moles of protein (F/P) as previously described (*30*).

COS-7 Cells Incubated with Fluorene−RGD Peptide Conjugate (2). COS-7 cells were plated onto 4-well glass chamber slides. Stock solutions of fluorene−RGD peptide conjugate **2** dissolved in DMSO were prepared at concentrations of either 1 or 10 μM. Diluted solutions in complete growth medium were then freshly prepared and placed over the cells for either a 1 or 2 h period. All cells were washed with PBS buffer (3×) and fixed using 3.7% formaldehyde solution for 5 min at room temperature.

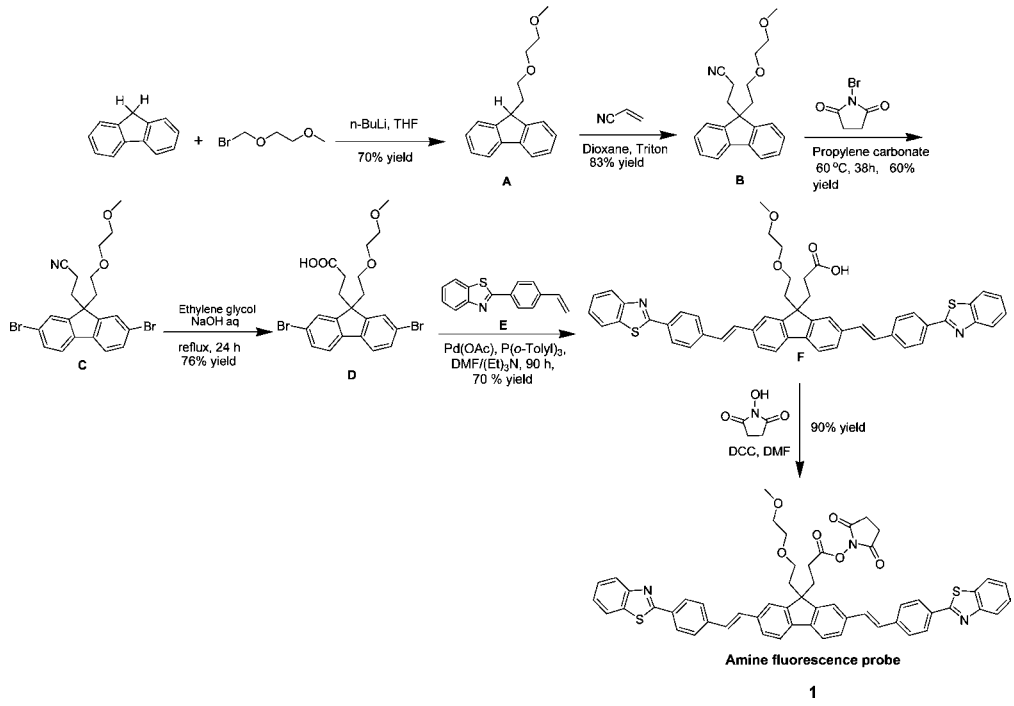
Immunofluorescence Analysis. HeLa Cells were fixed in PHEMO buffer (68 mmol/L PIPES, 25 mmol/L HEPES, 15 mmol/L EGTA, 3 mmol/L $MgCl_2$, 10% DMSO) with 3.7% formaldehyde, 0.05% glutaraldehyde, and 0.5% Triton X-100. Cells were washed in PBS buffer thrice for 5 min then blocked in 10% goat serum for 15 min. Microtubule staining was performed by incubating the cells with a primary antibody against tubulin from mouse, followed by incubating with the secondary antibody directed against mouse conjugated with amine reactive tag **1**.

One-Photon Spectral Measurements. Linear photophysical properties of new fluorescent probes were investigated in spectroscopic-grade solvents at room temperature. The steady-state absorption spectra were obtained with Agilent 8453 UV−visible spectrophotometer using 10 mm path length quartz cuvettes with dye concentrations of 1×10^{-5} M. The steady-state fluorescence spectra were measured with a PTI QuantaMaster spectrofluorimeter in 10 mm spectrofluorometric quartz cuvettes with dye concentrations of 1×10^{-6} M. All fluorescence spectra were corrected for the spectral responsivity of PTI detection system. Fluorescence quantum yields, *Q*, were measured for all compounds by a standard method (*31*), relative to Rhodamine 6G in ethanol ($Q = 0.94$) (*32*).

Conventional single-photon fluorescence images were obtained using an inverted microscope (Olympus IX70) equipped with a QImaging cooled CCD (Model Retiga EXi) and excitation mercury lamp 100 W. In order to improve the fluorescence background-to-image ratios, a customized filter cube (Ex 377/50, DM 409, Em 460/50) was used for the one-photon fluorescence images. The specifications of the filter cube were tailored to match the excitation wavelength of compounds **2** and **4**, and to capture most of its emission profile.

Two-Photon Absorption and Imaging Measurements. 2PA spectra of **1** were determined over a broad spectral region via a typical two-photon induced fluorescence (2PF) method relative to Rhodamine B in methanol and Fluorescein in water (pH = 11) as a standards (*33*, *34*). A PTI QuantaMaster spectrofluo-

Scheme 1. Preparation of the Succinimidyl Amine-Reactive Tag 1



rimeter and femtosecond Clark-MXR CPA-2010 laser that pumped an optical parametric generator/amplifier (TOPAS, Light Conversion), with pulse duration, ~140 fs, (fwhm), tuning range 580−940 nm, pulse energies ≤0.15 μJ, and 1 kHz repetition rate were used. Two-photon fluorescence measurements were performed in 10 mm fluorometric quartz cuvettes with dye concentrations of 3×10^{-5} M in DMSO. The quadratic dependence of two-photon induced fluorescence intensity on the excitation power was confirmed for each excitation wavelength.

Two-photon fluorescence microscopic images were obtained with a modified Olympus Fluoview FV300 microscope system combined with a tunable Coherent Mira 900F Ti:sapphire laser. The femtosecond NIR laser beam (with 220 fs pulse width and 76 MHz repetition rate) was tuned to 730 nm and used as a two-photon excitation source. The two-photon induced fluorescence intensity was collected by a 60× microscopic objective (UPlanSApo 60×, NA = 1.35, Olympus). A high-transmittance (>95%) short-pass filter (cutoff 685 nm, Semrock) was placed in front of the PMT detector of the FV300 scan head in order to filter off background radiation from the laser source (730 nm).

RESULTS AND DISCUSSION

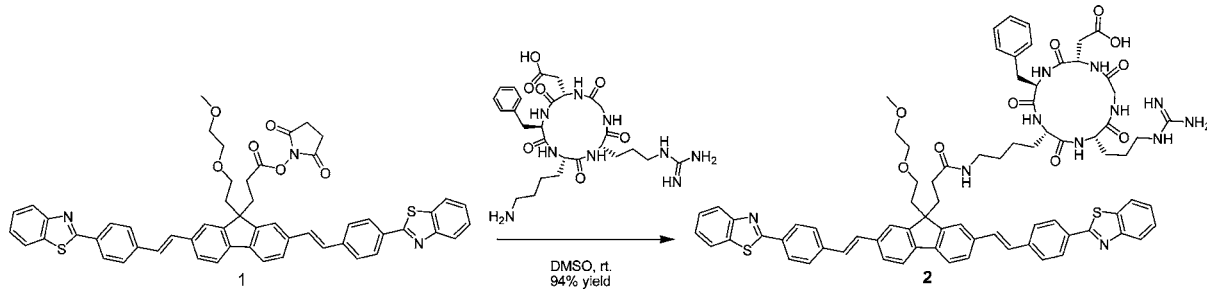
Synthesis and Characterization of the Fluorenyl Probes. Our previous results with 2PA fluorene-based dyes (*22*−*28*), encouraged us to further investigate this class of chromophores as two-photon excitable labels. Herein, we report the synthesis of novel two-photon excitable fluorescent labeling reagents, specifically designed to be used for molecular labeling. The symmetric hydrophobic compound 2,7-bis[4-(9,9-didecylfluoren-2-yl)vinyl]phenylbenzothiazole, an A-$\pi-\pi-\pi$-A archetype, comprises a rather promising chromophore and exhibited a 2PA cross section of ca. 1185 GM at 800 nm. Thus, we decided to design an amine reactive probe based on the same chemical structure of this chromophore.

Scheme 1. depicts the design of the amine reactive probe (**1**) and shows our straightforward strategy to incorporate the succinimidyl functionality as a reactive linker on the fluorenyl 9-position for further linkage with peptides or antibody or label a wide variety of biologically significant molecules. Synthesis of the reactive probe began with the monoalkylation of fluorene upon treatment with *n*-butyl lithium and 1-bromo-2-(2-methoxyethoxy)ethane in dry THF at −78 °C under nitrogen atmosphere. The product was purified via silica gel column chromatography to afford 9-[2-(2-methoxyethoxy)-ethyl]-fluorene (**A**) in 70% yield. The condensation of acrylonitrile in the presence of benzyltrimethylammonium hydroxide ("Triton B") as a catalyst with intermediate **A** via Michael addition reaction provided 3-{9-[2-(2-methoxyethoxy)-ethyl]-fluoren-9-yl}-propionitrile (**B**). Bromination of (**B**) with NBS in propylene carbonate produced intermediate (**C**) in 60% yield. The nitrile intermediate (**C**) was hydrolyzed with NaOH in ethylene glycol to afford 3-{2,7-dibromo-9-[2-(2-methoxyethoxy)-ethyl]-fluoren-9-yl}-propionic acid (**D**). 3-{2,7-Bis-[2-(4-benzothiazol-2-yl-phenyl)-vinyl]-9-[2-(2-methoxyethoxy)-ethyl]-fluoren-9-yl}-propionicacid (**F**) was prepared via efficient Pd-catalyzed Heck coupling reaction of **D** with 2-(4-vinylphenyl)benzothiazole (**E**) in 70% yield. Esterification reaction of intermediate **G** with *N*-hydroxysuccinimide was carried out in the presence of 1,3-dicyclohexylcarbodiimide (DCC), affording the succinimidyl amine reactive probe **1** in high yield (90%) as shown in Scheme 1.

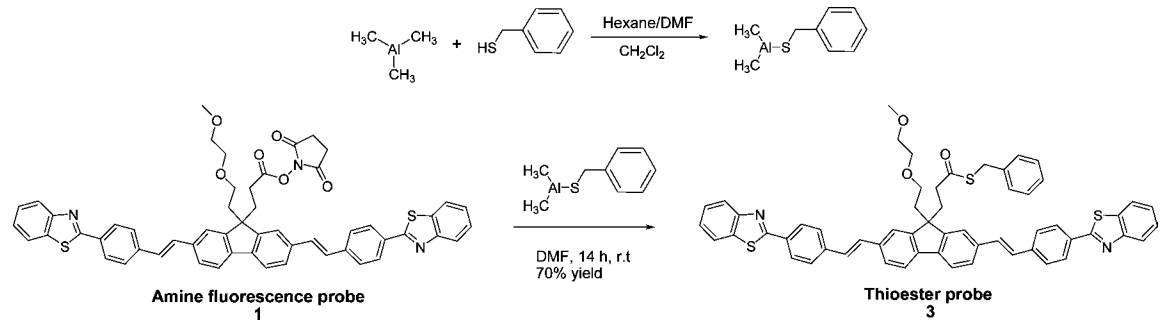
The utility of the activated ester was demonstrated by coupling chromophore **1** with RGDfK. Conjugation reaction of amine reactive probe **1** with commercial cyclopeptide (Ar-Gly-Asp-D-Phe-Lys) c(RGDfK) was carried out in DMSO at room temperature for 22 h, affording fluorene−RGD peptide conjugate (**2**) in high yield (Scheme 2). A similar protocol to the one described by Schuler et al. (*35*) was followed for the synthesis of the fluorene thioester probe (**3**), with slight modifications for the isolation and purification due to the specific properties of our probe (Scheme 3). This further demonstrates the versatility of amine-reactive probe **1**, as it can readily be converted to the thiol-reactive probe (**3**). All compounds were fully characterized by NMR and elemental)analysis or HR-MS.

Labeling of IgG. The use of specific antibodies labeled with fluorescent dyes to localize substances in tissues was first

Scheme 2. Preparation of the Fluorene-RGD Peptide Conjugate 2 with the Amine-Reactive Tag 1



Scheme 3. Preparation of the Thioester Probe 3 with the Amine-Reactive Tag 1



devised by A. H. Coons and associates (*36*). At first, the specific antibody itself was labeled and applied to the tissue section to identify the antigenic sites. Later, a more sensitive and versatile indirect method (*37*) was introduced. The primary, unlabeled antibody is applied to the tissue section, and the excess is washed off with buffer. A second, labeled antibody from another species, raised against the IgG of the animal donating the first antibody, is then applied. The primary antigenic site is thus revealed.

A major advantage of the indirect method is enhanced sensitivity. In addition, a labeled secondary antibody can be used to locate any number of primary antibodies raised in the same animal species without the necessity of labeling each primary antibody. There are many fluorophores used in labeling, including coumarin derivatives, phycobiliproteins, fluorescein, and rhodamine. The isothiocyanate derivatives of fluorescein and rhodamine are widely used to label antibodies. In addition, the newly introduced Alexa fluorochromes are a series of fluorescent dyes with excitation/emission spectra similar to that of commonly used probes under single-photon excitation (*38, 39*).

We previously reported the results of the conjugation of certain fluorene-based fluorophores with bovine serum albumin (BSA, fraction V) and Reelin (*40, 41*). BSA is an inexpensive commercially available protein, while Reelin is a large extracellular matrix glycoprotein, important in guiding neural stem cells in the central nervous system in normal development (*42, 43*).

Performance of the amine reactive probe **1** was studied by labeling of polyclonal antirat IgG. The conjugation of succidimidyl ester probe **1** with IgG was carried out according to standard methods (*30*). The fluorene−IgG conjugates were separated from unbound succidimidyl ester by gel filtration chromatography in saline phosphate buffer solution (PBS, pH 7.2). The conjugation did not lead to the quenching of the fluorescence signal of the succidimidyl ester. Thus, a series of experiments were carried out in order to evaluate (1) the maximum succinimidyl dye to protein molar ratio that can be attained without protein precipitation; (2) the optimum reaction time; and (3) the optical stability of the bioconjugate. The labeling degrees were determined spectrophotometrically. With

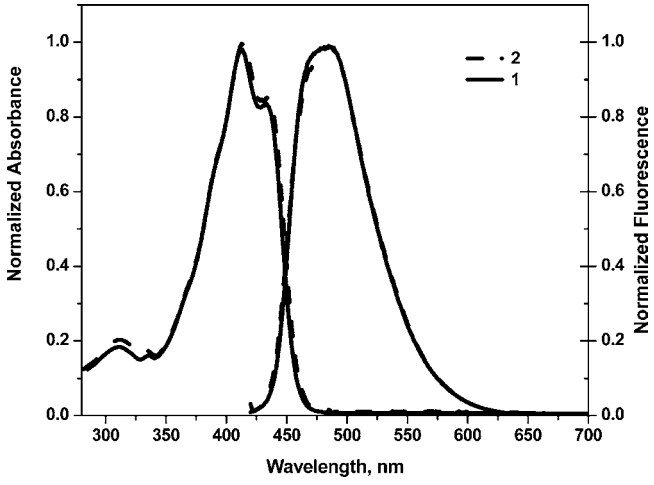


Figure 1. Normalized UV−visible absorbance and fluorescence emission spectra of amine-reactive tag **1** (—) $Qy = 0.68$, and fluorene−RGD peptide conjugate**2** (---) in DMSO $\lambda_{max}^{abs} = 413$ nm; $\lambda_{max}^{em} = 485$ nm; $Qy = 0.69$.

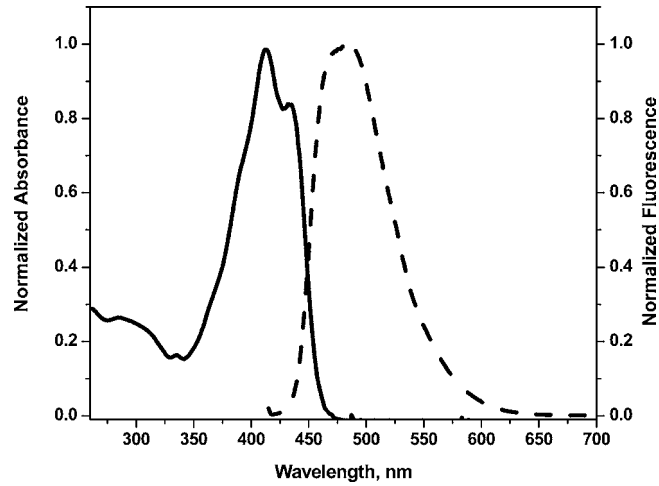

Figure 2. Normalized UV−visible absorbance (—) and fluorescence emission (---) spectra of thioester probe **3** in DMSO $\lambda_{max}^{abs} = 413$ nm; $\lambda_{max}^{em} = 485$ nm; $Qy = 0.67$.

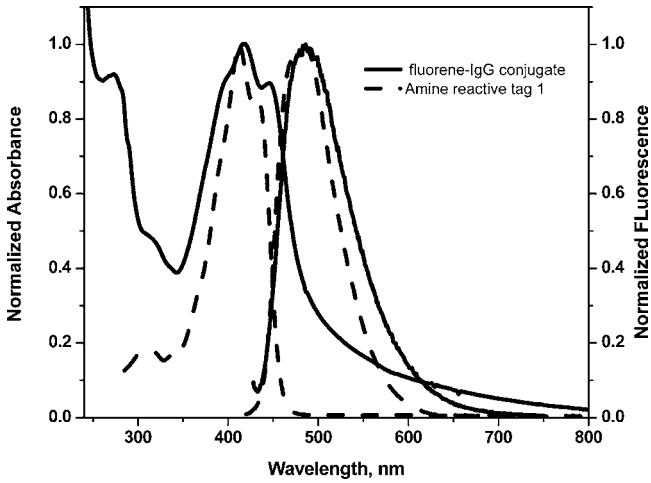

Figure 3. Normalized absorption spectra and steady-state fluorescence emission spectrum of amine-reactive tag **1** (—) and fluorene−IgG conjugate (---) in PBS buffer.

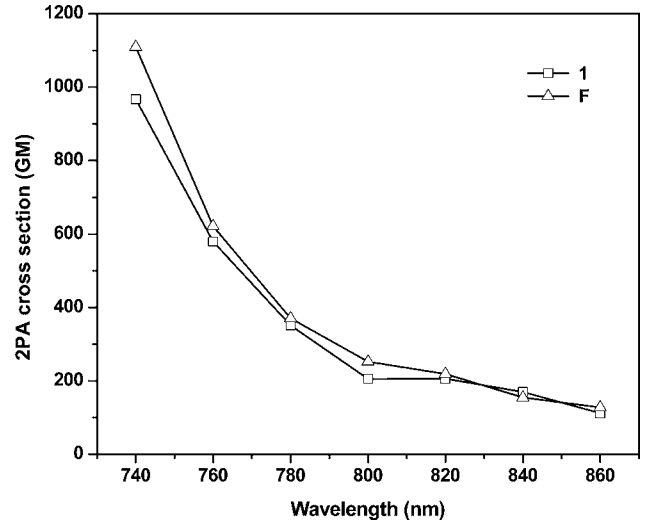

Figure 4. 2PA cross section values of carboxylic acid **F** and amine reactive tag **1** in DMSO, measured by the 2PF method using fluorescein at pH = 11 as reference.

succinimidyl derivative **1**, a degree of labeling of 3 and 6 fluorophores per IgG was obtained after a few hours of mixing the solutions containing the succinimidyl dye and the IgG, without precipitation of the conjugate. The intensities of the emission spectrum of the conjugates indicated that the signal intensity increased as the succinimidyl dye/protein molar ratio increased.

The normalized UV−visible absorption and steady-state fluorescence emission spectra of amine-reactive probe **1** and fluorene−IgG conjugate **4** in PBS (buffer pH 7.2) are shown in Figure 3. The fluorene−IgG conjugate exhibited absorption peaks corresponding to that of the IgG protein in the shorter-wavelength range (λ_{max} = 280 nm) as well as that of the fluorescent dye in the longer absorption range (λ_{max} = 416 and 447 nm), and exhibited an emission maximum at 445 nm (characteristic of the fluorenyl moiety). The absorption spectrum of the fluorene−IgG conjugate **4** showed only slight broadening compared to the absorption spectrum of the unbound fluorophore **1**.

Optical Properties of Fluorescent Markers. The RGD peptide substituent on the 9-position is not part of the chromophore's π-conjugated system of **1**; thus, there is no significant alteration of the photophysical properties of fluorene−RGD

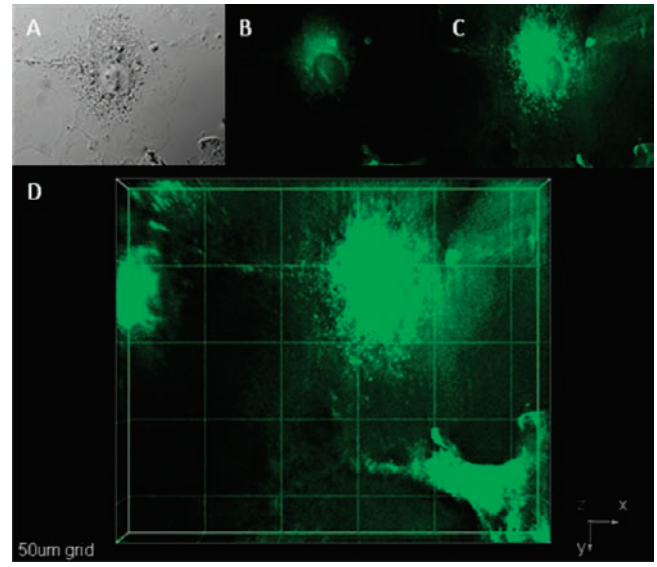

Figure 5. COS-7 cells in PBS media, incubated for 1 h with the fluorene−RGD peptide conjugate **2** from a 10 μM solution in DMSO; UPlanSApo, NA = 1.35, 60× oil immersion. (A) DIC, 34 ms; (B) one-photon fluorescence (Ex: 377/50-DM:409-Em: 525/40), 755 ms; (C) two-photon upconverted fluorescence, overlay of all planes, 730 nm; (D) 3D reconstruction from overlaid upconverted fluorescence images from complete field, 50 μm grid.

peptide conjugate **2** relative to succinimidyl amine reactive probe **1**. The absorbance maximum was observed at 413 nm for both derivatives with an emission maximum at 485 nm in DMSO. The fluorescence quantum yield (0.68) was nearly unaltered in fluorene−RGD peptide conjugate **2** (Figure 1). Additionally, no significant differences of the fluorene thioester **3** compared to the succinimidyl ester **1** were detected. The absorbance maximum was at 413 nm for both derivatives, and the fluorescence quantum yield (0.69) remained practically unaltered for the thioester (Figure 2).

2PA cross sections (δ) were obtained by the up-conversion fluorescence method using a femtosecond Ti:sapphire laser as excitation source (*33*, *34*). The uncertainty in the experimental δ values is estimated to be ±15%. The 2PA cross section measurements of symmetrical amine-reactive probe **1** and carboxylic intermediate **F** were performed in DMSO (1.6×10^{-3} M). Although, the symmetric fluorene derivatives **1** and **F** are not strictly centrosymmetric systems, they exhibit the same parity selection rules associated with centrosymmetric systems. As indicated in Figure 4, amine-reactive probe **1** and intermediate **F** show small 2PA in the first excited state, identified by the peak in the linear absorption spectrum located approximately at 415 nm (250 GM at 830 nm). This is expected given the symmetric structure of the A-$\pi-\pi-\pi$-A molecules **1** and **F**. The second 2PA peak at ~370 nm is a two-photon allowed state and exhibited a substantially higher 2PA cross section of ~1000−1100 GM at 740 nm (Figure 4).

Single- and Two-Photon Fluorescence and Cell Imaging. The ability of fluorene−RGD peptide conjugate **2** to be taken up into cells was examined using COS-7 cells (Figure 5a−d). Cells were incubated with a solution of 10 μM DMSO solution of chromophore **2**, and after 1 and 5 h incubation times, images were taken with a modified Olympus Fluoview FV300 microscope system. Strong fluorescence was observed after 5 h of incubation, with a homogeneous coloration of the cytoplasmic region. Differential interference contrast (DIC) and conventional (one-photon) fluorescence microscopic images of the stained cells are shown in Figure 5a,b. Two-photon fluorescence microscopy (2PFM) images of the fluorene−RGD peptide conjugate **2** containing cells were collected using a modified

(A) DIC, 350 ms; (B) one-photon fluorescence (Ex: 377/50-DM:409-Em: 525/40), 350 ms; (C) overlay of A and B; (D) one-photon fluorescence (Ex: 377/50-DM:409-Em: 525/40), 25 ms; (E) one-photon fluorescence intensity graphs, 25 ms. Arrows in B, D, and E show mitotic cells. Scale bar 10 μm.

Olympus Fluoview FV300 microscope system coupled to a tunable Coherent Mira 900F Ti:sapphire laser. Two-photon induced fluorescence was observed predominantly from the cytoplasmic region, consistent with the images collected via one-

photon fluorescence imaging (Figure 5c). 3D reconstruction from overlaid upconverted fluorescence images from the complete field is shown in Figure 5d.

Having confirmed the cellular uptake of the fluorescent probes, the fluorene−IgG conjugate was investigated and compared with the analogous Alexa 488 conjugate, known for its efficiency in microtubule staining. Amine-reactive dye **1** was conjugated on a secondary antibody (Antirat IgG). The images were acquired via confocal microscopy and shown in Figure 6, panels a−c. Imaging results with the fluorene−IgG conjugate were reproducible and in accordance with images using the Alexa Fluor 488 conjugate. Figure 6b visibly shows the localization of microtubules labeled with the bioconjugate. The fluorescence intensity of microtubules labeled with fluorene−IgG conjugate was comparable to that of Alexa Fluor 488, with the fluorene-based probe possessing both higher two-photon absorptivity and increased photostability.

Mitosis, the process by which identical copies of the replicated genome are distributed to the daughter cells at each cell division, depends on the action of a bipolar protein machine—the mitotic spindle. The action of mitotic spindles is crucial for the formation, maintenance, and reproduction of healthy organisms. Consequently, the morphology and dynamics of zygote spindles during the mitotic process contains abundant biological information (*44*, *45*). Here, labeling microtubules with amine reactive probe **1**, conjugated with the antirat IgG antibody, facilitated acquisition of images of spindles by confocal fluorescence microscopy at different stages of mitosis (Figure 7). Application of fluorene−IgG conjugate for investigating the ultrastructure of cells and tissues by one-photon and two-photon fluorescence microscopy greatly expands the possibilities for localization of antigens. In addition, a wide variety of fluorene conjugates of immunoglobulins of different specificities or a variety of other proteins can be prepared. Further, this method offers new possibilities to perform double labeling experiments with two antibodies at the ultrastructural level.

The high selectivity that this fluorene−IgG conjugate exhibited for microtubules may lead to interesting applications, e.g., cytometric assays for mitosis where co-staining would not be necessary. Simply recording the image with different exposure times may allow calculation of the average number of cells that are undergoing mitosis. In the case of Figure 8, a cell count can easily be made (Figure 8b,e) using longer exposure times (350 ms) and an intermediate fluorescence intensity threshold (shown in Figure 8e in light blue) to account for the overall number of cells by the fluorescence signal of their nuclei. Subsequently, a higher fluorescence intensity threshold can be set, and after recording the image with a shorter exposure time (25 ms, Figure 8d), mitotic cells can be accounted for based on this threshold (shown in green). In this particular example, if this picture represented the entirety of the cell population, 2 of the 20 cells (10%) would be undergoing mitosis. In addition, a higher fluorescence intensity signal for different stages of the mitotic process (anaphase, metaphase, and cytokinesis) was observed, and comparable relative fluorescence intensity signals were observed.

CONCLUSIONS

Probe **1** is a promising new candidate as a contrast agent for multiphoton fluorescence imaging, partciularly considering its high fluorescence quantum yield, high photostability, and suitably high two-photon absoprtivity in the NIR. An immunolabeling procedure employing this amine reactive probe demonstrated sensitivity and versatility of amine reactive probe **1**. In combination with efficient synthesis and availability of antibodies, this protocol represents a widely applicable procedure that offers a good alternative to traditionally used methods. Experimental results demonstrated the validity of the fluorene−IgG conjugate as an effective probe to image cell spindles at early mitotic developmental stages. The intrinsically less invasive physical character of two-photon excitation for biological imaging, coupled with stable, efficient 2PA probes, provides a powerful tool for studying such sensitive systems.

REVIEWS

Synthesis and Applications of Biomedical and Pharmaceutical Polymers via Click Chemistry Methodologies

Maarten van Dijk,[†,‡] Dirk T. S. Rijkers,[‡] Rob M. J. Liskamp,[‡] Cornelus F. van Nostrum,[†] and Wim E. Hennink*[,†]

Department of Pharmaceutics and Department of Medicinal Chemistry and Chemical Biology, Utrecht Institute for Pharmaceutical Sciences, Utrecht University, P.O. Box 80082, 3508 TB Utrecht, The Netherlands. Received February 26, 2009; Revised Manuscript Received June 19, 2009

In this review, the synthesis and application of biomedical and pharmaceutical polymers synthesized via the copper(I)-catalyzed alkyne-azide cycloaddition, the thiol−ene reaction, or a combination of both click reactions are discussed. Since the introduction of both "click" methods, numerous articles have disclosed new approaches for the synthesis of polymers with different architectures, e.g., block and graft copolymers, dendrimers, and hydrogels, for pharmaceutical and biomedical applications. By describing selected examples, an overview is given of the possibilities and limitations that these two "click" methods may offer.

INTRODUCTION

The use of polymers for biomedical and pharmaceutical applications has gained an enormous impact during the past decades. Polymers can be applied in drug delivery systems, as scaffolds for tissue-engineering and -repair, and as novel biomaterials (*1*). These applications have led to an increasing demand of well-defined polymers with tailorable properties. The emergence of the "click chemistry" concept greatly facilitated the synthesis of these polymers. Click chemistry provides very attractive possibilities for (bio)conjugation reactions, because it can be performed at ambient conditions with readily available starting materials. In recent years, click chemistry has also been applied for the synthesis of polymers with different architectures (such as block and graft copolymers), including polymers with pharmaceutical and biomedical applications. This review will focus on the different click chemistry strategies to synthesize this class of polymers and will describe some selected examples in more detail to highlight their applications in the biomedical and pharmaceutical field.

In 2001, Sharpless and co-workers coined the concept of "click chemistry" (*2*) to classify a particular set of nearly perfect reactions, among others, the Cu(I)-catalyzed 1,3-dipolar cycloaddition, vide infra. By means of the "click reaction" concept, large (bio)macromolecules can be synthesized by coupling small building blocks via heteroatom-containing linkages. Such a coupling reaction should meet several criteria: it should be modular, high-yielding, and generate only harmless side products, and it should be carried out under mild reaction conditions, preferentially in the presence of many other functional groups using readily available starting materials and reagents.

There are several well-known reactions that comply with the "click chemistry" concept, including the hetero-Diels−Alder reaction (*3*), the thiol−ene coupling (*4*), the Staudinger ligation (*5*−*7*), native chemical ligation (*8, 9*), the amidation reaction between thio acids and sulfonyl azides (sulfo-click) (*10*−

Table 1. List of Reviews Dealing with the Synthesis of Large (Multivalent) Systems and Macromolecules by the CuAAC

An overview of polymer synthesis and modification via the CuAAC.	Binder et al. (*19, 20*)
Review about click polymerization reactions as well as ligation and functionalization of polymers.	Meldal (*21*)
Reviews dealing with the CuAAC in material science.	Nandivada et al. (*22*), Lutz (*23*), and Johnson et al. (*24*)
Review about synthesis of peptidomimetics via CuAAC.	Angell et al. (*25*)
Overview of carbohydrates and peptide-based dendrimers/polymers.	Pieters et al. (*26*)
Reviews about the construction of biohybrid materials.	Dirks et al. (*27*) Le Droumaguet et al. (*28*) and Lutz (*29*)
Review with emphasis on the synthesis of well-defined polymer architectures.	Fournier et al. (*30*)
Review about various cross-linking methods of micelles including CuAAC.	Read et al. (*31*)
An overview of the synthesis of biodegradable polyesters by ring-opening polymerization and CuAAC.	Lecomte et al. (*32*)
A review about copper-free azide−alkyne cycloaddition reactions.	Lutz (*33*)
Other important reviews dealing with CuAAC.	Meldal and Tornøe. (*34*), Bock et al. (*35*), Moses et al. (*36*), Moorhouse et al. (*37*)

15), and presently the most popular and already mentioned copper(I)-catalyzed alkyne−azide cycloaddition (CuAAC) (*16*−*18*).

Since a large number of recent original publications and (specialized) reviews have been published during the past years on CuAAC (for a detailed list, see Table 1), we will focus in this review on the synthesis of polymers and/or their postsynthetic modification/functionalization by the CuAAC and the thiol−ene reaction. In addition, we will describe some selected examples of biomedically and pharmaceutically relevant polymers that have been synthesized by these two click reactions. This review covers the literature until April, 2009.

GENERAL CONSIDERATIONS

The Cu(I) catalysis of the well-known 1,3-dipolar cycloaddition reaction (CuAAC) between an azide and an alkyne (*38*) was discovered in 2002 independently by the groups of Meldal (*16, 17*) and Sharpless (*18*). In this cycloaddition reaction, an organic azide reacts with an alkyne to form a triazole ring, similar to the classical Huisgen cycloaddition reaction (*38*). However, in the presence of copper(I) the reaction proceeds faster even under ambient reaction conditions (Scheme 1A). Moreover, in the presence of copper(I) only the 1,4-disubstituted triazole ring is formed in contrast to the classical Huisgen cycloaddition reaction in which both 1,4- and 1,5-disubstituted triazole regioisomers are formed (*39*). Since this Cu(I)-catalyzed 1,3-dipolar cycloaddition reaction is very selective, it is highly compatible with almost all other functional groups present in biological macromolecules such as proteins, polysaccharides, and DNA/RNA. Additionally, the CuAAC can be performed in aqueous media with a high reaction rate and generally leads to good product yields. Moreover, recent studies showed that the 1,2,3-triazole moiety, which is formed during the Cu(I)-catalyzed 1,3-dipolar cycloaddition, is similar to the peptide-amide bond in terms of geometry. Therefore, the triazole moiety has been suggested as a mimic of a peptide amide bond and has been used for example as a dipeptide isostere in β-strands and α-helical coiled coils (*40*−*42*).

A potential drawback of the Cu(I)-catalyzed cycloaddition reaction for the synthesis of polymers aimed for biomedical and pharmaceutical applications is the cytotoxicity of Cu(I). This can be especially troublesome when it is difficult to remove the copper catalyst from the synthesized polymers. Therefore, the use of ring strain has been investigated as an alternative for Cu(I) as catalyst to activate acetylenes. Wittig and Krebs (*43*) had already reported in 1961 that the reaction between a cyclooctyne and phenyl azide resulted in the formation of a triazole functionality (Scheme 1C), and in 2004, Bertozzi and co-workers (*44*) demonstrated that the [3 + 2] cycloaddition of azides and cyclooctyne derivatives occurs under physiological conditions. However, the first generation of cyclooctynes was hampered with a relatively low reactivity toward azides, as compared to the CuAAC, resulting in long reaction times and lower coupling efficiencies. To improve their reactivity, Boons and co-workers (*45*) synthesized several 4-dibenzocyclooctynols (Scheme 1D). By introducing aromatic moieties to the cyclooctyne, additional ring strain was created, and also, better conjugation was achieved as an additional factor to increase the reactivity of the alkyne. However, the first generation of these cyclooctynes and 4-dibenzocyclooctynols was rather insoluble in water, and in an attempt to improve the reactivity and water solubility, Bertozzi and co-workers designed and synthesized a second generation of difluorinated cyclooctynes (*46, 47*) (Scheme 1E). These difluorinated cyclooctynes possess similar reaction kinetics as the Cu(I)-catalyzed cycloaddition reaction. Unfortunately, these difluorinated cyclooctynes are rather difficult to synthesize (*48*). A slightly different approach toward Cu-free click reactions was explored by Rutjes and co-workers (*49*). They used a tandem [3 + 2] cycloaddition-retro-Diels−Alder ligation method in which trifluoromethyl-substituted oxanorbornadiene derivatives react with an azide to form a triazole linkage (Scheme 1F). This approach was successfully applied for labeling proteins and to the synthesis of pegylated oligopeptides in various media at ambient temperature. Although the trifluoromethyl-substituted oxanorbornadiene derivatives are much easier to synthesize than difluorinated cyclooctynes, they have a lower reactivity toward azides compared to the difluorinated cyclooctynes. Recently, an overview of the development and perspective of copper-free azide−alkyne cycloadditions was given by Lutz (*33*).

While the CuAAC generally yields a 1,4-disubstituted 1,2,3-triazole, in some cases, however, (e.g., for the synthesis of certain enzyme inhibitors) the 1,5-disubstituted triazole is preferred (*50*). In order to obtain exclusively the 1,5-disubstituted 1,2,3-triazoles from organic azides and alkynes, the groups of Fokin and Jia (*51*) used a ruthenium(II) catalyst (Scheme 1B). This Ru-catalyzed process, RuAAC, exhibits a good scope with respect to both azides and terminal or internal alkynes (*52*) and functional group tolerance. In contrast to CuAAC, RuAAC requires more stringent reaction conditions with respect to temperature and solvent (*53, 54*), which hampers a broad application as a bioconjugation reaction for biologically relevant molecules.

Another reaction that is becoming increasingly popular as an attractive click reaction is the Michael addition between thiols and acrylates (*55*), acrylamides (*56*), vinyl sulfones (*57, 58*), or maleimides (*59*) to form thioethers (Scheme 2). This Michael addition reaction, which is also called thiol−ene coupling (TEC) or "thio-click" (*60, 61*), is highly efficient and orthogonal to a wide variety of functional groups. The thiol−ene coupling makes use of the high nucleophilicity of the sulfhydryl moiety and proceeds under physiological conditions. The formed thioether linkage is very stable under physiological conditions and resists a strong basic or acidic environment and is also stable toward reducing agents; however, it is susceptible toward oxidizing agents.

A drawback of the thiol−ene coupling reaction is the sensitivity of the free thiol functionality toward oxidation into

a disulfide. This unwanted side reaction can be overcome by excluding oxygen from the reaction medium or by adding reducing agents, such as TCEP, or by using protected thiol derivatives. Such protecting groups must meet several requirements: they have to be removed quantitatively under mild conditions and the byproduct should be nontoxic. Goessl and co-workers successfully protected the thiol functionality as a thio acetate (*65*, *66*). Thio esters are highly sensitive toward mild base and can be cleaved at pH 8.

A detailed discussion on the reaction rate of the thiol−ene coupling reaction was provided by Hoyle et al. (*67*). On the basis of extensive studies by Morgan et al. (*68*), the influence of both thiol and ene structure on the thiol−ene free radical reaction rate is directly related to the electron density on the ene moiety. Electron-rich enes react more rapidly than electron-poor enes, e.g., alkene ≈ vinyl ester > allyl ether > acrylate > N-substituted maleimide > methacrylate (*67*).

POLYPEPTIDE-BASED POLYMERS

There is great interest in the use of functional peptides as building blocks for the synthesis of peptide-based polymers, since these polymers can be applied for the design of drug delivery systems, scaffolds for tissue engineering and repair, and as novel biomaterials (*1*, *69*). However, the synthesis of peptide-based polymers imposes several major synthetic challenges. Current methods to synthesize such polymers require the elaborated use of protection groups and/or unstable preactivated building blocks (*70*−*72*), or the polymers have to be synthesized via protein engineering, which can be very challenging (*73*). Recently, new methods have been developed to synthesize peptide-based polymers by chemoselective ligation, where *unprotected* functional peptides are coupled by an orthogonal conjugation method to form polypeptide products. In particular, the CuAAC is very suitable, because the formed 1,2,3-triazole moiety is a mimic of a native peptide bond (*40*, *41*). In view of the scope of this review, native chemical ligation

(NCL) for the synthesis of peptide-based polymers is not discussed. A recent review on protein synthesis by NCL is given by Kent (*74*).

In 2005, Fan and co-workers (*75*) developed a protocol for the solid-phase synthesis of peptidotriazoles with alternating triazole and amide linkages in the backbone. The first peptidotriazole they synthesized consisted of four repeating units of 4-pentynoic acid and Fmoc-proline azide **1** (Figure 1). First, 4-pentynoic acid was grafted onto the resin with PyBOP/HOBt as coupling reagents. Next, Fmoc-proline azide was clicked in the presence of CuI/ascorbic acid/DIPEA/30% 2,6-lutidine/DMF, followed by the removal of the Fmoc group with 20% piperidine/DMF, and the cycle was repeated. After four cycles, the peptidotriazole was cleaved from the resin to yield the desired product **2** in high purity. To demonstrate the versatility of this approach and its compatibility with the common protecting groups used in peptide chemistry, the synthesis was repeated, replacing Fmoc-proline azide by side chain-protected tyrosine, aspartic acid, and lysine building blocks (Figure 1). Also, in this case the desired product **3** was obtained in high yield and purity.

Leigh and co-workers (*76*) developed synthetic methodologies in which the copper(I)-mediated alkyne−azide cycloaddition reaction was combined with a silver(I)-catalyzed TMS-alkyne deprotection (*77*, *78*), and this so-called "click−click" strategy was used to synthesize step-by-step oligomers of peptide triazoles (Scheme 3). The authors started with the tripeptide phenylalanyl-glycyl-glycinate hydrochloride and functionalized the C-terminus of this peptide with an alkyne and the N-terminus with a TMS-protected alkyne (compound **4**, Scheme 3). In the first reaction, they performed a click reaction with azide-containing pseudodipeptides, based on the amino acids phenylalanine **5**, leucine, proline, or N^{ϵ}-Boc-protected lysine. In the presence of $CuSO_4$/Na-ascorbate, an almost quantitative yield of monoclicked product was obtained after 18 h. After the first click reaction, the TMS group was removed by treatment with $AgBF_4$. The addition of the second azido pseudodipeptide **7** resulted in the formation of the ditriazole **8** (Scheme 3). Additional $CuSO_4$/Na-ascorbate was needed to drive the reaction to completion. This one-pot method can be a promising tool for peptide ligation reactions and the synthesis of peptide-based polymers.

Rather than a step-by-step method, Liskamp and co-workers. explored the one-step polymerization of azido-phenylalanyl-alanyl-propargyl amide as a model peptide under different reaction conditions (Scheme 4) (*79*), aiming to develop an efficient method for the synthesis of mimics of natural biopolymers with repetitive peptide sequences. It was demonstrated that the degree of polymerization was strongly dependent on the polymerization conditions (e.g., type of catalyst, monomer concentration, and reaction temperature). When the monomer was polymerized at room temperature with $CuSO_4$/Na-ascorbate as the catalyst, only relatively low molecular weight (M_n: 6.9 kDa) and mostly linear polypeptides were formed. When the same monomer was polymerized in the presence of CuOAc as

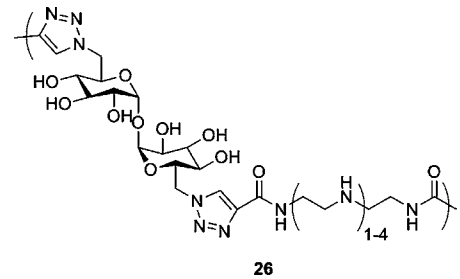

Figure 2. Structure of trehalose polymers synthesized by Reineke and co-workers (*89, 90*).

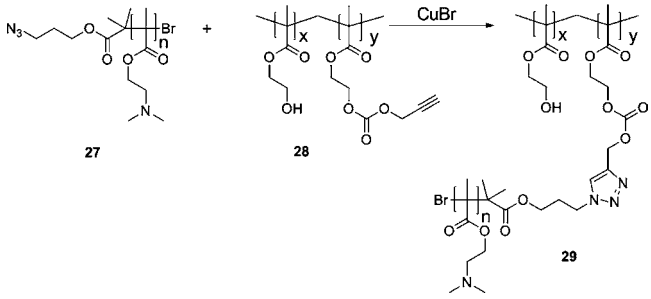
Scheme 8. Synthesis of Degradable-Brushed pHEMA-pDMAEMA (*102*)



catalyst using microwave irradiation at 100 °C, long linear dipeptide-based polymers were formed with an M_n up to 45 kDa (300 amino acid residues) as shown in Scheme 4 (approach A). Interestingly, when the monomer was polymerized at low monomer concentration, using CuOAc as catalyst and under microwave irradiation at 100 °C, cyclic oligomeric structures were formed (approach B, Scheme 4). In a followup study, these optimized polymerization conditions were used to synthesize biodegradable peptide-based polymers with functional groups, such as the ε-NH_2 group of lysine (*80*). The polymers based on the monomers azido-phenylalanyl-alanyl-lysyl-propargyl amide or azido-phenylalanyl-alanyl-glycoloyl-lysyl-propargyl amide were designed to contain recognition sites for proteases like trypsin and chymotrypsin. Moreover, the latter polymer also contains ester bonds that can be cleaved by chemical hydrolysis. It was shown that the number average molecular weight (M_n) of the polymers could be tailored between 4500 and 14 000 Da (33 to 100 amino acid residues) depending on the monomer concentration used during the polymerization. As anticipated, the synthesized polymers were cleaved by both proteases yielding low molecular weight degradation products. The polymer with the ester bond (polymers based on azido-phenylalanyl-alanyl-glycoloyl-lysyl-propargyl) was also degraded under physiological conditions ($t_{1/2}$ = 5 h) due to hydrolysis of the ester bond. In a similar approach, Guan and co-workers (*81*) recently reported on the synthesis of peptide-based polymers that can fold into well-defined β-sheets followed by a self-assembly into hierarchical nanostructures.

Taton and co-workers (*82*) developed a methodology for the synthesis of diblock copolypeptides by combining ring-opening polymerization (ROP) of N-carboxyanhydrides (NCA) combined with CuAAC-catalyzed click-chemistry. In their approach, azide- and alkyne-terminated poly(γ-benzyl-L-glutamate) (**9** and **12**, Scheme 5) and poly(N^{ε}-trifluoroacetyl-L-lysine) (**10** and **13**, Scheme 5) were synthesized by ROP of the corresponding NCA with an azide- or alkyne-containing initiator. The azide and alkyne polymers were subsequently conjugated in DMF at 50 °C with CuBr complexed by *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (PMDETA) as catalyst. After 36 h, the block copolymers (**11** and **14**) were obtained in almost quantitative yield (Scheme 5).

Emrick and co-workers (*83*) developed a method for the synthesis of biocompatible amphiphilic graft polyesters. In their approach, aliphatic polyesters with pendant acetylene groups were synthesized by ROP of α-propargyl-δ-valerolactone **15** with ε-caprolactone **16** (Scheme 6). These acetylene-functionalized polymers **17** were subsequently grafted with PEG and oligopeptides, using CuAAC and azide-terminated PEG or oligopeptides in the presence of $CuSO_4$/Na-ascorbate for 16 h at 80 °C. The amphiphilic graft polyesters were shown to be biocompatible by *in vitro* cytotoxicity evaluation, suggesting their suitability for a range of biomaterial applications.

GLYCOPOLYMERS

Carbohydrates are involved in a number of important biological processes such as cell−cell recognition and cell−protein interactions and play a role in the targeting of hormones. Moreover, antibodies and toxins make use of carbohydrates for selective recognition of their antigens and target receptors (*84*−*86*). However, individual protein−carbohydrate interactions are generally weak; therefore, protein-binding carbohydrates exist in higher-order oligomeric structures, presenting multiple bind-

ing sites, known as the "cluster glycoside effect" (*87, 88*). These multiple binding sites help to improve the weak individual interactions to achieve strong and selective interactions. Scientists have attempted to mimic this "cluster glycoside effect" by synthesizing various well-defined synthetic glycopolymers.

Depending on the method applied, such glycopolymers can be divided into two different classes. They can be synthesized either by polymerization of carbohydrate containing monomers (vide infra, Reineke et al. *89, 90*) or by postfunctionalization of polymers with carbohydrates. Especially for the latter approach, click chemistry turned out to be a valuable tool.

Several examples to obtain glycopolymers employing both CuAAC and the thiol−ene coupling reaction have been mentioned in the literature. Haddleton and co-workers have synthesized various glycopolymers from alkyne backbone-functionalized polymers and azide-functionalized carbohydrates via the CuAAC as shown in Scheme 7A (*91, 92*), such as various mannose- and galactose-containing multidentate ligands for studying lectin binding (*91*). In this approach, the alkyne-functionalized polymers were synthesized by transition-metal-mediated living radical polymerization (TMM-LRP) of methacrylate **19**. After polymerization, the TMS group was removed with TBAF and acetic acid, followed by the coupling of various protected and unprotected azide-functionalized carbohydrates via CuAAC in the presence of $[CuBr(Ph_3P)_2]$ and DIPEA (Scheme 7A).

Alternatively, Stenzel and co-workers (*93*) used the thiol−ene coupling reaction for the postsynthesis modification of glycopolymers. First, a block copolymer containing di(ethylene glycol) methyl ether methacrylate (DEGMA) and 2-hydroxyethyl methacrylate (HEMA) was synthesized via RAFT polymerization. Then, the blockcopolymer and a commercially available HEMA polymer were grafted with glucothiose in the presence of the photoinitiator 2,2-dimethoxy-2-phenyl-acetophenone (DMPA) under UV irradiation for 2 h (shown for homopolymer **24** in Scheme 7B). The resulting block copolymer was used to form thermo-responsive micelles that can be used as a potential drug carrier.

In a recent article by Diehl and Schlaad (*94*), the thiol−ene coupling reaction has been used to functionalize poly[2-(isopropyl/3-butenyl)-2-oxazoline] copolymers with various thiols (e.g., octanethiol, 3-mercaptopropionic acid, and 2-mercaptoethanol). Via this approach, these authors synthesized a series of thermosensitive glycopolymers with cloud points tunable over a wide temperature range.

In a recent article by Haddleton and co-workers (*95*), the synthesis of alkyne-functionalized polymers via chain transfer polymerization (CCTP) is described. The polymers obtained by

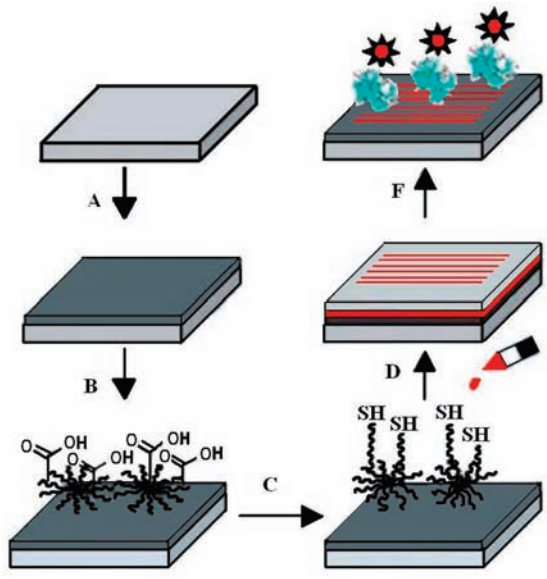

Figure 4. Schematic representation of the approach to immobilize proteins on a solid support (*110*). (A) activation of the surface; (B) attachment of dendrimers (aminocaproic acid linker, dendrimers); (C) functionalization with thiols; (D) drop casting of terminal-olefin-functionalized proteins and immediate coverage with a photomask; (E) removal of the mask. (Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission (*110*).)

this approach can be end-functionalized via the thiol−ene coupling reaction as well as the CuAAC reaction. In this article, several azide-functionalized carbohydrates were grafted via the CuAAC reaction onto the alkyne side chain of the polymers. The grafted polymers on their turn were end-functionalized using the thiol−ene coupling reaction with different thiols. The synthesized mannose-and galactose-containing glycopolymers were able to function as multivalent ligands for the recognition of lectins. The CCTP in combination with the thiol−ene coupling reaction and the CuAAC reaction is a powerful tool for the convenient synthesis of many different types of functional polymers and conjugates.

POLYMERS FOR NONVIRAL GENE DELIVERY

Gene therapy holds a great promise for the treatment of diseases with a genetic origin that are currently incurable. The success of gene therapy largely depends on the availability of suitable delivery vehicles. Although viral vectors display rather good transfection properties, both *in vitro* and *in vivo*, there are a large number of problems associated with the use of these vectors (*96*, *97*). Therefore, there is an increasing interest in the development of so-called nonviral gene delivery systems (*98*). Two major classes of nonviral systems can be distinguished, namely, those based on cationic lipids or those based on cationic polymers. However, generally speaking, the cationic polymers developed to date often display cytotoxicity effects likely due to interactions with proteins and phospholipid membranes. Therefore, new polymers with a significantly reduced cytotoxicity have to be developed. The click reaction can be a valuable tool to synthesize these new polymers for nonviral drug delivery systems.

Reineke and co-workers (*89*) exploited the CuAAC to synthesize a family of trehalose-based glycopolymers, e.g., **26** (Figure 2). They were inspired by the work of Dervan et al., who showed that macromolecules that contain various heterocyclic residues, such as derivatives of pyrrole and imidazole, are able to bind nucleic acids (*99*). Three polymers with different amine stoichiometry were synthesized from diazide functionalized trehalose monomers and dialkyne-amide comonomers in the presence of $CuSO_4$/Na-ascorbate. The polymers contained a trehalose unit for increased biocompatibility, an oligoamine unit for electrostatic interactions with DNA, and a triazole functionality for hydrophobic, van der Waals, and hydrogen-bonding interactions with nucleic acids (Figure 2).

All three newly synthesized polymers were effective as nucleic acid carriers in the absence as well as in the presence of serum. The polymer with the highest secondary amine density gave polyplexes with low toxicity and high cellular delivery. The transfection efficiency of the trehalose polymers was an order of magnitude higher than Jet-PEI, one of the most efficient *in vitro* gene delivery polymers, in serum-free conditions. In a second study (*90*), the same group investigated the influence of the molecular weight of the trehalose click polymer on polyplex stability and pDNA cellular delivery efficiency. In this study, it was shown that a higher degree of polymerization resulted in a higher polyplex stability, although no effect was observed in pDNA binding affinity, cellular uptake, and DNase protection in relation to the M_w.

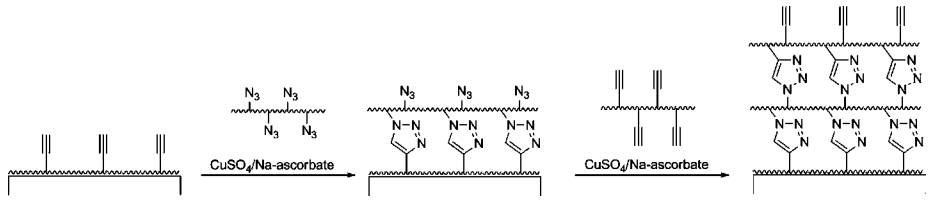
Ideally, suitable polymeric transfectants should be nontoxic, nonimmunogenic, and preferably biodegradable in a controlled manner. Furthermore, biodegradable polymers should yield degradation products with a molecular weight lower than 30 kDa, because these degradation products can be excreted by the kidneys (*100*, *101*). To reduce the cytotoxicity of cationic polymers, Hennink and co-workers (*102*) designed a high-molecular-weight polymer composed of a low-molecular-weight cationic poly(2-dimetylamino)ethyl methacrylate) (pDMAEMA) that was grafted onto a polymer backbone of an uncharged hydrophilic polymer, poly(hydroxyethyl methacrylate) (pHEMA), via biodegradable linkages. Both pDMAEMA and pHEMA were synthesized by atom transfer radical polymerization (ATRP). For this goal, pDMAEMA was end-functionalized with an azide (**27**), while pHEMA was randomly functionalized with acetylene moieties (**28**, Scheme 8). The polymers were "clicked" together via the CuAAC in DMF at 50 °C with CuBr as catalyst (Scheme 8). The molecular weight of the polymer as well as the number of grafts could easily be varied. Upon incubation at physiological conditions (pH 7.4, 37 °C), the carbonate ester bonds were readily hydrolyzed ($t_{1/2}$: 96 h). The molecular weight of the final main degradation product was very close to that of the starting pDMAEMA, indicating that the carbonate esters were quantitatively hydrolyzed. Furthermore, the synthesized polymers were able to condense DNA into small particles, which were able to transfect cells efficiently in the presence of endosome-disruptive INF/7 peptide. Finally, the polymers had a lower toxicity compared to high molecular weight pDMAEMA, making this an effective approach to reduce the toxicity of high-molecular-weight cationic polymers (*102*).

DENDRIMERS

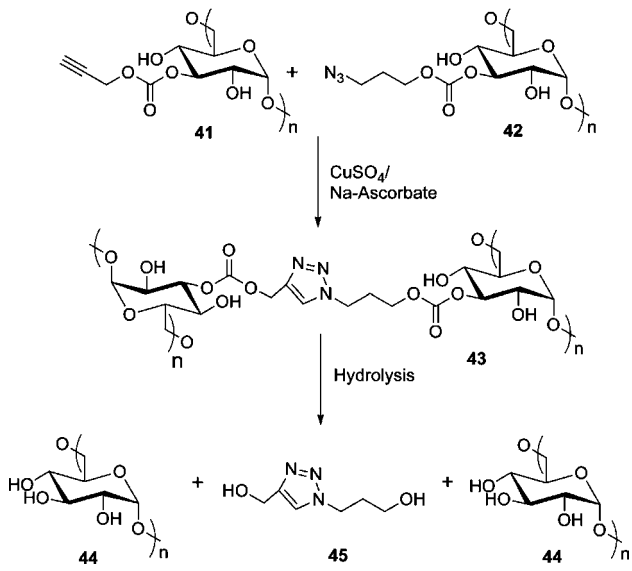
Dendrimers are highly branched well-defined polymers and among others used for the simultaneous presentation of biologically relevant but individually weakly interacting ligands (*103*). Multivalent ligands often bind much more strongly to the interacting protein than their monovalent counterparts (*103*−*105*). Pieters and co-workers (*106*) developed a versatile microwave-assisted CuAAC approach that allowed the conjugation of azido carbohydrates with different kinds of alkyne-bearing dendrimers (Figure 3). With this procedure, they were able to synthesize triazole glycodendrimers in high yields, up to the nonavalent level. These glycodendrimers can be used to increase affinities in various applications such as the binding with bacteria, bacterial toxins, and lectins.

In a similar approach, Liskamp and co-workers (*107*) used the microwave-assisted 1,3-dipolar cycloaddition reaction to

Scheme 10. Schematic Representation of the Approach Described by Caruso and Co-Workers for the Synthesis of Ultrathin pH-Responsive Polymer Films (*115, 116*)



Scheme 11. Synthesis and Hydrolysis of Dextran-Based Multilayers (*118*)



synthesize peptide-presenting multivalent dendrimers. The azido-peptides were mixed with the acetylene-functionalized dendrimers (e.g., **31**, Figure 3) in the presence of $CuSO_4$/Na-ascorbate in aqueous DMF and heated at 100 °C in a microwave reactor. The products were obtained in nearly quantitative yield in a relatively short reaction time (5−10 min). With this method, di-, tetra-, octa-, and hexadecavalent dendrimeric peptides were successfully synthesized. In a recent study, Liskamp and co-workers (*108*) used the same strategy as described above to synthesize ^{111}In-labeled DOTA-conjugated dendrimers with multivalent cyclic RGD peptides. The tetravalent ^{111}In-labeled RGD dendrimers had increased affinity toward the $\alpha_v\beta_3$ integrin receptor and had better tumor targeting properties than their monovalent congeners.

Recently, Hawker and co-workers (*109*) developed a facile and efficient method for the synthesis and end-functionalization of poly(thioether) dendrimers using the thio−ene coupling reaction. The synthesis of the dendrimers was started from the tris-alkene core 2,4,6-triallyloxy-1,3,5-triazine (**33**, Scheme 9). To this core, 1-thioglycerol (**34**) in the presence of catalytic amounts of photoinitiator 2,2-dimethoxy-2-phenylacetophenone was coupled by means of UV irradiation for 30 min at room temperature to yield the first-generation dendrimer **35**. Subsequent esterification of the hexa-hydroxy dendrimers with 4-pentenoic anhydride **36** yielded the ene-functionalized dendrimers **37**. Repeating the final two reaction steps resulted in the synthesis of dendrimers functionalized with 48 alkene functionalities. End-functionalization was also performed with the thiol−ene coupling reaction with suitable thiol-containing reagents, e.g., thioglycolic acid **38**, 4-(pyren-1-yl)butyl 2-mercaptoacetate **39**, and Fmoc-Cys-OH (**40**) as shown in Scheme 9.

Waldmann and co-workers (*110*) used dendrimers and the thiol−ene coupling reaction to immobilize proteins and other biomolecules onto solid surfaces in a patterned way. In detail, they first attached polyamidoamine dendrimers covalently to silicon oxide surfaces (Figure 4B). The dendrimers were extended with an aminocaproic acid spacer, and cystamine was coupled to this spacer and subsequently reduced to obtain a free thiol functionality (Figure 4C). Next, the silicon oxide wafers were incubated with terminal-olefin-functionalized proteins dissolved in ethylene glycol and covered with a photomask (Figure 4D). Subsequent irradiation led to patterning with protein adducts covalently attached via a thioether moiety. The amount of protein that was immobilized could be tailored by varying the irradiation time. With this approach, various biomolecules, like biotin, calf-intestine-alkaline phosphatase, the small GTPase Ras, and a phosphopeptide, were photochemically attached to the dendrimer-coated wafers. All biomolecules were successfully attached and retained their structure and activity. The authors anticipate that this method can be used for the controlled fabrication of structured assemblies of proteins on artificial surfaces.

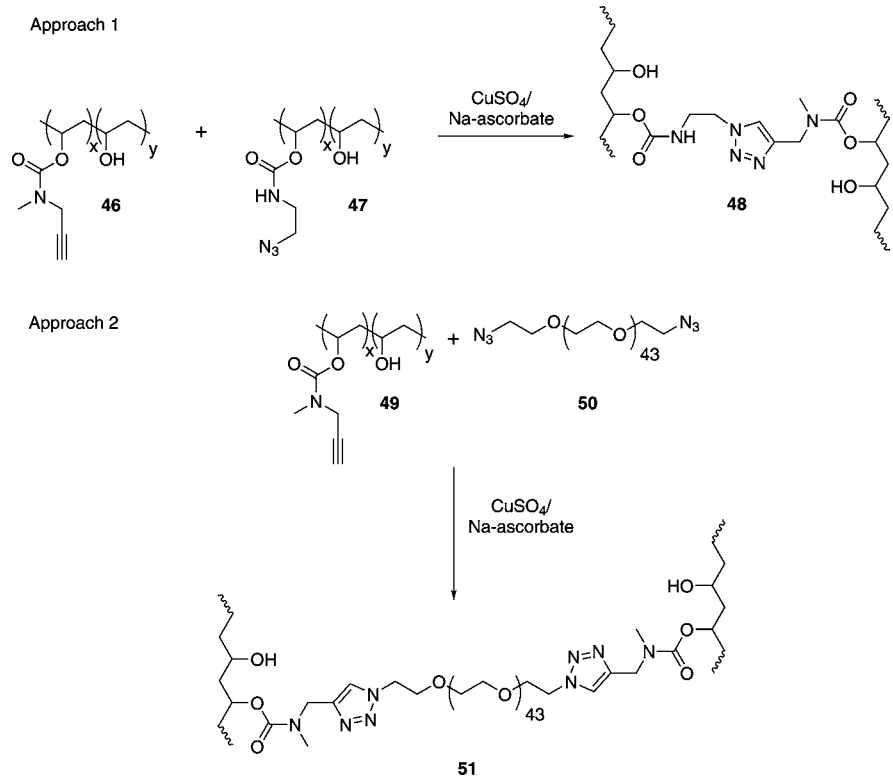
PREPARATION AND MODIFICATION OF MICRO- AND NANOPARTICLES

Nanoparticles have great potential in the biomedical and pharmaceutical field (*111*). Nanoparticles can, for example, serve as delivery vehicles for drugs (*112, 113*). However, current methods to encapsulate drugs in polymeric nanoparticles require the use of organic solvents or harsh conditions, which may result in significant loss of activity, especially if complex biomolecules are used as the active compound. Consequently, novel and mild approaches to obtain nanoparticles are highly desirable.

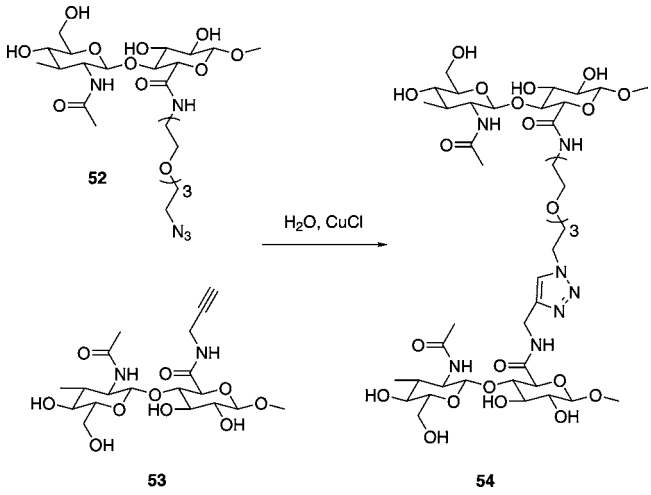
With the aim to prepare functionalized polymersomes from amphiphilic polystyrene-*block*-poly(acrylic acid), van Hest and co-workers (*114*) used ATRP to synthesize the block copolymers followed by the substitution of the bromine functional end group of the hydrophilic block by an azide. Upon slow addition of water to a solution of block copolymers in dioxane, the amphiphilic block copolymers self-assemble into polymersomes with surface-exposed azide functionalities. These azide-functionalized vesicles were used as scaffold for further conjugation with alkyne-functionalized dansyl, biotin, and enhanced green fluorescent protein using $CuSO_4$/Na-ascorbate in the presence of the ligand tris-(benzyltriazolylmethyl)amine (TBTA).

Caruso and co-workers developed a general approach for the layer-by-layer assembly of ultrathin polymer films on planar substrates (*115*) and particles (*116*) for the preparation of pH-responsive nanocapsules. In their approach, poly(acrylic acid) with either alkyne or azide functionalities were synthesized by living radical polymerization. Subsequently, the azide and alkyne functionalized poly(acrylic acid)s were alternately assembled on alkyne-functionalized silica particles, with $CuSO_4$/Na-ascorbate as catalyst (Scheme 10). The silica template was removed by treatment with NH_4F-buffered HF at pH 5. The "click capsules" showed pH reversible responsive behavior in a reversible manner, i.e., the capsule diameter varied between about 5 μm in acidic and 8 μm in basic conditions. This pH-responsiveness could be exploited to load and concentrate drugs inside the capsules. Moreover, the presence of azide or alkyne

Scheme 12. The Two Different Approaches to Synthesize PVA Hydrogels (*123*)



Scheme 13. Formation of Hyaluronic Acid Based Click Gels (*125*)



moieties on the outer shell of the capsules allows for the chemoselective postfunctionalization of the nanoparticles.

In a similar approach, De Geest and co-workers (*117*) synthesized dextran-based multilayer films and hollow capsules. By introducing carbonate ester bonds in the azide and alkyne linkages, the multilayers can be degraded by chemical hydrolysis (Scheme 11). In a subsequent article (*118*), the potential of the biodegradable dextran multilayers for drug delivery was examined. The microcapsules were loaded with fluorescein isothiocyanate-labeled dextran as a model drug compound and incubated at physiological conditions. It was shown that the drug release rate could be tailored by the cross-linking density of the dextran multilayers.

In a recent paper by Caruso and co-workers (*119*), the development of a thiol−ene version of the layer-by-layer assembly of polymer films on silica particles is described. In this approach, poly(methacrylic acid), containing either thiol groups or ene functionalities, was alternatively deposited with poly(vinylpyrrolidone) on silica particles under UV irradiation.

Schlaad and co-workers (*62*) used a thiol−ene coupling reaction for the synthesis of self-assembling peptide hybrid amphiphiles. They grafted cysteine and cysteine-containing dipeptides onto the hydrophobic block of polybutadiene-*block*-poly(ethylene oxide) polymer. The grafting of cysteine had little effect on micelle formation. However, when the dipeptide cysteinyl-phenylalanine was coupled to the amphiphilic polymer, vesicles and worm-like micelles were formed. More recently, Schlaad and co-workers (*63*, *64*) used the same method to synthesize polybutadienes modified with hydrophilic functionalities. The thiol−ene coupling reaction was used to incorporate thiol-containing molecules, in which the carboxylic acid or amine functional groups and amino acid residues were unprotected. With the incorporation of such titratable groups, the polymers were able to self-assemble into pH-responsive unilamellar or multilamellar vesicles.

Riguera and co-workers (*120*) reported an efficient method to synthesize polyion complex (PIC) micelles with the CuAAC catalyzed click reaction that are stable under physiological conditions. In their approach, azide-functionalized gallic acid-triethylene glycoside (GATG) dendrimers and PEG-GATG block copolymers were coupled to different alkynes functionalized with sulfate, sulfonate, or carboxylate groups in the presence of $CuSO_4$/Na-ascorbate. When the sulfated PEG-

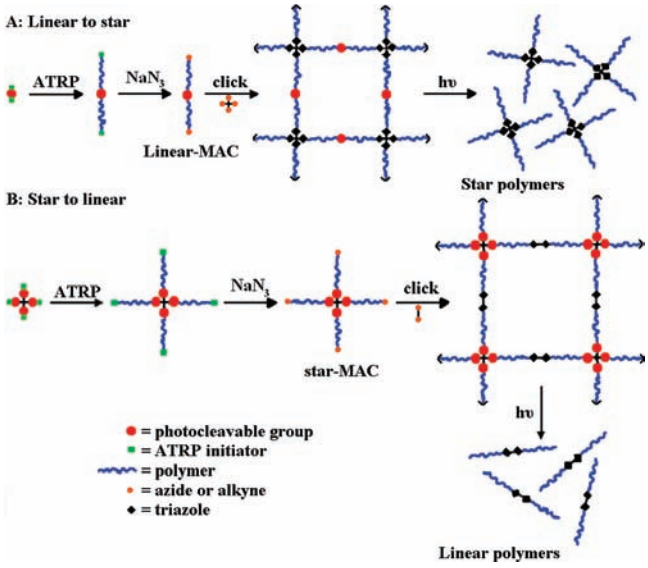

Figure 7. Two different approaches to synthesize photocleavable hydrogels (reproduced with permission from ref *128*).

GATG block copolymer was mixed in a stoichiometric ratio with poly(L-lysine), spherical micelles with a narrow size distribution were obtained.

In a recent article authored by Pine and co-workers (*121*), a new generic method for the covalent linkage of a wide variety of molecules to the surface of colloidal polymer microspheres via the CuAAC reaction has been described. In their approach, polystyrene particles containing 4-vinylbenzyl chloride moieties were converted into the corresponding azides and subsequently reacted with various alkynes to obtain triazole-functionalized microparticles. As a typical example, the authors functionalized polystyrene microspheres with two polyethylene oxide-based polymers. However, it has been stated that this approach is sufficiently general since it can readily be adapted to colloids that consist of other (polymeric) materials.

HYDROGELS

Hydrogels are three-dimensional, hydrophilic polymeric networks capable of absorbing large amounts of water (*122*). Hydrogels have received great interest over the past decades, since they can be used for a wide range of applications including drug delivery systems and scaffolds for tissue engineering and repair. In 2006, Hilborn and co-workers were the first to apply click chemistry to synthesize hydrogels (*123*). They synthesized poly(vinyl alcohols) (PVA) functionalized with either acetylene or azide groups (**46** and **47**, Scheme 12). Upon addition of $CuSO_4$/Na-ascorbate, a hydrogel was formed within a few minutes (**48**, Scheme 12). However, in order to retain the water solubility of the azide- or alkyne-functionalized PVA, only low degrees (1−5%) of modification were possible. In a second approach to synthesize PVA-based hydrogels, acetylene-functionalized polyvinyl alcohol **49** was cross-linked with telechelic bifunctional poly(ethylene glycol) diazide **50** (Scheme 12). This approach was superior in gel formation and gave higher values of gel fraction.

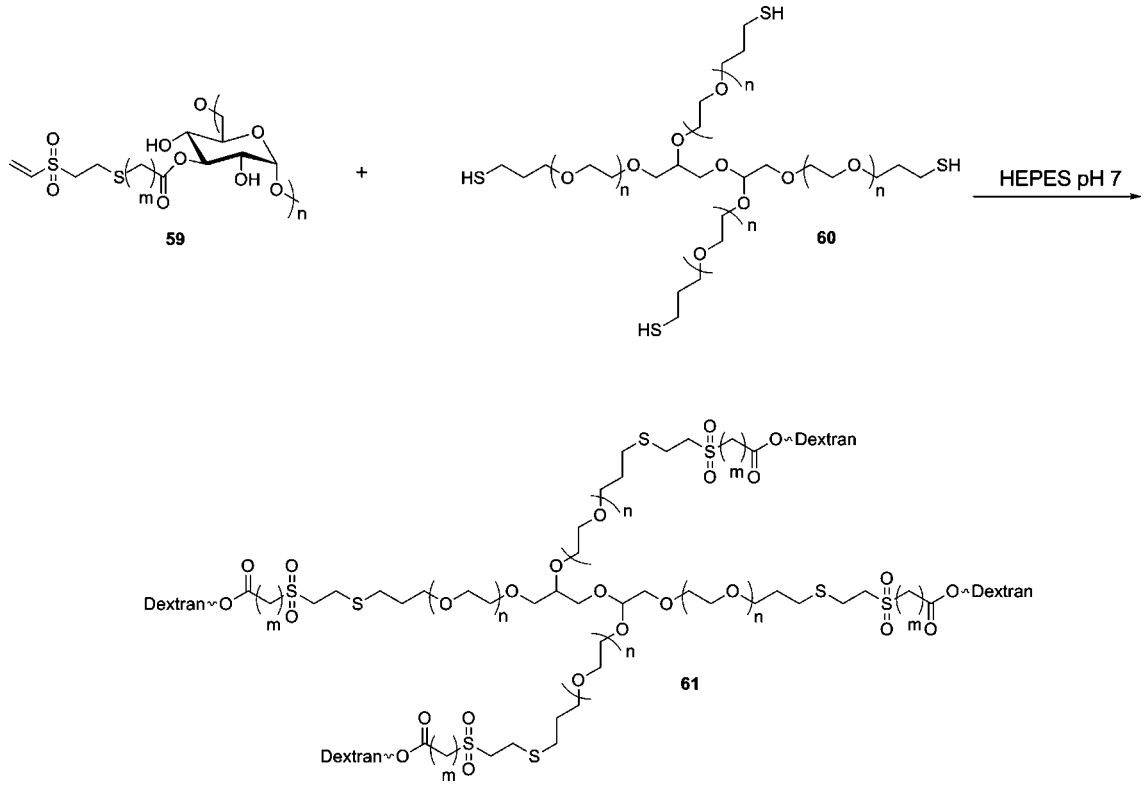
Hawker and co-workers used PEG as the main structural component for model "click" hydrogels. In their approach, diacetylene-functionalized telechelic PEG derivatives and tetraazide-functionalized PEG were coupled by "click chemistry" at room temperature using 2 equiv of PEG diacetylene, 0.4 equiv $CuSO_4$, and 1 equiv of Na-ascorbate. Under these conditions, the hydrogels were formed within 30 min, and fluorescence analysis revealed the presence of maximal 0.2% unreacted azide/acetylene moieties. By varying the length of the diacetylene PEG chain, they showed that the properties (swelling degree and max true stress) of the hydrogels could be tailored (*124*).

Lamanna and co-workers (*125*) developed a procedure for the formation of hydrogels based on hyaluronan derivatives suitable for tissue engineering applications. They synthesized hyaluronic acid bearing either azide or alkyne groups (**52** and **53**, Scheme 13). Hydrogels were formed within a few minutes by dissolving both components in H_2O in the presence of 1% w/v of CuCl (Scheme 13). Residual copper entrapped in the hydrogel was removed by dialyzing the hydrogel against an aqueous buffer containing EDTA as metal chelator. The synthesized hydrogels were evaluated for drug-release capabilities with doxorubicin **55** and benzidamine **56** as model drugs (Figure 5). Benzidamine was quantitatively released within hours, whereas the release of doxorubicin was prolonged over several weeks. The release rate could be tailored by varying the degree of cross-linking. The slower release of doxorubicin was explained by strong electrostatic interactions between the protonated amino group of doxorubicin and carboxylate groups of the hydrogels. The authors also argued that $\pi-\pi$ stacking interactions between the triazole ring and the aromatic moiety likely contributed to the slower release of doxorubicin.

Lamanna and co-workers also examined the suitability of their hyaluronan hydrogels as scaffolds for tissue engineering. Therefore, a hydrogel was formed in a YPD (yeast peptone dextrose) cell suspension and the gels were stored for 2 days at 28 °C. Subsequently, the gels were mechanically broken and the number of cells was counted, and 24 h later, 80% of the cells exhibited proliferating activity.

Anseth and co-workers (*126*) developed a procedure to integrate multifunctional photoreactive polypeptides into a hydrogel network. In their approach, they combined both the CuAAC and thiol−ene coupling reaction. First, they synthesized hydrogels by clicking tetraazide-functionalized four-arm star-shaped PEG **57** with diacetylene-functionalized peptide **58** (Figure 6). The hydrogels were formed within a few minutes

Scheme 14. Dextran Hydrogel Formation by Thiol−Ene Coupling (*135, 136*)



in the presence of 0.25 equiv $CuSO_4$ (based on azide functionality) and Na-ascorbate. Next, a cysteine containing fluorescently labeled peptide was incorporated by thiol−ene photocoupling to the Alloc protecting group present in the hydrogel.

Dubois and co-workers (*127*) synthesized adaptative and amphiphilic polymer conetworks based on hydrophilic poly(*N*,*N*-dimethylamino-2-ethyl methacrylate) (pDMAEMA) and hydrophobic poly(ε-caprolactone) (pCL) by a combination of ATRP, ROP, and CuAAC. In their approach, the azido-containing 2-(2-azidoethoxy)ethyl methacrylate (AEEMA) was copolymerized with DMAEMA by ATRP. The p(DMAEMA-*co*-AEEMA) copolymer was subsequently cross-linked with diacetylene-functionalized pCL, in the presence of CuBr complexed with 2,2′-bipyridine as a ligand at room temperature for 24 h to obtain a highly porous amphiphilic co-network.

Turro and co-workers (*128*) utilized ATRP and CuAAC for the synthesis of photodegradable polymeric model networks. For the synthesis of the networks, the authors employed two different approaches (Figure 7). In their first approach, linear azido-telechelic macromonomers (MAC) possessing a photocleavable group (nitrobenzyloxycarbonyl) at the center were synthesized by ATRP. Subsequently, both end groups of the linear polymers were reacted with NaN_3. The obtained azide-functionalized macromonomers were cross-linked with a small tetrafunctional alkyne in the presence of CuBr as catalyst and *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (PMDETA) as ligand. In a second approach, the authors started from a tetrafunctional ATRP initiator containing four photocleavable groups to yield four-armed star-shaped poly(*tert*-butyl acrylate) polymers. Next, the four end groups were converted into azide functionalities, and the star-shaped polymers were cross-linked with a linear bifunctional alkyne. Both model networks were degraded upon exposure to UV light of 350 nm to yield soluble well-defined polymer fragments. In a second paper, Turro and co-workers (*129*) optimized this procedure by substituting the CuAAC cross-linking with a strain-promoted azide−alkyne cycloaddition, thereby abolishing the need of a (cytotoxic) copper catalyst.

Zhou and co-workers (*130*) developed a strategy for the in situ gelation of poly(*N*-isopropylacrylamide-*co*-hydroxyethyl methacrylate) (p(NIPAAm-co-HEMA))-based polymers by the CuAAC. Two p(NIPAAm-co-HEMA)-based polymers, with either pendant azide or alkyne groups, were synthesized. Hydrogels were formed by dissolving the two polymers and incubating them with $CuSO_4$/Na-ascorbate as catalyst and PMDETA as ligand for 24 h at room temperature. The obtained CuAAC hydrogels had faster shrinking/swelling kinetics compared with traditionally synthesized p(NIPAAm) hydrogels.

Yang et al. (*131*) synthesized PEG-RGD peptide hydrogels for cell entrapment using the CuAAC. PEG is an ideal polymer for hydrogel formation, because the formed gels generally have a high water absorbing capacity and are resistant to protein adsorption. However, the viability of encapsulated cells in PEG hydrogels is generally low due to the nonadherent properties for the cells. By virtue of introducing RGD peptides into the PEG hydrogels, cell adhesion properties were increased, resulting in higher cell viability. For the PEG precursor of the hydrogel, the authors prepared tetra-acetylene PEG by esterification of tetra-hydroxy-terminated four-armed PEG with 4-pentynoic acid. As a cross-linking agent, they synthesized a series of diazide-functionalized RGD peptides by reacting RGD peptides with 6-azidohexanoic acid. Hydrogels were prepared by combining the acetylene-functionalized PEG and diazide-functionalized RGD peptides in the presence of $CuSO_4$/Na-ascorbate at ambient temperatures. The gelation time could be tailored between 2 and 30 min by variation of the catalyst or precursor concentration and by variation of the temperature. To investigate if the hydrogels could be used as cell delivery vehicle, the hydrogels were seeded with primary human dermal fibroblasts cells. The hydrogels without or at low RGD peptide loading were unable to adhere cells after 18 h. When the RGD peptide loading in the precursor solution was increased, the

attachment and proliferation of cells was also enhanced. These data hold promise to use these types of hydrogels as carriers for cell entrapment and tissue engineering.

In 2003, Stein and co-workers (*132*) reported a method, based on the thiol−ene coupling, to synthesize PEG-based hydrogels in situ. They used PEG-based copolymers containing multiple thiol groups synthesized from diamino-PEG and 2-mercapto-succinic acid. As cross-linking agent, PEG functionalized with vinylsulfone groups was used. Upon combining both PEG polymers, hydrogels with a water content higher than 90% were rapidly formed under mild conditions (pH 6.0−8.0 at room temperature). Furthermore, it has been shown that increasing the pH gave rapid gel formation, which is in line with the increasing nucleophilicity of the thiol functionality at higher pH values. The authors have demonstrated that the reaction between thiol and vinylsulfone is compatible with other functional groups present in, e.g., proteins, by carrying out a release study of fluorescein-labeled BSA, which showed quantitative release after 25 days.

Hubbell and co-workers (*133*) examined the formation of hydrolytically degradable PEG hydrogels via thiol−ene coupling. They used a four-armed and eight-armed PEG spacer functionalized with acrylate end groups and either dithiothreitol or PEG-dithiol as cross-linking agents. The hydrogels were prepared by mixing the acrylate-functionalized star-shaped PEG and dithiol in 1:1 stoichiometric ratio in PBS (pH 7.8) and incubated overnight at 37 °C to ensure complete conversion. The PEG-acrylate contains an ester bond that can be cleaved by chemical hydrolysis. The presence of the thioether group in the proximity of the PEG-acrylate ester greatly increases the sensitivity of the ester toward hydrolysis by several orders of magnitude (*134*). By altering the molecular weight of the PEG derivative, or by varying the concentration of either the cross-linker or the PEG-acrylate molecules, resulted in hydrogels with swelling ratios. The different swelling ratios also resulted in different degradation kinetics.

Feijen and co-workers (*135, 136*) synthesized biodegradable dextran hydrogels by thiol−ene coupling. The dextran hydrogels were formed in situ by mixing solutions of vinylsulfone dextran **59** (Scheme 14) and tetramercapto four-armed star poly(ethylene glycol) **60**. The degradation time of hydrogels **61** could be tailored by varying the length of the spacer of the dextran polymers and the degree of vinylsulfone substitution. To study the versatility of these gels as a drug delivery system, four model proteins (immunoglobulin, bovine serum albumin, lysozyme, and fibroblast growth factor) were entrapped inside the gel. The release of the proteins did not show a burst effect and depended on the degree of vinylsulfone substitution and dextran molecular weight.

Hoffman and co-workers (*137*) used the thiol−ene coupling method to synthesize heparin-based hydrogels. In their approach, heparin was first reacted with EDC/HOBt and an excess of cysteamine to obtain thiol-functionalized heparin. PEG-diacrylate was used as the cross-linking agent. The mechanical properties and gelation kinetics of the hydrogels could be tailored by the degree of thiol group substitution of heparin. The heparin-based hydrogels were degraded at physiological pH by chemical hydrolysis of the ester bond present in the PEG diacrylate cross-linker. To prove that the hydrogels are compatible with cells, the hydrogels were gelated in the presence of fibroblasts. After gelation, most of the cells (95%) retained their viability.

CONCLUSIONS

The CuAAC reaction as well as thiol−ene coupling reaction as discussed in this review allow the synthesis of well-defined polymers with tailored properties and provide very attractive possibilities for (bio)conjugation reactions. Several examples of the synthesis and applications of biomedical and pharmaceutical polymers synthesized by the CuAAC, the thiol−ene reaction, or a combination of both reactions were highlighted. In recent years, the CuAAC and thiol−ene reactions have been used to synthesize polymers with different architectures. e.g., block and graft polymers, dendrimers, and hydrogels, for pharmaceutical and biomedical polymers. Although the CuAAC and thiol−ene reactions have many advantages, they also have some drawbacks. The CuAAC reaction requires the need of a cytotoxic copper catalyst, which is sometimes difficult to remove, while the free thiol needed for the thiol−ene reaction is susceptible to oxidation. The development of new variations of these "click reactions", such as the strain-promoted click reaction, can address the problem of cytotoxic copper catalyst. Nevertheless, both the CuAAC and thiol−ene reactions have acquired central positions in the synthesis of polymers for biomedical and pharmaceutical applications, and it is expected that their importance for the design and synthesis of such polymers will increase rapidly in the coming years.

Cationic Glyco-Functionalized Single-Walled Carbon Nanotubes as Efficient Gene Delivery Vehicles

Marya Ahmed, Xiaoze Jiang, Zhicheng Deng, and Ravin Narain*

Department of Chemical and Materials Engineering, ECERF, University of Alberta, Edmonton, Alberta T6G 2G6, Canada, and Department of Chemistry and Biochemistry, Biomolecular Sciences Program, Laurentian University, 935 Ramsey Lake Road, Sudbury, Ontario P3E 2C6, Canada. Received May 29, 2009; Revised Manuscript Received September 16, 2009

Carbon nanotubes are an emerging class of nanomaterials that are receiving enormous attention in the field of biomedicines due to their biocompatibility, degradability, cell penetrating abilities, and, more specifically, their remarkable ability to localize in the nucleus of the cell without the need of nuclear localizing signals. They are used as drug and gene delivery agent for *in vitro* studies; however, their transfection efficiencies *in vitro* are still questionable. We report here the surface functionalization of single-walled carbon nanotubes (SWNTs) with cationic glycopolymers and their use as an *in vitro* gene transfer agent. The copolymer modified SWNTs are found to be biocompatible and exhibit transfection efficiencies that are comparable to the commercially available agent lipofectamine 2000.

The research efforts focused on the improvement of synthetic gene delivery vectors have led to the exploration of a variety of nanomaterials. The carbon nanotubes, although comparatively recent in the race, present important characteristics desirable for gene delivery purposes (*1*). They are reported to be non-cytotoxic, can mediate endocytosis, and are biodegradable. All these properties make them ideal for a gene delivery scaffold (*2*−*6*). Although a handful of reports mention the nucleic acid delivery to the cells with the help of carbon nanotubes, their transfection efficiency and cytotoxicity issues are still not fully explored (*4, 7*−*10*). The transfection efficiencies of modified carbon nanotubes were found to be low, and very few reports present cytotoxicity data of these modified nanomaterials (*8, 11*). The extensive use of carbon nanotubes in biomedical applications is highly dependent upon their surface chemistry, biocompatibility, and water solubility. The noncovalent approaches to anchor the nucleic acids on the surfaces of nanotubes are desirable to prevent the denaturation of DNA and to enhance its release from the gene delivery scaffold inside the cell (*4, 7, 8*). Another dominating factor in designing the ideal gene delivery vehicle is its compatibility toward living tissues. The cationic polymer grafted carbon nanotubes have been produced and are shown to mediate some degree of gene transfer, but their biocompatibility towards living systems is not known (*4, 8*). An ideal approach is to fabricate the surface of carbon nanotubes with biocompatible cationic ligands to yield gene delivery systems that simultaneously render low toxicity and high gene transfer ability to living cells. Herein, we report the facile synthesis of biocompatible cationic glycopolymer functionalized single-walled carbon nanotubes (SWNTs). The SWNTs produced are then used as potential gene delivery vehicles and are found to contain the transfection efficiencies that mimic widely used commercial standard, Lipofectamine 2000, with considerably low toxicity. To the best of our knowledge, facile functionalization of carbon nanotubes with cationic glycopolymer, their long-term stability, and their use as biocompatible gene delivery agents has not yet been reported.

A variety of reports discuss the fabrication of carbon nanotubes with water-soluble polymers or biomolecules to improve their water solubility and biocompatibility (*3, 12*−*14*). The surface functionalization of nanotubes with polymers is typically obtained by two covalent approaches, namely, "grafting from" and "grafting to" techniques (*15, 16*). The comparison of the "grafting from" method with "grafting to" reveals the significance of the latter and has been used to covalently attach the biocompatible moieties such as the carbohydrate and phosphorylcholine to the surface of SWNTs with high grafting density (*13, 17*). However, the reported functionalized carbon nanotubes were prepared via the atom transfer radical polymerization (ATRP) technique, which has questions about the toxicity of the residual copper (*13*). To obtain biocompatible water-dispersible carbon nanotubes for the *in vitro* uses, the need is to fabricate the surface of carbon nanotubes with biocompatible polymers by covalent bonding. The ideal candidate for this purpose is glycopolymers, which can be grafted on the carboxylic groups present on the surface of nanotubes via "grafting to" approach. The glycopolymers bearing pendant amino groups were prepared by using monomers, 3-aminopropyl methacrylamide (APMA), 3-gluconamidopropyl methacrylamide (GAPMA), and 2-lactobionamidoethyl methacrylamide (LAEMA) by the reversible addition−fragmentation chain transfer (RAFT) method, yielding diblock copolymers, while eliminating the possible toxic effects of residual metals. The cationic block polymers thus synthesized were P($APMA_{31}$-*b*-$LAEMA_{32}$) and P($APMA_{38}$-*b*-$GAPMA_{20}$) (Supporting Information Figure S1).

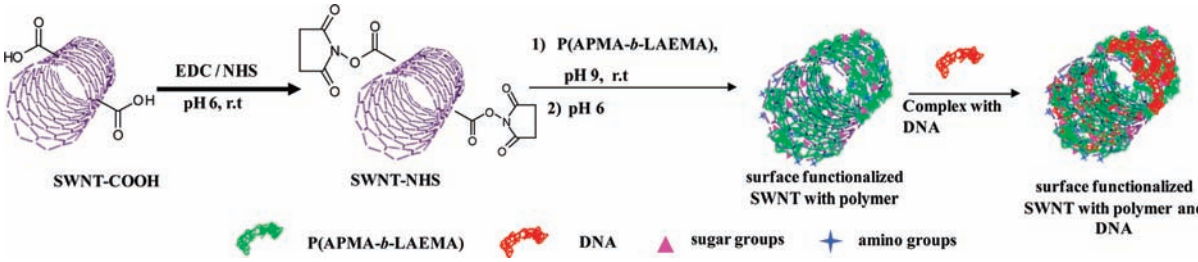
Scheme 1. Carboxyl Functionalized SWNTs Are Surface Functionalized with RAFT Prepared Block Copolymers[a]



[a] The cationic glycopolymer-functionalized SWNTs are further complexed with plasmid (pEGFP).

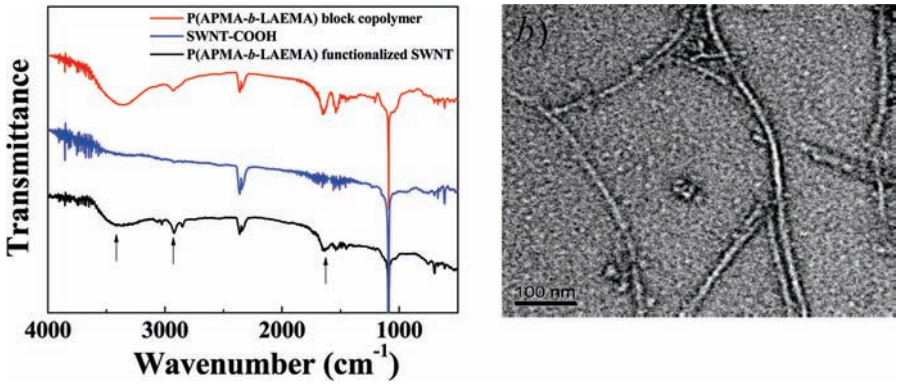


Figure 1. (a) IR absorption spectra showing the functionalization of SWNTs with P($APMA_{31}$-*b*-$LAEMA_{32}$) block copolymer (b) HRTEM image confirms the diameter of surface functionalized P($APMA_{31}$-*b*-$LAEMA_{32}$)-SWNTs.

The detailed synthesis and characterization of diblock copolymers P($APMA_{38}$-*b*-$GAPMA_{20}$) used for the functionalization of SWNTs have been reported in our group (*18*). The carboxyl groups present on the surface of SWNTs were conjugated to the amino groups of PAPMA by the 1-ethyl-3(3-dimethylaminopropyl)carbodiimide (EDC)-*N*-hydroxysuccinimide (NHS) coupling. In our experiments, the SWNTs were first sonicated for 3 h to disperse them into water. The presence of carboxyl groups on the surface increased their dispersion. The carboxyl groups on the surface were converted to succinimide-terminated surface by the addition of EDC/NHS reagents at pH 6 (Scheme 1). The cationic glycopolymers were then conjugated to the surface of SWNTs at pH 9, thus leading to the formation of surface glycopolymer functionalized SWNTs, which had high water solubility and showed no precipitation of SWNTs, even after months at room temperature. In contrast, unfunctionalized SWNTs were found to precipitate in 12 h under the same conditions. The cationic glycopolymer functionalized SWNTs were then centrifuged at 20 000 rpm for 2 h to remove the excess polymer, a technique that has largely been used in our group to purify the nanomaterials from their corresponding polymers.

The purified SWNTs were then characterized by IR spectroscopy. The comparison among original SWNTs, glycopolymers, and glycopolymer functionalized SWNTs is shown (Figure 1a). The spectrum of the original SWNTs reveals an absorbance at 1716 cm^{-1}, which is a characteristic of the carbonyl stretch of the carboxylic acid group. The subsequent functionalization of the carbon nanotubes with P($APMA_{31}$-*b*-$LAEMA_{32}$) block copolymer shows the characteristic and pronounced absorbance signals from the respective polymers. The acrylamide groups of the P(APMA-*b*-PLAEMA) block show IR absorptions bands at 3409, 2915, and 1642 cm^{-1}, and these peaks can be detected on the IR spectrum of the glycopolymer functionalized SWNTs. To further confirm the functionalization of SWNTs, UV−visible spectra were also recorded (see Supporting Information Figure S2). The spectra showed only a very small absorbance by original SWNTs solution for the presence of carboxyl groups on the surface of SWNTs. A sharp increase in the absorbance was noted for glycopolymer-functionalized SWNT in the range 200−350 nm, due to an increase in the solubility of functionalized SWNTs after the modification with water-soluble polymer chains. To determine the extent of functionalization or polymer content, the functionalized carbon nanotubes were further analyzed by thermogravimetric analysis. The polymer content was determined to be in the range 30−35% (see Supporting Information Figure 12). The functionalized SWNTs produced were assessed with high-resolution transmission electron microscopy (HRTEM), to determine the size of nanotubes after the functionalization (shown in Figure 1b). The samples were prepared by the immersion of a carbon-coated copper grid in the functionalized SWNTs aqueous solution followed by drying in vacuum. The images of functionalized SWNTs revealed an average diameter of around 20 nm.

To further explore the possible applications of glycopolymer-functionalized SWNTs for biomedical applications, the glycopolymer-functionalized SWNTs were conjugated to biotin to yield cationic glycopolymer-functionalized biotin labeled carbon nanotubes. For this purpose, the biotin-NHS was added into the glycopolymer-functionalized SWNTs solution at basic condition and stirred overnight. The purified mixture was then tested using HABA/avidin binding assay to detect the presence of biotin on the surface of functionalized SWNTs. The decrease in absorbance at 500 nm after the addition of biotinylated glycopolymer-functionalized SWNTs confirms the presence of biotin groups on the surface of functionalized SWNTs (Supporting Information Figure S3). The presence of amino groups on the surface of biocompatible cationic polymer functionalized nanotubes assures their further successful functionalization with the molecule of choice, as demonstrated with biotin. The novel synthesis of cationic glycopolymer-functionalized biotin labeled SWNTs introduces other possibilities for their use in various applications including targeted drug and gene delivery.

The extensive study of uptake mechanism of carbon nanotubes by human cells reveals the endogenous nature of this material to be endocytosed (*17, 19*). However, Jin et al. have shown that, like other nanomaterials, uptake of SWNTs by

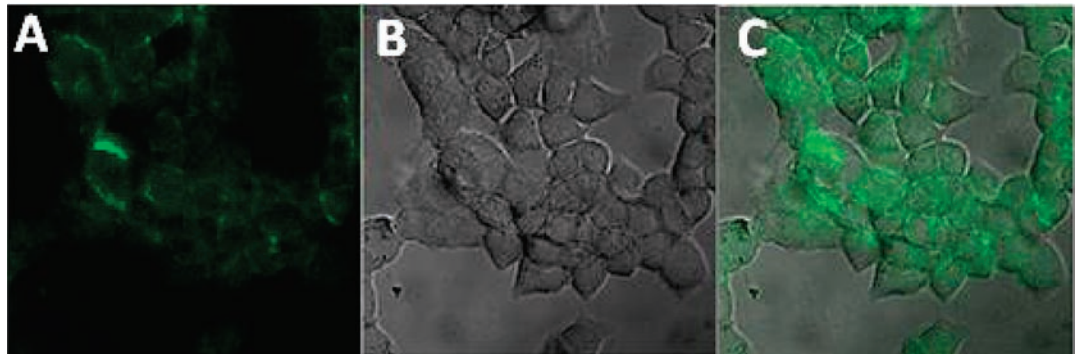

Figure 2. Confocal microscopic images of Hela cells, showing the uptake and localization of FITC-labeled-P($APMA_{31}$-*b*-$LAEMA_{32}$)-*f*-SWNTs at 37 °C. (A) Fluorescence images, (B) bright field images, (C) fluorescent image overlaid on bright field image.

human cells is also a size-dependent process (*20, 21*). The nanotubes with effective radius of 26.4 nm are found to be the most efficient in crossing the cell membrane barrier by receptor-mediated endocytosis (*20*). The glycopolymer-functionalized SWNTs prepared were studied for their cell penetrating abilities. For this purpose, 0.15 mg/mL of cationic SWNTs was first complexed with 4 μM fluorescein isothiocyanate (FITC)-labeled oligonucleotides, thus assuring the excess of the latter in the experiment. Hela cells grown on glass coverslips were incubated with FITC-oligonucleotide labeled SWNTs for 48 h, and the confocal microscopic images were obtained after extensive washing of coverslips with DPBS buffer. The images revealed the successful uptake of nanotubes by Hela cells, showing the disperse ability of nanotubes inside the cells. Although some nanotubes can be found attached to the surface of cells, most are either dispersed in the cytosol or can be traced in perinuclear regions (Figure 2). In contrast, FITC labeled oligonucleotides without SWNTs used as a control showed no fluorescent signal, when excited by laser at 490 nm to detect the presence of FITC dye.

The cytotoxicity assay was performed at different concentrations of cationic glycopolymer-functionalized SWNTs, and the results were expressed in terms of both concentration and mass of SWNTs used, for the purpose of comparison with both transfection studies and other literature (Supporting Information Figures S4 and S5). The functionalization of SWNTs with glycopolymer and glycoproteins has been reported previously (*4, 22*). The glycoprotein stabilized SWNTs are found to be involved in glycan−receptor interactions, thus binding to the surface of cell membrane, with no significant toxicity at the concentration of 0.1 mg/mL (*22*). We report the use of glycopolymer-functionalized SWNTs as gene delivery scaffolds, where the glycopolymer segment of the block copolymer not only participates in cell mediated interactions, but also masks the cationic component of the polymer to provide biocompatibility, thus eliminating the need of stealth barriers. The cytotoxicity assay of glycopolymer stabilized SWNTs reveals that, at very low concentrations of copolymer-functionalized SWNTs (4 μg/mL), the cell growth is promoted, owing to the glycopolymer segment of the functionalized nanotubes. The increase in concentration leads to the decrease in cell viability, and the cell viability is found to be ∼75% for up to 0.2 mg/mL of copolymer-functionalized SWNTs alone (Supporting Information Figures S4 and S5). Thus, it can be concluded that the carbohydrate component successfully masks the cationic character of the copolymer present on the surface of nanotubes.

As discussed earlier, the uptake of carbon nanotubes by receptor mediated endocytosis, their ability to protect DNA strands from denaturation, their ability to localize inside the nucleus, and their reported biocompatibility make them ideal vehicles for gene delivery purposes, and yet only a handful of reports discuss the gene delivery by carbon nanotubes (*4, 7−9, 23*). The comparison of efficiency of transfection is done by their corresponding polymers; for example, PEI is compared to PEI-grafted MWNTs and the latter is found to transfect at higher levels in 293 cells (*4*). It has already been well-understood that polymer stabilized nanomaterials tend to deliver genes more efficiently, compared to their corresponding polymers, due to the stability issues with the latter (*24−26*). Singh et al. compared the transfection efficiencies of single- and multiwalled carbon nanotubes, proving better transfection ability of SWNTs over MWNTs; however, no cytotoxicity studies are provided by them, while others report the cytotoxicity of nanotubes by assays that are now debatable (*4, 8, 11*). We present a novel type of functionalized SWNTs that show the transfection efficiencies that mimic that of Lipofectamine, with enhanced cell viability. The varying masses of glycopolymer-functionalized SWNTs were complexed with green fluorescence protein encoded plasmid (pEGFP), and the process of complexation was studied by agarose gel electrophoresis. The calculation of mass ratios was done by incubating the various volumes of SWNTs with 340 ng of pEGFP plasmid. The stock solution of initial concentration of 1 mg/mL of functionalized SWNT was used and 5, 10, 15, and 20 μL of SWNTs were incubated with 340 ng of plasmid separately. It was found that complete complexation of plasmid is obtained at w/w DNA to SWNTs ratio of 1:14.5, and the complexes were found to be retained in the wells of agarose gel (Supporting Information Figure S6). The transfection efficiencies were then obtained by incubating Hela cells at varying w/w ratios of SWNTs to DNA. The transfected cells were excited at $\lambda_{ex} = 490$ nm and the emission spectrum was collected at $\lambda_{em} = 520$ nm. The glowing cells detected under the microscope confirmed the expression of GFP proteins, which were then divided by total number of cells in the field of view, to obtain the percent cells transfected in the given treatment. Each experiment was performed in triplicate to calculate the random error between samples, and the experiments were repeated twice to confirm the reproducibility of the data. The values of transfection efficiencies obtained were normalized compared to plasmid alone treated cells to determine the percent value of transfection efficiency. It was found that the transfection efficiency was highest at w/w DNA to SWNT ratio of 1:58, due to the increase in net cationic component of the vehicle. As reported earlier, the higher transfection efficiencies obtained are attributed to strong noncovalent immobilization of DNA on the surface of SWNTs (*8*). The presence of net positive charge of the complex produces a "proton sponge" effect thus leading to the release of DNA in cytosol. The increase in net positive charge of the complex further increases the transfection ability of the vehicle, regardless of the type of cationic glycopoymer used for the surface functionalization of SWNTs (Figure 3).

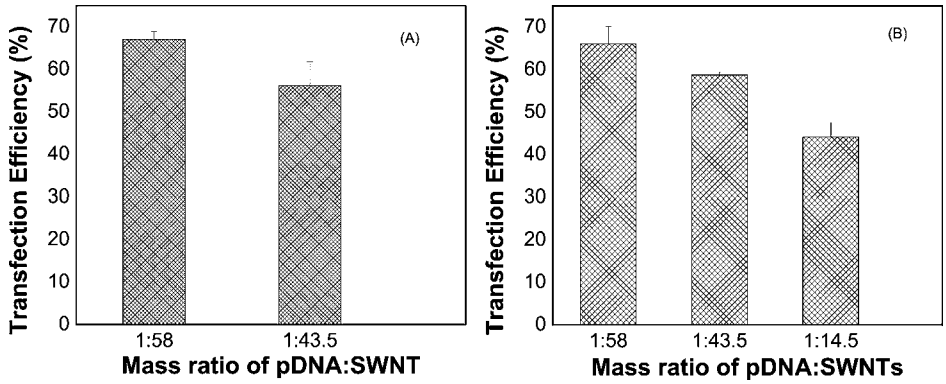

Figure 3. Transfection efficiencies of P($APMA_{31}$-*b*-$LAEMA_{32}$)-*f*-SWNTs after modification with pEGFP plasmid (A) and transfection efficiencies of P($APMA_{38}$-*b*-$GAPMA_{20}$)-*f*-SWNTs upon complexation with pEGFP-plasmid (B).

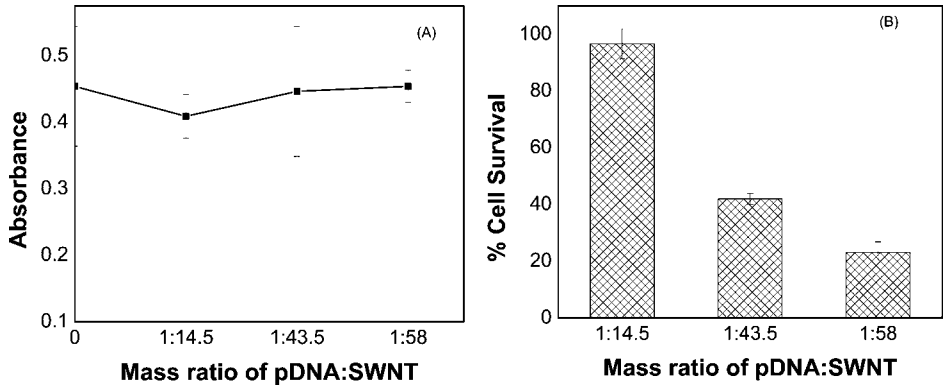

Figure 4. The comparison of cell viability assays after the treatment of Hela cells with P($APMA_{38}$-*b*-$GAPMA_{20}$)-*f*-SWNTs plasmid complex. (A) MTT assay of cell viability. (B) Trypan blue assay for cell viability.

The use of two types of surface-functionalized SWNTs, containing same cationic moiety but different glycopolymer segments, confirms that the transfection abilities of nanotubes is a function of the presence of cationic component (PAPMA) on the surface of the nanotubes, thus leading to the same DNA condensation abilities of nanotubes. The role of glycopolymer moieties (PLAEMA and PGAPMA) is limited to providing the biocompatibility and cell-mediated interactions to the vehicles. The cytotoxicity of carbon nanotubes was then assessed after transfection using two different assays, Trypan blue assay and MTT assay. (Figure 4 and Supporting Information Figure S6).

The cytotoxicity of carbon nanotubes is an uncertain but important parameter for their use in biomedical applications. The toxicity of carbon nanotubes is found to be dependent upon the type of cell line used, type and degree of surface functionalization of nanotubes, and type of test used to study the toxicity (*11*, *27*, *28*). Wrle-Knirsch et al. has demonstrated the need to use more than one independent viability tests to determine the accurate cell viability of SWNTs treated cells (*11*). We further confirm that the use of more than one cell viability tests is crucial, when dealing with new nanomaterials like CNTs, as their exact mechanism of interaction with viability tests is unclear. The cell viability results of cells treated under the same conditions as used for transfection experiments were compared by using MTT and trypan blue assay. The media alone and untreated cells were used as negative and positive controls, respectively, to calculate the percent cell viability after the treatments (Figure 4).

Liu et al. and other researchers have reported that MTT assay shows no net loss in cell viability before and after the treatment of cells with carbon nanotubes during the transfection process (*4*, *10*). We, hereby, report the same results, showing no loss in cell viability after the treatment of cells with gene delivery vehicle using MTT assay. In contrast, a concentration-dependent loss in cell viability of the transfected cells was found with trypan blue assay. The trypan blue assay also called the dye exclusion method involves a manual count of live and dead cells and is tedious but is more reliable than other photometric assays available. The comparison among photometric assays of cell viability after their treatment with carbon nanotubes has already been studied, and it has been reported that, compared to other assays, MTT shows a reduction in cell viability due to the possible interactions of nanotubes with formazan crystals. We suggest the need to compare the photometric tests with manual counting of cells after the treatment with carbon nanotubes, as the exact mechanism of interaction of carbon nanotubes with other photometric assays is not known.

It should also be noted that the viability of the transfected cells was improved in comparison to the cells treated with functionalized SWNTs in the absence of DNA for 12 h. The DNA complexation of nanotubes leads to a considerable decrease in the toxicity of the material, even after 24 h of exposure, possibly due to the decrease in the net cationic character of the nanotube complex. The toxicity results of transfected cells are also compared to those where cells are incubated with functionalized SWNTs alone. It can be seen that in the case of transfected cells 15 μg of SWNTs complexed with plasmid yield about 60 $\pm$ 12% cell viability, and the same cytotoxicity values are obtained when 7 μg of SWNTs (in the absence of plasmid) is incubated with cells for 12 h (Supporting Information Figures S4, S5, and S6). The results are similar to the other studies, where complexation of DNA to nanomaterials is found to decrease the toxicity and increase the solubility of material, causing an enhancement in their cellular uptake (*29*).The transfection

efficiencies of glycopolymer-functionalized SWNTs were compared to their cytotoxicity profiles. The increase in transfection efficiency is proportionally associated with an increase in toxicity of the material, due to an increase in the cationic component of the vehicle. However, a desirable contrast of cell viability and transfection efficiency is achieved at DNA/P($APMA_{31}$-*b*-$LAEMA_{32}$)-*f*-SWNT w/w ratio of 1:43.5. The cell viability is found to be 60 ± 12% accompanied by ~60% transfection efficiency (Figure 3a and Supporting Information Figure S6). A further increase in cationic component of the vehicle to DNA/SWNT w/w ratio of 1:58 noticeably decreases the cell viability, yielding ~25% viable cells, associated with less than 10% increase in transfection efficiency (Figure 3a and Supporting Information Figure S6). The DNA/SWNT w/w ratio of 1:43.5 showed the combination of transfection efficiency and cell viability that resembles commercially available standard Lipofectamine 2000 (Figures 3, 4, and Supporting Information Figures S6 and S8−S10). It was found that lipofectamine yields the transfection efficiency of 55 ± 5% with high toxicity values (~25%, measured by MTT assay) under the same conditions (Supporting Information Figure S10). Although two types of cationic glycopolymer-functionalized SWNTs show similar transfection efficiencies, owing to their similar cationic component, their toxicity profiles are quite different from each other. The toxicity profiles of the two types of nanotubes are found to be associated with their glycopolymer segments; the nanotubes with higher glycopolymer segment are less toxic and vice versa. As indicated by our results, although the cationic component of two types of functionalized nanotubes is the same P(APMA-*b*-LAEMA)-*f*-SWNTs are found to be less toxic than P(APMA-*b*-GAPMA)-*f*-SWNTs mainly due to the difference in their glycopolymer segment (Figure 4 and Supporting Information Figure S6). This further demonstrates the role of the glycopolymer segment in masking the cationic component of the gene delivery agent, thus contributing toward the successful synthesis of gene delivery vehicle with improved properties.

To summarize, we report here the facile synthesis, characterization, and *in vitro* studies of biocompatible cationic single-walled carbon nanotubes. The glycopolymer functionalized carbon nanotubes are found to have the potential to replace other commercially available gene delivery vehicles due to their high transfection efficiency and relatively low toxicity. Future studies will focus upon the functionalization of SWNTs with block copolymers of different compositions, with the idea to explore a wide range of block copolymer to find an appropriate composition of glycopolymer segment that can yield considerable transfection values with relatively low toxicity.

ACKNOWLEDGMENT

This work is supported jointly by Natural Sciences and Engineering Research Council of Canada (NSERC) and Ontario Centres of Excellence, Emerging Materials and Knowledge (OCE-EMK). The authors thank Dr. R. Lafrenie (Sudbury Regional Hospital) for his help in obtaining confocal images of cells and use of instruments.

Note Added after ASAP Publication: This paper was published ASAP with missed corrections on October 13, 2009. The revised version was published on October 20, 2009.

Materials and Methods

Materials

All chemicals were purchased from Sigma–Aldrich, Acros, or Pierce Chemicals and were used without further purification. High-purity single walled carbon nanotubes (SWNTs) (80–90%) were obtained from Carbon Solutions, Inc. The SWNTs had an average bundle length of 1–5 μm and an average bundle diameter of 2–10 nm and were used without further purification. The carboxylic acid content in the SWNTs was determined by Carbon Solutions and was estimated to be around 4–6 atom%. The biotinyl-*N*-hydroxysuccinimide ester (Biotin-NHS) and p(LAEMA$_{32}$-*b*- APMA$_{31}$) diblock copolymer were synthesized as previously described, and the degrees polymerization (DPs) of PAPMA and PLAEMA are 31 and 32, respectively, calculated from the ^{1}H NMR spectra. GPC trace of P(LAEMA-*b*-APMA) shows the copolymer has the molecular weight of 20,500 and a narrow polydispersity (1.21).

Characterization. ^{1}H NMR spectra of the monomers and polymers were recorded on a Varian 200 MHz instrument. Aqueous gel permeation chromatography analysis was performed on a Viscotek Instrument using a 0.5 M sodium acetate/acetic acid buffer as eluent, two Waters WAT011545 columns and a flow rate of 1.0 mL/min. Six near-monodisperse PEO standards (Mp = 1,010 - 101,200 g mol^{-1}) were used for calibration.

Infrared (IR) spectra were recorded on a Bomem MB series spectrometer. The analyses were performed with Win-Bomem Easy software. Thermogravimetric analysis (TGA) was performed on a TA 500 instrument at a heating rate of 5 ^{o}C/min for a temperature range of 25–900 ^{o}C.

Ultraviolet–visible (UV–vis) spectra of the functionalized SWNTs were recorded on a Biochrom Ultro- Spec 2100 instrument. Transmission electron microscopy (TEM) images were recorded using a Philips CM120 electron microscope at an accelerating voltage of 200 kV.

Confocal Microscopy

The fluorescent images were obtained using Zeiss LSM 510 Meta confocal microscope with 63x objective. The wavelengths of excitation and emission used were 490 nm and 520 nm, respectively.d

The preparation of glycopolymer Surface-functionalized SWNTs. The glycopolymer functionalized SWNTs were prepared from the P($LAEMA_{32}$-*b*-$APMA_{31}$) diblock copolymer and carboxyl functionalized SWNTs. A typical protocol was as follows. The SWNTs (20 mg) was added into aqueous solution (pH 6, 20 mL) of EDC (19.2 mg) and NHS (11.5 mg). The reaction mixture was sonicated for 3 h at room temperature. Then 5 mL aqueous solution of diblock copolymer (198.4 mg) was added into above active SWNT solution and changed the solution pH to 9. The mixture was sonicated for 4 h and stirred the reaction mixture overnight at room temperature. The solution was placed for 2 days for the precipitation of un-functionalized SWNT in water without any disturbance. The above solution was carefully decanted, and removed the solvent under vacuum. The obtained black solid was then dispersed into water. A dark solution was obtained with a tiny amount of a black, insoluble precipitate. The solution was filtered, and the dark solution was centrifuged to remove the free polymer chains under 20,000 rpm for 30 min and repeated three times. The final product (38 mg) was freeze-dried under vacuum for 2 days.

The preparation of biotinylated glyco-functionalized SWNTs.

Glyco-functionalized SWNT solutions were dispersed into water at pH 9 and sonicated for 30 min, 1 mL of DMF and Biotin-NHS was added into above aqueous solution. This mixture was sonicated for 2 h and stirred overnight at room temperature; the solvents were evaporated under reduced pressure. The residue was washed with acetone to remove free biotin molecules repeated three times. The black powder was dried overnight under vacuum.

Plasmid Preparation and Purification. pEGFP-N1, enhanced green fluorescent plasmid driven by cytomegalovirus (CMV) promoter, was transformed in supercompetent E. Coli cells and was amplified in 30 μg/mL Kanmycin containing LB broth media at 37 °C overnight with 225 rpm. After sufficient bacterial growth, the cells were pelleted by centrifugation at 2000*g* and 20 °C for 5 min followed by plasmid extraction using QIAGEN mini plasmid purification kit as per vendor's protocol. Plasmid purity was assessed by UV spectrophotometry ($A_{260/280}$ > 1.75), and by agarose gel electrophoresis.

DNA Complexation

DNA complexation of p($APMA_{38}$-*b*-$GAPMA_{20}$)-functionalized-CNTs and p($APMA_{31}$-b-$LAEMA_{32}$)-functionalized carbon nanotubes was studied using agarose gel electrophoresis. The varying concentrations of carbon nanotubes (0.05, 0.1, 0.15 & 0.20 mg/mL) were incubated with 340 ng of pEGFP-N1 plasmid and the complexes were loaded into 0.7% agarose gel. The gel was run for one hour at 70 V and the complexes were characterized after staining the gel with 0.5μg/mL of ethidium bromide. The images were obtained on an ultraviolet transilluminator.

Confocal Microscopy

Hela cells were grown in Dubelcco's modified eagle medium, DMEM containing 10% fetal bovine serum and 1% penicillin/streptomycin, in a humidified atmosphere with 5% CO_2 at 37 °C. Upon 80% confluency, cells were trypsinized and neutralized with the equal amount of

medium. The cells were then reseeded in a 6 well plate, in which each well contained sterile glass cover slips. The plate was incubated in humidified atmosphere at 37 °C and upon 80% confluency, 0.15 mg/mL p($APMA_{31}$-*b*-$LAEMA_{32}$) and p($APMA_{38}$-*b*-$GAPMA_{20}$) functionalized carbon nanotubes complexed with 4 μM FITC-labeled oligonucleotides containing medium was introduced in separate chambered cover glass. The other two wells served as controls, containing no treatment, and 4 μM FITC-labeled oligonucleotides in the medium, respectively. The cells were further incubated for 48 hours at 37 ˚C. The growth medium was then removed, and cells were washed several times with phosphate buffer saline. The cells were fixed with 4% paraformaldehyde solution at room temperature for 5 minutes, followed by washing with PBS. The cover glass was then mounted on microscopic glass slide and was studied under the microscope.

Transfection

Hela cells were maintained in Dulbecco's modified Eagles' medium, supplemented with 10% Fetal bovine serum at 37 ˚C, in a humidified 5% CO_2 atmosphere, as described above. Before the experiment, 10,000 Hela cells were seeded on a 96 well tissue culture plate and allowed to adhere over night. The test samples were prepared for each well by mixing 340 ng of pEGFP-plasmid with varying amounts of carbon nanotubes. The mixture was incubated for 15 minutes and was added to the cells, and the plate was incubated for 24 hours at 37 ˚C, in serum free medium. The cells were washed three times with Dulbecco's Phosphate Buffer (DPBS) and were allowed to grow for another 24 hours in fresh culture medium supplemented with 10% FBS. The gene expression was evaluated using fluorescent microscopy. The presence of GFP protein was confirmed using the emission spectrum of green fluorescence protein at 520 nm.

The transfection studies with Lipofectamine were done as described by standard protocol. The lipofectamine was incubated with pEGFP plasmid and complexes were transferred in 96 well plates containing 10,000 Hela cells. The media was changed after six hours and was replaced with fresh serum containing medium. The cells were allowed to grow for further 48 hours, and the gene expression was evaluated as described above.

Toxicity assay on Transfected cells using MTT Assay: Hela cells maintained at 80% confluency were seeded at 10,000 cells/well in 96 well plate and were allowed to adhere overnight. The varying concentrations of carbon nanotube-plasmid complex in serum free medium were added to each well and each experiment was done in triplicate, as describes above. After six hours the medium was changed to serum containing medium and cells were allowed to grow for another 48 hours. The cell viability was tested using MTT assay. The 25 µL MTT dye was added to each well and plate was incubated for 2 hours. Next 100 µL of MTT lysis solution was added to each well and cells were incubated overnight. Absorbance was measured at 570 nm with Power wave instrument. Survival percentage was calculated by comparison to untreated cells (100% survival).

Toxicity assay on Transfected cells using Trypan Blue Assay: Hela cells were seeded at 10,000 cells/well in 96 well plate and were allowed to adhere overnight. The varying concentrations of carbon nanotube-plasmid complex in serum free medium were added to each well and each experiment was done in triplicate, as describes above. After 24 hours the medium was changed to serum containing medium and cells were allowed to grow for another 24 hours. The cells were then trypsinized, neutralized and stained with trypan blue solution. The stained cells were then counted using hematocytometer and percent cell viability was determined by dividing the number viable transfected cells with the number of untreated cells.

Received September 14, 2009

The syntheses of novel near-infrared (NIR) dyes with excellent optical properties in biological tissues have driven the continued improvement of fluorescence imaging of deeply seated tumors. Bacteriochlorophyll *a* (Bchl), a dye synthesized by the phototrophic bacteria, *R. sphaeroids*, is particularly suited for deep tissue imaging due to its high absorbance coefficient and good fluorescence quantum yield in the NIR spectrum. However, obstacles that impede the development of this fluorophore are its poor stability and lack of tumor specificity. These issues ultimately limit its utility for tumor detection. Herein we describe a robust synthesis of a novel Bchl analog, bacteriochlorin e_6 bisoleate (BchlBOA), which is chemically stable, has excellent photophysical properties (ex, 752 nm; em, 762 nm) and is tailored for the incorporation into a tumor targetable high-density lipoprotein (HDL)-like nanoparticle (NP). Incorporating BchlBOA into HDL (HDL−BchlBOA) yielded 12 nm sized particles, corresponding well with the diameter of native HDL. Functional cell uptake studies showed that HDL−BchlBOA was taken up by cells expressing the HDL receptor, scavenger receptor B type I (SR-BI), and was inhibited by 25-fold excess native HDL. Furthermore, the NP was successfully detected in KB cancer cells both in vitro and in tumor xenografts. Taken together, these results demonstrate that we successfully synthesized and formulated a stable analog of Bchl that is capable of being incorporated within HDL-like NPs for tumor-targeted imaging.

INTRODUCTION

Near-infrared (NIR) fluorescence imaging of cancerous tumors offers several advantages over other imaging modalities. These advantageous include its noninvasive detection, good sensitivity, and utilization of nonionizing radiation. Since the absorbance coefficients of endogenous absorbers including water and hemoglobin are at a minimum within the NIR window (650−900 nm) (*1*), NIR fluorescent probes offer optimal spectral properties and can theoretically be used to visualize tissues as deep as 10 cm depending on tissue type and the imaging modality (*2*). Polymethine cyanine-based dyes are the most commonly used NIR probes. These dyes are very useful in designing probes with adjustable wavelengths because they can be tuned to desired wavelengths by altering the heterocyclic nucleus (indolenine or benzindolenine) and the number of double bonds ($n = 1-3$) in the polymethine chain. For example, the water-soluble and bioconjugatable CyDyes (*3*) such as Cy5 ($n = 2$, indolenine nucleus, Ex_{max}, 649 nm; Em_{max}, 670 nm), Cy5.5 ($n = 2$, benzindolenine nucleus, Ex_{max}, 676 nm; Em_{max}, 694 nm), and Cy7 ($n = 3$, indolenine nucleus, Ex_{max}, 743 nm; Em_{max}, 767 nm) are NIR active and proven to be useful in a wide range of in vivo imaging applications (*4*−*6*). Furthermore, the only FDA approved NIR dye, indocyanine green (ICG), also belongs to this family ($n = 3$, benzindolenine nucleus, Ex_{max}, 805 nm; Em_{max}, 830 nm, $\xi > 150\,000$ $M^{-1}\cdot cm^{-1}$ with a quantum efficiency ∼4−5%) and is approved for imaging of retinal vasculature (*7*) and monitoring hepatic function (*8*).

Another important class of exogenous probes are the porphyrin-based or porphyrin-like fluorophores (phthalocyanines, expanded porphyrins, porphycenes, etc.). Porphyrins are 18 π-electron aromatic macrocycles, where two of its peripheral double bonds are not required to maintain aromaticity. Thus, reduction of one or both of these bonds respectively leads to chlorins and bacteriochlorins with bathochromically shifted bands with higher extinction coefficients. Generally, the longest wavelength absorptions (and extinction coefficients) for porphyrin, chlorin, and bacteriochlorin are at 630 nm (ε ∼5 000 $M^{-1}\cdot cm^{-1}$), 660 nm (ε ∼45 000 $M^{-1}\cdot cm^{-1}$) and 760 nm (ε ∼75 000 $M^{-1}\cdot cm^{-1}$), respectively (*9*). Nature uses the optical properties of the reduced porphyrins to harvest solar energy for photosynthesis with chlorophylls and Bchls acting as both antenna and photochemical reaction center pigments. The NIR absorption and fluorescence of these natural dyes clearly make them potential candidates as contrast agents for NIR optical imaging, although they are better known for their applications as photodynamic therapy (PDT) agents due to their high triplet state and singlet oxygen quantum yields. Nevertheless, there are already some reports using NIR-active porphyrin-based fluorophores for cancer imaging (*10*−*13*) and the fact they are both NIR fluorophores and photosensitizers make them ideal candidates for image-guided therapy (*14*−*17*).

Bchl extracted from *R. sphaeroids* is a NIR fluorophore with excitation and emission profile (750−850 nm) highly suited for imaging deeply seated tumors. However, two issues which hinder the utilization of this agent for tumor imaging include (i) poor stability caused by rapid oxidation and (ii) lack of specificity for cancer tissue. Various investigators have attempted to address the poor stability of the Bchl molecule. These include replacing the central magnesium with other metal ions (e.g., palladium) to form more stable complexes (*18*), modifying

the isocyclic ring (*19*), and replacing the phytyl group at the propionyl residue either through transesterification or by conversion to an amide derivative (*20*). In particular, Pandey et al. have shown that naturally occurring unstable Bchl *a* can be converted to stable bacteriochlorins, bacteriopurpurin-18, and bacteriopurpurinimide (*19*). In this approach, converting the fused isocyclic ring to a cyclic imide moiety enhanced the stability and solubility of the Bchl analogs, while attachment of a variable alkyl substituent to the imide moiety allowed the lipophilicity of the molecule to be fine-tuned (*21*). In another elegant demonstration, Fiedor et al. found that inserting palladium into the Bchl ring significantly improves the stability of this molecule, however fluorescence properties of this complex is compromised (*22*). Nevertheless, this Bchl analog led to the development of the promising PDT agent Tookad, which is currently in clinical trials (*23*, *24*). So far there have been minimal efforts in developing target-specific Bchls and even fewer attempts in exploring the utility of stable Bchl analogs as NIR fluorescent probes.

High-density lipoproteins (HDL) are endogenous carriers used to transport hydrophobic compounds throughout the body. The structural/functional properties of these particles, ultrasmall size (7−12 nm) (*25*), long circulation time (*26*, *27*), nonimmunogenic, and biodegradable, also make them attractive as delivery vehicles for exogenous compounds. HDL's hydrophobic core facilitates the incorporation of hydrophobic compounds into this carrier, while the small size and favorable surface properties enable these particles to remain undetected by the reticular endothelial system as well as rendering them accessible to most tissues. Furthermore, some cancer cell lines have been shown to have a high expression of the HDL receptor, formally known as scavenger receptor type B1 receptor (SR-BI). Since HDL's core lipid transfer is mediated through the SR-BI pathway, targeting this receptor represents a novel way to deliver imaging agents to cancer tumors which overexpress this receptor. This paper outlines (1) a simple and high yield synthesis of a stable Bchl analog; (2) methods of actively incorporating this Bchl analog into HDL-like NPs (HDL BchlBOA); and (3) the utility of HDL−BchlBOA as a novel diagnostic agent for cancer imaging. The overall goal of this work is to combine the advances of both technologies to generate a new tool for the diagnostic imaging of cancers in vivo.

EXPERIMENTAL PROCEDURES

Reagents. All chemicals were of reagent grade and used as such. Reactions were carried out under nitrogen atmosphere and were monitored by precoated (0.20 mm) silica TLC plastic sheet (20 × 20 cm) strips (POLYGRAM SIL N-HR) and/or UV−visible spectroscopy. Silica gel 60 (70−230 mesh, Merck) was used for column chromatography. UV−visible spectra were recorded on a Varian (Cary-50 Bio) spectrophotometer. Fluorescence spectra were collected using a FluoroMax-4 (HORIBA Scientific, Kyoto, Japan) spectrofluorometer. Bacteriopheophorbide *a* (**1**) was synthesized from *R. sphaeroids* (Frontier Sciences, Utah). Proton NMR spectra were recorded on a Bruker AMX 400 MHz NMR spectrometer operating at 303 K. Proton chemical shifts (δ) are reported in parts per million (ppm) relative to $CDCl_3$ (7.26 ppm), or TMS (0.00 ppm). MS and purity data were obtained by a Waters Analytical HPLC equipped with a Waters 600 Controller, a Delta 600 pump, and a 996 Photodiode Array Detector and a Waters ZQTM mass detector (Waters Limited, Mississauga, ON). A reverse phase, Symmetry C18, 5 μm, 4.6 × 150 mm column (Waters, Made in Ireland) was used under an isocratic setting of $MeCN/H_2O$ for all compounds. The solvent flow rate was kept constant at 1.00 mL/min. All final products were found to be >95% pure.

Synthesis of BchlBOA. *Synthesis of Bacteriopheophorbide a (Bchl-acid 1).* Bacteriopheophorbide *a* (Bchl-acid **1**) was synthesized from Bchl which was extracted from *R. sphaeroids* in an inert atmosphere using 1-propanol following literature methods (*28*).

Synthesis of Bacteriochlorin e_6 Di-N-Boc-aminopropylamide (Bchl-2BOC 2). Bchl-acid **1** (330 mg, 0.54 mmol) was first dissolved in 20 mL of dichloromethane. To this solution, 160 mg of 4-*N*,*N*-dimethylaminopyridine (DMAP, 1.31 mmol) and 400 mg of *N*-Boc-1,3-diaminopropane (2.30 mmol) were added. This mixture was stirred under argon for 30 min at room temperature. Subsequently, 260 mg of dicyclohexylcarbodiimide (DCC, 1.26 mmol) was added, and the mixture was stirred for 40 h. The solvent was then removed by vacuum. The crude product was purified by silica gel column chromatography with 8% acetone in dichloromethane, and then with 4% methanol in dichloromethane. The desired product Bchl-2BOC **2** (368.3 mg) and a side-product Bchl-BOC-DCC **3** (140.8 mg) were obtained in 72% (0.39 mmol) yield and 26% yield (0.14 mmol), respectively.

Bchl-2BOC **2**: Mass calculated for $C_{51}H_{72}N_8O_9$: 941.17. Found by ESI-MS: 941.8 (M^+). ^{1}H NMR ($CDCl_3$, δ ppm): 9.31, 8.65, and 8.56 (each, s, 3H for 5, 10, 20-H), 7.30, 6.42, 6.07, and 5.98 (each, brs, 4H for 4 × NH), 5.21 (s, 2H, 15^1-CH_2), 4.32 (br, 1H for 18-H), 4.25 (brs, 1H, for 7-H), 4.23 (d, 1H, for 17-H), 4.14 (brs, 1H, for 8-H), 3.72 (s, 3H, for 15^2-CO_2CH_3), 3.69 (m, 2H, for 13^3-NCH_2), 3.39 (s, 3H, for 12-CH_3), 3.38 (m, 2H, 17^5-NCH_2), 3.32 (s, 3H, for 2-CH_3), 3.17 (s, 3H, for 3-$COCH_3$), 2.84−2.59 (m, 4H, for 13^5-CH_2N, 17^7-CH_2N), 2.36 (m, 1H, for 17^1-H), 2.22 (m, 1H, for 17^1-H), 2.04 (m, 2H, for 17^2-CH_2), 1.94 (m, 2H, for 8^1-CH_2), 1.82 (d, 3H, for 18-CH_3), 1.63 (m, 5H, for 7-CH_3, 13^4-CH_2), 1.40−1.23 (brs, 20H, for 17^6-CH_2, 13^9-$C(CH_3)_3$, 17^{11}-$C(CH_3)_3$), 1.08 (t, 3H, for 8^2-CH_3), −1.21 and −1.25 (each, s, 2H, for 2 × NH).

Bchl-BOC-DCC **3**: Mass calculated for $C_{56}H_{78}N_8O_8$: 991.27. Found by ESI-MS: 991.8 (M^+). ^{1}H NMR ($CDCl_3$, δ ppm): 9.29, 8.67, and 8.57 (each, s, 3H for 5, 10, 20-H), 7.14 and 5.16 (each, brs, 2H for 2 × NH), 5.16−5.35 (m, 3H, 15^1-CH_2 + NH), 4.20−4.33 (m, 4H for 18-H, 7-H, 17-H and 8-H), 3.72 (m, 2H, for 13^3-NCH_2), 3.70 (s, 3H, for 15^2-CO_2CH_3), 3.58 (s, 3H, for 12-CH_3), 3.35 (s, 3H, for 2-CH_3), 3.18 (s, 3H, for 3-$COCH_3$), 2.36 (m, 1H, for 17^1-H), 2.25−2.29 (m, 2H, for 13^5-CH_2N), 1.82−2.08 (m, 7H, for 17^1-H, 17^2-CH_2, 8^1-CH_2 and 2 × N−CH in cyclohexyl), 1.59 (d, 3H, for 18-CH_3), 1.52 (m, 2H, 13^4-CH_2), 1.39 (s, 9H, 13^9-$C(CH_3)_3$), 1.32 (m, 3H, for 7-CH_3), 0.83−1.25 (m, 23H, for cyclohexyl-H and 8^2-CH_3), −1.23 and −1.27 (each, s, 2H, for 2 × NH).

Synthesis of Bacteriochlorin e_6 Diaminopropylamide (Bchl-2NH$_2$ 4) and Bacteriochlorin e_6 Bisoleate (BchlBOA 5). Bchl-2BOC **2** 40 mg (0.043 mmol) was dissolved in 1.5 mL of trifluoroacetic acid (TFA). The solution was stirred first in an ice−water bath under argon atmosphere for 1 h, and then at room temperature for 1 h. The TFA was removed under vacuum, the crude product Bchl-2NH$_2$ **4** did not require further purification and was used directly for the next reaction.

The crude product Bchl-2NH$_2$ **4** was dissolved in 5 mL dichloromethane upon which 0.15 mL of diisopropylethylamine (DIPEA) was added to the solution. The mixture was then stirred under argon atmosphere at room temperature for 0.5 h, oleoyl chloride 0.15 mL was added into the mixture and stirred for an additional 4 h at room temperature. The solution was poured into 50 mL of ice water and washed with ice water three times (3 × 20 mL). The organic layer was dried over anhydrous Na_2SO_4 (100 mg) for 1 h. After the solvent was removed by vacuum, the crude product was purified by silica gel column chromatography with 5% methanol in dichloromethane. The desired product BchlBOA **5** (30 mg, 0.024 mmol) was obtained in 63% yield from two steps.

Bchl-2NH$_2$ **4**: Mass calculated for $C_{41}H_{56}N_8O_5$: 740.93. Found by ESI-MS: 741.5 (M^+).

BchlBOA **5**: UV−vis in $CHCl_3$ λ_{max}: 357 nm (ε, 8.6 × 10^4), 386 nm (6.5 × 10^4), 522 nm (2.4 × 10^4), and 752 nm (8.4 × 10^4).

Mass calculated for $C_{77}H_{120}N_8O_7$: 1269.83. Found by ESI-MS: 1270.2 (M^+). ^{1}H NMR ($CDCl_3$, δ ppm): 9.31, 8.67, and 8.57 (each s, 3H for 5-H, 10-H, and 20-H), 7.16, 6.36, 5.98, and 5.82 (each brs, 4H for 4 × NH), 5.31−5.15 (m, 6H, for 2 × CH═CH in oleoyl and 15^1-CH_2), 4.32 (brs, 1H, for 18-H), 4.25 (brs, 1H, for 7-H), 4.22 (brs, 1H, for 17-H), 4.13 (brs, 1H, for 8-H), 3.68 (s, 3H, 15-CO_2CH_3), 3.66 (m, 2H, for 13^3-NCH_2), 3.55 (s, 3H, 12-CH_3), 3.47 (m, 2H, 17^5-NCH_2), 3.30 (s, 3H, for 2-CH_3), 3.15 (s, 3H, for 3-$COCH_3$), 2.91−2.83 (m, 4H, for 13^5-CH_2N, 17^7-CH_2N), 2.37 (m, 1H, 17^1-H), 1.94−2.08 (m, 25H, 17^1-H, 13^{14}-CH_2−CH═, 17^{16}-CH_2−CH═, 13^{17}-═CH−CH_2, 13^{19}- ═CH−CH_2, 13^8-$COCH_2$, 17^{10} $COCH_2$, 17^2-CH_2, 13^{12}-CH_2, 13^{13}-CH_2, 17^{14}-CH_2, 17^{15}-CH_2, and 8^1-CH_2), 1.82 (d, 3H, 18-CH_3), 1.61 (d, 3H, 7-CH_3), 1.51 (m, 2H, 13^4-CH_2), 1.43 (m, 2H, 17^6-CH_2), 1.23−1.17 (brs, 34H, other H in oleoyl), 1.08 (t, 3H, 8^2-CH_3), 0.85 (m, 6H, 13^{24}-CH_3, 17^{26}-CH_3), −1.24 and −1.27 (each s, 1H, 2 × NH).

Apolipoprotein Preparation. Lipoproteins were isolated by sequential ultracentrifugation of human plasma using standard methods (*29*). Expired human plasma was obtained from the local blood transfusion services and was approved by the University Health Network's research ethics board.

Apolipoprotein A-1 (ApoA-1) was isolated from HDL by delipidation with organic solvents as reported by Scanu and colleagues (*30*). All incubation steps were conducted at −20 °C. Briefly, 1 mL of HDL in 0.1 M sodium phosphate buffer (pH 7.5) was pipetted into a 50 mL Falcon tube containing 50 mL of a precooled 3:2 ethanol/diethyl ether mixture. This solution was mixed in a rotating mixer for 6 h. The precipitate was pelleted by centrifugation at 2000 rpm for 10 min and the supernatant was decanted. After this step, the pellet was resuspended in 50 mL of fresh diethyl ether and mixed in a rotating mixer for an additional 18 h. Subsequently, the delipidated protein was subjected to 3 washes of diethyl ether. After the last step, each tube of delipidated ApoA-1 protein was resuspended in 1 mL of fresh diethyl ether, aliquoted and dried using a centrifuge under high vacuum.

Formulation of HDL−BchlBOA. HDL−BchlBOA was formulated by combining BchlBOA (0.35 mg), dimyristoylphosphatidylcholine (DMPC) (2.16 mg) and cholesterol oleate (CO) (0.08 mg) in a 5 mL glass tube. The mixture was dried by vortexing the sample under N_2 for 5 min. Once the solvent was evaporated, the sample was dried under vacuum for 1 h. The dried film was resuspended with 1 mL Tris buffered saline (10 mM Tris, 0.1 M KCl, 1 mM EDTA; pH 8.0; degassed) and transferred to a sonicator bath (Bransonic Model 5510, Branson, Danbury, CT) where it was sonicated for 1.5 h at 50 °C. The sample was diluted to 8 mL with Tris buffer and returned to the sonication bath at 40 °C. ApoA-1 (4 mg) dissolved in 1 mL of urea (4 M) was added dropwise to the lipid-dye complex over a period of 10 min. The formulation was then sonicated for an additional 50 min. Subsequently, the sample was removed from the bath and allowed to cool to room temperature before storing overnight (approximately 15 h) at 4 °C. The next day, the sample was passed through a 0.22 μm filter and concentrated to 2 mL using a 10 000 MW cutoff Amicon centrifugal filter device (Millipore, Billerica, MA) (980 g for 30 min). The sample was then purified by fast protein liquid chromatography (FPLC) using a Superdex 200pg 26/60 column (GE Healthcare, Piscataway, NJ) and stored at 4 °C until use.

Characterization of Formulation. *Chemical Composition.* The total protein content of the formulation was measured using a modified Lowry Protein Assay (Sigma-Aldrich, St. Louis, MO). BchlBOA concentration was measured by extracting the dye twice using a $CHCl_3$/MeOH mixture (2:1). The organic layer was dried by vacuum and redissolved in 1 mL $CHCl_3$. The concentration of BchlBOA in the sample was calculated from the molar extinction coefficient by measuring the absorbance at 752 nm.

Dynamic Light Scattering (DLS). The volume size distribution of the HDL−BchlBOA particles was obtained by DLS (Nanosizer ZS90, Malvern, Worcestershire, UK).

Transmission Electron Microscopy (TEM). TEM (Hitachi 7000, Japan) in combination with negative staining was used to visualize the morphology of the HDL-like NPs. Briefly, carbon film 400 mesh copper grids (Lakefield, QC, Canada) were glow discharged prior to addition of the sample. Ten microliters of purified HDL formulations diluted 1000−2000 times using distilled and deionized H_2O was pipetted onto the copper grid such that a droplet was formed. The droplet was allowed to stand on the copper grid for 1 min. Subsequently, 6 μL of 1% uranyl acetate was added to the droplet and allowed to stand for 1 min. All liquid was then removed by whisking the droplet away using filter paper. The sample was allowed to dry for 1 min before mounting into the apparatus. The acceleration voltage of the TEM was set to 75 kV. Samples were viewed at 100 000−150 000 times magnification.

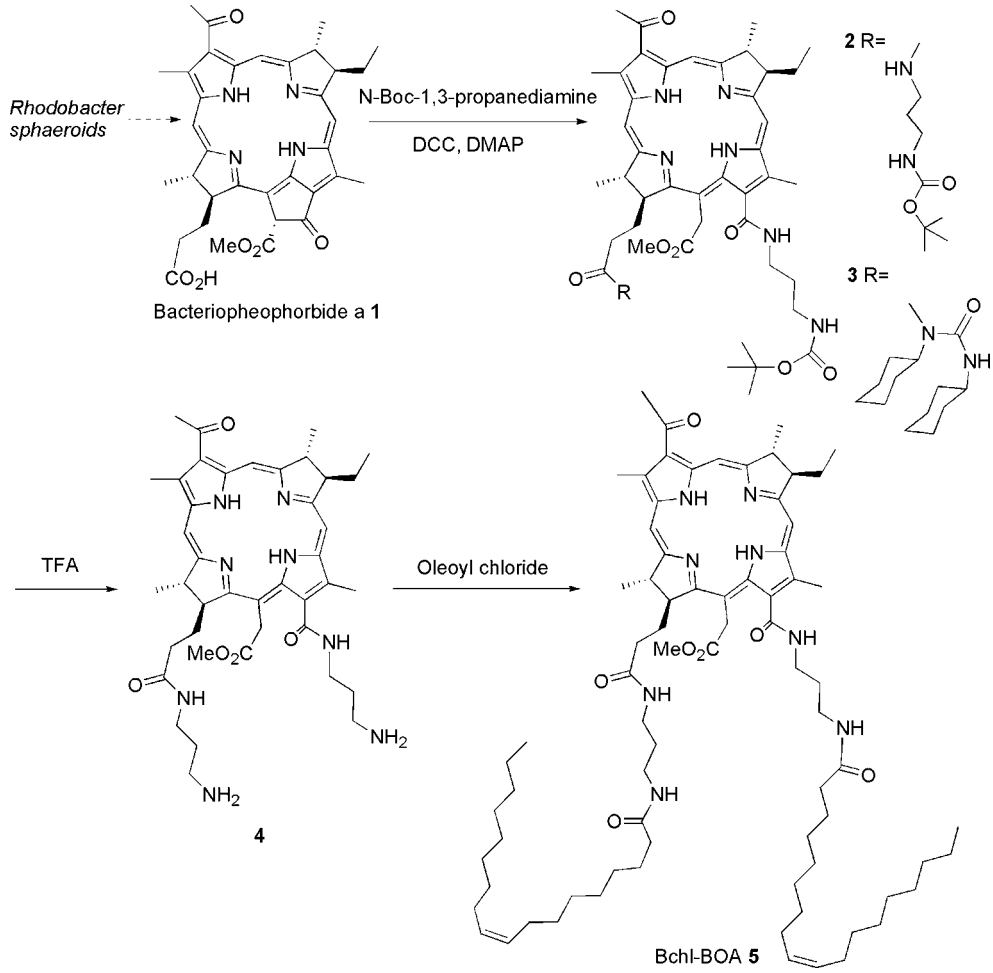
Cell Culture. All cells were cultured in 5% CO_2/95% air at 37 °C. KB cells were grown as a monolayer in a 125 cm^2 culture flask using modified Eagle's medium (ATCC 30−2003), supplemented with 10% fetal bovine serum (FBS). SR-BI positive ldlA[mSR-BI] cells were cultured in RPMI 1640 medium supplemented with 10% FBS. SR-BI negative ldlA7 cells were cultured in Ham's F-12 medium, supplemented with 2 mM L-glutamine, 1% penicillin/streptomycin, and 25% FBS.

Western Blot Analysis. ldlA[mSR-BI], ldlA7, and KB cells were cultured in a 6-wellplate. After confluence, protein was extracted from the cells using lysis buffer (20 mmol/L Tris, pH 7.5, 150 mmol/L NaCl, 1 mmol/L EDTA, 1 mmol/L EGTA, 1% Triton X-100, 2.5 mmol/L sodium pyrophosphate, 1 mmol/L β-glycerolphosphate) with a protease inhibitor cocktail (Sigma-Aldrich, St. Louis, MO) on ice for 10 min and centrifuged (11 000 g for 15 min, 4 °C). Supernatant protein levels were assayed using the Bradford method (Biorad Laboratories Inc., Hercules, CA). Twenty micrograms of each sample was separated on a 10% SDS-polyacrylamide gel and then transferred onto polyvinylidene difluoride membranes for standard Western blot analysis using monoclonal antibodies specific for SR-BI receptor (1:2000× dilution; AbCam, Cambridge, MA).

Cell Uptake Studies. ldlA[mSR-BI], KB, ldlA7 cells were seeded into 8-well Lab-tek chamber slides (0.8 cm^2/well) at a density of 3.0 × 10^4 cells per well. After 24 h, cells were washed with PBS followed by the addition of either cell media alone, cell media containing HDL−BchlBOA (8 μM), or cell media containing HDL−BchlBOA with 25-fold excess of HDL. The cells were allowed to incubate at 37 °C for 4 h after which the cells were washed twice with PBS and reincubated with 300 μL of incubation medium for imaging. Cell uptake was visualized using the Olympus FluoView 1000 laser scanning confocal microscope equipped with a Multiline Argon Laser and a 60× objective lens (oil; NA, 1.4). Fluorescence in the near-infrared was monitored from 700−800 nm using a tunable filter with a 515 nm excitation laser source.

Animal Studies. All animal experiments were conducted in accordance to the animal use protocol approved by University Health Network's animal care committee. Female athymic nude mice (7−8 weeks; 25 g) were purchased from Harlan Laboratories (Mississauga, ON). Tumor xenografts were generated in the right flank by inoculating mice subcutaneously with KB cells (3 × 10^6

Scheme 1. Synthesis of BchlBOA



cells) three weeks prior to the study. In order to decrease the background signal during fluorescence imaging, animals were fed a chlorophyll-free diet (TD.97184, Harlan Laboratories) 2 days before the imaging study.

In Vivo Fluorescence Imaging. Spectral reflectance fluorescence imaging was conducted on KB tumor-bearing mice using the Maestro in vivo imaging system (Cambridge Research and Imaging Inc., Woburn, MA). The NIR fluorescence reflectance system is comprised of a halogen light source with an excitation bandpass filter in the range of 641−681 nm and a 700 nm long-pass emission filter connected to a CCD camera. The image cube was taken from 700−800 nm in 10 nm steps, while the exposure time was set to 2000 ms.

Animals were prescanned to determine background autofluorescence. After prescanning, animals received an intravenous tail vein injection of 37 μM HDL−BchlBOA (dye concentration;

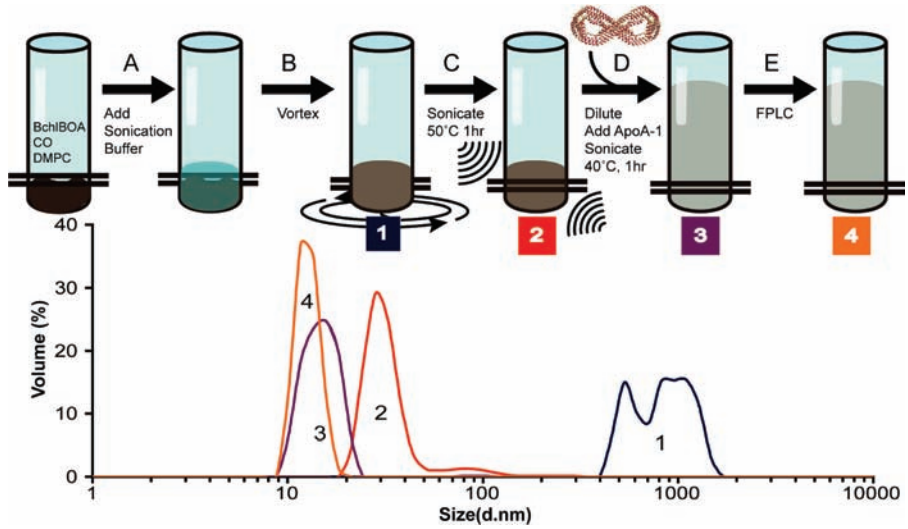


Figure 1. Schematic illustration of the formulation process for the incorporation of BchlBOA within HDL-like NPs. The size change of the particles in each step of the formulation is shown by DLS.

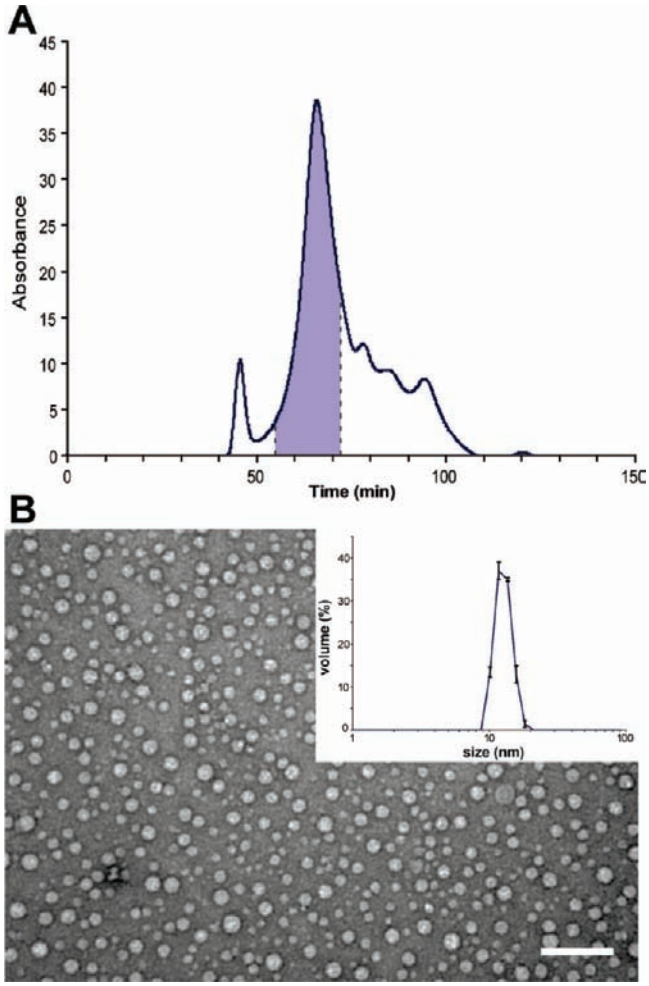

Figure 2. Purification and characterization of HDL−BchlBOA. (A) Purification of the formulated sample by size exclusion FPLC yielded three major size populations. The largest peak was collected as it corresponded with the size of native HDL (filled in blue). (B) The purified HDL−BchlBOA was sized for DLS (inset) and imaged by TEM at 100 000× magnification with 75 kV acceleration voltage. Scale bar equals 100 nm.

200 μL) and imaged at 1, 3, 6, and 48 h. After 48 h, animals were sacrificed and tissues were removed for tissue biodistribution characterization. Fifteen to 55 mg of tissue were weighed and homogenized in 1.5 mL phosphate-buffered saline. This homogenate then underwent organic extraction using $CHCl_3$:MeOH (2:1). The organic layer was removed and measured by fluorescence (excitation, 742 nm; emission, 762 nm; slit size, 5 nm).

RESULTS AND DISCUSSION

The synthesis of BchlBOA is outlined in Scheme 1. The final product, BchlBOA **5** was synthesized via the following 4-step procedure: (1) Bchl was extracted from *R. sphaeroids* (*15*), which was further hydrolyzed in dilute HCl to generate the key starting material, Bchl-acid **1**. (2) Bchl-acid was then reacted with *N*-Boc-1,3-diaminopropane in the presence of DMAP and DCC to yield the desired product Bchl-2BOC **2** in 72% yield as well as a minor side product, Bchl-BOC-DCC **3** in 26% yield. These products were obtained via (i) *N*-Boc-1,3-diaminopropane attack at the 13-C position of the β-keto ester, resulting in ring-opening to form an amide bond and (ii) a DCC-activated amidation reaction of the carboxylic acid located on the 17-C side chain. (3) Deprotection of the BOC group was carried out in TFA, and the product Bchl-2NH_2 **4** was used directly in the next step. (4) The desired final product, BchlBOA **5**, was synthesized through the reaction of Bchl-2NH_2 with oleoyl chloride in the presence of DIPEA in dichloromethane. The purity of the product was confirmed to be 96% by analytical HPLC and the overall yield for deprotection and acylation from Bchl-2BOC was 63%.

Native HDL particles transport lipophilic molecules such as triacylglycerides and cholesterol esters throughout the body by incorporating these molecules into its hydrophobic core. Introducing exogenous compounds to HDL particles can be challenging as the right conditions must be met to successfully incorporate compounds into the core of the particle. In general, the HDL core-loading works best with compounds containing a long unsaturated hydrocarbon chain (e.g., oleic or linoleic acid) or branched side chains (e.g., polyisoprenes such as phytol). Our strategy of incorporating the Bchl derivative into HDL was to attach dual unsaturated lipid "anchors" to the molecule. This strategy has been used in our lab and others to incorporate

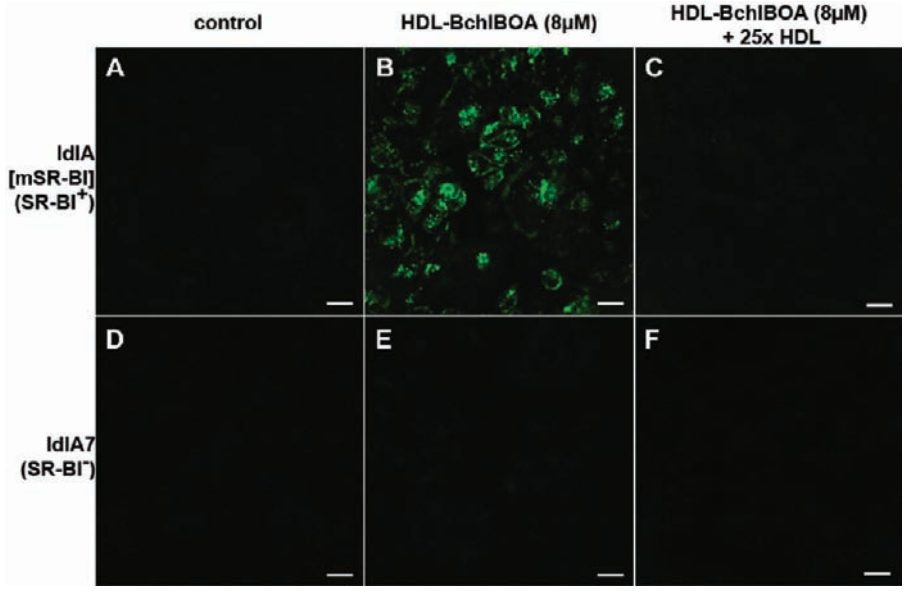

Figure 3. Representative fluorescence microscope images of cells treated with HDL−BchlBOA. Wells were seeded with ldlA[mSR-BI] (A−C) or ldlA7 (D−F) cells 24 h before imaging at a density of 3×10^4 cells per well. Final well volume was 200 μL. Cells either had no treatment (A,D), 8 μM HDL−BchlBOA (dye concentration) (B,E), or 8 μM HDL−BchlBOA (dye concentration) with 25-fold molar excess of HDL protein (C,F). Cells were excited at 515 nm and emission was captured from 700−800 nm. Scale bars correspond to 20 μm.

compounds such as bisoleoyl fluorescein (*31*), oleoyl-conjugated 5-fluorodeoxyuridine (*32*), bisoleoyl derivatives of silicon phthalocyanine, (*33*) and naphthalocyanine (*34*) into low density lipoproteins. Furthermore, attempts to incorporate oleoyl conjugated molecules into HDL have also been successful (*35*). By utilizing this strategy in the development of a novel HDL compatible fluorophore, we synthesized Bchl with bisoleate chains at the 13 and 17-C positions and successfully incorporated it into the HDL−BchlBOA.

The formulation of HDL−BchlBOA first involved preparing a thin film comprised of BchlBOA, CO, and DMPC. We found that a molar ratio of 22:1:2:1 (DMPC/CO/BchlBOA/ApoA-1) generated the desired HDL-sized NPs. In the initial steps, the addition of TRIS buffer and vortexing created a suspension of large emulsion particles, this is observed by the large and broad size distribution in DLS measurements (Figure 1). In order to prepare the sample for the addition of ApoA-1, we subsequently sonicated the formulation in a temperature-controlled bath sonicator at 50 °C for 1 h. Mechanical disruption of the lipid emulsion at this elevated temperature allowed for the generation of emulsion particles approximately 35 nm in diameter. At this point, the solution changed from an opaque appearance to a clear brown color. In the next step, ApoA-1 dissolved in 4 M urea, which served to maintain the protein in an unfolded state, was added over a period of 10 min to the diluted 8 mL emulsion. The concentration of urea decreased to 0.4 M upon addition to the sample, which allowed the protein to renature and interact with the lipid emulsion (*36*). Confirmation of this interaction and the formation of the desired HDL particles were validated by DLS size measurements as the diameter of the particle dropped to an average of 12 nm. This result corresponded well with the size of native HDL which ranges from 7−12 nm (*25*, *37*). Lastly, purification by FPLC allowed us to isolate a narrow size distribution of NPs and remove any remaining unbound ApoA-1 (Figure 2A). We next calculated the payload of BchlBOA within the HDL and found that there were on average 3 dyes per ApoA-1 protein, while the incorporation efficiency was calculated to be 40%. With the assumption that each HDL particle had between 2 to 3 molecules of ApoA-1 (*37*), this results in 6−9 molecules of dye per particle and represents a significant improvement on previous HDL-like NP formulations (*35*).

We next visualized our formulations by TEM to observe the morphology of our NP. Negative stain showed HDL−BchlBOA overwhelming possessed a spherical shape (Figure 2B). This shape was expected as neutral lipids (i.e., cholesterol oleate, BchlBOA) loaded into HDL particles will partition to the core and transform it into a spherical particle under favorable conditions (*38*).

To validate that HDL−BchlBOA retained similar functional properties as the native particle, cell uptake studies were performed. ApoA-1, the major protein found in HDL, is responsible for both the structural and functional properties of the native particle. Functionally, ApoA-1 is able to bind to the SR-BI receptor, which mediates the transfer of its cholesterol content into the host cell (*39*). Two Chinese hamster ovary (CHO) mutant clones, ldlA[mSR-BI] (ldlA7 with stably transfected mSR-BI receptor) and ldlA7 were used to delineate the high and low SR-BI receptor expression groups, respectively (*39*). In this study, we monitored the uptake of HDL−BchlBOA in these two cell lines. Under identical treatment conditions, HDL−BchlBOA was taken up exclusively by ldlA[mSR-BI] cells (Figure 3B) but was not taken up by ldlA7 cells (Figure 3E). Furthermore, the degree of uptake of HDL−BchlBOA by ldlA[mSR-BI] cells was successfully inhibited by a 25-fold excess native HDL (Figure 3C). These results indicate that the SR-BI mediated lipid transfer activity of HDL−BchlBOA was retained.

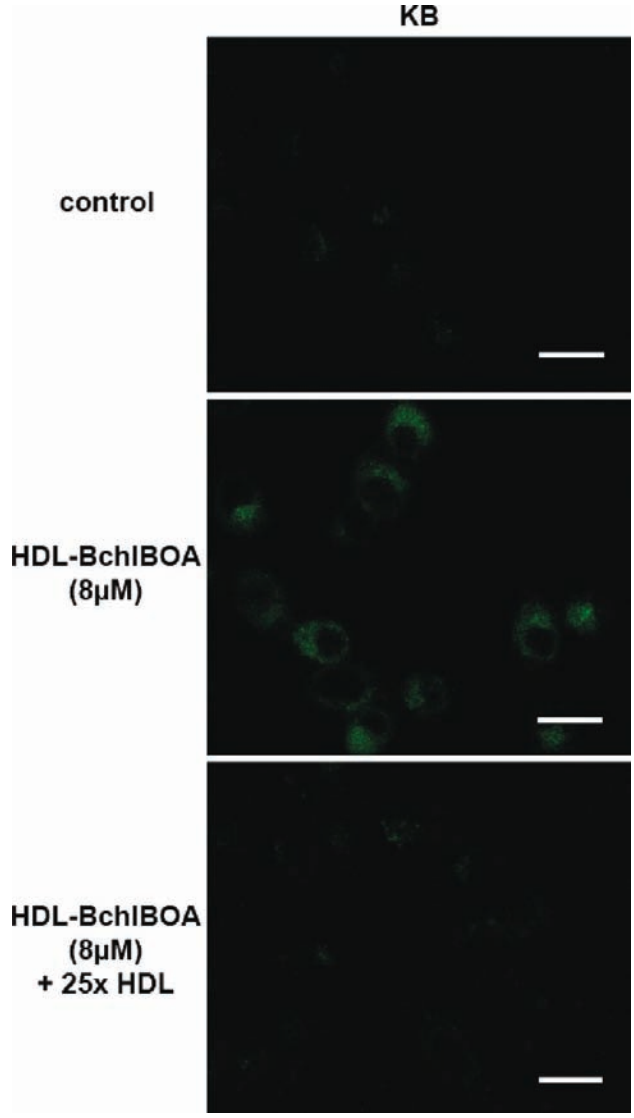

Figure 4. Fluorescence microscopic images of cells treated with HDL−BchlBOA. Cells were seeded with KB cells at a density of 3×10^4 cells per well 24 h before imaging. Final well volume was 200 μL. Cells either received no treatment (top), 8 μM HDL−BchlBOA (dye concentration) (middle), or 8 μM HDL−BchlBOA (dye concentration) with 25-fold molar excess of HDL protein (bottom). Cells were excited at 515 nm and fluorescence was captured from 700−800 nm. Scale bar corresponds to 20 μm.

The next question that needed to be addressed was whether HDL−BchlBOA can be taken up by cancer cells. Since KB cells express the SR-BI receptor, evidenced by the Western blot analysis of SR-BI expression (Supporting Information Figure S1), it was expected that HDL−BchlBOA should bind and transfer lipids to KB cells. KB cells were cultured and treated with the same conditions as the ldlA[mSR-BI] and ldlA7 cells. As expected, we observed a weaker but similar pattern of uptake as ldlA[mSR-BI] (Figure 4B). Furthermore, this uptake was also successfully inhibited by a 25-fold excess of HDL (Figure 4C). These results demonstrate that KB cancer cells are able to bind and take up lipids from HDL-like NPs through the SR-BI receptor.

To assess the tumor targeting capacity of HDL−BchlBOA, we employed a mouse tumor xenograft model. Athymic nude mice bearing KB tumors in the right flank were injected

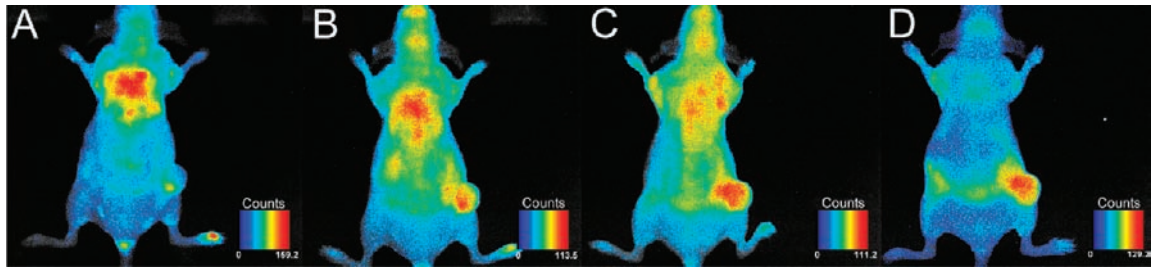

Figure 5. Spectral reflectance fluorescence images of tumor-bearing mice dosed with HDL−BchlBOA. Mice were dosed with 7.4 nmoles (200 uL) HDL−BchlBOA (dye concentration) and imaged at 1 h (A), 3 h (B), 6 h (C), and 48 h (D). Pseudo color images were captured with 2000 ms exposure.

intravenously with HDL−BchlBOA. Whole body distribution of the dye was monitored over 48 h by multispectral reflectance fluorescence imaging (Figure 5). We observed rapid accumulation of the probe in the chest area as early as 1 h. This fluorescence decreased over time, with a concomitant increase in signal intensity in the tumor vicinity. After 6 h, the signal was visualized intensely at the tumor site. Extraction of BchlBOA from various tissues after 48 h revealed that the liver and adrenal glands had the greatest accumulation of BchlBOA, followed by the spleen and tumor (data not shown). This pattern of fluorescence accumulation in the liver and adrenal glands was consistent with immunoblot studies conducted by Acton et al. which showed that the greatest SR-BI receptor expression in mice was found to be in these tissues (*39*). The fact that the HDL−BchlBOA signal remained visible in the tumor after 48 h can be explained by the long plasma circulation half-life of HDL (approximately 12 h) (*26*) as well as the enhanced permeability and retention (EPR) effect (*40*). The EPR effect allows NPs of a given size (10−100 nm) to penetrate through fenestrated vasculature into the tumor microenvironment (*41*). Furthermore, since the tumors generally do not have an effective lymphatic drainage system, NPs will tend to penetrate and accumulate around the tumor (*42*). Both of these effects enhance the probability of interactions between the particles and surface SR-BI receptors found on the KB cells.

Taken together, these results demonstrate that we successfully synthesized an imaging agent derived from Bchl that is stable and has excellent NIR fluorescence properties. We have also shown that this dye can be inserted into HDL-like NPs that retained its endogenous structure and function. More importantly, these NPs were delivered and visualized in cancer cells and implanted tumors. While the ability of the particle to distribute to cancer cells and tumor tissues are mediated by the SR-BI pathway, it is conceivable that a wide range of tumor-specific targets can be applied to HDL-like NPs such as the folate receptor or the prostate-specific membrane antigen. This will largely be dependent on the types of targeting ligands as well as the conjugation strategies. Examples of targeting ligands that may be conjugated to HDL-like NPs include folate (*43*, *44*), peptides, (*45*) and aptamer-based (*46*) moieties. Further work will be required to validate whether these targeting strategies can improve the tumor specificity of HDL−BchlBOA.

In addition to its NIR fluorescence properties, BchlBOA also has important implication for PDT. Currently, TOOKAD, a derivative of Bchl with similarities to BchlBOA is being investigated in phase II/III clinical trials as a PS for PDT in patients with recurrent prostate cancer (*24*). However, BchlBOA differs from TOOKAD in that (i) it is stabilized through modifications to the isocyclic ring, (ii) it is fluorescent, and (iii) can be incorporated into HDL-like NPs. These differences may be significant as we predict that HDL−BchlBOA may also potentially be used for NIR fluorescence-guided PDT of prostate cancer.

In conclusion, the present study outlines the synthesis of a novel Bchl-analog that is stable, fluorescent, and has dual lipid anchors for its efficient incorporation into HDL-like NPs. The resulting HDL−BchlBOA has similar characteristics to HDL in size and morphology. Furthermore, these particles can interact specifically with SR-BI receptors on both ldlA[mSR-BI] and KB cancer cell lines. This uptake was also observed in KB tumor xenografts. Our results demonstrate HDL−BchlBOA is a useful tool for in vivo molecular imaging. With this knowledge in hand, future work will continue investigating the applicability of this NP for cancer imaging and therapy. Emphasis will be placed on functionalizing the NP surface with ligands for specific targeting to tumor cells and tissues. The PDT efficiency of BchlBOA delivered in HDL will also be examined to determine the suitability of HDL−BchlBOA for image-guided therapy.

Received February 11, 2009; Revised Manuscript Received September 22, 2009

With the view to develop novel bioinspired nonviral vectors for gene delivery, we synthesized a series of cationic lipids with a neamine headgroup, which incorporates rings I and II of the natural antibiotic aminoglycoside neomycin B. Indeed, we reasoned that neamine might constitute a straightforward and versatile building block for synthesizing a variety of lipophilic aminoglycosides and modulating their characteristics such as size, topology, lipophilicity, number of charges, and charge density. Neamine derivatives bearing long dialkyl chains, one or two neamine headgroups, and four to ten protonatable amine functions were prepared through the selective alkylation of the 4′- or 5-hydroxyl function in ring I and ring II of neamine, respectively. The transfection activity of the twelve derivatives synthesized was investigated *in vitro* in gene transfection experiments using several mammalian cell lines. The results allowed us to unveil interesting structure−activity relationships and to identify a formulation incorporating a small neamine derivative as a highly efficient gene delivery system.

INTRODUCTION

The natural aminoglycosides are antibiotics broadly used in medicine for their antibacterial activity due to their ability to bind the bacterial rRNA and thus interfere with protein synthesis (*1*). Aminoglycosides were also reported to selectively bind *in vitro* to viral RNAs such as HIV DIS, RRE, and TAR RNA (*2, 3*). Recently, aminoglycosides were also found to allow, via binding to rRNA, the read-through of disease-causing nonsense mutations by the translation complex and therefore the synthesis of full-length active proteins; this read-through activity is presently being evaluated for the treatment of genetic diseases such as cystic fibrosis (*4*−*7*).

It was recently demonstrated that lipophilic derivatives of natural aminoglycosides, including tobramycin, kanamycin A (compound **1** in Chart 1), paromomycin (**2**), and neomycin B (**3**), were able to mediate transfections of either plasmid DNA (*8*−*12*) or siRNA (*13*).

A main feature of these lipophilic pseudo-oligosaccharides (bearing lipidic chains or cholesteryl groups) was their multivalent character due to the presence of four to six protonatable amine functions and thus allowing strong binding of the phosphodiester groups of DNA or RNA. It is noteworthy that these lipidic aminoglycoside derivatives, which carried up to six amine groups distributed over three or four rings, were synthesized from their natural aminoglycoside counterparts mainly through acylation of the most accessible and reactive amine function.

With regard to the development of gene delivery agents, it is widely recognized that the affinity of the vector for the DNA to be transferred as well as the size and the supramolecular organization of the complexes formed with DNA are key parameters for their transfection activity (*14*−*16*). The delineation of structure−activity relationships, which implies evaluating variations of many parameters such as the positive charge density and the lipophilicity balance, is thus highly important.

With the view of developing novel antiviral and antibiotic agents, we have previously reported a synthetic route for preparing 4′-, 5-, and 4′,5-neamine derivatives (*17*). Here, the neamine core was conjugated to peptide nucleic acids (PNA) targeting the HIV TAR RNA (*18, 19*). One of the PNA conjugates prepared was able to cleave TAR and inhibit viral replication (*18, 19*). A study of fluorescent PNA conjugates demonstrated that the presence of the neamine core in the PNA conjugates permitted their cellular uptake, whereas the PNA alone was not taken up by the cells (*19*).

Taking into account this last work and the previously reported transfection properties of lipidic derivatives of natural aminoglycosides (see above), we reasoned that it may be interesting to develop transfection agents based on the small aminoglycoside neamine (**4** in Chart 1) through its conjugation to lipophilic alkyl chains. Indeed, neamine, incorporating rings I and II of neomycin B, presents a higher charge density and is easier to modify on the hydroxyl groups than the natural aminoglycosides, thereby enabling the continued presence of all protonatable amine functions for DNA binding.

We herein report the synthesis and the gene transfection activity of a series of lipidic neamine derivatives. Indeed, neamine appeared to be a straightforward and versatile building block for synthesizing lipidic aminoglycosides and modifying their characteristics such as size, topology, number of charges,

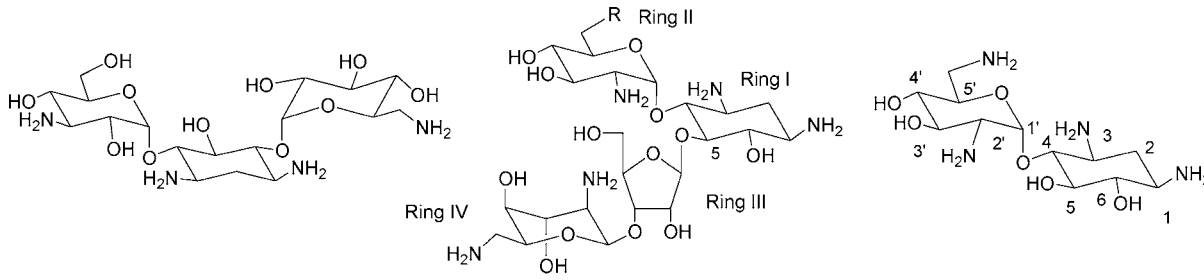
Chart 1. Structure of the Natural Aminoglycosides Kanamycin A, Paromomycin, and Neomycin B and of Neamine Prepared by Methanolysis of Neomycin B[a]



1: Kanamycin A: *Mw* = 484; 4 NH_2 **2**: Paromomycin: R= OH; *Mw* = 616; 5 NH_2 **4**: Neamine: *Mw* = 322; 4 NH_2
3: Neomycin B: R= NH_2; *Mw* = 615; 6 NH_2

[a] For each compound, the molecular weight (M_w, g/mol) and the number of amino groups (NH_2) are indicated. Neamine displays a higher positive charge as illustrated by the ratio value between the number of amino groups and the molecular weight: Ratio [NH_2/M_w] = 0.0083, 0.0081, 0.0098, and 0.0124 for kanamycin A, paromomycin, neomycin B, and neamine, respectively.

and charge density. In the present work, in contrast to the previously reported aminoglycosides derivatives (see above), a series of twelve compounds incorporating one or two neamine cores with four to ten protonatable (at pH 7) amine functions were prepared through the selective alkylation of the 4′- or 5-hydroxyl functions in rings I and II, respectively. The gene transfection experiments revealed interesting structure−activity relationships and allowed us to identify a highly efficient formulation based on a small neamine derivative with a single neamine core.

EXPERIMENTAL PROCEDURES

Materials. Dulbecco's Modified Eagle Medium (DMEM), Eagle's Minimum Essential Medium (EMEM), fetal bovine serum (FBS), OptiMEM, penicillin, streptomycin, and Lipofectamine (LFM; liposome formulation of DOSPA/DOPE 3/1, w/w) were purchased from Invitrogen (UK). The 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) was purchased from Sigma (Saint Quentin Fallavier, France). Two reporter plasmids were used: pEGFP-Luc (6.4 kb) and pTG11033 (9.6 kb), obtained from Clontech (UK) and Transgene (France), respectively. In all *in vitro* assays, we used the pEGFP-Luc which encodes a fusion of an enhanced green fluorescent protein (EGFP; excitation maximum at 488 nm, emission maximum at 507 nm) and the luciferase from the firefly *Photinus pyralis*. For the *in vivo* experiments, in order to facilitate the detection of the luciferase reporter activity, we used the plasmid pTG11033, which contains not only the firefly luciferase reporter gene under the control of the strong viral CMV promoter, but also the HMG-1 intron, which allows enhanced transgene protein synthesis (via increased mRNA export from the nucleus to the cytosol); this plasmid was used with highly purified synthetic D-luciferin (Interchim, Montluçon, France). All other chemicals were of cell culture and molecular biology quality.

Synthesis of the Most Transfection Efficient 4′-Neamine Derivatives 12b and 13b. For clarity purposes, we describe here only the synthesis of the neamine derivatives **12b** and **13b**, which were the most efficient for gene transfection. The synthesis and the characteristics of the other neamine derivatives studied herein (i.e., **11**, **12a**, **14b**, **15a**, **18**, **22**, **24**, **27**, **30**, and **32**) are available as Supporting Information. It should also be noted that the schemes presented here actually deal with the synthesis of all the different neamine derivatives investigated.

4′-*O*-(4-Bromobutyl) Protected Neamine Derivative 7 (Scheme 1). To a solution of **5** (2.9 g, 1.89 mmol) in DMF (58 mL) under argon atmosphere were added successively NaH (60% suspension, 761 mg, 19.0 mmol) and 1,4-dibromobutane (8.7 mL, 72.5 mmol). The mixture was stirred for 4 h at 70 °C. After cooling, CH_2Cl_2 and a saturated aqueous NH_4Cl solution were added. The organic layer was washed with water, dried over $MgSO_4$, filtered, and concentrated under reduced pressure. The residue obtained was chromatographed on alumina gel with a mixture of pentane/CH_2Cl_2 (70/30, v/v) to lead to the dialkylated product (6%) and the monoalkylated product **7**

Scheme 2[a]

(white powder, 54%, mp 132−133 °C). ^{13}C NMR ($CDCl_3$) δ 159.1, 159.0 ($COCH_3$) 147.0−146.0 (*C* arom.), 125.7−130.9 (*CH* arom.), 113.7−113.8 (*CH o*-OCH_3), 95.0 (C1′), 81.8, 81.6, 77.3, 73.8, 72.8, 71.9, 71.0, 70.8, 70.5, (C4, C5, C6, C3′, C4′, C5′, $OCH_2(CH_2)_3Br$, $2CH_2Ph$), 58.1, 53.0, 52.6 (C2′, C1, C3), 55.2 (OCH_3), 45.4 (C6′), 33.8 ($O(CH_2)_3CH_2Br$), 29.6, 29.2, 28.9(C2, $OCH_2(CH_2)_2CH_2Br$). LRMS (FAB$^+$, NBA) *m*/*z*: 1689 $[M+Na]^+$, 1665 $[M+H]^+$, 1423. HRMS (ESI$^+$) *m*/*z*: $[M+H]^+$ calculated 1665.7194, found 1665.7186.

4′-*O*-[4-(*N*,*N*-di-*n*-Octadecylamino)butyl] Neamine Derivative 12b (Scheme 2). Step b. To a solution of compound **7** (190 mg, 0.11 mmol) in DMF (5 mL) under argon atmosphere was added successively K_2CO_3 (110 mg, 0.79 mmol) and di-*n*-octadecylamine **9b** (60 mg, 0.11 mmol). The reaction mixture was stirred for 24 h at 70 °C. After cooling, the reaction mixture was filtered, then concentrated under reduced pressure. The residue was chromatographed on alumina gel with cyclohexane/CH_2Cl_2 (70/30, v/v) to lead to the protected derivative of **12b** in 30% yield. HRMS (ESI$^+$) *m*/*z*: $[M+H]^+$ calculated 2107.3832, found 2107.3847, $[M+Na]^+$ calculated 2129.3651, found 2129.3665.

Step c. The protected compound was dissolved in CH_2Cl_2/TFA (1/1, v/v, 4 mL) with anisole (0.1 mL). After 2 h stirring at room temperature (rt), solvents were removed under reduced pressure. H_2O and Et_2O were added and the aqueous layer washed twice with Et_2O before being concentrated and poured on a C18 reversed-phase column. After elution with a gradient of H_2O/MeOH, **12b** was obtained as the TFA salt with 67% yield. ^{1}H NMR (D_2O) δ 5.85 (d, $J_{1'-2'} = 4.0$ Hz, 1H, H1′), 4.04 (m, 2H, H3′, H5′), 3.89 (m, 1H, $OCH_2(CH_2)_3N$), 3.80 (dd, $J_{4-5} = J_{4-3} = 8.5$ Hz, 1H, H4), 3.67 (m, 2H, H5, $OCH_2(CH_2)_3N$), 3.55 (dd, $J_{6-5} = J_{6-1} = 9.5$ Hz, 1H, H6), 3.08−3.37 (m, 6H, H1, H3, H2′, H4′, 2H6′), 2.82−3.08 (m, 6H, $3NCH_2$), 2.41 (ddd, $J_{2eq-1} = J_{2eq-3} = 4.0$ Hz, $J_{2eq-2ax} = 12.0$ Hz, 1H, $H2_{eq}$), 1.40−1.75 (m, 9H, $H2_{ax}$, $OCH_2(CH_2)_2CH_2N$, $N[CH_2CH_2(CH_2)_{15}CH_3]_2$), 1.00−1.40 (m, 60H, $N[CH_2CH_2(CH_2)_{15}CH_3]_2$), 0.87 (t, $J = 6.7$ Hz, 6H, $2CH_3$). ^{13}C NMR (D_2O) δ 95.8 (C1′), 79.3 (C4′, C4), 75.2 (C5), 72.8 (C6), 72.4 ($OCH_2(CH_2)_3N$), 69.1, 68.4 (C3′, C5′), 53.8 (C2′), 51.2 ($3NCH_2$), 50.0 (C1), 48.4 (C3), 40.2 (C6′), 32.1, 30.2, 29.7, 29.2, 28.7, 26.5, 25.9, 22.7, 22.3, 20.5 (C2, $OCH_2(CH_2)_2CH_2N$, $[NCH_2(CH_2)_{16}CH_3]_2$), 13.8 ($2CH_3$). HRMS (ESI$^+$) *m*/*z*: $[M+H]^+$ calculated 898.8299, found 898.8297, $[M+Na]^+$ calculated 920.8119, found 920.8112.

4′-*O*-[4-(*N*-2-aminoethyl-*N*,*N*-di-*n*-octadecylamino)butyl] Neamine Derivative 13b (Scheme 2). The same procedure as described for the synthesis of **12b** (steps b and c) was applied to compound **7** (300 mg, 0.18 mmol) with *N*-2-aminoethyl-*N*,*N*-di-*n*-octadecylamine **10b** (114 mg, 0.20 mmol). **13b** was obtained in 42% yield in two steps. ^{1}H NMR (CD_3OD) δ 5.94 (d, $J_{1'-2'} = 4.0$ Hz, 1H, H1′), 4.07−4.17 (m, 2H, H3′, H5′), 4.01 (dd, $J_{4-5} = J_{4-3} = 9.6$ Hz, 1H, H4), 3.97 (m, 1H, $OCH_2(CH_2)_3N$), 3.66 (m, 1H, $OCH_2(CH_2)_3N$), 3.62 (dd, $J_{4-5} = J_{5-6} = 9.2$ Hz, 1H, H5), 3.40−3.70 (m, 7H, H3, H6, H6′b, $2NCH_2$), 3.31 (m, 1H, H2′), 2.99−3.24 (m, 9H, H1, H4, H6′a, $3NCH_2$), 2.47 (ddd, $J_{2eq-1} = J_{2eq-3} = 4.4$ Hz, $J_{2eq-2ax} = 12.0$ Hz, 1H, $H2_{eq}$), 2.01 (ddd, $J_{2ax-1} = J_{2ax-3} = J_{2eq-2ax} = 12.4$ Hz, 1H, $H2_{ax}$), 1.65−1.90 (m, 8H, $OCH_2(CH_2)_2CH_2N$, $N[CH_2CH_2(CH_2)_{15}CH_3]_2$), 1.20−1.50 (m, 60H, $N[CH_2CH_2(CH_2)_{15}CH_3]_2$), 0.90 (t, $J = 6.7$ Hz, 6H, $2CH_3$). ^{13}C NMR (CD_3OD) δ 95.7 (C1′), 79.7 (C4′), 78.1 (C4), 75.8 (C5), 72.9 (C6), 71.8 ($OCH_2(CH_2)_5N$), 70.0, 68.6 (C3′, C5′), 54.2 (C2′), 53.4 ($2NCH_2$), 50.1, 48.7 (C3, C1), 48.3, 48.0 ($2NCH_2$), 41.8 (NCH_2), 40.5 (C6′), 31.7, 29.4, 29.2, 29.1, 28.8, 28.5, 26.7, 26.1, 23.5, 22.7, 22.3 (C2, $OCH_2(CH_2)_2CH_2N$, $[NCH_2(CH_2)_{16}CH_3]_2$), 13.0 ($2CH_3$). HRMS (ESI$^+$) *m*/*z*: $[M+H]^+$ calculated 941.8722, found 941.8754.

Chemical Descriptions. MarvinSketch software [Marvin 5.0.2.1, 2008, ChemAxon (http://www.chemaxon.com)] was used for drawing, displaying, and characterizing chemical structures and substructures. The log *P* plug-in in this software calculates the octanol/water partition coefficient, which is used in QSAR analysis and rational drug design as a measure of molecular hydrophobicity. The calculation method used here is based on a modification of the method published by Viswanadhan et al. (*20*).

Cell Cultures. Three different cell lines were used. Two of them were obtained from the American Type Culture Collection (USA): A549, bronchial alveolar type II epithelial cells derived from a human pulmonary carcinoma (ATCC No. CCL-185); HeLa, epithelial cells derived from a human epithelioid cervical carcinoma (ATCC No. CCL-2). The third cell line used was 16HBE, human bronchial epithelial cells, kindly provided by D. Gruenert, University of Vermont, Burlington, VT, USA (*21*). These cells were grown in DMEM (A549 and HeLa) or EMEM (16HBE), supplemented with 100 units/mL penicillin, 100 μg/mL streptomycin, and 10% heat-inactivated fetal bovine serum (FBS), and maintained at 37 °C, 5% CO_2, in a humidified atmosphere.

Formulations and Preparation of Complexes. Each of the original neamine compounds synthesized in this study was formulated alone or in combination with the neutral lipid DOPE at a 1/1 molar ratio. All neamine derivatives were not miscible in chloroform but were highly soluble in water. So, for neamine formulations without DOPE, these molecules were directly

dissolved in sterile water. For neamine formulations with DOPE, a volume of DOPE dissolved in chloroform was first introduced into the glass vial, then chloroform was evaporated under vacuum to obtain a dry lipid film. Neamine compounds dissolved in an appropriate volume of sterile water were next added. All formulations were subsequently stored overnight at 4 °C. Before use, solutions were subjected to several cycles of sonication in a sonicator bath (Prolabo, France) and to vortex mixing, in order to obtain small vesicles. To prepare the cationic reagent/DNA complexes, plasmid DNA was first diluted in OptiMEM (except when otherwise stated) and then added to vector solutions, the mixtures being kept at room temperature for at least 30 min before use in order to allow the formation of the DNA complexes. Complexes characterized by different charge ratios were prepared, the charge ratio being defined as the ratio of the vector positive charges (assuming that all amine functions of the neamine headgroup were protonated) to the negative DNA phosphate charges.

DNA Condensation and Relaxation. The condensation of plasmid DNA by the cationic agents studied was investigated using ethidium bromide (EtB) intercalation into the DNA. Upon condensation, EtB is expelled from DNA and, thus, the fluorescence signal is decreased. Next, the effects of serum or dextran sulfate, as counteranions, were also studied, as these molecules can induce a relaxation of the preformed complexes, which results in recovery of fluorescence (*22*). These assays were performed in 96 well plates in OptiMEM (pH 7.4), in 0.9% NaCl (pH ~5.0), in 0.9% NaCl 20 mM HEPES (pH 7.3), or in 5% glucose (pH ~5.0). The maximum fluorescence signal was obtained when ethidium bromide (1.5 μg/mL final) was bound to plasmid DNA (1.0 μg/well). DNA was added to the wells containing reagents at different amounts in order to obtain different charge ratios (positive charges of the carrier divided by the negative charges of DNA). The fluorescence signals were measured using a Fluoroskan Ascent FL plate reader (Thermo-Electron Instruments, France) at excitation wavelength 530 nm and emission wavelength 590 nm. Thereafter, increasing amounts of serum or dextran sulfate were added to the complexes, and the effect on DNA relaxation was followed by measuring the fluorescence recovery.

***In Vitro* Transfections.** Transfections were performed as previously described (*23*), with the following modifications. Twenty-four hours before transfection, cells were seeded in 96 well plates at a density of 12 500 cells per well in a final volume of 200 μL (i.e., at about 70% confluency). Immediately prior to transfection, the growth medium was removed and replaced with 140 μL of OptiMEM per well. The transfection mixtures (60 μL, corresponding to 0.25 μg DNA, per well) were then added dropwise to the cell cultures, and cells were exposed to transfection reagents for 4 h. At the end of this incubation time, and before replacing the medium containing the transfection mixtures with complete growth medium, an aliquot of supernatant in each well was taken apart in order to conduct a cytotoxicity assay using the Toxilight kit (Cambrex, Belgium). Thereafter, cultures were maintained 48 h at 37 °C until reporter gene activity measurements. In order to estimate the effect of serum on gene delivery, some transfections were also performed in the presence of serum, i.e., in complete growth medium with no medium change before the addition of complexes onto the cell cultures.

***In Vitro* Reporter Gene Measurements: Luciferase and FACS-GFP Assays.** As all *in vitro* transfections were performed using a GFP-Luc plasmid, positively transfected cells expressed both the luciferase enzyme and the green fluorescent protein. Therefore, these cells can be detected either by luminescence or by fluorescence. For luciferase assays, cells were first lysed using the Passive Lysis Buffer (Promega, France), then centrifuged, and the luciferase activity in each supernatant was measured using a microtiter plate luminometer (Dynatech Laboratories, France). The total protein content of each supernatant was also quantified using the BC Assay kit (Interchim, France). Results were thus expressed as RLU (relative light units) per milligram of total protein. For FACS-GFP assays, cells were harvested and analyzed with a FACScan (Becton Dickinson, USA) by measuring the GFP emission considering the signals measured on two channels, FL1-channel (emission wavelength 520 nm) versus FL2-channel (emission wavelength 575 nm), as previously reported (*24*). Positive cells were those for which a FL1 signal greater than or equal to twice the FL2 signal was measured.

Cytotoxicity Evaluation. Cytotoxicity was evaluated by two different methods. (1) The Toxilight Assay is a chemiluminescent test (Cambrex, Belgium) used to quantitatively measure the release into the growth medium from damaged cells of a normally cytoplasmic enzyme (adenylate kinase). The toxicity assay was carried out as specified by the manufacturer, a few hours after addition of complexes onto the cells (in order to estimate early cytotoxicity). The relative light units measured here were proportional to the number of viable cells. Untreated cells were used as a reference (*2*). The total amount of extractable cell proteins, at 48 h after addition of the complexes onto the cells, was used as an index of the cell number present in each well. The cell density is indeed the result of (i) the number of cells initially plated, (ii) the normal or induced mortality depending on the treatment(s) applied, and (iii) the cell growth, normal or delayed. In this case, cytotoxicity data were expressed as the percentage of missing proteins compared to the total protein content of untreated cells. The deficit in total protein content was considered as an estimation of the final, cumulated, toxicities.

***In Vivo* Transfection.** Female Swiss OF1 mice of six to nine weeks old (Elevage Janvier, France) were housed and maintained at the university animal facility; they were processed in accordance with the Laboratory Animal Care Guidelines of the University. Complexes were prepared at room temperature in 5% glucose, 0.9% NaCl, or OptiMEM before administration to mice via intravenous injection. Mice were placed in a restrainer and 200 μL of complexes incorporating 50 μg of pDNA per mouse were injected into the tail vein within 5 to 10 s, using a 1/2 in 26-gauge needle and a 1 mL syringe. Twenty-four hours after transfection, mice were killed by cervical elongation and their lungs were removed for analysis. Luciferase expression *in vivo* was evaluated as previously described (*25*). Briefly, tissue pieces were washed in 1× PBS and rapidly frozen in liquid nitrogen, then disrupted and finally collected in 1× PLB (Promega, France). Complete lysis was achieved by vigorous shaking at 4 °C for 45 min, and the supernatant was obtained by centrifugation. Luciferase activity and total protein content were then evaluated as indicated above. Results were expressed as RLU per milligram of total proteins.

Statistical Analyses. Data are presented as means and standard deviations. Comparisons among groups were done by using the Student's *t* test assuming two-tailed distributions and unequal variances.

RESULTS AND DISCUSSION

Synthesis of the Lipophilic Derivatives of Neamine. We have previously reported a synthetic route for preparing 4′-, 5-,

[1]Abbreviations: LFM, Lipofectamine; CR, charge ratio; EtB, ethidium bromide; RLU, relative light unit; TFA, trifluoroacetic acid; EDC, 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide; HOBT, 1-hydroxybenzotriazole; rt, room temperature; Δ, heating; Tr, trityl; PMB, *p*-methoxybenzyl.

and 4′,5-neamine derivatives using trityl (Tr^1) and *p*-methoxybenzyl (PMB) groups for protecting the amine and hydroxyl functions, respectively (*17*). From some of the neamine derivatives described previously, a series of twelve 4′- and 5-neamine derivatives carrying long alkyl chains were synthesized: (i) seven lipidic neamine derivatives incorporating one neamine core (three derivatives bearing lipidic chains attached to the 5-oxygen atom and four with the lipid chains linked to the 4′-oxygen) and (ii) five lipidic derivatives characterized by neamine 5,5-dimers.

Derivatives Incorporating One Neamine Ring. The protected neamine derivative **8** (Scheme 1) previously prepared, which carries at the 5-position a hexamethylenic arm and a terminal bromine atom, was a main intermediate in the synthesis of the 5-neamine derivatives studied here.

As previously reported, it was obtained from the protected neamine derivative **6**, in which only the 5-hydroxyl function is free, by alkylation with 1,6-dibromohexane in the presence of NaH. Unfortunately, it was not possible to introduce at this position, in good yield, shorter alkyl arms from 6-halogenoalkanes in order to decrease the length of the linking chain in the transfecting agents prepared. Therefore, all 5-neamine derivatives prepared carry a first hexamethylenic arm attached to the 5-oxygen atom. The lipidic moiety (like bis-dodecyl or bis-octadecyl chains) of the molecules was linked to the end of the hexyl arm through a nitrogen atom as a conjugation center.

In contrast, selective alkylation of the 4′-hydroxyl function in the previously described compound **5** was feasible with 1,4-dibromobutane in the presence of NaH and allowed to prepare the novel 4′-bromobutyl derivative **7**, which has not previously been reported (Scheme 1). Starting from the 4′-bromobutyl (**7**) and the 5-bromohexyl (**8**) derivatives, two sets of derivatives incorporating only one neamine core were prepared. Through reaction of the 4′-bromo intermediate with triethylamine at 65 °C, it was easy to substitute the bromine atom for a triethylammonium group to obtain the derivative **11** (Scheme 2). The reaction of the 4′-bromo derivative **7** with didodecylamine **9a** and dioctadecylamine **9b** led in good yields to the potential transfection agents **12a** and **12b**, respectively (Scheme 2).

With the view to add to the lipidic chains a second nitrogen atom and an additional spacer, the two lipidic reagents **10a** and **10b** (Scheme 2) were prepared. The reaction of the 4′-bromo derivative **7** with reagent **10b** led to the dioctadecyl neamine derivative **13b** (Scheme 2). The corresponding 5-derivative **15a** and its didodecyl 5-analogue **14b** were also prepared from the 5-bromo neamine derivative **8** and the reagents **9b** and **10a**, respectively (Scheme 2).

5,5-Neamine Dimers. The five 5,5-dimers were synthesized using coupling reactions between prepared bifunctional reagents carrying lipidic chains and possessing either two carboxylic functions (**16**, **21**, **23**, and **26**) or two primary amine functions (**29**). These compounds were conjugated to the previously described neamine derivatives incorporating an aminohexyl arm (**17**), carrying a carboxylic acid function (**31**) or a bromine atom (**8**).

A first 5,5-dimer **18** carrying two dodecyl chains was obtained from the neamine derivative **17** and the dicarboxylic acid **16**. Compound **16** was prepared through reaction of the 1,2-diaminoethane derivative **10a**, in which one of the amine function carries two dodecyl groups, with benzyl bromoacetate (Scheme 3).

Two other coupling reagents possessing two carboxylic acid functions and carrying one (**21**) or two (**23**) octadecyl chains also were prepared from dibenzyl malonate **19** (Scheme 4).

Mono- and bis-alkylation of compound **19** with 1-bromooctadecane and, then, debenzylation led to the dicarboxylic acids **21** and **23**, respectively. The reaction of the monooctadecyl derivative **21** with the 5-aminohexyl neamine derivative **17** afforded the 5,5-neamine dimer **22**. It was not possible to obtain the corresponding dioctadecyl 5,5-dimer from the dioctadecyl dicarboxylic acid derivative **23**. During the coupling reaction, a decarboxylation of the reagent **23** occurred leading to the dioctadecyl derivative incorporating one neamine core **24** in good yield (Scheme 4). This compound is an interesting analogue of the derivative **14b** which was evaluated as a potential transfection vector.

Another dicarboxylic acid coupling reagent **26** was prepared from diethyl aminomalonate **25** through acylation of the amino

function with dodecyl carboxylic acid and saponification (Scheme 5). Reaction of the prepared reagent **26** with the 5-aminohexyl neamine derivative **17** afforded the dimer **27**.

Two other dimers **30** and **32** incorporating one dodecyl chain were obtained by condensation of the prepared 1,2,3-triaminopropyl derivative **29** with the 5-bromohexyl neamine **8** and the succinylated derivative **31**, respectively.

Transfection Properties of the Neamine Derivatives: Structure−Activity Relationships. The twelve neamine derivatives prepared, which constitute amphiphilic compounds, were evaluated as DNA transfection reagents. As gene transfection involves the formation of DNA complexes in which the DNA is condensed by the cationic amphiphiles, we first characterized the lipohilicity of the neamine derivatives and evaluated their DNA condensation ability by ethidium bromide exclusion and by DNA retardation on agarose gel electrophoresis.

Log P Values. The lipophilic character of the neamine derivatives prepared was estimated through the calculation of log *P* values (octanol/water partition coefficients) using the MarvinSketch software (http://www.chemaxon.com). For our twelve neamine derivatives, the log *P* values were scattered over a wide range, from −3.8 (**24**, most lipophilic compound) to −39.9 (**30**, most hydrophilic compound) (Supporting Information Table S1).

DNA Condensation Assays. DNA condensation can adequately be evaluated by ethidium bromide (EtB) exclusion, the increase in the amount of lipid added (thus in charge ratio) leading to a decrease in observed fluorescence. The EtB exclusion assay thus allowed us to classify the various neamine derivatives according to their efficiency to condense DNA (Figure 1). The ranking order, from the most efficient to the least, was as follows: **18** (5,5-dinea), **12a** (4′-mononea), **13b** (4′-mononea), **15a** (5-mononea), **12b** (4′-mononea), **24** (5-mononea), **14b** (5-mononea), and **22** (5,5-dinea). The other derivatives did not significantly condense the plasmid DNA, the fluorescence signal always remaining higher than 90% of the signal of DNA alone. DNA gel retardation assays were also performed (data not shown) and yielded results in good agreement with the EtB exclusion assays ($R^2 > 0.90$).

It is noteworthy here that the DNA condensing ability of the most efficient neamine derivatives was higher than that of the lipidic derivative of paromomycin (DOSP) (*13*). However, it was lower than that of the commercial multivalent Lipofectamine (LFM) and the monovalent arsonium-based lipophosphoramidate KLN47 (*26*) (Figure 1). Interestingly, the 5,5-dimer **18** carrying two dodecyl chains showed a stronger DNA condensation ability than the 5,5-dimers **30**, **27**, and **22**, which bear only a single fatty acid chain. This emphasizes the requirement of two close lipidic chains in a cationic lipid for efficient DNA condensation.

In Vitro Gene Transfection Experiments. In initial *in vitro* transfection experiments, ten neamine derivatives were evaluated for their ability to transfect a GFP-Luc plasmid into two types of mammalian cells (the HeLa and A549 cell lines). As cationic lipids are often formulated with DOPE (a neutral colipid, which is believed to enhance their activity via its fusogenic property), we also tested the effects of the addition of DOPE on the transfection activity of our neamine derivatives. Lipofectamine (LFM) and the lipidic derivative of paromomycin DOSP [DOSP/DOPE (*13*)] were used as positive controls. Flow cytometry assays were conducted, and observed percentages of transfected A549 cells (GFP positive cells) are shown in Figure 2. Supporting Information Figure S1 depicts the results obtained using HeLa cells.

First, the results obtained indicated that the different neamine derivatives studied, when used alone (i.e., without DOPE), displayed broad range abilities to transfect cell lines *in vitro*. Some compounds appeared as completely inefficient (**11**, **27**, **30**, and **32**). On the contrary, others produced highly significant GFP transgene expressions (e.g., **13b** and **15a**) which reached, depending on the cell lines evaluated, levels either comparable to or even higher than the ones obtained when using reference cationic lipids. Regardless of the two cell lines considered (HeLa and A549), the two best transfectionally effective derivatives

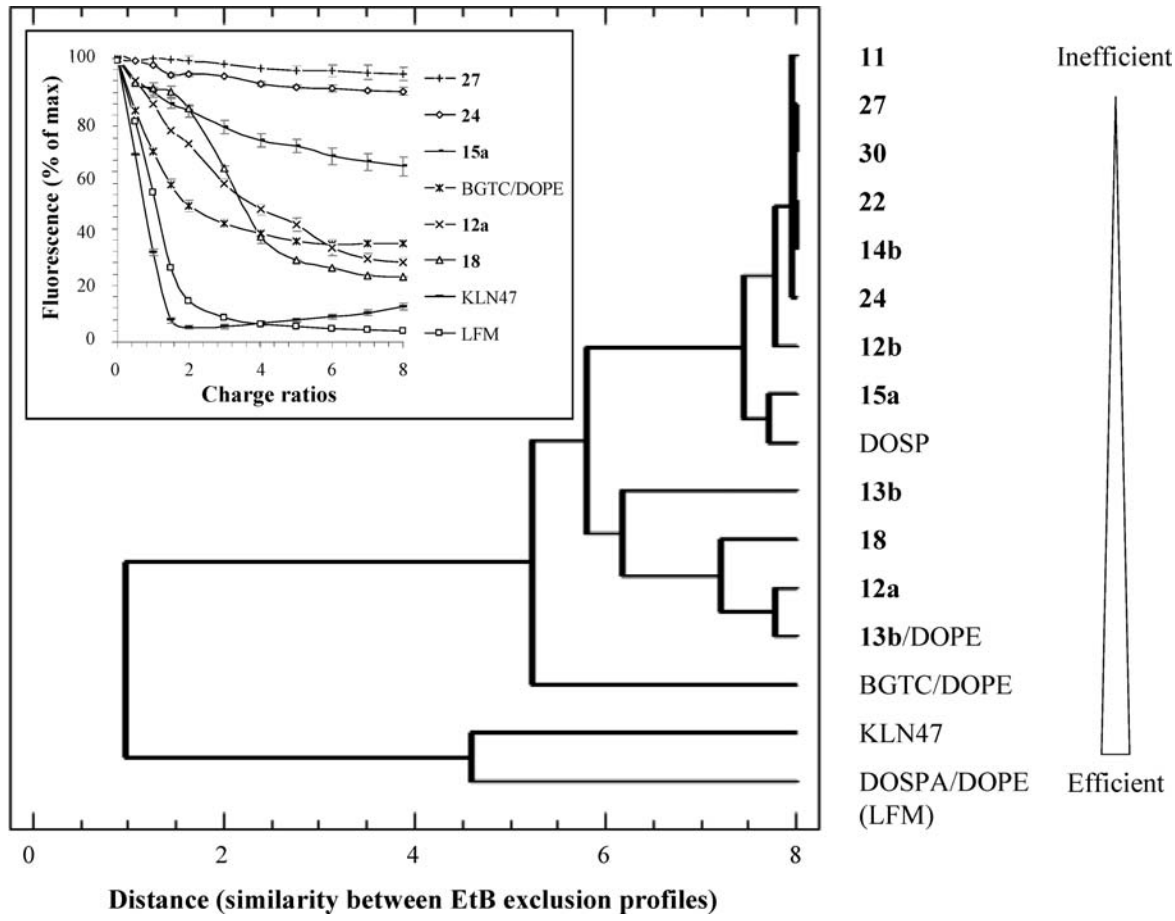

Figure 1. DNA condensation ability of neamine derivatives and some more standard cationic lipids as a function of the lipoplex charge ratio. Complexes were obtained by mixing in OptiMEM cationic liposomes at the required concentrations with plasmid DNA incubated first with ethidium bromide (EtB). The fluorescence decrease allowed the evaluation of nucleic acid entrapment within complexes (see Experimental Procedures section). Each test was performed in triplicate, and fluorescence measurements were obtained at several time points, from 30 min up to 1 h after mixing. The dendrogram summarizes the overall results obtained for all reagents tested, assuming that the more similar the EtB exclusion profiles between 2 reagents, the closer these 2 molecules in the tree. The reagents tested are clustered from the most efficient to complex DNA (i.e., LFM) to the least (i.e., **11**). **32**, not tested. Inset: profiles obtained with some neamine derivatives and other cationic lipids. Data are expressed as a percentage of the EtB fluorescence intercalated into DNA in the absence of carrier (mean ± SD with $n = 3$). See Supporting Information Scheme S1 for the chemical structure of neamine derivatives; **13b**/DOPE is **13b**/DOPE 1/1; BGTC/DOPE is BGTC/DOPE 3/2 (*27*); KLN47 (*26*); LFM (Lipofectamine, Invitrogen).

were **13b** then **15a**. Other derivatives showing weak (<1% positive cells) or undetectable efficiencies on both cell lines were **22**, **24**, **18**, **12a**, **11**, **27**, **30**, and **32**. Considering the sensitivity of this method (GFP reporter), it was not easy to further classify those reagents according to their transfection efficiencies.

Regarding the comparative efficiencies of formulations incorporating DOPE, we observed in general that the transfection reagents for which a detectable positive signal was measured when used alone became more efficient when they were combined with this helper lipid (Figure 2 and Supporting Information Figure S1). As an example, for **13b**/DOPE (1/1 molar ratio) compared with **13b** used alone, highly significant increases (from 2- to 10-fold) were measured with the A549 and HeLa cell lines (Figure 2 and Supporting Information Figure S1). Such a clear increase in the transfection efficiencies of the formulation with DOPE was also observed with other derivatives, especially with compounds **15a**, **24** (Figure 2), or **22** (Supporting Information Figure S1). The beneficial effect observed when formulating with DOPE may have several explanations. First, there may be a structuring effect of DOPE on the cationic liposomes formed by the neamine derivatives, as the latter contain only saturated lipid chains while DOPE contains two monounsaturated lipid chains. Of interest here, the **13b** derivative formulated with DOPE appears to complex DNA better than **13b** alone (Figure 1). Such a structuring effect may also be proposed for compound **22**, which contains only one long lipid chain (C18:0). Second, the fusogenic properties of DOPE may allow a better escape of the DNA from the endosome into the cytosol. Third, another beneficial effect of DOPE could be an increase of the global lipophylicity as reflected by the estimation of the log *P* values of equimolar cationic lipid/colipid formulations. Indeed, when formulated with DOPE, all derivatives undergo an increase in their log *P* value, and for some of them, e.g., **13b**, their log *P* values become close to that of monocationic lipids such as KLN47 and DOTAP (Supporting Information Table S1). Furthermore, it has been reported that the combination of cationic lipids characterized by different lipidic parts can lead to a significant increase in transfection efficiency (*28*, *29*). We have ourselves observed such a synergistic effect when associating two different cationic lipids, one with aliphatic chains and the other one with a cholesterol moiety (T. Le Gall, unpublished results). From this point of view, the formation of unstable lipid structures, with increased disassembling properties permitting a better release of the DNA, may be proposed here for DOPE-containing formulations of neamine derivatives with dodecyl chains such as **15a**.

As DOPE incorporating formulations enhanced transfection efficiencies, it allowed to more precisely classify the efficient neamine derivatives. Using A549 cells, the ranking order of

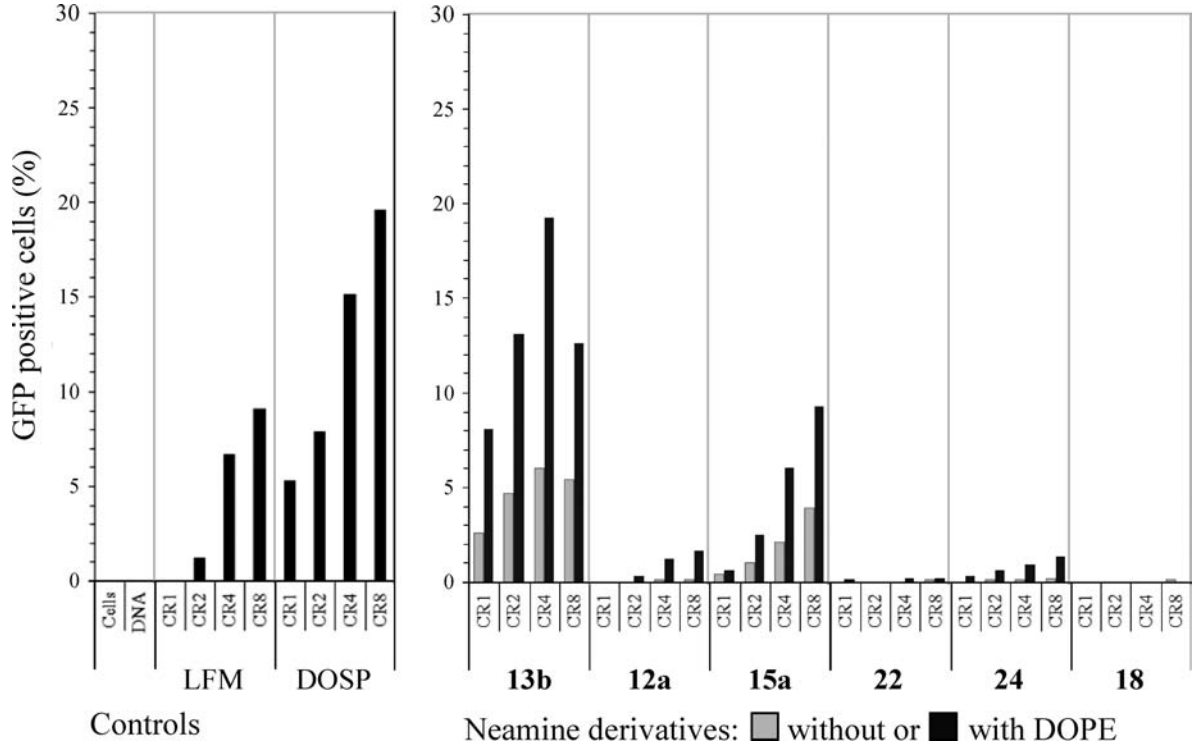

Figure 2. Flow cytometry measurements (GFP assays): transfection efficiencies of lipidic derivatives of neamine used alone or formulated with the colipid DOPE (molar ratio 1/1). The reagents indicated were complexed with DNA (pEGFP-Luc; see Experimental Procedures section) in order to obtain increasing charge ratios (CR), from CR1.0 up to CR8.0. The commercial Lipofectamine (LFM, DOSPA/DOPE, Invitrogen) and the paromomycin derivative [DOSP, DOSP/DOPE (*13*)] were used as cationic lipid references. Cell samples were analyzed by flow cytometry in order to estimate the gene delivery efficiency as a percentage of positive cells (GFP positive cells). Other derivatives (**11**, **27**, **30**, and **32**) were found to be completely inefficient, and thus, they are not indicated here. These results were obtained with A549 cells. The data obtained using HeLa cells provided similar observations.

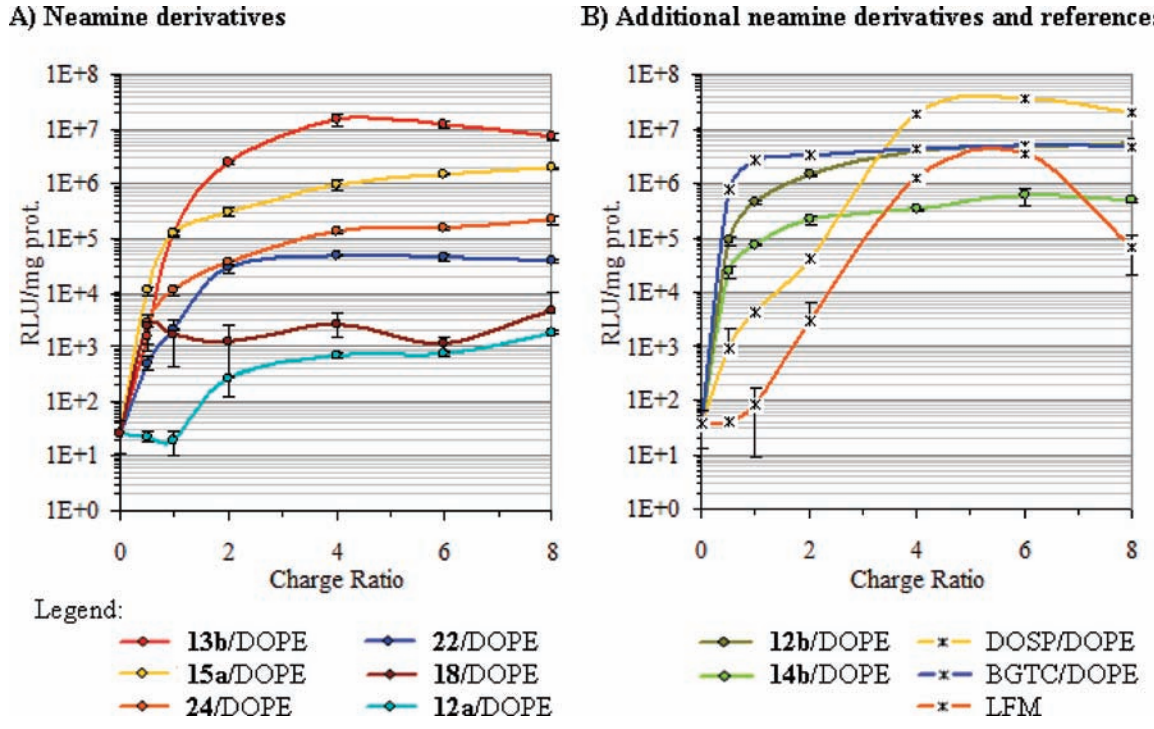

Figure 3. Luminometry measurements (luciferase assays): dose responses of the *in vitro* transfection activity of lipidic neamine derivatives formulated with the colipid DOPE (molar ratio 1/1). Luciferase reporter gene expression is indicated as a function of the charge ratio (CR) of lipoplexes, from CR0.5 up to CR8.0. The commercial Lipofectamine (LFM, Invitrogen), the paromomycin derivative [DOSP (*13*)] and the bisguanidinium tren-cholesterol BGTC [BGTC/DOPE 3/2 (*27*)] derivative were used as cationic lipid references. Cells were transfected as described in the Experimental Procedures section, using lipoplexes prepared by mixing DNA (pEGFP-Luc) with the required amounts of lipids. Data are expressed as relative light units (RLU) per milligram of total proteins (mean ± SD with $n = 3$). These results were obtained using A549 cells; experiments using HeLa and 16HBE cells provided similar observations (see Supporting Information Figure S2).

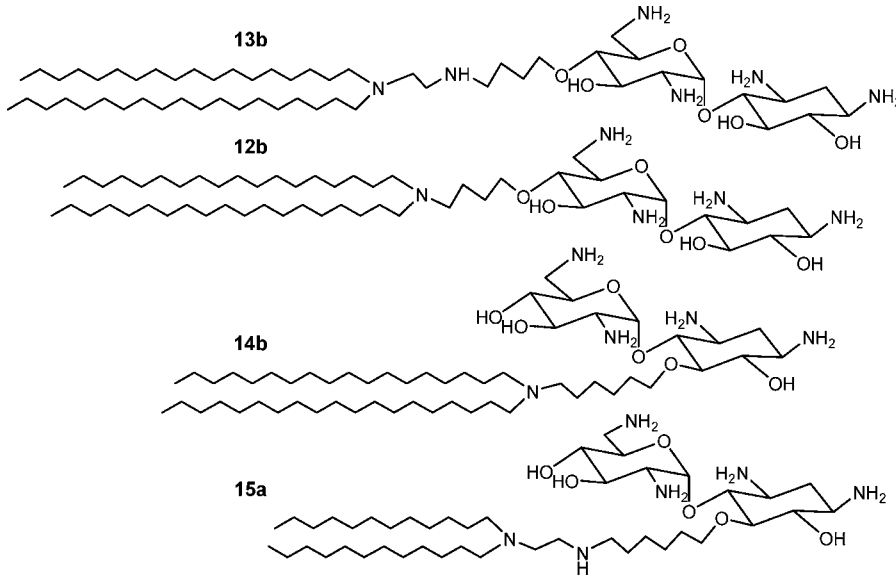
Chart 2. Structure of the Most Efficient Neamine-Based Vectors for Gene Transfection



compounds, from the most efficient to the least, was thus **13b**, **15a**, **12a**, **24**, and **22** (Figure 3). Of note, this order was the same using HeLa cells (Supporting Information Figure S1), except for compound **22**, which became more efficient than **12a**.

Following those measurements, additional experiments were performed in an attempt to confirm and further detail the results previously obtained. Three cell lines were used here (A549, HeLa, and 16HBE). Thus, the series of ten neamine derivatives plus two additional compounds (**12b** and **14b**) were evaluated, when formulated with DOPE (as it was found to significantly enhance the transfection efficiencies of neamine derivatives; see above) and using luminometry assays (as this is a more sensitive method allowing us to better distinguish between active and nonactive transfection compounds). These evaluations aimed at more precise characterization of the transfection efficiency of each compound in order to facilitate the delineation of structure−activity relationships. Lipofectamine (LFM), the lipidic derivative of paromomycin DOSP [DOSP/DOPE (*13*)], and the bisguanidinium tren-cholesterol BGTC [BGTC/DOPE 3/2 (*27*)] were used as positive controls. Observed levels of luciferase expression using A549 cells are shown in Figure 3. Data obtained using two other cell lines (HeLa and 16HBE) provided similar observations (Supporting Information Figure S2).

First, as previously reported, luminometry is indeed more sensitive than cytometry, as some derivatives found to be inefficient by cytometry yielded low but not null luminometry signals. Accordingly, it was possible to estimate here the minimal luciferase level required to detect GFP positive cells by cytometry (threshold at about 1×10^5 RLU/mg protein). Using A549 cells, neamine derivative efficiencies ranged from 2×10^3 (**12a**) up to 2×10^7 (**13b**) RLU/mg proteins (Figure 3).

Second, the results obtained by cytometry and luminometry were found to be consistent, as these two methods yielded similar ranking orders when classifying neamine derivatives according to their highest transfection efficiency (comparison between Figures 2 and 3A). Of note, the addition of DOPE enhanced the transfection efficiencies, as already mentionned above, but it did not affect the ranking order of the various derivatives according to their efficiencies (except for compound **22** used to transfect HeLa cells; Supporting Information Figure S1). Moreover, mostly identical trends were obtained using the three different cell lines, thereby allowing us to unveil general structure−activity relationships (see below). Globally, neamine/DOPE formulations could thus be classified from the most to the least efficient. In all experiments conducted, **13b** was the most efficient transfection reagent among all neamine derivatives tested. For example, using A549 cells, a **13b**/DOPE formulation was able to mediate transgene expression (GFP reporter, Figure 2, or Luc reporter, Figure 3) at levels either higher than LFM or of the same order of magnitude as DOSP/DOPE (comparison of maximum efficiencies of **13b**/DOPE, LFM, and DOSP/DOPE: 19.2%, 9.1%, 19.6% GFP and 1×10^7, 3×10^6, 4×10^7 RLU/mg protein, respectively). The next efficient compounds identified were **12b**, **14b**, and **15a**. Slightly efficient derivatives were **24**, **18**, and **12a**. Finally, **11**, **27**, **30**, and **32** were always found to be inefficient, regardless of the cell lines and the assays used. It is noteworthy here that compound **22** represented an exception. Depending on the cell lines used, this derivative (characterized by a headgroup with two neamine cores) displayed, when formulated with DOPE, very different efficiencies; for instance, it was able to reach high transfection levels (up to 1×10^6 RLU/mg protein) with 16HBE cells (Supporting Information Figure S2).

Delineation of Structure−Activity Relationships. By combining the data obtained for the different neamine derivatives and related to their chemical structures (Supporting Information Chart S1 and Table S1) with data from (i) DNA condensation assays (Figure 1) and (ii) *in vitro* gene transfection experiments (Figures 2, 3, and Supporting Information Figure S1, S2), it was possible to unveil interesting structure−activity relationships. First, a quite clear association was observed between the DNA condensing ability and the *in vitro* transfection efficiency, as the molecules inefficient for DNA condensation did not transfect cells *in vitro*. However, the reverse was not true, i.e., a high ability to condense DNA is not obligatorily associated with a high transfection activity. In fact, the most efficient compound identified in our DNA condensation assays (i.e., **18**) showed only weak activity in the transfection experiments.

Four compounds (**13b**, **12b**, **14b**, and **15a**) were actually identified as the most efficient neamine-based vectors. Their structures are shown in Chart 2. They are characterized by a headgroup bearing only one neamine core, which is linked to a lipid moiety consisting of two fatty acid chains. These vectors were more efficient than the more polar 5,5-dimers, whereas the derivatives with only one fatty acid chain were ineffective. Of note, an additional compound consisting of three neamine

cores linked together without any lipidic moiety was also totally ineffective (not shown), a finding highlighting the requirement of a sufficient hydrophobic part for transfection. Indeed, all the most efficient derivatives have a calculated log *P* in the range −7.9 to −12.8; i.e., they exhibit a lipophilic character equivalent to that of the previously reported lipidic aminoglycosides. These relatively slightly hydrophilic molecules do in fact condense DNA with different efficiencies. It is also noteworthy that the very polar derivative **11** which incorporates one neamine ring (log $P = -21.9$) was found to be inefficient for transfection, like the more polar 5,5-dimers (log $P = -29.7$ to -39.9). The 4′-derivative **24** was also less efficient for transfection, because it may be too lipophilic (log $P = -3.8$). However, it should be mentioned here that compounds **18** and **22** (log $P = -32.5$ and -22.7, respectively), characterized by headgroups incorporating two neamine cores, yielded significant gene transfection abilities. This was clearly observed with **22**/DOPE formulation used to transfect HeLa and 16HBE cells (Supporting Information Figures S1 and S2). It is also interesting to note here that the best transfection results were obtained with derivatives carrying two octadecyl chains (**13b**, **12b**, and **14b**, with log *P* values of −8.8, −8.7, and −7.9, respectively) in comparison to compounds incorporating two dodecyl chains (**15a**, **12a**, with log *P* = −12.8 and −14.4, respectively). Altogether, these data indicate that efficient gene transfection can be achieved with lipidic aminoglycoside derivatives incorporating only two rings carrying four positive charges, whereas the previously described aminoglycoside derivatives contained three to four rings bearing three to six positive charges (Figure 2). These results also emphasize the importance of parameters such as (i) the hydrophylicity/lipophilicity balance (amphiphilic character), (ii) the headgroup size and the resulting charge density, and (iii) the presence of two fatty acid chains (formation of lipidic bilayers).

Compound **13b** was the most efficient among these four best neamine derivatives. When compared to the other ones (Chart 2), **13b** is characterized by the fact that it combines the following features: (1) the attachment of the lipidic moiety at the 4′-position of the neamine headgroup and (2) the incorporation of a diaminoethyl group in the spacer linking the neamine core to the fatty acid chains. (1) On one hand, the 4′-neamine derivative **12b** appeared to be clearly more efficient than the corresponding 5-derivative analogue **14b** (Figure 3). Thus, attachment of the lipidic chains at the 4′-position, i.e., at an end of the neamine core, may allow "better" interactions in the DNA complexes (and hence a more efficient transfection) than attachment at the 5-position, in the middle of the neamine core. (2) On the other hand, incorporation of an additional diaminoethyl group, between the neamine headgroup and the lipidic chains, clearly improved the transfection activity of **13b**, in comparison with derivatives of similar lipophily, especially its analogue **12b**, which also carries two octadecyl chains but in which only this diaminoethyl group is absent. The importance of such an additional spacer for obtaining a more efficient transfection was confirmed with the 5-neamine derivative **15a** carrying two dodecyl chains; this derivative appeared indeed more efficient than the 4′-derivative **12a** also characterized by two dodecyl chains but without the diaminoethyl group. It may be hypothesized here that the beneficial effect on gene transfection of the incorporation of a diaminoethyl group in **13b** could be related to the fact that it provides the linker between the neamine headgroup and the octadecyl chains with a favorable length; in addition, as for other cationic lipids such as BGTC (*27*), the introduction of an additional protonable amine function may provide the vector with some endosomal buffering capacity, which could favor the endosomal escape of the DNA complexes. Indeed, at physiological pH, only one amine function in the diaminoethyl spacer should be protonated due to the electron-withdrawing effect of the first protonated nitrogen atom. Thus, at pH 7, compounds **12b** and **13b** should not differ in their number of positive charges. However, their charge near the lipidic moiety is probably differently located, as in **13b**, it is the secondary amine function that should be protonated (Supporting Information Scheme S1). Altogether, the diaminoethyl group in **13b** may provide (i) its linker with a favorable length, (ii) some endosomal buffering capacity, and (iii) some additional flexibility (between the polar headgroup and the lipidic moiety), a series of features which, when combined, could explain the better transfection activity measured with this derivative in our experiments. Finally, these considerations also invite the introduction of such a diaminoethyl group into more lipophilic dimers, especially into 4′,4′-dimers.

13b/DOPE Formulations: Further Characterization of Their Transfection Properties. *Cytotoxicity Evaluations and Comparison with Reference Cationic Lipid Systems.* In order to further characterize the transfection activity of the **13b** derivative, this compound formulated with DOPE (at molar ratio 1/1) was compared with other commercial or original cationic lipid formulations: (i) the commercially available Lipofectamine (LFM), (ii) the dioleyl-succinyl-paromomycin DOSP [DOSP/DOPE 1/1 (*13*)], and (iii) the bisguanidium-tren-cholesterol BGTC [BGTC/DOPE 3/2 (*27*)]. All these reagents were tested simultaneously under the same experimental conditions in order to compare both their transfection activity and their cytotoxicity. Regarding transfection efficiency, we measured luciferase expressions similar to those reported in Figure 3 and Supporting Information Figure S2. This indicated that **13b**/DOPE was generally as efficient as these control vectors for transfection of the different cell lines tested, in particular, as efficient as the recently reported aminoglycoside derivative DOSP (*13*).

Interestingly, among the four vectors evaluated here, the **13b**/DOPE was also characterized by a relatively low cytotoxicity (Figure 4), both (i) at the early time point of 4 h after transfection (toxicity assessed by measurement of the release into the culture medium of an enzyme normally located in the cytoplasm) and (ii) at the late time point of 48 h (toxicity assessed by measurement of the total amount of extractable proteins as an index of the number of cells). In addition, **13b**/DOPE formulations never produced the highest toxicity levels in these evaluations. Taken together, these findings indicate that a high transfection efficiency is not obligatorily associated with an increased cytotoxicity. This also validates the choice of **13b**/DOPE formulations for further evaluations (see below).

Storage Stability of Neamine Derivative Formulations. Another interesting feature of the **13b**/DOPE formulation was the finding that its transfection activity was conserved over time. Indeed, this is an important point to consider as lipid-based transfection reagents do not always meet this requirement; thus, instability of formulations can correspond to a major drawback (reproducibility) for the successful and wide use of a given cationic lipid.

The results obtained (Figure 5) clearly indicated that **13b**/DOPE was still able to transfect various cells lines, with high efficiency levels, even 3 years after its formulation in water. The observed efficiencies were indeed very close to those measured before (comparison of **13b**/DOPE levels in Figure 3 and Figure 5); they were still higher than or at least of the same order of magnitude as those observed with LFM. In addition, LFM dose responses were characterized by a "bell-shaped" curve, with a maximum efficiency at CR4, whereas **13b**/DOPE rapidly reached a high transfection level at CR1 and retained high levels at CR above. Of note, these storage stability properties were also observed with other neamine derivatives (**24** and **15a**; data not shown).

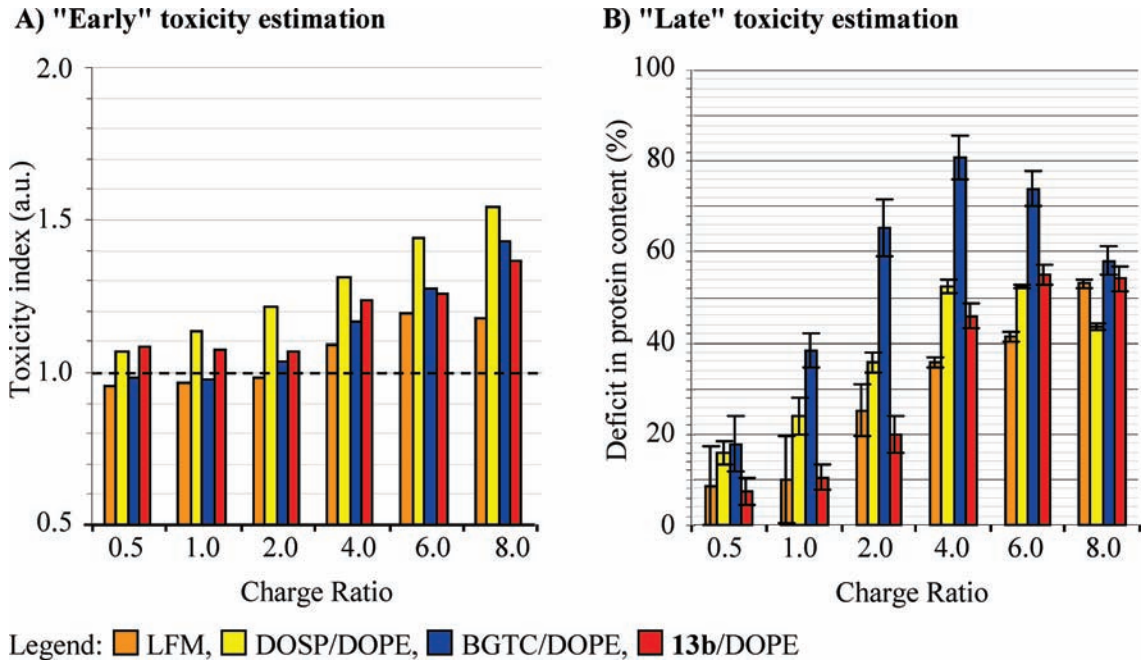


Figure 4. Cytotoxicity of **13b**/DOPE and some other reference gene transfer agents. The induced toxicity of **13b** formulated with DOPE (at molar ratio 1/1) was compared with other commercial or original cationic vectors: Lipofectamine (LFM, Invitrogen), the lipidic derivative of paromomycin DOSP [DOSP/DOPE 1/1 (*13*)], and the bisguanidium tren-cholesterol BGTC [BGTC/DOPE 3/2 (*27*)]. Estimations of cytotoxicities considered either the membrane integrity of cells through measurement of the level of cytoplamic enzyme adenylate kinase released into the growth medium (A; Toxilight, Cambrex; the minimum value is 1, it indicates an absence of cytotoxicity) or the content in total extractable proteins (B; the deficit in protein content corresponds to the percentage of missing proteins compared to the total protein content measured for untreated cells), as described in the Experimental Procedures section. These results were obtained using A549 cells; experiments using HeLa and 16HBE cells yielded similar observations.

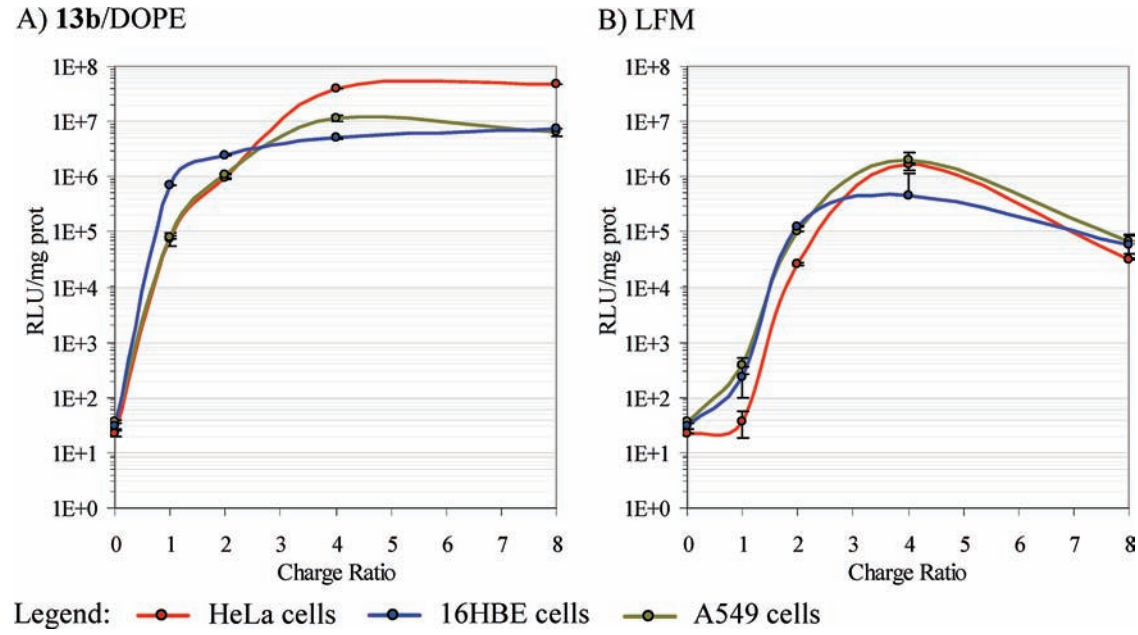

Figure 5. Transfection efficiency of **13b**/DOPE formulation after long-term storage as liposomes in water. A formulation of **13b**/DOPE prepared in water three years ago was here evaluated and compared with the commercial cationic lipid Lipofectamine (LFM, Invitrogen). Efficiencies were estimated using three different cell lines. Data are expressed as relative light units (RLU) per mg of total extractable proteins (mean ± SD with $n = 3$).

Toward the in Vivo Use of **13b***/DOPE: in Vitro Transfection Properties under Various Experimental Conditions.* Here, we first compared the transfection efficiency of the **13b**/DOPE lipoplexes prepared either in conventional OptiMEM or in isotonic saline or glucose, as these two latter media are suitable for *in vivo* administration.

The results showed that, although the use of isotonic sodium chloride or glucose allowed a significant improvement of DNA complexation compared to OptiMEM (data not shown), the transfection efficiency of the resulting complexes was lower than that of complexes prepared in OptiMEM; indeed, we observed in general a clear transfection activity decrease when using

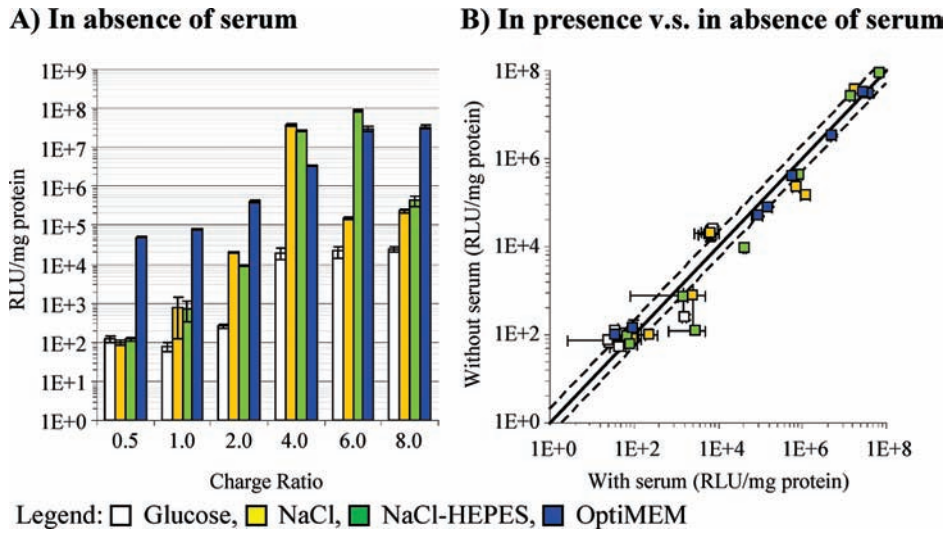

Figure 6. Effects of the complexation medium and of the presence of serum on the *in vitro* transfection efficiency of **13b**/DOPE. Luciferase reporter gene expression is indicated as a function of the charge ratio (CR) of lipoplexes, from CR0.5 up to CR8.0. Cells were transfected as described in the Experimental Procedures section using lipoplexes prepared by mixing DNA (pEGFP-Luc) with the required amounts of lipids, in 4 different solutions: (i) glucose (5%), (ii) NaCl (0.9%), (iii) NaCl-HEPES (0.9% NaCl, 20 mM HEPES), and (iv) OptiMEM. The complexes were then used to transfect cells either in the absence of serum (A; cells in OptiMEM) or in the presence of serum (cells in complete growth medium including 10% fetal bovine serum). The graph in B compares the transfection efficiencies obtained in those two conditions (transfection in presence versus in absence of serum). Data are expressed as relative light units (RLU) per milligram of total proteins (mean ± SD with $n = 3$). These results were obtained using A549 cells. The data obtained using HeLa and 16HBE cells provided similar observations.

complexes made in NaCl or NaCl-HEPES 1× (except at CR4 and 6) and only a very low efficiency when using complexes formed in glucose (Figure 6A). Here, the differences in DNA condensing abilities may be explained by differences in parameters such as ionic strength or pH of the media. Indeed, the pH may impact the complexation ability of reagents with ionizable amines such as **13b**. At pH 7.4, the electric charge *Z* of **13b** should be 4 or 5 (due to partial protonation with probably a mixture of differently protonated species), whereas at pH 5.0, this compound charge may be 6 (i.e., with all amines being fully protonated, as estimated with the MarvinSketch software). Of note, when complexation was performed in NaCl (at pH 5.0 or 7.0), the association with DNA was improved and, as well, DNA relaxation was much more difficult, as reflected by the higher amount of dextran sulfate required to completely recover the free DNA (Supporting Information Figure S3). Altogether, these results suggest that the best transfection conditions may be those leading to a complexation that is not too strong between the neamine vector and the DNA. Indeed, a very strong interaction between the vector and the DNA may be deleterious for transfection, as it may hamper the dismantling of the complexes during their cellular trafficking toward the cell nucleus. This is also supported by the results obtained with **18** showing that it was one of the best neamine compounds in DNA condensation assays (Figure 1) but a very inefficient neamine reagent to deliver DNA (Figure 2).

Next, we took into account that, when compared with *in vitro* transfection conditions, one major hurdle for *in vivo* transfection via intravascular administration is the presence of serum. Indeed, the anionic compounds present in the serum may interact with the cationic vectors, resulting in decreased transfection efficiency (*30*−*32*). Thus, investigation of the sensitivity to serum of a given transfection reagent may be of great help to predict its *in vivo* transfection efficiency, in particular, after systemic administration. Here, the transfection experiments performed in the presence or in the absence of serum did not reveal any significant difference regardless of the medium (OptiMEM, NaCl, or Glucose) used for the preparation of the **13b**/DOPE complexes ($p > 0.1$; Figure 6, comparison of panels A and B). These data indicate that the insensitivity to serum is a very general feature of **13b**/DOPE lipoplexes, which is of great interest when considering their *in vivo* use.

Combining **13b***/DOPE with Small PEI.* Additional experiments were performed in order to determine if neamine derivatives could be advantageously combined with other cationic reagents in strategies aiming at developing multimodular gene delivery systems. For instance, considering our neamine vectors as polyamines, we combined **13b**/DOPE and PEI 2 kDa (Sigma, France). In transfection experiments performed with 3 different cell lines, very different effects were measured: with increasing quantities of PEI polymer, there was a progressive increase for $1 \leq CR \leq 2$, then a progressive decrease for $4 \leq CR \leq 8$ (Figure 7 and Supporting Information Figure S4). These results extended the observations previously made by Lampela et al. for combinations of PEI 2 kDa with DOSPER, Lipofectamine, or DOTAP (*33, 34*). We confirmed that the synergy between PEI 2 kDa and cationic lipids might be, in a certain range (i.e., at low charge ratios), a general rule. However, the higher levels measured for whatever combinations does not exceed the higher level reached when using **13b**/DOPE alone, at CR4. Furthermore, antagonistic effects were also observed indicating that an optimization is required in each case. Concerning the cytotoxicity of such combinations, it was found that the synergy measured between PEI 2 kDa and **13b**/DOPE was not obligatorily associated with a higher cytotoxicity. Indeed, when compared with **13b**/DOPE, it was even possible to identify **13b**/DOPE/PEI 2 kDa combinations which were able to reach increased transfection efficiencies while displaying reduced cytotoxicities (data not shown). In addition, we also found that **13b**/DOPE may be part of the efficient formulations involving other lipidic neamine derivatives, other lipidic aminoglycoside derivatives (such as DOSK or DOSP), or even LFM, a fact thus highlighting its versatility (data not shown). Altogether, these data indicate that **13b**/DOPE can be advantageously used in the design of multimodular gene delivery systems in order to obtain higher transfection efficiencies with reduced toxicities.

In Vivo Administration of **13b***/DOPE Formulations.* Finally, following these various *in vitro* investigations, we recently also undertook *in vivo* transfection experiments with the aim of

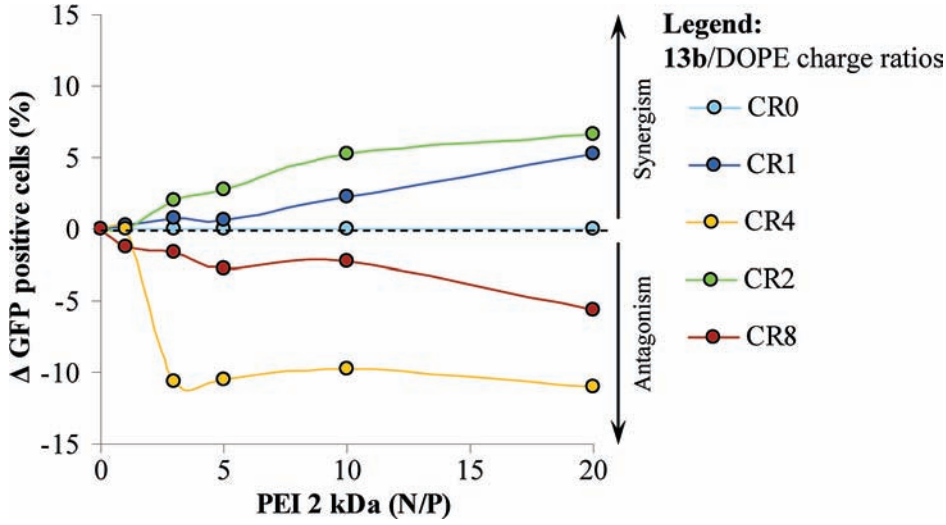

Figure 7. *In vitro* transfection activity for combinations of PEI 2 kDa and **13b**/DOPE 1/1. Lipoplexes (**13b**/DOPE mixed with DNA, from CR1.0 up to CR8.0), polyplexes (PEI 2 kDa with DNA, from N/P1 up to N/P20), and lipopolyplexes (combinations of PEI 2 kDa with DNA, from N/P 1 up to 20, + **13b**/DOPE, from CR1.0 up to CR8.0) were used to transfect cell lines as described in the Experimental Procedures section. For each CR, the variation of %GFP positive cells (Δ = % lipopolyplex − % lipoplex) is indicated [polyplexes alone (CR0) are ineffective, regardless of the N/P tested]. Thus, compared with a lipoplex at a given CR, a lipopolyplex is more efficient if a Δ value higher than 0 is measured, whereas it is less if a Δ value lower than 0 is obtained. These results were obtained using A549 cells. The data obtained using HeLa and 16HBE cells provided similar observations (see Supporting Information Figure S4).

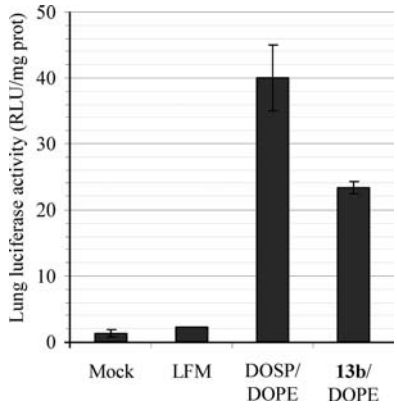

Figure 8. *In vivo* transfection efficiency of **13b**/DOPE lipoplexes. Lipoplexes were prepared at CR6, then administrated i.v. in mice. LFM and DOSP/DOPE were evaluated under same experimental conditions (except that these lipoplexes were prepared at CR4). Lung luciferase activity was measured 24 h later, on complete lung extracts. Mock corresponded to measurements on mice which have received the same amount of naked DNA (not associated with any reagents; $n = 2$, with 4 repeated measurement per animal sample).

transfecting the mouse lung. Preliminary results have indicated that, after intravenous injection, **13b**/DOPE formulations may be able to transfect the lungs *in vivo*. However, in spite of the *in vitro* insensitivity to serum (Figure 8), the luciferase signals measured *in vivo* were relatively weak; they were in fact much higher than those obtained with LFM and similar to those observed with the aminoglycoside derivative DOSP/DOPE formulation (Figure 8). Of note, these signals were, however, significantly lower than those obtained when using the cationic polymer PEI22 kDa (data not shown).

Interestingly, no lethality was observed in mice, regardless of the amount of **13b**/DOPE injected through the tail vein (with 50 μg pDNA per dose and at charge ratios up to 6). On the contrary, the PEI22 kDa is a transfection reagent well-known for its efficiency as well as toxicity. Thus, these data confirm that, as is widely recognized, *in vitro* results do not enable us to perfectly predict the *in vivo* behavior of a given gene delivery system. They also invite us to work out **13b**-based formulations for improved *in vivo* transfection. Accordingly, in ongoing work, we are attempting to design **13b**-based formulations optimized for different routes of *in vivo* administration. Here, it is of great interest to note that **13b**/DOPE could be beneficially incorporated into formulations with the cationic polymer PEI, as efficient *in vivo* transfection might require the development of sophisticated lipopolyplexes.

CONCLUSION

In conclusion, our results demonstrate that efficient gene transfection can be achieved with cationic lipids bearing a headgroup consisting of neamine, a compound which, in comparison to the natural aminoglycosides, incorporates only two rings and has an increased charge density. The most efficient derivative studied herein, **13b**, carries two octadecyl chains linked to a diaminoethyl spacer attached at the 4′-position of a neamine core. As discussed above, both the presence of that spacer and such an attachment position, i.e., at an extremity of the neamine core, appear to play a role in the increase of the gene transfection efficiency. Thus, our present work validates the interest of the neamine core as a straightforward and versatile cationic building block for the development of novel nonviral vectors for gene transfection.

With a view to future developments, the results obtained herein first invite us to perform some chemical modifications of the **13b** structure. For example, it might be interesting to introduce double bonds into the lipidic chains in order to modify their mobility. The replacement of aliphatic chains by a cholesterol moiety could also be envisaged in order to further modulate the fluidity/rigidity balance. Finally, another proposition originating from our study is the use of neamine in several copies associated inside a single molecule. Despite the fact that the most effective neamine derivatives identified herein contained only one neamine moiety, it has to be noted that two derivatives bearing a double neamine headgroup (i.e., compounds **18** and **22**) showed a (weak but not null) transfection efficiency. It is noteworthy that those two derivatives did not display all the beneficial characteristics this study has pointed out, in particular, the attachment of

the linker onto the neamine core as in **13b**. Thus, the synthesis of lipophilic neamine oligomers may constitute an interesting approach for the development of novel nonviral vectors for gene transfection, which can be investigated by taking into account all the critical parameters identified in the present work.

ACKNOWLEDGMENT

Synthesis and transfection properties of a series of lipidic neamine derivatives

Tony Le Gall, Isabelle Baussanne, Somnath Halder, Nathalie Carmoy, Tristan Montier, Pierre Lehn and Jean-Luc Décout

This material first provides more details about the synthesis and characteristics of the neamine derivatives **11**, **12a**, **14b**, **15a**, **18**, **22**, **24**, **27**, **30** and **32**. Next, the chemical structures of the 12 neamine derivatives evaluated in this study are indicated in Chart S1 and a comparison between some of their chemical features is shown in Table S1. In addition, the evaluation of the *in vitro* transfection efficiencies of the neamine derivatives is also more detailed: Figure S1 indicates the observed percentages of transfected HeLa cells (GFP-positive cells as estimated by flow cytometry) whereas Figure S2 shows the luciferase activities (luminometry assays) obtained when using the HeLa and 16HBE cell lines. For compound **13b**, supplementary data related to DNA condensation and relaxation as well as transfection activity when combined with small polyethylenimine (PEI 2 kDa, Sigma, France) are given in Figures S3 and S4, respectively. The literature cited here is detailed at the end of the document.

Synthesis and characteristics of neamine derivatives 11, 12a, 14b, 15a, 18, 22, 24, 27, 30 and 32.

General experimental and analytical conditions: ^{1}H NMR (400 MHz) and ^{13}C NMR (100 MHz) spectra were recorded with a BRUKER ADVANCE 400 spectrometer using the residual solvent signal as internal standard. LRMS were achieved with NERMAG spectrometer for the FAB, DCI and EI techniques, with an AUTOFLEX BRUKER spectrometer for the MALDI and with a ZQ WATERS for the ESI. HRMS were obtained from the Mass Spectrometry Service, CRMPO, at the University of Rennes I, France, using a MICROMASS ZABSPEC-TOF spectrometer and a VARIAN MAT311 spectrometer. Melting points were determined with a BUCHI 510 apparatus. Thin layer chromatographies were performed on silica gel (Alugram Sil G/UV_{254}) or alumina gel (Alugram Alox N/UV_{254}) from Macherey-Nagel and spots were detected either by UV-absorption, by charring with ninhydrin or with cerium molybdate. Preparative chromatographies were performed on alumina gel (MP Ecochrom Biomedicals, Act II-III acc. to Brockman), silica gel (Acros Organic, 0.060-0.200 mm, 60 Å) or on C_{18} reversed phase (Macherey-Nagel polygoprep 60-50 C_{18}). All starting materials were obtained from suppliers and used without further purification unless otherwise noted. DMF was distilled in the presence of CaH_2, THF over sodium with benzophenone, CH_2Cl_2 and CH_3CN over P_2O_5 then stored under argon atmosphere prior to use.

The neamine derivatives **5**, **6**, **8**, **17** and **31** have been previously described (*1, 2*) and the amines **10a, 10b** (*3, 4*) and **28** (*5*) were synthesized according to the literature.

Synthesis of neamine derivatives 11, 12a, 14b, 15a, 18, 22, 24, 27, 30 and 32.

4'-*O*-[4-(triethylammonium)butyl] neamine derivative 11 (Scheme 2). Step a: A solution of compound **7** (450 mg, 0.27 mmol) and triethylamine (4 mL) in DMF (10 mL) under argon

atmosphere was stirred for 24 h at 70°C. After cooling, the reaction mixture was concentrated under reduced pressure. The residue was chromatographed on alumina gel with 6% MeOH in CH_2Cl_2 to lead to the protected derivative of compound **11** in 53% yield. LRMS (MALDI, DHB) *m/z*: 1687.8 $[M+H]^+$, 1445.7 $[M-Tr+H]^+$, 1202.5 $[M-2Tr+H]^+$, 960.4 $[M-3Tr+H]^+$, 718.3 $[M-4Tr+H]^+$. HRMS (ESI^+) *m/z*: $[M+H]^+$ calculated 1686.9137, found 1686.9140.

Step c: The protected compound was dissolved in CH_2Cl_2/TFA (1/1, v/v, 4 mL) with anisole (0.1 mL). After 2 h stirring at rt, solvents were removed under reduced pressure. H_2O and Et_2O were added and the aqueous layer was washed twice with Et_2O before being concentrated and poured on a C18 reversed phase column. **11** was eluted with a gradient of H_2O/MeOH. The pure compound was obtained as the TFA salt with 90% yield. ^1H NMR (CD_3OD) 5.88 (d, $J_{1'-2'}$= 4.0 Hz, 1H, H1'), 4.06 (m, 2H, H3', H5'), 3.97 (dd, 1H, J_{4-5}= J_{4-3}= 9.6 Hz, H4), 3.90 (m, 1H, OCH_2(CH_2)$_3$N), 3.62 (m, 1H, OCH_2(CH_2)$_3$N), 3.57 (dd, 1H, J_{4-5}= J_{5-6}= 9.2 Hz, H5), 3.05-3.48 (m, 15H, O(CH_2)$_3$$CH_2$N, N($CH_2$$CH_3$)$_3$, H1, H3, H6, H2', H4', 2H6'), 2.40 (ddd, J_{2eq-1}= J_{2eq-3}= 4.0 Hz, $J_{2eq-2ax}$= 12.8 Hz, 1H, $H2_{eq}$), 1.93 (ddd, J_{2ax-1}= J_{2ax-3}= $J_{2eq-2ax}$= 12.8 Hz, 1H, $H2_{ax}$), 1.55-1.78 (m, 4H, OCH_2(CH_2)$_2$$CH_2$N), 1.23 (t, *J*= 6.8 Hz, 9H, 3CH_3). ^{13}C NMR (CD_3OD) δ 97.1 (C1'), 81.1 (C4'), 79.3 (C4), 77.2 (C5), 74.4 (C6), 73.3 (OCH_2(CH_2)$_3$N), 70.4, 70.1 (C3', C5'), 58.0 (3NCH_2), 55.8 (C2'), 51.6 (C1), 50.2 (C3), 42.0 (C6'), 29.9 (C2), 28.1, 19.9 (OCH_2(CH_2)$_2$$CH_2$N), 7.8 (3$CH_3$). LRMS ($ESI^+$) *m/z*: 478.18 $[M+H]^+$. HRMS (ESI^+) m/z: $[M+H]^+$ calculated 478.3605, found 478.3602.

4'-*O*-[4-(*N*,*N*-di-*n*-dodecylamino)butyl] neamine derivative 12a (Scheme 2). Step b: To a solution of compound **7** (300 mg, 0.18 mmol) in DMF (10 mL) under argon atmosphere was added successively K_2CO_3 (180 mg, 1.3 mmol) and di-*n*-dodecylamine **9a** (64 mg, 0.18 mmol). The reaction mixture was stirred for 24 h at 70°C. After cooling, the reaction mixture was filtered then concentrated under reduced pressure. The residue was chromatographed on

alumina gel with cyclohexane/CH_2Cl_2 (65/35, v/v) to lead to the protected derivative of **12a** with 48% yield. **Step c:** The protected compound was dissolved in CH_2Cl_2/TFA (1/1, v/v, 4 mL) with anisole (0.1 mL). After 2 h stirring at rt, solvents were removed under reduced pressure. H_2O and Et_2O were added and the aqueous layer washed twice with Et_2O before being concentrated and poured on a C18 reversed phase column. After elution with a gradient of H_2O/MeOH, **12a** was obtained as the TFA salt with 89% yield. ^{1}H NMR (CD_3OD) 5.92 (d, $J_{1'\text{-}2'}$= 3.8 Hz, 1H, H1'), 4.04-4.15 (m, 2H, H3', H5'), 4.00 (dd, $J_{4\text{-}5}$= $J_{4\text{-}3}$= 9.7 Hz, 1H, H4), 3.94 (m, 1H, OCH_2(CH_2)$_3$N), 3.65 (m, 1H, OCH_2(CH_2)$_3$N), 3.60 (dd, $J_{4\text{-}5}$= $J_{5\text{-}6}$= 9.2 Hz, 1H, H5), 3.27-3.49 (m, 4H, H3, H6, H2', H6'b), 3.09-3.23 (m, 9H, H1, H4', H6'a, 3NCH_2), 2.45 (ddd, $J_{2eq\text{-}1}$= $J_{2eq\text{-}3}$= 4.1 Hz, $J_{2eq\text{-}2ax}$= 12.4 Hz, 1H, H2$_{eq}$), 2.00 (ddd, $J_{2ax\text{-}1}$= $J_{2ax\text{-}3}$= $J_{2eq\text{-}2ax}$= 12.5 Hz, 1H, H2$_{ax}$), 1.60-1.85 (m, 8H, OCH$_2$(CH_2)$_2$CH$_2$N, N[CH$_2$$CH_2$($CH_2$)$_9CH_3$]$_2$), 1.24-1.42 (m, 36H, N[CH$_2$CH$_2$(CH_2)$_9$CH$_3$]$_2$), 0.90 (t, J= 6.7 Hz, 6H, 2CH_3). ^{13}C NMR (CD_3OD) δ 97.3 (C1'), 81.3 (C4'), 79.6 (C4), 77.3 (C5), 74.5 (C6), 73.4 (OCH_2(CH_2)$_3$N), 70.4, 70.1 (C3', C5'), 55.8 (C2'), 54.3 (3NCH_2), 51.6 (C1), 50.2 (C3), 42.0 (C6'), 30.0 (C2), 33.2, 30.9, 30.8, 30.7, 30.6, 30.4, 28.5, 27.7, 25.0, 23.9, 21.9 (OCH$_2$(CH_2)$_2$CH$_2$N, N[CH$_2$(CH_2)$_{10}$CH$_3$]$_2$), 14.6 (2CH_3). LRMS (ESI$^+$) *m/z*: 730.4 [M+H]$^+$, 426.4, 408.4, 240.3. HRMS (ESI$^+$) *m/z*: [M+H]$^+$ calculated 730.6422, found 730.6425.

5-*O*-[6-(*N,N*-di-*n*-octadecylamine)hexyl] neamine derivative 14b (Scheme 2). The same procedure as described for the synthesis of **12a** (steps b and c) was applied to compound **8** with di-*n*-octadecylamine **9b**. **14b** was obtained with 32% yield for two steps. ^{1}H NMR (CD_3OD) 5.85 (d, $J_{1'\text{-}2'}$= 4.0 Hz, 1H, H1'), 4.00-4.18 (m, 4H, H4, H3', H5', OCH_2(CH_2)$_5$N), 3.77 (m, 1H, OCH_2(CH_2)$_5$N), 3.49-3.66 (m, 3H, H3, H5, H6), 3.37-3.48 (m, 3H, H2', H4', H6'b), 3.20-3.32 (m, 2H, H1, H6'a), 3.08-3.20 (m, 6H, O(CH_2)$_5$$CH_2$N, N[CH$_2$$CH_2$($CH_2$)$_9CH_3$]$_2$), 2.43 (ddd, $J_{2eq\text{-}1}$= J$_{2eq\text{-}3}$= 4.0 Hz, $J_{2eq\text{-}2ax}$= 12.8 Hz 1H, H2$_{eq}$), 1.98

2-(*N*-(*N'*,*N'*-di-*n*-dodecyl)ethylamino)aminodiethanoic acid 16 (Scheme 3). Step a: To a solution of amine **10a** (209 mg, 0.52 mmol) in dry CH_3CN (5 mL) under argon atmosphere were added K_2CO_3 (218 mg, 1.6 mmol) and TBAI (194 mg, 0.5 mmol). The mixture was stirred under reflux 15 min before the addition of bromoethylbenzoate (362 mg, 1.58 mmol)

then 3 days. After cooling, the mixture was filtrated and concentrated under reduced pressure. The crude product was dissolved in CH_2Cl_2 and washed with water, an aqueous saturated $NaHCO_3$ solution then brine. The organic solution was dried over $MgSO_4$, filtrated and concentrated under reduced pressure. The residue obtained was chromatographed on alumina gel with a mixture of CH_2Cl_2/MeOH (98/2, v/v) to lead to the benzylic ester of **16** with 98% yield. ^{1}H NMR ($CDCl_3$) 7.32-7.40 (m, 10H, H arom.), 5.13 (s, 4H 2CO*CH*$_2$Ph), 4.14 (m, 2H, N*CH*$_2$CH$_2$N), 3.80 (td, *J*= 4.8 and 12.8 Hz, 2H, N[*CH*$_2$(CH$_2$)$_{10}$CH$_3$]$_2$), 3.57 (td, *J*= 4.4 and 12.8 Hz, 2H, N[*CH*$_2$(CH$_2$)$_{10}$CH$_3$]$_2$), 3.46 (s, 4H, 2CO*CH*$_2$*N*), 3.24 (m, 2H, N*CH*$_2$CH$_2$N), 1.72 (m, 4H, 2NCH$_2$*CH*$_2$(CH$_2$)$_9$CH$_3$), 1.23-1.36 (m, 36H, 2NCH$_2$CH$_2$(*CH*$_2$)$_9$CH$_3$), 0.89 (t, *J*= 6.4 Hz, 6H, 2*CH*$_3$). ^{13}C NMR ($CDCl_3$) δ 170.6 (*C*OOBn), 135.13 (*C* arom.), 128.8-128.4 (*CH* arom.), 68.1 (N*CH*$_2$CO), 66.9 (*CH*$_2$Ph), 60.9, 55.2, 48.2 (4N*CH*$_2$), 31.9, 29.6, 29.5, 29.4, 29.3, 29.0, 26.3, 22.7 (20*CH*$_2$), 15.3 (2*CH*$_3$). LRMS (DCI$^+$) *m/z*: 693 [M+H]$^+$, 366, 294, 250. **Step b:** The benzylic ester of **16** (130 mg, 0.19 mmol) was stirred in EtOH (2 mL) at rt with Pd/C (10%, 130 mg) and cyclohexadiene (177 L, 1.87 mmol) for 1 h. The mixture was filtrated on kieselguhr and concentrated under reduce pressure. The diacid **16** was obtained as a white solid with 86% yield and enough pure for doing the next step without purification. ^{1}H NMR ($CDCl_3$) 4.28 (m, 2H, N*CH*$_2$CH$_2$N), 3.77 (m, 2H, N[*CH*$_2$(CH$_2$)$_{10}$CH$_3$]$_2$), 3.48-3.67 (m, 6H, 2CO*CH*$_2$*N*, N[*CH*$_2$(CH$_2$)$_{10}$CH$_3$]$_2$), 3.26 (m, 2H, N*CH*$_2$CH$_2$N), 1.63 (m, 4H, 2NCH$_2$*CH*$_2$(CH$_2$)$_9$CH$_3$), 1.22-1.35 (m, 36H, 2NCH$_2$CH$_2$(*CH*$_2$)$_9$CH$_3$), 0.89 (t, *J*= 6.4 Hz, 6H, 2*CH*$_3$). ^{13}C NMR ($CDCl_3$) δ 173.5 (*C*OOH), 59.5 (N*CH*$_2$CO), 58.4, 55.5, 47.8 (4N*CH*$_2$), 31.9, 29.7, 29.6, 29.5, 29.4, 29.2, 26.4, 22.7 (20*CH*$_2$), 14.1 (2*CH*$_3$). LRMS (FAB$^+$, NBA) *m/z*: 513 [M+H]$^+$, 496, 468, 412, 366.

5,5-Dineamine derivative 18 (Scheme 3). Step c: Compound **16** (19.5 mg, 0.04 mmol) was dissolved in dry DMF (3 mL) under argon atmosphere. To the solution were added HOBT

(15.4 mg, 0.11 mmol) and EDC (21.7 mg, 0.11 mmol), then the mixture was stirred at rt for 30 min before the addition of a solution of **17** (200 mg, 0.11 mmol) in DMF (2 mL). The mixture was stirred at 60°C for 12 h. After cooling and concentration of the solution under reduced pressure, the crude product was dissolved in CH_2Cl_2 and washed successively with water, an aqueous saturated $NaHCO_3$ solution then brine. The organic layer was dried over $MgSO_4$, filtrated and concentrated under reduced pressure. The residue obtained was chromatographed on alumina gel with a mixture of CH_2Cl_2/MeOH (99/1, v/v) to lead to the protected dineamine compound with 55% yield. **Step d:** This compound dissolved in CH_2Cl_2 (2 mL) was treated with TFA (2 mL) and anisole (0.1 mL). After 12 h stirring at rt, the solvents were removed under reduced pressure. H_2O and Et_2O were added and the aqueous layer washed twice with Et_2O before being concentrated and poured on a C18 reversed phase column. **18** was eluted with a gradient of H_2O/MeOH and obtained as the TFA salt with 91% yield. ^{1}H NMR (CD_3OD) 5.85 (d, $J_{1'-2'}$= 3.8 Hz, 2H, H1'), 4.20 (m, 2H), 4.00-4.16 (m, 6H), 3.71-3.84 (m, 4H), 3.3-3.65 (m, 20H), 3.18-3.29 (m, 8H), 3.02-3.11 (m, 2H), 2.41-2.51 (m, 2H, $H2_{eq}$), 1.88-2.05 (m, 2H, $H2_{ax}$), 1.49-1.82 (m, 8H), 1.24-1.48 (m, 36H), 0.92 (t, *J*= 6.8 Hz, 6H, 2CH_3). ^{13}C NMR (CD_3OD) δ 171.2 (2*C*ONH), 162.0, 161.7 (*C*OCF_3), 121.1, 118.2, 115.3, 112.4 (CO*C*F_3), 92.7 (2C1'), 83.2 (2C5), 74.2 (2C4), 73.5 (2C6), 72.3 (2OCH_2(CH_2)$_5$N), 71.4 (2C4'), 70.8 (2C5'), 68.3 (2C3'), 60.3, 57.9, 57.5, 56.5 (6 NCH_2), 53.5 (2C2'), 50.2 (2C1), 49.2 (2C3), 40.2 (2C6'), 38.9 (2 N*CH2*CONH), 31.7, 29.8, 29.3, 29.2, 29.1, 29.0, 28.7, 28.0, 26.6, 25.8, 25.1, 22.3, 21.6 (2C2, 2OCH_2(CH_2)$_4$$CH_2$N, N[$CH_2$($CH_2$)$_{10}$$CH_3$]$_2$), 14.6 (2$CH_3$). LRMS (MALDI, DHB) *m/z*: 1782.6 $[M+4TFA]^+$, 1320.2 $[M+H]^+$, 966.8.

Dibenzyl 2-(octadecyl)malonate 20 (Scheme 4). Step a: To a THF solution of dibenzyl malonate **19** (0.5 mL, 2 mmol, 20 mL) under argon atmosphere at 0°C, were added NaH (60%

suspension, 96 mg, 2.4 mmol) and after 30 min stirring at rt, bromooctadecane (667 mg, 2 mmol). The mixture was stirred for 24 h, then, an aqueous saturated NH_4Cl solution was added. After separation of the organic and aqueous layers, the latter was washed 3 times with Et_2O. The organic layers were dried over $MgSO_4$, filtrated and concentrated under reduced pressure. The crude product was purified by chromatography on silica gel with a mixture of cyclohexane/CH_2Cl_2 (40/60, v/v) to lead to the alkylated product **20** with 64% yield. ^{1}H NMR ($CDCl_3$) 7.28-7.35 (m, 10H, *CH* arom.), 5.19 (s, 4H 2CH_2Ph), 3.46 (t, *J*= 7.6 Hz, 1H, $CH_2CH(CO_2Bn)_2$), 1.95 (m, 2H, $CH_3(CH_2)_{16}CH_2CH(CO_2Bn)_2$), 1.23-1.36 (m, 32H, $CH_3(CH_2)_{16}CH_2CH(CO_2Bn)_2$), 0.89 (t, *J*= 6.8 Hz, 3H, CH_3). LRMS (FAB$^+$,NBA) *m/z*: 559 $[M+Na]^+$, 538 $[M+H]^+$, 427.

2-(Octadecyl)malonic acid 21 (Scheme 4). Step b: The dibenzylic ester **20** (320 mg, 0.59 mmol) was stirred in EtOH/THF (4 mL, 1/1, v/v) at rt with Pd/C (10%, 320 mg) and cyclohexadiene (570 L, 5.96 mmol) for 3 h. The mixture was filtrated on kieselguhr and concentrated under reduce pressure. The diacid **21** was obtained as a white solid with 95% yield and enough pure for doing the next step without purification. ^{1}H NMR (DMSO-d_6) δ 3.14 (t, *J*= 7.6 Hz, 1H, $CH_2CH(CO_2H)_2$), 1.69 (m, 2H, $CH_3(CH_2)_{16}CH_2CH(CO_2H)_2$), 1.17-1.30 (m, 32H, $CH_3(CH_2)_{16}CH_2CH(CO_2H)_2$), 0.86 (t, *J*= 6.8 Hz, 3H, CH_3). ^{13}C NMR (DMSO-d_6) δ 171.6 (CO_2H), 51.9 ($CH_2CH(CO_2H)_2$), 31.2 ($CH_3(CH_2)_{16}CH_2CH(CO_2H)_2$), 29.5, 29.2, 28.9, 27.3, 22.6 ($CH_3(CH_2)_{16}CH_2CH(CO_2H)_2$), 14.4 ($CH_3$). LRMS (FAB$^+$, NBA) *m/z*: 396 $[M+K]^+$, 357 $[M+H]^+$.

5,5-Dineamine derivative 22 (Scheme 4). Step c: Compound **21** (14.3 mg, 0.04 mmol) was dissolved in dry DMF (3 mL) under argon atmosphere. To the solution were added HOBT (13.6 mg, 0.1 mmol) and EDC (19.2 mg, 0.1 mmol). The mixture was stirred at rt for 40 min before the addition of a solution of neamine derivative **17** (180 mg, 0.1 mmol) in DMF (3

mL). After 12 h stirring, the mixture was concentrated under reduced pressure. The crude product was dissolved in CH_2Cl_2 and washed successively with water, an aqueous saturated $NaHCO_3$ solution then brine. The organic layer was dried over $MgSO_4$, filtrated and concentrated under reduced pressure. The residue obtained was chromatographed on alumina gel with a mixture of CH_2Cl_2/cyclohexane (50/50, v/v) to lead to the dineamine protected compound with 37% yield. **Step d:** This compound dissolved in CH_2Cl_2 (2 mL) was treated with TFA (2 mL) and anisole (0.1 mL). After 12 h stirring at rt, solvents were removed under reduced pressure. H_2O and Et_2O were added and the aqueous phase washed twice with Et_2O before being concentrated and poured on a C18 reversed phase column. **22** was eluted with a gradient of H_2O/MeOH and obtained as the TFA salt with 35% yield. ^{1}H NMR (CD_3OD) 5.83 (d, $J_{1'-2'}$= 3.6 Hz, 2H, H1'), 4.01-4.16 (m, 8H, H4, H3', H5', OCH_2(CH_2)$_5$N), 3.74 (m, 2H, OCH_2(CH_2)$_5$N), 3.45-3.62 (m, 4H, H5, H6), 3.46-3.35 (m, 6H, H3, H4', H6'b), 3.32-3.15 (m, 6H, H1, H2', H6'a), 2.43 (ddd, J_{2eq-1}= J_{2eq-3}= 4.4 Hz, $J_{2eq-2ax}$ = 12.4 Hz, 2H, $H2_{eq}$), 2.19 (m, 1H, *CH*CONH), 1.98 (ddd, J_{2ax-1}= J_{2ax-3}= $J_{2eq-2ax}$= 12.4 Hz, 2H, $H2_{ax}$), 1.57-1.69 (m, 4H, O(CH_2)$_5$$CH_2$N), 1.48-1.55 (m, 2H), 1.25-1.45 (m, 48H), 0.92 (t, *J*= 6.8 Hz, 3H, CH_3). ^{13}C NMR (CD_3OD) δ 174.9 (2*C*ONH), 98.2 (2C1'), 83.3 (2C5), 74.4 (2C4), 73.4 (2C6), 72.3 (2OCH_2(CH_2)$_5$N), 71.6 (2C4'), 70.6 (2C5'), 68.2 (2C3'), 53.4 (2C2'), 50.1 (2C1), 49.2 (2C3), 47.9 (2*CH*CONH), 40.9 (2C6'), 38.7 (2O(CH_2)$_5$$CH_2$N), 35.8, 31.7, 29.8, 29.4, 29.1, 28.9, 26.3, 25.8, 25.0, 22.3 (2C2, 25CH_2), 13.0 (CH_3). LRMS (MALDI, DHB) *m/z*: 1185.7 $[M+Na]^+$, 1163.8 $[M+H]^+$, 716.5.

2-(Dioctadecyl)malonic acid 23 (Scheme 4). Step a: To a solution of the dibenzyl monoalkylmalonate **20** (300 mg, 0.56 mmol) in THF (20 mL) under argon atmosphere at 0°C, were added NaH (60% suspension, 50 mg, 1.25 mmol), and after 30 min stirring at rt, bromooctadecane (667 mg, 2 mmol). The mixture was stirred for 24 h at reflux. After cooling

at rt, an aqueous saturated NH_4Cl solution was added. After separation of the organic and aqueous layers, the latter was washed 3 times with Et_2O. The organic layers were dried over $MgSO_4$, filtrated and concentrated under reduced pressure. The crude product was purified by chromatography on silica gel with a mixture of cyclohexane/CH_2Cl_2 (70/30, v/v) to lead to the dibenzyl dialkylmalonate with 30% yield. ^{1}H NMR ($CDCl_3$) 7.27-7.35 (m, 10H, *CH* arom.), 5.13 (s, 4H 2CH_2Ph), 1.91 (m, 4H, $(CH_3(CH_2)_{16}CH_2)_2C(CO_2Bn)_2$), 1.20-1.36 (m, 30H, $(CH_3CH_2(CH_2)_{15}CH_2)_2C(CO_2Bn)_2$), 1.08 (m, 4H, $(CH_3CH_2(CH_2)_{15}CH_2)_2C(CO_2Bn)_2$), 0.92 (t, *J*= 6.8 Hz, 6H, 2CH_3). ^{13}C NMR ($CDCl_3$) δ 171.7 (2*C*ONH), 135.7 (2*C* arom.), 128.2, 128.5 (10*CH* arom.), 66.7 (2*CH*Ph), 57.8 ($(CH_3(CH_2)_{17})_2C(CO_2Bn)_2$), 32.2, 32.0, 29.8, 29.7, 29.6, 29.4, 29.3, 23.9, 22.7 ($(CH_3(CH_2)_{17})_2C(CO_2Bn)_2$), 14.2 (2$CH_3$). LRMS ($FAB^+$, NBA) *m/z*: 812 $[M+Na]^+$, 790 $[M+H]^+$, 613. **Step b:** The dialkylated product was debenzylated (124 mg, 0.16 mmol) following the same procedure as for the dibenzyl monoalkylmalonate **20**. The diacid **23** was obtained as a white solid with 91% yield and enough pure for doing the next step without purification. ^{1}H NMR ($CDCl_3$) 1.94 (m, 4H, $(CH_3(CH_2)_{16}CH_2)_2C(CO_2H)_2$), 1.18-1.45 (m, 64H, $(CH_3(CH_2)_{16}CH_2)_2C(CO_2H)_2$), 0.90 (t, *J*= 6.8 Hz, 6H, 2CH_3). ^{13}C NMR ($CDCl_3$) δ 57.9 ($(CH_3(CH_2)_{17})_2C(CO_2H)_2$), 32.0, 29.7, 29.4, 29.3, 24.9, 22.7 ($(CH_3(CH_2)_{17})_2C(CO_2H)_2$), 14.1 (2$CH_3$). LRMS ($FAB^+$, NBA) *m/z*: 632 $[M+Na]^+$, 610 $[M+H]^+$, 564, 546.

5-Neamine derivative 24 (Scheme 4). Step c: Compound **23** (15.8 mg, 0.026 mmol) was dissolved in dry DMF (3 mL) under argon atmosphere. To the solution were added HOBT (10.8 mg, 0.08 mmol) and EDC (15.2 mg, 0.08 mmol). The mixture was stirred at rt for 40 min before the addition of a solution of neamine derivative **17** (120 mg, 0.068 mmol) in DMF (3 mL). After 12 h stirring, the mixture was concentrated under reduced pressure. The crude product was dissolved in CH_2Cl_2 and washed successively with water, an aqueous saturated

$NaHCO_3$ solution then brine. The organic layer was dried over $MgSO_4$, filtrated and concentrated under reduced pressure. The residue obtained was chromatographed on alumina gel with a mixture of CH_2Cl_2/cyclohexane (40/60, v/v) to lead to the mononeamine protected compound with 35% yield. **Step d:** This compound dissolved in CH_2Cl_2 (2 mL) was treated with TFA (2 mL) and anisole (0.1 mL). After 12 h stirring at rt, the solvents were removed under reduced pressure. H_2O and Et_2O were added and the aqueous layer was washed twice with Et_2O before being concentrated and poured on a C18 reversed phase column. After elution with a gradient of H_2O/MeOH, **24** was obtained as the TFA salt with a quantitative yield. ^{1}H NMR (CD_3OD) 5.82 (d, $J_{1'-2'}$= 3.6 Hz, 1H, H1'), 3.99-4.08 (m, 4H, H4, H3', H5', OCH_2(CH_2)$_5$N), 3.76 (m, 1H, OCH_2(CH_2)$_5$N), 3.49-3.61 (m, 2H, H5, H6), 3.32-3.45 (m, 3H, H3, H4', H6'b), 3.15-3.27 (m, 3H, H1, H2', H6'a), 2.40 (ddd, J_{2eq-1}= J_{2eq-3}= 4.0 Hz, $J_{2eq-2ax}$ = 12.8 Hz, 1H, $H2_{eq}$), 2.18 (m, 1H, *CH*CONH), 1.89 (ddd, J_{2ax-1}= J_{2ax-3}= $J_{2eq-2ax}$= 12.8 Hz, 1H, $H2_{ax}$), 1.64 (m, 2H, O(CH_2)$_5$$CH_2$N), 1.49-1.60 (m, 4H), 1.20-1.50 (m, 72H), 0.92 (t, *J*= 6.8 Hz, 6H, 2CH_3). ^{13}C NMR (CD3OD) δ 177.6 (*C*ONH), 162.1, 161.7 (*C*OCF_3), 121.1, 118.2, 115.2, 112.4 (CO*C*F_3), 93.2 (C1'), 83.3 (C5), 75.0 (C4), 73.5 (C6), 72.2 (OCH_2(CH_2)$_5$N), 71.2 (C4'), 71.0 (C5'), 68.5 (C3'), 53.6 (C2'), 50.3 (C1), 49.2 (C3), 46.8 (*CH*CONH), 40.2 (C6'), 38.6 O(CH_2)$_5$$CH_2$N, 32.7, 31.7, 29.8, 29.4, 29.3, 29.2, 29.1, 28.7, 27.2, 26.4, 25.0, 22.3 (C2, 38CH_2), 13.1 (2CH_3). LRMS (MALDI, DHB) *m/z*: 990.9 $[M+Na]^+$, 968.9 $[M+H]^+$. HRMS (ESI^+) *m/z*: $[M+H]^+$ calculated 968.8718, found 968.8718.

2-(Dodecylamido)malonic acid 26 (Scheme 5). Step a: To a solution of dodecanoic acid (254 mg, 1 mmol) in CH_2Cl_2 (14 mL) at rt were added EDC (288 mg, 1.5 mmol) and HOBT (203 mg, 1.5 mmol) then, after 45 min stirring, the chlorhydrate **25** (254 mg, 1.2 mmol) and Et_3N (1 mL). 12 h later, the mixture was washed successively with water, HCl 1M, an aqueous saturated $NaHCO_3$ solution then brine. The organic layer was dried over $MgSO_4$,

filtrated and concentrated under reduced pressure. The residue obtained was chromatographed on silica gel with a mixture of CH_2Cl_2/MeOH (99:1, v/v) to lead to diethyl 2-(dodecylamido)malonate with 95% yield. ^{1}H NMR ($CDCl_3$) 6.45 (d, *J*= 6.8 Hz, 1H, *NH*), 5.18 (d, *J*= 6.8 Hz, 1H, NH*CH*$(CO_2)_2$), 4.29 (m, 4H, 2CH_3*CH_2*OCO), 2.30 (t, *J*= 7.6 Hz, 2H, *CH_2*CONH), 1.66 (m, 2H, *CH_2*), 1.32 (t, *J*= 7.2 Hz, 6H, 2*CH_3*), 1.27 (m, 16H, 8*CH_2*), 0.86 (t, *J*= 6.8 Hz, 3H, *CH_3*). ^{13}C NMR ($CDCl_3$) δ 172.9 (*C*ONH), 166.5 (2*C*OOEt), 62.6 (2CH_3*CH_2*OCO), 56.4 (NH*CH*$(CO_2)_2$), 36.1 (*CH_2*CONH), 31.9, 29.6, 29.5, 29.3, 29.2, 25.4, 22.7 (9*CH_2*), 14.1, 14.0 (3*CH_3*). LRMS (FAB^+, NBA) *m/z*: 358 $[M+H]^+$, 342, 328, 316, 297, 284, 277, 256, 228. **Step b:** This compound in EtOH (9 mL) was treated with NaOH aq. 2M at 70°C for 2 h. After cooling, the solution was neutralized with HCl aq. 1M. The solution was filtrated and concentrated under reduced pressure to give the diacid **26** with 90% yield, enough pure for doing the next step without purification. ^{1}H NMR (CD_3OD) 4.87 (m, 1H, NH*CH*$(CO_2)_2$), 2.25 (t, *J*= 7.2 Hz, 2H, *CH_2*CONH), 1.55 (m, 2H, *CH_2*), 1.24 (m, 16H, 8*CH_2*), 0.84 (t, *J*= 6.8 Hz, 3H, *CH_3*). ^{13}C NMR (CD3OD) δ 174.8 (*C*ONH), 168.1 (2*C*OOH), 48.2 (NH*CH*$(CO_2H)_2$), 35.0 (*CH_2*CONH), 31.7, 29.4, 29.2, 29.1, 28.2, 25.4, 22.4 (9*CH_2*), 13.0 (*CH_3*). LRMS (FAB^+, NBA) *m/z*: 302 $[M+H]^+$, 284, 256, 228, 200.

5,5-Dineamine derivative 27 (Scheme 5). Step c: The diacid **26** (13 mg, 0.043 mmol) was dissolved in dry DMF (3 mL) under argon atmosphere. To the solution were added HOBT (17.4 mg, 0.13 mmol) and EDC (24.7 mg, 0.13 mmol). The mixture was stirred at rt for 40 min before the addition of a solution of neamine derivative **17** (230 mg, 0.12 mmol) in DMF (2 mL). After 12 h stirring, the mixture was concentrated under reduced pressure. The crude product was dissolved in CH_2Cl_2 and washed successively with water, an aqueous saturated $NaHCO_3$ solution then brine. The organic layer was dried over $MgSO_4$, filtrated and concentrated under reduced pressure. The residue obtained was chromatographed on alumina

gel with a mixture of CH_2Cl_2/MeOH (99/1, v/v) to lead to the protected compound with 30% yield. **Step d:** This compound dissolved in CH_2Cl_2 (2 mL) was treated with TFA (2 mL) and anisole (0.1 mL). After 12 h stirring at rt, the solvents were removed under reduced pressure. H_2O and Et_2O were added then the aqueous layer was washed twice with Et_2O before being concentrated. The crude product was eluted on a C18 reversed phase column with a gradient of H_2O/MeOH. Pure compound **27** was obtained as the TFA salt with a quantitative yield. ^{1}H NMR (D_2O) 5.69 (d, $J_{1'-2'}$= 3.6 Hz, 2H, H1'), 3.71-3.94 (m, 8H, H4, H3', H5', OCH_2(CH_2)$_5$N), 3.68 (s, 1H, NCH(CONH)$_2$), 3.51-3.65 (m, 6H, OCH_2(CH_2)$_5$N, H5, H6), 3.30-3.49 (m, 6H, H4', O(CH_2)$_5$$CH_2$N), 3.10-3.27 (m, 6H, H3, H2', H6'b), 2.97-3.08 (m, 2H, H1, H6'a), 2.32 (ddd, J_{2eq-1}= J_{2eq-3}= 4.0 Hz, $J_{2eq-2ax}$= 12.8 Hz, 1H, H2$_{eq}$), 2.13 (t, J= 7.6 Hz, 4H, CH_3(CH_2)$_9$$CH_2$CO), 1.72 (ddd, J_{2ax-1}= J_{2ax-3}= $J_{2eq-2ax}$= 12.4 Hz, 1H, H2$_{ax}$), 1.28-1.50 (m, 10H), 1.01-1.22 (m, 20H), 0.71 (t, J= 7.2 Hz, 6H, 2CH_3). ^{13}C NMR (D_2O) δ 176.9 (CONH), 171.1 (2NHCO(CH_2)$_2$$C$ONH), 163.3, 163.0, 162.6, 162.3 (COCF_3), 120.7, 117.7, 114.9, 112.0 (COCF$_3$), 92.81 (2C1'), 82.6 (2C5), 73.3, 72.8 (2C4, 2C6, NCH(CONH)$_2$), 72.2 (2OCH_2(CH_2)$_5$N), 70.1 (2C4', 2C5'), 68.3 (2C3'), 53.2 (2C2'), 49.7 (2C1), 48.8 (2C3), 42.6, 40.0, 39.2, 35.6, 31.6, 29.3, 29.2, 29.0, 28.7, 28.3, 27.8, 25.8, 25.4, 24.6, 22.3 (2C2, 2C6', 20CH_2), 13.6 (CH_3). LRMS (MALDI, DHB) *m/z*: 1316.9 $[M+K]^+$, 1300.9 $[M+Na]^+$, 1278.9 $[M+H]^+$.

***N*-2-(1,3-diaminopropane)dodecylamide 29 (Scheme 5). Step a:** To a solution of dodecanoic acid (101.1 mg, 0.5 mmol) in CH_2Cl_2 (7 mL) were added at rt EDC (144 mg, 0.75 mmol) and HOBT (101.5 mg, 0.75 mmol) then, after 45 min stirring, the amine **28** (175.3 mg, 0.6 mmol). 2 h later, the mixture was washed successively with water, an aqueous saturated $NaHCO_3$ solution and brine. The organic layer was dried over $MgSO_4$, filtrated and concentrated under reduced pressure. The residue obtained was chromatographed on silica gel

with a mixture of CH_2Cl_2/MeOH (96/4, v/v) to lead to *N*-2-(*N*^{1},*N*^{3}-di-t-boc-1,3-diaminopropane)dodecylamide with 90% yield. ^{1}H NMR ($CDCl_3$) 7.0 (s, 1H, CH_2CONH), 5.40 (m, 2H, 2N*H*COOtBu), 3.76 (m, 1H, NH*CH*(*CH*$_2$NHBoc)$_2$), 3.36 (m, 2H, NHCH(*CH*$_2$NHBoc)$_2$), 3.19 (m, 2H, NHCH(*CH*$_2$NHBoc)$_2$), 2.17 (t, *J*= 8.0 Hz, 2H, *CH*$_2$CONH), 1.60 (m, 2H, *CH*$_2$), 1.46 (s, 18H, 6*CH*$_3$ tBu), 1.27 (m, 16H, 8*CH*$_2$), 0.89 (t, *J*= 6.8 Hz, 3H, *CH*$_3$). ^{13}C NMR ($CDCl_3$) δ 174.0 (CH_2*C*ONH), 157.5 (2*C*OOtBu), 79.8 (2*C* tBu), 52.7 (NH*CH*(CH_2NHBoc)$_2$), 40.8 (NHCH(*CH*$_2$NHBoc)$_2$), 36.9 (*CH*$_2$CONH), 31.9, 29.6, 29.5, 29.3, 29.2 (7*CH*$_2$), 28.3 (6*CH*$_3$ tBu), 25.6, 22.7 (2*CH*$_2$), 14.1 (*CH*$_3$). LRMS (FAB$^+$, NBA) *m/z*: 472 [M+H]$^+$, 416, 372, 360. **Step e:** This compound was treated in a solution of CH_2Cl_2/TFA (4 mL, 1/1, v/v) at rt for 1 h. After concentration of the mixture under reduce pressure, the diamine **29** was obtained with a quantitative yield enough pure for doing the next step without purification. ^{1}H NMR (CD_3OD) 7.0 (s, 1H, CH_2CONH), 5.40 (m, 2H, 2N*H*COOtBu), 3.76 (m, 1H, NH*CH*(*CH*$_2$NHBoc)$_2$), 3.36 (m, 2H, NHCH(*CH*$_2$NHBoc)$_2$), 3.19 (m, 2H, NHCH(*CH*$_2$NHBoc)$_2$), 2.17 (t, J = 8.0 Hz, 2H, *CH*$_2$CONH), 1.60 (m, 2H, *CH*$_2$), 1.46 (s, 18H, 6*CH*$_3$ tBu), 1.27 (m, 16H, 8*CH*$_2$), 0.89 (t, *J*= 6.8 Hz, 3H, *CH*$_3$). ^{13}C NMR (CD_3OD) δ 178.0 (CH_2*C*ONH), 47.6 (NH*CH*(CH_2NHBoc)$_2$), 42.1 (NHCH(*CH*$_2$NH$_2$), 37.1 (*CH*$_2$CONH), 33.2, 30.9, 30.8, 30.7, 30.6, 26.3, 23.9 (9*CH*$_2$), 14.6 (*CH*$_3$). LRMS (FAB$^+$, NBA) *m/z*: 272 [M+H]$^+$, 254, 225.

5,5-Dineamine derivative 30 (Scheme 5). Step f: The diamine **29** (24 mg, 0.047 mmol) was dissolved in dry DMF (4 mL) under argon atmosphere. To the solution were added successively K_2CO_3 (32 mg, 0.23 mmol) and neamine derivative **8** (200 mg, 0.12 mmol). After 24 h stirring under reflux, the mixture was cooled to rt and concentrated under reduced pressure. The crude product was dissolved in CH_2Cl_2 and washed successively with water and brine. The organic layer was dried over $MgSO_4$, filtrated and concentrated under reduced

pressure. The residue obtained was chromatographed on alumina gel with a mixture of cyclohexane/CH_2Cl_2 (50/50, v/v) then CH_2Cl_2 to lead to the protected compound with 50% yield. **Step d:** This compound dissolved in CH_2Cl_2 (2 mL) was treated with TFA (2 mL) and anisole (0.1 mL). After 24 h stirring at rt, the solvents were removed under reduced pressure. H_2O and Et_2O were added. The aqueous layer was washed twice with Et_2O before being concentrated. The crude product was eluted on a C18 reversed phase column with a gradient of H_2O/MeOH. The pure compound **30** was obtained as the TFA salt with 80% yield. ^{1}H NMR (D_2O) 5.69 (d, $J_{1'-2'}$= 3.6 Hz, 2H, H1'), 3.73-3.92 (m, 9H, H4, H3', H5', OCH_2(CH_2)$_5$N, NCH(CH_2NHCO)$_2$), 3.49-3.68 (m, 6H, OCH_2(CH_2)$_5$N, H5, H6), 3.31-3.43 (m, 12H, H3, H2', H4', H6'b, NCH(CH_2NHCO)$_2$), 3.12-3.25, (m, 8H, H1, H6'a, O(CH_2)$_5$$CH_2$N), 2.32 (ddd, 2H, J_{2eq-1}= J_{2eq-3}= 4.0 Hz, $J_{2eq-2ax}$= 12.4 Hz, 1H, H2$_{eq}$), 1.71 (ddd, J_{2ax-1}= J_{2ax-3}= $J_{2eq-2ax}$= 12.4 Hz, 1H, H2$_{ax}$), 1.32-1.51 (m, 12H), 1.05-1.29 (m, 24H), 0.76 (t, J= 7.2 Hz, 6H, 2CH_3). ^{13}C NMR (D_2O) δ 173.6 (CONH), 163.1, 162.7 (COCF_3), 120.6, 117.7, 114.8, 111.9 (COCF$_3$), 92.9 (2C1'), 82.6 (2C5), 73.3 (2C4), 72.7 (2C6), 72.2 (2OCH_2(CH_2)$_5$N), 70.0 (2C4', 2C5'), 68.3 (2C3'), 61.6 (NCH(CH_2NH)$_2$), 53.1 (2C2'), 49.7 (2C1), 48.8 (2C3), 39.9 (2C6'), 31.0, 29.2, 27.9, 24.8, 24.7 (2C2, CH_2), 13.5 (CH_3). LRMS (MALDI, DHB) *m/z*: 1102.9 $[M+Na]^+$, 1080.9 $[M+H]^+$, 800.6.

5,5-Dineamine derivative 32 (Scheme 5). Step g: The neamine derivative **31** (102 mg, 0.055 mmol) was dissolved in dry DMF (3 mL) under argon atmosphere. To the solution were added HOBT (15 mg, 0.11 mmol) and EDC (21.3 mg, 0.11 mmol). The mixture was stirred at rt for 40 min before the addition of a solution of diamine **29** (11.1 mg, 0.022 mmol) in DMF (2 mL). After 24 h stirring, the mixture was concentrated under reduced pressure. The crude product was dissolved in CH_2Cl_2 and washed successively with water, an aqueous saturated $NaHCO_3$ solution and brine. The organic layer was dried over $MgSO_4$, filtrated and

concentrated under reduced pressure. The residue obtained was chromatographed on alumina gel with a mixture of CH_2Cl_2/MeOH (98/2, v/v) to lead to the protected compound with 20% yield. **Step d:** This compound dissolved in CH_2Cl_2 (2 mL) was treated with TFA (2 mL) and anisole (0.1 mL). After 12 h stirring at rt, the solvents were removed under reduced pressure. H_2O and Et_2O were added. The aqueous layer was washed twice with Et_2O before being concentrated. The compound **32** was eluted on a C18 reversed phase column with a gradient of H_2O/MeOH. The pure compound **32** was obtained as the TFA salt with 80% yield. ^{1}H NMR (D_2O) 5.67 (d, $J_{1'-2'}$= 3.6 Hz, 2H, H1'), 3.96 (m, 1H, N*CH*$(CH_2NHCO)_2$), 3.76-3.90 (m, 8H, H4, H3', H5', O*CH*$_2(CH_2)_5$N), 3.48-3.63 (m, 6H, O*CH*$_2(CH_2)_5$N, H5, H6), 3.18-3.39 (m, 20H, H1, H3, H2', H4', H6'a, H6'b, O$(CH_2)_5$*CH*$_2$N, NCH(*CH*$_2$NHCO)$_2$), 2.34 (s, 8H, NHCO(*CH*$_2$)$_2$CONH), 2.28 (ddd, J_{2eq-1}= J_{2eq-3}= 4.0 Hz, $J_{2eq-2ax}$ = 12.4 Hz, 1H, H2$_{eq}$), 2.07 (t, *J*= 7.2 Hz, 2H, $CH_3(CH_2)_9$*CH*$_2$CO), 1.71 (ddd, J_{2ax-1}= J_{2ax-3}= $J_{2eq-2ax}$= 12.4 Hz, 1H, H2$_{ax}$), 1.28-1.52 (m, 10H), 1.04-1.25 (m, 24H), 0.92 (t, *J*= 7.2 Hz, 6H, 2*CH*$_3$). ^{13}C NMR (D_2O) δ 177.4 (*C*ONH), 174.9, 174.2 (2NH*C*O$(CH_2)_2$*C*ONH), 163.1, 162.8 (*C*OCF_3), 120.6, 117.7, 114.8, 111.9 (CO*C*F$_3$), 93.1 (2C1'), 82.8 (2C5), 73.9 (2C4), 72.9 (2C6), 72.2 (2O*CH*$_2(CH_2)_5$N), 70.4 (2C4'), 69.7 (2C5'), 68.6 (2C3'), 53.3 (2C2'), 49.8 (2C1), 48.8 (2C3), 40.4, 40.2, 39.2 (2C6', 2O$(CH_2)_5$*CH*$_2$N, NCH(*CH*$_2$NHCO)$_2$), 35.9 (N*CH*$(CH_2NHCO)_2$), 31.2, 29.3, 28.7, 28.6, 28.4, 28.2, 25.9, 25.3, 24.7, 22.0 (2C2, 22*CH*$_2$), 13.4 (*CH*$_3$). Chart S1. Chemical structure of the twelve neamine derivatives studied. For each derivative, the most likely charged species at physiological pH 7.4 is indicated, as determined with the MarvinSketch software [Marvin 5.0.2.1, 2008, ChemAxon (http://www.chemaxon.com)]. The four derivatives, which displayed the highest transfection activity, are here boxed.

Table S1. Comparison of some chemical features of lipidic derivatives of neamine and some others published cationic lipids.

	Cationic lipid	Mw (g/mol)	Z+ pH 7.4	Z+ pH 5.0	HG type	SP size (g/mol)	LD type	LogP	LogP+	References

Mw, molecular weight; Z+ pH 7.4 or pH 5.0, most likely positive charge number at physiological pH 7.4 or pH 5.0, respectively; HG type, headgroup structure distinguishing, for neamine derivatives, between compounds containing one or two neamines and the attachment position of the spacer onto the neamine core (4'-mononea, 5-mononea or 5,5-dinea); LD type, lipid domain structure indicating the length and the number of aliphatic chains (except for BGTC which is a cholesteryl derivative); SP size, sum of atomic masses in the spacer (SP) domain; LogP, partitioning value of ionic species (average value of octanol-water portioning coefficient); LogP+, partitioning value estimation for a formulation combining one molecule of cationic lipid + one molecule of neutral colipid DOPE (molar ratio 1/1). All those values were calculated using the MarvinSketch software [Marvin 5.0.2.1, 2008, ChemAxon (http://www.chemaxon.com)]. Cationic lipids are listed according to their logP values. Lipidic derivatives of neamine (see Scheme S1); DOST, DOSP, DOSK, DOSN [lipidic derivatives of tobramycin, paromomycin, kanamycin and neomycin, respectively (*6*)]; BGTC (*7*); KLN47 (*8*).

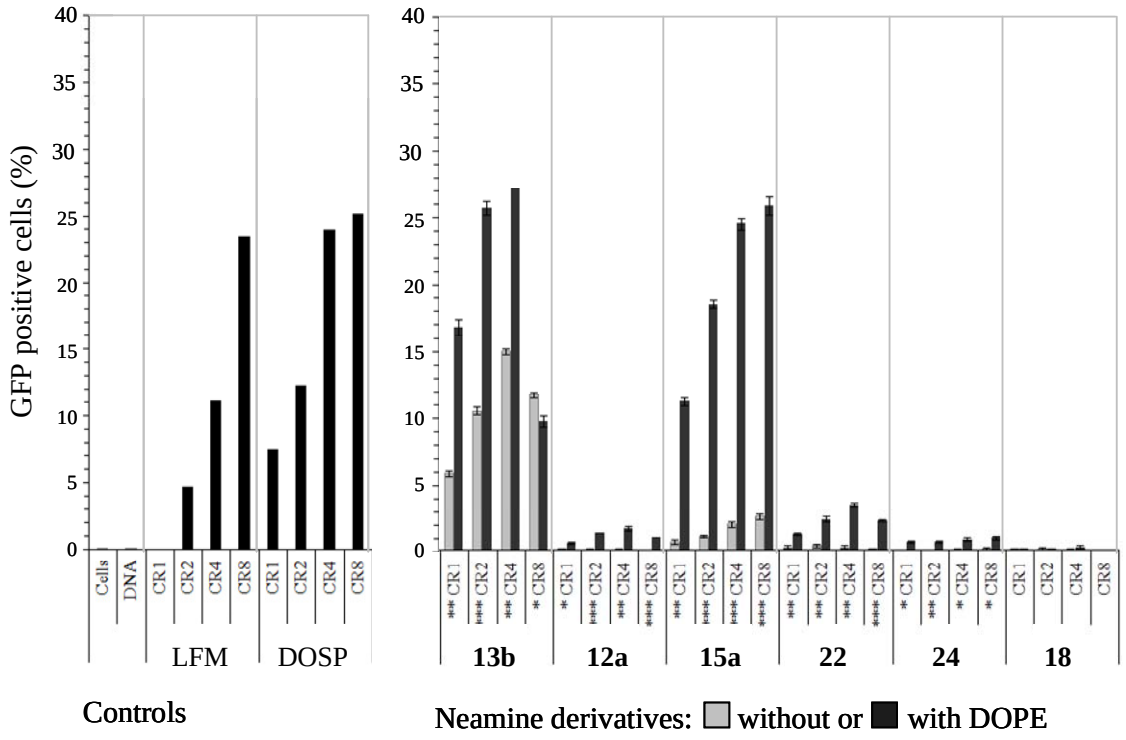

Figure S1. Flow cytometry measurements (GFP assays): transfection efficiencies of lipidic derivatives of neamine used alone or formulated with the colipid DOPE (molar ratio 1/1). The reagents indicated were complexed with DNA (pEGFP-Luc, see "Experimental Procedure" section) in order to obtain increasing charge ratios (CR), from CR1.0 up to CR8.0. The commercial Lipofectamine (LFM, DOSPA/DOPE, Invitrogen) and the paromomycin derivative [DOSP, DOSP/DOPE (*6*)] were used as cationic lipid references. Cell samples were analysed by flow cytometry in order to estimate the gene delivery efficiency as a percentage of positive cells (GFP positive cells). Other derivatives (**11**, **27**, **30**, and **32**) were found completely inefficient and, thus, they are not indicated here. These results were obtained with HeLa cells. Tests were performed in triplicates so efficiencies of formulations of neamine derivatives with or without DOPE can be compared (student t-test: *, $p < 0.05$; **, $p < 0.005$; ***, $p < 0.0005$).

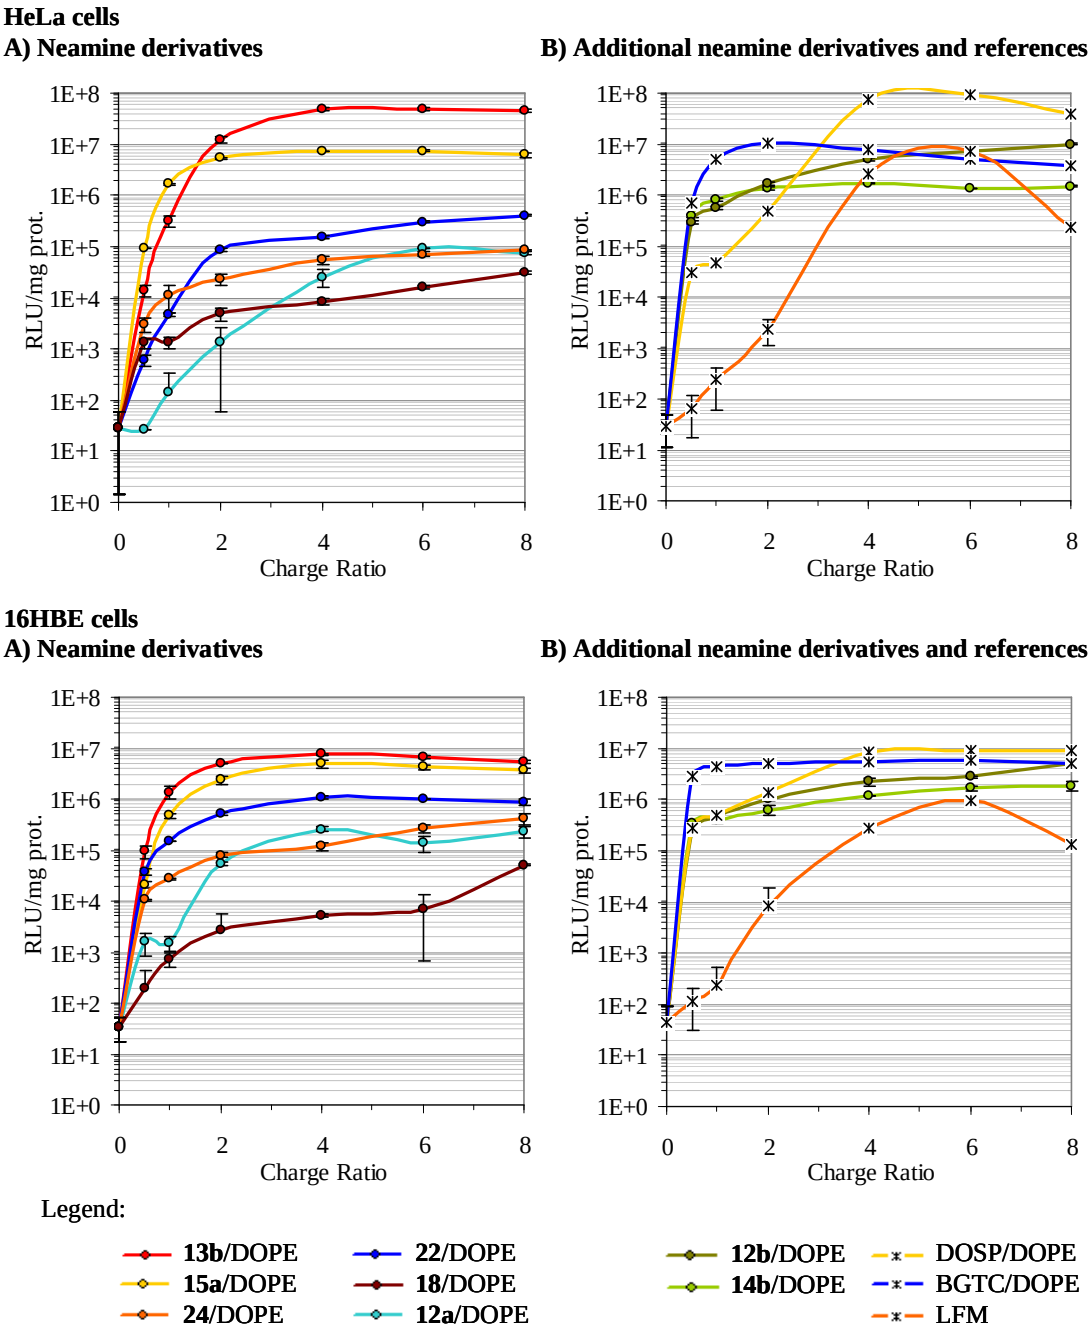

Figure S2. Luminometry measurements (luciferase assays): dose responses of the *in vitro* transfection activity of lipidic neamine derivatives formulated with the colipid DOPE (molar ratio 1/1). Luciferase reporter gene expression is indicated as a function of the charge ratio (CR) of lipoplexes, from CR0.5 up to CR8.0. The commercial Lipofectamine (LFM, Invitrogen), the paromomycin derivative [DOSP, (*6*)] and the bisguanidinium tren-cholesterol BGTC [BGTC/DOPE 3/2, (*7*)] derivative were used as cationic lipid references in those tests. Cells were transfected as described in "Experimental Procedure" section, using lipoplexes prepared by mixing DNA (pEGFP-Luc) with the required amounts of lipids. Data are expressed as relative light units (RLU) per mg of total proteins (mean +/- SD with n=3). These results were obtained using HeLa and 16HBE cells.

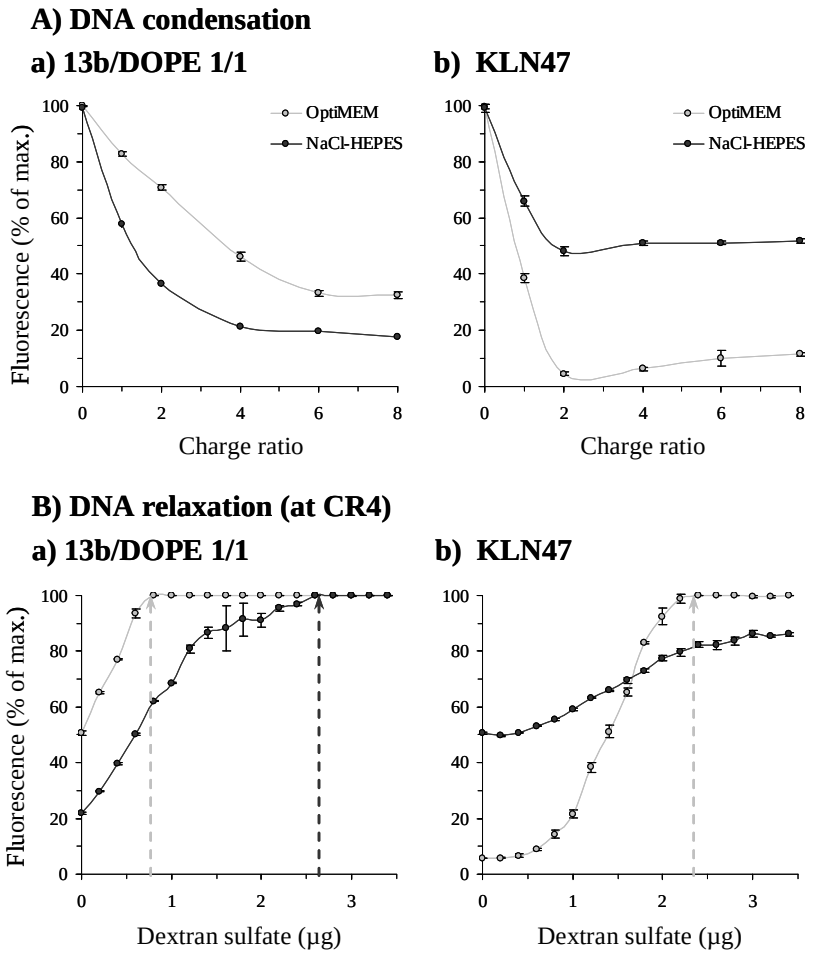

Figure S3. DNA condensation and relaxation assays with cationic liposomes 13b/DOPE 1/1 and KLN47. Complexes were obtained by mixing cationic liposomes at the required concentrations with plasmid DNA incubated first with ethidium bromide (EtB). The fluorescence decrease allowed the evaluation of nucleic acid entrapment within complexes (A; see "Experimental Procedure" section). Complexes at charge ratio 4 were then mixed with increasing quantities of dextran sulfate as a counter-anion. The recovery of fluorescence enabled to follow the DNA relaxation (B). The minimal quantity of counter-anion required to recover maximum fluorescence intensity can then be estimated (arrows). Assays were performed either in OptiMEM or in NaCl-HEPES (0.9% NaCl, 20 mM HEPES). Data are expressed as a percentage of the EtB fluorescence intercalated into DNA in absence of carrier (mean +/- SD with $n \geq 3$).

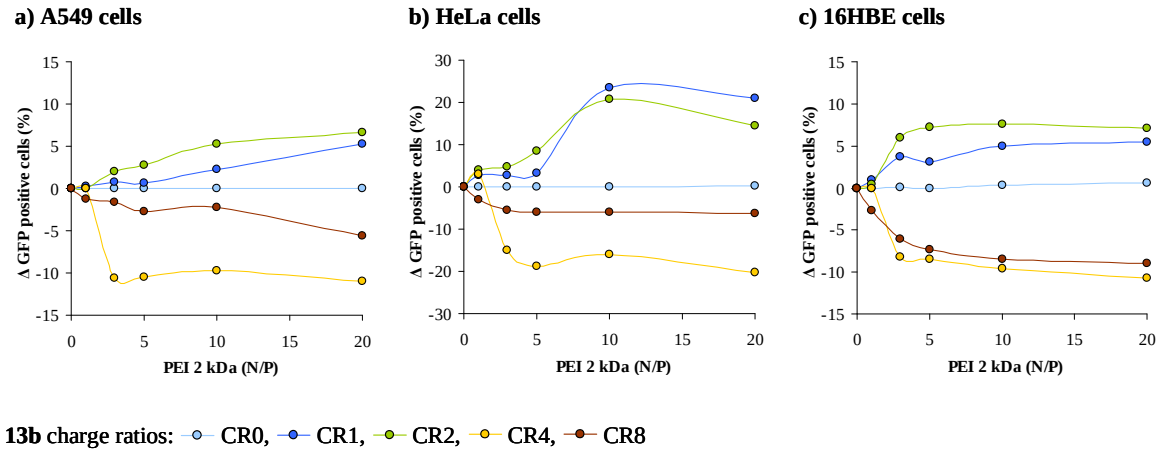

Figure S4. *In vitro* transfection activity for combinations of PEI 2 kDa and 13b/DOPE 1/1 with three different cell lines. Lipoplexes (**13b**/DOPE mixed with DNA, from CR1.0 up to CR8.0), polyplexes (PEI 2 kDa with DNA, from N/P1 up to N/P20) and lipopolyplexes (combinations of PEI 2 kDa with DNA, from N/P 1 up to 20, + **13b**/DOPE, from CR1.0 up to CR8.0) were used to transfect cell lines as described in "Experimental Procedure" section. For each CR, the variation of %GFP positive cells (Δ = % lipopolyplex - % lipoplex) is indicated [polyplexes alone (CR0) are ineffective, whatever the N/P tested]. Thus, compared with a lipoplex at a given CR, a lipopolyplex is more efficient if a Δ value higher than 0 is measured whereas it is less if a Δ value lower than 0 is obtained.

Polylipid nanoparticles (PLNP) have been shown to be very effective in delivering antioxidative genes in the treatment of liver injury in mice. To build on our previous studies and to further characterize PLNP formulated from polycationic lipid (PCL) and cholesterol, we report here the synthesis of multigram quantities of PCL and employ analytical tools, such as Raman spectroscopy of single PLNP and live-cell imaging of lipofection, for the physicochemical characterization of PCL, PLNP, and the transfection process. Mass spectrometry demonstrates the characteristics of polymeric lipids. Raman spectrum of PCL reveals the polymeric structure of the polymers. The presence of cholesterol in PLNP formulation did not markedly change the Raman spectrum. PLNP-derived polyplexes exhibit Raman spectra very similar to PLNP except that the C−H out-of-plane deformation mode of the polymeric lipid is significantly suppressed, indicating the interaction with plasmid DNA. Zeta potential measurement indicates a large DNA-carrying capacity of PLNP and their stability for *in vivo* gene delivery. The live-cell fluorescent imaging dynamically shows that PLNP exerts transfection efficiency similar to lipofectamine in leading to early reporter gene expression in live hepatic cells. In conclusion, polylipid nanoparticles possess a high DNA carrying capacity and lipofection efficiency, rendering them suitable for testing in large animals. The employment of novel state-of-the-art technologies in the study of lipofection represents the level of physicochemical and biological characterization that is needed to best understand the key elements involved in the lipofection process.

INTRODUCTION

Lipid nanoparticles (LNP) have been used widely for *in vitro* gene delivery; however, their potential for *in vivo* gene delivery has been hampered by stability issues in the bloodstream, poor targeting efficiency, and transient transfection efficacy (*1*). Polylipid nanoparticles (PLNP), formulated from polycationic lipid (PCL) and cholesterol, on the other hand, have been documented to be more stable than DOTAP-DOPE[1]or DOTAP-cholesterol formulations in the bloodstream (*2*). We have also shown that PLNP-derived polyplexes were effective in delivering reporter genes, human antioxidative genes (extracellular superoxide dismutase (EC-SOD) or catalase) to the liver for the treatment of acute liver injury caused by hepatotoxins, or an ischemia/reperfusion procedure in two separate preclinical model systems (*3*, *4*). These studies suggest that PLNP are a very effective gene transfer agent for liver-based delivery and have great potential to move from small animals to large animal trials as a step toward clinical applications (*5*). To develop an even more biocompatible gene delivery agent and to move this antioxidative gene approach from "bench to bedside", in-depth characterization of PCL, PLNP, and polyplexes, as well as feasible technologies for larger-scale synthesis of PCL, are needed. In this study, we employ state-of-the-art technologies, such as Raman microspectroscopy, mass spectrometry, and DeltaVision deconvolution microscopy (DVDM) for live cell imaging together with zeta potential measurements to further characterize PCL, PLNP, and PLNP-derived polyplexes. These novel technologies enable us to characterize the physicochemical features of PCL, PLNP, and PLNP-derived polyplexes, as well as the lipofection process, and further determine the stability of the polyplexes. We also describe modifications to our original method of PCL synthesis that enable multigram preparations of PCL sufficient for large animal experiments.

EXPERIMENTAL PROCEDURES

Synthesis of PCL. *Synthetic Procedures and Validation.* PCL (**1**) was prepared according to the synthetic route outlined in Figure 1. Prior to use, CH_2Cl_2 was immediately distilled from CaH_2. After reaction workup, solutions were dried using Na_2SO_4, and solvents were subsequently removed by rotary evaporation. Nuclear magnetic resonance (NMR) spectra were recorded with a General Electric QE-300 spectrometer (^{1}H at 300 MHz, ^{13}C at 75 MHz). Infrared spectra were recorded on a Mattson Genesis II FTIR 3000 spectrometer. Melting points are uncor-

rected. Elemental analyses were performed by Midwest Microlabs (Indianapolis, IN). All sonications were performed in a bath sonicator (Laboratory Supplies Inc., Hicksville, NY).

*3-Bromo-1,2-bis(tetradecanoyloxy)propane (**3**).* To a solution of 3-bromo-1,2-propane-diol (**2**) (9.20 g, 59.4 mmol) in CH_2Cl_2 (50 mL) were added triethylamine (16.5 mL, 119 mmol) and 4-(*N*,*N*-dimethylamino)pyridine (400 mg). The reaction mixture was cooled to 0 °C, and then myristoyl chloride (40.4 mL, 149 mmol) was added dropwise. The reaction was warmed to room temperature and quenched after 4 h by pouring over saturated aqueous $NaHCO_3$ (100 mL). The aqueous layer was separated and the organic layer was washed successively with saturated aqueous $NaHCO_3$, water, and brine, and then dried (Na_2SO_4). The solvents were concentrated in vacuum, the crude residue was dissolved in ethanol, and minimal water was added to provide a cloudy suspension. The solution was placed in the freezer overnight causing bromodiester **3** to precipitate as a white solid (31.4 g, 54.6 mmol, 92%); mp 40−41.5 °C; IR (neat) 2913, 2848, 1731 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.85 (t, J = 6.6 Hz, 6H), 1.23 (m, 40H), 1.59 (m, 4H), 2.29 (m, 4H), 3.48 (m, 2H), 4.21 (dd, J = 11.9, 5.6 Hz, 1H), 4.30 (dd, J = 11.9, 4.4 Hz, 1H), 5.18 (m, 1H); ^{13}C NMR ($CDCl_3$) δ 14.0, 22.6, 24.8, 29.0−29.8 (6 signals), 31.9, 33.9−34.1 (3 signals), 62.9, 69.9, 172.6, 173.0; Anal. Calcd for $C_{31}H_{59}O_4Br$: C, 64.68; H, 10.33. Found: C, 64.75; H, 10.32.

*3-(N-Methyl-N-(2-N′-acrylamide-N′-methylamino)ethyl)amino)-1,2-bis(tetradecanoyl-oxy)propane (**4**).* To a solution of bromo diester **3** (23.9 g, 42.8 mmol) in *N*,*N*-dimethylformamide (200 mL) was added *N*,*N*′-dimethylethylenediamine (DMF) (36.8 mL, 342 mmol) via a syringe. The reaction was stirred under an argon atmosphere at 70 °C. After stirring 45 min, DMF and the unreacted diamine were removed by vacuum distillation. The residue was suspended in CH_2Cl_2 (250 mL) and washed successively with saturated aqueous $NaHCO_3$, water, and brine, and then dried (Na_2SO_4). The solvent was removed, and the crude product was passed through a short column of silica gel, eluting with 15% MeOH/CH_2Cl_2, to afford the crude diamino diester as yellow oil (9.6 g).

To a solution of the crude diamino diester (9.6 g, 16.5 mmol) in CH_2Cl_2 (100 mL) at 0 °C were added triethylamine (2.3 mL, 16 mmol) and 4-(*N*,*N*-dimethylamino)pyridine (200 mg). Acryloyl chloride (1.6 mL, 25 mmol) was added dropwise to the resulting solution, and the reaction mixture was warmed to room temperature. After stirring 3 h, the reaction was quenched by pouring over saturated aqueous $NaHCO_3$. The layers were separated, and the organic layer was washed with water and brine, dried (Na_2SO_4), and then concentrated by rotary evaporation. The residue was purified by column chromatography (SiO_2), eluting with a 3:2 mixture of EtOAc/hexane, to give the diester acrylamide **4** as a light yellow oil (8.72 g, 13.7 mmol, 32%); IR (neat) 2921 2852, 1737, 1654, 1614 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.87 (t, J = 6.6 Hz, 6H), 1.25 (m, 40H), 1.59 (m, 4H), 2.30 (m, 7H), 2.57 (m, 4H), 3.00 (s, 1.5H)*, 3.09 (s, 1.5H)*, 3.41 (m, 1H)*, 3.50 (m, 1H)*, 4.06 (m, 1H), 4.30 (m, 1H), 5.15 (m, 1H), 5.67 (dd, J = 10.2, 2.10 Hz, 1 H), 6.30 (dd, J = 2.1, 16.8 Hz, 0.5 H)*, 6.32 (dd, J = 2.0, 16.7 Hz, 0.5 H)*, 6.60 (dd, J = 10.2, 16.8 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ 13.9, 22.5, 24.7, 28.9−29.4 (5 signals), 31.7, 34.0, 34.2, 36.0, 42.7, 43.0, 45.8, 48.2, 55.3, 56.3, 57.6, 58.0, 63.4, 63.6, 69.0, 69.2, 127.4, 127.6, 166.0*, 166.3*, 172.9, 173.1. Anal. Calcd for $C_{38}H_{72}O_5N_2$: C, 71.65; H, 11.39; N 4.40. Found: C, 71.32; H, 11.47; N 4.35. (*signals arising from amide stereoisomers).

N-(2-(*N*′-Acryloyl-*N*′-methylamino)ethyl)-*N*,*N*-dimethyl-*N*-[2,3-bis(tetradecanoyloxy)] propanammonium chloride (**5**). Acrylamide **4** (8.68 g, 13.6 mmol) was dissolved in methyl iodide (25 mL) and stirred at room temperature. After stirring for 18 h, methyl iodide was removed using a stream of argon. The crude residue was purified by column chromatography (SiO_2), eluting with a 9:1 mixture of CH_2Cl_2/MeOH. The product then was passed through a column of Dowex 1 × 8−400 ion-exchange resin (∼70 g), eluting with MeOH, to give **5** as a white solid (8.63 g, 12.6 mmol, 92%); IR (neat) 3564, 3358, 2954, 2916, 2848, 1743 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.84 (t, J = 6.2 Hz, 6H), 1.22 (m, 40H), 1.54 (m, 4H), 2.28 (m, 4H), 3.27 (s, 3H), 3.38 (s, 3H), 3.41 (s, 3H), 3.88 (m 2H), 4.04 (m, 4H), 4.29 (d, J = 13.8 Hz, 1H), 4.47 (dd, J = 2.6, 11.6 Hz, 1H), 5.59 (m, 1H), 5.73 (dd, J = 1.5, 10.5 Hz, 1H), 6.29 (dd, J = 1.5, 16.5 Hz, 1 H), 6.57 (dd, J = 10.4, 16.7 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ 13.9, 22.5, 24.6, 24.7, 29.0−29.5 (4 signals), 31.8, 33.8, 34.1, 36.1, 42.3, 51.9, 62.5, 63.3, 64.2, 66.0, 127.2, 128.5, 167.3, 172.5, 172.9.

*The Final Product, PCL (**1**).* Monomer **5** (4.32 g, 6.28 mmol) was suspended in nanopure water (400 mL) by sonication at 50 °C for 45 min. The resultant homogeneous suspension was degassed by bubbling a stream of nitrogen through the suspension for 20 min. The suspension then was heated to 80 °C and stirred vigorously while adding *n*-dodecyl mercaptan (432 mg, 2.13 mmol), followed by a solution of 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH) (175 mg in 45 mL H_2O, 0.645 mmol). The resulting mixture was stirred at 80 °C for 15 h, after which the reaction vessel was placed in a freezer overnight (−10 °C). After thawing at room temperature, the precipitated solids were filtered and washed successively with cold diethyl ether to remove trace mercaptan and then dried under vacuum to afford PCL (4.21 g, 97%) as a white solid with spectral characterization identical to that previously reported (*6*).

Mass Spectral Analysis of PCL. PCL (5 mg) was dissolved in 1 mL of isopropanol. Both a 0.17 M solution of *para*-nitroaniline (PNA) and a 0.5 M solution of 2,5-dihydroxybenzoic acid (DHB) were prepared in isopropanol and used as matrices. PNA has been used previously for the detection of phospholipids in positive- and negative-ion spectra (*7*). A 1 μL aliquot of the analytical solution was spotted in each of five different sample wells of a 100-spot stainless steel MALDI plate (Applied Biosystems, Foster City, CA). The matrix (1 μL) was then added on top of each sample spot (dried droplet method). After

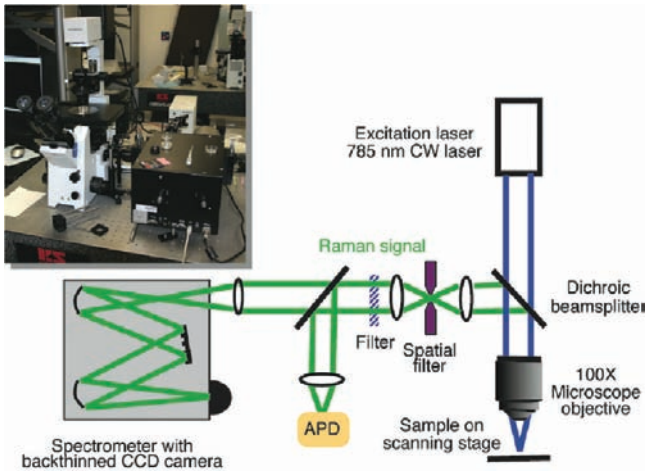

Figure 2. Schematic diagram of the Raman system combining a microscope, confocal detection system, and various laser sources. See the Methods and Materials part for details.

crystallization at ambient conditions, mass spectra were recorded on a Voyager Biospectrometry DE workstation (Applied Biosystems, Foster City, CA) equipped with a Nitrogen laser (λ = 337 nm). The extraction voltage was set to 20 kV. Mass spectra were acquired in both positive and negative modes.

Raman Micromicroscopy Analysis of PCL, PLNP, and PLNP-Derived Polyplexes. The Raman spectra of various LNP formulations were acquired using a Laser-Tweezers Raman microspectroscopy system, which is custom-built around a commercial inverted microscope platform (*8*). The main microscope frame consists of an Olympus IX-71 microscope, utilizing a 60×, NA 1.2, water immersion objective optimized for near-infrared operation. The laser source is an 80 mW, 785 nm diode-pumped solid-state laser, resulting in ~30 mW laser power in the microscope focus after passing multiple mirrors, a bandpass filter, and the microscope objective. The laser beam is focused to a diffraction-limited laser spot of ~500 nm diameter. The microscope is equipped with a mercury arc lamp for white-light fluorescence excitation through appropriate filters, as well as differential interference contrast for visualizing cells. Laser trapping and fluorescence excitation can be performed simultaneously. Spectroscopy is performed through an attached SP2300i spectrograph (Acton Research Corporation) and a back-illuminated thermoelectrically cooled deep-depletion CCD camera with 1340 × 1000 pixels (Figure 2).

The Use of a Fluorescence Deconvolution Microscopy System to Monitor the Lipofection Process. The automated fluorescence deconvolution microscopy system (*9*) (Personal DV, Applied Precision, LLC., Issaquah, WA) makes use of an Olympus IX-71 inverted optical microscope with a 250 W xenon illumination source, a 60× oil-immersion objective lens with a numerical aperture (NA) of 1.4 and a precision stepper-motor driven XYZ stage. The microscope is equipped with DAPI, FITC, TRITC, CY3, and CY5 filter sets, as well as 5 neutral density filters for the excitation source. It is capable of exciting fluorophores from the UV to the far-red and also collects transmitted light (bright field, differential interference contrast (DIC)) images. Image capture is achieved with a CoolSnap ES2 (Photometrics, Tucson, AZ)—a fast, high-resolution, high quantum efficiency, thermoelectrically cooled CCD camera. It can be used for both slow scan, high-resolution imaging of fixed samples or fast, high-sensitivity image capture of live cell samples.

The DeltaVision acquisition, image processing, and analysis software (*softWoRx 3.7.0*) run on a dual-processor personal computer running Cent OS Linux. The microscope is capable of separating up to 4 dyes and displaying triply labeled samples in a single image window through false colors. The DeltaVision software package automates the deconvolution computations, generates 3D reconstructions, and enables autofocusing, cell tracking, and live-cell imaging.

In our experiment, Hep G_2 cells were seeded on 35-mm-diameter round glass bottom culture dishes (MatTek Corp., Ashland, MA). The next day, cells were transfected with plasmid pEGFP-C1 by either PLNP or Lipofectamine, and then incubated at 37 °C. At specified time points, the culture dishes were mounted on the DeltaVision Deconvolution microscope. The temperature of the microscope stage was kept constant at 37 °C using an air-stream incubator (ASI-400, NevTek, Williamsburg, VA). GFP fluorescence of Hep G_2 cells was detected using a standard FITC filter set and corresponding bright field images were also collected. A series of images at different vertical focus positions resulting in optical sections (step size 0.1 μm) were captured with an image size of 512 by 512 pixels and setting binning to 2 × 2. The exposure time of between 0.1 to 0.3 s was sufficient to obtain images suitable for the dynamic range of the cooled CCD camera. Images were saved and processed using the DeltaVision software package (*softWoRx 3.7.0*) and Adobe Photoshop CS3.

Zeta Potential of PCL, PLNP, and Polyplexes. PLNPs were generated as reported previously and complexed with plasmid DNA at different charge ratios. The size distribution was determined by laser light scattering as reported previously (*10*). PLNPs or polyplexes in 2 μL were suspended in 2.5 mL water, and their zeta potentials were determined at room temperature in a Zeta Potential/Particle Sizer Nicomp 280 ZCS PSS-Nicomp Particle Sizing System (Santa Barbara, CA).

Statistical Analysis. The data of zeta potential in different charge ratios were analyzed by one-way variance test followed by multiple comparisons between groups with Newman-Keuls test. A *p*-value of less than 0.05 was considered as statistically significant.

RESULTS

Synthesis of PCL in a Multigram Quantity. The PCL synthesis proceeded from commercially available diol **2** by bisesterification using myristoyl chloride. Subsequent bromide displacement by *N*,*N*′-dimethylethylenediamine followed by reaction of the crude adduct with acryloyl chloride gave acrylamide **4**. Amine quaternization followed by counterion exchange using an established procedure (*11*) afforded acrylamide **5** as the chloride salt. The polymerization of **5** was accomplished by heating a suspension of **5** in water (ca. 15 mM) to 80 °C and then adding *n*-dodecyl mercaptan (*12*) and the water-soluble free radical initiator 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH) (*13*). The delay in addition of *n*-dodecyl mercaptan until the formulation of lipid nanoparticle with **5** differs from our previous protocol (*6*) and helps minimize conjugate addition of the thiol to the acrylamide. All intermediate products were validated by NMR spectral analysis, and the final polymeric product was determined in both negative and positive modes by mass spectral analysis (MALDI-TOF MS). The strongest MALDI-TOF MS signals were obtained with the use of *para*-nitroaniline (PNA) as the matrix. Although no detectable peaks were obtained in the negative mode, strong signals with maximal intensity at m/z = 651.6 were observed in positive-ion spectra, consistent with a polymeric product derived from monomer **5** (Figure 3). The product arising from conjugate addition of dodecyl mercaptan to the acrylamide moiety of **5** was observed at m/z = 853.6. Thus, our modified synthetic method produced PCL in multigram quantities, which is essential for generating enough PLNP for experiments in large animals.

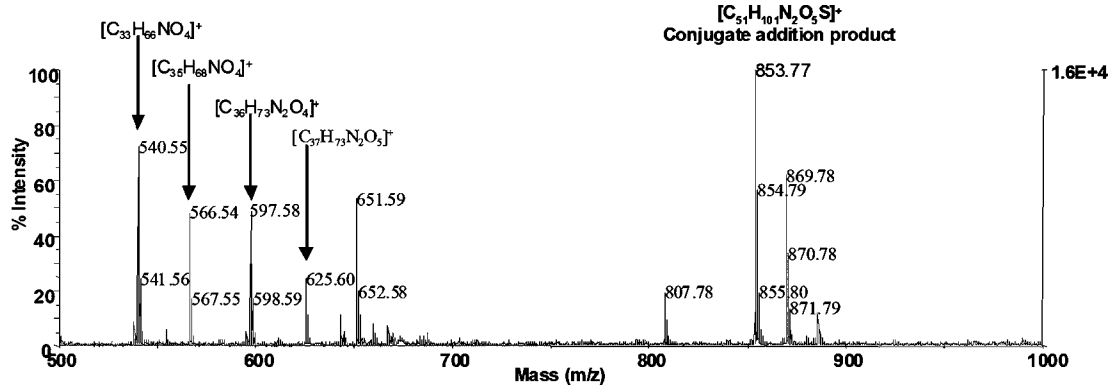

Figure 3. Mass spectral analysis of polycationic lipids. MALDI mass spectrum of PCL was obtained with the use of *para*-nitroaniline as the matrix. Mass spectra were recorded on a Voyager Biospectrometry DE workstation in both positive and negative modes. Strong signals with maximal intensity at $m/z = 651.6$ were observed in positive-ion spectra, indicating the product of polymerized cationic lipids (PCL).

Raman Spectroscopic Analysis of PCL, PLNP, and PLNP-Derived Polyplexes. We have obtained Raman spectra of the various starting materials at high concentration, such as plasmid DNA (3.6 μg/μL), pure lipofectamine, and pure cholesterol as received from the manufacturer, as well as unformulated PCL as synthesized (Figure 4A). For comparison, spectra of lipofectamine complexes with plasmid DNA (Figure 4B), as well as those of PCL vesicles, PLNP, and PLNP-derived polyplexes, were taken (Figure 4C). The Raman data from unformulated PCL are due to Raman scattering on carbon bonds, i.e., C−C, C═C, C−H, CH_2, and clearly show the polymeric nature of PCL (*14*, *15*). The most prominent peaks are C−C stretch modes in the 1100−1200 cm^{-1} and the 1300 cm^{-1} range, and the 1445 cm^{-1} methylene bending vibration in the polymer. Similar features with less pronounced peaks besides the 1445 cm^{-1} methylene deformation mode were found for lipofectamine and cholesterol. Cholesterol contains an additional strong C═C vibration at ~1670 cm^{-1}. The spectrum of plasmid DNA (Figure 4A) is dominated by DNA marker modes such as the 785 cm^{-1} cytosine ring breathing vibration, the 1090 cm^{-1} vibration from the phosphate backbone, the abundant 1442 cm^{-1} CH mode, and the 1575 cm^{-1} adenine vibration (*16*). In addition, this spectrum contains contributions from the solvent (Tris-EDTA buffer) at 1060 cm^{-1}, as well as from polysaccharides from bacterial lysate at 860 cm^{-1} (*15*, *17*). These endotoxins are, however, only present in this highly concentrated form of plasmid DNA, which was required to obtain its Raman spectrum. The DNA used for forming lipoplexes or polyplexes is free of endotoxins. The spectrum of lipofectamine remains unaltered upon dilution (data not shown). Lipofectamine-derived lipoplexes exhibit combined Raman peaks due to lipofectamine as well as DNA. Most noticeable are a weak 785 cm^{-1} cytosine breathing mode, the 1090 cm^{-1} vibration from the phosphate backbone, and the 1660 cm^{-1} amide I mode (Figure 4B). Raman spectra were acquired from individual optically trapped PCL, PLNPs, and PLNP polyplex vesicles within a 30 s signal integration time. Interestingly, PCL changes its spectrum between unformulated PCL and formulated PCL nanoparticles. Most notable is the addition of a strong 1001 cm^{-1} C−H out-of-plane deformation mode. C−H and C−C modes in this spectral range are known to be sensitive markers of acyl chain disorder (*8*, *14*). This has been widely observed in lipid vesicles. On the basis of these observations, we attribute this strong peak to the increased chain disorder in formulated PCL when compared to unformulated PCL powder. Interestingly, the addition of cholesterol to PCL nanoparticles to form PLNP does not noticeably change the Raman spectrum of these particles, i.e., the disordered state of the polymer chains is retained in the presence of cholesterol. PLNP-derived polyplexes undergo a marked change in their Raman spectrum when compared to PLNP. Here, the 1001 cm^{-1} C−H out-of-plane deformation mode is significantly suppressed due to interaction with plasmid DNA. We attribute this to strong interactions of the charged DNA backbone with the charged polymer chains, which apparently leads to strong ordering in the vesicle chain structure (Figure 4C). The presence of DNA in polyplexes is further confirmed by the presence of weak DNA markers, such as the 785 cm^{-1} cytosine breathing mode, the 1090 cm^{-1} phosphate vibration, and the 1660 cm^{-1} amide I mode.

Use of Fluorescence Deconvolution Microscopy to Dynamically Monitor Reporter Gene Expression. To dynamically determine the earliest expression of a reporter gene, enhanced green fluorescent protein (GFP), we employed a fluorescence microscopy imaging system for time-elapsed live cell imaging to compare the transfection efficiency of PLNP with lipofectamine. As shown in Figure 5, the earliest GFP expression in Hep G_2 cells was seen 60 min after PLNP-mediated transfection with a pEGFP-C1-EGFP plasmid at the charge ratio of 5:1 (Figure 5A,D), while focal and faint GFP expression was also seen in Hep G_2 cells 70 min after lipofectamine transfection (Figure 5G,J), indicating that lipid nanoparticle-mediated plasmid DNA entering a cell and the nucleus, i.e., the transcription of the reporter gene, is a rather fast process. GFP expression then became more intense and spread throughout Hep G_2 cells transfected either with PLNP (Figure 5B,C,E,F) or lipofectamine (Figure 5H,I,K,L). This observation indicates that the transfection efficiency of PLNP is at least as good as lipofectamine in Hep G_2 cells.

Zeta Potential, Charge Ratios, Size, and Visualization of PLNP and Polyplexes. In order to further determine the relationship of charge ratios and zeta potential of PLNP and PLNP-derived polyplexes, we mixed PLNP with plasmid DNA at various charge ratios, and measured the zeta potential and size of PLNP and PLNP-derived polyplexes at the same time. It is clear from Figure 6 that, for *in vitro* transfection at a charge ratio of 5:1, the zeta potential of polyplexes was slightly lower than PLNP without DNA ($p > 0.05$). For *in vivo* gene delivery at the charge ratio of 1.25:1, the zeta potential of the polyplexes was negative (-6.46 ± 0.97 mV), which is consistent with them being less reactive to serum proteins as reported previously (*2*). We also noticed that the size of polyplexes increased when PLNP were complexed with plasmid DNA. The polyplex size was within the range 200−400 nm, which are similar to many other lipid formulations reported (*18, 19*). The stability of our PLNP was further confirmed *in vitro* when PCL and PLNP vesicles were prepared by sonication to result in nanoparticles with a diameter of 149 ± 62 nm. Under the microscope, we were able to visualize the vesicles of both PCL and PLNP by their absorption of transmitted light (highlighted by a circle) (Figure 7A). The vesicles appear homogeneous in size and

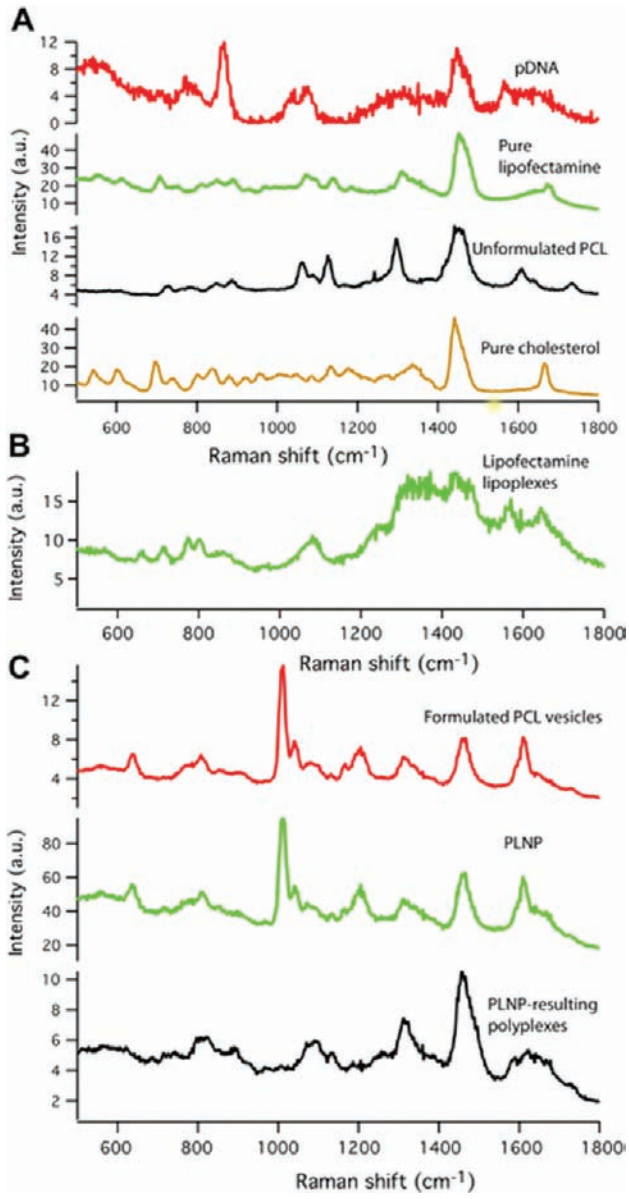

Figure 4. Representative Raman spectrum of pure compounds, nanoparticles, and lipoplexes or polyplexes. (A) Plasmid DNA (red), pure lipofectamine (green), unformulated PCL (black), and pure cholesterol (orange). (B) Lipofectamine-derived lipoplexes (green) in 30s signal integration time. (C) PCL vesicles (red), PLNP (green), and PLNP-derived polyplexes (black). The Raman spectrum was obtained in a Laser-Tweezers Raman microspectroscopy system, and representative spectrum is shown from each condition.

shape. The morphology of these particles did not change significantly after complexation with plasmid DNA (Figure 7B), whereas lipofectamine formed large aggregates in the presence of plasmid DNA (4 μL liposomes/2 μg DNA) (Figure 7C). These data indicate that our PLNP formulation is superior to lipofectamine in DNA binding capacity and particle stability when forming complexes with plasmid DNA.

DISCUSSION

In our previous study, a cationic acrylamide lipid was polymerized to form PCL (*6*). Our PLNP formulated from PCL and cholesterol have been considered as one of a few nonviral lipid nanoparticle formulations (*20, 21*) useful for *in vivo* gene transfer due to their nontoxic feature, high stability in the bloodstream, and superior transfection efficacy in mouse liver (*2, 6*). The preclinical proof-of-concept experiments in two separate model systems demonstrated that the delivery of antioxidative genes, either EC-SOD or catalase, or in combination, protected mouse from acute liver injury induced by hepatotoxins or hepatic ischemia/reperfusion procedures (*3, 4*). These studies were highlighted as "the basis for studies with larger animals and may help bridge the gap between the basic understanding of pathophysiologic processes in animal models towards a practical clinical application in liver transplantation" (*5*). In order to perform large animal experimentation, such as in pigs or nonhuman primates, or for clinical use, we developed a feasible synthetic route for synthesizing PCL on a relatively large scale. The purity of the final product with the polymeric features was verified by mass spectrometry; and PLNP were formulated with the final product and used in the experiments of this study.

Raman spectroscopy is a laser-based analytical technique that enables chemical characterization of molecules in microscopically small samples (*8*). Raman microspectroscopy is based on the inelastic scattering of photons by molecular bond vibrations and is a useful tool for the chemical analysis of lipids, lipoplexes, or polyplexes due to its ability to provide chemical group identification (*22*). A particular advantage of micro-Raman spectroscopy is its unrivaled sensitivity and its relative noninvasiveness, which enables the nondestructive analysis of nanoscopic compounds as small as 50 nm diameter (*8, 14*). We have employed Raman microspectral analysis in a number of studies (*23, 24*), including analyzing the chemical composition of individual triglyceride-rich lipoproteins (*25*). A Raman spectrum appears when a small portion of the photons from a monochromatic light source is scattered by interaction with the bonds resulting in a shift toward higher or lower frequencies. The energy difference between the incident and scattered photons corresponds to the vibrational energy of the specific molecular bond interrogated. A Raman spectrum obtained from lipids, DNA, or their complexes provides an intrinsic molecular fingerprint of these samples, and reveals characteristic information about macromolecular conformations (*8*). In order to further characterize the chemical features of PCL, PLNP, and PLNP-derived polyplexes, we employed a laser-tweezers Raman microspectroscopy system to observe morphologic changes in these particles after complexation with plasmid DNA and to acquire Raman spectra of polyplexes and compare them with lipofectamine lipoplexes. After carefully comparing with pure reagents for PLNP formulation and polyplex formation, we found that the Raman spectra of PCL exhibits polymeric characteristics of the synthetic polymer and that the spectra of PLNP indicate that they readily interacted with plasmid DNA and formed complexes without aggregation. Lipofectamine, on the other hand, was observed to form large aggregates devoid of specific interactions with DNA after complexation with plasmid DNA. These findings, which have not been reported, imply the feasibility of *in vivo* application of PLNP.

The appearance and extent of reporter gene expression in transfected cells are generally determined either by measuring activity of luciferase after lysing cells or by observing the onset of fluorescence from GFP expression at certain time points with a regular fluorescent microscope. It is generally believed that the lipofection process usually takes at least 6 h in transfected cells (*26*). In our previous experiments, we compared transfection efficiency in Hep G_2 cells between PLNP and lipofectamine by luciferase activity and cytotoxicity, and found that PLNP is less toxic than lipofectamine in primary hepatocytes and displayed transfection efficiency in Hep G_2 cells similar to lipofectamine (*6*). The automated fluorescence microscopy imaging system offers the possibility to dynamically monitor the transfection process in live cells, and we noticed that the earliest GFP appearance was within 1 h in Hep G_2 cells

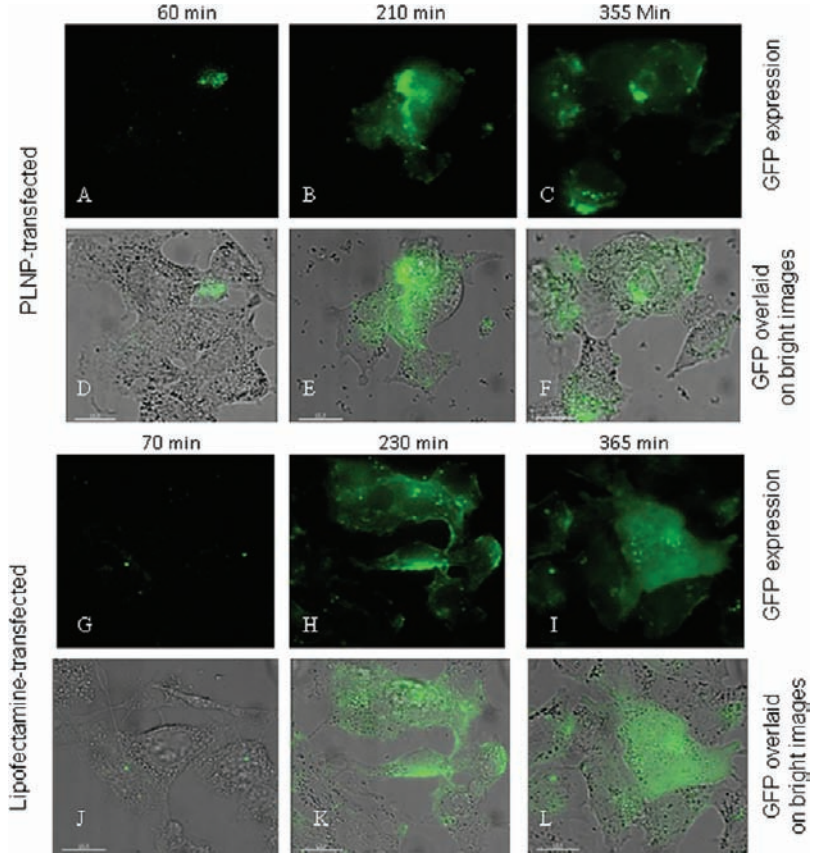

Figure 5. Representative vertical section images of automated fluorescence deconvolution microscopy examination of GFP expression in Hep G2 cells. After transfection, the culture well was mounted in the temperature-controlled platform. Image capture is achieved with a fast, high-resolution, high quantum efficiency, thermoelectrically cooled CCD camera at various time points as indicated. A, B, C and G, H, I representative images are selected from a stack of vertical section images of individual cells at indicated time points. C, D, E, and J, K, L are the overlaid images of A, B, C and G, H, I with their bright field images.

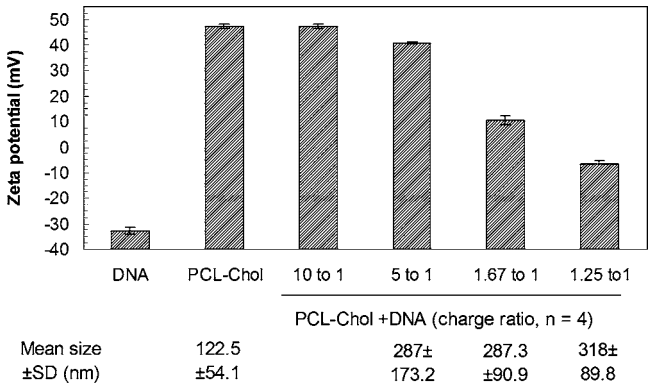

Figure 6. Zeta potential and size changes of PLNP formulation (PCL-Chol). The zeta potential and size were measured by a zeta potential/particle sizer at the charge ratios used for both *in vitro* and *in vivo* experiments ($n = 3$). It is found that the zeta potential was reduced to be neutral or even negative when the charge ratio was decreased to a range from 1.25 to 1, and that lipoplex size increased, but stayed within the 200−400 nm range.

transfected with PLNP, and a relatively faint GFP image was also seen in Hep G_2 cells transfected with lipofectamine 20 min later. Thereafter, the intensity and spread of GFP were similar in cells transfected by either PLNP or lipofectamine. Thus, we were able to dynamically monitor an early lipofection process in live cells over time. The time-lapsed imaging mode of the automated fluorescence deconvolution microscope minimizes long-term photobleaching by rapidly shuttering the excitation source on and off. The detection is based on a digital thermoelectrically cooled CCD camera, which enables us to quantitatively and dynamically determine GFP fluorescence (i.e., expression) levels in the cytoplasm over time. When specific dyes are used to indicate subcellular organelles, the DVDM system also allows detection of multiple, different-colored fluorescence signals simultaneously from cells with high sensitivity together with their morphology in three dimensions without damaging cells (*9*). The figure in Supporting Information is an example of this application. With this system, it is possible to investigate at a specific time point which subcellular organelles are involved in the lipofection process and critical events, such as intracellular trafficking of plasmid DNA, interaction, or synchronization of multiple subcellular organelles.

One of the critical features of cationic lipid, polymers, lipid nanoparticles, lipoplexes, or polyplexes is the zeta potential, which reflects charge force for nucleotide binding. Both size distribution and zeta potential may change after the formation of complexes with plasmid DNA. These two are important parameters of polyplex stability, and are even more critical when polyplexes are used for *in vivo* gene transfer. When forming polyplexes, the charge ratio will be a key factor affecting both zeta potential and transfection efficiency (*27*). A high zeta potential often benefits *in vitro* transfection, whereas neutral or negative zeta potential of lipoplexes or polyplexes may have less serum reactivity and is beneficial for complex stability in the bloodstream (*27, 28*). When similar transfection efficiency is reached, a lower charge ratio (positive charge from cationic lipid over negative charge in DNA) indicates that less cationic lipid is needed for maximal plasmid DNA binding, which indicates the carrying capacity of specific lipids. We have previously shown that our PLNP formulation exhibited similar transfection efficiency when the charge ratio was changed from

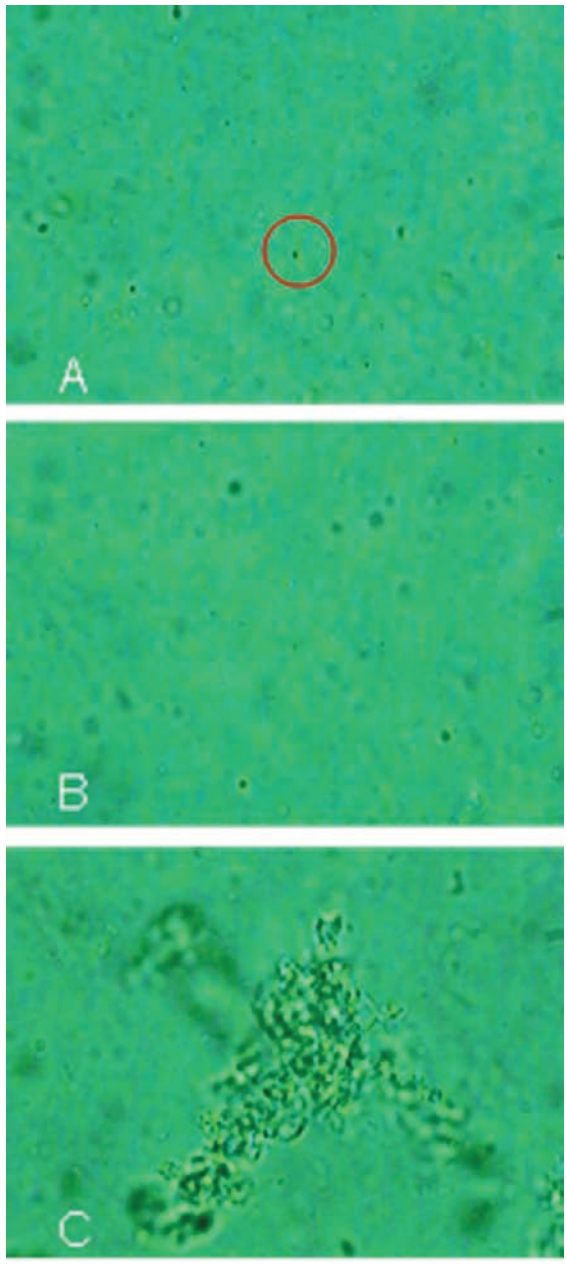

Figure 7. Visualization of lipid vesicles under a light microscope. (A) A PLNP vesicle was visualized under the microscope used for Raman spectromicroscopy analysis (600×), and it is marked with a circle. (B) Polyplexes derived from PLNP and plasmid DNA. (C) Lipoplexes derived from lipofectamine with plasmid DNA. The PLNP morphology of these particles did not change after complexation with plasmid DNA; however, lipofectamine formed large aggregates in the presence of plasmid DNA.

1:3 to 1:5, indicating higher DNA binding and carrying capacity of this formulation (*6*). In the present study, we found that the zeta potential was reduced to be neutral or even negative when the charge ratio was decreased to a range from 1.25 to 1, and the data indicate that this charge ratio is beneficial for *in vivo* delivery through intravenous administration because it may have less reactivity to negatively charged serum proteins. This is a key issue that is under-addressed in the field of lipofection. The net positive charge of polyplexes or lipoplexes is the principal reason for the formation of large aggregates after intravenous administration of lipoplexes or polyplexes and may affect tissue distribution and gene transfer efficacy in specific organs, such as livers when nonviral lipid nanoparticles are used as gene transfer vectors (*29*). The microscopic morphology of PLNP and polyplexes, as shown in Figure 7, further confirmed the stability after complexation with plasmid DNA, and there is a striking contrast to the formation of large aggregates of lipofectamine-derived lipoplexes. Therefore, our PLNP are useful for both *in vitro* and *in vivo* gene transfer as demonstrated in our previous studies and may also be useful in delivering siRNA, similar to other cationic lipid nanoparticles (*30*).

In summary, the employment of novel state-of-the-art technologies in the study of lipofection represents the level of physicochemical and biological characterization that is needed to best understand the key elements involved in the lipofection process. In the present study, we have described a refined method of PCL synthesis on a multigram scale. The data demonstrate that the morphology of PLNP derived from PCL did not change significantly after interaction with plasmid DNA, which is in striking contrast to the formation of large aggregates when using lipofectamine. The large DNA carrying capacity allows PLNP to be saturated with negatively charged plasmid DNA, and the negative zeta potential of PLNP-derived polyplexes is beneficial for *in vivo* stability. The Raman spectral signatures of PCL, PLNP, and polyplexes reflect the polymeric nature of PLNP and the close interaction of PLNP with plasmid DNA. These data are in concordance with the good stability observed for PLNP in the bloodstream and the higher transfection efficiency *in vivo* compared to other formulations of lipid nanoparticles.

ACKNOWLEDGMENT

We thank Mr. Souvik Biswas for his assistance in preparing samples for analysis. C.W.D. is grateful for the award of an R. Bryan Miller Fellowship from the UCD Department of Chemistry during the course of this study. This work was supported by grants from the NIH (DK069939) and the UCD Medical Center (Technology Transfer Grant to J.W.), from the National Science Foundation (to T.R.H.). The Center for Biophotonics, an NSF Science and Technology Center, is managed by the University of California, Davis, under Cooperative Agreement No. PHY 0120999. Part of the data was presented in the 11th Annual meeting of the American Society for Gene Therapy (ASGT), May 28−June 1, 2008, Boston, MA. Mr. Maung Nyunt received a travel award from the ASGT for the presentation.

Supporting Information Available: The use of the DVDM system enables us to section cells at 0.1 μm thicknesses, and a three-dimensional structure of a cell can be built from the sections at the *Z* axis. This material is available free of charge via the Internet at http://pubs.acs.org.

RNA interference is a promising therapeutic strategy for treatment of diseases, in particular, cancer. Despite a huge number of targets identified for different cancer types, there are no effective delivery strategies available so far. Polymeric delivery vehicles are often based on large macromolecules. Such approaches often lead to accumulation of toxicity and narrow therapeutic windows. In the current paper, an alternative approach is presented. Low molecular weight oligoethylenimine (OEI) 800 Da was hydrophobically modified through the Michael addition of different alkyl acrylates. An optimal structure containing ten hexyl acrylate residues per one OEI chain (OEI-HA-10) was found to be a promising candidate for siRNA delivery. Hydrophobic modification stabilized the siRNA polyplex structure, increased the colloidal stability of the nanoparticles, and provided lytic properties to OEI required for crossing cellular membranes in the delivery process. In addition, the acrylate ester bond enables fast degradation of OEI-HA-10 into far less toxic components. Further improvement of biological properties of the OEI-HA-10 polyplexes by different formulation strategies was demonstrated. In particular, a remarkable increase of biocompatibility without loss of efficiency could be achieved by coformulation of OEI-HA-10 with lauryl acrylate modified OEI-LA-5.

INTRODUCTION

Small interfering RNA (siRNA)[1]is a promising tool for both basic and applied biology. The ability to knock down essentially any gene of interest has led to an increased interest in identifying important therapeutic genes and develop siRNA-based treatment. This is particularly interesting for cancer, where a large number of disease-related genes have been understood (*1, 2*). However, the successful application of siRNA-based therapy still represents a great challenge. The in vivo application of siRNAs, in reality, poses many hurdles, especially in humans. One of the main hurdles is the optimization of the delivery strategy, especially the carrier systems. Generally, the carrier must be effectively bound to siRNA, ensuring high stability against dissociation of nucleic acid in physiological fluids. It must provide effective transport of siRNA to the cytosol of the target cells and show low toxicity. Accumulation of the carrier in the body leads normally to accumulation of the toxicity (*3*), which narrows the therapeutic window and limits the dosing frequency of the therapeutics. Therefore, relatively fast biodegradation of the carrier is a desired property for the application of transfection vectors in vivo.

Recently, several strategies for the development of polymeric carriers were introduced, which are mainly based on optimization of the conventional vectors for DNA delivery. Different polyethylenimines (PEIs), which are known to be powerful agents for DNA delivery, are far less effective for siRNA. Different approaches were utilized for the enhancement of their efficiency. In the case of linear PEI, the activity can be enhanced with "sticky" siRNA (ssiRNA) applied for polyplex formation (*4*). Acetylation of the amines of branched PEI or introduction of negatively charged carboxylic groups into structure remarkably increased the knockdown efficiency of the carrier (*5*). Large PEI macromolecules (>5 kDa) are generally nondegradable and cannot be cleared from the body. Thus, they are characterized by only limited potential for therapeutic applications. Low molecular weight PEIs are far less toxic, but also rather inefficient and require high excess of oligoamine in the formulation (*6, 7*). The polyplex stability of such formulations, especially in vivo, is a big concern. Covalent cross-linking of oligoamines by biodegradable linkers provides to the formulation the stability and efficiency of polyamines, and can be degraded in the body to excretable degradation products. Polyamidoamine approaches for cross-linking of oligoamines often lead to rather effective carriers (*8, 9*). However, slow degradation of amide bonds generally limits the therapeutic window of the formulation. Introduction of secondary break points into bifunctional diacrylate structures (i.e., disulfide) can provide much higher degradation rates (*10*). Degradable synthetic polypeptides (i.e., PLL) are rather inefficient in both DNA and siRNA delivery. Conjugation with endosomolytic agents enhanced efficiency of the carrier (*11*). "Dynamic polyconjugates" introduced by Rozema et al. (*12*) are based on biocompatible poly(vinyl alcohol) backbones modified by amine and hydrophobic alkyl groups. Such structures showed a pronounced lytic activity (*13*), which could be reversibly switched off by modification of amines with maleic anhydride-based reagent (*14*). These "dynamic polyconjugates" were rather nontoxic in vivo and showed good efficiency for delivery of siRNA to liver hepatocytes (*12*). Other hydrophobic pH-responsive polymer-based carriers were described by Convertine et al. (*15*). Copolymers

containing cationic binding block and pH-responsive hydrophobic block based on propylacrylic acid and butyl methacylate showed remarkable knockdown of the target genes with relatively low toxicity.

In the current paper, an alternative approach is presented. Instead of cross-linking, OEI 800 was hydrophobically modified by Michael addition of alkyl acrylates. As expected, such structures formed polyplexes with siRNA and demonstrated increased stability against dissociation. Structures with enhanced endosomolytic properties (in particular, hexyl acrylate modified OEI) were efficient in siRNA delivery. Furthermore, coformulation with different agents could significantly improve the parameters of toxicity and efficiency of the carrier. The optimized formulation could represent a promising carrier for delivery to cancer cells.

EXPERIMENTAL PROCEDURES

Materials. Ethyl, butyl, hexyl, and lauryl acrylate (EA, BA, HA, or LA respectively), were obtained from Sigma-Aldrich (Munich, Germany). The plasmid pEGFPLuc (Clontech Laboratories, Heidelberg, Germany) containing a CMV promoter driven fusion of the genes encoding for enhanced green fluorescent protein and luciferase was used for generation of stably transfected cells. Oligoethylenimine with an average molecular weight of 800 Da and all other chemicals were purchased by Sigma-Aldrich (Munich, Germany). Lipofectamine 2000 (LF2000), cell culture media, antibiotics, and fetal calf serum (FCS) were purchased from Invitrogen (Karlsruhe, Germany). Ready to use siRNA duplexes were purchased from Dharmacon (Lafayette, CO), namely, luciferase-siRNA: GL3 luciferase duplex: 5′-CUUACGCUGAGUACUUCGAdTdT-3′ (sense); control-siRNA: nontargeting control duplex: 5′-AUGUAUUGGCCUGUAUUAGUU-3′ (sense).

Modification of OEI by Ethyl, Butyl, and Hexyl Acrylate (EA, BA, and HA). PEI (1 g) was dissolved in chloroform. The solution was heated to 40 °C. The desired amount of acrylate was added to the solution under stirring. The reaction proceeded at 40 °C. After 4 h, the chloroform was removed by rotor evaporator. The waxy product was dissolved in 15 mL water and neutralized by HCl to pH 4−5 and freeze−dried. The gravimetric yields were generally between 80% and 140%. Some yields above 100% were due to additional mass of chloride as a counterion in the lyophilized sample. The modification degree was analyzed by ^{1}H NMR in D_2O on a Jeol JNMR-GX400 (400 MHz) or a Jeol JNMR-GX500 (500 MHz) spectrometer from the ratio between the peaks of OEI (δ 2.4−3.3 ppm) and methyl of acrylates ($\delta = 0.8$ for HA, $\delta = 0.9$ for BA, and $\delta = 1.3$ for EA). The modification degree was expressed as the number of modifications per OEI molecule. According to FTIR spectra recorded on a Jasco FT/IR-410 spectrometer (Jasco Labor and Datentechnik GmbH, Germany), a pronounced ester peak (1730 cm^{-1}) was detected. No significant amide band (1652 cm^{-1}) was found.

Modification of OEI by Lauryl Acrylate (LA). One gram of OEI was dissolved in chloroform and heated to 40 °C. After this, the calculated amount of lauryl acrylate (LA) was added dropwise to the OEI solution. The ratios of OEI to LA were 2.5, 5, and 7.5. The mixture was incubated for 4 h. The resulting solution was evaporated on a rotovap to 1/3 of the initial volume. An excess of diethyl ether was added resulting in a clear solution. After this, an excess of concentrated HCl (37% vol) was added, which resulted in precipitation of the product. The precipitate was filtered, washed with diethyl ether, frozen in liquid nitrogen, and dried under vacuum.

The composition of the products was determined by NMR as a ratio between methyl protons of LA (0.8 ppm) and a broad peak of OEI (2.4−3.3 ppm). The peak at 4.1 ppm represents the CH_2−O proton of the ester bond. It was found to be stable over time and show good proportionality to the weights of all other peaks of LA (2:3 if compared to methyl).

Preparation of Liposomes. Lipid mixtures were prepared as a film by chloroform evaporation method. Dioleoyl phosphatidylethanolamine (DOPE, Sigma-Aldrich, Germany), dioleoylphosphatidylcholine (DOPC, Sigma-Aldrich, Germany), and dipalmitoylphosphatidylcholine (DPPC, Sigma-Aldrich, Germany) were used.

For the preparation of liposomes, about 10 mg of lipid (DOPE, DOPC, DPPC or mixtures) was dissolved in 0.1 mL of ethanol under mild heating (50 °C). The solution containing 0.5, 1.0, 2.0, or 5.0 mg of lipid was added to Eppendorf tubes and flash-mixed with 1 mL of OEI-HA-10 solution (1 mg/mL in water pH ∼3). The turbid suspension of nanoparticles was formed in all cases. Mixing of lipid (1 mg in 100 μL ethanol) with 1 mL of HBG buffer (without OEI-HA-10) resulted in precipitation of the lipid. The final suspensions were sonicated for 1−2 min resulting in nearly clear solutions in the case of DOPE/OEI-HA10 (weight ratios 0.5, 1, and 2) and slightly opalescent solution in the case of DOPE/OEI-HA10 with a weight ratio of 5. The size of the nanoparticles was analyzed using photon correlation (Zetasizer Nano ZS, Malvern Instruments, Herrenberg, Germany). All nanoparticles were around 80−110 nm in diameter.

Preparation of Polymer Mixtures. For the preparation of OEI-HA-10/OEI mixtures, the amounts of OEI-HA-10 and OEI stock solutions were calculated according to the desired ratio in a final mixture (2/1, 1/1, or 1/2 w/w). The resulting solutions (1 mg/mL total OEI) were used as a stock for preparation of the polyplexes.

Polyplex Formation. In all studies, the composition of polyplexes was characterized by the w/w ratio of the polymer to nucleic acid in the mixture. The weight of modified OEIs represents the weight of lyophilized product, which was previously neutralized and, therefore, includes the mass of counterions (chloride). Formulations for siRNA delivery were prepared in HBG (20 μL) as follows: First, different concentrations of the nucleic acid and oligoamine formulations were diluted at various polymer/nucleic acid ratios in separate tubes in HBG (HEPES buffered glucose solution; 20 mM HEPES, 5% glucose, pH 7). Then, the HBG solution of oligoamine was added to the HBG solution of the nucleic acid, mixed and incubated for 30−40 min at room temperature to form stable complexes. In the case of LF2000, formulations with siRNA were prepared according to the manufacturer's standard protocol (Invitrogen).

Agarose Gel Retardation Assay. Polyplexes were prepared as indicated in the corresponding experimental settings containing 500 ng siRNA in 10 μL. Then complexes were mixed with loading buffer (6 mL glycerine, 1.2 mL 0.5 M EDTA, 2.8 mL H_2O, 0.02 g xylenecyanole) and placed into a 2.5% agarose gel in TBE buffer (trizma base 10.8 g, boric acid 5.5 g, disodium EDTA 0.75 g, and 1 L water) containing ethidium bromide (EtBr). Electrophoresis was performed at 80 V for 40 min and evaluated under UV-light.

Ethidium Bromide Exclusion Assay. siRNA condensation ability was evaluated in HBG (20 mM HEPES, 5% glucose, pH 7) using an ethidium bromide exclusion assay. Aliquots of the respective polymer were added stepwise to a siRNA solution (10 μg/mL) in HBG containing 400 ng/mL EtBr, and the decrease of fluorescence was measured in a Cary Eclipse fluorescence spectrophotometer (Varian Deutschland GmbH, Darmstadt, Germany). EtBr/siRNA fluorescence (λ_{ex} 510 nm and λ_{em} 590 nm) was set to 100% prior to addition of polycation, and results are given as relative fluorescence intensities to plain siRNA. Values are given as mean of triplicates ± SD.

Particle Size and Zeta-Potential Measurement. Particle size and zeta-potential of polyplexes were determined by laser light scattering using a Zetasizer Nano ZS (Malvern Instruments, Herrenberg, Germany). For measurement of zeta potentials, the polyplexes (prepared in HBG) were diluted with 1 mM NaCl to a final siRNA concentration of 10 μg/mL (total volume 1 mL). Values are given as mean of triplicates ± SD.

Degradation of Hydrophobically Modified Polyamines. Degradation of conjugates was investigated in an aqueous solution (1 mL, D_2O) at pH 7 at 37 °C. Resulting products were characterized by ^{1}H NMR spectroscopy. Degradation results in formation of alcohol with a peak at δ 3.6 different from those of ester at δ 4.1 (Supporting Information Figure 1). The percentage of degraded ester bond was expressed as the ratio δ 3.6/(δ 3.6 + δ 4.1).

Cell Culture. All cultured cells were grown at 37 °C in 5% CO_2 humidified atmosphere. For siRNA delivery experiments, murine neuroblastoma cells Neuro2A/EGFPLuc, human hepatoma cells HUH7/EGFPLuc stably transfected with the EGFPLuc gene, or human lung carcinoma cells H1299/Luc stably transfected with the luciferase gene (kindly provided by Abbott Laboratories, Chicago) were used. Neuro2A/EGFPLuc cells were grown in Dulbecco's modified Eagle's medium (DMEM, 1 g/L glucose), HUH7/EGFPLuc were grown in DMEM/Ham's F-12 medium, and H1299/Luc cells were grown in RPMI 1640 medium (4.5 g/L glucose), whereby all media were supplemented with 10% FCS, 4 mM stable glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin. All cells were seeded 24 h prior to transfection using 5000 cells per well in 96-well plates for analysis of protein expression. For the generation of stably transfected cells, the same protocol was used as previously reported (*5*).

Cytotoxicity of Polymers. Neuro2A/EGFPLuc cells (5000/well) were seeded into a 96-well plate in 100 μL medium. After 24 h, medium was replaced with 100 μL/well of serial dilutions of polymer stock solutions in serum containing (10% FCS) growth medium. After incubation at 37 °C for 48 h without medium change, the cell viability was analyzed using a MTT-assay. MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazoliumbromide) (Sigma-Aldrich, Germany) was dissolved in phosphate buffered saline at 5 mg/mL, and 10 μL aliquots were added to each well reaching a final concentration of 0.5 mg MTT/mL. After incubation for 1 h, unreacted dye with medium was removed. The purple formazan product was dissolved in 100 μL/well dimethyl sulfoxide and quantified by a plate reader (Tecan Spectrafluor Plus, Grödig, Austria) at 590 nm with background correction at 630 nm. The relative metabolic activity (%) related to untreated control cells was calculated by [A] test/[A] control × 100. Values are given as mean of triplicates ± SD.

Erythrocyte Lysis Assay. Freshly collected citrate buffered murine blood was washed several times with PBS, and erythrocytes were resuspended in HBG/10% FCS at a concentration of 4% (v/v). 75 μL of a polymer solution was mixed with 75 μL erythrocyte suspension in a 96-well plate (NUNC, V-bottom, Denmark). After incubation for 45 min at 37 °C under constant shaking, blood cells were removed by centrifugation and 80 μL of the supernatant was transferred to a new 96-well plate. Hemoglobin absorption was determined at 405 nm using a microplate reader (Tecan Spectrafluor Plus, Grödig, Austria). HBG/10% FCS and 1% Triton X-100 solution in PBS were used as negative and positive controls, respectively. Hemolysis is defined as percentage ($OD_{polymer} - OD_{buffer}$) × 100/($OD_{TritonX-100} - OD_{buffer}$). Values are given as mean of triplicates ± SD.

In Vitro Gene Silencing with siRNA. In vitro gene silencing experiments were performed in stably transfected Neuro2A/EGFPLuc, HUH7/EGFPLuc, and H1299/Luc cells using Luc-siRNA. siCONTROL was used as an unspecific control siRNA. In all experiments, siRNA delivery was performed in 96-well plates with 5000 cells per well in triplicates. Cells were seeded 24 h prior to transfection, and then, medium was replaced with 80 μL fresh growth medium containing 10% FCS or 50% FCS where indicated. Transfection complexes for siRNA delivery (20 μL in HBG) at different w/w ratios were added to each well and incubated at 37 °C without medium change for 48 h. In case of the 50% FCS experiments and H1299/Luc cells, a medium change was performed after 24 h with fresh serum containing (10% FCS) growth medium. Cells were washed with phosphate-buffered saline (PBS) and treated with 50 μL cell lysis buffer (25 mM Tris, pH 7.8, 2 mM EDTA, 2 mM DTT, 10% glycerol, 1% Triton X-100) 48 h following siRNA transfection. Luciferase activity in cell lysate (20 μL) was measured using a luciferase assay kit (100 μL luciferase assay buffer, Promega, Mannheim, Germany) on a luminometer for 10 s (Lumat LB9507 instrument, Berthold, Bad Wildbad, Germany). The relative light units (RLU) were related to untreated control cells.

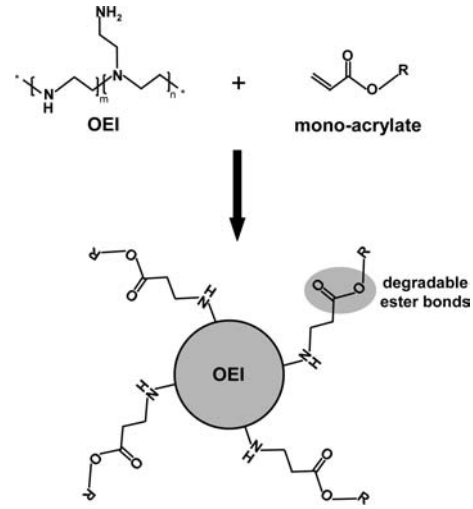

Figure 1. Structure of hydrophobically modified OEIs, which mediate steric stabilization of the polyplexes and cause cell membrane destabilization.

Statistical Analysis. Results are presented as mean ± s.d., and statistical significance of differences was evaluated by variance analysis (one-way ANOVA): p values smaller than 0.05 were considered to be significant, * $p < 0.05$.

RESULTS

Synthesis of the Polymers. All polymer products were synthesized by Michael addition of acrylate to the amines of OEI at 40 °C for 4 h (Figure 1). Higher temperature or longer reaction times are known to cause the aminolysis of the pendant ester bond resulting in cross-linking of the OEI units. Isolation was performed either by evaporation of residual acrylate at high vacuum (<100 mbar) or by precipitation of the product in diethyl ether. No unsaturation could be detected by proton NMR, which indicated effective isolation of the products from unreacted acrylate. Neutralization of the reactive amines before product isolation was essential to prevent slow cross-linking, even during storage at −20 °C (Zintchenko, unpublished observation). According to the FTIR spectra, no amide bond formation and consequently cross-linking could be detected in neutralized samples even after two years' storage at −20 °C. In addition, no peak of corresponding alcohol could be observed on ^{1}H NMR spectra during the storage period, indicating high stability of the products. The compositions of the products were close to

Table 1. Compositions of Hydrophobically Modified OEIs

acrylate	OEI/acrylate, feed mol/mol	OEI/acrylate, product mol/mol
OEI-EA-5	5	4.75
OEI-EA-10	10	9.03
OEI-BA-5	5	4.81
OEI-BA-10	10	9.44
OEI-HA-5	5	5.34
OEI-HA-10	10	10.5
OEI-LA-2.5	2.5	2.37
OEI-LA-5	5	5.4

the reaction feed (Table 1), indicating nearly quantitative reaction of the acrylate with OEI.

Biophysical Characterization of Polyplexes. The binding stability of the oligoamines to siRNA was studied by EtBr and gel shift assay. The EtBr assay was performed in low-salt HBG buffer. OEI and practically all modified oligoamines were effective in binding with siRNA. Only in the case of OEI-EA-10 was the binding significantly suppressed, presumably due to a steric barrier between the charges of siRNA and oligoamine introduced by the bulky acrylate group (data not shown).

Gel shift assay (in salt-containing TBE buffer) showed differences in polyplex stability (Supporting Information Figure 2). Unmodified OEI is quite ineffective in electrophoretic retention of siRNA. Modification by EA did not lead to any improvement of this property. Polyplexes of OEI-BA-5 showed much higher stability, whereas siRNA binding was slightly reduced again by higher BA modification (OEI-BA-10). Both modifications of higher hydrophobicity (HA, LA) were characterized by good binding affinity to siRNA.

Polyplexes with OEI were relatively small immediately after mixing in HBG. However, due to extremely low colloidal stability, rapid aggregation within several minutes was observed. No particles were found 30 min after mixing, probably due to fast sedimentation of aggregates. The same behavior was found in the case of EA and BA modified OEI. Only the in case of HA and LA modifications were polyplexes small and showed good colloidal stability at least 4 h after mixing (Supporting Information Tables 1 and 2). The short chains of OEI (even in excess) are not able to overcharge the polyplex particles and provide colloidal stability. The same was found also for EA and BA modified oligoamines. It seems to be that the hydrophobic interactions between oligoamines with long hydrophobic alkyl chains (HA and LA) could provide additional binding of excess oligoamine to the surface of the particle and, thus, provide improved stability of the polyplexes.

Similar to several endosomolytic peptides, the combination of hydrophobicity in oligoamine structure could increase the ability of the synthesized structures to lyse the lipid membranes and, thus, facilitate the delivery of siRNA into cytoplasm. Therefore, this property was studied by an erythrocyte lysis assay. The modifications with acrylate of low hydrophobicity (EA) were not able to lyse the erythrocytes (data not shown). The same corresponds to the oligoamines with the longest hydrophobic tail (LA). Only in the case of BA and HA modifications were significant lytic properties of the polymers observed (Supporting Information Figure 3).

Bioactivity of siRNA Formulations. Bioactivity of hydrophobically modified oligoamines with siRNA was evaluated by transfection of Neuro2A/EGFPLuc cells at different mixing ratios (w/w). Only OEI-HA-10 formulations containing around 10 HA residues per one OEI unit were able to induce efficient knockdown (Figure 2). Neither the formulations with short hydrophobic tails on oligoamine (EA and BA series) nor those with long (LA series) showed any reduction of luciferase activity (Supporting Information Figure 4). In addition, the formulations with lower degree of HA modification (OEI-HA-5) were

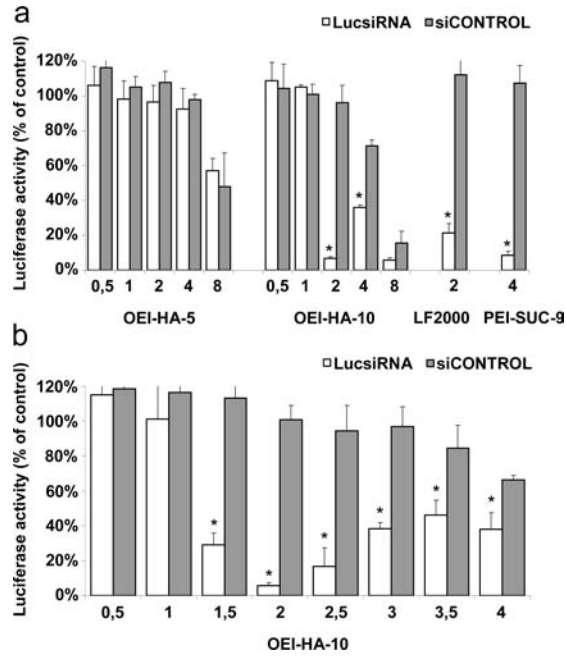

Figure 2. Induction of luciferase knockdown by siRNA formulations in Neuro2A/EGFPLuc cells with (a) OEI-HA-5 or OEI-HA-10 and (b) OEI-HA-10 tested in more detail at several w/w ratios. LF2000 and PEI-SUC-9 were used as reference formulations. White bars, LucsiRNA; black bars, siCONTROL. The numbers on the *x*-axis represent the mixing ratio oligoamine/siRNA (w/w) and LF2000/siRNA (w/w), respectively, in the formulations. Asterisks indicate statistical significance compared to control treated cells (* $p < 0.05$; ANOVA).

ineffective as well (Figure 2). The optimal knockdown efficiency of OEI-HA-10 formulations was observed at oligoamine/siRNA ratio of 2 (w/w) and was comparable to Lipofectamine 2000 and PEI-SUC-9 (*5*) formulations. Further increase of OEI-HA-10 content in the formulation led to a decrease of knockdown efficiency. The similar efficiency profile was found also on H1299/Luc and HUH7/EGFPLuc cell lines (Supporting Information Figure 5). Such unusual bell-shaped behavior cannot be explained by formation of polyplex aggregates, which (in the case of standard PEI) may mediate more efficient delivery of nucleic acid in comparison to small particles (*16*). Polyplex particles at all ratios under investigation were relatively small (Supporting Information Table 1). In addition, cytotoxicity of the formulations could not be the explanation, since the luciferase expression levels at the optimal ratio remain unaffected after transfection with a formulation of a control siRNA sequence. Importantly, the formulations caused significant knockdown even in the medium with high content of serum (50%) (Supporting Information Figure 6).

The toxicity of OEI-HA-10 is relatively high, which could lead to a high acute toxicity during in vivo applications and, thus, represent a problem (Figure 3a). The incubation of oligoamines OEI-HA-10 and OEI-LA-5 for 7 days at 37 °C in HBG buffer led to a remarkable decrease of the toxicity (Figure 3b), presumably due to degradation of the ester bonds. NMR studies revealed that up to 30% of ester bonds were degraded after 3 days of incubation at 37 °C and pH 7 (Supporting Information Figure 1). Thus, long-term toxicity does not seem to be problematic.

Improvement of OEI-HA-10 Formulation. Incorporation of active transfection agents into an appropriative formulation could often improve the physicochemical (solubility, stability, particle size, etc.) and biological parameters (efficiency and biocompatibility) of the final formulation. Helper lipids (*17*−*21*) or helper polymers (*22, 23*) could be utilized for this purpose. In order to improve the efficiency and toxicity profiles of OEI-

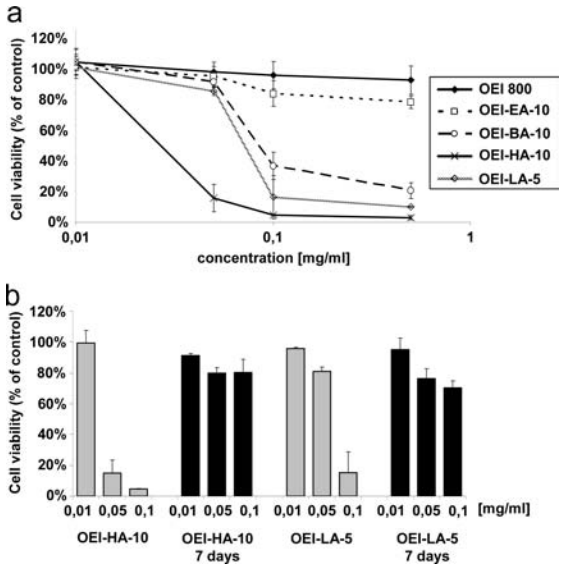

Figure 3. (a) Cell viability of Neuro2A/EGFPLuc cells as a function of concentration of modified oligoamines. (b) Cell viabilities before and after degradation of oligoamines. The black bars represent oligoamines which were incubated for 7 days in HBG buffer at 37 °C prior to application to the cell culture; the gray bars show oligoamines without preincubation.

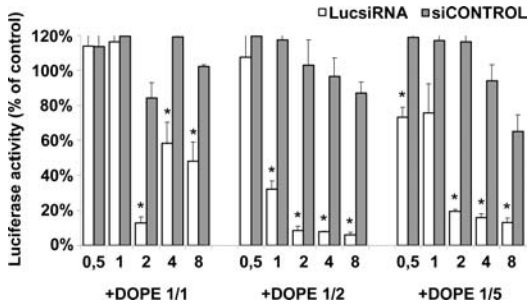

Figure 4. Induction of luciferase knockdown by DOPE/OEI-HA-10/siRNA formulations in Neuro2A/EGFPLuc cells. White bars, LucsiRNA; black bars, siCONTROL. The numbers on the *x*-axis represent the mixing ratio OEI-HA-10/siRNA (w/w) in the formulation. The OEI-HA-10/DOPE ratios were 1/1, 1/2, and 1/5 w/w as indicated under the *x*-axis. Asterisks indicate statistical significance compared to control treated cells (* $p < 0.05$; ANOVA).

HA-10/siRNA formulations, both approaches were utilized. First, OEI-HA-10 was combined with different helper lipids (DOPC, DPPC, and DOPE). Due to hydrophobic groups on OEI-HA-10, it could integrate into the lipid bilayer and improve the toxicity profile of the formulations. Second, the OEI-HA-10 formulation was diluted by nonmodified OEI or OEI-LA-5 as helper polymers, which were far less toxic in comparison to OEI-HA-10.

Combinations of OEI-HA-10 with DOPE led to some decrease of toxicity with a great improvement of the efficiency profile (Figure 4). In the case of the formulation with low content of DOPE (OEI-HA-10/DOPE 1/1 w/w), the efficiency profile was very similar to those of OEI-HA-10 alone, with a rather sharp optimum at polymer/siRNA w/w ratio of 2. The formulations with higher contents of DOPE behaved differently. The knockdown effect was persistent for a wide range of C/P mixing ratios. The optimal composition (OEI-HA-10/DOPE 1/2 w/w) induced the best knockdown, whereas a further increase of DOPE (1/5 w/w) in the formulation resulted in a decrease of the efficiency.

Formulations with DPPC and DOPC could also decrease the toxicity but also dramatically decreased the efficiency (Supporting Information Figure 7). Substitution of a certain amount of DPPC or DOPC with DOPE could not improve the efficiency of the formulations (data not shown).

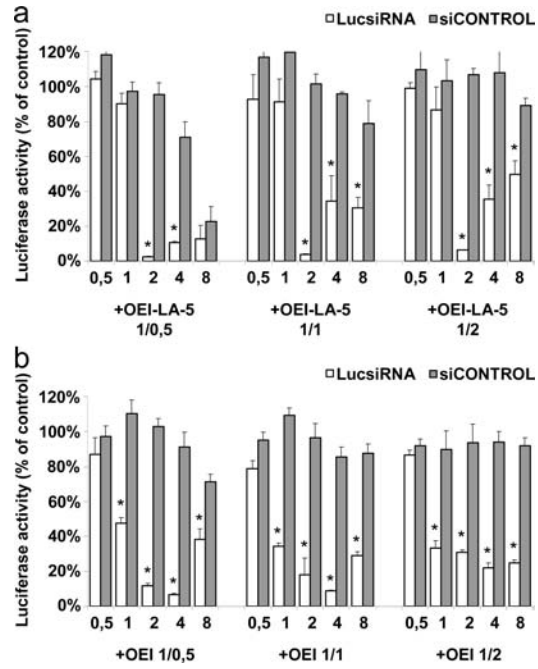

Figure 5. Induction of luciferase knockdown by (a) OEI-HA-10/OEI-LA-5/siRNA and (b) OEI-HA-10/OEI/siRNA formulations in Neuro2A/EGFPLuc cells. White bars, LucsiRNA; black bars, siCONTROL. The numbers on the *x*-axis represent the mixing ratio of total oligoamine/siRNA (w/w) in the formulation. The OEI-HA-10/OEI-LA-5 or OEI-HA-10/OEI ratios were 2/1, 1/1, and 1/2 w/w as indicated under the *x*-axis. Asterisks indicate statistical significance compared to control treated cells (* $p < 0.05$; ANOVA).

Substitution of a certain amount of OEI-HA-10 by relatively nontoxic low molecular weight OEI or OEI-LA-5 oligoamines in the formulation led to a remarkable decrease of the toxicity (Figure 5). A gradual increase of the ratio between OEI (or OEI-LA-5) and OEI-HA-10 in the formulation resulted in a gradual decrease in the toxicity of the formulations. Additionally, the efficiency profile was improved. For example, the OEI-HA-10/OEI 1/2 formulations induced efficient knockdown at lower mixing ratios in comparison to pure OEI-HA-10; the efficiency profile was less dependent on the mixing ratio. Importantly, unmodified OEI alone was not active at all studied mixing ratios and serves only as a helper reagent in the formulation.

DISCUSSION

The development of polymeric vectors for siRNA delivery is mainly attributed to the high molecular weight polyamines. Several classes of such carriers, which were previously proven to be effective in DNA delivery, were found to be effective in transfer of siRNA and knockdown of target genes. The application of high molecular weight structures for in vivo delivery often represents a problem due to relatively narrow therapeutic window. Being either nondegradable (e.g., PEI) or showing relatively slow degradation kinetics, such structures lead to accumulation of the toxicity after repeated application. Short oligoamines are far less toxic (*24*, *25*) and could be rapidly excreted from the body. However, the formulations show low stability in blood and low knockdown efficiency, mainly due to poor endosomolytic properties.

In the current paper, an alternative approach was evaluated. Instead of covalent cross-linking into high molecular weight structures, oligoamines were hydrophobically modified. Such a concept has several advantages. First, they are supposed to

have low half-life times in the organism, presumably due to low molecular weight, which is favorable for excretion and metabolism. Second, the hydrophobic interactions stabilize polyplexes during storage and after administration. Third, similarly to endosomolytic peptides, certain modifications could enhance the interaction with a cell membrane and promote transfer across the cell membrane barrier, for example, by lysis of the endosomes.

Most recently, in a parallel study the similar structures were derived for siRNA delivery as a result of chemical screening of a wide class of products of combinatorial synthesis (*19*). Their formulations showed high efficiency in knockdown of target genes in the hepatocytes and nasal epithelium (*19, 26*). Combining low molecular weight branched PEI with lipid moiety has been reported by Kim's group. Conjugates of cholesterol and short polyethylenimine (1.8 kDa) formulated with VEGF siRNA showed a moderate knockdown in vitro and significant reduction of tumor growth in vivo after intratumoral application (*27*).

In our study, oligoethyleneimine 800 Da was taken as an oligoamine and modified via Michael addition of different alkyl acrylates. An advantage of such structure (in comparison to modification by alkyl acrylamides) could be relatively rapid enzymatic degradation of ester bond in the body and renal clearance of the metabolite. Even in pH neutral buffer (without enzymes), the degradation of ester bond proceeds relatively quickly (Figure 3b).

OEI shows relatively poor condensation of siRNA in salt buffers. The incorporation of short alkyl chains of low hydrophobicity (EA modification) leads to a decrease of binding affinity to siRNA. In the case of BA modifications, OEI-BA-5 was quite effective in complexation, whereas at higher modification degree (OEI-BA-10) led to loss of condensation ability of oligoamine. Most probably, such an effect is due to steric barrier between the charges of siRNA and OEI introduced by a bulky alkyl-β-propionate group. A similar trend could also be seen in the case of HA modified OEI. Nevertheless, due to stronger hydrophobic interactions this effect is generally suppressed for longer alkyl chains (HA and LA) and the stability of the polyplex structure increases remarkably.

Among all oligoamines, only BA and HA modifications could effectively induce the erythrocyte lysis. The formulations with BA modified OEI as well as OEI-HA-5 were, however, quite unstable against aggregation even in salt-free HBG buffer. On the basis of combination of these two parameters, OEI-HA-10 was the only effective oligoamine for siRNA delivery. All other potentially active formulations either precipitated during the preparation step or were not able to be internalized due to the large size of the polyplex particles. Surprisingly, oligoamines with long hydrophobic tails (LA) did not show any ability to lyse the cell membranes. Even OEI-LA-5, despite similar hydrophilic/hydrophobic balance as OEI-HA-10, was rather ineffective in erythrocyte lysis.

Due to strong lytic activity, OEI-HA-10 formulations were relatively toxic in vitro, which led to enhanced acute toxicity and lethality during in vivo applications (Nicole Tietze, EW, AZ; our unpublished observations). Co-formulation with different lipophilic agents (DOPC, DPPC, DOPE liposomes) was able to decrease the toxicity of the formulations in vitro. However, in most cases (except DOPE) these led to inactivation of the formulations. Additionally, the strongest decrease of the toxicity corresponded to the strongest inactivation of the formulations. The DOPE/OEI-HA-10 formulations were only slightly less toxic in comparison to OEI-HA-10 alone, which set certain restrictions for application of such formulations in vivo. The efficiency was, however, greatly improved. Due to inverse head−tail symmetry of DOPE lipid, it is known to destabilize the bilayer structure after incorporation into lipid membranes. The endosomolytic character of the DOPE lipid seems to be the reason for improved efficiency of DOPE/OEI-HA-10 formulations.

The most promising optimization procedure was a dilution of OEI-HA-10 in the formulation by far less toxic but ineffective oligoamines, OEI and OEI-LA-5. Gradual decrease of the OEI-HA-10 content in the formulations led to a strong decrease of cytotoxicity. Importantly, no decrease of the efficiency was observed even for formulations containing as low as 33% (weight % to total oligoamine content) of OEI-HA-10. The combination with OEI-LA-5 (as compared with unmodified OEI) shows the advantage of colloidal stabilization, which could be potentially important during translation of the system to in vivo. Incorporation of OEI to the polyplexes decreases both colloid stability and stability against dissociation, whereas OEI-LA-5 significantly increases colloidal stability (Supporting Information Figure 8; Supporting Information Table 2). Such an optimized formulation, if stable in the bloodstream, could potentially serve as an effective system for siRNA delivery in vivo with low toxicity.

CONCLUSION

Hydrophobic modification of low molecular weight OEI by alkyl acrylates could lead to efficient carriers for siRNA delivery. In particular, OEI modified by ten hexyl acrylates was the most promising delivery vector. Such a structure underwent fast degradation even in pH neutral buffer. The polyplex stability against dissociation and colloidal stability of the polyplex particles was remarkably improved through hydrophobic interactions between OEI chains. The lytic properties of such an oligoamine ensure effective intracellular transport across cellular membranes, presumably by promoting escape from the endosomes. In addition, different formulation strategies, including helper lipid-based and polymer-based modification, could greatly improve the biocompatibility and efficiency of the carrier. Overall, hydrophobically modified oligoamines and their co-formulations represent a promising siRNA delivery approach that warrants further investigation.

Extension Arm Facilitated Pegylation of αα-Hemoglobin with Modifications Targeted Exclusively to Amino Groups: Functional and Structural Advantages of Free Cys-93(*β*) in the PEG-Hb Adduct

Dongxia Li,[†,‡] Tao Hu,[†,‡] Belur N. Manjula,[‡] and Seetharama A. Acharya*[,‡,§]

Cys-93(*β*) of hemoglobin (Hb) was reversibly protected as a mixed disulfide with thiopyridine during extension arm facilitated (EAF) PEGylation and its influence on the structural and functional properties of the EAF-PEG-Hb has been investigated. Avoiding PEGylation of Cys-93(*β*) in the EAF-PEG-Hb lowers the level of perturbation of heme pocket, α1*β*2 interface, autoxidation, heme loss, and the O_2 affinity, as compared to the EAF-PEG-Hb with PEGylation of Cys-93(*β*).The structural and functional advantages of reversible protection of Cys-93(*β*) during EAF PEGylation of oxy-Hb has been compared with Euro PEG-Hb generated by EAF PEGylation of deoxy Hb where Cys-93(*β*) is free in the final product. The αα-fumaryl cross-linking and EAF PEGylation targeted exclusively to Lys residues has been combined together for generation of second-generation EAF-PEG-Hb with lower oxygen affinity. The PEG chains engineered on Lys as well as PEGylation of Cys-93(*β*) independently contribute to the stabilization of oxy conformation of Hb and hence increase the oxygen affinity of Hb. However, oxygen affinity of the EAF-PEG-αα-Hb is more sensitive to the presence of PEGylation on Cys-93(*β*) than that of the EAF-PEG-Hb. The present modified EAF PEGylation platform is expected to facilitate the design of novel versions of the EAF-PEG-Hbs that can now integrate the advantages of avoiding PEGylation of Cys-93(*β*).

INTRODUCTION

PEGylation, conjugation with polyethylene glycol (PEG[1]) chains, can improve the therapeutic potentials of peptides and proteins by camouflaging the immune system and diminishing the *in vivo* glomerular filtration (*1*−*3*). Recently, PEGylation of hemoglobin (Hb) has emerged as a novel chemical approach to neutralize the vasoactivity of acellular Hb, a major obstacle for its therapeutic application as Hb based oxygen carriers (HBOC) (*4, 5*). The PEGylated bovine Hb developed by Enzon Inc. (*6*) is one of the early PEG-Hbs and carries ten copies of PEG-5K chain per tetramer on amino groups (*7*). Another PEGylation protocol, extension arm facilitated (EAF) PEGylation (*8*−*11*), has been developed by us recently. The 2-iminothiolane (IT), an internally cyclized form of *δ*-mercapto butyrimidate, is used to introduce *δ*-mercapto butirimidyl chain on the *ε*-amino groups of Hb. The newly engineered thiol group is then PEGylated using PEG maleimide.

The hexaPEGylated Hb, $(SP\text{-}PEG5K)_6$-Hb generated by the EAF PEGylation, has served as the model molecule to develop MP4 (a hexa-PEG-Hb at 4 g/dL) that is in phase III clinical trial. $(SP\text{-}PEG5K)_6$-Hb carries four PEG-5K chains on the extrinsic thiol groups engineered on the *ε*-amino groups and two on the intrinsic thiols of two Cys-93(*β*) residues of Hb. Thus, EAF PEGylation of oxy Hb introduces two PEG-5K chains by direct PEGylation of Cys-93(*β*) (i.e., without an extension arm). Cys-93(*β*) is located ∼1.4 nm from the heme and is adjacent to proximal His-92(*β*) that coordinates to the center iron of a heme (*12*). Proton NMR spectra has shown that chemical modification of Cys-93(*β*) significantly influences the heme pocket of the *β* chain (*13*). $(SP\text{-}PEG5K)_2$-Hb, a Hb derivative with PEGylation exclusively on Cys-93(*β*), shows a change in the Fe-proximal His residue stretching frequency (*14*). Manjula et al. (*15*) reported that $(SP\text{-}PEG5K)_2$-Hb exhibits a higher oxygen affinity and a lower Hill coefficient than Hb. PEGylation of Cys-93(*β*) also enhanced the autoxidation rate and the rate of heme loss from metHb (*16*). Thus, PEGylation of Cys-93(*β*) unfavorably influences the structural and functional properties of Hb. These unfavorable structural and functional changes could be minimized or eliminated in the EAF-PEG-Hb by avoiding PEGylation of Cys-93(*β*).

The high oxygen affinity of $(SP\text{-}PEG5K)_6$-Hb was one of the attractive features for Sangart in developing MP4. The high oxygen affinity is expected to achieve a targeted O_2 delivery *in vivo* to the hypoxic regions (*7*). The high O_2 affinity is also expected to minimize the O_2 unloading on the arterial side of circulation and thus reduce the possible vasoactivity that is induced through antoregulatory mechanism. Though high O_2 affinity of the EAF-PEG-Hb has been attributed to the PEGylation of Cys-93(*β*) initially (*15*), the EAF PEGylation of rHb[Cys-93(*β*)→Ala] suggested that the high O_2 affinity of the

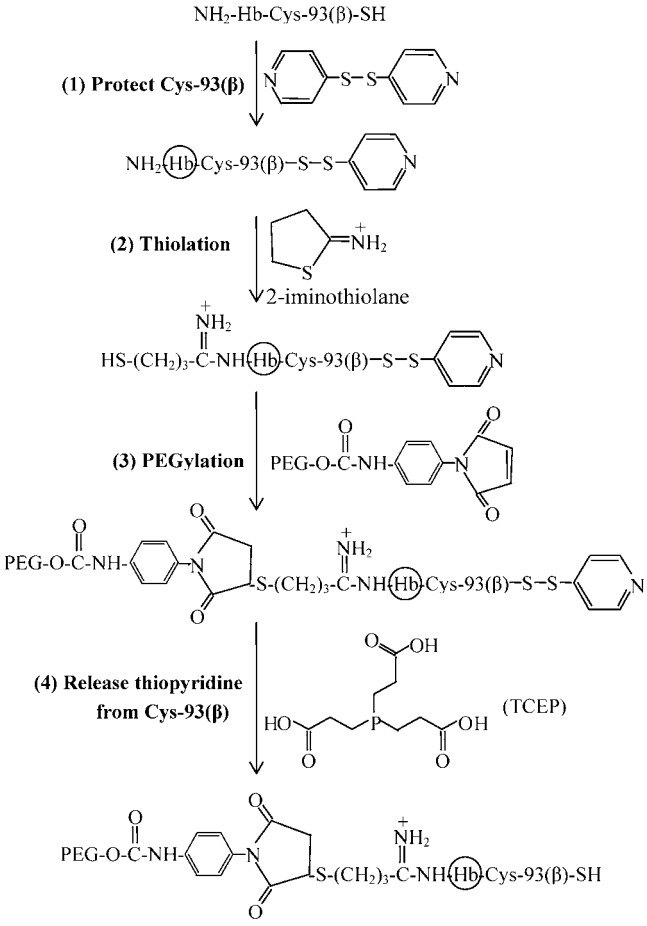

Figure 1. Schematic representation of the extension arm facilitated PEGylation of Hb with reversible protection of Cys-93(β).

EAF-PEG-Hb is an intrinsic aspect of the PEG-Hb and is presumably a consequence of the hydrated PEG-shell around Hb (*10*).

Recent studies have suggested that the O_2 affinity of the PEG-Hb may have to be lower than that of MP4 to achieve an efficient tissue oxygenation (*17*). The high oxygen affinity of the EAF-PEG-Hb represents the synergistic effects of EAF PEGylation at the amino groups and the direct PEGylation at Cys-93(β). Avoiding the direct PEGylation of Cys-93(β) may be necessary to generate the PEG-Hb with an O_2 affinity lower than the ones in the current version of the EAF-PEG-Hb. EAF PEGylation of deoxy Hb is an approach that can protect Cys-93(β) from PEGylation (*9, 36*). Reversible protection of Cys-93(β) during EAF PEGylation of oxy-Hb is an alternative approach developed in the present study.

EAF PEGylation platform has been modified here by designing reversible protection of Cys-93(β). Briefly, the thiol group of Cys-93(β) of oxy-Hb is converted to a mixed disulfide form by reaction with 4,4′-dithiopyridine (4-PDS), followed by EAF PEGylation of the modified Hb and the release of the thiopyridyl group using Tris(2-carboxy-ethyl) phosphine (TCEP) (Figure 1). A low oxygen affinity Hb, $\alpha\alpha$-fumaryl cross-linked Hb ($\alpha\alpha$-Hb), was also EAF PEGylated with protection of Cys-93(β) in order to generate a PEG-Hb with lower oxygen affinity. The influence of avoiding the PEGylation of Cys-93(β) on the generation of a doubly modified Hb ($\alpha\alpha$-cross-linking and EAF-PEGylation) has also been investigated. This modified EAF PEGylation platform is expected to integrate the structural and functional advantages of protection of Cys-93(β) in the EAF-PEG-Hbs.

EXPERIMENTAL PROCEDURES

Preparation of the PEG-Hbs. Human adult hemoglobin (HbA) was purified from human erythrocytes as previously described (*18*). $\alpha\alpha$-Hb was prepared as previously described (*19*). The conditions for EAF PEGylation were slightly modified from Manjula et al. (*9*). Briefly, HbA or $\alpha\alpha$-Hb at 1.0 mM (tetramer) was reacted with 10 mM maleimide phenyl-PEG5K (Malphe-PEG5K, Bioaffinity Inc., Rockford, IL) or 10 mM *N*-ethyl maleimide (NEM) in the presence of 5 mM IT in PBS buffer (pH 7.4) at 4 °C for 4 h. The resultant products are dialyzed extensively against PBS buffer (pH 7.4). For removal of free PEG, the sample was centrifuged at 6000 *g* using Centricon with 50 K cutoff membrane (Millipore) five times. The retentate was stored at −80 °C.

Preparation of the PEG-Hbs with Reversible Protection of Cys-93(β). HbA or $\alpha\alpha$-Hb at 0.25 mM (tetramer) was reacted with 5 mM 4-PDS in PBS buffer (pH 7.4) at 4 °C for 1 h. The resultant samples were dialyzed extensively against PBS buffer (pH 7.4). The absence of 4-PDS was confirmed by adding excess TCEP that did not change the absorbance at 324 nm as compared to the control. The concentrated modified Hb (1 mM as tetramer) was reacted with 10 mM Malphe-PEG5K or 10 mM NEM in the presence of 5 mM IT in PBS buffer (pH 7.4) at 4 °C for 4 h. NEM was added to terminate the reaction. The resultant samples were centrifuged at 6000 *g* using Centricon with 50 K cutoff membrane five times to remove excess free PEG. A large excess of TCEP is added to release the thiopyridyl moiety from the disulfide moiety. For removal of TCEP, the sample was centrifuged at 6000 *g* using Centricon with 50 K cutoff membrane five times. The retentate was stored at −80 °C.

Analytical Methods. Size exclusion chromatography (SEC) analysis was carried out on two Superose 12 columns (GE Healthcare, 1 × 31 cm^2) in series at room temperature. The columns were equilibrated and eluted with PBS buffer (pH 7.4) at a flow rate of 0.5 mL/min. Reverse-phase HPLC analysis was carried out on a Vydac C4 column (4.6 × 250 mm^2). The sample was eluted using a linear gradient of 35−50% acetonitrile containing 0.1% TFA in 100 min and then 50−70% acetonitrile containing 0.1% trifluoroacetic acid (TFA) in 30 min at a flow rate of 1.0 mL/min. SDS-PAGE analysis was carried out on a precast 14% tris-glycine gel (Invitrogen Inc.). Molecular radius of the Hb samples (1 mg/mL) was measured using a dynamic light scattering instrument (DynaPro, Protein Solutions, Lakewood, NJ).

Autoxidation Experiments. Autoxidation studies of the PEG-Hb are carried out by incubating the Hb samples at 25 μM (1.6 mg/mL in tetramers) in PBS buffer (pH 7.4) plus 0.3 mM EDTA in sealed tubes at 37 °C. Aliquots of the sample were taken out at various time intervals. The first-order autoxidation rate constant (k_{ox}) of the Hb sample was measured and calculated as in the method by Hu et al. (*16*). The PEG-Hbs (40 mg/mL) in PBS (pH 7.4) were mixed with the bovine plasma (Sigma) at a volume ratio of 1:1. These diluted samples were used to simulate 50% exchange transfusion of the blood volume. The percentage of plasma metHb was measured as previously described (*16*).

Heme Exchange Experiment. Heme exchange rate between metHb and human serum albumin (HSA) (Sigma) was measured as previously described (*20, 21*). MetHb was formed by reaction of oxyHb with potassium ferricyanide (*22*). The ferro- and ferricyanide were removed by passing the reaction mixture through a Sephadex G-25 column in 50 mM BisTris-Ac buffer (pH 7.5) containing 0.1 M NaCl. The heme exchange reaction was measured as in the method of Hu et al. (*16*).

Tetramer−Dimer Dissociation Constant. Tetramer−dimer dissociation constant (K_d) of the PEG-Hbs was measured essentially as Manning et al. (*23*). Briefly, Hb samples in PBS

buffer (pH 7.4) were diluted to a series of Hb concentrations and subjected to two Superose 12 columns (1 × 31 cm^2) in series. The columns were equilibrated and eluted with PBS buffer (pH 7.4) at the flow rate of 0.5 mL/min. αα-Hb was set as the tetramers for HbA. The PEG-αα-Hbs were set as the tetramers for the PEG-Hbs. The Hb samples in the presence of PBS buffer containing 0.9 M $MgCl_2$ were set as the dimers.

Circular Dichroism Spectroscopy. Circular dichroism (CD) spectra of the Hb samples were recorded on a JASCO-J815 spectropolarimeter (JASCO, Tokyo, Japan) at 25 °C with a 0.2 cm light path cuvette (310 μL). For the CD spectra from 250 to 200 nm, the Hb concentration was 1.3 μM as tetramer. For the CD spectra from 480 to 250 nm, the Hb concentration was 26.0 μM as tetramer. All the Hb samples were in PBS buffer, pH 7.4. The molar ellipticity (θ) is expressed in deg.cm^2/dmol on a heme basis.

Front-Face Fluorescence Measurements. Intrinsic front-face fluorescence measurements of the Hb samples were performed using a Shimadzu RF-5301 spectrofluorimeter at room temperature. The emission spectra were recorded from 300 to 350 nm using an excitation wavelength of 280 nm. Excitation and emission slit widths were both 5 nm. All the samples used were at Hb concentration of 6.0 mg/mL in PBS, pH 7.4. Cuvette with 1 cm path-length was used.

Oxygen Affinity Measurements. Oxygen equilibrium measurements of the Hb samples were carried out using Hem-O-Scan (Aminco) at 37 °C in PBS buffer (pH 7.4). Triplicate measurements for each sample were performed to obtain the averaged values of P_{50} (oxygen affinity) and Hill coefficient (n). The Hb samples were at Hb concentration of 0.5 mM as tetramer in the presence and the absence of 2.5 mM 2,3-DPG.

RESULTS

EAF PEGylation of Un-Cross-Linked Hb with Protection of Cys-93(β). *Size Exclusion Chromatographic Analysis of the PEG-Hbs.* The SEC pattern of the PEG-Hbs is presented in Figure 2A. The elution position of the PEG-Hb (curve c) is earlier than that of HbA (curve a). The elution pattern of the PEGylated bisthiopyridyl Hb (curve d) is slightly right-shifted and exhibits some asymmetry on the descending side of the peak. This is presumably due to the absence of PEGylation on Cys-93(β). Moreover, the elution pattern shows a small peak at the position of Hb, reflecting the presence of minor unPEGylated thiopyridyl Hb. The elution pattern shows no noticeable changes upon releasing the thiopyridyl group from Cys-93(β) (curve e).

Characterization of the PEG-Hb with Protection of Cys-93(β). *RP-HPLC Analysis of the PEG-Hbs.* RP-HPLC analysis of the PEG-Hbs is shown in Figure 3A. The HPLC pattern of Hb shows two peaks corresponding to β and α globin chains (curve a). Upon EAF PEGylation, the two globin chains decrease significantly, along with generation of one major and two minor elution peaks (curve b). These new peaks were estimated to correspond to the mono-, di-, and tri-PEGylated globin chains, according to the procedure by Hu et al. (*24*). The preferential PEGylation at β chain is apparently due to the efficient PEGylation at Cys-93(β). Since the absorbance of the PEG chains at 210 nm is very weak, the absorbance at 210 nm essentially detects the globin chains. Accordingly, the EAF-PEG-Hb has been calculated to carry ~5.7 PEG-5K chains per tetramer. The pattern of the PEGylated bisthiopyridyl Hb (curve c) shows minor thiopyridyl β-globin and unmodified α-globin, along with three new peaks. The peak for the monoPEGylated globin is asymmetrical and becomes symmetrical upon releasing the thiopyridyl moiety (curve d). This PEG-Hb was calculated to carry ~5.0 PEG-5K chains per tetramer. It should be mentioned that the sum of peak areas in the HPLC pattern of the individual samples are taken as 100% for calculating the level of PEGylation in the respective PEG-Hbs.

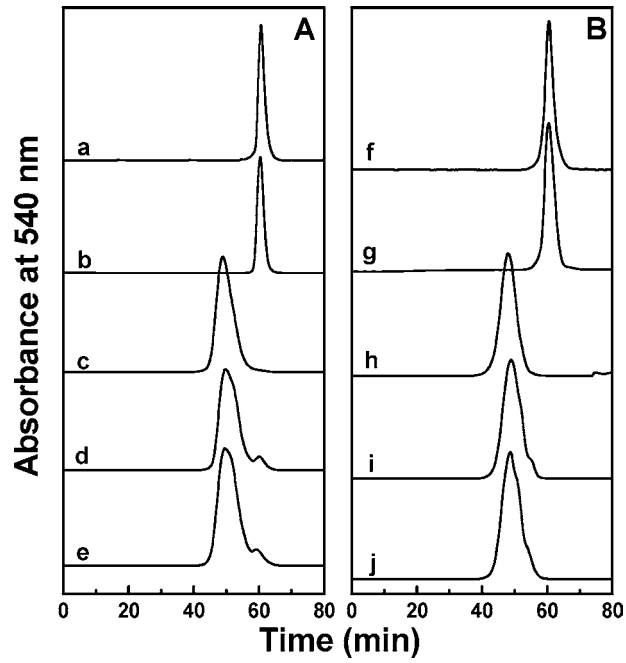

Figure 2. Size exclusion chromatography analysis of the PEG-Hb (A) and the PEG-αα-Hb (B). (a) HbA; (b) the bisthiopyridyl Hb; (c) the PEG-Hb without protection of Cys-93(β); (d) the PEGylated bisthiopyridyl Hb; (e) the PEG-Hb with free Cys-93(β); (f) αα-Hb; (g) the bisthiopyridyl αα-Hb; (h) the PEG-αα-Hb; (i) the PEGylated bisthiopyridyl αα-Hb; (j) the PEG-αα-Hb with free Cys-93(β). All samples were loaded on two HR10/30 Superose 12 columns at room temperature. The column was eluted with PBS, pH 7.4, at 0.5 mL/min.

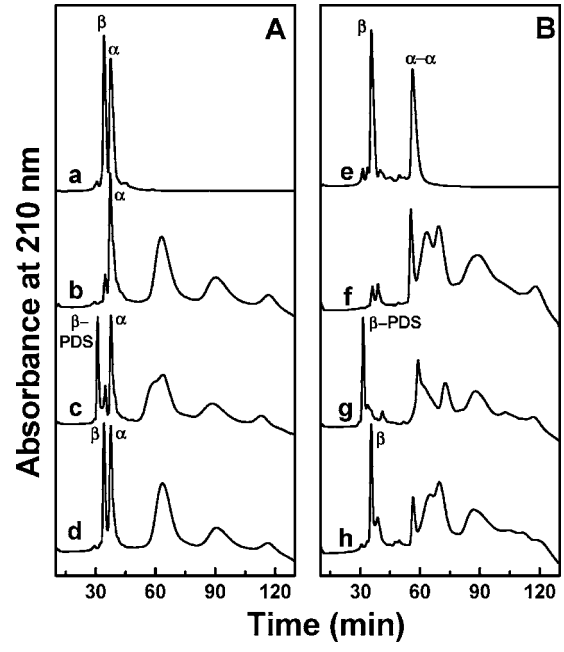

Figure 3. RP-HPLC analysis of the PEG-Hb (A) and the PEG-αα-Hb (B). (a) HbA; (b) the PEG-Hb; (c) the PEGylated bisthiopyridyl Hb; (d) the PEG-Hb with free Cys-93(β); (e) αα-Hb; (f) the PEG-αα-Hb; (g) the PEGylated bisthiopyridyl αα-Hb; (h) the PEG-αα-Hb with free Cys-93(β). The samples were loaded on a Vydac C4 column (0.46 × 25 cm^2). The column was eluted with a linear gradient of 35−50% acetonitrile containing 0.1% TFA in 100 min, followed by 50−70% acetonitrile containing 0.1% TFA in 30 min at 1.0 mL/min.

SDS-PAGE Analysis of the PEG-Hbs. The SDS-PAGE pattern of HbA shows a doublet band corresponding to α and β globin

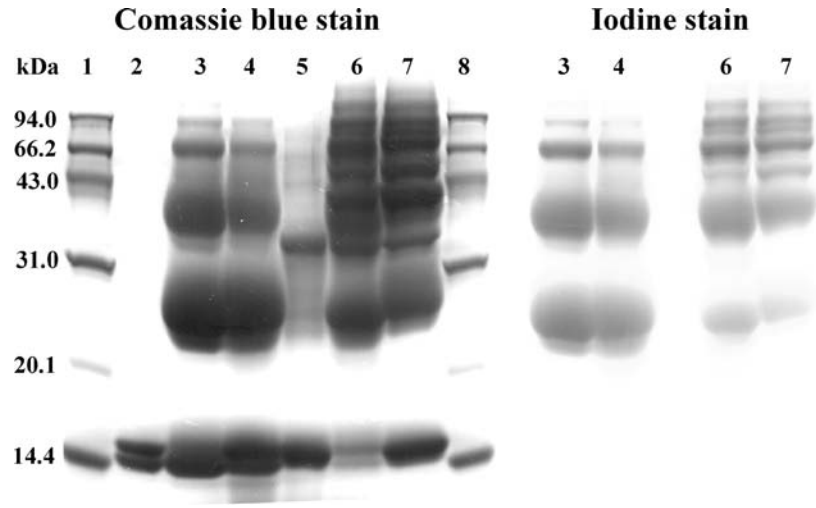

Figure 4. SDS-PAGE analysis of the PEG-Hbs and the PEG-αα-Hb. SDS-PAGE was carried out on a precast 14% Tris-glycine gel from the Invitrogen Corporation. Lanes 1 and 8, the molecular weight markers; lane 2, HbA; lane 3, the PEG-Hb; lane 4, the PEG-Hb with free Cys-93(β); lane 5, αα-Hb; lane 6, the PEG-αα-Hb; lane 7, the PEG-αα-Hb with free Cys-93(β). Proteins were identified by Coomassie blue staining. The PEG chain was detected by iodine staining.

Table 1. Molecular Radius of the PEG-Hb Samples

sample	radius (nm)	molecular volume (nm^3)
HbA	3.04	117.6
EAF-PEG-Hb without free Cys-93(β)	5.23	598.9
EAF PEG-Hb with free Cys-93(β)	4.94	504.7
αα-Hb	3.10	124.8
EAF-PEG-αα-Hb without free Cys-93(β)	5.52	704.2
EAF-PEG-αα-Hb with free Cys-93(β)	5.15	571.9

(~16 kDa) (lane 2, Figure 4). EAF PEGylation of HbA resulted in the appearance of four bands. Iodine staining confirms that these bands (lane 3) correspond to one globin conjugated with 1, 2, 3, and 4 PEG-5K chains. When Cys-93(β) is reversibly protected, these bands are essentially unchanged (lane 4) except that the band corresponding to the tetraPEGylated globin is noticeably reduced.

Molecular Radius of the PEG-Hbs by Dynamic Light Scattering. The molecular radius of Hb increased from 3.04 to 5.23 nm upon EAF PEGylation (Table 1). The molecular radius of the PEG-Hb decreased to 4.94 nm upon reversible protection of Cys-93(β), consistent with the results from the SEC and HPLC analysis.

Reactivity of Cys-93(β) of the PEG-Hbs. As reflected by the titration with 4-PDS (*25*), the PEG-Hb with protection of Cys-93(β) has two free thiols per tetramer (curve b, Figure 5) and its reactivity to 4-PDS is comparable to that of HbA (curve a). Since the change in the reactivity of Cys-93(β) in the oxy state can be considered as an indicator of a change at the $\alpha_1\beta_2$ interface in a chemically modified Hb, EAF PEGylation of Hb with protection of Cys-93(β) did not induce any perturbation at the $\alpha_1\beta_2$ interface of Hb. In contrast, the reactivity of Cys-93(β) of two other hexaPEG-Hbs, (Propyl-PEG5K)$_6$-Hb (curve c), and (Propionyl-PEG5K)$_6$-Hb (curve d) is significantly increased, indicating the structural perturbation at the $\alpha_1\beta_2$ interface of the two PEG-Hbs. It should be mentioned that (Propyl-PEG5K)$_6$-Hb and (Propionyl-PEG5K)$_6$-Hb are prepared using reductive alkylation and acylation chemistry, respectively, where the PEG chains are directly conjugated to the amine groups of Hb (*26, 27*).

Tetramer Stability of the PEG-Hbs. The K_d of HbA increased slightly upon EAF PEGylation with reversible protection of Cys-93(β) (Figure 6). In contrast, the K_d of the EAF-PEG-Hb increased significantly. However, the K_d of HbA increased slightly upon NEM modification and further marginally decreased upon reversible protection of Cys-93(β). This indicated that the NEM modification at Cys-93(β) has little effect on the K_d of Hb. Accordingly, the PEG chains conjugated at Cys-93(β) play a predominant role in the tetramer stability of the EAF-PEG-Hb. In contrast, the reductive alkylation and acylation chemistry based PEG-Hbs exist essentially as Hb dimers (*26, 27*).

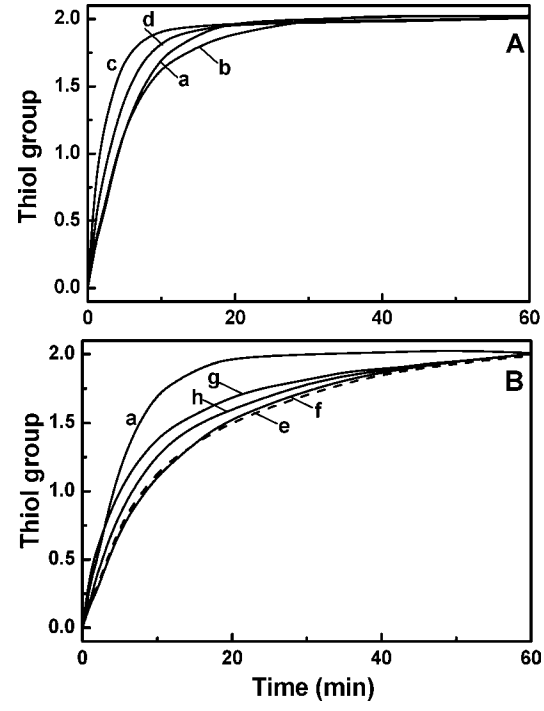

Figure 5. The reactivity of Cys-93(β) of the PEG-Hb (A) and the PEG-αα-Hb (B). HbA (a), the PEG-Hb with free Cys-93(β) (b), (Propyl-PEG5K)$_6$-Hb (c), (Propionyl-PEG5K)$_6$-Hb (d), αα-Hb (e), the PEG-αα-Hb with free Cys-93(β) (f), (Propyl-PEG5K)$_6$-αα-Hb (g), and (Propionyl-PEG5K)$_6$-αα-Hb (h) at the Hb concentration of 5 μM were incubated with 50 μM 4-PDS at room temperature in PBS, pH 7.4. The SH groups were estimated by measuring the conversion of 4-PDS to 4-thiopyridine at 324 nm as a function of time.

Structure and Function of the PEG-Hbs. *Circular Dichroism Study of the PEG-Hbs.* The L band (centered around 260 nm) is considered to be sensitive to the interactions between the heme and the surrounding globin, being influenced by the ligand interactions (*28*). As shown in the near-UV CD region,

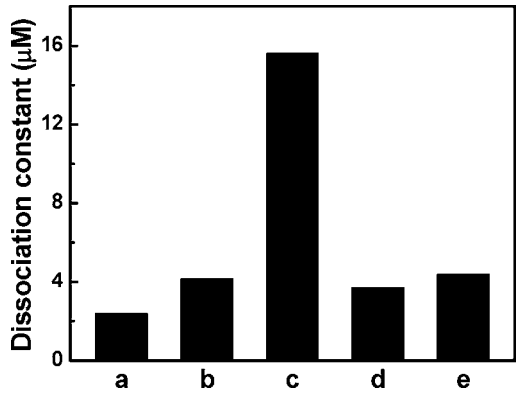

Figure 6. The tetramer−dimer dissociation constant of the PEG-Hb. HbA (a), the PEG-Hb with free Cys-93(β) (b), the PEG-Hb without free Cys-93(β) (c), the NEM modified thiolated Hb with free Cys-93(β) (d), and the NEM modified thiolated Hb without free Cys-93(β) (e) were loaded on the Superose 12 column for the dissociation constant measurement.

NEM modification of Hb did not alter the L band of Hb (Figure 7B). However, EAF PEGylation of Hb (Figure 7A) markedly decreased the L band of the proteins. Interestingly, reversible protection of Cys-93(β) restores the ellipticity of the L band of the EAF-PEG-Hb to the level of the unmodified Hb. Because the EAF-PEG-Hb can be taken as NEM conjugated with the PEG chains, it follows that the PEG chains conjugated at Cys-93(β) unfavorably alter the interactions between the heme and the surrounding globin chain.

The Soret band of Hb is informative of the interactions of the heme prosthetic group with the surrounding aromatic residues (*29*). It should be mentioned that all the Hb samples in the present study were in the oxy form and in the ferrous state. In the Soret region, the ellipticity with the maximal at 421 nm of HbA increased upon EAF PEGylation (Figure 7A) and NEM mediated modification (Figure 7B). However, the ellipticity of the EAF-PEG-Hb is slightly lower than that of the NEM modified Hb. In contrast, the ellipticity of the EAF-PEG-Hb decreased upon reversible protection of Cys-93(β). Thus, the reversible protection of Cys-93(β) reduced the perturbation of the heme environment of the EAF-PEG-Hb.

Intrinsic Front-Face Fluorescence of the PEG-Hb. Front-face fluorescence spectroscopy of Hb has been used to monitor the quaternary changes of Hb upon chemical modification of the protein. The fluorescence sensitivity has been assigned mostly to Trp-37(β) and reflects the conformational changes at the $\alpha_1\beta_2$ interface of Hb. When excited at 280 nm (Figure 8A), the fluorescence intensity of HbA (curve a) decreased upon EAF PEGylation (curve b) and the NEM modification (curve d). In contrast, reversible protection of Cys-93(β) increases the fluorescence intensity of the PEG-Hb (curve c) and the NEM modified Hb (curve e). Thus, the quaternary changes of the EAF-PEG-Hb around the $\alpha_1\beta_2$ interface is primarily a consequence of maleimide modification at Cys-93(β) and not a result of the PEG chains.

O_2 Affinity of the PEG-Hb. The P_{50} of HbA decreases from 14.4 to 6.9 mmHg upon EAF PEGylation, along with a decrease in the Hill coefficient (Table 2). The NEM modified thiolated Hb control showed a P_{50} (oxygen affinity) comparable to the EAF-PEG-Hb. This suggests that the PEG chains play a limited role in dictating the oxygen affinity of the EAF-PEG-Hb. However, the P_{50} of the PEG-Hb and the NEM modified Hb increased upon reversible protection of Cys-93(β), along with a slight decrease in the Hill coefficient. The PEG-Hb and the NEM modified Hb are essentially insensitive to the allosteric effector, 2,3-DPG. On the other hand, the adducts with reversible protection of Cys-93(β) exhibit a small but noticeable sensitivity to 2,3-DPG.

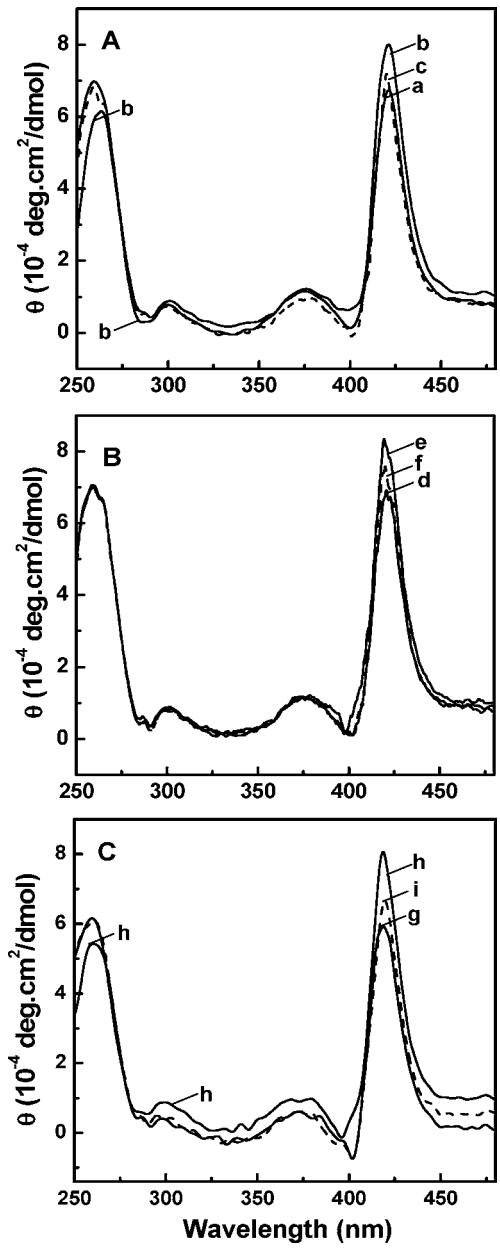

Figure 7. Circular dichroism spectra of the PEG-Hb (A), the NEM modified thiolated Hb (B), and the PEG-αα-Hb (C). Circular dichroic spectra of HbA (a), the PEG-Hb (b), the PEG-Hb with free Cys-93(β) (c), HbA (d), the NEM modified thiolated Hb (e), the NEM modified thiolated Hb with free Cys-93(β) (f), αα-Hb (g), the PEG-αα-Hb (h), and the PEG-αα-Hb with free Cys-93(β) (i). The Hb samples were recorded at 25 °C with a 0.2 cm light path cuvette (310 μL).

Autoxidation and Heme Loss of the PEG-Hbs. The autoxidation rate of PEG-Hb is an integrated result of the maleimide modification of the thiolated Hb and the conjugated PEG chains (*16*). Therefore, the NEM modified thiolated Hb was used as a control to investigate the autoxidation and the heme loss of the PEG-Hb.

Autoxidation of the PEG-Hb in PBS Buffer. As shown in Table 3, the autoxidation rate constant (k_{ox}) of HbA increased upon NEM modification and further increased upon conjugation of the PEG chains. The k_{ox} of the hexaPEG-Hb is marginally higher than that of the diPEG-Hb site-specifically modified at Cys-93(β) (*16*). The k_{ox} for the PEG-Hb and the NEM modified Hb decreased significantly upon reversible protection of Cys-93(β). Accordingly, PEGylation of Cys-93(β) makes a significant contribution to increasing the autoxidation of the PEG-Hb.

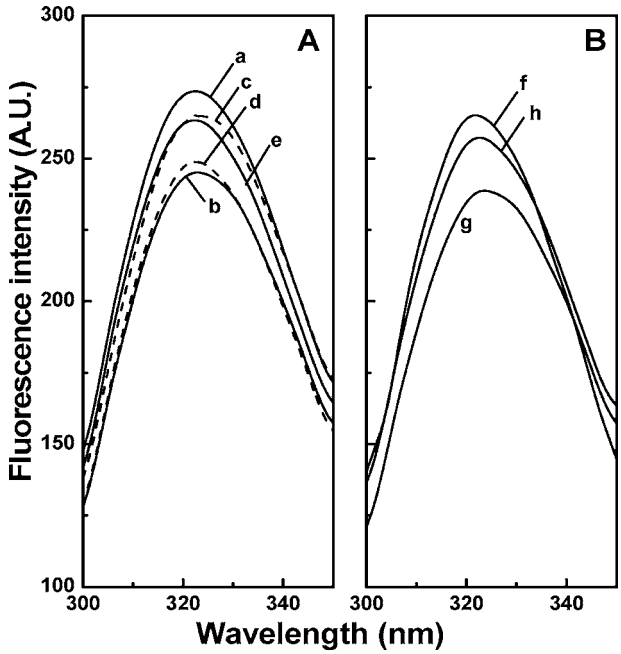

Figure 8. Intrinsic fluorescence emission spectra of the PEG-Hbs. (a) Hb; (b) the PEG-Hb without free Cys-93(β); (c) the PEG-Hb with free Cys-93(β); (d) the NEM modified Hb without free Cys-93(β); (e) the NEM modified Hb with free Cys-93(β); (f) αα-Hb; (g) the PEG-αα-Hb without free Cys-93(β); (h) the PEG-αα-Hb with free Cys-93(β). The excitation wavelength for the fluorescence emission was 280 nm. The measurements were performed using a Shimadzu spectrofluorimeter at room temperature at Hb concentration of 6.0 mg/mL in PBS, pH 7.4.

Table 2. Functional Properties of the PEG-Hbs[a]

sample	P_{50} (mmHg)/n	
	no effector	2.5 mM DPG
HbA	14.4/2.8	22.0/2.6
EAF-PEG-Hb without free Cys-93(β)	6.9/2.1	7.0/2.2
EAF-PEG-Hb with free Cys-93(β)	8.5/2.0	11.6/1.7
EAF-NEM-Hb without free Cys-93(β)	7.0/2.0	7.3/2.0
EAF-NEM-Hb with free Cys-93(β)	8.5/2.1	10.0/1.9
αα-Hb	30.5/2.4	36.4/2.0
EAF-PEG-αα-Hb without free Cys-93(β)	9.9/1.7	10.5/1.7
EAF-PEG-αα-Hb with free Cys-93(β)	18.5/1.7	21.5/1.5

[a] Oxygen equilibrium curves of the samples were measured at 37 °C in PBS (pH 7.4) at Hb tetramer concentration of 0.5 mM. The Hill coefficient is given in the parentheses. P_{50} is the partial oxygen pressure at 50% saturation and is expressed in mmHg on the left of the Hill coefficient.

Table 3. Autoxidation of the PEG-Hb at 37 °C[a]

sample	k_{ox} (h^{-1})
HbA	0.012
$(SP\text{-}PEG5K)_2$-Hb[b]	0.027
EAF-PEG-Hb without free Cys-93(β)	0.036

$(SP\text{-}PEG5K)_2$-αα-Hb[b]	0.036
EAF-PEG-αα-Hb without free Cys-93(β)	0.064
EAF-PEG-αα-Hb with free Cys-93(β)	0.042

[a] Fast heme loss rate constant. [b] Data obtained from Hu et al. (*16*).

constant (k_{fast}) of Hb (Table 4) increased significantly upon EAF PEGylation. Reversible protection of Cys-93(β) significantly decreased the heme loss rate and the k_{fast} of the PEG-Hb. Accordingly, PEGylation of Cys-93(β) significantly increased the heme loss of the PEG-Hb. Moreover, the NEM modified Hb showed a slightly higher heme loss rate and k_{fast} than its corresponding PEG-Hb. Therefore, the conjugated PEG chains can increase the heme stability of the PEG-Hb.

Autoxidation of the PEG-Hb in the Plasma. The PEG-Hb (40 mg/mL) is mixed with the plasma at equal volume to mimic the *in vivo* 50% exchange transfusion. As seen earlier with PEG-Hb (*16*), k_{ox} of the PEG-Hb is attenuated in the plasma as compared to that in PBS buffer (Table 5). The reversible

protection of Cys-93(β) further reduces the k_{ox} of the EAF-PEG-Hb in the plasma.

Design of the Second-Generation EAF-PEG-Hb, the EAF-PEG-αα-Hb. *Characterization of the EAF-PEG-αα-Hb with Reversible Protection of Cys-93(β).* The PEG-αα-Hb (curve h, Figure 2B) shows a higher hydrodynamic volume than αα-Hb (curve f). Besides, the PEG-αα-Hb shows a more symmetrical elution pattern than the PEG-Hb (curve c). The EAF PEGylated bis-thiopridyl αα-Hb (curve i) exhibits a slightly smaller hydrodynamic volume than the PEG-αα-Hb (curve h) and no essential change upon releasing the thiopyridyl groups from Cys-93(β) (curve j).

RP-HPLC patterns of the EAF-PEG-αα-Hb are presented in Figure 3B. The α-globin of Hb was right-shifted upon αα-fumaryl cross-link (curve e). The EAF-PEG-αα-Hb (curve f) has essentially no unmodified β-globin and small amount of αα-globin, along with the presence of mono-, di-, and tri-PEGylated globins. For the PEGylated bisthiopyridyl αα-Hb, the unPEGylated β-globin increased with the peak left-shifted, whereas the αα-globin decreased (curve g). Upon releasing the thiopyridyl moiety from Cys-93(β), the peak corresponding to the unPEGylated β-globin is right-shifted (curve h).

SDS-PAGE pattern of αα-Hb shows a new band with an apparent molecular weight of 32 kDa (lane 5, Figure 4). Some smaller additional bands are observed, possibly due to the presence of a small amount of impurity that is not well-separated from αα-Hb. It may be noted that the sample was not heated at 60 °C after chromatographic purification as done by Baxter to increase the purity of the αα-Hb. EAF PEGylation of αα-Hb generated several new bands (about six to eight) (lane 6). Reversible protection of Cys-93(β) did not essentially alter the pattern of the EAF-PEG-αα-Hb (lane 7), except for the intensity of the mono- and diPEGylated β-globin.

The molecular radius of the EAF-PEG-αα-Hb is slightly higher than that of the EAF-PEG-Hb and further slightly decreased upon reversible protection of Cys-93(β) (Table 1).

Structure of the EAF-PEG-αα-Hb. The reactivity of Cys-93(β) of αα-Hb is lower than that of HbA (Figure 5B). The EAF-PEG-αα-Hb with reversible protection of Cys-93(β) carries two thiols per tetramer (curve f). EAF PEGylation targeted exclusively to the amino groups has little influence on the reactivity of Cys-93(β) of αα-Hb (curve e). The PEG-αα-Hbs generated by reductive alkylation (curve g) and acylation chemistry (curve h) based PEGylation exhibit higher reactivity of Cys-93(β) than αα-Hb and the EAF-PEG-αα-Hb.

The presence of the αα-intramolecular cross-link slightly lowers the ellipticity of Hb in the Soret CD region (Figure 7C). EAF PEGylation of αα-Hb increases its ellipticity in the Soret region, reflecting the structural perturbation of the heme pocket upon PEGylation. However, reversible protection of Cys-93(β) can reduce this structural perturbation of the EAF-PEG-αα-Hb. The fluorescence studies (Figure 8B) further confirm that reversible protection of Cys-93(β) could stabilize the quaternary structure of the EAF-PEG-αα-Hb.

Autoxidation, Heme Loss, and Oxygen Affinity of the EAF-PEG-αα-Hb. Both αα-intramolecular cross-linking and EAF PEGylation significantly influence the k_{ox} of Hb (Table 3). When the two modifications are introduced into Hb simultaneously, the increase in k_{ox} is not additive. Presumably, the PEGylation induced increase in the k_{ox} of Hb is partly due to the destabilization of Hb tetramers. However, this destabilization is counteracted by the αα-intramolecular cross-link. On the other hand, the reversible protection of Cys-93(β) reduces the k_{ox} of the EAF-PEG-αα-Hb. The presence of αα-fumaryl cross-link in Hb and the PEG-Hb reduces the k_{fast} by 53% and 60%, respectively (Table 4). Reversible protection of Cys-93(β) further increases the heme stability of the EAF-PEG-αα-Hb (Figure 9B and Table 4).

The EAF-PEG-αα-Hb shows lower oxygen affinity than the EAF-PEG-Hb (Table 2). The oxygen affinity of the EAF-PEG-αα-Hb exhibits little sensitivity to the presence of 2,3-DPG. In contrast, it shows some sensitivity to the presence of 2,3-DPG upon protection of Cys-93(β). Thus, the quaternary structural features of Hb are conserved better in the EAF-PEG-αα-Hb upon protection of Cys-93(β). The high O_2 affinity of the EAF-PEG-Hb comes from the site-specific PEGylation of Cys-93(β) and EAF PEGylation of the amino groups. Introduction of αα-fumaryl cross-bridge and protection of Cys-93(β) could partially lower the O_2 affinity of the EAF-PEG-Hb.

DISCUSSION

EAF PEGylation of Hb was developed to simplify the surface decoration of Hb with the PEG chains and develop a non-vasoactive Hb derivative (*9*). This new PEGylation platform is a cost-effective protocol as exemplified in the development of MP4 by Sangart (*31*). Subsequent studies have established that the extension arm sandwiched between the amino groups and the PEG chains affords a unique structural advantage with Hb over the direct PEGylation platforms. EAF PEGylation has little impact on the tetramer stability of the PEG-Hb. In contrast, direct PEGylation destabilizes the quaternary structure of the PEG-Hb. We have now generated the hexaPEG-Hbs using the four PEGylation platforms, namely, EAF PEGylation (*9*), reductive alkylation (*26*), active ester chemistry (*27*), and thiocarbamoylation chemistry based PEGylation (*32*). The hexaPEG-Hbs generated by direct PEGylation exist essentially as Hb dimers (*26, 27*). On the other hand, the EAF-PEG-Hb is present predominantly as tetrameric species (Figure 5). The preclinical and clinical studies of MP4 have established that it does not induce any undesirable toxicity (*31*). Accordingly, the absence of toxicity in MP4 and the reported toxicity in Enzon PEG-bovine-Hb implicated by Baldwin et al. (*33*) may be related to the anticipated low tetramer stability of the Enzon product.

Recently, Kluger and his associates (*34*) have shown that EAF PEGylation increased the nitrite reductase activity of Hb, predominantly due to PEGylation of Cys-93(β). They suggested that this activity is responsible for the vasoinactivity of the PEG-Hb. Accordingly, avoiding PEGylation of Cys-93(β) may result in the vasoactivity of PEG-Hb. However, Cys-93(β) is free in the vasoinactive PEG-bovine-Hb (Enzon product) that was prepared using acylation chemistry based PEGylation. Besides, the Euro PEG-Hb, a product prepared using EAF PEGylation under deoxy condition to avoid PEGylation of Cys-93(β), was also vasoinactive (*35, 36*). Thus, the vasoinactivity of the PEG-Hb does not correlate to the presence of PEGylation of Cys-93(β).

Avoiding PEGylation of Cys-93(β) has a limited influence on the oxygen affinity of the EAF-PEG-Hb. This further confirms that the high oxygen affinity of the EAF-PEG-Hb is an intrinsic consequence of PEGylation and not a direct result of PEGylation of Cys-93(β). The same conclusion has been

drawn previously based on EAF PEGylation of rHb[Cys-93(β)→Ala] (*10*). We have also carried out the EAF PEGylation of bis thiopyridyl Hb under deoxy condition, isolated the PEGylated product, and released the thiopyridyl moiety. This EAF-PEG-Hb prepared under deoxy conditions exhibited an O_2 affinity comparable to the product generated under oxy condition.

The site selectivity of $(SP\text{-}PEG5K)_6$-Hb (*9*), MP4 (*37*), and Euro PEG-Hb (*36*) has been compared in Table 6. This confirms that EAF PEGylation of the amino groups is not quantitative except for PEGylation of Cys-93(β) in $(SP\text{-}PEG5K)_6$-Hb and MP4. Even though Euro PEG-Hb was generated under deoxy conditions, the pattern of PEGylation is generally comparable to those of $(SP\text{-}PEG5K)_6$-Hb and MP4. Moreover, Lys-40(α) is modified under the oxy condition, but not under the deoxy condition. Thus, PEGylation of Lys-40(α) may marginally influence the oxygen affinity of Hb. In addition, the amino groups of Hb accessible for EAF PEGylation are overlapping irrespective of the oxy or deoxy conditions used for PEGylation. Accordingly, we speculate that the hydrated PEG shell of the EAF-PEG-Hb with free Cys-93(β) leads to a preferential stabilization of the R state over the T state of Hb. This is the primary molecular aspect that increases the O_2 affinity of Hb on PEGylation. The site-specific PEGylation of Cys-93(β) increases the O_2 affinity of Hb (*15*), predominantly due to maleimide modification of Cys-93(β). These two molecular aspects are not additive and appear to significantly overlap each other.

The high O_2 affinity of MP4 is considered a desirable feature for HBOC, in terms of achieving a targeted O_2 delivery to the hypoxic areas and reducing the vasoactivity with the autoregulatory mechanism. Our present data establish that the reversible protection of Cys-93(β) of un-cross-linked Hb does not significantly decrease the oxygen affinity of the PEG-Hb (Table 2). Accordingly, design of new versions of MP4 with free Cys-93(β) essentially does not have an impact on the concepts of the new paradigms for the design of the HBOCs. This will provide an opportunity to evaluate the potential merits of avoiding PEGylation of Cys-93(β) in terms of the efficacy of the EAF-PEG-Hb. Besides, the new version of the EAF-PEG-Hbs with free thiols may also have an impact on counteracting the reperfusion injury during transfusion.

The optimum level of O_2 affinity of a PEG-Hb to achieve adequate tissue oxygenation without activating the autoregulatory principles has been the subject of intense study in recent years (*17, 35, 38, 39*). The Ajinomoto PEG-Hb (PHP) exhibits an O_2 affinity lower than that of unmodified Hb. However, the vasoinactivity of PHP is not comparable to that seen with Enzon PEG-bovine-Hb (*40*). The PEG-Hb with an oxygen affinity close to that of unmodified Hb (P50 around 15 mmHg) is being considered as a better choice for achieving adequate tissue oxygenation. The O_2 affinity of the PEG-$\alpha\alpha$-Hb with free Cys-93(β) is higher than that of $\alpha\alpha$-Hb but slightly lower than that of HbA. EAF PEGylation of $\alpha\alpha$-Hb is less efficient in increasing the O_2 affinity of $\alpha\alpha$-Hb. Presumably, the low oxygen affinity of $\alpha\alpha$-Hb is partially counteracted by the PEG shell to stabilize the oxy state of Hb.

The $\alpha\alpha$-Hb has been PEGylated by us using three PEGylation platforms, reductive alkylation chemistry, acylation chemistry, and the present modified EAF PEGylation. Comparison of the reactivity of Cys-93(β) suggests that the oxy conformation of Hb is stabilized to a maximum level by the propyl-PEG chains of $(Propyl\text{-}PEG5K)_6$-Hb, whereas to a minimal level by the EAF PEGylation. In the reductive alkylation based PEGylation, four of the six PEG chains are targeted to the four α-amino groups of Hb, while in the other two protocols, the PEG chains are targeted exclusively to the ε-amino groups. PEGylation on the α-amino groups is most effective in stabilizing the oxy conformation, while PEGylation of ε-amino by propionyl PEG chains reduces this propensity of the PEG shell. The oxygen affinity of the three PEG-$\alpha\alpha$-Hbs can reflect the stabilization of the oxy conformation by the PEG chains and correlates well with the reactivity of Cys-93(β). Engineering the extension arm between the ε-amino groups and the PEG chains further reduces this efficiency of the PEG shell to stabilize the R state of Hb.

Many intramolecularly cross-linked and/or oligomerized Hbs have been designed as potential HBOC. However, their application as oxygen therapeutics has been impeded due to their vasoactivity and/or autoxidation mediated toxicities. PEGylation of Hb has emerged as a new chemical approach to overcome the vasoactivity of acellular Hb. EAF PEGylation is a new cost-effective approach to neutralize their vasoactivity. Reversible protection of Cys-93(β) during EAF PEGylation has many beneficial effects on the EAF-PEG-Hbs. In the present study, EAF PEGylation of $\alpha\alpha$-Hb has been investigated as a second generation of the EAF-PEG-Hb with lower oxygen affinity. This modified EAF PEGylation approach is expected to integrate the structural and functional advantages of avoiding the PEGylation of Cys-93(β). On the other hand, it is expected to conserve the potential of PEGylation to neutralize the vasoactivity of Hb and have minimal perturbation of the quaternary structural aspects of Hb.

Efficient Site-Specific Radiolabeling of a Modified C2A Domain of Synaptotagmin I with $[^{99m}Tc(CO)_3]^+$: A New Radiopharmaceutical for Imaging Cell Death

Richard Tavaré, Rafael Torres Martin De Rosales, Philip J. Blower, and Gregory E. D. Mullen*

Division of Imaging Sciences, King's College London, St. Thomas' Hospital, London, SE1 7EH, United Kingdom. Received April 23, 2009; Revised Manuscript Received September 22, 2009

We describe the design and synthesis of a new Tc-99m labeled bioconjugate for cell-death imaging, based on C2A, the phosphatidylserine (PS)-binding domain of rat synaptotagmin I. Since several lysine residues in this protein are critical for PS binding, we engineered a new protein, C2AcH, to include the C-terminal sequence CKLAAALEHHHHHH, incorporating a free cysteine (for site-specific covalent modification) and a hexahistidine tag (for site-specific radiolabeling with $[^{99m}Tc(CO)_3(OH_2)_3]^+$). We also engineered a second derivative, C2Ac, in which the C-terminal sequence included only the C-terminal cysteine. These proteins were characterized by electrospray mass spectrometry, SDS/PAGE, and size exclusion chromatography and radiolabeled with $[^{99m}Tc(CO)_3(OH_2)_3]^+$. Conjugates of the proteins with the rhenium analogue $[Re(CO)_3(OH_2)_3]^+$ were also synthesized. Site-specific labeling was confirmed by performing a tryptic digest of rhenium tricarbonyl-labeled C2AcH, and only peptides containing the His-tag contained the $[Re(CO)_3]^+$. The labeled proteins were tested for binding to red blood cells (RBC) with exposed PS in a calcium dependent manner. Labeling 100 μg of C2AcH with $[^{99m}Tc(CO)_3(OH_2)_3]^+$ at 37 °C for 30 min gave a radiochemical yield of >96%. However, C2AcH that had first been conjugated with fluorescein maleimide or iodoacetamide via the Cys residue gave only 50% and 83% radiochemical yield, respectively, after incubation for 30 min at 37 °C. Serum stability results indicated that >95% of radiolabeled C2AcH remained stable for at least 18 h at 37 °C. Site-specifically labeled C2AcH exhibited calcium-dependent binding to the PS on the RBC, whereas a nonspecifically modified derivative, C2AcH-B, in which lysines had been modified with benzyloxycarbonyloxy, did not. We conclude that (i) the combination of Cys and a His-tag greatly enhances the rate and efficiency of labeling with $[^{99m}Tc(CO)_3(OH_2)_3]^+$ compared to either the His-tag or the Cys alone, and this sequence deserves further evaluation as a radiolabeling tag; (ii) non-site-specific modification of C2A via lysine residues impairs target binding affinity; (iii) ^{99m}Tc-C2AcH has excellent radiolabeling, stability and PS binding characteristics and warrants *in vivo* evaluation as a cell-death imaging agent.

INTRODUCTION

Apoptosis is an energy-dependent, genetically controlled process by which cell death is activated through an internally regulated suicide program (*1*). It results in the exposure of specific components of the inner leaflet of the plasma membrane, such as phosphatidylserine (PS), on the surface of the cell. In contrast to necrotic cell death, which occurs following exposure to high concentrations of endogenous or exogenous toxins, heat treatment, freeze−thawing, or other immediately disruptive insults, apoptosis tends to occur during less intense, chronic tissue insult. The ability to investigate and image apoptosis/necrosis, or "cell death", noninvasively in diseases such as cancer, heart disease, or immune rejection, is an important goal in monitoring response to treatment or assessment of tissue injury, and may also be of value in acquiring a deeper understanding of the pathophysiology of disease. In particular, the use of imaging techniques such as single photon emission computed tomography (SPECT) and positron emission tomography (PET) is assuming an important role in cell death imaging (*2*).

A common method of detecting externalized PS is the use of PS-binding proteins such as Annexin V or the C2A domain of synaptotagmin I. These are amphipathic molecules that bind to PS in a Ca^{2+}-dependent manner (*3, 4*). Neither Annexin V nor C2A can discriminate between PS on the outer or inner leaflet of lysed cells, and hence, neither can distinguish between apoptosis and necrosis (*5, 6*). Nevertheless, using a variety of radiolabeling strategies, labeled Annexin V and C2A have been evaluated in several preclinical cell death imaging studies, and Annexin V has also progressed to several clinical trials (*7*).

When radiolabeling small proteins such as these, it is often important to exert maximum control over the number and site of modifications to the molecule. This is starkly illustrated by the example of In-111-DTPA-N-TIMP-2, a radiolabeled recombinant protein designed for imaging of matrix metalloprotein (MMP) expression. The attachment of the first DTPA occurred at a single location and was accompanied by full retention of MMP binding; whereas attachment of a second led to complete loss of function (*8*). In the case of Annexin V, Tait et al. elegantly showed that nonspecific "amine-directed" labeling of Annexin V led to reduction or abolition of PS affinity and poor *in vivo* performance (*9*). Until recently, nearly all molecular imaging studies with Annexin V and C2A had been done using amine-reactive bifunctional agents (*10, 11*). In most cases, the extent and statistical distribution of modification have not been measured, and it has not been quantitatively demonstrated that the bioconjugates retain full bioactivity compared with unmodified protein. In cases such as these, the detrimental effects are compounded because the lowest affinity (most heavily modified)

protein molecules carry a disproportionately high radiolabel signal. The biodistributions of Annexin V derivatives were improved to some extent by refining the non-site-specific labeling methods, leading eventually to ^{99m}Tc-HYNIC-Annexin V (*12*).

Like Annexin V, C2A (~16 kDa) is vulnerable to inactivation by inappropriate modification. The Ca^{2+} binding sites within C2A-domain are surrounded by positively charged amino acids, among them several Lys residues, that were shown by mutagenesis to also be involved in phospholipid binding (*13, 14*). Since Lys residues are the usual site of modification for radiolabeling, great caution in bioconjugate synthesis and careful characterization of the products are required. C2A was first used as an MR cancer imaging agent in the form of a glutathione-S-transferase (GST) fusion protein which forms a noncovalent dimer of ~85 kDa. The GST-C2A protein was nonspecifically modified and covalently linked via Lys residues to either superparamagnetic iron oxide particles or the gadolinium complex of *S*-2-(4-isothiocyanatobenzyl)-DTPA (*p*-SCN-Bn-DTPA) (*15, 16*). This nonspecific labeling method resulted in a decreased affinity for PS (*17*). For SPECT imaging, ^{99m}Tc-labeled GST-C2A has been used in preclinical cardiac and cancer applications (*18, 19*). In these studies too, a non-site-specific method was employed: the fusion protein GST-C2A was treated with 2-iminothiolane to modify GST-C2A Lys amines to thiols then labeled with ^{99m}Tc-glucoheptonate.

Given these problems, producing recombinant protein conjugates to current good manufacturing practice (cGMP) standards with consistent batch-to-batch quality using non-site-specific modification for clinical imaging is problematic. Removal of any inactive or low-affinity protein prior to injection, if achievable at all, requires additional affinity chromatography purification steps (*16*). A cGMP cell death imaging agent developed for clinical application should be labeled site-specifically, reproducibly, efficiently, and at room temperature. Preferably, it should be a simple kit-based method providing a well-characterized, homogeneous, fully functional and stable product. Tait et al. approached this objective by genetically engineering a derivative with an N-terminal amino acid AG-GCGH tag, which can be labeled with ^{99m}Tc (*12, 20*). Others have recently genetically engineered a free Cys for the site-specific modification and radiolabeling of Annexin V (*21*). However, no derivative of C2A for site-specific labeling has yet been reported.

With this in mind, we have genetically engineered and recombinantly expressed C2A with a C-terminal domain designed for site-specific modification with maximum versatility, incorporating both a HexaHistidine tag (His-tag) and an additional cysteine residue. Here, the term site-specific refers to the ability to radiolabel a radiopharmaceutical via His-tag without interfering with its function. The His-tag can be used not only for immobilized metal affinity chromatography (IMAC) purification, but also in principle for site-specifically labeling with ^{99m}Tc using $[^{99m}Tc(CO)_3(OH_2)_3]^+$ (*22*), while the Cys can be used for site-specific covalent modification with prosthetic groups for optical or radiolabeling. The His-tag is nonimmunogenic and does not hinder the clinical development of His-tag -containing recombinant proteins (*23*−*27*). We have also engineered C2A with a single C-terminal Cys residue but no His-tag. This strategy should facilitate concomitant fluorescent histological evaluation of a SPECT signal for preclinical validation (see Scheme 1). In this paper, we report the use of this strategy to develop a site-specifically radiolabeled radiopharmaceutical for the imaging of cell death. We describe the labeling and modification properties of the new appended C-terminal amino acid sequence and the effect of modification on PS binding.

EXPERIMENTAL PROCEDURES

Molecular Biology. The pET-29b vector containing amino acid residues 140−267 of rat Synaptotagmin I, the C2A domain, (provided by Bazbek Davletov, University of Cambridge, UK) was used as a template for the polymerase chain reaction (PCR) and subsequent subcloning to create two variants, both without the inherent S-Tag domain in the vector: C2Ac (C2A with a single cysteine residue on the C-terminus) and C2AcH (C2A with a single cysteine residue on the C-terminus, a linker (KLAAALE), and a hexahistidine tag). The two constructs used the same forward primer: 5′-CAC ACA CAT ATG GAG AAA CTG GGA AAG CTC CAA with the reverse primer for C2Ac: 5′-CAC ACA AAG CTT TCA GCA TTT CTC AGC GCT CTG GAG ATC GCG and for C2AcH: 5′-CAC ACA AAG CTT GCA TTT CTC AGC GCT CTG GAG ATC GCG. The resulting PCR fragments were subcloned back into the pET-29b vector using the restriction enzymes NdeI and *Hin*dIII and sequenced (King's College London, Molecular Biology Unit, UK). After sequence confirmation, DNA constructs for C2Ac and C2AcH were transformed into the BL21 (DE3) strain of *Escherichia coli*. For both constructs, cultures in 10 mL of L-broth containing 50 μg/mL kanamycin (Sigma, Gillingham, UK) were grown overnight at 37 °C with agitation, and then added to 1000 mL L-Broth and grown at 37 °C with agitation until the OD_{600} reached 0.8. Expression was then induced by adding 1 mM isopropyl β-D-1-thiogalactopyranoside (IPTG) (Merck Chemicals, Nottingham, UK) followed by further

incubation at 37 °C with agitation for 4 h. Cells were then pelleted by centrifugation at 4100 relative centrifugal force (RCF) for 10 min at 4 °C and then frozen at −80 °C. Pellets were resuspended in 50 mL resuspension buffer (RB, 20 mM Tris-HCl pH 7.5, 150 mM NaCl, 1 mM EDTA, 0.1% Triton X-100, and Complete Protease Inhibitors (Roche Diagnostic, Burgess Hill, UK)). Suspensions were then sonicated four times for 15 s with 1 min intervals on ice and allowed to recover for 30 min on ice. The suspension was then centrifuged at 4 °C for 20 min at 35 000 RCF. For C2AcH purification, the supernatant was added to a 1 mL nickel column (GE Healthcare, Amersham, UK) at 1 mL/min using an AKTA FPLC (GE Healthcare, Amersham, UK), which had previously been equilibrated with nickel binding buffer (NBB, 20 mM Tris-HCl pH 7.5, 150 mM NaCl). The column was then flushed with 10 column volumes (CV) of NBB and washed with 20 CV of nickel wash buffer (NWB, 20 mM Tris-HCl pH 7.5, 150 mM NaCl, 50 mM imidazole). The protein was then eluted with 20 CV of nickel elution buffer (NEB, 20 mM Tris-HCl pH 7.5, 150 mM NaCl, 500 mM imidazole). Elution fractions containing protein were dialyzed overnight against 3 L NBB using a 7 kDa molecular weight cutoff dialysis tubing at 4 °C with gentle stirring. Four millimolar $CaCl_2$ was then added to dialyzed protein before addition to a 5 mL Heparin Column (GE Healthcare, Amersham, UK), which had previously been equilibrated with Heparin Binding Buffer (HBB, 20 mM Tris-HCl, 150 mM NaCl, 2 mM $CaCl_2$, pH 7.5) at 1 mL/min. The column was washed with 10 CV of HBB, and the protein was then eluted with 10 CV of Heparin Elution Buffer (HEB, 20 mM Tris-HCl, 200 mM NaCl, 10 mM EDTA, pH 7.5). To elute any dimer that may have formed, the column was eluted with 10 CV of Heparin Clean Buffer (HCB, 20 mM Tris-HCl, 1.5 M NaCl, 100 mM EDTA, pH 7.5). Any dimer present in this eluate was reduced with 10 mM dithiothreitol (DTT) for 4 h at RT and then loaded on a Sephacryl 100 size exclusion column (60 cm height, GE Healthcare, Amersham, UK) equilibrated with PBS such that the load volume did not exceed 5% of a column volume. C2Ac was purified using the heparin procedure and the elution pool was loaded on a Sephacryl 100 size-exclusion column as described above. The gel permeation elution peak was collected and the concentration was determined by absorbance at 280 nm using a calculated extinction coefficient of 12 210 M^{-1} cm^{-1}. Purified proteins were analyzed by SDS-PAGE, analytical HPLC-SEC, and LC-MS (University of Kent, UK). C2AcH was purified at 20 mg per liter culture and C2Ac was purified at 40 mg per liter culture.

Fluorescein-5-maleimide, *N*-(benzyloxycarbonyloxy) Succinimide and Iodoacetamide Conjugates of C2Ac and C2AcH. C2Ac and C2AcH were conjugated to fluorescein-5-maleimide (Sigma-Aldrich, Poole, UK). One millilitre of C2AcH or C2Ac (2 mg/mL in PBS) were mixed with a 5-fold molar excess of fluorescein-5-maleimide dissolved in 50 μL of dimethylsulfoxide (DMSO) and incubated at room temperature for 4 h. Unreacted fluorescein-5-maleimide was removed using a PD-10 column which had been pre-equilibrated with PBS. PD-10 fractions were monitored by UV absorbance at 280 nm and analyzed by SDS-PAGE and LC-MS. The fluorescein conjugates of C2Ac and C2AcH are referred to as C2Ac-F and C2AcH-F, respectively.

To generate a non-Cys-like "mutant", the thiol was modified with iodoacetamide. C2AcH was incubated at 2 mg/mL with a 1.5 molar excess of iodoacetamide (Sigma-Aldrich, Poole, UK) overnight at 4 °C. Unreacted iodoacetamide was removed using a PD-10 column and protein fractions were analyzed by SDS-PAGE and LC-MS. The iodoacetamide conjugate of C2AcH is referred to as C2AcH-A. The free thiol content of C2AcH and C2AcH-A was determined by Ellman's Reagent as described by the manufacturer (Pierce Biotechnology, Rockford, US) (*28*).

To generate a nonspecifically modified C2A protein for radiolabeling, C2AcH was derivatized with *N*-(benzyloxycarbonyloxy)succinimide (Sigma-Aldrich, Poole, UK) as described above except a 20 to 1 molar ratio of *N*-(benzyloxycarbonyloxy)succinimide to C2AcH was used with incubation for only 1 h, giving rise to C2AcH-B, and samples were analyzed by SDS-PAGE.

Flow Cytometry and Immunofluorescence. J774.2 murine macrophage cell line (ECACC, Porton Down, UK) were grown in DMEM (Invitrogen, UK) supplemented with penicillin (100 units/mL), streptomycin (100 μg/mL), L-glutamate (5 mM), fetal bovine serum (10%, Sigma), sodium pyruvate (1 mM), and HEPES (10 mM). To test the binding capability of C2Ac and C2AcH-F to necrotic and apoptotic cells, the fluorescein conjugates were incubated with control or etoposide (MBL International, Woburn, US) treated (15 μM, overnight at 1×10^6 cells/mL) murine macrophages and compared to Annexin V-FITC (Invitrogen, Vybrant Apoptosis Kit) using a FACS-calibur (Becton, Dickinson, Oxford UK) flow cytometry. Acquisition was performed according to commercial kit instructions.

For confocal microscopy, macrophages were plated at 5×10^5 cells per well in a 6-well cell culture plate on sterile glass coverslips. On day 2, cells were treated overnight with 15 μM etoposide or PBS control. Cells were washed 3 times in PBS and then 3 times in either cell binding buffer (CBB, 10 mM HEPES, 140 mM NaCl, 2 mM $CaCl_2$, pH 7.4) or cell nonbinding buffer (CNBB, 10 mM HEPES, 140 mM NaCl, 10 mM EDTA, pH 7.4). Coverslips were then incubated for 15 min in 200 μL of CBB or CNBB containing 2 μL propidium iodide (PI) and 3 μL of 0.6 μM C2AcH-F, washed 3 times with CBB or CNBB then 3 times in PBS, fixed with 4% paraformaldehyde (PFA) for 10 min at room temperature (RT), and washed a further 3 times in PBS. For immunostaining, cells were permeabilized in 0.1% Triton X-100 in 10% FBS for 10 min at RT. Anti-cleaved caspase-3 antibody (Cell Signaling Technology) was diluted 1:200 in 2% FBS and incubated with cells for 1 h at RT. Coverslips were washed 3 times in PBS and then incubated with Alexa Fluor 546 goat-anti-rabbit (Invitrogen) diluted 1:200 in 2% FBS for 1 h at RT. Coverslips were again washed 3 times in PBS, then 3 times in water before being mounted on a slide with fluorescent mounting medium (Dako). Slides where analyzed by confocal microscopy in the microscope core facility (University College London, UK).

Rhenium Labeling of C2AcH and C2AcH-A. Rhenium tricarbonyl (*fac*-$[Re(CO)_3(OH_2)_3]Br$) was prepared and characterized as previously reported (*29*). Briefly, $[Re(CO)_5]Br$ was refluxed in distilled H_2O for 24 h. The crude mixture was filtered, and the solution concentrated under vacuum to give *fac*-$[Re(CO)_3(OH_2)_3]Br$ as a light green powder in nearly quantitative yield. The final product was characterized by IR and ES-MS. C2AcH or C2AcH-A was labeled with rhenium by incubating 100 μg of C2AcH or C2AcH-A in 100 μL of PBS with a 10-fold molar excess of $[Re(CO)_3(OH_2)_3]Br$. This mixture was left to incubate at 37 °C for 30 min before being passed through a PD-10 column (Sephadex G-25, GE Healthcare). The protein was analyzed by SDS-PAGE and LC-MS.

To investigate whether rhenium tricarbonyl bound to the Cys, C2AcH was incubated with or without $[Re(CO)_3(OH_2)_3]Br$ as described above. After reacting, a 100 μL of PBS pH 8.0 was added to each of the C2AcH solutions and left overnight at 37 °C. The formation of a dimer was monitored by running equal amounts (as determined by A_{280}) of C2AcH with and without $[Re(CO)_3(OH_2)_3]Br$ on a nonreduced SDS/PAGE gel. Monomeric (~16 kDa) and dimeric (~32 kDa) of C2AcH bands were quantified using *ImageJ* analysis software (NIH, Bethesda, US).

In order to map the specific binding of rhenium tricarbonyl to the C-terminal CKLAAALEHHHHHH sequence, a tryptic digest was performed on rhenium tricarbonyl labeled and unlabeled C2AcH using a method previously described (*8*). Briefly, 100 μg of C2AcH in 100 μL was dissolved in 25 μL of 8 M urea and 100 mM ammonium carbonate. The urea was then diluted by the addition of water (75 μL) and modified sequence-grade trypsin (Promega) was added (10 μL of a 0.5 mg/mL solution) and incubated for 4 h at RT. Analysis was by rapid in-line reverse-phase HPLC/electrospray mass spectrometry (University of Kent, UK).

^{99m}Tc Labeling of C2Ac, C2AcH, C2Ac-F, C2AcH-F, C2AcH-A, and C2AcH-B. ^{99m}Tc pertechnetate eluted with saline from a Drytec generator (GE Healthcare, Amersham, UK) was converted to $[^{99m}Tc(CO)_3(OH_2)_3]^+$ using the Isolink kit (generously provided by Covidien, Petten, The Netherlands). Quality control was carried out according to manufacturer's instructions using instant thin layer chromatography (ITLC) and analysis with a gamma-ray TLC scanner (Lablogic, UK) and high-performance liquid chromatography (HPLC series 1200, Agilent, UK) equipped with an in-line gamma detector (Lablogic, UK). C2A proteins were labeled with ^{99m}Tc by incubating 100 μg of C2Ac, C2Ac-F, C2AcH, C2AcH-F, C2AcH-A, or C2AcH-B in 100 μL of PBS with up to 700 MBq of $[^{99m}Tc(CO)_3(OH_2)_3]^+$ in 100 μL. Unless otherwise stated, the labeling of all species was performed at a specific activity of 4 MBq/μg. However, to reproduce a high (clinically relevant) specific activity, C2AcH was also labeled at 7 MBq/μg. This mixture was left to incubate at either 10 or 37 °C for up to 120 min before radiolabeling efficiency was determined by ITLC. The same ITLC conditions were used as described above, and the radiolabeling efficiency was calculated as a ratio of the radiolabeled protein peak integral ($R_f = 0$) to the unincorporated $[^{99m}Tc(CO)_3(OH_2)_3]^+$ peak integral ($R_f = 1.0$). We also determined the labeling efficiency by passing the protein through a PD-10 column (Sephadex G-25, GE Healthcare). Labeling efficiency was calculated by comparing the amount of radioactivity associated with the eluted protein fraction versus unincorporated eluted (low molecular weight) radioactivity using a gamma counter (LKB Wallac, 1282 COMPUGAMMA) or dose calibrator (CRC-25R, Capintec, US). It should be noted that up to ~5% of activity remains bound to the PD-10 column. Binding of radioactivity to protein was also confirmed by SDS-PAGE of the protein fraction followed by electronic autoradiography of the gel (Cyclone phosphorimager, Perkin-Elmer, UK).

Binding of ^{99m}Tc Labeled C2AcH and C2AcH-B to PS on Red Blood Cells. The binding of radiolabeled C2AcH to PS on red blood cells (RBC) was performed according to a literature method (*30*). A commercial preparation of preserved human RBC was obtained from Beckman-Coulter (High Wycombe, UK). Calcium titrations of RBC were performed in a buffer of 50 mM HEPES-sodium, pH 7.4, 100 mM NaCl, 3 mM NaN_3, with 1 mg/mL BSA as carrier protein. Reactions were prepared with 1 nM ^{99m}Tc labeled C2AcH and calcium; RBC were then added, and the reaction (1 mL) was incubated for 8 min at RT. The cells were then centrifuged (3 min at 7500 RCF), the supernatant was removed, and the cells were resuspended in 1 mL assay buffer containing the same concentration of calcium used during the incubation step. The cells were centrifuged again, the supernatant was removed, and the pellet was resuspended in 0.7 mL assay buffer plus 10 mM ethylenediaminetetraacetic acid (EDTA) to release ^{99m}Tc labeled C2AcH bound in a calcium-dependent manner. After centrifugation to remove the RBC, the released ^{99m}Tc labeled C2AcH in the supernatant was measured using a gamma counter. The EC_{50} was calculated as described in the literature using the equation $Y = [Ca]^N/([Ca]^N + EC_{50}{}^N)$ (*30*) where $Y = B/B_{max}$, B is the observed amount of radiolabeled protein bound at a given calcium concentration, and B_{max} is the concentration of radiolabeled protein bound at saturating calcium concentrations. Curve fitting was performed using a nonlinear curve fit by a routine based on the Levenberg−Marquardt algorithm using *Kaleidagraph* (Synergy Software, Reading, US).

Serum Stability. C2AcH and C2AcH-F were labeled with 400 MBq $[^{99m}Tc(CO)_3(OH_2)_3]^+$ in 100 μL for 30 min or 1 h at 37 °C. After purification on a PD-10 column, 100 μL of labeled C2AcH or C2AcH-F was added to 400 μL human serum (Sigma, Poole, UK). As a control, 100 μL of labeled C2AcH or C2AcH-F was also added to PBS. The samples were then incubated at 37 °C. At 0, 3, 6, and 18 h, samples were taken and analyzed by ITLC using a mobile phase of methanol and 1% concentrated HCl. As a control, a separate ITLC of $[^{99m}Tc(CO)_3(OH_2)_3]^+$ and $[TcO_4]^-$ was performed in the same mobile phase. ITLC were then monitored using a radio TLC scanner (LabLogic, UK). Serum stability was calculated as the area under the protein peak ($R_f = 0$) versus the area under the curve of the remainder of the chromatogram $[^{99m}Tc(CO)_3(OH_2)_3]^+$ or $[TcO_4]^-$ $R_f = 1.0$).

RESULTS

Cloning, Preparation, and Characterization of C2Ac, C2AcH, C2AcH-F, C2AcH-A, and C2AcH-B. C2A was cloned into the pET-29d bacterial expression vector with the addition of a C-terminal site-specific Cys with and without a His-tag, forming two constructs C2AcH (with His-tag) and C2Ac (without His-tag), respectively (Scheme 1). After induced expression in *E. coli*, C2Ac and C2AcH were isolated from the soluble fraction. C2AcH was purified first via IMAC and further purified by heparin affinity chromatography in the presence of Ca^{2+}, while C2Ac was purified directly using heparin affinity chromatography. C2Ac and C2AcH were buffer-exchanged and purified by size exclusion chromatography (Figure 1a). C2AcH eluted as a single discrete peak with a retention time expected for a protein of ~16 kDa, with no evidence of significant aggregation or dimerization. C2AcH was analyzed by reduced and nonreduced SDS-PAGE, giving rise to a single monomeric band at the expected molecular weight (Figure 1b). The final protein products were analyzed by electrospray mass spectrometry (ES-MS) and were of the expected molecular weights (Table 1). C2AcH and C2Ac were modified with fluorescein maleimide, iodoacetamide, or *N*-(benzyloxycarbonyloxy)succinimide to give conjugates C2AcH-F, C2AcH-A, and C2AcH-B. These were analyzed by ES-MS. C2AcH-F was of the expected molecular weights for the addition of one fluorescein but also exhibited a second minor peak in the liquid chromatography, which by ES-MS is due to the addition of a second fluorescein molecule. For C2AcH-A, the addition of only one acetamide group, with no unconjugated C2AcH, was observed in the LC-MS (Table 1). The modification at the Cys residue was confirmed by Ellmans' Reagent, which showed no detectable free thiol in C2AcH-A, while the expected amount of free thiol was observed in C2AcH.

On forming C2AcH-B, the benzyloxycarbonyloxy conjugate of C2AcH, a minor fraction of the protein precipitated from solution. The soluble fraction did not give rise to any peaks in ES-MS and was therefore analyzed by nonreducing and reducing SDS/PAGE, giving rise to a single band at a lower molecular weight than C2AcH, indicating that the C2AcH-B had an altered conformation (data not shown).

C2AcH-F Binds to Apoptotic Cells in a Calcium Dependent Manner. The ability of C2AcH-F to bind apoptotic cells was monitored by the incubation of C2AcH-F with live murine macrophages in culture that had been treated with

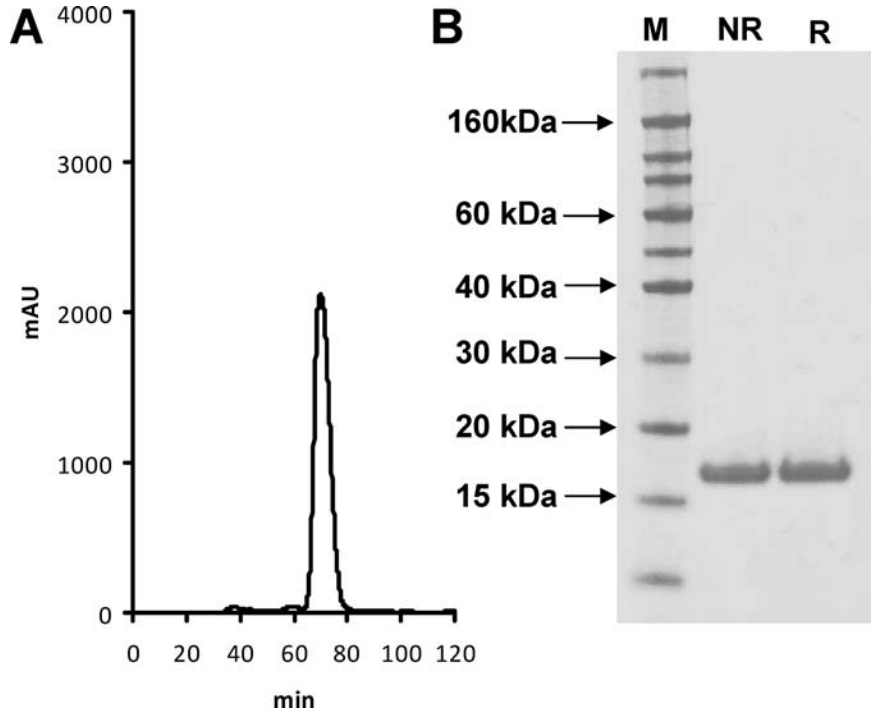

Figure 1. Size exclusion, SDS/PAGE, and ES-MS characterization of C2AcH. (A) After expression and purification by IMAC and heparin affinity chromatography, C2AcH was further purified by preparative size exclusion chromatography. In fast protein liquid chromatography (FPLC) size exclusion chromatogram shown, a discrete single peak with a retention time of 71 min as expected for a globular ~16 kDa protein compared to molecular weight standards (data not shown). (B) The single peak obtained from the preparative size exclusion chromatography was analyzed by reduced (R) and nonreduced (NR) SDS/PAGE electrophoresis. In the SDS/PAGE gel shown, a single band under both the nonreduced and reduced conditions of ~16 kDa was observed as compared to molecular weight markers (M). This indicates that C2AcH exists as a single species and no dimer is present.

Table 1. Summary of ES-MS Data of C2Ac and C2AcH Protein Conjugates and Peptides Post Tryptic Digest

protein (M)/peptide (P)	expected (Da)	found (Da)
C2Ac	14997	14998 $[M + H]^+$
C2AcH	16517	16518 $[M + H]^+$
C2AcH-A	16574	16575 $[M + H]^+$
C2Ac-F	15542	15542 $[M + H]^+$, 15524 $[M - H_2O]^+$; 15869 $[M + 2xF + H_2O]^+$
C2AcH-F	16944	16944 $[M + H]^+$, 16962 $[M + H_2O]^+$ 17389 $[M + 2xF]^+$; 17407 $[M + 2xF + H_2O]^+$
C2AcH-$^{187/185}$Re(CO)$_3$	16787	16787 $[M]^+$
LAAALEHHHHHH	705	705 $[P + 2H]^{2+}$
LAAALEHHHHHH-$^{187/185}$Re(CO)$_3$	840	840 $[P + Re(CO)_3 + H]^{2+}$
CKLAAALEHHHHHH	820	not observed
CKLAAALEHHHHHH-$^{187/185}$Re(CO)$_3$	956	956 $[P + Re(CO)_3 + H]^{2+}$

etoposide (Figure 2). After fixation, permeabilization, and staining with anti-cleaved caspase-3 confocal microscopy confirmed that, in the presence of calcium, C2AcH-F binds to the extracellular membrane of caspase 3 positive cells, while in the absence of calcium, there is no binding of C2AcH-F to the cell membrane. Therefore, after the labeling of C2AcH with fluorescein via the cysteine thiol, it retained its calcium-dependent function. Cells were also analyzed by flow cytometry by incubating live macrophages with C2AcH-F or Annexin V-FITC, and similar results were observed (data not shown).

Labeling of C2Ac, C2AcH, C2Ac-F, C2AcH-F, C2AcH-B, and C2AcH-A with $[^{99m}Tc(CO)_3]^+$ or $[Re(CO)_3]^+$. To compare the labeling efficiency of the proteins with $[M(CO)_3]^+$ (where M = ^{99m}Tc or Re), C2Ac, C2AcH, C2Ac-F, C2AcH-F, and C2AcH-A were labeled by incubating either $[^{99m}Tc(CO)_3(OH_2)_3]^+$ or 10-fold excess of $[Re(CO)_3(OH_2)_3]^+$ with the proteins (100 μg) at 10 or 37 °C for up to 120 min (Scheme 1). Radiolabeled proteins were purified on a PD-10 column and analyzed by SDS/PAGE and autoradiography (Figure 3). A radiochemical yield of >95% (as analyzed by ITLC) was achieved with 1 μg/μL of C2AcH (which possesses both a free Cys and His-tag) at 37 °C within 30 min (Figure 4). The radiochemical purity was 100%. Longer incubation times did not improve the radiochemical yield. However, when a 10-fold lower protein concentration of C2AcH (0.1 μg/μL) was used at 37 °C a radiolabeling yield of only 25% was achieved, which increased over time to reach 98% after 24 h (data not shown). When C2AcH was radiolabeled at the lower temperature of 10 °C for 30 min, radiochemical yields of 65% and 10% were achieved at protein concentrations of 1 and 0.1 μg/μL, respectively. In order to assess the contribution of the free Cys to the excellent radiolabeling efficiency of C2AcH, the Cys thiol was "blocked" using iodoacetamide. At a C2AcH-A concentration of 1 μg/μL, radiochemical yields of only ~83% at 37 °C and ~40% at 10 °C at 30 min were achieved. At a C2AcH-A concentration of 0.1 μg/μg, a radiochemical yield of 16% was achieved at 37 °C, which increased over time to reach 88% after 24 h (data not shown). When C2AcH-A was radiolabeled at the lower temperature of 10 °C for 30 min, radiochemical yields of 40% and 7% were achieved at protein concentrations of 1 and 0.1 μg/μL, respectively. When C2Ac (no His-tag) was radiolabeled, a maximum radiochemical yield did not exceed 15%, and did not improve upon further incubation or increase in temperature (data not shown). When C2AcH and C2AcH-A

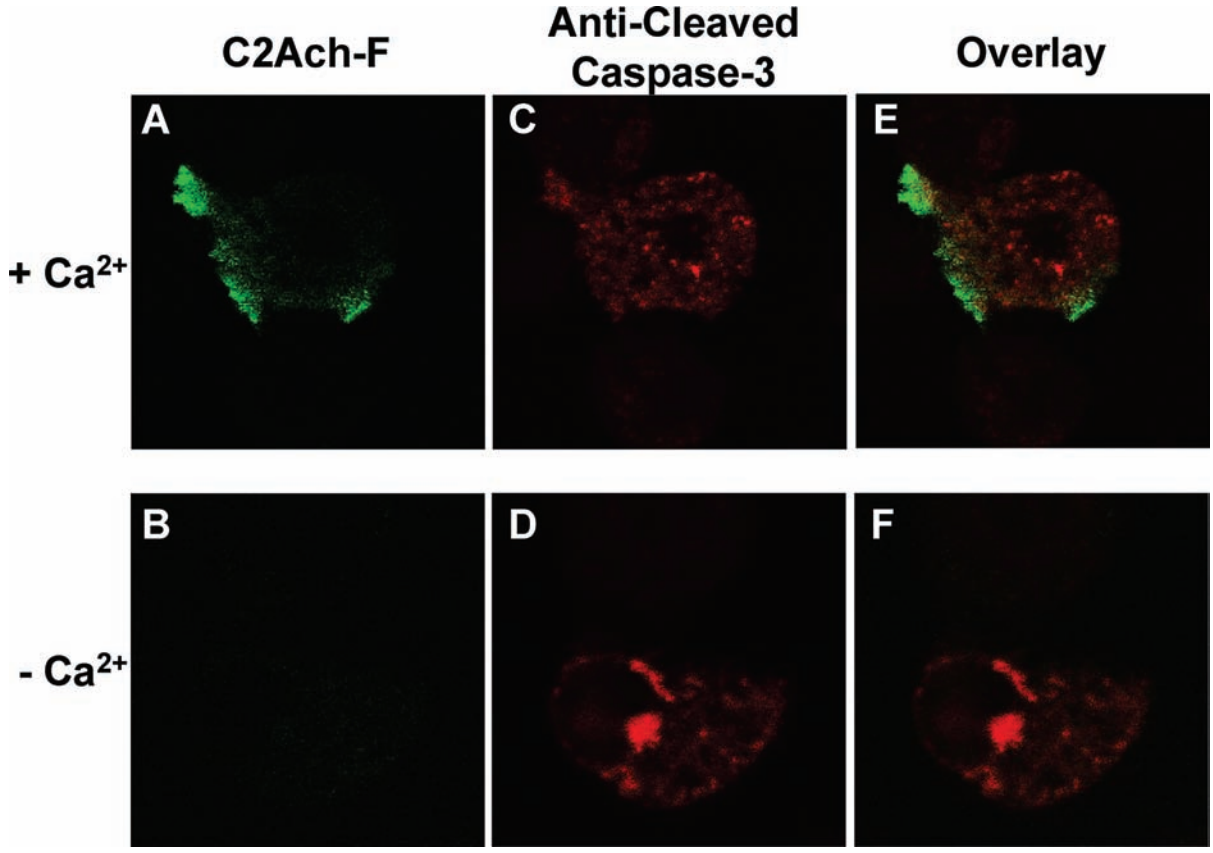

Figure 2. Confocal microscopy of apoptotic mouse macrophages stained with C2AcH-F and/or anti-cleaved caspase-3. C2AcH was site specifically modified at the Cys with fluorescein-maleimide. To show that C2AcH-F was functional and recognized apoptotic cells, C2AcH-F (panels A and B) was incubated with etoposide-treated macrophages in the presence (panels A, C, and E) and absence (panels B, D, and F) of 4 mM calcium. Cells were then permeabilized and stained for a specific intracellular marker of apoptosis, using rabbit anti-cleaved caspase-3 followed by an Alexa Fluor 546 goat-anti-rabbit secondary antibody (panels C and D). The C2acH-F (green) images and anti-cleaved caspase-3 (red) images were overlaid (panels E and F). C2Ac-F and anti-cleaved caspase-3 did not bind to live (non-apoptotic) cells (data not shown).

were radiolabeled at higher and more clinically relevant specific activities (i.e., 7 MBq/μg) at 37 °C for 30 min, radiolabeling efficiencies of 94% and 88%, respectively, were achieved.

Labeling of C2AcH and C2AcH-A with $[Re(CO)_3]^+$ was confirmed by ES-MS showing the correct molecular weight assuming that $[Re(CO)_3]^+$ replaces a proton (Table 1). Despite the presence of a 10-fold excess of $[Re(CO)_3(OH_2)_3]^+$ over protein, no evidence of proteins with more than one $[Re(CO)_3]^+$ attached to a protein was seen in the ES-MS data, suggesting that only one modification occurs per protein molecule. Furthermore, when a tryptic digest was performed on rhenium tricarbonyl labeled and unlabeled C2AcH, only peptides containing the amino acid sequence CKLAAALEHHHHHH or LAAALEHHHHHH contained only one $[Re(CO)_3]^+$ group (Table 1). The reaction of C2Ac with $[Re(CO)_3]^+$ under these conditions did not give rise to a detectable rhenium conjugate, and only unmodified C2Ac was detected by ES-MS. These results suggest that only the C-terminal domain is modified and that the Cys and His-tag act synergistically to improve significantly the rate and efficiency of labeling with $[^{99m}Tc(CO)_3]^+$ and $[Re(CO)_3]^+$, compared to protein with either the His-tag alone or the Cys alone.

To investigate whether $[Re(CO)_3]^+$ remained bound to the Cys, the dimerization of the protein by aerial oxidation of the Cys thiol group was used as a probe(Figure 5). Unmodified C2AcH undergoes extensive dimerization (approximately 67% of protein) after exposure to air at room temperature at pH 8.0 for 16 h, as detected by nonreducing SDS/PAGE analysis. On the other hand, C2AcH that had been incubated at 37 °C with an 10-fold excess of $[Re(CO)_3(OH_2)_3]^+$ overnight, resulting in a preparation in which only the C2AcH-$Re(CO)_3$ conjugate and no free C2AcH could be detected by ES-MS, dimerization was partially inhibited (30% of protein) but not completely blocked. One explanation of this is that the $Re(CO)_3$ fragment is engaged in binding with the Cys thiolate group, although not irreversibly, such that it can be made available for oxidation over time.

Site-Specifically ^{99m}Tc Labeled C2AcH Binds to Apoptotic Cells in a Calcium Dependent Manner. To determine whether or not radiolabeled C2AcH was still functional after radiolabeling, the protein was incubated with preserved red blood cells at varying concentrations of calcium from 0 to 10 mM (Figure 6). Binding of ^{99m}Tc labeled C2AcH to red blood cells can be detected with as little as 0.25 mM $CaCl_2$ with maximal binding observed at 4 mM $CaCl_2$. After nonlinear curve fitting ($R = 0.9996$), the EC_{50} of labeled C2AcH was calculated to be 0.76 mM of calcium, which is comparable to that observed for Annexin V (*30*), while for C2AcH-F, the EC_{50} was 1.03 mM (determined similarly, data not shown). To determine the comparative effect of non-site-specific lysine modification, C2AcH was incubated with a 20-fold excess of the NHS derivative *N*-(benzyloxycarbonyloxy)succinimide and the resultant modified protein, C2AcH-B, was radiolabeled with ^{99m}Tc tricarbonyl, giving radiochemical purity of >95%, and subjected to the same PS-binding assay. No C2AcH-B calcium dependent binding to cells was observed even at the highest concentration of Ca^{2+} of 10 mM (Figure 6).

Serum Stability of Radiolabeled C2AcH and C2AcH-F. The stabilities of C2AcH-$[^{99m}Tc(CO)_3]$ and C2AcH-F-$[^{99m}Tc(CO)_3]$ during incubation in PBS or serum over 18 h were determined (Table 2) using ITLC with gamma detection.

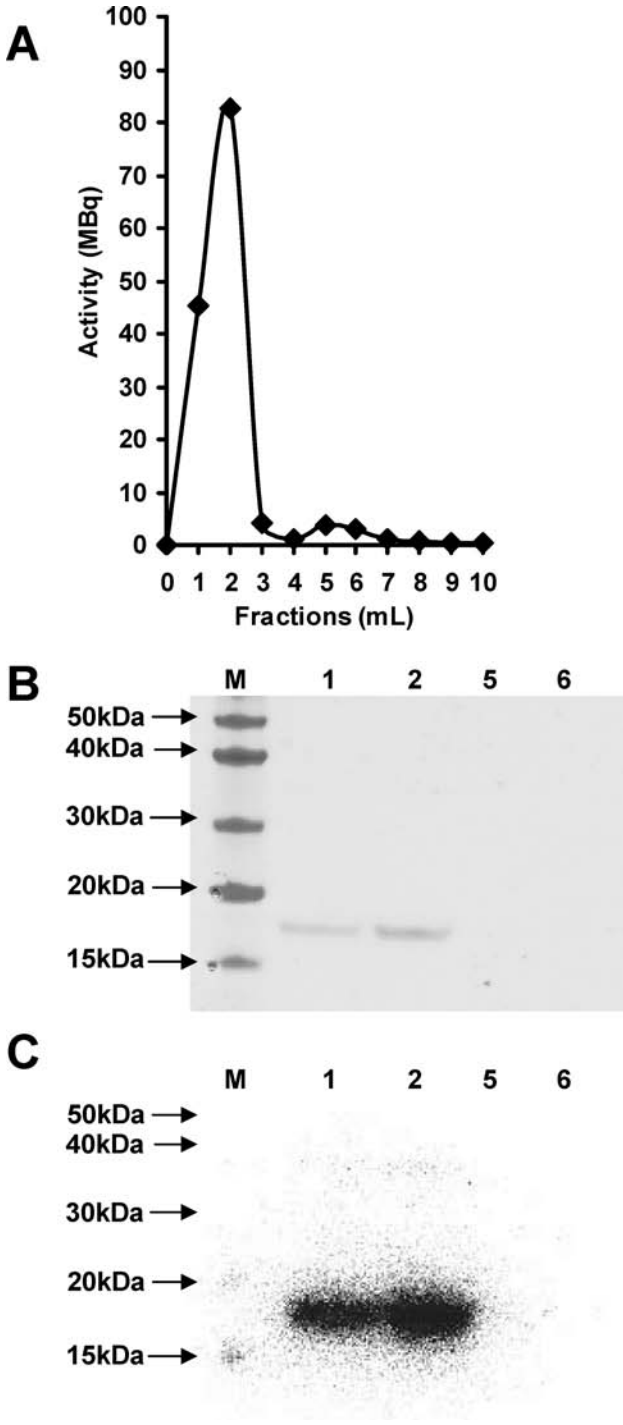

Figure 3. Radiolabeling, size exclusion purification, SDS/PAGE, and phosphor image analysis of C2AcH-[^{99m}Tc(CO)$_3$]. (A) C2AcH was radiolabeled with [^{99m}Tc(CO)$_3$ (OH$_2$)$_3$]$^+$ and purified on a PD 10 size exclusion column to remove any unincorporated radiolabel. In the graph shown, the eluted fractions (1 mL) were collected and the activity (MBq) per fraction was determined. (B) The labeled protein fractions 1 and 2 and unincorporated radiolabel fractions 5 and 6 from the PD-10 size exclusion column were then analyzed by SDS/PAGE electrophoresis under nonreducing conditions with molecular weight markers (M). In the SDS/PAGE gel shown, no activity was observed in lanes corresponding to fraction 5 and 6 presumably because the lower molecular weight radioactive species runs off the gel. (C) ^{99m}Tc radioactive markers were placed at the 15 and 20 kDa molecular weight protein markers on the SDS/PAGE gel and the image shown was acquired using a medium MultiSensitive phosphor screen for 30 s and analyzed using a phosphor imager (PerkinElmer Cyclone).

C2AcH-[^{99m}Tc(CO)$_3$], C2AcH-F-[^{99m}Tc(CO)$_3$], [^{99m}TcO$_4$]$^-$, and [^{99m}Tc(CO)$_3$(OH$_2$)$_3$]$^+$ were analyzed before in order to determine their migration on ITLC plates (data not shown). For C2AcH-[^{99m}Tc(CO)$_3$], only one radioactive peak, with $R_f = 0$, was observed for the duration of the stability study, both in PBS and in serum. However, C2AcH-F-[^{99m}Tc(CO)$_3$] after 18 h in serum gave rise to a second minor peak with $R_f = 1.0$ with approximately 5% of the radioactivity, while the PBS control showed little degradation.

DISCUSSION

To the best of our knowledge, the addition of the sequence CKLAAALEHHHHHH to the C-terminus of C2AcH represents the first use of a combination of a His-tag and a free cysteine residue as a tag for incorporation of imaging probes into recombinant proteins. Although it was designed for versatility, to allow the incorporation of both a ^{99m}Tc radiolabel via the His-tag and other imaging probes via covalent modification of the Cys, an unexpected benefit was that the efficiency of labeling with [^{99m}Tc(CO)$_3$]$^+$ dramatically increased, giving higher labeling yield and specific activity under mild conditions (37 °C, 30 min) than the His-tag alone (C2AcH-A, ~83%, C2AcH-F, ~60%) or Cys alone (C2Ac, ~15%). Radiochemical yields as measured by ITLC always exceeded 96% at a concentration of 1 μg/μL of C2AcH. This suggests that, with little further optimization, a simple kit-based labeling method could be developed without need for postlabeling purification. The present data indicate that, with the His-tag alone, a purification step would be required, adding unwanted complexity. Earlier reported ^{99m}Tc labeling conditions for model His-tagged proteins described conditions involving 15 to 30 min at 37 °C to achieve a 95% radiochemical yield (*22*). However, we have been unable to achieve this efficiency with C2AcH-A or C2AcH-F in which the Cys is blocked by acetamide or maleimide conjugation, respectively. Other groups also have reported that higher temperatures and/or longer incubation times maybe required to achieve adequate radiochemical yields with some His-tagged proteins (*31*).

The C2Ac construct without a His-tag was labeled with 15% radiochemical yield, which is comparable to reports in the literature for non-His-tagged proteins (*32*). This nonzero labeling efficiency raises the possibility that [Tc(CO)$_3$]$^+$-labeling may not be fully site specific for His-tags. However, in the mass spectrum of the [Re(CO)$_3$]$^+$ adducts, despite the presence of a 10-fold excess of [Re(CO)$_3$(OH$_2$)$_3$]$^+$ over protein, there is no evidence that more than one [Re(CO)$_3$]$^+$ binds to C2AcH and no evidence of any binding to C2Ac. This site specificity was confirmed by tryptic digest of C2AcH, which indicated that only peptide sequences containing the His-tag sequence contained the addition of only one [Re(CO)$_3$]$^+$. All other peptides from the tryptic digest were the same as unmodified C2AcH and did not show the addition of [Re(CO)$_3$]$^+$. However, it should be noted that, when [Re(CO)$_3$]$^+$ binds to the His-tag there are multiple potential regio- and steroisomers that can be formed upon complexation. Site specificity is also consistent with the excellent PS-binding affinity observed for C2AcH-[^{99m}Tc(CO)$_3$]. The calcium EC$_{50}$ data suggest that the PS-affinity of C2AcH-[^{99m}Tc(CO)$_3$] is slightly better than that of C2Ac-F. This is not unexpected, since the latter contains some non-site-specifically fluorescein-modified protein, as evidenced by the detection of some doubly modified protein in its mass spectrum.

The observation that conjugation with [Re(CO)$_3$]$^+$ markedly reduces dimer formation by thiol oxidation in air suggests that the thiol group is protected. One possible explanation for this observation is that the thiol binds to the metal. If this is the case, however, the Re−S interaction must be labile to some extent, because aerial oxidation is merely slowed and not completely blocked (Figure 5). In addition, if the thiol group plays a major part in maintaining the protein−metal bond one

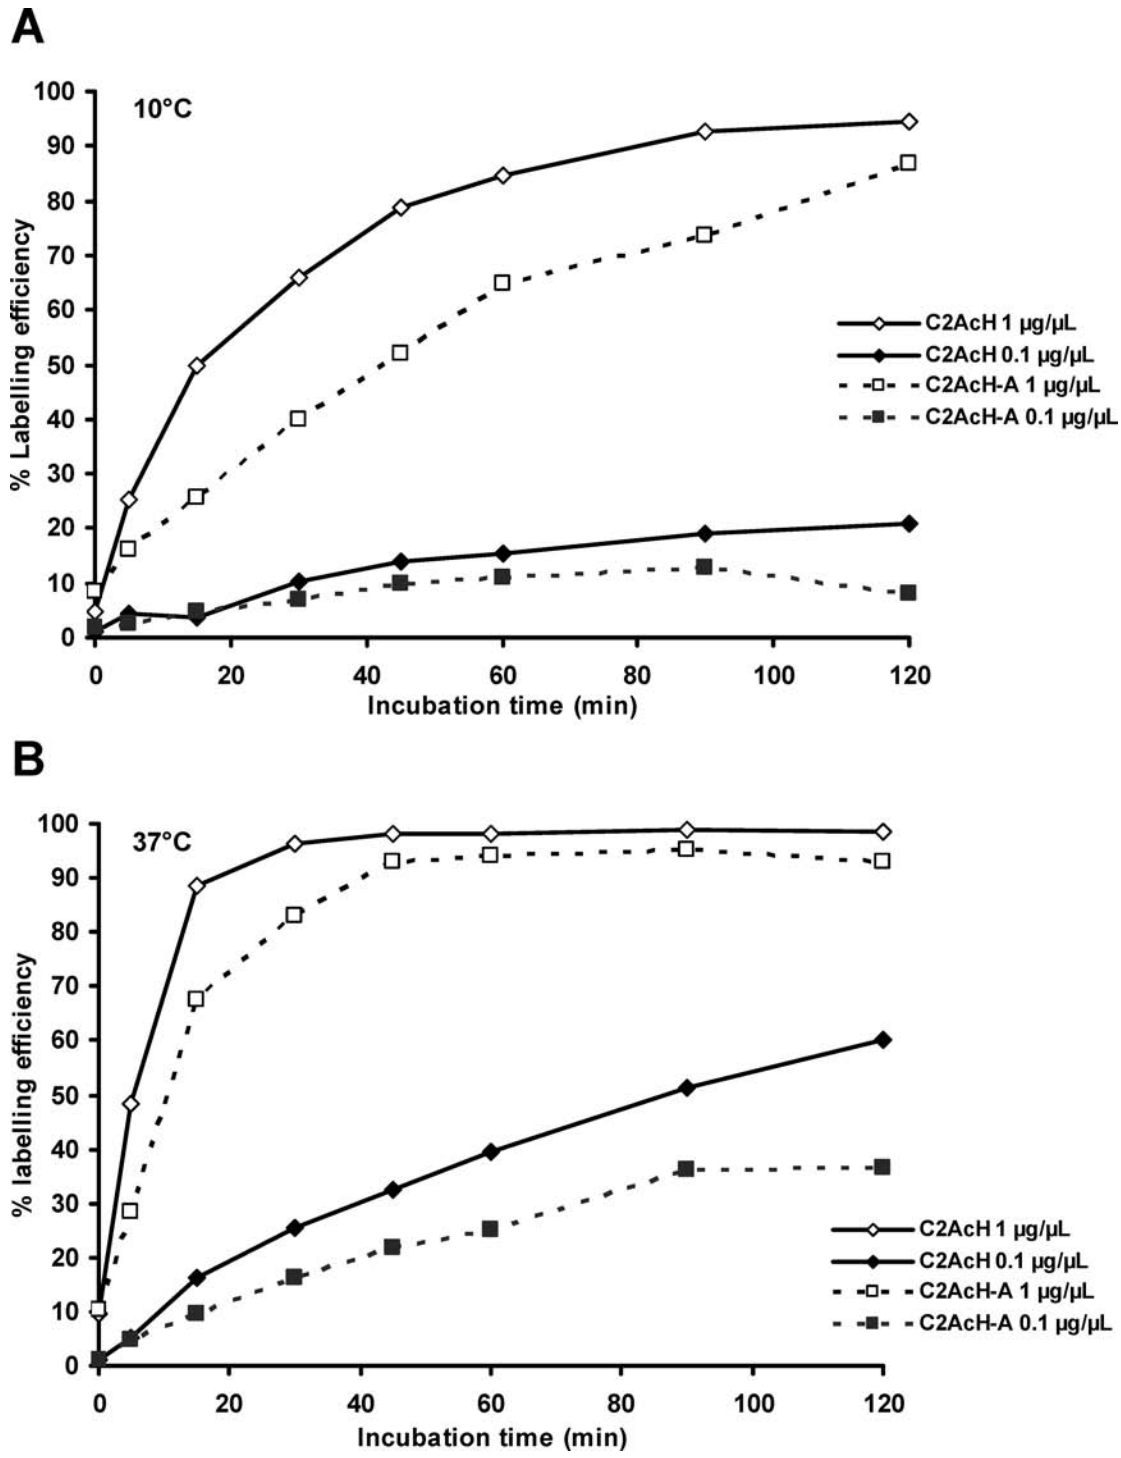

Figure 4. Radiolabeling efficiencies of C2AcH and C2AcH-A. (A) The C2AcH (solid line) and C2AcH-A (dashed line) were incubated with $[^{99m}Tc(CO)_3(OH_2)_3]^+$ at 10 °C for 120 min at a protein concentration of 1 μg/μL (open symbol) and 0.1 μg/μL (closed symbol). (B) The C2AcH (solid line) and C2AcH-A (dashed line) were incubated with $[^{99m}Tc(CO)_3(OH_2)_3]^+$ at 37 °C for 120 min at a protein concentration of 1 μg/μL (open symbol) and 0.1 μg/μL (closed symbol).

might expect C2Ac to undergo labeling more efficiently than is observed. An alternative model to account for the dimerization behavior is that the proximity of the $[M(CO)_3]^+$ (M = Tc, Re) group bound to the His-tag may induce a structural change or cause steric hindrance that inhibits disulfide bond formation without the need to invoke an M−S bond. In this model, the role of the Cys thiol may be important in the initial formation of the protein−metal complex, but not in the final structure. This is consistent with the serum stability results, which show only a marginal (possibly insignificant) loss in stability by blocking the Cys thiol group with fluorescein-maleimide. Given the well-established role of cysteine thiol groups as powerful nucleophilic catalysts in many enzymes, it is conceivable that the thiol or thiolate group acts as a local catalyst by performing the initial nucleophilic attack on the positively charged rhenium tricarbonyl complex, to form an intermediate containing a M−S bond, followed by displacement of the thiolate from the metal coordination sphere by histidine.

The results we described suggest that the combination of Cys and His-tag is an excellent efficient sequence for $[^{99m}Tc(CO)_3]^+$

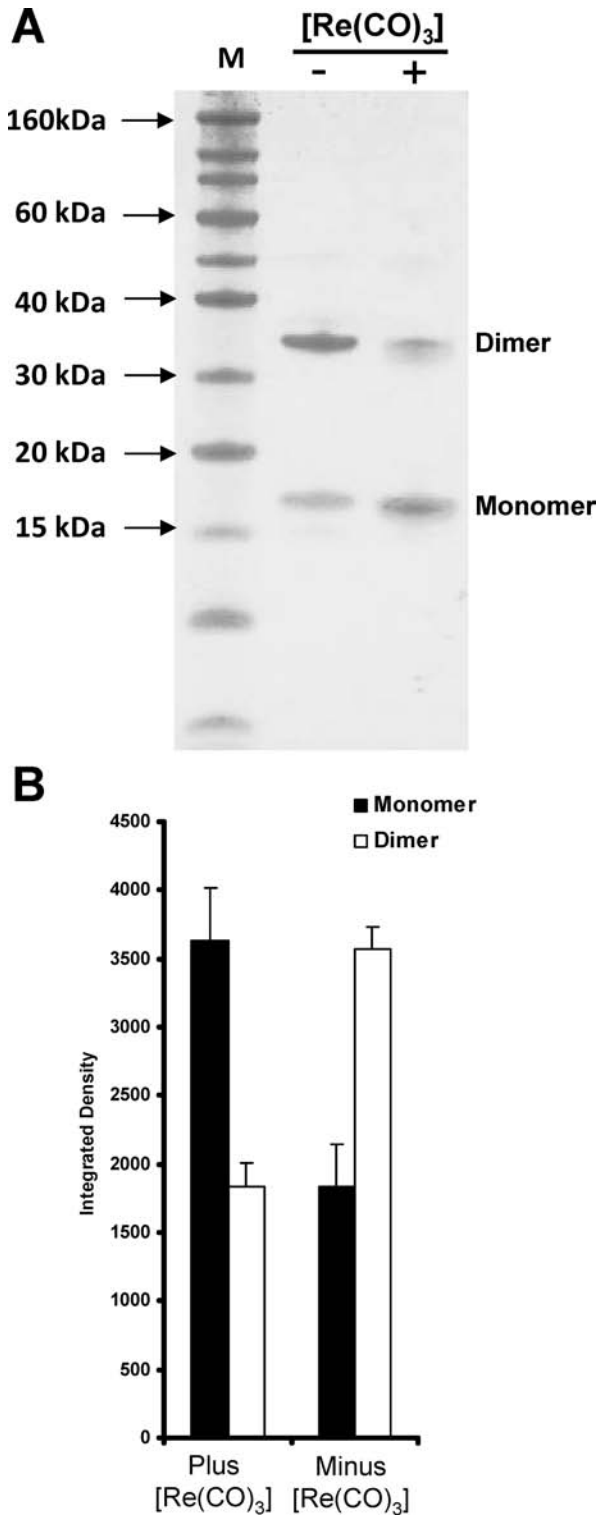

Figure 5. $[Re(CO)_3(OH_2)_3]^+$ reduces formation of dimeric C2AcH by binding to Cys. (A) C2AcH was incubated with and without $[Re(CO)_3(OH_2)_3]^+$ and shown is a nonreducing SDS/PAGE gel of samples after overnight incubation. M indicates molecular weight markers, and monomeric and dimeric C2AcH protein bands are indicated. (B) The monomer and dimer protein bands of C2AcH with and without $[Re(CO)_3(OH_2)_3]^+$ incubation were quantified using the *ImageJ* image analysis software. The data represent the mean of three samples with standard error bars.

labeling, with improved properties compared to the His-tag alone. The sequence deserves further investigation both in its own right and as a guide to further sequence optimization to

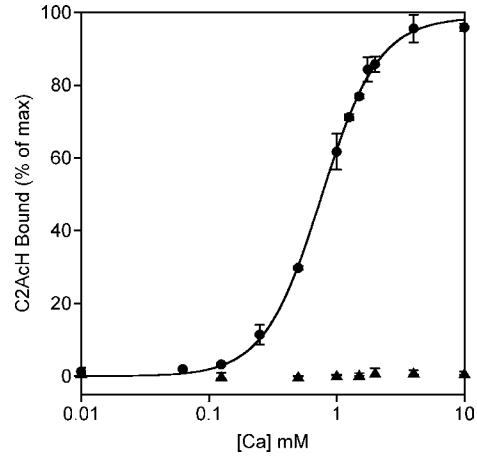

Figure 6. Site-specifically radiolabeled C2AcH binds to PS in a calcium dependent manner on RBC. Radiolabeled C2AcH (circles) or C2AcH-B (triangles) were incubated with preserved RBC in increasing calcium concentrations up to 10 mM. The cells were then washed and treated with 10 mM EDTA, and the activity eluted was counted using a gamma counter. The data are shown as the mean of three replicates with standard deviation error bars.

Table 2. Serum Stability of Technetium-Labeled C2AcH and C2AcH-F Proteins

		incubation time (hrs)			
		0	3	6	18
C2AcH	PBS control	99.54	99.34	98.81	99.22
	serum	99.15	98.58	98.23	97.88
C2AcH-F	PBS control	99.75	99.68	99.57	98.82
	serum	99.38	97.24	96.31	94.39

improve limits of specific activity/amount of protein that can be labeled, with greater specificity, under milder conditions for shorter labeling times.

The PS-binding assay results with these proteins further highlight the value of a site-specific approach to labeling. The site-specifically labeled conjugates C2AcH-$[^{99m}Tc(CO)_3]$ and C2AcH-F bound to PS on RBCs in a calcium-dependent manner, while nonspecifically modified C2AcH-B, formed by incubation with an excess of N-(benzyloxycarbonyloxy) succinimide before radiolabeling, did not bind to PS on RBCs even at the highest concentrations of calcium.

In conclusion, we have developed and characterized a new radiopharmaceutical for imaging cell death, based on C2A, the phosphatidylserine-binding domain of synaptotagmin I. It incorporates a novel $[^{99m}Tc(CO)_3]^+$- and $[Re(CO)_3]^+$-binding amino acid sequence that labels with excellent efficiency and site-specificity, with excellent serum stability, and is suitable for evaluation with other recombinant proteins for molecular imaging. The new site-specifically labeled C2AcH-$[^{99m}Tc(CO)_3]$ has excellent affinity for phosphatidylserine and warrants in vivo evaluation for cell death imaging in oncological, cardiovascular, and graft rejection preclinical models.

ACKNOWLEDGMENT

We thank Kevin Howland (University of Kent) and EPSRC Mass Spectrometry Service (University of Swansea) for performing the ES-MS, Bazbek Davletov (University of Cambridge) for supplying the original C2A plasmid, Chris Thrasivoulou (Univesrity College London) for help with confocal microscopy, Hector Knight (Covidien) for providing the Isolink kits, and Jim Ballinger and the Nuclear Medicine Department of Guy's and St Thomas' NHS Foundation Trust for supplying ^{99m}Tc pertechnetate. TSPO Targeted Dendrimer Imaging Agent: Synthesis, Characterization, and Cellular Internalization

Lynn E. Samuelson, Madeline J. Dukes, Colette R. Hunt, Jonathan D. Casey, and Darryl J. Bornhop*

Department of Chemistry, The Vanderbilt Institute for Chemical Biology and Vanderbilt-Ingram Cancer Center, Vanderbilt University, VU Station B 351822 Nashville, Tennessee 37235-1822. Received May 11, 2009; Revised Manuscript Received September 25, 2009

While it has become common practice for dendrimers to deliver imaging and therapeutic agents, there are few reported examples of cellular internalization of dendrimers. Moreover, targeting of dendrimers to the mitochondria in cells has not yet been reported. Previously, we have delivered small molecule imaging agents into glioma and breast cancer cells by targeting the translocator protein (TSPO; formerly known as the peripheral benzodiazepine receptor or PBR) with a family of high-affinity conjugable ligands. The 18 kDa multimeric TSPO is expressed in steroid-producing cells, primarily on the outer mitochondrial membrane. This protein is a prime candidate for molecular targeting because tumors and other disease-related cells contain high densities of TSPO. Here, we present the synthesis, characterization, and cellular internalization into C6 rat glioma cells of a TSPO targeted dendrimer imaging agent.

INTRODUCTION

Developments of clinically relevant molecular probes to image diseases or biological processes are essential for the advancement of personalized medicine. A variety of biomarkers specific to cancer and other diseases have been identified and used for therapeutic and/or imaging agent specific site delivery (*1*) (*2, 3*). For example, targeting proteins has been accomplished using antibodies (*4*), proteins (*5*), small molecules (*6*−*8*), nanoparticles (*9*−*11*), and dendrimers (*1, 12, 13*). Attachment of multiple different species to a single dendrimer has produced a single molecule which targets, images, and/or delivers a therapeutic dose to the site of disease (*14, 15*). The advantages of using dendrimers include (a) multiple moieties or multiple copies of the targeting agent on a single particle, (b) biocompatibility, (c) size solubility, and (d) tunability. However, the challenges of using dendermers include (a) the difficulty in characterization of functionalized molecule, (b) nonuniform distribution of the adduct(s), (c) complexity in determining the optimum size, and (d) ensuring that the targeting moiety retains activity after attachment to the dendrimer. It is clear that macromolecules will play an important role in personalized medicine; however, the current synthetic scaffolds are particularly ineffective in targeting intracellular receptors.

The translocator protein (TSPO, previously known as the peripheral-type benzodiazepine receptor or PBR) spans the mitochondrial membrane and has become an attractive receptor for therapeutics and targeted imaging (*16*). TSPO is associated with a number of biological processes including cell proliferation, apoptosis, steroidogenesis, and immunomodulation; yet, its exact physiological role is still not fully defined (*16*−*18*). Overexpression of TSPO has been shown in numerous types of cancer including brain, breast, colorectal, prostate, and ovarian cancers, as well as astrocytomas, hepatocellular, and endometrial carcinomas (*17*). Two well-characterized cell lines with high TSPO expression are C6 Rat Glioma cells (*19*) and MDA-MB-231 human breast cancer cells (*20*). Several small, high binding, selective molecules have been developed for TSPO and made into positron emission tomography (PET), magnetic resonance (MR), and optical imaging agents (*621*−*24*). While attractive, prior to this report macromolecules targeting TSPO have not been reported, possibly due to difficulty in internalizing synthetic molecules.

Dendrimers have been studied as potential delivery systems to target, image, and/or deliver a therapeutic specifically to diseased tissue because of their globular shape, multiple surface attachment sites, biocompatibility, tunable size, monodispersity, and low production cost (*25*). The multiple surface end groups available on a dendrimer allow for attachment of several moieties and or copies of each drug, ligand, or imaging agent. Furthermore, dendrimers can be adapted for advancements in coupling technology allowing them to be used with emerging targets, therapeutics, and imaging strategies. Multiple attachment points can provide increased therapeutic efficacy, reduced drug side effects, and increased signal-to-noise for improved imaging detection limits. Methods of targeting include attaching several copies of a binding molecule (small molecules, peptides, proteins, or antibodies) to the surface of the dendrimer to capitalize on polyvalency or the enhanced permeability and retention (EPR) effect where tumor accumulation occurs due to the particle size and the increased vasculature of the tumor (*26, 27*). Imaging with dendrimers is possible through the attachment of small molecule fluorophores (for optical), metal chelates (for fluorescence, MRI, PET and SPECT), or with a switch activated by a physiological process for enhanced tissue characterization (*28, 29*). Dendrimers can serve as effective prodrug scaffolds with the drug molecules being attached through a linkage which activates the drug in vivo once they reach the delivery site. Cleavage from the scaffold can occur through a change in pH, enzyme reaction, or slow degradation of the macromolecule (*29*). While internalization of large nanoparticles through the cellular membrane has been shown, targeting of specific organelles has scarcely been reported (*30, 31*). In this paper, we present the synthesis, characterization, cellular internalization, and mitochondria labeling of a dendrimer nanoparticle. Here, we demonstrate that a

functionalized fourth generation (G(4)-PAMAM) dendrimer particle, which targets an internal cellular receptor and binds that target by passing through the cellular membrane under normal physiological conditions and without the external perturbation of the cellular membrane, can be prepared, characterized, and imaged.

EXPERIMENTAL PROCEDURES

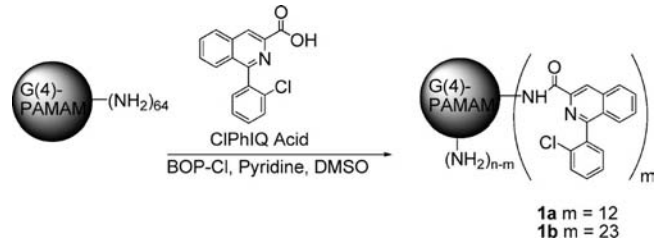
Materials. G(4)-PAMAM dendrimer in a 10% w/w solution of methanol was purchased from Fischer Scientific and pipetted into a preweighed vial immediately before use. The methanol was evaporated under a stream of $Ar_{(g)}$, and the resulting viscous oil was dissolved in water, frozen, and lyophilized to give a fluffy white powder. The mass of the dendrimer was determined by reweighing the vial and calculating the mass difference. 1-(2-Chlorophenyl)isoquinoline-3-carboxylic acid (ClPhIQ Acid) was synthesized in our laboratory as previously reported (*6*, *32*). All 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) and DOTA derivatives were purchased form Macrocyclics and used as received. All other chemicals were purchased from Fischer Scientific and used as is unless otherwise indicated.

MALDI-TOF MS were obtained on a PerSeptive Biosystems Voyager-DE STR mass spectrometer. Freshly recrystallized trans-indole acrylic acid (IAA) was used as the matrix in a 10 mg/mL solution of DMSO. The plate was spotted with 1 μL of a 10:1 solution of matrix to analyte. NMR spectra were obtained on a 400 MHz Bruker AV-400 instrument with a 5 mm *Z*-gradient broadband inverse probe. NMR spectra were obtained in d_6-dimethyl sulfoxide. UV−vis spectra were obtained on a Shimadzu 1700 UV−vis spectrophotometer. Fluorescence spectra were obtained using a ISS PCI spectrofluorometer at room temperature.

ClPhIQ-G(4)-PAMAM (1). First, ClPhIQ Acid (152.9 mg, 540 μmol) and benzotriazol-1-yloxytris(dimethylamino)-phosphonium hexafluorophosphate (BOPCl, 288.1 mg, 651 μmol) were dissolved in 2 mL of DMSO each. Triethyl amine (Et_3N, 100 μL) was added to the ClPhIQ Acid solution. The BOPCl solution was added to the ClPhIQ Acid solution. The mixture was stirred for 5−10 min (sometimes a change from clear to bright orange would occur) and was then added to a stirred solution of G(4)-PAMAM dendrimer (252.2 mg, 18 nmol) in DMSO (5 mL). The reaction was stirred at room temperature overnight. Unreacted ClPhIQ Acid was removed by diluting the solution 4-fold with water and placing the solution in an Amicon centrifugation molecular weight filter (molecular weight cutoff = 5 kDa) and concentrating the solution to approximately 500 μL via centrifuging at 3000 rpm (1419 × *g*) for 1 h. The solution was diluted and reconcentrated three times with water to wash any unreacted materials away. Finally, the solution was lyophilized to give 441.2 mg (100% yield) of a slightly yellow powder. The same procedure was followed for synthesizing the (ClPhIQ)12-PAMAM using fewer equivalents of ClPhIQ Acid and BOPCl. ClPhIQ30-G(4)-PAMAM: MALDI-TOF MS 19 500 amu ^{1}H NMR (300 MHz, $CDCl_3$) 8.8 (1H, s), 8.6 (1H, s), 8.2−8.5 (5H, m), 7.5−8.0 (9H, multi), 2.9 (3H, bs), and 3.1−3.5 (28H, m) ppm.

ClPhIQ-G(4)-PAMAM-Lissamine (2). G(4)-PAMAM (9 mg, 400 nmol) with or without ClPhIQ Acid was dissolved in 2 mL of dimethylformamide (DMF). Next, 23 μL of a 17.3 mM solution of Lissamine sulfonyl chloride was added to the stirred dendrimer solution. The reaction was stirred overnight followed by purification in Amicon centrifugation filters as described above and lyophilized to give 5.6 mg (61% yield) of a pink fluffy solid. The presence of the fluorophor was confirmed with UV−vis (max absorbance at 551 nm) and fluorescence (ex 551 nm, em 586 nm) spectroscopies. Specific conditions and yields provided above were for ClPhIQ23-G(4)-PAMAM, but UV−vis and fluorescence spectra were identical for ClPhIQ12-PAMAM and PAMAM-Liss.

Scheme 1. Synthesis of ClPhIQ-PAMAM



Cell Internalization Experiments. with G(4)-PAMAM-Lissamine derivatives: Either 20 000 C6 rat glioma or 40 000 MDA-MB-231 breast cancer cells were plated into collagen coated glass-bottomed microscopy (MatTeck) dishes and allowed to grow for two days in cell media. After two days, the cells had normal morphology and were attached, and approximately 20% confluent. G(4)-PAMAM-Lissamine compounds (with or without other moieties) were diluted to 1 μM (in ClPhIQ) with media from a 10 mg/mL (12 μM in ClPhIQ) stock solution in DMSO. The media over the cells was replaced with the media containing the fluorophor (either ClPhIQ-PAMAM-Liss or PAMAM-Liss) diluted as noted above and incubated for 6−12 h. The media was then poured off, and the cells were carefully rinsed 3−4 times with Dulbecco's Phosphate Buffered Saline (DPBS). The cells were imaged live. Both white light and fluorescence pictures were obtained.

For fixed cells, the rinsed cells were incubated at room temperature for 30 min with a 4% *para*-formaldehyde solution. The cells were carefully washed 4 times with DPBS and stored under DPBS at 4 °C until imaged (not longer than 1 week, typically overnight). Immediately before imaging, the fixed cells were incubated with a 25 nM solution of mitotracker green (MTG) for 10 min. Excess MTG was removed by four washings with DPBS and the cells were imaged. Cellular images were obtained using a A Nikon Eclipse TE2000-U fluorescence microscope (Lewisville, TX) equipped with a Nikon FITC-Texas Red filter sets employed for the in vitro imaging. The Texas Red filter (ex, 560−580 nm; polychromatic mirror, 585−665 nm; barrier filter, 600−650 nm) set was used to image Lissamine, and the FITC filter was used to image MTG (ex, 450−505 nm; polychromatic mirror, 510−555 nm; barrier filter, 515−545 nm). Fluorescence integration times ranged 100−5000 ms, but were typically 100−500 ms. All controls were integrated for at least 5000 ms. Sample homogeneity was maintained by keeping the samples under DPBS the entire time of imaging. For live cells, images were taken within 20 min after replacing media with DPBS and were discontinued if the cellular morphology changed in any way from the media containing morphology.

RESULTS AND DISCUSSION

The TSPO targeted dendrimer was synthesized using 1-(2-chlorophenyl)isoquinoline-3-carboxylic acid (ClPhIQ Acid), a precursor of the conjugable TSPO binding molecule previously reported (*6*). ClPhIQ Acid (Scheme 1) was activated with benzotriazol-1-yloxytris(dimethylamino)-phosphonium hexafluorophosphate (BOPCl), in pyridine and dimethyl sulfoxide (DMSO), and added to a solution of G(4)-PAMAM dendrimer in DMSO. An average of 12 and 23 ClPhIQ Acids were attached by reacting G(4)-PAMAM dendrimer with 15 and 30 mol equiv of the activated TSPO ligand, respectively, to obtain two ClPhIQ-PAMAM compounds, **1a** and **1b** (Scheme 1). Excess ClPhIQ Acid and coupling agent were removed by diafiltration with a molecular weight cutoff (MWCO) of 5 kDa. Both

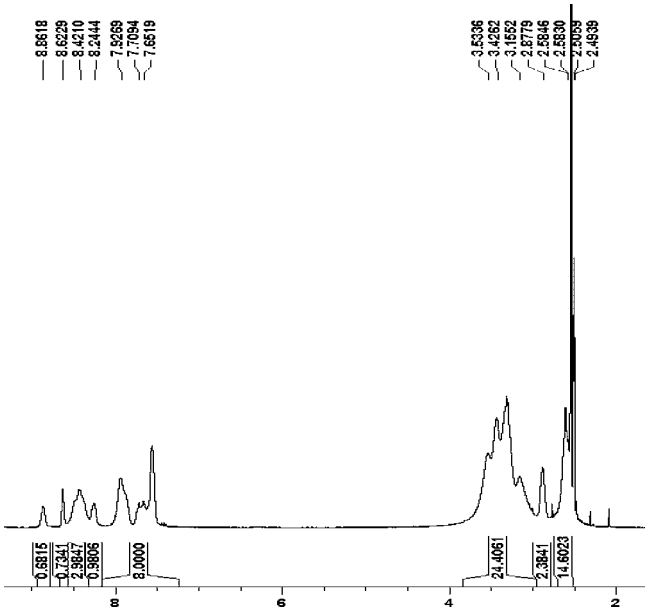


Figure 1. NMR of 23 ClPhIQ Acids attached to G(4)-PAMAM (ClPhIQ23-PAMAM).

ClPhIQ-PAMAM molecules were characterized with nuclear magnetic resonance (NMR) and matrix assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS).

The average number of TSPO ligands per dendrimer was estimated using NMR integrations. It was shown from proton NMR spectra of the PAMAM and ClPhIQ pieces individually that the aromatic proton signals are exclusively from the ClPhIQ Acids attached (7.0−7.9 ppm) to the particle, while the interior PAMAM methylenes are the only signal observed from 2 to 4 ppm and the amides are found from 8.4 to 9 ppm (Figure 1). By calculation, there are approximately 930 methylene protons in a G(4)-PAMAM dendrimer and 9 protons (all aromatic) per ClPhIQ Acid molecule. To determine the average number of ClPhIQ Acids per dendrimer, the integral from 7.0 to 8.2 was calibrated to 9 and the resulting integral from 2 to 4 ppm was divided into 930. As shown in Figure 1, we find 23 ClPhIQ Acids attached to the dendrimer when the dendrimer was reacted with 30 equiv of ClPhIQ Acid. NMR spectra indicate that 12 ClPhIQ acids are attached when 15 equiv of ligand are reacted with the dendrimer (data not shown). Interestingly, the amount of ClPhIQ that binds to the dendrimer nearly doubles (from 12 to 23) when doubling the amount of ClPhIQ in the reaction (from 15 to 30).

MALDI-TOF MS was also utilized to confirm the average number of ClPhIQ Acids attached to the dendrimer (Figure 2). First, a MALDI-TOF MS was acquired of the G(4)-PAMAM with the average molecular weight (MW) found to be 13 244 Da, significantly lower than the 14 215 Da of a G(4)-PAMAM without any of the widely reported structural defects (*33*). These defects include incomplete reactions, making one arm of the dendrimer consistently a generation behind, and side reactions that stop the expansion of that branch of dendrimer altogether. The ClPhIQ-PAMAM (**1a**) has an average MW of 16 513, and thus, by calculation has 12 ClPhIQ Acid molecules per PAMAM. This result is consistent with the NMR data, as was the number of ClPhIQ Acids per PAMAM for ClPhIQ-PAMAM (**1b**) with 23 ClPhIQ ligands attached. Additionally, it was calculated that ClPhIQ-PAMAM, **1b**, had approximately 24 ClPhIQ Acids per PAMAM, consistent with NMR data.

Following characterization of the ClPhIQ-PAMAM molecules with NMR and MALDI-TOF-MS, the dendrimer was further functionalized by reacting it with Lissamine rhodamine B sulfonyl chloride (Lissamine) in dimethyl formamide (DMF) overnight to give 1 or 2 Lissamine dyes per dendrimer (Scheme 2). The DMF was removed in vacuo and excess dye was removed by diafiltration (MWCO = 5000) in water. UV−vis and fluorescence were employed to characterize the optical imaging agent. Attaching the dye to the dendrimer produced a compound with an absorbance maximum at 571 nm (versus 563 nm for free dye) and a slightly red-shifted emission at 586 nm (versus 583 nm for free dye). A control compound (PAMAM-Liss), the agent absent of the targeting moiety, was synthesized similarly to the targeting agent by reacting G(4)-PAMAM dendrimer with Lissamine (Scheme 2). The PAMAM-Liss conjugate was also purified by diafiltration in which the first low molecular weight fraction was slightly pink (from dye) and subsequent washing resulted in lighter color until no color was present. A minimum of three colorless washings in the low molecular weight fraction were completed to provide pure ClPhIQ-PAMAM-Liss with no unreacted Lissamine dye. A molecular weight difference for the PAMAM and PAMAM-Liss of 500−600 amu was observed in the MALDI-TOF MS spectrum, consistent with an average of 1 dye per dendrimer. The small spectral shift in absorbance and emission was similar to the targeted moiety.

Finally, the solubility extraction coefficients between octanol and water were determined for both the PAMAM compounds by using the shake method. Briefly, the shake method for finding log *P* is determined by mixing an aqueous solution of the PAMAM-dye with a solution PAMAM-dye in octanol and allowing the two solvents to equilibrate. The absorbances of each layer (octanol and water) were then recorded and used to determine the concentration of dye in each layer. The log P for ClPhIQ-PAMAM-Liss is estimated to be 2.9, while that for PAMAM-Liss (no ClPhIQ) is 1.0. These log *P* values indicate that the ClPhIQ-PAMAM-Liss is more lipophilic than the PAMAM-Liss and therefore is more likely to interact favorably with the cellular membrane.

To evaluate the biological activity of the imaging agent, C6 rat glioma cells, shown to express a high concentration of TSPO (*34, 35*), were incubated with the dendrimer compounds **2b** and **3** for 12 h in collagen coated MatTek dishes and visualized by fluorescence microscopy. Live cell imaging was preformed immediately after rinsing the cells with PBS or saline to remove media and unbound or uninternalized imaging agent. A Nikon Eclipse TE2000-U fluorescence microscope (Lewisville, TX) equipped with Texas Red and FITC filter sets was employed for the in vitro imaging. As shown in Figure 3, the ClPhIQ-PAMAM-Liss labels the cell, while the control (PAMAM-Liss) does not produce fluorescence. As another control, cells were incubated with Lissamine rhodamine B sulfonyl chloride and again no fluorescence was observed (data not shown). The imaging experiments were performed in triplicate with observations being consistent with respect to absorbance and fluorescence intensity and the absence of fluorescence in the controls. We hypothesize that the dendrimer with the TSPO binding ligand (ClPhIQ-PAMAM-Liss, **2b**) produced bright, localized cellular fluorescence due to its ability to pass through the cellular membrane and bind to the target protein TSPO (Figure 3). Since ClPhIQ Acid conjugated dye is known to bind TSPO, glioma cells overexpress TSPO, and it is an organellular protein, we believe that the dendrimer labels the mitochondria by binding to TSPO. In the labeling experiment where the dendrimer without the targeting ligand (compound **3**) was used, no fluorescence was found in the cell (either intracellularly or at the membrane) at exposure times as long as 5 s. Taken together, these results indicate that the ClPhIQ moiety is necessary for cellular uptake of the dendrimer at labeling concentrations of 1 μM and equilibration times of 6−12 h.

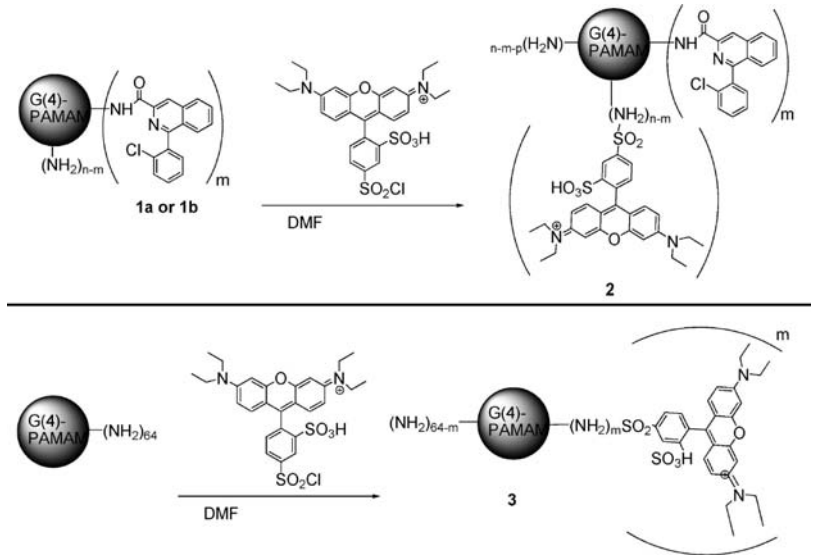
Scheme 2. Attachment of Lissamine Dye to PAMAM



To further confirm that the agent was intracellular, a series of *z*-stacked images (pseudoconfocal) were obtained allowing different regions of the cells to be viewed (Figure 4). These *z*-stacked images were accomplished by changing the lens position incrementally, moving the focal planes of the microscope through cells, and collecting the images by viewing fluorescence. In the center focal planes, there is a dark hole, consistent with the nucleus as shown in the fluorescence-DIC overlay (Figure 4). This observation suggests that the agent undergoes internalization, passive or active, and does not just label the membrane due to the lipophilic nature of the ClPhIQ moiety. Since only a small amount of out-of-focus light is observed in the membrane slices of the *z* stack (data not shown), labeling of the membrane appears to be negligible. Furthermore, fluorescence signal is observed through the cell to the entire nuclear membrane, but not in the nucleus, indicating uptake of the dendrimer by the cells but not the nucleus. Previously reported small molecule agents have not labeled the nucleus, although low concentrations of TSPO are present there (*24*). The reported macromolecular agent behaved as expected and targeted the mitochondria and was not taken up into the nucleus as indicated in Figure 4.

To further explore whether ClPhIQ-PAMAM-Liss was targeting the mitochondria, a co-incubation experiment was preformed. This was accomplished by first incubating C6 rat glioma cells with ClPhIQ-PAMAM-Liss as described above for the live cellular imaging, followed by fixation using paraformaldehyde, and then treating the cells with Mitotracker Green (MTG) according to the manufacturer's guidelines. The cells were then imaged using a Texas Red filter set to detect the Lissamine (red) fluorescence and a FITC filter set to detect the MTG (green) fluorescence. Figure 5 shows C6 rat glioma cells incubated with either ClPhIQ-PAMAM-Liss or the control, PAMAM-Liss. The DIC images in Figure 5A and G are present to indicate the location of the cells relative to fluorescence signal of ClPhIQ-PAMAM-Liss (Figure 5A) and PAMAM-Liss dosed cells (Figure 5G). Fluorescence from the imaging agent is displayed in red (Figure 5B) and fluorescence from the MTG as green (Figure 5C). As demonstrated above with live cell imaging, the ClPhIQ-PAMAM-Liss agent labels the fixed cells principally perinuclearly (Figure 5B). MTG was used in low concentration (25 nM) to ensure that it primarily labeled mitochondria in the cell. The MTG labels the mitochondria of cells, as shown by numerous investigators (*36*, *37*), particularly when used in low concentrations as those employed here (25nM). More careful investigation of the fluorescence signals allow insight into where the species are within the cell. Figure 5 panels D and E display co-registration of ClPhIQ-PAMAM-Liss and MTG with yellow indicating areas of overlap while red and green indicate areas where ClPhIQ-PAMAM-Liss (red) and MTG (green) are not coincident. It is encouraging to see that most of the red and green converge to yellow, indicating

that the majority of ClPhIQ-PAMAM-Liss is in the same location of the cell as the MTG. This good colocalization is further evidence that ClPhIQ-PAMAM-Liss is labeling the mitochondria and not other parts of the cell. As demonstrated in Figure 5 panels F—I and in the live cell imaging (Figures 3 and 4), fluorescence from the dendrimer is only detected if ClPhIQ Acid is incorporated into the dendrimer. In other words, images from cells inoculated with the control agent (PAMAM-Liss) exhibit no fluorescence (Figure 5I). MTG fluorescence was not affected (Figure 5C,F,H) by the presence or absence of dendrimer agent, and the cellular membrane was not perturbed by nonphysiological chemical or physical processes prior to or during the incubation with ClPhIQ-PAMAM-Liss. Of course, excess imaging agent was removed prior to fixation in all experiments. Taken together, the fluorescence images in Figure 5 indicate that the ClPhIQ-PAMAM-Liss is targeting the mitochondria and that the ClPhIQ ligand is necessary for this mitochondrial labeling to occur. The *z*-stacked images and coincubation experimental results indicate that the imaging agent is internalized into the cell through normal cellular functions.

Although no quantitative binding studies were completed, the agent binds with high enough affinity to remain in the cell after fixation, washing, and treatment with MTG. Studies beyond the scope of this report are necessary to determine the exact mechanism of cellular transport and binding; however, insight is shown into some initial experiments performed using shorter incubation times with the fluorescent agents (ClPhIQ-PAMAM-Liss and PAMAM-Liss). In these trials, no fluorescence was observed for either compound (with and without ClPhIQ ligand) after incubation for as long as 3 h (data not shown). It was only after a minimum of 6 h of incubation that fluorescence was found in the dosed cells. One possible explanation for this observation is that the dendrimeric compound is slowly taken up into the cell and the ClPhIQ is absolutely necessary for uptake. Another possibility is that the molecule freely enters and exits the cell and eventually binds the target (TSPO), that dye is completely removed (both inter- and intracellular) when the cells are rinsed immediately after incubating.

Imaging with IEC-6 cells was completed as an initial estimate as to whether the ClPhIQ-PAMAM-Liss would be taken up and bind mitochondria in cells that express low levels of TSPO. Since TSPO is necessary for cellular function, there are no cell lines that do not express TSPO. No fluorescence was seen when imaging the IEC-6 cells with ClPhIQ-PAMAM-Liss at dosing concentrations as high as 1 μM in dye (data not shown). The indication is that the ClPhIQ-PAMAM-Liss imaging agent is TSPO protein specific. Again, the mechanism of cellular uptake into the cell needs further investigation in order to pinpoint the exact mechanism of cellular uptake.

Further evidence of the utility of ClPhIQ-PAMAM-Liss was demonstrated by labeling MDA-MB-231 human breast cancer cells, an aggressive human cancer cell line. Like the C6 rat glioma cells, the MDA-MB-231 human breast cancer cells have been shown to overexpress TSPO (*20*). The cells were incubated with ClPhIQ-PAMAM-Liss following the same procedures as with the C6 rat glioma cells, fixed, and treated with MTG for coregistration investigations. The individual red and green fluorescence of ClPhIQ-PAMAM-Liss and MTG, respectively, in fixed MDA-MB-231 cells is demonstrated in panels A and C of Figure 6, while panels E and F show the lack of red fluorescence in the PAMAM-Liss treated cells. Association between the red and green (shown in yellow) is evident in the overlays of panels B and D indicating colocalization of the ClPhIQ-PAMAM-Liss and MTG. These additional results represent further evidence that ClPhIQ-PAMAM-Liss is able to label TSPO rich mitochondria in cancer cells.

The observations made in the cellular imaging experiments show that the ClPhIQ labeled dendrimers enter the cell and bind

the mitochondria, but do not appear in the nucleus or cellular membrane. The dendrimers without the ClPhIQ do not label the cell in any significant way. Although the molecules are small enough to enter through the cellular and nuclear membranes, as shown previously the literature suggests that it is not as trivial as size (*38*). First, dendrimers are structurally different than biological molecules such as proteins and antibodies. Biological molecules are typically well-defined, folded structures, while dendrimers are floppier, not well-defined structures. Second, the end functional groups dictate the interactions with the membranes, which may block or enhance the uptake of the compound, depending on the chemical interactions. In amine-terminated dendrimers, the amines can be protonated and do not pass through the lipophilic cellular membrane. Our observations in the cellular imaging experiments, along with the log *P* data, indicated that the lipophilicity of the ClPhIQ ligand allows for the dendrimeric molecule to pass into the cell.

In conclusion, a TSPO targeted imaging agent was synthesized using a G(4)-PAMAM backbone, ClPhIQ Acid, and Lissamine (ClPhIQ-PAMAM-Liss). The imaging agent was

characterized with MALDI-TOF-MS and NMR and imaged in C6 rat glioma and MDA-MB-231 human breast cancer cells. To our knowledge, this is the first example of a TSPO-targeted dendrimer and among the few dendrimeric compounds that are internalized into the cell under normal physiological conditions. Co-localization of the ClPhIQ-PAMAM-Liss and MTG indicates that the compound binds to the mitochondria. The ability for synthetic dendrimers to be internalized into the cell and target a specific protein is a step closer to understanding biological events at the molecular level and ultimately enabling personalized medicine; however, further investigation is required to determine the exact mechanism by which this agent enters the cell.

Received May 11, 2009; Revised Manuscript Received September 8, 2009

The main limitation of contemporary anticancer chemotherapy remains to be the insufficient specifity of the drugs for tumor tissue, which decreases the maximum tolerated dose due to severe side effects. Micellar drug delivery systems based on amphiphilic block copolymers with a very narrow size distribution (10 to 100 nm in diameter) is a novel innovative approach. Here, we report biological and pharmacological properties of polymeric micellar conjugate containing doxorubicin (DOX) covalently bound via hydrolytically cleavable hydrazone bonds to the micelle core. The system had a very low systemic toxicity (almost 20 times lower than free DOX) and long circulation in the bloodstream (with half of the dose after 24 h). Significant accumulation of tested micelles within the tumor was confirmed by fluorescent whole body imaging. Our new micellar system showed promising therapeutic activity against established murine EL-4 T-cell lymphoma; it was found that it is able to completely cure about 75% of tumor-bearing mice (with doses of either 1×150 mg DOX kg^{-1} or 2×75 mg DOX kg^{-1}, administered i.v.). Moreover, treatment with micelles in cured mice induced tumor-specific resistance. Up to 80% of these mice survived rechallenge with original but not with distinct tumor cells.

INTRODUCTION

The main handicap of classical chemotherapeutics is still their low specificity (*1*). The other limitations include poor water solubility of cytostatic drugs, their unfavorable pharmacokinetic profile, and induction of multidrug resistance.

One possible approach to overcome the disadvantages of the classical low-molecular-weight drug is its binding to a polymeric carrier (*2*−*4*). Conjugation to water-soluble polymers, such as poly[*N*-(2-hydroxypropyl)methacrylamide] (*5*, *6*) or poly(ethylene oxide) (*7*) increases the solubility in aqueous environment and significantly prolongs the plasma half-life. The half-life of free doxorubicin (DOX) in the blood circulation in a murine model is measured in tens of minutes, while polymeric derivatives are detectable in the blood even after tens of hours (*8*). The longer period in circulation and the high molecular weight of polymeric drug delivery systems (DDSs) improve passive accumulation in solid tumors due to the enhanced permeation and retention (EPR) effect (*9*, *10*).

Contemporary drug delivery research is focused on nanoscale delivery systems, such as liposomes, polymeric nanoparticles, or micelles (*11*). Among these, micellar drug delivery systems (MDDS) assembled from amphiphilic block copolymers with a very narrow size distribution (10 to 100 nm in diameter) might be a promising modality (*12*, *13*). They are characterized by a unique core−shell architecture, where hydrophilic blocks form a shell, which separates the core of hydrophobic polymer chains from the aqueous exterior. The hydrophobic core serves as the loading space for various therapeutic agents. The hydrophilic shell, which is the outer part, stabilizes the micellar particle in aqueous solutions. Poly(ethylene oxide) (PEO) is known to be nontoxic, nonimmunogenic, and soluble and therefore is often used as the micellar shell-forming block (*7*). PEO chains also avoid opsonization and interactions with other serum proteins, and successfully prevent recognition of such particles by the cells of the reticuloendothelial system (RES) (*14*). Micellar particles are passively accumulated in the tumor via an EPR effect (*15*).

In most studied polymeric micellar drug delivery systems are molecules of drug physically entrapped in the inner core by the use of hydrophobic interactions. However, additional selectivity may be achieved by binding the drug to the polymeric carrier by a bond preferentially cleavable in neoplastic tissues (*16*−*18*). For instance, the tissue of solid tumors has, due to hypoxia, a lower pH value than blood plasma (*19*). As a result, the use of bonds, which release the active drug from the inactive conjugate in a mildly acidic environment, such as the hydrazone bond (*6*, *20*, *21*), may be one of such improvements over the systems with physically entrapped drug. This is why we decided to use it in our system described in this paper.

One of the most promising anticancer drugs conjugated with the polymeric micelles is doxorubicin, which has been incorporated into the micelle core in both a hydrophobic and covalent manner (*18*, *22*−*24*). We have recently synthesized a polymeric micellar drug delivery system with anthracycline antibiotic doxorubicin bound in the micelle core via a hydrolytically labile hydrazone bond (see Scheme 1 for structure) (*21*), where the cleavage of bonds between DOX and polymer leads to hydrophilization of the micelle core, which triggers the destabilization and consequent disruption of the micelles. Free diblock unimers are quite small ($M_w = 10\,000$ Da) and will undergo renal elimination from the organism. The system design using poly(allyl glycidyl ether) as starting material of the core-forming block also brings some additional benefits in comparison with systems that use poly(amino acid) as the core-forming block (*18*); in particular, the synthesis of the polymeric conjugate is

significantly less complicated, e.g., it does not require synthesis monomers that are not commercially available. The poly(ethylene oxide)-*block*-poly(allyl glycidyl ether) may also be after polymerization effectively purified from homopolymers and other impurities by a method described in (Hruby et al. 25), so a very well-defined system may subsequently be prepared.

EXPERIMENTAL PROCEDURES

Materials. Allyl glycidyl ether (AGE, Sigma-Aldrich, USA) was dried with anhydrous magnesium sulfate and distilled under reduced pressure (bp 51 °C at 2 kPa), benzene (Lach-Ner Ltd., Czech Republic) was dried with sodium and distilled, tetrahydrofuran (THF; Lach-Ner Ltd., Czech Republic) was kept over sodium and distilled before use, and cyclohexane (Lach-Ner Ltd., Czech Republic) was dried with sodium metal and distilled before use. Poly(ethylene oxide) monomethyl ether (PEO, M_w = 5000), dimethyl sulfoxide (DMSO), hydrazine hydrate, DOX hydrochloride, and methyl sulfanylacetate were purchased from Sigma-Aldrich (USA) and were used without additional purification. Other chemicals were purchased from Lach-Ner Ltd. (Czech Republic) and were used without additional purification.

Dialysis tubing Spectra/Por 3 (molecular weight cutoff 3500 Da) was purchased from Serva Electrophoresis (Germany); Sephadex LH-60 and Sephadex G-25 gel permeation chromatography media as well as PD-10 desalting column were purchased from Amersham Pharmacia Biotech (Sweden). $^{111}InCl_3$ solution was purchased from Lacomed Ltd. (Czech Republic).

Synthesis of Micellar Conjugate. The micellar conjugate was prepared as described in using the poly(ethylene oxide)-*block*-poly(allyl glycidyl ether) with $M_{w[PEO)]}$ = 5000 Da and M_w = 1600 Da (PAGE, poly(allyl glycidyl ether)) as starting material synthesized according to Hruby et al. (*25*) (see Scheme 1). We have improved the DOX conjugation procedure (*21*); DOX was conjugated to the polymer carrier as follows: The hydrazide precursor α-methyl-poly(oxirane)-*block*-poly(3-{[({[hydrazinocarbonyl]methyl}sulfanyl)propoxy]methyl}oxirane) (1.28 g, 1.85 mmol hydrazide according to the N analysis), acetic acid (960 μL, 16.8 mmol), DOX hydrochloride (320 mg, 552 μmol), and anhydrous sodium acetate (1.44 g, 17.6 mmol) were dissolved in this order in the mixture of dry DMSO (24 mL)−dry methanol (24 mL), and then anhydrous sodium sulfate (960 mg, 6.76 mmol) was added. The mixture was stirred in the dark at room temperature for 48 h and centrifuged. The polymer was isolated from the supernatant according to procedure described in (*21*). To obtain a stabilized dry preparative D-lactose, the aqueous solution of the polymer containing D-lactose (5 mg D-lactose/1 mg polymer) was freeze−dried. The conjugate containing 17 wt % of DOX in polymer forms micelles in aqueous solutions with *z*-average hydrodynamic diameter D_H = 75 nm as determined by dynamic light scattering (DLS) at room temperature ($c_{polymer}$ = 1 mg mL^{-1}) on a Nano-ZS (Malvern, UK) zetasizer at the scattering angle ϕ = 173°. The DTS (Nano) program was used for the evaluation of the data.

To label the micelles with Dyomics 615 and diethylenetriamine pentaacetic acid (DTPA), respectively (see Scheme 2), the dry micellar formulation with D-lactose (420 mg, i.e., 70 mg polymer) was dissolved in *N*,*N*-dimethylacetamide (3.0 mL) and reacted with Dyomics 615 NHS ester (Exbio Ltd., Czech Republic, 1.4 mg) or, after removal of D-lactose by filtration, with DTPA dianhydride (1.4 mg), at room temperature for 1 h. The solution was then purified from unreacted label and solvent by gel permeation chromatography on Sephadex G-25 in water and freeze−dried with D-lactose as described above to form the dry formulation. The Dyomics 615 content, assayed spectrophotometrically in methanol (λ_{max} = 621 nm, ε = 200 000 L mol^{-1} cm^{-1}), was 1.1 wt % in polymer. The content of DTPA groups was sufficient to allow >90% labeling yield (see below) with ^{111}In even at 10× higher ^{111}In/polymer ratio than used for biological experiments.

Isotopic labeling of the micellar conjugate containing DTPA chelating groups with ^{111}In was done in ammonium acetate buffer according to Jalilian et al. (*26*). Briefly, the freeze−dried D-lactose stabilized micellar formulation (82.8 mg, 13.7 mg polymer) was dissolved in aqueous ammonium acetate (500 μL, 0.1 mol L^{-1}), and the aqueous $^{111}InCl_3$ solution (100 Bq mL^{-1}; 250 μL, 25 MBq) was added. The mixture was incubated at room temperature for 10 min, and then, the polymer fraction was separated by gel filtration on a PD-10 column using phosphate buffered saline (PBS) as a mobile phase. The solution of micelles (1800 μL) was immediately frozen and kept at −78 °C. It was melted and applied just before injection (see below).

Atomic Force Microscopy. AFM was used to determine the size and shape of the micelles after binding DOX into the hydrophobic part of the amphiphilic copolymer. The solution of micellar conjugate in distilled water (30 mg L^{-1} polymer) was deposited on mica substrate and after suction of redundant liquid was immediately evaporated under vacuum atmosphere (13 Pa). All measurements were performed under ambient conditions using a commercial atomic force microscope (Nano-Scope Dimension IIIa, MultiMode Digital Instruments, USA) equipped with a PPP-NCLR tapping-mode probe with reflex aluminum coating (force constant 41 nm^{-1}, drive frequency 161 kHz). The tapping mode AFM technique was used for all the images. The final analysis of obtained data was driven by *WSxN* 4.0 software (Nanotec Electronica, Spain). The results from AFM were compared with the results obtained from dynamic light scattering; for the method, see ref *21*.

In Vitro Experiments. *Cancer Cell Lines.* Six different cell lines of either human (metastazing colorectal carcinoma SW620; lymphoblastic leukemia CEM) or murine (fibroblasts 3T3; B cell lymphoma 38C13; monocyte-macrophage lymphoma P388; T-cell lymphoma EL-4) origin were used for in vitro studies. P388 cell line was a kind gift from Prof. Lefkovits from the University of Basel, Switzerland. All other cell lines were purchased from American type Culture Collection (ATCC, Rockville, MD, USA). For fluorescent whole body imaging, the EL-4 cell line (stably expressing Enhanced Green Fluorescent Protein; EL-4-$EGFP^+$) was used. Subline was established by our group (*27*). SW620 and CEM cells were cultivated in RPMI 1640 medium with extra L-glutamine (4 mM), penicillin (100 U mL^{-1}), streptomycin (100 U mL^{-1}), and 10% v/v fetal bovine serum. P388 cell line was cultivated in RPMI 1640 with extra L-glutamine (4 mM), nonessential amino acids (75 mg L^{-1}), sodium pyruvate (1.0 mM), penicillin (100 U $mL)^{-1}$, streptomycin (100 U mL^{-1}), and 10% v/v fetal bovine serum. 38C13 cell line was cultivated in RPMI 1640 with extra L-glutamine (4 mM), 2-mercaptoethanol (5×10^{-5} M), HEPES (10 mM), sodium pyruvate (1.0 mM), penicillin (100 U mL^{-1}), streptomycin (100 U mL^{-1}), and 10% v/v fetal bovine serum. EL-4 and EL-4-$EGFP^+$ T-cell lymphomas were cultivated in RPMI 1640 medium with extra L-glutamine (4 mM), sodium pyruvate (1.0 mM), 4.5 g L^{-1} glucose, penicillin (100 U mL^{-1}), streptomycin (100 U mL^{-1}), and 10% v/v fetal bovine serum. 3T3 fibroblasts were cultivated in D-MEM medium with extra L-glutamine (4 mM), HEPES (10 mM), 4.5 g L^{-1} glucose, penicillin (100 U mL^{-1}), streptomycin (100 U mL^{-1}), and 10% v/v fetal bovine serum.

Hemolytic Assay. Human blood was collected in 5 mL Heparin coated vacutainers (Greiner Bio-One, Austria) and centrifuged for 5 min at 3000 rpm. Blood was twice washed in fresh PBS (pH 7.4), and 4% human red blood cell (RBC) suspension was prepared. Micellar delivery system or Saponin from *Quillaja* bark (Sigma-Aldrich, USA) were added to RBC suspensions to achieve desired final concentrations (range for micelles 0.01−150 μg DOX equiv mL^{-1} and range for Saponin 0.01−10 μg mL^{-1}). All samples were incubated at 37 °C in a humidified 5% CO_2/95% air atmosphere for either 30 min or 24 h and then centrifuged for 5 min at 3000 rpm. As a positive control the absorbance in distilled water and as a negative control absorbance in PBS were used. The supernatants were spectrophotometricaly analyzed at 550 nm (Spectra Rainbow, Tecan, Austria). A value of hemolytic activity was calculated by considering absorbance of positive control as 100% hemolysis. Absorbance was determined using background absorbance in PBS (for Saponin samples) or, to overcome an effect of DOX absorbing light also at wavelength of the measurement, doxorubicin of the same concentration (for micellar samples).

In Vitro Cytostatic Activity. Cytostatic potential of micellar conjugate was assesed using a [^{3}H]thymidine incorporation assay on a panel of human as well as murine cancer cell lines. 96-well flat-bottomed microplates (NUNC, Denmark) were seeded with 200 μL of cancer cells: EL-4 - murine T-cell lymphoma (5×10^3 cells/well); 38C13 - murine B cell lymphoma (2×10^3 cells/well); 3T3 - murine fibroblastoma (2×10^4 cells/well); P388 - murine monocyte−macrophage lymphoma (2×10^4 cells/well); SW620 - human colorectal carcinoma (1×10^4 cells/well); CEM - human lymphoblastic leukemia (3×10^4 cells/well). Tested samples (in triplicate) were then added (50 μL) to the wells to achieve the desired DOX concentrations (range 0.0003−33 μg mL^{-1}). Plates were incubated at 37 °C in a humidified 5% CO_2/95% air atmosphere for 72 h (EL-4 cells for 48 h). 18.5 kBq (0.5 μCi) of [^{3}H]thymidine was added per well for the last 6 h of incubation. The cells were then collected onto glass fiber filters (Filtermat, Wallac, Finland) using a cell harvester (Tomtec, USA), and the radioactivity of the samples was measured in a scintilation counter (1450 MicroBeta TriLux, Wallac, Finland). Cells cultivated in fresh medium were used as controls. All IC_{50} values are the mean of four independent experiments.

In Vivo Experiments. *Maximum Tolerated Dose (MTD).* All animal studies described hereinafter were performed in accordance with the Act on Experimental Work with Animals (decrees no. 311/97, 117/87; and act no. 246/96) of the Czech Republic, which is fully compatible with the corresponding European Union directives. Tumor free C57BL/6 male mice were used for the determination of single dose MTD (i.v.) of the DDS. The doses applied in slow intravenous injection were in the range 200−400 mg DOX equivalent to 1 kg of body weight, six animals per group. Survival and changes of body weight of each animal were recorded every other day after administration.

Noninvasive In Vivo Whole Body Imaging. For in vivo experiments, murine T cell lymphoma EL-4 stably expressing enhanced green fluorescent protein (EL-4-$EGFP^+$) was used. Male C57BL/6 mice were inoculated subcutaneously with 2×10^5 EL-4-$EGFP^+$ lymphoma cells on the shaved right flank on day 0. The tumor volume at the time of the drug administration (day 7−8) was 200−400 mm^3. For better observing conditions, conjugate containing Dy-615 was used and mice were shaved with Opilca (GlaxoSmithKline, USA) at every monitoring point. Noninvasive visualizations of DDS accumulation in tumor site and treatment efficiency were performed on OV100 Whole Mouse System (Olympus Corp., Tokyo, Japan) containing an MT-20 light source and an Orca II ERG (Hamamatsu, Japan) CCD camera. Animals were anaesthetized by intraperitoneal injection of Narkamon Spofa 1% (Spofa, Czech Republic). EGFP of tumor was visualized with U-MWIB3 cube (Ex 460−495, Em 510IF), and Dy-615 labeled micelles were visualized with U-DM-CY5 cube (Ex 600−650, Em 660−740). Images were taken separately for each fluorescent channel and also transmitted light, and merged, and colorized in *AnalySIS* software 3.2.822 (SIS systems Germany).

Blood Levels and Tumor Accumulation via ^{111}In. Six C57BL/6 mice were injected i.v. (tail vein) with micellar DDS labeled with ^{111}In. The injected dose was 2 MBq ^{111}In (in 1.5 mg polymer dissolved in 200 μL PBS) per mouse at the time of application. The radioactivity levels in blood samples and tumor tissue samples were measured by gamma counter Minaxi 5000 (Canberra Packard, Austria) at selected time points (4, 24, 48, and 72 h) after injection. The measured radioactivities were corrected on the radioisotope decay ($T_{1/2}$ = 67.31 h).

In Vivo Antitumor Activity. Murine T cell lymphoma EL-4 was used for in vivo evaluation of antitumor activity of micellar formulation of DOX. Mice of inbred strain C57BL/6, obtained

from Animal Facility of the Institute of Physiology, Academy of Sciences of the Czech Republic, v. v. i., were inoculated subcutaneously with 1×10^5 EL-4 T-cell lymphoma cells on the right flank on day 0. Micellar conjugate was administered into the tail vein when the tumors were well-established, i.e., when the tumor volume reached 200−400 mm^3 (day 7−8). The animals were divided into 5 groups of 8 animals each. The animals were observed every second day for signs of tumor progression; measurements of tumor size were done using calipers. Tumor volume was calculated as $V = ab^2/2$ (a = longer diameter, b = shorter perpendicular diameter). Survival time and body weight of experimental animals were checked. All cured animals were observed for an additional 100 days after complete remission, and then they were challenged by subcutaneous re-transplantation by a lethal dose of EL-4 (1×10^5) cells. After re-transplantation, mice were checked and tumor growth was observed three times a week.

RESULTS

Preparation of Micellar DDS. An improved version of our previously described (*21*) doxorubicin (DOX)-containing micelles was used. The system is based on an amphiphilic diblock copolymer consisting of a poly(ethylene oxide) hydrophilic block, and a hydrophobic block containing doxorubicin bound via a pH-labile hydrazone bond (Scheme 1). The improvement consists of an increase of the DOX loading from the original 3% (w/w polymer) to 17% without the loss of stability of the micelles. This was achieved by modification of the method of DOX attachment; the conjugation was carried on using the pH-buffering system acetic acid−sodium acetate under anhydrous conditions (dimethyl sulfoxide−methanol mixture due to solubility of all components). The reaction is catalyzed by acid, but the conjugation using acetic acid alone or without catalysis always gave significantly lower yields of conjugation. For the buffering system used in this study, the conjugation yield was 85% (17 wt % DOX in polymer compared to theoretical 20 wt % in conjugation mixture), while for acid only or noncatalyzed reaction, it was never above 34% and yields drop significantly at higher DOX loadings (Hruby et al. (*21*)). D-Lactose was added as a cryoprotective to prepare the stable dry micellar formulation. It prevents aggregation of the micelles during freeze−drying and resolubilization.

The initial in vitro DOX release rate (hydrolysis at pH 7.4 and 5.5) was not significantly influenced in comparison to the previous system with lower drug loading (*21*); however, a plateau in the release curve (DOX release versus time) plausibly caused by equilibration due to reversible nature of the hydrazone bond formation−hydrolysis was somehow shifted to lower DOX release. AFM proved the shape and size distribution of the micelles. The micelles are of spherical shape, however, with somehow broader size distribution with average diameter (D) according to AFM 97 nm (Figure 1).

Hemolysis Assay. We found no hemolytic activity of the micellar conjugate of DOX in concentration ranging from 0.01 μg DOX equiv mL^{-1} to 150 μg DOX equiv mL^{-1}. Because of the absence of hemolytic activity, we do not expect any membrane related toxicity in vivo (Figure 2).

Proliferation Assay. The in vitro antiproliferative activity of the micellar conjugate was tested on six cell lines of different origin and sensitivity to free DOX (EL-4, 38C13, 3T3, SW620, P388, and CEM; Table 1). Micelle-conjugated DOX was 1 order of magnitude less potent than free drug for human cancer cell lines (SW620 and CEM) and for murine fibroblasts (3T3). Detected IC_{50} values of micellar DOX for 38C13, EL-4, and P388 cells were even higher by 2 orders of magnitude. The IC_{50} values were in the range 0.09−1.23 μg DOX equiv mL^{-1} depending on the cell line (Table 1).

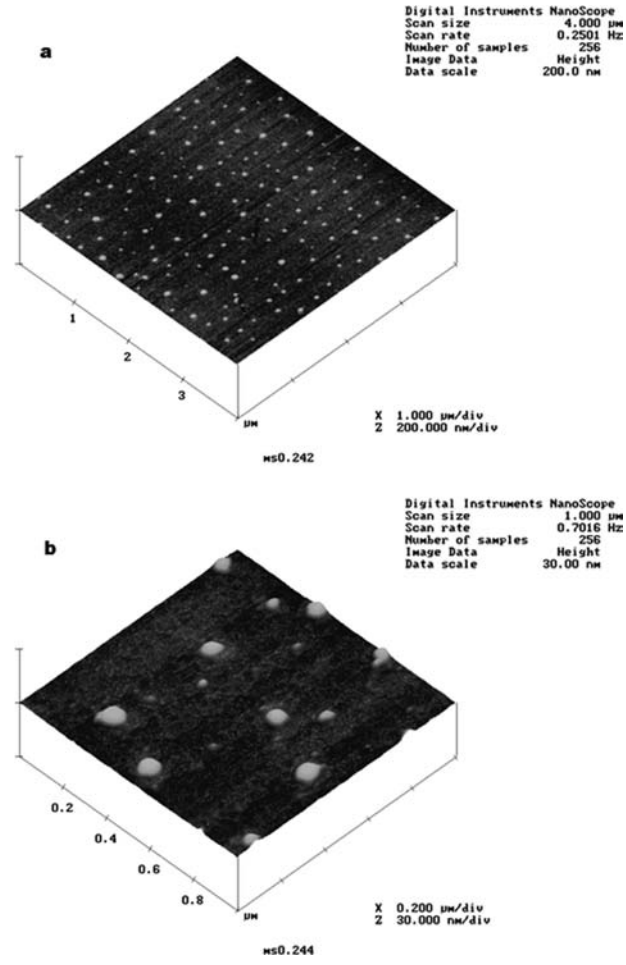

Figure 1. Atomic force microscopy image of the micelles on mica surface. (A) segment 4×4 μm^2, (B) detail 1×1 μm^2.

Maximum Tolerated Dose (MTD). The determination of maximum tolerated dose revealed extremely low systemic toxicity of the micellar conjugate. Up to dose 320 mg DOX equiv kg^{-1}, no body weight loss or other obvious symptoms of systemic toxicity were recorded. Significant loss of body weight (in the range 10−21%) was observed after application of 360 mg DOX equiv kg^{-1}, but all animals recovered and henceforth stayed without any obvious evidence of serious side effects. Dose 380 mg DOX equiv kg^{-1} killed one-third of the animals, while the dose 400 mg DOX equiv kg^{-1} was lethal for all animals (Figure 3). The MTD of the micelles 360 mg DOX equiv kg^{-1} is thus more than 1 order of magnitude higher compared to MTD of free DOX hydrochloride (15 mg/kg (*32*)).

Blood Levels and Tumor Accumulation. To analyze blood levels, micelles were labeled with ^{111}In. The chelating groups were introduced in the polymeric DOX conjugate by reaction with DTPA dianhydride, and the resulting conjugate was labeled with ^{111}In. For the first 24 h, we have seen a stabile concentration plateau. Then, the concentration of ^{111}In-labeled micelles in the blood slowly decreased. The half-life of the dose was determined in circulation after 24 h (Figure 4A), which is sufficiently long to ensure both prolonged exposure of the tumor cells to DOX and effective EPR effect.

In the tumor tissue, the indium-111 radioactivity increased for the first 24 h up to 8%, and then continuously decreased again after this peak (Figure 4B). In vivo tumor accumulation followed via Dyomics 615 fluorescence (Figure 4C) using OV100 Whole Mouse System corresponds well with the radioactivity measurements. Strong fluorescence signal was

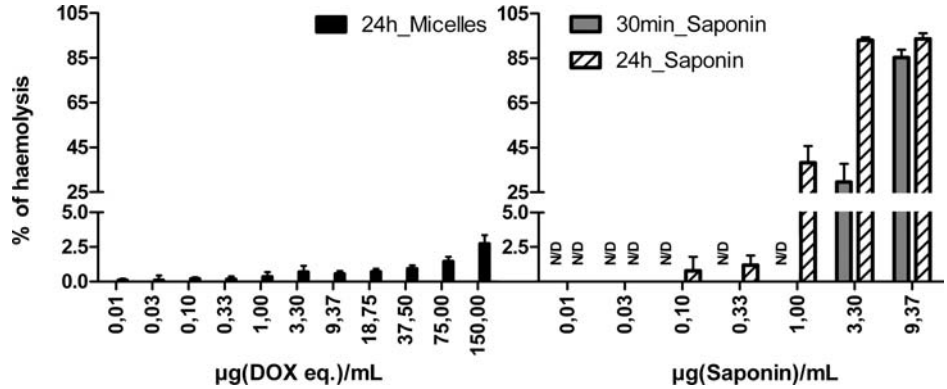

Figure 2. Percentage of hemolysis compared to values of distilled water (100% hemolysis) of human red blood cells caused by micellar drug delivery system or free Saponin (from Quillaja bark) with the SD values.

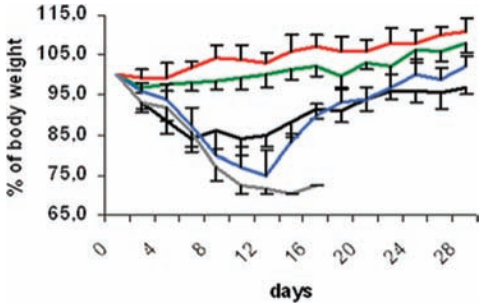

Figure 3. Micellar conjugate was intravenously administered to C57BL/6 mice, and changes in body weight as a sign of systemic toxicity were regularly recorded (red line, controls; green line,1 × 320 mg (DOX equiv) kg^{-1}; black line, 1 × 360 mg (DOX equiv) kg^{-1}; blue line, 1 × 380 mg (DOX equiv) kg^{-1}; gray line, 1 × 400 mg (DOX equiv) kg^{-1}).

Table 1. Cytostatic Activity Expressed as IC_{50} Values

	micellar DOX IC_{50} μg (DOX equiv)/mL	free DOX IC_{50} μg/mL	micellar DOX IC_{50}/free DOX IC_{50}
38C13	0.235 ± 0.066	0.005 ± 0.001	47
SW620	0.476 ± 0.237	0.011 ± 0.004	43.3
EL-4	1.113 ± 0.283	0.032 ± 0.018	34.8
P388	1.233 ± 0.521	0.058 ± 0.020	21.3
CEM	0.865 ± 0.238	0.068 ± 0.033	12.7
3T3	0.089 ± 0.026	0.009 ± 0.006	9.9

detectable only up to 24 h after micelle administration, and no evincible signal was obtained after 48 h or later.

In Vivo Antitumor Activity. The in vivo therapeutic efficiency of micellar DDS with DOX was tested both with single dose and with two subsequent doses (three days delay between the doses). The dose 1 × 75 mg DOX equiv kg^{-1} significantly prolonged the survival of the mice (Figure 5A), but no mice were completely cured, while the doses 2 × 75 mg DOX equiv kg^{-1} and 1 × 150 mg DOX equiv kg^{-1} completely cured 75% and 62.5% of mice, respectively (Figure 5A).

The cured mice were re-inoculated with the lethal dose of EL-4 cells (1×10^5 cells per mouse, i.e., the same dose as the first transplantation) 100−105 days after the original tumor was cured and left without treatment. Eighty percent of re-inoculated mice were able to destroy transplanted cells (Figure 5B), showing the establishment of very significant immunological memory against the EL-4 T-cell line, similar to the soluble HPMA-based derivative (*28*).

DISCUSSION

Formerly described synthesis of micellar system based on poly(allyl glycidyl ether)-*block*-poly(ethylene oxide) (*21, 25*) showed only very low loading efficiency (3% of DOX content). We have achieved significantly higher DOX loading (17%) by using acetic acid−sodium acetate pH-buffering system under anhydrous conditions. The most plausible explanation to why this environment gives high conjugation yields is that the buffering system maintains mildly acidic conditions required for the reaction and hinders electrostatic repulsive forces among the polymer and DOX molecules in solution by its ionic strength. Since the original system would become sensitive to aggregation in aqueous solution while increasing the DOX loading, here we have used a longer poly(ethylene oxide) block for stabilization (M_w = 5000 Da instead of 2000 Da).

When comparing the rate of in vitro DOX release (hydrolysis at pH 7.4 and 5.5), between previous system (*21*) and the one reported here (with higher drug loading), we have not seen any significant variations. This is the difference from micellar systems with a more hydrophobic core and a drug bound by an irreversibly cleavable bond, e.g., methotrexate bound to poly(ethylene oxide)-*block*-poly(2-hydroxyethyl-L-aspartamide) (*17*), where the drug release rate is significantly lowered by the increasing drug loading and does not reach equilibration plateau during in vitro release experiments. If the core is sufficiently hydrophobic, water activity in the core is significantly lower than in surrounding aqueous milieu, so the higher the drug loading is, the more hydrophobic the micelle core is, and the lower is water activity in it; due to this, the drug release rate slows down (in fact, in the extreme cases it is expected that drug is hydrolyzed predominantly from unimers). In the case of the DOX-containing micelles described in this study, the micelle core is probably sufficiently swollen with water even at higher DOX loadings, so the hydrolysis rate is not heavily influenced by lower water content in the micelle core. This is also supported by lower particle density (~0.1 g mL^{-1} polymer) calculated from light scattering.

Amphiphilic block copolymers are commonly used as micellar drug delivery systems (MDDS), as they allow preparation of colloid solution with a very narrow size distribution. The size of polymeric micelles may be set from 10 to 100 nm in diameter, which is a size suitable for passive accumulation via the EPR effect (*23*). The size of particles tested here obtained using AFM (D = 97 nm; Figure 1) was slightly higher than that determined by dynamic light scattering (hydrodynamic diameter D_H = 75 nm), which was interpreted to be an artifact of spreading and drying on the mica surface.

Due to their detergent properties, many amphiphilic molecules possess membrane disruptive properties (*29, 30*). Although amphiphilic diblock polymers are generally less toxic than low-molecular-weight surfactants due to lower critical micellar concentration and thus lower equilibrium concentration of the surface active unimer, their membrane toxicity may still be

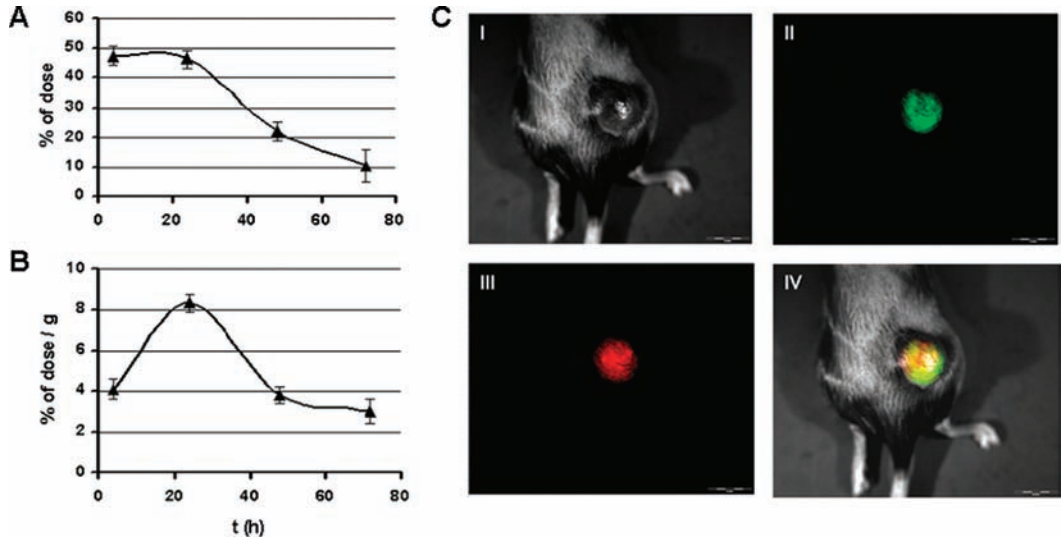

Figure 4. Pharmacokinetics of micellar conjugate in C57BL/6 mice. (A) Blood level of ^{111}In labeled micelles. (B) Tumor accumulation of ^{111}In labeled micelles. (C) EGFP expressing tumor cells were subcutaneously transplanted and tumor accumulation of the micellar conjugate (conjugated with fluorescent dye Dyomics 615) was followed by fluorescence imaging: I, bright-field; II, EGFP fluorescence; III, Dyomics 615 fluorescence; IV, merged (I + II + III).

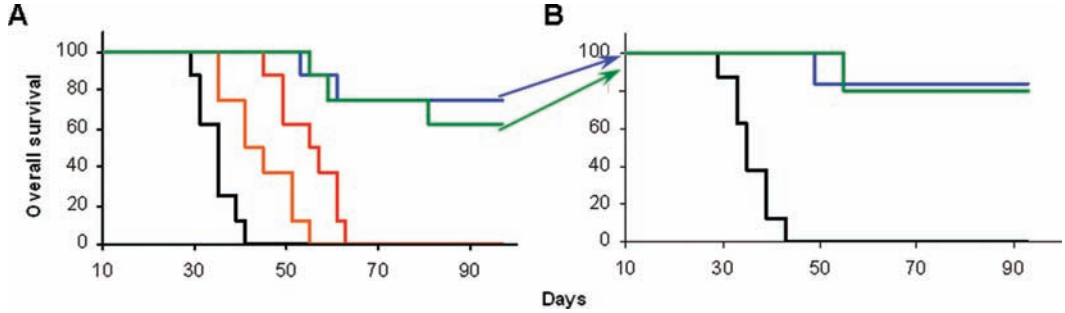

Figure 5. (A) Survival of mice bearing EL-4 T-cell lymphoma and treated with micellar DOX (black line, controls; orange line, 2 × 5 mg (DOX) kg^{-1}; red line, 1 × 75 mg (DOX equiv) kg^{-1}; blue line, 2 × 75 mg (DOX equiv) kg^{-1}; green line, 1 × 150 mg (DOX equiv) kg^{-1}). (B) Cured mice were re-transplanted with a lethal dose of the same cancer cells and left without treatment (black line, controls; blue line, mice previously cured with 2 × 75 mg (DOX equiv) kg^{-1}; green line, mice previously cured with 1 × 150 mg (DOX equiv) kg^{-1}). Displayed data represent a typical result of independent experiments ($P < 0.05$).

unacceptable. Our micellar DDS was designed to prolong the blood circulation period and maximize the efficiency of the EPR effect. Once within the tumor site, lower pH leads to DOX release, and consequently to the destabilization of the micelles. When the micellar architecture is broken down, the free diblock unimers can undergo the renal excretion and DOX acts at the site of micellar disruption as a free drug. There is a low risk that these nonassembled diblock unimers with their hydrophobic PAGE blocks could anchor and disrupt plasma membrane. However, neither micelles with attached DOX nor free diblock unimers of PAGE-block-PEO showed significant membrane toxicity to human red blood cells (Figure 2).

Most delivery systems based on polymer carriers usually exhibit decreased antiproliferative activity in in vitro system compared to free drug (*6, 31*). We assume that the lower in vitro antiproliferative activity of described MDDS is caused by slower cellular uptake and intracellular drug release due to their high molecular weight.

However, the increase in MTD compared to the free drug is convincing. Soluble polymers with bound drug exhibit an increase in MTD because the drug is inactive while bound to the polymer. Tested polymeric micelles showed a massive increase in MTD not only when compared with free DOX (*32*), but also when compared with other water-soluble copolymers with DOX bound via hydrazon bond (MTD ∼ 130 mg/kg (*28*)). This is probably caused by slow, gradual release of DOX from the micellar carrier (see our previous work (*21*)) for the in vitro release study showing the half-life 198 h at pH 7.4 and 8.62 h at pH 5.0), which allows the organism to detoxify/eliminate the DOX released within the organism.

Higher MTD, prolonged continuance in blood circulation, and efficient EPR effect together cured murine T-cell lymphoma (EL-4) bearing mice with a single dose of 150 mg DOX equiv kg^{-1} without any signs of side toxicity (loss of weight of animals) (Figure 3). This is a significant improvement compared with the effect of treatment with free DOX (2 × 5 mg kg^{-1}). Moreover, the fact that only one-third of the detected MTD (for micellar DOX) is efficient opens a wide therapeutical window for further improvement of therapeutic schedule. Such a possibility should be examined for more resistant tumors, where recently available polymeric derivatives of DOX are less effective. This MDDS is a new approach to those already described (*28, 33, 34*). Of course, it is clear that broad variability in tumor diseases would also require a broad range of structures of polymer drug carriers, thus opening space for development of various drug delivery systems differing in their physico-chemical and biological behavior. Importantly, except for the cytotoxic effect, the treatment with MDDS described here triggers long-lasting systemic anticancer resistance, similarly to what was reported for other HPMA-based polymeric systems bearing DOX (*35*) (Figure 5). This finding is extremely important as it potentially protects tumor-bearing host against

second (metastatic) cancer attack. Experiments with various types of polymer drug carriers are in progress to understand the involved immunological mechanisms and influence of the carrier structure on it.

Biological properties of the micellar drug carrier system containing DOX covalently bound via hydrazone bonds to the micelle core were investigated. The system has a very low systemic toxicity (almost 2 orders of magnitude higher maximum tolerated dose than free DOX on the DOX equivalent basis) and long circulation time (tens of hours). Promising therapeutical efficiency against the EL-4 T-cell lymphoma was found completely curing up to 75% of tumor-bearing mice. Moreover, treatment with micellar conjugate of DOX activated the immune system and established an effective antitumor immunological memory. Significant accumulation of the polymeric micellar system within the tumor site was found by noninvasive fluorescent whole body imaging.

Received May 14, 2009; Revised Manuscript Received August 24, 2009

In this study, we report on a novel, expedited solid-phase approach for the synthesis of biotinylated and fluorescently tagged irreversible affinity based probes for the chymotrypsin and elastase-like serine proteases. The novel solid-phase biotinylation or fluorescent labeling of the aminoalkane diphenyl phosphonate warhead using commercially available Biotin-PEG-NovaTag or EDANS NovaTag resin permits rapid, facile synthesis of these reagents. We demonstrate the kinetic evaluation and utilization of a number of these irreversible inactivators for chymotrypsin-like (chymotrypsin/human cathepsin G) and elastase-like serine proteases. Encouragingly, these compounds display comparable potency against their target proteases as their *N*-benzyloxycarbonyl (Cbz)-protected parent compounds, from which they were derived, and function as efficient active site-directed inactivators of their target proteases. We subsequently applied the biotinylated reagents for the sensitive detection of protease species via Western blot, showing that the inactivation of the protease was specifically mediated through the active site serine. Furthermore, we also demonstrate the successful detection of serine protease species with the fluorescently labeled derivatives "in-gel", thus avoiding the need for downstream Western blotting. Finally, we also show the utility of biotinylated and pegylated affinity probes for the isolation/enrichment of serine protease species, via capture with immobilized streptavidin, and their subsequent identification via de novo sequencing. Given their selectivity of action against the serine proteases, we believe that these reagents can be exploited for the direct, rapid, and selective identification of these enzymes from biological milieu containing multiple protease subclasses.

INTRODUCTION

The completion of the human genome sequencing project (*1*) has facilitated a comprehensive analysis of known and potential gene products which may represent novel targets for pharmacological intervention/modulation. Original estimates of the "druggable genome" (i.e., those genes that encode protein products predicted to possess structural domains or motifs which are likely to favor interactions with drug-like molecules) indicated that approximately 3000 genes belonged to this unique group (*2*). More recent functional genomic analysis of the druggable genome has been in close agreement with these earlier estimates, although, significantly, the proportion of the predicted major target families of proteins appears to have changed somewhat. For example, these latter studies indicate a reduction in the numbers of putative protein kinases and rhodopsin-like G-protein coupled receptors (GPCRs) and an increased number of putative protease targets which are potentially "druggable" (*3*). Proteases have long been regarded as important therapeutic targets, in recognition of their multifarious roles in numerous diseases, and much focus has been directed toward protease inhibition in pathological conditions. However, it is significant that, although many proteases have recently been identified through genomic analysis, only a small proportion (~15%) have been characterized through functional studies (*4*). Thus, the application of specific and sensitive protease detection methodologies that can be utilized in high-throughput proteomic formats to facilitate the functional identification of poorly characterized species is urgently required. A number of substrate approaches have previously been developed for the detection of protease activities, following electrophoresis from a range of biological samples (*5, 6*).

We have previously reported on the synthesis and methodologies for the profiling of serine proteases by utilizing biotinylated aminoacylchloromethanes (*7*) and cysteine proteases, using biotinylated peptidyldiazomethanes (*8*−*10*). Powers and co-workers (*11*) pioneered the development of potent and exquisitely selective peptide derivatives of diphenyl [1-(*N*-peptidylamino)alkyl] phosphonate esters as irreversible inactivators of the serine proteases and utilized biotinylated and fluorescently labeled derivatives to detect a range of serine proteolytic activities including lymphocyte serine proteases (granzymes) (*12, 13*). We have also reported on the application of such phosphonate-based inhibitors for the detection of trypsin-like serine proteases (*14*) and, more recently, on the development of an active site directed probe for dipeptidyl peptidase IV-like serine proteases, based on a biotinylated dipeptide proline diphenylphosphonate (*15, 16*). In a related approach, Cravatt and co-workers have employed fluorophosphonate derivatives of long-chain fatty acids for visualization and characterization of catalytically active serine hydrolases including fatty acid esterases and serine proteases (*6, 17*). Development of such "activity profiling" approaches has been particularly useful in assigning function to proteolytic enzymes from diverse biological milieu. Indeed, such approaches may be of particular utility in validating protease targets in disease processes where analysis of levels of transcription and translation of a protease do not necessarily correlate well with enzyme activity (*18*).

We now report on a novel solid-phase synthesis approach for the generation of active site directed affinity probes based upon aminoalkyl diphenyl phosphonates and their application for the profiling and characterization of serine proteases obtained

from a broad variety of biological sources. The synthetic scheme employs recently available NovaTag resin technology that enables the facile synthesis of activity probes bearing biotin or fluorescent tags and which can also incorporate pegylated spacer units, if desired. Using this approach, we have synthesized a number of affinity probes that target serine proteases with differing P1 specificities and demonstrate their detection by Western blot. Furthermore, the application of fluorescently tagged active site directed probes for "in-gel" detection is examined. We also demonstrate the utility of biotinylated and pegylated affinity probes for the isolation/enrichment of serine protease species, in this case, the *Pseudomonas aeruginosa* MucD peptidase (*19*), via exploitation of their interaction with immobilized streptavidin, and their subsequent *de novo* sequencing, using mass spectrometry.

EXPERIMENTAL PROCEDURES

Biotin-PEG NovaTag resin, EDANS NovaTag resin, and 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethylaminium hexafluorophosphate (HBTU) were purchased from Novabiochem, Nottingham, U.K. *N*,*N*-Dimethylformamide (DMF) was supplied by BDH Chemicals Ltd. (Poole, England). *N*,*N*-Diisopropylethylamine (DIPEA) and piperidine/DMF (20% v/v) were supplied by PerSeptive Biosystems Ltd. (Warrington, England). Succinic anhydride and dimethylamino pyridine were purchased from Aldrich Chemical Co., Poole, Dorset (UK). All chemicals and solvents were of the highest purity and were subjected to no further purifications prior to use. Horseradish peroxidase streptavidin was obtained from Vector Laboratories Ltd., Burlingame, CA, USA. SuperSignal West Pico Chemiluminescent Substrate was supplied by Pierce Biotechnology Inc., Rockford, IL, USA.

Synthesis of Active Site Probes. The protected aminoalkane diphenylphosphonate derivatives diphenyl-1-[*N*-benzyloxycarbonyl]-amino phenylethane phosphonate (Cbz.Phe^{P}(OPh)$_2$)[1] and diphenyl-1-[*N*-benzyloxycarbonyl]-amino isobutane phosphonate (Cbz.Val^{P}(OPh)$_2$) were prepared by reacting triphenylphosphite, benzyl carbamate and the appropriate aldehyde corresponding to the desired amino acid side chain according to the method of Oleksyszen et al. (*11*, *20*). Each of the

compounds was found to be correct by elemental analysis and ^{1}H NMR, and had melting points in close agreement with the literature values (*11, 20*). Each derivative was obtained as a 50/50 mix of the L and D enantiomers.

Removal of the Cbz-protecting group was achieved by treatment with HBr/acetic acid (~33% v/v) for 90 min at room temperature. The succinyl derivatives of each of the deprotected aminoalkyl diphenyl phosphonate were then prepared by reaction with succinic anhydride, in dry DMF, at room temperature, overnight, in the presence of 2.0 equiv of DIPEA. These succinyl derivatives were then used to acylate samples of Biotin-PEG NovaTag (Novabiochem: cat no 04−12−3908) or EDANS-NovaTag (Novabiochem: cat no 04−12−3904) resin. This was achieved by first removing the Fmoc-protecting group from the benzyl-linked amine of the resin, by treatment with piperidine/DMF (20%, v/v), for 15 min at room temperature. After standard washing procedures (*8*), the succinylated aminoalkyl diphenylphosophonates were then coupled to the newly exposed secondary amine grouping on the resin via HATU-mediated condensation. The labeled diphenyl phosphonate derivatives of phenylalanine and valine were then cleaved from the resin by treatment with TFA/H_2O/TIPS (95/2.5/2.5; v/v/v) for 90 min at room temperature.

Kinetic Evaluation of Affinity Based Probes. Stock solutions (10 mM) of each affinity based probe were diluted in the appropriate assay buffer to give final concentrations of 5 μM, 10 μM, 25 μM, 50 μM, and 100 μM, which are evaluated for inhibitory activity against each target proteinase using a standard microtiter plate assay. Fluorogenic substrate was added such that a final concentration of 50 μM in each well initiates the reaction. The inhibitory potency of each inhibitor was determined at five individual concentrations using a standard microtiter plate assay where the rate of substrate hydrolysis at 37 °C, in each instance, was monitored every 60 s over a period of 90 min by measuring the rate of increase of fluorescence at (excitation λ_{nm} 395 ± 45, emission λ_{nm} 460 ± 40) in a CYTOFLUOR Multiwell Plate Reader Series 4000 spectrofluorimeter. Each experiment is performed in triplicate. Typical progress curves are shown in Figure 2.

Labeling and Detection of Peptidases. *Electrophoresis.* Electrophoresis in the presence of sodium dodecyl sulfate (SDS) was performed by a modification of the method of Laemmli (*21*). Initially, SDS-PAGE was performed on NuPage Novex 4−12% Bis-Tris gels. Labeled proteins were denatured by boiling for 10 min in Laemmli treatment buffer. SeeBlue Plus2 prestained molecular weight standards were included in each gel.

Western Blotting. Electroblotting of the separated proteins was carried out using a modification of the methodology described first by Towbin et al. (*22*). Separated proteins were electroblotted onto Immobilon-P polyvinylidene difluoride (PVDF) membranes (Milipore) in NuPage Transfer Buffer (Invitrogen Ltd.). The running time was 2 h at 200 mA, at room temperature.

Detection of Labeled Peptidases. Labeled peptidases were detected using the methods previously described (*9, 16*).

Table 1. Mass Spectrum Analysis

reagent	predicted	observed
Bio-PEG-Suc-Val^P(OPh)$_2$	833.99	834.2/835.2
Bio-PEG-Suc-Phe^P(OPh)$_2$	882	882.2/883.2
EDANS-Suc-Phe^P(OPh)$_2$	635	636.3

Essentially, following protein transfer, unbound sites on the Immobilon-P PVDF membrane were blocked by incubation of the blot membrane in a 3% (w/v) solution of bovine serum albumin (BSA) in Tris-buffered saline (TBS; 0.05 M Tris/HCl, 0.1 M NaCl, pH 7.4) for at least 1 h at room temperature. After washing with TBS, the solution was discarded and replaced with streptavidin/horseradish peroxidase (Streptavidin-HRP) (Vector Laboratories) prepared at a dilution of 1 in 10 000 in blocking solution containing 0.3% BSA at room temperature for 45 min. The membrane was washed at least six times with TBS containing 0.1% Tween 20 and excess liquid removed. Horseradish peroxidase activity was detected by overlay with SuperSignal West Pico chemiluminescent substrate. After removal of the substrate, the blot was placed between acetate sheets and overlaid with photographic film in a film cassette. Films were exposed for ~30 s developed and fixed.

Direct Detection. For labeling studies employing EDANS-labeled probe, the method above was followed except that the electrophoresis unit was protected from light during each run. The gel was removed from the cassette, and labeled peptidases were viewed directly on a high-performance ultraviolet transilluminator (Ultraviolet Products Ltd., Cambridge, UK). Images were captured using a Syngene Gene-Genius Bioimaging system with on-board UV transilluminator or using standard photographic film.

Labeling of Recombinant MucD in Crude Cell Lysates. The MucD gene of *Pseudomonas aeruginosa* PA01 was amplified from genomic DNA by PCR and subsequently cloned into the *E. coli* expression vector pQE30 (Qiagen). Site-directed mutagenesis of the putative active site serine to an alanine at position 217 was carried out using site-directed mutagenesis kit (Stratagene) as per the manufacturers instructions. TOP10F' *E. coli* cells (Invitrogen) harboring empty pQE30 plasmid, wild-type MucD, and Ser-Ala active site mutant grown to early log phase (37 °C) were induced using isopropyl-β-D-1-thiogalactopyranoside (ITPG, 1 mM final concentration), prior to a further 3 h incubation. Cells were harvested and lysed by sonication in assay buffer (25 mM Hepes, 5 mM $CaCl_2$, pH 7.5). Biotinylated DPP probes (final concentration, 50 uM) were incubated with the freshly prepared lysates for 90 min at either 37 or 45 °C. Labeled peptidases were detected as described previously.

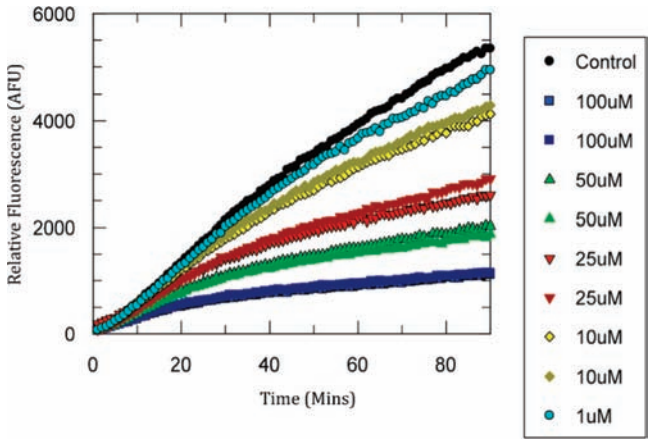

Figure 2. Typical progress curves for the generation of 7-amino-4-methylcoumarin from the chymotrypsin catalyzed hydrolysis of N-succinyl-Ala-Ala-Pro-Phe-NHMec in the presence of EDANS-succinyl-Phe^P(OPh)$_2$ The figures represent the best fit of data to the equation for irreversible inhibition (Walker and Elmore, 1984) of chymotrypsin by EDANS-succinyl-Phe^P(OPh)$_2$ in the presence of N-succinyl-Ala-Ala-Pro-Phe-NHMec. The inactivation studies were carried out at a fixed substrate concentration (50 μM) and varying concentrations of inactivator as indicated above.

Mechanism Based Affinity Capture of Recombinant MucD in Crude Cell Lysates. *Escherichia coli* TOP10F' cells harboring pQE30 plasmid expressing wild-type MucD and Ser-Ala active site mutant were grown to early log phase (37 °C) and induced using ITPG (1 mM final concentration), prior to a further 3 h incubation. Cells were harvested and lysed by sonication in MucD assay buffer (25 mM HEPES, 5 mM $CaCl_2$, pH 7.5). The Biotin-PEG-Suc-Val^P(OPh)$_2$ probe (final concentration, 50 μM) was incubated with the freshly prepared lysates for 90 min at 37 °C. Samples were subjected to affinity capture with strepavadin magnetic Dynabeads (dynal Biotech) and washed 6 times in PBS Tween 20 (0.1%). Samples were subjected to SDS-PAGE electrophoresis and stained with Brilliant Blue G - Colloidal Coomassie. Protein bands were excised from the Coomassie stained gel, treated with acetonitrile, and dried. Sequencing grade trypsin (Promega) was added, and samples were incubated at 30 °C overnight. Digested peptides were extracted from the gel pieces using 5% v/v trifluoroacetic acid and 50% v/v acetonitrile and dried. The samples were then rehydrated, desalted, and concentrated using in-tip reverse-phase resin (Zip Tip C18, Millipore). Using a Thermoquest LCQ Deca mass spectrometer, in nanospray mode, the samples were analyzed and MS/MS data collected by Xcalibur. Finally, MS/MS ion search was performed by Mascot (*23*), using the database NCBInr.

RESULTS

Synthesis of Affinity Probes. Our primary aim in this study was the development of a robust and broadly applicable solid-phase approach for the synthesis of diphenyl phosphonate activity probes for the serine proteinases. As an example, the synthetic scheme for the synthesis of the P_1-Phe containing inhibitor (Biotin-PEG-Phe^P(OPh)$_2$) is shown in Scheme 1. In essence, this inhibitor sequence was constructed from the succinyl-derivatized diphenyl phosphonate analogue of phenylalanine (**1A**), which in turn was prepared from the benzloxycarbonyl protected analogue (Cbz-Phe^P(OPh)$_2$). The synthesis of Biotin-PEG-Phe^P(OPh)$_2$ was expedited, using standard Fmoc solid-phase protocols, employing a CEM Liberty instrument, and using the recently developed Biotin-PEG NovaTag. We have found that the use of this solid-phase approach has eliminated the problems typically encountered with the solution-phase synthesis of biotin-containing derivatives, namely, poor solubility and sluggish coupling kinetics of biotin and its derivatives. We have incorporated the "PEG unit" into the inhibitor sequence to minimize steric hindrance limitations in the interaction between the biotin reporter group and streptavidin. This reporter moiety facilitates both the detection of labeled species using steptavidin horseradish peroxidase/alkaline phosphatase conjugated by Western blot and also the capture and purification inhibitor/protease complex for the purposes of sequencing by mass spectrometry (described below). The synthesis of EDANS-derived affinity probes follows exactly the same synthetic pathway as in Scheme 1, using the EDANS-NovaTag resin. The structures of the affinity-based probes synthesized in this study, according to Scheme 1, are shown in Figure 1. The identity of each compound was confirmed by electrospray mass spectroscopy, and the results shown in Table 1.

Kinetic Evaluation. The determined values for second-order rate constant, [A], for each inhibitor concentration were used

Table 2. Inhibitor Constants[a]

protease	inhibitor	k_i (min^{-1})	K_i (M)	$(k_i)/(K_i)$ (M^{-1} min^{-1})
chymotrypsin	Bio PEG-Suc-$Phe^P(OPh)_2$	0.119 ± 0.002	1.08×10^{-6}	1.11×10^5
cathepsin G	Bio PEG-Suc-$Phe^P(OPh)_2$	0.016 ± 0.003	2.59×10^{-6}	8.41×10^4
chymotrypsin	EDANS-Suc-$Phe^P(OPh)_2$	ND	ND	0.18×10^4
cathepsin G	EDANS-Suc-$Phe^P(OPh)_2$	0.029 ± 0.002	1.39×10^{-5}	0.22×10^4

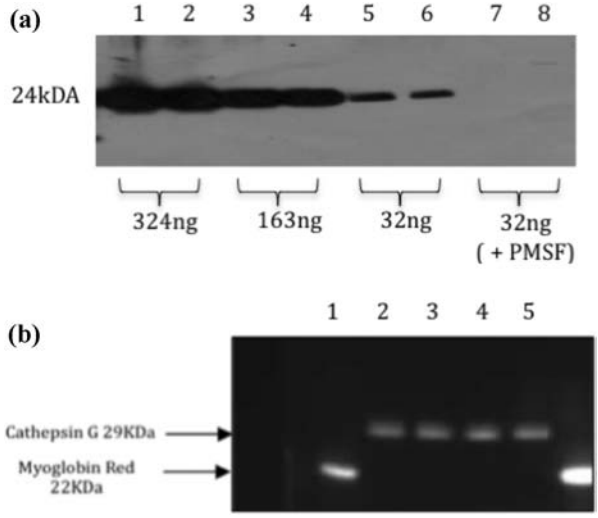

Figure 3. (a) Selective, active site directed labeling of recombinant human neutrophil elastase (HNE) by Biotin-PEG-succinyl-$Val^P(OPh)_2$ (20 μM). Lanes 1−2, 324 ng HNE; lanes 3−4, 162 ng HNE; lanes 5−6, 32 ng; lanes 7−8, 32 ng HNE preincubated with pretreated with Pefabloc (100 μM) for 15 min at 37 °C. (b) Direct visualization of purified cathepsin G protease affinity labeling using EDANS-succinyl-$Phe^P(OPh)_2$ (20 μM). Lane 1, SeeBlue prestained molecular weight markers; lanes 2−5 Cathepsin G (100 ng) incubated for 30 min with EDANS affinity based probe.

to determine the kinetic constants, K_i and k_i, for the kinetic scheme I, taken from Walker and Elmore (*25*). Progress curves were transformed using Grafit to give their linear transformations. Evaluation of the inhibitor constant K_i and the apparent first-order rate constant, k_i, for the irreversible inactivation was carried out using the methods of Tian and Tsou (*26*). A summary of determined overall second-order rate constants (k_i/K_i) for irreversible affinity-based probe inhibitors of each exemplar proteinase are shown in Table 2. In general, these compounds were found to be moderately potent irreversible inactivators of their target protease. The overall second-order rate constants are comparable to the corresponding Cbz-protected amino acid analogues Cbz-$Phe^P(OPh)_2$ (for Chymotrypsin; $k_i/K_i = (2.3 \pm 0.4) \times 10^4$ M^{-1} min^{-1}, Cathepsin G $k_i/K_i = (3.8 \pm 0.4) \times 10^3$ M^{-1} min^{-1}) and Cbz-$Val^P(OPh)_2$ (for human neutrophil elastase $k_i/K_i = (2.3 \pm 0.1) \times 10^3$ M^{-1} min^{-1}).

Proteinase Profiling. Initial profiling studies were performed on purified neutrophil elastase (HNE). Figure 3a illustrates the labeling of HNE using Bio-Peg-succinyl-$Val^P(OPh)_2$. In essence, samples of purified HNE were incubated with 20 μM biotinylated-inhibitor, for 30 min at 37 °C, prior to SDS-PAGE and Western blotting. Figure 3a shows a series of duplicates in which differing amounts of purified HNE are incubated with the fixed concentration of biotinylated inhibitor. From these results, it can be seen that, under these standard detection conditions, as little as 32 ng of protease can be detected, demonstrating the sensitivity of these irreversible probes. Crucially, the specificity of this probe was established by pre-inactivation of the protease using phenylmethanesulphonylfluoride (PMSF), which modifies the active site serine hydroxyl group, rendering the enzyme inactive. Preincubation of protease with PMSF prior to addition of the biotinylated probe completely blocked incorporation of the latter, indicating that it is active site directed.

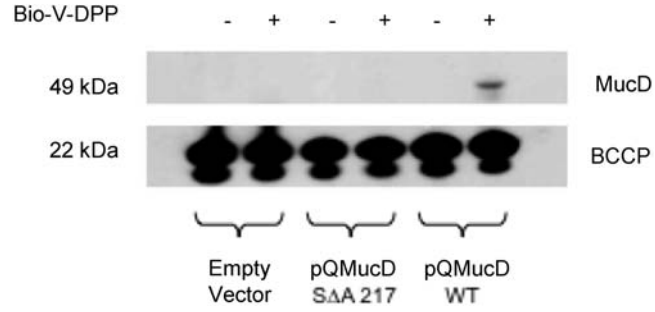

Figure 4. Bio-PEG-Succ-$Val^P(OPh)_2$ (Bio-V-DPP) specifically labels recombinant serine protease MucD in *E. coli* lysates. Bio-V-DPP (50 μM) was incubated (90 min, 37 °C) with sonicated pellets from *E. coli* cultures harboring pMucD and catalytically inactive SΔA217, with MucD expression induced with IPTG (1 mM) in all samples. Protein samples were then applied to SDS-PAGE and Western blotted; bands with incorporated biotin moieties were disclosed using streptavidin-HRP. Biotin carboxyl carrier protein (BCCP) is endogenously biotinylated and is used here as a loading control.

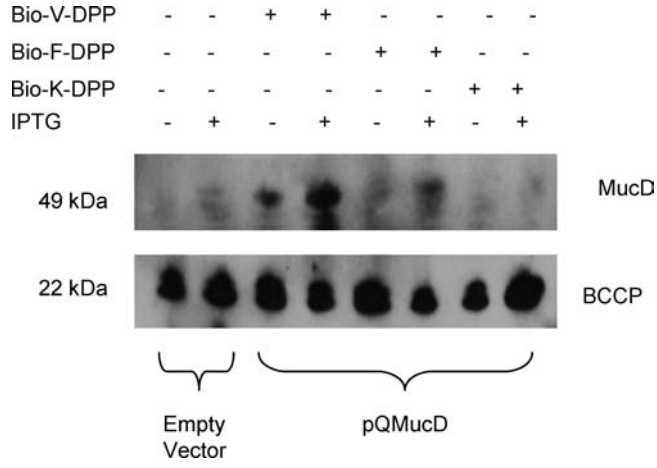

Figure 5. Biotinylated probes (50 μM) were incubated with sonicated cell pellets from cultures harboring pMucD, with MucD expression induced with IPTG (1 mM). Probes were incubated with sonicates for 90 min at 37 °C, prior to application to SDS-PAGE and Western blotting. Bands with incorporated biotin moieties are disclosed using streptavidin−HRP. Biotin carboxyl carrier protein (BCCP) is endogenously biotinylated and is used here a loading control.

The ability to detect protein species by Western blotting is a routinely used methodology, but it is not without its limitations. As it uses a number of steps beyond electrophoresis, including membrane transfer, blocking, and application of primary and/or secondary detection reagents, the process can frequently take a number of hours, if not overnight. Furthermore, the more steps involved, the more possibilities arise for human error in the visualization of the labeled proteins. Therefore, in an effort to circumvent these potential limitations, we have investigated the replacement of the biotin reporter with a fluorescent moiety to permit "in-gel" visualization. The direct labeling of cathepsin

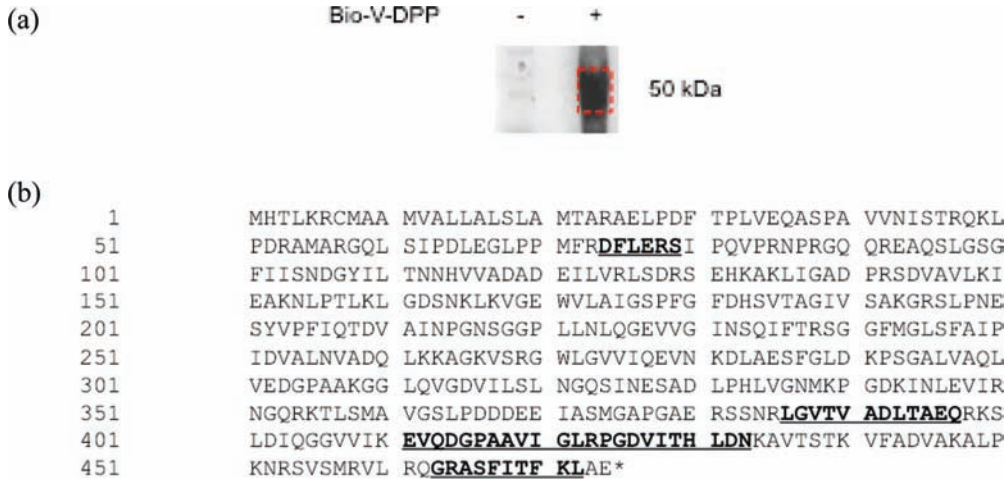

Figure 6. Capture and identification of MucD from *Pseudomonas aeruginosa* cell lysates. (a) Lysates probed with Bio-V-DPP were subsequently incubated with streptavidin agarose beads and captured proteins eluted, electrophoresed, and visualized by silver staining. A band at 50 kDa (see highlighted) was specifically captured in the presence of the probe and was subsequently excised and characterized by mass spectrometry. (b) Tryptic digestion of the protein in the band was performed and peptides subjected to MS/MS. MS/MS ion searches using MASCOT identified four peptides from *P. aeruginosa* MucD (Accession number NM_002516).

G (100 ng) using a fluorescently labeled affinity based probe (EDANS-succinyl-Phe^{P}(OPh)$_2$) is shown in Figure 3b.

Labeling, Capture, and Identification of Protease Species. Next, we wished to examine the application of these probes for the detection and identification of serine protease species in protein extracts. For these studies, we chose a model protease, MucD, from *P. aeruginosa.* MucD is an important mediator of virulence in *P. aeruginosa* infections (*26*) and is a negative regulator of alginate production (*27*). MucD mutants have been shown to exhibit reduced virulence in a number of different pathogen−host models (*26*). Furthermore, *P. aeruginosa* MucD inactivation results in decreased resistance to H_2O_2 and thermal kill (*28*). Therefore, selective inactivation of MucD may constitute a novel antivirulence approach in the treatment of *P. aeruginosa* infections.

To study the ability to label MucD using the diphenyl phosphonate probes, the open reading frame was cloned into an *Escherichia coli* expression vector (pQE30), from which the inducible expression of MucD could be stimulated using IPTG. The insertion of the open reading frame into pQE30 also facilitates the incorporation of an N-terminal hexahistidine tag, which allowed the visualization of the expressed recombinant protein at the anticipated 49 kDa in the presence of IPTG (data not shown). Next, lysates from IPTG-induced cultures expressing MucD were incubated with Bio-PEG-Suc-Val^{P}(OPh)$_2$, where we observed clear labeling of the recombinant enzyme (Figure 4, lane 6). A catalytically inactive mutant (SerΔAla217) was also prepared, and the probe failed to label this species, further demonstrating the need for the hydroxyl side chain in the Ser residue to which the diphenyl phosphonate probes react and bind.

On the basis of these findings, we then examined the P_1 specificity in the probes on the basis of their ability to label the recombinant MucD protein. Valine, phenylalanine, and lysine derived biotinylated diphenylphosphonates where incubated with MucD overexpressing bacterial lysates, and as anticipated, the Val probe showed labeling as before (Figure 5, lanes 3 and 4). Under the same conditions, labeling by the Phe-derived probe was also visualized, albeit at lower intensities than the Val probe (lanes 5 and 6). Conversely, under these conditions no binding of the Lys probe was observed. Collectively, these data suggest that the enzyme has a clear preference for hydrophobic residues in the P_1 position (Val > Phe) over the positively charged Lys derivative. Although no comprehensive substrate specificity profiling of *P. aeruginosa* MucD has yet been published, these results are perhaps unsurprising given that MucD is orthologous to the *Escherichia coli* periplasmic protease and chaperone HtrA (DegP) (*26*), which has a demonstrated P1 preference for valine (*29*).

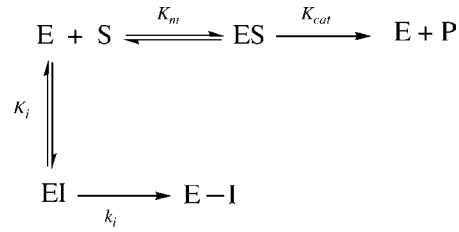
As we could identify and visualize the labeling of recombinant MucD, we then examined the application of the biotinylated Bio-PEG-Suc-V-DPP (Bio-V-DPP) probe to facilitate the capture and isolation of MucD from *P. aeruginosa* cultures. Cultures were lysed and incubated with the Bio-V-DPP probe as described and then incubated with streptavidin beads. Eluted proteins were analyzed by SDS-PAGE allowing clear visualization of a 50 kDa band specific to probe-treated samples (Figure 6a). This band was subsequently excised and protein species analyzed by mass spectrometry where it was established that MucD was successfully identified (Figure 6b). Analysis of the corresponding gel fraction from samples purified in the absence of probe did not facilitate the identification of MucD (data not shown), demonstrating that its capture and identification were dependent on the preincubation with the biotinylated probe. Collectively, these results show that these biotinylated reagents have applicability in not only the visualization of protease species, but also their activity-based capture, purification, and downstream characterization.

DISCUSSION

We have described a novel facile synthesis route for substrate-derived diphenyl phosphonate probes for the detection of serine proteases. During these studies, we have demonstrated the ability of these probes to label proteases, simply on the basis of their catalytic activity, and facilitate their downstream visualization. Using biotin reporter groups, we have demonstrated the ability to visualize bound species by Western blot. Furthermore, replacement of biotin with a fluorescent tag facilitates the direct sensitive analysis of bound species by SDS-PAGE, which has the advantage of circumventing the need for downstream Western blotting. Finally, we also demonstrate that the compounds synthesized here can be used for the affinity capture and retrieval of protease species from biological lysates.

Although the affinity-based probes developed in this study have been utilized here primarily for the detection and identification of bacterial/prokaryotic proteases, the kinetic evaluation studies were performed against eukaryotic pro-

Scheme 2. Kinetic Scheme for Irreversible Inhibitors Acting via a Complexing Mechanism, Taken from Walker and Elmore (1984)



teases, namely, bovine chymotrypsin, cathepsin G (from human leukocytes), and human neutrophil elastase demonstrate the broad applicability of these probes. Indeed, we have shown in a previous study that biotinylated proline diphenyl phosphonate derived inhibitors were capable of inactivation and labeling of dipeptidyl peptidase IV purified from porcine kidney (*16*). These observations, taken together with the extensive characterization of diphenyl phosphonate derived inhibitors against a wide range of serine protease already published in the literature (*11*−*13*, *15*, *16*), indicate that the affinity based probes described here will have utility in the detection, profiling, and identification of a wide range of serine proteases from both prokaryotic and eukaryotic sources. The ability to capture, purify, and characterize protease species on the basis of their catalytic activity represents a powerful discovery methodology rather than merely revealing additional members of known proteinase families through homology screening approaches. Therefore, the large-scale screening of complex protein milieu for protease species could highlight proteins of novel sequences/conformations that have yet to be demonstrated to possess proteolytic activity.

Whether assembling proteins onto nanoscale, mesoscopic, or macroscopic material surfaces, maintaining a protein's structure and function when conjugated to a surface is complicated by the high propensity for electrostatic or hydrophobic surface interactions and the possibility of direct metal coordination of protein functional groups. In this study, the assembly of a 1.5 nm CAAKA passivated gold nanoparticle (AuNP) onto FGF1 (human acidic fibroblast growth factor) using an amino terminal His_6 tag is analyzed. The impact of structure and time-dependent changes in the structural elements in FGF1and FGF1-heparin in the presence of the AuNP is probed by a molecular beacon fluorescence assay, circular dichroism, and NMR spectroscopy. Analysis of the results indicates that a time-dependent evolution of the protein structure without loss of FGF1 heparin binding occurs following the formation of the initial FGF1-AuNP complex. The time-dependent changes are believed to reflect protein sampling of the AuNP surface to minimize the free energy of the AuNP-FGF1 complex without impacting FGF1 function.

INTRODUCTION

With the use of nanomaterials for biological assays (*1*−*7*), the desire to develop robust linkages that possess adaptable chemistries to interface biological molecules with nanomaterials, yet have minimal structural impact on the protein, has become a rapidly growing area of interest. A plethora of assembly strategies exist, using cysteine or thiol modifications (*8*−*10*), botin−streptavidin interactions (*11, 12*), click chemistry (*13*), and transition metal mediated histidine binding (*14, 15*), to name a few of the typical approaches (*1, 16, 17*). Each of these strategies has advantages and disadvantages, but all of the strategies require engineering non-native sequences into the protein, a secondary metal ion mediator, or antibody−antigen recognition step to form the construct, thus limiting the ability to extrapolate the results to the broader recombinantly engineered proteins employed by the biological community. Many of the studies to date have assumed that the structural elements are marginally perturbed in the local site of binding correlating the structural changes to the effect of nanoparticle (NP) charge, NP structure, and the site of protein substitution (*9, 18, 19*). While studies have shown protein function (*18, 20*), there is a notable lack of studies that fully investigate the dynamic changes occurring to the protein construct during the nanomaterial−protein assembly. In analogy to formation of self-assembled monolayers of proteins onto a surface, engineering a linkage that does not perturb the protein structure is challenging since the profusion of interactions stemming from potential backbone and side chain interactions with the NP surface can lead to alteration of protein structure and thus to protein misfolding (*7, 21*−*25*) and a loss in protein function (*21, 24, 26*−*29*). As demonstrated in several phage display assays (*30, 31*) on metal and semiconductor surfaces, the surface-mediated exchange reactions are governed by the amino acid functional groups, as well as electrostatic and hydrophobic interactions with the side chain and backbone of the protein.

The hexa-histidine (His_6) modification is widely used by recombinant protein chemists because of its high affinity for metal chelation, thereby facilitating purification by Ni(II) chelation chromatography. Several groups, including our own, have explored the use of the His_6 tag for assembly onto NP surfaces (*15, 32*−*37*). Our earlier results on peptide assembly demonstrated that the His_6-tag allows for region-selective assembly of small peptides onto the surface of the 1.5 nm AuNP through formation of a Au−Nε imidazole bond (*37*). Here, we extend the use of the His_6 tag recombinantly engineered to the amino terminus of FGF1 (human acidic fibroblast growth factor) to form a AuNP-FGF1 construct in order to assess the structural and potential functional impact on the protein. FGF1 is an important protein that exhibits mitogenic (cell division) and angiogenic (wound healing) properties and has emerged as a candidate for revascularization strategies of cardiac muscle following ischemic events (*38*−*40*). FGF1 binds heparin on the surfaces of cells and can accommodate oligosaccharides of varying sizes in the positively charged heparin binding pocket (*41*), but requires at least an octasaccharide heparin for FGF receptor (FGFR) activation. In this study, we probe the time-dependent conformational changes of an FGF1 sym6ΔΔ mutant during the assembly of the protein onto a 1.5 nm AuNP passivated by CAAKA, a zwitterionic peptide passivant layer. The use of a zwitterionic passivant layer on the nanoparticle surface has been shown to decrease the likelihood of nonspecific interactions between the protein and AuNP (*9, 42*), which allows the passivating peptide to be displaced and the exchange of passivants to dominate the final assemblage. The FGF1 sym6ΔΔ mutant was used for this study rather than the native FGF1, since the mutant is more sensitive to competitive binding interactions due to a modest folding free energy ($\Delta G_f = -33.9$ kJ/mol, 8.1 kcal/mol) (*43*), yet exhibits increased thermal stability compared to wild-type FGF1. In addition, the lower

heparin binding affinity for the mutant will allow the impact of AuNP interactions with the protein to be assessed (*44*).

Analysis of the time-dependent changes in structure and function of FGF1 sym6ΔΔ and the heparin-bound analogue in the presence of the 1.5 nm AuNP is examined through the use of a combination of biophysical techniques, including CD, NMR, and molecular beacon kinetic assays, to assess the formation of the FGF1-AuNP conjugate. Observation of a time-dependent evolution of the FGF1structural elements over 18 h is observed and attributed to initial binding of FGF1 to AuNP at multiple locations on the protein surface followed by the more energetically favorable binding of the His_6 tail selectively to the AuNP surface. The time-dependent evolution is consistent with earlier results for peptide assembly onto a AuNP (*37*). The maintenance of structure and heparin binding ability for the FGF1 mutant confirms that the His_6 metal affinity tag (His-tag) used to enhance purification of recombinant proteins can be routinely utilized for site-specific assembly of recombinant proteins onto AuNP surfaces. The development of more robust methods for site-specific attachment that minimize nonspecific interactions while maintaining the structural integrity and functionality of a protein when appended to the surface of a nanometal is critical if these systems are to be used in biomedical technologies (*9, 10, 13, 45, 46*). Although not pursued in this study, region-selective coupling of the FGF1 without perturbation of the protein function may allow tracking FGF1 activity in cells via optical or electron microscopy methods.

Experimental Procedures. *Expression and Purification of sym6ΔΔ Mutant of Human FGF-1.* The amino-terminal His_6-tag (*47*) form of the sym6ΔΔ mutant of FGF-1 (*44*) (for simplicity referred to here as FGF1) was expressed and purified according to published procedures (*47*−*49*). Briefly, clarified cell lysate was purified by nickel affinity chromatography (HisPrep FF 16/10 column, GE Biosciences) followed by size exclusion chromatography (Superdex75 10/300 GL column, GE Biosciences). U-^{15}N-FGF was grown in M9 media with $(^{15}NH_4)_2SO_4$ as the sole nitrogen source and purified as above. FGF1-heparin complexes were formed by incubating low molecular weight heparin sodium salt (Sigma) with an equimolar solution of FGF1 for 30 min prior to all experiments.

Preparation of Au-CAAKA and Au-CAAKA-FITC. Au nanoparticles (1.5 nm AuNP) were passivated initially with triphenylphosphine (TPP) in toluene (*50*) and then ligand-exchanged with a zwitterionic peptide (CAAKA) to yield a water-soluble CAAKA-AuNP. The Au particle size was confirmed by electron microscopy and by UV−vis, noting the absence of a plasmon resonance at 520 nm, typically observed for AuNPs greater than 2.5 nm in diameter. For molecular beacon studies, CAAKA was labeled with fluorescein 5-isothiocyanate (FITC) (Sigma) through the lysine amine according to manufacturer instructions and purified by HPLC (C_{18}-RP) before being exchanged onto the AuNP.

Molecular Beacon Assay of FGF1 Assembly onto AuNP Surface. FGF1 or FGF1−heparin were exchanged onto Au-CAAKA-FITC in 50 mM sodium phosphate, 10 mM $(NH_4)_2SO_4$, 100 mM NaCl, pH = 7.5 (Buffer A), at a 1:1 protein to AuNP (1 μM) ratio at 25 °C. Exchange was monitored at 7 min intervals over an 18 h period using a nanometal surface energy transfer (NSET) (*51*) based molecular beacon assay based on dequenching of CAAKA-FITC fluorescence upon release from AuNP. The fluorescence spectra were collected from 300 to 600 nm in triplicate on a Cary Eclipse (Varian) in 1 cm path length cell (100 μL total volume) at 25 °C in Buffer A.

Time-Dependent Structural Changes in FGF1 by CD Spectroscopy. Circular dichroism (CD) spectra were collected between 190 and 260 nm with 0.5 nm steps and 1 s signal averaging on an AVIV 202 CD spectrometer at 25 °C in Buffer A using a 1 cm path length cell. Each sample, including buffer, was measured in triplicate and averaged before buffer subtraction. Sample concentrations were typically 5 μM FGF1 and/or 5 μM Au-CAAKA. The secondary structure content of FGF1 sym6ΔΔ mutant was analyzed in the CD spectra using *CDPro* software (*52*).

2D HSQC NMR Analysis of Protein Structural Perturbations. 2D-^{1}H,^{15}N HSQC experiments were performed on U-^{15}N-FGF1 on a Varian Inova spectrometer operating at 11.74T (Varian Inc., Palo Alto, CA). Protein concentrations were typically 200 μM in 100 mM phosphate, 200 mM $(NH_4)_2SO_4$, 100 mM NaCl at pH = 6.0 (Buffer B). HSQC spectra were collected over 8333 Hz (1500 Hz) and digitized by 1024 (220) complex points in the ^{1}H (^{15}N) dimensions in 16 scans per t_1 increment for a total data collection time of ∼45 min. Data collection for each HSQC spectrum was initiated at 0, 5, and 18 h following addition of Au-CAAKA. Data were processed with zero-filling to yield a final digital resolution of 4 and 15.7 Hz in ^{1}H and ^{15}N dimensions, respectively. Data processing was performed using NMRPipe and analyzed using NMR-View (*53*). Changes in resonance position ($\Delta\delta$) upon addition of CAAKA-Au were quantified as $\Delta\delta = [(\delta H)^2 + (\delta N/6)^2]^{1/2}$ (*54*).

RESULTS

Following secretion from the cell, FGF1 binds to heparin and the FGF1-heparin complex is then recognized by the FGF receptor to initiate signaling (*55*). Heparin has a net negative charge, and electrostatic interactions between heparin and the protein binding pocket impact the binding affinity of heparin to FGF1. A structural model indicating residue location and the electrostatic potential at physiological pH of FGF1 sym6ΔΔ is presented in Figure 1. The amino-terminal His_6-tag should minimally perturb the protein structure and, more importantly, the heparin binding pocket, as the His_6-tag will position the AuNP on the side of FGF1 opposite the heparin binding pocket. The assembly of the FGF1 onto the AuNP is expected to occur via a surface-mediated ligand exchange reaction of the CAKKA peptide passivant shell appended to the AuNP by the formation of the Nε imidazole−Au interaction. The presence of the roughly 2 nm positively charged heparin binding pocket on FGF1 increases the potential for deleterious interactions between the protein and the 1.5 nm AuNP, and thus, the hypoactive form of FGF1 (sym6ΔΔ mutant) is the ideal test case for assessing potential loss of protein activity in the presence of the AuNP.

To minimize potential heparin binding pocket interactions, the 1.5 nm AuNP is passivated with the zwitterionic peptide sequence CAKKA (Cys-Ala-Lys-Lys-Ala) (*9, 42*). The CAAKA peptide is ligated to the AuNP via a Au-*S* interaction via the reduced Cys (C) amino acid. Fluorescent labeling of the CAAKA passivant by FITC (fluorescein) appended to the Lys (K) allows the recovery of FITC photoluminescence (PL) to be used as a probe of CAAKA displacement from the surface of the AuNP. When the CAAKA-FITC fluorogenic agent is appended to the AuNP, the FITC PL is quenched via energy transfer (*51, 56*).

In Figure 2, displacement of the CAAKA-FITC passivant from the AuNP surface by FGF1 binding is observed to result in the onset of FITC PL. The loss of the CAAKA-FITC passivant (onset of FITC PL) from the AuNP exhibits bimodal kinetics for both the addition of FGF1 and FGF1-heparin to the 1.5 nm Au-CAAKA-FITC construct (Figure 2). No time-dependent optical changes in the Au-CAAKA-FITC construct are observed in the absence of added protein (not shown). The bimodal trajectory in Figure 2 is verified by *F*-statistics through the analysis of χ^2 by fitting a series of functions with increasing number of exponentials. Fitting to a single exponential resulted in large χ^2 values which were significantly reduced in a

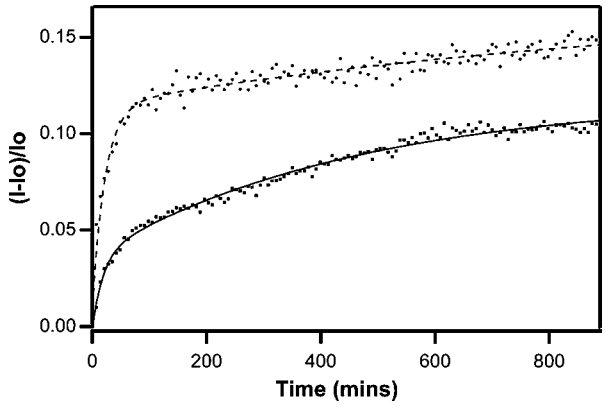

Figure 2. FGF1 and FGF1-heparin FITC PL intensity for the CAAKA-FITC displacement on the 1.5 nm AuNP surface byFGF1 (solid) and FGF1-heparin (dash). The PL intensity is monitored at 520 nm.

biexponential fit; fitting to a triexponential function did not significantly improve the quality of the fit according to the *F*-statistic.

Table 1 lists the experimentally fit rates and amplitudes for release of CAAKA-FITC upon addition of FGF1 or FGF1-heparin. The observed fast and slow rates are quite similar, within a factor of 2 for FGF1 and FGF1-heparin. However, the contribution to the total intensity recovery is reversed, with FGF1-heparin exhibiting higher amplitude for the fast phase, while FGF1 shows higher amplitude for the slow phase. The difference in rate and amplitude for CAAKA-FITC release between the FGF1 and the FGF1-heparin complex is intriguing and may reflect the fewer sampling configurations available for the heparin-bound FGF1 relative to FGF1 when interacting with the AuNP surface. The loss of conformational freedom arising from the binding of heparin to FGF1 eliminates the positive heparin binding pocket and reduces the conformational dynamics of the FGF1, which could lead to the observed differences in the rate of structural minimization for the two forms of FGF1.

Table 1. Calculated Rate and Amplitude Values for the Release of CAAKA-FITC from the Surface of a 1.5 nm AuNP when Treated withFGF1 or FGF1-Heparin

	fast phase		slow phase	
	rate (min^{-1})	amplitude (%)	rate (min^{-1})	amplitude (%)
FGFI	0.0532(0.0080)	23	0.0022(0.0002)	77
FGFI heparin	0.0446(0.0036)	67	0.0009(0.0005)	33

The FITC intensity trajectories in Figure 2 have not reached an asymptotic value within the time scale of the experiment, although extrapolation of the data to time infinity implies that both systems will achieve similar asymptotic values. The observed FITC PL recovery for FGF1 after 15 h is ~9% and ~14% for FGF1-heparin. Assuming a loading level of approximately 40 CAAKA-FITC based on the analysis of passivant exchange on AuNPs by Woehrle et al. (*57*), the displacement corresponds to between four and six CAAKA-FITC peptide passivants from the AuNP surface, four in the case of FGF and six in the case of FGF1-heparin. Assuming the peptide displacement results from one His residue interacting with the NP surface, this yields one protein per AuNP, which is consistent with our previous report of a single His_6 peptide binding to a AuNP (*37*).

Further evidence of a strong bonding interaction between the AuNP and the FGF1 is provided by chromatographic analysis using size exclusion and PAGE electrophoresis (Supporting Information Figures 1 and 2). Upon addition of FGF1 to a solution of AuNP in a 10:1 mol ratio, loss of the original sharp AuNP signal is observed by size exclusion analysis in Superdex75 after 1 h of mixing the AuNP and FGF1 (Supporting Information Figure 1). The signal loss in FGF1 is correlated with the appearance of a new broad feature at shorter retention time. The decrease in the FGF1 band is approximately 10% (~90% unchanged) for identical concentrations of FGF1, indicating approximately a 1:1 binding ratio. The broad feature for the AuNP-FGF1 assembly appears to have multiple components that could not be separated and is believed to reflect more than one binding motif at this short mixing time (1 h). The assumption from the optical assay for the FGF1-AuNP assembly having not fully evolved to the final structural conformation based on the biexponential rise time of the signal is consistent with the size-exclusion results. Further evidence of chromatographic stability is provided by Native-PAGE analysis of a 1: 1 ratio of FGF1 to AuNP (Supporting Information Figure 2). In the native PAGE, no free FGF1 is observed after treatment with the AuNP as evidenced by the lack of Coomassie blue stained FGF1 protein (lanes 4 and 7, Supporting Information Figure 2B). In addition, a slight mobility shift is observed for the AuNP due to the mobility difference of the FGF1-AuNP complex (lanes 4 and 7, Supporting Information Figure 2A). The small shift in the mobility between the AuNP and FGF1-AuNP and FGF1 (sane 3 vs 4) and the FGF1-heparin-AuNP (lane 3 vs 7) is consistent with the AuNP creating a strong assembly with the FGF1 protein.

Evidence of Structural Perturbation of FGF1 in the Presence of the AuNP. On the basis of the electrostatic map in Figure 1, the possibility that protein sampling gives rise to the observed dynamics is not surprising. The possibility for electrostatic and hydrophobic interactions can impact the secondary structure as well. In Figure 3, the CD spectrum of FGF1 prior to addition of the AuNP, 15 min, 6 h, and 24 h

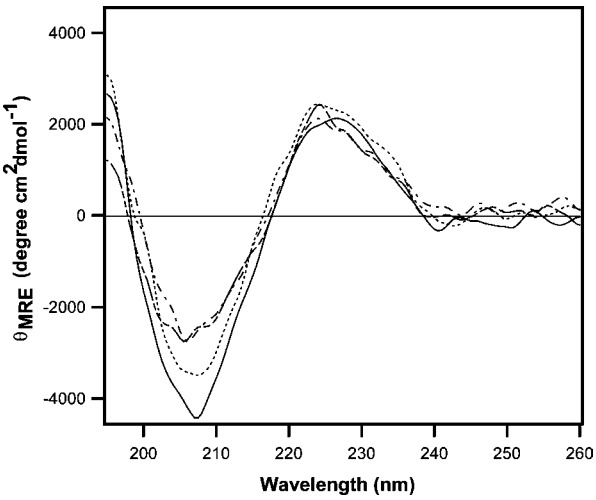

Figure 3. Circular dichroism spectra of FGF1 (—) and changes at 15 min (••••), 6 h (----), and 24 h (-•-) following the addition of Au-CAAKA to the FGF1 solution.

following addition of equimolar AuNP is shown. FGF1-heparin was not analyzed by CD spectroscopy.

The secondary structure of FGF1 are composed of β-sheet, β-turn, random coil, and α-helix character based upon crystallography and analysis by *CDPro* (*52*) fitting of the CD spectra. Using *CDPro* software, in the absence of the AuNP, FGF1 contains 35% β-sheet and 25% β-turn, with the remaining 40% attributed to random coil and α-helix character. Following addition of AuNP to FGF1, the 207 nm negative phase signal, which likely arises from a combination of α-helix and β-sheet signals, exhibits a loss of intensity during the first 6 h. The positive CD signal maximum at 230 nm, arising from β-turn, exhibits no substantial change over the entire experimental time domain. Analyzing the signal change in the presence of the AuNP indicates that a 10% increase in β-sheet and a 7% decrease in β-turn content occur for the FGF1−AuNP conjugate during the first 6 h, with minimal subsequent structural perturbations observed relative to the native FGF1 structure at longer experimental times.

A more detailed picture of the structural perturbations of FGF1 upon binding to the AuNP can be analyzed by 2D NMR when the experimental data for CAAKA-FITC release and the CD spectra suggest the FGF1-AuNP has approached a structural minimum. Inspection of the NMR data at 22 min (Supporting Information Figure 3) and 6 h (Supporting Information Figure 4) is intriguing but complicated by the fact that the structure is still evolving and thus exhibits more global changes in the protein; therefore, the discussion below is limited to the data obtained at 18 h exposure times (Figure 4) to simplify data interpretation.

Figure 4A shows the HSQC spectrum of FGF1 in the absence of the AuNP (cyan) and 18 h following addition of the AuNP (magenta). Comparison of the 2D NMR plots indicates that the vast majority of the residues of FGF1 are minimally impacted with the exception of the His_6-tag residues HT(I) and HT(II). The two resonances assigned, HT(I) and HT(II), are not observable immediately after exposure to the AuNP. Whether these changes in resonance intensity arise from altered conformational exchange or a true increase in transverse relaxation rates cannot be determined from these spectra. In addition, subtle changes are observable for the individual intensity and protein resonances following FGF1 interaction with the AuNP, particularly for protein residues in or near the His_6-tag region (Figure 1). S139 shows significantly lower resonance intensity 18 h after addition of AuNP (Figure 4B), whereas H124 and E60 show changes in resonance frequency with little affect on intensity. In general, the same residue changes for the 6 h time point are observed, but in addition, G19, V55, and I25 also show chemical shift changes (Supporting Information Figure 4). The intensity and resonance changes clearly indicate these residues are significantly impacted by addition of the AuNP.

Greater insight into the changes occurring at the individual protein residues in the presence of the AuNP can be deduced by plotting the change in chemical shift ($\Delta\delta$) in the HSQC experiment for individual protein residues relative to FGF1 in the absence of the AuNP (Figure 5) at 18 h and 6 h (Supporting Information Figure 5). Residues showing $\Delta\delta \geq 20$ Hz (digital resolution = 8.3 Hz on this scale) are considered significant and are labeled in the $\Delta\delta$ plot with their single letter abbreviation at position in the protein (Figure 1). A residue showing >100 Hz shift or a complete loss of intensity is artificially shown in the $\Delta\delta$ plot as a negative value.

The $\Delta\delta$ plots indicate that residues G19, E60, and H102, which are related structurally by the threefold symmetry of the FGF1 β-trefoil (*55*), along with Q43 and H124 show the largest chemical shift change between the protein in the presence and absence of the AuNP. The changes in the residue intensity and frequency are apparent at the earliest time point (22 min) and remain relatively constant through the 18 h time point (Figure 5). Residue G19 also shows a significant change, although a

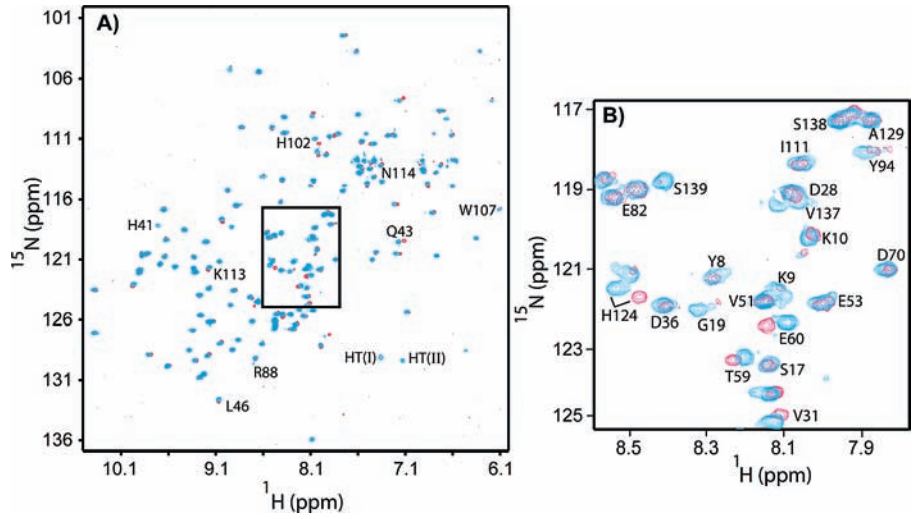

Figure 4. (A) $^1H-^{15}N$ HSQC NMR spectrum of FGF1 (cyan) and FGF1-AuNP (magenta) at 18 h. (B) Expanded representative region of HSQC spectra highlighting chemical shift changes, peak loss, and no change for FGF1-AuNP at 18 h postincubation.

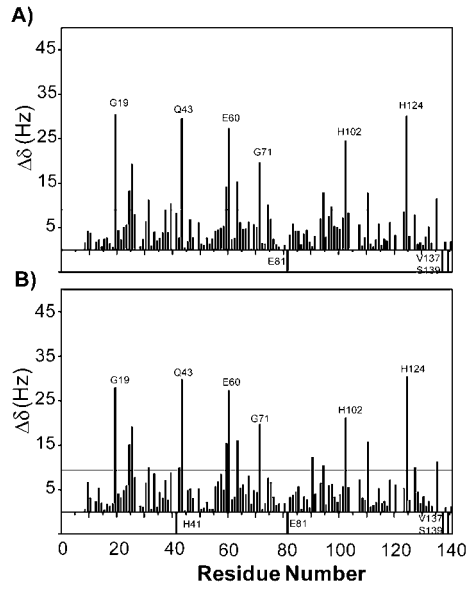

Figure 5. Δδ plot showing chemical shift differences and peak intensity loss (negative intensity) (A) 22 min and (B) 18 h incubation of FGF1 sym6ΔΔ with a 1.5 nm CAAKA passivated AuNP.

weak resonance G19 has a large shift in frequency implying that a structural perturbation may arise upon binding of the AuNP.

Residues H41, E81, V137, and S139 are not observed following the addition of AuNP and are represented as negative values in Figure 5. The signal loss for H41 may not be significant, as the loss of the resonance signal may reflect the weak native intensity observed for H41 in the FGF1 NMR spectra in the absence of the AuNP. However, the loss of E81, V137, and S139 is significant, as these are strong resonances in the FGF1 NMR spectra, implying that either a large frequency shift or a drastic change in dynamics for these residues occurs upon interaction of FGF1 with the AuNP. Residue E81 is located in close proximity to the His_6-tag region and changes in V137 and S139 are not surprising, since the C-terminal β-strand region is unstructured in both the His_6-tag (PDB accession 1JQZ or high-resolution 1RG8) and non-His_6-tag form of FGF1 (PDB accession 2AFG) and has a β-sheet interaction with the N-terminus β-strand. Changes in the N-terminal β-strand near the His_6-tag may indicate either ordering or disordering of the C-terminus β-strand upon AuNP binding.

Investigation of Heparin Binding in Presence of AuNP. NMR and crystallographic evidence for FGF1 binding with heparin suggest that heparin binding occurs through interactions with residues between G110-G120 and R122-A129, with large effects seen for residues K113 and K118 (*38, 40, 58*). On the basis of analysis of the NMR data for the FGF1-AuNP construct, the structural perturbations in FGF1 appear to be localized in the His_6-tag region and possibly the heparin binding pocket, which may potentially impact the heparin binding affinity. It is worth noting that changes in NMR resonances do occur in regions distal from the site of binding. For instance, it is well-known that heparin binding affects residues outside the heparin binding pocket (*40*).

A Δδ plot for heparin bound to FGF1 sym6ΔΔ in the absence of the AuNP calculated from the $^1H-^{15}N$ HSQC at 6 h (Supporting Information Figure 6) shows resonance and intensity perturbations for residues G19, D36, H42, R88, W107, K113, N114, and I130 (Figure 6B) in good agreement with previously reported NMR results on wild-type FGF1 (*38, 40, 58*). Comparison of the Δδ NMR plot derived from the $^1H-^{15}N$ HSQC spectra (Figure 6A) for adding heparin to FGF1 in the

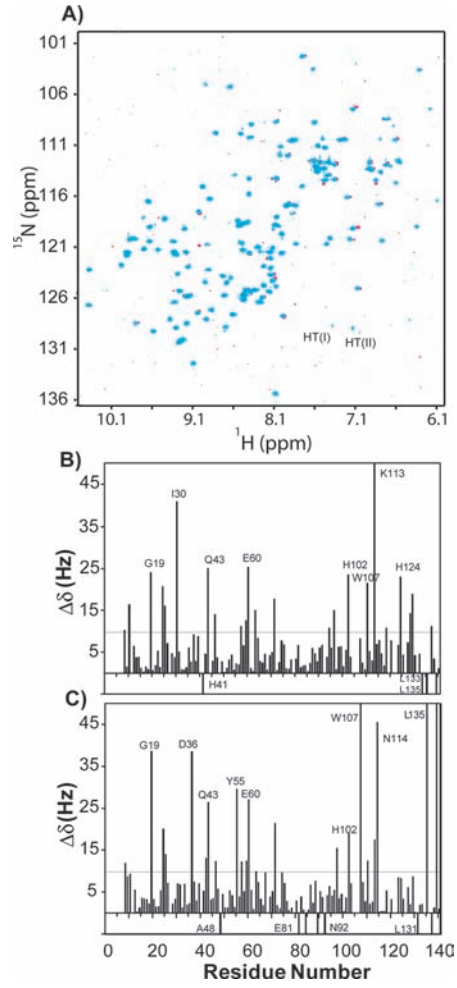

Figure 6. (A) $^1H-^{15}N$ HSQC NMR spectrum of FGF1 (cyan) and FGF1-heparin-AuNP (magenta) at 18 h. (B) Δδ plot showing chemical shift changes and loss of intensity (negative value) for (C) FGF1 with heparin and (B) FGF1 with heparin and AuNP after 18 h incubation.

presence and absence of AuNP (Figure 6C) shows similar perturbations as when AuNP is added to FGF1 in the presence and absence of heparin, indicating that the AuNP does not compete with heparin binding. Namely, residues W107, G110, K113, and N114 are impacted in the heparin−FGF1 alone and also show similar perturbations for the AuNP heparin−FGF1. In addition, residues A48, E81, L84, L89, and N92 show a complete intensity loss after 18 h with heparin and the AuNP (indicated as a negative value in Figure 4B), which is not observed in the absence of the AuNP. The loss of intensity of residues L89 and N92 is not surprising, since these residues are located in close proximity to the His_6-tag region in a flexible β-turn that has been shown to adopt significantly different structural conformations in FGF1/FGFR complexes (*59, 60*). The AuNP-specific changes are similar to those observed for FGF1 assembly onto the AuNP in the absence of heparin. Thus, the observation that a number of residues that are impacted only if the AuNP is present, including HT(I), HT(II), Y55, V137, and S139, and residues specific for experiments with heparin binding to FGF1 such as W107, G110, K113, and N114 also have chemical shift differences compared to FGF1 alone further confirms that both the AuNP and heparin remain bound after 18 h.

DISCUSSION

Our results show a strong time dependence for FGF1−AuNP complex formation. Correlating the changes observed in

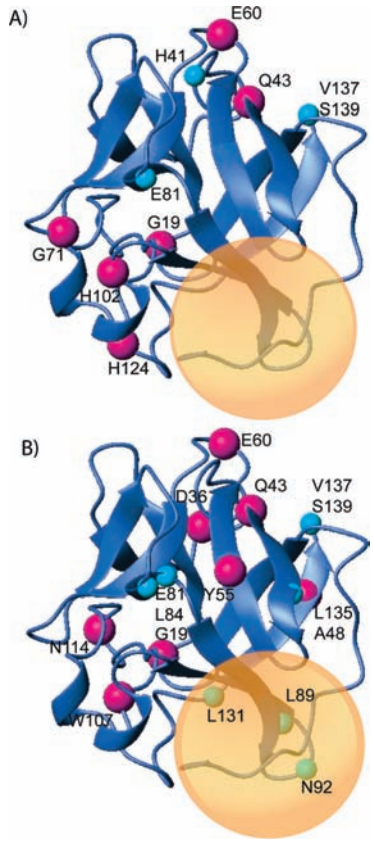

Figure 7. FGF1 crystallographic structure model (PDB ID: 1RG8) showing residues that exhibit chemical shift change (magenta), intensity differences (cyan), and His-tag (gold) affected by AuNP binding after 18 h for (A) FGF1 and (B) FGF1-heparin. The AuNP is overlaid in the His_6-tag region and does not represent a cocrystallized structure.

the NMR spectra for FGF1 and FGF1−heparin in the presence of the AuNP allows a model to be drawn indicating the regions of proposed AuNP interactions. Figure 7 shows the position of FGF1 residues that are most strongly affected by addition of AuNP after 18 h. Magenta balls indicate the position of backbone amides showing the largest $\Delta\delta$ values, and cyan indicates the positions of largest resonance intensity change. In addition to the residues of the His_6-tag, AuNP binding affects residues in β-turn regions, with little impact on β-sheet residues. A comparison of the affected residues (large or small) indicates that AuNP effects are noted in both positive and negative charge regions, and could be due to both nonspecific electrostatic interactions or motional dynamic changes, which are often seen with FGF1 flexibility changes upon heparin binding (*40*). The number and location of residues affected by AuNP binding in the NMR results are consistent with the relatively modest changes in secondary structure detected by CD. Importantly, the heparin binding pocket on the FGF1 remains largely unaffected by the AuNP binding, although the E81 residue (a surface residue in close spatial proximity to the His_6-tag region) is affected by AuNP binding. Comparison of the binding of FGF1-sym6ΔΔΔ in the absence of the His_6-tag could not be carried out due to the poor expression level and stability of FGF1 in the absence of the His_6 tag (*43*).

The bimodal kinetics for CAAKA release during the FGF1 assembly onto the AuNP can be attributed to one of two simple models, which may not be mutually exclusive. In one model, the bimodal nature of CAAKA-FITC release upon FGF binding reflects His_6-tag binding directly to readily accessible vertices and edges of the AuNP (*61, 62*) followed by slower release of CAAKA-FITC due to steric clash with the assembled FGF1. The zwitterionic CAAKA surface ligand is likely to minimize the nonspecific interactions, but given the degree of both positive and negative surface regions (Figure 1), electrostatic interactions between FGF1 and AuNP likely are inevitable. Alternatively, the bimodal kinetics may represent a rapid but nonspecific adsorption of FGF1 onto the AuNP followed by a slow rearrangement toward the more stable binding through the His_6-tag. The higher initial rate of assembly for FGF1−heparin would then reflect the fact that the His_6-tag is more favorable for binding than in FGF1 alone, or that the bound heparin eliminates some of the nonspecific adsorption by blocking the large positive charge region near the His_6-tag (Figure 1). Regardless of the mechanistic pathway for assembly, both models suggest an evolving interaction driven by protein sampling of the AuNP surface leading to a stable complex that minimally perturbs protein secondary structure or biological function by positioning the heparin binding pocket away from the His_6-tag-driven AuNP surface-mediated assemblage.

The correlation of the molecular beacon, gel electrophoresis, NMR, and CD spectroscopies supports a conclusion that the His_6-tag is the dominant interaction with the AuNP surfaces at long incubation times leading to small perturbations on the global FGF1 structure. The assembly arises from peptide displacement by the His residue leading to a His (Nε)-Au coordination. While it is surprising that the thiol (cys-) functionality is displaced by the His residue since thiols are strong coordinators of Au surfaces, the strong association of the His_6-tag reflects the enhanced thermodynamic stability for the His_6 residue arising from the multichelate effect, a common observation for metal−liagnd stabilization in metal coordination chemistry (*63*−*65*). The slow dynamics of assembly reflects minimization of the protein AuNP conjugate as the protein samples the AuNP surface. The ability to bind a AuNP to His_6-tag proteins opens another interfacial bridge between biology and nanoscience. This structure/function study of FGF1-AuNP binding provides evidence of stable, direct protein−Au conjugation without loss of normal function. The His_6-tag FGF1 sym6ΔΔ binding to the AuNP is stable in size-exclusion chromatography (Supporting Information Figure 1) and PAGE analysis (Supporting Information Figure 2) further confirming the suitability of the His_6-tag as a robust, stable linkage to a AuNP. This study enables further use of AuNP with recombinant His-tag proteins for intracellular delivery, biophysical studies, sensing, imaging, and other nanobiomedical applications.

ACKNOWLEDGMENT

The authors would like to thank Dr. Claudius Mundoma, Director of the Physical Biochemistry Facility in the Institute of Molecular Biophysics at Florida State, for help with circular dichroism measurements. The authors would also like to thank Dr. Tom Gedris and Steve Freitag in the NMR facility in the Department of Chemistry and Biochemistry at Florida State University. This work was supported by NIH NBIB-R0EB000832 (GFS) and NIH AI-R01021628 (TML).

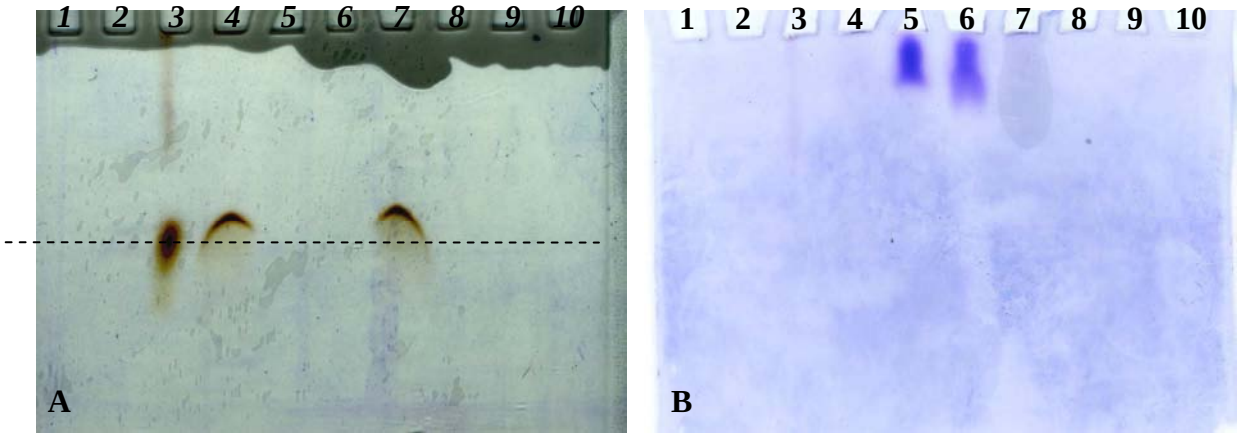
SUPPLEMENTAL FIGURE 1

Size-exclusion Chromatography (Superdex75) of FGF 10μM in Buffer A (----), concentrated Au-CAAKA in H_2O 1μM (••••), and FGF + Au-CAAKA at 10 μM : 1 μM (—) in Buffer A. The decreased absorbance at 13.5 mins (~10%) in the FGF + Au-CAAKA sample suggests that a 1 : 1 complex of FGF1 – Au-CAAKA forms without impacting the remaining FGF1 sample.



SUPPLEMENTAL FIGURE 2

10% TBE-PAGE (Native) pH = 8.8 electrophoresis gel representing an A) unstained and B) Coomassie Blue stained gel. The PAGE gel was run at 100 V for 90 mins. The lanes are identical in both gels such that (Lane 3) 25 μM Au-CAAKA; (Lane 4) 25 μM FGF + 25 μM Au-CAAKA; (Lane 5) 25 μM FGF; (Lane 6) 25 μM FGF + 25 μM heparin; and Lane 7) 25 μM FGF1-heparin + 25 μM Au-CAAKA . Lanes 1, 2, 8, 9, and 10 are empty.

The relative mobilities for each band in the unstained gel are 35.5 mm for Au-CAAKA, 31.0 mm for FGF1 + Au-CAAKA, and 30.4 mm for FGF1-heparin + Au-CAAKA. The mobility difference for FGF1 + Au-CAAKA and FGF1-heparin + Au-CAAKA compared to Au-CAAKA alone in the unstained gel, as well as the absence of protein bands in the Coomassie blue stained gel suggest that there is a 1 : 1 complex of FGF1 : Au-CAAKA.

Annexin A5-Functionalized Liposomes for Targeting Phosphatidylserine-Exposing Membranes

Boris Garnier,[†,‡] Anthony Bouter,[†] Céline Gounou,[†] Klaus G. Petry,[‡] and Alain R. Brisson*[,†]

Molecular Imaging and NanoBioTechnology, IECB, UMR-5248 CBMN CNRS-University Bordeaux1-ENITAB, Avenue des Facultés, F-33402 Talence, France, and INSERM EA-2966, University Bordeaux, 146 rue Léo Saignat, F-33076 Bordeaux, France. Received June 11, 2009; Revised Manuscript Received September 4, 2009

Long-circulating liposomes functionalized with cell-targeting elements and loaded with bioactive compounds present high interest as drug delivery nanosystems. We present here the synthesis and physicochemical characterization of liposomes containing PEGylated lipids covalently linked to oriented Annexin-A5 (Anx5) proteins, and we show that Anx5-functionalized liposomes are able to target phosphatidylserine (PS)-exposing membranes. The covalent coupling of Anx5 to liposomes is almost quantitative, which is mainly due to the high accessibility of the reacting groups. The influence of Anx5 functionalization on liposome aggregation was investigated by dynamic light scattering, showing that Anx5-functionalized liposomes are stable below a threshold density of 250 Anx5 molecules per liposome. Anx5-functionalized liposomes bind PS-containing membranes with very high efficacy, which is mainly due to the controlled orientation of the Anx5 at the liposome surface. A striking result, obtained by quartz crystal microbalance with dissipation monitoring, is that one single Anx5 molecule is able to anchor a liposome to a PS-containing supported membrane. Finally, we show by fluorescence microscopy that Anx5-functionalized liposomes bind PS-exposing apoptotic K562 cells with high specificity. This study demonstrates that Anx5-functionalized liposomes bind specifically to PS membranes and are thus potential candidates to deliver drug or imaging agents to sites of apoptosis or thrombosis.

INTRODUCTION

Liposomes are hollow lipid bilayer vesicles which have found practical applications as drug delivery systems, thanks to their intrinsic property of entrapping either hydrophilic compounds within their aqueous interior or hydrophobic compounds within their hydrophobic lipid boundary (*1*−*5*). Drug encapsulation provides several advantages over direct administration, such as preventing drug dilution, avoiding potential deleterious side effects, or reducing the volume of distribution of the drug (*6, 7*)}. Efforts have been developed to design liposomes that achieve long circulation times in the body in order to increase drug accumulation in the desired tissues and organs. Parameters have been identified which are important for increasing the circulation time of liposomes, in particular, a small (∼100 nm) size and the addition of a hydrophilic poly(ethylene glycol) (PEG) coat. Small size strongly reduces elimination of vesicles by body filters, while the attachment of a brush-like layer of PEG molecules helps them escape capture by cells from the reticuloendothelial system and prevents their accumulation in the liver or the spleen (*1*). The circulation half-life of PEGylated stealth liposomes extends to several hours, compared to a few minutes for uncoated vesicles (*8*).

The surface functionalization of liposomes with molecular recognition elements able to recognize and bind specific targets constitutes a major challenge in the field of drug delivery systems (*6, 9*−*12*). Liposomes exposing several types of cell recognition molecules, from small molecules like folic acid to large proteins like antibodies, have already been produced and used successfully as drug carriers *in vitro* as well as in mice (*13*).

Our aim is to develop long-circulating liposomal nanovectors functionalized with protein-based recognition elements. We present here our initial study which concerns the synthesis and characterization of PEGylated liposomes functionalized with the Annexin-A5 (Anx5) protein.

Anx5 is the prototype member of the annexin family, proteins which share the property of binding to membranes containing negatively charged phospholipids in a Ca^{2+}-dependent manner (*14*). Although the exact biological functions of annexins are still being debated, Anx5 has already found wide application both as a research tool and as a clinical tool for labeling cell membranes exposing phosphatidylserine (PS) molecules. It is indeed well-established that eukaryotic cell membranes present an asymmetric distribution of lipid molecules, with the majority of anionic phospholipids, particularly PS molecules, being located in the inner leaflet of the plasma membrane (*15*). The exposure of PS molecules on the cell membrane outer leaflet is a hallmark of several basic processes, such as apoptosis or programmed cell death (*16*) and blood platelet activation (*17*). The ability of Anx5 to bind PS-exposing membranes in a Ca^{2+}-dependent manner explains the use of labeled Anx5 proteins as research tools (*18*−*20*) and also as *in vivo* diagnostic agents to detect cell death in cancer chemotherapy, organ transplant rejection, or myocardial infarction (*21*−*23*). In addition, drug-targeting and drug-delivery strategies based on chimerical Anx5 entities coupled to various types of bioactive moieties have recently been proposed, e.g., for delivering thrombolytic enzymes to thrombotic sites or for delivering compounds intracellularly via Anx5-mediated endocytosis (*24, 25*).

Our first goal is to design liposomes functionalized with oriented Anx5 proteins in such a way that the Anx5 proteins maintain their property of binding to PS-exposing cells. The

structures of the soluble form (*26, 27*) and membrane-bound form of Anx5 (*28*−*31*) indicate that this protein presents a slightly bent shape with a convex membrane-binding face and an opposite concave face. On the basis of this structural knowledge, we have designed an Anx5-SH mutant protein harboring a unique sulfhydryl group inserted in a highly accessible loop on the concave face of the protein (*32*). We present here the synthesis and characterization of Anx5-functionalized PEGylated liposomes. Conditions of covalent functionalization were monitored by SDS-PAGE, and the interaction of Anx5-liposomes with PS-exposing model membranes was characterized in a systematic manner by quartz crystal microbalance with dissipation monitoring method (QCM-D). The QCM-D method is particularly well adapted for studying the interaction of proteins or proteolipid complexes with model membranes (*33*−*35*). The encapsulation property and the ability of Anx5-liposomes to bind PS-exposing apoptotic cells were investigated by fluorescence spectroscopy and microscopy, respectively.

EXPERIMENTAL PROCEDURES

Materials. 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC), cholesterol, 1,2-dipalmytoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (PEG_{2000}-DPPE), 1, 2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[maleimide-(poly(ethylene glycol))2000] (Mal-PEG_{2000}-DSPE), and 1,2-dioleoyl-*sn*-glycero-3-[phospho-L-serine] (DOPS) were obtained from Avanti Polar Lipids (Alabaster, AL, USA). All other chemicals were of ultrapure grade. Water was purified with a RiOs system (Millipore, St Quentin en Yvelines, France). STI-571 (imatinib mesilate) was from Novartis (Basel, Switzerland).

Buffer Preparation. A HEPES buffered saline (HBS) solution made of 10 mM HEPES, 150 mM NaCl, and 2 mM NaN_3 was prepared in ultrapure water. The pH was set at 7.4, except for Anx5 and liposome solutions used in covalent coupling reactions where pH was set at 6.3. Buffer solutions were supplemented with either 2 mM $CaCl_2$ or 2 mM EGTA for QCM-D and cell experiments, as indicated in the text.

Liposome Preparation. Liposomes were prepared by lipid film hydration (*36*) followed by extrusion, as briefly described here. Lipids were dissolved in chloroform, mixed in desired amounts, and the solvent was evaporated to dryness using a rotary evaporator during 20 min. Lipids were hydrated in HBS, resulting in multilamellar vesicles (MLVs), and homogenized by three cycles of freezing−thawing and subsequent vortexing. Large unilamellar vesicles (LUVs) were obtained by hand extrusion of the resulting lipid dispersion, passing the mixture twenty times through 0.1 μm polycarbonate filters with a LiposoFast extruder (Avestin, Sodexim, France). LUVs were composed of DOPC/cholesterol/Mal-PEG_{2000}-DSPE/PEG_{2000}-DPPE in proportions specified in each experiment. Small unilamellar vesicles (SUVs), composed of DOPC/DOPS (weight ratio 4/1), were obtained by sonication of a MLV suspension with a tip sonicator (Misonix, Farmingdale, NY), operated in a pulsed mode at 20% duty cycle for 30 min with refrigeration. Phospholipid concentrations were determined by phosphate analysis according to Rouser (*37*).

Annexin Protein Preparation. Rat recombinant AnxA5-SH and AnxA5-S-S-Anx5 dimers were produced and purified as described (*32*). The AnxA5-SH protein is a double mutant (C314S, T163C) in which the only cysteine in wt-Anx5 has been replaced by a serine (C314S) and a single cysteine has been introduced, at position 163 (T163C), in a highly exposed region on the concave face of the protein.

Covalent Coupling of Anx5-SH to Liposomes. To produce Anx5-SH proteins, Anx5-S-S-Anx5 dimers were reduced by incubation with 10 mM DTT in HBS at pH 6.3 for 30 min. Reduced Anx5-SH was purified on a HiTrap desalting column (GE-Healthcare, Brabant, Belgique) equilibrated with HBS at pH 6.3. Anx5-SH was mixed with desired amounts of LUVs containing Mal-PEG_{2000}-DSPE lipids, in HBS at pH 6.3, and incubated at least for 4 h at room temperature. The number of maleimide groups available for covalent coupling was calculated assuming that lipids are equally distributed among the two membrane leaflets and that only maleimide groups located on the outer leaflet are accessible.

Characterization of Covalent Coupling of Anx5-SH to Liposomes. A given amount of liposomes composed of DOPC/cholesterol/Mal-PEG_{2000}-DSPE (74/25/1 mol %) was incubated with Anx5-SH solutions of increasing concentration. The extent of coupling was analyzed by SDS-PAGE (*38*) using a 10% resolving gel and visualization of protein bands by Coomassie blue staining. Since free maleimides from the inner leaflet are exposed upon solubilization of the liposomes by SDS, the remaining free thiol groups of the suspension were blocked by addition of 5 μM *N*-ethylmaleimide for 4 h before running the gels.

Dynamic Light Scattering (DLS). DLS measurements were performed using an ALV laser goniometer, equipped with a 22 mW HeNe linearly polarized laser operating at a wavelength of 632.8 nm and an ALV-5000/EPP multiple τ digital correlator with 125 ns initial sampling time. The liposome suspensions were maintained at a temperature of 25.0 ± 0.1 °C in all experiments. The counting time was 300 s for each sample. The liposome composition was DOPC/cholesterol/Mal-PEG_{2000}-DSPE (70/25/5 mol %). Samples contained 200 μg phospholipids in a total volume of 900 μL, pH 7.4. All measurements were performed at three scattering angles (50°, 90°, 120°); the presented results correspond to 90° scattering. Data were analyzed using ALV Correlator Control software.

Quartz Crystal Microbalance with Dissipation Monitoring (QCM-D). QCM-D measurements were performed with a Q-SENSE E4 system (Q-SENSE, Gothenburg, Sweden) (*39*). Briefly, upon interaction of matter with the surface of a sensor crystal, changes in the resonance frequency, *f*, related to adsorbed mass (including coupled water), and in the dissipation, *D*, related to viscous losses in the adlayer are measured.

Measurements were performed in flow mode; i.e., the solution was continuously delivered to the measurement chamber (flow speed 150 μL/min) by the aid of a peristaltic pump (ISM935C, Ismatec, Zürich, Switzerland). The working temperature was 24 °C. Variations in resonance frequency (Δf) and dissipation (ΔD) were measured at several harmonics (15, 25, 35 MHz) simultaneously. Adsorbed masses, Δm, are calculated according to the Sauerbrey equation, $\Delta m = -C\Delta f_{norm}$, with the mass sensitivity constant $C = 17.7\ ng \cdot cm^{-2} \cdot Hz^{1-}$ and $\Delta f_{norm} = \Delta f_n / n$, with n being the overtone number (*40*). The presented Δm and ΔD values correspond to the fifth harmonics ($n = 5$, i.e., 25 MHz). Prior to use, the QCM-D sensor crystals were cleaned by two cycles of exposure to a 2% SDS solution for 15 min, rinsing with ultrapure water, blow-drying with nitrogen, and exposure to UV/ozone for 10 min, as described in Richter et al. (*41*).

A supported lipid bilayer (SLB) was formed on silica-coated quartz sensor crystals by deposition of SUVs made of DOPC/DOPS (4:1, w:w), as described in *refs* 41−43. After rinsing the chamber with Ca^{2+}-containing HBS to remove the excess of SUVs, solutions of functionalized vesicles were introduced in the chamber. The vesicle composition was DOPC/cholesterol/Mal-PEG_{2000}-DSPE 74/25/1 mol % for all experiments, except for experiments dealing with the influence of the PEG layer on targeting efficiency. In this latter case, three kinds of formulation

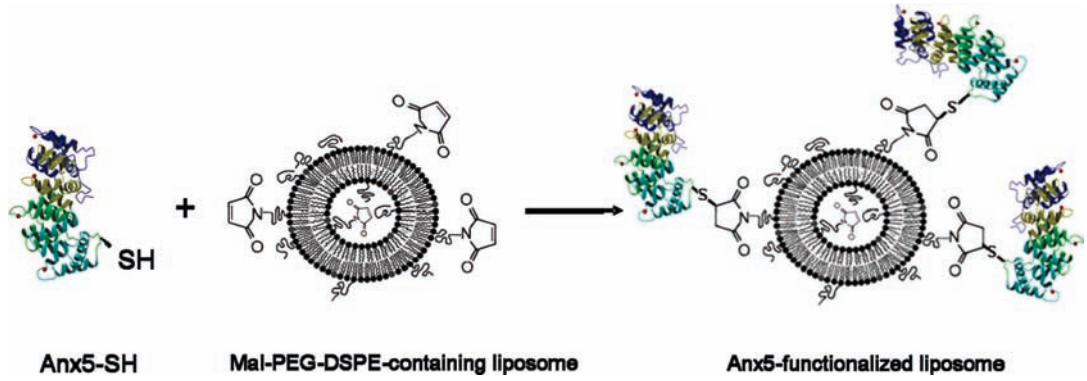

Figure 1. Scheme of covalent coupling of Anx5-SH to liposomes containing Mal-PEG_{2000}-DSPE.

were used: PEG_{2000}-DPPE × mol %/Mal-PEG_{2000}-DSPE 1 mol %/cholesterol 25 mol %/DOPC 74 − x mol %, with $x = 0$, 2, or 4 mol %.

Liposome Leakage Assay. The self-quenching property of the fluorescent dye sulforhodamine B was characterized by measuring the intensity of dye solutions of increasing concentrations.

The fluorophore was passively encapsulated into liposomes as follows. The dry lipid film was hydrated with a HBS solution containing 50 mM sulforhodamine B at pH 7.4. Vesicles were then prepared and covalently coupled to Anx5 as described above. Nonencapsulated dye molecules were discarded by gel filtration on a Sephacryl S-400 column (Amersham Bioscience, Buckinghamshire, UK). Leakage was followed by measuring the fluorescence intensity of the liposome solutions. Complete release of sulforhodamine B was achieved by addition of Triton X100 (100 μL at 0.5% v/v), and the proportion of fluorophore released was calculated as

$$\%\ \text{sulforhodamine}_{\text{free}} = \frac{I_t - I_0}{I_r - I_0}$$

where I_t is the fluorescence intensity after the desired period of time, I_0 is the fluorescence baseline, and I_r is the fluorescence after complete fluorophore release.

All measurements were realized with a Perkin Ellmer LS55 (Burckinghamshire, UK) at $\lambda_{exc} = 535$ nm and $\lambda_{em} = 595$ nm with emission and excitation slits of 2.5 nm. Two kinds of formulation were used: PEG_{2000}-DPPE 4 mol %/Mal-PEG_{2000}-DSPE 1 mol %/cholesterol 25 mol %/DOPC 70 mol %, and Mal-PEG_{2000}-DSPE 5 mol %/cholesterol 25 mol %/DOPC 70 mol %.

Cell Targeting *in Vitro*. A solution of 12.5 μM sulforhodamine B in HBS at pH 7.4 was passively encapsulated into liposomes, followed by covalent coupling of Anx5. Nonencapsulated dyes and excess Anx5 were discarded by filtration on an Amicon Ultra filter with a 100 kDa molecular weight cutoff (Millipore, Billerica, USA).

Bcr/Abl^+ K562 leukemic cells (*44*) were grown in RPMI 1640 medium (Gibco, Cergy Pontoise, France), supplemented with 30% fetal calf serum and a mixture of antibiotics (100 units mL^{-1} penicillin, 0.1 mg mL^{-1} streptomycin; Gibco). Cells were grown at 37 °C in humidified atmosphere and 5% CO_2. At J_0, K562 cells were resuspended at 3×10^5 cells/mL^{-1}. Twenty-four hrs later (J_1), 2 μM STI-571 was added to induce apoptosis (*45*). Twenty-four hrs later (J_2), 30 $\mu g_{phospholipids}$ of liposomes at a concentration of 300 $\mu g_{phospholipids}$/mL were added and incubated for 1 h at 37 °C before separation of the cells from unbound vesicles by centrifugation for 5 min at 200 g at 25 °C, followed by microscopy observations. The vesicles' composition was DOPC/cholesterol/Mal-PEG_{2000}-DSPE/PEG_{2000}-DPPE 70/25/1/4.

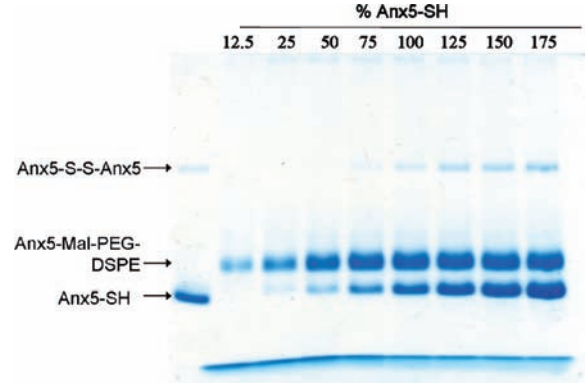

Figure 2. Quantitative analysis of the covalent coupling of Anx5-SH to liposomes containing Mal-PEG_{2000}-DSPE, by SDS-PAGE Fisrt lane: pure Anx5-SH. Following lanes: a fixed amount of liposomes, corresponding to 20 μg total phospholipid content, was incubated overnight with varying amounts of Anx5-SH. Prior to the SDS-PAGE analysis, a 5-fold excess of NEM was added to the samples to block unreacted thiol groups, and the mixture incubated for 4 h. The amounts of Anx5 are expressed both in micrograms and as the theoretical ratio of the (number of SH groups/number of accessible NEM groups) considering that half of the NEM groups are exposed on the outer lipid layer (from left to right: 0.825 μg to 11.55 μg or 12.5% to 175%).

Laser Scanning Confocal Microscopy. Live K562 cells (1.2×10^5 cells/cm^2) were mixed with liposomes containing sulforhodamine-B in 8-well Labteck plates (Nalc Nunc International). Image acquisition was performed with a Zeiss LSM510 laser scanning confocal microscope equipped with HeNe laser and with a Plan-Apochromat 63.0 × 1.40 oil objective lens (Carl Zeiss). Cells immerged in 0.5 mL of culture medium were excited with the 543 nm laser line (intensity set at 60% of maximal power) and their emission observed through a 560 nm long-pass filter. Photomultiplier detector voltage values (offset and gain) were adjusted on cells containing nonfluorescent samples for each set of experiments. The liposomes composition was DOPC/cholesterol/Mal-PEG_{2000}-DSPE/PEG_{2000}-DPPE 70/25/1/4.

RESULTS

Covalent Coupling of Anx5-SH to Liposomes. The covalent coupling of Anx5-SH proteins to liposomes containing lipid molecules exposing a maleimide group (referred to hereafter as Mal-liposomes) at their PEG distal end was achieved on preformed vesicles. The ligation reaction, represented schematically in Figure 1, was monitored by SDS-PAGE (Figure 2). For the protein alone, the major Anx5-SH band is accompanied by a minor band, of variable intensity, which corresponds to disulfide-bonded Anx5 dimers. After incubating Mal-liposomes with Anx5-SH, an additional band was observed, which is

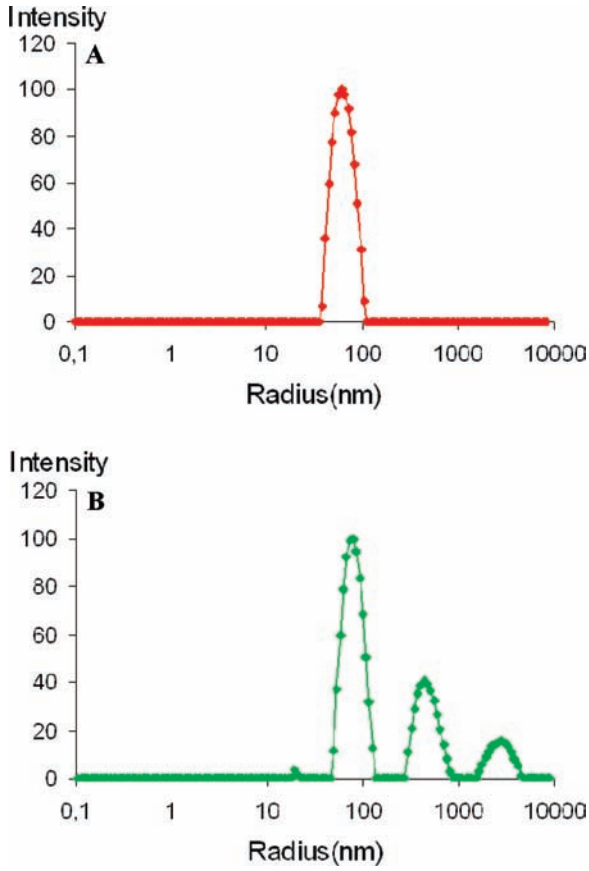

Figure 3. Dispersity of Anx5-functionalized liposome suspensions, by DLS size distribution profiles of Anx5-functionalized liposomes, determined by DLS at 90°. Densities of Anx5 per liposome: (A) 250; (B) 2000.

located slightly above the Anx5 monomer, as expected for covalent Anx5-PEG_{2000}-DSPE complexes. The molecular mass determined by MALDI-TOF mass spectrometry was 38 578 Da, in agreement with the theoretical value of 38 538 Da. Figure 2 shows that maximal coupling was obtained for a ratio between sulfhydryl groups and exposed maleimide groups close to a 1:1 stoichiometry. In these conditions, 80% of Anx5-SH was covalently coupled to Mal-liposomes. The fact that about 20% Anx5 remains uncoupled is attributed to partial hydrolysis of the maleimide group and to the spontaneous oxidation of Anx5-SH into Anx5 dimers, as indicated above. Complementary experiments indicated that maximal coupling was reached in 4 h at μM protein concentration and that the coupling efficiency was not influenced by the addition of nonmaleimidated PEG_{2000}-DPPE molecules (up to 4%) (data not shown).

Dispersity of Liposome Suspensions. The dispersity of liposome suspensions was monitored by DLS (Figure 3). Nonfunctionalized liposomes were uniform in size, with a mean radius of 60 ± 4 nm, as expected for 100 nm extruded liposomes (data not shown). We found that the liposome dispersity was highly dependent on the extent of Anx5 coupling. Up to 250 Anx5/vesicle, liposomes showed a homogeneous population with a radius of 62 ± 6 nm (Figure 3A). At higher values of Anx5/vesicle (≥250 Anx5/vesicle), aggregation occurred and precipitates were observed in the samples. The precipitates were found to be polydisperse with particle sizes ranging from hundreds of nanometers to several micrometers (Figure 3B).

Binding of Anx5-Functionalized Liposomes to Model Membranes, Monitored by QCM-D. In order to characterize the ability of Anx5-functionalized liposomes to bind to lipid membranes exposing PS molecules, we investigated the interaction of Anx5-liposomes with SLBs made of DOPC/DOPS (4:1, w:w), by the QCM-D method.

Figure 4A presents a reference experiment consisting of three steps: (1) the formation of a PS-containing SLB by adsorption and cooperative rupture of SUVs (arrow 1), followed by (2) the Ca^{2+}-dependent binding of Anx5 (arrow 2) and (3) the EGTA-induced desorption of Anx5 (arrow 3). The values obtained for the adsorbed mass and dissipation shift of a SLB, namely, 460 ng × cm^{-2} and ∼0 × 10^{-6}, respectively, and for a saturating Anx5 monolayer, namely, 275 ng × cm^{-2} and <0.1 × 10^{-6}, respectively, are in total agreement with reference values (*33, 41, 42*).

The injection of Anx5-functionalized liposomes over a PS-containing SLB was followed by a rapid and large increase of mass and dissipation, as illustrated in Figure 4B for liposomes grafted with a density of 8 Anx5/liposome. The values of adsorbed mass (2600 ng × cm^{-2}) and dissipation (43 × 10^{-6}) at saturation are characteristic of the extensive adsorption of flexible objects, as expected for liposomes linked via a PEG spacer (*35, 46*). The absence of liposome release upon rinsing with a Ca^{2+}-containing buffer (dashed arrow) indicates that functionalized liposomes are stably bound to the target SLB, in keeping with the known properties of Anx5 (*33*). As expected, vesicles were removed to a large extent from the SLB surface upon rinsing with an EGTA-containing buffer (arrow 3).

Control experiments showed that nonfunctionalized liposomes did not bind to PS-containing SLBs in the presence of Ca^{2+} and that Anx5-liposomes did not bind to PS-SLBs in the absence of Ca^{2+} (data not shown). Altogether, these results demonstrate that binding of Anx5-liposomes to PS-SLBs is mediated by Anx5 and reflects the specific formation of ternary Anx5-Ca^{2+}-PS complexes.

To assess the influence of Anx5 density on the efficiency of binding to PS-containing membranes, the mass of bound liposomes was monitored for various densities of Anx5-grafting (Figure 5). The binding of Anx5-liposomes increases with the density of Anx5 and reaches a maximum of about 3250 ng × cm^{-2} for a density of about 60 Anx5/liposome. Interestingly, liposome binding was observed at low Anx5 density, being detected down to an average density of 0.25 Anx5/liposome. The mass of adsorbed liposomes at an average density of 1 Anx5/liposome was 2045 ng × cm^{-2}. This indicates that one, or only a few, Anx5 molecules covalently linked to a liposome via a PEG spacer are sufficient to target a liposome to a membrane surface.

We used the system of Anx5-functionalized liposomes bound to a target membrane to address the following question: After formation of an elementary anchoring point to a target area, do lipid-bound ligands diffuse laterally within the liposome membrane and cluster at the target point? Anx5-functionalized liposomes containing various Anx5 densities were first immobilized on PS-containing SLBs, and then, the presence of Anx5 molecules accessible from the aqueous phase was assessed by measuring the Ca^{2+}-dependent binding of DOPC/DOPS (4:1) SUVs to SLB-bound liposomes (Figure 6). A signal of SUV binding was observed only when Anx5 density was higher than 125 Anx5/liposome. The absence of SUV binding at lower Anx5 density contrasts with the result presented before that one Anx5 is sufficient to immobilize one liposome on a SLB. We propose the following scenario: (i) as a first step, Anx5-functionalized liposomes bind to the PS-exposing SLB, which involves only one or a few Anx5 molecules; (ii) as the liposome membrane is fluid, Anx5-PEG-DSPE molecules diffuse laterally within the outer leaflet of the liposome; (iii) Anx5-PEG-DSPE molecules cluster at the target membrane; as a consequence, their density on the opposite liposome face is lower than the average density. SUV binding can only take place when Anx5 molecules are

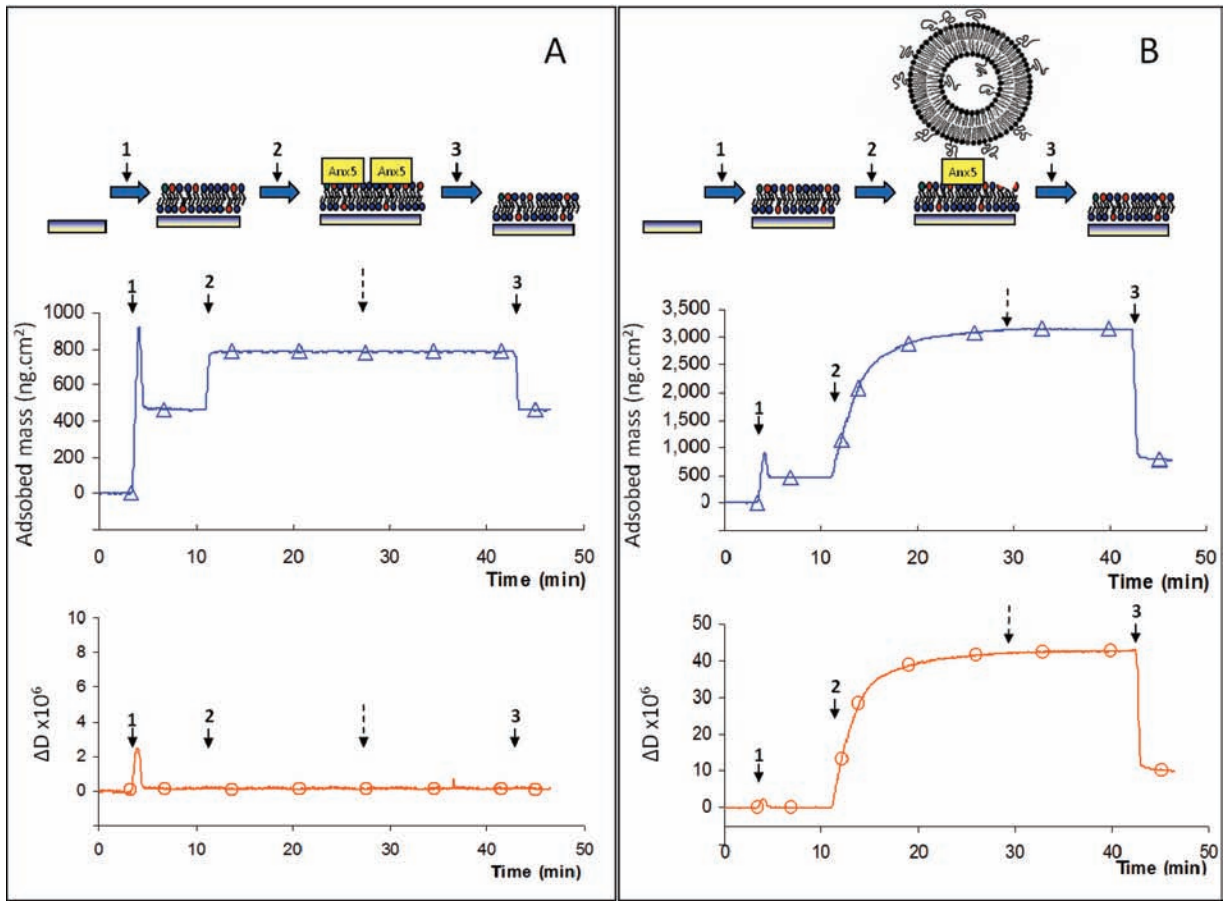

Figure 4. Binding of Anx5-functionalized liposomes to a solid supported lipid membrane, by QCM-D. Changes in adsorbed mass (Δ*m*, upper curves; open triangles) and dissipation (Δ*D*, lower curves; open circles) versus time upon successive injections of DOPC/DOPS (4:1, w:w) vesicles (arrow 1), Anx5 (arrow 2, A) or Anx5-functionalized liposomes (arrow 2, B), and EGTA-containing buffer (arrow 3). Rinses of the QCM-D chamber with a Ca^{2+}-containing buffer are indicated by a dashed arrow.

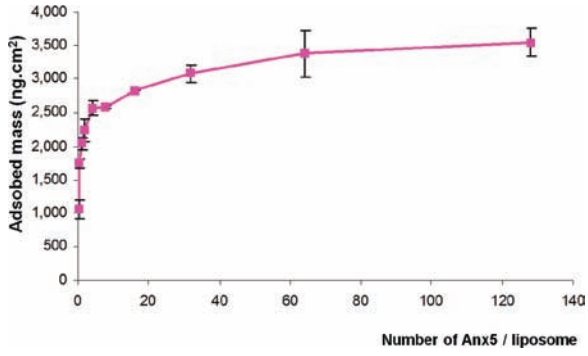

Figure 5. Influence of Anx5 density on the binding of Anx5-liposomes to DOPC/DOPS SLBs, by QCM-D. The adsorbed mass values correspond to plateau values from experiments similar to the one presented in Figure 4B.

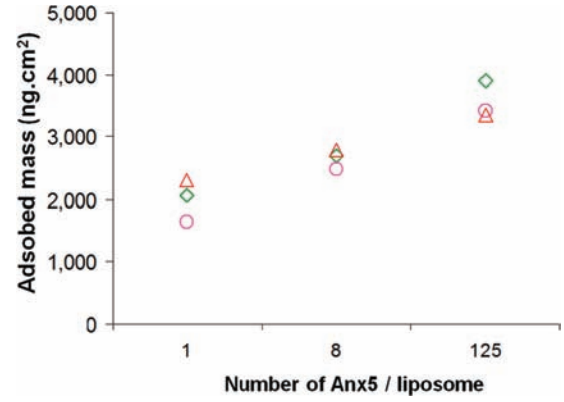

Figure 6. Influence of the PEG-layer density on binding of Anx5-functionalized liposomes to DOPC/DOPS SLBs. The adsorbed mass values correspond to plateau values from experiments similar to the one presented in Figure 4B. Open squares, 0% DPPE-PEG; open circles, 2% DPPE-PEG; open triangles, 4% DPPE-PEG.

present, in a sufficient number, at the liposome surface. This is achieved for an average threshold density of 125 Anx5/liposome.

We investigated also the influence of the PEG layer density on the targeting efficiency of Anx5-liposomes toward PS-exposing SLB. Figure 7 shows that the amount of PEG molecules present on the vesicle surface has a negligible influence on the amount of bound liposomes and thus on Anx5-mediated recognition of PS-SLBs.

Influence of Anx5 Conjugation on Liposome Membrane Stability. To investigate whether the conjugation of Anx5-SH affected the stability of liposomes, their membrane integrity was assessed by measuring the leakage of fluorescent dyes entrapped within the liposome interior.

First, we determined the self-quenching property of sulforhodamine-B solutions and found that fluorescence quenching takes place at dye concentration above 0.75 mM (Figure 8A). Sulforhodamine B was therefore encapsulated at 50 mM concentration. The leakage of fluorescent dyes was followed by measuring the fluorescence intensity of liposome solutions. Fluorescence intensity is expressed as a percentage of the maximal fluorescence intensity, which is obtained after solubilization of the liposomes with Triton X100, as shown in Figure 8B at 200 min.

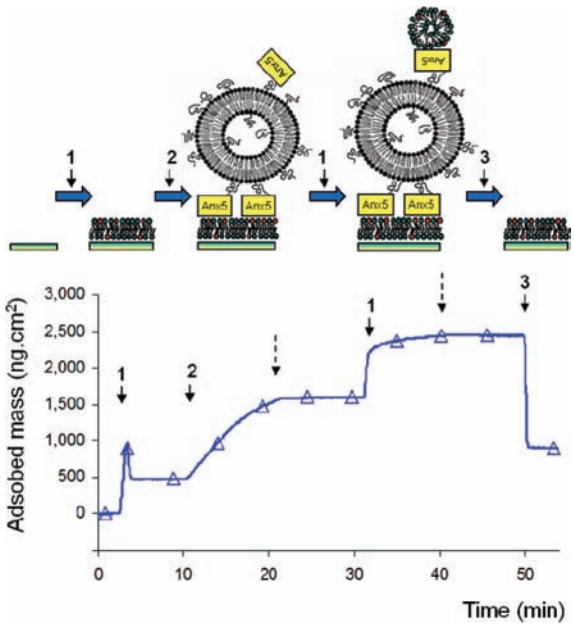

Figure 7. Binding of DOPC/DOPS vesicles to Anx5-functionalized liposomes anchored to a PS-SLB. Changes in adsorbed mass (Δm, open triangles) versus time, upon successive injections of DOPC/DOPS (4/1) vesicles (arrow 1), Anx5-functionalized vesicles (arrow 2), and EGTA-containing buffer (arrow 3). Rinses of the QCM-D chamber with a Ca^{2+}-containing buffer are indicated by dashed arrows.

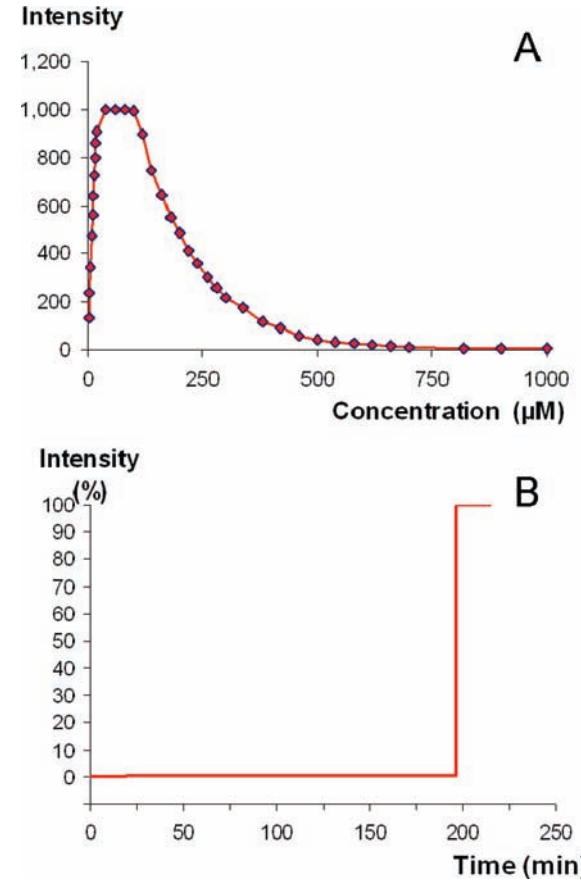

Figure 8. Analysis of the encapsulation properties of Anx5-functionalized liposomes, by fluorescence spectroscopy. (A) Self-quenching of sulforhodamine fluorescence. (B) Dequenching assay: leakage of entrapped sulforhodamine molecules was evaluated by measuring the increase of fluorescence intensity, in HBS at 23 °C. The liposomal formulation used for this experiment contained 1% Mal-PEG_{2000}-DSPE, and 80% of the accessible maleimide groups were conjugated to Anx5-SH. Complete release of fluorescent dyes from liposomes was induced by addition of 20% Triton X100. Extent of leakage was expressed as a percentage of the maximum fluorescence signal obtained after complete release.

No measurable leak of encapsulated dye was detected upon covalent coupling of Anx5-SH, nor after 10 h incubation of Anx5-liposomes in HBS buffer at 23 °C, for various formulations of Mal-liposomes (Figure 8B).

Targeting of Anx5-Grafted Liposomes to PS-Exposing Apoptotic Cells. The targeting of Anx5-grafted liposomes was then assessed on cellular systems, using Bcr/Abl^+ K562 leukemic cells (*44*) stimulated with 2 μM STI-571, an apoptosis-inducing compound in these cells (*45*). Apoptosis is accompanied by the exposure of PS molecules on the outer lipid layer of activated cells and derived cellular fragments (*16*). Anx5-grafted liposomes rendered fluorescent by encapsulation of 12.5 μM sulforhodamine B and fluorescence microscopy was used to follow the binding of liposomes to PS-exposing apoptotic cell membranes. About 30% of STI-stimulated K562 cells presented a homogeneous fluorescent labeling at their membrane surface (Figure 9A). Such a staining pattern is consistent with the fact that about 30% of the cells are induced in apoptosis. Control experiments showed that no binding of Anx5-grafted liposomes was observed on nonstimulated K562 cells (Figure 9D). Some parasite staining was visible, which is due to the presence of few necrotic cells or cell debris in cultured cells (Figure 9D).

DISCUSSION

Our aim is to develop long-circulating liposomal nanovectors functionalized with protein-based recognition elements for delivering imaging agents or drugs at specific cellular targets. The present study deals with the first step of this project, namely, the synthesis and characterization of liposomes functionalized with functional proteins and the analysis of their targeting efficiency. The choice of Anx5 as functionalizing agent had a twofold motivation. First, Anx5 binds with extremely high affinity to membranes exposing PS molecules, as evidenced by K_D values of 10^{-12} M or even lower, at millimolar Ca^{2+} concentrations (*47*), so that the targeting of Anx5-exposing vectors toward PS-exposing cells is expected to be highly efficient. Second, Anx5-liposomes have potential prognostic or therapeutic applications in *in vivo* imaging or drug delivery at sites of apoptosis in pathological association with atherosclerosis or ischemia (*21*, *48*, *49*).

This paper addresses the issues of covalent coupling of proteins to liposomes and of the correlation between the extent of functionalization and the efficiency of targeting.

The covalent grafting of Anx5-SH proteins to maleimide-exposing liposomes was found to be almost quantitative, as stoichiometric amounts of both species lead to an almost complete reaction in 4 h. In comparison, several studies have reported variable coupling yields (*50*−*53*), together with the need of excess lipid reactive groups to reach reasonable coupling rates. The high efficiency of the coupling reaction of Anx5-SH to Mal-PEG-liposomes is mainly due to the use of an engineered Anx5-SH with a unique and highly accessible sulfhydryl group (*32*), and to the high yield of the sulfhydryl-maleimide reaction. The efficiency of the coupling reaction of allowed us to analyze in detail the physicochemical and functional properties of Anx5-functionalized liposomes.

The size of Anx5-functionalized liposomes was investigated, because the size criterion is a determining parameter for the efficiency of drug delivery systems *in vivo*. The size of vesicles is known to affect both their circulation half-life and the volume available to load compounds. Large vectors would deliver high drug payload but would be retained by physical barriers playing

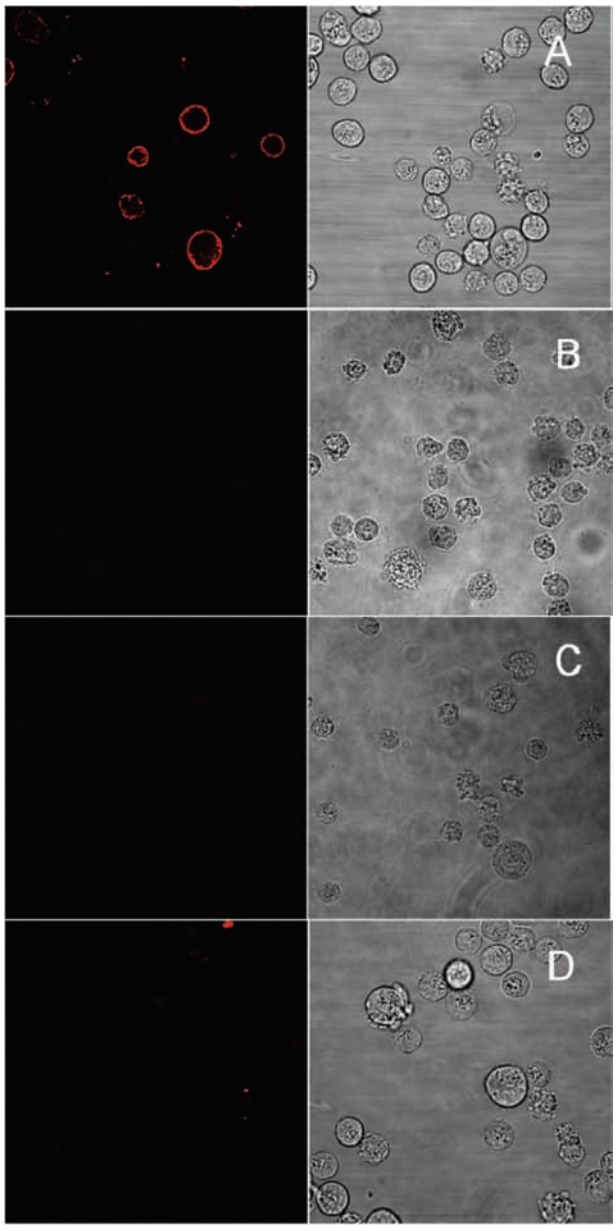

Figure 9. Interaction between K562 cells and liposomes, by laser scanning confocal microscopy. K562 cells, either untreated (B,D) or treated with 2 μM STI (A,C), were incubated for 1 h in a Ca^{2+}-containing RPMI 1640 medium with sulforhodamine-labeled liposomes, either nonfunctionalized (B,C) or Anx5-functionalized (A,D). A fluorescence image (left) and a bright-field image (right) of the same areas are presented for each condition. Image size: 145 μm × 145 μm. (A) untreated K562 cells incubated with nonfunctionalized liposomes; (B) STI-treated K562 cells incubated with nonfunctionalized liposomes; (C) untreated K562 cells incubated with Anx5-functionalized liposomes; (D) STI-treated K562 cells incubated with Anx5-functionalized liposomes.

the role of filters. On the other hand, small-sized liposomes would entrap a lower amount of drug and may present low circulation time, since below 70 nm, liposomes are removed from circulation by leaking out from blood vessels, mostly into liver cells (*1*). An optimal size accommodating both constraints of long circulation half-life and large volume for entrapping compounds is around 100 nm (*54*−*56*). We found that liposomal vesicles functionalized with low-to-moderate densities of Anx5, up to 250 Anx5/liposome, remain monodisperse and present a size, around 120 nm, in concordance with the use of 100 nm extrusion filters and compatible with their use *in vivo*. A density of 250 Anx5/liposome corresponds to coverage of about 1/4th of the liposome surface. We do not have a conclusive interpretation of the aggregation of Anx5-functionalized liposomes at higher Anx5 surface density, yet we speculate that this due to the change of the hydrophilic−hydrophobic balance of Mal-PEG-lipids after coupling of Anx5.

To determine the density of Anx5 providing optimal target binding efficiency, we used a model membrane system made of solid-supported lipid bilayers and measured the interaction of Anx5-functionalized liposomes to SLB in a systematic manner by QCM-D. SLBs with a PS content similar to PS-exposing apoptotic cells have been previously shown to be relevant models for studying the interaction of Anx5 or other PS-binding proteins (*33, 57*).The SLB/QCM-D assay is simple, fast, reproducible, and versatile and requires only a limited amount (few hundred micrograms) of functionalized liposomes.

Our results show that Anx5, once coupled to PEGylated lipids, maintains its ability to address liposomes toward PS-exposing membranes. As expected, the targeting efficiency depends on the number of Anx5-ligands per liposome. Increasing the Anx5 density increases both the total amount of bound liposomes at saturation (Figure 5) and the rate of liposome binding (data not shown). This result is in good agreement with studies carried out both *in vitro* (*52, 53, 58*−*60*) and *in vivo* (*61*). The value of about 60 Anx5/liposome corresponding to the plateau is in line with ligand densities of 30 to 80 ligands/liposome reported in other studies (*52, 53, 58*−*60*). Furthermore, as expected for ligands linked through a PEG spacer and regardless of the Anx5-SH density, the recognition efficiency is not impaired by the presence of a PEG coating, added to provide extended systemic circulation.

A major result of our study is that, statistically, one single Anx5 molecule is sufficient to target one liposome to a PS-exposing membrane. The estimation of the number of Anx5 is based on SDS-PAGE data and on a phospholipid determination assay (*37*). The main error in our calculations comes from the SDS-PAGE analysis, which we estimate to be less than a factor of 2. The fact that binding of liposomes is detected at a density of less than 1 Anx5 per liposome (namely, 0.25 Anx5/liposome) means that only 1/4th of the liposomes need to present one Anx5 in order for binding to be detected. This exceptional targeting efficiency must originate from the very high affinity of Anx5 for PS-membranes, the controlled orientation of Anx5, the use of a PEG spacer separating the Anx5 moiety from the liposome surface (*61, 62*), or a combination of these factors.

The combined results of DLS and QCM-D experiments allowed us to optimize the number of conjugated Anx5-SH/liposome. DLS measurements showed that less than 250 Anx5 molecules should be attached per liposome in order to avoid liposome aggregation. QCM-D experiments indicated that a density of 60 proteins/liposome ensures maximal targeting efficiency. As a consequence, for the rest of the study, we chose the following formulation: DOPC/cholesterol/Mal-PEG_{2000}-DSPE/PEG_{2000}-DPPE 70.75/25/0.25/4 mol % grafted with a density of 60 Anx5 per liposome. Liposomes with this formulation were also shown to be stable, retaining encapsulated fluorescent dyes.

The ability of Anx5-functionalized liposomes to deliver imaging agents to PS-exposing cells *in vitro* was further demonstrated by the specific labeling of PS-exposing apoptotic cells by Anx5-liposomes. Leukemic K562 cells were chosen for this study as a model system of PS-exposing cells. The staining pattern was limited to the periphery of the apoptotic cells, which indicates that Anx5-functionalized vesicles were not internalized. This result is in contrast with a recent study concluding to Anx5 internalization into apoptotic cells, which may be due to a difference in cells' properties (*25*).

As a side result of this study, the ability of Anx5-PEG-lipids to form ligand clusters at target sites was investigated. Anx5 is known to self-assemble into two-dimensional arrays of trimers on PS-containing membranes through two-dimensional diffusion in the membrane plane and protein−protein interaction (*30, 57*). We interpret the absence of binding of SUVs to SLB-bound Anx5-functionalized liposomes at Anx5 density lower than 125 Anx5 molecules/liposome as due to the clustering of Anx5-PEG-lipids at target sites.

In conclusion, these results demonstrate that Anx5-functionalized liposomes bind specifically to PS-exposing synthetic and natural membranes. These liposomal nanovectors are thus good candidates for delivering drugs or imaging agents to sites of apoptosis or thrombosis (*22*−*24, 63*).

ACKNOWLEDGMENT

We thank Nicolas Guidolin, Sébastien Lecommandoux, and Christophe Schatz for their help with DLS measurements. We are grateful to Emilie Bled for her experimental help and to Benoit Frisch for the gift of modified lipids at an early stage of this work. We thank Jean-Max Pasquet for introducing us to the K562 cells and his expert help and advices. We thank the members of the Consortium "Nanobioimaging" for helpful discussions. We acknowledge the financial support of the French National Research Agency programs ANR-Tecsan (grant 2006-15 "Nanobioimaging" to K.G.P.) and ANR-EMPB (grant 2007-021-01 "MP-NPAuA5 to AB) and the Conseil Régional d'Aquitaine to K.G.P. B.G. is recipient of a PhD fellowship from the ANR-Tecsan 2006-15.

Synthesis and Biological Evaluation of Clicked Curcumin and Clicked KLVFFA Conjugates as Inhibitors of β-Amyloid Fibril Formation

Myriam Ouberai, Pascal Dumy, Sabine Chierici,* and Julian Garcia*

Département de Chimie Moléculaire (DCM), UMR 5250, ICMG-FR, Université Joseph Fourier, BP 53, 38041 Grenoble Cedex 9, France. Received June 29, 2009; Revised Manuscript Received August 11, 2009

Abnormal aggregation of β-amyloid (Aβ) peptides into toxic aggregates has been identified as a key event in Alzheimer's disease (AD). Inhibition of this process has thus emerged as a major therapeutic track against AD. The present work describes the synthesis and *in vitro* study of a novel class of inhibitors. Two copies of Aβ-binding motifs (either curcumin or the KLVFFA peptide) are clicked via copper(I)-mediated azide−alkyne cycloaddition on a constrained cyclopeptide scaffold designed to interfere with Aβ aggregation. Our conjugates strongly inhibit amyloid fibril formation from $A\beta_{40}$ at low inhibitor to Aβ molar ratios (e.g., 0.02:1 in the case of the KLVFFA conjugate) at which Aβ-binding motifs alone are fully inactive (thioflavin T assays and atomic force microscopy observation). This work highlights the value of combining Aβ-recognition domains with a steric hindrance-inducing scaffold for preventing amyloid fibril formation.

INTRODUCTION

In Alzheimer's disease (AD), abnormal aggregation of β-amyloid (Aβ) peptides into toxic aggregates is one of the key pathogenic events (*1*−*4*). However, the exact nature of the toxic Aβ species is still a topic of debate. Insoluble Aβ fibrils with characteristic β-sheet structures as well as soluble protofibrils and other intermediates on the pathway toward mature fibrils have each been shown to induce neurotoxicity in cell culture (*2, 5*−*8*). Nevertheless, the current consensus states that Aβ has to be in an aggregated form in order to be toxic. For this reason, major efforts have been achieved to find molecules that can interfere with Aβ aggregation. The identification of the residues 16−20, KLVFF, of the β-amyloid peptide as a self-recognition element during Aβ assembly (*9*) led to the development of a series of short peptides incorporating this $A\beta_{16-20}$ region, which bind to Aβ and prevent its autoassociation (*10*). Then by modifying the peptides containing the Aβ-recognition motif with proline residues, N-methylated, D-, or charged amino acids, or organic reagents, other β-sheet breaker peptides have been identified and showed, in some cases, an activity on mouse models (*11*−*17*). Small organic molecules (*18*−*22*) have also been reported as inhibitors of Aβ peptide aggregation *in vitro*. Most of them present aromatic parts interfering, through hydrophobic interactions, with hydrophobic and aromatic residues of the misfolding Aβ peptides that are critical to fibril formation (*23, 24*).

However, a majority of the above inhibitors showed only a moderate inhibition efficiency attributed to their poor ability to interact over the large interface of interaction of Aβ peptides during the aggregation process or to interact simultaneously with the multiple binding surfaces (*18, 25*). High levels of plasticity of Aβ to accommodate to small molecules may also be involved. Novel classes of molecules were thus designed to yield more potent AD inhibitors. For instance, high Aβ-affinity compounds featuring multiple copies of an Aβ-recognition domain were developed in the aim to interact simultaneously with several binding sites of Aβ or several Aβ peptides. Several copies of KLVFF or its retro-inverso analogue, ffvlk, have been thus displayed onto a poly(ethylene glycol) (PEG) (*26*) or a dendrimer-based scaffold (*27*). These compounds showed stronger ability to block fibril formation *in vitro* than the corresponding monomers. An alternative approach consists in linking an Aβ-binding domain and a bulky element, designed to block Aβ's surface. The efficiency *in vitro* of the cholyl-LVFFA, reported a few years ago, can be attributed to the steric effects of the cholyl group that prevent the interaction with other Aβ peptides (*13*). More recently, this approach was highlighted by an original study. A high Aβ-affinity compound (Congo Red) was covalently attached to a synthetic ligand of the FK-binding protein (*25*). The recruitment of the bulky protein via its ligand prevents any interaction within a large surface and blocks aggregation. This system has shown an increased efficiency as compared to Congo Red alone and is one of the most efficient inhibitors of fibril formation reported so far.

In a previous work (*28*), we contributed to the field of AD inhibitors by investigating a tetramer of acridine on a cyclopeptide scaffold. Despite its moderate inhibition activity, the latter still contrasted strongly with the nonactive monomer. These results encouraged us to prepare more potent assemblies by displaying higher Aβ-affinity ligands on this scaffold, which is developed in our group (*29*). We chose the amyloid peptide mimick KLVFFA (*13*) and curcumin (*23, 30*) as the well-known ligand of Aβ and inhibitor of amyloid aggregation (Figure 1). Our new inhibitors thus feature two copies of the KLVFFA peptide or two copies of the curcumin molecule on the upper face of the cyclopeptide scaffold and four arginine residues on the lower face (Figure 1, compounds **9** and **10** respectively). By presenting two copies of KLVFFA or of the polyphenolic compound onto the cyclopeptide, we aim to associate a dimeric Aβ-binding region with the steric hindrance-inducing effect of the scaffold. Arginine residues were chosen first to improve the solubility of the hydrophobic ligands, but they may interfere with Aβ aggregation. The effect of arginine on aggregation and protein folding has been reported in the literature (*31, 32*). Even if the mechanism by which arginine affects aggregation and protein folding is not well understood, guanidinium groups of our conjugates may act as aggregation disrupting elements.

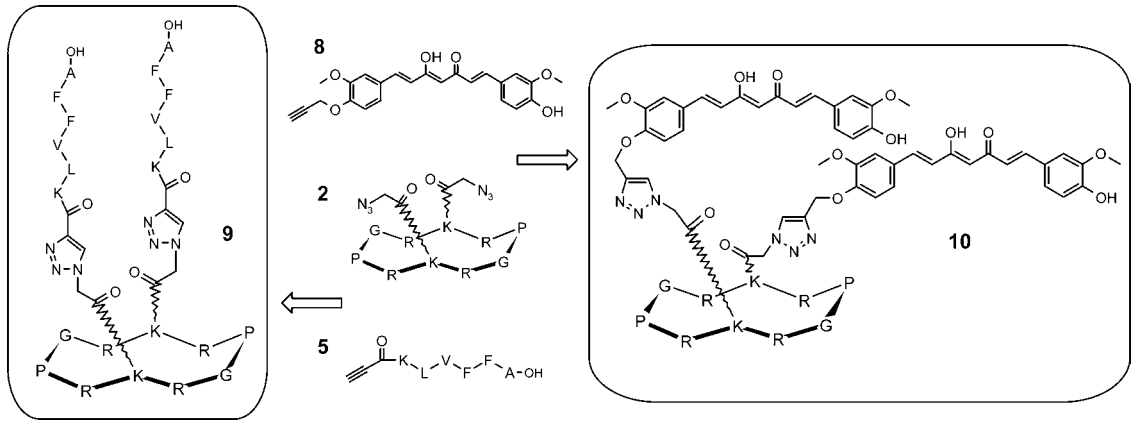

Figure 1. Design of conjugates **9** and **10**.

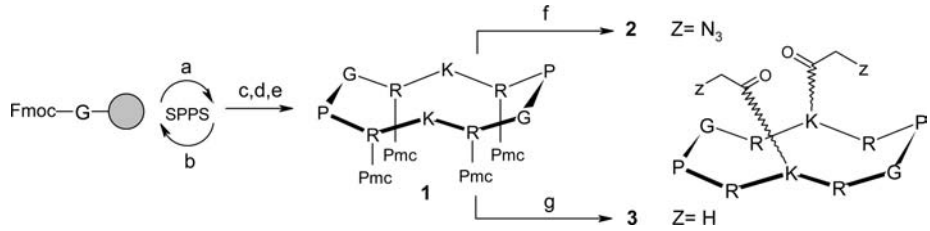
Scheme 1. Synthesis of the Azide-Functionalized Cyclodecapeptide 2 and Control Cyclodecapeptide 3[a]



[a] (a) Piperidine/DMF (1:4); (b) Fmoc-Xaa-OH (2 equiv), PyBOP (2 equiv), DIPEA (3−4 equiv), DMF; (c) TFA/CH_2Cl_2 (1:99), 10 min (three times); (d) PyBOP (1.2 equiv), DIPEA (3−4 equiv), DMF (0.5 10^{-3} M), 1 h; (e) Hydrazine/DMF (2:98), 2 h, 76% from the linear form of **1**; (f) (i) Azidoacetic acid (2.2 equiv), PyBOP (2.2 equiv), DIPEA, DMF (10^{-2} M), 2 h; (ii) TFA/H_2O (9:1), 2 h, 18% for **2** (2 steps); (g) (i) Ac_2O/Pyridine/DMF (1:2:7), 30 min; (ii) TFA/H_2O (9:1), 2 h, 64% for **3** (2 steps).

To assemble the Aβ-binding motifs (curcumin or KLVFFA) onto the cyclopeptide, we favored the copper(I)-mediated alkyne−azide cycloaddition (CuAAC) over the oxime bond ligation method used in our previous work (*28*). Despite its high chemoselectivity, oximation occurs in aqueous salt medium (sodium phosphate buffer) impairing the ligation efficiency of hydrophobic molecules. In contrast, the high versatility of CuAAC in terms of solvents and conditions (*33*−*35*), makes it more suitable for the synthesis of our conjugates.

In the present work, we describe the synthesis of conjugates **9** and **10** using the so-called click chemistry as well as their evaluation as inhibitors of $A\beta_{40}$ fibril formation using thioflavin T (ThT) assays and atomic force microscopy (AFM).

MATERIALS AND METHODS

All protected peptides were prepared by solid phase synthesis using Fmoc/*t*Bu strategy on an Advanced ChemTech 348 Ω synthesizer. The alkyne curcumin derivative **8** was prepared as reported in the literature (*36*).

RP-HPLC analyses and purifications were performed on Waters equipment consisting of a Waters 600E controller, a Waters 2487 Dual absorbance detector, and a Waters In-Line Degasser. The analytical column (Nucleosil C18, particles size 3 μm, pore size 120 Å, 30 × 4 mm^2) was operated at 1.3 $mL \cdot min^{-1}$ using linear A−B gradients in 15 min run time (solvent A, H_2O containing 0.1% trifluoroacetic acid (TFA); solvent B, CH_3CN containing 9.9% H_2O and 0.1% TFA). For reversed-phase high performance liquid chromatography (RP-HPLC) purifications, three columns were used in 30 min run time with linear A−B gradients: a preparative Delta-Pak column (C18 particles size 15 μm, pore size 300 Å, 200 × 25 mm^2) at 22 $mL \cdot min^{-1}$; a semipreparative Nucleosil 100-7 column (C18 particles size 7 μm, pore size 100 Å, 250 × 10 mm^2) at 5 $mL \cdot min^{-1}$; and a semipreparative Discovery BIO Wide Pore column (C5 particles size 10 μm, pore size 300 Å, 250 × 10 mm^2) at 5 $mL \cdot min^{-1}$. UV monitoring was performed most of the time at 214 and 250 nm. Mass spectra were obtained by electrospray ionization (ESI-MS) on a VG Platform II in positive mode.

Synthesis of Cyclopeptide 2 and Control Cyclopeptide 3 (Scheme 1). The linear peptide R(Pmc)-K(Dde)-R(Pmc)-P-G-R(Pmc)-K(Dde)-R(Pmc)-P-G was built up automatically on Fmoc-Gly-Sasrin resin (500 mg, 0.69 $mmol \cdot g^{-1}$) and cyclized (415 mg, $1.59 \cdot 10^{-4}$ mol) in dimethylformamide (DMF) (0.5 $mmol \cdot L^{-1}$) under high dilution using (Benzotriazol-1-yloxy)-tripyrrolidinophosphonium hexafluorophosphate (PyBOP) (100 mg, $1.91 \cdot 10^{-4}$ mol) and N-ethyldiisopropylamine (DIPEA) to adjust the pH to 8−9. The white solid powder obtained after precipitation in diethyl ether was solubilized in a solution of 2% of hydrazine in DMF to remove Dde protecting groups. The cyclopeptidic intermediate **1** (272 mg, $1.21 \cdot 10^{-4}$ mol) was then obtained by precipitation in diethyl ether (76% yield from the linear peptide). HPLC t_R = 10.1 min. ESI-MS calcd for $C_{106}H_{164}N_{24}O_{22}S_4$ 2253.1; found, 2253.6.

To access compound **2**, azidoacetic acid (*37*) was first coupled (18 mg, $1.78 \cdot 10^{-4}$ mol) on the lysine side chains of **1** (182 mg, $8.07 \cdot 10^{-5}$ mol). The reaction was performed during 2 h at r.t. in DMF (0.01 $mol \cdot L^{-1}$), with PyBOP (93 mg, $1.78 \cdot 10^{-4}$ mol) and DIPEA (pH to 8−9). Then Pmc protecting groups were removed using a solution of TFA/H_2O (9:1) (0.01 M). After 2 h, the solvent was evaporated, and the crude compound **2** was obtained by precipitation in diethyl ether (74 mg, 51% yield). It was purified by RP-HPLC (C18 Nucleosil column, 5−100% B in 30 min) to get pure compound **2** (26 mg, $1.43 \cdot 10^{-5}$ mol) as a white powder with 18% yield. HPLC t_R = 6.5 min. ESI-MS calcd for $C_{54}H_{94}N_{30}O_{12}$ 1354.7; found, 1354.4.

To get the control cyclopeptide **3**, precursor **1** (20 mg, $8.87 \cdot 10^{-6}$ mol) was first acetylated during 30 min in a mixture (0.01 $mol \cdot L^{-1}$) of Ac_2O/Pyridine/DMF (1:2:7). After evaporation of solvents, the acetylated intermediate was precipitated in

[a] Products were identified by ESI-MS analysis. [b] Conversion rates were determined by HPLC.

diethyl ether. The Pmc protecting groups were then removed by adding a solution of TFA/H_2O (9:1) (0.01 mol·L^{-1}). After 2 h, the mixture was concentrated under reduced pressure, and the crude product was precipitated in diethyl ether. Its purification by RP-HPLC (C18 Delta-Pak column, 5−100% B in 30 min) afforded pure compound **3** (9.8 mg, $5.67\cdot10^{-6}$ mol) as a white powder (64% yield). HPLC $t_R = 5.4$ min. ESI-MS calcd for $C_{54}H_{96}N_{24}O_{12}$ 1272.7; found, 1272.7.

Synthesis of Alkyne Aβ_{16-21} Peptide 5 and Control Aβ_{16-21} Peptide 7 (Scheme 2). The peptide precursor K(Boc)-L-V-F-F-A **4** was automatically assembled on 2-chlorotrityl-chloride resin (450 mg, 1.4 mmol·g^{-1}). The coupling of propiolic acid (120 μL, $1.89\cdot10^{-3}$ mol) on the *N*-terminal position was then performed with PyBOP (982 mg, $1.89\cdot10^{-3}$ mol) in 10 mL of DMF adjusted with DIPEA to pH 8−9. The mixture was stirred for 30 min at r.t. The coupling reaction was realized once again. After removing the Boc protecting group and releasing from the resin with a solution of TFA/H_2O (9:1), **5** (115 mg, $1.29\cdot10^{-4}$ mol) was obtained with 21% overall yield after purification by RP-HPLC (C18 Nucleosil column, 5−100% B in 30 min). HPLC $t_R = 9.3$ min. ESI-MS calcd for $C_{41}H_{57}N_7O_8$ 775.4; found, 775.4.

The Aβ_{16-21} peptide derivative **7** (Scheme 2) was also prepared from **4**. The supported peptide **4** (135 mg, 1.4 mmol·g^{-1}) was swirled in 10 mL of DMF adjusted with DIPEA to pH 8−9. Azidoacetic acid (189 mg, $9.30\cdot10^{-4}$ mol) and PyBOP (483 mg, $9.30\cdot10^{-4}$ mol) were added, and the mixture was stirred for 30 min at r.t. This procedure was realized once more. After removing the Boc protecting group and releasing from the resin with a solution of TFA/H_2O (9:1), the azide peptide **6** (42 mg, $4.56\cdot10^{-5}$ mol) was obtained with 25% overall yield after purification by RP-HPLC (C18 Nucleosil column, 5−100% B in 30 min). It (5 mg, $5.43\cdot10^{-6}$ mol) was then condensed at 40 °C for 20 h with 3-methoxy-1-propyne (522 μL, $6.18\cdot10^{-6}$ mol) in 510 μL of TFE/*t*BuOH/H_2O (30:15:1) in the presence of (+)-sodium L-ascorbate (55 μL, 0.1 M, $5.50\cdot10^{-6}$ mol) and $CuSO_4$ (27 μL, 0.1 M, $2.70\cdot10^{-6}$ mol). Compound **7** was obtained with 20% yield (1.1 mg, $1.11\cdot10^{-6}$ mol) after purification by RP-HPLC (C18 Nucleosil column, 10−100% B in 30 min). HPLC $t_R = 8.4$ min. ESI-MS calcd for $C_{44}H_{64}N_{10}O_9$ 876.4; found, 876.4.

Optimization of Triazole Linkage. All of the assays of the cycloaddition reaction described in Table 1 were carried out in 110 μL of solvents with $1.1\cdot10^{-6}$ mol of the azide cyclodecapeptide **2** (1.99 mg) and $2.42\cdot10^{-6}$ mol of the complementary alkyne compounds, peptide **5** (2.15 mg) or curcumin derivative **8** (0.98 mg). Conversion into final material was determined by HPLC.

Synthesis of Compound 9. Peptide **5** (7.9 mg, $8.88\cdot10^{-6}$ mol) and cyclopeptide **2** (7.3 mg, $4.03\cdot10^{-6}$ mol) were dissolved in 750 μL of trifluoroethanol (TFE)/H_2O/*t*BuOH (1:1:1). (+)-Sodium L-ascorbate (22 μL, 0.01 M, $2.20\cdot10^{-7}$ mol) and $CuSO_4$ (11 μL, 0.01 M, $1.10\cdot10^{-7}$ mol) were added, and the mixture was heated with a domestic microwave for 20 min. The product was purified by RP-HPLC (C5 column, 25−100% B in 30 min) to afford pure compound **9** (5.6 mg, $1.56\cdot10^{-6}$ mol) in 39% yield. HPLC $t_R = 7.7$ min. ESI-MS calcd for $C_{136}H_{208}N_{44}O_{28}$ 2907.4; found, 2906.9.

Synthesis of Compound 10. Curcumin derivative **8** (1.8 mg, $4.42\cdot10^{-6}$ mol) and cyclopeptide **2** (3.9 mg, $2.15\cdot10^{-6}$ mol) were dissolved in 200 μL of TFE/H_2O/dimethyl sulfoxide (DMSO) (1:1:2). (+)-Sodium L-ascorbate (20 μL, 0.01 M, $2.15\cdot10^{-7}$ mol) and Cu turning (20 mg) were added, and the mixture was heated at 60 °C for 7 h. The product was purified by RP-HPLC (C5 column, 25−100% B in 30 min) to afford pure compound **10** (1.7 mg, $6.48\cdot10^{-7}$ mol) in 30% yield. HPLC $t_R = 10.4$ min. ESI-MS calcd for $C_{102}H_{138}N_{30}O_{24}$ 2167.0; found, 2166.9.

Preparation of Aβ_{40} Peptide Stock Solution. Synthetic Aβ_{40} was prepared as previously described (*38*). For aggregation assays, a stock solution of Aβ_{40} was prepared. Then 2.7 mg of Aβ_{40} was dissolved in 200 μL of 1,1,1,3,3,3-hexafluoro-2-propanol to disassemble preformed aggregates. After lyophiliza-

tion, 1 mL of pure water was added to the peptide, and the solution was centrifuged at 12000*g* to remove eventual aggregates. The stock solution was divided into portions and stored at −20 °C until use. The stock concentration of Aβ_{40} was 500 μM.

Preparation of Compound Stock Solutions. Compounds **3**, **7**, **9**, and **10**, and curcumin were dissolved in DMSO/H_2O (1:1). Stock solutions of 5 to 20 mM were first prepared and then diluted with DMSO/H_2O (1:1) to get solutions of 500 μM to 0.5 μM. Final concentrations of DMSO in inhibition studies were less than 2%.

Fibril Formation Measurement of Aβ_{40}. Aggregation of Aβ_{40} was performed in 96-well black polypropylene microplates (Greiner). The aggregation buffer consists of 100 mM sodium phosphate buffer at pH 7.4 to which 200 mM sodium chloride was added. To each well (final volume = 100 μL), an aliquot of the Aβ_{40} peptide stock solution (10 μL) was mixed into 50 μL of the aggregation buffer in the presence of 10 μL of a 100 μM ThT solution, giving a final concentration of 50 μM in Aβ_{40} and 10 μM in thioflavin T (ThT). Then, aliquots of 2 μL of compounds **3**, **7**, **9**, and **10** and curcumin were added along with 28 μL of water. Microplates were sealed with a plastic sheet and incubated in a Molecular Devices Spectra MAX Gemini XS microplate reader at 37 °C.

Fibril Formation Measurement of Aβ_{40} with Preformed Fibrils. The seeded experiment was similar to the experiment described above except that preformed fibrils (5 μM) were added to each well. Performed fibrils were obtained after the incubation of fresh Aβ_{40} (50 μM) in aggregation buffer at pH 7.4 at 37 °C for 8 days and were sonicated for 10 s immediately before use.

Fluorescence Spectroscopy. Microplates were analyzed in a Molecular Devices Spectra MAX Gemini XS microplate spectrophotometer at 37 °C. Measurements of ThT binding were recorded once or twice daily using bandpass filters of 445 nm for excitation and 485 nm for emission, and a cutoff filter of 475 nm.

Atomic Force Microscopy. Study was performed on the NanioBio platform in Grenoble, France. An aliquot, 3 μL, from each inhibition study was withdrawn after 12 days of incubation and deposited onto freshly cleaved mica sheets for AFM inspection. The sample was incubated on mica for 2 min followed by three washes with 5 μL of water to gently remove the material not adsorbed to the substrate. The mica was dried in air for 1 h. In-air AFM images were acquired in noncontact mode in a vibration insulated environment, using a PicoPlus microscope (Molecular Imaging), equipped with a PicoScan-3000 controller. For imaging, we used single beam aluminum-coated cantilevers (type NSC36/ALBS, μMasch) with *Rc* <10 nm, 110−130 μm lengths, and nominal spring constant 0.6 N/m. The drive frequency was between 200 and 400 kHz.

RESULTS

Synthesis. The synthesis of conjugates **9** and **10** through CuAAC is summarized in Figure 1. The azide-substituted cyclodecapeptide **2**, the acetylene curcumin **8**, and the alkyne-functionalized KLVFFA **5**, were first prepared as complementary building blocks for the ligation by click chemistry.

Cyclodecapeptide **2** was obtained from intermediate **1** by coupling azidoacetic acid to the amine side chain of its lysine residues (Scheme 1). The noncommercial azidoacetic acid was extemporaneously prepared from bromoacetic acid and sodium azide as reported (*37*). A total conversion of **1** was observed by HPLC after a 2 h reaction with azidoacetic acid. Compound **2** was, however, obtained in low yield after arginine protecting group (Pmc) removal. The stability of the azido group under acidic conditions tends to support the formation of aggregates of **2** rather than degradation products during Pmc removal.

KLVFFA derivative **5** containing the Aβ_{16-21} sequence was efficiently prepared by solid phase peptide synthesis in 21% overall yield (Scheme 2). Propiolic acid, selected as the alkyne precursor, was introduced at the *N*-terminal position of the supported peptide. Curcumin derivative **8** (Figure 1) was obtained from propargyl bromide and curcumin as described in the literature (*36*).

The coupling of the building blocks **2**, **5**, and **8** by CuAAC was then performed and optimized (Table 1). In all reactions, a slight excess of the alkyne partner (**5** or **8**) as compared to the azide-containing cyclodecapeptide **2** was used (1.1 equiv/per azide group). The propensity of **5** to form aggregates is highly dependent on experimental conditions such as high concentration in aqueous media and the presence of salts. By using $CuSO_4$ with sodium ascorbate (NaAsc) as the reducting agent in *t*BuOH/H_2O, we observed the formation of a gel and no occurrence of the reaction (entry 1, Table 1). CuI as catalyst was further used in the presence of organic bases in DMF (entry 2, Table 1) (*39*, *40*). By using an organic solvent, we expected to improve the solubility of the peptide and to avoid its aggregation. Unfortunately, no reaction occurred up to 24 h at 60 °C, and only 11% of compound **9** was detected by HPLC after 76 h. We suspect the low conversion rate to be due to the instability of the catalytic system despite the special care undertaken (inert atmosphere and anhydrous DMF). In order to overcome the solubility issue and to limit the quantity of salt in the reaction mixture, we also considered using copper turning rather than the copper sulfate/NaAsc system. Trifluoroethanol (TFE) was added as cosolvent to improve solubility. After 4 h, a modest 16% conversion rate was obtained and the reaction mixture turned into a gel (entry 3, Table 1). If TFE seemed to improve the solubility, the coupling reaction appeared nevertheless too slow down as compared to the formation of the gel. We finally opted for using microwaves (MWs) to activate the reaction. A combination of Cu(I) with MWs in CuAAC has shown to complete reactions in a few minutes and in clean conditions (*41*). Under MW activation and in the presence of TFE as cosolvent, a complete conversion of **2** into **9** was observed in only 20 min with no gel formation. Conjugate **9** was isolated as a pure compound in 39% yield after semipreparative RP-HPLC purification and was characterized by ESI mass spectrometry.

In the case of the curcumin derivative **8**, several attempts were also necessary to efficiently form conjugate **10** (entries 5−7, Table 1). Similar to the KLVFFA peptide, the major issue to deal with was the precipitation of **8** in the reaction mixture because of its strong hydrophobicity (entry 5, Table 1). Using copper turning instead of $CuSO_4$/NaAsc and increasing the ratio of TFE (entry 6, Table 1) failed to avoid precipitation. We managed to achieve complete conversion of **2** into **10** after 7 h by replacing *t*BuOH with DMSO, by increasing the amount of organic solvent, and by using copper turning in NaAsc (entry 7, Table 1). Purification by RP-HPLC provided conjugate **10** as a pure compound in 30% yield.

To assess the specificity of the inhibitory response of our conjugates **9** and **10**, control compounds were needed. Cyclopeptide **3** and peptide **7** (Schemes 1 and 2) were prepared with this aim. Cyclopeptide **3** presenting acetylated functions instead of the clicked Aβ-binding elements was obtained from intermediate **1** in 64% yield (Scheme 1). The Aβ_{16-21} peptide **7** featuring a *N*-terminal triazole was obtained from intermediate **4** on the solid support (Scheme 2). Azidoacetic acid was coupled to the *N*-terminal end of **4** to obtain the azide-functionalized peptide **6** after release from the resin. The click reaction of **6** with 3-methoxy-1-propyne in the presence of NaAsc/$CuSO_4$ afforded **7** in only 20% yield. Addition of TFE in *t*BuOH/H_2O and heating at 40 °C for more than 20 h were not sufficient to

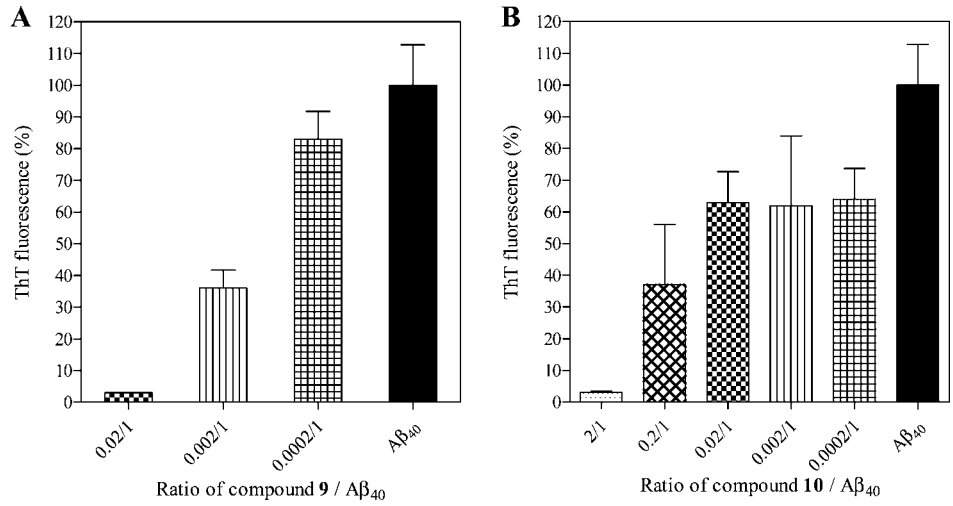

Figure 2. Aβ_{40} (50 μM) coincubated with compounds **9** and **10** in the indicated molar ratios (compound/Aβ_{40}) during 8 days. Values are the maximal fluorescence intensity at 485 nm compared to that of the control (Aβ_{40} with no inhibitor). Results are the mean ± standard deviation of 2−3 experiments.

prevent the precipitation of precursor **6**. Compound **7** was prepared prior to the use of MWs, in the synthesis of **9**, to efficiently activate the alkyne KLVFFA peptide **5** and avoid its precipitation (entry 4, Table 1). We presume that the activation by MWs of peptide **6**, whose solubility is similar to that of **5**, may improve the yield in compound **7**.

Thioflavin T Assay. Measurement of thioflavin T (ThT) fluorescence was used to evaluate the ability of conjugates **9** and **10** to inhibit Aβ_{40} fibril formation. We coincubated Aβ_{40} (50 μM) and ThT (10 μM) with a concentration range of each compound for a period of 8 days and studied the ThT fluorescence change at 485 nm. The relative change of ThT fluorescence (as compared to the condition of Aβ with no compound) was reported as a function of the molar ratio of tested compound to Aβ peptide (compound/Aβ_{40}). ThT was added directly to the fibril forming mixture as it has been shown to have little effect on the assembly process (*12, 42*). Control compounds were also studied in order to compare the activity of conjugates **9** and **10** with individual parts of their molecules: the single KLVFFA analogue **7**, curcumin, and cyclodecapeptide **3**. The results are presented in Figures 2 and 3. In order to check if the tested compounds can self-aggregate in the experimental conditions, we also performed ThT assays without Aβ_{40} (data not shown). At a 100 μM concentration which corresponds to the highest concentration of inhibitors used in the assays, neither compound **3** nor compound **10** showed ThT binding in the absence of Aβ_{40} after incubation for 8 days. On the contrary, we observed an immediate ThT fluorescence for compounds **7** and **9** at 100 μM and at a 10-fold lower concentration of 10 μM for **9**. These data indicate that, at these concentrations, compounds **7** and **9** bound ThT and formed structures with high β-sheet content by self-aggregation, whereas compounds **3** and **10** did not. Consequently, in the ThT assays in the presence of Aβ_{40}, compounds **7** and **9** were incubated at a maximum concentration of 10 μM and 1 μM, respectively.

Compound **9** with Aβ_{40} at a 0.02/1 ratio significantly reduced the ThT signal with an inhibition higher than 95% (Figure 2A). Even by reducing the ratio down to 0.002/1, more than 60% inhibition was still observed. Compound **10** required a higher 2/1 ratio to reduce 95% of ThT fluorescence (Figure 2B). At the 0.02/1 ratio, the ThT signal was still inhibited by 30%.

While compound **9** caused a strong reduction of ThT fluorescence at 0.02/1 and 0.002/1 ratios, the KLVFFA control **7** showed no inhibition on Aβ fibril formation (Figure 3A) at the same ratios. In the case of curcumin, significant reduction of the ThT signal was observed at 2/1 and 0.2/1 ratios, but no inhibition was observed at lower ratios (Figure 3B). Finally, no decrease in the ThT signal was observed for the scaffold alone, compound **3** (Figure 3C).

The capacity of compounds **9** and **10** in preventing fibril growth was also studied by ThT assay in the presence of preformed Aβ_{40} fibrils as seeds (Figure 4). The increase of ThT fluorescence at 485 nm was measured for 24 h after the addition of Aβ_{40} preformed fibrils (5 μM) on the mixture containing the compounds and fresh Aβ_{40} (50 μM). In comparison with unseeded experiments (Figure 2), compound **9** showed a more moderate activity in reducing fibril formation. At the 0.02/1 ratio, still 55% of ThT fluorescence remained (Figure 4). For compound **10**, a similar effect was observed in seeded and unseeded experiments with an inhibition around 85% at the 2/1 ratio.

AFM Observations. Samples were observed after 12 days of incubation of the compounds with Aβ_{40} in the same conditions as those used in the ThT assay (Figure 5). In the control sample of Aβ_{40} with no inhibitor, a number of long protofilaments of 1−4 μm in length and 5−10 nm in height were formed (Figure 5F). No fibril was observed for compound **9** at 0.02/1 ratio (Figure 5A). Compound **10** at 0.2/1 ratio showed much shorter fibrils than the control: 500 nm maximum length, 300 nm average, and 4 nm maximum height (Figure 5B). For compound **7**, the number of protofilaments observed at 0.2/1 ratio confirmed that the monomeric KLVFFA analogue alone is not able to inhibit fibril formation (Figure 5D). With curcumin at the 0.2/1 ratio with Aβ_{40}, long protofilaments (1−2 μm maximal length, 950 nm average) were detected (Figure 5E). With the scaffold alone, **3** at 2/1 ratio, shorter fibrils, compared to those of the control, were observed (0.3−1 μm), attesting an effect of **3** on fibril morphology (Figure 5C).

DISCUSSION

Synthesis. The azide−alkyne cycloaddition strategy required the synthesis of the cyclodecapeptide **2**, bearing two azido functionalities on the upper face, and of the KLVFFA and curcumin precursors **5** and **8**, displaying the suitable complementary alkyne functions (Figure 1). The alkyne monofunctional derivative **8** previously reported to prepare a clicked curcumin dimer (*36*) appeared to be well suited for our study. Consequently, we simply applied the described procedure from curcumin and propargylbromide. For the preparation of peptides

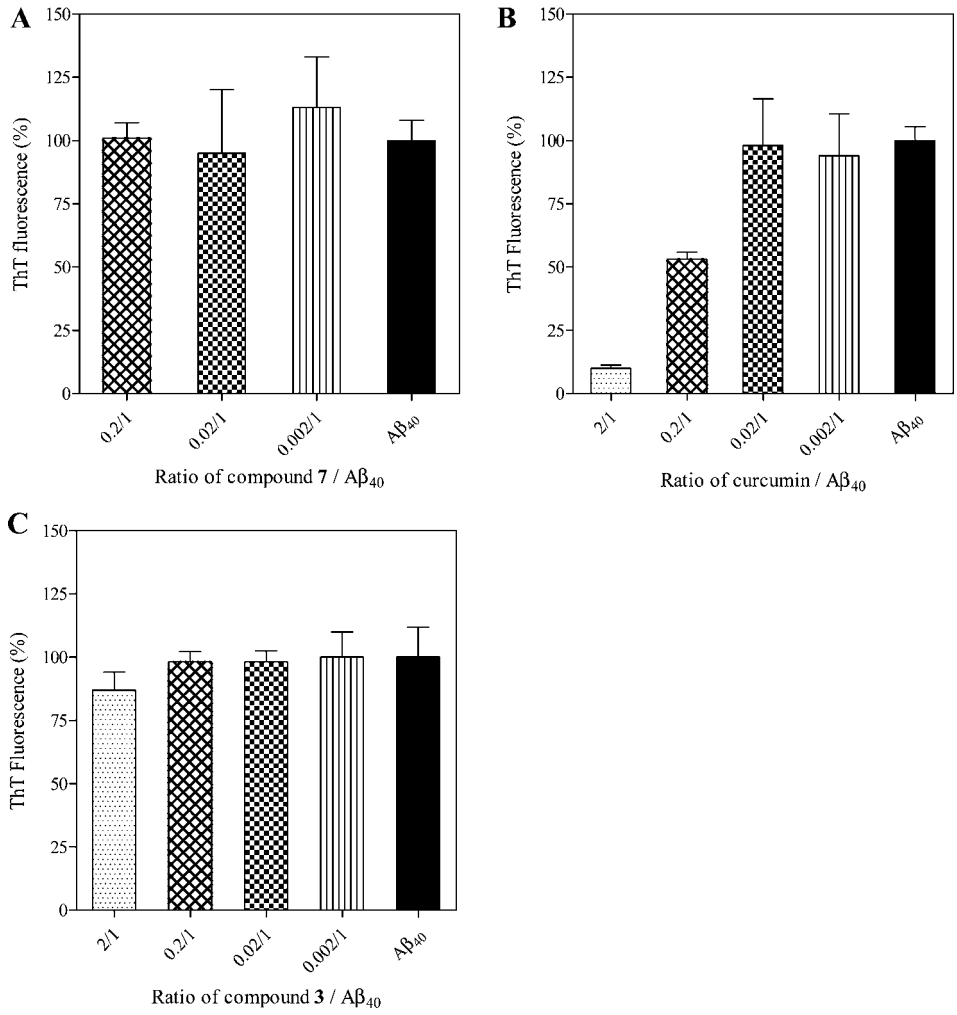

Figure 3. Aβ_{40} (50 μM) coincubated with control compounds **3**, **7**, and curcumin in the indicated molar ratios (compound/Aβ_{40}) during 8 days. Values are the maximal fluorescence intensity at 485 nm compared to that of the control (Aβ_{40} with no inhibitor). Results are the mean ± standard deviation of 2−3 experiments.

2 and **5**, a combination of solid and solution-phase syntheses was employed (Schemes 1 and 2). Azidoacetic and propiolic acids, selected as the azide and alkyne handles, respectively, have proven (*43*) to be convenient reactants to acylate peptides on their *N*-terminal end or amine side chains. They were efficiently tethered using PyBOP as coupling agent to the corresponding peptides in solution phase or on solid support in the case of **5**.

The ligation of the appropriate alkyne building block (**5** or **8**) to the azidocyclopeptide **2** was then considered. As we presumed, the major limitation to their ligation was their low hydrophilicity as well as the propensity of **5** to form aggregates. Indeed self-aggregation of amyloid sequence derivatives such as **5** are known to be highly promoted by certain experimental conditions such as manipulation at high concentration and the presence of salts (*44*, *45*). Concerning curcumin, its poor solubility in water is reported to be the major limitation to its biological use, justifying the development of more soluble derivatives (*36*). To address the solubility issue, we had to test several conditions of CuAAC (Table 1) in order to optimize the formation of the triazole linkage from our lipophilic derivatives. A wide number of CuAAC conditions have been reported in the literature that differ in Cu(I) sources, solvents, additives, or activation conditions (*33*). The catalyst can be introduced as a Cu(I) salt (CuI, CuBr, Cu(CH$_3$CN)$_4$PF$_6$...) with the use of base. It can also be generated *in situ* by oxidation of metal copper Cu(0) or by reduction of Cu(II) salts (CuSO$_4$) with

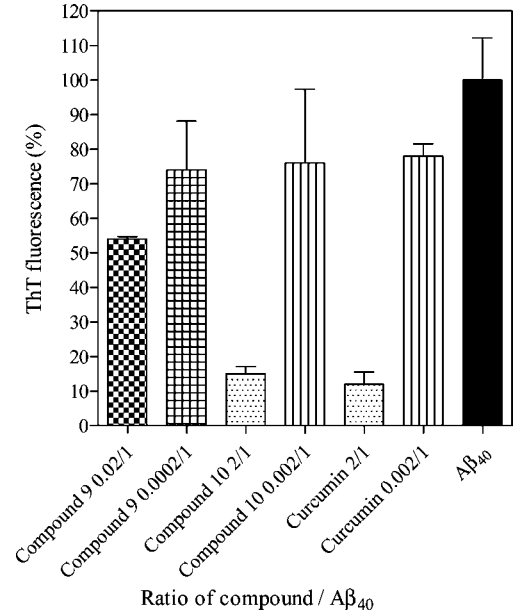

Figure 4. Fresh Aβ_{40} (50 μM) and preformed fibrils (5 μM) coincubated with compounds **9**, **10**, and curcumin in the indicated molar ratios (compound/Aβ_{40}) during 24 h. Values are the maximal fluorescence intensity at 485 nm compared to that of the control (Aβ_{40} with no inhibitor). Results are the mean ± standard deviation of 2−3 experiments.

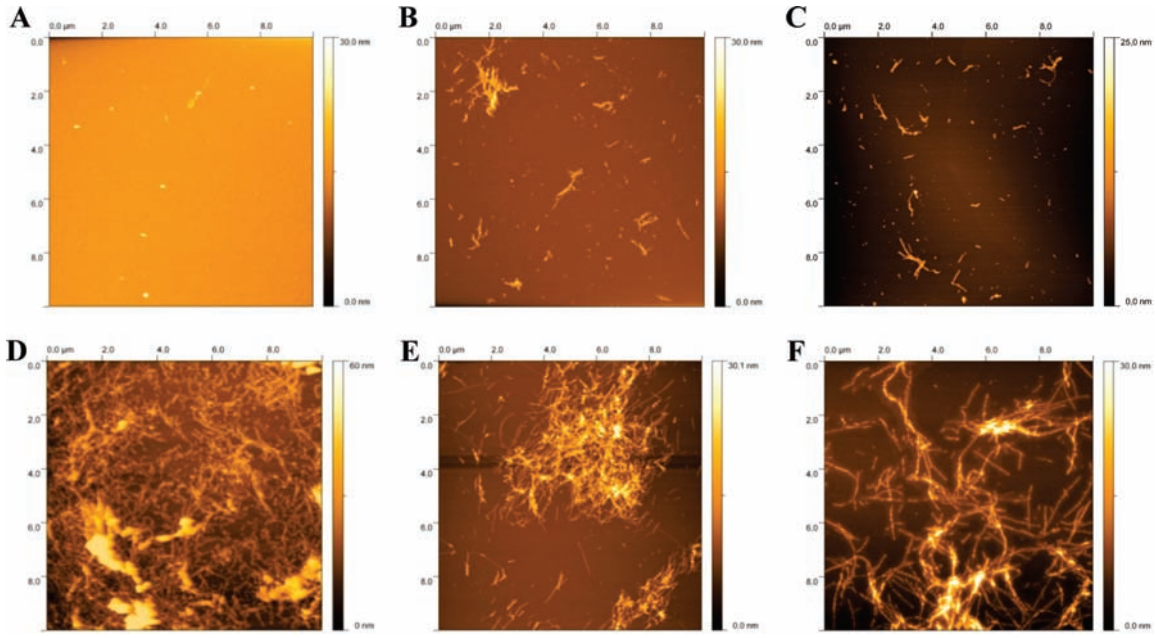

Figure 5. AFM images (height data) of protofilaments formed from Aβ_{40} (50 μM) after 12 days of incubation at 37 °C with the different compounds (scan size 10 μm). (A) compound **9**/Aβ_{40} 0.02/1, (B) compound **10**/Aβ_{40} 0.2/1, (C) compound **3**/Aβ_{40} 2/1, (D) compound **7**/Aβ_{40} 0.2/1, (E) curcumin/Aβ_{40} 0.2/1, and (F) Aβ_{40} with no inhibitor.

sodium ascorbate. The reaction can be performed in aqueous conditions, in various organic solvents (DMF, CH_3CN, THF, EtOH, DMSO...) or in organo-aqueous systems (*t*BuOH/H_2O, DMSO/H_2O...). Microwave irradiation has also be reported to shorten reaction times and to provide a selective conversion into the 1,4-substitued triazole similar to elevated temperature conditions.

The common procedure using copper(II) sulfate and sodium ascorbate as reducing agent in *t*butanol/water solution was first attempted. These conditions have indeed proved successful in conjugating azide-modified sugars or peptides onto alkyne-cyclopeptides (*46, 47*). This protocol, however, failed in the case of derivatives **5** and **8** because of their precipitation in the reaction medium.

Regarding the variety of reported CuAAC procedures, suitable conditions were finally found to access conjugates **9** and **10** from alkyne derivatives **5** and **8** (Table 1) in reasonable yields. To obtain the KLVFFA conjugate **9**, the addition of trifluoroethanol TFE as cosolvent and activation of the reaction by microwaves were found to give the best results (total conversion of **2** in only 20 min). A click reaction involving curcumin derivative **8** using the $CuSO_4$/NaAsc combination was reported in the literature to prepare the clicked curcumin dimer (*36*). In this study, the addition of chloroform in the *t*butanol/water solution was necessary to obtain the desired clicked product in a moderate 41% yield. In our case, the addition of TFE was not sufficient to avoid precipitation of **8**, and a combination of copper turning and NaAsc in a DMSO/water/TFE mixture was required to access conjugate **10**. It is worth noting that the use of a mixture of Cu(0) and sodium ascorbate is unusual. Indeed Cu(0), found as wire, turnings, powder, or nanoparticles, is usually employed alone or in combination with a Cu(II) source (*43, 48*). The active Cu(I) catalyst is then formed via comproportionation of the Cu(II)/Cu(0) complex. The success of this unusual combination can be explained by the presence of a significant amount of Cu(II) on the surface of the copper turning that was converted into Cu(I) with NaAsc.

***In Vitro* Inhibition Studies of Aβ_{40} Fibril Formation.** Synthetic fibrils made from Aβ_{40} monomers are commonly used *in vitro* for screening inhibitors. The formation of Aβ_{40} fibrils is monitored by fluorimetric assay using thioflavin T, a sensitive and highly specific dye to the characteristic cross-β-sheet structure of fibrils (*42, 49*). Even if the fluorescence in the ThT assay is well correlated with the highly ordered aggregation morphology, atomic force microscopy (AFM) observation is most of the time used in parallel to ensure that the observed effect is indeed due to fibril inhibition.

In this study, we performed both the ThT assay and AFM to evaluate our conjugates. In the ThT assay, we examined for each inhibitor candidate a range of concentrations and expressed the results in terms of inhibitor candidate to Aβ molar ratios. Using a constant concentration of Aβ_{40}, comparison of the relative potency of each inhibitor is facilitated. Compounds **9** and **10** showed a strong antiamyloidogenic effect since a significant inhibition of fibril formation from Aβ_{40} monomers was observed even at low molar ratios (Figure 2). Compound **9** displayed a high inhibitory activity as almost complete inhibition is observed at a 0.02/1 ratio of **9**/Aβ (Figure 2A). This is to compare with the control peptide KLVFFA **7**, which is totally inactive at up to 10-fold higher ratio (Figure 3A). Concerning compound **10**, an inhibition higher than 95% was observed at a 2/1 ratio. Compound **10** remained active at 0.02/1 and even at lower ratios where curcumin proved to be totally inactive (Figures 2B and 3B). These results demonstrate the benefit of the dimeric presentation of the Aβ-recognition motif in our assemblies to inhibit fibril formation. The synergistic effect is particularly impressive for compound **9**. With two copies of the KLVFFA peptide, this conjugate is at least 5-fold more active in blocking the formation of well ordered fibrils than the KLVFFA monomer **7** (considering the number of moles in KLVFFA subunits). This is in concordance with previously reported studies demonstrating the increased efficiency of multivalent KLVFF conjugates against Aβ peptide aggregation (*26, 27*). Moreover, conjugate **9** appeared 100 times more potent than conjugate **10**. The fact that the KLVFFA motif is not only a target recognition motif but also a part of the β-sheet breaker can explain this difference in activity.

The morphology of Aβ fibrils by AFM was consistent with the results of the ThT assays (Figure 5). No fibril was observed for conjugate **9** at the low 0.02/1 ratio, whereas fibrils were

detected with monomer **7**. AFM observation also confirmed that curcumin conjugate **10** is more active than curcumin in preventing Aβ_{40} aggregation at low concentrations. Indeed, at identical 0.2/1 ratio, long protofilaments similar to those observed in Aβ control were observed with curcumin, while much shorter fibrils were observed in the presence of **10**.

The possibility that the inhibitory effect of our conjugates is due to the nature of the cyclodecapeptide scaffold was also considered. The scaffold alone, compound **3**, showed no inhibition effect in the ThT assay (Figure 3C). However, AFM observation revealed that fibril morphology was affected. At high 2/1 ratio of **3**/Aβ, shorter fibrils than the Aβ control were observed. We suspect the arginine residues, previously shown to affect protein folding, to be involved (*31, 32, 50*). Guanidium groups of arginines were known to interact through hydrogen bonding interactions with the protein backbone or through π-electron−cation interactions with specific protein domains, such as aromatic amino acid side chains (*50*). Although there is insufficient evidence for drawing a firm explanation, interaction of arginines with aromatic side chains of Aβ peptides which are essential for aggregation could disturb the aggregation process leading to shorter protofilaments. Moreover, arginine residues may act by preventing the network of hydrogen bonds between the Aβ backbone amides, which is essential for the formation of an extended β-sheet fibril. The influence of arginine on Aβ-amyloid aggregate morphology has been reported using hybrid peptides (*51*). With an arginine hexamer R_6, fibrillar aggregates much shorter than Aβ alone were observed. With a KLVFF-R_6 hybrid, simultaneously featuring the KLVFF Aβ-recognition domain and the R_6 disrupting domain, no aggregate with fibrillar morphology was observed, but large globular-like clumps of material were observed. If arginine compounds may have very different effects depending on the context in which arginine was presented, this study confirms that arginine can have significant effects on the path of Aβ aggregation.

The Aβ fibril formation process is presumed to occur in two successive phases, precisely, nucleation followed by extension (*17*). During the nucleation phase, Aβ monomers self-assemble from a random coil structure into oligomers and aggregation-prone species that can aggregate once a critic concentration is reached. After the nucleus has formed, additional monomers rapidly form extended fibrils. This polymerization step starts when a shift to β-sheet structured protofibrils occurs. Inhibitors of fibril formation can thus act by binding to monomers or to aggregation-prone species during the nucleation phase or by binding to the nascent fibrils during the polymerization phase. Seeded experiments, where preformed fibrils are added to the Aβ aggregation mixture, enable one to follow only the exponential growth of fibrils and thus to identify specific inhibitors of Aβ polymerization (*13*). In such an experiment, both **9** and **10** decreased fibril growth, suggesting that they impair the Aβ polymerization process (Figure 4). However, in comparison with the corresponding unseeded experiments, the ThT fluorescence was higher at the same ratios, implying that they also disrupt the nucleation phase. Indeed, conjugate **9** proved to have an effect both on the initial nucleation phase and on Aβ polymerization (95% and 45% inhibition in unseeded and seeded experiments, respectively, at identical 0.02/1 ratios). Conversely, conjugate **10** mostly affects the polymerization phase since the difference between the two scenarios is less impressive (95% and 85% inhibition at 2/1 ratio).

Both conjugates **9** and **10** proved to be more effective than curcumin in preventing Aβ fibril formation. Indeed, at 0.02/1 molar ratio (i.e., 1 μM inhibitor concentration), conjugates **9** and **10** inhibit Aβ_{40} aggregation by 95% and 35%, respectively. At comparable ratios and by using the same experimental procedure, curcumin showed no inhibition at all. With our most potent inhibitor, conjugate **9**, inhibition occurs at 0.02/1 ratio, whereas most peptide inhibitors reported in the literature require much higher excess of Aβ. For instance, the small LPFFD peptide (*16*) and the cholyl-LVFFA (*13*), shown to significantly reduce Aβ_{40} amyloid formation, are active only at 10/1 and 1/1 ratios, respectively. In comparison with reported multimeric KLVFF conjugates, the activity of compound **9** is also very interesting. Maximum inhibition with PEG conjugates featuring either KLVFF or the retro-inverso peptide, ffvlk, (80% and 70%, respectively) were attained with 0.33/1 ratio for the hexamer and 1/1 for the dimer forms (*26*). Conjugate **9** is at least 8 times more active since 90% inhibition is obtained at 0.04/1 ratio (expressed as per mol of KLVFFA subunit). Our conjugate **9** also appears 100 times more active than a dendrimer, featuring four copies of KLVFF (90% inhibition of Aβ_{42} aggregation at 4/1 ratio) (*27*). Careful attention should, however, be paid when comparing to this dendrimer since it was tested against Aβ_{42} aggregation. It has indeed been shown with KLVFF analogues that some compounds could be more active on Aβ_{40} than on Aβ_{42} aggregation (*16*).

The potency of our conjugate **9** in preventing Aβ neurotoxicity remains to be evaluated. Concerning its potential use *in vivo* as a drug against AD, the ability to cross the blood−brain barrier (BBB) should be taken into account. Despite a recent study showing the efficiency of a non-BBB crossing anti-Aβ antibody in reducing amyloid deposits (*52*), this capability is a critical issue in drug development against AD. The high molecular weight of **9** is surely a limiting factor; however, the scaffold-based architecture of this conjugate allows facile modification with other components such BBB-crossing carriers (e.g., Tat peptide *53, 54*). Current progress in drug delivery materials across the BBB such as polymeric nanoparticles is also likely to promote in the near future the accessibility of drugs targeting AD (*55*).

CONCLUSIONS

This work confirms that the versatility of CuAAC is an indubitably powerful tool to assemble biomolecules. Aβ recognition domains have been efficiently clicked on a bulky cyclopeptidic scaffold to prepare inhibitors of Aβ amyloid fibril formation. In terms of inhibition, the arginine-rich scaffold covalently associated with two copies of the KLVFFA sequence has shown a potent effect on Aβ_{40} aggregation, whereas the curcumin conjugate exhibited a more modest effect. Although the exact mechanism is not fully understood yet, we assume that the dimeric presentation of KLVFFA favors interactions with Aβ peptides and that the scaffold acts as a disrupting element on Aβ aggregation. While previously reported inhibitors required equimolar ratio to Aβ or even higher, our most effective conjugate still induced 95% inhibition with a ratio as low as 0.02/1. Our strategy based on a modular assembly herein applied to conjugates targeting AD will likely be further exploited to develop inhibitors of others amyloid related disorders (*56*).

ACKNOWLEDGMENT

This work was supported by grants from the European FP6 EURAMY project "Systemic amyloidoses in Europe". We are grateful to the NanoBio program for the facilities of the Synthesis and Surface Characterization platforms. We also thank Dr. Martine Demeunynck for helpful discussions about synthesis.

Thiol-Reactive Derivatives of the Solvatochromic 4-*N*,*N*-Dimethylamino-1,8-naphthalimide Fluorophore: A Highly Sensitive Toolset for the Detection of Biomolecular Interactions

Galen Loving and Barbara Imperiali*

Departments of Chemistry and Biology, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, Massachusetts 02139. Received July 17, 2009; Revised Manuscript Received September 18, 2009

The solvatochromic fluorophore 4-*N*,*N*-dimethylamino-1,8-naphthalimide (4-DMN) possesses extremely sensitive emission properties due largely to the low intrinsic fluorescence it exhibits in polar protic solvents such as water. This makes it well suited as a probe for the detection of a wide range of biomolecular interactions. Herein we report the development and evaluation of a new series of thiol-reactive agents derived from this fluorophore. The members of this series vary according to linker type and the electrophilic group required for the labeling of proteins and other biologically relevant molecules. Using the calcium-binding protein calmodulin as a model system, we compare the performance of the 4-DMN derivatives to that of several commercially available solvatochromic fluorophores identifying many key factors important to the successful application of such tools. This study also demonstrates the power of this new series of labeling agents by yielding a fluorescent calmodulin construct capable of producing a greater than 100-fold increase in emission intensity upon binding to calcium.

INTRODUCTION

The solvatochromic properties of many environment-sensitive fluorophores have been exploited in a wide range of biological applications such as detecting protein−peptide binding events (*1*−*6*), monitoring changes in protein allostery (*7*−*12*), and reporting various forms of post-translational modification (*13*, *14*). These fluorophores possess emission properties that are highly sensitive to the nature of the immediate solvent environment. If that environment is altered in a manner that impacts the degree of exposure to water, then such an event could produce a significant change in one or more of the emission properties of the fluorophore (i.e., fluorescence lifetime, emission wavelength, and fluorescence quantum yield) (*15*). Since both intra- and intermolecular interactions of many proteins often involve a dynamic veiling and unveiling of discrete hydrophobic clefts or pockets within the topology of these macromolecules, an appropriately placed solvatochromic fluorophore can provide a general and facile method of detecting protein function or activation. Because of the adaptable nature of these tools for addressing an array of problems in the biological sciences, many classes of solvatochromic fluorophores are now commercially available in reactive forms ready for direct conjugation to proteins and other relevant biomolecules (*16*). This diversity offers greater prospects of identifying fluorescent constructs with signaling characteristics suitable for study.

A common application of solvatochromic fluorophores is the development of constructs in which the measured fluorescence change is integrally coupled to a perturbation in a specific aspect of protein structure. Such an approach is particularly advantageous when structural changes are too subtle to be detected by other fluorescence-based methods such as Förster resonance energy transfer (FRET) (*17*) and fluorescence polarization (FP) (*18*). However, a practical limitation often encountered when using many of the commercially available solvatochromic probes is that the magnitude of the observed fluorescence change rarely approaches the maximum potential obtained in the context of a typical solvent comparison study (*6*). The reasons for this observation are varied but can frequently be attributed in part to the high degree of intrinsic fluorescence exhibited by these fluorophores in water as well as insufficient sensitivity to changes in the local environment.

Herein we report the development of a new series of cysteine modifying agents, **1**−**4**, derived from the solvatochromic fluorophore 4-*N*,*N*-dimethylamino-1,8-naphthalimide (4-DMN). The principle advantage of this fluorophore, along with other members of the dimethylaminophthalimide family, is that it exhibits extremely low fluorescence quantum yields when exposed to polar protic solvents such as water (*6*). This greatly reduces the background signal thereby creating the effect of on−off or switch-like changes in the observed emission intensity with the potential to exceed ratios of 1000-fold. Furthermore, as previously reported we have determined that this fluorophore possesses significantly greater chemical stability than the other dimethylaminophthalimide dyes we have investigated (*6*), making it particularly suitable for applications that require prolonged exposure to a wide range of aqueous conditions relevant for most biological applications.

Much of our former work with the dimethylaminophthalimide dyes focused on the development of fluorescent amino acids for incorporation into small peptide-based probes designed to recognize and report binding to discrete protein motifs such as 14−3−3 domains (*19*), SH2 domains (*3*), and PDZ domains (*20*). While these efforts have proved highly successful, our current aim has been to expand the scope of applications to include the integration of these tools into native proteins. However, several fundamental differences must be considered when applying these tools in proteins versus short peptides. With increasing peptide length, the polymer chain exhibits greater potential for adopting higher order structure (*21*), leading, in some instances, to significant changes in the local environment of the attached fluorophore.

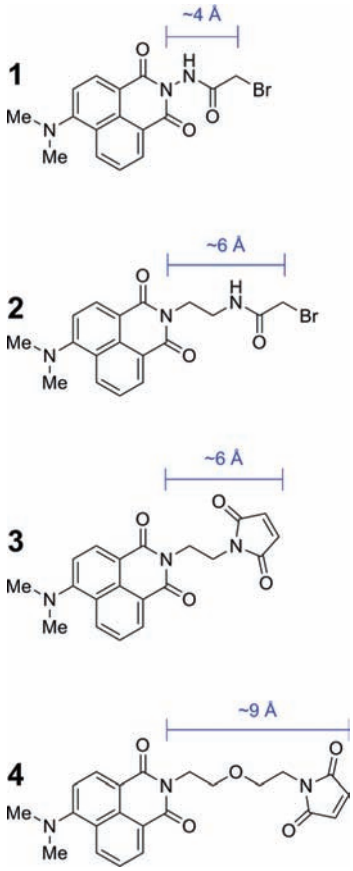
Chart 1. 4-DMN-Based Cysteine Modifying Agents



Such changes may include the degree of solvent exposure, the frequency of collisional quenching, and the emergence of local electrostatic fields. Additionally, the arrangement of the polymer chain around the dye could restrict certain vibrational modes responsible for nonradiative decay processes that compete with fluorescence. The influence of such structural elements and the effects they impart on the photophysical properties of the fluorophore are difficult to predict and can often complicate efforts toward developing useful fluorescent protein probes that utilize the full potential of the fluorescent tool. Hence, empirical screening approaches are typically required, leading us to focus on the development of a series of cysteine labeling agents. This offers a direct and facile method for the site-selective incorporation of these probes into proteins.

This study identifies key variables that influence the fluorescent response of labeled proteins to changes in protein structure, providing a general framework for understanding the ways in which solvatochromic tools may best be applied. Additionally, it reveals a systematic approach to developing future fluorescent protein probes for detecting various biomolecular interactions. The members of this new series of thiol-modifying agents vary according to the linker type and the nature of the electrophilic group necessary for cysteine labeling (Chart 1). Using the calcium-sensing protein calmodulin as a model system for our study, we demonstrate the power of this suite of solvatochromic tools to develop highly effective sensors of dynamic biomolecular interactions.

EXPERIMENTAL PROCEDURES

Synthesis of the 4-DMN Cysteine Modifying Agents (1−4). The 4-DMN derivatives **1**, **3**, and **4** were each prepared from a common precursor, **5**, which was synthesized according to the method described by Kollár et al. (*22*). The anhydride ring system of **5** offers a convenient point of attachment for introducing a diverse array of linker types with high yields. Compounds **6**, **7**, and **8** were obtained by refluxing a solution of **5** in anhydrous ethanol under an atmosphere of N_2 in the presence of hydrazine monohydrate, ethanolamine, and 2-(2-aminoethoxy)-ethanol, respectively. The intermediate **6** was then dissolved in dichloromethane with *N*,*N*-diisopropylethylamine and treated with bromoacetyl bromide to yield the labeling agent **1** (Scheme 1). Both compounds **7** and **8** were subjected to a modified Mitsunobu reaction developed by Walker (*23*) in order to install the maleimide group. The conditions of this reaction require dissolving triphenylphosphine in freshly distilled tetrahydrofuran under an atmosphere of N_2 before cooling to −78 °C. A solution of the diethyl azodicarboxylate was then added dropwise and stirred for several minutes to allow for the formation of the betaine. Solutions of either **7** or **8** were then transferred to the reaction vessel along with neopentyl alcohol. Again, the reaction was allowed to stir for several minutes to permit the formation of the reactive oxyphosphonium salt intermediate before adding solid maleimide. The reaction was run overnight at room temperature, producing compounds **3** and **4** (Scheme 1).

The preparation of compound **2** begins with commercially available 4-nitro-1,8-naphthalic anhydride, **9**. The anhydride, **9**, was dissolved in dimethylformamide with *N*,*N*-diisopropylethylamine and stirred as a solution of *N*-Boc-ethylenediamine was added via an addition funnel. The starting materials initially proceed to a ring-opened intermediate formed from the attack of the primary amine on the anhydride ring system. The free carboxylate of the intermediate was then activated using the coupling agents HOBt/HBTU to facilitate ring closure forming the naphthalimide, **10**. A suspension of compound **10** in isoamyl alcohol was refluxed under N_2 until fully dissolved, at which point 3-dimethylamino-propionitrile was added. The reaction was run overnight before isolating the product **11** in good yield. Finally, the Boc protecting group of **11** was removed using a solution of trifluoroacetic acid in dichloromethane to liberate the free amine, which was subsequently acetylated using bromoacetyl bromide under conditions similar to those used in generating compound **1**, giving the cysteine labeling agent **2** (Scheme 1).

Fluorescent Labeling and Isolation of Calmodulin Cysteine Mutants. The following procedure was performed on each of seven cysteine mutants of calmodulin (E11C, S38C, M76C, E87C, N111C, E114C, and M145C) as well as the wild-type, which served as a control to determine whether any of the labeling agents exhibited nonspecific labeling under the selected reaction conditions. All eight of the calmodulin constructs were labeled separately with one of the nine fluorophores (Charts 1 and 2) examined in this study [4-DMN derivatives **1**−**4**, 7-diethylamino-3-((((2-maleimidyl)ethyl)amino)carbonyl)-coumarin (MDCC), *N*,*N*′-dimethyl-*N*-(iodoacetyl)-*N*′-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)ethylenediamine (IANBD), 6-bromoacetyl-2-dimethylaminonaphthalene (BADAN), 5-((((2-iodoacetyl)amino)ethyl)amino)naphthalene-1-sulfonic acid (IAEDANS), and 1-(2-maleimidylethyl)-4-(5-(4-methoxyphenyl)oxazol-2-yl)pyridinium methanesulfonate (PyMPO)] (*16*) to yield the 72 possible combinations. Following the expression and purification of each calmodulin mutant, the protein concentration was adjusted to 100 μM in Tris-buffered saline (TBS, pH 7.4) containing 1 mM of the reducing agent tris(2-carboxyethyl)phosphine (TCEP) and allowed to incubate at 4 °C overnight. The proteins were then analyzed by SDS−PAGE gel under nonreducing conditions to confirm that the cysteine mutants were in the fully reduced state. Aliquots of each protein (0.6 mL) were then transferred to

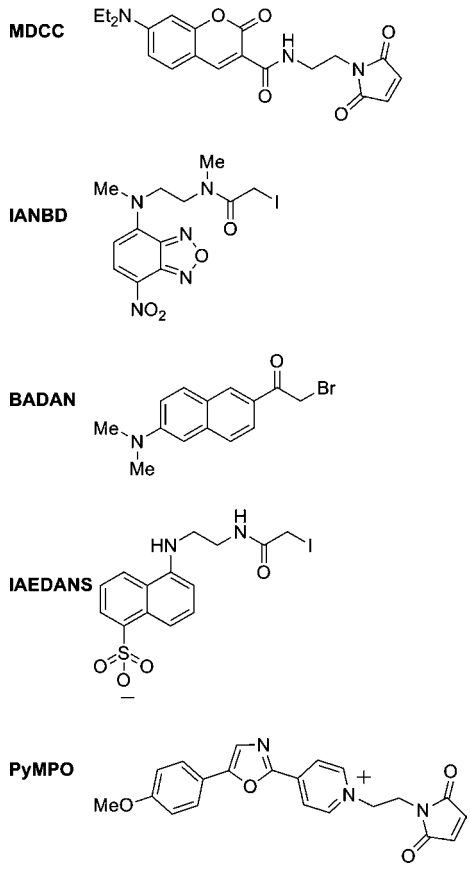
clear 1.7 mL microcentrifuge tubes to which 6 μL of the respective cysteine labeling agent was added from a 100 mM stock solution in DMSO. The final concentration of the labeling agent in each reaction was 1 mM. The reaction mixtures were inverted 4−6 times immediately following the addition of the labeling agent and allowed to react overnight in the dark at 4 °C. The following day, the microcentrifuge tubes containing the reaction mixtures were spun at 16,000*g* for 5 min at 4 °C to pellet any insoluble material before transferring the protein solutions to a 0.5 mL centrifugal filtering device (Millipore Ultrafree-MC, Durapore PVDF 0.22 μm). The samples were spun again at 16,000*g* for 5 min at 4 °C. The excess unreacted labeling agent in each reaction mixture was then removed using a 5 mL HiTrap desalting column obtained from GE Healthcare Life Sciences. The desalting columns were preequilibrated with TBS buffer (pH 7.4). The eluted fractions containing the labeled proteins were then quantified using the Bio-Rad protein assay where a stock solution of wild-type calmodulin of predetermined concentration was used to generate the standard curve. The labeling efficiency was determined by measuring the absorbance of the fluorophore for each construct at the corresponding wavelength of maximum absorption (λ_{max}). The calculated fluorophore concentration was then compared to the quantified protein concentration to establish the extent of protein labeling (see Supporting Information Table S1).

Fluorescence Studies of Calmodulin Mutants. Upon isolating the fluorescently labeled calmodulin constructs, stock solutions of each were prepared at 30 μM in TBS buffer (pH 7.4). Stock solutions of $CaCl_2$ (2 mM), EDTA (5 mM), guanidine hydrochloride (8 M), and the M13 peptide (*24*) (1 mM) were also prepared in TBS buffer (pH 7.4) and filtered through a 0.2 μm Nalgene cellulose acetate syringe filter prior to use. The fluorescence spectra of each construct were then measured in triplicate under five different conditions: (1) calmodulin construct only (5 μM); (2) calmodulin construct (5 μM) with $CaCl_2$ (200 μM); (3) calmodulin construct (5 μM) with $CaCl_2$ (200 μM) plus M13 peptide (10 μM); (4) calmodulin construct (5 μM) with M13 peptide (10 μM); and (5) calmodulin construct (5 μM) with guanidine hydrochloride (6.67 M). Additionally, each of these experimental conditions included 40 μM EDTA to ensure that no extraneous calcium, which may have been carried through the protein preparation, interfered with any of the fluorescence measurements. The samples were loaded in a 96 well black Polysorp Fluoronunc plate from NUNC, and the fluorescence spectra were measured for each

Chart 2. Commercially Available Solvatochromic Fluorophores



condition using a SPECTRAmax GEMINI XS plate reader from Molecular Devices. The total sample volume for each well was 200 μL. The excitation and emission settings selected for each construct are listed in Table S2 of the Supporting Information.

RESULTS

The calcium binding protein calmodulin (CaM) (Figure 1a), which has been extensively characterized by a number of research groups (*25*), was selected as the model system for a comparative study to evaluate the performance of the 4-DMN cysteine modifying agents **1**−**4**. CaM is a soluble protein that responds to sudden influxes of cytosolic Ca^{2+} levels (*26*) by rapidly chelating as many as four of these cations through specialized Ca^{2+}-binding motifs called EF-hands. The binding event induces an allosteric change in the N- and C-terminal domains of the protein resulting in the formation of two hydrophobic pockets, which can then bind critical hydrophobic residues of certain peptide motifs that are recognized by the protein (Figure 1b) (*25, 27*). One advantage to using calmodulin is that the wild-type protein is devoid of native cysteine residues. This characteristic affords considerable freedom in selecting discrete sites for cysteine mutagenesis and subsequent modification by a thiol-reactive agent. The exceptional attributes offered by this unique system provides a useful benchmark for our studies as numerous research groups (*12, 28*−*32*) over the last 30 years have attempted to develop CaM-based calcium sensors by labeling the protein at a variety of sites with various solvatochromic probes. However, despite extensive efforts, the reported changes in fluorescence emission are modest and typically encumbered by high background fluorescence, which strongly limits the utility of these constructs in certain applications such as fluorescence microscopy.

Based on careful examination of available X-ray and NMR structures of calmodulin in the apo-state (*33*), as well as the calcium-bound (*34*) and calcium-peptide-bound (*35*) states, seven sites were selected for cysteine mutagenesis (Figure 1a). The basis for the selection process was the identification of residues that are relatively solvent exposed when the protein exists in the apo-state and do not appear to play an important functional role that might be disrupted through mutagenesis and labeling. By exploring multiple sites spanning the breadth of the protein structure, it is possible to resolve trends that are site-dependent from those that are site-independent and better ascertain the robustness of those trends. Site-directed mutagenesis was performed on the wild-type template to introduce cysteine residues at two sites on the N-terminal domain (E11C

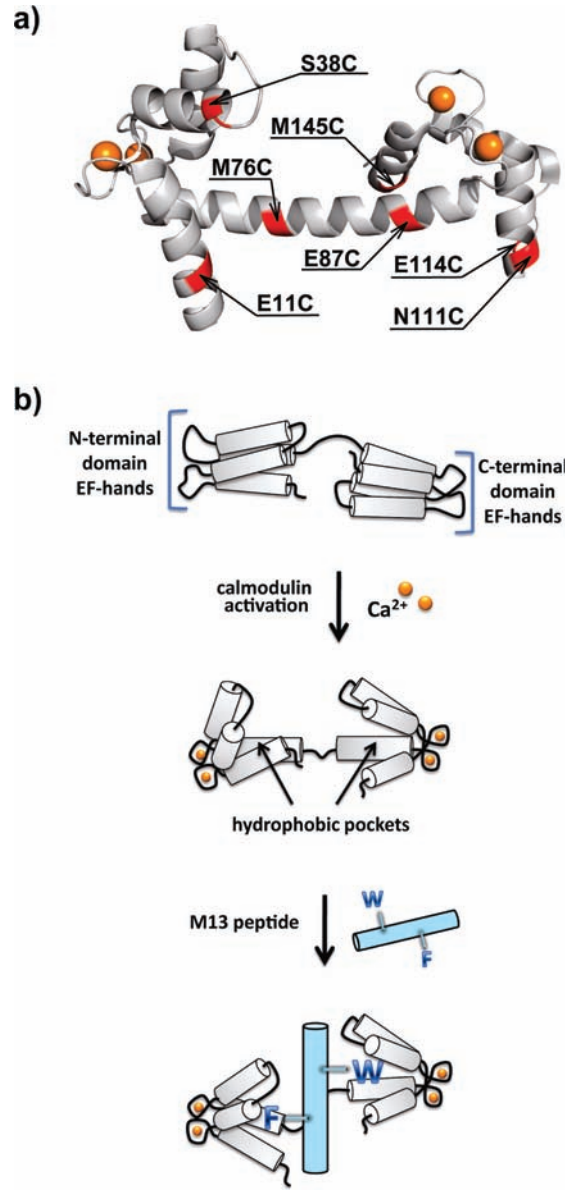


Figure 1. (a) Crystal structure of the Ca^{2+}−CaM complex deposited by Rupp et al. (PDB entry 1UP5) (*34*). The structure indicates the seven sites selected for cysteine mutagenesis (red). The bound calcium ions are indicated by spheres (yellow). (b) Ca^{2+} activation of a CaM mutant (gray) can result in the burying of an attached solvatochromic fluorophore within one of the newly formed hydrophobic pockets. In response, the fluorophore exhibits a change in one or more of the emission properties. Subsequent addition of the M13 peptide (cyan) can displace the fluorophore from the pocket through insertion of an aromatic side chain from the phenylalanine or tryptophan residue indicated here using the single-letter notation for amino acids.

and S38C), two sites within the linker region (M76C and E87C), and three sites in the C-terminal domain (N111C, E114C, and M145C).

In addition to the 4-DMN derivatives **1**−**4**, five commercially available solvatochromic fluorophores were also included in this study for comparison (Chart 2). These fluorophores provide a representative sampling of the major classes of solvatochromic probes that are currently available and commonly used at this time. The reagents vary fundamentally in size, shape, and hydrophobicity, and each exhibits distinct photophysical properties (*16*). For the comparison, we focused on common dyes that were available as thiol-reactive labeling agents possessing dimensions similar to that of the 4DMN derivatives. With a total of 9 fluorescent labeling agents and 7 cysteine mutants of calmodulin, the 63 possible fluorescent constructs were prepared for evaluation. The wild-type CaM construct was included as a control in the labeling experiments, although no significant background labeling was observed.

In order to gauge the capacity of each labeling agent to report a change in the structural state of the calmodulin mutants, fluorescence spectra were collected in the presence and absence of saturating calcium. Additionally, since the Ca^{2+}−CaM complex is capable of binding certain peptide motifs with high affinity, a known peptide binding partner commonly referred to as the M13 peptide (*24*) was also introduced to the fluorescent constructs, in the presence and absence of calcium, to observe whether further changes in the emission spectra occur. The constructs were compared by measuring the ratio of fluorescence intensity at the wavelength of maximum emission of the Ca^{2+}−CaM complex to that of the apo-state for the three examined conditions (saturating Ca^{2+}, saturating M13 peptide, and saturating Ca^{2+} with the M13 peptide).[1] The results of these studies are shown in Figure 2.

A common feature observed among most of the cysteine mutants of this study was the tendency to exhibit higher fluorescence intensity in the Ca^{2+}-bound state compared to that of the full Ca^{2+}−CaM−M13 peptide complex (Figure 2a-f). This propensity for the labeled constructs to display a diminished fluorescent signal in the presence of a native peptide-binding partner was general for all of the solvatochromic fluorophores, with the exception of the two charged species IAEDANS and PyMPO included in this study. The effect is attributed to a process of competitive displacement in which the fluorophore and ligand both compete for occupancy of the same hydrophobic binding site, thereby increasing the average exposure of the fluorophore to the surrounding solvent environment. However, this behavior was by no means a rule as many constructs included in this study, particularly those of the M145C mutant (Figure 2g), exhibited the greatest fluorescence intensity for the Ca^{2+}−CaM−M13 peptide complex.

A number of key trends emerged from the fluorescence screen. One among these was a pronounced dependence of the measured fluorescence change on the linker type for the 4-DMN series of compounds **1**−**4**. For instance, the E11C mutant exhibited a strong bias for the shortest linker of the series (4 Å), whereas the trend was the reverse for the S38C mutant, which yielded the best response with linkers of intermediate to longer length (6−9 Å). This result was largely site-dependent and yielded no clear pattern for determining the optimal linker type *a priori*. Hence, the process of identifying a construct with the desired fluorescence properties may best be accomplished through an empirical approach, utilizing the set of 4-DMN labeling agents as a combined suite.

The next revealed trend was the marked ability of the calmodulin cysteine mutants labeled with the 4-DMN derivatives, **1**−**4**, to produce greater signal increases in response to the presence of saturating calcium (or calcium plus the M13 peptide) over those modified by the other dyes considered in the study. Although in some cases these differences were modest, the overall trend demonstrated that this property was robust and relatively site-independent. This is particularly apparent for the S38C mutant (Figure 2b) labeled with compound **3**, which showed a greater than 100-fold increase in emission intensity upon binding calcium. Among the commercially available fluorophores, IANBD was the closest by comparison exhibiting only a 15-fold increase in intensity. Although the influence of linker type, which played a crucial role in obtaining optimal results with the 4-DMN fluorophore, was not examined when comparing the other commercial fluorophores, the limiting factor for those dyes was largely due to the high degree of intrinsic fluorescence that each exhibits in aqueous environments. This high background effectively reduces the maximum attainable signal-to-noise ratio despite these dyes being good fluorophores.

Results of the study also suggest that certain factors known to enhance hydrophilicity can negatively influence the capacity of a solvatochromic fluorophore to respond to perturbations within the local topology of the protein surface. This was particularly apparent among the two charged dyes included in the series (IAEDANS and PyMPO). Neither dye displayed significant changes in emission properties when the associated cysteine mutants were exposed to combinations of Ca^{2+} and the M13 peptide. By bearing a formal positive or negative charge, the energetic cost of desolvating these fluorescent species may negate any benefit gained by burying the aromatic ring systems deep within a hydrophobic pocket formed as the result of a conformational change to the protein structure. This would greatly impact the equilibrium of the buried versus solvated state, making these probes less sensitive to such structural dynamics despite otherwise exhibiting good solvatochromic properties. Although this trend was relatively site-independent for the mutants of the calmodulin protein, it is expected that these probes could be better suited for applications where the possibility of charge complementarity exists or where other molecular driving forces are responsible for the partitioning of the probes between two distinct environments (*36*).

DISCUSSION

In developing this series of 4-DMN cysteine labeling agents, an essential question we wished to address was whether there was value in utilizing an assortment of linker types or if this simply introduced an element of redundancy. The results of this study strongly indicate that the linker type does play a critical role in influencing the magnitude of the fluorescent response. For a solvatochromic probe to function optimally, it must directly interact with a feature of interest. If this feature happens to be a hydrophobic pocket located far from the point of attachment on the protein surface, then a longer linker would clearly be favored over one that is unable to span this distance (Figure 3a). However, a caveat of using a longer linker is that the greater range may inadvertently increase the probability that the fluorophore will encounter and bind a shallow hydrophobic patch that is unaltered by the structural state of the protein. Such a static interaction would produce an undesirable increase in the fluorescence background. In this instance, a shorter linker could prove better suited (Figure 3b). In fact, this appears to be the case for mutant E11C where compound **1** produced a much greater increase in fluorescence intensity than compound **4** upon

[1]For the fluorescent constructs of the M145C CaM mutant, all fluorescence measurements were made at the wavelength of maximum emission for the Ca^{2+}−CaM−M13 peptide complex instead of the of the Ca^{2+}−CaM complex since this state generally exhibited greater emission intensity.

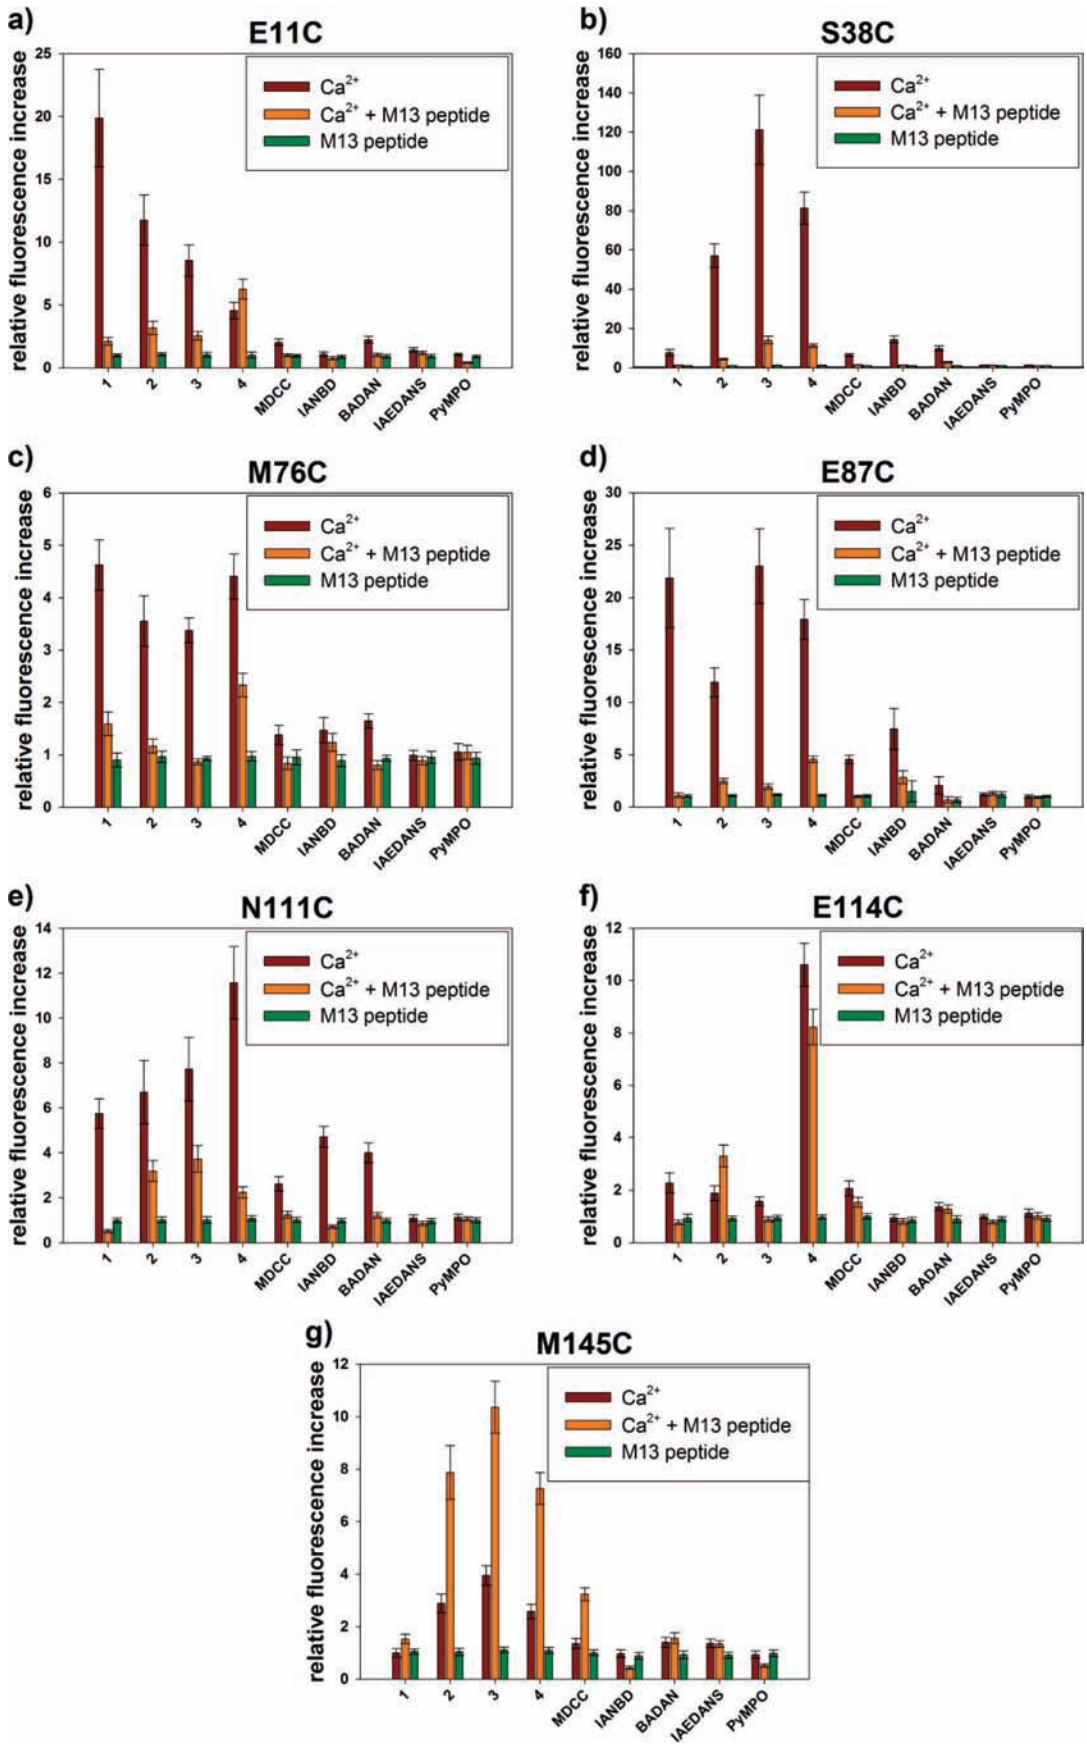

Figure 2. (a−g) Histograms indicating the fluorescence results obtained from the seven cysteine mutants examined in this study. The vertical bars represent the ratio of fluorescence intensity measured at the wavelength of maximum emission under the condition that yielded the brightest state for each construct with respect to that of the apo-state. The fluorophores are indicated along the horizontal axis below the associated results. For each condition, saturating levels of Ca^{2+} and/or the M13 peptide were used. The indicated errors represent the 90% confidence intervals determined from three trials.

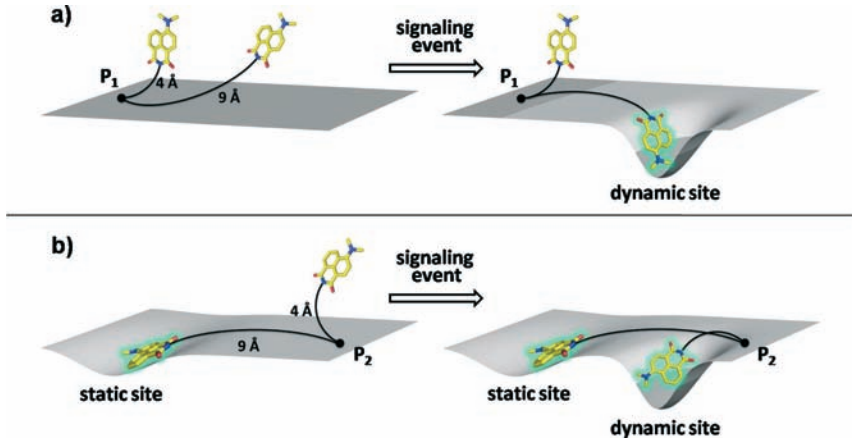

Figure 3. (a) Attachment point P_1 is located far from a hydrophobic pocket formed upon a structural change in the protein. Here, a longer linker is preferred to a shorter one. (b) Attachment point P_2 is located near the hydrophobic pocket formed in response to a structural change. Such sites may favor shorter linkers as longer linkers could tend to allow the fluorophore to encounter nonspecific hydrophobic patches that remain static with regard to the dynamics of protein topology. This would result in higher background fluorescence.

the addition of saturating Ca^{2+}. Both constructs displayed comparable emission intensities in the Ca^{2+} bound state. However, the apo-state of the construct labeled with **4** exhibited a fluorescence background that was roughly 5-fold greater than that of the construct with the shortest linker, resulting in the smaller observed increase.

Interference by background fluorescence is a phenomenon that affects all solvatochromic fluorophores and extends beyond the model system used in this study. Solvatochromic fluorophores often display somewhat different emission properties when appended to globular proteins such as calmodulin.[2] A bulky hydrophobic fluorophore protruding into the surrounding solvent environment demands a large enthalpic cost due to the disruption of the dense network of hydrogen-bonded water molecules. Consequently, the probe will exhibit a strong tendency to associate with any hydrophobic clefts or pockets formed by structural elements within the immediate vicinity to minimize this exposure. The degree of background fluorescence associated with these nonspecific interactions is largely site-dependent for a fluorophore of a given linker-type. This interference is further compounded by any intrinsic fluorescence already produced by the probe in water. A convenient method we have developed for measuring the background resulting from such effects involves comparing the emission spectra of the construct under both natured (TBS buffer at pH 7.4) and denatured conditions (TBS buffer at pH 7.4 with 6.67 M guanidine hydrochloride). This was performed with all 63 fluorescently labeled calmodulin constructs and the results summarized in Figure S2 of the Supporting Information. Although site-dependent background fluorescence appeared to be a critical limitation to many of the commercial dyes, this issue proved much less consequential for the 4-DMN derivatives because of the negligible degree of intrinsic fluorescence exhibited by these probes in water.

An ideal site for labeling would be one that precludes the solvatochromic fluorophore from forming any surface associations of this sort until a structural change in the protein has occurred. In practice, however, identifying an optimal labeling site is often challenging even when exceptional structural data for the protein is available. As a result, screening of a strategically selected series of cysteine mutants is typically required. When applied in combination with the series of 4-DMN labeling agents, this approach allowed us to readily identify a number of fluorescent mutants that respond sensitively and selectively to the formation of the $Ca^{2+}-$CaM complex. Additionally, although the 4-DMN labeled M145C mutants showed only a modest selectivity for the $Ca^{2+}-$CaM$-$M13 peptide complex over that of the $Ca^{2+}-$CaM complex, it is possible that a more extensive screen could yield a construct with greatly improved properties permitting access to a set powerful sensors of either state.

[2]We have observed similar effects in our work with SH2 domains, PDZ domains, and the regulatory light-chain of myosin.

CONCLUSIONS

In this study, the 4-DMN derivatives **1**$-$**4** were evaluated and compared with five other well-established solvatochromic fluorophores to address a number of critical factors pertaining to the successful application of such tools in detecting specific types of bimolecular interactions. These factors include the importance of linker type, the influence of hydrophobicity, and the deleterious effects of high intrinsic fluorescence.

Because of the rarity in which solvatochromic fluorophores exhibit the maximum potential fluorescence changes when used in many biological applications, the large intrinsic fluorescence exhibited by many of these probes in aqueous environments represents a critical issue that can ultimately be limiting. This matter is further compounded by the strong tendency for these probes to show a marked enhancement in fluorescent signal when appended to proteins as a result of nonspecific topological interactions. Because the 4-DMN derivatives possess such low intrinsic fluorescence in water, these effects are significantly less consequential.

Linker variety is a fundamental component to designing sensors that incorporate solvatochromic dyes and is a feature that is not typically examined systematically. Often, the linker is considered a passive component of fluorescent labeling agents, serving merely to connect the dye to the target molecule without interfering with native properties such as function or solubility. Here, we demonstrate that linkers play a more active role and can be a vital element in the optimization of the fluorescent response. When applied in combination with cysteine-scanning mutagenesis, the number of fluorescent constructs is greatly expanded, thereby increasing the potential for obtaining a sensor with the desired properties. We therefore present this series of labeling agents as a combined suite that offers the excellent properties of the 4-DMN dye in a format ready to meet the strict demands required by a wide spectrum of applications ranging from high-throughput screening assays to fluorescence microscopy.

10× TBS Buffer:

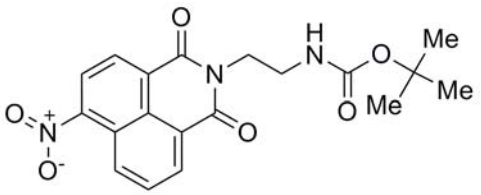
60.6 g Tris-HCl
87.7 g NaCl

Dissolved salts in 800 mL of distilled H_2O and adjusted pH to 7.3 with concentrated HCl. The volume was then adjusted to 1 L. Upon diluting 10× TBS buffer ten-fold with distilled H_2O, the pH should be 7.4. The final 1× TBS concentrations are 50 mM Tris-HCl, 150 mM NaCl, and pH 7.4. All references to solutions prepared in TBS buffer pertain to this recipe.

Synthesis of 4-*N,N*-dimethyl-1,8-naphthalimide cysteine modifying reagents:

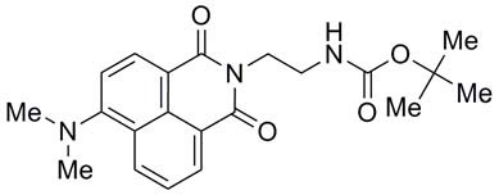
All reagents were procured from Sigma-Aldrich unless otherwise stated.

NMR and FT-MS of the following derivatives: ^{1}H and ^{13}C NMR spectra were recorded on a Varian Mercury 300 MHz NMR and Varian Inova 500 MHz NMR spectrometer. Chemical shifts (δ) for ^{1}H and ^{13}C NMR spectra are reported in parts per million (ppm) and are referenced to residual protium in the deuterated solvent. Coupling constants (*J*) are reported in Hertz (Hz) and multiplicities are abbreviated as singlet (s), doublet (d), triplet (t), and multiplet (m). High-resolution mass spectra were obtained using a Bruker Daltonics APEXIV 4.7 Tesla Fourier Transform Ion Cyclotron Resonance Mass Spectrometer (FT-ICR-MS).



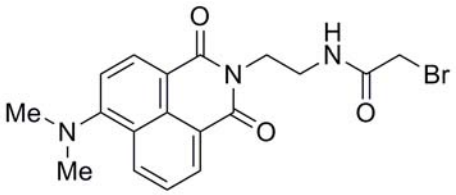
4-Nitro-*N*-(2-*tert*-butoxycarbonylamino-ethyl)-1,8-naphthalimide (10). Dissolved 4-nitro-1,8-naphthalic anhydride, **9** (9.2 g, 37.7 mmol), in 50 mL of DMF, then added DIPEA (17.9 mL, 102.9 mmol). In a separate flask, *N*-Boc-ethylenediamine was dissolved in another 50 mL DMF and added over 4 min to the solution containing the anhydride via an addition funnel. The reaction was allowed to

proceed for 1 hr at ambient temperature before adding the coupling reagents HOBt/HBTU (100 mL, 0.58 M each in DMF) to facilitate closure of the imide ring system. The reaction was allowed to proceed overnight. The next day, the reaction mixture was poured into a large separatory funnel containing 400 mL of diethyl ether and washed with brine (3 × 200 mL) to remove DMF (note- some precipitation of the product from the organic layer may be observed if left for extended periods of time). The organic layer was then dried with $MgSO_4$, filtered, and concentrated to dryness. The crude product was then purified by flash column chromatography using 3:1 hexanes/ethyl acetate to give a light cream colored solid (9.56 g, 24.8 mmol, 72.3% yield, R_f = 0.1 in 3:1 hexanes/EtOAc). ^{1}H NMR (300 MHz, $CDCl_3$, δ): 1.21 (s, 9H), 3.53 (m, 2H), 4.34 (t, 2H, J = 5.7 Hz), 4.97 (m, 1H), 7.94 (dd, 1H, J_1 = 8.7 Hz, J_2 = 7.5 Hz), 8.36 (d, 1H, J = 8.1 Hz), 8.65 (d, 1H, J = 8.1 Hz), 8.69 (dd, 1H, J_1 = 7.4 Hz, J_2 = 1.1 Hz), 8.77 (dd, 1H, J_1 = 8.7 Hz, J_2 = 0.9 Hz). ^{13}C NMR (300 MHz, $CDCl_3$, δ): 28.4, 39.3, 40.7, 79.5, 123.0, 123.7, 124.1, 127.0, 129.3, 129.5, 130.1, 130.1, 132.7, 149.7, 156.3, 163.0, 163.8. HRMS-ESI (*m/z*): $[M+Na]^+$ calcd for $C_{19}H_{19}N_3O_6$, 408.1166; found, 408.1188.



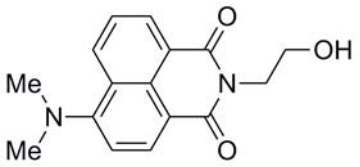
4-*N*,*N*-Dimethylamino-*N*-(2-*tert*-butoxycarbonylamino-ethyl)-1,8-naphthalimide (11). The 4-nitro-*N*-(2-*tert*-butoxycarbonylamino-ethyl)-1,8-naphthalimide, **10** (2.00 g, 5.19 mmol), was added to a 250 mL two-necked round-bottom flask equipped with a reflux condenser, rubber septum, and magnetic stir bar. The assembled reaction vessel was then charged with and inert atmosphere by evacuating the air under reduced pressure and purging with N_2 gas (3×). The flask then received 52 mL of isoamyl alcohol transferred by syringe through the rubber septum. The suspension was stirred as the temperature was raised to 132 ºC. Once the starting material dissolved, 3-dimethylamino-propionitrile (2.35 mL, 20.8 mmol) was added by syringe through the septum of the reaction vessel. The reaction

was refluxed for 22 hrs before stopping by concentrating the reaction mixture to dryness by rotary evaporation. The crude was then purified by flash chromatography using 7:3 hexanes/ethyl acetate to give an orange solid (1.47 g, 3.83 mmol, 74% yield, R_f = 0.25 in 1:1 hexanes/ethyl acetate). ^{1}H NMR (300 MHz, $CDCl_3$, δ): 1.31 (s, 9H), 3.10 (s, 6H), 3.51 (m, 2H), 4.34 (t, 2H, J = 5.6 Hz), 5.09 (br, 1H), 7.09 (d, 1H, J = 8.1 Hz), 7.64 (dd, 1H, J_1 = 8.6 Hz, J_2 = 7.4 Hz), 8.42 (dd, 1H, J_1 = 8.4 Hz, J_2 = 1.2 Hz), 8.46 (d, 1H, J = 8.1 Hz), 8.56 (dd, 1H, J_1 = 7.4 Hz, J_2 = 1.1 Hz). ^{13}C NMR (500 MHz, $CDCl_3$, δ): 28.2, 39.4, 39.8, 44.7, 78.9, 113.1, 114.5, 122.7, 124.7, 125.1, 130.2, 131.1, 131.2, 132.8, 156.0, 157.0, 164.3, 164.9. HRMS-ESI (*m/z*): $[M+H]^+$ calcd for $C_{21}H_{25}N_3O_4$, 384.1923; found, 384.1932.



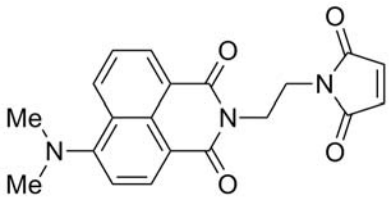
4-*N*,*N*-Dimethylamino-*N*-[2-(2-bromo-acetylamino)-ethyl]-1,8-naphthalimide (2). Dissolved **11** (0.50 g, 1.30 mmol) in dichloromethane (22.0 mL) in a 100 mL round-bottom flask. Cold trifluoroacetic acid (22.0 mL) was then added slowly over 5 min by addition funnel while stirring the reaction. The reaction was allowed to proceed at room temperature for 1.5 hrs before concentrating to dryness by rotary evaporation. The crude solid was redissolved in dichloromethane (100 mL) and washed with 2% $NaHCO_3$ aq. solution (100 mL). The aqueous layer was back-extracted with fresh dichloromethane (2 × 100 mL) and the organic layers were combined (total volume of 300 mL). The organic layer was dried with $MgSO_4$, filtered and concentrated to give the free amine as an orange solid. The free base was then transferred to a 250 mL Schlenk flask under an atmosphere of nitrogen and dissolved in dry dichloromethane (100 mL). The Schlenk flask was cooled to -15 °C in a 1:3 sodium chloride/ice bath. The bromoacetyl bromide (0.40 g, 1.96 mmol) was then added dropwise by syringe followed by *N,N*-diisopropylethylamine (0.25 mL, 1.43 mmol). The reaction was allowed to run for 5 min at -15 ºC before warming to room temperature. After 1.5 hrs, the reaction mixture was diluted to a total volume of 100 mL in dichloromethane and washed with 2% $NaHCO_3$ aq. solution (100 mL)

followed by a second wash with brine (100 mL). The organic layer was dried with $MgSO_4$, filtered, and concentrated by rotary evaporation. The product was purified by flash chromatography using 2:3 hexanes/ethyl acetate to give an orange solid (0.48 g, 1.19 mmol, 91% yield, R_f = 0.10 in 2:3 hexanes/ethyl acetate). The product was stored as solid at -20 ºC. ^{1}H NMR (300 MHz, $CDCl_3$, δ): 3.11 (s, 6H), 3.67 (m, 2H), 3.78 (s, 2H), 4.43 (t, 2H, J = 5.4 Hz), 7.09 (d, 1H, J = 8.1 Hz), 7.27 (br s, 1H), 7.64 (dd, 1H, J_1 = 8.6 Hz, J_2 = 7.4 Hz), 8.43 (dd, 1H, J_1 = 8.7 Hz, J_2 = 1.2 Hz), 8.46 (d, 1H, J = 8.4 Hz), 8.56 (dd, 1H, J_1 = 7.4 Hz, J_2 = 1.1 Hz). ^{13}C NMR (300 MHz, $CDCl_3$, δ): 28.9, 38.5, 40.4, 44.6, 113.1, 114.0, 122.4, 124.7, 124.9, 130.2, 131.2, 131.5, 133.0, 157.2, 164.4, 165.0, 166.0. HRMS-ESI (*m/z*): $[M+H]^+$ calcd for $C_{18}H_{18}BrN_3O_3$, 404.0610; found 404.0612.



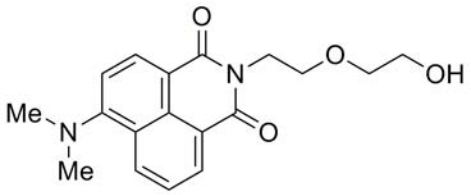
4-*N*,*N*-Dimethylamino-*N*-(2-hydroxy-ethyl)-1,8-naphthalimide (7). Added 4-*N,N*-dimethylamino-1,8-naphthalic anhydride, **5** (1.00 g, 4.15 mmol), to a 200 mL two-necked round-bottom flask equipped with a reflux condenser, magnetic stir bar, and rubber septum. The reaction vessel was then evacuated of air by applying vacuum and flushing with N_2 gas (3×). Anhydrous ethanol (42 mL) was then added to the flask by syringe. The suspension was stirred as the temperature was raised to reflux. The anhydride was still present as a solid as the suspension reached reflux until the addition of ethanolamine (0.28 mL, 4.56 mmol) by syringe. The slurry then turned to a clear deep orange solution. The reaction was allowed to proceed at reflux for 1.5 hrs then stopped by cooling to room temperature. The solvent was then removed using rotary evaporation and the crude placed under high vacuum overnight to remove excess ethanolamine. The product obtained was an orange solid requiring no further purification (1.18 g, 4.15 mmol, quantitative yield). ^{1}H NMR (300 MHz, $CDCl_3$, δ): 2.70 (br s, 1H), 3.10 (s, 6H), 3.95 (t, 2H, J = 5.3 Hz), 4.42 (t, 2H, J = 5.3 Hz), 7.06 (d, 1H, J = 8.1 Hz), 7.62 (dd, 1H, J_1

= 8.6 Hz, J_2 = 7.4 Hz), 8.40 (dd, 1H, J_1 = 8.4 Hz, J_2 = 1.2 Hz), 8.42 (d, 1H, J = 8.4 Hz), 8.52 (dd, 1H, J_1 = 7.5 Hz, J_2 = 1.2 Hz). ^{13}C NMR (300 MHz, $CDCl_3$, δ): 42.7, 44.7, 62.1, 113.1, 114.2, 122.6, 124.8, 124.9, 130.2, 131.3, 131.5, 132.9, 157.1, 164.9, 165.4. HRMS-ESI (*m/z*): $[M+Na]^+$ calcd for $C_{16}H_{16}N_2O_3$, 307.1053; found, 307.1059.

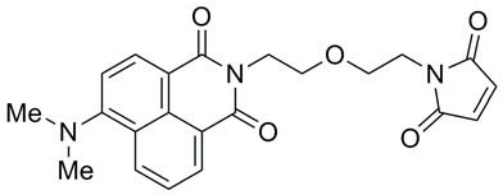


4-*N*,*N*-Dimethylamino-*N*-(2-maleimidyl-ethyl)-1,8-naphthalimide (3). Solid triphenylphosphine (0.42 g, 1.60 mmol) was added to an oven-dried 100 mL Kjeldahl-style Schlenk flask equipped with a magnetic stir bar and rubber septum. The flask was evacuated of air under high vacuum and charged with N_2 gas (3×). The triphenylphosphine was then dissolved in freshly distilled anhydrous THF. The reaction vessel was then cooled to -78 ºC by immersing the Schlenk flask in a dry ice/isopropanol bath. Next, diethyl azodicarboxylate (0.696 mL, 40% solution in toluene, 1.60 mmol) was added dropwise via syringe over 1.5 min. The mixture was allowed to stir for approximately 5 min to allow formation of the betaine. At this point, the reaction mixture was a pale yellow color. The alcohol, **7** (0.50 g, 1.8 mmol), was then added as a solid followed by neopentyl alcohol (0.07 g, 0.8 mmol) to form the oxyphosphonium ion intermediate. Once the two alcohols were fully dissolved, maleimide was added as a solid and the reacting mixture was allowed to warm to room temperature. The reaction was allowed to proceed at room temperature overnight before stopping by concentrating to dryness using a rotary evaporator. TLC indicated that the reaction only preceded 30-40%. The product was isolated by flash column chromatography using toluene with 5% methanol. The product was a bright yellow solid (0.13 g, 0.36 mmol, 22.4% yield, R_f = 0.24 in 1:1 hexanes/ethyl acetate) and was dissolved in DMSO for storage at -80 ºC in 100 mM aliquots. ^{1}H NMR (300 MHz, $CDCl_3$, δ): 3.06 (s, 6H), 3.94 (t, 2H, J = 5.1 Hz), 4.36 (t, 2H, J = 5.1 Hz), 6.58 (s, 2H), 7.04 (d, 1H, J = 8.4 Hz), 7.58 (dd, 1H, J_1 = 8.6 Hz, J_2 = 7.4 Hz), 8.36 (d, 1H, J = 8.1 Hz), 8.38 (dd, 1 H, J_1 = 8.7 Hz, J_2 = 1.2 Hz), 8.46 (dd, 1H, J_1 = 7.4 Hz, J_2 =

1.1 Hz). ^{13}C NMR (300 MHz, $CDCl_3$, δ): 36.2, 38.6, 44.6, 113.1, 114.3, 122.4, 124.7, 125.1, 130.2, 131.0, 131.3, 132.6, 133.9, 156.8, 164.0, 164.6, 170.7. HRMS-ESI (*m/z*): $[M+H]^+$ calcd for $C_{20}H_{17}N_3O_4$, 364.1292; found, 364.1308.

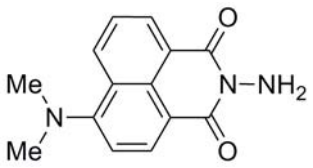


4-*N*,*N*-Dimethylamino-*N*-[2-(2-hydroxy-ethoxy)-ethyl]-1,8-naphthalimide (8). Added 4-*N,N*-dimethylamino-1,8-naphthalic anhydride, **5** (1.00 g, 4.15 mmol), to a 200 mL two-necked round-bottom flask equipped with a reflux condenser, magnetic stir bar, and rubber septum. The reaction vessel was then evacuated of air by applying vacuum and flushing with N_2 gas (3×). Anhydrous ethanol (42 mL) was then added to the flask by syringe. The suspension was stirred as the temperature was raised to reflux. The anhydride was still present as a solid as the suspension reached reflux until the addition of 2-(2-aminoethoxy)-ethanol (0.454 mL, 4.56 mmol) by syringe. The slurry then turned to a clear deep orange solution. The reaction was allowed to proceed at reflux for 1.5 hrs then stopped by cooling to room temperature. The solvent was removed by rotary evaporation and the crude placed under high vacuum overnight to remove excess 2-(2-aminoethoxy)-ethanol. The product was isolated by flash column chromatography using a gradient of 1:3 to 1:4 hexanes/ethyl acetate. The product was a dark orange oil (1.33 g, 4.05 mmol, 97.7% yield, R_f = 0.1 in 1:3 hexanes/ethyl acetate). ^{1}H NMR (300 MHz, $CDCl_3$, δ): 2.76 (br s, 1H), 3.07 (s, 6H), 3.66 (m, 4H), 3.82 (t, 2H, J = 5.6 Hz), 4.39 (t, 2H, J = 5.7 Hz), 7.05 (d, 1H, J = 8.4 Hz), 7.60 (dd, 1H, J_1 = 8.3 Hz, J_2 = 7.4 Hz), 8.38 (dd, 1H, J_1 = 8.6 Hz, J_2 = 1.1 Hz), 8.42 (d, 1H, J = 8.4 Hz), 8.51 (dd, 1H, J_1 = 7.4 Hz, J_2 = 1.1 Hz). ^{13}C NMR (300 MHz, $CDCl_3$, δ): 39.2, 44.6, 61.7, 68.4, 72.1, 113.1, 114.4, 122.7, 124.7, 125.0, 130.2, 131.1, 131.3, 132.8, 157.0, 164.2, 164.8. HRMS-ESI (*m/z*): $[M+H]^+$ calcd for $C_{18}H_{20}N_2O_4$, 329.1496; found, 329.1506.

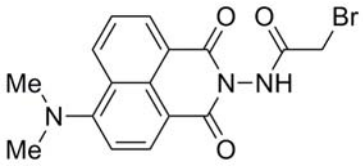


4-*N*,*N*-Dimethylamino-*N*-[2-(2-maleimidyl-ethoxy)-ethyl]-1,8-naphthalimide (4). Prior to assembling the Mitsunobu reaction, the alcohol, **8** (0.50 g, 1.51 mmol), was transferred to a 50 mL pear-shaped flask equipped with rubber stopper and placed under high vacuum overnight to remove trace water that may inhibit the reaction. An oven-dried 100 mL Kjeldahl-style Schlenk flask equipped with a magnetic stir bar and rubber septum was charged with solid triphenylphosphine (0.36 g, 1.37 mmol). The Schlenk flask was then evacuated of air by placing under high vacuum and charged with N_2 gas (3×). Freshly distilled dry THF (4 mL) was then transferred to the Schlenk flask by syringe and the triphenylphosphine stirred at ambient temperature until completely dissolved. This solution was then lowered to -78 ºC by immersing in a dry ice/isopropanol bath. Next, diethyl azodicarboxylate (0.597 mL, 40% solution in toluene, 1.37 mmol) was added dropwise via syringe over 2 min. The mixture was allowed to stir for approximately 5 min to allow formation of the betaine. At this point, the reaction mixture was a pale yellow color. Meanwhile, a solution of the alcohol, **8**, was prepared by dissolving in 6 mL of freshly distilled dry THF. This solution was then transferred very slowly to the reaction vessel by syringe to avoid raising the temperature. Once the transfer was complete, neopentyl alcohol (0.06 g, 0.69 mmol) was added as a solid. The reaction was allowed to stir approximately 5 min to allow formation of the oxyphosphonium ion intermediate. Solid maleimide (0.13 g, 1.37 mmol) was then added and the reaction was allowed to warm to room temperature and stirred overnight. The reaction was stopped by concentrating to dryness on the rotary evaporator and the product was isolated by flash column chromatography using 1:2 hexanes/ethyl acetate. The product was a bright yellow solid (0.15 g, 0.37 mmol, 24.4 % yield, R_f = 0.22 in 1:2 hexanes/ethyl acetate) and was dissolved in DMSO for storage at -80 ºC in 100 mM aliquots. ^{1}H NMR (300 MHz, $CDCl_3$, δ): 3.09 (s, 6H), 3.65 (m, 4H), 3.74 (t, 2H, J = 6.0 Hz), 4.34 (t, 2H, J = 5.9 Hz), 6.50 (s, 2H), 7.09 (d, 1H, J = 8.1 Hz), 7.63 (dd, 1H, J_1 = 8.4

Hz, J_2 = 7.2 Hz), 8.42 (apparent d, 2H, J = 8.1 Hz), 8.51 (dd, 1H, J_1 = 7.5 Hz, J_2 = 1.2 Hz). ^{13}C NMR (300 MHz, $CDCl_3$, δ): 37.2, 38.8, 44.7, 67.2, 67.6, 113.2, 114.9, 122.9, 124.8, 125.1, 130.2, 131.0, 131.1, 132.6, 133.8, 156.6, 163.9, 164.4, 170.5. HRMS-ESI (*m/z*): $[M+H]^+$ calcd for $C_{22}H_{21}N_3O_5$, 408.1554; found, 408.1567.



***N*-Amino-4-*N*,*N*-dimethylamino-1,8-naphthalimide (6)**. Added 4-*N,N*-dimethylamino-1,8-naphthalic anhydride, **5** (1.00 g, 4.14 mmol), to a 200 mL two-necked round-bottom flask equipped with a reflux condenser, magnetic stir bar, and rubber septum. The reaction vessel was then evacuated of air by applying vacuum and flushing with N_2 gas (3×). Anhydrous ethanol (42 mL) was then added to the flask by syringe. The suspension was stirred as the temperature was raised to reflux. The anhydride was still present as a solid as the suspension reached reflux until the addition of hydrazine monohydrate (0.402 mL, 8.29 mmol) by syringe. The slurry then turned to a clear deep orange solution. The reaction was allowed to proceed at reflux for 45 min then stopped by cooling to room temperature. The reaction mixture was diluted to a final volume of 200 mL with cold water to precipitate the product, which was then filtered and purified by flash chromatography using 1:3 hexanes/ethyl acetate. The product was a bright yellow solid (0.925 g, 3.624 mmol, 87.4 % yield, R_f = 0.23 in 1:3 hexanes/ethyl acetate). ^{1}H NMR (300 MHz, $CDCl_3$, δ): 3.09 (s, 6H), 5.26 (br s, 2H), 7.02 (d, 1H, J = 8.4 Hz), 7.58 (dd, 1H, J_1 = 8.4 Hz, J_2 = 7.5 Hz), 8.37 (dd, 1H, J_1 = 8.6 Hz, J_2 = 0.8 Hz), 8.38 (d, 1H, J = 8.4 Hz), 8.49 (dd, 1H, J_1 = 7.4 Hz, J_2 = 0.8 Hz). ^{13}C NMR (300 MHz, $CDCl_3$, δ): 44.8, 113.0, 113.4, 121.9, 124.6, 124.9, 128.7, 131.0, 131.5, 132.8, 157.3, 160.7, 161.0. HRMS-ESI (*m/z*): $[M+H]^+$ calcd for $C_{14}H_{13}N_3O_2$, 256.1081; found, 256.1083.



4-*N*,*N*-Dimethylamino-*N*-[2-bromoacetamido]-1,8-naphthalimide (1). The solid *N*-amino-4-*N,N*-dimethylamino-1,8-naphthalimide, **6** (0.50 g, 1.96 mmol), was transferred to an oven-dried 100 mL Schlenk flask along with a magnetic stir bar. The flask was then capped with a rubber septum and evacuated of air by placing under high vacuum followed by charging with N_2 gas (3×). The starting material was then partially dissolved in dry dichloromethane (39 mL) and stirred as *N,N*-diisopropylethylamine (0.357 mL, 2.15 mmol) was added through the septum via syringe. The Schlenk flask was then cooled to -15 ºC in an ice bath of 3:1 ice/NaCl. Once cooled, bromoacetyl bromide (0.255 mL, 2.94 mmol) was added to the suspension dropwise via syringe and stirred for 5 min before bringing the reaction vessel back to room temperature. A white solid, presumed to be a bromide salt, was observed precipitating from the reaction mixture over time. After allowing the reaction to run overnight, the mixture was diluted to a total volume of 100 mL in dichloromethane and washed with $NaHCO_3$ (3 × 50 mL). The organic layer was dried with $MgSO_4$, filtered, and concentrated on the rotary evaporator. The desired product was isolated by flash chromatography using 1:1 hexanes/ethyl acetate. The reaction yielded two products: the desired monoacylated product, **1** (0.24 g, 0.93 mmol, 47.6% yield, R_f = 0.10 in 1:1 hexanes/ethyl acetate), and a diacylated byproduct in nearly a 1:1 ratio. The desired product was stored as a solid at -20 ºC. ^{1}H NMR (300 MHz, $CDCl_3$, δ): 3.13 (s, 6H), 4.31 (s, 2H), 7.08 (d, 1H, J = 8.4Hz), 7.64 (dd, 1H, J_1 = 8.6 Hz, J_2 = 6.9 Hz), 8.44 (dd, 1H, J_1 = 8.4 Hz, J_2 = 1.2 Hz), 8.46 (d, 1H, J = 8.1 Hz), 8.57 (dd, 1H, J_1 = 7.5 Hz, J_2 = 1.2 Hz), 8.62 (br s, 1H). ^{13}C NMR (500 MHz, $CDCl_3$, δ): 26.5, 44.7, 113.2, 113.5, 122.3, 124.8, 125.1, 130.4, 132.0, 132.3, 133.7, 157.8, 161.6, 162.2, 164.5. HRMS-ESI (*m/z*): $[M+H]^+$ calcd for $C_{16}H_{14}BrN_3O_3$, 376.0291; found, 376.0304.

Synthesis of the M13 peptide:

The peptide used in this study represents a truncated form of the originally described M13 peptide discovered by Blumenthal et al. (1). The sequence encompasses only the minimum residues required to bind the Ca^{2+}-CaM activated complex. The residue numbering refers to that of the original fragment.

M13 Peptide

Residue #	N-term	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	C-term
Sequence	H_2N-	R	R	W	K	K	N	F	I	A	V	S	A	A	N	R	F	K	K	-$CONH_2$

The M13 peptide was prepared using standard Fmoc-based solid-phase peptide synthesis techniques (SPPS) (*2*) with 0.17 mmol/g loading Fmoc-NovaPEG Rink Amide resin LL (Cat. No. 01-64-0483, Novabiochem®). Fmoc-protected amino acids with the standard side-chain protecting groups were used: Fmoc-Ala-OH, Fmoc-Phe-OH, Fmoc-Ile-OH, Fmoc-Lys(Boc)-OH, Fmoc-Asn(Trt)-OH, Fmoc-Arg(Pbf)-OH, Fmoc-Ser(tBu)-OH, Fmoc-Val-OH, and Fmoc-Trp(Boc)-OH. Synthesis of the peptide began by coupling the first seven residues (positions 13-19) with an ABI 431A peptide synthesizer (Applied Biosystems). The synthesis was performed on the 40 μmol scale using 4 equiv of the Fmoc amino acids in each cycle. It had been discovered from earlier attempts at making the M13 peptide that the coupling efficiency was extremely low for residues incorporated after the alanine at position 10 in the sequence. This problem was overcome by using a pseudoproline dipeptide, Fmoc-Val-Ser($\Psi^{Me,Me}$pro)-OH (Cat. No. 05-20-1001, Novabiochem), for positions 11-12 in place of Fmoc-Val-OH and Fmoc-Ser(tBu)-OH. The remaining residues were coupled manually using 6 equiv of the Fmoc amino acids. The building blocks were dissolved to a final concentration of 50 mM in DMF containing a 1:1 mixture of HOBt/HBTU (50 mM each) with *N,N*-diisopropylethylamine (100 mM, 12 equiv). Each coupling reaction was allowed to proceed at room temperature for 30-45 min. The coupling efficiency was monitored using the TNBS test (*3*). Removal of the Fmoc group prior to each coupling step was performed using a 20% 4-methylpiperidine solution (4) in DMF (3 × 5 min). A Boc-Arg(Pbf)-OH residue was incorporated at the N-terminus of the peptide in order to yield the free α-amino group following cleavage from the solid support. The M13 mutant peptide was cleaved from the resin using a

solution of 96:2:2 TFA/H_2O/EDT for 3 hrs. The cleavage cocktail was then filtered and evaporated. The crude peptide was triturated with cold diethyl ether (3 × 10 mL) and purified by HPLC using a Waters 600E HPLC with a Waters 600 automated control module and Waters 2487 dual wavelength absorbance detector set at 228 and 280 nm. The separation was performed using a preparative YMC-pack, C_{18}, 20 × 250 mm reverse-phase column. A YMC-pack, C_{18}, 4.6 ×150 mm reverse-phase column was used for analytical HPLC. The following analytical HPLC method was used to characterize the peptide:

Time (min)	Flow Rate (mL/min)	H_20 % (with 0.1% TFA)	MeCN % (with 0.1% TFA)	Gradient
initial	1.00	93	7	linear
5.0	1.00	93	7	linear
40.0	1.00	0	100	linear

The peptide mass was determined by ESI-MS on a Mariner electrospray mass spectrometer (PerSeptive Biosystems).

Retention time (min)	ESI-MS (m/z) $[M+xH]^{x+}$ calcd	ESI-MS (m/z) $[M+xH]^{x+}$ found
21.6	740.9 [M+3]	740.6 [M+3]
	555.9 [M+4]	555.7 [M+4]
	444.9 [M+5]	444.8 [M+5]

Subcloning of codon-optimized CaM gene. The synthetic CaM construct ordered from Bio Basic Inc. was designed for optimal expression in *E. coli.* The gene was inserted into a high-copy pUC-57 vector for ease of amplification. The product was delivered as a lyophilized powder and also as a stab of transformed DH5α cells in LB agar with carbenicillin. A sterile loop was dipped in the stab and swabbed over a fresh LB agar plate containing carbenicillin (50 μg/mL). The plate was incubated overnight at 37 ºC. The next day, a colony was selected and amplified in order to isolate the vector using a Qiagen Plasmid Miniprep kit. The DNA was then quantified by Abs at 260 nm (0.11 μg/μl).

A double digestion of the amplified pUC-57(CaM) vector was performed simultaneously with the double digestion of the pET-14b vector. The reaction conditions were as follows:

pET-14b vector:		pUC-57 vector:	
1.28 μL	pET-14b (2.34 μg/μL)	27.0 μL	pUC-57 (0.11 μg/μL)
41.2 μL	dH_2O (sterile)	15.5 μL	dH_2O (sterile)
5.0 μL	10× NEB buffer 2	5.0 μL	10× NEB buffer 2
0.5 μL	100× BSA	0.5 μL	100× BSA
1.0 μL	XhoI	1.0 μL	XhoI
1.0 μL	NcoI	1.0 μL	NcoI
50.0 μL	total volume	50.0 μL	total volume

The reactions were allowed to proceed for 1 hr at 37 ºC before stopping with the addition of 12.5 μL of 5× DNA loading buffer. The both reaction mixtures were then loaded onto a 1% agarose gel and resolved at 110 V. The desired restriction products (the CaM insert of the pUC-57 vector and the linearized pET-14b expression vector) were cut from the gel and isolated using a QIAquick™ Gel Extraction kit. The subcloning vector and insert were then quantified on 1% agarose gel by comparing band intensities to those of the NEB 2-Log DNA ladder.

Two ligation reactions were assembled: one containing both the CaM insert and the pET-14b vector, and the other with only the pET-14b vector as a negative control. The reaction conditions were as follows:

vector (control)		vector + insert	
0.3 µL	pET-14b (120 ng/µL)	0.3 µL	pET-14b (120 ng/µL)
3.2 µL	dH_2O (sterile)	1.0 µL	CaM insert (15 ng/µL)
1.0 µL	T4 DNA ligase	2.2 µL	dH_2O (sterile)
0.5 µL	10× T4 ligase buffer	1.0 µL	T4 DNA ligase
		0.5 µL	10× T4 ligase buffer
5.0 µL	total volume	5.0 µL	total volume

Note- There were 36 µg of pET-14b vector in each reaction and 15 µg of the insert in the ligation. The insert is 480 bp and the vector is 4500 bp. This corresponds to a 4:1 molar ratio of insert to vector.

The reactions were allowed to proceed for 16 hrs at 16 ºC. The reactions were then used to transform two 30 µL batches of DH5α cells plated on LB/agar with 50 µg/mL carbenicillin. The next day, no colonies were observed for the negative control. Three colonies from the non-control plate were selected and amplified for sequencing. All selected colonies were determined to be the desired construct. The new vector, pET-14b[CaM], was transformed into BL21-Gold(DE3) competent cells from Stratagene for protein expression.

Cysteine mutagenesis of wild-type CaM gene:

These seven cysteine mutants of the CaM construct were prepared by site-directed mutagenesis using the following set of PAGE-purified primers along with the corresponding reverse compliments ordered on the 50 nmole scale from Operon:

E11C-
CTGACTGAAGAACAGATTGCGTGCTTTAAAGAAGCATTCAGCCTG

S38C-
GGGTACGGTGATGCGTTGTCTGGGTCAGAACCC

M76C-
CCTGACCATGATGGCCCGTAAATGCAAAGACACCGATTCCG

E87C-
CCGATTCCGAAGAAGAAATCCGTTGCGCTTTCCGTGTATTCGAC

N111C-
CTGCGCCATGTGATGACCTGCCTGGGCGAAAAACTGACC

E114C-
GTGATGACCAACCTGGGCTGCAAACTGACCGACGAAGAAG

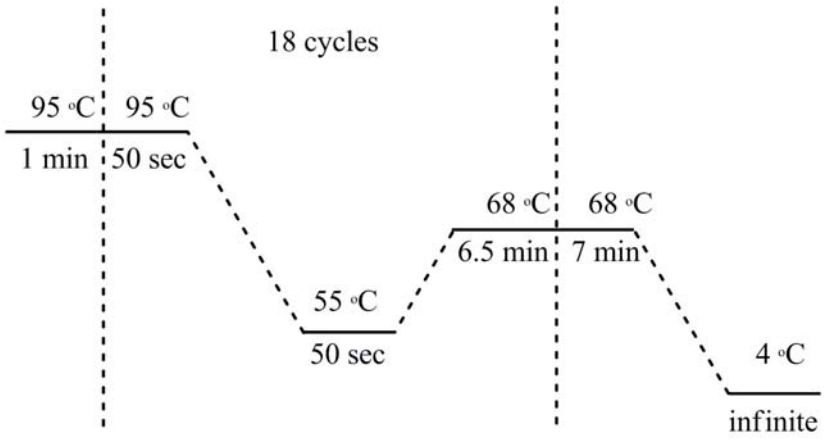
M145C-
CTATGAAGAATTTGTTCAGATGTGCACTGCGAAGCACCACCACC

Upon receiving the primers, stock solutions were prepared in sterile water (125 ng/µl). The reactions were assembled accordingly:

5.0 µL	10× Pfu Turbo rxn buffer.
0.5 µL	pET14b vector [CaM] (20 ng/µL)
1.0 µL	fwd primer (125 ng/µL)
1.0 µL	rev primer (125 ng/µL)
2.5 µL	dNTP's (10 mM each)
40.0 µL	dH_2O (sterile)
50.0 µL	total volume

A control reaction was also performed in which the primers were excluded from the reaction mixture. Next, 1 µL of Pfu Turbo (2.5 U/µL, Stratagene) was added to each reaction. The reaction solutions were mixed thoroughly by gentle pipetting, centrifuged briefly and loaded into an MJ-mini PCR machine from Bio-Rad. The PCR method employed was as follows:

PCR method:



After the PCR reaction was complete the parent vector was digested by adding 1 μL of DpnI (20 U/μL) to each reaction mixture. The reactions were then mixed with gentle pipetting and incubated at 37 ºC for 1.5 hrs each. The reaction mixtures were then used to transform XL1-blue DH5α cells obtained from Stratagene. Colonies from each transformation were selected and submitted for sequencing to confirm the desired constructs were obtained. The DNA from each of the chosen colonies was isolated using a Qiagen Miniprep kit.

Expression and purification of wild-type CaM and cysteine mutants:

The calmodulin constructs were designed with a C-terminal hexahistidine tag for easy purification of the expressed product. The CaM-His_6 mutants were transformed in BL21-Gold(DE3) competent cells from which 20% glycerol stocks were prepared for subsequent protein expression. The stocks were used to inoculate 5 mL LB-broth starter cultures containing carbenicillin (50 μg/mL). The starter cultures were allowed to grow overnight in a 37 ºC shaker at 225 rpm. The next day, the starter cultures were used to inoculate 1 L LB-broth cultures containing carbenicillin (50 μg/mL) and grown at 37 ºC with agitation at 225 rpm. The cultures were allowed to grow to an $OD_{600nm} \approx 0.5$ after which the 1 L shaker flasks were transferred to a 25 ºC shaker (225 rpm) for induction. The cells were induced with 0.1 mM IPTG and shaken for 4 hrs before harvesting at 5000 × g (4 ºC). The pellets were then resuspended in a 0.9% NaCl aqueous solution (30 mL) and transferred to 50 mL conical tubes to be repelleted for storage at -80 ºC.

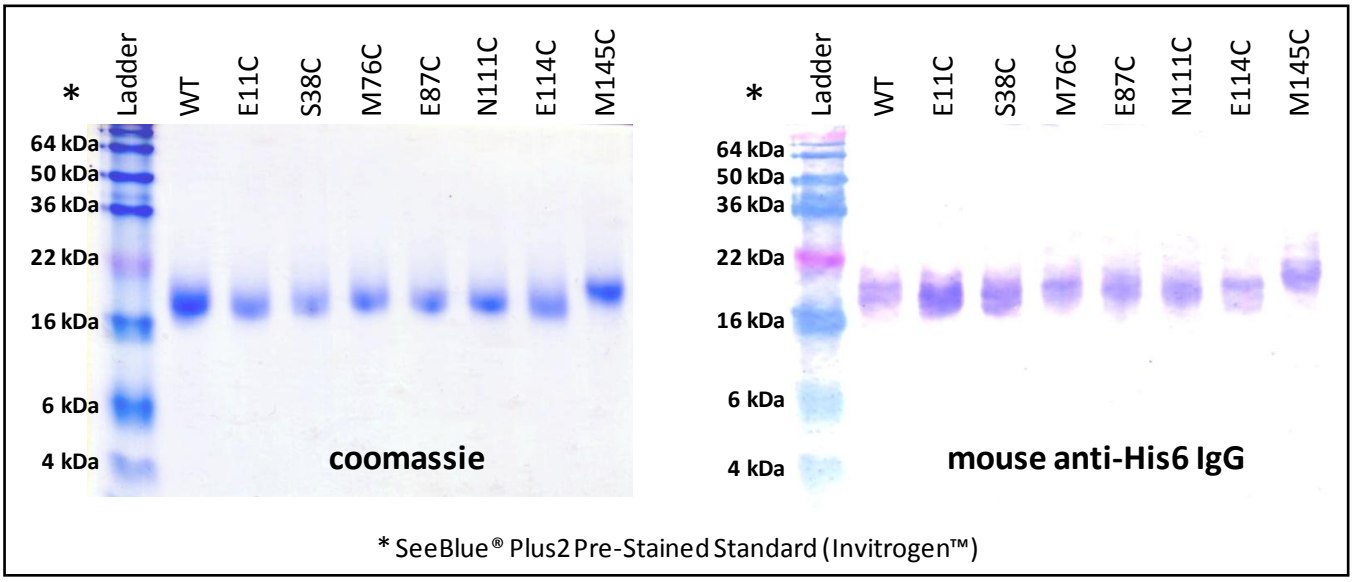
On the day of the protein preparation, the pellets were thawed at room temperature and resuspended in the following lysis buffer:

4 mL	10× TBS buffer
400 μL	NP-40 Alternative
4 mL	glycerol
40 mg	lysozyme
6 mg	dithiothreitol
40 μL	Protease Cocktail III (Calbiochem)
40 mL	final vol. after diluting with dH_2O

Once the pellets were fully resuspended, the cells were sonicated using a Branson Sonifier 450 at 50% power with a 30% duty cycle for 2 min at 4 ºC. The lysates were then transferred to 45 mL polycarbonate bottles and spun at 100,000 × g in a Type 28 rotor from Beckman Coulter to pellet DNA and other cellular debris. Meanwhile, a 5 mL bed of Ni-NTA agarose resin obtained from Qiagen was pre-equilibrated in TBS buffer for each construct. After the spin, the clarified supernatants were transferred to clean 50 mL conical tubes and mixed with the pre-equilibrated Ni-NTA agarose resin. The samples were tumbled gently on a rotisserie at 4 ºC for 1 hr to allow binding of the His-tagged proteins. The resin was then recovered by passing the lysates through 20 mL spin columns obtained from Bio-Rad. The resin was washed first with 4 mL of TBS buffer, then 4 mL of 10 mM imidazole in TBS buffer and then with 4 mL of 20 mM imidazole in TBS buffer at 4 ºC. The protein was then eluted in 6 × 1 mL fractions of 250 mM imidazole in TBS buffer at 4 ºC. The fractions were assayed for protein and combined appropriately. The imidazole was removed by dialysis using a 3.5 kDa MWCO Slide-A-Lyzer dialysis cassette from Pierce. The protein solutions were dialyzed against 3 × 2 L changes of TBS buffer. The protein concentrations were then quantified using the Bio-Rad protein assay solution. Protein yields were ~80 mg/L for the purified CaM mutants.

SDS PAGE (15% polyacrylamide) analysis was performed on the proteins to confirm purity by Coomassie staining. Western blotting of the gel also confirmed the presence of the poly-histidine tag when probed with the mouse anti-his IgG. After transferring to nitrocellulose for 1 hr at 4 ºC under 100 V, the nitrocellulose membrane was blocked with nonfat dry milk (3 g) in TBS buffer (30 mL) for approximately 4 hrs. The milk solution was then poured off and the membrane washed with TBST buffer (3 × 30 mL for 5 min each wash). Next, a 1:10,000 dilution in TBST (15 mL) of the mouse anti-his IgG was added to the nitrocellulose and incubated for 1 hr. The antibody solution was poured off and the nitrocellulose membrane was again washed with TBST buffer (3 × 30 mL) for 5 min each wash). A 1:10,000 dilution of the goat anti-mouse IgG(H+L) alkaline phosphatase conjugate in TBST (15 mL) was added to the nitrocellulose and incubated for 1 hr. The antibody solution was poured off and the nitrocellulose membrane was again washed with TBST buffer (3 × 30 mL) for 5 min each

wash). Last, 10 mL of 1-Step™ NBT/BCIP from Pierce was added and incubated with the nitrocellulose until the band was visible. The nitrocellulose was then washed with dH_2O and dried.



ESI-MS of expressed CaM constructs:

The cysteine mutants of the CaM-His_6 protein were also analyzed by mass spectrometry to confirm the identity of the isolated protein products. All eight of the expressed products matched the calculated molecular weights determine from the primary structures minus the N-terminal methionine due to methionine aminopeptidase activity in *E. coli*.

The protein masses were determined by ESI-MS on a Mariner electrospray mass spectrometer (PerSeptive Biosystems).

Labeling efficiencies:

The extent of labeling of each construct was determined by measuring the absorbance of the attached dye and dividing that value by the known extinction coefficient to calculate the dye concentration (Table S1). This value was then compared to the predetermined concentration of the protein construct to yield the ratios shown below.

Table S1

			Labeling ratio of CaM Mutants:							
Fluorophore:	Abs_{max} (nm)	ε (cm^{-1} M^{-1})[a]	Wild-type	E11C	S38C	M76C	E87C	N111C	E114C	M145C

Denaturing of fluorescent CaM constructs to determine background emission:

There exist two primary sources of background fluorescence directly associated with a solvatochromic fluorophore when used to develop a fluorescent protein probe. The first involves the intrinsic

fluorescence exhibited by the fluorophore when fully solvated by water. The second is a ramification of appending the fluorophore to the surface of a globular protein. This frequently results in a change in the photophysical properties of the fluorophore that would be expected if it were participating in some type of non-specific interaction with the local topology of the attached protein. By denaturing the protein in a concentrated solution of guanidine hydrochloride, the secondary and tertiary structures that may contribute to this effect are disrupted permitting one to determine the degree of background emission generated (Figure S1).

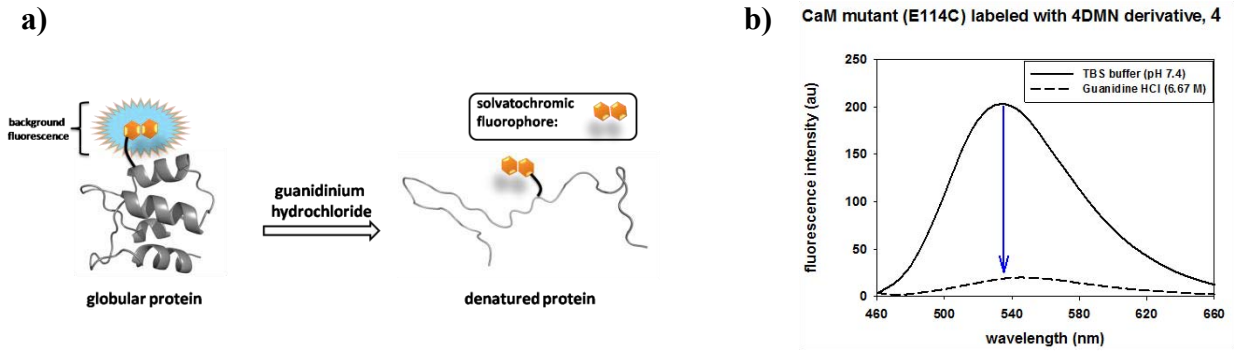

Figure S1. (a) Graphic depicting the tendency of solvatochromic fluorophore to exhibit background fluorescence when appended to a globular protein until denatured, thus fully exposing the fluorophore to the aqueous environment. (b) Example of a typical fluorescent response of a labeled CaM mutant under both natured and denatured conditions (TBS buffer versus guanidine hydrochloride solution at pH 7.4)

A series of experiments were conducted on each of the sixty-three fluorescent CaM constructs prepared in this study in which the degree of background fluorescence associated with the appending of the fluorophore to the protein was determine by measuring the emission spectra of the constructs in TBS buffer (pH 7.4) and guanidine hydrochloride (6.67 M, pH 7.4) and calculating the ratio of intensity at the wavelength of maximum emission in the natured state. The results of this work are displayed in Figure S2.

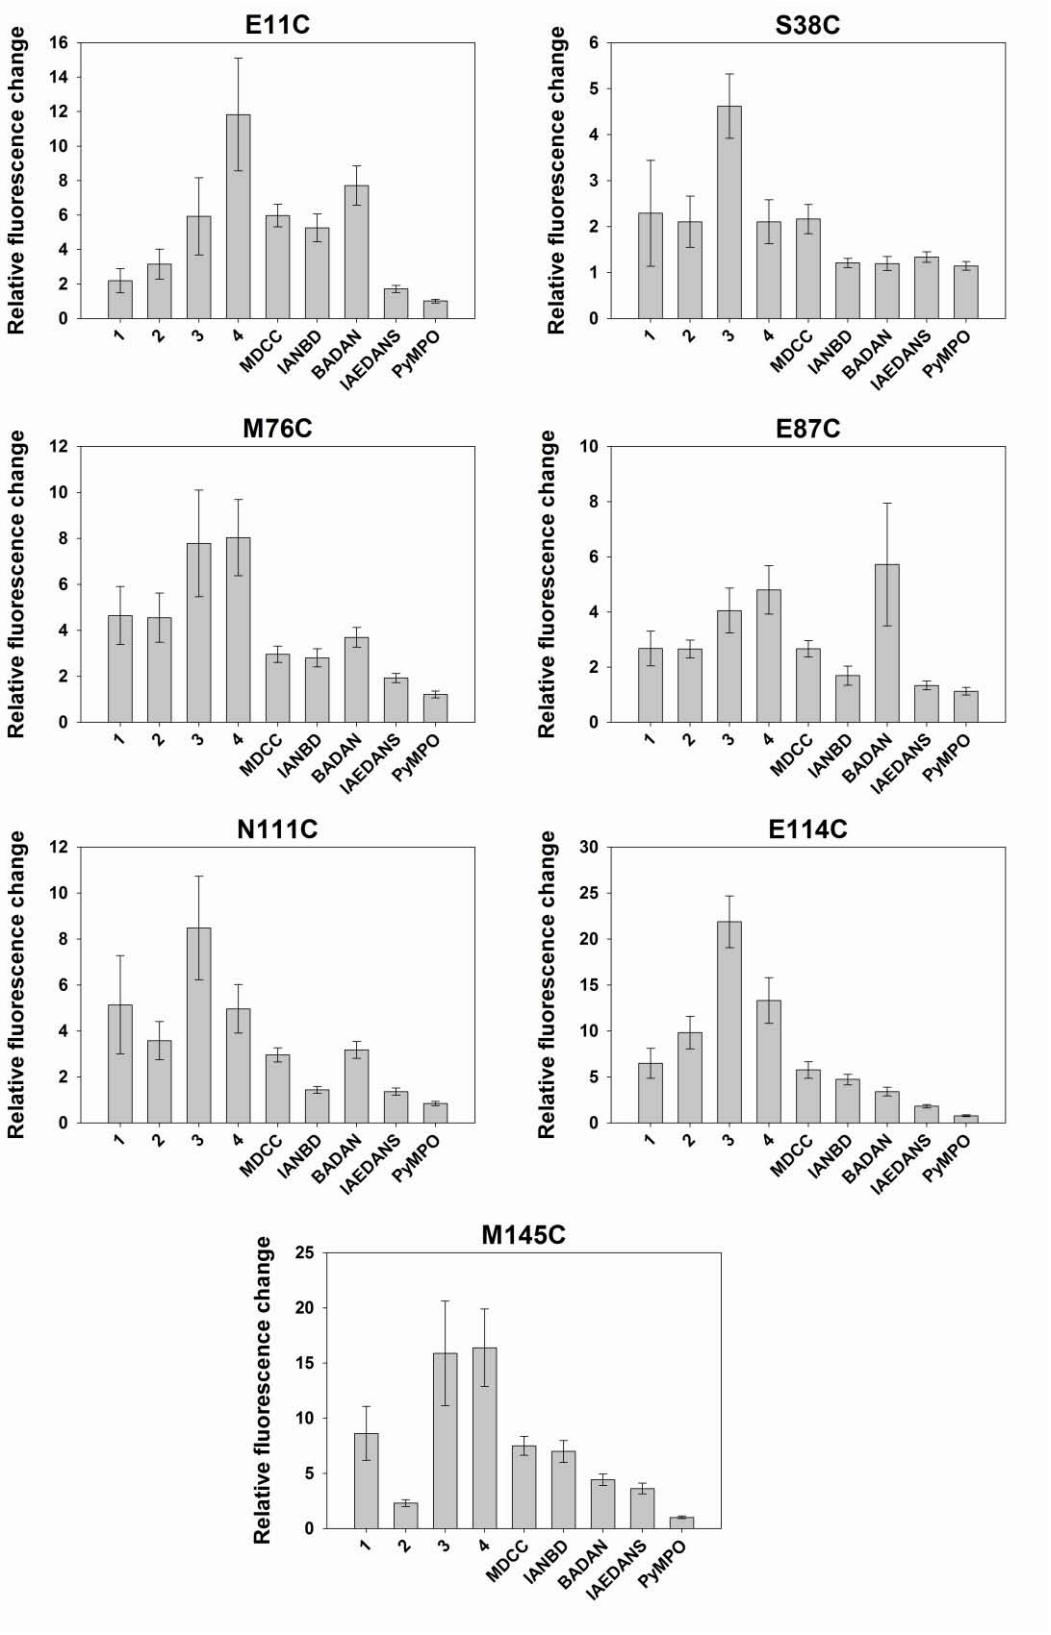

Figure S2. The fluorescent constructs were measured at a concentration of 5 μM in TBS buffer (pH 7.4) and guanidine hydrochloride (6.67 M, pH 7.4). The vertical bars represent the magnitude of the ratio of fluorescence in TBS buffer over that of the construct in the guanidine solution. A greater ratio indicates higher initial background fluorescence due to non-specific interactions of fluorophore with

local features of the attached protein. Indicated errors represent the 90% confidence interval for three trials.

PAMAM Dendrimers Conjugated with an Uncharged Gadolinium(III) Chelate with a Fast Water Exchange: The Influence of Chelate Charge on Rotational Dynamics

Miloslav Polášek,[†] Petr Hermann,*[,†] Joop A. Peters,[‡] Carlos F. G. C. Geraldes,[§] and Ivan Lukeš[†]

Department of Inorganic Chemistry, Faculty of Science, Universita Karlova (Charles University), Hlavova 2030, 128 40 Prague 2, Czech Republic, Biocatalysis and Organic Chemistry, Department of Biotechnology, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands, and Department of Biochemistry, Faculty of Science and Technology, Center of Neurosciences and Cell Biology, University of Coimbra, 3001-401 Coimbra, Portugal. Received July 20, 2009; Revised Manuscript Received October 9, 2009

A bifunctional ligand, DO3A-py^{NO-C} (DO3A-py^{NO-C} = 10-[(4-carboxy-1-oxidopyridin-2-yl)methyl]-1,4,7,10-tetraazacyclododecane-1,4,7-triacetic acid), was attached to different generations (G0, G1, G2, and G4) of ethylenediamine-cored PAMAM dendrimers (PAMAM = polyamidoamine). The gadolinium(III) complex of this ligand possesses one molecule of water in its first coordination sphere and has a unique combination of a short water residence lifetime (τ_M = 34 ns), a neutral overall charge, and a possibility for rigid attachment to molecules bearing primary amino groups. These favorable properties predestine the ligand for constructions of highly efficient nanosized contrast agents for magnetic resonance imaging (MRI). The coupling reaction between the carboxylic group on the pyridine-*N*-oxide moiety of the protected ligand molecule and primary amines in the dendrimers was achieved by an active ester method under nonaqueous conditions using the coupling agent TBTU. This reaction afforded conjugates with high loadings (80−100% of the theoretically available primary amines) and of high purity. The gadolinium(III) complexes of the conjugates were studied by variable-temperature ^{17}O NMR and ^{1}H NMRD measurements. The water residence lifetime (τ_M = 55 ns) found in the largest conjugate G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$, though somewhat longer compared to the "monomeric" complex, is still short enough not to limit the relaxivity. Surprisingly, compared with analogous conjugates with negatively charged chelates, the prepared uncharged compounds displayed much faster global rotational correlation times (τ_g) and lower relaxivities. This phenomenon can be explained on the basis of Coulomb interactions. The motion of the charged chelates is restrained due to interactions with their counterions and the chelates themselves, while the uncharged chelates are not affected. Comparison of the PAMAM-based conjugates bearing uncharged and (1−)-charged chelates based on relaxometric data, ^{1}H DOSY spectra, and SAXS measurements reveals that τ_g reflects the rotational motion of large segments (dendrons) of the conjugates rather than that of the whole macromolecule.

INTRODUCTION

Magnetic resonance imaging (MRI) is a powerful and rapidly developing diagnostic technique, which is indispensable for imaging of soft tissues. The basic MRI image reflects the concentration of ^{1}H nuclei in the 3D space; however, employing T_1 and T_2 relaxation times of protons helps to significantly improve the quality of the images. Though the use of contrast agents (CAs) is not essential to this technique, it is advantageous to use paramagnetic CAs to accelerate the relaxation of the ^{1}H nuclei.

Among the various available MRI contrast agents, the gadolinium(III) chelates with polydentate ligands, such as the macrocyclic DOTA and open-chain DTPA (Chart 1) and their various derivatives, are probably the most popular ones. These paramagnetic chelates act mainly as T_1-contrast agents. Since the discovery of these first-generation CAs, there has been a continuous effort to improve the properties of the chelates in order to obtain CAs with higher relaxivity (i.e., the efficiency expressed as relaxation rate enhancement per milimolar concentration of metal ion) and higher selectivity (*1*−*5*). The latest development moves toward targeted agents and the field of molecular imaging (*6*−*10*), which allows in vivo investigation of cellular molecular events involved in normal and pathological processes. However, the applicability of MRI contrast agents in molecular imaging encounters a tremendous obstacle in an unfavorable combination of low efficiency of the CAs and low concentration of the target receptors (*6, 7*).

There are, in principle, two basic strategies to overcome this limitation. (i) A high payload of paramagnetic metal ions can be delivered at the target by conjugating a large number of CA molecules with a macromolecule or a particle that is linked to a targeting vector. (ii) The efficiency of the individual CA molecules can be enhanced by rational design of the Gd(III) chelates. Preferably, both approaches should be combined in order to attain the maximum relaxivity. Important physicochemical parameters in this respect are the molecular tumbling (characterized by the rotational correlation time τ_R) and the mean residential time of the water molecule(s) in the coordination sphere of the Gd(III) ion (related to the water exchange by $\tau_M = 1/k_{ex}$). Both parameters should be optimized in order to attain the high relaxivity. Too fast or two slow water exchange can both limit the relaxivity; therefore, the values of τ_M should ideally be within the range 10−30 ns. The optimum of τ_R somewhat varies with the magnetic field and can be tuned by an attachment of the Gd(III) chelate to another molecule.

Chart 1. Structures of Ligands Discussed in This Work

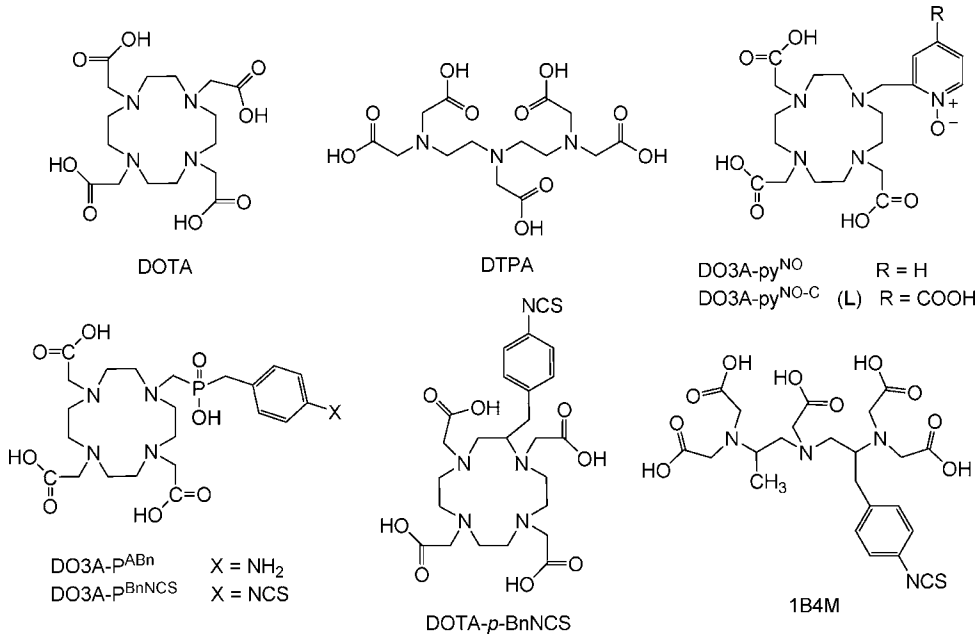

Chart 2. Selected Bifunctional Ligands and Modes of Their Attachment to PAMAM Dendrimers

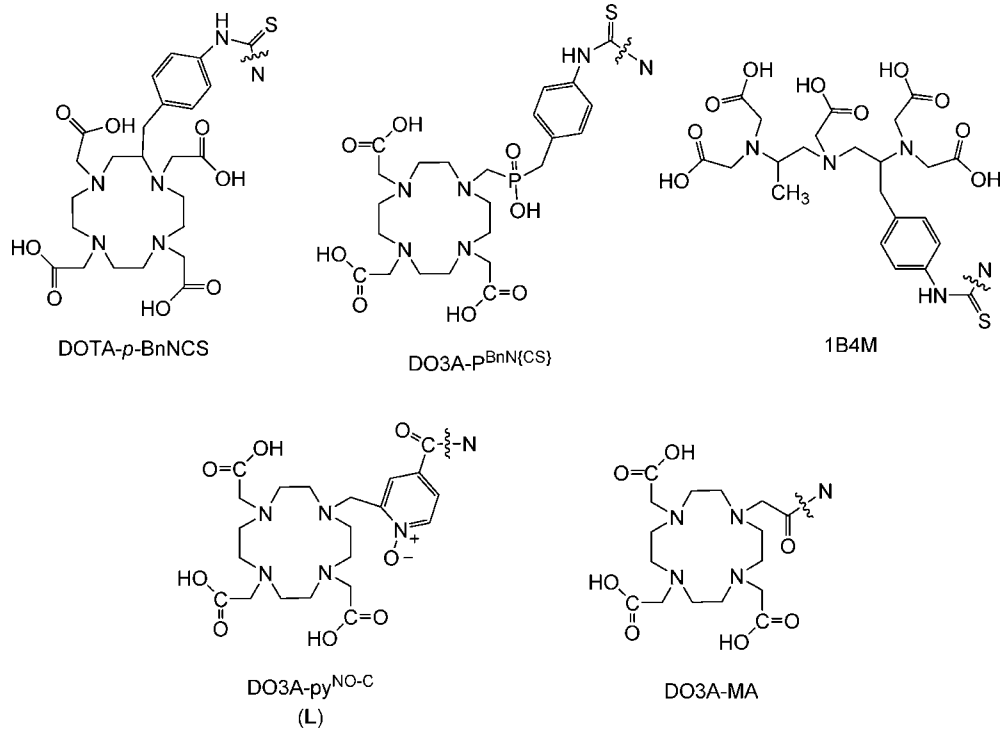


A number of different macromolecules have been explored as molecular scaffolds, spanning a vast range of sizes and chemical nature. Various Gd(III) chelates were covalently attached to dendrimers (*11*−*17*), modified polysaccharides (*18*−*21*), or linear polymers (*18*, *22*) or incorporated into micelles (*23*) and linear polymers (*24*−*28*). A widely used class of substrates for this purpose are the polyamidoamine (PAMAM) dendrimers (*11*−*16*) which provide well-defined, nearly spherical structures of tunable sizes and accordingly adjustable pharmacokinetic properties of the conjugates (*29*−*31*). PAMAM dendrimers have found applications in MRI visualizations of blood vessels (*32*, *33*), lymphatic system (*34*), or targeted imaging of tumors (*35*−*37*). In most of the reported cases, the relaxivity has been limited by a too-slow water exchange in the Gd(III) chelates. Only a few systems with fast water exchange have been presented until now (*14*, *15*). In all cases, it was found that the relaxivity can be additionally limited by a fast local motion of the attached chelates that cancels the effect of the slow overall motion of the conjugate (*14*, *15*, *38*).

The strategies to attach the Gd(III) chelates to macromolecules (Chart 2) include the most popular reaction between isothiocyanates and primary amino groups to form a thiourea bridge (e.g., in 1B4M (*9*, *10*, *29*, *31*, *32*, *34*, *39*), DOTA-*p*-BnNCS (*16*), DO3A-P^{BnNCS} (*15*) (see Chart 1), and others (*11*, *14*, *35*, *40*), the analogous reaction of isocyanates (*41*, *42*), and the formation of amide bonds either with (*12*) or without (*16*, *17*) the use of an additional spacer. The latter method is especially attractive,

as it can help to evade the problematic fast local motion by minimizing the number of atoms involved in the linking group.

Besides having optimal relaxivity (i.e., optimized values of τ_R and τ_M), the Gd(III) chelate should be sufficiently thermodynamically and kinetically stable in order to prevent complications arising from the recently discovered toxicity of some less stable contrast agents (*43*). In addition, the chelates of uncharged nature can be advantageous in several aspects: (i) there is lower osmolality of the intravenously injected solution; (ii) they might interfere less with the molecular recognition processes in molecular imaging applications; and (iii) uncharged chelates internalize into cells more easily than the charged ones, and therefore, they are more appropriate for cell labeling applications (*44*). Meeting all the requirements in one compound is an extremely challenging task, as some of the parameters cannot be changed without affecting the others.

Recently, we reported the synthesis and characterization of a new bifunctional derivative of DOTA bearing one pyridine-*N*-oxide pendant arm, ligand DO3A-py$^{NO\text{-}C}$ (**L**, Chart 1) (*45, 46*). The Gd(III) complex of this compound exhibits a water exchange rate that is optimal for MRI applications ($\tau_M = 34$ ns). The carboxylic group at the 4-position of the pyridine ring can be used for attachment of the ligand to any molecule bearing primary amino groups. Such an attachment minimizes the number of bonds that allow rotation and, therefore, should restrict the local motion. In addition, the attached Gd(III) chelates are electroneutral. This combination of properties makes the ligand **L** an interesting alternative to other existing bifunctional ligands for a variety of applications.

In this work, we describe the synthesis of G0 to G4 PAMAM conjugates of **L** that cover a vast range of molecular masses. The PAMAM dendrimers were chosen as good reference models, which allow a direct comparison of the properties with other conjugates. Unlike the aqueous conditions used in the preparations of the thiourea-bridged conjugates, our synthetic route required the combination of a nonaqueous chemistry, orthogonal protection of the acetate groups, activation and coupling of the pyridine-carboxylic group, and final deprotection. The properties of the gadolinium(III)-loaded conjugates were explored using ^{1}H and ^{17}O relaxometry, ^{1}H DOSY spectra, and SAXS measurements. For the first time, an uncharged gadolinium(III) complex endowed with a fast water exchange was attached to a macromolecule.

EXPERIMENTAL SECTION

Chemicals. D_2O (99.95% D) and CD_3OD (99.8% D) were purchased form Chemotrade. LiOH monohydrate was obtained from Lachema. Diisopropylethylamine (DIPEA) was received from Merck. 4-(Dimethylamino)pyridine (DMAP), *O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU), HOBt, EDC, HOAt, TSTU, and dry DMSO were purchased from Fluka. The solutions of polyamidoamine (PAMAM) dendrimers with ethylenediamine core of generations 0, 1, 2 (all 20 wt % in methanol), and 4 (10 wt % in methanol) were obtained from Aldrich. Trifluoroacetic acid (TFA, extra pure) was received from Acros. Dry acetonitrile was prepared by distillation from P_2O_5. The following extra pure chemicals were used for buffer preparations: ammonium acetate and anhydrous sodium acetate (both Fractopur), acetic acid, and 25% aqueous NH_3 (both p.a.) were purchased from Merck; NaOH (puriss) and citric acid monohydrate (puriss) were obtained from Fluka. High-purity deionized water and supragradient-grade acetonitrile (Scharlau) were used for HPLC. Methanol ANASOLV-P (Analytika, Czech Republic) was used for ultrafiltration. The Dowex 50 ion-exchange resin was purchased from Fluka. Complexes of the DO3A-P$^{BnN\{SC\}}$-containing dendrimers were available from previous studies (*15*).

Methods. Elemental analyses were performed at the Institute of Macromolecular Chemistry of the Czech Academy of Science (Prague). NMR spectra were acquired on Varian UNITY INOVA 400 and Varian NMRS 300. The chemical shifts were referenced on the signal of CHD_2OD (= 3.31 ppm, in CD_3OD) or *t*-BuOH (= 1.20 ppm, in D_2O). ES/MS spectra were recorded on a Bruker ESQUIRE 3000 with ion-trap detection in the positive mode.

MALDI-TOF MS. Spectra were acquired on a 4800 Plus MALDI TOF/TOF analyzer (Applied Biosystems/MDS Sciex) equipped with a Nd:YAG laser (355 nm, firing rate 200 Hz) in the linear positive ion mode. Samples were spotted onto the MALDI target and left to dry. Dried droplets were covered by the matrix solution (10 mg/mL sinapinic acid in 50% (v/v) acetonitrile and 0.05% (v/v) trifluoroacetic acid) and left to dry.

Ultrafiltration. The device consisted of an ultrafiltration cell 8050 (50 mL), CDS10 selector valve, and an RC800 mini-reservoir (800 mL). The membranes were selected according to their cutoff with respect to the molecular weights of the conjugates: PLAC (1 kDa, for G0 and G1 conjugates), YM3 (3 kDa, for G2), and YM10 (10 kDa, for G4). All ultrafiltration equipment was purchased from Millipore.

RP-HPLC. The HPLC system was composed of a Beta 10 gradient pump (ECOM, Czech Republic) equipped with an active mixer Knauer A0285 and a Topaz dual-UV detector (ECOM, Czech Republic). Experiments were performed on an XTerra RP8, 5 μm, 150 × 4.6 mm column (Waters) equipped with a Security Guard system (Phenomenex) holding a C8 cartridge. The mobile phase was continuously vacuum-degassed in a DG 3014 degasser (ECOM, Czech Republic). The mobile phase was mixed in the gradient pump from three stock solvents and solutions: CH_3CN (solvent A), H_2O with 0.1 vol % of TFA (mixture B), and H_2O (solvent C). The detector wavelengths were set to 210 and 289 nm. Concentrations of the samples were ~0.5 mg/mL. Injection volumes were 20 μL. The flow rate was maintained at 1 mL/min. Collecting and processing of the data were performed using Clarity (DataApex, Czech Republic) software.

SEC. Size-exclusion chromatography was performed on the system described above, on a TSKgel G2000SW 300 × 7.5 mm column equipped with a TSKgel SW Guardcolumn 75 × 7.5 mm (TOSOH Bioscience). A differential refractometer RIDK-102 (ECOM, Czech Republic) detector was attached in series after the UV-absorbance detector. The UV-absorbance wavelengths were set to 230 and 289 nm. A premixed 0.1 M sodium citrate buffer pH = 2.77 was used as the mobile phase. The flow-rate was maintained at 0.5 mL/min. The concentration of the samples was 1−2 mg/mL; the injection volumes were 20 μL.

^{1}H NMRD Profiles. The ^{1}H longitudinal relaxation rates (defined as $1/T_1$) were measured with a Stelar Spinmaster Spectrometer FFC-2000 using the field-cycling method. The range of magnetic fields was 0.00024−0.24 T (corresponding to 0.01−10 MHz proton Larmor frequency). Additional data points at 0.47 T (20 MHz) and 1.41 T (60 MHz) were obtained with Bruker Minispec mq-20 and Bruker Minispec mq-60 relaxometers, respectively. The T_1 values were determined using the standard inversion recovery pulse sequence. The measurements were performed at 25 and 37 (±1) °C.

^{17}O NMR Variable-Temperature Measurements. The ^{17}O NMR measurements were performed on a Varian UNITY INOVA 400 spectrometer (9.4 T, 54.22 MHz). The temperature was controlled with L-900 VT-unit and calibrated on ^{1}H signals of methanol and ethylene glycol (*47*). The samples were enriched to ca. 0.1% of ^{17}O by addition of $H_2{}^{17}O$ (30%, IsoTrade) and approximately 0.5% of *t*-BuOH was added as internal standard. Longitudinal relaxation times were measured

using the inversion recovery pulse sequence and transversal relaxation times by the Carr-Purcell-Meiboom-Gill spin echo pulse sequence. No spinning of the samples and no frequency lock were used. The BMS contributions to chemical shifts in the paramagnetic samples were determined from the differences of ^{1}H signals of *t*-BuOH between the diamagnetic and paramagnetic sample and were subtracted. The samples were kept in the probe for at least 10 min prior to the measurement to ensure temperature equilibration.

Fitting of Data. The simultaneous analyses of ^{1}H NMRD and ^{17}O NMR variable-temperature T_1, T_2, and chemical shift data were performed with the Micromath Scientist computer program using a least-squares procedure (for complete set of used equations, see Supporting Information).

DOSY. DOSY experiments were performed on 500 MHz Avance Bruker Spectrometer with a BBI Bruker 5 mm probe. The sequence for diffusion measurements included a stimulated echo using bipolar gradients. Diffusion time = 200 ms; gradient duration = 2 × 1.750 ms. Spectra were generated with NMRnotebook software, DOSY kit (NMRTec).

Small-Angle X-ray Scattering (SAXS). The SAXS experiments were performed using a pinhole camera (Molecular Metrology SAXS System) attached to a microfocused X-ray beam generator (Osmic MicroMax 002) operating at 45 kV and 0.66 mA (30 W). The camera was equipped with a multiwire, gas-filled area detector with an active area diameter of 20 cm (Gabriel design). Two experimental setups were used to cover the q range of 0.005−1.1 Å^{-1} ($q = (4\pi/\lambda)\sin\Theta$, where λ is the wavelength and 2Θ is the scattering angle). The scattering intensities were put on absolute scale using a glassy carbon standard.

MR Imaging. The contrast agent (G4-[Gd(H_2O)(do3a-py$^{NO\text{-}C}$)]$_{57}$) was intravenously applied to a healthy Lewis rat (Charles River, Germany). The dose was 125 μL of solution in 0.9% NaCl that was 181 mM per Gd(III). MR images of rat kidney prior to and after the application of CA were obtained at a 4.7 T Bruker MR spectrometer by T_{1w} gradient echo and spin echo sequences. Parameters of the gradient echo sequence were as follows: repetition/echo time TR/TE, 60 ms/3.7 ms; flip angle 30°; slice thickness, 2 mm; number of acquisitions, 16; scan time, 4 min 6 s; in-plane resolution, 234 μm. Parameters of the spin echo sequence were as follows: repetition/echo time TR/TE, 215 ms/12 ms; slice thickness, 2 mm; number of acqusitions, 8; scan time, 11 min 27 s; turbo factor, 2; in-plane resolution, 234 μm. The protocol was approved by the Ethical Committee of the Institute for Clinical and Experimental Medicine and the experiments were carried out in accordance with the European Communities Council Directive of 24 November 1986 (86/609/EEC). Evaluation of MR images was done using the software *ImageJ* (copyright NIH, USA).

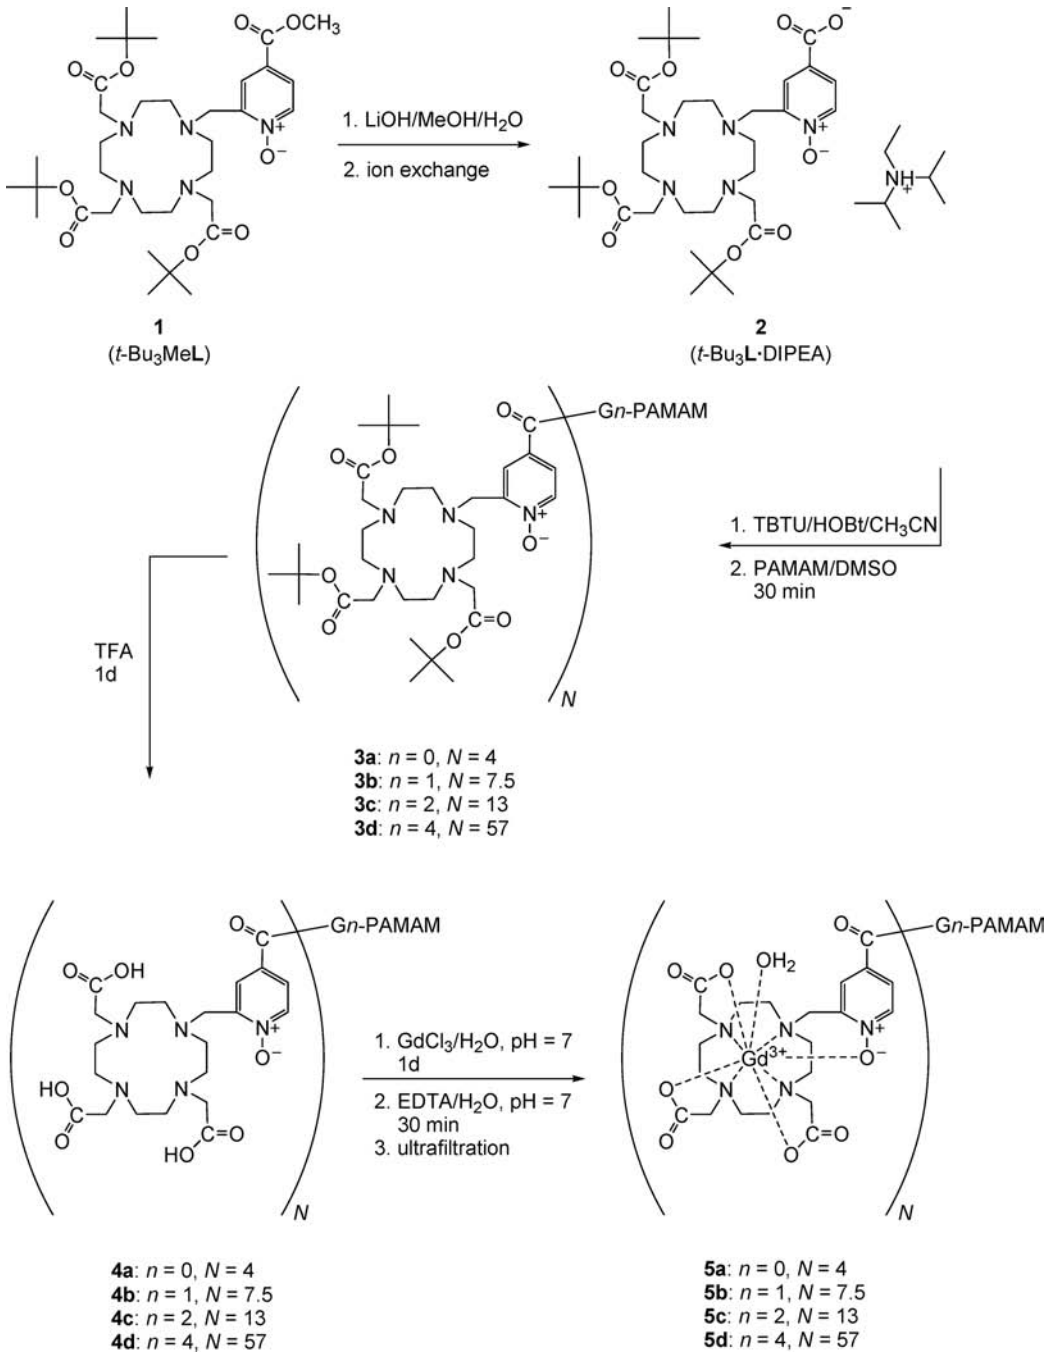
*Preparation of t-Bu$_3$***L**·*DIPEA Salt (***2***).* First, a column with Dowex 50 ion-exchange resin in H^+ cycle was prepared, and water in the column was exchanged for MeOH. A solution of DIPEA in MeOH was passed through until the ion-exchange resin was saturated with DIPEA. The excess of DIPEA was then flushed away with MeOH. A solution of 1.2 equiv of LiOH·H_2O (0.250 g, 5.96 mmol) in 5 mL of water was then added dropwise to a stirred solution of *t*-Bu$_3$Me**L** (**1**, 3.37 g, 4.96 mmol) (*45*) in 20 mL of MeOH at RT. After 10 min, RP-HPLC analysis confirmed complete hydrolysis of the methyl ester function (A/B/C: linear gradient from 20/40/40 to 40/40/20 in 10 min, 40/40/20 held for 5 min; retention times: *t*-Bu$_3$Me**L** 11.17 min, *t*-Bu$_3$**L** 9.50 min). The solution was then slowly passed through the column of Dowex 50. The yellow eluate was concentrated on a rotary evaporator, the residue was dissolved in benzene (100 mL), and the solution was freeze-dried. The product was obtained as a pale yellow solid foam (3.86 g, 97%). δ_H (300 MHz, CD_3OD) 1.38 (3 H, t, DIPEA $CH_2C\mathbf{H}_3$, J_{HH} = 7.5 Hz); 1.38 (12 H, d, DIPEA CH($C\mathbf{H}_3$)$_2$, J_{HH} = 6.6 Hz); 1.46 (18 H, s, *t*-Bu$_3$**L** −C(CH_3)$_3$); 1.47 (9 H, s, *t*-Bu$_3$**L** −C(CH_3)$_3$); 2.88−2.96 (8 H, m, *t*-Bu$_3$**L** ring CH_2); 3.08−3.14 (4 H, m, *t*-Bu$_3$**L** ring CH_2); 3.19−3.25 (4 H, m, *t*-Bu$_3$**L** ring CH_2); 3.23 (2 H, quartet, DIPEA C$\mathbf{H}_2$$CH_3$, J_{HH} = 7.5 Hz); 3.56 (2 H, s, *t*-Bu$_3$**L** CH_2CO); 3.70 (4 H, s, *t*-Bu$_3$**L** CH_2CO); 3.73 (2 H, septet, DIPEA C**H**(CH_3)$_2$, J_{HH} = 6.6 Hz); 4.08 (2 H, s, *t*-Bu$_3$**L** CH_2-py); 7.92 (1 H, dd, *t*-Bu$_3$**L** aryl, J_{HH} = 6.6 Hz, J_{HH} = 2.4 Hz); 8.08 (1 H, d, *t*-Bu$_3$**L** aryl, J_{HH} = 2.4 Hz); 8.36 (1 H, d, *t*-Bu$_3$**L** aryl, J_{HH} = 6.6 Hz). ESI-MS (*m*/*z*; found (calcd)) 666.1 (666.4) ($M+H^+$). Found: C, 57.16; H, 9.24; N, 9.70. Calc. for $C_{41}H_{74}N_6O_9$: C, 61.94; H, 9.38; N, 10.57%.

*General Procedure for the Synthesis of the Conjugates in the Form of t-Butyl Esters (***3a**−**3d***).* For preparation of about 300 mg of conjugate, the appropriate amount of methanolic solution of the dendrimer was weighed and evaporated on a rotary evaporator. The residue was dried in vacuum for 1 h and then dissolved in 2 mL of dry DMSO with HOBt (1.5 equiv per primary amino group of the dendrimer). The *t*-Bu$_3$**L**·DIPEA salt (1.5 equiv per primary amino group of the dendrimer) and TBTU (1.5 equiv per NH_2) were mixed and dissolved in dry acetonitrile (10 mL). The resulting solution was added dropwise (over period of 20 min) to a stirred solution of the dendrimer. The progress of the reaction was followed on RP-HPLC. After 30 min of stirring at RT, the reaction mixture was concentrated on a rotary evaporator. The residue was diluted with a MeOH/water mixture (1:1, v/v) to approximately 20 mL and filtered through a 0.22 μm syringe filter to the ultrafiltration cell. The solution was first concentrated in the cell to 10 mL and then continuously ultrafiltrated (solvent composition: 50% MeOH, 50% of 0.1 M aqueous NH_4OAc) until all low-molecular-weight compounds (i.e., the ligand, coupling agent, and DMSO) were removed (checked by RP-HPLC). This required approximately 150−200 mL of the solvent. The ultrafiltration was then continued with pure MeOH until at least 50 mL had run through. The obtained solution was then evaporated on a rotary evaporator; the residue was dissolved in 20 mL of benzene and then freeze-dried. The products were obtained as pale yellow solid foams with the yields 88−94%. δ_H (300 MHz, CD_3OD, 45 °C) 1.45−1.46 (s, −C(CH_3)$_3$); 1.47−1.48 (s, −C(CH_3)$_3$); 2.25−3.75 (overlapping CH_2 signals of **L** and the dendrimer); 3.96−4.03 (s, CH_2-py); 7.80−7.89 (m, arom.); 8.10−8.25 (m, arom.); 8.36−8.41 (m, arom.). MALDI-TOF-MS (only for G0-(*t*-Bu$_3$**L**)$_4$) (*m*/*z*; found (calcd)) 3109.4 (3108.0) ($M+H^+$).

*Cleavage of the t-Butyl Esters, General Procedure (***4a**−**4d***).* The conjugates obtained as *t*-butyl esters in the previous step (typically about 200 mg) were dissolved in neat TFA (ca. 10 mL) and stirred 24 h at RT. TFA was then removed on a rotary evaporator; the residue was dissolved in water (20 mL) and then neutralized with aqueous ammonia. The solution was transferred to the ultrafiltration cell, concentrated to 10 mL, and ultrafiltered continuously with 0.05 M aq ammonium acetate. After collecting ca. 100 mL of the filtrate, the solvent was exchanged for deionized water and the ultrafiltration was continued until another 100 mL of the filtrate was collected. The retained solution was then freeze−dried, and the products were obtained as pale yellow powders with the yields 76−84%. δ_H (300 MHz, D_2O, 60 °C) 2.40−3.80 (overlapping CH_2 signals of **L** and the dendrimer); 4.10−4.11 (s, CH_2-py); 7.72−7.82 (m, arom.); 8.30−8.43 (two overlapping m, arom.).

*Preparation of the Gd(III) Complexes, General Procedure (***5a**−**5d***).* The ligand−PAMAM conjugate (typically 100 mg) was dissolved in water (10 mL) and solid $GdCl_3$·$6H_2O$ (1.5 equiv relative to a number of the ligand molecules) was added. The pH was adjusted to 7 with 2 M NaOH. The mixture was stirred at RT for 24 h. Then, Na_2H_2EDTA (2 equiv relative to number of ligand molecules) was added and the pH again

Scheme 1. Synthesis of the Conjugates



adjusted to 7 with NaOH. The xylenol orange test gave a negative reaction showing that the excess of Gd(III) ions was chelated by EDTA. The solution was then continuously ultrafiltered with deionized water until all low-molecular-weight compounds were removed (controlled by SEC). The solution was either used in further steps or freeze−dried to afford the pure Gd(III)-loaded conjugates as light yellowish powders. Complexes with other trivalent ions were obtained analogously.

RESULTS AND DISCUSSION

Synthesis. An attachment of DO3A-py$^{NO\text{-}C}$ to PAMAM dendrimers through an amide bond between the carboxylic group on the pyridine ring of DO3A-py$^{NO\text{-}C}$ and the primary amino groups of the dendrimer required a selective protection of the carboxylic groups in the acetate pendant arms of the DO3A moiety. Therefore, the previously described *t*-butyl methyl ester **1** (Scheme 1) (*45*) was used as starting material. The methyl ester function on the pyridine ring was selectively hydrolyzed with LiOH in a MeOH/H_2O mixture. According to RP-HPLC, the reaction was selective and fully completed in a few minutes. The presence of Li^+ ions complicated the NMR spectra of the reaction product due to formation of Li^+ complexes. Therefore, the Li^+ cation was exchanged for protonated DIPEA on an ion-exchange resin. The resulting DIPEA salt of *t*-Bu$_3$**L** could then be obtained as a dry, solid foam upon freeze-drying from benzene solution. The successful exchange for DIPEA was confirmed by ^{1}H NMR.

The coupling was accomplished using TBTU coupling agent and DMSO/CH_3CN solvent mixture and afforded conjugates in high yields and with high loadings. Conditions for the coupling were optimized using reversed-phase HPLC (Supporting Information Figure S1). With this technique, we were also

Table 1. Loadings of the Dendrimers with *t*-Bu$_3$L

generation of dendrimer	*N* (theoretical)	*N* (average)[a]	loading (%)[b]
0	4	4.2	104
1	8	7.5	94
2	16	13.0	81
4	64	57.0	89

[a] The average of the two values calculated from ratios of the integral intensities of aliphatic/aromatic and aliphatic/*t*-butyl regions in ^{1}H NMR spectra. [b] The loadings were calculated from intensities in the ^{1}H NMR spectra, assuming that the dendrimers were ideal (without defects). This is possibly the reason why the loading for G0 exceeds 100%. The accuracy of the loadings given is estimated to be ±5%.

able to detect impurities in the resulting conjugates (Supporting Information Figures S1 and S2), which have not commonly been mentioned in previous reports. Analysis of the impurities was possible only for the G0 conjugate; however, it revealed that these stem from the starting PAMAM dendrimers that are prone to various defects (Supporting Information Figure S7). Similarly, defective dendrimers were detected also with SEC, where dimers (two dendrimers fused together) could be seen in both the starting dendrimers and the conjugates (Supporting Information Figures S5 and S6). The loadings of the dendrimers with ligand molecules were determined from integral intensities in ^{1}H NMR spectra of the conjugates in the *t*-Bu ester form (see Table 1 and Supporting Information Figures S3 and S4). After cleavage of the *t*-Bu esters in neat TFA, the Gd(III) complexes of the conjugates were prepared. Each step of the synthesis was followed by purification with ultrafiltration. More detailed discussions of the synthetic protocol and characterization is described in the Supporting Information.

Relaxometry. One of the crucial parameters that affect the relaxivity of macromolecular contrast agents is the exchange rate of water molecules coordinated to the central Gd(III) ion. A slow water exchange has been stated as the major relaxivity-limiting factor in a number of conjugates (*11, 13, 16, 40*). This is particularly true for various amide derivatives of DOTA and DTPA, where the carboxyl groups coordinated to the metal ion were utilized for a linkage to other molecules through an amide bond. The change in the local coordination environment of the Gd(III) ion results in a decrease of the water exchange rate (*11, 13, 16, 24*−*27*). Thus, it is apparent that the point of attachment of the chelate must be sufficiently far from the coordination cage around the central ion in order not to interfere with the water exchange process. In a previous study, we have demonstrated that derivatization of the DO3A-py^{NO} (Chart 1) at position 4 of the pyridine ring with a carboxylic group (leading to the ligand DO3A-py$^{NO\text{-}C}$) had no significant effect on the water exchange rate in the Gd(III) complexes (*45*). Therefore, linking of DO3A-py$^{NO\text{-}C}$ to the PAMAM dendrimers by forming an amide to the carboxyl on the pyridine ring should similarly have no effect on the water exchange rate. To test this hypothesis, variable-temperature ^{17}O NMR transversal relaxation rates of a solution of the largest prepared conjugate, G4-[Gd(H$_2$O)(do3a-py$^{NO\text{-}C}$)]$_{57}$, were measured to assess the water exchange rate (*1, 11*). The data are shown in Figure 1 and compared to the data of the "monomer", [Gd(H$_2$O)(DO3A-py$^{NO\text{-}C}$)]$^-$ complex. Both sets give almost the same shape of the curve showing that there is no significant change in the water exchange rate of the chelate after the attachment to the dendrimer. The whole set of data for the conjugate, G4-[Gd(H$_2$O)(do3a-py$^{NO\text{-}C}$)]$_{57}$, including the temperature dependences of the ^{17}O transversal (Figure 1) and longitudinal (Supporting Information Figure S8) relaxation rates, ^{17}O chemical shifts (Supporting Information Figure S8), and ^{1}H NMRD profiles at 25 and 37 °C (Figure 2), was fitted according to the equations of the Solomon-Bloembergen-Morgan (SBM) theory of paramagnetic relaxation (for the set of equations, see Supporting Information). The water residence time ($\tau_M = 1/k_{ex}$) in the conjugate ($\tau_M = 55$ ns) as determined by this method is slightly longer than that found in the monomer ($\tau_M = 34$ ns) (*45*). However, the value is still short enough not to limit the relaxivity of the conjugates. As there was no significant change in the ^{17}O transversal relaxation rates going from the monomer to the largest conjugate, we did not perform the ^{17}O studies on the smaller conjugates.

As the water exchange in the Gd(III) complex of DO3A-py$^{NO\text{-}C}$ is fast regardless of its attachment to other molecules, the main parameter limiting the relaxivity is the rotational correlation time τ_R. Therefore, any increase of this parameter (i.e., slowing down of the molecular tumbling) should be reflected in a growth of the relaxivity. Figure 3 shows that the relaxivity of the conjugates is roughly linearly proportional to the dendrimer generation. This corresponds to the proportionality of the global rotational correlation time τ_g to the molecular volume (as given by the Debye-Stokes-Einstein equation), which is approximately doubled with each generation. The data are compared with those for the analogous negatively charged conjugates of DO3A-P$^{BnN\{SC\}}$ (Chart 2) that display similarly fast water exchange rates in the Gd(III) complexes (*15, 48*). In all cases, the conjugates of DO3A-py$^{NO\text{-}C}$ give significantly lower relaxivities compared to the conjugates of DO3A-P$^{BnN\{SC\}}$ of the same generation.

A simultaneous fitting of the variable-temperature ^{17}O NMR data and ^{1}H NMRD profiles for the conjugate G4-[Gd(H$_2$O)(do3a-py$^{NO\text{-}C}$)]$_{57}$ to the appropriate equations allowed us to investigate the relaxometric properties in more detail. The model comprises the Lipari-Szabo approach (*1*), which discriminates between the local (τ_l) and global (τ_g) rotational correlation times on the basis of a general order parameter S^2. For $S^2 = 0$, the local and global motions are completely independent of each other, while for $S^2 = 1$, both motions are totally correlated. It has been shown that the water molecule coordinated to the Gd(III) ion can rotate around the coordination bond. As a consequence, the τ_l values for ^{1}H nuclei are systematically lower by a factor of 0.65 than those for ^{17}O nuclei (*14, 49*). This internal motion of the water molecule is part of the local motion, and therefore, only values of τ_l are different for ^{1}H and ^{17}O. For the simultaneous fit of ^{1}H and ^{17}O data, we included this effect in our model (see Supporting Information). The number of parameters involved in the fit required fixing of some of them to the values previously determined for the monomer (number of inner-sphere water molecules $q = 1$; activation energy for the water exchange $\Delta H_M = 45.5$ kJ mol^{-1}; hyperfine coupling constant $A/\hbar = -3.75 \times 10^6$ rad s^{-1}) (*45*) or to generally accepted values (distances $r_{GdH} = 3.1$ Å and $r_{GdO} = 2.5$ Å, the closest approach of outer-sphere water molecules $A = 3.5$ Å) (*50*). The fitted parameters were the water residential lifetime τ_M, rotational correlation times τ_l and τ_g, the activation energies for rotational motions E_l and E_g, the order parameter S^2, and the parameters governing the electronic relaxation Δ^2 and τ_v. A reasonable agreement of the simultaneous fit with the longitudinal ^{17}O relaxation rates was obtained only when either the quadrupolar coupling constant $\chi(1 + \eta^{2/3})^{1/2}$ or the Gd···O$_w$ distance were allowed to vary. However, adjusting r_{GdO} led to unrealistically small values (~2.2 Å) that are not supported by any experimental evidence (*46*). Therefore, the constant $\chi(1 + \eta^{2/3})^{1/2}$ was allowed to vary, resulting in 11.1 ± 1.4 MHz. This value is somewhat larger than the recently reported value obtained from molecular dynamics simulations (8.7 MHz) (*51*), but smaller than the value obtained for the monomer (13.8 MHz) (*45*). For the conjugate G1-[Gd(H$_2$O)(do3a-py$^{NO\text{-}C}$)]$_{7.5}$, only the ^{1}H NMRD profiles were used in the fit, with adjustable parameters being τ_l, τ_g, S^2, Δ^2, and τ_v; other parameters were fixed at the values of the best fit for the conjugate G4-[Gd(do3a-py$^{NO\text{-}C}$)]$_{57}$. The most important

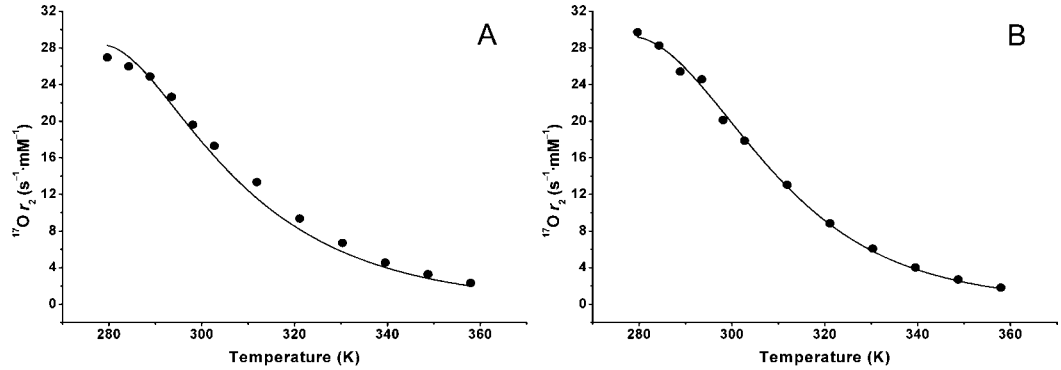


Figure 1. Temperature dependences of ^{17}O transversal relaxation rates of the macromolecular conjugate, G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$ (A), and the "monomeric" complex, [Gd(H_2O)(DO3A-py^{NO-C})]$^-$ (B, reproduced from ref *45*). The solid lines represent the results of the simultaneous least-squares fits.

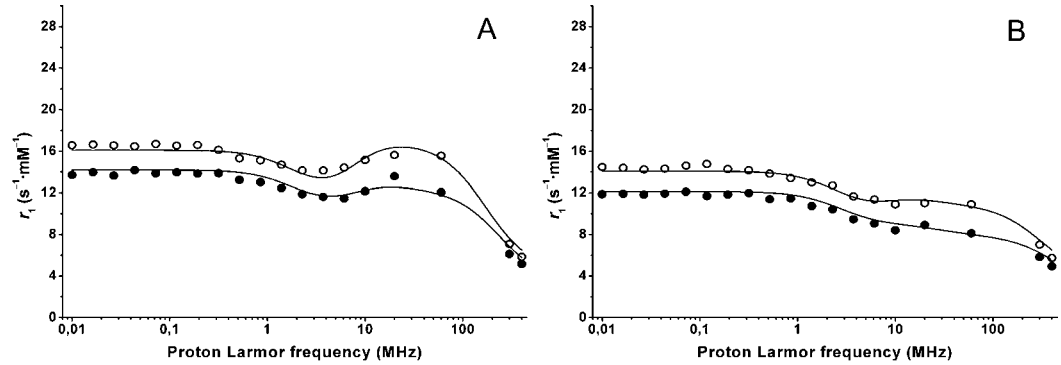

Figure 2. The ^1H NMRD profiles of G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$ (A) and G1-[Gd(H_2O)(do3a-py^{NO-C})]$_{7.5}$ (B) conjugates at 25 (empty circles) and 37 °C (filled circles). The solid lines represent the results of the simultaneous least-squares fits.

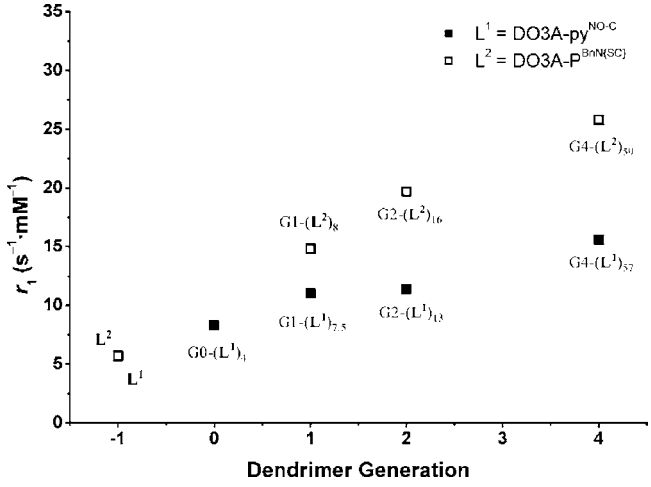

Figure 3. Dependence of relaxivity per mM Gd(III) (20 MHz, 25 °C) on the generation of the PAMAM dendrimers bearing electroneutral Gd(III) complexes of DO3A-py^{NO-C} (full squares) and negatively (1−)-charged Gd(III) complexes of DO3A-P$^{BnN\{SC\}}$ (open squares, data for ref *15a*.). The values at point −1 on the *x*-axis correspond to the "monomeric" chelates.

results of the fits are summarized in Table 2 and compared to similar conjugates and the corresponding "monomers" (for the full set of parameters, see Supporting Information).

From Table 2, one can deduce that the lower relaxivities in the conjugates of DO3A-py^{NO-C} are related to the shorter global rotational correlation times. The values of τ_g are approximately three times smaller than those for the corresponding conjugates of DO3A-P$^{BnN\{SC\}}$. By approximating the conjugates to spheres and using the Debye-Stokes-Einstein relation, this would correspond to a decrease in the radius by 30% going from the negatively charged conjugates of DO3A-P$^{BnN\{SC\}}$ to the uncharged conjugates of DO3A-py^{NO-C}. Changes in the radii of PAMAM dendrimers as a consequence of protonation/deprotonation of the terminal primary amines were reported in a number of simulation studies (*52*−*54*). The dendrimers were reported to adopt more expanded structures in the protonated state as a consequence of repulsive forces between the charges. This is analogous to the difference between the conjugates of DO3A-py^{NO-C} and DO3A-P$^{BnN\{SC\}}$, though the polarity of the charge in the Gd(III) chelates of DO3A-P$^{BnN\{SC\}}$ is opposite. However, recent analyses of NH_2-terminated PAMAM dendrimers by small-angle neutron scattering (SANS) (*55*, *56*) suggested that the size of the molecules is actually almost independent of the protonation state of the amino groups. The authors ascribe this fact to an enhanced counterion association inside the dendrimer molecule, which leads to shielding of the repulsive Coulombic forces between the charged terminal groups. The previously published simulation studies overestimated the changes in the size because they lacked proper models of the counterions (*57*). The role of counterions clearly cannot be disregarded when the properties of electroneutral and polyionic compounds are compared. One could argue that the SEC chromatograms (Supporting Information Figures S5 and S6) confirm the hypothesis that the charged (protonated) NH_2-terminated dendrimers are larger (give higher retention times) than the corresponding Gd(III)-loaded conjugates of DO3A-py^{NO-C}. However, the applied conditions (0.1 M sodium citrate pH = 2.77) are distinctively different from pure water, and the observed effect is most probably caused by citrate counterions traveling with the protonated dendrimers. Similar changes in retention times on SEC were observed after acetylation of the terminal amino groups (*58*). However, the retention times in SEC cannot be straightforwardly interpreted in terms of the molecular size when compounds with different chemical nature

[a] The values of τ_1 refer to the reorientation of $Gd-H_{water}$ vector. [b] Relaxivity at 20 MHz and 37 °C/25 °C. [c] A monomer corresponding to the G4-$[Gd(H_2O)(do3a\text{-}ma)]_{31}$ conjugate. [d] The value determined for G4-$[Gd(H_2O)(do3a\text{-}py^{NO\text{-}C})]_{57}$ was used in the fit.

are compared. For instance, the conjugates of DO3A-$py^{NO\text{-}C}$ and DO3A-$P^{BnN\{SC\}}$ could not be compared at the same conditions and needed different buffers for elution (acidic and neutral, respectively).

In order to compare the conjugates of DO3A-$py^{NO\text{-}C}$ and DO3A-$P^{BnN\{SC\}}$ by an independent method, ^1H DOSY experiments (DOSY = diffusion-ordered spectroscopy) on the diamagnetic analogues G4-$[Y(H_2O)(DO3A\text{-}py^{NO\text{-}C})]_{57}$ and G4-$[Y(H_2O)(DO3A\text{-}P^{BnN\{SC\}})]_{59}^{x-}$ were performed. The counterions in the latter case were sodium(I) cations. The expected difference in the size of the macromolecules should be reflected in the values of the diffusion coefficient. Surprisingly, both compounds gave the same value $D^{298} = (57 \pm 5) \times 10^{-12}$ m^2 s^{-1}, which, using a spherical model, corresponds to a hydrodynamic radius of 3.5 nm (Supporting Information Figure S9). The actual difference in the size is therefore either much smaller than the expected 30%, or virtually nonexistent. The expansion of the macromolecule due to repulsion between the charged chelates therefore does not take place and cannot be the reason for the observed differences in τ_g in our case. An alternative explanation may be found in redistribution of the mass within the dendrimer due to counterions balancing the charge on the terminal groups. This phenomenon was observed in SANS data (*55, 56*) and molecular dynamics simulations (*57*) in NH_2-terminated PAMAM dendrimers. When the groups are electroneutral, a substantial back-folding of the branches into the interior of the dendrimer occurs resulting in a relatively even distribution of the mass throughout the molecule. On the other hand, the charged terminal groups accompanied by the counterions tend to create a rather dense outer shell, leaving the interior of the dendrimer hollow (*55, 57*). The moment of inertia for the rotational motion is likely to vary between the two cases and, thus, may be reflected in the values of τ_g. However, the structure of the free dendrimers is relatively open and allows such changes to take place, while the structure of the conjugates may be significantly altered due to the bulkiness of the attached chelates.

To explore the conjugates from this point of view, small-angle X-ray scattering (SAXS) measurements on samples of G4-$[Gd(H_2O)(DO3A\text{-}py^{NO\text{-}C})]_{57}$ and G4-$[Gd(H_2O)(DO3A\text{-}P^{BnN\{SC\}})]_{59}^{x-}$ in aqueous solutions at neutral pH were performed (Supporting Information Figure S10). A large part of the scattering intensity belongs to the chelates holding the relatively heavy Gd(III) ions, and therefore, the technique should be able to distinguish between a preferential placement of the chelates on the periphery and their distribution throughout the interior of the dendrimer. Both cases should give different values of the radii of gyration, R_G. The found values of R_G were 27.6 ± 0.3 Å for G4-$[Gd(H_2O)(DO3A\text{-}py^{NO\text{-}C})]_{57}$ and 29.4 ± 0.2 Å for G4-$[Gd(H_2O)(DO3A\text{-}P^{BnN\{SC\}})]_{59}^{x-}$. So, also in this case, the difference is too small to give supporting evidence for such structural changes (for more information about the SAXS data analysis, see Supporting Information). Nevertheless, the SAXS patterns of the charged conjugate display interparticle correlation peaks at values of the scattering vector <0.05 $Å^{-1}$ (Supporting Information Figure S10). This behavior provides evidence of strong interparticle repulsion forces caused by the charge; these forces are absent in the uncharged conjugate. One can anticipate that, if the charge can restrict the whole molecules from approaching each other, it must also be an important factor for the motion of the charged chelates within the conjugate.

The data listed in Table 2 should be handled with caution, as they were obtained by different authors using slightly different models in the fits. Also, the relatively simple separation of the local and global rotational motions by the Lipari-Szabo approach has limited credibility in the case of PAMAM dendrimers, as these allow many degrees of motion within their structures. There is a question regarding how, and to what extent, the rotation of the whole macromolecule, its segment, and individual chelates will be reflected in the values of τ_1 and τ_g. However, there is no doubt that lower relaxivities of the electroneutral PAMAM-based conjugates are related to the rotational motion. First, this phenomenon is common to all PAMAM-based conjugates bearing electroneutral Gd(III) complexes, namely, the conjugates of DO3A-$py^{NO\text{-}C}$ and of DOTA-monoamides (*16, 59*) (see G4-$[Gd(H_2O)(do3a\text{-}ma)]_{31}$ in Table 2). Second, the relaxivity rises when a substantially more rigid molecular scaffold is used instead of the PAMAM dendrimers, while the chelates are kept uncharged. This is demonstrated effectively on Gadomer-17, a molecule that consists of a lysine-based dendrimer bearing DOTA-monoamide Gd(III) chelates. The relaxivity of Gadomer-17 at 37 °C surpasses that of the G4-PAMAM-based electroneutral conjugates despite the lower molecular weight and the longer water residence time of the former (Table 2) (*13*).

On the basis of the results presented here, we can derive the following model of the PAMAM-based conjugates. A high loading of the dendrimer with Gd(III) chelates induces a steric crowding that is released by migration of some of the chelates inside the dendrimer, resulting in relatively uniformly distributed mass throughout the volume of the macromolecule. This arrangement applies to conjugates of both neutral and charged chelates. However, the charged chelates are accompanied by

their counterions, which also enter into the interior of the dendrimer and largely compensate long-distance charge-related effects. As a consequence, the conjugates with charged chelates do not exhibit any swelling effect compared with the electroneutral conjugates, and their sizes are similar. The situation is different at smaller distances where the Coulombic interactions become important. The motion of the charged chelates is limited due to specific temporal arrangements of other ions in their vicinity. Any positional change thus requires either overcoming an activation barrier or rearranging the surrounding ions. While the axial rotation around bonds connecting the chelates to the dendrimer is likely to be unaffected, the rotational motion of the larger segments (beyond the next branching point) will be slowed by multiple Coulombic interactions. On the contrary, the neutral chelates are not restrained in their motion and undergo all movements allowed by the dendrimeric scaffold. This includes the rotation and translation of the terminal atomic chains bearing the chelates as well as motions of larger segments of the dendrimeric structure. We suggest that it is mainly the motions of the larger segments that affect the values of τ_g and the relaxivity.

This model can explain also the peculiar dependence of relaxivity on pH for the PAMAM-based conjugates. The relaxivity of the charged conjugates was reported to increase with the protonation of the inner tertiary amines of the dendrimer (*14*, *15*). For example, for G4 dendrimer, this occurs in the pH-range 4−7 (*60*). The higher relaxivities at lower pH correlate with the higher determined values of τ_g and were ascribed to expansion of the dendrimeric structure as a consequence of the repulsive interactions between the protonated amines and to enhanced rigidity of the scaffold (*14*, *15*). If true, this mechanism would have to be effective also for the conjugates with electroneutral chelates. However, the relaxivity of G4-[Gd(H_2O)(DO3A-py^{NO-C})]$_{57}$ gave no response to pH in the range 1−7 (Supporting Information Figure S12). The increase of relaxivity for the charged conjugates is thus probably given by electrostatic interactions between the negatively charged chelates inside the dendrimer and the protonated tertiary amines. Being fixed in the molecular scaffold, the positive charges in this case lead to a more efficient immobilization of the negatively charged chelates and, hence, to increased values of τ_g and relaxivity. Obviously, the electroneutral chelates cannot be affected by this interaction, and therefore, they do not respond to pH.

In addition to the small values of τ_g, the local rotational motion characterized by the values of τ_l in conjugates G1-[Gd(H_2O)(do3a-py^{NO-C})]$_{7.5}$ (τ_l = 124 ns) and G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$ (τ_l = 138 ns) is also relatively fast and, therefore, significantly contributes to the overall loss of relaxivity. These values are similar to those obtained for the other PAMAM-based conjugates (Table 2), despite the fact that the attachment through the amide group on the pyridine ring should be rigid. This can be attributed to the significant flexibility of the linking bonds following this amide in the dendrimer moiety. Figure 4 depicts simulated ^{1}H NMRD profiles based on relaxometric parameters obtained for the G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$ conjugate by varying parameters τ_l, τ_g, and S^2 to values obtained for other conjugates. The dashed line demonstrates the expected increase of relaxivity if the global rotational motion was the same as in the negatively charged conjugate G4-[Gd(H_2O)(do3a-p$^{BnN\{SC\}}$)]$_{59}^{x-}$. In the dotted line, the values of τ_l, τ_g, and S^2 were fixed to those of Gadomer-17, a conjugate with substantially enhanced rigidity. In this case, the relaxivity at around 30 MHz is increased 2.4-fold relative to G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$. These results suggest that, with an appropriate design of the scaffold, high-relaxivity conjugates may be obtained.

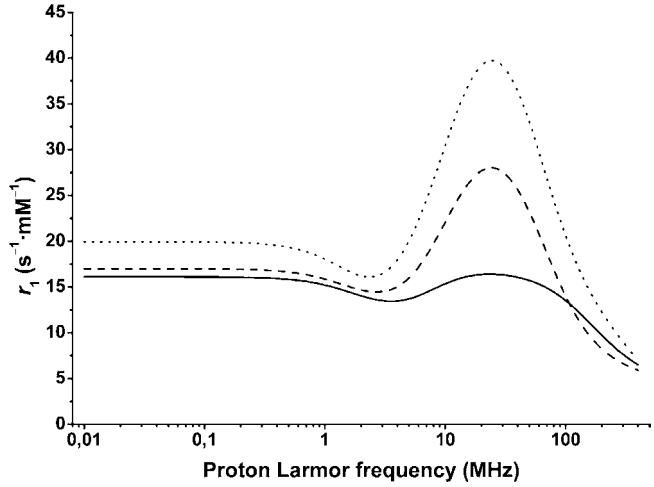

Figure 4. Simulation of ^{1}H NMRD profiles at 25 °C. Best fit of G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$ experimental data: τ_l = 138 ps, τ_g = 1040 ps, S^2 = 0.38 (solid line); τ_l = 138 ps, τ_g = 3050 ps, S^2 = 0.38 (dashed line); τ_l = 494 ps, τ_g = 3050 ps, S^2 = 0.50 (dotted line). The other parameters were the same as obtained for G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$.

The presented data show that the PAMAM dendrimers are not an appropriate scaffold for the binding of noncharged Gd(III) chelates if the main goal is to attain the maximal relaxivity. The flexibility of their structures leads to relatively fast global and local rotational motions of the conjugates that are detrimental to the efficiency. Therefore, other types of macromolecular scaffolds should be considered for this purpose. The macromolecular contrast agent Gadomer-17 is a nice example of such an uncharged system (*13*). A lysine-based dendrimer in this case provides a structure with sufficient rigidity, resulting in relatively high values of τ_l and τ_R (see Table 2). Consequently, the relaxivity of Gadomer-17 at 37 °C is considerably higher than the relaxivities of the G4-PAMAM-based uncharged conjugates, despite the lower molecular weight and the slower water exchange rate of the former. Another rigid system based on a polylysine dendrimer with an octasilsesquioxane core has been reported recently (*17*). Nonetheless, the commercial availability makes the PAMAM dendrimers still the first choice for the synthesis of new macromolecular contrast agents. The PAMAM conjugates with paramagnetic complexes are suitable for applications where a high number of gadolinium(III) ions per conjugate molecule and/or a well-defined molecular size is desired.

In Vivo Experiments. The electroneutral nature of the conjugates of DO3A-py^{NO-C} gives rise to concerns regarding whether the conjugates would be efficiently removed from the body through the renal system. We chose the conjugate G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$ for in vivo testing to determine the preferred route of excretion. Hyperintensity in rat kidney and urinary bladder was observed in all time points (10−90 min) with the maximum intensity of the signal at 60 min after contrast agent application (Supporting Information Figure S13); the signal difference at this time point was 63%. Surprisingly, no signal difference was noticed in the liver. Our results suggest that the modification of PAMAM dendrimers with Gd(III) chelates of DO3A-py^{NO-C} is compatible with the renal way of excretion.

CONCLUSIONS

We showed that the recently reported bifunctional ligand DO3A-py^{NO-C} can be efficiently coupled to other molecules through the carboxylic group at the pyridine ring through formation of an amide bond. The synthetic route for this

coupling was established. An improved design of the ligand ensures that the preferable fast water exchange observed for its Gd(III) complex is retained after the coupling. The combination of a noncharged chelate and a fast water exchange with a highly rigid spacer is unique. However, if flexible structures such as PAMAM dendrimers are used as the carrier molecules, the absence of electrostatic interactions between the attached chelates and surrounding ions endows the chelates with the motional freedom that is detrimental to the relaxivity of the conjugates. From a direct comparison of G4-PAMAM conjugates bearing uncharged and (1−)-charged Gd(III) chelates using several independent techniques, it can be concluded that it is the rotational motion of the large segments (dendrons) within the dendrimer that is responsible for the observed lower relaxivity of the electroneutral conjugates. Moreover, and contrary to the previous reports, the data suggest that the values of global rotational correlation times obtained from the fits of relaxometric data reflect mainly the motion of these large segments and not the motion of the whole conjugates. Such information may be useful in future developments of efficient electroneutral contrast agents.

ACKNOWLEDGMENT

Support from the Grant Agency of the Academy of Science of the Czech Republic (No. KAN201110651) and the Long-Term Research Plan of the Ministry of Education of the Czech Republic (No. MSM0021620857) are acknowledged. The work was carried out in the frame of COST D38 (MSMT OC 179) and the EU-supported NoE projects (6th FP) DiMI (No. LSHB-2005-512146) and EMIL (LSCH-2004-503569) and grant ENCITE, Seventh Framework Programme of EC, No. 201842. We thank Prof. Luce Vander Elst for the measurements of ^{1}H NMRD profiles, Prof. Jean-Marie Lehn for a support of and Dr. Lionel Allouche for the measurement of DOSY spectra, as well as Dr. Petr Jedelský for the MALDI-MS measurements. We also thank Dr. Daniel Jirák, Dr. Vít Herynek, and Dr. Milan Hájek for performing the MRI experiment. We acknowledge a help of Dr. Josef Pleštil in measurements and evaluation of SAXS data. M.P. is grateful for financial support through an early stage Marie Curie fellowship (MEST-CT-2004-7442). CFGCG acknowledges financial support from the Foundation of Science and Technology (FCT), Portugal (PTDC/QUI/70063/2006), and FEDER.

Synthesis and characterization of the conjugates

Coupling of *t*-Bu_3**L** to the PAMAM dendrimers was achieved by formation of an amide bond between the deprotected carboxylic group and the primary amines in PAMAM. In this way the local motion of DO3A moiety is minimized. The pyridine-*N*-oxide pendant arm is connected through two points to the Gd(III) chelates, which contributes to the rigidity of the system. Furthermore, the partial double-bond character of the amide bond provides additional rigidity. Altogether, it may be expected that this mode of attachment is considerably more rigid than attachments accomplished through benzyl-thiourea bridges (*1,2,3,4,5,6,7,8,9,10,11,12,13*) or through alkyl-chains.(*14,15,16*) Methods of peptide-coupling chemistry have been employed for the attachment of polydentate ligands to dendrimers and other similar substrates only marginally. Most of them rely on preactivation of the carboxylic acids to first afford an active ester, such as HOSu (*6,14,17,18*) or *p*-nitrophenol (*19*) ester, that is subsequently converted to the amide. Only a few examples have been described of couplings directly using EDC,(*20*) Py-BOP (*21*) or HBTU (*22*) as the coupling agents.

We have performed a fast HPLC-monitored screening of several coupling agents and methods using G0-dendrimer as the substrate (combinations: DCC + HOBt, EDC + HOBt, EDC + HOAt, TSTU and TBTU). TBTU gave the most satisfactory results regarding the yield and rate of the reaction. Due to the insolubility of *t*-Bu_3**L** in water and to avoid possible hydrolysis of the active ester intermediate, the coupling had to be performed in an organic solvent. The low solubility of the PAMAM dendrimers in most organic solvents limited the choice to DMSO. However, only a small amount of DMSO was necessary at the beginning of the reaction to ensure homogeneity of the solution, as the solubility of the dendrimer-conjugates in organic solvents increased with the progress of the reaction. Thus, the activation of the ligand was carried out in acetonitrile. The acetonitrile could easily be evaporated off, whereas the DMSO was conveniently removed by ultrafiltration. RP-HPLC chromatograms showed that the reaction was complete after 5 min. Maximum loading of the dendrimer with *t*-Bu_3**L** was achieved using 1.5 equiv. of *t*-Bu_3**L** and TBTU (per dendrimer primary amino group).

Guanidine side-products (*23*) were suppressed by addition of HOBt (see Figure S1). Some other impurities remained even after purification by ultrafiltration, showing that their molecular sizes are not significantly lower than that of the main product. Therefore, we assume that the minor peaks belong to the coupling products of defective dendrimer molecules. Various defects of PAMAM dendrimers, including missing branches and intramolecular loops, were reported in the literature for PAMAMs (*24,25*) or for the dendrimer core in Gadomer 17.(*26*) To test this hypothesis, we measured MALDI-TOF spectra of the product and of the main impurity found in G0-conjugate after their separation by RP-HPLC (Figure S7). The molecular peak of the main product matched the predicted mass of a perfect G0-dendrimer with four attached molecules of *t*-Bu_3**L** (calculated for $M+H^+$: 3108.0, found: 3109.4), whereas that of the side-product corresponded to a G0 dendrimer with one missing branch and three attached molecules of *t*-Bu_3**L** (calculated for $M+H^+$: 2346.5, found: 2346.1). Clearly, these impurities originate from defects present in the starting dendrimers. PAMAM dendrimers are mostly prepared by a divergent synthesis, which is prone to formation of various defects.(*24,25,27*) It is noteworthy that we could detect the impurities on reversed-phase HPLC thanks to the hydrophobic character of the conjugates in the *t*-butyl-ester form. Most of the previously reported conjugates were synthesized using the thiourea coupling without protection of the carboxylic groups and, thus, leading to highly polar species that were inseparable on RP-HPLC.

The impurities could be distinguished from the main product only for the smallest (i.e. G0 and G1) dendrimers. With higher generations, the differences between the retention times become smaller and only one broad peak is observed on HPLC (Figure S2). Unfortunately, attempts to characterize the conjugates of larger dendrimers (generation 1 and higher) by MALDI-TOF were unsuccessful. All low-molecular-weight compounds (including DMSO) were removed from the reaction mixtures by ultrafiltration in methanol.

The degree of substitution (loading) of the dendrimer surface with *t*-Bu$_3$**L** was determined from ^{1}H NMR spectra in CD_3OD at 45 °C. All exchangeable protons were assumed to be replaced with deuterium under these conditions (Figures S3–S4). The dendrimer loading *N* was calculated with

$$N = \frac{4 + 32 * \left(2^{G+1} - 1\right)}{H * R - 24},$$

where *G* is the generation of the dendrimer, *H* is the number of hydrogen atoms in one molecule of the ligand (i.e. 3 aromatic and 27 *t*-butyl protons) and *R* is the ratio of the integrals (aliphatic/aromatic or aliphatic/*t*-butyl). The loadings determined from aliphatic/aromatic and aliphatic/*t*-butyl signal ratios were generally in a good agreement with each other and the final loadings were calculated as averages of the two values (see Table 1). Therefore, the compositions of the conjugates could be determined with a higher accuracy before removal of *t*-butyl groups with TFA, assuming that the number of attached ligand molecules does not change during this deprotection. In all cases, the loadings were 80 – 100 %, showing that the coupling method is very efficient. One has to take into account that the numbers of the attached ligands were calculated for ideal dendrimers without any defects. This is the probable reason why, for the G0-conjugate, the loading exceeded 100 %. It can be deduced from the HPLC chromatograms that full loading was reached in G0-conjugate. In the other conjugates, full loadings were not reached probably due to bulkiness of the *t*-Bu$_3$**L** moieties.

The protective *t*-butyl groups were cleaved off quantitatively in neat TFA. The Gd(III) complexes were prepared with 50 % excess of gadolinium. The conditions for complexation were the same as for the DO3A-py$^{NO\text{-}C}$ monomer (24 h, RT, pH = 7).(*28*) The excess of gadolinium(III) was removed by chelation with EDTA followed by ultrafiltration. The complete removal of EDTA and of its Gd(III) complex was confirmed by SEC.

Size-exclusion chromatography was used to check the purity of the conjugates with respect to the molecular size. All low-molecular-weight compounds were efficiently removed by ultrafiltration. However, a small portion of conjugate with a higher molecular weight was observed in all cases except for the G0-conjugate, forming a “shoulder” with shorter retention time (Figure S5). This “shoulder” was found also in the PAMAM dendrimers used for the synthesis (Figure S6) and is likely due to a presence of “dimm

ers” (two dendrimer molecules fused together), which represent one type of structural deviations found in PAMAM dendrimers.(*24,25*) These impurities in the conjugates have not been mentioned previously by other authors, despite they were using the same commercial dendrimers for their syntheses.

Figure S1. RP-HPLC chromatograms of reaction mixtures of the preparation of the G0-conjugate with (bottom) and without (top) the use of excessive HOBt. Asterisks mark the peaks that were completely or partially suppressed by use of HOBt. G0-(*t*-Bu$_3$**L**)$_4$ is the main product; G0$_{3/4}$-(*t*-Bu$_3$**L**)$_3$ stands for the major impurity (identified by MALDI-TOF, see text). Gradient (A/B/C): from 20/40/40 to 50/40/10 in 15 min., 50/40/10 held for 5 min. Detection at 289 nm.

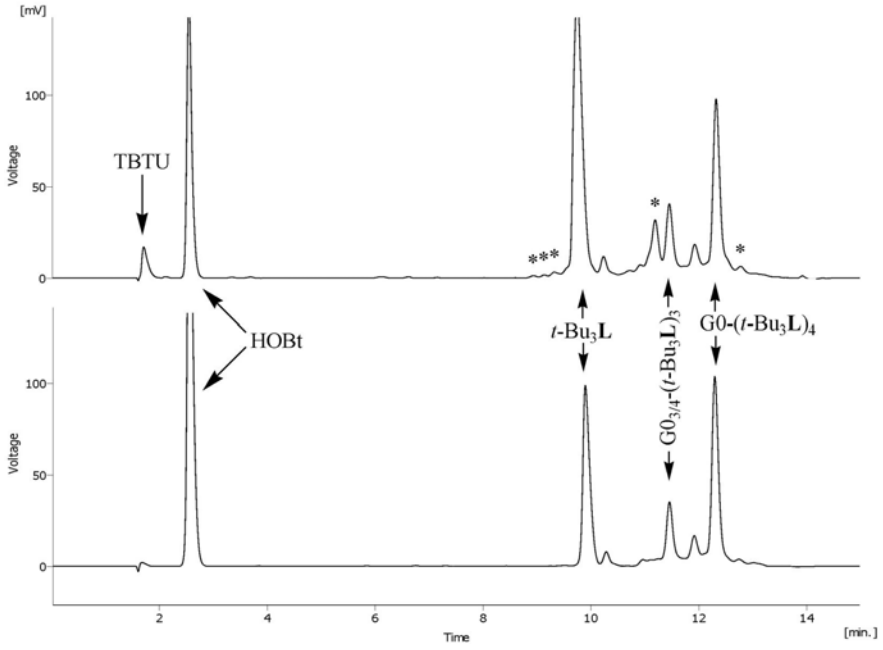

Figure S2. The RP-HPLC chromatograms of the prepared PAMAM dendrimer conjugates of various generations (G0, G1, G2, G4) after purification by ultrafiltration. Gradient (A/B/C): 20/40/40 to 50/40/10 in 15 min., 50/40/10 held for 5 min. Detection at 289 nm.

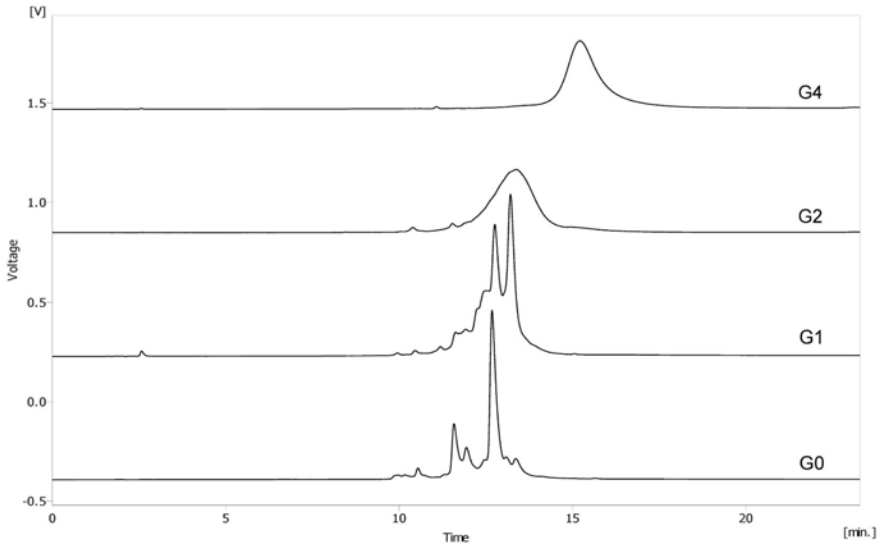

Figure S3. ^{1}H NMR spectra of conjugates G4-(*t*-Bu$_3$**L**)$_{57}$ and G2-(*t*-Bu$_3$**L**)$_{13}$ at 45 °C in CD_3OD. The asterisks denote (from left to right): residual O**H** and C**H**D$_2$ signals of the solvent and residual acetate C**H**$_3$.

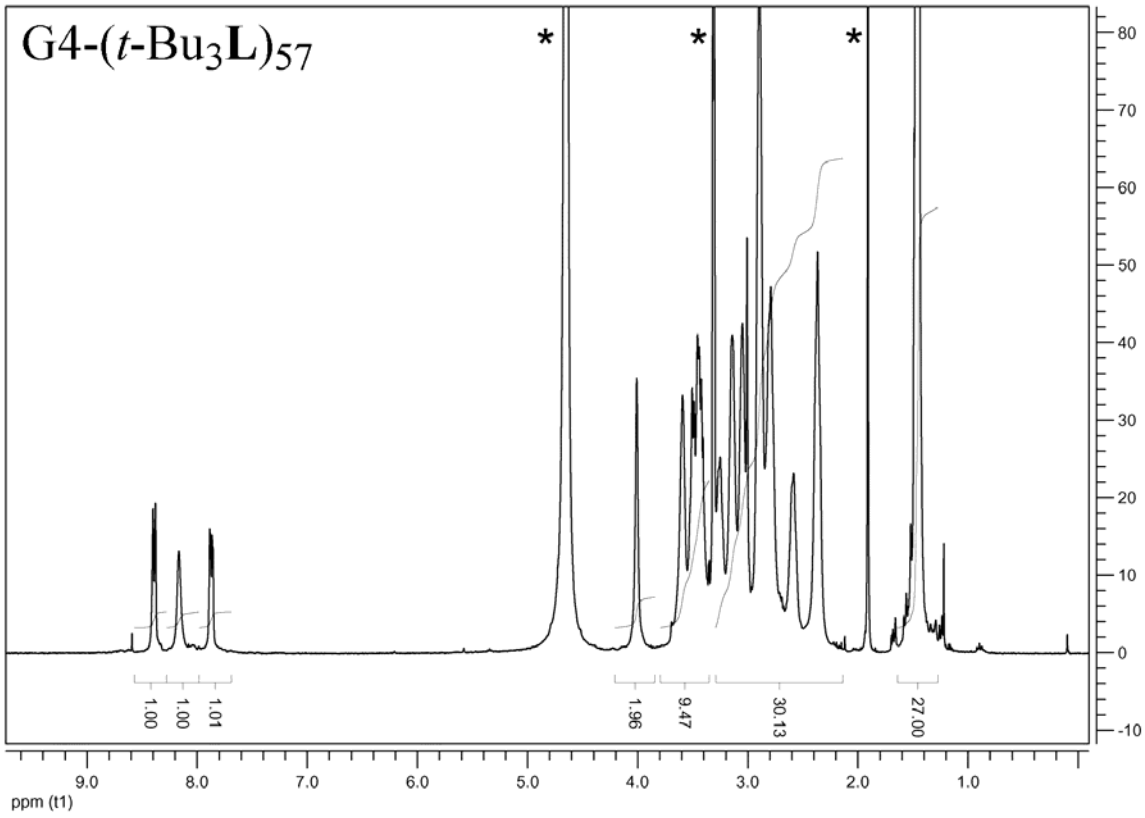

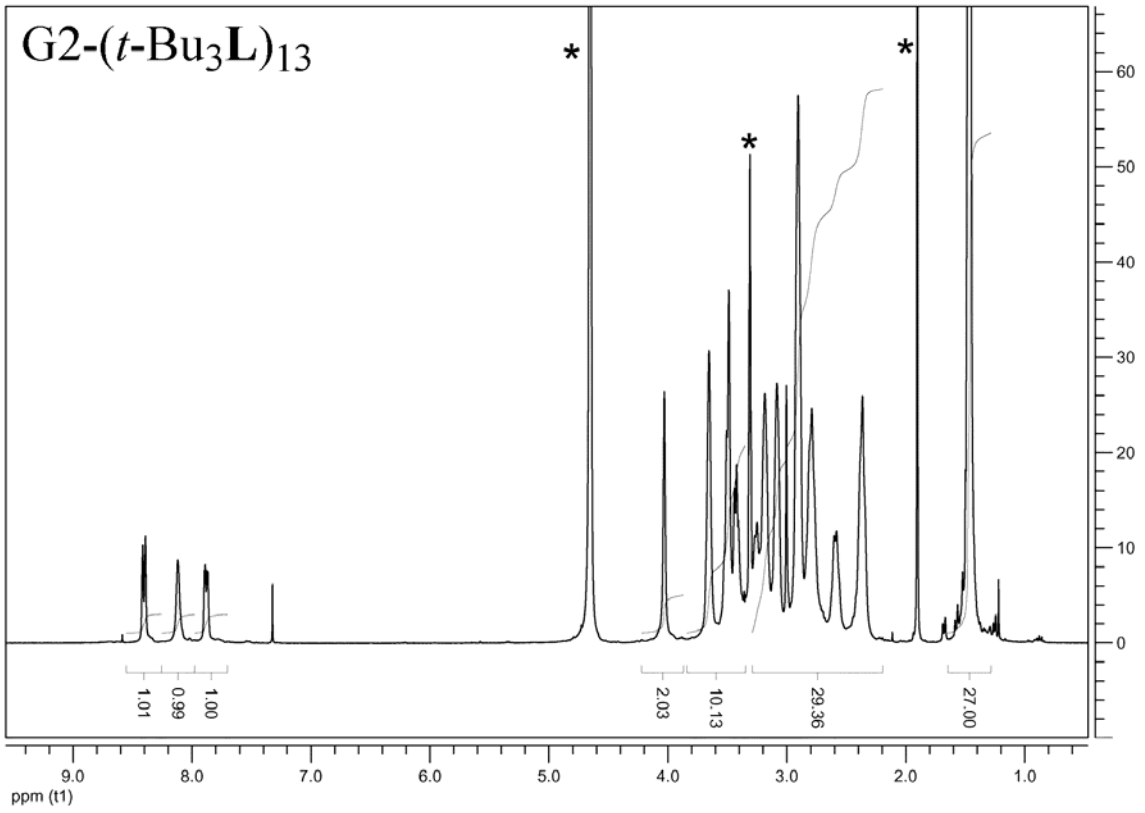

Figure S4. ^{1}H NMR spectra of conjugates G1-(*t*-Bu$_3$**L**)$_{7.5}$ and G0-(*t*-Bu$_3$**L**)$_4$ at 45 °C in CD_3OD. The asterisks denote (from left to right): residual O**H** and C**H**D$_2$ signals of the solvent and residual acetate C**H**$_3$.

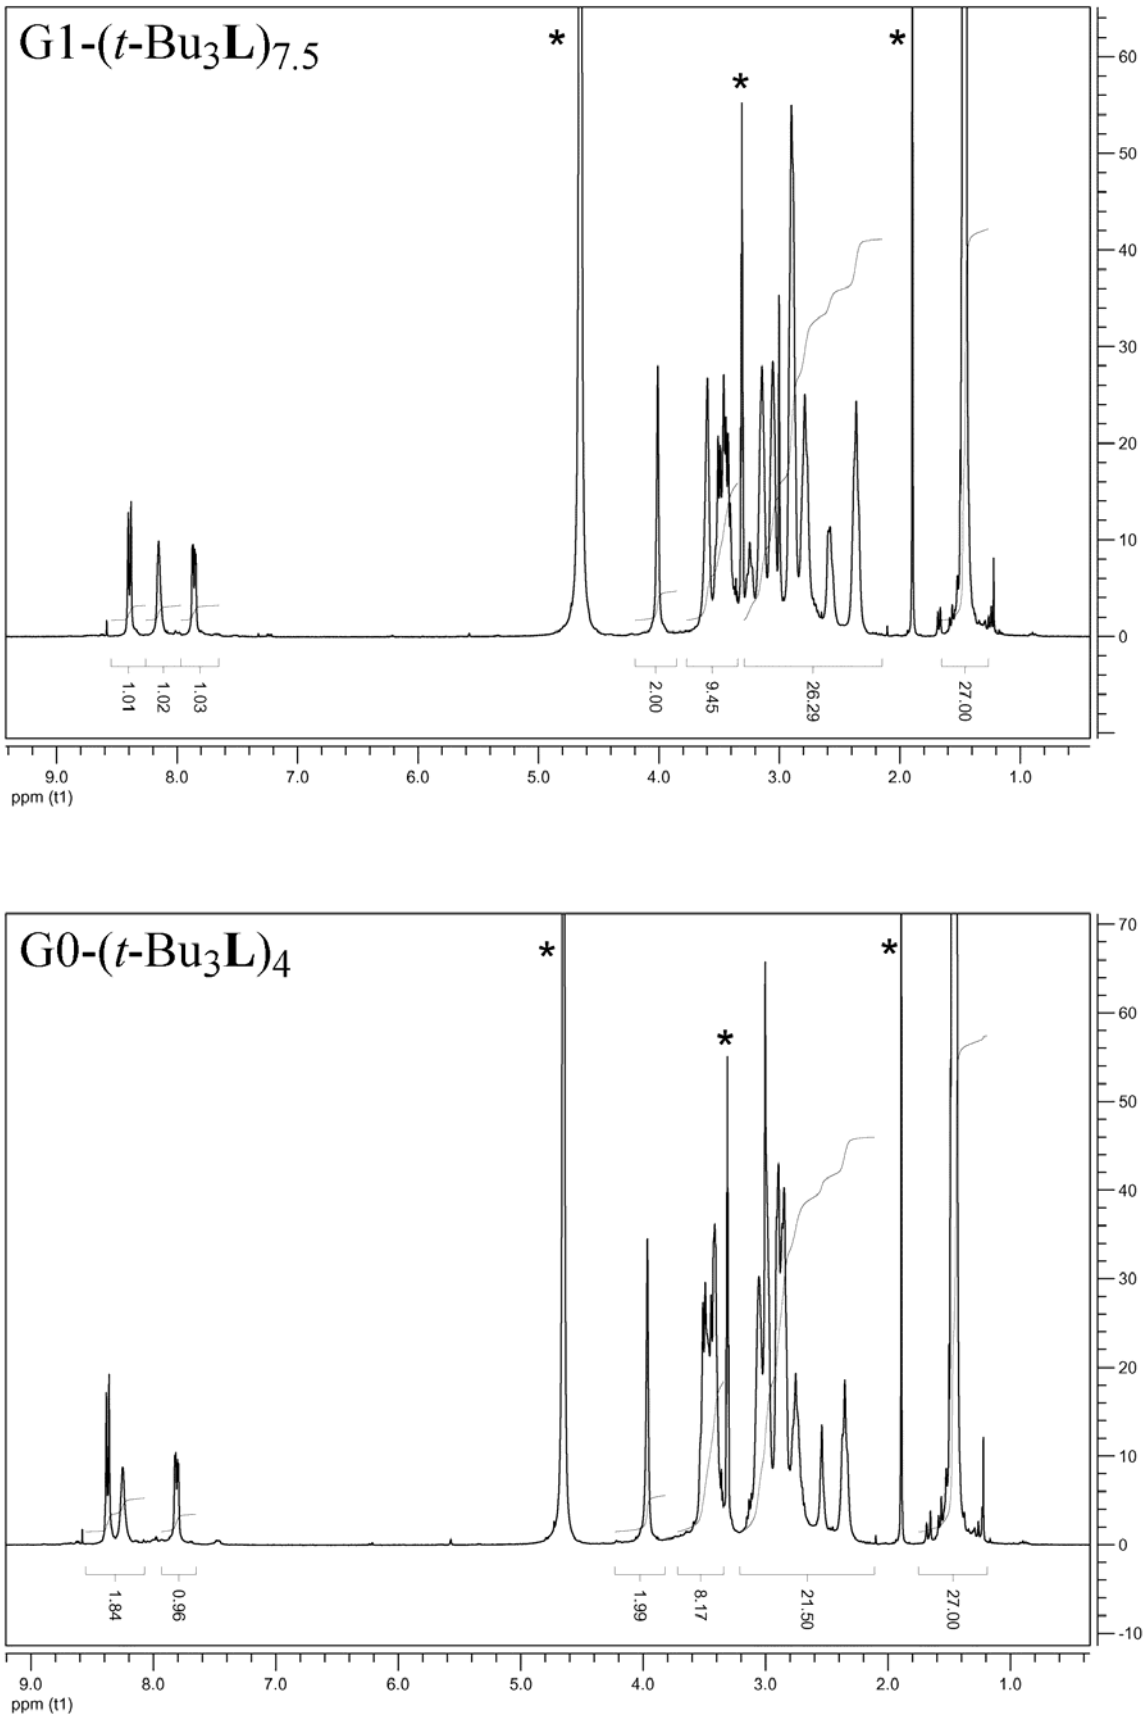

Figure S5. SEC chromatograms of the Gd(III) complexes of PAMAM-DO3A-py^{NO-C} conjugates in 0.1 M sodium citrate buffer (pH = 2.77, at 289 nm). The labels of the peaks indicate the generation of the PAMAM dendrimer (G0 – G4) and the average number of attached chelates. L-Gd stands for the "monomeric" $[Gd(H_2O)(do3a\text{-}py^{NO-C})]^-$ complex.

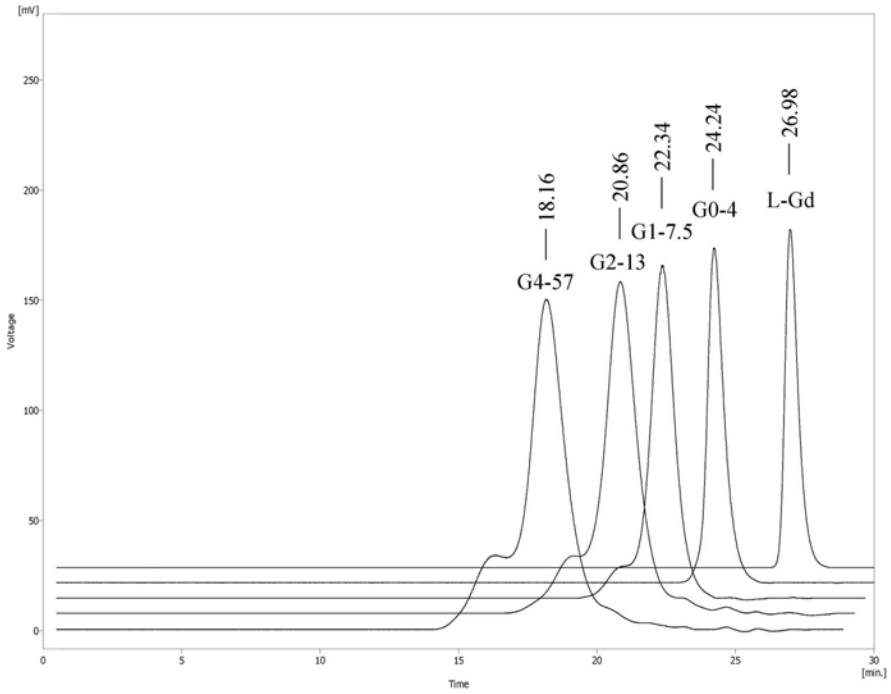

Figure S6. SEC chromatograms of the commercial PAMAM dendrimers (G0, G1, G2 and G4) used in the conjugation reactions (0.1 M sodium citrate buffer, pH = 2.77, refractive-index detection).

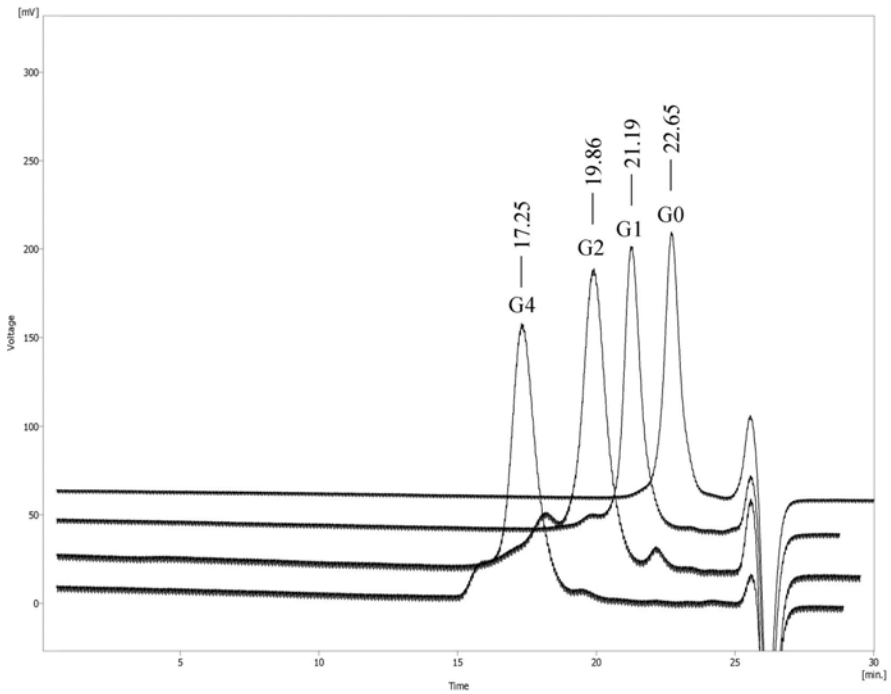

Figure S7. MALDI-TOF MS spectra of HPLC-separated main product (top) and main impurity (bottom) in the conjugate G0-(*t*-Bu$_3$**L**)$_4$. The patterns are due to loss of O-atoms from the *N*-oxides caused by ionization.

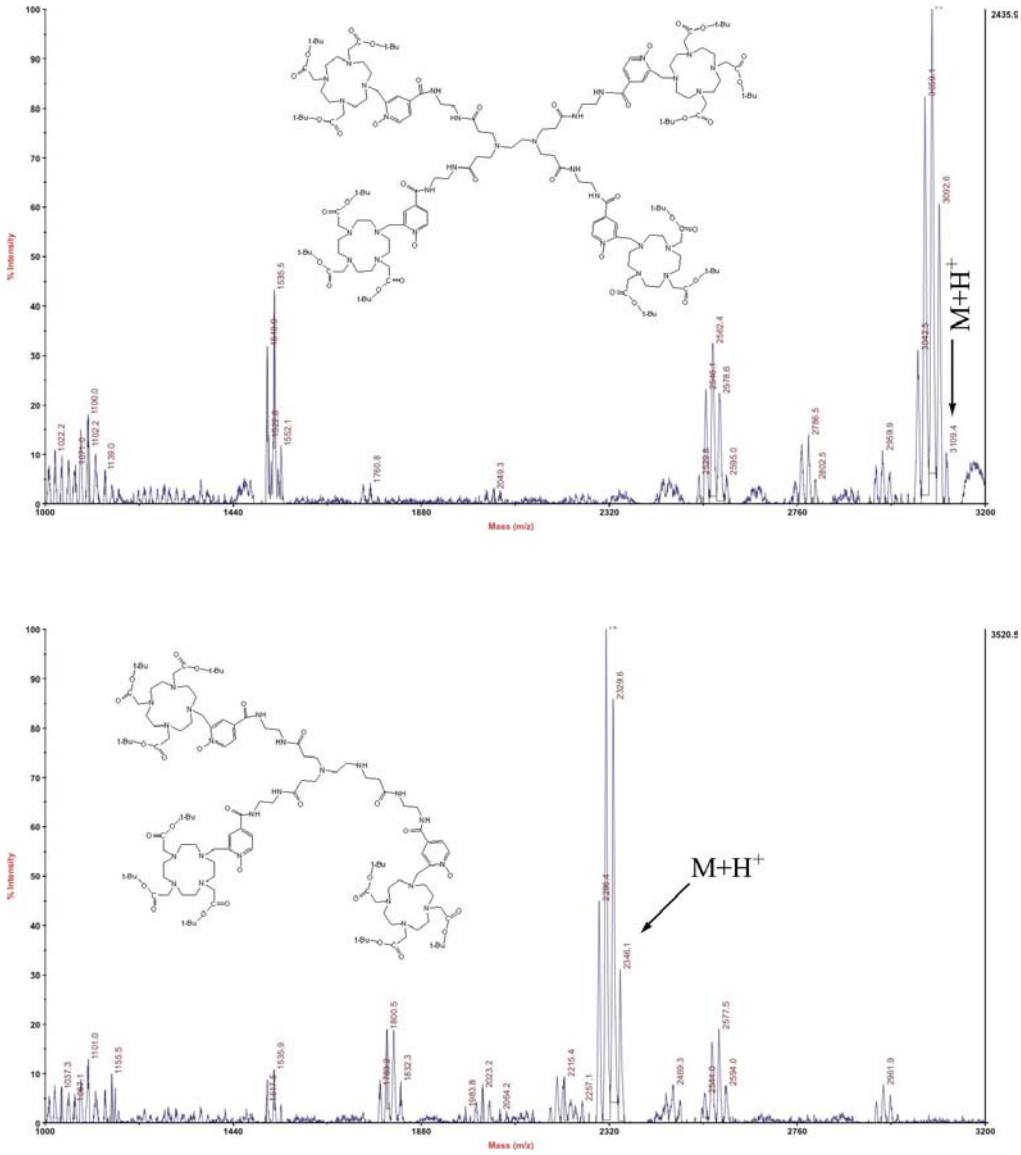

Figure S8. Variable-temperature ^{17}O longitudinal relaxation rates (left) and chemical shifts (right) of H_2O in solution of conjugate G4-[Gd(do3a-py$^{NO\text{-}C}$)]$_{57}$. The solid lines represent the results of a simultaneous least-square fit.

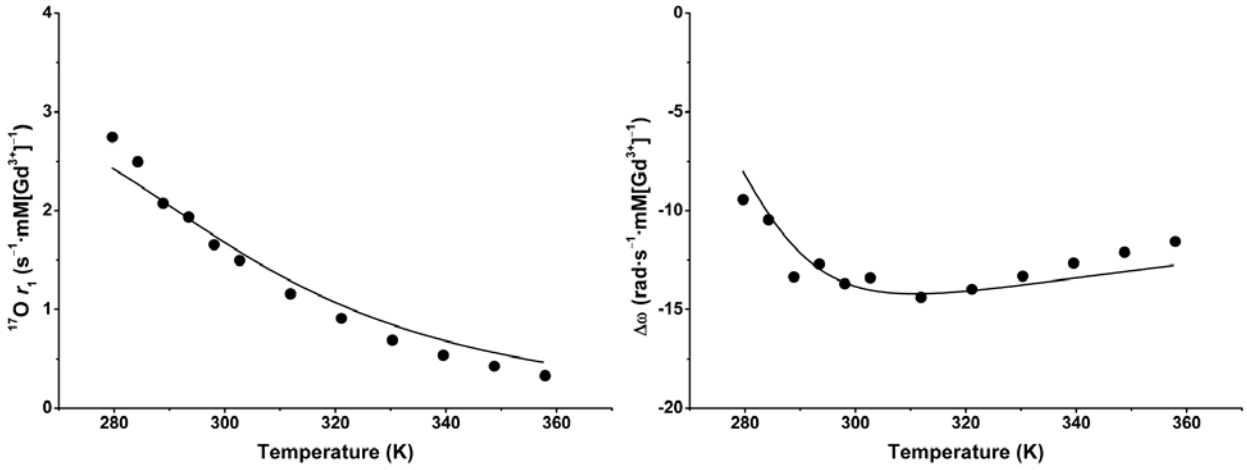

Table S1. Set of parameters obtained in a multiparameter least square fit of ^{17}O NMR variable-temperature data and ^{1}H NMRD profiles for G1- and G4-conjugates.

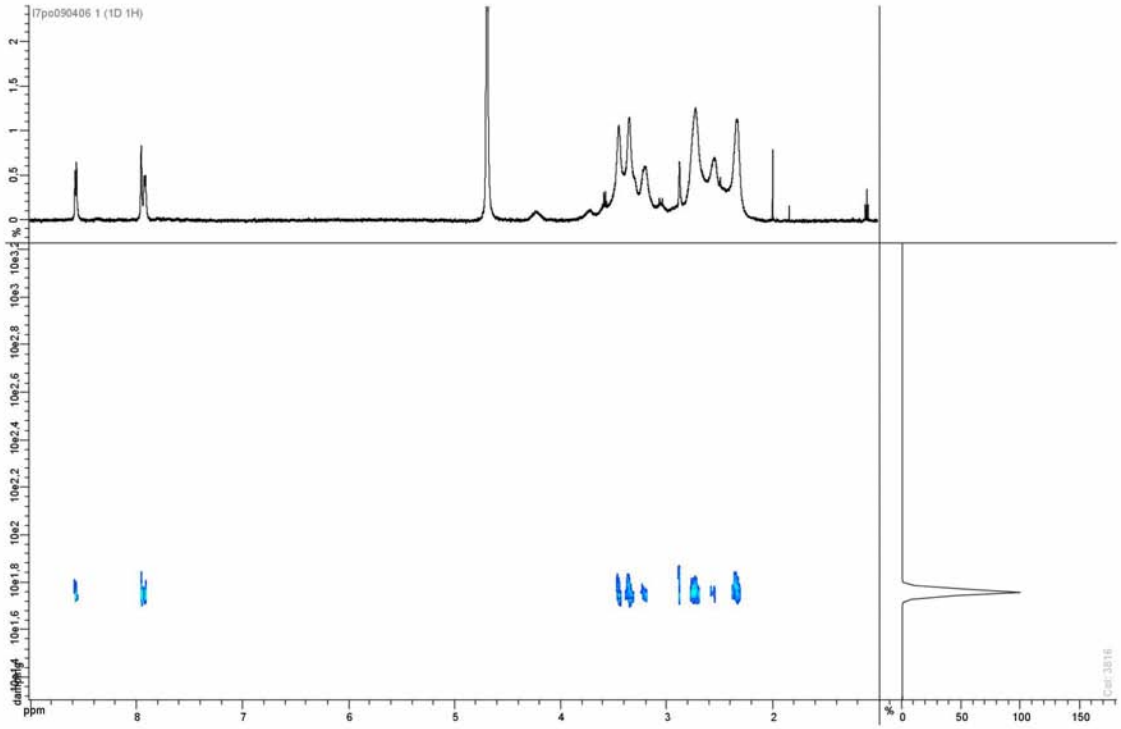
Parameter	G4-[Gd(do3a-py$^{NO\text{-}C}$)]$_{57}$	G1-[Gd(do3a-py$^{NO\text{-}C}$)]$_{7.5}$ [a]
$^{298}\tau_M$ / ns	55 ± 2	55 [b]
ΔH_M / kJ mol^{-1}	45.5	45.5
$^{298}\tau_v$ / ps	56 ± 1	49 ± 2
Δ^2 / 10^{19} s^{-2}	0.83 ± 0.02	1.05 ± 0.06
$^{298}\tau_g$ / ps	1040 ± 100	570 ± 30
$^{298}\tau_1$ / ps	138 ± 4[c]	124 ± 8[c]
E_{Rg} / kJ mol^{-1}	21.9 ± 2.7	21.9 [b]
E_{Rl} / kJ mol^{-1}	20.8 ± 1.1	20.8 [b]
S^2	0.38 ± 0.03	0.35 ± 0.03
$(A/\hbar)$ / 10^6 rad s^{-1}	–3.75	–3.75
r_{GdO} / Å	2.5	2.5
r_{GdH} / Å	3.1	3.1
A / Å	3.5	3.5
q	1	1
$\nu(1 + \eta^{2/3})^{1/2}$ / MHz	11.1 ± 1.4	11.1 [b]
C_{out}	0.02	0.02

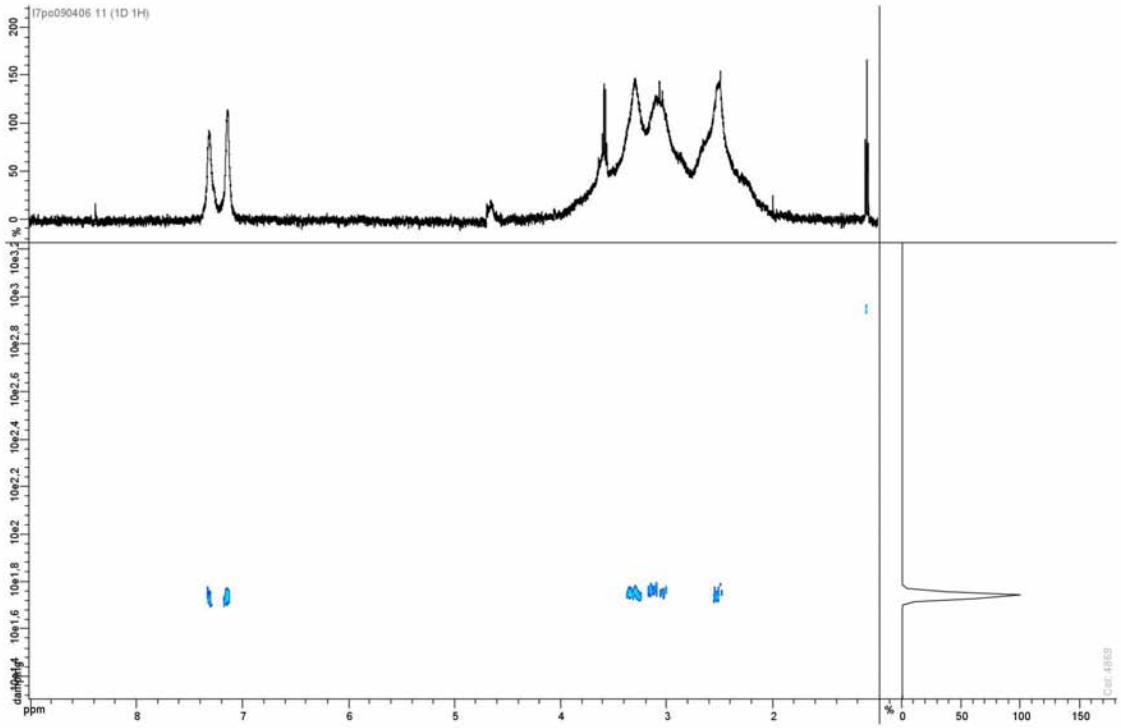
The underlined values were fixed during the fit. [a]The fit was based only on ^{1}H NMRD profiles. [b]Values were fixed to those obtained for G4-[Gd(do3a-py$^{NO\text{-}C}$)]$_{57}$. [c]The values of τ_1 refer to the reorientation of Gd–H_{water} vector.

Figure S9. ^{1}H DOSY spectra of the conjugates G4-[Y(H_2O)(do3a-py$^{NO\text{-}C}$)]$_{57}$ and G4-[Y(H_2O)(do3a-P$^{BnN\{SC\}}$)]$_{59}^{x-}$ (sodium salt) at 25 °C and pH = 7.

G4-[Y(H_2O)(do3a-py$^{NO\text{-}C}$)]$_{57}$



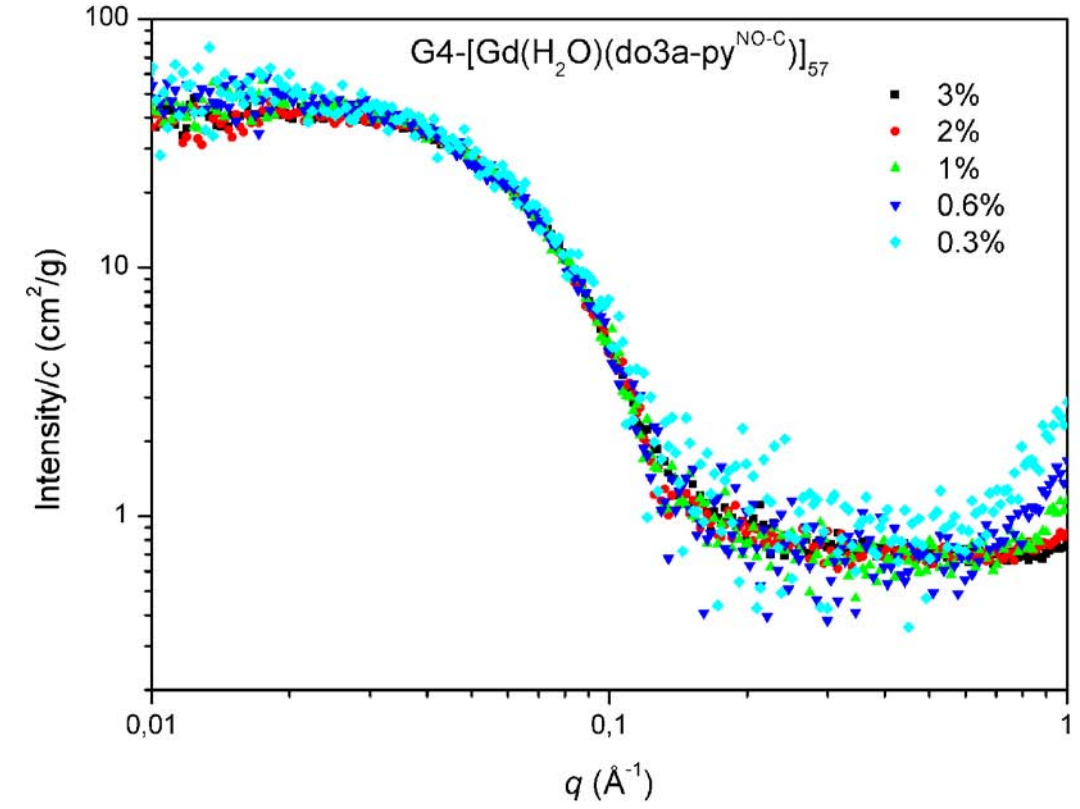
G4-[Y(H_2O)(DO3A-P$^{BnN\{SC\}}$)]$_{59}^{59-}$



SAXS data analysis

Each compound was dissolved in distilled water and diluted to five different concentrations from 0.3 to 3 %. The SAXS data were measured for each solution and the scattering intensities normalized to the concentration (Figure S10). The scattering curves displayed the same shape for both compounds for the values of the scattering vector $q >$ 0.05 Å^{-1}. However, for $q < 0.05$ Å^{-1} the curves were concentration-dependent and the dependence was significantly larger for the charged compound G4-[Gd(H_2O)(do3a-$P^{BnN\{SC\}}$)]$_{59}^{x-}$ (sodium salt). This phenomenon is typical for strong repulsive inter-particle interaction; however, it does not imply an existence of any particular distance within the system. The size of the conjugates was determined from the scattering curves using Guinier's approximation, which led to the values of radii of gyration $R_g = 27.6 \pm 0.3$ Å for G4-[Gd(H_2O)(do3a-$py^{NO\text{-}C}$)]$_{57}$ and 29.4 ± 0.2 Å for G4-[Gd(H_2O)(do3a-$P^{BnN\{SC\}}$)]$_{59}^{x-}$ (sodium salt). The data affected by the inter-particle interference ($q \leq q_{max}$) were not included in the analysis. The Figure S11 shows the comparison of the radii of gyration determined by us with the data obtained from SANS measurements on NH_2-terminated PAMAM dendrimers at high pH.(*29*) The values of R_g were plotted against the number of bonds involved in the chains going from the centre to the rim of the macromolecule, so that the size of the chelates is taken into account. It is clear from the plot that both conjugates studied by us fit very well to the dependence. Therefore, it can be concluded that the size of the conjugates is not significantly altered by the charge of the attached metal chelates.

Figure S10. SAXS scattering data at variable concentrations of the conjugates G4-[Gd(H_2O)(do3a-$py^{NO\text{-}C}$)]$_{57}$ and G4-[Gd(H_2O)(do3a-$P^{BnN\{SC\}}$)]$_{59}^{x-}$ (sodium salt) at 25 °C and pH = 7.



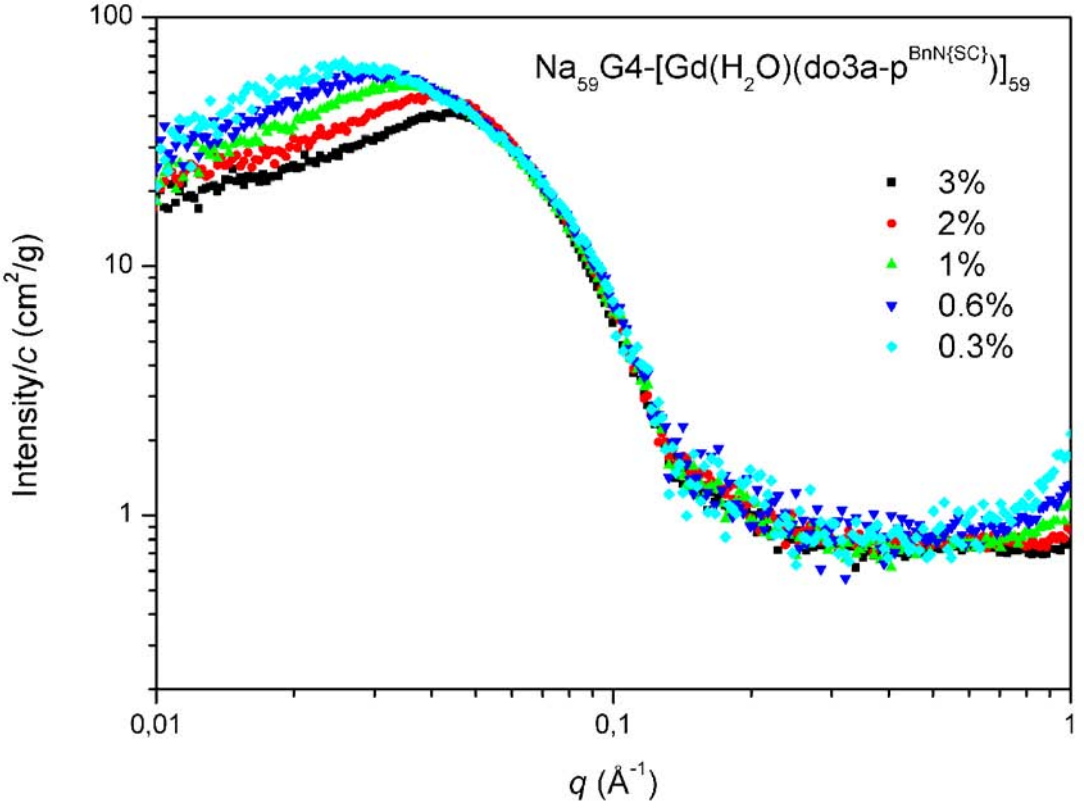


Figure S11. Radius of gyration vs. the number of bonds contributing to the total chain length from the centre to the rim of the macromolecule. Black squares: data for NH_2-terminated PAMAM dendrimers at high pH (no protonation) obtained from SANS (data taken from literature(*29*)).

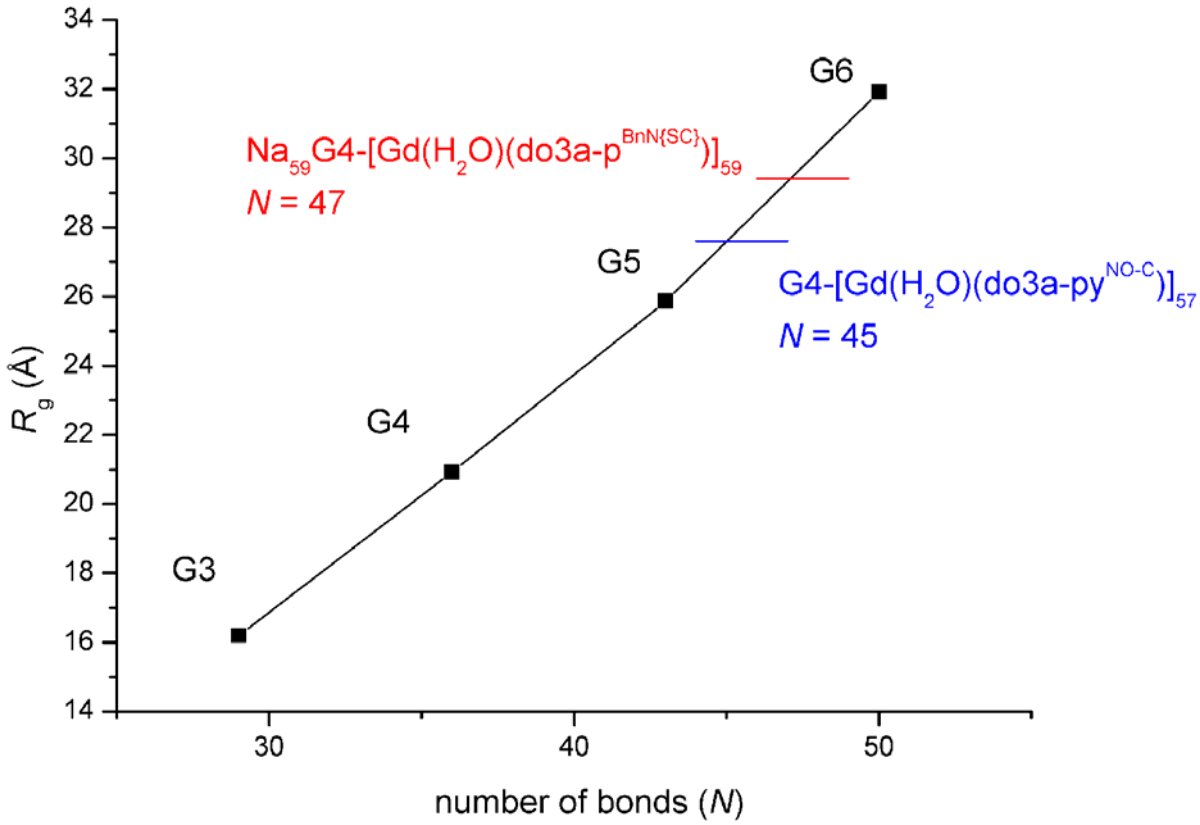

Figure S12. ^1H relaxivity of conjugate $G4\text{-}[Gd(H_2O)(do3a\text{-}py^{NO\text{-}C})]_{57}$ as a function of pH.

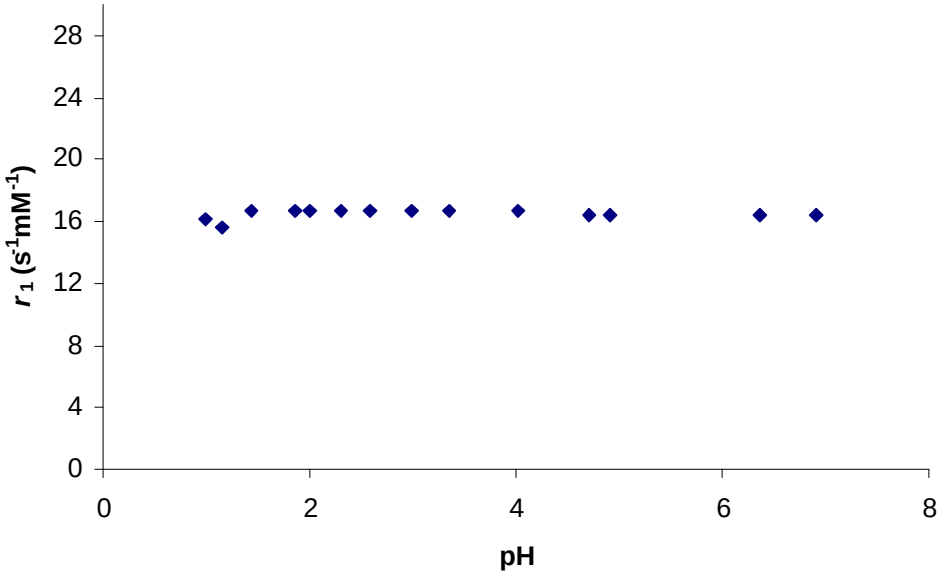

Figure S13. MRI scans of rat kidneys before (upper row) and 60 min after (lower row) intravenous administration of G4-[Gd(H_2O)(do3a-py^{NO-C})]$_{57}$ conjugate. From left to right: individual 2 mm thick slices. The arrow marks the highest image intensity enhancement in kidney.

Design, Synthesis, Characterization, and Biological Evaluation of Triazine Dendrimers Bearing Paclitaxel Using Ester and Ester/Disulfide Linkages

Jongdoo Lim,[†] Abdellatif Chouai,[†] Su-Tang Lo,[‡] Wei Liu,[‡] Xiankai Sun,[‡] and Eric E. Simanek*,[†]

Department of Chemistry, Texas A&M University, College Station, Texas 77843-3255, and Department of Radiology, University of Texas Southwestern Medical Center, Dallas, Texas 75390. Received July 22, 2009; Revised Manuscript Received September 14, 2009

The design, synthesis, characterization, and preliminary biological assessment of three dendrimers are reported. All three dendrimers, **1**−**3**, present twelve paclitaxel groups linked by acylation of the 2′-hydroxyl group. The linker for dendrimers **2** and **3** also includes a disulfide. Installation of the paclitaxel group relies on reacting twelve primary amines of a second generation triazine dendrimer, a scaffold available on kilogram scale, with a dichlorotriazine bearing the drug. This dichlorotriazine is available in four steps by (i) reacting paclitaxel with glutaric anhydride, (ii) activating with *N*-hydroxysuccinimide (NHS), (iii) treating the resulting ester with either 1,3-diaminopropane (for **1**) or cystamine (for **2** and **3**), and (iv), finally, reacting with cyanuric chloride. After reaction with the dendrimer, the resulting monochlorotriazine groups are reacted with 4-aminomethylpiperidine (AMP) and then a poly(ethylene glycol) (PEG) group of molecular weight 2 kDa. Two different PEG-NHS esters are employed that differ in lability. For **1** and **2**, the PEG incorporates an ester-linked succinic acid group. For **3**, the PEG incorporates an ether-linked acetic acid group. Both mass spectrometry and ^{1}H NMR spectroscopy prove valuable for determining the final ratios of dendrimer:paclitaxel:AMP:PEG. These values are typically 1:12:12:9. Cytotoxicity of these constructs using an MTT-based assay and PC-3 cells reveals IC_{50} values in the low nanomolar range with dithiothreitol and glutathione enhancing the toxicity of the disulfide-containing constructs **2** and **3**. Preliminary toxicology assessment of **1** suggests that it is well tolerated in vivo with preferential renal clearance. The elimination half-lives of all of the dendrimers appear shorter than predicted from the previous results. Tumor localization is observed for all the three dendrimers.

INTRODUCTION

The emerging field of polymeric therapeutics (*1*−*6*) captures attention with the prospect of improving the efficacy of conventional drugs by overcoming obstacles in their clinical use that might arise due to the drug's low solubility, high systemic toxicity, instability, low bioavailability, or rapid excretion. The architectures currently being explored represent an eclectic collection of linear polymers (*7, 8*), grafts (*9, 10*), stars (*11,12*), and other constructs (*13*) including dendrimers (*14*−*18*). Our interest in dendrimers stems from their globular shape and the opportunity to exploit multivalency. As monodisperse entities (or low dispersity mixtures), we hypothesize that the batch-to-batch behavior of these materials will be consistent; namely, reproducible pharmacodynamics and pharmacokinetics will be observed. Another inherent advantage of macromolecules is derived from their passive accumulation in solid tumors through the enhanced permeability and retention (EPR) effect (*19, 20*). In addition, some dendrimers display targeting ligands, biocompatible polymers, and reporting groups (*21*−*24*).

Triazine dendrimers have been our choice of scaffold due to their ease of synthesis. The differential reactivity of various amine nucleophiles with chlorotriazine derivatives allows us to prepare chemically diverse dendrimers at moderate to large scale (20 to 1000 g) with high purities (*23*−*30*). Here, the product of the kilogram-scale synthesis is intercepted with a drug-bearing dichlorotriazine (Scheme 1). This strategy—interception with a functional monomer—is of significance to us because the scope and limitations of this strategy have not been probed. The efforts reported serve as proof-of-concept for this potential: paclitaxel is elaborated successfully to a reactive dichlorotriazine and provides, on interception, a poly(monochlorotriazine) that is manipulated in two steps to yield the final pegylated target. We believe that this strategy will prove to be quite general.

We favor covalent attachment over noncovalent association of drugs. While the noncovalent encapsulation of hydrophobic drugs is straightforward, it is limited by drug loading and provides less control over release rates. As an alternative, covalent drug loading offers higher drug loading and a wealth of literature on biodegradable linkages including (i) acid-labile linkers for endosomal/lysosomal release including esters (*31, 32*), acetals (*33, 34*), and hydrazones (*35, 36*), (ii) reductively labile disulfide bonds (*37*) that can be cleaved by glutathione or other intracellular thiols, and (iii) enzymatically labile peptide linkers (*38*). Here, we attach paclitaxel with linkers that contain either an ester or an ester/disulfide pair.

Paclitaxel is a mitosis-inhibiting antitumor agent to treat patients with breast, ovarian, lung, head and neck cancers, and Kaposi's sarcoma (*39, 40*). The hydrophobic drug is, however, poorly water soluble (<0.1 μg/mL) and usually administered as Taxol with Cremophor EL or other cosolvent formulations that may cause severe allergic reactions in some patients (*41*). Solvent-free polymer-bound prodrugs have been pursued to improve the in vivo solubility, safety, and efficacy of the parent drug. Abraxane (*42, 43*) is an albumin-bound paclitaxel and approved for metastatic breast cancer with broad therapeutic interest. Xyotax (poliglumex) (*44*) is a poly(L-glutamic acid) paclitaxel conjugate and degradable to release paclitaxel or its derivatives from the polymer backbone by action of a lysosomal protease, cathepsin B, that is overexpressed in many tumors or

Scheme 1. General Strategy for Derivatization of Triazine Dendrimers by Interception with Functionalized Dichlorotriazine Monomers

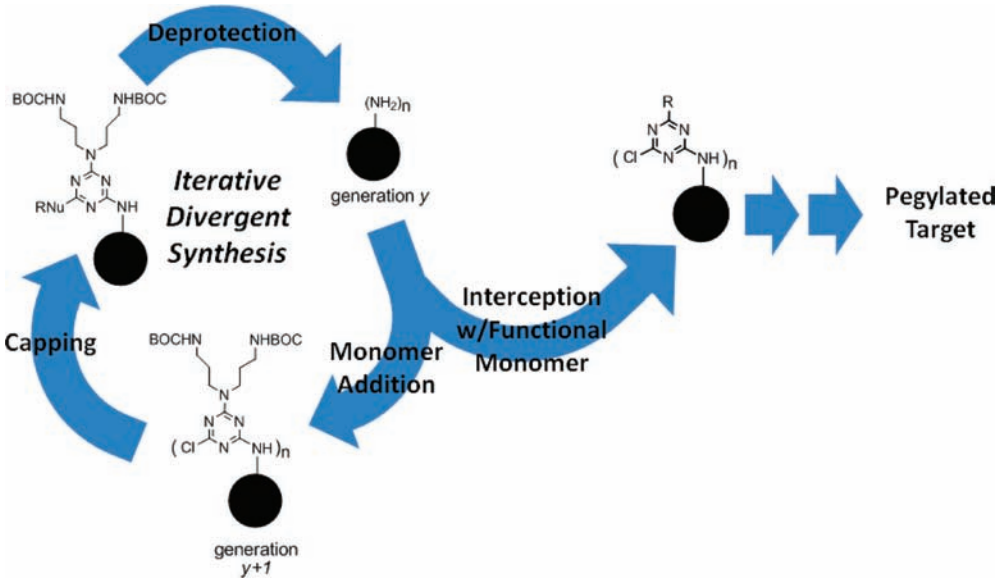

Chart 1. Dendrimers 1−3 with the Labile 2′-Ester and Disulfide Linkages[a]

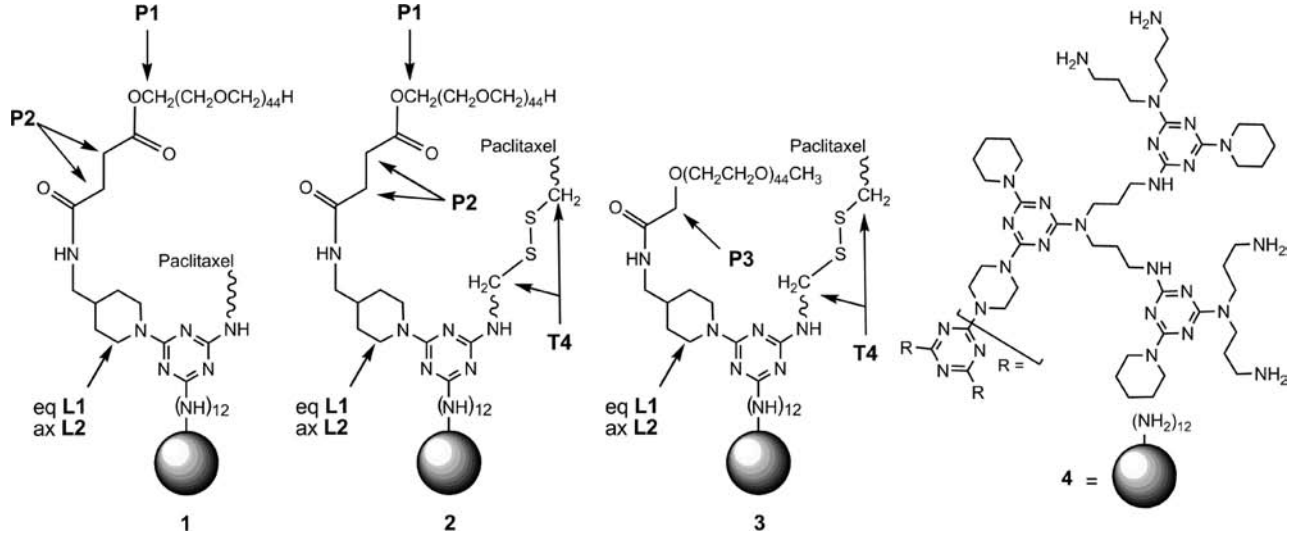


[a] The linkers for the PEG groups vary also. Additional atomic detail is available in Chart 2. The core of the dendrimer, **4**, is shown at the right. Labels refer to NMR spectra discussed later in the text.

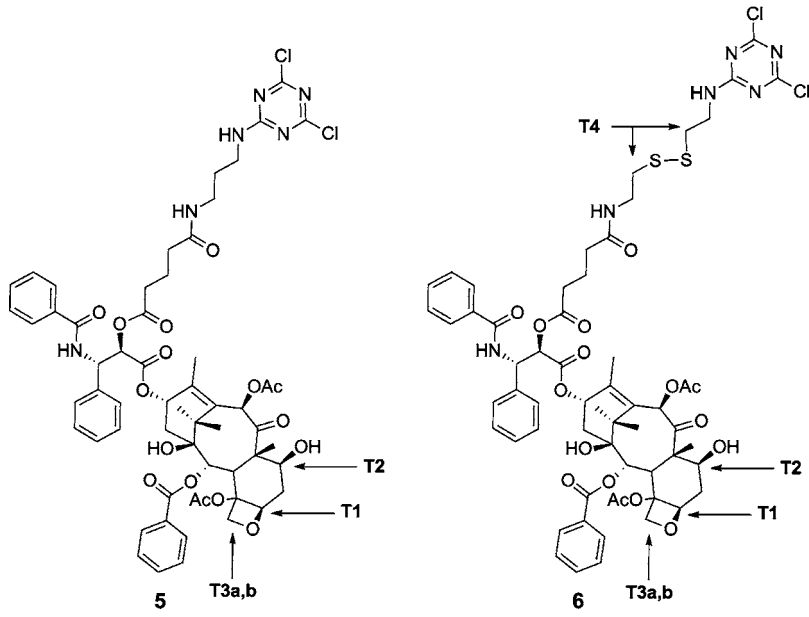
high estrogenic environments. Xyotax has been studied in phase III trials and has shown prolonged survival for women with advanced lung cancer (*45*). Other prodrugs such as PEG-TXL (a poly(ethylene glycol) conjugate of paclitaxel) (*46*) and HPMA-TXL (a *N*-(2-hydroxypropyl)methacrylamide copolymer conjugate of paclitaxel) (*47*) have shown some success in early clinical trials. Other macromolecular and pro-drug constructs based on paclitaxel have been recently described (*48*−*55*).

The goal of this manuscript is to communicate the design, synthesis, characterization, and preliminary biological assessment of dendrimers **1**−**3** shown schematically in Chart 1. Such studies set the stage for evaluations of efficacy in animal models of disease. While all three dendrimers present twelve paclitaxel groups appended by acylation of the 2′-hydroxyl group, the nature of the linker and the composition of the PEGylation reagent vary. The linker for dendrimer **1** offers a single biolabile linkage, the 2′-ester. The linker for dendrimers **2** and **3** also includes a disulfide. While PEG is appended through an amide linker to the triazines, the PEG reagent used in **1** and **2** includes a succinic acid ester, while the PEG reagent for **3** has a linking ether group. Biological assessments are also reported.

EXPERIMENTAL SECTION

General Synthetic Procedures. Paclitaxel was purchased from AK Scientific, Inc., or CEC. The NHS-mPEGs were purchased from NOF Corporation. The intermediates, **4** (*28*, *29*) and **5** (*30*) were prepared as previously reported. All other chemicals were purchased from Aldrich and Acros and used without further purification. All solvents were ACS grade and used without further purification. Diafiltration purification was performed with Amicon stirred ultrafiltration cell equipment (model 8400, YM 10 membrane, Millipore Corp.) at 35 psi of N_2. Size exclusion chromatography (SEC) was carried out using a Waters Delta 600 system and a Waters 2414 refractive index detector. A Suprema 10 μm GPC analytical column (1000 Å, 8 × 300 mm) was used with 0.1 M $NaNO_3$ as the eluent and a flow rate of 1 mL/min. NMR spectra were recorded on an Inova 300 or 500 MHz spectrometer in $CDCl_3$ or $CDCl_3$/MeOH-d_4

Chart 2. Dichlorotriazines 5 and 6 Are Available in Four Steps in 60% and 49% Overall Yields, Respectively



(10:1). All mass spectral analyses were carried out by the Laboratory for Biological Mass Spectrometry at Texas A&M.

Cytotoxicity. PC-3 cells (a human prostate cancer cell line) were cultured in T-medium (Invitrogen Corp., NY) at 37 °C in an atmosphere of 5% CO_2 and were passaged when reaching 75% confluence in a P100. T-Medium was supplemented with 5% FBS (Gemini Bio-Products, Woodland, CA) and 1× penicillin/streptomycin (Sigma, St. Louis, MO). The cells (2.5×10^3 cells/well in 50 μL T-medium) were plated in 96-well plates and incubated overnight for the treatment. A series of dilutions of **1**, **2**, and **3** at the paclitaxel concentration between 5 nM and 50 μM were prepared and added to the cells in the 96-well plates. For some studies, 10 μL of 10 mM of γ-L-glutamyl-L-cysteinyl-glycine (GSH, Sigma-Aldrich, St. Louis) or DL-dithiothreitol (DTT, Sigma-Aldrich, St. Louis) in PBS solution was added to each well, giving the final volume of 100 μL per well. Each treatment was duplicated in triplicates. After the three-day treatment, the cells were washed twice with 100 μL of prewarmed T-medium. After adding 100 μL of prewarmed T-medium to each well, 10 μL of the MTT reagent was added. The MTT assay was performed according to the described procedure in the cell proliferation colorimetric assay kit (Roche Diagnostics Corporation, IN). The absorbance of the formazan dye in each was measured on a SpectraMax M5 plate reader (Molecular Devices, Sunnyvale, CA). The IC_{50} data were calculated by GraphPad *Prism 5* (GraphPad Software, La Jolla, CA) and presented as the best-fit values and 95% confidence intervals. IC_{50} is the concentration of compound required to inhibit 50% of the cell growth compared to an untreated control.

Radiolabeling of 1, 2, and 3 with ^{125}I and Purification. IODO-GEN precoated iodination tubes (Pierce, Rockford, IL) were used for ^{125}I-radiolabeling of **1**, **2**, and **3** on Bolton-Hunter like groups attached at unreacted aminomethylpiperidine groups. IODO-GEN precoated tubes were rinsed with 1 mL of 10 mM PBS buffer (pH 7.5) before the labeling. To each IODO-GEN tube containing 15 nmol of dendrimer−taxol prodrug in 20 mM PBS was added ~600 μCi of Na^{125}I (2 μL of volume). The solution was kept at room temperature for 30 min with gentle swirling every 5 min. After radiolabeling reaction, the samples were further purified by using Millipore 10 k centrifugal filtration units. The reaction mixtures were loaded to the filter units and centrifuged at 14 000 rpm for 30 min to remove the free ^{125}I ion or other small molecular species. The products were then washed with 3 portions of 500 μL of 10 mM PBS. Radio-TLC or radio-HPLC was used to monitor the radiolabeling efficiency and determine the radiochemical purity of the three ^{125}I-labeled prodrugs.

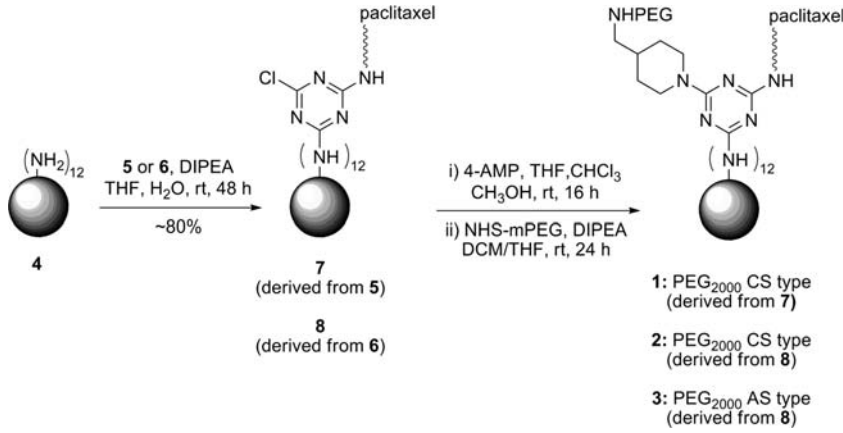
Biodistribution Studies in SCID Mice Bearing PC-3 Xenografts. PC-3 cells were subcutaneously implanted into both front flanks ($2-2.5 \times 10^6$ of cells in 100 μL) of male SCID mice at 6−8 weeks of age. Tumors were allowed to grow for 3−4 weeks. Once the tumors reached the size of 50−500 mg, the mice were randomized into 3 groups ($n = 4$; 4 h, 24 h, and 48 h). Each mouse was intravenously injected with 100 μL of ^{125}I-radiolabed **1**, **2**, and **3** (~5 μCi/ mouse). Mice were sacrificed at 4 h, 24 h, and 48 h postinjection (p.i.). Organs of interest (blood, heart, lung, fat, liver, spleen, kidney, stomach, intestines, muscle, femur, thyroid, brain, and tumors) were harvested and weighed, and radioactivity was quantified by γ-counter. Standards were prepared, weighed, and counted along with the samples for %ID/g and %ID/organ calculation. Statistical analysis was performed using *Prism 5.0* (Graphpad, San Diego, CA).

RESULTS AND DISCUSSION

This section is subdivided into three parts, the design and synthesis of these targets, their chemical characterization, and a preliminary biological assessment in vitro and in vivo.

Design and Synthesis. The design criteria employed to arrive at **1**−**3** included (i) the choice of a broad spectrum drug that presents challenges in delivery; (ii) the use of a dendrimer platform that was available at large scale; (iii) the adoption of established strategies for drug conjugation that too were scalable; and (iv) the development of a route that could be generalized to other drugs and/or linkers. We met these criteria using paclitaxel as the drug and esterification of the 2′-hydroxyl group for linkage to the dendrimer. We favor covalent attachment of the drug because it increases drug loading from 1 or 2 molecules sequestered noncovalently to 12. This strategy should enable controlled release through ester hydrolysis and/or disulfide reduction. The routes employed could be scaled readily to yield multigram quantities of material (Scheme 2). The dendrimer, **4**, (in its BOC-protected form) has been prepared on kilogram scale (*28*). The two dichlorotriazines, **5** and **6**, are synthesized in four steps in 60% and 49% overall yields, respectively (Chart

Scheme 2. Synthesis of 1−3



2). After paclitaxel is reacted with glutaric anhydride, the *N*-hydroxysuccinimide (NHS) ester is prepared as previously reported (*30*). Reaction of the ester with the excess amount of a diamine, either 1,3-diaminopropane or cystamine, gives free amine-terminated paclitaxel intermediates. Subsequently, these amines are reacted with cyanuric chloride using Hunig's base at 0 °C in THF for 1 h, to provide the desired dichlorotriazines, **5** and **6**. The generation three dendrimers, **7** and **8**, are respectively obtained from the reaction of **4** with either **5** or **6** using Hunig's base in THF/water for 48 h. Dendrimer **7** covalently carries twelve molecules of paclitaxel through ester linkage, while **8** carries the drug via both ester and disulfide linkages. The PEGylation of the amines of aminomethylpiperidine is accomplished using NHS-esters of PEG (2kDa) described as either CS type (succinate type; mPEG-O-$COCH_2CH_2CO$-NHS) or AS type (acetyl type; mPEG-O-CH_2CO-NHS). For the biodistribution study, radiolabeling groups are later incorporated by reacting an NHS-activated Bolton-Hunter reagent with the PEGylated dendrimers by taking advantage of unPEGylated aminomethylpiperidine groups.

Chemical Characterization. Synthesis and purification of dendrimers are followed by thin layer chromatography (TLC), ^1H and ^{13}C NMR, mass spectrometry, and gel permeation chromatography (GPC). MALDI-TOF MS showed all species presented appropriate molecular ions as $[M + H]^+$, $[M + Na]^+$, and/or $[M + K]^+$. Mass ions (*m*/*z*) of the poly(monochlorotriazine) dendrimers were observed at 16 657 for **7** (calculated mass: 16 567) and 17 481 for **8** (calculated mass: 17 503) (Supporting Information Figure S9). A ladder of peaks at lower mass region (~16 450) was found for **8** due to the fragmentation of the labile ester and disulfide bonds, most likely occurring during ionization.

PEGylated dendrimers **1**, **2**, and **3** were purified using ultrafiltration in deionized water over a week. GPC was used to analyze the PEGylated dendrimers using 0.1 M $NaNO_3$ (aq) as an eluent with a refractive index (RI) detector. As shown in the Supporting Information (Figure S10), the retention times of the analytes do not correspond to their molecular weights obtained from MALDI-TOF MS: **1** (10.1 min, 38.8 kDa), **2** (9.9 min, 36.6 kDa), and **3** (9.6 min, 33.9 kDa). We assume that either the hydrophobic interactions between the column matrix and the analyte affected the chromatography or that the increased hydrophobic nature promotes aggregation.

Figure 1 shows two regions of the ^1H NMR of PEGylated dendrimers that can be used to provide estimates of the degree of PEGylation. The peaks indicated derive from tethered paclitaxel (T1−T4; Chart 2), the linking aminomethylpiperidine group (L1,L2; Chart 1), and PEG (P1−P3; Chart 1). The Supporting Information includes complete NMR assignments of the spectra of these targets. The spectra are typified by resolved peaks of paclitaxel in the region of δ 4.8−8.2 ppm and a highly crowded upfield region populated by peaks from the PEG, paclitaxel, and dendrimer. The results provide support for our estimates of the degree of PEGylation derived from mass spectrometry (based on an average molecular mass of PEG of 2.3k Da as determined by MALDI-TOF MS). The theoretical integrations of paclitaxel protons (T1−T3) are in close agreement with experimental values. Discrepancy in the values of T4 are attributed to an inability to unambiguously integrate the signal. While we are inclined to believe that the reaction of AMP on the poly(monochlorotriazine) dendrimer proceeds almost quantitatively, ^1H NMR validates this belief; that is, the axial and equatorial protons of AMP appear in ratios that reflect almost a 1:1 correlation of drug to AMP. Accordingly, we infer that substoichiometric PEGylation derives from the conditions employed during PEGylation and is not due to a lack of amines installed during the AMP step. The overlapping signals of the ^1H NMR spectra make quantifying the degree of PEGylation inexact, but possible. The relatively close agreement of T-type and L-type signals leads us to assign overlap to these signals; that is, of the 2.64 protons expected for T3b and P1 of **1**, we assign 1.13 units of signal to T3b (an estimate based on T3a) leaving 1.51 units for P1. The result is that both P1 and P2 have 75% the expected area. We infer, accordingly, a ratio of 1:1:0.75 for paclitaxel/linker/PEG, which corresponds to 9 of the expected 12 chains. A similar ratio of 1:1:0.67 for paclitaxel/linker/PEG is seen for **2** corresponding to 8 PEG chains. The significant overlap between P3 and water in **3** allows us to place an upper limit on the degree of PEGylation: No more than 9 PEG appear attached. More likely, the number is closer to the estimate derived from mass spectrometry, 6 or 7. In summary, the targets are composed of 26 wt % drug and 9 PEG arms for **1**, 28 wt % drug and 8 PEG arms for **2**, and 30 wt % drug and 6.5 PEG arms for **3**, respectively (Table 1). Two Bolton-Hunter groups are incorporated into the PEGylated dendrimers for biodistribution study. The installation of the reporting groups was followed by ^1H NMR spectroscopy.

Biological Assessment. Cellular and in vivo toxicities of **1**−**3** were evaluated using an MTT assay. Briefly, the IC_{50} value reflects concentration required to inhibit 50% of cell growth compared with untreated control over a 72 h incubation (*56, 57*). In the assay, free paclitaxel administered as a DMSO solution showed an IC_{50} of 4.5 nM. The cytotoxicity of **1** was approximately 29 nM regardless of whether it was administered with or without 1 mM glutathione or 1 mM dithiothreitol. The toxicities of **2** and **3**, in contrast, increased from 74 nM without reductant to ~26 nM in the presence of 1 mM glutathione to ~13 nM in the presence of 1 mM dithiothreitol. While the similarities in toxicities between **2** and **3** are expected, we recognize a slight disparity between these values and that of **1**;

Table 1. Chemical and Pharmacokinetic Summary of Dendrimers (1−3)

		paclitaxel		PEG (2 kDa)		half-lives (h)	
dendrimer	MW (kDa)	number	linker	number	linker	$t_{1/2\alpha}$	$t_{1/2\beta}$
1	38.8	12	ester	9	ester	0.4	15.3 ± 0.8
2	37.8	12	ester/disulfide	8	ester	0.4	19.3 ± 2.1
3	32.9	12	ester/disulfide	6.5	ether	0.4	19.6 ± 0.7

that is, we would have expected all three constructs to behave equally in the absence of reductant. The drug-free control dendrimer was not evaluated, as similar PEGylated architectures show no toxicity up to millimolar concentrations.

On the basis of the results of the cytotoxicity study, dendrimer **1** was examined in vivo as a prelude to more detailed efficacy evaluations. Five Balb/c mice were given three doses intravenously of 60 mg/kg on days 0, 4, and 8, a dose corresponding to three times the maximum tolerated dose of paclitaxel. None of the mice showed any adverse effects over the whole experimental period of three weeks based on visual inspection of the organs or measured levels of alanine transaminase or blood urea nitrogen levels as compared to a control group of 5 mice that were administered saline on the same days. We believe that the observed low systemic toxicity coupled with the hypothesized selective accumulation (and release) in a tumor may offer an opportunity for therapeutic relevance. The results of such studies will be reported in due course.

Biodistribution Studies in Tumor-Bearing Mice. In vivo pharmacokinetics of **1**, **2**, and **3** was evaluated in PC-3 bearing SCID mice. As shown in Table 1, the distribution half-lives ($t_{1/2\alpha}$) to other organs appeared almost same (0.4 h) in all three dendrimers. The elimination half-lives ($t_{1/2\beta}$) were significantly shorter than those predicted from the previous biodistribution results: **1** (15.3 h), **2**(19.3 h), **3** (19.6 h). The predicted elimination half-lives for these three dendrimers was ∼30 h. Previously, we examined the relationship of molecular weight and elimination half-life over different classes of PEGylated dendrimers including polyesters, polylysines, and polytriazines (*25*). The plot suggested, regardless of the dendrimer class, the elimination half-lives were closely related to the number of PEG chains and molecular weight. Dendrimers **1**, **2**, and **3** (6.5 to 9 PEG chains and 33 to 39 kDa) were predicted to have about 30 h of elimination half-life considering the previously observed trends (Supporting Information). The shorter elimination half-lives of **1**, **2**, and **3** suggest that drug loading can affect biodistribution times.

The smallest dendrimer, **3** (32.9 kDa), containing the fewest PEG arms (6.5) showed a similar or longer elimination half-life compared to **2** and **3.** At this time, we are not willing to attribute this to stability of the PEG attachment or the likelihood that **3** may aggregate into polymeric micelles due to increased hydrophobicity communicated by a more exposed core.

Tumor localization was observed for all three dendrimers. Our interest in these dendrimers as generic platforms for drug delivery led us to measure tumor-to-blood and tumor-to-muscle ratios. Dendrimer **2** showed the highest tumor-to-blood ratio (1.7 to 1) and the highest tumor-to-muscle ratio (23.8 to 1) at 48 h postinjection (Figure 2). The dendrimers accumulated in liver and spleen presumably due to the sequestration by the reticuloendothelial system (RES). Satisfyingly, the majority of the dendrimers were excreted through urine (35−55%ID), while less than 4%ID were found in the feces (Table 2). The trend of decreasing liver and spleen accumulation over time coupled with little fecal elimination suggests that these materials warrant additional investigation even in light of the relatively low tumor accumulation observed. This level of tumor accumulation is not

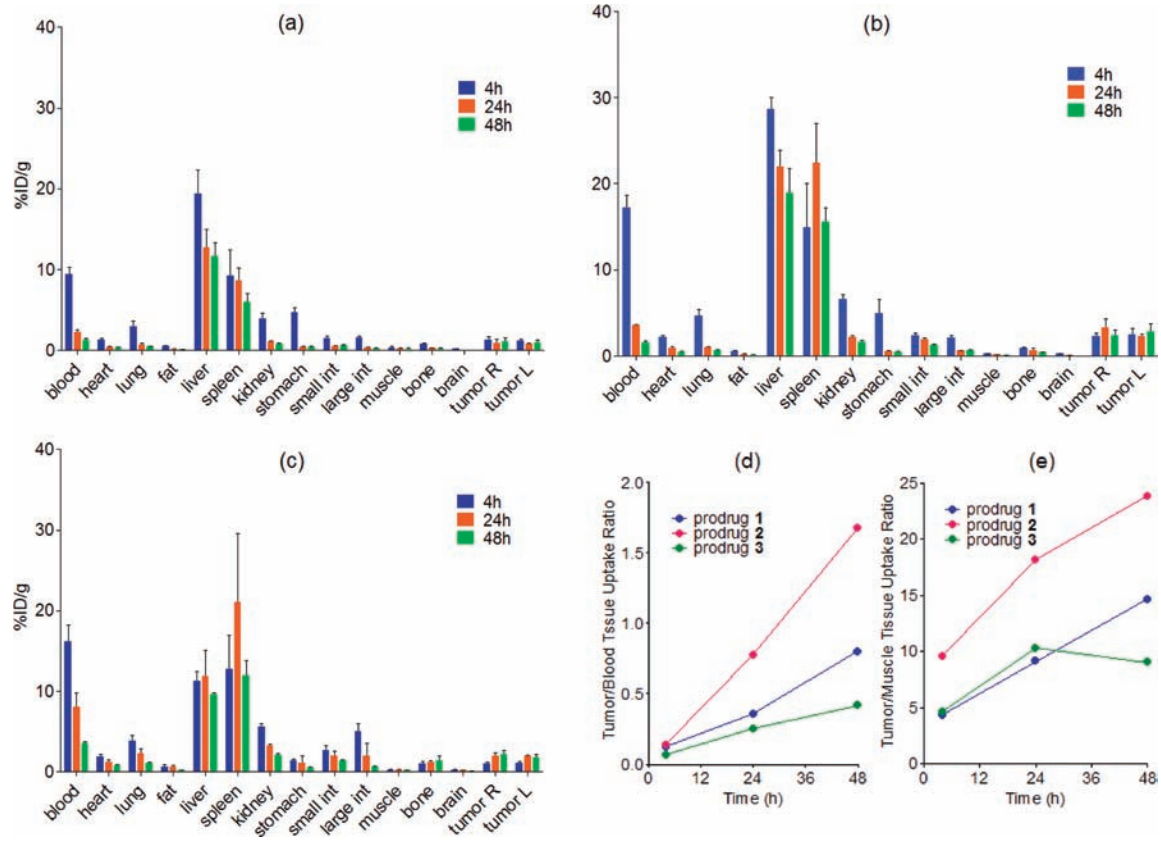

Figure 2. Biodistribution and tumor localization of the prodrugs (**1**−**3**) in SCID mice bearing PC-3 xenografts: (a) for **1**, (b) for **2**, and (c) for **3**; (d) and (e) showing tumor/blood and tumor/muscle uptake ratios at different time points, respectively.

Table 2. Cumulative Excretion Data of 1, 2, and 3 Found in the Urine and Feces

	%ID in urine			%ID in feces		
dendrimer	24 h	48 h	72 h	24 h	48 h	72 h
1	26.6	31.5	34.8	1.6	2.1	2.5

3	33.1	37.9	40.7	2.2	2.7	3.2

inconsistent with other macromolecular drug delivery constructs including poly(lysine) dendrimers decorated with camptothecin that have been described by Szoka and Fréchet (*58*). For comparison, and unlike Abraxane and Taxol formulations, tumor accumulation in mice appears rapid and sustained over time even with diminished levels in blood and organs. In contrast, both Taxol and Abraxane formulations show peak tumor levels within 2−3 h and drop significantly (∼3×) by 24 h (*59*). Separately, in rats both Taxol and Abraxane showed similar distributions in organs. Interesting, these distributions differ from those reported here. In addition, the primary route for elimination was fecal for Taxol and Abraxane constructs (*60*). This distinction should be taken with caution, as the reported constructs were evaluated by labeling the triazine dendrimer, whereas the preclinical studies involving Taxol and Abraxane reports rely on monitoring tritiated drug directly.

CONCLUSIONS

The three dendrimers (**1**, **2**, and **3**) provide compelling evidence that intercepting the iterative, divergent synthesis of triazine dendrimers with elaborate and reactive dichlorotriazines is an effective strategy for elaboration of these materials into candidate vehicles for drug delivery. The chemistry proceeds to yield pure material upon silica gel chromatography. Capping the resulting poly(monochlorotriazine) dendrimer with a diamine with differential reactivity followed by PEGylation provides materials whose composition is assignable, but are inherently more difficult to characterize due to heterogeneity within the PEG and incomplete reaction. The targets contain twelve molecules of paclitaxel (26−30 wt % drug) and six to nine PEG arms (43−54 wt % PEG). The targets described offer an entry point to probe hypotheses that range from the physical organic chemistry of drug release in vitro and in vivo, efficacy, to the impact the hydrolytically sensitive PEGs have on biodistribution. These constructs appear to be well tolerated in vivo at doses equal to 200% the maximum tolerated dose of paclitaxel. This low toxicity offers a variety of strategies for dosing. Tumor localization for the three dendrimers was observed at low levels, consistent with other formulations. The elimination half-lives were similar across all three constructs, but shorter than expected from previous studies. This observation suggests that drug may influence distribution times. Perhaps most interestingly, the distribution and route of elimination for these constructs appear to differ from those of current clinical interest, namely the free drug formulations of Taxol and Abraxane, although direct comparison is slightly more tenuous as our efforts track labeled dendrimer and not labeled drug. Further biological evaluation including in vivo efficacy study will be reported in due course.

ACKNOWLEDGMENT

We thank the National Institutes of Health (NIGMS R01 45650) and the Robert A. Welch Foundation (A 1430) for support.

Experimental Procedures

G2-(Taxol-COO-CS-PEG)$_{12}$ (1). A solution of 4-aminomethylpiperidine (0.73 g, 6.38 mmol) in chloroform (10 mL) was added to a solution of **7** (1.47 g, 8.86*10^{-2} mmol) in chloroform (90 mL), THF (20 mL), and methanol (0.5 mL). The solution was stirred under nitrogen for 16 h at room temperature. The solution was washed two times with brine, dried over $MgSO_4$, filtered, and then the volume was reduced to 40 mL *in vacuo*. After addition of DIPEA (0.4 mL, 2.30 mmol) and a solution of NHS-mPEG (CS type, MW 2 kDa, 2.80 g, 1.40 mmol) in dichloromethane (10 mL), the reaction solution was stirred under nitrogen for 24 h at room temperature and concentrated *in vacuo*. The residue was dissolved in deionized water and filtered. The resulting solution was diafiltrated to remove low molecular weight impurities using Amicon stirred ultrafiltration cell equipment and a YM 10 membrane (MWCO: 10 kDa) in deionized water over a week. The purified solution was evaporated under vacuum to afford **1** (3.07 g, 89% over two steps) as a colorless solid. The product was analyzed by size exclusion chromatography. ^{1}H NMR (500 MHz, $CDCl_3$+MeOH-d_4) δ 8.08 (d, *J* = 7.5, 24H), 7.72 (d, *J* = 7.5, 24H), 7.57 (t, *J* = 7.3, 12H), 7.49-7.25 (m, 120H), 6.30 (s, 12H), 6.10 (br, 12H), 5.88 (br, 12H), 5.64 (d, *J* = 6.5, 12H), 5.38 (d, *J* = 2.5, 12H), 4.93 (br d, *J* = 8.0, 12H), 4.65 (br, 24H), 4.33 (br, 12H), 4.24 (br, 12H), 4.19 (br, 12H), 3.75 (br, 12H), 3.61 (br m, PEG C**H$_2$**C**H$_2$**O), 3.34 (s, PEG C**H$_3$**O), 3.65-3.00 (br m, 216H), 2.60-1.46 (br m, 438H), 1.14 (s, 36H), 1.10 (s, 36H), 1.04 (br, 24H); MS (MALDI-TOF) calcd for complete PEGylation 45100, found 38800 $(M+H)^+$.

G2-(Taxol-COO-SS-CS-PEG)$_{12}$ (2). A solution of 4-aminomethylpiperidine (0.22 g, 1.93 mmol) in chloroform (10 mL) was added to a solution of **8** (0.47 g, 2.68*10^{-2} mmol) in chloroform (90 mL), THF (10 mL), and methanol (0.5 mL). The solution was stirred under nitrogen for 16 h at room temperature. The solution was washed two times with brine, dried over $MgSO_4$, filtered, and then the volume was reduced to 30 mL *in vacuo*. After addition of DIPEA (0.4 mL, 2.30 mmol) and a solution of NHS-mPEG (CS type, MW 2 kDa, 0.9 g, 0.45 mmol) in dichloromethane (10 mL), the reaction solution was stirred under nitrogen for 24 h at room temperature and concentrated *in vacuo*. The residue was dissolved in deionized water and filtered. The resulting solution was diafiltrated to remove low molecular weight impurities using Amicon stirred ultrafiltration cell equipment and a YM 10 membrane (MWCO: 10 kDa) in deionized water over a week. The purified solution was evaporated under vacuum to afford **2** (0.80 g, 79% over two steps) as a colorless solid. The product was analyzed by size exclusion chromatography. ^{1}H NMR (500 MHz, $CDCl_3$+MeOH-d_4) δ 8.09 (d, *J* = 7.5, 24H),

7.72 (d, *J* = 7.0, 24H), 7.57 (t, *J* = 7.3, 12H), 7.49-7.27 (m, 120H), 6.29 (s, 12H), 6.13 (br, 12H), 5.91 (br, 12H), 5.65 (d, *J* = 5.0, 12H), 5.39 (br, 12H), 4.93 (br d, *J* = 8.5, 12H), 4.68 (br, 24H), 4.35 (br, 12H), 4.25-4.20 (br m, 24H), 3.75 (br, 12H), 3.80-3.30 (m, PEG), 3.65-3.00 (br m, 216H), 2.80-1.40 (br m, 462H), 1.16 (s, 36H), 1.11 (s, 36H), 1.03 (br, 24H); MS (MALDI-TOF) calcd for complete PEGylation 46000, found 36600 $(M+H)^+$.

G2-(Taxol-COO-SS-AS-PEG)$_{12}$ (3). Dendrimer **3** (0.64 g, 73% over two steps) was synthesized using NHS-mPEG (AS type, MW 2 kDa) as described above. ^{1}H NMR (500 MHz, $CDCl_3$+MeOH-d_4) δ 8.09 (d, *J* = 7.5, 24H), 7.73 (d, *J* = 7.5, 24H), 7.58 (t, *J* = 7.0, 12H), 7.50-7.25 (m, 120H), 6.31 (s, 12H), 6.13 (br, 12H), 5.91 (br, 12H), 5.65 (br, 12H), 5.39 (br, 12H), 4.94 (br d, *J* = 8.5, 12H), 4.70 (br, 24H), 4.35 (br, 12H), 4.26 (br, 12H), 4.20 (br, 12H), 3.75 (br, 12H), 3.80-3.30 (m, PEG), 3.65-3.00 (br m, 216H), 2.80-1.40 (br m, 462H), 1.16 (s, 36H), 1.12 (s, 36H), 1.08 (br, 24H); MS (MALDI-TOF) calcd for complete PEGylation 46000, found 33900 $(M+H)^+$.

Installation of Bolton-Hunter Group on the PEGylated Dendrimers (1, 2, and 3). The NHS-ester Bolton-Hunter reagent (SHPP, 2.4 eq. based on PEGylated dendrimer) was added to the solution of the PEGylated dendrimer and DIPEA (3 eq. based on PEGylated dendrimer) in DCM (2 mL). The solution was stirred under N_2 for 24 h at room temperature and concentrated *in vacuo*. The residue was dissolved in deionized water and filtered. The resulting solution was diafiltrated to remove low molecular weight impurities using Amicon stirred ultrafiltration cell equipment and a YM 10 membrane (MWCO: 10 kDa) in deionized water over 3 d. The purified solution was evaporated under vacuum to afford a colorless solid. The product was analyzed by size exclusion chromatography.

Taxol-COO-SS-Cl$_2$ (6). First, the paclitaxel NHS-ester was prepared as previously reported.[30] To prepare cystamine, cystamine dihydrochloride was dissolved in a minimal amount of water, adjusted to pH 12 with 0.5 M NaOH, and then extracted with dichloromethane. A solution of the paclitaxel NHS-ester (3.30 g, 3.10 mmol) in dichloromethane (20 mL) was slowly added to an ice-bath cooled solution of cystamine (2.90 g, 19.04 mmol) and triethylamine (1.50 mL, 10.75 mmol) in dichloromethane (110 mL). After reaction under nitrogen for 30 min at 0 ^{o}C, the solution was neutralized with 1 M HCl, washed three times with brine, dried over $MgSO_4$, and then evaporated *in vacuo* to give the paclitaxel-cystamine as a white solid. A solution of cyanuric chloride (0.60, 3.25 mmol) in THF (10 mL) was added to an ice-bath cooled solution of the prepared paclitaxel-cystamine and DIPEA (1.0 mL, 5.73 mmol) in THF (60 mL). The solution was stirred for 1 h at 0 ^{o}C and concentrated *in vacuo*. The residue

was dissolved in dichloromethane, washed three times with brine, dried over $MgSO_4$, and then evaporated. The crude product was purified by silica gel chromatography (ethyl acetate:hexanes =4:1; TLC R_f = 0.21) to give **6** as a white solid (2.40 g, 62%). ^{1}H NMR (300 MHz, $CDCl_3$+MeOH-d_4) δ 8.09 (d, *J* = 6.9, 2H), 7.73 (d, *J* = 6.9, 2H), 7.59 (t, *J* = 7.1 Hz, 1H), 7.50-7.27 (m, 10H), 6.31 (s, 1H), 6.13 (t, *J* = 8.4, 1H), 5.91 (d, *J* = 3.9, 1H), 5.66 (d, *J* = 7.2, 1H), 5.41 (d, *J* = 3.9, 1H), 4.95 (d, *J* = 8.1, 1H), 4.34 (dd, *J* = 10.8, 6.6, 1H), 4.27 (d, *J* = 8.4, 1H), 4.21 (d, *J* = 8.4, 1H), 3.77 (d, *J* = 7.2, 1H), 3.68 (t, *J* = 6.5 Hz, 2H), 3.44 (m, 2H), 2.83 (t, *J* = 6.6 Hz, 2H), 2.72 (t, *J* = 6.6 Hz, 2H), 2.55-2.42 (m, 3H), 2.38 (s, 3H), 2.31-2.03 (m, 7H), 1.96-1.80 (m, 6H), 1.65 (s, 3H), 1.16 (s, 3H), 1.12 (s, 3H); ^{13}C NMR (75 MHz, $CDCl_3$+MeOH-d_4) δ 203.9, 173.4, 172.5, 171.0, 169.9, 169.5, 168.9, 168.8, 166.5, 165.7, 141.6, 136.6, 133.7, 133.4, 133.2, 131.9, 130.0, 129.5, 128.9, 128.5, 127.2, 126.7, 84.5, 81.0, 77.9, 76.5, 75.6, 74.9, 74.1, 72.0, 71.4, 58.1, 53.0, 45.8, 43.2, 40.0, 38.1, 37.2, 36.7, 35.7, 35.2, 34.6, 32.6, 26.4, 22.4, 21.8, 20.7, 14.3, 9.5; MS (MALDI-TOF) calcd for $C_{59}H_{66}Cl_2N_6O_{16}S_2$ 1248.3354, found 1271.3062 $(M+Na)^+$.

G2-(Taxol-COO-Cl)$_{12}$ (7). A solution of **4** (245 mg, 8.29*10^{-2} mmol) in water (2 mL) and THF (3 mL) was slowly added to a solution of **5** (1.43 g, 1.22 mmol) and DIPEA (0.4 mL, 2.30 mmol) in THF (15 mL). The solution was stirred for 48 h at room temperature and evaporated under vacuum. The residue was dissolved in dichloromethane, washed with brine, dried over $MgSO_4$, filtered, and evaporated under vacuum. The crude product was purified by silica gel chromatography (washed with ethyl acetate:dichloromethane:methanol = 8:8:1 and eluted with dichloromethane:methanol = 8:1; TLC R_f = 0.50 with DCM:MeOH = 8:1) to give **7** (1.18 g, 86%) as a white solid. The excess or unreacted paclitaxel-dichlorotriazine was recovered from the purification and reused. ^{1}H NMR (500 MHz, $CDCl_3$+MeOH-d_4) δ 8.11 (d, *J* = 6.0, 24H), 7.73 (br, 24H), 7.59 (br, 12H), 7.50-7.30 (m, 120H), 6.32 (s, 12H), 6.15 (br, 12H), 5.92 (br, 12H), 5.67 (br, 12H), 5.41 (br, 12H), 4.96 (d, *J* = 7.0, 12H), 4.36 (br, 12H), 4.27 (br, 12H), 4.22 (br, 12H), 3.88-3.16 (br m, 192H), 2.50-1.50 (br m, 378H), 1.17 (s, 36H), 1.13 (s, 36H); ^{13}C NMR (75 MHz, $CDCl_3$+MeOH-d_4) δ 203.8, 173.2, 172.3 (two lines), 170.9, 169.8, 168.8, 168.7, 166.5, 165.2, 164.8, 164.5, 141.6, 136.6, 133.7, 133.4, 133.1, 131.8, 130.0, 129.4, 128.9, 128.4 (br two lines), 127.2, 126.7, 84.4, 81.0, 77.8, 76.4, 75.6, 74.9, 74.1, 71.9, 71.4, 58.1, 53.0, 45.7, 44.1, 43.2 (br), 37.9 (br), 37.4(br), 36.6, 35.7 (br), 35.2 (br), 34.8 (br), 34.6, 32.7, 29.2, 28.7, 27.5 (br), 26.4, 25.7, 24.8, 22.4, 21.9, 20.7, 20.6, 14.4, 9.6; MS (MALDI-TOF) calcd for $C_{837}H_{1008}Cl_{12}N_{144}O_{192}$ 16566.98, found 16657.53 $(M+Na)^+$.

G2-(Taxol-COO-SS-Cl)$_{12}$ (8). A solution of **4** (175 mg, 5.92*10^{-2} mmol) in water (2 mL) and THF (3 mL) was slowly added to a solution of **6** (1.10 g, 0.88 mmol) and DIPEA (0.4 mL, 2.30 mmol) in THF (15 mL). The solution was stirred for 48 h at room temperature and evaporated under vacuum. The residue was dissolved in dichloromethane, washed with brine, dried over $MgSO_4$, filtered, and evaporated under vacuum. The crude product was purified by silica gel chromatography (washed with ethyl acetate:dichloromethane:methanol = 10:10:1 and eluted with dichloromethane:methanol = 8:1; TLC R_f = 0.50 with DCM:MeOH = 8:1) to give **8** (0.84 g, 81%) as a white solid. The excess or unreacted paclitaxel-dichlorotriazine was recovered from the purification and reused. ^{1}H NMR (300 MHz, $CDCl_3$+MeOH-d_4) δ 8.09 (d, *J* = 8.7, 24H), 7.73 (d, *J* = 7.2, 24H), 7.59 (t, *J* = 7.4 Hz, 12H), 7.52-7.28 (m, 120H), 6.33 (s, 12H), 6.14 (*J* = 8.9 Hz, 12H), 5.91 (d, *J* = 3.9, 12H), 5.67 (d, *J* = 6.6, 12H), 5.41 (d, *J* = 3.6, 12H), 4.95 (d, *J* = 9.3, 12H), 4.36 (dd, *J* = 10.7, 7.4, 12H), 4.27 (d, *J* = 8.4, 12H), 4.21 (d, *J* = 8.4, 12H), 3.80-3.20 (br m, 192H), 2.82-2.70 (br m, 48H), 2.50-1.50 (br m, 354H), 1.17 (s, 36H), 1.13 (s, 36H); ^{13}C NMR (75 MHz, $CDCl_3$+MeOH-d_4) δ 203.8, 173.2, 172.4, 170.8, 169.8, 168.8, 168.7, 166.4, 165.2, 164.8, 164.5, 141.6, 136.6, 133.7, 133.4, 133.1, 131.8, 130.0, 129.4, 128.9, 128.4, 127.2, 126.7, 84.5, 81.0, 77.8, 76.4, 75.5, 74.8, 74.1, 71.9, 71.3, 58.0, 53.0, 45.8, 44.1, 43.1 (br), 39.8, 38.1, 37.1, 35.7, 35.2, 34.5, 32.6, 27.5 (br), 26.3, 25.6, 24.8, 22.4, 21.8, 20.6, 14.3, 9.5; MS (MALDI-TOF) calcd for $C_{849}H_{1032}Cl_{12}N_{144}O_{192}S_{24}$ 17502.50, found 17480.67 $(M+H)^+$.

Effect of DOTA Position on Melanoma Targeting and Pharmacokinetic Properties of ^{111}In-Labeled Lactam Bridge-Cyclized α-Melanocyte Stimulating Hormone Peptide

Haixun Guo,[†] Jianquan Yang,[†] Fabio Gallazzi,[#] Eric R. Prossnitz,[‡,§] Larry A. Sklar,[†,‡,||] and Yubin Miao*[,†,‡,⊥]

College of Pharmacy, Cancer Research Treatment Center, Department of Cell Biology and Physiology, Department of Pathology, Department of Dermatology, University of New Mexico, Albuquerque, New Mexico 87131, and Department of Biochemistry, University of Missouri, Columbia, Missouri 65211. Received August 5, 2009; Revised Manuscript Received September 21, 2009

The purpose of this study was to examine the effect of DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) position on melanoma targeting and pharmacokinetics of radiolabeled lactam bridge-cyclized α-melanocyte stimulating hormone (α-MSH) peptide. Method: A novel lactam bridge-cyclized α-MSH peptide, Ac-GluGlu-CycMSH[DOTA] {Ac-Glu-Glu-c[Lys-Nle-Glu-His-DPhe-Arg-Trp-Gly-Arg-Pro-Val-Lys(DOTA)]}, was synthesized using standard 9-fluorenylmethyloxycarbonyl (Fmoc) chemistry. DOTA was directly attached to the α-amino group of Lys in the cyclic ring, while the N-terminus of the peptide was acetylated to generate Ac-GluGlu-CycMSH[DOTA]. The MC1 receptor binding affinity of Ac-GluGlu-CycMSH[DOTA] was determined in B16/F1 melanoma cells. Melanoma targeting and pharmacokinetic properties of Ac-GluGlu-CycMSH[DOTA]-^{111}In were determined in B16/F1 melanoma-bearing C57 mice and compared to that of ^{111}In-DOTA-Gly-Glu-c[Lys-Nle-Glu-His-DPhe-Arg-Trp-Gly-Arg-Pro-Val-Asp] (^{111}In-DOTA-GlyGlu-CycMSH; DOTA was coupled to the N-terminus of the peptide). Results: Ac-GluGlu-CycMSH[DOTA] displayed 0.6 nM MC1 receptor binding affinity in B16/F1 cells. Ac-GluGlu-CycMSH[DOTA]-^{111}In was readily prepared with greater than 95% radiolabeling yield. Ac-GluGlu-CycMSH[DOTA]-^{111}In exhibited high tumor uptake (11.42 ± 2.20% ID/g 2 h postinjection) and prolonged tumor retention (9.42 ± 2.41% ID/g 4 h postinjection) in B16/F1 melanoma-bearing C57 mice. The uptake values for nontarget organs were generally low (<1.3% ID/g) except for the kidneys 2, 4, and 24 h postinjection. Conclusions: DOTA position exhibited profound effect on melanoma targeting and pharmacokinetic properties of Ac-GluGlu-CycMSH[DOTA]-^{111}In, providing a new insight into the design of lactam bridge-cyclized peptide for melanoma imaging and therapy.

INTRODUCTION

Malignant melanoma is the most lethal form of skin cancer and the most commonly diagnosed malignancy among young adults with an increasing incidence in the United States. It is predicted that there will be 68 720 cases of malignant melanoma newly reported and 8650 fatalities in the year 2009 (*1*). Unfortunately, no curative treatment currently exists for metastatic melanoma due to its resistance to conventional chemotherapy and immunotherapy. It is highly desirable to develop novel effective diagnostic and therapeutic approaches to fulfill the desperate need in melanoma treatment. G protein-coupled melanocortin-1 (MC1) receptors are distinct molecular targets for developing peptide radiopharmaceuticals due to their overexpression on human and mouse melanoma cells (*2*−*6*). α-Melanocyte stimulating hormone (α-MSH) peptides can selectively target diagnostic and therapeutic radionuclides to MC1 receptors through specific peptide−receptor interaction for melanoma imaging and therapy (*7*−*19*).

Recently, we have reported a novel class of ^{111}In-labeled lactam bridge-cyclized α-MSH peptides as effective imaging probes for melanoma detection (*20, 21*). Unique lactam bridge-cyclization made the radiolabeled α-MSH peptides stable both *in vitro* and *in vivo*. Metal chelator DOTA was coupled to the N-terminus of the lactam bridge-cyclized α-MSH peptides for radiolabeling. ^{111}In-DOTA-GlyGlu-CycMSH exhibited high receptor-mediated melanoma uptake (10.40 ± 1.40% ID/g at 2 h postinjection) in B16/F1 melanoma-bearing C57 mice (*20*). Both primary melanoma and pulmonary melanoma metastases were clearly visualized by small animal SPECT/CT using ^{111}In-DOTA-GlyGlu-CycMSH as an imaging agent (*20, 21*), highlighting the potential applications of radiolabeled lactam bridge-cyclized α-MSH peptides as effective diagnostic and therapeutic agents for melanoma.

DOTA position (conjugation to N-terminus or toward C-terminus) of the radiolabeled linear α-MSH peptide has displayed a profound effect on melanoma and kidney uptakes of ^{111}In-labeled linear α-MSH peptide derivatives (*13*−*15*). For instance, DOTA was coupled to the N-terminus or toward C-terminus to generate ^{111}In-DOTA-MSHoct {^{111}In-DOTA-[β-Ala^3, Nle^4, Asp^5, D-Phe^7, Lys^{10}]-α-MSH$_{3-10}$} and ^{111}In-DOTA-NAPamide {[Nle^4, Asp^5, D-Phe^7, Lys^{11}(DOTA)-^{111}In]-α-MSH$_{4-11}$}, respectively. ^{111}In-DOTA-NAPamide exhibited 75% higher melanoma uptake and 63% less renal uptake than ^{111}In-MSHoct 4 h postinjection in B16/F1 melanoma-bearing C57 mice (*14*). In this report, we further examined the effect of

DOTA position on the melanoma and renal uptakes of ^{111}In-labeled lactam bridge-cyclized α-MSH peptide. A novel DOTA-conjugated lactam bridge-cyclized α-MSH peptide, namely, Ac-GluGlu-CycMSH[DOTA] was synthesized using standard 9-fluorenylmethyloxycarbonyl (Fmoc) chemistry. DOTA was directly attached to the α-amino group of Lys (toward C-terminus) in the cyclic ring, while the N-terminus of the peptide was acetylated to generate Ac-GluGlu-CycMSH[DOTA]. The melanoma targeting and pharmacokinetic properties of Ac-GluGlu-CycMSH[DOTA]-^{111}In were determined in B16/F1 melanoma-bearing C57 mice. Meanwhile, the effect of L-lysine coinjection on the renal uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In was examined in B16/F1 melanoma-bearing C57 mice.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Amino acid and resin were purchased from Advanced ChemTech Inc. (Louisville, KY) and Novabiochem (San Diego, CA). DOTA-tri-*t*-butyl ester was purchased from Macrocyclics Inc. (Richardson, TX). $^{111}InCl_3$ was purchased from Trace Life Sciences, Inc. (Dallas, TX). ^{125}I-Tyr^2-[Nle^4, D-Phe^7]-α-MSH {^{125}I-(Tyr^2)-NDP-MSH} was obtained from PerkinElmer, Inc. (Shelton, CT). All other chemicals used in this study were purchased from Thermo Fischer Scientific (Waltham, MA) and used without further purification. B16/F1 murine melanoma cells were obtained from American type Culture Collection (Manassas, VA).

Peptide Synthesis. Intermediate scaffold of Ac-Glu(OtBu)-Glu(OtBu)-Lys(Dde)-Nle-Glu(OtBu)-His(Trt)-DPhe-Arg(Pbf)-Trp(Boc)-Gly-Arg(Pbf)-Pro-Val was synthesized on Val-2-chlorotrityl chloride (Val-2ClTrt) resin using standard Fmoc chemistry by an Advanced ChemTech multiple-peptide synthesizer (Louisville, KY). A small aliquot of the scaffold material was cleaved and characterized by liquid chromatography−mass spectrometry (LC-MS) prior to further peptide synthesis and cyclization. The protecting group (Dde) of the Lys in the intermediate scaffold was removed by 2% hydrazine, and the branch moiety of the peptide was generated by coupling Fmoc-Lys(Dde) to the ε-amino group of the Lys in the intermediate scaffold manually. $(tBu)_3$DOTA was coupled to the α-amino group of Lys(Dde) in the peptide branch manually using standard Fmoc chemistry. The protecting group (Dde) of the Lys in peptide branch was removed by 2% hydrazine. After the removal of the (Dde) protecting group, the protected branched peptide was cleaved from the resin treating with 25% hexafluoroisopropanol (HFIP) and 5% triisopropylsilane (TIS) in dichloromethane (DCM) and characterized by LC-MS. Peptide cyclization between the acid moiety of Val and the ε-amino group of Lys in the peptide branch was achieved by overnight reaction in DMF in the presence of a mixture of 1 mM 1-hydroxybenzotriazole (HOBT), 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetranethyluronium hexafluorophosphate (HBTU), and *N*,*N*-diisopropylethylamine (DIEA). The protecting groups were totally removed by treating with a mixture of trifluoroacetic acid (TFA), thioanisole, phenol, water, ethanedithiol, and triisopropylsilane (87.5:2.5:2.5:2.5:2.5:2.5) for 2 h at room temperature (25 °C). The peptide was precipitated and washed with ice-cold ether for four times, purified by reverse-phase−high performance liquid chromatography (RP-HPLC), and characterized by LC-MS.

***In Vitro* Competitive Binding Assay.** The IC_{50} value of Ac-GluGlu-CycMSH[DOTA] was determined by *in vitro* competitive binding assay according to the method described previously (*20*). B16/F1 cells were harvested and seeded into a 24-well cell culture plate (5×10^5 cells/well) and incubated at 37 °C overnight. After being washed once with binding medium [Dulbecco's Modified Eagle's Medium with 25 mM *N*-(2-hydroxyethyl)-piperazine-*N*′-(2-ethanesulfonic acid), 0.2% BSA, and 0.3 mM 1,10-phenathroline], the cells were incubated at 25 °C for 2 h with approximately 50 000 cpm of ^{125}I-(Tyr^2)-NDP-MSH in the presence of increasing concentrations (10^{-13} to 10^{-6} M) of Ac-GluGlu-CycMSH[DOTA] in 0.3 mL of binding medium. The reaction medium was aspirated after incubation. Cells were rinsed with 0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS twice, and lysed in 0.5 mL of 1 N NaOH for 5 min. The activities associated with cells were measured in a Wallac 1480 automated gamma counter (PerkinElmer, NJ). The IC_{50} value of Ac-GluGlu-CycMSH[DOTA] was calculated by using *Prism* software (GraphPad Software, La Jolla, CA).

Complexation of the Peptide with ^{111}In. Ac-GluGlu-CycMSH[DOTA]-^{111}In was prepared using a 0.5 M NH_4OAc-buffered solution at pH 5.4. Briefly, 50 μL of $^{111}InCl_3$ (18.5−37.0 MBq in 0.05 M HCl), 10 μL of 1 mg/mL Ac-GluGlu-CycMSH[DOTA] aqueous solution, and 400 μL of 0.5 M NH_4OAc (pH 5.4) were added into a reaction vial and incubated at 75 °C for 45 min. After the incubation, 20 μL of 0.5% EDTA aqueous solution was added into the reaction vial to quench the reaction. The radiolabeled peptide was purified to single species by Waters RP-HPLC (Milford, MA) on a Grace Vadyc C-18 reverse-phase analytical column (Deerfield, IL) using the following gradient at a flow rate of 1 mL/min. The mobile phase consisted of solvent A (20 mM HCl aqueous solution) and solvent B (100% CH_3CN). The gradient was initiated and kept at 82:18 A/B for 3 min followed by a linear gradient of 82:18 A/B to 72:28 A/B over 20 min. Then, the gradient was changed from 72:28 A/B to 10:90 A/B over 3 min followed by an additional 5 min at 10:90 A/B. Thereafter, the gradient was changed from 10:90 A/B to 82:18 A/B over 3 min. Purified peptide sample was purged with N_2 gas for 20 min to remove the acetonitrile. The pH of final solution was adjusted to 7.4 with 0.1 N NaOH and normal saline for animal studies. Serum stability of Ac-GluGlu-CycMSH[DOTA]-^{111}In was determined according to the published procedure (*20*) by incubation in mouse serum at 37 °C for 24 h, and monitored for degradation by RP-HPLC.

Cellular Internalization and Efflux of Ac-GluGlu-CycMSH-[DOTA]-^{111}In. Cellular internalization and efflux of Ac-GluGlu-CycMSH[DOTA]-^{111}In were evaluated in B16/F1 cells as described by Miao et al. (*20*). After being washed once with binding medium, B16/F1 cells seeded in cell culture plates were incubated at 25 °C for 20, 40, 60, 90, and 120 min ($n = 3$) in the presence of approximately 160 000 counts per minute (cpm) of HPLC purified Ac-GluGlu-CycMSH[DOTA]-^{111}In. After incubation, the reaction medium was aspirated and cells were rinsed with 2×0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS. Cellular internalization of Ac-GluGlu-CycMSH[DOTA]-^{111}In was assessed by washing the cells with acidic buffer [40 mM sodium acetate (pH 4.5) containing 0.9% NaCl and 0.2% BSA] to remove the membrane-bound radioactivity. The remaining internalized radioactivity was obtained by lysing the cells with 0.5 mL of 1 N NaOH for 5 min. Membrane-bound and internalized ^{111}In activities were counted in a gamma counter. Cellular efflux was determined by incubating B16/F1 cells with Ac-GluGlu-CycMSH[DOTA]-^{111}In for 2 h, removing non-specific-bound activity with 2×0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS rinse, and monitoring radioactivity released into cell culture medium. At time points of 20, 40, 60, 90, and 120 min, the radioactivities on cell surfaces and in cells were separately collected and counted in a gamma counter.

Biodistribution Studies. All the animal studies were conducted in compliance with Institutional Animal Care and Use Committee approval. The biodistribution properties of Ac-GluGlu-CycMSH[DOTA]-^{111}In were determined in B16/F1 melanoma-bearing C57 female mice (Harlan, Indianapolis, IN).

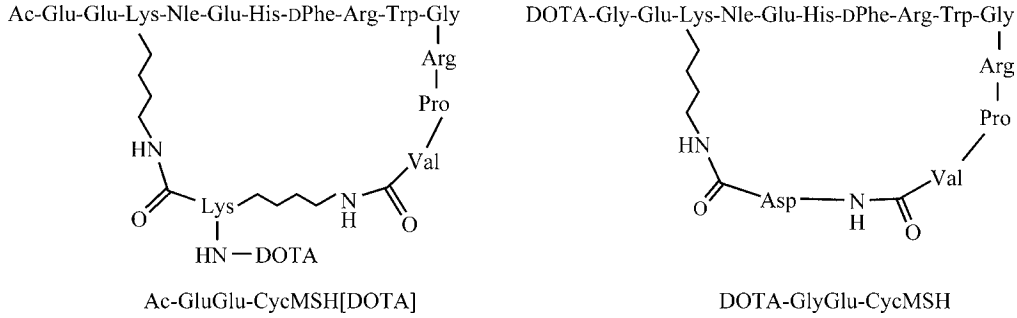

Figure 1. Schematic structures of Ac-GluGlu-CycMSH[DOTA] and DOTA-GlyGlu-CycMSH.

C57 mice were inoculated subcutaneously with 1×10^6 B16/F1 melanoma cells in the right flank for each mouse. After 10 days, when the weight of tumors reached approximately 0.2 g, 0.037 MBq of Ac-GluGlu-CycMSH[DOTA]-^{111}In was injected into each mouse through the tail vein. Groups of 5 mice were sacrificed at 0.5, 2, 4, and 24 h postinjection, and tumors and organs of interest were harvested, weighed, and counted. Blood values were taken as 6.5% of the whole-body weight. The specificity of the tumor uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In was determined by blocking the tumor uptake with the coinjection of 10 μg (6.07 nmol) of unlabeled NDP-MSH, a linear α-MSH peptide analogue with picomolar affinity for the MC1 receptor present on melanoma cells.

The effect of L-lysine coinjection on the renal uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In was examined in B16/F1 melanoma-bearing C57 as well. A group of 5 mice were injected with a mixture of 0.037 MBq of Ac-GluGlu-CycMSH[DOTA]-^{111}In and 15 mg of L-lysine. The mice were sacrificed at 2 h postinjection, and tumors and organs of interest were harvested, weighed, and counted. Blood values were taken as 6.5% of the whole body weight.

Imaging Melanoma with Ac-GluGlu-CycMSH[DOTA]-^{111}In. One B16/F1 melanoma-bearing C57 mouse was injected with 7.4 MBq of Ac-GluGlu-CycMSH[DOTA]-^{111}In via the tail vein. The mouse was anesthetized with 1.5% isoflurane for small animal SPECT/CT (Nano-SPECT/CT, Bioscan) imaging 2 h postinjection. The 9 min CT imaging was immediately followed by the SPECT imaging of whole body. The SPECT scans of 24 projections were acquired, and total acquisition time was 45 min. Reconstructed data from SPECT and CT were visualized and coregistered using InVivoScope (Bioscan, Washington, DC).

Urinary Metabolites of Ac-GluGlu-CycMSH[DOTA]-^{111}In. One hundred microliter of HPLC purified Ac-GluGlu-CycMSH[DOTA]-^{111}In (3.7 MBq) was injected into a B16/F1 melanoma-bearing C57 mouse through the tail vein. At 2 h after dose administration, the mouse was sacrificed and the urine was collected. The radioactive metabolites in the urine were analyzed by injecting aliquots of the urine into HPLC. A 20 min gradient of 18−28% acetonitrile/20 mM HCl was used for the urine analysis.

Statistical Methods. Statistical analysis was performed using the Student's *t* test for unpaired data to determine the significant differences between Ac-GluGlu-CycMSH[DOTA]-^{111}In with or without NDP-MSH coinjection and Ac-GluGlu-CycMSH[DOTA]-^{111}In with or without L-lysine coinjection described in biodistribution studies above. Differences at the 95% confidence level ($p < 0.05$) were considered significant.

RESULTS

To examine the effect of DOTA position on the melanoma and renal uptakes of ^{111}In-labeled lactam bridge-cyclized α-MSH peptide, a novel peptide of Ac-GluGlu-CycMSH[DOTA] was synthesized and purified by RP-HPLC. The identity of Ac-GluGlu-CycMSH[DOTA] was confirmed by electrospray ionization mass spectrometry (found MW 2220.5; calculated MW 2220.0). Ac-GluGlu-CycMSH[DOTA] displayed greater than 95% purity with 30% overall synthetic yield. The schematic structure of Ac-GluGlu-CycMSH[DOTA] is shown in Figure 1. Figure 2 illustrates the synthetic scheme of Ac-GluGlu-CycMSH[DOTA]. The competitive binding curve of Ac-GluGlu-CycMSH[DOTA] is presented in Figure 3. The IC_{50} value of Ac-GluGlu-CycMSH[DOTA] was 0.6 nM in B16/F1 melanoma cells.

The peptide was readily labeled with ^{111}In in 0.5 M ammonium acetate at pH 5.4 with greater than 95% radiolabeling yield. Ac-GluGlu-CycMSH[DOTA]-^{111}In was completely sepa-

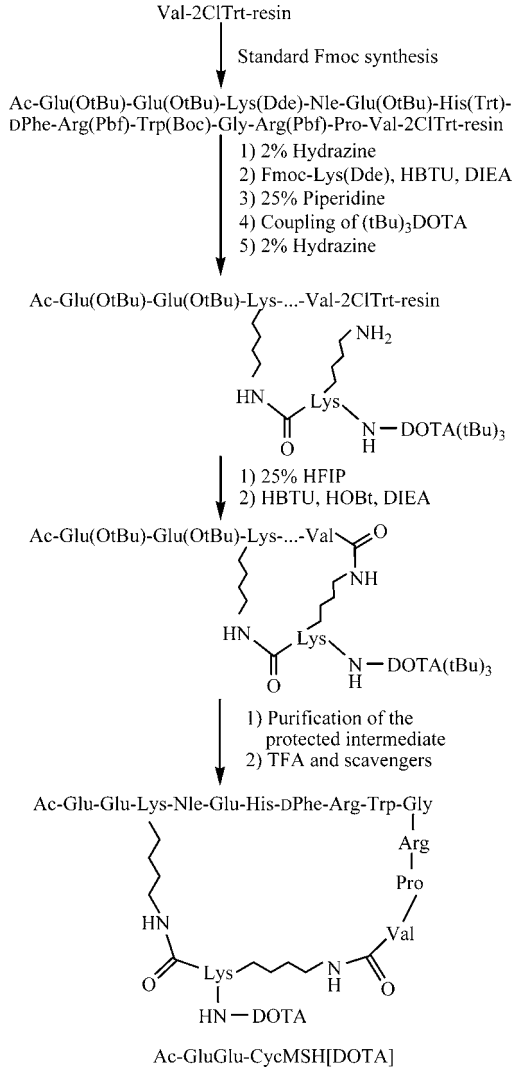

Figure 2. Synthetic scheme of Ac-GluGlu-CycMSH[DOTA].

rated from its excess nonlabeled peptide by RP-HPLC. The retention times of Ac-GluGlu-CycMSH[DOTA]-^{111}In and its nonlabeled peptide were 20.1 (Figure 4) and 15.5 min, respectively. The specific activity of Ac-GluGlu-CycMSH-[DOTA]-^{111}In was 7.41×10^8 MBq/g. Ac-GluGlu-CycMSH-[DOTA]-^{111}In showed greater than 98% radiochemical purity after the HPLC purification. Ac-GluGlu-CycMSH[DOTA]-^{111}In was stable in mouse serum at 37 °C. Only the Ac-GluGlu-CycMSH[DOTA]-^{111}In was detected by RP-HPLC after 24 h of incubation (Figure 4).

Cellular internalization and efflux of Ac-GluGlu-CycMSH-[DOTA]-^{111}In were evaluated in B16/F1 cells. Figure 5 illustrates cellular internalization and efflux of Ac-GluGlu-CycMSH[DOTA]-^{111}In. Ac-GluGlu-CycMSH[DOTA]-^{111}In exhibited rapid cellular internalization and extended cellular retention. There was 72.54 ± 3.10% of the cellular uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In activity internalized in the B16/F1 cells 40 min post-incubation. There was 81.12 ± 0.28% of the cellular uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In activity internalized in the cells after 2 h incubation. Cellular efflux results demonstrated that 68.60 ± 1.43% of the internalized Ac-GluGlu-CycMSH[DOTA]-^{111}In activity remained inside the cells 2 h after incubating cells in culture medium.

The melanoma targeting and pharmacokinetic properties of Ac-GluGlu-CycMSH[DOTA]-^{111}In were determined in B16/F1 melanoma-bearing C57 mice. The biodistribution results of Ac-GluGlu-CycMSH[DOTA]-^{111}In are shown in Table 1. Ac-GluGlu-CycMSH[DOTA]-^{111}In exhibited rapid and high melanoma uptake. The tumor uptake value was 12.11 ± 1.21% ID/g 0.5 h postinjection. There was 9.42 ± 2.41% ID/g of Ac-GluGlu-CycMSH[DOTA]-^{111}In activity remained in the tumors 4 h postinjection. The tumor uptake value of Ac-GluGlu-CycMSH[DOTA]-^{111}In gradually decreased to 3.64 ± 0.74% ID/g 24 h postinjection. In the blocking study, the tumor uptake value of Ac-GluGlu-CycMSH[DOTA]-^{111}In with 10 μg (6.07 nmol) of non-radiolabeled NDP-MSH co-injection were only 4.8% of the tumor uptake value without NDP-MSH co-injection at 2 h postinjection ($p < 0.05$), demonstrating that the tumor uptake was specific and receptor-mediated. Whole-body clearance of Ac-GluGlu-CycMSH[DOTA]-^{111}In was rapid, with approximately 78% of the injected radioactivity cleared through the urinary system by 2 h postinjection (Table 1). Normal organ uptakes of Ac-GluGlu-CycMSH[DOTA]-^{111}In were generally very low (<1.3% ID/g) except for the kidneys 2, 4, and 24 h postinjection. High tumor/blood and tumor/normal organ uptake

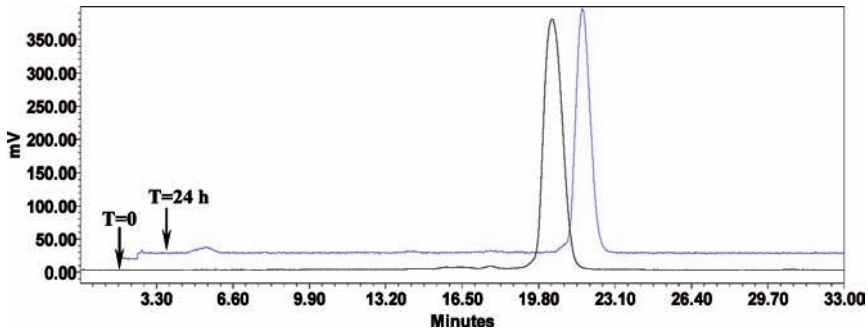

Figure 4. HPLC profile of radioactive Ac-GluGlu-CycMSH[DOTA]-^{111}In ($T = 0$) and mouse serum stability of Ac-GluGlu-CycMSH[DOTA]-^{111}In ($T = 24$ h) after 24 h incubation at 37 °C. The retention time of Ac-GluGlu-CycMSH[DOTA]-^{111}In was 20.1 min.

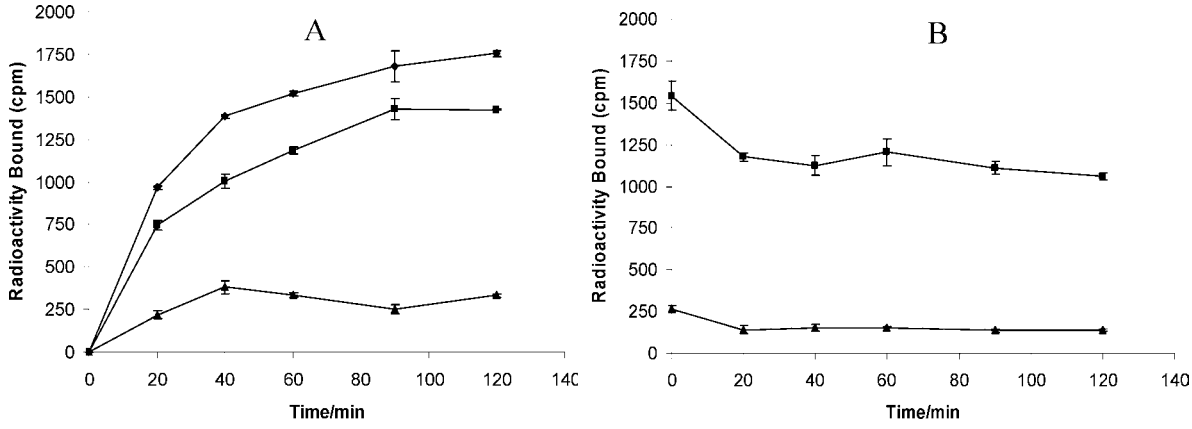

Figure 5. Cellular internalization (A) and efflux (B) of Ac-GluGlu-CycMSH[DOTA]-^{111}In in B16/F1 murine melanoma cells at 25 °C. Total bound radioactivity (◆), internalized activity (■), and cell membrane activity (▲) were presented as counts per minute (cpm).

[a] The data were presented as percent injected dose/gram or as percent injected dose (mean ± SD, $n = 5$). [b] $p < 0.05$ significance comparison of Ac-GluGlu-CycMSH[DOTA]-^{111}In with or without peptide blockade, and with or without L-lysine co-injection 2 h postinjection.

ratios were demonstrated as early as 0.5 h postinjection (Table 1). The renal uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In was 51.52 ± 6.17% ID/g 0.5 h postinjection, reached its peak value of 67.21 ± 8.63% ID/g 4 h postinjection, and gradually decreased to 21.09 ± 6.59% ID/g 24 h postinjection. Co-injection of 15 mg of L-lysine reduced the kidney uptake value of Ac-GluGlu-CycMSH[DOTA]-^{111}In to 18.35 ± 5.92% ID/g (70% reduction) without affecting the tumor uptake value 2 h postinjection (Table 1).

One B16/F1 melanoma-bearing C57 mouse was injected with 7.4 MBq of Ac-GluGlu-CycMSH[DOTA]-^{111}In through the tail vein to visualize the tumors at 2 h after dose administration. The whole-body SPECT image of the mouse was fused with CT image. The whole-body SPECT/CT image is presented in Figure 6. Flank melanoma tumors were visualized clearly using Ac-GluGlu-CycMSH[DOTA]-^{111}In as an imaging probe 2 h postinjection. Ac-GluGlu-CycMSH[DOTA]-^{111}In exhibited high tumor to normal organ uptake ratios except for the kidney, which was coincident with the biodistribution results. In view of the substantial renal uptake value of Ac-GluGlu-CycMSH[DOTA]-^{111}In in the biodistribution results, the urinary metabolites of Ac-GluGlu-CycMSH[DOTA]-^{111}In were analyzed by RP-HPLC at 2 h postinjection. The HPLC elution profile of Ac-GluGlu-CycMSH[DOTA]-^{111}In is shown in Figure 7. Eighty-three percent of Ac-GluGlu-CycMSH[DOTA]-^{111}In was transformed to two more polar metabolites, and only 17% of Ac-GluGlu-CycMSH[DOTA]-^{111}In remained intact at 2 h postinjection.

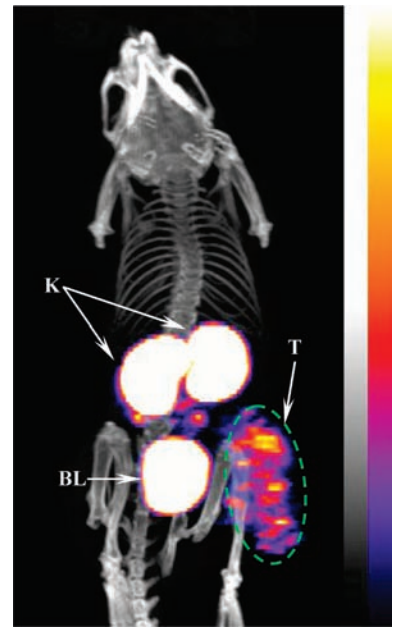

Figure 6. Whole-body image of Ac-GluGlu-CycMSH[DOTA]-^{111}In in B16/F1 flank melanoma-bearing C57 mice at 2 h postinjection. Tumor (T), kidneys (K), and bladder (BL) are highlighted with arrows on the image.

DISCUSSION

Both radiolabeled linear and cyclic α-MSH peptides have been reported to target the MC1 receptors for melanoma imaging and therapy (*4*−*22*). Cyclization of α-MSH peptides has been successfully used to improve the binding affinities and *in vivo* stability of peptides (*14*−*16*). In comparison with linear peptide, stabilization of secondary structures such as β-turns makes the cyclic peptide less flexible in conformation and better fit receptor binding pocket, enhancing the binding affinities of the cyclic peptides. Among the ^{111}In-labeled metal-cyclized, lactam bridge-cyclized and disulfide bridge-cyclized α-MSH peptides, ^{111}In-labeled metal-cyclized and lactam bridge-cyclized α-MSH peptides displayed higher melanoma uptake values and lower renal uptake values in B16/F1 melanoma-bearing C57 mice (*4*, *20*). We have recently developed a novel class of DOTA-conjugated lactam bridge-cyclized α-MSH peptides where the metal chelator DOTA was attached to the N-terminus of the peptide for radiolabeling. Both primary melanoma and pulmonary melanoma metastases were clearly imaged by small animal SPECT/CT using ^{111}In-DOTA-GlyGlu-CycMSH as an imaging probe (*20*, *21*).

Eberle and co-workers reported the profound effect of DOTA position on melanoma and kidney uptakes of ^{111}In-labeled linear

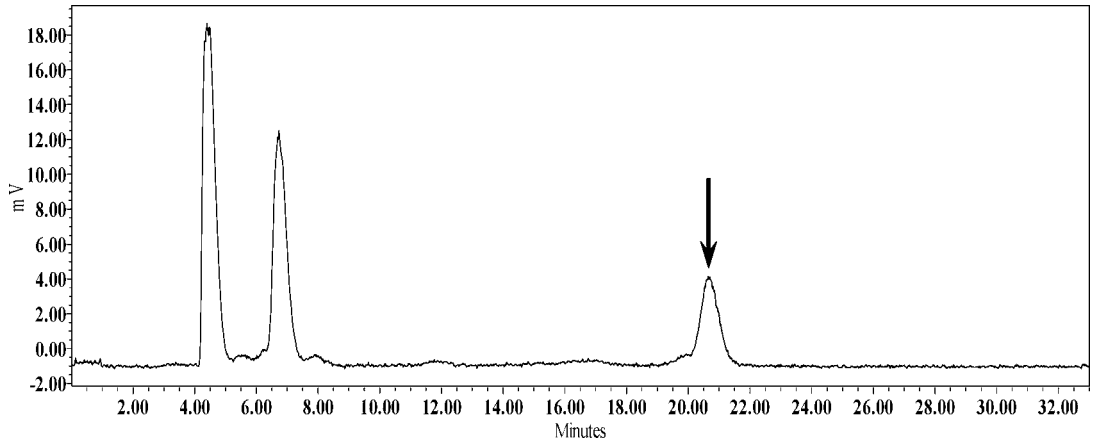

Figure 7. HPLC profile of radioactive urine sample of a B16/F1 melanoma-bearing C57 mouse at 2 h postinjection of Ac-GluGlu-CycMSH[DOTA]-^{111}In. The arrow indicates the retention time of the original compound of Ac-GluGlu-CycMSH[DOTA]-^{111}In prior to the tail vein injection.

α-MSH peptide derivatives (*14, 15*). Initially, DOTA was directly attached to the N-terminus of the peptide to yield ^{111}In-DOTA-MSH_{oct} {^{111}In-DOTA-[β-Ala^3, Nle^4, Asp^5, D-Phe^7, Lys^{10}]-α-MSH_{3-10}}, which exhibited 4.31 ± 0.30% ID/g tumor uptake 4 h postinjection in B16/F1 melanoma-bearing C57 mice (*14*). Thereafter, another ^{111}In-labeled linear α-MSH peptide derivative, namely, ^{111}In-DOTA-NAPamide {[Nle^4, Asp^5, D-Phe^7, Lys^{11}(DOTA)-^{111}In]-α-MSH_{4-11}} was developed by coupling DOTA to the ε-amino group of Lys in the C-terminus. Interestingly, coupling of DOTA toward the C-terminus of the linear peptide improved the tumor uptake and reduced renal uptake of ^{111}In-DOTA-NAPamide. At 4 h postinjection, ^{111}In-DOTA-NAPamide displayed 75% higher tumor uptake and 63% less renal uptake than ^{111}In-DOTA-MSH_{oct} (*14*), indicating that the DOTA position could dramatically affect the melanoma uptake and renal uptake of the radiolabeled α-MSH peptide. Hence, we examined the effect of DOTA position on the biodistribution properties of ^{111}In-labeled lactam bridge-cyclized α-MSH peptide in this study. DOTA was conjugated to the Lys in the cyclic ring, while the N-terminus of the peptide was acetylated to generate Ac-GluGlu-CycMSH[DOTA]. A Lys was used to connect DOTA (at α-amino group of the Lys) as well as to cyclize the peptide (through the epsilon amino group of the Lys). To eliminate the potential influence of the overall positive charge on the renal uptake of the radiolabeled α-MSH peptide, one more negatively charged Glu was introduced to replace the Gly at the N-terminus besides the acetylation of the N-terminus (Figure 1) to make the overall charge of Ac-GluGlu-CycMSH[DOTA] equal to that of DOTA-GlyGlu-CycMSH.

The structural change did not sacrifice the nanomolar binding affinity of Ac-GluGlu-CycMSH[DOTA] compared to DOTA-GlyGlu-CycMSH. Ac-GluGlu-CycMSH[DOTA] displayed 0.6 nM receptor binding affinity in B16/F1 cells, which was similar to that of DOTA-GlyGlu-CycMSH (0.8 nM). Ac-GluGlu-CycMSH[DOTA]-^{111}In exhibited rapid cellular internalization and extended cellular retention in B16/F1 cells (Figure 5), making Ac-GluGlu-CycMSH[DOTA]-^{111}In suitable for melanoma imaging. The shift of DOTA from the N-terminus toward the lactam bridge-cyclic ring did increase the melanoma uptake and retention. The tumor uptake values of Ac-GluGlu-CycMSH[DOTA]-^{111}In were 1.1, 1.3, and 1.5 times the tumor uptake values of ^{111}In-DOTA-GlyGlu-CycMSH 2, 4, and 24 h postinjection, respectively (*20*). Compared to the linear α-MSH peptide ^{111}In-DOTA-NAPamide, Ac-GluGlu-CycMSH[DOTA]-^{111}In exhibited 24.6% and 56.9% higher tumor uptake values 4 and 24 h postinjection, respectively. Flank melanoma tumors were clearly visualized by SPECT/CT using Ac-GluGlu-CycMSH[DOTA]-^{111}In as an imaging probe at 2 h postinjection (Figure 6). The SPECT imaging of tumors accurately matched the anatomical information from CT images. Ac-GluGlu-CycMSH[DOTA]-^{111}In displayed high tumor to normal organ uptake ratios except for the kidney. The high receptor-mediated tumor uptake and tumor to normal organ uptake ratios highlighted the potential of radiolabeled lactam bridge-cyclized α-MSH peptides as a novel class of peptide radiopharmaceuticals for melanoma imaging.

The liver uptake values of Ac-GluGlu-CycMSH[DOTA]-^{111}In were 3.8, 6.1, and 4.2 times the liver uptake values of ^{111}In-DOTA-GlyGlu-CycMSH 2, 4, and 24 h postinjection, respectively. The higher liver uptakes of Ac-GluGlu-CycMSH[DOTA]-^{111}In were likely due to its higher lipophilicity. Under the same HPLC gradient, Ac-GluGlu-CycMSH[DOTA]-^{111}In was washed out of the C18 analytical column later than ^{111}In-DOTA-GlyGlu-CycMSH. As shown in biodistribution results (Table 1) and SPECT/CT image (Figure 6), Ac-GluGlu-CycMSH[DOTA]-^{111}In was primarily excreted through the kidneys. Surprisingly, the renal uptake values of Ac-GluGlu-CycMSH[DOTA]-^{111}In were 4.6, 5.5, and 2.3 times the renal uptake values of ^{111}In-DOTA-GlyGlu-CycMSH 2, 4, and 24 h postinjection, respectively (*20*). The strategy of infusing basic amino acid such as lysine has been successfully employed to decrease the renal uptakes of radiolabeled metal-cyclized α-MSH peptides by shielding the electrostatic interaction between positively charged peptides and negatively charged surface of tubule cells (*5, 17, 22*). Therefore, 15 mg of L-lysine was co-injected with Ac-GluGlu-CycMSH[DOTA]-^{111}In to examine its effect in reducing the renal uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In. As we anticipated, co-injection of L-lysine dramatically reduced the renal uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In by 70% ($p < 0.05$) 2 h postinjection, demonstrating that the electrostatic interaction played a key role in the nonspecific renal uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In. The urine analysis showed that Ac-GluGlu-CycMSH[DOTA]-^{111}In was metabolized into two moieties that might be responsible for the activity retention in kidneys. Another way to decrease the renal uptake of the radiolabeled α-MSH peptide is to increase the overall negative charge of the peptide by introducing a negatively charged aspartic acid or glutamic acid into the peptide sequence. Introduction of a glutamic acid as a linker has successfully reduced the renal uptake values of ^{111}In-DOTA-GlyGlu-CycMSH by 44% compared to ^{111}In-DOTA-CycMSH {^{111}In-DOTA-c[Lys-Nle-Glu-His-DPhe-Arg-Trp-Gly-Arg-Pro-Val-Asp]} (*20*). Since we have demonstrated that shielding the electrostatic interaction dramatically reduced the renal uptake of Ac-GluGlu-CycMSH[DOTA]-^{111}In, it is likely that introducing a negatively charged amino acid between the DOTA and Lys in Ac-GluGlu-CycMSH[DOTA]-^{111}In will decrease the nonspecific renal uptake. Further decrease of the renal uptake will facilitate the

potential applications of radiolabeled lactam bridge-cyclized α-MSH peptides for melanoma imaging and therapy.

A potential application of this MC1 receptor-targeting peptide construct is to develop melanoma-specific dual-modality imaging agents. As demonstrated in this study and our previous work (*20*), no matter that the DOTA chelator was coupled to the N-terminus of ^{111}In-DOTA-GlyGlu-CycMSH or to the amino group of Lys in Ac-GluGlu-CycMSH[DOTA]-^{111}In, both ^{111}In-conjugates maintained high MC1 receptor binding affinities *in vitro* and *in vivo*. These results indicated that both amino groups at the N-terminus and at the Lys in the lactam bridge-cyclized peptide ring could be used to attach two different imaging tags for dual-modality imaging. For instance, both optical tag and radionuclide could be attached to the same lactam bridge-cyclized α-MSH peptide simultaneously to yield a dual-modality imaging peptide. The development of dual-modality imaging peptide would provide a robust imaging tool combining the advantages of both optical imaging and radioimaging for melanoma detection.

In conclusion, the shift of DOTA from the N-terminus toward the lactam bridge-cyclic ring increased the melanoma uptake and retention. DOTA position exhibited a profound effect on melanoma targeting and pharmacokinetic properties of Ac-GluGlu-CycMSH[DOTA]-^{111}In, providing new insight into the design of lactam bridge-cyclized peptide for melanoma imaging and therapy.

Received August 6, 2009; Revised Manuscript Received September 16, 2009

There is a need to synthesize new gene delivery vehicles that can deal with the problems of endosomal escape and nuclear entry. We propose cationic glycopolymer-stabilized gold nanoparticles as an effective gene delivery system. The cationic glyconanoparticles synthesized were revealed to be biocompatible and are resistant to aggregation in physiological conditions. The complexation of DNA to the cationic glyconanoparticles is determined by agarose gel electrophoresis. The localization of the DNA-glyconanoparticles inside the Hela cell line and their mechanism of uptake is studied by confocal microscopy. Finally, the efficacy of the glyconanoparticles as gene delivery vehicles *in vitro* is studied by their complexation with cyanine fluorescence protein encoded plasmid, and the transfection efficiency is found to be comparable to the commercially available control Lipofectamine 2000.

INTRODUCTION

Safety issues associated with viral gene delivery vehicles have led to the popularization of a variety of nonviral gene delivery vehicles, such as liposomes, cationic polymers, nanoparticles, and dendrimers (*1*−*10*). Another approach recommends the use of hybrid viral vehicles that are shown to produce high efficacy *in vitro*; however, the safety concerns associated with them cannot be ignored (*11*). In nonviral gene delivery vehicles, compared to those of lipoplex systems, polyplex-based ones can effectively promote vesicular escape and nuclear entry (*12, 13*). Polyethylenimine (PEI), despite its high toxicity, has been largely utilized as an effective gene delivery vehicle (*1*). Chitosan, a glucosamine-based polymer, is completely nontoxic and shows relatively low transfection efficiencies (*1*). The different chitosan modification approaches, including PEGylation and amination, have been reported to overcome the issues of gene delivery associated with these vectors (*1*). Reineke et al. has combined the high transfection abilities of PEI with low toxicity of chitosan, by synthesizing cationic glycopolymers of defined molecular weight, which show enhanced gene transfer ability with reduced toxicity (*14*). It has also been demonstrated that cationic polymer coated metallic nanoparticle-DNA complexes show enhanced gene transfer ability due to better DNA binding ability and increased stability in physiological conditions than their corresponding polyplexes (*15*−*17*). Although various macromolecule stabilized gold nanoparticles have been synthesized and their biological and chemical properties are reported (*18*−*22*), only a handful of papers discuss the *in vitro* uses of cationic gold nanoparticles as gene delivery systems (*7, 8, 17, 23, 24*). The use of gold nanoparticles as gene delivery vehicles is either facilitated by external forces or associated with significantly low transfection efficiencies, due to the possible entrapment of PEG-modified vehicles inside the endosomes (*7, 8*). Carbohydrate functionalized gold nanoparticles, also known as glyconanoparticles, are not only interesting due to their PEG-like biocompatibility, but are also found to be involved in cell-mediated interactions (*25*−*27*). The aforementioned strategies when combined can produce monodisperse, biocompatible, cationic glyconanoparticles as gene delivery vehicles that can enhance the cellular uptake by cell mediated interactions and lack the drawbacks of PEG stabilized vehicles, thus promoting higher transfection efficiencies (*3, 4, 28*). We have previously reported the comparison between transfection efficiencies of cationic glyconanoparticles of different core sizes (*29*). However, a complete study on the synthesis of cationic glyconanparticles prepared by UV radiation, their size control as a function of ligand concentrations and UV light intensity, and their mechanism of interactions with living cells has not yet been reported in detail (*29*).

Herein, we report a facile one-step synthesis of cationic glyconanoparticles as an effective gene delivery system. Well-defined cationic glycopolymers were first synthesized by the reversible addition−fragmentation chain transfer (RAFT) process and their cytotoxicity was determined. The cationic glyconanoparticles were then produced in one step using UV radiation (Scheme 1).

Photoirradiation process for the synthesis of unprotected gold nanoparticles, introduced by Scaiano et al., has been widely investigated (*30*−*32*). We have successfully synthesized the mixed monolayer stabilized gold nanoparticles using this technique (*31, 32*). The synthesis of cationic gold nanoparticles is achieved using the photoinitiator, Irgacure-2959, and the effect of concentration of glycopolymer and of the intensity of radiation on the size and polydispersity of nanoparticles is studied. The monodisperse cationic gold nanoparticles produced are further complexed with fluorescence-labeled oligonucleotides, and the confocal microscopy is performed to study the

mechanism of uptake of novel gene carrier and their colocalization in human cells. The pECFP plasmid is complexed with the cationic gold nanoparticles, and agarose gel electrophoresis is performed to determine the net charge on the surface of nanoparticles−plasmid complex. Finally, the transfection efficiency of the carrier with net positive charge is demonstrated in Hela cells, and it is found that cationic glyconanoparticles exhibit high transfection efficiencies with significantly low toxicity.

MATERIALS AND METHODS

Materials. All chemicals were purchased from Sigma-Aldrich and were used without purification.

Methods. *Polymer Characterization.* ^{1}H NMR spectra of the monomers and polymers were recorded on a Varian 200 MHz instrument.

Molecular weight and molecular weight distributions were determined by a conventional Viscotek gel permeation chromatography (GPC) system using aqueous eluents, two Waters WAT011545 columns at room temperature, and a flow rate of 1.0 mL/min using a 0.5 M sodium acetate/0.5 M acetic acid buffer as eluent. p(APMA) was characterized based on six near-monodisperse PEO standards (M_p = 1010−101 200 g mol^{-1}). p(APMA-*b*-GAPMA) was characterized based on seven near-monodisperse Pullulan standards (M_w = 5900−404 000 g mol^{-1}).

Dynamic Light Scattering (DLS). Dynamic light scattering measurements were performed at room temperature using a Viscotek DLS instrument having a He−Ne laser at a wavelength of 632 nm and Pelltier temperature controller. p(APMA-*b*-GAPMA) stabilized gold nanoparticle solutions were filtered through Millipore membranes (0.45 μm pore size). The data were recorded with Omni Size Software.

UV−vis Spectroscopy. UV−vis absorption spectra (400−800 nm) were recorded on a Cary UV 100 spectrophotometer from the aqueous solutions of p(APMA-*b*-GAPMA) gold nanoparticles at room temperature.

Confocal Microscopy. The fluorescent images were obtained using Zeiss LSM 510 Meta confocal microscope with 63× objective. The wavelengths of excitation and emission used were 552 and 575 nm, respectively.

Plasmid Preparation and Purification. pECFP-N1, enhanced cyan fluorescent plasmid driven by cytomegalovirus (CMV) promoter, was transformed in super competent *E. coli* cells and was amplified in 30 μg/mL Kanmycin containing LB broth media at 37 °C overnight with 225 rpm. After sufficient bacterial growth, the cells were pelleted by centrifugation at 2000*g* and 20 °C for 5 min followed by plasmid extraction using QIAGEN mini plasmid purification kit as per vendor's protocol. Plasmid purity was assessed by UV spectrophotometry ($A_{260/280}$ > 1.75) and agarose gel electrophoresis.

Block Copolymerization of APMA with GAPMA. *Diblock Copolymerization of 3-Aminopropyl Methacrylamide Hydrochloride (APMA) with 3-Gluconamidopropyl Methacrylamide (GAPMA) via Reversible Addition−fragmentation Chain Transfer Process (RAFT).* APMA was first polymerized using 4-cyanopentanoic acid dithiobenzoate (CTP) as chain transfer agent (CTA) and 4,4′-azobis(4-cyanovaleric acid) (ACVA) as initiator according to the previous report (*37*). Detail protocol was as follows: in a 10 mL Schlenk flask, APMA (2 g, 11.2 mmol) was dissolved in double distilled water (4 mL) before the addition of 2 mL CTP (52 mg, 0. 186 mmol, target DP_n = 60) and ACVA (16 mg, 0.038 mmol) 1,4-dioxane stock solution. After degassing via three freeze−thaw cycles, the flask was placed in a preheated oil bath to initiate the polymerization at 70 °C. After 3 h 45 min, the polymerization was quenched at 50% conversion. Resulting polymer was precipitated in acetone, and the residual monomer was removed by washing with 2-propanol. Subsequently, poly (APMA) (M_n = 5200 g·mol^{-1}; M_w/M_n = 1.23) was used as macro chain transfer agent (Macro-CTA) to synthesize p(APMA-*b*-GAPMA) diblock copolymer. As the second monomer, GAPMA (0.95 g) was added to p(APMA) solution (0.5 g in 7.5 mL double distilled water) followed by the addition of 0.1 mL ACVA (7.5 mg) *N*,*N*-dimethylformamide (DMF) stock solution. After degassing via three freeze−thaw cycles, the flask was placed in a preheated oil bath for 20 h at 80 °C. The diblock copolymer p(APMA-*b*-GAPMA) was precipitated in acetone followed by washing with methanol.

Synthesis of Block Copolymer Coated Au Nanoparticles in the Presence of Irgacure-2959 (IRGC). p(APMA-*b*-GAPMA) coated gold nanoparticles were synthesized by photoirradiation using Irgacure-2959 (IRGC) as a

photoinitiator. The molar ratios of $HAuCl_4$, IRGC, and p(APMA-*b*-GAPMA) in deionized water were 1:3:0.01, 1:3:0.02, or 1:3:0.05. p(APMA-*b*-GAPMA) with molecular weights 19.9 kDa (2.5 mg), 25 kDa (3.3 mg), were used. In a typical synthesis, required amount of p(APMA-*b*-GAPMA) were dissolved in deionized water and solution was added to $HAuCl_4$ (0.50 mg/mL) solution in deionized water. The mixture was stirred using a magnetic stirrer at room temperature for 20 min. Irgacure-2959 (15.3 mM, 1 mL) was dissolved in the mixture of deionized water and MeOH (4:1, v/v). The initiator solution was then added to the $HAuCl_4$ and p(APMA-*b*-GAPMA) mixture was stirred for 20 min. The photoirradiation of the reaction mixture was carried out using sixteen, twelve, eight, and four 75 W UV lamps at wavelength a 300 nm in a Rayonet photoreactor (Southern N.E. Ultraviolet Co.) After 5 min, the reaction mixture was taken off the photoreactor and stirred at room temperature. The gold nanoparticles produced were centrifuged at 20 000 rpm for 2 h to remove the excess of polymer. The pellet was resuspended in deionized water.

Serum Assay. The cationic glycopolymer stabilized gold nanoparticles of size 6 nm were resuspended in deionized water, phosphate buffer saline, and 10% v/v human serum separately to achieve the final concentration of 2.5 μM in each solution. Then, the change in size of gold nanoparticles was measured by UV−vis spectroscopy in the wavelength range 400−700 nm and by dynamic light scattering instrument.

DNA Complexation. DNA complexation of gold nanoparticles was studied using agarose gel electrophoresis. The varying concentrations of gold nanoparticles (45, 89, 139, 196 μM) were complexed with 340 ng of pECFP-N1 plasmid and the complexes were loaded into 0.7% agarose gel. The gel was run for 1 h at 70 V, and the complexes were characterized after staining the gel with 0.5 μg/mL of ethidium bromide. The images were obtained on an ultraviolet transilluminator.

Confocal Microscopy. Hela cells were grown in Dulbecco's modified eagle medium, DMEM containing 10% fetal bovine serum, and 1% penicillin/streptomycin in a humidified atmosphere with 5% CO_2 at 37 °C. Upon 80% confluency, cells were trypsinized and neutralized with equal amounts of medium. The cells were then reseeded in a 6 well plate, in which each well contained sterile glass coverslips. The plate was incubated in humidified atmosphere at 37 °C, and upon 80% confluency, 1.3 mM nanoparticles complexed with 1.1 μM TAMARA dye labeled oligonucleotides containing medium were introduced in chambered cover glass. The other two wells served as controls, containing no treatment and 1.1 μM TAMARA labeled oligonucleotides in the medium, respectively. The cells were further incubated for 3 h at 37 °C. The growth medium was then removed, and cells were washed several times with phosphate buffer saline. The cells were fixed with 4% *p*-formaldehyde solution at room temperature for 5 min, followed by washing with Dulbecco's phosphate buffer saline (DPBS). The cover glass was then mounted on a microscopic glass slide and was studied under the microscope.

Mechanism of Uptake of Gold Nanoparticles by Human Cell Line. *Temperature Dependent Uptake of Gold Nanoparticles.* The energy dependent uptake of TAMARA labeled gold nanoparticles was studied using the same procedure as described before (*35*). In summary, the cells were seeded in 6 well plates, containing glass coverslips. The plate was incubated in humidified atmosphere at 37 °C for 24 h. The medium was removed and was replaced with 9.5 μM nanoparticles complexed with 1.1 μM TAMARA labeled oligonucleotides containing medium. The plate was then incubated for 3 h at 4 °C. The cells were then washed several times with DPBS and fixed with 4% *p*-formaldehyde. The coverslip was then finally washed with DPBS and was mounted on microscopic glass slide. The glass slide was studied under confocal microscope.

Clathrin Dependent Uptake of Gold Nanoparticles. Hela cells were seeded in 6 well plates as described above; upon 80% confluency, the cells were pretreated with 0.45 M sucrose containing medium for 30 min at 37 °C. The medium was removed and cells were washed several times with DPBS. The medium containing 9.5 μM nanoparticles complexed with 1.1 μM TAMARA labeled oligonucleotides was added and cell were further incubated for 3 h. The cells were washed with DPBS and fixed with *p*-formaldehyde. The coverslip was mounted on a microscopic glass slide to study under confocal microscope.

Transfection. Hela cells were maintained in Dulbecco's modified Eagles' medium, supplemented with 10% fetal bovine serum at 37 °C, in a humidified 5% CO_2 atmosphere, as described above. Before the experiment, 2000 Hela cells were seeded on a 96 well tissue culture plate and were allowed to adhere overnight. The test samples were prepared for each well by mixing 0.35 μg of CFP plasmid with varying amounts of cationic gold nanoparticles. The mixture was incubated for 15 min and was added to the cells; the plate was incubated for 6 h at 37 °C, in serum free medium. The cells were washed three times with DPBS and were allowed to grow for another 48 h in fresh culture medium supplemented with 10% FBS. The gene expression was evaluated using fluorescent microscopy. The presence of CFP protein was confirmed using the emission spectrum of cyanine fluorescence protein at 490 nm.

Toxicity Assays. *Toxicity Assay for Glycopolymer. 1. Preparation of Polymer Stock Solutions.* All polymers were dissolved into Dulbecco's phosphate buffer at the final concentration of 0.6 mM. The samples were autoclaved, and different volumes of prepared solution were added into different volumes of DMEM medium to obtain the final concentrations of 2, 4, and 6 μM concentration of polymer in the medium.

2. Cytotoxicity Test. Cytotoxicity was characterized using MTT assay. Hela cells were plated in 96 well plates at density of 15 000 cells/well in 100 μL of serum and antibiotic supplemented growth medium. Cells were incubated for 24 h at 37 °C and 5% CO_2, after which time the growth medium was replaced with DMEM medium containing different concentrations of polymers, prepared above (pAPMA) and p(APMA-*b*-GAPMA). The cells were further incubated for 24 h under the same conditions, after which 25 μL of MTT dye was added to each well and plate was incubated for 2 h. Next, 100 μL of MTT lysis solution was added to each well, and cells were incubated overnight. Absorbance was measured at 570 nm. Survival percentage was calculated by comparison to untreated cells (100% survival).

Toxicity Assay on Transfected Cells. Hela cells maintained at 80% confluency were seeded at 2000 cells/well in 96 well plate and were allowed to adhere overnight. The varying concentrations of gold nanoparticle−plasmid complex in serum free medium were added to each well, and each experiment was done in triplicate. After 6 h, the medium was changed to serum containing medium, and cells were allowed to grow for another 48 h. The cell viability was tested using MTT assay, as described above.

RESULTS AND DISCUSSION

The carbohydrate molecules present on the surface of cells are involved in a variety of biological functions, including cellular recognition, cell adhesion, and cell growth regulation. The polyvalent interactions between carbohydrate−carbohydrate molecules and carbohydrate−protein molecules on the surface of a pathogen lead to their uptake by a living cell (*25*−*27*). These specific carbohydrate based cellular interactions can be exploited to design novel carriers for the gene and drug delivery purposes. A variety of protein and peptide stabilized nanopar-

ticles have been reported and their uptake by human cells is studied (*12, 17*). The studies have also shown that endosomal entrapment is also a major hindrance in the success of other gene delivery vehicles (*10*). The synthesis of cationic glyconanoparticles of 10 nm core diameter using cationic glycopolymer p($APMA_{31}$-*b*-$LAEMA_{32}$), has been previously reported (*29*); herein, we present a detailed study of the synthesis of cationic glycopolymer stabilized gold nanoparticles, using cationic glycopolymer p(APMA-*b*-GAPMA) of different molecular weights by photochemistry. The gold nanoparticles produced are stabilized with the diblock cationic glycopolymer p($APMA_{31}$-*b*-$GAPMA_{45}$) that serves a variety of purposes. The glycopolymer segment imparts the biocompatibility and mediates the cellular interactions with nanoparticles, while the cationic moiety provides the complexation of anionic macromolecules on the surfaces of nanoparticles. The synthesized cationic glycopolymer p(APMA-*b*-GAPMA) in this study has molar masses of 19.9 and 25.3 kDa with narrow molecular weight distributions ($M_w/M_n < 1.30$) (see Supporting Information Table S1 and Figure S1). In contrast to APMA homopolymer, cell viability studies revealed that the obtained sugar-containing diblock copolymer, p($APMA_{31}$-*b*-$GAPMA_{45}$), shows dramatically reduced toxicity at comparable polymer concentrations (see Supporting Information Figure S2). It is shown that toxicity of the block copolymer can be reduced up to 80%, as compared to that of PAPMA= APMA homopolymer. The cationic glycopolymers were subsequently used in the stabilization of gold nanoparticles. Monodisperse cationic glyconanoparticles were prepared *in situ* by the photoirradiation using Irgacure 2959 as photoinitiator. The photochemical approach for the synthesis of gold nanoparticles was first reported by Scaiano et al., and this method is extensively investigated in our group for both polymer and protein stabilized gold nanoparticles (*30*−*32*). The synthesized glyconanoparticles are stabilized by the primary amine pendant groups of the cationic glycopolymer, and therefore, they are expected to be more stable than thiol-stabilized gold nanoparticles due to the oxidative instability of the latter in physiological conditions (*33*). A recent study reports the physiochemical properties of gold nanoparticles stabilized by tertiary amines; however, detailed *in vitro* studies for this kind of nanoparticles are still to be investigated (*33*). The gold nanoparticles were synthesized using varying concentrations of polymer and UV radiation in an effort to achieve near-monodisperse cationic glyconanoparticles.

The results obtained by DLS indicated that the optimization of both parameters UV intensity and polymer concentration in solution are crucial to yield monodisperse nanoparticles of about 10 nm in diameter, as shown in Tables 1 and 2.

The gold nanoparticles produced were further analyzed by TEM and UV−vis spectroscopy to confirm the monodispersity of nanoparticles and to further support the DLS data obtained above (Figure 1; Supporting Information Figures S3, S4, S5). It can be seen that no shift in UV−vis spectrum was observed for the gold nanoparticles produced under different conditions, indicating that nanoparticles produced are of about the same size. TEM images obtained further confirmed the presence of nanoparticles of about 10 nm diameter.

The synthesis of gold nanoparticles was achieved with glycopolymers of molar masses of 19.9 and 25.3 kDa; however, no change in the size of nanoparticles as a function of molecular weight of polymer was observed, possibly due to the small difference in the molecular weight of the two polymers used (Supporting Information Table S3).

The cationic nanoparticles synthesized for *in vitro* gene delivery purposes not only are toxic, but also exhibit the aggregation tendency in biological fluids, due to the interaction of cationic moiety with serum proteins (*1*). Despite the drawbacks associated with PEGylated systems, the biocompatibility and stabilization of nanoparticles in biological fluid is usually obtained by the incorporation of a PEG layer (*1*). The cationic glyconanoparticles synthesized were studied for their stability in physiological conditions using DLS and UV−vis spectroscopy. The UV−vis spectrum shows that there is no shift in the spectrum of cationic glyconanoparticles, before and after their dispersion in saline solution and in serum indicating the stability of gold nanoparticles under physiological conditions. These results are in agreement with previously reported serum assay characterization of gold nanoparticles stabilized by cationic glycopolymer p(APMA-*b*-LAEMA), indicating that regardless of the type of glycopolymer moiety, it is the characteristic of cationic glyconanoparticles to maintain their dispersibility in physiological conditions (*29*). The quantitative results are then obtained by determining the size of gold nanoparticles before and after their dispersion in saline solution and in human serum by DLS, which show that there is no change in the size of gold nanoparticles before and after their dispersion in saline and in serum (Figure 1 and Supporting Information Table S4).

The study of uptake of cationic glyconanoparticles by Hela cells was performed using confocal microscopy. The TAMARA dye labeled oligonucleotides were complexed with slight excess of p($APMA_{31}$-*b*-$GAPMA_{45}$)-*f*-gold nanoparticles, to ensure the complete complexation of oligonucleotides and the complexes were incubated with Hela cells. The untreated Hela cells and TAMARA labeled oligonucleotides treated Hela cells were used as control (Figure 2).

It is apparent by confocal images that, although most of the nanoparticles seem to localize in the cytoplasm of the cells, few glyconanoparticles can be found entrapped in the endosomes (Figure 2, Supporting Information Figure S6). The presence of some of the nanoparticles in the endosomes of cells can be explained by the fact that the complexation of oligonucleotides with cationic glyconanoparticles is based upon electrostatic interactions. Although most oligos-modified-glyconanoparticles are positively charged due to slight excess of gold nanoparticles in the experiment, a few neutral complexes may form during the process, thus causing their entrapment in endosomes. The enhanced fluorescence images of oligonucleotide-labeled-glyconanoparticle incubated cells, compared to that of controls, confirm that the gene delivery vehicle successfully prevents oligonucleotides from degradation by cytosolic enzymes, even after 3 h of incubation inside the cell. The vesicular escape of

4	5.1×10^{-6}	1:3:0.005	224	5	3.3	0.17
5	5.1×10^{-6}	1:3:0.005	168	5	4.56	0.10
6	5.1×10^{-6}	1:3:0.005	112	5	4.85	0.11
7	5.1×10^{-6}	1:3:0.005	56	15	4.73	0.10

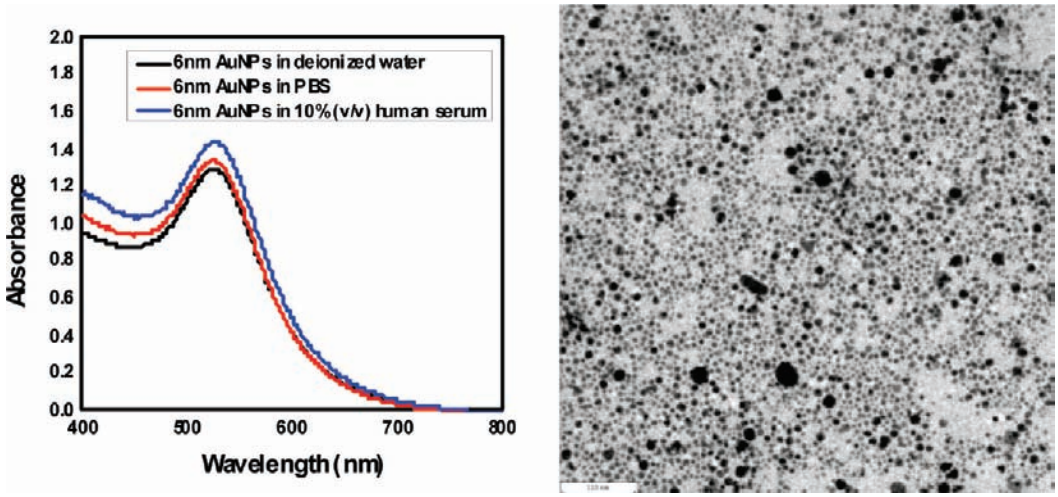

Figure 1. Dispersion of 2.5 μM gold nanoparticles in 10% v/v human serum. TEM micrograph (scale bar − 110 nm) of block copolymer p($APMA_{31}$-*b*-$GAPMA_{45}$) stabilized gold nanoparticles (entry-1).

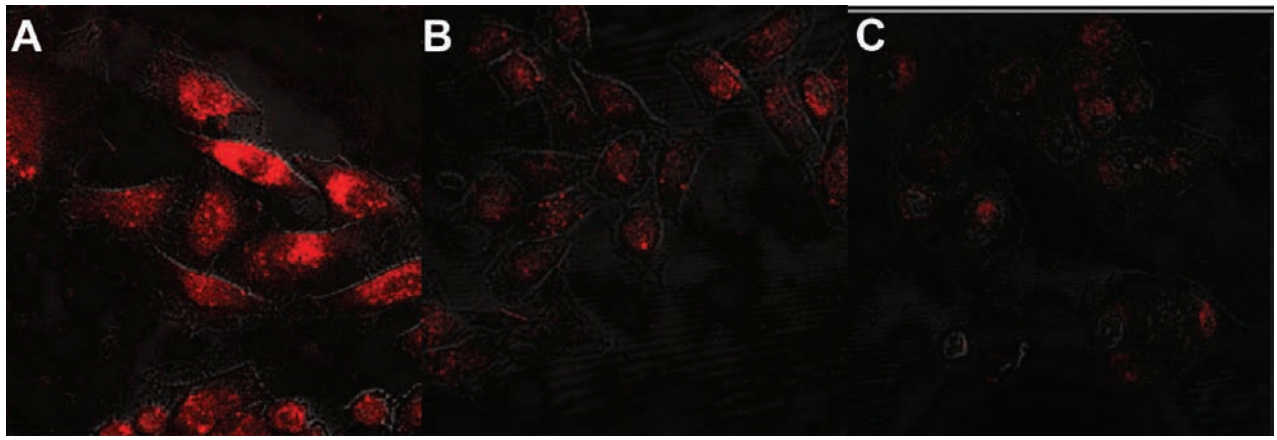

Figure 2. Confocal microscopy images of Hela cells labeled with (A) oligonucleotides complexed p($APMA_{31}$-*b*-$GAPMA_{45}$)-*f*-gold nanoparticles (entry-2), (B) oligonucleotides, and (C) no treatment.

gene delivery vehicle is apparent by the localization of glyconanoparticles inside the cytoplasm.

The mechanism of uptake of gene delivery carrier is a topic of interest to explore the possible routes adopted by the successful gene delivery vehicles. Funete et al. has compared the interaction of different carbohydrate monomers to the cell surface (*27*). It has been found that glucose modified glyconanoparticles are not endocytosed (*27*). The presence of cationic character, in combination with sugar residues, is expected to alter the mechanism of uptake of gold nanoparticles by cells (*1*). The mechanism of uptake of p($APMA_{31}$-*b*-$GAPMA_{45}$)-*f*-gold nanoparticles was studied in detail by exploiting energy dependent process of uptake by living cells and it was found that Hela cells at 4 °C show minimal or no uptake of synthesized nanoparticles, thus indicating that the uptake involves energy dependent processes. To further confirm that the lower uptake of nanoparticles observed at lower temperatures is not due to the physiological malfunctioning of the cells, as the presence of vacuoles in cells treated at lower temperatures is observed, the process was further investigated after the treatment of cells with hypertonic solution at 37 °C (*35*). The same fluorescently labeled gold nanoparticles were incubated with pretreated cells under the same conditions and the confocal images were obtained. The images show the minimum uptake of gold nanoparticles by Hela cell after the treatment with hypertonic medium compared to oligonucleotide-modified glyconanoparticle treated cells under normal conditions (Figure 3 and Supporting Information Figure S6).

The *z*-section images of cells taken from confocal microscope confirm that most of the nanoparticles though can associate themselves around the periphery of cells; they are not endocytosed (see Supporting Information Figure S7). Although a slight change in shape of some of the cells after treatment with hypertonic medium is seen, most of the cells maintain their physiological appearance. It is clear from the figure that cationic glyconanoparticles are capable of cellular interactions in the presence of endocytosis inhibitor, but they are not endocytosed. The cellular attachment of cationic glyconanoparticles can either be considered as a function of glycopolymer interactions to the glycoproteins of plasma membrane, or cationic segments of the nanoparticles can successfully mediate electrostatic interactions with anionic cell membrane. Thus, it can be concluded that the major route of uptake of nanoparticles is found to be receptor mediated endocytosis. It has been reported that uptake of polymer-DNA complexes by receptor mediated endocytosis leads to successful gene delivery (*1*). The major issue in this regard is the entrapment of gene delivery scaffold in the endocytic vesicles after their successful uptake (*1*). The localization of most of the nanoparticles in cytosol confirms that glyconanoparticles with net cationic character can successfully disrupt the endocytic vesicles, leading to the release of nanoparticles in the cytoplasm. This is one step forward toward the synthesis of gene delivery vehicles, where some recent works report the localization of vehicles inside the endosomes (*4, 36*).

The role of cationic glyconanoparticles as a novel gene delivery carrier was explored. The cyanine fluorescence protein-

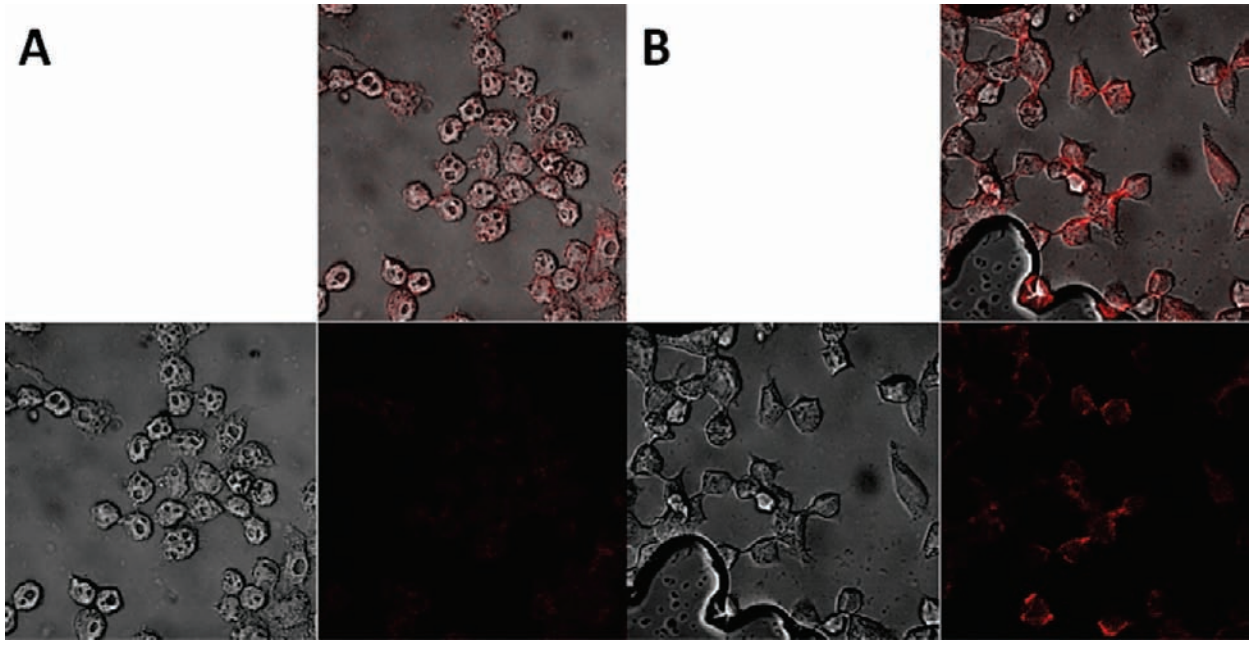

Figure 3. Confocal microscopy images of Hela cells incubated at (A) 4 °C, labeled with oligonucleotide-complexed gold nanoparticles stabilized with p($APMA_{31}$-*b*-$GAPMA_{45}$) (entry-2), (B) Hela cells pretreated with 0.45 M sucrose and incubated with oligonucleotide-complexed gold nanoparticles stabilized with p($APMA_{31}$-*b*-$GAPMA_{45}$) at 37 °C.

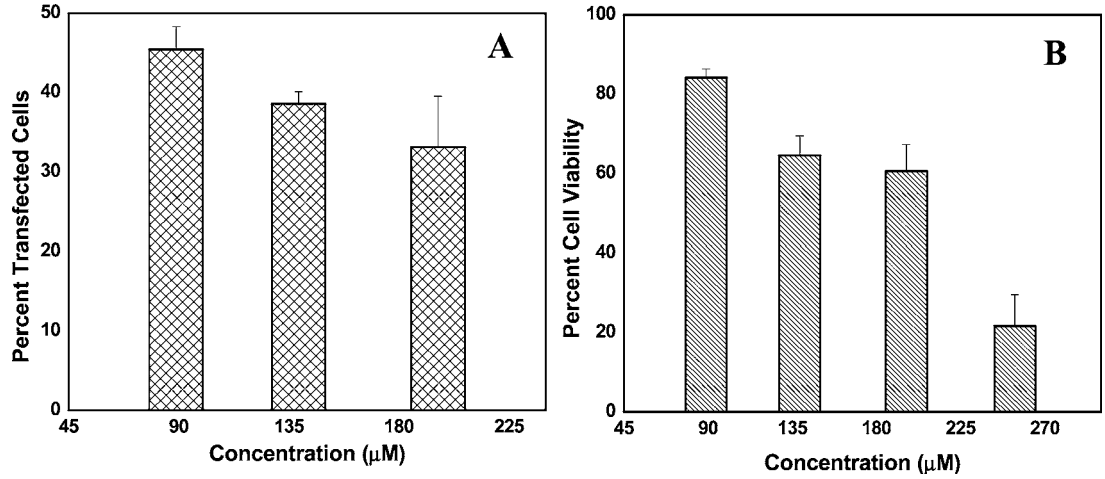

Figure 4. The gene transfection efficiencies and cell viability values of Hela cells upon treatment with cationic glyconanoparticle−plasmid complex. (A) Transfection efficiencies of p($APMA_{31}$-*b*-$GAPMA_{45}$)-*f*-gold nanoparticles in Hela cells upon their incubation with ECFP plasmid-nanoparticle complex at 37 °C. (B) Normalized viability of Hela cells transfected with glyconanoparticles−plasmid complex, determined by MTT assay (entry-1).

encoded DNA plasmid (pECFP-N1) was used to study the DNA complexation with the cationic glyconanoparticles by agarose gel electrophoresis. The plasmid is incubated with varying concentrations of p($APMA_{31}$-*b*-$GAPMA_{45}$)-*f*-gold nanoparticles, and it is found that the complete complexation of plasmid is obtained upon incubation with 89 μM gold nanoparticles (see Supporting Information Figures S8 and S9). The migration of complex was completely retarded upon incubation of the plasmid with 89 μM concentration of gold nanoparticles; it can be safely assumed that nanoparticle−plasmid complexes maintain their net cationic character, thus are able to mediate vesicular escape and are resistant to aggregation in physiological conditions.

Finally, the transfection experiments were performed to determine the efficacy of gold nanoparticles *in vitro*. The use of polyplex based nanomaterials for gene delivery purposes is a rapidly advancing field in gene therapy (*38*−*40*). Polymer stabilized metallic nanoparticles have also been employed for gene delivery purposes, and gold, due to its inert nature, is one of the most commonly used metals for this purpose (*41*). Sandhu et al. have reported the relatively high transfection efficiencies *in vitro* by using amphiphilic gold nanoparticles. However, the process was facilitated with chloroquine, and no cytotoxicity data were provided (*7*). Others describe significantly low transfection efficiencies of comparatively biocompatible gold nanoparticles based gene delivery scaffolds (*8*). Wang et al. have reported the transfection efficiency of cyclodextrin modified gold nanoparticles complexed with green fluorescence encoded protein (pEGFP) plasmid in MCF-7 cells. The gene delivery carrier is reported to be 100% cell viable at various N/P ratios; however, the maximum transfection efficiencies obtained are reported to be less than 10% (*8*). The study of transfection efficiencies of glyconanoparticles of different core sizes has shown that, regardless of the net negative charge on the surface of the complex, gold nanoparticles of 40 nm in core diameter show the highest gene transfection ability compared to the other

sizes of glyconanoparticles. The gold nanoparticles in the study were surface functionalized with cationic glycopolymer p(APMA$_{31}$-*b*-LAEMA$_{32}$) (*29*). Herein, we report the transfection efficiencies of biocompatible nanoparticles using cationic glycopolymer p(APMA$_{31}$-*b*-GAPMA$_{45}$). The transfection experiments were performed at various concentrations of gold nanoparticles, and the results indicated that transfection efficiencies were not significant compared to control (plasmid alone) when concentration of gold nanoparticles was less than 89 μM, possibly due to the net anionic character of the nanoparticles−plasmid complex, as determined by agarose gel electrophoresis. The significant transfection efficiencies (45−50%) with low toxicity values (∼85% cell viability) were observed upon the complexation of plasmid with 89 μM gold nanoparticles (Figure 4; see Supporting Information Figure S10).

The improved transfection efficiency of cationic glyconanoparticle−plasmid complexes in the absence of external force is attributed to the net cationic charge of the vehicle, thus leading to successful delivery of gene inside the cells. It should be noted that, despite possessing the same cationic component, the enhanced transfection efficiency of p(APMA-*b*-GAPMA) functionalized gold nanoparticles as compared to p(APMA-*b*-LAEMA) functionalized nanoparticles of the same sizes is attributed to higher glycopolymer component of the polymer (*29*). These results are in agreement with previous studies, which also show that the glycopolymer component of the carrier largely influences the transfection efficiencies (*14*).

As expected, further increase in the cationic character does not affect the transfection efficiency of the vehicle significantly, but does lead to significant toxicity to the cells, due to the presence of excess positive charge. These results are in agreement with the previous data where p(APMA-*b*-LAEMA)-*f*-gold nanoparticles of 10 nm core diameter are shown to exhibit the same behavior (*29*). The transfection efficiencies of novel gene delivery scaffolds were compared to that of commercially available control lipofectamine 2000. The previous experiments showed that lipofectamine can successfully transfect Hela cells and the transfection efficiency was found to be 55−60% with significant toxicity (20% cell viability). Although the transfection efficacy of glyconanoparticles was comparable to that of lipofectamine, the lower toxicity of glyconanoparticles was an obvious preference over the commercially available standard. Thus, the vehicle presents a desired compromise between two major issues: cell viability and transfection efficacy.

CONCLUSION

In short, we describe the facile synthesis of cationic glyconanoparticles using photochemistry. The size and polydispersity of gold nanoparticles were controlled by UV radiation and concentration of cationic glycopolymer. The near-monodisperse cationic glyconanoparticles produced were found to be resistant to aggregation in physiological conditions. The mechanism of uptake of this novel gene delivery vehicle was studied, and it was found that cationic nanoparticles produced undergo receptor mediated endocytosis following their vesicular escape, due to the net cationic character of the nanoparticles. Finally, the cationic nanoparticles were complexed with reported plasmid, and their transfection efficacy was determined. The results suggest that biocompatibility of nanoparticles and their easy uptake by cells followed by vesicular escape and nuclear entry, in the absence of external impulse, prove the successful fabrication of a novel type of gene delivery vehicle.

ACKNOWLEDGMENT

The author would like to thank Natural Sciences and Engineering Research Council of Canada for financial support of this research work.

Table S1. Summary of synthetic parameters for the RAFT copolymerization of APMA to GAPMA

Copolymer Type	Homopolymer[a]		Copolymer[b]	
	M_n	M_w/M_n	M_n	M_w/M_n
Poly($APMA_{45}$-*b*-$GAPMA_{54}$)	8,000	1.12	25,300	1.55
Poly($APMA_{31}$-*b*-$GAPMA_{45}$)	5,500	1.09	19,900	1.27

The evolution of the molecular weight with time for the polymerizations were studied with a conventional Viscotek GPC system using a 0.5 M sodium acetate / 0.5 M acetic acid buffer as eluent, two Waters WAT011545 columns at room temperature and a flow rate of 1.0 mL/min.

[a] Six near-monodisperse PEO standards (M_p = 1,010 - 101,200 g mol^{-1}) were used for calibration.

[b] Seven near-monodisperse Pullulan standards (M_w = 5,900 - 404,000 g mol^{-1}) were used for calibration.

The composition of the polymer p($APMA_{31}$-b-$GAPMA_{45}$) calculated by ^{1}H NMR

Dual-Modality Molecular Imaging Using Antibodies Labeled with Activatable Fluorescence and a Radionuclide for Specific and Quantitative Targeted Cancer Detection

Mikako Ogawa, Celeste A. S. Regino, Jurgen Seidel, Michael V. Green, Wenze Xi, Mark Williams, Nobuyuki Kosaka, Peter L. Choyke, and Hisataka Kobayashi*

Molecular Imaging Program, Center for Cancer Research, National Cancer Institute, National Institute of Health. Received August 13, 2009; Revised Manuscript Received September 21, 2009

Multimodality molecular imaging should have potential for compensating the disadvantages and enhancing the advantages of each modality. Nuclear imaging is superior to optical imaging in whole body imaging and in quantification due to good tissue penetration of γ rays. However, target specificity can be compromised by high background signal due to the always signal ON feature of nuclear probes. In contrast, optical imaging can be superior in target-specific imaging by employing target-specific signal activation systems, although it is not quantitative because of signal attenuation. In this study, to take advantage of the mutual cooperation of each modality, multimodality imaging was performed by a combination of quantitative radiolabeled probe and an activatable optical probe. The monoclonal antibodies, panitumumab (anti-HER1) and trastuzumab (anti-HER2), were labeled with ^{111}In and ICG and tested in both HER1 and HER2 tumor bearing mice by the cocktail injection of radiolabeled and optical probes and by the single injection of a dual-labeled probe. The optical and nuclear images were obtained over 6 days after the conjugates injection. The fluorescence activation properties of ICG labeled antibodies were also investigated by *in vitro* microscopy. *In vitro* microscopy demonstrated that there was no fluorescence signal with either panitumumab-ICG or trastuzumab-ICG, when the probes were bound to cell surface antigens but were not yet internalized. After the conjugates were internalized into the cells, both conjugates showed bright fluorescence signal only in the target cells. These results show that both conjugates work as activatable probes. In *in vivo* multimodality imaging by injection of a cocktail of radio-optical probes, only the target specific tumor was visualized by optical imaging. Meanwhile, the biodistribution profile of the injected antibody was provided by nuclear imaging. Similar results were obtained with radio and optical dual-labeled probes, and it is confirmed that pharmacokinetic properties did not affect the results above. Here, we could characterize the molecular targets by activatable optical probes and visualize the delivery of targeting molecules quantitatively by radioactive probes. Multimodality molecular imaging combining activatable optical and radioactive probes has great potential for simultaneous visualization, characterization, and measurement of biological processes.

INTRODUCTION

To date, *in vivo* molecular imaging techniques have made great progress due to improvements in imaging technology and the design of novel imaging probes. Several modalities are now utilized for molecular imaging, including nuclear imaging, optical imaging, MRI, and ultrasound (*1*−*3*). On the basis of the physical characteristics of the emitted signals and the signal detection systems, each modality has both advantages and disadvantages. As a result, multimodality imaging should have the potential for overcoming the disadvantages of a single modality by combining the advantages of more than one modality.

Both nuclear imaging and optical imaging have comparably high sensitivities; however, nuclear imaging is superior for quantification due to good tissue penetration of γ-rays and the ability to accurately measure count rate in tissue, which permits whole body quantitative imaging not only in small animals, but also in humans. However, it is impossible to control or "switch off" ionizing radiation *in vivo* because there are no bioavailable materials to quench γ-rays. Therefore, target specificity can be compromised by the high background signals originating from unbound or nonspecifically bound probes due to the "always on" feature of nuclear imaging probes, especially when slow-clearing probes including monoclonal antibodies are employed (*4*, *5*).

In contrast, optical imaging can be superior to nuclear imaging for target specificity because it can employ target-specific activatable systems. In these activatable systems, the fluorescent signal can be quenched by one of several mechanisms, and the quenched signal can subsequently be turned on in particular biological environments such as lowered pH. We and other groups have developed a number of target-specific activatable optical probes using several mechanisms, e.g., FRET-quenching, pH activation, self-quenching, and H-dimer formation (*6*−*13*). The fluorescent signals of these activatable probes are designed to be switched on only in the target cells or tissues. As a result, the background and nonspecific signal is dramatically reduced. However, optical imaging techniques are not quantitative, especially when the object is located deep to the skin because of significant signal attenuation in tissue. Near-infrared (NIR, emission spectra ∼700−850 nm) fluorescence is one of the potential solutions for overcoming this limitation, although the penetration of NIR is still lower than γ-rays (*14*−*16*). Among

the NIR dyes, indocyanine green (ICG) is a fluorescence dye that has long been approved by the FDA for clinical use in retinal angiography and for intraoperative assessment of liver function (*17, 18*). However, ICG-conjugated antibodies were considered not useful for molecular imaging, because all ICG-conjugated antibodies examined in the literature yielded faint fluorescent signals and were not successful even in *in vitro* assays (*19, 20*). Recently, we demonstrated that ICG-conjugated monoclonal antibodies are able to target cells expressing the receptor, during *in vivo* molecular imaging (*21*). The fluorescent signal of an ICG-conjugated monoclonal antibody is quenched when the probe is unbound or located outside of the target cell; however, it activates when the probe is bound and internalized into the target cells. Therefore, an ICG-conjugated antibody can specifically visualize the target tumor with minimal background signal.

In this study, multimodality imaging was performed by the use of a radiolabeled antibody and a target cell-specific activatable NIR fluorescence-labeled antibody. We employed FDA-approved monoclonal antibodies, panitumumab (anti-HER1) and trastuzumab (anti-HER2), as internalizing targeting ligands. These antibodies were labeled with ^{111}In and ICG for radio-optical imaging and tested in both HER1 and HER2 tumor-bearing mice using an injection of a cocktail of radiolabeled and optical antibodies and by the single injection of a dual-labeled antibody.

MATERIALS AND METHODS

Reagents. Panitumumab, a human anti-HER1 antibody, was purchased from AMGEN Inc. (Thousand Oaks, CA). Trastuzumab, a humanized anti-HER-2 antibody, was purchased from Genentech Inc. (South San Francisco, CA). ICG-sulfo-OSu was purchased from Dojindo Molecular Technologies (Rockville, MD). 2-(4-Isothiocyanatobenzyl)-diethylenetriamine pentaacetic acid (*p*-SCN-BzDTPA) was purchased from Macrocyclics (Dallas, TX). Carrier-free $^{111}InCl_3$ was purchased from Perkin-Elmer Health Sciences, Inc. (North Billerica, MA). All other chemicals used were of reagent grade.

Cell Culture. The HER1 positive cell lines, A431 and MDA-MB468, were used for HER1 targeting studies with panitumumab conjugates. For HER2 targeting studies by trastuzumab conjugates, the *HER2* gene transfected NIH3T3 (3T3/HER2) cell line was used. The cell lines were grown in RPMI 1640 (Life Technologies, Gaithersburg, MD) containing 10% fetal bovine serum (Life Technologies), 0.03% L-glutamine, 100 units/mL penicillin, and 100 μg/mL streptomycin in 5% CO_2 at 37 °C.

Synthesis of ICG Conjugated Antibodies. Panitumumab or trastuzumab (1 mg, 6.8 nmol) was incubated with ICG-sulfo-OSu (68 nmol) in 0.1 M Na_2HPO_4 (pH 8.5) at room temperature for 30 min. Then, the mixture was purified with a Sephadex G25 column (PD-10; GE Healthcare, Piscataway, NJ). The concentration of ICG was measured by absorption with the UV−vis system to confirm the number of fluorophore molecules conjugated to each antibody molecule under conditions of 5% SDS and 2-mercapto ethanol (2-ME) which diminish intermolecular interaction among ICG molecules and between ICG and the antibody. The number of ICG per antibody was ∼4−5.

Radiolabeling of Antibodies. Panitumumab or trastuzumab was reacted with 15-fold molecular excess of *p*-SCN-Bz-DTPA at pH 8.5 in sodium hydrogen carbonate buffer for 1 h at 25 °C. The Bz-DTPA conjugated antibodies were purified by dialysis using 1×PBS on an Amicon Ultra-4 centrifugal device with Ultracel-30 (Millipore, Danvers, MA). Indium-111 chloride (3.5 μL of 295 MBq stock in 0.05 M HCl) is added to the Bn-DTPA antibody conjugate (100 μg) in 25 μL 0.15 M NH_4OAc pH ∼7 and incubated for 1 h at room temperature. EDTA (5 μL of 0.1 M) was then added to quench the reaction mixture. The radiolabeled antibody was then purified using a Sephadex G-25 column (PD-10; GE Healthcare) eluted with 1×PBS. The radiolabeled antibody fraction was collected and the specific activities of the radiolabeled antibodies were 211 and 210 MBq/mg for ^{111}In-panitumumab and ^{111}In-trastuzumab, respectively. Radiochemical purities were assessed by radio-ITLC and were 81% and 88% for the ^{111}In-panitumumab and ^{111}In-trastuzumab, respectively.

Dual-Labeling of Antibody with ICG and ^{111}In. Trastuzumab (1 mg, 6.8 nmol) was incubated with ICG-sulfo-OSu (13.6 nmol) in 0.1 M Na_2HPO_4 (pH 8.5) at room temperature for 30 min. Then, the mixture was purified as described above. The number of ICG per antibody was ∼1. Trastuzumab-ICG was then treated with 15-fold molecular excess of *p*-SCN-BzDTPA. The resulted ICG and BzDTPA conjugated trastuzumab was labeled with ^{111}In and purified in the same manner as above. The specific activity was 404 MBq/mg and the radiochemical purity was 89%.

Immunoreactivity of Radiolabeled Conjugates. Immunoreactivity of ^{111}In-panitumumab, ^{111}In-trastuzumab, or ^{111}In-trastuzumab-ICG was determined using a previously described method in cultured cell lines (*22, 23*). In brief, aliquots of the radiolabeled antibodies (2.6 ng) were incubated for 1 h at 4 °C with 2×10^6 A431 or 3T3/HER2 for panitumumab or trastuzumab conjugates, respectively. The cell binding fraction was collected by centrifuge, and the radioactivity levels of the cell and supernatant fractions were counted in a gamma counter. Nonspecific binding to the cells was determined by adding excess unlabeled antibody.

Investigation of Fluorescence Characteristics of ICG Conjugated Antibodies in Vitro. The fluorescence characteristics of ICG conjugated antibodies were investigated by treating the conjugates with 5% SDS and 2-ME to diminish the hydrophobic interactions and separate the IgG chains. The change in fluorescence intensity for each conjugate was investigated with an *in vivo* imaging system (Maestro, CRi Inc., Woburn, MA) using 710 to 760 nm excitation and 800 nm long-pass emission filters.

Fluorescence Microscopy Studies. 3T3/HER2 or A431 cells were plated on a cover glass-bottomed culture well and incubated for 16 h. Then, trastuzumab-ICG or panitumumab-ICG was added to the medium (10 μg/mL), and the cells were incubated for either 1 or 8 h. Cells were washed once with PBS, and fluorescence microscopy was performed using an Olympus BX61 microscope (Olympus America, Inc., Melville, NY) equipped with the following filters: excitation wavelength 672.5 to 747.5 nm, emission wavelength 765 to 855 nm. Transmitted light differential interference contrast images were also acquired.

Animal Tumor Model. All procedures were carried out in compliance with the Guide for the Care and Use of Laboratory Animal Resources (1996), National Research Council, and approved by the local Animal Care and Use Committee. A431 cells (HER1+, HER2−, 2×10^6 cells) were injected subcutaneously in the left dorsum of the female nude mice (National Cancer Institute Animal Production Facility, Frederick, MD), and 3T3/HER2 cells (HER1−, HER2+, 2×10^6 cells) were injected subcutaneously into the right dorsum. The experiments were performed at 10−17 days after cell injection. For dual-labeled antibody studies by ^{111}In-trastuzumab-ICG, the following cells, MDA-MB468 (HER1+, HER2−, 2×10^6 cells), A431 (HER1+, HER2−, 2×10^6 cells), and 3T3/HER2 (HER1−, HER2+, 2×10^6 cells), were injected subcutaneously into the left flank, right buttock, and right flank, respectively.

***In Vivo* Multimodal Imaging Studies by Fluorescent and Radioactive Antibodies.** A cocktail of panitumumab-ICG (50 μg) and ^{111}In-panitumumab (4.2 MBq/10 μg) or trastuzumab-

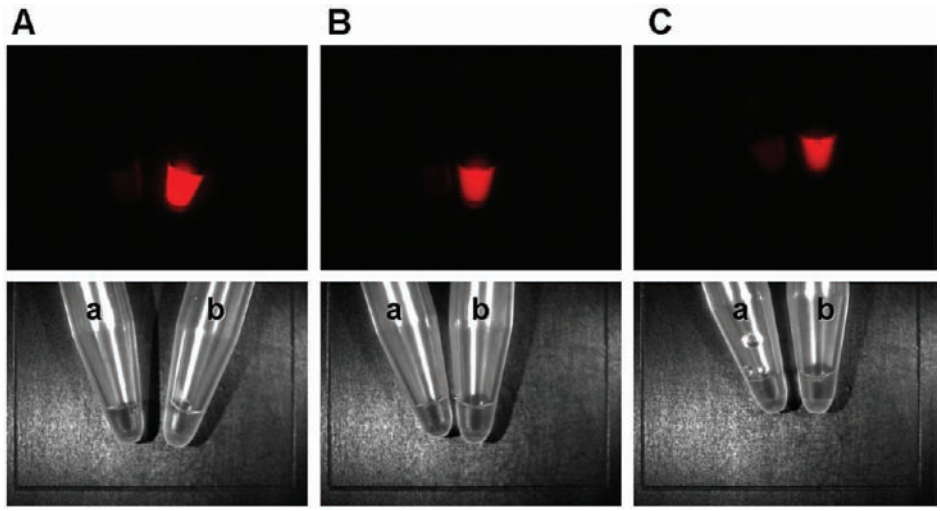

Figure 1. The fluorescence and white light images of antibody-ICG conjugates: (A) panitumumab-ICG, (B) trastuzumab-ICG, (C) BzDTPA-trastuzumab-ICG. (a) in PBS, (b) SDS and 2-ME added condition. In PBS, the conjugates have no fluorescence. Fluorescence is activated by SDS and 2-ME treatment.

ICG (50 μg) and ^{111}In-trastuzumab (4.2 MBq/10 μg) was injected intravenously into A431 and 3T3/HER2 tumor bearing mice ($n = 4$, each). The optical and nuclear images were obtained by Maestro (CRi Inc., Woburn, MA) and an in-house built flat panel gamma camera (Mobile Nuclear Imaging Camera, MONICA) imaging system, respectively, over 6 days after the injection.

For fluorescence imaging, a 710−760 nm band-pass filter was used for excitation and a long-pass filter over 700 nm was used for emission. The spectral fluorescence images consisting of autofluorescence spectra and the spectra from ICG were then unmixed based on their spectral patterns using commercial software (Maestro software, CRi, Inc., Woburn, MA). The regions of interest were placed on the ICG spectral images to measure the fluorescence intensities of the A431 and 3T3/HER2 tumors.

The scintigram of each mouse was obtained by 5 min scan with MONICA (see above) (*24*). Then, the images were processed using *Image-J* software (National Institutes of Health, Bethesda, MD, http://rsb.info.nih.gov/ij/). The regions of interest were placed on the scintigram, and the accumulated radioactivity was measured.

After the imaging on day 6, the mice were sacrificed with carbon dioxide and *ex vivo* images of the resected organs were obtained with both modalities as with the *in vivo* imaging. Then, the organs were weighed and counted in a gamma counter to calculate %ID/g. For histological validation, the dissected lesions were embedded in paraffin and stained with hematoxylin and eosin (H&E).

***In Vivo* Multimodal Imaging Studies with Dual-Labeled Antibodies.** To investigate the effect of pharmacokinetic properties on imaging by radio-optical labeled antibodies, ^{111}In-trastuzumab-ICG (3.8 MBq/60 μg) was injected intravenously into the three tumor bearing mice (A431 (HER1+), MDA-MB468 (HER1+), 3T3/HER2 (HER2+)). The optical and nuclear images were obtained over time and processed in the same manner as above.

RESULTS

Immunoreactivity of Radiolabeled Antibodies. The immumoreactivity values of the ^{111}In-panitumumab and ^{111}In-trastuzumab were 64% and 69%, respectively. The immunoreactivity of the dual-labeled probe, ^{111}In-trastuzumab-ICG, was 75%.

Fluorescence Quenching of ICG Conjugated Antibodies. The fluorescence quenching capacity was measured by treating the conjugates with SDS and 2-ME to dissociate the interactions between ICG molecules and between ICG and its antibody. The fluorescence intensity was very low before the SDS and 2-ME treatment (Figure 1). Intense fluorescence was detected after dissociation, and the quenching capacities were calculated at 17.4-, 19.1-, and 7.3-fold, for panitumumab-ICG, trastuzumab-ICG, and BzDTPA-trastuzumab-ICG, respectively.

***In Vitro* Fluorescence Microscopic Studies.** To investigate the fluorescence activation in the target cells, microscopy was performed. The results are summarized in Figure 2. Fluorescence was not observed for either panitumumab-ICG or trastuzumab-ICG after 0.5 h incubation, when the conjugates were still outside the cells and bound to cell surface receptors. After the conjugates were internalized into the cells after 8 h incubation, both conjugates showed bright fluorescence signal within the target cells. These results demonstrate that both panitumumab-ICG and trastuzumab-ICG are capable of activation; that is, the signal is switched on only within target cancer cells.

***In Vivo* Multimodality Imaging Studies.** The results of the cocktail injection of radiolabeled and fluorescently labeled probes are summarized in Figure 3 and Figure 4. With ^{111}In-panitumumab, radioactivity gradually accumulated in the target tumor (A431, HER1+), while the nontarget tumor (3T3/HER2) was not detected. ^{111}In-Trastuzumab showed both target-specific (3T3/HER2) and nonspecific (A431, HER1+) tumors. A high liver signal was observed in both antibodies. The biodistribution results were consistent with gamma scintigraphy (Figure 5). In contrast, fluorescent signal from both antibodies was activated beginning one day after the injection, although the background signal was detected just after the conjugate injections. Images of the dissected organs by both modalities confirmed these observations. That is, only the target specific tumors were visualized with optical imaging, while the biodistribution profile of the injected antibodies were provided by nuclear imaging.

To confirm that pharmacokinetic properties did not affect the results above, radio-optical dual-labeled trastuzumab was injected in mice bearing three tumors. The nuclear images showed A431 (HER1+) and liver uptake as well as 3T3/HER2 tumor uptake. MDA-MB468 (HER1+) tumor was not detected (Figure 3C). In contrast, fluorescent imaging only detected 3T3/HER2 tumor.

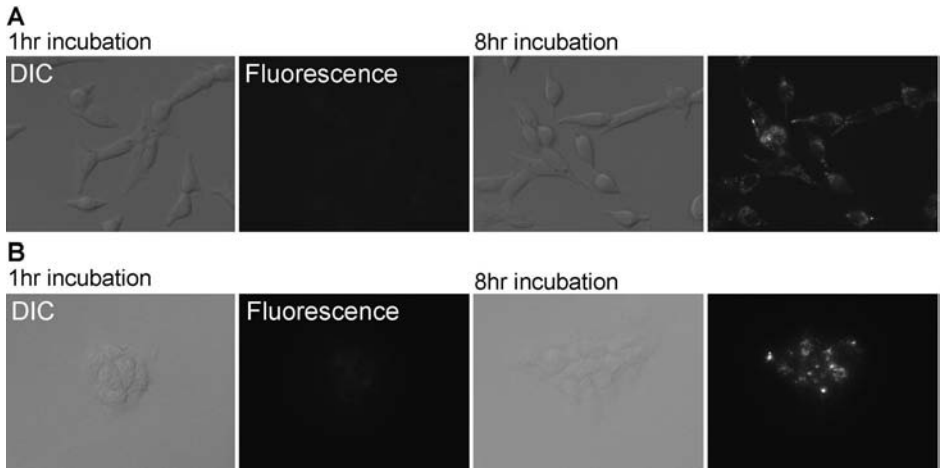

Figure 2. Fluorescence microscopy and differential interference contrast (DIC) images. A431 cells were incubated with panitumumab-ICG (A) and 3T3/HER2 cells were incubated with trastuzumab-ICG (B) for either 1 h or 8 h. The fluorescent signal was detected after internalization into the cells by 8 h incubation.

The H&E staining showed that the A431 tumor (HER1) had greater vascular density than 3T3/HER2 (HER2) tumor (Figure 3D).

DISCUSSION

Multimodality molecular imaging can provide molecular information *in vivo* using two more imaging technologies. Some investigators have already reported radio-optical labeling of probes and have succeeded in yielding nearly identical signals from both modalities despite differences in the physical characteristics of radiation and fluorescence signals (*25*−*30*). These imaging results reflect the biodistribution of the labeled probe because researchers generally have used "always on" optical probes, which yield signals similar to radionuclides. However, by acquiring different signals, i.e., "always on" and target-specific activatable probes ("conditionally on"), additional information could be obtained.

In this study, we showed that activatable fluorescence imaging was capable of cell-specific signal activation and thus highly specific imaging, while radioactive antibodies were more quantitative. The humanized antibodies, panitumumab (anti-HER1) and trastuzumab (anti-HER2), were selected as targeting moieties for molecular imaging in this study, because cancer-specific antigens are attractive "theragnostic" targets, and antibodies for these antigens are promising for seeing and treating cancers. Specific visualization of the target molecule is an important goal for accurate cancer characterization. At the same time, it is also important to visualize the delivery of targeted therapeutic molecules quantitatively for the effective treatment.

As expected, ICG-conjugated antibodies functioned as activatable optical probes emitting in the NIR and the baseline (non-internalized) fluorescence signal was vanishingly low *in vitro* (Figure 1). This was confirmed with microscopy of cultured cells as shown in Figure 2. When the probe is binding to the cell surface antigen (1 h of incubation), no fluorescence signal could be detected; however, when the conjugate was internalized (8 h of incubation), fluorescent signal was easily detectable. If the always on fluorescent probe was used for this investigation, the surface fluorescent signal can be clearly detected by 1 h incubation (Supporting Information Figure 1). Although the mechanism is still under investigation, we suggest that the strong negative charge due to the ICG's sulfonate groups might facilitate the interaction between the ICG and basic amino acid sequences on the IgG causing loss of fluorescence from ICG. By combination with the classic self-quenching system, ICG conjugated antibody might be able to produce high quenching capacities. In fact, the other NIR dye, cypate, which has a similar chemical structure to ICG with carboxylic acid groups instead of sulfonate groups, can label the peptides without the fluorescence quenching (*31, 32*).

Since sulfonate is a stronger acid than carboxylate, the negative charge effect should be weaker for cypate than ICG. Unlike other near-infrared dyes with carboxyl substitutes for sulfonate groups, free ICG is strongly incorporated with albumin probably for a similar reason. The lipophilicity might be another cause for fluorescence quenching by the hydrophobic interaction between dye molecule and hydrophobic amino acid sequences. However, DMSO did not affect the fluorescence dequenching of the ICG conjugated antibody (Supporting Information Figure 2) that suggests the minimal contribution of the hydrophobicity.

This unique feature of this ICG-conjugated antibody contributed to achieve fluorescence imaging with minimal background signal, when bound to the target and internalized into the living cells. In contrast, other researchers reported a few limited successes in the literature. Only weak fluorescence was observed, when ICG-conjugated antibodies were applied for *in vitro* assays using sliced tissue samples, although the fluorescence yield of the ICG-conjugates were slightly improved by changing the chemical linkage (*20*). Withrow et al. applied an ICG-conjugated antibody (cetuximab, anti-EGFR antibody) for imaging xenografted tumors in mice; however, they concluded that the sensitivity of this probe for cancer detection was low. This might be due to the smaller target numbers on the tumor cells or less efficient internalization process of the ICG-antibody conjugates than the cells, which we used in this study. Although their ICG-conjugated antibody appeared to be brighter than our quenched conjugate, a 7-fold larger amount of the ICG-conjugated antibody (350 μg) was injected into the mice; therefore, they might detect a fluorescence signal not only from tumor, but also from the background normal tissues, because a large amount of unbound probes remaining in the body could yield the fluorescence signal (*33*).

Then, we tested our multimodality imaging strategy by injecting radio-optically labeled antibody cocktails into the HER1+ and HER2+ tumor bearing mice. As expected, only the target-specific tumor was visualized by optical imaging (Figures 3 and 4). The observed background signal just after the ICG-conjugated antibodies injection might be due to the physiological excretion of noncovalently bound or catabolized ICG, which was dissociated from the antibody immediately after

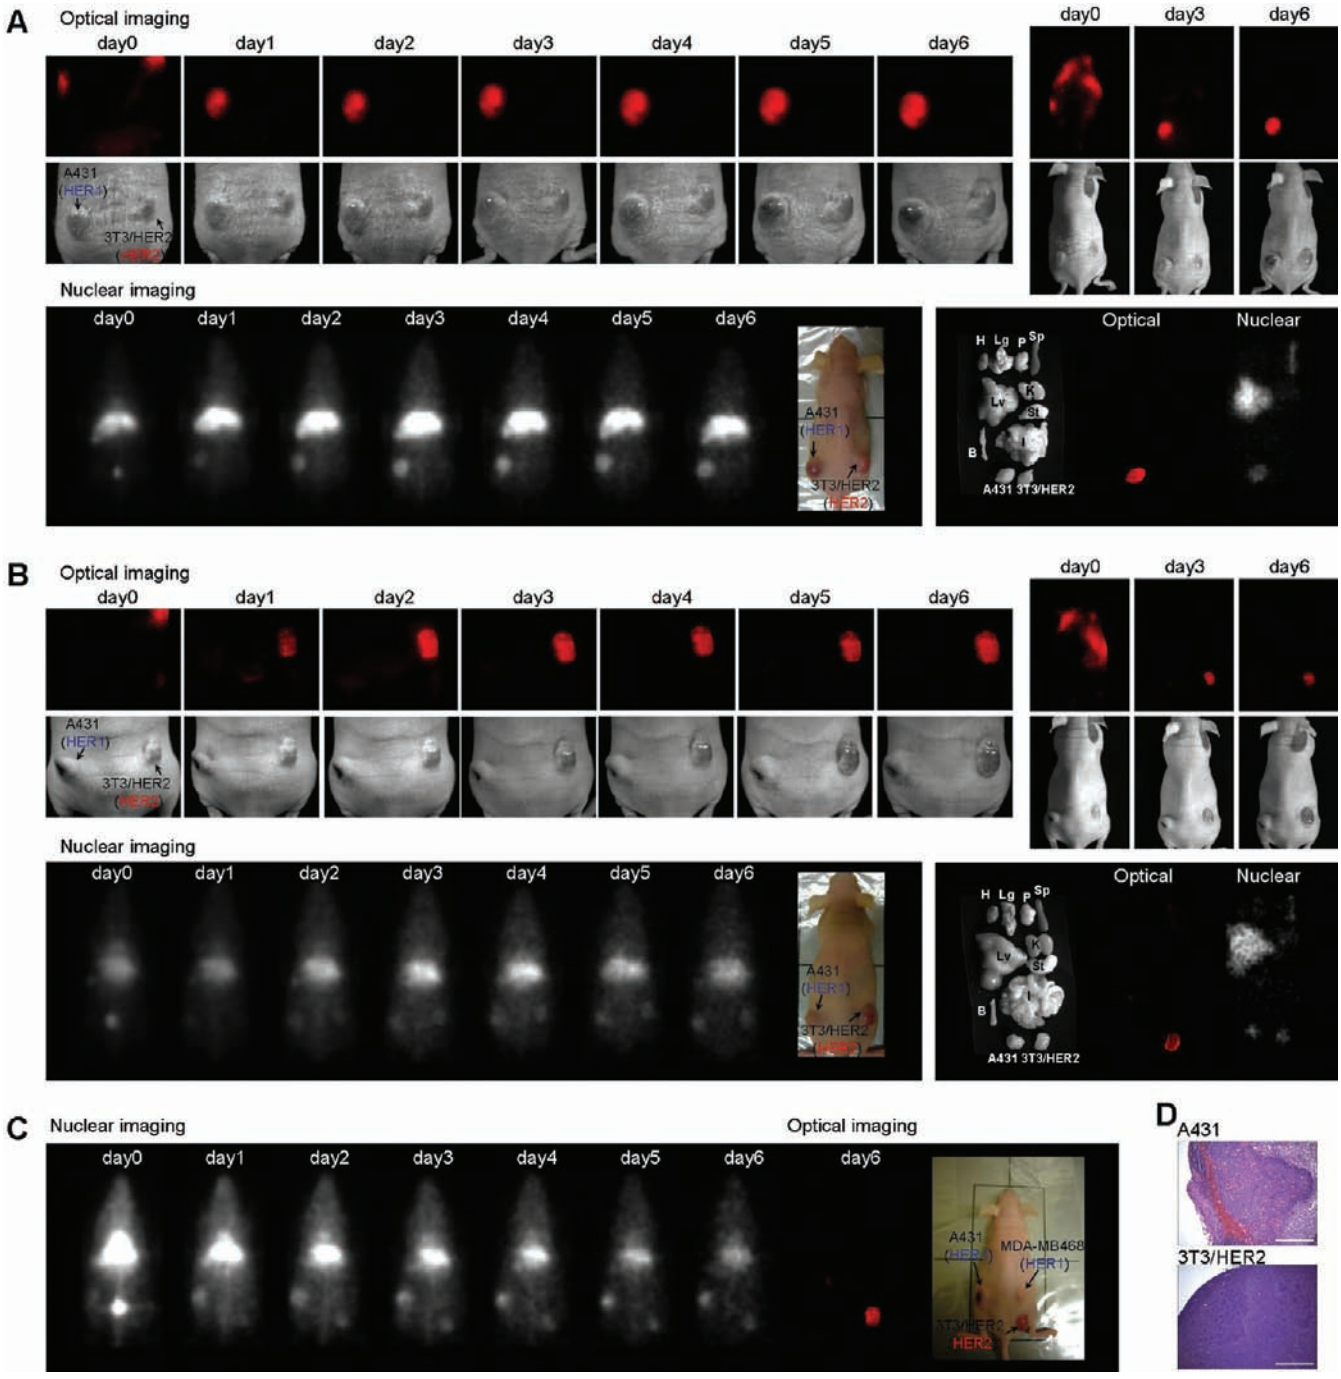

Figure 3. Multimodality imaging results after a cocktail injection of panitumumab-ICG and ^{111}In-panitumumab (A) or trastuzumab-ICG and ^{111}In-trastuzumab (B), and the results with dual-labeled probe, ^{111}In-trastuzumab-ICG (C). Only the target tumor was visualized by optical imaging; in contrast, antibody distribution could be determined by nuclear imaging. (D) HE staining of dissected tumors. The vascularity was higher in A431 tumor than 3T3/HER2 tumor. H, Heart; Lg, Lung; P, Pancreas; Sp, Spleen; Lv, Liver; K, Kidney; St, Stomach; B, Bone; I, Intestine.

the injection and complexed with albumin. The ICG-albumin complex is highly fluorescent, but it is rapidly eliminated from the body of normal subjects through the liver (*34*).

In contrast, radioactive signal could be detected from whole body (blood pool), the liver and the spleen as well as the target tumor. The nontarget tumor was also imaged in HER2 targeting studies. Since the vascularity of A431 tumor (HER1) was higher than 3T3/HER2 (HER2+) tumor (Figure 3D), the reason for the visualization of A431 tumor with ^{111}In-trastuzumab is thought to be its high blood supply and enhanced permeability and retention (EPR) effect (*35*, *36*). As indicated in Figure 5, a certain level of radioactivity remained in the blood especially for ^{111}In-trastuzumab even 6 days after the injection. The EPR effect depends only on the physical characteristics of the macromolecules injected and not on their binding characteristics, and thus, it often leads to nonspecific tumor uptake.

Thus, target-specific images were successfully obtained with activatable optical probes, while quantitative antibody biodistribution was provided by the "always on" radioactive probes. The difference between optical and nuclear imaging was not caused by differences in their pharmacokinetic properties, because the same results were obtained with the dual-labeled antibody (Figure 3C).

A limitation of optical imaging is difficulty in deep tissue detection. NIR fluorescence is one solution for this problem because of the better tissue penetration of NIR light in tissue

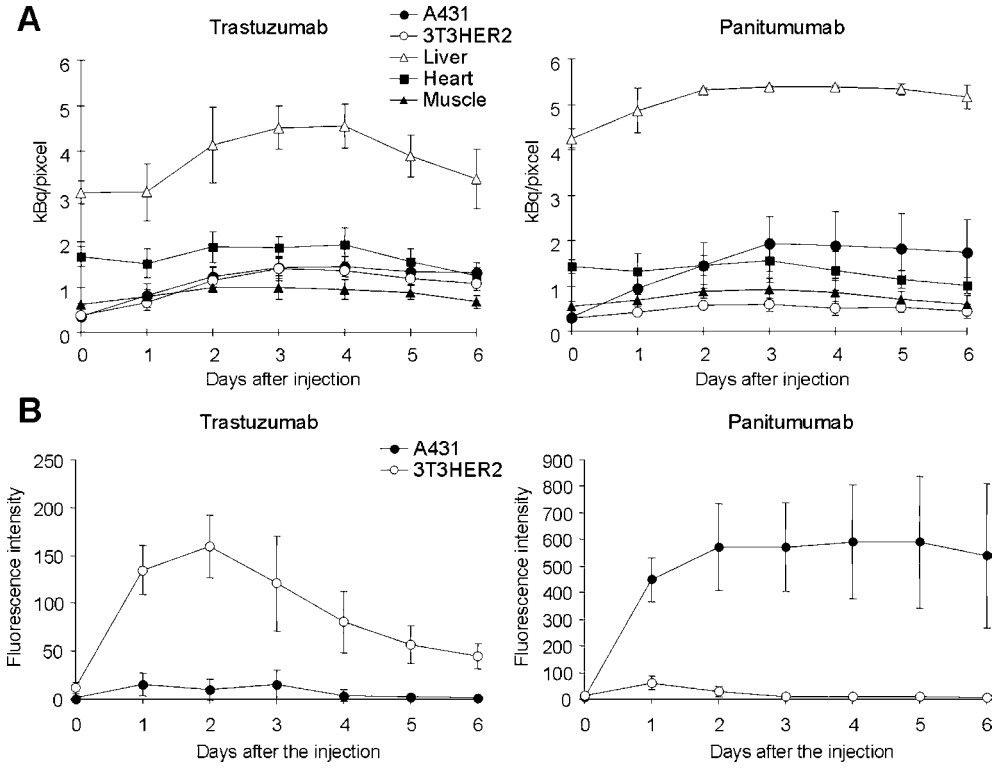

Figure 4. Time course of radioactivity (A) and fluorescence (B) intensities after the injection of a cocktail of panitumumab-ICG and ^{111}In-panitumumab or trastuzumab-ICG and ^{111}In-trastuzumab. High liver uptake was observed on radionuclide scans. The fluorescent signals were increased only in the target tumors, but the signal intensities of target and nontarget tumor were identical in ^{111}In-trastuzumab treated mice.

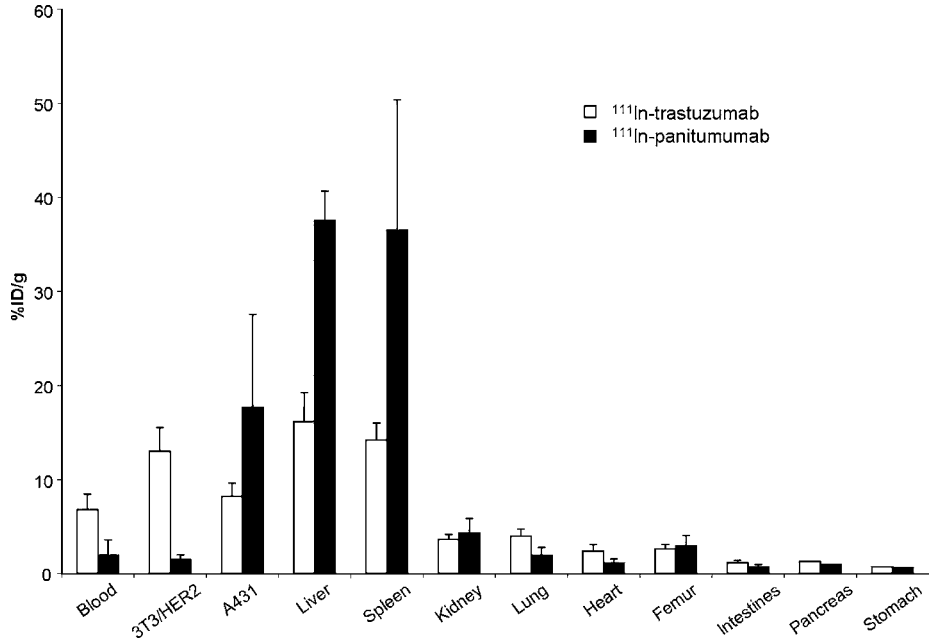

Figure 5. Biodistribution of ^{111}In-panitumumab and ^{111}In-trastuzumab immediately after obtaining 6 day images was shown. The biodistribution results were consistent with images obtained 6 days after injection taken with the MONICA dual camera system.

(*14*). Recently, diffuse optical tomography has improved the deep tissue sensitivity (*37*). This technique can visualize the target at ~50 mm depth volumetrically using NIR probes, and it might be applicable for human breast cancer imaging as well as small animal imaging. At the same time, optical imaging can make a significant contribution when it is utilized during endoscopy or surgery, because activatable optical probes can achieve fairly low background signals (*7, 8*). Thus, whole body imaging with radionuclides followed by optically guided surgery is a promising direction for multimodality imaging. Furthermore, optical imaging has the potential to add more functional information, for example, by using multicolor imaging or fluorescence lifetime imaging (*38*−*42*).

In conclusion, we characterized molecular targets with activatable optical probes, and visualized and quantified the delivery of targeted antibodies using radioactive labeling. Recently, the Molecular Imaging Center of Excellence stated that, "Molecular imaging is the visualization, characterization, and measurement of biological processes at the molecular and cellular levels in humans and other living systems" (*43*).

Multimodality molecular imaging, by combining activatable optical probes with radioactive probes, has great potential for achieving this definition.

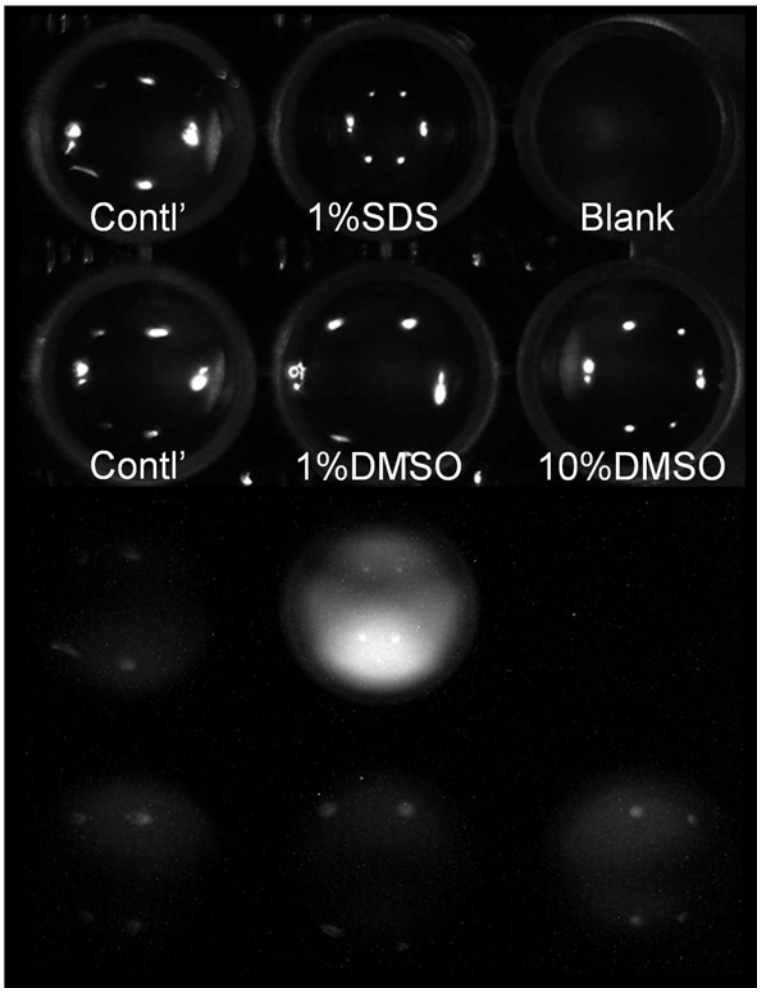
Supplemental figure 1. Always on conjugates show cell surface receptors

The always-ON fluorescence probe, trastuzumab-Rhodamine Green (A) and trastuzumab-Cy7 was incubated with 3T3/HER2 cells in the same manner as ICG conjugates. The surface fluorescence was detected after 1hr incubation, which shows the trastuzumab-Rhodamine Green and trastuzumab-Cy7 binding to the surface HER2 receptors. Many fluorescent dots were observed after the antibody internalization by 8hr incubation as well as the surface fluorescence with both conjugates.



Supplemental figure 2. DMSO does not de-quench the quenched ICG-trastuzumab conjugate.

The de-quenching capacity of the quenched trastuzumab-ICG compared SDS with DMSO. DMSO does not efficiently de-quench the quenched trastuzumab-ICG as SDS does.

TECHNICAL NOTES

A Wortmannin−Cetuximab as a Double Drug

Double drugs are obtained when two pharmacologically active entities are covalently joined to improve potency. We conjugated the viridin Wm with a self-activating linkage to cetuximab and demonstrated the retention of immunoreactivity by the conjugate. Though cetuximab lacked a growth inhibitory activity against A549 cells, the Wm−cetuximab conjugate had an antiproliferative IC_{50} of 155 nM in vitro. The chemistry of attaching a self-releasing Wm to clinically approved antibodies is general and, in selected instances, may yield antibody-based double drugs with improved efficacy.

INTRODUCTION

Double drugs are obtained when two pharmacologically active entities are covalently joined to obtain a molecule with an improved potency that often results from a change in physical properties of one of the active entities (*1, 2*). The ability of modified viridins like wortmannin (Wm) to self-activate by generating the active species Wm offers a mechanism for the design of self-activating viridin double drugs, where X (Figure 1A) is a pharmacologically active entity. We have previously shown that when X is a 70 kDa dextran, a pharmacologically inactive carrier, the resulting self-activating viridin (SAV) prodrug has an improved antiproliferative activity compared to wortmannin (Wm) due to the slow release of active Wm over the 48 h incubation period of the in vitro antiproliferative assay (*3*). This slow release also occurs in vivo, evident by the nanomolar concentrations of active viridin generated by micromolar concentrations of circulating SAV prodrug (*4*). The SAV prodrug is anti-inflammatory in animal models of lung inflammation and arthritis (*5, 6*), as well as being cytostatic in the A549 xenograft model (*4*).

Cetuximab is a monoclonal antibody that binds to the epidermal growth factor receptor, ErbB1, and generates antitumor activity through several mechanisms, including an antagonism of growth stimulation by growth factors and immune mediated mechanisms such as antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytolysis CDC (*7*−*9*). Consistent with a role for immune-mediated mechanisms in cetuximab's in vivo activity, cetuximab does not directly inhibit the proliferation of some cultured tumor cell lines, such as the A549 cell line used here (*10*−*12*).

We hypothesized that attaching wortmannin (Wm) to cetuximab using a self-activating linker employed with dextran-based SAV (compound **5a** of the current study) might yield a potentially general conjugation chemistry for the design monoclonal antibody based double drugs. A key pharmacokinetic property of blood half-life is comparable for the two materials, with human blood half-lives of 60−80 h for a 70 kDa dextran in humans (*13, 14*) and 112 h for cetuximab (*15*). Thus, it appeared that cetuximab, like a 70 kDa dextran, could serve as a reservoir of inactive Wm that slowly self-activated to yield the active species Wm, as we have shown on other occasions (*3, 4, 16*). We therefore hypothesized that cetuximab might serve as carrier for Wm, enhancing the antibody's antiproliferative activity and acting as a double drug.

EXPERIMENTAL METHODS

Reagents. Wortmannin (Wm) was a gift of the natural products branch of the National Cancer Institute. Fluorescein-labeled goat anti-human IgG (secondary antibody) was from Beckman Coulter. The NHS ester of 6-fluorescein-5-(and 6)-carboxamido-hexanoic acid (FAM) was from Molecular Probes.

Syntheses. The compounds employed are summarized in Figure 1. To obtain the self-activating Wm−cetuximab (**7a**), **2a** was synthesized and converted to the NHS ester of **2a** (*3*). To a solution of the NHS ester of **2a** (4 mg, 6 mmol) in DMSO (100 μL) was added 160 kDa monoclonal antibody cetuximab (3 mL, 10 mg/mL) in PBS. The solution was stirred and incubated at 37 °C for 1.5 h. The conjugate (**7a**) was purified with Sephadex G-50 in a 1 mM phosphate buffer at pH 7.0 followed by lyophilization. The number of moles of Wm per cetuximab were determined by its absorbance at 418 nm. Compound **7b** was prepared from **2b** in a similar fashion. The syntheses of **5a** and **5b**, which use a 70 kDa amino dextran carrier, have been described (*3*). The moles of Wm attached per mole of carrier were 4.5 (**7a**), 8.8 (**7b**), 7.8 (**5a**), and 13 (**5b**). To obtain the fluorescent compound **8**, cetuximab (1 mL,

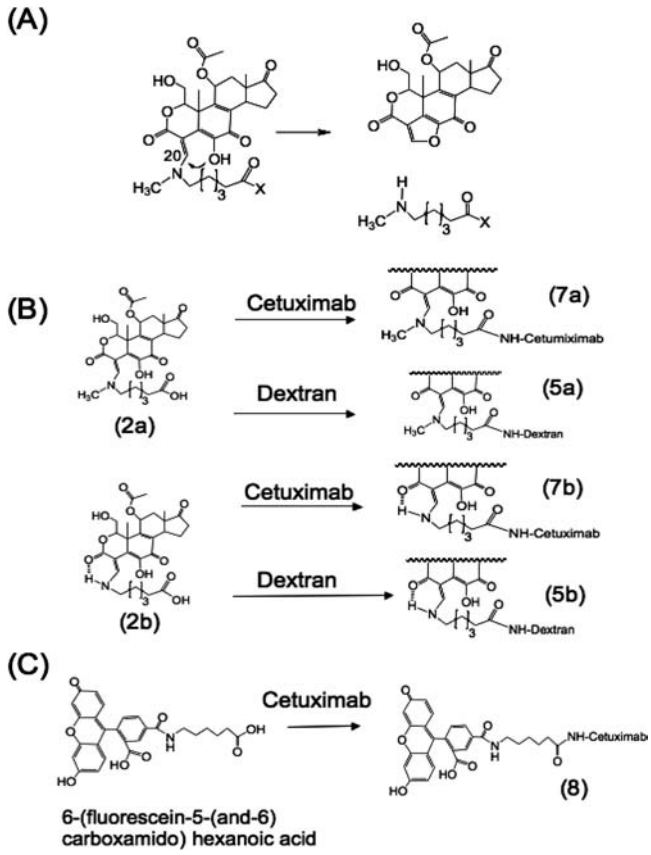

Figure 1. Self-activation of WmC20 derivatives and the compounds used. (A) Wm modified at C20 undergoes an intramolecular attack to yield Wm. The attack is independent of the group attached to the carboxyl group of the N(Me)hexanoic acid linker (*3*). (B) **2a** was converted to an NHS ester and reacted with the amines of cetuximab or amino-dextran (70 kDa) to yield **7a** or **5a**, respectively. Similar reactions were used with the Wm derivative **2b**, which features a secondary amine at C20, to yield **5b** or **7b**. "b type" WmC20 derivatives feature a hydrogen bond stabilization and do not self-activate to generate Wm. (C) An NHS ester of a fluorescein hexanoic acid was reacted with cetuximab to yield a fluorescent antibody **8**.

2 mg) was diluted with 1 M sodium bicarbonate buffer (pH 8.3, 100 μL). 3.91 μL of 5-FAM (10 mg/mL in DMSO) was added, and the mixture was stirred at room temperature for 1 h. The mixture was purified with PD10 column. Antibody concentration was determined by the BCA assay, while attached fluorescein was determined from its absorbance at 493 nm. There were 3.19 mol of fluorescein per mole of cetuximab.

Cellular Assays. All experiments used A549 cells (ATCC). Cells were maintained in F12−K medium, 10% fetal bovine serum, and 1% antibiotics of penicillin−streptomycin at 37 °C, 5% CO_2, and 95% humidity. To obtain antibody binding, cells were seeded at a density of 50 000 cells/well in 24-well culture plates and incubated overnight. Dilutions of antibodies in complete media (500 μL/well) were added. After incubation at 37 °C, cells were washed three times with HBSS, detached with trypsin, centrifuged (5 min at 200 × *g*), resuspended (200 μL cold HBSS), and analyzed by flow cytometry (FACSCalibur, Becton-Dickinson). Binding is expressed as the relative cellular fluorescence (RCF), which is the mean fluorescence intensity of treated cells divided by a similar value for untreated cells. To demonstrate immunoreactive cetuximab on the cell surface, cells were treated with cetuximab (37 °C, 10 nM, 1 h) and washed. Then, 500 μL of fresh media was added to each well, and the cells were incubated at 37 °C for 0, 1, 2, 3, 5, or 24 h. Cells were then detached by trypsinization, centrifuged, and resuspended in 100 μL FITC-labeled secondary antibody solution (50:1 dilution in HBSS). After 1 h incubation on ice, cells were washed three times with fresh HBSS and prepared for flow cytometry analysis as described above.

The amount of compound **8** bound per cell at saturation (10 nM) was determined as immunoreactive fluorescein using a fluorescein immunoassay (*17*). A sulforhodamine B (SRB) dye binding method was performed as an antiproliferative assay (*18*). Cells were allowed to proliferate for 48 h in the presence of increasing concentrations of drug as shown in Figure 3, where the drug concentration (*x*-axis) was plotted versus cell mass (*y*-axis). The IC_{50} is determined using a four-parameter equation (GraphPad *Prism* software) setting the maximum value as 100% and allowing the fit to generate a minimum nonzero cell mass value (the asymptote at high drug concentrations). On the basis of the reported doubling time of A549 of 22.9 h (http://dtp.nci.nih.gov/docs/misc/common_files/cell_list.html), complete growth inhibition would yield a cell mass of about 25% of control after the assay's 48 h incubation. The IC_{50}, therefore, is the midrange point for the change in cell mass (and not the point where cell mass is 50% of control). We term this an "antiproliferative assay" because it is run under conditions allowing cell proliferation, though no direct measurements of cell division were obtained.

RESULTS AND DISCUSSION

The self-activation the viridin Wm undergoes when modified at the C20 position by *N*-methyl hexanoic acid is shown in Figure 1A. An intramolecular attack of the C6 OH generates Wm, while the carboxyl group can be reacted with amines. WmC20 derivatives featuring a secondary amine at C20 (**2a**) and a tertiary amine at C20 (**2b**) were converted to NHS esters and attached to the amino groups of amino-dextran, to yield **5a** and **5b**, or to the amino groups of cetuximab to yield **7a** and **7b**. The compound designations shown in Figure 1B are from our previous communications, with new cetuximab-based compounds designated as **7a**, **7b**, and **8**. Thus, **2a**, **2b**, **5a**, and **5b** are the same as in our earlier publications, with the "a" designation referring to an N(Me) hexanoic acid, self-activating linker reacted with Wm's C20. The "b" designation refers to N(H)hexanoic acid based compounds, which do not self-activate due to an extra hydrogen bond stabilization shown in Figure 1B (*3, 16*).

We first characterized the binding of the fluorescein-labeled **8** to cells as shown in Figure 2A,B. Binding of **8** was determined as the relative cell fluorescence (RCF), that is the mean fluorescence intensity determined by FACS of cells incubated with **8** divided the mean fluorescence intensity of control cells. Preliminary experiments indicated that the binding of **8** to cells was rapid and independent of incubation times between 1 and 24 h. We then varied the concentration of **8** and determined a K_d of 0.40 nM as shown in Figure 2A. The amount of **8** bound per cell at a saturating concentration of 10 nM was determined by a fluorescein hapten immunoassay to be 56 400 ± 14 200 molecules per cell. Our estimate of the number of binding sites per cell was about 10-fold higher than Mukohara who used a FACS-based bead method (*12*), while we measured immunoreactive fluorescein from **8** after cell lysis.

To determine whether the attachment of Wm to cetuximab (as in **7a** and **7b**) resulted in a reduced immunoreactivity, a self-displacement assay (Figure 2C) was employed. We determined the immunoreactivity of the Wm-modified cetuximab **7a** by its ability to displace the binding of **8** (10 nM) from cells (Figure 2B). The similar decrease ($p > 0.05$ for all concentrations) in RCF produced by **7a** and cetuximab indicated the attachment of Wm to cetuximab, as occurred with **7a**, did not impair its immunoreactivity.

A surprising feature of the binding of **8** to A549 cells was lack of time dependence of this interaction, which suggested

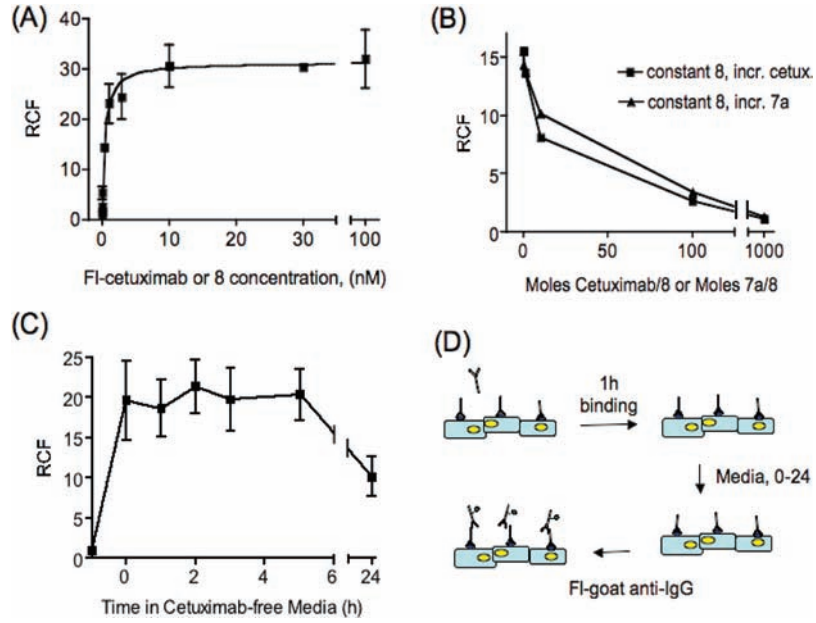

Figure 2. Binding of Fl-cetuximab (**8**) and Wm−cetuximab (**7a**) to cells. (A) Concentration dependence of the binding of Fl-cetuximab (**8**) to cells (K_d = 0.40 nM). (B) Immunoreactivity of **7a**. Cetuximab or **7a** blocked the binding of **8** to cells. Data indicating the retention of cetuximab on the cell surface are shown in (C) with the protocol summarized in (D). Cells were exposed to cetuximab for 1 h, washed, and incubated in media for varying amounts of time. Immunoreactive cetuximab on the cell surface was detected by a fluorescein-labeled goat anti-human IgG.

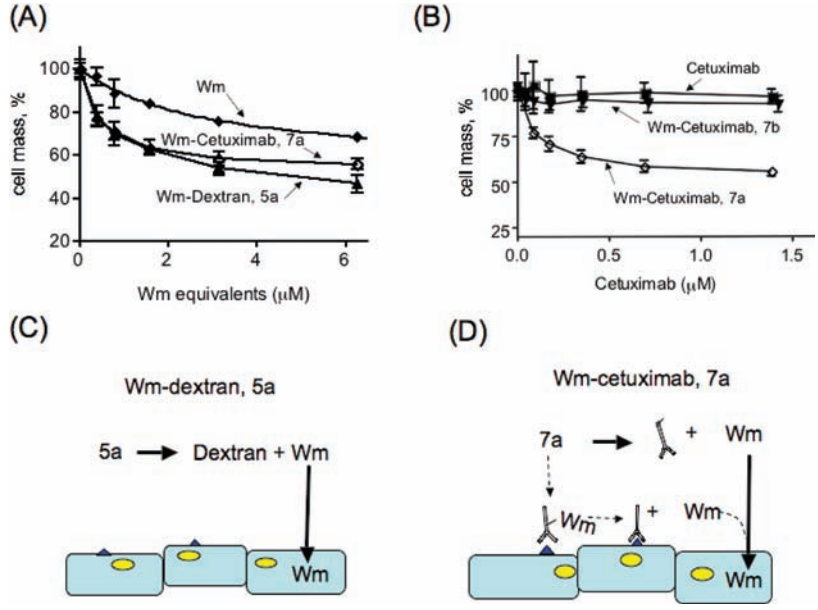

Figure 3. Increase in potency for the double drug, Wm−cetuximab. (A) Attaching Wm with a self-releasing linkage to either cetuximab or dextran increased its antiproliferative activity when data are plotted on a mole of Wm basis. (B) Attaching Wm with a self-releasing linker increases Wm potency when data were plotted on a cetuximab basis. (C) Schematic for the activity of Wm-dextran, **5a**. **5a** generates Wm outside of cells, which then enters cells. (D) Schematic for the behavior of Wm−cetuximab, **7a**. Like **5a**, **7a** releases Wm outside cells, which then enters cells. **7a** also bound cells and released Wm, but the major pathway (dark arrows) was Wm release into the bulk media, since the antiproliferative IC_{50} (Wm basis) was 700 nM **5a** and 690 nM for **7a**.

that **8** remained as a stable complex bound to its ErbB1 target receptor on the cell surface. To verify that this was in fact the case, we incubated cells with cetuximab (10 nM, 1 h), washed cells, and detected cell surface cetuximab by the addition of a fluorescein-labeled goat anti-human IgG. As shown in Figure 3C, the resulting RCF was essentially constant for 6 h and decreased to 50.6% of control at 24 h. A 50% decrease in cell fluorescence would be expected at 22.9 h based on the doubling time of A549 cells (see above). Thus, cetuximab appears not to be internalized by A549 cells.

We next assessed the antiproliferative activity of the Wm−cetuximab conjugates (**7a**, **7b**), with the dextran conjugates featuring the same linkages (**5a**, **5b**) serving as nonreceptor binding Wm controls. Representative curves for the decrease in cell mass as a function of concentration are shown in Figure 3A,B with IC_{50}s provided in Table 1. Cetuximab had no effect on the proliferation of A549 cells, consistent with the observations of others (*12*, *19*, *20*), though cetuximab has been shown to inhibit the growth of A549 xenografts (*10*, *11*), an effect that may reflect immune mediated killing, see above. On the basis of the similar IC_{50}s of **5a** and **7a** (Table 1), **5a** and **7a** release Wm into the media in a similar manner (Figure 3C,D). On the basis of the lack of internalization of cetuximab (Figure 2), **7a** was not internalized (Figure 3D).

Table 1. Antiproliferative Activity of Wortmannin−Cetuximab Conjugates[a]

compound	antiproliferative IC_{50} as cetuximab, (nM)	antiproliferative IC_{50} as Wm, (nM)
cetuximab	not detectable[b]	not detectable[b]
7a	155	700 ± 20
7b	>1000	>100 000
5a	not applicable	690 ± 20
5b	not applicable	>100 000
Wm	not applicable	11 400 ± 50

[a] Results from three assays on separate occasions are provided. [b] Depression of cell mass was too small for an accurate IC_{50} to be determined.

The antiproliferative activity of cetuximab was greatly enhanced by the attachment of Wm with a self-releasing linkage. That compound, **7a**, exhibited an IC_{50} of 153 nM on a per mole cetuximab basis (690 nM on a Wm basis at 4.5 Wm/per mole of cetuximab), while cetuximab lacked activity in this assay. This improvement in antiproliferative activity of **7a** relative to cetuximab was not due to an immune mediated binding of **7a**, since the IC_{50} of the self-activating dextran (**5a**) was 700 nM on a wortmannin basis, and not different from the IC_{50} of **7a** ($p > 0.05$). With both cetuximab and dextran carriers, the configuration at C20 was critical for activity, with nonreleasing C20 configurations of **5b** and **7b** showing no antiproliferative activity. The potency of Wm was greatly increased by its attachment to cetuximab with the self-releasing linkage. Wm has an IC_{50} of 11.4 μM against A549 cells, while **7a** had an IC_{50} of 690 nM on a per mole of Wm basis.

There are two conclusions from these studies. First, Wm could be attached to cetuximab at levels that did not affect its immunoreactivity but increased its antiproliferative activity. The experimental approach developed here, attachment of Wm followed by verification of immunoreactivity, could be employed to obtain slow Wm releasing, immunologically active, monoclonal antibodies. Second, the attachment of Wm to cetuximab increased the antiproliferative activity of both the antibody and Wm. This improvement occurred through the slow release of Wm into culture media, based on the similar antiproliferative IC_{50} of **5a** and **7a**.

Though we did not demonstrate the immune-mediated targeting of Wm to A549 cells in culture, this may still be possible in vivo with appropriate antibody/tumor combinations. The A549 line we employed is a Ras-driven tumor (*21, 22*), and the amount of Wm that must targeted to achieve a pharmacological effect might be considerably higher than for PI3 kinase driven tumors (see *refs* 23, 24). In addition, our Wm−cetuximab was not internalized by A549 cells, a fate common with cetuximab and other cell lines (*25*). Internalization of Wm−monoclonal antibodies and receptor recycling might lead to higher intracellular levels of Wm. Finally, a self-releasing Wm might be attached to a monoclonal antibody or protein with an immune-suppressive activity, which would then act as a pharmacologically active (but nontargeting) carrier for a slow Wm release. The slow release of Wm from **5a** is immune suppressive in animal models of lung inflammation and arthritis (*5, 6*). Wm is a potent antiangiogenic agent (*26*), offering a mechanism for immune suppression or inhibiting tumor growth without targeting.

From 1980 to 2005, some 206 monoclonal antibodies were studied in clinical trials with 12 being approved (*27*), offering a wide array of potential Wm−antibody double drugs. The conjugation of Wm with a self-activating linker to an approved monoclonal antibody offers a potential general chemistry for the design of double drugs, the pharmacological effectiveness of which will have to be evaluated for each antibody considered.

Box 750561, D-28725 Bremen. Received April 6, 2009; Revised Manuscript Received September 10, 2009

We have prepared nine new dodecaborate cluster lipids with potential use in boron neutron capture therapy of tumors. This new generation of boron lipids is only singly negatively charged and consists of a pyridinium core with C_{12}, C_{14}, and C_{16} chains as lipid backbone, connected through the nitrogen atom via a butylene, pentylene, or ethyleneoxyethylene linker to the oxygen atom on the dodecaborate cluster as headgroup. The lipids were obtained by nucleophilic attack of 4-(bisalkylmethyl)pyridine on the tetrahydrofurane, the dioxane, and a newly prepared tetrahydropyrane derivative, respectively, of *closo*-dodecaborate. All of these boron lipids are able to form closed vesicles in addition to some bilayers in the pure state and in the presence of helper lipids. The thermotropic behavior was found to be increasingly complex and polymorphic with increasing alkyl chain length. Except for two lipids, all lipids have low *in vitro* toxicity, and longer alkyl chains lead to a significant decrease in toxicity. The choice of the linker plays no major role with respect to their ability to form liposomes and their thermotropic properties, but the toxicity is influenced by the linkers in the case of short alkyl chains.

INTRODUCTION

Therapy for patients with malignant neoplasms, especially high-grade gliomas, melanomas, and their metastatic manifestations, has been only marginally successful with conventional treatments such as surgery or chemotherapy (*1*−*3*). Boron neutron capture therapy (BNCT) is focused on the treatment of these types of cancer. The therapy is based on the nuclear reaction that occurs when boron-10 is irradiated with thermal neutrons followed by nuclear fission to high-energy α-particles and lithium-7 nuclei. These products only act in a short range (cell diameter), which offers a selective damaging of the cancer cells if the boron-10 is selectively accumulated in the tumor and not in the surrounding healthy tissue. For successful treatment, a high amount of boron is necessary (10^9 B atoms per cell, or 20−30 μg per gram of tumor).

Only two substances are in clinical trials, boronophenylalanine (BPA) and mercaptododecaborate (BSH), but they do not reach "ideal" boron concentration in the tumor (*2*) and are hence not optimal boron delivery agents.

In the past, many prospective boron agents have been synthesized, but most of them show disqualifying features (*4*). Low molecular weight boron-containing nucleosides and nucleotides have been prepared for targeting hyperproliferating malignant cells (*5*, *6*). Sugar derivatives are synthesized for cell uptake via specific transporters into cells with increased metabolism (*7*). Another strategy is to obtain boron-containing agents for which target receptors are present in the plasma membrane of the tumor cell, possibly followed by translocation into the cell (*4*). Porphyrin and phthalocyanine derivatives (*8*−*12*) are a part of this category; they often exhibit high toxicity, however. High molecular weight boronated agents, such as antibodies and their fragments, have been prepared that can recognize tumor-associated epitopes (*13*−*15*). Their rapid clearance by the reticuloendothelial system and the necessity to couple enough boron to an antibody molecule for successful therapy are, however, disadvantageous.

Liposomes are promising transport systems for boron agents, as they can carry a large amount of boron. In addition, targeting with tumor-seeking entities, e.g., folate (*16*), EGF (*17*), or transferrin (*18*), makes selective transfer possible. The encapsulation of low molecular weight boron agents into the inner liposomal core has been studied in a variety of experimental systems (*19, 20*). For effective delivery of boron, low encapsulation efficiency, leakage upon storage or in contact with serum and the effect of the liposome structure in the presence of charged boron clusters (*21*) are disadvantages. These problems can be avoided by incorporating boron-containing lipids directly into liposomal membranes.

The first dodecaborate ether lipid has been described by Lee et al. (*22*). The subsequently published dodecaborate lipids have BSH as the headgroup (*23, 24*). These lipids show similarly low toxicity to BSH. All these boron lipids are doubly negatively charged.

Recently, we published the first dodecaborate cluster lipids with only one negative charge (*25*). The chemical structure of these boron lipids are shown in Scheme 1.

The new boron lipids in this study also have a single negative charge. We used ring-opening reactions of different oxonium derivatives of the dodecaborate cluster with *p*-bisalkylmethylpyridine as nucleophile. This allows facile preparation and the possibility to vary the structure of the hydrophobic part of the lipid. Commonly, *N*-methyl-*p*-bisalkylmethylpyridinium is

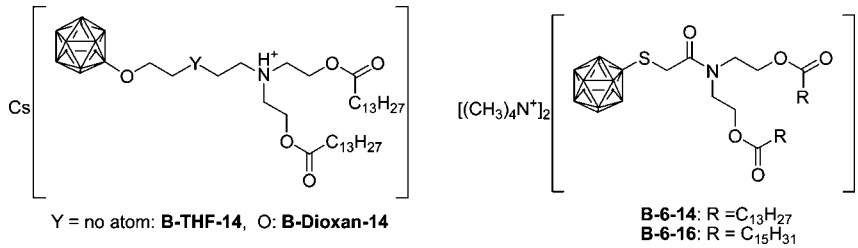
Scheme 1. Structures of the Boron Lipids: B-THF-14 and B-Dioxan-14 (left) (*25*) as well as B-6-14 and B-6-16 (right) (*24*)[a]



[a] In the icosahedral structures, each unsubstituted corner represents a B−H unit, and the substituted corner, a B atom. The cluster carries two negative charges which are omitted for clarity.

applied in lipoplexes (so-called SAINTs (synthetic amphiphiles for interdisciplinary nucleic acid therapy)) for gene therapy (*26*−*28*). We adapted this basic structure for the first time for boron lipids with potential use in BNCT.

EXPERIMENTAL PROCEDURES

General. A Bruker Esquire spectrometer was used for electrospray mass spectrometry. For boron-containing compounds, the peak with the highest intensity is given. To identify the charge of the compound isotope satellite peaks were used. NMR spectra were recorded on a Bruker DPX 200 spectrometer. IR spectra were collected on a BioRad FTS 155 using KBr pellet. Melting points were measured on a Büchi 512 melting point apparatus. Purity of the compounds was assessed by ESI mass spectrometry and ^{1}H-, ^{13}C-, and ^{11}B NMR spectroscopy, as it is known that the elemental analysis of dodecaborate containing compounds is not reliable (*29*, *30*).

Chemistry. *1-Tetramethylene-(3-oxa)-oxonium-closo-undecahydrododecaborate (−1), Tetrabutylammonium Salt (***1a***).* The convenient method recently described was used, in which closo-dodecaborate was reacted with hydrogen chloride in 1,4-dioxane in the presence of $NaBF_4$ (*31*).

*1-Tetramethyleneoxonium-closo-undecahydrododecaborate (−1), Tetrabutylammonium Salt (***1b***).* The same method as for **1a** was used, but replacing hydrogen chloride with *p*-toluenesulfonic acid (2 equiv) and tetrahydrofurane as solvent. The compound was identical to that described by Sivaev et al. (*32*).

*1-Pentamethyleneoxonium-closo-undecahydrododecaborate (−1), Tetrabutylammonium Salt (***1c***).* The same method as for **1b** was used, but the solvent was tetrahydropyrane instead of tetrahydrofurane. Yield 70%, mp 159 °C (lit. mp 159 °C (*33*). MS (ESI, acetonitrile, *m*/*z*) negative 227.1 [A$^-$], 695.6 [2 A$^-$ + N(n-$C_4H_9)_4^+$], 141.1 [$B_{12}H_{11}^-$]; positive 242.4 [N(n-$C_4H_9)_4^+$]. ^{1}H NMR (200 MHz, [D3] CD_3CN, 25 °C, TMS): δ = 1.32 (t, 12 H, −C*H*$_3$), 1.54 (m, 10 H, N$^+$−CH$_2$−CH$_2$−C*H*$_2$-, -O$^+$−CH$_2$−CH$_2$−C*H*$_2$-), 1.59 (m, 8 H, -N$^+$−CH$_2$−C*H*$_2$-), 1.64 (m, 8 H, -O$^+$−CH$_2$−C*H*$_2$-), 3.07 (m, 8 H, -N$^+$−C*H*$_2$-), 4.50 (t, 4 H, -O$^+$−C*H*$_2$-). ^{13}C NMR (200 MHz, [D3] CD_3CN, 25 °C, TMS): δ = 13.25, 19.76, 20.70, 23.74, 25.07, 58.76, 82.54. ^{11}B NMR (200 MHz, [D3] CD_3CN, 25 °C): −19.79 (1 B), −17.00 (10 B), 8.86 (1 B). IR (KBr): ν = 2962 (−C−H), 2873 (−C−H), 2492 (B−H), 1469 (−C−H), 1045 (−C−O−C−).

*4-(Bisdodecylmethyl)pyridine (***2a***), 4-(Bistetradecylmethyl)pyridine (***2b***), and 4-(Bishexadecylmethyl)pyridine (***2c***)* were synthesized as described by Meekel et al. *(34).*

General method for preparation of dodecaborate derivatives of SAINT lipids. **2** (0.42 g, 1 mmol) was suspended in 30 mL of dry acetonitrile and **1** (0.66 mmol) was added. The reaction mixture was refluxed for 4 days. The solvent was evaporated and the residue dissolved in methanol. After addition of cesium fluoride (0.15 g, 1 mmol) dissolved in methanol, a white precipitate as product was formed and filtered off. It was dried in oil pump vacuum.

4-(Bisdodecylmethyl)pyridinio-N-butoxy-undecahydro-closo-dodecaborate (−1), Cesium Salt (THF-SAINT-12). **2a** and **1b** were used. Yield 0.33 g (65%). MS (ESI, acetonitrile, *m*/*z*) negative 642.5 [A$^-$]; positive 132.8 [Cs$^+$]. ^{1}H NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 0.82 (t, 6H, −C*H*$_3$), 1.19 (m, 42 H, -(C*H*$_2$)$_{10}$CH$_3$, −O−CH$_2$−C*H*$_2$-), 1.62 (m, 6H, −C*H*$_2$−(C*H*$_2$)$_{10}$CH$_3$, −O−C*H*$_2$-), 1.91 (m, 2H, −C*H*$_2$−CH$_2$−N$^+$-), 2.86 (m, 1H, −C*H*-), 4.67 (m, 2H, −C*H*$_2$−N$^+$-), 7.93 (d, 2H, -C═C*H*-), 9.01 (d, 2H, -N$^+$═CH−). ^{13}C NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 14.84, 22.99, 27.56, 29.86, 30.79, 32.17, 35.65, 45.78, 60.25, 68.83, 127.39, 145.59, 166.68. ^{11}B NMR (200 MHz, [D6] DMSO, 25 °C): −23.28 (1 B), −17.24 (10 B), 6.62 (1 B). IR (KBr): ν = 2925 (−C−H), 2854 (−C−H), 2477 (−B−H), 1641 (-C═C−), 1468 (−C−H), 1159 (−C−N-), 1056 (−B−O−C-), 721 (═C−H).

4-(Bisdodecylmethyl)pyridinio-N-ethoxy-ethoxy-undecahydro-closo-dodecaborate (−1), Cesium Salt (Dioxan-SAINT-12). **2a** and **1a** were used. Yield 70%. MS (ESI, acetonitrile, *m*/*z*) negative 658.6 [A$^-$]; positive 132.9 [Cs$^+$]. ^{1}H NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 0.82 (t, 6H, −C*H*$_3$), 1.19 (m, 40H, -(C*H*$_2$)$_{10}$−CH$_3$), 1.61 (m, 4H, −C*H*$_2$−(CH$_2$)$_{10}$−CH$_3$), 2.86 (1 H, −C*H*-), 3.41 (m, 2H, B−O−C*H*$_2$-), 3.53 (m, 2H, −CH$_2$−C*H*$_2$−O−), 3.84 (m, 2H,−O−C*H*$_2$−CH$_2$−N$^+$-), 4.73 (m, 2H,-C*H*$_2$−N$^+$-), 7.92 (d, 2H, -C═C*H*-), 9.09 (d, 2H, -N$^+$═CH−). ^{13}C NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 13.96, 22.10, 26.70, 29.00, 31.28, 34.76, 44.90, 59.52, 67.27, 68.73, 72.63, 126.26, 143.35, 165.76. ^{11}B NMR (200 MHz, [D6] DMSO, 25 °C): −22.96 (1 B), −17.42 (10 B), 6.63 (1 B). IR (KBr): ν = 2919 (−C−H), 2852 (−C−H), 2478 (−B−H), 1643 (-C═C−), 1471 (−C−H), 1059 (−B−O−C-, −C−O−C-), 719 (═C−H).

4-(Bisdodecylmethyl)pyridinio-N-pentoxy-undecahydro-closo-dodecaborate (−1), Cesium Salt (Pyran-SAINT-12). **2a** and **1c** were used. Yield: 50%. MS (ESI, acetonitrile, *m*/*z*) negative 656.6 [A$^-$]; positive 132.8 [Cs$^+$]. ^{1}H NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 0.82 (t, 6H, −C*H*$_3$), 1.19−1.38 (m, 44H, -(C*H*$_2$)$_{10}$−CH$_3$, −O−CH$_2$−(C*H*$_2$)$_2$-), 1.61 (m, 6H, −C*H*$_2$−(CH$_2$)$_{10}$−CH$_3$, −C*H*$_2$−CH$_2$−N$^+$-), 1.89 (m, 2H, −O−C*H*$_2$-), 2.85 (m, 1H, −C*H*-), 4.53 (m, 2H, −CH$_2$−C*H*$_2$−N$^+$-), 7.97 (d, 2H, -C═C*H*-), 9.00 (d, 2H, -N$^+$═CH−). ^{13}C NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 14.10, 22.24, 26.76, 29.12, 30.61, 31.42, 34.87, 45.04, 60.03, 67.55, 126.88, 144.45, 166.04. ^{11}B NMR (200 MHz, [D6] DMSO, 25 °C): −22.99 (1 B), −17.42 (10 B), 6.60 (1 B). IR (KBr): ν = 3056 (═C−H), 2942 (−C−H), 2854 (−C−H), 2473 (−B−H), 1642 (-C═C−), 1468 (−C−H), 1160 (−C−N-), 1055 (−B−O−C-), 722 (═C−H).

4-(Bistetradecylmethyl)pyridinio-N-butoxy-undecahydro-closo-dodecaborate (−1), Cesium Salt (THF-SAINT-14). **2b** and **1b** were used. Yield 60%. MS (ESI, acetonitrile, *m*/*z*) negative 698.8 [A$^-$]; positive 132.9 [Cs$^+$]. ^{1}H NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 0.82 (t, 6H, −C*H*$_3$), 1.20 (m, 50 H, -(C*H*$_2$)$_{12}$CH$_3$, −O−CH$_2$−C*H*$_2$-), 1.61 (m, 6H, −C*H*$_2$−(CH$_2$)$_{12}$CH$_3$, −O−C*H*$_2$-), 1.91 (m, 2H, −C*H*$_2$−CH$_2$−N$^+$-), 2.86

(m, 1H, −C*H*-), 4.67 (m, 2H, −CH_2−N^+-), 7.93 (d, 2H, -C═C*H*-), 9.01 (d, 2H, -N^+═CH−). ^{13}C NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 13.93, 22.10, 26.65, 29.03, 29.93, 31.31, 34.73, 44.87, 59.30, 67.92, 126.46, 144.73, 165.76. ^{11}B NMR (200 MHz, [D6] DMSO, 25 °C): −22.52 (1 B), −17.86 − (−16.83) (10 B), 6.66 (1 B). IR (KBr): ν = 2924 (−C−H), 2854 (−C−H), 2477 (−B−H), 1642 (-C═C−), 1468 (−C−H), 1157 (−C−N-), 1056 (−B−O−C-), 721 (═C−H).

4-(Bistetradecylmethyl)pyridinio-N-ethoxy-ethoxy-undecahydro-closo-dodecaborate (−1), Cesium Salt (Dioxan-SAINT-14). **1a** and **2b** were used. Yield 60%. MS (ESI, acetonitrile, *m*/*z*) negative 714.8 [A^-]; positive 132.9 [Cs^+]. ^{1}H NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 0.82 (t, 6H, −CH_3), 1.2 (m, 48H, -(CH_2)$_{12}$−CH_3), 1.61 (m, 4H, −CH_2−(CH_2)$_{12}$−CH_3), 2.86 (1 H, −C*H*-), 3.40 (m, 2H, B−O−CH_2-), 3.54 (m, 2H, −CH_2−CH_2−O−), 3.84 (m, 2H,−O−CH_2−CH_2−N^+-), 4.73 (m, 2H,-CH_2−N^+-), 7.91 (d, 2H, -C═C*H*-), 9.10 (d, 2H, -N^+═CH−). ^{13}C NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 14.82, 22.99, 27.56, 29.9, 32.19, 35.59, 45.73, 60.41, 68.16, 69.65, 73.52, 127.15, 146.24, 166.62. ^{11}B NMR (200 MHz, [D6] DMSO, 25 °C): −22.67 (1 B), −17.65 − (−16.68) (10 B), 6.93 (1 B). IR (KBr): ν = 3059 (═C−H), 2924 (−C−H), 2853 (−C−H), 2473 (−B−H), 1643 (-C═C−), 1468 (−C−H), 1167 and 1109 (−C−N-), 1057 and 1027 (−B−O−C-, −C−O−C-), 722 (═C−H).

4-(Bistetradecylmethyl)pyridinio-N-pentoxy-undecahydro-closo-dodecaborate (−1), Cesium Salt (Pyran-SAINT-14). **1c** and **2b** were used. Yield 45%. 4-(Bishexadecylmethyl)pyridinio-N-pentoxy-undecahydro-closo-dodecaborate (−1), Cesium Salt (Pyran-SAINT-16). **1c** and **2c** were used. Yield 40%. MS (ESI, acetonitrile, *m*/*z*) negative 769.8 [A^-]; positive 132.9 [Cs^+]. ^{1}H NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 0.85 (t, 6H, −CH_3), 1.22−1.41 (m, 60H, -(CH_2)$_{14}$−CH_3, −O−CH_2−(CH_2)$_2$-), 1.63 (m, 6H, −CH_2−(CH_2)$_{14}$−CH_3, −CH_2−CH_2−N^+-), 1.92 (m, 2H, −O−CH_2-), 2.85 (m, 1H, −C*H*-), 4.55 (m, 2H, −CH_2−CH_2−N^+-), 7.96 (d, 2H, -C═C*H*-), 8.99 (d, 2H, -N^+═CH−). ^{13}C NMR (200 MHz, [D6] DMSO, 25 °C, TMS): δ = 14.10, 22.24, 26.76, 29.12, 30.61, 31.42, 34.87, 45.04, 60.03, 67.55, 126.88, 144.45, 166.04. ^{11}B NMR (200 MHz, [D6] DMSO, 25 °C): −23.69 (1 B), −17.30 (10 B), 7.13 (1 B). IR (KBr): ν = 2923 (−C−H), 2853 (−C−H), 2475 (−B−H), 1641 (-C═C−), 1466 (−C−H), 1159 (−C−N-), 1056 (−B−O−C-), 722 (═C−H).

N-Methyl-4-(dihexydecylmethyl)pyridinium Iodide (Me-SAINT-16). The compound was synthesized according to Sudhölter et al. (1982) (*35*) and Meekel et al. (*34*).

Preparation of Liposomes. The boron-containing lipids were either used in pure form or mixed with equal molar amounts of DSPC and cholesterol plus 2 mol % DSPE-PEG_{2000}. The lipid, or lipid mixture, was dissolved in chloroform and dried to a thin lipid film in a round-bottom flask. The lipid film was hydrated and dispersed by vortexing in 10 mM HEPES[1]buffer saline, pH 7.4 (150 mM NaCl, 10 mM HEPES). The resulting suspension was frozen and thawed in 10 cycles followed by extrusion (21 times) through a polycarbonate membrane with a pore diameter of 100 nm (Avestin, Mannheim, Germany) at a temperature of 50 °C. Final lipid concentration was 10 mM. Lipid content was measured by the Stewart assay (*36*), using appropriate standard curves for the individual lipids and ICP-MS measurements.

Liposomes could not be prepared from Dioxan-SAINT-12; the suspension obtained after hydration of the lipid film yielded larger particles, which could not be extruded even after ultrasound treatment.

For DSC measurements, the pure lipids were dispersed from a lipid film (obtained as described above) by hydration with 10 mM Hepes 100 mM NaCl, pH 7.4, through ten freeze−thaw cycles, and stored at 4 °C prior to measurement.

Inductively Coupled Plasma Mass Spectrometry (ICP-MS). ICP-MS was used to quantify boron in liposome preparations. The analysis was carried out in a ThermoElectron Element 2 ICP-MS apparatus, by measuring the signal for the boron-11 nuclide. The samples were treated with concentrated nitric acid (HNO_3) in the first dilution step and further diluted with water to concentration ranges appropriate for the sensitivity of the apparatus. The water produced by a Milli-Q system was used. The boron concentrations were determined by a calibration curve obtained from samples with known boron content. Indium was added as internal standard.

Cryotransmission Electron Microscopy (cryo-TEM). A small amount (~1 μL) of the liposome suspension (final lipid

[1]Abbreviations: HEPES, 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid; BNCT, boron neutron capture therapy; DSPC, distearoylphosphatidylcholine; BSH, $Na_2B_{12}H_{11}SH$; DSC, differential scanning calorimetry; DPPC, dipalmitoylphosphatidylcholine; TEM, transmission electron microscopy; ATP, adenosine triphosphate; BPA, boronphenylalanine; EGF, epidermal growth factor; SAINT, *s*ynthetic *a*mphiphiles for *i*nterdisciplinary *n*ucleic acid *t*herapy; ESI, electrospray ionization; ICP-MS, inductively coupled plasma mass spectrometry; DSPE, distearoylphosphatidylethanolamine.

concentration 5 mM) was transferred to a polymer-coated copper grid and shock-frozen from 25 °C by injection into liquid ethane. The vitrified samples were examined in a Zeiss EM LEO 912Ω electron microscope, operating at an accelerating voltage of 80 keV in filtered bright field image mode at $\Delta E = 0$ eV. The stage temperature was kept below 108 K, and images were recorded at defocus settings between 1 and 3 μm. Images were recorded by a slow scan charge-coupled device (SSCCD) camera using the minimal dose focusing device. To assess the reproducibility of the results, several images were recorded in different areas of the specimen.

Differential Scanning Calorimetry Measurements. Differential scanning calorimetry (DSC) measurements were carried out on a VP-DSC microcalorimeter from Microcal (Northhampton, MA), using the pure boron lipid (final lipid concentration 10 mM). The samples were degassed under vacuum prior to the measurement. For the up- and down-scans, a scan rate of 60 °C/h and a filtering period of 2 s were used. From each scan, a buffer background scan was subtracted. For data analysis, the software package ORIGIN (Microcal) was used. The buffer system for this measurement was 10 mM HEPES with 100 mM sodium chloride, pH = 7.4.

Viability Assay. The cell viability was determined with the CellTiter-Glo assay (Promega GmbH, Mannheim, Germany), which is based on the quantification of ATP, which is in turn proportional to the number of metabolically active cells.

The cell line V79 (lung fibroblasts of Chinese hamster) was cultivated with Ham's F10 medium and 10% fetal calf serum at 37 °C and 5% CO_2. Cells (20 000 per well) were seeded into 48-well plates and grown for 24 h. Then, the cells were incubated with different concentrations of boron-containing liposomes (DSPC/cholesterol/boron lipid (1:1:1 molar ratio) plus 2 mol % DSPE-PEG_{2000}) for 24 h. Then, 300 μL CellTiter-Glo reagent was added, and the luminescence was measured after few minutes (Microlumat Plus LB 96, EG & Bertold, Bad Wildbad, Germany). The average of two wells was compared with the average of eight untreated samples ($n = 2$).

The IC_{50} values were obtained by fitting a sigmoidal curve with the following equation:

$$f = \frac{a}{[1 + \exp(-(x - IC_{50})/b)]}$$

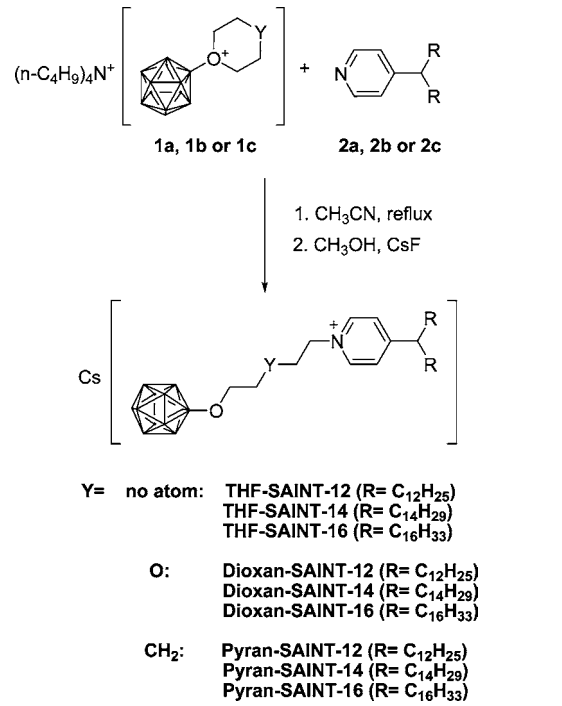
in which f corresponds to the percentage survival of cells, a corresponds to the response without inhibition, x to the concentration of the tested substance, b to the slope of the response curve at $c = IC_{50}$, and IC_{50} to the concentration of the tested substance that provokes 50% reduction of cell viability.

RESULTS

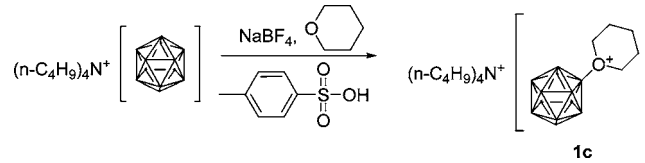
Chemistry. In this study, nine different dodecaborate cluster lipids were synthesized. All of them carry only one negative net charge. Recently, we published (*25*) the first boron lipids with a net charge of −1, but with a completely different basic structure. The lipids prepared here carry a bisalkylmethyl group on the *p*-position of a pyridine, which is *N*-alkylated with a linker carrying the dodecaborate cluster as polar headgroup. The lipids differ both in the alkyl chain length of the tails and in the linkers. For the connection of the dodecaborate cluster with the lipid backbone nucleophilic ring-opening reactions of tetrahydrofurane (THF), dioxane and tetrahydropyrane (THP) derivatives of the cluster with the alkylpyridinium compound (**2a**,**b**,**c**) were used (Scheme 2).

Semioshkin et al. (*37*) recently reported reactions of oxonium derivatives (THF and dioxane) with amines (also pyridine), but under different conditions and not applied to boron lipids. For the first time, we accomplished a ring-opening reaction with

Scheme 2. Synthesis of the Boron Lipids via Ring-Opening Reactions between the Alkylpyridnium Compound (2a,b,c) and the THF, Dioxane, and THP Derivative of the Dodecaborate Cluster, Respectively



Scheme 3. Synthesis of the Tetrahydropyrane (THP) Derivative of the Dodecaborate Cluster



the THP derivative of the cluster. The THP derivative had first been published by Peymann et al. (*33*) and had been prepared by alkylation of hydroxyundecahydro-*closo*-dodecaborate with dibromopentane, which requires two synthesis steps from the dodecaborate cluster to the THP derivative. We developed a reaction procedure that leads to the THP derivative from the unsubstituted cluster in one step and in good yields (Scheme 3).

The dodecaborate cluster is suspended in tetrahydropyrane, and 2 equiv *p*-toluenesulfonic acid and 5 equiv $NaBF_4$ are added. The product is obtained with a yield of 70%.

The synthesis of the alkylpyridinium compounds followed the work of Meekel et al. (*34*). The ring-opening reactions are carried out with the THF, dioxane, or THP derivatives of the cluster and 1.5 equiv alkylpyridinium compound (**2a**,**b**,**c**) in acetonitrile. The reaction yields are 50−70% for the THF and dioxane derivatives and 40−50% for the THP derivative, slightly depending on the length of the alkyl chain of the pyridine unit.

Physical Characterization and Liposome Preparation. The lipid film hydration and extrusion method at 50 °C was used to prepare liposomes from pure boron lipid. The structures formed were investigated by cryo-TEM (Figure 1).

The shortest chains with 12 carbons produce a mixture of liposomes and some open structures. THF-SAINT-12 (Figure 1a) forms predominantly closed vesicles but also some thick bilayers. The closed structures are heterogeneous in size; some of them are smaller than 100 nm, which is the diameter of the extrusion membrane pores. Pyran-SAINT-12 (Figure 1f) is able

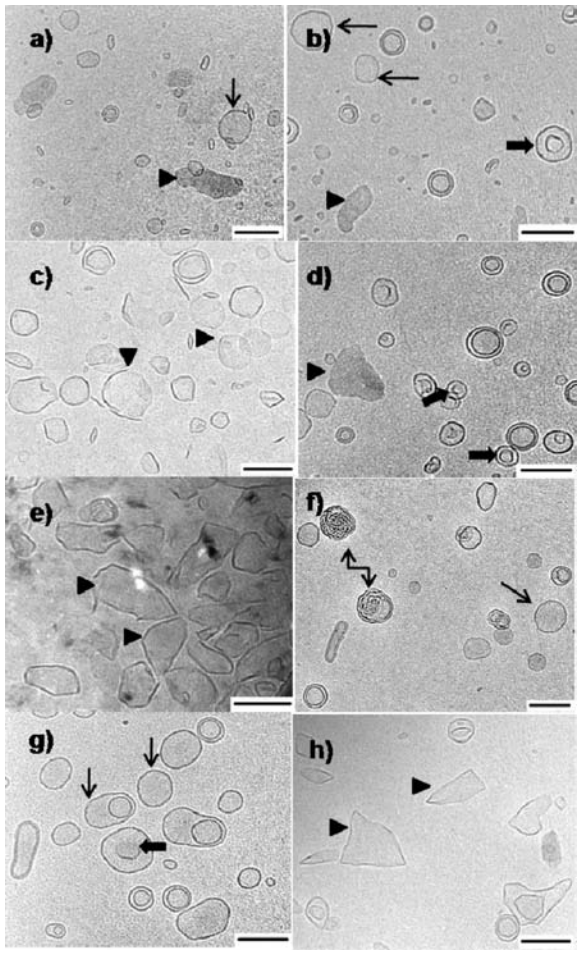


Figure 1. Cryo-TEM pictures from pure boron lipids: (a) THF-SAINT-12, (b) THF-SAINT-14, (c) THF-SAINT-16, (d) Dioxan-SAINT-14, (e) Dioxan-SAINT-16, (f) Pyran-SAINT-12, (g) Pyran-SAINT-14, (h) Pyran-SAINT-16. Scale bar 200 nm. Regular liposomes are indicated by ←, open structures by ▼, invaginated structures by thick arrows, and inverted structures by double-headed arrows.

to form liposomes, and inverted structures are observed. Closed structures are found in greatest abundance for all the three derivatives with 14-carbon chains. Only for THF-SAINT-14 and Dioxan-SAINT-14 are some bilayers observed. Interestingly, some of the liposomes show invagination. For the longer 16-carbon chains, the structures formed appear to be almost exclusively open. Several bilayers have edges bent upward, giving at first glance an impression of closed structures.

At the temperature of extrusion (50 °C) and preparation for cryo-TEM (25 °C), SAINT-16 derivatives are in the gel phase (see DSC data below), which is less favorable for the formation of liposomes. Extrusion at 65 °C and subsequent storage at 4 °C produces bilayer disks as well as closed liposomes (Figure 2a,b) in the case of THF-SAINT-16 and Dioxan-SAINT-16. This behavior is different from that of the lipid B-6−14, which forms very large bilayer sheets from liposomes below the phase transition temperature (*24*).

Interestingly, the choice of the spacer has no drastic influence on the morphology of the liposomes. Recently, we found drastic changes in the vesicle shape between the boron lipids B-THF-14 and B-Dioxan-14 (*25*) with change of the linker.

Cryo-TEM was employed also to visualize the structures formed when the boron-containing lipids had been mixed with helper lipids. For liposomal preparations, DSPC, cholesterol, and boron-containing lipid in the molar ratio of 1:1:1 plus 2 mol % DSPE-PEG_{2000} were used. THF-SAINT-12 (Figure 3a), THF-SAINT-14 (Figure 3b), and THF-SAINT-16 (Figure 3c) form liposomes in heterogeneous size. The liposome diameters differ from 100 nm, which is the pore size of the extrusion membrane, to 300 nm.

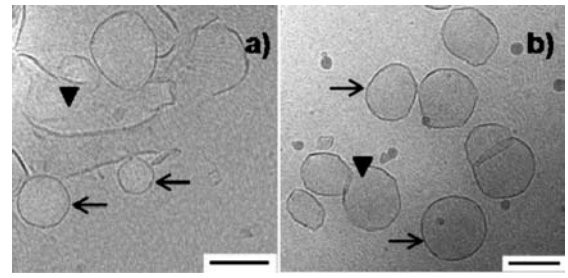

Figure 2. Samples from THF-SAINT-16 (a) and Dioxan-SAINT-16 (b) extruded at 65 °C and stored at 4 °C. Scale bar 200 nm. Regular liposomes are indicated by ←, open structures by ▼.

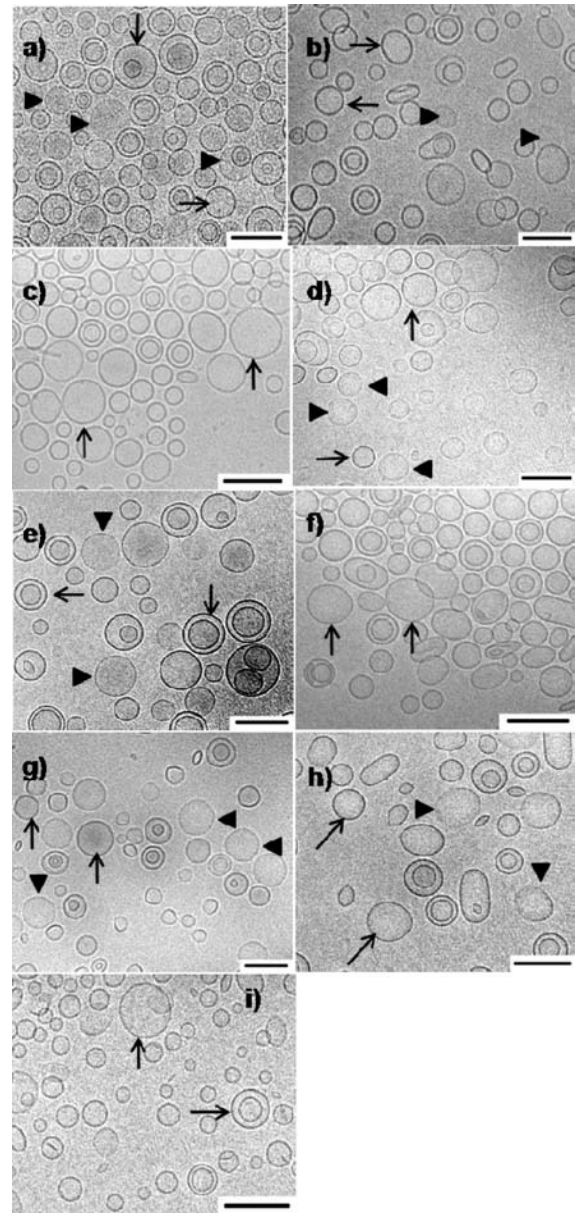

Figure 3. Cryo-TEM pictures of the liposomal preparations with helper lipids: DSPC/cholesterol/boron lipid (1:1:1) plus 2 mol % DSPE-PEG_{2000}: (a) THF-SAINT-12, (b) THF-SAINT-14, (c) THF-SAINT-16, (d) Dioxan-SAINT-12, (e) Dioxan-SAINT-14, (f) Dioxan-SAINT-16, (g) Pyran-SAINT-12, (h) Pyran-SAINT-14, (i) Pyran-SAINT-16. Scale bar 200 nm. Regular liposomes are indicated by ←, open structures by ▼.

For Dioxan-SAINT-12 (Figure 3d), Dioxan-SAINT-14 (Figure 3e), and Dioxan-SAINT-16 (Figure 3f), also liposomes can be observed in different sizes. By adding helper lipids, liposomal vesicles are also found for Pyran-SAINT-12 (Figure 3g), Pyran-SAINT-14 (Figure 3h), and Pyran-SAINT-16 (Figure 3i) with a size distribution. In general, the formation of liposomes is influenced by the chain length of the tails in the SAINTs. With mixtures containing the short-chain derivatives, an increased tendency to form open structures can be seen.

In the DSC measurements, no phase transition could be detected for any of the three SAINT-12 derivatives. This fact is, however, not surprising because Me-SAINT-12 (1-methyl-4-(bisdodecylmethyl)pyridinium chloride) has a phase transition at 0 °C (*34*), which is outside the range accessible by the DSC used.

The DSC profile of pure THF-SAINT-14 is shown in Figure 4a. From 4 to 20 °C, a broad peak with complex shape can be seen, which consists of two transitions at 13.8 and 16.8 °C. Both transitions change only insignificantly between the first and the second upscan. The two transitions might arise from the heterogeneity of the vesicle shapes and sizes (see Figure 1b). In the literature, it is known that small unilamellar vesicles (SUVs) give rise to a main transition different from that of multilamellar (MLVs) or large unilamellar vesicles (LUVs) (*38*). Interestingly, in the first upscan two further transitions at 33.0 and 66.5 °C can be observed, which disappear in the following upscans. Metastable subtransitions are described, e.g., for DPPC (dipalmitoylphosphatidylcholine) bilayers in gel phase (*39, 40*), which are reversible after storage at low temperatures for a few days. The transitions for THF-SAINT-14 are surprising in the liquid phase, and we have no evidence about the reversibility or explanation for structural changes in these phases. In cryo-TEM, no change in the vesicle shape was found after heating (pictures not shown here).

The temperature difference (approximately 4 °C) of the transition peaks between the up- and down-scans is remarkable; such strong hysteresis has only been described for the boron lipid B-THF-14 (*25*). Furthermore, it seems that the transitions in the downscan do not end at 4 °C and perhaps more transitions might follow. In contrast, Dioxan-SAINT-14 (Figure 4b) has a broad peak with a maximum at 12.3 °C. The broadness indicates that the liposome composition is heterogeneous, as can also be observed in cryo-TEM (see Figure 3d). The temperature difference (approximately 4 °C) of the transition peaks between the up- and down-scans is again remarkable. The transition does not end at 4 °C in the downscan. The DSC profile of Pyran-SAINT-14 (Figure 4c) shows a broad peak from 4 to 18 °C, similar to THF-SAINT-14. The maxima are located at 8.5 and 12.4 °C and are probably the main transitions. Meekel et al. (*34*) recorded a main transition of Me-SAINT-14 (1-Methyl-4-(ditetradecylmethyl)pyridinium chloride) at approximately 16 °C. We again attribute the two transitions to the heterogeneity of vesicle formation and size. No transitions in the downscan can be observed, which indicates that they are located outside of the temperature range in which the measurements were performed.

The DSC profile is more complex for all SAINT-16 derivatives (Figure 5). All of them show multiple transitions, which occur at similar temperatures; the transitions recur during all up- and down-scans. THF-SAINT-16 (Figure 5a) has a main transition at 56.0 °C. Sudhölter et al. (*35*) reported a main transition for Me-SAINT-16 (1-Methyl-4-(dihexadecylmethyl)pyridinium chloride) at 64 °C and we also detected it, although at 58 °C (data not shown here). THF-SAINT-16 passes through three further transitions at 24.9, 39.0, and 62.8 °C. A rich polymorphism in the DSC is known for N-methylated pyridinium cores depending on the counterion, with solid−solid

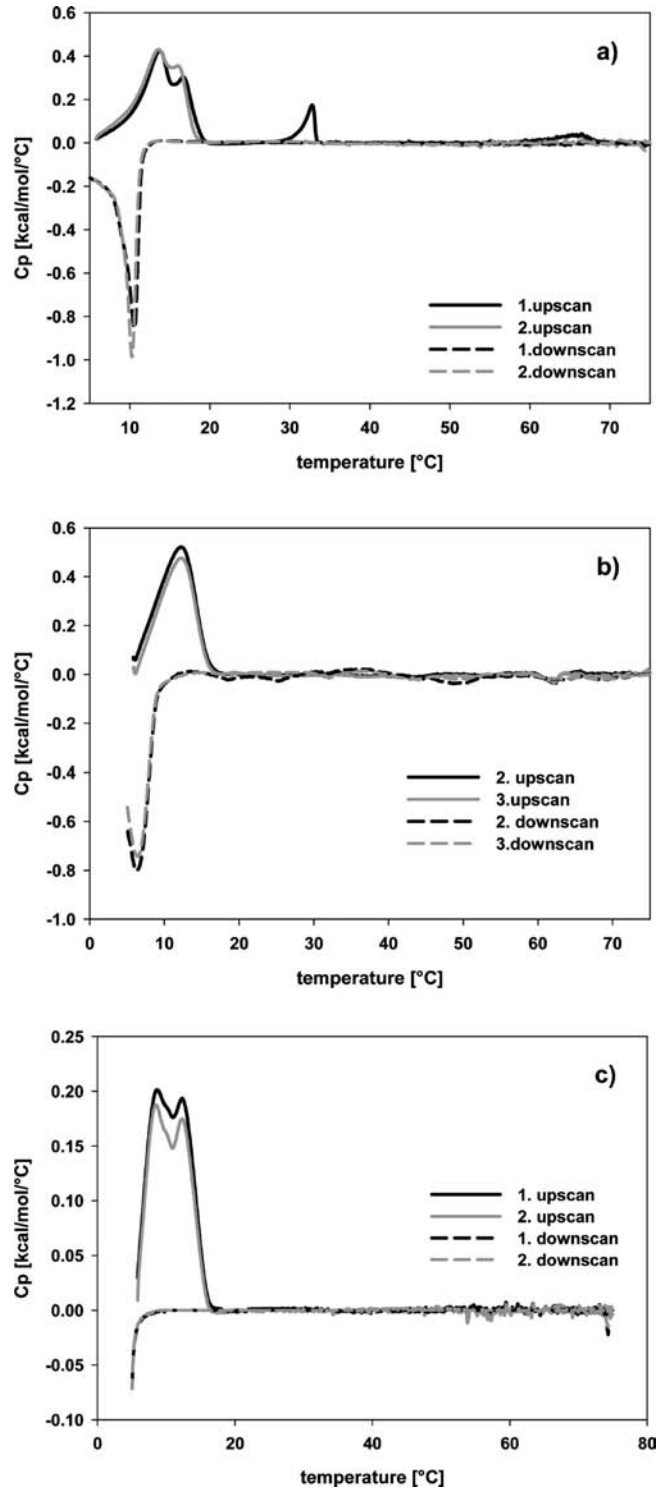

Figure 4. DSC of pure films of THF-SAINT-14 (a), Dioxan-SAINT-14 (b), and Pyran-SAINT-14 (c). Lipid concentration 5 mM.

transitions and transitions between smectic phases (*35*). Therefore, solid−solid and liquid−liquid transitions are not very special for this boronated pyridinium lipid.

A tilted smectic phase is described by Sudhölter et al. (*35*) for Me-SAINT-16 iodide. Molecular dynamics simulation would certainly be required for THF-SAINT-16 to answer precisely the question of lipid packing. In the downscan, only two transitions are visible. As can be seen in Figure 5b, Dioxan-SAINT-16 also has four transitions, which are located at 26.8, 39.9, 55.2, and 62.8 °C. Two solid−solid transitions can be noted, as well as a main transition at 55.2 °C and a liquid−liquid

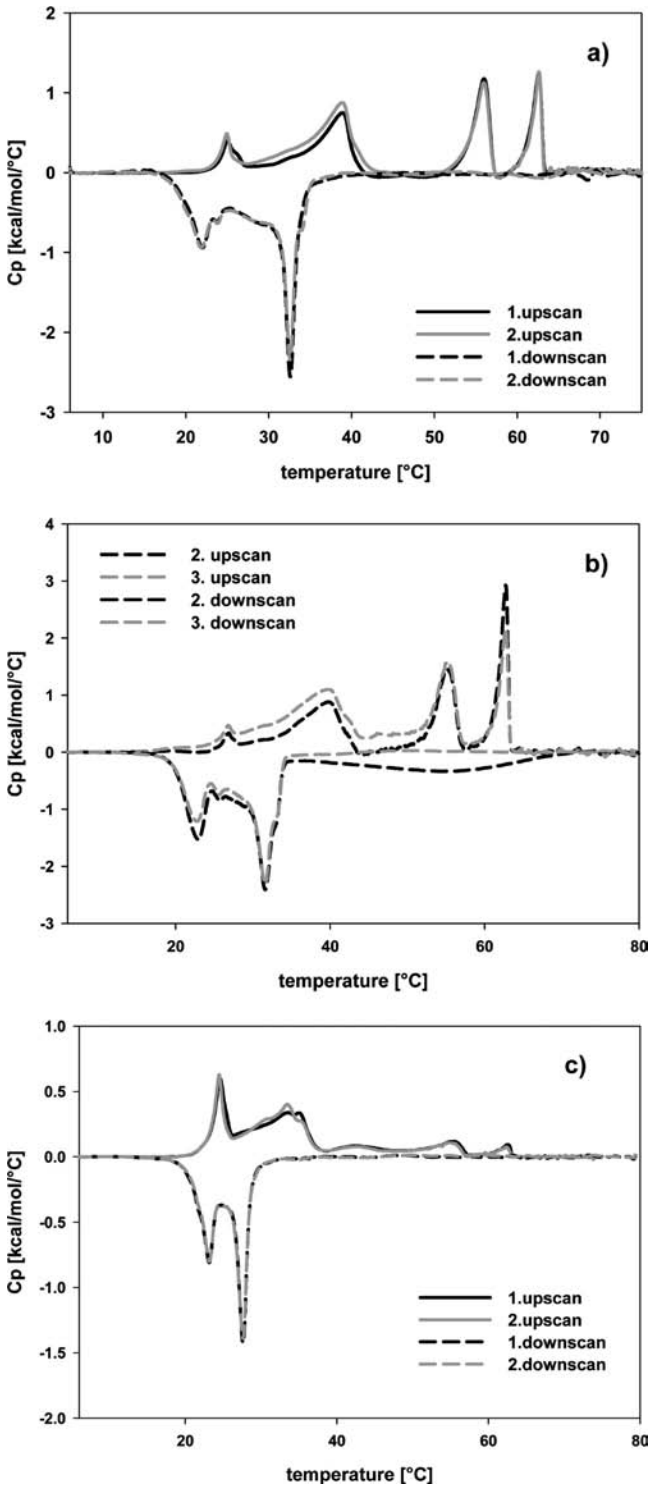

Figure 5. DSC of pure films of THF-SAINT-16 (a), Dioxan-SAINT-16 (b), and Pyran-SAINT-16 (c). Lipid concentration 10 mM.

transition at 62.8 °C, which is comparable to THF-SAINT-16. Again, only two peaks in the downscan can be observed. Pyran-SAINT-16 shows transitions in the same temperature region (24.4, 33.6, 55.1, and 62.4 °C) as THF-SAINT-16 and Dioxan-SAINT-16, but for Pyran-SAINT-16, the transitions at higher temperatures have very small enthalpies. We have no explanation for this, but it might be assumed that the transitions concern the same event of transitions as in THF-SAINT-16 and Dioxan-SAINT-16.

As summarized in Table 1, all investigated lipids have a low impact on cell viability except for Dioxan-SAINT-12 and Dioxan-SAINT-14 (Table 1). It seems that the choice of the linker influences the viability in the case of short alkyl chains. The dioxane linker leads to a higher toxic effect as compared to the THF or THP linker. This is contrary to the boron lipids B-THF-14 and B-Dioxan-14 where the introduction of an ether function in the hydrocarbon spacer leads to a decrease of toxicity (*25*).

Table 1. IC_{50} Values and Standard Deviations for All of the Tested Lipids[a]

name	log IC_{50} ± SD	IC_{50} [mM]
THF-SAINT-12	0.18 ± 0.02	1.5
THF-SAINT-14	0.51 ± 0.07	3.3
THF-SAINT-16	0.68 ± 0.01	4.8
Dioxan-SAINT-12	−0.56 ± 0.03	0.3
Dioxan-SAINT-14	−0.16 ± 0.14	0.7
Dioxan-SAINT-16	0.49 ± 0.02	3.0
Pyran-SAINT-12	0.27 ± 0.04	1.9
Pyran-SAINT-14	0.14 ± 0.02	1.4
Pyran-SAINT-16	0.54 ± 0.03	3.4

[a] For the determination of the cell viability, hamster V79 fibroblasts and the CellTiter-Glo assay were used.

The increasing alkyl chains lead to a significant decrease of toxicity in the case of THF-SAINT and Dioxan-SAINT lipids. This tendency is not well pronounced for the Pyran-SAINT lipids; however, the toxicity decreases by half from Pyran-SAINT-12 to Pyran-SAINT-16. Previously, we found a similar trend for the lipids B-6-14 and B-6-16 (*24*).

It seems that the linker influences the viability for longer alkyl chains less powerfully because the IC_{50} values are all in the same concentration range (4 mM ± 1.5 mM). Thus, for the SAINT-16 derivatives, the influence on cell viability depends only slightly on the nature of the linker, whereas this is not the case for shorter alkyl chains.

DISCUSSION

Synthesis of nine *closo*-dodecaborate cluster containing lipids was achieved. These SAINT derivatives are the first boron lipids with an alkylpyridinium core as lipid backbone. The lipids differ in their alkyl chain length and in the linker connecting the dodecaborate cluster with the lipid backbone. All of them are only singly negatively charged; thus, they are the second generation of boron lipids with a net charge of −1 (*25*). The net charge of liposomes influences the biological properties. The incorporation of negatively charged lipids into the liposomal membrane accelerates the opsonization and consequently the clearance of liposomes from the bloodstream (*41*). The decrease of lipid charge may, by reduced clearance, lead to longer retention times in the body in comparison to doubly negatively charged dodecaborate cluster lipids. Thus, dodecaborate cluster lipids with reduced net charge (up to a neutral molecule) might be desirable in regard to therapeutic efficacy.

The change in the negative net charge does not influence the toxicity of the dodecaborate cluster lipids against cells. Thus, the IC_{50} values of the SAINTs lie in the same concentrations range as B-6-14 (*24*). Studies of cell uptake are in progress for the SAINTs, B-Dioxan-14, B-6-14, and B-6-16, in order to investigate the influence of the different net charges in more detail.

Depending on the preparation temperature, the SAINT lipids are able to form closed liposomes in the absence of helper lipids and are stable after storing at 4 °C. The liposomes from pure boron lipid are able to transfer high amounts of boron to the tumor. Targeting with tumor-seeking entities probably allows selective accumulation.

Interestingly, the choice of the linker plays no major role with respect to liposome formation or thermotropic behavior. Recently, we reported about the lipids B-THF-14 and B-Dioxan-14 in which only the linker differs. For those lipids, the linker influences the vesicle formation as well as the DSC profile (*25*). The absence of the effect of the linker on toxicity observed here is very unexpected and makes it difficult to propose an optimal linker for further syntheses.

The length of the alkyl chains influences the properties of the lipids with regard to their thermotropic behavior, liposome formation in the absence and in the presence of helper lipids, and cell toxicity. Higher temperatures are necessary during the preparation of liposomes when the length of the chains increases. It must be pointed out that the helper and boron lipids should not differ significantly in their tail lengths. Therefore, DSPC, which is commonly used as helper lipid for *in vivo* experiments, is suitable for the SAINT-16 derivatives. Longer lipid tails lead to a decrease of toxicity and are consequently recommended for dodecaborate cluster lipids.

All SAINT lipids have been prepared as cesium salts. The purification of the lipids by precipitation from methanol could be achieved by addition of a solution of cesium fluoride in methanol; this is an elegant procedure and consequently recommended for synthesis strategies of boron lipids. In contrast to, e.g., the tetramethylammonium ion (which is toxic *in vivo*), the cesium ion does not carry a substantial toxicity on its own.

The new lipids, with the exception of Dioxan-SAINT-12 and Dioxan-SAINT-14, have low *in vitro* toxicity and hence might represent suitable boron carriers for BNCT. *In vivo* experiments on mice are in progress to proceed to the next stage toward successful treatment with BNCT.

ACKNOWLEDGMENT

The authors gratefully thank Dr. Uwe Schüßler for the ICP-MS measurements. We would also like to thank Lipoid GmbH for generous gifts of lipids. This work has been financially supported by the German Research Council DFG through a joint grant to DG, RS, and RPS.

Supporting Information Available: ^{1}H NMR, ^{13}C NMR, and ^{11}B NMR spectra; ESI mass spectra, and IR spectra of compounds **1c** and all SAINT lipids. This material is available free of charge via the Internet at http://pubs.acs.org.

Radiolabeled Cyclic RGD Peptides as Integrin $\alpha_v\beta_3$-Targeted Radiotracers: Maximizing Binding Affinity via Bivalency

Shuang Liu*

School of Health Sciences, Purdue University, 550 Stadium Mall Drive, West Lafayette, Indiana 47907. Received April 13, 2009; Revised Manuscript Received July 7, 2009

Integrin $\alpha_v\beta_3$ plays a significant role in tumor angiogenesis and is a receptor for the extracellular matrix proteins with the exposed arginine-glycine-aspartic (RGD) tripeptide sequence. These include vitronectin, fibronectin, fibrinogen, lamin, collagen, Von Willibrand's factor, osteoponin, and adenovirus particles. Integrin $\alpha_v\beta_3$ is expressed at low levels on epithelial cells and mature endothelial cells, but it is overexpressed on the activated endothelial cells of tumor neovasculature and some tumor cells. The restricted expression of integrin $\alpha_v\beta_3$ during tumor growth, invasion, and metastasis presents an interesting molecular target for both early detection and treatment of rapidly growing solid tumors. Over the past decade, many radiolabeled linear and cyclic RGD peptide antagonists have been evaluated as integrin $\alpha_v\beta_3$-targeted radiotracers. Significant progress has been made on their use for imaging integrin $\alpha_v\beta_3$-positive tumors by SPECT or PET. Among the radiotracers evaluated in preclinical tumor-bearing models, [^{18}F]Galacto-RGD (2-[^{18}F]fluoropropanamide c(RGDfK(SAA); SAA = 7-amino-L-glyero-L-galacto-2,6-anhydro-7-deoxyheptanamide) and [^{18}F]-AH111585 are currently under clinical investigation for visualization of integrin $\alpha_v\beta_3$ expression in cancer patients. However, their low tumor uptake, high cost, and lack of preparative modules for routine radiosynthesis will limit their continued clinical application. Thus, there is a continuing need for more efficient integrin $\alpha_v\beta_3$-targeted radiotracers that are readily prepared from a kit formulation without further postlabeling purification. This article will focus on different approaches to maximize the targeting capability of cyclic RGD peptides and to improve the radiotracer excretion kinetics from noncancerous organs. Improvement of tumor uptake and tumor-to-background ratios is important for early detection of integrin $\alpha_v\beta_3$-positive tumors and/or noninvasive monitoring of therapeutic efficacy of antiangiogenic therapy.

INTRODUCTION

Cancer is the second leading cause of death worldwide. Although the exact cause of cancer remains unknown, most cancer patients will survive after surgery, radiation therapy, and chemotherapy or a combination thereof if it can be detected at an early stage. Thus, accurate early detection is highly desirable so that appropriate therapy can be given before the primary tumors become widely spread.

Tumors produce many angiogenic factors, which are able to activate endothelial cells in established blood vessels and induce endothelial proliferation, migration, and new vessel formation (angiogenesis) through a series of sequential but partially overlapping steps. Angiogenesis is a requirement for tumor growth and metastasis (*1*−*7*). Without the neovasculature to provide oxygen and nutrients, tumors cannot grow beyond 1−2

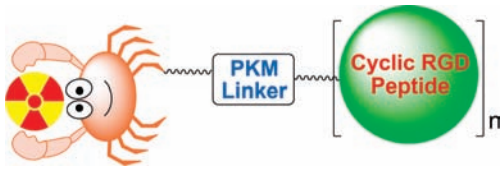

Figure 1. Schematic presentation of the radiotracer design. The targeting biomolecule is a multimeric cyclic RGD peptide. The PKM linker is used to modify radiotracer pharmacokinetics. For the metal-containing radiotracers, a multidentate BFC is often used to attach the metallic radionuclide to the targeting biomolecule. For ^{18}F-based radiotracers, an organic precursor or synthon is often needed to attach ^{18}F onto the multimeric cyclic RGD peptide.

mm in size. Once vascularized, the tumors begin to grow rapidly. The angiogenic process depends on vascular endothelial cell migration and invasion and is regulated by cell adhesion receptors. Integrins are such a family of proteins that facilitate the cellular adhesion to and the migration on extracellular matrix proteins in the intercellular spaces and basement membranes, and regulate cellular entry and withdraw from the cell cycle (*7*−*10*). Integrin $\alpha_v\beta_3$ serves as a receptor for extracellular matrix proteins with exposed arginine-glycine-aspartic (RGD) tripeptide sequence (*8*−*13*). These include vitronectin, fibronectin, fibrinogen, lamin, collagen, osteoponin, and adenovirus particles. Integrin $\alpha_v\beta_3$ is expressed at low levels on epithelial cells and mature endothelial cells; but it is highly expressed on activated endothelial cells in neovasculature of tumors, including osteosarcomas, neuroblastomas, glioblastomas, melanomas, lung carcinomas, and breast cancer (*14*−*16*). It has been demonstrated that integrin $\alpha_v\beta_3$ is overexpressed on both the endothelial cells and tumor cells in human breast cancer xenografts (*17*). The integrin $\alpha_v\beta_3$ expression correlates well with tumor progression and invasiveness of melanoma, glioma, ovarian, and breast cancers (*10*−*17*). The restricted expression of integrin $\alpha_v\beta_3$ during tumor growth, invasion, and metastasis present an interesting molecular target for diagnosis and treatment of the rapidly growing and metastatic tumors (*18*−*32*).

Over the past decade, many radiolabeled cyclic RGD peptides have been evaluated as radiotracers for imaging tumors by SPECT or PET (*33*−*68*). Several review articles have appeared covering the nuclear medicine applications of radiolabeled cyclic RGD peptide and nonpeptide antagonists as radiotracers for diagnosis and radiotherapy of integrin $\alpha_v\beta_3$-positive tumors (*17*−*29*). This article is not intended to be an exhaustive review of the current literature on radiolabeled RGD peptides and nuclear medicine applications. Instead, it will focus on different approaches to maximize their targeting capability and to improve the radiotracer excretion kinetics from noncancerous organs. Improvement of tumor uptake and tumor-to-background (T/B) ratios is important for both diagnostic and therapeutic radiotracers.

Radiotracer Design. Figure 1 shows a schematic illustration of an integrin $\alpha_v\beta_3$-targeted radiotracer. Cyclic RGD peptide serves as the targeting biomolecule to carry radionuclide to the integrin $\alpha_v\beta_3$ overexpressed on tumor cells and activated endothelial cells of tumor neovasculature. A multidentate bifunctional chelator (BFC) is used to attach the metallic radionuclide to the cyclic RGD peptide (*69*−*72*), whereas an organic precursor or synthon is often needed for the ^{18}F-labeling (*73*). The pharmacokinetic modifying linker (PKM) is used to improve the radiotracer excretion kinetics (*69*−*71*). For a new integrin $\alpha_v\beta_3$-targeted radiotracer to be successful, it must show clinical indications for high-incidence tumors (breast, lung, colorectal, prostate, and skin cancers). The radiotracer should have high tumor uptake and T/B ratios in a short period of time. To achieve this goal, the radiotracer should have a rapid blood clearance to minimize background radioactivity. Since most high-incidence tumors (breast, lung, and colorectal cancers) occur in the torso, renal excretion is necessary to avoid radioactivity accumulation in the gastrointestinal tract. The integrin $\alpha_v\beta_3$-targeted radiotracer should also be able to distinguish between benign and malignant tumors, to follow tumor growth and metastasis, and to predict therapeutic efficacy in integrin $\alpha_v\beta_3$-positive cancer patient. In addition, a kit formulation or preparative module is needed for routine preparation of the radiotracer in high yield and radiochemical purity at low cost.

Choice of Radionuclide. The choice of radionuclide depends largely on the clinical utility of radiotracer. For planar imaging and SPECT, more than 80% of radiotracers used in nuclear medicine departments are ^{99m}Tc compounds due to optimal nuclear properties of ^{99m}Tc and its easy availability at low cost (*69*−*72*). The 6 h half-life is long enough to allow radiopharmacists to carry out radiosynthesis and for physicians to collect clinically useful images. At the same time, it is short enough to permit administration of 20−30 mCi of ^{99m}Tc without imposing a significant radiation dose to the patient. The monochromatic 140 KeV photons are readily collimated to give high-quality images with high spatial resolution. The clinically most relevant radionuclides for PET include ^{18}F, ^{62}Cu, ^{64}Cu, and ^{68}Ga.

^{18}F is a cyclotron-produced isotope suitable for PET. It has a half-life of 110 min. For several years, ^{18}F-FDG (FDG = 2-fluoro-2-deoxyglucose) has been widely used as an imaging tool for diagnosis of cancers and brain and cardiovascular diseases. Despite its short half-life, the availability of preparative modules makes ^{18}F-labeled biomolecules much more accessible to researchers and clinicians in many clinical institutions.

^{62}Cu is a generator-produced radionuclide from the decay of ^{62}Zn. Its 9.7 min half-life allows repeated dosing without imposing a significant radiation burden to the patient. The commercially available ^{62}Zn−^{62}Cu generator has been successfully used in clinical trials (*74*−*77*). ^{64}Cu is another PET isotope useful for development of target-specific radiotracers. It has a half-life of 12.7 h and a β^+ emission (18%, E_{max} = 0.655 MeV). Despite poor nuclear properties, its long half-life makes it feasible to prepare, transport, and deliver the ^{64}Cu radiotracer for clinical applications. More importantly, recent breakthroughs in production of ^{64}Cu with high specific activity have made it more available to the small research institutions without on-site cyclotron facilities (*78*). ^{64}Cu is a viable alternative to ^{18}F for research programs that wish to incorporate high sensitivity and high spatial resolution of PET, but cannot afford to maintain the expensive radionuclide production infrastructure. Copper radionuclides and related radiochemistry have been reviewed by Blower et al. (*79*). Nuclear medicine applications of ^{64}Cu-labeled monoclonal antibodies and peptides have been reviewed by Anderson et al. (*75, 80*).

^{68}Ga is a generator-produced PET isotope with a half-life of 68 min. The ^{68}Ge−^{68}Ga generator can be used for more than a year, allowing PET studies without the on-site cyclotron. If the radiotracer is properly designed, ^{68}Ga could become as useful for PET as ^{99m}Tc for SPECT (*81, 82*). In support of this, the ^{68}Ga-labeled somatostatin analogues have been studied extensively for PET imaging of somatostatin-positive tumors in animal models and cancer patients (*83*−*91*). Gallium chemistry and related medical applications have been reviewed recently (*81, 82, 92*).

Bifunctional Chelators. The choice of BFC depends on the radionuclide. ^{18}F can be incorporated into the cyclic RGD peptide via a covalent bond without the need for BFC. In contrast, BFC is an important part of radiotracers containing a metallic radionuclide (*69*−*72, 92*). Among various BFCs (Figure 2), 6-hydazinonicotinic acid (HYNIC) is of great interest due to its high ^{99m}Tc-labeling efficiency (rapid radiolabeling and high

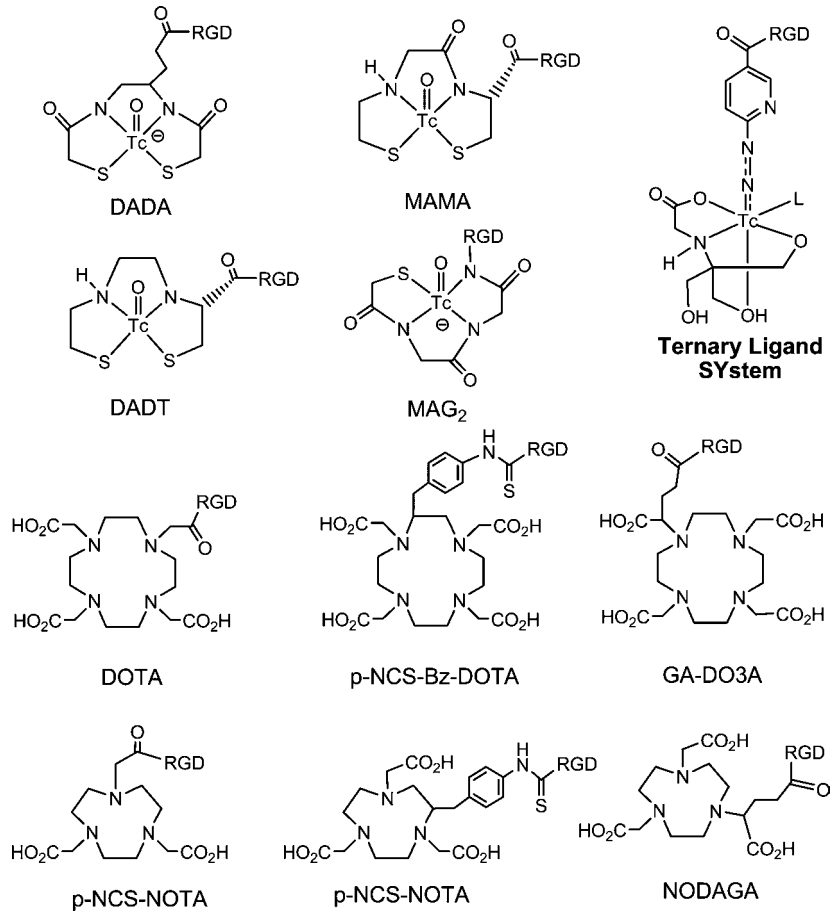

Figure 2. BFCs useful for radiolabeling of multimeric cyclic RGD peptides with ^{99m}Tc, ^{68}Ga, and ^{64}Cu. DADA (diamidodithiol), MAMA (monoaminemonoamidedithiol), MADT (diaminedithiol), MAG_2 (2-mecaptoacetylglycylglycyl), and HYNIC are particularly useful for ^{99m}Tc-labeling, while DOTA, NOTA, and their derivatives are excellent BFCs for chelation of ^{68}Ga and ^{64}Cu.

radiolabeling yield), the high solution stability of its ^{99m}Tc complexes, and the easy use of different coligands for modification of biodistribution characteristic of ^{99m}Tc-labeled small biomolecules (*93*). DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid), NOTA (1,4,7-tritazacyclononane-1,4,7-triacetic acid), and their derivatives (Figure 2) have been used as BFCs for ^{68}Ga and ^{64}Cu-labeling of small biomolecules (*84*−*91*). NODAGA is particularly useful for ^{68}Ga- and ^{64}Cu-labeling due to high hydrophilicity and in vivo stability of its ^{68}Ga and ^{64}Cu chelates. It has been reported that NOTA derivatives have much higher ^{68}Ga and ^{64}Cu-labeling efficiency than their DOTA analogues (*94*−*98*). The fast and efficient radiolabeling is especially critical for ^{68}Ga and ^{62}Cu due to their short half-life ($t_{1/2}$ = 68 min for ^{68}Ga and 9.7 min for ^{62}Cu).

PKM Linkers. In general, high lipophilicity often leads to more hepatobiliary excretion and/or high protein binding, which will result in longer blood retention of radioactivity. Hepatobiliary excretion is detrimental for improvement of T/B ratio. Thus, an important aspect of radiotracer development is to improve T/B ratios by modifying pharmacokinetics of radiolabeled cyclic RGD peptides. For example, the negatively charged small peptide sequences or amino acids have been proposed as PKM linkers to reduce renal uptake and kidney retention of radiolabeled small biomolecules (*70, 71, 92*). The di(cysteic acid) linker has successfully been used to improve the blood clearance and minimize the liver and kidney activity of radiolabeled nonpeptide integrin $\alpha_v\beta_3$ receptor antagonists (*99*−*102*). The Asp_3 and Ser_3 tripeptide sequences were also used to modify excretion kinetics of the ^{99m}Tc-labeled cyclic RGD peptide (*39*). Harris et al. reported the use of a PEG_4 (15-amino-4,7,10,13-tetraoxapentadecanoic acid) linker to improve the tumor uptake and T/B ratios of the ^{99m}Tc-labeled nonpeptide integrin $\alpha_v\beta_3$ receptor antagonists (*99*−*102*). Kessler et al. reported the use of HEG (hexaethylene glycolic acid) as the PKM linker for the ^{18}F-labeled cyclic RGDfE dimers and tetramers (*40*−*42*). Using the HEG linker also increases the distance between the cyclic RGD motifs. Chen et al. also found that the introduction of the PEG (polyethylene glycolic acid) linker can improve the tumor uptake and excretion kinetics of ^{125}I- and ^{18}F-labeled c(RGDyK) and ^{64}Cu-labeled $E[c(RGDyK)]_2$ (*48, 49, 54, 103*).

Targeting Biomolecules. Figure 3 shows several examples of cyclic RGD peptides that have high affinity and selectivity for integrin $\alpha_v\beta_3$. Among the radiotracers evaluated in preclinical tumor-bearing models, [^{18}F]Galacto-RGD (Figure 3: 2-[^{18}F]fluoropropanamide c(RGDfK(SAA); SAA = 7-amino-L-glyero-L-galacto-2,6-anhydro-7-deoxyheptanamide) and [^{18}F]-AH111585, the core sequence of which was originally discovered from a phage display library (as ACDRGDCFCG), are currently under clinical investigation for visualization of integrin $\alpha_v\beta_3$ expression in cancer patients (*104*−*109*). The results from imaging studies in cancer patients show that there is sufficient integrin $\alpha_v\beta_3$ expression for PET imaging and the accumulation of radiolabeled RGD peptide radiotracer correlates well with the integrin $\alpha_v\beta_3$ expression levels in cancer patients (*108, 109*). However, their relatively low tumor uptake, high cost, and lack of preparative modules for routine radiosynthesis will limit their continued clinical applications. Several steps of manual radiosynthesis and postlabeling purification often cause significant radiation exposure to radiopharmacists. Of course, this problem can be solved by developing preparative modules for routine radiosynthesis, which will definitely lead to added cost for the

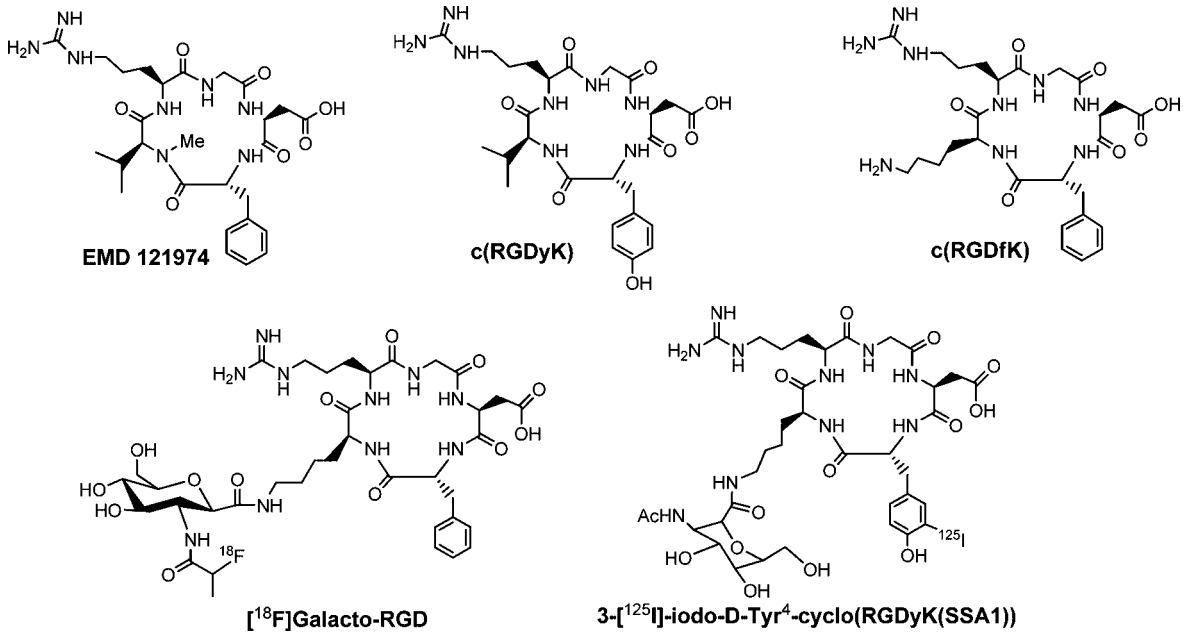

Figure 3. Chemdraw structures of cyclic RGD peptides useful as targeting biomolecules for the integrin $\alpha_v\beta_3$-targeted radiotracers. [^{18}F]Galacto-RGD (2-[^{18}F]fluoropropanamide c(RGDfK(SAA); SAA = 7-amino-L-glyero-L-galacto-2,6-anhydro-7-deoxyheptanamide) is currently under clinical investigation for visualization of integrin $\alpha_v\beta_3$ expression in cancer patients.

radiotracer. Thus, this is a continuing need for more efficient integrin $\alpha_v\beta_3$-specific radiotracers that are readily prepared from a kit formulation without further postlabeling chromatographic purification.

Maximizing Binding Affinity via Multimerization. *Cyclization to Improve Binding Affinity and Selectivity.* Many cyclic RGD peptides have been proposed as the integrin $\alpha_v\beta_3$ antagonists for treatment of cancer. It was found that incorporation of the RGD sequence into a cyclic pentapeptide framework (Figure 3) increases the binding affinity and selectivity for integrin $\alpha_v\beta_3$ over glycoprotein IIb/IIIa (*110*−*113*). After extensive structure−activity evaluations, it was concluded that the amino acid in position 5 has no significant impact on integrin $\alpha_v\beta_3$ binding affinity. The valine (V) residue in c(RGDfV) can be replaced by lysine (K) or glutamic acid (E) to afford c(RGDfK) and c(RGDfE), respectively, without changing the integrin $\alpha_v\beta_3$ binding affinity.

Cyclic RGD Dimers. To improve integrin $\alpha_v\beta_3$ binding affinity, multimeric RGD peptides, such as E[c(RGDfK)]$_2$, have been used to develop integrin $\alpha_v\beta_3$-targeted radiotracers. For example, Rajopadhye et al. were the first to use cyclic RGD dimers, such as E[c(RGDfK)]$_2$ (Figure 4), to develop diagnostic (^{99m}Tc) and therapeutic (^{90}Y and ^{64}Cu) radiotracers (*56, 57, 114, 115*). Recently, Chen et al. (*50, 51*) reported the ^{64}Cu- and ^{18}F-labeled E[c(RGDyK)]$_2$ (Figure 4) as PET radiotracers. Poethko et al. found that the RGDfE dimer [c(RGDfE)HEG]$_2$-K-Dpr-[^{18}F]FBOA (Figure 4) had much better targeting capability as evidenced by its higher integrin $\alpha_v\beta_3$ binding affinity and tumor uptake as compared to its monomeric analogue c(RGDfE)HEG-Dpr-[^{18}F]FBOA (*40*−*42*).

Cyclic RGD Tetramers and Octamers. Several groups have used the multimer concept to prepare cyclic RGD tetramers and octamers. For example, Boturyn et al. reported a series of cyclic RGDfK tetramers (*116*) and found that increasing the peptide multiplicity significantly enhanced the integrin $\alpha_v\beta_3$ binding affinity and internalization. Kessler et al. reported a cyclic RGDfE tetramer (Figure 5) that had better integrin $\alpha_v\beta_3$ binding affinity than its monomeric and dimeric analogues (*40*−*42*). Liu et al. reported the use of a cyclic RGDfK tetramer E[E-[c(RGDfK)]$_2$]$_2$ (Figure 5) for development of integrin $\alpha_v\beta_3$-targeted SPECT and PET radiotracers (*52, 64*−*68*). Chen et al. recently used ^{64}Cu- and ^{18}F-labeled cyclic RGD tetramer E[E[c(RGDxK)]$_2$]$_2$ and octamer E[E[E[c(RGDyK)]$_2$]$_2$]$_2$ for tumor imaging by PET (*52, 117*). Although the results from both in vitro assays and ex vivo biodistribution studies have demonstrated that radiolabeled (^{99m}Tc, ^{18}F, and ^{64}Cu) RGD tetramers and octamer have much better tumor targeting capability (higher integrin $\alpha_v\beta_3$ binding affinity and better radiotracer tumor uptake) than their dimeric analogues, it remains unclear whether the cyclic RGD motifs in E[E-[c(RGDxK)]$_2$]$_2$ (x = f and y) and E[E[E[c(RGDyK)]$_2$]$_2$]$_2$ are really multivalent in binding to integrin $\alpha_v\beta_3$. As the peptide multiplicity increases, the uptake of radiolabeled multimeric RGD peptides in the kidneys, liver, lungs, and spleen are also significantly increased. In addition, the cost for E[E[c(RGD-fK)]$_2$]$_2$ and E[E[E[c(RGDyK)]$_2$]$_2$]$_2$ is prohibitively high for development of integrin $\alpha_v\beta_3$-targeted radiotracers in the future. Thus, an alternate approach is needed to improve integrin $\alpha_v\beta_3$-targeting capability and minimize the radiotracer accumulation in noncancerous organs.

Maximizing Binding Affinity via Bivalency. *Factors Influencing Binding Affinity.* The success of E[c(RGDfK)]$_2$ as targeting biomolecules is very intriguing. Given the short distance (6 bonds excluding side-arms of K-residues) between two cyclic RGD motifs in E[c(RGDfK)]$_2$, it is unlikely that they would bind to two adjacent integrin $\alpha_v\beta_3$ sites simultaneously. However, the binding of one RGD motif to integrin $\alpha_v\beta_3$ will significantly increase the "local concentration" of a second RGD motif in the vicinity of integrin $\alpha_v\beta_3$ sites (Figure 6A). The "locally enhanced RGD concentration" may explain the higher tumor uptake of radiolabeled (^{99m}Tc, ^{111}In, ^{90}Y, ^{18}F, and ^{64}Cu) cyclic RGD dimers as compared to their monomeric analogues (*60*−*65*). To further improve the integrin $\alpha_v\beta_3$-targeting capability of cyclic RGD dimers, the distance between two cyclic RGD motifs must be increased so that they are to achieve simultaneous integrin $\alpha_v\beta_3$ binding (Figure 6B). The combination of "bivalency" and the "enriched local RGD concentration" is expected to result in higher integrin $\alpha_v\beta_3$ targeting capability of cyclic RGD dimers and better tumor uptake with longer tumor retention time for their corresponding radiotracers.

Improve Integrin $\alpha_v\beta_3$ Binding Affinity by Increasing Distance between Cyclic RGD Motifs. To demonstrate this

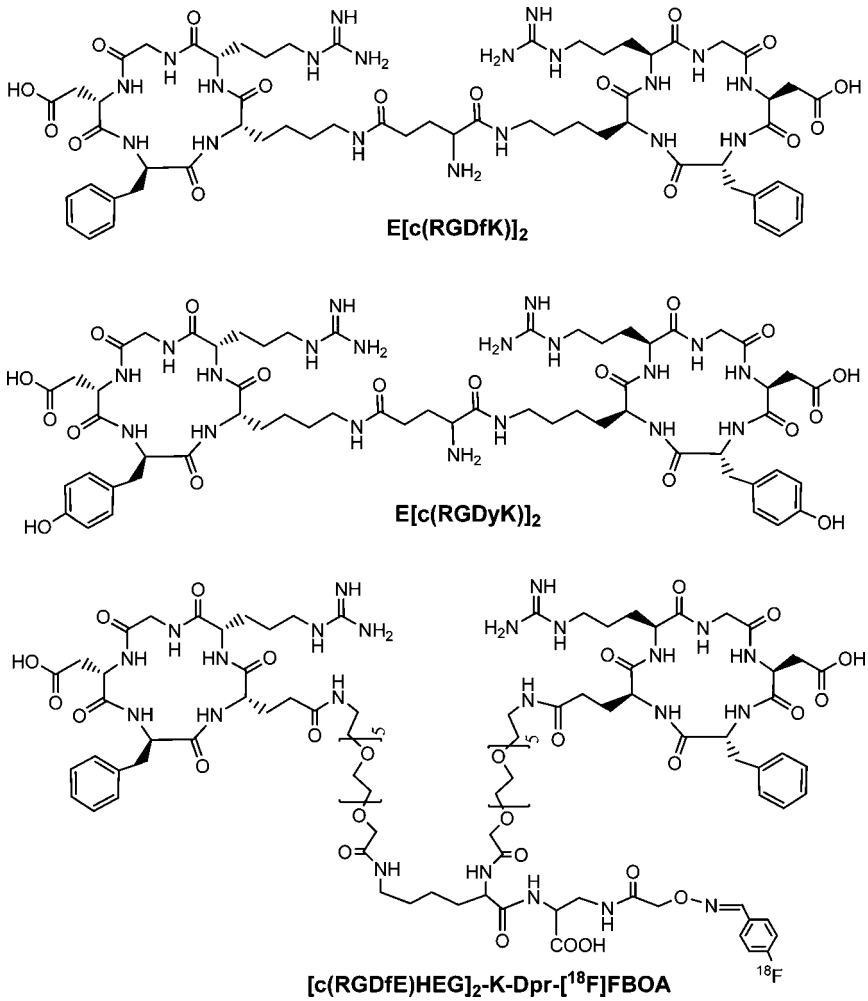

Figure 4. Cyclic RGD peptide dimers ($E[c(RGDfK)]_2$ and $E[c(RGDyK)]_2$) and $[c(RGDfE)HEG]_2$-K-Dpr-[^{18}F]FBOA.

concept, Shi et al. recently reported a series of cyclic RGD peptide dimers (Figure 7) containing triglycine (G_3) and PEG_4 linkers, which are used to increase the distance between two cyclic RGD motifs from 6 bonds in $E[c(RGDfK)]_2$ to 24 bonds in $3G_3$-dimer and 38 bonds in $3PEG_4$-dimer (*118, 119*). The integrin $\alpha_v\beta_3$ binding affinities (Table 1) against ^{125}I-echistatin bound to U87MG human glioma cells follow the order of HYNIC-tetramer ($IC_{50} = 7 \pm 2$ nM) > HYNIC-$2PEG_4$-dimer ($IC_{50} = 52 \pm 7$ nM) ~ HYNIC-$3PEG_4$-dimer ($IC_{50} = 60 \pm 4$ nM) ~ HYNIC-$3G_3$-dimer ($IC_{50} = 61 \pm 2$ nM) > HYNIC-PEG_4-dimer ($IC_{50} = 84 \pm 7$ nM) ~ HYNIC-dimer ($IC_{50} = 112 \pm 21$ nM) ≫ HYNIC-G_3-monomer ($IC_{50} = 358 \pm 8$ nM) > HYNIC-PEG_4-monomer ($IC_{50} = 452 \pm 11$ nM). These data indicate that the G_3 and PEG_4 linkers between two RGD motifs are responsible for the improved integrin $\alpha_v\beta_3$ affinity of HYNIC-$3G_3$-dimer and HYNIC-$3PEG_4$-dimer as compared to that of HYNIC-PEG_4-dimer. The higher binding affinity of HYNIC-tetramer is probably due to its two extra cyclic RGD motifs.

It is very important to note that the IC_{50} value depends largely on the radioligand (^{125}I-c(RGDyK) vs ^{125}I-echistatin) and tumor cell lines (U87MG vs MDA-MB-435) used in the competitive displacement assay. Caution should be taken when comparing the IC_{50} values of cyclic RGD peptides with those reported in the literature. Whenever possible, a "control compound", such as c(RGDfK) or c(RGDyK), should be used in each experiment.

Ternary ligand complexes [^{99m}Tc(HYNIC-$3PEG_4$-dimer)(tricine)(TPPTS)] (^{99m}Tc-$3PEG_4$-dimer) and [^{99m}Tc(HYNIC-$3G_3$-dimer)(tricine)(TPPTS)] (^{99m}Tc-$3G_3$-dimer) have been evaluated in the athymic nude mice bearing U87MG glioma and MDA-MB-435 breast tumor xenografts (*118, 119*). For comparison purposes, [^{99m}Tc(HYNIC-PEG_4-dimer)(tricine)(TPPTS)] (^{99m}Tc-PEG_4-dimer) and [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] (^{99m}Tc-tetramer) were also evaluated in the same tumor-bearing animal model (*118, 119*). As expected, the breast tumor uptake of ^{99m}Tc-$3PEG_4$-dimer and ^{99m}Tc-$3G_3$-dimer was comparable to that of ^{99m}Tc-tetramer (Figure 8A), and was >2× higher than that of ^{99m}Tc-PEG_4-dimer (*118*). These data suggest that $3PEG_4$-dimer, $3G_3$-dimer, and tetramer are most likely "bivalent" (Figure 6B), whereas PEG_4-dimer is monodentate (Figure 6A). If PEG_4-dimer were bivalent, HYNIC-PEG_4-dimer would have shared similar integrin $\alpha_v\beta_3$ binding affinity with HYNIC-$3PEG_4$-dimer and HYNIC-$3G_3$-dimer while ^{99m}Tc-PEG_4-dimer would have had tumor uptake comparable to that of ^{99m}Tc-$3PEG_4$-dimer and ^{99m}Tc-$3G_3$-dimer. In addition, ^{99m}Tc-$3PEG_4$-dimer and ^{99m}Tc-$3G_3$-dimer had kidney and liver uptake that was half that for ^{99m}Tc-tetramer, probably because $3PEG_4$-dimer and $3G_3$-dimer have only two RGD motifs. Therefore, ^{99m}Tc-$3PEG_4$-dimer and ^{99m}Tc-$3G_3$-dimer have significant advantages over ^{99m}Tc-tetramer with respect to T/B ratios (*118, 119*).

Multimeric ≠ Multivalent. It is critical to note that multimeric RGD peptides are not necessarily multivalent. There are two factors (bivalency and enhanced local RGD concentration) contributing to high integrin $\alpha_v\beta_3$ binding affinity of multimeric RGD peptides. The concentration factor exists in all multimeric RGD peptides regardless of the linkers. The key for bivalency is the distance between two cyclic RGD motifs. For example, this distance in $3PEG_4$-dimer (38 bonds) and $3G_3$-dimer (26

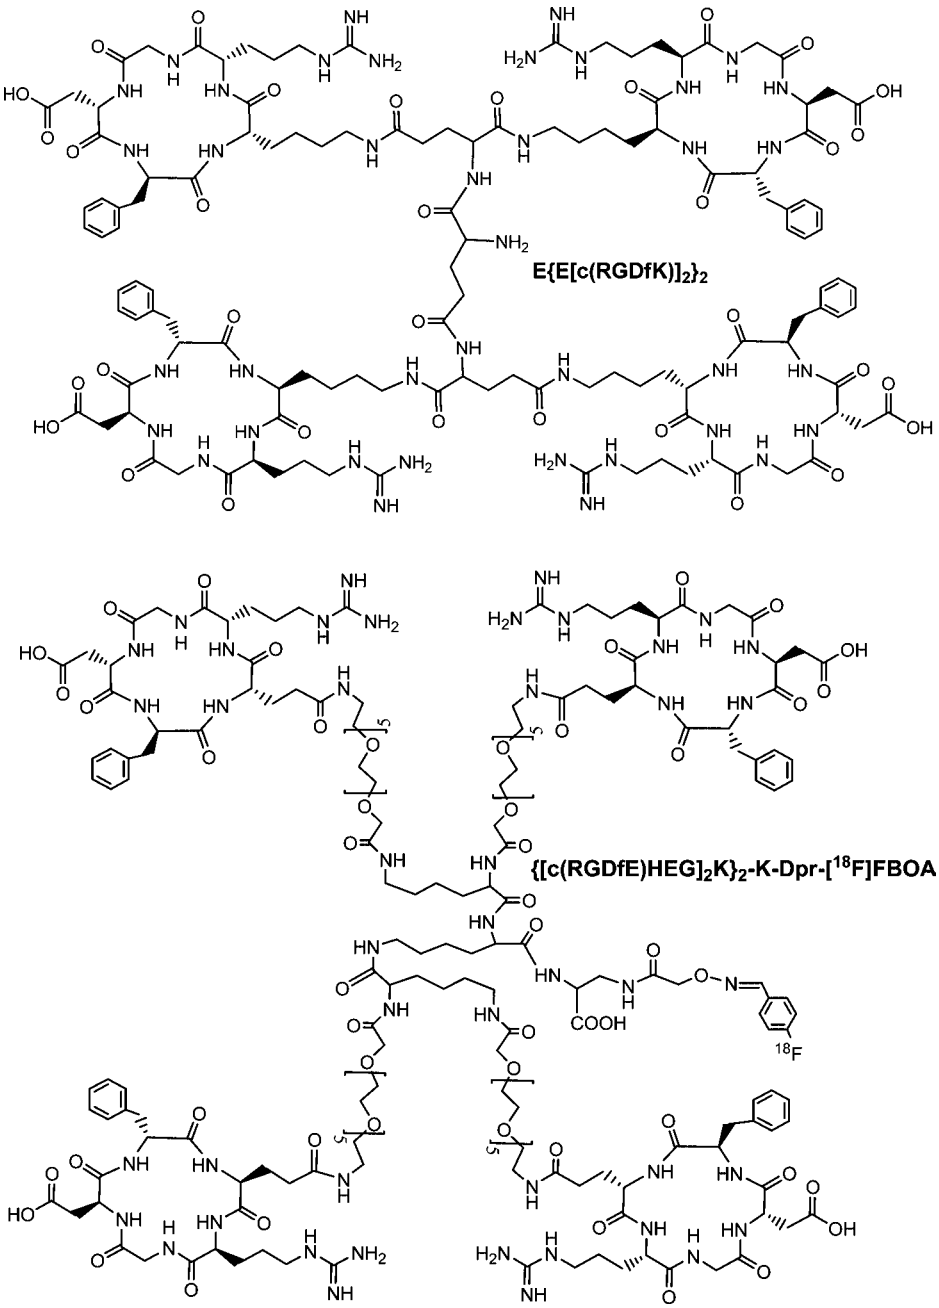

Figure 5. A cyclic RGDfK peptide tetramer, E{E[c(RGDfK)]$_2$}$_2$ and a ^{18}F-labeled cyclic RGDfE tetramer, {[c(RGDfE)HEG]$_2$K}$_2$-K-Dpr-[^{18}F]FBOA.

bonds) is long enough for them to achieve bivalency, which leads to the higher integrin $\alpha_v\beta_3$ binding affinity of HYNIC-3PEG$_4$-dimer and HYNIC-3G$_3$-dimer than that of HYNIC-PEG$_4$-dimer and the much higher breast tumor uptake (Figure 8A) for ^{99m}Tc-3PEG$_4$-dimer and ^{99m}Tc-3G$_3$-dimer as compared to that of ^{99m}Tc-PEG$_4$-dimer. In contrast, the concentration factor is responsible for the better binding affinity of HYNIC-tetramer than that of HYNIC-3PEG$_4$-dimer and HYNIC-3G$_3$-dimer. The fact that the breast tumor uptake of ^{99m}Tc-3PEG$_4$-dimer and ^{99m}Tc-3G$_3$-dimer is comparable to that of ^{99m}Tc-tetramer suggests that the contribution from the "concentration factor" might not be as significant as that from the "bivalency factor". In addition, the ability of a multimeric RGD peptide to achieve bivalency also depends on the integrin $\alpha_v\beta_3$ density. If the tumor integrin $\alpha_v\beta_3$ density is high, the distance between two neighboring integrin $\alpha_v\beta_3$ sites will be short, which makes it easier for the multimeric RGD peptide to achieve bivalency. If the integrin $\alpha_v\beta_3$ density is very low, the distance between two neighboring integrin $\alpha_v\beta_3$ sites will be long, and it might be more difficult for the same multimeric RGD peptide to achieve simultaneous integrin $\alpha_v\beta_3$ binding.

Relationship between Tumor Size and Radiotracer Tumor Uptake. The ability to quantify the integrin $\alpha_v\beta_3$ in vivo provides opportunities to select the patients more appropriately for antiangiogenic treatment and to monitor the therapeutic efficacy of integrin $\alpha_v\beta_3$-positive tumors (*120, 121*). The %ID tumor uptake reflects the total integrin $\alpha_v\beta_3$ level, while the %ID/g tumor uptake reflects the integrin $\alpha_v\beta_3$ density. Figure 8B shows the relationship between tumor size and tumor uptake (%ID and %ID/g) of ^{99m}Tc-3PEG$_4$-dimer. There was a linear relationship between tumor size and %ID tumor uptake with $R^2 = 0.9164$ (Figure 8B), suggesting that ^{99m}Tc-3PEG$_4$-dimer might be useful for monitoring tumor growth during antiangiogenic therapy (*118*). If the tumor uptake is expressed as %ID/g (Figure 8C), it seems that ^{99m}Tc-3PEG$_4$-dimer has a narrow window to achieve an optimal tumor uptake. When tumor size is small

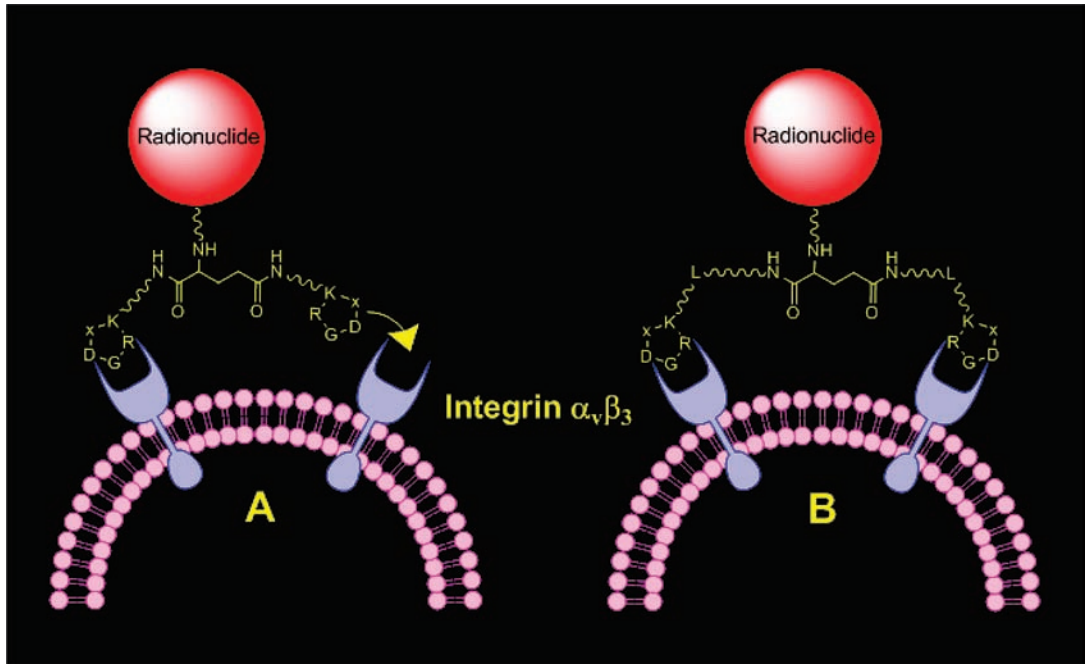

Figure 6. Schematic illustration of interactions between cyclic RGD peptide dimers and integrin $\alpha_v\beta_3$. (A) The distance between two RGD motifs is not long enough for simultaneous integrin $\alpha_v\beta_3$ binding. However, the RGD concentration is "locally enriched" in the vicinity of neighboring integrin $\alpha_v\beta_3$ once the first RGD motif is bound. (B) The distance between two RGD motifs is long due to the presence of two linkers (L). As a result, the cyclic RGD dimer is able to bind integrin $\alpha_v\beta_3$ in a "bivalent" fashion. In both cases, the end result would be higher integrin $\alpha_v\beta_3$ binding affinity for the multimeric cyclic RGD peptides.

(<0.05 g), there is little angiogenesis with low blood flow, and ^{99m}Tc-3PEG$_4$-dimer has low %ID/g tumor uptake. When the tumor size is 0.1 g−0.25 g, the microvessel density and integrin $\alpha_v\beta_3$ density are high. The %ID/g tumor uptake of ^{99m}Tc-3PEG$_4$-dimer is ~10%ID/g (Figure 8C). As tumors grow, the total integrin $\alpha_v\beta_3$ level is higher, and the %ID tumor uptake increases (Figure 8B). However, the microvessel density decreases due to maturity of blood vessels. The integrin $\alpha_v\beta_3$ density also decreases due to larger interstitial space (*122*). In addition, parts of the tumor may become necrotic, leading to the lower integrin $\alpha_v\beta_3$ density. As a result, larger tumors have lower %ID/g tumor uptake than smaller ones (Figure 8C).

Radiotracer Tumor Uptake and Tumor Cell Integrin $\alpha_v\beta_3$ Expression. Figure 9 compares the tumor uptake of ^{99m}Tc-3PEG$_4$-dimer and ^{99m}Tc-3G$_3$-dimer in athymic nude mice bearing U87MG glioma and HT29 colon cancer xenografts, and the integrin $\alpha_v\beta_3$ expression levels on U87MG glioma and HT29 cells. Both ^{99m}Tc-3PEG$_4$-dimer and ^{99m}Tc-3G$_3$-dimer have significantly higher uptake (%ID/g) in the glioma than HT29 tumors (Figure 9: top), which is supported by the presence of a higher level of integrin $\alpha_v\beta_3$ expression on U87MG glioma cells than those on HT29 cells (Figure 9: bottom). These data clearly show that the integrin $\alpha_v\beta_3$ level on tumor cells (U87MG > HT29) plays a significant role in the radiotracer tumor uptake. More fluorescent staining studies are needed to better quantify the contributions from the integrin $\alpha_v\beta_3$ expressed on the tumor cells and neovasculature in the tumor tissue.

^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer). Recently, Shi et al. (*123*) reported two cyclic RGD dimer conjugates: DOTA-3PEG$_4$-dimer and DOTA-3G$_3$-dimer (Figure 10). It was found that the integrin $\alpha_v\beta_3$ binding affinity (Table 1) follows the order of DOTA-tetramer ($IC_{50} = 10 \pm 2$ nM) > DOTA-3G$_3$-dimer ($IC_{50} = 74 \pm 3$ nM) ~ DOTA-3PEG$_4$-dimer ($IC_{50} = 62 \pm 6$, nM) > DOTA-dimer ($IC_{50} = 102 \pm 5$ nM) against ^{125}I-echistatin bound to U87MG glioma cells. Once again, bivalency is likely responsible for the higher integrin $\alpha_v\beta_3$ binding affinity of DOTA-3PEG$_4$-dimer and DOTA-3G$_3$-dimer than that of DOTA-dimer. This conclusion is completely consistent with the higher tumor uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) than that of ^{64}Cu(DOTA-dimer) (*123*). In contrast, the concentration factor is most likely responsible for higher integrin $\alpha_v\beta_3$ binding affinity of DOTA-tetramer than that of DOTA-3PEG$_4$-dimer and DOTA-3G$_3$-dimer, and the higher initial tumor uptake of ^{64}Cu(DOTA-tetramer) as compared to that of ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) (*123*). However, the uptake of ^{64}Cu-(DOTA-3PEG$_4$-dimer) in the liver and kidneys was significantly lower than that reported for ^{64}Cu(DOTA-tetramer) (*57*), due to the presence of four R-residues in E[E[c(RGDfK)]$_2$]$_2$ as compared to only two R-residues in ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) (*123*).

^{111}In(DOTA-3PEG$_4$-dimer) and ^{111}In(DOTA-3G$_3$-dimer). To explore the impact of radiometal chelates, ^{111}In(DOTA-3PEG$_4$-dimer) and ^{111}In(DOTA-3G$_3$-dimer) were evaluated in the same animal model (*124*). ^{111}In(DOTA-3PEG$_4$-dimer) and ^{111}In-(DOTA-3G$_3$-dimer) share the same DOTA chelator, have almost identical lipophilicity (log $P = -4.13 \pm 0.08$ and -4.20 ± 0.21, respectively), and show very similar metabolic stability (*124*). The tumor uptake of ^{111}In(DOTA-3G$_3$-dimer) is comparable to that of ^{111}In(DOTA-3PEG$_4$-dimer) (Figure 11A). Planar imaging studies showed that they both had very high tumor uptake with a long tumor retention and excellent tumor-to-background contrast (*124*). The activity accumulation in the chest and abdominal regions almost completely disappeared at 60 min p.i. The combination of the hydrophilic ^{111}In(DOTA) chelate with PEG$_4$/G$_3$ linkers is responsible for the low liver uptake for ^{111}In(DOTA-3PEG$_4$-dimer) and ^{111}In(DOTA-3G$_3$-dimer), leading to high tumor/liver ratios (Figure 11A). Both ^{111}In(DOTA-3PEG$_4$-dimer) and ^{111}In(DOTA-3G$_3$-dimer) also had low kidney and muscle uptake with very high tumor/kidney and tumor/muscle ratios (*124*). Their integrin $\alpha_v\beta_3$-specificity has been clearly demonstrated by the blocking experiment, in which ^{111}In(DOTA-3PEG$_4$-dimer) was used as the radiotracer and E[c(RGDfK)]$_2$ as the blocking agent (*124*). The RGD-specificity of ^{111}In-labeled cyclic RGD dimers was demonstrated by the higher integrin $\alpha_v\beta_3$ affinity of DOTA-3PEG$_4$-NS (IC_{50}

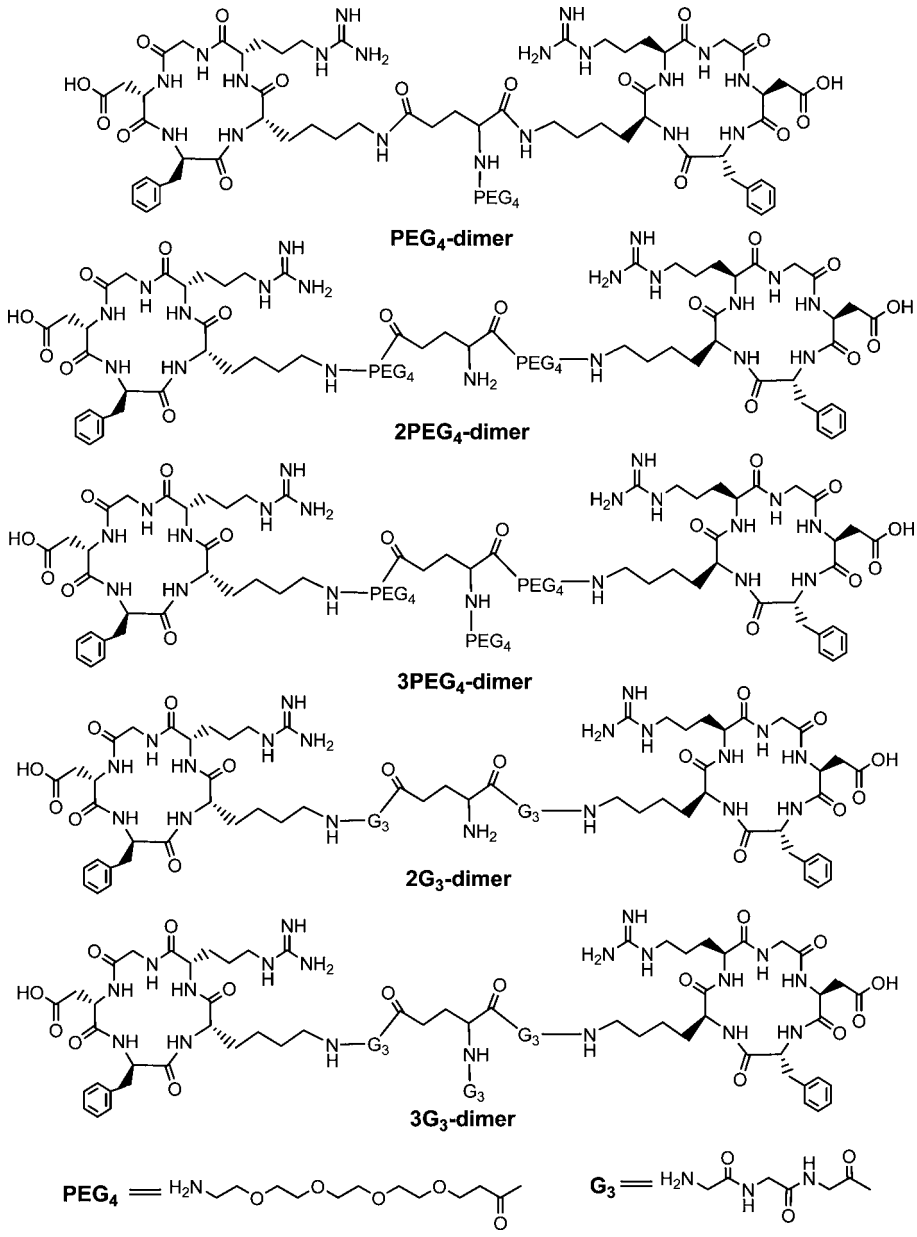

Figure 7. New cyclic RGD peptide dimers useful for the development of integrin $\alpha_v\beta_3$-targeted radiotracers. The PEG_4 and G_3 linkers are used to increase the distance between two RGD motifs and to improve radiotracer excretion kinetics from noncancerous organs.

Table 1. Integrin $\alpha_v\beta_3$ Binding Data for HYNIC-Conjugated Cyclic RGD Peptides against ^{125}I-Echistatin Bound to the Integrin $\alpha_v\beta_3$-Positive U87MG Human Glioma Cells

compound	radiotracer	IC_{50} (nM)

= 715 ± 45 nM; 3PEG_4-NS = PEG_4-E[PEG_4-(RGKfD)]$_2$, a scrambled nonsense peptide) than that of DOTA-3PEG_4-dimer (1.3 ± 0.3 nM), and the much better tumor uptake of ^{111}In(DOTA-3PEG_4-dimer) (10.06 ± 3.52%ID/g) than that of

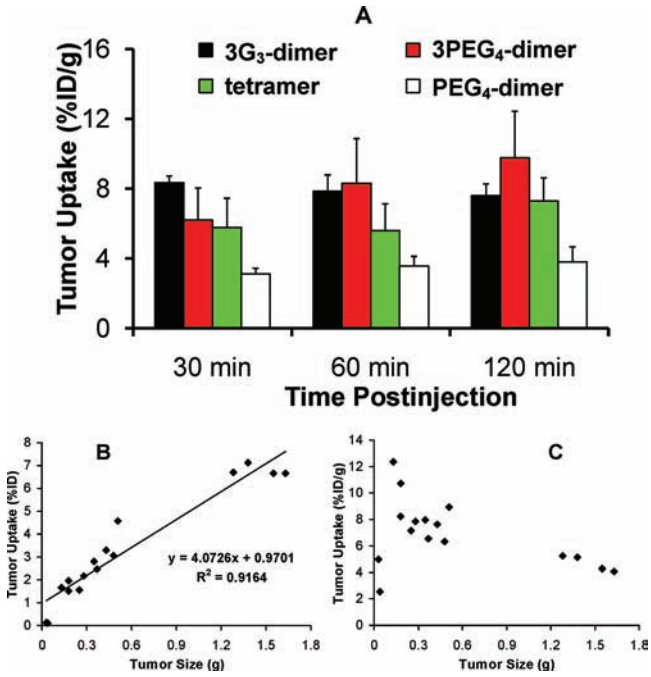

Figure 8. Top: direct comparison of the tumor uptake for ^{99m}Tc-PEG$_4$-dimer, ^{99m}Tc-3G$_3$-dimer, ^{99m}Tc-3PEG$_4$-dimer, and ^{99m}Tc-tetramer in athymic nude mice bearing MDA-MB-435 breast cancer xenografts (A). Bottom: the relationship between the tumor size and tumor uptake (B,C) of ^{99m}Tc-3PEG$_4$-dimer at 120 min p.i. in athymic nude mice bearing U87MG glioma xenografts. The linear relationship suggests that ^{99m}Tc-3PEG$_4$-dimer is for monitoring the tumor growth or shrinkage during antiangiogenic therapy.

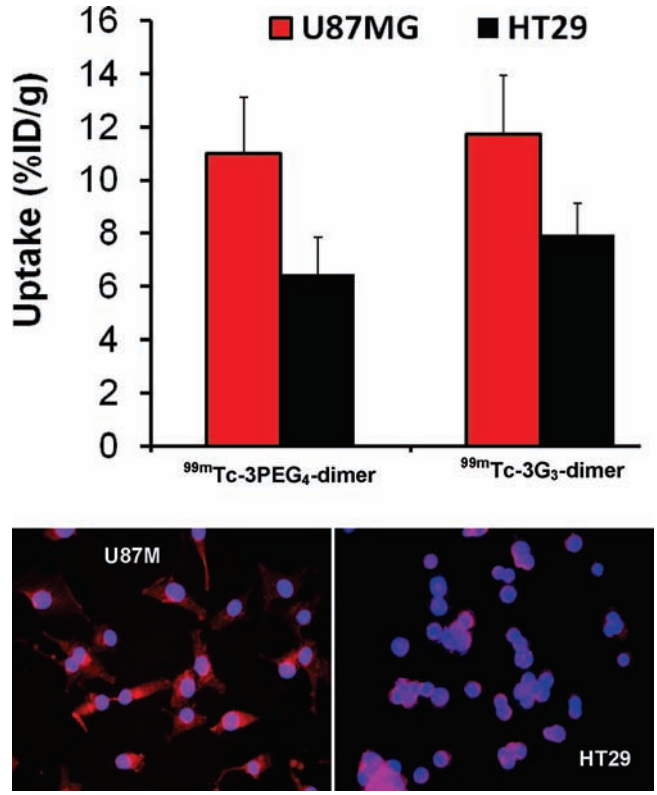

Figure 9. Top: Direct comparison of the tumor uptake for ^{99m}Tc-3PEG$_4$-dimer and ^{99m}Tc-3G$_3$-dimer in athymic nude mice bearing U87MG glioma and HT29 colon cancer xenografts. Bottom: Representative fluorescence microscopic images of U87MG glioma (left) and HT29 (right) tumor cells. The blue color indicates the presence cell nuclei (DAPI: 4′,6′-diamidino-2-phenylindole). The red color indicates the presence of integrin $\alpha_v\beta_3$ due to the binding of Alexa Fluor 488 conjugated mouse anti-human integrin $\alpha_v\beta_3$ monoclonal antibody LM609. These data show that the integrin $\alpha_v\beta_3$ level on tumor cells (U87MG > HT29) plays a significant role in the radiotracer tumor uptake.

^{111}In(DOTA-3PEG$_4$-NS) (0.30 ± 0.09%ID/g) in the same animal model. On the basis of the integrin $\alpha_v\beta_3$- and RGD-specificity of the ^{111}In-labeled cyclic RGD peptides, it has been suggested that their uptake in several normal organs (e.g., intestine, kidneys, liver, lungs, and spleen) might be also integrin $\alpha_v\beta_3$-mediated (*124*).

^{111}In(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3PEG$_4$-dimer) share the same DOTA-conjugate. In spite of their difference in radiometal, the tumor uptake ^{111}In(DOTA-3PEG$_4$-dimer) (10.89 ± 2.55 and 7.65 ± 3.17%ID/g at 30 and 240 min p.i., respectively) was close to that of ^{64}Cu(DOTA-3PEG$_4$-dimer) (8.23 ± 1.97 and 6.43 ± 1.22%ID/g at 30 and 240 min p.i., respectively). They also share similar uptake in normal organs. For example, the kidney uptake of ^{111}In(DOTA-3PEG$_4$-dimer) was 5.80 ± 0.95 and 2.78 ± 0.20%ID/g at 30 and 240 min p.i., respectively, and was comparable to that of ^{64}Cu(DOTA-3PEG$_4$-dimer) (6.59 ± 0.93%ID/g at 30 min p.i. and 2.81 ± 0.36% ID/g at 240 min p.i.). The liver uptake of ^{111}In(DOTA-3PEG$_4$-dimer) is 2.52 ± 0.57%ID/g at 30 min and 1.61 ± 0.06%ID/g at 240 min p.i., while ^{64}Cu(DOTA-3PEG$_4$-dimer) has liver uptake of 2.80 ± 0.35%ID/g at 30 min p.i. and 1.87 ± 0.51%ID/g at 240 min p.i. A similar conclusion can be made by comparing biodistribution properties of ^{64}Cu(DOTA-3G$_3$-dimer) and ^{111}In(DOTA-3G$_3$-dimer). These data suggest that the radiometal chelate (Figure 11B) has minimal impact on radiotracer tumor uptake and excretion kinetics.

^{68}Ga(NOTA-2PEG$_4$-dimer) and ^{68}Ga(NOTA-2G$_3$-dimer). We also prepared conjugates NOTA-2PEG$_4$-dimer and NOTA-2G$_3$-dimer (Figure 12: NOTA = 1,4,7-triaazacyclononane-1,4,7-tetracetic acid) and their ^{68}Ga complexes, ^{68}Ga(NOTA-2PEG$_4$-dimer), and ^{68}Ga(NOTA-2G$_3$-dimer) (*125*). The integrin $\alpha_v\beta_3$ binding affinity (Table 1) of NOTA-dimer (IC_{50} = 100 ± 3 nM), NOTA-2G$_3$-dimer (IC_{50} = 66 ± 4 nM), and NOTA-2PEG$_4$-dimer (IC_{50} = 54 ± 2 nM) were very close to those for DOTA-dimer (IC_{50} = 102 ± 5 nM), DOTA-3G$_3$-dimer (IC_{50} = 74 ± 3 nM), and DOTA-3PEG$_4$-dimer (IC_{50} = 62 ± 6 nM), respectively. These data further suggest that the G$_3$ and PEG$_4$ linkers between cyclic RGD motifs in dimeric RGD peptides make it possible for them to bind integrin $\alpha_v\beta_3$ in a bivalent fashion. The tumor uptake of ^{68}Ga(NOTA-2G$_3$-dimer) and ^{68}Ga(NOTA-2PEG$_4$-dimer) was much higher than that of ^{68}Ga(NOTA-dimer) in the same tumor-bearing animal model (*125*), suggesting that the addition of G$_3$ and PEG$_4$ linkers between two cyclic RGD motifs increases the radiotracer tumor uptake. In all cases, the tumors can be clearly visualized as early as 30 min p.i. with excellent contrast (Figure 12). It was also found that the tumor uptake of ^{68}Ga(NOTA-2PEG$_4$-dimer) in MDA-MB-435 breast tumor was significantly lower than that in U87MG glioma. Similar results were also obtained for ^{18}F-labeled 3PEG$_4$-dimer (*126*), which is consistent with that fact that the MDA-MB-435 breast tumors have lower integrin $\alpha_v\beta_3$ expression than U87MG glioma (*52*−*55*).

CONCLUSIONS

Over the past several years, many multimeric cyclic RGD peptides have been used to increase the integrin $\alpha_v\beta_3$-targeting capability. It was found that increasing the peptide multiplicity can significantly enhance their integrin $\alpha_v\beta_3$ binding affinity and improve the radiotracers tumor targeting ability. However, as peptide multiplicity increases, the uptake of radiolabeled multimeric RGD peptides is also significantly increased in normal organs. There is no significant advantage in using radiolabeled tetramers E{E[c(RGDxK)]$_2$}$_2$ (x = f and y) over their dimeric

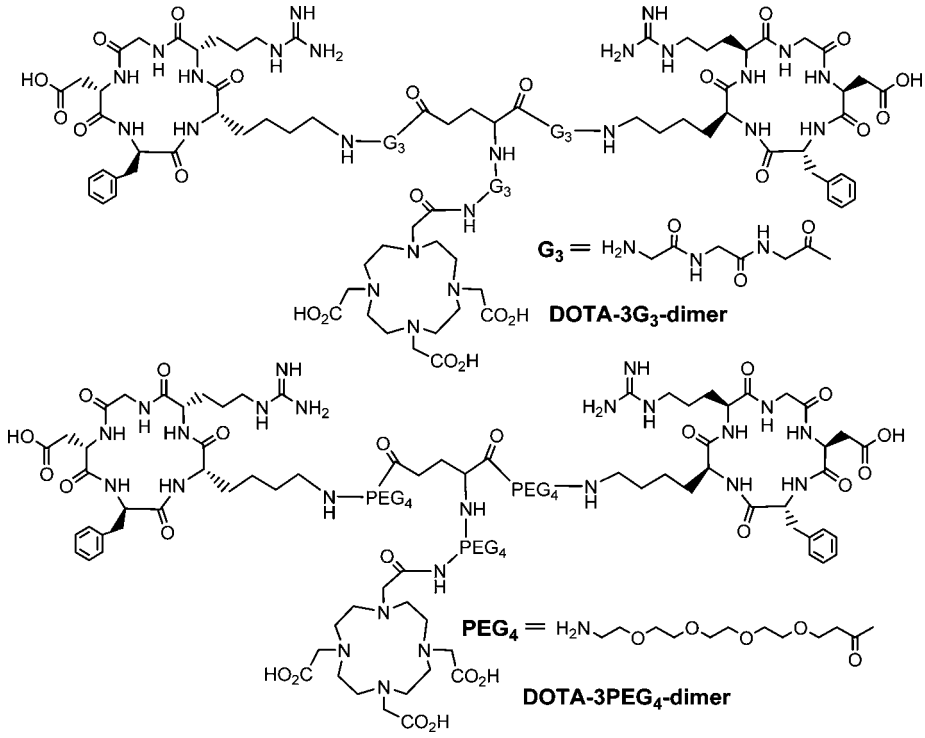

Figure 10. Structures of DOTA-3G_3-dimer and DOTA-3PEG_4-dimer.

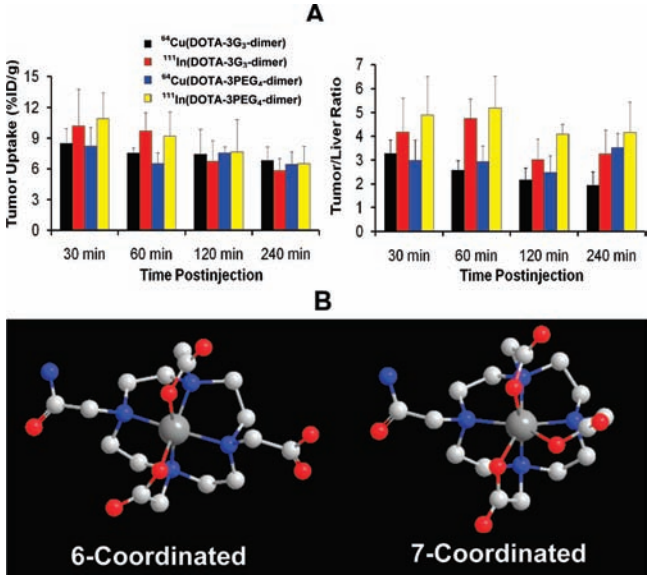

Figure 11. (A) Comparison of tumor uptake and tumor/liver ratios for ^{64}Cu(DOTA-3PEG_4-dimer), ^{64}Cu(DOTA-3G_3-dimer), ^{111}In(DOTA-3PEG_4-dimer), and ^{111}In(DOTA-3G_3-dimer) in athymic nude mice bearing U87MG human glioma xenografts. (B) Chem-3D presentation of ^{64}Cu(DOTA-monoamide) (6-coordinated) and ^{111}In(DOTA-monoamide) (7-coordinated).

analogues E[c(RGDxK)]$_2$ (x = f and y) with respect to T/B ratios. In addition, the cost for E{E[c(RGDxK)]$_2$}$_2$ (x = f and y), E{E[E[c(RGDyK)]$_2$]$_2$}$_2$ is too high for them to be useful for future radiotracer development.

Recent studies on cyclic RGD dimers suggest that two factors (bivalency and enhanced local RGD concentration) contribute to the high integrin $\alpha_v\beta_3$ binding affinity of multimeric cyclic RGD peptides (*118, 119, 123*−*126*). The concentration factor exists in all multimeric RGD peptides regardless of the linker length between two cyclic RGD motifs. To achieve bivalency, the distance between two RGD motifs must be long enough for them to bind the neighboring integrin $\alpha_v\beta_3$ sites simultaneously. Among the cyclic RGD peptides, 2PEG_4-dimer/3PEG_4-dimer and 2G_3-dimer/3G_3-dimer show most promising results with respect to the tumor uptake and T/B ratios of their radiotracers (^{99m}Tc, ^{111}In, ^{64}Cu, and ^{68}Ga). Thus, 2PEG_4-dimer/3PEG_4-dimer and 2G_3-dimer/3G_3-dimer are better integrin $\alpha_v\beta_3$-targeting biomolecules than the tetramer E{E[c(RGDfK)]$_2$}$_2$ with respect to their cost and the T/B ratios of their ^{99m}Tc, ^{111}In, ^{64}Cu, and ^{68}Ga radiotracers.

While current research efforts on the integrin $\alpha_v\beta_3$-targeted radiotracers have been focused on new cyclic RGD peptides, the formulation development for routine preparation of radiotracers is often neglected. It must be emphasized that it is common to use postlabeling chromatographic separation for improvement of radiotracer purity and specific activity for research purposes. In clinical settings, however, postlabeling purification is not practical. Regardless of the beauty of the science involved in the discovery of a new radiotracer, its success relies largely on the availability and capability to improve the quality of cancer patient's life. As a matter of fact, the main challenge for [^{18}F]Galacto-RGD and [^{18}F]-AH111585 to assume a widespread clinical utility is not their biological performance, but their clinical availability at reasonable cost. In this respect, the integrin $\alpha_v\beta_3$-targeted ^{99m}Tc radiotracers will offer significant advantages over their corresponding ^{18}F analogues because of the clinical availability of ^{99}Mo−^{99m}Tc generators, and the kit formulation for routine preparation of ^{99m}Tc radiotracers at low cost. However, both planar imaging and SPECT suffer a significant drawback with respect to quantification of the radiotracer "absolute" organ uptake, the speed of dynamic imaging, spatial resolution, and tissue attenuation.

The successful application of the ^{68}Ga-labeled somatostatin analogues for imaging tumors in cancer patients has clearly demonstrated that ^{68}Ga is an excellent alternative to ^{18}F. ^{68}Ga is available from an in-house commercially available ^{68}Ge/^{68}Ga generator (*127*−*129*), and its short half-life is best suited for the fast excretion kinetics of many ^{68}Ga-labeled small peptides. ^{64}Cu is another viable alternative to ^{18}F. The use of NOTA and its derivatives as BFCs allows the development of the kit

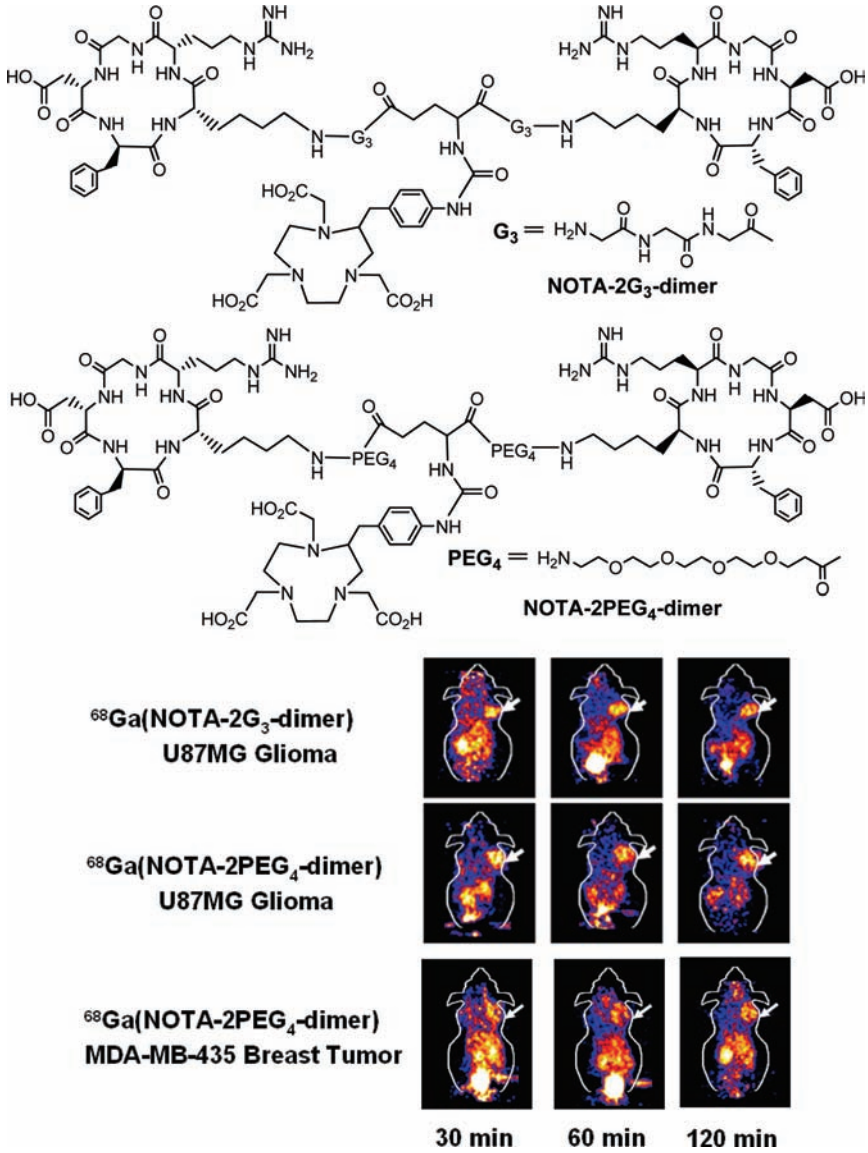

Figure 12. Top: Structures of NOTA-2G_3-dimer and NOTA-2PEG_4-dimer. Bottom: microPET images for ^{68}Ga(NOTA-2G_3-dimer) and ^{68}Ga(NOTA-2PEG_4-dimer). Arrows indicate the presence of tumors.

formulation for routine preparation of ^{68}Ga and ^{64}Cu radiotracers with high specific activity. In addition, ^{68}Ga(NOTA) and ^{64}Cu(NOTA) chelates have very high hydrophilicity, which is extremely important for improving the radiotracer clearance kinetics from noncancerous organs.

It is very important to note that integrin $\alpha_v\beta_3$ is also overexpressed on the activated endothelial cells during wound healing and postinfarct remodeling, in rheumatoid arthritis, and atherosclerotic plaque (*1*−*4, 130, 131*). The integrin $\alpha_v\beta_3$-targeted radiotracers have been proposed for imaging myocardial angiogenesis (*132*), inflammatory diseases (*133*), and hindlimb ischemia (*134*). Recent results showed that the ^{111}In-labeled nonpeptide integrin $\alpha_v\beta_3$ antagonist (RP748) was able to image the angiogenesis in the heart with myocardial infarction (*132*), and the radiotracer uptake in the infarct region was associated with the integrin $\alpha_v\beta_3$ expression level. The results reported by Pichler et al. suggest that [^{18}F]Galacto-RGD might be a powerful tool to distinguish between acute and chronic phases of T-cell mediated immune responses (*133*). Studies have also demonstrated the value of a ^{99m}Tc-labeled cyclic RGD monomer (NC100692) for imaging the integrin $\alpha_v\beta_3$ in rodent models of hindlimb ischemia (*134*). These promising results suggest that the newer and more effective integrin $\alpha_v\beta_3$-targeted radiotracers under development for tumor imaging might become valuable noninvasive markers of angiogenesis after ischemic injury, myocardial infarction, and inflammation. In addition, the combination of high tumor uptake, long tumor retention with favorable pharmacokinetics of ^{111}In(DOTA-3G_3-dimer) and ^{111}In(DOTA-3PEG_4-dimer) suggests that their corresponding ^{90}Y and ^{177}Lu analogues, M(DOTA-RGD) (M = ^{90}Y and ^{177}Lu; and RGD = 3G_3-dimer and 3PEG_4-dimer), might be useful for the treatment of integrin $\alpha_v\beta_3$-positive tumors.

ACKNOWLEDGMENT

The author would like to thank Dr. Xiaoyuan Chen at Stanford Medical School and Dr. Fan Wang at the Beijing University Medical Isotopes Research Center for their collaboration on the radiolabeled multimeric cyclic RGD peptides. This work is supported, in part, by Purdue University and research grants: R01 CA115883 A2 (S.L.) from the National Cancer Institute (NCI) and DE-FG02-08ER64684 from the Department of Energy.

Heparin−Paclitaxel Conjugates as Drug Delivery System: Synthesis, Self-Assembly Property, Drug Release, and Antitumor Activity

Ying Wang,[†,‡,§] Dingcheng Xin,[†,‡] Kaijian Liu,[†,†] Mingqiang Zhu,[†] and Jiannan Xiang*[,†,‡,§]

Biomedical Engineering Center, College of Chemistry and Chemical Engineering, and State Key Laboratory of Chemo/Biosensing and Chemometrics, Hunan University, Changsha, 410082, China. Received September 5, 2008; Revised Manuscript Received November 5, 2009

We have synthesized a series of novel prodrugs consisting of amphiphilic heparin−paclitaxel conjugates. Each prodrug in the series consists of a succinylated-heparin carrier conjugated to paclitaxel via a single amino acid spacer, either valine, leucine, or phenylalanine (prodrug1, prodrug2, and prodrug3, respectively). Unlike physically encapsulated drugs, these prodrugs can self-assemble to form nanoparticles in aqueous solution while still maintaining structural integrity for loading parent drug due to the dual hydrophilic/hydrophobic nature of the carrier and drug compound. The structure of prodrugs has been characterized by ^{1}H NMR, FT-IR, and GPC. Their morphology has been investigated by SEM. Our results show that these self-assembled nanoparticles have a narrow size distribution (140−180 nm) and form an approximately spherical shape composed of a paclitaxel core and carrier shell. The anticoagulant activity of all the prodrugs is sharply decreased compared to that of heparin, as measured by activated partial thromboplastin time (aPTT), thereby reducing the risk of severe hemorrhagic complication during systemic administration. Furthermore, the prodrugs exhibit better *in vitro* cell inhibition for MCF-7 cells than free paclitaxel. Flow cytometric analyses (FCM) have shown that MCF-7 cells treated with prodrugs are arrested in the G_2/M phase of the cell cycle. Meanwhile, these three prodrugs each exhibit unique hydrolysis properties under various physiological or plasma conditions. In particular, prodrug2 with leucine spacer may result in favorable hydrolysis of the ester bond between the amino acid and paclitaxel under physiological conditions. In mice, prodrug2 shows a similar ovarian tumor growth inhibition as paclitaxel and induces no obvious body weight loss. Hence, the prepared nanoscale prodrugs are expected not only to render structural integrity to the parent drug, but also enhance targeting capacity to solid tumors.

INTRODUCTION

Paclitaxel has shown significant antineoplastic activity against various human cancers. However, when clinically used, solubility and toxicity are two major problems. Previous attempts in paclitaxel prodrug design have been focused on improving its water solubility and decreasing its toxicity (*1*). The prepared water-soluble prodrugs of paclitaxel are mainly ester derivatives and phosphate derivatives, among others (*2*−*6*). In recent years, the use of macromolecules for the targeted delivery of anticancer agents has generated considerable interest due to the enhanced permeability and retention (EPR) effect in tumor tissues (*7*−*11*). Meanwhile, the pharmaceutical activity of self-assembled nanoscale drug delivery systems has recently attracted considerable attention (*12*−*16*).

Nanoscale drug delivery systems can increase parent drug solubility as well as enable passive targeting to the solid tumor. Generally, nanoparticle systems, such as amphiphilic block copolymer micelles, for drug delivery self-assemble into a hydrophobic inner core and a hydrophilic outer shell. Various hydrophobic anticancer drugs can thus be physically entrapped within the core of the copolymers. However, copolymer micelles are often not stable enough to maintain structural integrity for loading the moderately hydrophobic drug. Additionally, nanoparticles with diameters greater than 200 nm are readily scavenged nonspecifically by monocytes and the reticuloendothelial system (*17*, *18*). On the basis of these considerations, we sought to design a new class of drug delivery systems by chemical method that retain structural integrity for the parent drug while offering many desirable properties in physiological conditions.

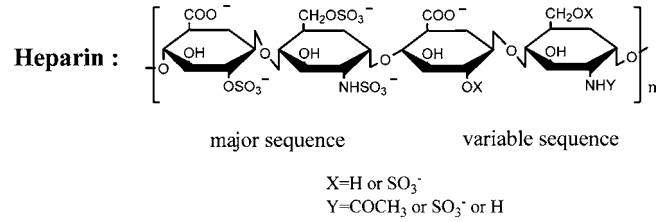

Figure 1. Structure of heparin.

Heparin is a biocompatible, biodegradable, and water-soluble natural polysaccharide with a complicated structure and is abundant in animal tissues (Figure 1). Heparin has attracted intense attention because it demonstrates a variety of biological activities including anticoagulant activity, inhibition of angiogenesis, tumor development, and proliferation of arterial smooth

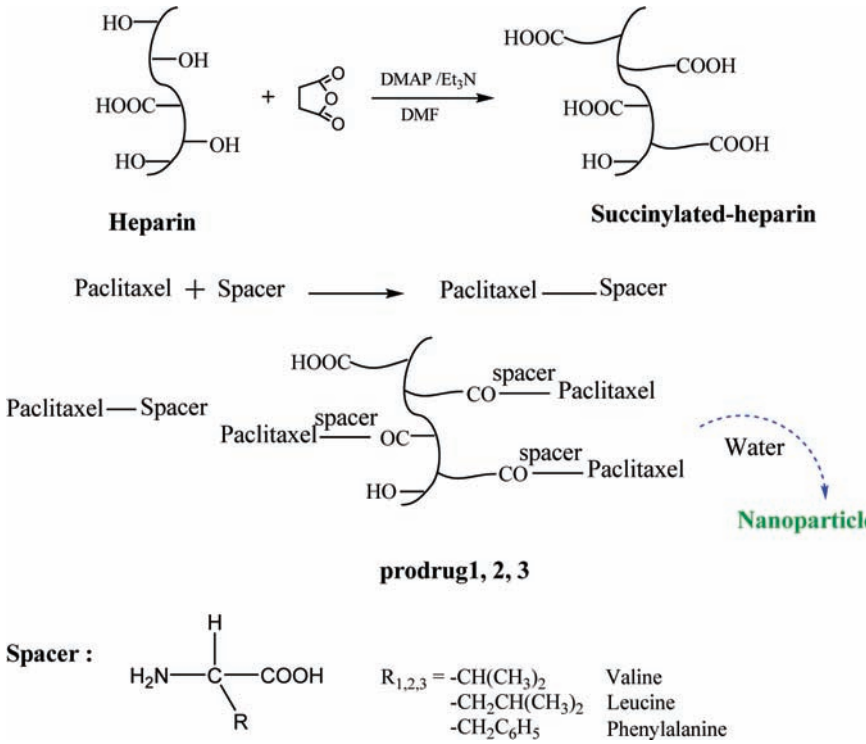
Scheme 1. Designed Strategy of the Prodrug



muscle cells (*19*, *20*). Meanwhile, chemically modified heparins are also known to effectively inhibit angiogenesis, metastasis, and tumor growth (*21*). It was reported that heparin derivatives with reduced anticoagulant activity have a great potential as antitumor drugs (*22*).

In this study, we conjugated a succinylated-heparin carrier to paclitaxel by inserting different amino acid as spacers, including valine, leucine, and phenylalanine (prodrug1, prodrug2, and prodrug3, respectively). Succinylated heparin was selected as a carrier in order to increase the drug loading capacity, in which the hydroxyl groups of heparin react with succinic anhydride under classical acylation conditions. Using this method, many more active carboxyl groups can be introduced to the carrier. The designed synthetic route of the prodrugs is in Scheme 1.

It has previously been reported that the particle size plays an important role in determining the biological response of the tissue to foreign biomaterials (*23*). Therefore, we investigated the behavior of the prepared prodrugs in aqueous solution and examined whether conjugation of paclitaxel to heparin by the different amino acid spacers would influence the physical properties and, consequently, the pharmacologic activity as compared with native paclitaxel. Finally, the *in vitro* cytotoxicity and *in vivo* antitumor effect of the prodrugs were evaluated against the MCF-7 human breast cell line and $SKOV_3$ human ovarian cell line compared with free pacitaxel.

EXPERIMENTAL SECTION

Materials. Heparin (sodium salt, from porcine intestinal mucosa, M_n = 12 kDa, 150 U/mg), *N*,*N*′-dimethylformamide (DMF), triethylamine, tributylamine, succinic anhydride, 4-dimethylaminopyridine (DMAP), 1-ethyl-3,3-dimethylaminopropyl carbodiimide hydrochloride (EDC), and *N*-hydroxysuccinimide (NHS) were purchased from Sinopharm Chemical Reagent Co. (Shanghai, China), and paclitaxel came from Tecano Science & Technology Co., Ltd. (Guangzhou, China). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium (MTT) was from Sigma. 732 cation-exchange resin, Sephadex G-25, and dialysis membrane (MWCO 3500) were purchased from Shanpu Co., Ltd. (Shanghai, China), Pharmacia (Piscataway, NJ), and Viskase Co., Inc. (Illinois, USA), respectively. 2′-Valyl-paclitaxel, 2′-leucyl-paclitaxel, and 2′-phenylalanyl-paclitaxel were prepared in our lab (*11*). All reagents were purified by distillation under nitrogen prior to use. Ultrapure water (Milli-Q, 18M·Ω) was used at all times in the experiment. The MCF-7 (breast carcinoma) cell line and $SKOV_3$ (human ovarian serous cystocarcinoma) cell line were kindly donated by the Institute of Life Science and Biotechnology in Hunan University.

Synthesis of Succinylated Heparin. Heparin sodium salt (0.25 g) dissolved in 20 mL of water was percolated through a 732 column (H^+ form, 100 mL) at 4 °C. The pH of the solution was adjusted to 6.0 by addition of tributylamine (2 mL). Excess tributylamine was eliminated by evaporating. The concentrated solution was diluted with water and lyophilized to yield tributylammonium salt (0.5 g). The tributylammonium salt (0.5 g) was dissolved in dry DMF (10 mL) and was then cooled down to 0 °C under a nitrogen atmosphere. Succinic anhydride (1.3 g, 13 mmol), triethylamine (1.31 g, 13 mmol), and DMAP (0.036 g, 0.3 mmol) were successively added, and the reaction was allowed to proceed at room temperature for 24 h under nitrogen. After cooling to 0 °C, cold ethanol (500 mL) was added. The precipitate was dissolved in water and passed through a 732 column (H^+ form, 200 mL) at 4 °C. Then, the product was purified by passing through a Sephadex G-25 column equilibrated in deionized water. The effluent was neutralized with 1 M NaOH and lyophilized as a white powder (0.20 g). ^{1}H NMR (D_2O): δ = 2.6 (−CH_2CH_2COOH, succinylated group). FT-IR (KBr): 1630 cm^{-1}, 1427 cm^{-1} (−COOH).

Synthesis of Succinylated-Heparin-Val-Paclitaxel (prodrug1). Succinylated heparin (0.20 g) was dissolved in dry DMF (20 mL) and maintained by gentle heating. 2′-Valyl-paclitaxel (48 mg, 0.05 mmol), EDC (19 mg, 0.1 mmol), and NHS (12 mg, 0.11 mmol) were successively added to the mixture, and the reaction was allowed to proceed at 35 °C for 24 h. After cooling to 0 °C, deionized water was gradually added and the solution was dialyzed against deionized water for 48 h in a

dialysis membrane. After lyophilization, prodrug1 (0.22 mg) was obtained as a white powder. Prodrug2 and prodrug3 were synthesized in a similar procedure as that of prodrug1. The ^{1}H NMR spectra showed the methyl group of valyl and leucyl at 0.92 ppm and 0.7 ppm in high field, respectively. In spite of the overlay of the benzene ring of paclitaxel in ^{1}H NMR, the δ-hydrogen of phenylalanyl was attributed to δ 7.2 ppm in low field. These results demonstrated that 2′-aminoacyl paclitaxel was successfully attached to succinylated heparin (see Supporting Information).

^{1}H NMR (D_2O: DMSO-d_6 = 1:2): δ = 0.7 ($-CH_3$, δ-Leu, prodrug2), 0.92 ($-CH_3$, γ-Val, prodrug1), 1.06 (17.16-CH_3, paclitaxel), 1.58 (19-CH_3, paclitaxel), 1.8 (18-CH_3, paclitaxel), 1.9−2.0 ($-NHCOCH_3$, succinylated heparin), 2.1 (C4-OAc, paclitaxel), 2.2 (C10-OAc, paclitaxel), 2.8 ($-CH_2CH_2-$CONH−, succinylated-heparin), 7.2 (δ-Phe, prodrug3), 7.4−8.1 (benzene ring, paclitaxel). FT-IR (KBr): 3068 cm^{-1} (−C−H−), 1533 cm^{-1}, 710 cm^{-1} (−C═C−).

Characterization of Prodrugs. The ^{1}H NMR spectra of the carrier and prodrugs were recorded on a Varian INOVA400 apparatus in D_2O and DMSO-d_6. The FT-IR spectra were determined by a FD-5DX infrared spectrum apparatus. In addition, the molecular weights of the prodrugs were determined using a 515 Waters GPC system equipped with a Waters Ultrahydrogel 250 column and Waters 410 refractive index detector. 0.1 mol/L NaCl was used as an elution solvent at a flow rate of 0.6 mL/ min, and the column temperature was maintained at 40 °C using poly(ethylene glycol) standards.

The mass of the succinylated group on the carrier was determined by quantitative analysis of ^{1}H NMR spectroscopy using pyridine as the internal standard, whose proton signal is δ 7.4, 7.9, and 8.4 ppm. The content of drug on the carrier was estimated by UV measurements based on a standard curve generated with known concentrations of paclitaxel in ethanol (λ = 228 nm) (*24*).

Size distributions and zeta potentials of prodrugs were measured at 25 °C using a Zetasizer Nano-Zs (Malvern Instruments, UK). The concentration of prodrugs in distilled water was kept constant at 0.3 mg/mL. SEM was used to observe the morphology of prodrugs in aqueous solution, which was performed on a JSM-6700F (JEOL, Japan). Prodrug was freeze−dried and mounted on a metal stub.

***In Vitro* Release of Paclitaxel from Prodrugs.** Prodrugs were dissolved in phosphate-buffered saline (0.01 M) at pH 5.0 and pH 7.4 or human plasma and mouse plasma (400 μL per mL of PBS 7.4, 0.01 M) at an equivalent paclitaxel concentration of 1 g/L. The solutions were incubated at 37 °C with gentle shaking. At selected time intervals, aliquots (500 μL) were removed and an equivalent PBS concentration was added to the solutions. The aliquots were extracted by chloroform, and the organic fraction was evaporated. At the same time, the residue was mixed with acetonitrile (1000 μL) and analyzed by HPLC.

The HPLC system consisted of a reverse-phase silica column (SepaxHP-C18, 4.6 × 250 mm, 5 μm, Sepax, USA), a mobile phase of acetonitrile, and 0.05% trifluoroacetic acid in water (60: 40) pumped (LC-20AT, Shimadzu) at a flow rate of 1.0 mL/ min. A 20 μL aliquot of sample was injected, and the column effluent was detected at 227 nm with a UV detector (SPD-20A, Shimadzu).

Anticoagulant Activity Assay. Anticoagulant activity of carrier and prodrugs, using heparin as the standard, was evaluated by measuring activated partial thromboplastin time (aPTT) using an Ellagic acid kit (Sun Biotech, China). The aPTT was recorded on a PRECIL C2000 Coagulometer. The aPTT was measured according to the manufacturer's procedure by using normal human plasma. Prodrugs and carrier (2.5 μg/mL, 25 μL) were added to 0.1 mL of citrated plasma, followed by adding 0.1 mL of aPTT reagent. This mixture was incubated at 37 °C for 2 min. Then, prewarmed $CaCl_2$ solution (0.1 mL, 0.025 mol/L) was added, and the time for fibrin clotting was recorded. The activity of heparin derivatives was calculated from the heparin standard curve (clotting time vs units/mg) (*25*).

***In Vitro* Cell Culture Cytotoxicity.** The cytotoxicity of the prodrugs and paclitaxel was determined using an MTT assay. MCF-7 cells were seeded at 100 000 cells/mL in a 96-well plate format in RPMI 1640 with 10% fetal bovine serum and 0.1% penicillin/streptomycin, at 37 °C, under a 5% CO_2 humidified atmosphere. After a 24 h incubation period, MCF-7 cells were subjected to various concentrations of prodrugs in 100 μL culture medium, and free paclitaxel was added as a DMSO stock solution (all performed at equivalent paclitaxel concentrations of 0.01, 0.1, 1, 10, and 100 μg/mL). Cells were then incubated at 37 °C for 48 h with each test material, and 20 μL of sterile MTT solution (0.5% w/v in PBS) was added to each well. After an additional 5 h incubation, the medium was removed and DMSO was added to dissolve the insoluble formazan dye which had formed. Cell viability was quantified by MTT dye absorption at 570 nm, which was recorded on a Microplate reader (Thermo Electron, China).

Flow Cytometric (FCM) Assay. Cell cycle analyses were performed on EPICS-XL flow cytometer (Beckman Coulter, USA) and data were analyzed by Mcycle software. MCF-7 cells were seeded on a 6-well plate and preincubated for 24 h, followed by coincubation with paclitaxel and prodrugs (an equivalent paclitaxel concentration of 100 μg/mL) for 6 h. The cells were then washed three times with PBS, detached by trypsinization, spun down by centrifugation, and dispersed again in PBS for FCM analysis.

***In Vivo* Antitumor Activity.** Athymic nude female nu/nu mice (7−8 weeks old) were injected with 200 μL of human ovarian serous cystocarcinoma cells ($SKOV_3$, 1×10^6) on the right flank. The tumors were allowed to grow for 10−12 days until their size reached between 9 and 25 mm^2. Mice were randomized into control and treatment groups (n = 4) and injected intraperitoneally with saline, free paclitaxel, or prodrug. The free paclitaxel was dissolved in DMSO and then diluted with saline. The paclitaxel and prodrugs (each at an equivalent dose of 30 mg/kg paclitaxel) were injected at seven day intervals. Tumor length (L), width (W) measurements, and body weight were recorded 2−3 times per week. Tumor weight was calculated according to the formula $(L) \times (W)^2/2$.

Statistical Analysis. Statistical analysis was performed to determine differences among the measured properties of each group. One-way analysis of variance was determined using a statistical program (*Statistical Package for the Social Sciences*, v 10.0, SPSS Inc., USA). To reject a null hypothesis, statistical significance was defined as $p < 0.05$. When there was statistical significance, multiple comparisons were determined using a least significant differences technique.

RESULTS AND DISCUSSION

In this study, we used succinylated heparin as a carrier, in which additional carboxyl groups were introduced to replace the hydroxyl groups of heparin via an O-acylation reaction. The aim of the design strategy was to increase the content of active groups linked with drug molecules and to investigate the behavior of prodrugs in aqueous solution. Amino acids are ideal linkers since, as bifunctional molecules, they provide both a reactive carboxyl group to conjugate with paclitaxel via an ester bond and an amino group that can be easily reacted with the carboxyl groups of the carrier via N-acylation reaction. Thus, we selected three amino acids—valine, leucine, and phenylalanine—as spacers, and synthesized 2′-aminoacyl paclitaxel. We first

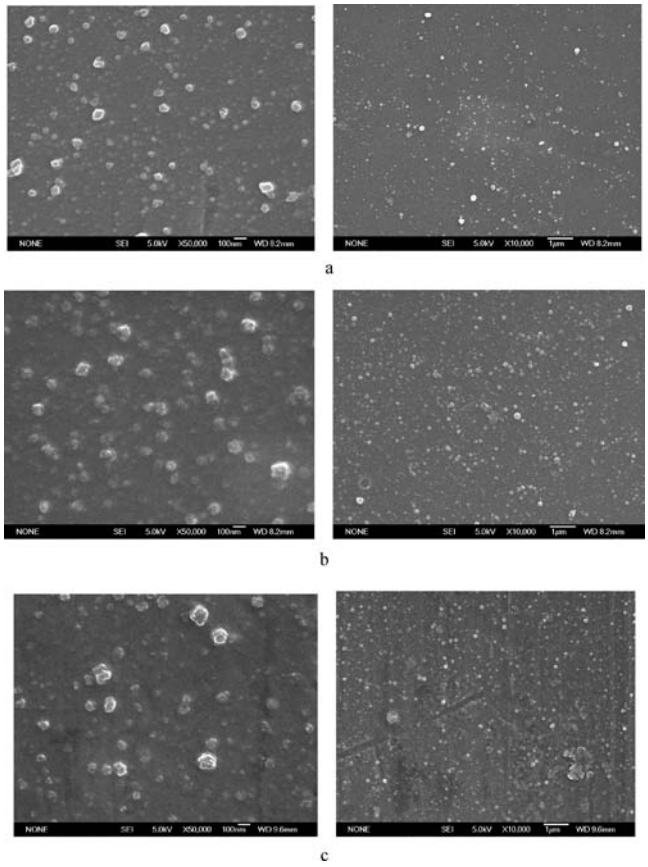


Figure 2. Scanning electron microscopy photographs of (a) prodrug1, ×50 000, ×10 000; (b) prodrug2, ×50 000, ×10 000; (c) prodrug3, ×50 000, ×10 000.

synthesized succinylated heparin using the classical O-acylation reaction conditions, and then 2′-aminocyl paclitaxel was introduced to the carrier in the presence of EDC and NHS, yielding amphiphilic heparin−paclitaxel conjugates as a type of novel prodrugs.

GPC measurement in aqueous phase showed the average molecular weight of succinylated heparin to be M_n ~12 957 with a polydispersity index (PDI) of about 1.8. However, the PDI of the prodrugs was significantly higher at 2.8−3.0, which may be due to the hydrophobicity of paclitaxel. Meanwhile, the weight percentages of succinyl groups and paclitaxel in the prodrugs were found to be about 8.5% and 35.4−39.1% using ^{1}H NMR and UV, respectively. During the experiment, the prodrugs self-assembled to form nanoparticles in aqueous solution, as supported by SEM and DLS (Figure 2 and Figure 3). The SEM micrograph of prodrugs showed an approximately spherical shape. The mean diameters of prodrug1, 2, and 3 measured by DLS were 141 ± 7, 171 ± 2, and 185 ± 2 nm, respectively, while the prodrugs had a zeta potential of approximately −21 to −31 mV (Table 1). The negative surface charge indicates that the hydrophobic paclitaxel species are buried within the carrier in aqueous solution while the carboxyl (COO^-) and sulfate (OSO_3^-) groups are exposed on the hydrophilic heparin shell. This further suggests that the prodrugs have formed a core/shell nanoparticle structure in aqueous solution.

Previously, Hashida and co-workers reported that the majority of fenestrates of the liver sinusoid have diameters smaller than 200 nm (*26*). Thus, large particles hardly reach the parenchymal cells of liver. It was also reported that smaller particles under 200 nm tend to selectively accumulate at tumor sites as a result of the EPR effect (*27*). Consequently, these prodrugs fall within the range required for passive tumor targeting.

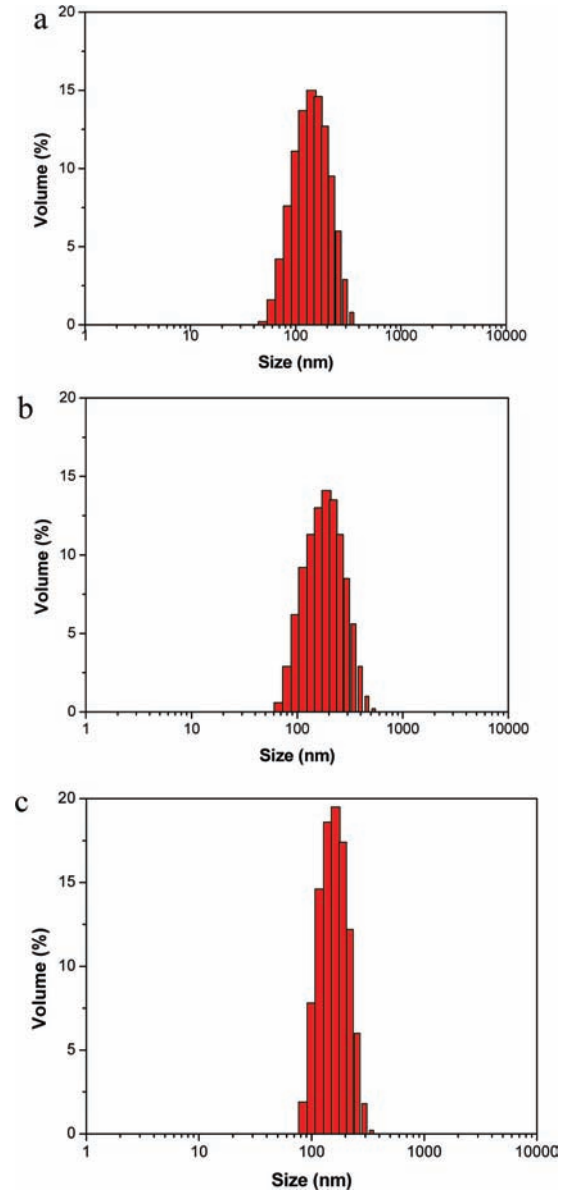

Figure 3. Size distribution of (a) prodrug1, (b) prodrug2, and (c) prodrug3 by DLS analysis in aqueous solution.

Table 1. Number Average Molecular Weights (M_n) and Polydispersity Indexes (PDI), as Determined by GPC, and Size, Polydispersity Index (PDI), and Zeta Potential of Prodrug as Determined by DLS

	GPC		DLS		
	M_n	PDI	particle size (nm)	PDI	zeta potential (mV)
succinylated heparin	12 957	1.8			
prodrug1	19 006	2.89	141 ± 7	0.14	−21.4 ± 4.59
prodrug2	19 287	2.81	171 ± 2	0.12	−22.1 ± 4.64
prodrug3	19 576	2.92	185 ± 2	0.21	−31.0 ± 8.35

These prodrugs were then subjected to chemical and plasma hydrolysis to test the paclitaxel release. The *in vitro* release time serves as a useful guide for formulation considerations and design of therapy protocols. Experiments performed under different conditions were reported in Figure 4. The hydrolysis rate of prodrugs was investigated by HPLC. As shown in Figure 4, a drug release half-life ($t_{1/2}$) of prodrug1 was similar with that of prodrug2 under physiological conditions. In the PBS, the amount of paclitaxel liberated from prodrugs increased as pH increased. Meanwhile, prodrug3 showed a much faster

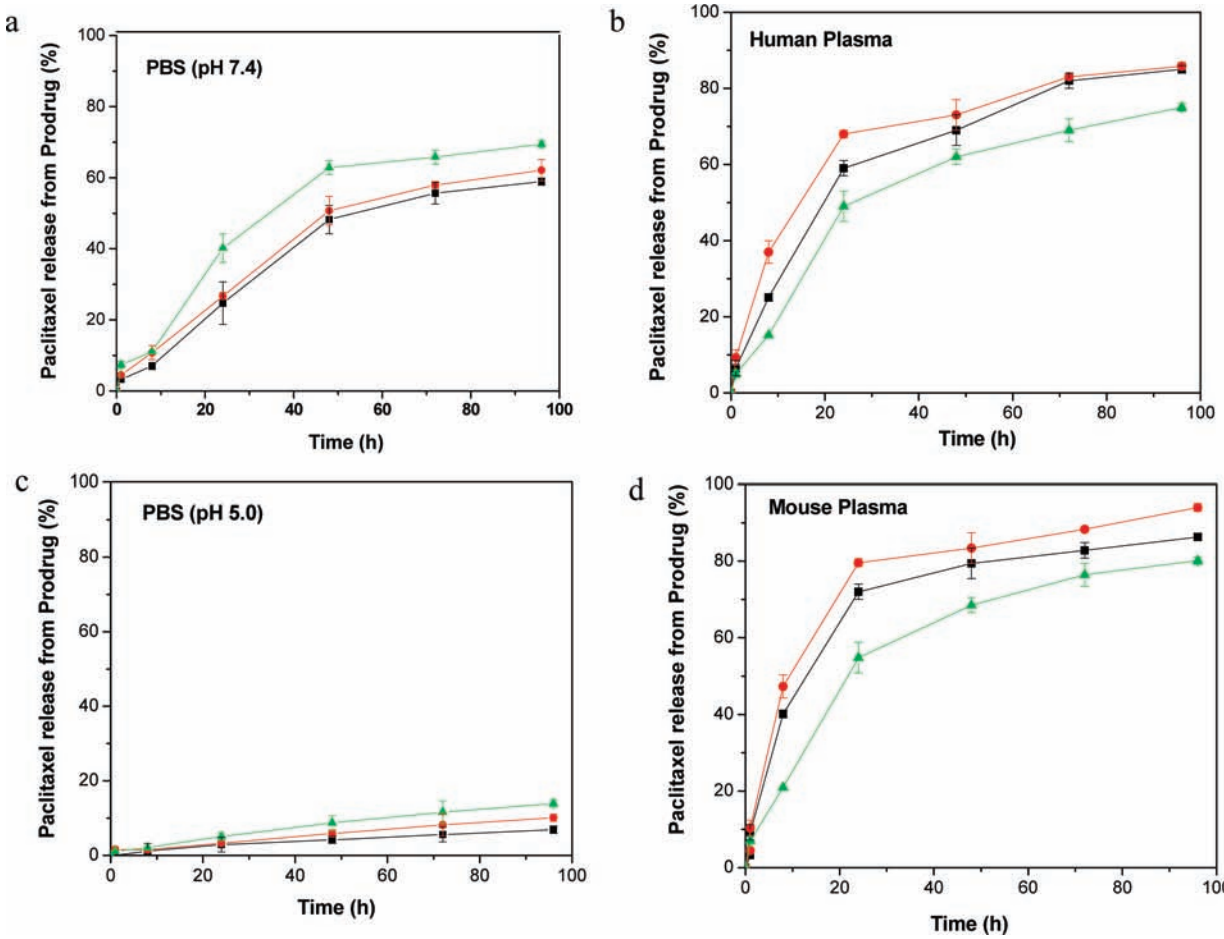

Figure 4. *In vitro* release profiles of paclitaxel from prodrug1 (black ■), prodrug2 (red ●), and prodrug3 (green ▲) under various conditions: (a) PBS in pH 7.4, (b) PBS in pH 5.0, (c) in human plasma, and (d) in mouse plasma. The data represent mean ± SD where $n = 3$.

release rate in PBS than that of any other prodrugs. Under physiological conditions, the amount of released paclitaxel was lower than that in plasma; more than 50% of paclitaxel was liberated from prodrugs under the plasma during 24 h. Additionally, the stability of prodrugs in mouse plasma was lower than that in human plasma.

Apparently, prodrug3 showed higher stability toward plasma compared with that of prodrug1 and prodrug2. This might be explained by steric hindrance from the phenylalanyl group, which might decrease the rate of release in enzymatic degradation. It has been reported that Leu derivatives are easily susceptible toward tritosomes using low-molecular-weight amino acid and dipeptide conjugates with paclitaxel (*28*). Hence, specific amino acids may result in favorable hydrolysis of the ester bond between the amino acid and paclitaxel when subject to changes in pH or upon entering the plasma. Therefore, prodrug2, which uses leucine as a spacer, can facilitate the release of pacitaxel from the carrier.

Although heparin has had a beneficial effect for cancer patients in some clinical trials, heparin therapy can be difficult to manage due to its anticoagulant potency and potential for inducing hemorrhagic complications. Therefore, we found it highly desirable to introduce chemical modification to the heparin moiety in order to reduce its anticoagulant activity. It was reported that chemically modified heparin derivatives with greatly reduced anticoagulant activity maintained nonanticoagulant effects, including antiadhesion, inhibition of angiogenesis, metastasis, and tumor growth (*29, 30*). The anticoagulant activities of succinylated heparin and prodrugs are shown in Table 2. The anticoagulant activities of succinylated heparin and prodrugs both decreased to some extent as compared to

Table 2. Loading Capacity, aPTT, IC_{50} of Carrier, Paclitaxel, and Prodrug by ^1H NMR, and Bioactivity Assays

	loading capacity (w/w %)	aPTT (U/mg)	IC_{50} (μg/mL)
succinylated heparin	8.5	109 ± 5	
paclitaxel			0.19
prodrug1	35.4	25 ± 6	0.10
prodrug2	37.8	54 ± 7	0.058
prodrug3	39.1	30 ± 4	0.06

that of heparin, but the activities of prodrugs decreased to a much greater extent. This might be attributed to the introduction of paclitaxel, which leads to a conformational change in heparin structure, resulting in decreased affinity to Antithrombin III and reduced effectiveness of the underlying anticoagulant mechanism (*31*). As a consequence, prodrugs with low anticoagulant activities could be safer and more effective drug delivery systems which decrease the high risk of excessive bleeding.

Cytotoxicity was studied by using an MTT assay to identify cells still active in respiration. Figure 5 summarizes the *in vitro* cytotoxicity results of prodrugs and paclitaxel in MCF-7 cell after 48 h. Prodrugs exhibited higher cytotoxicity than free paclitaxel. Specifically, IC_{50} values of prodrug2 and prodrug3 for MCF-7 were about 0.058 μg/mL and 0.06 μg/mL, respectively, which were about 3-fold lower than that of free paclitaxel (0.19 μg/mL). Prodrug2 therefore demonstrated significant anticancer activity. Although the hydrolysis rate of prodrug3 was slower than that of prodrug1 and prodrug2 in plasma, effective inhibition of MCF-7 for this prodrug was still observed.

Figure 6 shows the cell cycle profile of MCF-7 treated with paclitaxel and prodrugs. Since the cytotoxic activity of paclitaxel

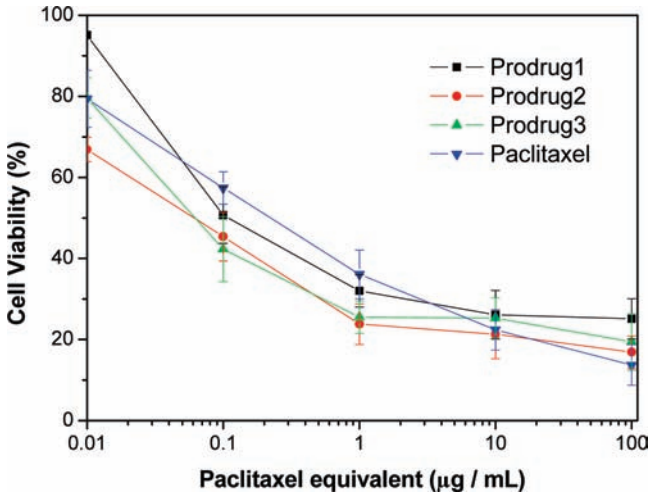

Figure 5. *In vitro* cytotoxicity of paclitaxel and prodrugs assessed using MCF-7 cells (MTT assay) after 48 h. The data represent mean ± SD where $n = 3$.

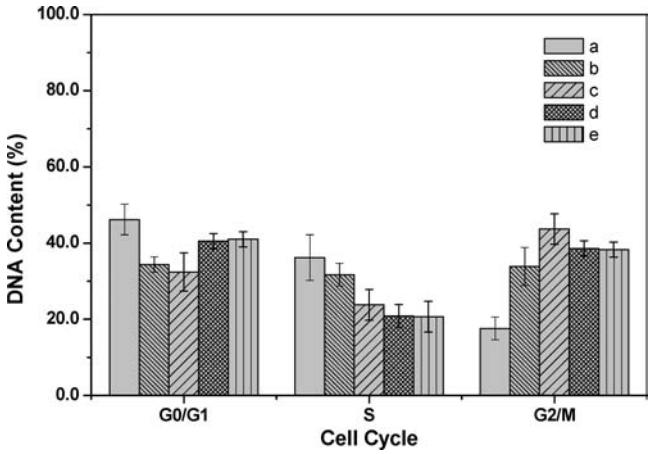

Figure 6. Flow cytometric analysis of the cell cycle profiles of MCF-7 cell treated with paclitaxel and Prodrugs for 6 h: (a) control cells, (b) paclitaxel, (c) prodrug1, (d) prodrug2, and (e) prodrug3. The data represent mean ± SD where $n = 3$.

is attributed to its stabilizing effect on microtubules necessary for spindle formation and cell division, paclitaxel has been shown to cause cell cycle arrest in the G_2/M phase and, ultimately, cell death through apoptotic mechanisms (*32*, *33*). As compared with control cells, the sharp peak observed for the G_0/G_1 phase was markedly attenuated and was observed instead of that for the G_2/M phase for cells treated with paclitaxel and prodrugs. Hence, paclitaxel progressively liberated from prodrugs can restrict MCF-7 cells in specific cell cycle stages.

We then evaluated the effectiveness of our prodrugs using an *in vivo* mouse model. The mice were treated with single i.p. injections of saline, free paclitaxel, and prodrugs at equivalent doses, and the tumor growth and body weight change were monitored daily as shown in Figure 7. The control group of mice showed a progressive increase in tumor growth for mean tumor volume up to day 32. The mice treated with free paclitaxel showed significant tumor growth inhibition compared with the control group. The treatment with prodrugs showed tumor growth inhibition to some extent. Although tumor growth inhibition induced by prodrugs was significant against the saline group ($p < 0.05$), it was not significantly different from that of free drug ($p > 0.05$). Free drug did, however, cause an obvious decrease in the body weight. In statistical summary (Table 3), the treatment induced by prodrugs indicated that body weight change was significantly different from that of free drug ($p <$ 0.05), and prodrug2 resulted in similar tumor growth inhibition to parent drug. These results implied that prodrugs induced less systemic toxicity; specifically, prodrug2 merited further investigation.

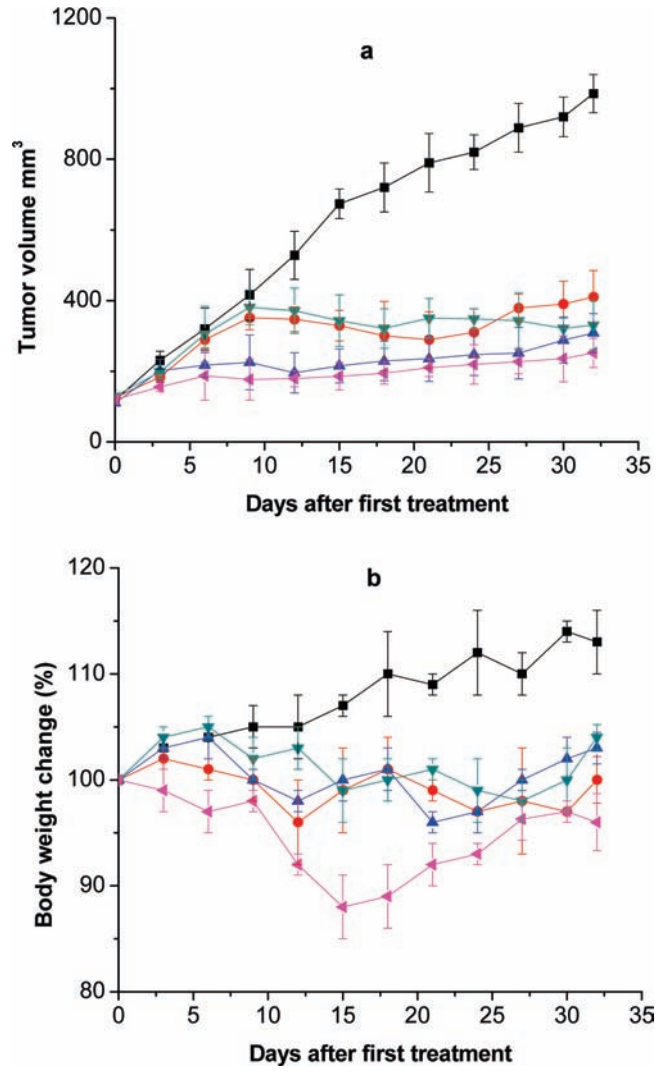

Figure 7. *In vivo* efficacy of Prodrugs and paclitaxel in nu/nu mice ($n = 4$) bearing $SKOV_3$ cells: (a) tumor growth; (b) body weight change. Mice were injected i.p. with 30 mg/kg paclitaxel equivalent dose: control (black), prodrug1 (red), prodrug2 (blue), prodrug3 (green), and paclitaxel (magenta).

Table 3. Antitumor Effect of Prodrugs after Intermittent Intravenous Administration in $SKOV_3$ Bearing Mice

treatment group	mean tumor volume (mm^3)[a] day 32	mean body weight change (%)[a] day 32 vs day 1
saline	986 ± 54	113 ± 3
prodrug1	410 ± 75[b]	100 ± 2.2[b,c]
prodrug2	308 ± 55[b]	103 ± 1.5[b,c]
prodrug3	330 ± 69[b]	104 ± 1.2[b,c]
paclitaxel	252 ± 41[b]	96 ± 2.7[b]

[a] Each value represents the mean ± SD of four mice. [b] Significant difference in comparison with the saline treated with controls ($p < 0.05$). [c] Significant difference in comparison with the paclitaxel-treated group ($p < 0.05$).

CONCLUSIONS

Distinctly different from physical encapsulation, a class of novel paclitaxel prodrugs was synthesized, one that can maintain the structural integrity of the loaded parent drug and self-assemble in aqueous solution. Meanwhile, the three prodrugs

we synthesized exhibited different hydrolysis properties under physiological conditions and plasma. In particular, prodrug2 showed favorable hydrolysis of the ester bond between the amino acid and paclitaxel. In order to increase the content of the drug, we use succinylated heparin with many more carboxyl groups as a carrier and different amino acids as a spacer between the carrier and paclitaxel. The nanoparticles self-assembled in aqueous solution, forming an approximately spherical shape composed of a paclitaxel core and carrier shell with diameter about 140−180 nm. Meanwhile, the results of our bioactivity and cytotoxicity assays showed that the prodrugs can be safe and effective as a novel drug delivery system. A cell cycle analysis studied by flow cytometry has shown that these prodrugs can block MCF-7 cells at the G2/M phase. In *in vivo* experiments, prodrug2 shows similar ovarian tumor growth inhibition to the parent drug while inducing no obvious body weight loss. Overall, our prepared prodrug2 offers promising potential for further clinical applications.

ACKNOWLEDGMENT

We thank Dr. Chunyi Tong from the Institute of Life Science and Biotechnology in Hunan University for his assistance with the experimental procedures during biomedical assays. Meanwhile, this work was supported by the Third Xiangya Hospital of Center South University. The authors are grateful for the financial support of 985 Foundation of Ministry of Education, the National High Technology Research and Development Program of China (grant no. 2007AA022006) and Department of Science and Technology Foundation of Hunan Province (grant no. 2009WK4005).

Transplatin-Conjugated Triplex-Forming Oligonucleotides Form Adducts with Both Strands of DNA

Meghan A. Campbell[†] and Paul S. Miller*

Department of Biochemistry and Molecular Biology, Johns Hopkins Bloomberg School of Public Health, 615 North Wolfe Street, Baltimore, Maryland 21205. Received January 8, 2009; Revised Manuscript Received November 5, 2009

Triplex-forming oligonucleotides (TFOs) can bind to polypurine·polypyrimidine tracts in DNA and, as a consequence, perturb the normal functioning of a targeted gene. The effectiveness of such antigene TFOs can potentially be enhanced by covalent attachment of the TFO to its DNA target. Here, we report that attachment of N-7-platinated guanine nucleosides to the 3′- and/or 5′-ends of oligopyrimidine TFOs enables these TFOs to form highly stable adducts with target DNA deoxyguanosines or deoxyadenosines that are adjacent to the TFO binding site. Such adduct formation stably anchors the TFO to its target. Depending on the sequences adjacent to the TFO binding site, adduct formation can occur on either strand of the DNA. Adduct formation by 3′,5′-bis-platinated TFOs can result in the formation of an interstrand cross-link between both strands of the DNA duplex. Formation of the adducts, which could be reversed by treatment with sodium cyanide, was dependent upon the ability of the TFO to bind to DNA and appeared to occur at a rate slower than that at which the TFO bound to the DNA duplex. The extent of adduct formation at 37 °C by platinated deoxyribo-TFOs diminished as the pH was increased from 6.5 to 7.4. In contrast, high levels (∼86%) of adduct formation by platinated 2′-*O*-methylribo-TFOs were observed at both pH 6.5 and pH 7.4. Platinated 2′-*O*-methylribo-TFOs were also shown to bind to plasmid DNA and inhibit transcription in vitro, and to inhibit plasmid replication in *E. coli* cells. These results suggest that platinum-conjugated TFOs may be good candidates for use as antigene agents.

INTRODUCTION

Over the past two decades, there has been considerable interest in developing oligonucleotides that can specifically inhibit gene expression. Two approaches that have received much attention are antisense oligonucleotides and siRNA. Both approaches target the RNA product of the expressed gene and ultimately result in destruction of this target. Because the RNA products are continuously produced when the gene is transcribed, the antisense oligonucleotide or siRNA must be present constantly in order to prevent their translation into protein.

An alternative approach that directly targets and inhibits gene expression utilizes triplex-forming oligonucleotides (TFOs). These oligonucleotides are designed to bind to double-stranded DNA at specific regions within the gene (*1*−*3*). As a consequence of this binding, transcription of the gene is inhibited or mutations are induced that result in aberrant expression of the gene. The potential advantages of the antigene strategy are the relatively few copies that need to be targeted and the possibility that targeting can permanently disable gene expression.

Triplex-forming oligonucleotides interact via the major groove by binding to polypurine tracts within the DNA target (*1*−*7*). Oligopurine TFOs utilize reverse-Hoogsteen hydrogen bonds to form A·A-G and G·G-C triads and are oriented antiparallel to the polypurine tract. Oligopyrimidine TFOs utilize Hoogsteen hydrogen bonds to form T·A-T and C^+·G-C triads and are oriented parallel to the polypurine tract. In this case, the N-3 of the cytosine of the C^+·G-C triad must be protonated in order to form a stable Hoogsteen interaction, and consequently, triplex stability diminishes with increasing pH.

Although TFOs can transiently block DNA transcription (*8*−*11*), inhibition of transcription can be enhanced considerably by linking the TFO covalently to the transcribed strand (*12*−*15*). Furthermore, covalent attachment of TFOs can provoke DNA repair leading to mutations in the targeted gene (*16*−*19*). For these reasons, efforts have been made to conjugate TFOs with functional groups that would enable the TFO to bind to its DNA target in an irreversible manner. Alkylating groups such as bromoacetamide (*20*, *21*) and chlorambucil (*22*, *23*) have been used successfully to covalently attach a TFO to DNA. In these cases alkylation occurs at the N-7 of a guanine adjacent to the TFO binding site. However, the alkylated guanine is prone to depurination, which would lead to a release of the TFO. TFOs have also been conjugated with derivatives of psoralen, a photoreactive molecule that intercalates into DNA and can form cyclobutane adducts with thymines upon irradiation with long wavelength UV light (*15*, *24*−*28*).

An alternative approach utilizes the ability of the cancer chemotherapeutic drug cisplatin to cross-link DNA. Cisplatin or *cis*-diamminedichloroplatinum(II) (*cis*-DDP) reacts primarily with the N-7 of purine bases to form a highly stable coordination complex (*29*−*31*). The primary target of cisplatin is guanine, and cisplatin can form both intrastrand and interstrand cross-links in DNA. Platinum compounds have been employed in several ways to cross-link TFOs to duplex DNA including tethering cisplatin to the 5′-end of a TFO (*32*, *33*), targeting an interruption in the polypurine tract with a transplatin-modified cytosine residue (*34*, *35*), and using transplatin monoadducts of guanine and cytosine to react within the Hoogsteen triad (*36*, *37*).

In the latter approach, a transplatin-modified dG, placed at the 5′-end of a TFO efficiently cross-linked to a guanine in the purine strand of the target DNA sequence. In contrast, a transplatin-modified dG placed at an internal position in the TFO was too destabilizing to allow efficient cross-linking. Cross-

[a] d, 2′-deoxyribo; mr, 2′-*O*-methylribo; C, 5-methylcytosine; Pt-G, N7-*trans*-diamminediaquaplatinum(II) derivative of guanine; and **bold**, TFO binding site. [b] Triplex melting temperatures were determined at pH 6.5 in triplex buffer containing 100 mM MOPS, 100 mM sodium acetate, and 2.5 mM magnesium acetate. ND, not determined. [c] Melting temperature of the target duplex at pH 6.5.

linking was found to be highly dependent upon pH, with virtually no cross-linking observed at pH 7.

In this article, we describe the binding and cross-linking properties of oligopyrimidine TFOs that have 5′-*trans*Pt-dG (Pt-TFO), 3′-*trans*Pt-dG (TFO-Pt), and bis-3′,5′-*trans*Pt-dG (Pt-TFO-Pt) modifications. We show that the platinum of a Pt-TFO can react with purines in either the purine or pyrimidine strand of a DNA target duplex and that it preferentially reacts with directly opposed G or A residues in the duplex. We also show that the platinum of a TFO-Pt, which can form adducts with purines in either strand of the duplex target, reacts more efficiently than the platinum of a Pt-TFO. Furthermore, the doubly modified TFO, Pt-TFO-Pt, can react with both strands of the duplex to form an interstrand cross-link. Finally, we show that TFO-Pt and Pt-TFO-Pt that consist of 2′-*O*-methylribonucleotides cross-link efficiently with their DNA target at physiological temperature and pH and can be used to disrupt *in vitro* transcription and prevent replication in *E. coli* of a plasmid containing a binding site for the TFO.

EXPERIMENTAL PROCEDURES

Protected 2′-deoxy- and 2′-*O*-methylribonucleoside-3′-*O*-bis(diisopropylamino)-β-cyanoethylphosphoramidites, and 2′-deoxy- and 2′-*O*-methylribonucleoside derivatized controlled pore glass supports (CPG) were purchased from Glen Research Inc. (Sterling, VA). 2′-*O*-Methylribo-5-methylcytosine phosphoramidite and 2′-*O*-methylribo-5-methyluridine derivatized CPG were purchased from ChemGenes Corp. (Ashland, MA). The base protecting groups were benzoyl (A and C) or isobutryl (G). 4,5-Dicyanoimidazole, 5-ethylthiotetrazole, Cap Mix A, Cap Mix B, and oxidizing solution were purchased from EMD Chemicals (Gibbstown, NJ). Phosphoramidite solutions were prepared using synthesis-grade acetonitrile that was dried and stored over calcium hydride. A platinum solution was prepared by incubating 5 mM *trans*-diamminedichloroplatinum(II) (*trans*-DDP) with 10 mM silver nitrate overnight at 37 °C. The resulting precipitate was pelleted by centrifugation, and the supernatant containing *trans*-diamminediaquaplatinum(II) dinitrate was stored in the dark at room temperature. MALDI-TOF mass spectrometry analysis was performed at the AB Mass Spectrometry/Proteomics Facility at The Johns Hopkins School of Medicine, with support from the National Center for Research Resources Shared Instrumentation, Grant 1S10-RR14702.

Synthesis of Oligonucleotides. The sequences of the oligonucleotides used in this article can be found in Table 1 and Figures 3−5 and 8. These oligonucleotides were synthesized on an ABI DNA synthesizer (model 3400), using phosphoramidite chemistry and standard automated procedures. The phosphoramidite solutions were made up to a concentration of 0.15 M, and 5-ethylthiotetrazole was used as the activating agent. Coupling times were 120 s for 2′-deoxyribonucleoside phosphoramidites and 360 s for 2′-*O*-methylribonucleoside phosphoramidites. The oligonucleotides were deprotected and removed from the solid support by incubating the CPG in a solution containing 300 μL of concentrated ammonium hydroxide and 100 μL of 95% ethanol for 3.5 h at 55 °C. The supernatant from this reaction was evaporated to dryness and the residue dissolved in 200 μL of 50% aqueous acetonitrile for storage at 4 °C. The crude oligonucleotides were purified by strong anion exchange HPLC on a Dionex DNAPac PA 100-4 250 mm column (Dionex Corp., Sunnyvale, CA), using a 30 min linear gradient of 0 to 0.5 M sodium chloride in a solution containing 100 mM Tris (pH 7.8) and 10% acetonitrile at a flow rate of 1.0 mL/min. The purified oligonucleotides were desalted on a C-18 Clarity Tube (Phenomenex, Inc., Torrance, CA). The concentration of purified oligomers was determined from their UV absorbance at 260 nm, using calculated extinction coefficients based on nearest neighbor approximations (*38*). The compositions of the oligonucleotides were confirmed by MALDI-TOF mass spectrometry, as shown in Table 1.

Preparation of *trans*-DDP Modified TFOs. The N7 position of the terminal guanines of the TFOs were platinated by dissolving the dried oligomer in an aqueous solution of 144 μM *trans*-diamminediaquaplatinum(II) dinitrate to give a final oligomer concentration of 0.2 nM. The solution was incubated at 37 °C for 2−3 h. The platinated TFOs were then purified by SAX-HPLC as described above, and their compositions were determined by MALDI-TOF mass spectrometry as shown in Table 1.

Thermal Denaturation Experiments. A solution of 1 μM **4RY** duplex and 1 μM TFO was prepared in triplex buffer (pH 6.5), which contained 100 mM MOPS, 100 mM sodium acetate, and 2.5 mM magnesium acetate. The solution was heated to 90 °C for 10 min, allowed to cool slowly to room temperature, and incubated overnight at 4 °C to anneal the triplex. The absorbance at 260 nm was monitored using a Cary 3E spectrophotometer as the solution was heated from 5 to 80 °C at a rate of 0.4 °C/min. The melting temperature was determined by plotting the first derivative of the absorbance versus temperature profile and is accurate to ±1 °C.

Determination of Binding of Platinum-Modified TFOs to DNA. The 5′-hydroxyl group of the pyrimidine strand of the target DNA duplex was labeled using polynucleotide kinase and γ-[^{32}P]-ATP at a specific activity of 10 Ci/mmol. The labeled strand was mixed with an equimolar amount of unlabeled complementary strand, and the solution was evaporated to dryness. The residue was dissolved in 100 μL of triplex buffer to a final duplex concentration of 1 μM. The solution was heated to 90 °C for 10 min and then slowly cooled to room temperature. Solutions containing 100 pmol of platinated TFO were evaporated to dryness, the residue dissolved in 10 μL of the labeled duplex solution, and the solution incubated overnight at 4 °C. A 2 μL aliquot of 50% glycerol was added to each sample, and the samples were electrophoresed on a 20% native polyacrylamide gel at 100 V and 4 °C in triplex buffer. The gel was imaged using a Fuji FLA-7000 phosphorimager.

Reaction of Platinum-Modified TFOs with DNA. One micromolar [^{32}P]-labeled duplex with a specific activity of 10 Ci/mmol was prepared as described above. Solutions containing 10−200 pmol of platinated TFO were evaporated to dryness and dissolved in 10 μL of the labeled duplex solution to a final concentration of 1−20 μM TFO. Each reaction mixture was incubated at 37 °C and quenched with 7 μL of formamide gel loading buffer. The samples were electrophoresed on a 20% denaturing polyacrylamide gel at 800 V. The gel was imaged by a Fuji FLA-7000 phosphorimager, and radioactivity in each band was quantitated using ImageGuage software.

Pt-TFO Cross-Link Reversal by Cyanide Treatment. Platinum-modified TFO (**t1d**, **t2d**, or **t3d**) was cross-linked to the target duplex using the procedure described above. The slower migrating band, which corresponds to the cross-linked product, was excised from the denaturing gel, and the gel slice was extracted by shaking in 20% acetonitrile solution containing 0.1 M ammonium acetate buffer (pH 6.25) for 48 h at 37 °C. The DNA was precipitated in 100% ethanol overnight at −20 °C and then centrifuged for 20 min at 4 °C. The pellet was resuspended in 70% ethanol and centrifuged for 10 min at 4 °C. The pellet was dried under vacuum and dissolved in either 20 μL of water or 20 μL of 200 mM sodium cyanide. Samples were incubated at 37 °C for 48 h and electrophoresed on a 20% denaturing polyacrylamide gel at 800 V. The gel was imaged by a Fuji FLA-7000 phosphorimager, and radioactivity in each band was quantitated using ImageGuage software.

TFO Binding Kinetics. Triplex formation results in a decrease in absorbance at 260 nm. This phenomenon has been employed previously to estimate the rate of third strand association (*39*, *40*). Separate solutions of 2 μM **t1d** and 2 μM **4RY** were prepared in triplex buffer (pH 6.5). The duplex solution (**4RY**) was annealed and stored overnight at 4 °C. Five hundred microliters of each solution was equilibrated at 37 °C, and the solutions were quickly, but thoroughly mixed in a 1 mL quartz cuvette to give a final concentration of 1 μM. The absorbance at 260 nm was immediately monitored using a Cary 3E spectrophotometer (1 data point/3 s) over the course of 20,000 s (5.56 h) at 37 °C. The k_{on} value was calculated using the Varian software supplied with the spectrophotometer using second order kinetics. The reported k_{on} value is an average of four independent experiments. The $t_{1/2}$ of binding was calculated using the equation $t_{1/2} = 1/(k_{on} \cdot [\text{duplex}]_0)$.

Construction of Plasmid p-GEM-TFO. Plasmid pGEM-3Z (Promega, Madison WI) was cut with *Eco*RI and *Hin*dIII, and the resulting linear DNA was purified by agarose gel electrophoresis. The *Hin*dIII restriction site is immediately adjacent to a T7 promoter sequence in the plasmid. One equivalent of the linearized DNA was ligated with 6 equivalents of duplex **5RY**, whose sequence is shown in Figure 8a, using T4 DNA ligase. The ligated DNA was then transformed into DH5α *E. coli* cells; the transformed cells were plated on LB agar plates supplemented with ampicilin, bromo-chloro-indolyl-galactopyranoside (X-gal), and isopropyl-β-D-thiogalactopyranoside (IPTG); and white colonies were selected. Individual colonies were grown in LB medium; plasmid DNA was isolated using a QIAprep Spin Miniprep kit (Qiagen Sciences); and the DNA was sequenced to confirm the presence of the **5RY** insert. The insert is oriented such that the **5Y** strand of the duplex is part of the plasmid strand that can be transcribed by T7 RNA polymerase.

Reaction of Platinum-Modified TFO t2mr with p-GEM-TFO. Solutions (10 μL) containing 500 ng of pGEM-TFO and 0 μM TFO, 10 μM nonplatinated TFO **2mr**, or 10 μM platinated TFO **t2mr** in buffer composed of 50 mM HEPES, 100 mM sodium chloride, and 5 mM magnesium chloride, pH 7.5, were incubated for 72 h at 37 °C. A 0.5 μL aliquot was removed from each reaction, and each aliquot was incubated in 9.5 μL of a solution containing 100 mM sodium chloride, 50 mM Tris-hydrochloride, 10 mM magnesium chloride, 1 mM dithiothreitol, pH 7.9, and 10 units of *Bgl*II for 2 h at 37 °C. A 5 μL aliquot of each digest was mixed with 5 μL of 20% glycerol loading buffer, and the solutions were electrophoresed on a 0.8% agarose gel containing Syber Green dye. The gel was scanned on a Fuji FLA-7000 imager.

Transcription of p-GEM-TFO DNA. pGEM-TFO treated with 0 μM TFO, 10 μM nonplatinated TFO **2mr**, or 10 μM platinated TFO **t2mr** as described above was incubated with *Hin*dIII for 2 h at 37 °C. Examination by agarose gel electrophoresis showed that all three plasmid preparations were completely linearized. Transcription was carried out using the Riboprobe System T-7 kit supplied by Promega. Each reaction contained between 1.5 to 11.6 ng of linearized plasmid DNA, 9.8 mM dithiothreitol, 40 units of RNasin inhibitor, 0.49 mM each of rATP/rCTP/rUTP, 11.8 μM rGTP, 50 μCi of α-^{32}-P-rGTP, and 19 units of T7 RNA polymerase in 20.4 μL of transcription buffer that consisted of 40 mM Tris-hydrochloride (pH 7.9), 10 mM sodium chloride, 6 mM magnesium chloride, 2 mM spermidine, and 0.05% Tween. The reactions were incubated for 1 h at 37 °C, passed through a Sephadex G-25 Micro-Spin column (GE Healthcare), and then electrophoresed on a 15% denaturing polyacrylamide gel at 800 V. The gel was phosphorimaged, the 42 nucleotide runoff products were quantified from the phosphorimage, and the amount of product was normalized to the amount of plasmid DNA used in the reaction.

Colony Formation by *E. coli* Transformed with p-GEM-TFO. Samples (150 pg each) of pGEM-TFO treated with 0 μM TFO, 10 μM nonplatinated TFO **2mr**, or 10 μM platinated TFO **t2mr** as described above were electroporated at 1.8 kV into electrocompetent DH5α *E. coli* cells in 40 μL of GYT medium that contained 1.25 mg/mL yeast extract, 2.5 mg/mL tryptone, and 10% glycerol. The cells were then immediately diluted with 1.0 mL of SOC medium that contained 20 mg/mL Bacto-tryptone, 5 mg/mL Bacto-yeast extract, 8.6 mM sodium chloride, and 2.5 mM potassium chloride, and then incubated with shaking at 37 °C for 1 h. The cells were then spread onto LB plates supplemented with ampicilin, and the plates were incubated overnight at 37 °C. Two separate experiments were carried out in triplicate, and the number of colonies formed was counted.

RESULTS AND DISCUSSION

Synthesis and Characterization of Platinated TFOs. Previous studies by Leng and co-workers had examined the ability of oligodeoxyribopyrimidine TFOs with a 5′-*trans*Pt-dG modification to form adducts with DNA (*36*, *37*). We have extended these studies to include oligodeoxyribopyrimidine and oligo-2′-*O*-methylribopyrimidine TFOs that contain 5′-, 3′-, and 5′,3′-*trans*Pt-dG modifications. The sequences of these TFOs and

the site targeted for triplex formation are shown in Table 1. The target duplex sequence (4RY) serves as a model for triplex formation with five cytosine residues within a 17 bp long polypurine tract and is similar to a previously studied purine target sequence found in the coding region of the polymerase gene of HIV-1 (*34*, *35*). Each of the TFOs consisted of either 2′-deoxyribonucleotides or 2′-*O*-methylribonucleotides and contained 5-methylcytosine (C) and 5-methyluracil (T) bases. One or both ends of the TFO contained guanine nucleosides that were platinated to give the monofunctional N-7 *trans*-$[Pt(NH_3)_2(G)(H_2O)]^+$ adduct. Platination of the TFOs was carried out by incubating the TFO in a solution containing *trans*-diamminediaquaplatinum(II) dinitrate at 37 °C. Under these conditions, platination occurs preferentially at the N-7 of the guanine of the TFO (*36*). Because addition of the platinum group adds a positive charge to the oligonucleotide, the platinated TFO can be separated from nonplatinated TFO by strong anion exchange HPLC (see Supporting Information, Figure S1). The compositions of the platinated TFOs were confirmed by MALDI-TOF mass spectrometry analysis (see Table 1). Additional peaks observed in the HPLC chromatograph (see Supporting Information, Figures S1 and S2) were isolated and identified by MALDI-TOF mass spectrometry as multiply platinated species. The overall yields of the purified and desalted Pt-TFOs were approximately 20−30%.

The TFOs were tested for their ability to bind to a DNA target sequence, **4RY**, by measuring the melting temperatures of the triplexes formed by the nonplatinated TFOs at pH 6.5, as shown in Table 1. The TFOs that consisted of deoxyribonucleotides, **1d**, **2d**, and **3d**, formed relatively stable triplexes whose third strands dissociated at approximately 50 °C, a temperature lower than the melting temperature of duplex **4RY**, 65 °C. We and others have shown previously that incorporation of 2′-*O*-methylribonucleotides can stabilize TFO binding (*40*−*45*). In accord with these findings, the TFOs containing 2′-*O*-methylribonucleotides, **2mr**, and **3mr**, formed triplexes that melted with a single transition at greater than 70 °C. Representative melting curves can be found in Supporting Information, Figure S3. Melting temperatures for the corresponding platinum modified TFOs were not determined because these TFOs were expected to form adducts with the DNA target. However, a previous study has shown that modification of a guanine at the end of a polypyrimidine TFO with a nonreactive platinum group resulted in a slight stabilization of a triplex formed by this TFO (*37*). Most likely this stabilization results from introduction of the positively charged platinum group. On the basis of this result, we expected that the platinated TFOs shown in Table 1 would form triplexes whose stabilities are comparable to those of the parent unmodified TFOs.

Adduct Formation between Platinated TFOs and DNA Duplexes. We examined the interactions of the platinated TFOs by electrophoretic mobility shift assays on native polyacrylamide gels. Each of the platinated deoxyribo-TFOs was incubated with DNA target duplex, **4RY**, at 4 °C, and the solution was then subjected to electrophoresis on a native polyacrylamide gel run at 4 °C to prevent dissociation of the triplex due to heating of the gel. As shown in Figure 1a, the mobility of **4RY** decreased in the presence of Pt-TFO, **t1d**, TFO-Pt, **t2d**, or Pt-TFO-Pt, **t3d**, a result consistent with triplex formation.

The platinated TFOs were then tested for their ability to form adducts with each strand of the target duplex. Increasing concentrations of the platinated TFOs were incubated at 37 °C with duplex **4RY** whose purine or pyrimidine strand was labeled with ^{32}P phosphate. The reaction mixtures were then subjected to electrophoresis on a denaturing polyacrylamide gel. As shown in Figure 1b, incubation of the target with Pt-TFO **t1d** resulted in 50% adduct formation with the purine strand, whereas only
