Derivatization of 11-α-Hydroxyprogesterone using Phosphoramidite Chemistry

Janne Ketola, Pertti Hurskainen, and Jari Hovinen*

PerkinElmer, Genetic Screening, P.O. Box 10, FI-20101 Turku, Finland. Received December 3, 2008; Revised Manuscript Received January 22, 2009

The well-known phosphoramidite chemistry routinely used in solid-phase oligonucleotide synthesis is exploited here in the preparation of steroid conjugates in solution. The applicability of the method is tested by conjugating one nucleosidic and one non-nucleosidic phosphoramidite building block to 11-α-hydroxyprogesterone. The suitability of one of the conjugates synthesized (**5**) for a competitive binding assay is also demonstrated.

INTRODUCTION

Steroids with additional functional and label groups are often needed for biochemical, diagnostic, microbiological, and medicinal applications. For example, in immunoassays haptens are coupled covalently to carrier protein prior to immunization. In competitive immunoassays, in turn, haptens coupled to label molecule are used as tracers. Most commonly, a spacer arm with a reactive ω-substituent is introduced into the steroid structure before the coupling reaction. Since the coupling site and the length and chemical structure of the spacer play a very important role in antibody recognition, a wide range of methods for steroid tethering have been developed (*1*−*3*).

Since the glucuronide bridge is a weakly antigenic subunit (*4*), steroid glucuronides have been widely used as tracers in competitive immunoassays. Although several efficient glucuronization reactions have been developed (*5*−*9*), derivatization of certain steroids is still challenging. One of the most difficult steroids to glucuronize is progesterone at position C11. The only reported synthesis of progesterone 11-α-glucuronide (**1**, Figure 1) is based on the classical Koenigs-Knorr method starting from glucuronolactone, which is initially converted to methyl 1-bromo-1-deoxy-2,3,4,-tri-*O*-acetyl-α-D-glucopyranoate followed by reaction with 11-α-hydroxyprogesterone (*4*). Accordingly, the synthesis is laborious, and the overall yield of the desired isomer is low. In addition, attachment of a label molecule to the carboxylic acid function of **1** is also needed.

Here is presented a simple method for the preparation of labeled progesterone derivatives using phosphoramidite chemistry. Also, the suitability of one of the steroid conjugates prepared for a competitive binding assay was tested.

EXPERIMENTAL PROCEDURES

General Methods. Adsorption column chromatography was performed on columns packed with silica gel 60 (Merck). 6-[*N*-4′-Carboxy-4-(dimethylamino)azobenzene]aminohexyl-1-*O*-(2-cyanoethyl)-(*N*,*N*-diisopropyl)phosphoramidite (dabcyl), **6**, and 11-α-hydroxyprogesterone were purchased from Glen Research and Sigma, respectively. 2′-Deoxy-5′-*O*-(4,4′-dimethoxytrityl)-3-{[4-(5-hexyn-1-yl)phenyl]-2,2′:6′,2″-terpyridine-6,6″-diyl]-methylenenitrilotetrakis(acetato)}uridine 3′-*O*-(2-cyanoethyl *N*,*N*-diisopropyl) phosphoramidite, **3**, was synthesized as disclosed in the literature (*10*). The DELFIA progesterone kit and DELFIA Inducer were from PerkinElmer (Turku, Finland). The oxidizer used was 0.1 M I_2 in pyridine/water from Sigma-Proligo. All solvents were from Merck, and they were used as received. HPLC was performed using a Shimadzu LC 10 AT instrument equipped with a diode array detector, a fraction collector, and a reversed-phase column (LiChrocart 125−3 Purospher RP-18e, particle size 5 μm). Mobile phase: (Buffer A) 0.02 M triethylammonium acetate (pH 7.0); (Buffer B) A in 50% (v/v) acetonitrile. Gradient: from 0 to 1 min 95% A, from 1 to 21 min from 95% A to 100% B. Flow rate was 0.6 mL min^{-1}. NMR spectra were recorded on a Jeol LA 400 spectrometer operating at 161.9 MHz for ^{31}P. The signal H_3PO_4 was used as an external reference. ESI-TOF mass spectra were recorded on an Applied Biosystems Mariner instrument.

Figure 1. Progesterone 11-α-glucuronide.

Reaction of 11-α-Hydroxyprogesterone with Phosphoramidites. General Procedure. The phosphoramidite (compound **3** (16.1 mg) or **6** (6.6 mg); 11 μmol) and 11-α-hydroxyprogesterone (**2**, 32 mg, 22 μmol; 2.0 equiv) were dissolved in a mixture of dichloromethane and acetonitrile (150 μL, 1:1, v/v). 1*H*-tetrazole in acetonitrile (250 μL, 0.45 M) was added, and the mixture was stirred for 1 h at RT after which the oxidizer (220 μL; 2.0 equiv) was added, and the mixture was stirred for an additional 5 min. All volatiles were removed in vacuo. The residue was dissolved in dichloromethane, washed with aq $Na_2S_2O_3$, dried over Na_2SO_4, and concentrated. Purification on silica gel (eluent 10% (v/v) methanol in dichloromethane) yielded the desired progesterone conjugates. Compound **4** (14.3 mg, 76%). ESI-TOF MS: found, 1709.25; calcd for $C_{95}H_{106}N_8O_{20}P^+$ 1709.87. Compound **7** (9.25 mg, 99%). ESI-TOF MS: found, 850.48; calcd for $C_{44}H_{61}N_5O_8PS^+$ 850.40.

11-α-Hydroxyprogesterone Labeled with a Nucleosidic Europium(III) Chelate. Compound **4** (12 mg, 7 μmol) was dissolved in dichloromethane (1 mL). TFA (40 μL) was added, and the mixture was stirred for 15 min at RT before methanol (1 mL) was added, and the stirring was continued for an additional 15 min. Water (1 mL) was added, and volatiles

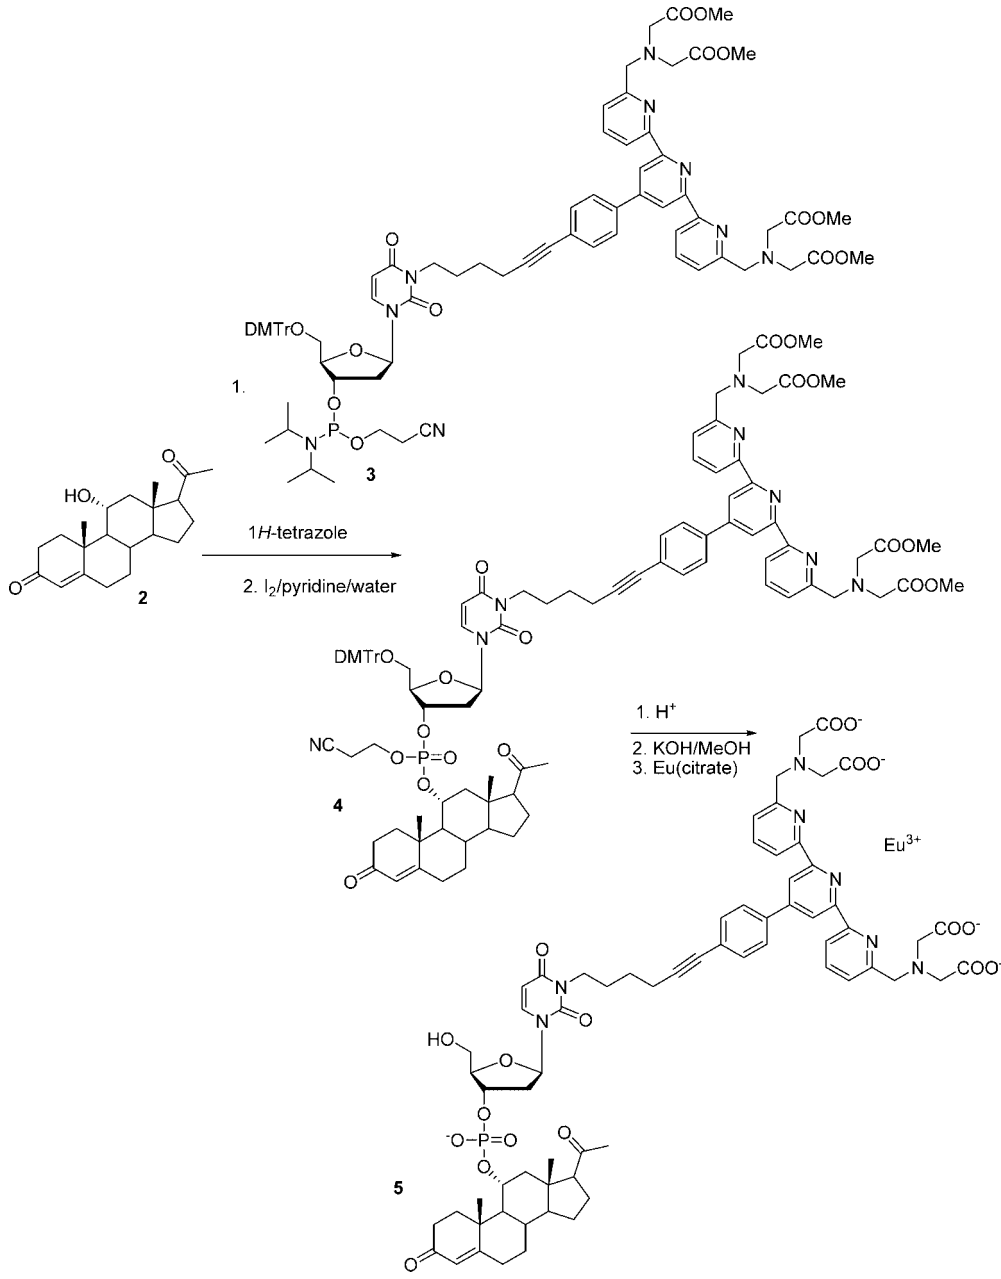
Scheme 1. Synthesis of Europium(III) Chelate Labeled 11-α-Hydroxyprogesterone



were removed in vacuo. Aqueous NaOH (0.1 M; 200 μL) was added, and the mixture was stirred for 3 h at RT, after which the pH was adjusted to 8.5 with 0.2 M HCl. Europium citrate (40 μL, 0.2 M) was added, and the mixture was stirred for 4 h. Compound **5** was precipitated from the reaction mixture by adding cold acetone (50 mL). Final purification was performed on HPLC. ESI-TOF MS: found, 1447.56; calcd for $C_{67}H_{73}EuN_7O_{18}P^+$ 1447.27. The product was stored at −18 °C.

11-α-Hydroxyprogesterone Labeled with Dabcyl. Compound **7** (54 mg, 0.066 mmol) was dissolved in THF (50 μL). Aq ammonia (25% v/v; 100 μL) was added, and the mixture was stirred for 10 min at RT before being concentrated in vacuo to give compound **8**. ^{31}P NMR ($CDCl_3$): δ −4.94. ESI-TOF MS: found, 795.33; calcd for $C_{41}H_{56}N_4O_8PS^-$ 795.36. The product was stored at −18 °C.

The Displacement Assay. Compound **5** was tested in a displacement assay using components of the DELFIA Progesterone kit. The assay was performed essentially as instructed in the kit manual. Accordingly, progesterone standards (25 μL) were added in triplicate to antirabbit IgG coated microtitration plate wells. The progesterone conjugate **5**, diluted with DELFIA progesterone assay buffer to 11.3 nM, was added to the wells (100 μL/well; final concentration 5 nM) followed by rabbit antiprogesterone antiserum diluted 1:10 in assay buffer (100 μL/well). The wells were shaken on DELFIA Plateshake (setting: slow) for 2 h at RT. After washing the wells four times in DELFIA Platewash using DELFIA wash solution, DELFIA inducer was added to the wells (200 μL/well). The wells were shaken on DELFIA Plateshake for 15 min (setting: slow) and then measured using a Victor 2V multiplate reader using the factory-set DELFIA Eu protocol. The results were analyzed using *GraphPad Prism* software (GraphPad Software, Inc.).

RESULTS AND DISCUSSION

Solid-phase oligonucleotide synthesis is routinely performed using phosphoramidite chemistry. The key step of this method is the highly efficient coupling reaction between the 5′-hydroxyl

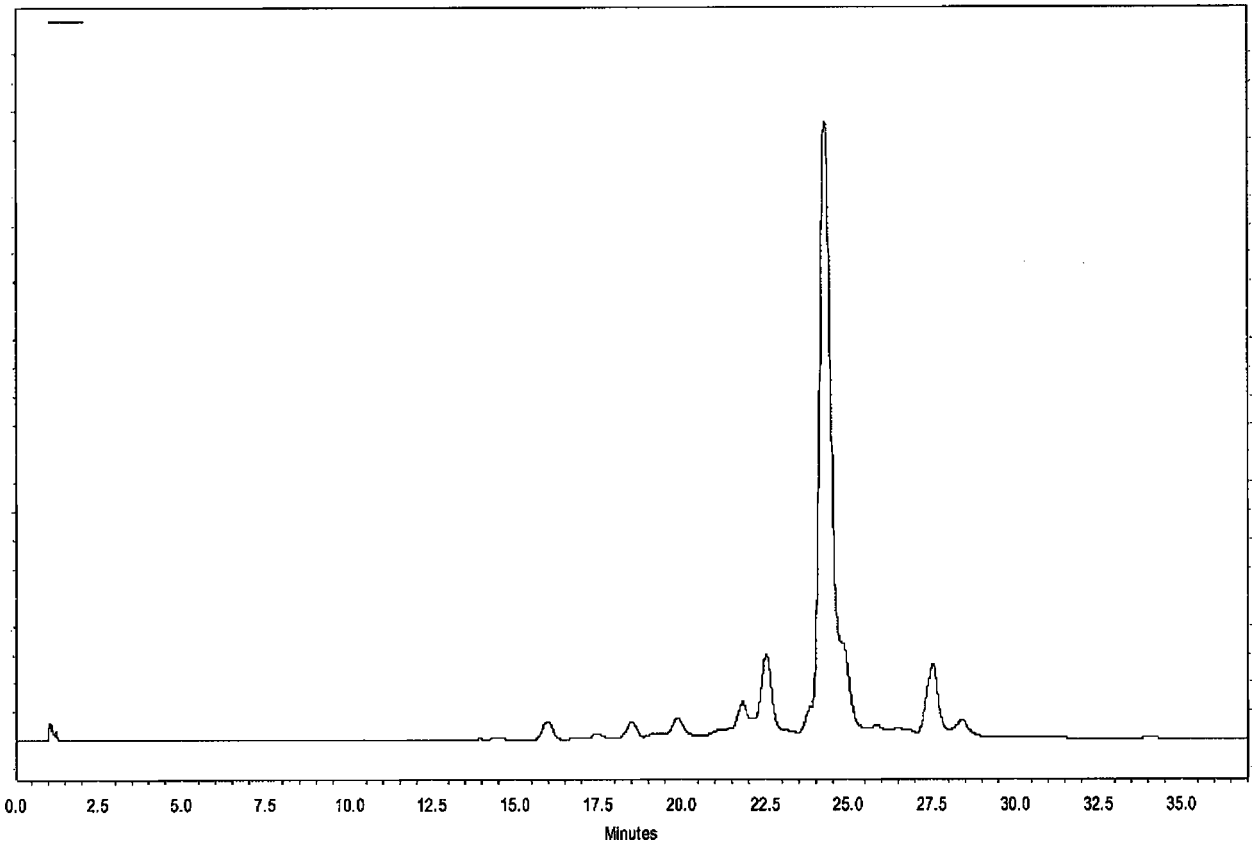


Figure 2. Reversed-phase HPLC trace of the progesterone derivative **5**, synthesized with the aid of the phosphoramidite **3** (crude reaction mixture) detected at 270 nm. The major peak (ca. 90% based on the integral areas) is the desired conjugate as judged on ESI-TOF MS. For chromatographic conditions, see Experimental Procedures.

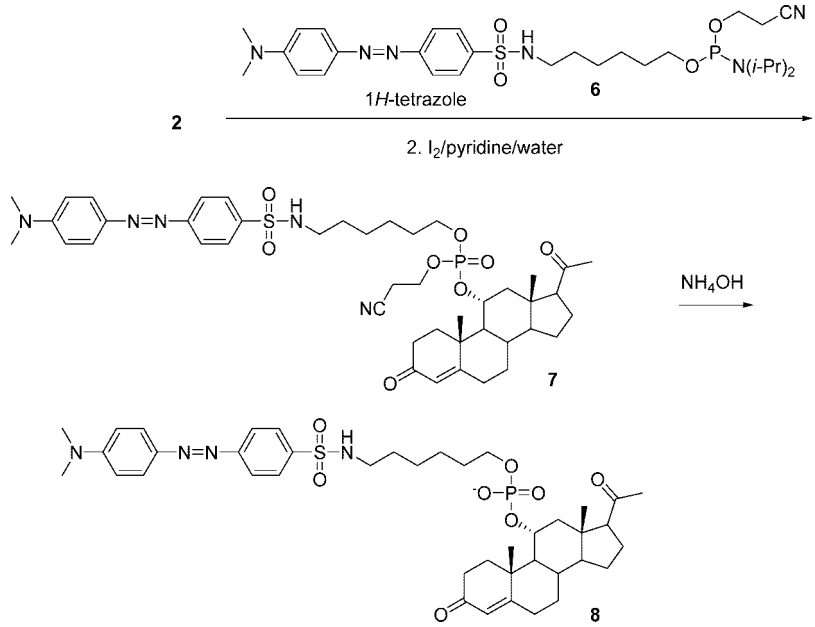
Scheme 2. Synthesis of 11-α-Hydroxyprogesterone Labeled with an Organic Dye



group of a nucleoside bound to a resin and a nucleoside 3′-phosphoramidite catalyzed by 1*H*-tetrazole. Oxidation of the phosphite triester formed by iodine gives rise to stable phosphotriesters. Removal of the protecting groups completes the synthesis. The method has been widely applied also to the preparation of oligonucleotide conjugates (*11*). Although few solution-phase phosphoramidite methods have been reported, they describe large-scale synthesis of unmodified oligodeoxyribonucleotides (*12, 13*).

In order to study the applicability of phosphoramidite chemistry for the preparation of steroid conjugates, 11-α-hydroxyprogesterone (**2**) was allowed to react with a nucleosidic terpyridine phosphoramidite (**3**) in the presence of 1*H*-tetrazole followed by iodine oxidation (Scheme 1). The desired product, **4**, was isolated by silica gel column chromatography in good yield. Removal of the DMTr and cyanoethyl protecting groups of **4** with TFA and sodium hydroxide, respectively, followed by treatment with europium citrate (*7*) yielded the progesterone

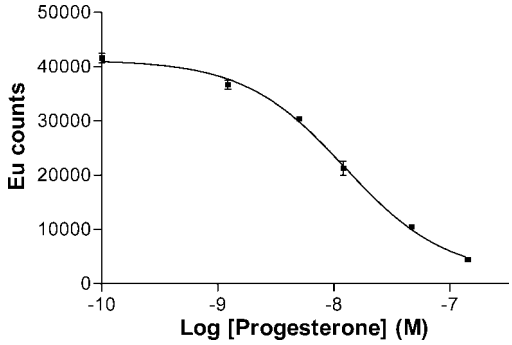


Figure 3. A competitive binding assay of 11-α-hydroxyprogesterone labeled with the nucleosidic terpyridine chelate. The experiments were performed with a 5 nM solution of compound **5** using a commercial progesterone kit and recommended protocols.

conjugate **5**. The product was easily isolated by precipitation from acetone. A reversed-phase HPLC trace (crude reaction mixture) of compound **5** is shown in Figure 2. The major peak is the desired steroid conjugate. The final purification was performed on HPLC.

The more general applicability of the method was also tested by allowing **2** to react with a commercially available dabcyl phosphoramidite **6** (Scheme 2). The reaction was practically quantitative giving compound **7** in 99% yield after purification on silica gel column chromatography. The final product, **8**, was obtained by standard ammonolysis.

Competition Assay. Figure 3 shows the competitive binding assay of progesterone. The experiment was performed with 5 nM of compound **5** using a commercial progesterone kit and the recommended protocols. It was found that antiprogesterone antiserum binds to compound **5**, and that progesterone displaces compound **5** from the antiserum. The assay using compound **5** was as sensitive as the commercial progesterone kit wherein progesterone 11-α-glucuronide (**1**) labeled with a europium(III) chelate is used. Accordingly, the glucuronide moiety can be replaced by a conjugate group including a deoxyribose subunit, the latter being considerably easier to synthesize.

As shown here, the phosphoramidite approach works well in the solution phase, too. Accordingly, steroid tethering using phosphoramidite chemistry may be the method of choice when conjugation of steroids at positions of low reactivity is needed. Since a wide range of phosphoramidites tethered to label groups is commercially available, the rather laborious post-labeling can also be avoided. Although the applicability of phosphoramidite chemistry is demonstrated here only for progesterone conjugation, the method is, in all likelihood, applicable to other steroids and other type of tracers as well, as long as the target molecule has a hydroxy group in its structure, and all other functional groups are protected. Since the reaction intermediates are fully protected lipophilic phosphotriesters, they can be easily purified by silica gel chromatography, with the final step thus comprising deprotection of the purified material. If desired, the method also allows the preparation of phosphorothioates simply by changing the oxidant (*14*). This might be needed if resistance toward nucleases is required.

REVIEWS

Molecular Imaging with Bioconjugates in Mouse Models of Cancer

Stephen Mather*

Barts and The London Queen Mary's School of Medicine and Dentistry, Centre for Cancer Imaging Institute of Cancer and the CR-UK Clinical Centre, St. Bartholomew's Hos, London, EC1A 7BE, United Kingdon. Received September 18, 2008; Revised Manuscript Received November 12, 2008

The definition of molecular imaging provided by the Society of Nuclear Medicine is "the visualization, characterization and measurement of biological processes at the molecular and cellular levels in humans and other living systems". This review gives an overview of the technologies available for and the potential benefits from molecular imaging at the preclinical stage. It focuses on the use of imaging probes based on bioconjugates and for reasons of brevity confines itself to discussion of applications in the field of oncology, although molecular imaging can be equally useful in many fields including cardiovascular medicine, neurosciences, infection, and others.

WHY PRECLINICAL MOLECULAR IMAGING

Researchers may wish to use molecular imaging for a number of reasons. Basic researchers in the in vivo sciences may wish to measure physiological parameters such as receptor or enzyme concentrations, organ function such as cardiac output or renal excretion, or metabolic processes such as bone turnover or glucose metabolism. All of these parameters are accessible by imaging. More common will be a desire to measure how these parameters change during disease. Since a major reason for the study of disease in small animals is to try and model human diseases in such species, it is important to compare the effects of a particular disease in mouse and man. If such a disease results in a change in a biological function, then there will normally be a desire to correct this change by the use of drugs or other interventions, and it will therefore be valuable to screen drugs to compare their effects on this function using imaging in an animal model before proceeding to clinical trials. If this is successful, then the subsequent application of the imaging technology in human subjects may prove useful as a biomarker for the assessment of the performance of a drug in such trials. The disposition of drugs in the body may be monitored by imaging in some case directly or alternatively after tagging with an imaging probe, and last (but not least), imaging studies in small animals can be very useful (essential in fact) for the development of clinically useful imaging agents and, to a lesser extent, for the validation of clinically applicable imaging protocols.

ANIMAL MODELS OF CANCER

Normal Animals. As the genetic mutations responsible for malignancy are identified, there is a desire to duplicate these changes in animal models in order to determine their phenotypic consequences, and many highly sophisticated systems have now been developed as described below. However, useful information can also often be gained by the use of much simpler animal models including normal rodents. The physiology of such animals bears many similarities to and some differences from that of man. Thus, the basic layout and function of most organs is preserved, and many of the functional molecules expressed

Published on Web 12/16/2008

in healthy tissues are also conserved. In the early stages of the development of a new biomolecular contrast agent, there is a need to assess its pattern of biodistribution, its stability in vivo, and its ability to interact with a molecular target in a biological environment. Such studies can often be performed in normal animals. Neuropeptide receptors, for example, are targets of current interest in radiopharmaceutical development (*1*), and such receptors are widely expressed in mice and often interact as efficiently as human receptors with radiolabeled complementary peptides. For example, the development of radiolabeled somatostatin analogues has been significantly informed by such studies (*2*). However, this is not always the case. For example, Maina et al. found significant differences between bombesin analogues in their ability to interact with gastrin-releasing peptide receptors originating from mouse and man (*3*). While such receptors may be highly conserved throughout mammals, their pattern of distribution may not be; for example, many neuropeptide receptors are highly expressed in the mouse pancreas but may not be expressed in the human organ (*4*). While the functional binding sites of receptors may be highly conserved across mammalian species, this is not necessarily true of the their nonfunctional framework regions, and this can cause problems in the study of monoclonal antibodies and their related constructs, which represent a very important class of biomolecular conjugates (*5*). Such molecules only rarely bind to the same sites as the native ligands, and many antibody-based agents that bind well to human-derived targets will not bind to their rodent equivalents. For such targets, it is therefore necessary to express the human homologue in a mouse background. Other differences between rodent and human physiology are quantitative rather than qualitative. It is well-recognized, for example, that the mouse heart beats much faster than the human and that mice breathe much faster. Because of the much smaller size, tissue perfusion times are much shorter, and compounds will show more rapid pharmacokinetics in mouse than man. Gastrointestinal transit times in man are roughly twice those in mice, and there are also differences in relative organ perfusion so that, for example, renal blood flow in the mouse is 75% of the blood volume per minute, while in man, it is only 15% (*6*).

Tumor-Bearing Animals. If the purpose of the preclinical imaging study is to predict the likely behavior of a drug or contrast agent in a patient with cancer, then it is likely that, at some stage, tumor-bearing animals will be utilized. These fall into several types depending on the source of the tumor, the immunocompetence of the host, and the degree of genetic manipulation employed.

Syngeneic Models. Perhaps the simplest model is the use of normal mice or rats bearing tumors derived from their own species. Tumors may arise spontaneously (although this is rare in normal laboratory strains); they may be induced by administration of carcinogens or transplanted by a variety of administration routes. Spontaneous and carcinogen-induced tumors have the advantage that they develop in a "natural" tumor environment. Thus, the blood supply and stromal and cellular interactions can be considered to closely mimic those occurring in human tumors apart from the fact that they involve murine rather than human homologues. Specific genetic mutations can be induced by the selection of appropriate carcinogens (*7*). The exogenous administration of tumor cells by typically subcutaneous, intravenous, or intraperitoneal routes, on the other hand, often results in the tumors developing in an unnatural location—pancreatic tumors in the lungs, for example—and this results in changes in the intratumoral signaling that might normally occur. Such approaches are, however, widely used, because it is quicker to produce the large numbers of animals often required for such studies. It is possible to use orthotopic routes of administration, i.e., to transplant the tumor to the same site as its origin, but although useful in superficial tissues such as the mammary gland (*8*), this is technically much more difficult to perform in less accessible organs, and most commonly, the precise anatomical microlocation of origin cannot be reproduced.

Xenogeneic Models. Perhaps the main limitation of syngeneic models is that the target molecules expressed within the tumor are of animal rather than human origin. If this represents a problem for the target of interest, then the next level of complexity is to implant cells of human origin in the mouse tissues. These can again be administered by various routes, although subcutaneous administration is by far the most common, since it is technically simple to perform and it is easy to monitor tumor growth, which is clearly visible. Since the administered cells are derived from a different species from the host, the animal's immune system would normally recognize them as foreign and mount an effective immune response against them, resulting in very low "take" rates—perhaps as low as 1 in 100. To overcome this problem, animals with disabled immune systems are normally used. In the past, this was often done by irradiation or treatment with cytotoxic drugs, but most commonly today, genetically immunodeficient animals are used, the most common being various strains of "nude" mice (or rats), which lack a thymus (*9*) and therefore cannot generate mature T-cells, or severe combined immunodeficient (SCID) mice (*10*), which have a mutation that prevents V(D)J recombination of DNA resulting in a complete loss of both humoral and cellular immune systems. "Take"-rates of close to 100% can be achieved following injection of human-derived tumor cells into such strains, making it easy to generate large numbers of relatively homogeneous tumor-bearing mice for imaging studies. Immunodeficient mice are more expensive (typically 5−10 times more) than their normal counterparts and, since they are very prone to infection, must also be housed in cages with a filtered air supply to prevent ingress of microorganisms. However, the nude/SCID mouse−human xenograft probably represents the most widely used animal model for preclinical imaging studies. A large number of well-characterized tumor types are available, which enables the expression of a great number of potential molecular targets in a living environment. Since these targets are of human origin, such models can successfully be used for contrast agents, which do not bind to mouse homologues such as antibody-based agents (*5*). However, such models still have their limitations: While the tumor cells may be of human origin, the stromal cells and blood vessels around them are derived from the murine host, and in particular, the immune environment in the tumor is very abnormal. In man, target molecule expression is rarely restricted to tumor cells but is also present at lower levels in normal tissues; however, this is not the case in such models where the patterns of expression on the host tissues are quite different from those on the implanted cells. Such problems can, to some extent, be addressed by the use of genetically modified animal models (*11*).

Genetically Modified Models. At the simplest level, genetic modifications can be employed to simply alter the nature of target molecule expression on the transplanted tumor cells. Although many different cell lines derived from spontaneously occurring tumors expressing many different combinations of target molecules exist, the use of transfected cell lines provides the potential for greater control over the nature, pattern, and levels of expression of these molecules. For example, it is possible to restrict expression to a particular receptor subtype, to vary the levels of expression from high to low, and to generate control cell lines which differ only in one specific detail from others. A good example of such an approach is the recent study by Ginj et al. which studied the uptake of somatostatin receptor

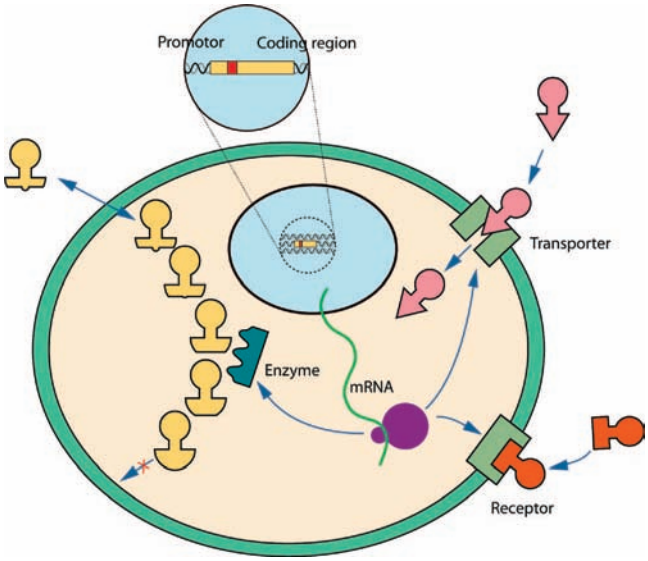

Figure 1. Reporter gene imaging. A gene coding for the expression of a desired reporter construct is introduced into cells. This construct is typically an enzyme such as HSV-TK, a transporter such as the sodium/iodide symporter, or a receptor such as the dopamine subtype 2 receptor. To image cells in which the transduced gene is present, a contrast agent consisting of a suitably tagged substrate that interacts with the construct is administered. If the reporter gene is present in the cell, it will result in increased uptake of the contrast agent. If the gene is not present, then there will no specific uptake of the agent.

subtype-specific antagonists in nude mice bearing transfected human embryonic kidney (HEK293) cell lines (*12*).

An increasingly popular application of genetically modified transplanted tumor cells is for "reporter-gene imaging" (*13*). The aim of such approaches is to put the expression of the target molecule under the control of a particular gene so that the effect of subsequent changes on the activity of this gene can be directly imaged by the binding of a contrast agent with the target molecule. As illustrated in Figure 1, the reporter gene will typically consist of a coding region—transcription and translation of which results in the cellular expression of the target molecule—and a promotor region, which determines the extent and level of transcription of the coding region. The reporting target molecule is typically an enzyme, a receptor, or a transporter, which interacts with a contrast agent in such a way as to increase its uptake by cells in which the reporter gene is active. An example of reporter gene imaging using the sodium/iodide symporter (NIS) reporter gene system is shown in Figure 2. Control of the level and site of transcription is provided by the promotor region of the reporter gene. Promotors may be strong or weak and result in constitutive expression in all tissues in which the gene is present or provide expression that is restricted to certain tissues (such as the prostate, for example) through the use of tissue-specific promoters. A list of some popular reporter gene systems is shown in Table 1. Promotors can also be rendered inducible by the incorporation of response elements that are either turned on or off by administration of drugs that interact directly or with transcription factors that bind to these elements (*11*). The advantages of such systems is that they allow transient expression of a protein that may be directly toxic and therefore compromise the design of the study, or even result in embryonic lethality, so that the function of a particular gene in a mature animal could not otherwise be determined. They also allow the results of different combinations of gene transcription to be studied in the same animal. Some examples of inducible promotor systems are shown in Figure 3.

Such genetic modifications are most simply applied by stable transduction of cells in culture with the gene of interest, followed

Figure 2. SPECT-CT scan showing uptake of ^{99m}Tc-pertechnetate mediated by the sodium/iodide symporter. Uptake is seen in the thyroid gland, the stomach, and around the rim of a tumor following viral transduction of the symporter gene (30).

Table 1. List of the Most Popular Report Gene Imaging Systems (Adapted from Ref 13)

imaging modality	reporter	ref(s)
optical reporter genes	fluorescent proteins	14,15
	luciferase	16,17
nuclear medicine reporter genes	herpes simplex virus-thymidine kinase-1	18,19
	dopamine-2 receptor	20,21
	sodium/iodide symporter	22,23
	norepinephrine transporter	24,25
	somatostatin receptor	26
MRI reporter genes	transferrin receptor	27
	ferritin	28,29

by administration of the cells to a (typically immunodeficient) animal. However, such models still suffer from many of the disadvantages described above. A model that more closely matches the phenotype of the ultimate human recipient can be provided by the generation of transgenic mice (*11*). In such animals, typically an additional human gene will be incorporated into the mouse genome so that on translation it is widely expressed in many mouse tissues and not only by cells that are exogenously administered. So-called "knock-in" mice were originally developed by microinjection of the transduct into the fertilized eggs of mice, followed by implantation and maturation in pseudopregnant foster mothers (*31*). However, this results in random, transient, and rather inefficient insertion into the genome and has more recently largely been replaced by the "gene targeting" approach shown in Figure 4 which resulted in 2007 in the award of the Nobel Prize to Capecchi, Evans, and Smithies (*32*). This involves the biosynthesis of a vector that contains human DNA homologous to the target mouse gene together with an antibiotic resistance sequence that enables successfully transduced cells to be selected. This vector is introduced into cultured embryonic stems cells obtained from harvested mouse blastocysts whereupon the vector is incorporated into a precise location in the genome of one or more cells

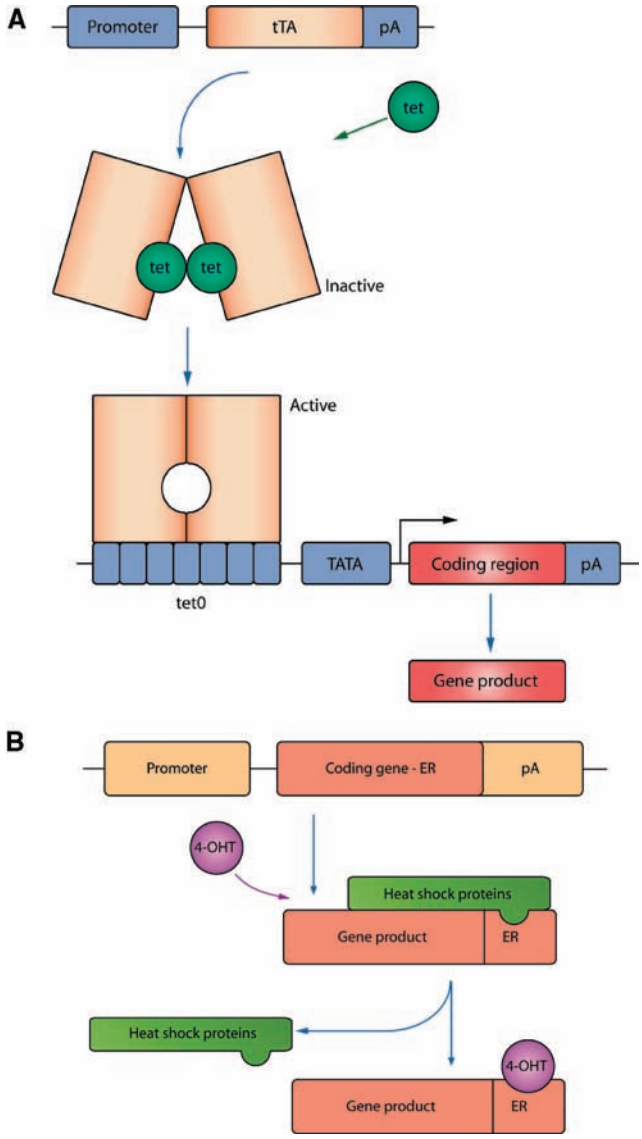

Figure 3. Inducible promotor systems (adapted from ref 11). (A) A tetracycline regulated transcriptional transactivator system. Cells are co-transfected with genes coding for a tetracycline-dependent transactivator, the desired gene expression of which is controlled by a promotor containing a concatamer of seven TetO sequences. In the presence of tetracycline, binding of the transactivator to the promotor is inhibited resulting in low or no levels of protein expression. In the absence of tetracycline, the transactivator binds and promotes transcription of the desired gene. (B) Tamoxifen-induced expression system. The desired gene is linked with that encoding for the transciption of a mutated ligand binding site from the estrogen receptor, and this results in the production of a fusion protein containing both sequences. In the absence of tamoxifen (4-OHT), heat shock proteins bind to the ER-domain of the protein and prevent its function. Addition of tamoxifen displaces the heat shock protein, allowing the protein to function correctly.

by a process known as homologous recombination. These cells can be selected by antibiotic treatment and implanted into foster mothers, which give birth to chimeric mice bearing cells derived from both the original and transduced cells. Further mating of the offspring with normal mice results in the birth of mice that carry only either the knock-in human gene or the original mouse gene. The human gene will be present in all the cells in the transgenic mice and, depending on its nature, will result in a pattern of molecular expression similar to that seen in man (*33*). Recent examples of the use of such models for imaging include a study of proliferation in gliomas using PET imaging (*34*) and the use of MRI for studying spontaneous lesions following insertion of a gene inducing tuberous sclerosis (*35*).

The last refinement of genetically modified animal model to be described here is the "knockout" mouse. Instead of resulting in the added expression of a human gene to a mouse background, this results in the disruption of function of a selected gene. The gene-targeting approach described above can also be used here, except that an inactivated mouse gene would be substituted for the human gene (*36*). However, another route to knockout mice is by site-specific recombination approaches such as the Cre-lox system (Figure 5). In such an approach, two transgenic mice must first be generated. One is a mouse that expresses the enzyme Cre recombinase, and the other is a mouse in which the gene of interest is flanked by two recognition sites—called "LoxP" sites. When these two strains are mated, some mice inherit both genes, and in these, the recombinase enzyme binds to the two LoxP sites, thereby tying together the ends of the target gene, preventing its transcription, and resulting in a mouse in which the function of this gene is lacking. Such models are very useful for determining the function of a particular gene or for studying the interaction of its gene product with contrast agents, an example of which is the study by de Jong et al. who elucidated the role of megalin in the tubular reabsorption of labeled peptides by the use of megalin-knockout mice (*37*). Potential disadvantages of the use of genetically engineered animals is that they are complex to produce and not generally available. These drawbacks are, to some extent, ameliorated by initiatives such as the NIH Transgenic Mouse consortium (http://www.nih.gov/science/models/mouse/index.html), which aims to improve the availability of transgenic models as well as provide a useful source of information.

Molecular Imaging Modalities. Each of the different imaging technologies that can be employed for molecular imaging has its own inherent strengths and weaknesses. These are summarized in Table 2 and will be discussed, together with the basic principles of each modality, below.

Radionuclide Imaging. As the name implies, radionuclide imaging maps the in vivo biodistribution of radiotracers. It comes in two distinct flavors, single photon emission tomography (SPECT) and positron emission tomography (PET). (For a useful overview on the instrumentation used for PET and SPECT imaging, see ref 38).

SPECT or gamma camera imaging is based on the detection of gamma photons or X-rays emitted by radionuclides decaying by electron capture or isomeric transition. After the administration of a contrast agent labeled with an appropriate radioisotope, the emitted radiation is picked up by a suitable detector (normally a sodium iodide crystal) and the distribution of γ rays converted into an electrical pulse and subsequently into an image. In order to remove scattered radiation and to ensure that the detected events can be traced back to their point of origin in the tissue, a collimator consisting of a sheet of lead containing many small parallel holes is placed between the subject and the detector system as shown in Figure 6. Radionuclides decaying in this fashion emit γ radiation with a range of energies, and for successful imaging, this energy must be high enough to penetrate the tissues of the body and interact with the detector but not so high that it passes completely through the crystal. For clinical imaging, the preferred energies lie in the range 80−250 keV, but for preclinical imaging, lower energies can be used owing to the lower attenuation provided by the smaller body mass. One of the advantages of single photon imaging is that the signals arising from photons of different energies can be discriminated, and so the images arising from two or three different radionuclides can be acquired simultaneously. Although radionuclide imaging is, in principle, one of the most sensitive imaging modalities, the sensitivity of SPECT imaging is degraded by the presence of the lead collimator, which absorbs the great majority of events issuing

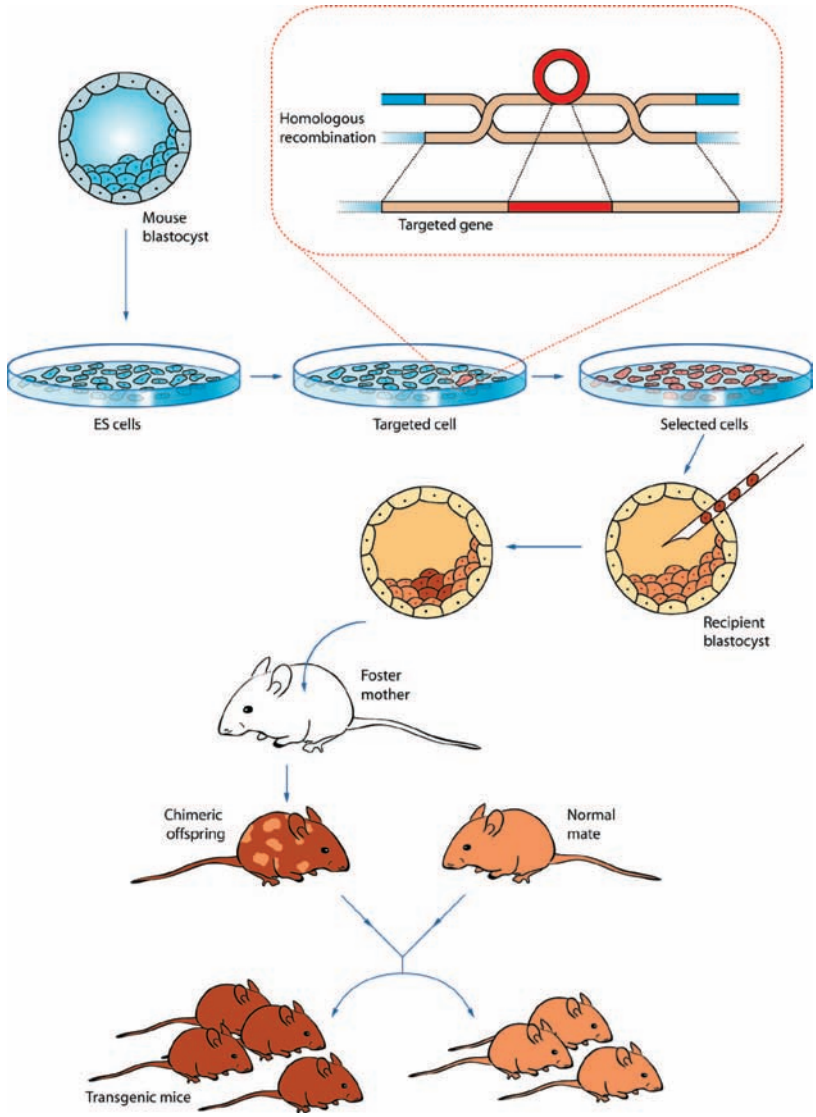

Figure 4. Gene targeting. Adapted from ref (*32*). Embryonic stem cells from mouse blastocyst are transfected with the gene of interest, which inserts by homologous recombination into the genome of the recipient cell. After selection, the cells are transferred to a recipient blastocsyt and implanted into the uterus of a foster mother. This results in the birth of mice who are chimeric for both the targeted cells and those of the parent blastocyst. Mating of these chimeric mice with normal mice results in the production of mice transgenic for the targeted gene by a process of normal Mendelian inheritance.

from the subject. The consequence is that only about 0.1% of the emitted γ rays are normally measured, and this results in a requirement for relatively high administered doses of radioactivity and long imaging times—typically on the order of tens of minutes.

PET imaging, in contrast, operates on a somewhat different principle. When a positron (a positively charged electron) is emitted by the nucleus of the radioactive atom, it almost immediately interacts with an electron in the immediate vicinity, and this interaction results in the production of two 511 keV γ rays emitted simultaneously in (almost) opposite directions. These photons are detected by a ring of detectors around the subject as shown in Figure 7, and when two such events are recorded simultaneously ("in coincidence"), they can be traced back to the point at which the annihilation occurs, thus creating a map of the distribution of the radioactivity in the animal. Because no collimation is required for PET imaging, it is much (about 100 times) more sensitive than SPECT imaging, and consequently, lower levels of radioactivity can be administered, larger numbers of radioactive events detected, and shorter imaging times used. The list of suitable positron emitting radionuclides for PET is not as extensive as those available for SPECT imaging, and because all PET isotopes result in the production of 511 keV photons, it is not possible to perform simultaneous multi-isotope acquisitions. Either radionuclide imaging approach is able to produce images with an intermediate resolution, typically around 1 mm for SPECT and 2 mm for PET in practice. For a detailed description of PET imaging technology, especially in combination with other imaging modalities, please see the reviews by Pichler et al. (*39*, *40*).

Both radionuclide imaging techniques are to a large degree quantitative—thus, the measured signal is directly proportional to the concentration of radioactivity in the tissue, which in turn *may* be proportional to the levels of the target molecule to which it binds. Consideration needs to be given to attenuation of the signal by overlying tissues, but this is less of a problem in small animals than in human-sized subjects, and provided that the system is appropriately calibrated, it is possible to draw quantitative conclusions from the images obtained (*41*). Because of the large numbers of events detected in PET imaging, it is possible, by the use of compartmental modeling, to calculate the molar concentration of radiotracer in a tissue of interest, provided that a measure of the arterial concentration of radioactivity (input function) can be obtained (*42*).

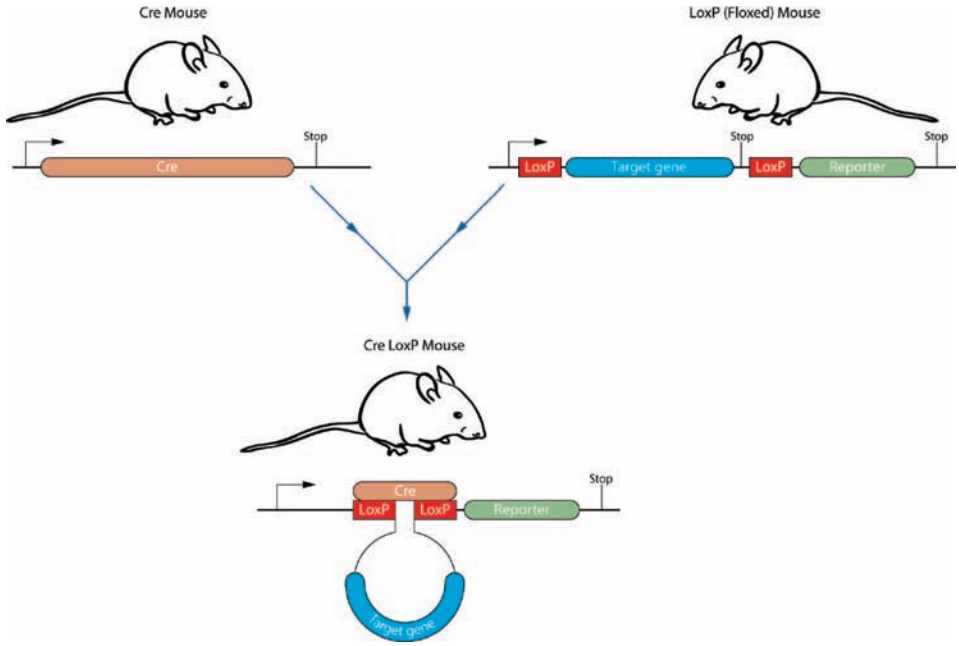

Figure 5. Adapted from ref 11. Generation of transgenic mice by Cre-Lox site-specific recombination. Introduction of Cre-recombinase and a "floxed" gene into a cell results in the floxed gene being inactivated and a reporter gene transcribed instead.

Table 2. Comparison of Small-Animal Imaging Modalities

modality	resolution	sensitivity	quantitation	time	cost
US	50 μm	v. low	-	minutes	low-medium
CT	50 μm	v. low	-	minutes	medium
MRI	25 μm	low	+	secs-tens of mins	v. high
PET	2 mm	high	+++	mins-tens of mins	high
SPECT	1 mm	high	++	tens of mins	high
BLI	5 mm	v. high	++	secs-mins	low
NIR	5 mm	high	+	secs-mins	low-medium

Optical Imaging. Optical imaging also comes in two distinct flavors—bioluminescence and fluorescence imaging. For a useful overview of the fundamentals of optical imaging, see ref 43. Bioluminescence imaging is a form of reporter-gene imaging and relies upon the emission of light generated in vivo by the action of luciferase enzymes produced by transduced cells. Although a very useful, sensitive, inexpensive, simple, and rapid imaging technique, it does not depend on the use of contrast agents and will therefore not be further discussed in this article.

Fluorescence imaging depends on the detection of fluorescent light induced by excitement of fluorophores in the animal tissues as illustrated in Figure 8. Fluorophores may be endogenously produced by transduction of tissues to express, for example, green or red fluorescent proteins, or may be exogenously administered in the form of fluorescent contrast agents. Fluorescence imaging is also a relatively inexpensive, sensitive, and rapid imaging technique, but the main disadvantage of both optical imaging modalities is the high degree of scatter and absorption of light by overlying tissues. This severely degrades the resolution of the system and also means that, apart from its use in very superficial tissues, it cannot be considered quantitative. A further disadvantage of fluorescent imaging over bioluminescence is the fluorescence that arises from normal tissues, in particular, from blood (hemoglobin) and foods in the stomach and intestines. This latter problem can be reduced by feeding animals on a special diet of non-chlorophyll-containing foods and the former by the use of fluorophores that emit light in the near-infrared (NIR) window of 650−900 nm. A number of new optical imaging techniques are seeking to overcome the problems of light scatter, such as time-domain (fluorescence lifetime) imaging (*44*), frequency domain imaging (*45*), and optical coherence tomography (*46*); however, such techniques to a large extent lose the advantages of simplicity and high sensitivity associated with planar imaging.

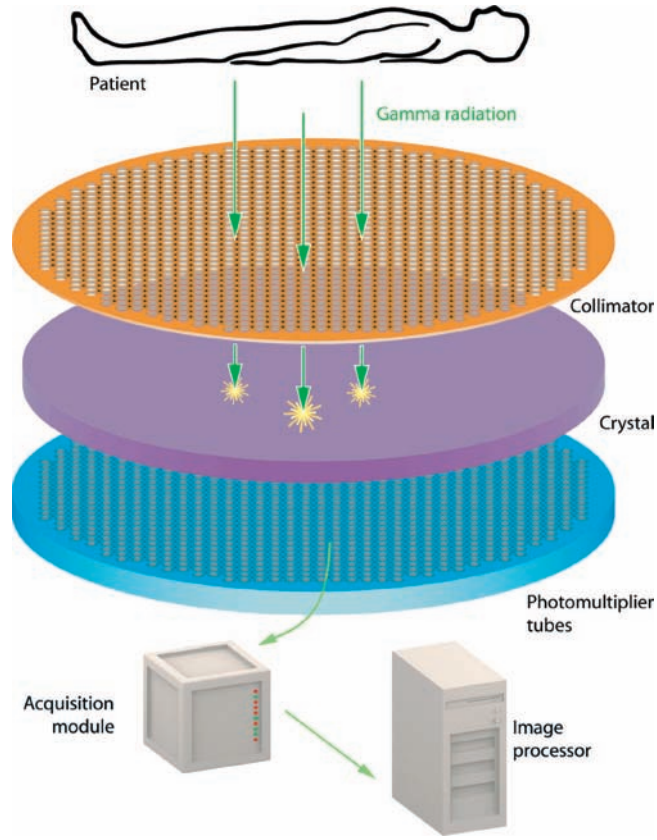

Figure 6. Principle of the gamma camera for SPECT imaging. Photons emitted from the patient after injection of a radiotracer pass through a lead collimator and impinge in a crystal producing a flash of light, which is detected by an array of photomultiplier tubes and converted into an image such as that shown in Figure 2.

Ultrasound Imaging. Ultrasound imaging depends on the reflection of high-frequency sound waves by anatomical struc-

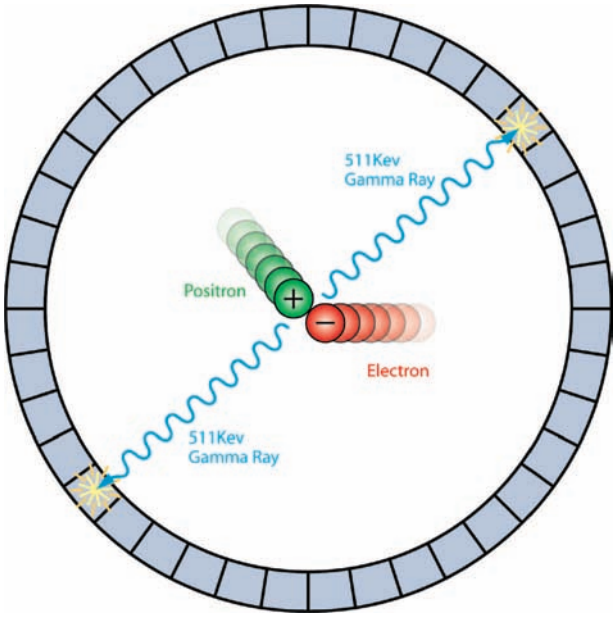

Figure 7. Principle of PET imaging. An emitted positron annihilates with a circulating electron resulting in the emission of two photons in opposite directions. Simultaneous interaction of these photons with crystals in a ring around the subject results in the detection of an event that can be traced back to the point of annihilation. Many millions of these events are built up into a PET image such as the example shown in Figure 11.

tures in the body, especially the boundaries between different tissue types (*47*) and, through the use of Doppler techniques, is particularly useful for measuring blood flow. An example is shown in Figure 9. It is a relatively inexpensive technique, which is simple and rapid to perform but is considered to be somewhat operator-dependent in its use. Since it is essentially an anatomical imaging tool, until recently ultrasound imaging would not have been considered part of the panel of molecular imaging techniques, but recent developments have resulted in a very significant increase in its use for small animal imaging. These developments hinge upon a combination of (i) the use of very high frequency probes, which emit sound waves with frequencies up to 100 MHz and result in a very high imaging resolution of the order of 25 μm, and (ii) ultrasound contrast agents based on the use of gas-filled microbubbles, although since such agents are too large to leave the vascular space, their application is limited to intravascular structures such as endothelial target molecules. A tradeoff against the excellent resolution of high-frequency ultrasound is its poor tissue penetration, and the sensitivity of detection of contrast agents is low (*48*). Modern semiautomated small animal ultrasound systems overcome to some extent the intraoperator variability of this modality, but it should still be considered a generally qualitative rather than quantitative tool.

Magnetic Resonance Imaging (MRI). MRI depends upon the measurement of the concentration and rates of relaxation of hydrogen atoms in a high magnetic field. The spinning single proton in a hydrogen atom creates a magnetic field, and each hydrogen atom therefore acts like a tiny magnet. In the absence of an external magnetic field, hydrogen nuclei magnetic moments are randomly oriented, but in the presence of an external magnetic field, a small proportion of the hydrogen protons align themselves in one of two directions, parallel or antiparallel to the net magnetic field producing a net magnetic field. The hydrogen atoms are not still but "precess" like a spinning top in the direction of the external magnetic field at a particular frequency known as the Larmor (or precessional) frequency. If a magnetic field pulse at the Larmor frequency is then applied perpendicular to the main magnetic field by a radiofrequency coil, the protons will absorb some energy and alter their alignment away from the direction of the main magnetic field. As well as changing direction, the protons also begin to precess "in phase" resulting in a net magnetic moment transverse to the external field, which induces a current and is detected in the transceiver coil. When the RF pulse is switched off, the protons give up the energy they have absorbed and start to return to their previous direction and to precess out of frequency. This results in a gradual increase in the longitudinal magnetization—called T1 or spin−lattice relaxation—and a gradual decrease in the transverse magnetization—called T2 or spin−spin relaxation. The rate at which these processes occur vary from tissue to tissue. These parameters can be converted into images that can be "weighted" toward T1 or T2 in order to increase the contrast between the tissues of interest. For a useful overview of the physics of MRI, see ref 49. Contrast agents in MRI work by influencing the T1 and T2 relaxation times. Most contrast agents are based on paramagnetic metals such as gadolinium, which have unpaired electrons in their outer shells. These interact with the water molecules in the vicinity resulting in a reduction in T1 relaxation times and a corresponding increase in signal intensity on T1-weighted images. Superparamagnetic iron oxide (SPIO) based agents on the other hand cause a significant reduction in T2 relaxation with a resultant decrease in image intensity on T2-weighted images.

Although MRI is a very powerful high-resolution anatomical imaging tool, its sensitivity for detection of changes at the molecular level is very low—typically 10^6 times lower than that of PET imaging, although this can be increased somewhat by the use of superparamagnetic contrast agents (*50*). It is probably the most expensive of the molecular imaging modalities, and long image acquisition times are often required, especially for high-resolution images and if low-strength magnetic fields are employed.

X-ray Computed Tomography (CT). CT imaging is not a molecular imaging tool per se since it provides only anatomical information as a result of the differential absorption of X-rays by different tissues. However, functional molecular imaging especially PET/SPECT is often combined with CT, either by using dual-modality instrumentation or by software image fusion, in order to provide enhanced anatomical localization of the functional information or, in the case of PET imaging, for attenuation correction.

BIOCONJUGATE CONTRAST AGENTS

All of the imaging modalities described above depend to some extent on the use of contrast agents to either provide or enhance the signals required for image generation. Irrespective of the modality employed, all molecular imaging contrast agents consist of (at least) two main components: (i) a targeting component that interacts with the target molecule of interest in vivo and (ii) a signaling component, sometimes called a "molecular beacon", which is detected by the instrument and provides information on the location and concentration of the signal, and consequently the target molecule. These two components are normally conjugated together to form a contrast agent using a range of chemistries, a rich variety of which are described every month in this journal. The targeting requirements for the contrast agent are essentially shared by each of the modalities—it should bind with high affinity and selectivity to the molecular target and show low-nonspecific binding to other tissues, should be stable in vivo, and be nontoxic. Stability is of particular importance in avoiding metabolites that might contribute to a signal but have lost their capacity for molecular targeting. The signaling component of the contrast agent, however, will be specific to the imaging method being used:

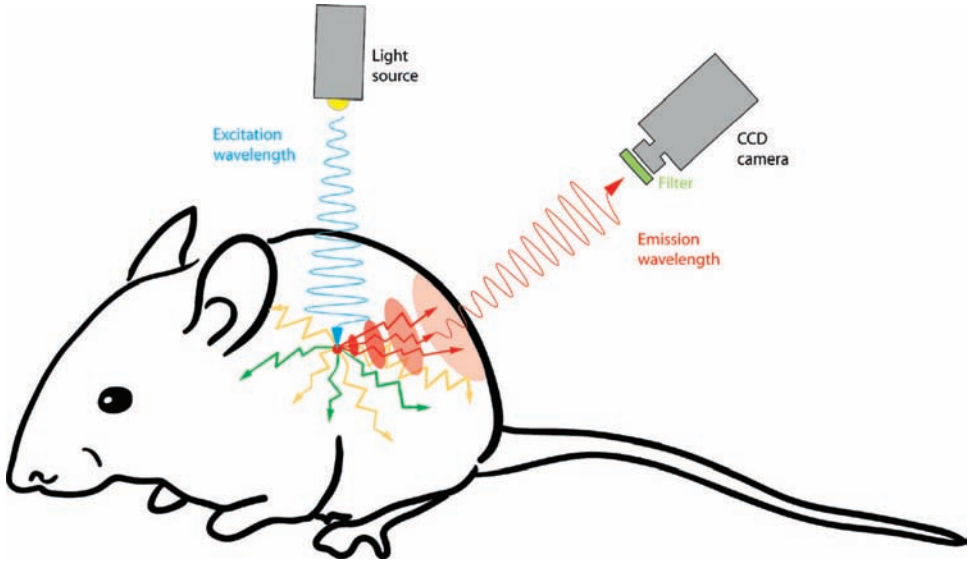

Figure 8. Fluorescence imaging. The presence of an endogenous or exogenously introduced fluorophore can be imaged following excitation with a laser. Scattering of the emitted light by tissue overlying the event results in absorption and degradation of the imaging resolution.

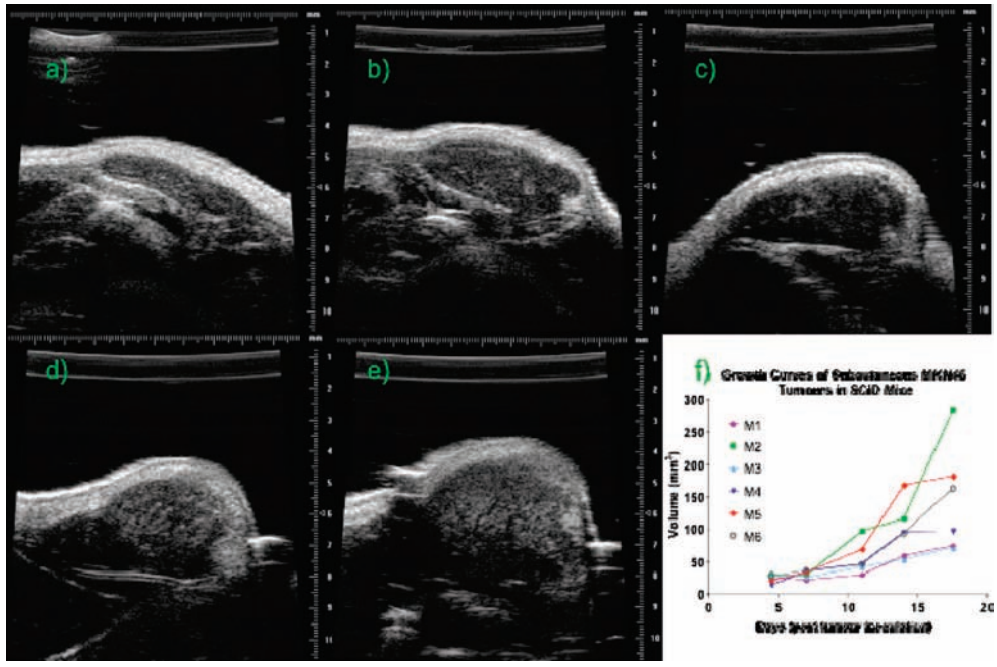

Figure 9. Example of ultrasound imaging. A subcutaneous MKN45 tumor on the right flank of a female SCID mouse (M1). (a−e) Sonograms showing the tumor 4, 7, 11, 14, and 17 days after inoculation, respectively. (f) Growth of MKN45 tumors measured by 3D ultrasound volume quantification.

radionuclides for PET/SPECT, fluorochrome for fluorescence imaging, microbubble for ultrasound, and paramagnetic chelate for MRI. The methodology used for attachment should ensure that the conjugation does not impact on the desired properties of the contrast agent (binding affinity, stability, etc.) but will depend on the chemical properties of the particular agent to be used, and when short-lived radionuclides are employed, clearance rates need to be commensurate with isotope lifetimes. The reader is again referred to elsewhere in this journal for many examples.

APPLICATIONS

Molecular Targets and Design Considerations. The performance of any molecular imaging approach is determined by the characteristics of the modality of choice, the contrast agent developed, and the molecular target of interest. Ultimately, the most important performance criterion for any imaging approach is the signal-to-noise ratio (SNR) that is achieved where "signal" represents the signal arising from the contrast agent that is bound to the target and "noise" represents the signal arising from background, which comprises nontargeted contrast agent plus that arising from extraneous "noise" intrinsic to the detection system. The higher the SNR, the better, in general terms, is the imaging approach, and therefore, the higher the signal and the lower the noise, the better.

There are many thousands of biochemical pathways that could usefully be explored with molecular imaging, and it is outside the scope of this review to discuss more than a few of these, but some general considerations apply in selecting targets worthy of pursuit (*52*, *53*). In the context of optimizing the SNR, the

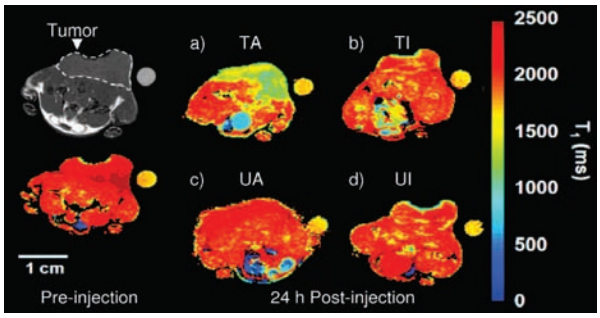

Figure 10. Example of a contrast enhanced MRI study. Reproduced with permission from ref 51. Transverse T1 maps of drug-treated and untreated tumors in animals injected with PS-active (GST-C2A-Gd) and PS-inactive (GST-C2A-Gd) contrast agents. Color scale indicates T1 values for image voxels. Images were acquired immediately before injection of contrast agent (a T1 map acquired from a tumor before injection is shown on the left-hand side) and at 24 h after injection. A reference capillary was placed adjacent to the tumors, the position of which is indicated on the grayscale image. (A) Drug-treated tumor in animal injected with PS-active GST-C2A-Gd (TA). (B) Drug-treated tumor in animal injected with PS-inactive GST-C2A-Gd (TI). (C) Untreated tumor in animal injected with PS-active GST-C2A-Gd (UA). (D) Untreated tumor in animal injected with PS-inactive GST-C2A-Gd (UI). Drug-treated tumor in animal injected with PS-active contrast agent shows greater accumulation 24 h after injection (A).

Figure 11. Example of PET-CT image of a mouse bearing a AR42J pancreatic tumor imaged with ^{18}FDG. Uptake is seen in the tumor (in the left thigh), muscle, brown fatty tissue, bladder, and intestines.

two most important considerations are accessibility and abundance. Since an interaction between the contrast agent and its target is the basis of the imaging approach, the tracer must be able to reach its destination. Targets located within the vascular lumen of the blood supply represent the most accessible site and those buried deep within the cell the least, while those expressed on the cell surface of tissues represent the middle ground. Consideration must be given to the way in which the ligand will reach its target. Extravascular delivery demands that the agent is able to leave the bloodstream, and in cancer, this is facilitated by the highly fenestrated capillaries present in many tumors. Intracellular delivery requires that the contrast agent pass through the cell membrane and into the appropriate intracellular compartment, and this places severe restrictions on its design.

While great emphasis is naturally placed on optimizing the interaction between the target and the contrast agent, in practice a greater impact on SNR can be made by reducing the background signal. Typically, only 1−2% of the administered dose will accumulate at the target at best. This leaves 98−99% of the dose free to contribute to the background. Consideration should therefore be given to reducing this contribution by accelerating blood clearance times, lowering nonspecific protein binding, and reducing accumulation in organs of excretion such as the liver, kidneys, and gastrointestinal tract. A significant impact on such parameters can be achieved by reducing the size and enhancing the hydrophilicity of the contrast agent by judicious choice of conjugation chemistry or by the introduction of pharmacokinetic modifiers such as poly(ethylene glycol) (*54*). If desired, metabolically labile chemical bonds can also be introduced to accelerate clearance from nontarget tisssues (*55*).

Drug Development. As indicated above, one of the main areas of application of preclinical imaging is in the field of pharmaceutical development. It is hoped that preclinical imaging has the potential to reduce the high attrition rates in the development of new drugs and the long time scales and great expense involved in this process. Applications can be found at all stages of the drug development process from evaluation of target expression through screening of candidate compounds, assessment of activity in animal models of disease to measurement of pharmacokinetics, comparisons of different formulations, and determination of appropriate doses for clinical trials. (For detailed reviews of the role of molecular imaging in drug development, please see *refs* 56, 57).

Biomarkers. In the field of oncology, there is particular interest in the development of imaging biomarkers as a result of the development of molecularly targeted therapies that aim to interact with a defined molecular target rather than induce relatively nonspecific toxicity and the desire the reduce unnecessary drug-related expenditure in the face of the increasing costs of novel drug treatments. Biomarkers provide a means of measuring a particular pathological process that is associated with the progression of a disease or the effectiveness of a drug used for its treatment. Most useful among the range of biomarkers is a "surrogate end point", which can be considered to provide a direct measure of the severity of a disease such as, for example, the measurement of blood glucose levels in diabetes. However, in the absence of such a direct correlative measure, any biomarker that provides an early indication of drug effectiveness or safety can be useful. Biomarkers can originate from many different types of measurement ranging in complexity (and cost) from the simple measurement of a chemical or cell type in a blood sample, e.g., CD-4 counts in HIV infection, through immunohistochemical analysis of biopsy samples, e.g., the Herceptest used to measure HER-2 expression in breast cancer, through to the use of imaging biomarkers.

The most widely used imaging biomarker in oncology is the anatomical imaging techniques to measure the size of tumor masses before and after treatment. To be most valuable, a biomarker should be universally applicable and generalizable to a range of situations and localities, and in order to standardize the use of MRI and CT in this regard, a set of criteria known as the RECIST criteria have been internationally agreed upon (*58*). However, although a reduction in the size of a tumor can be considered a useful indicator of cytotoxic treatments for cancer, which result directly in cell death, it may not be an appropriate measure of success of a

molecularly targeted treatment that may result only initially in tumoristasis. In such a situation, molecular imaging biomarkers may prove to be useful in a number of ways: the first requirement is to identify those patients who are most likely to benefit from a particular molecularly targeted treatment. An example is the use of antiangiogenic drugs targeted against the $\alpha_v\beta_3$ integrin. $\alpha_v\beta_3$ is one of the most widely explored targets for molecular imaging with preclinical imaging applications developed for all of the modalities described above including both gadolinium (*59*−*61*) and SPIO-based (*62*, *63*) agents for MRI, targeted microbubbles for ultrasound (*64*), and NIR probes (*65*) or quantum dots (*66*) for optical imaging. However, radionuclide imaging applications for both SPECT and PET have been most widely explored (*67*). Importantly, developments initially explored in the preclinical imaging arena have since been translated into clinical practice. For example, Beer at al. have shown that PET imaging with [(^{18})F]Galacto-RGD is able to measure the levels of $\alpha_v\beta_3$ integrin in patients with cancer (*68*) and explored its applicability in the context of breast (*69*) and head and neck (*70*) cancers.

Having identified those patients most likely to benefit from a particular treatment, the next aim is to identify a pharmacodynamic response (or lack of it) as soon as possible. This would be valuable for several reasons. Prediction of treatment failure early in the course of therapy would indicate that the treatment should be withdrawn to avoid unnecessary toxicity and expense and would provide an early indication that an individual should change to an alternative therapy before drug resistance mechanisms have been induced. Early detection of tumor sensitivity, on the other hand, indicates that treatment should be continued and also raises the possibility of treatment intensification, since any resulting side effects or increased costs could be justified by the likelihood of improved response.

By far, the most widely used imaging biomarker of treatment response is [(^{18})F] fluorodeoxyglucose (FDG) (see Figure 11). Glucose metabolism is intricately linked to many of the metabolic processes involved in the development of malignancy (for reviews, see refs 71, 72), and as a consequence, glucose transport and utilization are elevated in most types of cancer. Importantly, in the context of assessment of therapy response FDG uptake is often reduced following treatment with anticancer drugs, and its use is beginning to be clinically accepted as a standard biomarker of response (*73*). However, a number of questions arise relating to the use of FDG imaging in this regard. One issue is the actual cause of reduction in signal. In some cases, this reduction does appear to be due to a reduction in the number of metabolically active cells as a direct consequence of cell death and in such instances could therefore be considered a marker of treatment response; however, in other cases the reduction appears to be due to a translocation of the glucose transporter from the cell membrane to the cytosol (*74*). In other examples, the reduction in glucose metabolism seems to be a direct consequence of signaling downstream from the molecular target of the drug. Thus, treatment with rapamycin and its analogues results in a direct inhibition of glucose metabolism via the Akt and Hif-1α pathways (*75*), while in endocrine-sensitive breast cancer, transient stimulation of tumors with estradiol results in a consequent increase in FDG uptake, thereby predicting a likely response to endocrine therapies, because it indicates that the estrogen receptor system is functional (*76*). It could be argued therefore that although FDG imaging does provide a readout of drug activity, it cannot be considered to provide a surrogate end point in this regard. The other significant drawback of FDG imaging is that it is taken up not only by cancer cells but also by some metabolically active normal cells such as macrophages, as well as by microrganisms present in sites of infection. As a result of this perceived lack of specificity, efforts are being made to develop more specific imaging biomarkers of response.

One such approach is to try and measure the rate of cell proliferation. Perhaps the most widely explored imaging approach is the use of [(^{18})F] 3′-deoxy-3′-fluorothymidine (FLT) for PET (*77*). Retention of FLT by cells is primarily mediated by the action of the enzyme thymidine kinase-1 (TK1), which phosphorylates the tracer resulting in intracellular trapping. If cancer treatment results in a reduction in the rate of cell division within the tumor, then it would result in a down-regulation in the concentration of TK1 and a consequent reduction in FLT uptake. However, a reduction in TK1 can also be caused by drugs such as actinomycin D or cisplatin that have a direct effect on thymidine and DNA metabolism (*78*). On the other hand, the use of some drugs such as Fluorouracil that deplete the thymidine triphosphate pool can actually cause a transient increase in FLT uptake (*79*). Interpretation of the use of such agents therefore requires an understanding of the mechanism of action of the drug in use and its effects on DNA and thymidine metabolism.

An alternative means of assessing treatment response is to try and image cell death directly. One of the earliest events in the induction of this process in cancer therapy is apoptosis—also known as programmed cell death (*80*). The molecular events that occur in apoptosis are now well-understood, and a number of attempts have been made to develop imaging biomarkers that interact with these events (*81*). The most widely exploited of these is the translocation of phosphatidylserine (PS) from the inner to the outer surface of the cell membrane. Molecules such as Annexin V (*82*) or synaptotagmin (*51*, *83*) that bind to PS can be tagged with Molecular Beacons and potentially used to measure the induction of apoptosis after drug treatment (see Figure 10, for example). Because of the relatively large size of these targeting agents and their extracellular location, a variety of imaging modalities have been studied. PET and SPECT imaging probes again are the most widely explored (*81*), but contrast agents for optical imaging (*84*), gadolinium (*85*), and SPIO (*86*)-based MRI agents, as well as multimodality contrast agents (*87*), have been described.

CONCLUSIONS

A number of different imaging modalities in combination with a wide range of contrast agents can be employed to provide different types of information from small animal models of cancer and other diseases. Each technology has its own strengths and weaknesses, and each is able to provide unique insights into the status of biological pathways and processes of interest. Great care should be exercised, however, in directly extrapolating the information obtained in animal model systems to the human situation, but particularly in view of the increasing regulatory difficulties in performing experimental studies in human subjects, preclinical imaging can be very helpful in optimizing contrast agents and developing imaging protocols in order to reduce the number and complexity of studies in humans required to answer a particular medical or scientific question.

ACKNOWLEDGMENT

Thanks go to Kevin Brindle, Julie Foster, and Andrew Merron for examples of small animal images and to Tim Bacon for the illustrations.

Synthesis and Characterization of Circular Structures of i-Motif Tagged with Fluoresceins

Tianyan Zhou,[†] Xinming Li,*[,‡] Magdeline Tao Tao Ng,[§] Yifan Wang,[§] Ngee Mien Quek,[‡] Ji Luo,[‡] Weixing Yuan,[‡] Choon-Hong Tan,[§] Huaqiang Zeng,[§] and Tianhu Li*[,‡]

State Key Laboratory of Natural and Biomimetic Drugs, (Peking University), 38 Xueyuan Road, Haidian District, Beijing 100191, The People's Republic of China, Division of Chemistry and Biological Chemistry, School of Physical & Mathematical Sciences, Nanyang Technological University, 21 Nanyang Link, Singapore 637371, and Department of Chemistry, National University of Singapore, 3 Science Drive 3, Singapore 117543. Received October 23, 2008; Revised Manuscript Received January 27, 2009

Synthesis of a fluorescein-tagged circular structure of i-motif was accomplished during our investigations. The backbone circularity of this molecular probe and the presence of the fluorescent moiety within its structure were also confirmed through exonuclease hydrolysis and fluorescence spectroscopy.

Held together by hemiprotonated $C-C^+$ base pairing, i-motif is a four-stranded structural entity composed of two parallel-stranded duplexes zipped together in an antiparallel orientation (*1*−*15*). In vitro studies in the past demonstrated that such a tetraplex structural assembly could form by human telomere repeats $[d(C_3TAA)_n]$ and many other biologically significant cytosine-rich sequences (*8*−*15*) under some physiological-like conditions. Further investigations illustrated that some proteins isolated from *Drosophila* could selectively interact with cytosine-rich repeats of the centromere (*16*). In addition, the cytosine-rich strands of the human telomere were reportedly capable of being bound by some human nuclear proteins such as hnRNP K and ASF/SF2 (*17*). Consequently, it has been assumed that i-motif structures could play some significant roles in certain biological processes (*18*). With the aim of developing molecular probes that could be used to identify new types of i-motif-binding proteins, fluorescein-tagged circular i-motif was constructed in our laboratory recently. We present herein the design and synthesis of these new types of fluorescein-containing circular oligonucleotides as well as characterizations of these circular molecular probes by using exonuclease VII and fluorescence spectroscopy. It is our expectation that such newly designed probes could be useful for identifying a new i-motif-binding protein as well as determining the location and distribution of i-motif-binding proteins in acidic cancer cells upon the introduction of these probes through microinjection.

Our approaches for synthesizing a circular i-motif structure tagged with a fluorescein moiety (oligonucleotide **2**) are illustrated in Figure 1. A linear 32-mer oligonucleotide containing a fluorescein moiety covalently linked to carbon-5 of a thymine (oligonucleotide **1** in Figure 1a) was accordingly designed in our studies. The 5′-phosphate and 3′-hydroxyl ends of oligonucleotide **1** would be proximal to each other once this

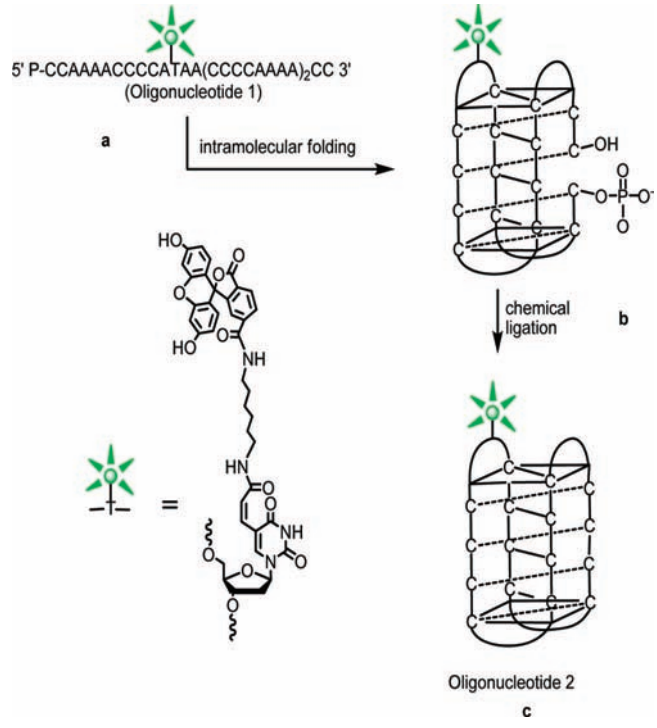

Figure 1. Schematic representation of the synthesis of a fluorescein-tagged circular structure of i-motif.

oligonucleotide self-assembles into intramolecular i-motif conformation (Figure 1b) under slightly acidic conditions (*1*, *2*). A new phosphodiester bond was expected to form between 5′-phosphate and 3′-hydroxyl ends upon the subsequent chemical activation. A mixture was accordingly prepared during our investigation that contained 1 μM sequence A, 100 mM MES (pH 5.0), and 50 mM KCl. This solution was heated next to 90 °C and kept at the same temperature for 3 min followed by cooling the mixture to 25 °C over 2 h to allow the formation of the i-motif structure (Figure 1b). The chemical ligation reactions

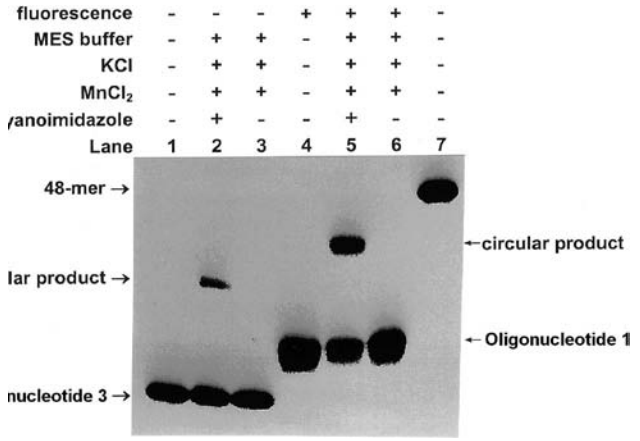

Figure 2. Electrophoretic analysis of the fluorescein-tagged circular structure of i-motif constructed through chemical ligation reactions. A linear precursor (oligonucleotide **1** or oligonucleotide **3**) with free 5′-hydroxyl terminus was labeled with [γ-^{32}P] ATP (GE Healthcare) at its 5′-end catalyzed by T4 polynucleotide kinase (New England Biolabs). A mixture containing 100 mM MES (pH 5.0) and 50 mM KCl and 1 μM linear precursor (oligonucleotide **1** or oligonucleotide **3**) was then kept at 90 °C for 3 min and further allowed to cool down to 25 °C over 120 min. The chemical ligation reactions were next initiated by addition of *N*-cyanoimidazole in the presence of $MnCl_2$, and the resultant solution contains 500 nM annealed linear precursor (oligonucleotide **1** or oligonucleotide **3**), 100 mM MES (pH 5.0), 50 mM KCl, 10 mM $MnCl_2$, and 10 mM *N*-cyanoimidazole. After being further incubated at 4 °C for 24 h, the reaction mixtures were analyzed by polyacrylamide gel electrophoresis (20%) followed by visualization using a PhosphorImager (Typhoon Trio, GE Healthcare). Lane 1: linear prescusor oligonucleotide (oligonucleotide **3**) alone. Lane 2: mixture of ligation reaction containing non-fluorescein-tagged linear oligonucleotide (oligonucleotide **3**). Lane 3: same reaction as in lane 2 except for the absence of **N**-cyanoimidazole. Lane 4: linear precursor oligonucleotide (oligonucleotide **1**) alone. Lane 5: mixture of ligation reaction containing fluorescein-tagged linear oligonucleotide (oligonucleotide **1**). Lane 6: same reaction as the one loaded in lane 5 except for the absence of **N**-cyanoimidazole. Lane 7: 48-mer oligonucleotide as a molecular weight marker.

were then initiated by addition of *N*-cyanoimidazole in the presence of $MnCl_2$ (*19*−*21*). After being further incubated at 4 °C for 24 h, the reaction was terminated by adding loading buffer. The resultant ligation products were analyzed by polyacrylamide gel electrophoresis.

As illustrated in Figure 2, a slow-moving band was observed (upper band of lane 5) when the ligation reaction of oligonucleotide **1** (Figure 1b) was activated by addition of *N*-cyanoimidazole, which corresponds to the desired fluorescein-labeled circular i-motif (*22, 23*) (Figure 1c). For comparison, a linear oligonucleotide (5′-pCCAAAACCCCATAACCCCAAAACCCCAAAACC-3′, oligonucleotide **3**) that contains no fluorescent tag was also designed and circularized (lane 2) during our investigations. As shown in Figure 2, a new band was generated as well in the circularization processes of oligonucleotide **3**. It is worth noting that the circularization product obtained from oligonucleotide **1** (fluorescein-tagged oligonucleotide) (lane 5) has a slower rate of mobility than that of oligonucleotide **3** (non-fluorescein-tagged oligonucleotide) (lane 2). The possession of an extra fluorescein moiety within oligonucleotide **1** could be the cause of the mobility shift difference between these two circular products (Figure 1c).

With the aim of confirming the absence of open ends in oligonucleotide **2**, the newly formed ligation product (upper band in lane 5 of Figure 2) was purified and further hydrolyzed with exonuclease VII (an exodeoxyribonuclease that degradates linear DNA from both 3′ and 5′ termini). As seen in Figure 3, there was an absence of degradation product observed when the purified ligation product was incubated with exonuclease VII

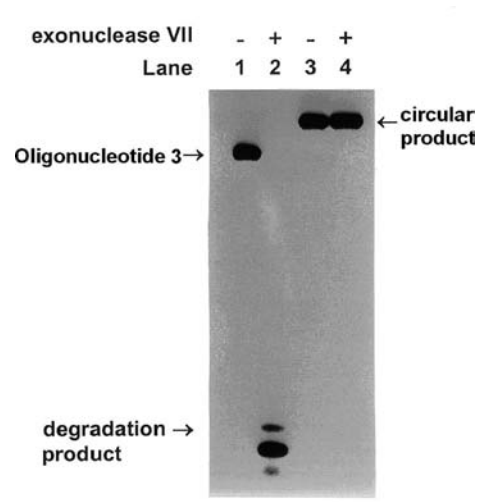

Figure 3. Hydrolysis of purified fluorescein-tagged circular i-motif (oligonucleotide **2**) by exonuclease VII. The ^{32}P-labeled reaction products in the upper band in lane 5 in Figure 2 were cut out and further purified. Solutions containing 100 mM Tris-acetate, 100 mM potassium phosphate, 16.6 mM ethylenediamine tetraacetic acid, and 20 mM 2-sulfanylethanol, pH 7.9, 10 units of exonuclease VII, and the newly purified ^{32}P-labeled oligonucleotides were then incubated at 37 °C for 2 h. The hydrolysis products were further analyzed using polyacrylamide gel electrophoresis (20%). Lane 1: 32-mer linear precursor oligonucleotide (oligonucleotide **3**) alone. Lane 2: the reaction mixture of 32-mer linear precursor oligonucleotide (oligonucleotide **3**) and exonuclease VII. Lane 3: fluorescein-tagged circular products (oligonucleotide **2**) alone. Lane 4: the reaction mixture of purified fluorescein-tagged circular products (oligonucleotide **2**) and exonuclease VII.

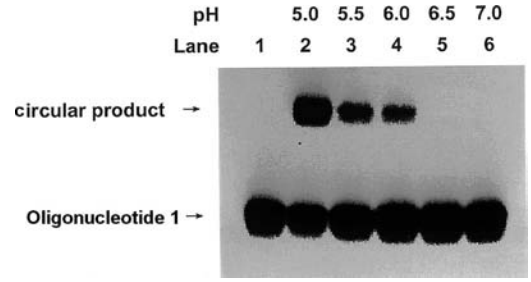

Figure 4. pH dependency of the circularization reaction of fluorescein-tagged linear oligonucleotide (oligonucleotide **1**). Ligation reactions were carried out in the same way as the one loaded in lane 5 in Figure 2 except that pH values of the buffer solutions were 5.0 (lane 2), 5.5 (lane 3), 6.0 (lane 4), 6.5 (lane 5), and 7.0 (lane 6), respectively. Lane 1: linear precursor oligonucleotide (oligonucleotide **1**) alone.

(lane 4 in Figure 3). For comparison, oligonucleotide **3** (a linear precursor) was also degraded by exonuclease VII under the same reaction conditions, which led to the complete disappearance of this linear precursor and generation of fast-moving degradation products (lane 2 in Figure 3). The complete resistance of the purified ligation product (oligonucleotide **2**) to the hydrolysis by this exonuclease is the indication that there is absence of open terminus within its backbone (*24*).

In addition, the variation of pH value on our circularization reactions was examined during our investigations. As shown in Figure 4, the efficiency of these ligation reactions decreased with the increase of pH values of the corresponding buffer solutions. The circularization reaction of oligonucleotide **1** proceeded in 45%, 11%, and 6% yields at pH 5 (lane 2), pH 5.5 (lane 3), and pH 6.0 (lane 4), respectively, while there were no circularization products from the reaction observable at pH 6.5 (lane 5) and pH 7.0 (lane 6). The above observations suggest

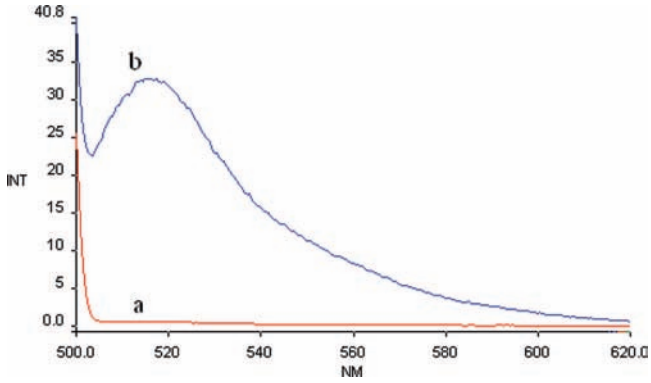

Figure 5. Fluorescence emission spectra of fluorescein-labeled circular i-motif (oligonucleotide **2**) (a) and non-fluorescein-labeled circular oligonucleotide (b). Samples containing 1 μM oligonucleotides and 10 mM Tris buffer (pH 7.0) were examined at 20 °C with excitation set at 495 nm using a fluorescence spectrometer (Perkin-Elmer LS 55).

that the formation of the i-motif structure is a prerequisite for the i-motif-based ligation reactions (*1*−*15*).

With the aim of confirming that the molecular moiety of fluorescein was indeed present in oligonucleotide **2**, fluorescence spectroscopic examinations were carried out in our studies. As seen in Figure 5, oligonucleotide **2** displayed an emission maximum at 520 nm when excited at 495 nm wavelength. For comparison, the circular product of oligonucleotide **3** (a non-fluorescence-tagged oligonucleotide) was also examined during our studies, which lacks emission from 500 to 620 nm. In addition, MALTI-TOF mass spectroscopic examination on oligonucleotide **2** and oligonucleotide **1** was carried out during our investigations. It turned out that the obtained molecular weights of the ligation product (oligonucleotide **2** in Figure 1) and its linear precursor (oligonucleotide **1** in Figure 1) were 10 145.35 Da (calculated molecular weight: 10 141.8 Da) and 10 163.09 Da (calculated molecular weight: 10 159.8 Da), respectively. The observed molecular weight difference between oligonucleotide **2**and oligonucleotide **1** was ∼18, which is consistent with the suggestion that a condensation reaction took place between the two termini of oligonucleotide **1**.

In conclusion, circular i-motif structure tagged with fluorescein was synthesized in our laboratory through chemical ligation reactions. Our subsequent studies confirmed that this newly obtained oligonucleotide resists the hydrolysis by exonucleases and the fluorescent moiety is indeed present in the ligation product. Since many cancer cells are acidic (*25*−*27*), it is our expectation that these newly designed fluorescein-labeled circular i-motifs could serve as useful probes for identifying new types of i-motif-interacting enzymes and other functional proteins in these fast-dividing cells.

ACKNOWLEDGMENT

The authors would like to express their gratitude to Ministry of Education of Singapore and Nanyang Technological University for financial support (ARC and SUG to T.L.).

Experimental Section

General Methods. All of our linear 32-mer oligonucleotide containing a fluorescein moiety covalently linked to carbon-5 of a thymine (Oligonucleotide 1 in Fig. 1) were purchased from Integrated DNA Technologies, Inc. (USA). A mixture containing 100 mM MES (pH 5.0) and 50 mM KCl and 1 μM linear precursor (Oligonucleotide 1) was kept at 90 °C for 3 min and was then allowed to cool down to 25 °C over 120 min. The chemical ligation reactions were next initiated by addition of N-cyanoimidazole in the presence of $MnCl_2$, and the resultant solution contains 500 nM annealed linear precursor (Oligonucleotide 1), 100 mM MES (pH 5.0), 50 mM KCl, 10 mM $MnCl_2$ and 10 mM *N*-cyanoimidazole. The reaction mixture was further incubated at 4 ˚C for 24 h and analyzed next using denaturing polyacrylamide gel electrophoresis. The ligating reagent used in the studies, N-cyanoimidazole, was prepared according to literature-reported procedures (20) starting with cyanogen bromide.

Folate Receptor Targeted Bimodal Liposomes for Tumor Magnetic Resonance Imaging

Nazila Kamaly,[†,‡] Tammy Kalber,[‡] Maya Thanou,[†] Jimmy D. Bell,[‡] and Andrew D. Miller*[,†,§]

Imperial College Genetic Therapies Centre, Department of Chemistry, Flowers Building, Armstrong Road, Imperial College London, London, SW7 2AZ, Metabolic and Molecular Imaging Group, Imaging Sciences Department, MRC Clinical Sciences Centre, Imperial College London, Hammersmith Hospital, London, W12 0HS, and ImuThes Ltd, Flowers Building, Armstrong Road, London SW7 2AZ, United Kingdom. Received June 1, 2008; Revised Manuscript Received February 8, 2009

Folate-targeted bimodal paramagnetic and fluorescent liposomes were developed and showed enhanced accumulation in a folate receptor expressing tumor model. These bimodal liposomes were composed of both a paramagnetic and a fluorescent lipid, and utilized a PEG-lipid amphiphile for prolonged in vivo circulation. The particles were formulated to ensure a size distribution of approximately 100 nm with a low polydispersity index. IGROV-1 cells were used to induce tumors in nude Balb/c mice, and the folate-targeted liposomes were injected intravenously. Rapid accumulation of the folate-targeted liposomes within the tumor tissue compared to nontargeted liposomes was observed. Furthermore, folate-labeled liposomes showed a 4-fold increase in tumor T_1 signal intensity at just 2 h postinjection with similar results being obtained for the nontargeted liposomes only 24 h postinjection. In addition, the folate-targeted liposomes were injected at half the nontargeted liposome dose, further demonstrating their effectiveness. Histological analysis of sectioned tumor slices revealed distinct fluorescence patterns between the targeted and nontargeted systems, with a more localized and hyperintense fluorescence signal observed from tumor sections post-folate-targeted liposome injections. These results demonstrate the effectiveness of folate targeting for dynamic real-time solid tumor MRI and provide insight into kinetics of targeted and nontargeted nanoparticles to solid tumors.

INTRODUCTION

Folate based targeting systems present an effective means of selectively delivering therapeutic or imaging agents to tumors (*1*−*11*). It has been shown that aggressive or undifferentiated tumors at an advanced stage have an increased folate receptor (FR) density, indicating that cancer therapy could benefit from the broad approach that FR mediated drug delivery offers (*12, 13*). The FR is overexpressed in several cancer types, such as brain, kidney, lung, and breast cancers, and, in particular, in epithelial carcinomas such as ovarian cancers (*14*). The FR ligand, folate (or folic acid), is a vitamin that is used for the biosynthesis of nucleotides and is utilized in high levels to meet the needs of proliferating cancer cells (*15*).

In addition to numerous drug delivery efforts, folate-targeted technology has been successfully applied to radio-imaging of therapeutic agents (*16*), fluorescence imaging of cancer cells (*17*), MRI contrast agents (*18*), and gadolinium liposomes (*19*). Choi et al. have demonstrated the use of folate-targeted iron oxide nanoparticles for the imaging of induced KB tumors and showed these particles to have a 38% signal intensity increase compared to controls (*20*). Successful tumor MRI with a nontargeted bimodal liposomal contrast agent was shown recently, whereby bimodal paramagnetic and fluorescent liposomes of ∼100 nm in size were seen to accumulate in a mouse xenograft model of ovarian cancer (*21*). Liposomes are able to accumulate within tumor tissue due to the widely reported enhanced permeation and retention effect (EPR) which relies on the passive accumulation of colloidal macromolecules of ∼40 kDa and above in tumors (*22*). The EPR effect arises due to aberrant tumor endothelium, which as a result of its "leakiness" allows the penetration of nanoparticles into tumor tissue. Liposome accumulation in tumor tissue could be improved through the use of receptor targeting moieties that are either postconjugated to the surface of liposomes or attached to lipids that become incorporated within the liposomal bilayer. Since FR binding affinity ($K_d = 1 \times 1^{-10}$ M) does not appear to be affected when its ligand, folate, is conjugated to an imaging agent or therapeutic moiety via its γ-carboxyl (*10, 23*), a folate ligand tethered onto the distal end of a lipidic PEG amphiphile allows for the development of a FR targeted liposomal system.

The human nasopharyngeal KB carcinoma cell line is considered to have the highest level of FR expression, yet the number of cases for this cancer are low in comparison to ovarian cancer, which has the highest frequency (>90% of cases) (*6*). In particular, the α-FR isoform which is a glycosyl phosphatidylinositol (GPI)-anchored membrane protein is highly expressed in ovarian carcinoma (*24*). Additionally, the α-FR isoform has also been shown to have a specific biomarker value, aiding in the identification of metastatic tumor site origin (*25*). Therefore, we were interested in using this receptor in order to test the efficacy of folate-targeted bimodal liposomes for the imaging of ovarian tumors using MRI. Folate-based liposomal drug delivery has been studied extensively (*7, 24, 26*); however,

the rate-enhancing effect of liposome accumulation in tumors due to folate targeting has not been studied dynamically in real time to a great extent. Effective tumor signal enhancement was anticipated, since the FR is expressed in significantly lower amounts in normal tissue, limited mainly to kidney tubuli, lung epithelium, and placenta tissue (*27*).

To asses the value of the addition of a targeting ligand on the rate and extent of accumulation of liposomes in solid tumors, FR targeted bimodal fluorescent and paramagnetic liposomes were formulated and compared to nontargeted liposomes by both MRI and fluorescence microscopy.

EXPERIMENTAL RESULTS

Materials. Phosphatidylethaolamine-lissamine rhodamine B (DOPE-Rhodamine), 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-methoxy(poly(ethylene glycol))-2000 (DSPE-PEG2000), and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[folate(poly-(ethylene glycol))-2000] (DSPE-PEG(2000)folate, ammonium salt) were purchased from Avanti Polar Lipids Inc. (Alabaster, AL, USA). All other chemicals were of analytical grade or the best grade available and purchased from Sigma-Aldrich (UK). Gadolinium (III) 2-{4,7-bis-carboxymethyl-10-[(*N*,*N*-distearylamidomethyl-*N*′-amido-methyl]-1,4,7,10-tetra azacyclododec-1-yl}-acetic acid (Gd.DOTA.DSA) was synthesized in-house as shown previously (*21*).

General Procedures. Liposome zeta potentials were recorded on a Nanoseries Nano-ZS zetasizer (Malvern instruments). Microscopy experiments were conducted on a Nikon Eclipse E600 microscope. FACS analysis was conducted on a Becton Dickinson FACSCalibur machine. ICP-AES experiments were run on a Varian VISTA PRO instrument. All MRI experiments were conducted on a 4.7 T Magnex magnet (Oxford, UK) with a Varian Unity Inova console (Palo Alto, CA, USA). All procedures on animals were carried out in accordance with UK Home Office regulations and the Guidance for the Operation of Animals (Scientific Procedures) Act (1986).

Liposome Preparations. All lipids were stored as stock solutions in anhydrous organic solvents ($CHCl_3$, MeOH, or a mixture of both), at −20 °C under argon. Liposomes were made with defined molar ratios of individual lipids to give a predetermined total lipid concentration of 15 (folate-targeted) or 30 (nontargeted) mg mL^{-1} in HEPES (20 mM, NaCl 135 mM, pH 6.5) for in vivo experiments. Targeted liposomes consisted of Gd.DOTA.DSA/DOPC/Cholesterol/DSPE-PEG2000/DSPE-PEG(2000)Folate/DOPE-Rhodamine 30/32/30/4/3/1 mol %, and nontargeted liposomes were made up of Gd.DOTA.DSA/DOPC/Cholesterol/DSPE-PEG2000/DOPE-Rhodamine 30/32/30/7/1 mol %. Appropriate volumes of each lipid stock were placed in a round-bottom flask (typically 5 mL) containing distilled $CHCl_3$ (500 μL) and stirred to ensure thorough mixing of the lipids. The solvent was slowly removed in vacuo to ensure production of an even lipid film. The film was rehydrated with buffer at a defined volume. The resulting solution was sonicated for 30 min (at 30 °C) for in vivo formulations in order to form gadolinium liposomes of appropriate size. For each preparation, the size of liposomes was measured by photon correlation spectroscopy (PCS) to ensure a size distribution of, on average, below 100 nm. Folate-targeted liposomes were prepared containing a total of ∼4.94 μmol of Gd and control nontargeted liposomes contained ∼9.87 μmol of Gd.

Zeta Potential Measurements of Folate-Targeted and Nontargeted Liposomes. Targeted or nontargeted liposomes were added to plastic electrode cuvettes (1 mL, total liposome concentration: 1.2 mg mL^{-1}) and their electrophoretic mobility measured. Measurements were carried out at 25 °C, on a Zetasizer Nanoseries, Nano-ZS.

Relaxivity Measurement of Folate-Targeted and Nontargeted Liposomes. Liposomes were prepared in HEPES (20 mM, NaCl, 135 mM, pH 6.5) buffer. These liposomes were prepared and diluted in order to obtain five different Gd atom concentrations ranging from 1.973 to 0.246 mM. The liposome solutions were placed in small Eppendorf tubes (200 μL), imaged at 4.7 T in the coronal plane, T_1 values obtained, and the molar relaxivity r_1 (mM^{-1} s^{-1}) determined. T_1 values were acquired using saturation recovery experiments performed with a standard spin−echo sequence and a 2 mm single slice acquisition (TR = 50, 100, 200, 300, 500, 700, 1200, 3000, 5000, 7000 ms, TE = 15 ms), number of signal averages; 2, FOV; 70 × 70 mm^2, collected into a matrix of 256 × 128.

Immunohistochemical Analysis of Folate Receptor Expression. At 48 h prior to FACS experiment, adherent IGROV-1, OVCAR-3, HeLa, and SKBR-3 cells were grown in RPMI media (folic acid free) with 10% FCS and 1% penicillin−streptomycin (Sigma-Aldrich). Cells were grown in 25 cm^3 culture flasks (5 × 10^5 cells per well, 5 mL of growth medium) and in a wet (37 °C) 10% CO_2/90% air atmosphere. The cells were grown until 80% confluence. The media was then removed and the cells washed with PBS. The cells were then treated with trypsin−EDTA (500 μL trypsin, 1 mM EDTA) for 2 min at 37 °C, then transferred to 25 mL Falcon tubes and centrifuged (1500 rpm for 5 min). The PBS was removed, and the cells were washed further with PBS and centrifuged (1500 rpm for 5 min). The cells were then incubated in 10% FCS, 1% NaN_3 solution (1 mL) for 1 h at 4 °C, then spun down (1500 rpm for 5 min), washed with PBS (1 mL), and then this washing step was repeated twice more. The primary antibody (mAb Mov18/ZEL, Axxora, UK) selective for the α-FR was then added to each Falcon (5 μg/mL in 3% BSA/PBS (total volume 1 mL)) and the cells incubated at 4 °C for 1 h (for each cell line, one tube contained no antibody). The cells were centrifuged (1500 rpm for 5 min) and washed with PBS (3 × 1 mL, followed by centrifugation), and the secondary antibody (goat antibody IgG, FITC conjugated, Santa Cruz Biotechnology, Inc., USA) was then added to the cells (1:1000 dilution, in 3% BSA/PBS (total volume 1 mL)) and the cells were incubated at 4 °C for a further hour. The cells were then washed with PBS (3 × 1 mL) and centrifuged (400 rpm for 5 min), diluted in 10% FCS/PBS 1% NaN_3 (1 mL), and analyzed for their FITC fluorescence on a flow cytometer.

Inductively Coupled Plasma−Atomic Emission Spectrometry (ICP-AES) Analysis of Cell Lysates Postincubation with Liposomes. At 48 h prior to gadolinium liposome uptake experiments, adherent IGROV-1 cells were grown in RPMI media (folic acid free) with 10% FCS and 1% penicillin−streptomycin (Sigma-Aldrich) in 48 welled plates. The cells were grown until 80% confluence. The media was then removed and replaced with fresh media (same volume as previous). Folate-targeted and nontargeted liposomes were added in a dose of 12 μg to each well, swirled to ensure even dispersion, and then incubated in a wet (37 °C) 10% CO_2/90% air atmosphere for 6 h. After liposome uptake, the cells were washed with PBS (2 × 200 μL) and then treated with lysis buffer (200 μL per well). Samples containing the cell lysate (200 μL) were submitted for ICP-AES measurements of ^{157}Gd content. Briefly, 150 μL of each sample was pipetted and diluted to 3.75 mL with 2% nitric acid to give a total dilution of 1 in 25 and then analyzed on a Varian VIST PRO instrument. All data were corrected for these dilutions, and a blank 2% nitric acid sample was also analyzed.

Mouse Tumor Model. IGROV-1 cells (5 × 10^6/1 mL PBS) were implanted into the flanks of 6−8 week old Balb/c nude mice for generation of subcutaneous tumors. After ∼2 weeks (estimated tumor weights 40−50 mg), the mice were anaesthetized with an isoflurane/O_2 mix and placed into a quadrature

^{1}H volume coil and positioned into the magnet. Baseline scans were obtained, and then the mice were injected intravenously via lateral tail vein with a 200 μL liposome solution (HEPES (20 mM, NaCl 135 mM, pH 6.5)) and imaged at 4.7 T (spin−echo sequence: TR = 400−2800 ms; TE = 10 ms; FOV = 45 × 45 cm^2; averages, 1; matrix size, 256 × 128; thickness, 2.0 mm; and 20 slices). The mice were imaged prior to injection to obtain baseline images and subsequently placed in the scanner at 2, 16, and 24 h postinjection intervals and scanned further.

Histology Experiments. Following MRI, the animals were sacrificed; and the tumors, livers, and kidneys were excised, frozen on liquid nitrogen, embedded in OCT (VWR) embedding fluid, and 10 μm thick sections cut, mounted on slides, and studied by fluorescence microscopy.

RESULTS

Folate Receptor Expression. In order to establish whether the IGROV-1 cell line, a human ovarian carcinoma cell line, expresses a sufficient level of the folate receptor, FACS analysis of four different cell lines was carried out. For this purposes, the α-folate receptor (α-FR) isoform, which is a folate transporter with restricted expression levels in normal tissues, was chosen. To measure the α-FR expression levels of the human ovarian cell lines IGROV-1, OVCAR-3, and HeLa (cervical cancer) cells, flow cytometry experiments were carried out. In addition to these cell lines, a breast cancer cell line (SKBR-3) was also analyzed as a negative control cell line with no α-FR expression. Cells were grown in folic acid free media and incubated with serum to block any nonspecific interactions. Immunostaining was carried out with a monoclonal antibody (mAb Mov18/ZEL) specific for the α-FR, and post incubation with this antibody, a secondary FITC labeled antibody (Goat antibody IgG, FITC conjugated), was allowed with the cells. Poststaining, the cells were fixed and analyzed by fluorescence microscopy.

From the FACS α-FR expression analysis (Figure 1), where all cell lines were cultured under the same standardized conditions using folate free cell culture medium, it was shown that the IGROV-1 cell line exhibited a distinctly higher level of α-FR expression. From these typical FACS data, the α-FR expression was measured to be in the order IGROV-1 ≫ OVCAR-3 > HeLa > SKBR-3 (three days postseeding).

Folate-Targeted Gadolinium Liposomes for Tumor Imaging. Having established the overexpression of the α-FR on the IGROV-1 cell line, folate-targeted gadolinium liposomes were prepared for specific cell receptor binding and uptake into IGROV-1 tumor cancer cells. These folate-targeted bimodal liposomes consisted of Gd.DOTA.DSA/DOPC/Cholesterol/DSPE-PEG2000/DSPE-PEG(2000)Folate/DOPE-Rhodamine 30/32/30/4/3/1 mol % (see Figure 2). The synthesis of Gd.DOTA.DSA, a lipidic T_1 MRI contrast agent, has been shown elsewhere (*21*). Briefly, Gd.DOTA.DSA is made from the metal-free ligand 2-{4,7-bis-carboxymethyl-10-[(*N*,*N*-distearylamidomethyl-*N*′-amidomethyl]-1,4,7,10-tetra-azacyclododec-1-yl}-acetic acid (DOTA.DSA) by the addition of a gadolinium source such as gadolinium chloride. DOTA.DSA is formed by amide coupling of *N*,*N*-distearylamidomethylamine with 2-(4,7,10-tris(2-*tert*-butyloxycarbonylmethyl)-1,4,7,10-tetra-azacyclododecan-1yl)acetic acid and the subsequent removal of the *tert*-butyl groups in acidic conditions (*21*).

Nontargeted bimodal control liposomes contained no targeting moiety and consisted of Gd.DOTA.DSA/DOPC/Cholesterol/DSPE-PEG2000/DOPE-Rhodamine 30/32/30/7/1 mol %. The serum aggregation of these liposomes was also assessed, and no significant change in liposome size was observed over a 24 h incubation period of folate-targeted and nontargeted liposomes in a 1:1 FCS/HEPES mixture at 37 °C (data not shown).

Relaxivity of Folate-Targeted Liposomes. The relaxivities of both the folate-targeted and nontargeted liposomes were measured by formulating liposomes with varying concentrations of the Gd.DOTA.DSA lipid to obtain five formulations with atomic Gd concentrations within the range 1.972 to 0.2466 mM. The r_1 and r_2 relaxivities measured for the folate-targeted liposomes were 1.30 mM^{-1} s^{-1} and 5.38 mM^{-1} s^{-1}, respectively. For the nontargeted liposomes, r_1 and r_2 were measured as 0.926 mM^{-1} s^{-1} and 5.096 mM^{-1} s^{-1}, respectively, and were comparable to the targeted liposomes relaxivities.

Zeta Potential Measurements. The zeta potentials of both the folate-targeted and nontargeted PEGylated liposomes were also obtained, and these values were found to be close to zero, indicating an overall neutral charge for these liposomes (zeta potential for folate-targeted liposomes was measured to be 3.21 ± 0.284 mV and that for the control nontargeted liposomes was 5.76 ± 0.0673 mV). These liposomes were also formulated using the thin-film technique and sonicated to obtain particles of approximately 100 nm in size with a polydispersity index of <0.5.

In Vitro IGROV-1 Cell Uptake Experiments. Having established that the IGROV-1 cell line overexpresses the FR receptor, to additionally ascertain the targeting efficacy of our folate ligand bearing liposomes to the IGROV-1 cell line, IGROV-1 cells were incubated with folate-targeted and nontargeted liposomes. After 5 h of incubation, the cells were washed and lysed, and the cell lysate destroyed with nitric acid and subjected to ICP-AES measurements of ^{157}Gd content. Figure 3 shows the amount of Gd in ppm that was measured from the cell lysate of IGROV-1 cells incubated with nontargeted liposomes (white bar), folate-targeted liposomes with 0.03 mol % folate lipid incorporated (black bar), and folate-targeted liposomes containing 3 mol % of the folate lipid (gray bar). It is evident that the higher folate ratio bearing targeted liposomes are taken up to a much greater degree by the IGROV-1 cells compared to the nontargeted liposomes and folate-targeted liposomes containing 100 times less folate-lipid.

In Vivo Tumor MRI. Folate-targeted Gd liposomes (total liposome concentration; 15 mg mL^{-1}) and nontargeted control liposomes (total liposome concentration; 30 mg mL^{-1}) were prepared in HEPES buffer (20 mM, NaCl, 135 mM, pH 6.5) and injected through the tail vein of tumor bearing mice, a method that ensures rapid entry of the liposomes into the blood circulation. Prior to injection, baseline MRI scans were obtained on a 4.7 T magnet in order to identify the tumor and measure T_1 baseline values. The mice were then imaged at 2, 16, and 24 h intervals postinjection. T_1-weighted images for each time point were obtained, and the percent signal enhancement as a result of the accumulation of the PEGylated gadolinium liposomes within the tumor tissue was calculated from T_1 values generated from the tumors. It was proposed that, due to the presence of the folate targeting moiety, an increase in tumor signal will be apparent postinjection by MRI, in comparison to the control liposomes (nontargeted). Indeed, this increase was apparent at just 2 h postinjection of the folate-targeted liposomes (see Figure 4).

The measured tumor T_1 values show that within just 2 h post i.v. injection the active and specific targeting effect of the folate liposomes is apparent and a substantial 65% T_1 reduction is achieved within 16 h postinjection compared to ∼15% for the nontargeted liposomes. This substantial enhancement is observed despite injection of folate-targeted liposomes at half the concentration of the nontargeted liposomes.

Figure 5 shows images of IGROV-1 tumors from mice injected with folate-targeted liposomes and control liposomes. The tumor signal enhancement of the targeted liposomes is visible at just 2 h postinjection, and this effect is persistent up to the 24 h imaging end point.

Histology of IGROV-1 Tumors. Following MRI, the mice were then sacrificed and the tumors excised, frozen, fixed, and

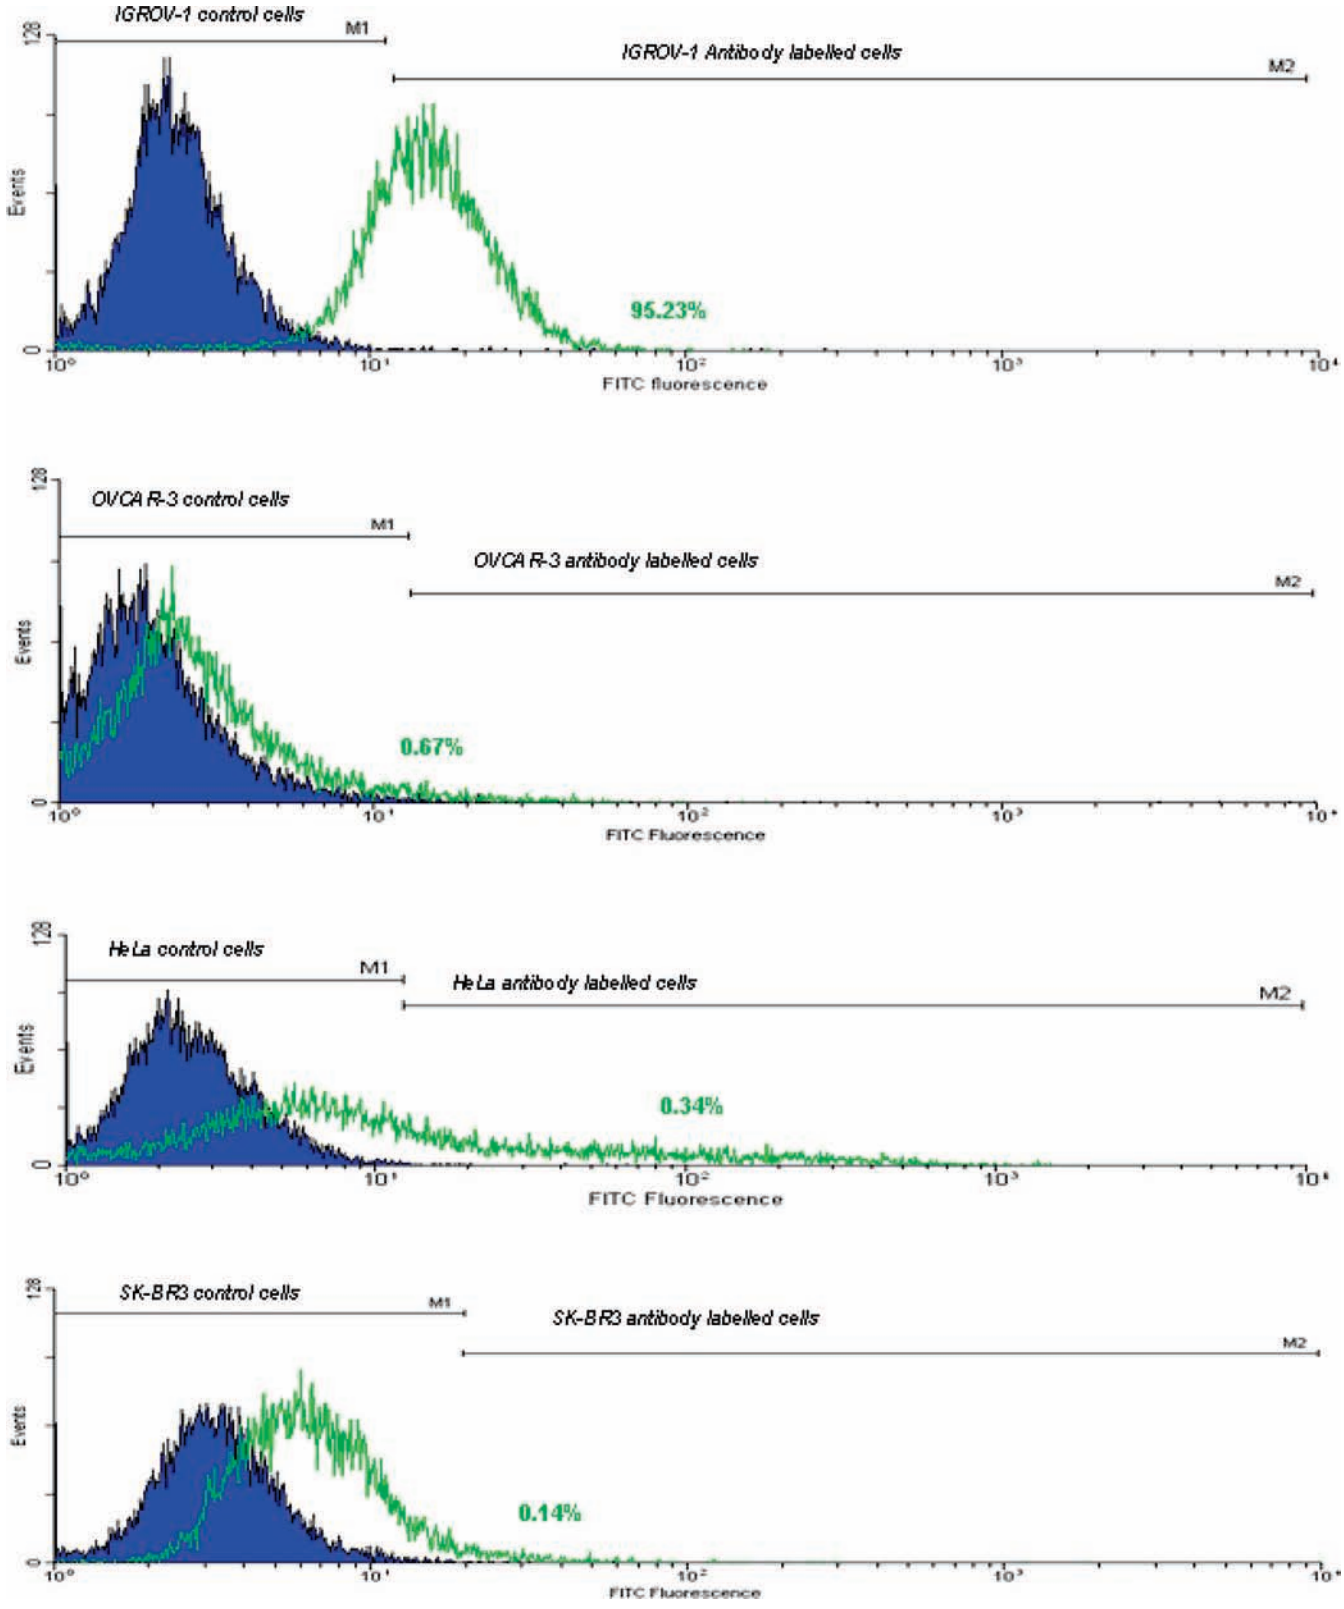

Figure 1. FACS analysis of four cell lines for α-FR expression levels.

sectioned for histological analysis. The inclusion of the fluorescent DOPE-Rhodamine lipid in the liposome formulation allows for postmortem analysis by fluorescence microscopy, which is a sensitive indication for the presence of liposomes within the tumor tissue. Figure 6 presents fluorescence microscopy images of sectioned tumors 24 h post folate-liposome injection. The presence of intense red fluorescence from these sectioned tumor slices is indicative of the accumulation of the targeted liposomes in the tumor tissue. The T_1 tumor signals measured (Figure 4) indicate a rapid accumulation of the targeted liposomes, and histological results show that the folate-targeted gadolinium liposomes may be accumulating at areas of hyperpermeability within the viable tumor tissue. In addition to the sectioned tumors, the liver and kidney tissue of the folate-

targeted liposome injected mice were also removed and analyzed for their fluorescence (see Figure 7). The results revealed that

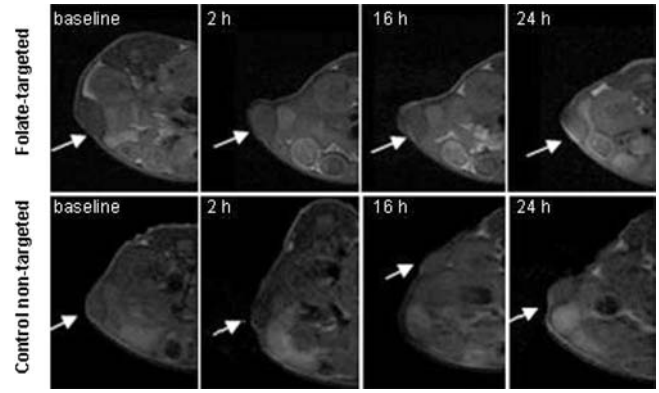

Figure 5. MRI of IGROV-1 tumor bearing Balb/C nude mice: top images are of mice injected with folate-targeted liposomes; bottom images are from control mice injected with nontargeted liposomes (white arrow shows location of tumor).

there is very little accumulation of the folate-targeted liposomes within the liver or kidney tissues 24 h post-administration and suggests their clearance from the liver and their major accumulation in tumor tissue as observed at this time point.

DISCUSSION

Liposomes not only are versatile carriers used successfully for drug delivery, but also present great potential when used in molecular imaging, as thousands of contrast agent molecules can be incorporated within a single particle, increasing contrast agent concentration. In this study, bimodal ligand-targeted paramagnetic and fluorescent liposomes were prepared and used to image xenograft tumors in mice. At just 2 h postinjection the folate-targeted liposomes had achieved a similar signal enhancement attained by the nontargeted liposomes at 24 h postinjection. In the case of the targeted liposomes, the folate ligand binds to the FR receptor in the IGROV-1 tumor, and as a result, the folate-targeted liposomes are effectively "halted" in place through receptor binding and are therefore unavailable for recirculation. We believe that this receptor-binding effect explains the rapid tumor signal enhancement at just 2 h postinjection of the folate-targeted liposomes (Figure 4). The nontargeted liposomes, on the other hand, may be able to recirculate in the blood and undergo several passages before becoming trapped and accumulating in the tumor. Since a 60%

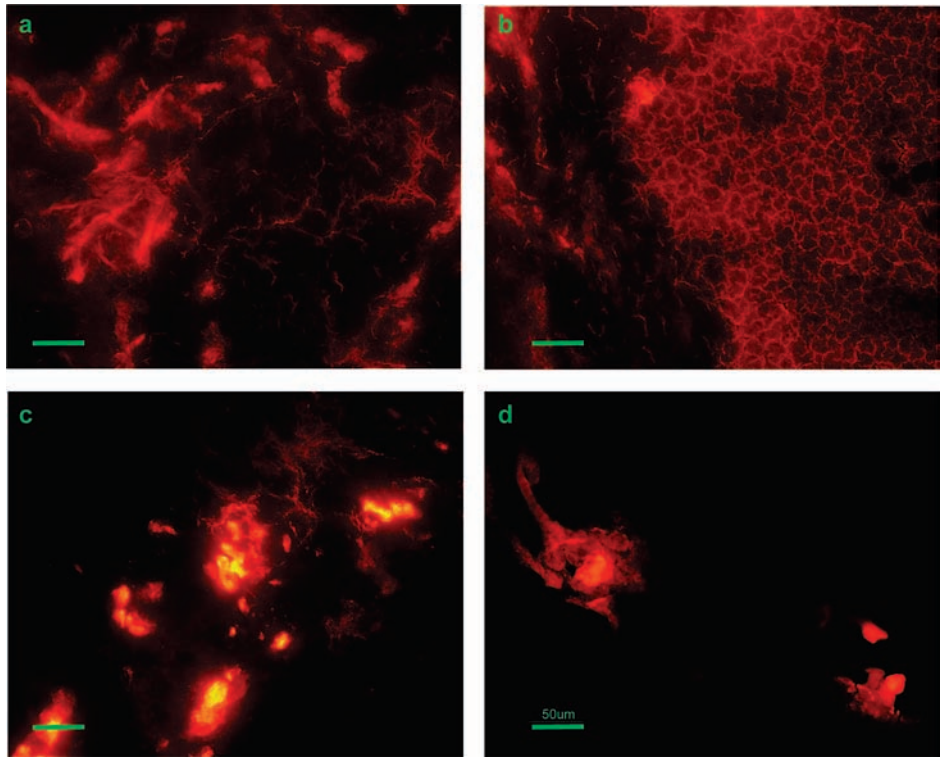

Figure 6. Fluorescence microscopy images of sectioned IGROV-1 tumors 24 h post liposome injection. (a) surface tumor slices, nontargeted liposomes, (b) midtumor slices, nontargeted liposomes, (c) surface tumor slices, folate-targeted liposomes, and (d) midtumor slices, folate-targeted liposomes (green bar represents 50 μm).

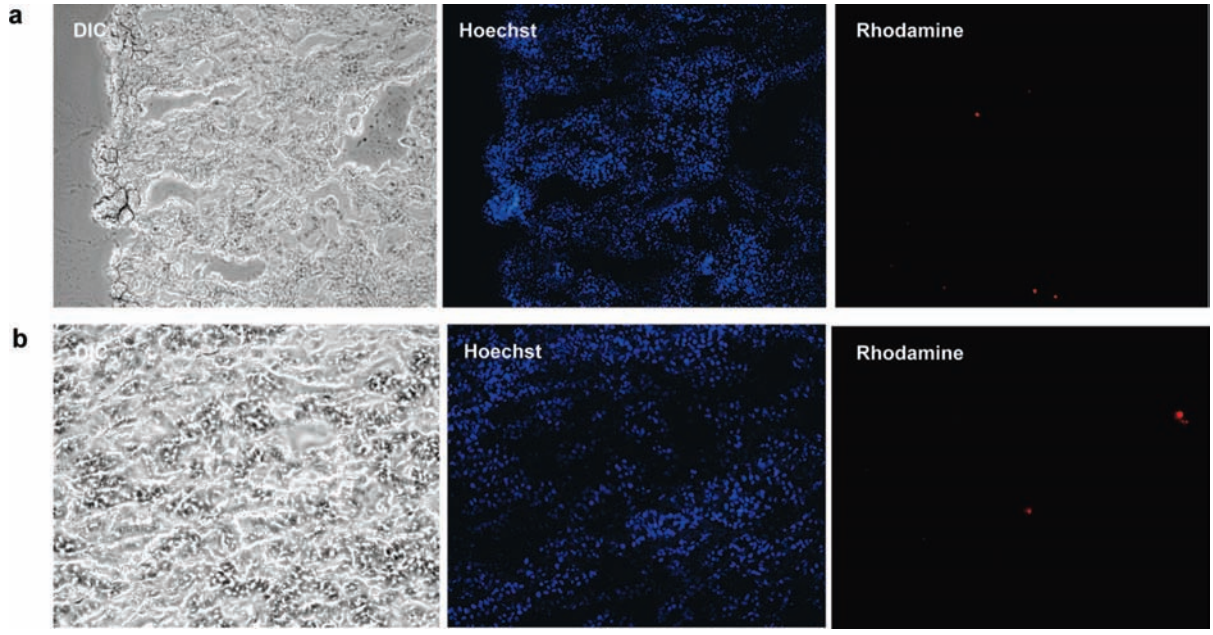

Figure 7. (a) Microscopy images of sectioned liver from tumor-bearing mice injected with folate-targeted liposome; the results show that there is no significant accumulation of the liposomes in the liver. (b) Microscopy images of sections from excised kidneys, where the presence of the fluorescent lipid DOPE-Rhodamine and therefore folate-targeted liposomes is minimal 24 h postadministration ($\times$20 magnification).

signal enhancement is achieved for the nontargeted liposomes only after 24 h postinjection, suggesting continuous circulation and gradual accumulation of these passively targeted liposomes. This is in line with current EPR theories, suggesting that the rate-limiting step for nontargeted liposomes is indeed extravasation (*28, 29*). These trends in active and passive targeting to tumors are also observed by others investigating the effect of targeting on the EPR mechanism (*30*).

The drop in tumor signal intensity at the 24 h postinjection time point for the folate-targeted liposomes is perhaps indicative of cellular internalization and endosomal or cytoplasmic retention of the liposomes and therefore the Gd signaling lipid.

The fluorescence pattern observed for the folate-targeted liposomes appears to be more localized, and the type of diffused and dispersed fluorescence observed for the passively accumulated liposomes is not reflected from these images (Figure 6). It has been suggested that, in particular with immunoliposomes targeted to tumors, there may exist a "binding site barrier" that affects targeted liposome binding in tumors. Weinstein et al. have suggested that immunoliposomes will not penetrate

deeply into the tumor but will bind to the first target cells encountered (*31*). The "binding site barrier" hypothesis suggests that antibodies or ligand-targeted nanoparticles bind to the first target cells they encounter, which retards their diffusion through the tumors (*32*). Additionally, the observed difference in tumor fluorescence localization may be due to macrophage activity within the tumor. A limitation to note is the complicating factor that tumor infiltrating macrophages are also likely to be FR positive. In fact, Turk et al. showed that FR targeted liposomes preferentially target macrophages even in the presence of FR+ tumor cells (*33*). This raises the possibility that FR+ tumor infiltrating macrophages may constitute the actual target cell population in solid tumors and thus will also be investigated in our future studies. A further elucidation for the distinction in fluorescence patterns observed in the case of the folate-targeted particles may be that these particles can distinguish between necrotic and viable tumor areas, leading to more intense fluorescence observed in the viable proliferating tumor areas where more folate-targeted liposomes are able to bind to the growing cells. On the other hand, the nontargeted liposomes cannot make this distinction and will be more uniformly distributed throughout the tumor due to a purely EPR dominating effect.

As such, it appears that the nontargeted gadolinium liposomes may show better penetration into solid tumors; however, the folate-targeted liposomes show a more rapid accumulation within the IGROV-1 tumors. Further work to clarify the localization of the folate-targeted liposomes within the tumor could involve the direct antibody staining of the sectioned tumor slices for α-FR expression.

The lack of fluorescence signal from the sectioned kidneys and liver of mice injected with both the folate-targeted and nontargeted liposomes (see Figure 7) is attributed to the heavily PEGylated nature of these particles and provides further evidence for their prolonged circulation and tumor accumulation through EPR.

In this study, we used a 3 mol % folate-PEG-lipid to ensure multivalency, and liposomes with this folate ratio were taken up in greater amounts by IGROV-1 cells compared to low folate ratio bearing liposomes (Figure 3). However, it has been shown that effective in vivo tumor folate targeting may only require less than 0.3 mol % of the ligand (*34*). It has been suggested that the folate receptor function is regulated by cellular folate requirements, and therefore, a small amount of folic acid is sufficient to trigger the down-regulation of the folate receptor cycle (*5*). However, the observed maximum 68% signal enhancement in our case for the folate-targeted liposomes may suggest that perhaps only a slight decrease in ligand ratio may be necessary to achieve even higher tumor signal enhancement rates. Further studies will focus on optimizing the folate molar ratio of liposomes for in vivo imaging.

Furthermore, it has been shown that the folate ligand indeed remains intact on the liposome surface during circulation. If the ligand is lost in vivo during circulation, the liposome particles would have lost the ability to bind to the tumor cells. Gabizon et al. tested the ligand−liposome association of folate-targeted liposomes in vivo using an ascetic tumor that did not express folate receptors (*12*). In this study, the injected folate liposomes were collected from the ascetic fluid 48 h after i.v injection and were tested ex vivo for their FR binding on relevant FR expressing cell lines. They successfully showed that the folate-targeted liposomes retain their FR receptor binding post in vivo injection and extravasation to the ascetic fluid. These findings in addition to our study suggest that folate targeting for the in vivo imaging of tumors presents a robust and broad platform for both tumor imaging and the delivery of therapeutic agents over a prolonged period of time to tumor tissue.

CONCLUSION

We have demonstrated the utility of folate-targeted liposomes for the imaging of solid tumors and compared these liposomes to nontargeted bimodal liposomes. The folate bearing liposomes showed over 4-fold increase in their accumulation rate at just 2 h postinjection as observed by a drop in tumor T_1 signal due to their effective targeting to the α-FR of the IGROV-1 tumor cells. Here, active targeting versus passive targeting to solid tumors was shown. The rapid and persistent tumor signal enhancement of the folate-targeted liposomes beyond the 24 h experimental end-point will be further investigated. Targeting solid tumors in vivo is challenging due to the rate-limiting step of extravasation and the limited potential for liposomes to diffuse within a solid tumor based on their size. In the quest for ever more optimal nanoparticles for the effective imaging of solid tumors, considerations of particle size, charge, and targeting elements are key requirements for successful particle development for tumor imaging.

ACKNOWLEDGMENT

We thank Dr. Ian McNeish (CRUK) for the kind gift of IGROV-1 cells and Ms. Lorraine Lawrence (Imperial College London) for assistance with histology experiments. Funding for Nazila Kamaly was provided by the GTC and MRC.

Received December 14, 2008; Revised Manuscript Received February 9, 2009

Here, we report on the synthesis and biological properties of a conjugate in which daunorubicin (Dau) as chemotherapeutic agent was attached through an oxime bond to gonadotropin-releasing hormone-III (GnRH-III) as targeting moiety. In vitro toxicity and the cytostatic effect of the conjugate on MCF-7 human breast and C26 murine colon cancer cell lines were determined, and the results were compared with those obtained for the free daunorubicin, as well as with the doxorubicin containing derivative. In vivo antitumor effect of daunorubicin−GnRH-III was studied on Balb/c female mice transplanted with C26 tumor. Our data indicate that the daunorubicin−GnRH-III conjugate had a lower toxic effect than the free daunorubicin and it was essentially nontoxic up to 15 mg (Dau content)/kg body weight. The treatment of the C26 tumor bearing mice with the conjugate led to tumor growth inhibition and longer survival time in comparison with the controls and with the administration of the free drug. When mice were treated twice with the conjugate (on days 4 and 7 after tumor transplantation), 46% tumor growth inhibition was obtained. In this case, the increase of the median survival time was 38% compared to the controls.

INTRODUCTION

Chemotherapy is still one of the primary modalities for the treatment of cancer. However, the application of free anticancer drugs has several drawbacks. Frequently applied high doses are required for the efficacy because of the fast elimination of the drugs from the circulation. Furthermore, the lack of selectivity generally results in toxic side effects. Also, the aquired or intrinsic multidrug resistance (MDR) of cancer cells may restrict the use of chemotherapy. Targeted chemotherapy has been developed to overcome these disadvantages (*1*, *2*) and it has been suggested as an alternative for differentiating healthy and afflicted cells (*3*). Tumor targeting is usually achieved by conjugation of the chemotherapeutic agent to a targeting moiety consisting of sugars (*4*), lectins (*5*−*7*), receptor ligands (*1*, *3*, *8*, *9*), or antibodies (*10*−*12*), which is specifically directed to certain types of binding sites on cancer cells.

One of the various targeted chemotherapeutic approaches is based on the finding that receptors of several peptide hormones (e.g., gonadotropin-releasing hormone (GnRH[1]), bombesin, somatostatin) are overexpressed on cancer cells compared to normal cells and organs. GnRH receptor (GnRH-R) expression was identified on different tumors (breast, ovarian, endometrial, prostate, renal, brain, pancreatic, melanomas, and non-Hodgkin's lymphomas) with high percentages in specimens (*1*, *13*, *14*).

The primary biological function of the hormonal decapeptide GnRH (also called LH-RH) is the regulation of gonadal functions by releasing gonadotropic hormones, luteinizing hormone (LH), and follicle stimulating hormone (FSH), and therefore it plays a pivotal role in vertebrate reproduction (*15*). However, it was demonstrated that high doses of human GnRH (hGnRH) and its superagonist analogues inhibit the growth of hormone-dependent mammary and prostate cancers through chemical castration (*16*). Some of the GnRH agonists and antagonists not only have an indirect effect on tumors, but also can affect the cancer cells directly by the interaction with GnRH receptors that activate a G-protein-dependent transducing mechanism (*17*−*19*).

GnRH derivatives not only might be anticancer agents, but also could serve as targeting moieties to deliver chemotherapeutic agents to tumor cells. Chemotherapeutic antineoplastic radicals including alkylating nitrogen mustard derivatives (e.g., D-melphalan), antimetabolites (e.g., methotrexate), and anthracycline derivatives (e.g., doxorubicin and 2-pyrrolinodoxorubicin), were conjugated to [D-Lys[6]]-GnRH through amide or ester bonds (*1*, *20*−*22*). However, in the case of the application of this superactive GnRH agonist as the targeting moiety, temporary damage to the pituitary was observed, which was recovered in about two weeks (*23*).

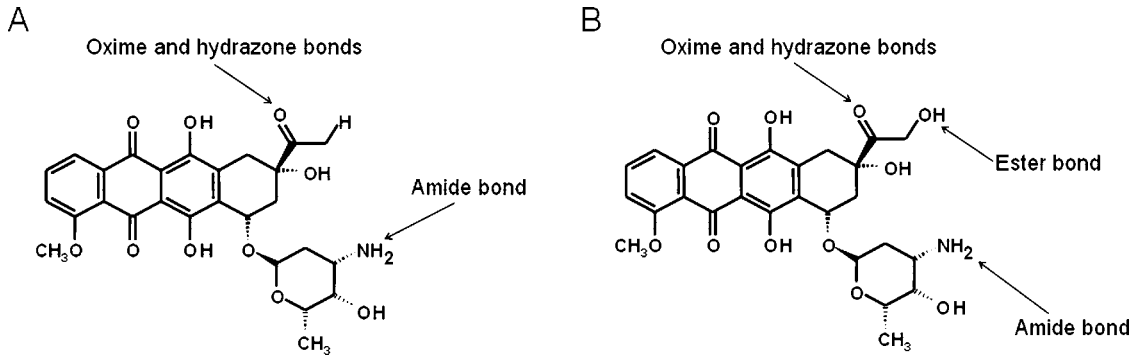

Figure 1. Conjugation sites of daunorubicin (A) and doxorubicin (B).

The antitumor effect of the conjugate Dox-[Lys^6]-GnRH (AN-152), which is currently in the phase III clinical trial, was studied on many types of tumors. The highest antitumor effect was determined on human epithelial ovarian cancers. The clinical trials are performed in female patients with LH-RH-receptor expressing gynecological tumors (advanced or recurrent ovarian and endometrial tumors).

The selectivity of the antitumor effect in targeted chemotherapy can be increased by using GnRH analogues that have lower binding to gonadotropic cells. One of the weak agonistic analogues of GnRH is the variant (Glp-His-Trp-Ser-His-Asp-Trp-Lys-Pro-Gly-NH_2; GnRH-III) isolated from sea lamprey (*Petromyzon marinus*) (*24*) that specifically binds to receptors on cancer cells and recognizes not only the high- but also the low-affinity binding sites of GnRH receptors (*25*). GnRH-III has 500−1000 times less potency in LH and FSH secretion both in vitro and in vivo indicating its selective antitumor activity (*26, 27*). It was also demonstrated that the modification of ^{8}Lys by conjugation (*28*), cyclization (*29*), Ala-scan (*30*), or dimerization (*31*) did not result in the loss of the antiproliferative activity of GnRH-III. However, the absence of the free ε-amino group of lysine decreased the endocrine effect of the compounds (*27, 31, 32*)

The aim of our study was to prepare bioconjugates in which daunorubicin (also called daunomycin, Dau) as the chemotherapeutic agent was covalently attached to GnRH-III as a targeting moiety with its own antiproliferative effect. Daunorubicin is an anthracycline derivative which differs from doxorubicin (Dox) in the substitution at the C-14 position (H instead of OH). It has been shown that daunorubicin has less cardiotoxic side effect than doxorubicin (*33, 34*). However, the lack of the aliphatic OH-group in daunorubicin prevents the possibility of synthesizing conjugates containing ester bonds (Figure 1). Also, the conjugation through the amino group of the aminosugar moiety (daunosamine) might lead to a significant loss of bioavailability of the compound (*32, 35*). Therefore, daunorubicin is not a common part of the conjugates tested in experiments for targeted chemotherapy. Here, we report on the conjugation of daunorubicin to GnRH-III(GFLG) via an oxime bond. In vitro and in vivo toxicity of the conjugate was studied. The cytostatic effect of the compound on MCF-7 human breast and C26 murine colon tumor cell lines was determined. The results were compared with those obtained for the free daunorubicin, as well as with the doxorubicin containing derivative. The in vivo antitumor effect of the GnRH-III(Dau=Aoa-GFLG) conjugate (throughout the manuscript, the conjugate will be abbreviated as Dau-GnRH-III) was studied on mice transplanted with C26 murine colon tumor xenograft.

The oxime bond containing Dau-GnRH-III conjugate had in vitro and in vivo antitumor effects and enhanced the survival of treated mice bearing C26 tumor compared to the untreated

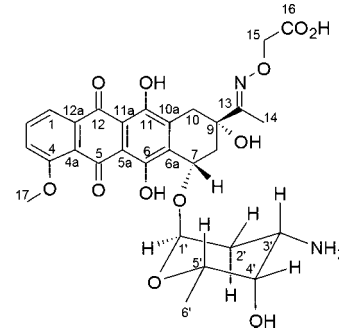

Figure 3. Numbering of atoms used for NMR assignments (arbitrary).

control group. The conjugate also prevented the toxic side effects of the free drug.

EXPERIMENTAL SECTION

Materials. All amino acid derivatives and MBHA resin were purchased from NovaBiochem (Läufelfingen, Switzerland) or Reanal (Budapest, Hungary). Scavengers, coupling agents, and cleavage reagents (*p*-cresol, dithiothreitol (DTT), *N*,*N*′-dicyclohexylcarbodiimide (DCC), *N*,*N*′-diisopropylcarbodiimide (DIPCI), 1,2-ethanedithiol (EDT), (benzotriazol-1-yloxy)-tris-(dimethylamino)phosphonium hexafluorophosphate (BOP), *N*-diisopropyl-ethylamine (DIEA), 1-hydroxybenzotriazole (HOBt), 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU), piperidine, trifluoroacetic acid (TFA), and hydrogen fluoride (HF)), as well as daunorubicin (Dau), doxorubicin (Dox), aminooxyacetic acid (Aoa), and Boc-aminooxyacetic acid (Boc-Aoa-OH), were Fluka

products (Buchs, Switzerland). Solvents for synthesis (dichloromethane (DCM) and *N*,*N*′-dimethylformamide (DMF)) were purchased from Reanal (Budapest, Hungary). HPLC-grade acetonitrile (MeCN) and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were from Sigma-Aldrich Kft (Budapest, Hungary).

Synthesis of Conjugates. Branched GnRH-III derivative (<EHWSHDWK(Aoa-GFLG)PG-NH_2; where <E is pyroglutamic acid) was built up on 4-methylbenzhydrylamine (MBHA) resin (1.04 mmol/g coupling capacity) using mixed Boc/Bzl and Fmoc/^{t}Bu chemistries as previously reported (*31, 36*). The first two amino acids (Gly and Pro) were attached as Boc-protected derivatives followed by the coupling of Fmoc-Lys(Boc)-OH to the peptidyl resin. After removal of the Boc protecting group from the $^\epsilon NH_2$ function of Lys, the GFLG tetrapeptide branch was prepared by Boc strategy. The remaining part of the GnRH-III sequence was built up by Fmoc strategy, except pyroglutamic acid, which was attached without any protection. The removal of the side-chain protecting groups, as well as the Boc-group from the *N*-terminus of the branch, was carried out with a mixture of TFA-water-EDT (95:2.5:2.5, v/v/v) at RT for 1 h. A part of the resin was used for the preparation of GnRH-III(GFLG) hormone derivative. On the other part of the resin, Boc-aminooxyacetic acid was attached to the *N*-terminus of the branch after preactivation with BOP reagent in the presence of DIEA (2 equiv each to the resin capacity). The Boc group was cleaved with a mixture of TFA-water-EDT (95:2.5:2.5, v/v/v) at RT for 15 min. After washing and neutralization, the peptide−resin was dried in a desiccator. After that, the peptides were cleaved from the resin with anhydrous HF in the presence of *p*-cresol and DTT (HF-*p*-cresol-DTT = 10 mL:1 g:0.1 g). The crude products were purified by semipreparative RP-HPLC and the purified compounds were characterized by analytical HPLC and mass spectrometry (Table 1). The yields were 54% (Aoa containing peptide) and 66% (GnRH-III(GFLG)) to the resin capacity.

The conjugation via oxime bond formation was carried out in 0.2 M sodium acetate buffer, pH 4.8. Daunorubicin or doxorubicin was used in 20% excess compared to the GnRH-III derivative. The reaction mixture was stirred at RT for 24 h; then, the conjugate was separated from the excess of anthracycline derivative by RP-HPLC. The yield was 72% in the case of daunorubicin and 70% in the case of doxorubicin. The purity of the conjugates was determined by analytical RP-HPLC, and the identity of the compounds was confirmed by ESI-ion trap mass spectrometry (Table 1; Supporting Information S3−S5). Conjugation of Dau to aminooxyacetic acid (compound prepared for NMR analysis) was carried out in the same way as described above (83% yield).

High-Performance Liquid Chromatography (HPLC). Analytical RP-HPLC was performed on a Knauer (H. Knauer, Bad Homburg, Germany) system using a Phenomenex Jupiter C_{18} column (250 mm × 4.6 mm) with 5 μm silica (300 Å pore size) (Torrance, CA) as a stationary phase. Linear gradient elution (0 min 0% B; 5 min 0% B; 50 min 90% B) with eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile−water (80:20, v/v)) was used at a flow rate of 1 mL/min. Peaks were detected at λ = 220 nm. The crude products were purified on a semipreparative Phenomenex Jupiter C_{18} column (250 mm × 10 mm) with 10 μm silica (300 Å pore size). The flow rate was 4 mL/min. The same eluents with a linear gradient of 20−60% B in 40 min were applied.

Mass Spectrometry (MS). Mass spectrometric analyses were carried out on a Bruker Daltonics Esquire 3000+ ion trap mass spectrometer (Bremen, Germany). Spectra were acquired in the 50−2000 *m*/*z* range. Samples were dissolved in acetonitrile−water = 1:1 (v/v) solvent mixture containing 0.1% acetic acid.

Liquid chromatography in combination with mass spectrometry (LC/MS) was carried out on a Bruker Esquire 3000+ ion trap mass spectrometer (Bruker Daltonics, Bremen, Germany) equipped with an Agilent 1100 HPLC system (Agilent, Waldbronn, Germany). Peptides were separated on a Vydac MS C_{18} column (150 × 1 mm; 300 Å, 3 μm) using a linear gradient from 90% solvent A (0.1% formic acid in water (v/v)) and 10% solvent B (0.1% formic acid in acetonitrile (v/v)) to 70% solvent B over 65 min and a flow rate of 50 μL/min. Spectra were recorded in positive ion mode in the 100−2000 *m*/*z* range.

^{1}H and ^{13}C NMR Study. The ^{1}H and ^{13}C NMR spectra were recorded in DMSO-d_6 solution in a 5 mm tube at RT, on a Bruker DRX-500 spectrometer at 500.13 (^{1}H) and 125.76 (^{13}C) MHz, with the deuterium signal of the solvent as the lock and TMS as the internal standard. The standard Bruker microprogram NOEMULT to generate NOE and to get DIFFNOE spectra was used with a selective pre-irradiation time (50 ms). DEPT spectrum was run in a standard manner, using only a $\Theta = 135°$ pulse to separate the CH/CH_3 and CH_2 lines phased "up" and "down", respectively. The 2D-COSY, 2D-HMQC, and 2D-HMBC spectra were obtained by using the standard Bruker pulse programs.

Enzymatic Digestion of Dau-GnRH-III Conjugate by Cathepsin B. Dau-GnRH-III was dissolved at a concentration of 0.1 μg/μL in 0.1 M NaOAc, 0.01 M DTT, pH 5, and then human liver Cathepsin B (Calbiochem, Germany; c = 0.4 μg/μL in 20 mM NaOAc containing 1 mM EDTA, pH 5) was added at an enzyme to substrate ratio of 1:50, w/w. The reaction mixture was incubated at 37 °C, and aliquots of 20 μL were taken after 5 min, 2 h, 4 h, 8 h, and 24 h (the reaction was quenched by adding 2 μL of acetic acid, followed by freezing the sample with liquid nitrogen). The digestion mixtures were analyzed by LC/MS.

A control experiment in which a solution of 0.1 μg/μL Dau-GnRH-III in 0.1 M NaOAc, 0.01 M DTT, pH 5, was incubated at 37 °C for 24 h was also performed.

Cells. MCF-7 cells (human breast adenocarcinoma cell line) were maintained in DMEM (Sigma Ltd., St. Louis, MO) containing 10% FCS (fetal calf serum, Sigma Ltd.), L-glutamine (2 mM), gentamicine (160 μg/mL) at 37 °C in a humidified 5% CO_2 atmosphere. C26 cells (mouse colon adenocarcinoma cell line) were cultured in DMEM F12 (Sigma Ltd.) containing 10% FCS (fetal calf serum), L-glutamine (2 mM), and pyruvate (1 mM) at 37 °C in a humidified 5% CO_2 atmosphere.

Cytotoxicity and Cytostatic Studies by MTT Assay. For the study of in vitro cytotoxicity, MCF-7 human breast or C26 murine colon cancer cells were plated into 96-well tissue culture plate in 100 μL culture medium with the initial cell number of 5×10^3 cells/well. The compounds used in the (5×10^{-4}) to

(2×10^2) μM concentration range were dissolved in fresh culture medium and added to the cells. After 6 h incubation at 37 °C, the amount of living cells was determined by MTT assay using 0.367 mg/mL final concentration of MTT in each well. After 3.5 h incubation with MTT, cells were centrifuged at 2000 rpm for 5 min, supernatant was removed, and crystals were dissolved in DMSO. The absorbance was measured using an ELISA-reader (Labsystems MS Reader, Finland) at $\lambda = 540$ nm and at $\lambda = 620$ nm as reference wavelengths. Statistical analysis of data was performed by Student's *t*-test of Origin7.5 at the 95% confidence level.

In the case of the measurement of cytostatic effect, cells were plated into 96-well tissue culture plates in 100 μL culture medium with an initial cell number of 5×10^3 cells/well, 24 h prior to the treatment. The compounds or serum free medium as a control were added to the wells in 100 μL in serum free medium at a 200 μL final volume. After 6 h incubation, cells were washed twice with serum free medium, and then fresh culture medium was added to each well. Cells were maintained at 37 °C for a further 72 h, and then the quantity of living cells was determined by MTT-assay as described above.

Four parallel measurements were performed in all cases, and they were repeated twice.

Acute Toxicity Measurement. First-generation hybrid BDF_1 (C57BL/6 female and DBA/2 male) adult female mice, weighing 22−23 g, specified pathogen free (SPF) from Department of Exprimental Pharmacology, National Institute of Oncology, Budapest, Hungary, were used. Colonies were used for these experiments. The animals were kept in macrolon cages at 22−24 °C (40−50% humidity), with a lighting regimen of 12/12 h light/dark. The animals had free access to tap water and were fed a sterilized standard diet (Charles River VRF1, autoclavable, Germany) ad libitum. The animals used in these studies were cared for according to the "Guiding Principles for the Care and Use of Animals" based upon the Helsinki declaration, and they were approved by the local ethical committe. Our permission for breeding and performing experiments with laboratory animals is valid up to 10/06/2010.

Daunorubicin and Dau-GnRH-III conjugate were dissolved in distilled water at a concentration that allowed the dose to be given at a volume of 0.1 mL/10 g body weight. In this experiment, 7−7 mice/group were used. The mice were treated by i.p. administration. Toxicity in mice was characterized on the basis of lifespan and body weight. Survival time was followed over 21 days.

In Vivo Antitumor Effect of Daunorubicin and Dau-GnRH-III Conjugate on Colon-26 Carcinoma. Balb/c female mice, weighing 22−24 g, kept under the same conditions described above were used in this experiment. Tumor tissue fragments (Colon-26 mouse carcinoma, SRI, Birmingham, AL) were transplanted (3−4 mm, ∼25 mg weight) subcutaneously (s.c.) into the intrascapulare region of the mice using a tweezers. In the first trial, the treatments started on day 7 after tumor transplantation by i.p. administration of the compounds dissolved in d.i. water. In this experiment, 5−5 mice/group were used. Except for the control group, the mice were treated with either free daunorubicin (once 5 mg (8.86 μmol)/kg body weight or 2 mg (3.55 μmol)/kg 5 times on every second day) or Dau-GnRH-III conjugate (once 62.5 mg/kg (26.6 μmol; 15 mg Dau content) or 20.8 mg/kg (8.86 μmol; 5 mg Dau content) 5 times on every second day. In the second experiment, tumor bearing mice (7 mice in each group) were treated twice with the conjugate using 62.5 mg (26.6 μmol)/kg. Treatments were carried out either on days 4 and 7 or days 7 and 10. In this case, the antitumor activity of the free GnRH-III(GFLG) was also studied. The hormone derivative was injected i.p. on days 4 and 7 using 45 mg (26.6 μmol)/kg body weight. The tumor growth inhibitory effect of various treatments was controlled 7 times within three weeks following the tumor transplantation using a digital caliper. Tumor volume was calculated using the following formula: $V = a^2 \times b \times \pi/6$ (where "*a*" and "*b*" mean the shortest and the longest diameter, respectively of a given tumor) (*37*). Changes of tumor volume and body weight were controlled and evaluated. Mean values and standard deviations were calculated. The evaluation of antitumor activity on the basis of survival time was evaluated as well. The survival probability was presented according to the Kaplan−Meier curve calculated/drawn by the MedCalc9 program.

RESULTS AND DISCUSSION

Due to the limited conjugation sites of daunorubicin (Figure 1), the drug was attached to GnRH-III derivative as homing device via oxime bond formation. The in vitro antitumor effect of the conjugate was determined on MCF-7 and C26 tumor cell lines. Similar experiments were performed with a conjugate containing doxorubicin instead of daunorubicin, as well as with the free drugs. In spite of the higher in vitro activity of the conjugate on MCF-7 tumor cells, the C26 tumor bearing mice was a suitable animal model for in vivo experiments, because C26 colon tumor is a fast-growing and aggressive tumor type. It is worth noting that colon carcinomas are rarely used for the study of in vivo antitumor activity.

However, the first results of the treatment of colon cancer bearing mice with Dox and Dox-[Lys^6]-GnRH (AN-152) were recently reported (*38*). The treatment of nude mice bearing HT-29 tumor started 14 days after tumor transplantation and continued for 55 days. The conjugate was administered intraperitoneally (i.p.) on days 1 and 28, whereas Dox (20.7 μmol/kg; 13.6 mg/kg) was injected only once on day 1. AN-152 (20.7 μmol/kg) inhibited the tumor growth by 41% (735 ± 158 mm^3 tumor volume), while Dox only by 28% (885 ± 201 mm^3) compared to the controls (1219 ± 372 mm^3). All animals were alive at the end of the experiment in the group treated with AN-152, but 6/9 mice Dox treated and 2/9 from the controls died. Some other colon tumors, such as HCT-116, HCT-15,

LoVo, and Colo320DM, were examined. A lower amount of compounds (6.9 μmol/kg) but more frequent treatments (days 1, 7, 11, 15, 22, 28, 49) were applied. The tumor growth inhibition of AN-152 was 20%, 75%, 67%, and 74%, respectively. These are the only reported data on the treatment of colon cancer bearing mice to which our results can be compared.

Conjugates. Daunorubicin, an antineoplastic agent widely used in tumor therapy, was attached to GnRH-III as a targeting moiety, which has itself an antiproliferative effect on cancer cells. The oxo group at the C-13 position was used as a conjugation site, because the acylation of the amino group of daunosamine by GnRH peptide led to the loss of biological activity (Figure 1). An oxime bond was formed between the keto group of daunorubicin and the aminooxyacetyl group of the GnRH-III derivative (Figure 2). As the oxime bond is relatively stable between pH 3 and 8 (*39*), as well as under in vitro and in vivo biological experimental conditions (*40*), an enzyme-labile GFLG tetrapeptide spacer was incorporated between the decapeptide and daunorubicin. This spacer sequence can be cleaved by lysosomal enzymes (e.g., Cathepsin B) (*41, 42*), and it was successfully applied in methotrexate and doxorubicin containing conjugates (*42, 43*). For comparative studies, the doxorubicin containing conjugate (Dox-GnRH-III) was also prepared under the same conditions. The purified conjugates were characterized by RP-HPLC and ESI-MS (Table 1; Supporting Information S3−S5).

^{1}H and ^{13}C NMR Analyses of the Carboxymethyloxime Derivative of Daunorubicin (Dau-Aoa-OH). A simple model compound was prepared in order to analyze the oxime bond structure of Dau conjugate. The structure of O-carboxymethyloxime is unambiguously evidenced by the ^{1}H and ^{13}C NMR data assigned on the basis of DEPT, 2D-COSY, 2D-HMQC, 2D-HMBC, and DNOE measurements (Figure 3). The relative configuration of the daunoseamine motif is clearly reflected from the split of the signals originated from the skeletal hydrogens and the mutual NOEs (3.7−4.2%) measured between the axial 3′-H and 5′-H protons. The broad singlets of 1′-H and 4′-H associated with weak vicinal couplings refer to their equatorial position, and consequently to the axial position of 1′-cycloalkoxy- and 4′-OH groups, respectively. The relatively small split (4.9 Hz) of the triplet from the 7-H cyclohexene proton points to its pseudoequatorial orientation. In the ^{1}H−^{13}C-HMBC spectrum, 7-H exhibits a cross peak with the C-13 signal originated from their 4*J* coupling along a special "W"-arrangement of the bonds transmitting the interaction. Accordingly, the cyclohexene ring condensed to antraquinone carries the pseudoequatorial oxime moiety in the trans position relative to the pseudoaxial daunosamine unit.

The weak NOEs (1.6−1.8%) detected between the 14-H methyl- and 15-H O-carboxymethyl protons in the oxime moiety with "*E*" configuration can be ascribed to the increased lifetime of the rotamer stabilized by a quasi six-membered chelate ring involving the imino nitrogen and the carboxyl proton [δ·(CO_2H) ∼ 14.0 ppm]. This downfield-shifted signal is considerably broadened due to exchange. The "*E*"-oxime configuration is also supported by the upfield-shifted carbon line of C-14 (10.8 ppm), of the which signal would be expected at around 16−17 ppm in a "*Z*"-oxime isomer.

Enzymatic Digestion of Dau-GnRH-III Conjugate by Cathepsin B. Cathepsin B, known to be overexpressed in cancer cells (*44*), is one of the lysosomal enzymes involved in the intracellular digestion of extracellular proteins taken up by endocytosis. The cleavage specificity of Cathepsin B can be used as a basis for controlled intracellular drug release. In the present work, oxime bond linked Dau-GnRH-III conjugate containing a GFLG tetrapeptide spacer between the anticancer drug and the GnRH-III decapeptide was subjected to Cathepsin B catalyzed hydrolysis. Liquid chromatography in combination with mass

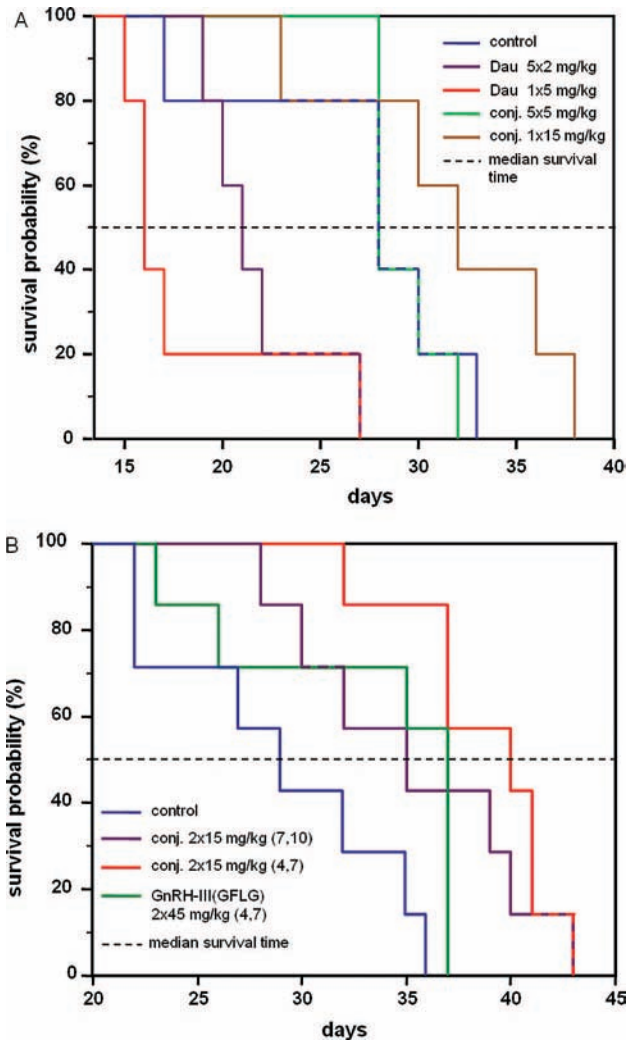

Figure 7. (A) Survival according to the Kaplan−Meier analysis. Control group compared to the groups treated with different doses of Dau or Dau-GnRH-III conjugate (B) Survival according to the Kaplan−Meier analysis. Control group compared to the groups treated twice with Dau-GnRH-III conjugate on different days or with GnRH-III(GFLG).

spectrometric analysis of the reaction mixture indicated several Cathepsin B cleavage sites, namely, the peptide bonds -Gly-Phe-, -Phe-Leu-, -Leu-Gly- inside the spacer sequence and the isopeptide bond -Lys(Gly)-. In addition, the cleavage of the peptide bond -^{7}Trp-^{8}Lys- in the GnRH-III sequence was determined (Figure 4A,C). Total ion chromatogram and mass spectra of each fragment produced by Cathepsin B digestion are presented in the Supporting Information S6 and S7. LC/MS analysis of a solution of Dau-GnRH-III which was incubated at 37 °C for 24 h revealed no degradation of the conjugate in the absence of Cathepsin B (Figure 4B).

In Vitro Cytotoxicity and Cytostatic Effect. In vitro cytotoxicity of free drugs and their GnRH-III conjugates was measured on MCF-7 tumor cell lines by MTT assay. The cells were incubated with the compounds in the (5.1×10^{-4}) to (2×10^{2}) μM concentration range for 6 h at 37 °C. Daunorubicin and doxorubicin elicited similar cytotoxicity with LC_{50} values of 0.67 and 0.68 μM, respectively (Table 2, Supporting Information S8). The conjugates were toxic at a higher concentration, with Dau-GnRH-III having significant higher toxicity than Dox-GnRH-III (LC_{50} values are 40.11 ± 25.31 μM and 85.18 ± 3.85 μM, respectively). Long-term tumor cell growth inhibition was also studied on MCF-7 and C26 tumor cell lines that express GnRH receptors (Supporting Information S1). In this case, cells were incubated with Dau-GnRH-III or Dox-GnRH-III conjugates for 6 h; then, the treated cells were maintained in fresh culture medium at 37 °C for a further 72 h. The Dau or Dox conjugates showed a higher cytostatic effect on MCF-7 tumor cells than on C26. The difference between the IC_{50} values of Dau-GnRH-III (3.94 ± 1.18 μM) and Dox-GnRH-III (5.38 ± 1.86 μM) was not significant on MCF-7 cells (Table 2, Supporting Information S8). On C26 tumor cells, the conjugates were less potent, and the Dau-GnRH-III conjugate had a lower IC_{50} value (22.46 ± 1.74 μM) than Dox-GnRH-III (46.10 ± 6.06 μM). The GnRH-III(GFLG) hormone derivative had no cytostatic effect in the 10^{-4}−10^{2} μM concentration range (IC_{50} > 100 μM).

In Vivo Toxicity. In vivo toxicity of the free daunorubicin and Dau-GnRH-III conjugate was studied on healthy BDF-1 female mice (7 mice in each group) in our preliminary toxicological experiments. The BDF-1 inbred mouse strain is internationally accepted for maintenance of the most transplantable tumors. Mice were treated i.p. once with 15 mg (26.6 μmol)/kg body weight free daunorubicin or equivalent daunorubicin containing conjugate (62.5 mg/kg, 24% Dau content). The experiment lasted for 21 days. All mice treated with the free drug died between days 10 and 12 (11.3 ± 0.76 days). However, all mice treated with the Dau-GnRH-III conjugate survived until the end of the experiment (day 21). The body weight of the Dau-GnRH-III treated mice slightly decreased during the first three days, and then it increased up to the body weight values observed in the case of the control group (Figure 5).

In Vivo Antitumor Effect. For the study of the in vivo antitumor effect, Balb/c mice were transplanted with C26 tumor (5 mice in each group), because the maintenance of colon-26 solid carcinoma tumor is realizable exclusively in Balb/c inbred mouse strain. Both free daunorubicin and Dau-GnRH-III conjugate showed a moderate in vivo antitumor activity on C26 colon tumor bearing mice. The first treatment in all cases was performed on day 7 after tumor trasplantation. The compounds were administered once or 5 times on every second day. Measurement of the tumor volume was continued until day 16 after tumor transplantation, because one mouse from the nontreated control group died on day 17. The application of the free drug at 5 mg (8.86 μmol)/kg body weight (only one injection) resulted in the most effective inhibition of the tumor growth (36.4% on average to the control) in one week after treatment (Figure 6A, Table 3). However, 4 of 5 mice died between days 15 and 17 (median survival day is 16; $p = 0.0009$, log-rank test) because of the toxicity of daunorubicin (Figure 7A). Using a lower dose of free daunorubicin, 5 × 2 mg (3.55 μmol)/kg, resulted in average 22.6% inhibition of tumor growth as compared to the control group before terminating the experiment (Figure 6A, Table 3). The toxic side effect of daunorubicin was also observed in this case, because the median survival time calculated from the Kaplan−Meier survival curve (*45*) was 21 days ($p = 0.0342$, log-rank test) compared with 28 days for control population (Figure 7A). A similar level of inhibition (22.3% on average) was determined in the case of Dau-GnRH-III conjugate treatment when 62.5 mg (26.6 μmol)/kg body weight dose was used (Figure 6A, Table 3). However, a lower dose (20.8 mg (8.86 μmol/kg) of conjugate was less effective even in the case of 5× repeated treatments of tumor bearing mice (15.7% on average) (Figure 6A, Table 3). Using the conjugate (62.5 mg/kg), the data of median survival time showed a moderate increase to the control (32 days (14.3%), $p = 0.1650$ log-rank test), while the increase was significant in comparison to the group of mice treated with free drug (>52%) (Figure 7A).

In the second experiment, the treatments with Dau-GnRH conjugate (62.5 mg (26.6 μmol)/kg) were carried out either on

days 4 and 7 or on days 7 and 10 after the transplantation of tumor xenograft. Significantly higher tumor growth inhibition was observed in both cases at the end of the experiment (46% and 32% inhibition, respectively, measured on day 21) (Figure 6B, Table 4). Even if the tumor growth was slower in this experiment, we could conclude that until day 11 the tumor volume decreased due to the treatments, with 70−80% tumor growth inhibition being detected during this time. The antitumor effect of the free GnRH-III(GFLG) hormone derivative was also studied. The data indicated slight but not significant inhibition (18%) of tumor growth compared to the control group at the end of the experiment. However, during the treatment period (until day 11) 30−40% tumor growth inhibition induced by the hormone peptide alone was observed using the same amount (26.6 μmol; 45 mg/kg) of peptide as was in conjugate (Figure 6B, Table 4). These data indicate that GnRH-III(GFLG) hormone derivative had its own in vivo antitumor effect on C26 colon cancer, which was only 40−50% of the inhibition determined in the case of treatment with the conjugate.

In this experiment, the median survival probability of the control and treated animals (on days 7 and 10 or 4 and 7) was 29, 35, and 40 days, respectively. The increase of the survival time of treated animals was 21% and 38% compared to the control group. The group of mice treated only with the GnRH-III derivative also showed increased survival time, but the last 4 of 7 mice died on day 37 after tumor transplantation; in this way, the median survival time cannot be used properly for comparison. However, the average survival time of the control group (29 days) and the group treated with GnRH-III derivative (33 days) shows 14% increase. According to the Kaplan−Meier curves, the longest survival (40 days) was found in the case of the group treated with Dau-GnRH-III conjugate on days 4 and 7 (compared to the control group, $p = 0.0009$, log-rank test).

The results show that the animals survived the lethal dose of daunorubicin if it was conjugated to GnRH-III derivative as a targeting moiety even in the case of repeated treatments. A single treatment with Dau-GnRH-III conjugate using 15 mg Dau content/kg body weight provided tumor growth inhibition similar to the treatment with daunorubicin 5 × 2 mg, but the lifetime was lengthened by using the conjugate instead of the free drug. Furthermore, the elevation of the number as well as the earlier start of treatments increased the efficiency of the conjugate. Significant tumor growth inhibition and survival of mice were observed in the case of treatment on days 4 and 7 using 62.5 mg (26.6 μmol)/kg body weight. Further optimization of the treatment schedule and doses (determination of MTD; maximal tolerated dose) is in progress.

CONCLUSIONS

In the present study, we report on the conjugation of daunorubicin to GnRH-III through the oxime bond. Considering the chemical and biological stability of the oxime bond, a tetrapeptide spacer cleavable by Cathepsin B was incorporated between the drug and the hormone. Dau-GnRH-III and Dox-GnRH-III conjugates had less but significant in vitro antitumor effects on MCF-7 human breast and C26 murine colon carcinoma cells compared to the free drugs. It is worth mentioning that daunorubicin conjugates previously prepared in our laboratory using branched-chain polypeptides with polylysine backbone (EAK and SAK) as carriers and *cis*-aconitic acid (cA) pH labile spacer had significantly less antiproliferative effect in vitro on C26 tumor cells (IC_{50} = 117.4 μM (cAD-SAK) and 629.9 μM (cAD-EAK)) and MDA-MB 435 P human breast cancer cells (IC_{50} = 195.2 μM for both) (*46*).

The in vivo antitumor effect of the new Dau-GnRH conjugate was determined on mice transplanted with a fast-growing, aggressive tumor type (C26 colon tumor). We found that higher daunorubicin content than the lethal dose was well-tolerated in the case of Dau-GnRH-III conjugate administration. Dau-GnRH-III could decrease the tumor growth similarly to daunorubicin (∼23%) in the case of a single treatment. The animals treated with Dau-GnRH-III had longer survival times compared to the untreated control group, while mice treated with the free drug died early. The repeated treatment with the conjugate (15 mg daunorubicin content/kg body weight) increased significantly the tumor growth inhibition (∼32%). We also found that the earlier start of the treatment had a positive effect on the efficiency (∼46% inhibition). In conclusion, the Dau-GnRH-III conjugate in which the components are connected by an oxime bond exhibited antitumor effect both in vitro and in vivo. To our knowledge, this is the first Dau-peptide conjugate containing an oxime bond that has in vivo antitumor activity. The conjugate was well-tolerated and did not show significant toxic side effects even in high doses. In spite of the significant tumor inhibition of Dau, the effect on survival was considerably decreased by the late toxic effect. In contrast to Dau, in addition to the tumor inhibitory effect, the prolongation of the lifetime was observed in the case of conjugate-treated tumor bearing mice. The pharmacological optimization of the treatment using the Dau-GnRH-III conjugate as well as the detailed study of the mechanism of action of the conjugate are in progress. Furthermore, in vitro and in vivo antitumor activity of Dau-GnRH-III conjugate will be tested on other types of tumors.

Received November 13, 2008; Revised Manuscript Received January 18, 2009

Sequence-specific camptothecins are useful tools to inhibit specifically gene expression. The camptothecins are attached to the 3′ end of triplex-forming oligonucleotides (TFO), sequence-specific DNA ligands that position the camptothecin moiety exclusively in proximity to their binding site. We studied here different gimatecan derivatives or analogues, a potent lipophilic camptothecin compound in clinical trials. We optimized the synthesis procedure in order to increase the yields and the purity and obtain the conjugates on a large scale. The greatly improved synthesis is now based on the conjugation of a bromoalkyl analogue of gimatecan to the 3′ phosphorothioate of the TFO. We showed that the most efficient conjugate, both in vitro and in HeLa cells, bears the TFO on position 7 of the gimatecan analogue, and it is more efficient than the previous camptothecin conjugates. In addition, the gimatecan-like moiety at the 3′ end of the TFO protects from nuclease degradation.

INTRODUCTION

Topoisomerase I (topo I) is a ubiquitous DNA-cleaving enzyme and an important therapeutic target in cancer chemotherapy (*1*). It controls tightly DNA topology by cleaving transiently DNA on one strand (formation of a cleavage complex), changing its topology by control rotation of the cleaved strand around the intact strand, and religating it to give an intact DNA (*2*). Camptothecins (CPTs, Figure 1), potent topo I poisons, reversibly trap the topo I in the covalent complex with DNA, inducing an accumulation of DNA damage that conducts to cell death (*3*). Two derivatives, topotecan and irinotecan, are used in clinics as anticancer agents. However, a major drawback to their use is the fact that CPTs and other topo I poisons exhibit limited sequence preference. The strategy that we have developed consists of targeting topo I poisons to a specific DNA site upon covalent linkage of the poison, such as CPT, to a sequence-specific DNA ligand and binding of the ligand to DNA. As DNA ligands, we have used triplex-forming oligonucleotides (TFO) and hairpin polyamides (MGB for minor groove binders) (*4*, *5*). We have shown that these sequence-specific CPTs are able to induce a topo I-mediated DNA cleavage specifically at the ligand binding site and represent a valid and efficient tool to inhibit the expression of a reporter gene in cells (*6*). In order to extend their use in vivo, it is necessary to optimize the synthesis of the TFO−CPT conjugates, their activity, and cellular stability. For the synthetic procedure, we aimed to increase the yield and scale-up the process; while to increase the chemical stability and the activity of the conjugates, we studied various derivatives or analogues of gimatecan (ST), a potent CPT derivative actually in clinical trials (*7*) (Figure 1). We tested the roles of (1) the attachment site of the TFO on CPT, (2) the linker arm between the two entities, and (3) the steric hindrance of the oxime substitution.

EXPERIMENTAL PROCEDURES

Mass determination was accomplished by electrospray ionization on a Q-STAR pulsar I (Appleura), and HPLC purifications were performed upon Agilent 1100 using a Xterra reverse-phase C_{18} column (4.6 × 50 mm, 2.5 μm). ^{1}H NMR spectra were recorded in Me_2SO-d_6 on a Varian spectrometer (300 MHz). Oligonucleotides (TFO, sequence reported in Figure 1B) were purchased from Eurogentec and purified using quick spin columns and Sephadex G-25 fine (Biorad). Concentrations were determined spectrophotometrically at 25 °C using molar extinction coefficients at 260 nm calculated from a nearest-neighbor model (*8*). All the drugs were dissolved in dimethyl sulfoxide. 10-HydroxyCPT and other chemicals were purchased from Sigma Aldrich. Radioactive gels were analyzed with a Typhoon 9410 (GE Healthcare) and quantified by ImageQuant. Cell media Dulbecco's modified Eagle's medium (DMEM) and Roswell Park Memorial Institute medium 1640 (RPMI) and other related products were from Invitrogen.

Chemistry. *Attachment of an Aminolinker Arm to 10-Hydroxy-CPT (10OH-CPT), NCPT, or 10-Hydroxy-Gimatecan (10OH-G), N10G.* 10OH-G was synthesized as previously described in ref 7. The synthesis of NCPT was described previously (*9*) and N10G was synthesized according to the same procedure. 6-BOC-aminohexylbromide (8.6 mg, 31 μmol) was reacted with 10OH-G (27 μmol) in anhydrous acetone (10 mL) 12 h at reflux in presence of K_2CO_3 (4.5 mg, 32 μmol). The reaction mixture was filtered and the solvent was removed. The residue was purified by column chromatography using a ethyl acetate/cyclohexane 6:4 as an eluent to give a yellow powder (13.1 mg, 19.7 μmmol (73%)). The protected compound was dissolved

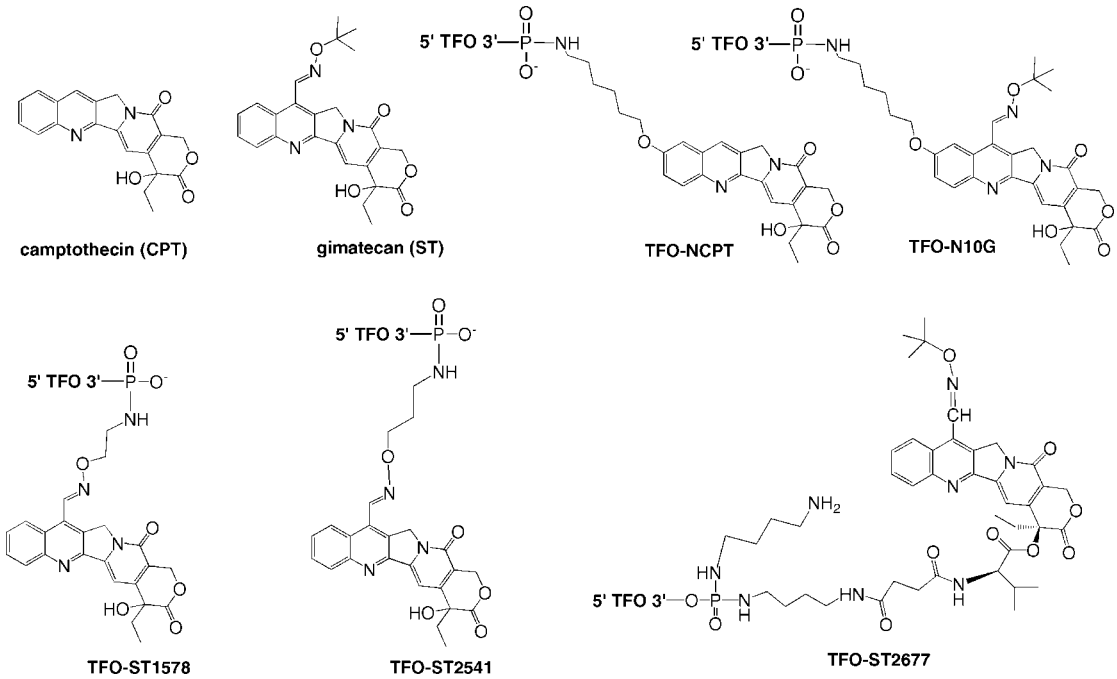

Figure 1. (A) Chemical structures of camptothecin (CPT), gimatecan (ST), and the TFO conjugates. (B) Target DNA and TFO sequence: the triplex site on the target is underlined and the CPT cleavage sites are indicated by arrows. M = 5-methyl-deoxycytidine and P = 5-propynyl-deoxyuridine.

in CH_2Cl_2 /TFA 1:1 and kept at room temperature for 10 min. Solvents were removed under reduced pressure to give a yellow powder (11.1 mg, 19.7 μmmol). ES-MS $[M+H]^+$: found 563.28, calculated 563.28 ($C_{31}H_{38}N_4O_6$). ^{1}H NMR (Me_2SO-d_6): δ (ppm) = 0.88 (t, 3H, J = 7.4 Hz), 1.35−1.65 (m, 15H), 1.79−2.26 (m, 4H), 2.71−2.83 (m, 2H), 4.15 (t, 2H, J = 6.3 Hz), 5.27 (s, 2H), 5.43 (s, 2H), 6.40 (s, 1H), 7.28 (s, 1H), 7.48−7.54 (m, 1H), 7.61 (m, 2H), 8.05 (d, 1H, J = 9.3 Hz), 9.32 (s, 1H).

Synthesis of 7-(2-Aminoethoxy)iminomethylcamptothecin, ST1578. This derivative was synthesized as previously described in ref 7.

Synthesis of 20-O-[N-succinyl-valine]-Gimatecan ST2677. A suspension of gimatecan (1 mmol), $Dy(OTf)_3$ (0.6 mmol), BOC-Valine (3 mmol), DMAP (3 mmol) in 15 mL of dry CH_2Cl_2 was cooled down to −10 °C and after 30 min DCC (3.1 mmol) was added. The reaction mixture was kept 30 min at −10 °C and then 2 h at room temperature. Upon completion, the reaction mixture was diluted with CH_2Cl_2 (20 mL), washed with 1 N aq HCl, the organic fraction was neutralized with sat $NaHCO_3$ and dried over anhydrous Na_2SO_4. Purification by chromatography on silica gel with CH_2Cl_2/MeOH 97:3 gave the desired product as a yellow solid in 92% yield. Rf = 0.72 in CH_2Cl_2/MeOH 96:4. MS (IS): $[M+H]^+$ = 647.1, mp 207 °C (dec).

After BOC-deprotection with CH_2Cl_2/TFA 75:25 at 0 °C and removal of the solvent and excess TFA under reduced pressure, the residue was dissolved in dry pyridine (10 mL), and succinic anhydride (2.5 mmol) was added at 0 °C. The reaction mixture was kept under stirring at room temperature for 1 h until completion. The solvent was removed under vacuum and then the residue dissolved in CH_2Cl_2 and washed with 0.5 N aq HCl. Chromatography on silica gel with CH_2Cl_2/MeOH 95:5 gave the final product with a 90% yield. Rf = 0.41 in CH_2Cl_2/MeOH 92:8. $[M+H]^+$ = 647.5. $[M-H]^-$ = 645.1. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 9.06 (s, 1H, CH), 8.39 (d, J = 8.3 Hz, 1H, CH), 8.29 (d, J = 8.3 Hz, 1H, CH), 7.89 (t, J = 7.7 Hz, 1H, CH), 7.79 (t, J = 7.7 Hz, 1H, CH), 7.69 (s, 1H, CH), 6.39 (d, J = 8.6 Hz, 1H, NH), 5.69 (d, J = 17.7 Hz, 1H, CH), 5.50 (d, J = 17.7 Hz, 1H, CH), 5.46 (s, 2H, CH_2), 4.57 (dd, J = 10.0 Hz, J = 5.3 Hz, 1H, CH), 2.6 (m, 7H, $3CH_2$+CH), 1.53 (s, 9H, tBu), 1.07 (d, J = 6.4 Hz, 6H, $2CH_3$), 0.92 (t, J = 7.1 Hz, 3H, CH_3).

Synthesis of 7-(3-Aminopropoxy)iminomethylcamptothecin ST2541. To a suspension of CPT-7-aldehyde (235 mg, 0.625 mmol), synthesized as in ref 7, in 20 mL of absolute ethanol, *O*-(3-aminopropyl)-hydroxylamine hydrochloride (203 mg, 1.25 mmol) and anhydrous pyridine (0.7 mL) were added. The solution was refluxed for 1 h. After cooling at room temperature, the precipitate was filtered and washed with cold ethanol and diethyl ether to give the title compound as a a yellow solid (138 mg, 49%), mp 187 °C (dec.). R_f = 0.11 CH_3OH/H_2O 9:1 (RP). ^{1}H NMR (300 MHz, DMSO-d_6): δ = 0.86 (t, H_3-18, J = 7.44 Hz), 1.86 (m, H_2-19), 2.07 (m, $-OCH_2CH_2CH_2NH_2$), 2.96 (m, $-OCH_2CH_2CH_2NH_2$), 4.43 (t, $H_2-OCH_2CH_2CH_2NH_2$, J = 5.95 Hz), 5.34 (s, H_2-5), 5.41 (s, H_2-17), 6.52 (bs, -OH), 7.35 (s, H-14), 7.70−8.04 (bs, $-NH_2$), 7.76 (dd, H-10, J = 7.44, 8.19), 7.90 (dd, H-11, J = 7.44, 7.82), 8.22 (d, H-9, J = 8.19 Hz), 8.60 (d, H-12, J = 7.82), 9.34 (s, CH=N).

The synthesis of SCR-CPT and TFO-Ph2 was previously described in ref 6. TFO-ST1578, TFO-NCPT, TFO-ST2541, TFO-L4-ST2677, and TFO-N10G were synthesized as described in refs 9, 10. In the case of ST2677, the CPT derivative was attached through a tetramethylene linker arm. As an example, the synthesis of TFO-N10G is reported.

Synthesis of Conjugate TFO-N10G. A sample of 500 μg (97 nmol) of 3′-phosphorylated oligonucleotide was precipitated as the hexadecyltrimethylammonium salt and dissolved in 50 μL of dry dimethylsulfoxide. Solutions of 4-dimethylaminopyridine (5 mg in 25 μL of DMSO, 41 μmol), dipyridyl disulfide (6.6 mg in 25 μL of DMSO, 30 μmol) and triphenylphosphine (7.9 mg in 50 μL of DMSO, 30 μmol) were added. After 15 min of incubation at room temperature, the activated oligonucleotide was precipitated from the mixture by the addition of 2% $LiClO_4$ in acetone. A solution of 10-aminohexyloxygimatecan (N10G) (0.5 mg, 1 μmol) in 50 μL of DMSO/water 8:2 was added to the activated oligonucleotide. The mixture was kept at room temperature for 2 h. The oligonucleotide conjugate was precipitated by the addition of 2% $LiClO_4$ in acetone, rinsed with acetone, and resuspended from the mixture with double-distilled water to be purified by reversed-phase HPLC using a linear acetonitrile gradient (0→80% CH_3CN in 0.2 M $(NH_4)OAc$)) to obtain 310 μg (54 nmol), yield 56%.

All conjugates were analyzed by UV spectrophotometry and mass spectrometry. TFO-NCPT: ES-MS $[M-H]^-$ = found 5589.5, calculated 5589. TFO-ST1578: ES-MS $[M-H]^-$ = found 5559.7, calculated 5560. TFO-N10G: ES-MS $[M-H]^-$ = found 5688.6, calculated 5688. TFO-ST2677: ES-MS $[M-H]^-$ = found 5596.1, calculated 5578. TFO-ST2541: ES-MS $[M-H]^-$ = found 5573.6, calculated 5574.

Synthesis of Bromoacetamido-ST1578. 3 mg (6 μmol) of ST1578 and 0.8 mg (7 μmol) of DMAP were dissolved in 200 μL of DMSO and 10 μL of TEA. 1 μL (11 μmol) of bromoacetylbromide was added, and the reaction mixture was stirred at room temperature for 2 h under N_2. 500 μL of CH_2Cl_2/acetone 9:1 was added, and the organic phase was extracted 3 times with 500 μL of water and then concentrated. The resulting residue was purified by reverse-phase HPLC using linear acetonitrile gradient (0−90% CH_3CN in 0.1% of TFA) to give a yellow powder (1.3 mg, yield 34%). ES-MS (*m*/*z*): found 554.08 and 556.09. $C_{25}H_{23}BrN_4O_6$ calculated 554.08 and 556.08.

Synthesis of Conjugate TFOPS-ST1578. The salt of a TFO-PS (300 μg, 60 nmol) (NH_4^+ as counterions) was dissolved in 14 μL of water, 7 μL of 18-crown-6, 1.4 μL of DTT 0.5 M, 0.5 mg (0.9 μmol) of bromoacetamide-ST1578 in 70 μL of DMF, and a catalytic quantity of KI were added. The reaction mixture was kept for 16 h at 45 °C. The crude mixture was diluted with 150 μL of water and extracted with a 15/85 v/v mixture of MeOH/CH_2Cl_2. The aqueous phase was concentrated and the oligonucleotide conjugate was purified by reverse phase HPLC using linear acetonitrile gradient (0−80% CH_3CN in 0.02 M (NH_4)OAc), to give 150 μg, yield 47%. MS (*m*/*z*): found 5632.6, calculated 5633.

Biology. *Sequence-Specific DNA Cleavage by the Conjugates.* Sequence-specific Topo I-mediated DNA cleavage was assessed as in ref 5 at 37 °C and pH 7.2. In the presence of the conjugates, the number of cleavage sites is reduced to one, located right downstream of the 3′-end of the triple helix site, as expected from the experimental design (Figure 1B).

Cell Cultures. Human HeLa cells were grown in DMEM supplemented with 10% heat-inactivated fetal bovine serum (FBS), 2 mM L-glutamine and 1% penicillin−streptomycin, at 37 °C and 5% CO_2.

Conjugates Stability in Cells or Cellular Media. Conjugates were 5′-OH labeled with [γ-^{32}P]ATP (GE Healthcare) by T4 polynucleotides kinase (New England Biolabs).

Stability Assay in RPMI 1640 or DMEM Medium Alone. 15 nM of each radiolabeled conjugate and TFOP (3′ phosphorylated TFO) were incubated at 37 °C in 300 μL of RPMI 1640 or DMEM medium (containing 10% FBS, 1% penicillin−streptomycin, and 2 mM L-glutamine). After 24 h and 72 h, 150 μL of this medium was precipitated in ethanol. Samples were then resuspended in 95% formamide and heated at 90 °C for 3 min before being loaded onto a denaturating 15% polyacrylamide gel (19:1 acrylamide/bisacrylamide) containing 7 M urea in 1 × TBE.

Stability Assay in HeLa Cells. This experiment was performed in a 96-well plate containing 125 μL of HeLa cells at a concentration of 122 000 cells/mL and 61 000 cells/mL, for 24 h and 72 h, respectively, in DMEM cell medium containing 10% FBS, 2 mM L-glutamine, and 1% penicillin−streptomycin at 5% CO_2 and 37 °C. 15 nM of each radiolabeled conjugate or TFOP were added. After 24 h or 72 h, the supernatant was precipitated in ethanol.

In parallel, after supernatant removal, the cells in the wells were lysed with 200 μL 10 mM Tris HCl pH 8, 10 mM EDTA, 0.5% Triton X-100, and incubated 15 min on ice, followed by centrifugation 15 min at 1500 *g* and 4 °C. The soluble supernatant was retired and treated with RNase A (50 μg/mL 20 min at 37 °C) and proteinase K (50 μg/mL 35 min at 50 °C) and precipitated in ethanol.

After ethanol precipitation, all samples were resuspended in 95% formamide and heated at 90 °C for 3 min before being loaded onto a denaturating 15% polyacrylamide gel (19:1 acrylamide/bisacrylamide) containing 7 M urea in 1 × TBE buffer.

Transient Expression Experiments. Transfections were performed by using Superfect (Qiagen) as described in ref 6. Both luciferase activities (*Pyralis* and *Renilla*) were measured in cell lyses by using the dual-Luciferase Reporter Assay System (Promega). A luminometer (Victor, Wallac) was used to measure light signal output. The experiments were run as triplicates. The results are reported as mean *Pyralis*/*Renilla* ratio and are further normalized to the ratio of the cells not treated by the conjugates. The total protein amount was measured with the Bio-Rad Protein assay, according to the manufacture instructions. Experiments were repeated from 3 times.

ICE (in vivo Complex of Enzyme) Bioassay. HeLa cell nuclei were prepared as described previously (*6*) and the in vivo Topo I link kit of TopoGEN, Inc. (Columbus, OH) was used to determine the ability of the conjugates to induce Topo I-mediated DNA breaks in treated HeLa cell nuclei. The recommended protocol was followed with a few modifications as described in ref 6. Fractions 1−4 contain free Topo I. DNA-Topo I covalent complexes can be detected in fractions 8−11 of the drug-treated samples. To quantify the amount of cleavage complexes formed in the presence of free or conjugated CPT, the percentage of signal in the fractions 8−11 was normalized to the total amount of Topo I signal in all fractions for each sample.

RESULTS AND DISCUSSION

Optimization of the Conjugate. We have already clearly shown that the efficacy of the conjugates depends on the potency of the inhibitor, the linker arm and the attachment site (*5, 11, 12*). Here, we chose to covalently link gimatecan (Figure 1), a very potent camptothecin derivative actually in clinical trials (*1, 7, 13*). Gimatecan has an oxime group that confers high antitumoral activity due to the lipophilic character of the compound, the improved pharmacokinetics, the more stable cleavage complexes, and the slower lactone ring opening (*7, 14*).

We tested different attachment points on gimatecan and its analogues (Figure 1A): positions 10 (N10G), 7 (ST1578), and 20 (ST2677). The first two attachment points gave very active conjugates in the case of CPT (*5*), while it has been shown that 20 ester derivatives of CPT (attachment of poly(L-glutamic acid), maleimide, or sugars) improve the intratumoral delivery and increase water solubility, giving enhanced antitumoral activity (*15*−*17*). In all experiments, we used, for comparison, CPT attached through position 10 (10-hydroxyCPT). 10-hydroxyCPT (10OH-CPT) and 10-hydroxygimatecan (10OH-G) were attached through an hexamethyleneamino linker to the 3′ phosphorylated TFO following the described procedure (*10*). ST2677 was attached through a tetramethylene linker following the same procedure, while ST1578 was reacted directly without the addition of a linker arm.

As TFO model system, we used the one previously described in our studies, consisting of a 16-mer triplex site and a pyrimidine-motif TFO containing 5-methyl-deoxycytidines instead of deoxycytidines and 5-propynyl-deoxyuridine instead of thymidines (Figure 1B) (*12*).

Figure 2A,B shows the ability of these newly synthesized conjugates (TFO-N10G, TFO-ST1578, TFO-ST2677) to induce topo I-mediated DNA cleavage at the target site. All conjugates strictly restricted DNA cleavage by topo I to the 3′-side of the duplex/triplex junction at site *b*. Cleavage at sites *a*, *c*, and *d* of

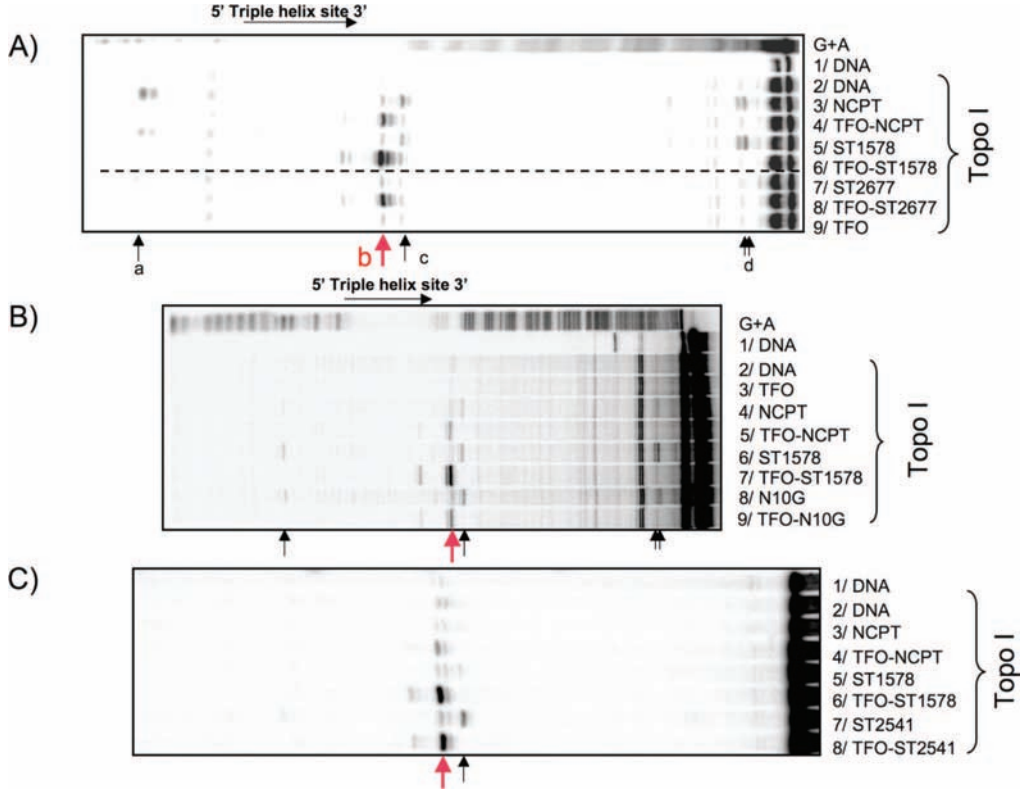

Figure 2. Cleavage products mediated by topo I were resolved on a 8% polyacrylamide gel containing 7 M urea. Adenine/guanine-specific Maxam−Gilbert chemical cleavage reaction were used as markers (lane G+A). (A) Target duplex alone (lane 1), incubated with 10 units of topo I (lane 2) and in the presence of 10 μM NCPT (lane 3); 1 μM TFO-NCPT (lane 4); 10 μM ST1578 (lane 5); 1 μM TFO-ST1578 (lane 6); 10 μM ST2677 (lane 7); 1 μM TFO-ST2677 (lane 8); and 1 μM TFO (lane 9). The three latter samples were investigated at pH 6.2, because the TFO does not contain the 5-propynyl-deoxyuridine modification that stabilizes the triplex at pH 7.2. (B) Target duplex alone (lane 1), incubated with 10 units of topo I (lane 2) and in the presence of 1 μM TFO (lane 3); 10 μM NCPT (lane 4); 1 μM TFO-NCPT (lane 5); 10 μM ST1578 (lane 6); 1 μM TFO-ST1578 (lane 7); 10 μM N10G (lane 8); and 1 μM TFO-N10G (lane 9). (C) Target duplex alone (lane 1), incubated with 10 units of topo I (lane 2) and in the presence of 10 μM NCPT (lane 3); 1 μM TFO-NCPT (lane 4); 10 μM ST1578 (lane 5); 1 μM TFO-ST1578 (lane 6), 10 μM ST2541 (lane 7); 1 μM TFO-ST2541 (lane 8).

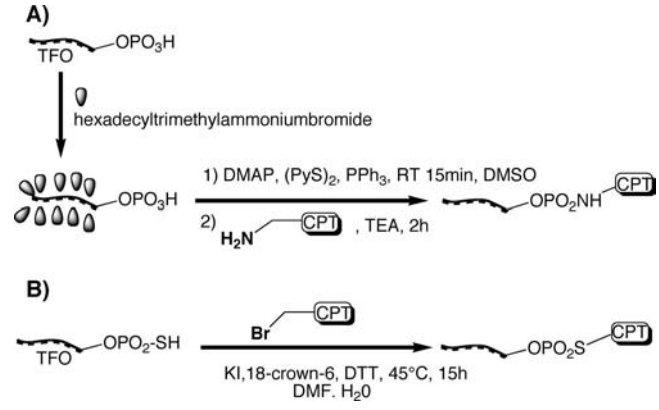
the free camptothecins completely disappeared. This is a strong indication that the enzyme has been targeted to a specific region. The efficacy of cleavage by TFO-ST1578 is six times stronger than the efficacy of cleavage by TFO-NCPT and three times stronger than the efficacy of cleavage by TFO-N10G. TFO-ST2677 is equivalent to TFO-NCPT. Therefore, the most efficient conjugate is the TFO-ST1578, where the TFO is attached to the oxime substituent in position 7.

To further optimize the TFO-ST1578 conjugate, we increased the length of the side chain on the oxime group of ST1578 by a methylene group, obtaining conjugate TFO-ST2541 (Figure 1A). As shown in Figure 2C, the two conjugates, TFO-ST1578 and TFO-ST2541, are equivalent in efficacy.

Optimization of the Synthesis. Biological tests need large amounts of conjugates; therefore, it is necessary to develop a large-scale synthesis. The question that we addressed was whether it is possible to do semipreparative synthesis in the liquid phase. We used two classical pathways (Scheme 1): (A) the reaction of a primary amino group of the drug on the terminal phosphate (P) of the TFO upon activation by triphenylphosphine and dipyridylsulfide, routinely used to synthesize TFO-CPT conjugates (*10*), and (B) the reaction of an halide linker arm on the drug to a terminal thiophosphate group (PS) on the TFO, used to couple daunomycin to TFOs (*18*). A major advantage of the latter is that the drug is attached to the TFO through a chemical bond resistant to acidic treatment.

Conjugate TFOPS-ST1578. An haloacetamido linker has been attached to the amino side chain of the ST1578 derivative and then reacted with the TFO bearing a thiophosphate group (PS) at the 3′ end (Figure 3A). While we were not able to obtain the iodoacetamido derivative of ST1578, the bromoacetamido one gave high yields of the wanted conjugate. The ability of the conjugate TFOPS-ST1578 to induce sequence-specific topo I-mediated DNA cleavage was compared to that of TFO-ST1578, obtained by procedure A (Figure 3B). The two conjugates give comparable results: they both induce a selective cleavage on the DNA at the site where the drug is positioned specifically by the formation of the triple helix with a comparable efficacy of cleavage.

Scheme 1. Two Chemical Pathways Were Used for the Formation of the Conjugates



Comparison of the Two Synthetic Pathways. The two methods were compared in parallel. Increasing quantities of TFO were engaged in the two pathways. At the end of the synthesis, a

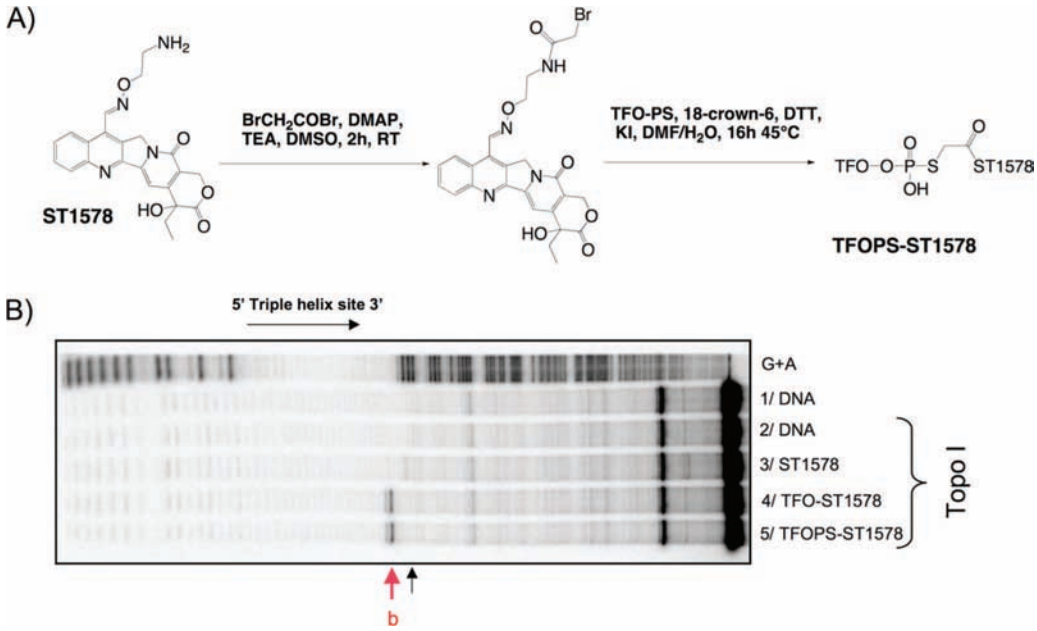


Figure 3. (A) Synthesis of TFOPS-ST1578. (B) Cleavage products mediated by topo I were resolved on a 8% polyacrylamide gel containing 7 M urea. Adenine/guanine-specific Maxam−Gilbert chemical cleavage reaction were used as markers (lane G+A). Target duplex alone (lane 1), incubated with 10 units of topo I (lane 2) and in the presence of 10 μM ST1578 (lane 3); 1 μM TFO-ST1578 (lane 4); and 1 μM TFOPS-ST1578 (lane 5).

Table 1. Yields of Pathway 1 where TFOP Was Reacted with ST1578 and of Pathway 2 where TFOPS Was Reacted with Bromoacetamido-ST1578 (Scheme 1 and Figure 3A)

TFO (mg)		1	2	5	10
total yield (%)	TFOP	61	51	26	21
	TFOPS	71	68	65	64

sample of the reaction mixture was analyzed by gel electrophoresis to determine the relative quantities of free oligonucleotide and of conjugate, in order to deduce the apparent yield of synthesis. In addition, after HPLC purification and characterization by UV−vis spectrometry and mass spectrometry, the final yield of the reaction was determined by standard quantification of the conjugate by UV absorbance. The yields obtained in the two pathways are compared in Table 1.

We observed an important decrease in yield upon increase of the quantities of TFOP engaged when pathway A was used. We think that this is due to the presence of CTAB in the reaction mixture during the precipitation with acetone/$LiClO_4$. Pathway B did not present this problem; the yields are constant, and furthermore, it works at higher quantities of TFOPS (up to 50 mg). In conclusion, pathway B presents several advantages: it is easier to carry out, is more reproducible, no side products are formed, large-scale synthesis is possible, the covalent linkage between the drug and the TFO is more stable, and the conjugate is equally efficient. Therefore, this is the pathway of choice for the liquid-phase synthesis of the conjugates.

Cellular Stability of the Conjugates. It is commonly known that unprotected oligonucleotides are rapidly degraded in cells by the action of nucleases and, in particular, 3′ exonucleases (*19*). Therefore, we tested whether the presence of the ST derivative at the 3′ end of the TFO would protect it from degradation. Unconjugated TFOP, phosphorylated at the 3′ end, was used as control. The 5′-radiolabeled TFOP or conjugates were added to RPMI 1640 or DMEM cell medium or to HeLa cells.

TFOP is strongly degraded both in the cellular media (RPMI 1640 and DMEM) and in cells. Noteworthy, the degradation of TFOP is higher in RPMI 1640 than in DMEM. This is related to the different composition of the two media (http://www.invitrogen.com/site/us/en/home/support/Product-Technical-Resources/media_formulation.116.html and http://www.invitrogen.com/site/us/en/home/support/Product-Technical-Resources/media_formulation.220.html). The presence of a camptothecin derivative, attached through position 7 or 10, protects the conjugates from nuclease degradation (Table 2). This is most evident after 72 h incubation. Samples were also analyzed by HPLC and MS: no free CPT or ST derivatives were found.

Table 2. Cellular Stability of the Conjugates[a]

	DMEM	RPMI	cells
TFOP	29	20	40
TFO-ST1578	80	74	100
TFO-ST2541	95	90	100
TFOPS-ST1578	95	97	100
TFO-NCPT	86	97	n.d.
TFO-N10G	100	95	98

[a] Percentage of the remaining amount of conjugate after 24 h incubation in DMEM or RPMI media or in HeLa cells. S.E. 5%. n.d. = not determined.

We also tested their stability in cells. Cells were lysed after 24 or 72 h, and the radiolabeled oligonucleotides were recovered and analyzed on a denaturing gel (Table 2, Supporting Information Figure 1). In general, degradation is less important than in just the cell media. However, we still observe a strong degradation of TFOP, while the conjugates are stable in these conditions, protected by the presence of the drug at their 3′ end. Once we had confirmed the chemical stability of the conjugates in cells, we tested their ability to modulate gene expression in cells.

Cellular Activity. The experimental design was described previously (*6*). Briefly, the duplex containing the triplex site and CPT cleavage sites a, b, and c was cloned in the pGL3 Promoter vector in the transcribed region upward of the *Pyralis* luciferase gene. This expression vector is cotransfected by Superfect together with the expression vector for *Renilla* luciferase (pRL-TK) in the absence or in the presence of different conjugates at the indicated concentration. 24 h after transfection, the cells are lysed and tested for luciferase activity. Figure 4A shows the mean value of the ratio between the

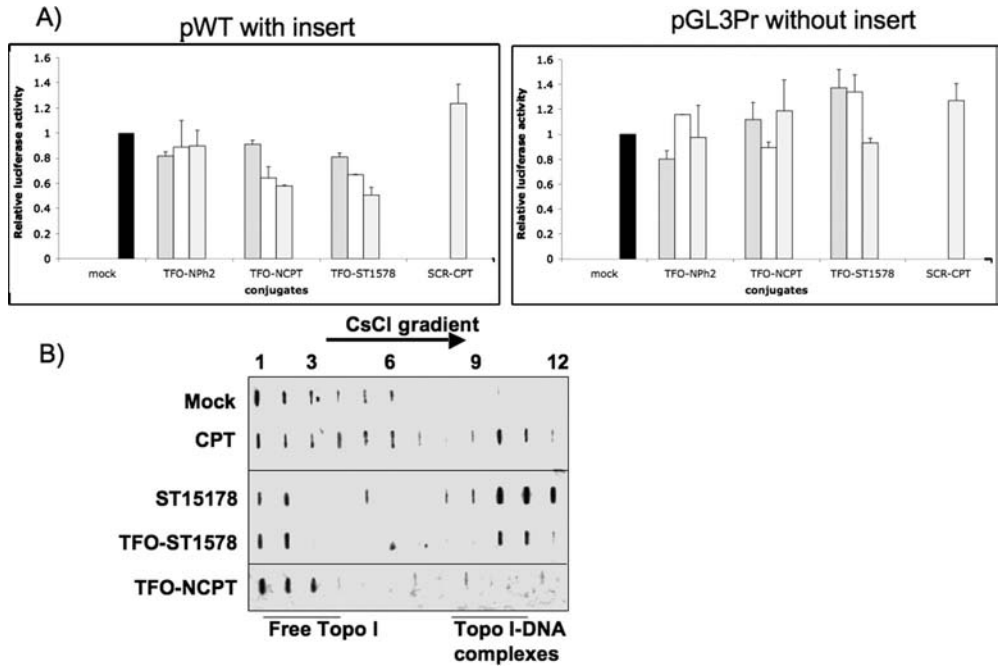

Figure 4. (A) HeLa cell lysates were assayed for firefly and *Renilla* luciferase activities after transfection by Superfect. The firefly luciferase construct was introduced with the control expressing vector RL-TK in the absence (black bars) or presence of the various oligonucleotides, TFO-NPh2, TFO-NCPT, TFO-ST1578, or SCR-CPT at 0.05 μM (hatched bars), 0.1 μM (white bars), or 0.5 μM (dotted bars). The results are presented as mean firefly/*Renilla* luminescence intensity ratios of triplicates (relative luciferase activity) and normalized to the value obtained in the absence of the oligonucleotides (none). Left panel, pWT construct at 24 h after transfection. Right panel, pGL3Pr control vector at 24 h after transfection. (B) Immunoblot analysis of topo I-DNA covalent complexes stabilized by topo I inhibitor in HeLa cell nuclei. 5×10^6 HeLa cell nuclei were incubated for 3 h at 37 °C in the presence or absence of compounds (5 μM). The lysates obtained were applied to a CsCl gradient and centrifuged overnight. Twelve fractions were collected and analyzed by the slot blot. Fractions 1−4 contained free topo I. Topo I/DNA covalent complexes were detected in fractions 8−11. Results are representative of three independent experiments.

luminescence signal of *Pyralis* and *Renilla* normalized to untreated cells.

We compared the activity of conjugate TFO-ST1578 to conjugate TFO-NCPT, the former being the most efficient conjugate in vitro of the gimatecan family. As control, we used the TFO linked at its 3′ end to NH_2-$(CH_2)_4$-NH_2 and then to a diphenylacetic acid (TFO-NPh2) to protect it from 3′-exonuclease degradation, and SCR-CPT, where CPT is attached through a NH_2-$(CH_2)_6$-NH_2 linker to an oligonucleotide, containing the same modified bases, that cannot bind to the target sequence. Clearly, while the controls have no effect even at 0.5 μM, the highest concentration tested, TFO-ST1578 efficiently inhibits luciferase expression up to 50% at 0.5 μM, slightly better than TFO-NCPT. TFO-ST2541 gave comparable results to TFO-ST1578, and both conjugates are active up to 72 h (Supporting Information Figure 2). The conjugates have no effect on the parent reporter gene plasmid pGL3Pr that has no insert (and thus no triplex can be formed).

In order to evaluate if TFO-ST1578 induced the stabilization of the topo I/DNA cleavage complex in cells, we performed ICE bioassays, which detect the formation of the covalent topo I/DNA complexes in cells (*20*). HeLa cell nuclei were incubated for 3 h at 37 °C with CPT or ST1578 alone or the conjugates or the control oligonucleotide TFO-NPh2. The samples were lysed with an ionic detergent, and proteins that were covalently attached to genomic DNA were separated from free proteins by sedimentation through a CsCl gradient by ultracentrifugation. As shown in Figure 4B, 12 fractions were recovered and analyzed by Western slot blot to detect the fractions containing topo I. In the control samples with no drug, topo I was found exclusively at the top of the CsCl gradient as free protein (fractions 1−3). In contrast, with drug-treated cells, Topo I was found in the top fractions as well as in the lower fractions 8−11 near the bottom of the gradient where the nucleic acids were localized (as judged from absorbance measurements at 260 nm), corresponding to TopoI/DNA complexes. In fact, in these complexes the enzyme is covalently linked to the DNA; therefore, the Topo I is found also in the fractions containing DNA (the lower fractions). Such complexes (bands in fractions 8−11) were visualized in the presence of CPT and ST1578, as expected, but also with conjugates and in particular with TFO-ST1578. These data indicate that TFO-ST1578 and TFO-NCPT are able to stabilize topo I/DNA complexes. Table 3 shows that the ratio of Topo I bound to DNA/TFO-ST1578 is very efficient in trapping the enzyme on the DNA.

Table 3. Ratio of the Topo I Bound/Topo I Free from ICE Experiments[a]

	Topo bound/Topo free
mock	0
CPT 5 μM	0.56
CPT 1 μM	0.40
ST1578 5 μM	3
ST1578 1 μM	1
TFO-NPh2	0.02
TFO-NCPT	0.32
TFO-ST1578	0.95

[a] S.E. 20%.

CONCLUSIONS

We have shown that the novel sequence-specific camptothecins based on gimatecan analogues are able to induce a targeted DNA cleavage mediated by topoisomerase I with a highly increased efficacy. Therefore, these triplex-forming gimatecan analogues are very promising for applications in cells. The synthesis of the camptothecin conjugates has been greatly improved upon use of halido derivatives and optimized for scale-up development. Finally, these new conjugates show an

increased resistance to nuclease degradation. In conclusion, a new step forward has been made in the development of a new family of compounds aimed at a targeted therapy.

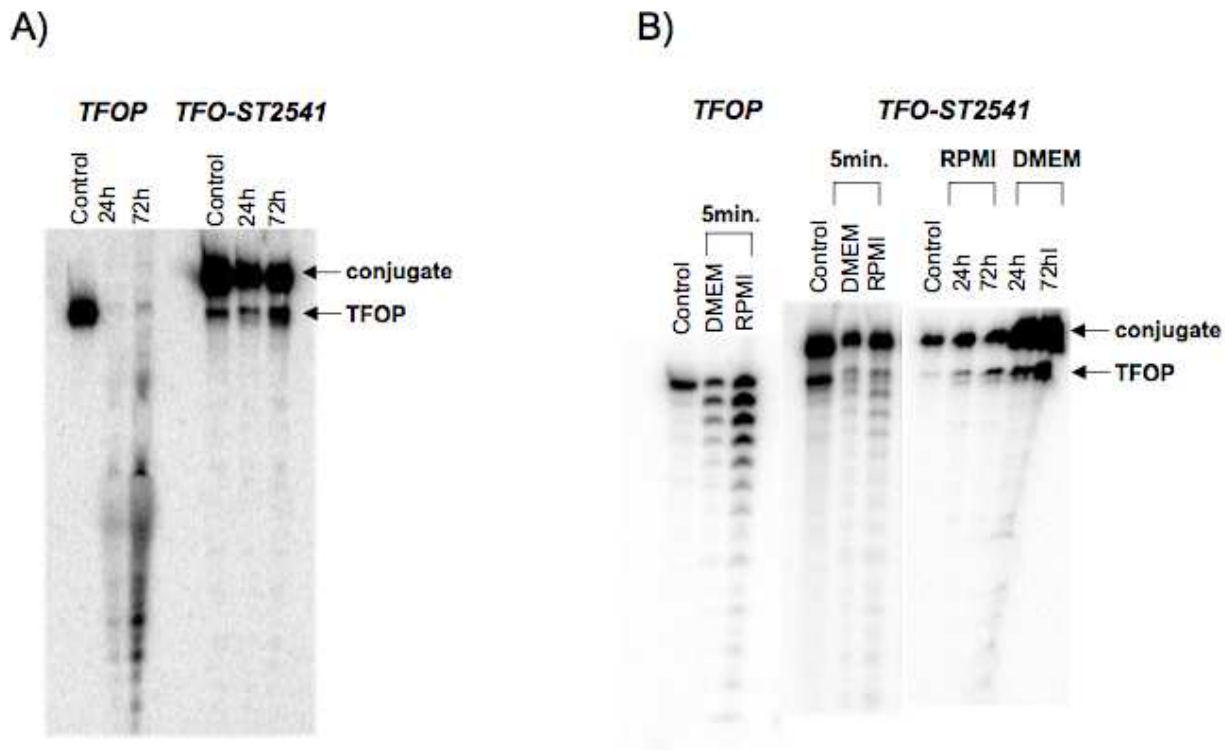
The chemical stability of the conjugates was evaluated in HeLa cells and in DMEM and RPMI1640 cellular media. The 5'-end radiolabeled oligonucleotides were incubated in cell culture medium containing 10% fetal bovine serum at 37°C or in 96-wells plate containing HeLa cells at 37°C and 5% CO_2. Aliquots were removed after 5 min., 24h or 72h and analyzed on a 20% denaturing gel. Figure S1 shows a typical result: conjugate TFO-ST2541 is protected from degradation by the ST derivative in 3' while the parent TFOP is degradated. Degradation is more important in the cell media (Fig.S1B) than in the cells directly (Fig.S1A).

Figure S1

A) Stability in HeLa cells at 24 and 72h for TFOP and TFO-ST2541. B) Stability in DMEM and RMPI1640 media: TFOP was collected after 5 min. incubation at 37°C, TFO-ST2541 was analyzed after 5 min., 24h and 72h. Control represents the radiolabled TFOP or TFO-ST2541 without further treatment.



Conjugates TFO-ST1578 and TFO-ST2541were able to inhibit the expression of *Pyralis* reporter gene in HeLa cells up to 72h after transfection with Superfect™. Conjugate TFO-NCPT was used as positive control and TFO-NPh2 and SCR-CPT as negative controls.

Figure S2

HeLa cell lysats were assayed for *firefly* and *Renilla* luciferase activities after transfection by Superfect™. The *firefly luciferase* construct was introduced with the control expressing vector RL-TK in the absence (black bars) or presence of the various oligonucleotides, TFO-NPh2, TFO-NCPT, TFO-ST1578 or HIV-CPT at 0.05 μM (hatched bars), 0.1 μM (white bars) or 0.5 μM (dotted bars). The results are presented as mean *firefly/Renilla* luminescence intensity ratios of triplicates (relative luciferase activity) and normalized to the value obtained in the absence of the oligonucleotides (none). Left panel, pWT construct at 72h after transfection. Right panel, pGL3Pr control vector at 72h after transfection.

Suitable glycan derivatives will find immediate application in the study of their interactions. Here, we present an efficient synthetic strategy to introduce a fluorescent tag functionalized with an amino group into a model disaccharide structure (lactose). This strategy led to the maintenance of bioactivity, checked by the study of the interaction of this bioconjugate with a plant lectin (mistletoe lectin 1) by NMR spectroscopy, computational docking, and surface plasmon resonance (SPR). To demonstrate the versatility of this approach, we immobilized the new glycan derivatives on different surfaces, and a comparative analysis is presented and can be successfully used for biomimetic carbohydrate−protein interaction studies on the SPR biochip.

INTRODUCTION

The emerging concept of the sugar code defines glycans as biochemically ideal for high-density coding and ascribes the table to translate these sugar-encoded messages into cellular responses to receptor proteins such as lectins. Because of the wide range of glycan functionality, it is obvious that the development of analytical procedures to probe carbohydrate−protein and carbohydrate−carbohydrate interactions and of suitably tailored glycans is a challenge with medical implications. In terms of synthetic aspects, there is a need for approaches that enable proper functionalization of the glycans. One of the strategies for glycan derivatization goes through the generation of amine reactive compounds by conversion of free glycans into glycosylamines (*1*−*3*). However, these glycosylamines derivatives are generally unstable so that they are recovered in poor yields, are readily hydrolyzed, and often afford undesirable side products.

Furthermore, it is well established that glycans with free reducing ends readily react by reductive amidation with primary aryl amine reagents, such as fluorescent compounds 2-aminopyridine (*4, 5*) or 2,6-diaminopyridine (*6*−*8*). However, for the first molecule, monoaminated derivatives preclude further derivatization of the obtained molecule, for instance, by biotinylation or by covalent attachment to protein carriers or solid supports. Also, in both methods the structural integrity of the glycan is modified, which may influence its biological function, e.g., its binding properties to lectins in biological information transfer.

At the same time, surface plasmon resonance (SPR) has proven particularly suitable for the study of lectin−carbohydrate interactions (*9*−*11*). A major issue in all surface-based techniques is the immobilization of the desired ligand onto a solid surface. Covalent attachment is preferred over other specific immobilization methods, such as biotin/streptavidin-mediated attachment or hydrophobic interactions, as it allows an easy control of the immobilization level. One of the more important requirements for a covalent carbohydrate immobilization on a surface is the spacer between the glycan and the surface. This linker chain should provide optimal presentation of glycans and prevent nonspecific binding (*12*). A number of investigators have tackled the challenges of carbohydrate immobilization. Mainly, one linker system has been devised for the attachment of carbohydrate to a surface. This approach relies on the formation of alkane thiolate monolayers on a gold surface (*13, 14*).

Here, we present an efficient synthesis of a new fluorescent-glycan that can readily be immobilized on different surfaces. This methodology involves the derivatization of a model disaccharide (lactose) with 1,5-diaminonaphtalene (DN). The new glycan derivative is detectable by UV−visible or fluorescence spectroscopy and, in addition, the free amino group enables its coupling to different surfaces functionalized with carboxylic groups in order to carry out SPR studies lowering the nonspecific interactions.

EXPERIMENTAL PROCEDURES

General Procedures. All commercial products were used without any further purification steps. TLC was used to monitor the course of the reactions on Kieselgel plates 60 F_{254} (SDS), a UV-lamp light as well as 10% H_2SO_4 in MeOH, and heating for compound visualization. Column chromatography was carried out, if necessary, on silicagel 60, AC, 40−63 μm (purchased from SDS). Elemental analysis and mass spectrometry were carried out by the Support Services (CAI) of the UCM.

NMR spectra were recorded on Bruker 250, 300, and 500 MHz equipment. Samples were dissolved in the appropriate deuterated solvent ($CDCl_3$ and D_2O), and chemical shifts (δ) are expressed in parts per million (ppm). If necessary for correct assignment, COSY and $^1H-^{13}C$ heteronuclear experiments were performed. Determination of protein concentration was carried out by the method of Bradford (*15*). SPR experiments were performed in a BIACORE-3000 SPR sensor chips, and solutions used for the SPR assays were purchased from BIAcore. The sensorgrams and fittings were processed by the software BIAEvaluation (version 4.1, 2003). Synthesis of compounds **1** to **3** followed published procedures (*16*).

Synthesis of 2-Oxoethyl-(2,3,4,6-tetraacetyl-β-D-galactopyranosyl)-(1→4)-2,3,6-triacetyl-β-D-glucopyranoside (4). Allyllactoside **3** (1 g, 1.48 mmol) was dissolved in anhydrous CH_2Cl_2 (50 mL) at −78 °C, and ozone was introduced in constant flow. After 40 min, remaining ozone was removed with a constant flow of argon for 5 min and an excess of $(CH_3)_2S$ (2 mmol). When the mixture lost its blue color, the cooling bath was removed, and the organic solvent was then evaporated (*R*f: 0.2, hexane/EtOAc 1:2). Purification of the final product was carried out by column chromatography (hexane/EtOAc 1:2), yielding **4** in 75% yield.

^1H NMR (250 MHz, $CDCl_3$): 9.65 (dd, $J = 1.43$, $J = 0.77$, 1H; H-1), 5.35 (dd, $J = 3.3$, $J = 2.5$ Hz, 1H, H-4″), 5.22 (t, $J = 9.3$ Hz, 1H; H-3′), 5.11 (dd, $J = 10.4$, $J = 7.8$ Hz, 1H; H-2″), 5.00 (dd, $J = 9.4$, $J = 7.8$ Hz, 1H; H-2′), 4.96 (dd, $J = 10.3$, $J = 6.8$ Hz, 1H; H-3″), 4.55 (d, $J = 7.9$ Hz, 1H; H-1′), 4.49 (d, $J = 7.8$ Hz, 1H; H-1″), 4.47 (dd, $J = 12.0$, $J = 2.2$ Hz, 1H; H-6′a), 4.26 (dd, $J = 16.0$, $J = 0.8$, 1H; H-1a), 4.17 (d, $J = 15.0$, $J = 0.8$, 1H; H-1b), 4.12 (dd, $J = 11.9$, $J = 2.4$ Hz, 1H; H-6″a), 4.08 (dd, $J = 12.1$, $J = 5.6$ Hz, 1H; H-6′b), 4.06 (dd, $J = 11.9$, $J = 5.7$ Hz, 1H; H-6″b), 3.87 (t, $J = 6.8$ Hz, 1H; H-5″), 3.81 (t, $J = 9.4$, 1H; H-4′), 3.62 (m, 1H; H-5′), 2.16−1.97 (21H; CH_3CO). ^{13}C NMR (63 MHz, $CDCl_3$): 200.04 (C-1), 170.33−169.03 (7-COO-), 101.00 (C-1″), 100.70 C-1′), 76.10 (C-4′), 74.21 (C-1), 72.80 (C-5′), 72.36 (C-3′), 71.10 (C-2′), 70.83 (C-3″), 70.60 (C-5″), 68.94 (C-2″), 66.48 (C-4″), 61.58 (C-6′), 60.70 (C-6″), 20.72−20.46 (7 -CH_3CO). Synthesis of 2-Bromoethyl-(2,3,4,6-tetraacetyl-β-D-galactopyranosyl)-(1→4)-2,3,6-triacetyl-β-D-glucopyranoside (5). To a solution of octaacetyl-lactose (500 mg, 0.74 mmol) in anhydrous CH_2Cl_2 (2 mL) at 0 °C (ice−water bath), 2-bromoethanol (63 μL, 0.89 mmol) was added, and the reaction mixture was stirred under argon atmosphere. After 30 min, $BF_3{\cdot}(EtO)_2$ (600 μL, 3.70 mmol) was dropped over the mixture at 0 °C for 1 h; afterward, the cooling bath was removed and stirred overnight at room temperature. The reaction mixture was finally added over a stirring ice−water bath. The aqueous fraction was extracted with CH_2Cl_2. The organic phase was washed with water, neutralized with $NaHCO_3$, and then again with water. Afterward, the organic phase was dried with Na_2SO_4, and the solvent was removed. Compound **5** was purified by a chromatography column (hexane/EtOAc 1:1). Yield: 40%.

^1H NMR (250 MHz, $CDCl_3$): 5.35 (dd, $J = 3.3$, $J = 2.8$ Hz, 1H; H-4″), 5.14 (t, $J = 9.8$ Hz, 1H; H-3′), 5.03 (dd, $J = 9.8$, $J = 7.8$ Hz, 1H; H-2″), 4.95 (dd, $J = 9.8$, $J = 3.3$ Hz, 1H; H-3″), 4.85 (dd, $J = 9.8$, $J = 7.8$ Hz, 1H; H-2′), 4.43 (d, $J = 7.8$ Hz, 1H; H-1′), 4.41 (d, $J = 7.8$ Hz, 1H; H-1″), 4.42 (dd, $J = 11.9$, $J = 2.4$ Hz, 1H; H-6′a), 4.13 (dd, $J = 11.9$, $J = 2.4$ Hz, 1H; H-6″a), 4.06 (dd, $J = 11.9$, $J = 5.6$ Hz, 1H; H-6″b), 4.02 (dd, $J = 11.9$, $J = 5.6$ Hz, 1H; H-6′b), 3.85 (m, 1H; H-5″), 3.74 (t, $J = 9.8$, 1H; H-4′), 3.73 (t, $J = 6.8$ Hz, 2H; H-1), 3.55 (m, 1H, H-5′), 3.37 (t, $J = 6.8$ Hz, 2H; H-2), 2.1−1.9 (21H; CH_3CO). ^{13}C NMR (63 MHz, $CDCl_3$): 170.76−169.49 (7-COO-), 101.45 (C-1″), 101.45 (C-1′), 76.55 (C-4′), 73.08 (C-5′), 72.92 (C-3′), 71.73 (C-2′), 71.33 (C-3″), 71.02 (C-5″), 70.19 (C-1), 69.42 (C-2″), 66.96 (C-4″), 62.22 (C-6′), 61.18 (C-6″), 30.33 (C-2), 21.29−20.94 (7 -CH_3CO). Analysis calculated for $C_{28}H_{39}BrO_{18}$: C, 45.23%; H, 5.29%. Found: C, 45.26%; H, 5.28%. FAB-MS: [M + Na] Calcd: 765.1300. Found: 765.1297.

Synthesis of 2-Iodoethyl-(2,3,4,6-tetraacetyl-β-D-galactopyranosyl)-(1→4)-2,3,6-triacetyl-β-D-glucopyranoside (6). To a solution of compound **5** (250 mg, 0.34 mmol) in acetone (25 mL), NaI (1.4 g, 9.36 mmol) was added. The mixture was stirred for 3 h at reflux temperature. When reaction was completed, solvent was removed, and the solid substance was redissolved in EtOAc and washed gently with water. Organic phase was then collected, dried with Na_2SO_4, filtered, and the solvent removed. Compound **6** was obtained in quantitative yield.

^1H NMR (250 MHz, $CDCl_3$): 5.37 (dd, $J = 3.3$ $J = 2.8$ Hz, 1H; H-4″), 5.22 (t, $J = 9.8$ Hz, 1H; H-3′), 5.13 (dd, $J = 9.8$, $J = 7.8$ Hz, 1H; H-2″), 4.97 (dd, $J = 9.8$, $J = 3.3$ Hz, 1H; H-3″), 4.92 (dd, $J = 9.8$, $J = 7.8$, Hz, 1H; H-2′), 4.54 (d, $J = 7.8$ Hz, 1H; H-1′), 4.49 (d, $J = 7.8$ Hz, 1H; H-1″), 4.45 (dd, $J = 11.9$, $J = 2.4$ Hz, 1H; H-6′a), 4.15 (dd, $J = 11.9$, $J = 2.4$ Hz, 1H; H-6″a), 4.08 (dd, $J = 11.9$, $J = 5.6$ Hz, 1H; H-6″b), 4.05 (dd, $J = 11.9$, $J = 5.6$ Hz, 1H; H-6′b), 3.80 (m, 1H; H-5″), 3.75 (t, $J = 7.2$ Hz, 1H; H-1), 3.71 (t, $J = 9.8$, 1H; H-4′), 3.63 (ddd, $J = 9.8$, $J = 5.0$, $J = 2.0$, 1H; H-5′), 3.24 (t, $J = 7.2$ Hz, 2H; H-2), 2.1−1.9 (21H; CH_3CO). ^{13}C NMR (63 MHz, $CDCl_3$): 170.80−169.51 (7-COO-), 101.48 (C-1″), 100.93 (C-1′), 76.58 (C-4′), 73.09 (C-5′), 72.98 (C-3′), 71.75 (C-2′), 71.34 (C-3″), 71.04 (C-5″), 70.91 (C-1), 69.43 (C-2″), 66.95 (C-4″), 62.22 (C-6′), 61.18 (C-6″), 2.63 (C-2), 21.33−20.95 (7 -CH_3CO). Analysis calculated for $C_{28}H_{39}IO_{18}$: C, 45.54%; H, 4.97%. Found: C, 45.52%; H, 4.96%. FAB-MS: [M + Na] Calcd: 813.1200. Found: 813.1780.

Synthesis of 2-[1′-(5′-aminonaphthyl)amino]ethyl-*O*-(2,3,4,6-tetraacetyl-β-D-galactopyranosyl)-(1→4)-2,3,6-triacetyl-β-D-glucopyranoside (7). *Method 1.* To a solution of aldehyde lactoside **4** (100 mg, 0.15 mmol) in anhydrous MeOH (5 mL), 1,5-diaminonaphthalene (DN) (117 mg, 0.74 mmol) and AcOH (20 μL) were added, and the reaction mixture was stirred at room temperature under argon atmosphere. After 1 h, compound **4** had reacted completely as determined by TLC (CH_2Cl_2/acetone 12:1), then $NaBH_3CN$ (19 mg, 0.30 mmol) was added, and the mixture was further stirred for 20 h at room temperature. The solvent was then evaporated, and EtOAc was added to the residue and quenched with brine and water. The organic phase was dried (Na_2SO_4), filtered, and the solvent removed with a vacuum pump. Compound **7** was purified by column chromatography (CH_2Cl_2/acetone 12:1) with 50% yield.

Method 2. To a solution of compound 6 (50 mg, 0.07 mmol) in the toluene anhydrous (5 mL) an excess of DN (5 eq) was added, the reaction mixture was stirred under argon atmosphere, at the reflux temperature of toluene. Reaction was monitored by TLC (CH_2Cl_2/MeOH 20:1). Product 7 was purified, by column chromatography (CH_2Cl_2/MeOH 20:1) and isolated in 70% yield.

^1H NMR (300 MHz, $CDCl_3$): 7.28 (t, $J = 7.4$ Hz, 1H; H-3), 7.20 (d, $J = 7.4$ Hz, 1H; H-4), 7.16 (d, $J = 7.4$ Hz, 1H; H-8), 7.12 (t, $J = 7.4$ Hz, 1H; H-7), 6.70 (d, $J = 7.4$ Hz, 1H; H-6), 6.52 (d, $J = 7.4$ Hz, 1H; H-2), 5.27 (dd, $J = 3.3$, $J = 2.8$ Hz, 1H; H-4″), 5.13 (t, $J = 9.2$ Hz, 1H; H-3′), 5.04 (dd, $J = 9.2$, $J = 7.8$ Hz, 1H; H-2″), 4.89 (dd, $J = 9.2$, $J = 3.3$ Hz, 1H; H-3″), 4.86 (dd, $J = 9.2$, $J = 7.8$ Hz, 1H; H-2′), 4.49 (d, $J = 7.8$ Hz, 1H; H-1′), 4.40 (dd, $J = 11.9$, $J = 2.4$ Hz, 1H; 6′a), 4.38 (d, $J = 7.8$, 1H; H-1″), 4.07 (dd, $J = 11.9$, $J = 2.4$ Hz, 1H; H-6″a), 4.03 (dd, $J = 11.9$, $J = 5.6$ Hz, 1H; H-6″b), 4.01 (dd, $J = 11.9$, $J = 5.6$ Hz, 1H; H-6′b), 3.86 (m, 1H; H-5″), 3.80 (t, $J =$

6.8 Hz, 1H; H-10), 3.72 (t, J = 9.2, 1H; H-4′), 3.57 (m, 1H; H-5′), 3.38 (t, J = 6.8 Hz, 1H; H-9), 1.8−2.01 (21H; CH_3CO). ^{13}C NMR (63 MHz, $CDCl_3$): 170.87−169.56 (7-COO-), 143.91 (C-1), 143.07 (C-5), 125.90 (C-3), 125.67 (C-8), 124.90 (C-4a), 124.64 (C-8a), 111.06 (C-4), 110.84 (C-7), 110.46 (C-6), 105.33 (C-2), 101.53 (C-1″), 100.89 (C-1′), 76.71 (C-4′), 73.18 (C-5′), 73.08 (C-3′), 72.03 (C-2′), 71.38 (C-3″), 71.04 (C-5″), 69.43 (C-2″), 68.77 (C-10), 66.97 (C-4″), 62.49 (C-6′), 61.18 (C-6″), 44.02 (C-9), 21.26−20.96 (7-CH_3CO). Analysis calculated for $C_{38}H_{48}N_2O_{18}$: C, 55.61%; H, 5.89%; N, 3.41%. Found: C, 55.62%; H, 5.88%; N, 3.41%. FAB-MS: [M + H] Calcd: 821.2975. Found: 821.2954.

Synthesis of 2-[1′-(5′-Aminonaphthyl)aminoethylene]-*O*-*β*-D-galactopyranosyl-(1→4)-*β*-D-glucopyranoside (8). To a solution of compound **7** in MeOH, catalytic amounts of MeONa were added. The reaction mixture was stirred at room temperature until complete conversion of the acetylated compound was observed by TLC (2-propanol/nitromethane/water, 10:9:2). The reaction mixture was then neutralized with Amberlite-IR 120 [H^+] and filtered. The filtrate was collected, and the solvent was removed. Compound **8** was obtained in quantitative yield.

^1H NMR (500 MHz, D_2O): The assignment is shown in Table 1 of the Supporting Information. ^{13}C NMR (125 MHz, D_2O): 143.42 (C-1), 141.28 (C-5), 126.38 (C-3), 126.08 (C-8), 125.05 (C-4a,C-8a), 113.20 (C-4), 112.64 (C-7), 112.33 (C-6), 107.48 (C-2), 103.20 (C-1″), 102.60 (C-1′), 78.52 (C-4′), 75.61 (C-5′), 75.17 (C-3′), 75.00 (C-2′), 74.56 (C-3″), 73.08 (C-5″), 72.77 (C-2″), 71.20 (C-10), 68.80 (C-4″), 61.31 (C-6′), 60.29 (C-6″), 44.00 (C-9). Analysis calculated for $C_{19}H_{31}N_3O_{11}$: C, 54.75%; H, 6.51%; N, 5.32%. Found: C, 54.78%; H, 6.53%; N, 5.32%. ESI-MS: [M + Na] Calcd: 526.2. Found: 548.9.

Synthesis of 20-Bromo-3,6,9,12-tetraoxatrieicosan-1-ol (9). To a solution of tetraethylen glycol (1 g, 5 mmol) in THF anhydrous, NaH (160 mg, 6.5 mmol) was added, and the reaction mixture was stirred under argon atmosphere at 0 °C. After 3 h, the reaction mixture was dropped over a solution of 1,8-dibromooctane (1.4 g, 5 mmol) under argon atmosphere at 0 °. After 4 h, NaBr formed, and the solvent was removed. Purification of the final product was carried out by column chromatography (CH_2Cl_2/MeOH 20:1), yielding **9** in 40%.

^1H NMR (300 MHz, $CDCl_3$): 3.62 (m, 16H, H-1 to H-8), 3.43 (t, 2H, J = 6.56 Hz, H-9), 3.38 (t, 2H, J = 7.03 Hz, H-19), 1.83 (q, 2H, J = 7.2 Hz, H-18), 1.55 (q, 2H, J = 6.90 Hz, H-10), 1.38 (m, 2H, H-11), 1.25 (m, 12H, H-12 to H-17).^{13}C NMR (125 MHz, $CDCl_3$): 72.63 (C-9), 71.52 (C-7), 70.61 (C-3,C-4,C-5,C-6), 70.28 (C-8), 70.05 (C-2), 61.50 (C-1), 34.00 (C-19), 32.89 (C-18), 29.56 (C-10,C-12,C-13,C-14, C-15), 28.72 (C-11), 28.18 (C-16), 26.13 (C-17). Synthesis of 20-Bromo-3,6,9,12-tetraoxatrieicosan-1-oic Acid (10). Over a solution of **9** (650 mg, 1.7 mmol) in acetone (50 mL), 1 mL of Jones reagent (2.4 mmol of CrO_3) was dropped, and the reaction was stirred for 30 min followed by the addition of a few drops of 2-propanol. Afterward, saturated NaCl solution (20 mL) was added to the mixture and stirred for an additional 30 min followed by the removal of the acetone. The aqueous mixture was extracted with CH_2Cl_2 (3 × 30 mL), and the solvent was then removed. Compound **10** was finally purified by column chromatography (CH_2Cl_2/MeOH 10:1) in 70% yield.

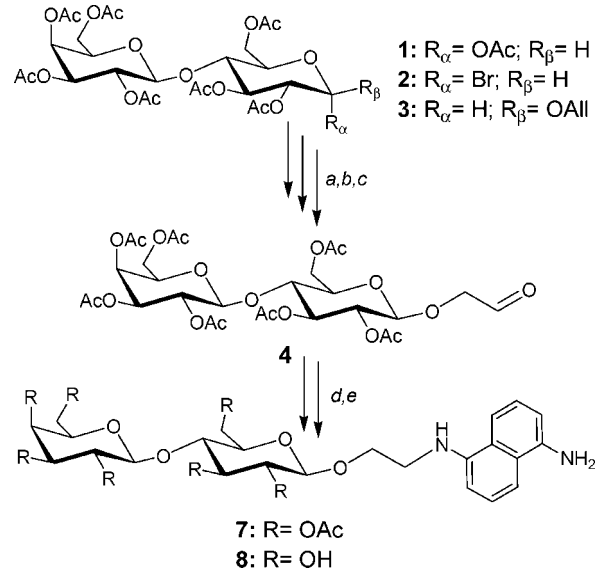
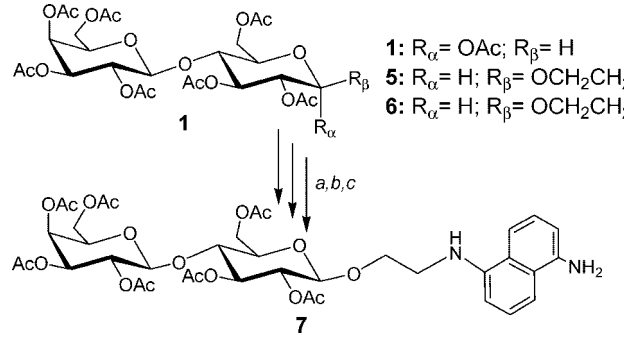
^1H NMR (300 MHz, $CDCl_3$): 6.71 (s, 1H, COOH), 4.13 (s, 2H, H-2), 3.56 (m, 12H, H-3 to H-8), 3.39 (t, 2H, J = 6.90 Hz, H-9), 3.34 (t, 2H, J = 6.85 Hz, H-14), 1.81 (q, 2H, J = 7.16 Hz, H-15), 1.52 (m, 2H, H-10), 1.34 (m, 2H, H-11), 1.28 (m, 6H, H-12,H-13 and H-14). ^{13}C NMR (125 MHz, $CDCl_3$): 173.03 (C-1), 72.07 (C-9), 71.97 (C-8), 70.84 (C-7), 70.74 (C-6), 70.65 (C-5), 70.45 (C-4), 70.34 (C-3), 69.11 (C-2), 34.44 (C-16), 33.10 (C-15), 29.70 (C-10), 29.55 (C-12), 29.00 (C-11), 28.41 (C-13), 26.24 (C-14). Analysis calculated for $C_{16}H_{31}BrO_6$: C, 48.12%; H, 7.82%. Found: C, 48.20%; H, 7.81%. ESI-MS: [M + Na] Calcd: 421.1. Found: 421.0.

Scheme 1. Synthesis of Fluorescent Glycans via Reductive Amination[a]



[a] (a) HBr, CH_2Cl_2 (90% yield). (b) Allyl alcohol, $HgBr_2$, HgO, CH_2Cl_2 (50% yield). (c) O_3, −78°C, CH_2Cl_2. (75% yield). (d) 1. DN, $AcOH_{cat}$, MeOH. 2. $NaCNBH_3$ (50% yield). (e) MeONa, MeOH (quantitative yield).

Scheme 2. Synthesis of Iodoethyl Derivative and Binding to the DN[a]



[a] (a) $BF_3 \cdot Et_2O$, Br-ethanol, CH_2Cl_2 (40% yield). (b) NaI, acetone, reflux (100% yield). (c) DN, toluene, reflux (70% yield).

Synthesis of 20-Mercapto-3,6,9,12-tetraoxatrieicosan-1-oic Acid (11). A solution of **10** (230 mg, 0.5 mmol) and thiourea (120 mg, 1.5 mmol) in 30 mL of water was heated to reflux temperature. After 6 h, NaOH (600 mg, 15 mmol) was added and the mixture stirred for an additional period of 6 h. The mixture was finally cooled to room temperature, and the pH was adjusted to 1 with concentrated HCl. The resulting solution was extracted with CH_2Cl_2 (3 × 20 mL). The combined extracts were dried (MgSO4), evaporated to dryness, and the resulting oil was purified by column chromatography (CH_2Cl_2/MeOH 5:2.) affording compound **11** with a 60% yield.

^1H NMR (300 MHz, $CDCl_3$): 8.23 (s, 1H, COOH), 4.00 (s, 2H, H-2), 3.56 (m, 12H, H-3 to H-8), 3.38 (t, 2H, J = 6.93 Hz, H-9), 2.58 (t, 2H, J = 7.35 Hz, H-19), 1.58 (m, 4H, H-10 and H-18), 1.20 (m, 14H, H-11 to H-17). ^{13}C NMR (125 MHz, $CDCl_3$): 173.03 (C-1), 72.07 (C-9), 71.97 (C-8), 70.84 (C-7), 70.74 (C-6), 70.65 (C-5), 70.45 (C-4), 70.34 (C-3), 69.11(C-2), 34.44 (C-16), 33.10 (C-15), 29.70 (C-10), 29.55 (C-12), 29.00 (C-11), 28.41 (C-13), 26.24 (C-14). Analysis calculated

Lectin Purification and Quality Controls. The galactoside-specific lectin from mistletoe (*Viscum album* agglutinin; VAA) was purified from aqueous extracts of dried leaves by affinity chromatography as a crucial step, using divinyl sulfone activation of Sepharose 4B and lactose as ligand for optimal yields (*17*, *18*). The purity of the product was ascertained by gel electrophosesis and gel filtration and the activity by solid-phase and cell-binding assays, and the activity of both binding sites in the 1α and 2γ subdomains (Trp/Tyr sites) was determined by spectroscopic methods (*19*−*22*).

Conformational Analysis and Molecular Recognition Studies. To record the nuclear Overhauser enhancements (NOE) of the compounds in the free state, a double pulse field-gradient spin−echo (DPFGSE) module was used (*23*). NOE intensities were normalized with respect to the diagonal peak at zero mixing time. Selective T_1 measurements were performed on anomeric and several other protons. Experimental NOEs were fitted to a double exponential function, as described (*23*) $f(t) = p0(e^{-p1t})(1 - e^{-p2t})$, where $p0$, $p1$, and $p2$ are adjustable parameters. The initial slope was determined from the first derivative at time $t = 0$, $f(0) = p0p2$. From the initial slopes, interproton distances were obtained by employing the isolated spin-pair approximation (ISPA).

STD experiments (*24*) were performed without saturation of the residual HDO signal for molar ratios between 20:1 and 50:1 of compound/lectin. A series of Gaussian-shaped pulses of 50 ms was run, with a total saturation time of the protein of 2 s and a maximum B1 field strength of 50 Hz. An off-resonance frequency of $\delta = 40$ ppm and on-resonance frequencies between $\delta = -1.0$ ppm (protein aliphatic signals region) were applied. In all cases, line-broadening of ligand protons was monitored. The STD experiments were repeated twice. Basically, similar results were obtained in both sets. In each case, the intensities were normalized with respect to the highest response, which always corresponded to the Gal H4 proton.

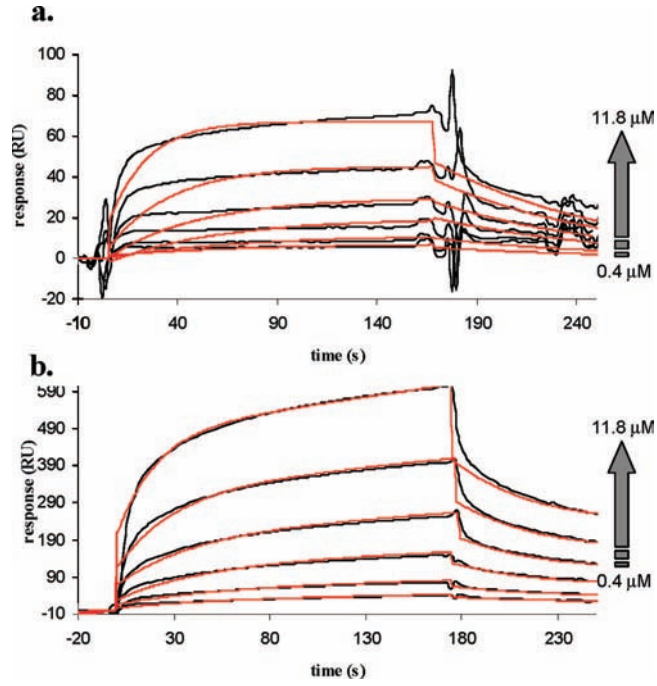

Figure 3. Kinetic study of the interaction between LacDN immobilized on a CM5 sensor chip and VAA. (a) Low density (96 RU). (b) High density (660 RU).

Table 1. Kinetic Parameters Determined by SPR of the Interaction between VAA and LacDN Immobilized on Different Surfaces (1:1 Langmuir Binding Model)

	kinetic study				steady state study
surface	k_{on} ($M^{-1}s^{-1}$)	k_{off} (s^{-1})	K_D (μM)	χ^2	K_D (μM)
C1 (111 RU)					11.9
CM5 (96 RU)	3.45×10^3	1.2×10^{-2}	3.3	3.7	15.3 ± 2.2
CM5 (660 RU)	2.79×10^3	1.7×10^{-2}	6.2	1.6	11.8 ± 1.0
SAM (530 RU)	3.0×10^3	9.2×10^{-3}	3.2	107	7.8 ± 0.1

For the bound ligands, trNOE experiments were performed as described previously (*25*, *26*). The cvff and cff91 force-fields were applied in computational conformational analysis, and also AMBER-based molecular mechanics and dynamics calculations for methyl β-lactoside were performed. Measurements were done with a freshly prepared ligand/lectin mixture, with mixing times of 100, 150, and 200 ms, at an approximately 30:1 molar ratio of ligand/protein. A concentration between 2−3 mM of the ligand was employed in all cases. No purging spin-lock period was employed to remove the NMR signals of the macromolecule background. First, line-broadening of the ligand protons was monitored after the addition of the lectin. Strong negative NOE cross-peaks were observed, in contrast to the free state, indicating binding of the sugars to the lectin preparation (*27*).

Additional experiments were performed with concanavalin A (ConA) as a receptor for negative control. ConA binds glucose or mannose moieties and displays no binding activity for galactose derivatives. No STD or trNOE signals were observed, thus indicating the specificity of the synthetic probe for galactose-binding proteins.

Table 2. Kinetic Parameters Determined by SPR of the Interaction between VAA and LacDN Immobilized on Different Surfaces (Bivalent Analyte Model)

surface	k_{on1} ($M^{-1}s^{-1}$)	k_{off1} (s^{-1})	k_{on2} ($M^{-1}s^{-1}$)	k_{off2} (s^{-1})	K_{D1} (μM)	K_{D2} (M)	χ^2
CM5 (96 RU)	1.64×10^3	4.4×10^{-2}	6.7×10^{-5}	3.1×10^{-4}	26.8	4.6	12
CM5 (660 RU)	8.09×10^2	6×10^{-2}	6.2×10^{-6}	1.2×10^{-3}	74.2	193	19
SAM (530 RU)	6.0×10^2	2.8×10^{-3}	2.4×10^{-5}	4.4×10^{-3}	4.66	183	114

Molecular Mechanics and Dynamics Calculations. All molecular mechanics and dynamics calculations for the free molecules were performed using the MAESTRO package and the MM3* force field (*28*). Charges were taken from the force field (all-atom charge option), and water solvation was simulated using the generalized Born GB/SA continuum solvent model (*29*). The torsion angles Φ are defined as H1Gal-C1Gal−O-C4Glc and Ψ as H4Glc-C4Glc−O-C1Gal. For the pendant chain, Φ chain is H1Glc-C1Glc-O-CH_2, and Ψ chain is C1Glc-O-CH_2−CH_2. The torsion angle around the C5−C6 linkage (ω) is defined as O5−C5−C6-O6. Two different conformers were considered gt ($\omega = +60°$) and gg ($\omega = -60°$) for the Gal and Glc moieties, respectively. The Φ/Ψ maps computed (*30*) from the 3 ns MD simulations (1.5 fs integration sep, 300 K) were built and analyzed as described (*31*). A temperature of simulation of 300 K was employed with a time step of 1.5 fs and an equilibration time of 100 ps. The total simulation time was 3 ns. The GB/SA solvation model was employed. The numbering is given in the corresponding scheme in the Supporting Information.

Docking Calculations. The prevalent conformer of **8** (as observed by NMR) was manually docked into the two carbohydrate-binding sites of VAA in the 1α and 2γ subdomains of the B-subunit of VAA by superimposing the terminal Gal residue (pdb code 1PUM). Then, different possibilities of arranging the side chain of the glycan were used as input geometries for AutoDock 3.0 simulations (*32*) with the multiple Lamarckian genetic algorithm. Only local searches were performed centered in the two experimental galactoside-specific VAA X-ray sites. Grids of probe atom interaction energies and electrostatic potential were generated by the AutoGrid program present in AutoDock 3.0. Grid spacings of 0.6 and 0.375 Å were used for the global and local searches, respectively. For each calculation, 100 docking runs were performed using a population of 200 individuals and an energy evaluation number of 3×10^6.

Immobilization of Compound 8 on a Carboxylated Surface (C1, Biacore). For the immobilization of the fluorescent lactoside **8**, a standard C1 chip (BIAcore) was activated by the injection of the amino coupling kit (BIAcore): EDC/NHS (35 μL) at a flow rate of 5 μL min^{-1}, at 28 °C, and 10 mM Hepes, 150 mM NaCl, pH 7.4 (HBS-P) as running buffer. At the same conditions of flow and temperature, a solution of **8** (1 mM, 150 μL) in 10 mM sodium acetate buffer, pH 4.5, was injected 3 consecutive times to get the maximum immobilization, followed by the injection of ethanolamine (1 M, 35 μL) to block the possible remaining active sites on the dextran matrix. The final response reached was 111 RU (flow cell-1). On a second flow cell, the activation and blocking standard procedures were carried out as described above, and it was left as the negative control of the interaction.

For the interaction assays, different concentrations (1.2, 2.9, 4.7, 5.9, 11.8, and 17.7 μM) of a solution of VAA in the running buffer were injected (15 μL), at a flow rate of 5 μL min^{-1}, at 28 °C. After the injection of the sample, the same buffer (without added protein) was injected to the sensor chip surface to allow dissociation. After a suitable dissociation phase, the sensor surface was regenerated for the next protein sample by injecting of 50 mM (5 μL) NaCl. The data were double reference subtracted, and the apparent K_D value was calculated by nonlinear fitting of the plot of R_{eq} versus the VAA concentration using the average model with steady-state affinity as given in the BIAEvaluation software from BIAcore.

Immobilization of Compound 8 on a Carboxylated Dextran Surface (CM5, Biacore). For the immobilization of the fluorescent lactoside **8** (flow cell-1), a standard CM-5 chip (BIAcore) was activated by injection of the amino coupling kit (BIAcore): EDC/NHS (35 μL) at a flow rate of 5 μL min^{-1}, at 28 °C, and 10 mM Hepes, 150 mM NaCl, pH 7.4 (HBS-P) as running buffer. At the same conditions of flow and temperature, a solution of **8** (1 mM, 180 μL) in 10 mM sodium acetate buffer, pH 4.5, was injected 3 consecutive times to get the maximum immobilization, followed by the injection of ethanolamine (1 M, 35 μL) to block the possible remaining active sites on the dextran matrix. The final response reached was 660 RU (flow cell-1). The same procedure was repeated to obtain less density of the immobilization on the SPR chip. In this case, LacDN **8** (96 RU) was immobilized on the surface (flow cell-2). On a third flow cell, the activation and blocking standard procedures were carried out as described above, and it was left as the negative control of the interaction.

For the interaction assays, different concentrations (0.4, 0.7, 1.7, 2.9, 5.9, and 11.8 μM) of a solution of VAA in the running buffer were injected (15 μL), at a flow rate of 5 μL min^{-1}, at 28 °C. After injection of the sample, the same buffer (without added protein) was flowed through the sensor chip surface to allow dissociation. After a suitable dissociation phase, the sensor surface was regenerated for the next protein sample by injecting of 50 mM (5 μL) NaCl. In each experiment the response unit (RU) was monitored as a function of time (sensorgram). The data were fitted to a single biomolecular reaction model using the BIAEvaluation software from BIAcore.

Immobilization of Compound 8 on a Self-Assembled Monolayer (SAM) Prepared with a Gold Chip (Au). Compound **11** was immobilized on a gold surface from an Au chip (Biacore) to create a SAM. For that purpose, a solution of **11** in water-P_{20} (10 μL) was injected on an Au chip, at a flow rate of 2 μL min^{-1}, at 25 °C. After each injection, the surface of the flow cell was washed with 50% MeOH (5 μL) and 75% MeOH (5 μL) at a flow rate of 5 μL min^{-1}, at 25 °C. The same procedure was repeated in another flow cell so that both cells reached a similar response in RU (720 and 1000 RU).

For the immobilization of the fluorescent lactoside **8**, the previous chip was activated by the injection of the amino coupling kit (BIAcore): EDC/NHS (35 μL) at a flow rate of 5 μL min^{-1}, at 25 °C, and 10 mM Hepes, 150 mM NaCl, pH 7.4 (HBS-P), as running buffer. At the same conditions of flow and temperature, a solution of **8** (1 mM, 150 μL) in sodium acetate 10 mM buffer, pH 4.5, was injected to get the maximum immobilization, followed by the injection of ethanolamine (1 M, 35 μL) to block the possible remaining active carboxylate groups of the SAM. The final response reached was 530 RU (flow cell-1). On a second flow cell, the activation and blocking standard procedures were carried out as described above, and it was left as negative control of the interaction.

For the interaction assays, different concentrations (1.1, 2.2, 4.4, 8.8, 17.7, and 35.3 μM) of a solution of VAA in the running buffer were injected (15 μL), at a flow rate of 5 μL min^{-1}, at 25 °C. After injection of the sample, the same buffer (without added protein) was injected to the sensor chip surface to allow dissociation. After a suitable dissociation phase, the sensor

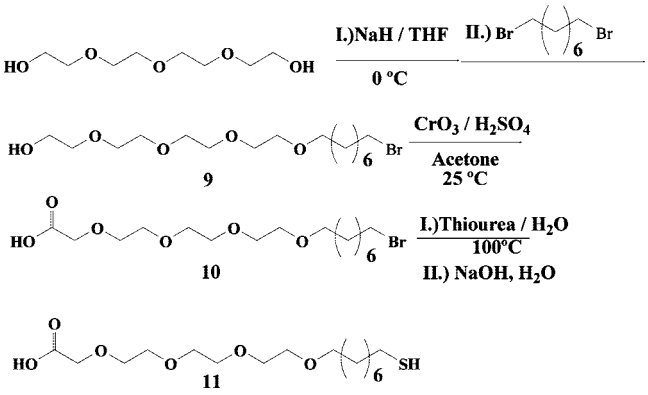

Figure 4. Synthesis of compound **11**.

surface was regenerated for the next protein sample by injecting 50 mM (5 μL) NaCl. The data collected were fitted to a single biomolecular reaction model using the BIAEvaluation software from BIAcore.

RESULTS AND DISCUSSION

Synthesis of New Fluorescent-Glycan. The first synthetic approach to obtain the fluorescent lactoside was via reductive amination (Scheme 1). On a first step, peracetylated lactoside **1** was activated via bromide derivative **2** (90% of yield), and finally, allyl alcohol was attached to the anomeric position in the presence of mercury oxide and mercury bromide (*16*), affording the desired allyl-lactoside **3** with the specific β-configuration and with 50% yield. Afterward, the functionalization of the allyl end was carried out by ozonolysis at −78 °C in CH_2Cl_2 to yield derivative **4** in 75% yield (*33*). This lactoside **4** is suitable for fluorescent labeling while keeping the naphthalene rings intact.

The fluorescent tag chosen for the labeling of the functionalized lactoside **4** was 1,5-diaminonaphthalene (maximum excitation at 320 nm, and maximum emission at 410 nm) (*34*). Reductive amination of compound **4** and DN was carried out in slightly acid conditions, and further reduction with $NaBH_3CN$ led to the formation of the desired fluorescent compound **7** in 50% yield. The overall yield of the synthesis of compound **7** via reductive amidation was 17%. Other authors have described access to fluorescent glycan derivatives from monoaminated pyridines in moderate yields of 29% (*35*). In our case, we introduced a diamine derivative with an improved yield, and in addition, the structure maintains a free amino group suitable for immobilization on activated surfaces.

Despite the fair yield of the overall process (17%), an alternative approach was explored to reduce the number of synthetic steps (Scheme 2). First, peracetylated lactose was functionalized with 2-bromoethanol to generate compound **5** in a yield, 40%, similar to that described in the literature (*35*). Bromine was then easily exchanged by iodine, passing after 2 h from **5** into the iodine derivative **6** in quantitative yield (*36*). With these two easy steps, the building block for the synthesis of fluorescent glycans was obtained. Consequently, the nuchleophilic substitution reaction was carried out with excess of DN (compound **6**/DN, 1:5) and in reflux of toluene to afford compound **7** in 70% yield. The overall yield of compound **7** via nucleophilic subtitution was 28%. In the final step, the protected compound **7** was deprotected using standard procedures in a basic milieu. In this way, the fluorescent glycan **8**, LacDN was obtained in quantitative yield.

Immobilization of the New Fluorescent-Glycoconjugates on Different Biochip Surfaces and Interaction Studies of *Viscum album* Agglutinin (VAA) by SPR. The new fluorescent-glycoconjugate (LacDN) has been synthesized with a fluorescent linker ending with an amino group that enables the immobilization of LacDN on a gold surface of a SPR biosensor chip functionalized with carboxylic groups (Figure 1).

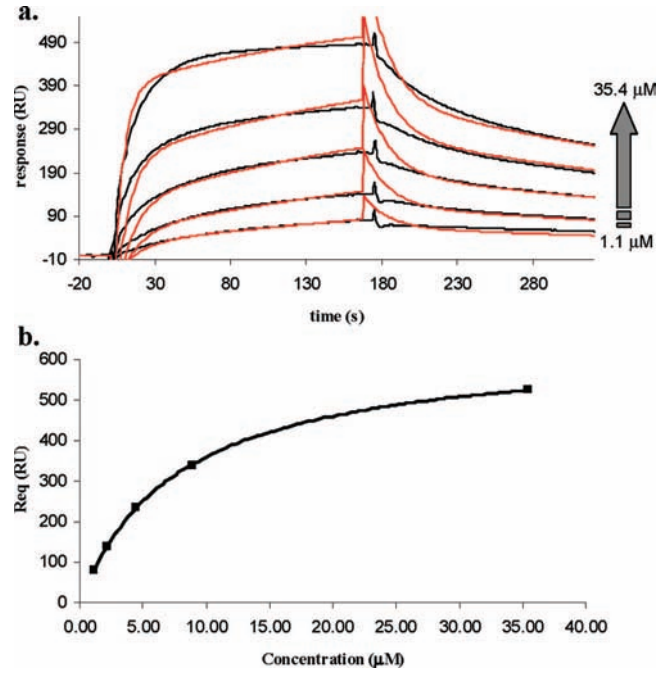

Figure 5. (a) Sensorgrams recorded for the interaction of VAA with LacDN immobilized on a SAM. (b) Steady state affinity study between VAA and LacDN immobilized on a SAM functionalized chip.

The first strategy was the immobilization of compound **8** (LacDN) on a C1 biosensor chip. The gold surface of the sensor chip C1 is directly functionalized with carboxymethyl groups, without the presence of a dextran matrix, and also has a low binding capacity. This surface is also useful for those interactions that may be affected by the presence of the matrix.

For that purpose, LacDN was immobilized in one of the flow cells of a C1 sensor chip, and an untreated flow cell was used as the reference surface for interactions studies. The optimal buffer for the immobilization was 10 mM sodium acetate, pH 4.5. After the immobilization and blocking with ethanolamine procedures, a response of 111 RU was reached. As model lectin, *Viscum album* agglutinin (VAA), a potent toxin and thus a potential biohazard, was tested to address the issues of whether the surface is bioactive. The K_D of VAA binding to LacDN was determined by titration of the surface with various VAA concentrations (1.2−17.7 μM) (data not shown). The K_D value was obtained from a nonlinear fit of the data in a plot of R_{eq} (response at equilibrium) versus the VAA concentration (Figure 2), and the data obtained afforded an apparent K_D value of 11.9 μM (Table 1).

The second strategy was the immobilization of compound **8** (LacDN) on a CM5 chip. The amino functionalized compound is covalently bound to the carboxymethylated dextran matrix that lays on the gold surface of the CM5 chip. The optimal buffer for the immobilization was 10 mM sodium acetate, pH 4.5. In order to evaluate the interaction, LacDN was immobilized on two different flow cells at different degrees of immobilization in the same sensor chip, to minimize the differences due to the dextran matrix. Finally, a third flow cell was activated, blocked, and used as negative control. In one flow cell, a very high density of LacDN was reached (660 Response Unit, RU). In a second flow cell, LacDN was injected to reach a comparatively low response (96 RU) to evaluate possible modifications in the behavior of the interaction due to the density of ligand immobilized.

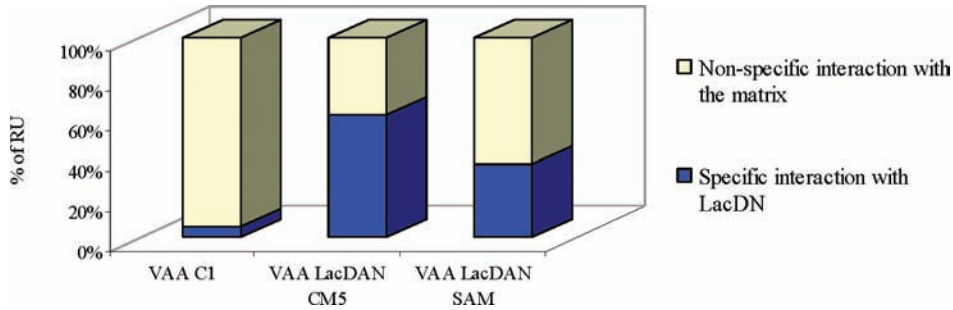

Figure 6. Percentage of specific binding compared to the nonspecific interaction of the lectin to the surfaces: C1, SAM and CM5.

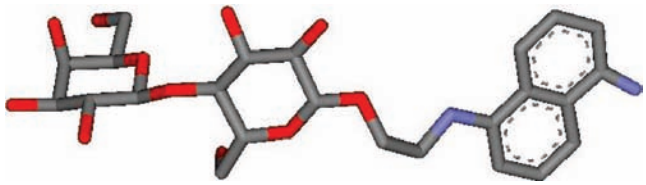

Figure 7. The major conformer of Lact-DN in solution as deduced from NMR experimental data and MD similations.

Afterward, the same VAA was tested to address the issues of whether the surface is bioactive and whether the density change may alter the kinetics. Figure 3 shows the binding of VAA to the sensor chip immobilized with two different densities of LacDN. Under both density surfaces (Figure 3), VAA associated relatively slowly, and the dissociation also proceeded gradually. Primarily, the binding curves obtained using concentrations of VAA from 0.4 μM to 11.8 μM were analyzed assuming a 1:1 (Langmuir) binding model. As shown in Figure 3, the absolute response in RU is drastically different in the two surfaces with different densities, but when data are fitted to a 1:1 kinetics, the apparent K_D is in the same micromolar range (Table 1). Thus, the surface is bioactive with an effect of density on k_{on}. It was found that the χ^2 values, which measure the closeness of the model fits and the experimental data, were consistently <10, indicative of a good curve fit (Table 1).

VAA has potentially two or more sugar binding sites (*37*, *38*), and for that reason the same data set was analyzed assuming bivalent binding. The bivalent binding model assumes that the analyte having two independent binding sites interacts with two receptor sites with identical binding properties. Detailed analysis of the bivalent analyte model of the interaction of the two surface densities of LacDN with VAA is summarized in Table 2. The kinetic analysis showed that the bivalent analyte model provides χ^2 values >10, indicative of a nonoptimal curve fit.

The fact that VAA has more than one binding site suggests that VAA makes more that one contact with the immobilized LacDN molecules on the chip surface. Althought the affinity of a multivalent interaction cannot be directly calculated from Biacore data, the apparent K_D value of the system was obtained from a nonlinear fit of the data in a plot of R_{eq} (response at equilibrium) versus the VAA concentration (data not shown), and the data obtained afforded an apparent K_D value of 11.3 μM for the low density surface and 11.8 μM for the high density surface (Table 1).

Finally, glycoconjugate **8** LacDN was immobilized on a chip where a self-assembled monolayer (SAM) was created by the injection of compound **11** over the gold surface of a commercial Au chip (Biacore).

This thiol-reactive heterobifunctional linker **11** was synthesized as described in Experimental Procedures (Figure 4). Tetra(ethylene glycol) reacted with 1,8-dibromooctane to afford compound **9** in 40% yield. Compound **9** was then oxidized with Jones reagent to afford **10** in good yield (70%). Finally, reaction with thiourea followed by base catalyzed hydrolysis afforded a thiol group and carboxyl containing compound **11** in 60%. The resulting monolayer was very homogeneous judging from the similar RU values obtained for both flow cells. The SAM was formed quickly and was quite stable due to the avidity of the thiol group for the gold. Several washings with 50% aqueous MeOH were required to eliminate the noncovalently bound linker.

In addition, the linker chains that form the SAM are functionalized at the free end with a carboxylic group to allow the covalent coupling of the desired compound to the surface. Therefore, a solution of LacDN (1 mM) in 10 mM AcONa/AcOH buffer, pH 4.5, was injected on this surface, and after the blocking procedure with ethanolamine, a final response of 530 RU was reached. VAA was chosen to perform interaction studies with the glycoconjugate immobilized on a SAM (Figure 5). For that purpose, different concentrations of VAA were injected, and the sensorgrams obtained were further analyzed. We analyzed these sensograms using two binding models in Bioevaluations sofwere. On a first attempt, we tried to adjust the data to a 1:1 kinetic model, and it was found that χ^2 values were <10, indicative of a good curve fit. We observed a k_{on} and k_{off} comparable to that observed for the CM5 surface giving a similar apparent K_D of 3.2 μM (Table 1). The same data set was analyzed assuming a bivalent binding model (Table 2). In this case, it was found that the χ^2 values were >10, indicative of a nonoptimal curve fit; for that reason, the sensograms of the SAM surface could not be analyzed with the bivalent model. In order to consider a multivalent binding model, only the results of the steady-state affinity determination were available. The apparent K_D value obtained by this methodology was 8.0 μM (Table 1).

Kinetic parameters obtained in the three surfaces studied (Table 1) are in the micromolar range, similar to those reported by André et al. (*39*) for the binding of VAA to galactose in the solid-phase assay in microplate wells.

The compound LacDN was immobilized on different surfaces (C1, CM5, and SAM) and an untreated flow cell was used as a blank surface for VAA lectin. The values of RU were obtained from the sensorgrams when VAA was injected over each sort of surface and were used to calculate the contribution (%RU) of nonspecific interaction of VAA lectin with the matrix and the contribution of the specific interaction of this lectin with the compound LacDN. As can be seen from Figure 6, the surface C1 showed stronger nonspecific interaction with the lectin (95%) than SAM (45%) and CM5 (33%). Of interest, CM5 is the one that showed the least nonspecific interaction with VAA lectin. Therefore, this is the surface of election to carry out carbohydrate−VAA lectin interaction through SPR when the glycoconjugate is the one immobilized on the chip.

Conformational Properties in the Free and Lectin-Bound States. The newly synthesized glycan carries a new group at the reducing end of the Glc moiety of lactose, which may affect

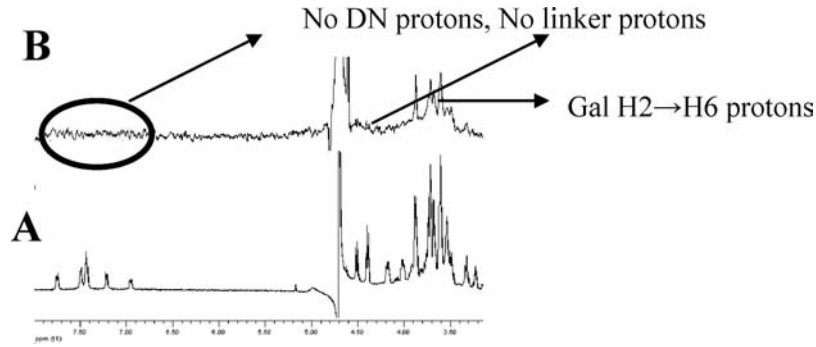

Figure 8. Interaction of LacDN with VAA. Trace A shows the regular 500 MHz ^{1}HNMR spectrum of LacDN at 300 K in the presence of VAA (30:1). Trace B shows the STD spectrum (saturation time 600 ms, on resonance irradiation at $\delta = -1$ ppm), showing only the Gal protons, especially H2, H3, H4, H5, and H6. Minor transfer to the Glc moiety and no transfer to the DN moiety is observed at this saturation time. When increasing the saturation time to 2 s, the Glc protons are also observed, as well as additional saturation transfer to the linker protons and even to the DN protons (not shown). In any case, the binding epitope clearly belongs to the Gal moiety.

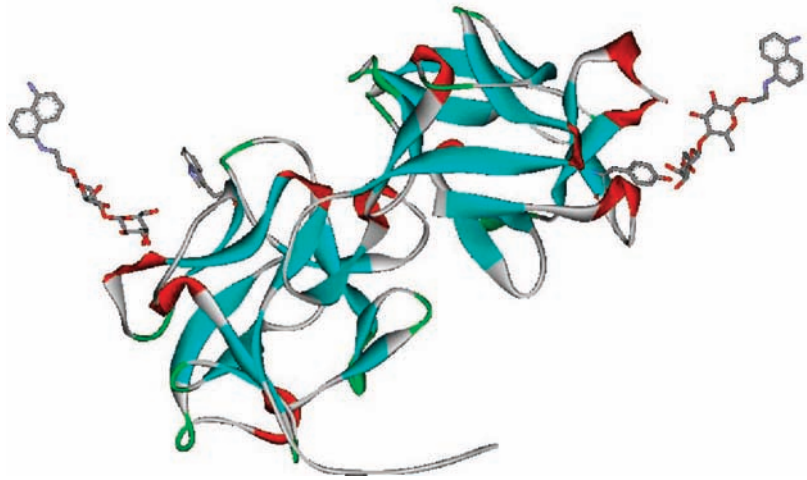

Figure 9. Three-dimensional model of the complex of VAA (coordinates taken from the Protein Data Bank, code 1PUM) with Lact-DN. Independent AUTODOCK simulations were performed with the Trp38 (top figure) and Tyr249 (bottom figure) binding sites as described in Experimental Procedures. The figures show the best result for both cases. No contacts between the linker or the DN moiety and the protein are observed. Key contacts are highlighted.

conformational or binding properties, when in contact to the protein surface.

To determine the free-state conformational space of LacDN, a combination of NMR experiments and molecular mechanics and dynamics calculations was performed. The ^{1}H NMR chemical shifts and coupling constants, as obtained at 500 MHz and 300 K, are given in the Supporting Information. The analysis of the coupling constants permitted us to assess whether the Glc and Gal rings keep the natural $^4C_1$(D) conformation. Then, the conformational preferences around the glycosidic linkage were assessed by NOE experiments. Only the expected inter-residue GalH1 to GlcH4 (overlapping with Glc H3) and GlcH6 NOEs were observed, indicating that LacDN adopts the natural exoanomeric syn-$\Phi\Psi$ geometry of lactose around the glycosidic linkage (*40, 41*). No intramolecular aromatic-sugar NOEs were observed, indicating that no stacking of the aromatic moiety onto the sugar faces takes place (*42*−*44*).

Thus, the pendant DN group stands away of the lactose moiety. A view of the major conformer, originating from the molecular mechanics calculations, is given in Figure 7. Moreover, MD simulations (3 ns, 300 K) that were performed rearrange the relative clause that the lateral chain, although flexible, only accesses a well-defined area of the available conformational space in terms of Φ/Ψ torsion angles (Figure S1, Supporting Information). The global minimum within this Φ/Ψ region is able to explain all of the NMR data (NOE contacts) in a satisfactory manner.

Having determined the free-state conformational behavior, we next studied binding and contact sites to the lectin, using saturation transfer difference (STD) experiments, and the bound-state conformation, using trNOE experiments.

The STD experiments demonstrated that the lectin recognizes LacDN. Clear STD signals for the sugar protons in the ligand were observed (Figure 8). The maximum enhancements were observed for the protons at the Gal moiety, followed by the contiguous protons at the Glc fragment and the linker and DN moieties, but only when the saturation time was increased. Smaller enhancements were evident at the linker, especially the CH_2 moiety contiguous to the Glc unit, while the DN protons showed moderate enhancements, indicating a minor interaction of this moiety with VAA. Additional experiments were performed with concanavalin A (ConA) as the receptor for the negative control. ConA binds glucose or mannose moieties and displays no binding activity for galactose derivatives. No STD or trNOE signals were observed, thus indicating the specificity of the synthetic probe for galactose-binding proteins.

The trNOE technique will answer the question on the conformation of the bound-state of the ligand, especially whether the derivatization may affect the selection of the low-energy conformer (*45*). At a 20:1 molar ratio of ligand/receptor, negative NOE cross-peaks, indicating binding, were only observed for the Gal and Glc moieties, whereas the linker protons only provide very weak (almost zero) cross-peaks. This result indicates that different degrees of mobility (different

effective correlation times) exist in the VAA-bound state for the different portions of the molecule. The Gal moiety is recognized by the lectin, and the lactose part increases the correlation time passing to the negative-NOE regime. In contrast, the linker and the DN moieties are less affected by the recognition of the Gal entity and are still in the weakly positive- or zero-NOE regimes. The observed NOEs for the Gal moiety are in agreement with those observed in the free state for LacDN (with positive NOEs for all the Gal, Glc, linker, and DN moieties; see Supporting Information) and lactose. Overall, cross-peak pattern indicates that the low-energy conformer is accommodated as the ligand (see Supporting Information).

To rationalize the interaction on the molecular level, the low-energy conformer, as observed by NMR, was docked into the binding sites by the program AUTODOCK. Two sites with different degrees of accessibility in the dimmer, i.e., the sites characterized by Trp38 in the 1α subdomain and by Tyr249 in the 2γ subdomain, are known (*46*). The conformer fit was very good in both cases (Figure 9). For both sites, the major interactions take place for the galactose moiety with very minor contacts for the remote glucose. In particular, for the Trp38 binding site, there is a clear stacking interaction between the indol moiety of Trp38 with H3, H4, and H5 of the galactose reisude, while Asp27, Asn47, and Lys41 provide polar contacts with the hydroxyl groups of Gal. Asp 27 provides a bidentate hydrogen bond to OH2 and OH3, and one additional hydrogen bond from the backbone carbonyl group to OH4, while Asn47 forms hydrogen bonds with OH3 and OH4. Lys41 also makes polar contacts with OH2 and OH3. Thus, the galactose moiety is fairly well bound by these aminoacid residues. In contrast, the glucose unit is only bound by two polar contacts between its OH2 and OH3 hydroxyl groups and the lateral chain of Asp26. For this site, no contacts between the DN moiety and the lectin were predicted in this model. For the Tyr249 binding site, now is the phenol ring, which provides stacking interactions to the galactose moiety, which is in turn involved in hydrogen bonds to the phenol hydroxyl through OH6. In addition, polar contacts between OH2, OH3, and OH4 to Asn235, Asn256, Asn256, and Glc257 are also observed in this model. Again, the Glc moiety is only involved in polar contacts with Glc238 through OH2 and OH3. Also, for this Tyr249 binding site, no contacts between the DN moiety and the protein were observed. This should be the case, unless drastic variations of the torsion angles around the Glc glycosidic torsion and the linker were considered, far from their low-energy regions. Thus, docking analysis was in accordance with the NMR-derived observations. The Gal moiety is the major contact site for VAA, the Glc gives tiny contacts, and the linker and the DN moieties remain in solution with distinct effective correlation time, which, in turn, produced different signs for the NOE cross-peaks of the different parts of the molecule. The predicted contacts by AUTODOCK are basically identical to those observed for the interaction with lactose in pdb entry 1PUM.

In conclusion, no major modifications of the presentation of lactose to a lectin takes place by attaching the DN moiety through a 2-carbon linker.

CONCLUSIONS

A new fluorescent glycan **8** has been prepared, and it can readily be conjugated to different surfaces. Three different matrices on a gold surface have been analyzed, plain surface, SAM, and dextran surface (CM5 Biacore chip), resulting in the CM5 chips showing the least nonspecific interaction in a carbohydrate-presenting surface, which are valuable probes for detecting lectins. Its fluorescent tag entails sensitive detection without affecting the ligand properties of the bioactive part.

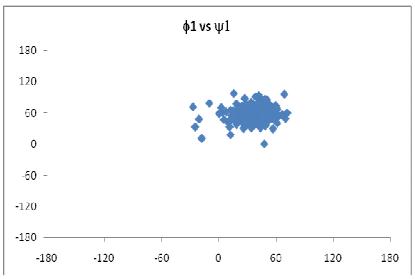
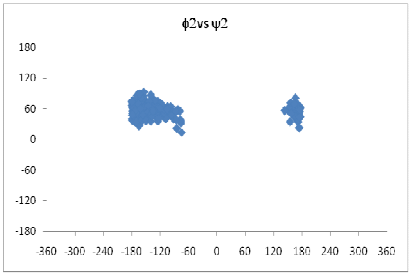
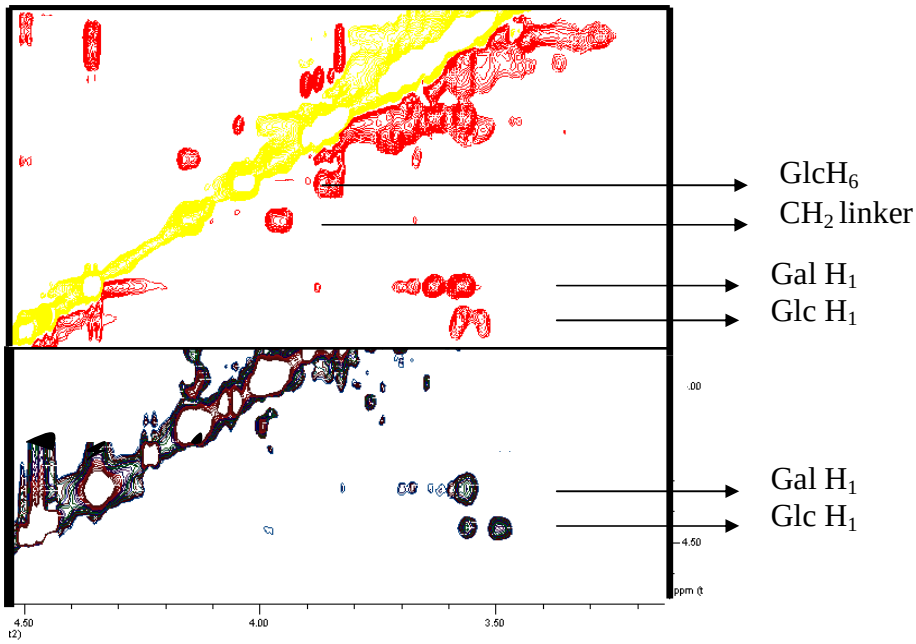
A) Scattered Φ1/Ψ1 map of LacDN, according to MD simularions (3 ns, 300 K, MM3* force field, GB/SA solvent model for water). Φ1/Ψ1 are defined as described in the experimental section. The map is basically identical to that calculated for lactose with major exo-anomeric syn Φ/Ψ geometry. **B)** Scattered Φ/Ψ map for the Glc-O-CH_2 moiety. Φ is defined as H1Glc-C1Glc-O-CH_2 and Ψ as C1Glc-O-CH_2-CH_2. The most stable geometry (with Ψ close 180º) places the linker away from the disaccharide moiety (see below).





3. Figure 2 Supporting information. Bottom panel. Key section of the trNOESY (mixing time, 200 ms) for the LacDN/VAA complex (20:1 molar ratio) at 500 MHz and 300 K. Negative NOE cross peaks indicating binding are only observed for the Gal and Glc moieties. Indeed, the linker protons only provide very weak (almost zero) cross peaks. This fact indicates that different mobility (different effective correlation times) exists in the VAA-bound state for the different moieties of the molecule. The Gal moiety is recognized by the lectin and the lactose part increases the correlation time passing to the negative-NOE regime. In contrast, the linker and the DN moieties are less affected by the recognition of the Gal entity and are still in the weakly positive- or zero-NOE regimes. The observed NOEs for the Gal moiety are in agreement with those observed in the free state (top panel).



4. Figure 3 Supporting information. A 3D model of the complex of VAA with LacDN at the Trp38 binding site. No contacts between the linker or the DN moiety and the protein are observed. In the bottom view, a surface representation of the protein is given.

Received July 29, 2008; Revised Manuscript Received February 3, 2009

The synthesis of new cyclic peptides comprising the 9−22 epitope ^{9}LKMADPNRFRGKDL^{22} sequence derived from HSV gD-1 is reported. In addition, we describe procedures for the preparation of cyclic peptide dimers and conjugates with an oligotuftsin derivative carrier. The binding of a monoclonal antibody, Mab A16, to the synthesized compounds was determined by enzyme-linked immunosorbent assay. It was demonstrated that cyclization decreased the binding activity of the antibody to the epitope. However, dimerization and conjugation could significantly increase the binding capacity of the cyclic epitope peptides. The attachment site in dimers and conjugates, as well as the topology of the construct, had a significant influence on the antibody recognition, while replacement of Met in position 11 by Nle had no marked effect.

INTRODUCTION

The application in human therapy of conventional vaccines consisting of either killed or live attenuated disease-causing organisms has some limitations such as the loss of efficacy due to the genetic variation of many viruses; difficulties in the production and storage of many vaccine preparations; and biohazard in both production and use of vaccines against lethal infections. To overcome these drawbacks, synthetic peptide-based vaccines have been developed; and they have advantages of being selective, chemically defined, and safe and can be prepared in large quantities (*1, 2*). However, it is known that the administration of a synthetic epitope peptide rarely elicits an appropriate immune response. Peptide epitopes are generally short and are not able to adopt the same conformation as in the native protein; in addition, they are subjected to fast in vivo degradation by proteases (*3*). In many cases, antibodies to synthetic peptides react strongly with the homologous peptides, but weakly or not at all with the original protein or the intact infectious agents (*4*). Several approaches have been developed in order to modify the immunorecognition of synthetic epitope peptides such as (i) incorporation in the same construct of both B- and helper T-cell epitopes (*5*); (ii) cyclization (*6*); (iii) conjugation of multiple copies of epitopes to synthetic or natural carriers (*7*); and (iv) dimerization or controlled polymerization of the peptide epitope (*8, 9*).

Herpes simplex virus, with two closely related serotypes (HSV-1 and HSV-2), is one of the most common infectious agents in humans. Glycoprotein D (gD) represents a major immunogenic component of the virion envelope (*10*), able to induce high titers of virus-neutralizing antibodies (*11, 12*). The *N*-terminal region of HSV gD-1, comprising residues 1−21 of mature gD, is known to be a strong antigenic site, and peptides from this domain are able to induce both B- and T-cell responses (*13*). In addition, gD is required for viral entry into the cells. gD can bind to at least three distinct cellular receptor proteins. These three receptors are herpes virus entry mediator (HVEM), nectin 1 and 2, and a modified form of heparan sulfate. The *N*-terminal domain of gD is the binding site to the HVEM receptor. The crystal structure of the gD-HveA complex revealed that, upon binding to the cellular receptor HVEM, the flexible *N*-terminal region of gD is folded into a fixed hairpin structure that contains the residues of gD required for binding to HVEM. Monoclonal antibody (Mab) A16 can inhibit the binding of gD to the cellular receptor HVEM. A16 monoclonal antibody was also used for selection of peptides from a random peptide library (RPL) displayed on the surface of a filamentous bacteriophage. The selected RPL-derived peptide and peptide 9−19 of gD-1 had approximately the same affinity for Mab A16. Immunization of mice with the phage-derived RPL-peptide as well as the gD-1 derived peptide (after conjugation to BSA) protected against a challenge with a lethal dose of herpes simplex virus type 1 (*14*).

Peptide 9−21 (LKMADPNRFRGKD) was shown to be the optimal epitope of the *N*-terminal part of gD for Mab A16, in which amino acids ^{13}Asp, ^{16}Arg, and ^{17}Phe are essential for Mab A16 recognition (*15*). The 9−21 peptide exhibited good antibody recognition in linear form, either free or conjugated to carriers. It was further demonstrated that the peptide could adopt a β-turn-like structure at residues ^{14}Pro and ^{15}Asn under appropriate conditions (*16*−*18*), leading to the hypothesis that cyclization might stabilize the bioactive conformation of the peptide and thus increase its antibody recognition. Cyclization might also mimic the fixed hairpin structure of gD needed for

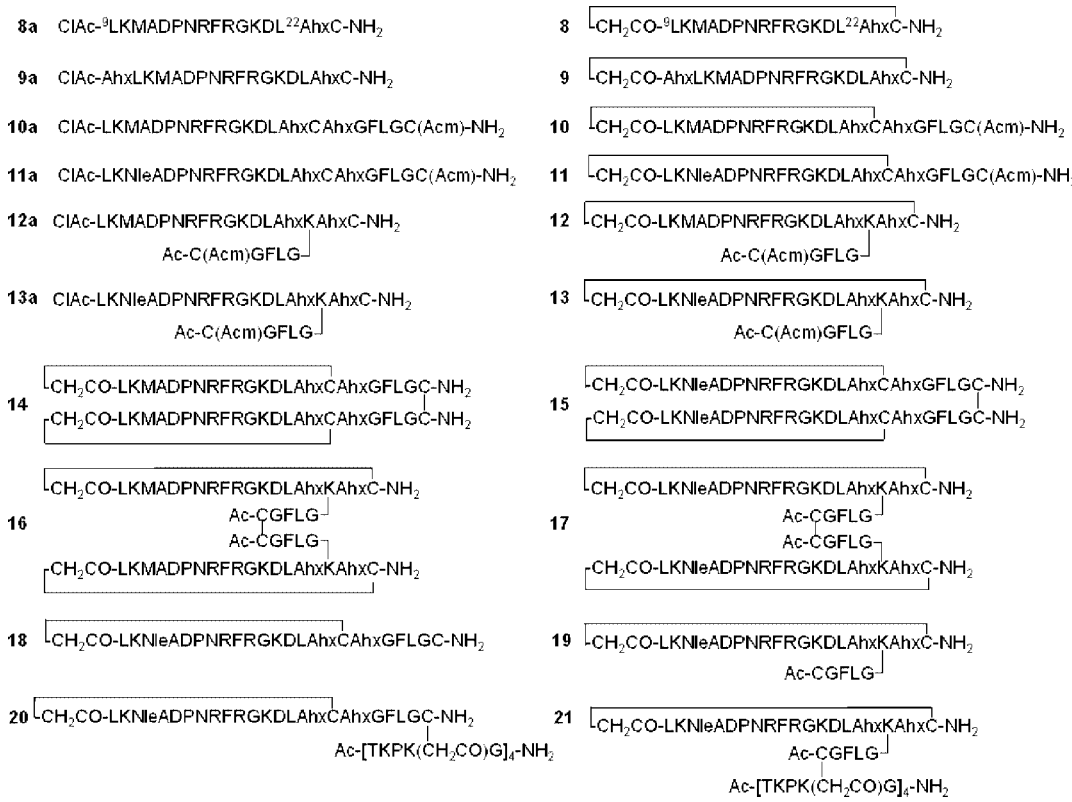

Figure 1. Chemical structure of cyclic epitope peptides (**8**−**13**, **18**, and **19**) derived from HSV gD-1, their precursors (**8a**−**13a**), dimer (**14**−**17**), and conjugated (**20**, **21**) derivatives.

binding to the HVEM receptor. In addition, cyclization might enhance the stability of the peptide against enzymatic degradation. However, for peptide 9−21 no effective cyclic version has yet been described (*19*).

In previous studies, we demonstrated that replacement of ^{11}Met in peptide 9−22 by homocysteine (Hcy) or cysteine (Cys) and replacement of ^{18}Arg by Lys made cyclization possible through a thioether bond between a chloroacetyl group at the ε-amino group of Lys and the thiol group of Cys or Hcy. The cyclic peptides (H-LK[XADPNRFK(CH_2CO)]GKDL-NH_2, where X = Cys or Hcy) thus obtained bound to the Mab A16 with three magnitudes lower efficiency than the linear analogues (*19*) and the Hcy cyclic peptide was more potent in competition ELISA than the Cys-containing version. In another study (*20*), the conjugation of linear (^{11}Nle)-9−22 peptides (replacement of Met by norleucine (Nle) in position 11 is permitted (*21*)) to carriers such as MAP-type lysine dendrimer (*22*), sequential oligopeptide carrier (SOC) (*23*), oligotuftsin derivative (OT20) (*24*), branched-chain SAK polypeptide with polylysine backbone (*25*), or the widely used protein keyhole limpet hemocyanine (KLH) (*26*) was performed. Results showed that the conjugates bound to Mab A16 by 1 order of magnitude more strongly than the linear epitope peptides, regardless of the carrier used. The disulfide dimers of peptide 9−22, either *C*- or *N*-terminally linked, also showed improved binding compared to the linear peptide, similarly to peptide 9−22 conjugated to oligotuftsin (*27*).

In line with the above-mentioned results, we describe here a new series of linear, cyclic, dimeric, and conjugated derivatives of the HSV gD-1 9−22 epitope. Large ring-size cyclic peptides (16 instead of 8 residues) derived from 9−22 epitope peptide of HSV gD-1 and their dimeric versions, as well as conjugates to OT20 carrier, were prepared, and their antigenicity was determined by enzyme-linked immunosorbent assay using Mab A16.

EXPERIMENTAL PROCEDURES

Materials. All amino acid derivatives were purchased from Senn Chemicals AG (Dielsdorf, Switzerland) or NovaBiochem (Läufelfingen, Switzerland). Rink-amide MBHA and 4-methylbenzhydrylamine (MBHA) resins were from NovaBiochem. Coupling agents (*N*,*N*′-diisopropylcarbodiimide (DIPCDI), 1-hydroxybenzotriazole (HOBt), *N*-ethyldiisopropylamine (DIPEA)), cleavage reagents (trifluoroacetic acid (TFA), hydrogenfluoride (HF), piperidine, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)), and scavengers (triisopropylsilane (TIS), *m*-cresol, *p*-thiocresol) were from Fluka (Buchs, Switzerland) or SDS (Peypin, France), except for *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU), which was from Matrix Innovation (Montreal, Canada). Tallium(III) trifluoroacetate ($Tl(tfa)_3$)) and 1,4-DL-dithiothreitol (DTT) were Fluka products, while acetic anhydride (Ac_2O) was purchased from Reanal (Budapest, Hungary). Solvents (dichloromethane (DCM), *N*,*N*-dimethylformamide (DMF), diethyl ether, methanol (MeOH), and acetic acid (AcOH)) for synthesis were obtained from SDS and Reanal. Acetonitrile for HPLC was from SDS or Sigma (Sigma-Aldrich Kft., Budapest, Hungary). Peptides **1**−**7** were synthesized as previously reported (*19*, *20*, *27*).

Synthesis of Linear Precursor Peptides (Peptides 8a−**11a; Figure 1).** Linear precursor peptides **8a**−**11a** were synthesized by solid-phase methodology on Rink amide MBHA resin using an ABI 433A synthesizer (FAST-MOC, 0.1 mmol scale chemistry). Eight molar excess of Fmoc-amino acids were used in HBTU-HOBt-DIPEA-mediated coupling reactions. Fmoc-Arg(Pbf)-OH, Fmoc-Lys(Boc)-OH, Fmoc-Asp(O^{t}Bu)-OH, and Fmoc-Asn(Trt)-OH were applied as side chain protected deriva-

[a] The numbers of the compounds correspond to the structures presented in Figure 1. [b] Experimental MWs were calculated from the multiple charged ions measured by a Bruker Daltonics Esquire 3000+ mass spectrometer. [c] RP-HPLC conditions: Column, Phenomenex Jupiter C_{18} (250 × 4.6 mm, 5 μm, 300 Å); gradient, 0 min 0% B; 5 min 0% B; 50 min 90% B; eluents, 0.1% TFA in water (A) and 0.1% TFA in acetonitrile−water (80:20, v/v) (B); flow rate, 1 mL/min; detection, λ = 214 nm.

tives. The side chain of the Cys residue involved in the cyclization was protected by a trityl group (Trt). In peptides **10a** and **11a**, the thiol group of the additional (*C*-terminal) Cys used for dimerization or conjugation was protected by acetamidomethyl group (Acm). After chain assembly and removal of the *N*-terminal Fmoc protecting group, the free amino terminus was chloroacetylated with 5 equiv of chloroacetic acid pentachlorophenyl ester (ClAc-OPcp) (*20*). The peptides were cleaved from the resin with TFA-TIS-water (95:2.5:2.5, v/v/v) at room temperature for 2 h. The crude peptides were precipitated with chilled anhydrous diethyl ether, isolated by centrifugation, redissolved in 10% acetic acid, and freeze−dried. Prior to cyclization, they were purified by semipreparative RP-HPLC and characterized by analytical RP-HPLC and ESI-MS.

Synthesis of Branched Precursor Peptides (Peptides 12a and 13a; Figure 1 and Scheme 1). The branched peptides were prepared on MBHA resin (0.62 mmol/g) by manual SPPS applying a mixed Boc-Fmoc strategy. Linear peptides with Met or Nle in position 11, elongated with the Ahx-Lys-Ahx-Cys tetrapeptide (where Ahx is ε-aminohexanoic acid) at the *C*-terminus, were built up by Boc chemistry using Boc-Arg(Tos)-OH, Boc-Lys(ClZ)-OH, Boc-Asp(OcHex)-OH, and Boc-Cys(Meb)-OH as side chain protected derivatives. The ε-amino group of Lys in the *C*-terminal extension as a future branching site was blocked with an Fmoc group. The protocol of the Boc synthetic cycle was the following: (i) deprotection with 40% TFA/DCM (2 + 20 min); (ii) DCM washing (5 × 0.5 min); (iii) neutralization with 5% DIPEA/DCM (4 × 1 min); (iv) DCM washing (4 × 0.5 min); (v) coupling of 3 equiv Boc-amino acid derivative/DIPCDI/HOBt in DCM-DMF 4:1 (v/v) solvent mixture (60 min); (vi) DMF washing (2 × 0.5 min); (vii) DCM washing (2 × 0.5 min); and (viii) monitoring by ninhydrin (*28*) or isatin assay (*29*). After completion of the synthesis of the linear peptide and prior to the Boc cleavage from the *N*-terminus, the peptide was further developed in the branch by Fmoc strategy. Fmoc-Gly-OH, Fmoc-Leu-OH, Fmoc-Phe-OH, Fmoc-Gly-OH, and Fmoc-Cys(Acm)-OH were built in step by step, manually. The protocol of Fmoc chemistry was the following: (i) DMF washing (3 × 1 min); deprotection with 2% DBU + 2% piperidine in DMF (4 times for 2 + 2 + 5 + 10 min); (iii) DMF washing (8 × 0.5 min); (iv) coupling of 3 equiv Fmoc-amino acid derivative-DIPCDI-HOBt in DMF; (v) DMF washing (3 × 0.5 min); (vi) DCM washing (2 × 0.5 min);

[c] Peptide (^{11}Nle) 9−22 (code 2) was included in all the competition ELISA assays performed. The amount required to obtain an OD_{490} of 1.00 was 3.4 ± 1.8 pmol. [d] Ref *20*. [e] Ref *19*. [f] Ref *27*.

and (vii) monitoring by ninhydrin assay. In the end, the Fmoc group was detached and the *N*-terminus of the branch was acetylated with Ac_2O/DIPEA/DMF (1:1:3, v/v/v) mixture. Finally, the Boc group was removed, and the free α-amino group was chloroacetylated with 5 equiv ClAc-OPcp in DMF. The peptide was cleaved from the dried resin simultaneously with the removal of the side chain protecting groups with liquid HF in the presence of *m*-cresol and *p*-thiocresol as scavengers (10 mL HF, 0.5 mL *m*-cresol, and 0.5 g *p*-thiocresol) at 0 °C for 90 min. The crude product was precipitated with dry diethyl ether. The solid material was filtered off, washed three times with diethyl ether, and then dissolved in 10% acetic acid prior to freeze−drying. The target peptide was obtained after purification by semipreparative RP-HPLC and characterized by analytical HPLC and mass spectrometry (MS) before cyclization.

Synthesis of Cyclic Epitope Peptides (Compounds 8−13; Figure 1 and Scheme 1). Cyclization of chloroacetylated linear epitope peptides by thioether bond formation was performed in 0.1 M Tris-HCl buffer, pH 8.0. The lyophilized solid material was added to the buffer solution (20 mL, 5 mg/mL final peptide concentration, in each case) in portions over 1 h. Then, the reaction was continued in a closed tube at RT for 3 h, and the cyclization reaction was monitored by analytical RP-HPLC. The reaction mixture was acidified with TFA and purified directly by semipreparative RP-HPLC. The yield of the cyclization was over 90% for each construct. The compounds were characterized by analytical RP-HPLC and ESI-MS (Table 1).

Dimerization of Cyclic Epitope Peptides (Compounds 14−17; Figure 1 and Scheme 2). Intermolecular disulfide bond formation was performed with Tl(tfa)$_3$ in TFA (*30*). The cleavage mixture contained 98% TFA, 2% anisole as a scavenger, and 0.6 equiv Tl(tfa)$_3$ (calculated for the cyclic epitope peptide). This mixture was cooled to 0 °C, and then the cyclic epitope peptide was dissolved at a concentration of 10 mg/mL. The reaction mixture was stirred at 0 °C for 90 min, and then the product was precipitated with dry diethyl ether, centrifuged, redissolved in 10% acetic acid, and freeze−dried. The crude peptide was purified by semipreparative RP-HPLC and characterized by analytical RP-HPLC and ESI-MS. Yields of the Met containing peptides were in the 50−55% range, while the Nle containing compounds were prepared with slightly better yields (58−65%).

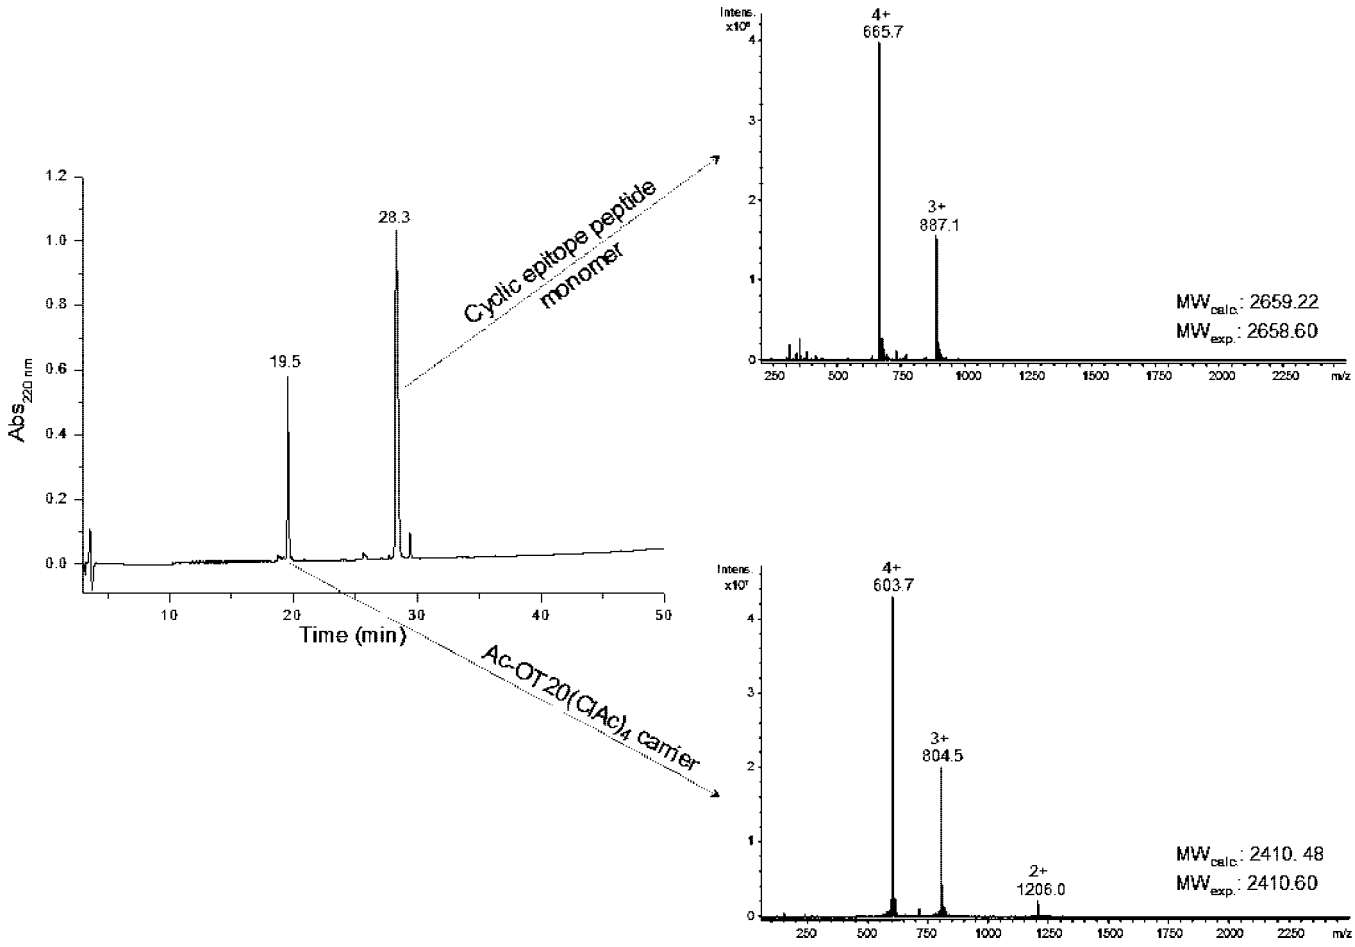

Figure 2. Conjugation of Ac-OT20(ClAc)$_4$ carrier with c[CH_2COLKNleADPNRFRGKDLAhxK(Ac-CGFLG)AhxC]-NH_2 (**19**) epitope peptide followed by RP-HPLC and mass spectrometry: 5 min reaction time.

Conjugation of Cyclic Epitope Peptides to Chloroacetylated Oligotuftsin Derivative (Compounds 20 and 21; Figure 1 and Scheme 2). Chloroacetylated oligotuftsin derivative (4 mg, 1.6 μmol) was dissolved in 0.1 M Tris−HCl buffer (pH 8.2) at a concentration of 1 mg/mL. The cyclic epitope peptide with the free SH-group (compounds **18** and **19** prepared by the reduction of dimer peptides **15** and **17**, respectively, Scheme 2) was added to the solution in small portions over an 8 to 12 h period. A 3-fold excess of epitope peptide derivative (calculated for each chloroacetyl group) was necessary for the complete alkylation reaction. The conjugation was monitored by RP-HPLC. As soon as only the conjugate with four copies of the epitope was observed beside the cyclic epitope peptide and its dimer, the reaction was terminated by acidification and then the mixture was purified by semipreparative RP-HPLC. The conjugate was characterized by analytical RP-HPLC and ESI-MS. The yield of the conjugation was in the range 70−75%.

Reverse-Phase High-Performance Liquid Chromatography (RP-HPLC). Analytical RP-HPLC was performed with a Knauer system (H. Knauer, Bad Homburg, Germany) using a Phenomenex Jupiter C_{18} column (250 × 4.6 mm I.D.) with a 5 μm silica (300 Å pore size) (Torrance, CA) as a stationary phase. Linear gradient elution (0 min 0% B; 5 min 0% B; 50 min 90% B) with eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile−water (80:20, v/v)) was used at a flow rate of 1 mL/min at room temperature. Peaks were detected at $\lambda = 214$ nm. The crude products were purified on a semipreparative Phenomenex Jupiter C_{18} column (250 × 10 mm I.D.) with 10 μm silica (300 Å pore size) (Torrance, CA). The flow rate was 4 mL/min. The same eluents with a linear gradient of 15−70% B over 40 min were applied.

Electrospray Ionization Mass Spectrometry (ESI-MS). Electrospray ionization mass spectrometry was performed with a Bruker Daltonics Esquire 3000+ mass spectrometer (Bremen, Germany), operating in continuous sample injection mode at 4 μL/min flow rate. Samples were dissolved either in a mixture of acetonitrile−water (1:1, v/v) or 50% MeOH, 1% AcOH in water. Mass spectra were recorded in positive ion mode in the *m*/*z* 50−3000 range.

Enzyme-Linked Immunosorbent Assay (ELISA). Throughout the ELISA studies, culture medium of the hybridoma cell line Mab A16 was used. The preparation of Mab A16 has been described earlier (*21*). Mab A16 was isolated after immunization of mice with extracts of HSV-1 infected cells. Hybridomas reactive only with HSV were isolated. The isolated hybridomas were screened for reactivity with HSV specific proteins and for unspecific reactivity according to the standard procedures for monoclonal antibodies. Mab A16 is reactive with glycoprotein D. It is a conformation-independent monoclonal antibody, classified together with Mabs LP14, ID3 as a group VII monoclonal antibody of gD (*21*). The core residues of the epitope of group VII Mabs is located within residues 9−19 of mature gD.

The competition ELISA was performed as previously described (*15*). Briefly, dilution series of linear peptide (^{11}Nle)-9−22 of gD and the different constructs of the epitope peptide were preincubated for 2 h at room temperature with "optimal" dilutions of Mab A16. After preincubation, the residual binding capacity of Mab A16 in the preincubation mixture was determined by ELISA in microtiter plate wells (Greiner Labortechnik, Germany) coated with the linear peptide (^{11}Nle)-9−22 (0.5 μg/well). As standard, a serial dilution of the peptide

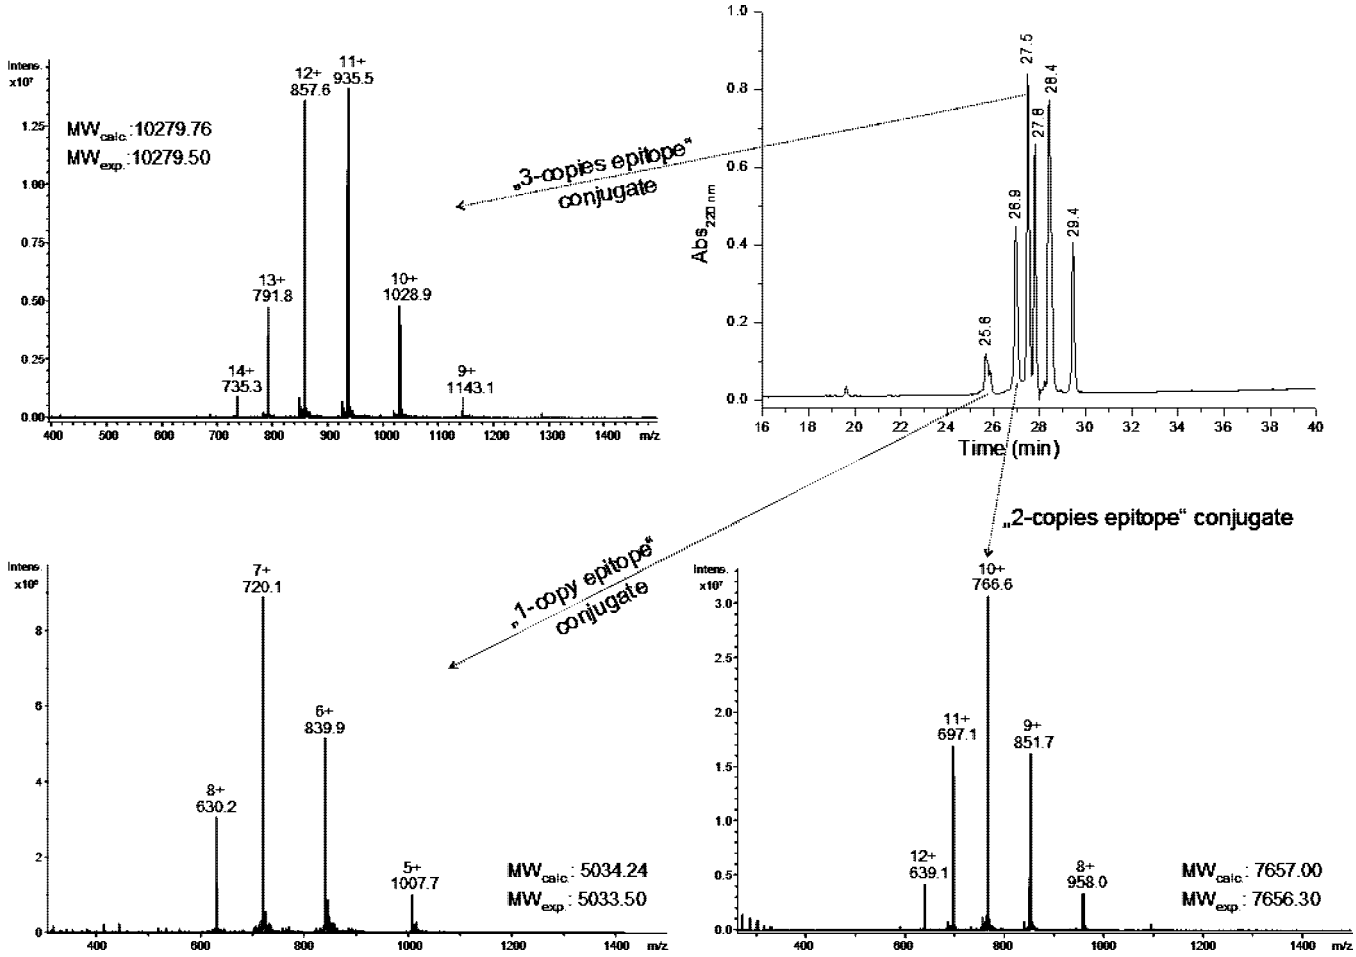

Figure 3. Conjugation of Ac-OT20(ClAc)$_4$ carrier with c[CH_2COLKNleADPNRFRGKDLAhxK(Ac-CGFLG)AhxC]-NH_2 (**19**) epitope peptide followed by RP-HPLC and mass spectrometry: 3 h reaction time.

(^{11}Nle)-9−22 with a fixed dilution of Mab A16 was always included: approximately 3 pmol peptide (^{11}Nle)-9−22 per 100 μL in the preincubation mixture resulted in a residual Mab A16, which gave an optical density of 1.0 at 490 nm (OD_{490}) on the coated peptide (^{11}Nle)-9−22. The relative amount of the epitope peptide constructs in the preincubation mixture required to give an OD_{490} of 1.0 was estimated graphically from plots of OD vs peptide concentrations. Data represent the average of at least three independent experiments for each compound.

RESULTS AND DISCUSSION

Here, we report on the synthesis, chemical characterization, and antibody binding of a new set of antigens derived from the sequence 9−22 of HSV gD-1. We investigated whether dimerization of the cyclic peptides and conjugation to an oligotuftsin derivative carrier influenced the binding to Mab A16 as compared to the monomeric form. Peptide 9−22, containing the sequence of 9−19 recognized by monoclonal antibody A16, was used. It is known that the binding activity of peptide 9−21 is higher than that of 9−19 and the addition of Leu at position 22 has no significant effect on antibody binding, but it is important to avoid the potential succinimide formation of a *C*-terminal Asp-amide or Asp-Ahx. For both the cyclization and the conjugation, we employed the thioether bond formation, which is known to provide a chemically and biologically stable linkage and allows the use of unprotected precursors (*31*). The fast intramolecular (cyclization) or intermolecular (conjugation) reaction between the haloacetyl group (in our experiments, chloroacetyl group) and the thiol group of Cys under slightly alkaline conditions provided the appropriate products with good yields and no significant side reactions.

Synthesis of Cyclic Derivatives of 9−22 Epitope Peptide of HSV gD-1. The 9−22 epitope peptide was elongated with ε-aminohexanoic acid (Ahx) either at the *C*-terminus of peptide **8a** or at both termini of the 9−22 sequence as in peptide **9a** (Figure 1). The cyclization of the peptides occurred between the chloroacetylated *N*-terminus and the thiol group of Cys attached to the *C*-terminus (compounds **8a** and **9a**). Thus, cyclic peptides **8** and **9** were obtained with a ring size of 55 and 62 atoms, respectively. These two cyclic derivatives were prepared with Met in position 11. However, peptides designed for dimerization and conjugation as well were synthesized either with Met (**10a**) or Nle (**11a**) in position 11 in order to analyze the effect of substitution of Met by Nle on the antibody recognition of the compounds.

Linear peptides **10a** and **11a**, similarly to peptides **8a** and **9a**, were synthesized by Fmoc chemistry, while their branched derivatives **12a** and **13a** were prepared by applying a mixed methodology of Boc and Fmoc chemistries (Scheme 1). In this case, the linear part containing the 9−22 epitope was built up using Boc amino acid derivatives, while for the synthesis of the branch, Fmoc strategy was utilized. Chloroacetylation of the *N*-terminus of the peptides was achieved by the use of chloroacetic acid pentachlorophenyl ester which provided products of higher purity than the chloroacetic anhydride. In the case of peptide **10a**, incorporation of a bromoacetyl (BrAc) moiety using bromoacetic anhydride was also attempted (data not shown). However, after cleavage of the peptide from the

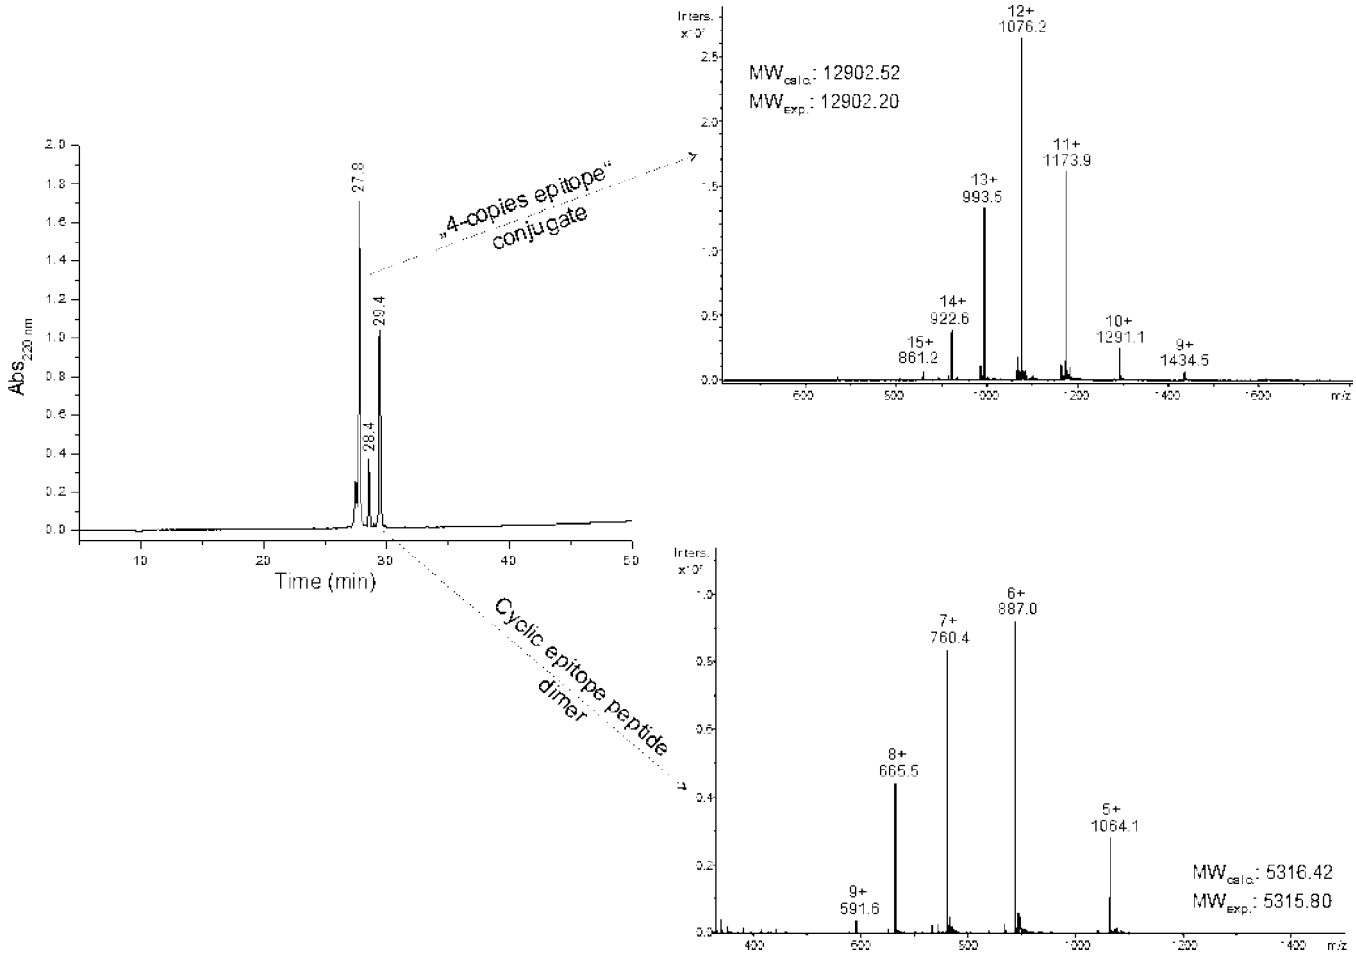

Figure 4. Conjugation of Ac-OT20(ClAc)$_4$ carrier with c[CH_2 COLKNleADPNRFRGKDLAhxK(Ac-CGFLG)AhxC]-NH_2 (**19**) epitope peptide followed by RP-HPLC and mass spectrometry: 24 h reaction time.

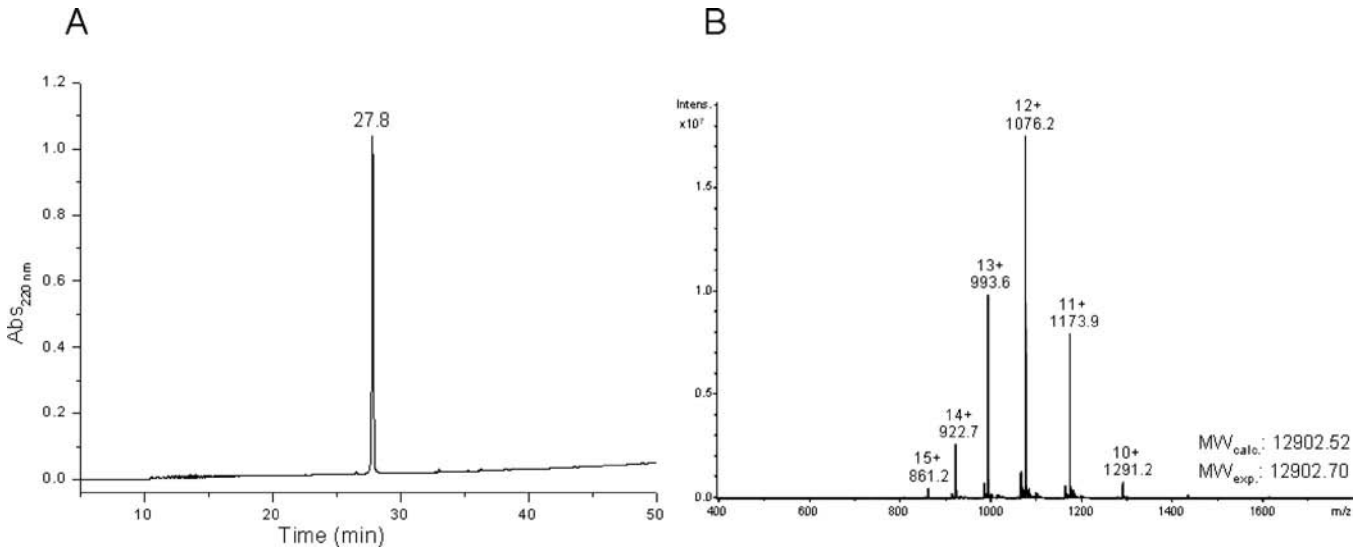

Figure 5. RP-HPLC profile (A) and ESI-ion trap mass spectrum (B) of purified conjugate **21**.

resin, a very complex crude product was detected by RP-HPLC. It was not stable even in freeze−dried form; a large number of byproducts were observed probably due to the reactivity of the BrAc group toward nucleophilic groups in the peptide (not only the thiol group) as well as to cross-linkage of peptide chains. On the basis of this observation, only chloroacetylated peptides were used in the further studies. In the linear peptide **10a**, the sequence at the *N*-terminal part was identical to the sequence in the peptide **8a**. The *C*-terminus was elongated by a hexapeptide consisting of an enzyme-labile sequence GFLG (*32*), with Cys and Ahx as spacer units. This Cys residue protected by Acm, which is stable under the acidic cleavage conditions as well as under the conditions of the cyclization procedure, provided the conjugation site in the dimerization reaction. In peptide **11a**, which is similar to peptide **10a**, Met was replaced with Nle. The cyclization of peptides **10a** and **11a** via thioether

bond formation yielded compounds **10** and **11**, respectively, each with a 55-atom ring. In linear peptides **12a** (^{11}Met) and **13a** (^{11}Nle), the Ahx-Lys-Ahx-Cys sequence was added to the *C*-terminus of the 9−22 epitope peptide. The *C*-terminal Cys was involved in a thioether cyclization with the *N*-terminal ClAc-group that yielded a 65-atom ring, while an additional Cys residue to be used for conjugation was included in an enzyme-labile (Ac-CGFLG) pentapeptide chain branching on the ε-amino group of the Lys near the *C*-terminus. The α-amino group of the Cys in this branch sequence was acetylated in order to prevent the fast formation of undesired disulfide bridge (*33*). Cyclization of peptides **12a** and **13a** provided **12** and **13**, respectively, with good yields. Compounds **10**−**13** were dimerized using $Tl(tfa)_3$ in a TFA solution. The disulfide bond formation was carried out at 0 °C for 90 min using 0.6 equiv of $Tl(tfa)_3$/Cys(Acm). Dimerization of compounds **10** and **12** with Met at residue 11 gave slightly lower yields, but no significant amount of methionine sulfoxide was detected. Cyclic dimers (compounds **14**−**17**) were isolated with fairly good yields (50−60%). Because the binding studies with Mab A16 (Table 2) indicated no significant differences between the recognition of cyclic dimer epitopes containing either ^{11}Met (11.8 pmol/100 μL (compound **14**) and 57.7 pmol/100 μL (compound **16**)) or ^{11}Nle (11.1 pmol/100 μL (compound **15**) and 41.4 pmol/100 μL (compound **17**)), only the Nle derivatives were used for further conjugation experiments. The dimers (compounds **15** and **17**) were reduced to their monomers with DTT (Scheme 2). The Cys connected to the spacer sequence (compounds **18** and **19**) was the conjugation site of the cyclic peptides in their coupling to the chloroacetylated oligotuftsin derivative carrier (Ac-[TKPK(ClAc)G]$_4$-NH_2). The conjugation was carried out in 0.1 M Tris−HCl buffer at pH 8.2 and monitored by RP-HPLC (Figures 2−4). After attachment of four copies of the cyclic epitope peptides to the carrier, the reaction was terminated by acidifying the solution with TFA. The conjugates (compounds **20** and **21**) were purified by semi-preparative RP-HPLC. The excess of Cys peptides was recovered after reduction with DTT. All cyclic peptides, their dimers, and conjugated derivatives were characterized by analytical RP-HPLC and ESI-MS (Figure 5). Data are summarized in Table 1.

Binding of Cyclic Derivatives of 9−22 Epitope Peptide of HSV gD-1 to Mab A16. Direct ELISA studies are often hampered by the different coating properties of the peptide constructs, which makes binding determination somehow unreliable. In our case, none of the dimers and conjugates of the cyclic peptides (compounds **14**−**17**) were able to bind to the ELISA plates. Therefore, competition ELISA was used to compare the antibody recognition of the compounds. Mab A16, which recognizes the 9−22 sequence in native gD (*9*), was used in this experiment. In a competition ELISA, only the binding properties of the compounds with Mab A16 in solution are measured, which gives more information on the binding properties of the peptide constructs.

Effect of Cyclization on Mab A16 Binding. No significant differences in binding were detected for various constructs with either Met or Nle at position 11 [79.1 (compound **10**, Met^{11}) vs 75.6 (compound **11**, Nle^{11}) and 88.0 (compound **12**, Met^{11}) vs 92.3 (compound **13**, Nle^{11}) pmol/100 μL]. This is in agreement with our previous results concerning linear peptides **1** and **2** (Table 2). Comparison between 16- and 8-residue cyclic peptides (e.g., **8** and **9** vs **3** and **4**, Table 2) showed that the larger ring clearly improved the antibody binding (79- and 273-fold, respectively). Whether this was due to less amino acids in the 8-residue cyclic peptides (compounds **8** and **9**) or to the modification of Arg at residue 18, it cannot be concluded. The cyclic peptides with hexapeptide spacer at the *C*-terminus (compounds **10**, **11**) or the branched ones (compounds **12**, **13**) had an approximately 2−3-fold lower binding activity to the Mab A16 than **8** and **9**. The binding activities of compounds **10** and **11** with the hexapeptide spacers were only slightly better than the binding of branched ones (compounds **12**, **13**).

Effect of Dimerization on Mab A16 Binding. Dimerization of the cyclic peptides **10**, **11**, **12**, and **13** resulting in compounds **14**, **15**, **16**, and **17**, respectively, increased the binding activity to Mab A16 in all cases. However, the disulfide bond formation at the *C*-terminus of the peptides (compounds **14**, **15**) led to higher antibody recognition of the cyclic dimer peptides than in the case of dimerization through the branching (compounds **16** and **17**). Both the Met and Nle containing derivatives (compounds **14** and **15**; 11.8 and 11.1 pmol/100 μL, respectively) had a higher binding activity to Mab A16 than the monomeric cyclic peptide without spacer sequences (compounds **8**, **9**; 28.6 and 28.0 pmol/100 μL, respectively). The binding capacity of dimers (57.7 (compound **16**) and 41.4 (compound **17**) pmol/100 μL), which had a disulfide bond between the branches, was better than that of their cyclic monomers (88.8 (compound **12**) and 92.3 (compound **13**) pmol/100 μL).

Effect of Conjugation on Mab A16 Binding. The binding data of the conjugates (compounds **20** and **21**) to the Mab A16 were surprising. In case of the conjugate (compound **20**) with the cyclic peptide containing a spacer and a Cys at the *C*-terminus (compound **18**) as the conjugation site, the binding affinity was dramatically decreased as compared to the monomer or dimer having the identical cyclic peptide (249.3 vs 75.6 (compound **11**) pmol/100 μL). In contrast, the other conjugate (compound **21**) in which the cyclic peptide was attached to the carrier through the branch showed excellent binding activity to the Mab A16 (7.2 vs 92.3 (compound **13**) pmol/100 μL). This binding capacity is comparable to the results of the linear epitope peptides as measured earlier (epitope construct **1** and **2**; Table 2). However, it is still 1 order of magnitude weaker than the binding of the OT20 conjugate containing the (^{11}Nle)-9−22C linear epitope peptide (**5**) and that of simple dimers of the linear peptide (**6**, **7**) (0.72, 0.74, and 0.66 pmol/100 μL, respectively; Table 2) (*25*).

CONCLUSION

The synthesis of cyclic forms of the epitope peptide 9−22 of gD-1, their dimers, and conjugates was carried out in this study. Dimers of cyclic peptides (without branches) and the cyclic peptide conjugated to an oligotuftsin derivative through the peptide spacer in the branch showed the highest binding activity to the Mab A16. Although a large variety of cyclic peptides and dimers of cyclic peptides were synthesized, a simple linear peptide 9−22 conjugated to OT20 and dimers of the linear peptide had the highest binding activity to the Mab A16. We hypothesize that only an accurate conformation of the cyclic constructs may result in higher binding activity than a linear construct with a potential to adopt the appropriate conformation. The strong binding activities of the dimers of the linear peptide are interesting. These results might be explained by binding of one peptide dimer molecule to both binding sites of one IgG or by cross-linking of IgG molecules. Mab A16 is directed against the native gD, as it is present in a cell infected by HSV. Therefore, another possible explanation of the strong binding of the dimer peptide 9−22 could be that gD in the native form during the virus infection has a dimer structure (*34*−*36*). We expected higher binding activity by cyclization of the epitope peptide 9−22, but our results showed that this was not the case. In addition, cyclization might enhance the stability of the peptide against enzymatic degradation. According to other results (*37, 38*) by our group, one can assume that conjugated cyclic peptides might have increased stability

in human serum compared to their linear versions. For this reason, in addition to compound **5** containing the linear epitope in the conjugate, compound **21** in which cyclic epitope was conjugated to OT20 carrier on its branch was selected for further development for the investigation of their immune response inducing potential. The results of these studies will be reported elsewhere.

Received June 13, 2008; Revised Manuscript Received January 27, 2009

The aim of this study was to investigate the influence of dendrimer surface properties on cellular internalization and intracellular trafficking in the human colon adenocarcinoma HT-29 cell line. Third-generation (G3) polyamidoamine (PAMAM) dendrimers were modified to contain either two lauroyl chains (G3L2), two propranolol molecules (G3P2), or two lauroyl and two propranolol molecules (G3L2P2) at the dendrimer surface. Surface-modified and unmodified dendrimers were labeled with fluorescein isothiocyanate (FITC) at an average molar ratio of 1:1. The mechanisms of cellular internalization and intracellular trafficking of dendrimers were analyzed by confocal laser scanning microscopy and flow cytometry. The internalization of G3 and G3P2 dendrimers involved both caveolae-dependent endocytosis and macropinocytosis pathways; internalization of G3L2P2 dendrimer appeared to involve caveolae-dependent, and possibly clathrin-dependent, endocytosis pathways; and internalization of G3L2 dendrimer occurred via caveolae-dependent, clathrin-dependent, and macropinocytosis pathways. Subcellular colocalization data indicated that unmodified and all surface-modified G3 PAMAM dendrimers were internalized and trafficked to endosomes and lysosomes. It is therefore apparent that the initial mode of dendrimer internalization into HT-29 cells is influenced by the surface properties of G3 PAMAM dendrimer.

INTRODUCTION

Due to their highly branched nature and the presence of multivalent surface groups that can be conjugated with drugs, polyamidoamine (PAMAM) dendrimers offer significant potential as versatile carriers for drug delivery (*1*). Our previous studies have established that the conjugation of propranolol, a P-glycoprotein substrate with poor bioavailability, to cationic PAMAM dendrimer increased drug solubility and enhanced the permeation of propranolol across Caco-2 cell monolayers (*2*). Numerous studies have reported that surface modification of dendrimers can cause significant changes in their biological properties, including cytoxicity and permeation through cell monolayers (*2*−*6*). Addition of lauroyl moieties to cationic PAMAM dendrimers has been reported to increase transcellular apical-to-basal transport of both dendrimer and dendrimer−drug conjugates in Caco-2 cells (*2*−*4, 7, 8*). Addition of FITC onto cationic G4 PAMAM dendrimer at a ratio of 8:1 resulted in a decrease in dendrimer cytotoxicity and significant increase in permeation through Caco-2 cell monolayers (*5*). A study of the influence of surface acetylation of cationic G2 and G4 PAMAM dendrimer on the viability of Caco-2 cells revealed that acetylation resulted in a significant decrease in cytotoxicity. Cytotoxicity decreased as the number of surface acetyl groups increased while the permeability across cell monolayers was maintained (*6*). These findings reveal that PAMAM dendrimers offer potential as nanoparticulate drug delivery systems. However, although surface modification is able to enhance transcellular dendrimer permeation, little is known of the precise influence of surface modification on the mechanism(s) of dendrimer cellular internalization and intracellular trafficking.

PAMAM dendrimers are able to traverse cell monolayers via paracellular and transcellular pathways (*2, 4, 5, 9, 10*), and the endocytosis pathway is believed to be an important route for dendrimer internalization. Kitchens et al. (*11, 12*) reported that uptake of cationic and anionic (G2, G4, and G1.5) PAMAM dendrimers into Caco-2 cells was via clathrin-dependent endocytosis, whereas cationic G4 PAMAM dendrimer were predominately internalized via a cholesterol-dependent route in B16F10 melanoma cells (*13*).

In this study, we investigated the effect of conjugating lauroyl and/or propranolol groups onto the surface of G3 PAMAM dendrimers on the mechanism of cellular internalization and subsequent intracellular trafficking in HT-29 cells, which are capable of clathrin-mediated endocytosis, caveolae-mediated endocytosis, and macropinocytosis (*14*−*19*).

G3 PAMAM dendrimers were employed since they are less cytotoxic than both G4 and G5 PAMAM dendrimers (*3, 4*) and were chosen in preference to G2 dendrimers, because the latter possess significantly fewer surface groups available for attachment of surface moieties. In addition, G2 and anionic dendrimers, e.g., G2.5, G3.5, demonstrate less apparent permeation through cell monolayers than G3 dendrimer (*4*).

A better understanding of the influence of the surface properties of dendrimers on their internalization mechanisms is important in the development of dendrimer-mediated drug delivery systems.

EXPERIMENTAL PROCEDURES

Materials. G3 PAMAM dendrimer was purchased from Dendritech Inc. (Michigan, USA). Sephadex G-25, fluorescein isothiocyanate (FITC), chlorpromazine hydrochloride, filipin III, 5-(*N*-ethyl-*N*-isopropyl) amiloride, nystatin, trypan blue, formaldehyde, and bovine serum albumin were purchased from Sigma-Aldrich Co. Ltd. (Gillingham, Dorset, UK). Saponin was obtained from Fluka (Steinheim, Germany). Cell culture materials, Lysotracker Red DND-99, Alexa Fluor 555 rabbit antigoat

IgG (heavy and light chains), Alexa Fluor 555 goat antirabbit IgG (heavy and light chains), and Alexa Fluor 555 conjugated transferrin (from human serum) were obtained from Invitrogen (Paisley, UK). Caveolin-1 (N-20) rabbit polyclonal IgG and tetramethylrhodamine-5-isothiocyanate (TRITC)-clathrin HC (C-20) goat polyclonal IgG were obtained from Santa Cruz Biotechnology (Heidelberg, Germany). Cytotoxicity detection kit (lactate dehydrogenase, LDH) was purchased from Roche Applied Science (Mannheim, Germany). All other chemicals were purchased from BDH Laboratory Supplier (Poole, Dorset, UK).

Synthesis of Surface-Modified G3 PAMAM Dendrimers. The synthesis of surface-modified PAMAM dendrimers containing two lauroyl chains (G3L2) was performed using 4-nitrophenyl chloroformate as a linker (*7*). Lauroyl alcohol, 200 mg (1 mmol), was dissolved in 5 mL of anhydrous tetrahydrofuran (THF), and triethylamine (TEA) 0.3 mL (2.1 mmol) was added. 4-Nitrophenylchloroformate, 417 mg (2 mmol), was dissolved in 1.5 mL of anhydrous THF, added dropwise to the mixture, and stirred for 24 h under nitrogen at room temperature. Following evaporation of solvent, the residue was dissolved in hexane/diethylacetate (85:15), filtered (Whatman No. 1), and purified by silica gel column chromatography using a hexane/diethylacetate (85:15) mobile phase. The mobile phase was applied with a flow rate of 120 mL per h, and 5 mL fractions were collected and analyzed by TLC (using the same mobile phase) to identify the purified compound. Purified lauroyl 4-(nitrophenyl carbonate) was characterized by ^{1}H NMR as described previously ($CDCl_3$): 0.88 (3H, t, J = 6.8, CH_3), 1.27−1.42 (18H, m, (CH_2)$_8$), 1.76 (2H, pentet, J = 7.0, CH_2), 4.29 (2H, t, J = 6.6, CH_2COO), 7.32−7.39 (2H, m, Ar-H_2 + Ar-H_6), 8.27−8.30 (2H, m, Ar-H_3 + Ar-H_5) (*7*). G3 PAMAM dendrimer, 0.21 mg (0.03 mmol), was dissolved in 20 mL of anhydrous *N*,*N*-dimethylformamide (DMF). Lauroyl (4-nitrophenyl carbonate), 0.06 mmol (2 lauroyl molecules/1 G3 PAMAM dendrimer), was dissolved in 5 mL of anhydrous DMF and added dropwise to the reaction mixture (Figure 1). The reaction was carried out, with stirring, at room temperature for 5 days. Lauroyl−G3 PAMAM conjugate (G3L2) (Figure 1-(1)) was purified by chromatography using Sephadex LH20 with a methanol/water (4:1) mobile phase applied at a flow rate of 90 mL per h. 1.5 mL samples were collected and absorbance measured at 230 nm. The ratio of lauroyl to G3 PAMAM dendrimer was verified by using ^{1}H NMR. The yield of G3L2 was 66.23% (w/w). ^{1}H NMR (d_4-MeOD): 0.89 (6H, CH_3), 1.29 (36H, (CH_2)$_9$), 1.43 (4H, CH_2), 2.38 (120H, CH_2C═ONH), 2.58 (120H, CH_2NH + CH_2N), 2.80 (124H, NCH_2), 3.31 (120H, *O*═CNHCH_2), 4.00 (4H, CH_2COO).

Synthesis of G3 PAMAM dendrimer conjugates containing either two propranolol molecules (G3P2) (Figure 1-(2)) or two propranolol molecules and two lauroyl molecules (G3L2P2) (Figure 1-(3)) employed chloroacetyl chloride as a linker (*2*). Propranolol base, 7.6 mmol, was dissolved in 20 mL of anhydrous dichloromethane (DCM) and TEA, 22.8 mmol, was added. Chloroacetyl chloride, 7.6 mmol, was added slowly and the reaction stirred for 1 h on ice. The dark brown solution obtained was sequentially washed once with equal volumes of saturated solutions of sodium bicarbonate and then sodium chloride. The organic layer was dried over anhydrous magnesium sulfate and evaporated to dryness. The crude residue was dissolved in mobile phase (hexane/diethylacetate (1:1)) and purified by silica gel column chromatography. The mobile phase was applied with a flow rate of 120 mL per h and 5 mL fractions collected and analyzed by TLC to identify fractions containing purified propranolol-*N*-chloroacetyl. Characterization of propranolol-*N*-chloroacetyl was by ^{1}H NMR and ^{13}C NMR. The yield of propranolol-*N*-chloroacetyl was 70.05% (w/w). ^{1}H NMR

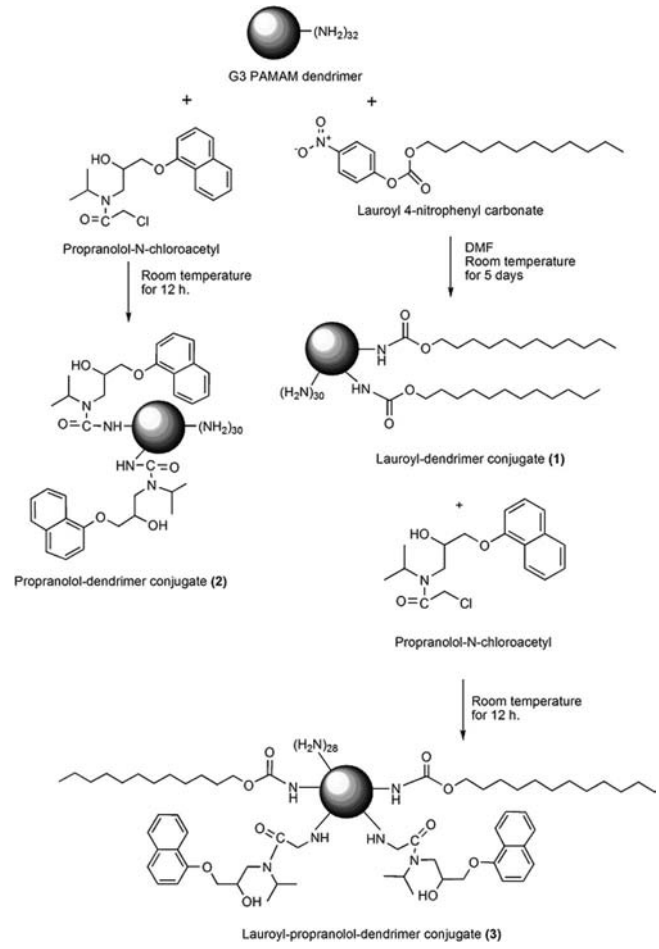

Figure 1. Synthetic scheme for surface modification of G3 PAMAM dendrimers.

($CDCl_3$): 1.30 (6H, dd J = 26.06 Hz, J = 6.71 Hz, (CH_3)CH), 3.66 (1H, dd, J = 14.6 Hz, J = 1.9 Hz (CH$_3$)CH), 3.72 (1H, dd, J = 14.6 Hz, J = 7.8 Hz (CH$_3$)CH), 4.09 (1H, m, CHN), 4.17 (2H, s, CH_2Cl), 4.21 (2H, m, CH_2O), 4.26 (1H, m, CHO), 6.84 (1H, d, J = 7.47 Hz, 1H, Ar-H_2), 7.45 (4H, m, Ar-H_3 + Ar-H_4 + Ar-H_7 + Ar-H_8), 7.79 (1H, m, Ar-H_6), 8.20 (1H, m, Ar-H_9). ^{13}C NMR: 21.0 (2 × CH_3), 41.0 (CH_2Cl), 46.1 (CH_2NCH), 49.8 ((CH$_3$)$_2$CHN), 69.4 (CHOH), 71.3 (CHCH_2O), 104.4 (CH, Ar), 120.3 (CH, Ar), 121.1 (CH, Ar), 124.8 (CH, Ar), 125.5 (CH, Ar), 126.0 (CH, Ar), 126.1 (C, Ar), 127.6 (CH, Ar), 134.0 (C, Ar), 153.5 (C, Ar), 168.9 (ONCCH$_2$).

In order to conjugate propranolol to dendrimer, either G3 PAMAM dendrimer, 0.21 mg (0.03 mmol), or G3L2 PAMAM dendrimer, 0.22 mg (0.03 mmol), was dissolved in 15−20 mL of anhydrous DMF. Propranolol-*N*-chloroacetyl, 0.06 mmol (1 propranolol molecules/1 G3 PAMAM dendrimer or 1 G3L2 PAMAM dendrimer), was dissolved in 5 mL of anhydrous DMF, added dropwise to the mixture, and stirred at room temperature for 12 h. Propranolol−G3 PAMAM conjugate (G3P2) was purified by column chromatography using Sephadex LH20 with methanol/water (4:1) mobile phase. The latter was applied at a flow rate of 90 mL per h. A series of 1.5 mL samples were collected and absorbance measured at 230 nm. The number of propranolol molecules attached was confirmed by using ^{1}H NMR. The yields of G3P2 and G3L2P2 were 31.01% and 54.37% (w/w), respectively. G3P2 (d_4-MeOD): 1.286−1.308 (12H, (CH_3)$_2$CH), 2.372 (120H, CH_2C═ONH), 2.583 (120H, CH_2NH + CH_2N), 2.789 (124H, NCH_2), 3.272−3.346 (120H, *O*═CNHCH_2), 3.593−4.695 (16H, CH_2NCH + CHN + CH_2O + HNCH_2C═ON + CHO), 6.878−7.046 (2H, Ar-H_2), 7.376−7.483 (8H, Ar-H_3 + Ar-H_4 + Ar-H_7 + Ar-H_8), 7.803−7.814 (2H,

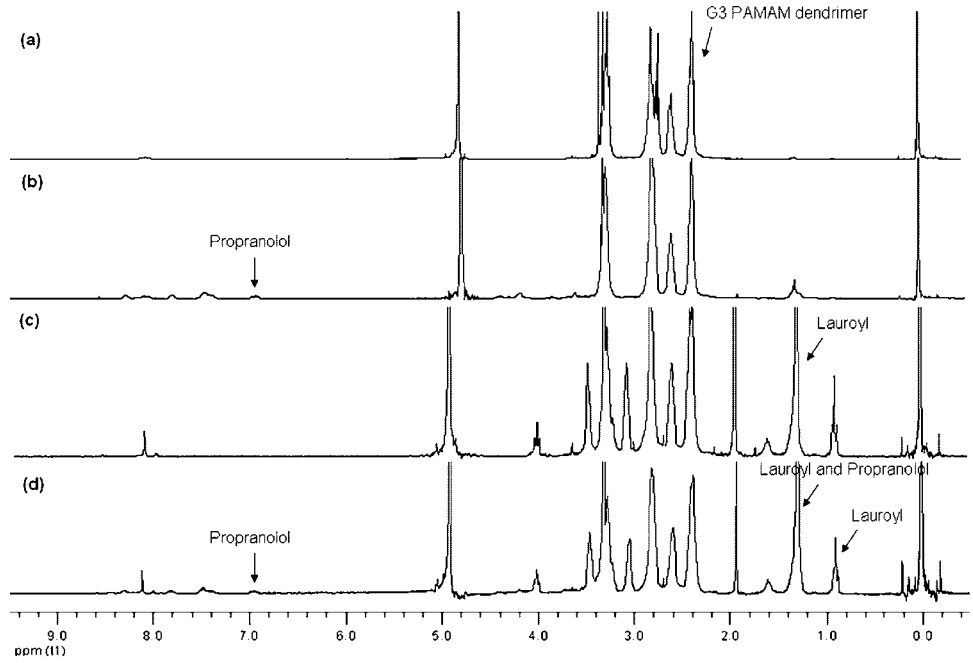

Figure 2. ^{1}H NMR spectra (270 MHz) of (a) G3, (b) G3P2, (c) G3L2, and (d) G3L2P2 PAMAM dendrimers (d_4-MeOD).

Ar-H_6), 8.293 (2H, Ar-H_9). G3L2P2 (d_4-MeOD): 0.89 (6H, CH_3), 1.23 (48H, (CH_2)$_9$ + (CH_3)$_2$CH), 1.54−1.67 (4H, CH_2), 2.46−2.53 (120H, CH_2C═ONH), 2.60 (120H, CH_2NH + CH_2N), 2.87 (124H, NCH_2), 3.05−3.06 (120H, *O*═CNHCH_2), 3.36−3.53 (16H, CH_2NCH + C*H*N + CH_2O + NHCH_2C═ON + C*H*O), 3.94−4.19 (4H, CH_2COO), 7.43−7.58 (8H, Ar-H_3 + Ar-H_4 + Ar-H_7 + Ar-H_8), 7.85 (2H, Ar-H_6), 8.23 (2H, Ar-H_9).

Preparation and Characterization of FITC-Labeled G3 PAMAM Dendrimers. G3 PAMAM dendrimer and surface-modified dendrimers were labeled with FITC via a thiourea bond between the isothiocyanate group of FITC and an amine group of PAMAM dendrimer, as described previously (*4*). Briefly, 15 mL of a methanolic solution of FITC containing 0.036 mmol was slowly added to 0.030 mmol of G3 PAMAM dendrimer (a molar ratio 1.2:1 of PAMAM dendrimer to FITC) in 15 mL PBS and stirred at room temperature for 24 h in the dark. FITC-labeled G3 PAMAM dendrimer was purified by size exclusion chromatography on a Sephadex G-25 column (mobile phase: phosphate buffered saline (PBS)). One milliliter fractions were collected and those containing FITC−dendrimer conjugate identified using TLC (mobile phase: chloroform/methanol/ammonia, 5:4:1). Fractions containing FITC−dendrimer were pooled and dialyzed against distilled water for 24 h to remove salts. Manipulations involving FITC-labeled dendrimers were carried out in a low-light environment. The ratio of FITC to dendrimer was confirmed using ^{1}H NMR.

Analysis of size distribution of FITC-labeled G3 dendrimer and surface-modified dendrimers was performed using dynamic light scattering (Zetasizer Nano, Malvern Instruments, UK) (*4, 20*). Samples were dissolved in PBS (10 mg/mL) and filtered through a Nalgene filter (0.2 μm pore size) into the scattering cell. All measurements were carried out at 37 °C. Diameters are represented as mean ± standard deviation of triplicate measurements.

Cell Culture. HT-29 cells (passage number 36−67) were maintained in Dulbecco's Modified Eagles Medium (DMEM) containing 10% (v/v) fetal calf serum, 2 mM L-glutamine, 10 mM nonessential amino acids, 50 IU/mL penicillin, and 50 μg/mL streptomycin at 37 °C in an atmosphere of 5% CO_2.

LDH Assay. Approximately 1×10^4 HT-29 cells/well were cultured in 96-well plates overnight. The cells were treated with chlorpromazine (5−50 μM), filipin (0.25−5 μg/mL), nystatin (5−50 μM), and EIPA (50−250 μM) for 4 h. To measure dendrimer cytotoxicity, 100 μL of supernatant was transferred into an optically clear 96-well plate. The LDH reaction mixture was freshly prepared according to the manufacturer's instruction (Roche Diagnostics), 100 μL added to each well, and the plate incubated for 30 min at 25 °C. The absorbances at 450 and 650 nm were measured using a multiplate reader (MRX, Dynatech Laboratories, Guernsey, UK).

Determination of the Effect of Endocytosis Inhibitors on Uptake of G3 PAMAM Dendrimers. Chlorpromazine (inhibitor of clathrin-dependent endocytosis) (*21, 22*), nystatin and filipin (inhibitors of caveolae-dependent endocytosis) (*23*−*25*), and ethyl isopropyl amiloride (inhibitor of macropinocytosis) (*26, 27*) were dissolved in Opti-MEM I medium containing 12.5 mM HEPES, pH 7.4. Approximately 1×10^6 HT-29 cells/well were seeded in 6-well plates and incubated at 37 °C in an atmosphere of 5% CO_2 until cells reached 80% confluency. Cells were washed twice with PBS and pretreated with Opti-MEM I medium with 12.5 mM HEPES pH 7.4 containing inhibitor (at the concentrations indicated in Figure 4) for 30 min at 37 °C in an atmosphere of 5% CO_2. FITC-labeled G3 PAMAM dendrimer and FITC-labeled surface-modified PAMAM dendrimers were added at a final concentration of 2.5 μM and cells incubated for 1 h. Following a 1 h incubation, cells were washed three times with ice-cold PBS and incubated with FITC-quench solution (PBS containing 0.4% w/v trypan blue) for 10 min to quench extracellular fluorescence. Cells were washed three times with ice-cold PBS and treated with 0.25% (v/v) trypsin−EDTA solution for 5 min at 37 °C. The cell suspension was centrifuged at 12 000 *g* for 3 min, the pellet resuspended in PBS, and intracellular fluorescence analyzed immediately by flow cytometry (Dako Cytomation, Glostrup, Denmark). A flow rate of less than 200 events/s and an excitation wavelength of 488 nm (530/40 bandpass filter) were employed.

Subcellular Localization of FITC-Labeled G3 PAMAM Dendrimers. HT-29 cells were seeded onto collagen-coated coverslips and grown to 70% confluency. DMEM growth medium was replaced with Opti-MEM I medium with 12.5 mM HEPES, pH 7.4, containing 2.5 μM FITC-labeled G3 PAMAM dendrimer or FITC-labeled surface-modified PAMAM den-

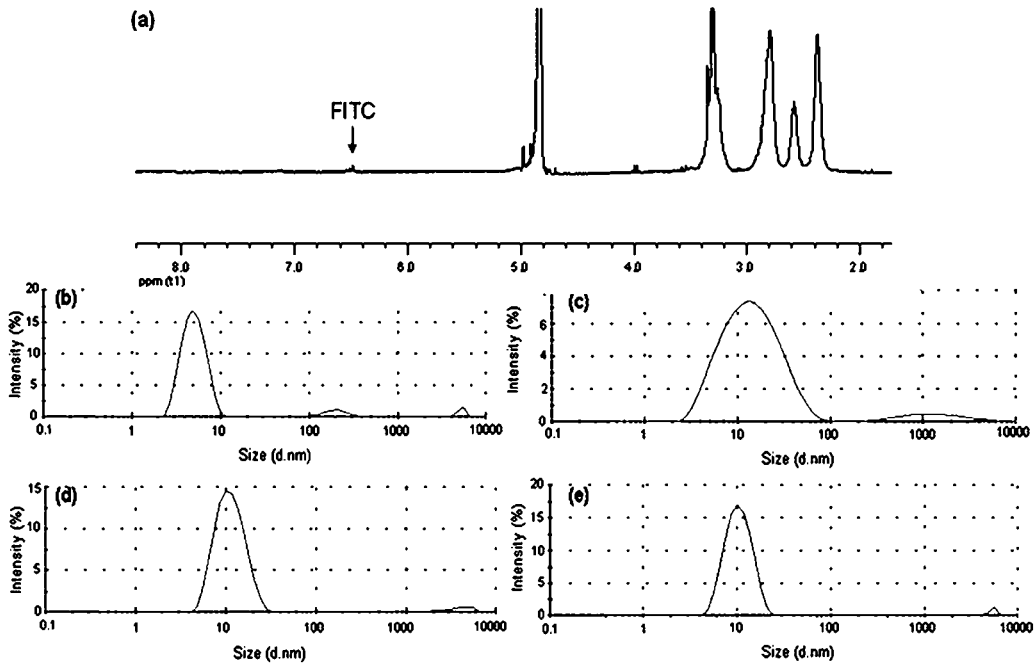

Figure 3. [1]H NMR spectra (270 MHz) of (a) FITC-labeled G3 PAMAM dendrimer and size distribution of (b) FITC-labeled G3, (c) FITC-labeled G3P2, (d) FITC-labeled G3L2, and (e) FITC-labeled G3L2P2 PAMAM dendrimers.

drimers. In immunofluorescence studies, cells were incubated for 1.5 h with dendrimer. In endosome localization studies, cells were incubated for 1 h, while in lysosome localization studies, cells were incubated for 12 h (G3), 3 h (G3P2), 6 h (G3L2), or 12 h (G3L2P2). Growth medium was removed, and cells were washed three times with ice-cold PBS.

For detection of clathrin and caveolin-1, HT-29 cells were fixed with 4% (v/v) formaldehyde in PBS for 10 min. Free aldehyde groups were quenched by incubating with 50 mM NH_4Cl for 10 min, and cells were then permeabilized by treatment with 0.1% (w/v) saponin in PBS. After three washes with PBS, permeabilized cells were incubated with PBS containing 5% (w/v) BSA to reduce nonspecific antibody binding and then incubated with either anticlathrin heavy-chain goat polyclonal IgG or anticaveolin-1 rabbit polyclonal IgG (1:100) for 2 h. Cells were washed three times with PBS and incubated with either Alexa Fluor 555 rabbit antigoat IgG or Alexa Fluor 555 goat antirabbit IgG (1:100) for 1 h. After thorough washing with PBS, coverslips were mounted onto microscope slides using mounting medium. Cell-associated fluorescence was analyzed by confocal laser scanning microscope.

Transferrin was used as a positive control of receptor-mediated endocytosis and trafficking into endosomes. Cells were incubated with Alexa Fluor 555-transferrin (50 μg/mL) in Opti-MEM I medium at 37 °C in an atmosphere of 5% CO_2 for either 10 min (G3P2, G3L2, G3L2P2) or 60 min (G3). Cells were washed with ice-cold PBS containing 0.5% w/v BSA and then with ice-cold PBS. Cells were fixed immediately with 4% w/v formaldehyde in PBS and treated with 50 mM NH_4Cl to quench residual formaldehyde fluorescence. Following further washing with PBS, coverslips were mounted onto microscope slides using mounting medium. Alexa Fluor 555-transferrin was visualized using confocal laser scanning microscopy.

For detection of lysosomes, HT-29 cells were incubated in Opti-MEM I medium containing Lysotracker Red DND-99 for 45 min at 37 °C. Cells were washed three times with PBS prior to confocal laser scanning microscopy.

Confocal Laser Scanning Microscopic Analysis and Image Processing. Cells were examined with a Zeiss LSM 510 Meta ConfoCor 2 using 63× oil immersion objective. FITC-labeled G3 PAMAM dendrimer or FITC-surface-modified PAMAM dendrimers were analyzed using an argon laser (excitation 488 nm; emission 505−550 nm). Lysotracker Red DND-99 or Alexa Fluor 555 labeled antibodies and Alexa Fluor 555−transferrin were analyzed using a helium/neon laser (excitation 543 nm; emission 560 nm). Images and a gallery of 30 optical sections (0.5 μm) through the *z* plane were collected and processed using Combi LSM-FCS and LSM Image Browser v4.0 software (Germany). Colocalization studies were carried out on three discrete regions of the microscope slide (with between 3 and 6 individual cells analyzed per slide). Data were analyzed using *ImageJ* v 1.410 (National Institutes of Health, USA). Channel overlap was determined by calculation of Pearson's coefficient and the true extent of three-dimensional colocalization defined by the Overlap Coefficient.

Statistical Analysis. Statistical analysis was carried out using one-way analysis of variance (ANOVA) followed by Dunnett's test (SPSS for Windows version 10.0). Probability values of $P < 0.05$ were considered to be significant.

RESULTS

Conjugation of Dendrimers with Lauroyl and Propranolol Molecules. [1]H NMR studies revealed that, on average, G3 PAMAM dendrimer (Figure 2a) was successfully conjugated with two propranolol molecules (Figure 2b), with two lauroyl chains (Figure 2c), and with both two lauroyl chains and two propranolol molecules (Figure 2d). The successful conjugation of lauroyl chains to the G3 PAMAM dendrimer is indicated by the additional peaks at the chemical shift 0.89−1.43 ppm, which confirmed the attachment of lauroyl chain onto G3 PAMAM dendrimer (Figure 2b). The number of lipid chains was calculated by comparing the peak integrations of the chemical shift at 1.29 ppm of lauroyl and at 2.38 ppm of PAMAM dendrimer (Figure 2b). Attachment of propranolol molecules to dendrimer is indicated by the additional peaks at the chemical shifts 1.29−1.31 ppm, 3.59−4.70 ppm, and 6.88−8.29 ppm. The integration of the peak between 7.43 and 7.49 ppm of propranolol and 2.38 ppm of PAMAM dendrimer revealed that two propranolol molecules were attached to G3 PAMAM

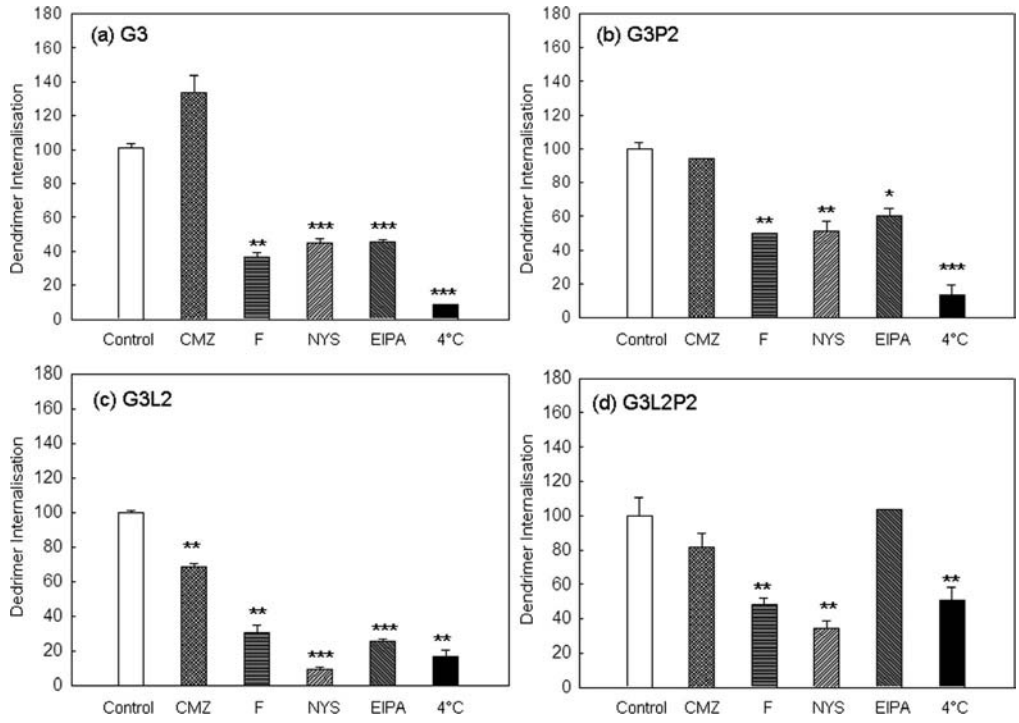

Figure 4. Effect of endocytosis and macropinocytosis inhibitors chlorpromazine 50 μM (CMZ), filipin 1 μg/mL (F), nystatin 50 μM (NYS), 5-(*N*-ethyl-*N*-isopropyl) amiloride 150 μM (EIPA), and low-temperature (4 °C) treatment on dendrimer internalization into HT-29 cells. Dendrimer accumulation in untreated cells was set at 100%. Data are given as mean ± SD of triplicate experiments. Statistical analysis was carried out using one-way analysis of variance (ANOVA) followed by Dunnett's test (* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$).

dendrimer (Figure 2c). However, there was an overlap between propranolol molecules and lauroyl moieties at a chemical shift of 1.23 ppm (Figure 2d). Therefore, the integration of peaks at chemical shift 0.89 of lauroyl moieties, 2.39−2.43 ppm of G3 dendrimer, and 6.90−7.01 ppm of propranolol were used to establish the presence of two lauroyl moieties and two propranolol molecules on the G3 dendrimer (Figure 2d).

Synthesis and Characterization of FITC-Labeled G3 PAMAM Dendrimers. ^{1}H NMR analyses indicated parent G3 PAMAM dendrimer (Figure 3a) and surface-modified dendrimers (data not shown) were successfully labeled with FITC at an average ratio of 1:1. Size distribution curves from dynamic light scattering for FITC-labeled G3 (Figure 3b), -G3P2 (Figure 3c), -G3L2 (Figure 3d), and -G3L2P2 (Figure 3e) PAMAM dendrimers yielded mean diameters of 5.18 ± 0.24, 17.00 ± 2.28, 11.81 ± 1.50, and 10.73 ± 0.01 nm, respectively. The data show that addition of the FITC label to the G3 dendrimer caused an increase of hydrodynamic diameter of approximately 1−2 nm. Addition of the lauroyl and/or propranolol groups to G3 PAMAM dendrimers resulted in an increase in hydrodynamic diameter of between 5.6 and 11.8 nm indicating successful attachment of moieties, with possible dimer and trimer formation due to chain entanglement (G3L2) and π-stacking of aromatic rings (G3P2). We also noted that the hydrodynamic diameter of G3L2P2 appeared to be less than that of G3P2, possibly a consequence of differing extents of dendrimer aggregation.

Effect of Dendrimers on Cell Viability. Studies were initially carried out to measure the viability of HT-29 cells exposed to dendrimer (2.5 μM). Viability of cells incubated with G3 was set at 100%, with viabilities of 100 ± 4.65%, 100 ± 4.65%, and 87.90 ± 2.60% observed for cells incubated with G3L2, G3P2, and G3L2P2, respectively.

Effect of Surface Modification on the Rate of Internalization of Dendrimers. The effect of surface modification on the rate of intracellular internalization of dendrimer into HT-29 cells was analyzed by flow cytometry. The rate of internalization of unmodified parent G3 dendrimer was 118.64 ± 0.22 absorbance units/hour (au/h). Addition of, on average, two lauroyl molecules to the parent dendrimer, to yield G3L2, significantly ($P < 0.05$) increased the rate of internalization to 235.74 ± 11.47 au/h. In contrast, the rate of uptake of parent dendrimer modified to possess, on average, two propranolol molecules (G3P2) at 49.10 ± 4.38 au/h, was significantly ($P < 0.001$) less than the uptake rate of G3 dendrimer. Addition of, on average, two lauroyl and two propranolol molecules to the parent dendrimer (G3L2P2) had no significant effect on the rate of internalization of modified dendrimer, 144.68 ± 6.64 au/h, compared to unmodified G3.

Effect of Endocytosis Inhibitors on the Internalization of Dendrimers. Studies were carried out using endocytosis inhibitors in order to examine the possible mechanisms of dendrimer internalization in HT-29 cells. Initial measurement of the cytotoxicity of endocytosis inhibitors showed that exposure of cells to chlorpromazine (50 μM) (*21*, *28*), filipin (1 μg/mL) (*12*), nystatin (50 μM) (*28*), and EIPA (150 μM) (*26*) resulted in cell viabilities of 74.22 ± 7.38% (compared to untreated cells at 100% viability), 78.23 ± 5.20%, 81.11 ± 6.01%, and 98.31 ± 0.61%, respectively. Confocal analyses of cells treated with endocytosis inhibitors at these concentrations revealed that cells possessed a healthy morphology, and subsequent inhibition studies were carried out using these inhibitor concentrations.

Flow cytometry studies were carried out to investigate the effects of endocytosis inhibitors on dendrimer internalization. Treatment of HT-29 cells with chlorpromazine (50 μM), an inhibitor of clathrin-dependent endocytosis, had no significant effect on the intracellular accumulation of FITC-labeled unmodified G3 dendrimer (Figure 4a), G3P2 (Figure 4b), or G3L2P2 (Figure 4d) but significantly reduced intracellular accumulation of lauroyl-modified (G3L2) dendrimer (Figure 4c). Treatment of cells with filipin (1 μg/mL) and nystatin (50 μM) (inhibitors of caveolae-dependent endocytosis) and incubation at reduced temperature (4 °C) significantly reduced intracellular accumulation of FITC-labeled unmodified G3 dendrimer and all of the dendrimer conjugates. EIPA (150 μM) (inhibitor of

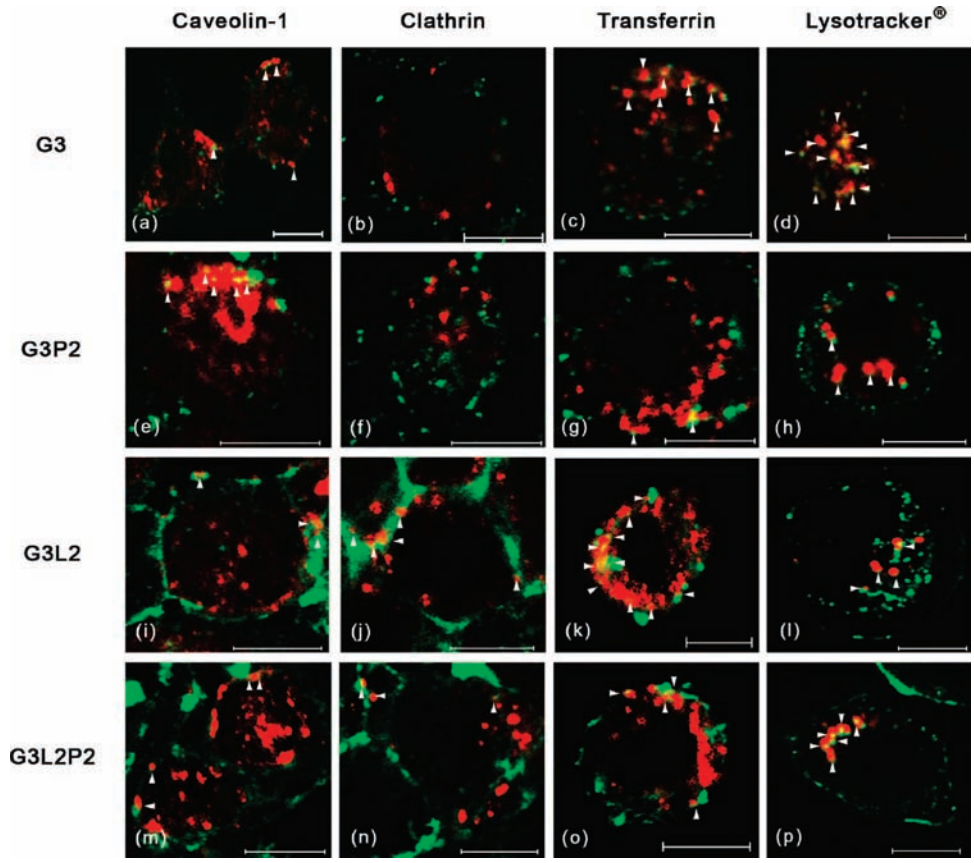

Figure 5. Subcellular localization of FITC-labeled G3 PAMAM dendrimers in HT-29 cells. HT-29 cells were incubated with the G3 dendrimers then either subjected to indirect immunostaining for caveolin-1 or clathrin or incubated with Alexa Fluor 555-transferrin or Lysotracker Red DND. Arrows indicate regions of colocalization of FITC-labeled dendrimers and endosome or lysosome marker.

macropinocytosis) significantly reduced intracellular accumulation of unmodified parent G3, G3P2, and G3L2 but had no significant effect on G3L2P2.

These findings suggest that cellular internalization of unmodified G3 dendrimer and G3P2 dendrimer conjugate occurs via both caveolae-dependent and macropinocytosis pathways. G3L2 dendrimer conjugate is internalized via clathrin-dependent, caveolae-dependent, and macropinocytosis pathways. However, internalization of G3L2P2 dendrimer conjugate appears to involve a caveolae-dependent endocytosis pathway.

Subcellular Localization of FITC Labeled-Unmodified and Surface-Modified G3 PAMAM Dendrimer in HT-29 Cells. To clarify further both the mechanism of internalization and the intracellular trafficking routes of dendrimers in HT-29 cells, subcellular colocalization of G3 PAMAM dendrimer and key endocytosis markers was investigated using confocal laser scanning microscopy. Clathrin was used as a marker of clathrin-dependent endocytosis and caveolin-1 as a marker of cavelae-dependent endocytosis. Transferrin undergoes receptor-mediated endocytosis and trafficks via the endosome pathway; therefore, Alexa Fluor 555-transferrin was used as an endosome marker. Lysotracker Red DND-99 was employed to identify lysosomes.

Unmodified FITC-labeled G3 dendrimer was localized both in the plasma membrane and intracellularly (Figure 5a,b,c,d, green). Indirect immunostaining of these cells with Alexa Fluor 555-caveolin-1 antibody showed caveolin-1 to be located predominantly in the plasma membrane, with some cytoplasmic localization (Figure 5a, red). Combining FITC and Alexa Fluor fluorescence revealed colocalization of G3 PAMAM dendrimer and caveolin-1 within the plasma membrane of HT-29 cells (Figure 5a, yellow). Confocal analyses of HT-29 cells indirectly immunostained with anticlathrin antibody showed fluorescence to be predominantly located at the plasma membrane (Figure 5b, red). However, negligible colocalization between FITC-labeled G3 dendrimer and clathrin were observed (Figure 5b). Alexa Fluor 555−transferrin was located both within the plasma membrane and intracellularly (Figure 5c, red). Areas of colocalization between G3 dendrimer and transferrin were observed both intracellularly and within the plasma membrane (Figure 5c, yellow). When HT-29 cells were incubated with FITC-labeled G3 dendrimer, sectioning in the *z*-plane indicated that fluorescence was associated with intracellular vesicle-like structures. Lysotracker Red DND was localized intracellularly (Figure 5d, red). Combining FITC and Alexa Fluor fluorescence of HT-29 cells incubated with FITC-labeled unmodified G3 dendrimer and Lysotracker Red DND-99 clearly revealed overlapping fluorescence of dendrimer and lysosome probe (Figure 5d, yellow).

The confocal images of HT-29 cells incubated with FITC-labeled G3P2 dendrimer revealed that fluorescence was associated both with the plasma membrane and with intracellular vesicle-like structures (Figure 5e, f, g, h, green), as was observed for FITC-labeled unmodified G3 dendrimer. FITC-labeled G3P2 dendrimer was found to colocalize with caveolin-1 (Figure 5e, yellow). There was negligible colocalization between this surface-modified G3 dendrimer and clathrin (Figure 5f), but colocalization with Alexa Fluor 555-transferrin (Figure 5g, yellow) and with Lysotracker Red DND (Figure 5h, yellow) was observed.

FITC-labeled G3L2 dendrimer localized at the plasma membrane, with some intracellular fluorescence observed (Figure 5i, j, k, l, green). This modified dendrimer colocalized with caveolin-1 (Figure 5i, yellow) and with clathrin (Figure 5j, yellow). These subcellular colocalization results are in

agreement with our finding that nystatin, filipin, and chlorpromazine reduce intracellular internalization (Figure 4c). FITC-labeled G3L2 dendrimer colocalized with Alexa Fluor 555−transferrin (Figure 5k, yellow) and was also observed to colocalize with Lysotracker Red DND (Figure 5l, yellow).

Incubation of HT-29 cells with FITC-labeled G3L2P2 dendrimer revealed FITC-associated fluorescence at the plasma membrane (Figure 5m, n, o, p, green). This modified dendrimer colocalized with caveolin-1 (Figure 5m, yellow) and with clathrin (Figure 5n yellow). Our studies revealed that FITC-labeled G3L2P2 dendrimer also colocalized with Alexa Fluor 555−transferrin (Figure 5o, yellow) and Lysotracker Red DND (Figure 5p, yellow).

All dendrimers and dendrimer conjugates studied are trafficked to lysosomes. In order to determine the effect of surface modification on the extent of dendrimer accumulation in lysosomes, semiquantitative analysis was carried out using *ImageJ* to obtain the overlap coefficient, which defines the extent of true 3-dimensional colocalization. The level of colocalization of G3 dendrimer with the lysosomal marker Lysotracker Red DND (overlap coefficient 0.8 ± 0.05) was significantly ($P < 0.0001$) higher than the colocalization levels observed with Lysotracker Red DND and G3P2 (0.5 ± 0.04), G3L2 (0.4 ± 0.07), or G2L2P2 (0.6 ± 0.08), suggesting that surface modification influences the extent of dendrimer trafficking to lysosomes.

DISCUSSION

Dendrimers are an attractive nanoparticulate drug delivery system which have been shown to significantly enhance delivery of several drugs such as propranolol, naproxen, terfenadine, 5-aminosalicylic acid, 5-fluorouracil, cisplatin, and doxorubicin (*2, 7, 8, 29*−*32*). However, little is known about the precise cellular mechanisms of dendrimer uptake and how modification of the dendrimer surface affect the internalization mechanism(s).

Cellular dendrimer internalization has been reported to involve both caveolae- and clathrin-mediated endocytosis (*11*−*13, 33*). In the HT-29 human intestinal adenocarcinoma cell line, confocal laser scanning microscopy revealed that caveolae and clathrin-1 were expressed in a manner consistent with the distribution patterns reported previously in HT-29 cells (*19*). All dendrimers studied colocalized with caveolin-1, as has been observed with the dendrimer−DNA complex in EAhy 926 cells (*33*), while G3L2 and G3L2P2 were found to colocalize with clathrin-1, consistent with our flow cytometry findings. The dendrimers used in the present study are cationic in nature, and several studies suggest that clathrin-dependent endocytosis may represent one of the most important pathways of internalization for several cationic lipoplexes in COS7, A549, and HeLa cells (*34*−*36*).

Subcellular colocalization studies revealed that all dendrimers colocalized with transferrin, consistent with studies that report that both FITC-labeled cationic and anionic PAMAM dendrimers (G2 and G1.5) colocalized with early endosomal antigen-1 (EEA-1) in Caco-2 cells (*11*) and with studies showing gold-labeled G3 PAMAM dendrimer localized into endosomes in Caco-2 cells (*37*).

To establish the effects of surface modification on the rate of intracellular internalization of dendrimers into HT-29 cells, flow cytometry studies were carried out. Associated with surface modification is a change in the size of dendrimer nanoparticles. These studies revealed no correlation between dendrimer size and either the rate or internalization mechanism of dendrimer uptake into HT-29 cells. These findings can be explained by the fact that linked with a change in size is a concomitant change in physicochemical characteristics, including charge and hydrophobicity, which have important roles in influencing interaction of nanoparticles with the cell surface.

Surface modification by the addition of, on average, two lauroyl molecules to G3 dendrimer significantly increased the rate of internalization. In addition, these studies revealed that G3 is taken up by both caveolae-mediated endocytosis and macropinocytosis. These results are in agreement with a reduction in cell-associated Orgeon green labeled G4 PAMAM dendrimer fluorescence observed in B16F10 murine melanoma cells in the presence of methyl-β-cyclodextrin (*13*) and the significant inhibition of uptake of second-generation dendrimer modified with 18 aminolaevulinic acid uptake in the presence of EIPA in PAM 212 cells (*27*). However, modification of G3 to G3L2 resulted in dendrimer internalization via clathrin-mediated endocytosis, as well as via caveolae-mediated endocytosis and macropinocytosis. These findings are consistent with those reported in Caco-2 cells in which the apparent permeability of G3 dendrimer modified with nine lauroyl moieties was reduced by inhibitors of clathrin-mediated endocytosis and caveolae-mediated endocytosis (Rachaneekorn Jevprasaphant, Antony D'Emanuele, David Attwood, Jeffrey Penny, unpublished results). Thus, modification of parent dendrimer with lauroyl moieties appears to offer an additional internalization pathway for G3 dendrimer uptake into HT-29 cells, and it is feasible that cellular uptake via an additional pathway has the potential to increase the rate of nanoparticle delivery.

The rate of intracellular internalization of G3 dendrimer possessing, on average, two propranolol molecules into HT-29 cells was significantly lower than that of unmodified G3 dendrimer. Furthermore, the rate-enhancing effect of lauroyl moieties on dendrimer uptake appeared to be negated in dendrimer possessing both lauroyl and propranolol moieties (G3L2P2). Multiple pathways are involved in the uptake of dendrimer and modified dendrimers into HT-29 cells, and the precise mechanism by which propranolol reduces the rate of dendrimer internalization is unknown. The plasma membrane is an extremely heterogeneous environment, possessing microenvironments with lipid, protein, and receptor profiles that differ significantly compared to the bulk of the plasma membrane. It is likely that the rate of dendrimer internalization is influenced by the physicochemical characteristics of the nanoparticles and the differential abilities of dendrimers to interact with the heterogeneous domains and microenvironments of the plasma membrane.

All dendrimers and dendrimer conjugates studied are trafficked into lysosomes, acidic organelles rich in hydrolytic enzymes. These findings are consistent with colocalization of FITC-labeled G1.5 and G2 PAMAM dendrimers with lysosome-associated membrane protein (LAMP-1) in Caco-2 cells (*11*). It is important to determine the relationship between surface modification and the extent of lysosome accumulation, since exposure to a hydrolytic environment may impact on the efficacy of dendrimer-mediated drug delivery. Semiquantitative colocalization studies revealed addition of lauroyl moieties to G3, to yield G3L2, resulting in significantly less modified dendrimer being trafficked into lysosomes. Similarly, semiquantitative colocalization studies revealed that, as with G3L2, significantly less G3P2 and G3L2P2 were associated with lysosomes compared to unmodified G3. It therefore appears that surface modification of G3 dendrimer influences not only the rate of intracellular accumulation in HT-29 cells, but also the extent of dendrimer accumulation within lysosomes.

CONCLUSION

Studies to elucidate the mechanisms and pathways of dendrimer internalization and trafficking are important, as they may

help define how surface modification may enhance cellular uptake of nanoparticulate dendrimer−drug complexes and potentially increase drug delivery across physiological cell barriers. The present study provides evidence that the surface properties of dendrimers influence the initial mode of dendrimer internalization in HT-29 cells. Modification of parent G3 dendrimer with lauroyl moieties increases the rate of intracellular uptake, a finding that could be exploited to increase the rate of oral drug delivery. In addition, modification of the nanoparticles with lauroyl moieties appears to reduce the extent of lysosomal accumulation, suggesting potentially less exposure of the dendrimer conjugate to the highly acidic lysosomal environment and hydrolytic enzymes, a potentially important issue when considering delivery of acid-labile drugs or drug conjugates. Thus, dendrimer modification with lauroyl chains is attractive, since it enhances the internalization kinetics of modified dendrimer into human intestinal epithelial cells and may have the potential for improving drug delivery via the oral route.

An Improved Cell-Penetrating, Caspase-Activatable, Near-Infrared Fluorescent Peptide for Apoptosis Imaging

Dustin Maxwell,[†] Qing Chang,[‡] Xu Zhang,[‡] Edward M. Barnett,[‡] and David Piwnica-Worms*[,†,§]

Molecular Imaging Center, Mallinckrodt Institute of Radiology, Department of Ophthalmology and Visual Sciences, Department of Developmental Biology, Washington University Medical School, St. Louis, Missouri 63110. Received July 14, 2008

Apoptosis is required for normal cellular homeostasis, and deregulation of the apoptotic process is implicated in various diseases. Previously, we developed a cell-penetrating near-infrared fluorescence (NIRF) probe based on an activatable strategy to detect apoptosis-associated caspase activity in vivo. This probe consisted of a cell-penetrating Tat peptide conjugated to an effector recognition sequence (DEVD) that was flanked by a fluorophore−quencher pair (Alexa Fluor 647 and QSY 21). Once exposed to effector caspases, the recognition sequence was cleaved, resulting in separation of the fluorophore−quencher pair and signal generation. Herein, we present biochemical analysis of a second generation probe, KcapQ, with a modified cell-penetrating peptide sequence (KKKRKV). This modification resulted in a probe that was more sensitive to effector caspase enzymes, displayed an unexpectedly higher quenching efficiency between the fluorophore−quencher pair, and was potentially less toxic to cells. Assays using recombinant caspase enzymes revealed that the probe was specific for effector caspases (caspase 3 > 7 > 6). Analysis of apoptosis in HeLa cells treated with doxorubicin showed probe activation specific to apoptotic cells. In a rat model of retinal neuronal excitotoxicity, intravitreal injection of *N*-methyl-D-aspartate (NMDA) induced apoptosis of retinal ganglion cells (RGCs). Eyecup and retinal flat-mount images of NMDA-pretreated animals injected intravitreally with KcapQ using a clinically applicable protocol showed specific and widely distributed cell-associated fluorescence signals compared to untreated control animals. Fluorescence microscopy images of vertical retinal sections from NMDA-pretreated animals confirmed that activated probe was predominantly localized to RGCs and colocalized with TUNEL labeling. Thus, KcapQ represents an improved effector caspase-activatable NIRF probe for enhanced noninvasive analysis of apoptosis in whole cells and live animals.

INTRODUCTION

Apoptosis is a mode of programmed cell death critical for maintaining tissue homeostasis in multicellular organisms (*1, 2*). Deregulation of the apoptosis pathway can lead to a variety of debilitating diseases including cancer. Cells undergoing apoptosis show characteristic morphological and biochemical features, including membrane blebbing, chromatin and nuclear condensation, and formation of membrane bound bodies (apoptotic bodies) (*3, 4*). Biochemical changes include DNA fragmentation, translocation of phosphatidylserine (PS) from the cytoplasmic to the extracellular leaflet of the plasma membrane, and protease activation.

Several strategies have been attempted to monitor the early stages of apoptosis (*5*−*8*). One common approach is to target exposed PS on the outer leaflet of the plasma membrane with annexin V (*5, 9*). Annexin V is a phospholipid binding protein with a high affinity toward PS. Conjugated radionuclides, magnetic nanoparticles, or fluorescent reporters to annexin V have been developed to monitor apoptosis. However, annexin V alone cannot distinguish apoptotic (membrane intact) from necrotic (membrane damaged) tissues in vivo. This problem is resolved in cellulo by using a secondary marker of membrane integrity, e.g., propidium iodide, but this strategy is rarely implemented properly in vivo. An alternative approach is to target a more specific mediator of the apoptotic process, such as caspase activation (*2, 10*−*12*). Caspases are a family of intracellular cysteine proteases pivotal for the initiation and execution of apoptosis. To date, 13 caspases have been identified in mammals, which can be divided into 2 groups, initiator and effector caspases, based on the lengths of their N-terminal prodomains. Initiator caspases contain prodomains of over 100 amino acids compared to the shorter prodomains of 30 amino acids found in effector caspases. Canonically, caspases exist as inactive zymogens in cells until pro-apoptotic signals activate initiator caspases. Once activated, the initiator caspases cleave downstream effector caspases, resulting in a proteolytic cascade that leads to cell death.

All caspases cleave the peptide bond C-terminal to aspartic acid residues. Initiator caspase recognize the WEHD/(L/V)EXD sequences, whereas effector caspases (caspase 3, 6, and 7) recognize the DEXD motif (*13, 14*). Several imaging probes have been developed that detect caspase activity, including examples of imaging probes that incorporate fluorescence resonance energy transfer (FRET) or self-quenching strategies, which result in fluorescence following activation by caspases (*15*−*19*). While these strategies minimize fluorescence in the native quenched state and amplify signal upon the enzyme-mediated release of the fluorophore, further improvements in delivery to the cell interior and pharmacokinetic properties of the agents are desired.

Recently, we reported the chemical and biochemical characterization of a first in class, small cell-penetrating apoptosis imaging probe, TcapQ (*20, 21*). Herein, we describe a second-

generation apoptosis imaging probe, KcapQ, that contains a modified all D-amino acid cell-penetrating peptide sequence and an L-amino acid cleavable domain. A lysine-arginine-rich cell-penetrating sequence (KKKRKV) is now responsible for cellular uptake, likely through macropinocytosis and/or a non-receptor-mediated endocytosis pathway (*22*−*28*). Flanked by a fluorophore (Alexa Fluor 647) and quencher (QSY 21) pair, the cleavable domain of this probe, DEVD, is specifically designed to recognize effector caspases. Upon recognition of effector caspases, the probe is internally cleaved, separating the fluorophore from the quencher. In this study, we examined the chemical/biochemical characteristics of KcapQ and evaluated its potential as an imaging agent to monitor retinal neuronal apoptosis in an animal model.

EXPERIMENTAL PROCEDURES

Synthesis and Characterization. Standard solid-phase N-α-Fmoc chemistry was used to synthesize the apoptosis probe KcapQ and the noncleavable probe D-KcapQ (Tufts University Peptide Synthesis Core, Boston, MA). Each probe contained an all-D cell-penetrating peptide comprising the SV40 TAg nuclear localization signal (KKKRKV) (*23*) linked to a cleavage sequence consisting of L- or D-amino acids (GKDEVDAPC) for the KcapQ and D-KcapQ, respectively. The N-terminus was acetylated and resin coupling afforded C-terminus amidation of the final product. For conjugation, in a small reaction vial, 1 mL of 2% hydrazine in DMF was added to 20 mg of peptide on resin to selectively remove the single Dde group protecting the lysine N-terminal of the DEVD sequence (*20*). After 20 min, the supernatant was decanted and analyzed by UV−vis spectroscopy to confirm removal of the Dde protecting group. This step was repeated until selective deprotection of the peptide was confirmed. To deprotected resin, 2 mol equiv of QSY21 succimidyl ester in DMF was added and the conjugation reaction allowed to proceed for 4−5 h. Peptide was cleaved and deprotected from resin using a trifluoroacetic acid (TFA) cleavage mixture [stock solution: 10 mL trifluoroacetic acid, phenol (0.75 g), thioanisole (0.5 mL), deionized water (0.5 mL), and ethanedithiol (0.25 mL)] followed by precipitation in cold ether. QSY21-labeled peptide was then isolated by centrifuging the sample (2000 *g*) and the collected pellet dried under argon (Ac-KKKRKVGK(QSY21)DEVDAPC-NH_2; *m*/*z* 2404.1; calcd 2404.2). Alexa Fluor 647 maleimide (Invitrogen) was dissolved in 1 mL of 0.5 M PBS buffer and added to the QSY21-labeled peptide. Conjugation to the C-terminal cysteine residue was allowed to proceed for 2 h. The final product, KcapQ, was purified using reverse-phase HPLC using a flow rate of 1 mL/min and a 5%/95% to 40%/60% acetonitrile/0.1% TFA/water/0.1% TFA gradient over 40 min (t_R = 17.3 min). KcapQ was collected by measuring absorbance at 214 and 600 nm to obtain >98% purity (KcapQ: Ac-KKKRKVGK(QSY21)DEVDAPC(AF647)-NH_2) and characterized by MALDI mass spectrometry (*m*/*z* 3384.6; calcd 3386.0). KcapQ was then lyophilized, dissolved in water, and stored at −20 °C.

Quantitative amino acid analysis (Texas A&M University Protein Chemistry Laboratory, College Station, TX) was used to calculate the stock concentration of KcapQ (203 μM). UV−vis spectra were acquired by diluting KcapQ in water and scanning from 500 to 900 nm. KcapQ molecular extinction coefficient was calculated using the pronounced blue-shifted peak at 605 nm (112 000 M^{-1}). All KcapQ and D-KcapQ working concentrations were prepared using this molecular extinction coefficient.

Toxicity Studies. HeLa cells were grown at 37 °C in an atmosphere of 5% CO_2 in DMEM (GIBCO, Grand Island, NY) supplemented with L-glutamine (1%) and heat-inactivated fetal bovine serum (10%). Cells were seeded into a 96-well plate at a concentration of 1×10^5 HeLa cells per well. KcapQ or TcapQ was added at concentrations of 0.01 μM, 0.1 μM, 1 μM, 5 μM, 10 μM, and 25 μM in triplicate. Background samples of culture medium and wells with cells in medium only served as controls. Toxicity assays were performed using cellTiter 96 AQueous nonradioactive cell proliferation assay (Promega, Madison, WI). At 24 and 48 h, 20 μL of a 1:20 dilution of MTS [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium] solution was added to each well and placed in an incubator for 1 h at 37 °C in a humidified, 5% CO_2 atmosphere. After 1 h, the absorbance at 490 nm was recorded using a colorimetric plate reader. Absorbance values from background control wells containing media only were subtracted from the all other absorbance values. Cell viability was calculated as percent untreated cells.

Biochemical Analysis of KcapQ. Enzyme assays were performed utilizing a fluorescence spectrophotometer (Cary Eclipse, Varian, Palo Alto, CA). KcapQ (0.5 μM, final concentration) was added to 450 μL of caspase buffer (100 mM NaCl, 50 mM HEPES, 10 mM DTT, 1 mM EDTA, 10% glycerol, and 0.1% CHAPS, pH 7.4) in a cuvette at 37 °C. Recombinant caspases 1−10 (CalBiochem, San Diego, CA) (5 U caspases 1−2, 4−10, and 50 U of caspase 3) were incubated in buffer for 20 min at 37 °C. Fluorescence intensity was monitored over time with measurements recorded every 15 s using a 5 nm slit width at 647 nm (excitation) and a 5 nm slit width at 665 nm (emission). Background fluorescence of probe alone was subtracted from assay fluorescence units, and all data were normalized to milligram of protein for each enzyme.

Kinetic Analysis of KcapQ Cleavage. Inhibition assays were performed using the reversible inhibitor DEVD-CHO (Calbiochem, LeJolla, CA). Caspase 3 (50 U) and caspase 7 (1 U) were incubated at 37 °C in 450 μL of caspase buffer with increasing inhibitor concentrations for 40 min. After 40 min, KcapQ (0.5 μM) was added to the mixture, and fluorescence intensity at 665 nm was monitored over 20 min at 37 °C. Linear regression analysis was used to calculate the cleavage rates at each inhibitor concentration. $EC_{50(i)}$ values were determined by nonlinear regression analysis. Apparent K_m values for KcapQ for each enzyme were calculated using the Cheng-Pruschoff relationship: $EC_{50(i)} = K_i(1 + [S])/K_m)$, where [S] is concentration of the KcapQ substrate (*29*). K_i values were calculated by determining the $EC_{50(i)}$ values of the fluorogenic substrate SUBII (Calbiochem) with 10 U of caspase-3 ($K_{i,cas3} = 0.08$) or 1 U of Caspase-7 ($K_{i,cas7} = 0.23$) (*21*). Apparent K_{cat} values were calculated using the equation $K_{cat} = V(K_m + [S]/[E][S])$, where V is the initial rate of cleavage, [S] is the concentration of substrate, and [E] is the concentration of enzyme.

Microscopy Images. HeLa cells were added to a 96-well plate at a concentration of 10 000 cells per well. After 24 h, culture media were replaced with media containing doxorubicin (10 μM final concentration) for 6 h. The cells were gently washed with PBS buffer, and KcapQ or D-KcapQ in MEBSS at a final concentration of 0.5 μM were added to wells for 20 min at 37 °C. All fluorescence images were captured using the InCell fluorescence microscopy imaging system (GE Healthcare) using a CY5 filter set at 20× magnification. Each condition was performed in triplicate, and 10 fields of view were captured for each well. All images were set to the same background level and brightness/contrast setting for analysis using *Image J* software.

Intravitreal Injections. Protocols for all experiments involving animals were approved by the Washington University in St. Louis Institutional Animal Care and Use Committee. Norway rats were anesthetized by intraperitoneal injection of 1 mL/kg of a solution containing 1 mL ketamine (100 mg/mL) and 0.15

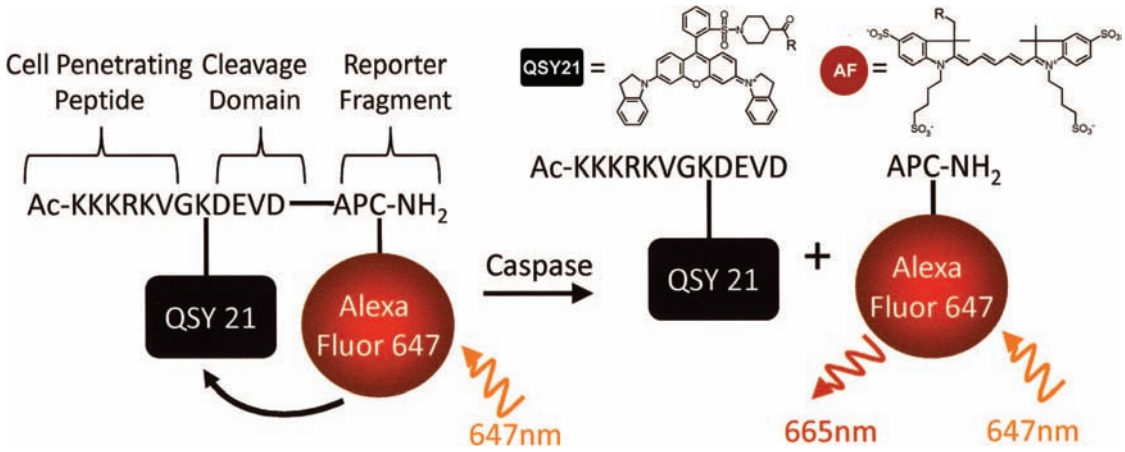

Figure 1. Schematic of KcapQ activation following cleavage by effector caspases. The DEVD cleavable sequence is flanked by an absorber (QSY21) and fluorophore (Alexa Fluor 647), which silence the reporter through intramolecular quenching. The cell-penetrating peptide sequence enables transport into the cell interior. Upon activation by caspase, the fluorophore is released inside target cells. The putative structure of Alexa Fluor 647 is from ref 45.

mL xylazine (100 mg/mL). The pupil was dilated with 1% tropicamide drops and intravitreal injections were performed using a 10 μL Hamilton syringe. To induce apoptosis in retinal ganglion cells, a 30 gauge syringe needle penetrated the sclera 2 mm posterior to the limbus and 5 μL of a 10 μM solution of *N*-methyl-D-aspartate (NMDA) was injected into the vitreous of the left eye. PBS injected into the right eye of each animal served as a control. After 16 h, 5 μL of a 200 μM solution of KcapQ or D-KcapQ in PBS was injected into the vitreous humor of each eye. At 2 h postinjection, the animals were euthanized and the globes enucleated. Experiments were performed in triplicate.

Preparation of Retina Tissue Sections. Eye cups were prepared from the harvested eye globes by removing the anterior segment (cornea and lens). Fluorescence images of the intact eye cups were collected using an Olympus macroscope equipped with a CY5 filter set. Images were acquired for 8 s. Immediately after fluorescence imaging, flat mounts were prepared by mounting the detached retina on a coverslip. Fresh retinal flat mounts were analyzed using an inverted Zeiss Axiovert 200 laser scanning confocal microscope equipped with a 633 nm He/Ne laser and a 650 nm long-pass filter to localize KcapQ. All images were recorded and target cells counted using a 40× objective.

TUNEL Labeling. Posterior ocular segments were fixed in 4% paraformaldehyde and paraffin embedded using standard techniques performed by the Tissue Support Center, Washington University. For TUNEL staining and confocal microscopy, vertical retinal sections (4 μm thick) were cut, deparaffinized, rehydrated, and then blocked with 10% normal donkey serum for 30 min. Tissue sections were washed three times with TBST (Tris-buffered saline with 0.1% Tween 20). Ethanol (70% v/v) was added to the sections and allowed to sit at −20 °C for 1 h. After 1 h, the sections were again washed with TBST and incubated with DNA-labeling solution (APO-BrdU TUNEL Assay Kit, Invitrogen) overnight at 37 °C. At the end of the incubation period, samples were rinsed with TBST and Alexa Fluor 488 dye-labeled anti-BrdU antibody was added to the tissue section. Samples were incubated overnight before analysis using confocal microscopy. TUNEL staining was detected with a Zeiss Axiovert 200 laser scanning confocal microscope with a 488 nm argon laser and a 520−560 nm bandpass filter. KcapQ localization was detected on the same sections with the 633 nm He/Ne laser and a 650 nm long-pass filter. All images were recorded using a 40× objective.

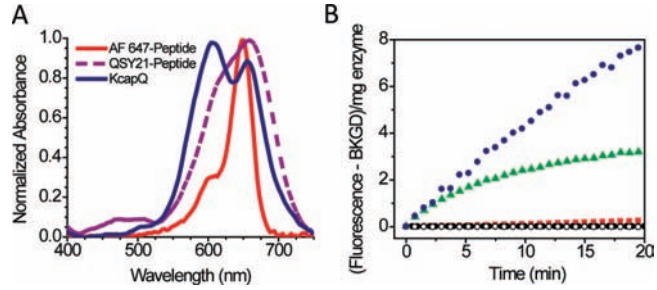

Figure 2. Chemical and biochemical characterization of KcapQ. (A) UV−vis spectra of KcapQ (blue line), QSY21-peptide (dash line), and Alexa Fluor 647-peptide (red line). Notice the increase in absorbance at 605 nm. (B) Recombinant enzyme assays of KcapQ normalized to milligrams of caspase for each enzyme (blue • caspase 3; green ▲ caspase 7; red ■ caspase 6; black • caspase 9; ○ D-KcapQ). Assays with effector caspases resulted in KcapQ activation, whereas assays with initiator caspases showed no proteolytic activity toward KcapQ.

RESULTS

KcapQ is a small, cationic cell-penetrating peptide that was designed to specifically recognize effector caspases (Figure 1). The caspase recognition sequence, DEVD, was flanked by a near-infrared emitting fluorophore (Alexa Fluor 647) and a quencher (QSY21) whose broad absorbance spectrum overlapped with the fluorophore emission spectrum (Figure 2A). Conjugation of the fluorophore and quencher to the peptide backbone was monitored by UV−vis spectroscopy. The absorption spectrum of the purified final product, KcapQ, revealed a substantial increase in the 605 nm peak compared to peptide conjugated to Alexa Fluor 647 alone. In its native state, the calculated quenching efficiency of the purified product in media was ∼96%.

To examine the selectivity of KcapQ, recombinant enzyme assays were performed by monitoring fluorescence intensity at 665 nm over time (Figure 2B). All data were normalized to milligram of enzyme. Data showed that KcapQ was highly selective toward the effector caspases 3, 6, and 7. In particular, KcapQ was cleaved at the highest rate by caspase 3, followed by caspase 7 and then caspase 6. In contrast, all initiator caspases showed essentially no activity (Table 1). Increasing the concentration of initiator caspases did not result in increased probe

Table 1. Cleavage Rate of KcapQ Incubated with Various Caspases

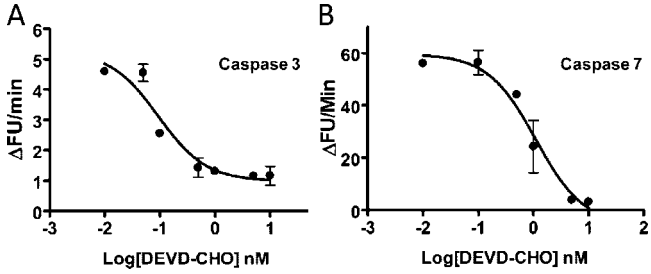

Figure 3. Inhibition curves of effector caspases interrogated with KcapQ. Increasing concentrations of the reversible inhibitor, DEVD-CHO, were incubated with 50 U caspase 3 (A) or 1 U caspase 7 (B) before the addition of KcapQ (0.5 μM). $EC_{50(i)}$ values were determined from analysis of cleavage rates (ΔFU min^{-1}) of KcapQ using nonlinear regression curve fitting. Data are presented as mean values $\pm$ SEM ($n = 2-3$ each).

Table 2. Kinetic Parameters of KcapQ Cleavage

caspase	$EC_{50(i)}$ (nM)	K_i (nM)	K_m (nM)	K_{cat} (FU min^{-1} μM^{-1})	K_{cat}/K_m (FU min^{-1} μM^{-1})/nM
3	0.09	0.08	3100	270 000	90
7	1.1	0.23	130	25 000	190

activation. To confirm the specificity of the probe, we tested D-KcapQ, a noncleavable version of the probe. D-KcapQ contained the identical amino acid sequence; however, the DEVD sequence consisted of noncleavable D-amino acid residues. No evidence of fluorescence activation was observed. To further characterize this probe, KcapQ was incubated with the caspase inhibitor DEVD-CHO, a highly specific reversible inhibitor of caspase 3, 6, and 7 (*30*). Inhibition studies were performed by preincubating each effector caspase with increasing concentrations of inhibitor (Figure 3). At each inhibitor concentration, the cleavage rate was calculated using a linear curve fit of the fluorescence−time data and plotted against inhibitor concentration. Using nonlinear regression analysis, single-site titration curves were determined to calculate the $EC_{50(i)}$ values for each effector caspase. From the $EC_{50(i)}$ values and the K_i values of DEVD-CHO, apparent K_m and k_{cat} values were calculated using the Cheng-Prusoff relationship (Table 2). From the k_{cat} data, we confirmed that KcapQ is preferentially cleaved by caspase 3 over caspase 7.

Following enzymatic characterization of KcapQ, live cell assays were performed to demonstrate intracellular delivery and apoptosis-induced probe activation. HeLa cells were pretreated for 6 h with 10 μM doxorubicin in culture medium (*31*), while cells incubated in culture medium alone served as a control. After pretreatment, KcapQ or its stereoisomer D-KcapQ (0.5 μM each) were incubated with the cells for 20 min prior to imaging. Figure 4 shows that KcapQ detected caspase activation in living cells. No fluorescence was observed with noncleavable D-KcapQ in doxorubicin-treated cells. The measured fluorescence emission for treated cells exposed to D-KcapQ was comparable to the fluorescence background observed with untreated cells, thus confirming the specificity of KcapQ.

To characterize any potential toxicity of KcapQ, we performed 24 and 48 h MTS assays to monitor cell viability in the continued presence of KcapQ (Figure 5). Increasing concentrations of KcapQ were added to a 96-well plate containing HeLa cells that were 50% confluent. Wells consisting of untreated cells and media only served as a control. Under these conditions, KcapQ showed no toxicity up to 25 μM concentration at 48 h. As a comparison, we tested TcapQ (*21*), a first-generation probe differing in cell-penetrating peptide sequence, under the same conditions. TcapQ produced a 50% loss of cell viability at 10 μM and a 90% loss of viability at 25 μM.

To determine if KcapQ could detect apoptosis in an in vivo model, apoptosis was induced in retinal ganglion cells (RGCs) using *N*-methyl-D-aspartate (NMDA). NMDA binds to and activates neuronal glutamate receptors, inducing excitotoxicity and subsequent apoptosis (*32*). The concentration of NMDA injected intravitreally, and the duration of exposure can be adjusted to restrict this effect predominantly to RGCs, thus serving as a model of RGC degeneration (*33, 34*). We recently reported that modified Tat-peptides enable robust uptake of conjugated fluorophore by RGCs (*35*). To stimulate RGC apoptosis in our animal model, NMDA was injected into the vitreous humor of the left eye. An identical injection of PBS into the right eye of each animal served as a control. After overnight pretreatment, KcapQ was injected into both the NMDA- and PBS-pretreated eyes. After 2 h, animals were euthanized and eyecups were immediately prepared by removing the lens and anterior segments. Figure 6A shows fluorescence images of fresh, intact eye cups. A significant amount of fluorescence signal could be observed in eye cups pretreated with NMDA and subsequently exposed to KcapQ. No fluorescence was observed in PBS-pretreated eyes injected with KcapQ or in NMDA-pretreated eyes injected with the control peptide D-KcapQ.

To more closely examine the pattern of probe activation, fresh retinal flat mounts were prepared from the harvested eye cups. Fluorescence microscopy confirmed a pattern of fluorescence in the NMDA-pretreated retina consistent with KcapQ activation in large cell bodies in the inner retina (Figure 6B). Minimal fluorescence was observed in the NMDA-pretreated eyes imaged with D-KcapQ or PBS-pretreated eyes imaged with KcapQ under identical conditions. Quantitatively, three different high-powered-fields showed 19 ± 5.5 and 2.3 ± 1.2 (mean $\pm$ SEM) labeled cells for NMDA-pretreated eyes imaged with KcapQ and D-KcapQ, respectively. Finally, vertical retinal paraffin sections were prepared from intact eye globes to enable localization of the fluorescent signal to specific retinal layers by confocal fluorescence microscopy. Examination of these retinal sections confirmed that the vast majority of probe activation was localized to large cell bodies in the RGC layer, consistent with RGCs (Figure 7). The pattern of fluorescent staining in the retina was consistent for all KcapQ samples. In a few sections, we observed sparse labeling of inner nuclear layer (INL) cells and small glial cells lining the nerve fiber layer (NFL), as would be anticipated with the NMDA-model, but no fluorescence was observed in any other retinal layers. Importantly, confocal fluorescence microscopy following TUNEL labeling of the same sections revealed colabeling of KcapQ positive cell bodies in the inner retina (Figure 7D, asterisks).

DISCUSSION

This study chemically and biochemically characterized a new self-quenching, caspase-activatable, near-infrared apoptosis imaging probe, KcapQ, and a noncleavable stereoisomer, D-KcapQ. Full chemical analysis of these probes showed that

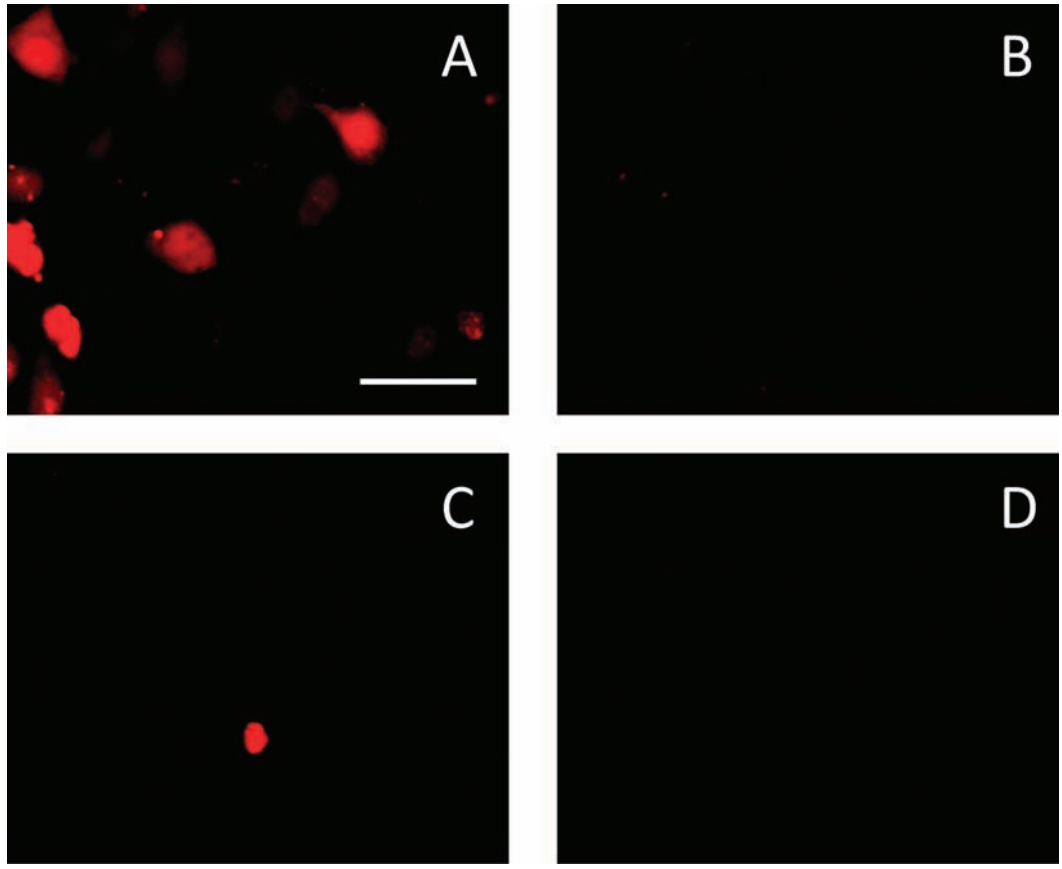

Figure 4. Representative fluorescence images of KcapQ activation during apoptosis in live cells. (A) Doxorubicin-treated (10 μM; 6 h) HeLa cells incubated with KcapQ (0.5 μM). (B) Untreated HeLa cells incubated with KcapQ (0.5 μM). (C) Doxorubicin-treated HeLa cells incubated with control D-KcapQ (0.5 μM). (D) Untreated HeLa cells incubated with control D-KcapQ (0.5 μM). Scale = 50 μm.

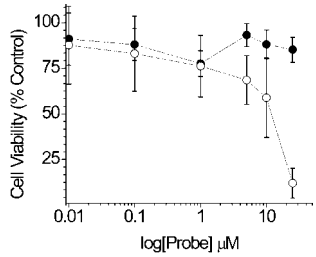

Figure 5. MTS cytotoxicity assays of KcapQ. Increasing concentrations of KcapQ (solid circles) and TcapQ (open circles) were incubated with HeLa cells for 48 h before the addition of MTS for analysis of cell viable mass. Data are presented as mean values ± SEM (n = 3 each).

they have identical mass, HPLC retention times, and UV−vis spectra. The absorbance spectrum of KcapQ displayed a striking increase in the 605 nm peak compared to the basic peptide conjugated to fluorophore alone, consistent with strong Coulombic intramolecular interactions in the quencher−fluorophore pair. The data suggested that the quenching mechanism occurred through n−π or π−π stacking rather than classical energy-transfer mechanisms, which rely strongly on spectral overlap in the fluorophore−quencher pair (*36, 37*). Preliminary studies replacing the Alexa Fluor 647 with a longer wavelength emitting fluorophore possessing no spectral overlap with QSY21 supported this hypothesis (data not shown). Indeed, there is precedence with other agents in which the proximity of the fluorophore and quencher pair to each other has been shown to quench a variety of fluorophores with no overlap in emission spectrum, as, for example, molecular beacons in which a single quencher was shown to quench numerous fluorophores spanning the visible region (*38*−*40*).

Biochemical studies showed that KcapQ was highly specific for effector caspases. KcapQ incubated with initiator caspases showed no increase in fluorescence intensity, demonstrating the selectivity of KcapQ toward effector caspases. Inhibition studies with the reversible inhibitor, DEVD-CHO, were performed to experimentally determine $EC_{50(i)}$ values for inhibition of caspase 3 and caspase 7 in the presence of KcapQ. This strategy allowed accurate spectrophotometric determination of cleavage rates independent of concentration-dependent artifacts produced by high concentrations of KcapQ (e.g., inner filter effects) and was used to derive apparent K_{cat} values (a measure of enzyme turnover rate). The data indicated that caspase 3 more readily cleaved KcapQ than caspase 7 by 11-fold, with K_{cat} values of 275 000 FU min^{-1} μM^{-1} and 25 000 FU min^{-1} μM^{-1}, respectively. However, a direct comparison of K_{cat}/K_m ratios, a measure of enzyme efficiency toward a specific substrate, revealed that KcapQ slightly preferred caspase 7, in part due to the high affinity of the peptide toward caspase 7. These findings were concordant with previously reported data from TcapQ (K_{cat}/K_m ratio: caspase 3, 7 = 60, 180, respectively) and provided evidence that the cell-penetrating peptide sequence of this class of probes had little effect on the overall resolved enzyme kinetics (*21*).

Live cell assays demonstrated that KcapQ could detect chemotherapy-induced apoptosis in HeLa cells. No activation was observed in treated cells with the noncleavable probe, D-KcapQ, or in untreated cells with KcapQ, confirming cleavage specificity. It should be noted that all assays were performed using live cells; fixing cells with 4% paraformaldehyde resulted in numerous false-positive fluorescence signals in both treated and untreated specimens as previously reported (*41*).

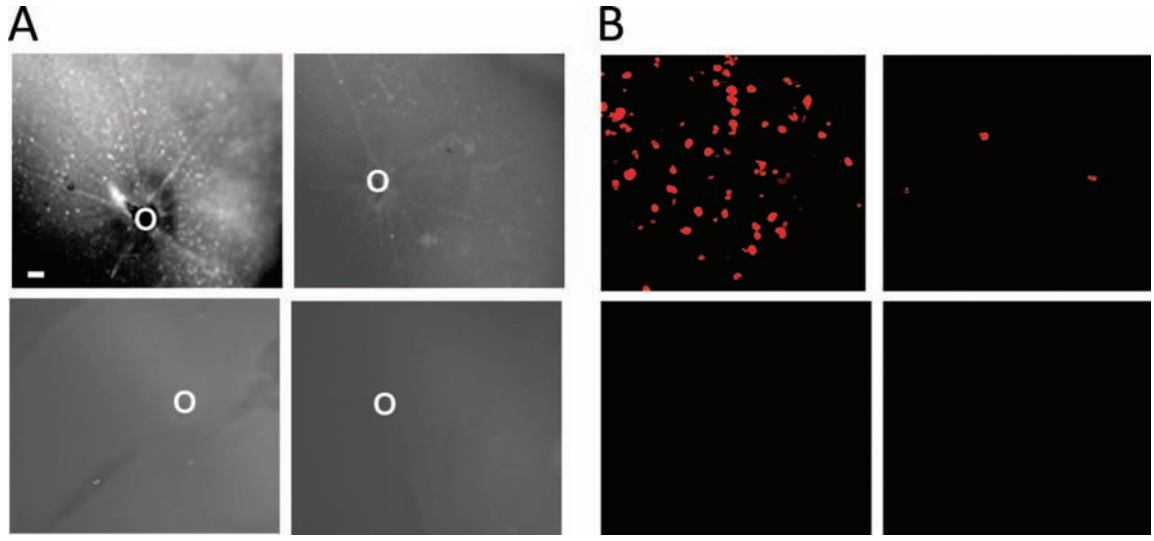

Figure 6. Fluorescence images of activated KcapQ in retinal ganglion cells in an in vivo model of induced neuronal apoptosis. (A) Fresh eye cup images of animals pretreated with NMDA for 16 h and imaged 2 h later with KcapQ or noncleavable-D-KcapQ. Top Left: NMDA-pretreated eye imaged with KcapQ. (C) Fluorescence immunohistochemistry showing TUNEL staining, again predominantly in the RGC layer. (D) Merged KcapQ fluorescence and TUNEL staining image. Brackets (]) indicate the nerve fiber layer (NFL), RGC layer, and inner nuclear layer (INL); asterisks indicate areas of colocalization of KcapQ and TUNEL positive signals in the RGC layer. Scale = 100 μm.

To characterize the "diagnostic index" of KcapQ (half-maximal toxic concentration (TC_{50}) divided by half-maximal diagnostically useful concentration), MTS assays were performed to measure HeLa cell viability after incubations with KcapQ for 24 and 48 h. KcapQ was shown to be nontoxic at doses as high as 25 μM. Because typical imaging experiments with KcapQ were performed at 0.5 μM, the "diagnostic index" of KcapQ would appear to be high ($\gg$50). By comparison, TcapQ, our first generation probe, was found to be toxic at higher concentrations, with a 90% reduction in cell viability at 25 μM. The difference between these probes is in the cell-penetrating peptide sequence. Whereas the KcapQ penetrating sequence is lysine-rich, the TcapQ penetrating sequence is composed of numerous arginine residues. Arginine residues contain positively charged guanidinium groups that have been shown to facilitate uptake of conjugated compounds into cells (*22, 25, 42*−*44*). Further supporting the argument that guanidinium moieties enhance cellular uptake, we have observed that TcapQ is more efficient in accumulating in apoptotic cells as judged by the relative intensity of fluorescent cells under identical conditions. While the TC_{50} for TcapQ was $\sim$10 μM, note that, at the concentrations of TcapQ useful in prior studies (0.5−1 μM), the diagnostic index would still be 10−20. There may be a coupling between high cell uptake and toxicity of cell-penetrating peptides, which requires a balanced approach to optimize the utility of these types of imaging agents. In this regard, because of the reduced toxicity, KcapQ may provide a reasonable compromise among diagnostic efficacy, signal intensity, and toxicity at diagnostically relevant concentrations of probe.

Examination of fresh eye cups and retinal flat mounts by epifluorescence imaging in a rat model of RGC degeneration showed that KcapQ could efficiently label RCGs that were undergoing apoptosis. Control samples showed minimal probe activation in the PBS-pretreated animals. Further examination of vertical retinal sections by confocal fluorescence microscopy confirmed that KcapQ activation was primarily localized to RGCs, as anticipated. Colocalization of TUNEL and KcapQ signals further confirmed that labeling was restricted to RGCs and occasional inner retinal cells undergoing apoptosis. The minimal fluorescence signal observed with KcapQ in PBS-pretreated samples was likely related to apoptosis due to the trauma of intravitreal injection itself. While we cannot exclude occasional false-positive signals from random probe activation, in each experiment, great precautions were taken to inject NMDA or PBS into the vitreous humor in a manner to minimize mechanical damage and subsequent elevation in intraocular pressure. To determine if the injection method caused apoptosis, mock-injections into the vitreous humor followed by KcapQ injection using a clinically applicable protocol, showed little probe activation in these tissue specimens (data not shown).

In conclusion, KcapQ, a new apoptosis imaging probe, is highly specific for effector caspases, preferentially cleaving caspase 3 over caspases 7 and 6. In our rat model of retinal

ganglion cell excitotoxicity, KcapQ specifically detects RGCs undergoing apoptosis. The near-infrared emission of KcapQ in combination with the accessibility and optimal optical properties of the mammalian eye makes this an attractive strategy to monitor neuronal loss in vivo. Future experiments developing KcapQ as a molecular imaging agent may aid the ability to diagnose and monitor treatment of many diseases, including neurodegenerative diseases of the eye, such as glaucoma.

ACKNOWLEDGMENT

Special thanks to Seth Gammon, Jayne Marasa, and Scott Harpstrite for valuable discussions, and the Hope Center for Neurological Diseases as well as the High-Throughput Core of the Molecular Imaging Center at Washington University for microscopy use and support. Received September 2, 2008; Revised Manuscript Received February 12, 2009

A new concept for modular biosurface engineering of titanium implants based on the self-assembly of complementary oligonucleotides was biochemically investigated and optimized. This study describes the synthesis and characterization (RP-HPLC and Sakaguchi assay) of oligodeoxyribonucleotide (ODN) conjugates of the hexapeptide GRGDSP containing the RGD sequence as the recognition motif for cellular adhesion receptors (integrins). The peptide was chosen exemplarily as a model molecule, because it is a simple but potent bioactive molecule and relatively well investigated. The conjugation products must fulfill two main requirements: (I) the ability to hybridize and (II) the preservation of biological activity of the RGD peptide for the enhancement of osteoblast adhesion. In the following text, the term "hybridization" is generally used for Watson−Crick base pairing. The ability of the conjugates to hybridize to surface-immobilized complementary ODN was verified by competitive hybridization with radiolabeled (^{32}P) complementary strands and by hybridization experiments using a quartz crystal microbalance (QCM). Surface hybridization was further characterized using different adsorption isotherms (e.g., Freundlich and Frumkin types), since the type of isotherm and the derived thermodynamic parameters may reveal characteristic differences between ODN and conjugates thereof. Biological activity of the conjugates was examined in vitro with osteoblasts. The cells were either cultured directly on the ODN-GRGDSP modified titanium implants or used for competition adhesion studies with dissolved ODN-GRGDSP conjugates. All results support the successful establishment of the new surface modification system. Hybridization of RGD peptide-modified nucleic acids to ODN-modified titanium implant materials is thus a promising method for osteoblast attachment in a modular and self-organizing system on implant surfaces.

INTRODUCTION

Titanium and its alloys are widely used in implantology because of their good biocompatibility. These materials show high corrosion resistance in vivo and toxicological harmlessness (*1*−*3*). An outstanding aim is the fast and stable integration of metallic implants into the surrounding bone tissue. Integration and healing problems, occurring in the cases of systemic diseases (diabetes, osteoporosis, etc.) or smokers or after previous radiation treatment, led to a call for implants with osseoconductive or even osseoinductive surfaces (*4*−*7*).

One of several approaches for creating bioactive surfaces is the immobilization of smaller fragments of proteins or artificial peptides containing certain recognition sequences, e.g., RGD peptides promoting specific cell adhesion (*8*−*13*).

Widely used immobilization procedures such as covalent attachment (*8*−*11*, *14*) and adsorption (*12*, *15*, *16*) suffer from certain disadvantages. These are predominantly the need for additional chemical surface modification with potentially toxic properties and weak interaction, respectively.

Furthermore, recently used methods for biosurface modification are restricted to one or a few substances introduced early during surface treatment. Therefore, we have developed a new method for modular and flexible biosurface engineering (*17*) that overcomes the aforementioned disadvantages. The presented new procedure consists of the following steps:

1. Nucleic acid anchor strands or functional nucleic acids such as aptamers (*18*) adsorb on the native oxide layer of the titanium material (Figure 1a).

2. Adsorbed nucleic acids are partially entrapped during anodic growth of the TiO_2 layer (Figure 1b).

3. Such fixed nucleic acid anchor strands (AS) hybridize either with complementary strands (CS) that are conjugated to biomolecules (e.g., RGD peptides, growth factors) and drugs (e.g., antibiotics, antiphlogistics), or with functional nucleic acids. Favorably, this is done according to the patients' needs prior to implantation during surgery (Figure 1c).

4. After implantation, specific tissue reactions can be induced by biomolecules (immobilized and/or released in a defined way) (Figure 1d).

Along with the favorable electrochemical immobilization procedure of anchor strands, the use of molecular self-organization via nucleic acid hybridization with various conjugates and functional nucleic acids allows a wide range of targeted surface modification. The great advantage of this system of biosurface engineering is thus characterized by its high modularity and flexibility.

After the proof of principle (*17*) and further optimization (*19*) of the anchor part of the immobilization system, synthesis and characterization of bioactive conjugates of nucleic acids was crucial for the advancement of the system. The hexapeptide GRGDSP was chosen as a biological active model substance for the conjugation with ODN, since the RGD sequence is a

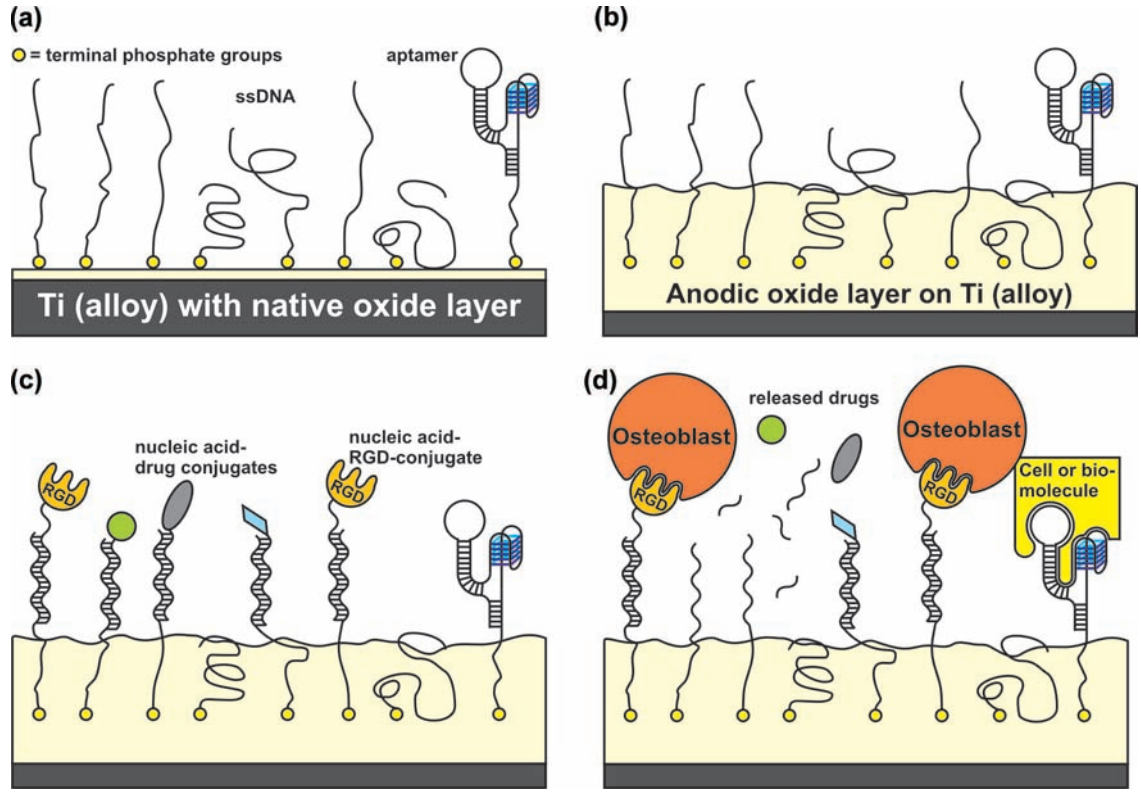

Figure 1. (a) Single-stranded anchors or functional nucleic acids (e.g., aptamers) are adsorbed via their terminal phosphate groups on the native oxide layer of titanium materials. (b) Anodic polarization leads to a partial entrapment of afore adsorbed nucleic acids in the thickened oxide layer. (c) Nucleic acid conjugates of bioactive molecules are hybridized to the single-stranded "anchor strands" (AS) fixed on the surface. (d) In the mammalian organism, osteoblasts can bind to RGD peptides on the surface. Aptamers can also bind cells or certain molecules. Both lead to faster integration into the surrounding bone. Released drugs from the surface-bound conjugates may be antibiotics, antiphlogistics, or growth factors.

ubiquitous adhesive motif in extracellular matrix proteins of bone cells and relatively well investigated. RGD peptides are widely used for surface modification and binding of osteoblasts (*8*−*13*).

In the course of synthesis and characterization of these GRGDSP conjugates, principal insight should be gained for the work with various more specific and potent bioactive molecules. To reach this aim, syntheses of conjugates were followed by analysis (RP-HPLC, Sakaguchi assay), hybridization experiments with the conjugates on titanium and using a QCM applying adsorption isotherms, and cell tests for biological activity in cell suspension and on titanium surfaces.

EXPERIMENTAL PROCEDURES

Oligodeoxyribonucleotides (ODN). Names/ synonyms, sequences, modifications, and suppliers:

Anchor Strand (AS). 5′ $^{2-}O_3$PO-CCA AAC CCG TCA ATC AAG TCT ACA CTG TTC CCA AAC CCG TCA ATC AAG TCT ACA CTG TTC-3′.

Thiolated Anchor Strand (HS-AS). 5′-HS-$(CH_2)_6$-CCA AAC CCG TCA ATC AAG TCT ACA CTG TTC CCA AAC CCG TCA ATC AAG TCT ACA CTG TTC-3′.

Complementary Strand (CS). 5′-CAG TGT AGA CTT GAT TGA CGG GTT T-3′.

Precursor for Radiolabeling of CS. 5′-CAG TGT AGA CTT GAT TGA CGG GTT-3′.

Noncomplementary Strand (NS). 5′-GCC ATA GTT TTT ATT AGG AGG TCG G-3′. Synthesis of the abovementioned strands: Thermo Scientific, Ulm, Germany. Radiolabeling using 3′-elongation with ^{32}P-dNTPs: Hartmann Analytic GmbH, Braunschweig, Germany.

Aminopropylated Complementary Strand (CS_C3). 5′-H_2N-C_3H_6-CAG TGT AGA CTT GAT TGA CGG GTT TGG GAA T-3′.

Aminohexylated Complementary Strand (CS_C6). 5′-H_2N-C_6H_{12}-CAG TGT AGA CTT GAT TGA CGG GTT TGG GAA T-3′.

Aminopropylated Noncomplementary Strand (NS_C3). 5′-H_2N-C_3H_6-GTC ATG TTG TGG TGA GCT AAT TCG GAA AGG C-3′.

Aminohexylated Noncomplementary Strand (NS_C6). 5′-H_2N-C_6H_{12}-GTC ATG TTG TGG TGA GCT AAT TCG GAA AGG C-3′. Synthesis of the abovementioned strands: Biozym Scientific GmbH, Germany.

Conjugate Synthesis. Substances, solutions, buffers, and devices: Sephadex G-25 Fine (Pharmacia Fine Chemicals AB, Sweden) swollen in sodium acetate buffer I, GRGDSP (Bachem AG, Switzerland), dimethyl sulfoxide (DMSO), disuccinimidyl suberate (DSS), disuccinimidyl tartrate (DST) (both Pierce Perbio Science, Germany), TRIS, $MgCl_2 \cdot 6H_2O$. Reaction buffer: 3 M NaCl, 1 mM $MgCl_2$, 0.1 M $NaHCO_3$, pH 8.3. Sodium acetate buffer I: 0.1 M $NaOOCCH_3$, pH 4.0. Sodium acetate buffer II: 1 mM $NaOOCCH_3$, pH 4.0. TRIS−NaCl: 100 mM NaCl, 50 mM TRIS, pH 8.5. Bicarbonate solution: 1 mM $NaHCO_3$, pH 8.5. DSS and DST: 27.15 mM in dry DMSO. ODN: 1 mM in sterile deionized H_2O (SDI H_2O). GRGDSP: 10 mM in reaction buffer. Chromatographic column: 0.7 × 50 cm, Econo System (BioRad Laboratories GmbH, Germany). Centrifugal filter devices: Centricon-3, exclusion size: 3000 Da (Millipore Corp.).

Conjugation was carried out according to Ruth (*20*). A chromatographic column with Sephadex G25 Fine was equilibrated with sodium acetate buffer II at 4 °C. A mixture of 40 μL ODN solution, 12 μL bicarbonate, and 40 μL DSS or DST

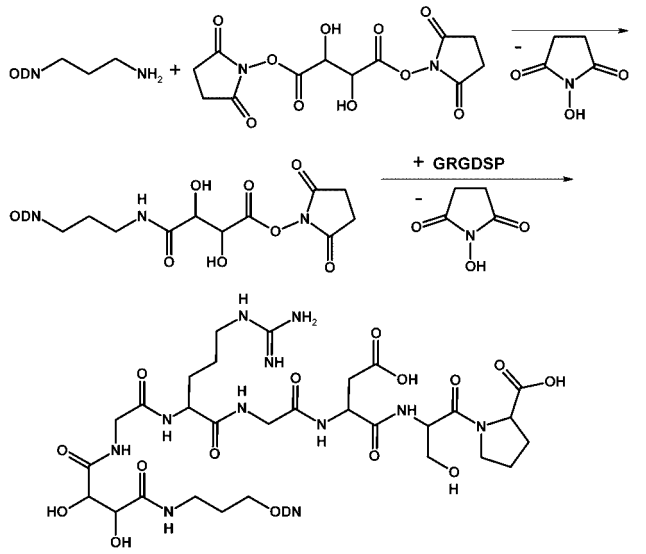

Figure 2. The conjugation reaction is exemplarily given for the aminopropylated ODN and disuccinimidyl tartrate (DST). In the other case, aminohexylated ODNs are coupled with disuccinimidyl suberate (DSS).

solutions, respectively, was mixed for 1−2 min, immediately dropped on the column, and eluted with sodium acetate buffer II at 4 °C and 0.5 mL/min. Absorbance of the collected fractions was determined at 260 nm to find those with activated ODN (first peak) which were then merged and concentrated in centrifugal filter devices at 5500 g. 100 μL of the concentrate were taken off for later analysis. Remaining activated ODNs were mixed with 40 μL of GRGDSP solution and adjusted at pH 8 with reaction buffer. Coupling took place for 18 h in the dark at room temperature and was followed by centrifugal filtration at 5500 *g* down to a volume of 0.5−1.0 mL that was then applied to a Sephadex G25 Fine column and eluted with TRIS−NaCl (pH 8.5) at 4 °C at 0.5 mL/min. Absorbance of the collected fractions was determined at 260 nm to find those with the conjugate. The merged product solutions were concentrated in centrifugal filter devices at 5500 *g*. To remove most of TRIS−NaCl, the concentrated conjugates were washed with SDI H_2O and concentrated in a centrifugal filter three times. Concentration determination by extinction measurements at 260 nm was based on calculated extinction coefficients of the ODN according to Puglisi (*21*).

Two coupling variants for conjugate synthesis were chosen: The aminopropylated ODN (CS_C3 and NS_C3) were activated with DST and the aminohexylated ODN (CS_C6 and NS_C6) with DSS before coupling with GRGDSP. Reaction equations are given in Figure 2 for the ODN_C3-DST coupling as example. The basic intention to use these two combinations was to realize (I) a different distance between the hybridizing ODN-domain and the adhesion peptide that might influence the biological activity and (II) a different hydrophobicity that might influence the separation using RP-HPLC.

RP-HPLC. HPLC column: C-18 monomeric reversed phase (150 mm × 4.6 mm, 5 μm; Grace Vydac). Precolumn: C-18; 5 μm; Grace Vydac. HPLC device: degasser, HPLC pump K-1001 (Wellchrom), solvent unit K-1500, dynamic mixing chamber, Wellchrom diode array detector K2800 (Knauer), autosampler (Holland Spark Midas (DataApex Comp.)). Software: *Knauer Eurochrom 2000 Basic Edition for Windows*, v 1.2. HPLC solvents: HPLC pure acetonitrile, triethylamine (TEA).

Sakaguchi Assay. The assay is based on Sakaguchi's original work (*22*) and later advancements thereof (*23*−*25*). Solutions: Reagent A: 1.25 g urea and 12.5 mg 1-naphthol in 25 mL 95% ethanol. Reagent B: 175 μL bromine in 25 mL 1.25 M NaOH. Arginine stock solution (1.435 M): 25 mg arginine in 100 mL SDI H_2O. Arginine working solution (0.359 M): 5 mL arginine stock solution and 15 mL SDI H_2O. Assay procedure: 25 μL of sample solution was mixed with 25 μL reagent A and 50 μL reagent B, then centrifuged. Reaction time allowed: 10 min. Immediately afterward, the spectrum was determined twice for each sample between 250 and 750 nm.

Electrochemical Immobilization of AS. Preparation of titanium samples: Discs (16 mm × 2 mm) were turned from round bar stocks of c.p. Ti (99.6 mass %) and ground down to a grain size of 26 μm (P600) with SiC abrasive paper. Subsequent sample etching was carried out in a mixture of 0.4 M hydrofluoric acid and 1 M nitric acid at room temperature (RT) for 2 min. After ultrasonic rinsing in SDI H_2O, samples were stored for 1 day in SDI H_2O in sterile bottles before use. Electrochemical cell: Custom product from acrylic glass in a conical shape with a gold wire acting as counter electrode. Reference electrode: Ag/AgCl. Salt bridge: buffer-agarose-filled plastic hose. Sample contact area to electrolyte: 1.8 cm^2. Potentiostat/Galvanostat: electrochemical system Voltalab 4.0 combined with a high-voltage booster HVB100 (Radiometer Analytical, Copenhagen). Ethanolic acetate buffer: 0.5 M acetate containing 5 M ethanol, pH 4.0. Anchor strand (AS): 400 nM in ethanolic acetate buffer. PBS (desorption) buffer: 200 mL 10× stock solution: 18 g NaCl, 0.462 g KH_2PO_4, 1.78 g Na_2HPO_4 in SDI H_2O, pH 6.85; pH of dilution 7.4−7.5. Immobilization procedure: 800 μL of the AS solution were put on the sample in the cell and left there 15 min for adsorption. After adding 2.2 mL of ethanolic acetate buffer, the cover with the gold electrode and the salt bridge was applied. Galvanostatic polarization at 7 mA/cm^2 was performed until a potential of 8 $V_{Ag/AgCl}$ was reached. The circuit was opened, and the salt bridge and gold electrode were removed. Ethanolic acetate buffer was used to rinse the cell three times. The sample was then dunked in SDI H_2O and immediately put in a well (12-well cell culture plate, NUNC Corp., Denmark) with 3 mL PBS. Desorption took place for 23 h in the dark.

Competitive Hybridization. Stock solutions: CS*: inactive CS and radiolabeled CS were mixed in a defined ratio (>99.5% nonlabeled) and filled up with SDI H_2O to give a 4 μM CS* stock solution. Competitor stock solutions (conjugates, GRGDSP, CS, and NS (both nonlabeled)): 4 μM solutions in SDI H_2O. Hybridization solutions: For each 3-fold experiment, 35 μL of CS* stock solution, 35 μL of competitor stock solution, 35 μL PBS (10×), and 245 μL SDI H_2O were mixed in a tube. Hybridization procedure: Tubes with hybridization solution were heated up to 95 °C for 2 min in a thermomixer and immediately shock-cooled for 5 min on ice (denaturation of possible secondary structures). Each sample carrying AS was placed in the center of a well in a 12-well cell culture plate. Empty wells and interstices between all wells were filled with SDI H_2O to prevent evaporation from samples. 100 μL of the hybridization solution was dropped and homogeneously spread on each sample. The 12-well plates were immediately placed in the dark. After 1 h, each sample was rinsed 4 times with 3 mL PBS and momentarily dunked into 300 mL SDI H_2O. Samples were dried in the dark and measured under a semiconductor radiation detector (PIPS, Canberra Ortec, Inc.). The determined count rate was used to calculate the amount of substance of CS* on the surface.

QCM Hybridization. Device: Q-Sense D300 (LOT-Oriel GmbH & Co. KG, Darmstadt, Germany): complete system with measurement chambers, electronics unit, and PC software for acquisition and analyzing. Sensor crystals: QSX 301 Standard Gold (LOT-Oriel), gold-coated quartz crystals with a sensing area of 1.13 cm^2. Substances: SDI H_2O, 6-mercapto-hexan-1-ol (MCH), PBS 10× stock solution, ethanol (undenatured)

(EtOH). Solutions: 70% EtOH in SDI H_2O, 400 nM thiolated anchor strand (HS-AS) in PBS, 1 mM MCH in PBS, 400 nM conjugate, CS or NS in PBS. Procedure: Loop and cell were disinfected with 70% EtOH and thoroughly rinsed with PBS. Frequency was observed in the third overtone (14.85 MHz). Further PBS was added to the cell until a stable frequency was reached. 1.5 mL HS-AS solution was filled into the loop and tempered for at least 10 min, and 0.5 mL HS-AS was then injected into the cell. Frequency change was observed until a stable value was reached and a further 0.5 mL HS-AS was added. After reaching the stable state, again the cell was rinsed and filled with PBS until frequency stability. 1.5 mL MCH was filled into the loop and tempered for at least 10 min, and 0.5 mL MCH was then injected into the cell. Frequency change was observed until a stable value was reached and a further 0.5 mL MCH added. After reaching the stable state again, the cell was rinsed and filled with PBS until frequency stability. Subsequently, the same procedure was carried out for the conjugates, CS, or NS. Obtained data were analyzed using the Sauerbrey equation (*26*) and adsorption isotherms. Fitting of adsorption isotherms: All tested isotherms were linearized, and processed data were checked for a linear dependence. For the tested isotherms, the following plots were analyzed by linear regression: Langmuir, $1/n_{ads}$ vs $1/c$; Freundlich, $\ln(n_{ads})$ vs $\ln(c)$; Temkin, $\ln(n_{ads})$ vs $\ln(c)$; Frumkin, $\ln(1/c)$ vs n_{ads}; own exponential type, n_{ads} vs e^c.

Osteoblast Adhesion. Substances: Cycloheximid (CHX), trichloroacetic acid (TCAA), [^{3}H]-thymidine (GE Healthcare Europe GmbH), HI (heat inactivated)-FCS (Th. Geyer Hamburg GmbH & Co. KG), McCoy's 5A medium (BioConcept GmbH), $Na_2HPO_4 \cdot 2H_2O$, KCl, KH_2PO_4, $CaCl_2$, $MgCl_2$, NaCl. Cell culture medium: McCoy's 5A w/o serum with 15% HI-FCS and 1 μCi [^{3}H]-thymidine/mL. Assay medium: McCoy's 5A with 100 μM CHX. PBS: 0.136 M NaCl, 2.7 mM KCl, 8.1 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 1.1 mM $MgCl_2$, 0.9 mM $CaCl_2$. Lysis buffer: 100 mM NaOH, 22 mM Na_2CO_3, 1% sodium dodecylsulfate. Functionality of ODN-GRGDSP conjugates in adhesion competition assay: Human osteosarcoma cells (cell line SAOS-2) were prelabeled with 1 μCi [^{3}H]-thymidine/mL of culture medium for 24 h and incubated for the last 3 h with 100 μM CHX. Cells were trypsinized, resuspended in assay medium, and incubated with 20 μM of conjugates or 10−40 μM GRGDSP peptide as a reference substance for 20 min at 25 °C. 25 000 cells/cm^2 were plated onto 24-well culture plates. After 2 h of incubation at 37 °C in 5% CO_2 atmosphere, the culture medium was removed and adherent cells were washed three times with PBS. During the last rinsing step, the cell culture dish was shaken for 5 min at 100 rpm. The cells were then fixed with 10% TCAA and rinsed with 96% ethanol. After cell lysis, the amount of incorporated [^{3}H]-thymidine that corresponds to the number of adherent cells was determined by liquid scintillation counting. Functionality of immobilized ODN-GRGDSP conjugates: Radiolabeling and harvesting of the SAOS-2 osteoblasts was done as described above. 25 000 cells/cm^2 were plated in 200 μL of assay medium onto the modified titanium samples. Two hours after incubation at 37 °C in 5% CO_2 atmosphere, the culture medium was removed and adherent cells were washed three times with PBS. All further experimental steps and analysis are performed as described before.

RESULTS

RP-HPLC. The chromatograms of the product fractions of the four synthesized conjugates are shown in Figure 3. All of them have a clear peak. To ensure that these peaks represent the conjugate, the arginine within the peptide was assayed via the Sakaguchi reaction.

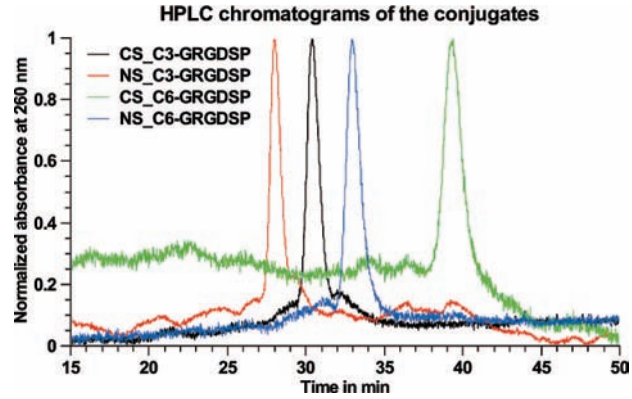

Figure 3. RP-HPLC chromatograms of the four conjugates.

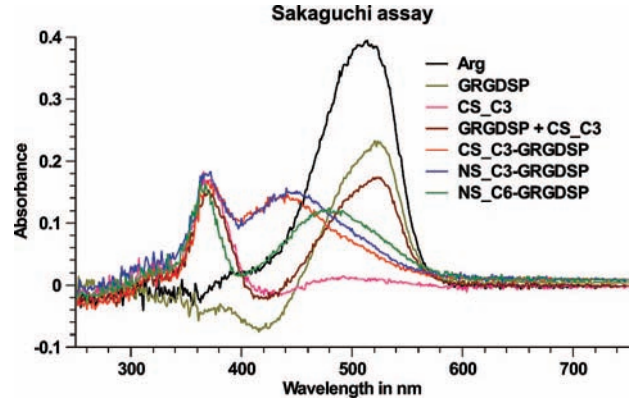

Figure 4. Selected absorption spectra of Sakaguchi products. Arginine, GRGDSP, and a mixture of GRGDSP and a modified nucleic acid precursor of the conjugate (CS_C3) show the expected absorption maximum at approximately 520 nm. The conjugates show a maximum shifted to shorter wavelengths.

Sakaguchi Assay. For verifying GRGDSP in the resulting conjugates, the arginine residue was derivatized and thus detected by Sakaguchi assay. The conjugates, their precursors as mixtures, and single components were treated with Sakaguchi reagents, and UV−vis spectra were obtained for each reaction product. Precursors and mixtures thereof were used as reference substances for the conjugates, and as visible in Figure 4, they show the expected absorption maximum at approximately 520 nm. Conjugates also exhibit a color after the Sakaguchi reaction but their absorption maximum is shifted to shorter wavelengths between 450 and 500 nm (Figure 4). Since these spectra only occur for the conjugates, one has to take into account that this shift is characteristic for such conjugates. Altogether, the Sakaguchi assay proves the presence of arginine and thus of GRGDSP in the conjugate. The observed shift in absorption maxima seems to be characteristic for the conjugates.

Competitive Hybridization. This key experiment should prove the mandatory ability of the conjugates to hybridize with surface-immobilized AS. For surface hybridization, we used radiolabel signaling in a procedure called "competitive hybridization": A mixture of a radiolabeled complementary strand (CS*) and the particular sample (conjugate, GRGDSP, etc.) was applied to the surface. In the case of a noncomplementary sample, all available anchor strands (AS) on the surface should hybridize with CS*. If the sample contains a complementary sequence, it competes with CS* for the AS. Thus, the amount of surface-bound CS* should be distinctly lower and a less intensive radioactive signal from the surface is proof for sample hybridization.

Results obtained using competitive hybridization with 1:1 mixtures of CS* and the analyte show that conjugates of

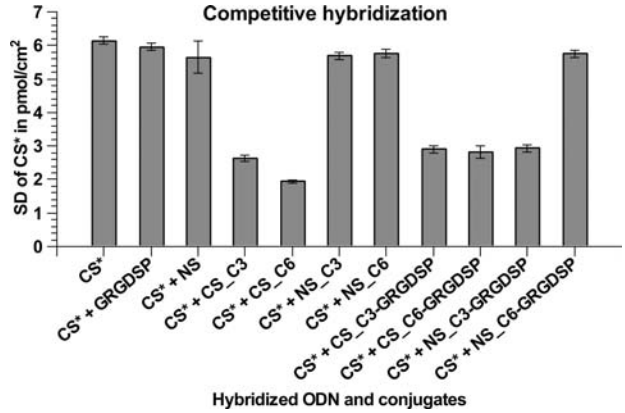

Figure 5. Competitive hybridization. Clearly declined amounts of radiolabeled CS* in the case of modified complementary strands and their conjugates prove their hybridizability. Noncomplementary strands, NS_C6-GRGDSP, and GRGDSP do not show an inhibitory effect on CS* binding, while NS_C3_GRGDSP caused a clear decline indicating nonspecific inhibitory effects on CS* hybridization. (SD - surface density).

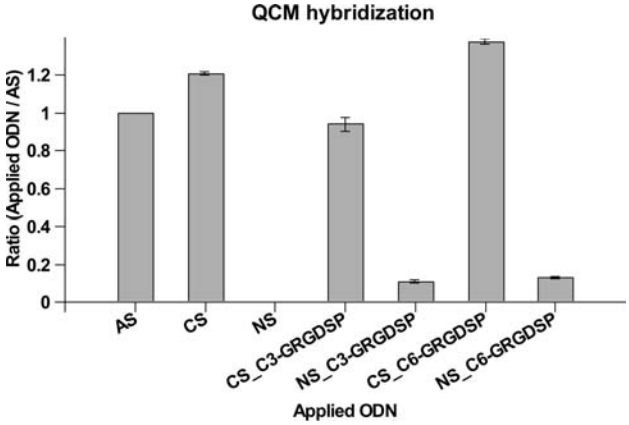

Figure 6. QCM hybridization experiments. The extent of binding of complementary conjugates (approximately 100% related to AS) to gold-coated quartz crystals modified with thiolated anchor strand (HS-AS) proves the ability to hybridize to surface-bound HS-AS, while non-complementary conjugates only show week nonspecific binding.

complementary strands are able to hybridize with anchor strands fixed in the anodic oxide layer, since the radioactive signal of CS* declined significantly (Figure 5). No difference was observed for the two spacer regions used for the CS conjugates.

QCM Hybridization. Gold-coated quartz crystals modified with thiolated anchor strands (HS-AS) as the approved system (*27*−*31*) were used to examine the surface hybridization of the conjugates and nonconjugated ODN, since the adaptation of our immobilization system to QCM measurements requiring anodic polarization of titanium-coated quartz crystals is still in progress. These experiments prove the preservation of hybridization ability of the complementary conjugates, since surface densities of up to 32 pmol·cm^{-2} were obtained. Noncomplementary conjugates show a small extent of binding with 2−3 pmol·cm^{-2}. These results are given in Figure 6 as relative numbers with respect to immobilized AS. Related to immobilized anchor strand, CS_C3-GRGDSP does not hybridize for 100%, while CS_C6_GRGDSP shows a higher extent of binding (>100%).

Surface hybridization was further examined in real time using adsorption isotherms. Fitted isotherms included the following types: Langmuir, Freundlich, Temkin, Frumkin (*41*, *43*, *44*), and an own exponential equation. A summary is given in Table 1.

Table 1. Summary of Suitable Hybridization Adsorption Isotherms for QCM Hybridization[a]

	type of isotherm				
strand	Langmuir	Freundlich	Temkin	Frumkin	own exponential
CS-C3-GRGDSP	N	N	Y	Y	Y
CS-C6-GRGDSP	N	N	N	N	Y
CS	N	Y	N	Y	Y

[a] Possibility to fit selected isotherm: Y - yes, N - no.

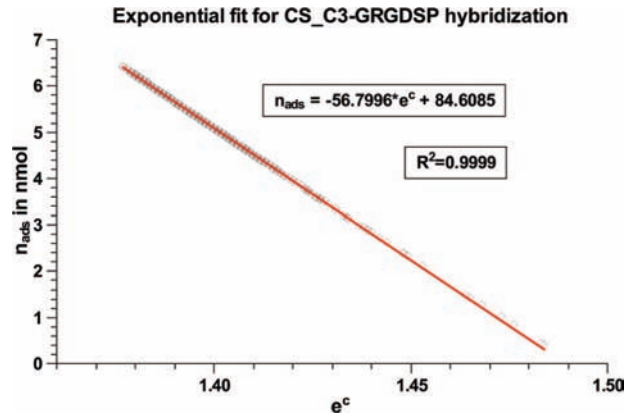

Figure 7. Empirically found exponential adsorption isotherm shown for CS_C3-GRGDSP as example. The fit shows excellent linearity.

Hybridization is analyzed for CS, CS_C3_GRGDSP, and CS_C6_GRGDSP. Neither of the species followed the Langmuir isotherm. Data for CS could perfectly be fit to the Freundlich model, but the conjugates could not. The Temkin isotherm could only be applied for CS_C3-GRGDSP, the Frumkin isotherm for CS_C3-GRGDSP and CS. However, all of the hybridization combinations can be fit by an empirically found exponential adsorption isotherm (*1*)

$$n_{ads} = k_1 \cdot e^c + k_2 \quad (1)$$

This empiric exponential isotherm for CS_C3-GRGDSP is exemplarily given in Figure 7. The term n_{ads} is the hybridized amount of substance, k_1 and k_2 are constants, and c is the concentration of the adsorbate.

Osteoblast Adhesion. For testing the functionality of dissolved and immobilized ODN-GRGDSP conjugates, two sets of in vitro experiments with osteoblasts were performed. The cells were (i) preincubated with the ODN-GRGDSP conjugates in order to occupy potential binding sites at the cell surface integrin receptors and inhibit their adhesion to cell culture plates (competition assay). (ii) Osteoblasts were plated onto ODN-GRGDSP modified titanium samples in order to promote adhesion by presentation of RGD binding sites to the cells (adhesion assay).

The results of the competition assay are shown in Figure 8a,b. The conjugates were able to suppress adhesion to the same or slightly higher extent than the GRGDSP control peptide. No differences in integrin blocking were observed for the two spacers of the conjugates.

Aminoalkylated ODNs were also able to suppress adhesion of osteoblasts on tissue culture polystyrene surfaces (Figure 8a). However, the conjugates always showed a higher suppression, indicating a specific effect of GRGDSP within the conjugate molecule. This is highlighted in Figure 8b where the effect of each aminoalkylated ODN is defined as 100% and the effect of the corresponding conjugate is shown relative to it. The only exception is NS_C6 and its conjugate, both exhibiting a similar effect.

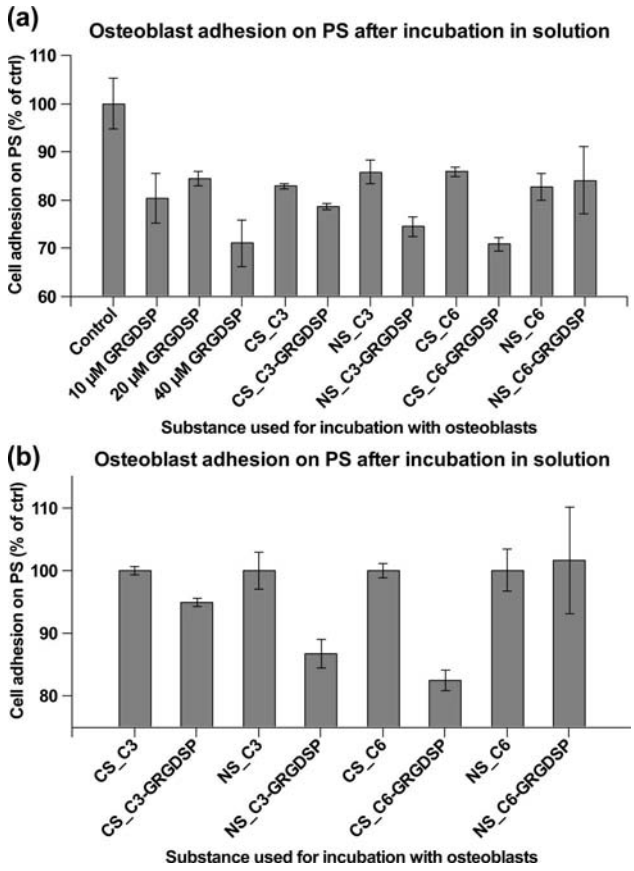

Figure 8. (a) Adhesion of SAOS-2 cells on polystyrene (PS) wells after incubation with different additives (competition assay). If no concentration is given, 20 μM were used. In the case of the control (ctrl), no additives were used. (b) Spotlighted results of part a. Adhesion of SAOS-2 cells on polystyrene (PS) wells after incubation with aminoalkylated ODN and their conjugates. Each ODN is normalized (100%), and the effect of its corresponding conjugate is given relative to it.

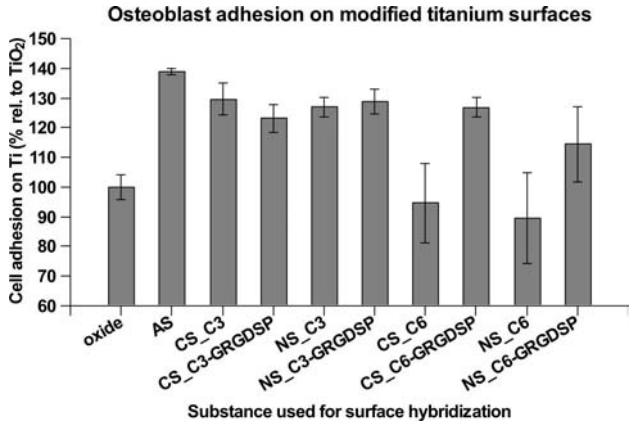

Figure 9. Adhesion of SAOS-2 cells on modified titanium surfaces. All samples were anodically oxidized to immobilize AS and later hybridized with the stated substances. Mere oxide layer and immobilized AS served as control.

Figure 9 shows osteoblast adhesion on titanium surfaces modified with AS and conjugates compared to merely anodically oxidized titanium (100%). Surfaces with immobilized AS exhibit the highest number of adherent cells, which indicates nonspecific interaction between AS and compartments of the cell membranes ("Specific binding" in this case only means interaction between integrins and the RGD peptide. All other interactions are regarded as "nonspecific".). In the case of treating AS-modified titanium with aminopropylated ODN and their conjugates, binding of the osteoblasts is lower than for AS alone and no clear difference between ODN and conjugates can be seen. If the AS-modified surface is treated with the aminohexylated ODN, there is a distinct decline in osteoblast binding compared to the other ODN species. However, their conjugates with GRGDSP show nearly the same adhesion behavior as the other ODN and conjugates. As already observed in suspension, different spacer properties do not affect the binding capacity of the RGD domain toward integrins of osteoblasts.

DISCUSSION

The aim of this work is the modular biosurface engineering of implants using nucleic acid self-organization in order to modify an implant surface according to special patients' needs. Therefore, full functionality of the conjugates must be assured for all stages of the immobilization and the implantation process. Storage conditions of the anchor strand modified implants have to ensure their hybridizability. The nucleic acid domain of the conjugate must retain its ability to hybridize when applied to AS-modified surfaces prior to implantation. Functional domains of the conjugates have to act properly in the body. We consider a working functional group in all stages of the production and application as crucial for its later functionality in the body. The obtained results must therefore be discussed from this point of view.

Analytical Characterization of the Conjugates. Successful conjugation had to be proven first. This was achieved combining RP-HPLC and the Sakaguchi reaction for assaying the conjugate fractions. RP-HPLC charts show single product peaks without major byproduct. The existence of arginine and thus of GRGDSP in the product fraction was successfully demonstrated using the Sakaguchi assay for arginine. Furthermore, the availability of the arginine for the reaction with 1-naphthol reinforces that the conjugation takes place via the amino terminus of glycine as intended and not accidentally via the guanidinium group of arginine. Thus, the integrin-binding domain RGD keeps its conformation and functionality. An interesting point for further scrutiny is the observed shift in the absorption maxima of the Sakaguchi products of the conjugates. This shift is presumed to be characteristic for ODN-GRGDSP conjugates. Possibly, the formed adduct interacts with the bases of the ODN. It must be a noncovalent interaction that is only possible in close proximity within a molecule, since the shift effect is not seen if mixtures of activated ODN and GRGDSP are subject to Sakaguchi assay. The different behavior of the more hydrophilic conjugates (CS_C3- and NS_C3-GRGDSP coupled with DST) and the more hydrophobic NS_C6-GRGDSP coupled with DSS supports the assumption of intramolecular interaction. The ODN_C3-DST conjugates have a shorter linkage domain, and therefore, the 1-naphthol adduct (λ_{max} = 450 nm) is closer to the nucleobases. In the case of NS_C6-GRGDSP (DSS), the longer linkage domain allows higher intramolecular flexibility and distances. This state is closer to the mere mixture and thus exhibits a shift that is not as high (λ_{max} = 485 nm). All these assumptions have to be subject to further examination, which might be the basis for the establishment of a special test for conjugates of RGD peptides and nucleic acids.

Hybridization Ability of the Conjugates. The experiments using competitive and QCM hybridization proved that our conjugates are able to hybridize to AS immobilized on titanium and gold surfaces. This highlights the retention of hybridizability under different conditions, which is the main functional prerequisite of the whole system for implant surface modification. Furthermore, the different spacer structure within the conjugate molecules does not affect the general ability to

hybridize but might slightly influence nonspecific binding on gold (QCM).

During competitive hybridization, the radioactive signal dropped to about 50% for equally concentrated mixtures of the competing strands. Noncomplementary strands (NS, NS_C3, NS_C6), the hexapeptide GRGDSP, and the NS_C6-GRGDSP conjugate do not interfere with CS* hybridization to surface-bound AS (Figure 5), since there is almost no loss in radioactive signal. In the case of NS_C3-GRGDSP, a competition with CS* occurred, although the conjugate is unable to hybridize specifically due to its noncomplementarity. Thus, the interaction must be based on other principles than hybridization. The conjugate may bind nonspecifically to the AS-modified titanium surface via hydrogen bonds of the bases, the sugar−phosphate backbone, or the peptide to AS and/or TiO_2, and/or via hydrophobic interactions between the bases of the strands ("Nonspecific" with respect to nucleic acids always means other interaction than Watson−Crick base pairing.). The conjugate might also interact with CS*, thus interfering with hybridization. The extent of nonspecific interaction might be very different for various conjugates, since they differ with respect to sequence, length, aminoalkylation, and linker molecule. Thus, certain noncomplementary conjugates might interact with ODN-modified surfaces. However, even if nonspecific interaction can occur hybridization is always more stable, predictable, and controllable, and therefore to be preferred.

The discrimination between CS and different conjugates thereof should also be reached using adsorption isotherms. Hybridization at surfaces is distinctly different from solution hybridization. The limited sites for hybridization and molecular interaction between the single strands and/or hybrids led to the treatment of surface hybridization as a special case of the adsorption process often called "adsorption hybridization". Therefore, adsorption isotherms are widely used for the characterization of surface hybridization (*32*−*40*). Mostly, the Langmuir isotherm (*41*) or modifications thereof are applied. Especially in the case of mismatched hybrids, the Sips isotherm (*42*) is observed (*32, 39*). Discrimination of perfectly matched and mismatched strands using adsorption isotherms was already achieved when surface hybridizations were characterized using Langmuir and Sips isotherms as reported by Peterson et al. and Stoermer et al. (*32, 39*). The Langmuir model is based on the assumption that there is a maximum surface density that can be reached and that all sites are energetically equivalent. However, the Sips isotherm deals with a distribution of energetically different sites. Since we do not assume such a distribution, the Langmuir isotherm as a special case of the Sips isotherm was applied first, also because the immobilized anchor strands represent a limited number of sites (N_{max}). Intermolecular forces and mutual interference are expected for the negatively charged nucleic acids hybridizing to the surface. The Frumkin isotherm (*43, 44*) describes such adsorption processes and was therefore applied to our system, too. Further applied isotherms included an own empirical exponential isotherm, the empirical Freundlich isotherm, and the Temkin isotherm that assumes a linear decline of adsorption heat with rising surface density (*44*).

As our results show, the Langmuir isotherm is not suitable to describe the surface hybridization of CS and their conjugates. This is reasonable, since one can expect an increase in intermolecular interaction with proceeding hybridization, which is not consistent with the Langmuir thermodynamic identity of all surface sites. The Temkin isotherm indicating a linear decline in adsorption heat could be fitted for CS_C3-GRGDSP hybridization, and CS hybridization could excellently be fitted with the empirical Freundlich isotherm. CS and CS_C3-GRGDSP hybridization could also be characterized using a Frumkin isotherm that takes intermolecular interaction into account. All hybridizations of the complementary species could be fitted by the empirically found exponential isotherm though the thermodynamic fundamentals are not yet clear. Even though the statistical basis is not yet broad enough, the different isotherms to fit hybridization indicate their potential for discrimination among different complementary species. Furthermore, kinetic and thermodynamic parameters can be obtained when the isotherms are analyzed. Thus, a clear discrimination between hybridization and nonspecific binding is possible. If the Frumkin isotherm (*2*) is suitable, data such as the energy of interaction of the molecules (E_i) (*3*) and the Gibbs free energy of surface hybridization (ΔG^0_{SH}) (*4*) can be calculated (*43, 44*) from the slope ($2a$) and the intercept ($\ln b$):

$$\ln \frac{\Theta}{(1-\Theta)c} = 2a\Theta + \ln b \tag{2}$$

$$E_i = -a2\Theta RT \tag{3}$$

$$\Delta G^0_{SH} = -2.3025RT \lg(55.5b) \tag{4}$$

In particular, the magnitude of ΔG^0_{SH} can give important information on the kind of binding (hybridization vs nonspecific binding).

These investigations will be broadened and extended to titanium-coated quartz crystals.

Biological Functionality of the Conjugates. The developed system for modular biosurface engineering must demonstrate its feasibility above all in the living system. The first experiments were done in vitro with osteoblast cell cultures. All conjugates were able to interact with osteoblasts in suspension, resulting in diminished cell adhesion on polystyrene even in a higher scale than with GRGDSP alone. However, the aminoalkylated ODNs also lead to a decline in cell adhesion after incubation. Obviously, ODNs can bind to osteoblasts, too, and subsequently reduce nonspecific binding on polystyrene. The principles of that interaction remain yet unclear. An explanation might be that our anchor strand has a kind of an aptamer functionality that might also be supported or induced by the substrate (induced fit) or that bases of a distinct sequence interact with RGD−peptides.

One must assume that the conjugates bind specifically to integrins via their RGD domain but also nonspecifically via their ODN compartment, while aminoalkylated ODNs only bind nonspecifically. This might explain why binding of the conjugates is even stronger than that of GRGDSP alone. In spite of the positive results, efforts have to be made to discriminate (specific) integrin binding and nonspecific binding in order to enable the evaluation of the specific effect of the conjugates.

Similar effects to the abovementioned were observed when osteoblasts were seeded on modified titanium surfaces. The conjugates hybridized to anodically immobilized AS increased osteoblast binding up to 125% compared to anodically thickened TiO_2. As in solution, the aminopropylated ODNs exhibit a nonspecific effect leading to increased osteoblast binding on modified Ti/TiO_2 in the same range as with conjugates. Thus, a clear discrimination between specific interaction with integrins and nonspecific interaction with ODN remains a problem for a proper evaluation of enhanced osteoblast adhesion. Beneficial biological effects of DNA immobilized on titanium have already been discussed by van den Beucken et al. (*45, 46*) earlier and might lead to enhanced osteoblast adhesion here, too. Only in the case of aminohexylated ODN and their conjugates can a clear difference be seen. However, the reason for the effect of NS_C6-GRGDSP is still dubious, since this conjugate is unable to hybridize to AS on the surface. As discussed above, this might be seen as a consequence of aptamer-like interaction. Future discrimination experiments for evaluation of the actual effect of GRGDSP within the conjugates should include the following:

more stringent adhesion/ desorption conditions using modified culture media with respect to parameters such as ionic strength and/or pH value; the use of different ODN sequences, thus reducing indefinable interactions (since different sequences are assumed to have different nonspecific effects).

Different properties of the conjugates (length, hydrophobicity) caused by the varied spacer molecule structures did not have an influence on biological activity. Such independence could be advantageous for further conjugations using other biomolecules and different linkers and linkage reactions.

CONCLUSIONS

As part of an ODN-based modular system for biosurface engineering in the field of implantology, conjugates of ODN and GRGDSP as recognition sequence for integrins were investigated in vitro. Successful conjugation could be proven using the Sakaguchi assay. The conjugates kept their ability to hybridize to different surfaces (Au, Ti) with immobilized anchor strands as shown with competitive and QCM hybridization on titanium and gold, respectively.

The comparison of the bound amounts of radiolabeled strands for different mixtures of conjugates (with respect to ratio and kind) in future experiments is expected to give information on the kind of interaction—hybridization or nonspecific binding.

First QCM experiments proved the applicability of adsorption isotherms for hybridization characterization. Experiments using the QCM will be extended to titanium-coated quartz crystals on which AS will be immobilized by anodic oxidation. For all QCM experiments (Au and Ti coating), the applicability of adsorption isotherms has to be scrutinized thoroughly, since surface densities of AS differ for gold (up to 32 pmol·cm^{-2}) and titanium (up to 7 pmol·cm^{-2}). Furthermore, the nonspecific interaction is different for both materials, which can influence the behavior. Types of isotherm and derived thermodynamic and kinetic data will be used for strand and conjugate discrimination. Again, the knowledge of surface hybridization kinetics is crucial for the planned patient-specific implant modification shortly before surgery.

Our future goal—an enhanced binding of osteoblasts on titanium implant materials within a modular and flexible system of surface modification—is achievable, since the in vitro experiments showed increased binding of osteoblasts on the conjugate-modified titanium surfaces. The nonspecific binding effects on merely anchor strand-modified surfaces suggest that osteoblasts may also bind to ODN or at least to certain ODN sequences. This effect has to be further scrutinized and might be used for cell attachment, too. Experiments in the near future, however, must focus on better discrimination between interactions of osteoblasts with conjugates or with ODN on surfaces, respectively. This is the prerequisite for a clear evaluation of the biological activity of the system if RGD is used. The analysis and separation of the conjugation products using chromatographic methods must be improved with respect to later in vivo experiments. Further interesting biomolecules such as VEGF (vascular endothelial growth factor) and BMP-2 (bone morphogenic protein) and antibiotics such as gentamycin have recently been conjugated to ODN to broaden the modularity and flexibility of the system and to study interactions if several conjugates are immobilized. This advanced system is under scrutiny at the moment.

ACKNOWLEDGMENT

Financial Support of the Deutsche Forschungsgemeinschaft (DFG), contract grant numbers WO494/14 and SCHW638/3-1, is greatly acknowledged. J. Michael would like to thank the Free State of Saxony and the Studentenwerk Dresden for their Graduate Grant. The authors would like to thank Dr. S. Taut and his staff of TU Dresden Central Radionuclide Laboratory for providing the analysis facilities and methodical support. We thank Dr. L. Renner of the Leibniz Institute of Polymer Research Dresden for supplying the QCM device and giving advice.

Biotin-Tagged Probes for MMP Expression and Activation: Design, Synthesis, and Binding Properties

Elisa Dragoni, Vito Calderone, Marco Fragai, Rahul Jaiswal, Claudio Luchinat,* and Cristina Nativi*

Magnetic Resonance Center (CERM) - University of Florence, Via L. Sacconi 6, 50019 Sesto Fiorentino, Italy, Department of Organic Chemistry, University of Florence, Via della Lastruccia 13, 50019 Sesto Fiorentino, and Department of Agricultural Biotechnology, University of Florence, Via Maragliano, 75-77, 50144 Florence, Italy. Received September 8, 2008; Revised Manuscript Received January 24, 2009

The design and synthesis of biotin chain-terminated inhibitors (BTI) showing high affinity for matrix metalloproteinases (MMPs) on one side and high affinity for avidin through the biotinylated tag on the other are reported. The affinity of the designed BTI toward five different MMPs has been evaluated and the simultaneous formation of a highly stable ternary system Avidin-BTI-MMP clearly assessed. This system will permit the development of new approaches to detect, quantify, or collect MMPs in biological samples, with potential applications in vivo.

INTRODUCTION

The design of molecular probes able to selectively bind biomolecular targets is gaining importance not only for their applications in molecular biology, but also for the development of new techniques for the early stage diagnosis and therapy of several pathologies (*1*). Rational drug design driven by structural data is currently applied to speed up the design of new candidate drugs in pharmaceutical research (*2*−*5*). The same approach is even more important to design molecular probes where, besides classical requirements, additive structural and functional features are required.

Matrix metalloproteinases (MMPs), also known as matrixins, are proteinases that participate in extracellular matrix (ECM) degradation (*6*) and in several extracellular processes (*7*−*10*). Under normal physiological conditions, the activity of MMPs is strictly regulated by transcription/activation of zymogens precursors, interaction with specific ECM components, and inhibition by endogenous inhibitors (TIMPs) (*11*−*14*). An imbalance of these activities may results in diseases such as atherosclerosis, thrombosis, or heart failure (*15, 16*). As a matter of fact, expression and activation of MMPs are increased in these pathologies, as well as in almost all human cancers, compared to physiological conditions (*17*). Indeed, ECM degradation by MMPs does promote tumor invasiveness. Furthermore, it has been recently demonstrated that MMPs carry out functions other than promotion of invasion, and that they likely take part in the development of cancer even before invasion. Noteworthy, the degree of overexpression of MMPs in cancer tissues is strictly associated with the level of tumor invasiveness and with its tendency to form metastasis. It is therefore apparent that the development of efficient molecular devices designed to reveal the overexpression of MMPs may be a powerful tool for the early detection of tumors and the assessment of their aggressiveness, as well as of cardiocirculatory problems (*18*).

* Prof. Claudio Luchinat, Magnetic Resonance Center (CERM), University of Florence, Via L. Sacconi 6, 50019 Sesto Fiorentino, Italy, e-mail: luchinat@cerm.unifi.it, Tel.: +390554574262, Fax: +390554574253; Prof. Cristina Nativi, Department of Organic Chemistry, University of Florence, Via della Lastruccia 13, 50019 Sesto Fiorentino, Italy, e-mail: cristina.nativi@unifi.it, Tel.: +390554573540, Fax: +390554573531.

Studies focused on the detection of overexpression of MMPs have already been reported (*19*) and probes to profile MMPs in tissues synthesized and tested (*20, 21*). In particular, hydrolyzable, near-infrared fluorescent molecules have been successfully tested in mice to detect fibrosarcoma (*22*). Unfortunately, this innovative technique suffers from the serious limitation represented by the limited penetration of light (a few millimeters); such a degree of penetration is only sufficient for the readout of superficial subcutaneous tumors (<10 mm).

An interesting approach to detect overexpression of MMP in atherosclerosis has also been published. Low molecular weight inhibitors, able to interact with the active site of MMPs involved in atherosclerotic plaque disruption, have been targeted with nuclear agents and tested in vivo (*23*−*25*). Although the results reported were extremely encouraging, the approach presented a scarce flexibility, due to experimental difficulties in preparing the targeted inhibitors and to limited availability of suitable nuclear agents.

A significant improvement in the development of MMP-conjugated probes to detect pathological events may be the rational design of biotin-labeled inhibitors (*26*), capable of binding to MMPs exclusively and with high affinity. These tagged molecules rely on the well-known avidin−biotin molecular recognition system and could be used in conjunction with commercially available biotin-labeled probes (i.e., radionuclide chelates) to efficiently detect pathological tissues by imaging the local overexpression of MMPs. The use of such molecules is not limited to in vivo imaging but can be extended to in vitro applications such as MMP purification by using avidin columns or devices.

Capitalizing on our expertise on expression and structural characterization of MMPs (*27*−*29*) and on the rational design and synthesis of MMP inhibitors (*30*−*35*), in the present paper we report the design and synthesis of carboxylic-containing, biotinylated inhibitors able to show high affinity for MMPs and at the same time able to strongly interact with avidin through the biotinylated tag.

In clinical therapy, selectivity of inhibitors for a specific MMP is dramatically important, so much so that the lack of selectivity is believed to have been the main reason for failures of clinical trials in the past. Often, the failure of clinical trials, due to the severity of the side-effects, was related to the chronic adverse

Published on Web 03/10/2009

effects of nonselective inhibitors. On the other hand, for the molecules proposed here, selectivity is not an issue as chronic use is not required. Indeed, ideal probes to detect overexpression of MMPs must not be selective inhibitors vs a specific MMP, but they should instead selectively recognize MMPs among other proteins. These new biotinylated molecules designed to bind to MMPs and to be recognized by avidin might therefore be successfully used in the in vitro collection/purification of MMPs, in the visualization of pathological tissues where MMPs are overexpressed, and to evaluate the aggressiveness of the pathology by monitoring, e.g., radioactivity. Moreover, it might be possible to test in vivo the efficacy of clinical treatments against a specific disease by just monitoring the level of MMPs produced during the therapy. In addition, such molecules can be easily employed for collecting and purifying MMPs from biological samples.

EXPERIMENTAL PROCEDURES

General. All reagents were commercially available and used as received. Dry solvents were prepared before use. The catalytic domain of the MMP-12 (G106-G263) was cloned into the pET21a (Novagen) using the restriction enzymes *Nde I* and *Xho I* (New England BioLabs). NMR spectra were recorded using a Varian Gemini 200, Varian Mercury 400 spectrometer, and a Brucker 700 spectrometer (HSQC). HPLC purification was performed using Althech Ultrasphere C-18 column (250 × 10 mm) and monitored with a Dionex photodiode array detector. SPR data were obtained using a BioRad ProteOn XPR36.

(*R*)-Methyl 2-(*N*-(bromomethyl)biphenyl-4-ylsulfonamido)-4-methylpentanoate (8). To a solution of **3** (600 mg, 1.66 mmol), 6-bromo-1-hexanol (450 mg, 2.49 mmol), and triphenylphosphine (872 mg, 3.32 mmol) in 17 mL of dry THF, 0.65 mL of DIAD (1.66 mmol) was added dropwise, in 1 h. The reaction was stirred at rt for 43 h, and then the solvent was removed in vacuo to give a yellow oil. After crystallization of the betainic side product (EtOAc/cyclohexane 1:8), the filtrate was concentrated in vacuum and the residue (3.20 g) was purified twice by flash column chromatography on silica gel (hexane/EtOAc 6:1, then CH_2Cl_2) to give pure **8** as a white solid (515 mg, 60% yield).

$[\alpha]^{25}_D$ +47.4 (c 1.13, $CHCl_3$). MP: 59−61 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.90−7.86 (part AA′ of an AA′MM′ system, J_{AM} = 8.8 Hz, 2H), 7.72−7.68 (part MM′ of an AA′MM′ system, J_{AM} = 8.8 Hz, 2H), 7.65−7.40 (m, 5H), 4.63−4.55 (dd, 1H, J = 5.6 Hz, J = 6.0 Hz), 3.46 (s, 3H), 3.40 (t, J = 6.8 Hz, 2H), 3.30−3.06 (m, 2H), 1.97−1.17 (m, 11H), 0.99−0.94 (m, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ 171.66, 145.27, 139.23, 138.26, 128.97, 128.38, 127.88, 127.26, 127.20, 58.09, 51.96, 45.95, 39.59, 33.86, 32.75, 31.19, 27.86, 26.36, 24.63, 22.99, 21.73. ESI-MS $[M + H]^+$ calcd 524.14. Found 524.11.

***tert*-Butyl (5-((4*S*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl)pentanamido)methylcarbamate (6).** A suspension of *N*-Boc-1,6-diaminohexane hydrochloride **5** (310 mg, 1.23 mmol) and NMM (0.14 mL, 1.23 mmol) in dry DMF (3 mL) was added to a slurry of D-biotin (300 mg, 1.23 mmol) and NMM (0.14 mL, 1.23 mmol) in dry DMF (10 mL), and the mixture was stirred at rt for 10 min. A solution of HATU (468 mg, 1.23 mmol) in dry DMF (3 mL) was added, and the mixture was stirred for 3.5 h. The reaction mixture was diluted with 20 mL of CH_2Cl_2 and washed with water: the organic layer was dried over anhydrous Na_2SO_4, and the solvent was removed in vacuo to give a yellow pale oil. Part of DMF was removed in vacuum to give 2.20 g of a yellow solid. The crude material was purified by flash column chromatography on silica gel (CH_2Cl_2/CH_3OH 6:1) to give **6** as a white solid (500 mg, 92% yield).

MP: 174−175 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ 6.17−6.07 (m, 2H), 4.70−4.56 (m, 1H), 4.55−4.49 (part A of an ABMN system, J_{AB} = 8.0 Hz, J_{AM} = 4.4 Hz, 1H), 4.36−4.29 (part B of ABX system, J_{AB} = 8.0 Hz, J_{BX} = 4.6 Hz, 1H), 3.24−3.10 (m, 5H), 2.97−2.71 (part MN of an AMN system, J_{MN} = 12.4 Hz, J_{AM} = 4.4 Hz, 2H), 2.22 (t, J = 7.0 Hz, 2H), 1.48−1.25 (m, 23H). ^{13}C NMR (50 MHz, $CDCl_3$) δ 173.80, 163.62, 155.91, 62.11, 60.56, 55.56, 40.56, 39.70, 35.65, 30.06, 29.87, 29.27, 28.61, 28.18, 28.09, 26.39, 26.25, 25.84. Anal. ($C_{16}H_{28}N_4O_4S$) C, 51.69; H, 7.62; N, 15.00.

(5-((4*S*)-2-Oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl)pentanamido)methanaminium (7). A solution of CF_3COOH (1.9 mL, 23.8 mmol) in dry CH_2Cl_2 (6.2 mL) was added to a suspension of **6** (480 mg, 1.08 mmol) in dry CH_2Cl_2 (4.6 mL). After 1.5 h, 10 mL of toluene was added and solvent was removed under vacuum to give a pale yellow oil. The oil was repeatedly washed with CH_3OH and $CHCl_3$; the compound **7** (490 mg, >90%) so obtained was used without any further purification.

^{1}H NMR (200 MHz, CD_3OD) δ 4.53−4.47 (part A of an ABMN system, J_{AB} = 8.0 Hz, 1H), 4.33−4.27 (part B of an ABX system, J_{AB} = 8.0 Hz, J_{BX} = 4.4 Hz, 1H), 3.23−3.14 (m, 3H), 3.00−2.87 (m, 5H), 2.73−2.67 (part M of an AMN system, J_{MN} = 12.4 Hz, 1H), 2.20 (t, J = 7.2 Hz, 2H), 1.72−1.40 (m, 12H). ^{13}C NMR (50 MHz, CD_3OD): 174.45, 164.54, 159.90, 62.07, 60.32, 55.74, 39.77, 39.40, 38.79, 35.54, 28.87, 28.53, 28.27, 27.24, 26.12, 25.75, 25.69.

(2*R*)-Methyl-4-methyl-2-(*N*-(((5-((4*S*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl)pentanamido)methylamino)methyl)biphenyl-4-ylsulfonamido)pentanoate (9). To a solution of **7** (236 mg, 0.69 mmol) in dry DMF (4 mL) were added 4 Å activated pellets molecular sieves (400 mg). The mixture was stirred at rt for 1 h. Cesium hydroxide monohydrate previously dried at 120 °C for 24 h (116 mg, 0.69 mmol) was added, and the solution was allowed to stir for 30 min. TBAI (250 mg, 0.69 mmol) and compoud **8** (360 mg, 0.69 mmol) was finally added and the mixture was stirred for 48 h. The crude material was purified by flash column chromatography on silica gel (CH_2Cl_2/CH_3OH 6:1) to give **9** (300 mg, 55%) as a pale yellow solid.

MP: 129−131 °C. ^{1}H NMR (200 MHz, CD_3OD) δ 7.91−7.41 (m, 9H), 4.58−4.48 (m, 2H), 4.34−4.28 (part B of an ABX syst, J_{AB} = 7.8 Hz, J_{BX} = 4.4 Hz, 1H), 3.43 (s, 3H), 3.26−3.14 (m, 4H), 3.04−2.74 (m, 6H), 2.21 (t, J = 7.0 Hz, 2H), 1.73−1.29 (m, 25H), 0.95 (ad, 6H, J = 5.4 Hz). ^{13}C NMR (50 MHz, $CDCl_3$) δ 174.45, 171.45, 164.47, 145.45, 138.97, 138.03, 128.71, 128.15, 127.70, 127.05, 126.80, 62.07, 60.32, 58.13, 55.72, 51.14, 47.60, 45.71, 39.79, 39.26, 38.73, 35.54, 30.97, 28.94, 28.50, 28.27, 26.18, 26.06, 25.94, 25.84, 25.69, 24.42, 21.93, 20.58. ESI-MS $[M + H]^+$ calcd 786.42. Found 786.50.

(2*R*)-4-Methyl-2-(*N*-(((5-((4*S*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4yl)pentanamido)methylamino)methyl)biphenyl-4-ylsulfonamido)pentanoic acid (4). To a solution of **9** (143 mg, 0.18 mmol) in 2.8 mL of THF/H_2O (1:1 v/v) LiOH·H_2O (15.1 mg, 0.36 mmol) was added and the mixture was stirred for 6 h at rt, then H_3PO_4 1 M was added (pH = 5); the solvent was removed in vacuum, and the solution was lyophilized. The solid obtained was redissolved in AcCN/H_2O 3:1 and purified by a reversed-phase semipreparative HPLC to give compound **4** (76 mg, 55%).

$[\alpha]^{25}_D$ +38.19 (c 0.33, CH_3OH). MP: 119−121 °C. ^{1}H NMR (400 MHz, CD_3OD) δ 7.96−7.38 (m, 9H), 4.49−4.46 (part A of an ABMN system, J_{AB} = 8.0 Hz, J_{AM} = 4.4 Hz, 1H), 4.41−4.37 (m, 1H), 4.30−4.27 (part B of an ABX system, J_{AB} = 8.0 Hz, J_{BX} = 4.6 Hz, 1H), 3.49−3.38 (m, 1H), 3.29−3.14 (m, 4H), 2.93−2.88 (m, 5H), 2.71−2.68 (part N of an AMN system, J_{MN} = 12.8 Hz, 1H), 2.19 (t, J = 7.2 Hz, 2H), 1.88−1.22 (m, 25H), 0.93 (at, J = 6.4 Hz, 6H). ^{13}C NMR (50 MHz, CD_3OD) δ 176.04, 174.39, 164.51, 144.75, 139.22,

128.64, 127.94, 127.79, 126.80, 126.76, 62.07, 61.02, 60.31, 55.72, 47.51, 45.04, 40.31, 39.77, 38.79, 35.54, 30.38, 28.96, 28.51, 28.27, 26.12, 25.92, 25.68, 25.56, 24.81, 22.17, 21.16. ESI-MS $[M + H]^+$ calcd 772.41. Found 772.54. Anal. ($C_{31}H_{45}N_5O_6S_2$) C, 57.43; H,7.08; N, 10.61.

(2*R*)-Methyl-2-(4-methoxy-*N*-(((5-((4*S*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl) pentanamido)methylamino)methyl)phenylsulfonamido)propanoate (12). To a solution of **7** (170 mg, 0.50 mmol) in dry DMF (2 mL), 4 Å activated pellets molecular sieves (280 mg) were added, and the mixture was gently stirred at rt for 1 h. Cesium hydroxide monohydrate, previously dried at 120 °C for 24 h, (84 mg, 0.50 mmol) was added, and the reaction mixture was stirred for 30 min. A solution of **11** (218 mg, 0.50 mmol) and TBAI (182 mg, 0.50 mmol) in DMF (1 mL) were finally added, and the mixture was stirred for 48 h at rt. The crude material obtained was purified by flash column chromatography on silica gel (CH_2Cl_2/CH_3OH 6:1) to give **12** (200 mg, 58%) as a pale yellow solid.

MP: 93−94 °C. ^{1}H NMR (200 MHz, CD_3OD) δ 7.78−7.70 (part AA′ of an AA′MM′ system, $J_{AM} = 9.2$ Hz, 2H), 6.95−6.94 (part MM′ of an AA′MM′ system, $J_{AM} = 9.2$ Hz, 2H), 4.58−4.47 (m, 2H), 4.38−4.32 (part B of an ABX system, $J_{AB} = 7.8$ Hz, $J_{BX} = 4.4$ Hz, 1H), 3.88 (s, 3H), 3.55 (s, 3H), 3.26−3.14 (m, 5H), 3.03−2.87 (m, 5H), 2.72−2.69 (part N of an AMN system, $J_{MN} = 12.6$ Hz, 1H), 2.20 (t, $J = 7.0$ Hz, 2H), 1.72−1.29 (m, 25 H). ^{13}C NMR (50 MHz, CD_3OD) δ 173.27, 171.80, 163.50, 162.71, 131.39, 129.28, 114.03, 68.21, 61.99, 60.22, 55.72, 55.18, 52.49, 52.26, 45.45, 40.70, 38.06, 35.78, 30.84, 29.85, 28.94, 28.15, 28.07, 26.33, 26.25, 26.03, 25.80, 23.16, 16.83. RESULTS AND DISCUSSION

Aryl-sulfonamide derivatives have been largely exploited to synthesize broad-spectrum MMP inhibitors. These scaffolds present different positions which can be easily functionalized by introducing new functional groups. This feature and their easy synthetic accessibility make sulfonamide derivatives suitable candidates to design biotin-tagged probes for MMPs. As zinc binding groups (ZBG), the carboxylic acid was selected despite its relatively weak affinity for the metal ion (*36*−*38*). The choice of a carboxylic acid to replace the most commonly used hydroxamic acid warrants higher stability of the inhibitor under physiological conditions (*39*) and provides better bioavailability (*40*).

Figure 1. Structure of the selected scaffolds **1** and **2**.

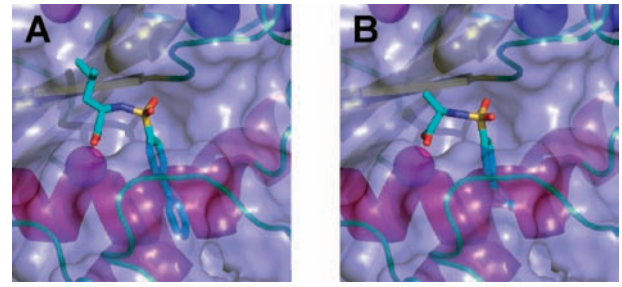

Figure 2. X-ray structure of the catalytic domain of MMP-12 complexed with **1** (A) and with **2** (B). Only the ligand binding site is shown for clarity.

In all MMPs, the flexibility of the protein loops forming the active site makes these enzymes able to modify the shape of the catalytic pocket to accommodate ligands with different structures (*41*−*44*). In particular, analyzing the structures available on the protein data bank, it is apparent that the volume of the S_1' cavity can be changed to host ligands bearing lipophilic groups of different size. However, in MMP-1 and MMP-7 the S_1' cavity is narrow as well as short "trucked" (MMP-7) such that bulky groups generally do not fit. Therefore, in order to probe all members of the MMP family, two scaffolds, bearing either a linear biphenyl moiety or a shorter methoxyphenyl group, were considered as possible bases for the synthesis of BTIs.

Among all the scaffolds evaluated, molecules **1** and **2** (Figure 1) were selected for their low K_i values against five different MMPs (see Table 1). Noteworthy, the two scaffolds exhibit a sizably different selectivity and affinity for the MMPs chosen. In particular, inhibitor **1**, due to the presence of a biphenyl moiety on the sulfonamide sulfur, showed inhibition constants in the nanomolar range. Only for MMP-1 and MMP-7 was the affinity in the low-micromolar range due to the relatively slim size of the S_1' pocket (*45*). Although still good, **2** is a weaker MMP inhibitor with micromolar values of K_i for all the MMPs tested.

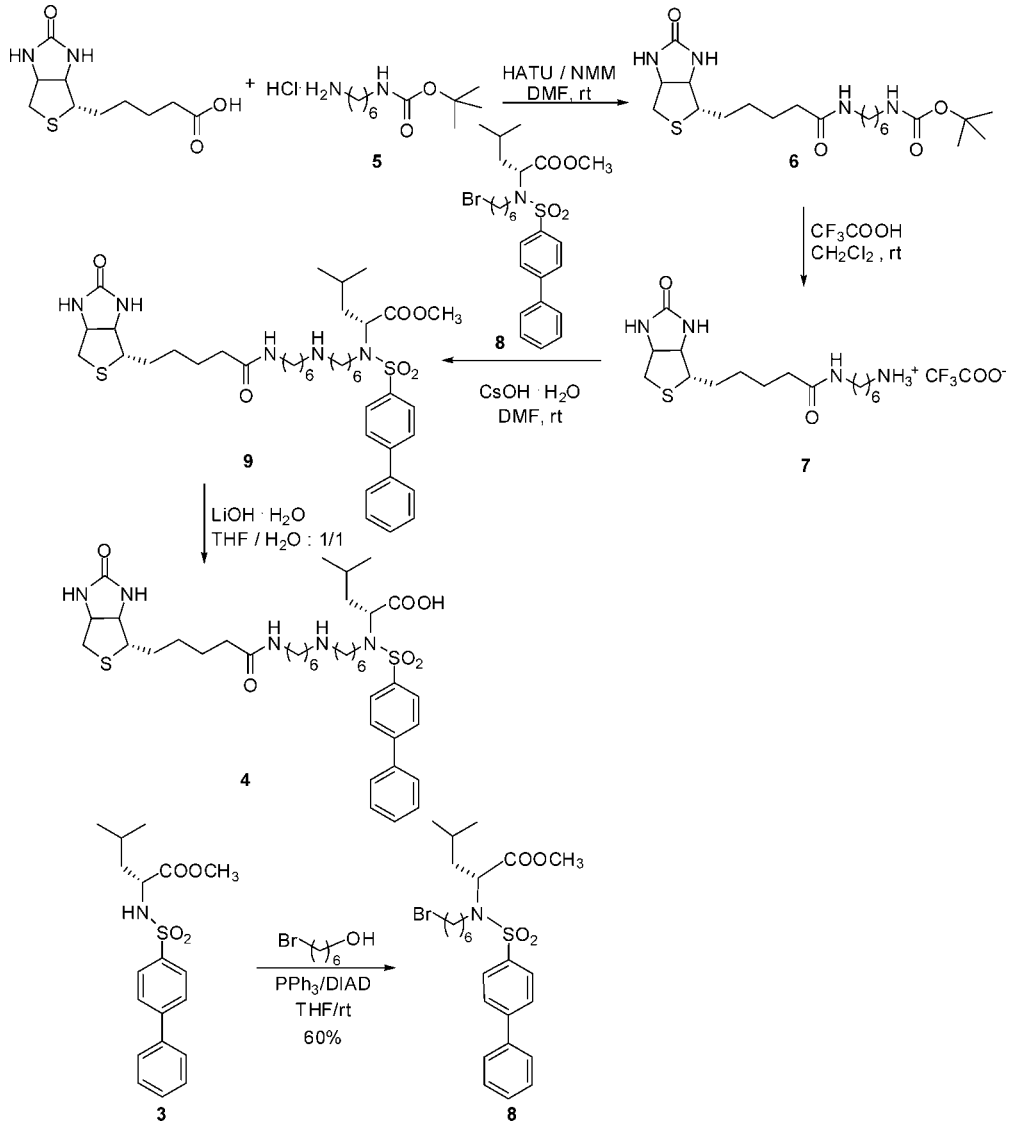
Matrix metalloproteinase 12 (MMP-12) performs proteolysis of several ECM components including elastin, laminin, and type IV collagen. The stability of the active MMP-12 catalytic domain in the presence of weak inhibitors, the relatively large S_1' pockets, and the high yield of the ^{15}N-enriched protein in minimal medium make this enzyme an ideal model to evaluate BTI candidates.

To explore the binding mode of the two scaffolds and to properly design the biotin tag derivatives, the two inhibitors were soaked in crystals of MMP-12 and the structure of the complexes solved by X-ray crystallography. Analysis of the crystal structures (see Figure 2) revealed that the inhibitors share a similar binding mode, with the catalytic zinc ion coordinated by the oxygens of the free carboxylate, the sulfonyl oxygen H-bonded with the NH of the Ala 182, and the liphophilic

Table 1. Inhibition Constants (K_i) of the Considered Compounds toward the Considered MMPs

compound	MMP-1	MMP-7	MMP-8	MMP-12	MMP-13
1	18 ± 2 μM	56 ± 6 μM	31 ± 4 nM	25 ± 2 nM	108 ± 12 nM
2	302 ± 25 μM	80 ± 9 μM	4.6 ± 5 μM	1.4 ± 0.2 μM	2.6 ± 0.3 μM
4	25 ± 3 μM	450 ± 50 nM	4 ± 0.5 nM	5 ± 0.6 nM	0.7 ± 0.2 nM
10	295 ± 40 μM	73 ± 7 μM	8 ± 1 μM	1.6 ± 0.2 μM	1.2 ± 0.1 μM

Scheme 1. Synthesis of BTI 4 and Bromosulfenamide 8



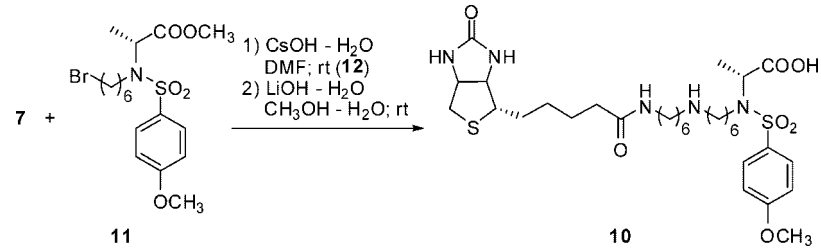
groups nested inside the S_1' pocket. The structural analysis accounts for the larger affinity of **1** for MMP-12 with respect to scaffold **2**, as observed in the enzymatic assays. Indeed, in the MMP-12−**1** complex, larger hydrophobic interactions result from the larger surface-to-surface contact area due to the presence of the biphenyl moiety. More important for the biotin tag inhibitor design was the solvent exposure of the sulfonamide nitrogen revealed by the crystal structures for both ligands. These structural data address the question related to the identification of the position where the tag can be inserted without spoiling the binding affinity.

A further critical point in developing efficient biotinylated probes for in vivo and in vitro applications is represented by the choice of a suitable linker able to prevent any steric clashes between avidin and the target biomolecule. While a too-short spacer may impair the ability of the probe to bind both MMP and avidin, the use of a too-long spacer could affect the bioavailability, stability, and solubility of the whole molecule. In particular, a too-long linker can increase the susceptibility of the probe to be split by enzymes such as the biotinidase that can degrade the molecule in vivo (*46*). Once more, the availability of the three-dimensional structure of both avidin−biotin complex (present in protein data bank, PDB code: 2avi) and **1**−MMP-12 complex has provided the background information needed for a rational molecular design of the biotin-tagged inhibitors we conceived (see Supporting Information).

A fourteen-membered spacer was designed to link the biotin residue to the carboxylic-methyl ester sulfonamide **3** (Scheme 1), that is the shorter, synthetically convenient linker allowing the probe to bind both MMP and avidin binding sites.

The biotinylated inhibitor **4** was obtained as shown in Scheme 1. Biotin was first reacted under known procedures (*46*) with the N-Boc-1,6-diaminohexane **5** to give the amido derivative **6** which, after removal of *tert*-butyloxy carbonyl protecting group, gave the trifluoroacetylammonium salt **7**. Compound **7** was treated with the bromosulfonamide **8** in the presence of cesium

Scheme 2. Synthesis of BTI 10



hydroxide, in dimethylformamide as solvent, to give the diastereomerically pure ester **9** in 55% yield. Removal of the methyl ester with lithium hydroxide/water from the latter afforded BTI **4** as a diastereomerically pure compound in 55% yield (Scheme 1). Following the synthetic pathway reported for **4**, the biotin-tagged MMP-12 inhibitor **10** was also prepared from **7** and bromosulfonamide **11**, as a diasteromerically pure compound (Scheme 2).

The affinity properties of the two BTI derivatives toward the selected MMPs were first evaluated by fluorimetric assay (see Supporting Information). The K_i values are reported in Table 1. While BTI **4** had lower K_i values as compared to the corresponding precursor **1**, BTI **10** exhibited comparable affinity with respect to its precursor **2**. The micromolar K_i of BTI **10** for all the tested MMPs unambiguously demonstrated that the latter is less interesting as a probe to detect these enzymes in vivo, though it might be suitable to collect and purify MMPs from biological samples. Conversely, BTI **4** exhibited a nanomolar affinity for all the MMPs considered (including MMP-7) except for MMP-1, for which the K_i was, however, still in the low micromolar range. The molecular details for the observed improved affinity were analyzed by investigating the BTI **4** -MMP-12 complex.

Several attempts aimed at obtaining the X-ray structure of the biotin tag inhibitors in complex with MMP-12, either by soaking or cocrystallization, failed, probably for steric reasons owing to the tag. Therefore, interaction of compound **1** and of its biotin tag derivative **4** with the catalytic domain of MMP-12 was further investigated following the chemical shift perturbations on $^{15}N-^{1}H$ HSQC spectra using ^{15}N-labeled protein samples. The chemical shift is a sensitive indicator of protein−ligand interactions and can be used to identify the binding site when the resonance assignment is available (*47*). The complete assignment of the catalytic domain of MMP-12 complexed with the weak inhibitor acetohydroxamic acid is available in our laboratory. Increasing amounts of **1** and **4** were added to 200 μM solutions of the protein up to an equimolar concentration. Although several NH signals were shifted by adding the inhibitors, as many as 134 and 129 cross-peaks belonging to protein adducts with **1** and **4**, respectively, were easily reassigned. The intensity of signals belonging to NH groups perturbed by the addition of the ligands decreased linearly, while new cross-peaks corresponding to the BTI-bound form of the protein appeared and gradually increased their intensity, in agreement with the effect produced by a slow-exchanging ligand.

The binding mode of ligands **1** and **4**, respectively, was analyzed and compared by reporting Garrett values [$\Delta\delta$(NH)] on a surface representation of the MMP-12 structure (Figure 3). As is evident from Figure 3, for both inhibitors, the region with significant $^{15}N-^{1}H$ HSQC spectral perturbations involves the catalytic pocket. The analysis of Garrett values rules out relevant additive interactions of the biotinylated tail present in BTI **4** with protein regions outside the catalytic pocket, suggesting a different origin for the observed improved affinity. In addition, a hypothetical binding mode with the biotinylated tail of BTI **4** fitting in the S_1' cavity can be completely excluded by the chemical shift perturbations on the $^{15}N-^{1}H$ HSQC spectra that are similar for **1** and **4** as well as by the K_i values of the BTI **10**, which, although biotinylated, showed a low affinity for the enzyme. Likely, extra interactions related to a better fit of **4** into the active site of the enzyme become possible when the fourteen-membered spacer is introduced on BTI **4**. These extra interactions are particularly evident for MMP-7 (Table 1) where the affinity increases by 2 orders of magnitude upon the introduction of the linker.

Although a high affinity for the target protein is a basic requirement for the proposed bifunctional ligand to play its role, only the ability of the latter to bind MMP and avidin simultaneously could prove its real efficacy as effective BTI.

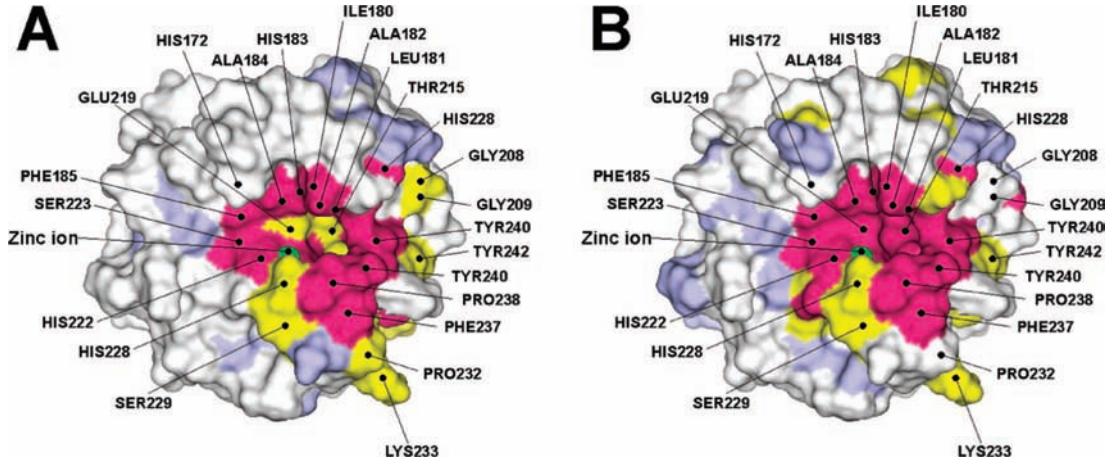


Figure 3. Surface representation of the residues of the catalytic domain of MMP-12 affected by chemical shift perturbation upon the addition of **1** (A) and of **4** (B). Areas of interaction with significant $^{15}N-^{1}H$ HSQC spectra perturbations are colored-coded according to the Garret values. Magenta, $\Delta\delta$(NH) > 0.1 ppm; Yellow, 0.1 > $\Delta\delta$(NH) > 0.05; Cyan, 0.05 > $\Delta\delta$(NH) > 0.03.

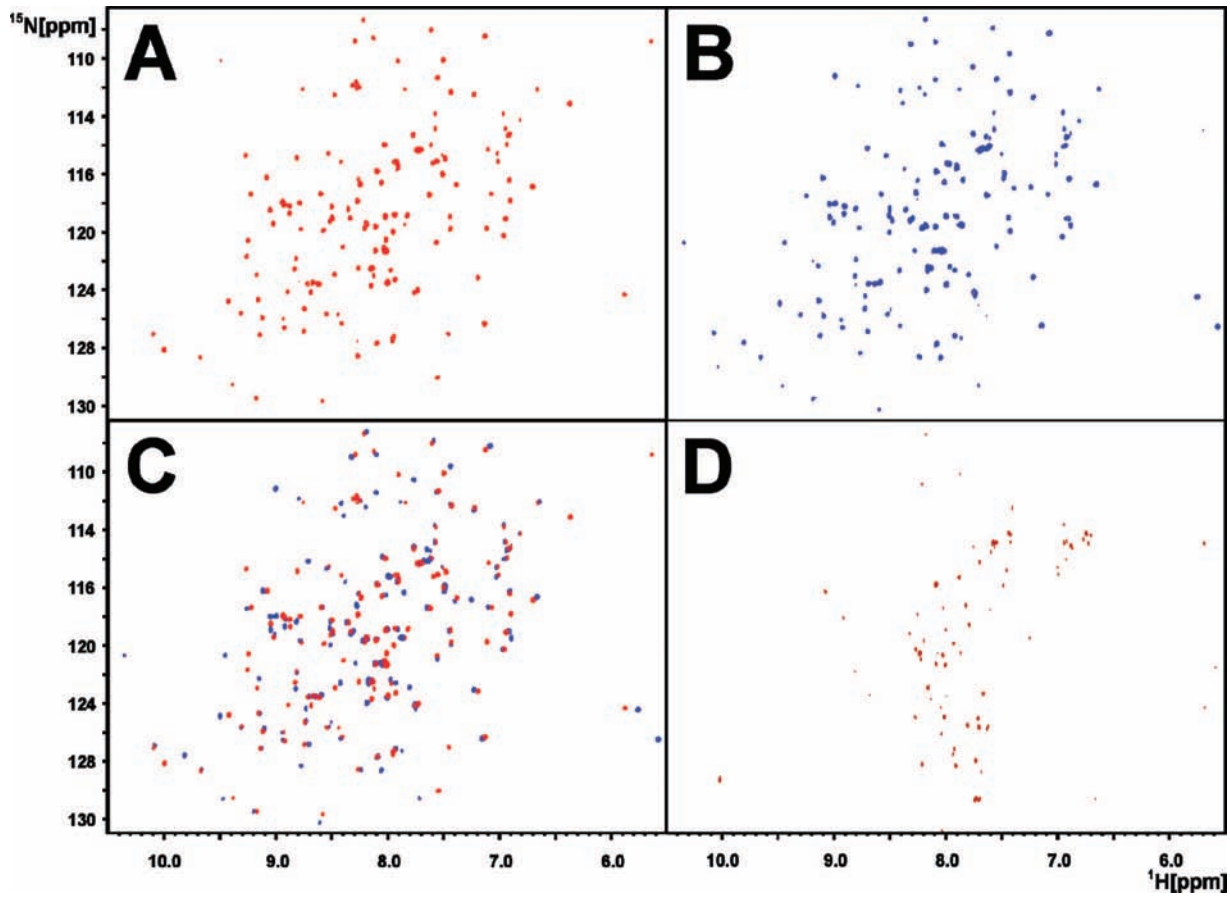

Figure 4. ^{15}N−^{1}H HSQC spectrum of MMP-12 catalytic domain in the absence (A) and in the presence (B) of compound **4** (equimolar concentration). The two spectra are superimposed to highlight the cross-peak shifts (C). The ternary complex formation Avidin-BTI-MMP is seen in panel D where most of the cross-peaks disappeared.

Two different approaches based on NMR spectroscopy and on surface plasmon resonance (SPR) were followed to demonstrate the ternary Avidin-BTI-MMP interaction. Several NMR parameters are strongly influenced by the molecular weight and by the dynamical properties of the investigated macromolecules. Classical NMR experiments such as ^{15}N−^{1}H HSQC usually performed to investigate biomolecules up to 30−40 kDa are inefficient for larger systems due to the fast transverse relaxation rate that broaden the signals beyond the detection threshold (*48*). Therefore, NH resonances can act as probes to investigate the formation of large protein−protein complexes (*49*). In the present case, the evolution of the NH signals of the ^{15}N MMP-12 catalytic domain complexed with the BTI **4** in ^{15}N−^{1}H HSQC spectra was exploited to monitor the interaction with nonlabeled avidin, given that the binding of the biotin moiety to one of the four binding sites on the tetrameric avidin should provide a 87 kDa complex. Since multiple binding for each avidin molecule may occur, even larger protein complexes are expected in solution. As shown in Figure 4 (panel D), the addition of an equimolar solution of the 65 kDa avidin to a solution of the ^{15}N-labeled catalytic domain of MMP-12 complexed with the BTI **4** caused the complete disappearance of all NH cross-peaks without any precipitation of the sample.

To exclude the presence of aspecific protein−protein interactions, avidin was added to a solution containing 200 μM of NNGH-inhibited-MMP-12 catalytic domain: in this case, no changes were detected in the HSQC spectra. Therefore, we can reasonably conclude that the strong protein−protein interaction, monitored by the ^{15}N−^{1}H HSQC experiments, is mediated by the BTI **4** which is able to bind MMP-12 and avidin and to prevent, at the same time, an extensive reciprocal reorientation of the complex subunits. Although NMR data allowed us to ascertain that **4** does bind both avidin and MMP-12 simultaneously, the micromolar concentrations used for these experiments do not provide information on how this simultaneous interaction may affect the nanomolar affinity of the inhibitor to MMP-12. Indeed, possible steric effects related to the presence of the hemopexin domain need to be evaluated to understand the real binding capability of the probe toward functionally active enzymes (*50*). In this respect, the availability of the active full-length MMP-12 allowed us to ascertain the efficiency of the biotinylated inhibitor to bind simultaneously avidin and the physiologically active enzyme and to quantify the effect of the hemopexin domain on the affinity constant.

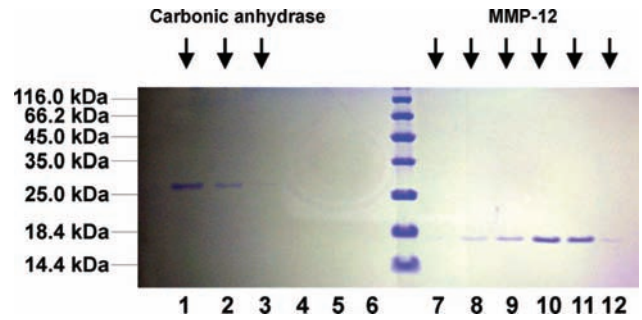

Figure 5. SDS PAGE analysis of the fractions shows an effective chromatographic separation of MMP-12 and carbonic anhydrase loaded on a monomeric avidin-bound column.

Surface plasmon resonance (SPR) is widely applied to investigate protein−protein and protein−ligand interactions. Information on affinity constant, on binding kinetics, as well as on binding enthalpy can be quickly obtained by using small

amounts of protein samples. In particular, the sensitivity of the SPR technique permits the investigation of high-affinity interactions and monitoring the formation of ternary complexes. SPR analysis was carried out using a ProteOn XPR36 parallel array biosensor equipped with avidin sensor chips (NLC). This chip has an avidin-coated surface that can be used to immobilize biotinylated molecules and macromolecules (*51*). In our study, BTI **4** was immobilized on channels 1−5 of the chip by injecting PBS-T buffered solutions of the biotinylated molecule at different concentrations. The sixth channel was left blank. The assay was performed by injecting solutions of the full-length MMP-12 on the chip channels and fitting the sensorgrams at four different concentrations. The measured K_D (4.6 ± 0.3 nM) (Supporting Information Figure S2) was comparable to the fluorimetric K_i measured for **4** vs the isolated catalytic domain of MMP-12 (BTI **4**−MMP-12 complex).

The employment of bifuctional ligand BTI **4** for the selective collection of matrix metalloproteinases from biological fluids has been evaluated by using a monomeric avidin-bound column (Pierce). An amount of 2.5 mg of BTI **4** was dissolved in 8.1 mL of Tris-buffer, and the solution (50 uL) was mixed with the same volume of an equimolar sample of MMP-12 (0.4 mM) dissolved into Tris buffer; 25 uL of the mixture so obtained was added to 50 uL of a solution of carbonic anhydrase from erythrocytes (0.1 mM in Tris-buffer). A monomeric avidin-bound column (0.6 mL of settled gel) was loaded with the solution of BTI **4**, MMP-12, and carbonic anhydrase; then, it was first eluted with 1.4 mL of Tris-buffer and subsequently with a solution of NNGH (1 mM, Tris buffer). Relying on the strong avidin−biotin interaction, the column blocked BTI **4**−MMP-12 complex, while carbonic anhydrase was completely washed out. Addition of nanomolar inhibitor NNGH displaced BTI **4** complexed to MMP-12, and the latter was so eluted and separated from carbonic anhydrase (Figure 5).

In summary, the present structure-based design led to the development of a potent biotin probe to bind matrix metalloproteinases for possible application in vitro and in vivo. The structural requirements defined through the analysis of the X-ray structures allowed selection of the position on the scaffold where the linker could be introduced and the correct length of the biotinylated tag. As defined by NMR analysis, the origin of the larger affinity observed for BTI **4** is a better fit of the selected scaffold in the catalytic pocket rather than additive interactions of the linker on the protein surface. The enzymatic assay demonstrated a nanomolar to low micromolar (MMP-1) affinity of **4** not only for MMP-12 but also for all the MMPs investigated. Furthermore, the evolution of the $^{15}N-^{1}H$ HSQC spectra upon the addition of unlabeled avidin to solution of ^{15}N MMP-12 clearly showed that the fourteen-member spacer used to link the biotin unit to carboxylic aryl sulfonamide inhibitor **1** ensures the simultaneous binding of the two proteins without permitting large interprotein mobility. SPR analyses clearly showed the ability of **4** to bind the functional active enzyme MMP-12 and avidin side-by-side. This simultaneous interaction did not affect negatively the nanomolar affinity of inhibitor **4** for MMP-12, given that the SPR data nicely reproduced the fluorimetric values measured for the BTI **4**−MMP-12 complex.

Protein Cloning, Expression and Purification

The cDNA encoding the catalytic domain of the MMP-12 (G106-G263) was cloned into the pET21a (Novagen) using the restriction enzymes *Nde I* and *Xho I* (New England BioLabs). One additional Methionine at position 105 was present in the final expression product. The expression vector encoding for the protein was transformed into competent *Escherichia coli* BL21 (DE3) Gold strain and colonies were selected for Ampicillin resistance. Bacteria were grown in LB medium containing 50 µg/ml Ampicillin in a shaker flask at 37°C. Protein expression was induced with 0.5 mM IPTG at an OD_{600} = 0.6 and cell growth was continued for a further 5 hours. For expression of ^{15}N and ^{13}C-enriched protein, the bacteria were grown in minimal medium containing ^{15}N enriched $(NH_4)_2SO_4$ and ^{13}C enriched glucose (Cambridge Isotope Laboratories). Cells were harvested by centrifugation, resuspended in a buffer containing 25% Sucrose, 50 mM Tris-HCl (pH 8), 0.1 M NaCl, 0.2 M EDTA, 1 mM DTT. 5-10 mg. Lysozyme was added to the resulting suspension and stirred for 15-20 min. at 4°C. A buffer containing 2% Triton, 50 mM Tris-HCl (pH 8), 0.1 M NaCl, 0.2 M EDTA, 1 mM DTT was added and sonicated (7-8 30-seconds cycles) and centrifuged at 40000 rpm for 20 min. at 4°C. The pellets were washed with 50 mM Tris, 5mM EDTA, 1mM DTT (pH 8) and centrifuged. The resulting inclusion bodies were solublized in 8 M Urea, 20 mM Sodium Acetate (pH 5). The insoluble material was removed by centrifuging at 9000 rpm for 10 min. Protein molecular weight and purity was checked on 15% Gel by SDS-PAGE.

Protein was purified with Ion Exchange chromatography using HiTrap SP column using a gradient of NaCl up to 350mM (6M Urea, 20mM Sodium Acetate, pH 5). The purified protein was refolded by serial dilution method. The protein was diluted to a final concentration of 0.10 mg/ml in 4 M Urea, 20 mM Tris-HCl, 10 mM $CaCl_2$, 0.1 mM $ZnCl_2$, 0.3 M NaCl (pH 7.2), dialysed overnight against same buffer (4 M Urea, 20 mM Tris-HCl, pH 7.2, 10mM $CaCl_2$, 0.1mM $ZnCl_2$, 0.3M NaCl) successively followed by two steps with Buffer B (2 M Urea, 20 mM Tris pH 7.2, 10 mM $CaCl_2$, 0.1 mM $ZnCl_2$, 0.3 M NaCl) for 8 hours, then finally 3 step of 8 hours each with Buffer C (20mM Tris pH 7.2, 10mM $CaCl_2$, 0.1mM $ZnCl_2$, 0.3M NaCl,). The protein solution was concentrated up to 5 ml and purified by size exclusion chromatography using High Load™ 16/60 Superdex™ 75 (Amersham Biosciences) and eluted with 20 mM Tris pH 7.2, 10 mM

$CaCl_2$, 0.1 mM $ZnCl_2$, 0.3 M NaCl and 0.2 M AHA. The eluted fractions were checked for purity on 15% Gel by SDS-PAGE and elution fractions containing protein were pooled and concentrated.

Crystallization, Data Collection and X-ray Structure Determination

Crystals of human MMP12, already containing AHA from the refolding process, grew at 20° C from a 0.1 M Tris-HCl, 30% PEG 8000, 200 mM AHA, solution at pH 8.0 using the vapor diffusion technique. The final protein concentration was about 14 mg/ml. The complexes have been obtained through soaking MMP12-AHA crystals with a solution containing the inhibitor itself.

The data were measured in-house, using a PX-Ultra copper sealed tube source (Oxford Diffraction). All the datasets were collected at 100 K and the crystals used for data collection were cryo-cooled without any cryo-protectant treatment. The crystals of all complexes had a mosaicity ranging from 0.6° to 0.8° and diffracted to a maximum resolution of 1.7 Å.

All the soaked adducts crystallize in the C2 space group with one molecule in the asymmetric unit.

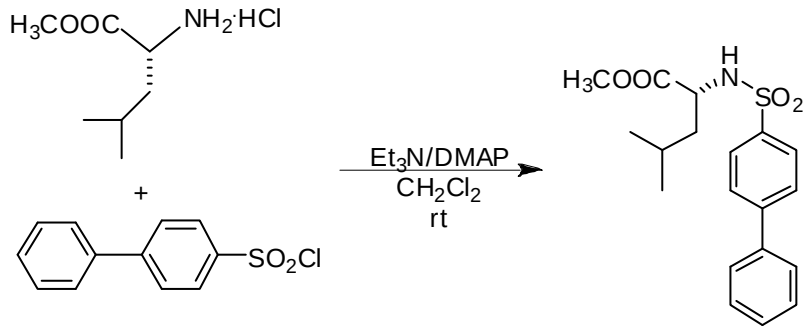
The data were processed in all cases using the program MOSFLM[1] and scaled using the program SCALA[2] with the TAILS and SECONDARY corrections on (the latter restrained with a TIE SURFACE command) to achieve an empirical absorption correction. Table 1 shows the data collection and processing statistics for all datasets.

The structures of the all adducts were solved using the molecular replacement technique; the model used was that of a molecule of human MMP12 (1Y93) from where the inhibitor, all water molecules and ions were omitted. The correct orientation and translation of the molecule within the crystallographic unit cell was determined with standard Patterson search techniques[3;4] as implemented in the program MOLREP.[5;6] The refinement was carried out using REFMAC[7] and for the metal ions anisotropic B-factors were also refined. In between the refinement cycles the models were subjected to manual rebuilding by using XtalView.[8] The same program has been used to fit the two inhibitors in the electron density. Water molecules have been added by using the standard procedures within the ARP/wARP suite.[9]

The stereochemical quality of the refined models was assessed using the program Procheck.[10] The Ramachandran plot for all structures is of very good quality.

Fluorimetric Assays: To assess the binding properties of compounds **1, 2**, **4** and **10** their abilities to inhibit the hydrolysis of fluorescence-quenched peptide substrate Mca-Pro-Leu-Gly-Leu-Dpa-Ala-Arg-NH_2 (Biomol, Inc.)[11] were tested. The analyses were carried out at 298 K in 50 mM HEPES buffer, containing 10 mM $CaCl_2$, 0.05% Brij-35, at pH 7, using 1 nM of MMP catalytic domains and 1 μM of peptide. The experiments were performed with peptide concentration much lower than K_i. The fluorescence (excitation$_{max}$ 328 nm; emission$_{max}$ 393 nm) was measured for 3 minutes after the addition of the substrate using a Varian Eclipse fluorimeter. Fitting of rates as a function of inhibitor concentration provided the K_i values.

Synthesis of compound 3:



3

A solution of D-leucine methyl ester hydrochloride (3.00 g, 16.5 mmol) in CH_2Cl_2 (80 mL) was cooled to 0°C, triethylamine (6.85 mL, 49.5 mmol) and a catalytic amount of DMAP were added. The mixture was stirred at room temperature for 10 min, then biphenyl-4-sulfonyl chloride (4.17 g, 16.5 mmol) was added. The reaction was stirred at room temperature for 4.5 h. The mixture was neutralized with HCl (3%, H_2O) and washed with brine (3x). The organic layer was dried over anhydrous Na_2SO_4 and the

solvent was removed in vacuo to give 8.00 g of a pale yellow solid. The crude material was purified by flash chromatography on silica gel (hexane/$CHCl_3$/EtOAc 2:5:1) to give **3** as a white solid (5.38 g, 90% yield).

Comparative Methods for Analysis of Protein Covalent Modification by Electrophilic Quinoids Formed from Xenobiotics

Bolan Yu, Zhihui Qin, Gihani T. Wijewickrama, Praneeth Edirisinghe, Judy L. Bolton, and Gregory R. J. Thatcher*

Department of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, University of Illinois at Chicago, 833 S Wood Street, Chicago, Illinois 60612. Received October 13, 2008; Revised Manuscript Received February 14, 2009

Conjugation of biotin and fluorophore tags is useful for assaying covalent protein modification. Oxidative bioactivation of selective estrogen receptor modulators (SERMs) yields reactive quinoid electrophiles that covalently modify proteins, and bioactivation is associated with carcinogenic and chemopreventive effects. Identification of the protein targets of electrophilic metabolites is of general importance for xenobiotics. Four methodologies using SERM derivatized biotin/fluorophore tags were compared for purification and quantification: (1) covert oxidatively activated tags (COATags; SERM conjugated to biotin); (2) dansylTags (SERM conjugated to fluorophore); and azidoTags (SERM azide derivatives) in a two-step conjugation to biotin, using either (3) Staudinger ligation or (4) click chemistry. All synthetic derivatives retained the estrogen receptor ligand characteristics of the parent SERMs. Model proteins with bioactivation by tyrosinase in buffer or cell lysates and liver proteins with *in situ* bioactivation in rat primary hepatocytes were studied by immunoassay and fluorescence. Comparison showed that the azidoTag/Staudinger method was sensitive but nonspecific, the azidoTag/click methodology had low sensitivity, and the dansylTag methodology failed to detect modified proteins in hepatocytes. The COATag methodology was judged superior, detecting 5 ng of modified protein *in vitro* and identifying protein targets in hepatocytes. In metabolism studies in rat liver microsomes, the azide group was metabolically labile, which was a contributing factor in not selecting the azidoTag methodology in the oxidative environments required for bioactivation. For study of the protein targets of electrophilic metabolites formed by *in situ* oxidative bioactivation, the COATag is both sensitive and specific and does not appear to suffer from poor cell permeability.

INTRODUCTION

Selective estrogen receptor modulators (SERMs[1]) are widely used in the clinic for the treatment and prevention of breast cancer, osteoporosis, and other indications in postmenopausal women (*1*). All SERMs and their active metabolites share common polyaromatic phenolic scaffolds that are redox active *in vitro* and *in vivo* (*2, 3*). Formation of *o*-quinones, quinone methides, and diquinone methides has been reported from the oxidative metabolism of SERMs (*4*−*7*). As reactive electrophiles, SERM quinoids can potentially covalently modify cellular proteins with varied selectivity. Protein families that are involved in estrogen metabolism, ER signaling pathways, and redox sensing are theoretically susceptible to modification by SERM quinoids. It has been reported that metabolic enzymes, such as GST-P1 and P450 isoforms, can be inhibited by raloxifene and other SERMs (*7*−*9*); modification of ER and histone H3 by estrogens and quinoids has been reported (*10*−*13*); and sensor proteins such as Keap1 involved in cellular defense are also likely targets (*14*). It is increasingly clear that damage or covalent modification of cellular proteins is related to both toxicity and cytoprotective mechanisms, which impacts the balance between carcinogenesis and chemoprevention for a variety of small molecules that form electrophilic, reactive intermediates (*14*). The correlation between the structural properties of these electrophiles and their biological targets is not yet clear; however, it is important to identify cellular targets of xenobiotics to understand the long-term biological consequences of exposure.

Identification of protein targets of electrophiles remains a technical challenge that is limited by a lack of efficient strategies for labeling targets in a physiological environment. Previous studies have widely used isotopically labeled electrophiles to analyze modified proteins (*15*−*18*); animals or cells were treated with radioactive electrophiles and were further analyzed by 1D/2D-PAGE and/or LC-MS/MS (*17, 19*). Antibodies that can recognize adducts formed from electrophiles such as 4-hydroxynonenal (4-HNE) and butylated hydroxytoluene (BHT) have also been used for protein identification (*15, 16, 18*); however, these techniques suffer from low coverage of adducted proteins and cross-reactivity. A more recent approach using tagged electrophiles is highlighted by the use of 4-HNE tagged with biotin to identify protein targets of 4-HNE (*20*). Whereas 4-HNE and commercially available tagged electrophiles (i.e., iodoacetamide) are inherently reactive, SERMs require oxidative bioactivation. Therefore, a novel methodology was developed, coined the covert oxidatively activated tag (COATag), in which a biotin linker is tagged to the partial structure of the xenobiotic. A COATag is not inherently reactive toward cellular proteins but requires bioactivation. The proof of principle study used a

COATag of the clinical benzothiophene SERM raloxifene (Figure 1) and oxidative enzymes to activate the SERM to a reactive electrophile (*7*). In combination with mass spectroscopy, the COATag methodology revealed the selective modification of protein targets in liver microsomes (*7*); furthermore, raloxifene and desmethylarzoxifene (DMA) COATags were employed in uterine microsomes to demonstrate bioactivation by peroxidases (*21*). Of the potential problems with the use of COATags *in vivo* or in intact cell systems, the potential cell impermeability caused by the hydrophilic biotin linker is common to all biotin conjugates (*22*−*24*).

Progress in chemical biology has offered new approaches for identifying the protein targets of reactive electrophiles in intact cells, using azide or alkyne tags, followed by conjugation with the complementary biotin linker (*20*). These techniques exploit the so-called bioorthogonal reactivity of the azide functionality to conjugate with biotin or with a fluorophore using the mild reaction conditions of the modified Staudinger ligation or click chemistry (*25, 26*). Wide usage has been reported in cellular protein labeling (*26*), activity-based protein profiling (*27*), and, recently, identification of cellular targets of electrophiles (*20*). In addition to biotin conjugation, fluorophore conjugates including dansyl, BODIPY, and rhodamine have been reported (*28, 29*). However, in a few papers problems have been highlighted, such as high background response, poor enrichment of modified proteins, and cellular impermeability (*20, 22, 23, 30*).

The objective is to identify cellular targets of electrophiles formed by metabolic bioactivation. In this paper, the scope and limitations of different SERM tagging strategies are explored using raloxifene or DMA as the drugs of interest, comparing preformed COATags and fluorophore tags with conjugation methodologies based upon the bioorthogonal azide group subject to either Staudinger ligation or click chemistry. Perhaps surprisingly, the original COATag methodology was seen as superior, at least in part because of the influence on chemical conjugation of the oxidative environment required for bioactivation.

MATERIALS AND METHODS

Reagents and Materials. All solvents and chemicals were purchased from Fisher Scientific (Itasca, IL) or Sigma-Aldrich Chemical (St. Louis, MO) unless stated otherwise. UltraLink Immobilized Monomeric Avidin, MagnaBind streptavidin beads, HRP-streptavidin, ECL Western blotting substrate, and Imperial protein stain kit were obtained from Pierce (Rockford, IL). Click-iT biotinylation kit for click chemistry and all 1D and 2D gel electrophorosis instruments and reagents including NuPAGE precast gels, XCell SureLock Mini-Cell, ZOOM IPGRunner System, and ZOOM strips were purchased from Invitrogen (Carlsbad, CA). [1,5-Bis [2-(dimethylamino)ethyl]amino]-4,8-dihydroxyanthracene-9,10 -dione] (DRAQ5) was purchased from Axxora (San Diego, CA). Rat liver microsomes were prepared according to an existing procedure (*6*). Phosphinyl biotin for Staudinger ligation, compound **9** for the synthesis of dansyl DMA, and dansyl alkyne **11** for the study of click chemistry model reaction were prepared according to published procedures (*21, 31, 32*).

Instrumentation. LC-MS/MS was carried out using an Agilent (Palo Alto, CA) ion trap mass spectrometer equipped with a model 1100 HPLC system and electrospray ionization source. Proteomic MS analysis used a Dionex Ultimate 3000 HPLC system linked to a Thermo Finnigan LTQ-FT mass spectrometer equipped with a nanospray interface. ^{1}H NMR and ^{13}C NMR spectra were obtained with Bruker AVANCE 300, UltraShield 400, spectrometers.

Synthesis of Azido Raloxifene and Dansyl DMA. *2-[1-(tert-Butoxycarbonyl)piperidin-4-yl]ethyl Methanesulfonate (***2***).* Mesyl chloride (2.5 mL, 32.7 mmol) was added dropwise to compound **1** (5.0 g, 21.8 mmol) and NEt_3 (6.0 mL, 43.6 mmol) in anhydrous THF (100 mL) cooled in an ice−water bath. The reaction mixture was stirred overnight at r.t. Most of the solvent was removed; residue was diluted with dichloromethane (200 mL), washed with brine, and dried with anhydrous $MgSO_4$. After filtration and concentration, the product was obtained as a white solid (5.2 g, 78%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 4.28 (t, 2H, J = 6.1 Hz), 4.07−4.11 (m, 2H), 3.01 (s, 3H) 2.64−2.73 (m, 2H), 1.66−1.71 (m, 5H), 1.45 (s, 9H), 1.11−1.19 (m, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 154.97, 79.57, 67.64, 43.93, 37.61, 35.79, 32.56, 31.92, 28.63.

*2-(N-tert-Butoxycarbonyl-4-piperidinyl)ethyl Azide (***3***).* Compound **2** (5.0 g, 16.3 mmol) dissolved in anhydrous acetonitrile (150 mL) and NaN_3 (4.3 g, 66 mmol) was added. The reaction mixture was refluxed overnight. Solvent was removed; the residue was diluted with dichloromethane (200 mL), washed with brine, and dried with anhydrous $MgSO_4$. After filtration and concentration, the product was obtained as a syrup with slight brown color (2.8 g, 80%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 4.04−4.09 (m, 2H), 3.30 (t, 2H, J = 6.4 Hz), 2.62−2.70 (m, 2H), 1.49−1.66 (m, 5H), 1.43 (s, 9H), 1.05−1.14 (m, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 154.91, 79.41, 48.90, 43.94, 35.34, 33.46, 31.94, 28.57.

*4-(2-Azidoethyl)piperidine Trifluoroacetate (***4***).* Compound **3** (1.2 g, 4.7 mmol) was dissolved in dichloromethane (10 mL), TFA (3.0 mL) was added, and the reaction was stirred at r.t. for 1 h. Most of the solvent was removed, and a mixture of ether and water (v/v 1:1, 100 mL) was added. The aqueous phase was separated and washed with ether (30 mL). The aqueous solution was isolated and concentrated to give the product as white solid (890 mg, 70%). ^{1}H NMR (DMSO-d_6, 300 MHz): δ 8.91 (bs, 1H), 8.61 (bs, 1H), 3.38 (t, 2H, J = 6.8 Hz), 3.22−3.26 (m, 2H), 2.75−2.92 (m, 2H), 1.77−1.81 (m, 2H), 1.55−1.71 (m, 1H), 1.44−1.51 (m, 2H), 1.20−1.36 (m,2H). ^{13}C NMR (DMSO-d_6, 75 MHz): δ 158.82, 158.40, 47.96, 43.01, 34.12, 30.57, 28.07.

*[4-(2-Azidoethyl)-1-piperidinyl]ethanol (***5***).* Compound **4** (1.2 g, 4.4 mmol) and 2-bromoethanol (333 μL, 4.5 mmol) were dissolved in anhydrous acetonitrile (20 mL), followed by addition of anhydrous K_2CO_3 (1.85 g, 13.5 mmol). The reaction mixture was refluxed overnight. After filtration and concentration, the residue was dissolved in ethyl acetate (100 mL) and washed with saturated NaCl aqueous solution. The organic phase was separated and concentrated to give a residue which was used in the subsequent step without further purification (610 mg, 68%). A small amount of sample was taken for proton NMR analysis to confirm the product identity. ^{1}H NMR (Acetone-d_6, 400 MHz): δ 3.55 (t, 2H, J = 5.9 Hz), 3.37 (t, 2H, J = 7.1 Hz), 2.88−2.91 (m, 2H), 2.43 (t, 2H, J = 5.9 Hz), 1.95−2.01 (m, 2H), 1.66−1.69 (m, 2H), 1.50−1.55 (m, 2H), 1.33−1.45 (m, 1H), 1.18−1.28 (m, 2H).

*(4-Fluorophenyl)[6-hydroxy-2-(4-hydroxyphenyl)benzo[b]thien-3-yl] Methanone (***7***).* Compound **6** (2.1 g, 7.7 mmol) and 4-fluorobenzoyl chloride (0.92 mL, 7.8 mmol) were dissolved in anhydrous dichloromethane (50 mL) and cooled in an ice−water bath, followed by addition of $AlCl_3$ (1.1 g). The reaction mixture was stirred at r.t. overnight. The reaction was cooled in an ice−water bath, ethanethiol (2.8 mL, 38.5 mmol) was added, and the mixture stirred at r.t. for 6 h. The reaction mixture was diluted with dichloromethane (200 mL) followed by addition of 20% HCl (5 mL) and H_2O (50 mL) with vigorous stirring. The organic phase was separated and further washed carefully with saturated aqueous $NaHCO_3$ and brine. After concentration, the product was purified by column chromatography (hexanes/ethyl acetate 1:1) to give a slightly orange solid (2.5 g, 88%). ^{1}H NMR (Acetone-d_6, 400 MHz): δ 7.77−7.81 (m, 2H), 7.55 (d, 1H, J = 8.8 Hz), 7.41 (d, 1H, J = 2.0 Hz), 7.21 (d, 2H, J = 8.4 Hz), 7.06 (t, 2H, J = 8.8 Hz), 7.69 (dd, 1H, J = 8.8 Hz, 2.0 Hz), 6.73 (d, 2H, J = 8.8 Hz). ^{13}C NMR (Acetone-d_6, 100 MHz): δ 192.99, 167.49, 164.98, 158.86, 156.43, 144.30, 140.83, 135.16, 133.74, 133.28, 133.18, 131.25, 130.45, 125.46, 124.72, 116.34, 116.21, 115.99, 107.82.

*[4-[2-[4-(2-Azidoethyl)-1-piperidinyl]ethoxy]phenyl][6-hydroxy-2-(4-hyroxyphenyl)benzo[b]thien-3-yl] Methanone (***8***).* Compound **5** (590 mg, 2.9 mol) was dissolved in anhydrous DMF (5 mL), 60% NaH (120 mg) was added, and the mixture was stirred at r.t. for 10 min. Compound **7** (150 mg, 0.4 mmol) was added, and the reaction mixture was stirred at r.t. overnight. The reaction was quenched by adding MeOH (0.5 mL) and diluted with ethyl acetate (30 mL) containing 5% MeOH, then washed with saturated aqueous $NaHCO_3$. The organic phase was separated and concentrated to give crude product, which was purified by column chromatography (CH_2Cl_2/MeOH 10:1) to give the product as a yellow foam (55 mg, 25%). ^{1}H NMR (Acetone-d_6, 400 MHz): δ 8.67 (bs), 7.73 (d, 2H, J = 8.8 Hz), 7.39−7.42 (m, 2H), 7.28 (d, 2H, J = 8.8 Hz), 6.94 (dd, 1H, J = 2.4 Hz, 8.8 Hz), 6.89 (d, 2H, J = 8.8 Hz), 6.75 (d, 2H, J = 8.4 Hz), 4.13 (t, 2H, J = 5.8 Hz), 3.37 (t, 2H, J = 7.2 Hz), 2.93−2.96 (m,2H), 2.71 (t, 2H, J = 6.0 Hz), 1.65−1.69 (m, 2H), 1.49−1.54 (m, 2H), 1.33−1.43 (m,1H), 1.17−1.26 (m, 2H). ^{13}C NMR (Acetone-d_6, 100 MHz): δ 193.30, 164.04, 158.70, 156.34, 141.93, 140.81, 134.13, 132.77, 131.41, 131.30, 130.97, 125.84, 124.64, 116.43, 115.83, 115.12, 107.85, 67.27, 57.92, 54.89, 49.57, 35.96, 33.89, 32.86.

*[4-[2-[4-(2-(Dansyl-ε-aminocapronamide)ethyl)-1-piperidinyl]ethoxy]phenyl] [6-Hydroxy-2-(4-hyroxy phenyl)benzo[b]thien-3-yl] Methanone (***10***).* Compound **9** (50 mg, 0.09 mmol) and Ph_3P (42 mg, 0.15 mmol) were dissolved in the mixture of THF (1 mL) and H_2O (20 μL) and stirred at r.t. overnight (solution A). Dansyl-ε-aminocaproic acid (93 mg, 0.17 mmol), *N*-hydroxyl succinimide (23 mg, 0.20 mmol), and DCC (46 mg, 0.22 mmol) were dissolved in anhydrous DMF (1 mL) and stirred at r.t. overnight (solution B). Solution A was concentrated to dryness, dissolved in DMF (300 μL), and added to solution B. The reaction mixture was stirred at r.t. overnight. After filtration, the solvent was removed under high vacuum. The residue was purified by column chromatography (CH_2Cl_2/MeOH 10:1 and 0.2% $NH_3 \cdot H_2O$) to give the product as a foam with slight green coloration (38 mg, 49%). ^{1}H NMR (Acetone-d_6, 400 MHz): δ 8.54 (d, 1H, J = 8.5 Hz), 8.40 (d, 1H, J = 8.7 Hz), 8.20 (dd, 1H, J = 7.2 Hz, 1.0 Hz), 7.52−7.61 (m, 4H), 7.30 (d, 1H, J = 1.9 Hz), 7.25 (d, 1H, J = 7.5 Hz), 7.18 (d, 1H, J = 8.6 Hz), 6.99 (t, 1H, SO_2NH), 6.82−6.88 (m, 7H), 6.73 (t, 1H, CONH), 4.00 (t, 2H, J = 5.8 Hz), 3.16−3.21 (m, 2H), 2.85−2.92 (m, 10H), 2.65 (t, 2H, J = 5.8 Hz), 1.98−2.01 (m, 2H), 1.61−1.64 (m, 2H), 1.14−1.41 (m, 13H). ^{13}C NMR (Acetone-d_6, 100 MHz): δ 172.94, 158.18, 156.66, 155.19, 152.71, 152.49, 140.38, 137.50, 137.36, 130.69, 130.58, 130.48, 129.61, 129.44, 128.59, 128.12, 126.61, 124.64, 124.15, 122.71, 120.41, 116.99, 116.55, 116.40, 115.99, 115.45, 108.80, 67.26, 58.33, 55.00, 45.59, 43.62, 37.26, 37.19, 36.46, 34.27, 33.95, 32.98, 26.73, 25.33.

*5-(Dimethylamino)-N-((1-(2-(piperidin-4-yl) ethyl)-1H-1,2,3-triazol-4-yl)methyl)naphthalene-1-sulfonamide (***12***).* Azide **4** (250 μM), alkyne **11** (50 μM), $CuSO_4$ (500 μM), Na ascorbate (1.0 M), and tris[(1-benzyl-1*H*-1,2,3-triazol-4-yl)methyl]amine (100 μM) were stirred at room temperature for 1 h. The reaction product was identified by LC-MS and was quantified using as internal standard, 5-(dimethylamino)naphthalene-1-sulfonamide. The reaction yield in the presence of H_2O_2 (0, 100, 500, 1000 μM) was quantified in this way.

Rat Liver Microsomal Incubation of Azido Raloxifene. A solution containing azido raloxifene (10 μM), rat liver microsomes (1.0 mg/mL), GSH (500 μM), and NADPH (1 mM) in 50 mM phosphate buffer (pH 7.4, 500 μL total volume) was incubated for 30 min at 37 °C. For comparison, GSH was omitted and/or raloxifene was used as substrate. The reactions were terminated by chilling in an ice bath followed by the addition of a mixture of methanol/acetonitrile (100 μL, 1:1 v/v) and perchloric acid (50 μL/mL). The reaction mixtures were centrifuged at 13 000 rpm for 10 min; aliquots (80 μL) of supernatant were analyzed using LC-MS/MS. The HPLC analysis of the microsomal incubation was performed using an Agilent Eclipse XDB-C18 column (4.6 × 250 mm, 5 μm) with UV absorbance detection at 316 nm. The composition of HPLC mobile phase was a mixture of two solutions: solution A, water with 10% methanol and 0.1% formic acid; solution B, acetonitrile with 0.1% formic acid. The mobile phase consisted of a linear gradient of solution B from 10% to 30% over 20 min, 20 min gradient of solution B from 30% to 60%, and then 60% to 90% of solution B over 5 min at a flow rate of 1.0 mL/min.

ER Competitive Binding Assays. Competitive displacement of [^{3}H] estradiol (E_2) radioligand (Amersham Biosciences, Piscataway, NJ) from full-length recombinant human hERα and hERβ (PanVera/Invitrogen, Carlsbad, CA) was assayed as described (*33*, *34*). The reaction mixture consisted of 5 μL of compound in DMSO, 5 μL of hERα (0.5 pmol) in ER binding buffer (consisting of 10 mM Tris-HCl (pH 7.5), 10% glycerol, 2 mM dithiothrietol, 1 mg/mL BSA), 5 μL of "Hot Mix" [400 nM, prepared fresh using 95 Ci/mmol [^{3}H] estradiol, diluted in 1:1 ethanol/ER binding buffer (NEN Life Science Products; Boston, MA)] and 85 μL of ER binding buffer. The incubation was carried out at room temperature for 2 h before 50% hydroxyapatite slurry (100 μL; HAPS) was added. The tubes were incubated on ice for 15 min with vortexing every 5 min. The appropriate ER wash buffer was added (1 mL), and the tubes were vortexed before centrifuging at 10 000 *g* for 1 min. The supernatant was discarded, and this wash step was repeated three times. The HAPS pellet containing the ligand−receptor complex was resuspended in 200 μL of ethanol and transferred to scintillation vials. An additional 200 μL of ethanol was used to rinse the centrifuge tube. Cytoscint (4 mL/vial; ICN, Costa Mesa, CA) was added, and the radioactivity was counted using a Beckman LS 5801 liquid scintillation counter (Schaumburg, IL).

Induction of Alkaline Phosphatase in Cultured Ishikawa Cells. The Ishikawa cell line was provided by R. B. Hochberg (Yale University, New Haven, CT) and was maintained in Dulbecco's modified Eagle medium (DMEM/F12) containing 1% sodium pyruvate, 1% nonessential amino acids (NEAA), 1% glutamax-1, 0.05% insulin, and 10% heat-inactivated FBS. The procedure of Liu et al. was used as described previously (*33*). Ishikawa cells (1.5×10^4 cells/190 μL/well) were preincubated in 96-well plates overnight in estrogen-free medium. Test samples (10 μL at varying concentrations in DMSO) were added to determine EC_{50} values, and the cells in a total volume of 200 μL media/well were incubated at 37 °C for 4 days. For the determination of antiestrogenic activity, 2×10^{-8} M estradiol was added to the 10 mL of media used to dilute the test samples. The induction plates were processed by washing the plates with PBS and adding 50 μL of 0.01% Triton X100 in 0.1 M Tris buffer (pH 9.8). Plates were subjected to a freeze−thaw (−80 °C for at least 24 h before warming on a plate warmer to 37 °C). An aliquot (150 μL) of 1 mg/mL *p*-nitrophenylphosphate (phosphatase substrate) in 0.1 M Tris buffer (pH. 9.8) was added to each well. The enzyme activity was measured by reading the release of *p*-nitrophenol at 405 nm every 15 s with a 10 s shake between readings for 16 readings using a Power Wave 200 microplate scanning spectrophotometer (Bio-Tek Instruments, Winooski, VT). The maximal slopes of the lines generated by the kinetic readings were calculated. For antiestrogenic determination, the percent induction as compared with the background induction control was calculated using % antiestrogenic induction $= 100 \times [1 - ((\text{slope}_{\text{sample}} - \text{slope}_{\text{cells}})/(\text{slope}_{\text{estrogen}} - \text{slope}_{\text{cells}}))]$.

Modification of Model Proteins. Model protein GST-P1 (0.3 mg/mL) or BSA (0.2 mg/mL) and tyrosinase (5000 units/mL) were incubated with 50 μM tags (25 mM stock in DMSO) in PBS (pH 7.4), at 37 °C for 1 h. The azidoTag modified proteins were subsequently biotinylated via the modified Staudinger ligation by reaction with 500 μM phosphinyl biotin reagent (P-biotin; 50 mM stock in DMSO) at 47 °C for 2 h or via click chemistry using Click-iT kit according to the manufacturer's instructions. Reaction mixtures were chilled on ice, and 20 μL aliquots were separated in MOPS running buffer on 4−12% NuPAGE gels (Invitrogen) and run on 200 V, 1 h, and detected with HRP-streptavidin (Pierce, 1:5000) after transblotting onto PDVF membrane and blocking overnight (5% nonfat milk). For studying modified proteins in whole cell lysate, azidoTag was incubated with GST-P1 and tyrosinase as described above, and unreacted tag was removed by 5000 MWCM microcon to yield modified protein ("azido GST-P1"). The azido GST-P1 was then added to MDA-MB-231 breast cancer cell lysates (1 mg/mL) prepared with detergent or sonication, in a w/w ratio of GST-P1 to cell lysate proteins of 1:10. Ligation efficiency and background response were compared via chemiluminescence (for azidoTag and COATag) or in-gel fluorescence (for dansylTag) using 300 nm UV illumination.

Modification of Proteins in Rat Primary Hepatocytes. The cryo-preserved rat hepatocytes were thawed according to the protocol (Celsis Technologies). On the day of assay, the vials containing the rat cryopreserved hepatocytes were removed from liquid nitrogen storage. The cells were thawed by gently shaking the vials in a 37 °C water bath. The hepatocyte suspension was transferred into the prewarmed 50 mL thaw medium, the cells were centrifuged at 50 *g* for 3 min, and the resulting pellet was resuspended in Krebs-Hensleit buffer (KHB) at the appropriate cell density for further experiments. Viability was determined using the trypan blue exclusion assay. Tags dissolved in DMSO were added to the hepatocyte cultures to give a final concentration of 50 μM, and the DMSO concentration was 0.1% (v/v). After incubation at 37 °C, 5% CO_2, in the dark for 2 h, the hepatocytes were washed three times with cold PBS, collected by centrifuge, and immediately frozen at −75 °C and stored for future analysis. For the azidoTag-treated hepatocytes, the whole cell proteins were harvested, lysed using 1% NP40/PBS, and endogenous biotinylated proteins were pulled down using 1 mg/mL MagnaBind streptavidin beads. The supernatants were collected, and biotin conjugation was performed via Staudinger ligation or click chemistry as described above. Ligation efficiency and background response were compared via chemiluminescence (for azidoTag and COATag) or in-gel fluorescence (for dansylTag).

Avidin Affinity Concentration. The separation of biotinylated proteins from the unbiotinylated proteins was performed on an Ultralink Immobilized Monomeric Avidin column according to the manufacturer's instructions. Briefly, a monovalent avidin column was washed sequentially with 12 mL PBS (pH 7.2), 10 mL biotin buffer (2 mM D-biotin in PBS) to block any nonreversible biotin binding sites, 10 mL glycine buffer (0.1 M glycine, pH 2.8), and finally 12 mL PBS again. The protein mixture (1 mL) was incubated on the column at room temperature for 1 h and then washed extensively with 18 mL PBS to remove unbiotinylated proteins, followed by 12 mL biotin buffer to elute biotinylated proteins, and finally 10 mL glycine buffer

to regenerate the column. The biotinylated protein eluate was concentrated to 250 uL by ultrafiltration through a 5000 MWCM centricon at 4000 *g* for 1 h, and aliquots were stored at −75 °C until analysis.

Confocal Microscopy. ER-positive MCF-7 cells were grown (1×10^6 cells/mL) on each of eight wells on a sterile Nunc chambered cover glass and incubated for 48 h at 37 °C with 5% CO_2 in phenol red free RPMI medium supplemented with 10% stripped FBS. MCF-7 cells were treated with 1 μM dansyl DMA for 18 h. Before imaging, cells were rinsed two times with PBS to remove the unincorporated dye and 1 μM of DRAQ5 stain was added to the cells to see nuclear staining. In separate experiments, MCF-7 cells were treated with 1 μM dansyl DMA, and confocal imaging was performed in 1 min intervals to see the time-dependent localization of dansyl DMA. Imaging was performed with a Zeiss LSM510 laser-scanning confocal microscope with the detector gain adjusted to eliminate the background autofluorescence. The fluorescence signal from dansyl DMA was monitored with a 345 nm UV laser and a 420 nm band-pass filter. DRAQ5 nuclear staining signal was monitored with 568 nm argon/krypton laser and a 650 nm line pass filter. A 63× (1.2 numerical aperture) water immersion objective was used for all experiments. Images were analyzed using the analysis tool provided in Zeiss biophysical software package.

Two-Dimensional PAGE. 2DGE was performed at room temperature using ZOOM stripes and ZOOM IPG Runner System according to the manufacturer's instructions with minor modifications. Total 140 μL loading sample contains 10 μL cell lysate enriched using the Monomeric Avidin column (400 ng/μL), 128 μL ZOOM 2D protein solubilizer 1, 1.4 μL DTT (1 M), 0.7 μL ZOOM Carrier ampholytes (pH 3−10), trace bromophenol blue, and deionized water. The mixture was loaded into ZOOM IPGRunner cassettes and rehydrated in ZOOM pH 3−10 NL strips at room temperature. Isoelectric focusing was conducted using the following voltage gradient: 175 V for 15 min, 175−2000 V ramp for 45 min, and 2000 V for 30 min. After focusing, the strips were equilibrated with 10 mL NuPAGE LDS sample buffer with sample reducing agent for 15 min, followed by incubation for 15 min with the same sample buffer supplemented with iodoacetamide (125 mM). In the second dimension, focused strips were then applied to the ZOOM 4−20% IPG gel, and the proteins were further separated by SDS-PAGE at 200 V for 60 min. Proteins were transferred to PVDF, probed with HRP-streptavidin, and visualized by chemiluminescence. In all separation experiments, broad-range 2D protein markers (Pierce) and dual color precision plus protein markers (Bio-Rad) were used for calibration of the first and second dimension gels, respectively. The figures represented results from multiple experiments.

Mass Spectrometic Anaylsis of Tryptic Digests. The concentrated biotinylated proteins from rat hepatocytes were separated by 1D gel electrophoresis as described above. The gel was stained by Coomassie blue, excised, and digested with trypsin as described previously (*23*). The peptide mixture (30 μL, 10 μg enriched proteins) was injected onto a reversed-phase column (75 μm × 150 mm Zorbax SB300 C-18, Agilent Technologies) connected to a Dionex Ultimate 3000 HPLC system and a Thermo Finnigan LTQ-FT mass spectrometer equipped with a nanospray interface. The samples were chromatographed using a binary solvent system consisting of A, 0.1% formic acid and 5% acetonitrile, and B, 0.1% formic acid and 95% acetonitrile, at a flow rate of 200 nL/min. A gradient was run from 15% B to 55% B over 60 min. The mass spectrometer was operated in positive ion mode with the trap set to data dependent MS/MS acquisition mode. The instrument was set to complete a mass scan from 400 to 1800 Da in 1 s. Peaks eluting from the LC column that had ions above 1000 arbitrary intensity units triggered the ion trap to isolate the ion and perform an MS/MS experiment scan after the MS full scan. After every MS scan in the ion trap, ions were then transferred to the isolation cell of the 7 T magnet in the FT where a high-resolution (up to 500 000 at *m/z* 400) and high mass accuracy (1 ppm) mass spectrum of the precursor ions was obtained. Data analysis was carried out using the Mascot software platform (Matrix Science, UK) *Bioworks 3.2* (Thermo Instruments, CA) and the *X!tandem* software platform. The library searching and denovo interpretation identified the detected proteins from the individual peptides. The results for all proteins detected were collected and listed by protein name, detected peptide sequence(s), and search score. The reports were exported to an XML file for inclusion in a result database that was finally analyzed using *Scaffold 2.1.0*. Identifications were accepted only for proteins with three unique peptide identifications matching high-quality MS/MS spectra.

RESULTS

Synthesis of SERM Tags and Labeling Reagents. Azido raloxifene is an analogue of raloxifene with close structural similarity. It was synthesized by a nucleophilic aromatic substitution reaction between intermediates **5** and **7** (Figure 2A). To prepare **5**, compound **4** was obtained according to the literature with minor modifications (*35*); the subsequent N-alkylation of **4** gave the desired product. Intermediate **7** was conveniently synthesized by a one-pot, two-step procedure that has been used for the preparation of raloxifene (*36*). The synthesis of azido DMA has been reported previously (*21*); in this study, the azide group was reduced to an amino group prior to acylation to give dansyl DMA (Figure 2B).

ER Ligand Binding and Antiestrogenic Activity. Radioligand displacement competitive binding to full-length recombinant ERα and ERβ was assayed to determine the ability of tags to retain the molecular recognition characteristics of the parent molecule. For the DMA tags and parent drugs, nanomolar binding affinity was maintained despite the addition of substantial molecular baggage to the 3-position piperidine side chain (Table 1). Thus, the tags retain high affinity for binding to ERα relative to the parent molecule, DMA, and to the drug molecule, arzoxifene. Expectedly, given the greater steric requirement for binding to ERβ, the tags performed somewhat less favorably compared to DMA, but still retained nanomolar binding affinity.

The Ishikawa endometrial cancer cell line, used as a reporter for ERα-mediated classical estrogenic activity, also reveals antiestrogenic activity in intact cells in the presence of competing estradiol. All tags retained antiestrogenic activity in Ishikawa cells (Table 1) and were devoid of estrogenic activity (data not shown). Complete correspondence of isolated ER binding with cellular activity is not guaranteed, because classical antiestrogenic activity is thought to require ligand binding to the ER, receptor dimerization, and translocation to the nucleus to form a nonproductive transcriptional complex at the ER response element (ERE). Therefore, in cell culture for an antiestrogen to retain the potency indicated from simple binding assays, it must freely enter the cytoplasm, and as part of a liganded ER complex translocate through the nuclear membrane, permitting binding at the ERE. The data suggest that all the SERM tags under study manifest this ability in Ishikawa cells.

Having determined that the synthetic probes retain ER binding capacity in cell culture, protein modification by these probes was examined.

Model Protein Modification by SERMs with COATag, AzidoTag, and DansylTag. To compare modification by SERMs of isolated proteins, using different tag and conjugation strategies, GST-P1 and BSA were chosen as model proteins. GST-P1 is a key detoxification enzyme in phase II metabolism,

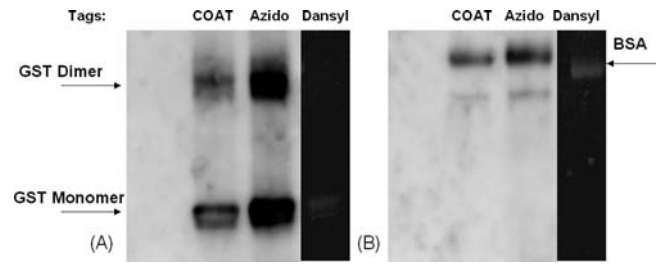

Figure 3. Modification of model proteins GST-P1 (A) and BSA (B) by COATag, azidoTag, and dansylTag. GST-P1 (0.3 mg/mL) and BSA (0.2 mg/mL) were incubated with tags (50 μM) and tyrosinase (5000 units/mL) in PBS (100 μL, pH 7.4) at 37 °C for 1 h. AzidoTag was further reacted with P-biotin (500 μM) at 47 °C for 2 h. Biotin tagged protein was visualized by Western blots using HRP-streptavidin; dansylTag was visualized by in-gel fluorescence (300 nm UV).

which has been reported previously to be a target for the raloxifene COATag, SERM quinoid metabolites, and *o*-quinones formed by oxidation of estrogens. GST-P1 contains four cysteine residues (Cys-14, Cys-47, Cys-101, and Cys-169); of these, Cys-47 and Cys-101 are highly susceptible to modification by quinoids derived from SERMs and estrogens (*7*, *9*, *37*). Alternately, BSA is a widely used model for study of protein modification by drugs (*38*). In model protein studies, tyrosinase was used to bioactivate the benzothiophene SERM moiety, since tyrosinase is not itself susceptible to covalent modification (*7*).

COATag, azidoTag, or dansylTag (50 μM) were incubated with either BSA or GST-P1 in the presence of tyrosinase, with solvent (DMSO) as vehicle control. The azidoTag modified proteins were subsequently labeled with biotin via the modified Staudinger ligation by reaction with phosphinyl biotin (P-biotin; 500 μM) at 37 °C for 2 h. Protein modification was detected by Western blots using HRP-streptavidin (for COATag and azidoTag) or in-gel fluoroscence (for dansylTag). Both GST-P1 and BSA were modified after incubation with tags for 1 h (Figure 3). GST-P1 readily oxidizes to form an intermolecular disulfide at Cys-47, leaving Cys-101 available for covalent modification (Figure 3A). Modification of GST-P1 dimer was not detected in the dansylTag incubation (Figure 3A). Densitometry indicated that the azidoTag appeared to give more protein modification than the COATag after incubation with GST-P1 for 1 h (Figure 3A). Explanations could rest on lower

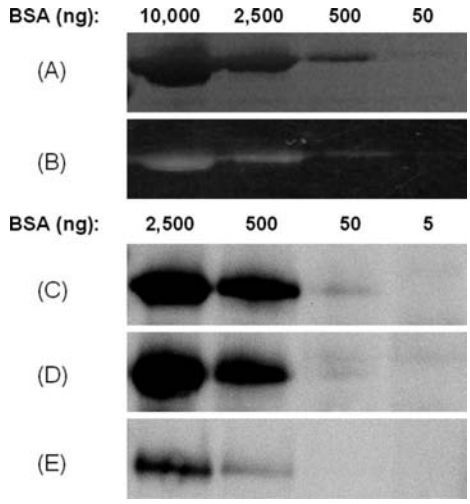

Figure 4. Comparison of sensitivity of different tag methodologies toward BSA (5 −10,000 ng per lane) after bioactivation of tags (50 μM) by tyrosinase (5,000 units/ml) in PBS (pH 7.4) at 37 °C for 1 h. AzidoTag was further conjugated with biotin via modified Staudinger ligation or click chemistry. The sensitivity was measured by Western blots using HRP-streptavidin (for COATag and azidoTag) or by in-gel fluorescence (for dansylTag). (A) Coomassie blue staining of BSA in the presence of dansylTag showing comparative sensitivity of protein dye staining. (B) In-gel fluorescence of BSA modified by dansylTag. (C−E) Western blots of BSA modified by COATag (C) and azidoTag/Staudinger (D) and azidoTag/click methodology (E).

reactivity of the COATag or on decreased tyrosinase oxidation rates for the COATag. In PBS, BSA was modified by all three tags (Figure 3B).

Sensitivity Comparison Using a Model Protein. From the study of the two model proteins, using tyrosinase as an oxidizing system, it was seen that protein modification can be observed using all three methodologies. However, it is critical to be able to detect low abundance proteins both in whole cell lysates and in future experiments with tissues. Therefore, the sensitivity of the four conjugation strategies was tested using BSA as model protein (avoiding the ambiguity resulting from GST-P1 dimerization). Varied amounts of BSA (5−10 000 ng) were incubated with tags, followed by workup. Electrophoresis on 1D gels visualized by immunoassay (for biotin-linked tags), in-gel fluorosence (for dansylTag), or Coomassie blue staining (for dansylTag) was used to quantify the relative response and sensitivity to the four methodologies: (1) COATag; (2) azidoTag/Staudinger; (3) azidoTag/click; (4) dansylTag.

The results showed that both COATag and azidoTag/Staudinger ligation methodologies were able to detect BSA modified in incubations with only 5 ng protein and quantify protein modification in incubations with 50 ng protein (Figure 4C,D). AzidoTag/click chemistry and dansylTag methodologies were 10-fold less sensitive (Figure 4B,E) and were comparable in sensitivity to Coomasie blue staining (Figure 4A).

The ability of oxidant systems to perturb the efficiency of conjugation by click chemistry was studied by the use of the click ligation between a model azide (*4*) and a dansyl tagged alkyne (*11*) (Figure 2B). As might be expected in the presence of H_2O_2 (0, 100, 500, 1000 μM), the efficiency of ligation was attenuated: 100%, 93%, 82%, and 52%, respectively. A solution of H_2O_2 does not fully mirror the oxidation potential of the catalytic oxidant systems under study, but the observations are in accord with the observed lower sensitivity of the azidoTag/click methodology. Although additional workup procedures could be used to mitigate against the oxidation of cuprous ion in click ligation, the addition of an extra step in the conjugation procedure is a disadvantage.

Application of Modified Staudinger Ligation and Click Chemistry in Cell Lysates. The conditions used for modified Staudinger ligation of azides with phosphinyl biotin (P-biotin) after cellular incubation are widely variable in the literature (*29*, *31*, *39*, *40*). Accordingly, time, temperature, and reactant concentrations were varied, in addition to variation of the common reagents used in cell lysis and SDS-PAGE. The model system selected to test the efficiency of each method in detecting modified protein in cell lysates was modified GST-P1 in MDA-MB-231 breast cancer cell lysates. AzidoTag was incubated with recombinant GST-P1 in the presence of tyrosinase and unreacted tag was removed by filtration to yield a protein mixture enriched in modified protein ("azido-GST"). Azido-GST was added to cell lysates, which contain no detectable endogenous biotinylated proteins (Figure 5A, lane 12), in a w/w ratio of GST-P1 to cell lysate proteins of 1:10. Modified Staudinger ligation and click chemistry were subsequently performed in the azido-GST cell lysate system, and ligation efficiency and background response were compared using Western blot.

The results showed that many variables influenced the azidoTag/Staudinger methodology, but most prominent was the high background response in the control experiment in the absence of azidoTag and presence of the P-Biotin (Figure 5A; lane 1). The concentration of P-biotin was critical for Staudinger ligation, with ligation being inefficient at lower P-biotin concentrations (Figure 5A; lane 4). Thus, reducing P-biotin concentration was not useful in reducing the nonspecific background. Increasing P-biotin concentration, incubation time, and temperature all enhanced ligation, but concomitantly increased the background signal (Figure 5A, Lanes 5−10). The reducing reagent DTT, commonly used to maintain reduced thiols, did not affect Staudinger ligation (Figure 5A, lanes 2,3), but detergents (i.e., NP40) interfered with the reaction (data not shown), consistent with previous reports (*39*). Even under optimal conditions, nonspecific labeling was observed (Figure 5A, lanes 5 and 8). Comparison reaction systems without azido-GST or P-biotin (Figure 5A, lanes 1 and 11) indicated that these nonspecific bands resulted from the reaction of proteins with P-biotin, which contains a benzoate ester moiety.

The azidoTag/click methodology was compared in the same model system consisting of cell lysate containing azido-GST, but in this case, using a commercial click labeling kit from Invitrogen requiring 1 h reaction at room temperature. The relative specificity of the azidoTag/click methodology was immediately apparent; both modified GST-P1 monomer and dimer were readily detected (Figure 5B, lane 1). Although modified GST-P1 dimer was also almost certainly present in the Western blots resulting from use of the azidoTag/Staudinger methodology, this band was obfuscated by the high nonspecific background of Staudinger ligation (Figure 5A, Lanes 2−10). The azidoTag/click methodology was specific and sensitive in this model system; no biotinylated proteins were detectable in the control incubation of unmodified GST-P1 in cell lysates after reaction with the click chemistry reagents (Figure 5B, lane 2).

Application of COATag and AzidoTag in Hepatocytes. The next step from assay of model proteins in cell lysates was to compare methodologies in intact cells. Hepatocytes contain high levels of metabolic enzymes that can oxidatively bioactivate SERMs to electrophilic quinoids. Primary rat hepatocytes were treated with either solvent control or the various tags (50−250 μM). The concentration and incubation time were optimized to give extensive protein modification in the absence of cell toxicity. The COATag was able to modify cellular proteins as shown by the concentration dependence of the immunoassay response, suggesting that the hepatocyte cell membrane is permeable to the COATag and confirming the high metabolic capacity of hepatocytes (Figure 5C). Major modification bands

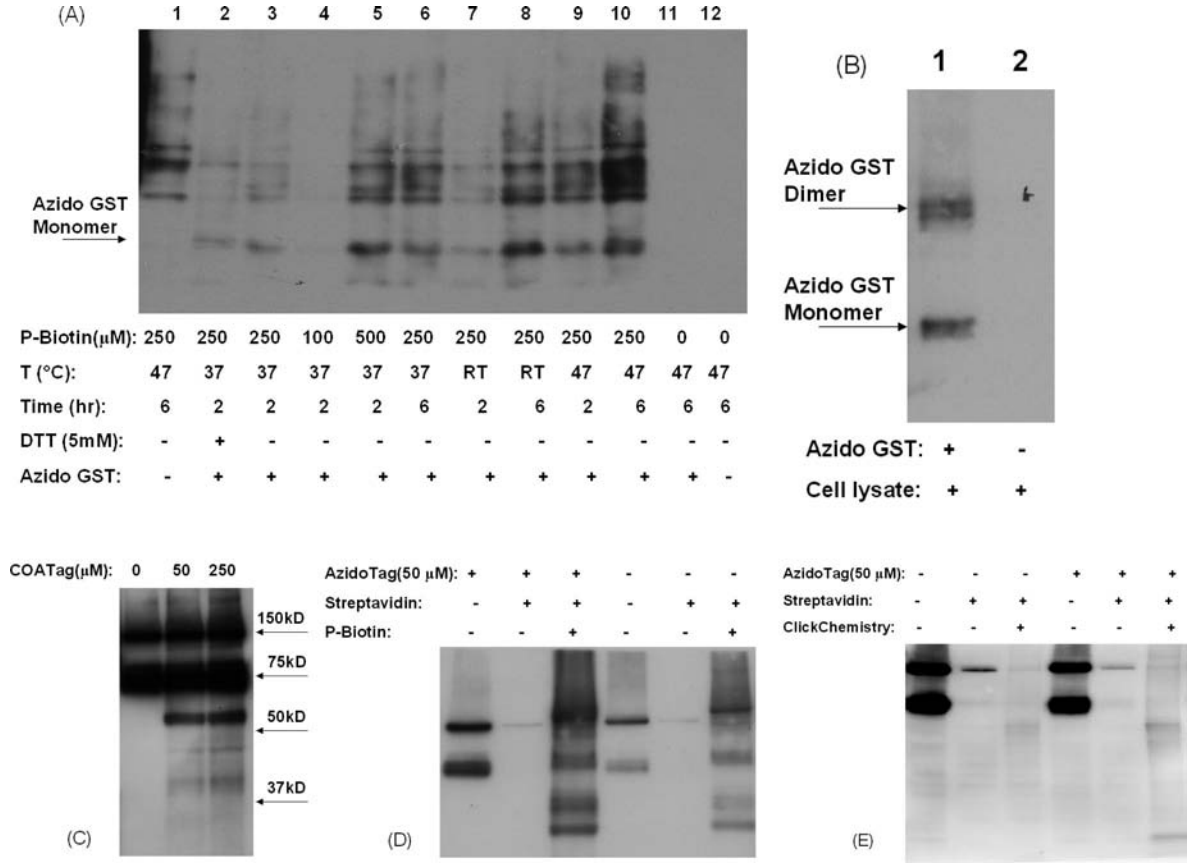

Figure 5. Comparison of protein tagging methodologies in rat primary hepatocytes. Upper: Application of modified Staudinger ligation and click chemistry for detecting modified protein targets in cell lysates. Biotin conjugation via modified Staudinger ligation or click chemistry is described in Materials and Methods. (A) Modified Staudinger ligation. Lane 1: cell lysate without azido GST-P1. Lanes 2−11: cell lysate with azido GST-P1 under varied conditions. Lane 12: cell lysate only. (B) Click chemistry. Lane 1: cell lysate + azido GST-P1. Lane 2: cell lysate only. Lower: Comparison of protein tagging methodologies in rat primary hepatocytes. Cells were incubated with COATag (C) or azidoTag (D,E) (50 μM) in KHB buffer for 2 h and then labeled via modified Staudinger ligation (D) or click chemistry (E).

were observed at about 60 kDa, 45 kDa, and 40 kDa, but low abundance proteins modified by SERM quinoids ranged from 15 kDa to 150 kDa (Figure 5C, lanes 2 and 3). A drawback in the COATag methodology is seen in the obfuscation of modification of proteins at 75 kDa and 150 kDa because of large amounts of endogenous biotinylated proteins (Figure 5C).

In the azidoTag treated hepatocytes, proteins were harvested and endogenous biotinylated proteins were pulled down using MagnaBind streptavidin beads (1 mg/mL). The supernatants were subsequently reacted with modified Staudinger ligation or click chemistry reagents. The capability to remove endogenous biotinylated proteins efficiently using streptavidin beads before conjugation of the tag using either Staudinger or click reactions represents an advantage of the azidoTag methodologies (Figure 5D,E). However, the azidoTag/Staudinger methodology again suffered from high nonspecific background response (Figure 5D, lane 6). Varying of the concentration of P-biotin was not effective in attenuating background (Figure 5A and Supporting Information). Using the azidoTag/click methodology, very minimal nonspecific background signal was observed; however, the ligation efficiency was lower than the COATag as reflected by the relatively weak visualization of only two bands of modified proteins (Figure 5E). The high nonspecific labeling associated with modified Staudinger ligation and low ligation efficiency of the azidoTag/click chemistry in hepatocytes led to abandonment of these methodologies.

Application of Dansyl Tag in Breast Cancer Cells and Hepatocytes. A major incentive for exploration beyond the COATag methodology was the anticipated poor cell membrane permeability of the large COATag, which must contain a relatively polar linker−biotin moiety to allow solubility at high micromolar concentrations. However, the hepatocyte experiments, where extensive protein modification was observed, suggest that the COATag is not inherently membrane impermeable (Figure 5C). A remote possibility was that the COATag was simply modifying extracellular proteins expressed by hepatocytes, but this was ruled out by study of cell culture supernatants prior to cell lysis (Supporting Information). The dansylTag (λ_{ex}337nm, λ_{em}492nm), which may share similar size and hyphophilicity with biotin tags, was studied in both hepatocytes and in ERα positive MCF-7 breast cancer cells, in order to visualize cell permeability using confocal fluorescence microscopy. In MCF-7 cells, the dansylTag rapidly penetrated the outer cell membrane in a time-dependent manner leading to relatively rapid accumulation in the cytoplasm (Figure 6A), but penetrated the nuclear membrane more slowly (after approximately 18 h incubation; Figure 6B). In hepatocytes, localization in the cytoplasm was also observed by fluorescence microscopy (data not shown); however, bands corresponding to modified proteins in hepatocyte lysates treated with dansylTag were not detectable by in-gel fluorescence (Supporting Information), indicating that the dansylTag methodology is not sufficiently sensitive for proteomic studies in intact cells.

Two-Dimensional Resolution of COATagged Proteins. As seen above, a drawback to the use of the COATag methodology is obfuscation of modified proteins by endogenous biotinylated proteins. The use of 2D gels to overcome this obstacle was explored in hepatocytes treated with COATag (50 μM). After incubation, cells were lysed, enriched, desalted, and concentrated; approximately 1 million hepatocytes yielded about 1 mg

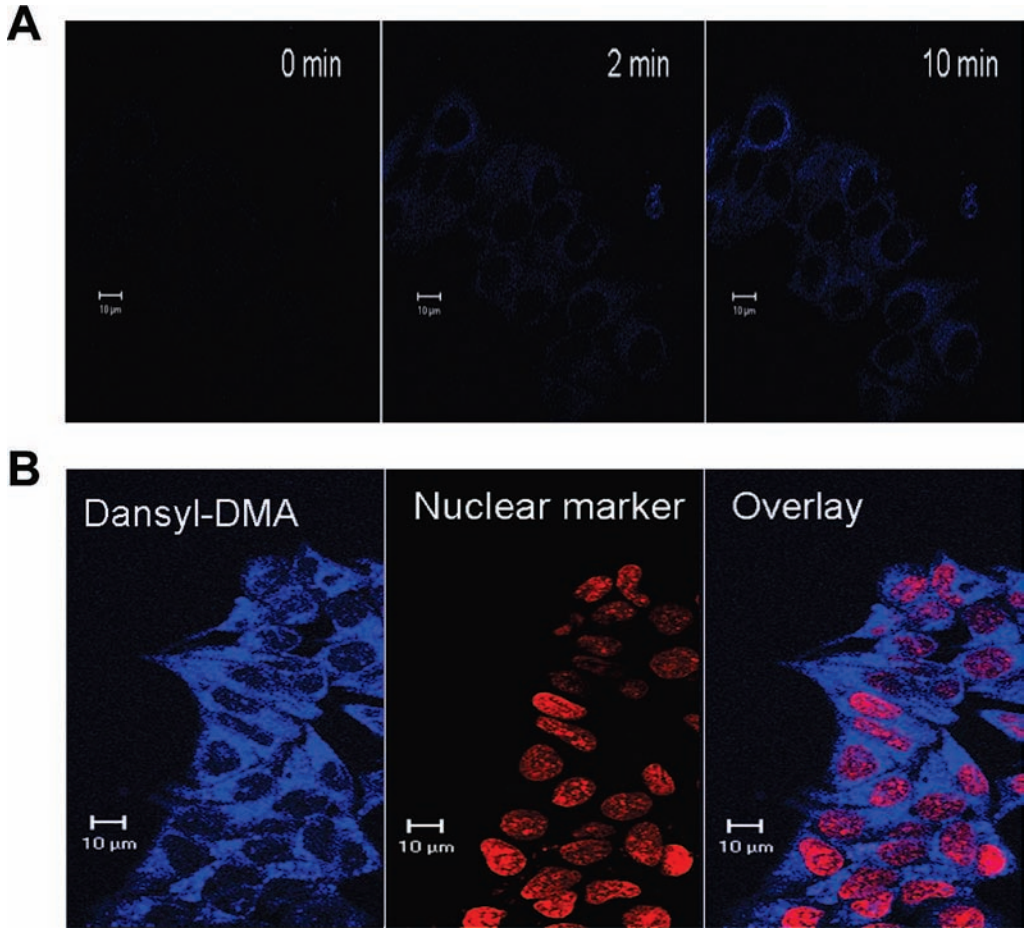

Figure 6. Localization of dansyl DMA in ERα positive MCF-7 cells. (A) Time-dependent localization of dansyl DMA (1 μM) in MCF-7 cells. (B) Localization of dansyl DMA (1 μM) in MCF-7 cells after 18 h treatment. The nuclear marker staining defines the location of the nucleus, and the overlay indicates the colocalization of dansyl DMA and the nuclear marker.

total protein; and after enrichment and purification, the yield was approximately 40 μg. Enriched proteins (4 μg aliquots) were separated by electrophoresis on 1D and 2D gels, followed by transfer and Western blot using HRP-streptavidin. 2D protein markers and solvent-treated hepatocytes provided controls and calibration.

Endogenous biotinylated proteins were observed at high concentration in hepatocytes (Figure 7A; lane 1). The COATag clearly modified a large number of lower molecular weight proteins that could be readily isolated by in gel digest and subsequent analysis and identification by mass spectroscopy (Figure 7A; lane 2), but several spots in the 2D gel were localized close to the bands of endogenous biotinylated proteins (Figure 7B), suggesting that proteomic methods would be required for definitive classification of endogenous and COAT-agged proteins. A large fraction of the COATag modified proteins were detected at pI 4−7, MW 20−75 kDa; these proteins were studied further by 2D electrophoresis and the comparison between COATag and vehicle treated hepatocytes revealed COATagged and endogenous biotinylated proteins. Approximately 30 spots were observed reproducibly in the COATag treated hepatocytes, in contrast to vehicle treated cells (Figure 7C,D).

Mass Spectroscopic Identification. Full proteomic analysis is not reported herein; however, in order to validate the use of the COATag methodology, several liver proteins were identified by MS analysis of in-gel digests. In addition to three modified proteins previously reported from rat liver microsomes, cytosolic glucose regulated protein, protein disulfide isomerase, and glutathione S-transferase, certain postulated target proteins such as peroxiredoxin-1 and heat shock proteins were also identified (Table 2).

Metabolism of AzidoTags. Several successful examples of the use of azidoTags have appeared in the literature, in particular using click chemistry for conjugation to various chemical "handles" including biotin. The reactions of azide and alkynyl functionalities are generally viewed as bioorthogonal and therefore inert to reactions in biological systems, which might confound analysis. However, since the purpose of the COATag methodology, and by extension the azidoTag, is to study electrophilic metabolites generated by oxidative bioactivation, examination of the metabolic stability of the azidoTag was warranted. As has been previously reported, raloxifene in liver microsomes is oxidized substantially and predominantly to the diquinone methide that is efficiently trapped by GSH. In this oxidative environment dominated by P450 3A4, the *o*-quinone and its GSH conjugate are minor products. The raloxifene azidoTag was observed to yield metabolites that were observed in the presence or absence of GSH (Figure 8A). These metabolites were further investigated by MS/MS and proven to be oxidative metabolites resulting from reaction and loss of the "bioorthoganol" azide moiety (Figure 8B). In addition to metabolism of the aliphatic azide, a spectrum of GSH conjugates of quinoid metabolites was observed to be qualitatively comparable to those observed for raloxifene itself (Figure 8A). Thus, the azidoTag was oxidized to quinoids, largely mirroring the parent drug, supporting its use as a probe for target proteins. However, the loss of the azido functionality in this same

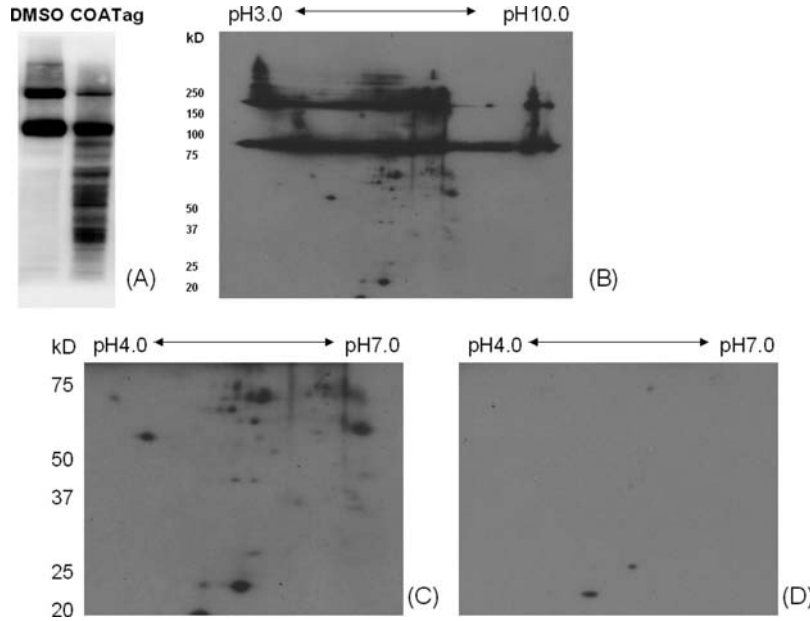

Figure 7. Two-dimensional resolution of COATag modified cellular proteins. Hepatocytes were incubated with COATag (50 μM) or DMSO in KHB buffer at 37 °C for 2 h. Approximately 4 μg of enriched modified proteins were analyzed using 1D (A) and 2D (B) gel electrophoresis and visualized using HRP-streptavidin. An expanded section of the 2D analysis of COATag modified proteins (C) is compared with the similar vehicle control experiment (D).

Table 2. Percent Coverage of Select Proteins Modified by Ral COATag in Rat Hepatocytes[a]

		Ral COATag[b]			
protein	accession#	ctrl.	rep. 1	rep. 2	rep. 3
78 kDa glucose-regulated protein precursor	IPI00206624	-	30.00	30.90	36.70
Protein disulfide-isomerase precursor	IPI00198887	-	14.10	7.27	12.40
Microsomal glutathione S-transferase 1	IPI00230889	-	-	26.50	
Glutathione S-transferase kappa 1	IPI00327079	-	-	-	27.40
Predicted Stress-70 protein, mitochondrial precursor	IPI00363265	-	9.72	25.90	11.60
Heat shock cognate 71 kDa protein	IPI00208205	-	12.70	10.50	-
Peroxiredoxin-1	IPI00211779	-	29.60	24.60	-

[a] This table presents select proteins identified from three independent experiments, in which rat primary hepatocytes were treated with raloxifene COATag (50 μM) or vehicle control. [b] The number value indicates the percent amino acid coverage of each protein identified by peptide fragmentation using LC-MS/MS analysis.

oxidative bioactivation process will inevitably decrease the sensitivity of the azidoTag methodology.

DISCUSSION

The COATag methodology was developed to study and identify the protein targets of electrophilic oxidative metabolites of small molecules (*7*). The proof-of-principle study focused on a clinical drug, the benzothiophene SERM raloxifene, which is oxidatively bioactivated to electrophilic quinoid metabolites (*4, 6*). The COATag technique was effective in identifying protein targets in microsomal incubations; including the abundant cytoplasmic disulfide isomerase proteins, chaperone proteins, and a detoxifying GST enzyme (*7*). In combination with protein-specific antibodies and mass spectroscopy, the COATag technique is transferable to other small molecules subject to bioactivation to electrophiles, including endogenous molecules such as estrogens and catecholamines. The technique has also been applied to assessment of the extent of protein modification and dependence on cofactors in microsomes (*21*). In order to proceed to identification of protein targets in intact cell incubations, the use of azidoTags was explored in anticipation of increased cell permeability relative to the larger more hydrophilic COATag.

The requirements for an effective tagging methodology are that the tagged small molecule must retain characteristics of the parent molecule including cell permeability and receptor binding characteristics. SERMs represent attractive subjects for study because side chain modification in COATags, azidoTags, and dansylTags does not significantly perturb binding to receptors that recognize the parent molecule; as demonstrated by the measured ER binding affinities and antiestrogenic activity in cell culture (Table 1). In contrast to tagging methodologies for inherently electrophilic biomolecules such as 9-HNE, the COATags and related tags studied herein require bioactivation to generate the electrophilic metabolites that target protein nucleophiles. Therefore, additionally, the tag must retain a similar metabolic profile to the parent molecule. Beyond these characteristics, tagging methodologies should provide sensitivity and specificity.

The use of biotin in affinity tags and the high-affinity binding of biotin by immobilized avidin provides effective systems for protein purification and enrichment. Biotin affinity tags and comparable fluorophore affinity tags have both been subject to widespread study and usage (*23*); however, it was not certain that tagging with biotin or fluorophore plus the required linker moieties would limit cell permeability and thus limit the use of these tagging approaches. An alternative approach is provided by the recent development of bioorthogonal reporter strategies in which azide-bearing molecules are labeled with biotin or a fluorophore via modified Staudinger ligation or click chemistry (*26, 27, 30, 31*). Azide is a small functional group assumed not to interfere with the properties of the parent molecule, including

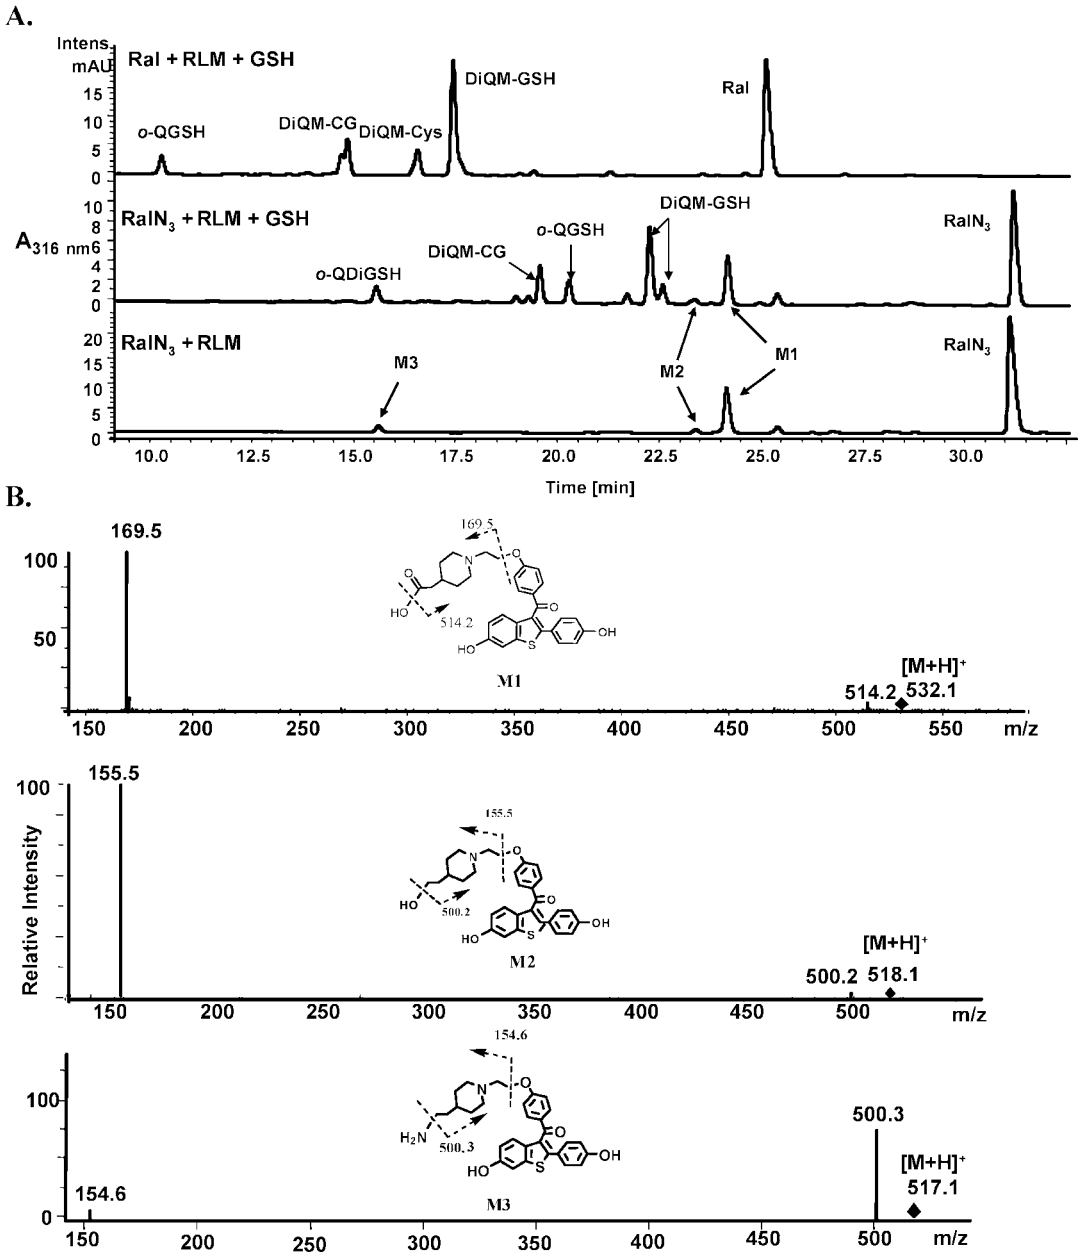

Figure 8. Metabolism of raloxifene azidoTag compared to raloxifene in induced rat liver microsomes. (A) Chromatograms of raloxifene and raloxifene azidoTag in microsomal incubations with and without GSH present to trap quinoid species. (B) MS/MS spectra and identification of azido raloxifene metabolites M1, M2, and M3 corresponding to annotations in (A). MS/MS spectra of GSH conjugates are presented in Supporting Information.

receptor binding, metabolism, and cell permeability, and is assumed to be biologically inert. In addition, a two-step labeling strategy offers multiple methods for downstream protein detection and purification.

Four tagging methodologies were compared as depicted in Figure 9: two one-step methods: method 1, COATag; and method 2, dansylTag; and two two-step methods: method 3, azidoTag/Staudinger; and method 4, azidoTag/click. The model systems employed were purified proteins (BSA and GST-P1), cell culture lysate, and primary cell cultures of rat liver hepatocytes. Both BSA, a highly abundant protein, and GST-P1, a known target of quinoid metabolites (*7*), contain thiol groups, which are susceptible to modification by SERM quinoids formed from bioactivation by oxidase/oxygenase enzymes such as tyrosinase. Hepatocytes are major cell mediators of metabolism *in vivo* including SERM metabolism and have been implicated in liver carcinogenesis caused by the archetypal SERM, tamoxifen (*41*). Hence, hepatocytes represent cells rich in both metabolic enzymes and cellular targets for SERM quinoid electrophiles. Previously, protein modification by COATags was observed to be time and concentration dependent (*7*). In this study, concentrations of tags employed (50 μM) were comparable with similar studies using tagged electrophiles. This concentration is suprapharmacological; however, the purpose of these studies is to identify cellular target proteins. It should also be noted that exposure time (1 h for model proteins and 2 h for hepatocytes) is much shorter than the long-term clinical exposure typical for SERMs.

In this study, the azidoTag/Staudinger methodology was found to offer high sensitivity but low specificity (Table 3). The modified Staudinger ligation reaction between triarylphosphine and azide functionalities produces an aza-ylide that is further stabilized by an electrophilic methyl ester via intramolecular cyclization (*31*). First introduced by Bertozzi, this ligation has been utilized for tagging and labeling surface proteins, expressed proteins, and engineered proteins in cells (*29*, *31*, *42*).

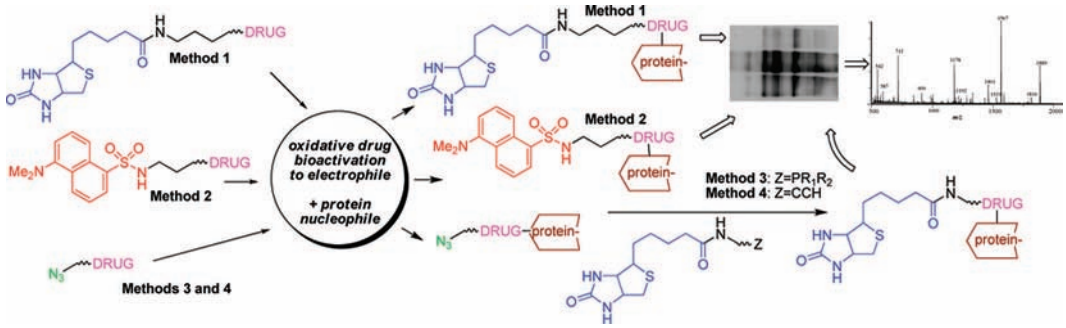

Figure 9. Schematic depiction of the four methodologies explored in this work culminating in proteomic analysis.

Table 3. Comparison of Tagging Methodologies[a]

tagging methodology	tag is ER ligand and active in cells?	sensitivity	specificity
Method 1 (COATag)	yes	higher	high[b]
Method 2 (dansylTag)	yes	lower	low
Method 3 (azidoTag)	yes	higher	N/A[c]
Method 4 (azidoTag)	yes	lower	high

[a] See Figure 9 for depiction of details of each method. [b] With the exception of natively biotinylated proteins. [c] Modified proteins not detectable from hepatocyte incubations.

The reaction is rapid in a physiological environment and is reported as compatible with living systems (*25*, *43*). Correspondingly, in this study, the azidoTag/Staudinger methodology efficiently labeled protein targets and detected nanogram level of modified proteins *in vitro* (Figures 3 and 4). Compared to the alternative methodologies studied, this methodology was highly sensitive.

Using purified proteins, the azidoTag/Staudinger methodology appeared superior; however, when applied to the more complex cell lysates and whole cell treatments, a high background from modified Staudinger ligation was observed (Figure 5A). Attempts to attenuate the nonspecific background reactivity, including optimization of Staudinger reaction conditions and reagents, failed (Figure 5A). Control experiments in cell lysates showed that the nonspecific background is linked to the second labeling reagent, P-biotin (Figure 5A), for which there is precedent in the literature (*20*). The nonspecific labeling of abundant proteins is possibly associated with reaction of the methyl benzoate group of P-biotin with protein amino groups. The nonspecific background obscures the detection of low-abundance protein targets of bioactivated metabolites limiting use of this method for analysis of protein modification by electrophilic metabolites in cells.

The azidoTag/click methodology was highly specific but suffered from low sensitivity. Click chemistry was first reported for activity-based protein profiling by Cravatt, in which the [2 + 3] cycloaddition of an alkyne and azide functional group was catalyzed by cuprous ion (*26*, *30*). In comparison to labeling via Staudinger ligation, click chemistry was considered to produce lower background (*20*). However, in the present study click chemistry both in model proteins and in cells was observed to have ligation efficiency much less than that of Staudinger ligation (Figures 4 and 5), and the methodology was observed to have lower detection sensitivity than either the COATag or azidoTag/Staudinger methodologies (Figures 4 and 5). Several studies have compared the efficiency of Staudinger ligation and click chemistry, describing varied time dependence for ligation efficiency and shorter reaction times for click ligation, but these studies have not reported the click methodology as having low sensitivity (*20*, *43*). A possible explanation for observed low sensitivity rests on the high oxidative capacity of the systems under study, containing either oxygenase (tyrosinase) or cytochrome P450 oxidase at high levels. Click ligation is catalyzed by Cu(I), which is attenuated by the oxidative environment that is essential for study of protein modification by the azidoTags. The attenuated efficiency of click ligation observed in the presence of H_2O_2 is compatible with the proposal. High ascorbate concentrations are used to maintain sufficient reduced copper ion for click ligation, but this is apparently not sufficient in highly oxidizing systems.

Metabolism studies in induced rat liver microsomes also reduced confidence in the use of the azidoTag methodologies, because the azide group was observed to be susceptible to metabolism to an amino group and subsequent oxidative metabolism normal for a primary amine. Although the oxidative loss of the conjugating azide group may be at acceptable levels for many applications, the focus of these studies is oxidative bioactivation; therefore, this is undesirable.

Fluorophore tagging is useful to provide an alternative or additional visualization method to biotin−avidin immunoassay, but the dansylTag methodology was the least sensitive of the methodologies compared herein. The most significant advantage of fluorophore tags is their use for direct imaging under fluorescence microscopy and by in-gel readouts (*24*). Fluorophore tags may be of comparable size and hydrophilicity to biotin tags limiting cell impermeability (*29*); however, the dansylTag proved invaluable in visualization of the cell permeability of tagged SERMs, rapidly accumulating in the cytoplasm in intact cells (Figure 6). The use of dansylTags and related fluorophore tagged SERMs in this regard is clear, but no detectable protein modification was observed by dansylTag in hepatocytes (Supporting Information). The in-gel fluorescence readout cannot be amplified in the same way as immunoassay signals. Important, cellular protein targets may be in low abundance; therefore, dansylTag is insufficiently sensitive for detection of protein targets in cells.

Biotin is a commonly used affinity tag for affinity labeling; the high affinity of avidin/streptavidin makes it a powerful tool for both detection and enrichment of probe-labeled targets (*23*). However, cell impermeability caused by biotin and its linker was a major concern for the generalized application of COATags to cells (*22*−*24*). The COATag used herein was observed to modify a large number of cellular protein targets in hepatocytes suggesting that the COATag is cell permeable. Cell permeability for the dansylTag in MDA-MB-231 cells was readily visualized, showing rapid access to the cytoplasm. The COATag was also observed to be a potent antiestrogen similar to the parent drug molecule in Ishikawa cells. Given the four-day incubation with Ishikawa cells, it cannot be ascertained if the COATag manifests slow nuclear membrane penetration as was observed with the dansylTag in MBA-MB-231 cells. Nevertheless, the COATag methodology appears applicable for whole cell and tissue studies. Given that SERMs are good ER ligands, their binding with and transportation by ER may assist transport of these COATags into the cytoplasm and nucleus in ER positive cells.

The COATag methodology also demonstrated high sensitivity and specificity and, furthermore, has the advantage of being a one-step labeling method, preventing sample loss during multistep experimental processing.

One inevitable limitation of COATags was the presence of endogenous biotinylated proteins, observed in high abundance in hepatocytes at 75 kDa and 150 kDa (Figure 5C). Biotin-dependent carboxylases are especially abundant in liver tissues (*44*). In many other cells, such as MDA-MB-231 cells (Figure 5A), endogenous biotinylated proteins may not present a problem; however, for generalization of the use of COATags, further separation and discrimination is required. Exploration of the COATag in primary hepatocytes followed by further separation using 2D PAGE illustrated one such approach. Interestingly, COATag modified proteins clustered at low molecular weight (20−75 kDa) and acidic pI (pH 4−7) (Figure 7); thiol-rich protein targets such as GST-P1 (MW, 23 kDa; PI, 6.9), Keap1 (MW, 69 kDa; pI, 6.0), and HSP70 (MW, 70 kDa; pI, 5.5) all occur within this range. The previous study of COATags in rat liver microsomes showed that the methodology is compatible with MS/MS analysis (*7*); therefore, antibodies specific for these potential targets and MS analysis can be used in combination, as a preferred methodology for future protein identification in cells treated with COATags. Preliminary MS-MS analysis was performed on gel digests using the COATag methodology, identifying modified cytosolic proteins previously described in liver microsomes (glucose regulated protein, protein disulfide isomerase, and glutathione S-transferase) (*7*) and certain proteins that were anticipated targets for quinoid electrophiles, such as peroxiredoxin-1 and heat shock proteins (Table 2), which were reported as targets for other electrophiles such as 4-HNE (*20*).

CONCLUSION

Endogenous small molecules, drugs, and xenobiotics are subject to oxidative bioactivation to electrophilic metabolites. SERMs are bioactivated to quinoids, implicated in carcinogenesis and chemoprevention, which illustrates the importance of understanding the cellular targets of such metabolites (*14, 45, 46*). Methodology development for detection and identification of cellular targets of electrophilic metabolites is therefore of importance in understanding and predicting the balance between cytotoxic and chemopreventive effects. In this study, four methodologies were studied and compared using purified protein targets and rat primary hepatocytes (Figure 9 and Table 3). Importantly, the azidoTag/click methodology, using the currently preferred combination of azide-tagged molecules with click chemistry ligation, was limited in this application by the high oxidative capacity of the systems under study, leading to both metabolic loss of the azide group and reduced sensitivity. The COATag methodology, introduced in 2005, demonstrated superior characteristics in this application. The presence of endogenous biotinylated proteins in hepatocytes was overcome by application of 2D gel separation and proteomic analysis.

We describe a new generation of tracers for molecular imaging of the cell surface receptors for epidermal growth factor (EGF). These receptors play a key role in the progression of many tumors and are major drug development targets. Our tracers are based on a recombinant human EGF expressed with a cysteine-containing tag that enables facile site-specific radiolabeling with ^{99m}Tc for single photon emission computed tomography or site-specific conjugation of ^{64}Cu PEGylated chelators for positron emission tomography. These tracers retain EGF activities *in vitro* and display selective and highly specific focal uptake in tumors *in vivo*. We expect that nuclear imaging of EGF receptors with these tracers will be useful for clinical diagnosis, therapeutic monitoring, and development of new drugs and treatment regimens.

INTRODUCTION

Tumor growth critically depends on growth factors, and epidermal growth factor (EGF) appears to be of particular significance for the progression of many tumors (*1*). EGF acts via transmembrane tyrosine kinase receptors (EGFR) and promotes cell proliferation, motility, and survival by activating STAT, MAPK, and PI3K/Akt pathways. Receptors for EGF are the major drug development targets, and several EGFR-directed therapeutics, including anti-EGFR antibodies and EGFR tyrosine kinase inhibitors, are entering the clinic. Currently, EGFR expression in individual patients is determined by immunohistochemical analysis of tumor biopsies. Clinical experience, however, revealed that only 10−25% of patients that are defined as EGFR-positive by immunohistochemical analysis respond to EGFR-directed therapeutics (*1*−*3*), and there is a poor correlation between EGFR immunohistochemistry and treatment outcome (*4*−*6*). Such poor predictive power is not particularly surprising because immunohistochemical analysis does not discriminate between active and inactive EGFR, while functional activity of the receptors appears to be critical for the prediction of response to EGFR-targeting therapeutics (*7*). Therefore, for more efficacious use of EGFR-targeting therapeutics, there is a need for information on EGFR activity in patients. In this respect, molecular imaging of functionally active EGFR could provide such information and might allow for (1) rational patient stratification, (2) rapid monitoring of responses to therapy, and (3) development of personalized treatment regimens.

Since ultimate proof of EGFR activity is binding and internalization of EGF, we consider EGF-based tracers the most suited for imaging of functionally active EGFR. To develop uniform EGF-based tracers, we have expressed EGF with an N-terminal Cys-tag, a 15-aa cysteine-containing fusion tag for site-specific conjugation of therapeutic and diagnostic payloads (*8*−*10*). Furthermore, since a functional EGF/EGFR complex contains two EGF molecules and two EGFR molecules, for this study we have also engineered a Cys-tagged dimeric EGF (dEGF) containing two genetically fused EGF moieties. We report here that EGF- and dEGF-based SPECT tracers can be prepared by direct radiolabeling of Cys-tag with ^{99m}Tc, while the corresponding PET tracers can be prepared by conjugating a PEGylated DOTA chelator to Cys-tag, followed by radiolabeling with ^{64}Cu. The favorable imaging and biodistribution characteristics of new EGF-based tracers, as well as the simplicity of their preparation, open the possibilities for further development.

EXPERIMENTAL PROCEDURES

Production of Cys-Tagged EGF and dEGF. The construction, expression, and purification of Cys-tagged EGF have been described recently (*8*). Briefly, EGF without a stop-codon was amplified by PCR from a DNA fragment encoding codon-optimized human EGF (kindly provided by Dr. P. T. Pienkos, Molecular Logix, Woodlands, TX), introducing NcoI sites to both termini of the PCR fragment, and cloned into an NcoI site of the pET/Hu-R4C(G_4S) vector for bacterial expression of proteins with Cys-tag (*10*). Clones with correct orientation of EGF were selected by colony PCR using T7-promoter-based sense and EGF-based antisense primers. The second copy of EGF including a stop-codon was cloned in-frame with the first EGF using the *Bam*HI site. The resulting plasmid encodes a 147-aa fusion protein comprising an N-terminal Cys-tag, a $(G_4S)_3$MG-linker, and EGF without a stop-codon connected to a second copy of EGF via a 9-aa linker SMAAIGSGF.

EGF and dEGF were refolded in red-ox buffer containing glutathione, and therefore, Cys-tag C4 thiol groups were protected in a mixed disulfide bond with glutathione in at least 90% of the protein. Prior to radiolabeling with ^{99m}Tc or conjugation of chelator, C4 thiol groups were deprotected by incubating the proteins with equimolar amounts of DTT at 25 °C for 20 min in 0.1 M Tris-HCl at pH 8.0 (*8*−*10*).

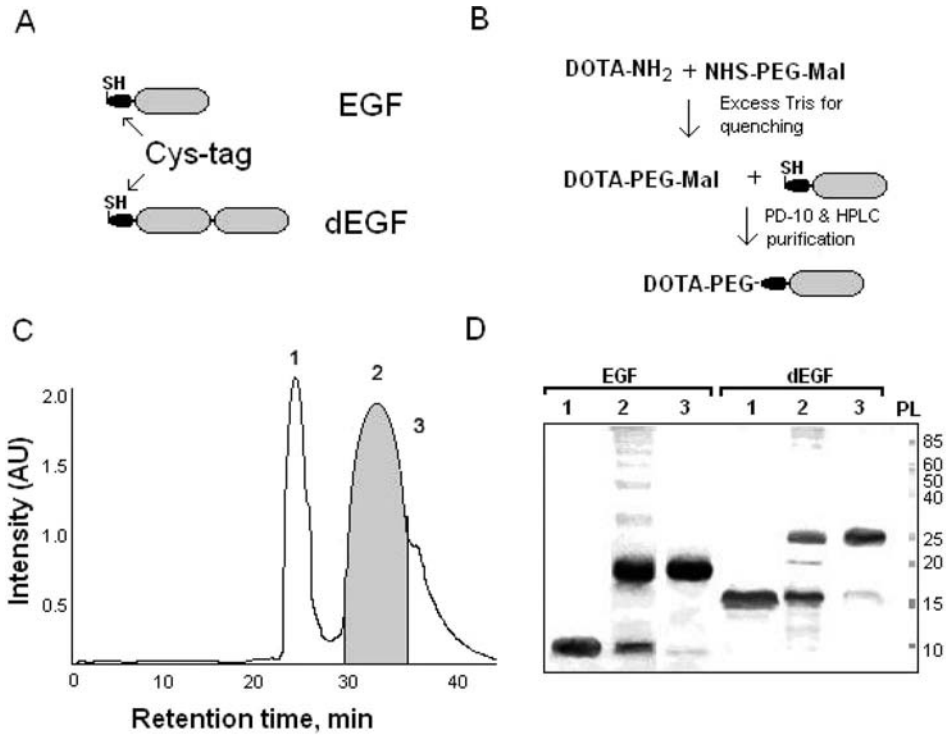

Figure 1. EGF and dEGF based conjugates. (A) Single or doubled copy of human EGF was cloned in-frame with the N-terminal Cys-tag (*9, 11*). Both proteins were expressed in *E.coli*, refolded into functionally active conformations in red-ox buffers, and purified via ion-exchange chromatography. (B) Flow chart of synthesis. (C) Separation of unmodified EGF (peak 1), EGF-PEG-DOTA (peak 2), and overmodified EGF-PEG-DOTA (peak 3) by RP-HPLC. Peak 2 (shown in gray) was collected, buffer-exchanged on a PD-10 column, and concentrated to 1−2 mg/mL. (D) Samples of unmodified EGF or dEGF (lanes 1), modification reaction mixtures (lanes 2), and RP-HPLC-purified products (lanes 3) were analyzed by reducing SDS−PAGE on 20% gels. PL, protein ladder (BioRad). Molecular weights are indicated in kDa.

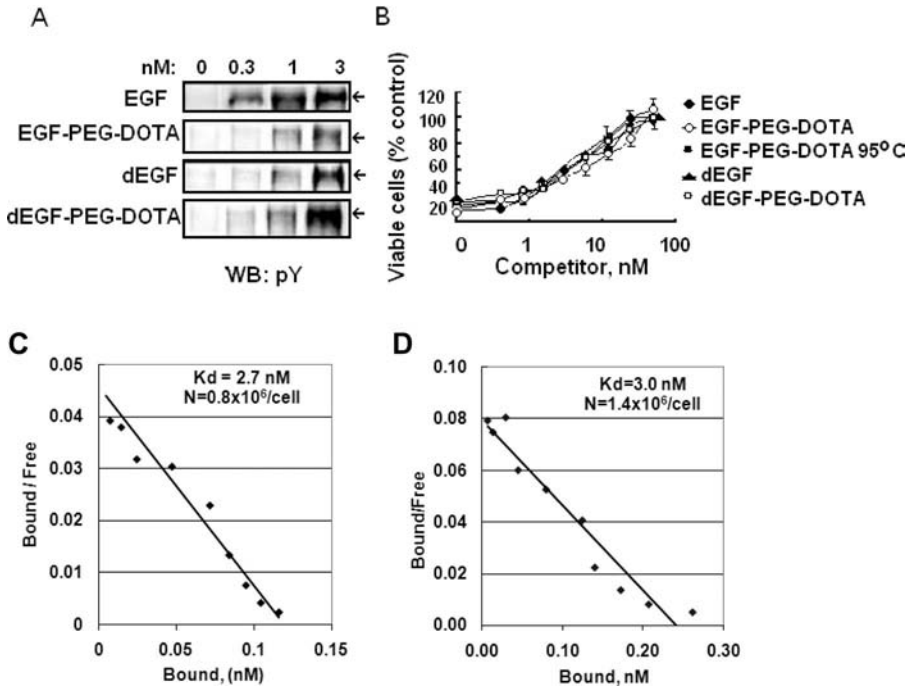

Figure 2. EGF- and dEGF-based conjugates are functionally active. (A) Induction of EGFR tyrosine autophosphorylation in rat F98/EGFR glioma cells. Arrows indicate positions of EGFR. 3.6×10^3 cell equivalents were loaded per one lane. (B) Competition with EGF-SLT fusion protein for binding to EGFR on human breast cancer cells MDA231luc. (C) Scatchard's analysis of EGF/Tc binding was undertaken with F98/EGFR cells. The values of K_d and N, the number of EGFR/cell, are indicated. (D) Scatchard's analysis of EGF-PEG-DOTA/Cu binding was undertaken with F98/EGFR cells. The values of K_d and N, the number of EGFR/cell, are indicated.

EGF and dEGF Direct Radiolabeling with ^{99m}Tc. Deprotected EGF or dEGF were radiolabeled, using a precursor complex [^{99m}Tc]-tricine, as described elsewhere for Cys-tagged single-chain VEGF (*9, 10*). Briefly, lyophilized tin-tricine reagent (a gift from Dr. J.-L. Vanderhyden, GE Healthcare, Piscataway, NJ) was reconstituted with 1.0 mL of degassed saline to give a final $SnCl_2 \cdot 2H_2O$ concentration of 0.6 mg/mL and a final tricine concentration of 20 mg/mL, pH 7.1. The

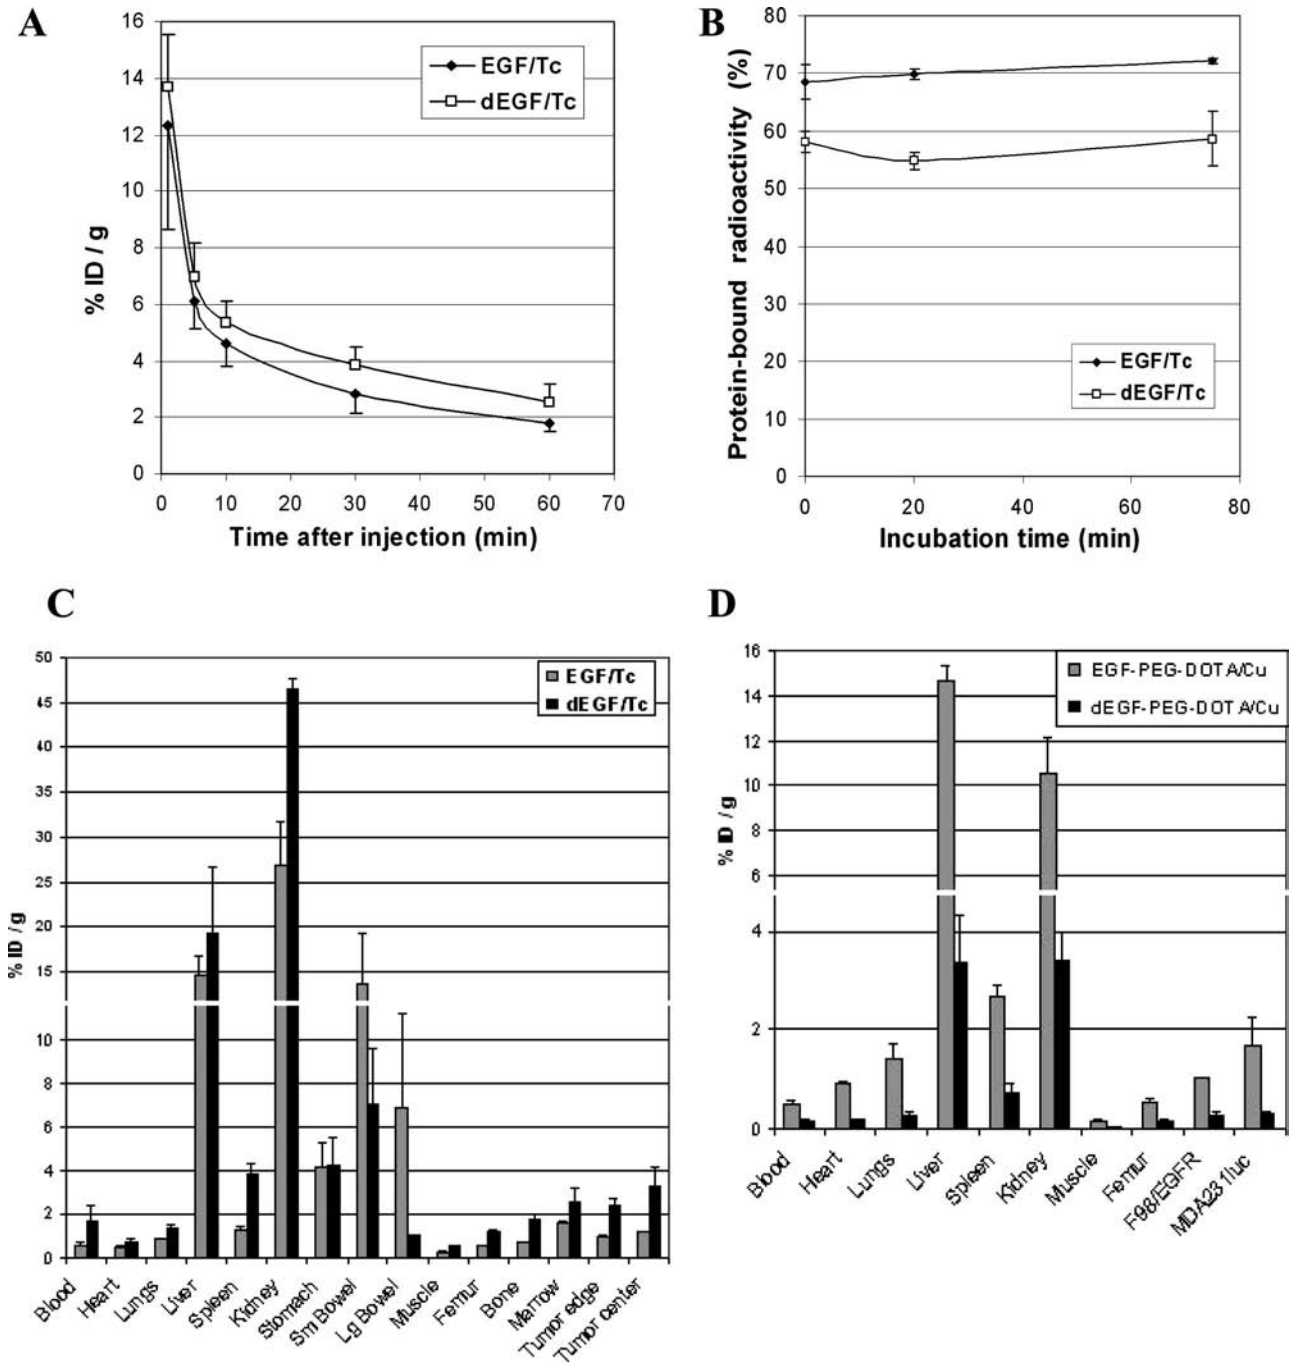

Figure 3. Tracer clearance, stability, and biodistribution. (A) Blood clearance of EGF/Tc and dEGF/Tc. (B) EGF/Tc and dEGF/Tc stability in murine plasma *ex vivo*. (C) Biodistribution of EGF/Tc (3.1 mCi/10 μg per mouse) and dEGF/Tc (0.81 mCi/13 μg per mouse) ($n = 4$ for every tracer) in 4 h after injection. (D) Biodistribution of EGF-PEG-DOTA/Cu (95 μCi/0.75 μg per mouse) and dEGF-PEG-DOTA/Cu (95 μCi/1.25 μg per mouse) in 22 h after injection ($n = 4$ for every tracer). Data for major organs are averaged for all tumor-bearing mice. Tumor uptake is averaged for specific tumors.

Table 1. Major Organ Uptake (%ID/g) for EGF-Based ^{99m}Tc Tracers

	EGF/Tc 3 h	dEGF/Tc 3 h	EGF-HYNIC/Tc/EDDA 4 h (*14*)	EGF-HYNIC/Tc 3 h (*13*)
kidney	27.0 ± 4.8	45.5 ± 1.4	96.3 ± 45.4	28.9 ± 14.0
liver	14.6 ± 2.3	24.5 ± 7.4	32.6 ± 13.2	29.2 ± 7.6

reaction mixture containing 10.0 μL of tin-tricine, 34 μg of deprotected protein, and 10 mCi of ^{99m}Tc-pertechnetate in a final volume of 50−100 μL was incubated for 30 min at 37 °C. Radiolabeled proteins, named EGF/Tc or dEGF/Tc, were purified by size-exclusion on PD-10 columns (GE Healthcare, Piscataway, NJ) equilibrated with phosphate-buffered saline (PBS). Specific activities ranged from 130 to 280 μCi/μg protein. The average purity before PD-10 purification was 45 ± 13% ($n = 13$), as judged by the amount of ^{99m}Tc eluted from PD-10 after the protein peak. Radiopurity after PD-10 was determined by ITLC using PBS as a solvent. We observed ^{99m}Tc batch-dependent variations of radiopurity in the range of 90−95%. The impurities migrated with the solvent front and appeared to arise from small and variable amounts of colloidal forms of ^{99m}Tc that were coeluted with radiolabeled protein from the PD-10 column but yielded migrating ^{99m}Tc under TLC conditions.

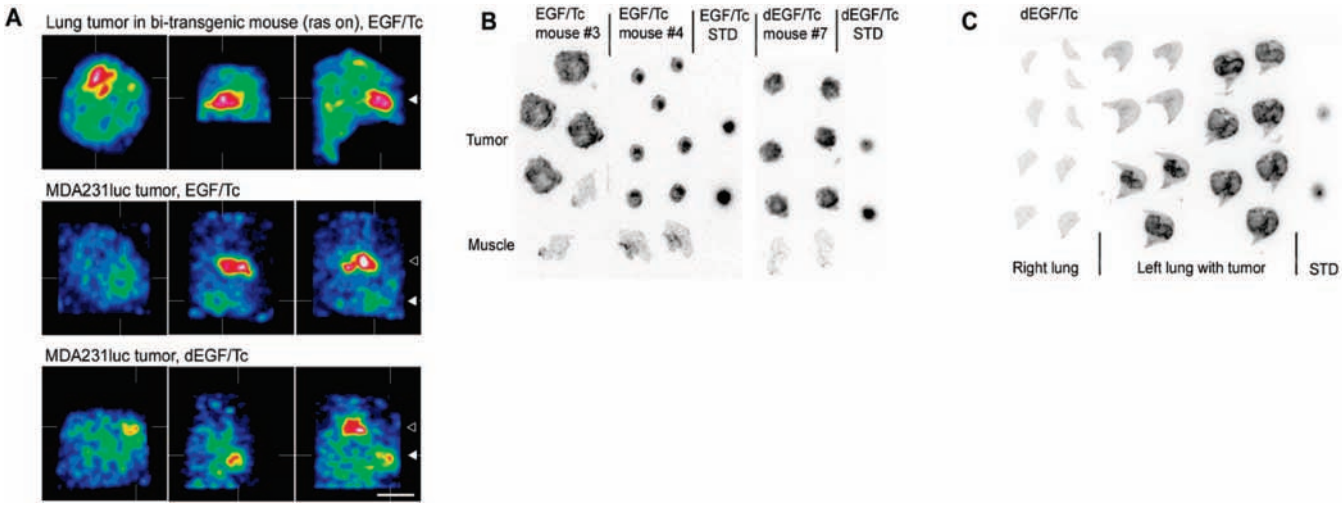

Figure 4. SPECT imaging and autoradiography. (A) SPECT images of mice injected with 3.1 mCi/10 μg of EGF/Tc or 1.7 mCi/13 μg dEGF/Tc per mouse. Representative transverse, sagittal, and frontal images are shown. Upper row: spontaneous lung tumor in bitransgenic mouse with ras-oncogene expression, EGF/Tc tracer. Middle row: orthotopic MDA231luc tumor, EGF/Tc tracer. Lower row: orthotopic MDA231luc tumor, dEGF/Tc tracer. The largest lung tumor and MDA231luc tumors are shown by white arrowheads. Open arrowheads show submandibular glands with nonspecific tracer uptake. The scale bar is 10 mm. (B) Autoradiographs of orthotopic MDA231luc tumors (25 days after cell injection). 3.1 mCi/10 μg per mouse of EGF/Tc or 1.7 mCi/13 μg of dEGF/Tc has been i.v. injected. STD is two spots of radioactivity equal 0.0016 and 0.0032% of injected dose. (C) Right (healthy) and left (tumor-invaded) lungs of a myc-on bitransgenic mouse injected with 4.5 mCi/20 μg of dEGF/Tc. STD is two spots of radioactivity equal to 0.0007 and 0.0014% of ID.

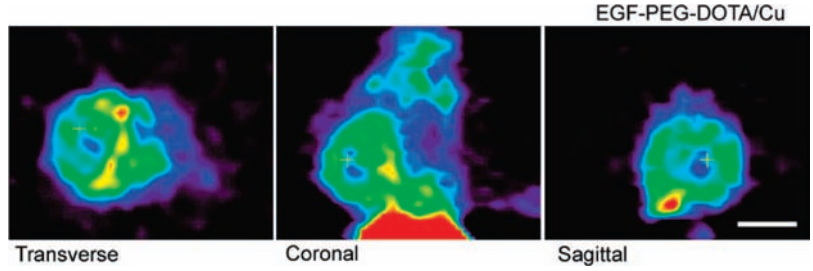

Figure 5. PET imaging. PET imaging of MDA231luc tumor (36 days after implantation). Representative transverse, coronal, and sagittal tomographic slices through the left mouse mammary fat pad tumor taken 3 h after an injection of 300 μCi of EGF-PEG-DOTA/^{64}Cu. The scale bar is 10 mm.

Radiolabeling of protected EGF and dEGF yielded ~20-fold less radioactivity in collected protein peaks, as compared with deprotected proteins. This low-level labeling is most likely due to the small amount of nonprotected C4 thiol groups generally present in preparations of Cys-tagged proteins.

Conjugation of DOTA to EGF or dEGF. DOTA was conjugated to EGF and to dEGF through a two-step procedure described elsewhere (*8, 10*), with minor modifications. Briefly, in step 1, functionalized DOTA was prepared by derivatization of *p*-NH_2-Bn-DOTA (2-(4-aminobenzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) (Macrocyclics, Dallas, TX) with 5 kDa of NHS-PEG-Mal, polyethylenglycol (PEG) containing an amino-reactive NHS group on the one end and a thiol-reactive maleimide on the other end of each PEG molecule (NOF America, Terrytown, NY). The reaction was performed at 2:1 DOTA to PEG molar ratio in a buffer containing 15 mM NaOAc, 50 mM Na_2CO_3, and 115 mM NaCl, pH 8.0. The reaction was incubated for 1 h at room temperature. Residual NHS was hydrolyzed by the addition of 1 M Tris HCl at pH 8.0 to a final concentration of 100 mM and incubated for 30 min. Functionalized DOTA-PEG-Mal was stored at −70 °C in small aliquots.

In step 2, the DOTA-PEG-Mal conjugate was added to freshly prepared deprotected protein at 2:1 maleimide to protein ratio and incubated for 1 h at room temperature. The reaction mixture was passed through PD-10 and then fractionated by RP-HPLC on a C4 column, which provided for a good separation of unmodified and PEGylated proteins. RP-HPLC purification was followed by solvent exchange on PD-10 to a buffer containing 0.1 M NaOAc at pH 5.5 and concentration of purified conjugates via reverse dialysis using Aquacide III powder (Calbiochem, San Diego, CA). Final preparations of EGF-PEG-DOTA and dEGF-PEG-DOTA were stored at °70 °C in small aliquots.

Radiolabeling of EGF-PEG-DOTA and dEGF-PEG-DOTA with ^{64}Cu. Conjugates were radiolabeled with ^{64}Cu, using a procedure developed previously for scVEGF-PEG-DOTA (*8, 10*). In a typical radiolabeling reaction, 20 μg of EGF-PEG-DOTA or dEGF-PEG-DOTA conjugate were mixed with 3.0−3.8 mCi of ^{64}Cu (Washington University Medical School, Saint Louis, MO) in 0.1 M NaOAc at pH 5.3−5.5 in the presence of DMSO (20% for EGF-PEG-DOTA and 30% for dEGF-PEG-DOTA) and incubated for 1 h at 55^o C. Residual free ^{64}Cu was sequestered by 1 mM EDTA. The reaction mixtures were passed through NAP-5 gel-filtration columns (GE Healthcare, Piscataway, NJ), yielding tracers with a specific activity of ~125 μCi/μg, for EGF-PEG-DOTA, and ~75 μCi/μg, for dEGF-PEG-DOTA.

Tissue Culture. F98/EGFR(F) rat glioma cells engineered to overexpress human EGFR were a kind gift from Dr. R. Barth (The Ohio State University, Columbus, OH). The high level of EGFR in these cells was supported by Scatchard analysis of radioligand binding, as described in the Results section. F98/EGFR(F) cells were grown in a 1:1 mixture of DMEM and F-12 nutrient mixture (Invitrogen, Carlsbad, CA), 5% FBS, and

2 mM L-glutamine. For prolonged cultivation, cells were maintained in 0.5 mg/mL of G418. For tumor implantation, cells were grown for 2−3 passages in complete medium without G418. MDA231luc cells expressing firefly luciferase were developed as described (*8*) from MDA-MB-231 mammary gland adenocarcinoma cells (ATCC # HTB-26) expressing a moderate level of EGFR, an average of 2×10^5 EGFR per cell (*11*). Approximately 5-fold difference in EGFR expression in MDA231luc and F98/EGFR(F) cells was supported by Western blot analysis of EGFR in cell lysates (data not shown). MDA231luc were cultured in high glucose DMEM (Invitrogen, Carlsbad, CA), 10% heat inactivated fetal bovine serum (FBS, HyClone, Logan, UT), and 2 mM L-glutamine. All cells were maintained at 37 °C and 5% CO_2.

Animals and Tumor Models. SCID mice (male, 5−6 week old) were purchased from Charles River Laboratories (Wilmington, MA). MDA231luc human breast carcinoma cells (*8, 9*) were implanted into the left axillary fat pad at 10^6 cells per mouse. F98/EGFR(F) rat glioma cells were implanted subcutaneously onto the right shoulder at 4.5×10^6 cells per mouse. The generation of spontaneous mouse lung adenocarcinomas in bitransgenic mice (FVBN original strain carrying *myc* or *ras* transgenes regulated by a tetracycline-inducible lung-specific promoter) has been described previously (*12*). The protocol for the animal studies was approved by the Stanford University Institutional Animal Care and Use Committee.

Stimulation of EGFR Phosphorylation in F98/EGFR(F) Cells. The EGFR tyrosine phosphorylation assay was performed as reported elsewhere (*8*). Briefly, near-confluent F98/EGFR(F) cells grown in 24-well plates were incubated overnight in serum-free DMEM, then shifted to serum-free DMEM with 0.5 mM sodium vanadate for 15 min at 37 °C. To stimulate EGFR tyrosine phosphorylation, proteins were added to cells to final concentrations in the range from 0 to 50 nM. After 10-min stimulation at 37 °C, cells were lyzed, separated by SDS−PAGE, and analyzed by Western blotting using phosphotyrosine-specific antibody PY clone PT-66 (Sigma, St Louis, MO). In these experiments, 3.6×10^3 cell equivalents were loaded per one lane.

Competition with EGF-SLT Fusion Cytotoxin for Binding to Cellular EGFR in MDA231luc Cells. MDA231luc cells were plated on 96-well plates 20 h before the experiment (1000 cells/well). Proteins were serially diluted in complete culture medium supplemented with EGF-SLT fusion cytotoxin (SibTech, Brookfield, CT) and added to cells in triplicate wells to a final EGF-SLT concentration of 1 nM and competitors ranging from 0 to 25 nM. EGF-SLT is highly toxic for MDA-231luc cells (IC_{50} of 50 pM); therefore, the ability of proteins to compete with EGF-SLT for binding to cellular EGFR can be readily measured by the numbers of surviving cells after a 72-h exposure. Viable cells were quantitated by CellTiter 96 AQ_{ueous} One Solution Cell Proliferation Assay kit (Promega, Madison, WI).

Scatchard's Analysis of Tracer Binding to Cellular EGFR. F98/EGFR(F) cells grown on 12-well plates were shifted to serum-free medium at room temperature for 45 min. Varying amounts of EGF/Tc or EGF-PEG-DOTA/Cu were added to cells in triplicate wells for 90 min, followed by two PBS and one high-salt (0.5 M NaCl in PBS) wash. Cells were lyzed in PBS containing 1% Triton X-100 and assayed for ^{99m}Tc or ^{64}Cu activity in a gamma counter (140 and 511 keV level, respectively, 20% window). Nonspecific binding was determined for the same amounts of labeled EGF supplemented with a 200-fold molar excess of cold EGF.

Stability of EGF/Tc and dEGF/Tc. For *in vivo* stability testing, Balb/c mice ($n = 2$) were injected via the tail vein with EGF/Tc (60 μCi/0.25 μg per mouse) or with dEGF/Tc (60 uCi/0.22 μg) and sacrificed 2 min later. Blood was collected and clarified by centrifugation. Plasma samples were incubated at 37 °C for 10, 20, and 75 min. Rough estimation of protein-bound radioactivity in 1-μL plasma aliquots was done by ITLC. Stability was also tested *in vitro* by incubating the tracers in PBS at room temperature followed by ITLC and SDS−PAGE analyses.

Blood Clearance and Biodistribution Studies. For blood clearance and biodistribution studies, tracers were injected via the tail vein, and serial ~50-μL blood samples were taken via the supraorbital sinus at various time points after injection. Tissue samples taken at specified time points were counted in a gamma counter along with three samples of standard activity (1/100 of injected dose). Results were calculated as the average of the percentage of injected dose (ID) or %ID per gram (g) of tissue ± one standard deviation of the mean.

SPECT Imaging and Autoradiography. For SPECT imaging, 1.7−4.5 mCi of tracer per mouse ($n = 4$) was injected via the tail vein. SPECT images were obtained 1 h after injection with the following parameters: 360° rotation, 64 steps, 30 s per step, 0.5 mm pinhole aperture, a 64 × 64 image matrix, and a 3.4 cm FOV using a small animal SPECT imaging gamma camera (A-SPECT, LumaGEM, Gamma Medica, Los Angeles). For autoradiography, tumors and pectoralis muscle from the healthy chest side were snap-frozen immediately after imaging, cryosectioned (60-μm thickness), and exposed to a phosphor storage screen for 16 h. For autoradiography of lung tumors, before freezing lungs have been perfused with 1% PFA in PBS followed by 20% sucrose in PBS. The phosphor screen images were read out with a laser digitizer at a resolution of 50 μm per pixel. Region of interest (ROI) analysis of radiotracer activity was performed using ImageQuant TL Software. The maximal cts/pixel of the rim and the average cts/pixel of the center of the tumor were normalized to corresponding contralateral pectoral muscle uptake (minimum cts/pixel).

PET Imaging. Two groups of tumor-bearing mice ($n = 8$) intravenously received 95 μCi of EGF-PEG-DOTA/Cu or dEGF-PEG-DOTA/Cu. Ten-minute static scans of mice in prone position were obtained on a microPET R4 rodent model scanner (Concorde Microsystems, Knoxville, TN) equipped with computer-controlled vertical and horizontal bed motion, with an effective axial field of view (FOV) of 7.8 cm and a transaxial FOV of 10 cm. Mice anesthetized with 2% isoflurane were placed near the center of the FOV to ensure the highest image resolution and sensitivity. The images were reconstructed by a two-dimensional ordered-subsets expectation maximum algorithm. No correction was necessary for attenuation and scattering. We obtained relative tumor or organ radioactivity concentrations from mean pixel values within the multiple ROI volumes. For biodistribution, tissue samples were taken at 22 h after injection and counted in a gamma counter along with three samples of standard activity (1/100 of injected dose). Results were calculated as the average of the percentage of injected dose per gram (%ID /g) of tissue ± one standard deviation of the mean.

RESULTS

Cys-Tagged EGF and dEGF and Site-Specific Conjugation of PEGylated DOTA Chelator. To make tracers for imaging EGF receptors, we used a previously described Cys-tagged EGF (*8*) and a newly engineered Cys-tagged head-to-tail EGF dimer (dEGF) (Figure 1A). We reasoned that since functional ligand/receptor complexes include two EGF molecules, dEGF might provide certain advantages in binding and/or internalization of tracers. EGF and dEGF were expressed in *E.coli*, recovered from inclusion bodies, refolded in red-ox buffer containing glutathione, and purified via ion-exchange chromatography (*8*). As

other Cys-tagged proteins refolded in red-ox buffer, EGF and dEGF proteins were recovered with the C4-thiol group in Cys-tag protected in a form of a mixed disulfide with glutathione. For direct radiolabeling with ^{99m}Tc or for conjugation of the DOTA chelator, the C4-thiol group was readily deprotected upon incubation with equimolar amounts of DTT.

The DOTA chelator was conjugated to the C4-thiol group in EGF or dEGF via a 5 kDa NHS-PEG-Mal linker, using a previously developed (*8*) two-step procedure (Figure 1B). First, NHS chemistry was used for conjugation of NHS-PEG-Mal to *p*-NH_2-Bn-DOTA, followed by quenching of unreacted NHS with excess of Tris HCl at pH 8.0. At the next step, the quenched reaction mixture, without further purification, was added to deprotected EGF or dEGF, and the resulting EGF-PEG-DOTA or dEGF-PEG-DOTA were purified by RP HPLC (Figure 1C). A typical preparation of RP HPLC purified EGF-PEG-DOTA or dEGF-PEG-DOTA contains less than 10% of unmodified or overmodified starting protein (Figure 1D).

Functional Activities of Proteins and Conjugates. Functional activities of EGF, dEGF, and the corresponding conjugates were tested in several cell-based assays. In a short-term assay (10 min), conjugates were tested for the ability to bind to EGFR and induce its tyrosine autophosphorylation. In this assay, both proteins and their conjugates displayed dose-dependent activities in a similar range (Figure 2A). Interestingly, EGF-PEG-DOTA was less active than EGF, while dEGF-PEG-DOTA was more active than dEGF. The latter data suggested that the presence of two PEG-DOTA moieties in the functional (EGF-PEG-DOTA)$_2$/EGFR$_2$ complex might be somewhat more detrimental for receptor binding than a single PEG-DOTA in the dEGF-PEG-DOTA/EGFR$_2$ complex.

In a long-term competition assay (3 days), conjugates were tested for their ability to protect EGFR-positive cells from EGF-SLT, a fusion cytotoxin, combining EGF and catalytic subunit A of Shiga-like toxin (Backer et al., submitted for publication). We reasoned that in this assay binding of EGF-based constructs to EGFR reaches equilibrium and therefore eliminates any kinetic effects that might affect short-term assays. We found that in this assay both parental proteins and corresponding EGF-PEG-DOTA and dEGF-PEG-DOTA displayed very similar activities (Figure 2B).

Since loading of the DOTA chelator with radionuclides takes place at elevated temperature, we also tested if such treatment would affect EGF activity. We found that incubation of EGF-PEG-DOTA conjugates in radiolabeling buffer at 95 °C for 30 min did not decrease its functional activity in the protection assay (Figure 2B).

Radiolabeling of Cys-Tagged EGF and dEGF with ^{99m}Tc. We have recently reported that Cys-tag in scVEGF can be directly radiolabeled with ^{99m}Tc using tin-tricine as a precursor complex and hypothesized that a similar radiolabeling can be undertaken with any Cys-tagged protein (*9*). Indeed, we found that deprotected EGF and dEGF, but not parental protected molecules, were readily radiolabeled with [^{99m}Tc]pertechnetate. After purification via size-exclusion chromatography on PD-10, we obtained EGF/Tc and dEGF/Tc tracers with specific activity in the range of 160−300 and 130−280 μCi/μg, respectively, and radiopurity in the range of 90−95%. The specific activity obtained through direct radiolabeling was compared favorably to the reported values 15−30 μCi/μg (*13*) or 82 μCi/μg (*14*) obtained after radiolabeling of the EGF-HYNIC conjugates with tin-tricin as a coligand, and 68 μCi/μg for EGF-HYNIC conjugates with EDDA as a coligand (*14*). As judged by a Scatchard analysis of EGF/Tc binding to F98/EGFR(F) cells, the procedure resulted in tracers with the expected low nanomolar affinity to EGFR (K_d = 2.7 nM) and indicated the presence of 0.8 × 10^6 EGFR/cell (Figure 2C). Notably, site-specifically radiolabeled EGF/Tc displayed 2−3-fold higher affinity to EGFR than that reported for EGF-HYNIC-Tc tracers obtained by random conjugation of the chelator, despite the fact that only one HYNIC molecule was conjugated per one EGF protein (*13*).

Radiolabeling of EGF- and dEGF-PEG-DOTA Conjugates with ^{64}Cu. The ^{64}Cu radiolabeling protocol was initially developed for scVEGF-PEG-DOTA conjugates (*8, 10*). As applied to EGF-PEG-DOTA and dEGF-PEG-DOTA, this procedure routinely resulted in a specific activity of ∼125 μCi/μg for EGF-PEG-DOTA and of ∼75 μCi/μg for dEGF-PEG-DOTA. As judged by Scatchard's analysis of binding of EGF-PEG-DOTA/Cu to F98/EGFR cells (Figure 2D), the K_d value of 3 nM and 1.4 × 10^6 of EGFR/cell for this tracer were close to that for the EGF/Tc tracer (see Figure 2C).

Stability, Blood Clearance, and Biodistribution Studies. ^{99m}Tc and ^{64}Cu radiolabeled tracers cleared rapidly from the circulation, with more than 95% of tracer cleared within 1 h after intravenous injection (Figure 3A for EGF/Tc). We found that these tracers are stable for at least 3 h at room temperature in PBS (not shown) and that radionuclides were protein-associated for at least 75 min at 37 °C in plasma (Figure 3B).

Biodistribution experiments with EGF/Tc and dEGF/Tc were performed on MDA231luc tumor-bearing mice (n = 4) with well-formed tumors at 25-day post implantation. At 3 h after intravenous injection, we found that uptake of dEGF/Tc in most organs, including tumors, was higher than that of EGF/Tc (Figure 3C). Interestingly, for both tracers, uptake at the edge of the tumor was very similar to uptake in the central tumor areas, suggesting that tracers are distributed throughout the tumor mass (Figure 3C). As summarized in Table 1, kidney uptake of EGF/Tc was ∼3-fold lower than that of EGF-HYNIC/Tc with EDDA as coligand (*14*), and comparable to that of EGF-HYNIC/Tc (*13*) with tricin as coligand. However, liver uptake of EGF/Tc was 2-fold lower than that for both EGF-HYNIC/Tc tracers (Table 1).

For biodistribution studies with EGF-PEG-DOTA/Cu and dEGF-PEG-DOTA/Cu, 95 μCi of either tracer were intravenously injected into mice (n = 4) 9 days after either MDA231luc or F98/EGFR tumor cell implantation, when tumors were just palpable (3−5 mm in diameter). We found that 22 h postinjection uptake of EGF-PEG-DOTA/Cu in all organs, including tumors, was ∼3-fold higher than that of dEGF-PEG-DOTA/Cu (Figure 3D). Interestingly, the uptake of both tracers in F98/EGFR(F) tumors was somewhat lower than in MDA231luc, despite the fact that the latter cells express ∼5-fold less EGFR in tissue culture (data not shown). We found this result very instructive since it indicated that only functional in vivo tests could provide meaningful information on the receptor activity *in vivo*.

SPECT Imaging and Autoradiographic Studies. SPECT tracers were tested in two tumor models: orthotopic MDA231luc breast carcinoma (*8*) and spontaneous mouse lung carcinoma in bitransgenic mice (*11*). In both models, the tracers readily accumulated in the tumors (Figure 4A).

We further explored EGF-based ^{99m}Tc tracers by autoradiography of cryosections prepared from two MDA231luc tumor-bearing mice immediately after whole-body SPECT imaging. As shown in Figure 4B, radioactivity in tumors was significantly higher as compared with that from contralateral muscles. For autoradiography analysis of a spontaneous lung tumor, we selected a mouse with only a left lung tumor, as detected by SPECT with dEGF/Tc tracer. As shown in Figure 4C, autoradiography confirmed that radioactivity was significantly higher in left lung cryosections, as compared with that in the right lung.

PET Imaging. PET tracers were tested in orthotopic MDA231luc breast carcinoma. The tracers readily accumulated in large (10−15 mm) MDA231luc tumors, as imaged at 3 h

after tracer injection (Figure 5A). In separate experiments, we observed a selective uptake of EGF-based PET tracers in barely palpable MDA231luc tumors, whose presence was validated by bioluminescent imaging after intraperitoneal injection of luciferine (data not shown).

DISCUSSION

We describe here a family of EGF-based tracers for SPECT and PET imaging of EGF receptors. The tracers are based on natural monomeric and on engineered dimeric EGF, expressed with cysteine-containing Cys-tag for site-specific conjugation of various payloads (*10*). To obtain SPECT tracers, C4 in Cys-tag is directly radiolabeled with ^{99m}Tc, while PET tracers are prepared by site-specific conjugation of a PEGylated chelator DOTA to C4, followed by radiolabeling with ^{64}Cu. Both procedures avoid random conjugation of chelating moieties to targeting proteins, thus yielding uniform functionally active tracers with high specific activities. Importantly, direct radiolabeling with ^{99m}Tc yields a stable SPECT tracer with specific activity higher than that reported for the tracers based on EGF-chelator conjugates (*12, 13*). Rather similar tumor uptake is obtained with tracers based on monomeric and dimeric Cys-tagged EGF, although there are differences in biodistribution patterns that need to be further explored.

Over the years, several groups reported SPECT, PET, and fluorescent tracers for imaging EGF receptors, based on EGF (*8, 11, 13*−*21*), anti-EGFR antibodies (*21*−*27*), and low-molecular weight EGFR inhibitors (*28*−*33*). Since all of these tracers invariably imaged EGFR-positive tumors in mouse models, the eventual selection of the best candidate for further development would be based on relative advantages in terms of production, specific activity, biodistribution, and specific, receptor-mediated tumor uptake. Taking into account these criteria, we reasoned that using EGF, a natural EGFR ligand, as a targeting vector would be particularly advantageous. First, only functionally active and therefore critical for disease progression EGFRs will bind and internalize an EGF-based tracer. In contrast, tracers based on low-molecular weight kinase inhibitors or anti-EGFR antibodies would bind to all EGFRs, regardless of their functional status, providing, in this respect, information similar to that derived from immunohistochemistry. Second, continuous internalization of EGF-based tracers by recyclable EGFR would lead to intracellular accumulation of a radionuclide, thereby improving a signal-to-background ratio. Third, the small size of EGF, relative to that of antibodies, would facilitate tumor penetration with vastly better nonspecific soft tissue and blood clearance rates. Finally as a human protein, EGF is not expected to be immunogenic.

Although several EGF-based tracers have been described previously (*11, 13*−*21*), we expect that functionally active and uniform tracers based on Cys-tagged EGF would provide major advantages because they eliminate heterogeneity associated with random conjugation of contrast agents to the protein. Furthermore, comparison of biodistribution data for various EGF-based SPECT tracers suggests that our tracers provide a lower liver uptake and a similar or a lower kidney uptake (Table 1). Furthermore, kidney and liver uptake for our EGF-based SPECT tracers are in the range of those found for Annexin-HYNIC/^{99m}Tc tracer (*34*), which was approved for clinical trials (*35*). However, detailed preclinical dosimetry studies would be required for assessing the developmental potential of tracers based on Cys-tagged EGF or dEGF.

It should be noted that, similar to the other tracers based on physiologically active molecules, there are reasonable concerns of potential harmful pharmacological effects of EGF-based tracers. To begin addressing such concerns, we can compare the anticipated doses of EGF-based tracers with the dose of recombinant EGF used in a recent clinical trial. The tracer dose can be estimated based on the clinical experience with another protein-based SPECT tracer, annexin-HYNIC/Tc, that was injected at an average dose of 6.9 mCi per 77 kg patient or approximately 90 μCi/kg (*35*). Considering that EGF/Tc is readily labeled to a specific activity of 200 μCi/μg, a similar dose of EGF/Tc would require an injection of the tracer at a level of only 0.45 μg/kg. However, a recent clinical study of recombinant EGF for the treatment of neonatal necrotizing enterocolitis (*36*) concluded that a dose of 0.1 μg/hour/kg may be safely given via continuous infusion for 6 days, leading to a cumulative dose well above the anticipated EGF-tracer dose. Thus, although a definitive answer to safety concerns regarding EGF-based tracers requires extensive experimentation, we expect that injection of tracer amounts of EGF for diagnostic imaging will have no adverse effects.

Improving Tumor Uptake and Pharmacokinetics of ^{64}Cu-Labeled Cyclic RGD Peptide Dimers with Gly_3 and PEG_4 Linkers

Jiyun Shi,[†] Young-Seung Kim,[†] Shizhen Zhai,[†] Zhaofei Liu,[‡] Xiaoyuan Chen,[‡] and Shuang Liu*[,†]

School of Health Sciences, Purdue University, West Lafayette, Indiana 47907, and Molecular Imaging Program at Stanford (MIPS), Department of Radiology & Bio-X, Stanford University, Stanford, California 94305-5484. Received October 22, 2008; Revised Manuscript Received February 16, 2009

Radiolabeled cyclic RGD (Arg-Gly-Asp) peptides represent a new class of radiotracers with potential for early tumor detection and noninvasive monitoring of tumor metastasis and therapeutic response in cancer patients. This article describes the synthesis of two cyclic RGD peptide dimer conjugates, DOTA-PEG_4-E[PEG_4-c(RGDfK)]$_2$ (DOTA-3PEG_4-dimer: DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid; PEG_4 = 15-amino-4,7,10,13-tetraoxapentadecanoic acid) and DOTA-G_3-E[G_3-c(RGDfK)]$_2$ (DOTA-3G_3-dimer: G_3 = Gly-Gly-Gly). Integrin $\alpha_v\beta_3$ binding affinities of cyclic RGD peptides were determined by competitive displacement of ^{125}I-echistatin bound to U87MG human glioma cells and follow the order of DOTA-E{E[c(RGDfK)]$_2$}$_2$ (DOTA-tetramer: IC_{50} = 10 ± 2 nM) > DOTA-3G_3-dimer (IC_{50} = 62 ± 6 nM) ~ DOTA-3PEG_4-dimer (IC_{50} = 74 ± 3 nM) > DOTA-E[c(RGDfK)]$_2$ (DOTA-dimer: IC_{50} = 102 ± 5 nM). The addition of PEG_4 and G_3 linkers between two cyclic RGD motifs in DOTA-3G_3-dimer and DOTA-3PEG_4-dimer makes it possible for them to achieve the simultaneous integrin $\alpha_v\beta_3$ binding in a bivalent fashion. Both ^{64}Cu(DOTA-3PEG_4-dimer) and ^{64}Cu(DOTA-3G_3-dimer) were prepared in high yield with specific activity being >50 Ci/mmol. Biodistribution and imaging studies were performed in athymic nude mice bearing U87MG human glioma xenografts. The results from those studies show that PEG_4 and G_3 linkers are particularly useful for improving tumor uptake and clearance kinetics of ^{64}Cu radiotracers from the nontumor organs, such as kidneys, liver, and lungs. There is a linear relationship between the tumor size and %ID tumor uptake, suggesting that ^{64}Cu(DOTA-3PEG_4-dimer) and ^{64}Cu(DOTA-3PEG_4-dimer) might be useful for noninvasive monitoring of tumor growth or shrinkage during antiangiogenic therapy. MicroPET imaging data clearly demonstrate the utility of ^{64}Cu(DOTA-3G_3-dimer) as a new PET radiotracer for imaging integrin $\alpha_v\beta_3$-positive tumors.

INTRODUCTION

Angiogenesis is a requirement for tumor growth and metastasis (*1*−*10*). Without neovasculature to provide oxygen and nutrients, tumors cannot grow beyond 1−2 mm in size. Once vascularized, previously dormant tumors begin to grow rapidly, and their volumes increase exponentially. Recent clinical and experimental evidence suggests that tumor growth and progression are dependent on angiogenesis and invasion, which share common regulatory mechanisms (*2, 5*). Angiogenesis is an invasive process characterized by endothelial cell proliferation and is regulated by cell adhesion receptors. Integrins are such a family of proteins that facilitate cellular adhesion to and migration on extracellular matrix proteins found in intercellular spaces and basement membranes, and regulate cellular entry and withdraw from the cell cycle (*5*−*13*). Integrin $\alpha_v\beta_3$ is a receptor for the extracellular matrix proteins with an exposed arginine−glycine−aspartic (RGD) tripeptide sequence (*5, 6, 9*). Integrin $\alpha_v\beta_3$ is normally expressed at low levels on epithelial cells and mature endothelial cells; but it is highly expressed on the activated endothelial cells in neovasculature of tumors, including osteosarcomas, glioblastomas, melanomas, lung carcinomas, and breast cancer (*11*−*19*). It has been demonstrated that integrin $\alpha_v\beta_3$ is overexpressed on both endothelial and tumor cells in human breast cancer xenografts (*20*). The integrin $\alpha_v\beta_3$ expression correlates well with tumor progression and invasiveness of melanoma, glioma, and breast cancers (*13*−*16, 18*−*20*). The highly restricted expression of integrin $\alpha_v\beta_3$ during tumor growth, invasion, and metastasis presents an interesting molecular target for the early detection of rapidly growing and metastatic tumors (*21*−*33*). In addition, it would be highly advantageous to develop an integrin $\alpha_v\beta_3$-specific radiotracer that could be used to noninvasively visualize and quantify the integrin $\alpha_v\beta_3$ expression level before, during, or after antiangiogenic therapy (*34*).

Over the last several years, many radiolabeled cyclic RGD peptides have been evaluated as potential radiotracers for imaging the integrin $\alpha_v\beta_3$-positive tumors by single photon emission computed tomography (SPECT) or positron emission tomography (PET) (*35*−*68*). The integrin $\alpha_v\beta_3$-targeted radiotracers have recently been reviewed extensively (*21*−*33*). Among the radiotracers evaluated in different preclinical tumor-bearing animal models, [^{18}F]-AH111585, the core peptide sequence originally discovered from a phage display library (such as ACDRGDCFCG), and [^{18}F]Galacto-RGD (2-[^{18}F]fluoropropanamide c(RGDfK(SAA); SAA = 7-amino-L-glyero-L-galacto-2,6-anhydro-7-deoxyheptanamide) are under clinical investigations for noninvasive visualization of integrin $\alpha_v\beta_3$ expression in cancer patients (*69*−*71*). The imaging studies in cancer patients show that the ^{18}F-labeled cyclic RGD peptides are able to target integrin $\alpha_v\beta_3$-positive tumors. However, the low tumor uptake, high cost, and lack of preparation modules for the ^{18}F-labeled monomeric cyclic RGD peptides impose a significant challenge for their continued clinical applications.

To improve integrin $\alpha_v\beta_3$ binding, multimeric cyclic RGD peptides, such as E[c(RGDfK)]$_2$ (dimer) and E{E[c-(RGDfK)]$_2$}$_2$ (tetramer), were used as targeting biomolecules to carry the radionuclide (e.g., ^{99m}Tc, ^{18}F, ^{64}Cu, and ^{111}In) to the integrin $\alpha_v\beta_3$ on tumor cells and endothelial cells of the tumor neovasculature (*41*−*43*, *47*−*68*). The results from the in vitro assays, ex-vivo biodistribution, and in vivo imaging studies clearly demonstrate that the radiolabeled (^{99m}Tc, ^{18}F, ^{64}Cu, and ^{111}In) multimeric cyclic RGD peptides, such as E{E[c(RGDxK)]$_2$}$_2$ and E[c(RGDxK)]$_2$ (x = f and y), have much better tumor targeting capability as evidenced by their higher tumor uptake with longer tumor retention times as compared to their monomeric RGD peptide counterparts (*47*−*68*). However, it remains unclear if the cyclic RGD motifs in E{E[c(RGDxK)]$_2$}$_2$ and E[c(RGDxK)]$_2$ (x = f and y) are indeed able to achieve simultaneous integrin $\alpha_v\beta_3$ binding in a bivalent fashion. In addition, the uptake of the radiolabeled (^{99m}Tc, ^{18}F, ^{64}Cu, and ^{111}In) multimeric cyclic RGD peptides in the kidneys and liver is also increased as the peptide multiplicity increases (*51*−*54*, *60*−*68*).

We recently reported the evaluation of two ^{99m}Tc-labeled cyclic RGD dimers, [^{99m}Tc(HYNIC-3PEG$_4$-dimer)(tricine)-(TPPTS)] (^{99m}Tc-3PEG$_4$-dimer: HYNIC = 6-hydrazinonicotinyl, 3PEG$_4$-dimer = PEG$_4$-E[PEG$_4$-c(RGDfK)]$_2$, PEG$_4$ = 15-amino-4,7,10,13-tetraoxapentadecanoic acid, and TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate) and [^{99m}Tc(HYNIC-3G$_3$-dimer)(tricine)(TPPTS)] (^{99m}Tc-3G$_3$-dimer: 3G$_3$-dimer = G$_3$-E[G$_3$-c(RGDfK)]$_2$ and G$_3$ = Gly-Gly-Gly), as new radiotracers for imaging integrin $\alpha_v\beta_3$ expression in the athymic nude mice bearing U87MG glioma and MDA-MB-435 breast cancer xenografts (*72*, *73*). The PEG$_4$ and G$_3$ linkers are used to increase the distance between two cyclic RGDfK motifs from 6 bonds (excluding the side arms of K-residues) in E[c(RGD-fK)]$_2$ to 26 bonds in 3G$_3$-dimer and 38 bonds in 3PEG$_4$-dimer so that they are able to achieve simultaneous integrin $\alpha_v\beta_3$ binding in a bivalent fashion and to improve the radiotracer excretion kinetics from noncancerous organs. Results from the $\alpha_v\beta_3$ integrin binding assay show that the addition of two PEG$_4$ or G$_3$ linkers between two cyclic RGD motifs makes 3PEG$_4$-dimer and 3G$_3$-dimer bivalent in binding to the integrin $\alpha_v\beta_3$. The results from ex-vivo biodistribution studies clearly demonstrate that PEG$_4$ and G$_3$ linkers are useful for improving the tumor uptake and clearance of ^{99m}Tc-3PEG$_4$-dimer and ^{99m}Tc-3G$_3$-dimer from the kidneys and liver. These promising results led us to prepare DOTA-3PEG$_4$-dimer and DOTA-3G$_3$-dimer (DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) and their corresponding ^{64}Cu complexes, ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer).

In this article, we present the synthesis and evaluation of ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) as PET radiotracers for imaging integrin $\alpha_v\beta_3$ expression in athymic nude mice bearing the U87MG glioma xenografts. We are particularly interested in ^{64}Cu because of its longer half-life ($t_{1/2}$ = 12.7 h) compared to that of ^{18}F ($t_{1/2}$ = 110 min). ^{64}Cu decays by β^+ emission (18% abundance, maximum β^+ energy of 0.655 MeV). It can be produced with high specific activity (*74*). All these factors make the ^{64}Cu-labeled cyclic RGD peptides very attractive as PET radiotracers. DOTA was chosen because it forms a highly stable ^{64}Cu chelate (*75*−*77*). The main objective of this study is to assess the impact of PEG$_4$ and G$_3$ linkers on integrin $\alpha_v\beta_3$ binding affinity of DOTA-conjugated cyclic RGD peptide dimers and on the tumor uptake and excretion kinetics of their ^{64}Cu radiotracers from noncancerous organs, particularly the kidneys and liver. The results from the integrin $\alpha_v\beta_3$ binding assay and biodistribution studies may also allow us to compare them with ^{64}Cu(DOTA-dimer) and ^{64}Cu(DOTA-tetramer).

EXPERIMENTAL SECTION

Materials. Chemicals were purchased from Sigma-Aldrich (St. Louis, MO). DOTA-NHS (1,4,7,10-tetraazacyclododecane-1-(*N*-hydroxysuccinimide acetate)-4,7,10-triacetic acid) was obtained from Macrocyclics Inc. (Dallas, TX). Peptide dimers, PEG$_4$-E[PEG$_4$-c(RGDfK)]$_2$ (3PEG$_4$-dimer) and G$_3$-E[G$_3$-c(RGDfK)]$_2$ (3G$_3$-dimer), were custom-made by Peptides International, Inc. (Louisville, KY). The ESI (electrospray ionization) mass spectral data were collected on a Finnigan LCQ classic mass spectrometer at School of Pharmacy, Purdue University. ^{64}CuCl$_2$ was produced using a CS-15 biomedical cyclotron at Washington University School of Medicine by the ^{64}Ni(p,n)^{64}Cu nuclear reaction.

HPLC Methods. HPLC Method 1 used a LabAlliance semiprep HPLC system (State College, PA) equipped with an UV/vis detector (λ = 254 nm) and Zorbax C$_{18}$ semiprep column (9.4 mm × 250 mm, 100 Å pore size). The flow rate was 2.5 mL/min. The gradient mobile phase started with 90% solvent A (0.1% TFA in water) and 10% solvent B (0.1% TFA in acetonitrile) to 85% solvent A and 15% solvent B at 5 min to 65% solvent A and 35% solvent B at 30 min, followed by an isocratic mobile phase with 50% solvent A and 50% solvent B at 32−36 min. The radio-HPLC method (Method 2) used the LabAlliance semiprep HPLC system equipped with a β-ram IN/US detector (Tampa, FL) and Zorbax C$_{18}$ column (4.6 mm × 250 mm, 300 Å pore size; Agilent Technologies, Santa Clara, CA). The flow rate was 1 mL/min. The mobile phase was isocratic with 90% solvent A (25 mM ammonium acetate buffer, pH 5.0) and 10% solvent B (acetonitrile) at 0−2 min, followed by a gradient mobile phase going from 10% solvent B at 2 min to 15% solvent B at 5 min and to 20% solvent B at 20 min.

DOTA-PEG$_4$-E[PEG$_4$-c(RGDfK)]$_2$ (DOTA-3PEG$_4$-Dimer). DOTA-NHS (4.6 mg, 11 μmol) and PEG$_4$-E[PEG$_4$-c(RGDfK)]$_2$ (5 mg, 2.8 μmol) were dissolved in DMF (2 mL). After the addition of triethylamine (10 mg, 10 μmol), the reaction mixture was stirred at room temperature overnight. The product was isolated from the mixture by HPLC purification (Method 1). The fraction at 19.5 min was collected. Lyophilization of the collected fractions afforded DOTA-3PEG$_4$-dimer as a white powder. The yield was 2.0 mg (∼34%) with >95% HPLC purity. ESI-MS (positive mode): m/z = 1058.59 for [M + H]$^+$ (1058.99 calcd. for [C$_{77}$H$_{103}$N$_{23}$O$_{23}$S]$^+$).

DOTA-G$_3$-E[G$_3$-c(RGDfK)]$_2$ (DOTA-3G$_3$-Dimer). DOTA-3G$_3$-monomer was prepared using the same procedure using DOTA-NHS (4.4 mg, 10.6 μmol) and G$_3$-E[G$_3$-c(RGDfK)]$_2$ (3 mg, 3.53 μmol). Lyophilization of the combined collections at ∼19.5 min (Method 1) afforded the expected product DOTA-3G$_3$-monomer. The yield was 1.6 mg (∼40%) with HPLC purity >95%. ESI-MS: m/z = 1154.17 for [M + H]$^+$ (1154.49 calcd. For [C$_{51}$H$_{72}$N$_{13}$O$_{16}$S]$^+$).

^{64}Cu-Labeling. To a 5 mL vial were added 50 μg of the DOTA-RGD conjugate (RGD = 3PEG$_4$-dimer or 3G$_3$-dimer) in 0.3 mL of 0.1 M NaOAc buffer (pH = 6.9) and 0.12 mL of ^{64}CuCl$_2$ solution (∼ 2.0 mCi) in 0.05 N HCl. The reaction mixture was heated at 100 °C for 30 min. After cooling to room temperature, a sample of the resulting solution was analyzed by radio-HPLC (Method 2). The radiochemical purity (RCP) for ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) was >95% with the specific activity of 300−400 mCi/μmol.

Dose Preparation. For biodistribution studies, ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) were prepared and then purified by HPLC (Method 2). Volatiles in the HPLC mobile phases were removed by rotary evaporation. The dose solution was prepared by dissolving the HPLC-purified ra-

diotracer in saline to a concentration of 10−25 μCi/mL. In the blocking experiment, E[c(RGDfK)]$_2$ was dissolved in the solution containing the radiotracer to give a concentration of 1.75 mg/mL. For microPET imaging studies, ^{64}Cu(DOTA-3G$_3$-dimer) was prepared by using 12 μg of DOTA-3G$_3$-dimer to react with about 2 mCi of ^{64}CuCl$_2$ in 0.3 mL of 0.1 M NaOAc buffer. After radiolabeling, ^{64}Cu(DOTA-3G$_3$-dimer) was purified with HPLC (Method 2). Volatiles in the HPLC mobile phases were removed by rotary evaporation. The residue was reconstituted in PBS to a concentration of ∼1 mCi/mL. The resulting solution was filtered with a 0.20 μm Millex-LG filter before being injected into animals. Each tumor-bearing mouse was injected with 0.1−0.2 mL of the filtered dose solution.

Solution Stability. For solution stability studies, ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) were prepared and purified by HPLC (Method 2). Volatiles in the HPLC mobile phase were removed by rotary evaporation. The HPLC purified ^{64}Cu radiotracers were dissolved in 25 mM phosphate buffer (pH 7.4) containing EDTA (1 mg/mL) to 1 mCi/mL. Samples of the resulting solution were analyzed by radio-HPLC (Method 2) at 0, 1, 2, 4, and 12 h post-purification.

Determination of Log *P* Values. Log *P* values of were determined using the following procedure: the ^{64}Cu radiotracer was purified by HPLC. Volatiles were removed completely under vacuum. The residue was dissolved in an equal volume (3 mL/3 mL) mixture of *n*-octanol and 25 mM phosphate buffer (pH 7.4). After stirring vigorously for ∼20 min, the mixture was centrifuged at a speed of 8,000 rpm for 5 min. Samples (in triplets) from *n*-octanol and aqueous layers were counted in a Perkin-Elmer Wizard-1480 γ-counter (Shelton, CT). The log *P* value was measured three different times and reported as an average of three independent measurements plus the standard deviation.

In Vitro Whole-Cell Integrin $\alpha_v\beta_3$ Binding Assay. The in vitro integrin binding affinity and specificity of cyclic RGD peptides were assessed via a cellular displacement assay using ^{125}I-echistatin as the integrin-specific radioligand. Experiments were performed on a U87MG glioma cell line by slight modification of a method previously described (*50, 52*). Briefly, the U87MG glioma cells were grown in Gibco's Dulbecco's medium supplemented with 10% fetal bovine serum (FBS), 100 IU/mL penicillin, and 100 μg/mL streptomycin (Invitrogen Co, Carlsbad, CA), at 37 °C in humidified atmosphere containing 5% CO_2. Filter multiscreen DV plates were seeded with 10^5 cells in binding buffer and incubated with ^{125}I-echistatin in the presence of increasing concentrations of cyclic RGD peptides. After removing the unbound ^{125}I-echistatin, hydrophilic PVDF filters were collected, and the radioactivity was determined using a gamma counter (Packard, Meriden, CT). The IC_{50} values were calculated by fitting the data by nonlinear regression using GraphPad Prism (GraphPad Software, Inc., San Diego, CA) and reported as an average of these samples plus the standard deviation.

Animal Model and Biodistribution Protocol. Biodistribution studies were performed using the athymic nude mice bearing U87MG human glioma xenografts in compliance the NIH animal experiment guidelines (Principles of Laboratory Animal Care, NIH Publication No. 86−23, revised 1985). The protocol was approved by Purdue University Animal Care and Use Committee (PACUC). Female athymic nu/nu mice were purchased from Harlan (Charles River, MA) at 4−5 weeks of age. The mice were implanted with 5×10^6 the U87MG human glioma cells into the upper left flank. Two to three weeks after inoculation, the tumor size was 0.2−0.5 g, and animals were used for biodistribution and imaging studies. Sixteen tumor-bearing mice (20−25 g) were randomly divided into four groups. The ^{64}Cu radiotracer (∼2.5 μCi in 0.1 mL saline) was administered into each animal via the tail vein. Four animals were euthanized by sodium pentobarbital overdose (100−200 mg/kg), exsanguinations, and opening of thoracic cavity at 5, 30, 60, and 120 min postinjection (p.i.). Blood samples were withdrawn from the heart through a syringe. Organs were excised, washed with saline, dried with absorbent tissue, weighed, and counted on a γ-counter (Perkin-Elmer Wizard-1480). Organs of interest included the tumor, brain, spleen, lungs, liver, kidneys, muscle, and intestine. Organ uptake was calculated as a percentage of the injected dose per gram of organ tissue (%ID/g). For the blocking experiment, each animal was administered with ∼2.5 μCi of ^{64}Cu(DOTA-3PEG$_4$-dimer) along with ∼350 μg of E[c(RGDfK)]$_2$ (∼14 mg/kg). At 1 h p.i., four animals were sacrificed by sodium pentobarbital overdose (100−200 mg/kg) for organ biodistribution. The organ uptake (%ID/g) was compared to that obtained in the absence of excess E[c(RGDfK)]$_2$ at the same time point. The biodistribution data and target-to-background (T/B) ratios are reported as an average plus the standard variation based on results from four animals at each time point. Comparison between two different radiotracers was made using the two-way ANOVA test (GraphPad Prim 5.0, San Diego, CA). The level of significance was set at $p < 0.05$.

MicroPET Imaging. MicroPET imaging was performed using a microPET R4 rodent model scanner (Concorde Microsystems, Knoxville, TN). The U87MG glioma-bearing mice ($n = 3$) were injected with ∼100 μCi of ^{64}Cu(DOTA-3G$_3$-dimer) via the tail vein, were then anesthetized with 2% isoflurane, and placed near the center of the FOV where the highest resolution and sensitivity are obtained. The 5-min static PET images were obtained at 60 min p.i. For the blocking experiment, a mouse bearing a U87MG tumor was injected with 100 μCi of ^{64}Cu(DOTA-3G$_3$-dimer) along with c(RGDyK) at the dose of 10 mg/kg. The 5-min static PET images were then acquired at 1 h p.i.

Metabolism. Normal athymic nude mice ($n = 2$) were used to evaluate the metabolic stability of ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer). Each mouse was injected with the ^{64}Cu radiotracer at a dose of ∼100 μCi in 0.2 mL of saline via the tail vein. The urine samples were collected at 30 and 120 min p.i. by manual void and were mixed with equal volume of 20% acetonitrile aqueous solution. The mixture was centrifuged at 8,000 rpm. The supernatant was collected, counted on a Perkin-Elmer Wizard-1480 γ-counter, and filtered through a 0.20 μm Millex-LG filter unit. The filtrate was analyzed by radio-HPLC (Method 2). The feces samples were collected at 120 min p.i. and were suspended in a 20% acetonitrile aqueous solution. The mixture was vortexed for 5−10 min. After centrifuging at 8,000 rpm for 5 min, the supernatant was collected, counted on a Perkin-Elmer Wizard-1480 γ-counter, and passed through a 0.20 μm Millex-LG filter unit. The filtrate was then analyzed by radio-HPLC (Method 2). The percentage radioactivity recovery was >95% (by γ-counting) for both urine and feces samples.

RESULTS

Synthesis of DOTA-RGD Conjugates. DOTA-3PEG$_4$-dimer and DOTA-3G$_3$-dimer were prepared by direct conjugation of 3PEG$_4$-dimer and 3G$_3$-dimer, respectively, with excess DOTA-NHS in DMF in the presence of a base, such as triethylamine. DOTA-3PEG$_4$-dimer and DOTA-3G$_3$-dimer were purified by HPLC (Method 1) and characterized by ESI-MS. The mass spectral data were completely consistent with the proposed formula. Their HPLC purity was >95% before being used for the integrin $\alpha_v\beta_3$ binding assay and ^{64}Cu-labeling.

Integrin $\alpha_v\beta_3$ Binding Affinity. The integrin $\alpha_v\beta_3$-positive U87MG human glioma cells were used for the integrin $\alpha_v\beta_3$-

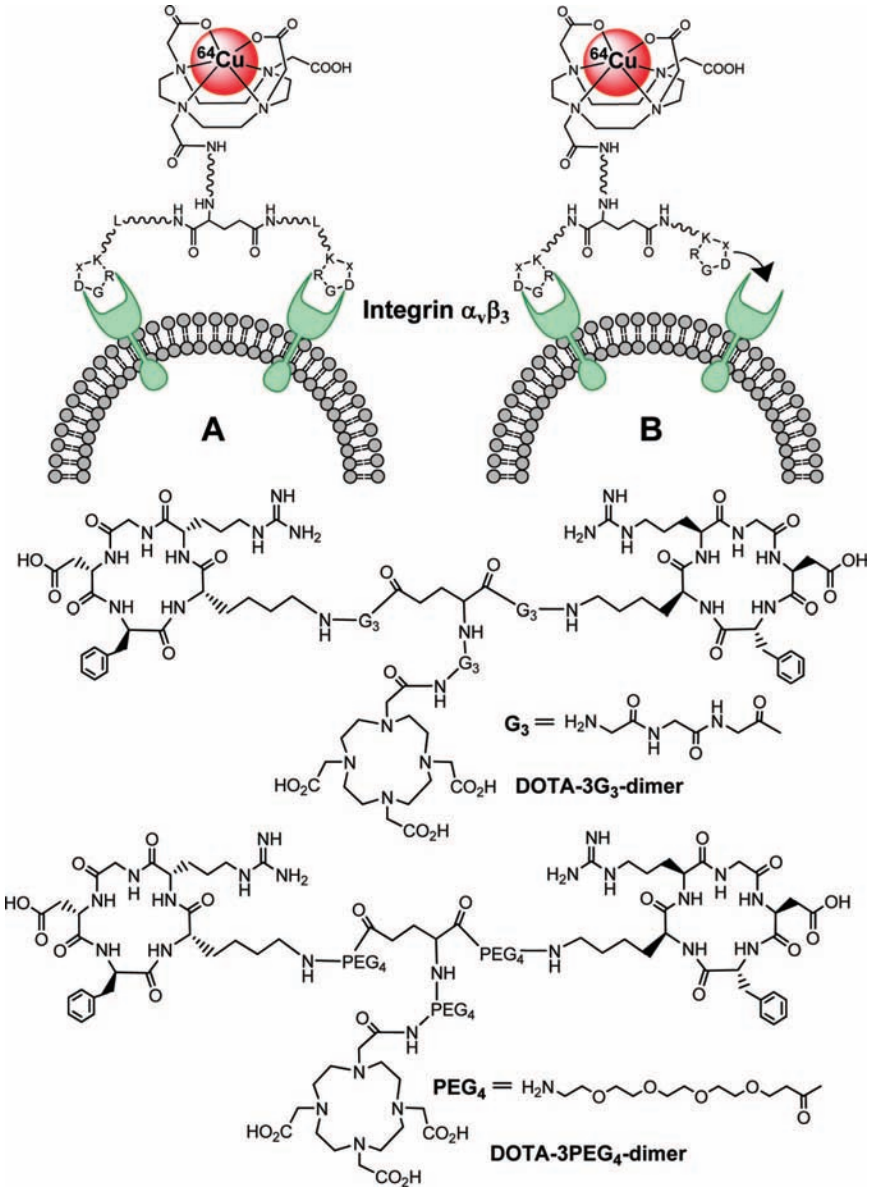

Figure 1. Novel DOTA-conjugated cyclic RGD dimers (DOTA-3G_3-dimer and DOTA-3PEG$_4$-dimer) and schematic illustration of interactions between cyclic RGD dimers and integrin $\alpha_v\beta_3$. (A) The distance between two RGD motifs is long, and the cyclic RGD dimer is able to bind integrin $\alpha_v\beta_3$ in a bivalent fashion. (B) The distance between two RGD motifs is not long enough for simultaneous integrin $\alpha_v\beta_3$ binding, but the RGD concentration is locally enriched in the vicinity of neighboring integrin $\alpha_v\beta_3$ once the first RGD motif is bound. In both cases, the result would be higher integrin $\alpha_v\beta_3$ binding affinity for the multimeric cyclic RGD peptides.

binding studies. We determined the integrin $\alpha_v\beta_3$ binding affinity of DOTA-3PEG$_4$-dimer and DOTA-3G_3-dimer by competitive displacement of ^{125}I-echistatin bound to U87MG glioma cells. For comparison purposes, we also evaluated DOTA-dimer and DOTA-tetramer using the same in vitro competition assay. The IC_{50} values for DOTA-dimer, DOTA-3PEG$_4$-dimer, DOTA-3G_3-dimer, and DOTA-tetramer were obtained from curve fitting from Figure 2 and were calculated to be 102 ± 5, 62 ± 6, 74 ± 3, and 10 ± 2 nM, respectively.

Radiochemistry. ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G_3-dimer) were prepared by reacting DOTA-3PEG$_4$-dimer and DOTA-3G_3-dimer, respectively, with $^{64}CuCl_2$ in the 0.1 M NaOAc buffer (pH 5.0). ^{64}Cu-labeling could be accomplished by heating the reaction mixture at 100 °C for 20−30 min. Both ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G_3-dimer) were analyzed using same radio-HPLC method (Method 2). Their HPLC retention times were 19.5 and 14.2 min, respectively. The RCP was >95% with the specific activity of 300−400 mCi/μmol for both ^{64}Cu(DOTA-3G_3-dimer) and ^{64}Cu(DOTA-3PEG$_4$-dimer). Their partition coefficients (*P* values) were determined in an equal volume mixture of *n*-octanol and 25 mM phosphate buffer (pH 7.4). The log *P* values were calculated to be −4.23 ± 0.21 and −4.84 ± 0.15, respectively, for ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G_3-dimer). ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G_3-dimer) were stable for >6 h after HPLC purification and remained intact for >6 h without any decomposition in the presence of EDTA (1 mg/mL in 25 mM phosphate buffer, pH 7.4).

Biodistribution Characteristics. Athymic nude mice bearing U87MG glioma xenografts were used to evaluate the biodistribution characteristics and excretion kinetics of ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G_3-dimer). Figure 3 illustrates the %ID/g organ uptake for ^{64}Cu(DOTA-3G_3-dimer) and ^{64}Cu-(DOTA-3PEG$_4$-dimer). In general, ^{64}Cu(DOTA-3G_3-dimer) had a rapid and very high tumor uptake at an early time point (8.50 ± 1.44%ID/g at 30 min p.i.). The tumor radioactivity washout of ^{64}Cu(DOTA-3G_3-dimer) was slow (7.55 ± 0.49%ID/g, 7.43 ± 2.41%ID/g and 6.79 ± 1.36%ID/g at 60, 120, and 240 min

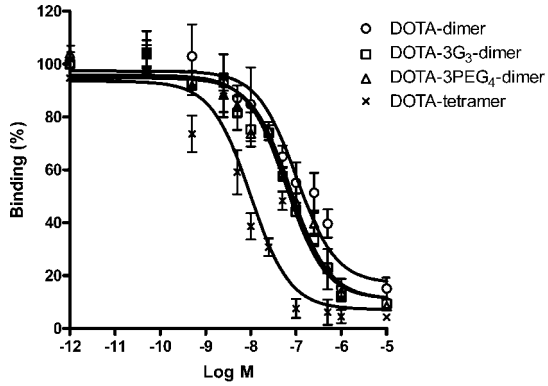

Figure 2. In vitro inhibition of ^{125}I-echistatin bound to integrin $\alpha_v\beta_3$ on U87MG glioma cells by DOTA-dimer, DOTA-3G$_3$-dimer, DOTA-3PEG$_4$-dimer, and DOTA-tetramer. Their IC$_{50}$ values were calculated to be 102 ± 5, 62 ± 6, 74 ± 3, and 10 ± 2 nM, respectively.

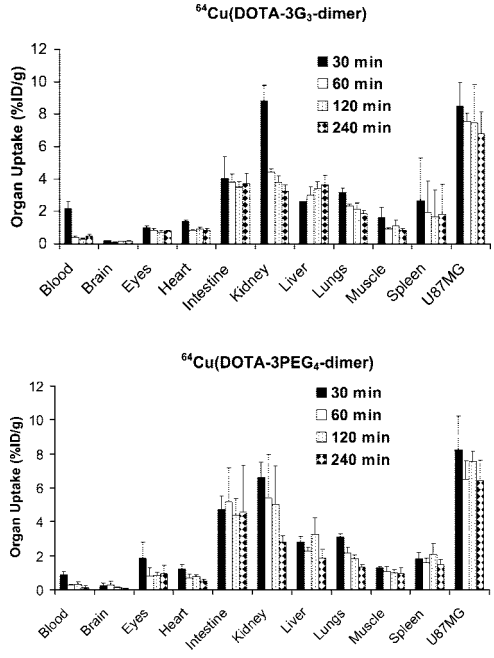

Figure 3. Biodistribution data for ^{64}Cu(DOTA-3G$_3$-dimer) and ^{64}Cu-(DOTA-3PEG$_4$-dimer) in athymic nude mice (n = 4) bearing U87MG glioma xenografts.

p.i., respectively). Its blood clearance was very fast (2.17 ± 0.45%ID/g at 30 min p.i. and 0.46 ± 0.15%ID/g at 240 min p.i.) with the tumor/blood ratios increasing from 4.01 ± 1.13 at 30 min p.i. to 24.31 ± 2.20%ID/g at 240 min p.i. The muscle uptake of ^{64}Cu(DOTA-3G$_3$-dimer) decreased steadily from 1.61 ± 0.66%ID/g at 30 min p.i. to 0.86 ± 0.08%ID/g at 240 min p.i., while the tumor/muscle ratios increased from 5.84 ± 2.49 at 30 min p.i. to 7.84 ± 1.15 at 240 min p.i. ^{64}Cu(DOTA-3G$_3$-dimer) also had a moderately high kidney uptake (8.83 ± 0.96%ID/g) at 30 min p.i.; but its kidney clearance was very fast (3.23 ± 0.40% ID/g at 240 min p.i.). The liver uptake of ^{64}Cu(DOTA-3G$_3$-dimer) was relatively low (2.60 ± 0.01%ID/g) at 30 min p.i. To our surprise, its liver uptake increased over the 4 h study period (3.01 ± 0.51%ID/g at 60 min and 3.62 ± 0.62%ID/g at 240 min p.i.). As a result, its tumor/liver ratio slowly decreased from 3.27 ± 0.56 at 30 min to 1.93 ± 0.56 at 120 min p.i.

^{64}Cu(DOTA-3PEG$_4$-dimer) also had very high tumor uptake (8.23 ± 1.97%ID/g, 6.49 ± 1.10%ID/g, 7.55 ± 0.62%ID/g, and 6.43 ± 1.22%ID/g at 30, 60, 120, and 240 min p.i., respectively) with fast blood clearance (0.87 ± 0.22%ID/g at 30 min p.i.

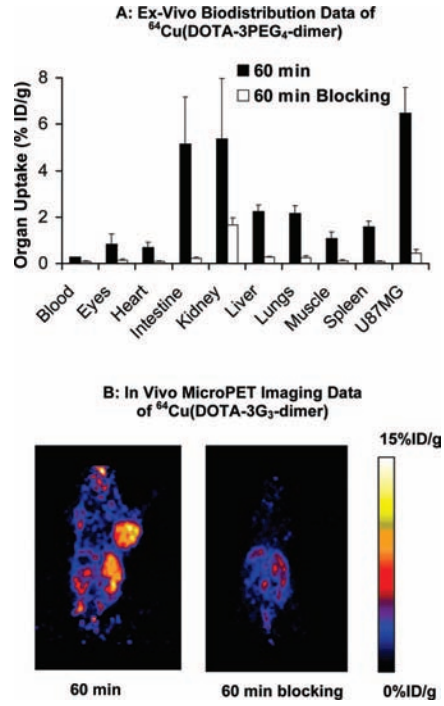

Figure 4. Biodistribution for ^{64}Cu(DOTA-3PEG$_4$-dimer) (n = 4) and in vivo microPET imaging data for ^{64}Cu(DOTA-3G$_3$-dimer) (n = 3) in athymic nude mice bearing U87MG glioma xenografts in the absence/presence of excess E[c(RGDfK)]$_2$ at 60 min p.i.

and 0.15 ± 0.07%ID/g at 240 min p.i.). As a result, its tumor/blood ratios increased steadily from 9.8 ± 3.3 at 30 min p.i. to 46.3 ± 15.1 at 120 min p.i.. ^{64}Cu(DOTA-3PEG$_4$-dimer) had a relatively low initial kidney uptake (6.59 ± 0.93%ID/g) at 30 min p.i. Its kidney uptake was 2.81 ± 0.36% ID/g at 240 min p.i., and the tumor/kidney ratio was 2.28 ± 0.31. The liver uptake of ^{64}Cu(DOTA-3G$_3$-dimer) was also low (2.80 ± 0.35%ID/g at 30 min p.i. and 1.87 ± 0.51%ID/g at 240 min p.i.); but its tumor/liver ratio remained relatively unchanged over the 4 h study period (2.98 ± 0.86 at 30 min to 3.52 ± 0.61 at 240 min p.i.). The muscle uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) (1.28 ± 0.11 and 0.95 ± 0.34%ID/g at 30 and 240 min p.i., respectively) was comparable to that of ^{64}Cu(DOTA-3G$_3$-dimer) (1.61 ± 0.66 and 0.86 ± 0.08%ID/g at 30 and 240 min p.i., respectively). The tumor/muscle ratio of ^{64}Cu(DOTA-3PEG$_4$-dimer) increased steadily from 6.48 ± 1.54 at 30 min p.i. to 7.24 ± 2.08 at 240 min p.i.

Blocking Experiment. The integrin $\alpha_v\beta_3$ specificity was demonstrated by coinjection of excess E[c(RGDfK)]$_2$ as the blocking agent (~14 mg/kg or ~350 μg per mouse) with ^{64}Cu(DOTA-3G$_3$-dimer). Such a high dose was used to ensure that the integrin $\alpha_v\beta_3$ is almost completely blocked. Figure 4A shows organ uptake of ^{64}Cu(DOTA-3G$_3$-dimer) at 60 min p.i. in the absence/presence of E[c(RGDfK)]$_2$. Coinjection of excess E[c(RGDfK)]$_2$ resulted in almost complete blockage of tumor uptake for ^{64}Cu(DOTA-3G$_3$-dimer) (0.43 ± 0.07%ID/g with E[c(RGDfK)]$_2$ vs 7.43 ± 2.41%ID/g without E[c(RGDfK)]$_2$). There was also a significant reduction in organ uptake of ^{64}Cu(DOTA-3G$_3$-dimer) in the eyes, heart, intestine, kidneys, lungs, liver, and spleen (Figure 4A).

MicroPET Imaging. Figure 4B illustrates the representative microPET images of the glioma-bearing mice at 1 h after administration of ~100 μCi of ^{64}Cu(DOTA-3G$_3$-dimer) in the absence or presence of excess E[c(RGDfK)]$_2$. We found that the tumor was clearly visualized with excellent contrast, suggesting that ^{64}Cu(DOTA-3G$_3$-dimer) is useful for imaging integrin $\alpha_v\beta_3$-positive tumors. In the presence of excess E[c(RGD-

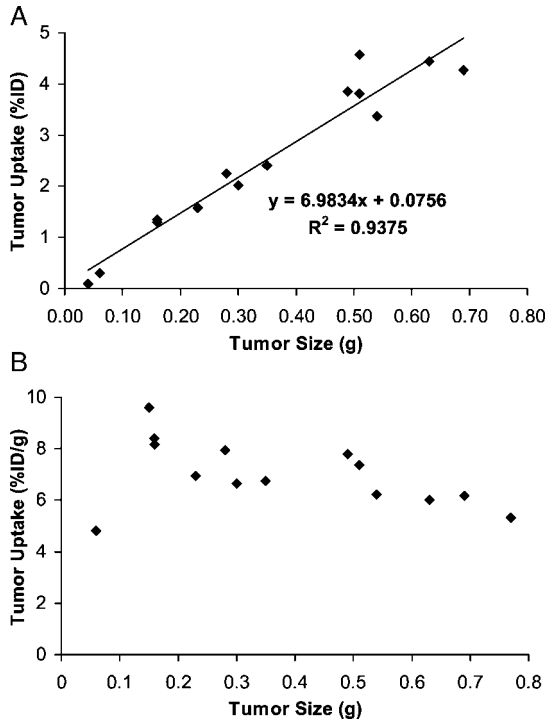

Figure 5. Relationship between tumor size and tumor uptake for ^{64}Cu(DOTA-3PEG$_4$-dimer) at 120 min p.i. in athymic nude mice (n = 7 with 14 tumors) bearing the U87MG glioma xenografts.

fK)]$_2$, the tumor uptake of ^{64}Cu(DOTA-3G$_3$-dimer) was almost completely blocked. The uptake of ^{64}Cu(DOTA-3G$_3$-dimer) was also blocked in many normal organs, in accordance with the biodistribution results shown in Figure 4A.

Tumor Size versus Tumor Uptake. During the biodistribution studies, we noticed that smaller tumors (<0.5 g) often have higher radiotracer uptake than large tumors. To further clarify the relationship between tumor uptake and tumor size, we added five extra glioma-bearing mice into the 120 min group for ^{64}Cu(DOTA-3PEG$_4$-dimer). The 120-min time point was chosen to avoid potential interference from the blood radioactivity and nonspecific radioactivity accumulation in the tumors. As illustrated in Figure 5A, there was a linear relationship between the %ID tumor uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) and tumor size (0.03−0.8 g; n = 7; tumor number = 14) with R^2 = 0.9375. The radiotracer %ID tumor uptake increases when tumor size increases. If the tumor uptake is expressed as %/ID/g (Figure 5B), ^{64}Cu(DOTA-3PEG$_4$-dimer) had a %ID/g tumor uptake of 6.5−10.0%ID/g with the tumor size in the range of 0.09 g−0.25 g. When the tumor size is >0.30 g, the tumor uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) was in the range of 6.0−7.0%ID/g. When the tumor size was <0.05 g, its tumor uptake was <5.0%ID/g.

Metabolic Properties. Figure 6 shows HPLC chromatograms of ^{64}Cu(DOTA-3PEG$_4$-dimer) (left) and ^{64}Cu(DOTA-3G$_3$-dimer) (right) in saline before injection, in urine at 30 min p.i. and 120 min p.i., and in feces at 120 min p.i. There were no metabolites detected in either urine and or feces samples from the mouse administered with ^{64}Cu(DOTA-3PEG$_4$-dimer). No metabolites were detected in the urine samples of the mouse administered with ^{64}Cu(DOTA-3G$_3$-dimer); but there was no intact ^{64}Cu(DOTA-3G$_3$-dimer) in the feces sample.

DISCUSSION

Previously, we reported the evaluation of ^{64}Cu-DOTA-dimer and ^{64}Cu-DOTA-tetramer as PET radiotracers for imaging integrin $\alpha_v\beta_3$ expression in athymic nude mice bearing MDA-MB-435 breast cancer and U87MG glioma xenografts (*50, 52*). The biodistribution studies clearly demonstrate that ^{64}Cu(DOTA-dimer) and ^{64}Cu(DOTA-tetramer) have better tumor uptake with longer tumor retention time than their monomeric counterparts. In this study, we prepared two new RGD dimer DOTA conjugates (DOTA-3PEG$_4$-dimer and DOTA-3G$_3$-dimer) and their ^{64}Cu complexes, ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu-(DOTA-3G$_3$-dimer). The in vitro competition assay shows that the integrin $\alpha_v\beta_3$ binding affinities of cyclic RGD peptide conjugates follow the order of DOTA-tetramer > DOTA-3G$_3$-dimer ~ DOTA-3PEG$_4$-dimer > DOTA-dimer. DOTA-3G$_3$-dimer (IC$_{50}$ = 62 ± 6 nM) and DOTA-3PEG$_4$-dimer (IC$_{50}$ = 74 ± 3 nM) share very similar integrin $\alpha_v\beta_3$ binding affinity with HYNIC-3G$_3$-dimer (IC$_{50}$ = 61 ± 2 nM) and HYNIC-3PEG$_4$-dimer (IC$_{50}$ = 51 ± 7 nM) (*72, 73*). Apparently, replacing HYNIC with DOTA does not have a significant impact on their integrin $\alpha_v\beta_3$ binding affinity and the radiotracer tumor uptake. This may explain why ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) have a tumor uptake very similar to that of ^{99m}Tc-3PEG$_4$-dimer and ^{99m}Tc-3G$_3$-dimer (*72, 73*).

There are two factors contributing to their high integrin $\alpha_v\beta_3$ binding affinity (Figure 1). The key for bivalency is that the distance between two RGD motifs in multimeric cyclic RGD peptides must be long enough to achieve simultaneous integrin $\alpha_v\beta_3$ binding. The distance between two cyclic RGD motifs is 6 bonds in E[c(RGDfK)]$_2$, 26 bonds in 3G$_3$-dimer, and 38 bonds in 3PEG$_4$-dimer (excluding the side arms of K-residues). The higher integrin $\alpha_v\beta_3$ binding affinity of DOTA-3G$_3$-dimer (IC$_{50}$ = 62 ± 6 nM) and DOTA-3PEG$_3$-dimer (IC$_{50}$ = 74 ± 3 nM) than that of DOTA-dimer (IC$_{50}$ = 102 ± 5 nM) strongly suggests that 2G$_3$-dimer and 3PEG$_3$-dimer are bivalent in binding to integrin $\alpha_v\beta_3$ (Figure 1A) and that the distance between the two cyclic RGD motifs in E[c(RGDfK)]$_2$ is probably too short for simultaneous integrin $\alpha_v\beta_3$ binding. This conclusion is well supported by the significantly higher tumor uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) (8.50 ± 1.44%ID/g and 6.79 ± 1.36%ID/g at 30 and 240 min p.i., respectively) and ^{64}Cu(DOTA-3G$_3$-dimer) (8.23 ± 1.97%ID/g and 6.43 ± 1.22%ID/g at 30 and 240 min p.i., respectively) as compared to that of ^{64}Cu(DOTA-dimer) (3.23 ± 0.57%ID/g at 30 min and 3.83 ± 0.22%ID/g at 240 min p.i.) in the same tumor-bearing animal model (*50*). If DOTA-dimer were able to bind to integrin $\alpha_v\beta_3$ in a bivalent fashion as DOTA-2G$_3$-dimer and DOTA-3PEG$_3$-dimer, they would have shared a similar integrin $\alpha_v\beta_3$ binding affinity, and ^{64}Cu(DOTA-dimer) would have had a tumor uptake similar to that of ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer). Even though DOTA-dimer is not bivalent, the binding of one cyclic RGD motif in E[c(RGDfK)]$_2$ may significantly increase local RGD concentration in the vicinity of neighboring integrin $\alpha_v\beta_3$ sites (Figure 1B). This may explain why ^{64}Cu(DOTA-dimer) has better tumor uptake than its monomeric counterpart (*50*).

The longest distance between the two adjacent cyclic RGD motifs in E[E[c(RGDfK)]$_2$]$_2$ is 16 bonds (excluding the side arms of K-residues). The integrin $\alpha_v\beta_3$ binding affinity of DOTA-tetramer (IC$_{50}$ = 10 ± 2 nM) is higher than that of DOTA-3G$_3$-dimer (IC$_{50}$ = 62 ± 6 nM) and DOTA-3PEG$_3$-dimer (IC$_{50}$ = 74 ± 3 nM), suggesting that DOTA-tetramer is also bivalent in binding to integrin $\alpha_v\beta_3$. The higher integrin $\alpha_v\beta_3$ binding affinity of DOTA-tetramer as compared to that of DOTA-3G$_3$-dimer and DOTA-3PEG$_3$-dimer is probably caused by the presence of two extra RGD motifs. This conclusion seems to be consistent with the fact that ^{64}Cu(DOTA-tetramer) has higher initial tumor uptake (9.93 ± 1.05%ID/g at 30 min p.i.) as compared to that of ^{64}Cu(DOTA-3PEG$_4$-dimer) (8.50 ±

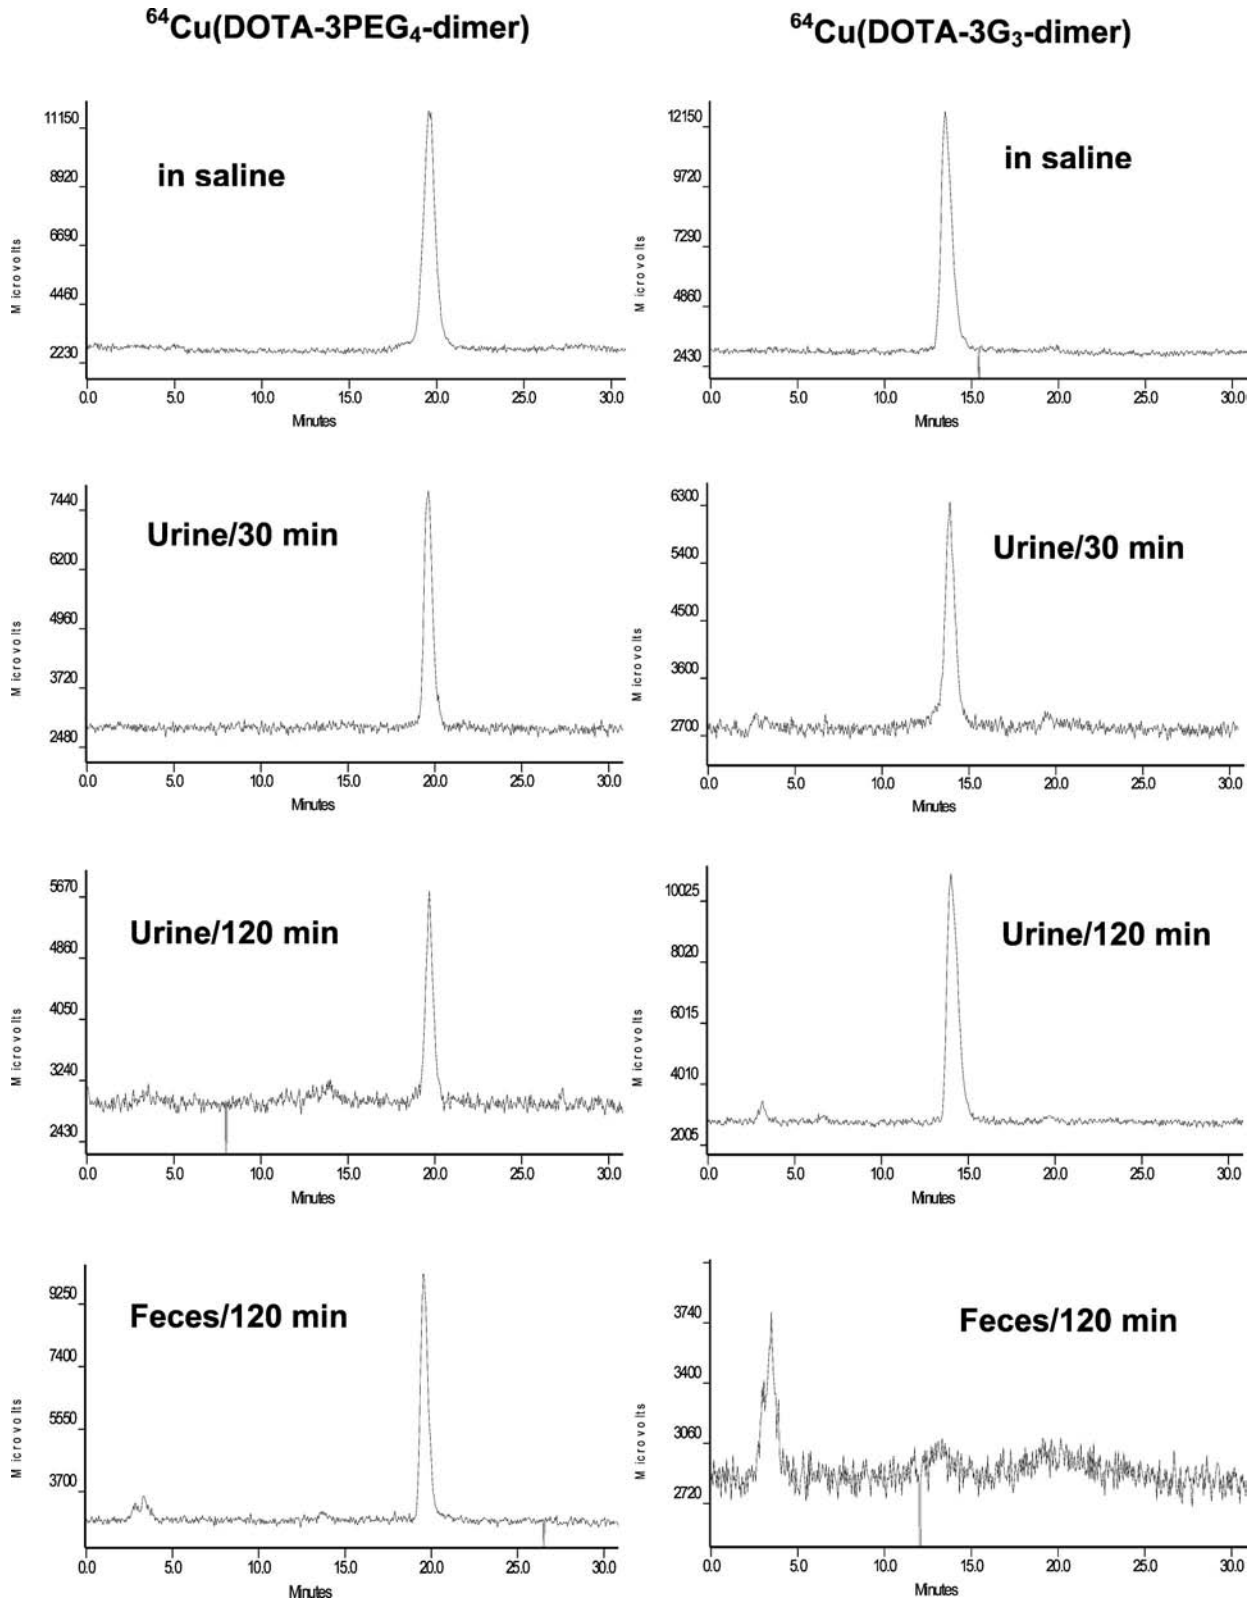

Figure 6. Typical radio-HPLC chromatograms (Method 2) for ^{64}Cu(DOTA-3PEG$_4$-dimer) (left) and ^{64}Cu(DOTA-3G$_3$-dimer) (right) in saline before injection, in urine at 30 and 120 min p.i., and in feces at 120 min p.i.

1.44%ID/g at 30 min p.i.) and ^{64}Cu(DOTA-3G$_3$-dimer) (8.23 ± 1.97%ID/g at 30 min p.i.) in the same tumor-bearing animal model.

However, ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) have significant advantages over ^{64}Cu(DOTA-tetramer) with respect to their uptake in noncancerous organs. For example, the liver uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) (2.25 ± 0.26%ID/g at 60 min p.i. and 1.87 ± 0.51%ID/g at 240 min p.i.) was significantly lower ($p < 0.01$) than that of ^{64}Cu(DOTA-tetramer) (4.38 ± 0.39%ID/g at 60 min p.i. and 3.57 ± 0.45%ID/g at 240 min p.i.) (*52*). As a result, the tumor/liver ratios of ^{64}Cu(DOTA-3PEG$_4$-dimer) (2.93 ± 0.66 at 60 min and 3.52 ± 0.61 at 240 min p.i.) were significantly better ($p < 0.01$) than that of ^{64}Cu(DOTA-tetramer) (1.98 ±

0.15 at 60 min p.i. and 2.35 ± 0.33 at 240 min p.i.). ^{64}Cu(DOTA-3PEG$_4$-dimer) has significantly ($p < 0.01$) lower kidney uptake (6.59 ± 0.93%ID/g at 30 min p.i. and 2.81 ± 0.36%ID/g at 240 min p.i.) than ^{64}Cu(DOTA-tetramer) (9.02 ± 0.56%ID/g at 30 min p.i. and 4.17 ± 0.35%ID/g at 240 min p.i.). The higher kidney uptake of ^{64}Cu(DOTA-tetramer) is probably caused by the presence of four R-residues, which are positively charged under physiological conditions, in E{E[c(RGDfK)]$_2$}$_2$ as compared to only two R-residues in both ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer). On the basis of both tumor uptake and T/B ratios of ^{64}Cu radiotracers, we believe that 3PEG$_4$-dimer and 3G$_3$-dimer are better targeting biomolecules than E{E[c(RGDfK)]$_2$}$_2$. In addition, the synthesis of E{E[c(RGDfK)]$_2$}$_2$ is much more challenging than that of either 3PEG$_4$-dimer or 3G$_3$-dimer. The cost for successful isolation of pure multimeric cyclic RGDfK peptides increases dramatically as peptide multiplicity increases. Therefore, 3PEG$_4$-dimer and 3G$_3$-dimer are better suited for future development of the integrin $\alpha_v\beta_3$-targeted radiotracers for imaging purposes.

Since the tumor uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) is almost completely blocked by coinjection of E[c(RGDfK)]$_2$, we believe that its tumor localization is indeed integrin $\alpha_v\beta_3$-mediated. Similar results were obtained for ^{64}Cu(DOTA-dimer) in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts (*50*) and ^{64}Cu(DOTA-tetramer) in athymic nude mice bearing U87MG human glioma xenografts (*52*). The uptake blockage in the eyes, heart, intestine, lungs, liver, and spleen suggests that major parts of the uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) in these organs is also integrin $\alpha_v\beta_3$-mediated. This conclusion is supported by the immunohistopathological studies (*53, 54*), which showed a strong positive staining of endothelial cells of the small glomeruli vessels in the kidneys and weak staining in the branches of the hepatic portal vein.

The ability to noninvasively quantify integrin $\alpha_v\beta_3$ level in vivo will provide new opportunities to more appropriately select patients for antiangiogenic treatment and more effectively monitor the therapeutic efficacy in integrin $\alpha_v\beta_3$-positive cancer patients (*34*). The %ID tumor uptake reflects the total integrin $\alpha_v\beta_3$ expression level, while the %ID/g tumor uptake reflects the integrin $\alpha_v\beta_3$ density. When the tumor is very small (<0.01 g or 100 m^3), there is little angiogenesis with very low blood flow. As a result, ^{64}Cu(DOTA-3PEG$_4$-dimer) has low %ID and %ID/g tumor uptake (Figure 5A and B). When tumors are in the range of 0.1−0.35 g (100−350 m^3), the microvessel and integrin $\alpha_v\beta_3$ density is high. The radiotracer %ID/g tumor uptake is high (Figure 5B) even though the %ID tumor uptake is relatively low (Figure 5A). As tumors grow, the total integrin $\alpha_v\beta_3$ level on tumor cells becomes larger, the microvessel density decreases due to maturity of blood vessels, and the integrin $\alpha_v\beta_3$ density also decreases due to larger interstitial space/pressure and higher collagen concentrations (*78*). Parts of the tumor may become necrotic, which also leads to lower integrin $\alpha_v\beta_3$ density in larger tumors. As a result, the %ID/g tumor uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) in larger tumors is lower than that of smaller ones (Figure 5B) even though its total %ID tumor uptake is higher (Figure 5A). The linear relationship between tumor size and %ID tumor uptake suggests that ^{64}Cu(DOTA-3PEG$_4$-dimer) might be useful for noninvasive monitoring of integrin $\alpha_v\beta_3$ expression in cancer patients. This assumption is supported by recent results obtained for the radiolabeled (^{18}F and ^{64}Cu) multimeric cyclic RGDyK peptides, which clearly showed that the %ID/g radiotracer tumor uptake was well correlated with the integrin $\alpha_v\beta_3$ density on the xenografted tumors of different origin (*52, 53*).

Metabolic degradation has been observed for ^{64}Cu(DOTA-dimer) and ^{64}Cu(DOTA-tetramer) in kidneys and urine samples (*50, 52*). In contrast, ^{64}Cu(DOTA-3PEG$_4$-dimer) has high metabolic stability during its excretion from the renal and hepatobiliary routes (Figure 6). Similar metabolic stability is also observed for ^{64}Cu(DOTA-3G$_3$-dimer) during its renal excretion; but it is completely metabolized during excretion from the hepatobiliary route. The PEG$_4$ and G$_3$ linkers have significant impact on the metabolic stability of ^{64}Cu-labeled RGD dimers probably due to the in vivo stability PEG$_4$ and G$_3$ linkers. It is important to note that the radioactivity detected in urine and feces samples represents only the portion of ^{64}Cu radiotracers excreted from renal and hepatobiliary routes. The remaining radioactivity is still trapped in normal tissues. Since the normal organ uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) can be blocked by the presence of excess E[c(RGDfK)]$_2$, it is reasonable to believe that the radioactivity accumulation inside normal organs is partially integrin $\alpha_v\beta_3$-mediated.

CONCLUSIONS

In this study, we prepared two novel cyclic RGD dimer conjugates: DOTA-3PEG$_4$-dimer and DOTA-3G$_3$-dimer. The integrin $\alpha_v\beta_3$ binding affinities follow the order of DOTA-tetramer > DOTA-3G$_3$-dimer ~ DOTA-3PEG$_4$-dimer > DOTA-dimer. Both DOTA-3G$_3$-dimer and DOTA-3PEG$_4$-dimer are bivalent in binding to integrin $\alpha_v\beta_3$, as evidenced by their higher integrin $\alpha_v\beta_3$ binding affinity as compared to that of DOTA-dimer and the higher tumor uptake of ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) than that of ^{64}Cu(DOTA-dimer). The PEG$_4$ and G$_3$ linkers are also useful for improving the radiotracer clearance from normal organs, such as kidneys, the liver, and lungs. The ex-vivo biodistribution studies show that there is a linear relationship between the %ID tumor uptake and tumor size, suggesting that ^{64}Cu(DOTA-3PEG$_4$-dimer) and ^{64}Cu(DOTA-3G$_3$-dimer) might be useful for noninvasive monitoring of tumor growth or shrinkage during antiangiogenic therapy. MicroPET imaging data clearly demonstrate the utility of ^{64}Cu(DOTA-3G$_3$-dimer) as a new PET radiotracer for imaging integrin $\alpha_v\beta_3$-positive tumors.

ACKNOWLEDGMENT

We thank Dr. Sulma I. Mohammed, the Director of Purdue Cancer Center Drug Discovery Shared Resource, for her assistance with tumor-bearing animal models. This work is supported, in part, by research grants R01 CA115883 A2 (to S.L.) from the National Cancer Institute (NCI), R21 HL083961-01 from National Heart, Lung, and Blood Institute (NHLBI), and DE-FG02-08ER64684 from the Department of Energy. The research performed at Stanford University is supported, in part, by NCI R01 CA119053, R21 CA121842, P50 CA114747, U54 CA119367, and R24 CA93862.

Development of a Dendritic Manganese-Enhanced Magnetic Resonance Imaging (MEMRI) Contrast Agent: Synthesis, Toxicity (in Vitro) and Relaxivity (in Vitro, in Vivo) Studies

Annabelle Bertin,[†] Jérôme Steibel,[‡] Anne-Isabelle Michou-Gallani,[§] Jean-Louis Gallani,[†] and Delphine Felder-Flesch*[,†]

Institut de Physique et Chimie des Matériaux de Strasbourg, UMR CNRS/ULP 7504, 23 rue du Lœss BP 43, 67034 Strasbourg Cedex 2, France, Laboratoire d'Imagerie et de Neurosciences Cognitives, UMR CNRS/ULP 7191, 12 rue Goethe, 67000 Strasbourg, France, and siRNA Therapeutics, NIBR Biologics Center, Novartis Institutes for Biomedical Research, Inc., 4002 Basel, Switzerland. Received October 28, 2008; Revised Manuscript Received January 26, 2009

A new dendritic manganese(II) chelate **1** has been evaluated by in vivo (relaxivity) and in vitro (toxicity and relaxivity) experiments as a manganese enhanced magnetic resonance imaging (MEMRI) contrast agent. Also, a comparison with its corresponding gadolinium(III) homologue **2** and the commercially available MEMRI agent MnDPDP (Teslascan, Amersham Health) was achieved in order to determine respectively the real influence of the paramagnetic ion in terms of toxicity and relaxivity for this precise treelike structure and the potential of **1** to be a favorable candidate for brain-targeting MRI. Complexes **1** and **2** displayed high hydrosolubility (0.1 M) and revealed no in vitro neuronal toxicity at concentrations as high as 1 mM. Considering manganese(II) complex **1**, the in vivo nontoxicity at 20 mM (100% rats survival) is very likely due to a slow diffusion of the compound, meaning a controlled release of the paramagnetic ions. Finally, T_1 relaxivity of 4.2 $mM^{-1}.s^{-1}$ for **2** and T_2 relaxivity of 17.4 $mM^{-1}.s^{-1}$ for **1** at 4.7 T were measured and are higher than that of the commercial MRI contrast agents GdDTPA and MnDPDP, respectively.

INTRODUCTION

The development of the current scientific techniques improves day by day the quality of human health and life. The field of medicine, in particular, has brought considerable improvement. Indeed, magnetic resonance imaging (MRI) is one of the most powerful diagnostic imaging tools in medicine, since it provides not only images with excellent anatomical details based on soft-tissue contrast, but also functional information in a noninvasive and real-time monitoring manner (*1*).

An MR image contrast is the result of a complex interplay of numerous factors, including the longitudinal (T_1) and transverse (T_2) relaxation times, proton density of the imaged tissues, and instrumental parameters. However, such contrast can be further improved by the administration of suitable paramagnetic species which affect longitudinal and transverse relaxation rates of the surrounding nuclei, mainly the water solvent protons (*2*).

Shortly after the development and market introduction of magnetic resonance imaging contrast media in 1988, their use became a worldwide established tool for improved medical diagnosis, and nowadays, developing effective, nontoxic, and organ-specific contrast agents (CAs) for in vivo image enhancement is a great current area of research (*3*−*10*). Indeed, today, contrast media are applied in approximately 30% of all MRI procedures.

Although most CAs are based on extracellular, low molecular weight gadolinium(III) chelates due to the seven unpaired electrons and relatively slow electronic relaxation of Gd(III) (*11*), a number of novel and more specific MRI contrast media (MRI-CM) containing other metals (Mn(II) chelates or iron oxide nanoparticles) (*12*−*14*) have been introduced. Notably, Mn(II) based MRI-CM are of great interest and especially in neuroscience research (*15*), since manganese (five unpaired electrons) has a natural human biochemistry, which may allow the design of target-specific CAs as a result of known biochemical uptake mechanisms.

CAs for manganese enhanced MRI (MEMRI) (*16*) have been investigated over the past decade, but so far, only two agents, the liver-specific manganese(II)-dipyridoxal diphosphate (MnDPDP, Teslascan, Amersham Health) and an oral agent containing manganese(II) chloride (LumenHance), have been available clinically for human use (*17*).

The present work describes the synthesis, toxicity (in vitro) studies, and relaxivity (in vitro and in vivo) measurements of a novel hydrophilic dendritic Mn(II) complex **1** (Figure 1) derived from diethylenetriamine pentaacetic acid (DTPA) with regard to its potential application in MEMRI dedicated to brain imaging. A dendritic approach to the preparation of such specific contrast agents appears promising, as the diversity of functionalization brought by the well-defined (on the opposite to polymers) and hyperbranched structure answers simultaneously all the criteria of biocompatibility, low toxicity, and specificity. Moreover, in addition to the multifunctionalization of a low molecular weight molecule, the dendrimer chemistry allows a versatility of size (according to the generation) and of physicochemical properties (hydrophilic, lipophilic). The resulting effects on stability (dendrimer effect), contrast qualities, and biodistribution of the contrast agents can then also clearly be identified.

EXPERIMENTAL PROCEDURES

Chemistry. GdDTPA was provided by Aldrich and Mangafodipir (MnDPDP or Teslascan) was purchased from Amer-

sham Health. Reagents and solvents were purchased reagent-grade from Sigma Aldrich and Alfa Aesar and used without further purification. Bromide **3** was prepared according to literature procedures (*18*). All reactions were performed in standard glassware under Ar, and solvents were, if necessary, purified by standard procedures prior to use. Evaporation and concentration were done at water-aspirator pressure and drying in vacuo at 10^{-2} Torr. Column chromatography: silica gel 60 (230−400 mesh, 0.040−0.063 mm) from E. Merck. NMR spectra: Bruker AM-300 (300 MHz), solvent peaks as reference, δ in ppm.

4: A mixture of methyl-3,5-dihydroxybenzoate (372 mg, 2.21 mmol), **3** (3.20 g, 4.87 mmol), and K_2CO_3 (1.53 g,11.06 mmol) in acetone (25 mL) was stirred at 65 °C for 68 h. The reaction mixture was filtered (celite), and the solvent was evaporated. The residue was taken up in a mixture of $CH_2Cl_2/H_2O_{sat.NaCl}$ (1:1) (600 mL). The organic layer was isolated, washed with $H_2O_{sat.NaCl}$ (2 × 300 mL), dried ($MgSO_4$), filtered, and evaporated to dryness. Column chromatography (SiO_2, acetone) afforded **4** (2.07 g, 1.56 mmol) in 71% yield. Yellow oil. ^{1}H NMR ($CDCl_3$): 3.38 (s, 18H), 3.53−3.87 (m, 60H), 3.91 (s, 3H), 4.13−4.19 (m, 12H), 4.96 (s, 4H), 6.67 (s, 4H), 6.79 (t, ^4J = 2 Hz, 1H), 7.28 (d, ^4J = 2 Hz, 2H). ^{13}C NMR ($CDCl_3$): 52.28, 59.00, 68.91, 69.72, 70.36, 70.53, 70.55, 70.68, 70.81, 71.93, 71.95, 72.32, 107.16, 107.29, 108.34, 131.78, 132.07, 138.30, 152.81, 159.71, 166.69. $C_{64}H_{104}O_{28}\cdot 1/2\ H_2O$: calc. C 57.72, H 7.89, O 34.27; found C 57.74, H 7.92, O 34.34.

5: 7.81 mL of $LiAlH_4$ (1 M in THF) was added dropwise to a solution of methyl ester **4** (7.38 g, 5.58 mmol) in THF (100 mL). After 20 h stirring at room temperature, the reaction mixture was neutralized by careful addition of MeOH (50 mL) and H_2O (50 mL), filtered (celite), and evaporated to dryness. Column chromatography (SiO_2, CH_2Cl_2/10% MeOH) afforded **5** (6.50 g, 5.03 mmol) in 90% yield. Yellow oil. ^{1}H NMR ($CDCl_3$): 1.72 (s, 1H OH), 3.38 (s, 18H), 3.53−3.87 (m, 60H), 4.13−4.19 (m, 12H), 4.63 (s, 2H), 4.93 (s, 4H), 6.52 (t, ^4J = 2 Hz, 1H), 6.62 (d, ^4J = 2 Hz, 2H), 6.67 (s, 4H). ^{13}C NMR ($CDCl_3$): 58.98, 61.72, 65.1, 68.85, 69.68, 70.46, 70.49, 70.51, 70.64, 70.76, 71.88, 71.91,72.26, 101.25, 105.66, 107.23, 132.17, 138.17, 143.61, 152.73, 160.00. $C_{63}H_{104}O_{27}\cdot H_2O$: calc. C 57.70, H 8.15, O 34.16; found C 57.81, H 8.16, O 34.03.

6: Triethylamine (TEA) (3.23 mL, 23.10 mmol)) was added dropwise to a stirred solution of diethylenetriaminepentaacetic dianhydride (0.84 g, 2.31 mmol) and **5** (3.00 g, 2.31 mmol) in dry CH_2Cl_2 (100 mL) heated to 50 °C. After 70 h stirring, the reaction mixture was concentrated to 10 mL and hexane (50 mL) was added. The resulting suspension was cooled to 6 °C for 24 h. The white precipitate obtained was filtered off, washed with hexane (3 × 50 mL), and dried. No further purification was necessary to yield pure ligand **6** (3.50 g, 2.10 mmol) with 91% yield. ^{1}H NMR ($CDCl_3$): 1.29 (t, ^4J = 7.2 Hz, 8H), 3.05 (m, 10H), 3.32 (s, 18H), 3.46−3.85 (m, 60H), 4.07−4.13 (m, 12H), 4.88 (s, 2H), 4.90 (s, 4H), 6.61 (s, 4H), 6.73 (t, ^4J = 2.4 Hz, 1H), 7.22 (d, ^4J = 2.4 Hz, 2H). ^{13}C NMR ($CDCl_3$):45.56, 49.73, 52.63, 55.59, 56.76, 59.03, 68.89, 69.73, 70.50, 70.53, 70.55, 70.69, 71.92, 72.30, 101.29, 105.70, 107.28, 132.22, 138.22, 143.66, 152.78, 160.03, 168.79, 169.96, 170.62, 173.05. Elemental analysis: calc. C 55.40, H 7.55, O 34.53, N 2.52; found C 55.37, H 7.55, O 34.50, N 2.52. Maldi-MS (negative mode): $[M]^-$ 1666.85 obtained for $C_{77}H_{125}N_3O_{36}$ (1667.80).

1: An equimolar solution of **6** (0.50 g, 0.30 mmol) and $MnCl_2\cdot 4H_2O$ (0.06 g, 0.30 mmol) in H_2O (30 mL) was stirred at room temperature for 12 h while maintaining pH at 6.5 by addition of 1 M aqueous solution of NaOH. The reaction mixture is then lyophilized. Impure complex **1** (presence of inorganic salts like NaCl) is then diluted in CH_2Cl_2 (30 mL). The organic phase obtained is washed with H_2O (2 mL) (decreasing reaction yield), dried ($MgSO_4$), filtered, and evaporated to dryness. Complex **1** is obtained as a yellow solid (0.47 g, 0.27 mmol) with 90% yield. Maldi-MS (negative mode): $[M\ Na]^{2-}$ 1741.77 obtained for $MnC_{77}H_{121}N_3O_{36}Na$ (1741.70).

2: An equimolar solution of **6** (0.50 g, 0.30 mmol) and $Gd(ClO_4)_3$ (0.25 g of a 50% solution in H_2O, 0.30 mmol) in H_2O (30 mL) was stirred at room temperature for 12 h while maintaining pH at 6.5 by addition of a 1 M aqueous solution of NaOH. The solution is then treated with Chelex resin (2 g) for 2 h before filtration and lyophilization. The absence of free gadolinium is checked by the Xylenol orange test (*19*). Complex **2** is obtained as a white solid (0.47 g, 0.25 mmol) with 89% yield (taking into account remaining perchlorates). Maldi-MS (negative mode): $[M\ Na]^-$ 1861.75 obtained for $GdC_{77}H_{123}N_3O_{37}Na$ (1862.69).

In Vitro Toxicity Studies. Rat pups were sacrificed by decapitation at 7 days of age, and neurons were isolated from the cerebellum and plated in multiwell plates coated with poly(D-lysine). The plates were incubated for 3 days to allow cell maturation to continue to some extend. At DIV 3 (day in vitro 3), the cells were exposed to 0.001 to 10 mM of the test products or to 0.001 to 100 nM of β-bungarotoxin. β-Bungarotoxin is a known neurotoxin that is not expected to decrease cell counts but has a striking negative effect on neuron-specific parameters. The cells were treated with the compounds for 2 days and then

analyzed as follows: Measure of the cell leakage resulting from membrane damage: lactate deshydrogenase is normally a cytoplasmic enzyme. When the integrity of the plasma membrane is compromised, it leaks into the culture medium, where it can be measured by a colorimetric assay (Roche, LDH Assay). As a positive control for the test, a few test wells in the plate were exposed to a strong detergent, 1% Triton X100, for 30 min (thus causing immediate and measurable release of LDH); then, 120 μL of culture media was collected from all the wells and analyzed. Immunostaining of the cells*:* the cells were fixed with 4% paraformaldehyde, permeabilized with 0.5% Triton X100, blocked with 5% BSA (bovine serum albumine), and incubated with an antibody for neuron-specific beta III tubulin (RandD). The secondary antibody used was a TRIC-labeled mouse antibody. The nuclei were stained with DAPI or Hoechst 33342. High cell content analysis (ArrayScan system, Cellomics Thermofisher): The ArrayScan system is an imaging approach that uses fluorescent probes and automated microscopy to quantify multiple cellular markers at the single-cell level. Fluorescence microscopy coupled to electronic imaging allows quantification of many cell-specific parameters, such as nucleus counts, intensity, size or shape of nuclei, quantification of signals in the cytoplasma, or specific organelles (e.g., neurites). The ArrayScan system consists of an optical system with a spatial resolution of 0.68 μm (Carl Zeiss), a triple band fluorescence emission filter set with matched single band excitation filters for selectively imaging Hoechst, FITC, or TRITC (model XF93, Omega Optical), and a CDD camera. The system is used to scan multiple fields in each well (images acquisition). In our studies, the images acquired were analyzed with an algorithm specialized for neurons, "neuronal profiling".

Commercial MnDPDP (Teslascan, Amersham Health) and **6** were suspended in 5% DMSO at a stock concentration of 500 mM (yellow solution for commercial Mangafodipir, white−yellow solution for **6**). A 10-fold serial working dilution down to 0.05 mM was done in 5% DMSO. **1**, **2**, and commercial GdDTPA were suspended in water at a stock concentration of 500 mM (orange tainted solution for **1**, yellow solution for **2**) and stored at −20 °C. A fresh 10-fold serial working dilution down to 0.05 mM was done in water. Four microliter aliquots of each working dilution were applied to the cells covered by 200 μL culture medium, i.e., a 50× further dilution step. In summary, the cells were exposed to the following final concentrations of product: 10, 1, 0.1, 0.01, and 0.001 mM. As a control, β-bungarotoxin, was included on each plate of cells at concentrations ranging from 100 nM (because of its neurotoxicity, 10^4 times less concentrated than the test compounds) down to 0.001 nM.

Relaxivity Studies. In vitro: All MRI experiments were carried out at 4.7-T using an MR magnet (Magnex Sci. Ltd., Oxford, United Kingdom). T_1 and T_2 values were determined for each complex at pH 6.5−7 as a function of concentrations and at various temperature. In vivo: all studies were performed in accordance with French animal protection laws and approved by the responsible governmental authority. The animals (rats and mice) were kept under anesthesia using a mixture of isoflurane and oxygen. After being relaxed, the animals were intubated and artificially ventilated with an animal respirator. Rats and mice were placed in a stereostatic device to immobilize the head, with an integrated facility to maintain the body temperature at 37 °C. An anatomically shaped ^{1}H surface coil for small animals (Rapid Biomedical GmbH, Würzburg, Germany) was positioned on the head to serve as a receiver for the MR signal. The system was then placed into a ^{1}H resonator for rats and mice, with an inner diameter of 69 mm that fits into the −20 cm MR magnet. Brain saggital and coronal slices were acquired with a repetition time (T_R) of 3.8 s (T_2-weighted) and 0.5 s (T_1-weighted), spin−echo time (T_E) of 40 ms (T_2-weighted) and 21 ms (T_1-weighted). Image acquisitions were based on a T_1-weighted spin−echo MRI sequence or T_2-weighted sequence, using CPMG sequence. All data were analyzed with *Matlab* software.

As physicochemical properties like pH must be taken into account for potential clinical applications, intraperitoneal (i.p.) or intraveinous (i.v.) injections were performed at physiological pH (7.4) using a saline solution of the tested compound at [10 mM].

RESULTS AND DISCUSSION

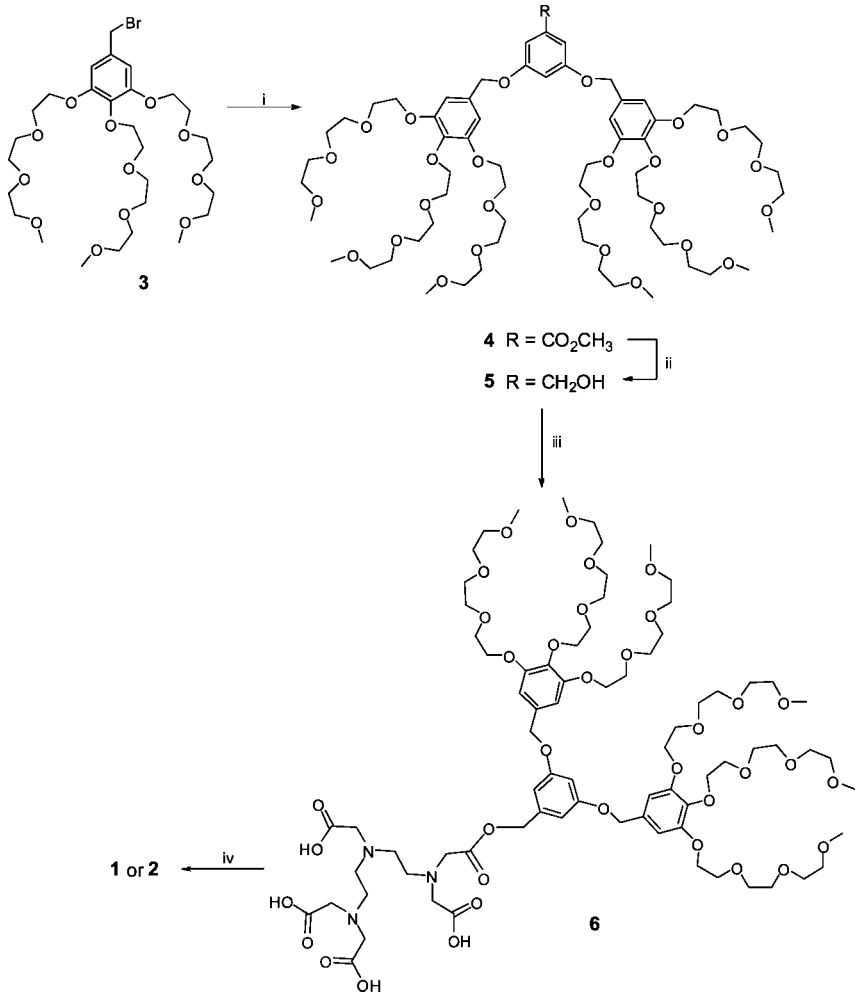
Chemistry. The Mn(II) and Gd(III) DTPA-derived complexes **1** and **2** were synthesized starting from the previously described bromo derivative **3** (*18*) as depicted in Scheme 1. The bromide **3**, in the presence of methyl 3,5-dihydroxybenzoate and potassium carbonate in acetone under reflux, led to the formation of methyl ester **4** with 71% yield. Then, reduction of ester **4** by $LiAlH_4$ in THF allowed the preparation of the corresponding benzyl alcohol **5** with 90% yield. Finally, the ligand **6** is obtained by reaction of benzyl alcohol **5** with commercial diethylenetriaminepentaacetic dianhydride in the presence of triethylamine in dichloromethane. After precipitation in hexane, the pure dendritic ligand **6** is obtained with 91% yield. Then, preparing the manganese(II) complex, an equimolar solution of ligand **6** and $MnCl_2$ in water is stirred at room temperature while maintaining the pH of the solution at 6.5. After workup, the manganese complex **1** is then obtained with 90% yield. The same procedure is followed to prepare the gadolinium complex (III) using $Gd(ClO_4)_3$. After treatment with Chelex resin, the lack of free gadolinium is checked by the Xylenol orange test (*19*). After lyophilization, the complex **2** is obtained with 93% yield.

Solubility and log *P*. The distribution of a molecule between aqueous and organic phases (partition coefficient P) determines in part its biological properties such as transport, membrane crossing, and bioavailability (distribution and accumulation). We measured the log *P* of our contrast agents by the so-called "shake flask" method recommended by the European Union (*20*). The results are presented in Table 1, as well as their hydrosolubility estimated by the turbidimetric method (*21*). As it can be noticed, the DTPA complexation induces a huge variation of the partition coefficient: indeed, if the log *P* is −0.47 for ligand **6**, it increases to −2.66 and −3.27 for gadolinium(III) and manganese(II) complexes **1** and **2**, respectively. Complexation therefore increases hydrophilicity, which is confirmed by hydrosolubility measurements: concentrations as high as 0.1 M in water can be reached for complexes **1** and **2**. Such values are extremely important and encouraging, knowing that the contrast is function of the paramagnetic species concentration. Moreover, as will be explained in the following, our compounds are still nontoxic in vitro and in vivo at such concentrations.

In Vitro Toxicity. Toxicity, which is primarily due to the action of manganese as a calcium channel blocker with effects on muscle electrophysiology and contractility, has limited the use of manganese salts as paramagnetic contrast agents (*22, 23*). Early research in MR imaging employed the use of $MnCl_2$ in dogs (*24*) and rats (*25*) as well as in vitro systems involving human blood (*26*). Nevertheless, $MnCl_2$ is the active component of Lumenhance, a commercial contrast agent used for gastrointestinal imaging (*27*).

Manganese complexes are relatively unstable in vivo and are dissociated in biological media. Indeed, manganese can be displaced by other divalent cations such as calcium, magnesium, or zinc. Due to this release, some concern exists about the potential long-term toxicity associated with the development and use of Mn-based contrast agents (*28*). Free manganese was shown to be teratogenic and mutagenic in several models (*29*).

Scheme 1[a]



[a] Reagents: (i) Methyl-3,5-dihydroxybenzoate, K_2CO_3, acetone, 60 °C; (ii) $LiAlH_4$, THF, Ar, 0 °C; (iii) diethylenetriamine pentaacetic dianhydride, CH_2Cl_2, TEA; (iv) for Mn complex **1**: $MnCl_2 \cdot 4H_2O$, pH 7; for Gd complex **2**: $Gd(ClO_4)_3$, H_20, pH 7.

Table 1. Hydrosolubility and Log *P* Values of the Dendritic Ligand 6 and Its Corresponding Mn(II) and Gd(III) Complexes 1 and 2, Respectively

compound	dendritic ligand **6**	Mn(II) complex **1**	Gd(III complex **2**
hydrosolubility ($mg.mL^{-1}$)	62 ± 7	172 ± 17	182 ± 18
hydrosolubility ($mmol.L^{-1}$)	37 ± 4	98 ± 10	97 ± 10
log *P*	−0.47	−3.27	−2.66

The teratogenic effect was also demonstrated after commercial MnDPDP injection (*30*, *31*). It was thus of great importance to show that our MEMRI complex **1** is nontoxic both in vitro and in vivo at concentrations as high as 1 to 10 mM, knowing that commonly used concentrations for MRI studies and in vivo experiments are 0.5 mM.

Cells used in this test were rat cerebellar neurons isolated from 7-day-old pups. These cells are useful tools for toxicity tests as they are primary cells, unmodified and without any genomic aberration. They represent a great intermediate between cell lines and tests on tissue sections or in vivo tests. Since our final aim is to target the brain and perform chemical engineering to increase such percentage of contrast agents reaching the brain, it appeared important to perform the in vitro toxicity tests on cerebellar neurons. Moreover, as those cells are the most sensitive cells, it becomes possible to conclude that if they are not affected then other less sensitive cells will also not be affected.

Neurons used in our in vitro assay are exposed to the complexed entities and to an unknown fraction of free ions released from the complexes, while in vivo neurons may be exposed to free ions released from the complexes. However, despite its limitations, the use of a cellular model based on functional primary cells has the advantage to allow monitoring of alterations on various levels: cell death, loss of cells, alteration of cellular membranes, alteration of the ability to form an healthy neuritic network. All these alterations can be quantified, thus allowing a direct comparison of the contrast agents and a basic characterization.

The assay is used for analyzing compounds in case of possible brain penetration and can be proposed more generally if there is a concern about potential neurotoxic effects. Cells were stained in order to visualize nuclei (DAPI), cytoplasm, and neurites (anti β-tubulin III): thus, alteration of the neuron-specific parameters such as nuclei number, number of neurons, mean neurite count, mean total neurite length, and mean neurite width and area reflects neurotoxicity.

Influence of the Paramagnetic Ion and Comparison with Commercial Products. From the selected images shown Figure 2, it can be seen that the higher concentration (10 mM) of all four tested compounds disrupts the neuritic network. At 1 mM, disruption remains strong in the corresponding selected image for MnDPDP and gadolinium complex **2**, while **1** and GdDTPA are better tolerated. In order to better apprehend, and in a quantitative manner, the potential toxicity of these compounds,

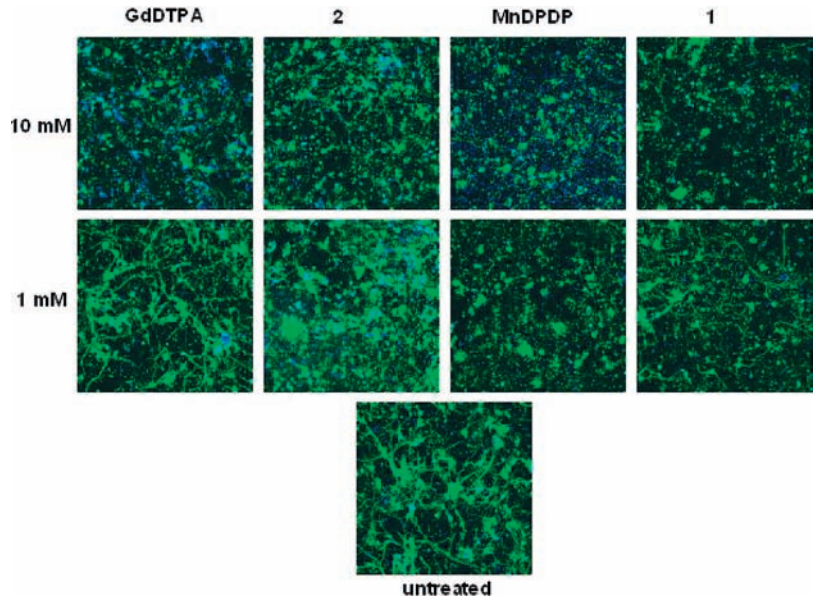


Figure 2. Pictures of treated neurons after staining for complexes **1** and **2** compared to commercial GdDTPA (Magnevist, Schering) and MnDPDP (Teslascan, Amersham Health) at 1 and 10 mM, together with untreated neurons.

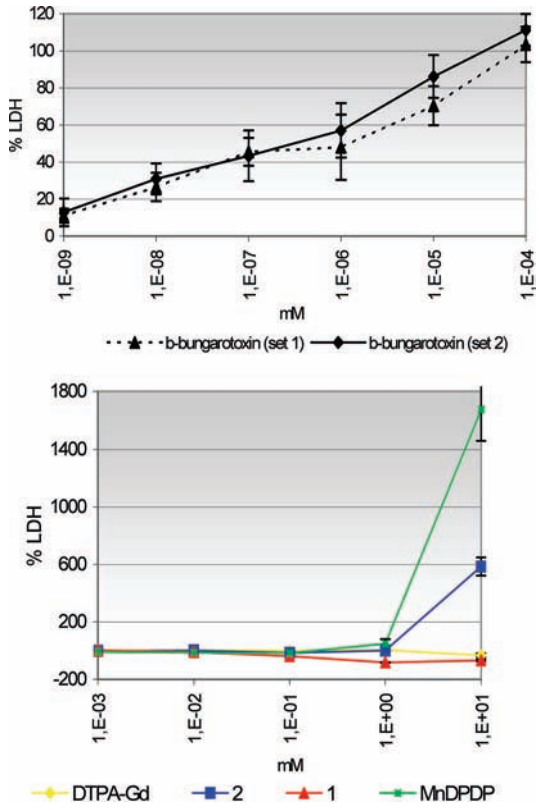

Figure 3. LDH efflux. Measurements of the cell leakage resulting from membrane damage of neuronal cells treated with increasing concentrations of dendritic complexes **1**, **2**, and commercial GdDTPA (Magnevist, Schering) and MnDPDP (Teslascan, Amersham Health).

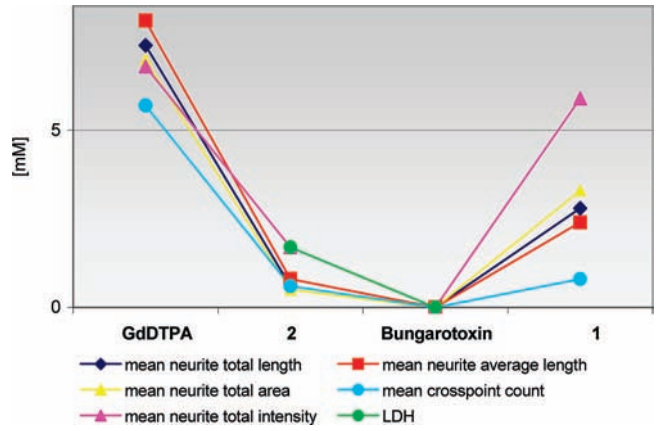

Figure 4. EC50 (mM) of all studied compounds.

we conducted a LDH release test (Figure 3). Indeed, the LDH measurement in the culture medium is a classical test for detection of overall toxicity: if the cell membranes lose their integrity, LDH, which is an enzyme present in the cytoplasm, is released in the supernatant culture, where it can be measured by a colorimetric test. Cells that have been exposed to the venom β-bungarotoxin also show dose-dependent membrane damage. **2** elicits a striking LDH release at 10 mM, confirming that this compounds compromises the membrane integrity at high concentration. MnDPDP is also strongly membrane damaging at 10 mM. Supernatants from wells with neurons treated with increasing concentrations of **1** show a loss in LDH activity. LDH release is a parameter that is proportional to cell number. In parallel, we observe that increasing the concentration of **1** induces loss of nuclei (data not shown). We can suggest that these two observations are linked. Nevertheless, the LDH test has shown that our complex **1** does not damage the cell membrane up to a concentration of 10 mM.

Thus, our in vitro neurotoxicity studies evidenced qualitatively (Figure 2) and quantitatively (Figures 3 and 4) that the manganese(II) dendritic complex **1** is no more toxic than the commercial GdDTPA at concentration up to 1 mM and is much less toxic than MnDPDP.

In Vitro Relaxivity Studies. *Influence of the Paramagnetic Ion and Comparison with Commercial Products.* The in vitro relaxivity measurements of dendritic complexes **1** and **2** allowed one to draw the linear relationships $r_{1,2} = f([M])$ (Figure 5), which where compared to the those recorded for one Gd-DTPA, $GdCl_3$, and the two principal MEMRI contrast agents, namely, $MnCl_2$ (only for animal experiments) and MnDPDP.

The observed relaxivities measured at 37 °C under 4.7 T are summarized in Table 2. The relaxation theory predicts that higher relaxation rates are obtained upon increase of the

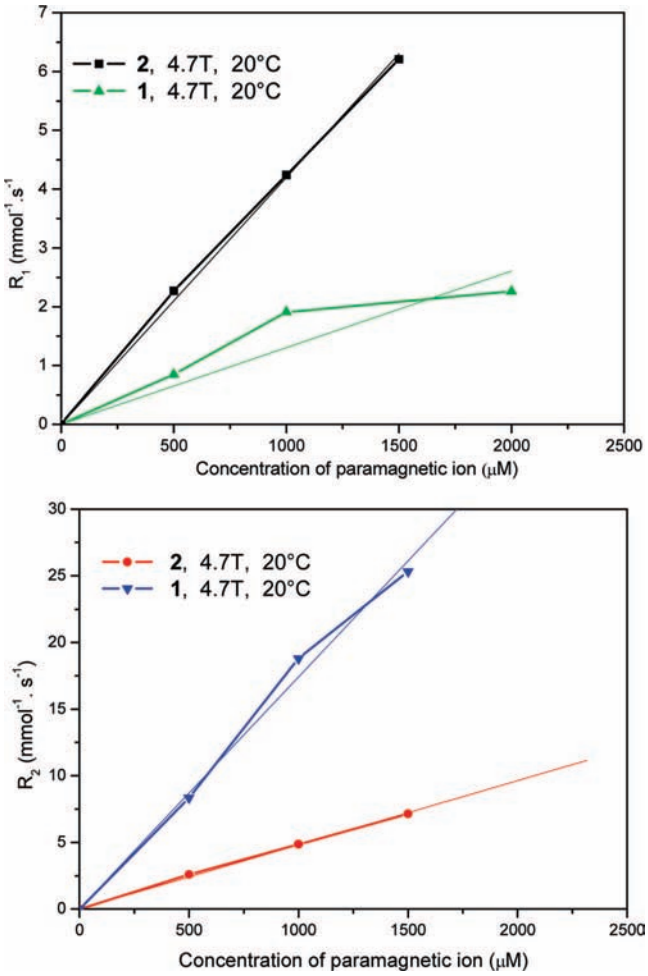

Figure 5. In vitro dose−response relaxivity studies of Mn(II) complex **1** and Gd(III) complex **2** at 4.7 T and 20 °C.

Table 2. r_1 and r_2 Relaxivities of 1, 2, GdDTPA, and MnDPDP in H_2O at 20 °C under 4.7 T

metal complexes	r_1 (mM^{-1}. s^{-1})	r_2 (mM^{-1}. s^{-1})
1	1.3	17.41
MnDPDP[a]	1.5 (1.3−1.7)	2.7 (2.6−2.8)
$MnCl_2$	3.59	48.42
2	4.2	4.82
GdDTPA[a]	3.2 (3.0−3.4)	4.0 (3.8−4.2)
$GdCl_3 \cdot 6H_2O$	18.63	28.2

[a] According to M. Rohrer, H. Bauer, J. Mintorovitch, M. Requardt, H.-J. Weinmann, *Invest. Radiol.* 40(*11*), **2005**, 715−724 for the 4.7 T values.

rotational correlation time of complexes (*32*). Since the molecular rotation correlation time (τ_R) is proportional to the molecular size, the attachment of low molecular weight paramagnetic gadolinium chelate to macromolecules can considerably enhance the relaxivity of the chelate unit and can extend the residence time in the cardiovascular system, with potential applications in MRI angiography (MRA) (*33*, *34*). However, macromolecular contrast agents tend to have less complete body elimination. In order for the complex to be excreted by kidneys and cleared from the blood pool quickly after being injected, the complex should have a molecular mass lower than 3.5 kD and also be hydrophilic. Thus, our PEG-based dendritic contrast agents may meet the satisfying conditions of both high relaxivity and low toxicity as confirmed by the following results.

In the case of the Mn(II)−DTPA complex, no water molecule is directly bound to the metal ion, which makes the outer-sphere relaxivity become the only relaxivity component. The in vitro relaxivities measured for **1** at 4.7 T are extremely encouraging: $r_1 = 1.3$ $(mM.s)^{-1}$ and $r_2 = 17.41$ $(mM.s)^{-1}$. One can see in Table 2 that, as expected, the highest relaxivities are obtained for $MnCl_2$ ($r_1 = 6.9$ $(mM.s)^{-1}$ and $r_2 = 37.5$ $(mM.s)^{-1}$), but the important point is that our dendritic Mn(II)-based complex **1** shows higher r_2 relaxivity (4 times higher) than that of the relative small molecular complex Mn-DPDP.

One can also point out that r_2 values measured at 4.7 T for the dendritic Gd(III)-based complex **2** are much lower than that of the corresponding Mn(II)-based complex **1** and r_1 and r_2 are of the same range as (as predicted by theory) and very close to the values recorded for Gd-DTPA. Thus, the dendritic architecture seems to have no substantial beneficial effect on the relaxivities.

In Vivo Relaxivity Studies. Given the fact that for a great number of MRI examinations the sensitivity is too low, the use of synthetic contrast agents is not only paramount but even mandatory. However, with the aim of rendering MRI an even more powerful technique, these contrast agents are confronted by the improvement of three factors: the spatial accuracy, the contrast resolution, and the examination time. The manganese(II) complex **1** has been synthesized in order to develop a nontoxic Mn^{2+} ion vehicle, knowing that these ions are highly toxic but for which the highest intracellular contrasts can be obtained. Moreover, as manganese is an essential nutrient for mammals and organisms, they have developed special carrier systems and selective cellular uptake mechanisms.

A possible strategy to reduce the in vivo toxicity of manganese(II) is to deliver Mn^{2+} to a specific site at an appropriate concentration (greatly reduce its concentration) and via a time-efficient manner (maintain a long diffusion). However, even if the MRI studies conducted on Gd(III) complex **2** showed the inability of the product to cross the healthy blood−brain barrier (BBB), they also highlighted a high vascular remanence (the contrast agent is circulating in the blood flow for at least 72 h), which is a behavior of good omen for use in functional imaging or for monitoring treatment.

The ability of Mn^{2+} to accumulate in active regions of the brain was first demonstrated in MRI by activity-induced manganese-enhanced MRI (AIM-MRI) (*35*). Unfortunately, AIM-MRI is a quite invasive method, as the contrast agent is infused after BBB opening with an hyperosmolar agent. Here, we chose a simple intraperitoneal (i.p) administration of **1** leading to interesting and useful anatomical contrast (Figure 6).

An aqueous isotonic saline solution (0.9% NaCl) of dendritic complex **1** was administered to a Long Evans male rat of 300 g via intraperitoneal injection (ip) at a 0.4 mmol/kg scale. As shown Figure 6, this injection led to a contrast increase in the rat brain on both the T_1- and T_2-weighted images. At 24 h after administration, the contrast is improved throughout the brain but heterogeneously, and details of the cytoarchitecture can be visualized as a result of the presence of Mn^{2+}. Similarly to other studies, on the T_1-weighted images, the contrast in the parenchyma is better at 24 h (b) while the contrast in the ventricle is maximal at 15 h (a) and gradually decreases after 48 h (c). The concentration of Mn^{2+} is minimal in the corpus callosum (a,b,d,e). The maximum concentration of Mn^{2+} is observed in the hippocampus region, the thalamus, and the cerebellum center (b,e). These results are consistent with previous studies performed on rats using intravenously injected $MnCl_2$ and would mean that Mn^{2+} ions enter the brain by release. However, on the opposite to $MnCl_2$, manganese chelation and probably the presence of the dendritic structure abolish the cardiovascular adverse side effects and effectively eliminate the problem of the Mn^{2+} retention in the tissues. In the case of our complex **1**, the toxicity disappearance is very likely due to a slow diffusion

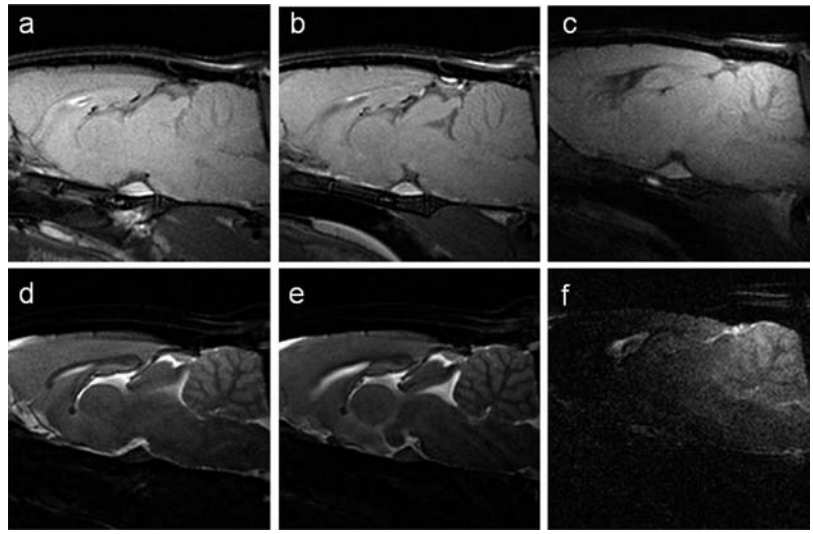

Figure 6. T_1 (a,b,c) and T_2 (d,e,f) MEMRI images obtained with complex **1**. (a,d) 15 h; (b,e) 24 h; (c,f) 72 h. Rat brain, at 0.4 mmol/kg, IP of a 20 mM solution of **1** in NaCl (150 mM); SMIS 4.7 T, 1 mm thickness, resolution 256 × 256, field of view 20 mm.

of the product, meaning a controlled release of the paramagnetic ions. In return, this follows a major loss of the relaxivity compared to $MnCl_2$. But still, the measured relaxivities for **1** are comparable to those obtained for commercial MnDPDP.

All these data support the view that, in spite of the lower effective magnetic moment of manganese, complex **1** and well-designed Mn(II) complexes can therefore be considered as viable alternatives to the currently used gadolinium(III) complexes as contrast agents for (ME)MRI. Considering brain imaging, this is mainly due to the rich biochemistry of manganese allowing absorption and transport of Mn^{2+} to the brain: the uptake of extracellular Mn^{2+} by a neuron is directly coupled to its physiological activity and function. This suggests potential applications not only for basic neurosciences but also for managing clinical neurological diseases such as Alzheimer or Parkinson, as well as other diseases showing disturbances in neuronal cell structures without disturbing the BBB.

ACKNOWLEDGMENT

We thank the French Ministry of Research for a fellowship to A. Bertin and CNRS for financial support. Pr. D. Grucker is warmly acknowledged for the in vitro relaxivity measurements. We also thanck E. Couzigné and B. Guignard for technical assistance.

***In vitro* relaxivity**

The contrast agent (CA) reduces locally the proton relaxation times. In the classic theory of NMR relaxation by Bloembergen et al. (*1*), it is predicted that the change in proton relaxation rate upon addition of paramagnetic ions to water is proportional to both the concentration and the square of the ion magnetic moment. But except gadolinium, all the lanthanides produce much smaller changes in relaxation rates than would be predicted by the magnetic moment of the alone ion (*2*, *3*). So other parameters should be taken into account.

The internal coordination sphere contribution to relaxivity can be described by the Solomon-Bloembergen-Morgan equation (Equation 1) (*4*-*6*):

$$\frac{1}{T_1} = \frac{3}{10}\frac{\gamma^4 \bar{h}^2}{b^6} r_0 \left[\frac{1}{1+\omega_0^2\tau_0^2} + \frac{4}{1+4\omega_0^2\tau_0^2} \right]$$

$$\frac{1}{T_2} = \frac{3}{20}\frac{\gamma^4 \bar{h}^2}{b^6} r_0 \left[3 + \frac{5}{1+\omega_0^2\tau_0^2} + \frac{2}{1+4\omega_0^2\tau_0^2} \right]$$

Equation (1)

where T_1 is the longitudinal relaxation time and T_2 the transverse relaxation time; τ_0 is the correlation time, ω_0 is the resonance pulse = $2\pi\nu_0$ where ν_0 is the resonance frequency. It is important to note that the dominant parameter in the Solomon-Bloembergen equations is the dipolar correlation time τ_C, defined in Equation (2) as

$$1 / \tau_C = l/\tau_R + l/\tau_S + 1 / \tau_M \qquad \text{Equation (2)}$$

where τ_R is the rotational correlation time, τ_S the electron-spin relaxation time and τ_M the residence lifetime of the water molecule in the inner coordination sphere of the paramagnetic ion. In principle all of these times can contribute to the value of τ_C, and thereby influence enhancement. In practice, τ_C will be determined by the term with the shortest time. Another feature to note is that T_1/T_2 is close to unity for most ions except for Mn^{2+}. This is explained by the fact that for this ion the scalar term in the Solomon-Bloembergen equation is an important contribution to R_2 (=1/ T_2) but not R_1 (=1/ T_1) (*7*).

The effect of one CA on the longitudinal and transverse relaxation times T_1 and T_2 is determined experimentally and measured as relaxivity r_1 and r_2 respectively) normalized to 1 mM concentration at a given magnetic field strength and is used to evaluate the CA efficiency

(*8-11*). So the enhanced relaxation ability of a paramagnetic solution is expressed by the relaxivity (r_i) defined as the slope of Equation (3) in $mM^{-1}. s^{-1}$:

$$(1/T_{1,2})_{observed} = (1/T_{1,2})_{diamagnetic} + r_{1,2}[M] \qquad \text{Equation (3)}$$

where $(1/T_{1,2})_{observed}$ and $(1/T_{1,2})_{diamagnetic}$ are water proton relaxation rates in the presence and absence of paramagnetic species, respectively, [M] is a concentration of a paramagnetic species (in this study [*M*] is either [Mn] or [Gd]), and $r_{1,2}$ is the specific relaxivity.

College of Chemistry and Molecular Sciences, School of Basic Medical Science, Wuhan University, Wuhan 430072, People's Republic of China, and Department of Polymer Science and Engineering, Zhejiang University, Hangzhou 310027, People's Republic of China. Received October 29, 2008; Revised Manuscript Received January 7, 2009

We present a novel nuclear targeting nanoprobe based on peptide functionalized gold nanoparticles and its surface-enhanced Raman scattering (SERS) in living cells. For the first time, we probe an original SERS signal from the living cell nucleus by using high-selectivity functionalized gold nanoparticles. The gold nanoparticles conjugated with SV-40 large T nuclear localization signal (NLS) peptide successfully enter the cell nucleus after the incubation with Hela cells and deliver the spatially localized chemical information of the nucleus, as well as the signature of chemicals that intruded subsequently. This new targeted nanoprobe is a nontoxic, biocompatible method for biological research, provided with multiple functions comprising subcellular targeting, intracellular imaging, and real-time SERS detection.

INTRODUCTION

Raman spectroscopy has long been regarded as a valuable tool for the identification of chemicals and biological samples (*1*−*3*). Within the past decade, this novel diagnostic method has attracted more and more interest because of its nondestructivity and low aqueous interference (*4*). At the same time, also along with the development of biomedical science, chemists and biologists have paid more attention to the components present in very low absolute amounts in living organisms. While the small cross sections required for Raman scattering have limited its use to the analysis of relatively concentrated samples, surface-enhanced Raman scattering (SERS) enables its advantage in the detection of very low concentration analytes, even single molecules (*5*−*7*). Generally, the Raman scattering in SERS takes place in the high local optical fields of noble metallic nanostructures, and this is the most important factor of the targeted study within a complex biological environment. As an effectual SERS substrate, gold nanoparticles are easily dispersed and are chemically stabler than silver nanoparticles, which enable them to be widely used for SERS in biomedical research (*8*−*10*).

Studying single living cells by SERS based on gold nanoparticles was first reported by Kneipp et al. (*11*). From then on, probing structural information of intracellular components using this biocompatible substrate was always a major purpose of such studies (*12*−*14*). In fact, there is an unarguable fact that the distribution of bare gold nanoparticles in cells is not under control. In recent years, purposeful SERS applications have been performed by functionalizing the nanoparticles with antibodies or other biomolecules that have a special receptor (*15,16*). The functionalized nanoparticles that also can be described as SERS targeting nanoprobes always contain Raman reporter molecules to highlight the positions of themselves by their high spectral specificity (*16*−*18*). More recently, this method has been successfully used in tumor detection on living animals (*8*). However, the Raman reporter modified targeting nanoprobe provides only the signature of the reporters and tends to be an imaging instrument rather than a detection probe, like the role of a fluorescent reagent or quantum dot; the application of the latter in targeting research is already proving to be excellent (*19*). In fact, delivering molecular structural information from the target analyte is the most important characteristic or advantage of SERS, which until now has not been possible by any other technique. The cell nucleus is a desirable target because the genetic information of the cell and transcription machinery reside there (*20*). Although many methods have succeeded in the nuclear targeted studies using gold nanoparticles, SERS has not been involved, because the functionalization might have blocked the metallic surface or imposed influence on the SERS spectra (*20*−*22*). Oyelere et al. (*23*) recently reported their nuclear targeting method by using gold nanorods, which has been shown to provide SERS information from the local biological environment together with significant influences originating from the functional molecules on the nanorods. Moreover, the targeting effect of the nanorods is not comparable to those using gold nanoparticles (*20*−*22*). The nanorods are distributed into both nucleus and cytoplasm, which is very similar to the distribution of bare gold nanoparticles in living cells observed in other work (*13*). Thus, developing a SERS probe for the detection of special targets remains urgent and will open a window for SERS application in the biomedical field.

In this paper, we show that the nuclear localization signal (NLS) peptide functionalized gold nanoparticles can locate effectively at the cell nucleus and deliver the molecular structural information from the nucleus without notable influence arising from the functionalization. By staining the cell nucleus with DNA intercalator, we are able to evaluate the ability of the nanoprobe to monitor the chemical changes in the nuclear environment.

EXPERIMENTAL PROCEDURES

Preparation of Nuclear Targeted SERS Probe. Gold nanoparticles with a diameter of ∼20 nm for SERS studies were prepared by reduction of gold (III) chloride hydrate using sodium

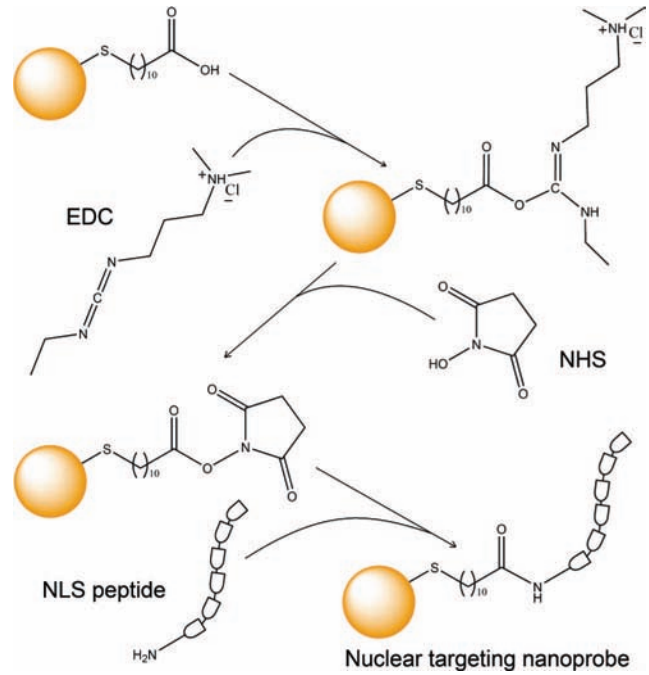
citrate. After centrifugation, the nanoparticles were resuspended in pH 7.3 borate buffer solution by ultrasonication. The concentrated suspension was then diluted in deionized water to a concentration of $\sim 10^{12}$ particles/mL. The nanoparticles were subsequently modified with 11-mercaptoundecanoic acid (11-MUA) (Aldrich) by adding a 30 μL aliquot of a 1 mM ethanol solution of 11-MUT to 3 mL of the aqueous nanoparticle suspension. Five microliters of 1 mM 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDC) (Sigma) and 2 μL of 1 mM *N*-hydroxysuccinimide (NHS) (Sigma) were added to the modified nanoparticle solution. After that, a 5 μL aliquot of a 0.75 mM SV-40 large T NLS peptide (GL Biochem Ltd.) aqueous solution was added, and the mixture was stirred for 24 h. At last, the product was centrifuged and resuspended in pH 7.4 PBS to a final concentration of $10^{10}-10^{11}$ particles/mL. The supernatant fluid after centrifugation was tested by HPLC (high performance liquid chromatography) to determine the number of NLS molecules on each nanoparticle. A control experiment was performed by using a NLS mutant peptide (KGGGPKKGRKVGG, GL Biochem Ltd.) connected to gold nanoparticles prepared in the same way as the nuclear targeted SERS probe.

Cell Culture and Targeting. Human cervix carcinoma cell line (HeLa) was purchased from China Center for Typical Culture Collection (CCTCC), and all reagents for the cell culture were purchased from Gibco. Cells were cultured in RPMI 1640 medium supplemented with 10% newborn bovine serum, 1% (w/v) glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin. After incubation at 37 °C in a humidified atmosphere containing 5% CO_2, the cells were resuspended for plating by removing the medium, rinsing three times with PBS, and rinsing the cells with fresh 0.25% trypsin, 1 mM EDTA-Na. Then, after incubation for another 3 min, the activity of trypsin was stopped by adding an equal volume of culture medium, and the cells were diluted to a concentration of 2×10^4 cells/mL. The resuspended cells (3 mL) were placed in a 35 mm Petri dish, permitted to adhere for 24 h, and then the functionalized nanoparticles (200 μL) were added in. After the mixture was incubated overnight at 37 °C, the culture medium was removed and 3 mL fresh medium was added to incubate for another 6 h. Additionally, the cells for DNA intercalator detection were incubated for 5 min with 10 μM 4′,6-diamidino-2-phenylindole (DAPI). Immediately before SERS mapping, the medium was removed, and the cells were rinsed three times in PBS. The cells involved in the SERS mapping (without DAPI staining) were fixed with paraformaldehyde (4% in PBS, pH 7.4) after the point by point scan and incubated subsequently for 40 min in the dark with 5 μM Hoechst 33258 (here, the fixed cells were only for fluorescence imaging). Then, the morphology of the cell nucleus was imaged by a fluorescence microscope (Leica).

Viability of the cells after incubation with the nanoprobe was tested by flow cytometric (FCM) analysis. In this experiment, the cells were incubated with the nanoprobe for 12 h and cultured subsequently for 12 h in fresh medium. After incubation, the cells were collected and washed three times with PBS and then suspended in 75% ethanol at 20 °C overnight. Fixed cells were centrifuged and washed with PBS twice. For detecting DNA content, cells were stained in the dark with propidium iodide (PI) (50 μg/mL) and 0.1% RNase A in PBS at 25 °C for 30 min. Stained cells were applied to a flow cytometer (Becton Dickinson). For each analysis, 10 000 events were recorded.

Raman Measurement. SERS spectra were obtained using a Jobin Yvon Raman microspectrometer (HR 800) with a 632.8 nm helium−neon laser at 13.6 mW with a 1 μm spot size. The objective used was an Olympus 50× long working distance lens (NA = 0.5) for both focusing the excitation beam on the sample and collecting the back-scattering light onto an air-cooled charge-coupled device detector. The collection time of each SERS spectrum was 1 s over a spectral range from 600 to 1700 cm^{-1}. Cells for the measurement adhered to a CaF_2 slide in the culture medium. When Raman mapping was performed, the scan over a single living cell was carried out on a computer-controlled *x*,*y* stage in 1 μm steps at a laser spot size of $\sim 1 \times 10^{-8}$ cm^2. Excitation intensities in the experiments of living cells were less than 1×10^5 W/cm^2, which ensures the safety of the living cells within the measurements. Peak frequencies and rapid checking of instrumental performance were calibrated with the silicon phonon line at 520 cm^{-1}.

Scheme 1. Preparation of the Nuclear Targeted Nanoprobe



Transmission Electron Micrograph (TEM). Cells incubated with the targeting probe for the TEM experiment were prepared by staining in 1% OsO_4, dehydrating in ethanol gradient, immersing in LR white embedding resin, and curing under UV light. Microtomed sections were then placed on grids and poststained with uranyl acetate and lead acetate. TEM measurements for the cells were performed on a JEOL JEM-100CXII microscope, and high-resolution TEM for the probe was performed on a JEOL JEM-2010 microscope.

RESULTS AND DISCUSSION

Scheme 1 shows the illustration of preparation of the nucleus targeted nanoprobe. EDC reacts with the carboxyl group on the modified nanoparticles, forming an amine-reactive O-acylisourea intermediate. This intermediate reacts with an amine on the peptide, yielding a conjugate of the two molecules joined by a stable amide bond (*24*). In our experiment, HPLC was employed to detect the NLS peptides, which were not conjugated to the gold nanoparticles and remained in the solution after the reaction. The result shown in the Supporting Information indicates that only a very small amount of the peptide molecules were detected and almost all of the peptide were immobilized on the gold surface because of the superfluous carboxyl group. Thus, the number of the peptide molecules per nanoparticle is ~700. More peptide coverage will lead to an increase of nuclear uptake (*25*) but may also influence Raman signal collection, as we have mentioned in the Introduction. High-resolution TEM images of the nanoprobe and naked nanoparticles are shown in Figure 1a,b, respectively. The functionalization resulted in a

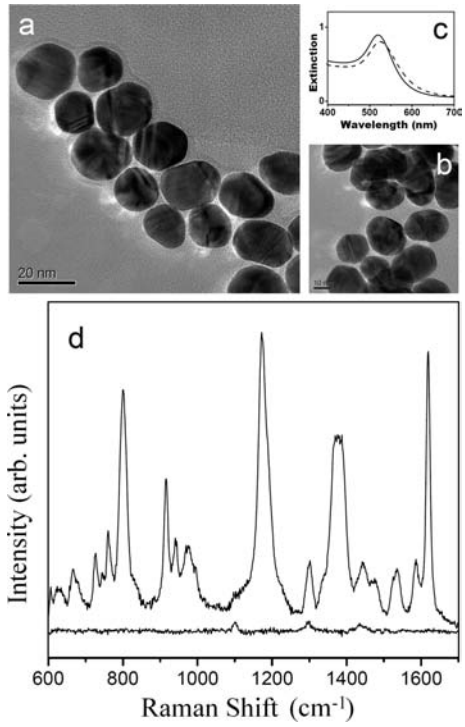


Figure 1. Transmission electron micrographs of the NLS peptide conjugated nanoparticle (nanoprobe) (a) and naked gold nanoparticles (b). (d) SERS spectra of the nanoprobe (lower spectrum) and CV (10^{-6} M) enhanced by the nanoprobe (upper spectrum).

low-contrast layer surrounding the metal and contributed a ~1.5 nm increment to the radius of the sphere. Figure 1c is the extinction spectra of the nanoparticles before and after the peptide modifying, obtained by using a Varian Cary 100 UV−vis spectrometer. The chemical change on the gold surface resulted in a 5 nm red shift of the surface plasmon because the citrate layer of the nanoparticles was disturbed by the conjugation. Also shown are the SERS spectra of the nanoprobe and its mixture together with 1×10^{-6} mM crystal violet (CV) (Figure 1d) obtained at an acquisition time of 1 s. The concentraton of the nanoprobe here is $10^{10}-10^{11}$ particles/mL, which is 15 times more than that of the nanoprobe used in the cell incubation. Although the signature of the nanoprobe is obtained at that condition, the relatively low SERS intensity of NLS peptide conjugated 11-MUA on the surface of the gold nanoparticles does not impose any notable influence on the SERS detection of CV. Theoretically, either chemical enhancement or electromagnetic enhancement emphasizes the adsorption or compact adjacency of the analyte and the metal surface (*26, 27*). The enhancement of CV by the nanoprobe indicates that the functionalization leads to a partial surface coverage of the gold nanoparticles and the product is capable of vibrational information delivery in aqueous solution.

Cultured cells were incubated with the nanoprobe as described in the Experimental Procedures, and the cell viability was tested by using FCM analysis in a broad concentration range of nanoprobe. The result shown in Figure 2 indicates that no evident apoptosis was caused by the nanoprobe even at a rather high concentration. Generally, after entry into the cell the NLS peptide will bring the particle to the nucleus by interaction with the pore complex and then cross the nuclear membrane (*20*). Raman mapping of living HeLa cells incubated with the targeting and control probe performed by the Jobon-Yvon system using a 50× long working distance objective is shown in Figure 3A. The mapping automatically merged by the

detection system contains an optical transmission image and a SERS image constructed by the total SERS intensity between 600 and 1700 cm^{-1}. These images only give the spatial information of the SERS. Several spectra which are selected as examples from 812 spectra (indicated by white arrows) in the mapping of the targeted cell will be discussed later. As shown

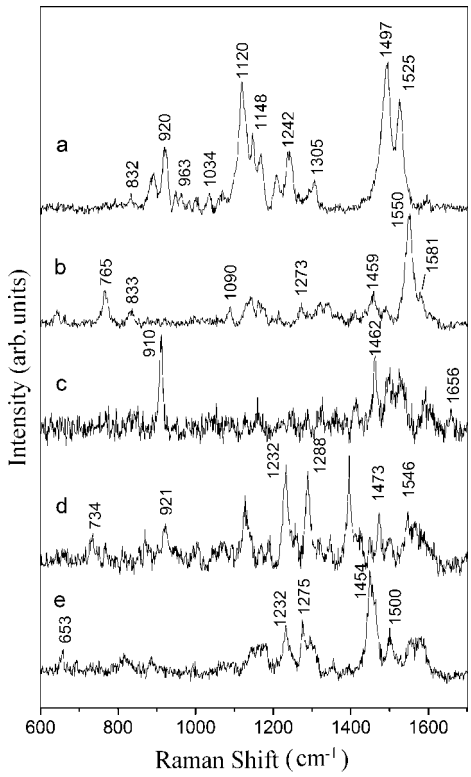

Figure 4. SERS spectra obtained from the nucleus of a single living cell incubated with the targeting nanoprobe at points 359, 334, 450, 506 and 532, respectively.

in the mapping, the SERS signals provided by the targeted probe tend to be in the center of the cell. In order to determine the distribution of the probe in the cell, or the position of the cell where the SERS signals come from, immediately after the SERS detection the cell was stained by Hoechst 33258, a bisbenzimide DNA intercalator which can highlight the nucleus by producing fluorescent emission at 461 nm while bound with DNA. The fluorescent image together with a differential interference contrast micrograph of the stained cell is presented in Figure 3 (B and C, respectively). It clearly shows in the figure that most of the SERS signals in the targeted mapping are generated in the location of cell nucleus and the signals in the control experiment are mainly from the cytoplasm. Additionally, in the electron micrograph (see Figure 3D) the nanoparticles were found inside the nucleus, which proves again that the nanoprobe is able to cross the nuclear membrane. Figure 3E is a typical electron micrograph of the nanoparticles inside the nucleus, and no evidence of membrane structure was found close by, which indicates that these nanoparticles were not in a special chemical environment inside the nucleus.

If this nanoprobe is to be a useful intracellular targeting tool, then one would expect to see the ability of chemical probing in the nucleus. Figure 4 shows the typical SERS spectra obtained from the cell nucleus at points 359, 334, 450, 506, and 532 of the mapping. Each of the spectra has received contributions originating from DNA backbone and bases. Deformations and rocking vibrations of CH_2 groups in deoxyribose appear at 1455−1462 cm^{-1} and 992−996 cm^{-1}, respectively. Spectrum a contains signatures of adenine base at 1305 cm^{-1} and of DNA backbone phosphate at 832 cm^{-1}, the frequency of both suggesting that the DNA molecule investigated has a right-handed double helix conformation, also known as the B form. Similar bands can also be found in spectra b and e, but no evidence of other DNA conformations (A and Z) was obtained during the experiment, which confirms that DNA of B form dominates

[a] Based on *refs* 12−14, 28, 29. [b] Abbreviations: ν, stretching; δ, deformation; ρ, rocking; γ, twisting; ω, wagging; s, symmetrical; Tyr, tyrosine; Phe, phenylalanine; Pro, proline; A, adenine; T, thymine; C, cytosine; G, guanine.

the cell nucleus. On the other hand, the SERS spectra also give conformational information on proteins, another main component of the nucleus. Spectrum c shows an amide I band at 1656 cm^{-1}, which indicates a protein α-helix. In spectra d and e, both characteristics of α-helix and β-sheet conformations are found according to amide III contributions at 1275 (α-helix) and 1232 cm^{-1} (β-sheet). The detailed SERS band assignments for these spectra are given in Table 1.

In addition to the detection of the original components in the nucleus, the nanoprobe is also propitious to deliver vibrational information from molecules intruded. The living cells were stained with DAPI, a DNA intercalator with great SERS activity, immediately after incubation with the nanoprobe, and SERS mapping was performed subsequently. Figure 5 shows the image recorded based on the band intensity at 1615 cm^{-1}, which is assigned to C═N stretching of DAPI in the nucleus. Characteristic DAPI signatures acquired outside using the nanoprobe are presented as trace A together with the SERS spectrum of DAPI obtained inside the stained nucleus at mapping point 510 for comparison. Both spectra show very similar SERS features of DAPI except for some band shifting due to the minor-groove binding at adenine−thymine sites of DNA. Typically, the C═N stretching vibration at 1607 cm^{-1} (spectrum A) shifted to 1615 cm^{-1} in spectrum B, which is very likely associated with the formation of conjugated systems between DAPI and DNA bases. Besides DAPI signatures, spectrum A also shows various contributions from cellular components. For example, the band at 1405 cm^{-1} can be assigned to symmetrical stretching vibration of COO^- in protein, and band 735 cm^{-1}

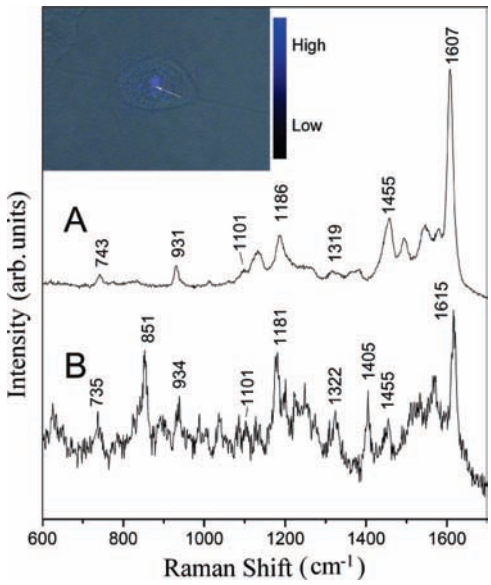

Figure 5. SERS spectra of DAPI obtained in solution (10 μg/mL) mixed with the NLS functionalized gold nanoparticles (A) and in a living cell nucleus (stained by DAPI) (B). The inset shows the SERS image which was collected according to the Raman intensity at 1615 cm^{-1}. The arrow indicates point 510 where spectrum B was obtained. Acquisition time: 1 s.

is a SERS characteristic of adenine. The targeting nanoprobe entered the cell before DAPI did, and the gold surface was still available for DAPI vibration to be enhanced. This result indicates that the gold surface has not been blocked even inside nucleus and the nanoprobe is capable of delivering real-time chemical changes in its vicinity.

CONCLUSIONS

We have demonstrated a targeting probing method for nucleus detection in living cells. The SV-40 large T NLS peptide functionalized gold nanoparticles can locate effectively at the cell nucleus after incubation with the cultured cells, allowing molecular probing of the nuclear components in vivo. Our SERS data provide abundant structural information for both nucleic acids and proteins without notable disturbance attributed to the functionalization. Moreover, by using DAPI as a test sample, we show that the targeting probe can also deliver the vibrations from molecules intruded subsequently, which enables this method to be a real-time targeting detection technique. The nanoprobe described in this study has the potential to be used in the research of drug delivery and cancer therapy.

ACKNOWLEDGMENT

W. Xie thanks the National Science Foundation of China (grants no. 30772058 and no. 20705025) for ongoing financial support of our work.

Supporting Information Available: HPLC result of the supernatant fluid after centrifugation in the preparation process of the nuclear targeted nanoprobe. This material is available free of charge via the Internet at http://pubs.acs.org.

HPLC (High Performance Liquid Chromatography) was employed to test the supernatant fluid after centrifugation in the preparation process of the nuclear targeted nanoprobe. This experiment was aimed at detecting the NLS peptides which were not conjugated to the gold nanoparticles and thus to determine the average number of NLS molecules on each nanoparticle.

Experimental Information

Column: 250*4.6 mm, Kromasil Normal phase C18-5 μm.

Mobile Phase A: 0.1% trifluoroacetic in water.

Mobile Phase B: 0.1% trifluoroacetic in acetonitrile.

Gradient:

Time(min)	A	B
0.1	90%	10%
15	80%	20%
15.01	0	100%
20	STOP	

Flow rate: 1.0 ml/min.

Wavelength: Sig=220 nm, Ref=399 nm.

Volume: 10 μL (The samples, including the supernatant fluid and the control, are lyophilized and redissolved to achieve a proper concentration for the detection).

Result

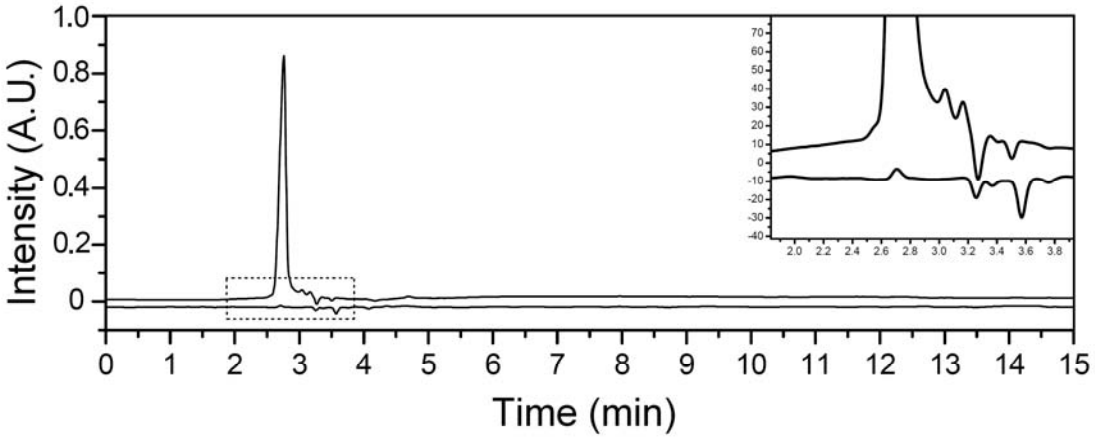

Figure 1. HPLC elution data of NLS peptide in the supernatant fluid after conjugating with 11-mercaptoundecanoic acid modified gold nanoparticles (lower line) and control experiment by using water instead of modified gold nanoparticles (upper line). The insert illustrates the data within the dashed pane.

Synthesis and Characterizations of New Lysine-Based Biodegradable Cationic Poly(urethane-co-ester) and Study on Self-Assembled Nanoparticles with DNA

Zheng-Yan Jian,[†] Jiunn-Kae Chang,[‡] and Min-Da Shau*[,‡]

Department of Chemical Engineering, National Cheng Kung University, Tainan 70101, Taiwan, and Department of Biotechnology, Chia-Nan University of Pharmacy and Science, Tainan 71710, Taiwan. Received November 19, 2008; Revised Manuscript Received February 16, 2009

To improve the self-assembly efficiency of nanoparticles with DNA, we synthesized lysine-based poly(urethane-co-ester) PMMD (**6**) and polyester PDMA (**8**) bearing ester linkages in the backbone and tertiary amines in the side chain. Both poly(urethane-co-ester) PMMD (**6**) and polyester PDMA (**8**), readily self-assembled with plasmid DNA (pCMV-β-gal) in HEPES buffer, were characterized by dynamic light scattering and zeta-potential. The results reveal that PMMD (**6**) and PDMA (**8**) were able to self-assemble particles with DNA and yield complexes with positive charges of 80−115 nm and 170−180 nm in size at mass ratios (W/W) of 2/1 and 20/1, respectively. The degradation studies indicate that the half-life of PMMD (**6**) in the HEPES buffer was 20 h at pH 7.4. Titration studies were performed to determine the buffering capacities of the polymers. In addition, the COS-7 cell viabilities in the presence of PMMD/DNA, PDMA/DNA, and PEI/DNA were studied. The results indicate that PMMD (**6**) is an attractive cationic poly(urethane-co-ester) for gene delivery and an interesting candidate for further study.

INTRODUCTION

Plasmid DNA has great potential as a therapeutic agent and in new vaccines (*1*). DNA-based pharmaceuticals largely depend on the characteristics of the delivery systems (*2*). To achieve controlled delivery of DNA to the target, vectors have been substantially developed. Because viral vectors have drawbacks such as the random insertion of viral sequences into the host chromosomes, indication of immunological responses, and limitations associated with DNA size, considerable attention has been given to nonviral vectors. Polycations (*3*−*9*) have been widely investigated in nonviral gene delivery in a variety of materials. Cationic polymers condense DNA into nanoparticles small enough to enter a cell, and protect negatively charged strands of DNA from nuclease degradation. Cytotoxicity and nonbiodegradability are concerns for long-term safety. Several amine-containing polymers, such as poly(urethane) (*4*, *10*), poly(2-(dimethylamino)ethyl methacrylate) (PDMAEMA) (*11*), poly(amido-amine) (*12*, *13*), poly(ethylene imine) (PEI) (*14*), poly(*N*-methyldietheneamine sebacate) (*15*), poly(amido ethylenimine) (*16*), PAMAM-PEG (*17*), and poly(ethylene glycol)s (*18*), have been synthesized. Release of the delivery vehicle from these sections into the cytoplasm is believed to be the limiting step in the transfection mediated by many cationic polymers (*19*). Molecular weights of polymers and the polymer/DNA ratio have been shown to be important for transfection efficiency. The molecular weight of a polymer affects the affinity between the cation-chain of the polymer and the anion-strand of DNA (*20*, *21*). Polyesters are biodegradable biomaterials that are used in a wide range of applications, including the controlled release of DNA-based therapeutic agents. These include the controlled degradation of the polymer and a great diversity of side groups and backbones. In this study, amine-containing polyester (PDMA) and poly(urethane-co-ester) (PMMD) were designed and synthesized. Their structures in correlation to DNA condensation capacity, biodegradability, and cytotoxicity are discussed in this article.

MATERIALS AND METHODS

Materials. 1,4-Butanediol diacrylate was purchased from Lancaster. L-Lysine methyl ester diisocyanate was from LDI, Kyowa Hakko Kogyo, Japan. 2-Hydroxyethyl acrylate (HEA), *n*-hexane, 2-dimethyaminoethylamine (DMAE), and glutaraldehyde were obtained from Fluka Co. (Switzerland). The solvent of *N*,*N*-dimethylformamide (DMF, Tedia co., USA) was dried over calcium hydride and distilled just before use. *N*-[2-Hydroxyethyl] piperazine-*N*′-[2-ethanesulfonic acid] (HEPES) was obtained from Sigma Co. (USA). *N*-Methyl dibenzopyrazine methyl sulfate (electron-coupling reagent) and sodium (2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-2*H*-tetrazolium-5-carboxanilide) (XTT) were purchased from Roche Co. (USA). The plasmid pCMV-LacZ (pCMV-βgal) (*4*, *22*) contained a CMV promoter to drive β-galactosidase (LacZ) gene expression (*4*, *14*, *23*). The plasmid DNA was amplified in *Escherichia coli* (DH5α strain) and purified using column chromatography (Qiagen Plasmid Mega kit, Germany). The purified plasmid DNA was dissolved in a tris(hydroxymethyl) methylamine-ethyldiaminetetraacetic acid (Tris-EDTA) buffer (pH 8.0) and determined using the ratio of UV absorbance at 260 nm/280 nm. Monkey SV40 transformed kidney fibroblast COS-7 cells were obtained from American type Culture Collection (ATCC, CRL-1651). The cells were cultured in Dulbecco's modified Eagle's medium (DMEM, GibcoBRL Co., Ltd.) supplemented with 10% FBS, 4.5 g/L glucose, 1.5 g/L sodium bicarbonate, and 4 mM L-glutamine, and maintained at 37 °C in a humidified 5% CO_2-containing atmosphere.

Polymer Characterizations. The structures of the polymers were characterized by nuclear magnetic resonance (NMR, Bruker AMX-400 spectrometer) and Fourier transform infrared (FT-IR, Mattson Galaxy Series 5000 spectroscope). The molecular weight and distribution of the polymer was determined

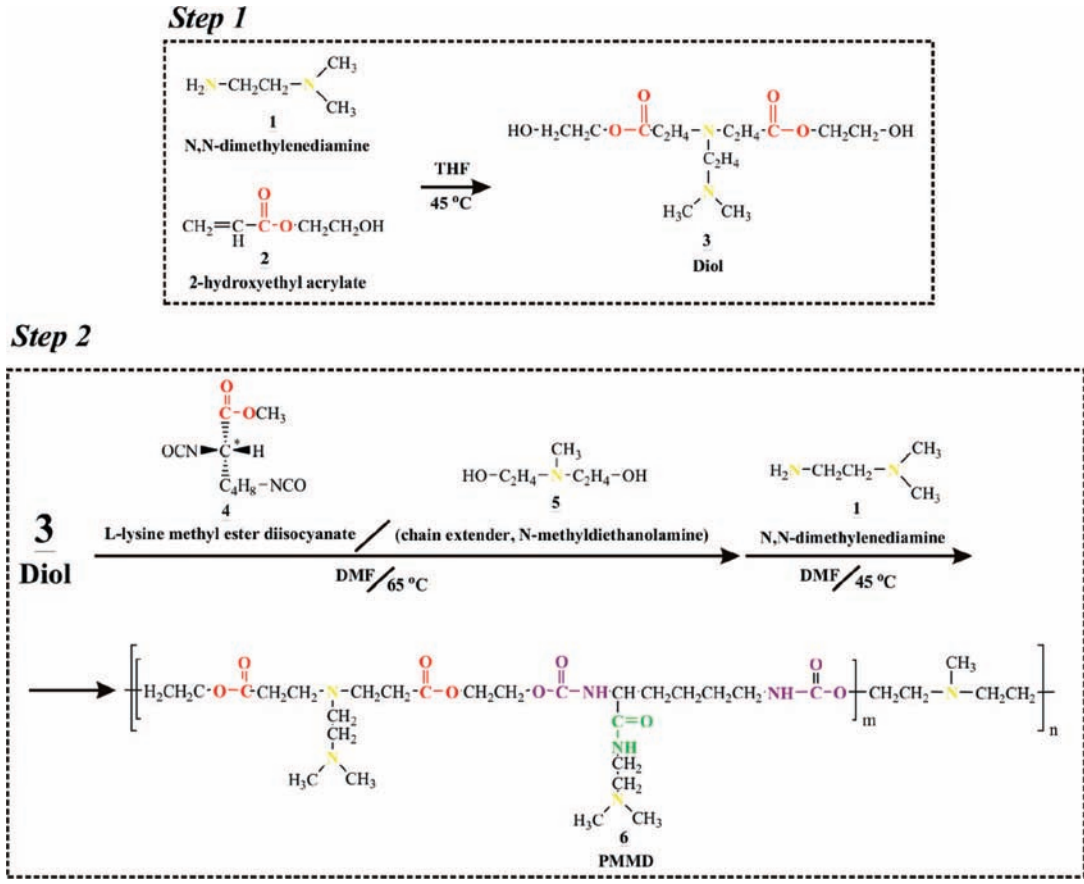
Scheme 1. Synthesis Scheme of PMMD



by gel permeation chromatography analysis (GPC, Waters Model LC-2410) based on polystyrene standards in THF.

Synthesis of PMMD (6). PMMD (**6**) was synthesized as shown in Scheme 1. HEA (**2**) and DMAE (**1**) with a molar ratio of 2/1 (-C═C/-NH_2) were mixed in THF in a three-necked reaction flask under a dry nitrogen purge and then heated to 45 °C to react for 24 h. The product was precipitated in anhydrous ethyl ether and vacuum-dried at 40 °C. The purity of diol (**3**) was about 98%. The diol (**3**) and polymers were characterized by FT-IR, ^{1}H NMR, and ^{13}C NMR.

Diol (3). ^{1}H NMR (400 MHz, d_6-DMSO, ppm) δ: 4.6 (1H, -$CH_2CH_2O\underline{H}$), 2.3−2.5 (6H, -$C\underline{H}_2C\underline{H}_2$-, -$C\underline{H}_2CH_2COO$-), 3.1 (2H, -$C\underline{H}_2COO$-), 4.1 (2H, -$COOC\underline{H}_2$-), 3.7 (2H, -$C\underline{H}_2OH$), 2.2 (6H, -$N(C\underline{H}_3)_2$). ^{13}C NMR (400 MHz, d_6-DMSO, ppm) δ: 57.5 (-$COOCH_2\underline{C}H_2$-), 60.2 (-$COO\underline{C}H_2CH_2$-), 53.9 (-$\underline{C}H_2COO$-), 59.3 ($N\underline{C}H_2CH_2$-), 58.9 ($N\underline{C}H_2CH_2N(CH_3)_2$), 59.1 ($NCH_2$-$\underline{C}H_2N(CH_3)_2$), 44.2 (-$N(\underline{C}H_3)_2$), 174.5 (-$\underline{C}OO$-).

The monomers of diol (**3**) and LDI (**4**) with an -OH/-NCO molar ratio of 2/1 were mixed and then heated to 70 °C to react using 0.5 wt % dibutyltin dilaurate as a catalyst. The chain extension was carried out by slowly adding MDEA (*N*-methyldiethanolamine) (**5**) to the isocyanate-terminated prepolymer until the -NCO/-OH molar ratio was 1/1. PMMD (**6**) was synthesized through the aminolysis reaction as previously reported (*4*).

PMMD (6). ^{1}H NMR (400 MHz, d_6-DMSO, ppm) δ: 2.0−2.2 (3H, $NC\underline{H}_3$), 2.3−2.5 (4H, -$C\underline{H}_2C\underline{H}_2N$), 3.1 (2H, -$C\underline{H}_2COO$-), 3.7−4.2 (4H, -$OC\underline{H}_2C\underline{H}_2O$-), 3.0 (1H, -$C\underline{H}CONH$-), 1.3−1.8 (6H, -$C\underline{H}_2C\underline{H}_2C\underline{H}_2$-), 3.6 (2H, -$C\underline{H}_2NHCOO$-), 3.7−4.2 (2H, -$NHCOOC\underline{H}_2$-), 3.6 (2H, -$CONHC\underline{H}_2$-), 5.3 (1H, -$CH_2N\underline{H}$-COO-), 5.7 (1H, -$COON\underline{H}CH$-), 7.0 (1H, -$CON\underline{H}CH_2$-). ^{13}C NMR (400 MHz, d_6-DMSO, ppm) δ: 43.7 ($N\underline{C}H_3$), 56.1 (-$CH_2\underline{C}H_2N$), 40.3 (-$\underline{C}H_2NHCOO$-), 22.3 (-$CH_2CH_2\underline{C}H_2CH_2NH$-COO-), 29.2 (-$CH_2\underline{C}H_2CH_2CH_2NHCOO$-), 31.8 (-$\underline{C}H_2CH_2$-$CH_2CH_2NHCOO$-), 53.6 (-$OOCNHC\underline{H}$), 36.5 (-$CONH$-$\underline{C}H_2CH_2N$), 58.6 (-$CONHCH_2\underline{C}H_2N(CH_3)_2$), 44.6 (-$CONH$-$CH_2CH_2N(\underline{C}H_3)_2$), 57.5 (-$CH_2COOCH_2\underline{C}H_2OOCNH$-), 60.2 (-$CH_2COO\underline{C}H_2CH_2OOCNH$-), 53.9 ($NCH_2\underline{C}H_2COO$-), 59.3 ($N\underline{C}H_2CH_2COO$-), 58.9 ($N\underline{C}H_2CH_2N(CH_3)_2$), 59.1 ($NCH_2$-$\underline{C}H_2N(CH_3)_2$), 44.2 ($NCH_2CH_2N(\underline{C}H_3)_2$), 156.1 (-$NH\underline{C}OO$-), 156.7 (-$OO\underline{C}NH$-), 162.5 (-$\underline{C}ONH$-),174.5 (-$\underline{C}OO$-).

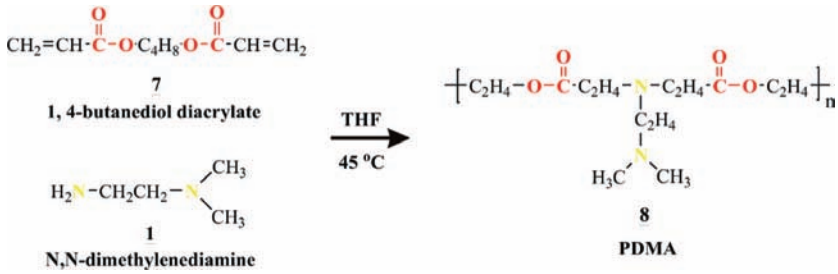
Synthesis of PDMA (8). PDMA (**8**) was synthesized via standard steps as shown in Scheme 2. 1,4-Butanediol diacrylate was added to (DMAE) (**1**) according to the method of Ferruti et al. (*3*, *24*, *25*).

PDMA (8). ^{1}H NMR (400 MHz, d_6-DMSO, ppm) δ: 3.7 (2H, -$COOCH_2C\underline{H}_2$-), 4.1 (2H, -$COOC\underline{H}_2CH_2$-), 3.1 (2H, -$C\underline{H}_2$-COO-), 2.3−2.5 (6H, -$C\underline{H}_2C\underline{H}_2$-, -$C\underline{H}_2CH_2COO$-), 2.2 (6H, -$N(CH_3)_2$). ^{13}C NMR (400 MHz, d_6-DMSO, ppm) δ: 57.5 (-$COOCH_2\underline{C}H_2$-), 60.2 (-$COO\underline{C}H_2CH_2$-), 53.9 (-$\underline{C}H_2COO$-), 59.3 ($N\underline{C}H_2CH_2$-), 58.9 ($N\underline{C}H_2CH_2N(CH_3)_2$), 59.1 ($NCH_2$-$\underline{C}H_2N(CH_3)_2$), 44.2 (-$N(\underline{C}H_3)_2$), 174.5 (-$\underline{C}OO$-).

Acid−Base Titration Assay of Polymers. Acid−base titration was used to evaluate the buffering capacity of synthesized cationic polymers. In this assay, 10 mg of PMMD (**6**) was dissolved in 10 mL of 150 mM NaCl. One hundred microliters of 1 N NaOH was then added to the solution to adjust the PH to 11.6 before it was titrated with acid. The solution was titrated with increasing volumes of 0.1 N HCl solutions, and the results were measured using a pH meter. The pH range of PDMA (**8**) was determined using the same procedure.

Hydrolytic Degradation of Polymers. PDMA (**8**) and PMMD (**6**) were dissolved in a buffer solution (pH 7.4 and pH 5.1) with a concentration of 10 mg/mL and then incubated in a water bath at 37 °C for various durations. After hydrolysis for various durations, the solution was dried in vacuum for several

Scheme 2. Synthesis Scheme of PDMA



hours to remove water. The molecular weight of the polymer was determined using gel permeation chromatography (GPC).

XTT Assay. The influence of the polymer concentration on cell viability was evaluated in a cell culture for various polymers. The cytotoxicities of PDMA (**8**)/DNA and PMMD (**6**)/DNA for comparison with that of PEI/DNA were evaluated using the XTT assay (*4*, *22*). In a 96-well plate, COS-7 cells were cultured in complete DMEM and then seeded at a density of 1.0×10^4 cells/well. The cells were incubated at 37 °C and 5% CO_2 in a humidified atmosphere for 24 h. Subsequently, the cells were incubated for 1 h in 200 μL of FBS-free DMEM containing polymer with various concentrations. The cells were incubated in DMEM as a negative control. After 1 h, the cells were washed with 200 μL of PBS solution and replaced by complete DMEM for a further 48 h of incubation. Then, 50 μL of XTT labeling mixture was added to each well, and the cells were further incubated at 37 °C for 1 h. Results are expressed as the relative cell viability (%) with respect to control wells containing culture medium.

Formation of Polymer/DNA Complexes. The polymer (10.0 mg/mL) was dissolved in 20 mM HEPES buffer (pH7.4), and its serial dilutions were made with the mass ratio of PMMD (**6**)/DNA (w/w) from 1/2 to 50/1. The complexes were then allowed to self-assemble in the HEPES buffer. They were incubated at room temperature for 30 min before measurements.

Characterizations of Polymer/DNA Complexes. The particle sizes and surface charges of the polymer/DNA complexes were determined by dynamic light scattering (Nicomp 380 system, USA) and electrophoretic mobility at 25 °C with a Zeta-potential system (Nicomp Instrument, USA).

DNA Gel Retardation Assay of Polymer/DNA Complexes. PDMA (**8**)/DNA complexes and PMMD (**6**)/DNA complexes were loaded into a 0.7% agarose gel containing ethidium bromide (0.3 μg/mL) in a tris-acetate-EDTA (TAE) buffer and electrophoresis performed at 100 V for 45 min. After electrophoresis, the DNA bands were visualized using UV-irradiation. PDMA (**8**)/DNA complexes and PMMD (**6**)/DNA complexes with ratios of 0.5/1, 1/1, 2/1, 3/1, 4/1, 5/1, 6/1, 20/1, and 50/1 (w/w) were prepared.

RESULTS AND DISCUSSION

Structural Characterizations of Diol (3), PMMD (6), and PDMA (8). Diol ($C_{14}H_{28}O_6N_2$), PMMD ($(C_{26}H_{48}O_9N_6)_m$-$C_5H_{11}N_1)_n$, and PDMA ($(C_{14}H_{26}O_4N_2)_n$ were synthesized as shown in Schemes 1 and 2. The synthesis of diol (**3**) containing tertiary amine in the backbone, in accordance with the synthesis of poly(amido amine), was reported by Ferruti et al. (*3*, *24*, *25*). Figure 1 shows the FT-IR spectra of the synthesized diol (**3**) and starting materials. The peaks at 3400 cm^{-1} (-OH, stretching, hydrogen bond), 1650 cm^{-1} (-C = C, stretching, alkene), and 1640 cm^{-1} (-NH_2, amide) disappeared from the starting materials, and a peak at 1740 cm^{-1} (C═O, stretching, ester) of diol (**3**) was observed. Figure 2 shows the FT-IR spectra of the synthesized PMMD and PDMA. The peaks at 1720 cm^{-1} (C═O, stretching, urethane), 1668 cm^{-1} (C═O, stretching, amide), 1537 cm^{-1} (N−H, bending, amide), and 3340 cm^{-1} (N−H, stretching, urethane) represent the absorptions of urethane groups in PMMD (**6**), as shown at the top of Figure 2. The peak at 1740 cm^{-1} (C═O, stretching, ester) represents the absorption of ester induced from PDMA (**8**), as shown at the bottom of Figure 2. The chemical shifts of characterized protons and carbons of diol, PMMD, and PDMA are shown in the Materials and Methods section. In addition, the GPC data of PMMD (**6**) and PDMA (**8**) show that the weight-averaged molecular weights were 17600 and 16800 with polydispersities of 1.8 and 1.7, respectively, relative to polystyrene standards in THF.

Size and Zeta-Potential analysis of Polymer/DNA Complexes. Figures 3 and 4 show the size and zeta-potential of PMMD (**6**)/DNA and PDMA (**8**)/DNA complexes at various mass ratios, determined using dynamic light scattering (DLS) and electrophoretic mobility at 25 °C with zeta-potential analysis. The size of complexes decreased with an increase of the mass content of the polymers until the mass ratio of PMMD (**6**)/DNA reached 2/1 and that of PDMA (**8**)/DNA reached 20/1. The results show that the average diameters (80−115 nm) of PMMD (**6**)/DNA and the average diameters (170−180 nm) of PDMA (**8**)/DNA fall within the optimal range (40nm−200nm) required for cellular endocytosis (*26*). The above data demon-

Lanes: (1) 400 ng DNA; (2) PMMD/DNA and PDMA/DNA (w/w) 0.5/1; (3) PMMD/DNA and PDMA/DNA (w/w) 1/1; (4) PMMD/DNA and PDMA/DNA (w/w) 2/1; (5) PMMD/DNA and PDMA/DNA (w/w) 3/1; (6) PMMD/DNA and PDMA/DNA (w/w) 4/1; (7) PMMD/DNA and PDMA/DNA (w/w) 5/1; (8) PMMD/DNA and PDMA/DNA (w/w) 6/1; (9) PMMD/DNA and PDMA /DNA (w/w) 20/1; (9) PMMD/DNA and PDMA/DNA (w/w) 50/1.

strates that PMMD (**6**) bearing urethane groups in the backbone condenses DNA better than PDMA (**8**) without the urethane group.

The zeta-potential of the resulting complex changed from negative charge to positive charge when the amounts of PMMD (**6**) and PDMA (**8**) increased. When the mass ratio of PMMD (**6**)/DNA complexes was higher than 2/1, the surface of pCMV-β-gal was fully occupied with the PMMD (**6**) molecules, forming positive charge complexes. When the mass ratio of PDMA (**8**)/DNA complexes was higher than 10/1, positive zeta-potentials of the complexes formed. Complexes with extra

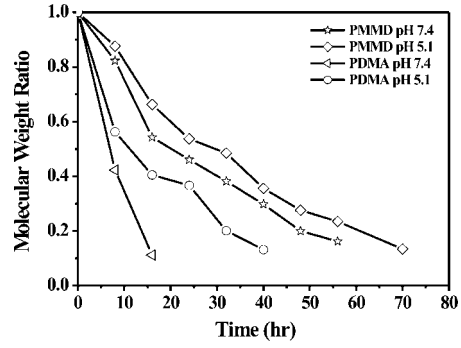

Figure 8. Hydrolytic degradation of PDMA (**8**) and PMMD (**6**), which were dissolved in a buffer solution (pH 7.4 and pH 5.1) with a concentration of 10 mg/mL and then incubated in a water bath at 37 °C for various durations. Degradation is expressed over time based on GPC data. (Molecular weight ratio: M_w after degradation/M_w before degradation).

positive charges on their surfaces had better interaction with the target cell membrane, resulting in an enhanced uptake.

DNA Gel Retardation Assay. The electrophoretic mobility behavior of free DNA, PMMD (**6**)/DNA, and PDMA (**8**)/DNA is shown in Figure 5. Increasing amounts of PMMD (**6**) and PDMA (**8**) led to the neutralization of DNA negative charges, as shown by gel retardation. The DNA mobility on agarose gel was influenced by the presence of PMMD (**6**) and PDMA (**8**). With a low mass ratio of PMMD (**6**) (2/1), plasmid DNA was totally retained, as indicated in lane 4. Plasmid DNA was partially retained by the presence of PDMA (**8**) at a mass ratio of 6/1 (lane 8) and totally retained at a mass ratio of 20/1 (lane 9). These results suggest that DNA was fully completed with PMMD (**6**) and PDMA (**8**) to form complexes, showing that amine groups of PMMD (**6**) and PDMA (**8**) with positive charges could interact with the charge of negative phosphate groups of DNA strands to form complexes.

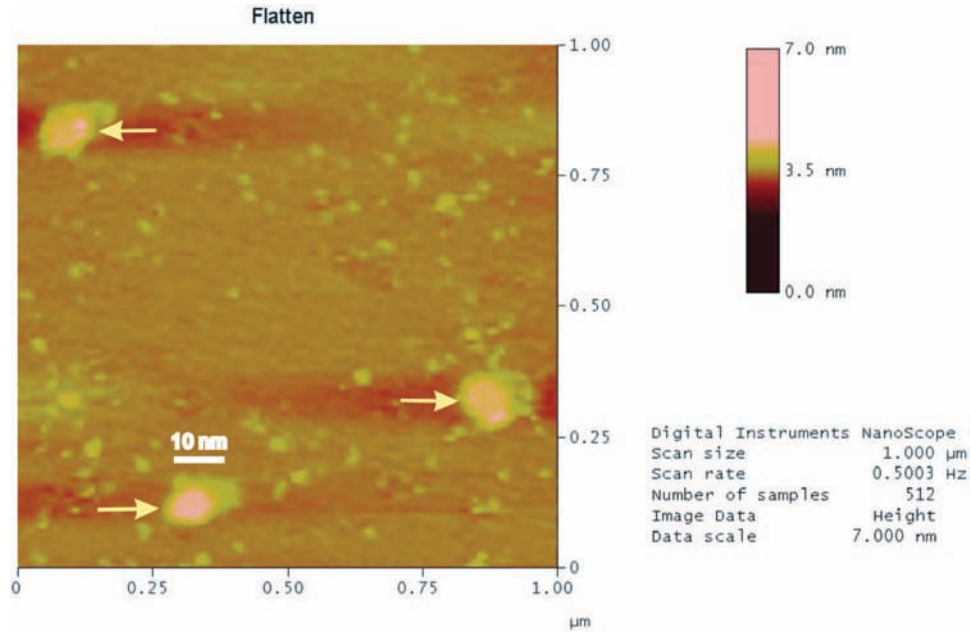

Figure 9. AFM (atomic force microscopy) of PMMD/DNA complexes at a mass ratio of 20/1.

Buffering Capacity of Polymers. Titration studies were performed to determine the buffering capacities of the various polymers regarding a proton buffering effect within the endosomal/lysosomal compartments of the cell (Figure 6). All of the polycation solutions had a pH of 11.5 to 11.8 after the addition of 1.0 N NaOH. The nonviral vector PEI showed a buffering capacity over a wide pH range, which is probably due to the high amount of amine functions present in the polymeric chain. The incorporation of tertiary amine content changed the buffering region of the polycation. PMMD (**6**) has more tertiary amine than PDMA (**8**) in the backbone and side chain. The data show the pH range of PMMD (**6**) to be between 11.5 and 5.4 and that of PDMA (**8**) to be between 11.5 and 7.5. It was found that the polymers with high tertiary amine content have a high buffering capacity.

Cytotoxicity of Polymer/DNA. A critical element for the gene delivery system is cytotoxicity. Cell damage resulting from a cytotoxic delivery system is deleterious because cells must be capable of supporting translation and transcription. To determine the cytotoxicity of PMMD (**6**)/DNA and PDMA (**8**)/DNA for comparison with that of PEI/DNA, we performed an XTT assay using the COS-7 cell line. Cells were incubated with increasing amounts of PMMD (**6**)/DNA and PDMA (**8**)/DNA (ranging from 5 μg/mL to 800 μg/mL) and PEI/DNA (ranging from 5 μg/mL to 20 μg/mL). The results show that PMMD (**6**)/DNA and PDMA (**8**)/DNA exhibited substantially lower toxicity on COS-7 cells than did PEI/DNA, as shown in Figure 7.

IC_{50} (defined as the concentration resulting in 50% inhibitory activity (cell death)) for PEI/DNA was around 15 μg/mL, whereas PMMD (**6**)/DNA and PDMA (**8**)/DNA had more than 75% viable cells even at a higher dose (800 μg/mL) with no significant change in cell morphology and proliferation relative to controls. We infer that poly(urethane-co-ester)/DNA can provide better cytotoxicity profiles than these presently used for PEI/DNA due to the introduction of amino groups and urethane units in the polycation backbone, which reduces the high charge density of the polycation.

In Vitro Hydrolysis of Polymers. Figure 8 shows the degradation profiles of polymers, which were monitored at 37 °C at buffer pH values of 5.1 and 7.4 in order to approximate the environments within endosmal vesicles and lysosome, respectively. The polymers generally degraded faster at pH 7.4 than at pH 5.1. PMMD (**6**) at pH 5.1 had a half-life of 32−33 h. In contrast, PDMA (**8**) was completely degraded in less than 16 h at pH 5.1. These results show that PDMA (**8**) exhibited a higher hydrolytic degradation rate than did PMMD (**6**) at pH 7.4 and 5.1.

AFM (Atomic Force Microscopy) Images of PMMD/DNA Nanoparticles. Figure 9 shows the atomic force microscopy (AFM) images of PMMD/DNA complexes at a mass ratio of 20/1. At a mass ratio of PMMD/DNA (20/1), nearly all complexes condensed to a roughly spherical shape. The discretely spherical images verify the very efficient DNA condensation obtained using PMMD. The AFM images of complexes were captured after the complexes were coated on mica and dried with compressed air. The observed dimensions, therefore, are different from the ones determined in aqueous media using DLS.

CONCLUSIONS

Poly(urethane-co-ester) (PMMD) with low cytotoxicity and high biodegradability was synthesized and then characterized using FT-IR, NMR, and GPC in this study. PMMD and DNA had a strong electrostatic interaction to self-assemble nanoparticles. The positive charges in the backbone and side chain of PMMD condense DNA to form DNA−polycation complexes. The complex efficiency was better than that of the polyester of PDMA, which resulted in numerous amine groups of PMMD with two tertiary amines in the backbone and two tertiary amines in the side chain. Biodegradable PMMD could potentially be used in a nonviral gene delivery system.

Synthesis of Linear Polyether Polyol Derivatives As New Materials for Bioconjugation

Zhongyu Li and Ying Chau*

Department of Chemical and Biomolecular Engineering, the Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong SAR, China. Received December 3, 2008

Linear polyether polyol (PEP) consisting of glycidol as repeating units is a flexible hydrophilic aliphatic polymer. The polyether main chain is similar to the widely used, biocompatible polymer poly(ethylene glycol) (PEG). While linear PEG has one or two terminal hydroxyl group(s), linear PEP distinguishes itself by the large number of pendant hydroxyl groups along the polyether main chain. We propose that this property of PEP represents a major advantage over PEG, namely, by providing multiple anchorage points and increasing the possibility for introducing different functional groups. As a first step to establishing PEP as a bioconjugation material, we modified the pendant hydroxyl groups on PEP and prepared a series of mono- and heterobifunctional derivatives with the potential to join various drug entities and biomolecules. The synthesis methods and the results of characterization are reported here.

INTRODUCTION

Poly(ethylene glycol) (PEG) is one of the most widely used bioconjugation materials nowadays in pharmaceutical and biomedical applications (*1*−*10*). It consists of ethylene oxide as repeating units, with one terminal hydroxyl group in the monomethoxy form (mPEG) or two in the unmodified form of PEG. PEG is useful for bioconjugation due to the following reasons: (i) lack of immunogenicity, antigenicity, and toxicity; (ii) high solubility in water and most organic solvents; (iii) extensive hydration and high flexibility of the main chain, which is at the basis of its antifouling property; and (iv) approval by FDA for human use. However, the presence of only one or two reactive groups at the ends of PEG chain means that only one or two entities (drug, peptide, protein, nucleic acid, and other biomolecules) can be attached onto PEG. This severely limits not only the loading capacity of such conjugate but also the design options for PEG-based drug-carrier systems. One solution is to arrange PEG chains into a branched architecture, such as star-like, hyperbranched, arborescent, and dendrimeric PEG (*11*−*16*). Alternating polyurethanes have also been prepared by polymerization of bis-succinate-PEG with amino acid containing three functional groups, such as lysine (*17*−*19*). However, these strategies require complicated synthesis procedures, and the number of reactive groups are still low.

Here, we take a different approach and start with linear polyether polyol (PEP). Composed of glycidol (and possibly ethylene oxide) as monomeric units, PEP is a flexible hydrophilic aliphatic polymer with multiple pendant hydroxyl groups along the main chain (Figure 1). The similarity in the polymer backbone with the extensively used PEG suggests that these two polymers may share the same characteristics of being hydrophilic, water-soluble, biocompatible, and resistant to protein adsorption (*2, 18*). In fact, it has been shown that both linear and hyperbranched polyglycidol are nontoxic and safe in vitro and in vivo (*20*−*22*).

From the point of chemical synthesis, PEP with low polydispersity and well-defined structure can be readily synthesized by anionic polymerization (*23*−*25*). By adapting existing methods of hydroxyl group modification, we convert the pendant hydroxyl groups into different functional groups to increase their reactivity (*2*). Since the number of hydroxyl groups can be controlled by the ratio of monomers during polymerization, we can readily vary the drug loading density on PEP at will. We also use orthogonal chemistry to synthesize a number of heterobifunctional PEPs to further increase the versatility of this polymer. The chemical varieties of the derivatives mean that different chemical agents and biomolecules including peptides and nucleic acids are amenable for attaching to PEP. The increased number of functional groups along the main chain enables this polymer to be more effective as a bioconjugation carrier than PEG, since (i) the payload is higher; (ii) multivalency is possible; (iii) colocalized delivery of different drugs and simultaneous presentation of biospecific ligands are allowed.

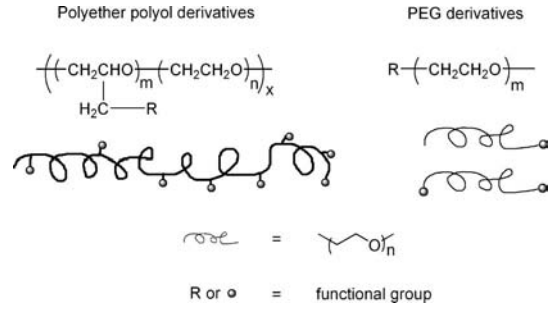

Figure 1. Polyether polyol derivatives and PEG derivatives.

MATERIALS AND METHODS

Materials. All starting compounds were used as received without additional purification except for those specified. Chemicals were purchased from Aldrich unless otherwise indicated. THF (Merck, 99%) was refluxed over sodium wire and distilled from sodium naphthalenide solution. Diethylene glycol monomethyl ether (Fluka, 99%) and DMSO (Merck, 98%) were distilled over CaH_2 under reduced pressure just before use. Ethylene oxide (EO, 99.7%) was purchased from Hong Kong Special Gas Company. Ethoxyethyl glycidyl ether (EEGE) and diphenylmethylpotassium (DPMK) were prepared

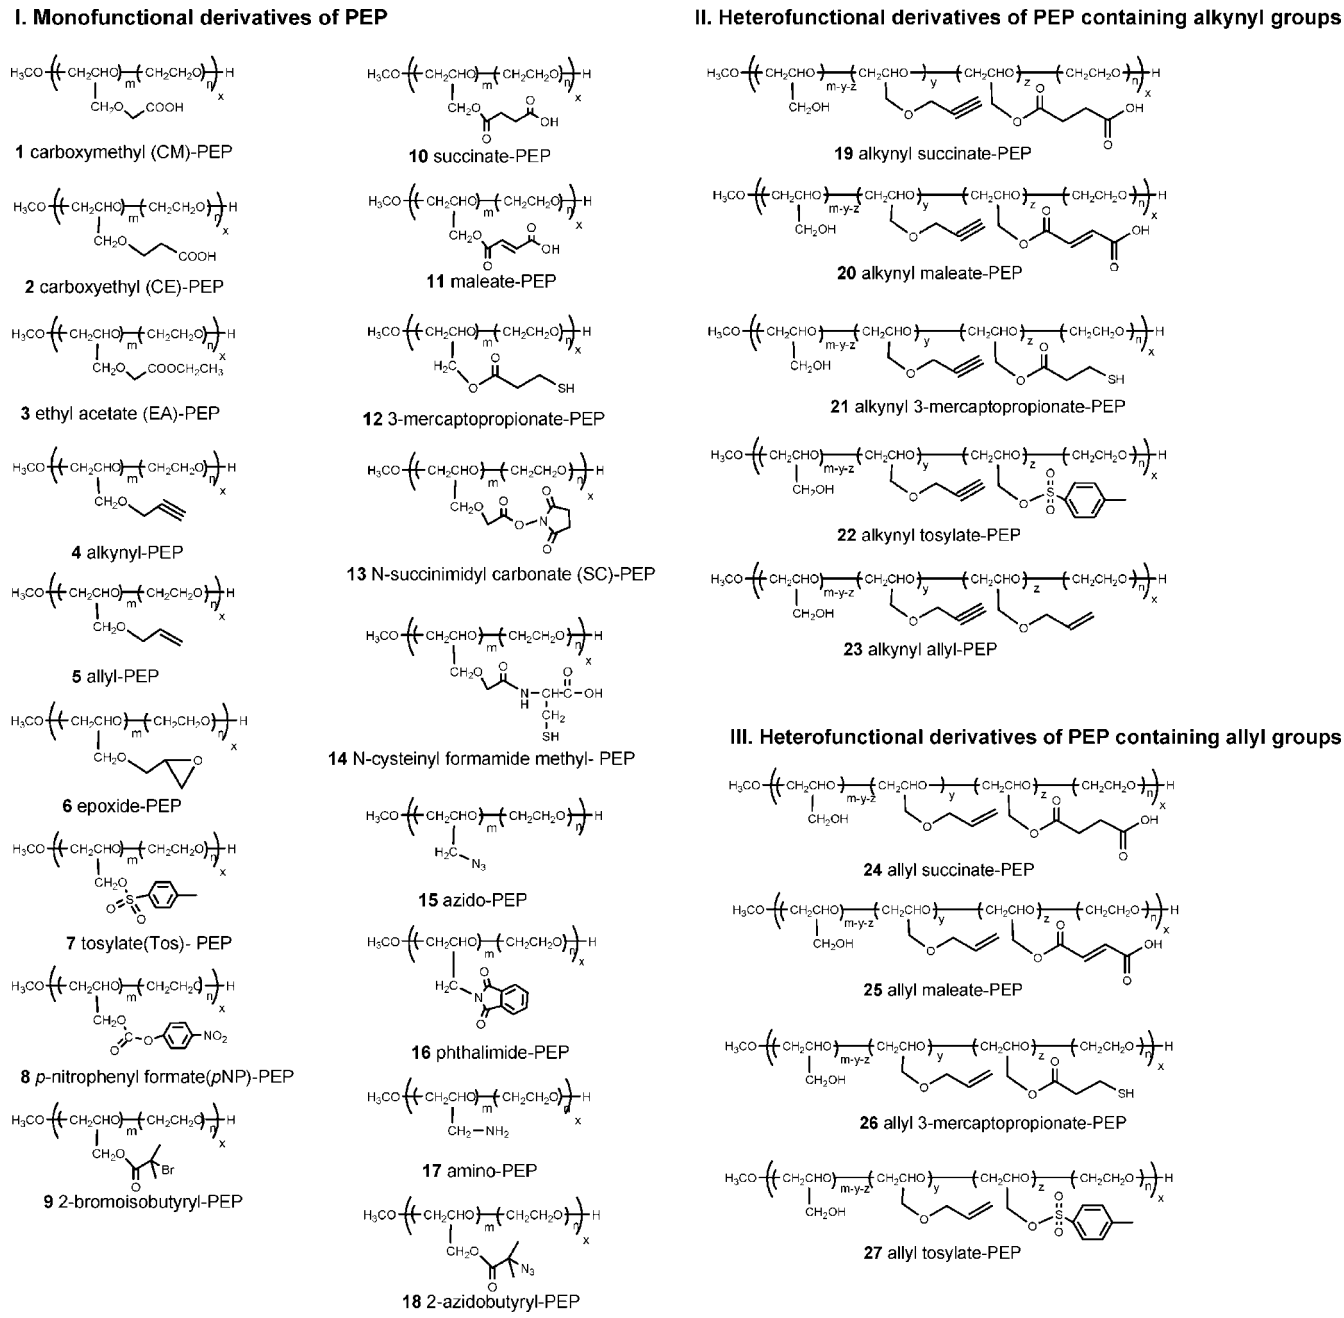

Figure 2. Structures and names of PEP derivatives that have been successfully synthesized and characterized.

as described elsewhere (*24*−*26*). An ultrafiltration separator and poly(ether sulfone) (PES) membranes with molar mass cutoff at 10k, 20k, 30k, and 50k g/mol as calibrated by globular proteins were purchased from the Shanghai Institute of Applied Physics, Chinese Academy of Sciences.

Methods. ^{1}H NMR and ^{13}C NMR spectra were obtained on a DMX 500 MHz spectrometer with tetramethylsilane (TMS) as the internal standard and $CDCl_3$ as the solvent. For poly(EEGE) and poly(EEGE-*co*-EO), gel permeation chromatography (GPC) was performed on a Waters HPLC system with a G1310A pump and a G1362A refractive index detector, using tetrahydrofuran (THF) as eluent at 35 °C with an elution rate of 1.0 mL/min. Two Styragel columns (HR 3 THF and HR4E THF, Waters) were calibrated by polystyrene standards (Polymer Source). For poly(Gly-*co*-EO), polyglycidol, and their derivatives, size exclusion chromatography (SEC) was performed in 0.1 M $NaNO_3$ at 40 °C with an elution rate of 0.5 mL/min on the same HPLC system. Ultrahydrogel 250 (Waters) and Ultrahydrogel 1000 (Waters) columns in series were calibrated by PEG standards (Polymer Source).

Synthesis of Polyether Polyol. Polyether polyol was synthesized in two steps similar to the published methods (*23*−*25*), except that EEGE molecules were used as monomers in addition to EO. PEEGE and poly(EEGE-*co*-EO) were first prepared using anionic polymerization. Acid deprotection of the precursor macromolecule afforded the homopolymer polyglycidol and the random copolymer poly(Gly-*co*-EO).

Poly(EEGE-co-EO). ^{1}H NMR (ppm) ($CDCl_3$): 1.19 (m, C**H**$_3$-CH_2-), 1.33 (d, -O-CH(C**H**$_3$)-O-), 3.38 (s, C**H**$_3$-O-), 3.45−3.85 (m, -C**H**$_2$C**H**$_2$O- and -C**H**$_2$C**H**O- of polyether polyol main chain and -C**H**$_2$-O-CH(CH_3)-), 4.69 (q, -O-C**H**(CH_3)-O-).

Poly(Gly-co-EO). ^{1}H NMR (ppm) ($CDCl_3$): 3.38 (s, C**H**$_3$-O-), 3.45−3.85 (m, -C**H**$_2$C**H**$_2$O- and -C**H**$_2$C**H**O- of polyether polyol main chain and the pendant -C**H**$_2$-OH groups). ^{13}C NMR (ppm) ($CDCl_3$): 58.3 **C**H_3-O-, 70.5−71.3 -**C**$H_2$$CH_2$O- and -**C**$H_2$CHO-, 80.4-$CH_2$**C**HO-, 60.7 and 63.9 -**C**H_2-OH.

Synthesis of Monofunctional Derivatives of Polyether Polyol. PEP derivatives are numbered according to Figure 2. Synthesis of the monofunctional derivatives of polyether polyol

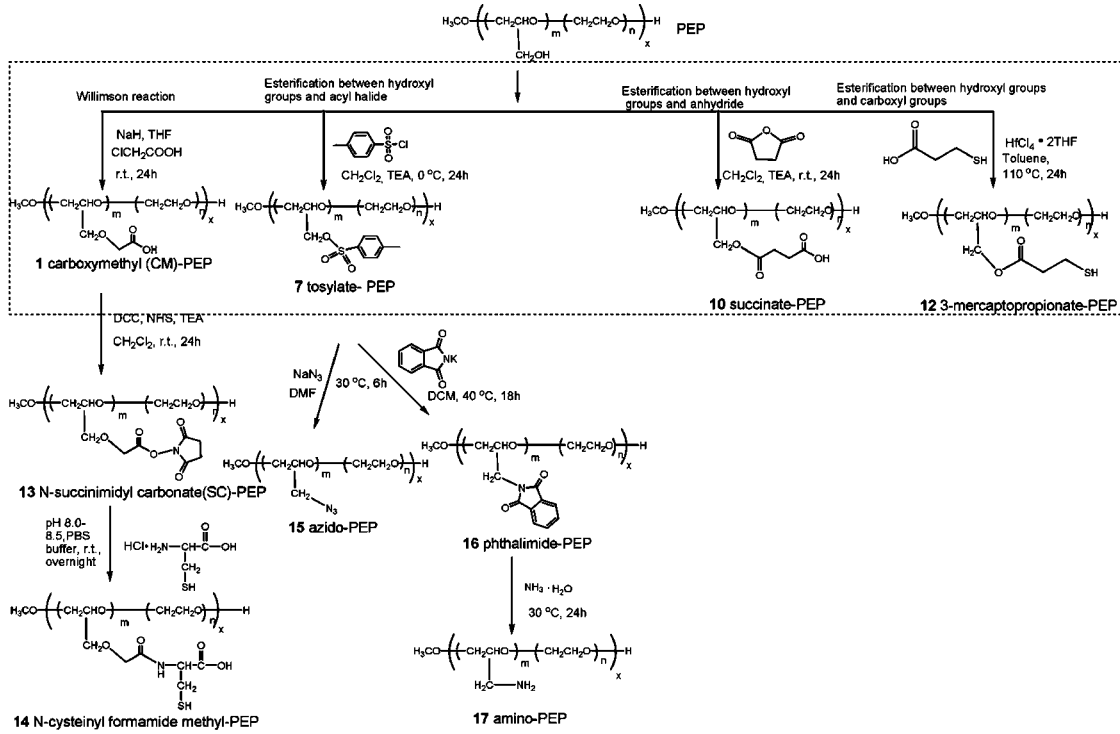

Figure 3. Chemical reactions and structures of the critical intermediate and final products resulting from the synthesis of monofunctional derivatives PEP. Representative PEP derivatives of each reaction type are shown as examples. Besides what is shown above, polyether polyol derivatives **2**−**6** were also synthesized by Williamson reaction, **8** and **9** by esterification between hydroxyl groups and acyl halide, and **11** by esterification between hydroxyl groups and anhydride groups.

(**1**−**18**) are summarized in Figure 3. The synthesis routes for PEP derivatives **1**−**12** can be classified into four categories: (1) Williamson reaction, (2) esterification between hydroxyl groups and acyl halide, (3) esterification between hydroxyl groups and anhydride, and (4) esterification between hydroxyl groups and carboxyl groups. PEP derivatives **13**−**18** are obtained by further reactions of PEP derivatives **1**, **7**, and **9**, respectively.

Williamson Reaction. Carboxymethyl (CM)-PEP (**1**), carboxyethyl(CE)-PEP (**2**), ethyl acetate (EA)-PEP (**3**), alkynyl-PEP (**4**), allyl-PEP (**5**), and epoxide-PEP (**6**) were synthesized by Williamson reaction to form ether bonds between the polymer and the residues (*27*−*31*). PEP derivatives **1**−**5** were synthesized in a homophase system, in which PEP reacted with 2-chloroacetic acid, 3-bromopropionic acid, ethyl bromoacetate, propargyl bromide, and allyl chloride respectively in THF with NaH (*27*). Synthesis of CM-PEP (**1**) shown in Figure 3, is described in detail here as a typical example. One gram PEP (M_n = 15.4 × 10^3 g/mol, 1.25 mmol hydroxyl groups) with moisture removed by azeotropic distillation with toluene just before use was reacted with 0.6 g NaH (2.5 mmol) in 10 mL anhydrous tetrahydrofuran (THF) at room temperature for 20 min, and then 0.43 g 2-chloroacetic acid (4.6 mmol) was added under vigorous stirring at room temperature for 24 h. After neutralization by hydrochloride solution, the solvent was removed by rotary evaporation. The product was purified by ultrafiltration. Filtered aqueous solution was concentrated to dryness, dissolved in dichloromethane (DCM), and dried over anhydrous $MgSO_4$. The filtrate was distilled under vacuum to remove DCM and dried in vacuo at 50 °C for 2 days, and a white product was obtained.

Epoxide-PEP (**6**) was synthesized in a heterophase system using tetrabutylammonium bromide (TBAB) as a phase transfer catalyst (PTC) (*29*). 0.5 g polyether polyol (M_n = 15.4 × 10^3 g/mol, 0.62 mmol hydroxyl groups), 0.018 g TBAB (0.055 mmol), and 0.248 g sodium hydroxide (6.2 mmol) in 5 mL of distilled water were mixed and reacted with 0.23 g epichlorohydrin (2.2 mmol) under vigorous stirring at 50 °C for 48 h. After the addition of 30 mL DCM, the organic phase was separated from the aqueous phase, dried over $MgSO_4$, filtered, and concentrated. The polymer was dissolved in water and purified by ultrafiltration. The filtered aqueous solution was concentrated to dryness, dissolved in DCM, and dried over anhydrous $MgSO_4$. The filtrate was distilled under vacuum to remove DCM and dried under vacuum at 50 °C for 2 days to afford a white product.

Esterification between Hydroxyl Groups and Acyl Halide. Tosylate (Tos)-PEP (**7**), *p*-nitrophenyl formate (*p*NP)-PEP (**8**), and 2-bromoisobutyryl-PEP (**9**) were synthesized by the esterification between PEP and *p*-toluenesulfonyl chloride(TsCl), *p*-nitrophenyl chloroformate, and 2-bromoisobutyryl bromide, respectively, in DCM with triethylamine (TEA) as a catalyst (*24*, *32*−*34*). Synthesis of Tos-PEP, as shown in Figure 3, is described here in detail as a typical example. Two grams of PEP (M_n = 15.4 × 10^3 g/mol, 2.5 mmol hydroxyl groups) with moisture removed by azeotropic distillation with toluene was reacted with 0.629 g *p*-toluenesulfonyl chloride (3.3 mmol) in the presence of 0.3 mL TEA in 10 mL anhydrous DCM at 0 °C for 24 h. The solvent was removed by rotary evaporation. The product was purified by ultrafiltration. The white precipitate of triethylamine hydrochloride was filtered off and washed with DCM. Filtered aqueous solution was concentrated to dryness, dissolved in DCM, and dried over anhydrous $MgSO_4$. The filtrate was distilled under vacuum to remove DCM and dried in vacuo at 50 °C for 2 days to yield a white product.

Esterification between Hydroxyl Groups and Anhydride Groups. Succinate-PEP (**10**) and maleate-PEP (**11**) were synthesized by the esterification (*35*−*37*) between PEP and succinic anhydride and maleic anhydride, respectively, in DCM with TEA as a catalyst. Synthesis of Succinate-PEP, as shown in Figure 3, is described here in detail as a typical example (*35*). 0.5 g PEP (M_n = 15.4 × 10^3 g/mol, 0.62 mmol hydroxyl groups) with moisture first removed by azeotropic distillation with toluene was reacted with 0.177 g succinic anhydride (1.77 mmol) in the presence of 0.1 mL TEA in 10 mL DCM at room temperature or 24 h. The solvent was removed by rotary evaporation. The product was purified by ultrafiltration. Filtered aqueous solution was concentrated to dryness, dissolved in

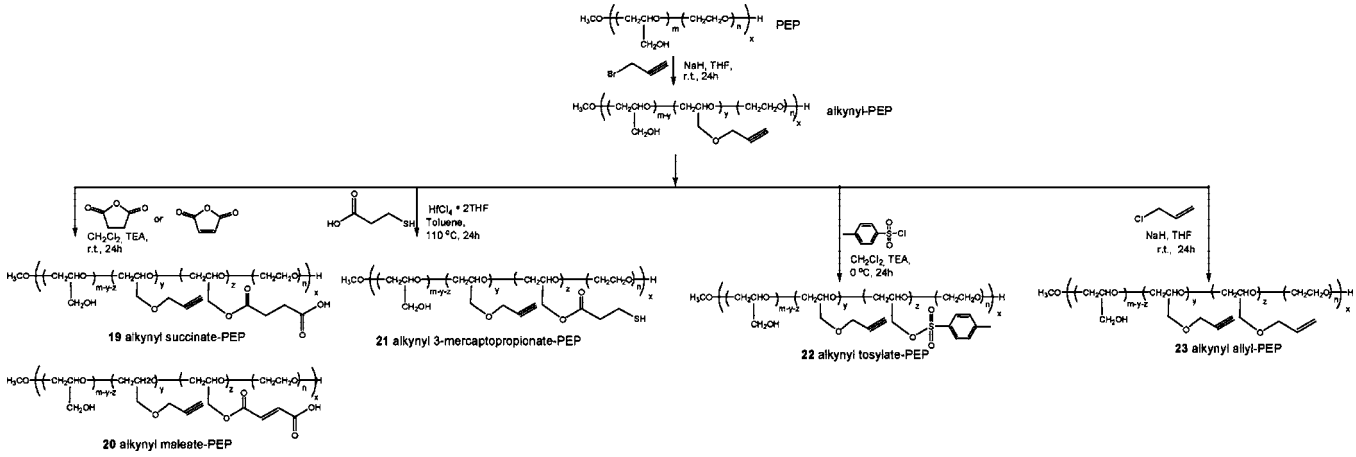

Figure 4. Synthesis of heterobifunctional polyether polyol derivatives containing alkynyl groups. (Similar methods are fit for synthesis of heterobifucntional PEP derivatives containing allyl groups).

DCM, and dried over anhydrous $MgSO_4$. The filtrate was distilled under vacuum to remove DCM and dried in vacuo at 50 °C to yield a white product.

Esterification between Hydroxyl Groups and Carboxyl Group. 3-Mercaptopropionate-PEP (**12**) was synthesized by the esterification (*38, 39*) between PEP and 3-mercaptopropionic acid. A typical experiment (Figure 3) was as follows: 2 g PEP ($M_n = 15.4 \times 10^3$ g/mol, 2.5 mmol hydroxyl groups) was dissolved in 20 mL toluene; then, 0.318 g 3-mercaptopropionic acid (MPA) (3 mmol) along with $HfCl_4 \cdot 2THF$ (2 mg, 0.004 mmol) were added and stirred at 50 °C under nitrogen. The reaction flask was equipped with an azeotropic distillation apparatus, and the mixture was refluxed at 110 °C under nitrogen for 24 h. Toluene was removed under reduced pressure. The crude product was dissolved in ethanol and was purified by an ultrafiltration membrane to remove low molar mass impurities under the pressure of nitrogen. Finally, ethanol was removed from the product by distillation and the remains were dried in vacuo at 50 °C for 2 days to afford a white product.

Other Reactions. N-Succinimidyl carbonate (SC)-PEP (**13**) was derived from CM-PEP (**1**) using a procedure adapted from Zalipsky et al. (*40*) Two grams CM-PEP ($M_n = 16.5 \times 10^3$ g/mol, 2.3 mmol carboxyl groups) was reacted with 0.824 g *N*,*N*′-dicyclohexylcarbodiimide (DCC, 4 mmol) and 0.46 g *N*-hydroxysuccinimide (NHS, 4 mmol) in the presence of 0.2 mL TEA in 10 mL DCM at room temperature for 24 h. The crude product was concentrated and filtered to remove the byproduct 1,3-dicyclohexylurea (DCU). The filtered solution was precipitated in diethyl ether. The product was redissolved in DCM and precipitated again in diethyl ether. This step was repeated twice, and the final product was dried in vacuo at 50 °C.

N-Cysteinyl formamide methyl-PEP (**14**) was derived from SC-PEP (**13**) using a procedure adapted from Zalipsky et al. (*40*) 0.39 g cystine hydrochloride (2.5 mmol) dissolved in 20 mL pH 8.0 phosphate buffer was reacted with 0.5 g SC-PEP ($M_n = 19.3 \times 10^3$ g/mol, 0.497 mmol SC groups), which was added in small aliquots. The solution was stirred vigorously at room temperature overnight. The product was purified by ultrafiltration. Filtered aqueous solution was concentrated to dryness, dissolved in DCM, and dried over anhydrous $MgSO_4$. The filtrate was distilled under vacuum to remove DCM and dried in vacuo at 50 °C.

Amino-PEP (**17**) was derived from Tos-PEP (**7**) via the formation of phthalimide-PEP (**16**). The method is modified from the synthesis route of amino PEG by Mutter et al. (*41*) 4 g PEP ($M_n = 15.4 \times 10^3$ g/mol, 5.0 mmol -OH groups) and 3.1 g phthalimide potassium (16.7 mmol) were dissolved in 50 mL DMF and heated at 40 °C with stirring for 18 h. The mixture was cooled and evaporated and dissolved in 200 mL DCM. The organic solution was washed with water (2 × 50 mL) and dried over magnesium sulfate. After filtration and evaporation under reduced pressure, phthalimide-PEP was precipitated in diethyl ether and dried in vacuo at 50 °C. 0.5 g phthalimide-PEP (**16**) ($M_n = 17.5 \times 10^3$ g/mol, 0.55 mmol phthalimide groups) was dissolved in ethanol (200 mL), and ammonia hydrate (40 mL) was added. The mixture was stirred at 30 °C for 24 h and then evaporated under reduced pressure. The crude product was dissolved in DCM and stirred for 24 h at room temperature. The solution was filtered and washed with water (2 × 50 mL) and dried over magnesium sulfate. The product, amino-PEP, was precipitated in diethyl ether and dried in vacuo at 50 °C.

Azido-PEP (**15**) and 2-azidobutyryl-PEP (**18**) were derived using similar methods from Tos-PEP (**7**) and 2-bromoisobutyryl-PEP (**9**), respectively. Synthesis of azido-PEP (**15**) illustrated in Figure 3 follows a method adapted from Mutter (*41*). 0.5 g Tos-PEP ($M_n = 20.1 \times 10^3$ g/mol, 0.478 mmol tosylate groups) was dissolved in 10 mL DMF, and then sodium azide was added under vigorous stirring at room temperature for 6 h. The product was purified by ultrafiltration. Filtered aqueous solution was concentrated to dryness, dissolved in DCM, and dried over anhydrous $MgSO_4$. The filtrate was distilled under vacuum to remove DCM and dried in vacuo at 50 °C to yield a white product.

Synthesis of Heterobifunctional Derivatives of Polyether Polyol. Synthesis of heterobifunctional derivatives **19**−**23** containing alkynyl groups is illustrated in Figure 4. As an example, the synthesis of alkynyl succinate-PEP is described here in detail. Alkynyl-PEP was obtained by Williamson reaction: 0.5 g alkynyl-PEP ($M_n = 16.2 \times 10^3$ g/mol, containing 0.25 mmol alkynyl groups and 0.59 mmol hydroxyl groups) with moisture removed was then reacted with 0.177 g succinic anhydride (1.77 mmol) in the presence of 0.1 mL TEA in 10 mL DCM at room temperature for 24 h. The solvent was removed by rotary evaporation. The product was purified by ultrafiltration. Filtered aqueous solution was concentrated to dryness, dissolved in DCM, and dried over anhydrous $MgSO_4$. The filtrate was distilled under vacuum to remove DCM and dried in vacuo at 50 °C to obtain a white product.

Synthesis methods for heterobifunctional derivatives **24**−**27** containing allyl groups follows similar routes, except that allyl chloride was first used to react with PEP to obtain allyl-PEP.

RESULTS AND DISCUSION

Synthesis and Characterization of Polyether Polyol (PEP). We have synthesized a number of polyether polyols which vary in their molar mass (from 6k to 20k g/mol) and

[a] The feed ratio of EEGE to EO. [b] The molar ratio of EEGE to EO in copolymer poly(EEGE-*co*-EO) measured by ^{1}H NMR. [c] The designed number-average molar mass of precursor polymer. [d] Number-average molecular weight and polydispersity of precursor polymer are determined by GPC. Polydispersity is equal to the ratio of weight-average molar mass and number-average molar mass. [e] Number-average molar mass and polydispersity of PEP are determined by SEC. [f] The number of hydroxyl groups in polyether polyol: $N_{OH} = N_{EEGE} + 1$, in which N_{EEGE} was calculated by the integration of the peak in shift 1.19 ppm (m, C**H**$_3$CH$_2$-) and the integration of the peak in shift 3.38 ppm (s, C**H**$_3$-O-) of ^{1}H NMR data of poly(EEGE-*co*-EO).

ratio Gly/EO (from 1:0 to 1:19) (Table 1). The molar mass of these polymers can be well controlled by the input amount of initiator and monomer, and the resulting polymers are uniform in size. This feature is essential for bioconjugation materials. The polymer size influences the pharmacokinetics and biodistribution (*42, 43*). We expect PEP to behave similarly to PEG: the small molar mass PEG is cleared rapidly from the body, while PEG larger than 20k g/mol exhibits prolonged circulation in the body. The size also affects the extravasation into tissues and the uptake by the reticuloendothelial system (*44*).

The number of hydroxyl groups present on PEP dictates the number of anchorage points for drug conjugation. This can be designed by the ratio Gly/EO, which is in turn controlled by the feed ratio EEGE/EO in making the precursor of PEP (Table 1). Compared to linear PEG, which has one or two linkage points, PEP is a more efficient carrier in terms of higher number of drug molecules per polymer. The ability to control the hydroxyl density means that we can optimize the drug loading density in the polymer design stage, and this will introduce more opportunities to improve drug potency by taking advantage of the multivalency effects (*45, 46*).

Polyether polyol has a main chain similar to that of PEG and pendant hydroxyl groups similar to those on polyvinyl alcohol (PVA). It therefore possesses the same advantage of high water solubility as these two polymers. Each oxygen atom on the polyether main chain is a good hydrogen bond acceptor capable of interacting with two water molecules, while the pendant hydroxyl groups act as hydrogen donors for the surrounding water molecules. This property of polyether polyol means that it is a good drug delivery carrier of normally water-insoluble drug molecules (*47*). In addition to confirming the good solubility of PEP in water, we have also assessed the solubility of polyether polyol in common organic solvents, since these properties influence the choice of reaction types, conditions, and purification methods in the subsequent preparation of PEP derivatives. While the solubility in polar solvent such as methanol is not greatly affected by the Gly/EO ratio, the solubility in nonpolar solvents such as THF, toluene, and DCM increases with decreasing Gly/EO ratio. This is expected from the decreasing hydrophilicity due to hydroxyl groups on the polymer. When the ratio Gly/EO is 1:19.2 or lower, PEP has the same solubility as PEG in these nonpolar solvents.. A simple procedure very often used to isolate PEG is ether precipitation. The efficiency of precipitating PEP in diethyl ether decreases with increasing Gly/EO ratio: a viscous gum was observed when Gly/EO > 1:5, sparing precipitate when Gly/EO = 1:9, and white powder precipitate when Gly/EO < 1:19.

Synthesis and Characterization of Derivatives of PEP. We have successfully prepared a series of PEP derivatives: 18 monofunctional derivatives and 9 heterobifunctional derivatives (Figure 2, Tables 2 and 3). They cover a variety of chemical reactivities commonly used for bioconjugation. The derivatives have been analyzed by NMR to confirm the identity of the functional groups (Supporting Information Tables S1 and S2). The most appropriate synthesis route for each type of derivative was identified and adapted from existing methods on hydroxyl group modification. Most of the reaction yield and conversion efficiency (from hydroxyl groups to the indicated functional groups) were satisfactory (Table 2).

Carboxyl-PEP and Its Active Esters. Amines commonly found on peptides and drug molecules are available for covalent attachment to a polymeric carrier (*2, 5*). The widely used chemistry is via the formation of amide linkage with carboxyl or an active ester. We have prepared a number of derivatives in this group, which vary in the strength of chemical reactivity, length of linker, stability in water, and the presence of an additional functional group (Table 2).

Although oxidation of hydroxyl groups on PEP by permanganate can easily generate carboxyl groups (*30*), we chose not to use this method due to the likelihood of polyether chain degradation. We have produced carboxyl-PEP via Williamson reaction (**1** and **2**) (Figure 3 and Table 2). For example, CM-PEP was generated with 2-chloroacetic acid. The conversion efficiency of this type of reaction, however, only reached 88%. This is because the carboxyl group on 2-chloroacetic acid depletes the anionic ion in the reactive chain, and the anionic carboxyl group lowers the activity of the neighboring halogen atom. This disadvantage was overcome by first preparing ethyl acetate-PEP (**3**), and CM-PEP was produced by subsequent saponification. The conversion efficiency improved to 99% (Table 2 and Supporting Information Table S1).

Modification of the polymer with succinic, glutaric, or maleic anhydride is a straightforward way to synthesize carboxyl polymer. The reaction can be readily driven to completion using an excess of anhydride as confirmed by ^{1}H NMR (Supporting Information Table S1). Unlike the Williamson reaction, this route produces carboxyl-PEP with a hydrolyzable ester linkage instead of the noncleavable ether linkage. Depending on whether the therapeutic molecules to be attached to PEP need to be released in an aqueous environment, one can choose the linkage of desired stability.

The reactivity toward amino group is higher for active ester than carboxyl group. SC-PEG (**13**) was prepared by condensing NHS with CM-PEP using DCC as the coupling agent. The conversion efficiency was only about 80%. A more efficient approach we found was by esterification with acyl halide. Easy and quantitative conversion was achieved by transforming hydroxyl groups into *p*-nitrophenyl formate groups (**8**) and tosylate groups (**14**). It should be pointed out that tosylate-PEP is also an important intermediate for producing azido-PEP (Figure 2).

Mercapto-PEP and Epoxide-PEP. This group of PEP derivatives can join covalently with the thiol groups on biomolecules or small drugs. The thiol linkage has been widely adopted in

[a] Yield (%) = $W_{product}/W_{precursor} \times 100\%$. [b] Conversion efficiency (%) = $[\text{functional group}]_{product}/[OH]_{precursor} \times 100\%$. [c] CM-PEP is synthesized by PEP reacting with 2-chloroacetic acid directly. [d] CM-PEP is synthesized by hydrolysis of ethyl acetate (EA)-PEP **5**.

attaching PEG to therapeutic molecules and proteins (*48, 49*). Epoxide-PEP is an electrophile of mild reactivity toward hydroxyl groups and amino groups and better reactivity toward thiols (*50*).

In our early attempts, 3-mercaptopropionate-PEP was prepared by esterification between hydroxyl groups and 3-mercaptopropionic acid in the presence of concentrated sulfuric acid as catalyst (*51*). We also tried to catalyze this reaction with DCC and DMAP. Both methods resulted in conversion efficiency of less than 10% according to ^{1}H NMR. The successful reaction reported in this paper used $HfCl_4 \cdot 2THF$, a recently developed and highly efficient catalyst, for the esterification between carboxyl groups and hydroxyl groups (*38, 39*).A gel was formed as a result of cross-linking between thiol groups in 3-mercaptopropionate-PEP. When the gel was treated with DL-dithiothreitol (DTT), sodium borohydride, or lithium aluminum anhydride, the disulfide bonds were reduced to thiol groups.

Amino-PEP. Compared with hydroxyl groups, primary amino groups have higher reactivity in nucleophilic substitution reactions, making them useful for conjugating with carboxyl groups and halide (*2*). The transformation of hydroxyl groups to amino groups was difficult, and the conversion efficiency was the lowest among all PEP derivatives. The reaction involved three steps: the conversion of hydroxyl group to tosylate group, followed by the formation of phthalimide, and finally the transformation of phthalimide into amino group. While the efficiency of the first step was

Table 3. Summary of Reaction Yield, Conversion Efficiency, and Reactivity of Heterobifunctional PEP Derivatives

[a] R_1functional group is -OCH_2CCH, the conversion efficiency is 30%. [b] The conversion efficiency here is the [R_2]/[OH]; therein, [R_2] is the number of -R_2 group in heterobifunctional PEP; [OH] is the total number of the -OH group in the original PEP. [c] R_1 functional group is -OCH_2CHCH_2; the conversion efficiency is 41%.

close to 100% according to ^{1}H NMR, the efficiency of subsequent steps suffered from the generation of a large amount of salt and high viscosity as a result of excess phthalimide potassium insoluble in methanol.

Azido-PEP and Alkynyl-PEP. Azido groups are able to react with alkynyl groups in cycloaddition to form a stable triazole linkage (*52, 53*). Since this "click chemistry" occurs in mild conditions, and the reaction is highly specific, it has found many applications in bioconjugation (*53*−*57*). This group of derivatives was prepared with high yield and conversion efficiency.

Dual Reactivities. The maleate and *N*-cysteinyl formamide methyl pendant groups provide dual reactivities, which make the PEP derivatives useful for conjugating with two different entities. This feature may be useful for developing drug carriers for combination therapy. The carboxyl groups and double bonds on maleate-PEP are reactive toward amino- and thiol-containing compounds, while the thiol and carboxyl groups on *N*-cysteinyl formamide methyl-PEP are reactive toward thiol- and amino-containing compounds. Although both *N*-cysteinyl formamide methyl-PEP and 3-mercapto-propionate-PEP are thiol-reactive, the former has a more stable linker (comprising an amide bond) than the latter (comprising an ester bond).

Heterobifunctional Polyether Polyol Derivatives. Heterobifunctional polymers provide more options for designing drug carriers. They are also useful spacers between surfaces and various ligands (*58*−*61*). Compared to heterobifunctional PEG, the synthesis and purification of heterobifunctional PEP derivatives are much simpler. Furthermore, controlling the ratio of the different functional groups is feasible. If PEG diol is modified to generate heterobifunctional groups, the separation among the modified PEG, the macromolecular intermediates, and the starting PEG is challenging, owing to the similarity in physical properties including size (*62*−*64*). Thus, heterobifunctional PEG is mostly prepared starting from anionic polymerization using a heterofunctional initiator (*65*−*72*). Since PEP carries multiple hydroxyl groups, they can be transformed into heterofunctional derivatives by successive modification steps. Separation between PEP derivatives and the small chemical reagents for modification can be readily achieved, for example, by membrane purification. We have demonstrated this approach by synthesizing two groups of heterobifunctional polyether polyol derivatives, one containing alkynyl groups and the other containing allyl groups (Figure 2, Table 3). The presence and the amount of different functional groups were characterized using NMR (Supporting Information Tables S1 and S2), which were tunable by the number of hydroxyl groups on PEP and the feeding amount of the modifying chemicals.

These heterobifunctional derivatives of polyether polyol are potentially useful as drug carriers for two different drugs. They can also be used to bind to a surface or coat a particle with one type of functional groups, leaving the other type of functional groups to couple with drugs, peptides, proteins, DNA, or imaging probes. The alkynyl series were designed to conjugate with azide-containing drugs or azide-modified peptides and proteins, and the allyl series to conjugate with thiol-containing compounds by the radical addition reaction in the presence of 2,2′-azobisiosobutyronitrile (AIBN) (*66, 67*).

CONCLUSION

A series of polyether polyol derivatives have been successfully prepared as materials for conjugating with drugs and biomolecules. The number of functional groups can be well-controlled. Heterobifunctional derivatives of polyether polyol can be readily prepared, and they should offer more flexibility in designing the next generation of polymer−drug conjugates.

LIST OF ABBREVIATIONS

AIBN	2,2′-azobisiosobutyronitrile
CM	carboxymethyl
CE	carboxyethyl
DCC	dicyclohexylcarbodiimide
DCM	dichloromethane
DCU	1,3-dicyclohexylurea

DMSO	dimethyl sulfoxide
DMAP	(dimethylamino) pyridine
DMF	*N*,*N*-dimethylformamide
DTT	DL-dithiothreitol
EA	ethyl acetate
EEGE	ethoxyethyl glycidyl ether
EO	ethylene oxide
Gly	glycidol
$HfCl_4 \cdot 2THF$	hafnium chloride·tetrahydrofuran
PEG	poly(ethylene glycol)
mPEG	monomethoxyl poly(ethylene glycol)
mTEG	triethylene glycol monomethyl
MPA	3-mercaptopropionic acid
NHS	*N*-hydroxysuccinimide
PG	polyglycidol
PEP	polyether polyol
Poly(Gly-*co*-EO)	poly(glycidol-*co*-ethylene glycol)
PBS	phosphate buffered saline
*p*NP	*p*-nitrophenyl formate
PTC	phase transfer catalyst
SC	succinimidyl carbonate
SEC	size exclusion chromatography
GPC	gel permeation chromatography
TEA	triethylamine
THF	tetrahydrofuran
TMS	tetramethylsilane
TsCl	*p*-toluenesulfonyl chloride
Tos	tosylate

Evaluation of ^{64}Cu(DO3A-xy-TPEP) as a Potential PET Radiotracer for Monitoring Tumor Multidrug Resistance

Shuang Liu,* Young-Seung Kim, Shizhen Zhai, Jiyun Shi, and Guihua Hou

School of Health Sciences, Purdue University, West Lafayette, Indiana. Received December 16, 2008; Revised Manuscript Received February 1, 2009

In this study, we evaluated the potential of ^{64}Cu(DO3A-xy-TPEP) (DO3A-xy-TPEP = (2-(diphenylphosphoryl)-ethyl)diphenyl(4-((4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)methyl)benzyl)phosphonium) as a PET (positron emission tomography) radiotracer for noninvasive monitoring of multidrug resistance (MDR) transport function in several xenografted tumor models (MDR-negative: U87MG; MDR-positive: MDA-MB-435, MDA-MB-231, KB-3-1, and KB-v-1). It was found that ^{64}Cu(DO3A-xy-TPEP) has a high initial tumor uptake (5.27 ± 1.2%ID/g at 5 min p.i.) and shows a steady uptake increase between 30 and 120 min p.i. (2.09 ± 0.53 and 3.35 ± 1.27%ID/g at 30 and 120 min p.i., respectively) in the MDR-negative U87MG glioma tumors. ^{64}Cu(DO3A-xy-TPEP) has a greater uptake difference between U87MG glioma and MDR-positive tumors (MDA-MB-231: 1.57 ± 0.04, 1.00 ± 0.17, and 0.93 ± 0.15; MDA-MB-435: 1.15 ± 0.19, 1.12 ± 0.20, and 0.81 ± 0.11; KB-3-1: 1.45 ± 0.31, 1.43 ± 0.16, and 1.08 ± 0.19; and KB-v-1: 1.63 ± 0.47, 1.81 ± 0.31, and 1.14 ± 0.22%ID/g at 30, 60, and 120 min p.i., respectively) than ^{99m}Tc-Sestamibi. Regardless of the source of MDR, the overall net effect is the rapid efflux of ^{64}Cu(DO3A-xy-TPEP) from tumor cells, which leads to a significant reduction of its tumor uptake. It was concluded that ^{64}Cu(DO3A-xy-TPEP) is more efficient than ^{99m}Tc-Sestamibi as the substrate for MDR P-glycoproteins (MDR Pgps) and multidrug resistance-associated proteins (MRPs), and might be a more efficient radiotracer for noninvasive monitoring of the tumor MDR transport function. ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi share almost identical subcellular distribution patterns in U87MG glioma tumors. Thus, it is reasonable to believe that ^{64}Cu(DO3A-xy-TPEP), like ^{99m}Tc-Sestamibi, is able to localize in mitochondria due to the increased plasma and mitochondrial transmembrane potentials in tumor cells.

INTRODUCTION

Cancer is the second leading cause of death worldwide. The most prevalent forms of the disease are solid tumors of the lung, breast, prostate, colon, and rectum. Although the exact cause of cancer remains unknown, most cancer patients will survive after surgery, radiation therapy, and chemotherapy or a combination thereof if it can be detected at an early stage. Therefore, accurate early detection is highly desirable so that various therapeutic regiments can be given before the tumors become widespread.

Multidrug resistance (MDR) remains a major obstacle in the treatment of cancer. The overexpression of multidrug resistance P-glycoproteins (MDR Pgps) and multidrug resistance-associated proteins (MRPs) in tumor cells has been shown to confer MDR onto drug-sensitive cells (*1*−*3*). Both MDR Pgps and MRPs belong to a large family of ATP-trafficking proteins that mediate the transport of a large number of drug molecules (*3*−*6*). Although the molecular mechanism is not entirely clear, the net effect of MDR Pgp and MRP overexpression is the reduced intracellular drug accumulation through an energy-dependent drug efflux in the MDR-positive cancer cells as compared with the drug-sensitive tumor cells (*5, 6*). While several different genes are associated with the MDR phenotype (*6, 7*), the MDR mediated by overexpression of MDR1 Pgp is one of the best characterized barriers to chemotherapeutics treatment. High levels of MDR1 Pgp expression have been detected in more than 50% of tumors (*8*−*11*). A correlation between the MDR1 Pgp expression and failure of chemotherapy or poor survival rates has been established (*11*). However, the lack of MDR1 Pgp in other MDR-positive tumors indicates that additional cellular changes also confer resistance to anticancer drugs (*12*−*15*). For example, MRP1 expression in retinoblastoma correlated well with the rare failure of chemotherapy (*16*). The lung resistance protein (LRP) and breast cancer resistance protein (BCRP) have also been observed in tumor cells (*17, 18*). More recently, the overexpression of a 40 kDa protein (P-40 or Annexin I) was reported in tumor cell lines without MDR1 Pgp (*19, 20*). Since MDR is a major obstacle in chemotherapy of cancer patients, there has been a continuing demand for radiotracers that are able to monitor the tumor MDR transport function in a noninvasive fashion (*21*−*27*).

Cationic radiotracers, such as ^{99m}Tc-Sestamibi and ^{99m}Tc-Tetrofosmin, tend to localize in tumor cells due to the increased negative mitochondrial potentials (*28*−*35*). ^{99m}Tc-Sestamibi and ^{99m}Tc-Tetrofosmin have been clinically used for both cancer early detection and noninvasive monitoring of the tumor MDR transport function by single photon emission computed tomography (SPECT) (*21*−*27, 30*). However, their diagnostic and prognostic values are often limited due to their insufficient tumor localization and high uptake in the heart, liver, and muscle, which makes it very difficult to detect small lesions in the chest and abdominal regions. Thus, there is an unmet medical need for radiotracers that are able to monitor noninvasively the MDR transport function in tumors.

Previously, we reported ^{64}Cu-labeled organic phosphonium cations, such as ^{64}Cu(DO3A-xy-TPEP) (Figure 1: DO3A-xy-TPEP = (2-(diphenylphosphoryl)ethyl)diphenyl(4-((4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)methyl)benzyl)phosphonium), as a potential PET (positron emission

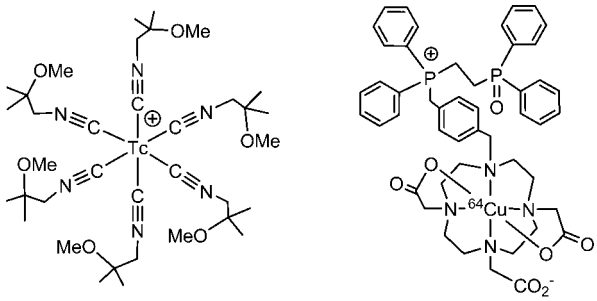

Figure 1. Structures of ^{99m}Tc-Sestamibi and ^{64}Cu(DO3A-xy-TPEP).

tomography) radiotracer in the athymic nude mice bearing U87MG human glioma xenografts (*36*−*39*). Both biodistribution and in vivo microPET imaging studies demonstrated that ^{64}Cu(DO3A-xy-TPEP) has higher tumor uptake with better tumor selectivity (as defined by their tumor/heart and tumor/muscle ratios) than ^{99m}Tc-Sestamibi (Figure 1). These promising results lead us to explore the potential of ^{64}Cu(DO3A-xy-TPEP) as a PET radiotracer for noninvasive monitoring of the MDR transport function in athymic nude mice bearing MDR-positive tumor xenografts.

The tumor cell lines used in this study include U87MG human glioma, MDA-MB-231, and MDA-MB-435 human breast cancer, KB-3-1 and KB-v-1. The U87MG glioma cell line was chosen because it has no overexpression of MDR1 Pgp (*40*−*42*). The U87MG cell line has been used for evaluation of the cellular uptake kinetics of ^{99m}Tc-Sestamibi and ^{99m}Tc-Tetrofosmin (*43*). MDA-MB-435 is the estrogen-independent human breast cancer cell line (metastatic ductal adenocarcinoma) and has a low level of MDR1 expression (*44*−*47*) and a high level expression of MRP2 and MRP4 (*47*, *48*). MDA-MB-231 is also an estrogen-independent human breast cancer cell line and is often considered "drug-sensitive" because it has little MDR1, MRP1, and BCRP overexpression (*47*, *48*). However, recent studies have clearly demonstrated that the MDA-MB-231 breast tumor cell line has a high level expression of P-40, a 40 kDa protein (*19*, *20*). The athymic nude mice bearing KB-3-1 and KB-v-1 tumor xenografts have been successfully used to evaluate cationic ^{99m}Tc and ^{68}Ga radiotracers (*49*−*56*), as well as luminescent probes (*57*). High level expression of MDR Pgps or/and MRPs will result in a rapid efflux of the cationic radiotracer from tumor cells and the significant reduction in tumor localization of the radiotracer. Since it has been used for imaging the tumor MDR transport function by SPECT (*21*−*27*), ^{99m}Tc-Sestamibi was the "control". We are interested in ^{64}Cu(DO3A-xy-TPEP) because of its high tumor uptake and rapid liver clearance in nude mice bearing the MDR-negative U87MG human glioma xenografts (*39*). The main objective of this study is to evaluate the potential of ^{64}Cu(DO3A-xy-TPEP) as a new PET radiotracer for noninvasive monitoring of MDR transport function in several xenografted tumor models. It is important to note that MDR is often mediated by a combination of MDR Pgps (particularly MDR1 Pgp) and MRPs. In addition, MDR Pgps and MRPs are also overexpressed in several normal organs involved in excretory functions, including kidneys and liver (*58*−*60*).

EXPERIMENTAL SECTION

Materials. Chemicals were purchase from Sigma/Aldrich (St. Louis, MO). ^{64}Cu was produced using a CS-15 biomedical cyclotron at Washington University School of Medicine by the ^{64}Ni(p,n)^{64}Cu nuclear reaction. Na^{99m}TcO$_4$ was obtained from a commercial DuPont Pharma ^{99}Mo/^{99m}Tc generator. Cardiolite vials were obtained as a gift from Bristol Myers Squibb Medical Imaging (N. Billerica, MA) and were reconstituted according to the manufacturer's package insert.

Methods. Radio-HPLC method used the LabAlliance HPLC system equipped with a UV/vis detector ($\lambda = 254$ nm), a β-ram IN-US detector, and Zorbax C_{18} analytical column (4.6 mm × 250 mm, 300 Å pore size). The flow rate was 1 mL/min with the mobile phase being isocratic with 90% solvent A (10 mM ammonium acetate) and 10% solvent B (acetonitrile) at 0−5 min, followed by a gradient mobile phase going from 10% B at 5 min to 60% B at 20 min.

Doses Preparation. ^{64}Cu(DO3A-xy-TPEP) was prepared according to the procedure described in our previous report (*39*) and was purified by HPLC. Volatiles in the HPLC mobile phases were evaporated under reduced pressure at room temperature. Doses were prepared by dissolving the residue to 20−30 μCi/mL in saline. The resulting solution was filtered with a 0.20 μm filter unit before being injected into animals. The injection volume for each animal was 0.1 mL.

Animal Models. Biodistribution studies were performed in compliance the NIH animal experiment guidelines (*Principles of Laboratory Animal Care*, NIH Publication No. 86−23, revised 1985). The animal protocol has been approved by the Purdue University Animal Care and Use Committee (PACUC). Female athymic nu/nu mice (5−6 weeks) were purchased from Harlan (Charles River, MA). The mice were implanted with 5 × 10^6 tumor cells into the mammary fat pad (MDA-MB-231 and MDA-MB-435 breast tumor cells) or shoulder flank (U87MG glioma, KB-3-1 and KB-v-1). U87MG glioma cells were cultured in the Minimum Essential Medium, Eagle with Earle's Balanced Salt Solution (nonessential amino acids sodium pyruvate) (ATCC, Manassas, VA). The MDA-MB-435 and MDA-MB-231 breast cancer cells were grown in the RPMI medium 1640 with L-glutamine (GIBCO, Grand Island, NY). The DMEM medium with 4.5 g/L D-glucose, L-glutamine, and 110 mg/L sodium pyruvate (GIBCO, Grand Island, NY) was used for KB-v-1 and KB-3-1 tumor cells. In all cases, 10% FBS (Sigma, St. Louis, MO) and 5% penicillin streptomycin (GIBCO, Grand Island, NY) were added into the medium just before use. All cell lines were grown in humidified atmosphere of 5% carbon dioxide. All procedures will be performed in a laminar flow cabinet using the aseptic technique. Two to four weeks after inoculation, the tumor size was in the range 0.1−0.5 g, and animals were used for biodistribution studies.

Biodistribution Protocol. Twelve tumor-bearing mice (20−25 g) were divided into four groups. Each animal was administered with ^{64}Cu(DO3A-xy-TPEP) (2−3 μCi) via tail vein. Three animals were euthanized by sodium pentobarbital overdose (100 mg/kg) at 5, 30, 60, and 120 min postinjection (p.i.). Blood samples were withdrawn from the heart. The tumor and normal organs (brain, eyes, heart, intestine, kidneys, liver, lungs, muscle, and spleen) were excised, washed with saline, dried with absorbent tissue, weighed, and counted on a Perkin-Elmer Wizard - 1480 γ-counter (Shelton, CT). The organ uptake was calculated as a percentage of the injected dose per organ (%ID/organ). The tumor uptake values are reported as an average ± standard deviation based on the results from three tumor-bearing mice, unless specified, at each time point. The normal organ uptake values are reported as an average ± standard deviation based on the results from fifteen tumor-bearing mice (three animals for each tumor type, and a total of five different tumor types) at each time point, unless specified. For comparison purposes,^{99m}Tc-Sestamibi was evaluated using the same protocol. Comparison between ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi was made using the one-way ANOVA test (GraphPad *Prism 5.0*, San Diego, CA). The level of significance was set at $p < 0.05$.

Table 1. Biodistribution Data for ^{64}Cu(DO3A-xy-TPEP) in Xenografted Tumor-Bearing Athymic Nude Mice[a]

organ	5 min	30 min	60 min	120 min
blood	9.52 ± 1.19 (n = 9)	2.09 ± 0.90 (n = 15)	1.30 ± 1.10 (n = 15)	0.84 ± 0.62 (n = 15)
brain	0.22 ± 0.06 (n = 9)	0.10 ± 0.09 (n = 15)	0.06 ± 0.05 (n = 15)	0.02 ± 0.02 (n = 15)
heart	4.04 ± 0.70 (n = 9)	1.25 ± 0.48 (n = 15)	0.92 ± 0.43 (n = 15)	0.55 ± 0.09 (n = 15)
intestine	4.06 ± 0.78 (n = 9)	3.23 ± 1.22 (n = 15)	2.87 ± 1.28 (n = 15)	2.61 ± 1.26 (n = 15)
kidney	31.79 ± 8.02 (n = 9)	6.77 ± 1.63 (n = 15)	4.11 ± 1.11 (n = 15)	2.98 ± 0.53 (n = 15)
liver	8.03 ± 1.33 (n = 9)	8.74 ± 3.30 (n = 15)	8.66 ± 4.85 (n = 15)	5.59 ± 1.39 (n = 15)
lungs	7.72 ± 0.74 (n = 9)	2.50 ± 0.61 (n = 15)	2.19 ± 0.91 (n = 15)	1.51 ± 0.18 (n = 15)
muscle	3.07 ± 0.45 (n = 9)	0.82 ± 0.39 (n = 15)	0.81 ± 0.98 (n = 15)	0.10 ± 0.06 (n = 15)
spleen	2.73 ± 0.31 (n = 9)	1.14 ± 0.37 (n = 15)	0.84 ± 0.40 (n = 15)	0.56 ± 0.17 (n = 15)
U87MG	5.27 ± 0.99 (n = 3)	2.09 ± 0.53 (n = 3)	2.58 ± 0.31 (n = 3)	3.35 ± 1.27 (n = 3)
MDA-MB-435	2.73 ± 0.55 (n = 3)	1.05 ± 0.19 (n = 3)	1.12 ± 0.20 (n = 3)	0.81 ± 0.11 (n = 3)
MDA-MB-231	3.54 ± 0.15 (n = 3)	1.57 ± 0.04 (n = 3)	1.10 ± 0.17 (n = 3)	0.93 ± 0.15 (n = 3)
KB-v-1		2.00 ± 0.48 (n = 6)	1.58 ± 0.47 (n = 6)	0.93 ± 0.22 (n = 3)
KB-3-1		1.97 ± 0.61 (n = 6)	1.46 ± 0.26 (n = 6)	1.16 ± 0.19 (n = 3)

[a] The tumor uptake is reported as an average ± standard deviation based on the results from three tumor-bearing mice, unless specified, at each time point. The normal organ uptake values are reported as an average ± standard deviation based on the results from fifteen tumor-bearing mice (three animals for each tumor type, and a total of five different tumor types) at each time point.

Blocking Experiment with Cyclosporin-A (Cys-A). In this experiment, each tumor-bearing mouse (n = 4) was treated with intraperitoneal injection of 0.1 mL DMSO solution containing 0.35 mg Cys-A (14 mg/kg) at 30 min before administration of radiotracer. In the "control" group (n = 4), each tumor-bearing mouse was treated with the same volume of DMSO solution without Cys-A. Four animals were euthanized by sodium pentobarbital overdose (100−200 mg/kg) at 30 min p.i. The ex vivo biodistribution was performed according to the procedure described above. The organ of uptake was calculated as a percentage of the injected dose per gram (%ID/g).

Subcelluar Distribution Characteristics. Subcellular distribution studies were performed using the athymic nude mice bearing U87MG glioma (n = 3) and MDA-MB-435 breast cancer (n = 3) xenografts according to literature method (*61*−*66*). Each tumor-bearing mouse was administered ∼30 μCi of ^{64}Cu(DO3A-xy-TPEP) via tail vein. Animals were sacrificed by intraperitoneal administration of sodium pentobarbital overdose (100−200 mg/kg) at 1 h p.i. The tumor was rapidly removed and placed immediately in ice−cold (4 °C) Buffer I, containing 230 mM mannitol, 70 mM sucrose, 3 mM 3-(*N*-morpholino)propanesulfonic acid (MOPS), 2 mM ethylene glycol tetraacetic acid (EGTA), and 0.2% bovine serum albumin (BSA) (w/v) with pH 7.2. The tumor tissue was then minced into 1−2 mm pieces and homogenized using a tissue grinder (Wheaton, NJ). The resulting mixture was centrifuged at 500*g* for 10 min at 4 °C. The supernatant (blood, extracellular components, and debris) was discarded, and the pellet was resuspended in 2 mL of ice−cold (4 °C) Buffer II (containing 110 mM KCl, 20 mM MOPS, 46 mM mannitol, 14 mM sucrose, 2 mM EGTA, pH 7.5). To the mixture was added 0.5 mg/mL of Trypsin protease (Gibco, Ground Island, NY). After 3 min homogenization, the protease reaction was terminated by adding 4 mL of Buffer II (4 °C) containing 0.2% BSA. The homogenate was centrifuged at 5000*g* for 5 min at 4 °C. Supernatant I was collected, and the pellet was resuspended in 5 mL of ice−cold (4 °C) Buffer II with 0.2% BSA. After centrifugation at 500*g* for 10 min (4 °C), pellet I (containing cellular fragments) was obtained. The supernatant was transferred and centrifuged at 3000*g* for 10 min (4 °C) to obtain the membrane fragment (supernatant II) and mitochondrial component (pellet II), respectively. Supernatant I, supernatant II, pellet I, and pellet II were counted by a Perkin-Elmer Wizard - 1480 automatic γ-counter (Shelton, CT). The percentage of radioactivity was calculated on the basis of the radioactivity counts in each subcellular component over the total radioactivity count before homogenization. The percentage of radioactivity recovery was calculated by the total radioactivity counts in supernatant I, supernatant II, pellet I, and pellet II over the total radioactivity count before homogenization. All data were reported as an average of three independent measurements. ^{99m}Tc-Sestamibi was evaluated using the same protocol for comparison purposes.

Western Blot Experiment. Western blot experiments were performed to demonstrate the presence or absence of MDR1 Pgp, MRP2, and MRP4 in different tumor tissues (U87MG glioma, MDA-MB-231, MDA-MB-435, KB-3-1 and KB-v-1). The tumor tissues (U87MG, MDA-MB-231, MDA-MB-435, KB-3-1, and KB-v-1) were harvested directly from the tumor-bearing nude mice. After homogenization, the tumor tissues (10−20 mg) were incubated with 500 μL of cell lysis buffer (Cell Signaling Technology, Danvers, MA) on ice for 5 min. The homogenates were centrifuged at 14 000*g* for 10 min. The supernatants were removed for further use. For tumor cells, MDA-MB-231 and MDA-MB-435, medium was removed at first. After washing with PBS, cells were incubated with cell lysis buffer (Cell Signaling Technology, Danvers, MA) on ice for 5 min. The tumor cells were scraped, and the mixture was sonicated briefly. The homogenates were centrifuged at 14 000*g* for 10 min. The supernatant was removed for further use. The protein content was determined by using the BCA Protein Assay Kit (Pierce, Rockford, IL). The protein (15 μg per lane) was subjected to electrophoresis on SDS-polyacrylamide gel at 160 V for 60 min and transferred electrophoretically on polyvinylidene difluoride membranes at 70 mA for 120 min. The blots were blocked with TBS-T containing 5% nonfat dry milk powder for 1 h. Then, the blotting membranes were incubated with 1 mL of the primary antibody (1:200) against MDR1 (JSB-1, mouse IgG_1 supernatant, Santa Cruz Biotechnology, CA), MRP2 (M2II-12, mouse IgG2a supernatant, Santa Cruz Biotechnology, CA), or MRP4 (M4I-10, rat IgG2a supernatant, Santa Cruz Biotechnology, CA) separately overnight. Primary antibody solution was removed, and the membranes were incubated for 1 h with secondary antibody (goat antimouse IgG-HRP, Santa Cruz Biotechnology, CA) diluted 1:5000. Finally, membranes were developed using the ECL Western Blotting Substrate (Pierce, Rockford, IL) according to the manufacturer's instructions. The positive control for MDR1 was Human PGP Membrane from BD Gentest (San Jose, CA). Human MRP2 Membrane (BD Gentest, San Jose, CA) was used as the positive control of MRP2.

RESULTS

Biodistribution Characteristics. The athymic nude mice bearing U87MG, MDA-MB-231, MDA-MB-435, KB-3-1, and KB-v-1 tumor xenografts were used to evaluate tumor uptake and biodistribution characteristics of ^{64}Cu(DO3A-xy-TPEP). For comparison purpose, ^{99m}Tc-Sestamibi was also evaluated in the

Table 2. Biodistribution Data for ^{99m}Tc-Sestamibi in Xenografted Tumor-Bearing Athymic Nude Mice[a]

organ	5 min	30 min	60 min	120 min

[a] The tumor uptake is reported as an average ± standard deviation based on the results from three tumor-bearing mice at each time point, unless specified. The normal organ uptake values are reported as an average ± standard deviation based on the results from nine tumor-bearing mice (three animals for each tumor type, and a total of three different tumor types) at each time point.

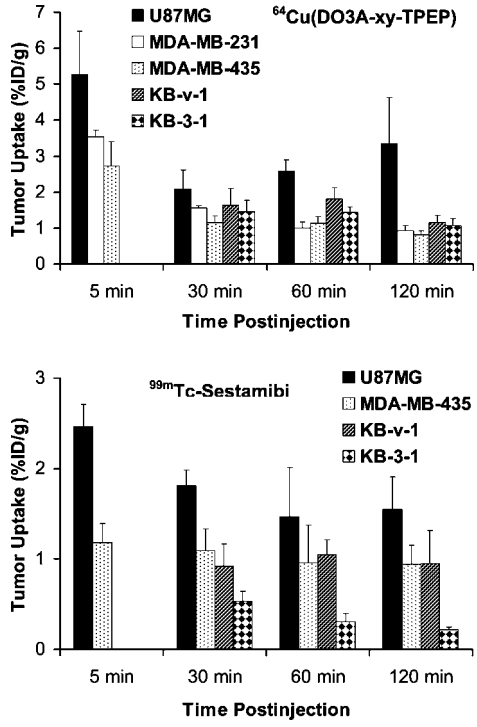

Figure 2. Comparison of tumor uptake for ^{64}Cu(DO3A-xy-TPEP) (top) and ^{99m}Tc-Sestamibi (bottom) in athymic nude mice bearing different tumor xenografts (U87MG glioma, MDA-MB-231, and MDA-MB-435 breast cancer, KB-3-1, and KB-v-1).

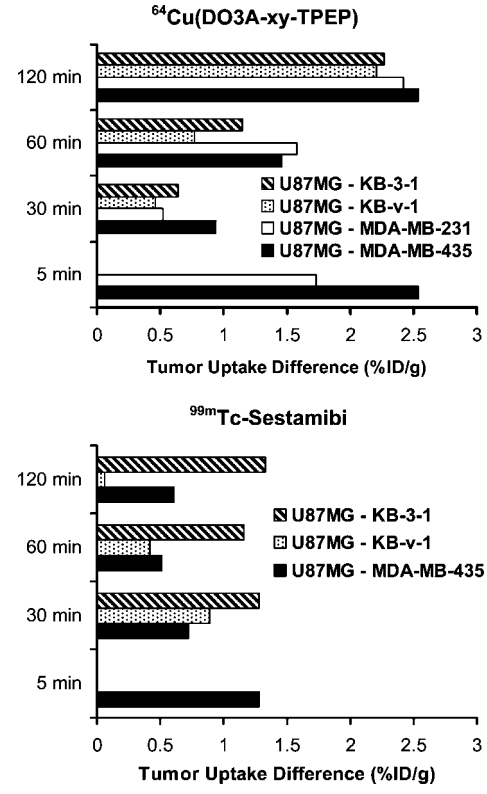

Figure 3. Tumor uptake difference between the MDR-negative U87MG glioma and the MDR-positive tumors (MDA-MB-231, MDA-MB-435, KB-3-1, and KB-v-1) for ^{64}Cu(DO3A-xy-TPEP) (top) and ^{99m}Tc-Sestamibi (bottom).

same animal model, since it has been clinically used for early cancer detection and for imaging MDR transport function in cancer patients (*21*−*27, 30*). Biodistribution data for ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi are summarized in Tables 1 and 2, respectively. Figure 2 compares the tumor uptake (%ID/g) of ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi. Figure 3 illustrates the tumor uptake differences between U87MG glioma and the MDR-positive tumors (MDA-MB-231, MDA-MB-435, KB-3-1, and KB-v-1) for ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi.

In general, the biodistribution of ^{64}Cu(DO3A-xy-TPEP) in noncancerous organs of the MDR-positive tumor-bearing mice was almost identical to that obtained from the mice bearing U87MG human glioma xenografts. There was no size dependence for the tumor uptake of ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi. However, ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi showed significant differences in their uptake in both tumors and normal organs. For example, ^{64}Cu(DO3A-xy-TPEP) had a rapid tumor washout in the MDR-negative glioma model between 5 min (5.27 ± 1.21%ID/g) and 30 min (2.09 ± 0.53%ID/g) p.i. due to its fast blood clearance, and a steady tumor uptake increase between 30 min (2.09 ± 0.53%ID/g) and 120 min (3.35 ± 1.27%ID/g) p.i. probably due to its slow kinetics to penetrate the cellular and mitochondrial transmembranes (*39*). In the MDR-positive tumor-bearing mice, ^{64}Cu(DO3A-xy-TPEP) showed a rapid tumor washout between 5 and 30 min p.i. (Figure 3: top), and its tumor uptake was relatively unchanged (ranging from 1.0%ID/g to 1.5%ID/g depending on the tumor type) in between 30 and 120 min p.i. The tumor uptake of ^{99m}Tc-Sestamibi decreased steadily in all four tumor-bearing animal models over the 2 h period (Figure 3: bottom). The most striking difference between ^{64}Cu(DO3A-xy-TPEP) (Table 1) and ^{99m}Tc-Sestamibi (Table 2) was their uptake in heart and muscle. For example, the heart uptake was <1% ID/g for ^{64}Cu(DO3A-xy-TPEP) at >30 min p.i., whereas ^{99m}Tc-Sestamibi had the heart uptake of 19.22 ± 7.62% ID/g at 5

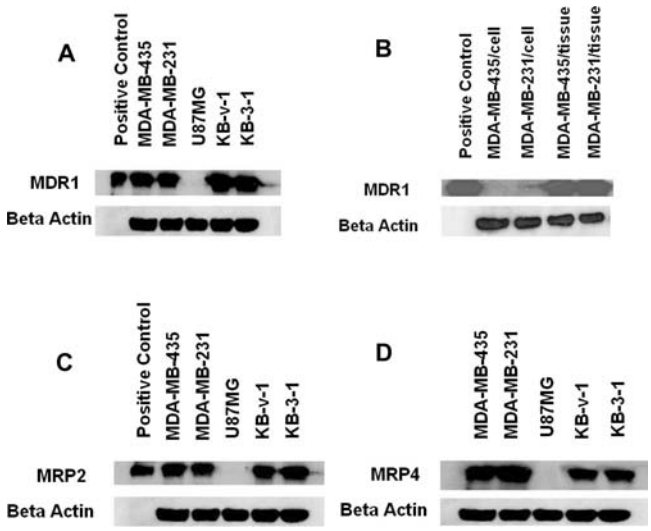

Figure 4. Western blot data to demonstrate the presence/absence of MDR1 (A,B), MRP2 (C), and MRP4 (D) in U87MG (MDR1, MRP2, and MRP4-negative), MDA-MB-435 (MDR1-negative in tumor cells but MDR1-positive in tumor tissue, MRP2 and MRP4-positive), MDA-MB-231 (MDR1-negative in tumor cells but MDR1-positive in tumor tissue, MRP2 and MRP4-positive), KB-v-1, and KB-3-1 (MDR1, MRP2, and MRP4-positive).

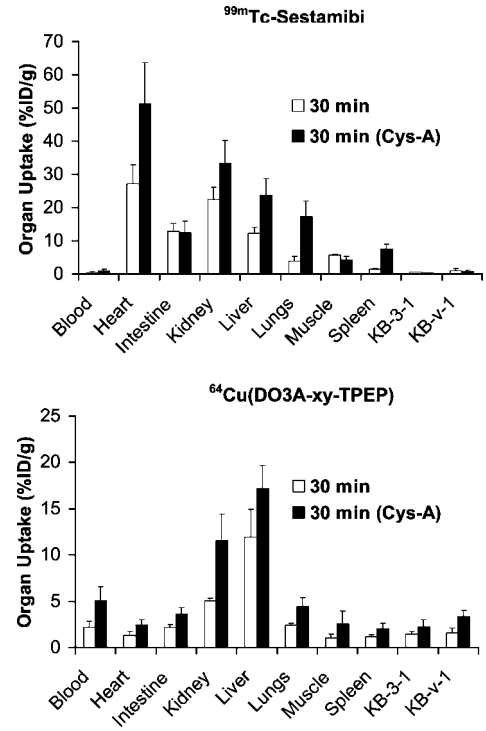

Figure 5. Impact of Cys-A on the uptake of ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi in selected organs of the athymic nude mice bearing KB-v-1 and KB-3-1 tumor xenografts.

min p.i. and 19.19 ± 5.32%ID/g at 120 min p.i. The muscle uptake of ^{64}Cu(DO3A-xy-TPEP) was undetectable at >30 min p.i. In contrast, ^{99m}Tc-Sestamibi had a high muscle uptake over the 2 h study period (4.84 ± 1.22 and 5.45 ± 1.24%ID/g at 5 and 120 min p.i., respectively). Another significant difference was their tumor uptake in the MDR-negative U87MG glioma and the MDR-positive tumor xenografts. For example, ^{64}Cu(DO3A-xy-TPEP) had the tumor uptake of 5.27 ± 0.99, 2.09 ± 0.53, 2.58 ± 0.31, and 3.35 ± 1.27%ID/g at 5, 30, 60, and 120 min p.i., respectively, in U87MG glioma. Its tumor uptake values in the MDR-positive tumors were significantly lower than that in glioma (Figure 2). The glioma uptake values of ^{99m}Tc-Sestamibi were 3.06 ± 0.94, 2.11 ± 0.38, 1.47 ± 0.54, and 1.55 ± 0.36%ID/g at 5, 30, 60, and 120 min p.i., respectively, and its uptake values in the MDA-MB-435 breast tumor were 1.18 ± 0.17, 1.09 ± 0.20, 0.96 ± 0.42, and 0.94 ± 0.21%ID/g at 5, 30, 60, and 120 min p.i., respectively.

Western Blot Experiments. Western blot experiments were performed to demonstrate the presence or absence of MDR1 Pgp, MRP2 and MRP4 in the U87MG, MDA-MB-231, MDA-MB-435, KB-3−1 and KB-v-1 tumor xenografts. Tumor cells were directly isolated from the tumor tissues. The total protein concentration was determined to be 4.5 ± 0.4, 4.0 ± 0.2, 3.3 ± 0.2, 4.3 ± 0.3, and 4.1 ± 0.2 mg/mL for the xenografted MDA-MB-435, MDA-MB-231, U87MG, KB-v-1, and KB-3-1 tumors, respectively. Figure 4 illustrates the Western blotting data for the U87MG, MDA-MB-231, MDA-MB-435, KB-3-1, and KB-v-1 tumor xenografts. The positive control was the Human PGP Membrane for MDR1 Pgp. The positive control for MPR2 was human MRP2 membrane. No positive control is commercially available for MRP4. The blotting data clearly demonstrated that there was very little or no expression of MDR1 Pgp, MRP2, and MRP4 in the U87MG glioma xenografts. However, there is a high expression of MDR1 Pgp, MRP2, and MRP4 in the MDA-MB-231, MDA-MB-435, KB-3-1, and KB-v-1 tumors.

It is important to note that MDA-MB-435 and MDA-MB-231 are often known "drug sensitive" or MDR1-negative breast cancer cell lines (*47, 48*). The results from Western blotting studies also showed that the MDA-MB-435 and MDA-MB-231 human breast cancer cell lines have little expression of MDR1 Pgp (Figure 4B). However, the MDA-MB-435 and MDA-MB-231 breast cancer cells isolated from the xenografted MDA-MB-435 and MDA-MB-231 breast tumors are MDR1-positive (Figure 4B). They also show a significant expression of MRP2 and MRP4.

Impact of Cys-A on Tumor Uptake and Radiotracer Liver Clearance Kinetics. To further demonstrate that the tumor washout is caused by the tumor MDR transport function, we performed blocking experiments using ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi as radiotracers in the athymic nude mice bearing KB-3-1 and KB-v-1 tumor xenografts. Cys-A, a well-known wide-spectrum MDR modulator (*67*), was injected as the blocking agent 1 h prior administration of ^{64}Cu(DO3A-xy-TPEP) or ^{99m}Tc-Sestamibi. The ex vivo biodistribution was performed at 30 min p.i. Figure 5 compares uptake of ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi in the tumor and selected normal organs in the absence/presence of Cys-A. As expected, pretreatment of the tumor-bearing mice with excess Cys-A resulted in a significant increase in tumor uptake of both ^{64}Cu(DO3A-xy-TPEP) (Figure 5: bottom) and ^{99m}Tc-Sestamibi (Figure 5: top). The tumor uptake difference was 0.83%ID/g in KB-3-1 and 1.70 KB-v-1%ID/g w/o Cys-A for ^{64}Cu(DO3A-xy-TPEP), while there was no significant difference for ^{99m}Tc-Sestamibi within experimental error, suggesting that ^{64}Cu(DO3A-xy-TPEP) might be a more efficient radiotracer for noninvasive monitoring of the MDR transport function.

In addition, the uptake of ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi in kidneys, liver, and lungs was also significantly increased, and the radioactivity excretion was delayed in the presence of Cys-A. For example, the liver uptake was 8.03 ± 1.33%ID/g for ^{64}Cu(DO3A-xy-TPEP) and 9.82 ± 2.12%ID/g for ^{99m}Tc-Sestamibi in the absence of Cys-A at 30 min p.i. In presence of Cys-A, however, the liver uptake values increased to 17.18 ± 2.47%ID/g for ^{64}Cu(DO3A-xy-TPEP) and 23.68 ± 5.08%ID/g for ^{99m}Tc-Sestamibi at the same time point. A similar increase (Figure 5) was also observed in the heart, kidneys, lungs, and spleen. The increase of muscle uptake of ^{64}Cu(DO3A-

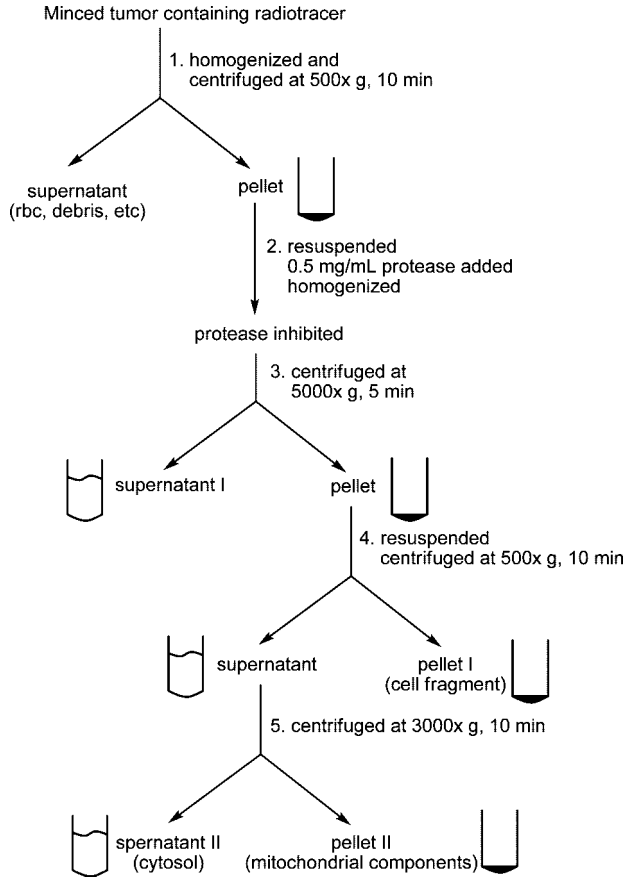

Figure 6. Schematic presentation of the standard differential centrifugation process.

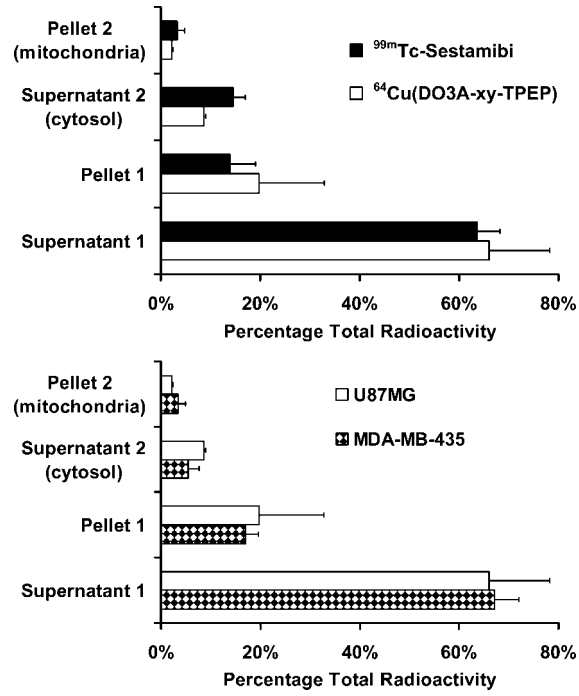

Figure 7. Top: subcellular distribution properties of ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi in U87MG human glioma xenografts. Bottom: direct comparison of subcellular distribution patterns of ^{64}Cu(DO3A-xy-TPEP) in the U87MG glioma and MDA-MB-435 breast tumor xenografts.

xy-TPEP) is probably caused by its high blood radioactivity accumulation in the presence of excess Cys-A. The impact of Cys-A on the excretion kinetics of ^{64}Cu(DO3A-xy-TPEP) was more significant than that of ^{99m}Tc-Sestamibi.

Subcellular Distribution Characteristics. We performed the subcellular distribution studies on ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi using the standard differential centrifugation method (Figure 6) according to the literature (*61*−*65*). The main objective of these studies is to elucidate the tumor localization mechanism of ^{64}Cu(DO3A-xy-TPEP). Figure 7 illustrates the subcellular distribution characteristics of ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi in the xenografted U87MG glioma and MDA-MB-435 tumors. The radioactivity recovery was >95% for both ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi. After cellular fractionation, the majority of the radioactivity was found in supernatants I (66.5 ± 12.5% for ^{64}Cu(DO3A-xy-TPEP) and 63.5 ± 4.7% for^{99m}Tc-Sestamibi) and II (8.5 ± 0.5% for ^{64}Cu(DO3A-xy-TPEP) and 14.5 ± 2.6% for^{99m}Tc-Sestamibi). Only a small portion of the radioactivity was found in the mitochondrial fraction (Figure 7: top) for ^{64}Cu(DO3A-xy-TPEP) (2.25 ± 0.21%) and ^{99m}Tc-Sestamibi (3.33 ± 1.50%). It is clear that ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi share almost identical subcellular distribution patterns in the U87MG glioma tumors. In addition, the subcellular distribution characteristics of ^{64}Cu(DO3A-xy-TPEP) are very similar in the xenografted U87MG glioma and MDA-MB-435 breast tumors (Figure 7: bottom).

DISCUSSION

During last two decades, cationic radiotracers, such as ^{99m}Tc-Sestamibi, have been widely used for early cancer detection and for noninvasive monitoring of the tumor MDR transport function by SPECT (*21*−*35*). The overwhelming emphasis of the prior literature has been focused on the tumor MDR transport function mediated by MDR1 Pgp most likely due to the fact that MDR1 Pgp is one of the best biologically characterized barriers to chemotherapy. It is very important to emphasize that the tumor MDR transport function can be mediated by MDR Pgps and MRPs (*1*−*11*), as well as other drug transporting proteins, such as LRP (*17*) and BCRP (*18*). Regardless of the source of MDR, the overall net effect is the rapid efflux of cationic radiotracers from tumor cells, which often leads to a significant reduction of the radiotracer tumor uptake. There is an inverse relationship between the radiotracer tumor uptake and the MDR transport function. If there is no MDR Pgps and/or MRPs in tumor cells, cationic radiotracers will have relatively high tumor uptake with no significant tumor washout. If there is a high level expression of MDR Pgps and/or MRPs, cationic radiotracers are expected to show a rapid tumor radioactivity washout with low tumor uptake. If the radiotracer is efficient as a substrate for MDR Pgps and MRPs, there would be less radiotracer uptake in the MDR-positive tumors. The ideal radiotracers useful for noninvasive monitoring of the tumor MDR transport function would be those which provide the largest uptake difference between the MDR-negative and MDR-positive tumors and have low uptake in noncancerous organs, such as the heart, liver, lungs, and muscle.

Since the uptake of ^{64}Cu(DO3A-xy-TPEP) in normal organs is almost identical in different xenografted tumor-bearing models, their tumor uptake difference should, in theory, reflect the MDR transport function in the MDR-negative vs MDR-positive tumors. For example, the U87MG glioma tumors have no significant expression of MDR1 Pgp and MRPs, as demonstrated by Western blot experiment (Figure 4). As a result, ^{64}Cu(DO3A-xy-TPEP) has a high initial tumor uptake and shows a steady uptake increase between 30 and 120 min p.i. (Figure 2: top). Similar results are obtained for ^{99m}Tc-Sestamibi (Figure 2: bottom). The xenografted MDA-MB-435, MDA-MB-231, KB-3-1, and KB-v-1 tumors all have high levels of MDR1 Pgp,

MRP2, and MRP4 expression (Figure 4A). As a result, both ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi show a significant washout from tumor over the 2 h period. Since ^{64}Cu(DO3A-xy-TPEP) has a greater tumor uptake difference between U87MG glioma and MDA-MB-231, MDA-MB-435, KB-3-1, and KB-v-1 than ^{99m}Tc-Sestamibi, it is reasonable to believe that ^{64}Cu(DO3A-xy-TPEP) is more efficient than ^{99m}Tc-Sestamibi as the substrate for MDR Pgps and MRPs and might be more efficient for noninvasive monitoring of the tumor MDR transport function. This conclusion is supported by the blocking experiments, which show a significant tumor uptake increase for ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi in the presence of excess Cys-A (Figure 5).

Both^{99m}Tc-Sestamibi and ^{99m}Tc-Tetrafosmin have been studied for their potential to monitor the tumor MDR in preclinical animal models and in clinical studies (*28*−*35*). The MDR1 Pgp and MRPs are also overexpressed in normal organs, such as kidneys and liver (*58*−*60*). As demonstrated in the blocking study (Figure 5), the preadministration of tumor bearing mice with excess Cys-A resulted in a significant increase of radioactivity accumulation in noncancerous organs, such as kidneys, liver, and lungs, and the delayed radioactivity excretion. Therefore, the MDR Pgp transport function is at least partially responsible of the fast efflux of ^{64}Cu(DO3A-xy-TPEP) from the kidneys, liver, and lungs.

The subcellular distribution characteristics of ^{64}Cu(DO3A-xy-TPEP) was compared with those of ^{99m}Tc-Sestamibi, a well-know radiotracer clinically useful for cancer detection by SPECT. The standard differential centrifugation technique has been successfully used to study the myocardial localization mechanism of cationic ^{99m}Tc radiotracers (*61*−*66*), such as ^{99m}Tc-Sestamibi. As expected, only a small fraction (3−4%) of ^{64}Cu radioactivity is found in the mitochondrial fraction, and the majority of the ^{64}Cu radioactivity is found in supernatants I and II. Almost identical distribution patterns were observed for ^{99m}Tc-Sestamibi. It has been suggested that tissue homogenization and differential centrifugation techniques may damage the mitochondrial structure (*61*−*66*), which allows the leakage of cationic radiotracers, such as ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi, from tumor mitochondria. Since ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi share almost identical subcellular distribution patterns in the U87MG glioma, we believe that ^{64}Cu(DO3A-xy-TPEP), like ^{99m}Tc-Sestamibi, is able to localize in the tumor mitochondria due to the increased plasma and mitochondrial transmembrane potentials in tumor cells as compared to normal epithelial cells (*68*−*72*). This conclusion is supported by the results from in vitro cellular assays, which showed that ^{64}Cu(DO3A-xy-TPP) (DO3A-xy-TPP: triphenyl(4-((4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)methyl)benzyl)phosphonium) was able to localize in U87MG human glioma cells (*36*).

CONCLUSION

In this study, we evaluated the potential of ^{64}Cu(DO3A-xy-TPEP) as a new PET radiotracer for noninvasive monitoring of MDR transport function in several xenografted tumor models. It is important to note that MDR is often mediated by a combination of MDR Pgps (particularly MDR1 Pgp) and MRPs. ^{64}Cu(DO3A-xy-TPEP) has a high initial tumor uptake and shows a steady uptake increase between 30 and 120 min p.i. in the MDR-negative U87MG glioma, which has little expression of MDR1 Pgp and MRPs. In the xenografted MDA-MB-435, MDA-MB-231, KB-3-1, and KB-v-1 tumors, which have high levels of MDR1 Pgp, MRP2, and MRP4, ^{64}Cu(DO3A-xy-TPEP) and ^{99m}Tc-Sestamibi show a significant tumor washout over the 2 h period. Since ^{64}Cu(DO3A-xy-TPEP) has a greater tumor uptake difference between the MDR-negative U87MG glioma and MDR-positive tumors (MDA-MB-231, MDA-MB-435, KB-3-1, and KB-v-1) than ^{99m}Tc-Sestamibi, we believe that ^{64}Cu(DO3A-xy-TPEP) is more efficient than ^{99m}Tc-Sestamibi as the substrate for MDR Pgps and MRPs and might be a more efficient radiotracer for noninvasive monitoring of the MDR transport function in tumors of different origin. Regardless of the source of MDR, the overall net effect is the rapid efflux of cationic radiotracers from tumor cells, which often leads to a significant reduction of the radiotracer tumor uptake.

ACKNOWLEDGMENT

Authors would like to thank Dr. Sulma I. Muhammed, the Director of Purdue Cancer Center Drug Discovery Shared Resource, Purdue University, for her assistance with the tumor-bearing animal model. This work is supported, in part, by research grants: R01 CA115883 A2 (S.L.) from National Cancer Institute (NCI), R21 EB003419-02 (S.L.) from National Institute of Biomedical Imaging and Bioengineering (NIBIB) and R21 HL083961-01 from National Heart, Lung, and Blood Institute (NHLBI).

Site-Specific Covalent Modification of RNA Guided by Functionality-Transfer Oligodeoxynucleotides

Kazumitsu Onizuka, Yosuke Taniguchi, and Shigeki Sasaki*

Graduate School of Pharmaceutical Sciences, Kyushu University, 3-1-1 Maidashi, Higashi-ku, Fukuoka 812-8582, Japan, and CREST, Japan Science and Technology Agency, 4-1-8 Motomachi, Kagaguchi, Saitama 332-0012, Japan. Received January 13, 2009; Revised Manuscript Received February 2, 2009

Efficient methods for the covalent modification of large RNA molecules should find significance utility as innovative biological tools as well as therapeutic methods. In this study, the development of a general method for site-specific RNA modification guided by the functional ODN template has been investigated. The ODN probe containing 6-thioguanosine was modified by the methylenediketone derivative to form the *S*-functionalized ODN. Site-specific and cytosine-selective RNA modifications were achieved by the functionality-transfer reaction from the sulfur atom of the functionalized probe to the amino group of the cytosine base of the target strand. It was shown that the base and site selectivity were due to the close proximity of the reactants in the DNA-RNA duplexes.

INTRODUCTION

A number of non-natural covalent modifications have been done for the structural and mechanistic studies of RNA (*1, 2*), manipulation of the gene expression at the single nucleoside level (*3*), single-molecule imaging (*4*), and so forth. Non-natural modifications are achieved by chemical synthesis, enzyme-mediated reactions, and combinations of both (*1*). The site-specific incorporation of a non-natural nucleoside into RNA by chemical reactions is a well-established method, but its drawback is that it cannot be directly applied to generate large, specifically modified RNAs. RNA fragments with natural and/or modified nucleotides can be joined by ligation with a ligase forming a large RNA. If the non-natural covalent modifications can be site-specifically made to RNA, the potential applications are numerous. However, only a limited number of methods showed potentials for use under physiological conditions. For example, DNA template-directed photoligation to the terminal site of RNAs was achieved through the 5-vinyl-2′-deoxyuridine, and is expected to allow the modification of small RNAs (*5*). The internal modification of large RNAs was made by a catalytic DNA molecule with a ligation ability (*6*). However, these methods have limitations because of the photoirradiation necessity in the former method or the large molecular size of the catalytic DNAs and the sequence dependency in the latter case. In this study, we have attempted to develop a general method for the site-specific RNA modification guided by the functionalized oligodeoxynucleotides.

Oligonucleotides and related oligomers with an attached chemically reactive accessory molecule have been used to perform chemical modification to RNA in a sequence-specific manner (*7*). Ideally, the accessory molecule needs to be stable under physiological conditions, and its reactivity should be induced on demand. UV irradiation is frequently used as an exogenous activation signal (*8*). The target strand itself was used for the generation of an active agent for alkylation (*9*). We have been developing an original strategy for the reactivity induction of the accessory molecules by taking advantage of minute environmental changes accompanied by nucleic acid hybridization. The first example was demonstrated by the hybridization-promoted cytosine-selective alkylation using the sulfide derivative of 2-amino-6-vinylpurine nucleoside, in which the stable sulfide precursor was spontaneously activated to the active vinyl species within the complementary duplex having the cytosine base at the target site (*10, 11*). The usefulness of this inducible alkylating agent was confirmed by enhancement of the intracellular antisense inhibition (*3*). Although the induction mechanism is not yet fully understood, the close proximity to the target cytosine base within the duplex is responsible for the selective activation of the sulfide precursor. This strategy was then expanded to the nitrosyl group transfer from the sulfur atom of 6-thioguanosine to the amino group of the cytosine base (*12*). Interesting results were that *S*-nitroso-6-thioguanosine in the ODN was much more stable than the corresponding monomer and that its reactivity was induced in close proximity to the cytosine base in the complementary duplex that affected the nitrosyl transfer to the amino group of the cytosine base. Cytosine deamination following the nitrosyl transfer reaction suggested a potential application as an artificial tool for RNA editing.

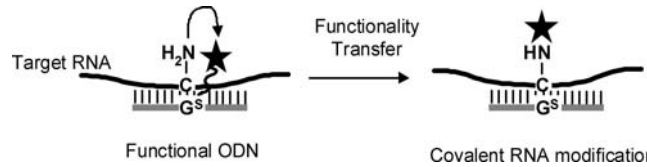

Figure 1. General strategy for site-specific RNA modification through the functionality transfer reaction from the *S*-functionalized 6-thioguanosine (Gs) to the amino group cytosine base.

These two early examples have demonstrated the validity of our strategy for the specific induction of reactivity in close proximity to the target cytosine base only by intrinsic changes in the microenvironment around the reactants. For further expansion of this strategy, we designed a new functionality-transfer reaction to the amino group of the cytosine base using the ODN incorporating *S*-functionalized 6-thioguanine, which may permit the site-specific covalent modification of RNAs with a variety of functional molecules for editing, tagging, fluorescence labeling, and so forth (Figure 1) (*13*). We now describe

in detail the design of the new functionality-transfer reaction and site-specific modification of RNA.

EXPERIMENTAL PROCEDURES

Synthesis of Oligodeoxynucleotides and Oligonucleotides. All oligonucleotides were synthesized by by the automated DNA synthesizer according to the conventional amidite chemistry. The cleaved oligonucleotides were purified by HPLC equipped with a ODS column using a linear gradient between the 0.1 M TEAA buffer and CH_3CN. The MALDI-TOF/MS data are summarized in Supporting Information Table S2.

3-Chloromethylene-4-phenylbutane-2,4-dione (5a) as a General Procedure for the Synthesis of 5b and 5c. A mixture of benzoylacetone (977 mg, 6.02 mmol), ethyl *ortho*-formate (2 mL, 12.02 mmol), and acetic anhydride (2 mL, 21.16 mmol) was heated at 130 °C for 2.5 h, then cooled to rt. The solvents were evaporated under vacuum to give the residue, which was purified by column chromatography (silica gel, hexane/AcOEt = 4:1) to afford 3-ethoxymethylene-3-benzolyacetone (1.09 g, 83%). IR (cm^{-1}): 1669, 1624, 1210. ^1H NMR (400 MHz, $CDCl_3$) δ ppm: 7.86 (2H, d, J = 7.9 Hz), 7.70 (1H, s), 7.55 (1H, tt, J = 7.5, 1.5 Hz), 7.44 (2H, t, J = 7.5 Hz), 4.06 (2H, q, J = 7.0 Hz), 2.20 (3H, s), 1.19 (3H, t, J = 7.0 Hz). ESI-MS (m/z): 219.1 ($[M + H]^+$).

A solution of the above compound (250 mg, 1.15 mmol) in 10% aqueous HCl−THF (0.2 mL−2 mL) was stirred at rt for 1 h and diluted with AcOEt (10 mL). The mixture was washed with H_2O, and the aqueous layer was extracted with AcOEt (6 mL × 2). The combined organic layers were washed with brine, dried over Na_2SO_4, and evaporated to dryness to give 3-hydroxymethylene-3-benzoylacetone as a crude oil (205 mg, 94%), which was used for the next reaction without further purification.

$SOCl_2$ (50 mL, 0.685 mmol) was added dropwise to a solution of the above oil (120 mg, 0.63 mmol) in dry toluene (1 mL) at rt, and the mixture was heated under reflux. After 5 h, $SOCl_2$ (50 mL, 0.685 mmol) was added to the reaction mixture, and the mixture was heated for an additional 4 h. The mixture was evaporated under vacuum, and the remaining reagent was removed by azeotropic evaporation with toluene to give brown solids, which were purified by column chromatography (silica gel, $CHCl_3$/hexane = 3:1) to give 3-chloromethylene-3-benzoylacetone as white needles (108 mg, 82%). mp 85−87 °C. IR (cm^{-1}): 3094, 1678, 1662, 1596, 1234. ^1H NMR (400 MHz, $CDCl_3$) δ ppm: 7.88 (2H, dd, J = 8.2, 1.4 Hz), 7.62 (1H, tt, J = 7.6, 1.2 Hz), 7.54 (1H, s), 7.49 (2H, t, J = 7.9 Hz), 2.20 (3H, s). ESI-MS (m/z): 231.0, 233.0 ($[M + Na]^+$).

2-Benzoyl-2-chloromethylene Acetic Acid Ethyl Ester (5b). This compound was synthesized from ethyl benzoyl acetate. ^1H NMR (400 MHz, $CDCl_3$) δ ppm: 7.89 (2H, d, J = 7.1 Hz), 7.63 (1H, s), 7.59 (1H, t, J = 7.1 Hz), 7.48 (2H, t, J = 7.6 Hz), 4.20 (2H, q, J = 7.2 Hz), 1.18 (3H, t, J = 7.2 Hz). IR (cm^{-1}): 1720, 1679, 1598, 1243, 1227. ESI-MS (m/z): 239.1 ($[M + H]^+$).

2-(Chloromethylene)-1,3-diphenylpropane-1,3-dione (5c). This compound was synthesized from dibenzoylmethane. ^1H NMR (400 MHz, $CDCl_3$) δ ppm: 7.95 (2H, d, J = 7.3 Hz), 7.83 (2H, d, J = 7.3 Hz), 7.61−7.55 (2H, m), 7.49−7.44 (4H, m), 7.28 (1H, s). IR (cm^{-1}): 1681, 1648, 1596, 1330, 1229. ESI-MS (m/z): 271.2, 273.2 ($[M + H]^+$).

Synthesis of DNA2a as the General Procedure of the Synthesis of DNA2b−2d. A solution of **5a** (25 mM in CH_3CN, 0.3 μL, 7.5 nmol) was added to a solution of DNA**1** (750 μM, 2 μL, 1.5 nmol) in a carbonate buffer (50 mM, 2.7 μL, pH 10). After 5 min, DNA**2a** was purified by HPLC for the MALDIMS measurement. The crude reaction mixture containing DNA**2a** was used for the functionality transfer reaction without HPLC purification.

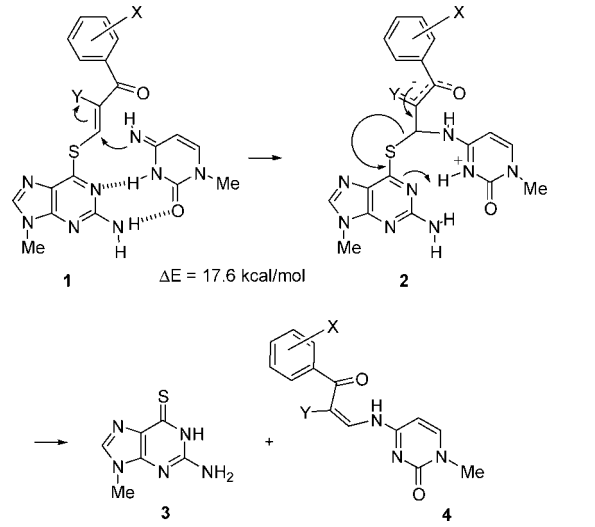

Figure 2. Design of the functionality-transfer reaction of the 6-thioguanine derivative modified with α,β-unsaturated carbonyl unit (**1**) to form the amino-modified cytosine (**4**) via the intermediate **2**. The hypothesized pathway using the imino tautomer of cytosine and diketone derivative (X = H, Y = $COCH_3$) was simulated by MOPAC (PM5).

Evaluation of the Stability of DNA2a as the General Procedure of the Evaluation of the Stability of DNA2b−2d. A solution of **5a** (25 mM in CH_3CN, 0.15 μL, 3.75 nmol) was added to a solution of DNA**1** (750 μM, 1 μL, 0.75 nmol) in a carbonate buffer (50 mM, 1.35 μL, pH 10). After 5 min, the mixture was diluted with ultrapurified water (24.5 μL) and neutralized with MES buffer (0.5 M MES and 1 M NaCl, 3 μL, pH 6.9). The formation of DNA**1** from DNA**2** (25 μM, pH 7.0) was analyzed by HPLC (column: SHISEIDO C18, 4.6 × 250 mm; solvent: A: 0.1 M TEAA buffer, B: CH_3CN, B: 10% to 30%/20 min, linear gradient; flow rate: 1.0 mL/min; monitored by UV detector at 254 nm).

Functionality Transfer Reaction From DNA2a to RNA3 to form RNA4 as the General Procedure for the Functionality Transfer Reaction. DNA**2a** (300 μM, 0.2 μL, 60 pmol), RNA**3** (50 μM, 1.0 uL, 50 pmol), and RNase OUT (40 u/μL, 0.75 μL, 30 u) were mixed in MES buffer (1 M NaCl, 0.5 M MES, 5 μL, pH 7), and the mixture was kept at rt. The reaction mixture was analyzed by HPLC (column: SHISEIDO C18, 4.6 × 250 mm; solvent: A: 0.1 M TEAA buffer, B: CH_3CN, B: 10% to 30%/20 min, linear gradient; flow rate: 1.0 mL/min; monitored by UV detector at 254 nm (Figures 3 and 4) or by monitoring the fluorescence at 518 nm with emission at 494 nm (Figures 5 and 6)).

RESULTS AND DISCUSSION

The design of the functionality-transfer reaction is shown in Figure 2. The conjugate addition of the amino group of the cytosine base to the α,β-unsaturated carbonyl group of the *S*-functionalized 6-thioguanine and the following elimination of 6-thioguanine might produce the *S* to *N* transfer reaction of the functional group. Prior to the synthetic investigation, the reactions within the complex resembling the natural G-C pair were simulated by MO calculations (MOPAC, PM5) using the diketone derivative (**1**, X = H, Y = $COCH_3$) as the starting material. A hypothesized transition state of the addition reaction from **1** to an intermediate **2** was simulated to have a relatively low activation energy with the imino tautomer of the cytosine base, similar to the NO-transfer reaction from the *S*-nitorosylated 6-thioguanine to the amino group of cytosine (Supporting Information Figure S1) (*12*). Also, a low activation energy was estimated for the elimination of 6-thioguanine (**3**) to form the

Panel B, comparison of the transfer rates of four dicarbonyl compounds. Arrows indicate the new peaks at 10 h after the reaction. The transfer reactions were performed using 30 μM of DNA**2** and 25 μM of RNA**3** in MES buffer at pH 7.0. HPLC: Column: SHISEIDO C18, 4.6 × 250 mm. Solvent: A: 0.1 M TEAA Buffer, B: CH_3CN, B: 10% to 30%/20 min, 30% to 100%/25 min, linear gradient. Flow rate: 1.0 mL/min. UV: 254 nm.

transformed product (**4**). It was expected that functional groups (X and Y) would be useful to adjust the reactivity of the α,β-unsaturated carbonyl group.

The investigation was started by a search of suitable α,β-unsaturated carbonyl compounds with different X and Y groups. It was shown in the preliminary experiments with monomers in organic solvents that the 2′-deoxy-6-thioguanosine derivative resembling **1** (X = $COCH_3$ or COOEt, Y = H) gave rise to the corresponding transferred product of the cytidine monomer, although the reaction slowly proceeded even at high concentrations (74% yield after 7 days at 0.1 M) (*13*). With the

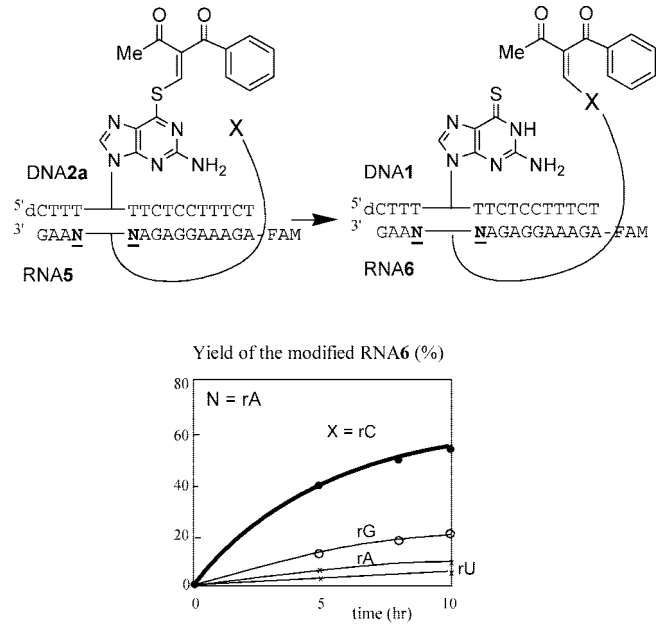

Figure 5. Selectivity to the cytosine base in the RNA substrates with *N* = rA or rC. The transfer reactions were performed at 25 °C using 1.2 μM of DNA**2** and 1 μM of RNA**5** in MES buffer at pH 7.0, followed by HPLC. The RNA**5** having the cytosine base next to the complementary position of 3′ rA-rU-rC or 3′ rC-rU-rA in the sequence of N-X-N produced no significant transferred product. HPLC: Column: SHISEIDO C18, 4.6 × 250 mm. Solvent: A: 0.1 M TEAA Buffer, B: CH_3CN, B: 10% to 30%/20 min, 30% to 100%/25 min, linear gradient. Flow rate: 1.0 mL/min; monitoring the fluorescence at 518 nm with emission at 494 nm.

The transfer reactions were performed at 25 °C using 1.2 μM of DNA**9** and 1 μM of RNA**7** in MES buffer at pH 7.0, followed by HPLC. HPLC: Column: SHISEIDO C18, 4.6 × 250 mm. Solvent: A: 0.1 M TEAA Buffer, B: CH_3CN, B: 10% to 30%/20 min, 30% to 100%/25 min, linear gradient. Flow rate: 1.0 mL/min; monitoring the fluorescence at 518 nm with emission at 494 nm.

expectation that the reaction of the reactants would be enhanced due to proximity effect in the duplex, we selected the dicarbonyl derivative as a potential candidate for the interstrand transfer reaction in this study. 6-Thioguanosine containing DNA**1** was synthesized as previously reported (*12*). The 1,3-dicarbonyl compounds were transformed into the corresponding 2-chloromethyldene derivatives (**5**) (Scheme 1), which were then mixed with DNA**1** in a carbonate buffer at pH 10 to rapidly produce the corresponding *S*-functionalized DNA**2** as the single

peak (Figure 3). Structures of the modified DNA**2** were confirmed by MALDI-TOF/MS and UV spectral changes (Supporting Information Figure S2 and Table S2). The modified DNA**2** was relatively stable, and slowly regenerated DNA**1** in the MES buffer at pH 7.0 with a half-life of ca. 350 h (DNA**2b**), 100 h (DNA**2c**), or 70 h (DNA**2a**), except for DNA**2d** with a half-life of 14 h.

An interstrand functionality-transfer reaction was carried out using DNA**2** and its complementary RNA substrates (Figure 4). The reaction progress was followed by HPLC (panel A in Figure 4), in which the peaks marked by arrows indicated the newly formed products, DNA**1** and RNA**4**. The transferred product RNA**4** was isolated and the structure was determined by MALDI-TOF/MS measurements. The effects of the diketone structure on the efficiency of the functionality transfer were compared using DNA**2a**−**d** with a different dicarbonyl unit (panel B in Figure 2). The transfer reactivity decreased in the order of R_1, R_2 = Ph, Me > Ph, Ph > Ph, OEt > Me, Me. In the aromatic series (R^1 = Ph), the reactivity was in the same order as the intrinsic reactivity as suggested by their half-lives in the buffer. Interestingly, DNA**2d** with the shortest half-life gave the lowest reactivity compared to the other aromatic series. As the dicarbonyl structure with R_1, R_2 = Ph, Me (DNA**2a**) possessed a moderate stability and the highest transfer reactivity, a further investigation was performed using this dicarbonyl functional group.

The base selectivity in the transfer reaction was investigated using DNA**2a** and RNA substrates. Selective transfer to the cytosine base was observed (Figure 5), and the transfer rates were much slower to the adenine, guanine, or thymine base (RNA**5** with N = dA; X = dT, dA, or dG). The RNA substrates (RNA**5**) having the cytosine base next to the complementary position (3′ N-X-N = rA-rU-rC or rC-rU-rA) showed a very slow reaction at the background rates, proving that only the cytosine base at the complementary position exhibited a high reactivity during the functionality-transfer reaction. The generality of this functionality-transfer reaction was investigated using DNA probe **9** and RNA substrates **7**. As well as the transfer reaction in the DNA**2a**−RNA**5** duplex, selective transfer to the cytosine base was confirmed (Figure 6). Thus, a new functionality-transfer reaction with a site selectivity to the cytosine base has been established using the *S*-functionalized 6-thioguanosine containing DNA.

In order to confirm that the transfer reaction takes place within the duplex, the CD spectra and the melting temperatures of the duplexes were measured by using nonreactive DNA**11**, **12**, which were prepared by the addition of 1-phenyl-2-propyn-1-one (*14*) to DNA**1**, **10**, respectively, under the same conditions described in Figure 3. The duplex formed with DNA**11** and RNA**5** (N = rA, X = rC) showed the T_m value of 49 °C (panel A in Figure 7). The T_m values of the duplexes of all the other combinations were in the range 43−49 °C (Supporting Information Table S1). The CD spectra of the DNA**11**−RNA**5** (N = rA, X = rC) duplex suggested that the duplex had a conformation between A and B types (panel B in Figure 7) (*15*). It is shown from the melting curve and CD spectra (panels A and C in Figure 7) that the RNA**7** has a hairpin-loop structure in an A-type conformation. Similarly, DNA**12** was shown to have a hairpin-loop structure in a B-type conformation (panel C in Figure 7). The changes of the CD spectra indicated that the hairpin-loop structure of RNA**7** was transformed to the duplex with DNA**12** in a conformation between A-type and B-type (panel C in Figure 7). It was also observed that the functionality-transfer rates from DNA**2a** to RNA**4** were independent of the duplex concentrations between 25 μM and 1 μM. These results have supported that site specificity and cytosine selectivity are made possible due to the close proximity between *S*-vinylated thioguanosine and the amino group of cytosine at the target site of the complementary strand within the duplex.

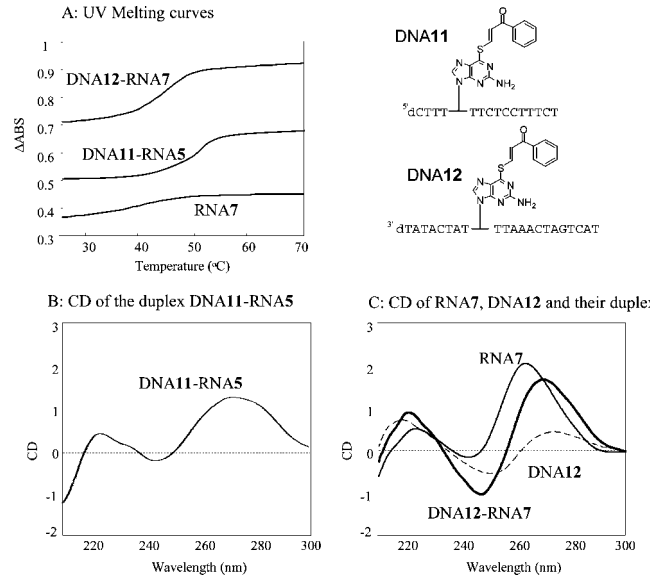

Figure 7. UV melting curves (panel A) and CD spectra (panels B and C). (A) Melting curves were measured using 1.3 μM of each DNA and RNA strands in 50 mM MES buffer at pH 7.0 containing 100 mM NaCl by monitoring at 260 nm. (B,C) CD spectra were measured by using 2.5 μM each DNA and RNA strands in 50 mM MES buffer containing 100 mM NaCl at pH 7.0.

CONCLUSIONS

In this study, the base- and site-selective modifications of the cytosine base of RNA have been successfully achieved using the newly designed functionality-transfer oligodeoxynucleotides. Experimental results have proven that the selectivity and efficiency arise due to the close proximity of the reactants in the DNA-RNA duplexes. As a variety of molecules such as fluorescent labeling groups and tagging molecules may be potentially transferred site-specifically to RNAs, this strategy will be useful for the development of a unique tool for the study of RNAs. If this functionality-transfer reaction is performed with the ODN with resistance to biological degradation, such a reactive ODN may be useful for covalent modification of RNAs under physiological conditions. A further study is now ongoing along this line.

Detection of Protein Phosphorylation on SDS-PAGE Using Probes with a Phosphate-Sensitive Emission Response

Alexander Riechers, Florian Schmidt, Stefan Stadlbauer, and Burkhard König*

Institute for Organic Chemistry, University of Regensburg, Regensburg, Germany. Received January 27, 2009

Fluorescent probes for the detection of protein phosphorylation on SDS-PAGE are presented. The probes were designed using a dinuclear metal-chelate phosphate recognition unit and an environmentally sensitive fluorophore. The specificity of the probes is determined by their binding site selectivity toward phosphate ions and the emission response induced by the change in the electrostatic environment of the fluorophore upon binding to a phosphorylated amino acid residue. The staining is fully reversible due to the noncovalent binding of the probe. Gel bands with less than 100 ng of phosphorylated α-casein are detectable with the new probes on a normal UV-table without specialized equipment like a laser-based gel scanner or a cooled camera detector.

INTRODUCTION

Staining of SDS gels is a standard technique in molecular biology. While silver and Coomassie staining are widely used for total protein staining, a number of stains selective for certain functional groups have emerged. Glycosylation (*1, 2*), His-tags (*3*), and phosphorylation (*4, 5*) are typical protein modifications targeted by selective gel stains reported so far. With respect to its biological importance, phosphorylation (*6, 7*) is widely regarded as the most significant post-translational modification. Phosphorylation plays an important part in signaling pathways, and it is estimated that 30% of the entire proteome becomes phosphorylated at some point (*8*). While there are phospho-specific antibodies available (*9, 10*), they require blotting of the proteins onto a polyvinyldifluoride (PVDF) or nitrocellulose membrane and may also be specific for additional epitopes in proximity to the phosphorylation site. Alternatively, ^{32}P-labeling of the proteins provides a very sensitive tool for detection of phosphorylation (*11, 12*); however, the handling and disposal of radioactive material are costly, potentially hazardous, and increasingly regulated. When staining for substoichiometric features such as phosphorylation, fluorescence detection is the method of choice due to its inherent sensitivity. The reported (*13*) and commercially available (*4, 5*) fluorescent phospho-specific stains gain their sensitivity from their binding site specificity. While other fluorescent probes for phosphorylated amino acids have been reported (*14*), their selectivity has only been demonstrated for peptides without other metal-chelating amino acids like histidine, tryptophan, or cysteine.

Herein, we report two novel phospho-specific gel stains based on the interaction of a metal-chelate binding site and a covalently attached fluorophore. We have previously described the binding of a bis-zinc(II)-cyclen triazine to phosphorylated serine and histidine (*15*). Since these artificial receptors showed high affinity under physiological conditions, we set about using this interaction in molecular biology. On the basis of these findings and a previously reported monozinc(II)-cyclen coumarin receptor (*16*), which changes its emission wavelength when bound to inorganic phosphate in solution, we designed fluorescently labeled bis-zinc(II)-cyclen triazine complexes for staining of phosphorylated proteins in SDS gels. Bis-zinc(II)-cyclen triazine was found to have a higher affinity toward phosphate than mononuclear zinc(II)-cyclen complexes and was therefore used as the recognition moiety. As fluorophores, we selected the widely employed carboxyfluorescein and 7-(diethylamino) coumarin, since a similar fluorophore has shown large solvatochromic emission shifts (*17*), which we associate to its sensitivity to the environment (*18*). The resulting probes **1** and **2** are depicted in Figure 1, while the emission response concept is shown in Scheme 1.

MATERIALS AND METHODS

Synthesis. Detailed information on the synthetic procedures and compound characterization data are provided in the Supporting Information.

Dephosphorylation by *λ*-PPase Treatment. Bovine α-casein (40 μg, purchased from Sigma-Aldrich) was treated with 400 U of *λ*-PPase (purchased from New England Biolabs) in Tris-HCl (50 mM), NaCl (100 mM), dithiothreitol (2 mM), $MnCl_2$ (2 mM), EGTA (0.1 mM), 0.01% Brij 35, pH 7.5, at 30 °C for 6 h.

SDS-PAGE. Proteins were resolved on minigels under denaturating and reducing Laemmli conditions on a PeqLab 45−1010-i apparatus. The gels consisted of a 4% acrylamide (w/v), 120 mM Tris-HCl (pH 6.8), 0.1% SDS (w/v) stacking

gel, and a 15% acrylamide (w/v), 375 mM Tris-HCl (pH 8.8), 0.1% SDS (w/v) running gel. A 25 mM Tris, 192 mM glycine, 0.1% SDS (w/v) running buffer (pH 8.3) was used. Protein samples were heated to 70 °C for 10 min with reducing and denaturating RotiLoad 1 sample buffer (purchased from Carl Roth, Germany) before being loaded onto the gel. The gels were run at 150 V until the proteins entered the running gel, and then the voltage was increased to 250 V. Water cooling was used during the entire run. Fixation was accomplished by treating the gels with 50% MeOH/10% AcOH twice, for 30 min and overnight, respectively.

Staining and Imaging. The gels were soaked in deionized water (4 × 10 min) before being treated with a solution of probe **1** or **2** in deionized water for 1 h with a probe concentration of 10^{-7} M. We found that destaining was not strictly necessary at this concentration; however, when the probes were used at higher concentrations, the gels could be destained by washing with deionized water until a nonfluorescent background was obtained. Due to their noncovalent binding mode (*19*), the probes could be completely removed by repeated washing of the gel with water. Conveniently, removal of the probes was not necessary for Coomassie restaining.

The gels were wrapped in cling film to prevent them from drying out and placed on a PeqLab Superbright UV table (λ_{ex} = 316 nm). Images were taken using either a Pentax K10D or a Traveler DC 8500. Emission spectra of individual protein bands were obtained using the same UV table and a Hamamatsu PMA-11 photonic multichannel analyzer. Data were acquired using the supplied PMA Optic software. A 455 nm long-pass filter was placed on top of the gel to prevent the UV light saturating the detector. Long-pass filters with a shorter cutoff proved unsuitable as they showed a strong fluorescence when subjected to the UV light.

After fluorescence imaging, a restain for total protein was accomplished with 0.1% Coomassie R-250, 50% MeOH, 10% AcOH for 1 h. Destaining was accomplished in 7% AcOH, 10% MeOH overnight. The gels were again wrapped in cling film and scanned using an office scanner.

RESULTS AND DISCUSSION

To evaluate the phospho-staining selectivity and sensitivity of our probes, a dilution series of phosphorylated bovine α-casein was electrophoretically resolved from the non-phosphorylated protein BSA. In addition, a sample of α-casein was de-phosphorylated using λ-PPase and used as a control to ensure the emission response would not depend on the amino acid composition of the protein. After fixation, the gels were stained and destained when necessary until little or no background was visible.

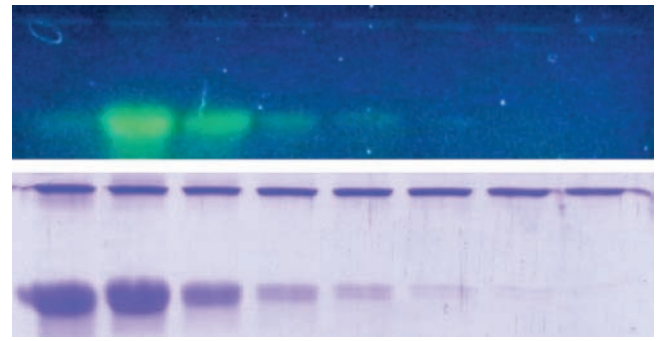

Figure 2. Gel stained with probe **1**. Each lane contains 1 μg BSA (66 kDa). From left to right: lane 1, 1 μg α-casein (23 kDa) dephosphorylated; lanes 2−8, 1 μg, 500 ng, 250 ng, 125 ng, 62 ng, 31 ng, 15 ng α-casein. Top image was taken on a UV table (λ_{ex} = 316 nm), lower image shows CBB R-250 total protein restain.

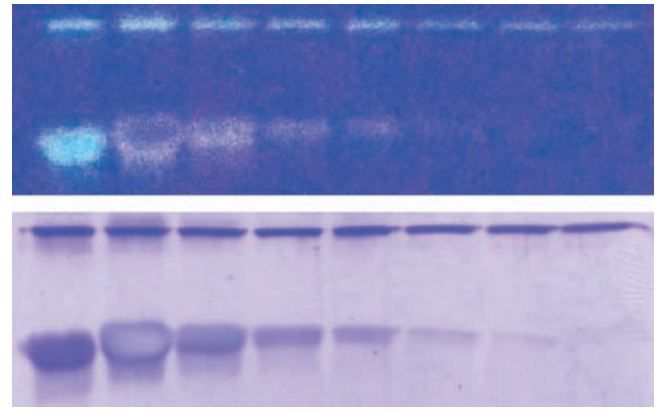

Figure 3. Gel stained with probe **2**. Each lane contains 1 μg BSA (66 kDa). From left to right: lane 1, 1 μg α-casein (23 kDa) dephosphorylated; lanes 2−8, 1 μg, 500 ng, 250 ng, 125 ng, 62 ng, 31 ng, 15 ng α-casein. Top image was taken on a UV table (λ_{ex} = 316 nm); lower image shows CBB R-250 total protein restain.

Probe **1** showed a distinct emission in the bands of phosphorylated α-casein, whereas the bands of de-phosphorylated α-casein and BSA are barely visible (Figure 2). Bis-zinc(II)-cyclen triazine complexes coordinate phosphate groups strongly, but we also expect an affinity of the probe to non-phosphorylated proteins due to the coordination of histidine by the bis-zinc(II)-cyclen triazine (*15*, *20*) or further unspecific interactions. However, these interactions do not interfere with the specific detection of phosphorylation: The emission of the probe is quenched, when bound to non-phosphorylated amino acid residues and the emission remains, when bound to phosphorylated amino acid residues. Similar emission quenching effects have been previously reported for the interaction of riboflavin with a zinc(II)-imidazole complex (*21*) and for zinc(II)-porphyrin with histidine (*22*). To prove that the observed effects originate from the coordination of the bis-zinc(II)-cyclen triazine complex and not from the binding of the fluorophore itself, a control gel was prepared and treated with carboxyfluorescein. No staining could be observed in this experiment.

When bound to phosphorylated α-casein, probe **2** showed a strong red-shift in the emission compared to unphosphorylated α-casein and BSA (Figure 3). We attribute this spectral change to the different electronic environments when the probe molecule is either unspecifically interacting with non-phosphorylated amino acid residues, such as histidine (unphosphorylated α-casein and BSA) or coordinating a negatively charged phosphorylated amino acid residue (phosphorylated α-casein). These findings are in agreement with the reported red-shift in emission of a monozinc(II)-cyclen coumarin complex upon

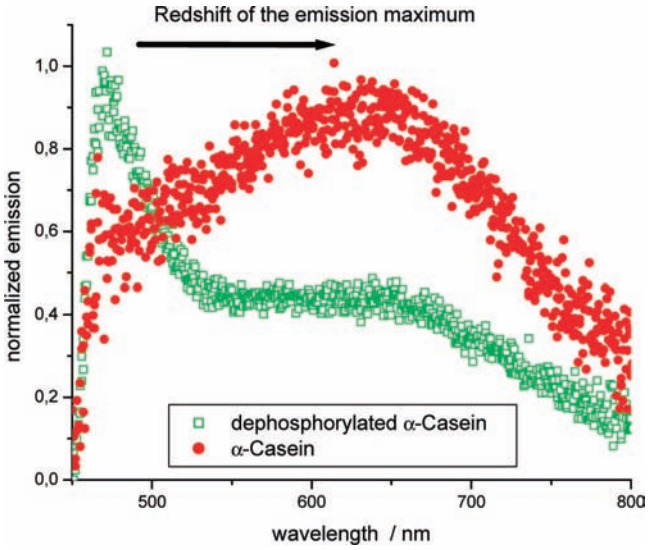

Figure 4. Normalized emission spectra of gel bands stained with probe **2** acquired through a 455 nm long-pass filter (λ_{ex} = 316 nm). BSA band showed the same spectrum as dephosphorylated α-casein (data not shown).

coordination to inorganic phosphate ions (*16*) To quantify this change in emission, fluorescence spectra of the gel bands were obtained using a photonic multichannel analyzer equipped with a fiber optic (Figure 4). As with probe **1**, a control gel was treated with the fluorophore itself, and again no staining was observed.

With both probes, the dilution series proved that 62 ng of phosphorylated α-casein is still detectable on a normal UV-table by the unaided eye (which was protected from UV light) while imaging was performed with common digital cameras. Hence, even without the use of specialized equipment like laser-illuminated gel scanners or cooled camera detectors as described in the protocols of commercially available phosphoprotein gel stains our probes reach similar limits of detection.

CONCLUSION

We have demonstrated the application of two new noncovalent, reversible, and fluorescent SDS-PAGE probes capable of indicating protein phosphorylation. The probes show different fluorescence responses discriminating phosphorylated from non-phosphorylated proteins. While probe **1** signals binding to a phosphorylated protein by a significant increase of emission intensity, probe **2** is the first phosphoprotein gel stain to change its emission spectrum upon binding to a phosphorylated protein. The probes achieve their selectivity through a combination of the specificity of the dinuclear metal chelate binding site toward phosphate oxoanions and a modulation of the chromophore emission due to the proximity of the phosphorylated amino acid. The environmentally sensitive fluorophore allows a clear distinction between phosphorylated and non-phosphorylated proteins on SDS-PAGE and allows the detection of 62 ng of phosphorylated α-casein on a normal UV-table. Evaluations of other metal-chelate fluorophore conjugates and applications of the existing probes to monitor signaling pathways are currently underway.

ACKNOWLEDGMENT

We thank Lorenz Fischer for help with the Hamamatsu PMA-11 analyzer and Andreas Grauer for help with the imaging. We are grateful to Jennifer Schmidt, Silke Kuphal, and Anja Katrin Bosserhoff for valuable discussions.

1. SYNTHESIS OF PROBES 1 AND 2

GENERAL

All reactions were performed under an inert atmosphere of N_2 using standard Schlenk techniques if not otherwise stated. A Varian Cary BIO 50 UV/VIS/NIR Spectrometer was used. A 1 cm quartz cell was purchased from Hellma and Uvasol solvents from Merck or Baker. Absorption and emission maxima are given in nm, molar absorptivities (ε) are given in M^{-1} cm^{-1}. IR spectra were recorded on a Bio-Rad FT-IR FTS 155 and a Bio-Rad FTS 2000 MX FT-IR using a Specac Golden Gate Mk II ATR accessory where stated. NMR spectrometers used were: Bruker Avance 600 (^{1}H: 600.1 MHz, ^{13}C: 150.1 MHz, T = 300 K), Bruker Avance 400 (^{1}H: 400.1 MHz, ^{13}C: 100.6 MHz, T = 300 K) and Bruker Avance 300 (^{1}H: 300.1 MHz, ^{13}C: 75.5 MHz, T = 300 K). The chemical shifts are reported in δ [ppm] relative to external standards (solvent residual peak). The spectra were analyzed by first order, the coupling constants are given in Hertz [Hz]. Characterization of the signals: s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, bs = broad singlet, psq = pseudo quintet, dd = double doublet, dt = double triplet, ddd = double double doublet. Integration is determined as the relative number of atoms. Assignment of signals in ^{13}C-spectra was determined with DEPT-technique (pulse angle: 135 °) and given as (+) for CH_3 or CH, (-) for CH_2 and (C_{quat}) for quaternary C. Error of reported values: chemical shift: 0.01 ppm for ^{1}H-NMR, 0.1 ppm for ^{13}C-NMR and 0.1 Hz for coupling constants. The solvent used is reported for each spectrum. Mass spectra were recorded on Varian CH-5 (EI), Finnigan MAT 95 (CI; FAB and FD) and Finnigan MAT TSQ 7000 (ESI). Xenon served as the ionization gas for FAB. Melting Points were determined on a Büchi SMP-20 melting point apparatus and are uncorrected. TLC analyses were performed on silica gel 60 F-254 with a 0.2 mm layer thickness. Detection was via UV light at 254 nm / 366 nm or by staining with ninhydrin in EtOH. For preparative column-chromatography, Merck Geduran SI 60 silica gel was used. Commercially available solvents of standard quality were used. Unless otherwise stated, purification and drying was done according to accepted general procedures (*1, 2*). Compounds **3** (*3*) and **5** (*4*) were synthesized according to literature known procedures.

SYNTHESIS OF PROBES 1 AND 2

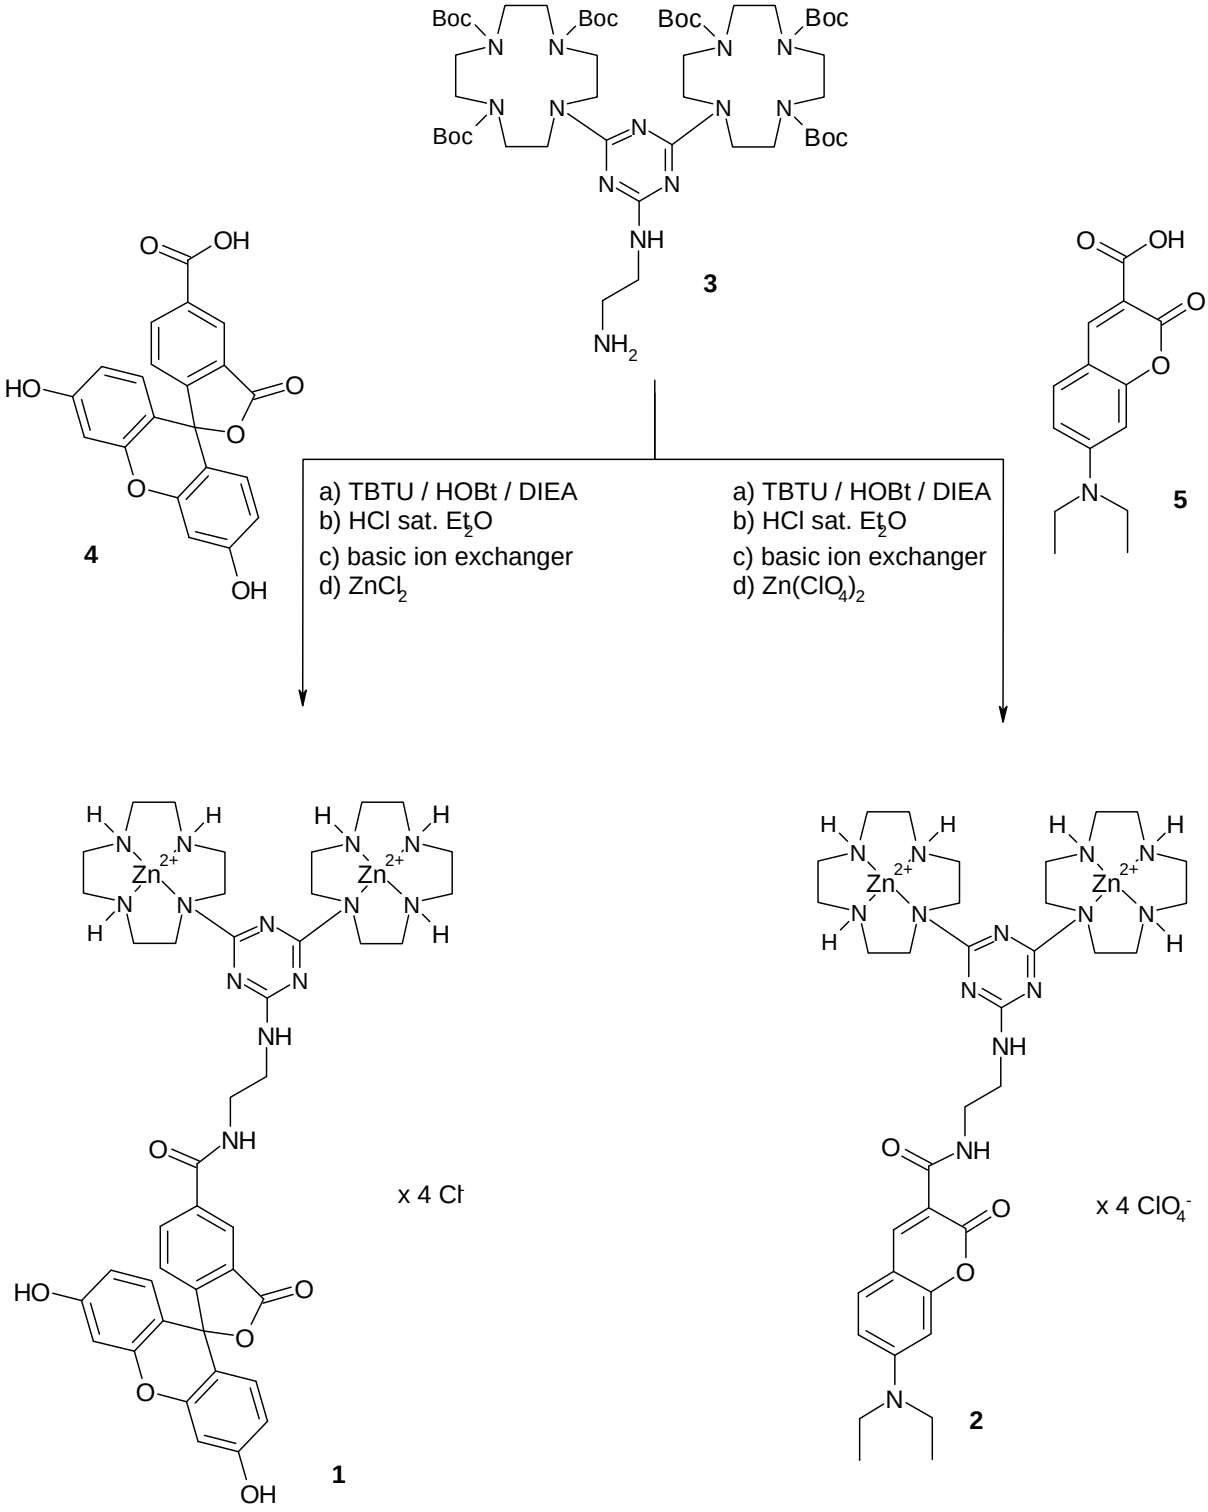

FIGURE S-1 Preparation of probes **1** and **2**

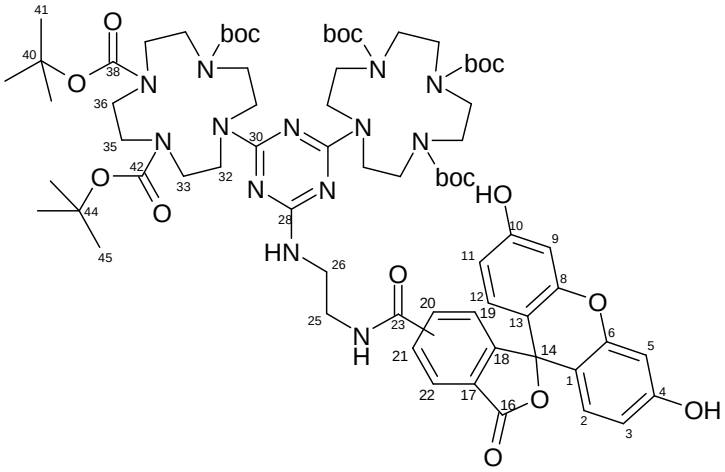


Regioisomeric 1,4,7-tri-tert-butyl 10,10'-{6-[2-(3',6'-dihydroxy-3-oxo-3H-spiro[isobenzofuran-1,9'-xanthene]-5/6-ylcarboxamido)ethylamino]-1,3,5-triazine-2,4-diyl}bis(1,4,7,10-tetraazacyclododecane-1,4,7-tricarboxylate) (**6**):

In a nitrogen flushed round bottom flask, regioisomeric 5-,6-carboxyfluorescein (0.15 g, 0.40 mmol) was dissolved in 10 mL of a mixture of dichloromethane and DMF (2:1), then DIPEA (0.17 g, 180 µL, 1.32 mmol) and HOBt monohydrate (0.07 g, 0.48 mmol) were added. While stirring, the mixture was cooled to 0°C in an ice water bath to add TBTU (0.15 g, 0.48 mmol). After 30 min, 1,4,7-tri-tert-butyl 10,10'-(6-(2-aminoethylamino)-1,3,5-triazine-2,4-diyl) bis (1,4,7,10-tetraazacyclo-dodecane-1,4,7-tricarboxylate) (**3**) (0.47 g, 0.44 mmol) was added in portions to the flask and the reaction mixture was heated to 40°C for 2h. Subsequently, the solvents were evaporated and the crude product was purified by column chromatography ($CHCl_3$: MeOH = 15 : 1) on flash-silica-gel yielding compound **6** as an orange amorphous solid (0.34 g, 0.23 mmol, 59%).

MP: 207°C

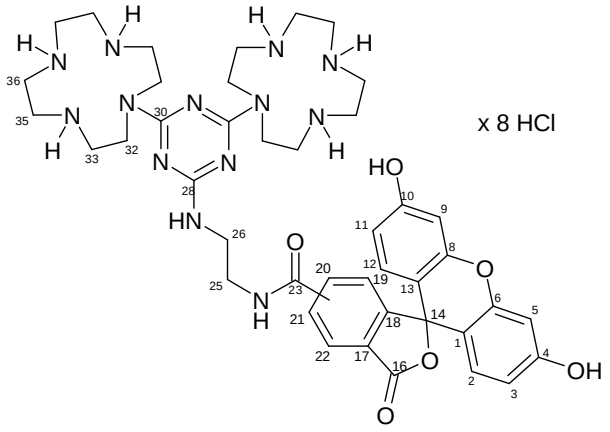
^{1}H-NMR (600 MHz, MeOD, COSY, ROESY, HSQC, HMBC): δ [ppm] = 8.36 (s, 0.7H, 22a), 8.13 (d, $^3J_{H,H}$ = 7.91 Hz, 0.7H, 20a), 8.07 (d, $^3J_{H,H}$ = 8.08 Hz, 0.3H, 21b), 8.03 (d, $^3J_{H,H}$ = 8.04 Hz, 0.3H, 22b), 7.61 (s, 0.3H, 19b), 7.24 (d, $^3J_{H,H}$ = 8.02 Hz, 0.7H, 19a), 6.68 (dd, $^3J_{H,H}$ = 1.75 Hz, $^5J_{H,H}$ = 1.75 Hz, 2H, 2+12), 6.57 (dd, $^4J_{H,H}$ = 8.71 Hz, $^5J_{H,H}$ = 8.71 Hz, 2H, 5+9), 6.52 (dd, $^3J_{H,H}$ = 8.72 Hz, $^4J_{H,H}$ = 2.31 Hz, 2H, 3+19), 3.99-3.20 (m, 36H, 25a/b, 26a/b, 32+33+35+36), 1.45-1.37 (m, 54H, 41+45)

^{13}C-NMR (150 MHz, MeOD, COSY, ROESY, HSQC, HMBC): δ [ppm] = 170.4 ($C_{quat.}$, 0.3C, 16b), 170.3 ($C_{quat.}$, 0.7C, 16a), 168.5 ($C_{quat.}$, 0.7C, 23a), 168.3 ($C_{quat.}$, 0.3C, 23b), 167.8 ($C_{quat.}$, 2C, 30), 167.5 ($C_{quat.}$, 0.7C, 28a), 167.3 ($C_{quat.}$, 0.3C, 28b), 161.3 ($C_{quat.}$, 2C, 4+10), 158.0 ($C_{quat.}$, 6C, 38+42), 156.7 ($C_{quat.}$, 0.7C, 18a), 1#54.4 ($C_{quat.}$, 0.3C, 18b), 153.9 ($C_{quat.}$, 2C, 6+8), 142.4 ($C_{quat.}$, 0.3C, 20b), 138.0 ($C_{quat.}$, 0.7C, 21a), 135.5 (+, 0.7C, 20a), 130.2 (+, 0.3C, 21b), 130.1 (+, 2C, 5+9), 128.5 ($C_{quat.}$, 1C, 17a/b), 126.1 (+, 0.3C, 22b), 125.6 (+, 0.7C, 19a), 124.8 (+, 0.7C, 22a), 124.0 (+, 0.3C, 19b), 113.7 (+, 2C, 3+11), 110.8 ($C_{quat.}$, 2C, 1+13), 103.7 (+, 2C, 2+12), 81.5 ($C_{quat.}$, 2C, 38), 81.4 ($C_{quat.}$, 4C, 42), 79.4 ($C_{quat.}$, 1C, 14), 51.4 (-, 16C, 32+33+35+36), 41.7 (-, 0.7C, 25a), 41.5 (-, 0.3C, 25b), 40.9 (-, 0.7C, 26a), 40.8 (-, 0.3C, 26b), 29.9 (+, 6C, 41), 28.8 (+, 12C, 45)

IR (ATR) [cm^{-1}]: ν = 3318, 2971, 2935, 1766, 1689, 1665, 1539, 1466, 1410, 1365, 1247, 1157, 1024, 852, 811, 751, 665

ES-MS (H_2O/MeOH + 10 mmol/L NH_4Ac): *m/z* (%) = 720.0 (100) [M + $2H^+$], 1439.0 (5) [MH^+]

UV (MeCN): λ (ε) = 454 (2175), 481 (1876)



Regioisomeric N-{2-[4,6-di(1,4,7,10-tetraazacyclododecan-1-yl)-1,3,5-triazin-2-ylamino]ethyl}-3',6'-dihydroxy-3-oxo-3H-spiro[isobenzofuran-1,9'-xanthene]-5-carboxamide octachloride (**7**):

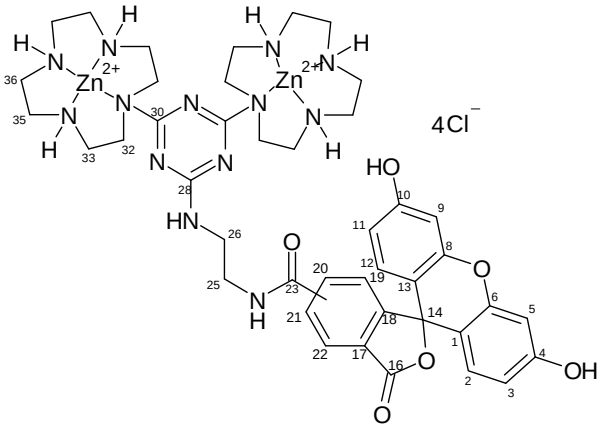
Compound **6** (80 mg, 0.05 mmol) was dissolved in as little dichloromethane as possible and cooled to 0°C before hydrochloric acid saturated diethyl ether (1.06 mL)

was added slowly to this solution. Stirring was continued for 16h while the reaction mixture was allowed to reach rt. Formation of a yellowish precipitate was observed. The desired product was obtained by evaporation of the solvent in vacuum as a red amorphous solid (50 mg, 0.05 mmol, quant.), which was deprotonated by ion exchange column on weakly basic anion exchanger resin.

^{1}H-NMR (600 MHz, D_2O, COSY, HSQC, HMBC): δ [ppm] = 8.43 (s, 2H, 24), 7.97 (s, 0.6H, 22a), 7.93-7.86 (d, $^{3}J_{H,H}$ = 7.37 Hz, 0.4H, 21b), 7.85-7.79 (d, $^{3}J_{H,H}$ = 7.40 Hz, 0.4H, 22b), 7.74 (bs, 0.6H, 20a), 7.44 (s, 0.4H, 19b), 7.02 (bs, 0.6H, 19a), 6.99-6.70 (m, 2H, 2+12), 6.61-6.41 (m, 2H, 3+11), 6.41-6.13 (m, 2H, 5+9), 3.87-3.39 (m, 12H, 25+26+36), 3.27-2.88 (m, 24H, 32+33+35)

^{13}C-NMR (150 MHz, D_2O, COSY, HSQC, HMBC): δ [ppm] = 179.9 ($C_{quat.}$, 2C, 30), 174.2 ($C_{quat.}$, 0.4C, 16b), 173.2 ($C_{quat.}$, 0.6C, 16a), 171.5 ($C_{quat.}$, 1C, 28), 170.1 ($C_{quat.}$, 0.4C, 23b), 169.5 ($C_{quat.}$, 0.6C, 23a), 167.2-166.3 ($C_{quat.}$, 2C, 4+10), 158.6-158.4 ($C_{quat.}$, 2C, 6+8), 157.9 ($C_{quat.}$, 0.6C, 18a), 157.2 ($C_{quat.}$, 0.4C, 18b), 143.7 ($C_{quat.}$, 0.4C, 20b), 140.7 ($C_{quat.}$, 0.6C, 21a), 135.6 ($C_{quat.}$, 0.4C, 17b), 135.2 ($C_{quat.}$, 0.6C, 17a), 131.9-131.5 (+, 2C, 2+12), 130.7 (+, 0.6C, 19a), 129.5 (+, 0.4C, 22b), 129.2 (+, 0.4C, 21b), 128.7 (+, 0.4C, 19b), 128.4 (+, 1.2C, 20a+22a), 123.3 (+, 2C, 3+11), 104.4 (+, 2C, 5+9), 46.5-45.2 (-, 12C, 33+35+36), 43.9 (-, 4C, 32), 40.8-40.6 (-, 1C, 25a/b), 39.9 (-, 1C, 26)

ES-MS (MeCN/TFA): *m/z* (%) = 280.1 (100) [M + 3H^{+}], 419.8 (63) [M + 2H^{+}], 838.5 (4) [MH^{+}], 874.4 (3) [MH^{+} + HCl]



Probe **1***:*

Deprotonated compound **7** (48 mg, 0.06 mmol) was dissolved in 2 mL of warm water, then zinc(II)-chloride (16 mg, 0.12 mmol) was added. After pH-adjustment to 7-8 with saturated $NaHCO_{3,\ aqu.}$, the mixture was heated to 100°C for 2h while stirring. The desired product was isolated by lyophilisation of the reaction mixture as a dark orange, amorphous solid (48 mg, 0.04 mmol, 75%).

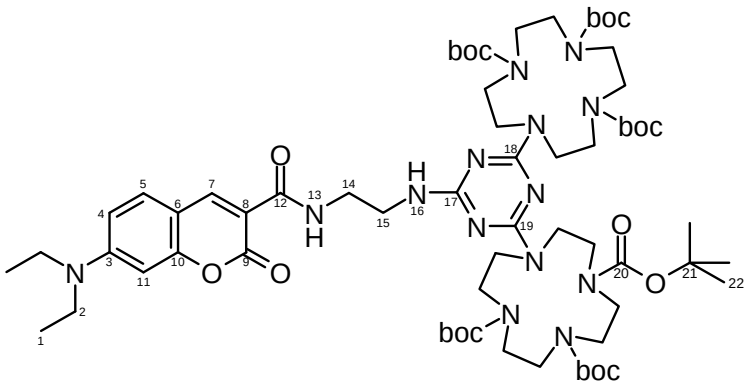
^{1}H-NMR (600 MHz, D_2O, COSY, HSQC, HMBC): δ [ppm] = 8.14-6.06 (m, 9H, *aryl*), 4.25-2.62 (m, 35H, *amide-NH+CH_2*)

^{13}C-NMR (150 MHz, D_2O, COSY, HSQC, HMBC): δ [ppm] = 174.1-103.2 ($C_{quat.}$&-, 24C, 1-23+28+30), 46.3-38.7 (-, 18C, 25+26+32-36)

ES-MS (H_2O/MeOH + 10 mmol/L NH_4Ac): *m/z* (%) = 511.4 (70) [M^{4+} - H^+ + CH_3COO^-], 481.8 (37) [M^{4+} - $2H^+$]

UV (40 mM TRIS-buffer, 10 mM $MgCl_2$, 2 mM DTE, pH 7.6): λ (ε) = 321 (6430), 497 (56320)

FLUORESCENCE (40 mM TRIS-buffer, 10 mM $MgCl_2$, 2 mM DTE, pH 7.6): exc. 494 nm, emission max. 526 nm



7-Diethylamino-2-oxo-2H-chromene-3-carboxylic acid {2-[4,6-bis-(1,4,7,10-tetraaza-cyclododec-1-yl)-[1,3,5]triazin-2-yl]-ethyl}-1,4,7-tricarboxylic acid tri-tert-butyl ester (**8**):

7-Diethylamino-2-oxo-2H-chromene-3-carboxylic acid (150 mg, 0.56 mmol), DIPEA (386 µL, 2.24 mmol), TBTU (203 mg, 0.63 mmol), and HOBt (97 mg, 0.63 mmol) were dissolved under nitrogen atmosphere in dry DMF (4 mL) under ice cooling and stirred for 1 h. Subsequently amine **3** (635 mg, 0.59 mmol) dissolved in DMF (2 mL) was added drop wise. The reaction was allowed to warm to room temperature and was stirred 30 min at room temperature and 3 h at 40 °C. The reaction progress was

monitored by TLC (chloroform/MeOH 97.5/2.5). After completion of the reaction the solvent was removed and the crude product was purified by flash column chromatography on flash silica gel (chloroform/MeOH 97.5/2.5; R_f (EE) = 0.60) yielding compound **8** (684 mg, 0.52 mmol, 93 %) as a yellow solid.

MP: 147 °C

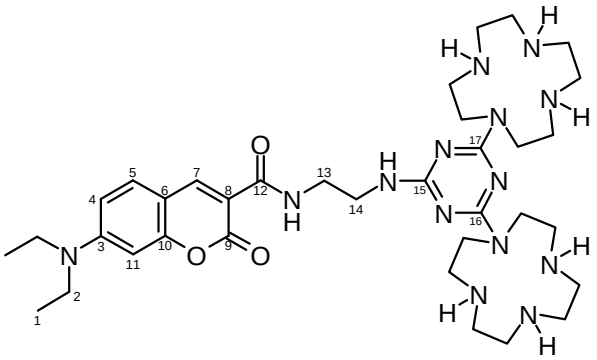
^{1}H-NMR (400 MHz; $CDCl_3$): δ (ppm) = 1.21 (t, ^{3}J = 7.1 Hz, 6 H, HSQC, COSY: $C^{1}H_3$), 1.40 (s, 18 H, HSQC, COSY: $C^{22}H_3$), 1.42 (s, 36 H, HSQC, COSY: $C^{22}H_3$), 3.11-3.76 (m, 36 H, $C^{14}H_2$, $C^{15}H_2$, cyclen-CH_2), 3.42 (q, ^{3}J = 7.1 Hz, 4 H, HSQC, HMBC, COSY: $C^{2}H_2$), 5.02 (bs, 1 H, NH^{16}), 6.46 (d, ^{4}J = 2.3 Hz, 1 H, HSQC, HMBC, COSY: $C^{5}H$), 6.82 (dd, ^{3}J = 8.9 Hz, ^{4}J = 2.4 Hz, 1 H, HSQC, HMBC, COSY: $C^{4}H$), 7.39 (d, ^{3}J = 8.9 Hz, 1 H, HSQC, HMBC, COSY: $C^{11}H$), 8.65 (s, 1 H, HSQC, HMBC, COSY: $C^{7}H$), 8.90 (m, 1 H, HSQC, COSY: NH^{13}).

^{13}C-NMR (100 MHz; $CDCl_3$): δ (ppm) = 12.4 (+, 2 C, HSQC, HMBC: $C^{1}H_3$), 28.41, 28.46 (+, 18 C, HSQC, HMBC: $C^{22}H_3$), 39.6 (–, 1 C, HSQC, HMBC: $C^{14}H_2$), 40.8 (–, 1 C, HSQC, HMBC: $C^{15}H_2$), 45.0 (–, 2 C, HSQC, HMBC, COSY: $C^{2}H_2$), 50.2 (–, 16 C, HSQC, HMBC: cyclen-CH_2), 79.6 (C_q, 6 C, HSQC, HMBC: C^{21}), 96.5 (+, 1 C, HSQC, HMBC, COSY: $C^{5}H$), 108.3 (C_q, 1 C, HSQC, HMBC: C^{6}), 109.9 (+, 1 C, HSQC, HMBC, COSY: $C^{4}H$), 110.1 (C_q, 1 C, HSQC, HMBC: C^{8}), 131.1 (+, 1 C, HSQC, HMBC, COSY: $C^{11}H$), 148.0 (+, 1 C, HSQC, HMBC, COSY: $C^{11}H$), 152.5 (C_q, 1 C, HSQC, HMBC: C^{3}), 156.2 (C_q, 6 C, HSQC, HMBC: C^{20}), 157.6 (C_q, 1 C, HSQC, HMBC: C^{10}), 162.5 (C_q, 1 C, HSQC, HMBC: C^{9}), 163.7 (C_q, 1 C, HSQC, HMBC: C^{12}), 165.8 (C_q, 3 C, HSQC, HMBC: C^{17}, C^{18}, C^{19}).

IR (ATR) [cm^{-1}]: $\tilde{\nu}$ = 2974, 2933, 1686, 1619, 1584, 1532, 1512, 1466, 1409, 1364, 1246, 1158, 971, 751.

UV ($CHCl_3$): λ_{max} (ε) = 419 (41020)

MS (ESI(+), DCM/MeOH + 10 mmol/L NH_4Ac): m/z (%) = 1324.0 (100) [MH^+), 612.5 (12) [M + 2 H^+]$^{2+}$, 562.5 (25) [M + 2 H^+ - boc]$^{2+}$, 512.4 (51) [M + 2 H^+ - 2 boc]$^{2+}$, 462.3 (55) [M + 2 H^+ - 3 boc]$^{2+}$, 412.3 (34) [M + 2 H^+ - 4 boc]$^{2+}$, 362.2 (17) [M + 2 H^+ - 5 boc]$^{2+}$.



7-Diethylamino-2-oxo-2H-chromene-3-carboxylic acid {2-[4,6-bis-(1,4,7,10-tetraaza-cyclododec-1-yl)-[1,3,5]triazin-2-ylamino]-ethyl}-amide (**9**):

Compound **8** (275 mg, 0.21 mmol) was dissolved in dichloromethane (4 mL) and cooled to 0 °C. Subsequently 4.5 mL of HCl saturated diethylether were added. The solution was stirred 15 min at 0 °C and an additional 20 h at room temperature. The solvent was removed in vacuo, the residue was redissolved in water and extracted with dichloromethane (3x). Subsequently the combined organic layers were dried over $MgSO_4$ and the solvent was evaporated yielding the protonated hydrochloride of compound **9** as a yellow solid in quantitative yield (213 mg, 0.21 mmol).

^{1}H-NMR (400 MHz; $CDCl_3$): δ (ppm) = 1.13 (t, ^{3}J = 7.3 Hz, 6 H, HSQC, COSY: $C^{1}H_3$), 2.97-3.54 (m, 24 H, HSQC, HMBC, COSY: cyclen-CH_2), 3.57-3.72 (m, 6 H, HSQC, HMBC: $C^{13}H_2$; HSQC, HMBC, COSY: $C^{2}H_2$), 3.75 (t, ^{3}J = 5.6 Hz, 2 H, HSQC, COSY: $C^{14}H_2$), 3.89 (bs, 8 H, HSQC, HMBC, COSY: cyclen-CH_2), 7.37-7.56 (m, 2 H, HSQC, HMBC: $C^{4}H$, HSQC, HMBC: $C^{5}H$), 7.96 (d, ^{3}J = 8.4 Hz, 1 H, HSQC, HMBC: $C^{11}H$), 8.72 (s, 1 H, HSQC, HMBC: $C^{7}H$).

^{13}C-NMR (100 MHz; $CDCl_3$): δ (ppm) = 10.1 (+, 2 C, HSQC, COSY: $C^{1}H_3$), 39.0 (–, 1 C, HSQC, HMBC: $C^{13}H_2$), 39.9 (–, 1 C, HSQC, HMBC: $C^{14}H_2$), 44.0 (–, 2 C, HSQC, HMBC, COSY: cyclen-CH_2), 44.3 (–, 6 C, HSQC, HMBC, COSY: cyclen-CH_2), 46.1 (–, 4 C, HSQC, HMBC, COSY: cyclen-CH_2), 47.7 (–, 2 C, HSQC, HMBC, COSY: cyclen-CH_2), 48.3 (–, 2 C, HSQC, HMBC, COSY: cyclen-CH_2), 52.6 (–, 2 C, HSQC, HMBC, COSY: $C^{2}H_2$), 108.8 (+, 1 C, HSQC, HMBC: $C^{5}H$), 117.6 (C_q, 1 C, HSQC, HMBC: C^{6}), 117.9 (C_q, 1 C, HSQC, HMBC: C^{8}), 118.1 (+, 1 C, HSQC, HMBC: $C^{4}H$), 132.5 (+, 1 C, HSQC, HMBC: $C^{11}H$), 143.2 (C_q, 1 C, HSQC, HMBC: C^{3}), 147.6 (+, 1 C, HSQC, HMBC: $C^{7}H$), 154.9 (C_q, 1 C, HSQC, HMBC: C^{10}), 155.2 (C_q, 1 C, HSQC, HMBC: C^{16}), 155.8 (C_q, 1 C, HSQC, HMBC: C^{15}), 161.4 (C_q, 1 C, HSQC, HMBC: C^{9}), 163.6 (C_q, 1 C, HSQC, HMBC: C^{17}), 164.1 (C_q, 1 C, HSQC, HMBC: C^{8}).

MS (ESI(+), MeCN/TFA): m/z (%) = 362.3 (100) $[M + 2\ H^+]^{2+}$, 723.5 (10) $[MH^+]$.

To obtain the free base of compound **9** a weakly basic ion exchanger resin was swollen for 15 min in water and washed neutral with water. A column was charged with resin (473 mg, 40.0 mmol hydroxy equivalents at a given capacity of 5 mmol/g). The hydrochloride salt (60 mg, 59 µmol) was dissolved in water, put onto the column and eluated with water. The elution of the product was controlled by pH indicator paper (pH > 10) and was completed when pH was again neutral. The eluate was concentrated and lyophilised to yield 43 mg (59 µmol, 100 %) of free base **9** as a yellow solid.

MP: 169 °C

^{1}H-NMR (600 MHz; D_2O): δ (ppm) = 1.04 (t, ^{3}J = 7.1 Hz, 6 H, HSQC, COSY: $C^{1}H_3$), 3.02 (bs, 8 H, cyclen-CH_2), 3.12 (bs, 16 H, cyclen-CH_2), 3.27 (q, ^{3}J = 7.0 Hz, 4 H, HSQC, HMBC: $C^{2}H_2$), 3.38 (t, ^{3}J = 4.6 Hz, 2 H, HSQC, HMBC: $C^{13}H_2$), 3.48 (t, ^{3}J = 5.2 Hz, 2 H, HSQC, HMBC: $C^{14}H_2$), 3.62 (bs, 8 H, cyclen-CH_2), 6.13 (d, ^{4}J = 1.8 Hz, 1 H, HSQC, HMBC, ROESY: $C^{11}H$), 6.58 (d, ^{3}J = 9.0 Hz, 1 H, HSQC, HMBC, ROESY: $C^{4}H$), 7.24 (d, ^{3}J = 9.2 Hz, 1 H, HSQC, HMBC, ROESY: $C^{5}H$), 8.09 (s, ^{4}J = 1.8 Hz, 1 H, HSQC, HMBC, ROESY: $C^{7}H$), 8.28 (bs, 1 H, HSQC, NH).

Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, Missouri 63110, and Department of Chemistry, University of Illinois, Urbana, Illinois 61801. Received July 22, 2008; Revised Manuscript Received February 11, 2009

No-carrier-added (NCA) ^{76}Br labeling of 4-(5-acetoxy-7-bromobenzoxazol-2-yl)phenyl acetate, a diacetate-protected estrogen-receptor beta (ERβ) selective ligand, was carried out successfully using [^{76}Br]bromide ion. The labeling was achieved via oxidative electrophilic destannylation of an organotin precursor molecule by modification of the leaving group (from Bu_3Sn to Me_3Sn) and the addition of methanol to the reaction mixture. The differences between the oxidative bromination reaction under small-scale macroscopic vs tracer level radiochemical conditions were explored in terms of effective brominating agents, which depend greatly on the nature of the solvent during the radiochemical bromination, and the potential interference by trace levels of highly reactive impurities in the reaction that compete for the desired bromination at the NCA level. Our observations, and our development of experimental protocols for successful radiobromination at the tracer NCA-scale, should be applicable to the synthesis of other radiobromine-labeled organic compounds of potential interest as PET radiopharmaceuticals and radiotherapy agents.

INTRODUCTION

Radiohalogenated organic compounds are commonly used in basic research and in the clinic as radiopharmaceutical probes for molecular imaging via positron emission tomography (PET[1]) or single photon emission computed tomography (SPECT). If labeled with a therapeutic nuclide, radiohalogenated compounds can be used for internal radiotherapy at the cellular level (*1*). Synthetic methods for radiofluorination and radioiodination have been extensively studied and reviewed (*2*−*5*). Radiobromination has been much less studied, especially regarding the effective brominating agents in radiobromination reactions (*6*, *7*).

Bromine-labeled compounds have some advantages over iodine-labeled compounds: the stronger C−Br bond results in less dehalogenation, and unlike iodide, bromide does not accumulate in the thyroid (*8*). Over the past two decades, interest in radiobromine has shifted from ^{77}Br and ^{82}Br to ^{76}Br (*8*). Radiopharmaceuticals labeled with ^{76}Br ($t_{1/2}$ = 16.2 h) are suitable for imaging slower physiologic processes than those labeled with ^{18}F ($t_{1/2}$ = 110 min). Furthermore, the decay scheme of ^{76}Br (57% positron and 43% electron capture) (*9*) gives it potential both for PET imaging and for radiotherapy. Finally, the ^{76}Br nuclide can be produced via the ^{76}Se(p,n)^{76}Br reaction on most medical cyclotrons (*10*).

Organic molecules often contain aromatic rings onto which ^{76}Br can be introduced by using very high specific activity [^{76}Br]bromide ion. Radiobromination at the tracer level produces products with the very high specific activities required for studying receptor-binding biological processes, but can differ from classical bromination and from radioiodination. Bromide is more difficult to oxidize than iodine, so harsher conditions are required for oxidative bromination. An effective brominating agent is also more reactive than an effective iodinating agent, so standard conditions for radioiodination might not be appropriate for radiobromination.

Major considerations for tracer-level synthesis are synthesis time (due to radioactive decay), specific activity (to achieve true tracer status), and relative stoichiometry. In classical electrophilic brominations, even those on a small scale, macroscopic amounts of the electrophilic brominating agent are used and are usually present in stoichiometric excess over the arene reactant. However, in true tracer-level, no-carrier-added electrophilic radiobromination reactions, the trace amount of "positive bromine" reacts with orders-of-magnitude excesses of a substrate in the presence of an excess of oxidizing agents. Because of this stoichiometric issue, the effective radiobrominating agent is likely to differ from that used in classical bromination. In addition, any highly reactive impurities present in tracer-scale

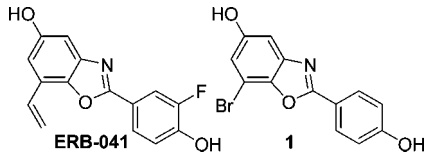

Figure 1. Structures of ERB-041 and **1**.

brominations might preferentially react with the "positive bromine", resulting in formation of bromine-substituted byproducts and reducing yield of the desired product. In contrast, in macroscopic scale reactions, the relatively tiny amounts of any highly reactive impurities compared to stoichiometric or excess bromine would produce chemically ignorable bromine-substituted byproducts. The lack of understanding and published information regarding effective agents for radiobromination of organic moieties has impeded development of some radiopharmaceuticals.

Compound **1** (Figure 1) (*11*), an analogue of ERB-041 (*11, 12*), is an estrogen receptor beta (ERβ) selective ligand with good binding affinity and excellent selectivity over estrogen receptor alpha (ERα) (*11, 12*). Once labeled with ^{76}Br, it is expected to have potential as a PET imaging agent for ERβ. Brominations of nonactivated organic compounds via electrophilic destannylation have been successful using unlabeled bromide and carrier-added [^{76}Br]bromide. However, no-carrier-added radiobrominations have been problematic. Difficulties in no-carrier-added radiolabeling of **1** with ^{76}Br led us to explore radiobrominations in greater detail.

Here, we report systematic exploration of reaction conditions leading to successful tracer-scale, no-carrier-added ^{76}Br radiobromination of aromatic compounds, most notably [^{76}Br]**2** (which can be deprotected to make [^{76}Br]**1**) via electrophilic destannylation. We also report investigation of other issues, including the effect of solvents, on ^{76}Br labeling of organic compounds including 5-bromo-2-furaldehyde **3**. These observations and the development of experimental protocols for successful tracer-scale radiobromination should find application for the radiobromination of other organic compounds.

EXPERIMENTAL PROCEDURES

General Information. All chemicals and solvents were obtained from commercial sources and used without further purification unless noted. The synthesis of compounds **2**, **4**, and **5** will be described elsewhere. Compound **6** was synthesized according to the literature (*13*). Bromine-76 was produced at the Washington University cyclotron facility on the Japanese Steel Works 16/8 cyclotron by the ^{76}Se(p,n)^{76}Br nuclear reaction on a ^{76}Se-enriched Cu_2Se target. Bromine-76 was recovered via a modified dry distillation method (*14*). Reversed-phase HPLC was performed with an ultraviolet detector and a radiation detector. Alltech Econosil or Altima C18 250 $\times$ 4.6 mm 10 μm or Agilent Zorbax SB-C18 250 $\times$ 4.6 mm 5 μm analytical columns were used for analysis. Acetonitrile and 0.1 M ammonium formate buffer (pH = 4.5) were used as the HPLC mobile phase. Ion chromatography (IC) was performed using a Dionex IonPac AS14A 250 $\times$ 4 mm column with UV at 210 nm and a radiation detector, with an elution solvent of 8 mM Na_2CO_3 and 1 mM $NaHCO_3$ aqueous solution. RadioTLC was performed using a Bioscan System 2000 imaging scanner.

Typical Procedure for Nonradioactive Synthesis of 4-(5-Acetoxy-7-bromobenzoxazol-2-yl)phenyl Acetate (2) from Precursor 4. Into a solution of **4** (100 μg) in acetic acid (100 μL), NH_4Br solution (3 μL, from a solution of 6 mg in 1000 μL water) and 3% peracetic acid in acetic acid (100 μL) were added. The reaction mixture was vortexed to homogeneity and allowed to react at ambient temperature. At 10 min, 10 μL of the reaction mixture was injected onto a reversed-phase HPLC (Alltech Altima C18 250 $\times$ 4.6 mm 10 μm), eluting with 60% acetonitrile 40% 0.1 M ammonium formate buffer (pH = 4.5) at a flow rate of 2 mL/min and UV detection at 285 nm. Compound **2** eluted at 8 min as the only product according to HPLC, and it was confirmed by comparison with authentic standard **2**.

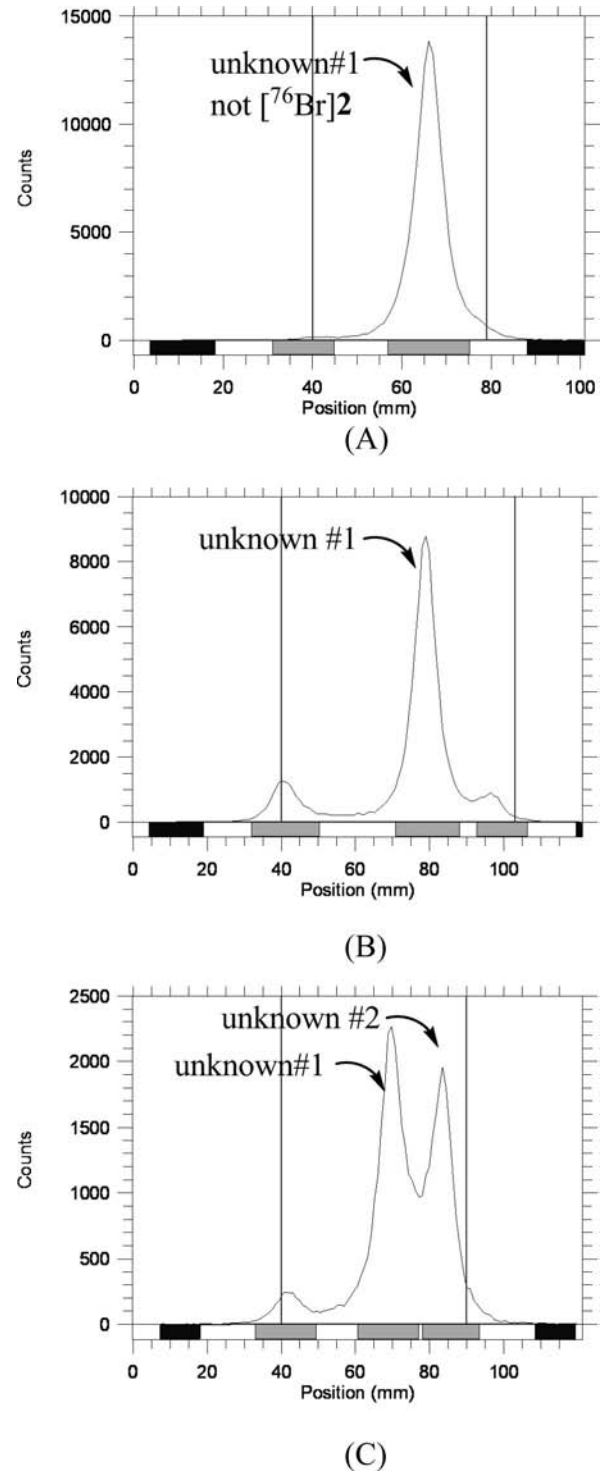

Figure 2. Radio-TLCs of attempted radiobrominations of **4** and a control reaction (performed in the absence of **4**), showing formation of unknown #1 and unknown #2. (A) Attempted radiobromination of **4**, using PAA. (B) Control reaction using PAA but no substrate **4**, (C) Attempted radiobromination of **4**, using CAT. Separations were on silica gel, 1:1 ethyl acetate/hexanes.

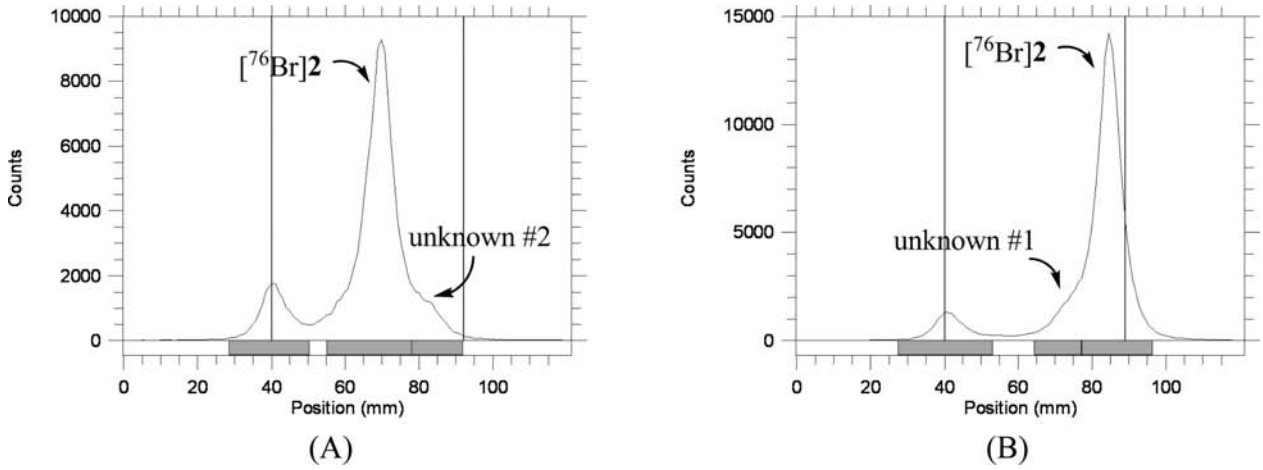

Figure 3. Radio-TLCs of successful synthesis of [^{76}Br]**2** developed in two TLC solvent systems (Silica gel). (A) 1:1 ethyl acetate/hexanes. (B) 10% methanol in dichloromethane.

Preparation of [^{76}Br]Bromide. A solution of [^{76}Br]bromide in 0.6 N ammonium hydroxide (up to 1 mL) was passed through a C18 SepPak (light) and a 0.45 μm nylon filter, which were conditioned by methanol (10 mL) and water (10 mL) beforehand and washed with water (100 μL) afterward. All collected activity was evaporated to dryness in a straight-sided shell vial (15 × 45 mm) in a heat block heated from ambient temperature to 130 °C and with a very gentle flow of N_2 over the top of the vial, which did not result in any loss of radioactivity; high gas flow can result in a significant loss of radioactivity. When the radioactivity was completely dry (less than 10 min), it was reconstituted in water, methanol, or acetic acid for the labeling reactions indicated below. Bromine-76 extracted in water or ethanol was used as is or dried directly at 130 °C.

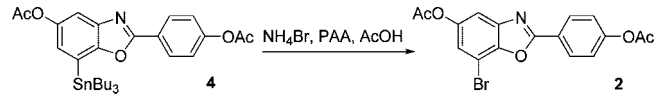
Typical Procedure for Attempted No-Carrier-Added Synthesis of [^{76}Br]2 from 4 and Control Reactions. A solution of [^{76}Br]Bromide (20−100 μCi) in water, methanol, or acetic acid (10−50 μL) was added to a solution of **4** (no **4** for control reactions) (100 μL), and then acetic acid (100 μL) and a solution of peracetic acid in acetic acid or methanol (100 μL) were added to the solution. Reaction mixture was vortexed to achieve homogeneity and analyzed by radio-TLC.

No-Carrier-Added Synthesis of [^{76}Br]2 from Precursor 5. To [^{76}Br]bromide (1.5 mCi), dried as described above and reconstituted in MeOH (100 μL), was added a solution of trimethyltin precursor **5** (1 mg) in acetic acid (100 μL), and the reaction vessel was vortexed. After addition of 1% peracetic acid in methanol (100 μL), the reaction vessel was vortexed again and then allowed to react at ambient temperature. The reaction was checked by radio-TLC (silica); >80% [^{76}Br]bromide was consumed, and roughly 60% was obtained as [^{76}Br]**2** within 30 min. [^{76}Br]**2** was distinguished from unknown #1 by developing the plates in 1:1 ethyl acetate/hexanes and 10% methanol in dichloromethane (Figures 2 and 3). Reversed-phase HPLC purified [^{76}Br]**2** was confirmed by silica radio-TLC and HPLC coinjection with authentic standard **2** ([^{76}Br]**2**: R_f = 0.55, 0.91 for 1:1 ethyl acetate/hexanes and 10% methanol in dichloromethane, respectively; HPLC Agilent Zorbax SB-C18 250 × 4.6 mm 5 μm analytical column, 65% acetonitrile, 35% 0.1 M ammonium formate buffer (pH = 4.5), 2 mL/min, 285 nm, t_R = 5.2 min; Unknown #1, 0.54, 0.75, and unknown #2, 0.85, 0.99, on silica gel TLCs developed in 1:1 ethyl acetate/hexanes and in 10% methanol in dichloromethane, respectively. (For HPLC of unknown #1, see Supporting Information.)

RESULTS AND DISCUSSION

Oxidizing Agents and Precursors. The most commonly used oxidizing agent for radioiodination and radiobromination is *N*-chloro-*p*-toluenesulfonamide sodium salt (Chloramine-T or CAT). Conditions have been optimized for radiobromination of activated phenol analogues using CAT (*15*), and these conditions have been used to label organic compounds, antibodies, and nanoparticles and for the direct and indirect labeling of peptides. Chloramine-T is not ideal for tracer-scale radiosyntheses, however, because simultaneous chlorination can reduce final effective specific activity if chlorinated byproduct cannot be separated from the desired radiobrominated product (*16*). Furthermore, elevated temperatures may be necessary to promote labeling of electron-poor substrates. Premixed hydrogen peroxide/acetic acid (H_2O_2/AcOH), in which peracetic acid (PAA) is the effective oxidizing agent, also has been used to synthesize receptor-binding radiopharmaceuticals (*17*−*19*). Currently, the use of PAA as oxidizing agent is growing because reaction conditions are mild and labeling is cleaner compared to products obtained using CAT and H_2O_2. As a result, PAA was used for our radiobromination studies.

Scheme 1. Bromination of 4 Using NH_4Br and PAA in Acetic Acid



When small organic compounds of interest as potential radiopharmaceuticals do not contain an electron-rich aromatic ring activated for electrophilic aromatic substitution (e.g., tyrosine), electrophilic demetalation is an elegant approach to radiobromination (*7*). Among the metals used in these reactions (boron, silicon, germanium, and tin), the tin precursors ($SnMe_3$ and $SnBu_3$ substituted) generally give the best results (*20, 21*). This method often allows an aromatic compound to be labeled regiospecifically, quickly, and in high yields, and so the organic tin precursors **4**, **5**, and **6** were used for our investigations.

Non-Radioactive Bromination of Tributyltin Precursor 4. Nonradioactive electrophilic aromatic substitution of the tributyltin diacetate precursor **4** with bromine under classical macroscopic (but low-scale) reaction conditions was carried out in acetic acid using PAA as the oxidizing agent (Scheme 1; Table 1). Destannylation took place quickly, and the desired bromine-substituted compound **2** was the major product by HPLC analysis of the reaction mixture. The yield was not determined due to the small scale of the reactions and difficulty in determining the amount of starting material consumed, but investigations using nonradioactive bromine as the limiting reagent (see below and Table 3) suggest that yields were high. When the PAA was reduced from 200 to 1 equiv relative to

[a] Data from single experiment. [b] **4** (100 μg, 0.17 μmol) in AcOH (100 μL). [c] A solution of NH_4Br (18 μg, 0.18 μmol) in H_2O (3.0 μL). [d] PAA in AcOH (100 μL). [e] Yields are given relative to that obtained in reaction #1, based on HPLC integrations of **2**.

NH_4Br, the reaction slowed, but a similar amount of **2** was obtained within 30 min (Table 1, entry 6), suggesting that oxidation of bromide by PAA is highly efficient under these conditions.

Chloramine-T and hydrogen peroxide/acetic acid were also investigated for their effectiveness in the classical oxidative bromination reaction (Table 2). In general, reactions were slower and yields lower with CAT, probably due to slower oxidation of bromide, but addition of acetic acid as a proton source significantly accelerated the reaction at room temperature. This is consistent with the reported oxidative bromination of tyrosine using CAT (*15*). At elevated temperatures, the amount of product obtained was similar to using 3% PAA. Hydrogen peroxide/acetic acid, which produces small amounts of PAA, did not give any detectable product by HPLC analysis. Hence, for classical oxidative brominations, it appears that PAA is more efficient than CAT and H_2O_2/AcOH. The lack of reaction using H_2O_2/AcOH is not surprising, because H_2O_2 in the absence of strong acid is a much weaker oxidizing agent for bromide than PAA (*22, 23*). Apparently, H_2O_2/AcOH does not produce enough PAA to result in detectable bromination products in classical, macroscopic oxidative brominations.

When bromide (NH_4Br) was the limiting reagent and its concentration was varied, the yield of **2** in classical oxidative brominations using PAA was determined by HPLC (Table 3). When bromide concentration was above 10^{-5} M, the yield was high (74% after 10 min and 76% after 30 min). When bromide was reduced to 10^{-6} M, close to but still higher than in the NCA radiolabeling reaction, the yield of **2** was reduced dramatically to roughly 25% after 10 or 30 min. For 10^{-7} M bromide, yields were just 5% after 10 or 30 min. (Because the average specific activity of [^{76}Br]bromide is more than 1000 Ci/mmol, the concentration of bromide is less than 10^{-6} mol/L for 1 mCi radioactivity in 1 mL solution.) In this series of reactions, amounts of other brominated products were too small to allow their identification.

No-Carrier-Added Radiobromination of Precursor 4: Formation of Unexpected Byproducts. (Scheme 2) Conditions were the same as those used for nonradioactive bromination reactions, shown in Tables 1 and 2. When NH_4[^{76}Br]Br was used in 0.6 N ammonium hydroxide without drying, a single radioactive byproduct (unknown #1, Figure 2A) was formed within 15 min, according to radioactive detection using thin layer chromatography (radio-TLC). Unfortunately, the R_f value of this peak is almost the same as that of the nonradioactive standard **2** in the developing solvents (1:1 ethyl acetate/hexanes), which caused some confusion. After the reaction mixture was diluted with water, however, this radioactive byproduct was converted completely to a more polar product. This initial radioactive byproduct (unknown #1) was also observed in the labeling of other compounds via electrophilic destannylation (data not shown).

It initially was assumed that unknown #1 was actually the desired radioactive product **2**, and the more polar product formed after dilution with water was due to radiolysis from the high-energy radiation of ^{76}Br. However, unknown #1 also was found later in a control reaction, in which no precursor **4** was added (Figure 2B). Therefore, the initially observed radioactive byproduct clearly was not the desired product **2**, nor was it any radioactive form of the tributyltin precursor **4**. Unknown #1 was also observed when CAT (Figure 2C) or H_2O_2/AcOH was used as the oxidizing agent, although its formation was slow with CAT. A second unknown, a very lipophilic radioactive byproduct (unknown #2, Figure 2C) was observed with CAT and only in the presence of substrate **4** (Supporting Information Figure S1).

Effect of Carrier and Solvent on Radiobromination of Precursor 4. With carrier NH_4Br in water added to the radiolabeling reaction ([bromide] = 5×10^{-4} M) and PAA as the oxidizing agent, desired product **2** was formed exclusively. Its identity was confirmed by HPLC analysis by coeluting with nonradioactive standard **2**. These results are consistent with our experiments conducting nonradioactive bromination with various bromide concentrations (Table 3). Thus, sufficient carrier results in efficient radiobromination of **4**, but with no carrier added, it would appear that [^{76}Br]bromide in NH_4OH reacts first with some unidentified, more reactive species present at trace levels, rather than replacing the tributyltin moiety in precursor **4**. Thus at tracer scale, unknown #1 is produced rather than the desired product **2** under otherwise classical reaction conditions.

When [^{76}Br]bromide was produced in water or ethanol, and either PAA or CAT as the oxidizing agent, unknown #1 was only a minor product. However, under these conditions, unknown #2 was the major product observed. With H_2O_2/AcOH as the oxidizing agent, no reaction was observed for [^{76}Br]bromide produced in water or ethanol (Table 4).

Exploration for the Source of the Radioactive Byproducts Unknowns #1 and #2. Efforts were taken to identify unknown #1 and to remove its source. We found that formation of unknown #1 was dominant and fast when ^{76}Br in NH_4OH was used without drying. This was true even with activated 1-methoxy-4-tributylstannylbenzene analogues, where the desired radiolabeling reaction is expected to be prompt (data not shown). Ammonium ion is reported to react very rapidly ($k = 10^7$ M^{-1} s^{-1}) with HOBr to form NH_2Br (*24, 25*), a species that has relatively feeble brominating activity (*25*). However, addition of NH_4OH or NH_4NO_3 in solution to control reactions of PAA and [^{76}Br]bromide ion (produced in water) produced no additional unknown #1.

A solution of [^{76}Br]Bromide ion in 0.6 N NH_4OH was analyzed by ion chromatography (IC) to evaluate the possibility that trace selenium could have catalyzed oxidative halogenations (*26*) to form unknown #1. It is possible that trace amounts of O_2 leaked into the system during hours-long high-temperature distillation could have oxidized trace selenium to form SeO_2, which can be extracted as SeO_3^{2-} in aqueous solution but can be separated from the bromide after IC purification. In these experiments, NO_3^- and SeO_3^{2-} were observed, and identified by comparison to retention times of NH_4NO_3 and SeO_3^{2-} (a solution of SeO_2) in aqueous solutions (Supporting Information Figure S2). However, IC purified [^{76}Br]bromide and crude [^{76}Br]bromide in NH_4OH produced radiolabeled unknown #1 exclusively in control reactions. Therefore, SeO_3^{2-} cannot be responsible for the formation of unknown #1.

The high-energy radiation of ^{76}Br is likely to cause some radiolysis, and indeed, formation of NO_3^- was observed in our reaction mixtures but not in plain 0.6 N NH_4OH. We also observed that production of unknown #1 increased with the length of time [^{76}Br]bromide remained in a NH_4OH solution

[d] Concentration of NH_4Br in the reaction mixture, added as a solution of NH_4Br in H_2O (3.0 μL). [e] Yields are based on bromide used as the limiting reagent and were determined by comparison with known concentrations of an authentic standard **2**.

and with the amount of radioactivity present. Although it has not been possible to identify unknown #1 or its source, its formation can be avoided by producing [^{76}Br]bromide in water or ethanol or by drying the activity immediately after its production in an NH_4OH solution.

Unknown #2, a radioactive, highly lipophilic compound, was also observed in radiolabeling reactions with the tributyltin precursor **4** when CAT was used as the oxidant (Figure 2C, Table 4, Supporting Information Figure S1). With [^{76}Br]bromide produced in water or ethanol, radiobromination of impurities present in the reaction mixture also contributed partially to the production of unknown lipophilic compounds (Supporting Information Figure S1). Furthermore, a solvent-related radioactive product was observed exclusively both in radiobromination of **4** and in its control reaction (no substrate **4**) when THF (inhibitor-free), DMF or acetonitrile was used in the experiments (Supporting Information Figure S3). These solvents have been documented in the literature as suitable for radiobromination.

We are unable to determine the chemical form of unknown #2, formed from the reaction with the tributyltin precursor **4**. It is more lipophilic than precursor **4** by silica gel TLC, and it is difficult to elute from a C18 Sep-Pak. It is resistant to 1 N LiOH treatment, but it can be converted to a polar product by treatment with trifluoroacetic acid (TFA). These characteristics suggest that unknown #2 still contains a tributyltin substituent.

Electrophilic substitution can take place at several sites on precursor **4** other than by *ipso* substitution of the tributyltin group, particularly on the aromatic rings, which are activated by several electron-donating substituents. Furthermore, the nitrogen of the benzoxazole could operate as a nucleophile to react with the electrophilic "positive bromine". Two examples from the literature support these possibilities. A similar highly lipophilic radiobrominated byproduct was produced by ^{76}Br radiobromination of 4-substituted-3,5-dimethoxytributylstannylbenzene (*27*), in which the benzene ring is activated by two methoxy groups. In that case, nonradioactive large-scale bromination produced the expected bromodestannylated product exclusively, while tracer-scale radiolabeling produced a radiobrominated product with the tributyltin substituent still present. In that reaction, the proton adjacent to the tributyltin on the benzene ring apparently was replaced by a radiobromine in preference to destannylation. Therefore, unknown #2 could be the product of electrophilic substitution of a proton on the activated benzene ring in **4**. Also, others have reported N-bromination as a byproduct, along with the desired product, in no-carrier-added bromination of a phenol analogue (*16*).

The low yield of the desired product **2** at low bromide concentrations (Table 3) is clearly due in part to competition with formation of unknowns #1 and #2, which are difficult to detect by HPLC in macroscopic-scale reactions using carrier-added or nonradiolabeled bromide but are readily apparent in tracer-scale radiobrominations.

Nature of the Active Electrophilic Brominating Agent in NCA Radiobromination Reactions: Dependence on Stoichiometry, Oxidant, and Solvent. If the reaction pathways for macroscopic nonradioactive (or carrier added) and tracer-scale NCA bromination are the same, both reactions should afford the same product. The differences we have observed could be due to differences in the nature of the effective brominating agents due to different levels of bromide in macroscopic versus tracer-scale reactions. Many effective brominating agents have been studied or suggested, including HOBr, H_2OBr^+, Br_2, BrCl, MeOBr, and AcOBr. Acetyl hypobromite was proposed as the effective brominating agent in acetic acid (*28*), and it is more reactive than Br_2 in electrophilic substitutions (*29*). Molecular bromine is about 10^3 times more reactive than HOBr in electrophilic substitution of *p*-xylene (*30*) and sodium *p*-anisate (*31*). Bromine chloride, about 2×10^3 times more reactive than Br_2 (*30*), has been proposed as an effective brominating agent under certain conditions (*32*) and is favored kinetically (*33*, *34*) and thermodynamically, especially in the presence of H^+ and Cl^- (*32*). When PPA or H_2O_2/AcOH is used as the oxidizing agent, HOBr is reported to form first (*23*). If the substrate does not react very rapidly with HOBr, HOBr will react further with excess of bromide to form Br_2. Formation of Br_2 is very fast ($k = 1.6 \times 10^{10}$ M^{-2} s^{-1}) (*35*, *36*) and thermodynamically favored ($K_{f(Br2)} = 2.53 \times 10^8$ M^{-2}) (Scheme 3) (*37*). However, formation of HOBr can be shifted depending on the solvent and pH of the solution (*22*, *23*, *30*, *38*). When CAT is the oxidizing agent, the mechanism is complicated, but BrCl has been proposed to be the effective brominating agent (Scheme 3) (*6*). However, BrCl can be converted to HOBr or its relatives easily by varying solvents and pH (*32*, *39*).

In the nonradioactive and carrier-added bromination of **4** (bromide $>10^{-5}$ M), the effective agent is most likely Br_2, which indeed was observed on TLC analysis ($R_f = 0.34$ in 1:1 ethyl acetate/hexanes, silica, visualized with I_2). In the no-carrier-added radiobromination, oxidation of bromide by peracetic acid is efficient, but bromide concentration is so low that formation of Br_2 is not likely. Therefore, at low bromide concentrations, the effective agent could be HOBr, AcOBr, H_2OBr^+, or MeOBr, depending on the solvent used and pH of the reaction solutions.

Molecular bromine and hypobromous acid may have different behavior in electrophilic substitution reactions. For example, HOBr has smaller steric requirements; HOBr afforded 38%

Scheme 3. Reactions that Form Active Electrophilic Bromination Species

$$AcOOH + Br^- + H^+ \rightarrow AcOH + HOBr$$

$$HOBr + Br^- + H^+ \rightarrow Br_2 + H_2O$$

$$H^+ + HOCl + Br^- \rightarrow H_2O + BrCl$$

ortho-derivative on *t*-butylbenzene compared to 10% for Br_2 (*40*). Hypobromous acid and related sources of "positive bromine" can introduce a substituent adjacent to bulky groups in an aromatic ring (*40*). Trifluoroacetyl hypobromite (CF_3-COOBr), a relative of HOBr, also produced different electrophilic substituted products from those of Br_2 on phenol analogues (*41*).

Unified Consideration of the Nature and Activity of the Bromination Reagent and the Reactivity of the Substrate. Outcomes of radiobromination likely can be determined by altering the effective brominating agent. In a tracer-scale radiolabeling reaction with an only moderately reactive substrate, the effective brominating agent can be affected by solvent and pH. If AcOH is the solvent, the effective brominating agent might be the very reactive AcOBr, resulting in low selectivity and creating undesired radioactive byproducts. This is quite likely with no-carrier-added radiobromination of **4**. The effective brominating agent is also affected by concentration of bromine; in the carrier-added radiolabeling reactions, the effective brominating agent is Br_2, and the desired product **2** is formed exclusively, just as in the classical bromination.

The rate of aromatic bromination varies from very slow to diffusion-controlled, depending on the activation and steric effects of substituents on the aromatic rings. When the substrate is very reactive toward electrophilic substitution (such as tyrosine), it will out-compete reactive impurities in the reaction medium, and the exact chemical nature of the effective bromination agent may be less important. However, electronic and/or steric effects can render a substrate less reactive than impurities in the reaction mixture. A bulky leaving group like the tributyltin of **4** could be changed to reduce the steric effect and perhaps shift a reaction toward production of the desired product, particularly if attention also is paid to the likely effective brominating agent.

Successful Synthesis of [^{76}Br]2. As a result of these observations, NCA radiobromination on the trimethyltin precursor **5** was attempted in acetic acid using peracetic acid as an oxidizing agent. The reaction afforded slightly better yields of **2** than the corresponding reaction with tributyltin precursor **4**, but yields were still <5% because of formation of unknowns #1 and #2. This result does support the idea that altering the reactivity of the precursor can increase production of the desired radiobromo−destannylation product.

The solvent used also significantly affects the reaction. The reaction occurred quickly in acetic acid, but the most likely effective brominating agent, AcOBr, is very reactive and thus less selective. When radiobromination was carried out in a mixture of acetic acid and methanol, the reactivity of effective brominating agents was reduced by the addition of methanol. The desired bromination product **2** was the major radioactive product (61 ± 16%, $n = 5$, by radio-TLC) (Figure 3). After purification by reversed-phase HPLC, [^{76}Br]**2** was obtained in 30% yield (from 1.5 mCi [^{76}Br]bromide) with good specific activity (Once [^{76}Br]**2** was converted to [^{76}Br]**1** by the treatment of 1 M LiOH solution, the specific activity of [^{76}Br]**1** was determined by HPLC to be up to 1000 mCi/μmol). Reversed-phase HPLC analysis confirmed that [^{76}Br]**2** coeluted with an authentic sample of unlabeled **2** and that the radiochemical purity was >99% (Figure 4). Therefore, by increasing the reactivity of the precursor toward the desired substitution and decreasing the reactivity of effective brominating agent, we were able to obtain the desired radiolabeled product [^{76}Br]**2** consistently and in good yields.

Other Radiobromination Reactions. Peracetic acid is considered to be the effective oxidizing agent when a mixture of hydrogen peroxide and acetic acid is used, and it has been used in the radiobromination of steroid ligands (*10*). When premixed 2:1 H_2O_2/AcOH (up to 6 h) was used for radiobromination of precursors **4** or **5**; however, no desired product was obtained, only rapid formation of unknown #1 (Table 4). This implies that the effective brominating agent from 2:1 H_2O_2/AcOH is not reactive enough to effect electrophilic substitution with these precursors.

Hydrogen peroxide/acetic acid (2:1) was also used in the radiobromination of a 5-tributyltin substituted furfural **6**, in which the electron-rich furan ring is deactivated slightly by the aldehyde group, to make [^{76}Br]**3** (Scheme 4). [^{76}Br]**3** was used in the synthesis of a ^{76}Br-labeled progestin 16α,17α-dioxolane for breast tumor imaging and radiotherapy (*42*). Four hours of premixing of 2:1 H_2O_2/AcOH was necessary to make enough PAA to afford a high yield of bromination product **3** (Table 5). However, when 1% PPA was used as the oxidizing agent in a mixture of acetic acid and methanol, no-carrier-added radiobromination of the tributyltin precursor **6** produced only a very lipophilic product, which likely retained the tributyltin group (Supporting Information Figure S4).

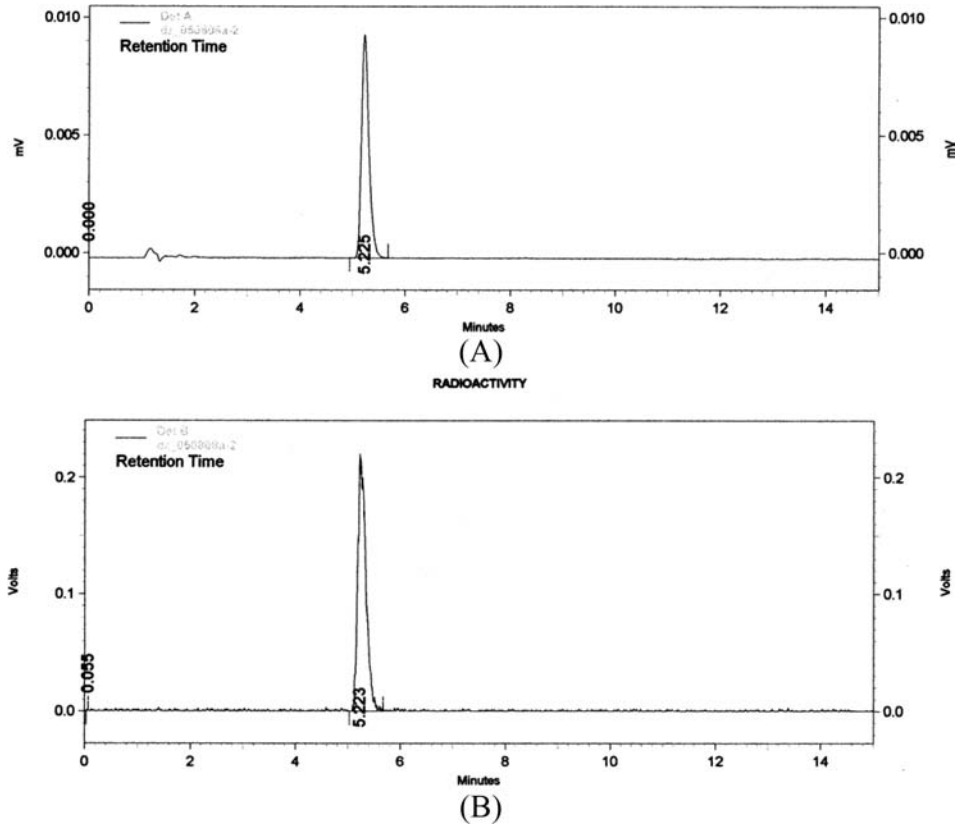

Figure 4. HPLC chromatographs of purified [^{76}Br]**2** coinjected with authentic **2**. (A) UV trace of **2** at 285 nm. (B) Radioactive trace of [^{76}Br]**2**. HPLC analysis was performed using Agilent Zorbax SB-C18 250 × 4.6 mm 5 μm analytical column and using 65% acetonitrile and 35% 0.1 M ammonium formate buffer (pH = 4.5) as mobile phase at a flow rate of 2 mL/min and UV at 285 nm.

Scheme 4. Radiobromination of 6

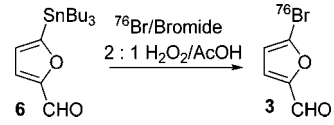

Table 5. Radiobromination of 6 Using 2:1 H_2O_2/AcOH

		premixing time (min) yield of **3** (%)[a]				
#	reaction time	0	30	60	120	240
1	15	8	30	39	62	84
2	30	11	41	53	70	84

[a] Radiochemical yield is determined by radioTLC.

As with unknown #2, this lipophilic product was not formed from a side reaction with solvents and is likely the product of electrophilic substitution other than by *ipso* substitution of the tributyltin on the furan ring under these reaction conditions, which provide a more reactive effective brominating agent than 2:1 H_2O_2/AcOH. When 1% PAA in freshly made 2:1 H_2O_2/AcOH was used, the radiobromo−destannylation product was formed exclusively, just as it was using premixed H_2O_2/AcOH. This observation is consistent with the proposed effective oxidizing agent PAA in the premixed H_2O_2/AcOH and suggests that solvent effects may contribute to the success of the radiobromination of **6**.

When this radiobromination was repeated using 1% PAA in 2:1 or 1:1 water/acetic acid to study the solvent effect, the desired product [^{76}Br]**3** was formed exclusively. Under these aqueous conditions, HOBr is probably the effective brominating agent. It is less reactive and more selective than the effective brominating agents present in acetic acid/methanol or the AcOBr in acetic acid alone. The reactivity of the effective brominating agent in different solvents increases in the order of water, methanol, and acetic acid.

In conclusion, tracer-scale NCA radiobromination differs from nonradioactive (or carrier-added) bromination and likely requires different effective brominating agents and careful attention to solvents. We suggest that the best results in tracer-scale NCA radiobromination can be achieved by considering the following:

(1) Removing highly reactive impurities that might consume the radiobromine in preference to the substrate. [Avoiding ammonium ions, carefully drying [^{76}Br]bromide and completely removing organic solvent residue from the substrate appeared to improve yields.]

(2) Increasing the specific reactivity of the precursor when possible. [Switching from the tributyltin precursor **4** to the trimethyltin precursor **5** improved yields.]

(3) Lowering the reactivity of the effective brominating agent. [Adding alcohols or water reduced side reactions and improved product yields.]

(4) Considering opportunities to reduce the number of steps. [We have shown that PAA very efficiently oxidizes bromide, and unlike CAT, PAA and solvents can be removed easily from the reaction mixture under a flow of N_2 or Ar (for nonvolatile substrate and products). This avoids extraction and/or drying in multistep reactions in which anhydrous conditions are needed, such as radiolabeling of steroids (*10*) and Bolton Hunter reagent (*43*).

SUMMARY AND CONCLUSION

Ipso substitution by electrophilic demetalation effectively introduces radiobromine regiospecifically into organic compounds containing aromatic rings, but competition can occur with other reactive sites, such as open positions on an activated aromatic ring and amine or amide groups. At the tracer level,

low reactivity of the substrate can result in competitive reactions with reactive impurities present in reagents or solvents, and this competition can be modulated by solvent and pH, which alter the effective brominating agent. Therefore, a clear understanding of the nature of effective brominating agents and the reactivity of the substrate is important in developing methods for radiobromination of organic compounds.

By considering these factors, we were able to label **2** and **3** from the two trialkyltin precursors **5** and **6** with ^{76}Br reliably and in good yield. We hope our strategy will help others achieve tracer-scale radiobromination of aromatic compounds of interest.

ACKNOWLEDGMENT

The authors thank Bill Margenau, Pat Margenau, Rajendra Singh, Lucie Tang, Grainne Biddlecombe, and Tom Voller for the production of [^{76}Br] isotope. In addition, special thanks go to Joanna B. Downer for excellent editorial assistance and helpful comments. This work was supported by grants from the National Cancer Institute (R24 CA086307 to M.J.W., and R01 CA25836 to J.A.K.).

Synthesis of [^{76}Br]5-bromo-2-furaldehyde ([^{76}Br]3)

Using premixed 2:1 hydrogen peroxide/acetic acid: [^{76}Br]NH_4Br (~10 mCi) was dried in a 5 mL Wheaton V vial at 130 $^{\circ}$C under very gentle N_2 flow. At ambient temperature, acetic acid (20 µL) and a solution of **6** (0.5 mg) in methanol (50 µL) were added, and the solution was vortexed before addition of 2:1 hydrogen peroxide/acetic acid (100 µL, pre-mixed for at least 4 h). Then the reaction mixture was vortexed to homogeneity. Upon completion of the reaction in 30 min (> 80% incorporation according to radio-TLC analysis: silica gel plate, 1:1 ethyl acetate/hexanes, R_f = 0.8), the reaction was quenched by addition of water (2 mL). [^{76}Br]**3** was confirmed by silica radio-TLC and HPLC co-injection with authentic standard **3**. HPLC: Alltech Econosil C18 250×4.6 10µ, 55% acetonitrile, 45% water, 1.5 mL/min, 254 nm, T_R = 4.5 min.

Using peracetic acid: Into a 5 mL Wheaton V vial containing dried [^{76}Br]NH_4Br (~0.9 mCi) were added a solution of **6** (0.3 mg) in methanol (30 µL) and acetic acid (10 µL). The mixture was vortexed to homogeneity, then 1% PAA in 2:1 hydrogen peroxide(35% in water)/acetic acid (60 µL) and the mixture was vortexed again. According to radio-TLC, >90% incorporation of [^{76}Br]bromide was observed within 7 min.

Note: The same procedure for using PAA in 1:1 or 2:1 water/acetic acid mixture. However, organic compounds have better solubility in hydrogen peroxide/acetic acid.

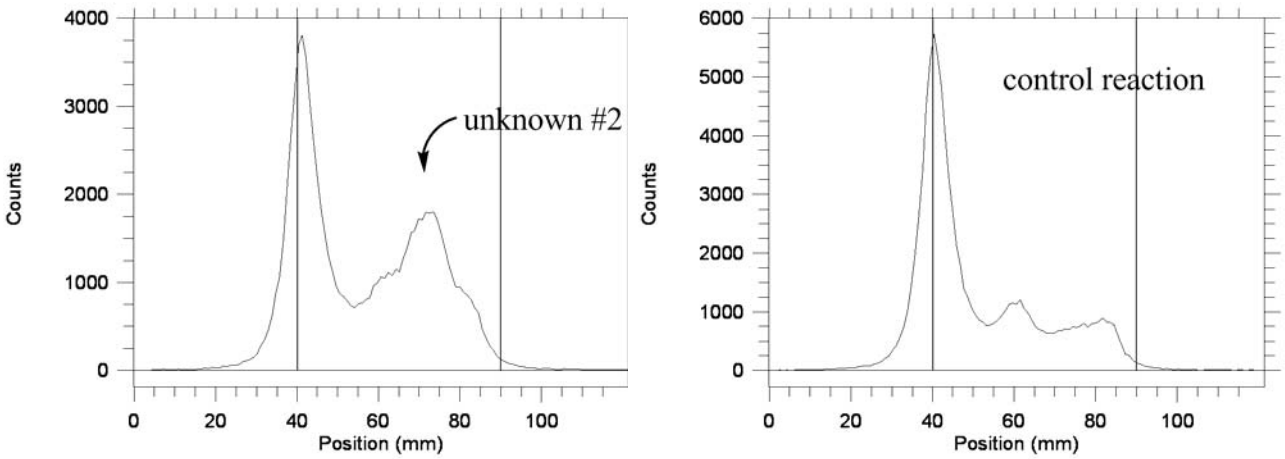

Figure S1. Radio-TLCs of radiobromination of **4** (a) and its control reaction (b) showing the lipophilic byproducts (Silica gel, 4:1 hexanes/ethyl acetate)

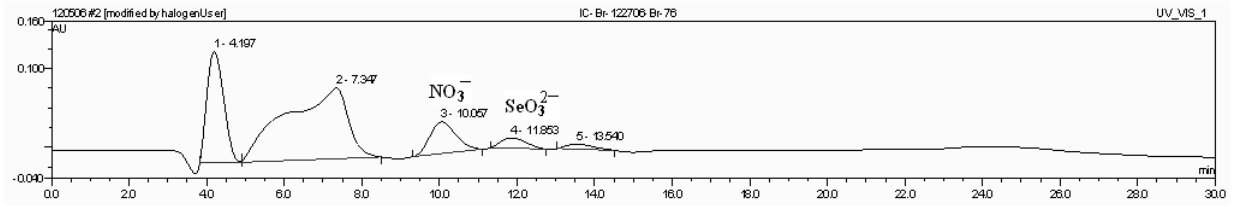
Reaction condition:

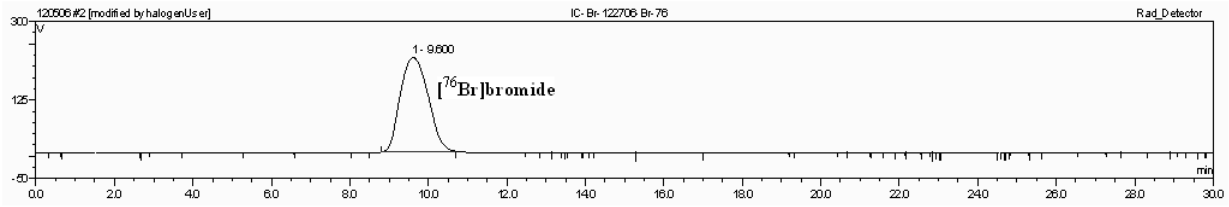
(a) ^{76}Br (produced in water, dried at 130 °C), acetic acid (100 µL), **4** (0.12 mg) in ethanol (20 µL), CAT (50 µL) from a solution of CAT (3.7 mg) in ethanol (2000 µL);

(b) ^{76}Br (produced in water, dried at 130 °C), acetic acid (100 µL), CAT (50 µL) from a solution of CAT (3.7 mg) in ethanol (2000 µL).

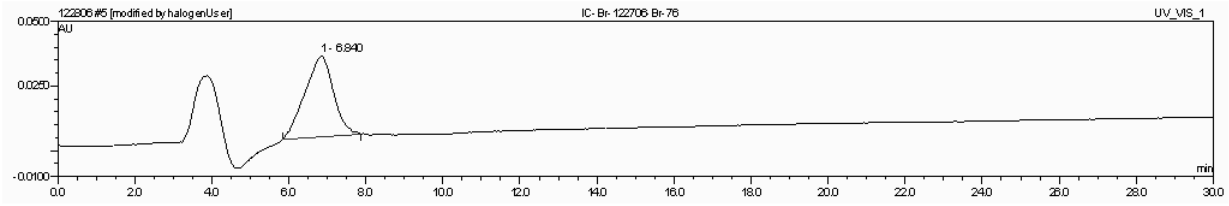
Note: Around 50% of the lipophilic byproducts was from the reaction with **4** (*panel a*), the rest was from the reaction with reactive species in the reaction mixture (*panel b*)



(a)



(b)



(c)

Figure S2. Ion Chromatography of [^{76}Br]bromide extracted in 0.6 N NH_4OH (a) UV trace at 210nm (b) radioactive trace (c) UV trace of 0.6 N NH_4OH only. (UV at 210 nm)

Note: Only [^{76}Br]bromide was observed in the IC, no other radioactive peaks were observed (*panel b*); no NO_3^- was observed in 0.6 N NH_4OH (*panel c*).

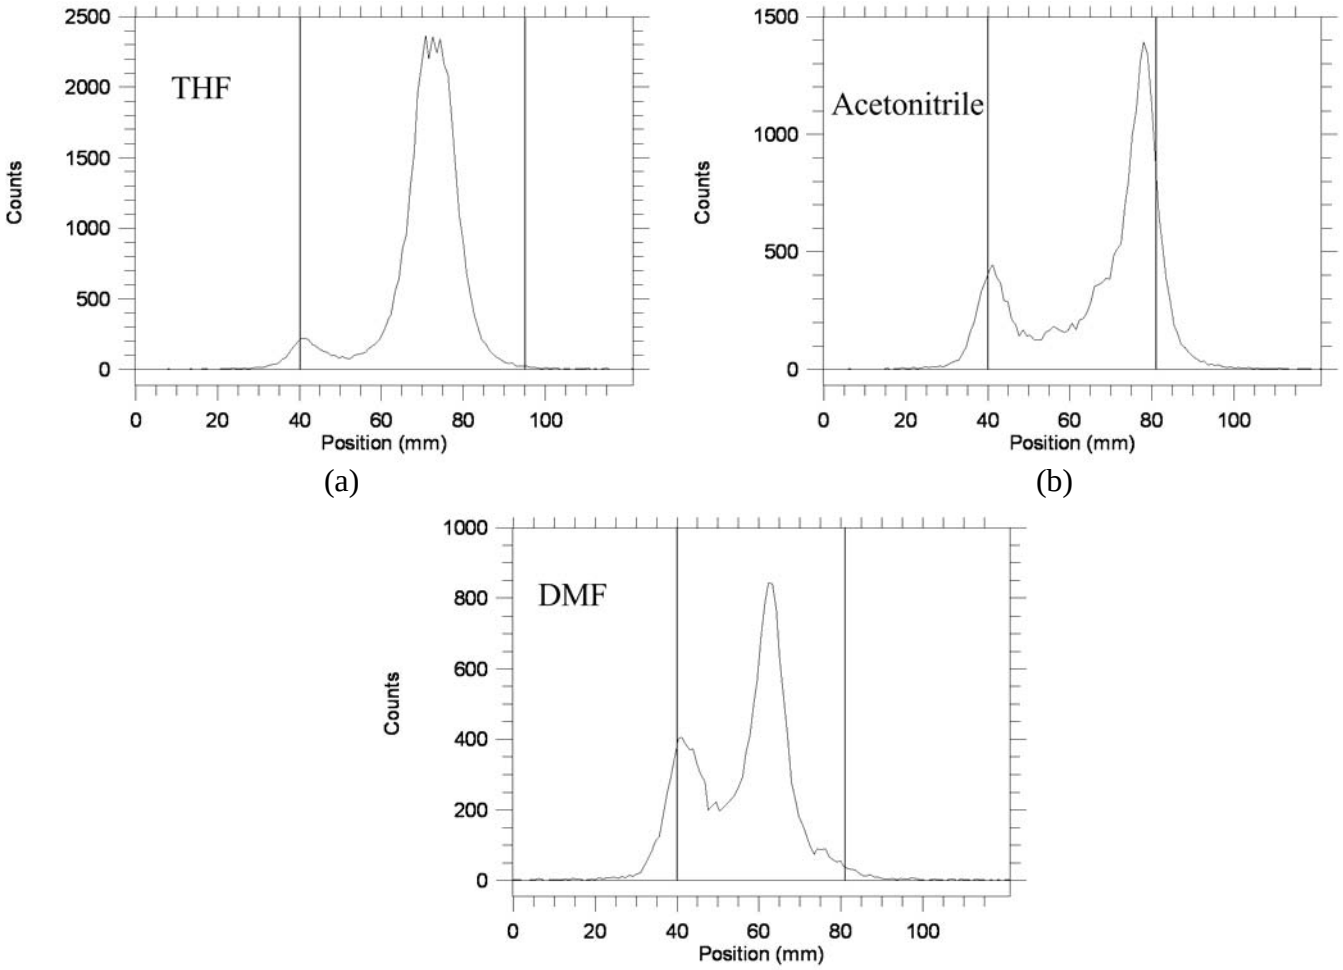


Figure S3. Radio-TLCs of control reactions using different solvents (a) THF (b) acetonitrile (c) DMF (Silica gel, 1:1 ethyl acetate/hexanes)

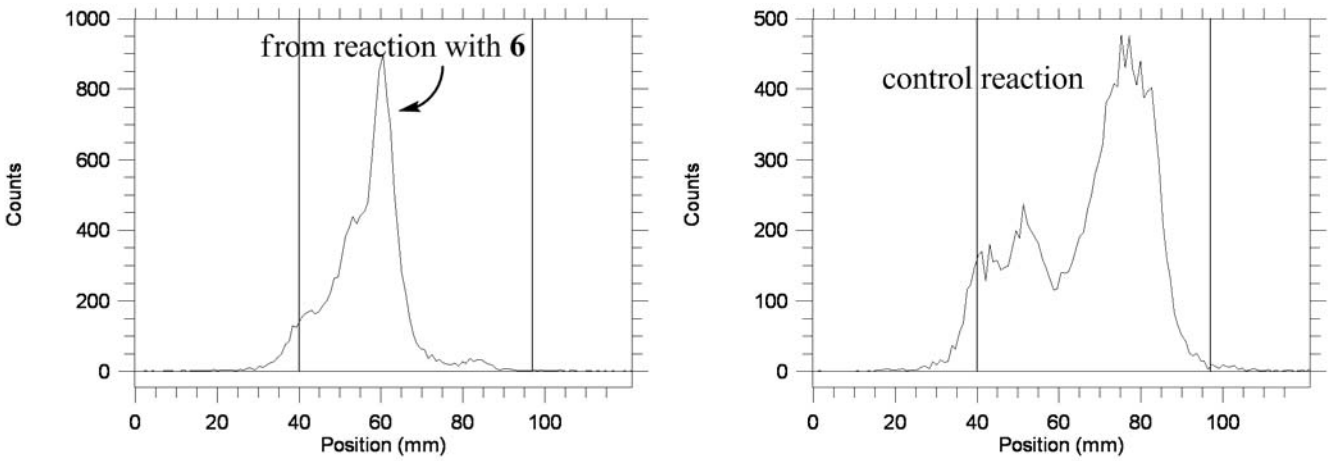
Reaction condition:

(a) ^{76}Br (dried, 20 µCi) in MeOH (10 µL), THF (200 µL), acetic acid (100 µL), PAA (1%) in MeOH (100 µL) (5 min);

(b) ^{76}Br (dried, 15 µCi) in MeOH (5 µL), MeCN (200 µL), acetic acid (50 µL), PAA (3%) in MeOH (100 µL) (10 min);

(c) ^{76}Br (dried, 15 µCi) in MeOH (5 µL), DMF (200 µL), acetic acid (50 µL), PAA (3%) in MeOH (100 µL) (10 min).

Note: A radioactive product was formed rapidly in the presence of THF, acetonitrile or DMF, respectively, in the above control reactions. These radioactive products were the same as those observed in the radiobromination of **4** or **5** when the above solvents were used.



(a) (b)

Figure S4. Radio-TLCs of radiobromination of **6** (a) and its control reaction (b) showing the formation of lipophilic byproducts (Silica gel, 1:12 ethyl acetate/hexanes)

Reaction condition:

(a) ^{76}Br in MeOH (10 µL), **6** (1.0 mg) in MeOH (100 µL), acetic acid (100 µL), PAA (1%) in acetic acid (100 µL);

(b) ^{76}Br in MeOH (10 µL), MeOH (100 µL), acetic acid (100 µL), PAA (1%) in acetic acid (100 µL).

Note: A major radioactive product (*panel a*) was observed in the reaction with tributyl precursor **6**; however, this product was more lipophilic than **6** according to the radio-TLC; this peak was not observed in the control reaction (*panel b*).

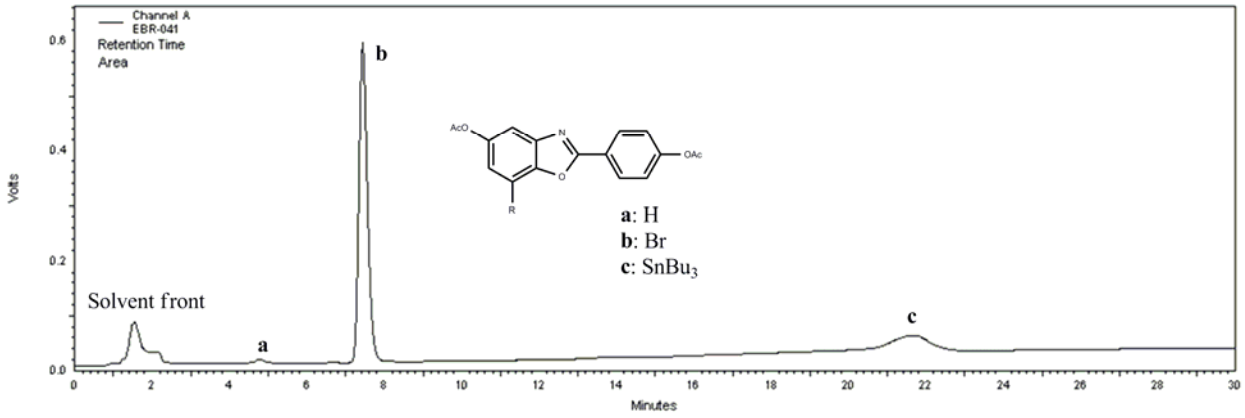


Figure S5. HPLC chromatograph of a non-radioactive synthesis of **2** from **4** using NH_4Br and PAA.

HPLC: Alltech Altima C18 250×4.6 mm 10µ, 285 nm, 2 mL/min; Gradient: Solvent A: Acetonitrile; Solvent B: ammonium formate buffer (0.1 M, pH = 4.5) A: 60%-90 % (0-20 min), 90% (20-30 min).

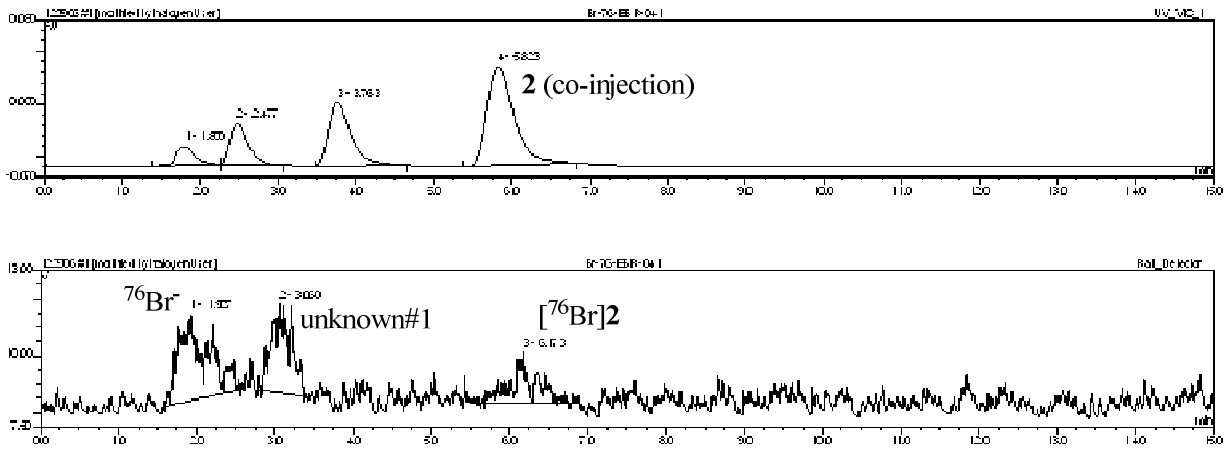

Figure S6. HPLC chromatographs of a reaction mixture from an attempted synthesis of [^{76}Br]**2** from **4**, showing [^{76}Br]Bromide, unknown #1, and [^{76}Br]**2** (co-injected with 2).

HPLC (Alltech Econosil, 250×4.6 mm, 10µ, 65% acetonitrile, 35% ammonium formate buffer (pH = 4.5), 2 mL/minun, 285 nm): [^{76}Br]bromide, t_R = 1.93 min, unknown #1, t_R = 3.06 min, [^{76}Br]**2**, t_R = 6.17 min, unknown #2 won't be eluted.

New Strategy for the Preparation of Clickable Peptides and Labeling with 1-(Azidomethyl)-4-[^{18}F]-fluorobenzene for PET

David Thonon,* Cécile Kech, Jérôme Paris, Christian Lemaire, and André Luxen

Cyclotron Research Center, Liege University, Sart-Tilman B.30, B-4000 Liege, Belgium. Received December 16, 2008; Revised Manuscript Received February 16, 2009

The alkyne-azide Cu(I)-catalyzed Huisgen cycloaddition, a click type reaction was used to label a peptide with fluorine-18. A novel solid phase synthesis approach for the preparation of clickable peptides has been developed and has also permitted the straightforward preparation of reference compounds. A complementary azide labeling agent (1-(azidomethyl)-4-[^{18}F]-fluorobenzene) has been produced in a four step procedure in 75 min with a 34% radiochemical yield (decay corrected). Conjugation of [^{18}F]fluoroazide with a model alkyne-neuropeptide produced the desired ^{18}F-radiolabeled peptide in less than 15 min with a yield of 90% and excellent radiochemical purity.

INTRODUCTION

Molecular imaging allows in vivo imaging of gene expression, optimizing drug therapy and imaging drug effect at the molecular and cellular level and may also be useful in detecting pathology at a predisease state (*1*). Thanks to its high sensitivity ($10^{-9}-10^{-12}$ M) and quantitative nature, positron emission tomography (PET[1]) is ideally suited to image molecular processes. Among a number of positron-emitting nuclides, fluorine-18 is particularly attractive for labeling biomolecules due to its favorable physical and nuclear properties.

The challenge for the radiochemist is to introduce a short half-life radioisotope (fluorine-18, $t_{1/2}$ 109.7 min) onto biomolecules that are specific to the biological process studied. As ^{18}F fluoride introduction onto organic compounds requires pretty harsh reaction conditions and is not compatible with H-acidic functions (*2*), biocompounds (e.g., peptides, proteins, antibodies, and oligonucleotides) are usually labeled with ^{18}F by means of prosthetic groups (*3*). A large number of ^{18}F labeled prosthetic groups have been developed (*4*), but none has emerged as a standard method because each has its own advantages and limitations (*5*). The main limitation of most advanced methods is that they are not site-specific as the labeling is accomplished through an amino group (N-terminus or lysine side chain), which is frequently contained in multiple copies in peptides. Therefore, the search for a rapid, selective, and generic method for radiolabeling biomolecules continues. Reactions defined as click reactions respond well to these criteria (*6, 7*). Moreover, these reactions are particularly well adapted to the preparation of radiopharmaceuticals as they require only benign reaction conditions and simple workup and purification procedures. Among these reactions, the Cu(I) catalyzed formation of 1,2,3-triazole using Huisgen 1,3-dipolar cycloaddition of alkynes with azides is the most explored reaction. In principle, this cycloaddition can be performed in the presence of water and oxygen and is orthogonal to any functional group and can thus be performed without the protection of other functional groups (*6, 7*).

For these reasons, our group and several other laboratories around the world have begun to evaluate this reaction to bind ^{18}F tagged molecules to biocompounds. In 2006, Marik and Sutcliffe reported the labeling of peptides bearing *N*-(3-azidopropionyl)-groups with volatile ω-[^{18}F]fluoroalkynes in 10 min with yields of 54−99% (coupling step) (*8*). Two other authors have recently reported the preparation of ^{18}F labeled synthons bearing both an alkyne function and a short polyethylene glycol linker to reduce volatility and obtain water solubility (*9, 10*). Various azido-containing molecules have been labeled with these bifunctional tracers. In particular, Li has labeled azido-RGD peptides in 20 min with a yield of 69% (coupling step). A more indirect approach has been followed by Ramenda and Wuest who have prepared a click building block by derivatizing the well-known *N*-succinimidyl-4-[^{18}F]fluorobenzoate [^{18}F]SFB with propargyl amine. This synthon has been used to label azido-neurotensin in 20 min with a yield of 66% (decay corrected, coupling step). Although a lot of effort has been applied to the preparation of an alkyne synthon, only one publication by Glaser and Årstad has described an azide synthon (*11*). After purification by distillation, 2-[^{18}F]fluoroethylazide was linked to a model peptide derivatized with propargylic acid in 15 min with a yield of 92% (decay corrected, coupling step).

In this technical note, we describe the radiosynthesis of a new azide synthon: 1-(azidomethyl)-4-[^{18}F]-fluorobenzene **[^{18}F]5** bearing an aromatic bound fluorine, which is known to be less susceptible to *in vivo* radiodefluorination (*12*). An original method to functionalize peptides with alkyne is also depicted. Finally, this new synthon has been used to label a model alkyne amino acid and an alkynylated neuropeptide by click chemistry (Figure 1).

EXPERIMENTAL PROCEDURES

General. All solvents and chemicals were of analytical grade and used without further purification. The [^{18}O]-enriched water was purchased from Cambridge Isotope Laboratories. Mass spectra were recorded with a Finnigan TSQ7000 mass spectrometer (ThermoElectronCorp.) operating in full-scan MS mode with an ESI+ source and with a Bruker Daltonics micrOTOF

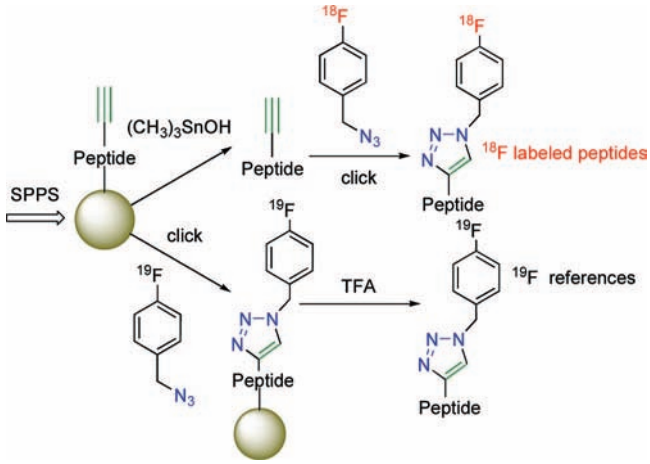

Figure 1. Synthetic strategies for the preparation of ^{18}F labeled peptides and ^{19}F references.

spectrometer (TOF-ES-MS). ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AM 400 (^{1}H at 400 MHz and ^{13}C at 100 MHz). ^{1}H and ^{13}C spectra were referenced to TMS using the ^{13}C or residual proton signals of the deuterated solvents as internal standards. HPLC analyses were run on a Waters system (616 pump, a manual Rheodyne injector, 996 PDA detector,and NaI(Tl) scintillation detector from Eberline) controlled by the Empower program. Analyses were performed on an XTerra C18 column from Waters (150 × 4.6 mm, 3.5 μM) with CH_3CN and H_2O containing 0.1% TFA mixture (proportions given in parentheses) at 1 mL/min. Preparative HPLC was performed on a SymmetryPrep C18 column from Waters (300 × 7.8 mm, 7 μM). A Gilson model 233 XL reactarray automatic injection system was remotely controlled to achieve the radiosynthesis of **[^{18}F]5**. A Bioscan TLC scanner model AR2000 was used for analysis of the ^{18}F labeled compounds. Radiochemical yields are given decay corrected and take into account the losses due to transfer. *p*-Iodophenylalanine has been synthetized according to Ousmer (*13*), and Fmoc protection was carried out according to the standard procedure (*14*). 4-Ethynyl-L-phenylalanine (**6**) has been prepared according Zimmer (*15*). Peptide synthesis were carried out on an automated solid phase peptide synthesizer PS3 (Protein Technologies) by a Fmoc strategy employing HBTU as the coupling reagent. Enantiomerically pure L-amino acids were obtained from IRIS Biotech.

Chemistry. *(S)-2-Amino-3-(4-(1-(4-fluorobenzyl)-1H-1,2,3-triazol-4-yl)phenyl)propanoic Acid (**8**).* Twenty milligrams of 4-ethynyl-L-phenylalanine (**6**) (0.106 mmol), 40 mg of copper (I) iodide (2 equiv., 0.210 mmol), 55 mg of DIEA (4 equiv., 0.424mmol), and 16 mg of 1-(azidomethyl)-4-fluorobenzene (**5**) (0.106 mmol) were mixed in 3 mL of DMF. This solution was stirred for 4 h. The solvent was eliminated under vacuum. The residue obtained was suspended in acetonitrile and pre-purified by dry flash chromatography on silicagel (the column was washed by EtOAc and MeOH, and compound **8** was eluted by MeOH/NH_3 25% 3:1). The solid obtained was finally purified by HPLC (4 mL/min, CH_3CN/H_2O 25:75, 0.1% TFA) to furnish 13 mg (0.038 mmol, 36%) of the desired compound. TOF-ES-MS: *m/z* 341.1413 for $[MH]^+$ ($C_{18}H_{18}FN_4O_2$, calculated [MW] 341.1408). ^{1}H NMR (CD_3OD), δ: 8.36 (s, 1H, CH triazole), 7.84 (m, 2H, H_{Ar}, C_6H_4), 7.40 (m, 4H), 7.13 (m, 2H, H_{Ar}, C_6H_4F), 5.64 (s, 2H, $CH_2C_6H_4F$), 4.29 (m, 1H, $C_{\alpha,Phe}H$), 3.33−3.17 (m, 2H, $C_{\beta,Phe}H_2$) ppm.^{13}C NMR (CD_3OD) δ 178.6 (C═O), 166.75 (d, J = 246 Hz, C−F), 134.4, 131.4, 130.0, 129.9, 129.8, 129.7, 125.9, 121.0, 115.3 (d, ^3J = 22 Hz, $C_{ortho\text{-}F}$), 52.9 ($\underline{CH_2}C_6H_4F$), 47.6 ($C_{\alpha,Phe}$), 35.7 ($C_{\beta,Phe}$) ppm.

*[Ac-Tyr(tBu)^1, Phe (≡)^4, Leu^5)]-Enk bound to Wang Resin **11**.* Four hundred milligrams of peptide **10** (≤0.250 mmol) still bound to the resin was suspended in 4.5 mL of a degassed mixture of DMF/NEt_3 (2:1). Then 179 mg of trimethylsilylacetylene (1.82 mmol) was added to the reaction mixture followed by 15 min of degassing. Then 25 mg of CuI (0.13 mmol) and 50 mg of $Pd(PPh_3)_2Cl_2$ (0.071 mmol) were added, and the suspension was stirred overnight. The reaction mixture was filtered through a Büchner funnel, and the resin was successively rinsed with DMF, H_2O, EtOH, and CH_2Cl_2 and dried under reduced pressure.

Two hundred milligrams (≤0.125 mmol) of the obtained solid was suspended in 20 mL of THF at −78 °C. To this suspension was added 1600 μL of a solution 1 M of tetrabutylammonium fluoride in THF. This mixture was first stirred for 15 min at −78 °C then 30 min at RT. The reaction mixture was filtered through a Büchner funnel, and the resin was successively rinsed with THF, H_2O, EtOH, and CH_2Cl_2 and dried under reduced pressure.

[Ac-Tyr^1, Phe (1-(4-fluorobenzyl))-1H-1,2,3-triazol-4-yl)^4, Leu^5]-Enk **13.** Eighty milligrams of peptide **11** bound to the Wang resin (≤0.05 mmmol), 18 mg of copper (I) bromide (2 equiv., 0.126 mmol), 47 mg of DIEA (0.360 mmol), and 9 mg of 4-fluorobenzyle azide **5** (0.060 mmol) were mixed in 3 mL of DMF. The reaction medium was stirred under an inert atmosphere at RT overnight. The suspension was filtered through a Büchner funnel and the resin was successively rinsed with DMF, H_2O, EtOH, and CH_2Cl_2. Final deprotection and cleavage from the resin was performed with a TFA mixture (TFA/H_2O/anisole = 90:5:5, 5.5 mL, 3 h). The suspension was filtered and the resin washed once again with TFA. The filtrate was evaporated to dryness. The obtained oily residue was dissolved in a minimum of TFA, and ether was added to precipitate the peptide. This suspension was centrifuged (2500 rpm, 10 min). The supernatant was eliminated, and the obtained solid was washed with ether. The compound was purified by preparative HPLC (CH_3CN/H_2O 40:60 containing 0.1% TFA). Elimination of the solvent provided 10 mg of the targeted compound (0.013 mmol; yield starting from the commercial Wang resin, 26%). TOF-ES-MS: *m/z* 773.3397 for $[MH]^+$ ($C_{39}H_{46}FN_8O_8$, calculated [MW] 773.3417).^{1}H NMR (CD_3OD), δ: 8.29 (s, 1H, CH triazole), 7.73 (d, 2H, H_{Ar}), 7.40 (m, 4H, H_{Ar}), 7.10 (m, 4H, H_{Ar}), 6.70 (d, 2H, H_{Ar}), 5.63 (s, 2H, $CH_2C_6H_4F$), 4,70 (m, 1H) and 4,40 (m, 2H) Cα,Tyr, Leu, ethynylPheH, 3.68−3.86 (m, 4H, Cα,GlyH), 2.87−3.33 (m, 4H, Cβ,Tyr, EthynylPheH2), 1.95 (s, 3H, CH3, acetyl), 1.68 (m, 1H, $CH(CH_3)_2$), 1.65 (m, 2H, $C_{\beta,Leu}$), 0.93 (m, 6H, $CH(CH_3)_2$).^{13}C NMR (CD_3OD) 178.2, 173.8, 172.4, 170.8, 170.8, 170.0 (C═O), 169.7 (d, J = 240 Hz, C-F), 156.0 (C-OH_{tyr}), 137.4,131.8 129.8, 129.7, 129.6, 128.6, 128.1,127.4, 125.3, 120.7 (CH triazole), 115.5 (d, ^3J = 21 Hz, $C_{ortho\text{-}F}$), 114.8 ($C_{ortho\ C\text{-}OH\ Tyr}$), 56.9 ($\underline{CH_2}C_6H_4F$), 55.7, 54.3, 52.8 ($C_{\alpha,Tyr,\ Leu,\ ethynylPhe}$), 42.6, 41.9 ($C_{\alpha,Gly}$), 40.1, 37.0, 36.34 ($C_{\beta,Tyr,\ Leu,\ ethynylPhe}$), 24.5, 21.9, 21.1, 20.4 ($CH_{3,Leu,\ Acetyl}$, CH_{Leu}) δ ppm.

*[Ac-Tyr(tBu)^1, Phe (≡)^4, Leu^5]-Enk **14**.* Eighty milligrams of peptide **11** bound to the resin (≤0.05 mmmol) was suspended in 3 mL of $(CH_2Cl)_2$. Forty-five milligrams of trimethyltin hydroxide (0.16 mmol) was added to this suspension at RT under nitrogen. The reaction mixture was refluxed (83 °C) overnight under an inert atmosphere. The suspension was filtered through a Büchner funnel and washed with $(CH_2Cl)_2$, CH_2Cl_2, MeOH, and EtOAc. The filtrate was brought to dryness under reduced pressure, and the resulting residue was dissolved in EtOAc, washed with an aqueous solution of HCl (0.05 N), and extracted with a 5% $NaHCO_3$ solution. The pH of the combined aqueous solution was lowered to 3−4 with 2.5 N H_2SO_4 and extracted with EtOAc. The combined organic solution was dried (Na_2SO_4) and evaporated to dryness to yield 8 mg of a colorless solid (0.012 mmol; yield starting from the commercial Wang resin, 24%). TOF-ES-MS: *m/z* 678.3489 for $[MH]^+$ ($C_{36}H_{48}N_5O_8$, calculated [MW]

Radiochemistry. *4-[18F]-Fluorobenzaldehyde* ***[18F]2***. No-carrier-added [^{18}F] fluoride was obtained by proton bombardment of an [^{18}O]-enriched water target via the $^{18}O(p,n)^{18}F$ reaction. The activity was trapped by passing the target water through a Sep-Pak light QMA cartridge (Waters) previously conditioned under carbonate form. Then, 500 μL of a 50:50 CH_3CN/H_2O solution of K_2CO3 (6 mg) and Kryptofix 222 (20 mg) were used to elute the fluoride from the cartridge into a heated conical glass vial (120 °C). This eluate (110−740 MBq) was brought to dryness by azeotropic distillation after the addition of acetonitrile (3 × 250 μL) under a gentle stream of nitrogen gas. 4-*N*,*N*,*N*-Trimethylammonium benzaldehyde triflate (0.064 mmol) in DMSO (1 mL) was added to the dried residue, and the mixture was heated at 130 °C for 5 min. The reaction medium was then diluted with water (15 mL). Labeling efficiency was checked by radio-TLC (silica gel, CH_2Cl_2; R_f values: [^{18}F]fluoride = 0; **[18F]2** = 0.6). HPLC analysis: t_R = 3.9 min (CH_3CN/H_2O 50/50 0.1% TFA). Radiochemical yield (decay corrected) = 65%.

1-(Bromomethyl)-4-[18F]-fluorobenzene ***[18F]4***. The crude labeled compound **[18F]2** (250 MBq) diluted in H_2O was adsorbed onto a C_{18} environmental Sep-Pak cartridge. $NaBH_4$ (125 mg dissolved in 4 mL of H_2O) was passed with a flow rate of 3 mL/min through the cartridge then washed with water (5 mL). The 4-[^{18}F]-fluorobenzyl alcohol formed was not isolated but directly converted into the corresponding bromide derivative by heating the Sep-Pak (50 °C) with a stream of hot air while passing 48% aqueous HBr (vol = 2.8 mL; flow rate = 3 mL/min) through the cartridge. After a delay of 4 min, an additional portion of concentrated HBr (1.4 mL) was passed in the same manner. After 4 min, heating was stopped, and 6 mL of an ammonium formate solution (pH 4.0) was added to the Sep-Pak. The bromide compound **[18F]4** was finally eluted with DMF (3.5 mL) and was checked by radio-TLC (silica gel, CH_2Cl_2; R_f values: **[18F]4** = 1.0; in *n*-hexane, R_f **[18F]4** = 0.3). HPLC analysis: t_R = 9.0 min (CH_3CN/H_2O 40/60 0.1% TFA). Radiochemical yield (decay corrected) from **2** was 75%.

1-(Azidomethyl)-4-[18F]-fluorobenzene ***[18F]5***. Compound **[18F]4** (150 MBq) in DMF (3.5 mL) was transferred into a reaction vial containing 500 mg of azido resin (1.9 mmol). This suspension was agitated for 15 min by gentle N_2 bubbling and then filtered. The resin was washed with 1 mL of DMF, then filtered again. The filtrates were combined and analyzed by radio-TLC (silica gel, CH_2Cl_2; R_f values: **[18F]5** = 1.0; in *n*-hexane, R_f **[18F]5** = 0.1). HPLC analysis: $t_{R\ =}$ 7.8 min (CH_3CN/H_2O 40/60 0.1% TFA). Radiochemical yield (decay corrected) from **[18F]4** 70%.

(S)-2-Amino-3-(4-(1-(4-[18F]-fluorobenzyl)-1H-1,2,3-triazol-4-yl)phenyl)propanoic Acid ***[18F]8***. A solution of 1-(azidomethyl)-4-[^{18}F]-fluorobenzene **[18F]5** (20MBq) in DMF (1 mL) was added to (*S*)-2-amino-3-(4-ethynylphenyl) propanoic acid (**6**) (*p*EPA, 0.6 mg, 0.0032 mmol), CuI (3.2 mg, 0.017 mmol), sodium ascorbate (25 mg, 0.13mmol), and DIEA (50 μL, 0.28 mmol). The mixture was stirred at room temperature for 15 min. The reaction mixture was then diluted with water (15 mL) and passed through a Sep-Pak Plus Short tC18 cartridge. The cartridge was washed with water (9 mL), and activity was eluted with CH_3CN (1.5 mL).

Analysis by radio-TLC (silica gel, EtOAc; R_f values: **[18F]8** = 0; C_{18}, CH_3CN/H_2O 50/50, R_f values, **[18F]8** = 0.5). HPLC analysis: t_R = 3.1 min (CH_3CN/H_2O 40/60 0.1% TFA). Radiochemical yield (decay corrected) from **[18F]5** 90%.

[Ac-Tyr[1], Phe (1-(4-[18F] fluorobenzyl))-1H-1,2,3-triazol-4-yl)[4], Leu[5]] Enk ***[18F]13***. A solution of [^{18}F] fluoroazide **[18F]5** in DMF (1 mL) was added to peptide **14** (2 mg, 0.0032 mmol), CuI (3.2 mg, 0.017 mmol), sodium ascorbate (25 mg, 0.13 mmol), and DIEA (50 μL, 0.28 mmol). The mixture was stirred at room temperature for 15 min.

Analysis by radio-TLC (silica gel, CH_2Cl_2; R_f values: **[18F]15** = 0; C_{18}, CH_3CN/H_2O 60/40, R_f values, **[18F]15** = 0.6). HPLC analysis: $t_{R\ =}$ 6.3 min (CH_3CN/H_2O 50/50 0.1% TFA).

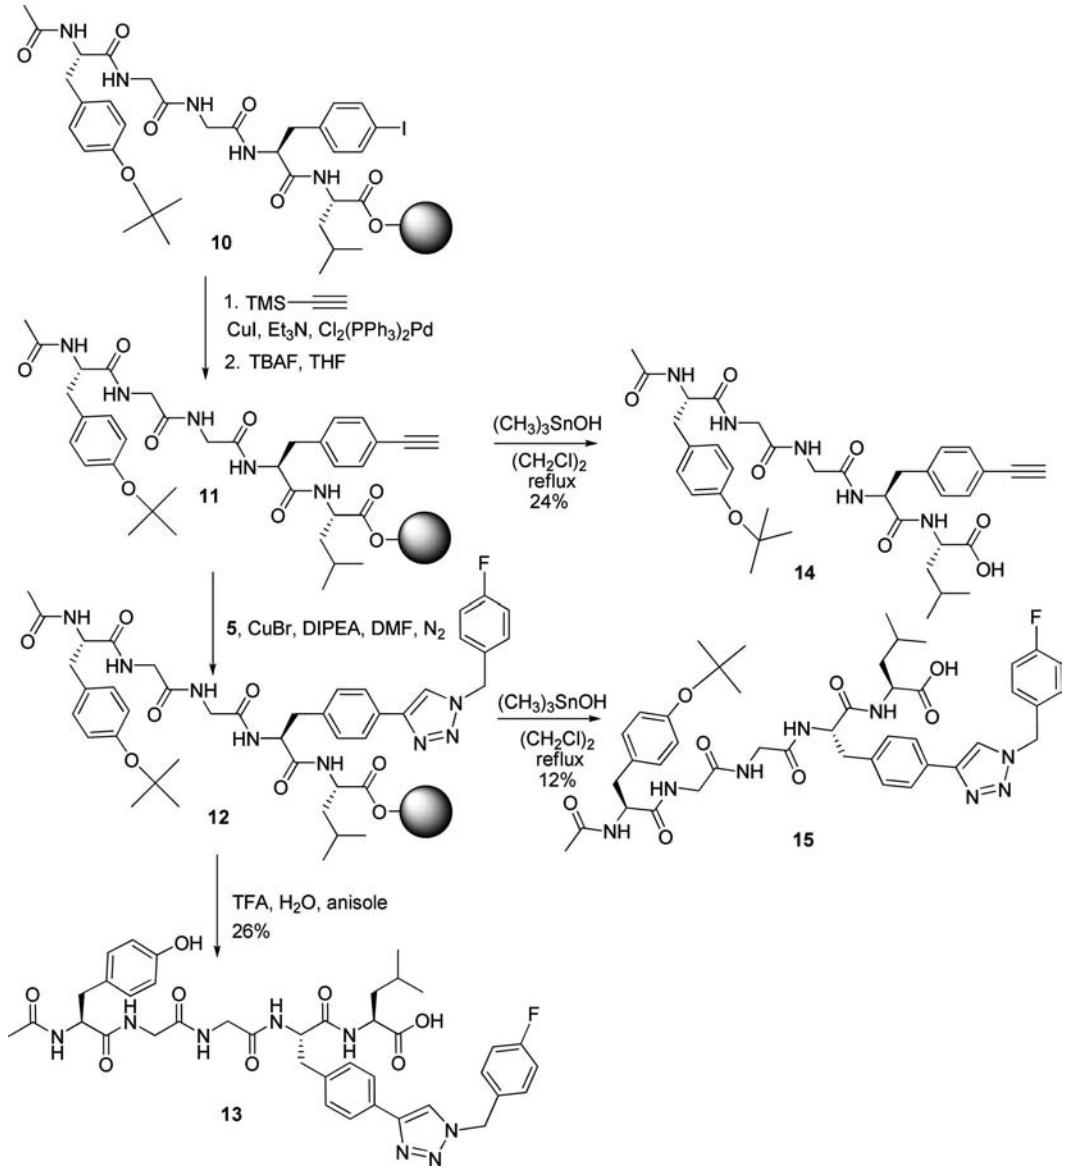
The reaction mixture was then diluted with water (15 mL) and passed through a Sep-Pak Plus Short tC18 cartridge. The column was washed with water (9 mL), and activity was directly eluted with TFA (1.5 mL) in the deprotection vial. Deprotection was finished under stirring in less than 3 min.

Analysis by radio-TLC (silica gel, CH_2Cl_2; R_f values: **[18F]13** = 0; C_{18}, CH_3CN/H_2O 50/50, R_f values, **[18F]13** = 0.30). HPLC analysis: $t_{R\ =}$ 5.6 min (CH_3CN/H_2O 40/60 0.1% TFA). Radiochemical yield (decay corrected) from **[18F]5** 90%. Radiochemical purity >95%.

RESULTS AND DISCUSSION

Synthesis. The strategy we have followed to functionalize peptides with alkynes was based on the Sonogashira reaction. This cross-coupling reaction between iodoaryl and alkyne is catalyzed by Pd^0 complexes in mild conditions and is insensitive to all side groups. Furthermore, functionalization through Sonogashira coupling generates regioselectively and quantitatively a very stable C-C bond (*16*). Therefore, we planned to introduce the residue *p*-iodophenylalanine, a non-natural amino acid, into the peptide chain and to convert it to *p*-ethynylphenylalanine through the Sonogashira coupling reaction of ethynyltrimethylsilane (Scheme 1). The direct introduction of an ethynyl group is also possible but is not compatible with trifluoroacetic acid (*17*), which is predominantly used in peptidic synthesis. Moreover, the synthesis of *p*-ethynylphenylalanine is more demanding than the simple preparation of *p*-iodophenylalanine (*13*, *18*). A similar approach has been described by Hoffmans who has used the Sonogashira coupling to label

Scheme 1. Synthesis of References (13, Deprotected, and 15, Protected) and Clickable Alkyne Peptide 14

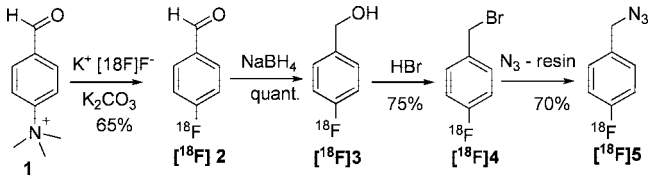


[Leu^5]Enkephalin (a neuropeptide that is a natural ligand of the opiate receptors) with ethynylferrocene (*19*). Thus, we have also chosen to use [Leu^5]Enkephalin as our model peptide because it is a small peptide, easy-to-handle to set up its labeling with fluorine-18 by click chemistry with 4-[^{18}F]fluorobenzyl azide. In the context of this work, no effort was made to preserve or improve the targeting ability or the in vivo stability of the labeled peptide. Readers interested in the imaging of the opiate receptors should read the following publications (*20*−*22*). Unlike Hoffmans, we decided to keep the [Leu^5]Enk peptide bound to the solid support (Wang resin) for the next steps to facilitate purification and isolation of the peptides **11**−**15**. The Sonogashira coupling between iodophenyl-derivatized peptide and trimethylsilylacetylene was carried out in conditions close to those described by Hoffmans. Excess reagents and catalysts were simply eliminated by filtration and washing. Completion of the reaction was checked by ES-MS after cleavage of small aliquots of the peptide by TFA. Deprotection of the alkyne group was achieved in the presence of TBAF in THF to furnish alkyne−peptide **11** still bound to the Wang resin.

Reference Compound Preparation. Conjugation of 4-ethynyl-L-phenylalanine (**6**) with 1-(azidomethyl)-4-fluorobenzene was conducted in DMF or acetonitrile, in the presence of DIEA and excess copper iodide (2 equiv.). When catalytic amounts of copper were used, the reaction did not start, possibly because of copper ion complexation by the amino acid (*23*). For cold chemistry, click conjugation of the peptide was carried out with the alkyne−peptide still bound to the resin support (Scheme 1). In the conditions used with 4-ethynyl-L-phenylalanine, compound **13** was obtained but iodo- and hydroxytriazole were also formed as secondary products. This problem was circumvented by replacing copper iodide with copper bromide and using an inert atmosphere. The reference peptide **13** was deprotected and removed from the resin by treatment with TFA. The protected reference peptide **15** was isolated by replacing the TFA treatment by a cleavage with trimethyltin hydroxide as described by Furlan (*24*). This solid phase method permits a rapid and easy preparation of reference peptides, which could be very valuable in a combinatorial approach.

Radiolabeling. The synthesis of 1-(azidomethyl)-4-[^{18}F]-fluorobenzene **[^{18}F]5**, a labeling agent for the subsequent click reaction, was carried out in four steps (Scheme 2) starting from the well-known nucleophilic fluorination of 4-formyl-*N*,*N*,*N*-trimethylanilinium triflate (**1**) (*25*−*28*). Radiofluorination was accomplished at 130 °C in DMSO for 5 min with an overall yield of 65%. This crude medium was diluted in

Scheme 2. Radiosynthesis of 1-(Azidomethyl)-4-[^{18}F]-fluorobenzene



water, then passed on a Waters C_{18} environmental Sep-Pak cartdrige to trap compound **2[^{18}F]**. This compound was reduced to 4-[^{18}F]-fluorobenzyl alcohol **[^{18}F]3** by slowly passing a solution of $NaBH_4$ in water through the C_{18} cartridge following a procedure previously described (*29, 30*). The alcohol formed was not eluted from the cartridge but directly converted to the bromide **[^{18}F]4** by passing 48% aqueous HBr by small portions through the C_{18} cartdridge. At RT, less than 25% of the alcohol was converted into the bromide derivative. Fortunately, by heating the cartridge at 50 °C via a stream of hot air, the conversion was nearly quantitative. After neutralization of the medium by passing an ammonium formate buffer, the bromide **[^{18}F]4** was eluted by DMF (CH_3CN, toluene, and CH_2Cl_2 were also used). The bromide was obtained with a radiochemical yield of around 75% (decay corrected). Previously, this bromination was conducted in solution using PBr_3 or Ph_3PBr_2 (*29, 31*), $SOBr_2$ (*32, 33*), HBr 48% (*34*), or gaseous HBr (*35*). None of these methods is well suited for an easily automated routine production. Our method avoids using gas reagents, and excess reagents are readily and easily eliminated. This methodology may be extended beyond the present application as the fluorobenzyl bromide synthon is a common structure in some radiopharmaceuticals used for PET imaging (*30, 31, 34*). Finally, 1-(azidomethyl)-4-[^{18}F]-fluorobenzene **[^{18}F]5** was formed using a commercially available azide exchange resin (azide on Amberlite IRA-400) as described by Hassner (*36*). In DMF at RT, the reaction was completed in 15 min using 500 mg of the resin. In a less polar solvent such as acetonitrile, the reaction was slower (75% of conversion after 25 min). Tests conducted in the laboratory have shown that this reaction is insensitive to the presence of water and carbonate or formate salts. Nevertheless, acidic media inhibit the reaction. Resin is simply eliminated by filtration and the targeted azide collected in solution in DMF, ready to use for click reactions.

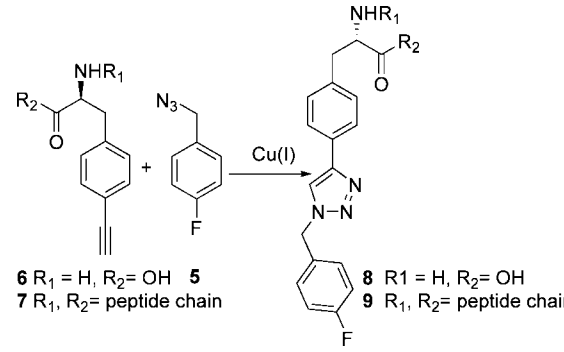
Hence, starting from 700 MBq [^{18}F]F^-, a total amount of 238 MBq (34%, decay corrected) of **[^{18}F]5** could be synthesized within 75 min.

Click Reactions with 1-(Azidomethyl)-4-[^{18}F]-fluorobenzene [^{18}F]5. Several catalytic systems have been described for Huisgen 1,3-dipolar cycloaddition (*6, 7*). In experiments to link [^{18}F]fluoroalkyne groups onto peptides, Marik and Sutcliffe have obtained better results using CuI than with Cu(I) generated *in situ* from copper sulfate and sodium ascorbate (*8*). Paradoxically, other teams have preferred *in situ* generation to click [^{18}F]fluoroprosthetic groups onto biomolecules. As we have obtained good results with copper (I) salts to prepare the cold references, we have chosen to follow the Marik and Sutcliffe approach. First, experiments with various conditions have been conducted on p-EPA (Table 1 and Scheme 3). The solvent greatly influences the reaction rate, which is much higher in DMF than in CH_3CN. This could be due at least partially to the better solubility of the alkyne in DMF. The reduction of the alkyne concentration also has a great impact on the reaction rate, which becomes insufficient at 0.003 M in the initial conditions (entry 4). Acceptable reaction rates were recovered by adding sodium ascorbate in the reaction medium (entry 5). Moreover, copper

Table 1. Influence of Reagent Concentration on the Radiochemical Yield for the Preparation of [^{18}F] 8 with 1-(Azidomethyl)-4-[^{18}F]-fluorobenzene [^{18}F]5 (RT, DMF)

alkyne (M)	CuI (M)	DIEA (M)	ascorbate (M)	solvent	reaction time (min)	yield (TLC)
0.050	0.105	0.600	0	AN	50	67%
0.050	0.105	0.600	0	AN:DMF 1:1	30	85%
0.05	0.105	0.600	0	DMF	7	90%
0.003	0.105	0.600	0	DMF	15	40%
0.003	0.017	0.280	0.130	DMF	15	95%

Scheme 3. 1,3-Dipolar Cycloaddition of 1-(Azidomethyl)-4-[^{18}F]-fluorobenzene with Alkyne Peptides or Amino Acid



ions and base concentrations can also be diminished when ascorbate is used since the reaction still completes in less than 15 min at RT. Thus, similar conditions have been applied to conjugate alkyne−peptide **14** with 1-(azidomethyl)-4-[^{18}F]-fluorobenzene **[^{18}F]5.**

Fast coupling was also observed by radio-HPLC: labeling of the peptide was finished in less than 15 min. The radiolabeled peptide was trapped on a t-C18 cartridge, washed with water, and eluted with TFA. Deprotection of the tyrosine residue was accomplished in less than 3 min, and the targeted labeled peptide was obtained with a yield of 90% (coupling step + deprotection, decay corrected) and a radiochemical purity >95%. We would also like to point out that these results were obtained at room temperature with very diluted solutions of alkyne (0.003 mmol/mL), which is about 10 times less than that used by Sirion, Ramenda, or Glaser. Similar results have been reported by Marik and Sutcliffe who also used a copper (I) salt and not the $CuSO_4$/sodium ascorbate catalytic system used by the other groups. The low quantity of peptide required facilitates the HPLC separation of the labeled peptide from the unlabeled peptide precursor, which is essential to obtain suitable chemical purity.

CONCLUSIONS

A novel strategy for the preparation of clickable peptides has been developed. It can be applied to any peptides modified beforehand to contain a non-natural iodophenyl group. As demonstrated here on a model peptide, this moiety can be simply introduced during the synthesis of the peptide by substituting the modified amino acid 4-iodophenylalanine for a phenylalanine residue.

Furthermore, as the selective monoiodination of tyrosine residue in peptides with IPy_2BF_4 has been reported by Espuña et al., our approach can also been extended to directly label tyrosine containing peptides (*37*). In cases where the peptide does not contain any Phe or Tyr groups, 4-iodobenzoic acid can be used to N-terminally modify the peptide eventually through an appropriate linker (*19*).

A new labeling agent 1-(azidomethyl)-4-[^{18}F]-fluorobenzene **[^{18}F]5** has been produced in 75 min with a 34% radiochemical

yield (decay corrected). These satisfying results for a four-step procedure have been obtained thanks to the exploitation of solid phase supported reactions and the absence of the solvent evaporation process that allow one to minimize the losses of time and radioactivity during reaction workup and purification. Moreover, this radiosynthesis has been fully automated in our laboratory. Although all of these advantages are present, this click labeling agent is obtained in a less straightforward manner than others produced in a single step (*8*, *10*, *11*). However, the radiocompound **[^{18}F]5** is advantageous in that it is nonvolatile and bears an aromatic bound fluorine, which is known to be less susceptible to *in vivo* radiodefluorination. For these reasons, it will be very interesting to produce 1-(azidomethyl)-4-[^{18}F]-fluorobenzene **[^{18}F]5** in one or two fast steps. Work in this direction is in progress in our laboratory. Furthermore, this compound has been bound very rapidly (10 min), at room temperature, with a very diluted solution of alkyne (0.003M), in mild conditions and with an excellent yield to a model alkyne−peptide.

Radioimmunoimaging with Longer-Lived Positron-Emitting Radionuclides: Potentials and Challenges

Tapan K. Nayak and Martin W. Brechbiel*

Radioimmune & Inorganic Chemistry Section, Radiation Oncology Branch, National Cancer Institute, National Institute of Health, Bethesda, Maryland 20892. Received July 15, 2008; Revised Manuscript Received October 12, 2008

Radioimmunoimaging and therapy has been an area of interest for several decades. Steady progress has been made toward clinical translation of radiolabeled monoclonal antibodies for diagnosis and treatment of diseases. Tremendous advances have been made in imaging technologies such as positron emission tomography (PET). However, these advances have so far eluded routine translation into clinical radioimmunoimaging applications due to the mismatch between the short half-lives of routinely used positron-emitting radionuclides such as ^{18}F versus the pharmacokinetics of most intact monoclonal antibodies of interest. The lack of suitable positron-emitting radionuclides that match the pharmacokinetics of intact antibodies has generated interest in exploring the use of longer-lived positron emitters that are more suitable for radioimmunoimaging and dosimetry applications with intact monoclonal antibodies. In this review, we examine the opportunities and challenges of radioimmunoimaging with select longer-lived positron-emitting radionuclides such as ^{124}I, ^{89}Zr, and ^{86}Y with respect to radionuclide production, ease of radiolabeling intact antibodies, imaging characteristics, radiation dosimetry, and clinical translation potential.

INTRODUCTION AND BACKGROUND

Applications of radiation in medicine have been described now for over 100 years. The use of radiation in medicine branches from many scientific discoveries, most notably the discovery of X-rays in 1895 and its use in surgery (*1*). Since that time frame, over the next 60 years critical advances in nuclear medicine technology and instrumentation have resulted in methodologies and technologies for the visualization of many of the body's organs, including liver and spleen scanning, brain tumor localization, and studies of the gastrointestinal tract by the injection of radionuclides (*2, 3*). The greatest potential use of radiation in medicine is its utility to provide diagnostic information of pathological processes before the outset of structural changes in an organ. In these applications, very small amounts of radioactive material most often labeled or conjugated to "smart" targeting agents such as antibodies, peptides, and small molecules are introduced into the body. These "smart" agents specifically target individual cells instead of just the general tissues or organs, and therefore provide more valuable information about actual pathology. One example of such "smart" targeting agents is the monoclonal antibody (mAb). Currently, 21 monoclonal antibodies (all intact) are approved by the U. S. Food and Drug Administration (U.S.F.D.A) for diagnosis and treatment of various illnesses.

Antibodies in Nuclear Medicine. Currently, radiolabeled antibodies are clinically used for numerous applications such as oncology and cardiology (*4, 5*). Use of radiolabeled antibodies for targeting specific organs in animals was explored almost half a century ago (*6, 7*). Radiolabeled antibodies have been used in the clinic for therapeutic and diagnostic purposes now for over 40 years (*8, 9*). In 1978, Goldenberg and colleagues successfully applied the principles of antibody−antigen binding by visualizing carcinoembryonic antigen (CEA) on tumors of patients with a history of cancer of diverse histopathology by injecting ^{131}I labeled goat IgG targeting CEA. However, the large-scale application of radiolabeled antibodies in the clinic was hindered due to low production yields and concerns of toxic immune reactions after injecting antibodies of animal origin into humans. The introduction of hybridoma technology for monoclonal antibody (mAb) production as developed by Kohler and colleagues along with the evolution of recombinant DNA technology has addressed many of these problems (*10*). Chimeric and humanized monoclonal antibodies and even completely human antibodies are now the standard. Numerous clinical studies have since been reported describing the use of radiolabeled intact antibodies for diagnosis of cancer using γ-scintigraphy and single photon emission tomography (SPECT) imaging (*4, 11*−*13*).

In spite of great successes in preclinical animal models, the promise of radioimmunoimaging by γ-scintigraphy has not fully lived up to expectations, mostly due to differences in biodistribution and pharmacokinetic characteristics between animals and humans, and limitations of γ-scintigraphy in terms of intrinsic spatial resolution (*14*). Radionuclides that decay with γ-energies lower than 100 keV produce too much scatter, while γ-energies over 250 keV are difficult to collimate and therefore pose a challenge for quantitative γ-scintigraphy. To overcome the disadvantages posed by γ-scintigraphy, attempts were made to exploit the superiorities of positron emission tomography (PET) for radioimmunoimaging. A single positron decay results in two 511 keV photons being emitted at 180°. Most

Table 1. Characteristics of Selected Longer-Lived Positron-Emitting Radionuclides for Radioimmunoimaging[a]

radionuclide	half-life	production	daughter (half-life)	β^+_{max} in MeV (β^+yields)	γ-energies in MeV (yields)	mean range (mm)	intrinsic spatial resolution loss (mm)	human studies
^{18}F	1.83 h	^{20}Ne(d, α)^{18}F ^{18}O(p, n)^{18}F	^{18}O (stable)	0.63 (97%)	0.14 (41%)	0.69	0.7	Yes
^{124}I	100.2 h	^{124}Te(p, n)^{124}I ^{124}Te(d, 2n)^{124}I ^{125}Te(p, 2n)^{124}I	^{124}Te (stable)	2.14 (24%)	0.60 (61%)	3.25	2.3	Yes
^{76}Br	16.0 h	^{76}Se(p, n)^{76}Br ^{75}As(^{3}He, 2n)^{76}Br	^{76}Se (stable)	3.98 (56%)	0.55 (74%)	5.07	5.3	Yes
^{52}Mn	134.2 h	^{52}Cr(p, n)^{52}Mn ^{51}V(^{3}He, 2n)^{52}Mn ^{52}Cr(^{3}He,t)^{52}Mn	^{52}Cr (stable)	0.58 (29%)	0.74 (90%)	5.00	0.6	Yes
^{55}Co	17.5 h	^{54}Fe(d, n)^{55}Co ^{56}Fe(p, 2n)^{55}Co	^{55}Fe (2.6 y)	1.50 (76%)	0.48 (20%)	5.74	1.6	Yes
^{7}Ga	9.4 h	^{66}Zn(p, n)^{66}Ga ^{63}Cu(4He,n)^{66}Ga	^{66}Zn (stable)	4.15 (56%)	1.03 (36.9%)	8.06	5.8	Yes
^{72}As	25.9 h	^{72}Ge(p, n)^{72}As	^{72}Ge (stable)	3.32 (88%)	0.83 (80%)	5.01	3.6	Yes
^{64}Cu	12.7 h	^{64}Ni(p, n)^{64}Cu ^{68}Zn(p, n)^{64}Cu ^{64}Ni(d,2 n)^{64}Cu	^{64}Ni,^{64}Zn (stable)	0.66 (18%)	-	0.70	0.7	Yes
^{86}Y	14.7 h	^{86}Sr(p, n)^{86}Y ^{nat}Rb(^{3}He, 2n)^{86}Y	^{86}Sr (stable)	3.15 (34%)	1.08 (83%)	2.46	1.8	Yes
^{89}Zr	78.4 h	^{89}Y(p, n)^{89}Zr ^{89}Y(d, 2n)^{89}Zr	^{89}mY (16 s)	0.90 (23%)	-	1.18	1.0	Yes

[a] Some of the data presented in the table were obtained from references (*4, 159*) and http://www.nndc.bnl.gov/nudat2/ (Nuclear Structure and Decay Data Searchable Database, National Nuclear Data Center, Brookhaven National Laboratory, USA) accessed on 03/07/2008.

PET cameras contain a circular array of detectors with coincidence circuits designed to capture 511 keV photons emitted in opposite direction and therefore offer much better resolution and counting efficiency as compared to conventional γ-scintigraphy and SPECT cameras (*15*). However, a major limitation challenging PET radioimmunoimaging was the half-lives of most of the routinely used PET radionuclides such as ^{18}F ($t_{1/2}$ = 1.8 h) and ^{11}C ($t_{1/2}$ = 0.3 h). The half-lives of routinely used PET radionuclides simply did not match well with the biological half-lives (up to several days) and pharmacokinetic parameters of slowly localizing intact antibodies. To overcome the initial blood pool uptake and slow localization of the intact antibody, antibody fragments (Fab) were labeled with ^{18}F for PET imaging. However, ^{18}F labeled antibody fragments failed to demonstrate high tumor localization as demonstrated by parent intact antibodies (*16, 17*). ^{18}F labeled antibody fragments were cleared from the tumor relatively more quickly than intact antibodies and then rapidly excreted through the urinary route delivering high radiation doses to the kidneys (*16, 17*). Numerous attempts have been made to modify intact antibodies to increase tumor uptake and residence time, and concomitantly decrease kidney uptake for successful PET with ^{18}F (*18, 19*). To date, results from these strategies have demonstrated low to moderate success. Another drawback of using ^{18}F as the choice of radionuclide for PET radioimmunoimaging is the cumbersome chemistry involved, which requires synthesis of ^{18}F labeled intermediate precursors for indirect labeling of antibodies with ^{18}F (*17, 20*).

As an alternative to the approach of modifying the antibody to match the physical characteristics of ^{18}F, the use of longer-lived positron emitters has been explored for radioimmunoimaging with intact antibodies (*21*−*23*). The half-lives of longer-lived positron emitters such as ^{124}I and ^{89}Zr (shown in Table 1) have a much closer match with the biological half-life of most intact antibodies. Antibodies labeled with longer-lived positron emitters can be imaged for 2−5 days after injection when the radioactivity in the blood pool has been cleared and target to background ratio is higher. In this report, we have examined the potentials and challenges of selected longer-lived positron-emitting radionuclides for radioimmunoimaging with intact antibodies. The criteria applied for selecting these longer-lived positron emitters (Table 1) includes previously published reports with antibodies or clinical studies, a potentially suitable half-life (10−140 h) versus biological half-life, an imageable positron emission, available or potentially available conjugation and radiolabeling chemistry, and reasonable or acceptable production logistics and radiation toxicity.

SELECTED LONGER-LIVED POSITRON-EMITTING RADIONUCLIDES FOR RADIOIMMUNOIMAGING

Numerous longer-lived positron-emitting radionuclides can be produced by cyclotrons, accelerators, and reactors. Selected longer-lived positron emitters ranging from halogens to metals are described below with respect to their production, feasibility of use in radiolabeling an intact antibody, biological applications, and imaging characteristics.

Iodine-124. Iodine (atomic radius of 1.3 Å and electronegativity of 2.66) belongs to Group VII of the periodic table. ^{124}I is a positron-emitting radionuclide with a complex decay scheme associated with numerous high-energy γ-emissions (0.6 MeV, 61% abundance) and high-energy positron emissions (2.14 MeV, 24% abundance) as shown in Table 1. ^{124}I ($t_{1/2}$ = 100.2 h) decays to a stable ^{124}Te daughter. The relatively longer half-life makes ^{124}I conducive for labeling intact antibodies for PET imaging over several days after administration. Additionally, the vast experience of radiolabeling proteins with the other Iodine radionuclides, i.e., ^{131}I, ^{125}I, and ^{123}I, promotes a significant level of confidence, since existing chemistry and protocols are directly applicable for use with ^{124}I.

Production of ^{124}I. ^{124}I can be produced by a conventional medical cyclotron using the ^{124}Te(p,n)^{124}I and ^{124}Te(d,2n)^{124}I reactions (Table 2). Typically, highly enriched tellurium dioxide is used as the target and ^{124}I is isolated using dry distillation with minimal impurities (*24*−*26*). The yield (<0.1 mCi/μAh) from the ^{124}Te(p,n)^{124}I reaction is low at 15 MeV (*27*). Alternatively, ^{124}I can be produced through a ^{125}Te(p,2n)^{124}I reaction with about four times higher yields than the commonly used ^{124}Te(p,n)^{124}I and ^{124}Te(d,2n)^{124}I reactions (*24, 27*). However, the production of ^{124}I through the ^{125}Te(p,2n)^{124}I reaction requires a medium−high-energy cyclotron, and impurities are relatively higher than the ^{124}Te(p,n)^{124}I reaction.

Table 2. Commonly Used Production Routes of Selected Longed-Lived Positron-Emitting Radioimmunoimaging and Corresponding Yields and Radionuclidic Impurities (adapted from ref 119)

radionuclide	commonly used production route	energy range (MeV)	calculated yield (MBq/μAh)	radionuclidic impurity
	^{124}Te(p, n)^{124}I	12 → 8	16	^{125}I (0.1%)
^{124}I	^{124}Te(d, 2n)^{124}I	14 → 10	17.5	^{125}I (1.7%)
	^{76}Se(p, n)^{76}Br	15 → 8	360	-
^{76}Br	^{75}As(^{3}He, 2n)^{76}Br	18 → 10	11	^{77}Br (1.6%)
	^{52}Cr(p, n)^{52}Mn	20 → 10	0.4	^{54}Mn (0.5%)
^{52}Mn	^{52}Cr(^{3}He, t)^{52}Mn	36 → 10	5.6	^{54}Mn (0.8%)
	^{54}Fe(d, n)^{55}Co	10 → 5	32	^{56}Co,^{57}Co (0.1%)
^{55}Co	^{58}Ni(p, n)^{55}Co	15 → 7	14	^{57}Co (0.5%)
^{66}Ga	^{66}Zn(p, n)^{66}Ga	13 → 8	433	-
^{72}As	^{72}Ge(p, n)^{72}As	18 → 8	93	^{71}As (10%)
	^{64}Ni(p,n)^{64}Cu	12 → 9	240	^{61}Cu (0.4%)
^{64}Cu	^{68}Zn(p, n)^{64}Cu	35 → 20	100	^{67}Cu (25%)
^{86}Y	^{86}Sr(p, n)^{86}Y	14 → 10	400	^{87}mY (3%)
^{89}Zr	^{89}Y(p, n)^{89}Zr	12 → 6	43	^{88}Zr (0.1%)

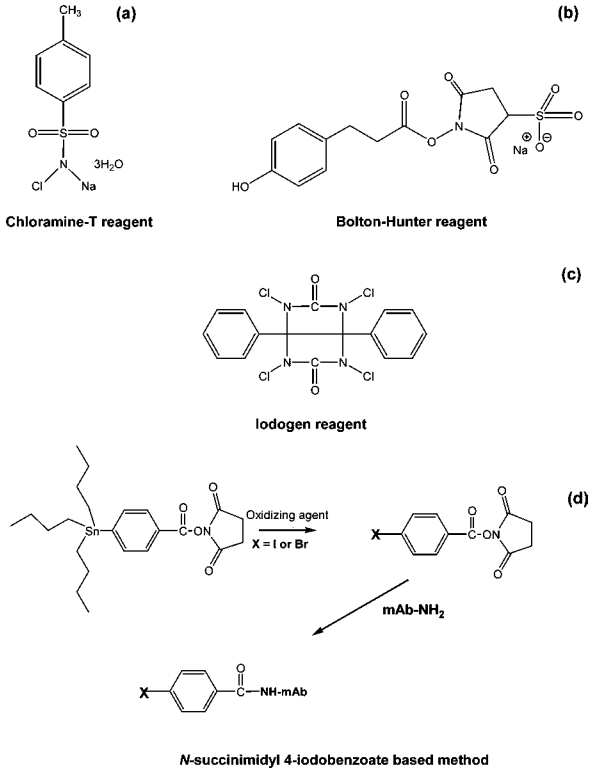

Figure 1. General scheme and reagents of radio-halogenation of intact antibodies using commonly used methods: (a) Chloramine-T method, (b) Bolton-Hunter method, (c) Iodogen method, and (d) *N*-succinimidyl 4-iodobenzoate based method.

Radiolabeling of Antibodies with ^{124}I. Radio-iodinated antibodies have been used for in vivo applications for more than 60 years (*6*, *7*, *28*, *29*). In the early 1960s, Hunter and co-workers described a method called the Chloramine-T method, to prepare high specific-activity radio-iodinated antibodies using *p*-toluene sulfonochloramide (Figure 1a) (*30*, *31*). Briefly, the Chloramine-T method is an oxidative method which involves exposure of the substrate to Chloramine-T in the presence of NaI for a short time, producing high specific activity proteins labeled with carrier-free radioiodine. However, the major disadvantage of the Choramine-T method is the risk of oxidation of thiol groups and protein denaturation due to the presence of high concentrations of strong oxidizing agent which can compromise the intended biological use of the antibody. As an alternative, an enzymatic method using lactoperoxidase as a catalyst was developed for iodination of antibodies (*32*, *33*). Lactoperoxidase catalyzes the oxidation of iodide using hydrogen peroxide as the enzyme substrate and is a milder oxidative agent than Chloramine-T. Due to the continuing concerns of protein denaturation and loss of biological activity by oxidizing agents, a newer technique (Bolton-Hunter method; Figure 1b) was later developed using iodinated 3-(4-hydroxyphenyl)propionic acid *N*-hydroxysuccinimide ester, which reacts with free amino groups in the protein molecule to attach the radioiodine-labeled groups by amide bonds (*34*, *35*). The Bolton-Hunter method is a nonoxidative technique that is less harsh on the proteins than alternative methods. Similarly, to avoid the interaction of oxidizing agent with the protein, an alternative solid-phase oxidation using 1,3,4,6-tetrachloro-3α,6α-biphenyl glycoluril (Figure 1c) was developed and is commonly called the Iodogen method (*36*). All of the above methods suffered from the drawback of in vivo deiodination in the presence of enzymes. To overcome in vivo deiodination, another method was developed using *N*-succinimidyl 4-iodobenzoate (PIB) (Figure 1d) to specifically label antibodies and proteins (*37*). This method produced a more stable radio-iodinated antibody as compared to methods like Bolton-Hunter, as PIB does not contain an *o*-phenol moiety, which protects PIB derivatives from the deiodinases that can act to delabel *o*-iodophenols that are formed with the other radio-iodination methods. As a result of increased in vivo stability, the uptake in the thyroid was dramatically reduced when a comparison was made between the same antibody radio-iodinated using the PIB and Chloramine-T methods (*37*). Many monoclonal antibodies are internalized via either clathrin-dependent or independent pathways. Antibodies rapidly internalized (within 2−4 h) via the clathrin-dependent endocytosis pathway are catabolized within lysosomes. Iodotyrosine is known to rapidly exit from the lysosome and the cell after catabolism, and as a result, target-to-background ratios are poor (*38*−*40*). In order to overcome the issue of catabolism of conventional radio-iodinated antibodies, dilactitol-tyramine (DLT) and radio-iodinated diethylenetriaminepentaacetic acid-appended peptides have successfully been used to residualize the radio-iodinated antibody within the cells (*41*−*44*). As a result of decreased catabolism, the tumor uptake of cell surface binding radio-iodinated antibodies was significantly higher than antibodies radiolabeled with the Chloramine-T method (*41*, *42*).

Detailed methodologies for radio-iodination of proteins can be found in a review article published in *Bioconjugate Chemistry* (*45*). Currently, most ^{124}I labeled antibodies are prepared using commercial iodination kits based on some of the above-described techniques.

Biological Studies with ^{124}I Labeled Antibodies. In the early 1990s, murine monoclonal antibody H17E2 recognizing placental alkaline phosphatase (PLAP) was radiolabeled with ^{124}I using the Iodogen method for targeting PLAP on HEp2 human tumor xenografts (*21*). The ^{124}I labeled H17E2 localized in the tumor for at least 7 days, demonstrating the feasibility of using monoclonal antibodies labeled with ^{124}I for tumor localization studies (*21*). The utility of antibodies labeled with ^{124}I for PET imaging, imaging feasibility, and quantification studies were studied by Pentlow and co-workers (*22*). In this study, when compared to ^{18}F, the spatial resolution was only slightly degraded while the linearity was the same (*22*). This technique was translated to in vivo application by measurements of human neuroblastoma tumors in rats which had been injected with ^{124}I labeled 3F8 antibody demonstrating that quantitative PET imaging of ^{124}I labeled antibodies was possible in biological systems. Use of ^{124}I in PET radioimmunoimaging was further demonstrated by c-erb B2 quantification and visualization in tumor xenografts for up to 160 h using ^{124}I labeled rat monoclonal antibody (ICR12) recognizing the external domain

of the human c-erb B2 proto-oncogene product (*23*). With advances in imaging instrumentation and technology, whole-animal PET studies were performed for noninvasive measurements of tumor vascular endothelial growth factor (VEGF) in animal model using ^{124}I-SHPP-VG76e (*46*). Similarly, ^{124}I labeled engineered antibodies have been evaluated for in vivo imaging (*47, 48*).

Numerous applications of ^{124}I in humans for PET imaging have since been reported (*49*−*51*). PET with anti-VEGF ^{124}I-HuMV833 was conducted on 20 patients with progressive solid tumors with moderate success (*52*). A recently published clinical study successfully used a carbonic anhydrase-IX targeted ^{124}I-cG250 antibody to accurately identify clear-cell renal carcinoma and to predict the aggressiveness of the disease, information that could be valuable in treatment decision-making (*53*).

Challenges. ^{124}I is available from numerous academic centers and is also available commercially through sources such as IBA Molecular, but it tends to be expensive. Current concerns remain high radiation dose and degraded image quality from high-energy γ-emissions and the loss of spatial resolution as a result of high-energy positrons (Table 1). The image quality is further degraded due to decrease in tumor/background ratio as a result of intracellular catabolism of ^{124}I. Typically, radioiodide localizes in the thyroid, delivering high radiation doses, and therefore, potassium iodide solution has to be infused before protein labeled with ^{124}I infusion to block thyroid uptake.

Bromine-76. Bromine (atomic radius of 1.1 Å and electronegativity of 2.96) also belongs to group VII of the periodic table.^{76}Br has a fairly high abundance (56%) of high-energy β^+ emission (3.9 MeV) and decays to a stable ^{76}Se daughter, as shown in Table 1. The half-life of 16.2 h also makes ^{76}Br one of the most attractive radionuclides for PET imaging using intact antibodies that exhibit slow clearance. The positron abundance of ^{76}Br is almost double that of ^{124}I (Table 1) and the C−Br bond is stronger than the C−I bond in organic compounds, therefore making it less susceptible to in vivo dehalogenation, thereby potentially minimizing concerns regarding background activity and associated toxicity (*54*). Due to the smaller atomic radius and greater electronegativity, ^{76}Br has greater polarity than ^{124}I. The increased polarity of ^{76}Br can alter biological properties and pharmacokinetics of the biomolecule, which can be either unfavorable or favorable depending upon the objective and purpose of the study (*55, 56*).

Production of ^{76}Br. ^{76}Br can be prepared using a low−intermediate energy medical cyclotron. Typically, ^{76}Br is produced through the ^{76}Se(p,n)^{76}Br reaction in which a highly enriched ^{76}Se target is bombarded with 15−16 MeV protons (*57*). Alternatively, ^{76}Br can also be prepared through the ^{75}As(^{3}He,2n)^{76}Br and ^{nat}Br(p, xn)^{76}Kr→^{76}Br reactions using high-energy (over 50 MeV) protons (*58, 59*). Purification and recovery of ^{76}Br is performed by dry distillation methods.^{76}Br produced through alternative routes contains other radionuclide impurities such as ^{77}Br and ^{75}Br, which may result in lower yields due to separation and purification. The calculated yield for ^{76}Br produced through the ^{76}Se(p,n)^{76}Br reaction is almost 32 times greater than ^{76}Br produced through the ^{75}As(^{3}He,2n)^{76}Br reaction (Table 2). Another disadvantage of ^{76}Br produced through the ^{75}As(^{3}He,2n)^{76}Br reaction is the ^{77}Br ($t_{1/2}$ = 57.03 h) impurity.

Radiolabeling of Antibodies with ^{76}Br. Numerous antibodies have been brominated using techniques and approaches similar to iodination such as Chloramine-T, enzymatic, *N*-succinimidyl *para*-(trimethylstannyl)benzoate (*60*−*62*). Bromination of antibodies by oxidative methods can be more difficult than iodination due to the lower oxidation potential of bromide. Therefore, more powerful oxidizing agents are used for sufficient yield of bromination, potentially proving deleterious to proteins. Recently, a method was described for indirect radiobromination of antibodies to prevent protein denaturation in the presence of strong oxidizing agents (*63*). In this method, indirect labeling was performed using the *p*-isothiocyanatobenzene derivative of the [^{76}Br]undecahydro-bromo-7,8-dicarba-*nido*-undecaborate-(1-) (^{76}Br-NBI) as a precursor molecule. ^{76}Br-NBI was prepared using the Chloramine-T method, and thereafter, the coupling was performed without intermediate purification in an "one-pot" reaction (*63*). This technique resulted in improved intracellular retention of the radiolabeled antibody and decreased the loss of biological activity caused by direct bromination with oxidizing agents. Similar indirect radio-bromination efforts have been reported using 4-hydroxyphenylethylmaleimide for site-specific bromination of a cysteine containing a variant of the anti-HER2 affibody (*64*).

Biological Studies with ^{76}Br Labeled Antibodies. Proteins have been brominated and evaluated in animals now for over 30 years (*60*). In the past decade, anti-CEA mAb 38S1 was radio-brominated and evaluated in animals (*65, 66*). A comparative study using ^{76}Br-38S1, ^{18}FDG, and ^{11}C-Met demonstrated the superiority of ^{76}Br-38S1 in successful identification and imaging of liver metastases in nude rats bearing human colon carcinoma (*67*). In recent years, more studies have been reported with ^{76}Br labeled intact antibodies and engineered antibodies for the purpose of PET imaging (*56, 63, 64, 68*). In a recent study, an ED-B fibronectin-binding human antibody derivative (L19-SIP) was labeled with ^{76}Br via an enzymatic approach using bromoperoxidase resulting in both radiolabeling yields and immunoreactivity of over 80% (*56*). This radio-brominated immunoconjugate with a standardized uptake value of over 2.4 enabled detailed small-animal PET imaging of tumor neovasculature in F9 tumor-bearing animals (*56*). However, long retention of radioactivity in blood and very slow renal excretion were also observed, and as a result, the background activity in nontarget organs was higher than that reported for the ^{125}I-labeled L19-SIP, illustrating the differences between iodinated and brominated antibody (*56*).

Clinically, small molecules labeled with ^{76}Br have been successfully used for *in vivo* quantitative PET neuroimaging (*69, 70*); although, few if any radio-brominated antibodies have been successfully used in the clinic.

Challenges. Besides the loss of intrinsic spatial resolution of about 5.3 mm due to high-energy positrons (3.98 MeV) (Table 1), one of the major problems with ^{76}Br is the availability and large-scale production. Enriched ^{76}Se is relatively expensive due to low natural abundance (1 mg/∼US $6), although target material recovery and recycling could obviate that aspect. This may be one of the contributing factors hindering commercialization of large quantities of ^{76}Br, although smaller quantities of ^{76}Br are available on request through MDS Nordion and Isotrace Technology. The β^+ energy of ^{76}Br is relatively higher than conventional PET radionuclides, which may pose concerns of radiation doses for diagnostic purposes; however, the same could be viewed as a potential advantage if actually used for therapeutic applications.

Manganese-52. Manganese (atomic radius of 1.8 Å and electronegativity of 1.55) belongs to group VIIB of the periodic table. ^{52}Mn ($t_{1/2}$ = 134.2 h) decays to a stable ^{52}Cr daughter. The half-life and suitable imaging characteristics as a result of optimum positron energy of 0.58 MeV (Table 1) makes ^{52}Mn one of the most attractive and under-utilized longer-lived positron emitters for PET imaging of intact antibodies.

Production. ^{52}Mn can be produced using the ^{52}Cr(p,n)^{52}Mn reaction by irradiating a high-purity Cr target with 16−17 MeV protons or by ^{51}V(^{3}He,2n)^{52}Mn using a high-energy cyclotron (*71*−*73*).

Radiolabeling of Antibodies with ^{52}Mn. Although ^{52}Mn seems to be a suitable candidate for radioimmunoimaging, relatively little effort has been made to label antibodies. Chelating agents such as dipyridoxyl diphosphate (*74*), macrocyclic Schiff-base ligands (*73*), cyclopentadienide (*74*), and porphyrin derivatives (*75*) have been suggested for Mn in different oxidation states. However, generation of stable^{52}Mn(II) labeled radioimmunoconjugates in aqueous conditions remains unclear due to complex redox chemistry.

To date, no peer-reviewed reports have been published describing the production or use of ^{52}Mn labeled antibodies.

Biological Studies with ^{52}Mn. Radio-manganese has mostly been used as a cationic perfusion tracer and as a tracer to study the involvement of manganese in degenerative neurological diseases (*71, 72, 75*).

Challenges. ^{52}Mn is one of the positron emitters that have been understudied in nuclear medicine. Therefore, production, chelation and conjugation chemistry, and biological effects of ^{52}Mn all need to be extensively studied prior to embarking on radioimmunoimaging application studies.

Cobalt-55. Cobalt belongs to group VIIIB of the periodic table. Cobalt has an atomic radius of 1.7 Å and electronegativity of 1.88. ^{55}Co decays to a longer-lived ^{55}Fe daughter ($t_{1/2} = 2.6$ y) mainly by positron emission of 1.5 MeV (76% abundant) with a half-life of 17.5 h [Table1].

Production of ^{55}Co. The ^{54}Fe(d,n)^{55}Co reaction has been used to obtain ^{55}Co in good yields (32 MBq/μAh) and acceptable purity of over 99% using a medical cyclotron (Table 2) (*76*). Alternatively, ^{55}Co can produced through ^{58}Ni(p,n)^{55}Co on a medical cyclotron but yields are less than half that of ^{54}Fe(d,n)^{55}Co reaction (Table 2). No-carrier-added ^{55}Co can be prepared using the ^{56}Fe(p,2n)^{55}Co reaction by bombardment with 28 MeV protons using a cyclotron or 40 MeV protons using a linear accelerator (*77, 78*). Better yields and decreased impurities of ^{56}Co are achieved when the reaction is carried out using 28 MeV protons and high-purity target material. Typically, radiochemical separation is performed by solvent extraction techniques (*78, 79*).

Radiolabeling of Antibodies with ^{55}Co. In studies performed at Brookhaven National Laboratory, an anti-CEA antibody fragment was labeled with ^{55}Co using cyclohexyl EDTA monoanhydride (CDTA-MA), 4-isothiocyanato-*trans*-1,2,-diaminocyclohexane *N,N,N′,N′*-tetraacetic acid (4-ICE) and diethylenetriamine pentaacetic acid dianhydride (DTPA-DA) as bifunctional chelating agents (*77*). The radiolabeling was carried out at pH 5.5 at room temperature with an incubation time ranging 2−4 h. All three of the immunoconjugates were obtained in high labeling yields and demonstrated good serum stability after 4 days (*77*).

Biological Studies with ^{55}Co Labeled Antibodies. ^{55}Co labeled anti-CEA F(ab′)$_2$ using DTPA-DA and 4-ICE as bifunctional chelating agents was evaluated in athymic mice bearing human colon carcinoma LS174T xenografts as a potential PET imaging agent (*77*). In the same study, to appraise the feasibility of the use of ^{55}Co as a PET tracer, a Jaszczak phantom study was performed on a whole body PET scanner, providing images of satisfactory resolution (*77*). In vivo biodistribution studies revealed the superiority of 4-ICE as a better ^{55}Co chelating agent as compared to DTPA-DA, as the tumor uptake of 4-ICE conjugated antibody was 2.8 times with greater conjugated antibody than that of DTPA-DA.

In the past,^{55}Co labeled bleomycin has been evaluated for imaging of tumors in preclinical and clinical settings (*76, 78, 80*). Other applications of ^{55}Co include evaluation of renal function (*79*). However, most applications of ^{55}Co in the clinic are in the field of neuro-imaging to assess neuronal damage in stroke and traumatic brain injury (*81, 82*).

Challenges. Since the initial reports of successful use of ^{55}Co in radioimmunoimaging in early 1990's, no peer-reviewed reports have been published in over 15 years that demonstrate the use of ^{55}Co in radioimmunoimaging. Issues surrounding appropriate chelation chemistry should be addressable extrapolation from the prior reports, and the use of 1,4,7,10-tetraaminocyclododecane-*N,N,N′,N′*-tetraacetic acid (DOTA) derivatives might also prove useful in this application. The dissociation kinetics of Co(II)-DOTA complexes has been suggested to be very slow at neutral and slightly acidic pH and therefore may offer better in vivo stability than DTPA complexes (*83, 84*). Cobalt has been used to determine the mean number of DOTA chelating groups conjugated per antibody using a metal-binding assay (*85, 86*). Size considerations might also direct one to investigate NOTA. This is an area of research that remains unsettled. Another potential challenge might be the radiation dose from the ^{56}Co impurity and the generated presence of the longer-lived ^{55}Fe daughter ($t_{1/2} = 2.6$ y) (*87*). It is known that uncomplexed cobalt localizes in the bone and liver, which could pose issues related to radiation toxicity in case the ^{55}Co complex is unstable in vivo (*88*).

Gallium-66. Gallium belongs to group III of the periodic table. Gallium has an atomic radius of 1.8 Å and electronegativity of 1.81. ^{66}Ga has one of the highest energies of the candidates considered here for PET imaging ($E_{max} = 4.15$ MeV, 56% abundant). Along with a complex spectrum of γ-rays, ^{66}Ga is one of the more difficult positron emitters for quantitative PET imaging. Although at the shorter end of this criterion, ^{66}Ga has a half-life of 9.4 h and has been explored for radioimmunoimaging in the past decade (*89, 90*).

Production of ^{66}Ga. ^{66}Ga can be produced using a medical cyclotron employing the ^{66}Zn(p,n)^{66}Ga reaction (Table 2) (*91*). Alternatively, ^{66}Ga can be produced by ^{4}He bombardment of natural copper targets by means of the ^{63}Cu (^{4}He, n) ^{66}Ga reaction (*89, 92, 93*). However, this method also yields an impurity in the form of ^{67}Ga ($t_{1/2} = 3.26$ d). Chemical purification of ^{66}Ga from the copper target using multiple techniques is described in detail in these published reports (*89, 92, 93*).

Radiolabeling of Antibodies with ^{66}Ga. The coordination chemistry of Ga(III) is well-established, as it is known that Ga(III) readily binds to the harder oxygen donor chelating agents (*94*). Initially, $GaCl_3$ is complexed as an acetate or a citrate, and this weak coordination complex is then used to prepare complexes of higher stability (*94*).

The monoclonal antimyosin antibody, Imciromab was labeled with ^{66}Ga in high yield (99%) by transcomplexation from an acetate buffer to the DTPA-conjugated protein (*89, 90*). One of the major concerns of using ^{66}Ga for labeling antibodies is the formation of the insoluble hydrolyzed $Ga(OH)_3$ species above pH 4.5. The radiolabeling had to be carried out in a pH range 3−4.5, which may potentially degrade intact antibodies. Suitable chelation chemistry for Ga(III) radionuclides that has been evaluated includes EDTA, DTPA derivatives, and DOTA, the latter of which may be adequately stable in vivo within the context of the half-lives of the positron emitting gallium radionuclides (*95*). A critical parameter for *in vivo* stability of the Ga(III)-complex is its relative stability to the Ga(III)-transferrin complex. The reported formation constant for Ga(III)-transferrin complex is $\log K_1 = 20.3$ (*96*), and the high plasma concentration of transferrin increases the risks of transchelation. The majority of the Ga(III) complexes used in nuclear medicine are thermodynamically stable and kinetically inert to exchange with transferrin in vivo. However, the complex formed with the chelator 1,4,7-triazacyclononane-*N,N′,N″*-triacetic acid (NOTA) is exceptionally stable and quite probably will emerge as the agent of choice for use with Ga(III) radionuclides (*97, 98*).

Moreover, NOTA is a more suitable chelating agent for Ga(III) labeled antibodies, as the Ga(III)-NOTA complex is formed at room temperature, and therefore, the protein is exposed to less harsh conditions as compared to heating as in the use of DOTA (*99*).

Biological Studies with ^{66}Ga Labeled Antibodies. ^{66}Ga-DTPA-antimyosin antibody was evaluated in dogs for imaging of myocardial necrosis by PET (*89*). Most biological applications of ^{66}Ga in molecular imaging have been with either peptides or small molecules, as the radiolabeling in acidic conditions is more favorable as compared to use with antibodies (*100*, *101*). The initial use of ^{66}Ga in humans dates back to 1954 (*102*), and in that study, ^{66}Ga was used to investigate bone disease. As compared to ^{66}Ga, short-lived positron emitter ^{68}Ga ($t_{1/2}$ = 1.1 h) obtained from a ^{68}Ge/^{68}Ga generator has gained immense popularity in recent years due to the availability of commercial ^{68}Ge/^{68}Ga generators and clinical successes with ^{68}Ga labeled somatostatin peptide (*103*, *104*). In spite of such a short half-life, excellent results have been obtained from a ^{68}Ga labeled trastuzumab fragment when studying the tumor response to the heat shock protein 90 (Hsp90) inhibitor 17-allylamino-17-demethoxygeldanamycin (17-AAG) (*105*, *106*). In these studies, a ^{68}Ga labeled Herceptin fragment was successfully used to image the pharmacodynamics of HER2 degradation in response to 17-AAG and was an earlier predictor of tumor response to 17-AAG therapy than ^{18}F-FDG PET (*105*, *106*). However, ^{68}Ga may not be a suitable candidate for imaging with intact antibodies because of their slower pharmacokinetics and tumor localization.

Challenges. Apart from unfavorable antibody radiolabeling procedures, the utility of ^{66}Ga in quantitative radioimmunoimaging is severely impaired by high positron energy (4.15 MeV), which results in the loss of intrinsic spatial resolution of about 5.8 mm and additional high-energy γ-emission (1.03 MeV) resulting to poor signal-to-noise ratio (Table 1). The half-life of 9.4 h may be relatively longer than existing radionuclides such as ^{18}F ($t_{1/2}$ = 1.83 h), but the half-life is shorter with respect to the blood clearance and tumor localization of an intact antibody. Traditionally, gallium (^{67}Ga) is used for bone scans, and therefore ^{66}Ga lost from the chelate (if any) will localize in the bones delivering high radiation dose.

Arsenic-72. Arsenic belongs to group III of the periodic table and has an atomic radius of 1.3 Å and electronegativity of 2.18. ^{72}As ($t_{1/2}$ = 25.9 h) decays to a stable ^{72}Ge daughter with 88% high-energy positron emission (Table 1). The longer half-life and positron abundance makes ^{72}As one of the more attractive potential candidates for PET radioimmunoimaging. ^{72}As can also serve as a potential imaging and dosimetry surrogate for the β^--emitting ^{77}As ($t_{1/2}$ = 38.4 h), which can be used for radioimmunotherapy.

Production of ^{72}As. ^{72}As can produced by irradiating an enriched germanium target using the ^{72}Ge(p,n)^{72}As reaction, but the radionuclidic purity is low due to the formation of ^{71}As (10%) as shown in Table 2 (*107*). The target material can be recovered by dry distillation for reprocessing. Alternatively, ^{72}As can be produced from ^{72}Se/^{72}As radionuclide generators based on solid-phase extraction and distillation in which ^{72}As can be eluted in aqueous solvents with over 40−70% yield with less than 0.1% contamination of ^{72}Se (*108*−*110*). Unfortunately, generator-based production of ^{72}As from ^{72}Se is tedious, as it requires over 35 MeV bombardment of natural germanium target with helium ions. Another limitation of the ^{72}Se/^{72}As radionuclide generator is the relatively short half-life of ^{72}Se (8.40 d).

Radiolabeling of Antibodies by ^{72}As. Radio-arsenic (^{74}As and ^{77}As) has been used to label the phosphatidylserine targeting chimeric monoclonal antibody Bavituximab (*111*). Bavituximab was first modified with *N*-succinimidyl *S*-acetylthioacetate (SATA) using a commercial kit. Direct labeling with radio-arsenic was performed after deprotection of the sulfhydryl groups using hydroxylamine (Figure 2). The resultant radioimmunoconjugate demonstrated good stability over 72 h during incubation in fetal bovine serum as determined by size-exclusion HPLC (*111*).

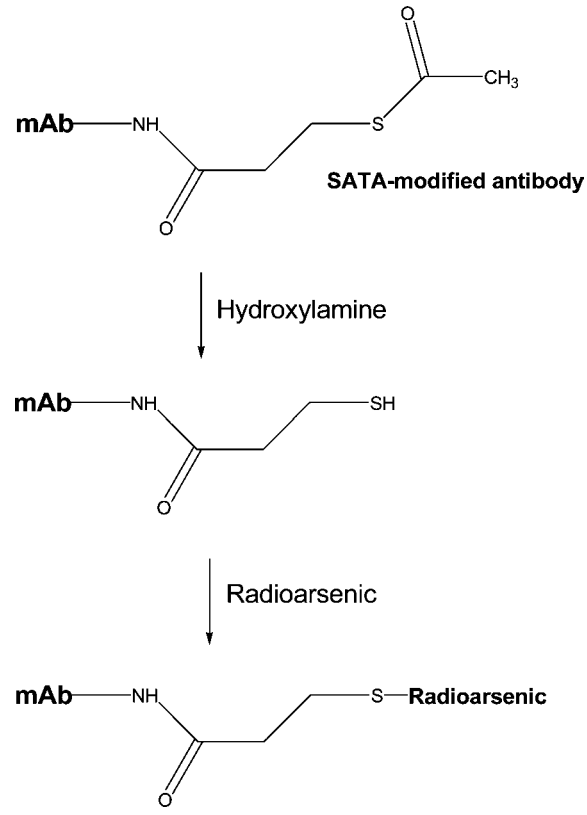

Figure 2. Representative scheme of radiolabeling intact antibodies with radio-arsenic using SATA approach.

Biological Studies with ^{72}As Labeled Antibodies. Bavituximab was labeled with ^{74}As ($t_{1/2}$ = 427 h, 30% positron emission) as a surrogate for ^{72}As for a proof of principle study and evaluated for PET imaging in rats bearing Dunning prostate R3327-AT1 tumors (*111*). Tumors were clearly visualized after 48 h with injection of 10 MBq of the radioimmunoconjugate with the highest tumor to background ratio being achieved at 72 h. Localization of the radio-arsenic labeled immunoconjugate was confirmed by autoradiography. This study demonstrated successful use of radio-arsenic in PET radioimmunoimaging. Although, it can be argued that ^{72}As is a better candidate for radioimmunoimaging with a more appropriate half-life and higher positron abundance. ^{72}As has been used in humans to study environmental toxicity caused by high doses of natural arsenic (*112*).

Challenges. Production of ^{72}As is limited to a few centers around the world, the issue of a steady supply of clinical grade ^{72}As remains unclear. There have been efforts by the United States Department of Energy to assist in the development of ^{72}As generators; yet, the availability of a commercial generator seems unlikely in the near future. Another drawback of ^{72}As is its association with a relatively high radiation dose that could restrict certain applications particularly when hematologic toxicity is a concern as the uncomplexed arsenic localizes in red blood cells (*88*).

Copper-64. Copper belongs to group IB of the periodic table and has an atomic radius of 1.6 Å, and an electronegativity of 1.90. ^{64}Cu has been a radionuclide of considerable interest for PET imaging due to its attractive physical and chemical

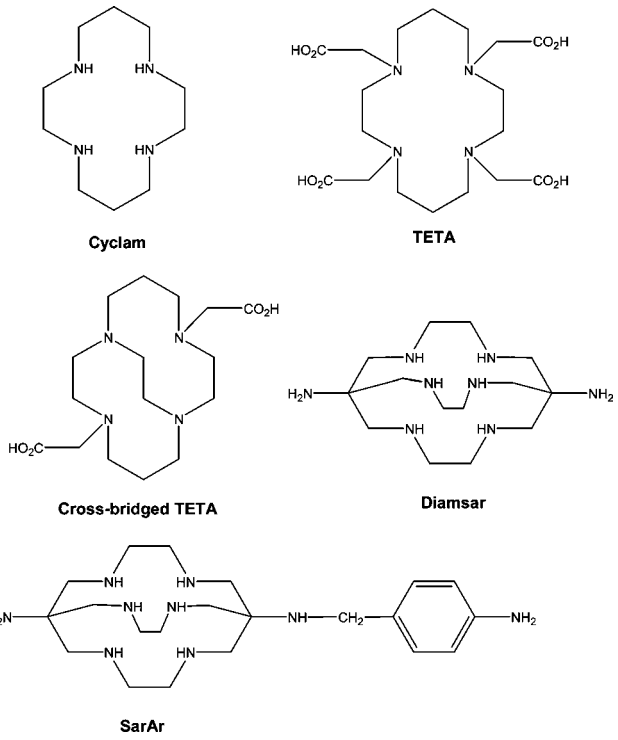

Figure 3. Selected chelating agents used for radiolabeling intact antibodies with ^{64}Cu.

properties. As compared to ^{18}F, ^{64}Cu has a longer half-life of 12.7 h and decays to stable ^{64}Ni and ^{64}Zn daughters. Besides the positron emission, ^{64}Cu also emits Auger electrons and has a β^--emission, and therefore could potentially be used for radioimmunotherapy (*113*). Imaging characteristics as a result of optimum positron energy (0.66 MeV) and no high-energy γ-emission are two of the biggest factors that make ^{64}Cu an attractive candidate for PET imaging (Table 1). The image quality and spatial resolution are equivalent to ^{18}F and require no major adjustments in data processing and analysis (*114*).

Production of ^{64}Cu. ^{64}Cu can be produced in numerous ways. Initially, ^{64}Cu was prepared by use of the ^{64}Zn(n,p)^{64}Cu reaction, but low yields and high contamination of ^{67}Cu, lead to the development of the ^{64}Ni(p,n)^{64}Cu reaction that was later employed to produce therapeutic quantities of ^{64}Cu (*115*−*117*). ^{64}Cu can also be produced through the ^{68}Zn(p,αn)^{64}Cu reaction using a high-energy instrument (*118*−*120*). ^{68}Zn(p,αn)^{64}Cu reaction gives a good yield, but the radionuclidic purity is as low as 75% and the final product contains around 25% of ^{67}Cu as shown in Table 2 (*118, 120*). High-yield production of good-quality ^{64}Cu has greatly improved over the past few years, and this radionuclide is now commercially available from several sources such as Trace Life Science, Isotrace Technologies, MDS Nordion, and IBA Molecular.

Radiolabeling of Antibodies with ^{64}Cu. Copper can exist in two primary oxidation states, Cu(I) and Cu(II). It has been demonstrated that kinetic inertness is more important than thermodynamic stability of Cu(II) complexes, as Cu(II) complexes of EDTA and DTPA rapidly dissociated in human serum and a Cu(II)-albumin complex was formed (*121*).

To improve the in vivo stability, antibodies have been labeled with ^{64}Cu using various bifunctional chelating agents (Figure 3) such as derivatives of 1,4,8,11-tetraazacyclotetradecane (cyclam) (*122*), 1,4,8,11-tetraazacyclotetradecane-*N, N′,N″,N‴*-tetraacetic acid (TETA) (*123, 124*), and DOTA (*125*). All these bifunctional chelates and their derivatives were unsuccessful in preventing metabolic processing of the ^{64}Cu complex, that is presumably a factor of the redox chemistry of Cu(II), causing elevated liver uptake. To overcome this *in vivo* instability of Cu(II) complexes, cross-bridged tetraamine chelating agents are currently being developed and evaluated (*126*). These cross-bridged chelating agents provide better geometric coordination and were inert in aqueous solutions (*126*). Most application of these chelating agents has been for labeling peptides (*127*). To the best of our knowledge, intact antibodies have not been labeled with ^{64}Cu using cross-bridged tetraamine chelating agents that required harsh radiolabeling conditions with high temperature and acidic pH that are not conducive for labeling heat- and acid-sensitive antibodies. To overcome these problems, a novel chelating agent SarAr 1-*N*-(4-aminobenzyl)-3,6,10,13,16,19-hexaazabicyclo[6.6.6]eicosane-1,8-diamine conjugated to anti-GD2 monoclonal murine antibody 14.G2a and the corresponding chimeric monoclonal antibody ch14.8 were evaluated recently (*128*). SarAr is based on the macrobicyclic sarcophagine cage structure and was modified to contain the reactive aminobenzyl group for conjugation with the antibody. At pH 5.0 and room-temperature conditions, the SarAr chelating agent forms a stable complex with Cu(II) within the multiple macrocyclic rings comprising the sarcophagine cage structure. Therefore, radiolabeling of SarAr-mAb was performed at less harsh conditions (*128*). The resulting radioimmunoconjugate was shown to be stable in the presence of liver proteins known to transchelate with ^{64}Cu (*128*). Alternately, attempts have been made to radiolabel antibodies with ^{64}Cu using porphyrin-based chelating agents (*129*).

Biological Studies with ^{64}Cu Labeled Antibodies. Numerous studies using ^{64}Cu labeled antibodies have been reported for PET radioimmunoimaging and radioimmunotherapy. Clinically approved antibodies such as Cetuximab and Abegrin have been labeled with ^{64}Cu for PET imaging in preclinical models (*130*−*132*). ^{64}Cu-DOTA-cetuximab was evaluated in mice bearing EGFR-positive and EGFR-negative tumors for quantitative PET imaging (*132*). In this study, ^{64}Cu-DOTA-cetuximab showed prominent uptake in EGFR-expressing tumors, but low accumulation in EGFR-negative tumors. A good linear correlation between the calculated %ID/g values as measured by PET imaging and the EGFR expression level as measured by Western blot was exhibited (*132*). Subcutaneous xenografts and peritoneal metastases were clearly visualized by PET imaging with an anti-L1-CAM antibody chCE7 labeled with ^{64}Cu in mice bearing L1-CAM tumors (*133, 134*). This PET study also revealed that radio-metabolites of the copper immunoconjugate nonspecifically localized in the lymph nodes through the reticuloendothelial system, which could be critical in imaging lymph node metastasis (*134*). Recent novel approaches for chelating agents and linkers have been used to decrease the liver uptake and increase the target/background ratio (*128, 135*). The evaluation of ^{64}Cu-SarAr-14.G2a demonstrated that the use of a better chelating agent could greatly improve the tumor/background ratio. MicroPET imaging confirmed significant uptake of the radioimmunoconjugate in GD-2-positive tumors, with minimal uptake in GD-2-negative tumors and nontarget tissues of interest such as the liver (*128*). Another use of ^{64}Cu labeled antibodies was to serve as a PET surrogate for ^{67}Cu-radioimmunotherapy (*13*). Compared with ^{67}Cu, it was found that the ^{64}Cu labeled antibody alone reduced tumor growth; however, a much higher dose (5 times higher) of ^{64}Cu was required to produce effects comparable to ^{67}Cu. Overall, the therapy with ^{64}Cu was largely ineffective in treating larger tumors (*136*). To date, there has been one clinical study that utilized ^{64}Cu-TETA-1A3 to evaluate 36 patients with suspected primary or advanced colorectal cancer (*137*). In this study, all patients had CT scans and PET scans 4 to 36 h after being injected with 370 MBq of ^{64}Cu-TETA-1A3 directed toward lipid antigens present in human colon carcinoma. The positive

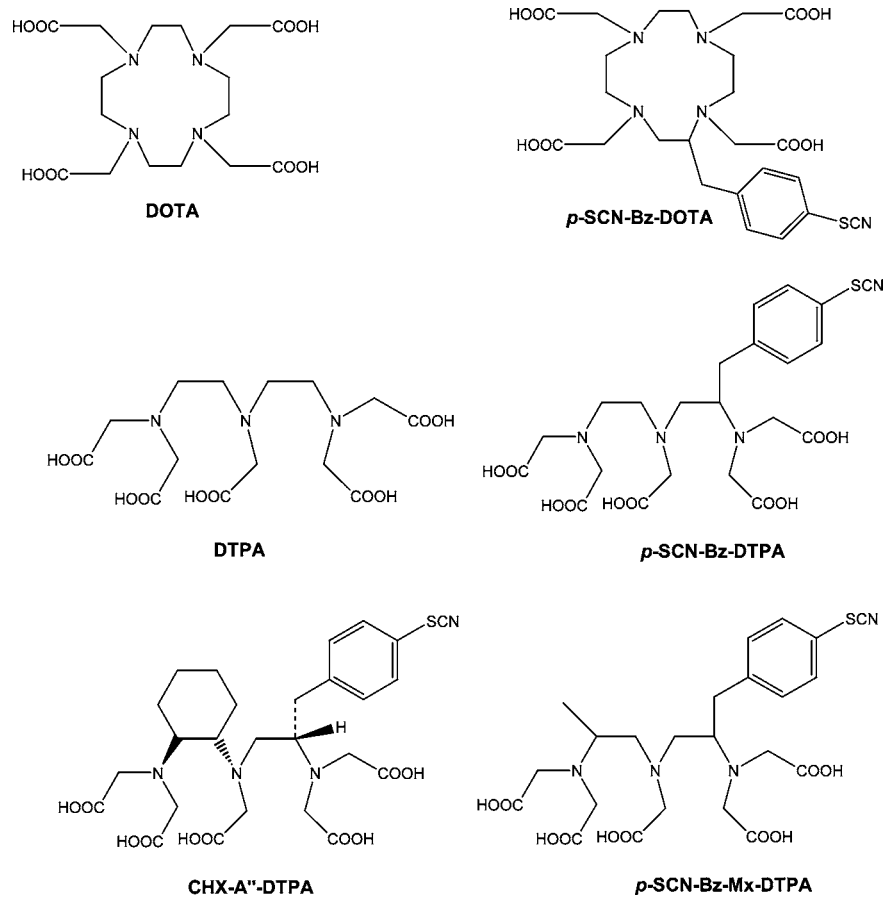

Figure 4. Selected chelating agents used for radiolabeling intact antibodies with $^{86}Y/^{90}Y$.

predictive value of ^{64}Cu-TETA-1A3 PET radioimmunoimaging was excellent, ranging from 89% (40/45) to 96% (43/45). The studies detected 11 new occult tumor sites including 9 small abdominopelvic foci less than 2.0 cm in diameter that were previously not detected by CT or MRI demonstrating that PET radioimmunoimaging with ^{64}Cu may have important applications in clinical oncology, particularly for detecting smaller lesions undetected by CT or MRI.

Challenges. Excellent results have been obtained while imaging intact antibodies with ^{64}Cu, but ^{64}Cu seems to be a more suitable candidate for imaging when applied to antibody fragments, diabodies, and other engineered targeting vectors which have faster localization and clearance (*124, 132*). Copper is a constituent of many metalloenzymes related to the cellular respiratory oxidation process (*88*). The release and accumulation of ^{64}Cu from most traditional radioimmunoconjugates in organs such as the liver remain a concern in spite of efforts to reduce the nonspecific uptake by developing better chelating agents and linkers.

Yttrium-86. Yttrium belongs to group IIIB of the periodic table. Yttrium has an atomic radius of 2.3 Å and electronegativity of 1.22. The primary purpose for exploring the viability of ^{86}Y for PET imaging was to use it as an imaging and dosimetry surrogate for the therapeutic radionuclide ^{90}Y, which has no imageable emission. ^{86}Y is an attractive candidate for studying ^{90}Y with its half-life of 14.2 h that allows imaging over several days.

Production of ^{86}Y. ^{86}Y can be produced on a medical cyclotron by irradiating $SrCO_3$ or SrO with 2−6 μA of beam current for <4 h applying the ^{86}Sr(p,n)^{86}Y reaction. As compared to $SrCO_3$, SrO is a superior target because it can withstand at least a 6 μA of beam current, which is a significant improvement over a maximum of 2 μA on the $SrCO_3$ target, resulting in yields that are almost doubled with minimum contaminants (*138*). At our own institution, we developed a simple and efficient semiautomated method to purify ^{86}Y, which does not compromise the biological properties of the ^{86}Y labeled antibody (*139, 140*).

Radiolabeling of Antibodies with ^{86}Y. In physiological conditions, the primary oxidation state of yttrium is Y(III). Chelation chemistry is well-established for Y(III) radionuclides, and several bifunctional derivatives of both DOTA and DTPA (Figure 4) have demonstrated their utility in this arena (*95*). The majority of the chelation chemistry for yttrium labeled antibodies was carried out with ^{90}Y and ^{88}Y. In 1976, ^{90}Y-DTPA was used for radionuclide therapy of brain tumors in patients (*141*), and since then, cyclic anhydride-DTPA was used to conjugate to antibodies for radiolabeling with ^{90}Y (*142*). However, when ^{90}Y-DTPA antibodies were evaluated in vivo, ^{90}Y was released from that DTPA and deposited in the bones, causing radiation toxicity (*143, 144*). In order to improve the in vivo stability of the radioimmunoconjugate, backbone-substituted DTPA derivatives such as *p*-isothiocyanatobenzyl-diethylenetriaminepentaacetic acid (SCN-Bz-DTPA) and a methyl derivative of *p*-isothiocyanatobenzyl-diethylenetriaminepentaacetic acid (SCN-Bz-Mx-DTPA also known as 1B4M-DTPA) (*143*−*145*) were evaluated. The 4-isothiocyanatobenzyl group (SCN-Bz) substituted onto the carbon backbone of DTPA for use in linkage to the antibody and the methyl groups were incorporated onto the backbone to sterically hinder the release of radiometal from the chelate. Comparative biological studies in mice demonstrated the superiority of backbone-substituted DTPA radioimmunoconjugates over cyclic anhydride DTPA radioimmunoconjugates (*143, 144*). With a better understanding of the coordination chemistry and geometry of DTPA derivatives, a cyclohexyl derivative of DTPA was developed,

which demonstrated excellent stability in vitro and in vivo (*146, 147*). Interestingly, stereochemistry of CHX-DTPA played a major role in in vivo stability of $^{90}Y/^{88}Y$ radioimmunoconjugate and subsequent bone uptake (*146, 148*). The single enantiomeric [(*R*)-2-amino-3-(4-isothiocyanatophenyl)propyl]-*trans*-(*S,S*)-cyclohexane-1,2-diamine-pentaacetic acid (CHX-A″-DTPA) radioimmunoconjugate was found to be more stable as compared to the corresponding diastereomeric pair of CHX-B-DTPA radioimmunoconjugates (*148*). After 7 days post-injection, bone uptake of the ^{88}Y labeled CHX-B′-DTPA or CHX-B″-DTPA radioimmunoconjugates was 5 times higher than that of the ^{88}Y labeled CHX-A″-DTPA radioimmunoconjugate (*148*). In order to further improve the stability, DOTA derivatives such as SCN-Bz-DOTA were explored for radiolabeling antibodies with ^{90}Y (*149, 150*). In a comparative study, it was found that DOTA conjugated antibody was more stable than the DTPA conjugated (*150*). Since then, numerous preclinical and clinical studies have been published reporting DTPA and DOTA based chelating agents for ^{90}Y radioimmunotherapy and thus extrapolating to ^{86}Y for PET imaging (*151*−*153*).

Biological Studies with ^{86}Y Labeled Antibodies. ^{86}Y labeled antibodies were most recently evaluated to perform dosimetry for ^{90}Y labeled antibodies used for radioimmunotherapy, as they were expected to be superior to ^{111}In labeled antibodies in terms of similarities in both chemical and biological behavior (*153*). Numerous studies have been reported with^{86}Y labeled antibodies including clinically approved trastuzumab (Herceptin) (*152, 154*) and cetuximab (Erbitux) (*154*). In a recent study, ^{86}Y-CHX-A″-DTPA-trastuzumab was evaluated in mice bearing intraperitoneal SKOV3 ovarian tumors (*152*). In this study, PET and MRI studies were performed to assess the therapeutic potential of ^{90}Y-CHX-A″-DTPA-trastuzumab using ^{86}Y-CHX-A″-DTPA-trastuzumab as an imaging surrogate for dosimetry. Intraperitoneal tumors were visualized by PET imaging 2 days after injecting ^{86}Y-CHX-A″-DTPA-trastuzumab, and the tumor localization was confirmed by MRI studies. ^{86}Y-CHX-A″-DTPA-trastuzumab localized to sites of disease with minimal normal organ uptake (*152*). In the study performed at our institution, we could clearly visualize LS-174T colon carcinoma xenografts in mice after 2 days of injecting ^{86}Y-CHX-A″-DTPA trastuzumab (tumor uptake was greater than 30% ID/g) (*154*). In the same study, the HER1-targeted ^{86}Y-CHX-A″-DTPA cetuximab was evaluated in mice bearing LS-174T colon carcinoma, SKOV3 ovarian carcinoma and DU-145 prostate carcinoma (*154*). All the tumors were clearly visualized at 1 day postinjection with the tumor uptake ranging from 20−30% ID/g.

Clinical use of ^{86}Y labeled agent used for dosimetry ^{90}Y labeled has been illustrated by the use of ^{86}Y-DOTA-Phe^1-Tyr^3-octreotide (SMT-487) for dosimetry of ^{90}Y-SMT-487 in patients with metastatic carcinoid tumors (*155*). The maximum dose that could be delivered to the tumor without exceeding the 23 Gy cutoff dose to kidneys was successfully calculated using PET imaging, and presumably reduced the incidence of potential renal toxicity caused by ^{90}Y-SMT-487 therapy.

Challenges. ^{86}Y is commercially available (Isotrace Technology) in a limited capacity and is also only available at centers capable of producing ^{86}Y on a regular basis. The high positron energy of 3.14 MeV (34% abundance) and additional γ-emission of 1.08 MeV (83% abundance) significantly affects the spatial resolution and image quality, respectively (Table 1). Uncomplexed ^{86}Y localizes in the bone and therefore can cause radiation toxicity in the events of "leakage" from the immunoconjugate and thus may be not a suitable candidate to image bone metastasis.

Zirconium-89. Zirconium belongs to group IVB of the periodic table and has an atomic radius of 2.2 Å and an electronegativity of 1.33. ^{89}Zr ($t_{1/2}$ = 78.4 h) decays to an ultrashort-lived daughter ^{89}mY ($t_{1/2}$ = 16 s) with a 23% β^+ emission and 77% electron capture (Table 1). Due to its appropriate half-life and imaging characteristics, ^{89}Zr labeled antibodies are currently being evaluated in the clinic as PET surrogates for both ^{90}Y and ^{177}Lu therapy studies despite the possibility of using the elementally matched ^{86}Y for ^{90}Y and ^{177}Lu possesses an imagable γ-emission (*156*).

Production of ^{89}Zr. ^{89}Zr can be produced through the $^{89}Y(p,n)^{89}Zr$ reaction in which inexpensive natural yttrium foil is irradiated with a 14−14.5 MeV proton beam and the target is separated by ion-exchange chromatography or solvent extraction (*26, 157, 158*). Alternatively, ^{89}Zr can also be produced through the $^{89}Y(d,2n)^{89}Zr$ reaction (*159*). A relatively high yield of 43 MBq/μAh is obtained with the $^{89}Y(p,n)^{89}Zr$ reaction with less than 0.2% impurity of ^{88}Zr ($t_{1/2}$ = 85 d and daughter ^{88}Y; $t_{1/2}$ = 105 d) (Table 2).

Radiolabeling of Antibodies with ^{89}Zr. Over the past 20 years, attempts have been made to label proteins and antibodies with ^{89}Zr using DTPA derivatives and porphyrins as chelating agents (*160, 161*). Proteins and antibodies were labeled with ^{89}Zr using desferal (Df) conjugates (*162, 163*). The process incorporates Df-groups onto monoclonal antibodies in a two-step procedure. Firstly, maleimide groups were incorporated into the protein with the assistance of succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC). In the second step, the thioester of Df formed by conjugation to SATA was further converted to a free thiol with hydroxylamine to facilitate reaction with the maleimide groups of the antibody with subsequent radiolabeling with ^{89}Zr. The final purified product was obtained through gel filtration (*162, 163*). This protocol was further modified by formation of *N*-succinyldesferrioxamine B of Df (N-SucDf) as an intermediate (*164*). In this method, the hydroxamate groups of N-sucDf were temporarily blocked with formation of the Fe(III) complex. The N-sucDf-Fe complex was then esterified and coupled to antibodies. Thereafter, Fe(III) was removed by reduction to Fe(II) and transchelation to EDTA. Finally, the mAb-N-sucDf is radiolabeled with ^{89}Zr at pH 7.2−7.4 after a 30 min incubation at room temperature (*164*).

Biological Studies with ^{89}Zr Labeled Antibodies. Considering the success of ^{90}Y-labeled mAbs in clinical radioimmunotherapy (*12, 151, 165*), ^{86}Y-labeled mAbs are currently being developed in preclinical models for clinical dosimetry purposes (*139, 152, 153*). The half-life of ^{90}Y is nearly 4 times greater than that of ^{86}Y, and therefore, predicting ^{90}Y dosimetry of slowly clearing antibody may not be feasible or even appropriate. For these reasons, ^{89}Zr was explored as one of the possible radionuclides that could be used for dosimetry analysis of ^{90}Y-labeled mAbs (*166*). Clinically used antibodies such as HER1-targeted cetuximab (*156*), VEGF-targeted bevacizumab (*167*), and CD-20-targeted ibritumomab tiuxetan have been labeled with the ^{89}Zr-Df conjugate (*168*). All the above studies demonstrated the use of ^{89}Zr labeled antibodies in quantitative PET imaging. Additionally, the tumor localization of the ^{89}Zr-mAb was similar to that of the $^{111}In/^{90}Y$-mAb.

Due to the feasibility in production and purification of ^{89}Zr labeled mAb, clinical studies were performed with CD44V6-specific chimeric mAb, U36 labeled with ^{89}Zr (*169*). In this study, ^{89}Zr−U36 was evaluated in patients with squamous cell carcinoma of the head and neck (HNSCC), who were at high risk of having neck lymph node metastases. All primary tumors (n = 17) as well as lymph node metastases in 18 of 25 positive levels (sensitivity 72%) and in 11 of 15 positive sides (sensitivity 73%) were detected using PET radioimmunoimaging (*169*). Interpretation of PET was correct in 112 of 121 operated levels (accuracy 93%) and in 19 of 25 operated sides (accuracy 76%). For CT/MRI, sensitivities of 60% and 73% and accuracies of

90% and 80% were found per level and side, respectively. ^{89}Zr-immunoPET demonstrated a sensitivity of 85% and accuracy of 95% as compared to sensitivity of 62% and accuracy of 88% for^{18}F-FDG-PET (*169*). Thus, this study demonstrated the utility and advantages of ^{89}Zr PET radioimmunoimaging in a clinical setting in comparison with CT/MRI and ^{18}F-FDG (*169*). Similarly, all known tumor lesions previously identified by ^{18}F-FDG were successfully imaged by ^{89}Zr-Df-Zevalin in a pilot PET imaging study in a patient with Non-Hodgkin's lymphoma (*168*).

Challenges. Uncomplexed ^{89}Zr localizes in the bone and can deliver a high radiation dose to the bone marrow. The need for stable chelation chemistry remains an important consideration with this element (*88*). In spite of the recent success of ^{89}Zr PET imaging, clinical-grade ^{89}Zr is not commercially available yet (although ^{89}Zr can be obtained from IBA Molecular on request). Another major disadvantage is the currently used ^{89}Zr-mAb production scheme. The currently used conjugation and radiolabeling schemes are often tedious and time-consuming and involve numerous steps that increase the margin for error for the cGMP (current good manufacturing practice) production. In the currently used procedure, the Fe(III) complex is first formed with desferal, which is then activated for conjugation through extension of the terminal amine with succinic anhydride followed by the conversion of the formed carboxylate into an active ester. After conjugation of the antibody, the Fe(III) is then reduced and displaced with ^{89}Zr (*164*). Alternate, simpler conjugation and radiolabeling schemes that can be successfully carried out at local radiopharmacies are warranted to bolster the increased appeal of ^{89}Zr PET radioimmunoimaging. One of the suggested applications of ^{89}Zr has been to use it as a surrogate for ^{90}Y and ^{131}I labeled antibodies; however, ^{89}Zr labeled antibodies, while close, also do not exactly match the biodistribution and pharmacokinetics of ^{90}Y and ^{131}I labeled antibodies (*168, 170*).

OPPORTUNITIES AND CHALLENGES

Production. The reliable large-scale availability of the longer-lived positron emitting radionuclides that is suitable for clinical applications is critical for potential clinical translation. Many of the described radionuclides such as ^{64}Cu, ^{76}Br, ^{86}Y, and ^{72}As can be produced in good yields at low-energy medical cyclotrons (*26*). Most of the longer-lived positron-emitting radionuclides are currently produced by employing low-energy nuclear reactions such as (p, n) and (d, n), which may require isotopically enriched targets that are usually expensive. Alternatively, a higher-energy dual-particle cyclotron or a multiparticle intermediate-energy cyclotron could be used for production of some these radionuclides employing nuclear reactions such as (p, xn) and (^{3}He, xn). Two of the most important criteria in medical application of positron emitters are quality and yield; hence the target material is critical. It is absolutely essential to produce target material that is economical, may be efficiently recovered for reuse, can withstand high-energy beam fluxes of charged particles, and most importantly, also be easily isolated from the product to yield high-purity final product. One such example that meets these criteria has been the production of ^{64}Cu. Originally, ^{64}Cu was produced through the ^{64}Zn(n,p)^{64}Cu reaction resulting in low yields and a high contamination of ^{67}Cu, unless highly enriched pure ^{64}Zn was used. The low yields compounded with contamination of the β^--emitting therapeutic radionuclide ^{67}Cu were impediments to routine large-scale clinical applications of ^{64}Cu for PET imaging. As an alternative, the ^{64}Ni(p,n)^{64}Cu reaction was employed to obtain higher yields and better-quality ^{64}Cu (*115, 116*). However, the biggest drawback of this method remains the cost of the highly enriched ^{64}Ni target material, which can be a hindrance in large-scale production of ^{64}Cu at multiple centers across the world. With better understanding and characterization of cross-section data, integral yields, and chemical processing methods, it is possible to obtain good-quality positron emitters in large yields using a medical cyclotron that can be potentially used for radioimmunoimaging. Most commonly used production routes of selected longer-lived positron emitters for radioimmunoimaging with their corresponding yields and radionuclidic impurities are listed in Table 2.

Imaging Characteristics. Two of the major factors impacting image quality are the additional γ-emissions and the energy of the positron, which can contribute to the background noise and the loss of intrinsic spatial resolution respectively. Some of the longer-lived positron-emitting radionuclides such as ^{76}Br, ^{72}As, ^{124}I, and ^{66}Ga have high-energy positron emissions, which result in loss of intrinsic spatial resolution and poor signal-to-noise ratios (Table 1). In clinical settings, both radiation dosimetry and chemistry as a result of inadequate specific activity and stability may limit the amount of radioactivity injected, thereby further degrading image quality. Loss of spatial resolution could also limit the use of radioimmunoconjugates labeled with some of the described longer-lived positron-emitting radionuclides for the detection of metastasis and smaller lesions, which could be critical for their use in assessing or predicting clinical outcomes. Successful attempts have been made to improve the image characteristics of high-energy positron emitters by developing methods to correct for scatter fractions and spurious coincidences (*171*−*173*). Image reconstruction algorithms have been developed, which include models of the statistical nature of nuclear decays and tomography responses that improve the spatial resolution and at the same time reduce the image noise (*114, 171*−*173*). Further advances in instrumentation and image processing may additionally improve spatial resolution and the ability to perform more accurate quantitative analysis. However, implementing these improvements in the clinic may be complex, as new instruments and imaging software will require FDA approval.

Potential Therapeutic Applications and Radiation Toxicity. Tumor therapy using antibodies carrying radioactivity has been reported now for over 50 years (*174, 175*). In 1966, McCradle and co-workers reported the use of ^{131}I labeled antibody to human fibrinogen as a clinical diagnostic and therapeutic agent (*8*). In this study, 50 patients with reported neoplasm were imaged, and a high percentage of patients showed positive scans for metastases to the brain, which was a remarkable achievement during that period when targeted noninvasive radioimmunoimaging was still in its infancy. This study demonstrated the value of molecular imaging with radiolabeled antibodies for the assessment of primary and metastatic lesions (*8*). In this same study, two previously imaged patients were treated with higher doses of ^{131}I labeled antibody to human fibrinogen resulting in regression of their lesions (*8*). Since that time, numerous studies have been reported demonstrating the utility of antibodies labeled with radionuclides such as ^{111}In, ^{177}Lu, and ^{64}Cu, which could be used for diagnosis as well as therapy (*4, 176*). For better clinical acceptance, cost−benefit effectiveness and numerous other reasons including the need of a surrogate radionuclide, a radiolabeled antibody that could be used as a diagnostic as well as therapeutic becomes a desirable combination.

One of the major concerns in radioimmunotherapy is the nonuniform absorbed dose distribution in the tumor resulting in less effective therapy in spite of dose escalation (*177*). One possible solution might be the use of longer-lived radionuclides with longer emission ranges, which may increase the mean

absorbed dose to the tumor, as they are more likely to penetrate into the tumor before decaying in the body than shorter-lived radionuclides (*178*). Longer-lived positron-emitting radionuclides can deliver high absorbed doses to the target site, as the doses delivered by positrons are as high as negatrons of the same energy. Considering the success of negatron-emitting radioimmunotherapy in preclinical and clinical studies, longer-lived positron-emitting radioimmunoconjugates may potentially be used for therapeutic applications. The longer half-life may minimize the effects of nonuniformity up to an extent. However, the choice of radionuclide will be based upon the function of biological and pharmacokinetic properties of the targeting antibody (normal organs uptake and clearance), disease state, physical half-life of the radionuclide, abundance and energy of the positron emission, and additional γ-rays. For example, assuming a biological half-life of 100 h and whole-body uniform distribution in an adult human, based on the values given in the International Commission on Radiological Protection (ICRP) publications, the effective dose from ^{52}Mn ($t_{1/2} = 134.2$ h) will be approximately 0.9−1.1 mSv/MBq as compared to 0.02−0.04 mSv/MBq from ^{64}Cu ($t_{1/2} = 12.7$ h) and 0.2−0.3 mSv/MBq from ^{76}Br ($t_{1/2} = 16.2$ h) (*159*). Another important parameter in terms of therapeutic applications of longer-lived positron emitters is the positron abundance and the dose rate; a dose rate of 2−3 cGy/h has been suggested as being required to overcome the proliferation of most types of tumor cells (*179*). Therefore, the portion of the total dose that is delivered below this rate is essentially unnecessary and can potentially pose a hazard. Theoretically, high-specific-activity longer-lived positron-emitting radioimmunoconjugates could be used for therapy; however, toxicity and dose to the normal organs may pose a few challenges and will depend on whether the radioimmunoconjugate is delivered systemically or locally.

Economics, Regulatory Affairs, and Clinical Acceptance. Currently, the use of PET in the clinical setting revolves around ^{18}F-FDG, which has great clinical acceptance, as it can be used to image most metabolically active tumors and lesions, irrespective of any expression of cell surface molecular targets such as EGFR and HER2/μ. This characteristic of ^{18}F-FDG can also be disadvantageous, as it does not provide information regarding the status of cell surface targets that could be essential for patients about to undergo immunotherapy or radioimmunotherapy. Under those circumstances, PET radioimmunoimaging could play a critical role in risk stratification. In the past year, sales of Herceptin (trastuzumab), Avastin (Bevacizumab), Rituxan (Rituximab), and Erbitux (Cetuximab) each all exceeded one billion U.S. dollars (*180*). On the basis of previous results, not all patients may respond to immunotherapy due to low-density of target expression or changes in the target levels. In all likelihood, not all patients undergo some form of diagnostic scan to evaluate the status of target in the progression of illness. PET radioimmunoimaging could serve as one of the potential tools for screening patients that may or may not respond to therapy, thereby acting as a cost containment tool. Contrary to that positive aspect, a sizable financial investment and commitment is required to develop a clinically FDA approved radiopharmaceutical. In order to recover the cost spent in developing the PET radioimmunoconjugate, sales and use volumes have to be significantly high, which will be directly related to the clinical acceptance of PET radioimmunoimaging.

The number of radiopharmaceuticals approved by the U.S. FDA in the past decade has been limited due to more scrutiny and a tedious approval process. Radiation toxicity and required preapproval studies could potentially be a major obstacle for the approval of radioimmunoconjugates labeled with longer-lived positron emitters. Thus, one can question the rationale behind the objective of developing a novel PET radioimmunoconjugate considering the level of required investment and resources versus failure to acquire approval of the agent by the FDA.

Other regulatory barriers include waste disposal of large quantities of longer-lived high-energy positron emitters, decontamination, occupational hazards, and the radiation exposure to normal population by outpatients undergoing high-dose longer-lived positron-emitting radionuclide protocols.

Lack of Standards for Calibration, Decay Characteristics. A recent study has highlighted the differences in published values of decay data and energies of some of the described radionuclides (*119*). These differences in values could impact the overall biological and dosimetry results, as the same amount of radioactivity quantified from dose calibrator and PET image could vary from institution to institution depending on the values used. Therefore, there is a need to establish standards for calibration of instruments for these longer-lived positron emitters to avoid variances which could result in errors.

Future Perspective. It is clear from the selected examples cited in this report that efforts are continuing to develop radioimmunoconjugates labeled with longer-lived positron-emitting radionuclides for PET imaging. The superiority of PET in radioimmunoimaging was demonstrated by a recent clinical study in which a comparison was made among ^{131}I-G250, ^{124}I-cG250, and ^{18}F-FDG for detection of metastatic renal-cell carcinoma (*53*, *181*). ^{131}I-cG250 was able to detect 30% of metastatic lesions as compared to 69% for ^{18}F-FDG (*181*); however, the results were far better when ^{124}I-cG250 was used, as the sensitivity of detection of tumor was 94% (*53*, *181*). When compared to ^{124}I-cG250, ^{131}I-cG250 did not provide the same resolution, contrast, or the potential for quantification as ^{124}I-cG250 (*53*). Considering the advantages of PET radioimmunoimaging, further efforts are warranted to improve PET instrumentation and image processing, increase production of clinical-grade high-yield longer-lived positron emitters, and continue to create efficient radiolabeling methods to produce high-yield biologically active stable radioimmunoconjugates in the least amount of time and variability. Lastly, the most critical criterion for successful clinical translation is that continued efforts have to be applied toward making wise selections of the most appropriate antibody matched with the most appropriate radionuclide for the desired application within an appropriate patient population. Important questions still remain unanswered: how many positron-emitting radionuclides need to be evaluated that will fulfill the desired objectives of radioimmunoimaging? What are the alternatives in case of unexpected unreliable availability of the radionuclide? Is it worth the capital investments related to PET imaging if techniques such as biopsies and CT imaging are going to remain the mainstay of cancer diagnosis? Can future generation SPECT systems be as good as currently used PET (*182*, *183*)? If so, then why develop newer positron-emitting products if ^{111}In based SPECT can offer precise quantitation in future? And finally, should there be a common set of criteria and guidelines for choosing the radionuclide?

In conclusion, we believe that radioimmunoimaging with longer-lived positron-emitting radionuclides holds significant promises, but several scientific and nonscientific challenges have to be conquered before realizing the true potentials of PET radioimmunoimaging with intact antibodies.

Effects of Branching Architecture and Linker on the Activity of Hyperbranched Polymer−Drug Conjugates

Omathanu Perumal,[#,†] Jayant Khandare,[‡] Parag Kolhe,[‡] Sujatha Kannan,*[,†] Mary Lieh-Lai,[†] and Rangaramanujam M. Kannan*[,‡]

Critical Care Medicine, Children's Hospital of Michigan, Wayne State University, Detroit, Michigan 48201, and Department of Chemical Engineering and Material Science, and Biomedical Engineering, Wayne State University, Detroit, Michigan 48202.
Received December 8, 2008; Revised Manuscript Received April 16, 2009

Drug release from hyperbranched polymer−drug conjugates and the subsequent activity are influenced by the branching architecture and the linker. To gain an understanding of these effects, we used hyperbranched polyol and G4-OH polyamidoamine (PAMAM) dendrimer with methyl prednisolone (MP) as the model drug. The drug was conjugated to dendrimer or polyol using a glutaric acid (GA) or a succinic acid (SA) spacer. Drug payload was the highest with polyol, while in the case of dendrimer, a higher payload was achieved with the GA than the SA spacer. Cell uptake of the polymer conjugates in A549 lung epithelial cells was higher than that of the free drug, and the conjugates largely localized in the cytosol. The anti-inflammatory activity of polymer conjugated MP, as measured by inhibition of prostaglandin synthesis, was the highest for MP-SA-dendrimer conjugate, followed by MP-GA-polyol conjugate, and then MP-GA-dendrimer conjugate. This study suggests that the branching architecture and spacer influence the drug payload and pharmacological activity of a drug−nanopolymer conjugate, which may significantly influence the in vivo efficacy of these nanodevices. This has key implications in the eventual in vivo efficacy of these nanodevices.

Polymer−drug conjugates are used to modulate drug pharmacokinetics and target the drug to the desired site (*1, 2*). Various linear polymer−drug conjugates have been investigated for improving the circulation half-life and intracellular targeting of drugs (*2*). However, linear polymers have limited drug payload capacity. Hyperbranched polymers (HBPs) can carry multiple copies of drug and/or targeting/imaging ligands (*3*). Depending on their branching architecture, these polymers are classified as "imperfectly branched" polymers or HBPs and "perfectly branched" polymers or dendrimers (*4*). Dendrimers are well-defined and monodisperse, with a controlled branching architecture. In comparison to dendrimers, HBPs are polydisperse, but their ease of synthesis (typically using one-pot reaction) makes them relatively cheaper to produce than dendrimers (*5, 6*). Both these polymers have core−shell architecture and can carry high drug payload due to the large number of tunable surface functional groups (*7, 8*). Earlier studies have shown that both HBPs and dendrimers can carry a high drug payload (*7, 8*). High drug payload polymeric conjugates were prepared with small molecules such as ibuprofen by directly conjugating the drug to the surface functional groups in HBPs and dendrimers (*7, 8*). However, the high density of surface functional groups poses steric hindrance, thus limiting the payload for large drug molecules such as steroids (*9*). Chemical spacers can be used to link the drug to the polymer to overcome the steric hindrance (*10*). Further, the spacers can also modulate the drug release from the polymer (*10*). In the present study, we investigated the conjugation of a model steroid drug, methylprednisolone (MP), to polyol and hydroxyl terminated polyamidoamine dendrimer (G4-OH) using glutaric acid (GA) and succinic acid (SA) as spacers. Comparative studies between linear and branched polymers have been reported in the literature (*11*).To our knowledge, this is the first report that compares the drug payload and pharmacological activity of drug−polymer conjugates between HBPs and dendrimers. The influence of the branching architecture of these two polymers and spacer on cell uptake and anti-inflammatory activity was tested in A549 human lung epithelial carcinoma cells.

Glutaric acid **2** (GA) was conjugated to C_{21} hydroxyl group of MP **1** using dicyclohexylcarbodiimide (DCC) as the coupling agent (Figure 1). This hydroxyl group is more favorable compared to C_9 (secondary) and C_{11} (tertiary) hydroxyl groups. The byproduct dicyclohexyl urea (DCU) was removed by filtration. In the next step, MP-GA conjugate **3** was dissolved in anhydrous dimethyl sulfoxide (DMSO) and conjugated with polyol **4** or G4-OH dendrimer in the presence of DCC to form polyol-GA-MP conjugate **5** or dendrimer-GA-MP conjugate (*9*). The solution was filtered to remove DCU and dialyzed against DMSO to remove unreacted components. The conjugate was characterized by ^{1}H NMR. A similar procedure was followed using succinic acid (SA) spacer where methyl prednisolone succinate (MPS) was conjugated to G4OH dendrimer. For cell uptake studies, both the free drug and the drug−polymer conjugate were further conjugated with fluoroisothiocyante (FITC) using DCC as the coupling agent (*9*). The absence of

free FITC was confirmed using TLC (*12*). Because of the use of homobifunctional spacers, there is a possibility of intermolecular cross-linking between dendrimers, leading to dimers and larger particles. Since we used low concentrations this was not observed and has been confirmed using HPLC and NMR spectroscopy previously (*9*).

Figure 2 shows the ^{1}H NMR spectrum of MP-GA-polyol conjugate. A broad singlet at δ 4.2 ppm corresponds to CH_2 protons of polyol, while the multiplets between δ 5.5 and 7.3 correspond to protons of MP. The NMR spectra for the other conjugates can be found in the Supporting Information. On an average, 25 molecules and 12 molecules of MP were conjugated to polyol and G4-OH dendrimer, respectively, using GA as the spacer (Table 1). On the other hand, 6 molecules of MP were conjugated to G4-OH using SA as the spacer. The polyol used in the present study has more functional groups than dendrimer (128 vs 64 groups), and this resulted in a higher drug loading in polyol. Furthermore, the "imperfect branching" architecture in polyol reduced the steric hindrance for conjugation of MP-GA to polyol. SA has a shorter alkyl chain than GA and this leads to a difference in drug payload between the two dendrimer conjugates. Further, MPS was used as the sodium salt, and therefore, the difference in acidity may also contribute to the difference in reactivity and lower drug payload with SA spacer. Nevertheless, the drug payload using MPS was higher than when free MP was directly conjugated to dendrimer (*9*). On average, 4−5 molecules of FITC were attached to the conjugates.

The cell uptake of FITC-labeled free drug and the conjugates was determined by measuring the intracellular fluorescence intensity using flow cytometry. Equivalent MP concentrations

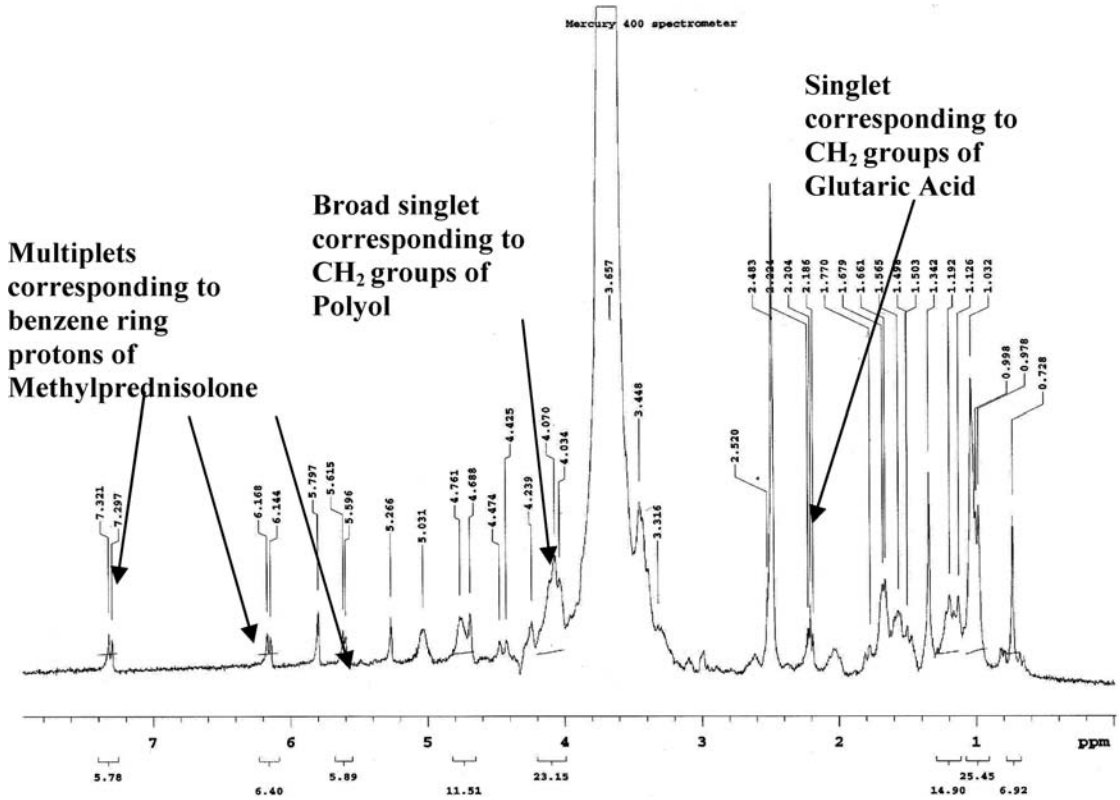

Figure 2. [1]H NMR spectrum of methylprednisolone-glutaric acid-polyol conjugate. The corresponding proton peaks are indicated in the spectrum. The spectra for the other conjugates were analyzed in a similar fashion and are not included for the sake of brevity. Proton integration method was used to calculate the drug payload.

were used for uptake studies. With respect to the zero time point, the fluorescence intensity was found to increase with time for free MP and MP−polymer conjugates (Figure 3). However, the cell uptake of the conjugates appears to be significantly higher ($p < 0.05$) than the free MP. This is despite the fact that the FITC concentration is higher for free MP compared to the conjugates (each MP molecule had a FITC attached to it, whereas the conjugates have approximately half the FITC for equivalent MP concentration). The uptake profiles for the two glutaric acid spacer conjugates (MPGD and MPGP) are not appreciably different (Figure 3). However, the conjugate with succinic acid spacer (MPSG) showed higher cell uptake than the other two conjugates. Both free MP and polymer-conjugated MP were predominantly localized in the cytosol (Figure 4a−e). In the case of the conjugates, there was extensive fluorescence around the perinuclear region, indicative of endocytotic uptake of the conjugates as opposed to diffuse fluorescence distribution with the free drug. Free MP enters the cell by passive diffusion, and cell entry by passive diffusion is nonspecific, which is dictated by the concentration gradient between the extracellular

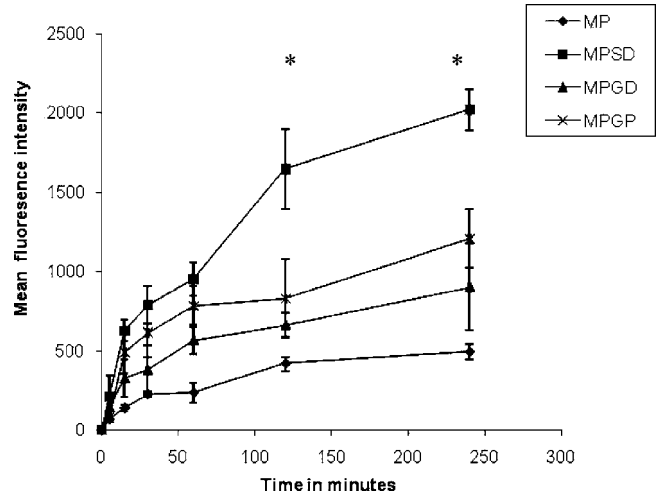

Figure 3. Cell uptake of free MP and polymer conjugated MP in A549 cells. and intracellular milieu (*13*). Unlike the free drug, the polymer conjugates enter the cell by specific endocytosis processes. The rate of endocytosis of polymers is influenced by a number of factors including molecular weight, surface charge, and hydrophilicity of the polymer (*13, 14*). We have previously shown that, at the concentrations used in this study, the polymers were found to be nontoxic to A549 cells (*15*). The difference in the hydrophilicity of SA and GA can be attributed to the difference in uptake of the dendrimer conjugates. On the other hand, the

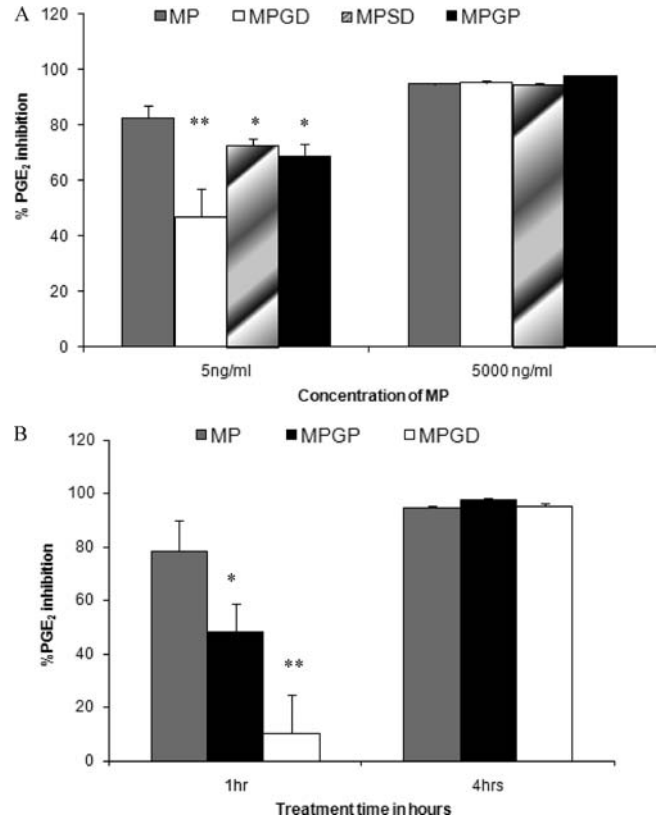

Figure 5. Inhibition of prostaglandin (PGE_2) synthesis after treatment with free drug and drug−polymer conjugates in A549 cells. (A) Percent inhibition of PGE_2 synthesis after treatment with two different concentrations of methyl prednisolone. The cells were treated with free drug or drug−polymer conjugates for 4 h. (B) Percent inhibition of PGE_2 synthesis after treating the cells for two different time periods with 5 μg/mL equivalent of methyl prednisolone. The percent inhibition represents the reduction in PGE_2 levels in comparison to control (A549 cells with prostaglandin induction but no treatment). Key: MP, free methyl prednisolone; MPSD, methylprednisolone-succinic acid-dendrimer; MPGD, methylprednisolone-glutaric acid-dendrimer; MPGP, methylprednisolone-glutaric acid-polyol. * Statistically significant ($p < 0.05$) when compared to the free MP treatment. ** Statistically significant when compared to other conjugates. All the values are mean of four measurements with standard error bars.

branching architecture did not appear to influence the cellular uptake of the conjugates, as the polyol and the dendrimer conjugates show a comparable uptake profile. This is not unexpected, as dendrimer and polyol do not differ much in their molecular weight and surface charge (Table 1). Both G4-OH dendrimer and polyol have no net surface charge and hence are expected to be transported by fluid-phase endocytosis through nonspecific interactions with the cell membrane (*15*).

The anti-inflammatory activity of conjugates was evaluated by their ability to inhibit cyclooxygenase enzyme (Cox-2) and suppress prostaglandin (PGE_2) synthesis in A549 cells. There was no significant difference in the activity of free and polymer conjugated drug at 5 μg/mL equivalent concentration of MP (Figure 5a). This is a significant result, since most polymer−drug conjugates show significantly less activity than the free drug in cells, even though they show better efficacy in vivo. The PGE_2 inhibition observed in the present study is consistent with the maximal inhibition reported for MP in A549 cells (*16*). When the activity was tested at a concentration (5 ng/mL) close to the IC_{50} of MP in A549 cells (*16*), the conjugates showed lower activity than free MP. Particularly, MP-GA-dendrimer conjugate showed significantly lower activity than the other two conjugates. Since an equivalent concentration of MP was used, the results show that the spacer has an influence on the release of free MP from the polymer. To further understand the influence of branching architecture, the activity was measured at shorter treatment time of 1 h. At short times, both the dendrimer and the polyol conjugates show lower activity than the free drug (Figure 5b). With time, the passive diffusion of free drug produces higher intracellular concentration, whereas the drug release from the conjugates is a much slower process. This may result in efficacies being comparable at the later time point.

As shown in Figure 5b, at shorter treatment time, there was a significant difference in the activity of polyol and dendrimer conjugates. The higher activity of polyol conjugates suggests that the imperfect branching architecture may allow easy access of the lysosomal enzymes to release the drug faster compared to the perfect branching architecture in dendrimer. At the same time, the polydispersity of polyol may also contribute to the difference in the activity of the conjugates.

Lysosomes in the cell are rich in enzymes that aid in releasing the free drug from the polymer conjugate (*17*). The release of free drug from the conjugate is influenced by many factors including the type of spacer, the stability of the chemical bond, distance of the spacer from the polymer backbone, the hydrophilicity of the surrounding medium, and steric overcrowding at the center of reaction (*18*). Both GA and SA have two ester bonds that connect the drug and polymer and can be cleaved by esterases. However, GA differs from SA by one carbon atom. This difference in the alkyl chain length seems to influence the enzymatic release of the free drug. Previously, Wiwattanapatapee et al. (*19*) have shown that the release of 5-amino salicylic acid from dendrimer conjugate is influenced by the carbon chain length in the spacer. Tang et al. (*20*) found that the DNA expression was enhanced when the dendrimer was scrambled by heat treatment. The authors attributed this effect to the increased conformational flexibility of dendrimer, which enabled DNA complexation and its subsequent release from the complex. Recently, Khandare et al. (*11*) reported that the release of paclitaxel in presence of esterase was faster from linear

polyethylene glycol (PEG) conjugate compared to dendrimer conjugate. On the other hand, the IC_{50} for antiproliferative activity of paclitaxel−dendrimer conjugate was 300 times lower than the paclitaxel−PEG conjugate. Since polyol has a higher drug payload, with the same given dose of the conjugate, polyol−MP conjugate will provide higher intracellular concentration when compared to the dendrimer−MP conjugate. Similarly, the drug loading and release of drug from the dendrimer−drug conjugate can be modulated by suitable choice of spacer. Further studies into the release kinetics of MP from the conjugates will provide better insights. However, the preliminary findings presented here show that drug payload and pharmacological activity of drug−polymer conjugates is influenced by the branching architecture and spacer chemistry, and these factors need to be considered in designing nanodevices for various therapies.

ACKNOWLEDGMENT

This research work was funded by the Wayne State University Nanotechnology initiative, Children's Research Center of Michigan (Children's Hospital of Michigan), and NIH−Pediatric pharmacology research unit supplement research funding (NIH 3U01HD-37261-04SI). We would like to thank Prof. David Bassett for the help with flow cytometry.

Experimental Procedures

Materials

Methylprednisolone USP, Methylprednisolone hemisuccinate, PAMAM-G4-OH (Mw ~ 14,279 Da, 64 end groups) and dicyclohexylcarbodiimide (DCC) were purchased from Aldrich Chemical Company. Hyperbranched polymer, polyol was obtained from Perstorp (Sweden). Glutaric acid (M_w~132 Da) was purchased from Matheson Coleman and Bell Company (Norwood, Ohio). Fluorescent probe fluoroisothiocyanate (FITC) was purchased from Fluka Chemical Company. Interleukin (IL-1β) and lipopolysaccharide (LPS) were purchased from Sigma, USA. ELISA kit for prostaglandin estimation was purchased from Cayman Chemical Company and dialysis membrane of molecular weight cut off of 3500 Da was obtained from Spectrapor, USA. Dimethyl sulphoxide (DMSO), dimethyl formamide (DMF), methanol and diethyl ether were purchased from Fischer Scientific, USA.

Synthesis of spacer-MP conjugate

Glutaric acid-MP conjugate was synthesized by a method reported by our group earlier (9). Briefly, MP (0.1 g, 0.265 mmol) and GA (0.036 g, 0.26 mmol) were dissolved in anhydrous DMSO. Dicyclohexilcarbodiimide (DCC) (0.056 g, 0.26 mmol) was added as a coupling agent to the above solution. The reaction was carried out for 24 hrs at room temperature and filtered to remove dicyclohexyl urea (DCU) obtained as a by-product during this reaction. The filtrate was evaporated under vacuum to obtain MP-glutarate conjugate. In case of succinic acid methylprednisolone succinate (MPS) was used as the

starting material and the same procedure as described above was used to conjugate it to the dendrimer.

Conjugation of MP-spacer to polymer

A molar ratio equivalent to 1: 50 of MP-GA conjugate to polymer or 1:10 of MPS to PAMAM dendrimer was dissolved in anhydrous dimethyl sulfoxide (DMSO). To this mixture DCC was added as coupling agent and the reaction was stirred for 2-3 days and filtered to remove DCU. The filtrate was dialyzed against anhydrous DMSO for 24 hours (dialysis membrane of M_w cut off = 3,500 Da) to remove unreacted reaction components. The conjugate was evaporated under vacuum and was characterized by ^{1}H NMR. The presence of dendrimer

Conjugation of FITC to free MP and polymer conjugates

The reaction was carried out by dissolving FITC and free MP (molar ratio of 1:1) or the polymer conjugate (molar ratio of 10:1) for 24 hrs at room temperature. At the end of the reaction, the solution was filtered to remove DCU. The resultant filtrate was dialyzed against anhydrous DMSO for 24 hours (dialysis membrane of molecular weight cut off = 3500 Da) to remove unreacted FITC and DCC. Further, free FITC was removed by using excess acetone. The absence of free FITC in all conjugates was verified by thin layer chromatography (TLC), using chloroform and methanol (1:1) as solvents. The conjugates were dried under vacuum to obtain FITC labeled conjugates and were characterized by ^{1}H NMR.

Cell culture

Human lung carcinoma epithelial cell line, A549 was obtained from Children's Hospital of Michigan Cell Culture facility. Cells were seeded in RPMI 1640 (Gibco-BRL) cell culture medium supplemented with 10% fetal bovine serum (FBS) and 1% penicillin-streptomycin at 37°C with 5% CO_2 in a cell culture incubator. The cells were sub-cultured every 48 hours and harvested from sub-confluent (60 to 70%) cultures using 0.05% trypsin-EDTA.

Cell uptake of fluorescent-tagged conjugates

A549 cells (1.2×10^5 cells/ml) were seeded on 60 x 15 mm culture plates using RPMI 1640 cell culture medium supplemented with 10% FBS and 1% penicillin-streptomycin. When the cells were 60% confluent, they were treated separately with free MP and the polymer conjugated MP (10µg/ml) for varying time periods upto 4 hours. At the end of the study, the cells were washed with phosphate buffered saline (PBS; pH 7.4), trypsinized and centrifuged at 1500 rpm for 5 minutes to obtain a cell pellet. The cells were then rinsed with PBS buffer, spun down twice, and resuspended in PBS, and subsequently analyzed using a flow cytometer (FACS caliber, Becton Dickinson, USA) by counting 10,000 events. The viable cells were gated and the fluorescence intensity was computed from the histogram plot.

Fluorescence microscopy

The procedure for cell culture and drug treatment was same as described in previous section. After treatment with the conjugates for 1 hour, the cells were washed with PBS and were observed under confocal microscope (Zeiss LSM 310) using a magnification of 63X 1.2. The emission and excitation wavelengths were 488 and 518 nm respectively for FITC.

Pharmacological activity of conjugates

A549 lung epithelial cells (2 x 10^5 cells/ml) were seeded in 24 well plates in RPMI medium supplemented with 10% FBS and 1% penicillin-streptomycin. When the cells were 60% confluent, the medium was removed and washed with serum free medium (SFM). Each well was treated with 500 µl of SFM and prostaglandin (PGE_2) secretion was induced by addition of 1.5 µg/ml of lipopolysaccharide (LPS) and 1µg/ml of interleukin (IL- 1β). After 30 minutes, the medium was removed and fresh SFM was added. Free MP and its conjugate (5 ng/ml or 5 µg/ml equivalent of MP) in ethanol was added. Control treatments with solvent, polymers and positive control with no treatment and negative controls without any PGE_2 induction were also studied. The supernatant was removed after 1 or 4 hours and analyzed for PGE_2 using a commercial ELISA kit. Results were represented as percent inhibition of PGE_2 with respect to control. All the results were subjected to *one-way ANOVA* at a significance level of $p<0.05$.

Synthesis and Application of a N-1′ Fluorescent Biotinyl Derivative Inducing the Specific Carboxy-Terminal Dual Labeling of a Novel RhoB-Selective scFv

L. Chaisemartin,[†,§] P. Chinestra,[†,§] G. Favre,[†] C. Blonski,[‡] and J. C. Faye*[,†]

INSERM U563, Département Oncogénèse, Signalisation et Innovation Thérapeutique, Institut Claudius Regaud, 31052 Toulouse, France, and Groupe de Chimie Organique Biologique, Laboratoire LSPCMIB - UMR 5068 CNRS, Université Paul Sabatier, Toulouse cedex 9, France. Received July 3, 2008; Revised Manuscript Received March 3, 2009

The fluorescent site-specific labeling of protein would provide a new, easy-to-use alternative to biochemical and immunochemical methods. We used an intein-mediated strategy for covalent labeling of the carboxy-terminal amino acid of a RhoB-selective scFv previously isolated from a phage display library (a human synthetic V_H + V_L scFv phage library). The scFv fused to the Mxe intein was produced in *E. coli* and purified and was then labeled with a newly synthesized fluorescent biotinyl cysteine derivative capable of inducing scFv-Mxe intein splicing. In this study, we investigated the splicing and labeling properties of various amino acids in the hinge domain between scFv and Mxe under thiol activation. In this dual labeling system, the fluorescein is used for antibody detection and biotin is used for purification, resulting in a high specific activity for fluorescence. We then checked that the purified biotinylated fluorescent scFv retained its selectivity for RhoB without modification of its affinity.

INTRODUCTION

In the postgenomic era and beyond, the generation of monoclonal antibodies for proteome research and of recombinant antibody fragments will be essential for research, diagnosis, and treatment. These molecules can be selected from huge antibody gene libraries against any target, by an in vitro panning procedure (*1*−*5*). After phage display, scFv peptides are selected and produced in *E. coli*. Their recognition and purification are facilitated by the addition of various tags, such as the 6x histidine stretch and/or cmyc domains. Whatever the tag used, secondary antibodies carrying the detection system (enzymatic activity or fluorescence) are required to visualize the scFv. However, two methodologies described the direct selection and obtention of fluorescent antibodies (*6*, *7*). In the present study, we aimed to overcome the need for a secondary antibody, by generating dual-labeled scFv by chemical site-specific modification.

Various techniques have been used for chemical protein labeling to date, but most are inapplicable due to limitations to the reactivity of the amino acid in aqueous buffers. Other organic solvent-based methods frequently induce protein denaturation and do not provide specific single-site modification. Antos et al. (*8*) recently showed that an oxidative deamination reaction could be used to strip the N-terminal amino group from various proteins. This technique is of limited scope, being restricted to proteins meeting the requirements of N-terminal solvent accessibility. Moreover, the reaction is not quantitative and generates a pool containing singly labeled and unlabeled proteins. Biotechnology has led to the development of enzyme-mediated labeling (which would be used in vitro) for the same purpose, for the analysis of protein activities in vivo (*9*) (*10*−*16*) while others have developed Halo Tag (*17*−*19*). Various small peptides able to permit vizualization have been fused to the protein of interest inducing fluorescence in the presence of biarsenical ligands (*16*, *20*−*22*), lanthanide binding tag (*23*−*28*), and protein domains (*29*). The labeling strategy described here makes use of the properties of intein splicing (*30*−*34*) and the previously described N-1′ functionalization of biotin (*35*). This strategy should be applicable to any protein of known amino acid sequence but was used here with a previously isolated scFv against the native RhoB GTPase, selected by phage display in our laboratory. As part of this study, we synthesized a new N-1′ biotin derivative able to induce intein splicing (Schemes 1; 2).

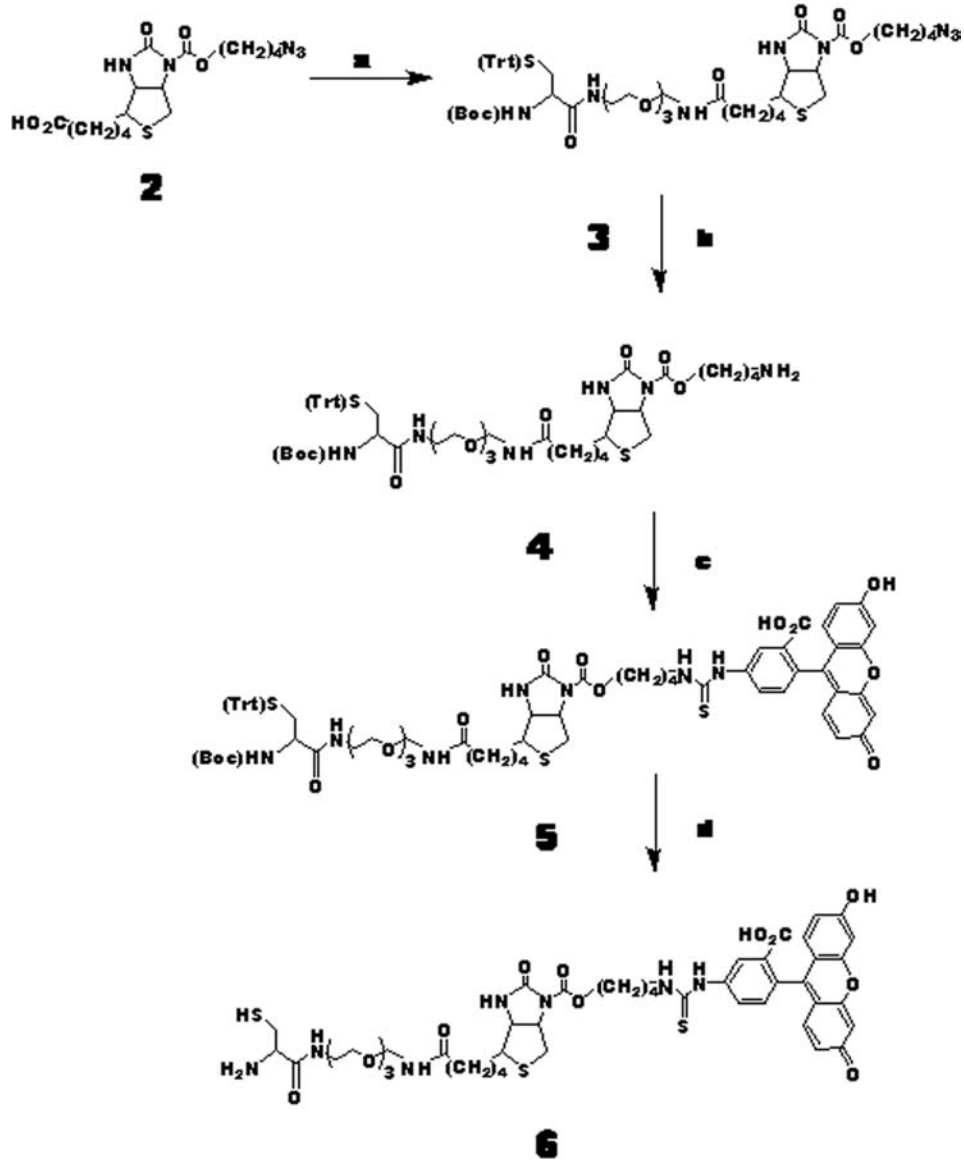
Scheme 2. Synthesis of 1-(L-Cysteinamido)-11-[1′-*N*-(4-(thiourea fluorescein)-1-butoxycarbonyl)-D-biotinamido]-3,6,9-trioxaundecane, Compound 6[a]

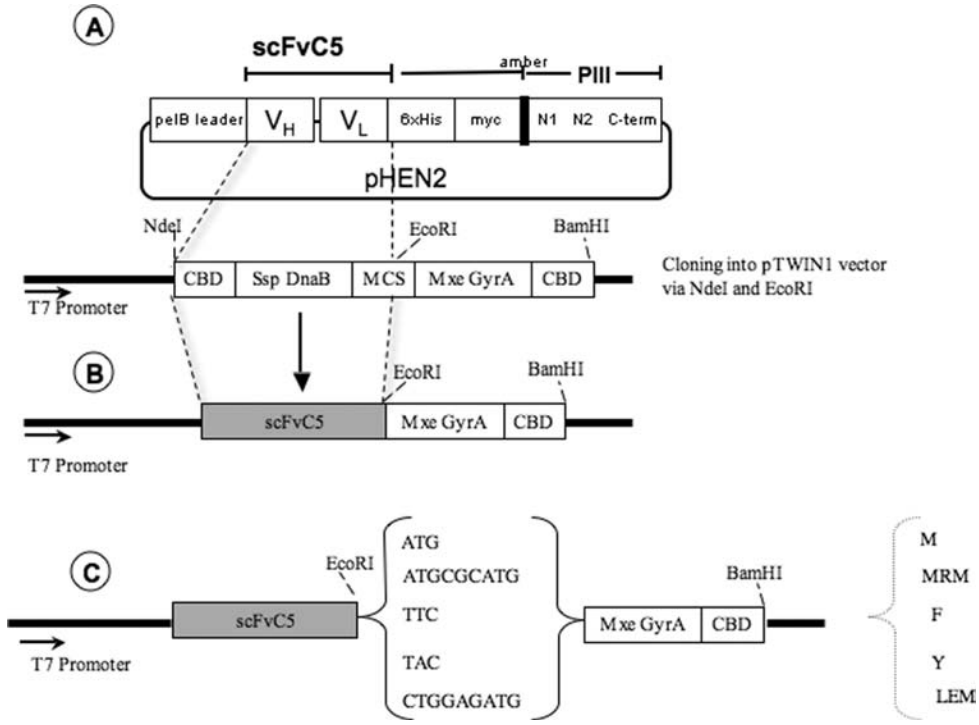


[a] (a) Under argon atmosphere, BOP + DIEA in CH_2Cl_2/DMF (3/2) at 0°C for 30 min, then **1′** added + DIEA, stirring for 24 h at room temperature, 93%; (b) $P(Ph)_3$ in THF with stirring for 12 h, then H_2O with stirring for a further 12 h, 68%; (c) CH_2Cl_2, $(Et)_3N$ at 0°C, then 12 h at room temperature; (d) CH_2Cl_2 TIS at room temperature for 5 h, 60%.

(Lancaster Synthesis), FITC (Molecular Probes), and amino acids and BOP (Novabiochem). All reactions involving nonaqueous solvents were carried out under a dry argon atmosphere. The progress of the reaction was monitored by analytical thin-layer chromatography (TLC) on silica gel Merck $60F_{254}$. Bands were visualized under UV (254 nm), with Pancaldi reagent (cerium IV, 5%), iodine, ninhydrin, or $KMnO_4$. Products were purified by flash chromatography on silica gel (Merck, 30−70 μm) or preparative reverse-phase HPLC (C18 Hyperprep, 250 × 21.2 mm, 8 μm). ^1H and ^{13}C NMR spectra were recorded on a Brücker AC 300 instrument, and chemical shift values (δ) are expressed in parts per million (ppm) with respect to the corresponding deuterated solvent. ESI mass spectra were recorded on a Nemag R10-10 machine. High-resolution FAB mass spectra were obtained from the Mass Spectrometry Service, CESAMO, Bordeaux.

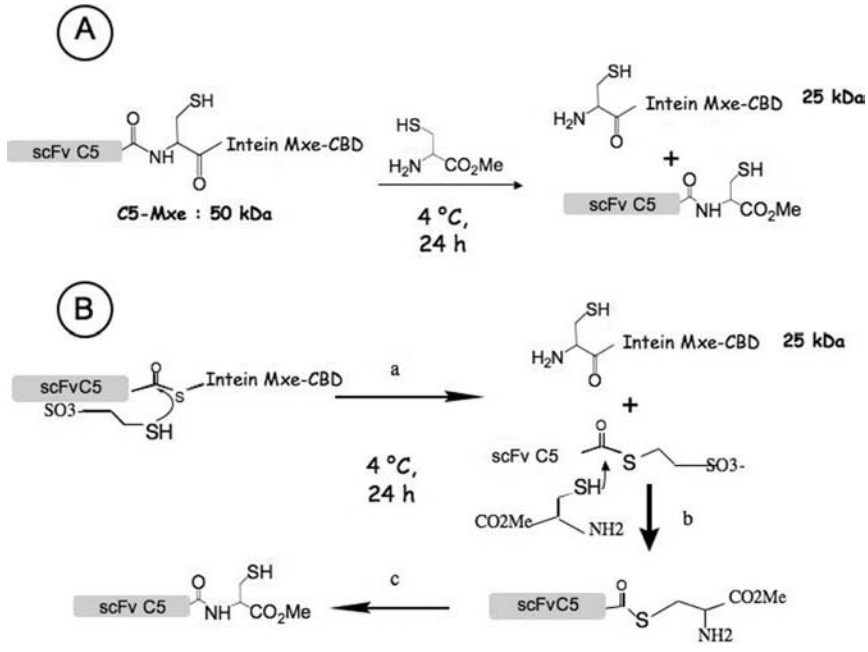
Chemicals. *1-(N-α-t-Boc-S-Trityl-L-cysteinamido)-11-azido-3,6,9-trioxaundecane, Compound **1**.* We synthesized 1-amino-11-azido- 3,6,9-trioxaundecane as described by Schwabacher et al. (*36*, *37*). To a stirred solution of *N*-α-t-Boc-*S*-trityl-L-cysteine (1 g, 2.2 mmol) in CH_2Cl_2 (50 mL) were added BOP (954 mg, 2.2 mmol) and DIEA (420 μL, 2.4 mmol). Stirring was continued for 30 min at 0 °C. We added 1-amino-11-azido-3,6,9-trioxaundecane (520 mg, 2.4 mmol) in CH_2Cl_2 (25 mL) and DIEA (420 μL, 2.4 mmol) to the mixture, which was stirred for 1 day at room temperature. The reaction mixture was washed successively with 1 M HCl (150 mL), 1 M $NaHCO_3$ (150 mL), and a sodium chloride saturated solution (brine) (150 mL). The organic layer was dried ($MgSO_4$) and the solvent evaporated under reduced pressure. The resulting crude product was purified by flash chromatography, using a gradient of 95/5 to 80/20 dichloromethane/ethyl acetate, to give **1** (1.31 g, 89%) as a slightly yellow oil: R_f = 0.27 CH_2Cl_2/AcOEt (8/2); MS (ESI) *m/z*: $[M + H]^+$ = 664.7; ^1H NMR (300 MHz, $CDCl_3$) δ(ppm): 7.37−7.31 (m, 6H, CH), 7.25−7.10 (m, 9H, CH), 6.37 (t, J = 6 Hz, 1H, NH), 4.83 (d, J = 6 Hz, 1H, NH), 3.89−3.78 (m, 1H, CH), 3.61−3.48 (m, 10H, CH_2), 3.46−3.40 (m, 2H, CH_2), 3.36−3.26 (m, 4H, CH_2), 2.69−2.57 (m, 1H, CH), 2.50−2.38 (m, 1H, CH), 1.35 (s, 9H, CH_3); ^{13}C NMR (300 MHz, $CDCl_3$) δ(ppm): 2 × 170.38, 3 × 144.47, 6 × 129.60, 6 × 128.06, 3 ×

Scheme 3. pHEN2 Vector and scFvC5-(X)-Mxe Constructs[a]



[a] A: Schematic representation of the pHEN2 phagemid vector (Griffin 1. library). pelB leader: signal peptide sequence of bacterial pectate lyase mediating secretion into the periplasmic space; V_H: variable fragment of the heavy chain; V_L: light chain; 6xHis: 6 histidine-tag; myc: myc-tag; amber: amber stop codon; N1, N2, C-term: portions of the N- and C-termini of phage capsid protein pIII. ScFvC5 (V_H V_L) amplified by PCR and inserted into the pTWIN 1 vector. B: Schematic representation of scFvC5 fused to the Mxe intein. C: Schematic representation of the various scFvC5-(X)-Mxe, constructed and checked for splicing efficiency.

Scheme 4. Splicing of scFvC5-(X)-Mxe[a]



[a] A: Cysteine carboxymethyl ester induces the formation of two products with a molecular mass of 25 kDa. Only the product containing the chitin binding domain (CBD) is detected by the anti-CBD antibody on western blots. B: Mesna catalyzes the activity of the carboxymethyl ester of cysteine, generating an intermediate in addition to the two initial products. As in A, only the product containing the chitin binding domain (CBD) was detected with an anti-CBD antibody on western blots. (a) Mesna reacts with intein, producing mxeCBD plus scFvC5 linked to mesna. (b) Binding of cysteine carboxymethyl ester to scFvC5.

126.90, 80.12, 70.64, 70.61, 70.38, 70.12, 70.07, 69.73, 67.10, 53.53, 50.69, 39.38, 34.31, 3 × 28.32.

1-(N-α-t-Boc-S-Trityl-L-cysteinamido)-11-amino-3,6,9-trioxaundecane, Compound 1′. One equivalent of compound **1** (1 g, 1.5 mmol) was dissolved in anhydrous THF (15 mL); 4 equiv of triphenylphosphine, $P(Ph)_3$ (1.58 g), was added and activation was allowed to occur for 12 h at room temperature. We then added water (4 mL) and maintained stirring for a further 12 h.

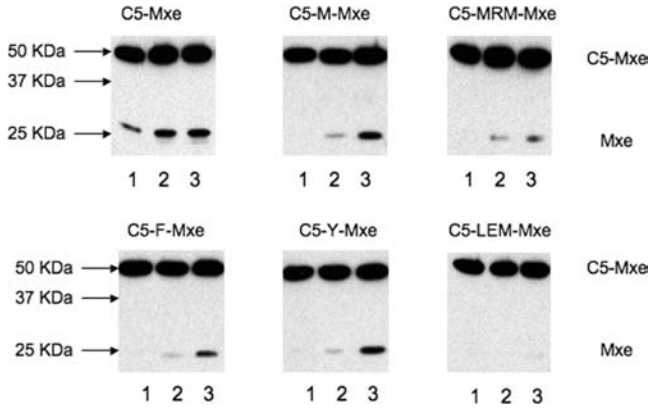


Figure 1. Western blot analyses, with anti-CBD antibody of the splicing induced by cysteine carboxymethyl ester alone. scFvC5-(X)-Mxe was generated and adsorbed onto chitin-coated plates, which were incubated with various concentrations of cysteine carboxymethyl ester: buffer alone (lane 1), 1 mM (lane 2), 10 mM (lane 3).

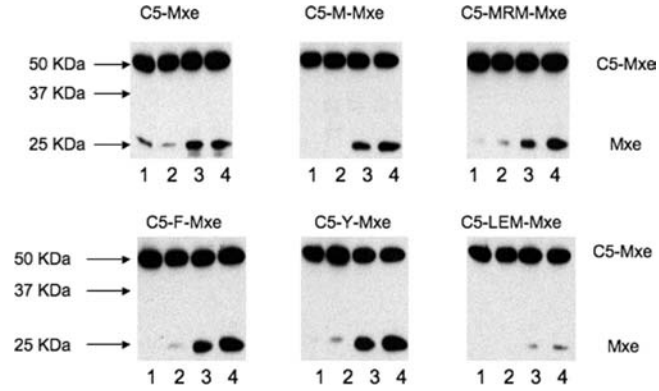

Figure 2. Western blot analyses, with antiCBD antibody, of the splicing induced by cysteine carboxymethyl ester in the presence of mesna (3 mM). scFvC5-(X)-Mxe was produced, adsorbed onto chitin-coated plates, and incubated with various concentrations of cysteine carboxymethyl ester in the presence of 3 mM mesna: buffer alone (lane 1), mesna (lane 2), mesna + 1 mM (lane 3), mesna + 10 mM (lane 4).

The mixture was concentrated under reduced pressure, diluted with 50 mL of water, and extracted with CH_2Cl_2 (10 × 50 mL). The resulting product was concentrated and purified by flash chromatography (dichloromethane/methanol, gradient 95/5 to 1/1), giving a pale yellow oil (0.91 g, 95%), **1′**: R_f = 0.15 CH_2Cl_2/MeOH (6/4); MS (ESI) *m/z*: $[M + H]^+$ = 638.6; ^{1}H NMR (300 MHz, $CDCl_3$) δ(ppm): 7.41−7.28 (m, 6H, CH), 7.28−7.01 (m, 10H, CH + NH), 5.19 (d, J = 9 Hz, 1H, NH), 4.01−3.86 (m, 1H, CH), 3.61−3.21 (m, 14H, CH_2), 2.75 (t, J = 6 Hz, 2H, CH_2), 2.61−2.36 (m, 2H, CH_2), 1.80 (s, 2H, NH_2), 1.35 (s, 9H, CH_3); ^{13}C NMR (300 MHz, $CDCl_3$) δ(ppm): 2 × 170.43, 3 × 144.50, 6 × 129.57, 6 × 127.98, 3 × 126.79, 79.86, 73.14, 2 × 70.51, 70.31, 70.09, 69.87, 66.85, 53.35, 41.52, 39.36, 34.62, 3 × 28.33).

1-(N-α-t-Boc-S-Trityl-L-cysteinamido)-11-[1′-N-(4-azido-1-butoxycarbonyl)-D-biotinamido]-3,6,9-trioxaundecane, Compound ***3.*** To a stirred solution of *N*-1′-(4-azido-1-butoxycarbonyl)-D-biotin **2** (*35*) (380 mg, 0.99 mmol) in CH_2Cl_2/DMF (3/2, 15 mL) at 0 °C were added BOP (436 mg, 0.99 mmol) and DIEA (190 μL, 1.1 equiv). After 30 min, a solution of **1′** (692 mg, 1.1 mmol) and DIEA (190 μL, 1.1 mmol) in CH_2Cl_2 (9 mL) was added dropwise, and the resulting mixture was stirred for 24 h at room temperature. The reaction mixture was concentrated under a vacuum and the residue dissolved in CH_2Cl_2 (50 mL). The resulting solution was washed successively with HCl (1 M, 150 mL), $NaHCO_3$ (1 M, 150 mL), and brine (150 mL) and then dried ($MgSO_4$) and the solvent evaporated off under a vacuum. The resulting crude product was purified by flash chromatography (CH_2Cl_2/MeOH, gradient 98/2 to 90/10) to give **3** as a pale yellow oil (0.93 g, 93%): R_f 0.2 (CH_2Cl_2/MeOH, 95/5); R_f = 0.2 CH_2Cl_2/MeOH (95/5); MS (ESI) *m/z*: $[M + H]^+$ = 1005.65 $[M + Na]^+$ = 1027.65; ^{1}H NMR (300 MHz, $CDCl_3$) $\delta\partial$ (ppm): 7.38−7.29 (m, 6H, CH), 7.29−7.10 (m, 9H, CH), 6.81 (s, 1H, NH), 6.66 (t, J = 6 Hz, 1H, NH), 6.55 (s, 1H) NHC_1O, 5.19 (s, 1H, NH), 4.76−4.68 (m, 1H, CH), 4.24−4.15 (m, 2H, CH_2), 4.15−4.04 (m, 1H, CH), 3.92−3.80 (m, 1H, CH), 3.60−3.20 (m, 18H, CH_2), 3.14−3.04 (m, 1H, CH), 3.04−2.87 (m, 2H, CH_2), 2.54−2.40 (m, 2H, CH_2), 2.10 (t, J = 6 Hz, 2H, CH_2), 1.80−1.45 (m, 8H, CH_2), 1.45−1.24 (m, 11H, CH_2, CH_3); ^{13}C NMR (300 MHz, $CDCl_3$) $\delta\partial$ (ppm): 1173.10, 2 × 170.78, 155.60, 151.85, 3 × 144.45, 6 × 129.58, 6 × 128.04, 3 × 126.87, 80.03, 70.48, 70.38, 70.34, 70.11, 69.83, 69.64, 67.03, 65.80, 62.65, 57.61, 55.21, 53.48, 50.95, 39.47, 39.18, 38.73, 35.51, 34.29, 3 × 28.34, 27.94, 27.87, 25.98, 25.48, 25.28;.

1-(N-α-t-Boc-S-Trityl-L-cysteinamido)-11-[1′-N-(4-amino-1-butoxycarbonyl)-D-biotinamido]-3,6,9-trioxaundecane, Compound ***4.*** To a solution of compound **3** (115 mg, 0.11 mmol) in dry THF (2 mL) was added triphenylphosphine (240 mg, 0.88 mmol). The resulting mixture was stirred for 12 h at room temperature. Water (2 mL) was then added, and the resulting mixture was stirred for a further 12 h. The solution was concentrated under reduced pressure, diluted with water (8 mL), and extracted 10 times with CH_2Cl_2 (20 mL). The combined organic layers were dried ($MgSO_4$) and evaporated under reduced pressure. The crude product was purified by flash chromatography (CH_2Cl_2/MeOH/Et_3N, 8/2/0.1). The resulting product was dissolved in CH_2Cl_2 (50 mL) and successively washed with HCl (1 N, 50 mL), $NaHCO_3$ (1 N, 50 mL), and brine (50 mL). The organic solution was dried ($MgSO_4$) and evaporated under reduced pressure to give **4** as a brown powder (73 mg, 68%): R_f = 0.17 CH_2Cl_2/MeOH (8/2 in the presence of 1% Et_3N); MS (ESI) *m/z*: $[M + H]^+$ = 979.65 $[M + Na]^+$ = 1001.75; ^{1}H NMR (300 MHz, $CDCl_3$) δ(ppm): 7.40−7.27 (m, 6H, CH), 7.27−7.09 (m, 9H, CH), 7.09−6.90 (m, 3H, NH, NH_2), 6.80−6.65 (m, 2H, NH × 2), 5.15−5.02 (m, 1H, NH), 4.77−4.60 (m, 1H, CH), 4.25−4.07 (m, 3H, CH, CH_2), 3.96−3.80 (m, 1H, CH), 3.60−3.25 (m, 16H, CH_2), 3.13−3.05 (m, 1H, CH), 3.01−2.80 (m, 4H, CH_2), 2.63−2.51 (m, 1H, CH), 2.51−2.40 (m, 1H, CH), 2.09 (t, J = 6 Hz, 2H, CH_2), 1.80−1.45 (m, 8H, CH_2), 1.45−1.25 (m, 11H, CH_2, CH_3); ^{13}C NMR (300 MHz, $CDCl_3$) δ(ppm): 173.25, 2 × 170.63, 156.31, 151.89, 3 × 144.44, 6 × 129.56, 6 × 128.03, 3 × 126.86, 80.04, 70.43, 70.36, 70.28, 70.08, 69.86, 69.67, 66.99, 66.24, 62.65, 58.06, 55.54, 53.45, 2 × 39,39, 39.13, 38.70, 35.72, 34.37, 28.54, 3 × 28.33 28.00, 3 × 25.42.

1-(N-α-t-Boc-S-Trityl-L-cysteinamido)-11-[1′-N-(4-(thiourea fluorescein)-1-butoxycarbonyl)-D-biotinamido]-3,6,9-trioxaundecane, Compound ***5.*** To a stirred mixture of compound **4** (220 mg, 0.23 mmol) and Et_3N (32 μL, 0.23 mmol) in dry CH_2Cl_2 (4 mL) at 0 °C was added dropwise a solution of FITC (87.4 mg, 0.23 mmol) in dry DMF (3 mL). The mixture was allowed to come up to room temperature, with stirring, over a period of 4 h and was then stirred for a further 20 h at room temperature. The reaction mixture was placed under low pressure to evaporate off the solvent, and the resulting crude residue was purified by flash chromatography (CH_2Cl_2/AcOEt/MeOH, 4/4/2), to give **5** as a yellow powder (240 mg, 78%): R_f = 0.32 CH_2Cl_2/AcOEt/MeOH (4/4/2); MS (ESI) *m/z*: $[M + Na]^+$ = 1390.50; ^{1}H NMR (300 MHz, DMSO) δ(ppm): 8.38−8.30 (m, 1H, CH), 7.96−7.68 (m, 4H, CH, NH × 3), 7.48−7.14 (m, 15H, CH, CH_2), 7.05−6.96 (m, 1H, CH), 6.77−6.61 (m, 6H, CH), 4.85−4.75

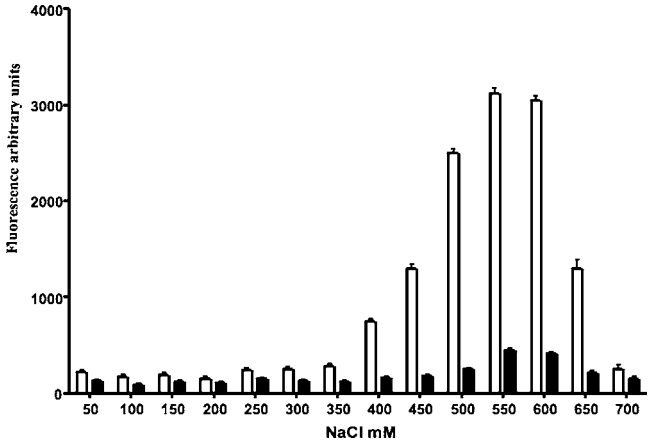

Figure 3. Fluorescence-linked immunosorbent assay of DEAE chromatography desorbed fractions. Labeled scFv C5 was loaded onto DEAE trisacryl and eluted with increasing concentrations of NaCl. Each fraction was then checked for binding to RhoA (white bars) and RhoB (black bars). The results shown are representative of a single experiment carried out in triplicate.

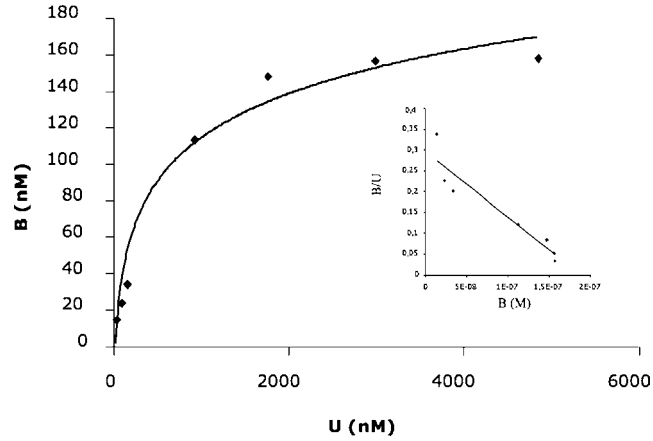

Figure 4. Binding study for compound **6**. Various concentrations of compound **6** (up to 6 μM) were loaded onto an avidin-coated plate, in the absence (total binding) or presence (nonspecific binding) of a large excess of biotin (1 mM). B was representative of the specific fluorescence (compound **6**) bound on avidin and U unbound. Representative data from one experiment of three performed in duplicate are shown. A Scatchard plot analysis is shown in the inset.

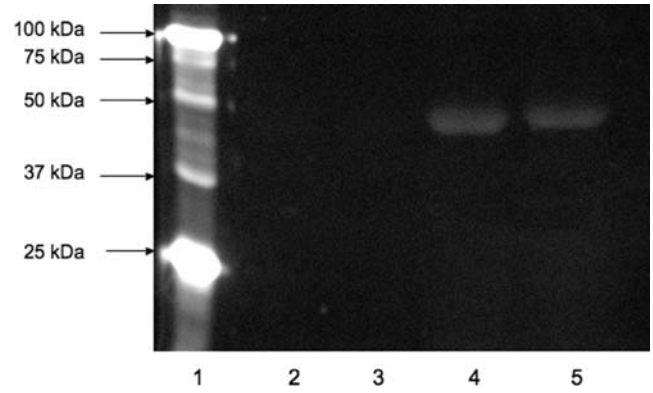

Figure 5. SDS- PAGE analysis of the eluate from streptavidin columns. The 500, 550, and 600 mM NaCl fractions from the DEAE column were pooled and loaded onto streptavidin beads. The beads were washed, and increasing concentrations were used for elution: 0.01 mM (lane 2), 0.1 mM (lane 3), 1 mM (lane 4), 10 mM (lane 5). The gel was illuminated under UV light (380 nm) for the detection of fluorescence.

(m, 1H, CH), 4.31−4.15 (m, 3H, CH, CH_2), 3.60−2.90 (m, 22H, CH, CH_2), 2.53 (m, 2H); 2.07 (t, 2H, CH_2), 1.70−1.20 (m, 10H, CH_2).

1-(L-Cysteinamido)-11-[1′-N-(4-(thiourea fluorescein)-1-butoxycarbonyl)-D-biotinamido]-3,6,9-trioxaundecane, Compound ***6.*** To a stirred solution of compound **5** (44 mg, 0.032 mmol) in CH_2Cl_2 (3 mL) at room temperature was added dropwise a solution of TIS (7 μL, 0.032 mmol) in CH_2Cl_2/TFA (2 mL, 75/25). After 5 h of stirring at room temperature, the reaction mixture was placed under low pressure conditions to evaporate off the solvent, and the resulting crude residue was purified by flash chromatography (CH_3CN/MeOH/H_2O; gradient 90/5/5 to 80/15/5) to yield **6** as an orange powder (20 mg, 60%): $R_f = 0.18$ CH_3CN/MeOH/H_2O (6/3/1); MS (ESI) *m/z*: $[M + H]^+ =$ 1026.3446 (theoretical mass: HRMS calculated for ($C_{47}H_{59}N_7O_{13}S_3$) ($[M + H]^+$), *m/z* 1026.3411); ^{1}H NMR (300 MHz, DMSO) δ(ppm): 8.28−8.19 (m, 1H, CH), 8.10−8.05 (m, 1H, NH), 7.90−7.82 (m, 1H, CH), 7.75−7.60 (m, 2H, NH), 7.15−7.05 (m, 1H, CH), 6.75−6.40 (m, 6H, CH), 4.80−4.70 (m, 1H, CH), 4.20−4.02 (m, 3H, CH, CH_2), 3.60−2.90 (m, 22H, CH, CH_2), 2.53 (m, 2H, CH_2), 2.07 (t, 2H, CH_2), 1.70−1.20 (m, 10H, CH_2).

Biological Agents. *Strains.* The bacterial strains used were *E. coli* DH5α for subcloning, BL 21 for Rho protein production, and ER 2566 (NEB) for scFvC5-intein chimeras.

ScFvC5 Selection and Production. The Griffin.1 library, a human synthetic V_H+V_L scFv phage library in a phagemid vector, and the positive control *E. coli* TG1 (TG1 containing an antityroglobulin clone) were generously provided by Fiona Sait of The Medical Research Council (Cambridge, England). We followed the protocol provided for the Griffin.1 library at http://www.mrc-cpe.cam.ac.uk (*38*), as previously described (*39*). Briefly, in the presence of GST-RhoA (to remove unspecific phages), phages were selected using recombinant GST-RhoB, coated on glutathione wells. After four rounds of selection/amplification, this led to the isolation of an scFv fragment subsequently referred to as C5. This fragment was then produced as a recombinant protein, from the PHEN plasmid (Scheme 3: A). This scFvC5 has not yet been completely characterized. Initial analyses have shown that it is selective for the native structure of RhoB, with a dissociation constant at equilibrium (K_D) of $5 \pm 3 \times 10^{-6}$ M.

Construction of ScFvC5-Mxe. This construction process was based on the prior work of L.-P. Tan et al. (*30, 31*) and C. Cui et al. (*40*) We used the pTWIN1 plasmid of the NEB IMPACT system as a vector and amplified the scFvC5 sequence by PCR with primers containing a 5′ *Nde*I site and a 3′ *Eco*RI site:

5′-GGAATTCCATATGCAGGTGCAGCTGCAGGAG-3′sense

3′-CGGAATTCTGCGGCCGCACCTAGGAC-5′ antisense

The amplified and digested DNA fragment was inserted (in place of the Ssp intein), between the *Nde*I and *Eco*RI sites of the pTWIN1 plasmid (Scheme 3B).

Construction of Mutated ScFvC5(-X)Mxe. Given the importance of the nature of the amino acids of the hinge domain between scFvC5 and intein for the induction of splicing, we generated five mutations in this hinge domain: methionine (scfvC5-MMxe), phenylalanine (scfvC5-Fmxe), tyrosine (scfvC5-YMxe), methionine-arginine-methionine (scfvC5-MRMMxe), and leucine-glutamic acid-methionine (scfvC5-LEMMxe). The various mutations were achieved by means of PCR using as the 3′ primer a common oligonucleotide, 5′-ACGATTGTT-TCGGGCTTT-3′, annealing the 3′ sequence of the *Bam*HI restriction site of pTWIN1, and, as the 5′ primer, sequences carrying the *Eco*RI site were used.

Amplified and digested DNA fragments were inserted between the *Eco*RI and *Bam*HI sites of the previously constructed scFvC5-pTWIN 1 plasmid (Scheme 3C). These plasmids were

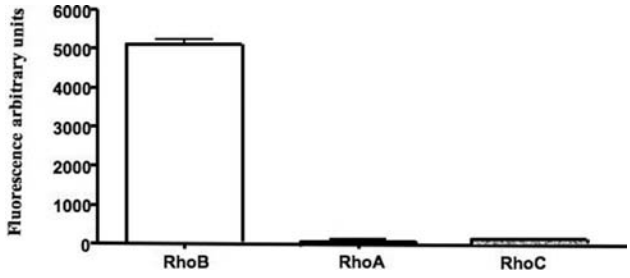

Figure 6. Fluorescence-linked immunosorbent assays of selectivity for RhoB. The streptavidin eluted with 1 mM biotin was diluted 1/20 and loaded onto Rho B (white bar), Rho A (black), or Rho C (gray)-coated plates.

constructed for the production in bacteria of an scFvC5 fragment fused to the mutated Mxe and tagged with a chitin-binding domain (CBD) from the pTWIN1 vector. This CBD was subsequently used to purify the protein of interest.

Production of scFvC5-X-Mxe Protein Chimeras. Transformed ER 2566 bacteria were grown at 37 °C in 50 mL of LB medium containing 100 μg/mL ampicillin to an OD_{600} of 0.6. Synthesis of the scFvC5-X-Mxe protein was then induced by incubation with IPTG (1 mM) for 18 h at 20 °C. Bacteria were harvested, centrifuged for 10 min at 4000*g*, resuspended in 5 mL of buffer A (HEPES (10 mM), NaCl (250 mM) pH 7.4), and subjected to six 10 s pulses of sonication on ice. The resulting lysate was centrifuged at 8500*g* for 30 min at 4 °C, and the supernatant was retained for subsequent experiments.

Induction of Splicing by the Carboxymethyl Ester of Cysteine. Supernatants were loaded on chitin-coated 96-well plates and incubated at 4 °C for 4 h. They were then washed three times with buffer A, and increasing concentrations of the carboxy methyl ester of cysteine were added. The mixture was then incubated at 4 °C for a further 24 h, or at 20 °C for 4 h. The plates were washed with buffer A, and 5 μL of 5% SDS at 80 °C was added to each well. Western blot analysis was then carried out with an antibody directed against the chitin binding domain (NEB Biolabs).

Induction of Splicing and Labeling with 1-(L-Cysteinamido)-11-[1′-N-(4-(thiourea fluorescein)-1-butoxycarbonyl)-D(+)-biotinamido]-3,6,9-trioxaundecane. We labeled only scFvC5-Y-Mxe using 100 mL of transformed bacteria. The bacteria were collected by centrifugation, and the pellet was resuspended in 10 mL of buffer A. The bacteria were lysed by sonication, and the 8500*g* supernatant was loaded at 4 °C onto 1 mL of chitin beads. The beads were washed with 4 × 5 mL of buffer A. We then added 2.5 mM of compound **6** in the presence of mesna (3 mM) in 300 μL of buffer A and incubated the beads at 4 °C for 24 h. The flow-through was salvaged and used in subsequent experiments.

*Partition of the Biotinylated Fluorescent scFVC5-Y (Biot-Fluo-scFvC5) from Unreacted Compound **6** and Unlabeled scfvC5-Y.* Anion exchange chromatography was carried out with 1 mL of DEAE Trisacryl resin from Pharmacia. The sample was diluted 1:5 in buffer B (HEPES 20 mM, pH 7.7) to adjust the NaCl concentration to 50 mM before loading. The column was then washed with 40 mL of buffer B supplemented with DTT (1 mM) and subjected to elution with buffer B plus DTT supplemented with increasing concentrations of NaCl (50 to 600 mM). Desorbed fractions were loaded, in the presence of BSA (10 mg/ml), onto 500 μL of streptavidin resin (Amersham). The resin was washed with 15 mL of buffer B supplemented with DTT and BSA and 15 mL of the same buffer without BSA. Elution was carried out with increasing concentrations of biotin (0−10 mM) in buffer B. The fraction eluted with 1 mM biotin (purified) was used in subsequent experiments.

Fluorescence-Linked Immunosorbent Assay (FLISA). The chimeric GST-RhoA, GST-RhoB, GST-RhoC proteins were produced in *E. coli*, as previously described (*41*). They were absorbed onto gluthatione-coated 96-well plates (Reacti-Bind Coated Black from Pierce). The plates were washed three times, with 200 μL of PBS each, and were then incubated with 100 μL of purified Biot-Fluo-scFvC5 (the 1 mM biotin fraction from streptavidin chromatography) for 1 h. The plates were washed was twice with 1 mM DTT in PBS, and the fluorescence of each well was determined with a spectrofluorimeter (Flite 2001 Fluorescence Reader from Perkin-Elmer).

Immunofluorescence. HeLa cells (ATCC, CCL-2) were grown on coverslips in Dulbecco's modified Eagle's medium (DMEM, Cambrex) supplemented with 5% fetal calf serum. They were fixed by incubation in paraformaldehyde (Cytofix) and permeabilized by incubation with Cytoperm (BD Biosciences). They were then incubated with 200 μL of Biot-Fluo-scFvC5 in the presence or absence of GST-RhoA (about 10 μg) or GST-RhoB (about 10 μg) for 1 h and washed twice with 500 μL of a 98/1/1 mixture of PBS/acetone/methanol. Control images were obtained with monoclonal anti-RhoB (sc8048) from Santa Cruz. Cell fluorescence was visualized with a Nikon Eclipse 90i microscope equipped with FITC fluorescence filters (Semrock) and a CoolsnapHQ^2 camera (Ropper). Images were acquired with NIS-Element Ar.

RESULTS

Synthesis of 1-(*N*-α-t-Boc-*S*-Trityl-L-cysteinamido)-11-amino-3,6,9-trioxaundecane 1′ (Scheme 1). With the aim of increasing the spacing between the biotin motif and the reacting cysteine and the scFv, we generated a poly(ethylene glycol) arm with a cysteine-reactive thiol at one end. This linker has been chosen in relation to Bucourt's work (*42*). Compound **1** was obtained with an 89% yield and was reduced in the presence of triphenylphosphine to obtain compound **1′** (95% yield). Boc and trityl protective groups were retained for subsequent experiments.

Synthesis of 1-(*N*-α-t-Boc-*S*-Trityl-L-cysteinamido)-11-[1′-*N*-(4-azido-1-butoxycarbonyl)-D-biotinamido]-3,6,9-trioxaundecane 3 (Scheme 2). The peptide bond between compounds **1′** and **2** generated in a previous study (*35*) was reproduced here by classical methods, yielding 93% purified product **3**.

Synthesis of 1-(L-Cysteinamido)-11-[1′-*N*-(4-(thiourea fluorescein)-1-butoxycarbonyl)-D-biotinamido]-3,6,9-trioxaundecane 6 (Scheme 2). A Staudinger reduction was used to generate **4**, the amino group of which was then reacted with FITC to give **5**.

Classical deprotection methods yielded 20 mg of an orange powder **6** with a final recovery rate of 29.6%. This final deprotection step was carried out three times to obtain the desired product with a good recovery rate. Given the small amount of compound **6** obtained, we checked product purity by a combination of NMR and high-resolution mass spectrometry, as elementary analysis would have consumed too much of the product.

Induction of Splicing by the Carboxymethyl Ester of Cysteine. Given the small amount of compound **6** available, we initiated the labeling study and defined the optimal conditions for splicing and labeling using a commercially available carboxymethyl ester of cysteine as the thiol reagent. Chimeric scFv-X-Mxe was produced and adsorbed onto a chitin plate. Splicing efficiency was assessed by Western blotting with an anti-CBD (fused to the Mxe intein) antibody (Scheme 4A). We aimed to select the sequence giving the lowest level of splicing in the absence of inducer and the highest level of splicing in the presence of inducer. As shown in Figure 1, the initial construct gave splicing in the absence of inducer (a; lane 1), and splicing levels increased with increasing concentrations of

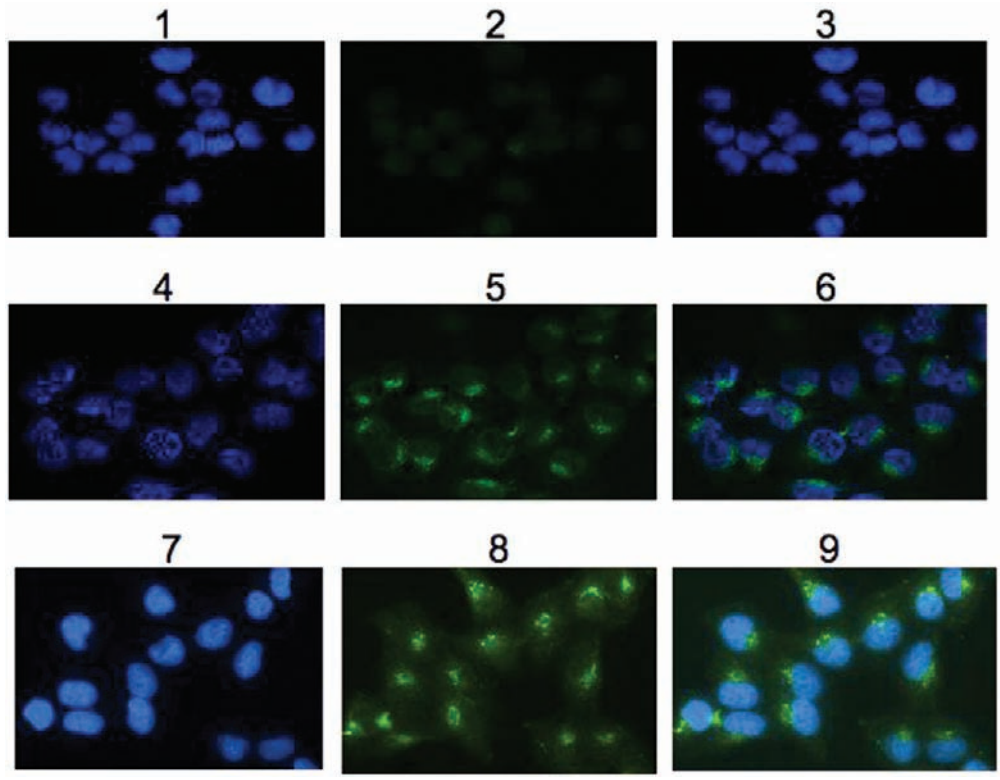

Figure 7. Immunofluorescence of RhoB in HeLa cells. The 1 μM biotin eluted fraction was diluted 1/10 and loaded onto HeLa cells in the presence of purified GST-RhoB (1, 2, 3) or in the presence of purified GST-RhoA (4, 5, 6). Nuclear DAPI labeling (1, 4) and (2, 5) fluorescence imaging. Merged image (3, 6). Control with commercial anti-RhoB (7, 8, 9).

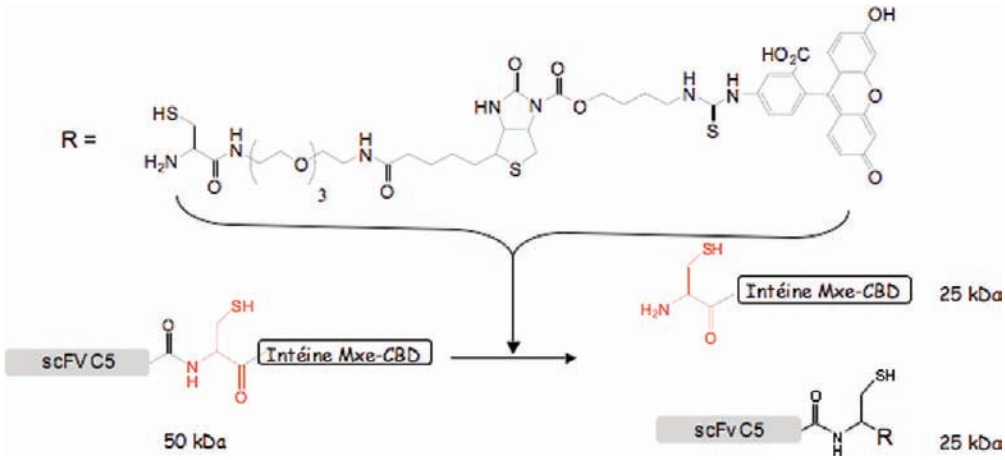
Scheme 5. Labeling of scFvC5 with Biotin−Fluorescein



cysteine carboxymethyl ester. The other five constructs gave no detectable splicing in the presence of buffer alone (c, b, d, e, f, lanes 1) and higher levels of splicing with the thiol, with the exception of scFvC5-LEM-Mxe, for which no splicing was observed with these treatments (f, lanes 1, 2, 3). We tried to increase the low splicing efficiency of the cysteine derivative by adding TCEP up to a concentration of 20 mM to maintain the thiol group of the cysteine derivative in its reactive form: no increase in the splicing efficiency of cysteine carboxymethyl ester was observed (data not shown). We also used mesna, another widely used catalyst (*31*, *33*, *43*, *44*), for this reaction. The addition of mesna (3 mM) to the splicing buffer increased the effect of the cysteine derivative but had no effect alone, in the absence of the cysteine derivative (Figure 2a−f, lane 1). The largest increase was obtained with scFvC5-F-Mxe and scFvC5-Y-Mxe (Figure 2d,e), but, given the mechanism of action of mesna (Scheme 4B), splicing may occur without labeling of the desired protein. The effect of buffer pH was then assessed. Each construct had its own pattern of response to buffers of different pH (from 6.5 to 9), but for scFv−C5-Y-Mxe in the presence of 3 mM mesna, the best splicing effect was obtained at pH 7.4 (data not shown).

At this stage using GST-RhoB as ligand, we have not found a difference in K_D between the original scFv-C5-Hisx6-c.myc with the new scFv−C5-Y-Mxe: $K_D = 5 \pm 3 \times 10^{-6}$ M.

Experiments performed at 20 °C for 4 h showed an increase in the splicing in response to the thiol inducer as compared to 4 °C. However, at 20 °C, the splicing occurred even in the absence of the thiol inducer (data not shown). Because this methodology will be also used to label in vivo (on viable cells) membrane receptors, cellular labeling must be performed at 4 °C previously to follow the spatiotemporal changes of receptor in living cells at 37 °C.

ScFvC5 Labeling. In vitro labeling was carried out with scFvC5-Y-Mxe, which gave the highest splicing efficiency in the presence of the cysteine derivative. Compound **6** was used in the presence of mesna (3 mM), and temperature (4 °C) and pH (7.4) conditions were selected to minimize protease activity and the structural deformation of the scFv and to make it possible to extrapolate the system to in vivo studies, for membranous protein labeling. Bacterial culture (100 mL of ER 2566 transformed with scFvC5-Y-Mxe plasmid) was lysed as described in the Materials and Methods, and the lysate was loaded onto a 1 mL chitin bead column. The column was washed three times with 20 mL of buffer A, and 300 μL of compound **6** (2.5 mM), dissolved in buffer A (pH adjusted to 7.4), was mixed with the beads in the presence of mesna (3 mM). After 24 h of contact with the beads, the flow-through containing the labeled scFvC5 was collected.

Purification of Labeled scFvC5. Capture on chitin beads gave a high level of purification of scFvC5-Y-Mxe from protein lysate, but the splicing induced by compound **6** and mesna essentially gave three products in the flow-through: unreacted compound **6**, unlabeled scFvC5 (which had reacted with mesna only), and labeled scFvC5. The calculated pI of scFvC5-Y given by the EMBL WWW Gateway to Isoelectric Point Service site was 5.4. We therefore used an anionic purification step to separate the proteins from the unreacted compound **6**. The NaCl concentration of the flow-through was adjusted to 50 mM, and the flow-through was loaded onto a DEAE trisacryl column. We added dithiothreitol (1 mM) to each buffer to inhibit the formation of disulfide bridges (between compound **6** and other compounds with SH groups). Increasing concentrations of NaCl were used to elute the labeled scFv, which was obtained at NaCl concentrations of 400 to 600 mM (Figure 3). We have shown that N′1 modifications of D-biotin result in a major loss of affinity for avidin (*35*). We made use of this property in the purification of labeled scFv on streptavidin, by adding biotin to the elution buffer. Scatchard plot analysis of the affinity between streptavidin and compound **6** (Figure 4) showed a K_D of 0.6×10^{-6} M, suggesting competitive desorption with biotin ($K_D = 10^{-13}$ M).

We mixed the three fractions (500−550−600 mM) from the DEAE trisacryl column and loaded the resulting mixture onto streptavidin magnetic beads, to remove unlabeled scFv and increase the specific fluorescence activity of the labeled product. The beads were washed, and the labeled scFvC5 was eluted with increasing concentrations of biotin. Labeled scFvC5-Y(BF-scFvC5) was eluted with 1 and 10 mM biotin, with the dimeric form of scFv the principal form obtained (Figure 5). Because this technology would be useful for in vivo labeling of membranous protein and to involve the cell capture of the biotin derivate at 37 °C, we have opted to induce Mxe intein splicing at low temperature (4 °C). If this temperature has lowered the scFv labeling efficiency it has maintained a good stability of the scFv. Assuming that the fluorescence quantum yield of the labeled protein was similar to that for compound **6**, the labeling yield (in relation to the quantity of compound **6** used) of the purified scFVC5 was about 2%, since recovery of labeled scFvC5 was around 5%.

Fluorescence-Linked Immunoassay. Small Rho (ABC) GTPases fused with the glutathione-sulfonyl-transferase (GST) were produced in *E. coli* and adsorbed onto a glutathione-coated 96-well plate. BF-scFvC5-Y retained specificity for RhoB (Figure 6).

We used the same technique to determine the dissociation constant at equilibrium of the BF-scFvC5-Y. Using GST-RhoB in the presence of increasing concentrations of BF-scFvC5-Y, the bound fraction was determined on glutathione beads, we found a $K_D = 1 \pm 1 \times 10^{-6}$ M on the same order of value as for the original scFvC5.

Immunofluorescence. Fixed and permeabilized HeLa cells were incubated with BF-scFvC5-Y in the presence and absence of RhoA (4, 5, 6) or RhoB (1, 2, 3). A single wash with PBS supplemented with DTT plus acetone (1%) and methanol (1%) did not result in the clear visualization of specific binding (data not shown). However, two washes gave the results shown in Figure 7. The time required for the accumulation of fluorescence was identical for the three treatments. RhoB detection with BF-scFvC5-Y (5,6) in cells was essentially in endosomal vesicles and was consistent with published results and with our own observations obtained with a commercial antibody (7, 8, 9) (*41*).

CONCLUSION

Given the need for methods for selective protein labeling in biology and biochemistry, we aimed to design a strategy for the labeling and purification of scFv directed against the small GTPase RhoB selected by phage display techniques. It was essential for this labeling to be selective and to have no effect on antigen-scFv recognition. On the basis of previous work on the synthesis of functionalized biotin N-1′ derivatives (*35*), we synthesized a biotin N-1′ fluorescein derivative carrying a thiol inducer of intein splicing on its valeric chain. This molecule double-labeled the scFv, its biotin moiety facilitating purification of the labeled protein and its fluorescein moiety opening up opportunities for the use of fluorescence-based technology. This study demonstrated the dual activity of the cysteine-biotin N-1′ fluorescein, which selectively labeled a new scFv targeting RhoB by intein splicing, and made it possible to use this molecule for immunofluorescence studies.

It has been shown that gastrin releasing peptide receptors (GRPRs) are overexpressed in various types of cancer cells. Bombesin is an analogue of the mammalian GRP that binds with high specificity and affinity to GRPRs. Significant research efforts have been lately devoted to the design of radiolabeled 8 or 14 aminoacid bombesin (BN) peptides for the detection (either with gamma or positron emitting radionuclides) and therapy (with β^- emitting radionuclides) of cancer. The specific aim of the present study was to further investigate the radiolabeled peptide structure and to determine whether the total absence of a linker or the use of a basic diverse amino acid linker could influence the biodistribution profile of the new compounds for specific targeting of human prostate cancer. Thus, two new derivatives with the structure Gly-Gly-Cys-X-BN[2−14], where linker X is either zero (I) or Orn-Orn-Orn (Orn: ornithine) (II) were designed and synthesized. The corresponding ^{99m}Tc-BN derivatives were obtained with high radiochemical yield (>98%) and had almost identical retention times in RP-HPLC with the $^{185/187}$Re complexes, which were also characterized by ESI-MS. Metabolic stability was found to be high in human plasma, moderate in PC-3 cells, and rather low in mouse liver and kidney homogenates for both BN derivatives studied. The BN derivative without the spacer was less stable in cell culture and liver homogenates. A satisfactory binding affinity to GRPRs, in the nanomolar range, was obtained for both BN derivatives as well as for their Re complexes, with BN (II) demonstrating the highest one. *In vitro* internalization/externalization assays indicated that ∼6% of BN (I) and ∼25% of BN (II) were internalized into PC-3 cells. *In vivo* evaluation in normal Swiss mice and in tumor bearing SCID mice showed that BN (II) presented higher tumor and pancreas uptake than BN (I). Small animal SPECT dynamic imaging, carried out after an injection of BN (II) in mice bearing PC-3 tumors, resulted in PC-3 tumor delineation with low background activity. Overall, this study performed for two new N_3S-X-BN[2−14] derivatives indicated that hydrophilicity and charge strongly affected the *in vitro* and *in vivo* binding properties and the biodistribution pattern. This finding is confirmed by SPECT imaging of BN (II), which is under further *in vivo* evaluation for detecting cancer-positive GRPRs.

INTRODUCTION

Bombesin, BN, is an active 14-amino acid neuropeptide (pGlu[1]-Gln[2]-Arg[3]-Leu[4]-Gly[5]-Asn[6]-Gln[7]-Trp[8]-Ala[9]-Val[10]-Gly[11]-His[12]-Leu[13]-Met[14]) originally isolated from the skin of the European frog *Bombina bombina* (*1*). Four bombesin receptors, for bombesin and its derivatives belonging to the G-protein receptor superfamily, have been cloned: NMB- receptor (NMBr or BB1), GRP receptor (GRPR or BB2), BN receptor (BRSr or BB3 or orphan), and BN receptor subtype 4 (BB4) (*2, 3*).

The bombesin mammalian counterpart, named gastrin-releasing peptide, GRP, is a 27-amino acid peptide sharing the same C-terminal heptapeptide with bombesin. This C-terminal BN 7−14 amino acid sequence (Gln[7]-Trp[8]-Ala[9]-Val[10]-Gly[11]-His[12]-Leu[13]-Met[14]) is considered to be essential for peptide biological activity and receptor binding affinity. Consequently, GRP and BN have essentially identical physiologic action (*4, 5*). The GRP receptor is widely expressed not only in the central nervous system and the gastrointestinal and respiratory tracts, where important physiologic functions take place, but is also found aberrantly in human malignancies including prostate, pancreatic, lung, breast, gastrointestinal, and colorectal carcinomas as well as in small cell lung cancer (*6, 7*). This overexpression in various neoplasias in reference to normal tissues, combined with the ability of GRPR agonists to be internalized, has led to the development of BN-based radiopharmaceuticals (*8*). In the majority of the studies, BN[7−14], which serves as a highly specific GRP-receptor binding motif, has been selected and radiolabeled with a variety of SPECT, PET, and therapeutical radionuclides (*9*). Most radiolabeled, BN-like peptides with substitutions or deletions at the 7−14 amino acid sequence (important for conferring agonistic or antagonistic properties) are N-terminally attached via various spacer arms or linkers to the radioisotope-chelating moiety.

Several peptide structures that provide stable ^{99m}Tc complexes attached on the N-terminal region of BN derivatives have been investigated. Garcia Garayoa et al. (*10−12*) reported the design and development of organometallic Re/^{99m}Tc$(CO)_3^{(I)}$ BN analogues by introducing non-natural amino acids and different spacers in the BN (7−14) sequence. It was concluded by the above study that the insertion of spacers had a clear influence on peptide uptake both in healthy organs and in tumors, leaving

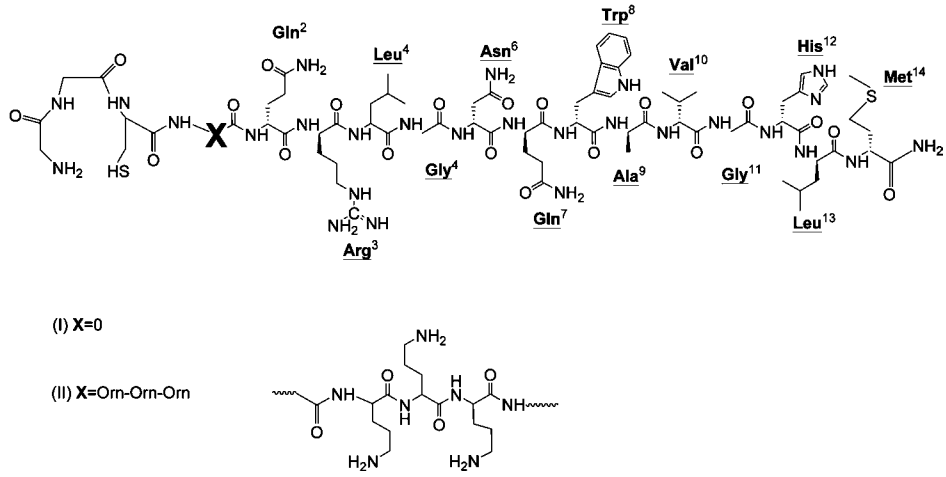

Figure 1. Structure and amino acid sequences of N_3S-X-BN[2−14] derivatives. BN(I): X = 0 (no spacer). BN(II): X = Orn-Orn-Orn.

the stability or receptor affinity unaffected. Smith et al. have studied ^{99m}Tc-complexes containing N_3S (*13*), tricarbonyl (*14, 15*), pyrazolyl (*16*), and "4 + 1" mixed ligand systems (*17*), N-terminally conjugated to BN(7−14) either directly or via spacer groups such as β-Ala, 5-Ava, 8-Aoc, 11-Aun, SSS, GGG, GSG, NNN, NNN-β-Ala, NNN-5-Ava, RRR, RRR- β-Ala, and RRR-5-Ava. Apart from ^{99m}Tc, which is among the most preferred radionuclides for imaging of the GRPR, for the design of BN-based radiopharmaceuticals labeled either with diagnostic [^{64}Cu (*18*−*21*), ^{68}Ga (*22*), ^{18}F (*23*), and ^{111}In (*24, 25*)] or therapeutic radioisotopes (^{64}Cu, ^{149}Pm, ^{153}Sm, ^{177}Lu, ^{90}Y, ^{111}In, and ^{188}Re) (*26*−*30*), BN structural modifications were also tried by the insertion of aliphatic, aminoacid, poly(ethyleneglycol), ether, and aromatic linking moieties. The main goal of all these efforts was to evaluate to what extent the length and the structure of the spacer or linking group would influence radiochemistry, metabolic stability, GRPR binding affinity, residualization of radioactivity in cancer cells, and pharmacokinetics of the labeled derivatives.

A traditional approach for radiolabeling BN derivatives with ^{99m}Tc is via stabilization of the $Tc^{(V)}O^{3+}$ metal core with ligands of the so-called N_3S type (*31*−*33*). Recently, our group (*34*) has focused on the design of BN derivatives in which the chelating moiety comprised a combination of amino acids X-Gly-Cys, where (X = Gly, methylglycine, dimethylglycine, and mercaptoacetic acid) N-terminally conjugated to the almost full length BN peptide, BN[2−14], through the hydrocarbon spacer arm Aca (6-aminohexanoic acid). A further comparative *in vivo* investigation (*35*) between the most promising derivative Gly-Gly-Cys-Aca-BN[2−14], resulting from the above study, and Gly-Gly-Cys-Aca-BN[7−14] showed that peptide chain length influenced the biodistribution of ^{99m}Tc-labeled derivatives. Taking into consideration the non-negligible liver uptake obtained with the peptides containing the six-carbon spacer, we further focused on the design of two novel BN[2−14]NH_2-like peptides. More specifically, the aliphatic spacer Aca was either eliminated or replaced by the non-natural basic amino acid sequence Orn-Orn-Orn (Orn = ornithine) (Figure 1). Previous studies of radiolabeled BN derivatives containing 3-, 5-, 8-, or 11-carbon spacers between the peptide and the chelator demonstrated that shortening the linker length liver uptake was reduced and pancreas was increased in nontumor bearing mice (*13*). Such considerations, together with an effort to make a full structure−activity relationship study, led us to the selection of a zero spacer in the case of BN (I) and of a more polar, charged linker in the case of BN (II). To the best of our knowledge, there are no other studies that have evaluated radiolabeled BN derivatives consisting of the BN[2−14] sequence conjugated to an N_3S chelator via no spacer or via a spacer containing the triaminoacid sequence of ornithines. The choice of three Orn as a spacer was made because we wanted to maximize the effect of the charge and thus to investigate whether, with the introduction of this polar linker in reference to no spacer, the hydrophilic character of the final compound dictates the biodistribution profile.

In the frame of the present study, the new BN derivatives were complexed with both ^{99m}Tc and $^{185/187}$Re(V) gluconate precursors. The nonradioactive rhenium complexes were characterized by liquid chromatography−electrospray ionization mass spectrometry (ESI-MS). Radiochemical identification, metabolic stability studies, *in vitro* assays including binding affinity, internalization/efflux studies as well as *in vivo* evaluation in normal Swiss mice and tumor (human prostate PC-3) bearing SCID mice are reported. The aim was to examine whether the modification of the spacer affected stability, affinity, lipophilicity, and the overall charge of the resulting ^{99m}Tc-BN derivatives and as a consequence the influence these changes exert on the *in vivo* profile of the resulting radiolabeled species.

EXPERIMENTAL PROCEDURES

Materials. The Fmoc-protected amino acids were purchased from the Chemical and Biopharmaceutical Laboratories (Patras, Greece), while the polystyrene resin was commercially available from Nova Biochem. Electrospray mass spectrum analyses were performed in the Mass Spectrometry and Dioxin Analysis Laboratory of NCSR "Demokritos". ^{99m}Tc, obtained in physiological saline as $Na^{99m}TcO_4$, was eluted from a commercial ^{99}Mo/^{99m}Tc generator (Mallinckrodt Medical, Petten, The Netherlands). The human prostate adenocarcinoma cell line was obtained from the American Type Culture Collection (ATCC). The product [^{125}I-Tyr^4]BN was purchased from Perkin-Elmer (Life Science Products, Boston MA, USA, Inc.; specific activity, 81.4 TBq/mmol, 10 μCi). Biodistribution studies were performed using female normal Swiss and SCID (severely compromised immunodeficient) mice (15−25 g) of the same colony and age, purchased from the Breeding Facilities of NCSR Demokritos. Reagents and media for cell culture were purchased from PAA Laboratories GmbH (Austria), and all other chemicals from Merck (Whitehouse Station, NJ 08889-0100 USA).

Instrumentation. Analytical reverse phase high performance liquid chromatography (RP-HPLCs) were performed on a Waters HPLC system (pump 616, detector 996 PDA) using a Hibar Pre-Packed Column RT 250−4, LiChrospher 100 RP-18 (5 μm) (250 mm, ID 4 mm, Merck). Semipreparative RP-HPLC was performed on a Waters (Milford, MA, USA) HPLC system

(pump 600E, detector UV-484). A 10 Nucleosil 7 C18 column [250 × 12.7 mm ID; Macherey-Nagel (Dueren, Germany)] was used. For (ESI-MS) mass spectral analysis, the test solution in 50% aqueous acetonitrile was infused into an electrospray interface mass spectrometer (AQA Navigator, Finnigan) at a flow rate of 0.1 mL/min, using a Harvant Syringe pump. Negative or positive ion ESI spectra were acquired by adjusting the needle and cone voltages accordingly. Hot nitrogen gas (Dominic-Hunter UHPLCMS-10) was used for desolvation at 170 °C. Instant thin layer chromatography (ITLC) measurements were made by electronic autoradiography (Instant Imager Packard-Canberra). Gamma decay detection of ^{125}I for the *in vitro* cell binding studies was performed on a γ counter (Model LB2111, Berthold detection system, Bad Wildbad, Germany). For internalization, efflux, and *in vivo* studies a multisample γ-counter system Packard Minaxi 5500 equipped with a 3″ NaI (Tl) crystal was used. Scintigraphic images were acquired on a pair of two square H8500 flat-panel PSPMT gently coupled to a NaI(Tl) crystal array (Bicron-St. Gobain), equipped with a parallel-hole lead collimator.

Solid Phase Peptide Synthesis. The BN derivatives were synthesized manually on a Rink-amide resin employing the Fmoc strategy as follows: Briefly, for coupling, an excess of Fmoc-protected amino acid and HOB*t* were dissolved in *N*,*N*′-dimethylformamide (DMF). The solution was cooled in ice, and then *N*,*N*′-diisopropylcarbodiimide (DIPC) was added. The reaction mixture was initially left for 10 min on ice, then for another 10 min at room temperature, and was finally added to the resin. The coupling efficiency was monitored by the Kaiser ninhydrin test (*36*). Removal of the N-terminal Fmoc group was achieved by repetitive treatment with 20% piperidine in DMF. The final product was cleaved from the resin using a cocktail of trifluoroacetic acid (TFA), thioanisol, ethanediol, phenol, H_2O, and triisopropylsilane (81.5/5/2.5/5/5/1, v/v/v/v/v/v). The crude product, obtained by precipitation with cold diethylether, was purified by semipreparative RP-HPLC. Elution was performed with a solvent system consisting of 0.05% TFA in water (solvent A) and 60% CH_3CN in solvent A (solvent B), by applying a linear gradient from 100% to 20% A in 47 min for BN (I) or from 100% to 50% A in 47 min for BN (II). The flow rate was 4.5 mL/min, and the peptide peaks were detected with a UV detector at 220 nm.

Conjugation of $^{185/187}$Re$^{(V)}$O-N$_3$S-BN Derivatives (Non-radioactive Complexes). Rhenium$^{(V)}$ oxo complexes of BN derivatives were prepared by ligand exchange reactions, starting from the preformed Re$^{(V)}$O gluconate precursor (*37*). An aqueous solution of both crude BN derivatives (10 and 20 mg, respectively) and a Re$^{(V)}$O gluconate solution were allowed to react at 60 °C for 2 h. The crude products were purified by semipreparative RP-HPLC. Elution was performed with a solvent system consisting of 0.05% TFA in water (solvent A) and 60% CH_3CN in solvent A (solvent B), by applying a linear gradient from 100% to 20% solvent A in 47 min for BN (I) and from 100% to 50% solvent A in 47 min for BN (II). The flow rate was 4 mL/min, and the peptide peaks were detected with a UV detector at 220 nm. The new Rhenium$^{(V)}$ oxo complexes of the BN derivatives were characterized by ESI-MS and RP-HPLC.

Conjugation of ^{99m}Tc$^{(V)}$O-N$_3$S-BN Derivatives (Radioactive Complexes). Radiolabeling of the BN derivatives was performed by radioisotope exchange from a ^{99m}Tc$^{(V)}$O gluconate precursor, (sodium gluconate being used as an intermediate exchange ligand for ^{99m}Tc, with stannous chloride as the reducing agent) (*38*). Thus, a solid mixture containing 1 g of sodium gluconate ($C_6H_{11}NaO_7$), 2 g of sodium bicarbonate ($NaHCO_3$), and 15 mg of stannous chloride ($SnCl_2$) was homogenized and kept dry. Three milligrams of the above mixture was dissolved in 1 mL of a sodium pertechnetate solution ($Na^{99m}TcO_4$), containing 370−555 MBq (10−15 mCi) of ^{99m}Tc. An aliquot of 200 μL of the above solution was added to 100 μL of an aqueous solution (pH 1−2) containing 75 ng of each BN derivative. The mixture (pH 6−7) was homogenized by vortexing and allowed to react at 37 °C for 20 min.

Radiochemical Analysis. The labeling efficiency of the radiolabeled products was followed for up to 6 h postlabeling and determined by analytical RP-HPLC. Elution was performed with a solvent system consisting of 0.1% TFA in water (solvent A) and 0.1% TFA in methanol (solvent B), by applying the following gradient: from 0% to 80% solvent B (1−20 min), 80% solvent B (20−23 min), 80% to 0% solvent B (23−25 min), and 0% solvent B (25−30 min) at a flow rate of 1 mL/min. The eluent was passed through a UV detector at 220 nm and through a sodium iodide scintillation detector, both connected to a computer for data analysis and storage.

The ^{99m}Tc$^{(V)}$O gluconate precursor and radioactive BN derivatives were also analyzed by ITLC on Silica Gel (ITLC-SG) strips. Briefly, 5 μL of the reaction mixtures were applied on two different strips (13 cm × 1 cm) of SG paper (application point: 2 cm from the bottom). The radiochromatographs were developed in saline (0.9% NaCl) and methylethyketone (MEK), respectively, over a distance of 10 cm. After drying, the radioactivity of the strips was measured by electronic autoradiography. When normal saline was used, the radioactive complexes migrated with the solvent front, while using MEK they remained at the application point.

Lipophilicity: log *D* Values. To a solution containing 500 μL of *n*-octanol and 500 μL of phosphate-buffered saline (PBS, pH 7.4), 10 μL of each radiolabeled BN derivative was added. The resulting solution was vortexed and centrifuged at 810*g* at 4 °C for 10 min. An aliquot of both saline and octanol layers was collected, and the activity was measured in a γ-counter. The log *D* value was calculated as the log ratio of the radioactivity in the organic and aqueous phases (mean of three samples).

Cell Culture. Human androgen-independent prostate cancer cells (PC-3) were grown in DMEM Glutamax-I, supplemented with 10% (v/v) fetal bovine serum (FBS), 1% L-glutamine, and 1% penicillin/streptomycin. Cells were incubated in a controlled humidified atmosphere containing 5% CO_2 at 37 °C and were subcultured weekly after being detached from the flask surface by trypsin/EDTA solution (0.25%).

Metabolic Stability. *(I) Human Plasma and PC-3 Cell Culture.* The metabolic stability of the radiolabeled BN derivatives was studied in human plasma as well as in PC-3 cell culture. A blood sample from healthy donors in heparinized polypropylene tubes was immediately centrifuged at 2240*g* at 4 °C for 10 min, and the supernatant (plasma) was collected. One hundred microliters (3.7−7.4 MBq or 100−200 μCi) of each radiolabeled BN derivative was incubated with 900 μL of plasma at 37 °C. Fractions were withdrawn at 5, 15, 30, and 120 min, treated with ethanol (2:1 EtOH/aliquot, v/v) (*39*), centrifuged at 16 000*g* at 4 °C for 20 min, filtered through a Millipore GV (0.22 μm) filter, and analyzed by RP-HPLC as described above. *In vitro* degradation in cell culture was studied by incubation of 450 μL of a PC-3 cell suspension (2−2.5 × 10^6/mL) with 50 μL (3.7−7.4 MBq or 100−200 μCi) of each radiolabeled BN derivative at 37 °C. After incubation, fractions were withdrawn at 5, 15, and 30 min and treated with 1:1 acetonitrile/ethanol containing TFA (0.01%) (3:1 CH_3CN/EtOH/aliquot, v/v) (*10*). The mixture was centrifuged at 16 000*g* at 4 °C for 20 min, filtered, and analyzed by RP-HPLC.

(II) Kidney and Liver Homogenates. The metabolic stability was evaluated by incubation of each radiolabeled BN derivative in homogenized mouse liver and kidney samples at 37 °C. Liver

or kidneys were extracted from mice, rapidly rinsed with cold water, and immersed in 500 μL of chilled 50 mM Tris/0.2 M sucrose buffer, pH 7.4, where they were homogenized. Aliquots of 50 μL of each radiolabeled BN derivative (3.7−7.4 MBq or 100−200 μCi) were added to ca. 450 μL of tissue homogenates, containing the same amount of protein as this was determined by a colorimetric method using a BCA protein assay reagent (Pierce, Rockford, IL). Fractions withdrawn at 5 and 15 min were treated with ethanol (2:1 EtOH/aliquot, v/v) (*40*), centrifuged at 16 000*g* at 4 °C for 20 min, filtered through Millipore GV (0.22 μm) filter, and analyzed by RP-HPLC.

In Vitro Cell Binding Studies. The IC_{50} values of the new BN derivatives were assessed by a competitive cell binding assay utilizing [^{125}I-Tyr^4]BN as the GRPR specific radioligand and [Tyr^4]BN as a control compound. PC-3 cells suspended in a medium containing 1% FBS, 0.125% BSA, 0.25 mM PMSF, 1 μg/mL aprotinin, and 50 μg/L bacitracin were distributed in 24-well plates and incubated at 37 °C for 1 h in the presence of 25 000 cpm ^{125}I-[Tyr^4]BN (2200 Ci/mmol) and increasing concentrations of each BN derivative or its complex with nonradioactive $^{185/187}$Re, ranging from 10^{-12} to 10^{-6} M. In this assay, [Tyr^4]BN was used as the control peptide. After incubation, the cells were washed twice with cold wash buffer and lysed with 1 N NaOH. Radioactivity bound to the cells was counted in a γ-counter. IC_{50} values were calculated by nonlinear regression analysis, using the GraphPad Software (San Diego, CA, USA) Prism 4 computer fitting program. Experiments were carried out three times in duplicate.

Internalization and Efflux Analysis. For the *in vitro* internalization analyses, PC-3 cells were distributed in six-well plates (1−1.5 × 10^6 cells per well) at 37 °C in 5%CO_2/air atmosphere overnight in culture medium (DMEM with 10% FBS, L-glutamine, and 1% penicillin/streptomycin). On the day of the experiment, the medium was removed, and the cells were washed twice with cold wash buffer and were incubated in 1.2 mL of internalization medium (DMEM containing 1% FBS) in the presence of 100 000−300 000 cpm of each radiolabeled BN derivative (in 150 μL of 0.5% BSA/PBS buffer corresponding to ∼200 fmol of total peptide) at 37 °C for 5, 15, 30, 60, 90, and 120 min. Specificity of internalization was evaluated in the presence of 1 μM unlabeled native BN. Upon completion of the incubation, cells were washed twice with cold PBS to discard unbound peptide. Surface bound activity was removed by washing the cells twice for 5 min each time with an acid wash (50 mM glycine−HCl/0.1 M NaCl buffer, pH 2.8). The amount of internalized peptides was recovered by solubilizing the cells with 1 N NaOH at 37 °C. The internalized radioactivity (% of total added) was determined using a multisample γ-counter system.

Externalization studies of the maximum internalized radioactivity were also performed after a 30 min internalization period. The medium was discarded, and the cells were washed three times with cold buffer. New medium was added, and the cells were incubated at 37 °C. Sampling at 0, 15, 30, 60, and 90 min postinternalization was performed by an initial cold buffer wash of the cells, followed by acid wash (for removal of surface bound activity), as previously described, and finally by treatment with 1 N NaOH to extract the radioactivity remaining trapped. Results are expressed as the percentage of total bound activity for each time point. Internalized and remaining radioactivity were calculated as a function of time by using a Microsoft Excel program.

Biodistribution Analysis in Normal Swiss Mice. The *in vivo* behavior was studied in normal female Swiss mice (average weight 20 ± 2 g) by injecting 100 μL (50−75 ng/100 μL) (5.5 MBq or ∼0.15 mCi) of each radiolabeled BN derivative, diluted in saline (pH 7.0), via the tail vein. Animals were sacrificed at predetermined time intervals of 15, 30, 60, and 120 min postinjection (p.i.), and the main organs were removed, weighed, and counted, together with samples of blood, muscle, and urine, in a γ-counter system. In comparison to a standard of the injected solution, results were expressed as a percentage of the injected dose (%ID) per organ and per gram of each organ or tissue. For total blood radioactivity calculation, blood is assumed to be 7% of the total body weight. Receptor blocking studies were also carried out with coadministration of an excess amount (100 μL, 1 mg/mL) of native BN. Animals were sacrificed 30 min postinjection, and the tissues were removed, weighed, and counted as previously described. *In vivo* studies were performed in compliance with the European legislation for animal welfare. All animal protocols have been approved by the Hellenic Authorities.

Biodistribution Analysis in PC-3 Tumor Bearing SCID Mice. For the implantation of tumors, PC-3 cells freshly suspended in medium were subcutaneously injected in the left front flank at a concentration of 10^7 cells/animal. Tumors were allowed to grow for two to three weeks. Animals were fed with autoclaved rodent food and water *ad libitum* before and during the time of tumor growth. On the day of assay, the mice were injected via the tail vein with 100 μL of a solution of each radiolabeled BN derivative in saline, pH 7.0 (7.4 MBq or ∼0.2 mCi corresponding to 100−125 ng of total peptide), and were sacrificed at 30 and 60 min p.i. [BN (I)] and at 30, 60, and 120 min p.i. [BN (II)]. For the determination of nonspecific uptake, blocking experiments were performed, in which three mice received excess amounts of native BN (100 μL, 1 mg/mL) along with the radiolabeled BN derivatives and sacrificed at 30 min postinjection.

Dynamic γ-Camera Imaging. Evaluation of the novel SPECT radiolabeled BN derivatives was performed by dynamic imaging studies using a high resolution dedicated small animal γ-camera. Tumor-bearing mice were anaesthetized with 100 μL of 10% xylazine and 5% ketamine, 10 mg/kg mouse body weight prior to scanning, and positioned to the animal bed. One hundred microliters of approximately 7.4 MBq (∼0.2 mCi) of BN (II) was administered through the tail-vein prior to anesthesia. These imaging studies of 10 min per frame were performed up to 120 min p.i.

Statistical Analysis. All data are expressed as the mean of values ± standard deviation (mean ± SD). Data comparison was performed by using Student's *t*-test. $P < 0.05$ was considered significantly different.

RESULTS

Synthesis and Characterization. Synthesis of the two new BN derivatives was performed following an Fmoc-based SPPS protocol. The BN derivative without spacer [BN (I)] was obtained at a yield of about 40%. The introduction of the spacer Orn-Orn-Orn [BN (II)] led to a significant reduction in the yield. Thus, <10% of [BN (II)] was obtained. The chemical purity was higher than 95% for both derivatives, as determined by analytical RP-HPLC. Both derivatives were characterized with MS-ESI (Table 1).

Conjugation of $^{185/187}$Re$^{(V)}$O-N$_3$S-BN Derivatives (Nonradioactive Complexes). The nonradioactive complexes of the two new crude BN derivatives obtained after the exchange ligand reaction were purified by semipreparative RP-HPLC and characterized by analytical RP-HPLC and ESI-MS (Table 1). The retention times of the $^{185/187}$Re-$^{(V)}$ON$_3$S-BN derivatives, compared to those of the respective radioactive complexes, were similar after their co-injection into RP-HPLC, confirming that $^{185/187}$Re and ^{99m}Tc form complexes of similar structure (Table 2).

Table 1. Mass Spectra Analysis of the Pure BN Derivatives and of Their Complexes with Nonradioactive $^{185/187}$Re

N_3S-**X**-BN[2−14] derivative	molecular mass (calcd.) (Da)	molecular mass (found) (Da)
(I)	1725.9	1725.8 (*m/z*: 863.9, $[M + 2H]^{2+}$)
(II)	2068.4	2068.8 (*m/z*: 690.6, 1035.4 $[M + 3H]^{3+}$, $[M + 2H]^{2+}$)
$^{185/187}Re^{(V)}ON_3S$-**X**-BN[2−14] derivative	molecular mass (calcd.) (Da)	molecular mass (found) (Da)
(I)	1924.9	1925.6 (*m/z*: 963.8, $[M + 2H]^{2+}$)
(II)	2267.6	2268.0 (*m/z*: 757.0, 1135.0 $[M + 3H]^{3+}$, $[M + 2H]^{2+}$)

Table 2. Analytical Data of N_3S-X-BN[2−14] and log $D_{(O/W)}$ for Their ^{99m}Tc Derivatives[a]

$^{185/187}Re^{(V)}ON_3S$-**X**-BN[2−14] derivative	R_T[b] (min)	$^{99m}Tc^{(V)}ON_3S$-**X**-BN[2−14] derivative	R_T[b] (min)	log $D_{(o/w)}$[c] ± SD
(I)	15.8	(I)	16.1	−1.60 ± 0.03[d]
(II)	13.9	(II)	14.2	−1.72 ± 0.03[d]

[a] Elution system: flow 1 mL/min; A, 0.1% TFA/H_20; B, 0.1% TFA/MeOH. [b] R_T: retention time. [c] log $D_{(o/w)}$ partition coefficient between *n*-octanol and PBS (pH 7.4). [d] Significant differences ($p < 0.05$) between BN derivatives (I) and (II).

Radiolabeling−Radiochemical Analysis. Radiolabeling of the two new BN derivatives with ^{99m}Tc was performed by the preconjugation approach using the $Tc^{(V)}O$ gluconate precursor as an intermediate exchange ligand. A two-strip ITLC-SG method for the analysis of a precursor showed that no amount of either pertechnetate $^{99m}TcO_4$ or of colloidal ^{99m}Tc was present. The radiochemical yield for both BN derivatives was higher than 98%, providing a single radioactive species, as detected by both RP-HPLC and paper chromatography (ITLC-SG). The stability of the new derivatives, tested up to 6.0 h postlabeling, remained high (>90%). The RP-HPLC retention time of BN (I) was 16.1 min, whereas that of BN (II) was lower, 14.2 min, indicative of its higher hydrophilic nature (Table 2). The lipophilicity of the two radiolabeled BN derivatives under study was evaluated by determining the log *D* partition coefficient values between *n*-octanol to PBS, at pH 7.4 (Table 2).

Metabolic Stability. *(I) Human Plasma and PC-3 Cell Culture.* The rate of catabolism of both new ^{99m}Tc-labeled BN derivatives was higher in cell culture than in human plasma. After 120 min of incubation, the radiolabeled BN derivatives remained intact in human plasma at a percentage of 60%. After 30 min of incubation with PC-3 cells, ∼30% of the radioactivity corresponded to the intact BN (I), while ∼50% of BN derivative (II) was found still intact at the same time period. Thus, the spacer group Orn-Orn-Orn did not greatly affect plasma stability, while it slightly increased cell stability.

(II) Kidney and Liver Homogenates. Enzymatic degradation tested in kidney and liver homogenates was found to occur after just 5 min of incubation. Thus, in kidney homogenates, BN derivatives (I) and (II) remained intact >40% and >45%, respectively, the rest being metabolized to more hydrophilic species of lower retention times. Further incubation for 15 min led to a percentage of 20−30% intact peptide for both BN derivatives. Catabolism in liver was much faster in the case of BN (I), which, within 5 min of incubation, was almost totally degraded, while degradation rates of BN (II) were found to be substantially slower (Figure 2).

In Vitro Cell Binding Studies. The binding affinity of N_3S-X-BN[2−14] and of their $^{185/187}$Re complexes for the GRPR was evaluated in the human prostate adenocarcinoma cell line PC-3. A typical sigmoid curve for displacement of ^{125}I-[Tyr^4]BN from PC-3 cells as a function of increasing concentration of all five different cold ligands used was obtained. The determined IC_{50} values are summarized in Table 3. BN derivative (I) (with or without Re) was less efficient in inhibiting the binding of ^{125}I-[Tyr^4]BN on PC-3 cells than [Tyr^4]BN (control). BN (II) (free of or complexed with Re) showed better affinity than BN (I).

Internalization and Efflux Analysis. The grade of uptake (internalization) and efflux (externalization) as a function of time of the two radiolabeled BN derivatives under study was assessed in human cancer PC-3 cells at 37 °C, in the presence (blocking experiments) or absence of native BN. Figure 3 reports the results of this study. Within the first 30 min of incubation, the proportion of radioactivity migrating into the cells increased significantly and remained at this level for 2 h.

More specifically, relative to the cell-associated activity after 5 min of incubation, 34% of BN (I) and 66% of BN (II) were internalized, attaining a value of 78% and 88% after 120 min, respectively. Although the membrane-bound activity was rather similar between the two radiolabeled BN derivatives, the internalized activity related to the total added substantially differed from one derivative to the other with the value for BN (II) being almost 5-fold higher than that for BN (I) (Figure 3A). To evaluate the externalization of ^{99m}Tc-conjugates from PC-3 cells after 30 min of incubation, cells were washed with acid wash buffer, for removal of surface-bound activity and then were further incubated in the medium. Measurements up to 90 min postincubation showed that around 53% of BN (I) and 63% of BN (II) remained trapped in the cells (Figure 3B).

Biodistribution Analysis in Normal Swiss Mice. Comparative *in vivo* studies in physiological experimental models at 15, 30, 60, and 120 min postinjection for both studied derivatives are summarized in Figure 4. Both ^{99m}Tc-Bombesin derivatives demonstrated fast blood clearance with the blood levels of BN (II) [0.51 ± 0.06 and 0.16 ± 0.06 (%)ID/g)] being lower than those of the BN (I) [1.00 ± 0.17 and 0.46 ± 0.05 (%)ID/g)], at 60 and 120 min p.i., respectively. Statistical evaluation (*t*-test) of the data sets of the two studied BN derivatives at 60 and 120 min demonstrated *p*-values <0.01 and <0.001. No significant uptake or retention in the stomach was observed, indicating that there is minimal, if any, release of free $^{99m}TcO_4^-$ derived from *in vivo* degradation of ^{99m}Tc of the N_3S complex. Liver activity values were relatively low, compared to the activity accumulated at the other normal tissues and seem to correlate with the log *D* values (Table 2). Similar to that in the liver, intestinal uptake was relatively low. The predominant excretion route for both studied derivatives was via the kidneys to urine. The higher kidney retention found for BN (II) is attributed to the increase of the overall positive charge of this derivative due to the presence of ornithine. The GRPR-positive pancreas also showed high uptake, significantly inhibited by the coadministration of an excess amount of blocking agent, while for BN (II), accumulation was significantly higher [27.89 ± 7.78, 16.72 ± 3.57, and 10.26 ± 1.64 (%)ID/g] at 15, 30, and 60 min p.i. as compared to [13.38 ± 3.99, 9.49 ± 3.31, and 5.20 ± 3.88 (%)ID/g] of BN (I). Statistical evaluation (*t*-test) of the data sets of the two studied BN derivatives at 15, 30, and 60 min demonstrated *p*-values <0.05.

Biodistribution Analysis in PC-3 Tumor-Bearing SCID Mice. Both ^{99m}Tc-bombesin derivatives were further tested *in vivo* in PC-3 tumor-bearing mice. The results are presented in Table 4. Tumor sizes in this study varied from 0.1 to 0.5 g. The greater portion of the ^{99m}Tc-Bombesin derivatives cleared efficiently from the bloodstream within 60 min p.i., with blood values being 0.52 ± 0.05 and 1.07 ± 0.12 (%)ID/g for radiolabeled BN (I) and BN (II) derivatives, respectively. They were mainly excreted into the urine via the kidneys. Both BN (I) and BN (II) were capable of rapidly targeting the GRP

receptor positive tissues, that is, the pancreas as well as the PC-3 tumor, within 30 min p.i. [(11.08 ± 2.76, 4.56 ± 0.95) (%)ID/g for BN (I) and (11.07 ± 4.2, 5.23 ± 2.10) (%)ID/g for BN (II)]. Specificity of *in vivo* delivery of the two novel BN derivatives was demonstrated with blocking by coadministration of an excess amount of the nonradiolabeled native BN at 30 min p.i.. In this case, uptake in the pancreas and PC-3 tumor was found to be significantly reduced ($p < 0.05$). Comparative studies between the radiolabeled derivatives BN (I) and BN (II) at 60 min p.i., indicated distinct differences in the uptake in both receptor-rich organs. In particular, BN (I) showed a significant reduction of accumulation in the tumor (1.02 ± 0.18%ID/g) and pancreas (4.17 ± 0.99%ID/g) related to 30 min p.i. BN (II) showed a more favorable, statistically different biodistribution ($p < 0.01$), in the tumor (7.14 ± 0.87%ID/g) and pancreas (27.59 ± 6.86%ID/g) than BN (I). Tumor-to-nontarget ratios of BN (II) were also significantly higher than those of BN (I) for the organs and tissues examined (blood, muscles, liver, and kidneys) ($p < 0.05$) at 60 min p.i. Tumor retention of BN (II) was also observed at 120 min p.i. (7.92 ± 0.79%ID/g) demonstrating even higher tumor/blood ratios than that for 60 min p.i. ($p < 0.05$). Moreover, intestinal uptake of BN (II) reached a maximum at 120 min p.i. (6.75 ± 0.91%ID/g) while liver accumulation was relatively low at the same time point (2.62 ± 0.17%ID/g).

Dynamic γ-Camera Imaging. The localization of ^{99m}Tc-labeled BN (II) in PC-3 tumor-bearing mice exhibited considerably higher tumor uptake than radiolabeled BN (I). This was further evaluated by γ-ray scintigraphy. The PC-3 tumor at the right front flank was visible with clear contrast from the adjacent background as early as 10 min after injection and remained observable up to 120 min p.i. Prominent uptake was also observed in the kidneys. Clearance of the radioactivity through the urinary bladder was evident as well (Figure 5). In contrast, the same tumor was not visualized in another SCID mouse, which had received a high dose of native BN along with the radiolabeled BN (II) derivative (Figure 6).

DISCUSSION

Much attention has been recently focused on radiolabeled BN-like peptides with different types of metal chelators, peptide sequences, and spacer groups (*9, 41*). As far as the spacer attaching the ^{99m}Tc-chelating moiety onto the peptide is concerned, this may be just an inactive moiety not affecting the properties of the parent molecule, but it may also be a pharmacokinetic modifier, able to improve stability, binding affinity, internalization into the tumor cells and biodistribution (*42*). Suitable spacer groups include peptides (amino acids linked together) alone (*18−22*), nonpeptide groups (for example a hydrocarbon chain from 3 to 9 carbon atoms) (*16, 24, 34, 35*) or a combination of an aminoacid sequence and a nonpeptide spacer (*17, 23, 25, 32*).

In the framework of the present study, the new BN derivatives were prepared by the well-established technique of solid-phase peptide synthesis (SPPS). The radiolabeling of BN derivatives was accomplished by a transchelation reaction. Prior to reaction with the selected amino acid chelator, Gly-Gly-Cys, ^{99m}Tc was reduced and complexed with the labile gluconate ligand. Nonradioactive $^{185/187}Re$ complexes of the BN derivatives, used for structural characterization, were prepared by the same method, as Re and Tc are both elements of the VIIB row of the periodic table and display the same complexation chemistry. The claim that $^{185/187}Re$- and ^{99m}Tc-BN derivatives have the same structure was verified by their similar retention times after their co-injection in a RP-HPLC column. The radiolabeled BN derivatives (I) and (II) were easily obtained in a yield higher than 98%. These results are consistent with previous studies, which demonstrated that N_3S ligand systems form stable peptide conjugates, obtained in high yield and high specific activity by transchelation from rhenium or technetium (V) gluconate precursors (*16, 31*).

Stability assays were performed in order to evaluate whether spacer modifications were sufficient for maintaining the stability of the ^{99m}Tc-BN derivatives (I) and (II) *in vivo* to ensure efficient delivery of radioactivity at the target. The stability of these new BN derivatives was determined *in vitro* in human plasma, human prostate cancer PC-3 cells, and in liver and kidney homogenates. After incubation at 37 °C, a higher stability was observed in plasma, where both derivatives remained intact at a level of 60% after 120 min. It is worthwhile to mention that during the first crucial 15 min of incubation the percentage of intact BN (I) and (II) was about 80 and 70%, respectively. In contrast,

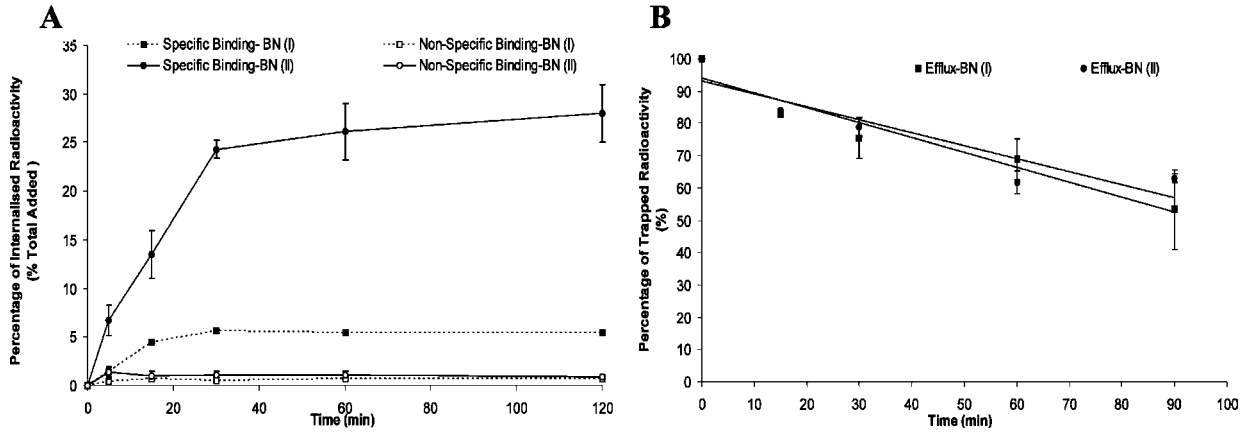

Figure 3. Internalization (A) and externalization (B) after maximum internalization (30 min of incubation at 37 °C) of the two $^{99m}Tc^{(V)}ON_3S$-**X**-BN[2−14] derivatives. Data represent the percentage of internalized and trapped radioactivity into the cells, in relation to the totally added radioactivity [BN (I), ■; BN (II), ●]. Vertical bars indicate standard deviation (SD). Results represent the mean of 2−3 experiments ± SD, each performed in triplicate.

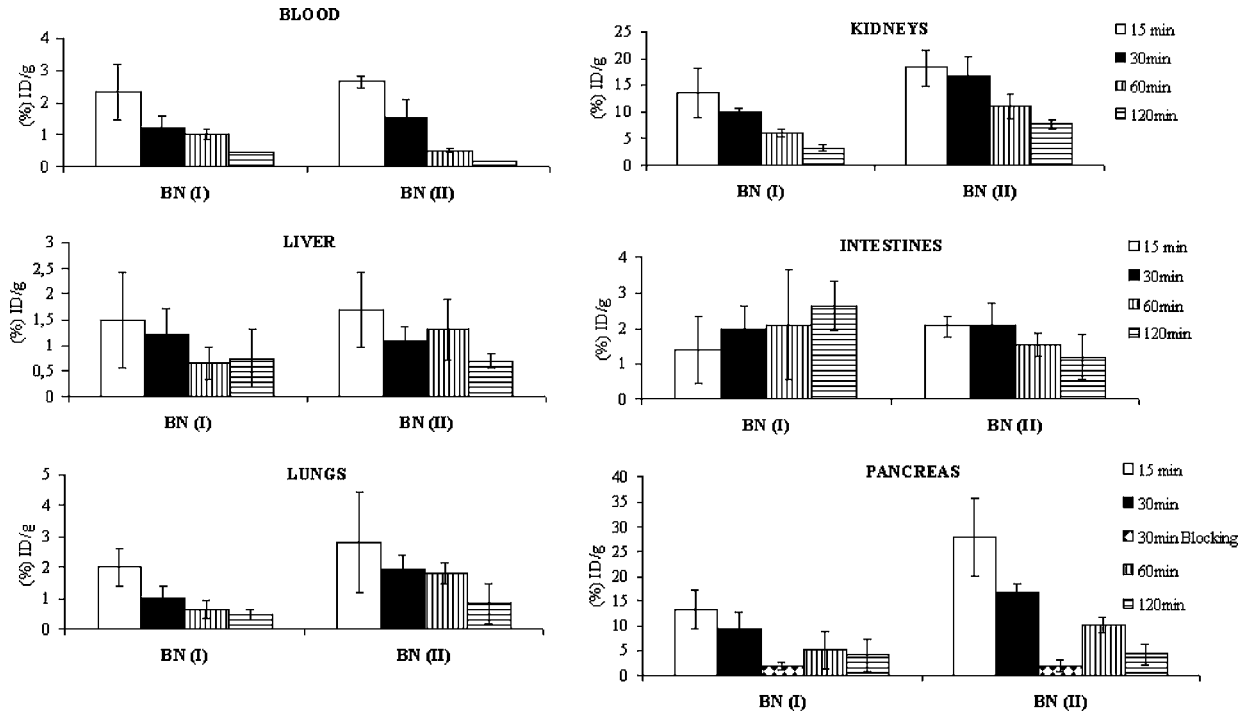

Figure 4. Comparative study of tissue or organ uptake for the two new $^{99m}Tc^{(V)}ON_3S$-X-BN[2−14] derivatives in normal Swiss mice at the time intervals of 15, 30, 60, and 120 min. Biodistribution values represent the mean ± standard deviation of %ID/g (3−5 animals were used per time point). Blocking studies were performed by coinjection of 3 animals with excess amounts of native BN.

the degradation was much faster in PC-3 cells, being more prominent for BN (I) than for BN (II). Nevertheless, a rapid catabolism in tumor cells would not necessarily be a problem, if the peptide is quickly internalized, and the metabolic products remain trapped inside the cell (*13*). However, even lower stability was found in liver and kidney homogenates with various metabolites of lower R_T values being formed, but in all cases, nondetectable technetium traces were released from the breakdown of the amino acid chelator ^{99m}Tc-Gly-Gly-Cys. Overall, results obtained during the metabolic stability study demonstrated that the insertion of the spacer group Orn-Orn-Orn seems to stabilize the resulting derivative (II) in cell culture and keep it more stable during exposure to the proteolytic action of liver enzymes. This is possibly due to the presence of the 3 nonnatural amino acids, which are not so easily recognized by the proteolytic liver enzymes.

The binding affinity of BN (I) and (II) for GRP receptors was in the nanomolar range, comparable to that of [Tyr^4]-BN and to those reported for Triaza-X-BBN (7−14) (X = SSS, GSG, GGG, and b-Ala) (*18*) and $Re(H_2O)(CO)_3$-Dpr-X-BBN (X = NNN, NNN-βAla, and NNN-5Ava) (*43*). The highest affinity among the tested BN derivatives was observed in the case of BN (II), while its complex with $^{185/187}$Re had the second better binding affinity for the GRPR. Once the radioactive BN derivative is residualized within cancer cells upon binding on the cell surface of GRPRs, then a specific delivery of diagnostic/therapeutic dose occurs. Experiments designed to determine the fraction of both studied ^{99m}Tc-derivatives internalized within the PC-3 cells showed that there were significant differences in the amount internalized for each of them at all time points. BN (II) showed a much higher degree and rate of internalization than BN (I). Even if the IC_{50} values of the unlabeled derivatives are similar, the internalization level of ^{99m}Tc-BN (I) is lower than ^{99m}Tc-BN (II). This discrepancy could be explained by the presence of the hydrophilic linker of Orn-Orn-Orn that leads to a final conformation of the whole complex of radioconjugate−

Table 4. Biodistribution Data of Radiolabeled BN (I) and (II) Derivatives in Female SCID Mice Bearing PC-3 Tumors[a]

[a] Results are expressed as the mean ± standard deviation of %ID/g (3 animals were used per time point). [b] Blocking study was performed by co-injecting 3 animals with an excess amount of native BN along with the radiolabeled BN derivative. [c] Statistical analysis with †,§p values and *,**$p <$ 0.05 being considered significantly different versus unblocked. [d] ND = not determined.

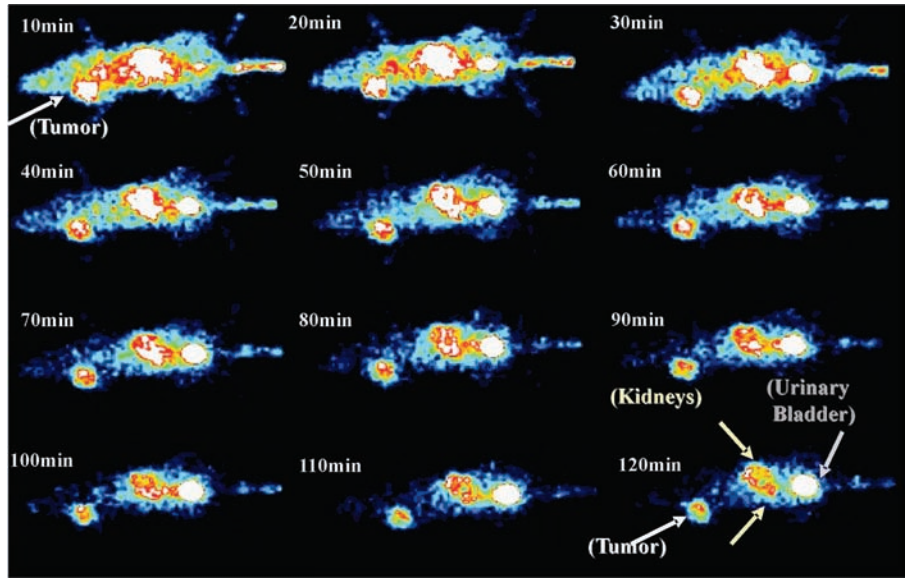

Figure 5. Gamma-ray dynamic images of 10 min per frame up to 120 min of a tumor bearing mouse for radiolabeled BN derivative (II). Arrows in white, yellow, and gray indicate the presence of the tumor, kidneys, and urinary bladder, respectively.

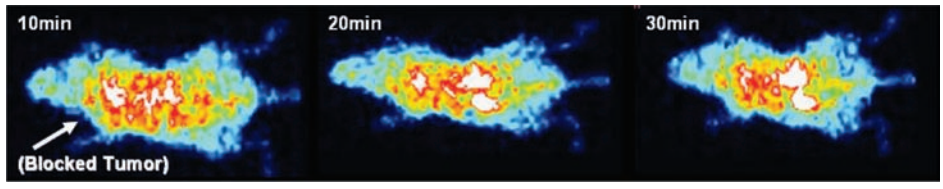

Figure 6. Gamma-ray dynamic images of 10 min per frame up to 30 min of a blocked tumor bearing mouse (PC-3 onto the right front flank) for radiolabeled BN (II). The arrow (in white) indicates the presence of the blocked tumor.

receptor, which probably induces penetration into the cells. This high level of internalization of BN (II) explains in part its superior *in vivo* properties compared to those of BN (I). Efflux studies indicated that the BN derivatives were rather rapidly released from PC-3 cells. Thus, about a half-for BN (I) and less than a half-for BN (II) of the internalized radioactivity was released in the first 90 min, probably due to the ability of functional intracellular proteases to degrade them. The rate of residualization of radioactivity inside cells is in accordance with other reports (*16*, *17*). In view of the design of radiolabeled BN peptides for therapy, new analogues should be developed with higher retention time into the cells.

An ideal pattern of biodistribution is one in which any radioactivity not bound to the receptive positive organ receptors or tumor is rapidly cleared from the blood and efficiently excreted without retention in any normal organ (*9*, *42*). In fact, during biodistribution studies in healthy mice, uptake in the pancreas of the derivative (II) from 15 to 60 min p.i. was higher than that of derivative (I). Clearance of radioactivity from the pancreas with time is probably due to excessive enzymatic

activity in this organ. Similar behavior has been reported for other ^{99m}Tc-labeled BN analogues such as ^{99m}Tc-Demobesin I (*39*) and [^{99m}Tc−P_2S_2]BN(7−14) (*44*). Specificity of the novel radiolabeled BN derivatives for the GRPR-rich healthy positive tissues (such as the pancreas) was confirmed by *in vivo* blocking after coadministration of native BN. The main clearance route of radioactivity for both derivatives was via the kidneys to urine. Although the changes in the linker sequence had a considerable effect on the reduction of liver accumulation, kidney values remained high enough, 7.73 ± 0.90% I.D./g, at 120 min p.i. for BN(II), while for the BN (I) derivative, they were 3.24 ± 0.57% I.D./g since more positively charged compounds are known to accumulate in the kidneys (*22*). However, an entirely renal route of excretion is preferable to a partly hepatobiliary clearance (*45*). Nonetheless, for prostate cancer radioimaging, there is high demand for achieving minimal accumulation of radioactivity in the abdominal area (intestines, stomach, liver, kidneys, and bladder). Thus, decreasing the lipophilicity of the radiolabeled BN derivatives serves to increase renal/urinary excretion, which is not preferable for detecting prostate tumors. Minimization of bladder interference can be achieved by several strategies such as differential timing of the images so as to highlight prostate gland and bladder drainage by means of an indwelling tube (*46*). In clinical practice, patients are asked to void the bladder before scintigraphy.

Results from the *in vivo* investigation in SCID mice, presented in Table 4 for BN (I) and (II), showed distinct differences in the biodistribution pattern of the two compounds in both receptor-positive and nontarget organs. Nevertheless, at the early time point of 30 min p.i., BN (I) showed tumor and pancreas uptake (4.56 ± 0.95 and 11.08 ± 2.76% I.D./g) values comparable to the corresponding values of BN (II) (5.23 ± 2.10 and 11.07 ± 4.2% I.D./g). The activity accumulated within the receptor-rich organs was quickly washed out at 60 min p.i. (1.02 ± 0.18 and 4.17 ± 0.99% I.D./g) for BN (I). However, a significant uptake of BN (II) in the GRPR-bearing tumor and pancreas was observed at 60 and 120 min p.i.. The greater accumulation of BN (II) in the pancreas may be explained by the higher receptor densities in this tissue in relation to the tumor and by the better penetration in the pancreatic acini cells in comparison to the weak vasculatory architecture of the PC-3 tumor (*47*). Receptor-bearing tissues, such as the tumor and pancreas present a relatively high uptake 30 to 60min p.i., with values remaining high up to 120 min p.i.. Pancreatic retention for BN (II) in SCID mice compared to that in normal mice is not fully understood. However, similar differences in the values of the pancreas concerning healthy animals and those with tumors have also been observed in a recent report by Faintuch et al., which compares ^{99m}Tc-HYNIC-BN with ^{99m}TcN(PNP6)-Cys-BN, and have been attributed to the different animal models used (*46*). Moreover, the washout of BN (II) from the PC-3 tumor is slow unlike its rate of externalization from PC-3 cells. This discrepancy may be due to the fact that the higher polarity of BN (II) probably favors pancreas and tumor penetration and retention (*48*). However, it should also be taken into consideration that the human tumor-bearing models are supported by murine vasculature architecture (*49*). It seems that the approach of using normal mice as a screening tool for GRPR targeted radiopharmaceuticals may be inadequate for predicting *in vivo* uptake in GRPR positive tumors (*25*). Furthermore, tumor to background ratios that are quite high at 60 min p.i. increased or remained constant at 120 min p.i. in the case of blood and muscles, respectively, illustrating a very good profile of BN (II) for GRPR targeted applications. GRPR specificity was confirmed by the receptor-blocking study at 30 min p.i. where the inhibition of uptake in these tissues was effective for both derivatives, by co-injection with a high dose of native bombesin. Similar trends were also observed for the other BN receptor positive organs, such as the intestines, where uptake of the radiolabeled BN derivatives was significantly reduced by coadministration of native bombesin (data not shown). It is also important to notice, as has already been mentioned in the case of healthy mice, that these modifications performed at the spacer site led to nonsignificant hepatic uptake and that the main clearance route of ^{99m}Tc radioactivity from the SCID mice is via the renal system. Nevertheless, the structure of spacer Orn-Orn-Orn did have an important effect on the retention of radioactivity in the kidneys of SCID mice, which was higher relative to what was observed with normal mice as also referred to by others (*25*). Obviously, this persistent kidney retention that the BN (II) derivative demonstrated is not optimal and is higher than that of BN (I). But as BN (II) has shown among the highest tumor and pancreas targeting efficacy of the ^{99m}Tc-BN conjugates of this type, following the Tc-labeled BN derivatives reported by Nock et al. (*39*) and Cescato et al. (*50*), this can be a problem only in the application of this compound for therapy due to potential nephrotoxicity (*25, 51*). To our knowledge, it may be possible to accelerate the wash out of BN (II) from kidneys by coadministration of polyornithine (more than 5 chain length), an approach that has been suggested in a previous report by Behe et al. (*52*), where uptake of ^{111}In-DTPA-DGlu^1-minigastrin in the kidneys was blocked by the use of polyglutamic acids.

A direct comparison of the tumor uptake observed for BN (I) and (II) with other publications using ^{99m}Tc-labeled bombesin derivatives is somehow difficult since in most of the reports, the C-terminal amidated BN(7−14) sequence or other stabilized forms of it were studied, while in the present study, the whole bombesin sequence is used. The full length sequence was proved by Gourni et al. (*35*) to lead to practically exclusive renal elimination. Radiochemical investigations of ^{99m}Tc(H_2O)(CO_3)-Dpr-SSS-BN(7−14) in PC-3 tumor-bearing mice by Smith et al. showed that tumor uptake was higher at 1 h p.i. (3.68 ± 0.92% I.D./g) than BN (I) and lower than BN (II) (*14*). The same group has also studied the pharmacokinetic properties of ^{99m}Tc(H_2O)(CO_3)-Dpr-NNN-βAla-BN(7−14) in PC-3 tumor-bearing mice, where two tumors were developed on the bilateral flank with accumulations of 2.79 ± 0.95% I.D./g and 3.28 ± 1.18% I.D./g at 1 h. p.i (*43*). Tumor uptake and retention were lower compared to ^{99m}Tc(H_2O)(CO_3)-Dpr-SSS-BN(7−14), which also seemed to be superior to ^{99m}Tc(H_2O)(CO_3)-Dpr-NNN-βAla-BN(7−14) for imaging prostate tumors. Results from the *in vivo* evaluation of ^{99m}Tc(CO_3)-pyrazolyl-X-BN(7−14) in SCID mice bearing xenografted human prostate PC-3 tumors by S. Alves et al. showed that maximum tumor uptake (1.76 ± 0.79% I.D./g and 1.76 ± 1.20% I.D./g) at 1 h p.i. for SSS and GGG linkers was higher when compared to that of BN (I) and lower than that of BN (II) (*16*). In a recent study with ^{99m}Tc(I)-BN derivatives consisting of different neutral or charged polar linkers (*53*), it was shown that by introducing a single negative charge in the form of β^3hGlu, the *in vivo* profile was improved exhibiting higher tumor uptake and retention. This general concept of inserting polar rather than lipophilic linkers, between the chelator and the binding sequence and ameliorating in this way the biodistribution pattern (higher tumor uptake and retention), has also been supported by our results as well as by a recent study of Garayoa et al. with ^{99m}Tc(CO)$_3$-glycated-BN derivatives (*48*). More specifically, ^{99m}Tc(I)-Ala(^{N}TG)-βAla-βAla-(Cha^{13}, Nle^{14})-BN(7−14) exhibited accumulation similar to that of BN (II) and higher than that of BN (I) at 30 min p.i. and a notable tumor localization at further studied time points.

The scintigraphic dynamic images obtained in SCID mice bearing human PC-prostate cancer tumors demonstrated an easy delineation of the neoplastic region by the BN (II) derivative

up to 120 min p.i.. At the same time, low background accumulation was observed, which is consistent with the biodistribution data and the tumor/tissue ratios reported.

CONCLUSIONS

Significant progress has been made over the past years in the development of new radiolabeled candidates for targeting peptide receptors, by separation of the radiolabeling area from the receptor-targeting peptide moiety. The structural tuning introduced in the N_3S-BN[2−14] derivatives, via the concept of modifications at the spacer site is very promising in order to visualize GRP receptors expressed at cell membranes of various tissues. Using Orn-Orn-Orn as a spacer compared to no spacer at all resulted in higher stability and greater internalization of the ^{99m}Tc-labeled species in cells, in a considerably better uptake in target-specific pancreatic and tumor tissue and finally in high-quality SPECT images. From previous studies, it is generally accepted that high and persistent localization of radioactivity in kidneys is caused by long residence times of radiometabolites generated after lysosomal degradation, following glomerular filtration and subsequent reabsorption into renal cells (*54*). On the basis of these findings, efforts are being made to inhibit tubular reabsorption of radiolabeled peptides by competitive blockage (*52*), charge modification with amino acid substitutions (*10*, *11*, *55*), and PEGylation (*22*, *56*). More wide-ranging modifications of the spacer are necessary to promote an efficient excretion of ^{99m}Tc-BN based radiopharmaceuticals of this type without significant retention in any normal organs such as the kidneys.

ACKNOWLEDGMENT

We thank Dr. Leondios Leondiadis for ESI-MS analyses performed at the Mass Spectrometry and Dioxin Analysis Lab, NCSR "Demokritos". The present work has been financially supported by the General Secretariat for Research and Technology.

Investigation of Novel Bis- and Tris-tetraazamacrocycles for Use in the Copper-64 (^{64}Cu) Radiolabeling of Antibodies with Potential To Increase the Therapeutic Index for Drug Targeting

Martalena Ramli,[§,†,‡] Suzanne V. Smith,*[,‡] and Leonard F. Lindoy[†]

Centre for Radioisotopes and Radiopharmaceuticals, Gd 11, Kawasan PUSPIPTEK, Serpong, Tangerang, Banten, 15314, Indonesia, School of Chemistry, F11, University of Sydney, 2006, Australia, and Australian Nuclear Science and Technology Organisation (ANSTO), PMB 1, Menai, NSW, 2234, Australia. Received August 6, 2008; Revised Manuscript Received April 3, 2009

The ^{64}Cu complexes of a series of mono-, bis-, and tris-tetraazamacrocycles have been prepared, and their stability in human sera has been assessed. The ligands forming the most stable Cu^{2+} complexes were then conjugated to the B72.3 antibody (mAb). Conditions for conjugation of the ligands to the mAb were optimized for the concentration of protein, ligand, pH, temperature, and time. The optimum moles of Cu^{2+} attached to the mAb were as high as 3.5 for **L2** and 5.5 or 2.7 for **L5**, and the immunoreactivity was ≥80%. Biodistribution of the radioimmunoconjugates showed good tumor localization and target-to-background ratios that were significantly enhanced compared to those achieved with monotetraazamacrocyclic derivatives.

INTRODUCTION

Over the years there has been considerable interest in the use of azamacrocycles and their derivatives for $^{67/64}$Cu-labeling of target agents, such as intact and fragmented antibodies and peptides (*1*−*15*). The tetraazamacrocycles and their polyaminocarboxylate and polyaminophosphonate derivatives are known to form thermodynamically stable complexes with Cu^{2+}. When radiolabeled with $^{64/67}Cu^{2+}$, serum stability studies and animal studies show that they are relatively stable under physiological conditions. Formation of their respective $^{64/67}Cu^{2+}$ complexes has been reported to be highly dependent on pH, temperature, ligand concentration, and reaction time. This variation is thought to be largely due to the concentrations of the radioisotopes being low (usually less than 10^{-6} M) and the pH (*5*). A comparison of the biodistribution behavior of selected $^{67/64}Cu^{2+}$ complexes of the tetraaza-, polyaminocarboxylate, and polyaminophosphonate ligand systems has shown that the charge and the lipophilicity of their respective Cu^{2+} complexes may also have an effect on their distribution in animals (*5, 16*).

The majority of the literature concerned with the use of azamacrocyclic derivatives for $^{64/67}Cu^{2+}$ radiolabeling of antibodies describe the use of polyaminocarboxylate macrocyclic derivatives, even though the unsubstituted tetraazamacrocycles have been reported to have a higher log *K* for Cu^{2+} and tend to show enhanced selectivity for Cu^{2+} over other biological cations (*9*). Zimmerman *et al*. compared a series of five bifunctional copper chelators, CPTA-*N*-hydroxysuccinimide, DO3A-L-*p*-isothiocyanatophenylalanine, DOTA-PA-L-*p*-isocyanatophenylalanine, DOTA-glycyl-L-*p*-isocyanatophenylalanine, and DOTA-triglycyl-L-*p*-isocyanatophenylalanine for $^{67/64}Cu^{2+}$ radiolabeling of the chimeric antibody, anti-L1-CAM antibody chCE7 (see Figure 1) (*17*). These workers found that the immunoreactivity and biodistribution of the final ^{67}Cu−mAb chCE7 conjugates were greatly affected by the type and number of ligands attached. Interestingly, they reported that the best tumor to normal tissue ratios were achieved using the unsubstituted azamacrocyclic system to form the ^{67}Cu-CPTA-labeled antibody.

Attempts to increase radioactivity at the target site in cancer therapy have involved various strategies that range from increasing the number of single metal-binding sites directly linked to a monoclonal antibody (mAb) (as mentioned above) to the deployment of streptavidin−biotin or "pre-targeting strategies" linking technologies (*18*−*21*). Unfortunately, increasing the number of ligands attached directly to the target agent often compromises the antibody immunoreactivity and the result of this approach can be highly variable from one antibody to another.

Two- and three-step linking strategies involving the streptavidin−biotin system can achieve faster blood clearance. Here the radiolabel is attached to either the streptavidin or the biotin. The smaller molecules clear more quickly compared to whole antibodies and can yield high target to background ratios more rapidly than the conventional approach. The design of such systems is also quite flexible and can be adapted to a wide range of diseases. However, the preferential clearance of the radiolabeled streptavidin via the kidney and of the biotin derivatives via the liver (due to the presence of biotin receptors) can result in undesirable high radiation dose to these organs.

We are interested in exploring the use of new multi-ligand systems for radiolabeling antibodies. Such systems provide an increased number of metal binding sites on the antibody without changing the number of attachment sites. A series of new mono-, bis-, and tris-ring macrocyclic bifunctional compounds of types **L1**−**L5** for use in radiolabeling monoclonal antibodies have been synthesized. (see Figure 2) (*22*). These new bis- and tris-cyclic ligands have the potential to yield radioimmunoconjugates with enhanced specific activities compared to corresponding single-ring systems, since two or three metal ions may potentially be attached via each linkage site on the mAb between the bifunctional compound and the mAb.

The present report describes the optimization of conditions for the formation of the 1:1 ^{64}Cu complexes of **L6**, **L7**, and

bution of the resultant ^{64}Cu radioimmunoconjugates was investigated in nude mice bearing the colorectal LS174t tumors.

EXPERIMENTAL PROCEDURES

Materials and Equipment. Unless otherwise mentioned, all materials were of analytical grade and used without further purification. B72.3 mAb was obtained from Bioquest, Australia. All water used for experimental purposes was Milli-Q grade. Radioisotope ^{64}Cu was supplied by the National Medical Cyclotron (Sydney), with specific activity of up to 1.4×10^{11} MBq/g. The protein assay kit was obtained from Bio-Rad. Protein absorbance was measured on a Bio-Rad plate reader. Silica-gel impregnated glass fiber sheet for instant thin layer chromatography (ITLC-SG) was purchased from Gelman Science. Immulon 2, 1×12 strips used for measuring immunoreactivity were obtained from Dynatech. Freeze-dried immunoconjugate was prepared on a Dynavac freeze-dryer. The HPLC apparatus (Waters) consisted of a 625 pump, a 625 controller, 484 absorbance detector fitted with a 50 μL sample loop (Rheodyne), a Bio-Sep-Sec S3000 (75 mm $\times$ 7.8 mm) guard, and a Bio-Sep-Sec S3000 300 mm $\times$ 7.8 mm column (Phenomenex). Vivaspin 500 (MCO 5.000) protein filter was used for purification of both the immunoconjugates and radioimmunoconjugates (Viva Science-Sartorius).

Formation of Complexes of Type ^{64}Cu−L (L = L6, L7, L8, L9, or L10). The effect of pH on the complexation of Cu^{2+} with L was investigated. Buffers at pH 3−8 were employed: 0.1 M glycine in 0.1 M sodium chloride (pH 3.0), 0.1 M succinate (pH 4.0), 0.1 M acetate buffer (pH 5.0), 0.1 M sodium phosphate (pH 6.0, 7.0, and 8.0). A typical complexation study involved dissolving a known ligand concentration ($\sim 10^{-6}$ M) in the chosen buffer solution and a known concentration of Cu^{2+} (doped with $^{64}Cu^{2+}$) in the same buffer. The molar ratios of metal ($^{64}Cu^{2+}/Cu^{2+}$) to ligand were respectively **L2**, **L7**, **L8** = 1; **L9** = 2; **L10** = 3. The reaction mixtures were then heated at 37 °C for 30 min. The formation of each complex was monitored by ITLC-SG using a method similar to that described previously (*10*).

Table 1. Mobile Phases Used for Monitoring the Formation of ^{64}Cu−L Complexes (where L = L6, L7, L8, L9, or L10)

		R_f	
ligand	eluent	^{64}Cu−L	$^{64}Cu^{2+}$
7 and **6**	0.15 M ammonium acetate, pH 6.5	<0.3	>0.9
8	water/conc ammonium hydroxide, 65:1	>0.9	<0.1
9 and **10**	0.1 M acetate buffer (pH 4.5)/ethanol, 9:1	<0.1	>0.9

In order to monitor the formation of the $[^{64}Cu-\mathbf{L6}]^{2+}$, $[^{64}Cu-\mathbf{L7}]^{2+}$, $[^{64}Cu-\mathbf{L8}]^{2+}$, $[^{64}Cu_2\text{-}\mathbf{L9}]^{2+}$, and $[^{64}Cu_3\text{-}\mathbf{L10}]^{4+}$ complexes, various mobile phases were investigated for the separation of the complexes from free ^{64} Cu^{2+}. Table 1 lists the observed optimum mobile conditions.

Stability of the ^{64}Cu−L Complexes in Human Serum. The stability of each complex of type ^{64}Cu−L in human serum was investigated. Typically the complex was diluted (1/10 v/v, pH 7.5) in human serum (0.22 μm filtered) and incubated at 37 °C. At set intervals (2, 24, 48, and 72 h) a sample (0.1 mL) was withdrawn and loaded onto a Sephadex-G25 size exclusion column [0.6 cm $\times$ 50 cm, which had been previously equilibrated with 0.01 M PBS, pH 7.2, and preblocked with 10% bovine serum albumin (400 μL)]. The column was eluted with 0.01 M PBS, pH 7.2. The elution of serum protein was monitored by an UV monitor (at 280 nm), and fractions (1 mL) were collected and monitored for radioactivity by a γ counter. The UV and radioactivity elution profiles were then overlaid. The percentage of radioactivity was associated with the protein and radioisotope complex determined.

Formation of the Immunoconjugate of L5−mAb. The conditions for conjugation of **L5** to mAb were optimized for reaction time, pH, concentration of antibody, molar ratio of EDC and molar ratio of ligand.

Two strategies were employed in these studies: (i) post-conjugation, where the $^{64}Cu^{2+}$−L complex of the bifunctional ligand was initially formed and then this product was conjugated to the protein and the efficiency of reaction was monitored over time; (ii) pre-conjugation, where the ligand was initially conjugated to the protein under various conditions (e.g., pH, concentration of mAb, molar ratio of EDC, and molar ratio of ligand) and the resultant conjugate radiolabeled with $^{64}Cu^{2+}$.

The formation of the immunoconjugate of **L5**−mAb using EDC was carried out according to a procedure recommended by the commercial supplier (*23*). Typically a freshly prepared EDC solution (dissolved in 0.1 M (2-[*N*-morpholino]ethanesulfonic acid)-NaCl, MES buffer) was added to mAb (in 0.1 M MES buffer). A solution of **L5** (in 0.1 M MES, buffer) was subsequently added to the above mixture. The reaction mixture was incubated at 37 °C for 30 min, after which time the resultant mixture was purified by washing (4×500 μL of 0.2 M acetate, pH 4.0, and followed by 3×500 μL of 0.1 M phosphate buffer, pH 7.2) on a protein filter (MCO, 5000). The purified immunoconjugate was recovered, and its protein concentration was then measured. The purified immunoconjugate (100 μg) was transferred to 2.5 mL vials and then freeze-dried.

The freeze-dried immunoconjugate, **L5**−mAb, was dissolved in water (250 μL). An excess of $^{64}Cu^{2+}$ solution (of known

concentration and specific activity) in 0.2 M succinate buffer (1/10, v/v), pH 4.0, was added to a solution of **L5**−mAb. The reaction mixture was incubated at 37 °C for 30 min, after which time the radioimmunoconjugate that had formed was purified by washing (5 × 500 μL of 0.2 M acetate, pH 4.0, followed by 3 × 500 μL of 0.1 M phosphate buffer, pH 7.2) on a protein filter (MCO, 5000). The purified radioimmunoconjugate was then quality controlled by ITLC (mobile phase, 0.01 M EDTA in PBS, pH 7.2) or size exclusion chromatography on Sephadex G-25 (eluted with 0.01 M PBS, pH 7.2). Radioactivity associated with protein was determined using a γ counter or dose calibrator. Protein concentration was determined using Bio-Rad protein assay. The amount of cross-linking of protein was determined using a BioSep column 3000 (eluted with 0.1 M PBS, pH 7.2).

The relative immunoreactivity was determined by comparing the immunoreactivity of the new radioimmunoconjugates with that of the ^{125}I−mAb. The mAb (similar to the one radiolabeled with ^{64}Cu) was radiolabeled with ^{125}I according to Fracker and Speck (*24*), resulting in one iodide per mAb. Two plates (Immulon 2, consisting of 6 × 12 strips) were then prepared; the first measured specific binding and the second non-specific binding. Serially diluted mucin from 4 to 2 ng/mL in 0.05 M PBS, pH 7.2 (100 μL/well), was added to the first plate. Glycine (control for non-specific binding) was plated in parallel onto the second plate. The plates were covered and incubated overnight at 4 °C. Each well was then washed with 0.05% Tween-20 in 0.05 M PBS, pH 7.2 (2 × 200 μL). The wells were blocked with 0.05% Tween-20 in 0.05 M PBS, pH 7.2 (200 μL), for 2 h at 37 °C, then washed with 0.05% Tween in 0.05 M PBS, pH 7.2 (3 × 200 μL). Standard (^{125}I−mAb) and ^{64}Cu−L−mAb solutions (100 μL), 4 μg/mL in 0.05% Tween-20 in 0.05 M PBS, pH 7.2, were added to the first three rows and to the second three rows of wells of each plate, respectively. The plates were incubated for 1.5 h at 37 °C before washing with 0.05% Tween-20 in 0.05 M PBS, pH 7.2 (3 × 200 μL). Finally, the plates were washed with 0.05 M PBS, pH 7.2, and shaken dry. The strips were then removed, and each was counted using a γ counter. Specific binding of the antibody was determined by subtracting the average counts for glycine from the average counts for mucine strips at the same concentration. A saturation curve, correlating absorbance with antigen (in this study it was mucine) concentration, was plotted. A comparison of the saturation curve, generated for standard antibody and test antibody, was used to assess the relative immunoreactivity.

Effect of Reaction Time (Post-conjugation). Typically, **L5** was complexed with $^{64}Cu^{2+}$ [the molar ratio of Cu^{2+}:**L5** was 2] in 0.2 M succinate buffer, pH 4.0, and the resultant complex $[^{64}Cu_2-\mathbf{L5}]^{4+}$ was then conjugated to mAb (3.5 mg/mL at a molar ratio of 23) using EDC as the activating agent (molar ratio of EDC/mAb was 572) in pH 5.0 buffer. The reaction was monitored for up to 2 h, sampling at 15, 30, 60, 120 min. The percentage of $[^{64}Cu_2-\mathbf{L5}]^{4+}$ associated with mAb was determined by size exclusion chromatography (Sephadex-G25 column), eluting with 0.1 M PBS, pH 7.2.

Effect of pH, Concentration of mAb, Molar Ratio of EDC, and Molar Ratio of Ligand to mAb (Preconjugation). Typically, all reactions were allowed to continue for up to 30 min at 37 °C. The resultant conjugated **L5**−mAb was purified and then radiolabeled with $^{64}Cu^{2+}$, and the resultant product was purified as described above. The percentage of $[^{64}Cu_2-\mathbf{L5}]^{4+}$ associated with mAb was determined by size exclusion chromatography on a Sephadex-G25 column (eluted with 0.1 M PBS, pH 7.2). The range of reaction conditions employed is summarized as follows. (i) For effect of pH, **L5** was conjugated to mAb (3.5 mg/mL) (molar ratio **L5**:mAb = 114) at pH 4.5, 5.0, 5.5, or 6.0 using a molar ratio of EDC:mAb of 572. (ii) For effect of mAb concentration, **L5** was conjugated to mAb employing various concentrations of the latter (1.7, 2.6, 3.5, and 4.4 mg/mL; molar ratio **L5**−mAb of 114) at pH 5.0 with a molar ratio of EDC:mAb of 572. (iii) For effect of molar ratio of EDC:mAb, **L5** was conjugated to mAb (3.5 mg/mL; molar ratio **L5**:mAb of 114) at pH 5.0 with varying molar ratio of EDC:mAb of 114, 228, 572, 1145. (iv) For effect of molar ratio of **L5**:mAb, **L5** was conjugated to mAb (3.5 mg/mL) using molar ratios of 23, 57, 114, 229 at pH 5.0, with molar ratio of EDC:mAb of 572.

The $^{64}Cu^{2+}$−**L6**−mAb and $^{64}Cu^{2+}$−**L7**−mAb were prepared using the optimum conditions developed in the previous studies using **L5**.

Non-specific Binding of $^{64}Cu^{2+}$ to mAb. Non-specific binding of $^{64}Cu^{2+}$ to mAb was determined by incubating mAb (30 μg) in 0.1 M phosphate buffer, pH 7 (125 μL), and 10-fold molar excess of ^{64}Cu solution in succinate buffer, pH 4.0 (1/10, v/v). The reaction mixture was incubated at 37 °C for 30 min. Any ^{64}Cu−mAb that might have formed as a result of nonspecific binding of $^{64}Cu^{2+}$ with mAb was monitored by ITLC (mobile phase with 0.01 M EDTA in 0.01 M PBS, pH 7.2).

Animal Studies. Animal studies were carried out with the approval of the Animal Care and Ethics Committee (ACEC) at ANSTO under protocol numbers 2002/164. Nu/nu and Balb/C mice were purchased from the University New South Wales (Australia). LS174T cells (human colon adenocarcinoma cell line) were purchased from the American Type Culture Collection (ATCC) and cultured at ANSTO. Nude mice aged between 6 and 8 weeks (females) were subcutaneous injected with 100 μL of a 1 × 10^7 LS174t cell/mL suspension in PBS. Tumors were allowed to grow to approximately 0.7 × 0.7 cm (over 2 weeks).

Radioimmunoconjugates ^{64}Cu−**L2**−mAb and ^{64}Cu−**L5**−mAb were prepared according to the optimal conditions described above. Typical specific activities were 20.6 MBq/mg [corresponding to 3.5 Cu^{2+} or 3.5 ligands per antibody for the ^{64}Cu−**L2**−mAb] and 30.5 MBq/mg [corresponding to 5.5 Cu^{2+} or 2.7 ligands per antibody ^{64}Cu−**L5**−mAb]. The solutions were diluted to approximately 6 MBq/mL in 0.9% saline, and the solution was filtered (0.22 μm) prior to injection into nude mice bearing LS174T tumors. Nude mice bearing LS174T tumors were injected with 100 μL of 0.60 MBq (on 29 μg protein) for ^{64}Cu−**L2**−mAb or 0.64 MBq (on 21 μg of mAb protein) for ^{64}Cu−**L5**−mAb. At the required time interval each mouse was anaesthetized with CO_2 for cardiac puncture and then sacrificed by cervical dislocation (three mice per time point). Individual mice were dissected, and the organs and selected tissues were removed and weighed. Associated radioactivity was determined using a γ counter. The percentage of the injected dose in each organ as well as the percentage of the injected dose per gram was calculated.

RESULTS

Complexation of $^{64}Cu^{2+}$ by L6−L10. The effect of pH on the formation of the ^{64}Cu−L (L = **L6**−**L10**) complexes is shown in Figure 3.

The complexation of $^{64}Cu^{2+}$ at pH 3.0 and 37 °C over 30 min by the mono-rings **L6** and **L7** only reached 70% and 81%, respectively. However, raising the pH of the reaction mixture to ≥4.0 resulted in complete complexation of the available $^{64}Cu^{2+}$. In contrast to the above, complete formation of ^{64}Cu−**L8** was not achieved at pH ≤ 7.0. At pH 6.0 only 25% of this complex was formed. The complete formation of ^{64}Cu−**L8** was achieved only at a pH ≥ 8.0

Incomplete formation of $^{64}Cu_2$−**L9** occurred over the pH range investigated after 30 min at 37 °C. At pH ≥ 4.0 it was found that only between 65% and 68% of the above species had formed. In contrast, the related mononuclear complex of

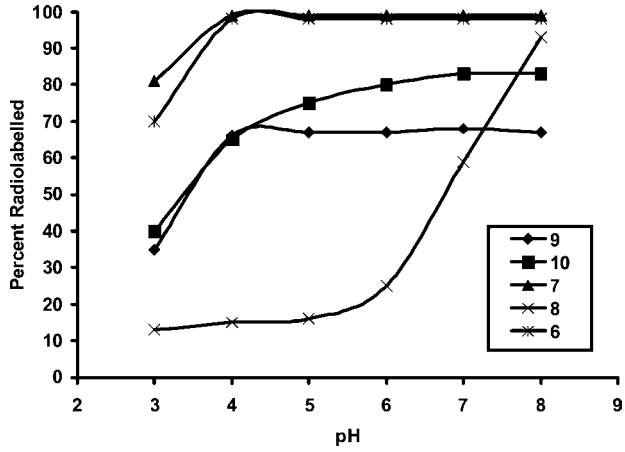

Figure 3. Percent of $^{64}Cu^{2+}$ complexed with various ligands at micromolar concentrations at 37 °C within 30 min. For additional information concerning copper-ligand loading under other conditions, see text.

the mono-ring ligand **L6** was formed in >95% under the same conditions. Complexation of $^{64}Cu_2$−**L9** at ≥95% was only achieved after the reaction mixture (pH 5.0) was heated at 50 °C for 1 h.

There was also no complete formation of $^{64}Cu_3$−**L10** when $^{64}Cu^{2+}$ was reacted with **L10** (at 37 °C for 30 min) in a 3:1 molar ratio over the range of pH values shown in Figure 3. At pH 3.0 only 40% of the metal is bound to **L10**. This percentage increased with increasing pH. By pH 4.0 the percentage of complex formed was 65. Nevertheless, by pH ≥ 8.0 complexation was still not complete, with only 83% of $^{64}Cu^{2+}$ bound.

Human Serum Stability Studies. The mono-ring complexes of types ^{64}Cu−**L6** and ^{64}Cu−**L7** were found to be stable in human serum over 72 h (≤0.5% loss of $^{64}Cu^{2+}$). However, the ^{64}Cu−**L8** complex was observed to break down rapidly in human serum. This is not surprising given that the formation constant (log K_1) for the complex of the unsubstituted parent of **L8,** dioxocyclam, is only 8.75 (*5*), whereas it is 27.2 for the Cu^{2+} complex of cyclam **(**1,4,8,11-tetraazacyclotetradecane), the parent compound for both **L6** and **L7**. Furthermore, the value for dioxocyclam with Cu^{2+} is significantly lower than for the Cu^{2+} complex of histidine (log K = 17.5). As a consequence, trans-metalation of $^{64}Cu^{2+}$ to serum protein is expected to proceed readily *in vivo*. Once complex is forced to >95% using the conditions described above, the resulting bis-Cu complex of **L9** is stable in serum. This stability was comparable to the complexes of the single ring systems **L6** and **L7** described above.

The behavior of the three-ring, ^{64}Cu complex of **L10** in human serum is not as straightforward as that of the above-mentioned complexes. As mentioned already, **L10** incorporates two different ring types (two "a" rings that are similar to the ring in **L6** and a "b" ring that is similar to the ring in **L8**) and only binds 83% of the $^{64}Cu^{2+}$ when reacted at pH 8.0 with **L10** in a 3:1 molar ratio. The complex formed can thus be expressed as $[^{64}Cu_n$−**L10**$]^{m+}$ where n is >2 but <3. As expected, the stability of this species in serum does appear to resemble that observed for a combination of ^{64}Cu−**L6** and ^{64}Cu−**L8**. Hence, for the reasons discussed above any loss of $^{64}Cu^{2+}$ from the complex is postulated to correspond to loss from ring "b".

When **L10** was reacted at pH 8.0 with 3 molar equivalents of $^{64}Cu^{2+}$, 83% of the $^{64}Cu^{2+}$ was taken up by this ligand. The complex formed can be expressed as $[^{64}Cu_n$−**L10**$]^{m+}$ where n is >2 and <3. The stability of this species in serum would be expected to resemble those for $[^{64}$Cu−**L8**$]^{2+}$ and $[^{64}$Cu−**L6**$]^{2+}$. For $[^{64}Cu_n$−**L10**$]^{m+}$ this seems to be the case. After 24 h of incubation, 20% of the $^{64}Cu^{2+}$ had been released from $[^{64}Cu_n$−**L10**$]^{m+}$. However, after 48 h, there was no further significant (within experimental error) amount of $^{64}Cu^{2+}$ released from this complex. Hence, any loss of total $^{64}Cu^{2+}$ from the complex is postulated to correspond to mainly loss of $^{64}Cu^{2+}$ originally bound to ring "b", again for the reasons discussed above (Table 2).

When **L10** was reacted with $^{64}Cu^{2+}$ (in 0.1 M succinate buffer, pH 4.0) in a 1:3 ratio, 65% of the $^{64}Cu^{2+}$ was taken up by **L10**, and it was assumed that the two "a" rings were the ones to participate in complex formation. When this complex was incubated in human serum there was only a nominal 2% of $^{64}Cu^{2+}$ released over the 24 h incubation time. Within experimental error, such a percentage is insignificant. No further release (≤0.5%) was observed to occur at the completion of the 72 h incubation time.

When $^{64}Cu^{2+}$ was reacted with **L10** in a 2:1 molar ratio, it was found that 98% of the $^{64}Cu^{2+}$ was bound to **L10** to form $[^{64}Cu_2$−**L10**$]^{4+}$ (in 0.1 M succinate buffer, pH 4.0). Again, within experimental error, this represents essentially complete uptake by two macrocyclic sites. When this complex was incubated in serum, it was found that there was no significant (≤0.5%) loss of $^{64}Cu^{2+}$ to the serum over 72 h. This is in accord with $^{64}Cu^{2+}$ binding to the two "a" rings, behavior that is in accord with that observed for **L6**.

Radiolabeling of Antibodies. *Effect of Reaction Time (Postconjugation).* Ligand **L5** was complexed with $^{64}Cu^{2+}$ in succinate buffer at pH 4.0, and the resultant complex was then conjugated to mAb using EDC in pH 5.0 buffer. The formation of **L5**−mAb conjugates was followed and analyzed at set intervals of 15, 30, 60, and 120 min. The percentage of $[^{64}Cu_2$−**L5**$]^{4+}$ associated with mAb reached 23% at 30 min, and no further significant change in the percentage of $[^{64}Cu_2$−**L5**$]^{4+}$ associated with mAb was noted after 120 min. Nakajima and Ikada (*27*) reported that EDC is stable at neutral and higher pH but will reduce to about 65% after 25 min in weakly acidic conditions (pH 4.0). This may explain why there was no increase in percentage of $[^{64}Cu_2$−**L5**$]^{4+}$ associated with the mAb after 30 min.

pH Employed for the Conjugation Reaction. The influence of pH on the formation of **L5**−mAb (subsequently quantified as the molar ratio of bound $^{64}Cu^{2+}$:mAb) is shown in Figure 4. The number of calculated ligands was based on the assumption that **L5** binds only two $^{64}Cu^{2+}$ ions. Over the pH range 4.0−6.0 no significant difference in the molar ratio of $^{64}Cu^{2+}$:mAb in the $^{64}Cu^{2+}$−**L5**−mAb conjugate occurred. The results also showed that there was no significant cross-linking of protein molecules.

The influence of mAb concentration on the formation of **L5**−mAb (subsequently quantified as the molar ratio of $^{64}Cu^{2+}$:mAb) (see Figure 5) and on any inter-antibody cross-linking

Table 2. Stabilities of the $[^{64}Cu_n$−L$]^{m+}$ Complexes in Human Serum (Indicated by the Percentage of $[^{64}Cu_n$−L$]^{m+}$ That Remains as an Intact Complex after the Listed Incubation Period)

molar ratio L/Cu			% $^{64}Cu^{2+}$−L complex remaining after the following incubation period				
L10	$^{64}Cu^{2+}$	pH	0 h	24 h	48 h	72 h	% ^{64}Cu lost from complex
1	3	8	83	63	63	63	20
1	3	4	65	62	62	62	3
1	2	4	98	98	98	98	0

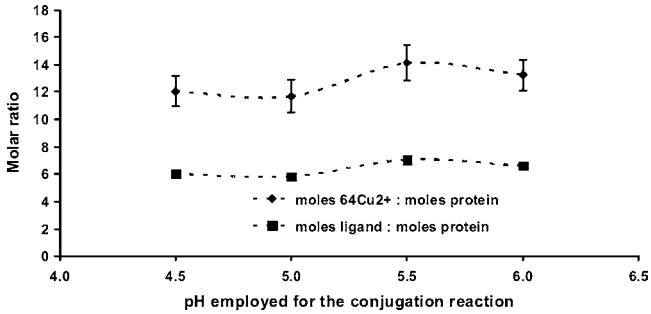

Figure 4. Effect of pH on the conjugation of **L5** to mAb. Reaction conditions are as follows: molar ratio mAb:EDC:**L5** = 1:572:114; [mAb] in the final reaction mixture, 3.5 mg/mL; 0.1 M MES buffer; reaction time, 30 min; temperature, 37 °C.

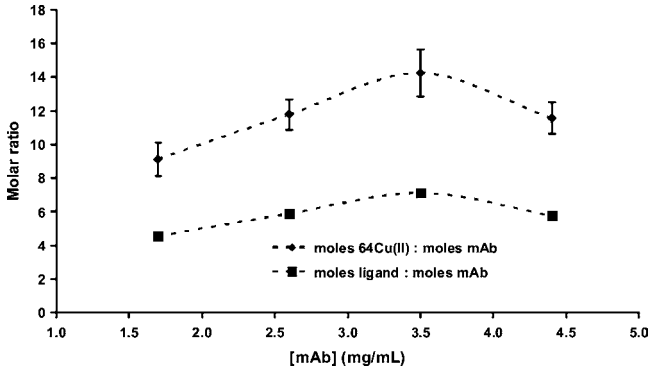

Figure 5. Effect of concentration of protein in the final reaction mixture on the formation of **L5**−mAb. Reaction conditions are as follows: molar ratio mAb:EDC:**L8** 71 = 1:572:114; reaction time, 30 min; 0.1 M MES buffer, pH 5.0; temperature, 37 °C.

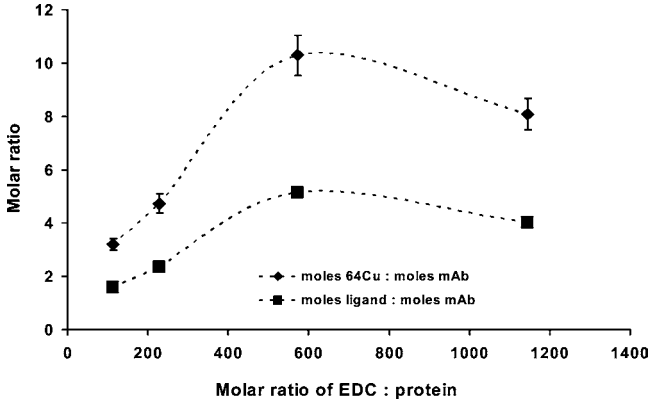

Figure 6. Effect of the molar ratio of EDC:mAb on the formation of **L5**−mAb. Reaction conditions are as follows: molar ratio mAb:**L5** = 1:114; [mAb] in the final reaction mixture, 3.5 mg/mL; reaction time, 30 min; 0.1 M MES buffer, pH 5.0.

was investigated by HPLC. Data show a slight increase in the molar ratio of $^{64}Cu^{2+}$:mAb when the mAb concentration was increased from 1.7 to 2.6 mg/mL but no further change at 3.5 mg/mL, and higher concentrations were observed. The inter-antibody cross-linking was <3% for all concentrations except at 4.4 mg/mL where it was ≤6%.

The influence of the molar ratio of EDC to mAb on the formation of **L5**−mAb is shown in Figure 6. Efficiency of radiolabeling increased significantly as the EDC molar ratio to protein increased from 114 to 572, with a slight decrease at 1145. Inter-antibody cross-linking remained low at <4% for all EDC:protein ratios except at 1145 where it increased (>5%), which explains the apparent decrease in radiolabeling efficiency at the higher EDC ratio.

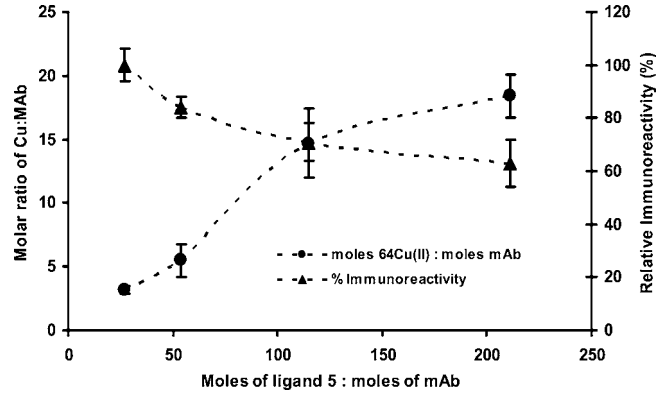

Figure 7. Influence of molar ratio of ligand **5**:moles of mAb on the formation of **L5**−mAb. Reaction conditions are as follows: molar ratio mAb:EDC = 1:572; [mAb] in the final reaction mixture, 3.5 mg/mL; reaction time, 30 min; 0.1 M MES buffer, pH 5 at 37 °C.

*Effect of Molar Ratio of Ligand **L5**:mAb on the Formation of **L5**−mAb.* Figure 7 summarizes the influence of the molar ratio of **L5**:mAb on the formation of **L5**−mAb. As expected, the molar ratio of $^{64}Cu^{2+}$:mAb increased with an increase in the moles of ligand **5**:moles of mAb ratio in the conjugation reaction. The immunoreactivity of ^{64}Cu−**L5**−mAb with a molar ratio of $^{64}Cu^{2+}$:mAb < 5.5 (corresponding to approximately 2.7 ligands per mAb) was found to be satisfactory (>80%). When the ratio of $^{64}Cu^{2+}$:mAb was >14 (corresponding to approximately 7 ligands:mAb), the immunoreactivity of ^{64}Cu−**L5**−mAb was substantially reduced (≤71%) and was not considered acceptable for *in vivo* studies.

Once the optimum conditions for the formation of **L5**−mAb were established, they were applied to the production of the **L1**−mAb and **L2**−mAb immunoconjugates. That is, **L1** and **L2** were reacted with the mAb at the molar ratio of mAb:ligand:EDC = 1:57:572. The concentration of mAb was fixed to 3.5 mg/mL, and the reaction was allowed to continue for 30 min in 0.1 M MES, pH 5.0 and 37 °C. The final products were isolated and characterized by HPLC; the ratios of purified $^{64}Cu^{2+}$:mAb were found to be 3.0 ± 0.3 and 3.4 ± 0.3 for **L1**−mAb and **L2**−mAb, respectively. Immunoreactivity for the radioimmunoconjugates was satisfactory (>80%), and as a result, they were selected for further evaluation in tumor bearing mice.

Biodistribution of Radioimmunoconjugates. The resultant specific activity for ^{64}Cu−**L2**−mAb was 20.6 MBq/mg which corresponds to 3.5 Cu^{2+} (or 3.5 ligands) per antibody. The specific activity for ^{64}Cu−**L5**−mAb was considerably higher at 30.5 MBq/mg, which corresponds to 5.5 Cu^{2+} (or 2.7 ligands) per antibody. Solutions of each ^{64}Cu radioimmunoconjugate were then diluted with 0.9% saline solution to approximately 6 MBq/mL, and 100 uL of this solution was injected into each nude mouse. The biodistribution of ^{64}Cu−**L2**−mAb and ^{64}Cu−**L5**−mAb in LS174T tumor-bearing nude mice is presented in Figure 8.

The primary objective of the animal studies was to assess whether the ^{64}Cu−**L5**−mAb containing less **L5** ligands per antibody molecule but more $^{64}Cu^{2+}$ binding sites would have similar uptake to the ^{64}Cu−**L2**−mAb. In fact, the biodistribution studies clearly illustrate that the uptake of ^{64}Cu−**L2**−mAb in the tumor over the time interval investigated appears broadly similar to that observed for ^{64}Cu−**L5**−mAb. The total accumulated radioactivity at 24 and 48 h was 23.7 ± 4.3% ID/g and 35.3 ± 11.2% ID/g, respectively, for ^{64}Cu−**L2**−mAb and 20.6 ± 2.2% ID/g and 29.6 ± 1.1% ID/g for ^{64}Cu−**L5**−mAb. While the total activity at the tumor site for ^{64}Cu−**L5**−mAb is similar to that for ^{64}Cu−**L2**−mAb, the former achieves this uptake with only 70% of the antibody conjugate.

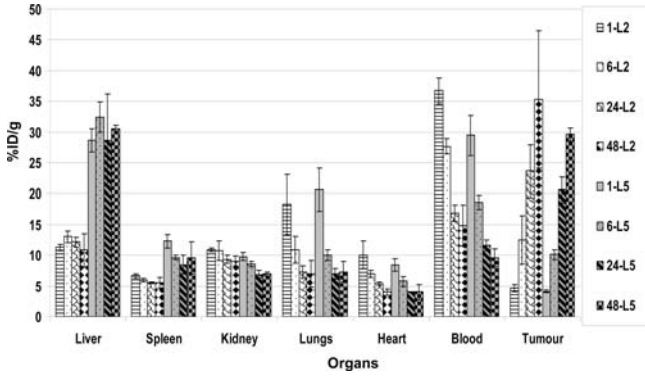

Figure 8. Biodistribution of ^{64}Cu−**L2**-mAB and ^{64}Cu−**L5**−mAb in nude mice bearing LS174T tumor.

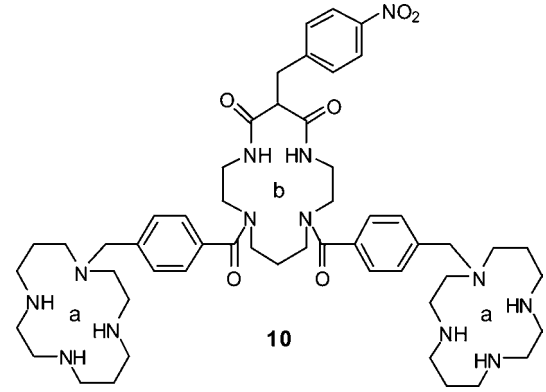

Figure 9. [13-(4-Nitrobenzyl)-4(11-(4-aminobenzoyl)-1,4,8,11-tetracyclotetradecane),8-(1-aminobenzoyl)-1,4,8,11-tetracyclotetradecane)]-1,4,8,11-tetracyclotetradecane-12,14-dione.

Examining the radioactivity remaining in the blood at 48 h indicates that the clearance of ^{64}Cu−**L5**−mAb (9.6 ± 1.5% ID/g) appears to be faster than that for ^{64}Cu−**L2**−mAb (14.6 ± 3.3% ID/g). The accumulation and retention of ^{64}Cu−**L5**−mAb (30.5 ± 0.6% ID/g at 48 h) in the liver were approximately 3-fold higher than for ^{64}Cu−**L2**−mAb (10.9 ± 2.7% ID/g at 48 h) over the time interval investigated.

DISCUSSION

The present study involves an investigation into whether tris- or bis-macrocyclic bifunctional ligands (i.e., **L5**, **L4**) are more efficient for radiolabeling an antibody compared to monomacrocyclic ligands (**L1**, **L2**, and **L3**). The complexation of the $^{64}Cu^{2+}$ with the ligands given in Figure 2 was investigated over a range of conditions (i.e., pH, buffer, and temperature) but all at equimolar concentration of M:L where L: represents the available binding site in the bifunctional ligand. The results showed that **L6** and **L7** complexed $^{64}Cu^{2+}$ efficiently (>95%) at >pH 4; however, complexation by **L8** was only efficient at >pH 8. This behavior is broadly similar to that observed for the (unsubstituted) parent compound of **L8** reported by Cutler *et al*. (*25*). Under related conditions these workers observed that only 25% complexation of the unsubstituted parent occurred at pH 5.5 at 37 °C after 1 h. This undoubtedly reflects the presence of the two amide groups in **L8**, since for strong complexation these groups need to be deprotonated. Thus, as found for the parent amide ligand, the formation of ^{64}Cu−**L8** in this study was found to be strongly pH dependent, with higher pH values required to promote complete complexation.

Complexation of $^{64}Cu_2$−**L9** was only achieved after the reaction mixture (pH 5.0) was heated at 50 °C for 1 h. Previous reports (*26*) have discussed the Cu^{2+} complexation behavior of the parent unsubstituted bis-macrocycle ligand **L9** and indicated that weak metal−metal communication is present that reflects the proximate locations of the Cu^{2+} ions. While statistical effects and charge repulsion considerations will result in weaker binding of copper in the second cavity of this ligand, these factors are likely to influence the non-complete complexation of two Cu^{2+} ions by **L9** under the conditions investigated in this study.

The three ring systems did not form the $^{64}Cu_3$−**L10** complex under any of the conditions investigated in this study. Maximum $^{64}Cu^{2+}$ labeling efficiency of 65% was achieved at pH 4, and at pH ≥ 8.0, 83% of **L10** was labeled. While statistical effects are expected to influence copper binding to the second and third rings in this case, inhibition of binding due to charge repulsion was expected to be negligible because of the considerably larger spacing of the three macrocyclic rings in **L10** compared to the two ring system in **L9**. By analogy with the formation of ^{64}Cu−**L6** and ^{64}Cu−**L8** (and the structures of the corresponding ligands) the two "a" rings in **L10** are expected to behave similarly to that in **L6** while the "b" ring is expected to be broadly similar to that in **L8** (see Figure 9). Hence, on the basis of the formation of ^{64}Cu−**L6**, it is expected that the two "a" rings of **L10** will dominate in binding $^{64}Cu^{2+}$ ions at lower pH values (such as at pH 4.0), and this was in accordance with the observed behavior. When **L10** was reacted with a 2 molar ratio of $^{64}Cu^{2+}$ (at pH 4.0, 37 °C for 30 min), it was found that 98% of the $^{64}Cu^{2+}$ bound under these conditions; that is, effectively complete binding had occurred. At higher pH values it is expected that the "b" ring might start to participate in coordinating $^{64}Cu^{2+}$. However, at pH ≥ 8.0 the percentage of $^{64}Cu^{2+}$ bound to **L10** had only increased marginally and, unlike the situation for **L8**, was found to be well short of the "ideal" value of ≥95%.

Collectively the complexation and serum stability results indicate that the mono-ring ligands **L6** and **L7** are suitable for use in radiolabeling mAbs with $^{64}Cu^{2+}$. Namely, these ligands bind $^{64}Cu^{2+}$ in a rapid manner at pH 4.0 and 37 °C (a pH value at which the formation of non-specific binding between $^{64}Cu^{2+}$ and mAb is not significant) as well as yielding stable $^{64}Cu^{2+}$ complexes in human serum. As the mono-ring complex of ^{64}Cu with **L8** was found to be rather unstable in human serum, its use was not pursued further for protein radiolabeling. While the double-ring **L9** yielded a ^{64}Cu complex that is stable in human serum, its formation was conducted at 50 °C. Such conditions were considered inappropriate for radiolabeling the mAb.

The complexation and serum stability collectively showed that only anilino derivatives **(L1**, **L2**, and **L5**) of **L4**, **L9**, and **L10** were appropriate for conjugating to the mAb. Hence, the conjugation of **L5** was optimized for a range of conditions (i.e., pH, concentration of EDC, mAb, and molar ratio of ligand to mAb). The optimum condition for the formation of **L5**−mAb was found to be a molar ratio of mAb:ligand:EDC = 1:57:572 and a mAb reaction concentration of 3.5 mg/mL. The reactions were conducted at pH 5.0 at 37 °C and found to be complete within 30 min. These conditions were also used for the production of the **L1**−mAb and **L2**−mAb immunoconjugates. Purified **L1**−mAb and **L2**−mAb were found (by HPLC) to have similar $^{64}Cu^{2+}$:mAb ratios ([3.0 and 3.4 (±0.3), respectively], and for **L5**−mAb they were ∼5.5 (corresponding to 2.7 ligands per mAb). Immunoreactivity for all radioimmunoconjugates was found to be satisfactory (>80%).

The primary objective of the animal studies was to assess whether the ^{64}Cu−**L5**−mAb containing less **L5** ligands per antibody molecule but more $^{64}Cu^{2+}$ binding sites would have similar uptake to the ^{64}Cu−**L2**−mAb. The biodistribution conducted over 48 h showed that the uptake of ^{64}Cu−**L2**−mAb in the tumor was similar to that observed for ^{64}Cu−**L5**−mAb.

The total accumulated radioactivity at 48 h was 35.3 ± 11.2% ID/g and 29.6 ± 1.1% ID/g, for ^{64}Cu−**L2**−mAb and ^{64}Cu−**L5**−mAb, respectively. While the total activity at the tumor site for ^{64}Cu−**L5**−mAb was similar to that for ^{64}Cu−**L2**−mAb, however, the former radioimmunoconjugate achieves this uptake with only 70% of the antibody conjugate. Clearance from all organs except the liver were comparable for these radioimmunoconjugates. The accumulation and retention of ^{64}Cu−**L5**−mAb in the liver were approximately 3-fold higher than for ^{64}Cu−**L2**−mAb over the time interval investigated. The clearance of ^{64}Cu−**L5**−mAb was found to be faster than that for ^{64}Cu−**L2**−mAb. There are a few factors that have been reported to influence the high uptake and slow clearance of radioabeled mAbs or peptides in organs such as the liver. These include the stability of the metal complex involved, the type of linker between the metal complex and the mAb, the charge on the metal complex, and the lipophilicity of the radioimmunoconjugate and/or radiometabolites (*5*, *28*−*33*). In this instance the high uptake and retention of radioactivity in the liver by the ^{64}Cu−**L5**−mAb is most probably a reflection of the increase in lipophilicity of **L5** compared to **L2**. The serum stability studies with the $[Cu_n-\mathbf{L5}]^{2n+}$ and $[Cu-\mathbf{L2}]^{2+}$ showed no significant breakdown (<0.5%) for both complexes over 72 h. The apparent stability of the ^{64}Cu−**L5**−mAb at the tumor site also supports the proposal that the ^{64}Cu−**L5** complex of this radioimmunconjugate is reasonably stable *in vivo*.

As the peptide bond generated in the synthesis of each of the radioimmunoconjugates, ^{64}Cu−**L5**−mAb and ^{64}Cu−**L2**−mAb, is the same, it is unlikely that the difference in the liver uptake reflects the presence of this linker type. The increased lipophilicity arising from the presence of phenyl group(s) has been suggested to aid a radioimmunoconjugate and/or a radiometabolite to be cleared preferentially via the liver (*32*). However, as the liver is also the natural site for bioaccumulation and metabolism of Cu^{2+}, it is the more likely rationale for the observed slow clearance of ^{64}Cu from the liver for both new radioimmunoconjugates.

Several classes of bifunctional chelators (from open chain to macrocyclic) have been used for radiolabeling mAbs with either ^{64}Cu or ^{67}Cu. A tetraazacarboxylate derivative, bat (Figure 1), has been used to radiolabel Lym-1 mAb with ^{67}Cu (*34*). While the animal models are quite different, the trends in behavior of the new ^{64}Cu radioimmunoconjugates relative to ^{67}Cu−bat lym-1 mAb *in vivo* are worth noting. For both ^{64}Cu−**L2**−mAb and ^{64}Cu−**L5**−mAb the tumor to blood ratios increased with time. The increases in this ratio for ^{64}Cu−**L2**−mAb and ^{64}Cu−**L5**−mAb at 24 and 48 h were found to be quite substantial (^{64}Cu−**L2**−mAb, 1.4 ± 0.4 at 24 h to 2.4 ± 1.3 at 48 h; ^{64}Cu−**L5**−mAb, 1.8 ± 0.3 at 24 h to 3.1 ± 0.6 at 48 h). Compared to the bat radioimmunoconjugate mentioned above, the present ^{64}Cu radioimmunoconjugates show greatly enhanced stability *in vivo*. This clearly reflects the increased kinetic stability of the tetraazamacrocyclic systems **L2** and **L5** compared to that of the tetraaza-substituted, tetraazacarboxylate derivative bat (*34*).

In summary, the results for the new ^{64}Cu radioimmunoconjugates, ^{64}Cu−**L2**−mAb and ^{64}Cu−**L5**−mAb, are in accord with greater uptake at the tumor site than occurs for the related systems mentioned above. They also show greater stability at the tumor site and higher tumor to blood ratios than those reported previously for the system incorporating the substituted tetraaza macrocycle, bat. Perhaps the most significant result of the present study is the similar uptake at the tumor site of ^{64}Cu−**L2**−mAb and of ^{64}Cu−**L5**−mAb. The latter achieved high tumor uptake with significantly less antibody and less chemical modification of the protein. This illustrates the potential of the new multiring tetraazamacrocycle system, **L5**, for generating higher specific radioimmunoconjugates.

Protein Delivery with Transportans Is Mediated by Caveolae Rather Than Flotillin-Dependent Pathways

Delivery of large bioactive cargoes into cells with the help of cell-penetrating peptides (CPPs) is mostly based on endocytic processes. Here we map the cellular pathways used by transportan and transportan 10 (TP10) for protein transduction in HeLa cells. CPP-mediated cellular delivery is often suggested to be lipid-raft-dependent; therefore, we used flotillin-1, caveolin, Rab5, and PI3P as markers to elucidate the involvement of these particular endosomal pathways in the protein uptake process. Confocal laser scanning and electron microscopy reveal only a negligible overlap of avidin/neutravidin conveyed into cells by transportans with the raft marker flotillin-1 or early endosomal markers Rab5 and PI3P. However, about 20% of protein−CPP complexes colocalize with the caveolar/caveosomal marker caveolin, and down-regulation of caveolin-1 by siRNA treatment leads to the inhibition of the CPP-mediated protein uptake by 30−50%. On the contrary, the lack of flotillin-1 increases rather than decreases the CPP-mediated protein transport. The participation of the caveolin-1-dependent pathway in CPP-mediated protein delivery was also corroborated by using caveolin-1 knockout mouse embryonic fibroblasts.

INTRODUCTION

The cellular transport of bioactive but low-permeable molecules using cell-penetrating peptides (CPPs) has been under intense investigation as an alternative mode for drug delivery for the past 15 years. During this period, the number of peptides with putative membrane-translocating abilities has grown dramatically and has also led to the broadening of the meaning of the term CPP toward less explicit characteristics (*1*). Currently CPP is considered a relatively short peptide being capable of gaining access to the cell interior by means of different mechanisms, including endocytosis, and having the capacity to promote the intracellular delivery of covalently or noncovalently attached bioactive cargoes. The main focus of CPP studies has now shifted to improving the specificity of targeting and characterization of the functionality of delivered cargo in cells. However, knowledge about the cell entry mechanism(s) is still of high importance, as the mode of internalization determines addressing of the cargo and thereby its residual activity.

Some CPPs are capable of using a nonvesicular cellular entry mechanism under certain conditions (*2*−*6*). However, in these studies the peptide was carrying a small cargo, a fluorescent tag (*2, 3, 6*) or a short peptide (*4, 5*), and the observed diffuse cellular staining, which is thought to reflect a nonvesicular internalization mode, was detected at high peptide concentrations or low temperature. Still, most peptide−cargo constructions, especially large ones, gain entry to the cell interior by inducing endocytic processes, i.e., within various types of plasma-membrane-derived vesicles (*7*−*9*). The rapidly accumulating knowledge about endocytosis mechanisms and intracellular targeting pathways also necessitates a more detailed analysis of routes involved in CPP-mediated cargo delivery and a better definition of the transport vesicles used.

CPPs as relatively unspecific ligands have been associated with many endocytosis routes. Clathrin-mediated endocytosis (CME[1]) is the most common for down-regulation of a variety of plasma membrane receptors. Although different receptors may utilize highly specifically regulated mechanisms, the CME seems to be the general route of uptake (*10*−*12*). Without the specification of the exact mode of CME, this pathway has been shown to be active in CPP-mediated cargo delivery in several experimental systems, although with different efficacy (*13, 14*). In addition, caveolae may participate in CPP-mediated cargo delivery. Caveolae are abundant in some cell types, and their functions extend from endocytosis to cell signaling (*15*). Interestingly, internalization of Tat-GFP fusion protein has been demonstrated to proceed using the caveolar pathway (*16, 17*) but has also been reported to use macropinocytosis (*7*). Macropinocytosis is initiated by certain stimuli (*18*), and it is reported that CPPs activate the cellular signaling cascades and subsequent macropinocytosis in analogy with growth factors as stimuli (*19, 20*). The least characterized/understood type of vesicular transport, clathrin- and caveolin-independent endocytic pathway, is active in pathogen internalization and also in some physiological processes. Simian virus 40 (SV40) has been shown to enter even caveolin-1 (Cav-1) knockout cells, which express dominant-negative Eps15 that interferes with the assembly of the clathrin-coated pits and the formation of caveolae. Accord-

ingly the internalization of SV40 is dependent on cholesterol, microtubules, and Arf1 (*21*). In addition, the internalization of cholera toxin B subunit (CtxB) is not inhibited in cells depleted of functional dynamin and Arf6, and it takes place by inducing formation of a tubular network that is not present in cells with active dynamin and Arf6 (*22*). The network formation was dependent on cholesterol (*22*), suggesting that lipid rafts play a significant role in this type of cellular trafficking. However, the lack of adequate methods for assessing the dynamics of lipids in membranes of living cells limits the studies to using mainly the raft-associated proteins (*23*). Recently, flotillin was suggested to be a membrane-organizing marker protein of lipid rafts. Endocytosis of CtxB subunit via flotillin-positive domains takes place independently of dynamin, and the formed vesicles do not contain proteins characteristic to CME or caveosomes (*24*).

We have described the cellular routing of complexes of transportan and TP10 with protein earlier based on morphological features of used endocytic vehicles (*8, 14*). However, we could not define the nature of a substantial fraction of vesicles that contained complexes of protein and transportan/TP10 by any of the used cellular markers and endocytic inhibitors (*8*). As the recently mapped flotillin-1-marked endocytic pathway and the CPP-mediated cellular delivery are both cholesterol-dependent and flotillin-1-defined membrane areas and endocytic vesicles do not overlap with the clathrin- or caveolin-dependent route (*24, 25*), we analyzed the cellular traffic of complexes of transportan/TP10 and avidin/neutravidin in relation to this novel lipid raft marker. We also included caveolin as a marker of specific type of membrane rafts in cells lacking the typical caveolae. The role of cholesterol rich membrane domains and the respective proteins in transportan/TP10-mediated protein was elucidated by down-regulation of flotillin-1 and caveolin-1 using siRNA. In addition, the cellular localization of complexes in relation to early endosomal markers Rab5 and phosphatidylinositol-3 phosphate (PI3P) was mapped in order to disclose the early steps of transportan-mediated delivery. Our data demonstrate that flotillin-containing lipid rafts do not participate in CPP-mediated delivery, and their absence rather increases translocation efficiency.

EXPERIMENTAL PROCEDURES

Reagents. For immunomicroscopy experiments, the following antibodies (Ab) were used: mouse monoclonal anti-PI3P (Echelon Biosciences, UT), rabbit polyclonal anticaveolin (cat no 610059, BD Transduction Laboratories, Belgium), anti-Rab5 (AbCam, UK), polyclonal antiflotillin-1 (Santa Cruz Biotechnology, Heidelberg, Germany), and mouse monoclonal anti-β1 integrin (anti-CD29, BD Transduction Laboratories). Alexa Fluor (AF) 488- or AF 594-conjugated antimouse and antirabbit antibodies, AF 594-conjugated transferrin and cholera toxin B subunit (CtxB), avidin−Texas Red, and Oligofectamine were bought from Invitrogen (UK). FITC-labeled avidin, saponin, and sodium thiosulfate pentahydrate were from Sigma-Aldrich and Nanogold-Fab′ fragments of goat antirabbit IgG and HQ Silver kit were purchased from Nanoprobes (Yaphank, NY). siRNA against flotillin-1 (sc-35391), caveolin-1 (sc-44202) and nonspecific siRNA (sc-37007) were acquired from Santa Cruz Biotechnology.

Peptide Synthesis. Transportan (GWTLNSAGYLLGKINLKALAALAKKIL-NH_2), TP10 (AGYLLGKINLKALAALAKKIL-NH_2), and pTat (GRKKRRQRRRPPQ-NH_2) were synthesized stepwise on a 0.1 mmol scale on an automated peptide synthesizer (Applied Biosystems Model 431A) using the *t*-Boc solid-phase peptide synthesis strategy. *tert*-Butyloxycarbonyl amino acids were coupled as hydroxybenzotriazole esters to a *p*-methylbenzylhydrylamine resin (Neosystem, Strasbourg, France) to obtain C-terminally amidated peptides. Biotin was coupled manually to the side chain of Lys13 or Lys7 in transportan and TP10, respectively, or to N-terminus of pTat. The final cleavage and purification of peptides was performed, as described earlier (*14*). The molecular weights of biotinylated peptides were determined by MALDI-TOF mass spectroscopy (prO-TOF 2000, PE Biosciences) and calculated molecular weights were obtained each time.

Cell Culture. Human cervical carcinoma cell line HeLa (ATCC CCL-2), wild type mouse (C57bl6/J) embryonic fibroblasts, and embryonic fibroblasts from caveolin-1 knockout 3T3 mouse (ATCC-CRL-2753) were cultured in a humidified atmosphere containing 5% CO_2 at 37 °C in Iscove's Modified Dulbecco's Medium (IMDM) (Gibco, Invitrogen, UK) supplemented with 10% fetal bovine serum (FBS) (PAA Laboratories, Austria), 100 IU/mL penicillin, and 100 μg/mL streptomycin (Gibco, Invitrogen, UK).

Confocal Laser Scanning Microscopy. An amount of 5×10^4 cells were seeded one day before experiments onto round glass coverslips (Ø 12 mm, Menzel-Glazer, Germany) on a 24-well plate. Cells were incubated with 0.15 μM Texas Red (TxR)- or FITC-labeled avidin and 0.5 μM biotinyl-CPP in 400 μL of serum-free IMDM at 37 °C for 30 min. Biotinylated transportan and TP10 were dissociated with 10 mg/mL leucine before formation of complexes with avidin in order to reduce the aggregation of peptides and the size of subsequently forming complexes. After incubation, the medium with CPP−avidin complexes was removed, the cells were rinsed twice with PBS and fixed for 2 h either with PLP fixative (2% paraformaldehyde, 75 mM lysine-HCl, and 10 mM sodium periodate in 75 mM phosphate buffer, pH 7.4) or with 4% paraformaldehyde for 30 min for staining with antibodies against flotillin-1/Rab5/β1-integrin or PI3P/caveolin, respectively. The cells were permeabilized either with 0.1% Triton X-100 (anticaveolin), 0.5% saponin (anti-PI3P) for 5 min, or with a solution of 0.01% saponin and 0.1% BSA in sodium phosphate buffer for 8 min, which also acted as a blocking solution (flotillin-1, Rab5, β1-integrin). Nonspecific binding sites were blocked with 10% w/v nonfat dry milk solution in PBS for 1 h (anticaveolin) or with 10% heat-inactivated goat serum (anti-PI3P). After treatment with the respective AF-labeled secondary antibodies, the coverslips were mounted in 30% glycerol in PBS.

For control experiments, AF 594-labeled transferrin and CtxB were applied to cells at 20 μg/mL and 3 μg/mL, respectively, for indicated time periods. For low temperature experiments, cells were precooled for 15 min followed by uptake of peptide−protein complexes/CtxB during 30 min on ice and treated for Flot-1 visualization as indicated above.

Images were obtained with Nikon EZ-Z1 confocal microscope using excitation at 488 nm (for Alexa Fluor 488) and 543 nm (for Texas Red, AF 594) or with Olympus IX81 inverted microscope equipped with FluoView 1000 confocal system using excitation at 488 nm (for AF 488) and 559 nm (for Texas Red, AF 594). In both cases the systems were run in sequential scanning mode, where only one laser was active at a time, to avoid spectral overlap. Obtained images were processed with Adobe Photoshop 7.0.

Down-Regulation of Flotillin-1 and Caveolin-1. An amount of 4×10^4 cells were seeded onto 12-well culture plates one day before siRNA transfections. Transfection was performed with duplex RNA oligonucleotides against flotillin-1 or caveolin-1, or nonspecific siRNA using Oligofectamine (Invitrogen), according to the manufacturer's instructions in two consecutive days. Concentrations of siRNA for single transfection were 0.1 μM for flotillin-1 (Flot-1) and nonspecific siRNA. Caveolin-1 (Cav-1) siRNA was applied at 0.1 and 0.2 μM on consecutive days. For the cotransfection of Flot-1 and Cav-1, the concentration of both siRNA was 0.1 μM per transfection. On day 4 the

cells were incubated 30 min in 700 μL of serum-free medium containing CPP−protein complexes at the same concentrations as in confocal microscopy experiments. The complex-treated cells were trypsinized (0.025% trypsin supplemented with 0.01% EDTA in PBS) for 10 min prior to FACS analysis to remove the membrane-bound but noninternalized avidin. The remaining extracellular fluorescence was quenched by addition of trypan blue into the cell suspension (final concentration 0.015%), and 3×10^4 cells were counted per sample. Measurements were performed in duplicates, and the results are presented as a mean of three separate experiments.

Western Blot. 10^5 HeLa cells were seeded onto six-well plates and treated with Flot-1 and/or Cav-1 siRNA at the same concentrations as described above. Forty eight hours after the second siRNA treatment, the cells were scraped off the dishes and pelleted by centrifugation, and the wet cell mass was weighed for determination of the protein amount. Cells were lysed in 2 × SDS sample buffer and sonicated, and 0.5 μg of protein per lane was separated on 15% SDS-PAGE. Proteins were transferred to polyvinyl difluoride (PVDF, Applied Biosystems) membrane, blocked in 5% solution of nonfat dry milk in PBS, and treated with primary antibodies against Cav, Flot-1 (0.5 and 0.4 μg/mL, respectively), or β-actin as internal control (0.6 μg/mL). After incubation with alkaline phosphatase (AP)-conjugated antirabbit (Flot-1, Cav) or antimouse (anti-β-actin) secondary antibody (1:2500), the protein bands were visualized with AP substrate BCIP/NBT treatment. Intensities of protein bands of specific size (47 kDa for Flot-1, 21−24 kDa for Cav, and 42 kDa for β-actin) were analyzed by Image J 1.38x.

Electron Microscopy. HeLa cells were seeded onto glass coverslips in 24-well plates and grown to 90−100% confluency. Cells were incubated with complexes of biotinylated transportan, TP10, or pTat and colloidal gold-labeled neutravidin at 37 °C for 1 h. CPP−protein complexes were preformed by incubating neutravidin−gold (*d* 10 nm, 1:100 or 1:200 dilution) (*8*) with biotinyl-CPP at room temperature in a minimal volume for 5 min. Solution with complexes was diluted with culture medium to a final peptide concentration of 1.5−3 μM according to experiment and applied to cells.

Pre-embedding Immunolabeling. The cells treated with CPP−neutravidin complexes were fixed for immunoelectron microscopy with PLP fixative at room temperature for 2 h and permeabilized with 0.01% saponin and 0.1% BSA in 0.1 M sodium phosphate buffer for 8 min. After permeabilization, the cells were incubated with anticaveolin (1:50) or antiflotillin-1 antibodies (1:30) for 1 h and treated with 1.4 nm nanogold-conjugated Fab′ fragments of secondary antibodies (1:60) for an additional 1 h. The nanogold label was magnified by silver enhancement according to manufacturer's protocol for 2−5 min, followed by gold-toning with 0.05% gold chloride (*26*). After postfixation with 1% osmium tetroxide in the 0.1 M sodium cacodylate buffer (pH 7.4), cells were dehydrated and embedded in epoxy resin. Ultrathin sections were cut parallel to the coverslip, poststained with uranyl acetate and lead citrate, and examined with a JEM-100S (JEOL, Japan) or FEI Tecnai 10 (Philips, Netherlands) transmission electron microscope at 80 kV. The scanned electron microphotos were analyzed and processed with Adobe Photoshop 7.0.

Statistical Analyses. Confocal fluorescence figures are representative of at least two independent experiments. Data from the FACS experiments and western band quantification are the mean ± SD ($n = 4-6$). The down-regulation of flotillin-1 was quantified in CLSM images by using FluoView10-ASW 1.6 software. Images of cells treated either with nonspecific or flotillin-1 specific siRNA were recorded with identical microscope settings. The regions of interest (ROI) that were chosen at the plasma membrane based on the β1-integrin staining and in the cytoplasmic areas were analyzed separately on 6−10 *z*-sections from seven cells (>40 sections for each pool). The results are shown as the percentage of flotillin-positive pixels of all pixels from the analyzed ROI. The colocalization of CPP−protein complexes with caveolin or flotillin-1 was quantified by counting vesicles in randomly selected 20 cells in thin sections by TEM. The number of vesicles containing respectively CPP−protein complexes, caveolin, or flotillin-1 or both, the CPP−protein complexes, and endocytic markers was counted and the percentage of colocalization of CPP−protein with Cav/Flot-1 was calculated (Table 1).

Table 1. Quantitative Analysis of Colocalization of Cell-Delivered Neutravidin and Lipid Raft Marker Proteins in TEM Images[a]

	flotillin-1		caveolin	
content of vesicle	TPb	TP10b	TPb	TP10b
CPP−protein complexes	158	242	467	183
Flot-1/Cav	522	644	942	1396
CPP−protein and Flot-1/Cav	23	33	93	28
% of colocalization	14.5[b]	13.6[b]	20	15.3

[a] The caveolin- or flotillin-1-positive and CPP−protein complex-containing vesicles were counted in 20 randomly selected cells, and colocalization is presented in percents. [b] Colocalization of CPP−protein complexes with flotillin-1 was detected almost exclusively in the perinuclear region. The degree of colocalization at the plasma membrane was lower than 5%.

RESULTS

Transportan and TP10 Do Not Direct the Cargo Protein to Flotillin-1-Dependent Endosomal Pathways. To unravel the internalization mode of transportan-mediated cargo delivery, we mapped the localization of the peptide−protein complexes in relation to flotillin-1, previously described as a marker of a specific type of lipid rafts (*24*). The flotillin-1 (Flot-1) positive areas showed almost no overlap with complexes of avidin and biotinylated transportan or TP10 when evaluated by confocal microscopy (Figure 1A,B). Almost no colocalization could be detected inside cells whereas some overlap was observed at the plasma membrane after 30 min incubation with peptide−protein complexes. At the plasma membrane, colocalization was mostly detected as smaller flotillin-marked focuses covered with a bigger irregular peptide−protein aggregate (Figure 1A−C). The loci of flotillin-1 were detected as a dense punctate staining on the plasma membrane, in the cytoplasm, and on the cellular projections while the majority of complexes assembled into larger structures, which were associated with the outer membrane, as detected by confocal microscopy (Figure 1A−C). As reported previously, cholera toxin B subunit uses (CtxB) uses flotillin-dependent endocytosis as one route for cell entry (*24*); therefore, we used CtxB for proving the relevance of this pathway in our system. After 30 min incubation of HeLa cells with the toxin, we detected CtxB in perinuclear structures showing partial overlap with Flot-1 (Figure 4A), confirming the functionality of this pathway in HeLa cells and corroborating the results published by Glebov et al. In parallel to confocal microscopy (CLSM) we used transmission electron microscopy (TEM), which allows identification of cellular structures by morphology at a higher resolution level. The complexes of biotinylated CPP and neutravidin (bigger gold particles) were detected as bigger aggregates, which localized mostly to the extracellular side of the plasma membrane, cell protrusions, and vesicular structures in the cytoplasm (arrows in Figure 1D−F). Flot-1 protein (smaller gold particles), on the contrary, was detected in specific loci at the cytoplasmic side of the plasma

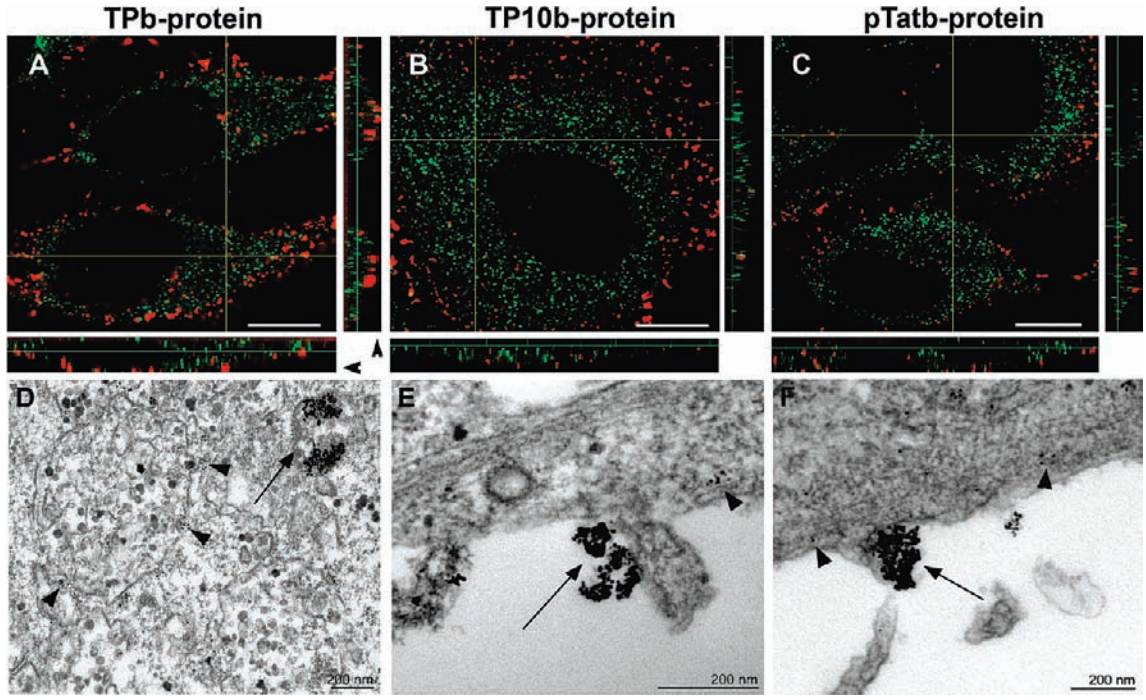

Figure 1. Localization of CPP−protein complexes in HeLa cells in relation to flotillin-1. For CLSM experiments, cells were incubated for 30 min with 0.5 μM biotinylated transportan (A), TP10 (B), or pTat (C) complexed with 0.15 μM avidin−Texas Red (red). Flotillin-1 was visualized with antiflotillin-1 pAb and AF 488-conjugated secondary Ab (green). A single optical section of cells is presented, which is indicated with a green line on the *z*-projections. Yellow lines in the *xy*-projection indicate the location of *z*-projections, and arrowheads indicate the apical part of cells in *z*-projections. (D−F) TEM images of cells incubated with complexes of neutravidin−gold (10 nm, arrows) and 1.5 μM biotinylated transportan (D), 3 μM TP10 (E), or pTat (F) for 1 h. Flotillin-1 is visualized with antiflotillin-1 pAb and secondary antibody tagged with nanogold (1.4 nm) particles (arrowheads in D−F). The bar in CLSM images represents 10 μM.

membrane (arrowheads in Figure 1E,F) but also on the membranes of multivesicular endosomes (arrowheads in Figure 1D) in the cytoplasm. Although the complexes of CPP−neutravidin were found close to the location sites of flotillin-1 protein, we could not detect colocalization between Flot-1 and CPP−protein complexes at the plasma membrane by TEM (Figure 1E,F). However, a small population of the intracellular vesicles containing TP/TP10−protein complexes also included Flot-1 protein. The same results were obtained with biotinylated Tat peptide complexed with avidin−Texas Red (CLSM) or neutravidin−gold (TEM) (Figure 1C,F). For transportan and TP10−protein complexes, overlapping structures with Flot-1 in TEM sections were estimated to remain around 14% of the total number of complex-containing vesicles (Table 1). Still, as revealed by quantitative analysis, the colocalization of TP/TP10−protein complexes with Flot-1 on the membrane areas and in the cortical cytoplasm was insignificant, only 1−5%, and the vesicles containing both markers were almost exclusively observed in the perinuclear region. We also performed CLSM experiments using a shorter incubation time, as peptide−protein complexes might pass the flotillin-positive vesicles earlier. However, after 10 min of incubation, very few complexes had internalized, and the colocalization between Flot-1 and TP/TP10−protein complexes was rarely detected on the plasma membrane (data not shown). In addition, we conducted experiments at a lower incubation temperature to assess the initial interaction of complexes with the plasma membrane. Although the peptide−protein complexes were not taken up by cells after 30 min incubation at 4 °C, the complexes interacted with the plasma membrane in a similar manner and colocalization with flotillin-1 was identical to that observed at physiological temperature (Supporting Information Figure 1A−C). CtxB interacted with the plasma membrane at 4 °C less avidly, but still colocalized with Flot-1 at certain loci, and no intracellular staining was detected (Supporting Information Figure 1D).

Transportan and TP10 Avoid the Early Endosomal Pathway Marked by Rab5 and PI3P in the Cellular Delivery of Cargo Protein. In order to assess whether the early endosomal pathway is exploited in peptide-mediated protein transport, we characterized the cellular localization of CPP−avidin complexes in comparison to Rab5 and PI3P, markers of early endosomes. The analogous rare intracellular colocalization of CPP−protein complexes as seen with flotillin-1 was also detected with PI3P (Figure 2A,B) and Rab5 (Figure 2D,E) as observed by CLSM after 30 min incubation. On the contrary, marked overlap was detected between PI3P/Rab5 and transferrin (Figure 2C,F), a marker of clathrin-dependent endocytosis, which passes early endosomes. Though both the CPP−protein complexes and PI3P/Rab5 were confined to punctate structures in cells and on the plasma membrane, they clearly represented different localization areas. Somewhat surprisingly the shorter (10 min) incubation time also revealed even less colocalization between the internalized CPP−protein complexes and Rab5 or PI3P at the plasma membrane, and a small amount of complexes was detected inside cells (Supporting Information Figure 2). Transferrin, on the contrary, entered the cell interior rapidly, already in 10 min (Supporting Information Figure 2). Again, in cases of rare overlap, the focuses stained by anti-Rab5 or anti-PI3P antibody were situated in the middle of large conglomerates of CPP−protein complexes. The negligible role of the PI3P-dependent pathway in CPP-mediated protein delivery (Figure 2A,B) correlates well with our unpublished results showing that internalization of TPb/TP10b−avidin complexes was not influenced in HeLa cells where the activity of PI3-kinase was inhibited by wortmannin treatment (data not shown).

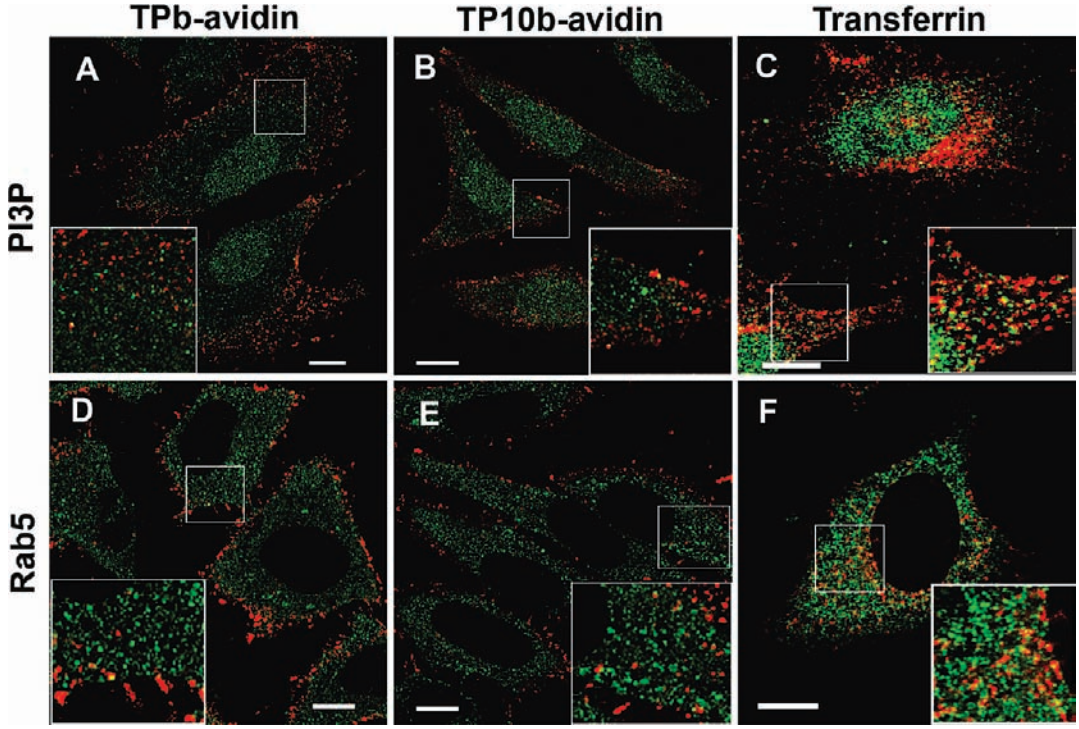

Figure 2. Localization of transportan- and TP10−protein complexes in HeLa cells in relation to Rab5 and PI3P. Cells were incubated for 30 min with 0.5 μM biotinylated transportan (A, D), TP10 (B, E) complexed with 0.15 μM avidin−Texas Red, or with AF 594-conjugated transferrin (20 μg/mL, C, F). To visualize PI3P and Rab5, cells were stained with anti-PI3P mAb (A, B) or anti-Rab5 pAb (D, E) and with appropriate AF 488-conjugated secondary Ab (green). A single optical section from the equatorial level of cells is presented. The bar represents 10 μM.

A Fraction of CPP−Protein Complexes Is Targeted to Caveolae. Earlier reports have demonstrated the involvement of caveolae-dependent endocytosis in both CPP internalization and the CPP-mediated cargo delivery (*16, 17*). Our results obtained by electron microscopy have shown that TP/TP10−protein complexes enter cells often in small (50−100 nm in diameter) morphologically caveosome-like or noncoated vesicles. Therefore, we looked for the presence of caveolin in these structures by both immunofluorescence and immunoelectron microscopy using antibody against all caveolin (Cav) isoforms. Indeed, a fraction of CPP−protein complexes colocalized with caveolin on the plasma membrane and in cells as observed by confocal microscopy. A higher number of colocalization could be detected on the plasma membrane than in the cytoplasm for all peptide−protein complexes. About 30% of CPP−avidin complexes on the membrane and 20% inside the HeLa cells exhibited similar localization to caveolin by visual estimation of CLSM images (Figure 3A−C). As expected, CtxB known to be also endocytosed via caveolae (*27*), exhibited a good overlap with caveolin-positive cell areas (Figure 4B). The results of electron microscopy revealed that most of the small vesicles or bigger rosette-like structures had caveolin on the cytosolic side (small gold particles in Figure 3D), and these structures were always located in close proximity to actin fibers. Although the caveosomes were abundant in the cortical cytoplasm, most of them did not contain the TP/TP10−neutravidin complexes (bigger gold particles). However, several of the TP/TP10−protein, as well as pTat−protein complexes, were found to reside in the Cav-positive vesicles in the perinuclear region (arrows in Figure 3G and 3H). The presence of both TP/TP10−neutravidin complexes and caveolin was also detected in bigger vesicles (0.4 μm), which had small caveosomes at close proximity or were connected to them (arrowheads in enlarged section of Figure 3E). Among complex-containing endosomal structures, about 20% for TP and 15% for TP10 were also marked by caveolin (Table 1) as revealed by the quantitative analysis of TEM results. The overlap of pTat−protein with caveolin-positive structures was comparable to that of TP−protein and caveolin, reaching about 20% (data not shown). About one-third of all CPP−protein complex-containing vesicles that did not contain caveolins were found in close proximity to caveosomes as shown in Figure 3F. It might have led to some overestimation of the degree of colocalization when using confocal microscopy (Figure 3A−C). In addition, from the analysis of TEM images we found that the overall number of caveosomes in control cells was about 2-fold lower than in cells incubated with CPP−protein complexes, indicating a triggering of caveolae internalization by CPPs.

Down-Regulation of Caveolin-1 Inhibits Transportan/TP10-Mediated Protein Delivery, but Down-Regulation of Flotillin-1 Has No Effect. In parallel with the colocalization experiments we down-regulated the Flot-1 with siRNA to see whether the lack of cellular Flot-1 interferes with the uptake of peptide−protein complexes. Surprisingly, the used siRNA decreased the Flot-1 concentration only moderately, to 40−50% as estimated by quantification of Western blot results (Figure 5A). Flotillin-1 seemed to be down-regulated differently in the plasma membrane and central cytoplasm; therefore, we visualized the plasma membrane with β1 integrin antibodies and analyzed the amount of Flot-1 at plasma membrane and in cytoplasm separately (see Experimental Procedures). The quantification corroborated that the down-regulation was more efficient at the plasma membrane compared to the cell interior, reaching 75−80% decrease of the Flot-1 signal in plasma membrane areas whereas the concentration of flotillin-1 in intracellular structures was reduced less than 2 times (Figure 5B). The uptake of TP/TP10−protein complexes by Flot-1 down-regulated cells, however, was not influenced (Figure 5C). Analogously to Flot-1, we checked whether depletion of Cav-1 from the plasma membrane influences the TP/TP10-mediated protein delivery. siRNA treatment yielded about 70−80% down-regulation of cellular Cav-1 protein expression as quantified by Western blot (Figure 5A). The decrease in Cav-1 concentration inhibited the uptake of TP10−protein complexes by 40−50%

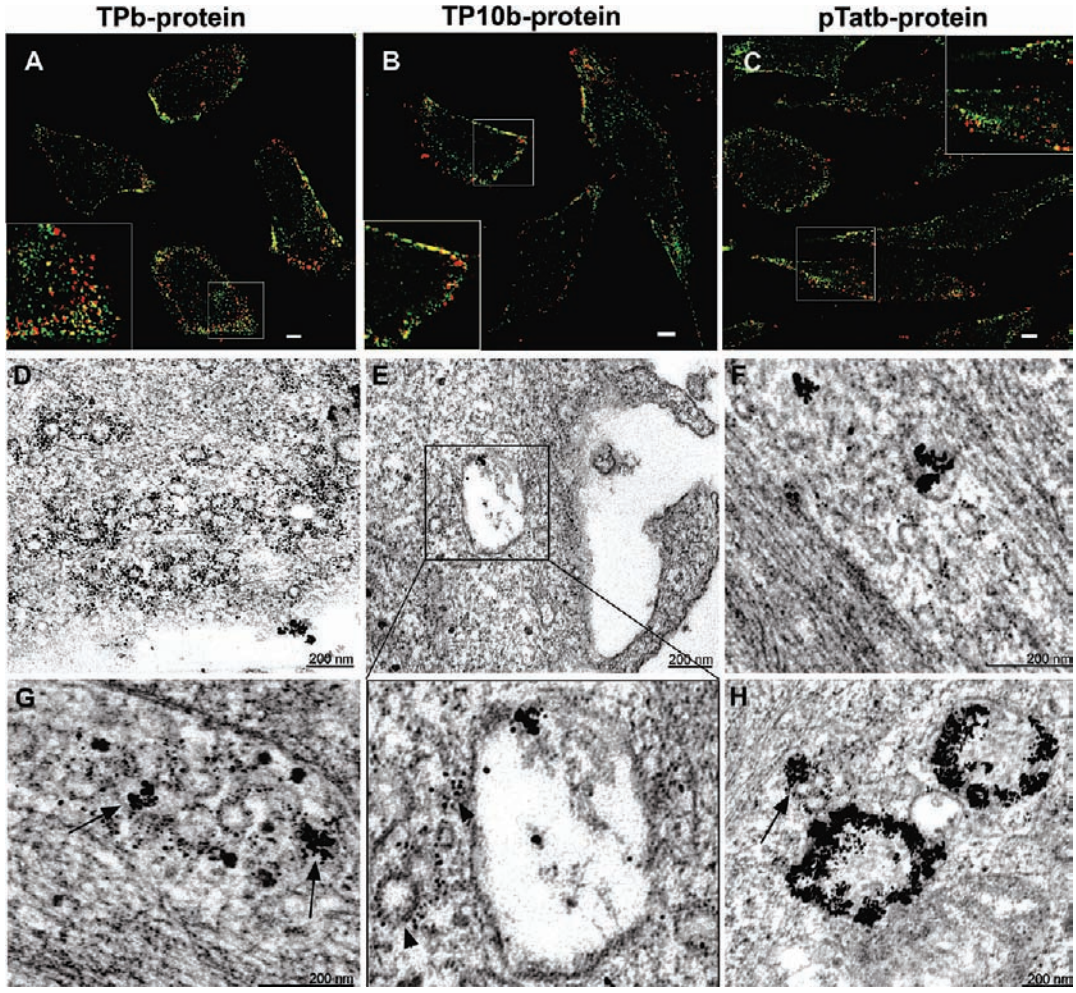

Figure 3. Localization of CPP−protein complexes in HeLa cells in relation to caveolin. Cells were incubated for 30 min with 0.5 μM biotinylated transportan (A), TP10 (B), or pTat (C) complexed with 0.15 μM avidin−Texas Red (red). To visualize the cellular caveolin, cells were stained with anticaveolin pAb and with appropriate AF 488-conjugated secondary Ab (green). A single optical section from the equatorial level of cells is presented. (D−H) TEM images of cells incubated with complexes of neutravidin−gold (10 nm, arrows) and 1.5 μM biotinylated transportan (D, G), TP10 (E), or pTat (F, H) for 1 h. Caveolin is visualized with anticaveolin pAb and 1.4 nm gold particle-conjugated secondary antibodies. The bar in CLSM images represents 10 μM.

while the TP-mediated transport was slightly less affected (Figure 5D). The coapplication of Flot-1 and Cav-1 siRNA did not lead to an additional inhibitory effect on the protein delivery as compared to Cav-1 knock-down (Figure 5E). In addition to the impaired protein uptake in caveolin-1 down-regulated cells by CLSM, the colocalization between the CPP−protein complexes and the remaining caveolin was markedly decreased for both peptides, most probably due to the lower amount of membranous caveolin (data not shown). However, by visual estimation the amount of membrane-associated complexes in Cav-1 down-regulated cells was on the same level with untreated control cells, indicating that the interaction with plasma membrane is not inhibited by a deficit of Cav-1. On the other hand, the extensive trypsin digestion and trypan blue quenching used in the FACS analysis helped to remove the loosely bound CPP−protein complexes from the cell surface and to diminish the extracellular signal, respectively. These treatments led to lower signal intensity and more correct estimation of the reduction in protein transduction in flow cytometry assays.

To completely exclude the induction of caveolin-1-dependent pathways by CPPs, we conducted analogous experiments in Cav-1 knockout mouse embryonic fibroblasts (MEFs). The results obtained by flow cytometry and confocal microscopy corroborated the high impact of Cav-1-dependent pathways on the uptake of avidin induced by peptides. The transduction yield of avidin into Cav-1 knockout MEFs was 60−70% lower than to wild-type fibroblasts for both TP10 and transportan. In analogy with the HeLa cells, the absence of caveolin-1 interfered with transportan-mediated delivery slightly less than that of TP10 (Figure 6A). Visualization of caveolins with anticaveolin antibody revealed its marked colocalization with TP/TP10−protein complexes in wild type MEFs (Figure 6B,D), which correlates well with the results obtained in HeLa cells. As expected, in Cav-1 knockout MEFs we detected the presence of caveolin-2 isoform at a very low level (*28*), which did not overlap with peptide−protein complexes (Figure 6C,E), corroborating the substantial role of membranous caveolin-1 in protein delivery with transportans.

DISCUSSION

The plasma membrane is a complex cellular organelle, being simultaneously a portal and a barrier for all metabolites. Cell-penetrating peptides are under intense study as carriers, which cross this barrier together with biologically active cargo. On the other hand, their ability to penetrate through membranes also represents an interesting scientific phenomenon per se. The endocytic processes have proven to mediate the CPP/CPP−cargo entry, and the role of pathways that originate from the lipid rafts and/or caveolae is often emphasized (*7, 16, 29*). Involvement of rafts is usually suggested based on the decreased cellular uptake of CPPs by cells depleted of cholesterol in the plasma membrane after treatment with methyl-β-cyclodextrin. However,

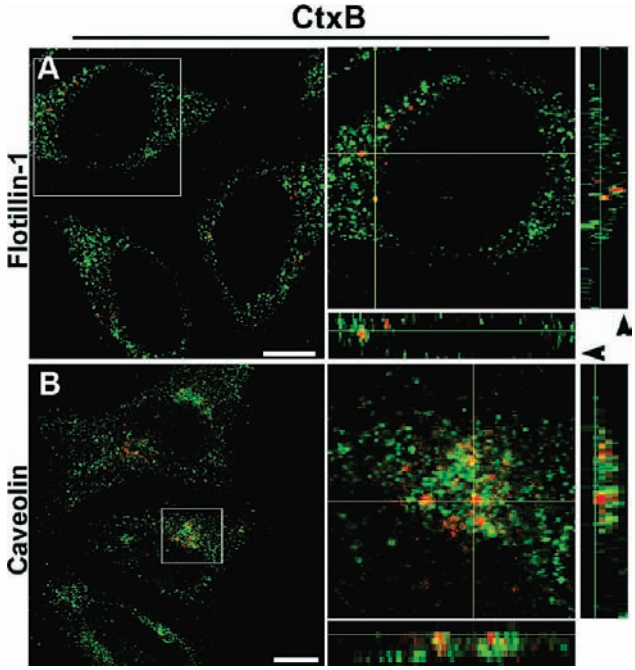

Figure 4. Localization of cholera toxin B subunit (CtxB) in relation to cellular flotillin-1 and caveolin. After incubation of HeLa cells with Alexa Fluor 594-conjugated CtxB (3 μg/mL, red) for 30 min, the cells were stained with antiflotillin-1 (A) or anticaveolin (B) polyclonal antibodies and with Alexa Fluor 488 conjugated secondary Ab (green). Enlarged sections of indicated areas are depicted on the right column with *z*-projections. Yellow lines in enlarged sections indicate the location of *z*-projections, and arrowheads indicate the apical part of cells in *z*-projections. Scale bar 10 μM.

it does not distinguish between the caveolar and raft-mediated pathways, which have different cellular destinations. Removal of cholesterol also influences other endocytic processes and might lead to changes in cell morphology (*30*). Moreover, very recently 60% of cellular cholesterol was demonstrated to localize in the inner leaflet of plasma membrane and endocytic recycling compartment in chinese hamster ovary cells (*31*), suggesting that cholesterol depletion might substantially interfere with the organization of lipids in the cytoplasmic leaflet of membranes and also endocytosis. Continuously accumulating data about the nature and complexity of endocytosis and involvement of its different types in CPP mechanisms prompted us to reassess the initial steps of CPP-mediated protein delivery. We chose flotillin-1 and caveolin as markers for two types of plasma membrane microdomains, and Rab5 and PI3P for characterization of early endosomal vesicles, to elucidate their involvement in TP/TP10-mediated protein delivery into HeLa cells. Cholesterol- and sphingolipid-rich rafts represent highly heterogeneous populations of functionally distinct membrane domains. The availability of caveolae-independent but morphologically similar endocytic pathways involved in the SV40 cell entry was recently demonstrated by two groups in parallel (*21, 22*). In analogy with CPP-mediated delivery into cells, this type of endocytosis is dependent on plasma membrane cholesterol and dynamin activity. Flotillins, in turn, are shown to be responsible for the assembly of a particular type of rafts, which participate in clathrin- and caveolin-independent endocytosis (*24*). Coassembly of flotillin-1 and flotillin-2 into microdomains induces formation of membrane invaginations that are morphologically reminiscent of caveolae and considered to be capable of forming intracellular vesicles, which localize in the cortical cytoplasm and look similar to caveosomes but lack caveolin-1 (*32*). According to our earlier electron microscopy results, the vesicular pathway of TP/TP10-mediated protein uptake also resembled by morphology the noncaveolar, flotillin-1-dependent internalization mode described by Frick and co-workers. Therefore, we assessed the putative involvement of a flotillin-1-dependent internalization pathway in the cellular translocation of TP/TP10−protein complexes. However, somewhat unexpectedly we could not find the colocalization of CPP−protein complexes with flotillin-1 on the plasma membrane or inside cells by immunocytochemical analysis either by confocal or by electron microscopy. In addition, efficient down-regulation of flotillin-1 in the plasma membrane, using siRNA silencing, increased rather than decreased the CPP−protein uptake, corroborating the microscopy results and suggesting that the flotillin-1-dependent pathway has a negligible, if any, role in CPP-mediated protein delivery. The cholera toxin B subunit, used in this study for assessing the activity of the flotillin-dependent pathway, can enter cells via several endosomal pathways (*22, 33*). Therefore, CtxB could only with great circumspection be considered a marker of the flotillin-dependent endocytic route. Unfortunately, no specific cargo has been characterized for the flotillin-mediated pathway yet, making the explicit evaluation of the role of this mechanism difficult. For the sake of clarity, we also checked the localization of cell-transduced protein in relation to flotillin-2, but in analogy with flotillin-1 no significant overlap was detected (data not shown). On the other hand, based on the experiments with flotillin-1 and -2, we could not exclude the participation of lipid rafts in delivery by CPPs, as the nature of lipid rafts is not unambiguously characterized yet. Moreover, the possibility that complexes indeed show equal or even better uptake in partially flotillin-1-depleted cells suggests that the phospholipids of nonraft areas of the plasma membrane might also play a role in CPP internalization mechanisms (*34, 35*), independently or in concert with the cell surface proteoglycans. Considering the ability of transportan to modulate the dynamics of the membrane lipids (*36*), and taking into account that the location and function of cell surface proteoglycans is probably interfered in flotillin-1-deficient cells, one can imagine that the changed properties of the plasma membrane could lead to the vesicular uptake mode(s) that is not common to cells with a properly organized membrane. The involvement of another cholesterol-dependent pathway, caveolar endocytosis, has been demonstrated in both the cellular uptake of Tat peptide and pTat-mediated cargo delivery (*16, 17*). Recent data about caveolae not just merely as a subtype of rafts but as an independent membrane structure (*37*−*39*), encouraged us to include it in the study. Our CLSM results demonstrated that approximately 30% of CPP−avidin complexes exhibited similar localization to caveolin, and a higher overlap was observed at the plasma membrane than inside cells. Still, electron microscopy revealed a somewhat lower degree of colocalization (15− 20%) of complexes with caveolin-positive vesicles, especially in the cortical cytoplasm where the main fraction of caveosomes was found. Electron microscopy results revealed that the CPP−neutravidin complexes and caveolin localized often in very close proximity, which might have led to the overestimation of the degree of colocalization by CLSM. However, we cannot exclude that the smaller ratio of colocalization detected in electron microscopy could be caused by different isoelectric points of avidin and neutravidin and by the higher affinity of avidin to negatively charged components of the plasma membrane. Still, after caveolin-1 down-regulation by 60−70%, a substantial inhibition of CPP-mediated protein uptake was detected by FACS analysis, which emphasizes the importance of caveolin-1-containing membrane areas in the internalization process. Moreover, the finding that the amount of caveosomes in cells incubated with CPP−protein complexes is about 2-fold higher than in untreated cells might suggest the induction of caveolae-dependent endocytosis, which contributes most to the TP/TP10-mediated protein delivery among the observed endosomal pathways. The

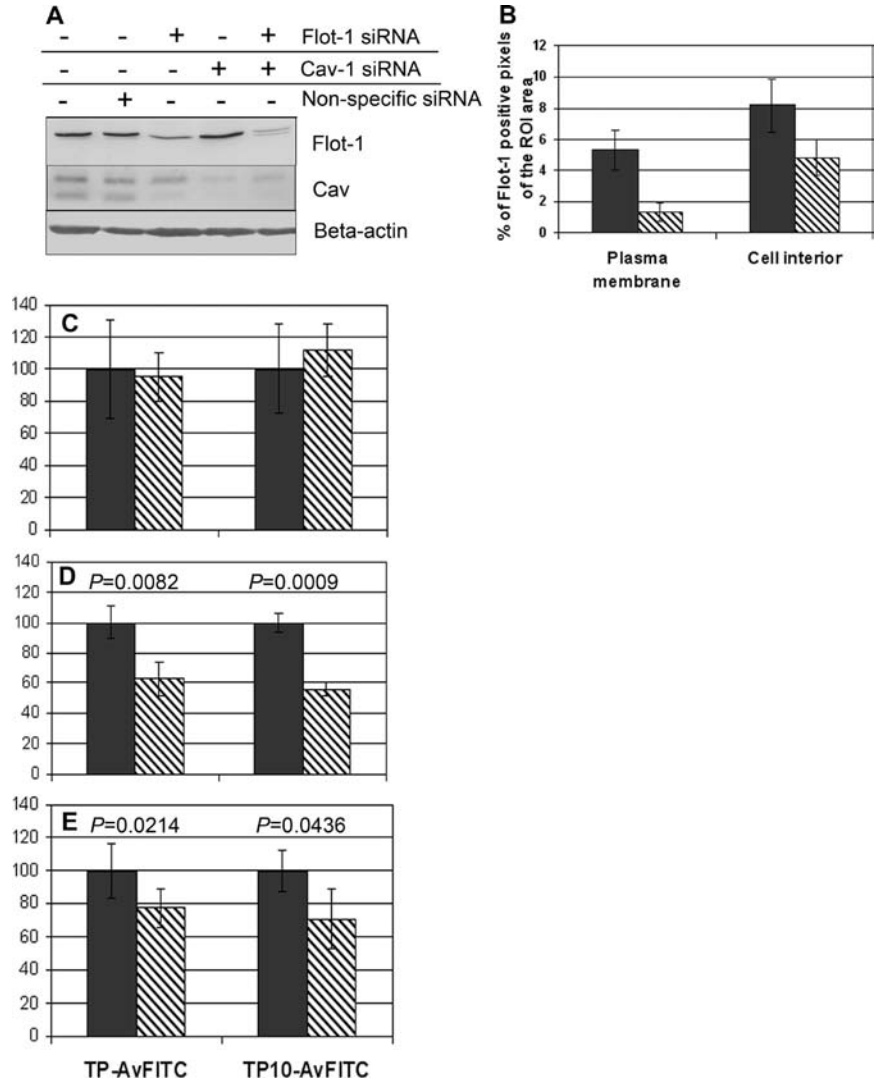

Figure 5. (A) Effect of down-regulation of flotillin-1 and caveolin-1 by siRNA on protein cellular delivery by transportan and TP10. (A) Estimation of protein concentration after siRNA treatment by Western blot. Characteristic result of three separate experiments is depicted. Proteins (0.5 μg per lane) were detected with anti-Flot-1 pAb (upper panel), anti-Cav pAb (middle panel), or anti-β-actin mAb as loading control (lower panel). (B) Quantification of the flotillin-1 in the plasma membrane and intracellular structures by the analysis of z-sections of CLSM images of cells treated with nonspecific (gray bars) or Flot-1 specific siRNA (striped bars) and stained for Flot-1 and β1-integrin to visualize the plasma membrane. Results show the percentage of Flot-1-positive pixels of all pixels from the analyzed areas. (C, D) The uptake of complexes by siRNA-treated cells. HeLa cells were treated with nonspecific (gray bars) or specific siRNAs (striped bars) against Flot-1 (C), Cav-1 (D), or both Flot-1 and Cav-1 siRNAs (E) and incubated with complexes of biotinylated TP/TP10 (0.5 μM) and avidin−FITC (0.15 μM) for 30 min prior to FACS analysis. Protein delivery efficiency into cells treated with nonspecific siRNA is represented as 100%. Error bars represent standard deviation, and statistical relevance is characterized with *P* values.

confocal micrographs reveal that siRNA treatment led to strong reduction of caveolin-positive areas from the plasma membrane and marked loss from intracellular structures. However, the lack of caveolin-1 in plasma membrane inhibits the TP10-induced protein uptake more strongly than that of transportan, and this trend is also observable when the protein delivery by transportans is compared in wild type and caveolin-1 knockout MEFs. CLSM shows rather comparable colocalization between caveolin and avidin complexed with both transportans in normal HeLa cells. Electron microscopy, on the contrary, revealed a slightly higher occupancy of caveolin-coated vesicles by TP−neutravidin than by TP10 complexes, which is in discrepancy with the cellular uptake data in Cav-1 siRNA-treated cells. The results might suggest that although transportan−protein complexes occupy more caveosomes in cells than TP10, it could more flexibly switch between different endosomal pathways. Our earlier results demonstrated that about 10−15% of TP/TP10−protein complexes localized in transferrin-containing vesicles showing the involvement of clathrin-mediated endocytosis in the uptake of complexes both by fluorescence and by electron microscopy (*8*). In addition, the hyperosmolar medium known to interfere with the clathrin-mediated endocytosis inhibited the avidin delivery in HeLa cells to the same extent, corroborating the proportion of the clathrin-dependent mechanism in transportan-mediated protein delivery (*14*). Assuming good concordance of results obtained by three above-mentioned methods and relatively low contribution of the clathrin-dependent pathway in the complexes' uptake, we did not apply a siRNA-included knock-down for evaluating the role of this pathway. The electron microphotos demonstrated that a substantial amount of cell-transduced protein was confined in macropinosome-like big vesicles (*8*), implicating that several endocytic pathways were active in CPP-mediated protein transduction. On the basis of this, we suggest that in conditions where the functioning of one entry route is restrained, TP/TP10 target the cargo into other/unimpaired endocytic pathways, although with smaller efficiency and depending on the features of the particular peptide. The further intracellular targeting of

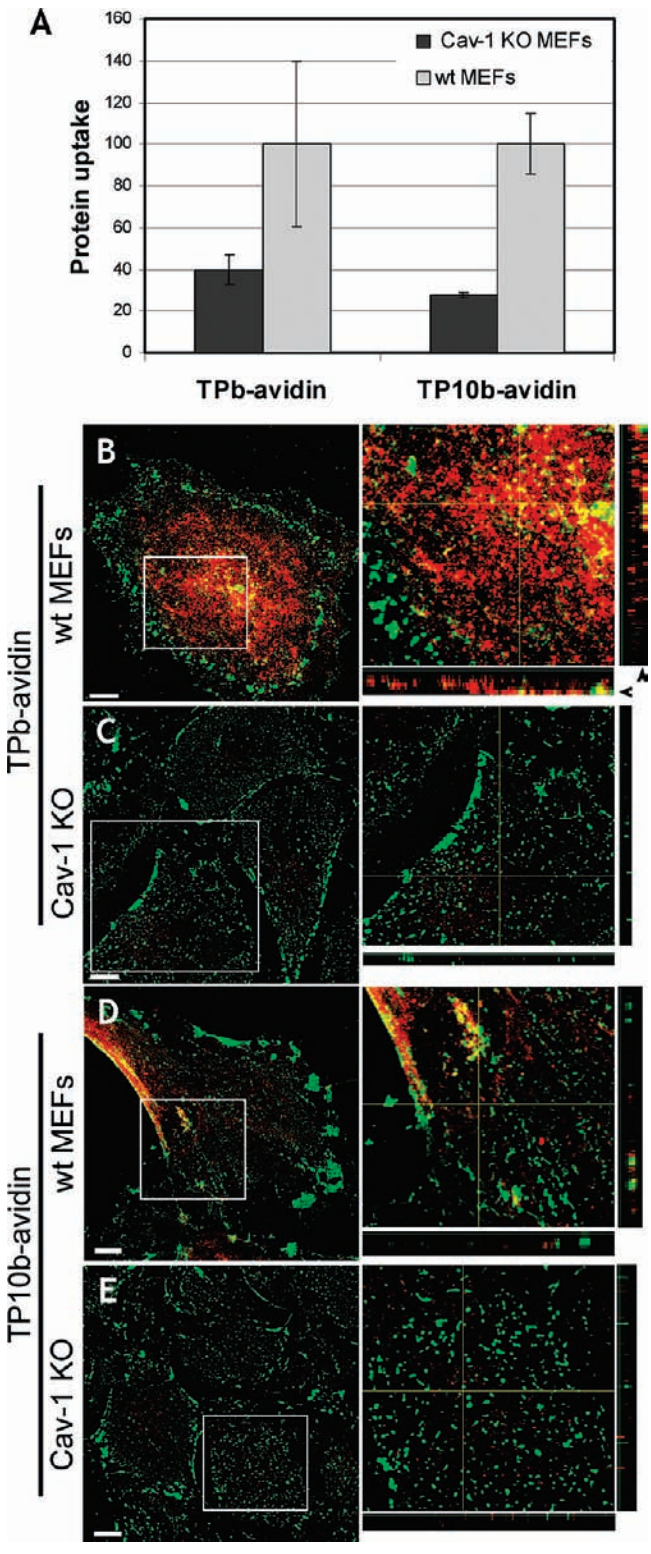

Figure 6. Internalization and localization of transportan/TP10−protein complexes in cells lacking caveolin-1. Wild-type or caveolin-1 knockout MEFs were incubated with complexes of biotinylated TP/TP10 (0.5 μM) and avidin−FITC (0.15 μM) for 30 min and analyzed by FACS (A) or confocal microscopy (B−E). The protein uptake into wt MEFs is presented as 100% in A. (B−E) Cells were stained with anticaveolin pAb and AF 594 conjugated secondary Ab (red) for visualizing caveolins. The caveolin signal in caveolin-1 knockout cells is very weak and rather diffuse, representing the localization of residual caveolin-2 (C, E). Images shown are merged from all optical slices, and the enlarged sections with *z*-projections are taken from indicated places and presented in the right column. Arrowheads indicate the apical part of cells in *z*-projections, and the bar represents 10 μM.

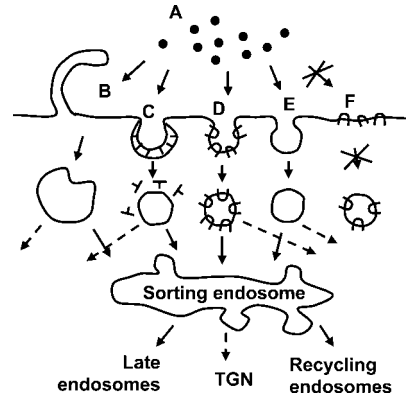

Figure 7. Endocytic pathways used for cellular entry by transportan/TP10−protein complexes. The scheme includes our earlier data (*8*). The complexes of peptide and protein (A) can enter cells via macropinocytosis (B), clathrin- (C) or caveolae (D)-mediated endocytosis, and clathrin- and caveolin-independent endocytosis (E). The flotillin-mediated pathway (F) is not utilized. Intracellular trafficking routes are indicated by solid arrows, putative directing is represented by dashed arrows. TGN-trans-Golgi network.

CPP-transduced cargos is even more important than the starting point. Upon long-time incubations, the majority of cargo protein delivered into cells by CPPs accumulates in LAMP2-containing structures in the perinuclear region (*8*) and is targeted to digestion (*3*). Therefore, mapping of the early steps of CPP-mediated delivery might provide valuable information for finding a way to induce liberation of cargo molecules from the endosomal structures before direction to degradation. The small GTPase Rab5 and PI3P are both typical constituents of early endosomes, and both of them are also reported to have role in macropinocytosis (*40*). In addition, the lateral transport between early endosomal vesicles and caveosomes has been shown to be Rab5-dependent (*38*). However, most of the CPP−protein complexes were observed to evade early endosomes since only a negligible fraction of complexes showed colocalization with Rab5 or PI3P after 10 or 30 min. Furthermore, the treatment of cells with wortmannin, a specific inhibitor of phosphoinositide 3-kinase, did not inhibit the CPP-induced protein transport into HeLa cells, which is in line with an earlier study by Payne et al. (*41*). Although early endosomes are reported to be capable of receiving contents from caveosomes (*38*), the fraction of TP/TP10 protein complexes that internalized in caveolin-positive vesicles might avoid early endosomes by using other transport route(s), probably analogous to SV40 (*42*). Still, the caveolar pathway is considered to lead to the Golgi complex, but only a minor part of TP/TP10−protein complexes is targeted there as we showed earlier (*8*). Although the CPP−protein complexes seem to avoid being trapped into early endosomal structures after translocation into HeLa cells, upon longer incubation they accumulate in vesicles containing endolysosomal marker protein LAMP2 (*8*). Recently, it has been reported that at least three endocytic pathways are used for cellular entry by CPPs: macropinocytosis, clathrin-mediated, and caveolar/lipid raft-mediated endocytosis (*5*). Our results on protein cellular delivery are well in line with this study suggesting analogous concurrently acting endocytic uptake mechanisms, and in our system the caveolin-dependent pathway but not the flotillin-1-mediated route is preferentially used. However, the intracellular targeting of complexes seems to avoid canonical trafficking pathways (schematic representation in Figure 7). Additionally, there is a fraction of small vesicles induced by CPPs and mediating the internalization of cargo molecules, which we have not been able to classify using markers of known endocytic pathways, and flotillin-1 did not help with filling this gap.

ACKNOWLEDGMENT

We thank M. Kure, T. Toivonen, M. Lindman, and A. Strandell for excellent technical assistance in electron microscopy, M. Ehandi for peptide synthesis, S. Ingerpuu for anti-β1-integrin antibody, and H. Räägel for critical reading of manuscript. The work was supported by grants from Estonian Science Foundation (ESF 5588 and 7058), European Community Program QLK3-CT-2002-01989, Swedish Research Council (VR-NT, VR-Med), Academy of Finland, and University of Tartu (PP1TI07902).

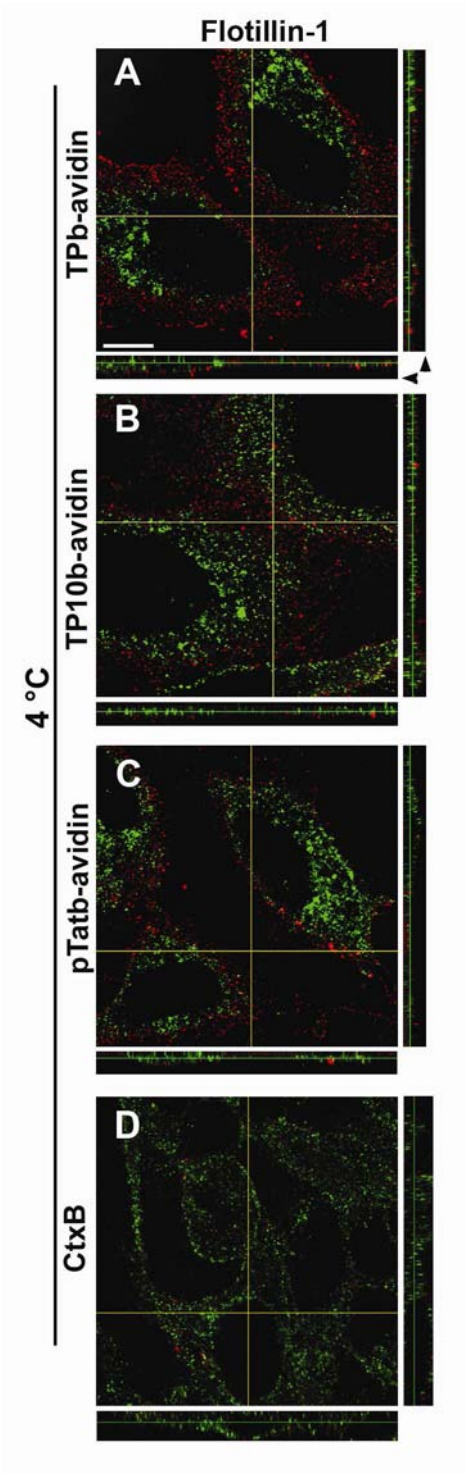

Figure S1. Localization of transportan-, TP10, pTat-protein complexes or cholera toxin B (CtxB) subunit in HeLa cells in relation to Flot-1 at low temperature. Cells were pre-cooled on ice for 15 min and incubated for 30 min with 0.5 μM biotinylated transportan (A), TP10 (B) or pTat (C) complexed with 0.15 μM avidin-Texas Red (red), or with 3 μg/mL of CtxB-AF 594 (D, red) in relation to Flot-1 at low temperature. To visualize Flot-1, the cells were stained with anti-Flot-1 polyclonal antibody and with anti rabbit Alexa Fluor 488-conjugated secondary Ab (green). A single optical section of cells is presented indicated with green line

on the z-projections and yellow lines in xy-projection indicate the location of z-projections. Arrowheads indicate the apical part of cells in z-projections. Scale bar 10 μM.

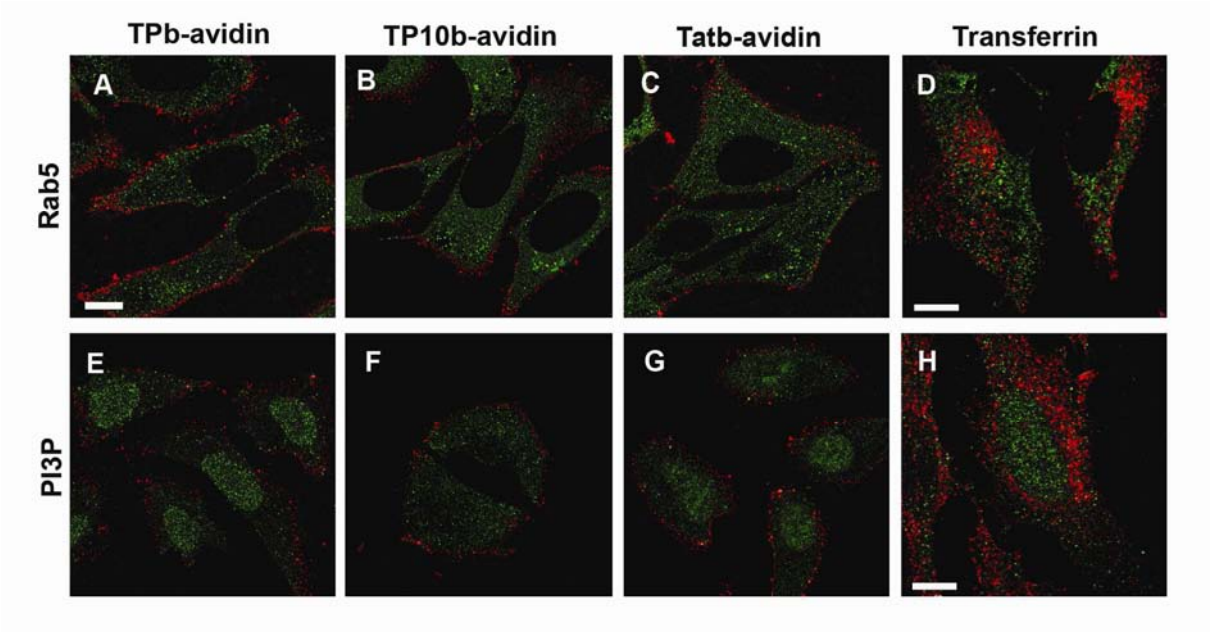

Figure S2. Localization of transportan-, TP10- and pTat-protein complexes in HeLa cells in relation to Rab5 and PI3P after short-time incubation. Cells were incubated at 37 ºC for 10 min with 0.5 μM biotinylated transportan (A, E), TP10 (B, F) or pTat (C, G) complexed with 0.15 μM avidin-Texas Red, or with 20 μg/mL transferrin-AF 594 (D, H, red). To visualize PI3P and Rab5, the cells were stained with anti-Rab5 pAb (A-D) or anti-PI3P mAb (E-H), respectively and with appropriate AF 488-conjugated secondary Ab (green).

Synthesis and Characterization of an ^{111}In-Labeled Peptide for the in Vivo Localization of Human Cancers Expressing the Urokinase-Type Plasminogen Activator Receptor (uPAR)

Dijie Liu,[†,§] Douglas Overbey,[†,§] Lisa Watkinson,[†,§] and Michael F. Giblin*[,†,‡,§]

Truman Memorial Veterans' Administration Hospital, Columbia, Missouri 65201, Department of Radiology, University of Missouri—Columbia School of Medicine, Columbia, Missouri 65211, and The Radiopharmaceutical Sciences Institute, University of Missouri—Columbia, Columbia, Missouri 65211. Received October 10, 2008; Revised Manuscript Received March 6, 2009

This study describes the synthesis and preliminary biologic evaluation of an ^{111}In-labeled peptide antagonist of the urokinase-type plasminogen activator receptor (uPAR) as a potential probe for assessing metastatic potential of human breast cancer in vivo. The peptide (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(DOTA)-NH_2 was synthesized and conjugated with the DOTA chelating moiety via conventional solid-phase peptide synthesis (SPPS), purified by reversed-phase HPLC, and characterized by MALDI-TOF MS and receptor binding assay. In vitro receptor binding studies demonstrated an IC_{50} of 240 ± 125 nM for the peptide, compared with IC_{50} values of 0.44 ± 0.02 and 0.75 ± 0.01 nM for the amino terminal fragment (ATF) of the urokinase-type plasminogen activator (uPA) and full-length uPA, respectively. In vivo biodistribution studies were carried out using SCID mice bearing MDA-MB-231 human breast cancer xenografts. Biodistribution data was collected at 1, 4, and 24 h postinjection of ^{111}In-DOTA-peptide, and compared with data obtained using a scrambled control peptide as well as with data obtained using wild-type ATF radiolabeled with I-125. Biodistribution studies showed rapid elimination of the ^{111}-labeled peptide from the blood pool, with 0.12 ± 0.06% ID/g remaining in blood at 4 h pi. Elimination was seen primarily via the renal/urinary route, with 83.9 ± 2.2% ID in the urine at the same time point. Tumor uptake at this time was 0.53 ± 0.11% ID/g, resulting in tumor/blood and tumor/muscle ratios of 4.2 and 9.4, respectively. Uptake in tumor was significantly higher than that obtained using a scrambled control peptide that showed no specific binding to uPAR ($p < 0.05$). In vitro and ex vivo results both suggested that the magnitude of tumor-specific binding was reduced in this model by endogenous expression of uPA. The results indicate that radiolabeled peptide uPAR antagonists may find application in the imaging and therapy of uPAR-expressing breast cancers in vivo.

INTRODUCTION

The urokinase-type plasminogen activator (uPA) system plays an important role in the progression of many types of cancer (*1*−*4*). Binding of uPA to its receptor (uPAR) initiates a proteolytic cascade that ultimately results in degradation of extracellular matrix (ECM) components and activation of matrix metalloproteases (MMP's). These processes in turn lead to tumor invasion and metastasis. Components of the uPA system, including uPAR, are overexpressed in various cancers, including human breast, prostate, and colorectal cancer, and overexpression is correlated with poor prognosis due to increased rates of metastatic relapse (*5*−*11*). The proven correlation between uPAR expression and metastatic potential provides an opportunity to develop an *in vivo* imaging agent, which can both help define a subset of breast cancer patients at increased risk for metastatic disease and localize and ultimately treat metastatic disease.

Seminal research by Blasi, Ploug, and others (*1, 2, 4, 12*−*15*) has clarified the functional elements of uPAR that are required for its interaction with uPA and with other proteins, including integrins and fibrinogen. uPA is a 54 kDa glycosylated serine protease that catalyzes the conversion of plasminogen to plasmin. Binding of pro-uPA to uPAR (CD87) results in proteolytic activation, yielding two-chain high molecular weight uPA (tc-HMW-uPA). uPAR is a glycosylphosphatidylinositol (GPI)-anchored receptor for uPA and serves to concentrate uPA activity at the invasive front of tumor masses. Human uPAR is a 283 amino acid single chain protein, and is a member of the Ly-6/uPAR/α-neurotoxin family of proteins. In structure, it is arranged into three finger-like domains that enfold the uPA ligand within a central binding cavity. Binding of uPA to uPAR in this fashion serves to focalize uPA activity in such a way as to facilitate invasion of uPAR-expressing cancers by activation of a proteolytic cascade that breaks down extracellular matrix components and allows cancer cell migration into vasculature and lymphatics (*2*).

The aim of this study was to investigate the applicability of radiolabeled uPA antagonists to the detection of uPAR-expressing cancers in vivo. A series of small peptide inhibitors of the uPA−uPAR interaction have previously been developed (*15*), which demonstrate high affinity for uPAR. We have synthesized and characterized one such inhibitor, modified to contain a C-terminal DOTA chelating moiety, labeled the resulting compound with ^{111}In, and compared its in vivo

biodistribution profile to that of ^{125}I-ATF using SCID mice bearing MDA-MB-231 human breast cancer tumor xenografts.

MATERIALS AND METHODS

Materials. ATF was obtained from American Diagnostica, Inc. Na^{125}I was obtained from Perkin-Elmer. DOTA-mono-NHS-ester and Fmoc-L-Lys-monoamide-DOTA-tris (tBu ester) were obtained from Macrocyclics, Inc. Rink Amide MBHA peptide synthesis resin and protected Fmoc-amino acids were obtained from Novabiochem. MALDI-TOF mass spectral analyses were performed by the Proteomics Center at the University of Missouri—Columbia. $^{111}In_3$ was obtained from Mallinckrodt Medical, Inc. as a 0.05 N HCl solution. MDA-MB-231 cells were obtained from the American Type Culture Collection (ATCC). SiRNA's and antiurokinase antibodies were obtained from Santa Cruz Biotechnology. All solvents were either ACS certified or of HPLC grade, obtained from Fisher Scientific and used as received. Other reagents were purchased from Aldrich Chemical Co., Gibco, and Pierce.

Peptide Synthesis and Purification. Peptides were synthesized by standard solid phase peptide synthesis (SPPS) techniques, employing Fmoc protected amino acids and either DOTA-mono-NHS-ester or Fmoc-L-Lys-monoamide-DOTA-tris (tBu ester) as building blocks. Polypeptides were assembled on Rink Amide MBHA resin, acetylated via HoBT/DCC activation of 5-fold excess acetic acid in 3:1 NMP/DMSO, then cleaved from the resin and deprotected using a 36:2:1:1 mixture of TFA/thioanisole/water/ethanedithiol. The addition of DOTA-mono-NHS-ester to the ε-amino group of the C-terminal lysine residue of (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K-NH_2 was carried out with 0.1 M Na_2HPO_4, pH 8, for 3.5 h at room temperature, using a 10−20-fold excess of DOTA NHS ester.

DOTA-conjugated peptides were purified by high performance liquid chromatography (HPLC). HPLC was performed on a Shimadzu system equipped with an SPD-20A UV detector and an in-line sodium iodide crystal radiometric detector. HPLC solvents consisted of H_2O containing 0.1% trifluoroacetic acid (solvent A) and acetonitrile containing 0.1% trifluoroacetic acid (solvent B). Conditions: A Phenomenex Jupiter C-18 (5 μm, 300 Å, 4.6 × 250 mm) column was used with a flow rate of 1.5 mL/min. Gradient purification of all compounds was achieved during a linear 30 min ramp from 35% B to 45% B, followed by column rinse and reequilibration.

Radiolabeling. For the synthesis of ^{111}In-labeled compounds, aliquots of $^{111}In_3$ (0.2−2.5 mCi, 7.4−92.5 MBq, 4−50 μL) were added to solutions of (NAc-dD-CHA-F-dS-dR-YLWS-βAla)$_2$-K-K(DOTA)-NH_2 and scrambled negative control peptide (NAc-dD-W-dS-LY-dR-FS-CHA-βAla)$_2$-K-K(DOTA)-NH_2 (10−20 μg) in 0.4 M ammonium acetate (200 μL). The pH of the reaction mixture was adjusted to 6.0. The reaction mixture was incubated for 1 h at 80 °C. After 1 h, an aliquot of 0.002 M EDTA (50 μL) was added to the reaction mixture to complex unreacted $^{111}In^{3+}$. The resulting conjugates were purified to homogeneity by RP-HPLC. The ^{111}In-metalated conjugates eluted between 0.5−1.5 min after the associated nonmetalated species. Purified ^{111}In-DOTA conjugates were then concentrated by passing through a 3 M Empore C-18 HD high performance extraction disk (7 mm/3 mL) cartridge and eluting with 100% ethanol (400 μL). The concentrated fractions were immediately diluted 2-fold by the addition of 0.1 M NaH_2PO_4, then reduced in volume under a stream of $N_{2(g)}$, and finally diluted with 0.1 M NaH_2PO_4 buffer, pH 7.0, to a final activity of approximately 2 μCi/ 100 μL.

The amino terminal fragment of uPA was iodinated essentially according to a previously published protocol (*13*). Briefly, 2−10 μg of the Amino Terminal Fragment of uPA (ATF) was iodinated using 0.2−1 mCi Na^{125}I following ^{125}I activation using Iodogen precoated tubes (Pierce). After a 10-min incubation in 25 mM Tris and 0.4 M NaCl, pH 7.5, the reaction was quenched by the addition of excess free tyrosine and purified by fractionation on a D-Salt size exclusion cartridge (Pierce).

In Vitro/Ex Vivo Receptor Binding Assays. Binding affinity of urokinase antagonists was measured by competition against ^{125}I-ATF using whole MDA-MB-231 human breast cancer cells. Prior to incubations of peptide competitors and radiolabeled tracer with whole cells, cells were briefly rinsed with 50 mM glycine HCl and 100 mM NaCl, pH 3.0, then neutralized with 0.2 volume 0.5 M HEPES and 100 mM NaCl, pH 7.4, to strip away endogenous uPA. Cells were then rinsed and suspended in binding buffer, PBS/0.2% BSA, pH 7.4. Cells (3×10^6) suspended in binding buffer were incubated at 37 °C for 1 h in the presence of approximately 20−30,000 cpm ^{125}I-ATF and increasing concentrations of unlabeled peptide competitors. After the incubation, the reaction medium was aspirated, and cells were washed three times with binding buffer. The radioactivity bound to the cells was counted in a Packard Riastar gamma counting system. Experiments were performed in triplicate, and average values were used for the calculations. The specific activity of the tracer was 50−100 μCi/μg.

SiRNA Studies. MDA-MB-231 cells were maintained in RPMI 1640 supplemented with 10% FBS, 2 mM L-glutamine, 1 mM sodium pyruvate, 10 mM HEPES, 0.1 mM MEM nonessential amino acids, and 50 μg/mL gentamicin. SiRNA transfections were performed using lipofectamine 2000 (Invitrogen) according to the manufacturer's instructions. Briefly, 2×10^5 MDA-MB-231 cells were seeded in 6-well plates in antibiotic-free medium and reached 30−50% confluence by the time of transfection. Forty picomoles of uPA siRNA (Santa Cruz Biotechnology)/5 μL lipofectamine 2000 transfection complexes were added to each well and incubated at 37 °C for 4 h. Control siRNA (Santa Cruz Biotechnology) and no-transfection controls were run in parallel. Each assay was performed in triplicate. Forty-eight hours post-transfection, effectiveness of siRNA knockdown was assessed by receptor binding assay without acid stripping of endogenous uPA, Western blot, and RT-PCR.

Immunoblot Analysis. Whole cell MDA-MB-231 lysates were prepared 48 h post-transfection and separated by 10% SDS−PAGE, followed by transfer to a PVDF membrane. Loading volumes were normalized on the basis of cell number equivalents. After blocking in 5% nonfat milk, 0.1% Tween-20, and Tris-buffered saline (TTBS) at RT for 1 h, membranes were probed with primary antibodies in blocking solution for 1 h at RT, followed by extensive washing in TTBS. Goat antirabbit and goat antimouse IgG-HRP (Santa Cruz Biotechnology) were used for the detection of immunoreactive proteins by chemiluminescence. Primary antibodies used were rabbit anti-uPA and mouse anti-β-Actin (Santa Cruz Biotechnology).

Reverse Transcription-PCR Analysis. Total RNA from MDA-MB-231 cells 48 h post-siRNA transfection was extracted using Trireagent (Molecular Research Center) and the Qiagen RNeasy kit. Five micrograms of total RNA was applied to synthesize first-strand cDNA using SuperScript reverse transcriptase III (Invitrogen), and PCR was performed in a 25 μL total volume containing 12.5 pmol of primers. The following primers were used: uPA sense 5′-TGC GTC CTG GTC GTG AGC GC-3′ and uPA antisense 5′-CTA CAG CGC TGA CAC GCT TG-3′ to amplify a 780-bp uPA fragment after 35 cycles at 94 °C for 1 min, 55 °C for 1 min, 72 °C for 1 min (*31*). For control GAPDH, the following primers were used: sense 5′-CTT CAT TGA CCT CAACAT GGT TT-3′ and antisense 5′-GGC ATT GCT GAT GAT CTT GAG G-3′ to amplify a 346-bp GAPDH fragment after 23 cycles of 94 °C for 30 s, 63 °C for 30 s, and 72 °C for 1 min.

Biodistribution Studies. Four- to 5-week old female ICR SCID (severe combined immunodeficient) outbred mice were obtained from Taconic (Germantown, NY). The mice were housed four animals per cage in sterile microisolator cages in a temperature- and humidity-controlled room with a 12-h light/12-h dark schedule. The animals were fed sterile rodent chow (Ralston Purina Company, St. Louis, MO) and water *ad libitum*. Animals were housed one week prior to inoculation of tumor cells and anesthetized for injections with isoflurane (Baxter Healthcare Corp., Deerfield, IL) at a rate of 2.5% with 0.5 L/min oxygen through a nonrebreathing anesthesia vaporizer.

MDA-MB-231 human breast cancer cells were injected on the bilateral subcutaneous (s.c.) flank with $\sim 5 \times 10^6$ cells in a suspension of 100 μL 3:1 PBS/Matrigel per injection site. MDA-MB-231 cells were allowed to grow *in vivo* four to five weeks postinoculation, developing tumors ranging in size from 0.06−0.53 g. The biodistribution and uptake of (NAc-dD-CHA-F-dS-dR-YLWS-βAla)$_2$-K-K(^{111}In-DOTA)-NH$_2$, scrambled negative control peptide (NAc-dD-W-dS-LY-dR-FS-CHA-βAla)$_2$-K-K(^{111}In-DOTA)-NH$_2$, and ^{125}I-ATF in tumor bearing SCID mice was studied. The mice (average weight, 25 g) were injected with aliquots (50−100 μL) of the radiolabeled peptide solution (55−90 kBq) via the tail vein. Tissues, organs, and tumors were excised from animals sacrificed at 1, 4, and 24 h p.i., weighed, and counted. Radioactivity was measured in a Wallac 1480 automated gamma counter, and the percent-injected dose per gram tissue was calculated. Differences in organ uptake between the two ^{111}In-labeled peptides were analyzed by Student's *t*-test. Differences at the 95% confidence level ($P < 0.05$) were considered significant. Animal studies were conducted in accordance with the highest standards of care as outlined in the NIH Guide for Care and Use of Laboratory Animals and the Policy and Procedures for Animal Research at the Harry S. Truman Memorial Veterans' Hospital, and according to approved protocols.

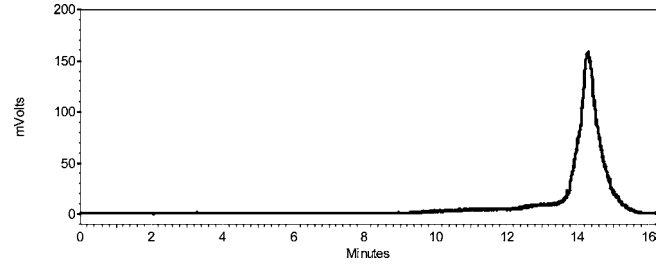

Figure 2. HPLC chromatogram of purified (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(^{111}In-DOTA)-NH$_2$. The ^{111}In-peptide elutes at 14.1 min, while the unlabeled peptide has a retention time of 13.6 min.

RESULTS

Synthesis and in Vitro Characterization. The peptides (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(DOTA)-NH$_2$ (Figure 1) and (NAc-dD-W-dS-L-Y-dR-F-S-CHA-βAla)$_2$-K-K(DOTA)-NH$_2$ were synthesized by standard solid phase peptide synthesis techniques, utilizing two distinct synthetic routes. In the first instance, (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(DOTA)-NH$_2$ was synthesized using a Boc-protected ε-amino group on the C-terminal lysine residue. Following addition of the N-terminal D-aspartic acid residue, the Fmoc-peptide was acetylated on resin via HoBT/DCC activation of 5-fold excess acetic acid in 3:1 NMP/DMSO. Following acetylation, the peptide was cleaved from the resin in a standard deprotection/cleavage mixture, and the free amino group of the C-terminal lysine was conjugated to an activated NHS ester of DOTA. In the second route, the scrambled negative

Table 1. Calculated and Observed Molecular Weights and IC_{50} Values of DOTA-Peptides

peptide	$(M + H)^+$ calc.	$(M + H)^+$ obs.	IC_{50} (nM)
(NAc-dD-CHA-F-dS-dR-YLWS-βAla)$_2$-K-K(DOTA)-NH_2	3301.5	3301.7	240 ± 125
(NAc-dD-W-dS-LY-dR-FS-CHA-βAla)$_2$-K-K(DOTA)-NH_2	3301.5	3301.7	

control peptide (NAc-dD-W-dS-L-Y-dR-F-S-CHA-βAla)$_2$-K-K(DOTA)-NH_2 was synthesized using preconjugated Fmoc-L-Lys-monoamide-DOTA-tris(t-Bu ester), followed by acetylation with HoBT/DCC activated acetic acid, and cleavage from the resin. In each case, the final products were purified by C18 RP HPLC, and masses were confirmed by MALDI-TOF MS (Table 1 and Figure 2).

The peptide (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(DOTA)-NH_2 contains a core uPAR-binding sequence (dD-CHA-F-dS-dR-Y-L-W-S) originally developed using phage display and combinatorial chemistry techniques (*14*, *15*). The affinity of this peptide construct for uPAR was measured using MDA-MB-231 human breast cancer cells and ^{125}I-labeled ATF. The ability of (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(DOTA)-NH_2 to competitively displace ^{125}I-ATF from intact cells was 300−600-fold lower than that of either uPA or ATF, indicating that the dimeric peptide has relatively low affinity for uPAR (Figure 3 and Table 1). The effect of scrambling the peptide sequence was to completely abolish competitive displacement of ATF (Figure 3), demonstrating the specific nature of (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(DOTA)-NH_2 binding to uPAR.

Biodistribution. In vivo biodistribution studies were carried out using SCID mice bearing MDA-MB-231 human breast cancer tumor xenografts. Animals were injected with ^{111}In-labeled peptides and sacrificed 1, 4, and 24 h postinjection (Table 2). Both the uPAR-targeting peptide and the scrambled control peptide cleared rapidly from the bloodstream, primarily via the renal/urinary route. At 4 h pi, uptake of (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(^{111}In-DOTA)-NH_2 in blood and muscle were 0.12 ± 0.06% ID/g and 0.06 ± 0.02% ID/g, respectively, while uptake in tumor was 0.53 ± 0.11% ID/g. For comparison, uptake of the matched scrambled control peptide in blood and muscle were 0.15 ± 0.04% ID/g and 0.12 ± 0.02% ID/g, respectively, at this time point, while tumor uptake dropped significantly ($p < 0.05$) to 0.36 ± 0.05% ID/g.

In vivo results obtained using ^{111}In-labeled peptide uPA antagonists were compared to those obtained using ^{125}I-labeled ATF, a molecule with an approximately 600-fold higher affinity for uPAR. As shown in Table 3, tumor uptake of ^{125}I-ATF only exceeded blood levels at 24 h pi, although this did not reach significant levels. At this time point, however, tumor uptake was significantly lowered by coinjection of excess unlabeled ATF ($p < 0.05$), again demonstrating the specific nature of the tumor uptake observed.

Ex Vivo/in Vitro Studies. To address the issue of uPAR binding capacity in the SCID/MDA-MB-231 model system used here, tumor xenografts were excised from SCID mice following 4−5 weeks of in vivo growth and assayed for ^{125}I-ATF binding with or without stripping of endogenous uPA. Figure 4 demonstrates that specific binding of uPAR-targeted ligands is decreased 4−5-fold due to receptor occupancy by endogenously produced uPA.

To further demonstrate that uPAR-targeted agents could be used to quantify uPA binding sites, we used a uPA-specific set

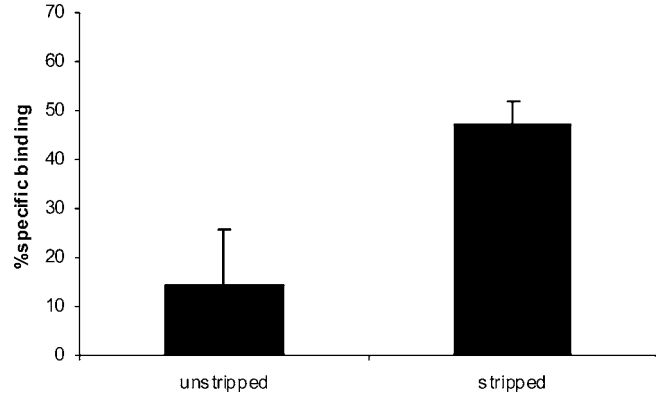

Figure 4. Specific binding of ^{125}I-ATF to MDA-MB-231 tumor cells ex vivo. MDA-MB-231 tumor xenografts were harvested from SCID mice following 4−6 weeks of in vivo growth. Tumors were physically dissociated in a buffered collagenase solution, and specific binding of ^{125}I-ATF was measured using either native preparations or cell preparations stripped of endogenous uPA with pH 3.0 buffer.

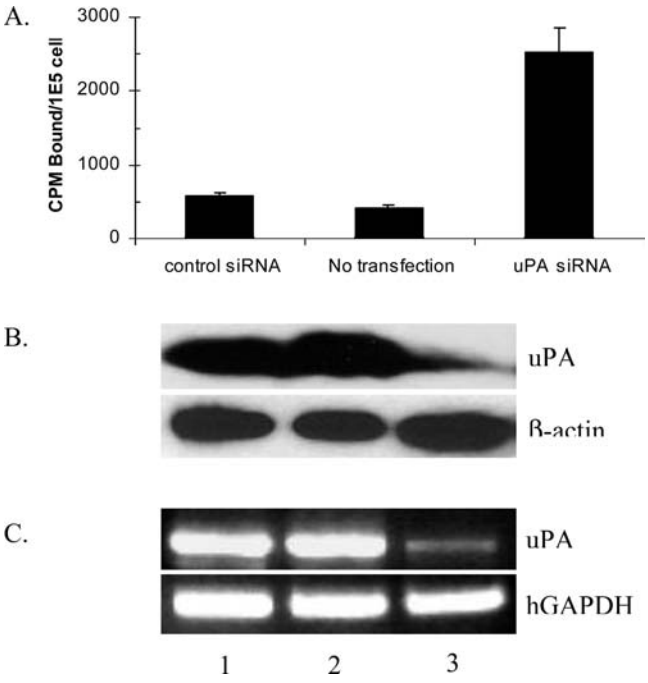

Figure 5. (A) Binding of ^{125}I-ATF to MDA MB-231 cells following knockdown of endogenous uPA production using a uPA-specific set of siRNA's. (B) Western blot demonstrating uPA knockdown 2 days post-transfection of MDA-MB-231 cells. (C) RT-PCR demonstrating decreased uPA message in siRNA transfected MDA-MB-231 cells. Lane 1, control siRNA; lane 2, no-transfection; lane 3, uPA siRNA.

of siRNAs to specifically knock down uPA expression in MDA-MB-231 cells. As seen in Figure 5, binding of ^{125}I-uPA to MDA-MB-231 cells is significantly increased ($p < 0.01$) approximately 4.4-fold following siRNA-mediated knockdown of endogenous uPA in an in vitro model system. This increase in specific binding is correlated with decreases in both uPA mRNA and protein expression as determined by RT-PCR and Western blot (Figure 5).

DISCUSSION

In this study, the synthesis and characterization of a low molecular weight peptide uPAR antagonist with an appended DOTA chelating moiety was described. This construct specifically displaced ^{125}I-labeled ATF with an IC_{50} of 240 ± 125 nM, a characteristic that was completely lost upon alteration of the primary peptide sequence employed. The affinity of (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(DOTA)-NH_2 for uPAR was lower than expected from previously published data obtained for related constructs (*15*−*17*). This is due to a number of structural differences between these compounds. (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(DOTA)-NH_2 is distinct from previously synthesized peptides in being N-terminally acetylated, C-terminally amidated, in the appended DOTA moiety C-terminal to the branching lysine residue, and in the chirality of the N-terminal aspartate residue.

The in vivo biodistribution of the ^{111}In-labeled peptide was compared with that of ^{125}I-labeled ATF and was significantly different at all time points examined. At 1 and 4 h pi, blood levels of each radiotracer were distinctly different, with the higher molecular weight ATF fragment demonstrating significantly slower clearance (Tables 2 and 3). ^{125}I-labeled ATF uptake was higher than (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(^{111}In-DOTA)-NH_2 uptake in all normal tissues at these time points, with the exception of liver and kidney, which demonstrated higher levels of ^{111}In-peptide. Clearance of the ^{111}In-peptide occurs through both hepatobiliary and renal/urinary routes, and liver and kidney retention at 4 h pi was higher than is usually observed for peptides in this molecular weight range (*17*−*23*). Increased liver and kidney retention is still observed for the ^{111}In-labeled branched peptide relative to ^{125}I-ATF at 24 h pi, suggesting a structural mechanism of retention, perhaps due to the branched nature of this construct, distinct from normal residualization of ^{111}In-DOTA-amino acid conjugates.

With respect to specific retention of radiolabeled compounds in tumor tissue, significant ($p < 0.05$) blockade of ^{125}I-ATF uptake was only achieved at 24 h pi, when tumor uptake was 34% blocked by preinjection of 2 mg/kg unlabeled ATF 1 h prior to the injection of ^{125}I-ATF. Because of its more rapid clearance from blood and most normal tissues, (NAc-dD-CHA-F-dS-dR-Y-L-W-S-βAla)$_2$-K-K(^{111}In-DOTA)-NH_2 tumor uptake was significantly ($p < 0.05$) higher than that of the scrambled matched control peptide as early as 4 h pi, with 47% higher uptake at this time point.

The peptide uPAR antagonist discussed in this work was originally synthesized as part of a combinatorial library of peptides targeting uPAR (*15*). This combinatorial library was synthesized to further search conformational space for highest affinity uPAR binders, using lead peptides derived from earlier bacteriophage peptide display libraries (*14*). One of these peptides, termed AE105 in the original work (*15*), has served as the uPAR-targeting vector in two recent publications (*16*, *17*). In these studies, analogues of the AE105 parent peptide were N-terminally labeled with a DOTA moiety, with or without intervening linker residues, which served to coordinate imaging ^{64}Cu (*17*) or therapeutic ^{213}Bi (*16*). In the work described here, a dimeric peptide most closely related to AE120 in Ploug et al. (*15*) has been modified by the addition of DOTA C-terminal to a branching lysine residue.

In the report by Knör et al. (*16*), the assembly of a dimeric construct resulted in increased specific binding of radiolabeled peptide to uPAR-expressing cells in vitro relative to N-terminally labeled linear monomeric peptides. This is in agreement with increased binding affinities of dimeric peptides reported originally in the development of this class of uPAR antagonists (*15*), although the radiopharmaceutical construct was unique in having an N-terminal, rather than C-terminal, branchpoint. On the basis of the higher affinity of a dimeric construct, Knör et al. subsequently used it in an in vivo model of human ovarian cancer and demonstrated tumor uptake of the ^{213}Bi complex of 2.2 ± 0.4% ID/g at 1.5 h pi (*16*). This value is similar to the tumor uptake of 1.48 ± 0.28 at 1 h pi described in this article, although the values are not directly comparable due to differences in the model system, radioisotope, and experimental protocol. Additionally, the specificity of tumor uptake of the ^{213}Bi-labeled peptide in vivo was not addressed.

Li and co-workers have also recently published data relating to the use of radiolabeled uPAR antagonists for in vivo imaging of U87MG human glioma tumor xenografts (*17*). In this instance, an N-terminally DOTA-labeled AE105 analogue was used to deliver the PET radionuclide ^{64}Cu to uPAR-expressing cells. In this instance, the DOTA chelating group was directly linked to the amino group of the N-terminal L-aspartic acid residue of monomeric AE105. Tumor uptake in this model system was increased 2−5-fold relative to both the N-terminally modified dimeric construct of Knör et al. as well as the C-terminally modified dimeric construct described here (7.6 ± 0.9% ID/g at 1 h pi, as measured by PET imaging). Given the differences in experimental design among the three studies to date, more research will be required to directly compare these and similar analogues to define the optimal structure of uPAR-targeted molecular imaging agents.

One factor that could be responsible for differences in tumor uptake between different model cell lines is expression of

endogenous uPA, resulting in the blockade of available sites for binding of uPAR antagonists. The most widely used protocols for the measurement of binding of radiolabeled uPAR ligands in vitro typically employ an acid stripping step, during which endogenously produced uPA is removed, thereby unmasking previously blocked uPAR. Knör and co-workers spoke to this issue by demonstrating tracer binding to OV-MZ-6 cells without prior acid stripping (*16*), suggesting that this cell line produces lower amounts of uPA than does the MDA-MB-231 line employed in this study. As shown in Figures 4 and 5 in this work, binding of ^{125}I-ATF to MDA-MB-231 cells is increased when they have either had endogenous uPA removed by acid stripping (Figure 4) or have had endogenous expression of uPA reduced by the application of specific siRNAs (Figure 5). The fact that the increase in binding observed in Figure 4 was seen following excision of MDA-MB-231 human tumor xenografts from SCID mice following 4−5 weeks of in vivo growth suggests that autocrine saturation could be responsible for reduced tumor uptake in vivo using this model system. Additionally, the MDA-MB-231 human breast cancer cell line is known to produce high levels of uPA, which has been proposed to be correlated with its high degree of invasiveness in in vitro assays (*7, 24*). Last, the low specific tumor uptake of ^{125}I-ATF at 24 h pi provides further evidence that the similarly low uptake of the ^{111}In-DOTA-peptide at 4 h pi is not due solely to the lower affinity of the ^{111}In-labeled radiotracer but is primarily the result of occupancy of uPAR sites within the tumor by endogenously expressed uPA.

uPA is a 54 kDa glycoprotein with well-defined modular domains separated by a flexible linker region. Proteolysis of uPA yields a 36 kDa C-terminal domain that is catalytically active plus an 18.5 kDa amino terminal fragment (ATF) that is responsible for binding to uPAR. The structure of ATF has been solved both by NMR and crystallographic methods (*25, 28*). The ATF is itself composed of two independent domains, a C-terminal kringle domain attached via a flexible linker to an N-terminal growth factor-like domain (GFD). Receptor binding can be further localized within the ATF primarily to the GFD, within the N-terminal 45 amino acids of the ATF. The GFD shares significant homology to the epidermal growth factor (EGF), and binding of GFD to uPAR is mediated in large measure by a disulfide stabilized Ω loop region between residues 18−32 of the molecule. Numerous small peptides that behave as structural mimics of this receptor-binding region have been synthesized and characterized (*14−17, 26−29*), including the lead peptide composing the targeting moiety of the construct described here.

The development of low molecular weight uPAR antagonists as imaging agents for the detection of uPAR-expressing malignancies will potentially have relevance both to patient stratification and therapy monitoring. Several different approaches to cancer therapy have been described that target elements of the urokinase-type plasminogen activator system. These include inhibition of uPA enzymatic activity (*30*), blockade of uPA/uPAR binding (*14, 15*), targeted delivery of therapeutic radionuclides to uPAR-expressing tumors (*16*), and RNA interference (*31*). Targeted knockdown of uPA by a variety of methods, including delivery of siRNAs, shRNAs, or antisense RNAs, is currently under active investigation for cancer therapy (*24, 31, 32*). Such reductions in in vivo expression of uPA have been shown to reduce the metastatic potential of tumor cells and to reduce the rate of tumor growth. In the context of uPA-targeted RNA interference, imaging agents such as the type described here could provide a direct measure of treatment efficacy in vivo, by generating increasing signals proportional to the degree of uPA knockdown. With respect to the blockade of uPA/uPAR binding, such a probe could facilitate the delivery of inhibitors by enabling real-time monitoring of dosages required for inhibition of probe signal generation. Probes of the type illustrated here could ultimately provide a complementary imaging modality to optical sensors of uPA activity currently under development (*33, 34*). Further experiments are currently underway to develop the correlation suggested here between receptor occupancy and radiotracer uptake in vivo.

ACKNOWLEDGMENT

This material is the result of work supported with resources and the use of facilities at the Harry S. Truman Memorial Veterans' Hospital, Columbia, MO, 65201 and the Department of Radiology, University of Missouri—Columbia School of Medicine, Columbia, MO 65211. This work was funded by a United States Department of Veterans' Affairs Biomedical Laboratory Research and Development Service VA Merit Award, a National Cancer Institute Center grant (1 P50 CA103130-01), and a United States Department of Defense Concept Award (BC032697).

Morandi, 30, 20097 S. Donato M.se (MI), Italy. Received October 16, 2008; Revised Manuscript Received March 30, 2009

The mesophilic organism *Lysinibacillus sphaericus* CCM 2177 produces the surface (S)-layer protein SbpA, which after secretion completely covers the cell surface with a crystalline array exhibiting square lattice symmetry. Because of its excellent *in vitro* recrystallization properties on solid supports, SbpA represents a suitable candidate for genetically engineering to create a versatile self-assembly system for the development of a molecular construction kit for nanobiotechnological applications. The first goal of this study was to investigate the surface location of 3 different C-terminal amino acid positions within the S-layer lattice formed by SbpA. Therefore, three derivatives of SbpA were constructed, in which 90, 173, or 200 C-terminal amino acids were deleted, and the sequence encoding the short affinity tag *Strep*-tag II as well as a single cysteine residue were fused to their C-terminal end. Recrystallization studies of the rSbpA/STII/Cys fusion proteins indicated that C-terminal truncation and functionalization of the S-layer protein did not interfere with the self-assembly capability. Fluorescent labeling demonstrated that the orientation of the crystalline $rSbpA_{31-1178}$/STII/Cys lattice on solid supports was the same, like the orientation of wild-type S-layer protein SbpA on the bacterial cell. In soluble and recrystallized rSbpA/STII/Cys fusion proteins, *Strep*-tag II was used for prescreening of the surface accessibility, whereas the thiol group of the end-standing cysteine residue was exploited for site-directed chemical linkage of differently sized preactivated macromolecules via heterobifunctional cross-linkers. Finally, functionalized two-dimensional S-layer lattices formed by $rSbpA_{31-1178}$/STII/Cys exhibiting highly accessible cysteine residues in a well-defined arrangement on the surface were utilized for the template-assisted patterning of gold nanoparticles.

INTRODUCTION

Crystalline bacterial cell surface layer (S-layer) proteins form the outermost cell envelope component of prokaryotic organisms. They are composed of identical protein or glycoprotein subunits, which completely cover the cell surface during all stages of bacterial growth and division. Even after isolation from the cell wall, S-layer proteins have the intrinsic tendency to self-assemble into crystalline arrays in suspension or to recrystallize on solid supports, such as silicon wafers, gold chips, silanized glass, or plastic materials, on polyelectrolytic microcapsules, on Langmuir lipid films, on liposomes, and at the air−water interface (*1*−*5*). General aspects of the structure of S-layer proteins have been examined quite extensively, such as the ultrastructure of the lattice, and the binding and anchoring of S-layer proteins to the underlying cell envelope through the so-called S-layer-homology (SLH)-domains. Together with the high density and regular arrangement of functional groups in the S-layer lattice, this specific feature opens a broad application potential in biotechnology, molecular nanotechnology, and biomimetics (*3*). In previous studies, mainly carboxyl groups in the S-layer lattice were exploited for covalent binding of biologically active macromolecules, such as enzymes, antibodies, or ligands for the production of S-layer-based biosensors (*3*), solid-phase dipstick style immunoassays (*6*−*8*), or affinity matrices based on self-assembly products (*9*). The possibility to change the properties of S-layer proteins by genetic engineering offers new ways for tuning their functional and structural features as required in nanobiotechnology as well as in material sciences.

The S-layer protein SbpA of *Lysinibacillus sphaericus* CCM 2177 consists of a total of 1,268 amino acids (including a 30-amino-acid-long signal peptide). SbpA self-assembles into a square (p4) lattice structure with a center-to-center spacing of the morphological units of 13.1 nm. The self-assembly process is strongly dependent on the presence of bivalent cations (*10*). In their absence, SbpA stays in the water-soluble state, which means that the self-assembly process of this S-layer protein is dirigible (*11*). The N-terminal part of SbpA possesses 3 typical S-layer homologous (SLH) motifs and an additional 58 amino acid-long SLH-like motif that recognizes a distinct type of secondary cell wall polymer (SCWP), consisting of 8 to 9 disaccharide repeating units, as the proper anchoring structure in the rigid cell wall layer (*10*). These specific interactions can be exploited for an oriented binding of SbpA on solid supports precoated with SCWP to generate monomolecular protein lattices (*12*).

The gene *sbpA*, encoding this S-layer protein, has been sequenced, cloned, and expressed in *Eschericia coli* HMS174(DE3) (*13*). Studies on the structure−function relationship of SbpA revealed that deletions of up to 237 C-terminal amino acids do not interfere with the ability to self-assemble into the square lattice structure. However, the deletion of 350 amino acids was linked to a change from square (p4) to oblique (p1) lattice symmetry (*14*). An N- and C-terminally truncated form was capable of self-assembling into the square (p4) lattice structure with lattice parameters similar to that formed by the full-length SbpA. These findings indicated that the segment between amino acid 203 and 1,031 is responsible for the self-assembly process and for pore formation (*14*).

[a] Cloning sites are in bold text (NcoI at the 5′-end and XhoI at the 3′-end of the coding sequence); Strep-tag II is underlined; and cysteine residue is in italic text and is underlined.

Recent studies have shown that bacterial S-layer proteins can be used for controlled deposition of inorganic material, which can be achieved by using the S-layer lattices as templates for direct precipitation of metals from solution or by binding preformed metallic and semiconductor nanoparticles (*15*−*18*). In this context, gold nanoparticles formed on cells and purified S-layer protein of *Bacillus sphaericus* JG-A12 after incubation with Gold(III) solution in the presence of H_2 as reducing agent were characterized by X-ray absorption spectroscopy, UV−vis spectroscopy, and X-ray powder diffraction (*19*). In another approach, the self-assembly of dendrimer-encapsulated platinum nanoparticles on S-layer proteins from the archaeon *Sulfolobus acidocaldarius* and the gram-positive *Deinococcus radiodurans* was used to create patterned nanoparticle arrays with potential technological applications (*20*).

In the present study, C-terminal functionalization of the S-layer protein SbpA combined with targeted chemical modification was used to identify amino acids that are located at the surface of the S-layer lattice and therefore accessible for binding of functional molecules or nanoparticles. A C-terminal cysteine residue was introduced with the aim to produce structured crystalline monolayers on solid supports offering free sulfhydryl groups for the activation with various heterobifunctional cross-linkers and covalent attachment of differently sized (macro)molecules. Binding of gold nanoparticles to the surface located cysteine residues should finally lead to the formation of regularly ordered nanoarrays.

MATERIAL AND METHODS

Cloning and Expression of the Genes Encoding the S-Layer Fusion Proteins rSbpA$_{31-1178}$STII/Cys, rSbpA$_{31-1095}$/STII/Cys, and rSbpA$_{31-1068}$/STII/Cys. For amplification of the genes encoding the C-terminally truncated forms rSbpA$_{31-1178}$, rSbpA$_{31-1095}$ and rSbpA$_{31-1068}$, chromosomal DNA of *Lysinibacillus sphaericus* CCM 2177 was used as a template. Isolation of chromosomal DNA and PCR amplifications were performed as described in ref 21. General procedures for DNA manipulations were carried out as reported in ref 22. The oligonucleotide forward primer *sbpA37* as well as the reverse primers *sbpA II/3*, *sbpA II/4*, and *sbpA II/5* (all listed in Table 1) introduced the cloning sites *NcoI* and *XhoI* at the 5′- and 3′-ends, respectively. In comparison to the wild-type S-layer protein, the reverse primers led to the C-terminal deletion of 90, 173, or 200 amino acids in the respective proteins, as well as to the fusion of *Strep*-tag II and a single cysteine residue to the C-terminal end. Cloning of pET28a (Invitrogen), carrying the genes *sbpA*$_{(93-3534)}$/*STII*/*Cys*, *sbpA*$_{(93-3285)}$/*STII*/*Cys*, and *sbpA*$_{(93-3204)}$/*STII*/*Cys* in *E. coli* TG1 (Stratagene), was done as described in ref 13. For the selection of positive transformants, kanamycin was added at a final concentration of 30 μg/mL. Heterologous expression of the genes *sbpA*$_{(93-3534)}$/*STII*/*Cys*, *sbpA*$_{(93-3285)}$/*STII*/*Cys*, and *sbpA*$_{(93-3204)}$/*STII*/*Cys* in *E. coli* BL21Star (DE3) One Shot (Invitrogen) was performed as described in ref 21. Samples of the *E. coli* BL21(DE3) cultures were taken before and 4 h after the induction of expression. For all three S-layer fusion proteins, preparation of samples for SDS−PAGE analysis was carried out as described by Laemmli (*23*). Immunoblotting with a polyclonal rabbit antiserum raised against the S-layer protein SbpA of *Ly. sphaericus* CCM 2177 was performed as described previously (*24*).

Isolation of the Three S-Layer/STII/Cys Fusion Proteins from the Host Cells and Purification. Isolation of the three different truncated SbpA fusion proteins carrying *Strep*-tag II and a cysteine residue at the C-terminal end was performed as previously described (*21*) except that only degassed buffers were

used, and additionally 1,4-dithio-D,L-threitol (DTT, GERBU) in a final concentration of 1 mM was added as reducing agent to all buffers to prevent the formation of disulfide bridges between the C-terminally located cysteine residues. Purification of the fusion proteins by gel permeation chromatography (GPC) using a Superdex 200 column (Pharmacia; Upsala, Sweden) in 2 M guanidine hydrochloride (GHCl) in 50 mM Tris-HCl/150 mM NaCl buffer (pH 7.2) and 1 mM DTT was done as described before (*25*). Fractions containing rSbpA$_{31-1178}$/STII/Cys, rSbpA$_{31-1095}$/STII/Cys, or rSbpA$_{31-1068}$/STII/Cys were pooled, dialyzed against degassed Milli-Q water containing 1 mM DTT for 18 h at 4 °C, analyzed by SDS−PAGE, lyophilized, and stored at −20 °C.

Investigation of the Self-Assembly and Recrystallization Properties of rSbpA$_{31-1178}$/STII/Cys, rSbpA$_{31-1095}$/STII/Cys, and rSbpA$_{31-1068}$/STII/Cys by Transmission Electron Microscopy (TEM) and Atomic Force Microscopy (AFM). To investigate the ability of the three rSbpA/STII/Cys fusion proteins to form self-assembly products in suspension, 2 mg of GPC-purified fusion protein were dissolved in 1 mL of 5 M GHCl in 50 mM Tris-HCl buffer (pH 7.2) with 1 mM DTT and dialyzed against degassed Milli-Q water containing 1 mM DTT and 10 mM $CaCl_2$ for 18 h at 4 °C. For recrystallization on solid supports, the fusion proteins dissolved as described above were dialyzed against degassed Milli-Q water containing 1 mM DTT. Then, 1 mg of lyophilized peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177, prepared according to *refs* 10 *and* 13, was added to 1 mL of the solution containing the monomeric S-layer fusion protein. To induce the recrystallization process, 10 mM $CaCl_2$ was added, and the suspensions were stirred for 18 h at 4 °C.

To investigate the ability of monomeric rSbpA/Cys fusion proteins to recrystallize on poly-L-lysine coated copper grids, the GHCl-extracts were dialyzed against distilled water for 18 h at 4 °C. After centrifugation for 5 min at 16,000*g*, the clear supernatants containing nonassembled S-layer protein were incubated with poly-L-lysine (Sigma P2636) coated copper grids according to the procedures described in ref 26.

For electron microscopical examination, 30 μL of the solution containing self-assembly products or recrystallization products was transferred onto a carbon-coated electron microscope grid, which had been rendered hydrophilic by glow discharge. Negative staining of the samples with 2.5% uranyl acetate was performed as described in ref 26. Electron micrographs were taken with a Philips CM 12 transmission electron microscope (Philips Eindhoven, The Netherlands) operated at 80 kV in low-dose mode.

AFM measurements of rSbpA/STII/Cys fusion proteins recrystallized on silicon wafers were performed on a Digital Instruments Nanoscope IIIa (Santa Barbara, CA) with a J-scanner (nominal 130-μm scan size). Silicon wafers (100, p-type, boron-doped, resistivity 25−45 Ω cm; MEMC, Italy) were cut into pieces of 1 × 1 cm and precleaned as previously described in ref 27. The rSbpA/STII/Cys fusion proteins (0.1 mg/mL in recrystallization buffer: 0.5 mM Tris/HCl, pH 9, 10 mM $CaCl_2$) were recrystallized on the silicon wafers as reported in ref 16. The scanning was carried out in contact mode under fluid (100 mM NaCl, pH 7.5). For imaging, standard 200-μm-long oxide-sharpened silicon nitride cantilevers (NanoProbes, Digital Instruments, INC) with a nominal spring constant of 0.06 N/m were used. The scan speed was approximately 6 Hz, and the applied force was kept minimized during scanning to prevent the tip from modifying the sample surface.

Immunoblotting for Detection of the C-Terminally Fused *Strep*-tag II and Surface Accessibility Screens by Immuno Dot Assays. For immunoblotting, monomeric fusion proteins were subjected to SDS−PAGE and transferred to a nitrocellulose membrane by semidry-blotting as described previously (*24*). For detection of *Strep*-tag II, membranes were incubated with a monoclonal mouse anti-*Strep*-tag II antibody (IBA) diluted 1:350 in 2% Blocking Reagent GE in 0.1 M TBS (Tris-buffered saline) for 2 h at room temperature. After several washing steps and incubation with antimouse IgG-alkaline phosphatase (ALP) conjugate (Sigma), diluted 1:5,000 in 2% Blocking Reagent GE in 0.1 M TBS, for 1 h at room temperature, detection was accomplished by treatment with 5-bromo-4-chloro-3-indolyl phosphate and nitroblue tetrazolium chloride (BCIP/NBT, Roche).

To investigate the surface accessibility of *Strep*-tag II within the S-layer lattice, the three different SbpA fusion proteins were recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177. Recrystallization products were dried onto a nitrocellulose membrane, and immuno dot assay using monoclonal mouse anti-*Strep*-tag II antibody and antimouse IgG-ALP conjugate was performed as described in ref 28.

Chemical Modification of the Cysteine Residues in Monomeric rSbpA$_{31-1178}$/STII/Cys Fusion Protein by Linkage of Differently Sized Preactivated Macromolecules. A monomeric solution of rSbpA$_{31-1178}$/STII/Cys was produced by dissolving 1 mg of S-layer fusion protein in 1 mL of 5 M GHCl in 50 mM Tris/HCl buffer (pH 7.2) with 1 mM DTT and dialyzing against degassed Milli-Q water containing 1 mM DTT. After removal of DTT by PD10 desalting columns, the protein solution was mixed with a 2-fold molar excess of methoxypoly(ethylene glycol)maleimide (m-PEG-mal, Nektar therapeutics) with a size of 5 or 20 kDa, respectively, overlaid with nitrogen and incubated overnight at 4 °C.

For modification of the cysteine residues with differently sized macromolecules via a heterobifunctional cross-linker, solutions containing momomers of rSbpA$_{31-1178}$/STII/Cys were mixed in a molar ratio of 1:2 with Protein A (Sigma), carbonic anhydrase (Sigma), or the major birch pollen allergen (rBet v1), which was preactivated with *m*-maleimidobenzoyl-*N*-hydroxysulfosuccinimide ester (Sulfo-MBS, Piercenet). For that purpose, 2 mg of Protein A, carbonic anhydrase, or Bet v1 was dissolved in conjugation buffer, PBS (0.1 M, pH 7.2), and Sulfo-MBS, prepared according to the manufacturer's recommendations, was added in a 10-fold molar excess. The mixture was incubated for 2 h at 4 °C. The excess unbound cross-linker was removed by using desalting columns (PD10, GE Healthcare) equilibrated with the conjugation buffer. Chemical modification was checked by SDS−PAGE analysis (gel shift assay).

Investigation of the Recrystallization Properties of the SbpA$_{31-1178}$/STII/Cys/Carbonic Anhydrase Conjugates by TEM and Detection of the Enzyme on the Surface of the S-Layer Lattice. For recrystallization, conjugates between carbonic anhydrase and rSbpA$_{31-1178}$/STII/Cys (1 mg/mL in recrystallization buffer: 0.5 mM Tris/HCl, pH 9, and 10 mM $CaCl_2$) were mixed with 1 mg of peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177, and the solution was stirred at 4 °C overnight. The formation of recrystallization products was checked after negative staining by TEM. For detection of the preactivated carbonic anhydrase bound to the cysteine residues on the S-layer lattice, immuno dot assays were carried out. For this, recrystallization products were washed three times with Milli-Q water, and 10 μL of the sample solution was dried on a nitrocellulose membrane. The membrane was blocked with 2% Blocking Reagent GE (Applichem Biomedica) in 0.1 M TBS overnight at 4 °C followed by incubation with rabbit anticarbonic anhydrase antibody (Sigma), diluted 1:5,000 in 2% Blocking Reagent GE in 0.1 M TBS, for 2 h at room temperature. After several washing steps and incubation of the membrane with antirabbit IgG-ALP conjugate (Sigma), diluted

1:5,000 in 2% Blocking Reagent GE in 0.1 M TBS, for 1 h at room temperature, detection was accomplished by treatment with BCIP/NBT.

Binding of a Fluorescent Thiol-Reactive Dye to Crystalline Monolayers Formed by rSbpA$_{31-1178}$/STII/Cys. For site-specific-labeling, rSbpA$_{31-1178}$/STII/Cys was recrystallized overnight under rotation in recrystallization buffer (0.5 mM Tris/HCl, 10 mM $CaCl_2$, pH 9) on microparticles, which were based on silicon dioxide (SiO_2) in aqueous solution (3 μm SiO_2-particles; Fluka). Subsequently, the particles were incubated with 7-diethylamino-3-(4′-maleimidylphenyl)-4-methylcoumarine (CPM; Invitrogen) for 30 min at room temperature. The thiol-reactive coumarin, CPM is very weakly fluorescent until reacted with the thiol-group of the cysteine residue producing a conjugate with excitation and emission maxima of ~384/470 nm. The covered particles were washed three times with Milli-Q water and analyzed by using a fluorescence microscope (Nikon Eclipse TE 2000-S) with the filter DAPI. Wild-type S-layer protein SbpA recrystallized on SiO_2-particles as well as SiO_2-particles without S-layer protein, used as blanks, were measured under the same conditions. For measurement of excitation and emission spectra of the samples (protein concentration 0.1 mg/mL), the luminescence spectrometer LS 55 (PerkinElmer, Shelton CT, U.S.A.) was used. Fluorescence spectroscopy of the protein samples was carried out by wavelength scan with a scan speed of 500 nm/min in a quartz cuvette (1 cm). The band-pass for both the excitation and emission monochromators was 5 nm. Emission spectra were recorded at a fixed wavelength of the excitation maximum and excitation spectra at a fixed wavelength of the emission maximum. For the measurement of the emission and excitation spectra, 2 mL of 50 mM Tris/HCl buffer (pH 8) was mixed with 50 μL of SiO_2-particles covered with rSbpA$_{31-1178}$/STII/Cys or 10 μL of rSbpA$_{31-1178}$/STII/Cys solution (protein concentration 1 mg/mL) and stirred in a quartz cuvette with a magnetic stirring shaft. After 360 s, 100 μL of 2 mM fluorophore was added, and 1800 s later excitation and emission were measured. For reference studies, the sole fluorophore, soluble rSbpA$_{31-1178}$/STII/Cys without dye, soluble wild-type SbpA incubated with the dye, wild-type SbpA recrystallized on microparticles incubated with the fluorophore, and SiO_2-particles alone or incubated with the fluorophore were analyzed.

Chemical Modification of the Cysteine Residues of Recrystallized rSbpA$_{31-1178}$/STII/Cys with Carbonic Anhydrase via a Heterobifunctional Cross-Linker. Preactivation of carbonic anhydrase with Sulfo-MBS was carried out as described above. Recrystallization products consisting of rSbpA$_{31-1178}$/STII/Cys recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 were incubated with preactivated carbonic anhydrase for 2 h at 4 °C. To remove unbound preactivated carbonic anhydrase the recrystallization products were washed with Milli-Q water three times. For detection of the preactivated carbonic anhydrase bound to the cysteine residues on the S-layer lattice, immuno dot assays using rabbit anticarbonic anhydrase antibody (Sigma) and antirabbit IgG-ALP conjugate (Sigma) were carried out as described above.

Binding of Colloidal Gold Nanoparticles to Monolayers Formed by rSbpA$_{31-1178}$/STII/Cys on Peptidoglycan-Containing Sacculi of *Ly. sphaericus* CCM 2177. Recrystallization products consisting of rSbpA$_{31-1178}$/STII/Cys fusion protein recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 as well as self-assembly products of the fusion protein were incubated with 75 μL of colloidal gold (5 nm, $HAuCl_4$ in Tris/HCl, pH 7.2, Sigma) at room temperature for 20 min and then centrifuged for 10 min at 13,400 rpm. The procedure was repeated 2 times, then the pellet was washed three times with Milli-Q water and resuspended in 15 μL of Milli-Q water, and unstained samples were investigated by TEM. As a control, the same procedure was carried out with (a) self-assembly products formed by wild-type SbpA and (b) recrystallization products prepared with wild-type SbpA recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177.

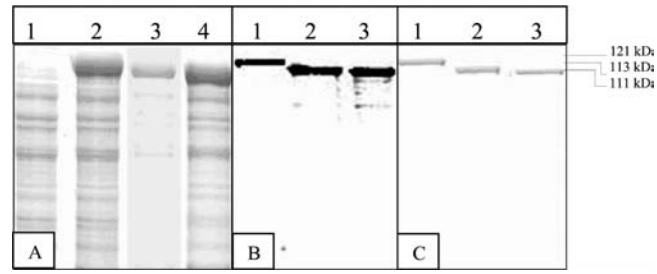

Figure 1. (A) SDS−PAGE analysis of SDS-extracted whole cells of *E. coli* BL21star(DE3) harboring plasmid pET28a/*sbpA*$_{(93-3534)}$/*STII*/*Cys* before the induction of expression (lane1); *E. coli* BL21star(DE3) harboring plasmid pET28a/*sbpA*$_{(93-3534)}$/*STII*/*Cys* (lane2); *E. coli* BL21star(DE3) harboring plasmid pET28a/*sbpA*$_{(93-3285)}$/*STII*/*Cys* (lane3), *E. coli* BL21star(DE3) harboring plasmid pET28a/*sbpA*$_{(93-3204)}$/*STII*/*Cys* (lane4), respectively, 4 h after the induction of expression. (B) Immunoblot analysis of rSbpA$_{31-1178}$STII/Cys (lane 1), rSbpA$_{31-1095}$/STII/Cys (lane 2), and rSbp$_{A31-1068}$/STII/Cys (lane 3) using a polyclonal rabbit antiserum raised against the S-layer protein SbpA of *Ly. sphaericus* CCM 2177. (C) GPC-purified fusion protein rSbpA$_{31-1178}$STII/Cys (lane 1), rSbpA$_{31-1095}$/STII/Cys (lane 2), and rSbpA$_{31-1068}$/STII/Cys (lane 3).

Image Processing. Electron microscopical images were recorded on 35 mm negative film (Kodak Fine Grain 5302, Eastman Kodak, Rochester, NY) and subsequently digitized with a Nikon Film Scanner (Model Super Cool Scan 4000 ED; Nikon Tokyo, Japan) at a resolution of 4000 dpi. Estimates of the lattice vectors of the gold nanoparticle superlattice were determined from digital diffraction patterns after Fourier transform of the image data. An accurate lattice fit, where gold nanoparticles at interlattice positions were also sorted out, was performed by using cross-correlation averaging (CCA) (*29*). Cross-correlation is a matched filtering image processing technique allowing reliable and almost fully automatic image averaging for near-periodic structures. First of all, a reference motif is cross-correlated with the image in order to indicate similar regions in the image. A superposition of small regions centered on each cross-correlation peak position lead to an improvement of the signal-to-noise ratio. Vectors pointing from positions on a least-squares fitted lattice toward actually found positions yield a graphical representation of the displacement field (*29*). The lattice parameters (two base vectors and a vector offset) were determined by minimizing the squared deviation between nanoparticle positions found in the course of CCA and ideal lattice sites. The root-mean-square deviation (r.m.s.) is a convenient measure of the degree of order in the superlattice of gold nanoparticles. Image processing software was developed in house.

RESULTS

Cloning and Expression of the Genes Encoding the Three S-Layer Fusion Proteins rSbpA$_{31-1178}$/STII/Cys, rSbpA$_{31-1095}$/STII/Cys, and rSbpA$_{31-1068}$/STII/Cys. PCR products were ligated into the pET28a vector, cloned in *E. coli* TG1, and then established in *E. coli* BL21(DE3) for expression. Biomass samples were harvested before and at 4 h after induction of expression and subjected to SDS−PAGE analysis. In comparison to noninduced *E. coli* BL21(DE3) cells (Figure 1A, lane 1), in samples from *E. coli* BL21(DE3) cultures induced to express the genes encoding rSbpA$_{31-1178}$/STII/Cys, rSbpA$_{31-1095}$/STII/Cys, and rSbpA$_{31-1068}$/STII/Cys, additional high molecular mass protein bands were observed on SDS-gels (Figure 1A,

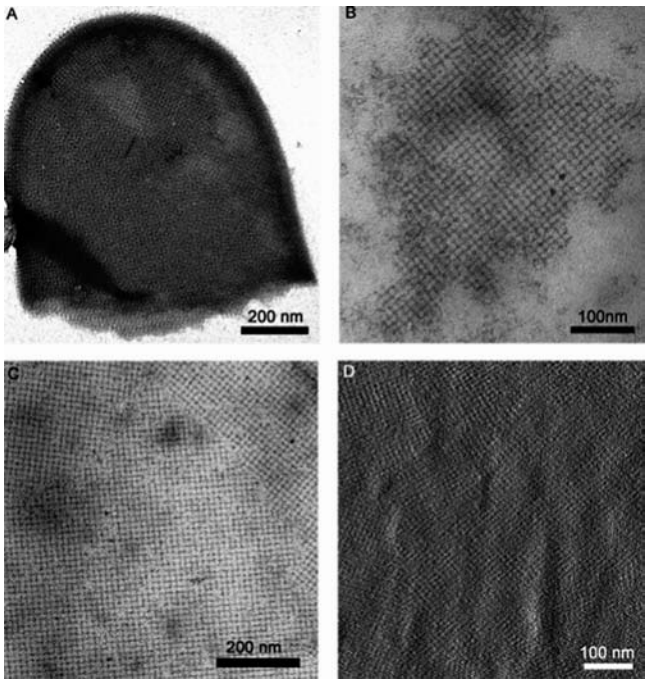

Figure 2. Electron micrograph of negatively stained preparations demonstrating the formation of the square S-layer lattice by the fusion protein rSbpA$_{31-1178}$STII/Cys on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 (A); of rSbpA$_{31-1178}$STII/Cys self-assembly products in suspension (B); rSbpA$_{31-1178}$STII/Cys recrystallized into a closed monolayer consisting of numerous randomly oriented patches on poly-L-lysine coated EM-grids (C); and AFM image of rSbpA$_{31-1178}$STII/Cys recrystallized into a closed crystalline monolayer on a silicon chip (D).

lanes 2, 3, and 4). These additional protein bands had apparent molecular masses of 121,000 Da, 114,000 Da, and 111,000 Da, respectively, which corresponded to the theoretical molecular masses estimated for the three fusion proteins of 121,345 Da, 113,720 Da, and 111,241 Da, respectively. Immunoblotting using the polyclonal rabbit antiserum raised against the S-layer protein SbpA of *Ly. sphaericus* CCM 2177 revealed a strong cross-reaction with each of the three additional protein bands (Figure 1B, lanes 1, 2, and 3).

Isolation of the Three rSbpA/STII/Cys Proteins from the Host Cells and Purification and Investigation of the Recrystallization Properties. As derived from SDS−PAGE analysis of samples collected during the isolation procedure, all three fusion proteins had accumulated in the insoluble fraction of the lysed *E. coli* BL21(DE3) cells (data not shown). After purification by GPC, single protein bands with an apparent molecular mass of 121,000 Da, 114,000 Da, or 111,000 Da, respectively, were detected on SDS-gels (Figure 1C, lanes 1, 2, and 3). Recrystallization on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 was induced by the addition of 10 mM $CaCl_2$ to monomeric solutions of the rSbpA fusion proteins. To avoid potential dimer formation caused by the C-terminally fused cysteine residue, which would disturb the recrystallization process, 1 mM DTT was added to the recrystallization buffer. As shown by transmission electron microscopy for the derivative rSbpA$_{31-1178}$/STII/Cys (Figure 2A), all three rSbpA derivatives recognized peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 as binding sites and recrystallized into the square lattice structure with a center-to-center spacing of the morphological units of 13.1 nm, which is typical for the S-layer protein SbpA. In this approach, the specific recognition mechanism between the N-terminal SLH-domain of the S-layer protein and the SCWP in the peptidoglycan-containing sacculi was used for oriented binding of the fusion proteins on the solid support. As shown by negative staining for rSbpA$_{31-1178}$/STII/Cys, all three

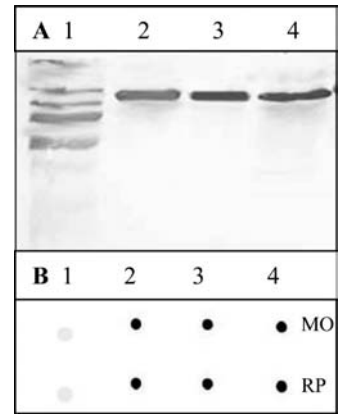

Figure 3. (A) Immunoblot analysis of rSbpA$_{31-1178}$STII/Cys (lane 2), rSbpA$_{31-1095}$/STII/Cys (lane 3), and rSbpA$_{31-1068}$/STII/Cys (lane 4) using monoclonal mouse anti-Strep-tag II antibody. Lane 1, bench mark ladder (All blue). (B) Immuno dot assay indicating the accessibility of the C-terminal Strep-tag II of rSbpA$_{31-1178}$STII/Cys (lane 2), rSbpA$_{31-1095}$/STII/Cys (lane 3), and rSbpA$_{31-1068}$/STII/Cys (lane 4) in a monomeric state (MO) or recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 (RP). In lane 1, corresponding samples prepared with wild-type SbpA showed no cross-reaction with the monoclonal mouse antibody raised against STII.

rSbpA/STII/Cys fusion proteins were able to reassemble in suspension into flat double layer sheets with a maximum size of 2 μm, clearly exhibiting the square lattice structure (Figure 2B). These results demonstrated that neither the C-terminal deletions nor the fusion of the *Strep*-tag II and the single cysteine residue interfered with the recrystallization and the cell wall binding properties of the S-layer protein. As shown for rSbpA$_{31-1178}$/STII/Cys in Figure 2C, all three rSbpA/STII/Cys fusion proteins were capable of recrystallizing into closed crystalline monolayers consisting of numerous randomly oriented patches on poly-L-lysine coated EM-grids. Additionally, AFM analysis of the three rSbpA/STII/Cys fusion proteins recrystallized on silicon chips clearly demonstrated the formation of closed monolayers displaying the square lattice structure (shown in Figure 2D for rSbpA$_{31-1178}$/STII/Cys). Comparison of the recrystallization behavior of the three differently truncated fusion proteins revealed that the derivative rSbpA$_{31-1178}$/STII/Cys was able to recrystallize into closed crystalline monolayers showing a good long-range order on solid supports (Figure 2A−D), whereas rSbpA$_{31-1095}$/STII/Cys and rSbpA$_{31-1068}$/STII/Cys showed a more patch-like recrystallization pattern (data not shown).

Investigation of the Accessibility of *Strep*-tag II in Water-Soluble and Recrystallized rSbpA/STII/Cys Fusion Proteins. The presence of *Strep*-tag II at the C-terminus of all three rSbpA/STII/Cys fusion proteins was confirmed by immunoblotting with a monoclonal mouse antibody raised against *Strep*-tag II. All three fusion proteins showed significant cross-reactions with the anti-*Strep*-tag II antibody (Figure 3A, lanes 2−4). Immuno dot assays of the three fusion proteins in a water-soluble state as well as those recrystallized on peptidoglycan-containing sacculi showed a good accessibility of *Strep*-tag II on the surface of the S-layer lattice (Figure 3B). These findings indicated that the accessibility of the *Strep*-tag II was not reduced in recrystallized S-layer fusion proteins. However, equal color-intensity of the dots indicated that minor differences in accessibility of the differently truncated C-termini of the three derivatives cannot be estimated with this method. Wild-type SbpA recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177, used as a control, showed no reaction with the antibody against *Strep*-tag II (Figure 3B, lane 1).

Targeted Chemical Modification of the Cysteine Residue of Monomeric rSbpA$_{31-1178}$/STII/Cys with Differently Sized Preactivated Macromolecules. To assess the surface accessibility of the cysteine residue at the C-terminal end of folded monomers

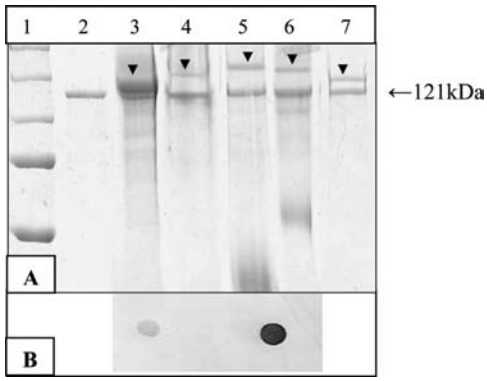

Figure 4. (A) Examination of the surface accessibility of the C-terminal cysteine residue of monomeric rSbpA$_{31-1178}$/STII/Cys fusion protein by targeted chemical modification with differently sized macromolecules. Bench mark ladder (All blue, Biorad laboratories, Hercules, CA) (lane 1); GPC-purified rSbpA$_{31-1178}$/STII/Cys (lane 2); rSbpA$_{31-1178}$/STII/Cys chemically modified with sulfhydryl-specific PEG-maleimide 5 kDa (lane 3) and 20 kDa (lane 4) as well as rSbpA$_{31-1178}$/STII/Cys modified with protein A (M_r = 42 kDa) (lane 5), carbonic anhydrase (M_r = 29 kDa) (lane 6), or rBet v1 (M_r = 17 kDa) (lane 7) preactivated with the heterobifunctional cross-linker Sulfo-MBS. The positions of modified (upshifted) bands are indicated by arrows. (B) Immuno dot assay using rabbit anticarbonic anhydrase antibody indicating the presence of carbonic anhydrase on the surface of the monolayer formed by recrystallization of rSbpA$_{31-1178}$/STII/Cys-Sulfo-MBS-carbonic anhydrase conjugate on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 (right dot). Left dot: recrystallization products consisting of wild-type SbpA recrystallized on PGS of *Ly. sphaericus* CCM 2177 showed no signal.

of rSbpA$_{31-1178}$/STII/Cys in solution (Figure 4A, lane 2), sulfhydryl-specific PEG-maleimide modification was performed. The modification with m-PEG-mal, size 5 and 20 kDa, resulted in an increase of the molecular mass of the protein visible as a gel shift on SDS−PAGE corresponding to the molecular mass of the respective m-PEG-malemide (Figure 4A, lanes 3 and 4). By the addition of DTT, the upshift of the rSbpA$_{31-1178}$/STII/Cys-PEG conjugate could be reversed (data not shown), which indicated that the cysteine residues of the mutant were specifically PEGylated.

Consistently, chemical modification of the cysteine residues of monomeric SbpA$_{31-1178}$/STII/Cys fusion protein with the differently sized macromolecules Protein A, (M_r 42 kDa), carbonic anhydrase (M_r 29 kDa), or rBet v1 (M_r 17 kDa) via the heterobifunctional cross-linker Sulfo-MBS, resulted in an increase of the molecular mass as calculated for the sum of the theoretical masses of the truncated S-layer protein plus the respective macromolecules (Figure 4A, lanes 5, 6, and 7). The modification pattern of the mutant indicated the presence and accessibility of the cysteine residues in the monomeric fusion protein. Although during all stages of the experiment DTT was added, and the solutions and buffers were degassed, the monomeric mutant could not be completely modified, which indicated that maybe irreversible oxidation of the sulfhydryl groups of some of the cysteine residues has occurred. Increase of the molar ratio between rSbpA$_{31-1178}$/STII/Cys and the respective preactivated macromolecule (from 1:2 to 1:10) did not result in an increase in the modification rate.

Investigation of the Recrystallization Properties of rSbpA$_{31-1178}$/STII/Cys Conjugated with Carbonic Anhydrase via a Heterobifunctional Cross-Linker by TEM and Detection of the Enzyme on the Surface of the S-Layer Lattice. Electron microscopy of the recrystallization products showed that modification of the S-layer fusion protein with the preactivated carbonic anhydrase did not interfere with its recrystallization properties (data not shown). Immuno dot blots of recrystallization products with an antibody raised against carbonic

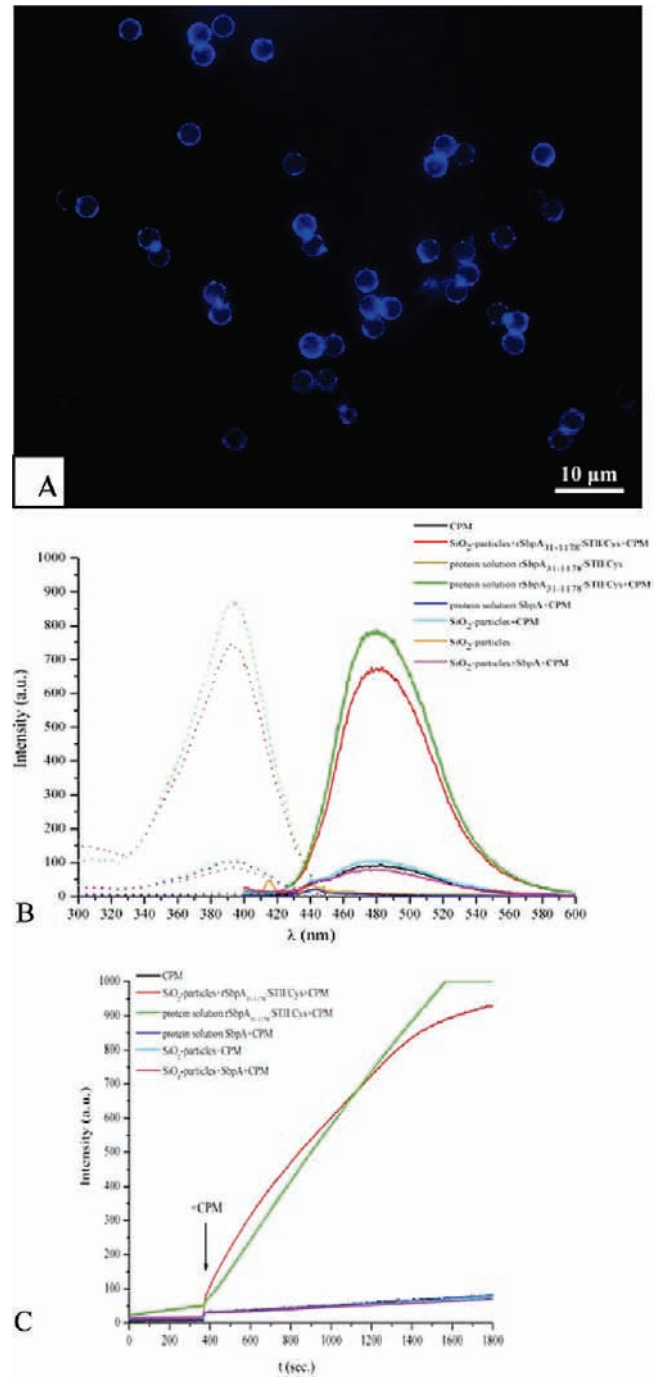

Figure 5. (A) Fluorescent micrograph of rSbpA$_{31-1178}$/STII/Cys recrystallized as a monolayer on SiO_2-microparticles and incubated with CPM indicating surface exposure of the C-terminally fused cysteine residue. (B) Fluorescent excitation and emission spectrum of the fusion protein rSbpA$_{31-1178}$/STII/Cys−CPM conjugate in solution or recrystallized on SiO_2-particles showing an excitation peak at 388 nm and an emission peak of 480 nm, which was in good accordance with the values (384 nm/470 nm) reported for the dye. As expected, the thiol-reactive coumarin, CPM alone, was very weakly fluorescent without reaction with a thiol group. Soluble rSbpA$_{31-1178}$/STII/Cys without dye, soluble wild-type SbpA incubated with the dye, wild-type SbpA recrystallized on microparticles incubated with the fluorophore, and the SiO_2-particles alone or incubated with the fluorophore, used as references, did not show a significant fluorescence intensity. (C) A time dependent increase of fluorescence was recorded for rSbpA$_{31-1178}$/STII/Cys−CPM conjugates in solution or recrystallized on SiO_2-particles, whereas soluble wild-type SbpA or SbpA recrystallized on SiO_2-particles as well as SiO_2-particles (all incubated with the dye for 30 min), used as a control for nonspecific interactions with CPM, reached no significant value.

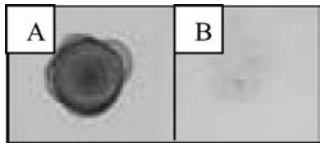

Figure 6. Immuno dot assay using rabbit anticarbonic anhydrase antibody demonstrating that carbonic anhydrase preactivated with the heterobifunctional cross-linker Sulfo-MBS could be successfully bound to rSbpA$_{31-1178}$/STII/Cys recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 (A). Wild-type SbpA recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177, used as a control, showed no reaction with the antibody against carbonic anhydrase (B).

anhydrase, performed to confirm the presence of the carbonic anhydrase on the surface of the S-layers lattices, showed a clear signal (Figure 4B, right). Wild-type SbpA recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177, used as a control, showed no reaction with the antibody against carbonic anhydrase (Figure 4B, left).

Fluorescent Labeling of the C-Terminal Cysteine Residue of Recrystallized rSbpA$_{31-1178}$/STII/Cys. To investigate the spatial accessibility of the C-terminal cysteine residue within the fusion protein lattice, rSbpA$_{31-1178}$/STII/Cys was recrystallized on SiO_2-particles and incubated with methylcoumarine (CPM), known as a thiol-reactive dye, which is only fluorescent if the binding between the thiol-group and the dye proceeds. As derived from former studies performed by using rSbpA (*10*, *13*), because of the specific physicochemical properties of its N-terminal part, the S-layer fusion protein was expected to recrystallize with its inner surface on the SiO_2-particles, thereby leaving the C-terminally fused cysteine residue exposed to the ambient environment. As shown by fluorescence microscopy, an oriented binding of rSbpA$_{31-1178}$/STII/Cys on SiO_2-particles could be demonstrated by obtaining a significant fluorescence signal after labeling the cysteine residues with methylcoumarine (Figure 5A). This led to the conclusion that the cysteine residues are located on the surface of the crystalline monolayer formed by rSbpA$_{31-1178}$/STII/Cys on SiO_2-particles and are accessible for modification with CPM. Compared to these data, wild-type protein SbpA recrystallized on SiO_2-particles or SiO_2-particles alone, used as blanks, showed no fluorescence signal (data not shown). Determination of the excitation and emission spectra of the rSbpA$_{31-1178}$/STII/Cys−CPM conjugates in solution or recrystallized on SiO_2-particles revealed an excitation peak at 388 nm and an emission peak at 480 nm (Figure 5B), which was in accordance with the reported values of E_x/E_m (nm) 384/470 for the dye. As described by the manufacturer, the thiol-reactive coumarin, CPM alone was very weakly fluorescent without reaction with a thiol group (Figure 5B). Soluble rSbpA$_{31-1178}$/STII/Cys without dye, soluble wild-type SbpA incubated with the dye, wild-type SbpA recrystallized on microparticles incubated with the fluorophore, and the SiO_2-particles alone or incubated with the fluorophore, used as references, did not show a significant fluorescence intensity (Figure 5B). A time dependent increase of fluorescence was recorded for rSbpA$_{31-1178}$/STII/Cys−CPM conjugates in solution or recrystallized on SiO_2-particles (Figure 5C), whereas soluble wild-type SbpA or SbpA recrystallized on SiO_2-particles as well as SiO_2-particles (all incubated with the dye for 30 min), used as a control for nonspecific interactions with CPM, reached no significant value (Figure 5C).

Chemical Modification of the Cysteine Residues of Recrystallized rSbpA$_{31-1178}$/STII/Cys. By performing immuno dot assays, it could also be shown that preactivated carbonic anhydrase could be successfully bound to rSbpA$_{31-1178}$/STII/Cys, which was recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 (Figure 6A). This result clearly indicated that the C-terminal cysteine residue at amino acid position 1,178 is surface exposed and accessible also in the recrystallized fusion protein rSbpA$_{31-1178}$/STII/Cys. Wild-type SbpA recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177, used as a control, showed no reaction with the antibody against carbonic anhydrase (Figure 6B).

Formation of Gold Nanoparticle Arrays on Crystalline Monolayers Formed by rSbpA$_{31-1178}$/STII/Cys and Image Processing. Cysteine residues located on the surface of the S-layer lattice formed by rSbpA$_{31-1178}$/STII/Cys on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 were used for covalent binding of gold nanoparticles with a diameter of 5 nm. A TEM image of the resulting regularly arranged gold nanoparticle array is shown in Figure 7A. Similar results could be obtained when self-assembly products formed by rSbpA$_{31-1178}$/STII/Cys were used as binding templates for a well-organized arrangement of gold nanoparticles (Figure 7B). The superlattice of the gold nanoparticles resembled the underlying square symmetry of the S-layer lattice formed by the fusion protein where every S-layer subunit carries one cysteine residue, and four subunits form one morphological unit. Base vector lengths were ~13.5 nm. An accurate lattice fit was obtained by cross-correlation averaging (CCA) where approximately 90% of the found nanoparticles in the image could be assigned to lattice

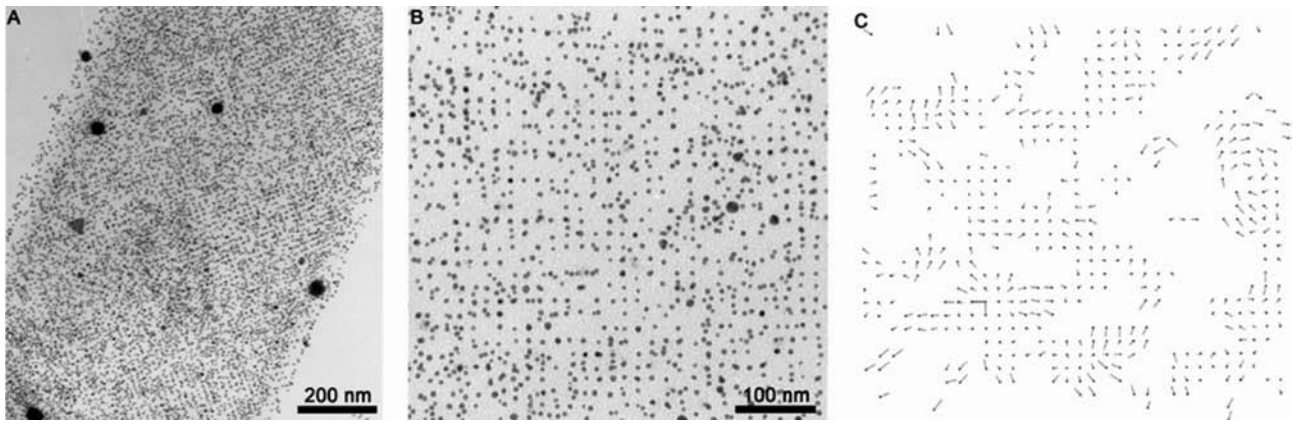

Figure 7. TEM micrograph of gold nanoparticles covalently bound to (A) recrystallization products consisting of rSbpA$_{31-1178}$/STII/Cys fusion protein recrystallized on peptidoglycan-containing sacculi of *Ly. sphaericus* CCM 2177 and (B) double-layered self-assembly products formed in suspension by rSbpA$_{31-1178}$/STII/Cys. (C) Cross-correlation averaging (CCA) of B. Bold dots mark positions at the nearest points on a least-squares fitted lattice. Small lines emanating from them indicate the direction and displacement (magnified 5 times) to the actually found positions, thus mapping the displacement field.

points (Figure 7C). The averaged root-mean-square deviation was found to be ~6% of the base vector lengths (~0.8 nm).

If recrystallization products consisting of wild-type SbpA recrystallized on PGS of *Ly. sphaericus* CCM 2177 were used, no binding of gold nanoparticles could be detected (data not shown). When double-layered self-assembly products formed by wild-type SbpA were used, gold nanoparticles were only found at incomplete regions of the double layer where the inner face of the S-layer lattice was accessible (data not shown). These findings led to the conclusion that the formation of regularly arranged gold nanoparticles on $rSbpA_{31-1178}$/STII/Cys monolayers is the result of specific binding of the nanoparticles to the sulfhydryl groups of the cysteine residues exposed on the outer face of the S-layer lattice.

DISCUSSION

In recent years, on the basis of the work on binding preactivated macromolecules, it has been demonstrated that metal and semiconducting nanoparticles can be bound in regular arrangements to native S-layer protein lattices by nonconvalent bonds (e.g., electrostatic interactions) or by covalent bounds after EDC activation (*15*−*17*). An alternative strategy for exploiting S-layer lattices as patterning elements for producing regularly ordered nanoparticle arrays in a much more controlled and specific way relates to genetically engineered S-layer proteins incorporating binding peptide domains.

The aim of the present study was to identify amino acid residues that are located on the surface of the S-layer lattice formed by the S-layer protein SbpA of *Ly. sphaericus* CCM 2177, which should serve as binding sites for functional macromolecules or for metal nanoparticles. Preliminary studies on the structure−function relationship of SbpA revealed that the N-terminal part of SbpA functions as a cell wall binding domain and that the truncated form $rSbpA_{31-1068}$, devoid of 200 C-terminal amino acids, was more surface accessible compared to the C-terminus of the full-length $rSbpA_{31-1268}$ (*13*). These results and the fact that various SbpA fusion proteins exhibit C-terminally fused functional domains (e.g., streptavidin (*30*), birch pollen allergen (*13, 31*), camel antibodies (*12, 32*), enhanced green fluorescent protein (*25*), and extremophilic enzymes (*33*)) on the surface of the S-layer lattice revealed that the SbpA-C-terminus must be exposed on the outer face of the S-layer lattice. Therefore, in the present study, for performing a refined surface accessibility screen in the domain between amino acid position 1,068 and 1,268, three different C-terminally truncated forms of SbpA carrying the short affinity tag *Strep-tag* II and a single cysteine residue at the C-terminal end were cloned and heterologously expressed in *E. coli*. Considering that the S-layer protein completely covers the cell surface of *Ly. sphaericus* CCM 2177 and that an aqueous environment is required for the diffusion of nutrients and metabolic degradation products, it can be expected that hydrophilic amino acid residues are exposed on the surface of the S-layer lattice. Therefore, three different hydrophilic amino acid residues within the C-terminally domain of SbpA were chosen as sites for the functionalization with STII and the cysteine residue. As S-layers usually do not possess sulfur-containing amino acids, the insertion of a single cysteine residue into the S-layer protein sequence is particularly attractive since the whole sulfur chemistry can be applied to covalently attach functional entities via the introduced cysteine residue. As reported in ref 34, a single cysteine residue has been inserted at various amino acid positions along the self-assembling domain of the S-layer proteins SbsB of *Geobacillus stearothermophilus* PV72/p2. In accordance with results from this study demonstrating that the replacement of selected amino acids by cysteine residues did not dramatically alter the structure of the S-layer protein SbsB (*34*), in the present work, electron microscopical examination revealed that all three rSbpA/STII/Cys fusion proteins retained their self-assembling and recrystallization ability. Recrystallization studies performed by TEM and AFM revealed that the SbpA derivative $rSbpA_{31-1178}$/STII/Cys (devoid of 90 C-terminal amino acids) turned out to be the best candidate for further modification experiments because of its ability to recrystallize into closed crystalline monolayers showing a long-range order on solid supports. This feature represents a prerequisite of regular nanoarrays used as templates for the organized arrangement of nanoparticles.

To conclude, one of the aims of current nanobiotechnological research is the bioinspired synthesis of nanostructured materials with novel mechanical or electrical properties. In the present study, for the first time, a natural self-assembly system based on a genetically engineered bacterial surface-layer protein was used for the bottom up fabrication of regularly arranged gold nanoparticles.

ACKNOWLEDGMENT

This work was supported by the FP6 EC-STREP project NASSAP 13523, by the Austrian Science Fund (FWF) Project P18510-B12 as well as by the US Air Force Office of Scientific Research (AFOSR) projects F49620-03-1-0222, FA9550-06-1-0208, and FA9550-07-0313. We thank Jacqueline Friedmann for performing the AFM studies and Manfred Tesarz for excellent technical support.

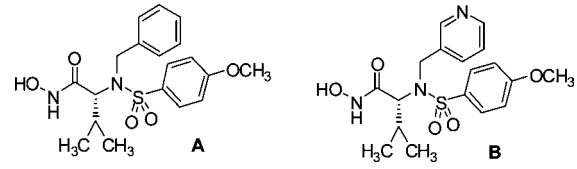
Received October 20, 2008; Revised Manuscript Received March 11, 2009

The assessment of matrix metalloproteinase (MMP) activity in vivo is highly desirable in various human diseases such as cancers. Hydroxamic acids based on CGS27023A or CGS25966 are nonpeptidyl lead structures that specifically target activated MMPs in vivo. The aim of this study was the modification and fluorescent labeling of these lead structures to develop a highly affine, nonpeptide MMP inhibitor (MMPI)-ligand for molecular optical imaging of activated MMPs. An 11 step synthesis was developed involving a PEGylated benzyl derivative as a spacer to minimize the interactions between the activated MMP and the dye of conjugate **11** with an azide as a protected amino function. After reducing the azide (Staudinger reaction) and labeling with Cy5.5, we obtained a CGS-based MMP inhibitor **11** with a fluorescent signaling flag. To evaluate the biological properties of this photoprobe, three human cancer cell lines (A-673, HT-1080 and BT-20) were characterized with respect to their MMP-2 and -9 (gelatinases) expression levels (real-time PCR) and protein levels (Western blotting). Initially, fluorogenic inhibition assays were used to assess the MMP inhibition potential. The PEGylated CGS **10** showed complete inhibition of MMP-2 and MMP-9 activities in vitro both for purified MMP-2/-9 (active and pro-forms) and MMP-2/-9 containing cell culture supernatants. To test the imaging potential in biological tissues, gelatinase activity was measured on tumor cryostat sections of the above-mentioned tumor cells using FITC-labeled dye-quenched gelatin. Gelatinase positive tumors revealed strong binding of CGS-Cy5.5 **11**, while gelatinase negative tumors were not targeted. In conclusion, this new CGS-based MMP photoprobe has a high affinity for MMP-2 and -9 and is thus a promising candidate for sensitive imaging of MMP activity in various diseases in patients.

INTRODUCTION

Matrix metalloproteinases (MMPs) are a family of currently more than 24 known mammalian emzymes, which are able to degrade structural components of the extracellular matrix (ECM) and basement membranes with overlapping substrate specificities (*1*−*3*). On the basis of their specificity, the MMPs are classified into collagenases, gelatinases, stromelysins, and matrilysins. (*4*) MMPs are secreted as inactive pro-enzymes (zymogens). A mechanism termed cysteine switch (*5*) initiates the activation of the MMPs, which are subsequently tightly controlled by several endogenous inhibitors, e.g., the plasma inhibitor α2-macroglobulin and the four tissue inhibitors of metalloproteinases (TIMPs) (*6*). MMPs and TIMPs participate in physiological tissue remodelling processes that require the disruption of ECM barriers to allow cell migration and the modification of the matrix microenvironment. Elevated MMP expression and activity has been found in numerous human diseases, including inflammatory processes, cancer, and atherosclerosis (*7*, *8*). Especially, MMP-2 and -9 play a crucial role in local and metastatic invasion of cancer. One of the earliest events in the metastatic spread of cancer is the invasion through the basement membrane and proteolytic degradation of the extracellular matrix proteins, such as, collagens, laminin, elastin and fibronectin, etc., and nonmatrix proteins. MMPs are thus important regulators of tumor growth, both at the primary site and in distant metastases. Given that MMPs are clearly implicated in many human cancers, these represent important targets for imaging tumor biology (*9*, *10*).

Scheme 1. Structures of CGS25966 (A) and CGS27023A (B)



In this study, the synthesis of a MMP ligand based on the broad-spectrum inhibitor lead structures CGS27023A and CGS25966 (Scheme 1) is described. A polyethylene glycol (PEG) spacer group containing the amino functionality was successfully inserted to enable labeling with fluorescent dyes without significantly changing the MMP binding potential. The conjugation of the fluorescent dye Cy5.5 was accomplished by forming an amide bond under standard conditions. Enzyme activity assays, blocking experiments with the unlabeled CGS

10, and in vitro binding studies with CGS-Cy5.5 **11** confirmed a high binding potential of the probe to the target proteins.

EXPERIMENTAL PROCEDURES

Materials and Methods. All chemicals, reagents, and solvents for the synthesis of the compounds were of analytical grade and were purchased from commercial sources. For the labeling procedure, DNA-grade dimethylformamide was used. Melting points (uncorrected) were determined on a Stuart Scientific SMP3 capillary melting point apparatus. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker ARX 300 (Bruker BioSpin GmbH, Rheinstetten, Germany). Mass spectrometry was performed using a QUATTRO LCZ (Waters Micromass, Manchester, UK) spectrometer with a nanospray capillary inlet.

Synthetic Organic Chemistry. *Tetraethyleneglycol Dimethanesulfonate.* Methanesulfonyl chloride (317 mL, 470 g, 4.1 mol) was added dropwise over a period of 4 h to a solution of tetraethylene glycol (347 mL, 388 g, 2 mol) in dichloromethane (1.8 L) and triethyl amine (570 mL, 415 g, 4.1 mol) at 0 °C. The mixture was stirred at ambient temperature for an additional 16 h, and the resulting precipitate was filtered off. Concentration of the filtrate yielded an orange oil, which was used without further purification. Yield: 596 g (1.7 mol, 85%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 3.08 (s, 6H, SO_3CH_3), 3.65−3.68 (m, 8H, OCH_2CH_2O), 3.76−3.78 (m, 4H, $SO_3CH_2CH_2$), 4.37−4.40 (m, 4H, $SO_3CH_2CH_2$). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 37.6 (SO_3CH_3), 68.9 ($SO_3CH_2CH_2$), 69.2 ($SO_3CH_2CH_2$), 70.4, 70.5 (OCH_2CH_2O). MS (ES^+) *m*/*e* = 373.1 $(M + Na)^+$, 351.1 $(M + H)^+$.

*2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethyl Methanesulfonate (**1**).* To a solution of the dimesylate (83.4 g, 272 mmol) in dimethyl formamide (600 mL) sodium azide (10.6 g, 163 mmol) was added, and the reaction mixture was stirred at 120 °C for 5 h. Most of the dimethyl formamide was removed in vacuo. The crude product was dissolved in ethyl acetate (400 mL) and washed with water (5 × 200 mL) and brine (200 mL) and dried over magnesium sulfate. After removing the solvent, the resulting oil was chromatographed on a silica gel column (cyclohexane/EtOAc 2/1 to 1/1) to give a light yellow oil. Yield: 17.2 g (58 mmol, 36%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 3.08 (s, 3H, SO_3CH_3), 3.64−3.69 and 3.76−3.79 (m, 14H, OCH_2CH_2O and $OCH_2CH_2N_3$), 4.37−4.40 (m, 2H, $SO_3CH_2CH_2$). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 37.6 (SO_3CH_3), 51.0 (CH_2N_3), 68.8 ($SO_3CH_2CH_2$), 69.3 ($SO_3CH_2CH_2$), 69.9, 70.4, 70.5 (OCH_2CH_2O). MS (ES^+) *m*/*e* = 319.1 $(M + Na)^+$, 297.1 $(M + H)^+$.

*4-(2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethoxy)benzaldehyde (**2**).* To a solution of 14.2 g (47.8 mmol) of methansulfonate **1** and 9.16 g (75 mmol) of 4-hydroxybenzaldehyde in 200 mL of dimethyl formamide, 49 g (150 mmol) of cesium carbonate was added, and the resulting suspension was stirred at 100 °C for 2 h. After cooling to room temperature, 400 mL of ethyl acetate and 400 mL of water were added, and the organic layer was extracted with 1 N NaOH (150 mL) three times. After washing with water (3 × 150 mL) and brine, drying over magnesium sulfate, and removing the solvent, the crude product was chromatographed on a silica gel column (toluene/acetone 10/1) to give a yellow oil. Yield: 11.6 g (36 mmol; 75%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 3.36−3.39 (m, 2H, $OCH_2CH_2N_3$), 3.65−3.74 (m, 10H, OCH_2CH_2O), 3.87−3.90 (m, 2H, $PhOCH_2CH_2$), 4.20−4.23 (m, 2H, $PhOCH_2CH_2$), 7.02 (d, 2H, Ph*H*, $^3J_{HH}$ = 7.5 Hz), 7.82 (d, 2H, Ph*H*, $^3J_{HH}$ = 7.5 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 50.5 (CH_2N_3), 67.6, 69.3, 69.9, 70.5, 70.6, 70.7 (OCH_2CH_2O), 114.7 (Ph*C*H), 125.2 (q-Ph*C*CHO), 131.8 (Ph*C*H), 163.7 (qPh*C*O), 190.7 (Ph*C*HO). HRMS (ES^+): calcd. ($C_{15}H_{21}N_3O_5Na$) = 346.1373; found = 346.1379.

*(4-(2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethoxy)phenyl)methanol (**3**).* To a solution of 4-(2-(2-(2-(2-azidoethoxy)ethoxy)ethoxy)-ethoxy)benzaldehyde **2** (26.47 g, 82 mmol) in 300 mL of methanol, sodiumborhydride (4.65 g, 123 mmol) was carefully added at 0 °C. After stirring for 2 h at 0 °C, the excess sodiumborhydride was destroyed by adding 1 N HCl. The solvent was removed, and the resulting crude product was chromatographed on a silica gel column (cyclohexane/ethyl acetate 1/1) to give a colorless viscous oil. Yield: 23.66 g (73 mmol; 89%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 2.11 (bs, 1H, O*H*), 3.34−3.37 (m, 2H, $OCH_2CH_2N_3$), 3.63−3.72 (m, 10H, OCH_2CH_2O), 3.83−3.86 (m, 2H, $PhOCH_2CH_2$), 4.11−4.13 (m, 2H, $PhOCH_2CH_2$), 4.58 (s, 2H, CH_2OH), 6.87 (d, 2H, Ph*H*, $^3J_{HH}$ = 7.2 Hz), 7.26 (d, 2H, Ph*H*, $^3J_{HH}$ = 7.2 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 50.5 (CH_2N_3), 64.7 ($PhCH_2OH$), 67.4, 69.6, 69.9, 70.5, 70.7 (OCH_2CH_2O), 114.5 (Ph*C*H), 128.4 (q-Ph*C*CHO), 133.3 (Ph*C*H), 158.2 (qPh*C*O). HRMS (ES^+): calcd. ($C_{15}H_{23}N_3O_5Na$) = 348.1530; found = 348.1522.

*4-(2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethoxy)benzyl-2,2,2-trifluoro-acetate (**4**).* Benzylalcohol **3** (8.5 g, 26.2 mmol) was dissolved in dry tetrahydrofurane (50 mL), and trifluoroacetic acid anhydride (6.83 g, 4.5 mL, 32.5 mmol) was added slowly with stirring, and the mixture was heated to reflux for 30 min. After cooling to room temperature, the mixture was diluted with diethyl ether (150 mL) and washed with saturated $NaHCO_3$. The ether layer was dried with magnesium sulfate and concentrated to give a light yellow oil. Yield: 10.48 g (25 mmol, 95%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 3.35−3.38 (m, 2H, $OCH_2CH_2N_3$), 3.63−3.73 (m, 10H, OCH_2CH_2O), 3.85−3.88 (m, 2H, $PhOCH_2CH_2$), 4.14−4.16 (m, 2H, $PhOCH_2CH_2$), 5.28 (s, 2H, CH_2OCOCF_3), 6.93 (d, 2H, Ph*H*, $^3J_{HH}$ = 7.2 Hz), 7.31 (d, 2H, Ph*H*, $^3J_{HH}$ = 7.2 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 50.5 (CH_2N_3), 67.4 ($PhCH_2O$), 69.5, 69.8, 70.5, 70.7 (OCH_2CH_2O), 114.4 ($COCF_3$, $^1J_{CF}$ = −284 Hz), 114.7 (Ph*C*H), 125.4 (q-Ph*C*CHO), 130.5 (Ph*C*H), 157.3 ($COCF_3$, $^2J_{CF}$ = −42 Hz), 159.5 (qPh*C*O). ^{19}F-NMR ($CDCl_3$, 282 MHz): δ (ppm) = −75.1 (CF_3). HRMS (ES^+): calcd. ($C_{17}H_{22}F_3N_3O_6Na$) = 444.1358; found = 444.1355.

*1-(2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethoxy)-4-(bromomethyl)benzene (**5**).* Benzyl trifluoroacetate **4** (10.4 g, 25 mmol) was dissoled in dry tetrahydrofurane (50 mL), and dry lithium bromide (2.75 g, 32 mmol) was added with stirring. The mixture was heated to reflux for 20 h. After removing the solvent, the dark brown oil was chromatograhed on a silica gel column (cyclohexane/ethyl acetate 1/1) to give yellow oil. Yield: 8.4 g (21.6 mmol, 87%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 3.34−3.38 (m, 2H, $OCH_2CH_2N_3$), 3.62−3.71 (m, 10H, OCH_2CH_2O), 3.83−3.86 (m, 2H, $PhOCH_2CH_2$), 4.10−4.13 (m, 2H, $PhOCH_2CH_2$), 4.49 (s, 2H, CH_2Br), 6.87 (d, 2H, Ph*H*, $^3J_{HH}$ = 7.2 Hz), 7.30 (d, 2H, Ph*H*, $^3J_{HH}$ = 7.2 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 50.5 (CH_2N_3), 33.8 ($PhCH_2Br$), 67.3, 69.5, 69.8, 70.3, 70.5, 70.7 (OCH_2CH_2O), 114.7 (Ph*C*H), 129.9 (q-Ph*C*CHO), 130.3 (Ph*C*H), 158.7 (qPh*C*O). HRMS (ES^+): calcd. ($C_{15}H_{22}BrN_3O_4Na$) = 410.0686, 411.0716, 412.0667, 413.0696; found = 410.0690, 411.0721, 412.0671, 413.0702.

*(R)-Methyl-2-(4-methoxyphenylsulfonamido)-3-methylbutanoate (**6**).* A solution of D-valine methylester (12.56 g, 75 mmol) in 35 mL of pyridine was cooled to 0 °C and 4-methoxybenzylsulfonyl chloride (15.5 g, 75 mmol) was slowly added. The resulting solution was stirred for 2 days at room temperature while a precipitate was formed. The suspension was diluted with 200 mL of dichloromethane and washed with 1 N HCl (200 mL), water (3 × 150 mL), and brine. After drying over magnesium sulfate, the solvent was removed to give the desired product with sufficient purity. Yield: 21.4 g (71 mmol, 95%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 0.87 (d, 3H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8 Hz), 0.94 (d, 3H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8

Hz), 1.97−2.08 (m, 1H, C*H*(CH_3)$_2$), 3.47 (s, 3H, COOCH_3), 3.70 (dd, 1H, (COO)C*H*, $^3J_{HH}$ = 5.2 Hz and 10.2 Hz), 3.86 (s, 3H, PhOCH_3), 5.20 (d, 1H, N*H*, $^3J_{HH}$ = 10.2 Hz), 6.96 (d, 2H, Ph*H*, $^3J_{HH}$ = 9 Hz), 7.76 (d, 2H, Ph*H*, $^3J_{HH}$ = 9 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 17.4, 18.9 (CH(CH_3)$_2$), 31.5 (*C*H(CH_3)$_2$), 52.2 (COOCH_3), 55.6 (PhOCH_3), 60.9 (COO*C*H), 114.0 (Ph*C*H), 129.4 (Ph*C*H), 131.1 (qPhCSO_2), 162.9 (qPh-*C*OCH_3), 171.8 (*C*OOCH$_3$). HRMS (ES^+): calcd. ($C_{12}H_{17}NO_5SNa$) = 310.0720; found = 310.0721.

*(R)-Methyl-2-(N-(4-(2-(2-(2-(2-azidoethoxy)ethoxy)ethoxy)ethoxy)-benzyl)-4-methoxyphenyl-sulfonamido)-3-methylbutanoate (***7***).* To a solution of (*R*)-methyl-2-(4-methoxyphenyl-sulfonamido)-3-methyl-butanoate **6** (3.1 g, 10.1 mmol) and 1-(2-(2-(2-(2-azidoethoxy)-ethoxy)ethoxy)ethoxy)-4-(bromomethyl)benzene **5** (4 g, 10.3 mmol) in 100 mL of butanone potassium carbonate (7 g, 50 mmol) was added, and the resulting suspension was stirred for 4 h at 60 °C. After removing the solvent, the crude product was diluted with dichloromethane (150 mL) and washed with water (3 × 150 mL) and brine. The solution was dried over magnesium sulfate, filtered, and chromatographed on a silica gel column (cyclohexane/ethyl acetate 3/2) to give a colorless viscous oil. Yield: 4.56 g (7.5 mmol, 73%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 0.75 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.5 Hz), 0.80 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.5 Hz), 1.89−1.97 (m, 1H, C*H*(CH_3)$_2$), 3.41 (s, 3H, COOCH_3), 3.37−3.41 (m, 2H, OCH$_2$CH_2N$_3$), 3.66−3.73 (m, 11H, OCH_2CH_2O, COOC*H*), 3.84−3.88 (m, 5H, PhOCH$_2$CH_2, PhOCH_3), 4.09−4.12 (m, 2H, PhOCH_2CH$_2$), 4.33 (AB, 1H, $^2J_{HH}$ = 11.8 Hz, PhCH_2), 4.58 (AB, 1H, $^2J_{HH}$ = 11.8 Hz, PhCH_2), 6.80 (d, 2H, $^3J_{HH}$ = 8.6 Hz, Ph*H*), 6.91 (d, 2H, $^3J_{HH}$ = 8.9 Hz, Ph*H*), 7.30 (d, 2H, $^3J_{HH}$ = 8.6 Hz, Ph*H*), 7.69 (d, 2H, $^3J_{HH}$ = 8.9 Hz, Ph*H*). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 19.6 (CH(*C*H$_3$)$_2$), 28.5 (*C*H-(CH_3)$_2$), 48.2 (N*C*H$_2$Ph), 50.7 (*C*H$_2$N$_3$), 51.4 (COO*C*H$_3$), 55.6 (PhO*C*H$_3$), 66.1 (COO*C*H), 67.4 (PhO*C*H$_2$), 69.8, 70.0, 70.7, 70.8, 70.9 (O*C*H$_2$*C*H$_2$O), 113.7, 114.1 (Ph*C*H), 129.4, 129.5, 130.1 (q-Ph*C*CH$_2$, Ph*C*H), 131.9 (q-Ph*C*SO$_2$), 158.1, 162.6 (qPh*C*O), 170.8 (*C*OO). HRMS (ES^+): calcd. ($C_{28}H_{40}N_4O_9SNa$) = 631.2414; found = 631.2416.

*(R)-2-(N-(4-(2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethoxy)benzyl)-4-methoxyphenylsulfon-amido)-3-methylbutanoic acid (***8***).* To a solution of the methyl ester **7** in tetrahydrofuran, methanol and water (8:1:1, 100 mL) lithium hydroxide (2.4 g, 100 mmol) was added, and the resulting suspension was stirred at room temperature for 2 days. After removing the solvent, the crude product was purified on a silica gel column (cyclohexane/ethyl acetate 2/1 with 2.5% acetic acid) to give a colorless sticky oil. Yield: 9.1 g (15.3 mmol, 78%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 0.75 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.5 Hz), 0.89 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.5 Hz), 1.92−2.00 (m, 1H, C*H*(CH_3)$_2$), 3.36−3.40 (m, 2H, OCH$_2$CH_2N$_3$), 3.66−3.71 (m, 11H, OCH_2CH_2O, COOC*H*), 3.84−3.88 (m, 5H, PhOCH$_2$CH_2, PhOCH_3), 4.09−4.14 (m, 2H, PhOCH_2CH$_2$), 4.38 (AB, 1H, $^2J_{HH}$ = 15.7 Hz, PhCH_2), 4.58 (AB, 1H, $^2J_{HH}$ = 15.7 Hz, PhCH_2), 6.79 (d, 2H, $^3J_{HH}$ = 8.6 Hz, Ph*H*), 6.89 (d, 2H, $^3J_{HH}$ = 8.9 Hz, Ph*H*), 7.27 (d, 2H, $^3J_{HH}$ = 8.6 Hz, Ph*H*), 7.71 (d, 2H, $^3J_{HH}$ = 8.9 Hz, Ph*H*), 10.53 (bs, 1H, COO*H*). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 19.7 (CH(*C*H$_3$)$_2$), 28.3 (*C*H(CH_3)$_2$), 48.4 (N*C*H$_2$Ph), 50.6 (*C*H$_2$N$_3$), 55.6 (PhO*C*H$_3$), 66.0 (COO*C*H), 67.3 (PhO*C*H$_2$), 69.7, 70.0, 70.6, 70.7, 70.8 (O*C*H$_2$*C*H$_2$O), 113.8, 114.1 (Ph*C*H), 129.1 (q-Ph*C*CH$_2$), 129.6, 130.2 (Ph*C*H), 131.6 (q-Ph*C*SO$_2$), 158.1, 162.7 (qPh*C*O), 175.1 (*C*OOH). HRMS (ES^+): calcd. ($C_{27}H_{38}N_4O_9SNa$) = 617.2252; found = 617.2259.

*(R)-2-(N-(4-(2-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)ethoxy)benzyl)-4-methoxyphenylsulfon-amido)-N-hydroxy-3-methylbutanamide (***9***).* A suspension of *N*-hydroxy-2-pyridone (500 mg, 4.5 mmol) in dichloromethane (25 mL) was subsequently treated at room temperature with acid **8** (1.8 g, 3 mmol) and 2-morpholinoethyl isocyanide (631 mg, 0.62 mL, 4.5 mmol). Stirring was continued for 19 h after which time the formation of the intermediate pyridine active ester was complete. The solution was treated at 0 °C with TMSO-NH_2 (473 mg, 0.56 mL, 4.5 mmol), and stirring was continued at 0 °C for 7 h. The solution was washed with saturated aqueous $NaHCO_3$ (75 mL) and water (3 × 75 mL). The aqueous layer was additionally washed with dichloromethane (100 mL), and the combined organic layers were dried over magnesium sulfate and subsequently filtered. The crude product was chromatographed on a silica gel column (cyclohexane/ethyl acetate 1/1 → 1/4) to give a colorless and highly viscous oil. Yield: 930 mg (1.53 mmol, 51%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 0.50 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.5 Hz), 0.79 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.5 Hz), 2.10−2.15 (m, 1H, C*H*(CH_3)$_2$), 3.37−3.40 (m, 2H, OCH$_2$CH_2N$_3$), 3.66−3.75 (m, 11H, OCH_2CH_2O, C*H*CON), 3.84−3.89 (m, 5H, PhOCH$_2$CH_2, PhOCH_3), 4.09−4.12 (m, 2H, PhOCH_2CH$_2$), 4.45 (AB, 1H, $^2J_{HH}$ = 15.4 Hz, PhCH_2), 4.57 (AB, 1H, $^2J_{HH}$ = 15.4 Hz, PhCH_2), 6.79 (d, 2H, $^3J_{HH}$ = 8.6 Hz, Ph*H*), 6.88 (d, 2H, $^3J_{HH}$ = 8.9 Hz, Ph*H*), 7.27 (d, 2H, $^3J_{HH}$ = 8.6 Hz, Ph*H*), 7.61 (d, 2H, $^3J_{HH}$ = 8.9 Hz, Ph*H*), 9.36 (bs, 1H, CON*H*OH). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 19.2, 19.8 (CH(*C*H$_3$)$_2$), 27.3 (*C*H(CH_3)$_2$), 48.0 (N*C*H$_2$Ph), 50.7 (*C*H$_2$N$_3$), 55.6 (PhO*C*H$_3$), 63.7 (NHCO*C*H), 67.4 (PhO*C*H$_2$), 69.7, 70.0, 70.6, 70.7, 70.8 (O*C*H$_2$*C*H$_2$O), 114.1, 114.2 (Ph*C*H), 129.0 (q-Ph*C*CH$_2$), 129.4, 130.5 (Ph*C*H), 131.7 (q-Ph*C*SO$_2$), 158.2, 162.9 (qPh*C*O), 167.2 (*C*ONHOH). HRMS (ES^+): calcd. ($C_{27}H_{39}N_5O_9SNa$) = 632.2361; found = 632.2360.

*(R)-2-(N-(4-(2-(2-(2-(2-aminoethoxy)ethoxy)ethoxy)ethoxy)benzyl)-4-methoxyphenylsulfon-amido)-N-hydroxy-3-methylbutanamide (***10***).* To a solution of the hydroxamic acid **9** (900 mg, 1.48 mmol) in THF (50 mL) was added at room temperature triphenylphosphine (500 mg, 1.9 mmol), and stirring was continued for 16 h. The solution was treated with water (34 μL, 1.9 mmol), and after stirring for an additional 3 h, the solvent was removed. The crude product was chromatographed on a silica gel column (ethyl acetate/methanol 2/1 with 2% triethylamine) to give colorless foam. Yield: 410 mg (0.7 mmol, 47%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ (ppm) = 0.54 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.5 Hz), 0.81 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.5 Hz), 2.16−2.18 (m, 1H, C*H*(CH_3)$_2$), 3.45−3.87 (m, 18H, PEG-CH_2, C*H*CON, PhOCH_3), 4.07−4.09 (m, 2H, PhOCH_2CH$_2$), 4.40 (AB, 1H, $^2J_{HH}$ = 15.4 Hz, PhCH_2), 4.65 (AB, 1H, $^2J_{HH}$ = 15.4 Hz, PhCH_2), 6.41 (bs, 2H, NH_2) 6.77 (d, 2H, $^3J_{HH}$ = 8.6 Hz, Ph*H*), 6.86 (d, 2H, $^3J_{HH}$ = 8.9 Hz, Ph*H*), 7.27 (m, 2H, Ph*H*), 7.63 (d, 2H, $^3J_{HH}$ = 8.9 Hz, Ph*H*). ^{13}C NMR ($CDCl_3$, 75 MHz): δ (ppm) = 19.1, 19.7 (CH(*C*H$_3$)$_2$), 27.1 (*C*H(CH_3)$_2$), 40.8 (*C*H$_2$NH$_2$), 47.6 (N*C*H$_2$Ph), 55.5 (PhO*C*H$_3$), 63.6 (NHCO*C*H), 67.4 (PhO*C*H$_2$), 69.6, 70.0, 70.2, 70.5, 70.6 (O*C*H$_2$*C*H$_2$O), 114.0, 114.1 (Ph*C*H), 129.3 (q-Ph*C*CH$_2$), 129.5, 130.3 (Ph*C*H), 132.2 (q-Ph*C*SO$_2$), 157.9, 162.7 (qPh*C*O), 166.7 (*C*ONHOH). HRMS (ES^+): calcd. ($C_{27}H_{41}N_3O_9SH$) = 584.2636; found = 584.2635.

Fluorochrome Conjugation. The amino-functionalized derivative 10 (1.0 mg, 1.71 μmol) was dissolved in 400 μL of dry dimethylformamide provided with 10 μL of triethylamine. To this solution, Cy5.5 NHS ester (Amersham Bioscience) (1 mg, 0.9 μmol) was added. The reaction mixture was vortexed for 2 h at room temperature in the dark. Purification of the Cy5.5-labeled derivative **6** was performed by gradient-HPLC using a Knauer system with two K-1800 pumps, an S-2500 UV detector, and a RP-HPLC Nucleosil 100−5 C_{18} column (250 mm × 4.6 mm). Eluent A was water (0.1% TFA). Eluent B was acetonitrile (0.1% TFA). The gradient was from 99% A to 40% A over 19 min, holding for 5 min, and back to 99% in 1 min at a flow rate of 5.5 mL/min, and detection was at λ = 254 nm. The appropriate fractions (t_R = 14.5 min) were collected, lyophilized, redissolved in 1 mL of water, and finally stored at

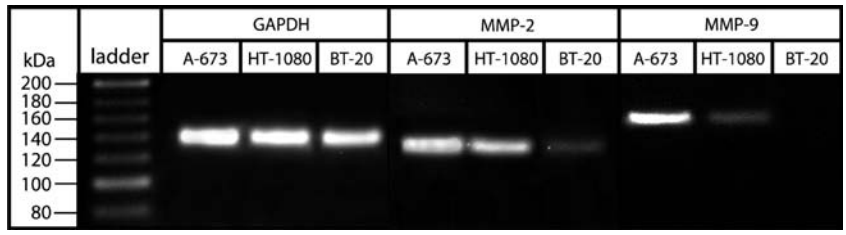

Figure 1. qRT-PCR was performed with primer pairs listed in Table 3, specific for MMP-2 and MMP-9, and normalized to the housekeeping gene GAPDH. After calculation of the RER for A-673, HT-1080, and BT-20, the amplified qRT-PCR products (GAPDH, 141 bp; MMP-2, 128 bp; and MMP-9, 160 bp) were analyzed by 2% gel electrophoresis.

−20 °C. The average content of **11** was 0.39 ± 0.02 μmol/mL (≈ 43%) as determined by fluorometer measurements with λ_{abs} = 678 nm and ε_{678} = 250000 $M^{-1}cm^{-1}$. MS (ES^-): *m*/*e* = 483.6 (100%), 484.0, 484.3, 484.6, 485.0 $[M]^{3-}$; 725.8, 726.3, 726.7, 727.4 $[M + H]^{2-}$.

Cell Culture. Three human carcinoma cell lines, purchased from ATCC (Manassas, VA, U.S.A.), were cultivated in the following media: fibrosarcoma HT-1080 (CCL-121) in RPMI-1640, mamma carcinoma BT-20 (HTB-19), and rhabdomyosarcoma A-673 (CRL-1598) in DMEM. Media (Invitrogen Corporation, San Diego, CA) were supplemented with 10% fetal calf serum (FCS), 1% penicillin and streptomycin (Biochrom AG, Berlin, Germany), 2 mM L-glutamine (Gibco BRL), and 13.5 mM sodium bicarbonate when using A-673 cells. Cells were grown routinely in T75 flasks, incubated at 37 °C in a 5% CO_2 humidified air atmosphere until the cultures were confluent (80−100%); medium was changed every 3−4 days. Cells were incubated with trypsin/EDTA, and cell numbers were determined in triplicate, counting only the viable cells able to exclude trypan blue (Sigma-Aldrich Chemie GmbH, Munich, Germany). For zymography, 107 cells were washed three times in serum-free medium and incubated in 3 mL of freshly FCS-free medium. After an incubation time of 48 h, the supernatant was collected and stored at −20 °C. For RNA isolation, 107 cells were incubated in FCS-containing media for further 24 h and washed with Dulbecco's phosphate-buffered saline (D-PBS) (Gibco BRL). Ten milliliters of medium was added to adherent cells, which were removed with a cell scraper and harvested by centrifugation (7 min, 1800*g*).

RNA Isolation and cDNA Synthesis. Total RNA was isolated from harvested cells (see above) using the PureLink Microto-Midi Total RNA Purification System (Invitrogen GmbH, Karlsruhe, Germany) according to the manufacturer's instructions with minor modifications. To remove possible genomic DNA contaminations, a DNase I digestion step was included between the washing steps. A reaction mix, consisting of OBI DNase I digestion buffer and RNase-free DNase I (20 units/μL), was added directly to the surface of the HiBind spin column for 15 min at room temperature. RNA was eluted with RNase-free DEPC-treated water and stored at −86 °C until use. The RNA quality was assessed on a 1% agarose gel, and its concentration was determined by UV spectroscopy at 260/280 nm with a NanoDrop photometer (Peqleb GmbH, Erlangen, Germany). First-strand cDNA was synthesized in a 20 μL reverse transciptase reaction mixture using the RevertAid First Strand cDNA Synthesis Kit (MBI Fermentas, St. Leon-Roth, Germany). Two micrograms of total RNA was denatured at 65 °C for 10 min and subsequently placed on ice. The no-template (NT)-control contained DEPC-treated water instead of RNA. Then, 5× reaction buffer, 1 mM of each nucleotide triphosphate, 20 units of RiboLock ribonuclease inhibitor, and 0.5 μg Oligo-(dT)18 primer were added and incubated at 25 °C for 5 min. After the addition of 200 units of RevertAid M-MuLV reverse transcriptase, the reaction mixtures were incubated according to the supplier's instructions. The no-reverse-transcription (NRT)-control contained DEPC-treated water instead of reverse transcriptase. Synthesized cDNA, the NT-, and NRT-control were stored at −20 °C until use.

Quantitative RT-PCR. All quantitative real-time polymerase chain reactions (qRT-PCR) were performed in a total volume of 20 μL, containing 5 μL of synthesized cDNA (or NTC or NRTC), 1 μL of SYBR Green I (1:600 diluted in DMSO) (Biozym Scientific GmbH, Oldendorf, Germany), 0.2 mM of each nucleotide triphosphate, 1× PCR-buffer, 50 μM of each primer (see Table 3), 1 mM $MgCl_2$, and 2.5 units of Taq DNA polymerase (New England Biolabs, Frankfurt a. M., Germany). To assess the accuracy of the procedures, triplicate aliquots of total RNA were used to produce cDNA in parallel reactions. QRT-PCR was accomplished using the Eppendorf Mastercycler EP Gradient (Eppendorf AG, Hamburg, Germany). The cycle conditions consisted of an initial step at 95 °C for 10 min followed by an amplification program for 40 cycles of 15 s at 95 °C, 30 s at 60 °C, 30 s at 72 °C, and 15 s at 78 °C with fluorescence acquisition. To distinguish primer dimers from the specific amplicon, the amplification program was followed immediately by a melting program consisting of 1 min at 95 °C, 1 min at 65 °C, and a gradual increase to 90 °C at a rate of 0.5 °C per second with fluorescence acquisition at each temperature transition. Linearity over the 20- to 40-cycle range and similar primer efficiencies were established by standard dilution curves (data not shown). The relative expression level of the target genes MMP-2 and -9 was normalized on the expression level of the internal housekeeping gene glycerinaldehyde-3-phosphate-dehydrogenase (GAPDH). All threshold cycle (*Ct*) values were determined in triplicate and obtained from the Eppendorf Mastercycler EP Gradient software. The relative expression ratio (RER) was determined with the comparative delta *Ct* (Δ*Ct*) method in addition to the kinetic PCR efficiency correction, using the relative expression software tool (REST). Amplified qRT-PCR products were separated by 2% agarose gel electrophoresis (Biozym Scientific GmbH, Oldendorf, Germany), stained with ethidium bromide, and visualized by UV transillumination. Fragment sizes were determined using the O'RangeRulerTM 20-bp DNA ladder (MBI Ferments, St. Leon-Rot, Germany).

Zymography. Gelatin zymography was performed in a sodium dodecyl sulfate (SDS)−polyacrylamide electrophoretic gel (PAGE) as described previously with minor modifications (*27*). Protein concentrations of collected FCS-free cell supernatants were derived with a Quant-iTTM Protein Assay Kit, using the Qubit fluorometer (Invitrogen GmbH, Karlsruhe, Germany). Thirty micrograms of total protein of each sample was mixed with (4×) SDS sample buffer without reducing agent and added to a 5% stacking and 7% separating SDS gel (containing 0.85 g/L gelatin). Positive controls included the following recombinant human enzymes: pro-MMP-2 (R & D Systems GmbH, Wiesbaden, Germany), active MMP-2 (Calbiochem, Wiesbaden, Germany), and pro/active MMP-9 (Sigma-Aldrich Chemie GmbH, Munich, Germany); the protein weight marker Precision Plus Dual Color (Bio-Rad Laboratories GmbH,

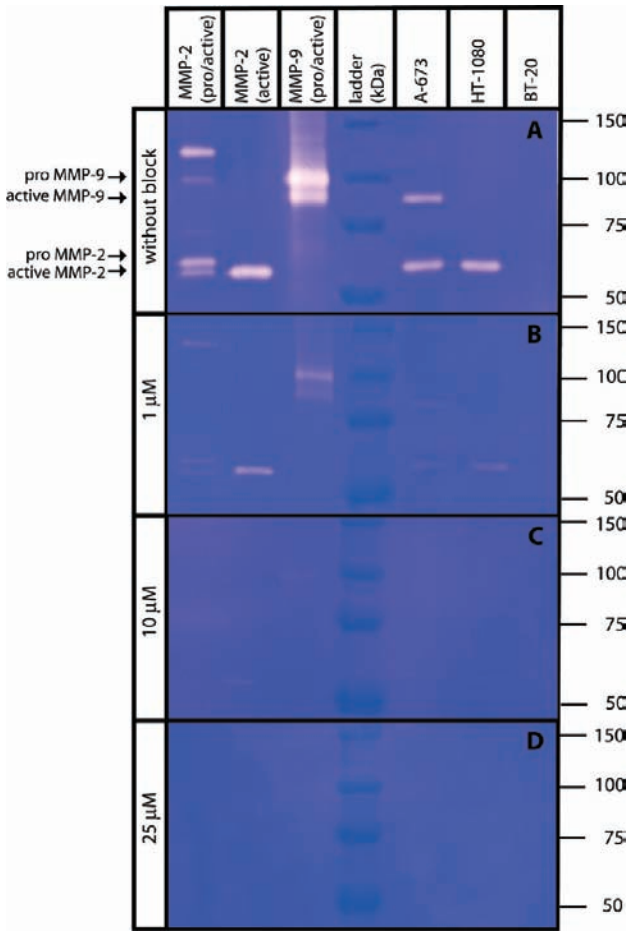

Figure 2. Gelatinolytic activities of purified MMP-2 (pro-form, 72 kDa; active form, 64 kDa) and MMP-9 (pro-form, 92 kDa; active form, 84 kDa) as well as that of collected supernatants of A-673, HT-1080, and BT-20 cells were assessed by zymography (A). Zymograms incubated overnight at 37 °C in buffers with varying concentrations of the unlabeled probe **10** show significant inhibition of MMP-2 and -9 by **10** (B−D). MMP-2 and -9 activities of purified enzymes and supernatants were completely inhibited by CGS concentrations ≥25 μM (D).

München, Germany) was also used. Gels were run for 120 min at 130 V and 4 °C in Tris-glycine SDS running buffer until the bromophenol blue front reached the bottom of the gel. After electrophoresis, the gels were washed with distilled water containing 2.5% Triton X-100 (30 min, room temperature) to renature proteins in the gel by the removal of SDS. Subsequently, the gels were incubated overnight at 37 °C with gentle shaking in incubation buffer (50 mM Tris-HCl at pH 7.8 and 10 mM $CaCl_2$). The incubation buffer contained 0 μM, 1 μM, 10 μM, or 25 μM unlabeled CGS-probe **10**. Zymograms were successively stained/destained with 1% Coomassie Brillant Blue G-250 dissolved in 10% ethanol and 5% acetic acid at room temperature for 120 min. Enzymatic activity was visualized through negative staining with Coomassie Brilliant Blue R-250 (Bio-Rad Laboratories GmbH, München, Germany). MMP-2/-9 activity was visible as clear zones of gelatin degradation against a dark blue background of stained gelatin. All gels were run under identical conditions with the same batch of reagents.

Routine Cryostat Sections and Fluorescence Microscopy. Three million cancer cells were injected subcutaneously into 7−9-week-old nude mice (nu/nu, Charles River, Germany). For in situ zymography and in vitro fluorescence binding assays, tumors with a size of approximately 7 × 10 mm were dissected, embedded into Tissue Freezing Medium (Leica Instruments, Nussloch, Germany), rapidly frozen by 2-methyl-butanol with cooled liquid nitrogen, and stored at −86 °C for sectioning. Embedded tumors were cut into 8 μm sections using a cryostat (Leica, Wetzler, Germany). For fluorescence microscopy, a Nikon TE 2000-S microscope (Tokyo, Japan) was employed, equipped with epifluorescence optics (AHF Analysentechnik AG, Tübingen, Germany). Images were recorded with a Nikon DXM1200F camera, using the NIS-Elements BR 2.30 software (Nikon, Tokyo, Japan). Fluorescence images, which had to be compared, were captured at identical illumination conditions with identical exposure time and system settings for digital image processing.

In Vitro Fluorescence Binding Assay and in Situ Zymography. Two hundred eighty picomoles of CGS-Cy5.5 (**11**), diluted in D-PBS (Gibco BRL), was given on unfixed air-dried cryostat sections and incubated, light protected, for 45 min at room temperature. Slides were washed in PBS (3 × 5 min) and air-dried for 5 min. Afterward, gelatinolytic activity of these cryostat sections was demonstrated using FITC-labeled dye-quenched (DQ)-gelatin, provided with the EnzCheck Gelatinase Assay Kit (EnzChek; Molecular Probes, Leiden, The Netherlands), as described previously with minor modifications (*26*). The DQ-gelatin, a specific enzymatic substrate detectable by fluorescence microscopy, is brought into close contact with cryostat sections of unfixed tissue. Proteolysis by gelatinases, such as MMP-2 and -9, yields cleaved gelatin-FITC peptides that are fluorescent so that green fluorescence indicates sites with gelatinolytic activity in tissue. At first, 1% low melting temperature agarose (Biozym Scientific GmbH, Oldendorf, Germany) was melted in D-PBS and cooled down to 37 °C, and DQ-gelatin (1 mg/mL) was added (1:200). Subsequently, a drop of the agarose−gelatin mixture was given to A-673 or BT-20 cryostat sections. All slides were incubated and light protected, at room temperature for 45 min. At the end of the incubation period, the DQ-gelatin was removed, and without fixation or wash steps, a drop of Fluoromont-GTM (Biozol Diagnostica GmbH, Eching, Germany) and a coverslip were added. Cleavage of DQ-gelatin was localized and photographed by fluorescence microscopy (emission, 535 nm; and excitation, 480 nm). Binding of CGS-Cy5.5 (**11**) to A-673 and BT-20 cryostat sections was assessed by emission of 700 nm and excitation of 620 nm.

RESULTS AND DISCUSSION

Since MMPs are involved in the regulation of the tumor microenvironment as well as expressed and activated in many types of human cancers, this distinct enzyme class appears to be a relevant molecular target for imaging of cancer. (*11*) MMP-2 and -9 are most consistently detected in malignant tissues in which they are associated with tumor aggressiveness, metastatic potential, and poor clinical prognosis *(12, 13)*.

Chemistry. The PEGylated benzyl derivative **5** was prepared as illustrated in Scheme 2. Mesylation of tetraethylene glycol and subsequent monosubstitution with sodium azide on a large scale gave the PEGylated azide derivative **1** in a satisfactory yield. Nucleophilic substitution of the mesyl moiety with 4-hydroxybenzaldehyde and subsequent reduc-

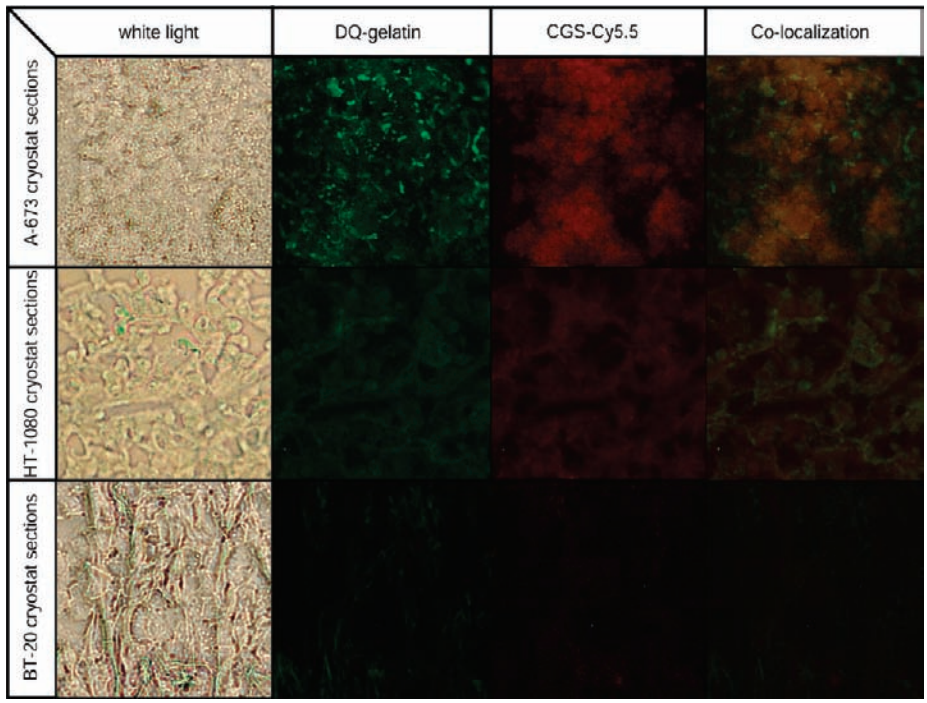

Figure 3. Gelatinolytic activity of A-673 (top), HT1080 (middle), and BT-20 (bottom) cryostat tumor sections was assessed by in situ zymography using FITC-labeled dye-quenched (DQ)-gelatin. In tissues with gelatinolytic activity, the DQ-gelatin was cleaved by MMP-2/-9 and resulted in green fluorescent signals. Binding of CGS-Cy5.5 (**11**) to MMP-2/-9 containing cryostat sections was demonstrated in an in vitro fluorescence binding assay. Incubation of the tumor sections with CGS-Cy5.5 resulted in high binding to A-673 sections (intense Cy5.5-based red fluorescence), a moderate binding to HT1080 sections, and low binding to BT-20 sections (low red fluorescence)). Additionally, FITC- and CGS-Cy5.5-based fluorescence was colocalized.

tion with sodium borhydride yielded the PEGylated benzyl alcohol **3**, which was converted into the benzyl bromide **5** in two steps (*14*).

On the basis of the known sulfonamide **6**, the secondary amine was benzylated and the ester hydrolyzed under mild conditions with lithium hydroxide in a THF/MeOH/water mixture (Scheme 3) Carboxylic acid **8** was directly converted into hydroxamic acid **9** with a silyl protected hydroxylamine and subsequent basic hydrolysis (*15*). For labeling with the NHS-ester of the commercially available cyanine dye Cy5.5, it

was necessary to reduce the azide function by a Staudinger reduction to get the precursor **10** in good yields.

The amino functionalized compound **10** was used for the conjugation of Cy5.5. The reaction was carried out in dry DMF with triethyl amine as the base (Scheme 3). Conjugate **11** was purified by reversed phase HPLC on an analytical column by collection of the appropriate fractions. After lyophilization and redissolving in PBS, the sample showed a purity of >97% (HPLC). The labeled ligand was verified by mass spectrometry with a triple negative charged ion emerging at 100% intensity.

With a molecular mass of 1,45 kDa, the resulting photoprobe belongs to the class of small molecule tracers. We and other groups are engaged in the development of MMP-targeted nonpeptide radiotracers for the in vivo detection of activated MMPs by positron emission tomography (PET) and single photon emission computed tomography (SPECT) (*16*−*20*). Recently, we successfully transferred the tracer concept to the optical imaging (OI) approach (*22*). A major advantage of OI is the opportunity to directly correlate signals in vivo with high resolution ex vivo techniques (e.g., fluorescence microscopy). A direct coregistration of biological expression patterns and the biodistribution of the tracer are thus feasible (see Figure 3). Moreover, the stability of the label and the lack of signal decay allow measurements over several days. With respect to clinical applications, small targeted probes could potentially allow endoscopic or laparoscopic tumor detection with high signal-to-noise ratios (SNRs). Imaging in the near-infrared spectrum (λ = 650−950 nm) shows very efficient tissue penetration as the absorption by water and hemoglobin is relatively low (diagnostic window) (*21*, *22*). Moreover, the tracer's excitation and emission spectra were identical to that of the Cy5.5 dye (ex, 678 nm; em, 692 nm).

Enzyme Studies in Vitro. A synthetic fluorogenic broad-spectrum MMP substrate was used in vitro to measure the activity of recombinant active human MMP-2 and -9 in the presence and absence of the unlabeled CGS **9** and **10**. The resulting inhibition potencies for several MMPs were determined as IC_{50} values and calculated from a nonlinear regression curve fit of the concentration-dependent reaction rates. This fluorogenic enzymatic activity assay yielded binding affinities of **9** and **10** to MMP-2 and -9 in the nanomolar range (Table 1).

MMP-2 and -9 Transcription, Translation, and Activity Tests. Three human cancer cell lines (rhabdomyosarcoma A-673, fibrosarcoma HT-1080 and breast carcinoma BT-20) were characterized regarding their genomic, proteomic, and functional MMP-2 and -9 expression levels. Cells were analyzed by quantitative real-time-PCR (qRT-PCR), secreted MMP proteins of collected supernatants were detected by Western blot analysis (data not shown), and MMP-2/-9 activities were verified by zymography.

In qRT-PCR analysis, the mRNA expression of the target genes MMP-2 and -9 was normalized by the internal housekeeping gene GAPDH since all three cancer cell lines (A-673, HT-1080, and BT-20) revealed nearly identical GAPDH mRNA levels. Using the software tool REST (*23*), the relative expression ratios (RER) of the target genes were determined as shown in Table 2. After determination of the RERs, amplified qRT-PCR products were analyzed in a 2% gelelectrophoresis as shown in Figure 1. Highest MMP-2 and -9 mRNA levels could be obtained for A-673, which therefore represented a MMP-2 and -9 positive cell line for the study of the binding affinity of CGS-Cy5.5 **11** to secreted gelatinases. HT-1080 cells showed high MMP-2 levels but weak MMP-9 mRNA levels. BT-20 cells expressed MMP-2 in very low amounts as compared to A-673 and HT-1080 cells. The MMP-9 mRNA level of BT-20 cells was lower than detectable levels; BT-20, therefore, was used as a cell line with very low gelatinase activity in our study.

Table 2. MMP-2 and -9 Expressions of the Carcinoma Cell Line A-673, HT-1080, and BT-20 Were Analyzed by qRT-PCR Analysis[a]

	A-673	HT-1080	BT-20
MMP-2 RER	23.0	12.7	1.0
MMP-9 RER	33.0	1.0	0

[a] The relative expression ratios (RER) for the target genes MMP-2 and -9 were determined by the software tool REST.

MMP-9-rev	CCTCCCTTTCCTCCAGAACAG	

Furthermore, gelatinolytic activities of collected supernatants from A-673, HT-1080, and BT-20 cells were analyzed by gelatin zymography. Purified MMP-2 and -9 (pro-/active forms) were used as controls (Figure 2A). Two prominent bands of gelatinolytic activity could be observed for the MMP-9 standard: the upper band exhibits the pro-form (92 kDa) and the lower band the active form (84 kDa). Purified pro-MMP-2 (72 kDa) and active MMP-2 (64 kDa) were identified accordingly. Furthermore, active MMP-2 was secreted by A-673 and HT-1080 cells. Active MMP-9 could only be detected in the supernatant of A-673 cells. Supernatants of BT-20 cells showed no detectable MMP-2 and -9 activities in zymography (Figure 2A). MMP-2 and -9 activities of the supernatants, analyzed with zymography, nicely correspond to the determined MMP-2-/9 relative expression ratios (RER) of the cells, analyzed by qRT-PCR. In following experiments, zymograms were incubated in buffers containing different amounts of the nonlabeled probe **10**. Varying the concentrations of the nonlabeled probe from 1 μM to 25 μM (Figure 2B−D) demonstrated its inhibition potential. Gelatinolytic activities of purified enzymes and cell supernatants were completely inhibited in the presence of 25 μM unlabeled CGS **10** as shown in Figure 2D, indicating efficient inhibition of MMP-2 and -9 by the probe.

Additionally, MMP-2 and -9 proteins in the collected supernatants were assessed by Western blotting with polyclonal antibodies, which recognize the latent and active MMP-2 and -9 forms. Western blot analysis and purified enzymes confirmed the results obtained with zymography (data not shown (*24*)).

Cellular Fluorescence MMP-Binding Assay of the Cy5.5-Labeled CGS (11) Using Cryostat Sections in Vitro. In situ zymography was used to proof high (A-673), weak (HT1080),

and low (BT-20) MMP-2 and -9 activities of respective tumor cryostat sections. Gelatinolytic activity was visualized in thin tissue sections by FITC-labeled dye-quenched (DQ)-gelatin, resulting in green fluorescence only in the case of enzymatic conversion. As expected, high extracellular and cellular green fluorescence was observed in the majority of regions of A-673 tumor sections (Figure 3) proving high MMP-2 and -9 activities of A-673 tumors suggested by the previous qRT-PCR and zymography experiments. Accordingly, BT-20 sections showed very low FITC-based fluorescence signals and only weak green fluorescence at the tumor border (Figure 3). In the fluorescence binding assay, MMP-2 and -9 containing A-673 tumor cryostat sections were treated with PBS containing 280 pmol of CGS-Cy5.5 **11**. High Cy5.5-based red fluorescence was obtained for A-673 sections as demonstrated in Figure 3. These results suggest high binding affinity of the labeled probe to gelatinases, secreted by the A673 tumor. In contrast, incubation of BT-20 sections showed only weak red fluorescence and revealed low binding of CGS-Cy5.5 **11** (Figure 3). CGS-Cy5.5- and FITC-based fluorescence signals were found colocalized, and further proof that activated MMPs can be detected with the newly developed photoprobe.

Alternative imaging approaches have been previously described in the literature (*25*). Large self-quenched molecules, e.g., allowed one to assess MMP expression in vivo via enzymatic activation of the probe. While this approach is a highly sensitive method for the detection of MMP activity, large molecule size (app. 400−500 kDa) and thus long blood half-life may be undesirable for translational imaging approaches.

CONCLUSIONS

The aim of this work was the development of a nonpeptide MMP inhibitor for optical imaging of MMP-2 and -9 activities. We have chosen CGS 25966 as the lead structure and developed a route for the synthesis of an amino-PEG-derivatized compound that can be used for the conjugation of common amino-reactive fluorescent markers such as Cy5.5. Thus, we obtained a near-infrared fluorescent photoprobe for the imaging of MMP-2 and -9. Using techniques such as qRT-PCR and zymography, the MMP-2 and -9 expressions of three human cancer cell lines was analyzed. The rhabdomyosarcoma cell line A-673 showed high MMP-2 and -9 levels, whereas the fibrosarcoma cell line HT-1080 exhibits lower levels and the breast carcinoma cell line BT-20 only marginal levels of MMP-2. MMP-2 and -9 activities of the three cell supernatants were verified by zymography. In subsequent blocking experiments, zymograms were incubated with different concentrations of unlabeled CGS **10**. Incubation with ≥ 25 μM unlabeled inhibitor revealed efficient binding and inhibition of MMP-2 and -9 activities. Additionally, gelatinolytic activity of A-673 and BT-20 cryostat sections was determined by in situ zymography using the DQ-gelatin technique. High binding affinity of CGS-Cy 5.5 **11** to MMP-2 and -9 containing A-673 tumor cryostat sections was demonstrated in an in vitro fluorescence binding assay. Thus, MMP-2 and -9 imaging with the fluorescent labeled probe **11** is feasible and should further be developed toward a molecular imaging approach to monitor disease processes such as invasion, metastasis, and angiogenesis in cancer in vivo being associated with activated MMP-2 and -9.

ACKNOWLEDGMENT

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 656 projects A2/A4), the European Union Community (IP sixth framework; grant no. LSHG-CT-2003-503259 (Mol. Img) and MoldDiag-Paca LSHB- CT-2006-018771), the Interdisziplinary Centre of Clinical Research (FG3), and the European Institute for Molecular Imaging (EIMI). Matrix-assisted laser desorption/ionization-time-of-flight mass spectrometry (MALDI-TOF MS) is a promising tool for large-scale screening of body fluids for the early detection of human diseases. Proteins, peptides, and metabolites present in cells, tissues, or in body fluids constitute the molecular signatures of individuals. The design and generation of material-based platforms for capturing molecular signatures from body fluids has gained increasing interest in recent years. Highly selective materials are attractive candidates for a wide range of applications in biofluid proteomics. We have therefore developed a procedure based on mesoporous silica particles for the selective binding and enrichment of low molecular weight plasma/serum proteins by MALDI MS analysis (Terracciano, R., Gaspari, M., Testa, F., Pasqua, L., Cuda G., Tagliaferri, P., Cheng, M. C., Nijdam, A. J., Petricoin, E. F., Liotta, L. A., Ferrari, M., and Venuta, S. (2006) Selective binding and enrichment for low-molecular weight biomarker molecules in human plasma after exposure to nanoporous silica particles. *Proteomics 6,* 3243–3250). Mesoporous silica beads (MSB) are able to harvest peptides from plasma and serum by means of nanosized porous channels with high surface area, while excluding large size proteins. Moreover, the absorption properties can be modified since the pore walls can be functionalized with different chemical species due to the high concentration of silanol groups at the surface. In this study, we performed derivatization of MSB with different functionalities, and we evaluated the derivatized materials for plasma and urine peptidomic profiling. Aminopropyl, *N*-(2-aminoethyl)-3-aminopropyl, and *N*,*N*,*N*′ tris-carboxymethyl ethylene diamine, have been introduced onto the mesoporous silica surfaces in order to modulate selective peptide enrichment. We also explored various experimental conditions in order to optimize the performance of chemically modified MSB in the peptide profiling of human plasma and urine. These new derivatized mesoporous surfaces, in addition to the previous nonderivatized MSB, constitute an extended and reliable platform of five distinct chromatographic phases with defined surface functionality and porosity. Several plasma and urine peptides were extracted from derivatized MSB and then profiled by MALDI-TOF MS. The reproducibility of sample preparation by different functionalized beads was evaluated via three replicate analyses of plasma and urine samples. Lower coefficients of variation in the mass values and peak intensities resulted for plasma in comparison to those of urine samples; nevertheless, these where satisfactory for diagnostic purposes. For human urine, a linear correlation was found between spiked peptide concentrations and their peak areas ($R^2 > 0.98$) with a limit of detection in the low-nanogram per milliliter range, thus confirming the high sensitivity of the methodology, previously demonstrated for human plasma. Different panels of peptide repertoires have thus been collected from highly porous substrates chemically conjugated with different functional groups, and these may be used in biomarker discovery for disease diagnosis.

INTRODUCTION

The comparison of protein expression between healthy individuals and patients is one of the promising tools for biomarker identification. A fast and sensitive protein profiling method for biomarker discovery is an essential prerequisite for high-throughput and large-scale clinical studies. The establishment of proteomic approaches to biomarker discovery and disease profiling in recent years has tested the limits of existing tools for the capture and detection of low-abundance proteins in biological samples. The ability to isolate target proteins from complex protein mixtures, as well as improving the sensitivity toward peptides of low abundance, is a challenge for mass spectrometric analysis.

Proteomic pattern analysis by mass spectrometry (MS) is emerging as the preferred tool for robust and rapid expression profiling studies (*1*−*9*) and represents an alternative to the classical and laborious two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) (*10*).

For biofluids, surface-enhanced laser desorption/ionization-time-of-flight (SELDI-TOF) or matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) MS are rapidly growing in popularity because of their ability to screen and discover multiple biomarkers simultaneously in clinical proteomics. In addition, SELDI-TOF MS and MALDI-TOF MS focus especially on the low molecular mass region analytes (1000−20000 Da), which include the small proteins, protein/peptide fragments, and peptides that constitute the peptidome or fragmentome, which are often overlooked by traditional techniques (*11, 12*).

Affinity binding reagents have played a crucial role in the translation of proteomic discoveries to clinical diagnostics due to their ability to isolate target proteins from complex protein mixtures (*13*). The design and generation of material-based

platforms for capturing molecular signatures written in body fluids have also gained increasing interest in recent years (*14*−*17*). Additionally, novel bioconjugate materials, designed specifically for microscale genomic and proteomic analyses, are facilitating new separation techniques (*18, 19*). Mesoporous silica has captured considerable interest for a diverse range of applications, such as catalysis, filtration and separation, molecular collection and storage, nanofluidics, medical imaging, drug delivery, and sensors (*20*). Recently, our group has explored a new application of mesoporous silica. We have previously developed a strategy based on mesoporous silica beads (MSB) for profiling low molecular weight plasma peptides (*21*). In later correlated studies, nanoporous silicon and glass beads were used to harvest distinct subsets of the proteome from serum/plasma samples (*22, 23*).

According to IUPAC nomenclature, porous materials are divided into 3 classes: microporous material with a pore diameter below 2 nm, mesoporous material with a pore diameter between 2 and 50 nm, and macroporous material with a pore diameter above 50 nm. We speculated that mesopores would have the right dimensions for tunable peptide entrapment, while micropores might be too small and macropores too large for such a purpose. Given the high surface area, we demonstrated that mesoporous silica offered the desired adsorptive capacity for binding and enrichment of low molecular weight peptides present in human plasma (*21*). These results encouraged us to further investigate and explore the use of MSB as harvesting materials not only for human plasma but also for other clinically relevant body fluids such as human urine. The present study starts from the rationale that the absorption properties of mesoporous silica can be modified since the pore walls exhibit a high concentration of silanol groups on the surface, which can be functionalized with different chemical species. Aminopropyl, *N*-(2-aminoethyl)-3-aminopropyl, and *N*,*N*,*N*′-tris-carboxymethyl ethylene diamine (TED) have been introduced onto mesoporous silica surfaces in order to selectively modulate peptide enrichment. Plasma and urine peptides were extracted from derivatized mesoporous silica beads and then profiled by MALDI-TOF MS. The reproducibility of the method was also evaluated for the beads with different groups, both for plasma and urine samples. Depending on the chemical group and the chromatographic features, different subproteomes in plasma and urine were extracted and converted into reproducible MALDI profiles.

EXPERIMENTAL SECTION

Reagents and Materials. Reagents for sol−gel synthesis, sodium silicate solution, fumed silica, tetraethylorthosilicate (TEOS), 3-aminopropyltriethoxysilane (APTES), and hexadecyltrimethylammonium bromide [$C_{16}H_{25}N(CH_3)_3Br$] (CTABr), were purchased from Sigma Aldrich, (St. Louis, MO, USA). Polyoxyethylene(10)isononylphenylether (Nonfix10), was obtained from Condea (Houston, TX, USA), *n*-(Trimethoxysilylpropyl)ethylenediaminetriacetic acid and trisodium salt (EDA-TAS, 50 wt.% in water) were purchased from Gelest Inc. (Tullytown, PA, USA). Pluronic P123 (poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) triblock copolymer, $PEO_{20}PPO_{70}PEO_{20}$) was obtained from BASF (Mount Olive, NJ, USA). Acetonitrile (ACN, HPLC grade) and trifluoroacetic acid (TFA, ACS grade) were purchased from Merck (Darmstadt, Germany).

The MALDI matrix *R*-cyano-4-hydroxycinnamic acid (CHCA) was purchased from Fluka (St. Louis, MO, USA). Peptide and protein standards, for mass spectrometer external calibration, were prepared from the Sequazime peptide mass standard kit (Applied Biosystems, Framingham, MA, USA). Angiotensin I and adrenocorticotropic hormone, ACTH (clip 1−17), for the spiking experiment were purchased from Sigma (St. Louis, MO, USA).

The water used was obtained from a Milli-Q water purification system (Millipore, Bedford, MA, USA).

Preparation of Materials. *MSB-A and MSB-B Preparation.* Mesoporous silica beads A and B were obtained according to two different synthetic procedures described elsewhere (*24, 25*).

Preparation of Material SBA-15 and Large Pore Mesoporous Silica Materials. *SBA-15 Mesoporous Material.* SBA-15 mesoporous material has been synthesized using a triblock-copolymer neutral surfactant PEO_{20}-PPO_{70}-PEO_{20} (Pluronic P123) in accordance with the procedure described by Zhao et al. (*26*). In a typical preparation, 4.0 g of Pluronic P123 was dissolved in 30 g of water and 120 g of 2 M HCl solution with stirring at 35 °C. Then 8.50 g of TEOS was added to the solution under vigorous stirring at 35 °C and maintained like this for 20 h. The mixture was aged at 80 °C overnight without stirring. The solid product was recovered, washed, and air-dried at room temperature.

Large Pore Mesoporous Silica Material. Large pore mesoporous silica spheres were synthesized by using TEOS as the silica source, P123 as the template, CTABr as the cosurfactant, and ethanol as the cosolvent. Typically, 0.3 g of triblock copolymer P123 and 0.05 g of CTABr were dissolved in a solution formed by mixing 6 mL of 2 M HCl, 3 mL of H_2O, and 2.5 mL of ethanol. Then, 1 mL of TEOS was added to the aqueous solution at room temperature under magnetic stirring. The reactant molar ratio TEOS/P123/CTAB/HCl/EtOH/H_2O in the final reaction mixture was 1:0.011:0.031:2.67:9.18:116. After 30 min of stirring, the solution was transferred to a Teflon-lined steel Parr autoclave and heated at 80 °C for 5 h and then kept at 120 °C for 12 h. The white precipitate was recovered by filtration, dried at 90 °C for 24 h, and calcined in air at 550 °C for 5 h to remove the templates.

Preparation of Functionalized MSB-C, MSB-D, and MSB-E. In the preparation of 3-aminopropyl mesoporous silica (MSB-C) 0.6 g of calcined mesoporous material SBA-15 were suspended and stirred for 40 h in a solution obtained by dissolving 2.5 mL of 3-aminopropyltriethoxysilane in 10 mL of ethanol at room temperature. The suspension had been filtered, washed, and dried.

In the preparation of *N*-(2-aminoethyl)-3-aminopropyl mesoporous silica (MSB-D), 0.6 g of calcined mesoporous material SBA-15 was suspended and stirred for 8 h in a solution obtained by dissolving 2.3 mL of *N*-(2-aminoethyl)-3-aminopropyltrimethoxysilane in 10 mL of ethanol under reflux. The suspension was filtered, washed, and dried.

In the preparation of *N*-(3-propyl) ethylenediaminetriacetic acid, trisodium salt mesoporous silica (MSB-E) and 0.4 g of calcined large pore mesoporous silica were suspended in a solution obtained by dissolving 1.0 mL of *N*-(trimethoxy silylpropyl)ethylenediaminetriacetic acid and trisodium salts 50% in water. The suspension was stirred under reflux for 6 h and then filtered, washed, and dried.

Material Characterization. All of the samples were characterized by X-ray diffraction on powder (XRD), thermogravimetrical analysis (TG), energy dispersive spectroscopy (EDS), X-ray microanalysis, and nitrogen adsorption−desorption isotherms. The XRD spectra were acquired on a Philips PW1710 diffractometer using Cu−Kα radiation (40 kV, 20 mA) over the range $1° < 2\theta < 15°$ with a rate scan of 0.005 2θ/s. TG analyses were carried out with a Netzsch STA 409 apparatus between 20 and 850 °C at a ramp of 10 °C/min in air with a flow rate of 5 cc/min. EDS chemical analyses were performed using a scanning electron microscope FEI Quanta 200.

Surface area of the samples was obtained by Brunauer-Emmet and Teller (BET) linearization in the pressure range 0.05−0.2 P/P_0. The nitrogen adsorption−desorption volumetric isotherms at 77 K were measured on a Micrometritics Asap 2010 apparatus. Average pore diameter was calculated according to the BJH (Barret−Joyner−Halenda) model applied to the desorption branch of the isotherm.

Plasma Collection. Venous blood samples were obtained from a total of 10 healthy adult males (age range 25−45 years) after they provided written informed consent.

Blood intended for plasma preparation was collected into the following tubes: BD Plus Plastic K2EDTA, 10 mL, # 367525 (BD Bioscience, Franklin Lake, NJ, USA). The samples were centrifuged at 1300*g* for 10 min under refrigerated conditions (2−6 °C). The resultant plasma was immediately transferred into 2 mL Eppendorf vials and frozen in aliquots at −80 °C.

Urine Collection. Midstream, first-void morning urine samples were collected from healthy consenting male volunteers after they provided written informed consent. For each participant, the urine sample (150 mL) collected in standard urine container flasks without additives or preservatives, was centrifuged at 1000*g* for 10 min at 4 °C. The supernatant was aliquoted and immediately stored at −80 °C.

Preparation of Samples. MSB were incubated with the plasma or urine sample for 1 h at room temperature. The beads were subsequently separated from the supernatant by centrifugation, and the washing step was performed according to the protocol optimized for each bead functionality (see the next subsections). The bound peptides were eluted using the appropriate CHCA solution, and 1 μL of this eluate was then deposited on the MALDI probe and analyzed by MALDI-TOF.

MSB Protocols for Human Plasma Peptidome Harvesting. For MSB-A and MSB-B, which have no functionalities, we used the following protocol. Briefly, aliquots (5 mg) of MSB were mixed with 500 μL of diluted human plasma sample (100 μL of plasma in 400 μL of deionized water) and shaken at room temperature for 1 h. The suspension was centrifuged at 2000*g* for 2 min, and then the MSB were separated from the supernatant and washed with deionized water (4 × 100 μL). After the last wash, bound species were directly extracted into 100 μL of a matrix solution, made up of 4 mg/mL CHCA in a 1:1 (v/v) mixture of acetonitrile and 0.1% TFA.

For MSB-C and MSB-D, with, respectively, the aminopropyl and *N*-(2-aminoethyl)-3-aminopropyl groups, two sets of experimental conditions for peptide harvesting were tested. In a first set of experimental conditions, aliquots (5 mg) of beads were preconditioned with 250 μL of 25 mM Tris HCl at pH 8.8 for 5 min. MSB were then mixed with 500 μL of diluted human plasma sample (100 μL of plasma in 400 μL of deionized water) and shaken at room temperature for 1 h. The suspension was centrifuged at 2000*g* for 2 min, and then the MSB were separated from the supernatant and washed with 25 mM Tris HCl at pH 8.8 (2 × 100 μL). In a second set of experimental conditions, aliquots (5 mg) of beads were directly mixed with 500 μL of diluted human plasma sample (100 μL of plasma in 400 μL of deionized water) and shaken at room temperature for 1 h. The suspension was centrifuged at 2000*g* for 2 min, and then the MSB were separated from the supernatant and washed with 25 mM Tris HCl at pH 8.8 (2 × 100 μL). In both cases, after the last wash, the bound species were directly extracted into 100 μL of a matrix solution, made up of 4 mg/mL CHCA in a 1:1(v/v) mixture of acetonitrile and ammonium formate (100 mM). To determine the pH value for optimal biomarker elution, the pH of the elution solution was adjusted to the values of 3, 4, and 5.

For MSB-E, a surface-derivatized with the TED group, we adopted the following protocol. Aliquots (5 mg) of beads were preconditioned with 60 μL of HCl 10 mM, followed by 60 μL of ammonium acetate buffer at pH 6.6; this process was repeated twice. The MSB were then mixed with 500 μL of diluted human plasma sample (100 μL of plasma in 400 μL of deionized water) and shaken at room temperature for 1 h. The suspension was centrifuged at 2000*g* for 2 min, and then the MSB were separated from the supernatant and washed twice with ammonium acetate buffer at pH 6.6, followed by a third washing step with 100 μL of deionized water. After the last wash, the bound species were directly extracted into 100 μL of a matrix solution, made up of 4 mg/mL CHCA in a 1:1 (v/v) mixture of acetonitrile and 0.5% TFA. Extraction conditions were also tested in a solution of CHCA in ACN and formic acid (70:30 v/v).

In all preparations, after centrifugation at 2000*g* for 2 min, 1 μL of supernatant CHCA solution with the extracted peptides was analyzed by MALDI-TOF MS. The samples were manually spotted by a pipettor onto the MALDI probe.

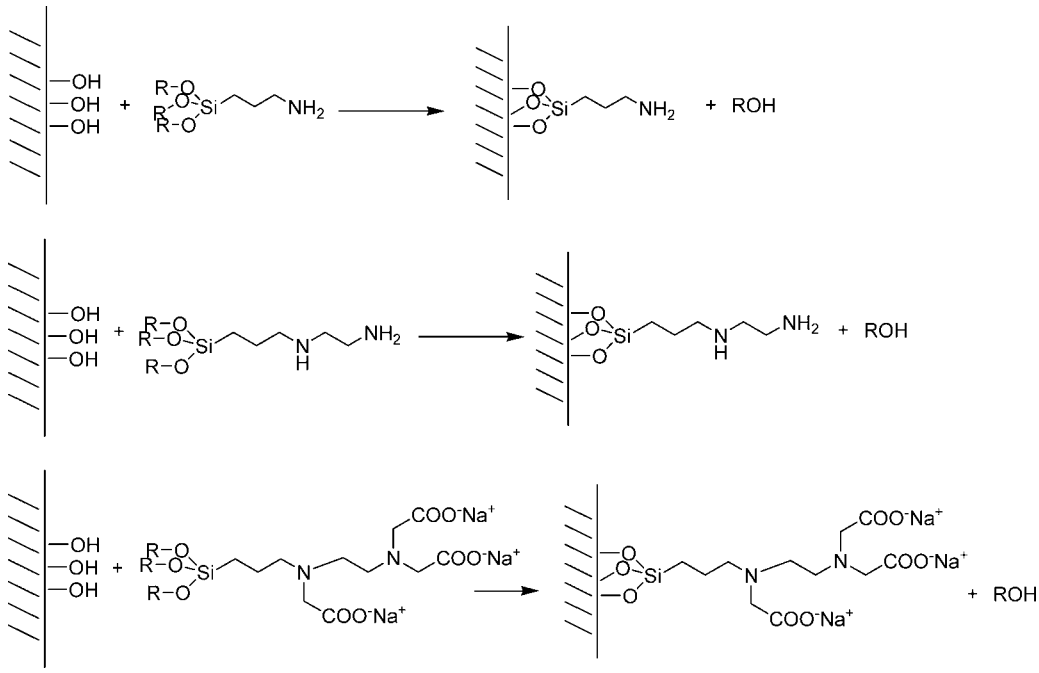
MSB Protocols for Human Urine Peptidome Harvesting. For nonderivatized MSB-A and MSB-B, the following protocol was adopted. Aliquots (2 mg) of MSB were mixed with 125 μL of 4-fold concentrated human urine sample and shaken at room temperature for 1 h. The suspension was centrifuged at 2000*g* for 2 min, and then the MSB were separated from the supernatant and washed with 0.1% TFA (4 × 100 μL). After the last wash, the bound species were directly extracted into 15 μL of a matrix solution, made up of 4 mg/mL CHCA in a 1:1 (v/v) mixture of acetonitrile and 0.1% TFA.

For MSB-C and MSB-D, derivatized, respectively, with the aminopropyl and *N*-(2-aminoethyl)-3-aminopropyl groups, two sets of experimental conditions for peptide harvesting were tested. In a first set of experimental conditions, aliquots (2 mg) of beads were preconditioned with 50 μL of 25 mM Tris HCl at pH 8.8 for 5 min. The MSB were then mixed with 125 μL of 4-fold concentrated human urine sample and shaken at room temperature for 1 h. The suspension was centrifuged at 2000*g* for 2 min, and then MSB were separated from the supernatant and washed with 25 mM Tris HCl at pH 8.8 (2 × 100 μL) and subsequently with deionized water (2 × 100 μL). In a second set of experimental conditions, aliquots (2 mg) of beads were directly mixed with 125 μL of 4-fold concentrated human urine sample and shaken at room temperature for 1 h. The suspension was centrifuged at 2000*g* for 2 min, and then the MSB were separated from the supernatant and washed with 25 mM Tris HCl at pH 8.8 (2 × 100 μL). In both cases, after the last wash, bound species were directly extracted into 40 μL of a matrix solution, made up of 4 mg/mL CHCA in a 1:1 (v/v) mixture of acetonitrile and ammonium formate (100 mM, pH 3).

For MSB-E, surface-derivatized TED, we adopted the following protocol. Aliquots (2 mg) of beads were preconditioned with 60 μL of 10 mM HCl, followed by 60 μL of ammonium acetate buffer at pH 6.6; this process was repeated twice. The MSB were then mixed with 120 μL of a 4-fold concentrated human urine sample, and the resulting slurry was shaken at room temperature for 1 h. To determine the pH value for optimal biomarker harvesting, the pH of the resulting slurry was also adjusted to pH 4.5. The suspension was centrifuged at 2000*g* for 2 min, and then the MSB were separated from the supernatant and washed twice with 100 μL of ammonium acetate buffer at pH 6.6, followed by a third washing step with 100 μL of deionized water. After the last wash, the bound species were directly extracted into 60 μL of a matrix solution, made up of 4 mg/mL CHCA in a 1:1(v/v) mixture of acetonitrile and 0.5% TFA.

In all preparations, after centrifugation at 2000*g* for 2 min, 1 μL of supernatant CHCA solution with the extracted peptides

Scheme 1. Functionalization of Mesoporous Silica



was analyzed by MALDI-TOF MS. The samples were manually spotted by a pipettor onto the MALDI probe.

Urine Sample Processing with Standard Peptides. Urine samples were spiked with angiotensin I and adrenocorticotropic hormone, ACTH (clip 1−17), at eight different concentrations: 1000, 500, 250, 125, 62.5, 26, 6.5, and 3.7 ng/mL for angiotensin I, and 1614, 807, 404, 202, 101, 42, 10.5, and 6 ng/mL for ACTH (clip 1−17). The samples were processed with MSB-C as described in the previous section in three independent assays.

MALDI MS Analysis. MALDI MS analysis was performed on a MALDI-TOF mass spectrometer (Voyager DE-STR, Applied Biosystems, Foster City, CA) equipped with a 337 nm nitrogen laser. Analyses were performed in linear positive-ion mode using delayed extraction. The acceleration voltage was 20 kV, the guide wire was 0.05% of the accelerating voltage, the grid voltage was 91.5%, and the delay time was 220 ns. Five 100-laser shots were averaged for each mass spectrum. All spectra were processed using Data Explorer Software (Applied Biosystems, Framingham, MA). All experiments were carried out at least in triplicate to ensure the reproducibility of the spectra. All signals with a signal-to-noise (S/N) ratio > 10 in a mass range of 1100−10000 for plasma and 1100−6000 for urine were collected in the Data Explorer Software. Peptide sequencing was carried out on a 4800 MALDI-TOF/TOF mass spectrometer (Applied Biosystems, Foster City, CA) equipped with a neodymium:yttrium−aluminum-garnet laser emitting at $\lambda = 355$ nm with a 200-Hz firing rate.

RESULTS AND DISCUSSION

The possibility of synthesizing mesoporous materials with regularly sized pores by means of the supramolecolar templating of a sol−gel process represents a starting point for the design of functional nanostructured materials. The MSB used in our approach belong to the class of ordered mesoporous silica synthesized for the first time in 1992 by the hydrolysis and condensation of inorganic precursors (the sol−gel process) in the presence of surfactant micelles (templates) (*27*).

The term ordered in this context means that the pores are ordered. It is widely accepted that when the mesopore diameter is sufficiently large for the comfortable entrapment of biomolecules, analytes penetrate deep into mesoporous networks rather than become adsorbed onto the external surface (*28*). The analytes entrapped by the mesoporous channels and consequently the resulting peptidomic profile of a given body fluid or complex protein mixture depend greatly on the size of the mesopores. Another way to modulate the selectivity of substrates may be by introducing functional groups. Indeed, it has been demonstrated that 17 and 70 nm pore sized aminopropyl-coated glass beads were able to adsorb serum peptides, but in a number ranging from one to a few dozens (*23*). On the contrary, hundreds of peptides were retained when mesoporous silica particles (MSB-A and MSB-B) containing pores with a size in the range of 2−3 nm were used (*21*). Therefore, we prepared a series of hybrid mesoporous silica in order to differentially modulate the selective binding and enrichment of low molecular weight proteins (LMWP) from plasma and urine, without significantly changing the physical properties (pore size, pore volume, and surface area) of the previously used MSB-A and MSB-B (*21*).

Briefly, hybrid inorganic−organic materials are produced when chemically active groups are covalently linked to the inorganic framework of mesoporous materials either by postsynthesis grafting or by the simultaneous condensation of siloxane and organic siloxane precursors, in which the latter contain a nonhydrolyzable Si−C bond (*29*).

In our case, three hybrid materials with different functional groups, namely, aminopropyl-, *N*-(2-aminoethyl)-3-aminopropyl-, and *N*-(3-propyl) ethylenediaminetriacetic acid, were prepared by postsynthesis modification of two different mesoporous silica obtained using Pluronic P-123, a triblock-copolymer neutral surfactant. The derivatization procedure is shown in Scheme 1. The derivatized particles MSB-C, MSB-D, and MSB-E were characterized according to analyses described in the Experimental Section to obtain information on the size, pore size, shape, surface area, and pore volume (more details on the materials are available in Supporting Information). The beads show an irregular shape, with the average pore size being approximately 4 nm for MSB-C and MSB-D, and 7 nm for MSB-E, and surface area in the order of 200 to 300 m^2/g. A more detailed description of textural properties of these new hybrid materials along with the previously used silica A and B is reported in Table 1. As briefly reported in the Experimental

Table 1. Textural Properties of Mesoporous Silica Bead Platforms

MSB	Functional group	Pore size diameter[(a)]	Pore volume[(b)]	BET Surface area[(c)]
MSB-A	-O-	2.6 and 4.2	0.30	406
MSB-B	-OH	2.7	0.78	848
MSB-C	$-(CH_2)_3-NH_2$	4.3	0.39	273
MSB-D	$-(CH_2)_3-NH-(CH_2)_2-NH_2$	4.6	0.41	310
MSB-E	$-(CH_2)_3-N(-(CH_2)_2-N(-COO^-Na^+)-COO^-Na^+)-COO^-Na^+$	7.0	0.41	171

[a] Pore size is expressed in nm. [b] Pore volume is expressed in cm^3/g. [c] Surface area is expressed in m^2/g.

Section under the paragraph on material preparation, MSB can be readily synthesized by a simple, inexpensive procedure. Additionally, given the good mechanical properties, (rigidity and stability), MSB can act as an excellent substrate for the pretreatment of body fluids.

Plasma and urine represent convenient diagnostic specimens for clinical analysis. Metabolites and peptides from these body fluids have the potential to serve as reliable indicators of the progression from a normal to a diseased state. Human urine contains the proteins filtered from blood within the glomerulus as well as the proteins secreted from the kidneys and the urogenital tract. Changes in kidney and urogenital tract function may be detected in the urine proteome. In addition, as a filtrate of blood, urine contains protein components that are similar to those found in the blood. Therefore, pathological changes in human organs, which could be found in blood, may also be reflected and detected in urine. In this sense, urine proteome analysis could be used in disease diagnostics (*30*).

In spite of multidimensional liquid chromatography-MS, which is usually unsuitable for clinical high-throughput screening, MALDI-TOF MS represents a key tool for rapidly analyzing clinical samples. Unfortunately, salts, lipids, and high concentrations of proteins in plasma as well as high concentrations of salts and metabolic wastes in urine make it difficult to detect and analyze peptides by MS. MSB represent a rapid procedure for reducing plasma and urine complexity prior to mass spectrometric analysis.

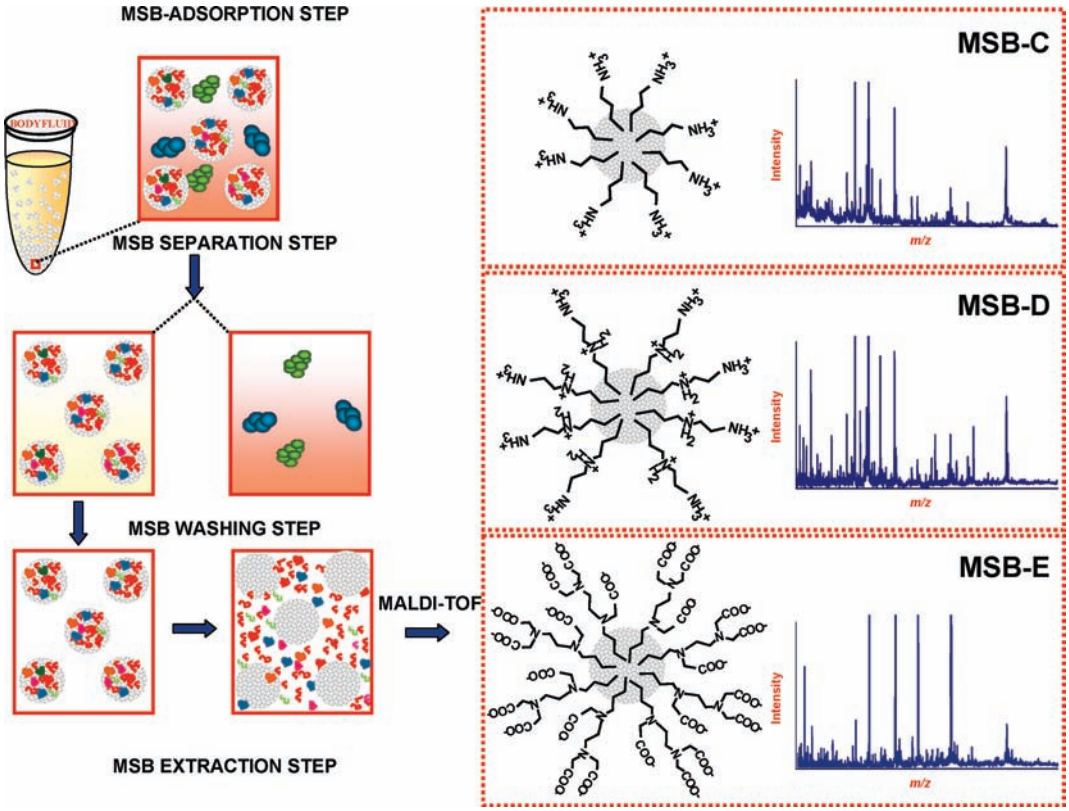
We have tested the new derivatized mesoporous silica beads for the generation of molecular signatures from plasma and urine samples. In MSB-A and MSB-B, previously tested on plasma only, peptide harvesting is largely regulated by the mesoporous properties and the electrostatic interactions of the silica (MSB-A) and the silanol groups (MSB-B) with the peptides (*21*). In the new hybrids, MSB-C, MSB-D, and MSB-E, weak basic and acid functionalities present on the surface differently modulate the electrostatic interactions toward a particular subset of negatively or positively charged peptides. In particular, in MSB-C, the aminopropyl group has one ion-exchange site with a pK_a of 9.8, while MSB-D, which contains both a primary and secondary amine (PSA), exhibits two ion-exchange sites (pK_a 10.1 and 10.9). MSB-E, derivatized with the chelating *N*,*N*,*N*′-triscarboxymethyl ethylene diamine group (TED), offers the possibility of forming pentadentate complexes when used in conjunction with specific metal ions used for the separation of proteins (*31*). Moreover, TED contains weak acid groups whose conjugate bases can act as weak cation exchangers; therefore, MSB-E also possesses cation exchange properties in addition to its chelating character. In this exploratory study, we tested this substrate as a weak cation exchanger. More detailed and additional investigations are planned by our group to study the feasibility of using this substrate as an immobilized metal affinity chromatography (IMAC) material (*32*).

In Scheme 2, we illustrate the workflow of the derivatized MSB for MALDI-TOF analysis of plasma and urine peptidome. It is divided into four main steps: adsorption, separation, washing, and extraction.

In the first step, a small amount of the particles are simply suspended in plasma or urine and left to act as sponges. During this step, only peptides and proteins with sizes smaller than or comparable to the pore size are adsorbed into the mesochannels. Moreover, given the specific chemical functionality present on the mesoporous surface, the adsorption process will also be driven by the electrostatic interactions of the positively (arginine, lysine, histidine) or negatively (glutamic and aspartic acids) charged residues of the peptides and proteins present in the plasma or urine, with the chemical groups conjugated to the mesoporous silica surface. Typically, the adsorption of body fluid peptides into MSB can often change with pH. Thus, in a neutral solution, MSB-C and MSB-D (pK_a around 10) retain a positively charged surface, which can adsorb negatively charged peptides. On the contrary, MSB-E possesses a negatively charged surface, which can adsorb positively charged peptides. From this point of view, our strategy in choosing the appropriate experimental conditions was driven by the chemical group conjugated to silica pore walls. In the Experimental Section, we report the detailed conditions used for each derivatized surface. Different pH values were tested in order to ensure that the maximum number of peptides were captured from plasma and urine. We found that for MSB-C, a primary amine phase, and MSB-D, a primary and secondary amine phase (PSA), better working conditions (in terms of plasma and urine peptide adsorption) were obtained in a pH range between 8 and 9, rather than under neutral conditions (data not shown). For MSB-E, containing the TED group, we also observed a strong pH dependence on the adsorption efficiency. In Figure 1, we report the comparison between the MALDI-TOF mass spectra of urinary peptides captured by MSB-E at two different pH values. When the (concentrated) urine sample was incubated with MSB-E at pH 6.6, we observed an increase in the number of peptides detected by MALDI-TOF mass spectrometry (Figure 1a) in comparison to that at pH 4.5 (Figure 1b).

In our experience with MSB, we found that the separation and washing steps were critical in order to ensure MALDI spectra of good quality. Separation of the beads from the supernatant requires gentle centrifugation and preferably a single pipettor aspiration, in order to avoid diffusion of adsorbed peptides into the mother liquor. At the same time, washing needs to be as fast as possible. The washing step is crucial in order to

Scheme 2. Workflow Diagram of Plasma and Urine Sample Preparation with Mesoporous Silica Beads (MSB)



eliminate salts and other contaminants, which can interfere with MS analysis. Too many washes should be avoided due to the risk of sample loss. To overcome these problems, different washing conditions were tested, and the best compromise was found when the number of washes did not exceed three (data not shown).

Our derivatized beads have ionizable groups; therefore, the elution parameters are affected by a number of factors, and the ionic strength, temperature, and pH of the eluent may play a crucial role. In order to prevent the degradation of the human plasma and urine peptides harvested on the beads and to make

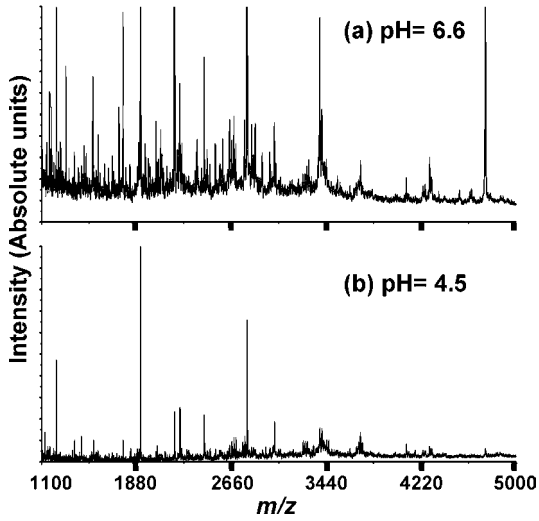


Figure 1. MALDI-TOF spectra of peptides extracted from a urine sample by weak cation mesoporous silica beads using two different pH values during the adsorption step. The resulting spectrum at pH 6.6 (a) reveals an increased number of peptide peaks compared to that in the spectrum at pH 4.5 (b).

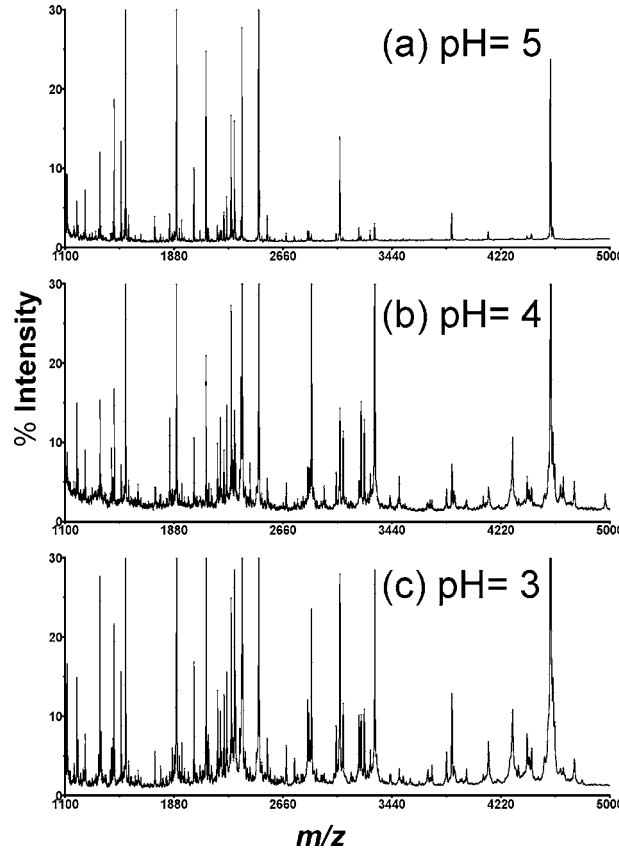

Figure 2. Effect of pH during the extraction step, on the mass spectral profiles of plasma processed with mesoporous silica beads derivatized with an aminopropyl group (MSB-C). The figure shows the change in the plasma profile when plasmatic peptides are extracted from the beads at pH 5 (a), pH 4 (b), and pH 3 (c). The optimal MS profile is obtained using a CHCA solution in ACN and 100 mM ammonium formate at pH 3 (c).

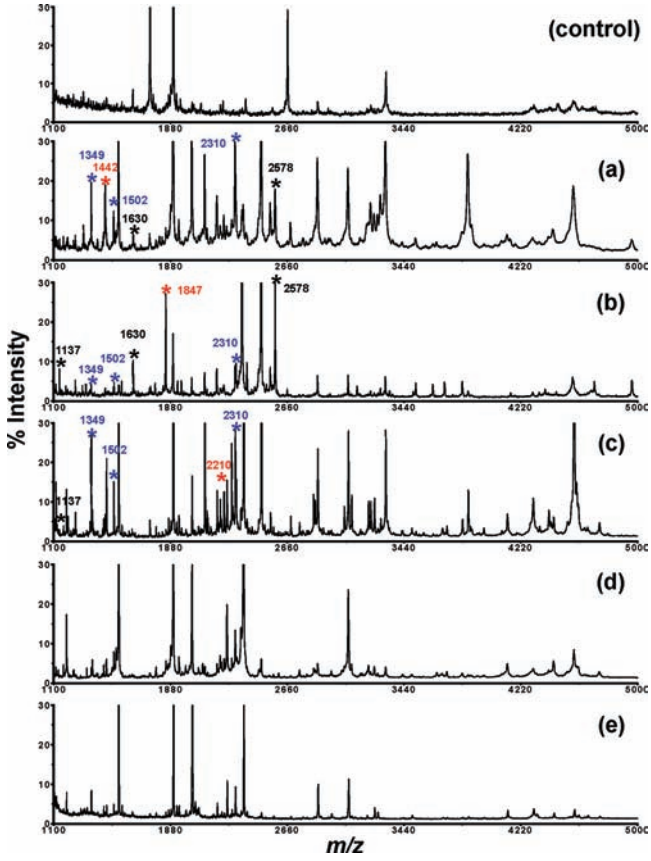

Figure 3. MALDI-TOF spectra of peptides extracted from human plasma using different mesoporous silica beads (MSB). Human plasma samples were incubated with mesoporous beads followed by washing and elution with a matrix CHCA solution. Eluates from MSB-A (a), MSB-B (b), MSB-C (c), MSB-D (d), and MSB-E (e) were analyzed by MALDI-TOF MS. The top panel (control) shows the MALDI spectrum of an unprocessed plasma sample. Asterisks mark peaks, sequenced by MS/MS experiments, which are retained by a single MSB (indicated in red), by two different MSB (indicated in black), or by all three MSB analyzed (indicated in blue).

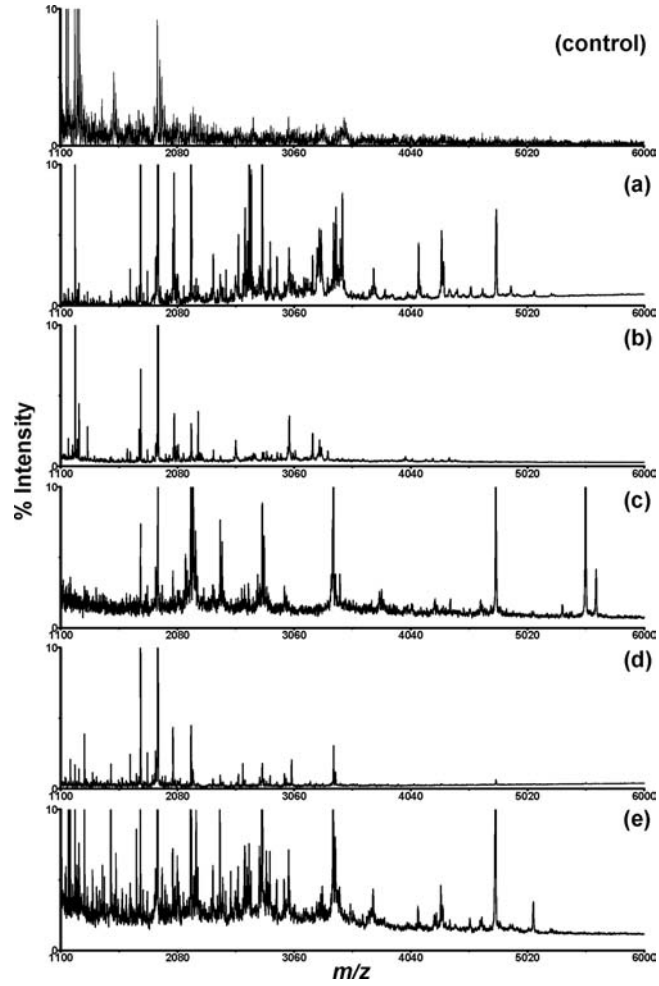

Figure 4. Processed MALDI spectra of peptides extracted from human urine samples using five different beads. The mass range from 1100 to 6000 Da is shown. Human urine was analyzed using MSB-A (a), MSB-B (b), MSB-C (c), MSB-D (d), and MSB-E (e). The top panel (control) shows the MALDI spectrum of an unprocessed urine sample.

the analysis more rapid, one elution step at room temperature was preferred to fractionation, which requires more time. Moreover, the extraction was performed directly with the matrix solution for MALDI-TOF analysis. CHCA was used as the matrix because it is more suitable for peptide analysis compared to other matrices used for MALDI-MS (sinapinic acid or DHB). Different elution parameters, in particular the eluent composition and pH, were assessed in order to maximize the elution of all of the adsorbed peptides in one step. We observed different MALDI MS spectra when plasma peptides were extracted from MSB-C at three different pH values (Figure 2). Comparing elution at pH 5 (Figure 2, panel a) and elution at pH 4 (Figure 2, panel b), the most significant differences were observed with increased mass signals in the *m/z* range between 2600 and 5000 at pH 4. The most efficient peptide extraction was accomplished at pH 3. We observed no substantial differences in peptide patterns when comparing the MALDI spectra at pH 4 and 3 (Figure 2, panels b and c) apart from a substantial variation in the relative signal intensities. Therefore, for anionic mesoporous beads, optimal elution conditions were obtained with a CHCA solution in ACN and 100 mM ammonium formate at pH 3. Plasmatic and urinary peptides bound to siloxane (MSB-A) and silanol (MSB-B) beads were eluted satisfactorily with a CHCA solution in ACN and 0.1% TFA 1:1 (v/v). For cationic beads, a solution of CHCA in ACN and 0.5% TFA (50:50, v/v) was more efficient compared to a solution of ACN and formic acid (70:30, v/v, data not shown).

MSB-E	119	119	0

[a] The number of peaks detected in the range between 1100 and 10000 Da with a S/N > 10.

The working conditions used for capturing, washing, and eluting the plasma and urine peptides, in order to ensure the best MALDI-TOF profiling in terms of the number of peaks detected, reproducibility, signal-to-noise ratio, and signal intensity are summarized in Tables S1 and S2 of Supporting Information.

Representative examples of the profiles of human plasma and urine obtained with different bead types, using the experimentally determined optimal conditions, are shown in Figures 3 and 4.

The use of MSB appears to provide sufficiently rich fingerprints of plasma and urine, as revealed by comparing the mass spectra of unprocessed plasma (Figure 3, control) and urine

(Figure 4, control) to mass spectra generated after MSB processing (Figure 3 and 4).

All MALDI spectra were generated using the same settings in the range from 800 to 10000 Da, imposing the stringent condition of a signal-to-noise ratio of higher than 10 for peak detection (see Experimental Section). Apart from some peak clusters related to the matrix CHCA used in MALDI analysis in the range between 800 and 1100 Da, most of the detected signals for all of the bead functionalities were in the range from 1100−5000 for plasma and 1100−6000 for urine, exhibiting some sporadic high intensity peaks outside this range. The numbers of peaks detected over the entire range from 1100 to 10000, in the case of plasma samples processed with the various kinds of silica, are reported in Table 2. Among all bead types, aminopropyl-derivatized MSB-C provided the best performance in resolving the plasma peptidome (160 peaks detected), thus indicating that mesoporous silica materials with a pore size of roughly 4 nm and with a surface area of around 270 m^2/g could be the starting point for future chemical tailoring aimed at increasing the affinity for plasma peptides. Our results extend the findings of Geho and co-workers, who used aminopropyl-coated 17 and 70 nm pore-sized glass beads from Sigma for serum fractionation, obtaining, however, only a few dozen peptides (*23*). The data presented here (Table 2) strongly suggest that, besides functionalization, tuning the pore size, pore volume, and the surface area of mesoporous silica may also be a viable approach to biomarker harvesting. Future development of our technology along this line will include surface functionalization with alkyl and aryl groups, which could increase the hydro-

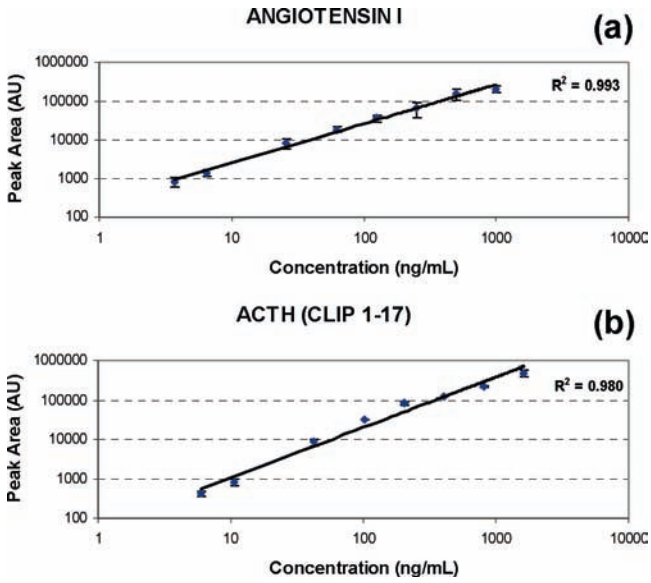

Figure 5. Peak areas of the tested peptides spiked in the urine sample, plotted against their concentrations. The assayed peptides are (a) angiotensin I (1297.51 *m*/*z*) and (b) adrenocorticotropic hormone (ACTH; clip 1−17; 2094.46 *m*/*z*). A linear equation is used in curve fitting. The error bars are the standard deviations of the mean peak areas.

phobicity of the mesoporous silica and allow the selective capture of hydrophobic peptides for mass spectrometric assays.

MSB-A and MSB-B, previously tested on plasma samples (*21*), have also been tested for urine in this investigation exhibiting very good mass coverage in the *m*/*z* range 1100−6000 (Figure 4, panels a and b). Urine analysis using MSB-A in fact produced 92 signals, while a lower number of peaks was generated in this range by MSB-B (40 peaks) (Table 3). MALDI spectra from anionic beads MSB-C and MSB-D show 82 and 44 peaks, respectively. Very high mass coverage is observed in the case of MSB-E with 199 peaks detected (Figure 4, panel e and Table 3). Mass profiles obtained from urine processed by MSB-C and MSB-D share many features in common as shown in Figure 4c and d, but closer examination and comparison of the *m*/*z* values and peak intensities reveal a higher efficiency for MSB-D at low *m*/*z*, ranging from 1100 to 1880 in comparison to that of MSB-C. In the case of plasma, a few common peaks are more abundant when MSB-D is used instead of MSB-C (Figure 3, panels c and d). One possible explanation for the lower efficiency of MSB-D in comparison to that of MSB-C is the different chemical functionalities present on the mesoporous surface. It may be speculated that the *N*-(2-aminoethyl)-3-aminopropyl groups of MSB-D possess higher selectivity toward plasma and urine components in comparison to that of the aminopropyl group of MSB-C.

For plasma samples, there are very few signals in the mass spectrum generated by MSB-E (Figure 3, panel e). Although valuable for selective binding studies, MSB-E does not provide the best choice for plasma peptidome profiling. On the contrary, this kind of beads significantly amplifies the peak detection of urine peptides as clearly shown in Figure 4e.

These results indicate that different mesoporous silica with unique surface characteristics produce different MALDI mass spectra for an identical plasma or urine sample; hence, these MSB could be used to obtain complementary proteomic information with high sample throughput.

To assess the selectivity of sample processing with MSB, as proof-of-principle we identified by MALDI-TOF/TOF some peaks, both from nonfunctionalized (MSB-A and MSB-B) and from functionalized (MSB-C) silicas. Therefore, in a preliminary analysis, we randomly selected for identification the following peaks, retained from plasma by MSB-A, MSB-B, and MSB-C: peak at *m*/*z* 1442, retained by MSB-A only; peak at *m*/*z* 1847, retained by MSB-B only; peak at *m*/*z* 2210, retained by MSB-C only; peaks at *m*/*z* 1630, and 2578, retained by MSB-A and MSB-B but not MSB-C; peak at *m*/*z* 1137, retained by MSB-B and MSB-C but not MSB-A; finally, peaks at *m*/*z* 1349, 1502, and 2310, retained by all three MSB examined. The selected peaks are marked with an asterisk in the mass spectra shown in Figure 3 panels a, b, and c. The amino acid sequences of each of the selected peptide are shown in Table 4, together with the corresponding mass errors and signal-to-noise ratios. Interestingly, peaks extracted selectively by a single MSB corresponded to specific peptides of unique sequence (Table 4), strongly suggesting that sample processing with MSB is compatible with peptidomic analysis. Moreover, even when the same peptide is extracted from plasma by more that one MSB, there is often a significant difference in the signal-to-noise ratio. For instance, the peptide at *m*/*z* 2578, retained by both MSB-A and MSB-B, is characterized by a signal-to-noise ratio of 63.05 in the mass spectrum of the MSB-A eluate and of 257.95 in the mass spectrum of MSB-B eluate, further suggesting that each MSB determines a significant increase in specific peptide components (Table 4).

Considering the stringent conditions used for peak detection, a signal-to-noise ratio of greater than 10, the MALDI spectra generated from plasma and urine, after MSB processing, resulted in a remarkable improvement in peak detection compared to that in the SELDI spectra reported in the literature (*23, 33*−*35*). In contrast to the SELDI chip arrays, MSB, with their greater surface area, can provide higher binding capacity, and moreover, the possibility of thoroughly washing the beads allows the effective removal of salts and other contaminants, which could negatively affect MALDI spectra quality. This particular limitation of SELDI, which resides in the small surface area of its flat chips directly used as MALDI targets, is also reported elsewhere (*36*). In a recent study, Tempst and co-workers specifically report that the use of porous particles for sample pretreatment is more sensitive than surface capture on chips because particles have a larger combined surface area than small-diameter spots (*14*).

Before peptidome analysis based on mass spectrometric screening can proceed from the bench to the bedside, a large number of important obstacles need to be overcome, among which are the valid and reproducible analyses of peptide patterns (*37, 38*). For this reason, we have investigated the reproducibility of the peptidome profiling of human plasma and urine by derivatized MSB in combination with MALDI-TOF MS. Plasma and urine samples were run in triplicate with all of the sample preparation methods, then the spectra obtained were used for data analysis. Triplicate MALDI spectral readouts of plasma and urine samples processed by the derivatized MSB are shown in Supporting Information (Figures S7 and S8).

The reproducibility of the mass spectra was evaluated with respect to the relative peak intensities and mass accuracy; variability was measured by coefficient of variance (CV). Tables 5 and 6 list CVs of the *m*/*z* values and the intensities of peaks randomly selected over a wide mass range for plasma and urine, respectively. In the plasma experiments, average CVs of 0.014%, 0.018%, and 0.0041% of the mean *m*/*z* values were obtained for MSB-C, MSB-D, and MSB-E, respectively. The average CV of the mean intensity values was 14.36% for MSB-C and 7.94% both for MSB-D and MSB-E (Table 5), ensuring good reproducibility for MALDI MS-based profiling studies. In the urine experiments, the average % CV corresponding to the mean *m*/*z* values was 0.027% for MSB-C, 0.0091% for MSB-D, and 0.017% for MSB-E. The mean CVs of the signal intensities for

3.7	1297.33	0.014	0.07	6.0	2097.11	0.017	0.04

[a] The *m/z* values are the means from three independent experiments.

10 urinary signals were 17.17% (ranging from 4% to 33%) for MSB-C, 9.63% (ranging from 0 to 17%) for MSB-D, and 12.51% (ranging from 0 to 28%) for MSB-E (Table 6).

In order to provide more information about the robustness, reproducibility, and linearity of the methodology, we added internal standards to urine before processing with MSB-C with a series of dilutions of angiotensin I (*m/z* 1297.51) and adrenocorticotropic hormone ACTH (clip 1−17) (*m/z* 2094.46). The analysis of 3 replicates of urine aliquots spiked with these two standard peptides at decreasing concentrations showed that there was a linear correlation between peak area and peptide concentration ($R^2 > 0.98$) in the range of 1 to 2000 ng/mL (Figure 5). We were able to detect these standard peptides in human urine with concentrations as low as 3.7 ng/mL for angiotensin I and 6.0 ng/mL for the fragment 1−17 of ACTH (Figure 5). Therefore, also for human urine, we confirmed the low-nanogram per milliliter sensitivity of the methodology, previously demonstrated for human plasma (*21*).

The precision and the accuracy of the MSB-MALDI-TOF MS methodology was evaluated as percentage error on the theoretical mass values, resulting for the tested standards with vaues <0.032% and 0.02% for *m/z* 1297.51 and 2094.46, respectively (Table 7).

Overall, these data with CVs obtained for both plasma and urine indicate that protein profiling by MSB, in combination with MALDI-TOF MS, is reliable and robust, in other words, reproducible and that valid peptide patterns are obtained, which ensure that the variations in the spectra reflect biological differences in protein concentration rather than systematic variability.

CONCLUSIONS

In summary, we have tested MSB with different surfaces for plasma and urine mass spectrometric profiling. Different conditions for adsorption/binding and elution of plasma and urine peptides have been accurately evaluated for each functionality to determine the best performances in terms of peptide extraction and MALDI data generations. MSB-A and MSB-B previously tested for plasma samples (*21*) have now been tested for urine, demonstrating a high efficiency in peptide enrichment. Aminopropyl derivatized MSB-C produced the highest number of peaks for plasma samples, whereas for urine, the largest number of peaks were obtained with TED functionalized MSB-E.

Derivatization of mesoporous silica materials with the aminopropyl group increases specific plasma peptide subset recognition in comparison to that of nonfunctionalized mesoporous silica materials. At the same time, TED groups on the mesoporous silica surface significantly amplify peak detection for urine peptides. These results indicate that different mesoporous silica with unique surface characteristics produce different MALDI mass spectra for identical plasma or urine samples; hence, these MSB could be used to obtain complementary proteomic information using high sample throughput. Predictably, robotic sample preparation will improve reproducibility compared to that of manual procedures; thus, we have plans to develop an automated sample procedure, starting from the sample incubation with the beads to spotting on the MALDI probe.

Finally, functionalized MSB can be readily prepared by a simple and low-cost procedure; the method described is fast and easy to perform for processing body fluids prior to MS analysis, thus minimizing the possible degradation of biological samples. We strongly believe that this platform is suitable for preliminary biomarker discovery studies.

ACKNOWLEDGMENT

We thank Dr. Christopher I. Fincham and Professor Susan Gerbi for critical reading of the manuscript and Dr. Marco Carbone for technical support. We are also indebted to Dr. Matthias Glükmann and Dr. Dietrich Merkel from Applied Biosystems (Darmstadt) for the skilled support in MS/MS sequencing. This work was supported in part by an AIRC 2005 grant, by a Ministero della Salute, Dipartimento dell' Innovazione (Direzione Generale della Ricerca Scientifica e Tecnologica) 2006 grant, and by a PRIN 2006 grant "Innovative approaches for the development of nanostructured devices for the analysis of plasma/tissue proteome in breast cancer" from the MIUR of Italy to R.T.

Protein pharmacokinetic modulation is becoming an important tool in the development of biotherapeutics. Proteins can be chemically or recombinantly modified to alter their half-lives and bioavailability to suit particular applications as well as improve side effect profiles. The most successful and clinically used approach to date is chemical conjugation with poly(ethylene glycol) polymers (PEGylation). Here, therapeutic protein half-life can be increased significantly while retaining biological function, reducing immunogenicity and cross-reaction. Naturally occurring alternatives to such synthetic polymers could have major advantages such as lower side effects due to biodegradability and metabolism. Polysialic acid (PSA) has been investigated as a pharmacokinetic modulatory biopolymer with many successful examples in preclinical and clinical development. Single-chain Fvs (scFvs) are a choice antibody format for human therapeutic antibody discovery. Because of their small size, they are rapidly eliminated from the circulation and often are rebuilt into larger proteins for drug development and a longer half-life. Here we show that chemical polysialylation can increase the half-life of an antiplacental alkaline (PLAP) and anticarcinoembryonic antigen (CEA) scFv (F1 and MFE-23, respectively) 3.4−4.9-fold, resulting in a 10.6−15.2-fold increase in blood exposure. Amine-directed coupling of the MFE-23 scFv reduced its immunoreactivity 20-fold which was resolved by site-specific polysialylation through an engineered C-terminal thiol residue. The site-specifically polysialylated MFE-23 scFv demonstrated up to 30-fold improved tumor uptake while displaying favorable tumor:normal tissue specificity. This suggests that engineering antibody fragments for site-specific polysialylation could be a useful approach to increase the half-life for a variety of therapeutic applications.

INTRODUCTION

Protein drugs are often compromised by limitations arising from their complex molecular structure. Factors such as proteolytic degradation, uptake by cells of the reticuloendothelial system, renal removal, and immunocomplex formation all lead to rapid elimination from the blood before effective concentrations are reached (*1*). This results in an undesirably short therapeutic window. The over-riding factors which contribute to these pharmacokinetic limitations are size, stability, and immunogenicity (*2*).

Polymer conjugation using poly(ethylene glycol) (PEGylation) has been one of the most successful approaches to improving protein pharmacokinetics (*3*). PEG is a neutral polymer that can bind water molecules, forming a 'watery cloud' around the protein (*4*). This gives the conjugate a larger hydrodynamic volume compared to its true molecular weight, affecting its pharmacokinetics and pharmacodynamics in the body (*4*). In addition to its size, the protein surface is modified and biological epitopes are shielded from potential immune responses or degradation. A number of PEGylated proteins have been approved for clinical use, e.g., PEGasys (PEG-interferon) for the treatment of chronic hepatitis C infections (*5*), and Cimzia (certolizumab pegol), a PEGylated anti-TNFα Fab for Crohn's disease (*6*). However, since PEG is a synthetic polymer, there are concerns about its metabolism and immunogenicity. Uptake by cells of the reticuloendothelial system has been reported, and PEG can accumulate in lysosomes, leading to toxicity (*7*). Repeated administration of PEG conjugates resulted in the production of anti-PEG antibodies (*8*). More recently it was shown that PEG-infusion-related side effects include unwanted complement activation (*9*). Taken together, the uncertainty in the metabolism and immune responses has led to the search for natural alternatives.

Molecules which are inconspicuous to the innate and adaptive immune systems are more likely to survive for prolonged periods in the circulation. Polysialic acid (PSA: polymers of *N*-acetylneuraminic (sialic) acid) (*10*) is one such molecule and offers a natural alternative to PEG. PSA is a human polymer found almost exclusively on NCAM (neural cell adhesion molecule) where it plays an antiadhesive function in brain development (*11*). The highly hydrophilic nature of PSA results in similar hydration properties to PEG, giving it a high apparent molecular weight in the blood. This increases circulation time since no receptors with PSA specificity have yet been identified (*12*).

PSA is also synthesized by bacteria such as *Neisseria meningitidis* and some *Escherichia coli* where it is synthesized as a capsule (*10*). Bacterial PSA is chemically and immunologically similar to human PSA and is naturally degraded by sialidases (e.g., neuraminidase); unlike PEG, it is metabolized as a natural sugar molecule by tissue sialidases (*13*). Pioneered by Gregoiadis et al. (*14*, *15*), PSA has been developed for

clinical use. Reductive amination of the nonreducing end of the oxidized PSA allows chemical conjugation via primary amine groups on proteins, and the therapeutic benefits of PSA conjugation have been demonstrated with aspariginase (*16*) and insulin (*14*) for the treatment of leukemia and diabetes, respectively. Recent clinical data from trials with polysialylated insulin (SuliXen) and erythropoietin (ErepoXen) showed that these biopharmaceuticals were well tolerated and had improved pharmacokinetics [http://www.lipoxen.com/news.aspx]. More recently, we have shown that Fab fragments can be chemically polysialylated with a range of different lengths and ratios of linear PSA chains (*17*). Polysialylation of an antitumor Fab resulted in a 5-fold increase in blood exposure (bioavailability) with a corresponding 3-fold increase in tumor uptake compared to the unmodified Fab (*17*).

The use of recombinant antibody fragments has been increasingly investigated for therapeutic applications, as they are versatile and offer many advantages over current therapies using whole immunoglobulins (*18*). Because of their smaller size and lower molecular complexity, antibody fragments such as single-chain Fvs (scFvs) can be easily selected from combinatorial libraries and more readily expressed in a bacterial expression system, leading to rapid and inexpensive production (*19*). For therapy in vivo, the smaller size allows for faster tissue penetration; however, the targeted absolute uptake of such species may be limited by the subsequent faster clearance rate through glomerular filtration (*20*). We hypothesized that chemical polysialylation of a scFv would result in more favorable pharmacokinetic properties. The approach of modulating antibody pharmacokinetics by chemical polysialylation has not been applied to these molecules. Normally, antibody fragments are rebuilt into whole human immunoglobulins or constructed into fusion proteins which generally increases antibody size and hence decreases blood clearance (*20*). However, polysialylation may have advantages in terms of time and complexity as well as the advantages over chemical PEGylation already described.

The scFv used in our studies was MFE-23, a well characterized anti-CEA (carcinoembryonic antigen) scFv with a K_d of approximately 2 nM (*21, 22*). MFE-23 has been previously investigated in clinical trials for imaging (*23, 24*) and therapeutic use (*25, 26*). We compared the effectiveness of random, amine-directed chemical conjugation of PSA (*14, 17*) with site-specific, thiol-directed chemical conjugation. The latter method presents a number of advantages in the control of polymer attachment because it is distant from the antigen binding regions and limited only to hydrophilic and therefore normally surface-exposed thiol sites which generally are not involved with protein conformation and bioactivity.

Our results show that both amine-directed and site-specific polysialylation resulted in scFv-immunoconjugates with extended pharmacokinetic parameters, improved tumor uptake, and improved kidney to blood ratios. However, the amine-directed conjugation method resulted in reduced immunoreactivity. This problem was overcome by site-specific polysialylation on an engineered C-terminal thiol peptide.

EXPERIMENTAL PROCEDURES

Materials. Polysialic acid of 11 kDa was from Sigma. CEA antigen was supplied by Calbiochem; CEA-positive LS174T cell-line supplied by the EACC and grown in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal calf serum and 50 IU/mL of penicillin and streptomycin (Invitrogen). Unless stated, immunochemicals were from Sigma. Mouse anti-PSA-NCAM monoclonal IgM was from Chemicon. Carrier-free ^{125}I-NaCl was supplied by Amersham Pharmacia Biotech. Bacterial cultures were grown with 2TY media supplemented with 0.1 mg/mL ampicillin (Sigma) for selection purposes.

Cloning of MFE-23-cys scFv Construct. The pUC119 expression plasmid containing the scFv MFE-23 gene was used as a template to produce the mutant MFE-23-cys construct (*21*). Oligonucleotides incorporating restriction sites for recombinant subcloning, as well as mutations to include a C-terminal thiol group, were used to flank the scFv gene and allow PCR amplification of the mutant scFv MFE-23-cys. The forward primer was LMB3; 5′-CAGGAAACAGCTATGAC-3′, while the reverse primer cysMFE; 5′-GGCAGCAACGCCAAGT-GCGGCCG**CACAACCTCCGCCACC**CTGTTTC. AGCTC-CAGCTTGGTGCC-3′ contained a realigned *Nco* I site (underlined) and $(Gly)_4$Cys peptide (bold). The PCR product was subcloned into the pHEN2 vector as an *Nco* I/*Not* I fragment and DNA sequence verified.

Production and Purification of F1, MFE-23, and MFE-23-cys scFvs. F1 was used as a non-CEA binding negative control scFv. F1 binds to human placental alkaline phosphatase (PLAP) and was selected from a phage display library [Wright, Ph.D. thesis, University of London, 2003]. Protein expression of F1, MFE-23, and MFE-cys scFvs was initiated by growing single colonies of newly transformed *E.coli* HB2151 bacteria in 2TY media with 0.1 mg/mL ampicillin overnight shaking at 250 rpm and 37 °C. When a culture OD_{600nm} of 0.6−0.8 was reached, IPTG was added to a final concentration of 0.1 mM. The induced culture was then left to grow overnight at 30 °C and 250 rpm during which time protein expression occurred. Induced cultures were centrifuged at 10 000 rpm, and the supernatant from which protein was to be purified was supplemented with benzamidine (final concentration 2 mM) and kept on ice where possible to minimize protein degradation. The supernatant was concentrated 10-fold by ultrafiltration and dialyzed into phosphate-buffered saline (PBS). The scFv protein was purified by immobilized metal affinity chromatography using TALON according to the manufacturer's instructions. Pure protein was eluted with 200 mM imidazole and stored at 4 °C. ScFv proteins were further purified using a HiLoad 10/30 Superdex-75 HR gel filtration column equilibrated with PBS and compared to previously run protein standards. Samples were further analyzed for the presence of protein by Coomassie staining and Western blotting. The presence of a functional thiol in the MFE-23-cys scFv was confirmed by coupling a fluorescein maleimide (Pierce Chemicals) reporter group, electrophoresing by SDS-PAGE, and visualizing the protein band by fluorescence imaging compared to nonthiol containing MFE-23 scFv (data not shown) or by binding to CEA-positive LS174T cells and analyzing by flow cytometry (data not shown).

Chemical Polysialylation. The PSA used in this work was colominic acid (linear α-(2−8) linked *N*-acetylneuraminic acid) purified from the capsular coating of *E. coli* K1, supplied as a 11 kDa polymer (average molecular weight), which is equivalent to ∼35 units of sialic acid. The average molecular weight (nominal mass) of these polymers was determined by gas-phase chromatography by Viscotek Europe Ltd. (*14*). For the purpose of F1 and MFE scFvs-PSA conjugation by reductive amination, PSA (colominic acid) was oxidized with 0.1 M periodate as described (*14, 17*). The oxidized material was dialyzed extensively against a 0.01% ammonium carbonate buffer (pH 7.4) at 4 °C, concentrated by reverse dialysis on a bed of polyethylene glycol (8 kDa), lyophilized, and stored at −80 °C until required. Oxidized PSA was added to 5 mL of protein (0.2 mg/mL) to give a 2-fold molar excess in a glass tube. The sample was mixed gently and supplemented with 20 mg of $NaCNBH_4$. The tube was sealed and rotated at 37 °C for 48 h to allow the conjugation reaction to occur. For thiol conjugation, scFv samples were dialyzed extensively against 50 mM Tris-HCl buffer pH 7.0 concentrated to 0.5 mg/mL and made up to a final volume of 950 μL. Protein was reduced by addition of 50

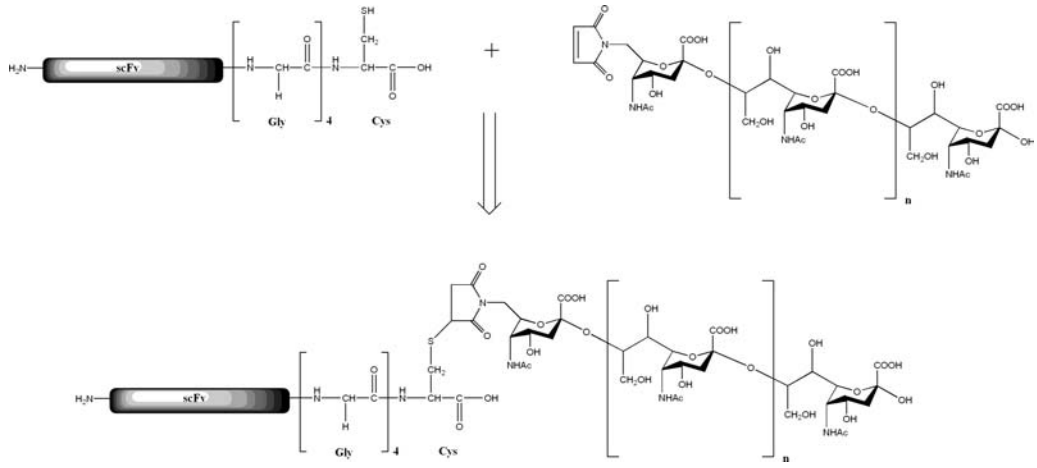

Figure 1. Schematic diagram of coupling. Showing the structure of the PSA maleimide and the scFv with a glycine-cysteine C-terminal peptide. The resulting chemical conjugate is shown.

μL of TCEP-HCl to give a final concentration of 2.5 mM and incubated for 90 min at room temperature. Reactive maleimide-PSA (made by the addition of 5-fold molar excess of N-[β-maleimidopropionic acid] hydrazide (Pierce) to colominic acid aldehyde dissolved in 0.1 M sodium acetate, vortex mixed, wrapped in foil and incubated at 37 °C for 2 h on a rotary mixer followed by ethanol precipitation) was added to the reduced protein sample to give a 25 molar excess of PSA/protein, mixed gently, and incubated at room temperature for 2 h. In both methods, the conjugated material was purified from free PSA by addition of $(NH_4)_2SO_4$ to give a 70% saturated solution. The sample was rotated for 5 min at room temperature followed by 30 min on ice. The mixture was then centrifuged at 5000 rpm for 5 min, and the resulting pellet resuspended in 1 mL of 100% saturated $(NH_4)_2SO_4$. The precipitation procedure was then repeated and the pellet dissolved in minimal PBS followed by extensive dialysis. Finally, the conjugated sample was analyzed by SDS-PAGE and characterized for polysialylation efficiency by resorcinol assay. A scheme of the coupling is shown in Figure 1.

Determination of PSA:Fab Ratios. The resorcinol assay was based on the method by Svennerholm (*27*) and allowed the amount of colominic acid present in a sample relative to known standards to be measured. The resorcinol agent (0.25 mM cupric sulfate, 0.2% resorcinol, 80% concentrated HCl made up with distilled water) was freshly prepared, and at least five colominic acid standards were prepared within the 40−400 μg/mL range were made. In triplicate, 100 μL of standard and test samples was added to 100 μL of resorcinol agent. The tubes were sealed, and the mixture was heated for 30 min at 95 °C. Once the tubes had cooled, 400 μL of ethanol was mixed in. Finally, the absorbance at 560 nm was measured for 250 μL of each sample and standards in a microplate assay. The standard values were used to construct a calibration curve from which the colominic acid content of the test samples could be determined. A molar value was determined according to the mean PSA length used in test samples, and similarly a protein concentration was determined for samples using the Coomassie Plus protein assay kit compared to protein standards. With these values, a PSA to protein molar ratio was calculated.

Western Blot Analyses. Protein gels for Western analysis were transferred to a nitrocellulose membrane, blocked in PBS/5% Marvel milk protein, and then incubated with either anti-His_6 specific (Qiagen) or anti-PSA specific (Chemicon) antibodies followed by antimouse HRPO conjugates (Sigma). The blot was developed using enhanced chemiluminescence and exposed to high performance autoradiography film.

Gel Filtration of Proteins and Conjugates. Gel filtration was carried out using a Superdex-200 column equilibrated with PBS run at 1.5 mL/min at 4 °C on a Biologic DuoFlow system. Native molecular weight standards were used to calibrate the column. Eluted protein were monitored at absorbencies of 280 nm (protein) and 214 nm (peptide bonds).

Protein Radioiodination. Protein samples were radioiodinated using Pierce iodination tubes. To precoated tubes, 100 μL of the Tris iodination buffer was added followed by 10 μL (1.0 mCi) $Na^{125}I$. The activated iodide was then removed and added directly to the protein solution (1 mL of 0.2−0.5 mg/mL) for iodination. The reaction was allowed to take place for 8 min. To end the reaction, 50 μL of scavenging buffer (10 mg/mL tyrosine in PBS) was added and mixed. After 5 min incubation, the iodinated sample was dialyzed against PBS.

Bioactivity by ELISA Analysis. Flat-bottom 96-well ELISA plates coated with CEA antigen at 2 μg/mL in PBS were used. After three washes with PBS/0.1% Tween-20 and three PBS washes, the plate was then blocked with 5% PBS/Marvel for 1 h at 37 °C and washed again. Binding activity of the anti-CEA scFvs and conjugates were established by serially diluting samples across test wells in 1% Marvel/PBS for 1 h at 37 °C. Following a repeat of the wash steps, detection of bound scFv was made by incubating with 'one-step' HRP conjugated anti-His antibody for 1 h at 37 °C. For the purpose of PSA detection, the plate was incubated first with primary anti-PSA IgM followed by secondary anti-IgM HRP for 1 h at 37 °C. In both cases, incubation with detection antibodies was terminated by washing the plates as described above and binding detected using BM Blue POD substrate. The development was stopped with 1 M H_2SO_4 and the absorbance measured at 450 nm. Sigmoidal curves were fitted to ELISA data to determine K_d values using SigmaPlot using the one-site saturation ligand-binding equation.

Pharmacokinetic and Biodistribution Studies. Female nude BALB/c mice, 6−8 weeks old (Harlan UK), were used for in vivo studies. All in vivo research was carried out under a UK Home Office project license PPL 70/5833. Human tumor xenografts were set up by injecting mice subcutaneously into the left flank with 0.1 mL containing up to 10 million LS174T cells. Tumour growth was monitored and took 3−4 weeks to reach the required 5−8 mm diameter for subsequent work. For tissue analyses, up to 100 μL radiolabeled samples (5−10 μg) were injected intravenously into the mouse tail vein. At the appropriate time points (typically 0.5, 2, 6, 24, and 48 h) mice were culled by exsanguination under terminal anesthesia. Immediately, blood was collected by cardiac puncture and

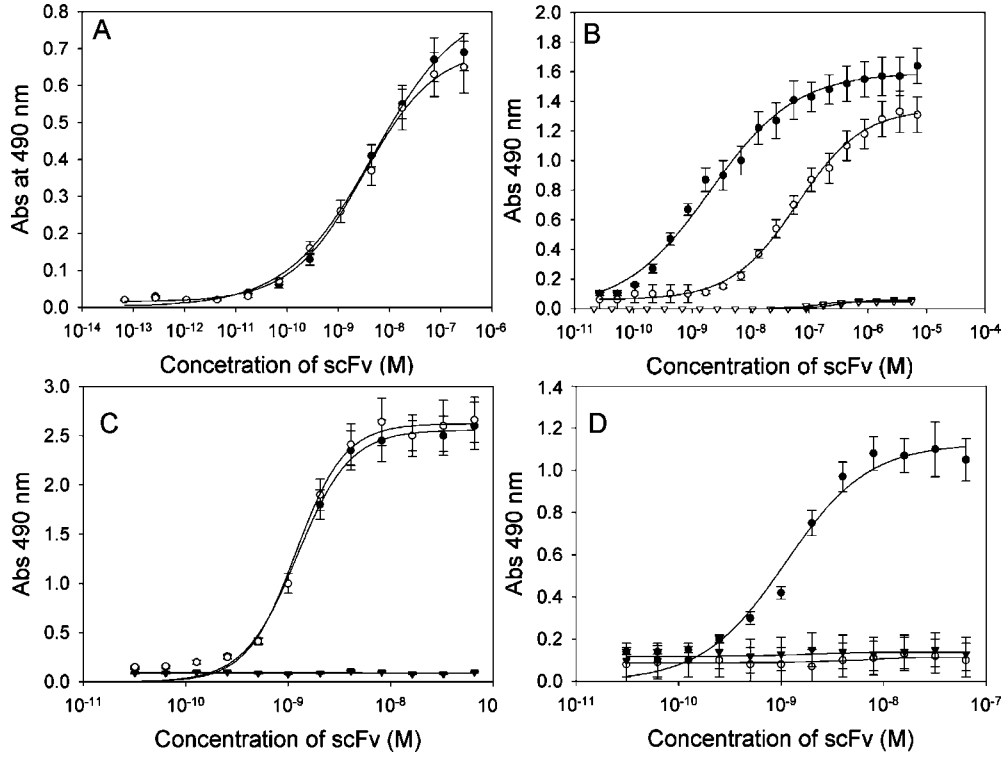

Figure 2. ELISAs of scFvs and scFv−PSA conjugates on immobilized CEA. (A) MFE-23 (○) and MFE-23-cys scFv (●) binding curves showing near identical affinities of 2.4 nM and 2.5 nM, respectively. (B) MFE-23 scFv binding curve before (●) and after (○) amine-directed coupling with PSA. F1 scFv binding curve before (▼) and after (▽) amine-directed PSA coupling. (C) MFE-23-cys (○) retains binding affinity after thiol-directed PSA coupling (●) detected with anti-His_6 antibody, whereas free PSA alone is not immunoreactive (▼). (D) The same experiment as (C), detected with an anti-PSA antibody, confirms binding and also polysialylation.

transferred to a sample tube. The mouse was then dissected, and tissues were collected for biodistribution analysis. Radioactivity was counted using a gamma counter. Values were expressed as a percentage of the initial injected dose per gram of tissue (% id/g). For studying in vivo blood clearance pharmacokinetics, data values were fitted using SigmaPlot to equations that conform to the two-compartmental intravenous model of clearance, which takes into account the biexponential clearance phases, distribution phase and elimination phase, of single intravenous doses. This is described by the exponential decay, double, four-parameter equation $y = ae^{-bx} + ce^{-dx}$, where the distribution phase clearance rate ($t_{1/2\alpha}$) can be determined by ln 2/*b*, and the elimination clearance rate ($t_{1/2\beta}$) can be determined by ln 2/*d*. The area under the curve values for blood clearance were determined using the macros available within SigmaPlot to represent protein blood bioavailability.

RESULTS

Purification and Characterization of scFv MFE-23-cys. The MFE-23-cys scFv constructed and expressed in *E. coli* showed a 5-fold lower level (∼1 mg/L) of protein expression than the parental scFv, probably because of the formation of incorrectly folded intermediates and mixed disulfides due to the unpaired cysteine as seen previously (*28*). As expected, the amount of monomeric MFE-cys scFv was even lower due to the presence of disulfide-linked scFv dimers and, additionally, noncovalent dimers (*29*) which were resolved by size-exclusion chromatography (see Supporting Information Figure S1). This led to a final yield of MFE-cys scFv monomer of around 0.5 mg/L of bacterial culture. The binding activity of the MFE-23-cys scFv relative to that of the unmodified scFv was determined by ELISA (Figure 2a). Similar K_d values were determined for the MFE-23-cys and MFE-23 scFvs of 2.5 and 2.4 nM, respectively (derived by fitting a curve using SigmaPlot) which implied that the additional thiol peptide in the MFE-23-cys scFv did not alter its antigen binding affinity. Fluorescein coupling confirmed the functionality and 1:1 stoichiometry of the C-terminal thiol and also demonstrated the ability for thiol conjugates to bind to live cells by FACS (data not shown).

Table 1. Mean PSA Coupling Ratio of the Three scFvs Used in This Study

ScFv species	mean PSA:scFv molar ratio
F1	1.5
MFE-23 (amine)	1.4
MFE-23-cys	1.1

Chemical Polysialylation of scFvs. F1 and MFE-23 were initially polysialylated by amine coupling at low (1:1 to 1:2) molar ratios. Resorcinol tests showed that the substitution ratios were approximately 1:1.5 (Table 1). However, the amine-coupled polysialylated MFE-23 scFv showed a 20-fold reduced immunoreactivity compared to the unmodified scFv (Figure 2b). This suggested that the process modified one or more key lysine residues in the MFE-23 scFv. Thiol coupling using the maleimide-activated PSA yielded a ratio of ∼1:1 with fully immunoreactive scFv (Figure 2c). Reducing/SDS-PAGE gel analysis compared amine- and thiol-coupled scFvs (Figures 3 and 4). Both the amine-coupled MFE-23 and F1 scFvs displayed a broad polydispersed migration pattern, characteristic for a protein conjugate of hetergenous mass composition (Figure 3). The thiol-coupled MFE-23-cys conjugate produced a less polydispersed immunoconjugate compared to the amine-coupled antibodies, suggesting a more defined molecular species. Both conjugates eluted from a gel filtration column in the excluded/void volume, indicating a larger apparent size (>300 kDa rather than the theoretical size of 41 kDa) or hydrodynamic radius. Proteins of molecular weight greater than 300 kDa are not resolved, and therefore it was not possible to determine the true apparent sizes of the scFv−PSA conjugates (see Supporting

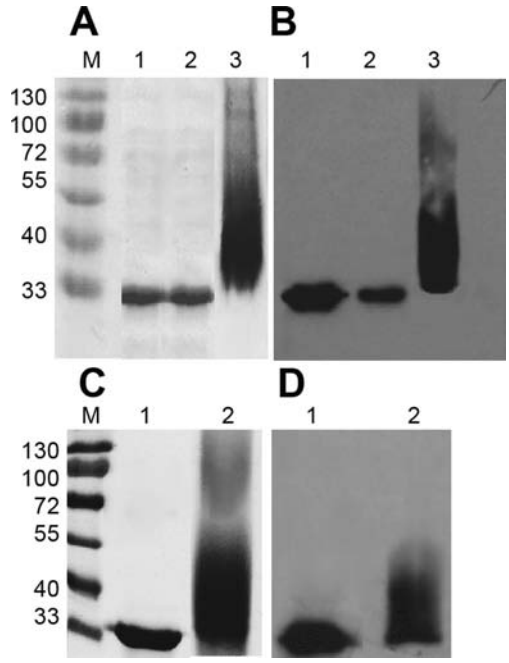

Figure 3. SDS-PAGE and blotting of amine-conjugated scFv. (A) Coomassie-stained gel of protein markers (M), MFE-23 scFv (1), MFE-23 scFv process control (2), and polysialylated MFE-23 scFv (3). (B) as in A, detected with anti-His_6 in a Western blot. (C) Coomassie-stained gel of protein markers (M), F1 scFv (1), and F1-PSA (2). (D) as in B, detected with anti-His_6 in a Western blot.

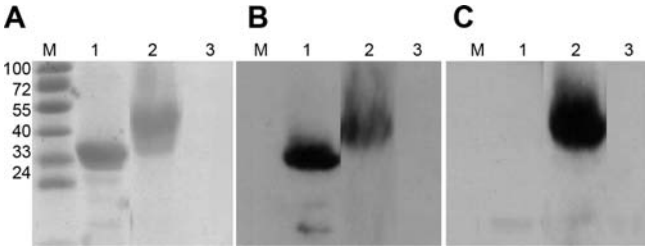

Figure 4. SDS-PAGE and blotting of thiol-conjugated scFv. (A) Coomassie-stained gel of protein markers (M), MFE-23 scFv (1), and polysialylated MFE-23-cys scFv (2), free PSA (3). (B) as in A, detected with anti-His_6 in a Western blot. (C) as in A, detected with anti-PSA in a Western blot.

Information Figure S1). Coomassie stained SDS-PAGE gels and Westerns blots of samples analyzed under reducing conditions showed that the amine-directed conjugates, despite being coupled at low molar ratios to obtain as close to 1:1 coupling as possible, had higher ratios and were much more dispersed in terms of molecular weight. The longer smear suggests high multiples of PSA conjugates even though the mean ratio was 1.4−1.5:1. This was in contrast to the 1.1:1 ratio seen with the site-specific coupled scFv and more importantly, the lower level of heterogeneity.

The presence of the PSA chain was confirmed by immunodetection of the PSA chain by ELISA (Figure 2d) or Western blotting (Figure 4c) as well as the resorcinol assay (Table 1). In each case, the PSA chain alone was undetectable by ELISA or Western blot unless conjugated to a protein.

MFE-23 scFv affinity was consistently in line with published values (around 2 nM) whether unmodified or thiol-coupled to PSA, detected using anti-HIS_6 or anti-PSA antibodies.

Anti-PSA detection by ELISA and Western blot confirmed that the scFvs had been chemically conjugated with the PSA polymer. Free PSA was unable to interact with the ELISA plates and migrated too rapidly on the SDS-PAGE gel (because of its high negative charge) for either to be detected by antibodies. This confirms that the PSA association was covalent and insignificant amounts of free PSA were present in the preparations.

Biodistribution and Pharmacokinetic Studies of MFE-cysPSA11 scFv in a Tumor-Bearing Murine Model. In vivo experiments showed that polysialylation conjugation of scFv led successfully to an increased blood half-life in all cases. We first assessed the effects of polysialylation on the F1 scFv which had no specificity for CEA-expressing LS174T human xenografts (Figure 5a). The blood half-life (beta elimination phase, $t_{1/2}\beta$) for F1-PSA increased almost 3.5-fold (Figure 5a and 5b, Figure 6, Table 2) from 5.6 h to 19.3 h with a 10-fold increase in blood exposure (bioavailability area under the blood clearance curve, Figure 6a, Table 2). Not unexpectedly, polysialylation conjugation also resulted in higher concentrations of scFv in normal tissues. However, this was observed in all tissues, and there was no specific effect on tumor uptake (Figure 5b). We next assessed the effect of polysialylation on biodistribution of MFE-23 (Figure 5c and 5d, Figure 6, Table 2). A greater increase in $t_{1/2}\beta$ was seen for the amine-coupled MFE-23 scFv (a 4.8-fold increase to 20.9 h) and bioavailability (15.2-fold increase). However, compared to the unmodified MFE-23 scFv which localized well and specifically (Figure 5c), the MFE-23-Lys-PSA conjugate was less effective in specifically targeting to the LS174T tumors (Figure 5d, Figure 6b). Consistent with previously published work, the MFE-23 scFv accumulates in this tumor model with a tumor:blood ratio of around 14:1 by 24 h, but the amine-coupled immunoconjugate had a ratio of 1.4 at this point. There was, however, some specificity for MFE-23-Lys-PSA for tumors compared to organs such as kidney, liver, spleen, and muscle.

The reduced immunoreactivity upon amine coupling was likely to account for these observations, and this was confirmed by analyzing the uptake and biodistribution of the fully active MFE-23 cys-PSA immunoconjugate (Figure 5e, Figure 6, Table 2). Once again, polysialylation led to an increased blood half-life but lower than that of the multiply substituted amine conjugates. The $t_{1/2}\beta$ increased 3.6-fold to 15.6 h and the bioavailability increased 9.8-fold Figure 6a. This increase led to increased tumor uptake compared to the faster-clearing unmodified MFE-23 scFv. Greater than 2-fold increase in tumor exposure was seen (Figures 5e and 6b) with the percentage uptake per gram of tumor increasing approximately 2-fold at 6 h (4% to 8.2%) and at 24 h (4.5% to 9.6%). There was 30-fold more scFv in the tumor by 48 h (0.1% to 3.3%). The higher tumor uptake caused by increased blood half-life was at the expense of lower tumor:tissue ratios (Figure 6c). However, there was still significant selectivity, with tumor:blood ratios of 4.4:1 at 24 h and 10.3:1 at 48 h. Throughout, it was observed that all tissue;blood ratios of polysialylated antibodies <1 indicating that polysialylation did not impart nonspecific binding.

DISCUSSION

We have employed chemical conjugation of PSA to scFv antibodies in order to extend their biological half-life. We have tested the immunoreactivity of the conjugates and investigated their biodisribution and ability to localize specifically to human tumors in murine models. All the scFvs showed an increase in apparent molecular weight as a result of conjugation. Although there was some heterogeneity of the immunoconjugates due to the polydisperse nature of naturally occurring PSA, this was consistent with previous observations (*14, 16, 17*).

Many researchers have previously used surface-exposed (*30, 31*) or engineered (*32, 33*) thiol groups for nondisruptive chemical conjugations. The use of mammalian systems often circumvents expression and yield problems (*32*). Furthermore, the incorporation of thiol sites for specific PSA conjugation

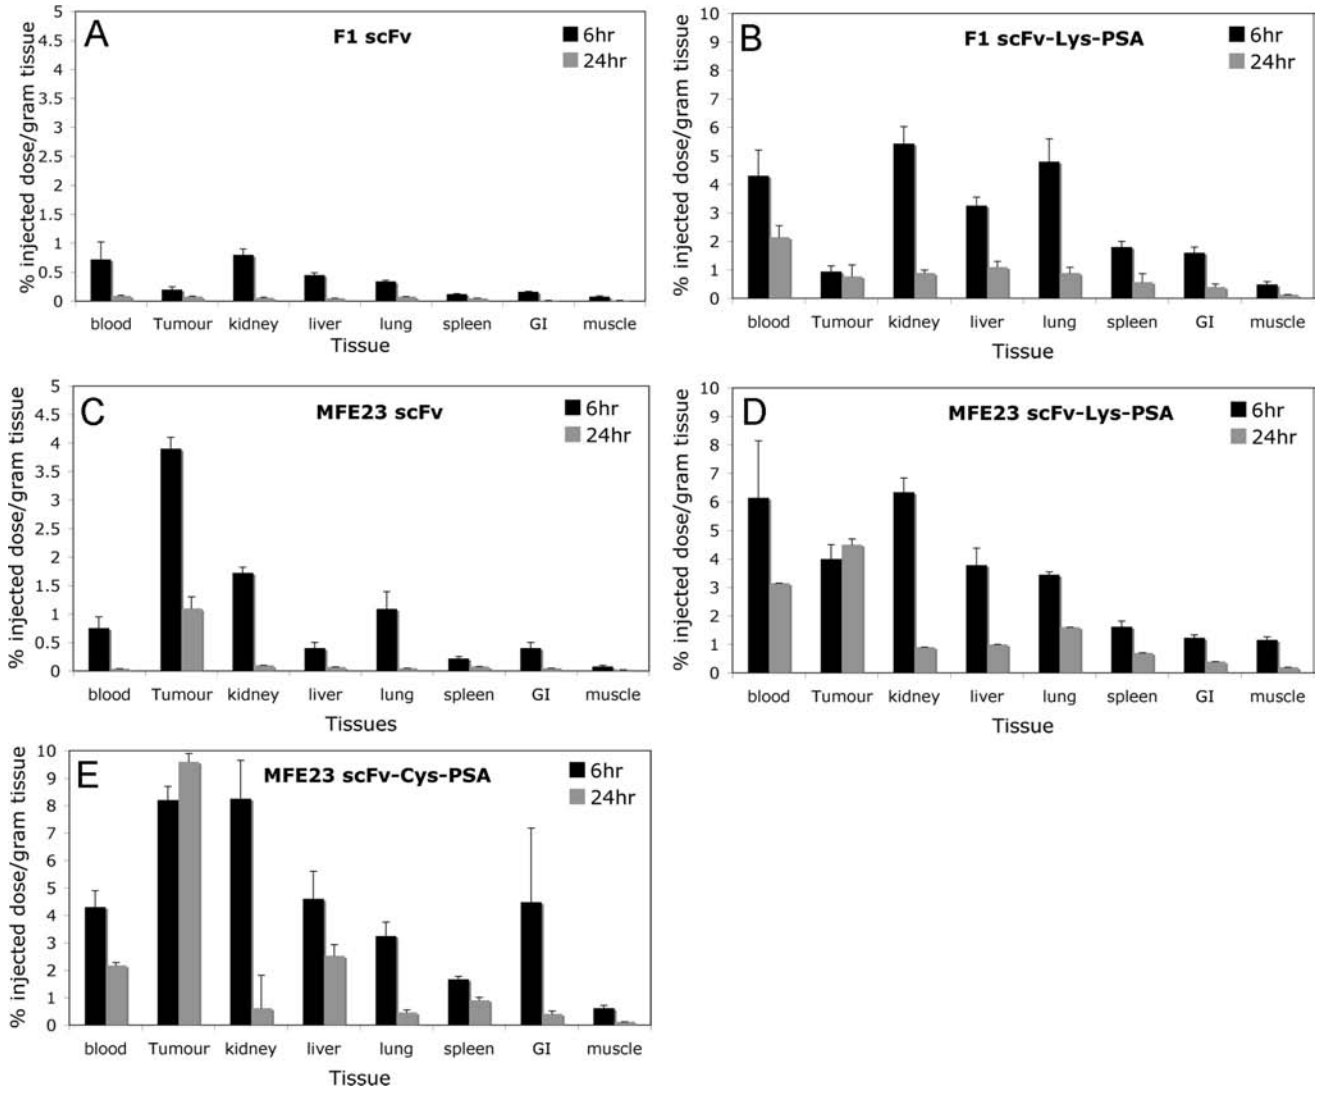

Figure 5. Biodistribution of scFvs and immunoconjugates in LS174T tumor model at 6 and 24 h time points. Percentage injected dose of radiolabeled protein per gram of tissue was determined for F1 scFv (A), amine-coupled F1 scFv-PSA (B), MFE-23 scFv (C), amine-coupled MFE-23 scFv-PSA (D), and thiol-coupled MFE-23-cys-PSA (E).

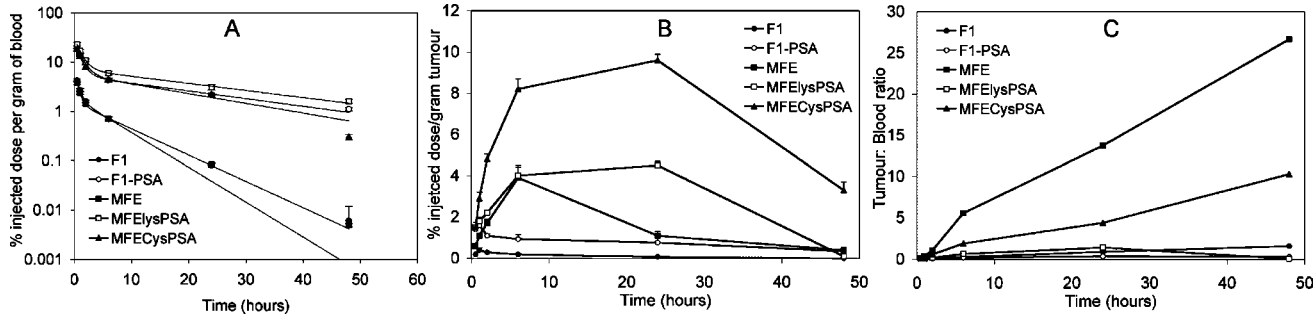

Figure 6. Pharmacokinetic profiles derived from full biodistribution study in LS174T tumor model over 48 h. (A) Blood clearance profile, (B) tumor uptake profile, and (C) tumor to blood ratio profile of F1 scFv (●), amine-coupled F1 scFv-PSA (○), MFE-23 scFv (■), amine-coupled MFE-23 scFv-PSA (□), and thiol-coupled MFE-23-cys-PSA (▲).

should result in a more reproducible, homogeneous product that can be more definitively characterized as has been shown for scFv−PEG immunoconjugates (*33*). This is of particular importance for any subsequent biopharmaceutical interest which requires definitive characterization to be determined for the purpose of therapeutic applications. By applying this methodology for PSA conjugation, it is believed that the longevity of antibodies in circulation can be improved without compromising its bioactivity or structural integrity.

Our immunoreactivity experiments with the PSA conjugations revealed that the thiol-specific conjugation method was superior to amine conjugation. The retention of protein bioactivity observed after thiol-specific PSA conjugation of the scFv MFE-23 has mirrored the success of other groups that have used thiols for chemical attachments. PEGylation of proteins, which represents the biggest contribution of polymer conjugates to the biopharmaceutical industry, has recently shown various successes in thiol-specific conjugation such as in the C-terminal

Table 2. Summary of Pharmacokinetic Parameters[a]

ScFv species	t1/2α (h)	t1/2β (h)	Area under blood clearance curve (bioavailability or blood exposure)
F1	0.43 ± 0.04	5.6 ± 0.12	13.03
F1-PSA	0.88 ± 0.19	19.3 ± 0.91	137.7
MFE-23	0.42 ± 0.01	4.3 ± 0.5	12.3
MFE-23-Lys-PSA	0.78 ± 0.03	20.9 ± 1.5	186.6
MFE-23-Cys-PSA	0.7 ± 0.07	15.6 ± 3.7	120.6

[a] The biodistribution experimental data are shown in Figures 4 and 5. The blood clearance profile was fitted to a biexponential decay model and $t_{1/2}\alpha$ and $t_{1/2}\beta$ determined. The bioavailability or blood exposure was determined by calculating the area under the blood clearance curve.

PEGylation of the thrombin cofactor thrombomodulin (*34*), modulating longevity of hemoglobin using different lengths of PEG (*35*), and PEGylation of an scFv (*33*), a *Pseudomonas*-derived immunotoxin (*36*) and a clinically approved antibody (*6*) have all been described using thiol-specific conjugation. However, increasing protein longevity through site-specific thiol PEGylation was demonstrated as early as 1990 with a 4-fold increased systemic exposure using conjugated interleulin-2 (*31*). The thioether linkage is well-characterized and used in many examples such as in the production of immunotoxins, suggesting that such bonds are stable and can lead to increased longevity in vivo (*37*).

Our study was concerned with investigating an alternative method to pharmacokinetic engineering as well as to illustrate the benefits of site-specific polysialylation over the more unpredictable amine coupling method. Reductive amine coupling was previously shown to work well for an antiplacental alkaline phosphatase (PLAP) Fab fragment with little loss in bioactivity; however, the similar approach used for the MFE-23 scFv led to a 20-fold reduction in affinity. By introducing a C-terminal cysteine residue on to the recombinantly expressed scFv it was anticipated that the free thiol group could be used to introduce a PSA chain through the formation of a thioether link, which would result in a more homogeneous coupled product that retained full bioactivity. The loss of reactivity could be explained by the chemical modification of the CDR-H1 loop in the scFv (*22*). A similar situation arose in the anti-HER2 scFv, C6.5 which had a undesirably situated lysine residue in the CDR-H3, which was not required for binding. This was subsequently replaced by mutagenesis to an alanine resulting in chemical conjugates which retained immunoreactivity (*38*).

The main reason for chemically modifying scFvs with PSA is to modulate their half-lives so that they clear more slowly, accumulate to higher levels in the target tissues (tumors in this case), but still retain some high degree of selectivity (e.g., high tumor:blood ratios). Whole immunoglobulins characteristically clear slowly with half-lives in the region of 3−5 days, resulting in tumor:blood ratios >1 after about 48 h (*20, 39*). Single-chain Fvs clear in a few hours but have tumor:blood ratios of >20:1 at this time. This research has shown that site-specific polysialylation can impart a blood clearance half-life (in murine models) slower than scFvs (4−5 h) or Fab (around 10 h), better blood bioavailability (2−3 fold better than some Fabs and only 2−3 lower than some whole IgGs), and specificity ratios much more favorable than whole immunoglobulins. Polysialylated scFvs, easily and inexpensively prepared, could represent a viable alternative to whole IgG without the concerns associated with the Fc-domain (*39, 40*). In vivo analyses confirmed the pharmacokinetic benefit of chemical polysialylation, but unlike the nonspecific approach shown to be successful with the H17E2 Fab (*17*), site-specific coupling was required to maintain scFv function. In all three examples shown here, polysialylation resulted in around 3- to 5-fold increase in blood clearance and around 10-fold increase in bioavailability. There was a less than 2-fold increase in the alpha-phase (distribution) blood clearance, suggesting that the main pharmacokinetic enhancement was in the systemic elimination phase. The pharmacokinetic extension observed here is likely due to the increase in apparent size, stabilizing the protein and excluding it from renal clearance. This is consistent with the increased size observed by size-exclusion chromatography (>300 kDa), due to the hydrophilic polymer binding noncovalently to a network of water molecules as has been proposed for PEG conjugates (*40*).

There have been many approaches to pharmacokinetic engineering (*20, 41*), with PEGylation being the most commonly used. The greatest potential for the present approach is in the modification of antibody fragments against blood-borne factors such as tissue necrosis factor (TNFα), interleukin-6 (IL-6), or vascular endothelial cell growth factor (VEGF). Longer bioavailability will lead to more pronounced inhibition, leading to an improved therapeutic potential. Although often problematic during expression in *E. coli*, but less so in mammalian systems, multiply appended C-terminal thiols will allow the coupling of defined numbers of PSA chains which could lead to pharmacokinetic refinement for a particular therapeutic purpose.

In conclusion, this work has shown that random amine-directed coupling of PSA to scFvs is successful but not optimal. Favorable conjugation is achieved by site-specific coupling of PSA to engineered C-terminal thiols. The latter approach leads to antibody fragments with full immunoreactivity and increased blood half-life leading to higher tumor uptake but with improved specificity ratios compared to other antibody formats.

ACKNOWLEDGMENT

This work was funded by a Lipoxen Technologies-BBSRC/CASE studentship to MPD and AC (ref. no. 01/A2/C/07249). We would like to thank Dr. Peter Laing and Prof. Gregory Gregoriadis for useful discussions and members of the Imperial College CBS Unit for advice and technical help with the in vivo experiments.

Supporting Information Available: The gel filtration chromatograms of the MFE scFv, MFE-Cys scFv, and MFE-Cys−PSA conjugate are shown in Figure S1. This material is available free of charge via the Internet at http://pubs.acs.org.

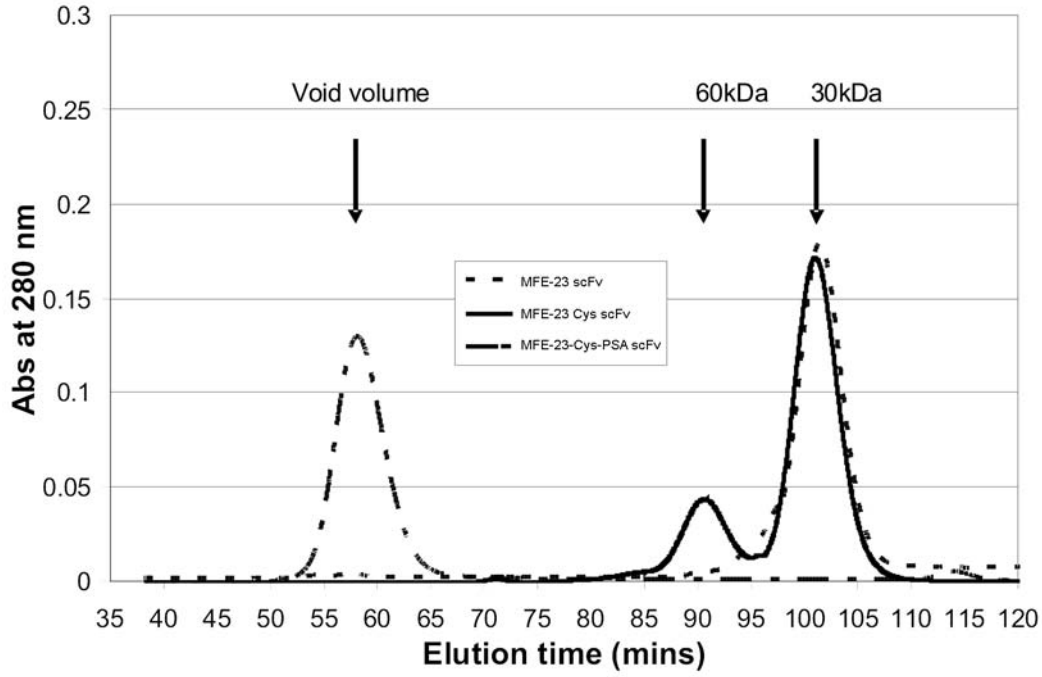
SUPPORTING FIGURE S1



GEL FILTRATION PROFILES OF SCFVS AND SCFV-CYS-PSA CONJUGATE

Gel filtration on a Superdex-200 column shows that the scFvs migrate with native molecular weights as expected (scFv, dashed line, 30kDa; scFv-Cys, 60kDa, bold line). The size of the scFv-Cys-PSA conjugate (scFv-Cys-PSA, >300kDa, broken dashed line) was unable to be determined accurately.

Studies of Poly(ethylene glycol) Modification of HM-3 Polypeptides

Kang Zhou,† Xiaoqing Zheng,† Han-Mei Xu,* Jie Zhang, Yaqing Chen, Tao Xi, and Tingting Feng

Department of Life Science and Technology, China Pharmaceutical University, Nanjing, 210009, P. R. China. Received December 4, 2008; Revised Manuscript Received April 7, 2009

An RGD modified endostatin-derived synthetic peptide, named HM-3, is a polypeptide angiogenesis inhibitor previously synthesized in our laboratory. Its robust inhibitory effects on endothelial cell migration and tumor growth have been demonstrated by in vivo and in vitro activity assays. The RGD integrin recognition sequence enables the selective binding of HM-3 and its specific targeting to tumor cells that express high levels of integrin. However, the drug has relatively short half-life in vivo, thus requiring administration twice a day to achieve its optimal in vivo antitumor efficacy. In the current study designed to prolong HM-3 half-life, we used methoxy-poly(ethylene glycol)-aldehyde (mPEG-ALD) to specifically modify its N terminus and optimized the reaction condition via monitoring the modification by reverse-phase high-performance liquid chromatograph (RP-HPLC) under varying stoichiometric ratios ($n_{\text{mPEG10k-ALD}}$:$n_{\text{HM-3}}$), reaction times, and pH values. The maximal modification rate was achieved in a reaction when substrates mPEG10k-ALD and HM-3 were mixed at the molar ratio of 2:1 in a pH 6 phosphate buffer after 4 h incubation at room temperature. The reaction product of this optimal reaction was purified to 96% purity by RP-HPLC. Compared with HM-3, the newly modified PEG_{10k}-HM-3 was shown to be more active in the inhibition of angiogenesis in the chorioallantoic membrane of chick embryos (CAM), its rate of in vitro degradation in serum was markedly reduced, and its in vivo half-life was prolonged by 5.86-fold relative to unmodified HM-3 after intravenous injection into male SD rats.

INTRODUCTION

Endostatin, the C-terminal fragment of collagen XVIII, with a molecular weight of 20-kDa, can specifically inhibits endothelial cell proliferation and migration, and reduces vascularization and blood flow in gliosarcoma (*1*). It also dramatically inhibits growth of the various primary tumors in mice. Interaction of endostatin with integrin implicates its potential targets for function (*2, 3*). Endostatin binds one atom of zinc (Zn) per monomer via the three histidines in the NH_2 terminus of the molecule (histidines 1, 3, and 11) and aspartic acid 76 (*4*−*6*).

Numerous attempts have been made to produce biologically active endostatin via recombinant DNA technology (*7*). However, when expressed in *E. coli*, recombinant endostatin accumulated as inclusion bodies in the cytoplasm. During in vitro renaturation or the refolding process, the recovery of soluble and active endostatin was very low and most of the protein precipitated again during the refolding process owing to the renaturation of proteins containing multiple disulfide bonds (*8*−*10*). A highly efficient production of biologically active endostatin, with large quantity and low cost, urgently needs both further structure−function relationship investigation and its potential application as antitumor remedy. To achieve this goal, several groups have synthesized and studied the peptides that correspond to the partial sequence of endostatin (*11*−*16*).

Two groups have reported the activity of a peptide containing an 11 amino acid peptide (ES-2, IVRRADRAAVP) derived from the amino terminus of endostatin (*11, 12*). In our previous study, we found that the 11 amino acid peptide dramatically inhibited angiogenesis on the chorioallantoic membrane of chick embryo (CAM) in vivo but had no antitumor effect in tumor-bearing mice. We speculate that this difference might be caused by lesser distribution of the drug to tumor tissue in mouse models than that in chick embryos. In order to validate this hypothesis, a new strategy that increases the target delivery of the peptide to tumor is needed. In the past decade, many molecules with RGD peptide have been described as efficiently delivering drugs to tumor vasculature endothelium (*17, 18*). Therefore, in our previous study, we get a RGD-modified endostatin-derived synthetic peptide HM-3 (IRRADRAAVPG-GGGRGD); it displayed higher antitumor effects (*19*). Safety experiments were conducted to study the possible toxic effects of HM-3; there no evidence of toxicity in the treated animals. These results show that HM-3 is an effective and safe peptide as an anticancer drug.

However, in the in vivo pharmacokinetic studies, the half-life of HM-3 in male SD rats was measured at 27.66 ± 7.37 min. This indicates that, in any future clinical applications, higher doses or more frequent administration is required to maintain sufficient drug concentration in the blood, which in turn will exacerbate toxic effects on the patients.

Protein modification is an effective method to improve efficacy and prolong drug half-lives. PEG modification of drugs can enhance protein solubility and stability, slow down drug metabilization within the body, reduce or eliminate immunogenicity, increase circulation time in the bloodstream, and lengthen administration intervals (*20, 21*). Lee et al. (*16*) and Na et al. (*23, 24*) have successfully modified polypeptide drugs using PEG, prolonged in vivo clearance half-lives of glucagon-like peptide-1 and salmon calcitonin (sCT), and enhanced their pharmacokinetic properties and efficacy. This current study was aimed at identifying the appropriate PEG modifying reagents suitable for HM-3, to achieve the optimal combination of biological and pharmacokinetic properties following the specific

modification, ultimately to provide a promising lead for development of new antitumor drugs.

MATERIALS AND METHODS

1. Materials. HM-3 (99% purity) was chemically synthesized. mPEG$_{10k}$-ALD (80% purity) was purchased from Beijing Kaizheng Biotech Development Co. Ltd., batch number 080540. Trifluoroacetate (TFA), acetonitrile (ACN), and sodium cyanoborohydride were purchased from TEDIA, ROE Scientific Inc., and Shanghai Darui Fine Chemicals Co. Ltd., respectively.

White leghorn chicken embryos and male SD rats were purchased from Nanjing Medical Instrument Factory and New Drug Screening Center at China Pharmaceutical University, respectively.

2. Methods. *2.1. PEG Modification of HM-3 and Purification.* A series of reactions were set up using varying stoichiometric ratios ($n_{\text{mPEG10k-ALD}}$:$n_{\text{HM-3}}$)of mPEG$_{10k}$-ALD and HM-3 (1 mg, 1 mg/mL) in phosphate buffers (0.1 mol/mL) at pH 5, 6, and 7. The final concentration of sodium cyanoborohydride was 0.05 mol/mL.

Sample aliquots were taken after 2, 3, and 4 h; then, glycine was added to terminate the reactions. The reaction mixtures were first analyzed for the modification rate by RP-HPLC on a C18 column (150 × 4.6 mm, 5 μm, YMC). The mobile phases contained 0.1% TFA in ACN (solution B) and 0.1% TFA in water (solution A), and was applied as a gradient of 10−100% solution B (or 90−10% solution A). Detection wavelength was set at 220 nm. The flow rate was at 1 mL/min, and the running time was 15 min.

The reaction products were further purified by a semipreparative RP-HPLC with a C18 column. The mobile phases were 0.1% TFA in ACN (solution B) and 0.1% TFA in water (solution A), and was applied as a gradient of 35−50% solution B (or 65−50% solution A). The detection wavelength was set at 220 nm; the flow rate was at 3 mL/min, and the running time was 20 min.

2.2. Validation of Reaction Products. Modification products were analyzed by RP-HPLC and SDS-PAGE electrophoresis. For the SDS-PAGE identification, reaction mixtures were separated on a SDS-PAGE gel comprising 5% stacking gel and 16% separation gel. The gel was stained with Coomassie brilliant blue, and destained until the background was washed off. For the HPLC identification, the polypeptide substrate and the reaction products were analyzed by RP-HPLC as described above in section 2.1, and their HPLC chromatograms were compared.

2.3. In Vitro Stability of PEG$_{10k}$-HM-3 in Serum. In aliquots of 0.9 mL SD rat serum, 0.1 mL of HM-3 (6 mol/mL), PEG$_{10k}$-HM-3 (6 mol/mL), and saline buffer were added into separate tubes and incubated in a 37 °C water bath. At 0, 2, 6, 10, 15, 20, 25, 50, and 60 min of incubation, 0.1 mL aliquots were taken and precipitated with perchloric acid. After centrifugation to obtain the supernatants, RP-HPLC analysis was carried out to measure the drug concentration in the supernatants, and retention percentages were calculated.

2.4. In Vivo Pharmacokinetics of PEG$_{10k}$-HM-3. Male SD rats weighing roughly 200 g were used, and blood samples were taken the day before the experiment as control. PEG$_{10k}$-HM-3 (35 mg/kg) was injected via tail vein, and blood samples were collected through the canthus at different time points and stored at −70 °C before use. Blood samples were precipitated with perchloric acid and centrifuged. The supernatants were analyzed by RP-HPLC to measure the drug concentration. The pharmacokinetic parameters in SD rats were calculated using the *DAS* v1.0 (Drug and Statistics for Windows) software and then subjected to statistical analyses.

2.5. CAM Angiogenesis Assays. In 7 day chick embryos, after the air chamber was opened, the shell membrane was removed and sealed by a transparent tape to form a pseudoair chamber which also serves as transparent observation windows. After a 1 day stabilization period, the transparent tape was cut open, and a drug carrier plate with a 5 mm diameter was placed in the chamber. Ten microliters of each test reagent was added onto the plate. The physiological saline and endostatin (8 mg/mL) were used as negative and positive controls, respectively. In the experimental groups, HM-3 (1 mg/mL) and PEG$_{10k}$-HM-3 (6.6 mg/mL) were used (1 mg/mL HM-3 and 6.6 mg/mL PEG-HM-3 yield equal molar concentrations). After 48 h incubation at 37 °C, the pseudoair chambers of chick embryos were opened and fixed in the fixative (formaldehyde−acetone, 1:1) for 5 min. The chick embryo was subsequently removed, and the CAM was carefully peeled off from the eggshell and laid out flat for photography. The medium−small blood vessels within a radius of 5 mm from the center of the carrier plate were counted and subjected to statistical analysis.

3. RESULTS

3.1. PEG Modification of HM-3 and Purification of the Modification Product. A series of modification reactions were set up by mixing mPEG-ALD and HM-3 at different molar ratios under conditions with varying buffer pH and reaction time. The reaction mixtures were analyzed by RP-HPLC to assess effects on the reactions by different conditions. The results (Figure 1A) showed that there was only one single peak for the modification product, and the maximal modification rate of 88.7% was achieved when the substrate molar ratio ($n_{\text{mPEG10k-ALD}}$:$n_{\text{HM-3}}$) was set at 2, and the reactions were incubated for 4 h at RT in a pH 6 phosphate buffer. The reaction time and substrate molar ratio have the most profound effects on the modification rate.

Reaction products were purified through semipreparative RP-HPLC. Analyses showed that the purity of the products was greater than 96% (Figure 1B).

3.2. Product Validation. After HM-3 modification by mPEG-ALD, the product was shown as a single band by electrophoresis analysis (Figure 2), and RP-HPLC chromatograms (Figure 1) also revealed the presence of a single peak, confirming that only one modification product was generated from the modification reaction.

3.3. In Vitro Serum Stability of PEG$_{10k}$-HM-3. Multiple enzymes are present in the blood that can degrade polypeptides and proteins. After the drug was mixed with serum and incubated at 37 °C, RP-HPLC analysis was performed to measure drug retention percentage in the serum at different time points. The degradation rate of HM-3 in serum was very high, as HM-3 became undetectable after only 15 min incubation. By contrast, 48.8% of PEG$_{10k}$-HM-3 remained intact after 15 min (Figure 3), and 16.5% could still be detected after 60 min. These results demonstrate that, after modification, the polypeptide became less susceptible to the degradative enzymes in the serum, and its stability was markedly enhanced.

3.4. In Vivo Pharmacokinetic Behaviors of PEG$_{10k}$-HM-3. After intravenous injection into male SD rats, the drugs before and after modification were tested for a panel of pharmacokinetic parameters. The results (Table 1 and Figure 4) showed significantly improved in vivo pharmacokinetic behavior of the drug after PEG modification. The half-life of HM-3 in the blood of these rats was 27.66 ± 7.37 min. After the modification, the half-life of PEG$_{10k}$-HM-3 was 162.08 ± 36.57 min, which was 5.86-fold longer than that of the unmodified drug, and the clearance rate was measured at 566.34 ± 56.68 L/min/kg, 141.59-fold slower relative to the unmodified HM-3. The area under the curve (AUC) was increased by 123.47-fold to reach

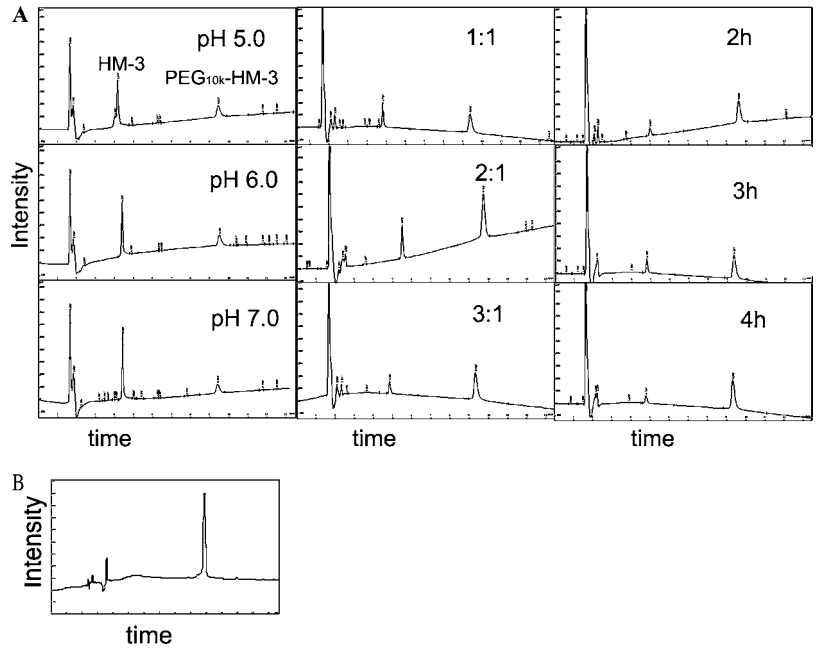

Figure 1. RP-HPLC analysis of reaction mixtures obtained by reaction of mPEG-ALD with HM-3 at different pHs, molar ratios ($n_{mPEG\text{-}ALD}$:$n_{HM\text{-}3}$), and reaction times as indicated. Analysis was performed on a C18 column with water/acetonitrile/TFA as eluent and a flow rate of 1 mL/min, and peaks were monitored at 220 nm (A). RP-HPLC analysis of the PEGylated HM-3 Purification (B).

61 623.73 ± 4564.47 ng/L min. Finally, the average residence time of the modified PEG_{10k}-HM-3 was 69.39 ± 6.21 min.

3.5. Inhibitory Effects on Angiogenesis in the CAM Model. 48 h after drug administration into the chick embryos, medium and small blood vessels were counted within the 5 mm radius from the center of the drug carrier plate. The results demonstrated significant inhibitory effects of PEG_{10k}-HM-3 on angiogenesis. Compared with the negative control, both vessel number and branching were significantly reduced after treatment

Table 1. Pharmacokinetic Parameters after PEGylated HM-3 Administration to SD Rats[a]

	$T_{1/2}$ (min)	Cl (L/min/kg)	MRT (min)	AUC (ug/L min)
PEG_{10k}-HM-3	162.08 ± 36.57	566.34 ± 56.68	69.39 ± 6.21	61.62 ± 4.56
HM-3	27.66 ± 7.37	4.00 ± 0.80		0.49 ± 0.13

with either PEG_{10k}-HM-3 or HM-3 (Figures 5 and 6). The blood vessels were as follows: endostatin 30 ± 5.0, HM-3 34.7 ± 7.3, and PEG10K-HM-3, 25.7 ± 5.6.

Moreover, PEG_{10k}-HM-3-treated CAMs showed much lower density of medium−small blood vessels and fewer to almost

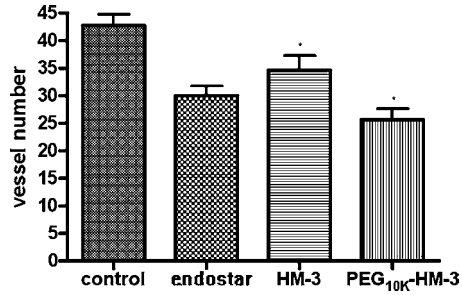

Figure 6. Blood vessels of chick chorioallantonic membrane treated with endostain (8 mg/mL), HM-3 (1 mg/mL), and PEG_{10k}-HM-3 (6.6 mg/mL) for 48 h. Values are represented as mean ± SD ($n = 8$). *$p < 0.05$ vs control group, $p < 0.05$ (HM-3 group vs PEG10k-HM-3 group).

no small vessels adjacent to the drug carrier plate compared with the control samples (Figure 6). The diameter of blood vessels in PEG_{10k}-HM-3-treated sample also seemed smaller. Together, these results indicate a more potent antiangiogenesis activity after HM-3 was modified.

4. DISCUSSION

HM-3 is an 18-amino-acid polypeptide synthesized in our laboratory. Previous studies found that it has robust antitumor activities, especially against liver and stomach tumors. HM-3 exhibits no overt toxic side effects and therefore may have great potential in cancer therapy. However, most protein and peptides have short half-lives in vivo, and the plasma half-life of HM-3 is only 10−27 min. In animal experiments, we had to administer the drug twice daily via tail intravenous injection to achieve significant antitumor activity. To improve HM-3 therapeutic potentials for future applications, this current study sought to increase its in vivo half-life using PEG modification.

Due to its nontoxic and nonimmunogenic properties, PEG has been widely used in drug modification to increase drug half-life without compromising activity. For polypeptides, many factors may affect modification reactions, including reaction time, temperature, substrate molar ratio, and so on. The current study reports a systematic optimization of these parameters.

mPEG-ALD is one group of modifying agents which can react with free amino groups, and the modifications typically occur at the N termini and lysine residues of proteins (*25*). The HM-3 polypeptide contains no lysine residue (*19*), therefore it could only be modified at its N terminus. The RP-HPLC chromatogram (Figure 1) showed only one peak for the modification product, and protein gel electrophoresis also confirmed the single identity. We have also tried to determine the precise molecular weight by MODI-TOF. However, this was not successful, possibly because the modification product was difficult to ionize.

A series of substrate molar ratios were tested. The maximal modification rate was obtained when the ratio of mPEG10k-ALD:HM-3 was 2 (Figure 1). The modification rate increased over time and reached the peak at 4 h. Different pH values were also tested and did not show significant effects on the reaction (Figure 1). Previously, Kinstler et al. documented an important characteristic of mPEG-ALD when they tried to modify G-CSF with PEG under acidic conditions (pH = 5); coupling of aldehyde and α-amino group was highly selective. This is because, under low pH, the N termini of proteins are susceptible to protonation (*25*−*27*), therefore conducive to site-specific modification. Given that HM-3 is a polypeptide with an isoelectric point greater than 11, optimal reaction conditions for mPEG-ALD should be a buffer system with a working range pH 6−9.5. For this reason, we selected pH 6 phosphate buffer as the final reaction system.

Previous in vivo studies have shown that HM-3 is mainly distributed in liver and kidney after administration (data not shown). Concerted action of various enzyme systems in the blood, liver, and kidney, as well as glomerular filtration, leads to in vivo fast degradation of HM-3 and short retention time in the body. However, after HM-3 was modified by PEG, its metabolic rate in the blood was reduced, and the half-life became longer. This could be due to several reasons. First, PEG may occupy the surface area of the drug, consequently blocking binding of degradative enzymes to the drug. Second, the size of the drug became larger after modification, which may reduce the loss due to glomerular filtration. As a result, the metabolic rate was decreased, and the circulation time in the body was increased. Our studies provide preliminary evidence for improved pharmacodynamic and pharmacokinetic behaviors of the drug. Future experiments are needed to validate these results.

After HM-3 modification and purification, the antiangiogenesis activity was shown to be significantly enhanced in the CAM experiment. CAM models are widely used models for angiogenesis study. In this isolated in vivo system, the drug can be directly delivered to the target site; since the chick embryos remain viable during the entire experiment, the drug metabolism is active. However, such metabolic activities are still largely different from the metabolic flux in live animals. Therefore, functional analysis of PEG_{10k}-HM-3 requires more detailed animal experiments under in vivo conditions. If PEG_{10k}-HM-3 can be administered only once a day and still achieve or exceed the antitumor activities we previously observed with HM-3 by twice-daily administration, our experimental approach would be considered a success. In addition, the immunogenicity of PEG_{10k}-HM-3 needs to be tested. Previously, we have attempted to generate mono- and polyclonal antibodies of HM-3 for radioimmunassays. The molecular weight of HM-3 is only 1788, which makes it difficult to generate antibodies. After it was coupled with a macromolecule (BSA), antibodies of high titer and specificity were obtained. It remains to be further investigated whether modification of HM-3 $mPEG_{10k}$-ALD might trigger immunogenic reaction in animals for antibody production. Furthermore, our previous experiments demonstrated that HM-3 had no overt toxic side effects on animals. Acute toxicity tests performed in mice showed that the maximum tolerable dose of HM-3 is 1926 mg/kg, more than 600-fold higher than its effective dose (3 mg/kg). Toxicological studies should also be carried out for $mPEG_{10k}$-ALD modified HM-3. Future therapeutic applications require that the modified product displays high antitumor activity while maintaining low immunogenicity and toxicity.

Received December 5, 2008; Revised Manuscript Received March 27, 2009

Determining arterial macrophage expression is an important goal in the molecular imaging of atherosclerosis. Here, we compare the efficacy of two synthetic, high density lipoprotein (HDL) based contrast agents for magnetic resonance imaging (MRI) of macrophage burden. Each form of HDL was labeled with gadolinium and rhodamine to allow MRI and fluorescence microscopy. Either the 37 or 18 amino acid peptide replaced the apolipoprotein A-I in these agents, which were termed 37pA-Gd or 18A-Gd. The diameters of 37pA-Gd and 18A-Gd are 7.6 and 8.0 nm, respectively, while the longitudinal relaxivities are 9.8 and 10.0 $(mM\ s)^{-1}$. 37pA has better lipid binding properties. In vitro tests with J774A.1 macrophages proved the particles possessed the functionality of HDL by eliciting cholesterol efflux and were taken up in a receptor-like fashion by the cells. Both agents produced enhancements in atherosclerotic plaques of apolipoprotein E knockout mice of ~90% ($n = 7$ per agent) and are macrophage specific as evidenced by confocal microscopy on aortic sections. The half-lives of 37pA-Gd and 18A-Gd are 2.6 and 2.1 h, respectively. Despite the more favorable lipid interactions of 37pA, both agents gave similar, excellent contrast for the detection of atherosclerotic macrophages using MRI.

Heart disease is now the primary cause of mortality in the world (*1*). The most common factor behind adverse cardiovascular events is rupture of vulnerable plaques caused by atherosclerosis (*2*). As such, there is a significant motivation to image atherosclerotic tissue for diagnosis, to characterize disease stage, and to monitor the effect of therapy (*3, 4*). One of the favored courses of action is to noninvasively image atherosclerotic plaques using magnetic resonance imaging (MRI) (*5, 6*), since this imaging modality has high spatial resolution and excellent soft tissue contrast and does not expose the patient to ionizing radiation. While MRI without contrast can determine plaque morphology and some features of plaque composition, targeted contrast agents are required to fully determine the cellular composition of the plaque.

Macrophages are key in the progression of atherosclerosis, entering the intima as monocytes and being activated to macrophages via interaction with and uptake of modified low density lipoprotein until they become foam cells and eventually forming the necrotic lipid core associated with unstable plaques (*7*). Furthermore, macrophage content has been identified as a key biological marker of vulnerable plaques. As a result, several methods have been proposed for molecular imaging of these cells in diseased arteries, for example, using targeted gadolinium-labeled micelles (*8, 9*) or dextran coated iron oxides (*10*) for MRI, iodine nanoparticles for computed tomography, (*11*) or ^{18}F-2-fluoro-2-deoxyglucose and ^{64}Cu labeled nanoparticles with positron emission tomography (*12, 13*).

We have previously reported the use of gadolinium (Gd^{3+}) and fluorophore modified high density lipoprotein (HDL), an endogenous nanoparticle naturally targeted to atherosclerotic plaques, to image macrophage burden in the abdominal aorta of a mouse model of atherosclerosis (*14, 15*). A restriction to the translation of this methodology to the clinic is the absence of a ready commercial source of apo A-I. Therefore, we recently reported preliminary data on a synthetic, MRI-active HDL formulation based on the amphiphatic peptide 37pA and gadolinium labeled phospholipids (*16*). 37pA, which mimics the properties of the major protein component of HDL, apoA-I (*18*), is composed of 37 amino acid residues and binds to lipidic particles strongly (*19*).

We report here the synthesis of an MRI-active HDL-based contrast agent formed using 18A, another apoA-I mimicking peptide composed of only 18 amino acid (*20*) residues, and an extensive comparison of this and the 37pA-based agent. The advantage of 18A over 37pA is that this shorter peptide is easier and less expensive to synthesize ($1584 for 18A vs $3541 for 37pA; both figures are for 100 mg, 95% purity, Global Peptide Services). The lipid binding properties of 18A, however, are inferior to those of 37pA, the peptides having an egg phosphatidylcholine exclusion pressure of 30 and 41 dyn/cm, respectively (*19*). The superior lipid binding properties of 37pA may result in a better MR enhancement of the arterial wall, since the gadolinium-labeled phospholipids in the HDL mimetic are held together more strongly and may be delivered to the atherosclerotic plaque with greater efficiency. Nevertheless, it is unclear if this would affect the efficacy of the agents for in vivo MR imaging studies. In this report we compare the 18A-based agent with the 37pA-based agent by investigating their physical properties, in vitro macrophage efflux, in vitro macrophage uptake, and MR imaging efficacy in apolipoprotein E knockout (apoE-KO) mice. In addition, the biodistribution and

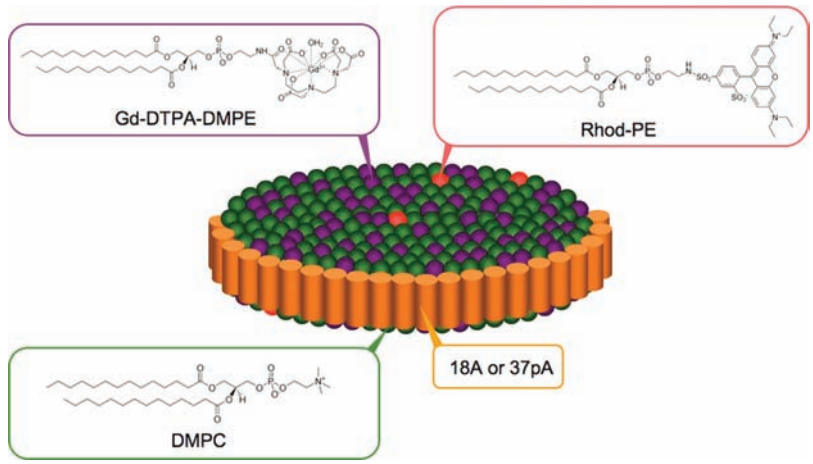

Figure 1. Schematic depiction of the agents used in this study. DMPC is dimyristoylphosphatidylcholine, Gd-DTPA-DMPE is gadolinium 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine diethylenetriamine pentaacetic acid, and Rhod-PE is 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl)ammonium salt.

pharmacokinetics of the agents were assessed. As will be shown, despite theoretical advantages of 37pA, comparable imaging efficacies were obtained with the 18A peptide.

EXPERIMENTAL PROCEDURES

Materials. Dimyristoylphosphatidylcholine (DMPC), gadolinium 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine diethylenetriamine pentaacetic acid (Gd-DTPA-DMPE), and 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl)ammonium salt (Rhod-PE) were all purchased from Avanti Polar Lipids and used as received. Cy5.5-labeled dimyristoylphosphoethanolamine (Cy5.5-PE) was synthesized as described below. The peptides 18A (sequence, DWL KAF YDK VAE KLK EAF) and 37pA (sequence, DWL KAF YDK VAE KLK EAF PDW LKA FYD KVA EKL KEA F) were synthesized by Global Peptide Services (Fort Collins, CO) at 95% purity. Cell culture supplies were purchased from Invitrogen (Carlsbad, CA).

Nanodisk Synthesis. To form synthetic, MRI-active HDL using 18A, a 200:200:1 mixture by mass of DMPC, Gd-DTPA-DMPE, and Rhod-PE (25 mg) was dissolved in a 1:4 mixture of methanol and chloroform. A lipid film was formed under vacuum from this solution, which was hydrated with a solution of 18A in 5 mL of 1× PBS such that there was 1 mg of peptide for each 2.5 mg of phospholipids used. The resulting mixture was heated at 65 °C for 45 min before being sonicated for 30 min on ice to form nanodisks, which were purified via centrifugation, filtration, and washing. This product was termed 18A-Gd and was characterized by dynamic light scattering (DLS), gel permeation, gel electrophoresis, relaxometry, gadolinium quantification, protein analysis, and phosphate quantification. Details of the characterization methodology may be found in ref 16. 37pA-Gd and Gd micelles (micelles forming using the same phospholipid mixture as for 18A-Gd and 37pA-Gd but without any peptide) were synthesized as previously described (*16*). A schematic depiction of 18A-Gd and 37pA-Gd is displayed in Figure 1. The disklike structure of such phospholipid−peptide aggregates has been established by ourselves (*16*) and others (*17*).

Cy5.5-PE Synthesis. For incorporation in the synthetic HDL nanoparticles, Cy5.5 monoreactive NHS esters were conjugated to dimyristoylphosphoethanolamine (DMPE). Typically, 50 μmol of DMPE and 50 μmol of stearoylhydroxyphosphatidylcholine (SHPC) was dissolved in 3 mL of a 4:1 chloroform/methanol solvent mixture. The solvents were removed from this solution to form a lipid film, which was subsequently hydrated for 30 min via agitation with 5 mL of a 0.1 M sodium bicarbonate aqueous solution (pH ∼8.4) at room temperature to form micelles. After this, 20 mg of Cy5.5 mono-NHS ester was dissolved in 250 μL of DMSO, which was added to the DMPE-SHPC micelle aqueous solution. The mixture was stirred overnight at 4 °C under nitrogen atmosphere to allow the conjugation of Cy5.5 to the lipids. A 50 kDa Vivaspin molecular weight cutoff tube was used to separate unconjugated Cy5.5 mono-NHS ester from Cy5.5 conjugated lipid micelles by washing 10 times with water until the residue was completely colorless. The Cy5.5 micelles were subsequently freeze-dried for 3 days to remove all water, after which they were dissolved in a 20:1 chloroform/methanol mixture.

Macrophage Uptake of Reconstituted HDL. J774A.1 murine macrophage cells were cultured in DMEM supplemented with 10% FBS and 1% streptomycin/penicillin. The cells were passaged 5 times before the incubations took place. The cells were grown to 70−80% confluency before being plated in black, nonfluorescent 96-well plates the day prior to incubation. For these studies agents labeled with Cy5.5-PE instead of Rhod-PE were used. 18A-Gd or 37pA-Gd was added to one row (12 wells) for each condition, with untreated cells and wells incubated with media only or Gd micelles as controls. The cells were incubated at a concentration of 0.02 mM Gd at time points from 1 to 24 h. Further experiments were carried out where the incubation time was held constant at 2 h and the concentration of the agent varied from 0.01 to 0.16 mM Gd. Incubations were performed where the agent uptake at 0.02 mM and 2 h was compared with macrophages also incubated with a 10-fold excess (by protein content) of non-Cy5.5 labeled 18A-Gd or 37pA-Gd. Last, the agent uptake of macrophages and smooth muscle cells (derived from Wistar rats as described below) was compared. After incubation, the medium was removed and the cells were washed with cold (4 °C) PBS three times and fixed with 4% paraformaldehyde. The cells were imaged in the plates using an IVIS imaging system 200 (Xenogen, Alameda, CA). The plates were illuminated for 5 s using a 150 W quartz halogen lamp filtered by the 615−665 nm Cy5.5 excitation band, while the emission was quantitatively recorded using the 695−770 nm Cy5.5 emission filter. Images were analyzed, and the fluorescence from each well was determined using the software supplied with the IVIS system.

Smooth Muscle Cell Isolation and Culture. Rat airway smooth muscle (ASM) cells were isolated from 10-week-old male Wistar rats. Rats were intraperitoneally injected with pentobarbital sodium (35 mg/kg), and the tracheas were asepti-

cally excised and placed in Ca^{2+}, Mg^{2+}-free Hanks balanced salt solution (HBSS) (Sigma). The isolated tracheas were cleaned of connective tissues, cut longitudinally through the cartilage, and enzymatically dissociated with filtered HBSS containing 0.2% collagenase type 2 (Worthington Biochemical Corporation, Lakewood, NJ) for 30 min in a shaking water bath at 37 °C. Dissociated cells in suspension were centrifuged and resuspended in Dulbecco's modified Eagle's medium (DMEM)−Ham's F12 medium (1:1 v/v) (Sigma) supplemented with 10% FCS (GIBCO) and 100 U/mL penicillin and 100 μg/mL streptomyocin (GIBCO). Cells were plated on Petri dishes and grown until confluence at 37 °C in humidified air containing 5% CO_2. The medium was changed every 48 h, and confluent cells were passaged with 0.25−0.02% EDTA solution (GIBCO). ASM cells in culture were elongated and spindle shaped, grew with typical hill and valley appearance, and stained positively for the smooth muscle specific protein α-Actin. Cells were used at the second passage.

Animal Model of Atherosclerosis. Both apoE-KO and wild type mice were used in this study. The apoE-KO mice were an average of 10 months old and fed a high cholesterol diet to induce plaque development for an average of 8 months prior to use in these experiments. The wild type mice were fed an ordinary chow diet and were the same average age. All mice were male and were housed and maintained at the Mount Sinai Animal Facility. The Mount Sinai School of Medicine Institute of Animal Care and Use Committee approved all experiments.

In Vivo MR Imaging. In vivo MRI was performed using a 9.4 T, 89 mm bore MRI system (Bruker Instruments, Billerica, MA). The imaging system and methodology are extensively described in ref 8. After a preinjection baseline MRI scan, mice were injected via a tail-vein catheter. Subsequent scans were carried out at 24, 48, 72, and 96 h postinjection. $n = 7$ apoE-KO mice and $n = 2$ wild type mice were injected with 18A-Gd, and the same group sizes were used as in the previous 37pA study. Use of the medical image analysis software package eFilm allowed the MR signal intensity of various tissues from the different time points to be ascertained and the percent change in normalized enhancement ratio (% NER) postinjection to be calculated. Normalization of the MR signal intensity in the aorta wall was performed by rebasing with the signal from the adjacent muscle to create the value *W*. The % NER was found from the difference between *W* from the postinjection scans and *W* from the prescan divided by *W* from the prescan and multiplied by 100, as per the method described in ref 8.

Confocal Microscopy. ApoE-KO mice were sacrificed 24 h after injection with contrast agent. The mice were perfused with saline at physiological pressure and their aortas removed. Then 3 mm pieces of the aorta were embedded in Tissue-Tek optimal cutting temperature media (Sakura Finetek, Torrance, CA), frozen, sectioned, and fixed in paraformaldehyde. These sections of aorta were stained with Alexa 647-CD68, a macrophage specific antibody conjugated to a fluorophore before the section was fixed in a DAPI (nuclei specific) containing agent and coverslipped. Confocal laser scanning microscopy on aortic sections was performed using a Zeiss LSM 510 META microscope (Carl Zeiss, Oberkochen, Germany) in an inverted configuration. Colocalization of rhodamine (contrast agent) and CD68 staining (macrophages) in the confocal microscopy images was quantified using an in-house developed image analysis software tool based in MatLab R2007b (Natick, MA).

Pharmacokinetics and Biodistribution. To determine the pharmacokinetics of 37pA-Gd, 18A-Gd, and Gd micelles, a 50 μmol/kg dose of the agent was injected into apoE-KO mice whose hair on their lower limbs had been removed to allow access to the saphenous veins. Blood (10−20 μL) was drawn from these veins at 5 min, 30 min, 1 h, 2 h, 3 h, 4 h, 24 h, and 48 h after injection and placed into preweighed vials containing 80 μL of heparin. The vials were weighed again to determine the volume of blood drawn, the density of blood being taken to be 1.05 g/mL (*21*). The gadolinium content of the blood for each time point was determined by inductively coupled plasma mass spectrometry (ICP-MS) performed on the blood−heparin mixture and adjusting for the blood volume. Half-lives were calculated from analysis of the variance of blood gadolinium content over time with the MatLab software package using a biexponential model.

The biodistribution was determined for 37pA-Gd and 18A-Gd at 48 h after injection of the agents into apoE-KO mice at a 50 μmol/kg dose. The animals were sacrificed by perfusion with saline administered via the left ventricle of the heart. The liver, kidneys, heart, spleen, and lungs were removed, weighed, and homogenized before analysis via ICP-MS for determination of Gd content. The per unit weight gadolinium content thus found was multiplied by the organ wet weight and divided by the injected dose to give the biodistribution. Cantest Ltd. (Burnaby, Canada) performed all ICP-MS analyses.

Statistical Analysis. Data populations were compared using Student's *t* test (two-tailed, heteroscedastic). Populations were considered to be significantly different if $p < 0.01$.

RESULTS

Characterization. The average diameter of the 18A-Gd particles was found via DLS to be 8.0 ± 0.3 nm. By use of gel electrophoresis, the size was found to be approximately 7.6 nm. The corresponding values for the 37pA-Gd complex are very similar, being 7.6 nm by both techniques. FPLC gave only one peak in a narrow size distribution, indicating high product purity. The longitudinal relaxivity was found to be 10.0 ± 0.2 mM^{-1} s^{-1}, which is not significantly different from relaxivities reported for previous HDL-based contrast agents that used the same gadolinium chelating phospholipid (*14, 16*). The gadolinium, phosphorus, and protein analyses gave a relative mass ratio of Gd-DTPA-DMPE/DMPC/18A of 1.18:1.10:1, which deviates somewhat from the input values of 1.25:1.25:1 and indicates a less efficient particle formation than for the 37pA-Gd agent (whose values were 1.23:1.23:1). This may be due to the lower lipid binding parameters of 18A compared to the dual domain peptide 37pA (*19*).

Macrophage Cholesterol Efflux. HDL-based particles have therapeutic properties in terms of their anti-inflammatory action as well as their ability to retrieve cholesterol from atherosclerotic plaques and transport it to the liver for excretion (*7*). A common measure of this latter property is macrophage cholesterol efflux, i.e., the quantity of cholesterol removed from macrophages by an agent (*22*). We performed such experiments using 18A-Gd and 37pA-Gd, while native HDL (CSL Behring, Bern, Switzerland) was used as a comparison and bovine serum albumin (BSA) was used as a control (phospholipid-only species are well established to give substantially lower macrophage cholesterol efflux than synthetic HDL nanoparticles (*22*)). Each agent was used with the same concentration of peptide/protein. The efflux produced by HDL after 4 h was 8.15 ± 0.27% of the total, for 18A-Gd 12.82 ± 0.29%, for 37pA-Gd 9.89 ± 0.20%, and for BSA 1.61 ± 0.19%. Thus, HDL, 18A-Gd, and 37pA-Gd produce significantly more cholesterol efflux than the control, BSA. Both 18A-Gd and 37pA-Gd removed more cholesterol than the native HDL used, which is unsurprising as the HDL used in this study was more highly lipidated than the peptide-based nanoparticle and so can accept a lesser amount of cholesterol from the macrophages. That this 18A complex produces a greater level of efflux than the 37pA complex is consistent with the results of investigations carried out by Davidson et al. (*22*).

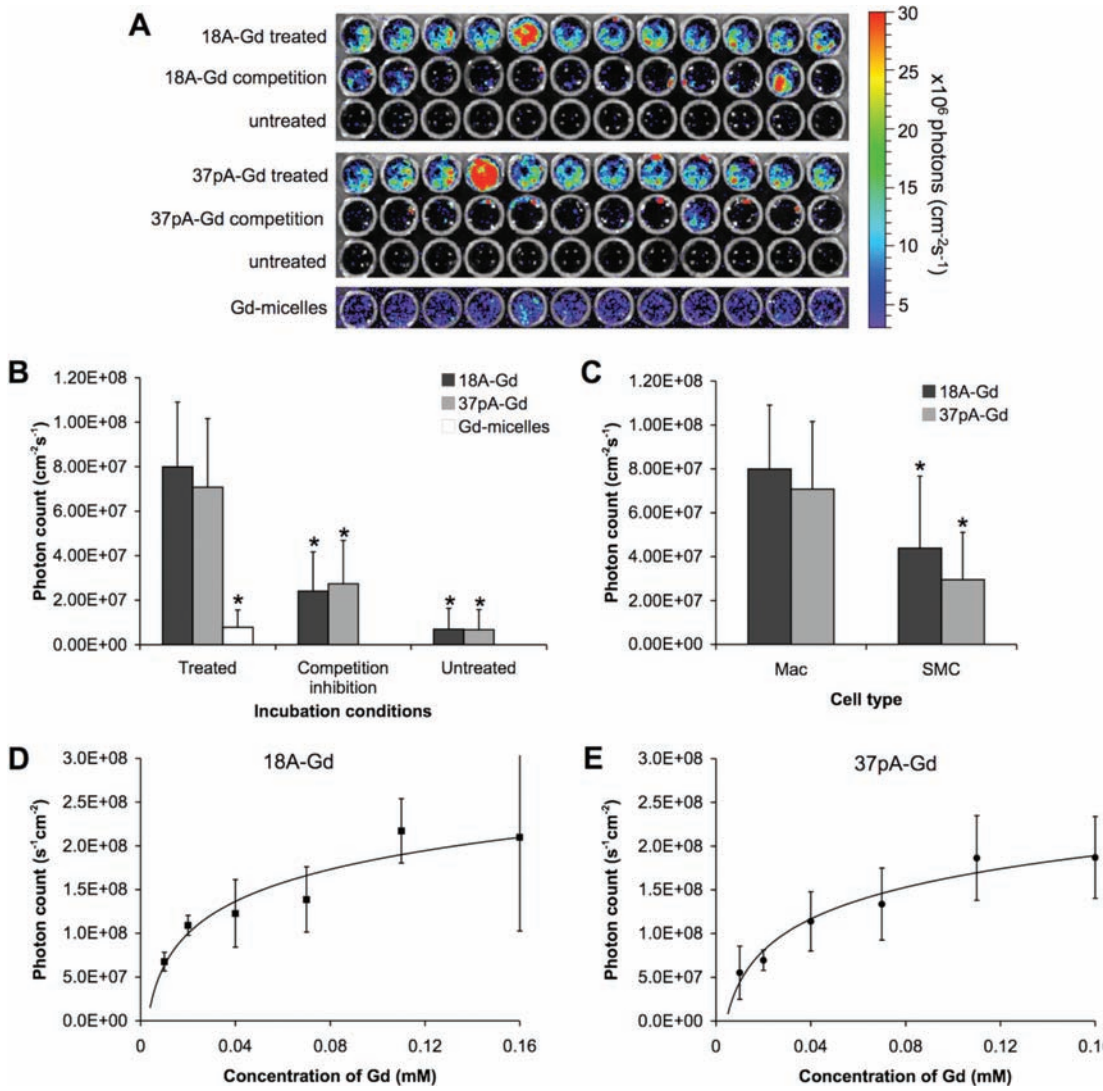

Figure 2. In vitro uptake of Cy5.5 labeled synthetic HDL agents in J774A.1 murine macrophages. Uptake was assessed using an IVIS 200 fluorescent imaging system. (A) Fluorescent images of cells treated with 18A-Gd or 37pA-Gd, with 18A-Gd or 37pA-Gd, and a 10-fold excess of agent without Cy5.5, untreated cells or treated with Gd-micelles. (B) Quantified fluorescence of macrophages compared with macrophages under competition−inhibition conditions and untreated macrophages. Incubation conditions were 2 h and 0.02 mM (by Gd) of agent. * indicates $p < 0.01$ compared to the treated macrophage cells. (C) Comparison of the uptake of 18A-Gd and 37pA-Gd in macrophages and smooth muscle cells. (D) and (E) show the quantified fluorescence of 18A-Gd and 37pA-Gd, respectively, when incubated for 2 h at the indicated concentrations (the solid lines are logarithmic lines of best fit generated by a Matlab program). Error bars are equal to 1 standard deviation, and $n = 12$ in all cases.

Macrophage Uptake of 18A-Gd and 37pA-Gd. To investigate in vitro effectiveness of 18A-Gd and 37pA-Gd and whether uptake was a receptor-like specific process, we performed extensive incubations of Cy5.5-labeled formulations of the agents with murine macrophages. Plates of incubated cells were analyzed using a fluorescence imaging system, resulting in images such as those shown in Figure 2A. We found that uptake increased over time until 4 h, after which increases in uptake were insubstantial (see Supporting Information Figures S1 and S2), suggesting a saturable process. Cy5.5 was used in these experiments because of the lower adsorption of light by biological components in the wavelengths in which this fluorophore emits compared to rhodamine, allowing better quantification of particle uptake (*23*). Macrophages incubated under competition-inhibition conditions (i.e., with a 10-fold excess of unlabeled agent in addition to the labeled agent) exhibited significantly less fluorescence than macrophages incubated with labeled agent only (Figure 2B), suggesting specificity. Furthermore, smooth muscle cells incubated with the agents took up significantly less agent than macrophages incubated under the same conditions (Figure 2C). Lastly, when macrophages were incubated with 18A-Gd and 37pA-Gd at concentrations ranging from 0.01 to 0.16 mM Gd, the uptake increased only slightly when the concentration increased from 0.04 to 0.16 mM Gd (parts D and E of Figure 2), again suggesting a saturable process. Taken together, these data strongly indicate that the uptake of these synthetic HDL particles is a specific, saturable process that is receptor-like in its characteristics. This would be compatible with interactions with HDL-interacting membrane proteins highly expressed by macrophages. The uptake of 18A-Gd and 37pA-Gd was not found to differ significantly. In comparison, macrophages took up Gd micelles to a much lesser extent than for 18A-Gd or 37pA-Gd, in the concentration range 0.01−0.16 mM Gd (parts A and B of Figure 2, Supporting Infomation Figure S3). Furthermore, the uptake was linear, indicating uptake through an aspecific pathway and confirming the need for the peptides to produce a macrophage specific agent.

In Vivo MR Imaging. Representative images of the aorta of an apoE-KO mouse preinjection and 24 h postinjection with 18A-Gd are displayed in Figure 3A (left panels, the enhanced structure below the aorta in the postimage for 18A-Gd is a lymph node, which typically accumulates injected nanoparticles sub-

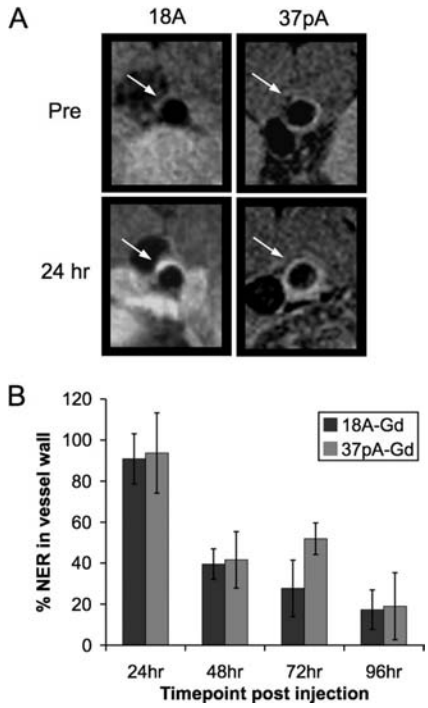

Figure 3. (A) Representative MR images of the aorta of apoE-KO mice preinjection and 24 h postinjection with 18A-Gd (left panels) and 37pA-Gd (right panels). (B) Summary of the mean normalized enhancement ratio (% NER) at 24, 48, 72, and 96 h in the aorta walls of apoE-KO mice injected with 18A-Gd or 37pA-Gd. Error bars are 1 standard deviation.

stantially). Visual inspection of the images indicates that there is significant enhancement of the image intensity in the aorta postinjection with 18A-Gd and that the enhancement is comparable to that observed postinjection with 37pA-Gd (Figure 3A, right panels). The results of analysis of the images from seven mice for each agent imaged preinjection and 24, 48, 72, and 96 h postinjection with each agent are displayed in Figure 3B.

18A-Gd gives an average enhancement in the aorta wall of 91% at 24 h before declining steadily to 17% at 96 h. Application of this agent to wild type mice gave only insignificant enhancements (<8%, data not shown) in the aorta wall. Injection of Gd micelles (composed of the same phospholipids as 18A-Gd and 37pA but without any peptide) into apoE-KO mice gave a maximum of 16% enhancement, which occurred at 24 h. This value was significantly less than that of 18A-Gd and 37pA-Gd, showing the importance of the peptides for targeting the particles to atherosclerosis. The enhancement for 37pA-Gd at the 24 h time point was slightly higher at 94%, but upon comparison of the data for 18A-Gd and 37pA-Gd using Student's *t* test, the difference in the average enhancement at this time point was not found to be significant. In addition, the differences were not significant at 48 or 96 h; however, for the 72 h time point the difference in the average enhancement produced by the two agents was found to be significant at the 1% level.

Confocal Microscopy. A typical confocal microscopy image of an aorta section excised from an apoE-KO mouse injected 24 h previously with 18A-Gd is displayed in Figure 4. As can be seen, there is a high level of rhodamine (red) signal in the plaque, in agreement with the MR imaging data that indicated plaque enhancement. The rhodamine colocalizes extensively with the macrophage staining (green), resulting in patches of yellow color in the merged image, indicative of macrophage specificity. Analysis of the confocal microscopy image using

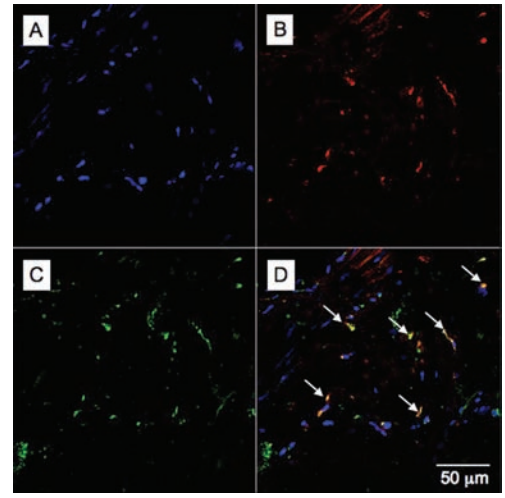

Figure 4. Confocal microscopy images of aortic tissue excised from an apoE-KO mouse injected with the 18A-Gd agent 24 h prior to excision: (A) DAPI staining for nuclei (blue); (B) rhodamine channel (red) indicating areas of 18A-Gd uptake; (C) Alexa 647:CD68 staining for macrophages (green). (D) Merging of the previous three images reveals the affinity of agent 18A-Gd for macrophages (yellow).

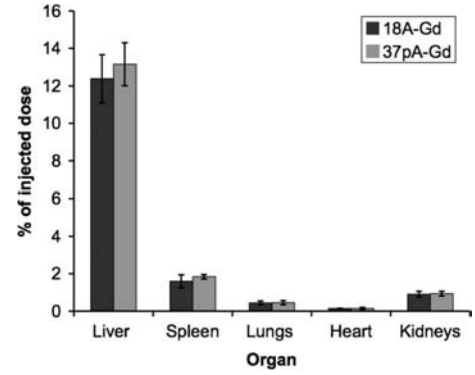

Figure 5. Biodistribution of 18A-Gd and 37pA-Gd between the liver, spleen, lungs, heart, and kidneys at 48 h given as the percentage of the injected dose. Error bars are equal to 1 standard deviation, and $n = 3$ in each case.

an in-house developed software tool revealed that 93% of the rhodamine signal colocalizes with CD68 positive regions, confirming the visual impression of macrophage specificity. In sections of the aorta that did not bear atherosclerotic plaques, no rhodamine signal could be observed (see Supporting Information Figure S4).

Pharmacokinetics and Biodistribution. The pharmacokinetics of 18A-Gd, 37pA-Gd, and Gd micelles were determined by analysis of blood drawn sequentially from mice injected with the agents. The half-life of 18A-Gd was found to be 2.1 ± 0.1 h and the half-life was 2.6 ± 0.3 h for 37pA-Gd and 2.4 ± 0.3 h for Gd-micelles, with no significant difference between them, meaning the agents can be directly compared. The biodistributions of 18A-Gd and 37pA-Gd at 48 h are displayed in Figure 5, given as the percentage of the injected dose. As can be seen, the vast majority of the retained dose is in the liver, with only a minor quantity in the spleen and negligible amounts in the lungs and heart. The levels of agent found in the kidneys are high compared to many contrast agents, but HDL is known to interact with these organs (*24*). The differences in biodistribution between the two agents are not statistically significant.

DISCUSSION

In this report, we compared the physical properties, in vitro macrophage interactions and in vivo imaging efficacy of two

different HDL-based MRI agents. Both contained apoA-I mimicking peptides, one being 37pA and the other being 18A. The physical properties of the two agents are very similar, excepting a superior efficiency of lipid binding in the case of 37pA-Gd. In terms of the in vitro properties, 18A-Gd appears to have a slight advantage. Macrophage efflux measurements show 18A-Gd to interact with these cells to a greater extent than 37pA-Gd, which is in agreement with previous studies by Davidson et al. (*22*). It could be the case that poor lipid binding properties are advantageous for interactions with macrophages, at least in the case of efflux, giving the particle the flexibility to distort to accept cholesterol. We have shown the agents 18A-Gd and 37pA-Gd to have receptor-like mediated uptake in vitro. 18A and 37pA have both been shown by others to bind to proteins highly expressed on macrophage cells (*18, 24*), while we have recently shown HDL particles whose core is modified to contain gold, iron oxide, or quantum dot nanoparticles to be internalized into macrophage cells (*25*). Taken together, the evidence suggests that membrane proteins highly expressed on macrophages allow the specific uptake of 18A-Gd and 37pA-Gd observed in vivo as part of a receptor-mediated endocytic process.

The in vivo imaging properties of the two contrast agents are not significantly different, both giving excellent enhancement in atherosclerotic plaque of apoE-KO mice at 24 h postinjection, compared to precontrast imaging. Immunofluorescence performed upon excised aortas of mice injected with 18A-Gd gave a similar level of colocalization with macrophages as 37pA-Gd. The pharmacokinetics of the agents are interesting, as they are relatively short and correspond more to those observed for micellar agents (*26*) than for lipoproteins ($t_{1/2} = 6$ h) (*27*). This could be due to enhanced rate of clearance due to the negative charge of the particles (*28*) (the gadolinium lipids have an overall negative charge). For studies of this sort, it is preferable to acquire postinjection images at time points at least 5 times the half-life of the contrast agent. As the half-life of the agents was around 2.5 h, it might be that better contrast in the aorta could occur in scans acquired at 12.5 h postinjection. In terms of biodistribution, both agents have very similar properties.

While increases in signal were observed in the aorta wall upon administration of the synthetic HDL agents, it is important to note that hyperintense areas were found, such as in the top left for both 18A-Gd and 37pA-Gd in Figure 3A. Additionally, there were sections of the aorta in both the animals depicted in this figure that bore atherosclerotic plaques, but the increase in signal was very small. As these agents are macrophage specific, this suggests that the hyperintense plaques are macrophage-rich and thus bear hallmarks of vulnerable plaques.

Molecular imaging of cardiovascular disease is critical for the early detection and monitoring of atherosclerosis. In the current study we present a low cost and potentially translatable agent for the in vivo MR imaging of intraplaque macrophages. Other groups have proposed iron oxide based MR agents, which are desirable from both a safety (liver cells safely excrete iron) and efficacy (strong T2* effects) point of view. However, clinical studies using Sinerem/Combidex (Guerbet, France) reveal that this ultrasmall iron oxide particle must be administered as an infusion to both increase efficacy and reduce toxic effects. Additionally, but importantly, there are some serious limitations to imaging negative contrast caused by iron oxide in the vessel wall (*29*). Therefore, we feel that our agent may offer some significant advantages over the alternatives that have been proposed. In addition, agents based on such peptides may be rerouted to other molecular targets (*30*), so this platform is not limited to macrophage imaging.

In summary, the HDL-based, MRI-active contrast agents 18A-Gd and 37pA-Gd have been extensively investigated as to their physical properties, in vitro macrophage interactions, potential as in vivo molecular imaging agents for macrophages in atherosclerosis, and their excretion. The two agents have similar effectiveness with respect to in vivo imaging; however, the 18A particles exhibit better cholesterol efflux. On the basis of these findings and because of the fact that the smaller 18A peptide is less expensive to manufacture, we recommend the 18A peptide be used for future investigations. We plan to continue to investigate 18A-Gd via testing in rabbit models of atherosclerosis using clinical scanners and to create new molecular imaging contrast agents based on this peptide.

ACKNOWLEDGMENT

We gratefully acknowledge Dr. Gustav Strijkers of the Eindhoven University of Technology for assisting with the MRI sequences. We thank Daniel Samber of Mount Sinai School of Medicine for developing the confocal image analysis software tool. We thank Joanne Stocks of Mount Sinai School of Medicine for providing the smooth muscle cells. We thank CSL Behring, Bern, Switzerland, for their kind gift of reconstituted HDL. Partial support was provided by NIH/NHLBI ROI HL71021, NIH/ NHLBI HL78667 (Z.A.F., E.A.F.). Confocal microscopy was performed at the MSSM-Microscopy Shared Resource Facility and supported by NIH-National Cancer Institute Grant 5R24 CA095823-04, National Science Foundation Grant DBI-9724504, and NIH Grant 1 S10 RR0 9145-01.

Supporting Information Available: Method for macrophage efflux determination and further details of the MRI scanning setup; figures displaying the uptake of 18A-Gd and 37pA-Gd in macrophages as a function of time (Figures S1 and S2), the uptake of Gd micelles in macrophages as a function of concentration (Figure S3), and a confocal microscopy image of the aorta of an apoE mouse where there are no macrophages (Figure S4). This material is available free of charge via the Internet at http://pubs.acs.org.

SUPPORTING INFORMATION FOR: 'COMPARISON OF SYNTHETIC HDL CONTRAST AGENTS FOR MR IMAGING OF ATHEROSCLEROSIS'

David P. Cormode[1], Rohith Chandrasekar[2], Amanda Delshad[1], Karen C. Briley-Saebo[1], Claudia Calcagno[1], Alessandra Barazza[1,3], Willem J. M. Mulder[1], Edward A. Fisher[3*], and Zahi A. Fayad[1*].

METHODS

Macrophage cholesterol efflux

J774A.1 murine macrophages (ATCC, Manassas, VA) were incubated overnight with 15 μg/ml cholesterol and 0.5 μCi/ml [^{3}H]cholesterol in 0.2% BSA-DMEM. After an equilibration period of 3 h with 1 μg/ml of F-1394 in 0.2% BSA-DMEM, efflux was initiated by the addition of 50 μg/ml of acceptor agent (by protein mass). 100 μl aliquots of the medium were collected after 4 h, and the [^{3}H]cholesterol measured by liquid scintillation counting (LSC). In order to measure the [^{3}H]cholesterol present in the cells, cell lipids were then extracted by incubating the cell monolayers overnight in isopropanol. After lipid extraction, the total [^{3}H]cholesterol present in lipid extract was measured by LSC and the efflux calculated as percentage of total. Such efflux experiments were carried out with 18A-Gd, 37pA-Gd, HDL and bovine serum albumin.

MRI scanning

Mice were scanned using the following protocol. The abdominal aorta was identified in a coronal section on a localizing sequence. T1-weighted MRI was performed using a black blood sequence. Twenty-two contiguous 500 μm-thick slices with a microscale in-plane resolution of 101 μm were acquired using a spin echo sequence with a 256 × 256 matrix size. The repetition time (TR) and echo time (TE) for the T1W images were 800 and 8.6 ms, respectively. An inflow saturation band of 3 mm was used with a slice gap of 3 mm for additional luminal flow suppression. Sixteen signal averages were used for a total imaging time of 55 min per scan. A saturation pulse was used to eliminate signal from fat tissue and better delineate boundary of the aortic wall and minimize chemical shift artifacts. After a preinjection, baseline MRI scan, mice were injected, via a tail-vein catheter with a 50 μmol Gd/kg dose of the synthetic HDL contrast agents. The mice were scanned again at 24 hours post-injection. n=7 apoE-KO mice were injected with each agent. Use of the medical image analysis software package eFilm allowed the MR signal intensity of various tissues from the different time points to be ascertained and the percent change in normalized enhancement ratio (% NER) post-injection to be calculated. Normalization of the MR signal intensity in the aorta wall was performed by rebasing with the signal from muscle adjacent to the aorta.

5,10,15,20-Tetrakis(4-(2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranosylthio)-2,3,5,6-tetrafluorophenyl)porphyrin **2a** and its Zn(II), Pd(II), and Pt(II) complexes **2b**, **2c**, and **2d** were prepared in excellent yields by nucleophilic substitution of the corresponding free-base porphyrin and metalloporphyrins with acetyl 2,3,4,6-tetra-*O*-acetyl-1-thio-*β*-D-glucopyranoside. Deprotection of **2a**, **2b**, **2c**, and **2d** by alkaline hydrolysis afforded the corresponding S-glucosylated porphyrin **3a** and its metal complexes **3b**, **3c**, and **3d**. The structures and purity of all new photosensitizers were confirmed by elemental analysis and ^{1}H, ^{13}C, and ^{19}F NMR, UV−vis, and steady-state luminescence spectroscopy. The relative efficiency of singlet oxygen ($^1O_2$) production increased in the order of free-base fluoroporphyrins (**2a** and **3a**) < Zn(II) complexes (**2b** and **3b**) < Pd(II) complexes (**2c** and **3c**), which can be explained in terms of the heavy-atom effect, while the $^1O_2$-producing efficiency of Pt(II) complexes (**2d** and **3d**) were exceptionally low. In vitro photocytotoxicity of these eight S-glucosylated photosensitizers was examined in HeLa cells. Although all protected photosensitizers **2a**, **2b**, **2c**, and **2d** showed no photocytotoxicity, the photosensitizers **3a**, **3b**, and **3c** exerted potent photocytotoxicity. These results clearly indicated that the sugar moieties of **3a**, **3b**, and **3c** act as not only water-solubility-enhancing functionalities but also cellular-uptake-enhancing elements. Photocytotoxicity testing of **3a**, **3b**, and **3c** in the presence of reactive oxygen species inhibitors suggested that $^1O_2$ is the major mediator of cell death. Hence, the Zn(II) and Pd(II) complexes **3b** and **3c** are promising photosensitizers having cellular uptake-facilitating units (sugar moieties) and enhanced $^1O_2$ generation due to the heavy-atom effect.

INTRODUCTION

In photodynamic therapy (PDT[1]), an administered-photosensitizer is taken up by malignant cells and subsequent irradiation with light causes the generation of cytotoxic reactive oxygen species (ROS) that kill the cells (*1*−*7*). Thus, critical factors in PDT are the distribution of the photosensitizers and the site of photoirradiation. Tumor-specific accumulation of photosensitizers is extremely important, because ROS also attacks healthy cells, resulting in significant side effects. One promising approach is conjugation of a tumor-specific element to the photosensitizer. [2-^{18}F]2-Deoxy-2-fluoroglucose ([^{18}F]FDG) is a well-known diagnostic drug that is widely used in positron emission tomography (*8*). [^{18}F]FDG takes advantage of the enhanced uptake of glucose by malignant cells. Hence, much effort has been devoted to the development of photosensitizers incorporating biologically active sugar moieties in order to improve the water-solubility and to enhance uptake by tumor cells. Li et al. reported the synthesis and biological properties of glycoconjugated photosensitizers bearing galactose, lactose, galactosamine, and glucosamine (*9*). They demonstrated the sugar-dependent photocytotoxicity of glycosylated photosensitizers in radiation-induced fibrosarcoma tumors, which express galectin-3. Momenteau et al. reported the systematic synthesis of seventeen 5,10,15,20-tetraphenylporphyrin (H_2TPP) deriva-

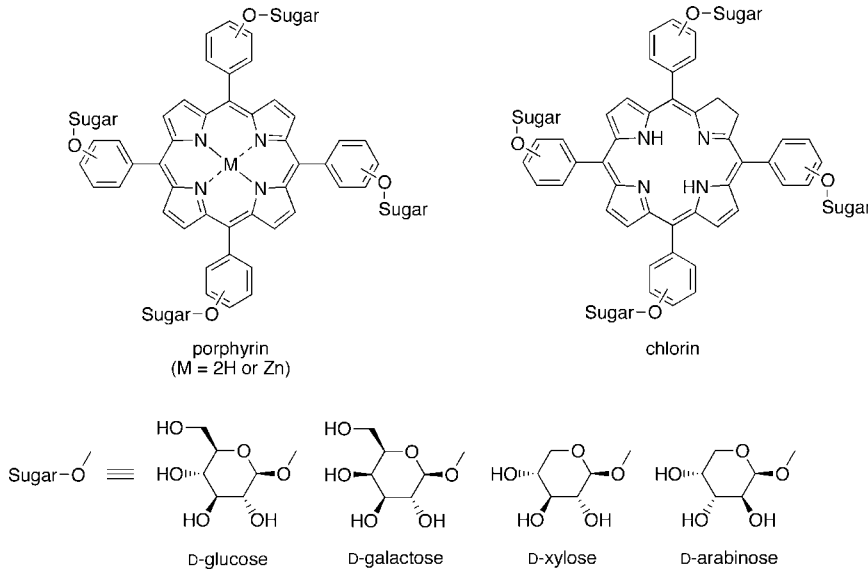

Chart 2. Photosensitizers Having Metal Ions

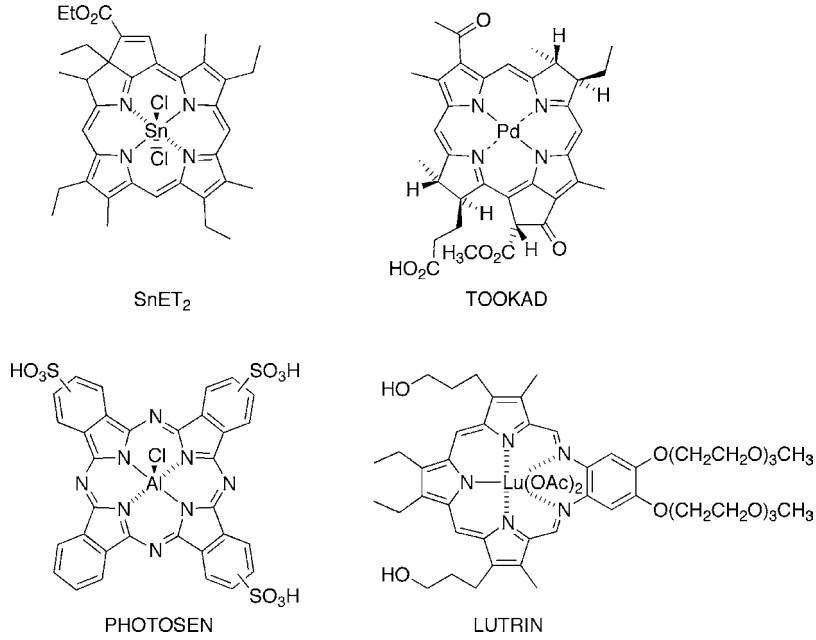

tives bearing glucose, galactose, maltose, and glucosamine (*10, 11*). They examined the efficiency of singlet oxygen ($^1O_2$) generation, partition coefficients, and photocytotoxicity in KB cells. While no differences were found in the photophysical properties of glycosylated porphyrins in organic solvents, the photocytotoxicity in KB cells depended on the sugar moiety. They suggested that the differences in photocytotoxicity might have arisen from differences in the sugar-dependent cellular uptake. Previously we have systematically synthesized porphyrin and chlorin derivatives having O-glycosylated phenyl groups at the meso positions (Chart 1) and demonstrated enhanced cellular uptake and sugar-dependent photocytotoxicity in HeLa cells (*12*−*16*).

In addition to the requirement for efficient cellular uptake, a photosensitizer must generate ROS efficiently for successful PDT. Since singlet oxygen ($^1O_2$) is thought to be involved in porphyrinoid-based PDT, the $^1O_2$ quantum yield (Φ_Δ) is likely to be a crucial factor for photocytotoxicity. In general, energy transfer from a photosensitizer to an oxygen molecule occurs in the excited triplet state. So, efficient intersystem crossing from the excited singlet state to the triplet state is a key process in $^1O_2$ generation. Because this spin-forbidden process is promoted by spin−orbit coupling, which is a function of Z^4 (Z is atomic number), heavy atoms should increase the $^1O_2$ quantum yield; this is the well-known heavy-atom effect (*17*). Several metalloporphyrin derivatives or analogues have been approved for PDT or are under clinical trial (Chart 2). For example, $SnET_2$ is a tin complex of etiopurpurin and is used in clinical treatment of cutaneous malignancies and age-related macular degeneration. The Φ_Δ value of $SnET_2$ is 0.71 ± 0.1 in acetonitrile (*18*). Bacteriochlorophyll is an attractive candidate due to the very large absorption bands in the near-infrared region but is photochemically unstable even in dim light. The introduction of palladium into bacteriopheophorbide, giving TOOKAD, improves the photostability and provides an excellent triplet yield of over 0.99 (*19*). Therefore, the combination of glycosylation and complexation with metal ion seems to be a promising design approach for PDT photosensitizers. However, relatively severe conditions are required for complexation, especially in the case of late transition metal complexes and are incompatible with porphyrins having delicate functional

groups, such as sugar moieties. Hence, complexation with the heavy metal ion should be done prior to introduction of sugar moieties. This strategy requires a selective and high-yield conjugation reaction between porphyrin and sugar units. Boyle et al. have developed nucleophilic substitution reaction of pentafluorophenyl groups of fluorinated porphyrin with thiolate anion (*20*), and Drain et al. applied this methodology to the synthesis of glycoconjugated fluorinated porphyrin using thioglycoside (*21*). We adopted this synthetic strategy, to design glycoconjugated metalloporphyrins that were expected to show both enhanced cellular uptake owing to glycosylation, and efficient $^1O_2$ generation owing to the heavy-atom (Zn, Pd, and Pt) effect. Here, we report the synthetic details and photophysical properties of these glycoconjugated metalloporphyrins and the results of evaluation of their in vitro photocytotoxicity in HeLa cells.

EXPERIMENTAL SECTION

Materials and Methods. All chemicals used were of analytical grade. Tetraphenylporphyrin tetrasulfonic acid (TPPS) and 1,3-diphenylisobenzofuran (DPBF) were purchased from Sigma-Aldrich Japan (Chiba, Japan). 5,10,15,20-Tetrakis(2,3,4,5,6-pentafluorophenyl)porphyrin (**1a**), 5,10,15,20-tetrakis(2,3,4,5,6-pentafluorophenyl)porphyrinato zinc(II) (**1b**), 5,10,15,20-tetrakis(2,3,4,5,6-pentafluorophenyl)porphyrinato palladium(II) (**1c**), 5,10,15,20-tetrakis(2,3,4,5,6-pentafluorophenyl)porphyrinato platinum(II) (**1d**), and acetyl 2,3,4,6-tetra-*O*-acetyl-1-thio-*β*-D-glucopyranoside (**4**) were prepared according to the literature (*22*−*24*). Preparative gel permeation chromatography (GPC) was performed on an LC-908 recycling preparative high-performance liquid chromatography (HPLC) system (Japan Analytical Industry Co., Ltd., Tokyo, Japan) equipped with two polystyrene columns (JAIGEL-2.5H and JAIGEL-2H), with $CHCl_3$ as an eluent. Preparative HPLC was carried out on octadecylsilyl-bound silica gel (Mightysil RP-18, 20 mm $\phi \times$ 250 mm, Kanto Chemical Co., Inc., Tokyo, Japan). ^{1}H, ^{13}C, and ^{19}F NMR spectra were recorded on JNM-EC600 (600 MHz, JEOL Ltd., Tokyo, Japan) and JNM-AL400 (400 MHz, JEOL Ltd., Tokyo, Japan) instruments. Electronic absorption spectra in DMSO were recorded on a V-570 spectrophotometer (JASCO Co., Ltd., Tokyo, Japan). Steady-state luminescence spectra in DMSO were recorded on a FP-6300 spectrofluorometer (JASCO Co., Ltd., Tokyo, Japan). Elemental analyses were performed on a Perkin-Elmer 2400 series II CHNS/O elemental analyzer (Perkin-Elmer. Inc., MA, USA).

Stock solutions of photosensitizers were prepared by weighing the dried photosensitizers and dissolving them in dimethyl sulfoxide (DMSO, Wako Pure Chemical Industries, Osaka, Japan) and kept in freezer (−30 °C) until use. The absorbance of each well was determined with a plate reader (Multiscan JX, Thermo Fisher Scientific Co., Yokohama, Japan).

5,10,15,20-Tetrakis(4-(2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranosylthio)-2,3,5,6-tetrafluorophenyl)porphyrin (2a). S-Glucosylated porphyrin **2a** was prepared by a slight modification of the literature method (*21*) to prevent the formation of over-S-glucosylated porphyrins (vide infra). Porphyrin **1a** (64.9 mg, 66.6 μmol), S-glycoside **4** (113 mg, 278 μmol), and diethylamine (3.0 mL) were dissolved in *N*,*N*-dimethylformamide (DMF) (30 mL). The resulting mixture was stirred at ambient temperature for 24 h, diluted with $CHCl_3$ (30 mL), washed with water (30 mL × 5), and dried over Na_2SO_4. The solvent was removed under reduced pressure. The crude product was purified by column chromatography (silica gel, gradient from $CHCl_3$ to $CHCl_3$: AcOEt = 7: 3) followed by preparative GPC to give **2a** (116 mg, yield 74.0%) as a brown purple solid. Anal. Calcd for $C_{100}H_{86}O_{36}N_4F_{16}S_4 \cdot 2H_2O$: C, 50.30; H, 3.80; N, 2.35. 5,10,15,20-Tetrakis(4-(β-D-glucopyranosylthio)-2,3,5,6-tetrafluorophenyl)porphyrin (3a). The synthesis of porphyrin **3a** reported in the literature (*21*) was modified as follows to obtain highly pure sample for in vitro photocytotoxicity testing. Porphyrin **2a** (51.1 mg, 21.7 μmol) was dissolved in CH_2Cl_2 (10 mL) and CH_3OH (10 mL). Sodium methoxide was added to adjust the pH to 9. This mixture was refluxed for 1 h at 45−50 °C. The reaction mixture was neutralized with acetic acid and evaporated to dryness. The crude product was purified by preparative HPLC (CH_3CN:H_2O = 1: 1). The collected fraction was desalted by dialysis using a cellulose ester membrane (molecular weight cutoff: 1000). Lyophilization of the desalted aqueous sample solution gave **3a** (24.9 mg, yield 68.8%) as a dark red powder. Anal. UV−vis (c = 4.65 μM, DMSO, path length = 1 cm, 25 °C): λ/nm ($\epsilon \times 10^{-3}$/$M^{-1}\cdot cm^{-1}$) = 394 (30.7), 507 (2.37), 539 (2.41). FL (c = 4.65 μM, DMSO, path length = 1 cm, λ_{ex} = 394 nm, 25 °C): λ/nm = 651, 698, 795.

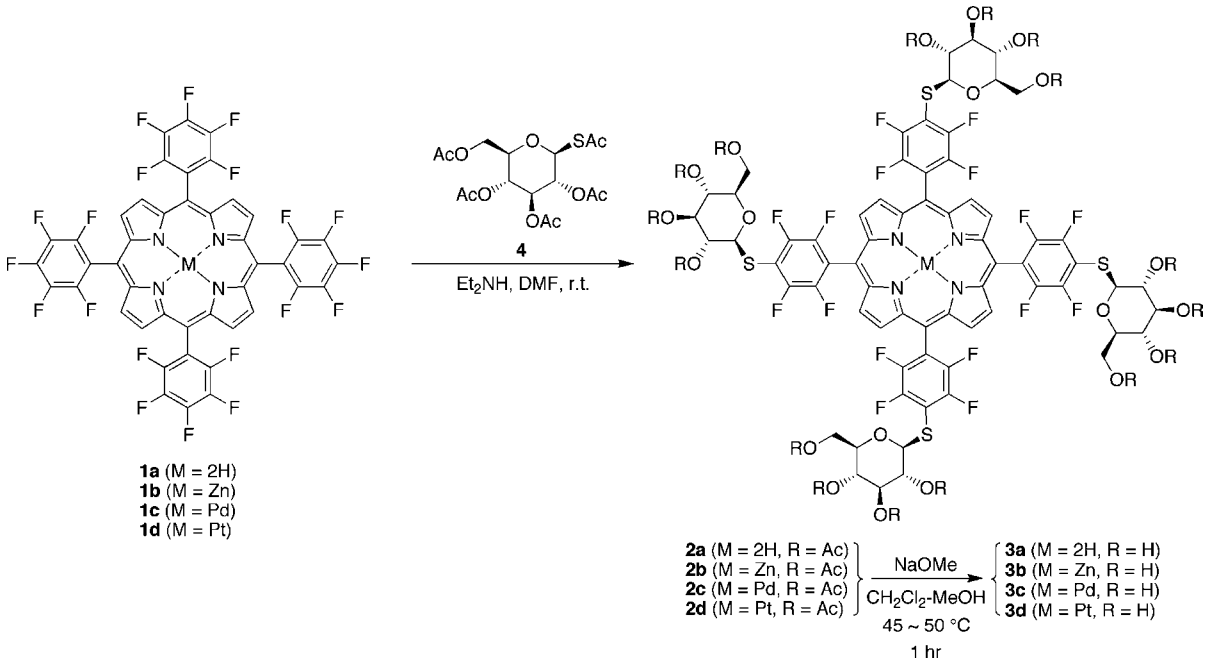
Luminescence Quantum Yield. Photosensitzers were dissolved in DMSO to adjust the absorbance of 0.15 at the Soret band and placed in a square quart cell (1 cm). The luminescence intensity were determined by using spectrofluorometer. Luminescence quantum yield (Φ) was determined by a relative method using aqueous TPPS solution (Φ_{ref} = 0.1) as a standard (*25*).

Degradation Rate Measurement of DPBF. Photosensitizer (c = 3.7 μM) and DPBF (c = 102 μM) were dissolved in DMSO and placed in a square quartz cell (1 cm). Oxygen gas was introduced through the solution for 1 min in prior to photoirradiation. The solution was then exposed to light from

Scheme 1. Synthesis of S-Glucosylated Porphyrin and Its Metal Complexes



a 100 W halogen lamp (KBEX-102A, USHIO Inc., Tokyo, Japan) through a Y-50 cutoff filter ($\lambda > 500$ nm, Toshiba Co., Tokyo, Japan) at 37 °C. The concentration of DPBF was monitored by measuring the absorption at 418 nm. The rate constant k' (s^{-1}) was estimated by the first-order plot of the DPBF concentration as a function of the irradiation time.

In Vitro Cellular Uptake Measurement. HeLa cells (ATCC CCL-2) were obtained from Dainippon-Sumitomo Pharmaceutical (Osaka, Japan). They were grown in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal calf serum (FCS) (Hyclone Laboratories, Inc., Logan, UT). The cellular uptake of **3a** in HeLa cells was examined as follows: HeLa cells (3×10^4 cells/well) in 0.5 mL of DMEM containing 10% FCS were plated in a 24-well plate (Nalge Nunc International, Naperville, IL) and incubated for 24 h (37 °C, 5% CO_2). Five hundred microliters of 2 μM **3a** in DMEM containing 10% FCS and 2% DMSO was added to each well. The cells were then incubated from 1 to 24 h in the presence of the photosensitizer. The photosensitizer concentration in each well was 1 μM in DMEM containing 10% FCS (final DMSO content was 1% in all cases). The cells were washed twice with Dulbecco's phosphate-buffered saline (PBS) and lysed in 150 μL of DMSO to extract the photosensitizer. The fluorescence intensity of the extracts was measured with a plate reader using excitation and emission wavelengths of 430 and 635 nm, respectively. The fluorescence intensity of photosensitizers was estimated by subtracting the averaged background from the averaged fluorescence intensity of extracts. The cellular uptake amount of **3a** was determined by using a calibration plot obtained with the photosensitizer in DMSO. Each cellular uptake amount reported is mean value from by three replicate experiments.

In Vitro Photocytotoxicity Test. The photocytotoxicity of the eight S-glucosylated photosensitizers and TPPS in HeLa cells was examined as follows: HeLa cells (5×10^3 cells) in 100 μL of DMEM containing 10% FCS were plated in a 96-well plate (Nalge Nunc International, Naperville, IL) and incubated for 24 h (37 °C, 5% CO_2). One hundred microliters of a photosensitizer in DMEM containing 10% FCS and 2% DMSO was added to each well. The plate was then incubated for a period from 10 min to 24 h. The photosensitizer concentration was varied from 0.09 to 0.5 μM in DMEM containing 10% FCS (final DMSO content was 1% in all cases). After the irradiation, the cells were washed twice with PBS, and then 100 μL of DMEM containing 10% FCS was added to each well. The cells were exposed to light from a 100 W halogen lamp, equipped with a water jacket, through a Y-50 cutoff filter. The light intensity was adjusted by using a UV−vis power meter (ORION/TH, Ophir Optronics Ltd., Jerusalem, Israel). The light dose was calculated as the product of light intensity ($mW \cdot cm^{-2}$) and irradiation time, and the irradiation time was adjusted to obtain the desired light dose of 16 $J \cdot cm^{-2}$. The mitochondrial activity of NADH dehydrogenase of the cells in each well was measured at 24 h after photoirradiation using WST-8 reagent (10 μL) from Cell Counting Kit-8 (Dojindo, Tokyo, Japan) according to the manufacturer's instructions. Then, the absorbance at 450 nm

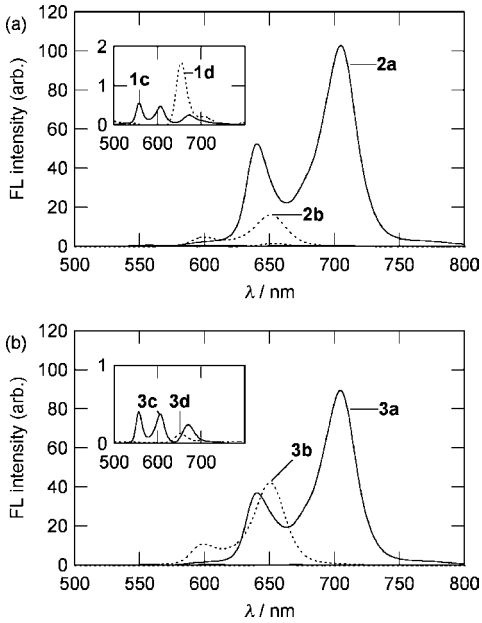

Figure 2. Steady-state luminescence spectra of S-glucosylated photosensitizers **2a** (2.30 μM), **2b** (6.10 μM), **2c** (4.74 μM), and **2d** (4.29 μM) (a) and the deprotected compounds **3a** (5.35 μM), **3b** (5.16 μM), **3c** (5.45 μM), and **3d** (4.65 μM) (b) in DMSO at 25 °C.

was measured using a plate reader. The percentage cell survival was calculated by normalization with respect to the value for no drug treatment.

In Vitro Photocytotoxicity Test in the Presence of Reactive Oxygen Species (ROS) Inhibitor. HeLa cells (5×10^3 cells) in 100 μL of DMEM containing 10% FCS were plated in a 96-well plate and incubated for 24 h (37 °C, 5% CO_2). One hundred microliters of a S-glucosylated photosensitizer (**3a**, **3b**, **3c** and **3d**) in DMEM containing 10% FCS and 2% DMSO was added to each well, and the plate was incubated for 24 h. The photosensitizer concentration was 0.1 μM (**3a**), 0.1 μM (**3b**), 0.1 μM (**3c**), and 2 μM (**3d**) in DMEM containing 10% FCS (the final concentration of DMSO was 1% in all cases). The cells were washed twice with PBS, and then 100 μL of DMEM containing 10% FCS (control) or 100 μL of ROS quencher (5 mM sodium azide (NaN_3) as a singlet oxygen ($^1O_2$) quencher or 40 mM D-mannitol (Man) as a hydroxyl radical (•OH) scavenger) in DMEM containing 10% FCS was added to each well. The plate was further incubated for 2 h (37 °C, 5% CO_2) and then exposed to light under the same conditions as described in the previous section. At 30 min after photoirradiation, the medium was replaced with fresh medium. Cell survival was determined by means of the same protocol as described in the previous section.

Statistical Analysis. All statistical evaluations were performed using Student's *t*-test. All values for cellular uptake and cytotoxicity are expressed as mean ± standard deviation.

RESULTS AND DISCUSSION

Synthesis of S-Glucosylated Photosensitizers. Porphyrin **1a** was prepared by condensation of pyrrole with pentafluorobenzaldehyde using a modification of the Lindsey method in 61.2% yield (*21*). Zn(II), Pd(II), and Pt(II) complexes (**1b**, **1c**, and **1d**, respectively) were prepared from **1a** by a conventional complexation method using $Zn(CH_3CO_2)_2$, $PdCl_2$, or $K_2[PtCl_4]$ as the metal source in 64.0, 69.4, and 76.4% yields, respectively (*22*, *23*). On the other hand, S-glycoside **4** was prepared by condensation of 1,2,3,4,6-penta-*O*-acetyl-1-thio-β-D-glucopyranose and thioacetic acid in the presence of $ZrCl_4$ as a Lewis acid catalyst in 76.8% yield (*24*). The S-glucosylated photosensitizers **2a**, **2b**, **2c**, and **2d** were synthesized by nucleophilic substitution at the para-position of the pentafluorophenyl groups of **1a**, **1b**, **1c**, and **1d** with S-glycoside **4** (Scheme 1). Drain et al. reported the synthesis of **2a** using 8 equiv of thioglucoside **4** in DMF (*21*). However, we observed the formation of penta-S-glucosylated porphyrins as a major product. Hence, we used 4 equiv of thioglucoside **4** with respect to the free-base porphyrin **1a** or metalloporphyrin **1b**, **1c**, or **1d** for the synthesis of S-glucosylated porphyrins **2a**, **2b**, **2c**, and **2d**. The reactions were conducted in DMF at ambient temperature using diethylamine as a base to yield **2a** (74.0%), **2b** (74.1%), **2c** (83.1%), and **2d** (85.3%). ^{1}H and ^{13}C NMR spectra of **2a**, **2b**, **2c**, and **2d** showed only one set of glucopyranosyl peaks owing to the C_4 symmetry of these molecules. ^{19}F NMR spectra of **2a**, **2b**, **2c**, and **2d** showed two peaks with equal intensities and an AA′XX′ splitting pattern ($^3J_{F-F}$ = 24 Hz and $^5J_{F-F}$ = 12 Hz), indicating para substitution of tetrafluorophenyl groups. Metal complexation, namely Zn(II), Pd(II) and Pt(II), caused a lower-field shift of the ^{19}F peak at the ortho position in the order of **2a** (−136.43) < **2b** (−135.97) < **2c** (−135.45) < **2d**, (−135.42), which is in good accordance with Pauling's electronegativity values (1.65, 2.20, and 2.28 for Zn(II), Pd(II), and Pt(II)) (*26*). This suggests that there is substantial electronic interaction between the porphyrin ring and the tetrafluorophenyl ring, even though these two rings are thought to be perpendicular to each other. Deprotection of the S-glucosylated photosensitizers **2a**, **2b**, **2c**,

Table 3. Relative Rate Constant *k* of DPBF Photodegradation in DMSO[a]

	1a	2a	2b	2c	2d	3a	3b	3c	3d
k	1.67	1.14	1.90	2.02	0.24	1.00	1.75	1.98	0.32

[a] Normalized to that of TPPS; condition: $[\text{photosensitizer}]_0 = 3.7\ \mu\text{M}$, $[\text{DPBF}]_0 = 102\ \mu\text{M}$, $\lambda > 500$ nm.

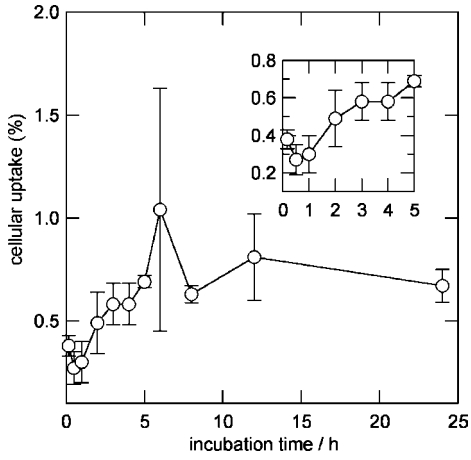

Figure 3. The cellular uptake amount of S-glucosylated porphyrin **3a** by HeLa cells as a function of incubation time. The cellular uptake amount represents the percentage of the total amount of photosensitizer added. Values are the mean ± standard deviation of three replicate experiments.

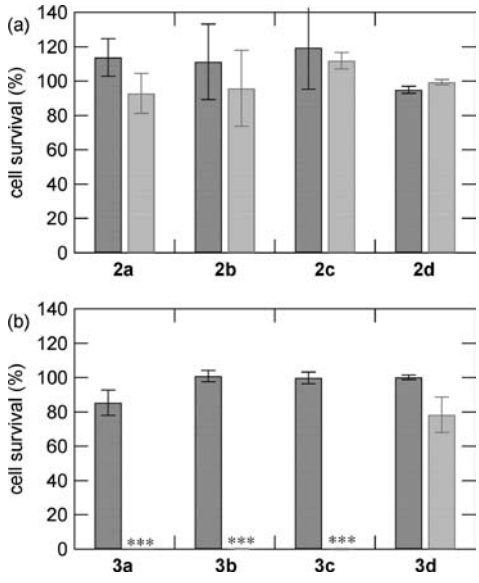

Figure 4. Dark cytotoxicity (left bar) and photocytotoxicity (right bar) of S-glucosylated photosensitizers **2a**, **2b**, **2c**, and **2d** (a) and the deprotected compounds **3a**, **3b**, **3c**, and **3d** (b) in HeLa cells. The concentration of photosensitizers was 0.5 μM. The light dose applied was 16 J·cm^{-2}. Values are the mean ± standard deviation of six replicate experiments. ***Significant difference, $p < 0.001$ vs dark.

and **2d** was carried out using sodium methoxide in a mixture of CH_3OH and CH_2Cl_2. A small amount of S-glycoside cleavage was detected by reverse-phase high-performance liquid chromatography (RP-HPLC) with an octadecylsilyl-bound silica gel column and electron-spray time-of-flight (ESI-TOF) mass spectrometry. The crude product was successfully purified by preparative RP-HPLC using a mixture of CH_3CN and H_2O (1:1). Eventually, four deprotected photosensitizers **3a**, **3b**, **3c**, and **3d** were obtained in 67.9−81.1% yield. The ^{1}H, ^{13}C and ^{19}F NMR spectra of **3a**, **3b**, **3c**, and **3d** supported the structures shown in Scheme 1, and all S-glucosylated photosensitizers were confirmed to be pure by elemental analysis.
